Complexes of substituted benzothiazoles. 1. Cobalt(II), copper(II), and zinc(II) complexes of 2,2′-*o*-phenylenebisbenzothiazole; a potential N or S donor ligand

JOHN CHARLES THOMAS RENDELL AND LAURENCE KENNETH THOMPSON[1]
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received July 4, 1978

JOHN CHARLES THOMAS RENDELL and LAURENCE KENNETH THOMPSON. Can. J. Chem. **57**, 1 (1979).

A series of cobalt(II), copper(II), and zinc(II) complexes of the title ligand are reported. 1:1 complexes of cobalt and zinc, $M(OBT)X_2$ (M = Co, Zn; X = Cl, Br, I, NCS), have four-coordinate pseudo-tetrahedral stereochemistries while for copper (X = Cl, Br), distorted square geometries are suggested. Six-coordinate 1:1 derivatives are also obtained for cobalt and copper, $M(OBT)(NO_3)_2$ (M = Co, Cu), while the 1:2 derivative $Cu(OBT)_2(ClO_4)_2 \cdot 2H_2O$ may be square planar. OBT appears to coordinate as an N_2 donor in all cases. Preliminary X-ray data confirm a distorted square CuN_2Cl_2 structure for the copper chloride complex. Hydrogen bonded chloroform solvate molecules appear to be present in three cobalt complexes (X = Cl, Br, NCS).

JOHN CHARLES THOMAS RENDELL et LAURENCE KENNETH THOMPSON. Can. J. Chem. **57**, 1 (1979).

On décrit une série de complexes du cobalt(II), du cuivre(II) et du zinc(II) avec le coordinat ci-dessus. Les complexes 1:1 du cobalt et du zinc, $M(OBT)X_2$ (M = Co, Zn; X = Cl, Br, I, NSC), sont tétracoordonnés et possèdent une structure pseudo-tétraédrique, tandis qu'une géométrie carrée déformée est proposée dans le cas du cuivre (X = Cl, Br). On obtient également des composés 1:1 hexacoordonnés du cobalt et du cuivre, $M(OBT)(NO_3)_2$ (M = Co, Cu), alors que le composé 1:2 $Cu(OBT)_2(ClO_4)_2 \cdot 2H_2O$ pourrait être plan carré. Dans tous les cas, le coordinat OBT joue le rôle de donneur N_2. Les données préliminaires de diffraction des rayons X confirment la structure plane carrée CuN_2Cl_2 du complexe chloré du cuivre. Trois complexes du cobalt (X = Cl, Br, NCS) semblent renfermer des molécules du solvant, le chloroforme, retenues par liaisons hydrogène.

[Traduit par le journal]

Introduction

The current surge of interest in metalloprotein model systems has revealed that imidazole nitrogen and thioether sulphur functional groups are likely to be involved in coordination to copper in both Type I and Type III copper metalloproteins (ref. 1 and references therein). Benzothiazole has heterocyclic sulphur and pseudo-imidazole functional groups, the former being a poor Lewis base. Studies on the complexes of benzothiazole and 2-substituted benzothiazoles (R = NH_2, CH_3, Cl) (2–8) reveal that with first row transition element ions (M = Fe, Co, Ni, Cu, Zn) benzothiazole is *N*-bonded, except in a few cases involving bridging benzothiazole (4) in which it is assumed to behave as a bidentate ligand involving both N and S donation. The polyfunctional benzothiazole ligand 2,6-(dibenzothiazol-2-yl)pyridine (9) has been shown to behave as an N_3 donor, rather like 2,2′,2″-terpyridyl, in its complexes with manganese(II), iron(II), and nickel(II). The ligand 2-(*o*-hydroxyphenyl) benzothiazole behaves as an NO donor to copper(II) (10).

Studies on the cobalt(II), copper(II), and zinc(II) complexes of the ligand 2,2′-*o*-phenylenebisbenzo-

thiazole (OBT) (Fig. 1) reveal that OBT behaves as an N_2 donor. Reaction of the ligand (OBT) with cobalt(II), copper(II), and zinc(II) salts in ethanol or acetone leads to a series of tetrahedral, octahedral, and square complexes whose structures have been established by electronic, vibrational, and esr spectra, magnetism and conductance data, and an X-ray structure.

Experimental

Electronic spectra were recorded on a Cary 17 spectrometer, infrared spectra were obtained with a Perkin-Elmer model 283 spectrometer, and electron spin resonance spectra were recorded at −196°C on a Varian E-3 X-band spectrometer, the magnetic field strength being calibrated with an nmr probe and with Mn(II) in MgO powder. Magnetic susceptibilities were obtained at room temperature by the Faraday method with a Cahn model #7600 Faraday Magnetic Susceptibility system, coupled to a Cahn gram electrobalance and conductance data were obtained with a General Radio Company bridge with impedance comparator and a constant temperature bath adjusted to 25°C. Microanalyses were carried out in part in the Chemistry Department at Memorial University with a Perkin-Elmer model #240 Elemental Analyzer and by Atlantic Microlab, Inc., Atlanta, Georgia. Metal analyses were determined by Atomic Absorption with a Varian Techtron AA-5, after digestion of the samples in concentrated HNO_3 or aqua-regia.

Metal Complexes of OBT

OBT was synthesized according to the procedure of Rai and Braunwarth (11). Hydrated or anhydrous metal salts were employed.

$Co(OBT)X_2(CHCl_3)_n$ ($X = Cl, Br, NCS$; n = 1; $X = I$, n = 0) $Co(OBT)(NO_3)_2 \cdot 2H_2O$

Stoichiometric amounts of the appropriate metal salt and OBT were dissolved separately in hot ethanol and the solutions were mixed and stirred with heating for 15 min. The resulting solutions were filtered and reduced in volume to induce crystallization. Some difficulty was encountered in obtaining crystals and it was found that addition of acetonitrile to concentrated solutions of the complexes resulted in the formation of crystalline products. Recrystallization was effected from chloroform and the complexes were dried under vacuum.

$Cu(OBT)X_2$ ($X = Cl, Br, NO_3$)

Stoichiometric amounts of the appropriate metal salt and OBT were dissolved separately in hot ethanol and the solutions were mixed. Crystalline products were obtained rapidly, which proved to be fairly insoluble in most solvents. The chloro- and bromo-compounds were recrystallized from dichloromethane and dried under vacuum while the nitrato-complex was recrystallized from chloroform.

$Cu(OBT)_2(ClO_4)_2 \cdot 2H_2O$

Stoichiometric amounts of the metal salt and OBT were dissolved separately in hot ethanol containing about 5% triethylorthoformate. On mixing the solutions a light khaki green precipitate was obtained which was washed with an ethanol/triethylorthoformate mixture and dried under vacuum.

$Zn(OBT)X_2(acetone)_n$ ($X = Cl, Br$, n = 1; $X = I, NCS$, n = 0)

Stoichiometric amounts of the metal salt and OBT were dissolved separately in hot acetone and the solutions were mixed. Crystalline products were obtained and were dried under vacuum.

Analytical data for the complexes are given in Table 1.

Results and Discussion

Cobalt Complexes

The cobalt complexes $Co(OBT)X_2$ (X = Cl, Br, NCS, I) exhibit electronic spectra, both in solution and in the solid state, typical of pseudo-tetrahedral cobalt(II) (Table 2). The splitting of the three components of ν_2 is quite large, falling in the range 3130–3850 cm^{-1}, suggesting a crystal field of lower symmetry than T_d. Systems of the type CoL_2Br_2 (L = 4Etpy, 2Etpy) have comparable spectra with large splittings of ν_2 (12). The general similarity between the spectra and ligand field parameters of the OBT complexes and Co(benzothiazole)X_2 (X = Cl, Br, I) (7) and Co(benzimidazole)X_2 (X = Cl, Br, I, NCS) (13) coupled with the absence of any intense bands, which could possibly be associated with sulphur-to-metal charge transfer, suggests that in these systems OBT coordinates as a bidentate ligand via two nitrogen atoms. The iodo-complex displayed a high intensity band around 22 500 cm^{-1}, both in the solid state and in solution; this is assigned to I → Co charge transfer (14).

The pink cobalt nitrate complex, $Co(OBT)(NO_3)_2 \cdot 2H_2O$, has an electronic spectrum typical of a pseudo-octahedral system (Table 2). Two moderately intense bands are observed, and the spectrum bears a close resemblance to that of $Co(\alpha\text{-picoline})_2(NO_3)_2$, a six-coordinate pseudo-octahedral complex with bidentate nitrate groups (15). Again it appears that OBT is behaving as a bidentate N_2 donor.

Conductance measurements in nitromethane (Table 3) indicate that the cobalt complexes are all essentially non-ionised in solution at 10^{-3} *M*. The iodo-complex exhibits the highest molar conductance indicating a small degree of dissociation. It was noted that this complex was somewhat more sensitive than the others to hydrolysis in wet solvents. The cobalt nitrate complex appears to be a non-electrolyte in freshly prepared nitromethane solution but on standing some dissociation occurred (approximately 20 mho mol^{-1} cm^2 after 12 h). Magnetic moments (Table 3) are typical for pseudo-tetrahedral cobalt(II) systems, with the exception of the chloride complex which has a moment somewhat higher than one

would expect for systems of this type (3, 4, 13). The higher magnetic moment (5.18 BM) associated with the nitrato complex confirms the pseudo-octahedral nature of this system (15, 16).

The infrared spectra of all the cobalt complexes show a general similarity where vibrations associated with the ligand are concerned. A sharp band of medium intensity in the range 2985–2995 cm^{-1} is assigned to CH stretch (ν_1, A_1) in chloroform (Table 4) in the complexes $Co(OBT)X_2 \cdot CHCl_3$ (X = Cl, Br, NCS). In addition, a strong band around 740 cm^{-1} in these complexes is assigned to a chloroform deformation mode (ν_5, E). These bands are absent in the cobalt iodide complex and also in the copper and zinc halide complexes. Chloroform exhibits the ν_1 band at 3034 cm^{-1} in the vapour phase, while the ν_5 band occurs in the range 760–770 cm^{-1} for the gaseous or liquid phases. Shifts in these bands in the cobalt OBT complexes from their free solvent positions are consistent with a hydrogen bonded chloroform molecule and it is assumed that the coordinated anions act as acceptor sites (ref. 17 and references therein). Prolonged drying of these complexes under vacuum at moderate temperatures does not remove the solvent molecule.

The complex $Co(OBT)(NCS)_2 \cdot CHCl_3$ exhibits two bands due to CN stretch (2070, 2058 cm^{-1}) which are associated with two isothiocyanates in an approximately C_{2v} environment. A low energy band at 473 cm^{-1} (Table 4) can be assigned to NCS bending in an *N*-bonded thiocyanate (18). The ligand has a fairly rich spectrum in the far infrared region but in general the observed bands are not affected very much by coordination. Other bands below 350 cm^{-1} can be associated with metal–ligand vibrations (Table 4) (3, 4, 19).

The cobalt nitrate complex exhibits nitrate fundamentals (20) and combination bands (21) typical of bidentate nitrate, in keeping with the proposed monomeric nature of the complex (Table 4). Absorptions at 290, 268 cm^{-1} are tentatively assigned to Co—O stretch (3). It is apparent from the high energy region of the spectrum that water is present in this compound, even after prolonged drying. However, it is assumed that the water molecules occupy lattice sites and are not coordinated to the metal.

Copper Complexes

The electronic spectra of the copper complexes (Table 2) can be divided into two groups according to the presence or absence of moderately intense bands in the range 19 000 – 25 000 cm^{-1}. The complexes $Cu(OBT)X_2$ (X = Cl, Br) are characterized by absorptions at 17 000 cm^{-1} or below whose intensities are too low to be associated with charge transfer transitions and are assigned to *d–d* transitions. Bands of much higher intensity are found in the range 19 000 – 25 000 cm^{-1} and it is suggested that these are associated with ligand-to-metal charge transfer transitions. The nitrate complex does not exhibit bands above 17 000 cm^{-1} which can be associated with charge transfer and although the perchlorate complex has a fairly intense shoulder around 24 000 cm^{-1}, this may well be associated with a *d–d* transition.

Benzothiazole complexes $Cu(benzothiazole)_2X_2$ (X = Cl, Br) are reported by two groups to exhibit *d–d* bands in the range 12 500 – 13 700 cm^{-1} in the solid state, associated with polymeric, halogen bridged pseudo-octahedral structures (3, 4). Higher energy bands above 20 000 cm^{-1} are reported but are not discussed and it is assumed that in these complexes the benzothiazole acts as a nitrogen donor ligand. 2-(*o*-Hydroxyphenyl)benzothiazole (PBS) has been shown to form a *trans*-planar CuN_2O_2 complex in which the benzothiazole groups are nitrogen

bound. A *d–d* band occurs around 17 000 cm^{-1} and bands at 22 700 and 24 100 cm^{-1} are assigned to $\pi^* \leftarrow \pi$ or $\pi^* \leftarrow$ n intraligand transitions (10).

The copper nitrate complex exhibits an electronic spectrum which is essentially the same in both solid state and solution (Table 2) and is typical of a pseudo-octahedral system of the type $CuL_2(NO_3)_2$ (L = α-picoline, quinoline, isoquinoline) (15). OBT is assumed to behave as an N_2 donor. The mull transmittance spectrum of the perchlorate complex, $Cu(OBT)_2(ClO_4)_2 \cdot 2H_2O$ shows a *d–d* band at 16 700 cm^{-1} and a more intense high energy shoulder at 24 000 cm^{-1}. Square coplanar CuN_4 systems would be expected to exhibit two major transitions at fairly high energy with the higher energy band appearing at 20 000 cm^{-1} or higher. $Cu(LE)_2(ClO_4)_2$ (LE = 1,2-bis(2′-pyridyl)ethane) is assumed to have a square planar CuN_4 structure and exhibits bands at 18 200 and 21 600 cm^{-1} (22). $Cu(LP)_2(ClO_4)_2$ (LP = 1,2-bis(2′-imidazolin-2′-yl) benzene) has bands at 16 000 and 21 000 cm^{-1} attributable to a CuN_4 square planar structure.[2] The large separation in energy between the two bands observed in the spectrum of the perchlorate complex of OBT can be rationalised in terms of a square CuN_4 system in which axial perturbation is either reduced to a minimum or absent. Molecular models suggest that a *trans* arrangement of two OBT ligands about a square planar metal centre would effectively block both axial sites. As an alternative explanation the band at 24 000 cm^{-1} could be associated with a $\pi^* \leftarrow \pi$ or $\pi^* \leftarrow$ n intraligand transition while the lower energy absorption at 16 700 cm^{-1} could be assigned to a *d–d* transition in a *cis*-octahedral species involving two coordinated water molecules (infrared data suggest the possibility of coordinated water).

Recent reports of copper thioether complexes and their relation to 'blue' copper proteins (1, 23, 24) indicate that σ(S)→Cu LM charge transfer bands for thioether systems occur as fairly intense bands in the range 22 000 – 31 000 cm^{-1}. Copper complexes of 2,5-dithiahexane and 3,6-dithiaoctane have charge transfer bands of moderate intensity in the range 22 000 – 26 000 cm^{-1}, assigned to S→Cu charge transfer (25). Complexes with less polarizable amine type ligands, e.g. $Cu(en)_2^{2+}$ and its alkylated derivatives (26, 27) exhibit σ(N)→Cu charge transfer absorptions at ca. 40 000 cm^{-1}. OBT can be considered as a bis-imidazole (N_2) or as a bis-sulphur donor (S_2) or as a mixed ligand if NS coordination takes place. As a sulphur donor ligand it would perhaps be expected to exhibit S→Cu charge transfer at comparable energies to those mentioned previously. It is probably unwise to compare imidazoles with simple amines but it is unlikely that N→Cu charge transfer for imidazole systems would occur below 30 000 cm^{-1}. In a recent paper describing copper complexes of the tripod ligand tris(2-benzimidazylmethyl) amine, no bands below 30 000 cm^{-1} could be associated with imidazole N→Cu charge transfer (28).

The halide complexes exhibit fairly intense bands at 24 100 cm^{-1} (Cl) and 19 200 cm^{-1} (Br) in their solid state spectra which are assigned to π-halogen→Cu charge transfer (29, 30). Lower energy bands for the chloro complex at 13 600 cm^{-1} and 17 200 cm^{-1} are assigned to *d–d* transitions associated with a four coordinate species having an almost square arrangement of donor atoms. Solution studies on this species indicate the presence of the charge transfer band but a shift to lower energy of the *d–d* bands. This can be interpreted in terms of the pseudo-square solid state species becoming more tetrahedral in solution. The bromo complex exhibits an intense band at ca. 19 000 cm^{-1} both in the solid state and in solution, which is assigned to a πBr → Cu charge transfer transition while lower energy bands at 16 000 and 13 000 cm^{-1} can again be associated with *d–d* transitions in a four-coordinate species with a stereochemistry in between square and tetrahedral.

Although the charge transfer bands in the halide complexes fall in a range consistent with S→Cu charge transfer, this assignment has been excluded because of the large difference in energy observed for this band in the chloro- and bromo-derivatives and their otherwise general similarity. Recent X-ray data[3] confirm this assignment and show that the complex $Cu(OBT)Cl_2$ has an almost square planar CuN_2Cl_2 structure (Fig. 2).

Conductance measurements (Table 3) on the copper complexes indicate the perchlorate complex to be a 1:2 electrolyte in nitromethane, while the halide and nitrate complexes appear to be largely non-

ionised. Storing of nitromethane solutions of the halide complexes for extended periods of time induced decomposition of these systems. Magnetic moments (Table 3) appear to be normal for systems of this type.

Copper halogen stretching vibrations have been identified in the far infrared spectra (Table 4) of the halide complexes, suggesting an approximately C_{2v} environment for these groups around the copper centre. Lorenz *et al.* (10) observed a band in the infrared spectrum of $Cu(PBS)_2$ at 352 cm^{-1} which was assigned to Cu—N stretch for a nitrogen bound benzothiazole. No such band was observed in the spectra of the copper halide derivatives of OBT and between 240 and 370 cm^{-1} the only bands observed were those due to copper halogen stretching. Nitrate fundamentals and combination bands (20, 21) indicate bidentate nitrate groups for the complex $Cu(OBT)(NO_3)_2$ and low energy bands at 322, 305 cm^{-1} are assigned to Cu—O stretch.

Electron spin resonance parameters are summarised in Table 5. Frozen glass spectra in nitromethane of the nitrate and perchlorate complexes are typical of axial species. Resolvable nitrogen superhyperfine splitting is observed in the case of the nitrate complex but is absent in the perchlorate derivative. In contrast the room temperature spectrum of the perchlorate complex in nitromethane shows nitrogen superhyperfine splitting while the nitrato derivative does not. Spin Hamiltonian parameters are similar to those for $Cu(MeIm)_4(ClO_4)_2$ and $Cu(LP)_2(ClO_4)_2$ (Table 5) in nitromethane, although values of $g_{\|}$ are somewhat higher than those expected for a CuN_4 chromophore and suggest mixed NO in plane donor atoms, which would certainly be the case for the nitrate complex.[2]

Frozen glass spectra for the halide complexes in dichloromethane gave rather poorly defined signals at 77 K with little evidence for copper hyperfine splitting. Room temperature powder spectra are consistent with distorted square four-coordinate systems. The spectra are characterised by narrow line widths (15–18 G at half height in the $g_{\perp}$ region) and while no splitting due to copper nuclear spins is apparent only two resonance peaks are clearly re-

solved. Narrow line widths have been observed in the solid state spectra of sulphur bound systems, e.g., $Cu(3,5\text{-dithiahexane})_2(BF_4)_2$ (31), but clearly in this case we are dealing with a nitrogen bound system. Other CuN_2Cl_2 systems, e.g., Cu[2-(2-dimethylaminoethyl)pyridine]Cl_2 (32), Cu(sparteine)Cl_2 (33), have similar solid state spectra but larger g values, in keeping with the more tetrahedral nature of these complexes.

Zinc Complexes

Analytical and infrared spectral data confirm the four-coordinate pseudo-tetrahedral nature of these systems. Metal halogen vibrations compare with those observed for both the cobalt and copper halide complexes and metal–ligand vibrations, associated with metal–nitrogen stretch, are observed as fairly strong bands in the range 212–218 cm^{-1}.

Bis(acetylacetonato)copper(II) was sensitized by some ketones with a wide range of triplet energies to undergo photodecomposition to give the same products as that obtained in the direct photolysis but with much better efficiency. Other sensitizers such as fluorenone and aromatic hydrocarbons failed to sensitize the reaction. There exists no correlation of the sensitizer triplet energies with the sensitization results. This, and rapid quenching processes, indicated that the classical energy transfer process was unlikely. The sensitization process by an electron transfer within an encounter complex was proposed to explain the decomposition of $Cu(acac)_2$; the calculated free energy changes (ΔG) associated with the electron transfer from the available data support the proposal. Chemical reactions of excited state anthracene and 1-cyanonaphthalene with $Cu(acac)_2$ may also occur. Irradiation of $Cu(acac)_2$ in the presence of triphenylphosphine and benzophenone led to an excellent yield of $Cu(acac)(PPh_3)_2$ without causing precipitation of copper(I) complexes.

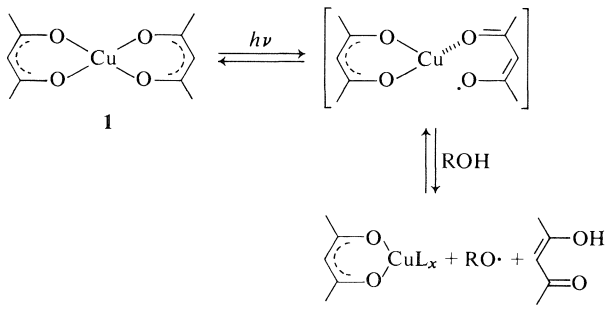
On a sensibilisé du bis(acétylacétonato) cuivre(II) par quelques cétones couvrant une gamme étendue d'énergies d'états triplets provoquant une photodécomposition conduisant aux mêmes produits que par photolyse directe mais avec une meilleure efficacité. D'autres sensibilisateurs comme la fluorénone et des hydrocarbures aromatiques n'ont pas réussi à sensibiliser la réaction. Il n'existe aucune corrélation entre les énergies triplet des sensibilisateurs et les résultats des sensibilisation. Ce résultat et le fait que le processus d'extinction est rapide indiquent que le transfert classique d'énergie est peu probable. Le processus de sensibilisation par un transfert d'électron à l'intérieur d'un complexe de rencontre a été proposé pour expliquer la décomposition du $Cu(acac_2)$; les changements calculés d'énergie libre (ΔG) associée avec les transferts d'électrons disponibles à partir de données publiées sont en accord avec les propositions. Il peut aussi se produire des réactions chimiques entre les états excités de l'anthracène et du cyano-1 naphtalène avec le $Cu(acac)_2$. L'irradiation du $Cu(acac)_2$ en présence de triphénylphosphine et de benzophénone conduit à un excellent rendement du $Cu(acac)(PPh_3)_2$ sans provoquer de précipitation de complexes du cuivre(I).

[Traduit par le journal]

In connection with other research projects we have undertaken investigations of photochemical decomposition of bis(acetylacetonato)copper(II) (**1**) in organic solvents. While there are many photochemical studies of other first row transition metal β-diketonate complexes (1, 2), only one report (3) on photodecomposition of copper(II) β-diketonate complexes can be found in the literature. This and other studies (1, 4–6) of copper compounds use direct irradiation of solutions and have reported observations of reduction of copper(II) to copper(I) or metallic copper. Direct photodecomposition of copper(II) β-diketonates in alcohols, however, occurs only by irradiation of the charge transfer band of the ligand-to-metal type (CTTM) (3) at 230–250 nm and gives low quantum yields of <0.04. These studies have led the authors to propose the following mechanism



1

where L is a ligand derived from solvent. The copper(I) complex thermally decomposes to Cu^0 as reported previously (7). Noting earlier studies

0008-4042/79/010008-09$01.00/0

that transition metal complexes have marked activity as quenchers for the triplet states of organic molecules (8–10), we have decided to investigate the sensitized photodecomposition of bis(acetylacetonato)copper(II) in detail. In a recent publication (4) it was briefly mentioned that benzophenone and acetophenone sensitize the photodecomposition of polyfluorinated copper β-ketoacetonates. The general reaction pattern is reported here.

Results

In preliminary experiments methanol solutions of bis(acetylacetonato)copper(II), $Cu(acac)_2$, were irradiated in a conventional immersion type quartz photocell. This apparatus was clearly unsatisfactory because of the deposition of black precipitates followed by the formation of lustrous metallic copper mirrors, both of which obstructed the incident light. Nevertheless, we confirmed several features of the photodecomposition reported (3), e.g., (*i*) the blue colour of $Cu(acac)_2$ disappeared slowly under nitrogen to form metallic copper with a quartz but not a Pyrex filter, (*ii*) the photolysate, on exposure to air, was slowly converted to a blue solution of $Cu(acac)_2$, and (*iii*) under oxygen, the Cu(II) complex was irreversibly decomposed on irradiation.

In order to avoid the deposition problems, an apparatus as shown in Fig. 1 was designed in which the solution was irradiated from overhead with Hanovia Mercury lamp (SH 616 A0130, 140 W). This set-up proved to be satisfactory for semi-quantitative experiments, although it may not be a suitable apparatus for accurate quantitative studies. Since $Cu(acac)_2$ in alcohol solutions absorbs light strongly at λ_{max} 293 nm (ε, 23 500) which tails to the 370 nm region with $\varepsilon \sim 600$ at 330 nm, concentrations for the sensitizations were adjusted so that sensitizers absorb part or all of the incident light energy. Irradiation of a methanol solution of $Cu(acac)_2$ (5.7 mmolar) containing 6.3 mmolar of benzophenone under nitrogen gave a suspension of black precipitate in 3 h with concurrent discharge of the blue colour. On continued irradiation, the suspension changed to lustrous copper particles suspended in a colourless solution (or gave a copper mirror) in 18 h. The progress of the photoreaction was monitored by following the decrease of the absorption band of $Cu(acac)_2$ at 630 nm. The yield of copper was determined by colorimetry to be quantitative. The colourless solution contained acetylacetone (78%), as determined by high pressure liquid chromatography (HPLC) and uv spectroscopy, and formaldehyde (50% as its 2,4-DNPH); benzophenone was recovered quantitatively and the absence of benzpinacol was ascertained. Irradiation of an ethanol solution of $Cu(acac)_2$ in the absence of benzophenone through a quartz filter under similar conditions took more than 24 h to cause a 10% decrease in the intensity of the band at 630 nm.

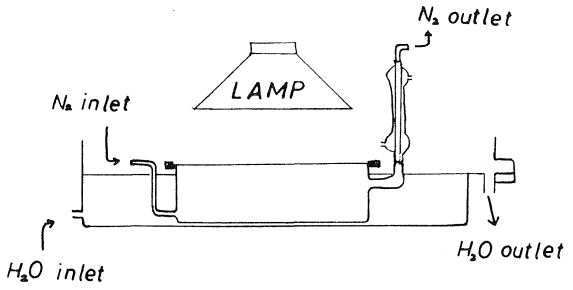


FIG. 1. Photolysis apparatus.

The metallic copper suspension, obtained after photolysis, was stable under nitrogen. However, on exposure to air it dissolved slowly and reverted quantitatively to give $Cu(acac)_2$ with the original concentration. This occurred more rapidly under oxygen purging; in both cases benzophenone was recovered nearly quantitatively. The suspension of the black precipitate in the transparent solution also reverted quantitatively to the original $Cu(acac)_2$ solution under oxygen and to half of the original $Cu(acac)_2$ concentration under nitrogen as determined by uv spectroscopy; metallic copper was also deposited in the latter case.

The effect of solvent was such that the sensitized photodecomposition of $Cu(acac)_2$ in ethanol caused appearance of the black precipitate within 30–40 min and in isopropanol within 15 min. In both cases copious amounts of the black suspension were formed rapidly as irradiation proceeded. The suspension was transformed to metallic copper (100% and 98%, respectively) on prolonged irradiation in 3 and 1 h, respectively. The yields of acetylacetone were analysed to be 84% and 76%, and the oxidation products of the solvents, acetaldehyde and acetone, were determined to be 38% and 69%, respectively. Benzophenone was recovered in high yields in both cases.

Under similar conditions, the benzophenone-sensitized photodecomposition of $Cu(acac)_2$ in tetrahydrofuran solution followed a similar pattern, i.e., disappearance of the 630 nm band in 1.5 h and complete reduction to Cu^0 in 6 h. However, oxidation products of THF could not be isolated. In benzene and chloroform the photodecomposition occurred very slowly but the colour changed to deep green and was not pursued further. The pattern of photo-

chemical changes in 1:1 mixtures of benzene–methanol or chloroform–methanol were the same as those observed in the alcohol solutions.

In the presence of $<0.1\ M$ 1,3-pentadiene, benzophenone-sensitized photodecompositions of $Cu(acac)_2$ ($6 \times 10^{-3}\ M$) were not retarded, but when the concentration of the diene was 0.15 or 0.70 M, the black precipitate was formed in lesser amounts. In the presence of $1.14 \times 10^{-2}\ M$ triethylamine the photodecomposition was not retarded, and benzophenone was not consumed. When the photodecomposition was carried out in methanol in the presence of 0.6 M cyclohexene, dicyclohexenyl was formed, as shown by tlc and vpc analyses, together with the formation of a copper mirror and recovered benzophenone.

As the primary photodecomposition product was the black precipitate, its identity was investigated. Its ready disporportionation to $Cu(acac)_2$ and Cu^0 appeared to be similar to the behaviour of a cuprous complex, $Cu(acac)\cdot 2.5NH_3$, prepared by Nast *et al.* (7). The black precipitate when treated with ethanol solution of triphenylphosphine under nitrogen gave a white crystalline compound analyzing as $Cu(acac)(PPh_3)_2$. Benzophenone sensitized photolysis of $Cu(acac)_2$ in the presence of triphenylphosphine gave a colourless, clear solution without formation of the black precipitate. From this photolysate the above crystalline compound (94%), acetylacetone (80%) and acetaldehyde (42% as 2,4-DNPH) were obtained. The compound was not formed in the dark. It exhibited identical ir and nmr data as those of $Cu(acac)(PPh_3)_2$ reported in the literature (11).

Other sensitizers were investigated in order to gain an insight to the mechanism of the photodecomposition. The results are summarized in Table 1. Photodecomposition of $Cu(acac)_2$ could be sensitized by anthrone, benzophenone, biacetyl, and xanthone (shown in order of decreasing efficiency). In all these sensitized decompositions the black precipitate, metallic Cu, and acetylacetone were formed in nearly stoichiometric yields and the sensitizers were recovered almost quantitatively. Vapour phase chromatographic analyses of the recovered anthrone and biacetyl showed small peaks that were assumed to be minor photoproducts of the sensitizers as they are known to decompose photolytically (12). Other sensitizers shown in Table 1 failed to photodecompose $Cu(acac)_2$ as indicated by uv and visual observation. Except in a few cases to be described below, the sensitizers were recovered quantitatively and no acetylacetone or black precipitate was obtained.

Fluorenone failed to sensitize the photodecomposition of $Cu(acac)_2$ in methanol or isopropyl alcohol on prolonged irradiation. Although in the latter solvent the absorption maximum at 630 nm was shown to shift to ~680 nm, no product other than the starting material was recovered from the photolysate in either solvent. Photolysis of a methanol solution containing $Cu(acac)_2$ and anthracene immediately precipitated the dimer of the latter (13). On prolonged irradiation the dimer was obtained in 70% yield and 60% of the $Cu(acac)_2$ was recovered. Trace amounts of other unidentified products were also detected by vpc but no acetylacetone was obtained. In the phenothiazine sensitized photodecomposition only 60% of $Cu(acac)_2$ was recovered and trace amounts of other products were detected by tlc. While prolonged photolysis gave a dark brown solution, phenothiazine was recovered in ~80% yield.

An attempted sensitization with 1-cyanonaphthalene did not cause reduction to the black precipitate but proceeded slowly to show a 15% decrease of the optical density at 630 nm and deposited a small amount of blue precipitate. The ir and melting point were identical with the compound obtained by reaction of $Cu(acac)_2$ in methanolic KOH solution for which structure **2** was assigned from ir, uv, and visible spectra (14). The authors (14) determined the magnetic moment to be 0.75 BM. The paramagnetic nature was shown by broad nmr and esr signals. The elemental analysis of our product indicated an empirical formula of $Cu(acac)OCH_3$. The ir spectrum showed, in addition to the ir peaks of $Cu(acac)_2$, absorption at 2820, 1070, and 560 cm^{-1} (but no absorption above 3000 cm^{-1}), indicating the presence of a methoxide moiety. A chloroform solution of the blue precipitate was evaporated to give a residue which showed an identical ir (KBr) spectrum to that of $Cu(acac)_2$. The mass spectrum of the blue precipitate showed *m/e* peaks at 386, 355, 324, and 261 (100%) corresponding to M^+, $M^+ - [OCH_3]$, $M^+ - 2[OCH_3]$, and $M^+ - [Cu(OCH_3)_2]$. The fragmentation pattern below *m/e* 263 was very similar to that of $Cu(acac)_2$. Structures **3** and **4** besides **2** could be suggested for the compound; **4**, however, appears to satisfy the mass spectral data better than the others.

Phenothiazine	5.0	EtOH	62[f]	—	—	−

[a]The progress of reactions was followed by uv spectroscopy at 630 nm and the recovered materials were analysed by vpc, tlc, and in some cases by isolation. The details are described in the results.
[b]Unless specified otherwise, $E_{(A/A^-)}$ in dimethylformamide (38).
[c]The triplet energies were quoted from ref. 39.
[d]The $E_{(A/A^-)}$ was obtained in CH_3CN as reported in ref. 24. If E_s = 89.4 kcal/mol was used for the calculation, ΔG = −8.1 kcal/mol.
[e]Quoted from ref. 26.
[f]The approximate E_T calculated from the triplet absorption maximum at 460 nm (33).

Discussion

The results described above show that certain carbonyl compounds sensitize the photodecomposition of $Cu(acac)_2$ much more efficiently than direct photodecomposition. The product patterns in both cases are the same, i.e., acetylacetone and a copper(I) acetylacetonate complex are the primary photoproducts. The latter thermally disproportionates to Cu^0 and $Cu(acac)_2$ under nitrogen or is oxidized to $Cu(acac)_2$ under oxygen. Heterogeneity of the reaction can be avoided by running the photolysis in the presence of triphenylphosphine whereby the intermediate copper(I) complex could be intercepted to form soluble $Cu(acac)(PPh_3)_2$; this provides a direct proof that a copper(I) complex is the primary photoproduct. Since in the presence of 0.1 M acetylacetone, where the incident light is mostly absorbed by acetylacetone (see Table 1), $Cu(acac)_2$ does not decompose, it is concluded that the slow direct photodecomposition is not catalysed by acetylacetone. The reaction pathway can be expressed by reactions [1]–[4] where S* is an excited state sensitizer.

[1] $Cu(acac)_2 + S^* \longrightarrow Cu(acac) +$  $+ S$

5

[2] $Cu(acac) + xL \longrightarrow Cu(acac)L_x$

[3] $Cu(acac) + 2PPh_3 \longrightarrow Cu(acac)(PPh_3)_2$

[4] $Cu(acac)L_x \xrightarrow{N_2} Cu(acac)_2 + Cu^0 + xL$

Since disproportionation of the copper(I) complex as in reaction [4] is rather slow in the solvents used in comparison to photodecomposition of $Cu(acac)_2$ (see reactions [1] and [2]) the black precipitate always appears first followed by the slow appearance of metallic copper. In ethanol or propanol, the photodecomposition of reactions [1] and [2] occurs much faster as seen by the rapid disappearance of the blue colour of the $Cu(acac)_2$ solution and immediate heavy deposition of the black precipitate. In the presence of triphenylphosphine the step of reaction [4] is circumvented and the sensitized photodecomposition occurs rapidly under homogeneous conditions. Provided that triphenylphosphine does not affect the rate of reaction [1], these conditions might allow quantitative studies of the sensitized photodecomposition in a homogeneous solution.

Stoichiometrically, the reduction of copper(II) to copper(0) via copper(I) in the sensitized photodecomposition must be coupled with the oxidation reaction of alcohols to carbonyl compounds. The mechanism of the oxidation might be related to the way an acetylacetonate ligand acquires a hydrogen to form acetylacetone. That the redox processes take place by radical mechanism is suggested by the following observations. Firstly, poor H-atom donating solvents, such as benzene and chloroform, do not promote the photoreduction. Secondly, the sensitized photoreduction occurs in alcohols with a decreasing order of efficiency of isopropyl alcohol > ethanol > methanol, which coincides with the efficiency order (15) in which these alcohols donate an α-hydrogen (but not hydroxy hydrogen) (3) by a radical mechanism. Finally, the formation of dicyclohexenyl in the sensitized photodecomposition of

$Cu(acac)_2$ in the presence of cyclohexene is consistent only with a radical mechanism. Therefore the yet unproven acetylacetonatoxy radical **5** might be suggested as the reactive intermediate in mediating the oxidation reaction by abstraction of an α-hydrogen of alcohols as shown in reactions [5] and [6]. Further, if a competing electron transfers from Cu(acac) to **5** is assumed to occur (reaction [7]), it is possible to explain the order of the photoreduction efficiency in these alcohols.

[5] $\mathbf{5} + RCH_2OH \rightarrow CH_3COCH_2COCH_3 + R\dot{C}HOH$

[6] $2R\dot{C}HOH \rightarrow RCH_2OH + RCH{=}O$

[7] $\mathbf{5} + Cu(acac) \rightarrow Cu(acac)_2$

Various mechanisms could operate in the sensitization step of reaction [1]. A hydrogen atom transfer from alcohol to $Cu(acac)_2$ mediated by the triplet state sensitizer as in reactions [8] and [9] is attractive in view of the well established reaction pattern of the benzophenone triplet state (16).

[8] $^*(C_6H_5)_2CO + RCH_2OH \rightarrow (C_6H_5)_2\dot{C}OH + R\dot{C}HOH$

[9] $(C_6H_5)_2\dot{C}OH + Cu(acac)_2 \rightarrow (C_6H_5)_2CO + Cu(acac) + acacH$

This mechanism, however, suffers inconsistency in that the H-abstraction by the benzophenone triplet is fairly slow ($k = 1.8 \times 10^6\ M^{-1}\ s^{-1}$ from isopropanol) and readily quenched by 1,3-pentadiene (16).

The direct photodecomposition has been speculated to occur by an internal redox process arising from the excitation of the charge-transfer or the ligand-to-metal band (CTTM) at 243 nm ($E \sim 119$ kcal/mol), based on which the acetylacetonatoxy radical **5** has been proposed as the intermediate (3). Since $Cu(acac)_2$ shows no emission, the energy levels of its excited states are unclear. While the sensitized photodecomposition might be assumed to proceed from a yet undefined excited state of $Cu(acac)_2$ by an internal redox mechanism similar to that proposed for direct photolysis, evidence as shown in Table 1 is against a classical triplet energy transfer mechanism (17) from excited states of the sensitizers to the ground state of $Cu(acac)_2$. For example, the order of sensitization efficiency, i.e., anthrone > benzophenone > biacetyl > xanthone, does not agree with the order of the lowest triplet energies of the sensitizers. It is also apparent none of these ketones has a singlet state energy high enough to successfully activate the CTTM band transition for $Cu(acac)_2$.

There are many investigations on the mechanism of sensitized reactions in metal complexes (18–21). It was found that (18–21) the luminescent excited state of polypyridineruthenium(II) complexes is quenched by various metal ions or complexes by either electron transfer or energy transfer mechanisms depending on the nature of the quenchers. In particular, this state of the ruthenium(II) complexes can act as an electron donor as well as an acceptor for a wide range of quenchers. On the other hand, Wilkinson (22) and others (23) have observed that the quenching efficiencies of the triplet states of organic compounds by iron and other coordination complexes are dependent on the relative energy levels of interacting states, from which energy transfer is put forward as the mechanism of quenching. While reinterpretation of Wilkinson's results (22) by an electron transfer mechanism might reveal more details, the present sensitized decomposition is not likely to occur by energy transfer for reasons given.

From the results of kinetic flash photolysis investigations Hammond and co-workers (24) have recognized that some transition metal complexes quench triplet states of a variety of sensitizers efficiently and that k_q are not correlated with the sensitizer triplet energy levels. The rate constants are $k_q \geq 10^9\ M^{-1}\ s^{-1}$ with very little variation. They have concluded that either the complexes have low lying excited states to which they can be promoted by energy transfer or with these complexes quenching does not involve energy transfer (24). In the present case, the former assumption is untenable from the pattern as shown in Table 1. An extremely high quenching rate of benzophenone excited states by $Cu(acac)_2$ is evident in the present investigation. The inefficient retardation of benzophenone-sensitized $Cu(acac)_2$ decomposition by 1,3-pentadiene indicates that the sensitization process is much faster than the quenching of the lowest triplet benzophenone by the diene, the rate constant (25) of which has been calculated to be $3.75 \times 10^9\ M^{-1}\ s^{-1}$. Triethylamine, which quenches triplet state benzophenone at a rate constant (26) of $2.3 \times 10^9\ M^{-1}\ s^{-1}$, does not retard the sensitized $Cu(acac)_2$ decomposition at all. Both observations indicate that an excited state benzophenone is quenched by $Cu(acac)_2$ with a rate constant at least an order of magnitude higher than these constants, or say $\sim 3 \times 10^{10}\ M^{-1}\ s^{-1}$. Such a rate constant is in the region of the diffusion-controlled bimolecular encounter rate constant (27), in methanol at 20°C $k_{diff} = 1.8 \times 10^{10}\ M^{-1}\ s^{-1}$. Since the uv spectrum of a methanol solution containing $Cu(acac)_2$ and benzophenone is essentially a composite of the individual uv spectra, formation of a ground state complex is not evident.

The sensitization of reaction [1] is thought to occur by electron transfer from the ligand of $Cu(acac)_2$ to excited states of the sensitizers (S*) via an unspecified encounter complex (and/or exciplex) as shown in reactions [10] and [11]. The free energy

change (ΔG) associated with the electron transfer in the encounter complex (reaction [10]) is represented by reaction [12] in which $E_{(D/D^+)}$ is the oxidation potential of the donor, $E_{(A/A^-)}$ the reduction potential of the acceptor, and ΔE_{0-0} the excited state energy of the acceptor in the present case (26, 29). The coulombic attraction term $e_0^2/\varepsilon\alpha$ in a polar medium with encounter distance of ca. 7 Å is small and is omitted in the calculation. Reaction [12] has been proposed by Rehm and Weller (28) from kinetic analysis of quenching and has been successfully applied by others (26, 29) to account for sensitization by electron transfer.

[10] $Cu(acac)_2 + S^* \rightleftarrows [Cu(acac)_2\text{---}S^*]$
Encounter complex
$\rightleftarrows Cu(acac)_2{}^{+\bullet}\text{---}S^{-\bullet}$
Solvated ion pair

[11] $Cu(acac)_2{}^{+\bullet}\text{---}S^{-\bullet} \rightarrow Cu(acac)_2{}^{+\bullet} + S^{-\bullet}$

[12] $\Delta G(\text{kcal/mol}) = 23.06[E_{(D/D^+)} - E_{(A/A^-)} - e_0^2/\varepsilon\alpha] - E_{0-0}$

In the present case, $E_{(D/D^+)}$ of $Cu(acac)_2$ is calculated (26, 30) from its ionization potential (IP = 7.75 eV) (31). These calculations (Table 1) show that the electron transfer to the triplet state of the first four ketones is spontaneous but to other sensitizers it is not, in general agreement with the observed experimental results. In polar alcoholic solvents, the electron transfer is complete as in reaction [10] and the ion pair separation of reaction [11] is probably facilitated wherefrom reactions of the individual radical ions may be observed.

The subsequent reactions of these radical ions remain a matter of conjecture at present. Among various possibilities reactions [13]–[14] might be proposed to conclude the photoreduction in analogy to those proposed for sensitized addition to olefins (29).

[13] $Cu(acac)_2{}^{+\bullet} \rightarrow Cu(acac)^+ + \mathbf{5}$

[14] $Cu(acac)^+ + S^{-\bullet} \rightarrow Cu(acac) + S$

In addition to the quenching process described so far, excited states of anthracene and 1-cyanonaphthalene (and probably of fluorenone) in alcohols appear to undergo unknown and slower chemical reactions to cause consumption of $Cu(acac)_2$ and/or to give other products, such as $[Cu(acac)(OCH_3)]_2$, rather than the reduction products. These reactions were not studied further but must occur at comparable rates to the photoreduction. Fluorenone has been shown to possess a $\pi \rightarrow \pi^*$ transition as its lowest triplet state and to be photostable in alcohols (32). Formation of the dimer from photolysis of anthracene has been well known for some time (13). The singlet excited state of 1-cyanonaphthalene is a good electron acceptor from β-phenylalkyl ethers and diphenylethylene and has been successfully used to sensitize photoreaction of these substrates (29). It should be mentioned that in the photolysis of 1-cyanonaphthalene and $Cu(acac)_2$, 1,3-pentadiene (0.3 M) did not retard the formation of $[Cu(acac)(OCH_3)]_2$.

The triplet states of fluorenone and anthracene have been shown to be quenched by $Cu(acac)_2$ in benzene solution at rate constants of 1.0×10^9 and 0.6×10^9 M^{-1} s^{-1}, respectively, as determined by flash photolysis (24). As fluorenone is photostable in alcoholic solution (32), we could not observe the extent of quenching by $Cu(acac)_2$ using stationary state methods. The reason for quenching of these excited states without decomposition of $Cu(acac)_2$ is not immediately clear. If the proposed mechanism for the sensitized $Cu(acac)_2$ decomposition is accepted, it might suggest that, in fluorenone and anthracene sensitization, the solvated ion pairs are readily decayed to the ground state through the reverse electron transfer.

In methanol solution the phenothiazine triplet state has been shown to be quenched by electron transfer to metal ions to give phenothiazine cation radical and the reduced metal ions provided the reduction potentials of the latter are favorable (33); the quenching rate constant by Cu^{2+} ion was determined to be 6×10^9 M^{-1} s^{-1} in methanol. The failure to photolytically reduce $Cu(acac)_2$ by phenothiazine photosensitization suggests that reduction of the complex by the direct electron transfer to the metal does not occur. The free energy change associated with the direct electron transfer from the triplet excited state phenothiazine or carbazole to $Cu(acac)_2$ are calculated from reaction [12] to be −37 and −27 kcal/mol, respectively. The negative experimental results might be taken as an indication that this mode of electron transfer is not operating.

In summary, there are compelling reasons to believe that excited states of these organic sensitizers are quenched by $Cu(acac)_2$ by accepting one electron from $Cu(acac)_2$ and/or by entering other chemical reactions with $Cu(acac)_2$: operation of the classical energy transfer is unlikely.

Experimental

Melting points (mp) were determined on a Fisher-Johns apparatus and were uncorrected. Infrared spectra (ir) were obtained with a Perkin-Elmer 457 spectrophotometer, ultraviolet and visible spectra with a Cary 17 spectrophotometer, mass spectra with a Hitachi-Perkin-Elmer RMU-6E instrument, and nmr spectra with a Varian A56/60 spectrometer in $CDCl_3$ using TMS as an internal standard. Vapour phase

chromatographic analyses were performed on a Varian 1200 (flame ionization detector) with a 10% SE-30 (6 ft × 1/8 in.) column. The gas chromatographic – mass spectra (gc–ms) used a 20% SE-30 (10 ft × 1/8 in.) column in a Varian 1400 which was directly coupled to the mass spectrometer. High pressure liquid chromatography was carried out with a Varian Model LC-4010-1 using a Porasil C-400 (37–75 μ) column. Elemental analyses were carried out by M. K. Yang on a Perkin-Elmer 240 microanalyzer.

Materials

Sensitizers were commercially available and purified by recrystallization, vacuum sublimation, or combinations of both. $Cu(acac)_2$ was prepared by the known method (34) and recrystallized from benzene. Solvents were previously distilled and stored over molecular sieves. Tetrahydrofuran (THF) was distilled from lithium aluminum hydride and stored over sodium. Nitrogen gas (Union Carbide of Canada) was scrubbed with a Fieser's solution and dried with sulfuric acid before being introduced to the reaction vessel.

Photolysis Procedure

The photolysis apparatus (Fig. 1) consisted of a cylindrical vessel fitted with a condenser, a Pyrex plate cover, and a gas inlet tube. A solution of $Cu(acac)_2$ (~100 mg) and sensitizer in 100 ml of solvent under nitrogen was irradiated with a 140 W Hanovia mercury lamp (SH 616 A 0130) at running water temperature. The progress of the reaction was followed by examining the decrease in the visible absorption of $Cu(acac)_2$ at ~630 nm. After photolysis copper was filtered and determined, after dissolution in HNO_3 (1:1), by colorimetric methods (35). The filtrate was distilled, the first fraction being collected with a receiver (cooled on a dry ice – methanol bath) containing a 2,4-DNPH solution. The yellow precipitate was filtered and recrystallized to afford the 2,4-DNPH of volatile carbonyl compounds. The second fraction containing the major part of the solvent was analyzed by HPLC to give only one peak which had the same retention times with acetylacetone. The concentration of acetylacetone was calculated from its uv absorption at λ_{max} 273 nm. The residue was analyzed by vpc or tlc. Sensitizers and/or products were separated when possible by preparative tlc or column chromatography on silica gel.

Benzophenone Sensitization

(a) In Methanol

A solution of $Cu(acac)_2$ (150 mg, 0.57 mmol), benzophenone (112 mg, 0.64 mmol) in methanol (100 ml) was irradiated to give a black solid after ~3 h. Irradiation for 18 h gave metallic copper suspension. The filtered solution showed no absorption at 630 nm. Copper (98%) was separated by filtration using a sintered glass funnel. A cold trap containing 15 ml of 2,4-DNPH solution was used to trap volatile compounds during filtration. A yellow precipitate was filtered out, washed, and dried under vacuum to give the 2,4-dinitrophenylhydrazone of formaldehyde (55 mg, 46%); the solid was recrystallized from methanol:H_2O, mp 166–168°C (lit. mp 166°C) (36). The filtrate was evaporated in a flash evaporator to give a solid (107 mg, 96%); mp 48–50°C; the ir spectrum superimposable with that of benzophenone. The distillate was analysed by HPLC to give one peak corresponding to acetylacetone. The uv spectrum of the distillate with 100-fold dilution showed λ_{max} 273 nm, O.D. = 0.52. The yield of acetylacetone was estimated from the O.D. (0.76 mmol, 67%). A similar photolysis was run in the presence of cyclohexene (250 mg). Copper was filtered. The solvent in the filtrate was evaporated to a small volume. Both tlc and vpc analysis showed the presence of benzophenone and dicyclohexenyl.

(b) In Ethanol

A solution of $Cu(acac)_2$ (120 mg, 0.46 mmol), benzophenone (112 mg, 0.64 mmol) in ethanol (100 ml) was irradiated to give a black solid after 1 h. After 3 h metallic copper suspension was observed and the absorption at 630 nm of a filtered aliquot disappeared. Usual work-up of the photolysate gave copper (100%), acetylacetone (0.77 mmol, 84%), and benzophenone (104 mg, 93%), the 2,4-DNPH of acetaldehyde (29 mg, 28%); mp 146–148°C; lit. mp 147°C (ref. 36, p. 320).

(c) In Isopropyl Alcohol

A solution of $Cu(acac)_2$ (50 mg, 0.19 mmol), benzophenone (112 mg, 0.64 mmol) in isopropyl alcohol (100 ml) was photollyzed to give a black solid after 15 min. After 1 h copper suspension was formed and no absorption at 630 nm was observed. Copper (98.4%) was filtered out and determined by the usual method (35). The filtrate was distilled (3 ml) into a receiver containing a 2,4-DNPH solution to give a solid (33 mg, 73%) which was recrystallized from ethanol–H_2O to give the 2,4-DNPH of acetone; mp 124–126.5°C (lit. mp 126°C) (37). The remainder was flash evaporated to give benzophenone (98 mg, 88%). HPLC analysis of the distillate showed the presence of acetylacetone (0.29 mmol, 76%) as determined by the O.D. at λ_{max} 273 nm.

(d) In THF

A solution of $Cu(acac)_2$ (200 mg, 0.77 mmol), benzophenone (164 mg, 0.94 mmol) in THF (100 ml) was irradiated to give a black solid after 3.5 h. After 7 h metallic copper was formed and the absorption at 630 nm disappeared. Copper (43 mg, 89%) was filtered. The filtrate was flash evaporated to give a yellow oil (214 mg). Analysis by vpc showed the presence of benzophenone and two minor compounds which were not identified. Acetylacetone (0.94 mmol, 61%) was determined by the O.D. at 273 nm.

(e) In the Presence of PPh_3

A solution of $Cu(acac)_2$ (100 mg, 0.38 mmol), benzophenone (112 mg, 0.64 mmol), and PPh_3 (240 mg, 0.92 mmol) in ethanol (100 ml) was irradiated for 2 h to give a colorless solution. The absorption at 630 nm had disappeared. The solution was distilled and the distillate was worked up as usual to give acetaldehyde (42%) and acetylacetone (80%). The residue was treated with ether and filtered to give a white solid (242 mg, 92%); mp 176–179°C; ir (Nujol) 1598, 1583, 1508, 745, and 700 cm^{-1}; nmr ($CDCl_3$) δ 1.76 (s, 6H), 5.08 (s, 1H), and 7.21 (s, 30H). The ir and nmr spectra were identical with those of $Cu(acac)(PPh_3)_2$ (37). *Anal.* calcd. for $C_{41}H_{37}CuO_2P_2$: C 71.65, H 5.4; found: C 71.76, H 5.5. Preparative tlc of the residue on silica gel (elution with CH_2Cl_2) gave benzophenone (109 mg, 97%) and PPh_3 (43 mg, 0.16 mmol).

Fluorenone Sensitization

(a) In Methanol or Isopropyl Alcohol

A solution of $Cu(acac)_2$ (100 mg, 0.38 mmol) and fluorenone (200 mg, 1.10 mmol) in 100 ml of solvent was irradiated for 28 h. The visible spectra of the photolysate showed no decrease of O.D. at 630 nm. After work-up $Cu(acac)_2$ and fluorenone were recovered.

1-Cyanonaphthalene Sensitization

(a) In Methanol

$Cu(acac)_2$ (100 mg, 0.38 mmol) in methanol (100 ml) was irradiated in the presence of 1-cyanonaphthalene (100 mg, 0.65 mmol) for 48 h. A blue solid (15 mg) was filtered off, washed with methanol, and dried under vacuum; mp 205–209°C; ir (KBr) 2820, 1590, 1530, 1400, 1360, 1275, 1070, 1025, 775, 560, and 460 cm^{-1}; ms (%) 386 (M^+, 0.6), 355 (1.0), 324 (20.4), 261 (100), 246 (75), 231 (56), 225 (6.4), and 43 (41). *Anal.* calcd. for $C_6H_{13}O_3Cu_2$: C 37.21, H 5.16; found: C

36.81, H 5.04. $[Cu(acac)(OMe)]_2$ was prepared by the method of Bertrand and Kaplan (14) and was identical, by ir and mass spectra, to the product obtained above. After work-up of the filtrate 76 mg of $Cu(acac)_2$ were recovered. Analysis by vpc indicated that 1-cyanonaphthalene was recovered unchanged.

(b) In Ethanol or THF

Solutions were irradiated for 48 h. After the usual work-up, the starting materials were quantitatively recovered.

Photolysis in the Presence of Other Sensitizers

Xanthone

A solution of $Cu(acac)_2$ (100 mg, 0.38 mmol) and xanthone (250 mg, 1.27 mmol) in methanol (100 ml) was irradiated for 48 h to give metallic copper suspension. A 50% decrease was observed in the 630 nm band. The usual work-up of the solution gave copper (48%) and acetylacetone (30%) determined as before. $Cu(acac)_2$ and xanthone were recovered in 40% and 96%.

Biacetyl

A solution of $Cu(acac)_2$ (100 mg, 0.38 mmol) and biacetyl (5 g, 48 mmol) in ethanol (120 ml) was irradiated to give a black solid after 1 h. After 6.5 h metallic copper was formed and no absorption was observed at 630 nm. Copper was filtered and determined as usual in 81% yield. The filtrate was analyzed by vpc to show two major and five minor peaks. The major peaks were shown to be biacetyl and acetylacetone by peak matching.

Anthrone

A solution of $Cu(acac)_2$ (100 mg, 0.38 mmol) and anthrone (86 mg, 0.45 mmol) in ethanol (120 ml) was irradiated to give a black solid after 15 min. Irradiation for 3.5 h gave metallic copper suspension and the solution showed no absorption at 630 nm. Filtration attempts were unsuccessful due to the colloidal nature of copper. The solution was flash evaporated to give a red–brown solid (99 mg). After treatment with ether, copper (92%) was filtered and determined as usual. The filtrate was evaporated to give a yellow solid (74 mg). Treatment with acetone (10 ml) gave an unidentified white solid (12 mg); mp 136–142°C; ir (KBr) ~3500, 1470, 1190, 1035, 780, 740, 700, 670, 650, and 640 cm^{-1}. The vpc of the filtrate showed one major peak, matching in retention time with anthrone, and one unidentified minor peak. Acetylacetone (68%) was determined from the distillate.

Anthracene

A solution of $Cu(acac)_2$ (100 mg, 0.38 mmol) and anthracene (100 mg, 0.56 mmol) in methanol (100 ml) was photolyzed to give white crystals after 15 min. Irradiation for 28 h showed an ~60% decrease in absorption at 630 nm. Formation of copper was not observed. The solution was filtered to give anthracene dimer (76 mg, 76%); mp 274–276°C (lit. mp 275°C) (13); ir (Nujol) 1300, 1220, 1160, 945, 820, 770, 760, and 680 cm^{-1}; ms (%), 356 (M^+, 4.5) and 178 (100). The filtrate was flash evaporated to give a blue solid (120 mg). Analysis by tlc on silica gel (elution with CH_2Cl_2) showed two major spots (R_f ~0.95 and 0.15) and one minor spot (R_f ~0.5). Preparative tlc on silica gel (elution with CH_2Cl_2) gave $Cu(acac)_2$ (85 mg, 85%), anthracene (18 mg, 18%), and an unidentified solid (8 mg) with ir (KBr), 2940, 1720, 1680, ~1600, 1450, 1290, 920, 740, 695, and 670 cm^{-1}.

Phenothiazine

A solution of $Cu(acac)_2$ (100 mg, 0.38 mmol) and phenothiazine (120 mg, 0.6 mmol) in ethanol (120 ml) was irradiated for 48 h to give a dark brown solution. The absorption at 630 nm decreased about 80%. The solution was flash evaporated to give a brown solid (176 mg). After treatment with acetone (20 ml) a blue solid (56 mg) was separated; the ir spectrum was superimposable with that of $Cu(acac)_2$. Analysis of the filtrate by vpc showed only one peak corresponding to phenothiazine by comparison with authentic sample.

Carbazole, Phenanthrene, Pyrene, Perylene, and Acetylacetone

A solution of $Cu(acac)_2$ (100 mg, 0.38 mmol) and the sensitizer in ethanol (120 ml) was photolyzed for 24 h. No decrease was observed in the absorption of the 630 nm band. After work-up the unchanged starting materials were recovered.

Acknowledgements

This research project was carried out in part by Y. L. Chow and the research group of Kyoto University during the former's visit at the University, January–April 1976. Y. L. Chow wishes to thank the Kyoto University 70th Anniversary Memorial Foundation for a generous award and the research group of Professor Kaji for discussion and hospitality.

The authors are grateful to the National Research Council of Canada for financial support of this research project. Grateful acknowledgement is made to Dr. R. K. Pomeroy for helpful discussion and suggestions.

Milieux hyperbasiques: Synthèse de cyclanones α-cyanées par cyclisation anionique d'amides-nitriles

MARC LARCHEVEQUE ET PATRICK MULOT

Laboratoire de Synthèse Organique associé au C.N.R.S., Université Pierre et Marie Curie, tour 44–45, 4, place Jussieu 75230, Paris Cédex 05, France

Reçu le 28 mars

MARC LARCHEVEQUE et PATRICK MULOT. Can. J. Chem. **57**, 17 (1979).

Les amides ω-cyanés sont aisément préparés par action d'un cyanure alcalin sur un amide ω-halogéné. Sous l'action des dialkylamidures de lithium en solution dans l'éther, ils conduisent à la formation exclusive d'un anion en α du groupe cyano. Celui-ci peut alors réagir sur la fonction amide pour conduire à des cyclanones α-cyanées diversement substituées.

MARC LARCHEVEQUE and PATRICK MULOT. Can. J. Chem. **57**, 17 (1979).

ω-Cyano *N,N*-disubstituted amides are conveniently prepared from halogenated amides by treatment with alkaline cyanides. By reacting them with powerful bases such as lithium dialkylamides in ether, these cyano amides may be metallated in α position to the cyano group only. When they are warmed up, the anions react with the amide group to afford α-cyano cyclanones by an intramolecular cyclisation.

Introduction

Les cyclisations de Dieckmann et de Thorpe–Ziegler ont été fréquemment utilisées en chimie organique pour préparer des cyclanones diversement substituées (1). Ces réactions sont, malgré tout, d'un emploi relativement limité en synthèse car elles sont difficilement applicables aux composés dissymétriques. Les produits de départ sont en effet, dans ce cas, d'un accès difficile; de plus, on isole en général après réaction des mélanges car la différence d'acidité entre les hydrogènes en α des fonctions F_0 et F_0' (**1**, $F_0 = F_0'$ = ester ou nitrile) qui est due à la présence d'un groupe R électrodonneur, est trop faible pour conduire à la formation d'un anion unique (2). D'autre part, la réversibilité de cette réaction (qui peut être contrôlée dans certains cas (3)) contribue également à la complexité de la réaction.

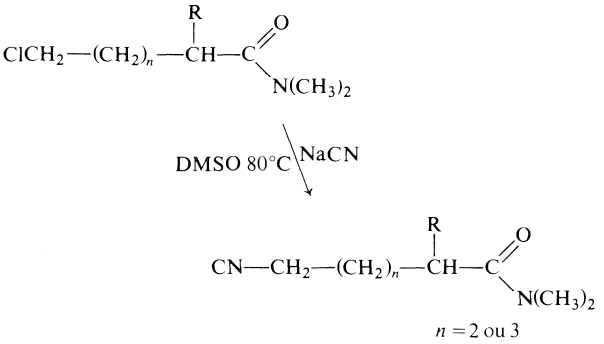
$$F_0—CH_2—(CH_2)_n—CHR—F_0'$$

1

Au cours de notre travail, nous avons essayé d'accroître le champ d'application de ces réactions et de remédier à leurs inconvénients en utilisant des composés porteurs de deux fonctions F_0 et F_0' différentes. Nous avons fait appel aux ω-cyano amides et nous proposons une méthode qui permet d'accéder directement à partir de ces composés à des cyclanones α-cyanées par cyclisation anionique.

Préparation des amides ω-cyanés

L'intérêt présenté par l'emploi de ces amides est double: (*i*) il existe une différence de pK_a assez importante entre les hydrogènes en α des deux fonctions; il est donc possible dans des conditions bien définies d'arracher un hydrogène plutôt que l'autre et d'effectuer ensuite une cyclisation anionique; (*ii*) les amides ω-cyanés dissymétriques sont aisément accessibles à partir des amides chlorés. Ceux-ci sont obtenus suivant une méthode déjà décrite par condensation d'un dérivé chloro-bromé sur un carbanion d'amide (4). On passe ensuite à l'amide-nitrile par action du cyanure de sodium dans le DMSO.

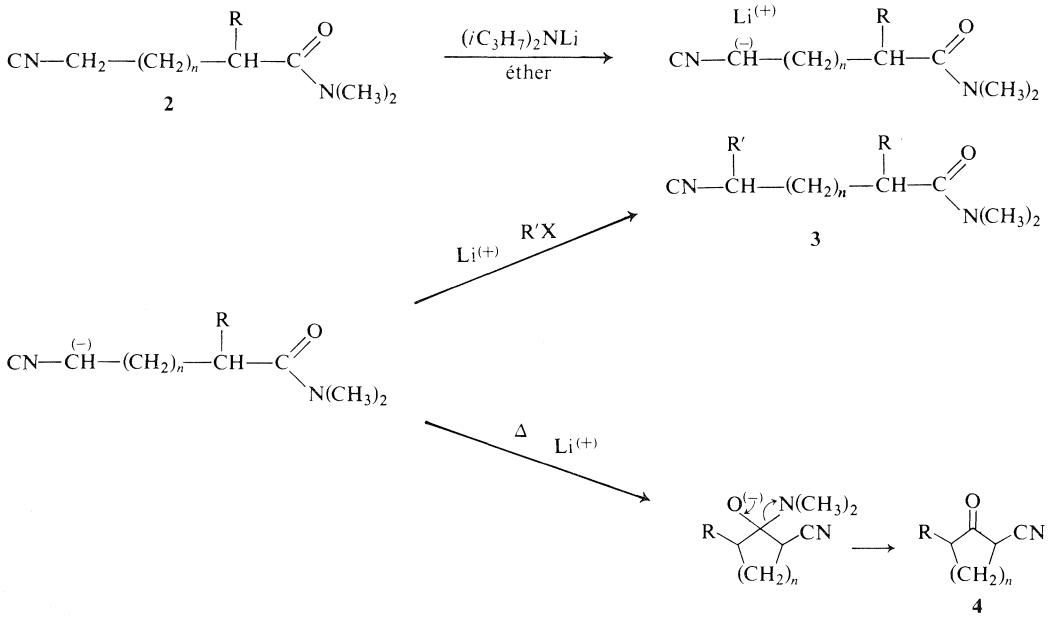


La réaction s'effectue avec de bons rendements (tableau 1) pourvu que l'on opère dans le DMSO. En milieu alcoolique on observe de nombreuses réactions parasites.

Cyclisation basique des amides ω-cyanés

La réaction de cyclisation nécessite la formation d'un carbanion qui puisse ensuite s'additionner sur l'amide par réaction intramoléculaire. Le milieu utilisé pour effectuer une telle opération doit donc être suffisamment basique pour former le carbanion en α du nitrile ($pK_a \sim 25$) en quantité appréciable

0008-4042/79/010017-04$01.00/0



sans pour autant l'être trop, ce qui conduirait également à l'attaque en α de l'amide ($pK_a \sim 29$).

L'hydrure de sodium est à éviter: il n'est pas assez réactif et l'hétérogénéité du milieu ne favorise pas la formation du carbanion en α du groupe cyano. Par contre, les "amidures activés" (Li—Et_2NH—C_6H_6—HMPT) qui servent à préparer les amides ω-chlorés sont trop réactifs; ils conduisent à une proportion notable de goudrons indistillables. Nous avons finalement choisi les dialkylamidures de lithium en solution dans l'éther. Ceux-ci donnent avec les amides nitriles **2** une réaction propre contrairement à ce que l'on observe lorsqu'on opère dans le THF.

La température joue un rôle important et il est nécessaire d'additionner la base à température relativement basse si l'on veut éviter des réactions parasites d'auto-condensation du carbanion: on opère en général vers −40°C. On observe dans ces conditions uniquement la formation du carbanion en α du nitrile. Celui-ci peut ensuite, si on laisse le milieu réactionnel se réchauffer vers −20°C, réagir sur la fonction amide; on isole alors après hydrolyse acide les cétones α-cyanées **4** avec de bons rendements (tableau 2). Il devrait également, en théorie, être possible de piéger cet anion par un électrophile convenable (par exemple un dérivé halogéné) de façon à obtenir le nitrile-amide bisubstitué **3**. En opérant dans l'éther nous avons effectivement observé cette réaction, mais nous n'avons jamais réussi, quelle que soit la température du milieu réactionnel, à dépasser

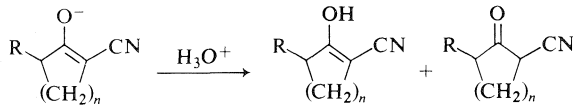
[a]Les rendements sont donnés en produits isolés.

un rendement de 25% en produit **3**. La réaction de substitution nucléophile s'effectue trop lentement sur le dérivé halogéné (surtout en milieu éther) pour concurrencer la réaction de cyclisation.

Celle-ci permet donc de préparer les cycles pentagonaux et hexagonaux avec de bons rendements. Par contre, les diverses tentatives faites pour l'appliquer aux cyclobutanones ont échoué: la réaction des amides γ-cyanés (**2**, $n = 1$) avec les dialkylamidures de lithium en solution dans l'éther ne fournit que des goudrons.

Nous avons observé que les dérivés obtenus sont particulièrement acides. Ils sont en fait isolés après hydrolyse sous forme de sels **5** et il est nécessaire de traiter ceux-ci par l'acide chlorhydrique à 50% pour libérer les céto-nitriles. Il faut noter que ces composés ne se présentent pas toujours sous forme cétonique. Ils sont partiellement énolisés et on isole fréquemment des mélanges contenant une forte proportion de composés **6**. Celle-ci dépend de la

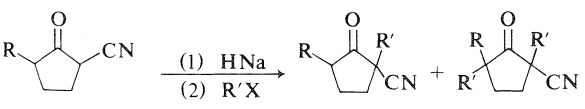


5 **6** **4**

nature du radical R et elle est particulièrement élevée dans le cas des cycles cyclopentaniques où elle peut dépasser 80%. Ce résultat est en désaccord avec celui de Kulp *et al.* (5) qui isole, lors de la synthèse de cyano-5 dialkyl-2,2 cyclopentanones, des composés ne comportant qu'une seule bande CN à 2250 et une bande CO à 1750 cm^{-1}. Par contre, les cyano-2 cyclohexanones se présentent presque exclusivement sous forme cétonique.

Nous avons indiqué ci-dessus que nous n'avions pas réussi à préparer les amides-nitriles **3** avec de bons rendements: il n'est donc pas possible dans ces conditions de synthétiser directement les α-cyano cyclanones α,α′-disubstituées **7**. On peut néanmoins les préparer par alkylation ultérieure des α-cyano cyclanones monosubstituées **4**. Ces composés analogues aux dérivés de la série malonique peuvent en effet être très aisément métallés. Nous avons vérifié que cette alkylation s'effectuait avec de bons rendements.

Le traitement par l'hydrure de sodium dans l'éther suivi d'une addition d'iodure de méthyle conduit à l'obtention d'un mélange de composé **7** (R = C_2H_5, R′ = CH_3) et de produit α,α′-dialkylé dans la proportion 85:15 (rendement global, 87%). Ainsi, il est possible par cette méthode d'accéder à des composés polyfonctionnels qui sont, particulièrement en série cyclopentanique, des intermédiaires de synthèse intéressants.



4 **7**

Partie expérimentale

La structure des différents produits a été confirmée par infrarouge et rmn. Les spectres infrarouges ont été effectués sur un spectrophotomètre Perkin Elmer 457 sous forme de film. Les spectres rmn ont été enregistrés sur un appareil Perkin Elmer R 24 à 60 MHz dans le tétrachlorure de carbone et en utilisant le tétraméthyl silane comme référence interne. La pureté des produits a été contrôlée par cpv (colonne SE 30 de 2.5 m). Les analyses centésimales sont correctes à ±0.25% pour le carbone et ±0.35% pour l'hydrogène.

Amides ω-chlorés

Cette réaction est décrite dans la réf. 4. Cependant les produits suivants n'avaient pas été synthétisés.

Chloro-5 méthyl-2 N,N-*diméthyl pentanamide*—rendement 75%; pé 126°C/13 Torr; ir: 1640 cm^{-1} (C=O); rmn δ: 1.07 (3H, d, J = 6.0 Hz, CH_3), 1.67 (4H, m, CH_2), 2.67 (6H, d, J = 8.0 Hz, $N(CH_3)_2$), 3.51 (2H, t, J = 6.0 Hz, $ClCH_2$).

Chloro-5 éthyl-2 N,N-*diméthyl pentanamide*—rendement 84%; pé 144°C/13 Torr; ir: 1645 cm^{-1} (C=O); rmn δ: 0.84 (3H, t, J = 6.0 Hz, CH_3), 1.55 (6H, m, CH_2), 2.97 (6H, d, J = 8.0 Hz, $N(CH_3)_2$), 3.47 (2H, t, J = 6.2 Hz, $ClCH_2$).

Chloro-5 isopropyl-2 N,N-*diméthyl pentanamide*—rendement 73%; pé 86°C/0.1 Torr; ir: 1640 cm^{-1} (C=O); rmn δ: 0.89 (6H, d de d, J = 6.0 Hz, $(CH_3)_2CH$), 1.62 (4H, m, CH_2), 2.96 (6H, d, J = 7.3 Hz, $N(CH_3)_2$), 3.12 (2H, m, $ClCH_2$).

Chloro-5 isobutyl-2 N,N-*diméthyl pentanamide*—pé 113°C/0.5 Torr; ir: 1645 cm^{-1} (C=O); rmn δ: 0.89 (6H, d, J = 6.0 Hz, $(CH_3)_2CH$), 3.00 (6H, d, J = 8.6 Hz, $N(CH_3)_2$), 3.47 (2H, t, $ClCH_2$).

Chloro-6 éthyl-2 N,N-*diméthyl hexanamide*—pé 109°C/0.8 Torr; ir: 1640 cm^{-1} (C=O); rmn δ: 0.89 (3H, t, J = 6.0 Hz, CH_3), 1.1–1.9 (8H, m, CH_2), 3.00 (6H, d, J = 9.0 Hz, $N(CH_3)_2$), 3.51 (2H, t, J = 6.6 Hz, $ClCH_2$).

Chloro-6 isopropyl-2 N,N-*diméthyl hexanamide*—pé 103°C/0.5 Torr; ir: 1650 cm^{-1} (C=O); rmn δ: 0.80 (6H, d de d, J = 6.6 Hz, $(CH_3)_2CH$), 1.1–2.0 (8H, m, CH_2), 3.00 (6H, d, J = 8.3 Hz, $N(CH_3)_2$), 3.52 (2H, t, J = 6.5 Hz, $ClCH_2$).

Amides-nitriles

Mettre dans un réacteur 0.3 mol de cyanure de sodium pulvérisé et 90 cm^3 de DMSO distillé sur hydrure de calcium. Chauffer à 90°C et additionner lentement 0.22 mol d'amide ω-chloré. Laisser chauffer le milieu réactionnel jusqu'à 120°C (environ 15 min). Refroidir, filtrer et distiller.

Méthyl-2 cyano-5 N,N-*diméthyl pentanamide*—pé 104°C/0.5 Torr; ir: 2240 (C≡N), 1635 cm^{-1} (C=O); rmn δ: 1.07 (3H, d, J = 6.0 Hz, CH_3), 2.37 (4H, m, CH_2CO et CH_2CN), 3.00 (6H, d, J = 9.0 Hz, $N(CH_3)_2$).

Ethyl-2 cyano-5 N,N-*diméthyl pentanamide*—pé 117°C/0.8 Torr; ir: 2240 (C≡N), 1630 cm^{-1} (C=O); rmn δ: 0.84 (3H, t, J = 7.3 Hz, CH_3), 2.38 (4H, m, CH_2CO et CH_2CN), 3.00 (6H, d, J = 9.2 Hz, $N(CH_3)_2$).

Isopropyl-2 cyano-5 N,N-*diméthyl pentanamide*—pé 128°C/0.05 Torr; ir: 2240 (C≡N), 1635 cm^{-1} (C=O); rmn δ: 0.91 (6H, d, J = 7.3 Hz, $(CH_3)_2CH$), 2.38 (4H, m, CH_2CO et CH_2CN), 3.00 (6H, d, J = 9.0 Hz, $N(CH_3)_2$).

Isobutyl-2 cyano-5 N,N-*diméthyl pentanamide*—pé 136°C/0.1 Torr; ir: 2245 (C≡N), 1640 cm^{-1} (C=O); rmn δ: 0.89

(6H, d, J = 6.0 Hz, $(CH_3)_2CH$), 2.33 (4H, m, CH_2CO et CH_2CN), 3.00 (6H, d, J = 9.8 Hz, $N(CH_3)_2$).

Méthyl-2 cyano-6 N,N-*diméthyl hexanamide*—pé 119°C/0.01 Torr; ir: 2245 (C≡N), 1640 cm^{-1} (C=O) rmn δ: 0.92 (3H, d, J = 6.0 Hz, CH_3), 2.30 (4H, m, CH_2CO et CH_2CN) 2.94 (6H, d, J = 9.0 Hz, $N(CH_3)_2$).

Ethyl-2 cyano-6 N,N-*diméthyl hexanamide*—pé 119°C/0.01 Torr; ir: 2255 (C≡N), 1640 cm^{-1} (C=O); rmn δ: 0.88 (3H, t, J = 6.2 Hz, CH_3), 2.37 (4H, m, CH_2CO et CH_2CN), 3.00 (6H, d, J = 9.0 Hz, $N(CH_3)_2$).

Isopropyl-2 cyano-6 N,N-*diméthyl hexanamide*—pé 124°C/0.08 Torr; ir: 2240 (C≡N), 1640 cm^{-1} (C=O); rmn δ: 0.89 (6H, d, J = 6.5 Hz, $(CH_3)_2CH$), 2.31 (4H, m, CH_2CO et CH_2CN), 3.00 (6H, d, J = 8.00 Hz, $N(CH_3)_2$).

α-Cyano cyclanones

Préparer 0.05 mol de diisopropylamidure de lithium par addition de butyllithium sur la diisopropylamine à 0°C. A −40°C couler goutte à goutte l'amidure préparé sur l'amidenitrile dissous dans 20 cm^3 d'éther. Le milieu réactionnel se prend en masse, mais redevient homogène dès que l'on revient à température ambiante. Après avoir agité 3 h à température ambiante, hydrolyser avec 5 cm^3 d'eau glacée. Le milieu réactionnel se prend à nouveau en masse. Filtrer, laver le précipité à l'éther, puis le dissoudre dans une solution à 50% d'acide chlorhydrique. Une couche organique relargue. Décanter, laver la couche aqueuse à l'éther, sécher la couche organique, chasser les solvants. Ne pas distiller car les produits sont très fragiles.

Cyano-2 méthyl-5 cyclopentanone—ir: 2245 et 2205 (C≡N), 1750 (C=O), 1630 cm^{-1} (C=C); rmn δ: 1.09 (3H, m, CH_3), 1.3–2.5 (5H, m, CH_2), 3.0–3.5 (1H, m, CH et OH).

Cyano-2 éthyl-5 cyclopentanone—ir: 2240 et 2200 (C≡N), 1745 (C=O), 1640 cm^{-1} (C=C); rmn δ: 0.95 (3H, d de t, CH_3), 1.31–1.90 (6H, m, CH_2), 1.95–2.52 (2H, m, CH et OH).

Cyano-2 isopropyl-5 cyclopentanone—ir: 2250 (C≡N), 1750 cm^{-1} (C=O); rmn δ: 0.91 (6H, m, $(CH_3)_2CH$), 1.6–2.5 (6H, m, CH_2), 3.0–3.5 (1H, m, CN—CH—CO).

Cyano-2 isobutyl-5 cyclopentanone—ir: 2240 (C≡N), 1735 cm^{-1} (C=O); rmn δ: 1.03 (6H, d, $(CH_3)_2CH$), 1.65–2.05 (8H, m, CH_2), 3.3–3.5 (1H, m, CN—CH—CO).

Cyano-2 méthyl-6 cyclohexanone—ir: 2240 (C≡N), 1720 cm^{-1} (C=O); rmn δ: 1.04 (3H, d de d, J = 6.0 Hz, CH_3), 1.64–2.70 (7H, m, CH_2), 3.3–3.6 (1H, m, CO—CH—CN).

Cyano-2 éthyl-6 cyclohexanone—ir: 2240 (C≡N), 1720 cm^{-1} (C=O); rmn δ: 0.98 (3H, d de d, J = 7.0 Hz, CH_3), 1.4–2.6 (9H, m, CH_2), 3.3–3.6 (1H, m, CO—CH—CN).

Cyano-2 isopropyl-6 cyclohexanone—ir: 2245 (C≡N), 1720 cm^{-1} (C=O); rmn δ: 0.94 (6H, d, $(CH_3)_2CH$), 1.5–2.6 (8H, m, CH_2), 3.2–3.7 (1H, m, CO—CH—CN).

Cyano-2 éthyl-5 méthyl-2 cyclopentanone

Additionner goutte à goutte 0.05 mol de cyano-2 éthyl-2 cyclopentanone sur une suspension de 0.05 mol d'hydrure de sodium dans du THF (25 cm^3). Maintenir la température en-dessous de 30°C. Agiter 3 h puis additionner lentement 0.05 mol d'iodure de méthyle dilué dans 10 cm^3 de THF. Chauffer ½ h à 50°C; hydrolyser; extraire à l'éther. Laver la coucher organique à l'hyposulfite; sécher sur sulfate de magnésium. On isole un mélange de produit monoalkylé et bisalkylé qui est purifié par distillation sous vide poussé. La chromatographie gazeuse (colonne SE 30 de 3 m chargée à 10%) et la rmn du ^{13}C indiquent une composition de 85:15 en produit mono- et bisalkylé.

Structure and bonding in cyclic phosphoramidates as determined by carbon-13 magnetic resonance[1]

GERALD W. BUCHANAN AND FREDERICK G. MORIN
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received June 15, 1978

GERALD W. BUCHANAN and FREDERICK G. MORIN. Can. J. Chem. **57**, 21 (1979).

^{13}C chemical shifts and ^{13}C–^{31}P couplings are reported for 11 cyclic phosphoramidates of ring sizes from four to nine. Vicinal couplings are compared with those of carbocyclic analogs and provide insight regarding the degree of nitrogen lone pair delocalization into the N—P bond. For six-membered and larger rings, there appears to be nearly complete lone pair delocalization, i.e., a trigonal planar nitrogen atom. In azetidine derivatives the nitrogen lone pair remains localized, giving rise to a highly puckered ring conformation. Pyrrolidine derivatives are viewed as having a nitrogen with a partially delocalized electron pair.

GERALD W. BUCHANAN et FREDERICK G. MORIN. Can. J. Chem. **57**, 21 (1979).

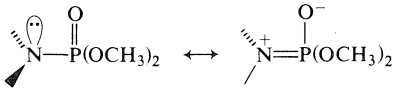
On rapporte les déplacements chimiques ^{13}C et les constantes de couplage ^{13}C–^{31}P de onze phosphoramidates cycliques dont la grandeur du cycle varie de quatre à neuf. On compare les couplages vicinaux à ceux des analogues carbocycliques et on obtient ainsi des informations relatives au degré de délocalisation de la paire d'électrons non-partagée de l'azote dans la liaison N—P. Dans le cas des cycles à six chaînons ou plus, il semble que la délocalisation de la paire d'électrons non-partagée soit complète, à savoir que l'atome d'azote adopte une forme planaire bigonale. Dans les dérivés de l'azétidine, la paire d'électrons non-partagée de l'azote reste localisée provoquant un plissement du cycle. On considère que la paire d'électrons non-partagée de l'azote dans les dérivés de la pyrrolidine est partiellement délocalisée.

[Traduit par le journal]

Introduction

Since the advent of commercially available ^{13}C Fourier Transform spectrometers, the application of ^{13}C–heteronuclear spin coupling to structural analysis has been widespread. Coupling interactions between ^{13}C and ^{31}P seem particularly useful. In these laboratories, attention has been paid to the study of carbocyclic hydroxy phosphonates (1, 3, 4) and phosphonates (2) via ^{13}C chemical shifts and ^{13}C–^{31}P couplings through one to five bonds.

When a nitrogen atom is bonded to phosphorus, the interesting question arises as to the degree of nitrogen lone pair delocalization into the N—P bond (below).



(*a*) (*b*)

In cyclic systems, vicinal ^{13}C–^{31}P couplings are known to depend on the dihedral angle between the coupled atoms, at least to a first approximation (5, 6).

If the ring nitrogen atom becomes trigonal planar (resonance form (*b*) above), then the dihedral angles from ^{31}P to vicinal ring carbons will be substantially altered, relative to the case (*a*) of a pyramidal nitrogen. With the expectation that the degree of nitrogen lone pair delocalization should be, to some extent, a function of ring size, we have synthesized a series of cyclic phosphoramidates with ring sizes from four to nine. Conformational conclusions are based on both coupling and chemical shift arguments.

Results and Discussion

Spectral Assignments

Routinely the ^{13}C spectra were recorded using complete ^{1}H noise decoupling. Subsequently the single frequency off-resonance decoupling procedure was employed to identify CH_3, CH_2, CH, and quaternary carbons. Selective ^{1}H decoupling was occasionally used, and the effects of molecular symmetry were often valuable assignment aids.

Chemical Shifts

The ^{13}C shieldings for **1**–**11** are presented in Table 1, with the corresponding structures and numbering scheme shown in Fig. 1. In Table 1, values in parentheses indicate uncertain assignments. For compounds **3**, **4**, and **8**, the OCH_3 groups are diastereotopic (7) and have small chemical shift differences (ca. 0.1–0.2 ppm).

For the piperidine derivatives, **1** and **5**, the ^{13}C shifts alone do not permit detailed structural con-

*0.2–0.3 *M* solutions in $CDCl_3$.

clusions. It is interesting to note, however, that introduction of the $-P(O)(OCH_3)_2$ group on N induces only minor shifts (<1 ppm) at each carbon relative to piperidine itself (8). From this result it can be suggested that there is no appreciable contribution in **1** and **5** from a chair form in which the phosphorus is axial, since this would be expected to shield C-3,5. In the cyclohexyl compound (2) the $-P(O)(OCH_3)_2$ is sterically bulky, $-\Delta G^0$ being in excess of 3.0 kcal/mol. Additionally, it is clear that substitution of S for O (**5** vs. **1**) has little effect.

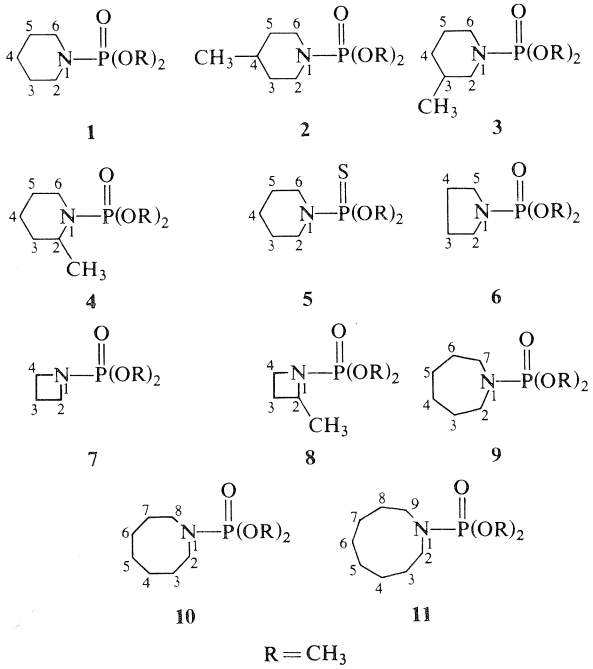

FIG. 1. Structures and numbering scheme for phosphoramidates.

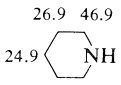


For compound **2**, the CH_3 at C-4 is suggested to be equatorial. This follows from comparison of the C-2,6 shifts in **1** and **2**. Since these are only 0.6 ppm different, it is clear the CH_3 is not axial to any large extent, since the γ shielding would be manifest at C-2,6 relative to **1**. One can calculate the CH_3 substituent effects to be α_{eq} = 6.6 ppm (deshielding) and β_{eq} = 8.5 ppm (deshielding). These values are not greatly different from those of methylcyclohexane (9): α_{eq} = 5.6 ppm and β_{eq} = 8.9 ppm. Similar conformational arguments apply to the 3-CH_3 compound **3**, where again no notable γ shielding is present compared to **1** and an equatorial CH_3 is likely.

By contrast, results for **4** are clearly indicative of an axial CH_3 at C-2. Both ring carbons which are potentially γ-*gauche* to an axial 2-CH_3 are shielded relative to **1**: namely C-6 by 6.3 ppm and C-4 by 5.5 ppm. Also, C-2 of **4** is deshielded by only 1.3 ppm compared to **1**, i.e., α_{ax} = +1.3 ppm. Thus the α effect of an axial CH_3 in **4** is very similar to that in the methyl cyclohexanes (9), where α_{ax} = +1.4 ppm, whereas α_{eq} = +5.6 ppm.

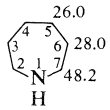
Further discussion regarding the degree of nitrogen lone pair delocalization, and hence the overall ring geometry, will follow in the coupling constant section.

^{13}C shieldings for pyrrolidine (10) are indicated below. Substitution of the $-P(O)(OCH_3)_2$ function for H on the nitrogen (compound **6**) causes essentially no shift at C-2,5 and only a small deshielding (1 ppm) at C-3,4. These results are not interpretable in terms of a definite conformation for **6** but they do rule out an envelope form with pyramidal nitrogen,

having an axial or quasi-axial dimethylphosphono group, since there is no upfield shift at C-3,4.

For the azetidines **7** and **8**, substitution of the CH_3 at C-2 of **8** induces downfield shifts of the expected magnitude (11) at the α and β positions (i.e., C-2 and C-3, respectively) relative to **7**. Interestingly, C-4 of **8** is shielded by 3.9 ppm relative to **7**, which suggests an axial CH_3 in a puckered azetidine ring. Further discussion will be presented to support this view in the coupling constant section.

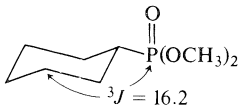
In the seven-membered ring compound **9**, the shifts are again not greatly different from those of the simple amine (12) below. The nearly identical shifts at C-2 probably reflect offsetting deshielding β effects (by phosphorus) and shielding γ effects (by oxygen) in all the phosphoramidates compared to the parent amines.



Coupling Constants

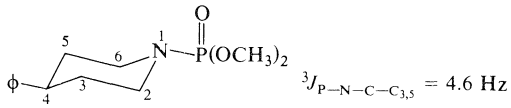
Geminal and vicinal ^{13}C–^{31}P couplings are presented in Table 2. In all materials, geminal J values of 5.8 ± 0.2 Hz were noted between ^{31}P and the OCH_3 carbon but since these values were essentially invariant, they are not included in the table. All the other geminal couplings are rather small, i.e., less than 4.5 Hz, and trends are difficult to extract from the data. The vicinal J values, however, show a rather spectacular variation with ring size and can, we feel, give insight into both ring geometry and the degree of nitrogen lone pair delocalization in these molecules.

For compound **1**, a vicinal J of 4.6 Hz is found between ^{31}P and ^{13}C via the P—N—$C_{2,6}$—$C_{3,5}$ path. This is a remarkably low value in light of the 16.2 Hz coupling in the corresponding carbocyclic phosphonate below (2).



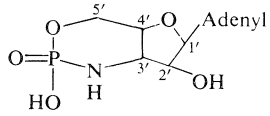
There are three possible sources for this dramatic reduction of ^3J, which are as follows: (*i*) contribution from an axial —$P(O)(OCH_3)_2$ group in a ring with a pyramidal nitrogen; (*ii*) a reduction owing to the influence of the more electronegative nitrogen (vs. carbon) in the coupling path; and (*iii*) a trigonal nitrogen, which reduces the dihedral angles relative to the case of pyramidal nitrogen.

Possibility (*i*) can be ruled out from our low temperature experiments (to −120°C) in which the spectra are essentially identical to those obtained at room temperature. Also, couplings for the compound below (only one isomer can be synthesized) are nearly identical to those for **1**.

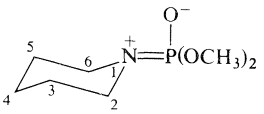


14

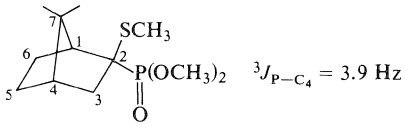
The findings of Morr *et al.* (13) indicate that the presence of an N atom in the coupling path does not cause large reductions of $^3J_{PNCC}$ relative to $^3J_{PCCC}$. For the cyclophosphate (below), via the path P—N—$C_{3'}$—$C_{2'}$, θ = 180° and ^3J = 10.6 Hz. Since ^3J values for **1**–**5** are ca. 4 Hz, it is unreasonable to propose that the dihedral angles (θ) for **1**–**5** are also near 180°.



Accordingly, for **1**–**5** we envisage a flattened chair conformation with a trigonal planar nitrogen atom (below), which renders the overall ring geometry akin to that of cyclohexanone. The dihedral angle for the paths P—N—$C_{2,6}$—$C_{3,5}$ is about 120° leading to reduced ^3J values ranging from 3.6 to 4.8 Hz. The



recent work (6) in which a plot of $^3J_{CP}$ vs. dihedral angle was illustrated for phosphonates, predicts a ^3J of ca. 4 Hz for θ = 120°, in excellent agreement with our findings. The coupling from ^{31}P to C-4 in the model compound below (θ = 120°) is 3.9 Hz (6).



It might be argued that the S—CH_3 group has a perturbing effect on ^3J in this model but we have recently found[2] that an S—CH_3 has essentially no influence on $^3J_{CP}$, for a given dihedral angle, relative to a hydrogen substituent.

[2]G. W. Buchanan and J. H. Bowen. Unpublished observations.

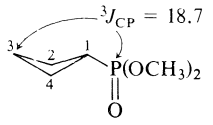
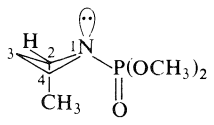
*nr is < 0.6 Hz.

The case of the azetidine derivatives **7** and **8** is in sharp contrast to that of the piperidine derivatives **1**–**5**. Comparison of $^3J_{CP}$ for **7** with that of its carbocyclic analog (**12**) shows nearly identical values of 18–19 Hz. In **7** and **8**, the resonance form in which



12

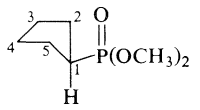
nitrogen is trigonal planar will be much less favourable than in **1**–**5** owing to increased bond angle strain in the four-membered ring. In fact, the ^3J of 18.7 in **12** indicates close to 180° dihedral angle between ^{31}P and C-3 (2, 6), i.e., a highly puckered cyclobutane ring. The close correspondence in **7** and **8** would indicate that the azetidine is also highly puckered, with an essentially pyramidal nitrogen atom. In **8**, the tendency of the axial CH_3 and the equatorial —$P(O)(OCH_3)_2$ groups to minimize their steric interactions will lead to increased puckering and accordingly a slightly larger $^3J_{CP}$ in **8** (20.4 Hz) than in **7**, since the P—N—$C_{2,4}$—C_3 angle will expand to near 180° as the P—N—C_2—CH_3 angle opens to near 90°. This latter expansion is reflected in the non-resolvable (<0.6 Hz) ^3J between the CH_3 and ^{31}P in **8**. We therefore formulate the preferred conformation of **8** as shown below.



8

An alternative to a highly puckered azetidine ring which would also give rise to a dihedral angle of 180°, is a planar structure. Recent theoretical studies on the structure of azetidine itself, however, indicate that a planar form is of considerably higher energy than the puckered conformer (14). Electron diffraction studies on azetidine (15) give a large puckering angle of 33°. Substitution of the sterically bulky dimethylphosphono group on N should, if anything, increase the degree of puckering, and thus we favor an interpretation based on a highly puckered, rather than a planar four-membered ring.

For the pyrrolidine derivative **6**, $^3J_{P-N-C-C_{3,4}}$ is 9.0 Hz compared to 12.3 Hz for the carbocyclic system **13** shown below. In view of the results for the



$^3J_{P-C-C-C_{3,4}}$ = 12.3

13

four- and six-membered rings, we suggest that the five-membered analog is an intermediate case. The significant reduction of 3.3 Hz for ^3J in **6** vs. **13** could result from a minor (ca. 25%) contribution from the resonance form with a trigonal planar nitrogen, with the major contribution being the tetrahedral nitrogen moiety. The $P(O)(OCH_3)_2$ group will be equatorial, predominantly.

For the seven-, eight-, and nine-membered rings (**9**, **10**, **11**, respectively), ^3J values are in the narrow range of 3.3 to 3.7 Hz. Although the carbocyclic analogs were synthesized, the ^3J values could not be extracted from the spectra owing to peak overlap. Shift reagents were not added since these would

likely alter the conformations and render comparisons of data meaningless. The only materials related to **9**, **10**, and **11** are the carbocyclic hydroxy phosphonates (3), which exhibit $^3J_{P-C-C-C}$ values of 10.9, 8.8, and 6.7 Hz, respectively, for seven-, eight-, and nine-membered ring compounds. The considerably smaller values in **9** → **11** seem to indicate trigonal nitrogen, since values for hydroxy phosphonates are known to be appreciably lower (3–4 Hz) than for phosphonates of similar geometry (1–3). It seems reasonable that these larger rings should be able to accommodate a trigonal planar nitrogen and thus the ^3J values for **9–11** are rather close to those of **1–5**.

Infrared Spectroscopy as a Probe for N Lone Pair Delocalization

For a series of acyclic phosphoramidates, $(OR)_2P(O)NHR$, and thiophosphoramidates, $(OR)_2P(S)NHR$, the P—N vibration occurs in the range 953–965 cm^{-1} (25). This is intermediate between that for a single bond (ca. 700 cm^{-1}) and a double bond (ca. 1300 cm^{-1}) and accordingly it is suggested that there is partial double bond character in the N—P bonds.

In the materials examined here, no clear trends emerge from the infrared spectral data. Interpretations are complicated by the fact that P=O stretching occurs very near the position of P=N stretching (ca. 1300 cm^{-1}).

We propose, therefore, that $^{13}C-^{31}P$ vicinal coupling constitutes a valuable addition to available techniques for monitoring nitrogen lone pair delocalization into N—P bonds.

Experimental

Spectra

^{13}C spectra were obtained via previously described techniques (1), on a Varian XL-100-12 NMR spectrometer, operating at 25.16 MHz, for compounds **1**—**11** and **13**. A Varian CFT-20 instrument was employed in the case of **12**, with a 2000 Hz sweep width and 8K data points.

Materials

For amines of ring size of five and above, the following general procedure was used to prepare the *N*-dimethylphosphono derivatives. To a solution of amine (2 equiv.), CCl_4 (1 equiv.) in an equal volume of ether at 0–5°C was added dimethyl phosphite (1 equiv.) dropwise with stirring. The reaction mixture was stirred at room temperature for ½ h, the hydrochloride salt filtered, the solvent evaporated and the residue distilled. Compounds obtained in this fashion were:

Compound ***1***—bp 85–90°C/3 Torr, n_D^{20} 1.4513 (lit. (16) bp 119°C/15 Torr, n_D^{20} 1.4528).

Compound ***2***—bp 100–102°C/2.5 Torr, n_D^{20} 1.4509. *Anal.* calcd. for $C_8H_{18}NO_3P$: C 46.37, H 8.76, N 6.76, P 14.95, O 23.16; found: C 46.31, H 8.59, N 6.82, P 14.87.

Compound ***3***—bp 91–92°C/2 Torr, n_D^{20} 1.4519. *Anal.* found: C 45.98, H 8.72, N 6.73, P 15.01.

Compound ***4***—bp 92–94°C/4 Torr, n_D^{20} 1.4554. *Anal.* found: C 46.22, H 8.72, N 6.74, P 14.63.

Compound ***6***—bp 90–93°C/3 Torr, n_D^{20} 1.4498 (lit. (17) bp 56–57°C/0.6 Torr, n_D^{20} 1.4498).

Compound ***9***—bp 94–96°C/1.5 Torr, n_D^{20} 1.4620. *Anal.* calcd. for $C_8H_{18}NO_3P$: C 46.37, H 8.76, N 6.76, P 14.95, O 23.16; found: C 46.31, H 8.52, N 6.81, P 14.79.

Compound ***10***—bp 112–115°C/3 Torr, n_D^{20} 1.4662. *Anal.* calcd. for $C_9H_{20}NO_3P$: C 48.86, H 9.11, N 6.33, P 14.00, O 21.69; found: C 48.70, H 9.18, N 6.25, P 14.34.

Compound ***11***—bp 111–112°C/4 Torr, n_D^{20} 1.4714. *Anal.* calcd. for $C_{10}H_{22}NO_3P$: C 51.05, H 9.43, N 5.95, P 13.17, O 20.40; found: C 51.27, H 9.31, N 5.80, P 13.11.

N-*Dimethylphosphonoazetidine (****7****)*

This compound was prepared as follows. 1-Azido-3-iodopropane (1.0 g, 4.7 mmol), prepared from acrolein by the published method (18), and 0.58 g (4.7 mmol) of trimethyl phosphite were stirred in 75 ml of pentane at room temperature for 5 days. Extra phosphite (2.0 mmol total) was added occasionally. After the pentane was evaporated off, the residue was distilled to yield **7**, bp 66°C/2 Torr (lit. (19) bp 108–109 °C/11 Torr).

N-*(Dimethylphosphono)-2-methylazetidine (****8****)*

This was synthesized from 2.25 g 3-azido-1-iodobutane (0.01 mol) (18) and 1.55 g trimethyl phosphite (0.0125 mol) in 75 ml pentane. The mixture was stirred for 3 days at room temperature and the excess phosphite removed under vacuum. The residue was judged pure by ^1H and ^{13}C nmr.

N-*(Dimethylthiophosphono)piperidine (****5****)*

This compound was prepared as follows. To 4.0 g piperidine (0.047 mol) in 50 ml anhydrous ether at 0°C was added dropwise 3.52 g (0.22 mol) dimethyl chlorothiophosphate with stirring. The mixture was stirred at room temperature for 1 h, filtered, concentrated, and distilled (bp 68–72°C/1.5 Torr, n_D^{20} 1.5002 (lit. (20) bp 80°C/3.0 Torr.).

*Dimethylphosphonocyclobutane (****12****)*

This compound was prepared by methods previously described (2), from cyclobutanone via cyclobutane-1,1-dithiol (21) and subsequently the methyl thiophosphonate (22), which was desulfurized using Raney nickel. For **12**, n_D^{20} 1.4440 (lit. (23) n_D^{25} 1.4442).

*Cyclopentyl Phosphonate (****13****)*

Dimethyl phosphite (11.0 g, 0.1 mol) in 30 ml toluene was brought to reflux in a 100 ml three-necked flask equipped with an efficient condenser and dropping funnel. To this was added a slurry of 4.09 g cyclopentene (0.06 mol) and 0.366 g dibenzoyl peroxide (0.0015 mol). Reflux was continued for 3 h and the toluene and excess dimethyl phosphite were removed under vacuum. The resultant 1.3 g sample was chromatographed on silica gel with ether as solvent to give the product with ^1H nmr identical to that of the literature (23); n_D^{20} 1.4521 (lit. (23) n_D^{25} 1.4511).

N-*Dimethylphosphono-4-phenylpiperidine (****14****)*

To 4-phenylpiperidine (2.0 g, 12.4 mmol), triethylamine (1.57 g, 15.5 mmol) and carbon tetrachloride (2.38 g, 15.5 mmol) in 40 ml anhydrous ether, maintained at 5°C, was added dropwise dimethyl phosphite (1.57 g, 14.3 mmol). The reaction mixture was stirred overnight, filtered and the solvent removed by rotary evaporation. The resultant oil slowly crystallized. Recrystallized from ethanol–hexane, mp 72–73°C; ^1H nmr ($CDCl_3$) δ: 7.23 (s, aromatic, 5H), 3.7 (d, J = 11.5 Hz, CH_3O—P, 6H), 3.4–3.9 (m, 2H), 2.3–3.1 (m, 3H), 1.6–2.0 (m, 4H).

^{13}C and ^{1}H nuclear magnetic resonance spectroscopy of C-19 and 6β-methyl substituted steroids: long-range shift effects in conformational analysis

KATHERINE NÁSFAY SCOTT[1] AND THOMAS HAROLD MARECI

Veterans Administration Hospital, and Department of Radiology, University of Florida, Gainesville, FL 32610, U.S.A.

Received April 13, 1978

KATHERINE NÁSFAY SCOTT and THOMAS HAROLD MARECI. Can. J. Chem. **57**, 27 (1979).

^{13}C and ^{1}H nmr spectra were obtained and assigned for nine C-19 substituted cholest-5-enes, three 6β-substituted 19-norcholest-5(10)-enes, and several related steroids. ^{13}C chemical shift effects have previously not been studied in either C-19 substituted steroids or in cholest-5(10)-enes. In the present study, substituent effects on the ^{13}C chemical shifts of the α, β, γ, and δ carbons were evaluated in detail. Although the substituent in C-19 substituted and 6β-methyl substituted steroids is less rigidly oriented with respect to the rest of the molecule than in ring-substituted steroids, similar shift effects were observed. In cholest-5-enes the observed ^{13}C and ^{1}H shift effects and the temperature dependence of the ^{13}C shifts indicate that the preferred orientation of the C-19 substituent is *anti* to C-1. The relative stabilities of the rotamers can be attributed to the orientation of the C-19 substituent with respect to the double bond. This interpretation is supported by the fact that the preferred orientation of the iodine in 6β-iodomethyl-19-norcholest-5(10)-en-3β-ol has the same spacial relationship with respect to the double bond, i.e., *gauche* to C-5 and C-7.

KATHERINE NÁSFAY SCOTT et THOMAS HAROLD MARECI. Can. J. Chem. **57**, 27 (1979).

On a enregistré les spectres rmn de ^{13}C et de ^{1}H et fait les attributions pour neuf cholestènes-5 substitués en C-19, trois nor-19 cholestènes-5(10) substitués en 6β et plusieurs stéroides apparentés. Les effets de déplacement chimique de ^{13}C n'ont encore fait l'objet d'une étude ni pour les stéroides substitués en C-19, ni pour les cholestènes-5(10). Dans le présent travail, on évalue en détail les effets des substituants sur les déplacements chimiques de ^{13}C des carbones α, β, γ et δ. Bien que le substituant dans les stéroides substitués en C-19 ou sur le groupe méthyle en position 6β, soit orienté moins rigidement par rapport au reste de la molécule que dans les stéroides substitués sur le cycle, on a observé des effets de déplacement semblables. Dans les cholestènes-5, les effets de déplacement de ^{13}C et de ^{1}H et l'influence de la température sur les déplacements de ^{13}C indiquent que le substituant en C-19 adopte une orientation préférentielle *anti* par rapport à C-1. On peut attribuer les stabilités relatives des rotamères à l'orientation du substituant en C-19 par rapport à la double liaison. Cette interprétation est renforcée du fait que l'orientation préférentielle de l'iode dans l'iodométhyl-6β nor-19 cholestén-5(10) ol-3β possède la même relation spatiale par rapport à la double liaison, soit *gauche* par rapport à C-5 et C-7.

Introduction

Since steroids are rigid structures, long-range effects of substituents on ^{13}C chemical shifts have previously been correlated with the spacial relationship between the carbons and the ring substituent. Substituents γ-*gauche* or -eclipsed to a given carbon produce shielding; when *anti* to the carbon the effect is generally deshielding (ref. 1 and references cited therein). The direction and the magnitude of the shifts depends on the degree of substitution of the intervening carbons. This conclusion has also been reached from theoretical considerations (2). In ring-substituted hydroxy steroids, methyl-*trans*-decalols, and methylnorbornanols, substituents in the *syn*-axial configuration substantially deshield δ carbons (3–5). Deshielding of carbons four bonds from the substituent is not peculiar to hydroxy substituents or cyclic systems, but has also been observed for methyl substituents and acyclic compounds (6, 7). However, the crowded *syn*-axial δ configuration has ca. 3 kcal/mol interaction energy (8); therefore, more stable orientations of the substituent are favored and deshielding δ effects are seldom observed in acyclic systems.

The γ and δ effects are of very obvious utility in stereochemical assignment of rigid systems. In addition, since these γ and δ effects are frequently quite substantial (2 ppm or larger), it seemed to us that they might be utilized for conformational analysis of less rigid systems which have rotation of the sub-

0008-4042/79/010027-11$01.00/0

stituent about one bond. Accordingly we examined substituent effects in some C-19 and 6β-methyl substituted steroids.

The effect of introducing substituents at the C-19 methyl of steroids has previously not been investigated (9). Rotation of the methyl group about the bond between C-10 and C-19 allows for various orientations of the C-19 substituent relative to the rest of the molecule. An nmr investigation of C-19 substituted steroids could show whether substituent effects in this less rigid system follow the trends established for substitution on the steroid ring and whether these effects could be used to establish any orientational preference of the substituent. For this reason we report ^{13}Cmr and ^{1}Hmr data on the several C-19 substituted cholest-5-enes and related steroids shown in Fig. 1. We examined several 19-hydroxy substituted cholest-5-enes, since the effect of hydroxy substitution has been most widely studied in steroids. Because we wanted to study conformational effects, bulky substituents, such as iodo and *p*-toluenesulfonyl, were also examined. Our results show that the preferred orientation for the C-19 substituent is *anti* to C-1. We attribute the relative stabilities of the rotamers in the cholest-5-enes to the orientation of the C-19 substituent with respect to the double bond. To test this interpretation, we also investigated the orientational preference of a different double-bonded steroid, 6β-iodomethyl-19-norcholest-5(10)-en-3β-ol.

^{131}I labelled **4***a* and **8***a* are two adrenal radioimaging agents approved for human use and are thus of considerable biological and radiopharmaceutical interest.

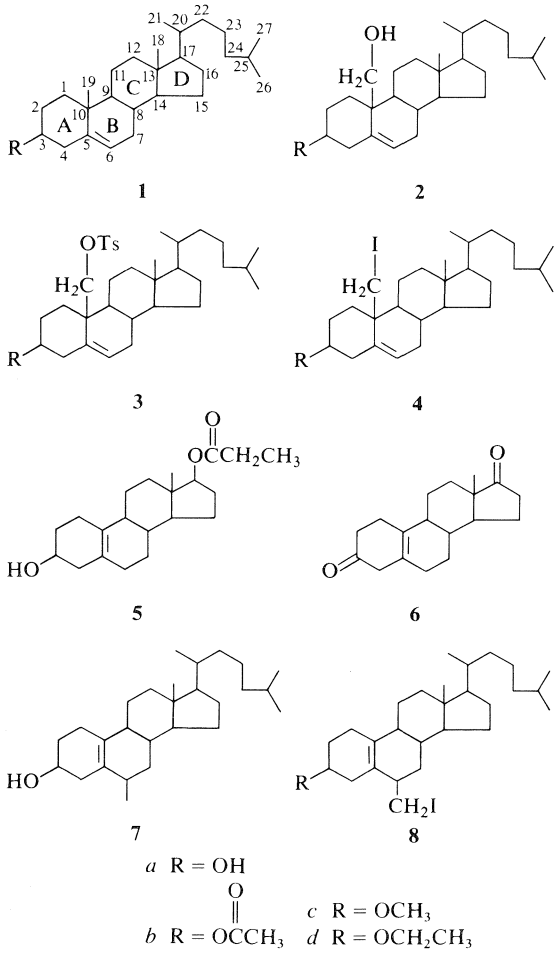

FIG. 1. Compounds studied: **1***a*, cholest-5-en-3β-ol; **2***b*, cholest-5-en-3β,19-diol 3-acetate; **3***a*, cholest-5-ene-3β,19-diol 19-*p*-toluenesulfonate; **4***a*, 19-iodocholest-5-en-3β-ol; **5**, estr-5(10)-ene-3β,17β-diol 17-propionate; **6**, estr-5(10)-ene-3β,17β-dione; **7**, 6β-methyl-19-norcholest-5(10)-en-3β-ol; **8***a*, 6β-iodomethyl-19-norcholest-5(10)-en-3β-ol.

Results and Discussion

A. ^{13}C Nuclear Magnetic Resonance

Spectral Assignments

The ^{13}C chemical shifts obtained in this study are summarized in Table 1. Chemical shifts for **1***a*, **1***b*, and **1***c* have been reported previously (10–13). The chemical shifts in Table 1 for these compounds agree with the literature values to 0.6 ppm or better, which is in the range expected for solvent and concentration effects. Our assignments for **1***a*, **1***b*, and **1***c* agree with those originally reported (10–13) except for the reversal of the assignments of C-12 and C-16, as noted for cholesterol (14) and some cholestanes (15) and later confirmed for several related steroids (16–19).

In assigning the remaining compounds, it was assumed that the D ring and the C-17 side chain were least affected by substitution. Indeed, these resonances changed little in the cholesterol series of compounds and were assigned on this basis. The expected shifts of the remaining carbons for each of the compounds were predicted from the observed shifts of appropriate model compounds and from known substituent effects. Agreement between observed and predicted shifts was sufficient to permit preliminary assignment. Then the specific assignments were confirmed by establishing the type of carbon (methyl, methylene, methine, quaternary) by a combination of low power broadband decoupling (LPBBD) or single frequency off-resonance decoupling (SFORD) of the protons. Unequivocal assignment of all but a few resonances could be achieved by the above procedure. Ambiguities in assignment remained only for those few resonances for which the spectrum contained close-lying resonances of carbons with the same number of attached hydrogens or where the SFORD spectra did not establish the num-

ber of attached hydrogens. Possible alternative assignments are indicated in Table 1.

The expected chemical shifts of the individual compounds were predicted as follows: The shifts of **2***b* and of **2***c* were predicted from the observed shifts of **1***b* and **1***c* and the —OH substituent effect observed in 2,2-dimethyl-1-propanol (11*b*, 20). The observed steroid shifts of **3** were very similar to those of **2***b* and **2***c* and were assigned on this basis. We determined the shifts for *p*-toluenesulfonyl chloride (C-1′ 141.8; C-2′, C-6′ 127.1; C-3′, C-5′ 130.3; C-4′ 146.9; CH_3 21.8) and this permitted the assignment of the tosyl resonances of **3**. The shifts of **4** were predicted from the observed shifts of **1** and the iodine substituent effect observed for 1-iodopentane (11*c*, 21).

To facilitate our assignment of **8***a*, which is the first ^{13}Cmr assignment of a 5(10)-ene steroid, we obtained and assigned spectra **5**, **6**, **7**, and **8***c*. Compound **7** was obtained by $LiAlH_4$ reduction of **8***a* and **8***c* was obtained by methylating **8***a*. Since there are major discrepancies among the previously reported ^{1}Hmr data for **8***a* (22–25), we report the assignment of the ^{13}Cmr spectrum of this compound in somewhat more detail to show that ^{13}Cmr unequivocally confirms the structure as 6β-iodomethyl-19-norcholest-5(10)-en-3β-ol. Each of **7**, **8***a*, and **8***c* shows the same eight resonances as those observed for the C-17 side chain in all the other cholesterol compounds of this series and these resonances were assigned to C-20 through C-27. The chemical shifts of C-18 and the C- and D-ring carbons of **7**, **8***a*, and **8***c* were predicted from the observed shifts of **1***a* and the effect of the removal of the C-19 methyl. This effect was obtained by comparing the shifts of testosterone and 19-nortestosterone (10, 11*a*, 19). The agreement between observed and predicted shifts was 0.1–1.0 ppm. The larger deviations, which occurred for the C-ring carbons, undoubtedly reflect the additional structural differences in the A and B rings between **1***a* and compounds **7**, **8***a*, and **8***c*.

The principal differences between the ^{13}Cmr spectrum of **8***a* and its isomer, **4***a*, occur in the A- and B-ring resonances, which means that the structural differences between **4***a* and **8***a* must be in the A and B rings. By LPBBD we showed that both olefinic carbons of **8***a* had no directly attached hydrogens; therefore, the double bond had to be either between C-5 and C-10 or C-9 and C-10. In the ^{1}Hmr spectrum of **8***a*, the CH_2I protons form the AB part of an ABX pattern, confirming that the CH_2I is attached to a CH carbon. Therefore, the C=C(CH_2I) possibility for quaternary olefinic carbons could be eliminated. In the ^{13}Cmr spectrum of 5α-pregn-9(10)-ene-16α-methyl-17α,21-diol-3,20-dione 21-acetate, we obtained olefinic resonances at 145.6 and 117.0 ppm for the C-9 to C-10 double bond. According to the CH_2I substituent effects observed in **4**, the attachment of CH_2I anywhere on the A or B rings could not have changed these olefinic shifts to those observed in **8***a* (125.5 and 133.9 ppm), thus the C-9 to C-10 double bond possibility for **8***a* is eliminated.

We then assigned ^{13}Cmr spectra of **5** (an authentic sample (26) was kindly provided by Prof. S. G. Levine for this purpose) and of **6**. The C- and D-ring carbon shifts of **6** were predicted from the observed shifts of 19-norandrost-4-ene-3,17-dione (10, 11, 19). The propionate side-chain carbons of **5** could easily be identified from the corresponding shifts (27.9 and 9.2 ppm) which we obtained for isopropyl propionate. The shifts of C-18 and the C- and D-ring carbons of **5** were predicted from the shifts of testosterone 17-acetate (10, 11*a*) and the effect of the removal of the 19-methyl. The A- and B-ring carbons of **5** and **6** could then be matched carbon by carbon and assigned if the effect of carboxylation at C-3 was added to the observed shifts of **5**. This effect was obtained by comparing the observed shifts of cholestan-3β-ol with those of cholestan-3-one (10, 11*a*,*b*, 19).

Once we had assigned the spectra of **5** and **6**, the A- and B-ring resonances of **7** could be predicted by adding the 6β-methyl effect (4) to the observed shifts of **5**. The shifts of **8***a* were then obtained by adding the iodine substituent effect to the observed shifts of **7**. Carbons 2, 3, and 4 of **8***a* were further identified by comparison with **8***c*, which gave the same resonances as **8***a*, except C-3 was deshielded by 9.1 ppm and C-2 and C-4 were shielded by 3.6 and 3.1 ppm, respectively. Thus, by the above detailed analysis of the ^{13}Cmr spectra of the five compounds **5**, **6**, **7**, **8***a*, and **8***c*, we could unequivocally confirm that the structure for **8***a* is as indicated.

Effect of Oxygen or Iodine Substitution α and β Effects

The ^{13}C chemical shift effects of oxygen or iodine substitution are summarized in Table 2. Hydroxylation at C-19 deshields the α carbon by 43.4 ppm and the β carbon by 4.9 ppm. These shift effects are similar to the 41.4 and 5.0 ppm deshieldings observed for the α and β carbons of 2,2-dimethyl-1-propanol (11*b*, 20). Tosylation at C-19 gives 50.6 and 3.6 ppm deshielding of the α and β carbons, respectively. Thus the *p*-toluenesulfonyl substituent deshields the α carbon 7.2 ppm more and the β carbon 1.3 ppm less than the OH. Although these effects are smaller, they are analogous to the changes observed between the shifts of ethyl sulfate (69.6 and 14.5 ppm, ref. 12*b*) and ethanol (57.3 and 17.9 ppm, refs. 11*b* and 20).

The α carbon in each of the iodine substituted

[a]In ppm from TMS. Positive substituent effects indicate a downfield shift. Values in parentheses are known substituent effects in model compounds.
[b]Chemical shifts of the two compounds that were compared to obtain the substituent effects.
[c]A is 2,2-dimethyl-1-propanol, refs. 11*b* and 20; B is 2,2-dimethylpropane, refs. 11*b* and 20; C is ethyl sulfate, ref. 12*b*; D is ethane, refs. 27 and 11*d*; E is 1-iodopentane, refs. 21 and 11*c*; F is pentane, refs. 21 and 11*c*.

steroids is shielded by about the same extent (8.1 to 8.7 ppm), which is about 2 ppm larger than the 6.5 shielding observed in 1-iodopentane. The reason for the larger shielding in the steroids is not apparent. The β carbon in the cholest-5-enes is deshielded by 1.6 to 2.0 ppm and in the 5(10)-ene by 8.2 ppm. These values are smaller than the 11.3 ppm deshielding of the β carbon in 1-iodopentane (21, 11*c*). The lesser shielding of the β carbons in the steroids can be attributed to the greater degree of substitution for C-6 in **8***a* and particularly C-10 in **4**. Decreased β substituent effects with increased branching were first observed for norbornyl derivatives (28) and then confirmed for the decalols (3*b*) and for various steroids (3*b*, 5, 29).

γ *Effects*

In C-19 substituted steroids, rotation about the C-10 to C-19 bond gives the staggered rotamers, **I**, **II**, and **III** (Fig. 2). The rotamers are nonequivalent and may have unequal population. For the 6β-iodomethyl compounds rotation about the iodomethyl to C-6 bond yields the staggered rotamers, **A**, **B**, and **C** (Fig. 2). At room temperature, none of the rotamers are 'frozen out' and the observed chemical shift is a rotationally averaged shift. However, from the observed ^{13}C and ^{1}H chemical shifts we were able to establish the relative populations of the rotamers.

A recent reinterpretation of the γ effect (30) and the data on hydroxy steroids in ref. 5 show that large (2.3 to 8.3 ppm) upfield γ-*gauche* effects are possible if the substituent removes a 1,3-diaxial proton–proton interaction. If no such interaction is removed by the substituent, the γ-*gauche* effect will be much smaller (0.1 to 0.9 ppm). In the present compounds, 1β-H gives a 1,3-diaxial type interaction with the C-19 protons and 7β-H with the 6β-methyl protons. These interactions are removed by the substituent only in rotamer **II** and rotamer **A**, respectively. The

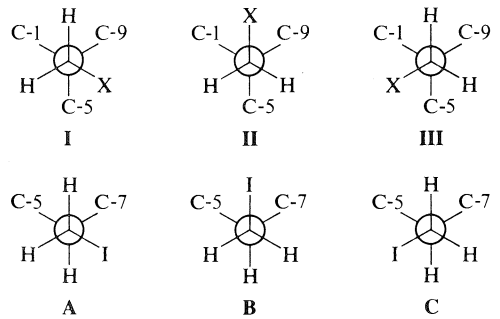

FIG. 2. Upper row: The three staggered rotamers (**I**, **II**, and **III**) of the C-19 CH_2X group in C-19 substituted cholest-5-enes. The C-19 to C-10 bond is into the plane of the paper. Lower row: The three staggered rotamers (**A**, **B**, and **C**) of the 6β-iodomethyl group of 6β-iodomethyl-19-norcholest-5(10)-en-3β-ol. The 6β-iodomethyl to C-6 bond is into the plane of the paper.

substantial shielding (−3.8 to −4.7 ppm) of C-1 in the 19-O compounds shows that rotamer **II** is appreciably populated in these compounds, whereas the lack of shielding effect on C-1 (−0.1 to +0.2 ppm) indicates that rotamer **II** is not well populated in the 19-I compounds. (The difference in relative populations of the 19-I and 19-O compounds will be discussed in subsequent sections.) The 3.0 ppm shielding of C-7 in **8** shows that rotamer **A** has appreciable population.

Since C-5 has no hydrogen, the large shielding (−3.9 to −6.4 ppm) of this carbon cannot be accounted for by the removal of the 1,3-diaxial interaction but must be due to linear electric field shift effects. (See subsequent sections.)

δ *Effects*

In 10-methyl-*trans*-decalols, methylnorbornanols, and some hydroxy steroids, larger positive (+2 ppm or greater) δ substituent effects were observed for carbons in the *syn*-axial conformation relative to the OH (3, 4). In 31 monohydroxylated cholestanes and androstanes, about 80 examples of interaction between the OH and the δ carbon were examined (5). Of the five possible orientations, $\delta_1 - \delta_5$ (3*b*, 5), only the δ_1 *syn*-axial configuration showed large (2.0 to 3.8 ppm) deshielding effects (5). Although most of the observed interactions were between OH and CH_3, several interactions were between OH and ring methylene carbons (e.g., 1β-OH and C-11).

In the present series of 19-O compounds, C-6 is consistently strongly deshielded (5.3 to 5.6 ppm). C-6 is δ_1 relative to the 19-O only in rotamer **I**. (See Table 3.) Thus the strong deshielding of C-6 in the compounds indicates that rotamer **I** has appreciable population. In this configuration, C-8 too is δ_1 to the 19-O. Indeed, C-8 is the only other δ carbon which shows a substantial deshielding (0.8 to 1.4 ppm).

In the present 19-O compounds, the δ_1 effect on C-6 is larger and on C-8 somewhat smaller than the 1.4 to 3.8 ppm deshielding effects previously observed in ring-substituted steroids, methyl-*trans*-decalols, and methylnorbornanols (3–5). Some of the deshielding of C-6 may be due to linear electric field shift (LEFS) effects (31, 32), since these effects can be substantial on sp^2 carbons (33, 34). The oxygen–carbon bond acts as a dipole, polarizing the charge distribution of the C=C in such a manner as to shield the carbon closer to the polar group and deshield the carbon farther away. Using eqs. [2]–[4] of ref. 33*a*, we estimated the LEFS on C-5 and C-6 in the 19-OH compounds. The appropriate distances and angles were obtained from molecular models, dipole moments from ref. 35, and LEF coefficients from ref. 33*b*. The LEFS thus estimated for C-5 and C-6 in the rotamers are: **I** −4.8 and 1.0; **II** −1.7 and 1.4;

III −0.1 and 0.6 ppm, respectively. Since the value of the LEF coefficient may involve errors up to a factor of 2 (33*b*), clearly these LEFS are only estimates. Nonetheless, they account for a substantial part of the observed shift effect on C-5 but only for a fraction of the observed effect on C-6. The LEFS suggest that **I** is most populated.

There are additional reasons why the δ_1 effect on C-6 is large. First, the sp^2 hybridized C-6 does not necessarily experience the same δ_1 effect as the sp^3 hybridized carbons. Whether the δ_1 effect on sp^2 carbons is generally larger than on sp^3 carbons cannot be stated at this time, since the present series of compounds and those in ref. 9 represent the only report of δ_1 effects on sp^2 carbons. Second, in monohydroxylated cholestanes and androstanes, smaller δ_1 effects were observed for the more rigid molecules and also for larger OH to δ_1 carbon distances (5). Indeed, the very small (−0.1 and +0.4 ppm) δ_1 effect on C-7 in the 15β-hydroxyl compounds was attributed to the considerably larger (ca. 30%) than usual internuclear distance between the oxygen and δ_1 carbon. In rotamer **I** of the 19-O compounds, the C-8 to O internuclear distance has the usual (2.5 ± 0.2 Å) value, whereas the C-6 to O internuclear distance is considerably larger (3.1 ± 0.2 Å). However, there is reason to believe (see the following two paragraphs) that the preferred orientation of the substituent is not precisely *anti* C-1 but slightly rotated toward the C-5 eclipsed position. This would increase the substituent to C-8 distance and account for the lower δ_1 effect on this carbon.

Recently, a shorter T_1 (hence slower rotation rate) was observed for the C-19 methyl in androst-5-ene than in androstan-17-one (36) and was attributed to a lower energy of the preferred conformer in the 5-ene. In the 17-ketone, the C-19 methyl group has *syn*-axial interactions with the axial protons on carbons 2, 4, 6, 8, and 11. In the 5-ene, the interaction with the axial proton on C-6 has been removed; this is believed to account for the lower energy of the preferred rotamer in this compound.

In the present work, the stability of one staggered rotamer over another is most probably due to the presence of the C=C. Since C-6 has no H, the bulky substituent (OH or I) in **I** experiences fewer nonbonded proton interactions, which accounts for the lower energy. Furthermore, the nonbonded interaction between the substituent and 8β-H can be decreased if the substituent is slightly rotated toward the C-5 eclipsed position and since there is no 6β-H, this will *not* result in an increased interaction between the substituent and the 6β-H.

Thus we postulate that because of the double bond, the nonbonded interaction between the substituent and the 8β-H in **I** is less severe than the interaction between the substituent and 11β-H in **II**. And furthermore that it is much less than the combined nonbonded interactions between the substituent and the axial protons on C-2 and C-4 in **III**. If this is so, then the relative populations of the rotamers should be **I** > **II** ≫ **III**. Furthermore, the more bulky the substituent on C-19, the more rotamer **I** would be stabilized, relative to rotamer **II**. This may well explain why rotamer **II** is populated for the 19-O compounds but not for the 19-I compounds. (The covalent radius of iodine is almost twice that of oxygen.)

For the 6β-iodomethyl compound similar considerations would predict that the nonbonded interaction between the substituent and 8β-H in **B** is less severe than the interaction between the substituent and 4β-H in **C**. Hence **B** would be of lower energy than **C**. But because there are no δ_1 interactions in rotamer **A**, this rotamer may be of lowest energy. We will give experimental evidence in subsequent paragraphs to show that the relative populations of rotamers **I**, **II**, **III** and of **A**, **B**, **C** are indeed as predicted.

The strong deshielding of C-6 in the 19-I compounds and of C-10 in **8***a* is consistent with the δ_1 interaction between these carbons and iodine, if the most populated rotamers are **I** and **B**, respectively. Since C-8 is also δ_1 to the iodine in these rotamers, the much smaller substituent effect at C-8 most likely arises from the slight rotation of the substituent toward the C-5 eclipsed position, as previously discussed for the 19-O compounds. The difference in iodine substituent effect between C-8 and C-6 is identical to the difference in oxygen substituent effect between these carbons.

The lack of deshielding effects at C-2 and C-4 for the 19-substituted compounds and at C-4 for **8** shows the absence of δ_1 interaction for these carbons, hence negligible population of rotamers **III** and **C**. (See Table 3.) Thus by the analysis of all the γ and δ effects, we established that the rotamers with appreciable populations are **I** for the 19-I compounds, **I** and **II** for the 19-O compounds, and **A** and **B** for **8**.

TABLE 3. Spacial relationship[a] between the substituent and the δ carbon in the staggered rotamers[b]

[b]Substituent effect at +34°C (shifts of **2***b* − shifts of **1***b*) subtracted from substituent effect at −20°C (shifts of **2***b* − shifts of **1***b*).
[c]Substituent effect at +34°C (shifts of **10***a* − shifts of **9**) subtracted from substituent effect at −20°C (shifts of **10***a* − shifts of **9**). Positive values indicate increased deshielding at −20°C. Spectra were run at 3500 Hz sweep width, therefore, the shifts are known with ±0.04 ppm precision.

We then examined the temperature dependence of the 19-hydroxy substituent effect to establish whether rotamer **I** or **II** is of lower energy. Similarly, the temperature dependence of the 6β-iodomethyl iodine substituent effect was used to establish the relative population of rotamers **A** and **B**.

Temperature Dependence of the C-19 Hydroxy and of the 6β-Iodomethyl Iodine Substituent Effects

^{13}C spectra were obtained for compounds **1***b*, **2***b*, **7**, and **8***a* over the temperature range of +34 to −20°C. The solubilities in chloroform decreased to such an extent that it was not practical to obtain spectra below −20°C. Thus the conformational equilibrium could be studied only in the fast exchange limit. This generally provides only a first approximation to the equilibrium (11*e*); therefore, the relative rotamer populations obtained in this manner should be considered indicative rather than conclusive.

By comparing the chemical shifts at +34 and −20°C, the temperature dependences shown in Table 4 were obtained. As expected, the temperature dependence of the substituent effects over the 54°C temperature range was small; however, many of the observed effects were 4 to 14 times as large as the experimental error, and therefore can be considered significant. The α and β effects show substantial changes, which are not readily analyzable, since these effects are a composite of inductive, resonance, and steric effects (11*b*, 20).

The temperature dependence of the hydroxy γ effects is only on the order of the experimental error. The hydroxy δ effects are larger (2 to 14 times as large as the experimental error). If rotamer **I** is of lower energy, then decreasing the temperature should further increase the population of rotamer **I** relative to rotamer **II**. Inspection of Table 3 and the expected shifts of the δ carbons (δ_1 strong deshielding, δ_2 moderate deshielding, δ_3 and δ_4 very small effect, δ_5 moderate shielding (5)) allows us to predict deshielding of C-2, C-6, C-8 and shielding of C-4 and C-11 at lower temperature. This is indeed the experimentally observed trend.

For **8***a* the temperature dependence of the δ effects is smaller and of the γ effect slightly larger than for **2***b*. Half of these effects (at C-4 and C-10) indicate that rotamer **B** is of lower energy, whereas the other two effects (at C-7 and C-8) indicate that rotamer **A** is of lower energy. This can only be interpreted to mean that neither **A** nor **B** predominates. Thus from the careful consideration of the γ and δ substituent effects and their temperature dependence, the following relative rotamer populations are indicated: **I** > **II** ≫ **III** and **A** ~ **B** ≫ **C**. These relative populations are consistent with the hypothesis that it is the presence of the double bond in these compounds which accounts for the relative energies of the rotamers. Moreover, since the energy of **B** is comparable to that of **A**, the stabilizing effect of the double bond is substantial.

Recent data on three 19-hydroxy-4-en-3-one steroids (9) show strong shielding of C-5 and strong deshielding of C-4. More importantly, C-2 is now moderately shielded (+0.6 to +1.2 ppm). These shifts indicate that rotamer **III** has an appreciable population; that is, the 19-OH has the same orientation with respect to the C=C as it did in the 5-ene steroids.

X-ray crystallography showed the 19-OH conformation to be **III** for 19-hydroxyandrost-4-ene-3,17-dione but to be out-of-ring (rather than **I**) for androst-5-ene-3β,17β,19-triol 17-*p*-bromobenzoate (37). The discrepancy between the X-ray and our data for the 5-ene may indicate conformational differences between the crystalline form and the solution, or interaction between the 19-OH and the bulky 17β substituent, or both. However, when there are two substituents on C-19, as in [19-*R*]- and [19-*S*]-19-methylandrost-5-ene-3β,17β,19-triol, the methyl was in the over-B-ring position. The fact that both

diastereomers have the bulkier methyl group in the over-B-ring position suggests that this is the least energy conformation (37).

B. ^1H *Nuclear Magnetic Resonance*

Spectral Assignments

In the ^{1}Hmr spectra only the 3-H, 6-H, and methyl protons were assigned. The results are summarized in Table 5. The spectral assignments relied heavily on previously published steroidal assignments (38). We have previously published the ^{1}Hmr data for compounds **4***a* and **8***a* elsewhere (25), but have included them in Table 5 for the sake of completeness. Our observed ^{1}Hmr data for **8***a* agree with those reported by Kojima and co-workers (22, 24) but not with those of Basmadjian *et al.* (23). The peak positions and intensities reported by Basmadjian *et al.* are not possible for steroids containing the C-20 cholestane side chain (25, 38*a*, 39, 40).

Substituent Effects on Proton Chemical Shifts

The more important effects of substitution on the proton chemical shifts are summarized in Table 6. The largest substituent effect is the nonequivalence of the 19-CH_2 protons in all the C-19 substituted compounds. This nonequivalence is the result of the rotationally averaged chemical shifts of the protons in the three rotamers shown in Fig. 2. Since the rotamers are different, the rotationally averaged chemical shifts of the protons will be different, even if the rotamers were of equal probability. Therefore, the observed nonequivalence of the 19-CH_2 protons does not yield any information about the relative population of the rotamers. However, the nonequivalence of the protons confirms that the rotamers are sufficiently different to cause appreciable (0.2 ppm) chemical shift difference.

The 19-OH deshields the 18-CH_3 by 0.06 ppm. Since the 18-CH_3 is many bonds removed from the 19-OH substituent, the effect must be long range in nature, such as magnetic anisotropy and dipole–dipole interactions. Both of these effects are inversely proportional to the cube of the distance between the affected proton and the substituent (38*b*). Table 7

TABLE 7. Effect of β-hydroxy substitution on C-18 methyl proton chemical shifts

Substituent	18-H[a] (ppm) Ref. 38c	Ref. 41	r[b] (Å)
6β-OH	+0.042	+0.033	4.8
7β-OH	+0.033	+0.022	4.2
8β-OH	+0.183		2.0
11β-OH	+0.242	+0.242	2.0
12β-OH	+0.067		2.6

[a]Relative to unsubstituted androstane. Positive values indicate downfield shift.
[b]Approximate (±0.2 Å) distance from the oxygen nucleus to the nearest proton of the C-18 methyl, as measured from molecular models. The same distance in the rotamers of **2** is **I**, 3.1 Å; **II**, 3.1 Å; **III**, 5.1 Å.

shows some of the previously observed (38*c*, 41) effects of B- and C-ring β-OH substitution on the 18-CH_3. This table also contains the approximate distance from the oxygen nucleus to the nearest proton in the 18-CH_3 and this distance in the three rotamers of Fig. 2. Only the 12β-OH substituent effect of 0.067 ppm is comparable to the 0.06 ppm effect observed for the 19-OH substituent. The 8β- and 11β-OH effects are much larger because of their close proximity to the 18-CH_3 and the 6β- and 7β-OH effects are smaller because of the larger distance. It is noteworthy that only in rotamers **I** and **II** is the distance comparable to the distance in the 12β-OH compound. The distance in rotamer **III** is considerably larger and would yield smaller substituent effects than observed. Therefore, the 19-OH substituent effects on the 18-CH_3 proton chemical shifts further support the conclusion reached from ^{13}C chemical shift effects that rotamers **I** and **II** predominate at room temperature. Furthermore, the 0.38 to 0.40 ppm deshielding of the 6β-H by the 19-OH suggests close proximity of the oxygen and the 6β-H and, hence, the predominance of rotamer **I**.

The 19-I substituent effect on the proton chemical shifts are comparable to those of the 19-OH substituent. This suggests that for the 19-I substituted compounds, also, rotamer **I** predominates. The 19-OTs substituent deshields the methyl protons at C-18 and C-21, and also the 3β-*O*-methyl of **3***c*, undoubtedly because of the ring current effect of the aromatic ring. However, because the deshielding effect of the aromatic ring can extend to distances of several ring radii (42), and because the *p*-toluenesulfonyl substituent group is internally flexible, no statement can be made from the ^1Hmr data about the relative population of the rotamers in the 19-OTs compounds.

Conclusions

Since this is the first investigation of long-range shift effects in the conformational analysis of substituted methyls in steroids, it remains to be seen whether this method is generally applicable. However, the present study shows the feasibility of utilizing γ and δ effects for conformational analysis of some steroid derivatives even when the rotamers are rapidly interconverting. The method should be applicable to short side chain conformers in other rigid ring systems and, to a more limited extent, to highly branched acyclic compounds. A large shielding γ effect is expected for rotamers in which the substituent removes a 1,3-diaxial proton–proton interaction. The δ_1 interaction will act as an indicator by deshielding carbons in rotamers with appreciable population. Moreover, if the carbons δ_1 to the substituent have protons to give nonbonded interaction with the substituent, the rotamer is expected to be destabilized in proportion to the number of these interactions. Thus the observed γ and δ effects may establish which rotamers are appreciably populated. In the case of more than one highly populated rotamer, the temperature dependence of these shift effects may establish the relative stabilities of the rotamers.

Experimental

Nuclear Magnetic Resonance

Nuclear magnetic resonance spectra were obtained with a Bruker model HX-90 spectrometer equipped with a fast Fourier transform system using a Nicolet model 1083 computer. Proton spectra were obtained at 90.00 MHz and ^{13}C spectra at 22.63 MHz spectrometer operating frequencies. The samples were dissolved in a stock solution of deuteriochloroform which contained 5% by volume hexafluorobenzene (the fluorine signal served as the field-frequency stabilization signal) and tetramethylsilane in 1% by volume concentration for ^1Hmr spectra and 10% by volume concentration for ^{13}Cmr spectra. Solution concentrations ranged from 0.05 to 2.0 *M* and were dictated by the amount of sample available. The ^{13}Cmr shifts could be determined with 0.05 ppm precision and ^1Hmr shifts with 0.01 ppm precision, except for 0.1 ppm precision for the very broad H-3 resonance.

Materials

Compounds **1***a*, **1***b*, **6**, and 5α-pregn-9(10)-ene-16α-methyl-17,21-diol-3,20-dione 21-acetate were commercially available. An authentic sample of **5** (26) was kindly supplied by Dr. S. G. Levine.

The remaining compounds were synthesized by known methods in the following sequence: **1***b* → 5α-bromo-cholestan-3β,6β-diol 3-acetate (43–46) → 5α-bromo-6β,19-oxidocholestan-3β-ol 3-acetate (43, 44, 46, 47) → **2***b* (43, 44, 48); **2***b* → **3***b* (43–45); **3***b* → **4***b* (44, 49); **3***a* and **4***a* were prepared from **3***b* and **4***b*, respectively (43, 44); **4***a* → **8***a* (25); **8***a* → **7** (22).

Compound **1***c*, was synthesized by the action of perchloric acid on **1***a* in trimethylorthoformate (43, 50). The same method was also used to prepare **8***c* from **8***a*. Compound **4***c* was similarly prepared from **4***a* by the use of triethyl orthoformate (43). The reaction sequence for the remaining 3β-methoxy derivatives, **2***c*–**4***c*, started with **1***c* and was as for the 3-acetates described in the previous paragraph (43).

All compounds tested gave satisfactory elemental analyses and had melting points as reported in the literature. All solid compounds were found to be spectroscopically pure by ^{13}Cmr and ^1Hmr. Compounds **7**, **8***a*, and **8***c* were oils. High pressure liquid chromatographic separation of **8***a*, as previously de-

scribed, yielded a pale yellow glass, which was shown by ^{13}Cmr to be >98 mol% pure (25). Compounds **7** and **8***c* were not purified by high pressure liquid chromatography but the impurities detected by ^{13}Cmr and ^{1}Hmr did not interfere with the spectroscopic analysis, except possibly for the assignment of C-5 in **8***c* (see Table 1).

Acknowledgments

Financial support was provided by the Medical Research Service of the Veterans Administration. We are indebted to Drs. H. L. Holland, P. R. P. Diakow, and G. J. Taylor for letting us use some of their data before publication. This led to a reassignment of C-1 and C-7 in our 19-O compounds and aided the discussion of results for the 5-ene compounds. We thank Dr. S. G. Levine for providing a sample of **5** and Dr. J. A. Owoyale for the syntheses of the 3β-methoxy and 3β-ethoxy derivatives. We are greatly indebted to Dr. M. W. Couch for the syntheses of all other compounds and to Dr. C. M. Williams for initiating the research project.

C-Stannane derivatives of carbohydrates[1]

LAURANCE D. HALL, PAUL R. STEINER,[2] AND DIANE C. MILLER
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received June 7, 1978

LAURANCE D. HALL, PAUL R. STEINER, and DIANE C. MILLER. Can. J. Chem. **57**, 38 (1979).

Triphenyltin lithium (**1**) was reacted separately with 1,2:3,5-di-*O*-methylene-6-*O*-tosyl-α-D-glucofuranose (**2**), with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (**4**), and with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside (**6**), to form in each case a sugar–stannane derivative having a stable carbon–tin bond. These products have been studied by ^{1}H and ^{13}C nmr spectroscopy.

LAURANCE D. HALL, PAUL R. STEINER et DIANE C. MILLER. Can. J. Chem. **57**, 38 (1979).

On a fait réagir le triphénylstannyl lithium (**1**) avec le di-*O*-méthylène-1,2:3,5 *O*-tosyl-6 α-D-glucofurannose (**2**), avec l'anhydro-2,3 *O*-benzylidène-4,6 α-D-allopyrannoside de méthyle (**4**) et avec l'anhydro-2,3 *O*-benzylidène-4,6 α-D-mannopyrannoside de méthyle (**6**); on a obtenu dans chacun des cas un dérivé sucre–stannane comportant une liaison carbone–étain stable. On a étudié ces produits au moyen de la spectroscopie rmn de ^{1}H et du ^{13}C.

[Traduit par le journal]

Introduction

Organotin compounds are finding (3) an ever increasingly wide range of industrial applications in areas ranging from the formation of wood preservation and marine antifouling paints, to food packaging (where they are used as stabilizers in polyvinylchloride films). Prompted by the fact that carbohydrate derivatives can be either water soluble or, when suitably substituted, soluble in organic media, we have investigated the synthesis of sugar–tin conjugates in which a tin moiety is covalently coupled to a sugar via a tin–carbon bond. It might be anticipated that such derivatives could have interesting biological properties resulting from the combined presence of the sugar and metal moieties; there is some basis for this speculation in the form of sucrose–triaryltin conjugates which have recently been shown[3] to be effective in marine antifouling paints.

From a more academic standpoint there is also a need for organo–tin materials which have defined conformations in solution to serve as models for further (4) evaluating the stereospecific dependencies of various spectroscopic parameters of tin, particularly scalar, spin–spin couplings. The success of such measurements is dependent both on the molecule having a conformation which can be determined with reasonable confidence using 'conventional' methods and an nmr spectrum which is sufficiently well resolved to enable transitions from the subspectra of the two molecules which are substituted by a magnetic isotope of tin (^{117}Sn, 7.54% or ^{119}Sn, 8.62%) to be detected in the presence of the substantially higher abundance of molecules which bear a nonmagnetic tin isotope (83.62%). As will be seen later, although the sugar derivatives we have synthesized are not perfectly satisfactory, they nevertheless provide an abundance of interesting data. In the following discussion, we describe the routes to the synthesis of derivatives having an organotin (specifically, in this case, a triphenyltin) moiety attached to either a primary, or a secondary, carbon atom of a sugar. We also document the use of ^{1}H and ^{13}C nmr to evaluate the primary structure and the solution conformation of these substances.

Results and Discussion

Synthesis

The two synthetic routes reported here both involve nucleophilic attack on a suitably activated sugar substrate by triphenyltin lithium (**1**) from triphenyltin chloride and lithium metal by the method of Tamborski *et al.* (5).

Synthesis of a sugar substituted at a primary centre is exemplified by the reaction of triphenyltin lithium (**1**) with 1,2:3,5-di-*O*-methylene-6-*O*-tosyl-α-D-glucofuranose (**2**). Thin-layer chromatography showed that the reaction was essentially completed after 2 h and work-up, as described in the Experimental, afforded a colourless crystalline product **3** in 43% yield, mp 108–110°C. The elemental microanalytical data and ^{1}H nmr parameters indicated that **3** has the structure (1,2:3,5-di-*O*-methylene-α-D-glucofuranos-6-yl) triphenylstannane. Important in the latter interpretation was the observation of the characteristically

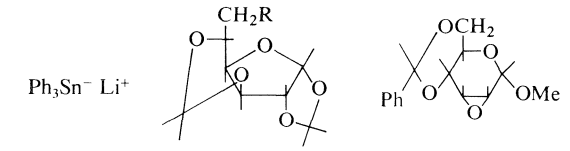
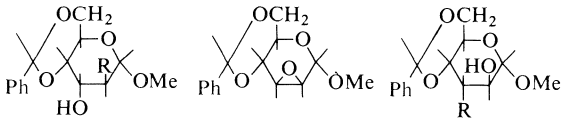
intense resonances of the protons of the triphenyl moiety and the pronounced high-field shift of the protons attached to the same carbon as the triphenyltin moiety; in benzene-d_6, the H-6 resonances of the tin product **3** were at τ 8.5 whereas those of 1,2:3,5-di-*O*-methylene-α-D-glucofuranose (**8**) came at ca. τ 6.65; see Experimental for Fig. 1 caption.

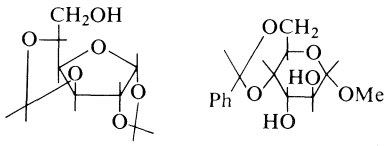
Attention was next directed to the more challenging problem of attaching a tin substituent to a secondary carbon centre. To our pleasant surprise we found that the triphenyltin lithium (**1**) reacted



1 **2** R = OTs; **3** R = $SnPh_3$ **4**



5 R = $SnPh_3$ **6** **7** R = $SnPh_3$



8 **9**

almost instantaneously with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (**4**). A colourless solid product was obtained after conventional work-up, in 75% yield, mp 67–69°C, which was subsequently identified as (methyl 4,6-*O*-benzylidene-α-D-altropyranoside-2-yl) triphenylstannane (**5**). In like fashion, methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside (**6**) gave in 94% yield (methyl 4,6-*O*-benzylidene-α-D-altropyranoside-3-yl) triphenylstannane (**7**), mp 166–168°C.

Nuclear Magnetic Resonance Spectra and Conformational Properties

Proton Data

The ^1H chemical shifts and coupling constants for the triphenyltin derivatives **3**, **5**, and **7** are summarized in Table 1 together with, for comparison purposes, the data for 1,2:3,5-di-*O*-methylene-α-D-glucofuranose (**8**) and methyl 4,6-*O*-benzylidene-α-D-altropyranoside (**9**).

That the parameters for the ring protons of **3** and **8** are so closely similar implies that both derivatives have similar solution conformations, probably ap-

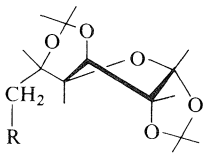
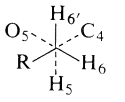
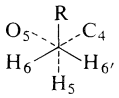
proximating to the $^3T_2$ conformation shown in **A**. More interesting are the very substantial differences between the two sets of parameters for the protons associated with C-5 and C-6. It seems reasonable to ascribe the change in the geminal coupling from −6 Hz for **8** to −13.3 Hz for **3** to the difference in 'electronegativity' between —OH and —$SnPh_3$ substituents. In the absence of adequate reference data it is not sensible to attempt a quantitative interpretation of the vicinal ^1H–^1H couplings. Nevertheless we depict below in **B**, **C**, and **D** the three noneclipsed rotamers about the C-5—C-6 bond of **3** with the corresponding rotamers for **8** depicted in **E**, **F**, and **G**. From the data given in Table 1, it appears **3** favours either rotamer **B** or **D** and examination of molecular models suggests that rotamer **B** is the more favoured because of the substantial steric interaction in **D** between the sugar ring and the triphenyltin moiety.



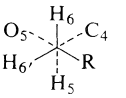
A



B R = $SnPh_3$
E R = OH

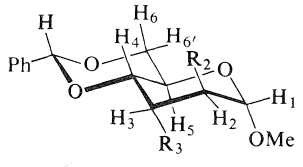


C R = $SnPh_3$
F R = OH

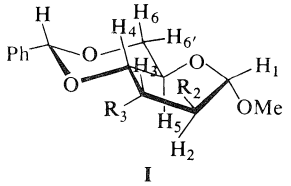


D R = $SnPh_3$
G R = OH

We had anticipated that opening of the epoxide ring of **4** would occur by nucleophilic attack on C-2 and this was confirmed by the finding that the H-2 resonance of **5** was shifted to high field (τ 6.93) of the other ring protons; see Experimental for Fig. 2 caption. The vicinal, ring proton coupling constants for **5** are close to those reported by Coxon (6) for derivatives of methyl 4,6-*O*-benzylidene-α-D-altropyranoside (**9**) and measured by us for **9** itself. Without repeating here Coxon's earlier discussion, it is clear that the triphenyltin moiety of **5** has seriously perturbed the pyranose ring from the $^4C_1$ conformation depicted in **H**.



H



I

That the triphenyltin moiety of **7** was attached to C-3 was evidenced by the high-field shift of H-3, thus confirming that the ring-opening of **6** had also followed the expected course. Although the vicinal ^1H–^1H couplings serve to confirm that this product has the α-D-altropyranose configuration it is noteworthy that $J_{3,4}$ is substantially larger (5.9 Hz) than the equivalent coupling of either **5** (2.5 Hz) or **9** (2.9 Hz). It is tempting to simply ascribe this differential to an electronegativity effect of the tin moiety, yet, if that were so, it is difficult to understand why a similar enhancement is not also observed for $J_{2,3}$, which is, if anything, smaller (2.1 Hz) for **7** than for **8**. An alternative explanation is that the pyranose ring is distorted by steric interaction involving the triphenyltin moiety towards the skew conformation, $^OS_5$, depicted in **I**; this conformational change would diminish the dihedral angle between H-3 and H-4 and this would be accompanied by an increase in $J_{3,4}$. In the absence of more comprehensive reference data is is clearly not fruitful to pursue this point too far. Nevertheless, it seems more than coincidental that whereas the H-3 resonance of **5** appears to have a normal shift, the H-2 resonance of **7** is shifted to high field by ca. 2 ppm. A field shift of this magnitude clearly reflects a substantial interaction between the H-2 proton and the ring current of the aromatic rings of the triphenyltin moiety.

Carbon-13 Data

Assignments of the ^{13}C nmr spectra were based on the selective proton decoupling technique summarised in the Experimental and the ^{13}C shifts for derivatives **3**, **5**, and **7** are summarised in Table 2. These data are unexceptional. That the carbon which bears the tin substituent is invariably the higher-field resonance suggests that this is a reliable criterion for assigning positional isomerisation in this class of sugar–tin conjugates, more reliable in fact than the analogous ^1H shifts, see Experimental for Fig. 3 caption.

Tin Coupling Constants

The remainder of this discussion will be concerned with the coupling constants between the two magnetic isotopes of tin and suitably disposed ^1H and ^{13}C nuclei and with their stereospecific dependencies.

It proved to be very difficult to detect in either the 100 MHz or 270 MHz proton spectra of derivatives **3**, **5**, and **7** any satellites arising from coupling with the ^{117}Sn and ^{119}Sn nuclei, mainly because the satellite transitions were for the most part obscured by the transitions of the protons of those molecules substituted by a nonmagnetic tin isotope. The only clearly resolved tin couplings in the spectra of **5** are with H-1 (25.8 Hz) and with H-2 (73.4 Hz) and for **3** with H-3 (56.2 Hz).

In contrast to the ^1H spectra, the ^{13}C resonances were sufficiently well dispersed, even at 20 MHz,

[a]Sign assumed by analogy with the literature (12).

for the $^{117}Sn–^{119}Sn$ satellite transitions to be readily detectable; see Experimental for Fig. 4 caption. The various coupling constants obtained from the spectra of derivatives **3**, **5**, and **7** are summarised in Table 3. Although it was simple to separately resolve the ^1J couplings of the ^{117}Sn and ^{119}Sn nuclei, the ^2J and ^3J couplings were too small and both the latter sets of data given in Table 3 are averaged values. The magnitudes of these data are in general agreement with values previously reported (4, 5) for cycloalkyl derivatives of tin; thus the ^1J couplings should be larger than the ^3J couplings which should in turn be larger than the ^2J couplings.

The literature data for ^3J ($^{13}C–Sn$) couplings are concisely summarised in Fig. 2, with the familiar (7) cos function being given in [1]; see Experimental for Fig. 5 caption. Although the solution conforma-

$$[1] \qquad J_{obs} = 30.4 - 7.6 \cos\theta + 25.2 \cos 2\theta$$

tions of the derivatives **3** and **7** are by no means as well defined as we had originally hoped, it is instructive to compare their ^3J ($^{13}C–Sn$) couplings, as well as those of **5**, with the data of Fig. 2; as we shall see the conformations previously proposed for all three derivatives appear to be consistent with the observed couplings.

Let us start with the C-2 substituted derivative **5** for which a $^4C_1$ chair conformation **H** had been previously proposed. The coupling between the tin and C-4 substituents cannot be precisely determined, but must lie between 0 and 0.3 Hz. According to the data of Fig. 5 this implies a dihedral separation between the C-4—C-3 and C-2—Sn bonds of 70–100°; conformation **H** would require a dihedral angle of ~95°.

Turning now to the C-3 substituted derivative **7** for which the $^OS_5$ conformation **I** had been suggested, we note that we now have two ^3J couplings to consider, the coupling with C-1 (32.8 Hz) which we must ascribe to a dihedral angle of ca. 130 or 35°, and the coupling with C-5 (15.7 Hz) which should correspond to an angle of ca. 110 or 58°. Since it is impossible to distort a pyranose ring to achieve a dihedral angle of 35°, the C-1 coupling must correspond to the dihedral angle of 130°. Because of the *trans*-fused junction between the pyranose and benzylidene rings limits the extent of possible conformational distortion for the pyranose ring, it is impossible to obtain a dihedral angle between the C-3—Sn and C-4—C-5 bonds of less than ~50°, we must assume that the C-5 coupling corresponds to a dihedral angle of 112°, it happens that the $^OS_5$ conformation **I** previously nominated for **7** would require this angle to be 112°.

Conformational assignments for acyclic derivatives which ignore conformational time averaging are necessarily simplistic so the discussion of the ^3J coupling between C-4 and the tin substituent of **3** cannot be expected to be definitive. Yet the observed coupling (ca. 60 Hz), which can only correspond to a large dihedral angle, is in excellent agreement with the previous assignment of **B** as being the favoured rotamer about the C-5—C-6 bond.

Conclusions

As we noted in the Introduction, we were somewhat disappointed that the tin derivatives **3**, **5**, and **7** did not all have undistorted conformations, since this appeared, at first, to vitiate the major reason for this project. Nevertheless, the agreement between

the conformations deduced by 'conventional' proton nmr methods and the angles based on the ^{13}C—Sn couplings described previously in the literature, and here, provides a compelling, albeit less direct, substantiation for the basic premise that sugar–metal derivatives do provide convenient model systems for heteronuclear nmr studies.

As a final comment we draw attention to the fact that the axial triphenyltin substituent at C-3 but not that at C-2, results in deformation of the conformation of the pyranose ring. This is a perfectly reasonable finding but it has an important implication, namely, that it would now appear to be very worthwhile to evaluate the conformational preferences of other substituents attached to the C-3 position of this altroside system to evaluate their ability to cause conformational distortions. Included in this category could be any of the following: $—C(Me)_3$, $—C(Ph)_3$, $—X(Me)_3$, and $—X(Ph)_3$ where X = Si, Sn, Pb, or P^V.

Experimental

All solutions were concentrated under reduced pressure using a Buchi rotary evaporator. All melting points were determined using a Hoover Unimelt (6406-K) instrument and are uncorrected. All optical rotations were determined for acetone solutions using a Perkin-Elmer 141 polarimeter.

Thin-layer chromatography (tlc) was performed on silica gel G (Merck) using toluene–ether (1:2) and detection by charring with H_2SO_4. All reactions were performed in anhydrous solvents under an atmosphere of dry nitrogen; solvents were dried, distilled, and then stored over molecular sieves.

Triphenyltin chloride (95+ %) was obtained from Alfa Products (Danvers, MA) and was used after recrystallisation from methanol–chloroform and drying at 80°C using Drierite as the dessicant at ca. 0.8 Torr for 24 h. Lithium metal rods (technical grade) were obtained from Fisher Scientific Co., Chemical Manufacturing Division (Fair Lawn, NJ).

Proton nmr spectra were measured at 100 MHz with a Varian XL-100 (15) spectrometer fitted with a Varian 620L (16K) computer; and at 270 MHz with the prototype of a home-built spectrometer based on a Bruker WP-60 console, a Nicolet 1080 computer (16K), a Nicolet 293 pulse controller unit, a Diablo Disk, and an Oxford Instruments Superconducting solenoid. The 270 MHz radiofrequency was derived from the Bruker Console by mixing with the output of a Hewlett Packard frequency synthesiser using a mixing technique developed in this laboratory (8).

Carbon-13 nmr spectra were measured with a CFT-20 spectrometer. The selective proton decoupling experiments used a heteronuclear decoupler, described previously (9); see Fig. 6 caption below.

Nuclear Magnetic Resonance Spectra

Detailed nmr spectra of certain of the materials discussed in this manuscript have been placed in the Depository of Unpublished Data.[4] The full captions of those figures are listed below to provide the reader with a summary of the spectral information which is available. Fig. 1. Continuous-wave ^1H nmr spectrum (100 MHz) of (1,2:3,5-di-*O*-methylene-α-D-glucofuranose-6-yl) triphenylstannane (**3**) (at top) and of 1,2:3,5-di-*O*-methylene-α-D-glucofuranose (**8**) (at bottom), both measured in benzene-d_6 solutions. The peak marked * is from an impurity. Fig. 2. Fourier transform ^1H nmr spectrum (270 MHz) of (methyl 4,6-*O*-benzylidene-α-D-altropyranoside-2-yl) triphenylstannane **5** in benzene-d_6 solution, showing the spectral assignments and the ^1H–Sn coupling constants. Fig. 3. Natural abundance ^{13}C nmr spectra in benzene-d_6 solutions (ca. 0.3 m) of *A*, (1,2:3,5-di-*O*-methylene-α-D-glucofuranose-6-yl) triphenylstannane (**3**) and *B*, 1,2:3,5-di-*O*-methylene-α-D-glucofuranose (**8**). Fig. 4. Natural abundance ^{13}C nmr spectrum of (methyl 4,6-*O*-benzylidene-α-D-altropyranoside-2-yl) triphenylstannane (**5**) in acetone-d_6 solution (0.3 *M*) showing the normal resonances and the tin satellites of the C-1, C-2, and C-3 resonances. (PW 7; PD 0; NT 80 000; AT 1.023 s.) Fig. 5. Magnitudes of $^3J(^{119}Sn–^{13}C)$ coupling constants plotted as a function of the dihedral angle between the $^{119}Sn—^{13}C—C$ bonds. (This diagram is reproduced by permission of the authors of ref. 4.) Fig. 6. Natural abundance ^{13}C nmr spectra of (methyl 4,6-*O*-benzylidene-α-D-altropyranoside-2-yl) triphenylstannane (**5**) benzene-d_6 solution (0.3 m); *A*, with complete proton decoupling and *G*, with the decoupler gated off during the spectral acquisition. The spectra *B*–*F* show the effect of selective irradiation of individual proton resonances.

Preparation of Triphenyltin Lithium

NOTE: It was found that the reaction to form triphenyltin lithium worked well only when the surface of the lithium metal was very clean. It was found necessary to clean the metal surface in dry methanol and then to quickly rinse the piece of metal in dry tetrahydrofuran before adding it to the solvent in the reaction vessel.

Following the procedure of Tamborski *et al.* (6), 2.5 g, (6.5×10^{-3} mol) of triphenyltin chloride in ca. 15 ml tetrahydrofuran was added to a well-stirred solution containing lithium shavings (0.55 g, 0.08 mol) and tetrahydrofuran. Within about 15 min, heat was evolved and the reaction mixture became a dark olive-green colour. The solution was stirred for 1–2 h. after which time it was filtered through glass wool and immediately used for the following reactions. Yields for this reaction have been reported (4, 5) to be 50–75%.

Preparation of (1,2:3,5-Di-O-methylene-α-D-glucofuranose-6-yl) Triphenylstannane (3)

Triphenyltin chloride (2.5 g, 6.5×10^{-3} mol) in tetrahydrofuran were reacted with an excess of lithium metal in the manner described above, for 2 h, filtered through glass wool and added, dropwise, to a stirred solution of 1,2:3,5-di-*O*-methylene-6-*O*-tosyl-α-D-glucofuranose (10) (1.5 g, 4.2×10^{-3} mol) in tetrahydrofuran (25 ml). After 4 h, tlc indicated that all the tosylate had reacted. The reaction mixture was then poured into water (250 ml) and neutralized with ammonium chloride. The mixture was extracted with chloroform (3 × 5 ml) and the chloroform solution dried over magnesium sulfate, after which the solvent was removed under reduced pressure. Any contaminating hexaphenylditin was precipitated by adding cold anhydrous diethyl ether and filtering off the crystals. The ether was then evaporated to yield a white crystalline material which was subsequently identified as **3**; yield, after one recrystallization (benzene – light petroleum, bp 30–60°C was 1 g (43.5%), mp 108–110°C, $[\alpha]_D^{25}$ +60.00° (*c* 2.37). *Anal.* calcd. for $C_{26}H_{26}O_5Sn$: C 58.13, H 4.88; found: C 57.90, H 4.86.

Preparation of (Methyl 4,6-O-Benzylidene-α-D-altropyranoside-2-yl) Triphenylstannane (5)

Triphenyltin chloride (2.5 g, 6.5×10^{-3} mol) and lithium metal (0.5 g, 0.08 mol) were reacted as described above, filtered, and added, dropwise, to a stirred solution of methyl

2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (11) (1.0 g, 3.78×10^{-3} mol) in tetrahydrofuran (ca. 25 ml). The reaction appeared to be instantaneous, as the dark olive-green colour of the triphenyltin lithium disappeared immediately upon addition; however, to ensure complete reaction, the mixture was stirred for 1 h. After work-up, as described for **3**, 2.6 g (75% yield) of a crystalline compound was obtained, subsequently identified as **5**, mp 67–69°C, $[\alpha]_D^{25}$ +5.91° (*c* 2.15). *Anal.* calcd. for $C_{32}H_{32}O_5Sn$: C 62.47, H 5.24; found: C 63.88, H 5.31.

Preparation of (Methyl 4,6-O-Benzylidene-α-D-altropyranoside-3-yl) Triphenylstannane (7)

Triphenyltin chloride (1.25 g, 3.25×10^{-3} mol) was reacted with lithium metal shavings (0.55 g, 0.08 mol) in the manner described above, filtered, and added, dropwise, to a stirred solution of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside (11) (0.37 g, 0.6×10^{-3} mol) in tetrahydrofuran (ca. 25 ml). After work-up, as for **3**, a foamy syrup was obtained. This syrup solidified after 12 h under vacuum; yield 0.81 g (94%), mp 166–168°C, $[\alpha]_D^{25}$ +91.0° (*c* 1.97). *Anal.* calcd. for $C_{32}H_{32}O_5Sn$: C 62.47, H 5.24; found: C 62.01, H 5.40.

Acknowledgments

It is a pleasure to thank the National Research Council of Canada for their support of this work via operating grants to L.D.H. (A 1905). Funds for the components of the 270 MHz nmr spectrometer came from the University of British Columbia (Chemistry Department and the President's Emergency Research Equipment Fund).

The preparation of dimethyl 4-(1-chloroethyl)-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate and its reaction with nucleophilic reagents are described. Potassium cyanide, potassium succinimide, or methanolic triethylamine gave, stereospecifically, 4,5-dihydroazepines in which substituents at C(4) and C(5) are *trans*, whereas potassium thiocyanate afforded only the corresponding 4-(1-thiocyanatoethyl)-1,4-dihydropyridine. Sodium hydrosulfide afforded a mixture of 8-thia-2-azabicyclo[3.2.1]oct-3-ene-4,7-diesters epimeric at C(7), whereas potassium carbonate in aqueous dimethyl sulfoxide yielded an 8-oxa-2-azabicyclo-[3.2.1]oct-3-ene-4,7-diester. The stereochemistry of these bicyclic compounds is established using nmr spectroscopy. In acid media, dimethyl 2,5,7-trimethylazepine-3,6-dicarboxylate and a 4-methoxy-4,5-dihydroazepine rearranged to give 1,4-dihydropyridine derivatives; a mechanism for this ring contraction is suggested.

BRIAN GREGORY, ERIC BULLOCK et TENG-SONG CHEN. Can. J. Chem. **57**, 44 (1979).

On décrit la préparation du (chloro-1 éthyl)-4 dihydro-1,4 diméthyl-2,6 pyridinedicarboxylate-3,5 de diméthyle et ses réactions avec des réactifs nucléophiles. Le cyanure de potassium, le sel de potassium de la succinimide ou la triéthylamine éthanolique conduisent d'une façon stéréospécifique aux dihydro-4,5 azépines dans lesquelles les substituants en C(4) et en C(5) sont *trans*; toutefois le thiocyanate de potassium ne fournit que la (thiocyanato-1 éthyl)-4 dihydro-1,4 pyridine. L'hydrosulfure de sodium conduit à un mélange de thia-8 aza-2 bicyclo-[3.2.1] octène-3 diesters-4,7 épimères en C(7) alors que le carbonate de potassium dans le diméthylsulfoxyde aqueux fournit une oxa-8 aza-2 bicyclo[3.2.1] octène-3 diester-4,7. On a déterminé la stéréochimie de ces composés bicycliques à l'aide de la spectroscopie rmn. En milieu acide, le triméthyl-2,5,7 azépinedicarboxylate-3,6 de diméthyle et une méthoxy-4 dihydro-4,5 azépine se transforment pour donner des dérivés dihydro-1,4 pyridines; on suggère un mécanisme pour cette contraction de cycle.

Studies, by us and others, show that the rearrangement reactions of 4-chloromethyl-1,4-dihydropyridines e.g., **1** or **2**, with nucleophilic reagents have afforded useful routes to several different heterocyclic ring systems (1 and references therein). As part of some related work, we required the 4-(1-chloroethyl)-1,4-dihydropyridine **3**, in which the carbon bearing the potential leaving group, chlorine, is labelled by attachment of a methyl group. Such a compound is clearly useful for stereochemical and mechanistic studies of some of these nucleophile-induced rearrangement reactions and is the subject of the present report.

Reaction of 1,2-dichloropropyl ethyl ether with methyl 3-aminocrotonate gave, in moderate yield, the chloroethyl compound **3** whose spectroscopic properties were in accord with the assigned structure. In particular, the ^{1}Hmr spectrum contained a three-proton doublet at δ 1.34 and a one-proton partly obscured double quartet at δ 4.02 which arise from the methyl and methine protons, respectively, of the chloroethyl group, and the ultraviolet (2, 3) and infrared spectra (2) were typical of Hantsch-type dihydropyridines. The mass spectrum was, however, temperature dependent. At reasonably low temperatures, the compound behaved as a typical 1,4-dihydropyridine and showed a base peak due to a pyridinium cation formed by loss of chloroethyl radical (cf. ref. 4). As the inlet temperature was increased, ions arising from loss of hydrogen chloride from the molecular ion became increasingly important and the mass spectrum then resembled that of the azepine **15**.

Reaction of the chloroethyl compound **3** with sodium cyanide in dimethyl sulfoxide gave, after chromatography, methyl 4-cyano-2,5-dimethylpyrrole-3-carboxylate and a less soluble product **9** whose long wavelength ultraviolet absorption maximum appeared at a shorter wavelength and was more intense than that of the starting dihydropyridine, a characteristic of 4,5-dihydroazepines (2). The ^{1}Hmr spectrum showed, in addition to singlets due to methyl groups at C(2) and C(7), methyl esters and NH, a three-proton doublet at δ 0.94, a one-proton multiplet at δ 3.73, and a one-proton doublet at δ 4.34 due to the CH_3—CH—CH(CN)—

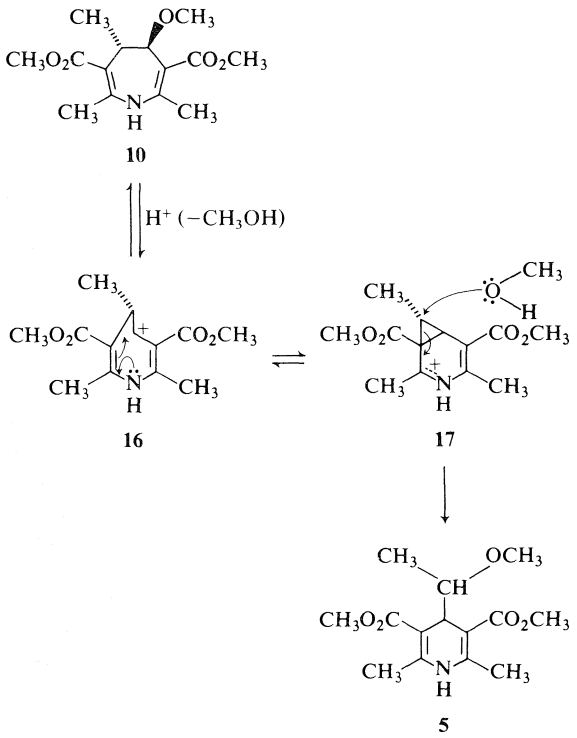
system. Further, the doublet at δ 4.34 showed a coupling of 6.2 Hz which is consistent with the protons at C(4) and C(5), and therefore the cyano and methyl substituents on these carbon atoms having a *trans* relationship.[2] Since no *cis* isomer was detected, either the reaction had occurred stereospecifically to give the *trans* isomer or alternatively any *cis* isomer formed had been converted to the *trans* isomer through base-catalysed formation of a carbanion at C(4). To distinguish between these possibilities, dihydroazepines having groups incapable of stabilization of a carbanion at C(4) have been prepared. Thus when the chloroethyl compound **3** was solvolyzed in methanol containing triethylamine, the 4-methoxy-4,5-dihydroazepine **10** was obtained. The presence in the ^{1}Hmr spectrum of a doublet, $J = 6.6$ Hz, at δ 4.60 again confirmed the *trans* configuration of substituents at C(4) and C(5). Similarly the chloroethyl compound **3** reacted with potassium succinimide in ethanol to give the *trans*-4-succinimino compound[3] **12** (the doublet at δ 5.31 showed $J = 6.0$ Hz). The ring expansion reactions of the chloroethyl compound **3** are thus stereospecific. From a study of the kinetics of the reaction of cyanide ion with 4-chloromethyl-1,4-dihydropyridines, e.g. **1**, Eisner and co-workers (5) have suggested a ring-expansion mechanism which involves elimination to form an intermediate azepine, e.g. **14**, followed by 1,4-addition of hydrogen cyanide. The azepine **14** was shown to be converted to racemic 4-cyano-4,5-dihydroazepine **7** (only one enantiomer is shown for convenience) by the action of cyanide ion (5). Similarly, we have shown that the reaction of the 2,5,7-trimethylazepine **15** with potassium cyanide in methanol occurs, in this case, stereospecifically to give racemic *trans*-4-cyano-4,5-dihydroazepine **9** in good yield, along with a lesser amount of the *trans*-4-methoxy compound **10**. The trimethylazepine **15** used in this experiment was obtained by the action of sodium ethoxide in ether or potassium carbonate in dimethyl sulfoxide on the chloroethyldihydropyridine **3**, or by pyrolysis of the methoxy- or succiniminodihydroazepines **10** and **12**, respectively. At ambient temperatures, the nmr spectrum of **15** showed extreme broadening of the C(4)-methyl resonance in the δ 0.55–1.15 region. At 80°C, however, a sharp spectrum was obtained which showed in addition to singlets due to methyl esters and methyl groups at C(2) and C(7), a doublet at δ 0.88 ($J = 7.0$ Hz), a multiplet at δ 2.88, and a doublet at δ 5.23 ($J = 7.0$ Hz).

Earlier we have shown that diethyl 4-cyano-4,5-dihydro - 2,7 - dimethylazepine - 3,6 - dicarboxylate **8** may be converted in alkaline media to ethyl 4-cyano-2,5-dimethylpyrrole-3-carboxylate and ethyl acrylate (2). Accordingly, when the cyano compound **9** was

[2]In related 4,5-dihydroazepines, values of J_{AX} and J_{BX} of 6.0–8 and 0–1.6 Hz, respectively, have been reported. Examination of Dreiding models reveals approximate dihedral angles for H_A—C—C—H_X and H_B—C—C—H_X of 158 and 80°, respectively. If the substituent at C(4) occupies a pseudo-equatorial configuration, then H_A is *trans* to H_X whereas H_B is *cis* to H_X providing that the Karplus relationship is obeyed.

[3]Reaction of the chloromethyl compound **1** with potassium succinimide gave the corresponding succinimino compound **11** (see Experimental).



SCHEME 1

treated with potassium hydroxide in methanol, the products obtained were methyl crotonate, methyl 3-aminobutyrate, and methyl 4-cyano-2,5-dimethylpyrrole-3-carboxylate. The formation of methyl crotonate provides confirmation that the unsaturated ester originates from the ring carbon atoms C(5), C(6) and the ester group at C(6), and is in agreement with the postulated mechanism (6) which involves the formation of an intermediate 2-azabicyclo[3.2.0]heptene. The 3-aminobutyrate probably arises by Michael addition of ammonia, formed by competing base-catalysed hydrolysis of dihydroazepine **9** to methyl crotonate. When the cyanodihydroazepine **9** was treated with aqueous methanolic silver nitrate, the products included a furo[2,3-*b*]pyridine, a pyrrolo[2,3-*b*]pyridine, and a 2-oxo-1,2,3,4-tetrahydropyridine derivative (7).

Reaction of the methoxydihydroazepine **10** with methanolic hydrogen chloride yielded the methoxyethyldihydropyridine **5** (58%), the chloroethyldihydropyridine **3** (30%), and dimethyl 2,6-dimethylpyridine-3,5-dicarboxylate (5%). The formation of **5** is envisaged as proceeding via a carbonium ion mechanism as outlined in Scheme 1. Thus acid-catalyzed loss of methanol is believed to give a resonance-stabilized homoallyl–allyl carbonium ion **16** which is in equilibrium with the resonance-stabilized cyclopropylcarbinyl-type carbonium ion **17**.[4] Nucleophilic attack on **17** by methanol, as shown, would afford the methoxyethyl compound **5**, whereas competitive attack by chloride ion on the same cation would give the chloroethyl compound **3**. The conversion of cyclopropylcarbinyl compounds to homoallyl compounds in acidic media has precedent in the reaction of cyclopropylcarbinols with hydrochloric acid (8) and the acid-catalysed conversion of 3,5-cyclocholestan-6-yl compounds to cholesteryl derivatives (9 and references therein). The mechanism shown in Scheme 1 is essentially the reverse of a plausible mechanism for ring expansion of dihydropyridines **1**–**4** involving homoallylic participation and electron release from nitrogen. The origin of dimethyl 2,6-dimethylpyridine-3,5-dicarboxylate is not clear at the present time but it is believed to involve the action of oxygen on the methoxyethyl compound **5** in the presence of acid.[5] When the methoxydihydroazepine **10** in ether was reacted with hydrobromic acid, the bromoethyl compound **4** was formed in high yield. Similarly the 4*H*-azepine **15** reacted with concentrated hydrochloric or hydrobromic acids to give the chloroethyl and bromoethyl compounds **3** and **4**, respectively. In this case it is considered that the carbonium ion **16** is generated by *N*-protonation of the 4*H*-azepine. Acid-catalysed ring contraction of related azepine derivatives has been reported by Anderson and Johnson (6).

The reactions of the chloroethyl compound **3** with some sulfur nucleophiles have been examined. Thus reaction with potassium thiocyanate in methanol afforded the 4-(1-thiocyanatoethyl)-1,4-dihydropyridine **6** in good yield. Retention of the dihydropyridine ring system in such substitution reactions is rare and has been reported in examples involving iodide ion (5) or thiourea (1) only.

Reaction of the chloroethyl compound **3** with sodium hydrosulfide in ethanol afforded two isomeric products. Each product showed a base peak in the mass spectrum at *m/e* 185 owing to loss of methyl crotonate, peaks due to saturated and un-

[4]For convenience, we have represented this mechanism as proceeding via an equilibrating pair of carbonium ions **16** and **17**. We have no evidence at the present time which allows a choice between this and the corresponding nonclassical carbonium ion.

[5]When diethyl 2,6-dimethyl-4-methoxymethyl-1,4-dihydropyridine-3,5-dicarboxylate was allowed to stand in chloroform containing a trace of hydrogen chloride in the presence of air, the methoxymethyl substituent was eliminated and diethyl 2,6-dimethylpyridine-3,5-dicarboxylate was formed (B. Gregory, unpublished observations). This is reminiscent of the mass spectral fragmentation of this compound and may involve a radical reaction. 4-Alkyl-1,4-dihydropyridines do not behave in this way.

saturated esters in the infrared spectrum, and ultraviolet spectra in accord with the presence of an alkyl 1,4,5,6-tetrahydronicotinate chromophore (10). These spectroscopic properties and the ^{1}Hmr spectra were consistent with the formulation of the isomers as dimethyl 1,3-dimethyl-8-thia-2-azabicyclo[3.2.1]-oct-3-ene-4,7-dicarboxylate stereoisomers. The formation of such products clearly involves sulfhydryl-induced ring expansion to give, by analogy with the cyanide and methoxide reactions, the *trans*-4-thiol **13**. Michael addition of the thiol group or its conjugate base to C(7) of the unsaturated ester would give, after protonation, the *exo*- and *endo*-7-methoxycarbonyl compounds **18** and **19**. In addition to singlets due to methyl esters and methyl groups at C(1) and C(3), the ^{1}Hmr spectrum of each isomer showed a three-proton doublet, a one-proton multiplet, and two one-proton doublets consistent with the presence of the CH—CH(CH_3)—CH system. For each isomer, the lower field doublet (lowered by presence of adjacent sulfur, and due to the proton at C(5)) exhibited similar coupling constants (J = 4.7 and 4.8 Hz) showing that the stereochemistry at C(6) was similar in the two compounds, and confirming that the methyl at C(6) has an *endo* configuration.[6] The higher melting, less soluble major component and the lower melting, more soluble minor component showed doublets at δ 2.55 (J = 7.4 Hz) and δ 3.16 (J = 3.0 Hz), respectively. Examination of Dreiding molecular models of **18** and **19** shows dihedral angles between C(6)-H and C(7)-H of 120 and 0°, respectively. Using the Karplus curve, the higher melting isomer is therefore assigned the *endo*-7-methoxycarbonyl structure **18** and the lower melting isomer consequently has the *exo*-7-methoxycarbonyl structure **19**. The lower melting isomer **19** was easily epimerised to the more stable compound **18** using sodium methoxide in refluxing dioxan. Ashby and Eisner (11) obtained the 8-thia-2-azabicyclo[3.2.1]oct-3-ene **20**[7] but no *exo*-7-methoxycarbonyl isomer **21**, by the action of potassium hydrosulfide on the chloromethyl compound **1**. It would therefore appear that the steric requirement of the *endo*-6-methyl group is responsible for some degree of stabilization of the *exo*-7-methoxycarbonyl compound **19**.

Prolonged treatment of the chloroethyl compound **3** with potassium carbonate in aqueous dimethyl sulfoxide afforded, in low yield, a crystalline product $C_{13}H_{19}NO_5$ whose infrared and ultraviolet spectra closely resembled those of the foregoing sulfur bridge compounds **18–20** and left little doubt that it was an oxygen bridged analogue. In addition to singlets due to nonequivalent methyl esters, two methyls attached to sp^2 and sp^3 carbon atoms, and a three-proton doublet (methyl at C(5)), the ^{1}Hmr spectrum showed one-proton signals at δ 2.55 (doublet J = 3.9 Hz), 2.93 (double quartet, J = 7.0, 3.9 Hz), 4.61 (singlet), and 4.63 (broad singlet due to NH). The multiplicity of the δ 2.93 signal and the low field position of the δ 4.61 signal leave no doubt that these signals are caused by hydrogens attached at C(6) and C(5), respectively, and the signal at δ 2.55 must therefore be due to hydrogen at C(7). The singlet nature of the hydrogen at C(5) is explainable only if the methyl at C(6) occupies an *exo* position, allowing the proton at C(6) to have an *endo* configuration and giving a dihedral angle[8] near 90°. The *endo* and *exo* bonds at C(7) make dihedral angles of approximately 0 and 120° at the *endo* hydrogen at C(6); the observed interproton coupling constant of 3.9 Hz is more consistent with a dihedral angle of 120° (cf. J = 7.4 and 3.0 Hz for **18** and **19**, respectively). The methoxycarbonyl group at C(7) is therefore assigned an *endo* configuration and the stereochemistry of the compound is therefore that shown in **22**. In dihydroazepines **9**, **10**, and **12** and the sulfur bridged compounds **18** and **19**, the attacking nucleophile has occupied a position *trans* to the methyl group on the adjacent carbon atom. The *cis* relationship between oxygen bridge and methyl at C(6) in compound **22** may mean that a different mechanism is involved in its formation, e.g., elimination with ring expansion to give the azepine **15** followed by attack of hydroxide at C(2) to give **24** and intramolecular Michael addition of the hydroxyl to C(5). 8-Oxa-2-azabicyclo[3.2.1]octene derivatives[9] have not, to our knowledge, been reported previously, although it has been suggested (14) that the properties of a compound formulated as **25** by Anderson and Johnson (15) are in better agreement with the oxygen bridged structure **23**. The reported (15) spectroscopic properties of this compound show many similarities to those of compound **22**.

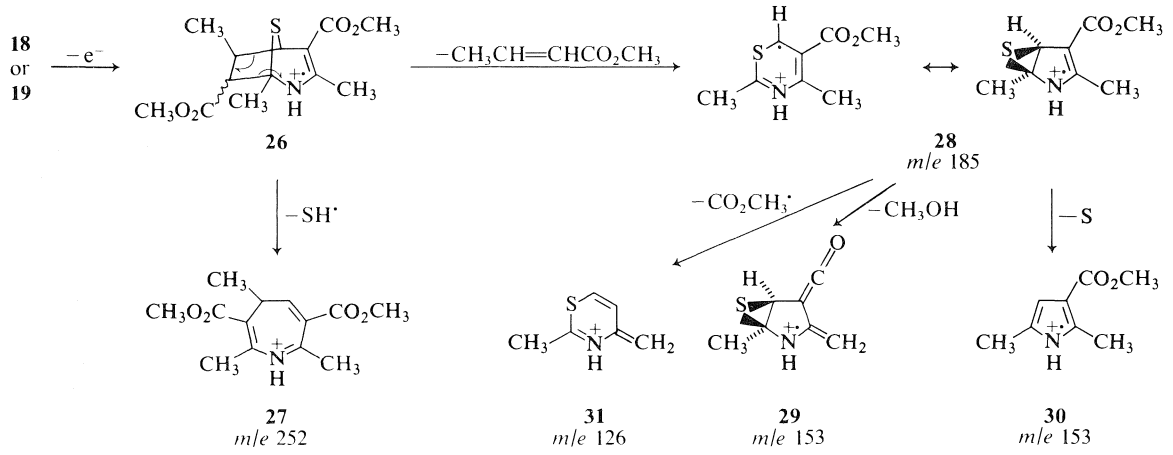
The electron-impact-induced fragmentations of **18**, **19**, and **22** were very similar, although some differences were observed. The major fragmentation pathways for **18** and **19** are shown in Scheme 2 and

[6]The dihedral angle between the hydrogen at C(5) and an *endo*-hydrogen at C(6) is close to 90° and would therefore be expected to result in a coupling constant close to zero.

[7]This structure was later confirmed in an X-ray study (12) although some reassignment of ^{1}Hmr signals was necessary.

[8]The dihedral angle between the C(5)-H bond and the *exo* bond at C(6) is approximately 34°; if the proton at C(6) had an *exo* configuration a coupling constant of about 5 Hz would be expected by analogy with compounds **18** and **19**.

[9]An 8-oxa-2-azabicyclo[3.2.1]octane is known (13).



SCHEME 2

TABLE 1. Accurate mass measurements on compounds **18** and **22**

Compound	Ion structure	Ion composition	Mass	
			Found	Required
18	**27**	$C_{13}H_{18}NO_4$	252.1243	252.1236
	28	$C_8H_{11}NO_2S$	185.0511	185.0510
	29	C_7H_7NOS	153.0256(major)	153.0248
	30	$C_8H_{11}NO_2$	153.0785(minor)	153.0790
	31	C_6H_8NS	126.0375(major)	126.0378
	—	—	126.0078(minor)	—
22	$M - CO_2CH_3\cdot - CH_3OH$	$C_{10}H_{12}NO_2$	178.0869(minor)	178.0868
	Unknown	$C_{10}H_{10}O_3$	178.0632(major)	178.0630
	32	$C_8H_{11}NO_3$	169.0741	169.0739
	33	$C_7H_8NO_3$	154.0521(major)	154.0504
	34	$C_8H_{10}O_3$	154.0664(minor)	154.0630

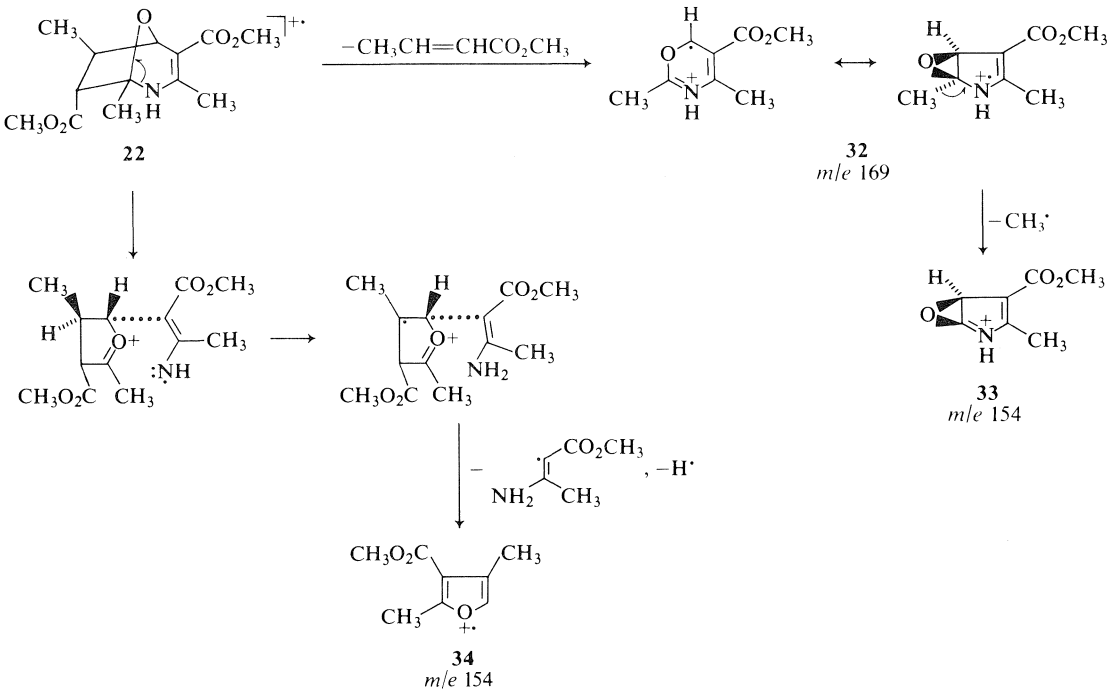
are supported by accurate mass measurements (see Table 1). The prominent ion at *m/e* 252 results from loss of hydrosulfide radical from **26** and may have structure **27**. Loss of methyl crotonate (cf. ref. 11) from the molecular ion **26** yields a resonance-stabilized cation **28** which subsequently loses methanol, sulfur, or methoxycarbonyl radical to yield ions **29**, **30**, or **31**, respectively. Ions formed by successive loss of methoxycarbonyl and methanol are observed at *m/e* 226 and 194 but this is a relatively minor pathway.

In the case of **22**, the base peak again arises by loss of methyl crotonate to give ion **32** (see Scheme 3); an abundant ion $C_7H_8NO_3$ may arise by loss of methyl from **32** and may be represented by **33**. In addition to expected loss of methoxyl radical, methoxycarbonyl radical, or methoxycarbonyl radical and methanol to give ions at *m/e* 238, 210, and 178, a further pathway results in the formation of a minor ion $C_8H_{10}O_3$ and may be represented by structure **34**. This latter pathway would appear to be initiated by loss of a lone pair electron from the bridge oxygen of **22**. Although it is well known that thioethers have lower ionization potentials than ethers (16 and references therein), the failure of the sulfur bridged compounds **18** and **19** to fragment by such a pathway may be explained by the lesser ability of sulfur to stabilize an adjacent carbonium ion resulting in the decreased importance of α cleavage in thioethers relative to ethers (17). An example of a compound containing both ether and thioether groups has been reported to fragment by initial loss of an electron from oxygen despite the ionization potential values (18).

The 4-succinimino-4,5-dihydroazepine **11** showed activity at 100 mg/kg po in an antihypertensive assay using spontaneously hypertense rats. However, no hypotensive activity was observed in conscious normotensive rats (100 mg/kg po), a normotensive anesthetized dog (up to 10 mg/kg iv), or a renal hypertensive dog (25 mg/kg, po).

Experimental

Details concerning spectral measurements, analyses, etc., are provided in an earlier publication (1). Vapour phase chromatography measurements were obtained using a Beck-



SCHEME 3

man GC-2A gas chromatograph equipped with column No. 70007 (Carbowax 4000 dioleate on C-22 Firebrick) operated at 70°C and 12 psi pressure of helium. Accurate mass measurements were obtained using a Varian MAT 311 mass spectrometer. Spin decoupling experiments were performed using a Bruker WP80DS Fourier Transform nmr spectrometer.

Dimethyl 4-(1-Chloroethyl)-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate (3)

A mixture of 1,2-dichloropropyl ethyl ether (40 mL) and methyl 3-aminocrotonate (48 g) in benzene (50 mL) was stirred at room temperature for 2 days. Water (300 mL) and ether (300mL) were added, and after shaking, the organic layer was collected. The aqueous layer was extracted with ether (3 × 300 mL) and the combined ether extract was then washed with water (2 × 50 mL), dried ($MgSO_4$), filtered, and evaporated. Crystallization from benzene yielded colorless crystals of **3** (18.2 g, 30%), mp 169–170°C; ir ν_{max}: 3429 (NH, free), 3318 (NH, bonded), 1697 (unsaturated ester), 1649 cm^{-1} (C=C); uv λ_{max} (ε): 232 (16 850), 339 nm (7300); ^{1}Hmr δ: 1.34 (d, J = 6.6 Hz, CH_3—CHCl—), 2.38 (s, methyls at C(2), C(6)), 3.78 (s, methyl esters), 4.02 (partly obscured double q, J = 5.0, 6.6 Hz, —CHCl—CH_3), 4.41 (d, J = 5.0 Hz, H at C(4)), 6.22 (s, NH); ms *m/e*: 287 (<1%, M^+, ^{35}Cl), 224(100), 220(34), 219(41), 192(99.5), 191(33), 160(82), and 132(51). *Anal.* calcd. for $C_{13}H_{18}ClNO_4$: C 54.26, H 6.31, N 4.87, Cl 12.32; found: C 54.44, H 6.08, N 4.80, Cl 12.28.

Dimethyl 4-Cyano-4,5-dihydro-2,5,7-trimethylazepine-3,6-dicarboxylate (9)

(*a*) The chloroethyl compound **3** (4.0 g) and sodium cyanide (1.6 g) in dimethyl sulfoxide (30 mL) were stirred at room temperature for 48 h. After addition of water (200 mL) the reaction mixture was extracted with ether (3 × 200 mL). The ether solution was washed with water (2 × 30 mL) and the solvent evaporated under reduced pressure to give a pale yellow solid (3.5 g) which tlc revealed to be two components. Recrystallization from ether – petroleum ether afforded the less soluble cyano compound **9** as white prisms (2.41 g, 63%), mp 147–148.5°C; ir ν_{max}: 3416 (NH, free) 2246 (C≡N), 1709 (unsaturated ester), 1696 (unsaturated ester), and 1633 cm^{-1} (C=C); uv λ_{max} (ε): 229 (14 400), 326 nm (16 300); ^{1}Hmr (Varian HA 100) δ: 0.94 (d, J = 6.8 Hz, methyl at C(5)), 2.34 (s, methyl at C(7)), 2.39 (s, methyl at C(2)), 3.73 (m, signal obscured by singlets at δ 3.73, 3.74, C(5)-H), 3.73 and 3.74 (s, s, methyl esters), 4.34 (d, J = 6.2 Hz, C(4)-H), 6.17 (s, NH); the doublets due to H at C(4) and methyl at C(5) became singlets on irradiation at 373 Hz; ms *m/e*: 278(26, M^+), 247(35), 179(100), 159(21), 121(21), 119(26), 118(28), 42(28). *Anal.* calcd. for $C_{14}H_{18}N_2O_4$: C 60.42, H 6.52, N 10.07; found: C 60.31, H 6.37, N 9.96.

The more soluble component was obtained by removal of solvent from the mother liquor and recrystallization from benzene to give methyl 4-cyano-2,5-dimethylpyrrole-3-carboxylate as white prisms (0.58 g, 23%), mp 180.5–181.5°C; ir ν_{max}: 3435 (NH, free), 3251 (NH, bonded), 2233 (aryl C≡N), 1710 cm^{-1} (aryl ester); uv λ_{max} (ε): 211 (15 000), 263 nm (8700); ^{1}Hmr δ: 2.35 and 2.47 (s, s, methyls at C(2), C(5)), 3.80 (s, methyl ester); ms *m/e*: 178 (66, M^+), 163(53), 147(100), 146(47), 145(32), 118(32), and 42(44). *Anal.* calcd. for $C_9H_{10}N_2O_2$: C 60.67, H 5.66, N 15.71; found: C 60.75, H 5.88, N 15.71.

(*b*) The 4*H*-azepine **15** (0.310 g) and potassium cyanide (0.150 g) in methanol (25 mL) were stirred for 10 h at room temperature. The mixture was then poured into ice water (100 mL) and extracted with ether (3 × 60 mL). The ether extract was washed with water (3 × 15 mL), dried ($MgSO_4$), filtered, and evaporated under reduced pressure. The residue was recrystallized from ether – petroleum ether to give the cyano compound **9** (0.085 g). The mother liquor was evaporated and the residue separated by preparative tlc on silica gel G to yield more cyano compound **9** (0.172 g; total yield 75%) and the methoxy compound **10** (0.016 g; 5%); both were identical with the authentic compounds.

Base-catalyzed Rearrangement of Cyanodihydroazepine ***9***

To the cyano compound **9** (300 mg) in methanol (10 mL) was added potassium hydroxide (65 mg) in methanol (2 mL) and the solution heated under reflux on the steam bath for 2 h. Most of the methanol was then distilled off slowly and the rest was distilled under reduced pressure and collected in a Dry Ice cooling trap. The distillate was separated, using vapour phase chromatography, into methyl crotonate, identified by its retention time and mass spectrum and a second component. This latter product, formed in trace amounts, was identified as ethyl 3-aminobutyrate by comparison of retention time and infrared and mass spectra with authentic material.

The residue from the distillation was dissolved in methanol (5 mL) and poured into ice water (50 ml). The precipitate was collected and recrystallized from benzene to give white prisms, mp 180–181°C, shown to be identical with the methyl 4-cyano-2,5-dimethylpyrrole-3-carboxylate which was obtained in the preparation of the 4-cyano-4,5-dihydroazepine **9**.

*Dimethyl 4,5-Dihydro-4-methoxy-2,5,7-trimethylazepine-3,6-dicarboxylate (**10**)*

The chloroethyl compound **3** (3.1 g) and triethylamine (1.5 mL) in methanol (250 mL) were heated in an oil bath at 50°C for 48 h. Methanol was then removed on the rotary evaporator and the residue was treated with ether and water. After separation the ether layer was washed with water, dried ($MgSO_4$), filtered, and evaporated. The residue was recrystallized from ether – petroleum ether to give colorless prisms **10** (2.65 g, 87%), mp 157–159°C; ir ν_{max}: 3418 (NH), 1701 (unsaturated ester), 1634 cm^{-1} (C=C); uv λ_{max} (ε): 231 (12 750), 325 nm (15 550); ^{1}Hmr (Varian HA 100) δ: 0.77 (d, J = 6.8 Hz, methyl at C(5)), 2.29, 2.36 (s, s, methyls at C(7) and C(2)), 3.29 (s, *O*-methyl), 3.55 (partly obscured double q, J = 6.6 and 6.8 Hz, C(5)-H), 3.72 (s, methyl esters), 4.60 (d, J = 6.6 Hz, C(4)-H), and 5.68 (s, NH); the multiplicity of the signal at δ 3.55 was confirmed by irradiation at 462 Hz when the multiplet at δ 3.55 collapsed to a clearly discernible q (J = 6.8 Hz); irradiation at 356 Hz decoupled doublets due to H at C(4) and methyl at C(5) to singlets; ms *m/e*: 283 (10, M^+), 252(15), 251(33), 236(23), 220(35), 219(38), 192(100), 191(28), 176(25), 160(64), 132(40). *Anal.* calcd. for $C_{14}H_{21}NO_5$: C 59.36, H 7.47, N 4.94; found: C 59.15, H 7.60, N 4.87.

Reaction of Dimethyl 4,5-Dihydro-4-methoxy-2,5,7-trimethylazepine-3,6-dicarboxylate ***10*** *with Methanolic Hydrogen Chloride*

To the methoxydihydroazepine **10** (300 mg) in dry methanol (5 mL) was added 0.2 *M* methanolic hydrogen chloride solution (10 mL). The solution was stirred at room temperature for 0.5 h, then evaporated under reduced pressure and the excess hydrogen chloride removed by adding dry ether and evaporating *in vacuo* three times. The residue was separated by preparative tlc on silica gel G.

The band of highest R_F exhibited the light blue fluorescence characteristic of Hantsch dihydropyridines under ultraviolet light. Elution, evaporation and crystallization from benzene afforded dimethyl 4-(1-chloroethyl)-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate **3** (92 mg, 30%), mp 165–167°C, which was shown to be identical with authentic material by comparison of ir, uv, ^{1}Hmr, and mass spectra.

The second band yielded dimethyl 4-(1-methoxyethyl)-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate **5** (175 mg, 58%), mp 127–129°C; ir ν_{max}: 3430 (NH, free), 3306 (NH, bonded), 1696 (unsaturated ester), 1650 cm^{-1} (C=C); uv λ_{max} (ε): 233.5 (14 050) 347 nm (6700); ^{1}Hmr δ: 0.97 (d, J = 6.5 Hz, CH_3—CH), 2.31 (s, methyls at C(2), C(6)), 3.16 (partly obscured double q, J = 5.0 and 6.5 Hz, C*H*—CH_3), 3.31 (s, methoxyl), 3.76 (s, methyl esters), 4.34 (d, J = 5.0 Hz, C(4)-H), 6.31 (s, NH); ms *m/e*: 283 (0.0006, M^+), 225(22), 224(100), 192(24). *Anal.* calcd. for $C_{14}H_{21}NO_5$: C 59.36, H 7.47, N 4.94; found: C 59.32, H 7.49, N 5.05.

The last band was eluted using methanol and, after passage through a short column of basic alumina and sublimation *in vacuo*, afforded white prisms of dimethyl 2,6-dimethylpyridine-3,5-dicarboxylate (12 mg, 5%), mp 98–99°C (lit. (19) mp 100–102°C).

*Dimethyl-4-(1-Bromoethyl)-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate (**4**)*

To the methoxydihydroazepine **10** (200 mg) in ether (50 mL) was added concentrated hydrobromic acid (0.5 mL) in a separatory funnel. The mixture was shaken for 5 min and the ether layer was washed with water (3 × 5 mL). After removal of ether the residue was recrystallized from benzene – petroleum ether to give the bromoethyl compound **4** as white prisms (213 mg; 91%), mp 164–165°C; ir ν_{max}: 3431 (NH, free), 3320 (NH, bonded), 1700 (unsaturated ester), 1653 cm^{-1} (C=C); uv λ_{max} (ε): 233 (14 550), 333 nm (7050); ^{1}Hmr δ: 1.54 (d, J = 6.8 Hz, CH_3—CHBr), 2.38 (s, methyls at C(2), C(6)), 3.77 (s, methyl esters), 4.14 (partly obscured double q, J = 5.2 and 6.8 Hz, C*H*Br—CH_3), 4.43 (d, J = 5.2 Hz, H at C(4)), 6.09 (s, NH); ms *m/e*: 251(26), 224(94), 220(27), 219(40), 192(93), 191(25), 160(82), 149(34), 132(50). *Anal.* calcd. for $C_{13}H_{18}NO_4Br$: C 47.00, H 5.46, N 4.22, Br 24.05; found: C 47.07, H 5.55, N 4.37, Br 24.18.

*Dimethyl 4,5-Dihydro-2,5,7-trimethyl-4-succiniminoazepine-3,6-dicarboxylate (**12**)*

The chloroethyl compound **3** (2.87 g) was added to a stirred solution of potassium succinimide (1.4 g) in absolute ethanol (60 mL) at room temperature. After 48 h the solvent was removed under reduced pressure and the residue recrystallized from chloroform – ether – petroleum ether to give the succinimino compound **12** as white prisms (2.58 g; 74%), mp 180–181°C; ir ν_{max}: 3410 (NH), 1701 (unsaturated ester and succinimino carbonyls), 1623 cm^{-1} (C=C); uv λ_{max} (ε): 235 (10 450), 328 nm (14 650); ^{1}Hmr (Varian HA 100) δ: 0.97 (d, J = 7.2 Hz, methyl at C(5)), 2.18 (s, methyl at C(7)), 2.46 (s, methyl at C(2)), 2.51 (s, —CH_2—CH_2— of succinimino group), 3.35 (double q, J = 6.0 and 7.2 Hz, H at C(5)), 3.63 (s, methyl esters), 5.31 (d, J = 6.0 Hz, H at C(4)), 5.91 (s, NH); the C(5)-H multiplet became a doublet (J = 6.0 Hz) on irradiation at 99 Hz; the C(4)-H doublet and C(5)-CH_3 doublet became singlets on irradiation at 336 Hz, and the C(5)-H multiplet became a quartet on irradiation at 534 Hz; ms *m/e*: 350 (5, M^+), 251(57), 236(19), 220(33), 219(51), 192(100), 191(32), 179(26), 176(24), 160(79), 132(49). *Anal.* calcd. for $C_{17}H_{22}N_2O_6$: C 58.27, H 6.33, N 8.00; found: C 58.05, H 6.45, N 7.84.

*Dimethyl 4,5-Dihydro-2,7-dimethyl-4-succiniminoazepine-3,6-dicarboxylate (**11**)*

In a similar manner, the chloromethyl compound **1** (3.0 g) and potassium succinimide (1.4 g) in absolute ethanol (80 mL) gave, after recrystallisation from chloroform – petroleum ether, the succinimino compound **11** as white prisms (2.78 g, 75%), mp 192.5–193.5°C; ir ν_{max}: 3410 (NH), 1705 (ester and imide carbonyls), 1622 cm^{-1} (C=C); uv λ_{max} (ε): 235 (11 800) 330 nm (13 800); ^{1}Hmr (Varian HA 100) δ: 2.23 (s, methyl at C(7)), 2.40 (dd, J = 1.0, 14.0 Hz, H at C(5)), 2.44 (s, methyl at C(2)), 2.52 (s, succinimino methylene groups), 3.22 (dd, J = 6.5, 14.0 Hz, H at C(5)), 3.61 (s, methyl ester), 3.64 (s, methyl ester), 5.52 (dd, J = 1.0, 6.5 Hz, H at C(4)), 5.78 (s, NH); ms *m/e*: 336 (6, M^+), 237(66), 206(31), 205(35), 179(40),

178(100), 177(21), 146(97), 118(42), 99(47), 59(35), 56(42). *Anal.* calcd. for $C_{16}H_{20}N_2O_6$: C 57.14, H 5.99, N 8.33; found: C 57.05, H 6.09, N 8.22.

*Dimethyl 2,4,7-Trimethyl-4*H*-azepine-3,6-dicarboxylate (**15**)*

(*a*) The chloroethyldihydropyridine **3** (2.5 g) was stirred with powdered anhydrous potassium carbonate (2.0 g) in dimethyl sulfoxide (35 mL) at room temperature for 5 h and then poured into cold water (120 mL). The product was extracted with ether (3 × 50 mL) and the ether extract was washed with water (3 × 20 ml) and dried ($MgSO_4$). After removal of solvent, the residue was distilled from a Späth tube at 110–115°C (bath temperature) and 0.03 Torr to give the 4*H*-azepine **15** as a pale yellow oil (1.8 g, 82%); ir ν_{max}: 1723 and 1702 cm^{-1} (unsaturated esters); uv λ_{max} (ε): 213 (8200), 295 nm (7150); ^{1}Hmr (CCl_4) at room temperature: δ 0.55–1.15 (v br., centred at 0.85, nuclear methyl), 2.05–2.45 (br, centred at 2.25, nuclear methyl), 2.40 (s, nuclear methyl), 3.75 and 3.78 (s, s, methyl esters); ^{1}Hmr at 80°C; δ 0.88 (d, J = 7.0 Hz, methyl at C(4)), 2.20 and 2.38 (s, s, methyls at C(2) and C(7)), 2.88 (m, H at C(4)), 3.73 and 3.76 (s, s, methyl esters), and 5.23 (d, J = 9.0 Hz, H at C(5)); ms *m/e*: 251 (34, M^+), 236(13), 220(28), 219(47), 192(100), 191(34), 176(24), 160(90), 159(21), and 132(47). *Anal.* calcd. for $C_{13}H_{17}NO_4$: C 62.13, H 6.82, N 5.57; found: C 62.08, H 6.75, N 5.73.

(*b*) The reaction of sodium ethoxide in dry ether with the chloroethyl compound **3** afforded the 4*H*-azepine **15** (yield 76%).

(*c*) The 5-methyl-4-succinimino-4,5-dihydroazepine **12** (150 mg) was pyrolyzed at 175–180°C in a sublimation tube containing small glass beads to increase the residence time. The product was then distilled at the same temperature and 0.03 Torr to give a colorless oil **15** (82 mg, 76%) which had identical ir, uv, ^{1}Hmr, and ms with the product of preparation *a*.

(*d*) The 4-methoxy-5-methyl-4,5-dihydroazepine **10** (100 mg) was pyrolyzed at 160°C, using the same experimental technique as that of preparation *c*, to give the 4*H*-azepine **15** (65 mg; 73%) as a colorless oil.

Reactions of the 4H*-Azepine*

(*a*) To the 4*H*-azepine **15** (450 mg) in ether (50 mL) was added concentrated hydrochloric acid (1 mL). The reaction mixture was shaken for 5 min and then ice water (10 mL) added. The ether layer was separated, washed with water (3 × 5 mL), dried ($MgSO_4$), filtered, and evaporated. The residue was crystallized twice from benzene to give white crystals of the chloroethyl compound **3** (435 mg, 84%), mp 168–169°C.

(*b*) To the 4*H*-azepine **15** (220 mg) in ether (50 mL) was added concentrated hydrobromic acid (0.5 mL). After shaking for 5 min, the reaction was worked up as above to give white prisms of the bromoethyl compound **4** (246 mg, 85%), mp 164–165°C, after recrystallization from benzene – petroleum ether.

*Dimethyl 1,4-Dihydro-2,6-dimethyl-4-(1-thiocyanatoethyl)-pyridine-3,5-dicarboxylate (**6**)*

A solution of the dihydropyridine **3** (1.4 g) and potassium thiocyanate (0.6 g) in methanol (50 mL) was heated under reflux for 2 h. The solution was evaporated *in vacuo* and the residue dissolved in ether (80 mL). The ether solution was washed with water (3 × 10 mL), dried ($MgSO_4$), concentrated to 10 mL, and petroleum ether added to yield the product (1.31 g, 87%), mp 142–145°C. After two recrystallizations from ether – petroleum ether, the thiocyanato compound **6** was obtained as white prisms, mp 149–150.5°C; ir ν_{max}: 3428 (NH free), 3306 (NH, bonded), 2154 (thiocyanate), 1699 cm^{-1} (unsaturated ester); uv λ_{max} (ε): 233 (17 350), 341 nm (6700) ^{1}Hmr δ: 1.38 (d, J = 7.2 Hz, CH_3—CH), 2.39 (s, methyls at C(2), C(6)), 3.36 (double q, J = 5.0 and 7.2 Hz, C*H*—CH_3), 3.79 (s, methyl esters), 4.42 (d, 5.0 Hz, H at C(4)), and 6.91 (s, NH); ms *m/e*: 251(37), 224(60), 220(31), 192(100), 191(30), 160(64), 132(38). *Anal.* calcd. for $C_{14}H_{18}N_2O_4S$: C 54.18, H 5.85, N 9.03, S 10.33; found: C 54.10, H 5.81, N 8.97, S 10.39.

*Dimethyl 1,3,6-Trimethyl-8-thia-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate (**18** and **19**)*

The chloroethyl compound **3** (1.5 g) was added to a solution of sodium hydrosulfide (0.8 g) in ethanol (50 mL) and the mixture heated to 65°C on a water bath for 5 h. After cooling, the reaction mixture was poured into cold water (200 mL) containing ammonium chloride (5 g) and the solution was extracted with ether (3 × 200 mL). After washing with water (3 × 30 mL) and drying ($MgSO_4$), the ether extract was evaporated to dryness. The residue was recrystallized from benzene – petroleum ether to give the 6-*endo*-methyl-7-*endo*-methoxycarbonyl isomer **18** as colorless prisms (0.78 g, 52%), mp 163–164°C; ir ν_{max}: 3408 (NH, free), 3307 (NH, bonded), 1737 (saturated ester), 1689 cm^{-1} (unsaturated ester); uv λ_{max} (ε): 231 (2850), 291 nm (12 900); ^{1}Hmr δ: 1.06 (d, J = 7.0 Hz, methyl at C(6)), 1.77 (s, methyl at C(1)), 2.30 (s, methyl at C(3)), 2.55 (d, J = 7.4 Hz, H at C(7)), 3.04 (m, J = 4.8, 7.0 and 7.4 Hz, H at C(6)), 3.74 (s, methyl esters), 4.68 (d, J = 4.8 Hz, H at C(5)), and 4.99 (s, NH); ms *m/e*: 285 (55, M^+), 252(30), 226(19), 220(16), 194(26), 185(100), 153(86), 126(60), 84(42), 59(33), and 42(37). *Anal.* calcd. for $C_{13}H_{19}NO_4S$: C 54.72, H 6.71, N 4.91, S 11.24; found: C 54.59, H 6.54, N 4.78, S 11.34.

From a second crop, needles of the more soluble 6-*endo*-methyl-7-*exo*-methoxycarbonyl isomer **19** were separated by hand from a trace of **18** and recrystallized from benzene – petroleum ether to give the pure product **19** (0.51 g, 34%), mp 144–146°C; ir ν_{max}: 3423 (NH, free), 3322 (NH, bonded), 1734 (saturated ester), and 1687 cm^{-1} (unsaturated ester); uv λ_{max} (ε): 293.5 nm (13 550); ^{1}Hmr δ: 0.99 (d, J = 6.5 Hz, methyl at C(6)), 1.83 (s, methyl at C(1)), 2.31 (s, methyl at C(3)), 3.09 (m, J = 3.0, 4.7, and 6.5 Hz, H at C(6)), 3.16 (d, overlapping signal at δ 3.09, J = 3.0 Hz, H at C(7)), 3.70 (s, methyl esters), 4.77 (d, J = 4.7 Hz, H at C(5)), and 5.09 (s, NH); ms *m/e*: 285 (71, M^+), 252(64), 226(14), 220(40), 194(13), 185(100), 153(98), 126(55), 84(11), 59(29), and 42(30). *Anal.* calcd. for $C_{13}H_{19}NO_4S$: C 54.72, H 6.71, N 4.91, S 11.24; found: C 54.60, H 6.64, N 5.05, S 11.09.

The lower melting, more soluble isomer was converted to the higher melting, less soluble, more stable epimer by refluxing with sodium methoxide in dioxane for 5 h.

*Dimethyl 1,3,6-Trimethyl-8-oxa-2-azabicyclo[3.2.1]oct-3-ene-4,7-dicarboxylate (**22**)*

A stirred mixture of the chloroethyl compound **3** (3 g) and potassium carbonate (1.5 g) in dimethyl sulfoxide (40 mL) and water (15 mL) was heated at 65°C in the dark and under a nitrogen pressure of 50 Torr for 3 days. After cooling the reaction mixture was poured into aqueous ammonium chloride (300 mL, 1%) and the product extracted into chloroform (3 × 25 mL). The chloroform extract was washed with water (3 × 10 mL), dried ($MgSO_4$), filtered, evaporated, and the residue crystallized from aqueous dioxane to give colorless prisms of the bicyclic compound **22** (0.92 g, 33%), mp 173–175°C; ir ν_{max}: 3522 (NH), 1742 (saturated ester), 1690 (unsaturated ester), 1606 cm^{-1} (C=C); uv λ_{max} (CH_3OH) (ε): 288 nm (15 000); ^{1}Hmr δ: 1.11 (d, J = 7.0 Hz, methyl at C(6)), 1.70 (s, methyl at C(1)), 2.09 (s, methyl at C(3)), 2.55 (d, J = 3.9 Hz, H at C(7)), 2.93 (double q, J = 7.0 Hz,

3.9 Hz, H at C(6)), 3.62 (s, methyl ester), 3.64 (s, methyl ester), 4.61 (s, H at C(5)), 4.63 (br, s, NH); spin decoupling resulted in the expected changes in multiplicity of signals at δ 1.11, 2.55, and 2.93; ms *m/e*: 269(37, M^+), 238(22), 210(34), 194(16), 178(54), 169(100), 168(24), 164(25), 154(76), 150(22), 136(32), 122(22), 43(36), 42(31). *Anal.* calcd. for $C_{13}H_{19}NO_5$: C 57.98, H 7.11, N 5.20; found: C 57.97, H 6.98, N 5.12.

Alkaloid F_k-5, isolated from *F. kralikii*, has been shown to be fumaritine *N*-oxide. The structure was established by ^1H and ^{13}C nmr and by mass spectrometry and confirmed by reduction of F_k-5 to fumaritine. The ^{13}C spectra of fumaritine and its *N*-oxide are discussed.

H. G. KIRYAKOV, DONALD W. HUGHES, BALA C. NALLIAH et DAVID B. MACLEAN. Can. J. Chem. **57**, 53 (1979).

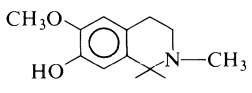
On a montré que l'alcaloïde F_k-5 isolé du *F. kralikii* est le *N*-oxyde du fumaritine. On a déduit la structure en se basant sur des spectres rmn du ^1H et du ^{13}C et sur la spectrométrie de masse; on l'a confirmée par réduction du F_k-5 en fumaritine. On discute des spectres rmn du ^{13}C de la fumaritine et de son *N*-oxyde.

[Traduit par le journal]

An examination of the alkaloids of *Fumaria kralikii* Jord. has recently been reported (1). Five alkaloids of established structure, 1-adlumine, protopine, cryptopine, *d*-parfumine, and fumarofine were obtained. In addition *O*-methylfumarofine (2) was isolated for the first time from nature and a new alkaloid, designated F_k-5, was reported. The authors considered F_k-5 might be a member of the spirobenzylisoquinoline group of alkaloids but there was no direct evidence to this effect.

Alkaloid F_k-5 (**1**) (mp 204°C) was a polar compound, eluted from an alumina column with 10% methanol in benzene. It contained a broad band (2500–3500 cm^{-1}) in its ir spectrum indicative of a strongly hydrogen-bonded compound. The authors reported that in its ^1H nmr spectrum in DMSO there were two aromatic singlets and an aromatic AB quartet. The presence of one methoxy, one methylenedioxy, and one *N*-methyl group was also apparent.

We report here further studies on the alkaloid that have led to the elucidation of its structure. The mass spectrum showed a weak molecular ion at *m/e* 371 corresponding in composition to $C_{20}H_{21}NO_6$. The molecular ion had fragment ion peaks corresponding to the loss of oxygen, water, and CH_3O. The most intense ion appeared at *m/e* 192 corresponding in composition to $C_{11}H_{14}NO_2$. Ions of this composition are frequently found in isoquinoline alkaloids, including spirobenzylisoquinolines (3), that have the structural feature **a**. The mass spectrum



a

however did not provide other structural information.

In this study the ^1H nmr spectrum (Table 1) was reexamined in DMSO-d_6 and also in alkaline D_2O in which the alkaloid was readily soluble in contrast to its behaviour in DMSO. The solubility in base is in agreement with the presence of a phenolic hydroxyl as inferred above. Although the DMSO spectrum was similar to that previously reported (1), three additional resonances were found in the low field region. There was a broad singlet at 8.81 ppm which was attributed to a hydrogen-bonded phenolic proton. A pair of doublets was also observed at 6.40 and 5.33 ppm with a coupling constant of 7.6 Hz. The addition of D_2O to this sample removed the signals at 8.81 and 5.33 ppm and caused the doublet at 6.40 ppm to collapse to a sharp singlet. This result indicated the presence of a secondary alcohol function.

The high field region of the alkaline D_2O spectrum had two singlets of area three at 3.73 and 3.11 δ that were assigned to methoxy and *N*-methyl groups, respectively. The chemical shift of the *N*-methyl resonance suggested that it was bonded to a quaternary nitrogen. In the high field region there was also an AB quartet with the signals centred at 3.90 and 3.34 δ, with a coupling constant of 15.5 Hz. Four

[b]Solvent: $CDCl_3$.

other protons also absorbed in this region giving a complex pattern. The low field region of the spectrum had a pair of overlapping doublets centred at 5.92 δ, assigned to a methylenedioxy group, and four singlets in the region 6.1–6.9 ppm, one of which integrated for two protons giving a total of five protons in this region. In view of the DMSO spectra, four of the five signals are very likely aromatic in character. We were however unable to interpret these data in terms of a unique structure for the alkaloid despite the relatively simple spectrum.

The ^{13}C nmr spectrum (both broad-band and off-resonance were recorded) was however more revealing; the data are recorded in Table 2 in terms of the structure eventually deduced for the alkaloid. In the aliphatic region of the spectrum the methoxy and *N*-methyl resonances were readily assigned by virtue of their residual coupling in the off-resonance spectrum and the assignments were confirmed by selective proton decoupling. There were three signals assigned to methylenes at 27.6, 38.0, and 64.8 ppm, a methine at 77.2 ppm and a quaternary carbon at 90.6 ppm. The presence of a quaternary carbon centre was the first evidence from the present study in support of the premise enunciated earlier (1) that F_k-5 might be a spirobenzylisoquinoline alkaloid. In the low field region of the spectrum there was a signal at 103.1 assigned to the methylene of a methylenedioxy group and twelve signals attributed to aromatic carbons. Four of these signals were at significantly lower field than the others and were assigned to aromatic carbons bonded to oxygen, four others were bonded to hydrogen, and the remaining four were fully substituted.

A consideration of these data led us to conclude that F_k-5 was an *N*-oxide either of fumaritine (4) (Fig. 1) or an isomer of fumaritine in which the phenolic hydroxy and methoxy group are interchanged or an isomer in which the hydroxyl function has a different configuration, or both. Accordingly we treated F_k-5 with SO_2, a reagent known to convert *N*-oxides to tertiary amines (5), and isolated the resulting product. Examination revealed that the reduction product was indeed fumaritine **2** by comparison of its spectroscopic properties with those of an authentic specimen.

The ^{13}C nmr spectrum of fumaritine was recorded and the data are shown in Table 2 along with those of F_k-5. Signals were assigned by comparing the spectra to those of alkaloids previously studied (6, 7). Except for the resonances assigned to C-8 and C-13 the chemical shift assignments are very similar to those of ochrobirine and yenhusomine both of which have saturated five-membered rings (7). The fact that C-8 resonates at lower field may be a consequence of the substitution pattern of the five-membered ring (8). Carbon-13, which does not carry an OH function, was identified from the off-resonance spectrum and was found at lower field than the methylene in ochotensimine (7). In ochotensimine

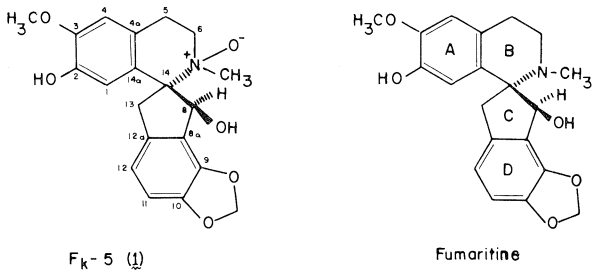

FIG. 1. Structures of F_k-5 (**1**) and fumaritine (**2**).

the methylene at C-8 may be shielded through a steric interaction with the aromatic substituent at C-9.

The ^{13}C spectrum of fumaritine *N*-oxide differs from fumaritine in several important respects. The conversion of the nitrogen to its *N*-oxide has the most pronounced effect on the neighboring carbon atoms, namely the *N*-methyl, the quaternary carbon at C-14, and the methylene at C-6. The chemical shift changes are of the same order as those observed for the *N*-oxides of *N*-methylpiperidine (9), the *Nuphar* alkaloids (10), and strychnine (11). These changes are attributed to the combined inductive effect of the positively charged *N*-atom and the β-substituent effect of the oxygen. The changes observed for the aromatic resonances of ring A of F_k-5 relative to fumaritine at C-1, C-2, C-3, and C-4a may be attributed to the change from phenoxide to phenol at C-2. The ^{13}C chemical shifts of guaiacol are known (12) and are reproduced in the accompanying formulas (Fig. 2) along with those of the anion of guaiacol obtained in basic D_2O. The changes observed for this acid–base pair are very similar to those found in ring A of F_k-5 (spectrum was recorded in alkaline D_2O) relative to fumaritine itself, a similar acid–base pair. One may therefore be reasonably confident of the assignments recorded in Table 2.

By making use of selective proton decoupling experiments it was possible to correlate proton resonances in F_k-5 with the ^{13}C resonances. In this way it was found that the signal at 6.23 was associated with the proton at C-8 geminal to the OH function, that the two protons at 6.89 were at C-11 and C-12, and that the signals at 6.15 and 6.65 were associated with the protons at C-1 and C-4, respectively. In Table 1 the chemical shifts are recorded

FIG. 2. The ^{13}C chemical shifts of guaiacol and its anion.

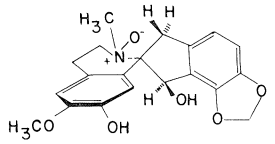

FIG. 3. Proposed conformation of fumaritine *N*-oxide (F_k-5).

of those protons of F_k-5 and fumaritine that have been established.

To determine the configuration of the nitrogen substituents in F_k-5, a series of nOe experiments were performed. Previous studies on sibiricine (13) which has the same substituents and configuration at C-8 produced a 25% enhancement of the H-8 resonance when the N—CH_3 was irradiated. Irradiation of the methoxy group in fumaritine (4) resulted in a 24% nOe for H-4. Several experiments on two samples of F_k-5 in alkaline D_2O produced a 20% nOe for H-4 during irradiation of the OCH_3 group whereas a less than 5% change in peak intensity was observed for H-8 when the N—CH_3 was irradiated. These results not only provided additional confirmation of the assignment of H-4 but also indicated a large internuclear separation between the NCH_3 and H-8. Of the possible configurations and conformations about the nitrogen that were examined from molecular models, the one with the methyl in a pseudoaxial position directed away from H-8 (Fig. 3) appears to fit the above data.

Experimental

The ^{13}C nuclear magnetic resonance spectra were recorded on a Bruker WH-90 Fourier transform spectrometer at 22.62 MHz and a temperature of +35°C. Sample concentrations ranged from 0.14 to 0.92 *M* in either D_2O (using DMSO as an external reference) or $CDCl_3$ (using TMS as an internal reference). Spectra were recorded over a 6000 Hz sweep width using 16K data points (1.359 s acquisition time). A pulse width of 3.4 μs (15.6° pulse angle) was used. The alkaloid spectra were obtained in 6000 to 50000 scans.

^1H nuclear magnetic resonance spectra and nOe experiments were performed on a Varian HA-100 spectrometer in the frequency sweep mode. The concentration of F_k-5 in the nOe sample was 0.16 *M* in alkaline D_2O (glass distilled) which also contained 2 mmol EDTA. The sample was sealed under vacuum after three freeze–pump–thaw cycles. *tert*-Butyl alcohol-OD was used as an internal reference and lock in the aqueous samples. The chemical shifts are reported in ppm downfield from DSS (2,2-dimethyl-2-silapentan-5-sulphonate). In the fumaritine samples $CDCl_3$ and TMS were used as solvent and reference, respectively. The ^1H spectra of F_k-5 in DMSO-d_6 were recorded at 90 MHz on a Bruker WH-90 Fourier transform spectrometer. Sample concentration was approximately 0.06 *M*. Spectra were obtained in 32 scans using a pulse width of 3.0 μs (67.5° pulse angle). The sweep width was 1200 Hz in 8K data points (3.411 s acquisition time). TMS was used as an internal reference.

Mass spectra were determined on a C.E.C. 21-110B mass spectrometer at an ionizing voltage of 80 eV and a source temperature of 200–250°C. The high resolution spectra were

recorded on plates and accurate mass measurements were made by using perfluorokerosene as a marker (14). The composition of all ions discussed in this paper have been checked by high resolution mass spectrometry and agree with calculated values within ± 0.005 amu. Infrared spectra were obtained on a Perkin-Elmer 283 spectrometer.

Reduction of N-*Oxide (5)*

Sulphur dioxide was bubbled through an aqueous solution of F_k-5 (90 mg in 5 ml H_2O). The progress of the reaction was followed by observing the precipitation of the free amine which redissolved as the solution became more acidic. The reaction mixture was then neutralized and extracted repeatedly with CH_2Cl_2. The extracts were dried and evaporated to produce a compound as a foam which gave spectral data identical with fumaritine; ^1H nmr: see Table 1; ir ($CHCl_3$) ν_{max}: 3550, 2880, 1590, 1275, 1100 cm^{-1}.

Received May 11, 1978

R. MELANSON and F. D. ROCHON. Can. J. Chem. **57**, 57 (1979).

The crystal structure of [Pt(diethylenetriamine)(guanosine)]$(ClO_4)_2$ has been determined by X-ray diffraction. The crystals are orthorhombic, space group $P2_12_12_1$, with $a = 12.486(6)$, $b = 13.444(7)$, $c = 14.678(11)$ Å, and $Z = 4$. The structure was refined by block-diagonal least-squares analysis to a conventional R factor of 0.050 and a weighted $R_w = 0.045$.

The coordination around the platinum atom is square planar. Guanosine is bonded to platinum through N(7). The purine planar ring makes an angle of 62.7° with the platinum coordination plane. The structure is stabilized by hydrogen bonding.

R. MELANSON et F. D. ROCHON. Can. J. Chem. **57**, 57 (1979).

La structure cristalline de [Pt(diéthylènetriamine)(guanosine)]$(ClO_4)_2$ a été déterminée par diffraction des rayons-X. Les cristaux appartiennent au groupe d'espace orthorhombique $P2_12_12_1$, avec $a = 12.486(6)$, $b = 13.444(7)$, $c = 14.678(11)$ Å et $Z = 4$. Les coordonnées atomiques et les facteurs thermiques anisotropes ont été affinés par moindres-carrés (matrice diagonale) jusqu'à $R = 0.050$ et $R_w = 0.045$.

La coordination autour de l'atome de platine est plane. La guanosine est liée au platine par l'atome N(7). Le plan du groupement purine fait un angle de 62.7° avec le plan de coordination du platine. La structure cristalline est stabilisée par des ponts hydrogènes.

Introduction

Recently we have started a study of the molecular and crystal structure of a series of platinum nucleoside complexes (1). Guanosine is believed to play an important role in the interaction of platinum antitumour drugs with DNA. In a recent communication (2, 3) the crystal structure of the [Pt(ethylenediamine)-(guanosine)$_2$]$^{2+}$ cation was reported. Intermolecular hydrogen bonding between the —NH_2 group of the ethylenediamine ligand and the carbonyl group of the guanine was observed. The authors suggested that this hydrogen bonding might be important in the Pt—DNA interaction in view of the fact that anti-tumour activity of *cis*-[Pt(amine)$_2$X$_2$] complexes decreases markedly along the series $NH_3 \sim NH_2R > NHR_2 \gg NR_3$ (4).

The present compound [Pt(diethylenetriamine)-(guanosine)]$(ClO_4)_2$ was studied partly to determine the role of the C=O group, if any, on the amine ligand.

Experimental

[Pt(dien)(guanosine)]$(ClO_4)_2$ (where dien = diethylenetriamine) was prepared by the following method. $AgClO_4$ was added to an aqueous solution of [Pt(dien)Cl]Cl and mixed. After filtering the AgCl precipitate, guanosine was added in a 1:1 proportion to the solution which consisted of [Pt(dien)-H_2O]$(ClO_4)_2$. The mixture was stirred and then filtered. The aqueous solution was allowed to evaporate slowly. Crystals of [Pt(dien)(guanosine)]$(ClO_4)_2$ were then obtained.

A set of precession photographs indicated the $P2_12_12_1$ space group in the orthorhombic system. The cell parameters were calculated by least-squares refinement of the setting angles of 15 independent peaks centered on a Syntex P$\bar{1}$ diffractometer using graphite monochromatized MoKα radiation.

Crystal Data

$PtCl_2C_{14}H_{26}N_8O_{13}$ mw = 780.40

Orthorhombic $P2_12_12_1$, $a = 12.487(6)$, $b = 13.444(7)$, $c = 14.678(11)$ Å, $Z = 4$, $V = 2464(2)$ Å^3, $D_m = 2.09(2)$ g cm^{-3} (flotation), $D_x = 2.103$ g cm^{-3}, λMoK$\alpha = 0.71069$ Å, μMoK$\alpha = 62.9$ cm^{-1}, and $T = 22$°C.

Collection and Reduction of Intensity Data

The intensity data were collected from a crystal having 9 faces with approximate dimensions of 0.15 × 0.20 × 0.25 mm. A total of 4023 independent reflections were measured in the region of $2\theta < 60°$ by the $2\theta/\theta$ scan technique using MoKα radiation. During the data collection, three standard reflections were measured after every 47 reflections. Their variations were less than 2% from their respective means. The reflections for which the intensity was less than $2.5\sigma(I)$ were considered as unobserved. The standard deviation $\sigma(I)$ was calculated as already described (5). An absorption correction based on the equations of the crystal faces was applied to the 2501 observed reflections. The transmission factors varied from 0.441 to 0.504. The data were then corrected for the Lorentz and polarization effects. The scattering factors of Cromer and Waber (6) were used for platinum, chlorine, oxygen, nitrogen, and carbon, those of Stewart *et al.* (7) were used for hydrogen. The anomalous dispersion terms (8) of platinum and chlorine were included in the calculations.

Structure Determination

The position of the platinum atom was easily located from the three-dimensional Patterson map. The positions of all the other atoms, except the hydrogen atoms, were obtained by structure factor and Fourier map calculations. The refinement of the parameters was carried out by block-diagonal least-squares methods. In the early stages of refinement, unit weight was assigned to all observed reflections. Later, individual weights w according to the equation $1/w = a + bF_o + cF_o^2$ were calculated. The constants of the equation were adjusted

0008-4042/79/010057-05$01.00/0

to make the distribution of $w|\Delta F|^2$ almost constant with respect to $|F_o|$ and sin θ/λ ($a = 35.589$, $b = -0.4508$, and $c = 0.00154$). The hydrogen atoms in the diethylenetriamine ligand and on the carbon atoms and on N(1) in the guanosine moiety were fixed at their calculated position[1] (C—H distance = 0.95 Å and N—H distance = 0.85 Å) and assigned isotropic temperature factors of 6.0 Å^2. The refinement of the scale factor, the coordinates and anisotropic temperature factors of all the non-hydrogen atoms converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.050$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.045$. The final difference Fourier map did not show peaks higher than ± 0.8 e Å^{-3}. Attempts to find, on the final difference Fourier map, the hydrogen atoms that could not be calculated, were not successful. The torsion angles within the ribose segment, confirmed the expected *D*-configuration of the molecule. The *R* factor for the other enantiomorphic structure was much higher (0.062) indicating that the coordinates of Table 1 correspond to the absolute structure.

The calculations were carried out with a Cyber 73 computer and the programs used have already been described (5). A table of observed and calculated structure factors is available.[1]

Results and Discussion

The refined atomic parameters are listed in Table 1. A list of the anisotropic temperature factors is available.[1] A labelled stereoscopic view of the ion [Pt(dien)guanosine)]$^{2+}$ is shown in Fig. 1. (The size of the ellipsoids corresponds to a 50% probability.) The bond lengths within the ions are shown on Fig. 2, and the bond angles on Fig. 3.

As expected, guanosine is bonded to the platinum atom through the N(7) atom. The coordination around the platinum atom is square planar. The weighted best plane was calculated through the five atoms. The deviations from this plane are: Pt, −0.002; N(4), 0.0807; N(5), −0.0045; N(6), 0.0746; and N(7), 0.057 Å. The angles around platinum are close to the expected 90° and 180° but there are some distorsions. The N(4)—Pt—N(5) and N(5)—Pt—N(6) angles (84.7°) are smaller than the N(4)—Pt—N(7) and N(6)—Pt—N(7) angles (98.2, 92.4°). The N(4)—Pt—N(6) angle (168.5°) is also smaller than expected. A slight strain caused by the tridentate ligand is responsible for these deviations from the ideal square planar coordination. The Pt—N bond lengths (1.97–2.04 Å) are normal and agree well with the published results (1–3, 5, 9–11). The four methylene groups of the dien ligand all lie on one side of the plane of the nitrogen atoms.

The purine ring is planar. The weighted best plane was calculated through the nine atoms. The deviations from this plane are: N(7), −0.012; N(9), 0.028; N(3), −0.008; N(1), 0.002; C(8), −0.020; C(4), −0.013; C(5), 0.015; C(6), 0.015; and C(2), −0.011 Å. The deviations of the substituents on the ring are as follows: N(2), −0.101; O(6), 0.024; and C(1′), −0.067 Å (esd = 0.014 to 0.021 Å). Since N(2) plays an important role in the hydrogen bonding system of the crystal, it might explain the slight non-planarity of the substituent. The purine planar ring makes an angle of 62.7° with the platinum coordination plane.

The bond lengths in the purine ring vary from 1.29 to 1.46 Å. They are similar to those found in guanosine rings mentioned in a review by Voet and Rich (12). They are almost identical to those found in guanosine dihydrate (13). The bond angles also seem normal and agree well with the published results mentioned above. The bond angles within the five-member ring vary from 105 to 111°. In the six-membered ring, the range is from 111° to 128°. As

[1]Lists of structure factors, calculated hydrogen positions, and anisotropic thermal parameters are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

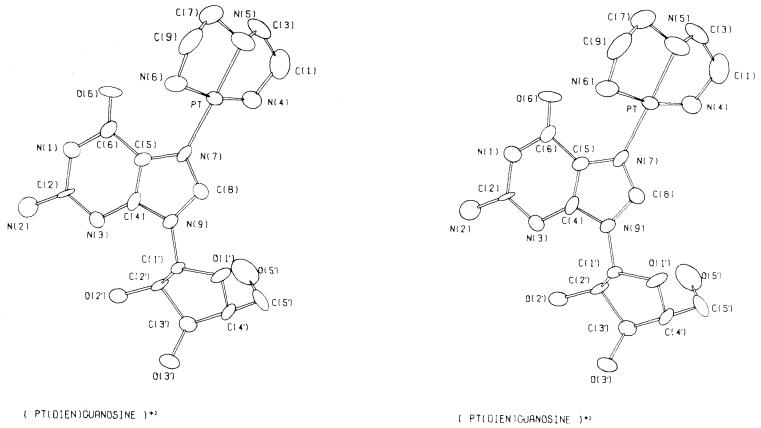

FIG. 1. Stereoscopic view of the $[Pt(dien)(guanosine)]^{2+}$ ion.

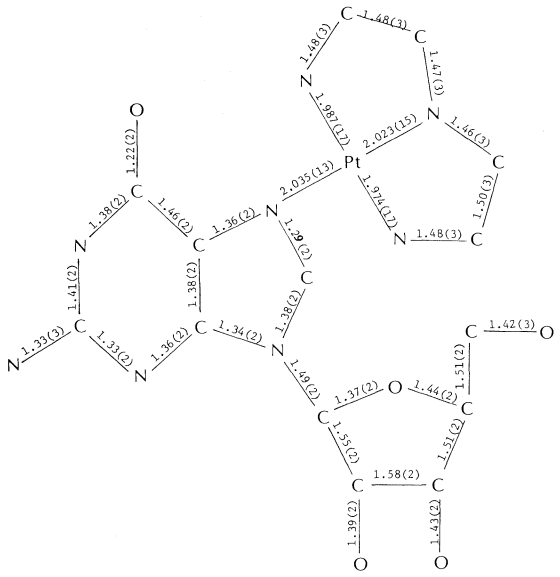

FIG. 2. Bond lengths within the $[Pt(dien)(guanosine)]^{2+}$ ion.

Singh has pointed out (14), the internal ring angle at a nitrogen atom is greater if the N atom is covalently bound to an extra-annular H atom than if the N atom has no extra-annular attachment. Here C(6)—N(1)—C(2) = 126° while C(2)—N(3)—C(4) = 113°.

The glycosyl bond is normal (1.49 Å) (12). The angles in the ribose ring are close to the tetrahedral values. O(1′), C(1′), C(3′), and C(4′) are coplanar within 2σ and C(2′) is 0.57 Å distant from that plane on the same side as C(5′) and N(9). This corresponds to the C(2′) *endo* conformation. The dihedral angle between the purine and the ribose planes is 30.3°.

The torsion angles within the ribose group are listed in Table 2. The conventions suggested by Sundaralingam (15) and Trueblood and co-workers (16, 17) have been used. The torsion angle O(1′)-C(1′)N(9)C(8), ϕ_{CN}, is −17° and defines an *anti* conformation about the glycosidic bond. The C(5′)—O(5′) bond is in a *gauche–gauche* conformation relative to the ribose group: $\phi_{OO} = -68$ and $\phi_{OC} = 51°$.

The bond lengths and the bond angles in the perchlorate ions are shown in Table 3. The distances vary from 1.32 to 1.42 Å. The standard deviations are quite large (0.016 to 0.030 Å), probably because the thermal parameters of the oxygen atoms are fairly large. The bond angles are close to the tetrahedral values (106 to 111°).

A packing diagram is shown in Fig. 4. In most nucleoside crystal structures, base stacking plays a very important role. In this structure base stacking

*The conventions suggested by Sundaralingam (15) and Trueblood and co-workers (16, 17) have been used.

is not a very important packing factor since the perchlorate ions are located between the bases. Hydrogen bonding is probably the predominant packing effect in this structure. The most important hydrogen bonds are listed in Table 4. All the hydrogens attached to the oxygen and nitrogen atoms in the guanosine group are involved in strong hydrogen bonds. O(2′)—H of each ribose group is intramolecularly hydrogen-bonded to N(3). The two other hydroxyl groups O(3′)—H and O(5′)—H are involved in hydrogen bonds with the perchlorate ions. N(1) and N(2) also play an important role in the system, forming intermolecular hydrogen bonds, N(1)—H with O(2′) and N(2)$\begin{smallmatrix}\text{H}\\\text{H}\end{smallmatrix}$ with both O(3′) and O(6). The role of the diethylenetriamine ligand in the hydrogen bonding system is doubtful. The most probable hydrogen bonds are shown in Table 4. The longer distances and the less favourable angles, especially those involving platinum, seem to suggest that these bonds are weaker.

In the crystal structure of the [Pt(ethylenediamine)-(guanosine)$_2$]$^{2+}$ cation (2, 3), the authors observed an intermolecular hydrogen bond between the carbonyl group of guanine and the —NH_2 group of ethylenediamine. The distance was 2.78 Å indicating a strong interaction. The bond angle was not given, but it appeared very favourable. The authors

			Pt—N(6)...O(6)	79(1)
N(6)—H...O(5′)	$\frac{1}{2} - z, 1\frac{1}{2} - y, \frac{1}{2} + z$	2.98(2)	C(9)—N(6)...O(5′)	93(1)
			Pt—N(6)...O(5′)	142(1)
			N(6)...O(6)...N(2)	96(1)

suggested that this hydrogen bonding could be an important factor in the Pt–DNA interaction since the anti-tumour activity of *cis*-[Pt(amine)$_2$X$_2$] decreases in the order $NH_3 \sim NH_2R > NHR_2 \gg NR_3$.

In the present structure, the carbonyl group of guanosine (O(6)) would be strongly intermolecularly hydrogen bonded with the amino group of guanosine (N(2)). It might also form a weaker intramolecular hydrogen bond with the $-NH_2$ of diethylenetriamine (N(6)). The angle N(6)...O(6)...N(2) is 96°.

It is therefore difficult at the moment to evaluate the importance of hydrogen bonding between the amine ligand and the nucleoside in the Pt—DNA interaction. More data are needed before attempting to discuss in detail this possible mechanism of interaction of platinum drugs.

Conformational dissymmetry. Circular dichroism of amino acid and peptide complexes

E. A. SULLIVAN[1]

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 26, 1978

E. A. SULLIVAN. Can. J. Chem. **57**, 62 (1979).

A number of Pd(II) and Pt(II) complexes of amino acids and dipeptides have been isolated and characterized. The solution and solid-state circular dichroism of the amino acid complexes show a fairly consistent pattern, which is opposite to that shown by the dipeptide complexes. Some of the problems associated with the interpretation of the spectra in terms of spectroscopic assignment and structural features are discussed.

E. A. SULLIVAN. Can. J. Chem. **57**, 62 (1979).

On a isolé et caractérisé un certain nombre de complexes du Pd(II) et du Pt(II) avec des acides aminés et des dipeptides. Le dichroïsme circulaire, à l'état solide et en solution, des complexes avec les acides aminés présente des caractéristiques cohérentes; ceci est à l'opposé du comportement des complexes des dipeptides. On discute de quelques-uns des problèmes associés avec l'interprétation des spectres en termes d'attributions spectroscopiques et de caractéristiques de structures.

[Traduit par le journal]

The circular dichroism associated with the *d–d* transitions of amino acid and peptide complexes has been the study of extensive investigation, the impetus for which stems ultimately from an interest in the nature of metal–protein binding. Most studies have concentrated on the square coplanar species formed with Ni(II) and Cu(II) (1), which are labile in solution. Wide limits of conformational flexibility are allowed to coordinated amino acid ligands (2), a fact which complicates the unresolved problem of identifying the particular (chiral) stereochemical features which generate the optical activity in the *d*-electron transitions (1, 3–5).

Although some studies, involving solution-generated species of Pd(II) with amino acid derivatives, have been reported (6), this paper describes the circular dichroism of a number of amino acid and dipeptide complexes of Pd(II) and Pt(II), all of which have been isolated and characterized. The spectra were recorded in solution and also in KBr matrices in order to determine the effects on the circular dichroism in various environments.

Results

In Figs. 1 and 2 are shown the absorption and circular dichroism spectra of the mono amino acid complexes of Pd(II) and Pt(II) respectively, and in Fig. 3 the spectra of the bis-amino acid complexes of Pd(II). All the aqueous spectra of the mono complexes were determined in 0.2 *M* KCl in order to suppress standing concentrations of aquo species which are rapidly and extensively formed in the absence of Cl^- ions. The solid-state linear absorption spectra are very similar to those obtained in solution, except that the charge-transfer bands tend to shift to lower energies.

The solution absorption spectra of the Pd(II) and Pt(II) mono- and bis-amino acid complexes usually show two discernible major components; in the case of $[Pt(S\text{-ala})Cl_2]^-$, the bands occur at 30 600 cm^{-1} and 34 000 cm^{-1}. In the Pd(II) amino acid complexes the bands are less distinct, the solution spectra usually consisting of a broad composite band with a shoulder on the low energy side; for the mono complexes the shoulder occurs near 24 000 cm^{-1} and for the bis complexes, near 28 000 cm^{-1}. In similar Pd(II) and Pt(II) ammine complexes the lower energy component of the *d*-electron manifold has been identified as the $d_{xy} \rightarrow d_{x^2-y^2}$ spin-allowed transition while the higher energy component was assigned to the spin-allowed $d_{xz},d_{yz} \rightarrow d_{x^2-y^2}$ promotion (6, 7). The same assignments will be applied to the amino acid complexes, and will be referred to as the *A* and *E* transitions respectively. Ideally, each transition requires to be identified and assigned and then the corresponding components compared for a series of compounds. As will be seen from the present data, extensive overlap between components generally precludes unambiguous assignments.

Whatever the actual assignment of the shoulder band in the solution absorption spectra of the mono and bis complexes, if it corresponds to the same transition for these complexes, then there is a fairly consistent CD sign pattern, both in solution and the

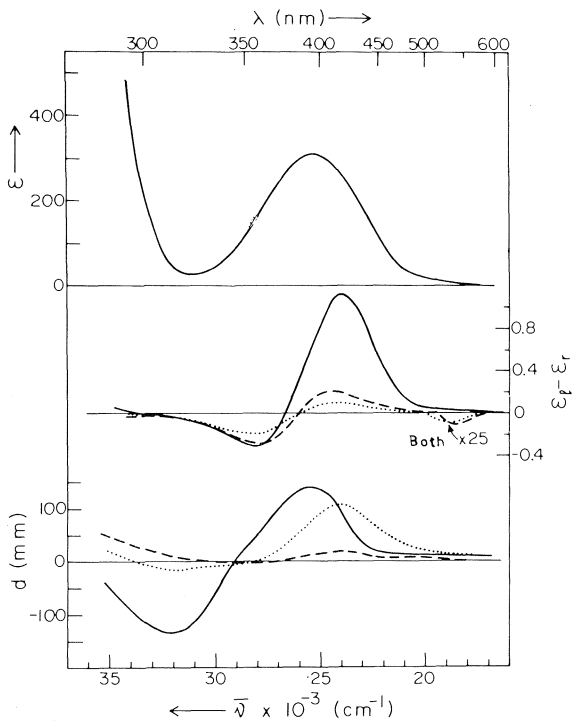

FIG. 1. The circular dichroism spectra of K[Pd(*S*-ala)Cl_2] (···), K[Pd(*S*-ser)Cl_2] (---), and K[Pd(*S*-pro)Cl_2] (—) in 0.2 *M* KCl aqueous solutions (middle) and in 1% KBr matrices (bottom). The top diagram is the absorption spectrum of K[Pd(*S*-pro)Cl_2] in 0.2 *M* KCl solution; the other complexes show similar spectra. In the middle diagram, the triplet region of both the *S*-serine and *S*-alanine complexes are × 25.

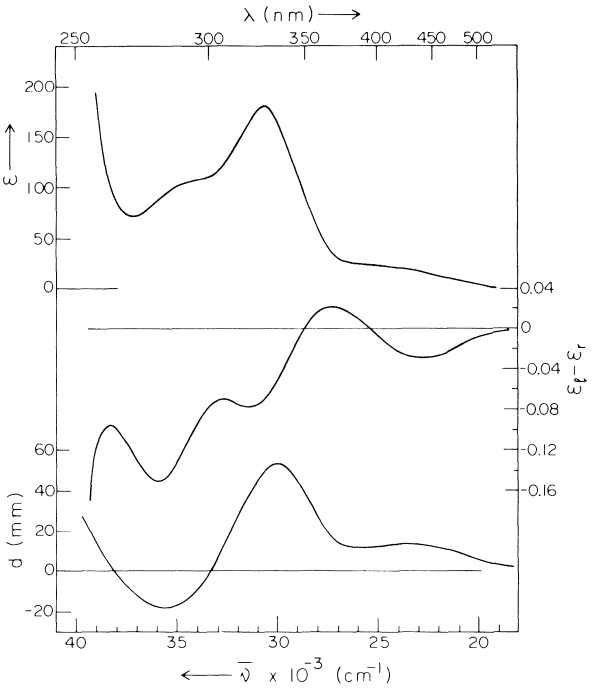

FIG. 2. The absorption (top) and circular dichroism spectra (middle) of K[Pt(*S*-ala)Cl_2] in 0.2 *M* KCl aqueous solution. The bottom diagram refers to the spectrum in a 1% KBr matrix.

solid state. Thus, at the same energy position corresponding to the shoulder in the solution absorption spectra, the CD spectra of all the complexes show a positive band in the solid state and in solution. For the Pt(II) mono complex, however, this region of the solution CD shows a negative band; some Pd(II) amino acid amide complexes also show this behaviour, the sign of the band depending on the particular solvent (8). In the region of the *E* transition, the amino acid complexes all show negative CD although the position of the band varies between complexes, particularly for the solid-state spectra. It is notable that the proline mono complex with its fixed δ-conformation and chiral (*S*) nitrogen atom shows by far the strongest CD. Strong positive CD in the region of the *A* transition (and negative CD in the region of the *E*) has been associated with the vicinal effect of a chiral nitrogen atom in the *S*-absolute configuration (9). Although the circular dichroism of the proline complex retains the same form in the solid, the two (solid-state) bands are displaced to higher energies compared to the seemingly corresponding bands in solution.

The two isomers of [Pd(*S*-ala)$_2$] slowly equilibrate in aqueous solution and the rate constant k, for the approach to equilibrium, as well as the equilibrium constant K, has been determined spectrophotometrically at 30°C in neutral water solution.

$$\textit{trans}\text{-[Pd(}S\text{-ala)}_2\text{]} \rightleftharpoons \textit{cis}\text{-[Pd(}S\text{-ala)}_2\text{]}$$

For the composite constant $k = 1.1 \times 10^{-4}\ s^{-1}$ and $K = 6.0$, reflecting 86% of the *cis*-isomer at equilibrium. The equilibration is remarkably clean, since both the pairs of near ultra-violet isosbestic and isodichroic points are maintained throughout 5 half-lives of reaction.

The isomerism has been tentatively assigned on the basis of the relative intensities of the *d–d* bands of the two isomers. Considering only the donor atom symmetry, the *trans*-isomer is centrosymmetric, while the *cis* is not, hence the latter is expected to have the more intense spectrum (Fig. 3). In the Pd(II) bis-glycinato complexes, the *cis*-isomer has the greater absorptivity (10).

The circular dichroism spectra of the two isomers in water solution are nearly identical and the pattern

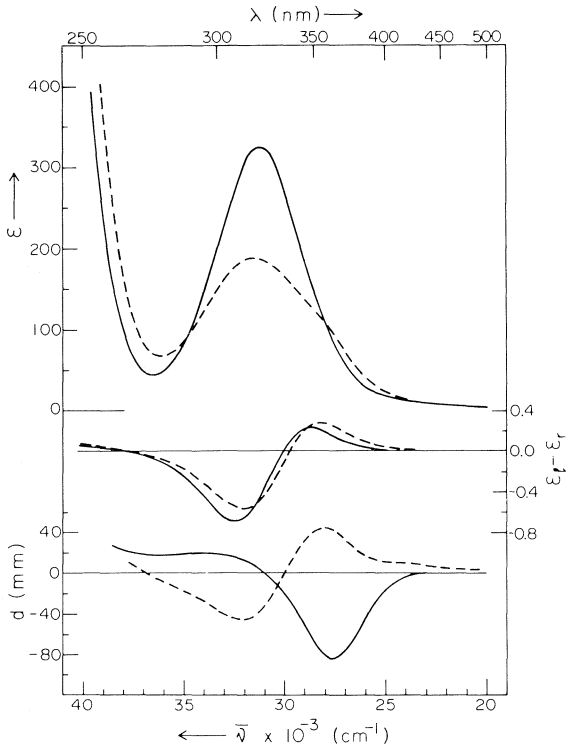

FIG. 3. The absorption and circular dichroism spectra of *cis*-[Pd(*S*-ala)$_2$] (—) and *trans*-[Pd(*S*-ala)$_2$] (---) in water solutions. The bottom diagram refers to spectra in 1% KBr matrices.

is the same as that observed for the mono *L*-amino acid complexes in solution. Unlike the *trans*-species and the mono complexes, however, the *cis*-[Pd(*S*-ala)$_2$] species in the solid state shows an almost enantiomorphic spectrum.

The spectra of the dipeptide complexes Cs[Pd(gly-*S*-ala)Cl] and Cs[Pd(*S*-alagly)Cl] are shown in Figs. 4 and 5. Upon dissolution in water, both complexes immediately aquate to give the species [Pd(dipeptide)H_2O] in dilute solution. Beer's law is obeyed exactly, for concentrations between 2×10^{-3} and 1×10^{-4} *M* in complex, and the addition of Cl^- ions results immediately in new spectra which are shifted to the red as would be expected if the aquo ligand is replaced by chloride. Further addition of KCl to 0.2 *M* KCl solutions of the complexes does not affect the spectra.

The circular dichroism spectra of the chloro complexes in 0.2 *M* KCl solution show three spin-allowed circular dichroism bands; the negative bands at 27 000 cm^{-1} and 25 500 cm^{-1} for the [Pd(*S*-alagly)Cl]$^-$ and [Pd(gly-*S*-ala)Cl]$^-$ ions, respectively, are assigned to the *A* transition and the higher energy couplets to a split *E* band. (At 22 500 cm^{-1}, the [Pd(*S*-alagly)Cl]$^-$ ion shows an additional

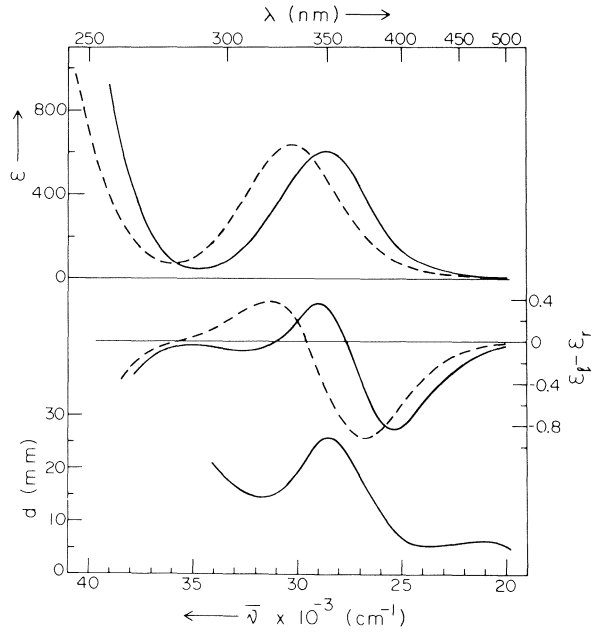

FIG. 4. The absorption and circular dichroism spectra of Cs[Pd(gly-*S*-ala)Cl] in 0.2 *M* KCl aqueous solution (—), and of [Pd(gly-*S*-ala)H_2O] in water (---). The bottom diagram refers to the Cs[Pd(gly-*S*-ala)Cl] complex dispersed in a 1% KBr matrix.

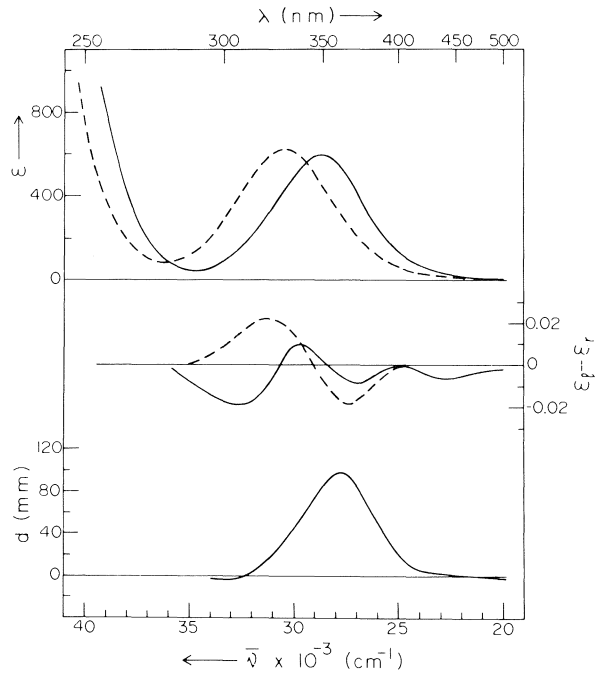

FIG. 5. The absorption and circular dichroism spectra of Cs[Pd(*S*-alagly)Cl] (—) in 0.2 *M* KCl aqueous solutions and of [Pd(*S*-alagly)H_2O] (---) water solution. The bottom spectrum refers to a 1% KBr matrix of Cs[Pd(*S*-alagly)Cl].

negative band which is assigned to a spin-forbidden transition.) Apparently, the effective symmetry of the chloro complexes is low enough for the *E* band to lose its degeneracy. In the solid state, each chloro complex shows a positive band which is difficult to associate with any of the corresponding CD bands shown in solution.

In the CD spectra of the aquo complexes, the lower energy (negative) bands probably represent *A* transitions (in part at least), but since there is no indication of the effective symmetry of these complexes, the assignment of the higher energy (positive) band is uncertain. If the *E* band is split, it is not resolved.

Discussion

The spectra of the complexes described in this investigation differ somewhat in intensity from those obtained from previous solution studies (6). This is perhaps not surprising, in view of the uncertainty as to the identity of species in (equilibrium) mixtures of reactants.

Spectroscopic assignments are also uncertain, but CD patterns for the series of complexes may be compared. Thus, the CD spectra of the mono and bis complexes of Pd(II) and Pt(II) are quite similar. Despite the variety of ring conformations and sidechain dispositions available to chelated amino acids (2), the solution CD of the complexes are remarkably similar to those of analogous diamine complexes (11).

The solid-state CD spectrum of *cis*-[Pd(*S*-ala)$_2$] and the solution CD spectra of the aquo dipeptides are very similar, if the positions of the respective maxima in the solution absorption spectra are matched. Notably, however, these CD spectra are almost enantiomorphic to the solid-state CD of the *trans*-isomer and the solution CD of both *cis*- and *trans*-isomers, even though all four complexes have the same donor atoms (2N, 2O). For the various complexes, differing effective donor atom symmetries could perhaps provide a rationalization for this behaviour. In the solid state, the effective symmetry of the *trans*-isomer might be approximately D_{4h} (although formally D_{2h}) and that of the *cis*-isomer could be C_{2v} or lower. The structures of a number of *cis*-bis complexes of Cu(II) and Pd(II) show axial orientations of amino acid sidechains (12, 13), so perhaps crystal packing requirements could result in low effective symmetry for such complexes. In that case it might not be unreasonable to expect the solid-state CD of the *cis*-isomer to resemble that of the aquo dipeptide complexes (if the effective symmetry of the complexes were the same and for ligands with the same absolute configuration), and yet at the same time differ from that of the *trans*-isomer and the solution species.

It is difficult to rationalize the consistencies in the CD spectra of the mono and bis amino acid complexes and the 'reversed' pattern of the aquo dipeptide complexes in terms of either the vicinal effect of chiral carbon atoms (3), conformation of ligands (4), donor atom distortions (5), or the disposition of C_α-sidechains (1). Furthermore, sign patterns may be determined largely by the effective symmetry of the complexes (14). Whatever the origins of optical activity in chiral metal complexes, until some of the more fundamental problems are resolved, the use of circular dichroism to probe the metal coordination in complicated structures such as metallo-enzymes, requires extreme caution.

Experimental Section

Absorption spectra were measured on a Unicam 800A spectrophotometer, and solution CD spectra were obtained with a Roussel-Jouan Dichrographe II. KBr discs (1% in complex in 100 mg total sample) were prepared as described elsewhere (5). The solid-state CD spectra were obtained with a Durrum JASCO J-20 spectrophotometer with a SS-20 CD attachment; the ordinate units are deflection in mm for a sensitivity of 5 mdeg cm^{-1}. The kinetics of the *cis–trans* isomerization of [Pd(*S*-ala)$_2$] were followed at 318 nm using a Cary 16 spectrophotometer.

In this article we use the abbreviations: *S*-alaH = *L*-alanine; *S*-serH = *L*-serine; *S*-proH = *L*-proline; *S*-alaglyH$_2$ = *L*-alanylglycine; gly-*S*-alaH$_2$ = glycyl-*L*-alanine.

K[Pt(*S*-ala)Cl$_2$] was prepared by the published method (15).

The K[Pd(*L*-amino acid)Cl$_2$] complexes were prepared by the following aqueous reaction:

$$PdCl_2 + \begin{matrix} KAc \\ \text{or} \\ K_2CO_3 \end{matrix} + L\text{-amino acid} \rightarrow K[Pd(L\text{-amino acid})Cl_2] + HAc$$

where Ac = acetate. The products were precipitated with ethanol (or acetone for the alanine complex) and recrystallized from water by the same precipitating agent.

Anal. calcd. for K[Pd($C_3H_6NO_2$)Cl$_2$]: C 11.8, H 2.0, N 4.6, Cl 23.3; found: C 12.0, H 2.0, N 4.7, Cl 23.2.

*K[Pd(*S*-ser)Cl$_2$]*

Anal. calcd. for K[Pd($C_3H_6NO_3$)Cl$_2$]: C 11.2, H 1.9, N 4.4, Cl 22.1; found: C 11.2, H 2.0, N 4.4, Cl 22.0.

*K[Pd(*S*-pro)Cl$_2$]*

Anal. calcd. for K[Pd($C_5H_8NO_2$)Cl$_2$]: C 18.2, H 2.4, N 4.2, Cl 21.4; found: C 18.3, H 2.7, N 4.2, Cl 21.3.

[Pd(*S*-ala)$_2$] precipitates as a yellow solid when a solution of PdCl$_2$, *L*-alanine, and excess LiCl is slowly neutralized with NaHCO$_3$.

trans-[*Pd(*S*-ala)$_2$*]

The crude product (1 g) from above was dissolved in boiling water (50 ml). The solution was filtered and set aside at 25°C for 2 days. The *trans*-isomer separated as large yellow plates; mp 150–155°C (dec.). The aqueous filtrate was retained.

Anal. calcd. for [Pd($C_3H_6NO_2$)$_2$]: C 25.5, H 4.3, N 9.9; found: C 25.6, H 4.2, N 9.8.

cis-[*Pd(*S*-ala)$_2$*]

To the above filtrate was added ethanol (250 ml) and then ether (250 ml) and the mixture was set aside at 0°C for 12 h. The crude product (0.4 g) was collected and then stirred in

water (20 ml) at 15°C for 15 min. The mixture was filtered and ethanol (150 ml) was added to the filtrate. Upon scratching the sides of the flask, the *cis*-isomer began to form. After allowing the solution to stand at 0°C for 12 h, the yellow needles were collected. They were recrystallized from cold water by the addition of ethanol (0.25 g). mp 230°C (dec.).

Anal. found: C 25.6, H 4.2, N 9.9.

The dipeptide complexes Cs[Pd(dipeptide)Cl] were prepared by neutralizing with $CsCO_3$ a solution containing stoichiometric amounts of $PdCl_2$ and the dipeptide, then precipitating the crude product with ethanol and acetone. The complexes were recrystallized from a small volume of water by careful addition of ethanol and acetone. The pure complexes were deposited as small needles, of a yellow to orange-yellow colour.

Circular dichroism of palladium(II) and platinum(II) diamine complexes

E. A. SULLIVAN[1]

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 27, 1978

E. A. SULLIVAN. Can. J. Chem. **57**, 67 (1979).

An identifiable relationship exists between the absolute configuration of chiral diamine ligands and the circular dichroism of their complexes with palladium(II) and platinum(II). Complexes which contain simple *C*-substituted diamines with the *R*-absolute configuration show positive circular dichroism in the region associated with the $^1A_{1g} \rightarrow {}^1E_g$ transition, both in solution and the solid state. There is no general consistency in the sign of the $^1A_{1g} \rightarrow {}^1A_{2g}$ transition, and only for solution does the sign of the net circular dichroism show a correlation with the absolute configuration of the ligands.

E. A. SULLIVAN. Can. J. Chem. **57**, 67 (1979).

Il existe une relation qui peut être identifiée entre la configuration absolue de ligands diaminés chiraux et le dichroïsme circulaire de leurs complexes avec le palladium(II) et le platine(II). Les complexes qui comportent des diamines simples, substitués sur le *C* et de configuration absolue *R*, présentent un dichroïsme circulaire positif dans la région associée à la transition $^1A_{1g} \rightarrow {}^1E_g$ tant en solution qu'à l'état solide. Il n'y a pas de relation générale pour le signe de la transition $^1A_{1g} \rightarrow {}^1A_{2g}$ et l'on ne retrouve qu'en solution une relation entre le dichroïsme circulaire net et la configuration absolue des ligands.

[Traduit par le journal]

Ligand field CD spectra provide an empirical basis for differentiation between the various kinds of dissymmetric stereochemical features in chiral metal complexes (1). Attempts have been made to correlate absolute configuration of metal complexes with features in the CD spectra but no agreement has been reached as to whether absolute configuration should be correlated with the sign of specific bands (2–4) or with the net CD over the whole *d*-electron manifold (5). In order to assess the general applicability of such correlations, the solution and solid-state CD spectra of a series of diamine complexes of Pd(II) and Pt(II) have been examined. These complexes were chosen because they are sufficiently stable to be sure of the species present.

Spectroscopic assignments have been established for Pd(II) and Pt(II) complexes (6), and the approximate location of these transitions (3, 6) is shown in Fig. 1. The two *d–d* excitations which are both magnetic dipole allowed and spin allowed (i.e. $d_{xy} \rightarrow d_{x^2-y^2}$ and $d_{xz,yz} \rightarrow d_{x^2-y^2}$) will be subsequently referred to as the *A* and *E* transitions respectively.

Typical linear absorption spectra and CD spectra for solution and the solid state are shown in Figs. 2–5. The solid-state spectra of Pt(*R*-pn)Cl_2 (Fig. 4) are not typical, but resemble the behaviour of Pt(en)Cl_2 in which cooperative effects dominate the spectrum (7). The position of the absorption band

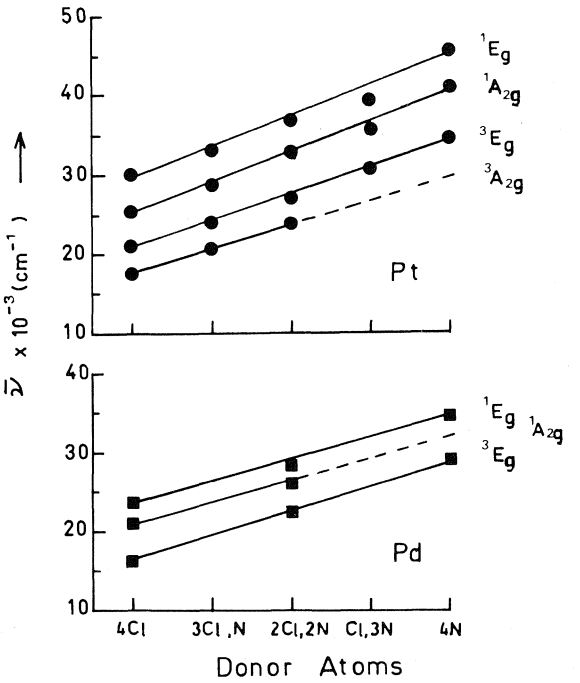

FIG. 1. Absorption energies for *d–d* transitions in chloroammine complexes of Pt(II) and Pd(II). From the data of Chatt *et al.* (6) and Ito *et al.* (3).

maxima in the linear absorption spectra of the Pt(II) complexes are generally unaffected by changes in the media, but the absorption spectra of the Pd(II) complexes consist of a composite band, the maximum

[1]Present address: Faculty of Engineering Science, University of Western Ontario, London, Ont., Canada N6A 5B7.

0008-4042/79/010067-04$01.00/0

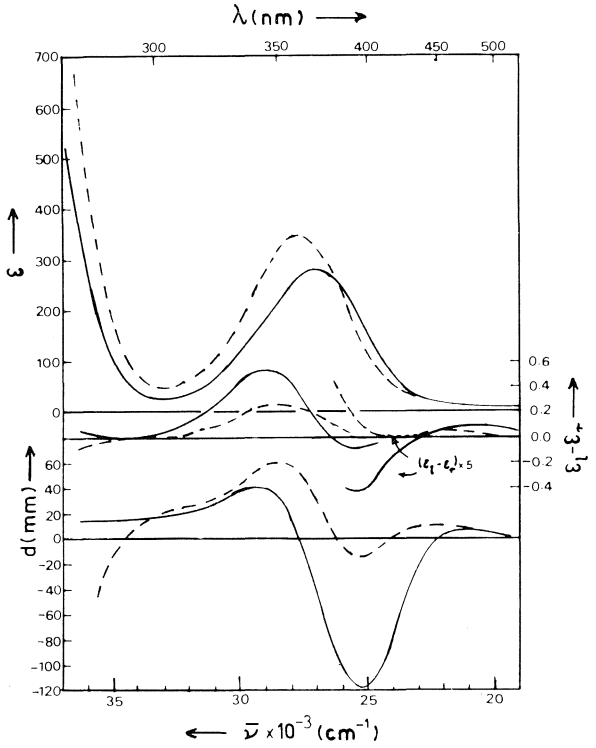

FIG. 2. Absorption and CD spectra of [Pd(*R*-pn)Cl_2] (—) and [Pd(*R*,*R*-dmtn)Cl_2] (---) in 0.2 *M* KCl. Bottom curves are the solid-state CD spectra.

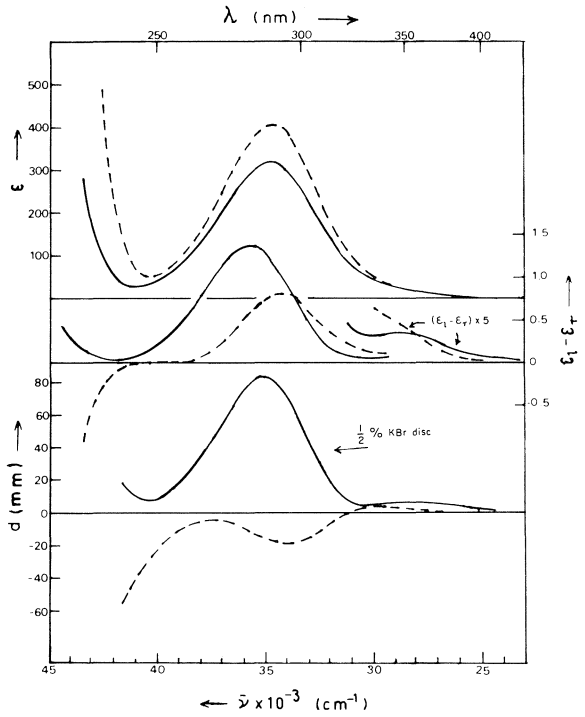

FIG. 3. Absorption and CD spectra of [Pd(*R*-pn)$_2$]$Cl_2 \cdot H_2O$ (—) and [Pd(*R*,*R*-dmtn)$_2$]$Cl_2 \cdot H_2O$ (---) in water. Bottom curves are the solid-state CD spectra.

of which varies considerably according to the medium. Thus for Pd(*R*-pn)Cl_2, the solution maximum occurs at 27 100 cm^{-1} (for 0.2 *M* KCl solution), whereas in a KBr disc or a Nujol mull it occurs at 25 700 – 26 000 cm^{-1}. However, despite these large apparent shifts (which probably reflect changes in the relative intensity of the components under the absorption manifold), the positions of the corresponding extrema in the solution and solid-state CD spectra do not change. These extrema occur at frequencies which correspond to the expected positions of the *A* and *E* components, as determined by Gaussian analysis of the solution absorption spectra (3, 6). With the bis-complexes, unambiguous assignments are not always possible, owing to extensive overlap between components. The CD signs associated with the regions of the *A* and *E* transitions are summarized in Table 1.

The experimental results for Pd(II) and Pt(II) complexes show, as in the case of octahedral Co(III) complexes (4), that there is no general consistency in the sign of the *A* band, regardless of whether the spectra are obtained from solution or the solid state. Moreover, it is doubtful whether the net CD sign can in general (8) give a reliable indication of absolute configuration, since it can be envisaged that component band intensities alone could determine the net sign of a composite band of overlapping transitions. Table 1 shows that the net CD sign obtained from the solid-state spectra exhibits a variable sign. The sign of the net CD of the solution spectra does show consistent behaviour for the present series of complexes, as in an impressive number of other cases (9), and may therefore serve as a useful index of absolute configuration, but this consistency may also result if the rotational strength associated with a particular transition dominates the solution CD spectrum. Such is the case for the *E* band in complexes of Pd(II) and Pt(II) (3), as well as other metals such as Co(III) and Rh(III) (2, 10). Indeed, the sign of the *E* band is the one consistent feature in the present series of complexes, when this band can be identified.

Both in solution and the solid state, complexes which contain simple (*C*-substituted) diamines with the *R*-absolute configuration show positive CD in the region associated with the *E* transition; this relationship is obtained irrespective of whether the chelate rings carry aliphatic or aromatic substituents.

It has been noted previously (3) that for a number of metal complexes in which the chelate rings are fixed in the λ-conformation, positive CD is associated with the *E* band (3) and that this sign persists for

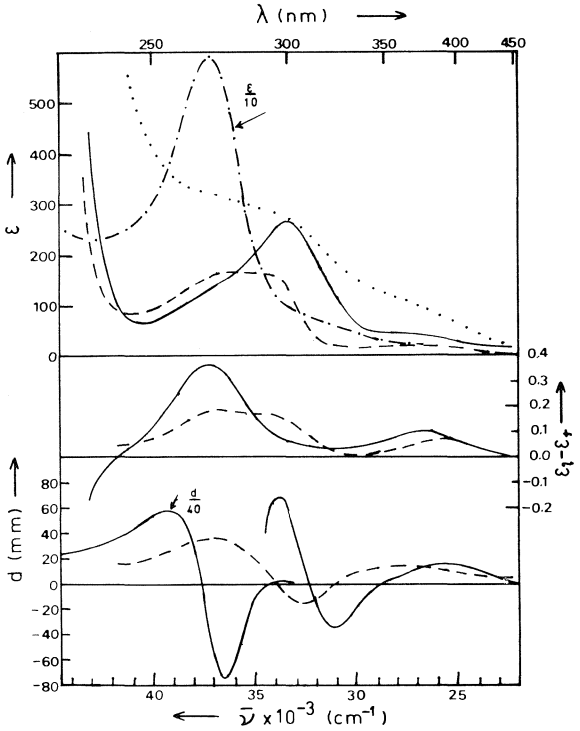

FIG. 4. Solution absorption and CD spectra of [Pt(*R*-pn)Cl_2] (—) and [Pt(*R*,*R*-dmtn)Cl_2] (fresh solution) (---) in 2 *M* HCl; relative solid-state absorption spectra of [Pt(*R*-pn)Cl_2] (·····) and [Pt(*R*,*R*-dmtn)Cl_2] (···). Bottom curves are the solid-state CD spectra.

different solvents and for the solid state (4). This investigation extends the results to a wider range of complexes and ligands and suggests that the sign of the *E* band (if it can be determined unambiguously) may be a useful and quite general criterion of absolute configuration.

Experimental

Absorption spectra were measured on a Unicam 800A spectrophotometer and the solution CD spectra were obtained with a Roussel-Jouan Dichrographe II. The solid-state spectra were obtained with a Durrum JASCO J-20 spectrophotometer with a SS-20 CD attachment. The CD for the solid state is reported in terms of the deflection *d*, in mm, at a sensitivity of

[a]Complex insoluble in water; solvolyses in dipolar aprotic solvents.
[b]Sign uncertain; band obscured.
[c]Composite band.
[d]Solid-state effects dominate spectrum; assignments uncertain.
[e]Parentheses denote most probable sign.

5 mdeg cm^{-1}. KBr discs contained 1% of complex in 100 mg of total sample, unless otherwise stated.

Abbreviations for the diamines are as follows: *R*-pn = (−)-1,2-diaminopropane; *R,R*-dmtn = (−)-2,4-diaminopentane; *R*-phenen = (−)-1,2-diaminophenylethane; *R,R*-stien = (+)-1,2-diamino-1,2-diphenylethane (stilbenediamine).

The ligands *R*-pn, *R,R*-dmtn, and *R,R*-stien were prepared according to methods described in the literature (4). During the preparation of *R*-phenen (11) partial racemization occurred. The ligand was resolved via the (+)-tartrate salt and the resolving agent was removed by the method of Bailar *et al.* (12). The absolute configuration of the ligands has been established by absolute crystal structure determinations (13), or by chemical correlations (14). The general preparation for the complexes has been previously reported (15).

Use of scaled-particle theory in the assessment of the Ph_4As^+/Ph_4B^- assumption for single ions

MICHAEL H. ABRAHAM AND ASADOLLAH NASEHZADEH
Chemistry Department, University of Surrey, Guildford, Surrey, England

Received May 17, 1978

MICHAEL H. ABRAHAM and ASADOLLAH NASEHZADEH. Can. J. Chem. **57**, 71 (1979).

A novel method for the assessment of the Ph_4As^+/Ph_4B^- assumption for free energies of transfer of single ions has recently been suggested by Treiner, and used by him to deduce that the assumption is not valid for transfers between water, propylene carbonate, sulpholane, dimethylsulphoxide, *N*-methyl-2-pyrrolidone, and perhaps also dimethylformamide. The basis of the method is the estimation of the free energy of cavity formation by scaled-particle theory, together with the hypothesis that the free energy of interaction of Ph_4As^+ (or Ph_4B^-) with solvent molecules is the same in all solvents, $\Delta G_t^0(\text{int}) = 0$. It is shown in the present paper that (*a*) whether or not the Ph_4As^+/Ph_4B^- assumption applies to transfer to a given solvent depends on which other solvent is taken as the reference solvent in Treiner's method, (*b*) the calculation of the cavity free energy term by scaled-particle theory and by the theory of Sinanoglu – Reisse – Moura Ramos (SRMR) yields values so different that the method cannot be considered reliable, (*c*) the calculation of cavity enthalpies and entropies for Ph_4As^+ or Ph_4B^- by scaled-particle theory yields results that are chemically not reasonable, (*d*) the hypothesis that $\Delta G_t^0(\text{int}) = 0$ conflicts with SRMR theory, and (*e*) the conclusions reached by Treiner are not in accord with recent work that in general supports the Ph_4As^+/Ph_4B^- assumption for solvents that are rejected by Treiner.

MICHAEL H. ABRAHAM et ASADOLLAH NASEHZADEH. Can. J. Chem. **57**, 71 (1979).

Treiner a récemment proposé une méthode nouvelle destinée à étudier la validité de l'hypothèse Ph_4As^+/Ph_4B^- pour les énergies libres de transfert des ions simples. Faisant appel à cette méthode, cet auteur a déduit que l'hypothèse n'est pas applicable aux transferts entre l'eau, le carbonate de propylène, le sulfolane, la diméthylsulfoxyde, la *N*-méthylpyrrolidone-2 et peut être aussi la diméthylformamide. Cette méthode se fonde, d'une part, sur une estimation de l'énergie libre de formation d'une lacune, selon la théorie des sphères rigides et, d'autre part, sur l'hypothèse à l'effet que l'énergie libre d'interaction de Ph_4As^+ (ou Ph_4B^-) avec les molécules de solvant demeure la même dans tous les solvants, soit $\Delta G_t^0(\text{int}) = 0$. Dans le présent travail, on démontre (*a*) que l'hypothèse Ph_4As^+/Ph_4B^- peut s'appliquer ou ne pas s'appliquer au transfert dans un solvant donné, tout dépend de la nature de l'autre solvant qui sert de solvant de référence selon la méthode de Treiner, (*b*) que les valeurs de l'énergie libre des lacunes calculées selon la théorie des sphères rigides d'une part, et selon la théorie de Sinanoglu–Reisse–Moura Ramos (SRMR) diffèrent à un point tel qu'on ne peut se fier à la méthode, (*c*) que les enthalpies et les entropies des lacunes pour Ph_4As^+ et Ph_4B^- telles que calculées selon la théorie des sphères rigides ne sont pas chimiquement raisonnable, (*d*) que l'hypothèse à l'effet que $\Delta G_t^0(\text{int}) = 0$ est en contradiction avec la théorie SRMR et (*e*) que les conclusions de Treiner sont en désaccord avec les travaux récents qui, d'une manière générale.

[Traduit par le journal]

Introduction

There is now available a large quantity of data on the thermodynamics of transfer of neutral combinations of ions between various solvents (1–4). For many purposes it is convenient to separate the thermodynamic parameters into cationic and anionic contributions through single-ion transfer values, using some extra-thermodynamic assumption in order to assign these single-ion values. Parker and co-workers (5–7) have extensively examined a number of such assumptions, and have suggested that the Ph_4As^+/Ph_4B^- assumption is the most reliable to date. On this basis, they assigned single-ion values for free energies, enthalpies, and entropies of transfer from water to a number of nonaqueous solvents. Concurrently with the studies of Parker, a number of other workers (8–10) used the correspondence plot method to assign single-ion entropies of transfer, also from water to nonaqueous solvents. Abraham (1) pointed out that the above two methods of assigning single-ion entropies of transfer yielded results in reasonable agreement with each other for transfers between water and many nonaqueous solvents, although for transfers between water and alcohols the two methods disagreed (4) by about 7 cal K^{-1} mol^{-1}. Quite recently, Treiner (11) put

0008-4042/79/010071-06$01.00/0

forward a novel method of examining the Ph_4As^+/Ph_4B^- assumption through the use of scaled-particle theory as outlined by Pierotti (12). Treiner concluded that for free energies of transfer, the Ph_4As^+/Ph_4B^- assumption was valid for transfers from water to methanol, ethanol, acetonitrile, and formamide but was not valid for transfer to dimethylformamide (DMF), dimethylsulphoxide (DMSO), sulpholane, propylene carbonate (PC), or *N*-methylpyrrolidone (NMPy). These conclusions of Treiner are so different from those of Parker (5–7) and of Abraham and Namor (1, 4) that we thought it useful to re-examine Treiner's method and to investigate the application of Treiner's method to enthalpy and entropy data. Results on entropies should be extremely interesting because the correspondence plot method leads to a quite independent set of single ion entropies of transfer which for many solvents agrees with the Ph_4As^+/Ph_4B^- assumption.[1]

Results using Scaled-particle Theory

(A) Free Energy of Transfer of Ph_4As^+ and Ph_4B^-

The free energy of solution of a hard-sphere solute in a given solvent is obtained through eq. [1]

$$[1] \quad \Delta G_s^0 = \Delta G^0(\text{cav}) + RT \log (RT/V) + \Delta G^0(\text{int})$$

where ΔG^0(cav) is the work required to create a suitably sized cavity in the solvent, calculated by scaled-particle theory, $RT \log (RT/V)$ is a correction term, and ΔG^0(int) is the energy of interaction of the solute with the surrounding solvent molecules. For transfer of the solute from a reference solvent 1 to another solvent 2, the free energy of transfer is given by eq. [2].

$$[2] \quad \Delta G_t^0 = \Delta G_t^0(\text{cav}) + RT \log (V_1/V_2) + \Delta G_t^0(\text{int})$$

Treiner set ΔG_t^0(int) = 0 in eq. [2], calculated ΔG_t^0 for a solute of diameter 8.4 Å (the diameter of Ph_4As^+ or Ph_4B^-), and then compared the resulting values with the observed free energies of transfer. He suggested that if calculated and observed values agreed to within about 30% the Ph_4As^+/Ph_4B^- assumption could be regarded as valid, but if the difference was greater than 30% the assumption should not be used.

We adopt a slightly different procedure that takes into account the electrostatic contribution to the free energy of transfer of a charged solute, as calculated by the recent theory of Abraham and Liszi (14). We write therefore

$$[3] \quad \Delta G_t^0 = \Delta G_t^0(\text{cav}) + \Delta G_t^0(\text{int}) + \Delta G_t^0(\text{elec})$$

For simplicity we include in the term ΔG_t^0(cav) the calculated cavity term together with the correction term $RT \log (V_1/V_2)$. We then calculate ΔG_t^0(cav) and ΔG_t^0(elec), we take ΔG_t^0 as the observed value, and we then deduce the value of the remaining term ΔG_t^0(int). Treiner's criterion corresponds to the situation that if the deduced value of $\Delta G_t^0(\text{int}) \leq \sim 3$ kcal mol^{-1}, the Ph_4As^+/Ph_4B^- assumption is valid, but if $\Delta G_t^0(\text{int}) > \sim 3$ kcal mol^{-1} the assumption should not be used. Details of the calculation are in Table 1 for the solvents that Treiner studied plus the additional solvents 1-propanol, acetone, 1,2-dichloroethane (1,2-DCE), and 1,1-dichloroethane (1,1-DCE).[2] As expected, our calculations lead to the same results as found by Treiner. For transfers from water to methanol, ethanol, 1-propanol, formamide, and acetonitrile, the interaction term is small enough to take the Ph_4As^+/Ph_4B^- assumption as valid; for all the other solvents the assumption (on Treiner's hypothesis) must be questioned. We stress that our criterion based on the actual value of the interaction term leads in general to the same conclusions as does Treiner's (percentage) criterion. We used the actual value because workers (5–7) are interested in whether the assumption holds to within a given value rather than to within a given percentage value.

A difficulty not pointed out by Treiner is that choice of reference solvent is completely arbitrary. In Table 1 we also recalculate all results to acetonitrile as a reference solvent. It now appears that for transfers to solvents water, ethanol, 1-propanol, formamide, acetone, and 1,1-DCE the Ph_4As^+/Ph_4B^- assumption is valid (on Treiner's hypothesis), and for transfers to the other solvents the assumption is questionable. Clearly, by altering the reference solvent, it is possible to obtain quite different values for ΔG_t^0(int) and hence quite different conclusions as to the validity of the Ph_4As^+/Ph_4B^- assumption.

Even more serious is Treiner's basic hypothesis that ΔG_t^0(int) = 0 for transfer of Ph_4As^+ and Ph_4B^-.[3] We can see no reason why this interaction term should be zero. The Ph_4As^+/Ph_4B^- assumption, for free energies of transfer, is simply that:

$$[4] \quad \Delta G_t^0 \text{ for } Ph_4As^+ = \Delta G_t^0 \text{ for } Ph_4B^-$$

[1]Recent work by Gritzner (13) shows that when bisphenylchromium(I)/bisphenylchromium(II) is used as a reference redox system, single-ion free energies of transfer from acetonitrile to methanol, DMF, DMSO, NMPy, and to some extent PC, agree well with values calculated using the Ph_4As^+/Ph_4B^- assumption.

[2]Values of $\Delta G_t^0(Ph_4As^+ + Ph_4B^-)$ recently found by Kim (18) agree very well with those in Table 1.

[3]This is the fundamental hypothesis used by Treiner. Thus only if the deduced value of ΔG_t^0(int) is zero or small (say < 3 kcal mol^{-1}) is the Ph_4As^+/Ph_4B^- assumption considered to be reasonable.

TABLE 1. Free energies of transfer from water or from acetonitrile for the Ph_4As^+ (or Ph_4B^-) ion with cavity terms calculated by scaled-particle theory, in kcal mol^{-1} at 298 K[a]

			ΔG_t^0 from water				ΔG_t^0 from acetonitrile

1,2-Dichloroethane	1.2458	5.08	−4.6	4.2	−8.3	−8.7	−6.1	−0.3
1,1-Dichloroethane	1.1680	5.07	−7.8	4.3	−3.9	−7.4	−1.7	1.0

[a]All free energies refer to the mol fraction scale, and are for Ph_4As^+ or Ph_4B^-.
[b]Solvent density.
[c]Solvent diameter in Å.
[d]This is the combined term $[\Delta G_t^0(\text{cav}) + RT \log (V_1/V_2)]$, calculated for a solute of diameter 8.4 Å.
[e]Calculated by the method of Abraham and Liszi for a solute of diameter 8.4 Å.
[f]Determined from interaction = total − cavity − electrical.
[g]Taken from refs. 1 and 4 unless indicated, and corrected to the $Ph_4As^+ = Ph_4B^-$ convention.
[h]Obtained through rearrangement of the values in the previous two columns.
[i]From ref. 2.

Now since the diameters of the two species are equal, the terms $\Delta G_t^0(\text{cav})$ and $\Delta G_t^0(\text{elec})$ will be the same for the two species, and we are left with:

[5] $\Delta G_t^0(\text{int})$ for $Ph_4As^+ = \Delta G_t^0(\text{int})$ for Ph_4B^-

It is not clear why these interaction terms should be small or zero in order for the Ph_4As^+/Ph_4B^- assumption to apply. If, however, the $\Delta G_t^0(\text{int})$ terms can take any value, then there is no basis for Treiner's criterion at all. Thus in Table 1 it could be argued, for example, that the Ph_4As^+/Ph_4B^- assumption applies to PC and that for this solvent the interaction term happens to be particularly large.

(B) Enthalpy of Transfer of Ph_4As^+ and Ph_4B^-

The enthalpy of solution of a hard-sphere solute is given by eq. [6]

[6] $\Delta H_s^0 = \Delta H^0(\text{cav}) - RT + \alpha pRT^2 + \Delta H^0(\text{int})$

where αp is the coefficient of thermal expansion of the solvent. If we include the electrostatic energy of a charged solute, the resulting expression for the transfer of a solute is eq. [7]

[7] $\Delta H_t^0 = \Delta H_t^0(\text{cav}) + \Delta H_t^0(\text{int}) + \Delta H_t^0(\text{elec})$

where for simplicity the term $\Delta H_t^0(\text{cav})$ now includes $(\alpha p_2 RT^2 - \alpha p_1 RT^2)$. Details of the calculations are in Table 2 with water as the reference solvent. If Treiner's hypothesis applies also to enthalpies, then $\Delta H_t^0(\text{int})$ should be zero or small (say again <3 kcal mol^{-1}) for the Ph_4As^+/Ph_4B^- assumption to be valid. Use of such a hypothesis results in the extraordinary situation that for transfer from water to every solvent in Table 2, the Ph_4As^+/Ph_4B^- assumption cannot be valid. Clearly, the use of scaled-particle theory plus the hypothesis that $\Delta H_t^0(\text{int})$ should be zero for Ph_4As^+ and Ph_4B^- does not lead to any meaningful results.

(C) Entropy of Transfer of Ph_4As^+ and Ph_4B^-

Combination of the equations for free energy and enthalpy will yield an expression for the entropy of transfer of a charged solute. There is, however, an important proviso in that, as applied by Pierotti, the entropy of interaction is taken as zero. Thus if $\Delta S_s^0(\text{int}) = 0$ it follows that $\Delta S_t^0(\text{int}) = 0$; the final expression for ΔS_t^0 becomes:

[8] $\Delta S_t^0 = \Delta S_t^0(\text{cav}) + \Delta S_t^0(\text{elec})$

Since there are no unknown interaction terms in eq. [8], it should be possible, if scaled-particle theory really does apply to solutes such as Ph_4As^+ and Ph_4B^-, to calculate values of ΔS_t^0. Details are in Table 3 with water as the reference solvent. There is total disagreement between all the calculated and observed values, so that for transfers from water it is now clear that scaled-particle theory cannot account for the entropy term. It is possible by choice of some other reference solvent to obtain agreement for a few transfers, but in general these results demonstrate that scaled-particle theory is of little use in

TABLE 2. Enthalpies of transfer from water for the Ph_4As^+ (or Ph_4B^-) ion with cavity terms calculated by scaled-particle theory, in kcal mol^{-1} at 298 K

attempts to calculate entropy changes for Ph_4As^+ and Ph_4B^-.

Results using the Sinanoglu – Reisse – Moura Ramos (SRMR) Method

A quite different method of obtaining cavity terms was suggested by Halicioglu and Sinanoglu (15) and applied recently by Reisse and Moura Ramos (16). These latter workers make no attempt to calculate the interaction term but deduce this term from the expression:

$$[9] \qquad \Delta P_t^0(\text{int}) = \Delta P_t^0 - \Delta P_t^0(\text{cav})$$

where $P = G$, H, or S. We use exactly the same procedure as Reisse and Moura Ramos to calculate the cavity terms and, like these workers, then deduce the interaction term from eq. [9]. In the SRMR method, the molar volume of the solute is used, rather than its diameter, and we took values given by Millero (17) of $\bar{V} = 245.6$ ml mol^{-1} for Ph_4As^+ and $\bar{V} = 295.6$ ml mol^{-1} for Ph_4B^-. Although the cavity terms differ a little in these two cases, the differences from one solvent to another are negligible. We give in Table 4 the results for Ph_4As^+, but these can be taken as being the same as those for Ph_4B^- within

TABLE 4. Free energies of transfer from acetonitrile of Ph_4As^+ with cavity terms calculated by the SRMR method, in kcal mol^{-1} at 298 K[a]

Solvent	Cavity[b]	Electrical[c]	Interaction[d]	Total (observed)[c]
Water	19.1	−1.8	−8.9	8.4
Methanol	−1.6	−0.2	4.2	2.4

1,2-Dichloroethane	3.4	5.4	7	−0.8	−0.9	0
1,1-Dichloroethane	0.2	2.1	7	−3.5	−5.6	−7

[a]The terms on the scaled-particle theory are ΔG_t^0(cav) + $RT \log (V_1/V_2)$ and ΔH_t^0(cav) + $\alpha p_2 RT^2 - \alpha p_1 RT^2$; ΔG_t^0 and ΔH_t^0 in kcal mol^{-1} and ΔS_t^0 in cal K^{-1} mol^{-1}.
[b]SRMR calculated values are approximate ones.

about 0.1 kcal mol^{-1}. In the case of SRMR theory, it is difficult to take into account contributions due to solvent reorganisation. Since this effect will be much more important for water than for any other solvent, the SRMR calculation for water will be less reliable than calculations for other solvents.[4] We therefore took acetonitrile as the reference solvent in Table 4; the results in Table 1 provide a direct comparison between SRMR calculation and scaled-particle theory. For transfers from acetonitrile to several solvents there are considerable differences in the ΔG_t^0(cav) terms as calculated by the two methods (see Table 5). The SRMR results (Table 4) can be interpreted using the approach of Reisse and Moura Ramos to the effect that there are, indeed, large variations in ΔG_t^0(int) with change of solvent so that, contrary to Treiner's hypothesis, ΔG_t^0(int) cannot be regarded as small or zero for Ph_4As^+ or Ph_4B^-.

In Table 5 we compare the calculated cavity terms in free energy, enthalpy, and entropy on the two

[4]We note also that the term used by Sinanoglu to correct for loss of translational entropy of the solute in solution, R ln [V(gas)/$\bar{V}$(solvent)], overestimates the translational entropy in solution, since the available volume in solution is less than the solvent molar volume, $\bar{V}$. However, for transfer from one solvent to another there is so much cancellation that values of ΔG_t^0(cav) and ΔS_t^0(cav) are not greatly affected by errors in this term. We are grateful to Professor Reisse for clarifying this point.

theories. There are such differences in the values calculated by the two methods that it seems quite unrealistic to attempt deductions as to the validity of the Ph_4As^+/Ph_4B^- assumption on the basis of calculated cavity terms.

In our view all the above considerations suggest that the validity of the Ph_4As^+/Ph_4B^- assumption cannot usefully be investigated by the method of Treiner, and we cannot see any basis for the previous rejection of the assumption. It is of interest that quite recently Kim (18) has strongly supported the Ph_4As^+/Ph_4B^- assumption, in terms of free energy, for the very solvents rejected by Treiner (11).

Although several workers (19, 20) have applied scaled-particle theory to the transfer of large ions and have obtained reasonable agreement between the calculated cavity term and the observed free energy (19) or enthalpy (20) of transfer, it is noticeable that such agreement is always limited to transfers between water and aqueous organic mixtures. For example, Treiner (11) calculated ΔG_t^0(cav) for the transfer of Ph_4As^+ from water to aqueous ethanol and found good agreement with the observed ΔG_t^0 value. But inspection of Table 1 shows that for transfer from water to ethanol itself, the two terms differ by 1.6 kcal mol^{-1} and for the corresponding enthalpy function the terms differ by no less than 8.6 kcal mol^{-1} (Table 2). It seems clear that in non-aqueous solvents, scaled-particle theory cannot usefully be applied to transfers of large ions. Whether or not the agreement observed in the more aqueous media is an artifact is a matter of opinion. We note that Tenne and Ben-Naim (21), in connection with calculations on free energy, state that it is impossible to apply scaled-particle theory alone for mixtures of water and ethanol.

University Chemical Laboratory, University of Kent at Canterbury, Canterbury, Kent, England

Received April 12, 1978

BRIAN B. HASINOFF. Can. J. Chem. **57**, 77 (1979).

The kinetics of the binding of Br^- to Fe(III) were studied as a function of $[H^+]$ and $[Br^-]$ on a high pressure laser temperature jump apparatus up to 2.76 kbar. At constant $[H^+]$ the pseudo first order rate constant for formation of $FeBr^{2+}$ showed little dependence on pressure or on $[Br^-]$ over the range 0.02 to 1.9 *M*. The results were interpreted by a mechanism in which Fe^{3+} and $FeOH^{2+}$ react with Br^- to form ion pairs prior to formation of their inner sphere complexes. The kinetic activation volume for the conversion of the Fe^{3+},Br^- ion pair to $FeBr^{2+}$ appears to be quite negative, consistent with an associative interchange (I_a) mechanism.

BRIAN B. HASINOFF. Can. J. Chem. **57**, 77 (1979).

On a étudié la cinétique de la liaison du Br^- au Fe(III) en fonction de $[H^+]$ et de $[Br^-]$ à l'aide d'un appareil à saut de température activé par un laser à haute pression opérant jusqu'à 2.76 kbar. A $[H^+]$ constante, la constante de vitesse de pseudo premier ordre pour la formation du $FeBr^{2+}$ n'est que faiblement influencée par la pression ou la $[Br^-]$ à des concentrations allant de 0.02 à 1.9 *M*. On a enterprété les résultats en termes d'un mécanisme dans lequel le Fe^{3+} et le $FeOH^{2+}$ réagissent avec le Br^- pour former des paires d'ions avant la formation de leurs complexes de sphères internes. Il semble que le volume d'activation cinétique pour la conversion de la paire d'ions Fe^{3+}, Br^- en $FeBr^{2+}$ soit assez négative; ceci est en accord avec un mécanisme d'échange associatif (I_a).

[Traduit par le journal]

High pressure kinetic studies of the reaction of Fe^{3+} with Cl^- (1) and with NCS^- (2) have provided evidence for the existence of an associative interchange mechanism for ligand substitution. In contrast, the more labile $FeOH^{2+}$ species is thought to undergo ligand substitution by a dissociative interchange mechanism. Previous high pressure kinetic studies of ligand binding to Co^{2+}, Ni^{2+}, Zn^{2+}, and Cu^{2+} (3, 4) yielded results consistent with a dissociative interchange mechanism as suggested by Eigen and Wilkins (5).

This study extends the Fe(III) pressure work to another anionic ligand, Br^-. Product yield, kinetic and spectrophotometric experiments have been independently used to evaluate an ion pair formation constant for reaction of Fe(III) and Br^- (6). Earlier kinetic studies (7, 8) indicated the $[H^+]^{-1}$ dependence of the reaction rate but did not include the effect of ion pairing. It must be noted that the extent of formation of $FeBr^{2+}$ cannot be made large under reasonable conditions and it is necessary to construct an interpretation from judicious combinations of values derived from both equilibrium and kinetic experiments. The direct analysis of the more uncertain parts of the kinetics produce parameters in agreement with the constraints imposed by combined considerations and, consequently, are most probably significant.

Experimental

Reagents

All reagents ($Fe(NO_3)_3$, NaBr, $NaClO_4$, $HClO_4$, and $Cu(NO_3)_2$) were of analytical reagent grade. Solutions of HBr, $HClO_4$, and NaOH were determined by titration. The total ionic strength in the reaction solutions was kept constant by the addition of $NaClO_4$ to solutions containing NaBr and $HClO_4$ or to solutions containing HBr, $HClO_4$, and NaOH. $Fe(NO_3)_3$ was 5.0 m*M* in all solutions. The rate and equilibrium constants are on a molality scale reduced to molarity at 1 bar.

Apparatus

The high pressure ruby laser temperature jump apparatus and the analysis of the exponential relaxation curves have been described (1, 3). A 1.6°C temperature jump was produced in the thermostatted (±0.1°C) reaction solution by absorbing the 694 nm laser radiation with 0.02 *M* $Cu(NO_3)_2$. Representative oscilloscope traces of the relaxation process are shown in Fig. 1. Experiments conducted on a joule heating temperature jump apparatus (Messanlagen, Göttingen) at 400 nm with a 5°C jump indicated the absence of any effect of

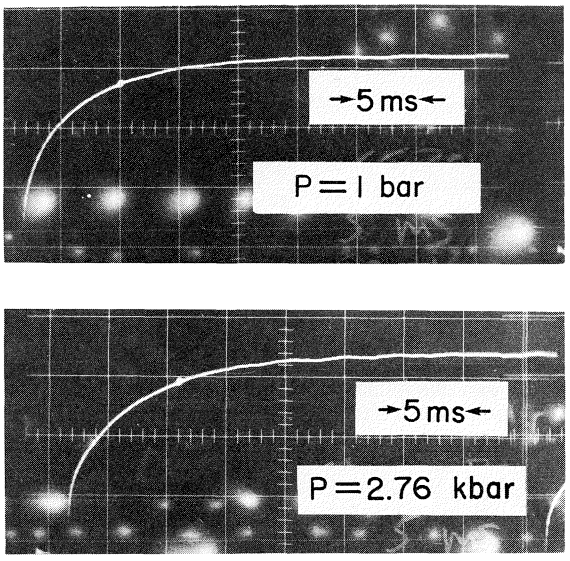

FIG. 1. Oscilloscope traces of voltage vs. time for the relaxation observed for the reaction of Fe(III) and Br^- at 1 bar and 2.76 kbar with $[H^+] = 0.525\ M$, $[Br^-] = 1.9\ M$, $[Fe(III)]_\Sigma = 5.0\ mM$, $T = 25.0°C$, and $\mu = 2.0\ M$. The temperature jump of 1.6°C was produced by a ruby laser. The large horizontal divisions are 5 ms.

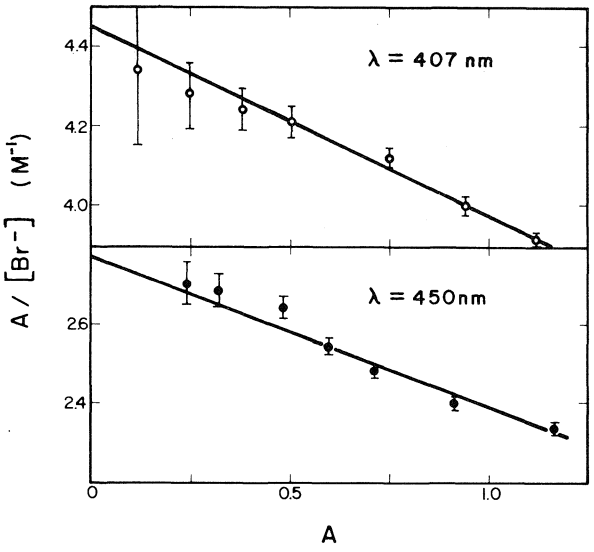

FIG. 2. $A/[Br^-]$ vs. A observed for the reaction of Fe(III) and $[Br^-]$ at 25.0°C with $[H^+] = 2.00\ M$ and $\mu = 2.0\ M$ and $[Fe(III)]_\Sigma$ held constant at 5.0 mM. The slopes yield K (eq. [1]). The solid straight lines are from weighted linear least-squares analyses. The error bars are the standard deviations used in the weighted linear least-squares analyses; assuming an error in A of 0.0025.

$Cu(NO_3)_2$. Only a single exponential relaxation process was detected in a search over a wide range of sweep speeds. Thus any kinetic contribution from higher Fe(III) bromide complexes can be ruled out. An interference filter or a blue colored glass filter of maximum transmission in the region of maximum $FeBr^{2+}$ absorption (408 nm) provided monochromatic light for the photometric detector. A Unicam SP8000 spectrophotometer with a thermostatted cell block was used for equilibrium measurements at 1 bar. Changes in light transmission with pressure were measured with a 10-turn off-set potentiometer.

Results

Equilibrium

The binding of Br^- to Fe(III) may be interpreted in terms of

$$[1] \qquad K = [FeBr^{2+}]_\Sigma/[Fe^{3+}]_\Sigma[Br^-]$$

where $[FeBr^{2+}]_\Sigma$ includes all inner sphere complex absorbing species and $[Fe^{3+}]_\Sigma$ includes all other non-absorbing species including outer sphere complexes. Absorbances, A, were used to determine K by plotting $A/[Br^-]$ vs. A (Fig. 2) similar to (6) and yielded from linear least-squares slopes, K's of $0.38 \pm 0.04\ M^{-1}$ and $0.48 \pm 0.03\ M^{-1}$ at 450 nm and 407 nm, respectively. This indicates only small outer sphere complexation. Previous determinations of K at 25°C have yielded values of $0.37\ M^{-1}$ ($\mu = 1.0\ M$) (6); $0.61\ M^{-1}$ ($\mu = 1.2\ M$) (9); and $0.5 \pm 0.2\ M^{-1}$ ($\mu = 1.092$) (10). The agreement is reasonable considering the low stability of the complex.

Using an average K of $0.43\ M^{-1}$ in eq. [1] and the absorbance at 440 nm at 1 bar the product of molar absorptivity and path length was calculated for $FeBr^{2+}$. Assuming this product remains, to a first approximation, constant with pressure, from the absorbances observed at higher pressures values of K were determined. From solutions with $[Br^-]$ of 0.2 M and 0.5 M, K's were determined at each pressure and their average values plotted in Fig. 3 as log K. The variation of the equilibrium constant with pressure is related to the molar volume of the reaction, ΔV, by (11)

$$[2] \qquad \Delta V = -RT\,(\partial \ln K/\partial P)_T$$

Since the K data of Fig. 3 show significant curvature, the data were least-squares fit to an equation of the form $\log K = a + bP + cP^2$ yielding: log K at 0 bar of -0.370 ± 0.002, from b and eq. [2] at 0 bar $\Delta V = 8.1 \pm 0.2\ cm^3\ mol^{-1}$, and from c and the derivative of eq. [2] $(\partial\Delta V/\partial P)_T = -2.3 \pm 0.2\ cm^3\ mol^{-1}\ kbar^{-1}$. Also plotted in Fig. 3 is the pressure variation of log K_a obtained at a single $[H^+]$ of $7.1 \times 10^{-3}\ M$ for the reaction $Fe^{3+} \rightleftharpoons FeOH^{2+} + H^+$ where $K_a = [FeOH^{2+}][H^+]/[Fe^{3+}]$ but at $\mu = 1.5\ M$ and 24.2°C and $\lambda = 325$ nm. The absorbance changes observed were small (from 0.18 at 1 bar to 0.15 at 2.76 kbar). A density correction for the pressure dependence of the molar absorptivity was not made as in ref. 2 ($\Delta V_a = 3.0 \pm 0.5\ cm^3\ mol^{-1}$ at

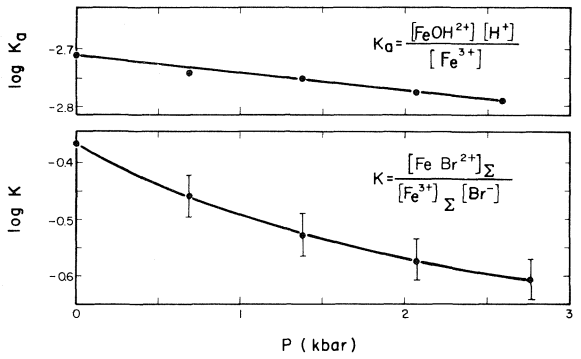

FIG. 3. Plots of log K_a and log K vs. pressure. Values of K_a were determined from absorbance measurements at 325 nm at 24.2°C and $\mu = 1.5$ *M*. Values of K were obtained at 440 nm at 25.0°C, $[H^+] = 1.00$ *M* and $\mu = 2.0$ *M*. The solid lines are least-squares calculated. Their slopes yield their respective volumes of reaction. The error bars are average standard deviations from the averaged K's.

25°C and $\mu = 0.2$ *m*) since it is well known that both density changes and band shifts can cause changes in molar absorptivities. A least-squares fit to the equation $\log K_a = a + bP$ yielded $\Delta V_a = 1.6 \pm 0.1$ cm^3 mol^{-1} and $a = -2.715 \pm 0.004$. A density correction alone to the molar absorptivities would yield a slightly higher ΔV_a, close to that in ref. 2.

Kinetic

The kinetics of the binding of Br^- to Fe(III) were studied on a stopped flow apparatus at wavelengths from 400 to 500 nm at a constant $[H^+] = 2.00$ *M* and with $[Br^-]$ varying from 0.02 to 1.43 *M*. The single exponential process characterized by the pseudo first order rate constant for approach to equilibrium, k_{obs}, showed little or no $[Br^-]$ dependence (Table 1) as previously reported (6); thus it is dominated by dissociation. The joule heating temperature jump experiments (Table 1), with $[H^+] = 1.00$ *M* and $[Br^-]$ varying from 0.05 to 1.90 *M*, yielded similar results. The lack of $[Br^-]$ dependence

TABLE 1. Rate constants and reciprocal relaxation times for the reaction of Fe(III) and Br^- at 25.0°C and ionic strength 2.0 *M*

Joule heating temperature jump[a]		Stopped flow[b]	
$[Br^-]$ (*M*)	τ^{-1} (s^{-1})	$[Br^-]$ (*M*)	k_{obs} (s^{-1})
0.05	127	0.02	37.0
0.10	120	0.05	49.3
0.20	123	0.10	53.4
0.50	123	0.20	54.4
1.00	126	0.50	50.4
1.00[c]	132	1.00	50.9
1.90	120	1.43	47.3

[a]Average standard deviation on τ^{-1} is 6 s^{-1}, $[H^+] = 1.00$ *M*.
[b]Average standard deviation on k_{obs} is 2 s^{-1}, $[H^+] = 2.00$ *M*.
[c]Solution also contained 0.02 *M* $Cu(NO_3)_2$.

of the rates was confirmed by linear least-squares analyses. Slopes of k_{obs} and the reciprocal relaxation times, τ^{-1} vs. $[Br^-]$, were both zero within one standard deviation.

In the reaction of Br^- with Fe(III) the reactions of Fe^{3+} and $FeOH^{2+}$ with Br^- to form an ion pair prior to formation of their respective inner sphere complexes may be usefully considered as resolvable steps.

[3]
$$\begin{array}{ccccc} Fe^{3+} + Br^- & \xrightleftharpoons{K_1} & Fe^{3+},Br^- & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & FeBr^{2+} \\ \Big\uparrow\Big\downarrow K_a & & \Big\uparrow\Big\downarrow K_b & & \Big\uparrow\Big\downarrow K_c \\ FeOH^{2+} + Br^- & \xrightleftharpoons{K_2} & FeOH^{2+},Br^- & \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} & FeOHBr^+ \end{array}$$

where $K_b = [FeOH^{2+},Br^-][H^+]/[Fe^{3+},Br^-]$; $K_c = [FeOHBr^+][H^+]/[FeBr^{2+}]$; $K_1 = [Fe^{3+},Br^-]/[Fe^{3+}][Br^-]$; and $K_2 = [FeOH^{2+},Br^-]/[FeOH^{2+}][Br^-]$. With $[Br^-] \gg [Fe(III)]_\Sigma$ and $[H^+] \gg K_a$, K_b, K_c, K_aK_2/K_1 and fast proton and ion pair equilibria, both the reciprocal relaxation time and k_{obs} obtained by mixing are given by:

$$[4] \quad k_{obs} = \frac{K_1[Br^-]}{1 + K_1[Br^-]}\left(k_1 + \frac{k_2K_b}{[H^+]}\right) + k_{-1} + \frac{k_{-2}K_c}{[H^+]}$$

From a consideration of eqs. [1] and [3] it is readily seen (6, 12) that the equilibrium constant of eq. [1] is an apparent equilibrium constant only and as such is a composite of the rate and equilibrium constants of eq. [3]. Yet it behaves as a simple equilibrium (eq. [1]). At high $[H^+]$ this apparent equilibrium constant is, in terms of the ion pair equilibrium and ion pair – inner sphere rate constants, given by

$$[5] \quad K = K_1(k_1/k_{-1} + 1)$$

and from eq. [3]

$$[6] \quad k_{-2}K_c = k_{-1}k_2K_b/k_1$$

combining eqs. [4]–[6] yields:

$$[7] \quad k_{obs} = \left(\frac{K_1}{K - K_1}\right)\left(k_1 + \frac{k_2K_b}{[H^+]}\right) \times \left(\frac{1 + K[Br^-]}{1 + K_1[Br^-]}\right)$$

$$[8] \quad k_{obs} = \left(k_{-1} + \frac{k_{-2}K_c}{[H^+]}\right)\left(\frac{1 + K[Br^-]}{1 + K_1[Br^-]}\right)$$

It is useful at this point to qualitatively examine the significance of the data of Table 1. The lack of

[a]Predicted values of k_{obs} are those obtained from the parameters of Table 3 substituted in eq. [7].

any observable $[Br^-]$ dependence on the rates indicates that only the terms of eq. [4] containing the dissociation rate constants k_{-1} and k_{-2} for the inner sphere complexes make any measurable contribution to k_{obs}; thus $k_{obs} \simeq k_{-1} + k_{-2}K_c/[H^+]$. Further, from eq. [8], for k_{obs} to show a lack of $[Br^-]$ dependence K and K_1 must be similar in value. It is important to realize that this conclusion can also be reached from product yield experiments (6) where $K_1 = 0.83K$ can be obtained. From eq. [5], then, $k_1/k_{-1} = 0.2$. These relationships are of importance for the analysis which follows.

Taking logarithms and differentiating eq. [5] gives

$$[9] \quad \Delta V = \Delta V_1 + (\Delta V_1^{\ddagger} - \Delta V_{-1}^{\ddagger}) \frac{k_1/k_{-1}}{k_1/k_{-1} + 1}$$

where the activation volume (11) is

$$\Delta V^{\ddagger} = -RT(\partial \ln k/\partial P)_T$$

The laser temperature jump relaxation data obtained at pressures up to 2.76 kbar are given in Table 2. It is worth noting that k_{obs} does not show an appreciable dependence on pressure. This conclusion was confirmed by linear least-squares analysis. The apparent $\Delta V^{\ddagger}$, $-RT(\partial \ln k_{obs}/\partial P)$, is zero within one standard deviation in three out of four cases. Since $k_{obs} \simeq k_{-1} + k_{-2}K_c/[H^+]$ the conclusion may be reached that neither k_{-1} nor $k_{-2}K_c$ have much of a pressure dependence and hence have small activation volumes. (This conclusion is further reinforced from the pressure dependence of k_{-1} obtained from extrapolations to $1/[H^+] = 0$ yielding an average $\Delta V_{-1}^{\ddagger}$ of -2 ± 1 cm^3 mol^{-1}.) This result may be combined with the equilibrium results to yield further information. From eq. [9] at 0 bar with $\Delta V = 8.1$ cm^3 mol^{-1}, $k_1/k_{-1} = 0.2$ and $\Delta V_{-1}^{\ddagger} = -2$ cm^3 mol^{-1} it is seen that $\Delta V_1 + 0.17\Delta V_1^{\ddagger} = 6$ cm^3 mol^{-1}. But without knowledge of ΔV_1 the value of $\Delta V_1^{\ddagger}$ cannot be obtained. However, it is well known that the formation of an ion pair between two oppositely charged ions leads to a decrease in electrostriction (11) with a consequent increase in the volume of electrostricted water. This conclusion is reinforced by theory (14) and has also been confirmed experimentally. Reaction volumes for the ion pairs following are: 10 ± 3 cm^3 mol^{-1} for Be^{2+},SO_4^{2-} (12) at 25°C and $\mu = 1.0\ M$; 16 ± 0.5 cm^3 mol^{-1} for $Co(NH_3)_6^{3+}$,SO_4^{2-} (13) at 30°C and $\mu = 0.1\ m$. If in fact ΔV_1 for Fe^{3+},Br^- is larger than 6 cm^3 mol^{-1}, as would seem likely, then $\Delta V_1^{\ddagger}$ must be negative.

An alternative and more quantitative analysis of the data of Table 2 is as follows. Substitution of $k = k_0 \exp(-P\Delta V^{\ddagger}/RT)$ with k_0 the rate constant at 0 bar and the equivalent equilibrium constant expression in eq. [7] yields k_{obs} as a function of four variables ($[H^+]$, $[Br^-]$, P, and K) and five parameters (k_1 and k_2K_b at 0 bar, and $\Delta V_1^{\ddagger}$, $\Delta V_{2b}^{\ddagger}$, and ΔV_1) if K_1 at 1 bar is fixed from $K_1 = 0.83K = 0.36\ M^{-1}$. The best fit values are given in Table 3. Since eq. [7] by virtue of its $K - K_1$ term is more sensitive to physically reasonable values of K_1 (K must be larger than K_1 at all pressures) the parameters of eq. [8] were obtained from a four-parameter analysis using the value of ΔV_1 obtained from the non-linear least-squares analysis of eq. [7]. The initial parameter estimates for the iterative non-linear procedure were obtained graphically and from linear least-squares methods. The non-linear confidence limits on the parameters are somewhat more conservative than the standard deviations listed in Table 3. For example the non-linear confidence limits yield an upper and lower bound of $\Delta V_1^{\ddagger}$ of -11 and -23 cm^3 mol^{-1}. Overall the relative standard deviation of the fit is 3%.

The non-linear computer analysis must be viewed in its proper perspective in assessing the reliability of the parameters obtained. The first point to be made in this regard is that five parameters are being determined from only 20 data points which statistically is a fairly small number. It must also be remembered

TABLE 3. Activation and reaction volumes for the reaction of Fe(III) and Br^- at 25.0°C and ionic strength 2.0 M[a]

Parameter	$\Delta V^{\ddagger}$ or ΔV ($cm^3\ mol^{-1}$)	Value of parameter at 0 bar[b]	Reaction step
k_1	-19 ± 4	$4.4\pm1.6\ s^{-1}$	$Fe^{3+},Br^- \rightarrow FeBr^{2+}$
k_{-1}	-2 ± 4	$22\pm7\ s^{-1}$	$FeBr^{2+} \rightarrow Fe^{3+},Br^-$
k_2K_b	-15 ± 3	$15\pm2\ M\ s^{-1}$	—
$k_{-2}K_c$	2 ± 2	$72\pm9\ M\ s^{-1}$	—
K_1	11 ± 1	$0.36\ M^{-1}$	$Fe^{3+} + Br^- \rightleftharpoons Fe^{3+},Br^-$
K_a[c]	1.6 ± 0.1	$1.9\times10^{-3}\ M$	$Fe^{3+} \rightleftharpoons FeOH^{2+} + H^+$
K	8.1 ± 0.2[d]	$0.43\pm0.07\ M^{-1}$	—

[a]All errors quoted are standard deviations from non-linear least-squares analysis only and do not represent the reliability of the individual parameters.
[b]At $[H^+] = 1.00\ M$, $P = 1$ bar, and low $[Br^-]$ these parameters predict $k_{obs} = 94 \pm 11\ s^{-1}$ which compares to $k_{obs} = 105\ s^{-1}$ (6) at $\mu = 1.00\ M$ and 22°C; $k_{obs} = 82 \pm 16\ s^{-1}$ (7) at $\mu = 1.7\ M$ and 22°C; and $k_{obs} = 220 \pm 40\ s^{-1}$ (8) at $\mu = 1.2\ M$ and 25°C.
[c]At 24.2°C and $\mu = 1.5\ M$.
[d]At 0 bar.

that the accuracy of the temperature jump method is not as high as some other kinetic methods. A second point is that the analysis assumes that the activation and reaction volumes of eqs. [7] and [8] do not vary with P. This is probably a reasonable assumption but nevertheless is an assumption that is introduced without any knowledge as to its validity. Introduction of compressibility terms would increase the number of parameters from 5 to an unacceptable 8. A third and even more general point is that the parameters are very dependent on the model used. While eq. [3] is a reasonable and generally accepted mechanism for ligand substitution, inclusion of further intermediates in eq. [3], solvent separated ion pairs, for example, would necessarily lead to different rate expressions than those used. Nonetheless, the parameters do meet the constraints outlined in the paragraphs above which explored the qualitative features of this difficult reaction.

Discussion

The results of the qualitative analysis of the kinetics described in the Results section lead to a number of firm qualitative conclusions. One is that the lack of $[Br^-]$ dependence on the rate is due to the relatively large size of the last two terms of eq. [4]. Further, the pressure dependence of k_{obs} is small leading to the conclusion that $\Delta V_{-1}^{\ddagger}$ is small. Consideration of these facts with knowledge of the volume of reaction ΔV leads to the further conclusion that $\Delta V_1^{\ddagger}$ is negative *if* ΔV_1 is larger than 6 $cm^3\ mol^{-1}$.

All of these qualitative conclusions are confirmed by the non-linear least-squares quantitative analysis which combines both kinetic and equilibrium data and which is subject to the qualifications given in the Results section. The value of $\Delta V_1 = 11\ cm^3\ mol^{-1}$ determined from eq. [7] for formation of the Fe^{3+},Br^- ion pair is positive as might be expected (11) for a reaction leading to a loss of electrostricted water. The magnitude of ΔV_1 is reasonable in comparison to similar reactions (12, 13) but is somewhat larger than the theoretical value of 5.4 $cm^3\ mol^{-1}$ (but at $\mu = 0\ M$) obtained from the Hemmes equation (1, 14). In the absence of a direct measurement of ΔV_b and ΔV_c the significance of the composite activation volumes for k_2K_b and $k_{-2}K_c$ is unknown.

A negative activation volume is usually indicative of bond formation in the transition state (11). The volume of a partially bonded species in the transition state would be less than a ion paired non-bonded species. Thus, the $\Delta V_1^{\ddagger}$ of $-19\ cm^3\ mol^{-1}$ indicates an associative process for substitution of Br^- into the inner coordination sphere of Fe^{3+}. The negative activation volumes for Br^-, Cl^-, and NCS^- substitution on Fe^{3+} contrast sharply to positive activation volumes found for substitution on $FeOH^{2+}$ by Cl^- of $7.8 \pm 1\ cm^3\ mol^{-1}$ (1) and by NCS^- of $6.6\ cm^3\ mol^{-1}$ (2) which are due to dissociative loss of water in the transition state (5).

The activation volume ($\Delta V_1 + \Delta V_1^{\ddagger}$) of the product K_1k_1 of $-8 \pm 4\ cm^3\ mol^{-1}$ compares to that obtained from the Cl^- (1) study of $-4.5 \pm 1.1\ cm^3\ mol^{-1}$ and $\sim 0\ cm^3\ mol^{-1}$ (individual determinations ranged from -4.9 to $4.4\ cm^3\ mol^{-1}$) for NCS^- (2). The previous indirect determinations of $\Delta V_1^{\ddagger}$ for the reaction of Fe^{3+} with Cl^- (1) of $-9.9\ cm^3\ mol^{-1}$ and with NCS^- (2) of $-1.2\ cm^3\ mol^{-1}$ were also taken to indicate an associative ligand substitution reaction.

Further evidence for the associative character of ligand substitution on Fe^{3+} is afforded by comparing the formation rate constants (the product K_1k_1) of Cl^-, Br^-, and NCS^-. All are singly charged unprotonated ligands and thus minimize ambiguity as to which protonated species is reactive. Thus, K_1k_1 for

NCS^- (2) is 122 $M^{-1}\,s^{-1}$, for Cl^- (1) 4.8 $M^{-1}\,s^{-1}$, and for Br^- 1.6 $M^{-1}\,s^{-1}$, almost an 80-fold variation. Generally dependence of a formation rate constant on the nature of the entering ligand is evidence for an associative reaction. The variation in K_1k_1 must be largely due to k_1 as K_1 would be expected to be relatively constant for ligands of the same charge type.

The reason for the change in mechanism from dissociative to associative in going from $FeOH^{2+}$ to Fe^{3+} may be due to the large charge of Fe^{3+} (15). The higher charge density of Fe^{3+} might be expected to raise the energy required to dissociate the cation–water bond, thus favouring an associative mechanism. Swaddle (16) has even suggested that there is a general change in mechanism (excluding cobalt), from dissociative interchange to associative interchange, in going from the divalent to the trivalent transition metals.

Spectroscopic studies of mercury(II) acetate complexes of some tertiary phosphines[1]

ELMER C. ALYEA AND SHELTON A. DIAS

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received March 10, 1978

ELMER C. ALYEA and SHELTON A. DIAS. Can. J. Chem. **57**, 83 (1979).

Mercury(II) acetate complexes of the type $(R_3P)_nHg(OAc)_2$, where $n = 1$ and 2, and R_3P = $(p\text{-tolyl})_3P$, $(p\text{-F-}C_6H_4)_3P$, Ph_2MeP, Ph_2EtP, and $PhEt_2P$ have been prepared in good yields. Only the 1:1 adduct is formed with $(o\text{-tolyl})_3P$. Conductance measurements in nitromethane show that these complexes are non-electrolytes. The 1:1 adducts are monomeric in dichloroethane but the 1:2 adducts are extensively dissociated. Tentative assignments for ν(COO), ν(Hg—O), ν(Hg—P) are made from the infrared and Raman spectral data. The correlation of the coordination chemical shifts, $\Delta\delta(^{31}P)$, with the coupling constants $^1J(^{199}Hg\text{–}^{31}P)$ of the complexes is discussed with respect to the bulkiness and the basicity of the phosphine ligands.

ELMER C. ALYEA et SHELTON A. DIAS. Can. J. Chem. **57**, 83 (1979).

On a préparé, avec de bons rendements, des complexes de l'acétate mercurique du type $(R_3P)_nHg(OAc)_2$ où $n = 1$ et 2 et R_3P = $(p\text{-tolyl})_3P$, $(p\text{-F-}C_6H_4)_3P$, Ph_2MeP, Ph_2EtP et $PhEt_2P$. Il ne se forme que l'adduit 1:1 avec le $(o\text{-tolyl})_3P$. Des mesures de conductivité dans le nitrométhane montrent que ces complexes ne sont pas des électrolytes. Les adduits 1:1 existent sous forme de monomères dans le dichloroéthane; toutefois les adduits 1:2 sont fortement dissociés. On a proposé des attributions préliminaires pour les ν(COO), ν(Hg—O), ν(Hg—P) observées dans les spectres infrarouges et Raman. On discute de la corrélation qui existe entre les déplacements chimiques de coordination, $\Delta\delta(^{31}P)$, et les constantes de couplage, $^1J(^{199}Hg\text{–}^{31}P)$, des complexes en relation avec l'encombrement et la basicité des ligands phosphines.

[Traduit par le journal]

Introduction

Spectroscopic and structural studies in our laboratory have recently involved mercury(II) complexes of tertiary phosphines containing bulky substituents. The characterization of these complexes by solution measurements (1, 2) was often hampered by their low solubility, which is partly governed by the nature of the anion. The latter was shown, by X-ray analysis of $[(Cy_3P)Hg(NO_3)_2]_2$ (3) and $(Cy_3P)Hg(SCN)_2$ (4), to also determine the coordination geometry of the mercury atom. Subsequently we have found that mercury(II) acetate complexes of tertiary phosphines are much more soluble than the analogous halide complexes, enabling the present characterization in solution of complexes involving phenyl-substituted phosphines with a range of steric and electronic properties.

Relatively few complexes of mercury(II) acetate are known (see, for example, ref. 5) and there are only two reports (6) on complexes with a phosphine ligand.[2] The complex bis(trimethylphosphine)mercury(II) acetate was considered to contain two-coordinate mercury and ionic acetate groups (6*a*). However, the complex $(Bu_3^tP)Hg(OAc)_2$ was determined to have a monomeric trigonal bipyramidal structure (8*a*). Very recently we reported (2) that the complexes $(Ph_3P)_2Hg(OAc)_2$ (8*b*), $(Ph_3P)Hg(OAc)_2$ (8*b*), $(Cy_3P)_2Hg(OAc)_2$, $(Cy_3P)Hg(OAc)_2$, and $[(o\text{-tolyl})_3P]Hg(OAc)_2$ also have non-ionic structures. The effects of the carboxylate groups on the nature of the phosphine complexes of mercury(II) carboxylates have been investigated in an independent study (8*b*). In the present study, we report the vibrational and nmr spectroscopic investigation of a series of mono and bis tertiary phosphine – mercury(II) acetate complexes with a variety of tertiary phosphines.

Experimental

General Procedures

Mercury(II) acetate and tertiary phosphines were commercial samples. Solvents were purified and dried following standard procedures. Microanalyses were performed at M-H-W Laboratories, Garden City, Michigan. Melting points were determined with a Gallenkamp melting point apparatus in open capillary tubes and are uncorrected. Molecular weights were measured in dichloroethane solution using a Hitachi-Perkin-Elmer 115 osmometer. Conductivity measurements were obtained for nitromethane solutions with a Yellow Springs conductivity bridge using a conductivity cell with platinum electrodes.

[1]Presented in part at the American Chemical Society/Chemical Institute of Canada Joint Meeting, Montreal, P.Q., Canada, May/June 1977.

[2]Mercuration reactions are, however, more widely studied (7).

[c]In 1,2-dichloroethane for ca. 5×10^{-3} *M* solutions.
[d]Isolated with one molecule of dichloromethane.

Infrared spectra were obtained with a Beckman IR-12 spectrophotometer; solid state spectra were recorded as Nujol and Halocarbon mulls between CsI plates whereas solution spectra were obtained using matched KBr cells of 0.2 mm path length. Raman spectra were obtained for samples sealed in capillaries with a Jarrell-Ash spectrometer using the 514.5 nm line of a Spectra-Physics 165 laser. ^1H nmr spectra were recorded on a Varian A-60 spectrometer with TMS as reference standard and ^{31}P nmr spectra were measured with a Bruker WP-60 FT spectrometer at 24.3 MHz using the side-band technique with 85% H_3PO_4 as reference in a concentric capillary.

Preparation of the Complexes

All of the mercury(II) acetate complexes were prepared by the general method already outlined for mercury(II) halide complexes of tertiary phosphines (1, 2). The suspension of mercury(II) acetate in ethanol, benzene, or dichloromethane disappeared immediately as it was allowed to react with either a 1:1 or 1:2 molar ratio of tertiary phosphine at ambient temperature under dry dinitrogen. The white solids obtained by evaporation of the solvent were normally recrystallized from dichloromethane/diethyl ether or dichloromethane/hexane. In the case of $(Et_2PhP)_2Hg(OAc)_2$, the product was obtained as a colourless viscous oil and its purity deduced from its ^1H nmr spectrum. The complex $(Ph_3P)Hg(OAc)_2$ was also formed by the reaction of methyl mercury acetate with Ph_3P in a 1:1 molar ratio in dichloromethane solution.[3] Product yields were in the 70–99% range. Although stable in the solid state towards decomposition on exposure to air and moisture, the products decomposed gradually with the deposition of metallic mercury upon standing in solution.

Results and Discussion

Some of the physical properties and the analysis of the new series of complexes are listed in Table 1. Tri(*o*-tolyl)phosphine forms only a 1:1 adduct with mercury(II) acetate. Attempts to prepare higher adducts using as much as sixfold excess of phosphine still afforded only the 1:1 adduct, but in slightly higher yields. This behavior parallels that previously reported (1) for mercuric halides and thiocyanate with tri(*o*-tolyl)phosphine and tris(*tert*-butyl)phosphine and clearly reflects the steric bulkiness of these phosphines. Tolman used CPK molecular models to define "cone angles" for phosphines; estimated values for $(o\text{-tolyl})_3P$, $Bu_3{}^tP$, and Ph_3P are 194°, 182°, and 145°, respectively (9). X-ray structural studies of several metal complexes give experimentally derived cone angles in relatively good agreement with Tolman's estimates, and further, provide a quantitative description of the steric requirements of the phosphine ligands in terms of a "ligand profile" (3, 4, 8*a*, 10, 11).

All of the complexes prepared in this study are white solids which are stable towards air in the solid state. However, in solution the stability appears to decrease as the number of alkyl substituents increases. The complex $Hg(OAc)_2(PPhEt_2)_2$ could not be obtained in a solid form but its purity was verified by ^1H nmr spectroscopy. Molecular weight determinations in dichloroethane show that the 1:1 adducts are monomeric whilst the 1:2 adducts undergo dissociation. Since all of the complexes are essentially non-electrolytes in nitromethane, the dissociation in solution must involve the following equilibrium:

$$[1] \qquad Hg(OAc)_2(PR_3)_2 \rightleftarrows Hg(OAc)_2(PR_3) + PR_3$$

Nuclear magnetic resonance studies, discussed below, confirmed the existence of equilibrium [1].

[3]The full characterization of $(Ph_3P)_nHg(OAc)_2$ ($n = 1, 2$) is described in the independent study of triphenylphosphine complexes of several substituted mercury acetates (8*b*).

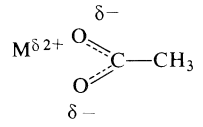
Vibrational Spectral Studies

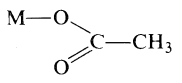
Spectroscopic measurements in solution were facilitated by the solubility of all the complexes in common organic solvents. The infrared study was mainly concerned with an attempt to determine the mode of coordination of the acetate group. The solid state and solution infrared absorptions associated with the asymmetric (ν_8) and the symmetric (ν_3) stretching frequencies of the acetate moiety for all the complexes are given in Table 2. Although assignment of the asymmetric stretch of the COO group could be made quite unequivocally, the assignment of the corresponding symmetric stretch was sometimes difficult due to the occurrence of methyl deformation frequencies and phosphine bands in the same region. Comparison of both solid and solution data with the spectra of the free phosphines or their mercury(II) halide complexes normally overcame any ambiguity in the assignment.

The acetate group is known to interact with a metal ion in the four following principle ways (12). In addition, types **3** and **4** occur less commonly with unsymmetrical modes of coordination. Infrared studies relating these modes of bonding of the acetate group to metals to changes in C—O frequencies have focused on the $\nu_{asym}(COO) - \nu_{sym}(COO)$ separation ($\Delta\nu$ or $\nu_8 - \nu_3$) (12–16). Though earlier work (15) suggested that the magnitude of $\Delta\nu$ was not a reliable criterion of the mode of acetate coordination, recent correlations of the infrared spectra of metal acetates with X-ray structural evidence for modes **2–4** show that qualitative application of this criterion is possible (12). Waddington and co-workers found that the divergence of $\Delta\nu$, as compared to the free ion value of 164 cm^{-1} for sodium acetate, was greatest for type **2** since in unidentate acetate groups the ν_8 and ν_3 frequencies correspond approximately to C=O and C—O; values of $\Delta\nu$ may exceed 500 cm^{-1} for some Group 4 acetates (12). Chelating bidentate acetate groups (type **3**) normally have $\Delta\nu$ less than 100 cm^{-1}, whilst the bridging mode of coordination (type **4**) leads to $\Delta\nu$ values nearer 150 cm^{-1}, i.e., similar to the free acetate value of $\Delta\nu$ (12). Obviously, intermediate situations with unsymmetrical modes of bonding are expected to give rise to $\Delta\nu$ values that are between those shown by types **2** and **3**, and a distinction from type **4** would not be possible from this infrared criterion alone.

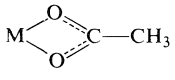
In the present series of complexes, with the exception of the $(p\text{-F—}C_6H_4)_3P$ complexes, $\Delta\nu$ lies in the range 172–215 cm^{-1}. Since the conductance and molecular weight measurements rule out types **1** and **4** acetate interaction, we conclude that the



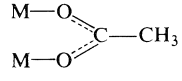
1



2



3



4

mode of coordination is intermediate between types **2** and **3**, i.e., unsymmetrically bidentate. The similarity of the solid state and solution values for the 1:1 complexes suggests that the structure is the same in both media. The change in $\Delta\nu$ values from the solid state to solution for the 1:2 complexes is compatible with their dissociation according to equilibrium [1]. An X-ray structural determination for $Hg(OAc)_2(PBu_3^t)$ (*8a*) ($\Delta\nu = 172\ cm^{-1}$) has confirmed that the mercury atom is in a distorted trigonal bipyramidal geometry by virtue of the acetate groups being unsymmetrically chelated and spanning axial and equatorial sites. Values of ca. 185 cm^{-1} for $\Delta\nu$ for nearly all of the 1:1 and 1:2 adducts thus indicate that the mode of acetate bonding is similar to that found by X-ray analysis. Exceptions to the normal value of $\Delta\nu$ for these complexes are observed for the two complexes involving $(p\text{-F—}C_6H_4)_3P$. The higher values of $\Delta\nu$ suggest that the oxygen atoms of the unsymmetrically bound acetate group are quite inequivalent, and indeed, for the 1:1 adduct in solution and the 1:2 solid adduct of $(p\text{-F—}C_6H_4)_3P$, two kinds of acetate groups are apparently present. Values of ca. 380 cm^{-1} for $\Delta\nu$ in these cases are compatible with unidentate coordination (type **2**) and it is noteworthy that $Hg(OAc)_2$ itself, for which two-coordination has been assigned (17), has $\Delta\nu = 270$ cm^{-1}. The only other complexes reported in this work which display splitting of the ν_3 and ν_8 modes are both $(p\text{-tolyl})_3P$ complexes. The separation of peaks in these instances are not clearly interpretable and may only arise from lattice effects or vibrational coupling, though inequivalent acetate groups are the more probable cause; similarly $Hg(OAc)_2(PBu_3^t)$, which has equivalent unsymmetrically bound acetate groups, has peaks assignable to ν_8 at 1575 cm^{-1}, 1560 cm^{-1}, and 1540 cm^{-1} (*6b*). At the same time, it is well to remember that $\Delta\nu$ for bridging acetate groups would also be expected to be near 150–200 cm^{-1} and thus dimeric structures in the solid state for the 1:1 adducts cannot be ruled out in the absence of an X-ray analysis.[4]

Raman spectra were obtained for most of the complexes in the region below 1800 cm^{-1}. Due to the difficulty in assigning the relatively weak ν_3 absorption, these spectra were of little assistance in making assignments of acetate bonding type. However, all of the spectra obtained show a strong bond in the range 223–164 cm^{-1} (Table 2) that can be assigned to the symmetric mercury–oxygen stretching frequency. This absorption occurs at 274 cm^{-1} in the Raman spectrum of $Hg(OAc)_2$ (17). Similarly, following our assignment in phosphine complexes of mercuric halides and thiocyanate (1), a strong to medium band in the range 150–114 cm^{-1} (Table 2) may be assigned to ν(Hg—P).

Nuclear Magnetic Resonance Spectral Studies

Table 3 lists the ^1H nmr spectral data for the complexes and the corresponding phosphines. In general, the phosphine resonances shift downfield upon coordination in both series of complexes; the shift is, expectedly, greater for the 1:1 series. A similar trend is exhibited by the acetate methyl signals. More interestingly, for both the 1:1 and 1:2 series, the acetate methyl signal appeared as a single peak and the phosphine groups produced a single set of absorptions. This observation prompted an investigation, to be discussed below, of the lability of these systems. A simple integration of the distinct acetate methyl signal against the aromatic signals afforded an immediate indication of the composition of a complex and its purity.

Phosphorus-31 nmr data are in Table 3. All of the 1:1 complexes except $Hg(OAc)_2(PPh_3)$ and $Hg(OAc)_2[P(p\text{-F—}C_6H_4)_3]$ showed ^{31}P spectra having two small satellite peaks due to coupling with mercury-199 nuclei ($I = 1/2$; natural abundance 16.8%). No splitting was observed for mercury-201 ($I = 3/2$; natural abundance 13.2%). The observation of a single broad peak and the absence of the expected triplet pattern of relative intensity of approximately 8:84:8 (18) for the two complexes mentioned above clearly indicate dissociation and exchange of the phosphine, which are fast on the nmr time scale. In the 1:2 series none of the complexes show the ^{199}Hg satellites at room temperature, which again shows the lability of the phosphine complexes on the nmr time scale. Observation of the ^{199}Hg–^{31}P coupling was made by recording the spectra at 183 K, which is consistent with the slowing down of the ligand exchange reaction via equilibrium [1].

Reduction of the temperature to observe the ^{199}Hg–^{31}P coupling also produced shifts of the ^{31}P signal and an increase in the value of $^1J(^{199}Hg\text{–}^{31}P)$ for complexes in both series (Table 3). The observation of changes in phosphorus chemical shifts with decreasing temperature is, at best, qualitative since 85% H_3PO_4 cannot be used as a reference at 183 K. On the other hand, the increase of the coupling constant with decrease in temperature is a significant result. For example, the value of $^1J(^{199}Hg\text{–}^{31}P)$ for $Hg(OAc)_2(PPh_3)_2$ increased from 5024 Hz at 230 K

[4] $Hg(OAc)_2(PCy_3)$, which shows peaks in the ν_8 region in the solid state at 1605 cm^{-1}, 1595 cm^{-1}, and 1575 cm^{-1}, has been determined to have a dimeric structure involving both bridging and unsymmetrically bidentate acetate groups (*11c*). X-ray analysis of $Hg(OAc)_2[(o\text{-tolyl})_3P]$ is also underway.

TABLE 3. Proton[a] and phosphorus-31[b] nuclear magnetic resonance data for the complexes[c]

Compound	Acetate-CH_3[d]	Phosphine peaks	Free phosphine peaks	Assignments	Chemical shift ppm (δ)[b]	Coordination chemical shift, ppm (Δδ)[e]	$^1J(^{199}Hg–^{31}P)$ Hz

[a]In deuteriochloroform with TMS as internal standard; values are in ppm (δ).
[b]In dichloromethane with 85% H_3PO_4 as reference standard; positive chemical shifts are downfield.
[c]Measured at room temperature unless noted otherwise.
[d]Peak is singlet; occurs at 1.93 for $Hg(OAc)_2$ in dimethylsulfoxide-d_6.
[e]$\Delta\delta = \delta(\text{complex}) - \delta(PR_3)$.
[f]Peak due to dichloromethane also observed for the sample.

(2) to 5503 Hz at 183 K. Since the coupling constant should be independent of the rate of phosphine exchange, an explanation for the increased magnitude with decreasing temperature is not readily apparent. Further studies are needed to determine which one (or more) of the several factors (19) which influence $^1J(^{199}Hg–^{31}P)$ are important.

As expected, the 1:1 complexes show larger coupling constants (ca. 8500 Hz) than the corresponding 1:2 complexes (ca. 5500 Hz). As Grim previously explained for some $HgX_2(PR_3)_n$ (n = 1, 2) complexes (18), the greater values of $J(^{199}Hg–^{31}P)$ are explicable in terms of greater electron deficiency of mercury in the case of the 1:1 complexes. Similarly, the observed coupling constants and coordination chemical shifts are greater for these acetate complexes than for the corresponding halide complexes (2).

Two of the critically important factors that determine the magnitude of $\Delta\delta$ are the electronegativities of the substituents on the phosphorus atom and the bond angles between the substituents (19, 20). Parameters which reflect these factors are the basicities, given by pK_a values (21), and cone angles (9) of the phosphines. Consideration of the magnitude of the coordination chemical shift for the present complexes shows the importance of these factors. In both series of complexes, $\Delta\delta$ increases in magnitude from Ph_3P to Et_2PhP; the lowest $\Delta\delta$ values occur as expected for the complexes of Ph_3P, which has the lowest pK_a (2.73 as compared to 6.25 for Et_2PhP) and the least change in its C—P—C bond angles (20) in forming a complex. The greater values of $\Delta\delta$ for the $(p\text{-F—}C_6H_4)_3P$ complexes may initially seem surprising as fluorine is an electron-withdrawing substituent. However, the upfield position of the ^{31}P chemical shift of $(p\text{-F—}C_6H_4)_3P$ relative to Ph_3P perhaps indicates that electron density on phosphorus is greater, thus leading to greater σ-bond strength with mercury.

The relatively high value of $\Delta\delta$ for $Hg(OAc)_2$-[(*o*-tolyl)$_3$P] requires explanation, since the bulkiness of the phosphine should result in lower σ-interaction with mercury as compared to (*p*-tolyl)$_3$P, which would have similar basicity. The high $\Delta\delta$ value is anomalous and can be attributed to the unusually high resonance position of (*o*-tolyl)$_3$P itself. The latter effect, believed to be caused by an interaction of the ortho methyl groups with the phosphorus lone pair, would be lost upon coordination (9, 22). Consequently the "true" $\Delta\delta$ value for $Hg(OAc)_2$[(*o*-tolyl)$_3$P] would be much less than that observed for $Hg(OAc)_2(Ph_3P)$, as expected due to the large steric effect. The relatively low value (ppm) of $\Delta\delta$ for $Hg(OAc)_2(Bu_3^tP)$ (2) is much less than expected based on the basicity of Bu_3^tP, which would be near that reported for Me_3P (i.e., pK_a = 8.65) (21) because of the similar electronegativity of the methyl and *t*-butyl groups (23). The much lower $J(^{199}Hg–^{31}P_3)$ value for $Hg(OAc)_2(Bu_3^tP)$ must also be a consequence of the steric bulk of Bu_3^tP (θ = 182°) (9). Indeed, the C—P—C angles in $Hg(OAc)_2$-(Bu_3^tP) average 112° (8*a*) as compared to C—P—C angles near 104° for Ph_3P in its complexes (24). Preliminary ^{31}P nmr measurements for $Hg(OAc)_2$-$(PCy_3)_n$ (n = 1, 2) (2) also indicate that the large steric requirements of the phosphine lead to lower $\Delta\delta$ and $J(^{199}Hg–^{31}P)$ values than anticipated from the pK_a (9.6) of Cy_3P.

Ligand Exchange Studies

Several complexes were investigated by variable temperature ^1H and ^{31}P nmr spectral measurements to confirm the occurrence of ligand exchange. The observation of ^{199}Hg satellites at room temperature in the ^{31}P nmr spectra of most of the 1:1 complexes indicates that dissociation and exchange are not extensive. For example, the satellite peaks sharpen noticeably at 253 K as compared to room temperature in the spectrum of $Hg(OAc)_2$[(*o*-tolyl)$_3$P] in dichloromethane solution; at 183 K the side peaks are very sharp and $J(^{199}Hg–^{31}P)$ has increased only a small extent. We cannot comment on the significance of the upfield shift in $\Delta\delta$ because 85% H_3PO_4 is not useful as a standard at the low temperature. Addition of (*o*-tolyl)$_3$P in a 3:1 molar ratio to a dichloromethane solution of $Hg(OAc)_2$[(*o*-tolyl)$_3$P] at room temperature gives a ^{31}P nmr spectrum showing only a broad (half-width of 350 Hz) signal at -22.6δ. Cooling this solution to 183 K gives a spectrum with a peak at $+7.2\delta$ due to the complexed phosphine (but without satellite peaks) and a peak at -31δ due to the free phosphine. Dissociation is apparently only slight for the 1:1 complex but addition of free phosphine greatly enhances the exchange rate.

The ^{31}P nmr spectrum of $Hg(OAc)_2(PPh_3)_2$ in dichloromethane solution at room temperature showed only a broad (half-width 189 Hz) signal, and its position at $+29.4\delta$ is only slightly upfield from the signal of the 1:1 complex. Addition of free phosphine in 2:1 and 4:1 molar ratios gave spectra with peaks at $+5.6\delta$ (half-width 80 Hz) and -1.0δ (half-width 42 Hz) respectively. The gradual shift of the averaged signal (of bound and free phosphine) toward the resonance position of Ph_3P itself indicates that dissociation occurs, followed by rapid exchange according to equilibrium [1]. At 183 K, $Hg(OAc)_2$-$(PPh_3)_2$ in dichloromethane solution shows the expected triplet pattern, with $J(^{199}Hg–^{31}P)$ = 5503 Hz, and the main resonance peak at +33.2 Hz. Both

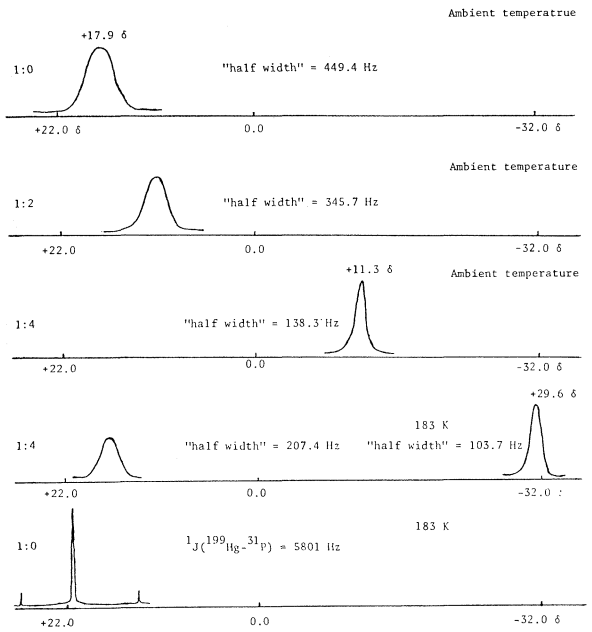

FIG. 1. Phosphorus-31 nmr exchange studies of $Hg(OAc)_2(PMePh_2)_2$ in dichloromethane solution; molar ratios for complex to phosphine are indicated.

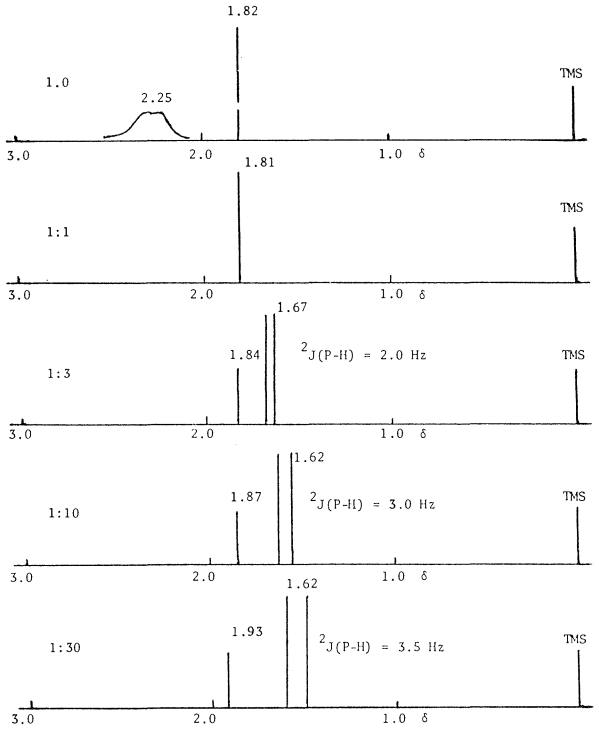

FIG. 2. Proton nmr exchange studies of $Hg(OAc)_2(PMePh_2)_2$ in deuteriochloroform solution at ambient temperature; molar ratios for complex to phosphine are indicated.

dissociation and exchange are retarded at the low temperature.

The most detailed investigation of exchange was performed on $Hg(OAc)_2(PMePh_2)_2$. The ^{31}P nmr studies are schematized in Fig. 1. The behaviour of this 1:2 complex closely parallels that found for $Hg(OAc)_2(PPh_3)_2$, in which dissociation is appreciable and phosphine exchange is fast on the nmr time scale. The ^1H nmr spectral results, obtained as a function of temperature and of methyldiphenylphosphine concentration, support the same conclusion. The ^1H nmr spectrum of $Hg(OAc)_2(PMePh_2)_2$ in deuteriochloroform is virtually unchanged from 243 K (broad singlet at 2.30δ, sharper singlet at 1.88δ) to 308 K (2.23δ, 1.83δ). However, sharpening of the broad singlet due to the methyl protons occurs at 323 K (half-width 13 Hz); the doublet observed at 333 K at 2.21δ ($^2J(^1H-^{31}P)$ = 10 Hz) probably arises from the increased proportion of $Hg(OAc)_2(PMePh_2)$ in solution at the higher temperature. Figure 2 illustrates the ^1H nmr spectra behaviour at ambient temperature as phosphine is added to a deuteriochloroform solution of $Hg(OAc)_2(PMePh_2)_2$. The resonance position of the methyl protons of the acetate groups remains a singlet near 1.85δ so that it is unlikely that higher phosphine–mercury complexes are formed in the presence of excess methyldiphenylphosphine. The complex itself at ambient temperature shows a broad peak at 2.25δ that moves upfield toward the free phosphine (methyl) position as increasing amounts of methyldiphenylphosphine are added. Throughout the addition of free phosphine, the phosphine methyl resonance position represents the weighted average in chemical shift and coupling constant of the resonances of complexes and free phosphine since rapid exchange is taking place. Similar exchange phenomena which only involve internal coupling have been discussed for $CH_3AuP(CH_3)_3$ (25), $Ni(PR_3)_4$ (26), and $(n\text{-}Bu_3PSe)_2HgX_2$ complexes (27).

Acknowledgements

We are grateful to the National Research Council of Canada for an operating grant. Raman spectra were obtained through the courtesy of Professor D. E. Irish, University of Waterloo. We also thank Dr. A. Woon-Fat for his assistance in obtaining the ^{31}P nmr spectra and Dr. C. A. Tolman for a preprint of his review.

Triphenylphosphine complexes of mercury(II) acetate and fluoroacetates. Preparation, characterization, and spectral studies[1]

TIM ALLMAN, RAM G. GOEL, AND PIERRE PILON

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received April 3, 1978

TIM ALLMAN, RAM G. GOEL, and PIERRE PILON. Can. J. Chem. **57**, 91 (1979).

Triphenylphosphine reacts with mercury(II) acetate and fluoroacetates to form complexes of the types $Ph_3PHg(O_2CR)_2$, $(Ph_3P)_2Hg(O_2CR)_2$, and $(Ph_3P)_3Hg(O_2CR)_2$, where R = CH_3, CH_2F, CHF_2, or CF_3. The 1:1 and 2:1 have been isolated and characterized by elemental analysis, molecular weight, and conductance measurements and by vibrational and nmr spectroscopic studies. The formation of the 3:1 complexes is inferred by ^{31}P nmr spectral measurements at 183 K. Both the 1:1 and 2:1 complexes are indicated to be monomeric molecular species in which the O_2CR groups are bidentately bonded to mercury. The Hg—O and Hg—P stretching frequencies for these complexes have been assigned by infrared and Raman spectral measurements. The ^{199}Hg–^{31}P spin–spin coupling constants and the ^{31}P coordination chemical shifts for the 1:1 as well as the 2:1 complexes increase in the order: $O_2CCH_3 < O_2CCH_2F < O_2CCHF_2 < OCCF_3$. Correlations between $^1J(^{199}Hg$–$^{31}P)$ values, ^{31}P coordination chemical shifts, and the pK_a values for the carboxylic acids are discussed.

TIM ALLMAN, RAM G. GOEL et PIERRE PILON. Can. J. Chem. **57**, 91 (1979).

La triphénylphosphine réagit avec l'acétate et les fluoroacétates mercuriques pour former des complexes de type $Ph_3PHg(O_2CR)_2$, $(Ph_3P)_2Hg(O_2CR)_2$ et $(Ph_3P)_3Hg(O_2CR)_2$ où R = CH_3, CH_2F, CHF_2 et CF_3. On a isolé les adduits 1:1 et 2:1 et on les a caractérisés grâce à leur analyse élémentaire, à leur poids moléculaire, à des mesures de conductivité et à des études de spectroscopies vibrationnelles et rmn. On a déduit que des complexes 3:1 se forment en se basant sur des mesures spectrales de rmn ^{31}P effectuées à 183 K. Il semble que les complexes 1:1 et 2:1 sont des espèces moléculaires monomères dans lesquelles les groupes O_2CR sont doublement lié au mercure. On a attribué les fréquences de vibration de valence Hg—O et Hg de ces complexes grâces à des mesures spectrales infrarouges et Raman. Les constantes de couplage spin–spin ^{199}Hg–^{31}P de même que les déplacements chimiques de coordination ^{31}P des complexes 1:1 et 2:1 augmentent dans l'ordre: $O_2CCH_3 < O_2CCH_2F < O_2CCHF_2 < OCCF_3$. On discute des corrélations entre les valeurs des $^1J(^{199}Hg$–$^{31}P)$, des déplacements chimiques de coordination ^{31}P et des valeurs des pK_a des acides carboxyliques.

[Traduit par le journal]

Introduction

Due to their electrophilic nature, mercury(II) carboxylates, particularly, the acetate and trifluoroacetate are important reagents for mercuration and oxomercuration reactions (1). However, the reactions of these active electrophiles with electron-pair donor ligands have received little attention.

In a recent investigation (2–5) on the tri-*tert*-butylphosphine complexes of zinc(II), cadmium(II), and mercury(II), the complex $Bu^t_3PHg(O_2CCH_3)_2$ (2, 4) was prepared. In contrast to the mercury(II) halide complexes, $Bu^t_3PHgX_2$ (2, 5), which have a dimeric tetrahedral structure, the acetate complex $Bu^t_3PHg(O_2CCH_3)_2$, has a monomeric pentacoordinate structure in the solid state as well as in solution (4). Crystal structure determination (4) showed that the acetate groups in $Bu^t_3PHg(O_2CCH_3)_2$ are bonded to the mercury in an asymmetrically bidentate manner giving rise to a distorted trigonal bipyramidal coordination around mercury. One oxygen atom of each CH_3CO_2 group is tightly bound in the equatorial plane of the mercury atom and the other oxygens form weak bonds above and below this plane. The only other reported phosphine complex of a mercury(II) carboxylate is $(Me_3P)_2Hg(O_2CCH_3)_2$ (6*a*) which has been assigned an ionic structure containing the linear $(Me_3P)_2Hg^{2+}$ cation and ionic acetates. In the present work, reactions of triphenylphosphine with mercury(II) acetate and haloacetates have been investigated. The preparation, characterization, and vibrational and magnetic resonance spectroscopic studies of the complexes prepared in this work are reported herein. Concurrent with this work, Alyea and Dias (6*b*) have investigated mercury acetate complexes of several other tertiary phosphines.

Results and Discussion

Triphenylphosphine reacts with mercury acetate and fluoroacetates to form 1:1, 2:1, and 3:1 complexes. However, the 3:1 complexes could not be isolated. Attempts to isolate complexes of mercury(II) chloroacetates were also unsuccessful due to the decomposition of mercury(II) chloroacetates. For example, the reaction of triphenylphosphine with mercury(II) trichloroacetate in 1:1 or 2:1 mole ratios afforded the complexes Ph_3PHgCl_2 or $(Ph_3P)_2HgCl_2$ as the sole mercury(II)-containing species.

The analytical, molecular weight, and conductance data for the complexes isolated in the present study are given in Table 1. All the compounds listed in Table 1 are air-stable, white crystalline solids. They are soluble in polar organic solvents, sparingly soluble in benzene, and insoluble in hexane or light petroleum ether. All the compounds decomposed on or near melting. The results of molecular weight measurements (Table 1) show that all the complexes exist as monomeric molecular species in 10^{-2} M solutions in 1,2-dichloroethane or chloroform.

The molecular weight measurements on 1,2-dichloroethane solutions of $(Ph_3P)_2Hg(O_2CCH_3)_2$, in the 10^{-2}–10^{-3} M concentration range, gave values in the 600 to 500 range indicating some dissociation of the complex according to the following equation:

$$(Ph_3P)_2Hg(O_2CCH_3)_2 \rightleftharpoons Ph_3PHg(O_2CCH_3)_2 + PPh_3$$

Molecular weight measurements for other complexes in this concentration range, however, showed no evidence for such a dissociation. Molar conductances for 10^{-3} M solutions of the complexes in dichloromethane were found to be less than 0.5 ohm^{-1} cm^2 mol^{-1}. Conductance measurements in nitromethane, however, show that the 2:1 complexes of mercury(II) fluoroacetates are ionized to the extent of 10 to 20%.

Vibrational Spectral Studies

The CO_2 stretching frequencies for both 1:1 and 2:1 complexes were assigned by comparing their infrared spectra with those of uncomplexed mercury(II) carboxylates and free triphenylphosphine. The observed CO_2 stretching frequencies for the complexes in the solid state as well as in dichloromethane are listed in Table 2. The data in Table 2 show that the CO_2 stretching frequencies in the solid state are not very different than those observed in solution. Therefore, the structures of the complexes do not appear to change in going from solid state to solution. The occurrence of more than one band in the region of antisymmetric CO_2 stretching frequency can be caused by coupling of vibrations of the two carboxylate groups. In view of the molecular nature of the complexes in solution, the possibility of ionic or carboxylate bridged polymeric structures can be ruled out. The antisymmetric CO_2 stretching frequency for a monodentately bonded carboxylate ligand (7–10) is significantly higher than the frequency for the free ion (7, 11, 12). Since the antisymmetric CO_2 stretching frequencies for the complexes listed in Table 2 are lower than those observed for monodentately bonded carboxylates (7–10), the carboxylate groups in all the complexes appear to act as chelating bidentate ligands. Two oxygen atoms of a chelating bidentate carboxylate ligand may be coordinated to a metal atom either symmetrically or unsymmetrically (9). Although it is difficult to distinguish between the symmetrically and asymmetrically bonded carboxylate groups by infrared spectroscopy, it is noteworthy that the CO_2 stretching frequency for the 2:1 complex $(Ph_3P)_2Hg(O_2CCH_3)_2$ are very similar to these observed for $Bu^t{}_3PHg(O_2CCH_3)_2$ which is known to contain asymmetrically bonded bidentate acetates (4). For the 1:1 complex, $Ph_3PHg(O_2CCH_3)_2$, the symmetric CO_2 stretching frequency is not significantly altered but

[a]In cm^{-1}. Abbreviations: ir, infrared; R, Raman; v, stretching frequency; m, medium; s, strong; sh, shoulder.

the antisymmetric stretching frequency is increased by 15 cm^{-1}. Similar differences in the CO_2 stretching frequencies are observed between 1:1 and 2:1 complexes of fluoroacetates. These differences can arise due to the weakening of the Hg—O bonds in the 2:1 complexes. Thus, the 1:1 complexes can be assigned a five-coordinate structure and the 2:1 complexes can be assigned a six-coordinate structure.

The assignments for the Hg—O stretching frequencies for the complexes, in the solid state, can be made by comparing their infrared spectra with those of the mercury(II) carboxylates and free phosphine. For example, the infrared spectrum of mercury(II) acetate shows a strong band at 309 cm^{-1} due to the antisymmetric Hg—O stretching frequency[2] (13). This band is not present in the infrared spectrum of either $Ph_3PHg(O_2CCH_3)_2$ or $(Ph_3P)_2Hg(O_2CCH_3)_2$. For $Ph_3PHg(O_2CCH_3)_2$, a strong infrared band is observed at 267 cm^{-1} which can be assigned to a Hg—O stretching frequency since no band is observed in this region in the spectrum of triphenylphosphine (14). The Hg—O stretching frequencies for other complexes were assigned in a similar manner and the assigned frequencies are listed in Table 2. By comparing the Raman spectra of the solid complexes with those for the mercury(II) carboxylates and triphenylphosphine, the Hg—P stretching frequencies for the complexes can be assigned with reasonable confidence. The assigned values are listed in Table 2. The Hg—P stretching frequencies for a number of phosphine complexes of mercury(II) halides and pseudohalides have been determined (5) in this laboratory.[3] The values for the Hg—P stretching frequencies given in Table 2 are in complete accord with the Hg—P stretching frequencies for the mercury(II) halide and pseudohalide complexes of triphenylphosphine.[3]

Two trends are evident from the data on Hg—O and Hg—P stretching frequencies. First, in each series of complexes, the Hg—O stretching frequency decreases and the Hg—P stretching frequency increases as the electron withdrawing power of the carboxylate groups increases ($CH_3CO_2 < CH_2FCO_2 < CHF_2CO_2 < CF_3CO_2$). Second, for a given carboxylate, the Hg—O and the Hg—P stretching frequencies are higher for the 1:1 complex. The first observation is in accord with the fact that the more electron withdrawing carboxylate groups will give rise to weaker Hg—O bonds and will create a larger electron deficiency at the mercury which in turn will result in the strengthening of the Hg—P bond. The second trend is also consistent with the electroneutrality principle. The addition of another phosphine to the 1:1 complex will increase the electron density at the mercury atom making it a weaker Lewis acid.

Nuclear Magnetic Resonance Spectral Studies

The ^1H nmr spectra for the 1:1 as well as the 2:1 complexes, at ambient temperatures, showed a multiplet due to the phenyl protons and a singlet due to the acetyl or fluoroacetyl protons. The phenyl multiplet was shifted downfield from the multiplet observed for free triphenylphosphine.

The ^{31}P nmr spectral data for all the complexes studied in this work are listed in Table 3. As can be

[2]The vibrational spectra of mercury(II) acetate have been interpreted in terms of a centrosymmetric linear structure of C_{2h} skeletal symmetry (13).

[a]In dichloromethane at 183 K and an ambient temperatures, the positive δ values are downfield from external H_3PO_4 standard.

seen from the data in Table 3, the ^{31}P nmr spectra of $Ph_3PHg(O_2CCH_3)_2$, $(Ph_3P)_2Hg(O_2CCH_3)_2$, and $(Ph_3P)_2Hg(O_2CCH_2F)_2$, at ambient temperatures, consist of a single peak. The spectra of the remaining complexes showed a triplet consisting of a main peak and two satellite peaks due to ^{199}Hg—^{31}P spin–spin coupling.[4] These results show that the complexes $Ph_3PHg(O_2CCH_3)_2$, $(Ph_3P)_2Hg(O_2CCH_3)_2$, and $(Ph_3P)_2Hg(O_2CCH_2F)_2$, like the triphenylphosphine complexes of mercury(II) halides and pseudohalides, undergo a fast phosphine exchange at room temperature whereas the remaining complexes are non-labile on the nmr time scale. Satellites due to the ^{199}Hg—^{31}P spin–spin coupling were observed for all the complexes when the ^{31}P nmr spectra were measured at 183 K.

The data in Table 3 show that the $^1J(^{199}Hg–^{31}P)$ values at 183 K are higher than the values at ambient temperatures. The ^{199}Hg—^{31}P spin–spin coupling for the phosphine complexes of mercury(II) halides is also reported to increase with decreasing temperatures (15). The increase has been attributed to a decrease in the rate of phosphine exchange. However, we believe that further investigations are required to explain this phenomenon.

As shown by the data in Table 3, the $^1J(^{199}Hg–^{31}P)$ values for the 1:1 complexes are about 50% higher than those for the 2:1 complexes. Similar differences in the magnitudes of ^{199}Hg—^{31}P spin–spin coupling constants are observed between the 1:1 and 2:1 phosphine complexes of mercury(II) halides (16–18).

[4]Mercury has two isotopes, ^{199}Hg and ^{201}Hg, which have nuclear spins. ^{199}Hg has a spin of 1/2 and is present in 16.86% natural abundance, ^{201}Hg has a spin of 3/2 and is present in 13.24% natural abundance.

^{31}P nmr spectral data (17, 18) for mercury(II) halide complexes also show that both the $^1J(^{199}Hg–^{31}P)$ values and the coordination chemical shifts, Δδ (Δδ = δ (complex) − δ (free phosphine)), for the 1:1 complexes (which are dimeric) as well as for the 2:1 complexes (which are monomeric) increase with the electronegativity of the halogen. As shown in Fig. 1, the plots of $^1J(^{199}Hg–^{31}P)$ values for both 1:1 and 2:1 complexes against the pK_a values of the parent carboxylic acids give straight lines. The plots of $^1J(^{199}Hg–^{31}P)$ values against the coordination chemical shifts, Δδ (shown in Fig. 2), also give straight lines. The observed variations in the $^1J(^{199}Hg–^{31}P)$ values in each series of complexes, thus, clearly show that the magnitude of the ^{199}Hg—^{31}P spin–spin interaction is determined by the electron deficiency of mercury in the given mercury(II) carboxylate. Similarly, the magnitude of the coordination chemical shift in these complexes also appears to be determined by the electron withdrawing power of the carboxylate ligands. However, a comparison of the chemical shifts of the fluoroacetate complexes shows that for a given fluoroacetate the chemical shifts for the 2:1 complexes is higher than that for the 1:1 complex. Furthermore, the chemical shifts for the 3:1 complexes, $(Ph_3P)_3Hg(O_2CCH_2F)_2$, $(Ph_3P)_3Hg(O_3CCHF_2)_2$, and $(Ph_3P)_3Hg(O_2CCF_3)_2$, are significantly different whereas the $^1J(^{199}Hg–^{31}P)$ values for the three complexes are very similar (*vide infra*). Therefore, the correlations between coupling constants and coordination chemical shifts observed in the present work as well as in previous studies cannot be very meaningful.

In contrast to the mercury(II) halide complexes which contain four-coordinate mercury(II), the

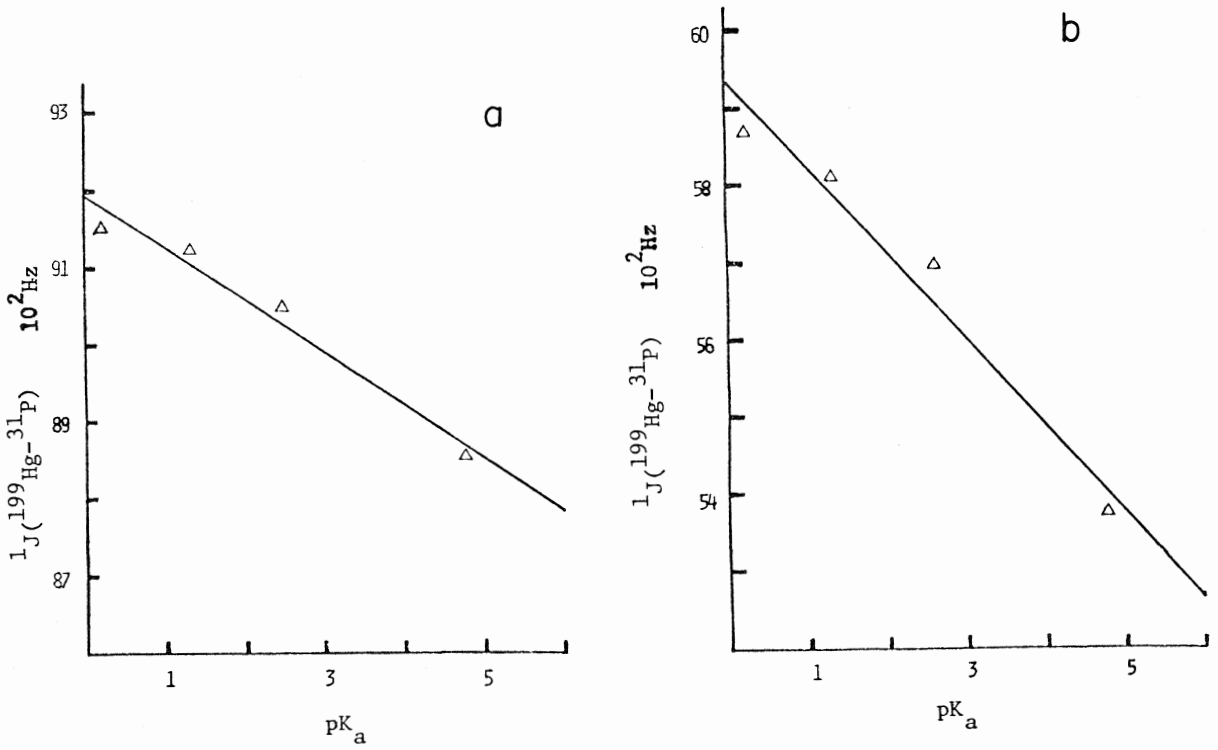

FIG. 1. Plot of $^1J(^{199}Hg–^{31}P)$ values of (*a*) 1:1 and (*b*) 1:2 complexes against the parent carboxylic acids.

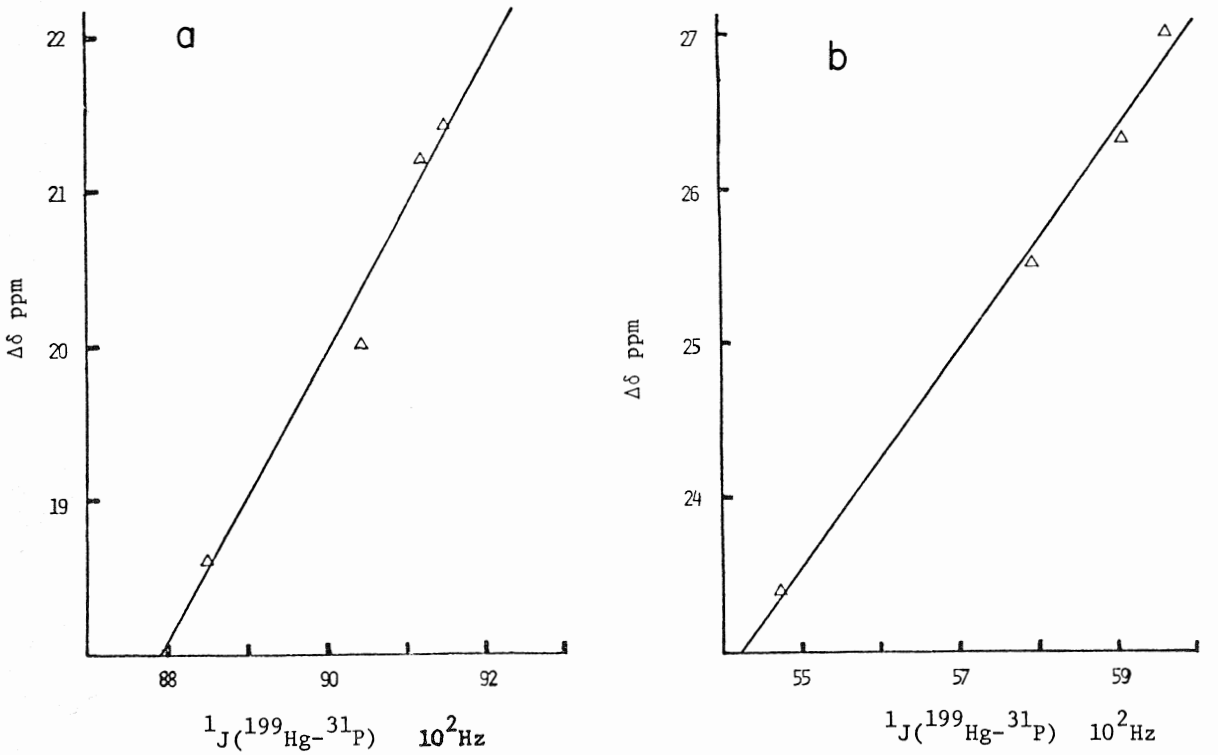

FIG. 2. Plot of $^1J(^{199}Hg–^{31}P)$ values of (*a*) 1:1 and (*b*) 1:2 complexes against the coordination chemical shifts, Δδ.

carboxylate complexes most likely contain five- and six-coordinate mercury. However, the $^1J(^{199}Hg–^{31}P)$ values for both types of carboxylate complexes are larger than those for the corresponding halide complexes. This is in accord with the stronger electrophilic character of mercury(II) carboxylates as compared with mercury(II) halides.

^{31}P nmr spectra of dichloromethane solutions of 2:1 complex containing excess triphenylphosphine, at ambient temperatures, consisted of a single broad line. However, the ^{31}P nmr spectra of these solutions, at 183 K, showed a triplet due to the 2:1 complex, a singlet due to free phosphine, and another triplet due to the formation of a new complex. For the given carboxylate, the chemical shifts and the $^{199}Hg–^{31}P$ coupling constants due to the new complex were invariant when the phosphine:mercury mole ratio was varied from 3 to 12. From the integration of the peaks it was established that the new complex contains three moles of phosphine per mole of mercury. No ^{31}P nmr evidence was found for the presence of any other phosphine containing species in solution. The $^1J(^{199}Hg–^{31}P)$ values and chemical shifts for the 3:1 complexes are listed in Table 3. The data in Table 3 show the $^1J(^{199}Hg–^{31}P)$ values for the 3:1 complexes $(Ph_3P)_3Hg(O_2CCH_2F)_2$, $(Ph_3P)_3Hg(O_2CCHF_2)_2$, and $(Ph_3P)_3Hg(O_2CCF_3)_2$ are invariant whereas the complex $(Ph_3P)_3Hg(O_2CCH_3)_2$ has a slightly smaller $^1J(^{199}Hg–^{31}P)$ value. We, therefore, conclude that the complexes $(Ph_3P)_3Hg(O_2CCH_2F)_2$, $(Ph_3P)_3Hg(O_2CCHF_2)_2$, and $(Ph_3P)_3Hg(O_2CCF_3)_2$ contain the three-coordinate cation, $(Ph_3P)_3Hg^{2+}$, whereas the complex $(Ph_3P)_3Hg(O_2CCH_3)_2$ is a penta-coordinated species in which the acetate anions are very weakly coordinated to the three coordinate $(Ph_3P)_3Hg^{2+}$ moiety.

The formation constants, K, for the 3:1 complexes were calculated by ^{31}P nmr measurements in dichloromethane and calculated values are listed in Table 4. The observed variations in the values of the formation constants for the 3:1 complexes are in accord with the variations in the electron withdrawing power of the carboxylate ligands. The failure to isolate these complexes is not surprising in view of the low values of their formation constants. The instability of the 3:1 complexes is most likely due to the relatively low basicity of triphenylphosphine (19). Work on the mercury(II) carboxylate complexes of more basic phosphines is in progress in our laboratory.

TABLE 4. Formation constants (K†) for the $(Ph_3P)_3Hg(O_2CCR)_2$ complexes at 183 K[a]

Complex	K†
$(Ph_3P)_3Hg(O_2CCH_3)_2$	1.66
$(Ph_3P)_3Hg(O_2CCH_2F)_2$	5.20
$(Ph_3P)_3Hg(O_2CCHF_2)_2$	22.70
$(Ph_3P)_3Hg(O_2CCF_3)_2$	1630

[a] K† = $[(Ph_3P)_3Hg(O_2CCR)_2]/[(Ph_3P)_2Hg(O_2CCR)_2][Ph_3P]$. Values calculated by using concentrations in mol/L. Estimated error in integration of the nmr signals is about 10%. At least five independent measurements were made to determine each K value.

Experimental

Materials

Triphenylphosphine (Eastman Kodak) was recrystallized twice from hot ethanol. Mercury(II) chloroacetates and fluoroacetates were prepared by the reaction of appropriate haloacetic acid with reagent grade mercury(II) oxide following the procedure of Deacon and Taylor (20). Reagent grade mercury(II) acetate was used without further purification. All the solvents were dried following standard procedure.

Physical Measurements

Elemental analyses were performed by M.H.W. Laboratories, Garden City, Michigan. Melting points were determined with a Gallenkamp melting point apparatus using open capillary tubes and are uncorrected. Molecular weights in 1,2-dichloromethane were determined with a Hitachi-Perkin-Elmer 115 osmometer. Molecular weights measurements in chloroform were performed at Galbraith Laboratories, Knoxville, TN. Conductance measurements were made at 25°C using a Yellow Springs Conductivity bridge and a conductivity cell with platinized platinum electrodes. Infrared spectra were recorded in the region 4000 to 300 cm^{-1} using a Beckman IR-12 spectrophotometer and in the region 400 to 150 cm^{-1} using a Perkin-Elmer 180 spectrophotometer. Spectra, in the solid state, were measured on mulls in Nujol and Halocarbon oil using KRS-5 or polythene discs. Sealed NaCl cells of 0.1 mm path length were used to record the spectra in solution. Raman spectra, in the solid state, were measured with a Jarrell-Ash spectrophotometer using the 5145 Å exciting line of an argon ion laser. The samples were sealed in glass capillary tubes. Attempts to obtain the Raman spectra, in solution, were not successful. The infrared and Raman frequencies are accurate to ± 3 cm^{-1}. ^{31}P nmr spectra were obtained on a Bruker HFX-60 Fourier transform spectrometer. ^1H nmr spectra were recorded with a Varian A60 spectrometer.

Preparation of 1:1 and 2:1 Complexes of Mercury(II) Acetate and Fluoroacetates

Mercury(II) acetate or fluoroacetate (2 mmol) and triphenylphosphine (2 mmol or 4 mmol) were dissolved separately in dry ethanol. The solution of triphenylphosphine was added dropwise, with stirring, to the solution of mercury(II) salt to give a clear solution. The solvent was removed with a rotary evaporator to give the desired product in quantitative yield. The product was dissolved in a minimum volume of dichloromethane and the solution was made cloudy by adding light petroleum ether dropwise. Upon cooling, white crystals were obtained which were filtered off and dried *in vacuo*.

Attempted Preparation of $(Ph_3P)_3Hg(O_2CCF_3)_2$

(*a*) Equimolar amounts of $(Ph_3P)_2Hg(O_2CCF_3)_2$ and triphenylphosphine were dissolved in dichloromethane. After stirring the solution for 1 h, the solvent was removed *in vacuo* at −78°C to give a white solid. The infrared spectrum of the solid in the CO_2 stretching frequency region was similar to that of $(Ph_3P)_2Hg(O_2CCF_3)_2$. Upon washing the solid with light petroleum ether it was readily separated into $(Ph_3P)_2Hg(O_2CCF_3)_2$ and Ph_3P.

(*b*) A dichloromethane solution containing equimolar amounts of 2:1 complex and triphenylphosphine was stirred for 1 h and then cooled to −95°C. Cold hexane (−95°C) was added dropwise, with stirring, to the cold solution (−95°C) to give a white precipitate which was allowed to stand for 1 h at −95°C and then filtered off. It was characterized to be $(Ph_3P)_2Hg(O_2CCF_3)_2$. Unreacted triphenylphosphine was recovered from the filtrate.

Attempted Preparation of Complexes of Mercury(II) Trichloroacetate

No reaction occurred when a suspension of mercury(II) trichloroacetate (1 mmol) in 50 ml ethanol was mixed with an ethanol solution of triphenylphosphine (2 mmol). Upon refluxing the mixture a clear solution was formed. White crystals of $(Ph_3P)_2HgCl_2$ were recovered in 90% yield upon cooling the solution. A similar reaction of $Hg(O_2CCCl_3)_2$ and Ph_3P in equimolar ratio afforded Ph_3PHgCl_2 in almost quantitative yield.

The dependence of ionization and excitation energies for the *cis*-azo group upon bond angle

N. Colin Baird

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 14, 1978

N. Colin Baird. Can. J. Chem. **57**, 98 (1979).

Ab initio molecular orbital calculations using STO-3G and 4-31G basis sets have been performed for *cis*-HNNH and *cis*-CH_3NNCH_3 as a function of angle about the nitrogens, and for the cyclic molecules diazirine (**1***a*) and diazetine (**1***b*); in all cases the ground states of the neutral system and of the cation and anion and the first singlet excited state of the neutral molecule were studied. The optimum HNN angles for the cation and neutral excited $n_-\pi^*$ singlet state of HNNH are significantly larger than for the anion and neutral ground state. Thus the ionization energy and singlet excitation energies for *cis*-azo systems pass through a maximum in the region around a nitrogen angle of about 100°. The implications of these calculations to the excitation and photoelectron spectra of cyclic *cis*-azo compounds is discussed in some detail, as is the origin of the variation in stability with angle of the n_- molecular orbital. Due to the heavy involvement of carbon, the n_- MO in diazirine does not follow the angle trends established by the HNNH calculations.

N. Colin Baird. Can. J. Chem. **57**, 98 (1979).

On a effectué des calculs *ab initio* d'orbitales moléculaires faisant appel à des bases STO-3G et 4-31G pour le *cis*-HNNH et le *cis*-CH_3NNCH_3 en fonction de l'angle autour des azotes ainsi que pour des molécules cycliques comme la diazirine (**1***a*) et la diazétine (**1***b*); dans chacun des cas, on a étudié les états fondamentaux du système neutre, du cation et de l'anion ainsi que le premier état excité singulet de la molécule neutre. Les angles optimum HNN du cation et de l'état excité $n_-\pi^*$ singulet et neutre du HNNH sont beaucoup plus élevés que ceux de l'anion et de l'état fondamental neutre. Ainsi l'énergie d'ionisation et les énergies de l'excitation singulet des systèmes azo *cis* passent par un maximum pour un angle de l'azote d'environ 100°. On discute en détail des implications de ces calculs en relation avec les spectres photoélectroniques et d'excitation des composés azo *cis* de même que des origines de la variation de stabilité avec l'angle de l'orbitale moléculaire n_-. A cause de la forte implication du carbone, la OM n_- de la diazirine ne suit pas les tendances d'angle déterminé par les calculs du HNNH.

Introduction

We have proposed that the substantial variations in the position of the uv–visible absorption maximum for the *cis*-azo chromophore are due primarily to changes in the CNN angle, since this angle determines the stability of n_-, the "lone pair" MO from which the lowest-energy excitation occurs (1). Recently Turro and co-workers have questioned this correlation since they claim ". . . there is no clear relationship of the absorption maxima of three-, four-, and five-membered ring compounds . . . with either the bond angle, the n_+–n_- orbital energy splitting, or the lowest ionization potential . . .", but rather agree with the conclusion (of Houk, Chang, and Engel (2)) that ". . . the wavelength of the n,π* absorption maximum is controlled more by factors which influence the energy of the π* orbital rather than the n_- orbital" (3). To attempt to resolve this controversy, we have undertaken to extend our calculations on *cis* —N=N— systems to angles less than 105° (the lower limit in our initial communication) and to improve the quality of the wavefunctions, as well as to study explicitly the positive and negative ions of such molecules and to investigate the relationships between excitation energy and ionization energy.

Method of Calculation

All calculations reported herein were generated using "*ab initio*" molecular orbital theory. The energies and wavefunctions for the open-shell species (i.e. the cations, the anions, and the $n_-\pi^*$ triplet state of the neutral molecules) were determined by the restricted open-shell theory of Roothaan (4). The MO's for the $^1(n_-\pi^*)$ state of HNNH and derivatives were taken as those determined for the $^3(n_-\pi^*)$ state; in this approximation the energy of the former exceeds that of the latter by twice $K_{n_-\pi^*}$, the exchange integral between the two orbitals. For the ground state of the neutral molecules, the Roothaan closed-shell method was used to determine the optimum single-determinant orbitals for the $...n_+^2\pi^2n_-^2(\pi^*)^0$ configuration. The energy of the ground state was then calculated by allowing this configuration to interact with the doubly-excited $...n_+^2\pi^2n_-^0(\pi^*)^2$ configuration. (The interaction between configurations increases with HNN angle, and peaks at 180°

0008-4042/79/010098-06$01.00/0

at which point the configurations are degenerate before interaction.) This extent of CI yields the correct degeneracy at 180° between the lowest two singlet states (if identical MO's are employed for both states).

The atomic orbital basis sets used in the calculations were the STO-3G and the 4-31G expansions (with standard molecular exponents) of Pople and co-workers (5). A few calculations were done with a basis in which six 1*s* "polarization functions" of exponent 0.5 and centred in the molecular plane were added to the usual minimal STO-3G basis centered on the atoms. Two of these six functions were placed 1.00 au from one nitrogen such as to make $\pm 120°$ angles with the NN axis, and similarly for two functions at the other nitrogen. The remaining two polarization functions were located ± 1.0 au above and below the midpoint of the NN bond.

The nitrogen–nitrogen and nitrogen–hydrogen bond distances in *cis*-HNNH (C_{2v} symmetry assumed) were fixed at the experimental values of 1.25 Å and 1.03 Å found for the *trans* isomer (6). (Alteration of these distances by a few hundredths of an Angstrom did not alter significantly the shapes of the energy curves discussed herein.) For *cis*-CH_3NNCH_3 and the cyclic systems, the NN separation was again taken as 1.25 Å, and the carbon–nitrogen distances were assumed to be 1.47 Å. The carbon–hydrogen distances in methyl groups were taken as 1.093 Å whereas those in ring systems were assumed to be 1.080 Å. The CC distance in the four-membered ring was chosen as 1.54 Å; the heavy-atom framework here and in all other systems was assumed planar. The HCH angles were taken as exactly tetrahedral in CH_3NNCH_3, and as 110° and 120° respectively in the four- and three-membered rings. C_{2v} symmetry was also assumed for all the carbon–nitrogen systems; the conformation in *cis*-CH_3NNCH_3 has the inplane hydrogens pointing inward (toward each other), since this is predicted by the calculations as the more stable conformation of this symmetry.

Results and Discussion

Theoretical Predictions

The variation in calculated energy (STO-3G) with bond angle about nitrogen is illustrated in Fig. 1 for the ground and lowest n_π* singlet excited state of planar, *cis*-diimide and for the ground states of the $HNNH^+$ and $HNNH^-$ ions.[1] The optimum bond angles for the ground states of the neutral molecule and anion are about 30° less than for the cation and excited HNNH singlet (see Table 1 for details).

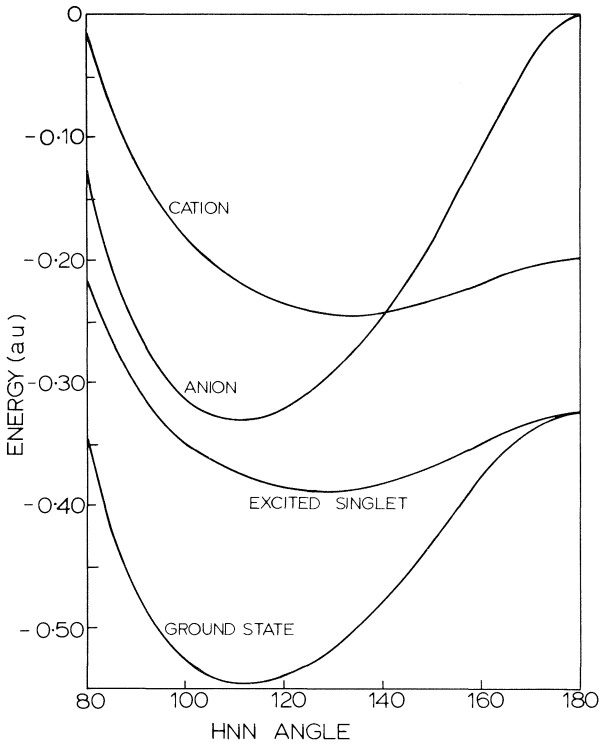

FIG. 1. STO-3G energy vs. HNN angle in *cis*-HNNH (offset by −109 au).

Clearly, the excitation energy to the n_π* singlet and the first ionization energy both should increase in magnitude continuously as the angle about nitrogen is bent away from linearity to about 110°, as obtained in our previous calculations for azomethane (1). However, for angles less than about 100°, the slope upwards of the ground state energy curve for HNNH is greater than that for either the excited singlet or the positive ion; thus *the excitation and ionization energies should decrease as the angle is decreased further toward 80°*. These effects are illus-

TABLE 1. Calculated bond angles in *cis*-HNNH systems

HNNH state	Angle (deg) when basis set = STO-3G	4-31G
Ground state (no CI)	112	115
Ground state (with CI)	112	115
n_π* singlet	128	135
Cation (ground state)	134	137
Anion (ground state)	111	115

[1]Note that electron capture to form the anion is predicted to be endothermic by these calculations, as is usual for *ab initio* calculations using Hartree–Fock–Roothaan theory.

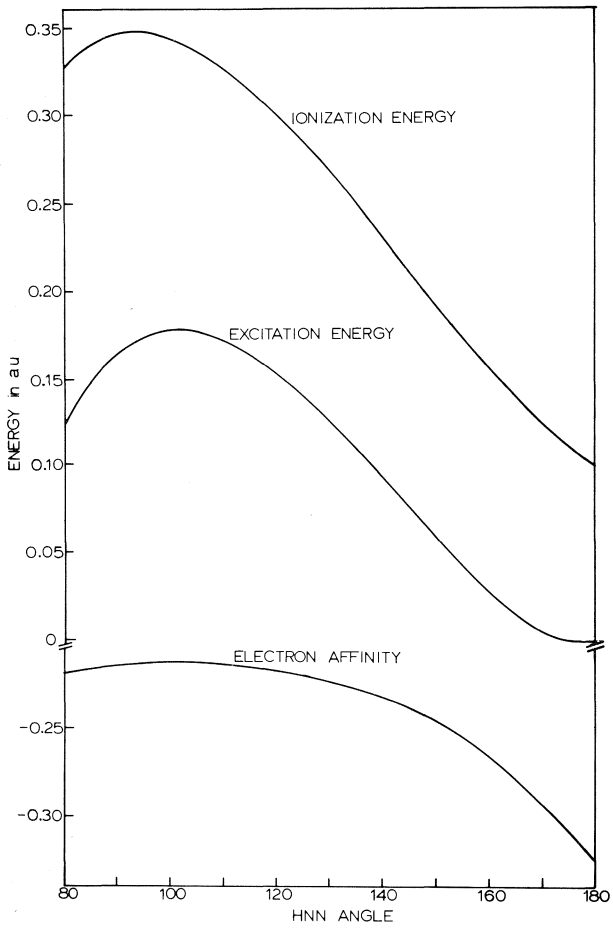

FIG. 2. Calculated (STO-3G) excitation energy to the $n_-\pi^*$ singlet state, ionization energy from the n_- MO, and electron affinity in *cis*-HNNH vs. HNN angle.

trated in the plots of excitation energy and ionization energy in Fig. 2; since the shapes of the curves are not altered significantly in changing the basis set from STO-3G to 4-31G, only the former are displayed. Preliminary calculations revealed that the shapes of these curves are essentially unchanged when the more expensive basis which includes polarization functions is employed; for reasons of economy, then, this basis was not used subsequently. Note also that on the basis of MINDO/2 calculations, Heilbronner and co-workers found the orbital energy for n_-, and the energy gap between the n_- and n_+ MO's, in HNNH both were minimum at angles of about 100° (7), in semiquantitative agreement with the present results.

One measure of the stability of the π^* orbital is the calculated electron affinity for HNNH; i.e. the energy difference between the ground states for the neutral and anionic species. From the plot of electron affinity versus angle in Fig. 2 it is clear that in the 80°–140° region at least, the stability of π^* varies rather less with angle than does that of n_-.

The correlation of excitation energy with ionization energy from STO-3G calculations is shown in Fig. 3; in the limit at 180° the curve becomes linear with a slope of unity. In the 105°–150° range the correlation is close to linear but the excitation energy increases only 0.7 times as fast as does the ionization energy as the bending is increased. The variation of excitation and ionization energies is a double-valued function in the 80°–105° region since the excitation energy peaks at a larger angle and falls more rapidly with decreasing angle thereafter than does the ionization energy.

In order to judge the relevance of these results for HNNH to *cis*-azoalkanes, STO-3G calculations for *cis*-azomethane at CNN angles of 130°, 150°, and 170°, and for the three- and four-membered rings **1***a* and **1***b* were performed; the results are summarized

1*a* **1***b*

in Table 2. The *difference* between each quantity and the corresponding value for *cis*-HNNH at the same HNN angle is given in parentheses below each entry. Obviously the excitation energy is virtually unaffected by the substitution of alkyl groups for the hydrogens, whereas the ionization energy is lessened by an almost constant factor of ~0.05 au (1.4 eV). The correlation of both properties with angle thus holds at least for the 80°–180° range. However, the magnitude of the substantial stabilization of the n_- "hole" in the cation may depend upon the nature of the alkyl group or ring involved. (In contrast, the π^* MO is at least 97% localized on the nitrogens in all the systems studied herein for both the excited state and the anion.)

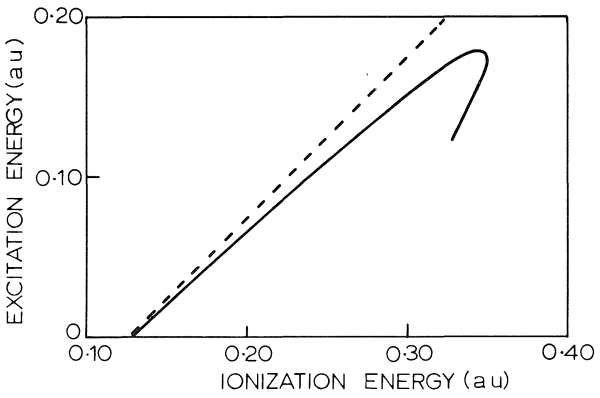

FIG. 3. Calculated (STO-3G) excitation energy vs. calculated ionization energy in *cis*-HNNH.

Comparison with Experiment

To test our theoretical predictions, we considered the experimental data collected by Turro and co-workers (3) for the wavelength of highest transition probability and for the lowest ionization energy of nineteen cyclic azoalkanes. This data was characterized by the size of the (smallest) ring involved in each case and is summarized in Table 3 for 4-, 5-, and 6-membered rings. Clearly the wavelengths for the absorption maxima fall into three nonoverlapping groups, each of which is rather sharply defined in terms of the standard deviation. (Two systems listed by Turro and co-workers are not included in these averages. In one, their **8**, there is a carbonyl chromophore in the molecule as well. The interaction between the almost-degenerate —N=N— and —C=O excitations would account for the abnormally low wavelength of this system. Thus the ionization energy, but not the excitation energy, for **8** is included in the averages and standard deviations. The other, their **17**, contains a three-membered ring which may well alter the angle at —N=N—.) Thus the data clearly support our previous contention that the singlet–singlet excitation energy in *cis*-azoalkanes is controlled predominantly by the CNN angle. In addition, the prediction in the present calculations that the excitation energy should pass through a maximum value near a 100° bond angle is supported by the fact that the decrease in wavelength observed in going from six- to five-membered rings is not continued but rather reversed in going from five- to four-membered rings.

TABLE 3. Correlation of experimental data with ring size

Ring type[b]	Wavelength (nm) of absorption maximum[c]	Ionization energy for n_- MO (in eV)	Molecules in set[a]
4-Membered	351 ± 4	$8.9_4 \pm 0.1_0$	2, 3, 19
5-Membered	332 ± 7	$8.7_3 \pm 0.1_9$	4–7, 8,[d] 9, 16, 18
6-Membered	383 ± 10	$8.2_0 \pm 0.1_0$	10–13, 14,[e] 15

[a]All data are from ref. 3, and the numbering scheme refers to that used in the same paper.
[b]When the —N=N— unit is a component of two rings in the polycyclics, the molecule is listed under the smallest ring size involved as it is assumed primarily to determine the CNN angle.
[c]In hexane solution.
[d]Included only in ionization energy set; see text for discussion.
[e]No ionization energy is reported for **14** in ref. 3 and thus it is included only in the absorption calculations.

The correlation in Table 3 between ring size and ionization energy is consistent with the prediction that ionization energy should increase as the CNN angle decreases (at least down to about 92°). The distinction between the four- and five-membered ring groups is not clear-cut; the larger standard deviations here are not unexpected given the rather extensive delocalization of the "n_- hole" expected from the calculations (see above) for the cation. The lack of a reversal in order between the ionization energies for the four- and five-membered rings is consistent with the prediction (see Fig. 2) that this quantity peaks at an angle 5°–10° less than that for excitation energy. (The rough equality in ionization potentials implies the two systems probably lie on opposite sides of the peak.)

In Fig. 4 the wavelength of absorption maximum is plotted against ionization energy for the fifteen cyclic azoalkanes discussed in Table 3. Although the degree of scatter is large, the trends are not inconsistent with the hook-shaped, double-valued theoretical curve (Fig. 5).

The excitation and ionization energies predicted in Table 2 for the three-membered ("diazirine") ring clearly are much greater than expected from extrapolation of the curves in Fig. 2. (The HNNH calculations cannot be extended to angles lower than 80° since the hydrogen atom separation becomes equal to or less than that in H_2!). The large increase in ionization energy of 1.5 eV calculated in going from the four- to three-membered ring is of the same order of magnitude as that of 0.9 eV observed in the transition between the permethyl

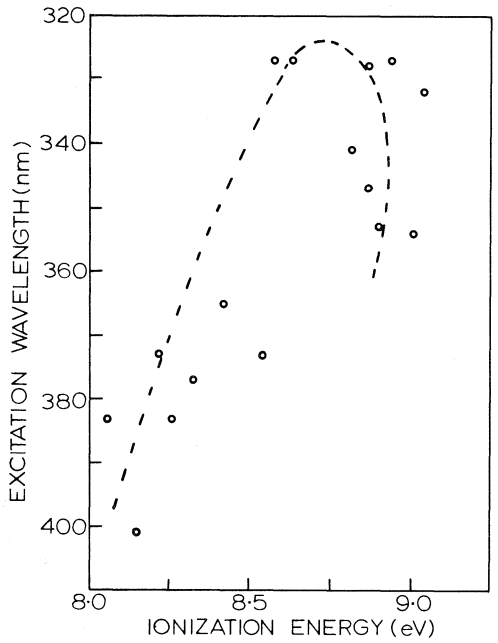

FIG. 4. Experimental excitation energy vs. experimental ionization energy for *cis*-azo systems.

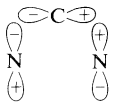
derivatives of these rings (8). The calculated *decrease* of 0.4 eV in excitation energies for the same process is difficult to test due to the lack of experimental results for diazirines; however, it is clear that the excitation energies for the latter are equal to or less than those for four-membered rings. The breakdown in the excitation energy-ionization energy-bond angle correlations are due to the unusual electronic structure of the highly-strained three-membered rings. Inspection of the "n_-" MO for diazirine reveals it is actually more concentrated on carbon than on the nitrogens, and is really a bonding (rather than nonbonding) MO of the type Walsh described for cyclopropane:



This qualitative difference in the nature of the highest-occupied orbital is the basis for our exclusion of three-membered rings containing —N=N— from the correlations discussed above; obviously the stability of this MO will be increased substantially due to its acquisition of substantial C—N bonding character.

The Stabilization of the n_- Orbital

At this stage it is useful to consider the variations in the electronic structure of the normal *cis*-azo chromophore which occur upon bending. As discussed above, most of the change in excitation

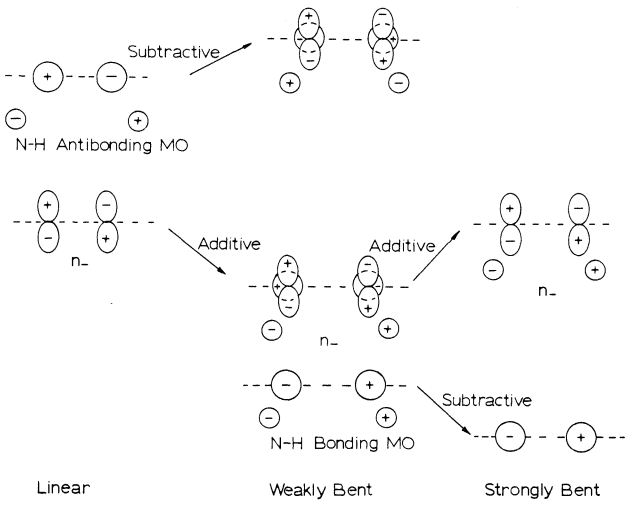


FIG. 5. Interaction of antisymmetric MO's in HNNH upon bending of HNN angle (schematic).

energies in the region of interest is caused predominantly by changes in stability of the n_- orbital. Overall this antibonding "lone pair" MO is stabilized by $\sim 5\frac{1}{2}$ eV by bending the HNN angle from linearity to 95°. This stabilization is due mainly to the acquisition of substantial $2s_N$ orbital character by n_- which, for reasons of symmetry, is completely $2p$ in character in the linear molecule.[2] The drain of $2s$ character into n_- comes mainly from the (empty) antisymmetric N—H antibonding MO and is depicted symbolically in Fig. 5. The calculated bond angles for the HNNH species (Table 1) agree with the Walsh-like view that n_- is stabilized significantly by bending, since the extent of bending is much less when n_- is only singly-occupied (cation and neutral molecule excited singlet) compared to when it is doubly-occupied (anion and neutral ground state). The variation with angle of the $2s_N$ character of n_- is graphically illustrated in Fig. 6 where the unpaired electron density in the $2s$ orbital of each nitrogen is plotted against HNN angle for both the cation and the $n_-\pi^*$ triplet state. For both states the contribution of $2s_N$ to n_- increases sharply as the HNN angle is bent from linearity, but the contribution peaks near an angle of 120° and declines thereafter. Again this behavior can be understood by considering the Walsh diagram involved. In particular, as n_- is stabilized by acquiring $2s_N$ character (from the N—H antibonding MO), its interaction with the antisymmetric combination of (filled) N—H *bonding* orbitals increases according to perturbation theory (since the strength of such interactions varies inversely as the

[2]For background to this type of perturbation theory discussion, see refs. 9 and 10.

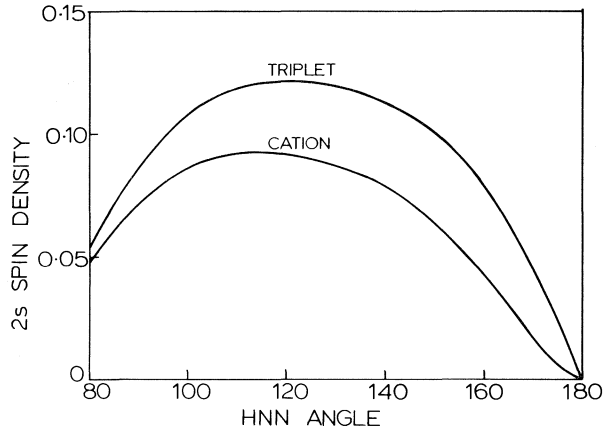

FIG. 6. Unpaired spin density (by STO-3G calculation) vs. HNN angle for triplet and cationic HNNH.

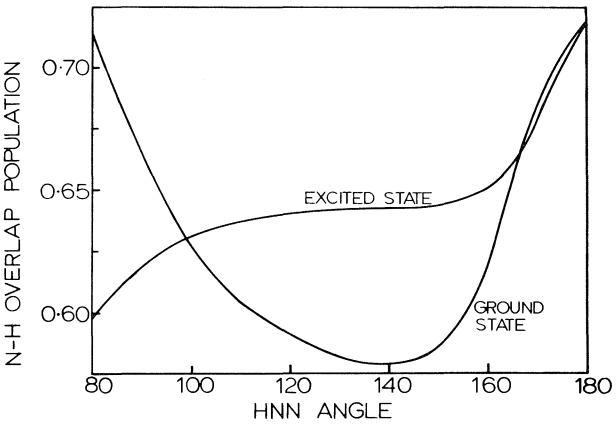

FIG. 7. Nitrogen–hydrogen overlap population vs. HNN angle in *cis*-HNNH.

energy gap between the original levels). Such interaction allows the lower, N—H bonding MO to steal $2s_N$ character from n_ and to donate to n_ some N—H bonding character (see bottom part of Fig. 7).

Both Houk *et al.* (2) and Turro and co-workers (3) have noted a correlation between ionization energy and the rate for decomposition of the singlet excited state (via N_2 extrusion). From their data it is clear that the rate is significantly smaller for those systems we classify in Table 3 as containing six-membered rings, compared to those which contain five- and four-membered rings. From the variations in N—H overlap population with angle illustrated in Fig. 7 one would expect the rates to decrease in the order of six- < five- < four-membered rings. The expectation of Turro and co-workers that excitation from n_ weakens the C—N bonds (3) is observed in the present calculations for HNNH and for the alkyl derivatives *only* for small angles (< 100°).

For reference, the total energies calculated for the molecules discussed herein are listed in Tables 4–6, available from the Depository of Unpublished Data.[3]

Conclusions

The analysis of the present calculations and of existing experimental spectra indicates that the excitation energy to the n_π* singlet state and the ionization energy from the n_ MO are determined primarily by the angle about the nitrogens in *cis*-azo molecules. Although the excitation energy and ionization energy versus angle curves are continuous, they peak at somewhat different angles in the 100° region, thus complicating correlations between the experimental parameters. An additional complication is the substantial delocalization of the hole in n_ through the molecule in the positive ions (but not the neutral excited state). Analysis of the MO's leads to the conclusion that the highest occupied MO in the three-membered diazirine ring (**1***a*) is different qualitatively from the n_ MO in the other systems considered and therefore one should not expect the properties of **1***a* to correlate smoothly with those of the larger rings.

Cobalt(II), nickel(II), and copper(II) complexes of di- and tetrapeptides containing tyrosine and glycine residues

MOHAMED S. EL-Ezaby,[1] JASSIM M. AL-HASSAN, NAMEK F. EWEISS, AND FARIDA AL-MASSAAD

Department of Chemistry, Faculty of Science, University of Kuwait, Kuwait

Received December 5, 1977[2]

MOHAMED S. EL-EAZBY, JASSIM M. AL-HASSAN, NAMEK F. EWEISS, and FARIDA AL-MASSAAD. Can. J. Chem. **57**, 104 (1979).

The solution equilibria of di- and tetrapeptides containing tyrosine and glycine residues have been investigated in absence and presence of cobalt(II), nickel(II), and copper(II) ions. The equilibrium constants have been determined by pH titration at 30°C and $\mu = 0.1$ *M* ($NaNO_3$) in 80% by weight DMSO – water mixed solvent. Protons are ionized from terminal (protonated amino and carboxyl) groups as well as from peptidic nitrogens. Complexes of 1:1 composition of metal ion – tetrapeptides were formed in quite a wide range of pH; also 1:1 complexes of the metal ions – dipeptides were formed in solution under the same conditions. Other higher complexes cannot be proved to form in the pH range studied. The complexes of these metal ions with glycine and *O*-Bzl-L-tyrosine were also studied under the same experimental conditions as control experiments and their equilibrium constants were calculated.

MOHAMED S. EL-EAZBY, JASSIM M. AL-HASSAN, NAMEK F. EWEISS et FARIDA AL-MASSAAD. Can. J. Chem. **57**, 104 (1979).

On a étudié l'équilibre en solution de di- et de tétrapeptides contenant des résidus de tyrosine et de glycine en l'absence et en présence d'ions cobalt(II), nickel(II) et cuivre(II). On a déterminé les constantes d'équilibre par titration de pH à 30°C et à une valeur de $\mu = 0.1$ *M* ($NaNO_3$) dans un solvant mixte contenant 80% en poids de DMSO dans H_2O. Les protons des groupes terminaux sont ionisés (les groupes amino et carboxyle protonés) de même que ceux des azotes peptidiques. Il y a formation de complexes de composition 1:1 d'ions métalliques:tétrapeptides sur un grand intervalle de pH; il y a aussi formation de complexes 1:1 d'ions métalliques:dipeptides en solution dans les mêmes conditions. On n'a pas pu mettre en évidence la formation de complexes plus élevés aux conditions de pH étudiées. On a aussi étudié les complexes de ces ions métalliques avec la glycine et la *O*-Bzl-L-tyrosine dans les mêmes conditions expérimentales comme expériences de contrôle; on a calculé leurs constantes d'équilibre.

Introduction

Metal ions have been reported to play an important role in biological systems. Investigation of the reactions of some metal ions with compounds containing peptide groups in strongly alkaline solutions concluded that these reactions were due to ring formation by the metal ions with amino and peptidic nitrogens of the peptide under consideration (1). Confirmation of the existence of the metal–peptide linkage was reported from infrared studies (2, 3). In addition, considerable experimental evidence (4–7) indicated that the bonding of Cu(II) to serum albumin involves both the α-amino terminal plus one or more peptide nitrogen atoms.

Although the hydrogen atom in the peptide linkage is not very acidic, yet in the presence of some metal ions like Co(II), Ni(II), and Cu(II), the peptide group loses a proton and forms a metal–N(peptide) bond (8-11). However, Kim and Martell (8, 9) proposed the presence of copper bonds to the peptidic nitrogens without loss of the hydrogen ion. Further structural (12*a*) and spectral (13, 14) studies showed that the proton adds to the peptidic oxygen rather than to the peptidic nitrogen which is kinetically inert (11).

Generally, oligopeptide complexes with divalent metal ions like Pd(II), Cu(II), Ni(II), and Co(II) have a square-planar geometry (15). Other geometries found are either square-pyramidal (12*b*) or square-pyramidal with two co-ordinated water molecules (12*c*). On the other hand, dipeptides have the possibility of forming bis(dipeptide) complexes with an octahedral arrangement of donor groups (16).

It was reported (17) that the presence of the copper – amino acid complexes in human serum enhances the uptake of copper by liver tissues. This effect has also been seen in rapid transport of Cu(II) between plasma and cells in other systems (17, 18).

Because of the importance of the study of the kinetics and mechanism of the transfer of metal ions

between peptides and amino acids, we report in this work cobalt(II), nickel(II), and copper(II) complexes with di- and tetrapeptides containing *O*-Bzl-L-tyrosine and glycine residues.

The purpose of this study is to define the role of the peptidic as well as the terminal amino and carboxylic groups in the studied peptides with regards to chelation in isolation from the effect of the phenolic hydroxyl group of the tyrosyl residues. However, as a study of the fully unprotected same tyrosyl peptides would give some new information as to the influence of the phenolic group in the complexation reaction, it is our future intention to compare the results reported here with those to be obtained for the free fully unprotected same tyrosyl peptides.

Experimental

Reagents

Cobalt, nickel, and copper nitrates were a BDH product (AR grade). Aqueous stock solution (0.1 *F*) was standardized by EDTA titration. Commercial sodium nitrate was recrystallized twice from water. Stock solution (0.5 *F*) of sodium nitrate was prepared in 80% by weight dimethyl sulfoxide (DMSO) – water medium. Mixed 80% by weight DMSO (spectral grade) – water solvent was used as diluent. DMSO was checked titrimetrically for acidic and basic impurities prior to dilution with water.

Compound*		
Number	Formula	Abbreviation
Dipeptides		
1	Cl^-H^+-(*O*-Bzl)-L-Tyr-Gly-OH	D_1
2	Cl^-H^+-Gly-(*O*-Bzl)-L-Tyr-OH	D_2
3	Cl^-H^+-Gly-Gly-OH	D_3
4	Cl^-H^+-(*O*-Bzl)-L-Tyr-(*O*-Bzl)-L-Tyr-OH	D_4
Tetrapeptides		
5	Cl^-H^+-(*O*-Bzl)-L-Tyr-Gly-Gly-(*O*-Bzl)-L-Tyr-OH	T_1
6	Cl^-H^+-Gly-(*O*-Bzl)-L-Tyr-Gly-(*O*-Bzl)-L-Tyr-OH	T_2
7	Cl^-H^+-(*O*-Bzl)-L-Tyr-Gly-(*O*-Bzl)-L-Tyr-Gly-OH	T_3
8	Cl^-H^+-Gly-(*O*-Bzl)-L-Tyr-(*O*-Bzl)-L-Tyr-Gly-OH	T_4

*(*O*-Bzl)-L-Tyr = the phenolic OH function of L-tryosine is protected by benzyl group; Gly = glycine.

The dipeptides **1**–**4** and the tetrapeptides **5**–**8** were prepared and purified as described in literature (19). O-Bzl-L-tyrosine was prepared using the method of Wunsch *et al.* (20). Glycine, a BDH product, was used without further purification.

Because of solubility problems, accurately weighed amounts of the tetrapeptides, dipeptides, *O*-Bzl-L-tyrosine and glycine were dissolved in DMSO. The stock solutions were about 3×10^{-2} *F*. Equivalent amount of hydrochloride acid was only added to glycine.

Measurements

A Radiometer pH meter, model 63, equipped with Radiometer glass and reference electrodes types G 202 C and K 104, respectively, was used for pH titrations. The pH meter was standardized before use with Radiometer buffers of pH 4.00, 7.00, and 9.1. Solutions of ligand or of ligand and metal ion were titrated with standard carbonate-free sodium hydroxide solution (0.102 or 0.098 *F*) delivered from calibrated automatic burette type Metrohm Herisau Multi Dosimat E 415, accurate to ±0.005 ml. In each titration the initial volume of the solution was 25.0 ml. The ionic strength was adjusted to 0.10 by the addition of the concentrated sodium nitrate solution. In a typical titration, aliquots of ligand, metal ion, and sodium nitrate stock solution were mixed such that the solvent mixture was 80 wt.% DMSO – water (molar ratio nearly 1:1). The mixture was adjusted to 25.0 ml by adding the required amount of diluent. The temperature of the solution was maintained at 30.0°C in a tightly covered thermostated titration cell. The solution was mechanically stirred. A complete titration consisted of successive additions of 0.01–0.02 ml of the titrant. Half minute after each addition the stirring motor was stopped and the pH-meter reading was taken. The titration was continued until pH-meter could not be kept steady or reached pH 11.00. The range of the concentration of the metal ions and ligands were $(0.5–1.0) \times 10^{-3}$ *F* and $(0.495–2.0) \times 10^{-3}$ *F*, respectively.

Due to the probable uptake of oxygen by Co(II) complexes, their titrations in this study has been done under anaerobic (by flushing purified N_2 through the titration cell) and aerobic conditions. Titration results coincided in both cases at pH_0's less than 8.50. However, appreciable differences in the titration curves were observed at higher pH values; under aerobic conditions being slightly lower.

The pH-meter readings in 80 wt.% DMSO – water solution are converted to hydrogen ion concentration (H^+) by means of the widely used equation of Van Uitert and Haas (21), namely

$$[1] \qquad -\log [H^+] = pH_0 + \log U_H$$

where U_H is the correction factor for the solvent composition and ionic strength. For this purpose, readings were made on a series of solutions containing known amounts of nitric acid and sodium nitrate such that the ionic strength is equal to 0.10 in 80 wt.% DMSO – water medium in the pH range 1.00–4.00. In addition, readings of pH were taken for universal buffers (22) at the same solvent composition in the pH range 3.50–10.75. From the known stoichiometric $[H^+]$, a value of

log $U_H = 1.00 \pm 0.01$ was obtained for 80 wt.% DMSO – water medium of $\mu = 0.10$ at 30°C.

The ionic product of water in 80 wt.% DMSO – water medium at 30.0°C was determined potentiometrically (23). Potential measurements were made with the same pH-meter described above. The glass electrode used was the same as described above. The AgCl, Ag electrode was prepared from Radiometer (P 4011) silver Billet Electrode by electrolysis in chloride solution (0.1 *M*).

Cell A glass electrode/solution A: $HCl(C_1)$, $KNO_3(C_2)$,

in solvent S/AgCl, Ag

Most of the measurements began with cell A, containing a known volume of 80 wt.% DMSO – water solution of hydrochloric acid and potassium nitrate of known concentrations represented by C_1 and C_2. The same procedure was then followed with cell B,

Cell B glass electrode/solution B: NaOH (C_3), NaCl (C_4)

in solvent S/AgCl, Ag

that initially contained known volume of 80 wt.% DMSO – water with appropriate concentrations of sodium hydroxide and sodium chloride such that

$$C_1 + C_2 = C_3 + C_4$$

The equation used to calculate the equilibrium quotient is

$$[2] \quad pK_W = \frac{E_A - E_B}{K_2} + \log \frac{C_4}{C_3 C_1^2} \simeq -\log C_H C_{OH}$$

assuming that the activity of water to be unity in all solutions, where

$$E_A = K_1 + K_2 \log C_1^2 + K_2 \log (\gamma^{\pm})_A^2$$

$$E_B = K_1 + K_2 \log \frac{K_W C_4}{C_3} + K_2 \log (\gamma^{\pm})_B^2$$

where K_1 = standard potential of the cells, $K_2 = 58.6$ mV, and $\gamma^{\pm}$ = mean activity coefficient for the solute ions. The mean value of pK_W obtained was 15.04 ± 0.12.

The electronic spectra of the Co(II)–, Ni(II)–, and Cu(II)–tetrapeptides systems were taken at different pH values using Cary 17 spectrophotometer at room temperature (25 ± 1°C).

Results and Discussion

The reaction between the ligand, the divalent metal ions, and protons can be represented as follows:

$$[3] \quad jL + qM + rH \rightleftharpoons L_jM_qH_r \text{ (charges omitted)}$$

where L stands for the ligand, M stands for Co(II), Ni(II), or Cu(II), and *j*, *q*, and *r* are the stoichiometric coefficients.

Typical titration curves of the systems under consideration are shown in Fig. 1. In absence of metal ions the protonation and deprotonation equilibria are

$$[4] \quad L + H^+ \rightleftharpoons LH^+$$

$$\beta_{101} = \frac{[LH^+]}{[L][H^+]}$$

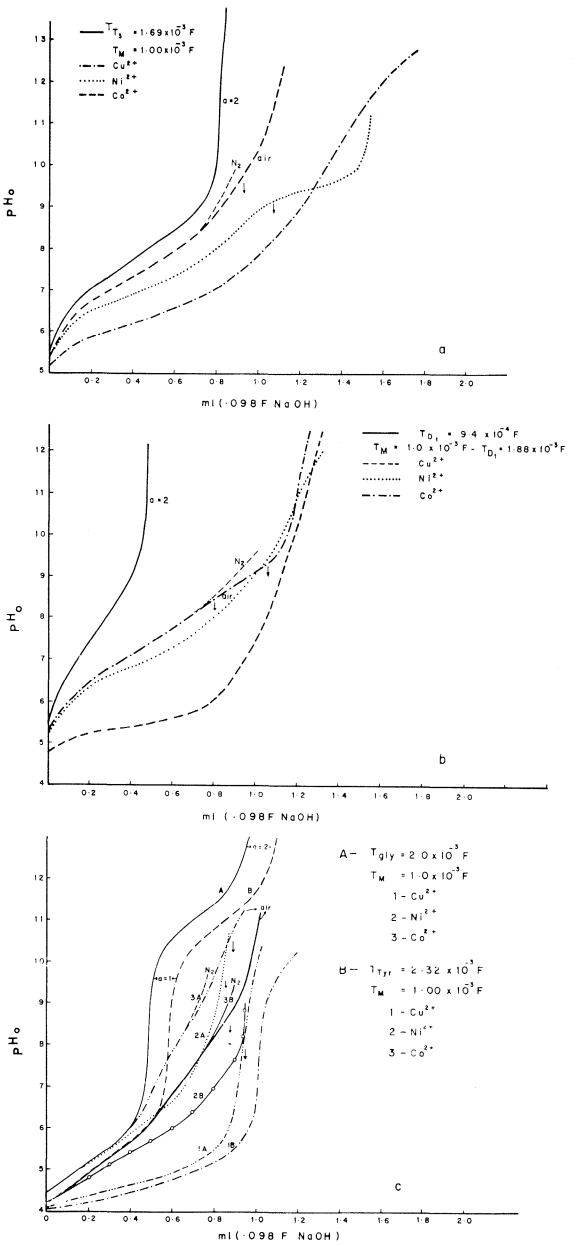

FIG. 1. Titration curves in absence and presence of the metal ions Cu^{2+}, Ni^{2+}, and Co^{2+}, (*a*) T_3 system, (*b*) D_1 system, (*c*) Gly and *O*-Bzl-L-Tyr systems.

$$[5] \quad L \rightleftharpoons LH_{-1} + H^+$$

$$\beta_{10-1} = \frac{[LH_{-1}][H^+]}{[L]}$$

The titration curves of dipeptides and tetrapeptides show only sharp inflection at *a* (the ratio of number of moles of base per number of moles of ligand) equal to 2 at pH_0 values greater than 10.0.

On the other hand, titration curves of the protonated *O*-Bzl-L-tyrosine and glycine show two inflections in the pH_0 range ~3.8–9.0 and the other at pH_0 values greater than 11.0. Programme MINIQUAD (24) and its modified version MINIQUAD 75 (25) were used to calculate the equilibrium constant of reactions [4] and [5]. The values are depicted in Table 1. By analogy to the acid–base equilibria of amino acids and their related compounds, one expects that reaction [4] deals with the protonation of the carboxylate group and reaction [5] with the deprotonation of the protonated amino group. Amide protons of dipeptides and tetrapeptides cannot be simply ionized even in strongly alkaline solution (26), a behaviour usually encountered by all peptides in absence of metal ions. The deprotonation constants of tetrapeptides can be arranged in the descending order of $T_3 > T_1 > T_4 > T_2$ and those of dipeptides in the order $D_4 > D_1 > D_2 > D_3$. These orders reflect the relative basicities of the amino groups in these compounds. The basic nature of the amino group in tetrapeptides and dipeptides is obviously lower than that in *O*-Bzl-L-tyrosine and glycine as evidenced from the log form of their deprotonation constant, Table 1. On the other hand, the protonation constants of the tetrapeptides and dipeptides are greater than those of *O*-Bzl-L-tyrosine and glycine. These differences in behaviour may be attributed to decrease in electronic density on the nitrogen of the amino group as the electronic transmission from the carboxylate group decreases in the presence of peptide linkages.

The Metal Ion Complexes of Tetrapeptides

Typical titration curves of the divalent metal ions – tetrapeptides systems are shown in Fig. 1*a*. Although no precipitation of any kind was observed in the copper(II) systems in the pH_0 range used, yet slight precipitation was observed at pH's > 9.6 in nickel(II) systems and > 10.6 in the cobalt(II) systems. During the titration the color of the solution changed considerably. Although clear inflections in the titration curves cannot be located, yet 4–5 moles of base per mole of copper(II) or nickel(II) and 3–4 moles of base per mole of cobalt(II) could be assumed to be consumed in these systems. MINIQUAD programmes have been used to test different models of equilibrium reactions (eq. [3]). The assessment was done by using the crystallographic R factor and X_i^2 values obtained by the forementioned programmes. In each case, the addition of one extra species gave an increased R value, a greater X_i^2 value, or both. The model which met these conditions is as follows:

$$LH^+ \rightleftharpoons L + H^+$$

[6] $$L + M^{2+} \rightleftharpoons MLH_{-1}^{+} + H^+$$

[7] $$L + M^{2+} \rightleftharpoons MLH_{-2}^{0} + 2H^+$$

[8] $$L + M^{2+} \rightleftharpoons MLH_{-3}^{-} + 3H^+$$

[9] $$L + M^{2+} \rightleftharpoons MLH_{-4}^{2-} + 4H^+$$

The log values of β_{jqr}'s for the equilibrium reactions [6]–[9] are listed in Table 1. Table 2*a*, on the other hand, shows the stepwise equilibria of M^{2+} tetrapeptide systems and their equilibrium constants.

From the order of arrangement of the deprotonation constants of the tetrapeptides in absence of metal ions, one expects that the order of the stability constants of their metal ions complex equilibria (MLH_{-1}^{+}) will be quite reversed, i.e. $T_2 > T_4 > T_1 > T_3$. This was found to be true in the systems of copper(II) complexes, in particular, and to a certain extent in the nickel(II) and cobalt(II) system. This conclusion indicates strongly that ring closure first occurs through coordination of the terminal groups of the tetrapeptides with copper(II). The situation is not quite clear in the cases of nickel(II) and cobalt(II) systems. Generally, the order of complexing of these metal ions with a particular tetrapeptide follows the Irving–Williams series (27) (Table 2*a*) which suggests high spin complexes in octahedral crystal field. In fact, it was not possible to detect complexes of compositions other than 1:1. This conclusion implies that coordination sites other than the C- or N-terminals may be involved in complex formation. The other coordination sites may be available through the nitrogen atom of the peptidic linkage. This type of linkage may facilitate deprotonation of the peptidic protons at lower pH values than it should be in absence of metal ions. This behaviour has been previously reported for other similar systems (17). The stepwise deprotonation constants of the MLH_{-1} complex show monotonic decrease in magnitude as they are deprotonated consecutively, Table 2*a*, a behaviour which may be interpreted as due to increase in electron density as peptidic protons dissociate.

It is also quite clear that the order of complexing ability of LH_{-2}, LH_{-3}, and LH_{-4} of a particular tetrapeptide follows also Irving–Williams series (27).

However, the log form of the deprotonation constants of MH_{-1}, MLH_{-2}, and MLH_{-3} of the divalent metal ion complexes, under consideration, do not follow a particular trend with respect to the type of the tetrapeptide. This is probably due to the effect of structure conformation of the tetrapeptide. However, the effect of sequence of each tetrapeptide does not seem to be clear. In the case of the depro-

tonation of $CuLH_{-1}$, the order of arrangement is $T_4 > T_2 > T_1 > T_3$, in the case of $CuLH_{-2}$ the order is $T_3 > T_2 > T_4 > T_1$, and in the case of $CuLH_{-3}$ the order is $T_3 > T_2 > T_1 > T_4$. The order of arrangement in the case of Ni(II) and Co(II) systems is not similar to that of the Cu(II) systems. This may be attributed to the difference in ionic radii of the former metal ions from the latter ions.

From the foregoing results, one cannot predict easily which peptide group will lose its proton first. However, it can be concluded that pentacoordinated complex species may be formed with the loss of all or some of the peptidic protons in addition to that of the terminal carboxylic group. It is not unreasonable to assume that water molecule or hydroxide ion may occupy the vacant hexacoordinate site of the metal ions.

Figure 2 shows a typical distribution diagram of various complex species at different pH values.

The electronic spectra of Co(II)–, Ni(II)–, and Cu(II)–tetrapeptides systems revealed the possible presence of different complex species at different pH values. In the Cu(II) system (Fig. 3), the spectra show hypsochromic shift with increase in intensity as pH increases in the 500–800 nm range. This was attributed to the *d–d* transition exhibited by copper(II) ions in possibly an octahedral field. The increase in intensity in the ligand bands (<430 nm) was explained as due to electronic transitions within the ligand as a result of metal ions perturbation. However, the spectra of Ni(II) and Co(II) were more or less similar to the ligand spectra except that the intensity is higher. A shoulder at ~400 nm and ~480 nm in case of Ni(II) and Co(II), respectively, was observed and attributed to the *d–d* transition in both cases.

The Metal Ion Complexes of the Dipeptides

Solutions of the Cu(II), Ni(II), and Co(II) exhibit various colors as their pH_0 increases in the course of titration. While no precipitation was observed in the Cu(II) systems in the pH_0 range used, colored precipitates in both Ni(II) and Co(II) systems were formed, depending on the system, initial concentrations of the reactants, and pH_0 of the medium. Typical titration curves of Cu(II), Ni(II), and Co(II) dipeptide systems are shown in Fig. 1*b*. Sharp inflections in these curves are noted at pH_0's > 6.0. These inflections correspond approximately to 3–4 moles of base to one mole of metal ions. The model which fits the experimental findings has been found to correspond to the following equilibrium reactions.

$$LH^+ \rightleftharpoons L + H^+$$

[10] $$L + M^{2+} \rightleftharpoons MLH_{-1}^{+} + H^+$$

[11] $$L + M^{2+} \rightleftharpoons MLH_{-2} + 2H^+$$

*The log β of Cu(II) complexes with glycine in aqueous solutions are 7.72 and 6.89, respectively (26). The log β of Ni(II) complexes with glycine in aqueous solutions are 5.55 and 4.62, respectively (26). The log β of Co(II) complexes with glycine in aqueous solutions are 4.77 and 4.22, respectively (26).

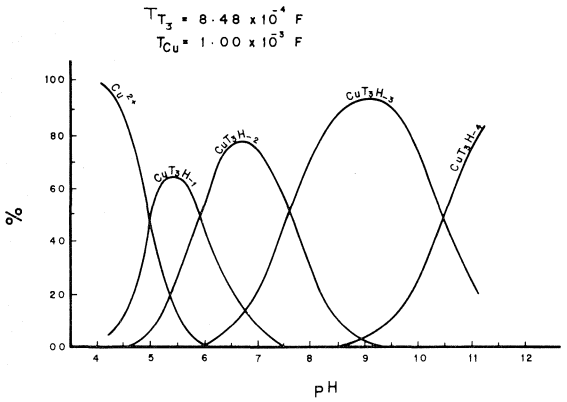

FIG. 2. Distribution diagram of the molecular species of T_3–Cu^{2+} system at various pH values.

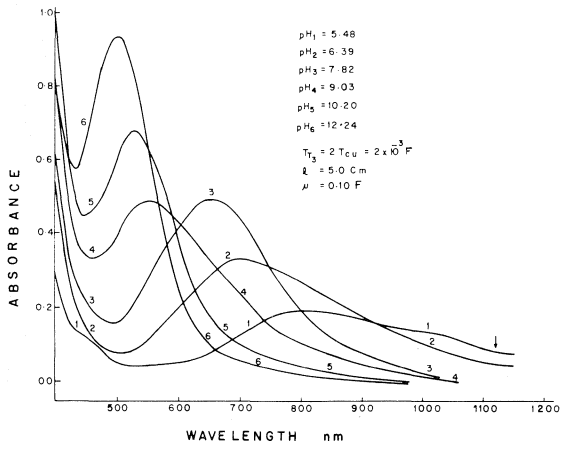

FIG. 3. Electronic spectra of T_3–Cu^{2+} system at different pH values.

The equilibrium constants of the reactions [10] and [11] are listed in Table 1. It is quite interesting to note that the constant of the equilibrium reaction [10] cannot be calculated for the Cu(II) system, contrary to the Ni(II) and Co(II) systems. This may be accounted for as due to the large polarizing power of the Cu(II) ions in comparison to that of Ni(II) and Co(II) ions; which facilitates loss of protons from the ligand, even that of the peptidic group. Few reports have discussed the loss of peptidic protons of dipeptides in presence of metal ions (8) in aqueous solutions. Metal–dipeptide complexes of 1:2 stoichiometry cannot be detected under the experimental conditions used in this work, similar to what have been found in the metal tetrapeptide systems. This conclusion is contrary to what one expects specially in Ni(II) and Co(II) systems where octahedral configuration is favourable. However, this can be attributed to the steric hindrance of the bulky *O*-Bzl-L-tyrosine residue in D_1, D_2, and D_4 in particular and/or the formation of neutral complex species incapable of attracting other ligand species in the mixed solvent under consideration. The order of arrangement of 1:1 complex of Ni(II) with the dipeptides follows the opposite order of arrangement of the deprotonation constants of the dipeptides, i.e., $D_3 > D_2 > D_1 > D_4$. This behaviour probably indicates that chelation occurs through the N and O terminals of the dipeptides similar to what have been shown for the Cu(II)–tetrapeptides systems. On the other hand Co(II) systems do not show this trend which may indicate that the N and O terminals are not simultaneously involved in the complex formation. The order of arrangement is $D_1 > D_4 > D_2 > D_3$, Table 2*b*. For a particular dipeptide, the order of stability of MLH_{-1} follows Irving–Williams series. Moreover, the order of the stability constants of the formation of MLH_{-2} shows the same sequence, i.e. Cu(II) > Ni(II) > Co(II) (Table 2*b*).

The Metal Ion Complexes of Glycine and O-*Bzl*-L-*Tyrosine*

Figure 1*c* shows typical titration curves of the divalent metal ions – glycine and *O*-Bzl-L-tyrosine systems. Sharp inflections were obtained at 2 moles of base per mole of metal ions for 1:1 metal-to-ligand ratios and four moles of base per mole of metal ions for 1:2 ratios. These were only observed in the copper(II) systems. Nickel(II) and cobalt(II) titration systems did not show such clear inflection points. However, 2–4 moles of base per mole of metal ions may be assumed to be consumed in these systems as the case of copper(II) systems. The model equilibrium reactions which successfully explained

these experimental data is as follows:

$$LH^+ \rightleftharpoons L + H^+$$

[12] $$L + M^{2+} \rightleftharpoons MLH_{-1} + H^+$$

[13] $$2L + M^{2+} \rightleftharpoons M(LH_{-1})_2 + 2H^+$$

Table 1 depicts the values of the stability constants of the equilibria [12] and [13] and Table 2*c* lists the corresponding stepwise constants. As was expected, the order of stability of the complexes follows that of Irving–Williams series. They are 2–4 units greater than those calculated for systems studied in aqueous solutions (26), which may be attributed to the solvent effect. The larger β values of the 1:1 complexes of glycine and *O*-Bzl-L-tyrosine compared to those of dipeptides and tetrapeptides are indicative of their stronger binding towards these metal ions. The formation of five-membered chelate complex is usually more favourable over other possibilities. However, the stability of the divalent metal complexes of dipeptides and tetrapeptides is enhanced more due to coordination with the peptidic nitrogen atoms. This enhancement, on the other hand, inhibits further chelation with other ligand molecules, a situation not encountered in the case of glycine and *O*-Bzl-L-tyrosine.

Conclusions

The observed difference in the log β_{101} value (Table 1) for Gly and *O*-Bzl-L-Tyr in 80 wt.% DMSO – water from the corresponding values in water only (Table 2*c*) is attributed to solvent effect. The higher electron density over the oxygen atom in DMSO compared to that in water renders the protonated amino group less electronegative and, consequently, the acidic proton of the carboxylic group will be more firmly held, i.e. log β_{101} is higher. On the other hand, solvation of the carboxylate ions of the dipolar species by water molecules and subsequent ease of abstraction of a proton from the terminal protonated amino group is not possible by an aprotic solvent as DMSO. This is confirmed by comparing the low values of log β_{10-1} of either Gly or *O*-Bzl-L-Tyr in 80 wt.% DMSO – water mixture with those in water only (Tables 1 and 2).

For the protonation equilibria in the case of di- and tetrapeptides, the same solvent effect is still operating, i.e., log β_{101} should be higher. Besides, one should also consider that as the protonated amino and carboxylic groups are now far apart from each other due to increase in chain length, the protonation constant in these ligands will be higher than the corresponding values in Gly or *O*-Bzl-L-Tyr systems (Tables 1 and 2).

For the deprotonation equilibria of di- and tetrapeptides, log β_{101} values are, as expected, higher than the corresponding values of Gly and *O*-Bzl-L-Tyr due to the effect of chain length. On the other hand, solvent effect has more or less no observed role.

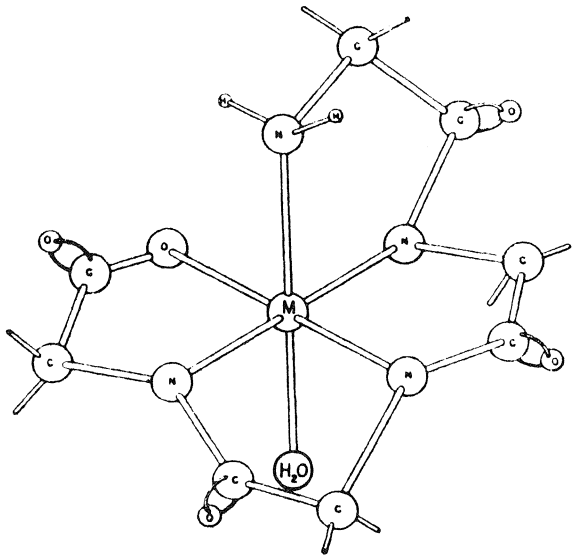

FIG. 4. Possible structure of the complex.

It is also clear that chelating properties of glycine and *O*-Bzl-L-tyrosine copper(II) ions are more pronounced than those of tetrapeptides, evidenced by the values of β_{11-1}. However, the enhanced loss of the peptidic protons by the metal ions probably increases the chelating effect of tetrapeptides over that of glycine and *O*-Bzl-L-tyrosine and even over that of dipeptides (cf. Table 2). Although the structures of these complexes have not been determined, it is not unreasonable to assume that they may have the structure shown in Fig. 4, in which penta-coordinated complex species is present. The vacant hexa-coordinate site may be occupied further by a water molecule or a hydroxide ion.

Ethylenediamine-*N*,*N*′-diacetic acid complexes with divalent manganese, zinc, cadmium, and lead: a thermodynamic study

R. J. GUALTIERI, W. A. E. MCBRYDE, AND H. K. J. POWELL

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received June 2, 1978

R. J. GUALTIERI, W. A. E. MCBRYDE, and H. K. J. POWELL. Can. J. Chem. **57**, 113 (1979).

The four protonation constants are reported for the dianion of ethylenediamine-*N*,*N*′-diacetic acid (H_2L), 25°C, I = 0.10 M (KNO_3), (log k_i = 9.60, 6.51, 2.12, 1.3). log K(potentiometric) and ΔH(calorimetric) data are reported for the formation of the complexes [ML], M = Mn^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+} (log K = 6.87, 10.99, 9.16, and 10.66; ΔH = −2.9, −24.4, −16.7, and −28.0 kJ mol^{-1} respectively). The complexes [ZnL] and [PbL] undergo (aqua) proton dissociation reactions, [ML] + $H_2O \rightleftharpoons$ [ML(OH)] + H^+; log K_D = −10.56 and −11.02, ΔH_D = +60.7 and +38.5 kJ mol^{-1}, respectively. Potentiometric and nmr studies indicate that the ligand undergoes a slow (metal catalysed) hydrolysis or rearrangement in aqueous acid.

R. J. GUALTIERI, W. A. E. MCBRYDE et H. K. J. POWELL. Can. J. Chem. **57**, 113 (1979).

On rapporte les quatre constantes de protonation du dianion de l'acide éthylènediamine *N*,*N*′-diacétique (H_2L), à 25°C, I = 0.10 M (KNO_3), (log K_i = 9.60, 6.51, 2.12 et 1.3). On rapporte des données de log K(potentiométrique) et ΔH(calorimétrique) pour la formation des complexes [ML], M = Mn^{2+}, Zn^{2+}, Cd^{2+} et Pb^{2+} (log K = 6.87, 10.99, 9.16 et 10.66; ΔH = −2.9, −24.4, −16.7 et −28.0 kJ mol^{-1}, respectivement). Les complexes [ZnL] et [PbL] subissent des réactions de dissociation protonique (aqua), [ML] + $H_2O \rightleftharpoons$ [ML(OH)] + H^+; log K_D = −10.56 et −11.02, ΔH_D = +60.7 et +38.5 kJ mol^{-1}, respectivement. Des études rmn et potentiométriques indiquent qu'en milieu aqueux le ligand subit une hydrolyse lente (catalysée par les métaux) ou une transposition.

[Traduit par le journal]

Introduction

In the course of testing a new calorimetric system the complexing reactions of ethylenediamine-*N*,*N*′-diacetic acid (H_2L) with the divalent ions of Mn, Zn, Cd, and Pb were studied. The formation of the Mn, Zn, and Cd complexes (also Co, Ni) had been the subject of an earlier potentiometric and calorimetric study (1). However, this work did not consider the protonation reactions of the acetato groups in the zwitterion H_2L, $(-CH_2\overset{+}{N}H_2CH_2COO^-)_2$. Subsequent studies (2–4) have indicated log K values of ca. 2.4 and 1.8 for these reactions; thus the reaction $H_2L + H^+ \rightarrow H_3L^+$ will be important in the pH range in which NiL forms (2.5–3.5) and in which CoL and ZnL form (3.5–4.5). Further, McLendon *et al.* (5) have reported the formation of the species $[Co(HL)]^+$ (as well as [CoL] and $[CoL(OH)]^-$), and Schroeder and Johnson (3) reported $[M(HL)]^+$ (also [ML], $[ML(OH)]^-$, and $[M_2L]^{2+}$), M = Pb, Zn, although species $[M(HL)]^+$ were not reported by Degischer and Nancollas (1) for Co or Zn, nor for Ni which complexes at lower pH (6).

This work reports the four protonation constants for the diacetato anion L^{2-}, and enthalpy data for the formation of HL^- and H_2L. Log K and ΔH values are reported for the formation of [ML], M = divalent Mn, Zn, Cd, Pb, and of [ML(OH)], M = Zn, Pb. It was observed that solutions of the ligand and metal ions were not stable; for solutions kept at 25°C titration curves showed a steady increase in pH with time, especially at $\bar{n}_L > 0.8$. Nuclear magnetic resonance studies established that a slow decomposition or rearrangement of the ligand occurs in aqueous acid solution.

Experimental and Results

Materials

Ethylenediamine-*N*,*N*′-diacetic acid, EDDA (Aldrich 15, 818-6), was twice recrystallised from hot water. A sample of commercial EDDA required soxhlet extraction with 10% v/v methanol/ethanol (24 h) to remove adsorbed impurities before recrystallisation. The formula weight by titration against KOH, using Gran's plot to determine the end point was 176.6; calcd 176.2.

Stock solutions of $Mn(ClO_4)_2$, $Zn(NO_3)_2$, $Cd(NO_3)_2$, and $Pb(NO_3)_2$ were prepared from Analar grade reagents and acidified, ca. 2.5 × 10^{-3} M HNO_3. Stoichiometry was confirmed by titration against standard EDTA, using appropriate indicators and pH (7, 8).

pH Measurements

A Beckman Calomel electrode and Beckman E-2 glass electrode were used in conjunction with a Radiometer digital pH meter PHM 52. The electrodes were calibrated as a [H^+] probe by titration of HNO_3 into solutions of KNO_3 (p[H^+] 2.0–2.7), KNO_3/HNO_3 (p[H^+] 1.5–2.0), acetic acid (p[H^+] 3.7–5.8) (9), and potassium hydrogen phthalate (p[H^+] 4.0–

5.9) (10), and of KOH into KNO_3 ($p[H^+]$ 10.8–11.8), μ = 0.10 *M* (KNO_3). All pH(measured) − $p[H^+]$ data were colinear within experimental error, the least-squares line for 90 data points being $pH_m = (1.012 \pm 0.001)p[H^+] + (0.037 \pm 0.003)$.

Ligand protonation was studied by titration of (*i*) HNO_3 (0.9944 *M*), or (*ii*) KOH (0.5475 *M*), from a Gilmont micrometer syringe into solutions of H_2L (ca. 3×10^{-3} *M*) and KNO_3 (*I* = 0.10 *M*). The step-wise protonation constants in Table 1 were computed from derived $\bar{n}_H$(obs) − pH data by use of the least-squares procedures detailed elsewhere (11). ($\bar{n}_H$ is the average number of protons bound per ligand molecule.) The protonation constants were determined for 5 titrations each of 50–60 data points in the range $\bar{n}_H$ 0.25–3.0; *R* factors (12) of ca. 0.25 were achieved and there were no systematic trends in the residuals, $\bar{n}_H$(obs) − $\bar{n}_H$(calcd) (13). (At $\bar{n}_H$ 3.0 the solution composition was 21% H_4L, 57% H_3L, 22% H_2L.)

Titration of KOH into solutions of ligand (ca. 4.3×10^{-3} *M*), metal salt (ca. 4.0×10^{-3} *M*), and KNO_3 gave titration curves with buffer regions (at pH 5.4–6.8, 3.3–4.5, 4.2–5.4, and 3.5–4.8 for Mn, Zn, Cd, and Pb, respectively) followed by end points corresponding to the addition of two moles of OH^- per mole of metal ion, i.e. the reaction

$$M(aq)^{2+} + H_2L + 2OH^- \rightarrow [ML] + 2H_2O$$

plus one mole of OH^- per mole of excess acid (HNO_3) and per mole of excess ligand. In each case a second buffer region followed at pH > 10. The Zn–EDDA and Pb–EDDA solutions were stable at high pH; Cd–EDDA solutions showed a downward drift in pH at pH > 10 and a gelatinous precipitate was apparent at pH 11. The Mn–EDDA solutions became increasingly sensitive to O_2 at high pH. Titration solutions under N_2 developed a pale amber colour at pH > 10; on exposure to air these solutions rapidly became deep amber and precipitated MnO_2. The two buffer regions were interpreted in terms of reactions [1] and [2], respectively. Values of $\log K_1$ and $\log K_D$ are given in Table 2.

$$[1] \qquad M(aq)^{2+} + L^{2-} \overset{K_1}{\rightleftharpoons} [ML]$$

$$[2] \qquad [ML] + H_2O \overset{K_D}{\rightleftharpoons} [ML(OH)]^- + H^+$$

All metal–ligand solutions were freshly prepared and/or stored at 4°C between titrations. Solutions (Zn, Cd) maintained at 25°C gave titration curves which displaced to higher pH at ca. 0.02 pH/12 h at $\bar{n}_L$ 0.2–0.8 and 0.1–0.3 pH/12 h at $\bar{n} > 0.9$.

Calorimetric Measurements

An LKB 8700-1 calorimeter was modified as follows. The polyethylene titrant coil was replaced by a glass titrant line (2 mm od) which entered the submerged outer container of the calorimeter via one of the support chimneys and had a single coil 7.5 cm in diameter inside this container. Titrant was delivered from a Gilmont micrometer syringe. Time-resistance measurements were effected by feeding the out-of-balance signal from the dc bridge into a Hewlett-Packard 419 A dc null voltmeter; the amplified signal was fed to a strip chart recorder (Hewlett-Packard Moseley 7101B). The precision of the system was estimated from electrical calibrations. The ratio of electrical heat input to measured resistance change (interpolated from the recorder trace and bridge settings before and after 'reaction') was reproducible to ±0.2% for reactions of 5–14 J. The accuracy of the system was checked by determining the enthalpy change for protonation of aqueous 2-amino-2-hydroxymethylpropane-1,3-diol (tris) with HCl; the mean and standard deviation of 7 measurements (measured heat change ca. 13 J) was −47.2 ± 0.2 kJ mol^{-1} (lit. (14, 15) −47.48 and −47.44 kJ mol^{-1}).

For the protonation of L^{2-}, buffered solutions of ligand (ca. 6.5×10^{-3}, $\bar{n}_H$ 0.2–0.3, *I* 0.10 *M* KNO_3) were titrated in the calorimeter with HCl (ca. 1 *M*). The determination of ΔH_i values from the measured heat changes (ca. 6.5–10 J, corrected for the heat of dilution of HCl titrant (16) and for the neutralization of OH^- (17) produced by reaction [3]), and the changes in solution composition between successive titration points, followed procedures detailed previously (18).

$$[3] \qquad H_2O + \text{ligand} \rightleftharpoons OH^- + \text{ligand,}H^+$$

The step-wise enthalpy changes given in Table 1 were determined from 12 data points (3 titrations).

For the complexes [ML] (and $[ML(OH)]^-$) calorimetric measurements involved titration of HNO_3 (ca. 1 *M*) into solutions of metal salt (ca. 6×10^{-3} *M*), EDDA (ca. 6.7×10^{-3} *M*), and KNO_3 (*I* = 0.10 *M*) buffered to appropriate pH by addition of KOH ($\bar{n}_L = 0.8$ or $[ML(OH)]^-/C_M = 0.3$); i.e. the enthalpy changes for (*i*) protonation,

$$[ML(OH)]^- + H^+ \rightarrow [ML]$$

and (*ii*) dissociation,

$$[ML] + nH^+ \rightarrow M(aq)^{2+} + H_nL^{(n-2)+}$$

of the complex were determined. Measurements were restricted to the composition range for which $[H_3L]/C_L < 0.02$, i.e. pH > 3.8 and $\bar{n}_L > 0$, 0.45, 0, and 0.3 for Mn, Zn, Cd, and Pb respectively. The composition of the calorimeter solution at each titration point was determined by solving the three mass balance equations (expressions for the stoichiometric concentrations, C_L, C_M, and C_H) for $[H^+]$ and [ligand]; the iterative procedure adopted was based on an initial estimate of $[H^+]$ obtained from a parallel titration on the calorimeter

solution. The measured heat changes were corrected for the heat of dilution of HNO_3 (19), for the neutralization of OH^- (17) (reaction [3]), and for the protonation of ligand not coordinated to the metal ion. The enthalpy changes for the well separated reactions [1] and [2], ΔH_1, ΔH_D, were calculated from $Q_{corr} = R\Delta H_i$ where R is the change in the number of moles of [ML] or $[ML(OH)]^-$, respectively, between successive titration points. Results (mean ± standard deviation, 6–10 data points) are given in Table 2.

Nuclear Magnetic Resonance Measurements

Nuclear magnetic resonance spectra were recorded on a Varian T-60 spectrometer for solutions of EDDA in D_2O/CF_3COOH at pH = 0.8 and 2.25, using TMS as external standard.

Discussion

Ligand Protonation

The first and second protonation reactions of the dianion $(—CH_2NHCH_2COO^-)_2$ have been studied by several workers and the log k_i values are similar to those reported in this study (Table 1). It is probable that discrepancies arise mainly from the method of estimating $[H^+]$ from the measured pH (11). In this work the electrode pair was calibrated directly as a $[H^+]$ probe, at the same ionic strength as for the titrations, by use of buffers for which $[H^+]$ could be calculated from known concentration quotients (CH_3COOH) (9) or from known thermodynamic equilibrium constants and activity coefficient expressions for individual ions (phthalic acid) (10), and by use of HNO_3 and KOH solutions of known stoichiometry. For KOH solutions $p[H^+]$ was calculated assuming $pK_w = 13.778$ for 0.10 *M* KNO_3 (20).

Yamada *et al.* (4) have reported values of log k_3 and log k_4 for carboxylate protonation of the zwitterion $(—CH_2\overset{+}{N}H_2CH_2COO^-)_2$ (2.37, 1.85, 1 *M* $NaClO_4$) while Schroeder and Johnson (3) and Harris and Martell (2) have reported values for log k_3 (1.54, 1 *M* $NaClO_4$, and 2.36, 0.10 *M* KNO_3, respectively). The measurement of log k values at low pH in aqueous solution is prone to large uncertainties in the calculations, and in this work measurements were restricted to pH ≥ 2.2, at which ≤21% of the ligand exists as H_4L^{2+}. Although our value of log k_4 carries a significant uncertainty the existence of this species in solution is confirmed by the low values of R (0.22%) and $\sigma_{\bar{n}}$ (±0.005) obtained in calculations; by assuming $k_4 = 0$, a value of log $k_3 = 2.31 \pm 0.02$ was obtained (in agreement with Harris and Martell (2)) but R (2.9%) and $\sigma_{\bar{n}}$ (±0.06) were significantly higher.

The values reported for ΔH_1 and ΔH_2 were derived from 11 titration points and the least-squares fitting of ΔH_i ($Q_{obs} = \alpha\Delta H_1 + \beta\Delta H_2$) gave a standard deviation of ±0.07 *J* in Q_{obs} (ca. 0.8%). Our results are ca. 15% higher than those of Silva and Samões (21) (temperature coefficient method) and ΔH_1 is ca. 6% higher than that reported by Degischer and Nancollas (1). No attempt was made to measure ΔH_3 and ΔH_4. It was anticipated that these enthalpy values for carboxylate protonation would be very small (22); subsequent calorimetric work on metal–EDDA species was limited to the pH range where $([H_3L] + [H_4L])/C_L < 0.02$.

Ligand Stability

It was observed that the pH of solutions of Zn or Cd and EDDA increased with time at 25°C. The pH increased by ca. 0.01–0.02/12 h in the composition range $\bar{n}_L = 0.1$–0.8, and by ca. 0.03 (Zn) or 0.1 (Cd)

at $\bar{n}_L = 0.9$. Solutions stored at 4°C gave reproducible titration curves after 12 and 24 h. The increase in pH, and decrease in calculated values of K_1, were consistent with either a rearrangement or hydrolysis of the ligand to give product(s) which were more basic and/or weaker complexing agents. An nmr study on a solution of EDDA in D_2O/CF_3COOH at pH 2.25 ($\bar{n}_H \sim 3.0$) established a slow reaction with a half-life of ca. 14 days at 25°C; zinc ions (Zn/EDDA ~ 1) increased the reaction rate ca. 1.5-fold. The resonance for N—CH_2—CH_2—N protons of EDDA broadened and split, indicating the non-equivalence of the two nitrogen atoms in the product species, while the resonance for —CH_2—COOH methylene protons split into two new downfield absorptions. An hydrolysis reaction to give glycollic acid and ethylenediamine-*N*-acetic acid, or an intramolecular condensation to give a cyclic amide, $\overline{CH_2CH_2NHCH_2CO}NCH_2COOH$, has products consistent with the observed pattern of nmr resonances. Comparison with the spectrum for glycollic acid in the reaction medium established that this was not a reaction product (glycollic acid resonance was ca. 1–2 Hz downfield from the low field —CH_2COOH resonance).

Metal Complexes

log *K* values for the formation of complexes [ML] and [ML(OH)] are given in Table 2 and compared with those reported by other workers. Individual values of log K_1 showed no drift in the range $\bar{n}_L$ 0.1–0.9 for freshly prepared solutions and thus it is unlikely that protonated species $[M(HL)]^+$ are formed. (For solutions aged at 25°C log K_1 decreased by ca. 0.21 as $\bar{n}_L$ increased from 0.1 to 0.9, an observation which would be consistent with formation of a protonated complex. It is possible that the postulates of species $[M(HL)]^+$, M = Co, Zn, Pb (3, 5), are based on data for aged solutions.) The published value (5) of log *K* ($[CoL] + H^+ \rightleftharpoons [Co(HL)]^+$) = 4.20 gives a value of log *K* ($Co(aq)^{2+} + HL^- \rightleftharpoons [Co(HL)]^+$) = 5.8 which is greater than log *K* for the cobalt(II)–glycinate complex (5.1) (23); one would expect bidentate HL (—$OOCH_2\overset{+}{N}H_2$-$CH_2CH_2NHCH_2COO^-$) to form a less stable complex than glycine cf. the relative stabilities of cobalt(II) complexes and amino acids $\overset{+}{N}H_3(CH_2)_x$-$CH(NH_2)COO^-$ (24). The published values of log *K* for $[M(HL)]^+$, M = Cu, Pb, Zn, give rise to a similar disparity with the data for glycine.

The log K_1 values reported here are uniformly lower (ca. 0.2) than those reported by Degischer and Nancollas (1). This discrepancy relates in part to their neglect of log k_3 (e.g. for Mn we calculate log $K_1 = 6.93 \pm 0.05$ by use of their log k_1 and log k_2) and in part to the different methods of estimating $[H^+]$ from pH_m (for a discussion on this point see ref. 11). The ΔI values reported for [MnL] and [ZnL] are in close agreement with those of Degischer and Nancollas (1), but the value for [CdL] is significantly different (this work, 5 titrations). Values for [PbL] and $[ML(OH)]^-$ have not been reported previously.

The entropy changes for formation of [ML] complexes are all similar; this could be interpreted as indicating a similar reaction for each metal ion, viz.

$$M(aq)^{2+} + L^{2-} \rightarrow [ML(H_2O)_x] + (6 - x)H_2O$$

However, the partial molal entropies of the reactant ions $M(aq)^{2+}$ are very different (−83.7, −106.5, −61.1, and +23 J K^{-1} mol^{-1} for Mn, Zn, Cd, and Pb respectively (25)). Assuming that the entropies for the larger, neutral, complex species [ML] may be less dissimilar, the sum

$$\Delta S + \bar{S}_{M(aq)^{2+}} (= (6 - x)\bar{S}_{H_2O} + \bar{S}_{[ML]} - \bar{S}_L)$$

can then be used to infer differences in the nature of the species $[ML(H_2O)_x]$. The values of $\Delta S + \bar{S}_{M(aq)^{2+}}$ for Mn, Zn, Cd, and Pb are 38, 22, 58, and 133 J K^{-1} mol^{-1}, respectively, suggesting that for Pb the term $(6 - x)H_2O$ is significantly larger, i.e. the Pb atom has a lower co-ordination number in the complex, probably four, as compared with six for the other ions. The difference of ca. 90 J K^{-1} mol^{-1} in $\Delta S + \bar{S}_{M(aq)^{2+}}$ for Pb and the other metals represents the contribution to ΔS from the release of *n* more water molecules from the co-ordination sphere of the Pb atom, i.e.

$$n\bar{S}_{H_2O} + \bar{S}_{[PbL]} - \bar{S}_{[ML(H_2O)_n]} \sim 90 \text{ J K}^{-1} \text{ mol}^{-1}$$

Given that $\bar{S}_{H_2O} = 70$ J K^{-1} mol^{-1} (16) a value of $n = 2$ would appear consistent with the experimental data.

The significantly different values of both ΔH_D and ΔS_D for the formation of $[ZnL(OH)]^-$ and $[PbL(OH)]^-$ afford further evidence for different structures for these two ions. The negative value of ΔS_D for $[PbL(OH)]^-$ would be consistent with the loss of entropy of a solvent water molecule ($[PbL] + H_2O \rightarrow [PbL(OH)]^- + H^+$; ΔS_D − 82 J K^{-1} mol^{-1}) in contrast to the deprotonation of a co-ordinated water molecule ($[ZnL(H_2O)_2] \rightarrow [ZnL(OH)H_2O]^- + H^+$; ΔS_D + 2 J K^{-1} mol^{-1}). The value of $\Delta S'$ for the reaction

$$[ML] + OH^- \rightarrow [ML(OH)]^-$$

is given by $\Delta S' = \Delta S_D + \Delta S_W$ where ΔS_W(= +80 J K^{-1} mol^{-1}) (16) is for the reaction $H^+ + OH^- \rightarrow H_2O$. The values are +82 and −2 J K^{-1} mol^{-1} for

TABLE 3. Comparison of some thermodynamic data for formation of ML complexes where L = aminopolycarboxylate or polyamine. The data are for $t \sim 25°C$, $\mu \sim 0.1$ ($-\Delta H$, in kJ mol^{-1}; ΔS in J K^{-1} mol^{-1})

Zn and Pb respectively; these may be compared with values for complexes $[ML(H_2O)_n]^{2+}$ ($n \neq 0$) where L is a triamine ligand: M = Cu^{2+}, L = 3-azaheptane-1,7-diamine ($\Delta S' = +66$ J K^{-1} mol^{-1}) (26), 4-azaheptane-1,7-diamine (47) (ref. 27), 3-azahexane-1,6-diamine (58) (ref. 28); M = Zn^{2+}, L = 4-azaheptane-1,7-diamine (47), 3-azahexane-1,6-diamine (94) (ref. 28).

It is appropriate to compare the results of this work with comparable data for other aminopolycarboxylic acids. The extensive compilation by Wright, Holloway, and Reilley (29) deals mainly with ethylenediaminetetraacetic acid and structurally related ligands which are 6-dentate ligands. It is probably more suitable to compare a 4-dentate ligand where the number of bonds formed and solvent molecules displaced may be the same as for EDDA. In Table 3 are compiled data from standard sources (23, 30) showing such comparisons. As 4-dentate ligands NTA (one nitrogen, three oxygen donors) and TRIEN (four nitrogen donors) are listed. There are few obvious inferences to be drawn from this information. In all the cases listed EDDA stands intermediate between NTA and TRIEN, with clear evidence of the greater energy of the metal–nitrogen bonds as apparent in the greater enthalpy decreases in passing through the sequence NTA → EDDA → TRIEN. This is particularly the case with the d^{10} acceptor ions Zn^{2+} and Cd^{2+}. The near equivalence of $-\Delta G_1$ in passing from NTA to EDDA suggests an isokinetic relationship among the metal complexes of these two ligands, but further investigation is required before such speculation should be undertaken.

The addition of 2,4-dinitrobenzenesulphenyl chloride to 1,3-disubstituted allenes: a reexamination

DENNIS G. GARRATT AND PIERRE BEAULIEU

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received June 29, 1978

DENNIS G. GARRATT and PIERRE BEAULIEU. Can. J. Chem. **57**, 119 (1979).

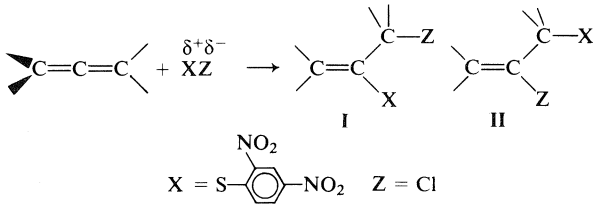
The reaction of 2,4-dinitrobenzenesulphenyl chloride with eight alkyl 1,3-disubstituted allenes in methylene chloride solution has been investigated. In contrast to earlier reports, attack by sulphur is found to occur exclusively at the central allenic carbon. The direction of approach of sulphenyl chloride leads preferentially to the formation of the *E* isomers in accord with the concept of steric approach control. The ratio of *E* to *Z* alkene is found to increase as the bulk of the substituent group *cis* to the arylthio group increases. We observe, however, very little regioselectivity with respect to which of the mutually perpendicular π bonds of the allene system is attacked, suggesting the presence of an effective mechanism for transmission of inductive effects to the more distant double bond.

DENNIS G. GARRATT et PIERRE BEAULIEU. Can. J. Chem. **57**, 119 (1979).

On a examiné la réaction du chlorure de dinitro-2,4 benzènesulfényle avec huit allènes dialkylés aux positions 1 et 3 dans le chlorure de méthylène. Contrairement à certains travaux antérieurs, on observe que l'atome de soufre attaque exclusivement le carbone allénique central. L'approche du chlorure de sulfényle se fait selon une direction qui conduit de préférence à la formation des isomères *E*, comme le prévoit le concept de contrôle par l'approche stérique. Il y a augmentation du rapport entre les alcènes *E* et *Z* lorsque la taille du substituant en position *cis* par rapport au groupe arylthio augmente. Cependant, on note très peu de régiosélectivité dans l'attaque des doubles liaisons π mutuellement perpendiculaires du système allénique. Ce fait laisse supposer qu'il existe un mécanisme efficace pour transmettre les effets inductifs à la double liaison la plus éloignée.

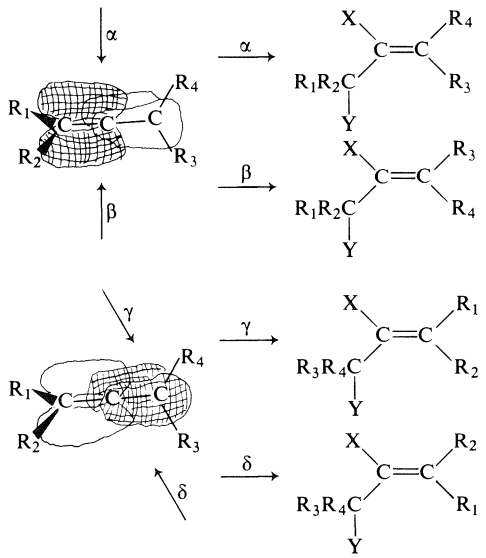
[Traduit par le journal]

It has been reported by Jacobs and Kammerer (1) that 2,4-dinitrobenzenesulphenyl chloride adds to 2,3-pentadiene, 2,3-hexadiene, and 3,4-heptadiene to give products of both type **I** and type **II** regio-



chemistry, the major adduct being of type **I** (eq. [1]). In contrast, no type **II** products were detected under similar reaction conditions from reactions involving 1,2-cyclononadiene, 1,2-cyclotridecadiene, or 1,3-di(1-adamantyl)allene. These results are at variance with those of others (2) which indicate that a given electrophile generally yields products of only one regiochemical type.

The anomalous nature of these results suggested to us that perhaps an alternative interpretation might be applicable. When the two substituents on a given terminal allenic carbon atom are different, there exist two possible directions of approach by the electrophile as shown in Scheme 1.



SCHEME 1

Because of the *orthogonality* of the π systems, this leads to a series of *E* and *Z* isomers. Thus in the general case, $R^1R^2C{=}C{=}CR^3R^4$, where $R^1 \neq R^2 \neq R^3 \neq R^4$, there exist eight possible addition products for an unsymmetric electrophile.

CH_3	C_2H_5	53:47	66:34	86:14
CH_3	iC_3H_7	52:48	65:35	95: 5
CH_3	tC_4H_9	42:58	69:31	100: 0

We wish to present experimental evidence which has a direct bearing upon this question.

Results

The addition of 2,4-dinitrobenzenesulphenyl chloride (DNBSC) to eight alkyl 1,3-disubstituted allenes, **1**–**8**, at ambient temperature in methylene chloride solution has been investigated. The kinetically controlled product distributions are given in Table 1.

RCH=C=CHR′

1 R = CH_3, R′ = CH_3

2 R = CH_3, R′ = C_2H_5

3 R = CH_3, R′ = iC_3H_7

4 R = CH_3, R′ = tC_4H_9

5 R = C_2H_5, R′ = C_2H_5

6 R = iC_3H_7, R′ = iC_3H_7

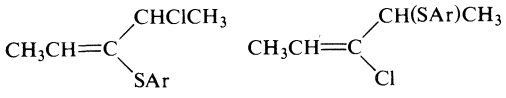
7 R,R′ = —$(CH_2)_6$—

8 R,R′ = —$(CH_2)_{10}$—

Although no variations in product ratios were observed during the course of the reaction, slow isomerizations were found to occur over a period of weeks. Analysis of ^1H and ^{13}C nmr spectra of the respective adducts suggests that these compounds are all formed via regiospecific attack of the arylthio moiety on the central allenic carbon giving mixtures of the isomeric *E* and *Z* alkenes.

For example, DNBSC reacts with 2,3-pentadiene, **1**, to give a 64:36 mixture of two adducts, **9** and **10**. The corresponding reaction with an unsymmetric allene, such as 2,3-hexadiene, yields four adducts. Spectral parameters are summarized in Tables 2–4.

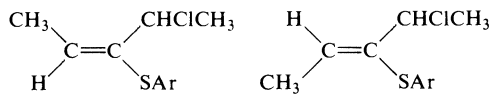
The original assignments of **9** and **10**, by Jacobs and Kammerer (1), as 4-chloro-2-penten-3-yl and 3-chloro-2-penten-4-yl 2′,4′-dinitrophenyl sulphides (see structures **9′** and **11**, configuration undefined)



9′ **11**

as assigned by Jacobs

were based on the chemical shifts of the vinyl protons (H_3 of Table 2) and the methine protons (H_4 of Table 2) using $ClCH_2C(SAr)=CH_2$, the product of the reaction of DNBSC with propadiene, as the model system. An examination of the literature suggests that the isomeric 3,4-dichloro-2-pentenes may be better models. Byrd and Caserio (3) have reported the following ^1H nmr parameters: *E* isomer δ H_3 5.74, H_4 5.10; *Z* isomer δ H_3 5.93, H_4 4.67. A comparison of these values with those of Jacobs and Kammerer (1) and with those given in Table 2 indicates that our alternative assignments as *E*- and *Z*-4-chloro-2-penten-3-yl 2′,4′-dinitrophenyl sulphide are also consistent with the available data.



9 **10**

These regiochemical assignments are substantiated by the ^{13}C nmr chemical shifts of the methine carbons (C_3, Table 3). Thus Jacobs and Kammerer (1) assigned the major adduct **9** as that having a chlorine bonded to the methine carbon whereas the minor component of structure **11** would have the arylthio group bonded to the methine carbon. One would therefore expect the methine carbon of the major adduct to resonate at lower field because of the known dependence of ^{13}C chemical shifts on the relative electronegativities of the substituents (Cl 2.99; S 2.48). In contrast we observed resonances at δ 54.8 and 61.5. This, of course, might be interpreted in terms of a reversal of the initial assignments but model systems[1] such as *E*-2-(*RS*)-, 5-(*RS*)-, and *E*-2-(*RS*)-, 5-(*SR*)-5-chloro-3-hexen-2-yl 4′-chlorophenyl sulphide exhibit *CH*(SAr) carbon resonances at δ 45.4, 45.3, and *CH*$ClCH_3$ carbon resonances

[1]G. H. Schmid, S. Yeroshalmi, and D. G. Garratt. Unpublished results.

at δ 56.9, 56.8, therefore suggesting that both **9** and **10** have allylic chlorines. An examination of one bond coupling constants ($J_{3,3}$, Table 4) confirms this. Thus $J_{3,3}$ for **9** and **10** is, respectively, 151.6 and 150.6. These values are in the range expected for a carbon directly bonded to a halogen, e.g., CH_3Cl ^1J = 148.65, CH_3Br ^1J = 150.5, CH_3I ^1J = 150.3 vs. $(CH_3)_2S$ ^1J = 138.5 (4).

Further indication of the correctness of our assignments is found in the mass spectra of **9** and **10** which exhibit α cleavage with loss of a $CHClCH_3$ radial fragment from the molecular ion. No fragments were observed which could be rationalized in terms of the loss of a radical or formation of a cationic species of the formula $CH(SAr)CH_3$, as would have been anticipated from an adduct of structure **11**.

The assignment of configuration for **9** and **10** as *E* and *Z*, respectively, follows from several criteria based on ^1H and ^{13}C chemical shifts and coupling constants. From Table 2 it is seen that for trisubstituted alkenes of this type the chemical shift of the proton H_3 is shielded in the *E* isomer relative to that of the corresponding *Z* isomer and that H_4 is deshielded in the *E* isomer relative to that of the corresponding *Z* isomer. This trend is seen in the reported values of numerous other 3,4-disubstituted-2-pentenes (3, 5).

In accord with the available data for similarly substituted systems the allylic proton–proton coupling constant $^4J_{HC=CCH}$ (*cis*) is observed to be slightly larger than $^4J_{HC=CCH}$ (*trans*) thus allowing **10** to be assigned the *Z* configuration in agreement with the proton chemical shift data (6). One must take care in the interpretation of $^4J_{H,H}$ values, however, since they are quite small and change their stereochemical proportionality depending upon the nature of the remaining substituents used to define the alkene system (7).

Of more diagnostic value are vicinal carbon–proton coupling constants of the form $^3J_{CC=CH}$. The values for $^3J_{CC=CH}$ (*cis*) and $^3J_{CC=CH}$ (*trans*) are normally widely different, the ranges just overlapping, with the *trans* coupling being larger than the corresponding *cis* interaction (8). An examination of Table 4 indicates that $J_{3,1}$ ($\equiv {}^3J_{CC=CH}$) is in accord with our configurational assignments and thus reinforces our initial analysis.

These assignments are furthermore confirmed by the observed ^{13}C chemical shifts. The stereochemical dependence of ^{13}C chemical shifts is well documented (9). One of the most useful trends of this sort is the *γ-gauche* interaction, whereby the presence of a γ substituent oriented *cis* to the carbon under observation leads to a shielding relative to the corresponding system with the substituent oriented *trans*. Based on this criterion one expects the methine

NOTE: Couplings marked with a * refer to the next carbon on the chain. Thus $J_{4,4}$ should read $J_{5,5}$ and $J_{9,9}$ as $J_{8,8}$ etc. Owing to problems of overlapping signals it was not possible to measure all coupling interactions between carbon and hydrogen.

carbon bonded to chlorine (C_3 of Table 3) to be shielded in the *E* isomer relative to the *Z* isomer. For example, C_3 of **9** resonates at δ 54.8 whereas C_3 of **10** resonates at 61.5. Little difference in chemical shifts would be expected for C_9 (see Table 3) in these isomers, since C_9 is always experiencing a *cis*-γ interaction.

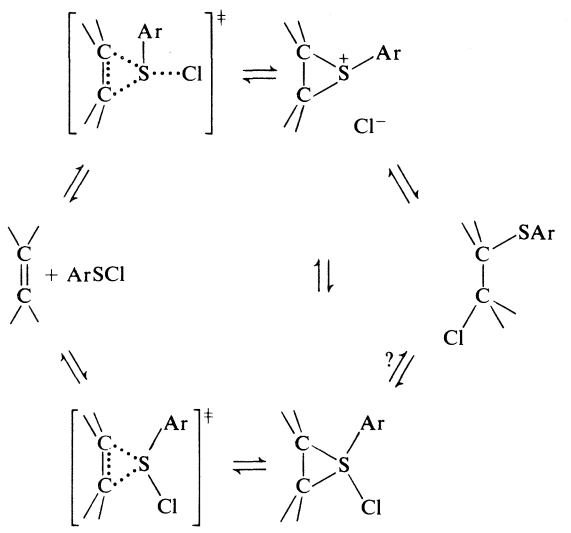
Discussion

From our data is it clear that the regiochemistry of the reaction of 2,4-dinitrobenzenesulphenyl chloride with 1,3-disubstituted allenes corresponds to exclusive attack by sulphur on the central allenic carbon. In all cases the *E* isomer is found to be formed preferentially, in contrast to related studies of the halogenation and mercuration of acyclic 1,3-disubstituted allenes (see for example refs. 5*a–c* and 10). The ratio of *E* to *Z* alkene is found to increase as the bulk of the substituent group ($CH_3 < C_2H_5 < iC_3H_7 < tC_4H_9$) *cis* to the arylthio group increases. It is interesting to note, however, that the alkyl substituent on the double bond which is attacked does not affect this ratio to any degree. Furthermore we observe very little regioselectivity with respect to which of the mutually perpendicular π bonds of the allene system is attacked, suggesting the presence of an effective mechanism for the transmission of the inductive electron donation of the alkyl groups to the remote double bond.[2]

The reaction of sulphenyl halides with alkenes is generally considered to follow an Ad_E2 mechanism (11) similar to the one first proposed by Kharasch and Buess (12) as shown in Scheme 2. The first step is believed to be rate-determining formation of a thiiranium ion which subsequently undergoes nucleophilic attack by the halide ion in a fast step.

The mechanistic path for the analogous addition to allene is less clear. The observation of second-order kinetics for the reaction of DNBSC with phenylpropadiene (13) and for the reactions of benzene- and 4-chlorobenzenesulphenyl chlorides with propadiene and its six methyl-substituted derivatives (14) is in accord with the Ad_E2 mechanism.

The reaction of DNBSC with partially resolved 2,2-dimethyl-3,4-hexadien-1-ol has been reported (15) to give an optically active cyclic adduct **12**, consistent with the formation, during addition, of an unsymmetric intermediate such as the alkylidenethiiranium ion **13** or an alkylideneepisulphurane **14** (see Scheme 3) (16). The extent to which the reaction is truly stereospecific has, however, yet to be determined. The available data, therefore, although consistent with the proposed intermediates do not rule out the presence of alternative species, such as allylic carbonium ions, on the reaction coordinate.



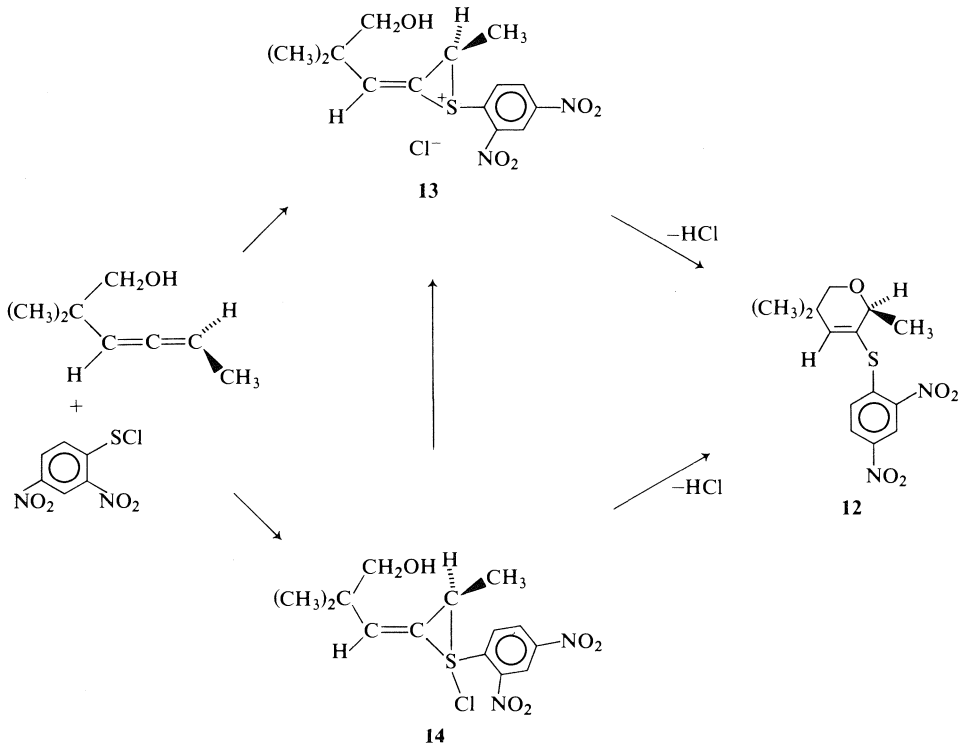
SCHEME 2

As can be seen from Scheme 1, a complicating factor in these studies is the presence of up to four competing reaction pathways, corresponding to the four independent modes of approach to the allenic system. Reducing the problem to one of only two competing pathways is, however, readily accomplished by examining the cases of symmetric allenes. In Scheme 4 a generalized reaction path for the additions is given. If one ignores for the time being the probable occurrence of a cyclic intermediate, such as **13′** or **14′**, the most likely species would be a nonplanar allylic carbonium ion **15**. One would anticipate however that **15** will undergo rapid bond rotation to give the resonance stabilized allylic ion, **16**.

If the activation energy for product formation is very small compared with the barrier height for interconversion among the allylic ions or for that matter between any of the proposed cyclic species, the ratio of products is equal to the ratio of the population of the starting states.

An examination of Scheme 4 indicates that such a scenario is equivalent to stating that the ratio of products corresponds to the percentage of attack on each face of the π system, or in other words reflects the direction of approach of the electrophile towards the allenic system. The same argument holds if one considers the nonplanar allylic ions or the alkylidenethiiranium ions, etc. Within the context of this

[2]Kinetic evidence for the transmission of substituent effects across both double bonds of allenes has recently been reported for the reaction of 4-chlorobenzenesulphenyl chloride and benzenesulphenyl chloride with the methyl-substituted allenes. See ref. 14.



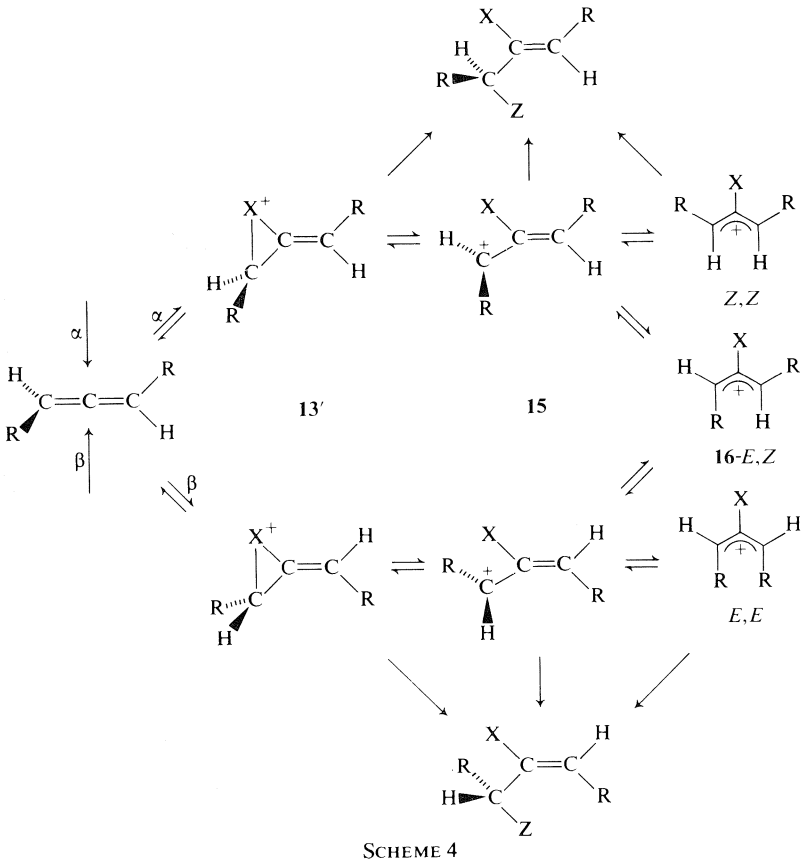
SCHEME 3

mechanism one would expect to observe 'steric approach control' where the steric interactions in the transition state are of the long range type between attacking reagent (DNBSC) and the substrate molecule (allene), which is in its ground state geometry (17).

Alternatively, if the activation energy of the reaction is large compared with the barrier to interconversion between intermediates of opposite configuration (for example, *E*- and *Z*-alkylidenethiiranium ions or *Z*,*Z*- and *E*,*Z*-allylic ions), the proportion of the products will in no way reflect the relative populations of the ground state configurations but will depend only on the activation energies of the processes leading to these products. Stated somewhat differently this implies that the ratio of two products formed from one starting material depends only on the difference in the free energy levels of the two transition states (18).

The available data appear to be in accord with the first scenario, our product distributions reflecting steric approach control. If the latter situation were of importance one would anticipate a predominance of the *Z* isomer under conditions where optical activity is conserved. For example, were the barrier to interconversion of the *E*- and *Z*-alkylidenethiiranium ions low, as a result of a fast reversible elimination–addition sequence, the activation energies for product formation would reflect the propensity for nucleophilic attack on the back side of the three-membered rings. Steric factors in such a case would be expected to favour attack on the less hindered *Z*-alkylidenethiiranium ion. The activation energy for attack on the ion of *Z* configuration should, therefore, be lower than the activation energy for attack on the *E* configuration leading to the preferential formation, stereospecifically, of *Z* alkenes. This is, however, the opposite to what we observed under conditions of kinetic control.

The presence of only one adduct from the reaction of DNBSC with 1,2-cyclononadiene, **7**, can now be rationalized in terms of steric hindrance to approach at one face of each double bond (Scheme 5). Studies using Dreiding models clearly indicate that attack on **7** to give the *Z* isomer would involve attack on the most hindered face of each double bond (i.e., from the inside of the ring). Similar results have been previously reported by Moore and Bertelson (16). The formation of both *E* and *Z* alkenes from 1,2-cyclotridecadiene, **8**, is indicative of the greater conformational flexibility of the 13 carbon ring system compared to rings of 9 or 10 carbons. Comparing the *E* to *Z* ratios for addition to 1,2-cyclotridecadiene, **8** (*E*:*Z* ≡ 86:13) and 3,4-heptadiene, **5** (*E*:*Z* ≡



SCHEME 4

80:20) further indicate that the steric constraints imposed on **8** by its cyclic structure are no larger than those of the acyclic allene **5**.

Experimental

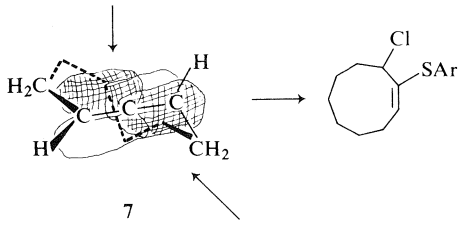
Proton and carbon-13 nmr spectra were run on Varian Associates HA-100 and FT80 spectrometers, respectively. Determination of carbon–proton coupling constants was based on first-order analysis of the fully coupled natural abundance ^{13}C spectra.

2,4-Dinitrobenzenesulphenyl Chloride

This was prepared by the method of Kharasch and co-workers (19).

Allenes

2,3-Pentadiene was commercially available from Chemical Samples Co.; 2,3-hexadiene, 3,4-heptadiene, 5-methyl-2,3-hexadiene, 5,5-dimethyl-2,3-hexadiene, 2,6-dimethyl–3,4-heptadiene, 1,2-cyclononadiene, and 1,2-cyclotridecadiene were prepared by the methods of Doering and LaFlamme (20), Skatteböl (21), and Moore and Ward (22).



SCHEME 5

The Reaction of 2,4-Dinitrobenzenesulphenyl Chloride with Allenes

General Procedure

To a solution of 2,4-dinitrobenzenesulphenyl chloride (1.40 mmol) in 10 ml of anhydrous methylene chloride was added an equivalent (1.40 mmol) of the respective allene. The mixture was stirred at room temperature for a period of approximately 6 days until no further reaction was observed. After the solvent was evaporated, the residual oil which corresponded to a quantitative yield, was analyzed by ^1H and ^{13}C nmr and mass spectroscopy. No variation in product distribution was observed during the course of the reactions.

Molecular reorientation in solid *sym*-triazine[1]

J. A. RIPMEESTER
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9
AND
R. K. BOYD
Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received June 14, 1978

J. A. RIPMEESTER and R. K. BOYD. Can. J. Chem. **57**, 128 (1979).

Molecular motion in solid *sym*-triazine was investigated using continuous wave and pulsed ^{1}H nmr methods between 290 and 350 K. In addition, the potential energy profile of the *sym*-triazine molecule as a function of orientation in the crystal lattice was calculated. From the nmr results, only one motional process was identified, in-plane reorientation of *sym*-triazine molecules with an activation energy of 15 kcal/mol. This is in agreement with the potential energy calculation which also shows that the reorientation takes place between equivalent sites.

J. A. RIPMEESTER et R. K. BOYD. Can. J. Chem. **57**, 128 (1979).

Opérant entre 290 et 350 K et faisant appel à des méthodes de rmn du ^{1}H pulsées et en fonction continue, on a étudié les mouvements moléculaires de la *sym*-triazène solide. De plus, on a calculé le profil du potentiel d'énergie de la molécule de *sym*-triazine en fonction de son orientation dans le réseau cristallin. Sur la base des données rmn, on a pu identifier un seul processus de mouvement, une réorientation dans le plan des molécules *sym*-triazine avec une énergie d'activation de 15 kcal/mol. Ce résultat est en accord avec le calcul d'énergie potentielle qui montre aussi que la réorientation se produit entre deux sites équivalents.
[Traduit par le journal]

Introduction

At ambient temperature and pressure, *sym*-triazine consists of transparent, easily sublimable crystals. These characteristics are some of the criteria used by Timmermans (1) to denote the class of 'plastic crystals.' Since general molecular reorientation and self-diffusion are other characteristics of plastic crystals, it was thought to be of interest to further investigate molecular motion in *sym*-triazine. Previously (2), threefold, in-plane reorientation was identified in both the high and low temperature phases of *sym*-triazine using ^{14}N nuclear quadrupole resonance, and motional rates were studied as far as the fade-out temperature near 280 K.

We have measured ^{1}H nmr linewidths and second moments between ~200 K and the melting point at 359 K and static and rotating frame ^{1}H spin–lattice relaxation times between ~280 and 340 K. In addition, the potential energy profile for the rotation of a *sym*-triazine molecule at its lattice site was calculated using an atom–atom approximation to the intermolecular forces.

Experimental

sym-Triazine was purchased from Aldrich Chemical Co. and was vacuum sublimed several times before use. Samples for the nmr measurements were prepared by sealing in Pyrex tubes small quantities of *sym*-triazine after outgassing by freeze–pump–thaw cycles. ^{1}H nmr lineshapes were recorded at a frequency of ~56 MHz using a marginal oscillator spectrometer with field modulation and lock-in detection. Second moments were calculated from the lineshape by a numerical integration procedure. ^{1}H spin–lattice relaxation times were measured at a frequency of 10 MHz using a Bruker SXP pulse nmr spectrometer; rotating frame relaxation times were made using a 90° pulse followed immediately by a variable length spin-locking pulse of amplitude 14 G.

The model used to estimate the potential energy profile for in-plane rotation of a *sym*-triazine molecule at its lattice site was identical in all essential respects to that used earlier (3) for the case of pyrazine. The charge distribution within the molecule was taken from published calculations (4). In addition, the nitrogen atom with its lone pair was simulated by an isoelectronic C—H group, with a bond length of 0.7 Å and a bond dipole moment of 2.2 D (3). Two sets of parameters for the C—C, C—H, and H—H potential energy functions were used; the first (5) is characterised by 'hard' repulsive contributions for H-atom interactions and the second (6) by 'softer' repulsions.

Results and Discussion

The potential energy profiles for the rotation of a *sym*-triazine molecule at its lattice site, calculated using the 'hard' and 'soft' repulsion parameters and the X-ray structure (7) of solid *sym*-triazine are shown in Fig. 1. They are qualitatively similar and show that the motion of the *sym*-triazine molecule consists of in-plane jumps of 120° between indis-

[1]NRCC No. 17065.

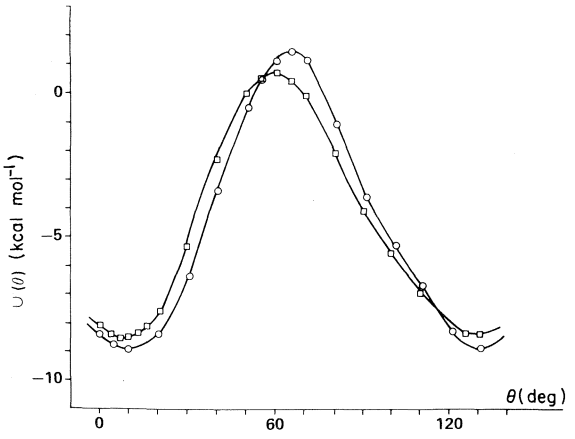

FIG. 1. Potential energy profile for the *sym*-triazine molecule on rotation in its molecular plane (circles, 'hard' repulsion parameters; squares, 'soft' repulsion parameters).

tinguishable orientations of the molecule with respect to the crystal lattice. The calculated activation energy for the thermally activated motion (twice the difference between potential minima and maxima (8, 9)) is 18 kcal/mol for the 'soft' repulsion parameters and 21 kcal/mol for the 'hard' repulsion model.

^{1}H nmr spectra, obtained between 200 and 340 K, were structureless, broad lines. Second moments calculated from suitably digitized lineshapes are shown in Fig. 2; motional narrowing is evident between 250 and 315 K. The limiting low and high temperature second moment values were 3.5 ± 0.1 and 0.72 ± 0.03 G^2, respectively. Theoretical second moments were calculated for two models. The first of these was a static model; Van Vleck's (10) equation was used to calculate the lattice sums using proton coordinates derived from a neutron diffraction study (11). Interactions of protons with other nuclei were neglected. The second model was a dynamic one, where the *sym*-triazine molecules were allowed to jump between the three potential wells evident from the potential energy profiles. Further details of calculations of this nature, made using the equations derived by Michel *et al.* (12), are given elsewhere (13); it suffices to give the results here. The theoretical second moments were 3.25 and 0.77 G^2 for the static and dynamic models, respectively, in good agreement with the limiting low and high temperature experimental second moments of 3.5 ± 0.1 and 0.72 ± 0.3 G^2.

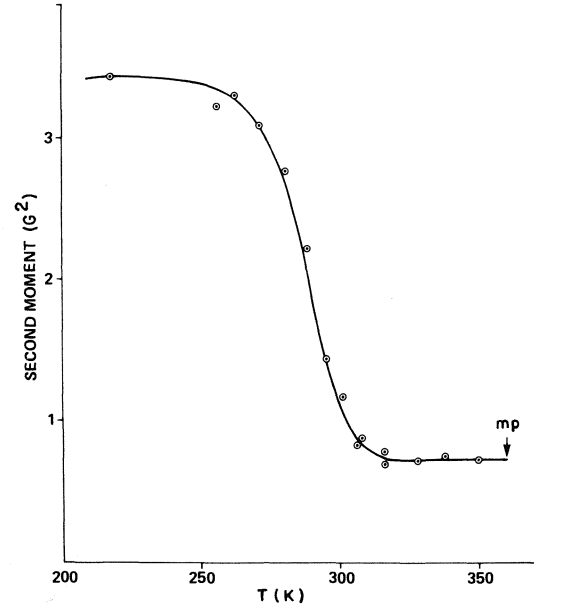

FIG. 2. ^{1}H second moments for solid *sym*-triazine shown as a function of temperature.

Figure 3 shows the static (T_1) and rotating frame ($T_{1\rho}$) spin–lattice relaxation times as a function of inverse temperature. T_1 decreases monotonically with increasing temperature, $T_{1\rho}$ has a minimum of 0.72 ms at 314 K. Spin–lattice relaxation, in this instance, is brought about by modulation of both intra- and inter-proton dipolar interaction by means

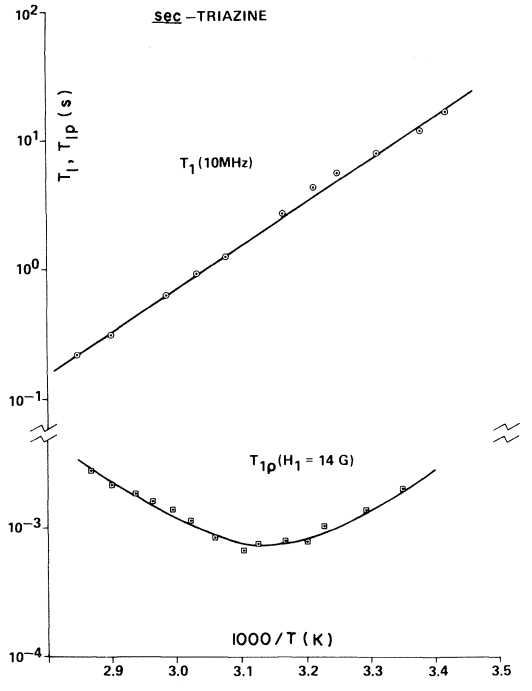

FIG. 3. Static and rotating frame (T_1 and $T_{1\rho}$, respectively) ^{1}H relaxation times of solid *sym*-triazine plotted as a function of inverse temperature (solid lines are calculated, see text).

of the threefold reorientations of *sym*-triazine molecules. The appropriate equations are (14);

$$T_1^{-1} = \frac{2}{3}\gamma^2\Delta M_2 \left\{\frac{\tau_c}{1 + \omega^2\tau_c^2} + \frac{4\tau_c}{1 + 4\omega^2\tau_c^2}\right\}$$

$$T_{1\rho}^{-1} = \frac{2}{3}\gamma^2\Delta M_2 \left\{\frac{2.5\tau_c}{1 + \omega^2\tau_c^2} + \frac{\tau_c}{1 + 4\omega^2\tau_c^2} + \frac{1.5\tau_c}{1 + 4\omega_1^2\tau_c^2}\right\}$$

where γ is the proton gyromagnetic ratio, ω is the radiofrequency used, and ΔM_2 is the portion of the second moment modulated by the motion. The motional correlation time τ_c is assumed to follow Arrhenius behaviour according to $\tau_c = \tau_0 \exp(\Delta E/RT)$ where ΔE is an activation energy. The solid lines in Fig. 2 were calculated with the following choice of parameters; $\Delta M_2 = 2.84$ G^2, $\tau_c = 6.62 \times 10^{-17} \exp(7550/T)$, indicating a reorientational activation energy of 15.0 kcal/mol. This ΔM_2 value, 2.84 G^2, is in good agreement with the value obtained by subtracting the limiting high temperature second moment from the limiting low temperature second moment, namely 2.75 G^2.

The activation energies indicated by the energy profile calculations are also in general agreement with the experimental value. The result obtained for the 'soft' repulsion model seems preferable in two respects. First, the calculated minimum in the potential profile is closer to the experimentally determined (7) crystallographic orientation than is the case for the 'hard' repulsion model; secondly, the calculated activation energy, ($\sim$18 kcal mol^{-1}) for the thermally activated motion is closer to the experimental value (15 kcal mol^{-1}) than the theoretical value ($\sim$21 kcal mol^{-1}) obtained using large repulsive parameters.

The two profiles (Fig. 1) do, however, agree on the main qualitative feature of the motion, viz. that it consists of in-plane jumps of 120°, between indistinguishable orientations of the molecule with respect to the crystal lattice. This is consistent with the observation of an ordered lattice of *sym*-triazine molecules by diffraction studies (7, 11). There should therefore by *no* thermal anomaly *directly* associated with the onset of this motion, since no disorder is thereby produced. The thermal transition previously observed (15) to occur between about 170 and 215 K involved a large-scale change in the crystal structure.

The qualitative feature of the crystal structure of *sym*-triazine, which accounts for in-plane motion by 120° jumps, is the same as that shown previously (16) to account for the difference in crystal packing between *sym*-triazine and benzene. In neither case are the electrostatic contributions of much importance; rather, any attempt to replace a nitrogen atom with its lone pair by a C—H group, e.g., substituting a benzene molecule for a triazine, in the *sym*-triazine lattice, results in short H---H and H---lone pair distances, with consequent large repulsive contributions to the total intermolecular potential energy. This is the basic reason (16) why benzene packs in the 'herring-bone' pattern, rather than in the 'parallel-stack' structure of *sym*-triazine; similarly, rotation of one *sym*-triazine molecule, by 60° in its plane, replaces all N lone pair groups by C—H groups. The discrepancy in the corresponding effective bond lengths ($\sim$0.7 Å as opposed to $>$1.0 Å) is sufficient, within the tight packing of the *sym*-triazine structure, to introduce large H—H repulsive interactions which dominate the potential energy of the rotated molecule.

Previously (2), threefold molecular reorientation of *sym*-triazine molecules has been identified at temperatures below $\sim$270 K using ^{14}N nqr measurements. In these studies (2), the activation energy for the motion was found to be 14 kcal/mol from spin–lattice relaxation measurements between 200 and 250 K and 15 kcal/mol from the exchange broadening contribution to spin–spin relaxation between $\sim$250 and 275 K. Thus the ^{14}N nqr values are in good agreement with the ^{1}H nmr value obtained between 290 and 350 K.

In concluding, we can state that all methods, including the diffraction (7, 11), ^{14}N nqr (2) and ^{1}H nmr measurements, as well as the potential calculations are consistent with a model where *sym*-triazine molecules reorientate in the plane of the molecule about the molecular threefold axis.

Carbon-13 spectra of 2,5-dihydrothiophenes and their 1,1-dioxides

JOHN M. MCINTOSH

Department of Chemistry, University of Windsor, Windsor, Ont., N9B 3P4

Received June 23, 1978

JOHN M. MCINTOSH. Can. J. Chem. **57**, 131 (1979).

The complete carbon-13 nmr spectra of 16 alkylated 2,5-dihydrothiophenes and 10 sulfones derived from them are reported. No significant interactions between C-2 substituents and C-5 are noted and stereochemical determinations based on this γ effect are not possible. On oxidation to the sulfones, C-2 and C-5 are dramatically deshielded but C-3 and C-4 are shielded. A possible explanation for this effect is presented.

JOHN M. MCINTOSH. Can. J. Chem. **57**, 131 (1979).

On rapporte les spectres rmn du ^{13}C complets de 16 dihydro-2,5 thiophènes alkylés et de 10 sulfones qui en dérivent. On ne note aucune interaction importante entre les substituants en C-2 et en C-5; des déterminations de stéréochimie basées sur cet effet γ ne sont donc pas possibles. L'oxydation en sulfones provoque un déblindage important en C-2 et en C-5; les C-3 et C-4 sont blindés. On propose une explication possible de cet effet.

[Traduit par le journal]

Recently, we have been concerned with the preparation of substituted 2,5-dihydrothiophenes (**1**) and the utilization of these as precursors of conjugated dienes for use in the Diels–Alder reaction. Central to this problem is the question of the stereochemistry of **1**. Since the conversion to dienes ([1]) is known to be completely stereospecific, the stereochemistry of **1** controls both that of **3** and of the Diels–Alder products. We have previously determined the stereochemical composition of **1** by analysis of **3** (2) but a

[1] 
1 **2** **3**

direct method for this determination would be preferable. The ^{13}C nmr chemical shifts of organic compounds are well known to be extremely sensitive to steric effects (3) and therefore we have investigated the carbon spectra of a series of **1** and **2** to ascertain if predictable trends could be detected which would allow differentiation of stereoisomers.

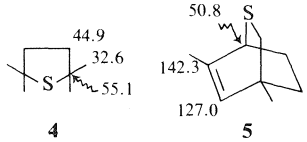
Experimental

The compounds used were prepared as previously outlined (ref. 1 and references therein and refs. 4 and 5). ^{13}C nmr spectra were obtained as approximately 2 *M* solutions in $CDCl_3$ in 5-mm tubes on a Bruker CXP-100 instrument operating in the FT mode at 22.64 MHz and are reported in ppm downfield from TMS as internal standard. A flip angle of 36° was used and 3K–5K transients were collected for the noise-decoupled spectra. Single frequency off-resonance spectra required ca. 60K transients. In all cases the spectral width was 6000 Hz, quadrature detection was employed, and 8K data points were collected. Assignments of specific absorptions were made on the basis of off-resonance experiments, trends appearing within each series, and relative peak intensities. Where ambiguities exist, the absorptions are bracketed.

Results and Discussion

The spectra of **1** and **2** which bear only alkyl substitution are tabulated in Table 1. The stereochemistry of all these compounds was known from previous studies (2). Table 2 lists the spectra of some **1** and **2** which bear a carbomethoxy group at C-3.

Inspection of Table 1 (compounds **15**–**23**) reveals several trends. Carbon atoms attached directly to divalent sulfur absorb in the range of 39–60 ppm, depending on the degree of substitution. The α effect of a methyl group at C-2 falls in the range of 8–11 ppm, whether or not there is a substituent at C-3. (Compare **15**, **16**, **18**, **20** and **21**, **22**, **23**.) This value is in good agreement with the usual range of values in comparable hydrocarbons. The specific shifts are surprisingly close to similarly substituted cases which have considerably different molecular geometries (e.g., **4** (6), **5** (7)).



4 **5**

Neither the degree of substitution nor the relative stereochemistry at C-2 affects the chemical shift of C-5 significantly but the olefinic carbons are affected

in a manner analogous to the carbocyclic relatives (ref. 3, p. 78). Thus, the original aim of direct stereochemical analysis cannot be achieved.

For discussion purposes the chemical shifts of compounds **6**–**14** (3, 8, 9) are given in Fig. 1. From these data the following conclusions can be drawn. In both the saturated and unsaturated series, the α effect of divalent sulfur is deshielding (ca. −6 ppm), whereas the β-effect is deshielding in the saturated case ($\Delta\delta_{C\rightarrow S} = -5.8$) but shielding in the unsaturated one ($\Delta\delta_{C\rightarrow S} = +1.8$). This can be most conveniently rationalized on the basis of the differing molecular geometries of these ring systems. Compounds **9** and **10** have been shown (10, 11) to possess an essentially planar ring system whereas **6** and **7** are similar in shape to **8** (12). Appreciable *cis*-1,3-hydrogen γ interactions in **8** cause a shielding of the carbon atoms. When sulfur which lacks the hydrogens and has a considerably larger covalent radius than carbon is introduced, these 1,3 interactions are reduced, leading to the observed deshielding at C-3. Oxidation of **6** to **7** reintroduces these γ interactions resulting in little difference in the shifts of C-3 in **7** and **8** ($\Delta\delta_{C\rightarrow SO_2} = 0.4$). In the unsaturated series, distortion

[a]Relative to internal TMS; values in parentheses may be interchanged.

of the valence angle at C-3 by introduction of the large sulfur atom could account for the shielding at C-3 in **9** and further shielding is caused by introduction of a γ effect upon oxidation to **10**. The difference in magnitude of the shielding effect in the two series introduced by oxidation to the sulfones ($\Delta\delta_{S\rightarrow SO_2} = +6.2$ for the saturated system and +5.6 for the unsaturated one) can best be attributed to the differing ring geometries which result in reduced steric interactions in the planar system **10**. In the present work (Table 1) the same effects can be seen (compare **15–23** with **24–28**) where the shieldings ($\Delta\delta_{S\rightarrow SO_2}$) of C-3 and C-4 range from 3.5 to 5.5 ppm depending on the substitution pattern.

Whereas the effect of the introduction of S—O bonds on C-3 is different in the saturated and unsaturated systems, the data in Table 1 show that the same is not true for substituents at C-2. Previous

33–38	−15.4	+2.5	+5.1	−3.4

[a]A negative value indicates a deshielding effect.

work on the sulfoxides **13** and **14** (6) has shown that the C-2 methyl substituent *cis* to oxygen is strongly shielded ($\Delta\delta_{S\rightarrow SO} = 11$) but the effect on the *trans*-methyl group is smaller but still significant ($\Delta\delta_{S\rightarrow SO} = 8.3$). In the present work, all substituents at C-2 and C-5 are eclipsed with an S—O bond and this is reflected in shieldings of 8–12 ppm for methyl substituents (compare **16–25**, **17–26**, **23–28**) and 7.5–9.5 for methylene groups (compare **16–25**, **17–26**, **21–27**, **23–28**).

Turning to the data shown in Table 2, the same type of trends can be distinguished. Again the shielding of C-3 and C-4 are significant ($\Delta\delta_{S\rightarrow SO_2} =$ 2.5 to 7.2), the larger effect being uniformly at C-4. Also, although the effects of oxidation on C-2 and C-5 are approximately equal in **29** and **35**, the deshielding is affected dramatically by the degree and type of substitution. The data in Table 3 illustrate this point. No clear trend can be established from the available data. The chemical shift of the carbonyl group appears very insensitive to substitution at C-2.

In conclusion, the use of ^{13}C nmr to determine the stereochemical composition of 2,5-dihydrothiophenes does not appear to be feasible, presumably due to the planar ring which minimizes across-the-ring steric interactions. However, the chemical shift trends outlined may be useful in future structure determinations of sulfur heterocycles.

RAYMOND M. MORRISON, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **57**, 135 (1979).

Crystals of tetrakis(4-methylpyridine)cobalt(II) hexafluorophosphate, $C_{24}H_{28}CoF_{12}N_4P_2$, are tetragonal, space group $I4_1/acd$, $a = 18.434(7)$, $c = 18.818(6)$ Å, $Z = 8$. The structure was solved by direct and Fourier methods. The positional and anisotropic thermal parameters were refined by full-matrix least-squares methods to $R = 0.072$ for 346 observed reflexions. The structure consists of discrete $[Co(4\text{-mepy})_4]^{2+}$ and PF_6^- ions. The structure of the cation is a distorted tetrahedron of 4-methylpyridine ligands around cobalt (crystal symmetry S_4) and that of the anion is a distorted octahedron of fluorines around phosphorus (crystal symmetry C_2).

RAYMOND M. MORRISON, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **57**, 135 (1979).

Les cristaux de l'hexafluorophosphate du tétrakis(méthyl-4 pyridine) cobalt(II), $C_{24}H_{28}CoF_{12}N_4P_2$, sont tétragonaux, groupe d'espace $I4_1/acd$, $a = 18.434(7)$, $c = 18.818(6)$ Å, $Z = 8$. On a résolu la structure par des méthodes directes et de Fourier. On a affiné les paramètres thermiques anisotrope et de position par la méthode des moindres carrés (matrice complète) jusqu'à une valeur de $R = 0.072$ pour les 346 réflexions observées. La structure comporte des ions $[Co(Me\text{-}4Py)_4]^{2+}$ et PF_6 séparés. La structure du cation implique un tétraèdre déformé comportant des ligands méthyl-4 pyridine autour du cobalt (symétrie cristalline S_4) alors que celle de l'anion implique un octaèdre déformé comportant des fluors autour du phosphore (symétrie cristalline C_2).

Introduction

As a part of a study involving the synthesis and characterization of transition metal complexes containing anions of strong acids (1–4), we have synthesized a series of compounds, CoL_4A_2 (L = pyridine or 4-methylpyridine, A = PF_6^- or AsF_6^-). On the basis of spectral and magnetic data (3, 4), it was postulated that these compounds had structures involving tetrahedral coordination of neutral ligands around cobalt and non-coordinated anions. In order to confirm the structural assignments for this group of compounds and to determine more precisely the stereochemistry about cobalt and the arrangement of ions, we have now completed a single crystal X-ray diffraction study of $Co(4\text{-mepy})_4(PF_6)_2$.

Experimental

$Co(4\text{-mepy})_4(PF_6)_2$ was prepared as described previously (3). A saturated, filtered solution of the complex in a 1:1 mixture of dichloromethane and chloroform was allowed to evaporate slowly in an inert atmosphere chamber. After 1–2 weeks, the deep red-purple solution gave large elongated tetragonal crystals of the same color. The crystals were hygroscopic and were stored in the inert atmosphere chamber; however, the sealing of the crystals in Lindemann capillaries was done quickly in air and no apparent decomposition of the crystals was observed. The preliminary Weissenberg and precession photographs indicated a tetragonal space group and the systematic absences ($hkl: h + k + l = 2n + 1$; $hk0: h(k) = 2n + 1$; $0kl: l(k) = 2n + 1$; $hhl: l = 2n + 1$, $2h + l \neq 4n$) gave the space group as $I4_1/acd$ (D_{4h}^{20}, No. 142) (5).

The crystal chosen for data collection was mounted on a Datex-automated GE XRD-6 three-circle diffractometer equipped with a Mo-K_α ($\lambda = 0.7107$ Å) X-ray source with the

0008-4042/79/020135-04$01.00/0

c axis and the ϕ axis coincident. The unit cell parameters were determined by least-squares refinement on 12 manually centered reflections. Crystal data are: $C_{24}H_{28}CoF_{12}N_4P_2$, tetragonal, space group $I4_1/acd$, $a = 18.434(7)$ Å, $c = 18.818(6)$ Å, $V = 6395$ Å^3, $Z = 8$, $\rho_{calcd} = 1.50$ g cm^{-3}, $\mu = 7.60$ cm^{-1}.

Intensities were collected for $2\theta \leq 40°$, the scan range was $1.80 + 0.8$ (tan θ) with a speed of 2°/min, and the background was counted at the beginning and the end of each scan for 10 s. The strongest reflections were remeasured using a lesser current and extra zirconium filters and a second crystal (instrumental difficulties caused a delay of several months between the initial data collection and the remeasurement of the strong reflections; the second crystal was similar to the first, in size, shape, and orientation). The reflection 3 $\bar{3}$ 2, the intensity of which fluctuated randomly for the two crystals throughout data collection, was measured at intervals of 40 reflections and was used to scale the reflection data of the two crystals. The total number of independent reflections collected was 749. Lorentz and polarization factors were applied and standard deviations were calculated from $\sigma^2(I) = S + B + (0.04S)^2$ where S is the scan count and B is the background count. No absorption correction was made, since the absorption coefficient is low. A total of 347 reflections was considered observed with $I > 3\sigma(I)$ above the background.

Structure Determination

Although attempts to solve the structure with Patterson methods were unsuccessful, direct methods gave the solution. A total of 131 reflections with $E > 1.4$ and the computer programs TANS were used in the sign determining process. The starting set consisted of eight reflections, one for origin definition, five from Σ_1 relationships and two symbolic phases. Of the four sets generated, the one set which determined the phases of all reflections was used. The resulting E map gave cobalt at 8*a* (1/2,1/4,1/8, symmetry S_4) and phosphorus at 16*e* (0.10,0,1/4, symmetry C_2). Successive difference Fourier maps gave the position of the other ten non-hydrogen atoms; the resulting R value was 0.123 with isotropic temperature factors.

For the next three cycles of least-squares refinement, all atoms were given anisotropic temperature factors (symmetry constrained (6, 7) in the case of cobalt and phosphorus), a weighting scheme ($F_o \leq F^*$, $w = 1.0$; $F_o > F^*$, $w = F^*/F_o$; F^* = average $F_o = 80$) was employed, and the anomalous scattering (8) of cobalt and phosphorus was included. The values of R and R_w were 0.072 and 0.092 for 346 reflections (one reflection 4 −11 5 was considered poorly measured and is omitted, $F_o = 27.0$; $F_c = 2.0$). A subsequent cycle of least squares gave a maximum parameter shift of 0.024σ. The hydrogen atom positions were not determined. The observed and calculated structure factors have been placed in the Depository of Unpublished Data.[1] The final positional and thermal parameters are given in Tables 1 and 2.

Results and Discussion

The structure consists of distinct $[Co(4\text{-mepy})_4]^{2+}$ cations and PF_6^- anions. The closest contact between the cations and anions is 3.28(3) Å for F(2)...C(6), which is just less than the van der Waals contact distance of 3.35 Å for a fluoride and a methyl group (9). The closest contact between cobalt and the anions is 4.21(2) Å to F(1), which is well out of the range for interaction. Figure 1 shows a stereoview of the packing of the nearest anions about the cation. The Co...P distance is 5.499(4) Å and the P...Co...P angles are 100.54(2)° and 129.35(4)°. The other Co...P distances in the lattice are all greater than 8.0 Å.

Figure 2 shows a stereoview of the cation. The cobalt atom has crystallographic S_4 symmetry. The distortion of the cation from tetrahedral symmetry is shown by the compression along the S_4 axis and the orientation of the rings. The compression is shown by the N—Co—N angle of 101.2(9)° for one S_4 operation and 113.8(5)° for two successive S_4 operations. Tetrahedral symmetry would require both angles to be 109.47°. The atoms of the 4-methylpyridine moiety are planar within experimental error but the cobalt atom lies 0.28 Å out of this plane; the angle between the S_4 axis and the plane of the ring is 28°; tetrahedral symmetry (T_d) would require the angle to be 0° or 45°.

The bond lengths and angles are shown in Table 3. The values for the atoms of the ring are similar to those of pyridine derived from a microwave study (10) and 4-methylpyridine in other structures (ref. 11, for example). The values for the hexafluorophosphate anions are similar to those normally found for this anion. The thermal parameters indicate large thermal motion, as has been observed by other authors (11–18). As noted (17), this anion would be expected to have large temperature factors and show considerable apparent distortion due to it having nearly spherical symmetry.

Compounds of the type CoL_4A_2, where L is pyridine or a substituted pyridine and A is an anionic ligand such as perchlorate, tetrafluoroborate, trifluoroacetate, methylsulfate, or trifluoromethylsulfate (19–23) have pseudo-octahedral structures with *trans*-coordinated anions. Because of its very weak ligating ability, the PF_6^- anion is not coordinated to cobalt in $Co(4\text{-mepy})_4(PF_6)_2$, the co-

[1]Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Received June 15, 1978

KENNETH R. BREAKELL, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **57**, 139 (1979).

The synthesis and coordinating properties of the tridentate tris-chelating ligand, methyl tris(3,5-dimethylpyrazol-1-yl)gallate, $MeGa(N_2C_5H_7)_3^-$, are described. Carbonyl and nitrosyl carbonyl compounds of manganese, molybdenum, and tungsten incorporating this ligand are detailed. The ready conversion of the above ligand to the less sterically demanding tris-chelating 'hydroxy' ligand $[MeGa(N_2C_5H_7)_2(OH)]^-$ occurs in attempted syntheses of the 'η^3-allyl' complexes, $[MeGa(N_2C_5H_7)_3]M(CO)_2$'$\eta^3$-allyl', (where M = Mo or W, 'η^3-allyl' = η^3-C_3H_5, η^3-C_4H_7). The tridentate chelating nature of this 'hydroxy' ligand is conclusively demonstrated in the crystal structure determination of the complex, $[MeGa(N_2C_5H_7)_2(OH)]$-$Mo(CO)_2(\eta^3\text{-}C_4H_7)$. Crystals of this complex are monoclinic, $a = 14.020(4)$, $b = 10.110(1)$, $c = 15.493(7)$ Å, $\beta = 111.58(3)°$, $Z = 4$, space group $P2_1/n$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to a final R of 0.40 and R_w of 0.043 for 3374 reflections with $I \geq 3.5\sigma(I)$.

KENNETH R. BREAKELL, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **57**, 139 (1979).

On décrit la synthèse et les propriétés coordinantes du ligand tridentate tris-chélatant, méthyl tris(diméthyl-3,5 pyrazolyl-1)gallate, $MeGa(N_2C_5H_7)_3^-$. On donne des détails concernant des composés carbonyl- et nitrosylcarbonyl du manganèse, du molybdène et du tungstène incorporant ce ligand. Le ligand ci-haut se transforme facilement en ligand "hydroxy" tris-chélatant stériquement moins empêché: $[MeGa(N_2C_5H_7)_2(OH)]^-$ lorsque l'on essaye de synthétiser les complexes "η^3-allyle", $[MeGa(N_2C_5H_7)_3]M(CO)_2$ "η^3-allyle" (où M = Mo ou W, "η^3-allyle" = $\eta^3C_3H_5$, η^3-C_4H_7). On a démontré d'une façon concluante la nature chélatante tridentate de ce ligand "hydroxy" à l'aide d'une détermination de la structure cristalline du complexe $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$. Les cristaux de ce complexe sont monocliniques, $a = 14.020(4)$, $b = 10.110(1)$, $c = 15.493(7)$ Å, $\beta = 111.58(3)°$, $Z = 4$, groupe d'espace $P2_1/n$. On a résolu la structure par des synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.40 et de R_w de 0.043 pour 3374 réflexions avec $I \geq 3.5\sigma(I)$.

Introduction

Numerous examples of the coordination chemistry of tris(pyrazol-1-yl) borate ions, $RB(N_2C_3H_3)_3^-$, where R = H or alkyl, have been described (1). A recent paper (2) discussed a similar gallium ligand, $MeGa(N_2C_3H_3)_3^-$, and contrasted its coordinating ability with that of its boron analogues. A more electron-rich transition metal centre was created in the gallium complexes, with a greater degree of steric protection afforded the chelated metal. The introduction of methyl groups in the 3 or 3,5 positions of the pyrazolyl rings in the boron ligands led to some anomalous reactions in complex ions of the type $RB(N_2C_5H_7)_3Mo(CO)_3^-$ (3). The present paper describes the synthesis of the very sterically demanding gallium ligand, $MeGa(N_2C_5N_7)_3^-$ (incorporating three 3,5-dimethylpyrazolyl moieties), its coordinating ability in transition metal complexes, and its unusual propensity to convert to the less sterically demanding ligand, $MeGa(N_2C_5H_7)_2(OH)^-$, in some of its reactions. The tris-chelating nature of the latter system is confirmed conclusively in the X-ray crystal structure determination of the compound $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$.

Experimental

Starting Materials

Air-sensitive materials were handled in a glove-box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over lithium aluminum hydride and was used immediately following distillation. Benzene was dried by refluxing over molten potassium prior to distillation. Sodium hydride (Alfa) and 3,5-dimethylpyrazole were used as supplied. Methyl gallium dichloride was prepared by a standard procedure (4) from gallium trichloride (5) and tetramethylsilane. Molybdenum and tungsten hexacarbonyls were used as supplied (Strem). Manganese pentacarbonyl bromide was pre-

pared from dimanganese decacarbonyl (Strem) by a standard route (6). Allyl bromide and 2-methylallyl chloride were distilled under nitrogen prior to use, and isoamyl nitrite was used as purchased (MCB).

Preparative Details

Sodium Methyl Tris(3,5-dimethylpyrazol-1-yl)gallate $Na^+[MeGa(N_2C_5H_7)_3]^-$

$$MeGaCl_2 + 3Na^+(N_2C_5H_7)^- \xrightarrow[\text{r.t.}]{\text{THF}} Na^+[MeGa(N_2C_5H_7)_3]^- + 2NaCl$$

Methyl gallium dichloride (4.51 g, 29.0 mmol) in THF solution was treated with a 3-molar equivalent of sodium 3,5-dimethylpyrazolide (10.25 g, 86.9 mmol) in the same solvent. The mixture was stirred for 2 days and the white precipitate (NaCl) was then filtered off and washed with THF. The filtrate and the washings were made up to a standard volume and aliquots of the resulting solution were employed in subsequent reactions.

Preparation of $Na^+[MeGa(N_2C_5H_7)_3]M(CO)_3^-$ *Salts* $M = Mo, W$

$$Na^+MeGa(N_2C_5H_7)_3^- + M(CO)_6 \rightarrow Na^+[MeGa(N_2C_5H_7)_3]M(CO)_3^- + 3CO$$

In a typical reaction equimolar amounts of the gallium ligand solution and a THF slurry of the appropriate hexacarbonyl were mixed in a sealed bulb. The mixture was warmed for several days at ~80°C and the CO evolved then measured to confirm the completion of the reaction. The air-sensitive clear yellow solution of the tricarbonyl salt was then made up to standard volume and aliquots used in subsequent reactions.

Preparation of $[MeGa(N_2C_5H_7)_3]Mo(CO)_2NO$

To a THF solution of $Na^+[MeGa(N_2C_5H_7)_3]Mo(CO)_3^-$ was added an excess amount of isoamyl nitrite, and the resulting mixture was warmed briefly. Gas evolution was observed and from the product solution an orange-red material was obtained. This was recrystallized from benzene yielding well-formed orange-red crystals of the desired product. Analytical and ir data are reported in Table 1.

Preparation of $[MeGa(N_2C_5H_7)_3]W(CO)_2NO$

This compound was prepared in an identical manner to that described above using $Na^+[MeGa(N_2C_5H_7)_3]W(CO)_3^-$ as starting material and refluxing with an excess amount of isoamyl nitrate.

Preparation of $[MeGa(N_2C_5H_7)_3]Mn(CO)_3$

$$Na^+MeGa(N_2C_5H_7)_3^- + Mn(CO)_5Br \xrightarrow{\text{THF}} [MeGa(N_2C_5H_7)_3]Mn(CO)_3 + NaBr + 2CO$$

Equimolar amounts of the gallium ligand (1.78 g, 4.52 mmol) and manganese pentacarbonyl bromide (1.24 g, 4.52 mmol) were refluxed in THF solution until gas evolution had ceased. The solid isolated from the filtrate from the reaction mixture was recrystallized from benzene to yield an off-white crystalline material which pulverized to a chalky, white powder. Analytical and ir data are reported in Table 1.

Attempted Preparation of $[MeGa(N_2C_5H_7)_3]Mo(CO)_2(\eta^3\text{-}C_4H_7)$

To an aliquot of $Na^+[MeGa(N_2C_5H_7)_3]Mo(CO)_3^-$ solution an excess of 2- methylallyl chloride was added.

$$Na^+[MeGa(N_2C_5H_7)_3]Mo(CO)_3^- + \text{excess } C_4H_7Cl \xrightarrow[\text{reflux}]{\text{THF}} NaCl + CO + [MeGa(N_2C_5H_7)_3]Mo(CO)_2(\eta^3\text{-}C_4H_7)$$

As expected, CO evolution was observed and the reaction was deemed complete at the cessation of this evolution. The solid isolated from the filtrate from the reaction was recrystallized from benzene to give well-formed yellow crystals. The product was not the expected compound but the hydroxy derivative $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ (see Table 1).

Attempted Preparation of $[MeGa(N_2C_5H_7)_3]W(CO)_2(\eta^3\text{-}C_4H_7)$

Following the same procedure as described in the above reaction on intractable dark orange glue was obtained as product. An alternate route was therefore followed using $(MeCN)_3W(CO)_3$ as starting material (7).

$$[1]\quad (MeCN)_3W(CO)_3 + \text{excess } C_4H_7Cl \xrightarrow[\text{r.t.}]{\text{THF}} (MeCN)_2W(CO)_2(\eta^3\text{-}C_4H_7)(Cl) + MeCN + CO$$

$$[2]\quad (MeCN)_2W(CO)_2(\eta^3\text{-}C_4H_7)(Cl) + Na^+MeGa(N_2C_5H_7)_3^- \xrightarrow{\text{THF}} [MeGa(N_2C_5H_7)_3]W(CO)_2(\eta^3\text{-}C_4H_7) + 2MeCN + NaCl$$

An excess of 2-methylallyl chloride was added to a slurry of $(MeCN)_3W(CO)_3$ (1.125 g, 2.88 mmol) in THF at room temperature. The color of the mixture changed from yellow to red and the product was a clear solution. The gallium ligand (1.13 g, 2.88 mmol) in THF was added with a concomitant change of color to orange and the formation of a white precipitate. The isolated filtrate yielded a solid which gave well formed yellow crystals from benzene solution. These were not the expected compound but again a hydroxy derivative $[MeGa(N_2C_5H_7)_2(OH)]W(CO)_2(\eta^3\text{-}C_4H_7)$ (see Table 1).

Attempted Preparation of $[MeGa(N_2C_5H_7)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$

Attempts to prepare this complex from $Na^+[MeGa(N_2C_5H_7)_3]Mo(CO)_3^-$ and excess C_3H_5Br were unsuccessful, an intractable sticky dark yellow material resulting from the reaction. However, employing $(MeCN)_3Mo(CO)_3$ (0.872 g, 2.88 mmol) as starting material and reacting with excess C_3H_5Br followed by an equivalent of $Na^+MeGa(N_2C_5H_7)_3^-$ (1.13 g, 2.88 mmol) ligand, a yellow solid was obtained from the resulting THF solution. This gave well formed yellow crystals from benzene solution. Again the product was a hydroxy compound, $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(\eta^3\text{-}C_3H_5)$ (see Table 1), rather than the expected complex.

Spectra

Mass spectra were recorded on a Varian MAT CH4 Mass spectrometer at 70 eV with an ion source temperature of 100–180°C. Infrared spectra were recorded on a Perkin Elmer 457 spectrophotometer either as Nujol mulls or as solution spectra in cyclohexane or methylene chloride solvents. Proton nmr spectra were recorded in C_6D_6 solution on Varian XL-100 and Bruker WP-90 console 270 spectrometers. F.T. techniques were employed in recording the spectra of complexes of low solubility.

X-ray Crystallographic Analysis of $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$

The crystal was mounted in a general orientation and had dimensions of ca. 0.36 × 0.48 × 0.53 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 24 reflections measured on a diffractometer with graphite monochromatized MoK_α radiation (λ = 0.71073 Å). Crystal data (at 21°C) are:

$C_{17}H_{25}GaMoN_4O_3$ fw = 499.07
Monoclinic, a = 14.020(4), b = 10.110(1), c = 15.493(7) Å, β = 111.58(3)°, V = 2042(1) Å^3, Z = 4, ρ_c = 1.623 g cm^{-3}, $F(000)$ = 1008, $\mu(MoK_\alpha)$ = 20.2 cm^{-1}. Absent reflections: $h0l$, $h + l \neq 2n$ and $0k0$, $k \neq 2n$ define uniquely the space group $P2_1/n$ (alternate setting of $P2_1/c$, C_{2h}^5, No. 14).

Intensities were measured with graphite monochromatized MoK_α radiation on an Enraf-Nonius CAD-4 diffractometer. A variable speed ω scan over a range of r = (0.80 + 0.45 tan θ) degrees in ω was employed. The scan was extended at both ends by r/4 for background measurement. Data were measured to 2θ = 60°. Crystal orientation was monitored every 150 reflections and the intensities of the 3 check reflections, measured every hour of X-ray exposure throughout the data collection, remained constant to within ±1.5%. After data reduction, an absorption correction was applied using the Gaussian integration method (8, 9). Transmission factors ranged from 0.429 to 0.510. Of the 5906 independent reflections measured, 3374 (57.1%) had intensities greater than 3.5σ(I) above background where $\sigma^2(I) = S + B + (0.04S)^2$ with S = scan count and B = normalized background count.

The positions of the Mo and Ga atoms were determined from the three-dimensional Patterson function and those of the O, N, and C atoms from a subsequent difference map. After full-matrix least-squares refinement of all non-hydrogen atoms with anisotropic thermal parameters to R = 0.059, a difference map gave the positions of all 25 hydrogen atoms which were included in subsequent cycles of refinement with isotropic thermal parameters.

The scattering factors of ref. 10 were used for non-hydrogen atoms and those of ref. 11 for hydrogen atoms. Anomalous scattering factors from ref. 12 were used for the Mo and Ga atoms. The weighting scheme $1/\sigma^2(F)$ where σ(F) is derived from the previously defined σ(I) gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic type I extinction correction (Lorentzian distribution) was applied (13–15); the final value of g was 1.0(1) × 10^4. Convergence was reached at R = 0.040 and R_w = 0.043 for 3374 reflections with $I \geq 3.5\sigma(I)$. For all 5906 reflections R = 0.091 and R_w = 0.050. On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.09 and 0.56σ respectively. The mean error in an observation of unit weight was 0.9591. A final difference map showed maximum fluctuations of −2.0 to 0.8 e Å^{-3} near the heavy atoms and was essentially featureless elsewhere. The final positional and thermal parameters appear in Tables 2 and 3 respectively.[1] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (16) using the computer program MGTLS. The rms standard error in the temperature factors, σU_{ij} (derived from the least-squares analysis) is 0.0031 Å^2. Analysis of the entire molecule (rms ΔU_{ij} = 0.0057 Å^2) gave physically reasonable rigid-body parameters. The bond lengths have been corrected for libration (17) using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values. Corrected bond angles do not differ by more than 0.15° from the uncorrected values in Table 5. Torsion angles in the three chelate rings are given in Table 6.

Results and Discussion

The integrity of the tris-chelating ligand MeGa-

[1]The structure factor table and Table 3 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

$(N_2C_5H_7)_3^-$ has been proven by the isolation of the two nitrosyl complexes and the tricarbonyl manganese compound. In all three of these compounds the sterically demanding gallium ligand has the required space to occupy the three facial positions demanded by its geometry in the octahedral complexes. Attempted introduction of larger substituents into the $MeGa(N_2C_5H_7)_3M(CO)_3^-$ ions (M = Mo or W) does not yield the expected complexes but, instead, the observed hydroxy species, or intractable products. The origin of the 'OH' group in these complexes is puzzling since all solvents were dried and the 'yields' of 'OH' products were high and uncontaminated with the expected tris-chelate complexes. It is tempting to speculate abstraction of the 'OH' from the THF solvent but further studies will be necessary to establish this as its origin.

Infrared Spectra

Selected vibrations from the infrared spectra of the complexes are recorded in Table 1. It is noteworthy that the bands for the tungsten compounds are somewhat lower than the bands for the corresponding molybdenum compounds, a phenomenon which is becoming well documented (2, 3, 18, 19). Comparison of the ν_{CO} frequencies for the present 'η^3-allyl' complexes with the ν_{CO} frequencies of similar complexes (Table 7) bearing different uninegative 6-electron ligands indicates that the $[MeGa(N_2C_5H_7)_2(OH)]^-$ ligand creates a more electron-rich transition metal centre with consequent lowering of the ν_{CO} frequencies. The bond length data discussed below are consistent with these observations.

Mass Spectra

The six complexes listed in Table 1 were all sufficiently volatile and stable to give readily observable parent ion signals in their mass spectra. The results indicate the same monomeric nature for the products in the gas phase as is suggested by other evidence for the compounds in solution, and as has been demonstrated conclusively for the complex, $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$, in the solid state by X-ray structural determination. In all six spectra the expected fragmentation patterns were observed (2) and the intensity ratios of the individual peaks in multi-peak signals agree closely with theoretical predictions based on the percentage isotope compositions of the contributing metal atoms.

^1H Nuclear Magnetic Resonance Spectra

Nitrosyl Complexes

The ^1H nmr spectra for the two nitrosyl compounds are reported in Table 8. In these complexes the three 3,5-dimethylpyrazolyl groups occupy two sets of positions and the H^4 proton and the Me^3 and Me^5 groups give two signals each in the predicted 2:1 intensity ratio.

Hydroxy Complexes

The main features recorded in these three spectra (Table 8) are explicable in terms of an octahedral

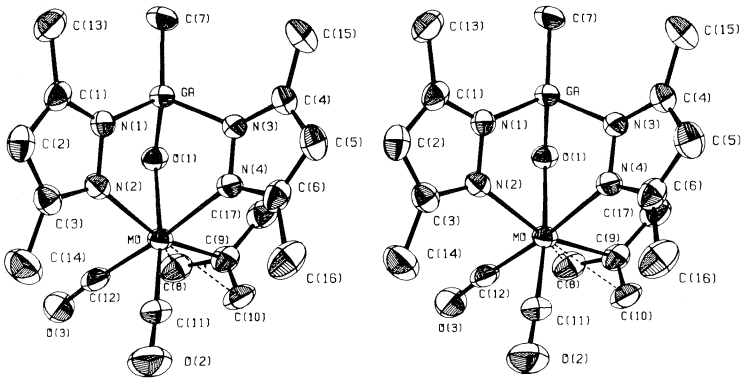

FIG. 1. Stereoview of $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$. 50% thermal ellipsoids are shown. Hydrogen atoms have been omitted for the sake of clarity.

TABLE 4. Bond lengths (Å) with estimated standard deviations in parentheses

(*a*) Non-hydrogen atoms

	Length			Length

(*b*) Bonds involving hydrogen atoms

	Length	
Bond	Value	Mean
O—H	0.65(6)	
C(sp^2)—H	0.74–0.98(5–6)	0.89(8)
C(sp^3)—H	0.76–1.13(6–11)	0.92(9)

structure for the complexes in C_6D_6 solution similar to that demonstrated for $[MeGa(N_2C_5H_7)_2(OH)]$-$Mo(CO)_2(\eta^3\text{-}C_4H_7)$ in the solid state (see Fig. 1). Thus, the two 3,5-dimethylpyrazolyl groups are different and give two sets of signals for the H^4, Me^4, and Me^5 protons in all three spectra in the ratio of 1:1. The signals due to the protons on the η^3-2-methylallyl and η^3-allyl groups have been assigned following assignments for comparable complexes (21, 22) and also using assignments given in ref. 23. In addition to the expected couplings the H_{syn} protons display further splittings in all three spectra. The origin of these additional couplings may be partly the result of H_{syn}–H_{anti} *geminal* coupling although this is usually quite small ($\leq$1 Hz (24)). All three spectra clearly indicate that the 'n^3-allyl' groups are not undergoing rapid rotation about the M...'n^3-allyl' axis in solution, a process which would make both *syn* protons equivalent and both *anti* protons equivalent.

X-ray Crystallographic Analysis of $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$

The crystallographic analysis of dicarbonyl-[methylbis(3,5-dimethylpyrazol-1-yl)hydroxygallato-(*N*(2),*N*(2)′,*O*)](η^3-2-methylallyl)molybdenum confirms the tridentate chelating nature of the $MeGa(N_2C_5H_7)_2(OH)^-$ ligand. Molecular models indicate that the steric crowding inherent in the $[MeGa(N_2C_5H_7)_3]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ molecule is drastically reduced in the hydroxy complex $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ (Fig. 1). The Ga...Mo distance of 3.329(1) Å in the present study is considerably shorter than the distance of 3.67 Å found for $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$ (2).

The hydroxy bridge effectively creates much more space in positions *trans* to the 3,5-dimethylpyrazolyl groups in octahedral complexes. The Mo atom has distorted octahedral coordination geometry with the $\eta^3\text{-}C_4H_7$ group occupying an octahedral coordination site *trans* to a 'pyrazolyl' nitrogen atom and acting as a π-donating ligand (Mo—C = 2.334(6), 2.263(5), and 2.359(6) Å). The Mo—N distances (2.283(4) and 2.242(4) Å)) are significantly different, the bond *trans* to the $\eta^3\text{-}C_4H_7$ group being shorter (as expected). There is a small (1.7σ) difference between the two M—C(O) distances (1.920(5) and 1.933(6) Å), the shorter being *trans* to the OH bridge. The Mo—O bond length of 2.272(4) Å is rather long (for steric reasons).

Steric effects are the dominant factor in the bond length inequalities mentioned above as well as in the following notable features of the present structure. The 'pyrazolyl' ring *trans* to the 'allyl' group is planar (χ^2 = 2.25) with both methyl carbon atoms and both metal atoms significantly displaced from the mean plane (Mo, 0.0499(4), Ga, −0.0993(6),

C(13), −0.063(8), and C(14), −0.035(9) Å). The other 'pyrazolyl' group, *cis* to the 2-methylallyl, is severely distorted. The five-membered ring is significantly non-planar ($\chi^2 = 16.8$) and both metal atoms are considerably displaced from the mean plane (Mo, −0.2097(4), Ga, 0.6670(5) Å) while only one of the methyl carbons is out of plane (C(16), 0.071(8) Å). The torsion angle Ga[N(3)—N(4)]Mo, ideally zero, is 26.9(3)°, Ga[N(1)—N(2)]Mo is 5.2(3)°.

Relative to the structure of **1**, $[MeGa(N_2C_3H_3)_3]$-$Mo(CO)_2(\eta^3\text{-}C_3H_5)$, there are several notable differences. Both Mo—N distances lie between those in **1** (*cis*, 2.328(3) and 2.309(3), *trans*, 2.232(3) Å). Substitution of allyl by 2-methylallyl increases the central Mo—C(allyl) distance from 2.228(5) to 2.263(5) Å without changing the two other Mo—C(allyl) distances. All of the Mo—'allyl' distances in the present structure are in good agreement with those found for the related boron complex $[HB(N_2C_3H_3)_3]$-$Mo(CO)_2(\eta^3\text{-}C_4H_7)$ (24). The Mo—C(O) bonds are about 2σ shorter than those in **1** (1.936(5) and 1.948(5) Å) and significantly shorter than those in the boron complex (1.958(5) and 1.959(5) Å), at the same time the C—O distances are longer (mean values 1.176(2), 1.162(2), and 1.151(1) Å, respectively, for the present structure, **1**, and the boron complex). These data are consistent with the ν_{CO} ir values (Table 7 and ref. 2) and suggest that a more electron-rich Mo centre is created by the hydroxy ligand with consequent increased back bonding from the metal to the antibonding orbitals of the carbonyl groups. The M—C—O groupings are significantly more bent (173.5(5) and 173.7(5)°) than in **1** (177.2(5) and 176.5(5)°) and the OC—Mo—CO angle is reduced from 81.2(2)° to 75.7(2)°.

The coordination about the gallium atom is distorted tetrahedral. The two Ga—N bond lengths are significantly different (1.962(4) and 1.943(4) Å), the longer one being associated with the *trans* 'pyrazolyl' group which has the shorter Mo—N bond. Both Ga—N bonds are significantly longer than their counterparts in **1** (1.938(4), 1.922(4), and 1.917(3) Å). Other bond lengths in the molecule are as expected.

The trivalent oxygen atom has pyramidal coordination (mean angle at O(1) is 110.5°). The four carbon atoms of the $\eta^3\text{-}C_4H_7$ group are coplanar ($\chi^2 = 1.3$) but three of the four methylene hydrogen atoms are significantly displaced from the mean plane (H(8a), 0.18(5); H(8b), −0.40(6); H(10a), −0.39(5); H(10b), 0.11(6); Mo, 2.0126(4) Å). The crystal structure consists of discrete molecules, the shortest non-bonded distance between molecules being Ga...O(3) $[\frac{1}{2} - x, y - \frac{1}{2}, \frac{1}{2} - z]$, 3.222(4) Å.

Densities and kinematic viscosities of tetra-*n*-butylammonium iodide – nickel(II) chloride melts

NURUL ISLAM, ABDUL MAROOF, AND ISMAIL KOCHI[1]

Department of Chemistry, Aligarh Muslim University, Aligarh 202001, India

Received April 12, 1978

NURUL ISLAM, ABDUL MAROOF, and ISMAIL KOCHI. Can. J. Chem. **57**, 147 (1979).

Densities and kinematic viscosities of molten mixtures of nickel(II) chloride in tetra-*n*-butylammonium iodide have been measured as functions of temperature and composition. The data on the kinematic viscosity have been analyzed using both Arrhenius and non-Arrhenius type equations. The heat of activation, the entropy of activation, and the free energy of activation for viscous flow have been computed. At higher concentrations a slight tendency towards non-Arrhenius viscous behaviour is observed. The free energy of activation helps in describing the overall composition dependence of kinematic viscosity.

NURUL ISLAM, ABDUL MAROOF et ISMAIL KOCHI. Can. J. Chem. **57**, 147 (1979).

On a mesuré, en fonction de la température et de la composition, les densités et les viscosités cinématiques de mélanges fondus du chlorure de nickel(II) dans de l'iodure de tétra-*n*-butylammonium. On a analysé les données de viscosimétrie cinématique en faisant appel à des équations de type Arrhénius et à d'autres qui ne le sont pas. On a calculé la chaleur d'activation, l'entropie d'activation et l'énergie libre d'activation pour un écoulement visqueux. A des concentrations élevées, on a observé une tendance faible vers un comportement visqueux qui n'est pas du type Arrhénius. L'énergie libre d'activation permet de décrire la relation entre la composition globale et la viscosité cinématique.

[Traduit par le journal]

Introduction

There are two well known types of viscosity–temperature behaviour of liquids or molten salt systems, namely, Arrhenius and non-Arrhenius. In the higher temperature ranges the behaviour usually is Arrhenius and tends to non-Arrhenius as the temperature is lowered. There are established analytical expressions (1–5) to explain separately both of these types of behaviour. However, in a certain region of temperature both Arrhenius and non-Arrhenius behaviours may be expected to exist so that neither the Arrhenius nor the non-Arrhenius equation for the analysis of viscosity versus temperature data may apply. The non-Arrhenius viscous behaviour has also been found to increase with the supercooling of the system. Thus, at a particular temperature region in a binary molten mixture, the Arrhenius viscosity may change into non-Arrhenius as the solute concentration increases provided that the added solute causes an increase in the supercooling of the molten system. In order to further understanding of such anticipated shifts in Arrhenius or non-Arrhenius behaviour with respect to temperature as well as composition regions, measurements are reported in this paper of the viscosities of binary melts of nickel chloride and tetrabutylammonium iodide (TBAI).

Experimental

Tetra-*n*-butylammonium iodide (Fluka, AG) was used as solvent in the molten state. Anhydrous nickel chloride was prepared (6) from its recrystallized hexahydrate using purified thionyl chloride (Riedel). Preparation of samples and the measurements were made in a glycerol bath thermostatted to ± 0.1°C. During the preparation of samples the transference of salt was done in an inert atmosphere. The extent of solubility of $NiCl_2$ in tetraalkylammonium halide solvent was reported (7) as up to ~33 mol%. Densities were measured in a calibrated dilatometer of ~3.0 ml capacity with graduated stem of 0.01 ml divisions. Cannon-Ubbelohde viscometers of viscometer constants 0.0355 and 0.0286 cSt/s were used for viscosity measurements in the range 388–418 K. Accuracies of density and viscosity measurements were estimated to be $\pm 0.3\%$ and $\pm 0.1\%$, respectively.

Results and Discussion

The mean molecular weight and the mean molar volume of the TBAI + $NiCl_2$ melt decrease with increasing [$NiCl_2$] whereas a gradual increase has been observed in the case of the density, ρ. The densities of these binary molten mixtures also show a linear dependence on temperature (Table 1).

The kinematic viscosities, ν, of the molten mixtures under study obtained from the products of the viscometer constant and the times of fall are listed in Table 2 as functions of temperature and composition. Plots of the logarithms of the kinematic viscosities versus inverse temperature (Fig. 1) were found to be almost linear. However, the solutions of 23.99 and 30.12 mol% appear to have a tendency for slight

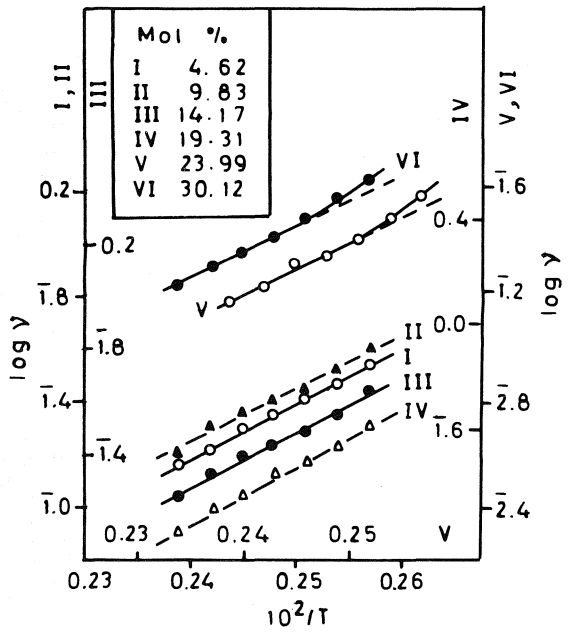

FIG. 1. Arrhenius plots for the kinematic viscosities of TBAI + $NiCl_2$ melts.

deviations from linearity particularly at lower temperatures. Similar plots have also been obtained with respect to absolute viscosities. The linearity of the Arrhenius plots in the case of mixtures of lower concentrations (4.62, 9.83, 14.17, and 19.13 mol%) may be visualized as due to two factors, namely, (*i*) the higher temperature range of the data, and (*ii*) less association of the type $\{[(C_4H_9)_4N^+]_2[NiCl_2I_2^{2-}]\}_x$ to form cluster-like structures in the molten system. The latter factor may also be considered as the cause for the solidification of molten mixtures of lower concentration encountered on cooling; the occurrence of such associations permitted supercooling of the two mixtures of higher concentration and probably caused deviations from Arrhenius behaviour (Fig. 1).

Assuming that the temperature dependence of viscosity is Arrhenius in all the molten mixtures (within the experimental temperature range), an attempt has been made to describe the viscosity data through the Eyring's expression (2). Recently Eyring's expression has been preferred over Andrade (1) equation owing to the fact that the activation free energy term in the exponential part enables an interpretation of the composition dependence of viscosity in liquid mixtures (8). However, in the present case, in order to account for the kinematic viscosity instead of absolute viscosity, η, Eyring's expression has been modified to

$$[1] \qquad \nu = \eta/\rho = (hN/\bar{M}) \exp [\Delta G^*/RT] = A \exp [\Delta H^*/RT]$$

where h is Planck's constant; N, Avogadro's number; $\bar{M}$, the mean molecular weight; ΔG^*, the free energy of activation; ΔH^*, the heat of activation; R, the gas constant; T, the absolute temperature; and $A = (hN/\bar{M}) \exp [-\Delta S^*/R]$; ΔS^* is the entropy of activation. The data on kinematic viscosity have been fitted to [1] by least-squares and the computed values of the parameters A and ΔH^* are given in Table 3. From the values of A the entropies of activation were computed using the expression

$$[2] \qquad \Delta S^* = R[\ln (hN/\bar{M}) - \ln A]$$

The values of ΔS^* so obtained are also included in Table 3.

It is apparent from Table 3 that the values of ΔS^* are positive, unlike the case during conductance flow

TABLE 3. Computed parameters of eq. [1] for TBAI + $NiCl_2$ melts

Mol%	ln A	ΔH^* (cal/mol)	Standard deviation in ν	ΔS^* (eu)
4.62	−13.67	9771.1	0.0062	4.50
9.83	−12.83	9217.6	0.0119	2.90
14.17	−13.13	9492.5	0.0125	3.56
19.31	−13.59	9812.2	0.0111	4.55
23.99	−14.05	10113.9	0.0131	5.53
30.12	−13.71	9967.2	0.0064	4.95

where negative values have usually been reported (9, 10). Positive values for ΔS^* during viscous flow were also reported (11) in the case of associated liquids. Such positive values of ΔS^* indicate that the flowing species attain higher entropy after activation. It may, therefore, be visualized that the viscous flow involves simpler flowing entities and that breaking of some bonds appears to take place before the initiation of flow in order to produce these flowing entities from the associated species.

An attempt has been made to account for a slightly non-Arrhenius viscous behaviour by least-squares fitting the kinematic viscosity data to an equation of the form

$$[3] \qquad \nu = A'T^n \exp [B/(T - T_0)]$$

where A', n, B, and T_0 are empirical constants. This equation has been reported (12) to describe the temperature dependence of the kinematic viscosities of organic liquids and was approximated from an expression based on the significant liquid structure theory.

The least-squares fitted values of the parameters of [3] are given in Table 4 along with the standard deviations in ν. It may, however, be noted that even though the linear plots of $\log(\nu/T^n)$ versus $1/(T - T_0)$ support the suitability of [3], too much significance should not be given to the computed parameters unless the deviation from Arrhenius behaviour is large.

The nature of composition dependence of kinematic viscosities of the present systems may be understood from Fig. 2. From 4.62 to 14.17 mol% an increase of ~20% in kinematic viscosity has been observed. It decreases by about 12% from 14.17 to 23.99 mol% and then increases by ~15% from 23.99 to 30.12 mol%. Accordingly, the kinematic viscosity isotherms show maxima at 14.17 mol% and minima at 23.99 mol%.

On the other hand, it is worthwhile to note the apparently invariant nature of ΔH^* and ΔG^* with concentration from Tables 3 and 5, respectively, as well as from the almost parallelism of the plots of log ν versus $1/T$ (Fig. 1). This implies that the composition dependence of kinematic viscosity is mainly

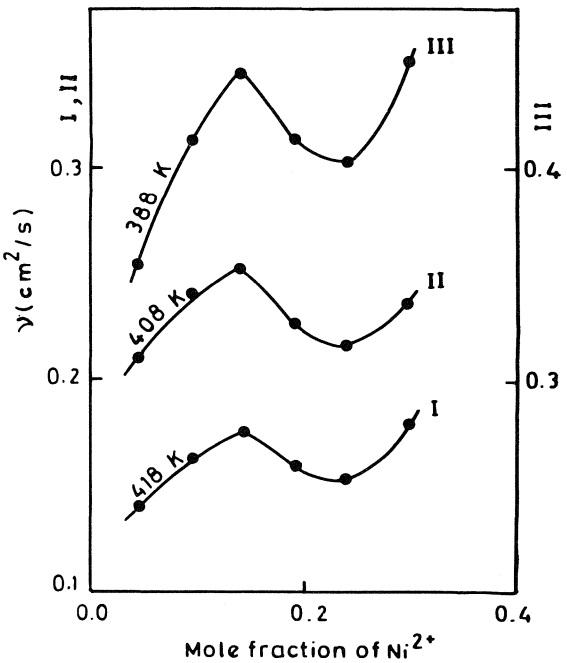

FIG. 2. Kinematic viscosity vs. composition isotherms for TBAI + $NiCl_2$ melts.

determined by that of the pre-exponential factor of [1] which in turn is related to the entropy of activation through [2]. Therefore, it may be visualized that the variation of ν with concentration is essentially guided by the entropy change involved in the breaking of associated species.

Furthermore, the variation of ν with concentration described above may also be viewed quantitatively through [1]. Equation [1], after accounting for the linear concentration dependence of log $(hN/\bar{M})$ (Fig. 3*a*), takes on the form

$$[4] \qquad \log \nu = \log A_0 + Qc + \Delta G^*/2.303RT$$

or

$$[5] \qquad \log \nu = \log A_0 + (\Delta G^* + Q'c)/2.303RT$$

where Q is the slope of the plot of log $(hN/\bar{M})$ versus composition; c, concentration in mole fraction; $Q' = 2.303RTQ$; and A_0 is the value of $(hN/\bar{M})$ for the pure solvent. The suitability of [5] to describe the concentration dependence of ν of the system under study is apparent from the linearity of the log ν versus $(\Delta G^* + Q'_c)$ isotherms drawn at 418 and 388 K (Fig. 3*b*). Similar isotherms may also be obtained at other experimental temperatures. Now, by considering ΔG^* as a composition independent factor [4] may be expressed as

$$[6] \qquad \log \nu = A' + Qc$$

where $A' = \log A_0 + \Delta G^*/2.303RT$. However, the

TABLE 5. Free energies of activation (cal/mol) for TBAI + $NiCl_2$ melts

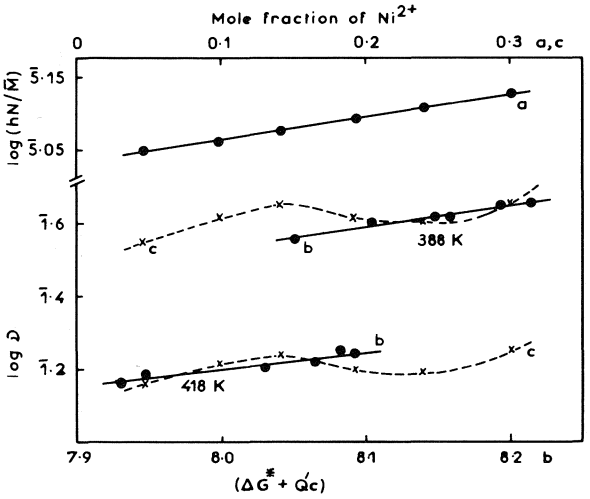

FIG. 3. (*a*) Plot of log $(hN/\bar{M})$ vs. mole fraction of Ni^{2+}; (*b*) plot of log ν vs. $(\Delta G^* + Q'_c)$; and (*c*) plot of log ν vs. mole fraction of Ni^{2+} for TBAI + $NiCl_2$ melts.

plots of log ν versus *c* are non-linear (Fig. 3*c*) which shows the inadequacy of [6] in describing the composition dependence of kinematic viscosity. This suggests that such a dependence of ν cannot be attributed to the changes in the pre-exponential factor alone. Therefore, although the change in ΔG^* with concentration is smaller, it appears to participate, along with the changes in the pre-exponential factor, in describing the overall dependence of kinematic viscosity on concentration.

Electrical conductance and thermal behaviour of some manganese(II) carboxylates

SAMUEL OLUYEMI ADEOSUN
Department of Chemistry, University of Ife, Ile-Ife, Nigeria

Received July 7, 1978

SAMUEL OLUYEMI ADEOSUN. Can. J. Chem. **57**, 151 (1979).

Data are presented on the heats of phase transitions and electrical conductances of the even chain length manganese(II) carboxylates from octanoate to octadecanoate inclusive. The total entropy change for the transition crystal → isotropic liquid is small indicating a high degree of aggregation in the isotropic liquid. This behaviour is similar to that of the cadmium carboxylates.

Plots of log specific conductivity against inverse temperature show curvature. Attempts to fit the data to the Vogel–Tammann–Fulcher equation

$$\kappa = A \exp [-C/(T - T_0)]$$

showed non-random deviations. Instead, the data were interpreted in terms of a simple dissociation equilibrium for which the enthalpy change is ~ 240 kJ mol^{-1}.

SAMUEL OLUYEMI ADEOSUN. Can. J. Chem. **57**, 151 (1979).

On rapporte des mesures de la chaleur de transition de phase et de la conductance électrique pour les composés du manganèse(II) avec les carboxylates à chaîne paire, depuis l'octanoate jusqu'à l'octadécanoate inclusivement. La transition cristal → liquide isotope ne produit qu'une faible variation totale d'entropie, ce qui dénote une formation importante d'agrégats dans le liquide isotope. On a noté un phénomène semblable pour les carboxylates de cadmium.

Quand on porte le logarithme de la conductivité spécifique en fonction de l'inverse de la température, on observe une courbure. On a tenté d'ajuster à ces données l'équation de Vogel–Tammann–Fulcher,

$$\kappa = A \exp [-C/(T - T_0)]$$

mais les écarts n'étaient pas aléatoires. Les données ont plutôt été interprétées en fonction d'un équilibre de dissociation simple faisant intervenir une variation d'entalpie de ~ 240 kJ mol^{-1}.
[Traduit par le journal]

Introduction

The electrical conductances of several molten metal carboxylates have been reported (1–4). The conductance behaviour of these compounds depends crucially on the nature of the metal ion. For example the Arrhenius plots for conductance of sodium and zinc carboxylates (2, 3) are linear while those of lead and cadmium (3, 4) show curvature. The curvature observed for the lead and cadmium soaps have been interpreted in terms of a simple dissociation equilibrium which is near completion at high temperatures.

Differential thermal analysis studies, coupled with optical observations on a hot-stage microscope, reveal that many metal carboxylates form mesophases (5–12). Mesophase formation in some divalent metal carboxylates has also been studied by Spegt, Luzzati, and co-workers (13–16) using X-ray diffraction technique. The number and type of mesophases formed by these soaps also vary with the nature of the metal ion as well as the carboxylate chain length. For example, it has been reported that lead(II) carboxylates form mesophases (11). The phase sequence for the dodecanoate and lower chain length soaps is crystal → $G_{(smectic)}$ → $V_{2(cubic\ isomorphous)}$ → liquid while for tetradecanoate and longer chain length soaps, the V_2 phase is absent and the G phase melts directly into the liquid phase. On the other hand, zinc soaps do not form mesophases but undergo solid → solid phase transitions only (12).

So far, no data have been reported in the literature on the electrical and thermal properties of any transition metal carboxylate and it would be of interest to see how the physical properties of transition metal soaps compare with those of the main group metals already studied. We have, therefore, examined the electrical and thermal properties of the even chain length manganese(II) carboxylates from octanoate to octadecanoate inclusive.

Experimental

Materials

The fatty acids were B.D.H. samples and were stated to have minimum 99% purity by glc assay. They were used without further purification. The manganese(II) chloride used was an Analar B.D.H. product.

Preparation of the Soaps

The soaps were prepared by matathesis in alcohol solution

0008-4042/79/020151-06$01.00/0

(1). The potassium soap was first prepared by the reaction of potassium metal with the stoichiometric amount of the acid in ethanol. The manganese soap was then obtained by the reaction of a stoichiometric amount of manganese(II) chloride in a minimum amount of water with the potassium soap in ethanol. The product was filtered, washed with water and acetone, and dried in a vacuum oven. The product was recrystallised from hot benzene. Infrared spectra showed that the soaps were dry and free of excess acid. The melting points and elemental analysis results for the soaps are shown in Table 1.

Lawrence (17) had earlier reported the preparation of manganese(II) octadecanoate for which he reported a melting point of 473 K. This value is much higher than the value of 392 K observed in the present study. However, we have shown that many of the products reported by some earlier workers are probably basic carboxylates. For example, we showed (4) that the samples of cadmium hexanoate and octanoate having extremely high melting points reported by Spegt and Skoulios (18) were basic carboxylates. It is therefore very likely that the manganese octadecanoate reported by Lawrence is a basic carboxylate. We believe that our samples are pure as indicated by the elemental analysis data in Table 1. It should be noted that Lawrence did not report elemental analysis data for his product.

Physical Measurements

Conductivities were measured in a cell with blackened platinum electrodes. The cell was joined to a socket which could be fitted with a vacuum tap. The cell was filled with the material, evacuated, and immersed in a furnace. The temperature of the furnace was controlled by a Pye-Ether Mini temperature controller, type 19–90B. Conductance measurements were made from about 10 K above the melting point of the material to just below its decomposition point using a Wayne–Kerr B224 conductivity bridge. Conductivities were measured upon heating the sample and upon cooling. The values obtained in both cases agree within experimental error. Duplicate runs also agree within experimental error. The cell constant was measured between each run using 0.01 Demal KCl solution.

DTA measurements were made on a Mettler TA 2000 Analyser which was calibrated with pure indium metal. The materials were premelted and about 20 mg samples were weighed into the standard aluminium crucibles of the analyser using a Kahn Electrobalance. The samples were then scanned at a heating rate of 1 K min^{-1}. Measurements were made in duplicate on at least three separate samples. Peak areas were determined by cutting and weighing the chart paper. Specific heats were determined by the method of base line displacement and optical observations were made on a polarising hot-stage microscope.

Results and Discussion

Quantitative DTA

The manganese(II) carboxylates show two DTA peaks except the octadecanoate which show three peaks. This observation is consistent with the fact that, in general, increase in carbon chain length in a homologous series of metal carboxylates results in an increase in the number of polymorphic phases present (19). The first polymorphic phase is described as phase I in Table 2 while the second polymorphic phase observed in manganese octadecanoate has been described as phase II.

On heating, the crystal first changed into a highly viscous phase which later passed into the isotropic liquid phase. However, visual observation under a hot-stage polarising microscope did not help in characterising the structures of the mesophases. No definite visible sign of changes in texture were observed at the phase transition temperatures when viewed under a hot-stage microscope.

TABLE 1. Melting points and elemental analyses

Carbon chain length	mp (K)	%C		%H	
		Theory	Found	Theory	Found
8	376–377	56.30	56.14	8.80	8.71
10	379–380	60.45	60.45	9.57	9.41
12	387–388	63.58	62.89	10.15	9.97
14	385	66.01	66.24	10.60	10.48
16	388–389	67.96	68.15	10.97	10.89
18	392	69.57	69.85	11.27	11.44

The thermodynamic data for the phase changes are summarised in Table 2 together with their standard errors. A noteworthy feature of the quantitative results is the increase in the total enthalpy and entropy changes with increasing chain length of the soaps. Figure 1 shows a plot of ΔS_{total} (i.e. the total entropy change accompanying the transition, crystal → isotropic liquid) against chain length of the soap. Although the plot is not accurately linear, it can be seen that ΔS_{total} is strongly chain length dependent, increasing with increasing chain length. This is consistent with the idea that the major step in the fusion process is the disordering of the hydrocarbon chains. The values of ΔS_{total} for the manganese carboxylates are significantly smaller than those of the corresponding lead and zinc carboxylates but close to those of the cadmium soaps. For example, the value of ΔS_{total} for manganese octadecanoate is 152 ± 4 J mol^{-1} K^{-1} while those of lead, zinc, and cadmium octadecanoates are, respectively, 311 ± 10, 256 ± 8, and 177 ± 5 J mol^{-1} K^{-1} (11, 12). This probably suggests that the isotropic liquid phases of manganese and cadmium carboxylates are more ordered than those of the lead and zinc carboxylates. We have earlier proposed that the cadmium carboxylates consist of cylindrical micelles in the liquid phase (12) while those of lead consist of spherical micelles (11). This is consistent with the extremely high values of the viscosities of the cadmium soaps (4) when compared to those of the lead compounds (20). It is, therefore, tempting to speculate that the liquid phase of the manganese carboxylates may also consist of cylindrical micelles similar to those of the cadmium carboxylates.

The values of the heat capacities of the manganese carboxylates in the solid phase are presented in Fig. 2. The values increase linearly with temperature suggesting that some subtle structural changes occur

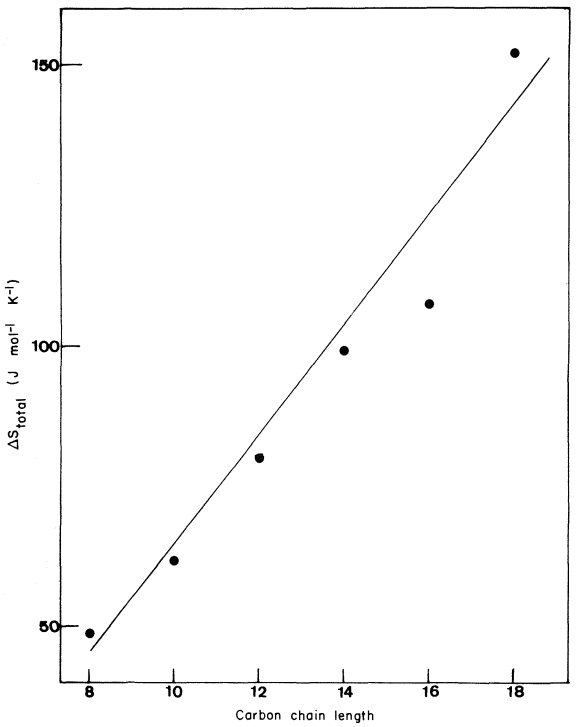

FIG. 1. Total entropy change for the process, crystal → liquid.

in the solid phase with increasing temperature. The heat capacity values in the liquid phase are also summarised in Table 3. The values are constant over the temperature range studied. The values of the heat capacities of the cadmium soaps have been included in Table 3 for comparison. It can be seen that the two sets of heat capacity data are not significantly different.

Electrical Conductance

The conductance data are presented in Fig. 3 where values of log κ are plotted against inverse temperature for all the compounds studied. Results of duplicate runs are also included in the plots. The specific conductances of the manganese carboxylates are bigger than those of zinc salts but smaller than the corresponding salts of lead and cadmium. For example, at 433 K the value of κ for manganese octadecanoate is 1.258×10^{-4} S m^{-1} while the values for lead, zinc, and cadmium octadecanoates are respectively, 1.201×10^{-2}, 2.511×10^{-5}, and 2.513×10^{-2} S m^{-1}.

One notable feature of the plots is that they show curvature. Similar curvature of Arrhenius plots has been observed in certain molten salt mixtures (21) and it has been suggested that such curvature may arise if the liquid is close to its ideal glass transition temperature. Cleaver *et al.* (22) observed non-linear

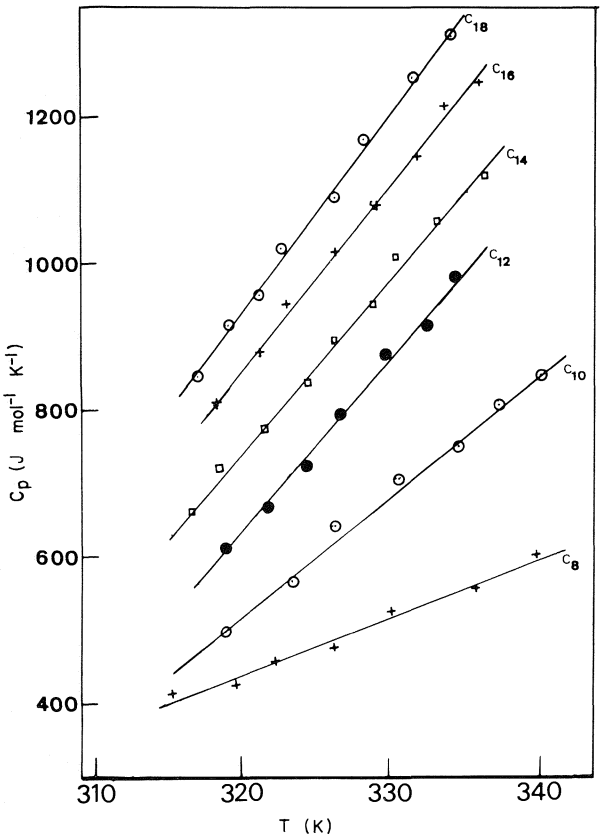

FIG. 2. Molar heat capacities of the solid manganese carboxylates.

Arrhenius plots for the conductance and viscosity of fused sodium polysulphides and fitted their data to the Vogel–Tammann–Fulcher equation:

$$[1] \qquad \kappa = A \exp [-C/(T - T_0)]$$

where A, C, and T_0 are constants. Angell (21) has interpreted T_0 as the temperature at which there is zero configurational entropy in the liquid phase and this has been identified with the ideal glass transition temperature.

We attempted to fit the conductance data of the manganese carboxylates to eq. [1] by using a computer program which systematically varied T_0 to find a minimum in the standard deviation of fits of $\log \kappa$ against $1/(T - T_0)$. In all cases, the standard deviations were non-random which suggests that our results cannot be adequately interpreted in terms of the glass-forming theory. Similar attempts to fit the conductance data of lead and cadmium carboxylates (which also show non-linear Arrhenius plots) to eq. [1] have been unsuccessful (3, 4). Instead, a simple dissociation theory has been proposed to explain the conductance behaviour of lead and cadmium carboxylates (3, 4). Following the model

*Values are from ref. 12.

proposed for these bivalent metal carboxylates, it is proposed that manganese carboxylate dissociates according to the scheme

$$MnA_2 \rightleftharpoons Mn^{2+} + 2A^-$$

where the MnA_2 and A^- ions may be aggregated in the melt. Assuming that the major current carrier is the Mn^{2+} ion rather than the more bulky species, and that it moves by a simple activated process then the following expressions (3) can be obtained at low

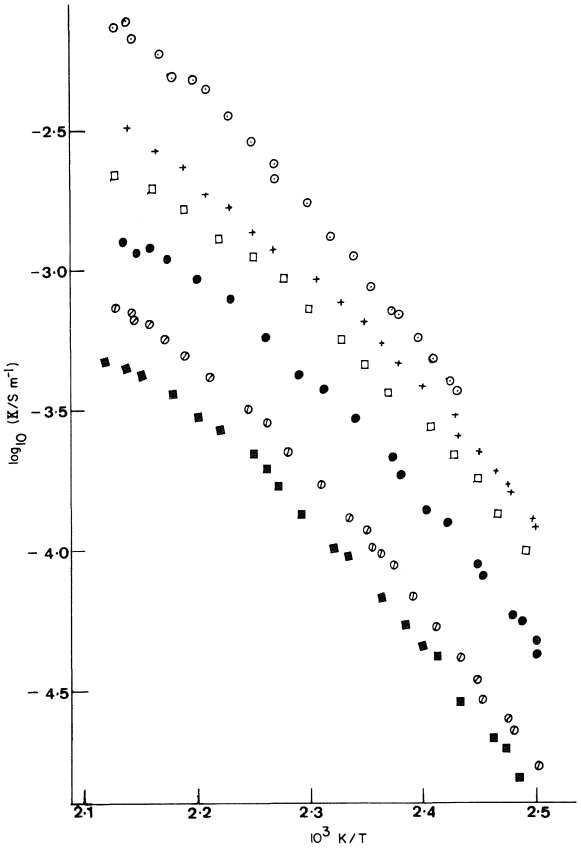

FIG. 3. Semilogarithmic plots of specific conductivity against inverse temperature for molten manganese carboxylates: ○, C_8; +, C_{10}; □, C_{12}; ●, C_{14}; ⊙, C_{16}; ■, C_{18}.

degrees of dissociation for the specific and equivalent conductance (λ).

$$[2] \qquad \log \kappa = \log Q - \frac{\Delta H^{\ddagger} + \Delta H/3}{2.303RT}$$

$$[3] \quad \log \lambda + \frac{\Delta H^{\ddagger} + \Delta H/3}{2.303RT} = \log \frac{NeA}{4} + \frac{\Delta S^{\ddagger} + \Delta S/3}{2.303RT}$$

where $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, ΔH, and ΔS are the enthalpies and entropies of activation for movement of the Mn^{2+} ion and for the dissociation, respectively, and

$$[4] \quad \log Q = \log \frac{NeA}{2V_m} + \frac{1}{2.303R}(\Delta S^{\ddagger} + \Delta S/3)$$

where V_m is the molar volume of the soap. At low degrees of dissociation, a plot of $\log \kappa$ against $1/T$ should be linear with slope of $(\Delta H^{\ddagger} + \Delta H/3)/2.303R$, according to eq. [2]. Table 4 shows values of $\Delta H^{\ddagger} + \Delta H/3$ calculated from such plots. It can be seen that these values are reasonably constant within limits of experimental error and suggest that the major current carrier must be the same in all the carboxylates studied; most certainly the Mn^{2+} ion.

It is possible to have a rough idea of how the combined entropy term varies with chain length. The first term on the right hand side of eq. [3] is unlikely to be strongly chain length dependent. Thus a plot of the left hand side expression in eq. [3] against chain length will demonstrate the dependence of the combined entropy term, i.e., $\Delta S^{\ddagger} + \Delta S/3$ on the chain length of the carboxylate. Values of λ can be obtained from the specific conductance data (κ) but this requires knowledge of the molar volumes (V_m) of the manganese carboxylates. We attempted to measure V_m values for the manganese soaps by the same pycnometric technique used for the lead and zinc carboxylates (3). Unfortunately this method was not suitable for the manganese soaps because of the abnormally high viscosities of these compounds which made complete elimination of air bubbles in the melt extremely difficult. However, the molar volumes of corresponding carboxylates of lead, zinc, and cadmium differ by at most 0.5% from each other (3, 4). For example, values of V_m at 500 K for lead, zinc, and cadmium carboxylates are, respectively, 738.81×10^{-6}, 738.24×10^{-6}, and 737.00×10^{-6} m^3. It is, therefore, reasonable to assume that the molar volumes of the manganese soaps will not be significantly different from those of the other bivalent metal soaps. We have, therefore, computed values of λ for the manganese carboxylates using the molar volume data of the corresponding lead soaps. Figure 4 shows a plot of $\log \lambda + (\Delta H^{\ddagger} + \Delta H/3)/2.303RT$ against chain length. The slope of the plot shows that the entropy term decreases by 1.96 J K^{-1} per carbon atom. This value can be compared with those for zinc (1.86) and cadmium (1.60) carboxylates.

TABLE 4. Low temperature limiting slopes for conductance

Carbon chain length	$\Delta H^{\ddagger} + \Delta H/3$ (kJ mol^{-1})
8	98 ± 3
10	102 ± 4
12	100 ± 6
14	98 ± 3
16	99 ± 4
18	98 ± 4

According to the dissociation theory, the metal carboxylate is completely dissociated in the high temperature region. In this region, the plot of $\log k$ against $1/T$ should tend to a second linear portion with slope corresponding to $\Delta H^{\ddagger}$. Unfortunately this region was not reached before the manganese soaps started to decompose. However, it has been shown that the value of $\Delta H^{\ddagger}$ for Pb^{2+} ion, calculated in this manner, is in good agreement with that found for molten lead halides (3). The activation energy for conductance of manganese(II) chloride is 19.6 kJ mol^{-1} (23) which suggests that $\Delta H^{\ddagger}$ for

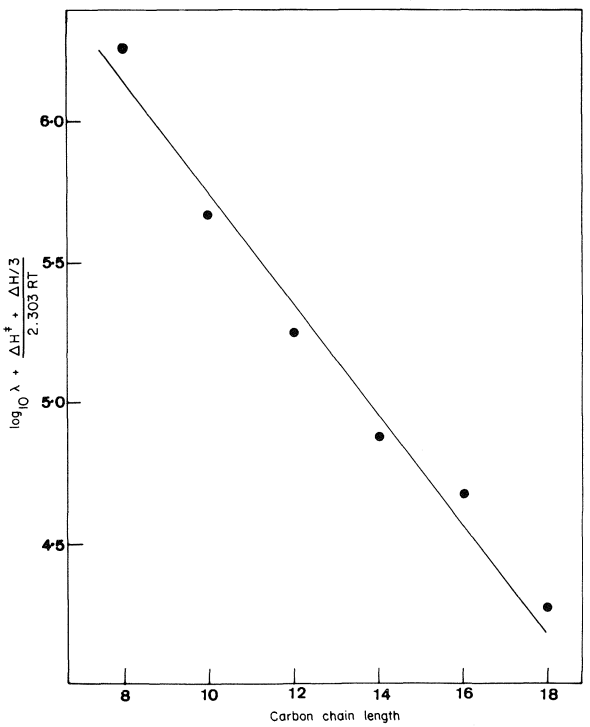

FIG. 4. The dependence of the entropy-containing term, $\log \lambda + (\Delta H^{\ddagger} + \Delta H/3)/2.303RT$ on carbon chain length of the manganese carboxylates.

Mn^{2+} ion must be close to this value. Using this value of $\Delta H^{\neq}$, the value of ΔH for the manganese carboxylates can be shown to be about 240 kJ mol^{-1}. This value is much higher than that obtained for the lead carboxylates ($\sim$88 kJ mol^{-1}) and slightly bigger than that of cadmium carboxylates ($\sim$190 kJ mol^{-1}), suggesting that the manganese–carboxylate bond is extremely strong.

Taken together with the DTA data, these results suggest that the structure of the manganese carboxylates in the melt is similar to that of the cadmium soaps for which cylindrical micelles have been postulated (12). Viscosity data (4) on the cadmium soaps show that the contribution of the methyl and head groups to the activation energy for viscous flow ($\sim$71 kJ mol^{-1}) is much bigger than that for the lead soaps ($\sim$15 kJ mol^{-1}) (20) which implies that a considerable amount of work must be done against coulombic and dipolar forces in the cadmium carboxylates to cause the movement of the unit of flow. It would, therefore, be useful to measure the viscosities of the manganese carboxylates. Unfortunately we were unable to obtain reliable viscosity data due to operational difficulties similar to those encountered with the molar volume measurements. However, visual observation suggests that the manganese carboxylate melts must have abnormally high viscosities.

WINNIE WONG-NG and S. C. NYBURG. Can. J. Chem. **57**, 157 (1979).

A synthetic intermediate expected to be a *spiro*benzylisoquinoline bromo-derivative proved, on X-ray crystal structure analysis, to be the title compound, a chloro-derivative with the isoquinoline nitrogen ring-closed. Crystals belong to the monoclinic system, space group $P2_1/c$, $a = 13.68(2)$, $b = 10.81(2)$, $c = 22.12(4)$ Å, $\beta = 129.2(4)°$, $Z = 4$ molecules per cell. Intensity data were collected by diffractometer and the structure refined to a conventional R of 0.051.

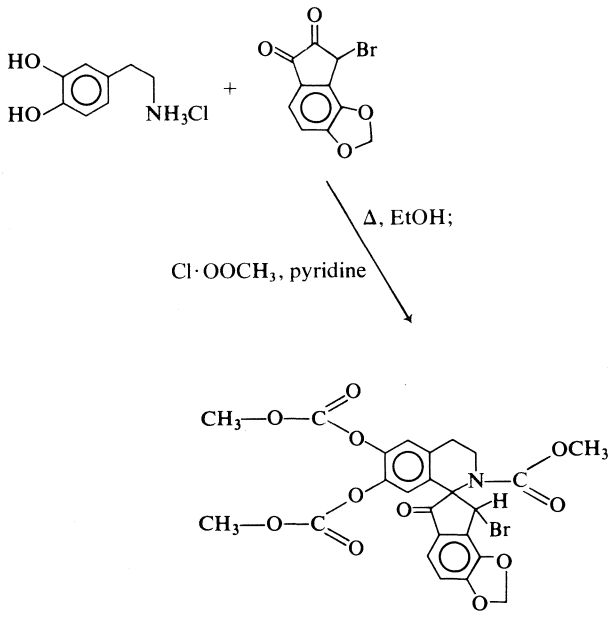
WINNIE WONG-NG et S. C. NYBURG. Can. J. Chem. **57**, 157 (1979).

On croyait qu'un intermédiaire de synthèse était un dérivé bromé d'une *spiro*benzylisoquinoléine; une analyse de la structure cristalline par rayons-X a permis de prouver que l'intermédiaire est plutôt le composé mentionné dans le titre, un dérivé chloré dans lequel l'azote de l'isoquinoléine fait partie d'un cycle fermé. Les cristaux appartiennent au système monoclinique, groupe d'espace $P2_1/c$, $a = 13.68(2)$, $b = 10.81(2)$, $c = 22.12(4)$ Å, $\beta = 129.2(4)°$. $Z = 4$ molécules par maille. On a recueillie les données d'intensité à l'aide d'un diffractomètre et on a affiné la structure jusqu'à une valeur de R conventionnelle de 0.051.

[Traduit par le journal]

Introduction

One of the steps involved in the Pictet–Spengler route to *spiro*benzylisoquinoline alkaloids has typically been as follows:



1

Since the local conformation is of interest a crystal structure analysis of the assumed material **1** was undertaken.

Experimental

Colourless crystals were kindly supplied by Professor S. McLean and from one of these a single fragment was cut ca. 0.31 × 0.18 × 0.48 mm. This was used for X-ray analysis.

Approximate cell dimensions and the systematic absences were established photographically. Refined cell dimensions were obtained from fourteen diffractometer-centered reflections. (The crystal proved to have neither the structure nor empirical formula of **1**. Full crystallographic data are given later.)

Intensity data were collected on a computer-automated four circle Picker diffractometer using Ni-filtered CuKα radiation and pulse height analyser in θ–2θ scan mode at 2° min^{-1} in the range $0 < \sin\theta < 0.87$. The scan range, adjusted for dispersion, was 2°, and a total of 3851 independent reflections was recorded with a standard at every 30 measurements. The standard intensity did not vary significantly. The standard deviation in raw intensity, $\sigma(I)$ was taken as $[a(\text{peak} + \text{background}) + aI^2 + 0.02I]$ where a = attenuation factor; thus $\sigma(F_o)$ was taken as $[(\sigma(I)/Lp) + 0.02F_o^4]^{1/2}/2F_o$ where Lp is the Lorentz-polarization factor and $0.02F_o^4$ makes some allowance for instrument instability. Absorption corrections were not made. The 2894 reflections having $F_o > 2\sigma(F_o)$ were taken as significant and used for structure analysis.

The 289 largest E values (> 1.5) were used in direct method routines MULTAN (1) and TANFOR[1]. Neither yielded intelligible results. All reflections with l odd are very weak implying heavy atoms at $y = \frac{1}{4}, \frac{3}{4}$. (Omitting l odd reflections and phasing only on E's with l even was not helpful; no chemical sense could be made of the peaks having false $P2_1/m$ symmetry.) The l odd and l even reflections were then separately normalised and, using MULTAN, and E map was obtained which was chemically intelligible but did not correspond to formula **1**. Attempts at refinement yielded consistently high R values.

0008-4042/79/020157-03$01.00/0

Not until the putative bromine site was allowed to have variable occupancy was it clearly established to be chlorine. The molecular weights of the most promising chemical structure $C_{25}H_{20}NO_{13}Cl$ (577.61) and of the putative $C_{24}H_{20}NO_{11}Br$ (578.06) were too close for the measured density to be decisive. However, the mass spectrographic pattern of isotopic abundance confirmed that the former of the two empirical formulas was correct. Crystal data are as follows.

$C_{25}H_{20}NO_{13}Cl$ fw = 577.61
Monoclinic, $P2_1/c$, $a = 13.68(2)$, $b = 10.81(2)$, $c = 22.12(4)$ Å, $\beta = 129.2(4)°$, $V = 2534(28)$ Å^3, $Z = 4$, $\rho_o = 1.51$, $\rho_c = 1.50$ g cm^{-3}, 25°C, CuKα, $\lambda = 1.5418$ Å, μ(CuKα) = 14.91 cm^{-1}.

Refinement by full matrix anisotropic least-squares ORFLS[2] (using dispersion corrections $f' = 0.348$, $f'' = 0.702$ for chlorine) was uneventful. All hydrogen atom positions were allowed to vary but their isotropic temperature factors were fixed at $B = 6$ Å^2. The final unweighted R value was 0.051.

Final atomic coordinates are listed in Table 1. Observed and calculated structure factors and thermal parameters have been placed in the Depository of Unpublished Data.[3]

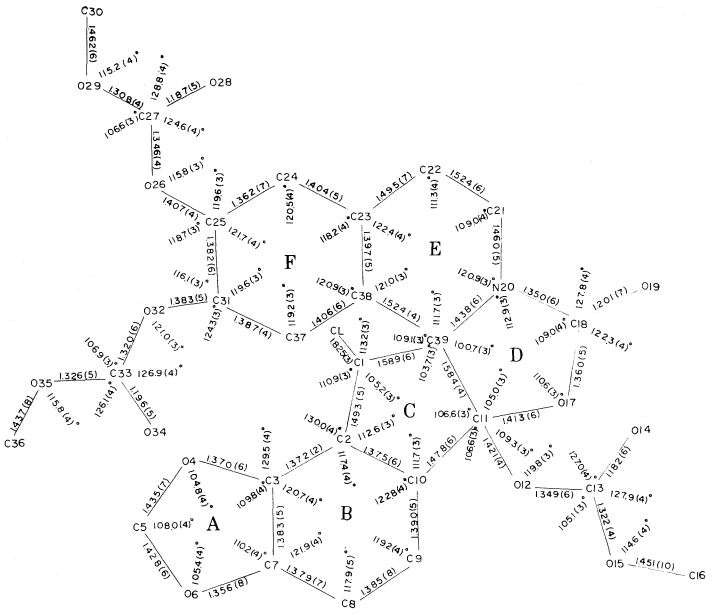

FIG. 2. Bond lengths (Å) and bond angles (deg).

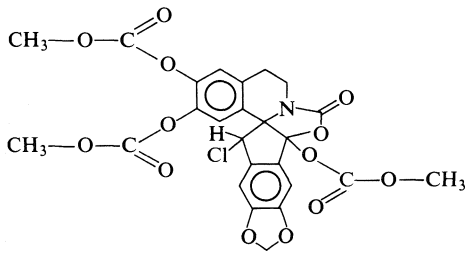
plot with all hydrogen atoms except H(1) omitted is given in Fig. 1, and bond lengths and angles in Fig. 2.

The two striking differences in structure compared with the expected **1** are the replacement of bromine by chlorine and, instead of acetylation of N(20), its closure to form an oxazolone ring. (There is evidence, however, that a compound of type **1** is actually formed in the reaction but remains in solution.[4])



2

The chlorine atom lies *syn* to C(39)—N(20), C(39) itself being significantly out of the plane of ring F (0.090(4) Å) indicating some strain at C(38). C(5) is 0.183(5) Å out of the plane of ring B and the rest of ring A.

The two methoxycarbonyloxy groups at C(25) and C(31) lie at different angles to their adjacent planes, namely, 57.1(5)° and 84.4(3)°, respectively. In both cases there are hydrogen atoms close to the ketoxy oxygen atoms: O(28)—H(5) [x, $\frac{1}{2} - y$, $z - \frac{1}{2}$], 2.34(6) Å, O(34)—H(37) (intramolecular), 2.29(7) Å and O(34)—H(8) [$\bar{x} - 1$, $\bar{y}$, $\bar{z}$], 2.36(6) Å. The bond lengths in the three methoxycarbonyloxy groups are self-consistent, the C—O bonds adjacent to the central carbon atom being relatively short and the outer C—O bonds relatively long in each case.

The preparation and characterisation of 1,1,2,2-tetramethyl-1,2-diacyloxyditin(IV) compounds

THOMAS BIRCHALL AND JAMES P. JOHNSON

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 28, 1978

THOMAS BIRCHALL and JAMES P. JOHNSON. Can. J. Chem. **57**, 160 (1979).

Reaction of hexamethylditin with haloacetic acids results in the production of 1,1,2,2-tetramethyl-1,2-diacyloxyditin(IV) compounds in good yield. Infrared, Raman, ^{1}H and ^{13}C nmr, and ^{119}Sn Mössbauer data have been interpreted in terms of a tetramethylditin species asymmetrically bridged by two acyloxy groups to give each tin a five-coordinate environment.

THOMAS BIRCHALL et JAMES P. JOHNSON. Can. J. Chem. **57**, 160 (1979).

La réaction de l'hexaméthylétain avec les acides haloacétiques conduit à la formation de composés tétraméthyl-1,1,2,2 diacyloxy-1,2 étain(IV) avec de bons rendements. On interprète les données de l'infrarouge, de Raman de la rmn du ^{1}H et ^{13}C et de Mössbauer du ^{119}Sn en termes d'espèces tétraméthyldiétain pontées d'une façon asymétrique par deux groupes acyloxy fournissant à chaque étain un environnement penta-coordonné.

[Traduit par le journal]

Introduction

Solvolysis of tetramethyl tin by strong acids leads to production of the $[(CH_3)_3Sn^+]$ and $[(CH_3)_2Sn^{2+}]$ ions which are strongly solvated in the reaction media (1). Isolation of $(CH_3)_3SnX$ and $(CH_3)_2SnX_2$ can be accomplished under appropriate conditions (2, 3). Several spectroscopic studies have been carried out, where $X = [RCOO^-]$, in order to establish the mode of coordination of the acetate to the central tin and hence the geometry about the tin atom (4–10). The five coordinate nature of tin in $R_3Sn(O_2CR)$ has been definitely established by X-ray crystallography, and the Sn—O axial bond lengths were found to be significantly different (11, 12).

In attempting solvolyses of hexamethylditin, we obtained nmr evidence for the presence of tetramethylditin species in solution. We now present details of the preparation and spectroscopic analyses for a number of ditin haloacetates. Compounds of this kind have been prepared before by the reaction of R_2SnH_2 ($R = C_6H_5$, *n*Bu) with carboxylic acids (13, 14). In the case of the $R_4Sn_2X_2$ systems there is uncertainty about the nature of the structures of these compounds in solution and in the solid state (15, 16). Our data are consistent with a five coordinate tin environment in solution and the solid state.

Experimental

Preparation

In a typical preparation 0.283 mol of trichloroacetic acid and 10 mL of chloroform were introduced under dry nitrogen into a two necked 100 mL flask containing a stirring bar. The flask was cooled in an acetone–ice bath. Hexamethylditin, 0.024 mol, was added via a 10 mL syringe through a rubber septum cap onto the stirred cold acid–chloroform mixture. An immediate slow but steady gas evolution occurred. After ~12 h the gas evolution had ceased and 90 mL of distilled water were added to the pale orange mixture which was allowed to warm to room temperature. The colour was discharged and the mixture was filtered through a fine glass frit under suction. The white solid was washed with 140 mL distilled water to give 12.963 g of product. Further work up of the filtrate yielded a further 1.173 g for a total yield of vacuum dried product of 95.1%.

A similar procedure was used for the preparation of the other compounds, all of which are white solids. No ditin species were obtained from the reactions with the $—CBr_3$, $—CH_3$, $—CH_2I$, or —CH acids. Analytical data are summarized in Table 1. Carbon and hydrogen were determined by Chemalytics Ltd. while Sn was determined gravimetrically by standard procedures (17).

Infrared spectra were recorded, as Nujol mulls, on a Perkin-Elmer 283 and a Nicolet 7000 F.T.I.R.; Raman spectra were recorded with a Spectro-Physics He/Ne (6328 Å) or an Ar ion (5145 Å) laser using a Spex 1400 spectrophotometer system; ^{1}Hmr spectra were obtained using a Varian H.A. 100, or E.M. 390 or a Bruker W.H. 90. This latter instrument was also used to obtain ^{13}Cmr spectra. Mössbauer spectra (^{119}Sn) were recorded using an Elscint AME 40 drive system operating in the constant acceleration mode with automatic folding of the triangular waveform. The transmitted radiation, through a Pd filter, was detected by a $Kr–CO_2$ (1 atm) proportional counter and fed to a Tracor-Northern multi-channel analyzer operating in the up-down multi-scaling mode. Samples were finely ground powders, intimately mixed with Apiezon N Grease, and sandwiched in a copper holder between thin aluminum foils. These samples contained ~10 mg natural tin/cm^{-2} and were rigidly held in a Liquid Transfer Cryotip system manufactured by Air Products and Chemicals Inc. The source was $Ca^{119}SnO_3$ obtained from Amersham-Searle, and was maintained at room temperature. Temperatures were monitored by means of a calibrated iron-doped gold chromel thermocouple and a Hewlett-Packard 419A DC null voltage detector. Spectra were computor fitted using a programme written by Stone (18) and modified by D. G. Grundy of the Department of Geology, McMaster University. The instru-

ment was calibrated using a $^{57}Co/Rh$ source and a standard iron foil. All isomer shifts were measured relative to SnO_2 as zero.

Results and Discussion

Hexamethylditin can react with substituted acetic acids, with gaseous evolution, according to either [1] and/or [2].

[1] $(CH_3)_6Sn_2 \xrightarrow[-H_2]{RCOOH} (CH_3)_3Sn(O_2CR)$ **1**

$$\xrightarrow[-CH_4]{RCOOH} (CH_3)_2Sn(O_2CR)_2$$ **2**

[2] $(CH_3)_6Sn_2 \xrightarrow[-CH_4]{RCOOH} [(CH_3)_2Sn(O_2CR)]_2$ **3**

$$\xrightarrow[-H_2]{RCOOH} (CH_3)_2Sn(O_2CR)_2$$

Both pathways, if carried out under the most vigorous conditions, ultimately result in species **2**. These reactions can be monitored very conveniently by ^1H nmr and such a study allows one to chose the correct conditions so that the yield of **3** can be optimised.

The nature of **3** is of interest since a number of structures are possible (Fig. 1). The tin atoms could be four-coordinate, with monodentate acetate, as in **4**, or be five-coordinate as in **5**–**7**. In **5** the acetate groups bridge $(CH_3)_2Sn—Sn—(CH_3)_2$ units intermolecularly to give a polymeric structure. On the other hand, intramolecular bridging acetates could bond in a symmetric fashion, as indicated in **6**, or asymmetrically to give two C—O and two Sn—O distances as in **7**.

Infrared and Raman Spectra

The application of vibrational spectroscopy to structural elucidation is often fraught with difficulty, particularly when the molecules contain as many atoms as those discussed here. However, judicious use of infrared and Raman spectroscopies and simple group theoretical treatments can provide valuable

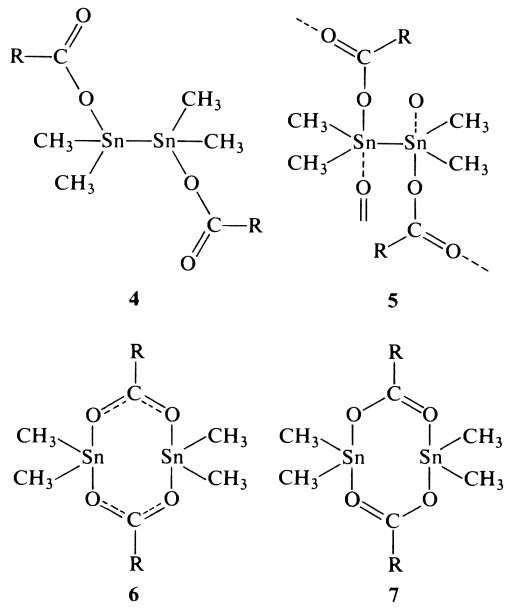

FIG. 1. Possible structures for $(CH_3)_4Sn_2(O_2CR)_2$.

structural information. In our initial investigations the presence of a tin–tin bond was established by nmr and is discussed below. Examination of the solid state Raman spectra of these compounds shows the presence of a strong vibration at $\sim 205\ cm^{-1}$, which is absent, or very weak, in the infrared spectra. The Raman spectrum of the $—CCl_3$ derivative in $CHCl_3$ also shows this strong band, which is polarized, and is assigned to the tin–tin stretch. The vibrational spectra are summarized in Table 2.

In order to simplify the assignment of the spectra we decided to treat the C_4Sn_2 moiety separately from the acyloxy unit. Twelve normal modes are expected from the C_4Sn_2. How these vibrational modes will be distributed between ir and Raman active modes will be determined by the overall symmetry of the molecule. Previous workers (7, 8) have established that the carbon–tin symmetric and asymmetric stretches

occur in the 520–550 cm^{-1} region of the spectrum. Two bands are present in this region in both the ir and Raman spectra of the molecules reported here. These can be assigned to the symmetric and asymmetric stretches associated with the $—SnC_2$ group. That these stretches in the ir are not identical to those in the Raman is apparent on close examination of Table 2. In all cases the symmetric stretch is at lower frequency in the ir than in the Raman, while the reverse is true for the asymmetric stretch. There is then mutual exclusion of bands in the ir and Raman, indicating the presence of an inversion centre in the molecule as a whole and a point group symmetry of C_{2h} is assigned. Five of the modes associated with the C_4Sn_2 moiety have been assigned on this basis in Table 2.

Comparison of these spectra in the acyloxy region with $(C_6H_5)_4Sn_2(O_2CR)_2$ and $(CH_3)_3Sn(O_2CR)$ allows identification of the ν_sCO_2 and $\nu_{as}CO_2$ modes. The relevant bands are compared in Table 3. Agreement between the three series of compounds is good for the solid state spectra suggesting that the acyloxy ligands are similarly bonded in all three types of molecules. In solution $(CH_3)_3Sn(O_2CR)$ has been shown to be largely monomeric (7, 8) but with some degree of association, while X-ray crystallography has shown that $\phi_4Sn_2(O_2CCH_3)_2$ (19) and $(CH_3)_3Sn(O_2CR)$ (11, 12) have bridging acyloxy groups which complete five-coordination about the tin atoms. The vibrational spectra of the ditin compounds strongly suggest that the acyloxy groups bridge the two tin atoms intramolecularly in these methyl derivatives, as has been established for the phenyl compound (19). The fact that, for the methyl and phenyl (15) compounds, neither ν_sCO_2 nor $\nu_{as}CO_2$ changes on going from the solid state to solution suggests that their structures are the same in the two phases. The difference between $\nu_{as}CO_2$ and ν_sCO_2 should reflect the difference in C—O bond strengths and hence the asymmetry of the acyloxy bridge. Examination of the data in Table 3 suggests that the most asymmetric situation should occur in the $—CCl_3$ and $—CHF_2$ cases, while the more symmetrically bonded cases should be $—CH_2Cl$ and $—CF_3$. The asymmetry in the C—O bonds should be reflected in the Sn—O distances.

Mössbauer Spectra

Tin-119 Mössbauer spectroscopy has proved extremely valuable in structural studies of organo–tin systems (20). We present such data for all of the compounds discussed in Table 4. No significant room temperature absorptions were observed for these compounds. All spectra appear as simple doublets (Fig. 2) having line widths of about 1 mm s^{-1}. The isomer shifts are slightly greater than those found for $(CH_3)_3Sn(O_2CR)$ (7, 9) systems but are very similar to the shifts for the $(C_6H_5)_4Sn_2(O_2CR)_2$ series (16). However, while the earlier workers (7, 9) report changes in isomer shift with different R groups, we find no such variation. This indicates that the *s* electron density at the tin nucleus does not change through our series of compounds.

Changes in the quadrupole splitting values do occur and, although these changes are small, the trend is to decreasing values as R becomes less electron withdrawing. A similar trend has been com-

TABLE 4. ^{119}Sn Mössbauer data for $(CH_3)_4Sn_2(O_2CR)_2$ at 77 K

*mm s^{-1} ± 0.03.
†This compound was used to derive a partial quadrupole splitting of − 0.807 mm s^{-1} for the $(CH_3)_2Sn(O_2CR)_2$ fragment.

mented upon in relation to the difference between the asymmetric and symmetric vibrations of the CO_2 group. The quadrupole splitting values are large, ~3.6–4.0 mm s^{-1}, and only slightly smaller than the corresponding values for the analogous $(C_6H_5)_4Sn_2(O_2CR)_2$ compounds (16). Such values are just those that would be predicted by the point charge model for a five-coordinate tin (21): the sign, which was not determined here, should be negative. This means that there is more electron density in the *xy* plane than there is along the *z* axis, which presumably contains the O—Sn—O atoms. Herber's criterion that $\Delta/\delta > 2.1$, for five-coordination (22) is also satisfied for these compounds. Calculation of the quadrupole splittings for these compounds using the approach of Bancroft *et al.* (23) gives excellent agreement with experiment, if five coordination is assumed. Finally, since $(C_6H_5)_4Sn_2(O_2CCH_3)_2$ has been shown to be monomeric and have five-coordinate tin atoms, we believe that tetramethyl derivatives reported here have the same basic structure.

It has been found that for $(CH_3)_3SnO_2CCH_3$ and $(CH_3)_3SnO_2CCF_3$, there is an increase in the quadrupole splitting of 0.54 mm s^{-1} from the former to the latter and the Sn—O distances are 2.205(3), 2.391(4), and 2.18(1) and 2.46(2) Å, respectively (12). The trifluoroacetate has somewhat more asymmetric bonds to the tin and in addition there is a slight increase in the average Sn—O distance, 2.32 Å for the $—CF_3$ compared to 2.298 Å for the $—CH_3$ compound. Although these differences are small they are paralleled by the trends in the quadrupole splitting. On the basis of the trends we observe in the quadrupole splittings for the $(CH_3)_4Sn_2(O_2CR)_2$ series we expect a similar increase in the average Sn—O distance from the monochloracetate to the trifluoracetate. We are presently trying to obtain crystallographic evidence for such changes.

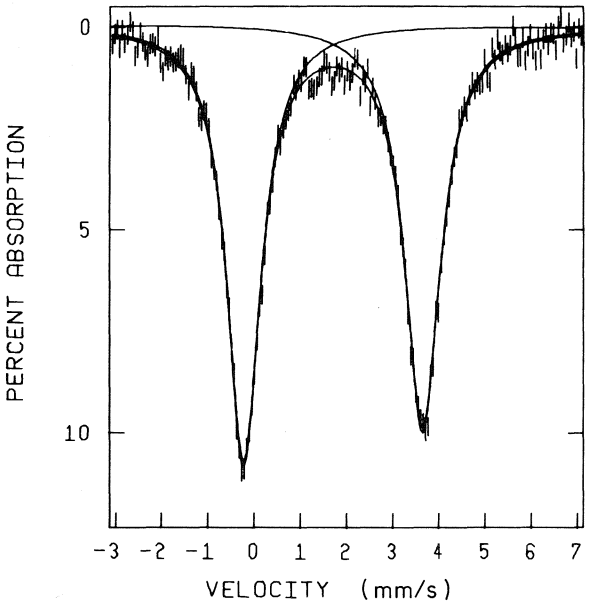

FIG. 2. ^{119}Sn Mössbauer spectrum of $(CH_3)_4Sn_2(O_2CCF_3)_2$ at 77 K.

Nuclear Magnetic Resonance Spectra

Nuclear magnetic resonance spectra (^{1}H and ^{13}C) have been recorded and the data are summarized in Table 5. The chemical shifts of the ^{1}H and ^{13}C nuclei follow the generally accepted trends and will not be commented upon further. All of the compounds show ^{117,119}Sn satellite peaks associated with the methyl groups confirming that the methyl groups are indeed bonded to tin. Furthermore, these satellites occur in two groups, those arising from $J_{^{117,119}Sn—C—^1H}$ and those from $J_{^{117,119}Sn—Sn—C—^1H}$: the ^{13}C spectra also show the same pattern. The coupling to the far tin indicates that the tin–tin bond is intact in solution. The tin–carbon and tin–hydrogen coupling constants vary slightly as the acyloxy groups are changed but there does not appear to be any systematic variation. Since $J_{Sn—C}$ is dependent upon the *s* character in the tin–carbon bond, the constant values for $J_{^{117,119}Sn—^{13}C}$ are consistent with the Mössbauer results where it was found that the isomer shift, which also depends on *s* character, remains unchanged throughout the series.

The magnitude of $J_{^{117,119}Sn—C—^1H}$ has been used to infer the coordination of the tin in $(CH_3)_3Sn(O_2CR)$ (4, 5, 9). Coupling constants in the range 55–60 Hz have been taken as an indication that the trimethyl tin acetate was monomeric and hence that the tin was four-coordinate in solution. However, other molecules containing the $(CH_3)_3Sn$ moiety in which the tin must be four-coordinate, e.g., $(CH_3)_3M—Sn(CH_3)_3$ (M = C, Si, Ge, or Sn), have $J_{^{119}Sn—C—^1H}$ ranging from 47–49 Hz. Recently, Mathiasch (24, 25) has reported nmr data for $(CH_3)_4Sn_2X_2$ (X = Cl, Br, I, H) which have four-coordinate tin atoms and the two-bond tin–hydrogen coupling constants range from 52.2–53.5 Hz, considerably lower than the coupling constants for the supposedly four-coordinate tin in $(CH_3)_3SnO_2CR$. It should be noted also that $J_{^{119}Sn—^{13}C}$ for $(CH_3)_4Sn_2X_2$ (23) range from 257 to 281 Hz and are much lower than the corresponding values (344 to 349 Hz) for the acyloxy compounds (Table 5). It would seem preferable to infer the geometry about the tin in the acyloxyditin compounds by comparing their nmr data with the ditin compounds of Mathiasch (24).

*Satellite doublets not resolved.

Because coupling constants for $(CH_3)_4Sn_2(O_2CR)_2$ are increased considerably over those for $(CH_3)_4Sn_2X_2$, we conclude that the five-coordination established in the solid state, for the acyloxy compounds, is maintained in solution. Simons and Graham (4) have shown that the addition of excess pyridine to solutions of $(CH_3)_3SnO_2CR$ results in an increase in $J_{^{119}Sn-C-^1H}$ from ~59 to 68 Hz, and this was taken as an indication of a change from four- to five-coordination about the tin. Addition of excess pyridine to solutions of $(CH_3)_4Sn_2(O_2CR)_2$ produces no significant change in $J_{^{119}Sn-C-^1H}$ (60.2 to 62.1 Hz). We take this as further confirmation of the five-coordinate tin environment in solution.

Conclusions

We have described a new preparative route to a series of tetramethyldiacyloxyditin(IV) compounds and examined these by a variety of spectroscopic methods. The compounds have been shown to have a planar tetramethylditin moiety in which the acyloxy ligand bridges both tin atoms: each tin is then five-coordinate. This structure persists in solution.

Molybdenum, tungsten, and manganese carbonyl compounds incorporating novel tridentate chelating dimethyl(1-pyrazolyl)(ethanolamino)gallate ligands

KENNETH S. CHONG AND ALAN STORR

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received May 18, 1978

KENNETH S. CHONG and ALAN STORR. Can. J. Chem. **57**, 167 (1979).

The coordinating properties of the tridentate tris-chelating ligand, $[Me_2Ga(OCH_2CH_2NH_2)(N_2C_3H_3)]^-$, and its three methyl substituted derivatives (methyl substitution on the amino nitrogen and the 3,5 positions of the pyrazolyl ring) have been studied in a series of molybdenum, tungsten, and manganese carbonyl compounds. Mixed allyl carbonyl and nitrosyl carbonyl compounds of both molybdenum and tungsten have been characterized, and a series of tricarbonyl manganese compounds studied. All the complexes are monomeric octahedral species having the tris-chelating ligands in *fac* coordination. Steric factors influence the arrangement of the three remaining groups in the mixed octahedral complexes (i.e. allyl carbonyl and nitrosyl carbonyl derivatives) and particular site preferences are inferred from spectroscopic measurements.

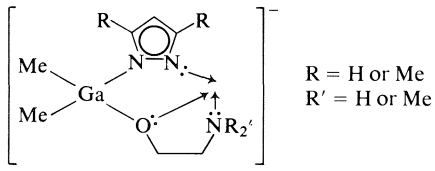
KENNETH S. CHONG et ALAN STORR. Can. J. Chem. **57**, 167 (1979).

On a étudié les propriétés de coordination du ligand tridentate tris-chélatant $[MeGa(OCH_2CH_2NH_2)(N_2C_3H_3)]^-$ et de trois de ses dérivés méthylés (substitution du méthyle sur l'azote de l'amine et sur les positions 3 et 5 du cycle pyrazolyle) avec une série de composés carbonylés du molybdène, du tungstène et du manganèse. On a caractérisé des composés mixtes allylcarbonyle et nitrosylcarbonyle du molybdène et du tungstène et on a étudié une série de composés du manganèse tricarbonyle. Tous les complexes sont des espèces octaédriques monomères portant les ligands tris-chélatants en coordination *fac*. Des facteurs stériques influencent la disposition des trois autres groupes dans les complexes octaédriques mixtes (comme dans les dérivés allylcarbonyle et nitrosylcarbonyle) et l'on a déduit des préférences particulières des sites à partir de mesures spectroscopiques.

[Traduit par le journal]

Introduction

A series of four anionic tridentate chelating ligands of the type **1** has been synthesized.



1

Previous reports dealt with octahedral complexes of the first row transition elements (Mn → Zn) incorporating the ligand **1** where R = H and R′ = H (1) and binuclear transition metal complexes (Co → Zn) using the ligand **1** where R = H and R′ = Me (2). The present account expands the study of these two ligands and introduces two additional ligands where R = Me, R′ = H, and R = Me, R′ = Me in **1**.

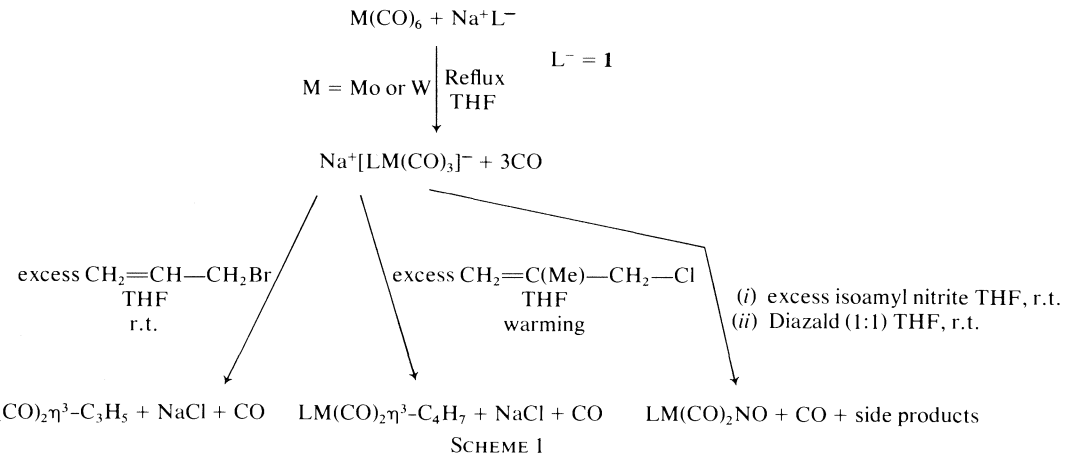
The coordinating properties of the four ligands have been investigated in a series of carbonyl, allyl carbonyl, and nitrosyl carbonyl compounds of molybdenum, tungsten, and manganese. The ligands are thought to occupy three *fac* positions in the octahedral complexes with the remaining positions occupied either by three carbonyl ligands or by two carbonyl ligands plus a nitrosyl or a 'η^3-allyl' ligand. The uninegative ligands, **1**, act as six electron donors and, as such, are compared with other six electron donors (viz. η^5-$C_5H_5^-$, $HB(N_2C_3H_3)_3^-$, and $MeGa(N_2C_3H_3)_3^-$) in similar carbonyl compounds. The effects of substitution of methyl for hydrogen on the 3,5 positions of the pyrazolyl moiety, on the amino nitrogen, and on the 2 position of the η^3-allyl group, are discussed.

Experimental

Starting Materials

Air sensitive materials were handled in a glove box under an atmosphere of oxygen-free, dry, nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over lithium aluminum hydride and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. Pyrazole and 3,5-dimethylpyrazole (K and K Laboratories) and sodium hydride (Alfa Inorganic) were used as supplied. Ethanolamine and *N,N*-dimethylethanolamine were refluxed over anhydrous $CaSO_4$ and distilled prior to use. Allyl bromide and 2-methallyl chloride were distilled under nitrogen prior to use. Molybdenum and tungsten hexacarbonyls were used as supplied (Strem). Manganese pentacarbonyl bromide was prepared from dimanganese decacarbonyl (Strem) by a standard route (3). Isoamyl nitrite (MCB) and Diazald (Aldrich) were used

0008-4042/79/020167-07$01.00/0



SCHEME 1

as purchased and gallium trimethyl was prepared as described previously (4).

Preparative Details

Ligand Synthesis

All four ligands were prepared as THF solutions by the same general route described previously for **1** where R = H, R′ = H (1), and where R = H, R′ = Me (2). These THF solutions of the ligands were employed in all subsequent reactions since isolation of the solid sodium salts of the ligands was impracticable. The THF solutions from the ligand syntheses were made up to standard volumes and accurately measured aliquots used in the preparations described below.

Preparations of Molybdenum and Tungsten Carbonyl Complexes

The general method employed for the preparation of these compounds (Scheme 1) was to react 1:1 molar ratios of the metal hexacarbonyls and the ligand sodium salts in THF to produce extremely air-sensitive yellow solutions of the sodium salts of the $LM(CO)_3^-$ ions. These solutions were then reacted with an excess of the appropriate 'allyl' halide, isoamylnitrite, or an equimolar amount of Diazald to produce the desired product. The crude materials isolated from THF solution were recrystallized from benzene solvent to give yields of approximately 50% for the 'allyl' compounds and the same approximate yield for the nitrosyl compounds if prepared using Diazald, but much lower yields of approximately 15% using isoamylnitrite. Analytical and selected ir data for the pure compounds are presented in Table 1. For a given ligand the stability of the compounds towards air was found to be nitrosyl > η^3-allyl > η^3-2-methallyl and W > Mo. Even in solution the tungsten nitrosyl compounds remained unchanged after exposure to air for several days. The production of the $LMo(CO)_3^-$ ions in solution required refluxing the reactant mixture for 24–48 h depending on the nature of the ligand. For the $LW(CO)_3^-$ ions even longer reaction times were necessary with reflux times of 70–100 h, not uncommon for reactions involving the more sterically demanding ligands. The second stage of the preparations were much more facile and frequently occurred at ambient temperatures (Scheme 1). The lower reactivity of $W(CO)_6$ compared with that of $Mo(CO)_6$ is further illustrated in our inability to prepare the tricarbonyl anion of tungsten incorporating the most sterically demanding ligand **1**, where R = Me and R′ = Me. The tungsten compound listed in Table 1 and bearing this ligand and a η^3-C_3H_5 group was prepared via an alternate route utilizing $(MeCN)_3W(CO)_3$ (5) as a starting material:

$$[1]\quad (MeCN)_3W(CO)_3 + \text{excess } C_3H_5Br \xrightarrow[\text{r.t.}]{\text{THF}} (MeCN)_2W(CO)_2(\eta^3\text{-}C_3H_5)Br + MeCN + CO$$

$$[2]\quad (MeCN)_2W(CO)_2(\eta^3\text{-}C_3H_5)Br + Na^+L^- \xrightarrow[\text{r.t.}]{\text{THF}} LW(CO)_2(\eta^3\text{-}C_3H_5) + NaBr + 2MeCN$$

where L^- = **1** (R = Me and R′ = Me). Attempts to prepare the analogous tungsten compound having a 'η^3-C_4H_7' ligand via the same route did not produce the desired complex.

Manganese Carbonyl Complexes

The four manganese tricarbonyl compounds were prepared directly from pentacarbonyl manganese bromide and the ligand salts in THF. The reaction mixtures were refluxed for ~16 h, the precipitated sodium bromide removed, and the crude products isolated from the THF solutions recrystallized from benzene solvent.

$$Mn(CO)_5Br + Na^+L^- \xrightarrow[\text{r.t.}]{\text{THF}} LMn(CO)_3 + NaBr + 2CO$$

Analytical and selected ir data are collected in Table 1 for these complexes. The compounds were considerably more air-sensitive than the molybdenum and tungsten compounds, with crystalline samples being noticeably oxidized after several hours' exposure to air

Spectra

Mass spectra were recorded on a Varian MAT CH4 mass spectrometer at 70 eV with an ion source temperature of 100–180°C. Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer and ^{1}H nmr spectra on a Varian XL-100 spectrometer. For complexes of low solubility ^{1}H nmr spectra were obtained using FT techniques.

Results and Discussion

Analysis of mass spectral, ir, and ^{1}H nmr data (see below) for the complexes listed in Table 1, points to a monomeric octahedral structure for the whole

TABLE 1. Analytical data for complexes

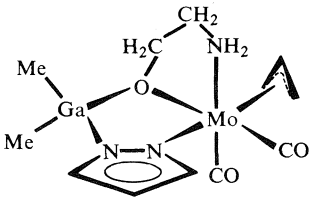
range of compounds studied. Further, it is proposed that the tridentate ligands are *fac* ligands in all the complexes. A schematic representation of a typical molybdenum complex, $[MeGa(N_2C_3H_3)(OCH_2CH_2NH_2)]Mo(CO)_2\eta^3\text{-}C_3H_5$, is shown in **2**.



2

Infrared Spectra

$LMn(CO)_3$ Complexes

Three strong bands in the ν_{CO} region (see Table 1) for all four $LMn(CO)_3$ complexes indicate that the *unsymmetrical* ligand L occupies three facial positions in the octahedral structures, with the three CO groups occupying the remaining set of facial positions. A *mer* arrangement for L in these complexes would lead to two weak ν_{CO} bands and one strong ν_{CO} band in the ir spectra of the complexes (6).

$LM(CO)_2X$ Complexes (M = Mo or W; $X = \eta^3\text{-}C_3H_5$ or $\eta^3\text{-}C_4H_7$)

The ν_{CO} region of the ir spectra of these fifteen

complexes (see Table 1) showed, with two exceptions, two sharp strong bands of equal intensity, indicating a *cis* arrangement of the CO ligands in the complexes (6). This does not distinguish between a *mer* or *fac* arrangement for the ligand L about the central metal atom (1). However, molecular models indicate that the *fac* arrangement allows greater steric freedom to the X groups, particularly in the position *trans* to the pyrazolyl nitrogen (see **2**). The position *trans* to the amino nitrogen is slightly more crowded with the position opposite the oxygen atom least favored sterically. Evidence for the *fac* arrangement of L in the $LM(CO)_3^-$ ions is found in the ir spectra for these ions in THF solution. Two equally strong ν_{CO} bands are apparent with the one at lower frequency being much broader (unresolved *e* mode) than the higher frequency band (a_1 mode). A *fac* arrangement of the *unsymmetrical* ligand would be expected to give three strong ν_{CO} bands whereas a *mer* arrangement would give two weak bands and one strong band in the ν_{CO} region of the spectrum (6).

In the two complexes where more than two ν_{CO} bands occur in the ir spectra in cyclohexane solution (M = Mo or W; L where R = H, R′ = H; X = η^3-C_4H_7) the presence of more than one isomer is indicated. It is noteworthy that in CH_2Cl_2 solution these same complexes show but two ν_{CO} bands, an observation which suggests that the different isomers in cyclohexane solution may be due to different fixed orientations of the 'η^3-C_4H_7' group located in the same octahedral position, rather than two different positional isomers for the octahedral complexes. The effect of solvent on isomer distribution in this type of complex has been documented previously (7, 8).

Comparison of the ν_{CO} frequencies for the 'η^3-allyl' complexes incorporating the ligand **1** with the ν_{CO} frequencies of similar complexes bearing different uninegative 6-electron ligands indicates that the novel ligands described herein create a more electron-rich transition metal centre. The pertinent ν_{CO} values for the (ligand)$Mo(CO)_2\eta^3$-C_3H_5 series of compounds are listed in Table 2. The lower ν_{CO} values observed in the new complexes indicate an increased d_π–π^* back-bonding from the molybdenum atom to the carbon monoxide ligands when compared with the previously described systems. This presumably results from a more electron-rich transition metal centre which may be created by either an increased σ donation to the Mo atom from the new ligands, or may arise from reduced backbonding from the Mo atom to the L ligand acceptor orbitals. A combination of the two effects may well be responsible. The substitution of methyl groups for hydrogen atoms on the pyrazolyl (3,5 positions) and ethanolamino (nitrogen atom) moieties results in a slight decrease in the ν_{CO} values. This may reflect the inductive effect of these methyl groups with consequent increase in the σ-donor characteristics of the ligand system, although reduced back-bonding to L because of enhanced steric crowding and less favorable d_π–π orbital overlaps could also be an important factor.

TABLE 2. Carbonyl stretching frequencies for some $LMo(CO)_2\eta^3$-C_3H_5 complexes (cyclohexane solution)

L	ν_{CO} (cm^{-1})		Reference
η^5-C_5H_5	1970, 1963, 1903, 1889		9
$HB(N_2C_3H_3)_3$	1959	1874	10
$MeGa(N_2C_3H_3)_3$	1948	1860	7
1, R = H; R′ = H	1938	1850	This work
1, R = Me; R′ = Me	1931	1843	This work

As previously observed for similar complexes (7, 10, 11) the ν_{CO} bands in the tungsten compounds are approximately 10–20 cm^{-1} lower than those for the corresponding molybdenum compounds.

$LM(CO)_2NO$ Complexes (M = Mo or W)

The four molybdenum and four tungsten complexes reported in Table 1 displayed the expected ν_{CO} and ν_{NO} vibrations in their ir spectra (CH_2Cl_2 solutions). Two ν_{CO} bands are observed of approximately equal intensity but with the lower frequency band (asymmetric stretch) being much the broader of the two. Again a *cis* arrangement of the two CO ligands is suggested. One broad band is observed for the ν_{NO} stretching vibration in all the complexes. The ν_{CO} and ν_{NO} bands are 20 cm^{-1} lower in the W compounds than in the corresponding Mo derivatives, but within a particular series, changing the nature of L has little effect on the positions of the bands.

The presence of isomers so clearly demonstrated by the ^1H nmr spectra of these complexes in C_6D_6 solutions (see below) is not revealed by their ir spectra in CH_2Cl_2 solutions. Perhaps the different isomers give closely similar ir band positions and are therefore not detectable as separate entities by ir methods. It is, however, noteworthy that although of equal intensity the two ν_{CO} bands are very different in band width. The lower frequency ν_{CO} band is approximately three times broader (half-height band width) than the higher frequency ν_{CO} band. This phenomenon is not observed in the 'η^3-allyl' complexes discussed above where the two ν_{CO} bands are of equal intensity and sharpness.

*All τ values relative to $\tau(C_6H_6) = 2.84$ ppm, τ(TMS) = 10.00 ppm. $J_{HCCH} \simeq 2$ Hz (pyrazolyl ring). s = singlet, d = doublet, t = triplet, br = broad.

C_6D_6 solutions are listed in Table 3. In all of the molybdenum derivatives the spectra suggest the presence of one isomer for the octahedral complexes in solution. This would indicate either a fixed conformation for the 'η³-allyl' groupings or a fast rotation of these groupings about the Mo···'η³-allyl' axis. The former is most likely the correct interpretation but planned variable temperature ^{1}H nmr studies, above and below room temperature, should lead to a definitive answer. In one molybdenum compound (where R′ = Me, R″ = Me and R = H, see Table 2) the N—*Me* and Ga—*Me* signals were quite broad indicating the possibility of slow fluxionality for these groups in this complex. In the same complex, however, the R″ = Me signal and the pyrazolyl proton signals were quite sharp. The structure depicted in **2** is suggested for these complexes, with the 'η³-allyl' groups being in the sterically preferred position opposite the pyrazolyl moiety. The alternate arrangement most likely to occur would place the 'η³-allyl' groups opposite the amino nitrogen in the octahedral complexes, and indeed this arrangement may be preferred where the amino group is substituted and the pyrazolyl group unsubstituted. (See discussion below on 'nitrosyl' isomers.)

The spectra of the tungsten 'η³-allyl' complexes are very similar to their molybdenum counterparts with the exception of the compound where R = R′ = H and R″ = Me. For this particular complex two sets of signals for the pyrazolyl protons and the Ga—*Me* protons plus a broad R″ = Me signal indicate the presence of two distinguishable isomers in the C_6D_6 solution. As discussed in the ir section, it is probable that these two isomers correspond to different orientations of the η³-C_4H_7 group in the complex rather than to different positional isomers.

$LM(CO)_2NO$ Complexes (M = Mo or W)

Selected ^{1}H nmr data for these complexes in C_6D_6 solution are reported in Table 4. In all cases the presence of two isomers is suggested by the appearance of two sets of signals in the spectra. In contrast to the 'orientation isomers' postulated to explain the presence of two isomers in one of the tungsten 'η³-allyl' derivatives described above, the isomers

arising in the nitrosyl compounds must necessarily be positional isomers. The fact that only two sets of signals are observed in the spectra indicates that only two positions of the octahedral anions $LM(CO)_3^-$ are susceptible to NO substitution. Accepting that the ligand L is *fac*, the most favored positions for substitution, sterically, are first the position opposite the pyrazolyl nitrogen, and second the position opposite the amino nitrogen. The expected preference for substitution in the position opposite the pyrazolyl moiety is substantiated by the observed ratios for the two isomers in the solutions. Thus considering the ratios in Table 4 and using **2** it is straightforward to assign the two groups of proton signals to their respective positional isomers. It is noteworthy that only when the 'pyrazolyl' moiety is unsubstituted and the 'amino' nitrogen fully substituted do the two positions become equally favorably towards NO substitution. Conversely, when the 'pyrazolyl' moiety is substituted in the 3,5 positions, and the 'amino' nitrogen unsubstituted, NO substitution in the position opposite the 'pyrazolyl' nitrogen is favored over NO substitution in the position opposite the 'amino' nitrogen to the extent of 5:1. Attempts at separation of the two isomers for selected complexes by column chromatography have so far proved unsuccessful. If future attempts are more rewarding crystallographic structural studies will be carried out on the separated isomers to confirm the above predictions listed in Table 4.

Mass Spectra

The 27 complexes listed in Table 1 were all sufficiently volatile and stable to give readily observable parent ion signals in their mass spectra, which corresponded to monomer species in the vapour phase. The appearance of signals due to other ions in all of the spectra indicated fragmentation patterns which are predictable for the various complexes. The intensity ratios of the individual peaks in all multi-peak signals agreed closely with theoretical predictions based on the percentage isotope compositions of the contributing metal atoms. In all 27 spectra signals due to the five-membered ring ions, $\overline{M—\text{'pyrazolyl'}—Ga—O}^+$, were observed indicating a facile loss of the '$—CH_2—CH_2—NR_2$' moiety from the octahedral complexes, and the intrinsic stability of the five-membered ring system.

Currently under investigation are ligands incorporating amino thiols, in place of amino alcohols in

the present systems, and also ligands of higher denticity created by reacting suitable HX precursors with the $Me_3Ga(N_2C_3H_3)^-$ ion.

A. WALLACE CORDES, PAUL F. SCHUBERT, and RICHARD T. OAKLEY. Can. J. Chem. **57**, 174 (1979).

The crystal structure of 1,4-diphenyl-2,2′,3,3′,5,5′,6,6′-octamethylcyclo-1,4-diphospha-2,3,5,6-tetrasilahexane, $(PhPSi_2Me_4)_2$, has been determined by single crystal X-ray diffraction. The crystals are monoclinic, space group $P2_1/c$, with $a = 9.866(1)$, $b = 11.921(1)$, and $c = 11.324(2)$ Å, $\beta = 104.31(1)°$, $Z = 2$, and $\rho_{calcd} = 1.15$ g/cm^3. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.060 and R_w of 0.078, for 1173 reflections with intensities greater than 3σ. The $(PhPSi_2Me_4)_2$ molecule lies on a crystallographic centre of symmetry, and the six-membered P_2Si_4 ring has a chair conformation with equatorial phenyl groups. The endocyclic angles at P (104.4(1)°) and Si (104.9(2)°) are intermediate between those found in cyclic hexaphosphine and hexasilane molecules, and the Si—Si and P—Si distances of 2.345(3) and 2.252(4) Å, respectively, correspond to single bond lengths, with no appreciable evidence for secondary $p\pi \rightarrow d\pi$ bonding between phosphorus and silicon. The Si—C (1.867(8) Å) and P—C (1.828(7) Å) bond lengths are also normal. The variations in the Si—P—C (101.6(2)°, 108.6(2)°), P—Si—C (range 106.2(3)–120.0(3)°), and Si—Si—C (range 105.8(3)–113.7(3)°) angles indicate that the positions of the exocyclic methyl and phenyl groups are influenced by both intra- and intermolecular steric forces.

A. WALLACE CORDES, PAUL F. SCHUBERT et RICHARD T. OAKLEY. Can. J. Chem. **57**, 174 (1979).

Faisant appel à la diffraction des rayons X par des monocristaux, on a déterminé la structure cristalline du diphényl-1,4 octaméthyl-2,2′,3,3′,5,5′,6,6′ cyclodiphospha-1,4 tétrasilahexane-2,3,5,6, $(PhPSi_2Me_4)_2$. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$ avec $a = 9.886(1)$, $b = 11.921(1)$ et $c = 11.324(2)$ Å, $\beta = 104.31(1)$, $Z = 2$ et $\rho_{calcd} = 1.15$ g/cm^3. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale R de 0.060 et R_w de 0.078 pour les 1173 réflexions avec des intensités plus grandes que 3σ. La molécule $(PhPSi_2Me_4)_2$ se trouve au centre de symétrie et le cycle à six chaînons P_2Si_4 adopte une conformation chaise avec les groupes phényles en position équatoriale. Les angles endocycliques au niveau du P (104.4(1)°) et du Si (104.9(2)°) sont intermédiaires entre ceux trouvés dans des molécules d'hexaphosphines et d'hexasilanes cycliques et les distances Si—Si et P—Si qui sont respectivement 2.345(3) et 2.252(4) Å correspondent à des longueurs de liaisons simples et l'on ne trouve aucune indication à l'effet qu'il existe une liaison secondaire $p\pi \rightarrow d\pi$ entre le phosphore et le silicium. Les longueurs des liaisons Si—C (1.867(8) Å) et P—C (1.828(7) Å) sont aussi normales. Les variations dans les angles Si—P—C (101.6(2)°, 108.6(2)°), P—Si—C (allant de 106.2(3)–120.0(3)°) et Si—Si—C (allant de 105.8(3) à 113.7(3)°) indiquent que les positions des groupes méthyles et phényles exocycliques sont influencées à la fois par des forces stériques intra- et intermoléculaires.

[Traduit par le journal]

Introduction

The molecular structures of a variety of homocyclic polysilanes $(R_2Si)_n$ (1, 2) and polyphosphines $(RP)_n$ (3–7) have been described, but to the present time there have been no reports concerning the structural characteristics of mixed phosphorus–silicon ring systems. We are currently investigating the physical and chemical properties of such compounds (8), and as a part of this work we have determined the crystal and molecular structure of 1,4-diphenyl-2,2′,3,3′,5,5′,6,6′-octamethylcyclo-1,4-diphospha-2,3,5,6-tetrasilahexane (**1**), the first such characterization of a compound containing an uncoordinated silylphosphine moiety.[2]

[1]Present address: Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4.

[2]NOTE ADDED IN PROOF: Since the submission of this article the structures of $P_4(SiMe_2)_3$ and $P_7(SiMe_3)_3$ have been reported (20).

1

Experimental

Crystals suitable for X-ray work were obtained by slow cooling of a warm, saturated benzene/hexane (1:1) solution. The approximately cubic crystal used for all data collection had external faces roughly parallel to, and on the same side of the centre of, the 100, −100, 011, 0 −1 −1, 17 −1 0, −7 −3 8, and 230 faces at face-to-centre distances of 0.15, 0.15, 0.26, 0.26, 0.27, 0.24, and 0.25 mm, respectively. The crystal was sealed in a glass capillary under an atmosphere of nitrogen and mounted with the 001 reflection parallel to the ϕ axis of the diffractometer. A least-squares refinement of 15 values of 2 sin θ/λ for 2θ values between 50 and 87° (λCuK_α = 1.5418 Å) gave cell constants (at 22°C) of

$C_{20}H_{34}P_2Si_4$ fw = 448.78

a = 9.866(1), b = 11.921(1), c = 11.324(1) Å, β = 104.31(1)°, V = 1290.5 Å^3, and ρ_{calcd} (for Z = 2) = 1.15 g cm^{-3}.

The experimental density was not measured because of the extreme air sensitivity of the compound. Systematic absences uniquely indicated the space group $P2_1/c$; two molecules per unit cell in this space group require a centrosymmetric molecule.

Intensities were measured using Ni-filtered radiation on a manual GE-XRD-5 diffractometer. A θ–2θ scan ($2\theta_{max}$ = 120°) at 2° min^{-1} over 2° was used, with 10 s background counts taken at the end of the scan. Four reflections measured periodically indicated a 10% loss in intensity (of instrumental origins) on the third day of the six days of data collection; a simple correction was made for this situation. The μ value was 32.16 cm^{-1} for the crystal used; an absorption correction with summation points every 0.0075 cm gave a range of correction factors (for **1**) of 0.47 to 0.68. Of the 2042 reflections measured, 1173 had intensities greater than 3σ, where $\sigma^2(I)$ = scan + 9 background counts + $(0.05I)^2$. Seven of these reflections were excluded from the refinement data because of evidence for extinction.

The structure was solved by direct methods, and refined by Fourier and full-matrix least-squares procedures. The neutral atom scattering factors of ref. 9 were used for the refinement; anomalous dispersion corrections were made for phosphorus and silicon (10). All of the hydrogen atoms were located on difference maps. Positional parameters of all but two of the hydrogen atoms were refined in the least-squares treatment; two of the phenyl hydrogen atoms were constrained to calculated positions because of the unreasonable positions that they assumed when included in the least-squares matrix. The weighting scheme $w = 1/(2F_{min} + F_o + 2F_o^2/F_{max})$ for the full-matrix refinement (163 parameters, reflection/parameter ratio 7/1) gave a final R = 0.060, R_w = 0.078, a standard deviation of an observation of unit weight = 0.41, and no dependence of $\Delta F/\sigma(F)$ on either F or sin θ. On the final cycle of refinement all the non-hydrogen positional shifts were less than 0.09σ. A final difference Fourier gave a maximum peak of 0.45 e/Å^3, which is equal to 7% of the peak value for carbon on a regular Fourier map. Measured and calculated structure factors for the observed data have been placed in the Depository of Unpublished Data.[3]

Results and Discussion

The crystal structure of the title compound consists of discrete molecules of $(PhPSi_2Me_4)_2$. Figure 1 is an ORTEP drawing which shows a general view of the molecule and gives the crystallographic numbering scheme. Atomic coordinates are given in Table 1, and the anisotropic thermal parameters of the non-hydrogen atoms deposited in Table 2. The derived bond distance and valence angle information is presented in Tables 3 and 4. The six-membered P_2Si_4 ring exists in a chair conformation with a crystallographically imposed centre of symmetry, with no evidence of disorder.

Many of the structural features observed in $(PhPSi_2Me_4)_2$ are related to those found in the homocyclic molecules $(SiMe_2)_6$ (1) and $(PhP)_6$ (3)[4] and, for purposes of comparison, the valence, dihedral and torsion angles of the three molecules are listed in Table 5,[5] along with those expected for an idealized cyclohexane chair. All three molecules have chair conformations and, as in $(PhP)_6$, the phenyl groups on phosphorus in $(PhPSi_2Me_4)_2$ occupy equatorial positions. The degree of puckering of the chairs is significantly different and, as expected, is dependent on the size of the internal ring angles. Thus, in $(SiMe_2)_6$, where the endocyclic angle (111.9(5)°) is close to the tetrahedral value, the dihedral (131.8(2)°) and skeletal torsion (53.5(3)°) angles vary only slightly from those of the 'ideal' C_6H_{12} conformation. In $(PhP)_6$, the smaller ring angle leads to a more folded chair, with smaller dihedral (96.8(1)°) and larger torsion (85.0(1)°) angles. The geometry of the P_2Si_4 ring in $(PhPSi_2Me_4)_2$ then represents a compromise between those of the two homocyclic molecules; the valence, dihedral and torsion angles are all intermediate between the values found in the Si_6 and P_6 rings. The cross-ring distances Si(2)—Si(3) (3.550(3) Å), P(1)—Si(2′) (3.641(2) Å), and P(1)—Si(3′) (3.654(2) Å) are all slightly shorter than the sum of the van der Waals radii (4.20 and 3.90 Å for Si—Si and P—Si interactions, respectively) (11), and the equalization of the

[3]A copy of the observed and calculated structure factor table is available, at a nominal charge, upon request, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[4]The two forms of $(PhP)_6$ are nearly identical. The structural parameters of the trigonal modification, which include anisotropic thermal refinement, will be used throughout this discussion.

[5]Here and elsewhere in this paper, integers quoted in parentheses refer to estimated standard deviations for single-valued parameters, and indicate ranges of results for the averages of chemically equivalent parameters.

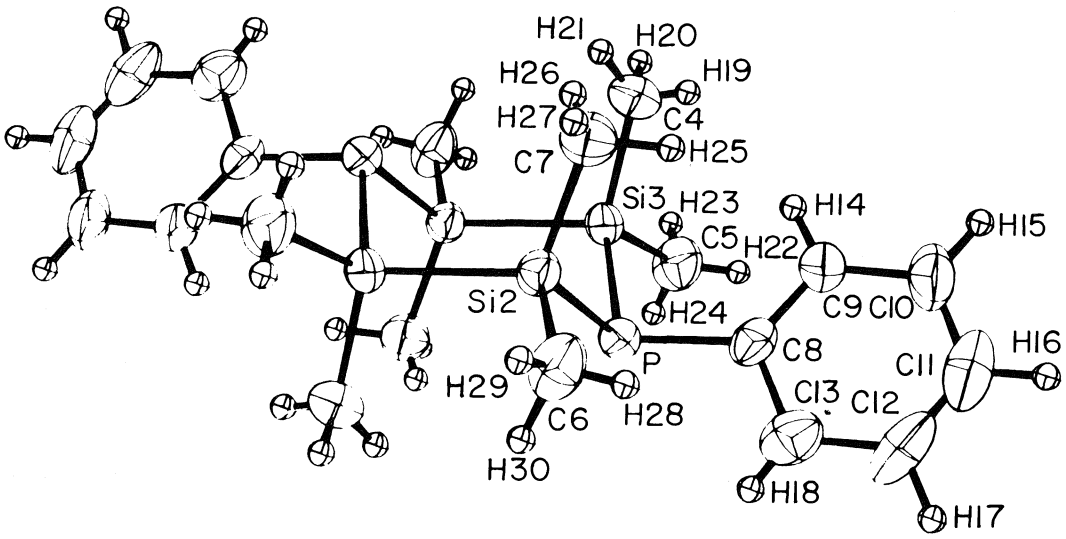

FIG. 1. An ORTEP drawing of the $(PhPSi_2Me_4)_2$ molecule, showing the atom numbering scheme used. Non-hydrogen thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms have been given an isotropic β of 1.0 in this drawing in order to clarify the figure.

[a]H(16) and H(17) were constrained to the positions given (see text). All hydrogen atoms were assigned isotropic thermal factors of β = 5.0.

endocyclic angles is probably necessary so as to increase an otherwise overly close Si(2)—Si(3) contact, and thereby minimize the repulsive interactions between the axial methyl groups (*vide infra*).

The differences in some of the chemically equivalent Si—Si—C and P—Si—C angles and the bent orientation of the phenyl group suggest that the methyl and phenyl group positions are strongly influenced by inter- and intramolecular steric forces. The angle of the phenyl group with respect to the P_2Si_4 ring is the most apparent distortion (Si(2)—P(1)—C(8) is 101.6(2)° and Si(3)—P(1)—C(8) is 108.6(2)°) and appears to be the result of the packing pattern as shown in the *xz* projection of Fig. 2. Although none of the intermolecular contacts are less than the sum of the corresponding van der Waals' separations (11), the three nearest C—C contacts (C_{10}—C_{11}, C_{10}—C_{12}, C_{11}—C_{11}), the shortest C—H contact (C_{10}—C_{18}), and one of the H—H intermolecular contacts (H_{15}—H_{18}) are all involved in the phenyl–phenyl packing and are indicated by dotted lines in Fig. 2. One of the axial (the C(4)) methyl groups also experiences a close intramolecular contact with the phenyl ring; the H(14)—H(19) distance is slightly less than the expected van der Waals' separation (2.40 Å) (11). The less pronounced rotation of the phenyl ring about the P—C bond than is found in $(PhP)_6$ (compare the P—P—C—C and Si—P—C—C torsion angles in Table 5) probably occurs to alleviate this phenyl–methyl repulsion. The equatorial C(5) methyl group appears to be slightly perturbed by a neigh-

bouring phenyl ring (H(23) to H(16) at $x - 1, y, z$ is 2.48 Å).

In contrast to $(SiMe_2)_6$, where the Si—Si—C angles are nearly equal, the Si—Si—C and P—Si—C angles in $(PhPSi_2Me_4)_2$ vary significantly (by 8 and 14°, respectively), probably as a result of both inter- and intramolecular interactions. The largest of these, the two P—Si—C(axial) angles, are caused by cross-ring axial–axial repulsions. The C—C distance for this contact is 3.679(3) Å, which is considerably

shorter than the 4.21 Å found in $(SiMe_2)_6$ and the van der Waals' distance (4.17 Å) for two methyl groups (11). In spite of these distortions, the mean C—Si—C angle (108.0(2)°) is similar to that in $(SiMe_2)_6$ (108.1(5)°), and the nearly equivalent Si—C bonds are only marginally shorter than in $(SiMe_2)_6$, where the axial (1.880(8) Å) and equatorial (1.897(12) Å) bonds are of unequal length. The P—C bond (1.828(7) Å) is slightly shorter than in $(PhP)_6$ (1.843(7) Å), the contraction probably being caused by the different geometries at phosphorus; the mean angle at phosphorus in $(PhPSi_2Me_4)_2$ (104(4)°) is greater than in $(PhP)_6$ (97(3)°), and the σ-bonds are expected to have a greater *s*-character associated with them. The phenyl ring is planar within experimental error ($\chi^2 = 4.7$), and the values of the mean C—C bond (1.38(4) Å) and C—C—C valence angle (120(2)°) are as expected.

The silicon–silicon distance of 2.345(3) Å corresponds to a normal single bond, the value being similar to those observed in $(SiMe_2)_6$ (2.338(6) Å) (1), $(OSi_2Me_4)_2$ (2.35 Å) (12), and silicon metal (2.352 Å) (13). The phosphorus–silicon bond length (2.252(4) Å) is close to the value obtained from vapour phase electron studies on $(H_3Si)_nP(Me_{3-n})$ ($n = 1, 3$) (2.245–2.249 Å) (14), but significantly shorter than in the recently determined structures of the cation $(Me_2P(SiMe_3)_2)^+$ (2.292(5) Å) (15) and the molybdenum complex $(CO)_4Mo(PPhH(Si_2Me_4)$-PPhH) (2.266(1) Å) (16), where the lone pair on phosphorus is coordinated directly to a competing acceptor centre. Although the shorter bonds in the free phosphines can be construed as the result of $p\pi$–$d\pi$ conjugation between phosphorus and silicon, as has been suggested to be the cause of the increased ionization potentials (17) and low inversion barriers (18) of such compounds, the effect is small, and must be viewed with caution. The shortening of the P—Si bond in $(PhPSi_2Me_4)_2$ by 0.035 Å from the normal single bond distance[6] is entirely consistent with the contraction expected from bond polarity contributions (19). However, similar effects should also be present in the complexed molecules, and changes in σ-hybridization between the 3- and 4-coordinate phosphorus atoms would be expected to shorten the bonds to the latter. The observed differences are thus hard to rationalize on a simple electronic basis, but in the absence of more detailed information from a wider selection of such compounds, it seems premature to speculate too deeply as to their cause. However, the results of the present work do confirm that the structural effects of P → Si π-bonding are small.

[6]Estimated by summing the covalent radii of phosphorus in $(PhP)_6$ and silicon in $(SiMe_2)_6$.

Bis(ditertiaryphosphine) complexes of rhodium(I). Synthesis, spectroscopy, and activity for catalytic hydrogenation

BRIAN R. JAMES AND DEVINDER MAHAJAN

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received August 11, 1978

BRIAN R. JAMES and DEVINDER MAHAJAN. Can. J. Chem. **57**, 180 (1979).

Rhodium(I)–bis(ditertiaryphosphine) complexes of the general formula $Rh(P\frown P)_2Cl$ ($P\frown P = Ph_2P(CH_2)_nPPh_2$, $n = 1$–4, and (+)-diop (diop = 2,3-*O*-isopropylidene 2,3-dihydroxy-1,4-bis(diphenylphosphino)butane) have been prepared by treating $[Rh(cyclooctene)_2Cl]_2$ with the appropriate ditertiaryphosphine. The $n = 1$ and $n = 4$ and diop species are five-coordinate in the solid state and in non-polar solvents, while the $n = 2$ and 3 species contain ionic chloride. The cationic complexes $Rh(P\frown P)_2{}^+X^-$ were prepared from the $Rh(P\frown P)_2Cl$ species by adding AgX ($X = SbF_6$, PF_6, BF_4). Reaction of the chloro complexes with borohydride has yielded the hydrides, $HRh(P\frown P)_2$, for the $n = 2$ and 3 diphosphines, and for (+)-diop. ^1H and ^{31}P nmr, as well as visible spectral data, are presented: a solvent-dependent deshielding of *ortho* protons of the phenyl groups is observed in some of the complexes, and the ligand CH_2 protons are coupled to the rhodium in the $Rh(Ph_2PCH_2PPh_2)_2{}^+$ cation; the P atom in this bis(diphenylphosphino) ligand shows an usual high field shift on coordination to rhodium.

Preliminary kinetic data for catalytic hydrogenation of methylenesuccinic acid show that the cationic and hydrido complexes are more active than the corresponding chloro complexes, and that activity generally increases with increasing chain length of the diphosphine.

BRIAN R. JAMES et DEVINDER MAHAJAN. Can. J. Chem. **57**, 180 (1979).

On a préparé des complexes de bis(phosphines ditertiaires)rhodium(I) de formule générale $Rh(P\frown P)_2Cl$ ($P\frown P = Ph_2P(CH_2)_n PPh_2$, $n = 1$–4 et (+)-diop (diop = *O*-isopropylidène-2,3 dihydroxy-2,3 bis(diphénylphosphino)-1,4 butane) en faisant réagir le $[Rh(cyclooctène)_2Cl]_2$ avec la phosphineditertiaire appropriée. Les espèces où $n = 1$, $n = 4$ et diop sont pentacoordonnées à l'état solide et dans des solvants non-polaires alors que les espèces où $n = 2$ et $n = 3$ contiennent du chlorure ionique. On a préparé les complexes cationiques $Rh(P\frown P)_2{}^+X^-$ à partir des espèces $Rh(P\frown P)_2Cl$ auxquelles on a ajouté du AgX ($X = SbF_6$, PF_6, BF_4). La réaction des complexes chlorés avec le borohydrure conduit aux hydrures, $HRh(P\frown P)_2$, pour les diphosphines où $n = 2$ et 3 et pour le (+)-diop. On présente les spectres rmn ^1H et ^{31}P de même que les spectres dans le visible: dans quelques-un des complexes, on observe un déblindage des protons *ortho* des groupes phényles qui dépend du solvent et, dans le cation $Rh(Ph_2PCH_2PPh_2)_2{}^+$, les protons du CH_2 du ligand sont couplés au rhodium; l'atome de P de ce ligand bis(diphénylphosphino) subit un déplacement usuel vers les hauts champs par coordination avec le rhodium.

Des données cinétiques préliminaires concernant l'hydrogénation catalytique de l'acide méthylènesuccinique montrent que les complexes cationiques et hybrido sont plus actifs que les complexes chloro correspondants et que généralement l'activité augmente avec une augmentation de la longueur de la chaîne de la diphosphine.

[Traduit par le journal]

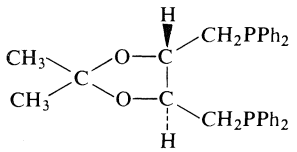
Introduction

Although the bis(ditertiaryphosphine) $Ph_2P(CH_2)_nPPh_2$ complexes of iridium(I) and iridium(III) have been studied fairly extensively (1–4), few details have been reported for the rhodium analogues. The $Rh(dpe)_2X$ complexes,[1] X = H, Cl, ClO_4, are well-known (5), and in terms of activation of small gas molecules and catalytic activity, the crystal structure of the cationic dioxygen complex $Rh(dpe)_2O_2{}^+PF_6{}^-$ has been reported (6). The $Rh(dpe)_2Cl$ complex is a 1:1 electrolyte in polar solvents (2, 5), and is ineffective as a catalyst for hydrogenation of olefinic substrates under mild conditions (2, 7). The $Rh(dpe)_2{}^+$ cation is unreactive toward H_2 (8, 9).

Our interest in these bis(diphenylphosphino) systems increased after our finding that an isolated $HRh[(+)\text{-diop}]_2$ complex was an efficient catalyst for asymmetric hydrogenation of certain prochiral olefinic carboxylic acids under mild conditions (10, 11). The illustrated diop ligand can be considered,

[1]Ligand abbreviations used for $Ph_2P(CH_2)_nPPh_2$: $n = 1$, bis(diphenylphosphino)methane or dpm; $n = 2$, 1,2-bis(diphenylphosphino)ethane or dpe; $n = 3$, 1,3-bis(diphenylphosphino)propane or dpp; $n = 4$, 1,4-bis(diphenylphosphino)butane or dpb. $P\frown P$ signifies generally a chelating diphosphine.

0008-4042/79/020180-08$01.00/0



(+)-diop

for example, as a derivative of the dpb ligand, and this led us to look at the bis[$PPh_2(CH_2)_nPPh_2$] systems, including the hydrido, chloro, and cationic complexes, with a view to learning more of reactivity patterns generally as a function of *n*. Such data have appeared on the use of 1:1 rhodium(I)/$Ph_2P(CH_2)_nPPh_2$ hydrogenation catalysts formed *in situ* from rhodium(I) precursors (12), and, depending on the media, the catalysts may be neutral or cationic (13).

The synthesis and characterization of various bis(diphenylphosphino) complexes are reported in this paper along with some preliminary data concerning their catalytic activity for hydrogenation of the prochiral substrate, methylenesuccinic acid. We (11) and Kagan's group (14) have reported earlier on the characterization of the cationic complexes $Rh(diop)_2^+$ and $H_2Rh(diop)_2^+$, and Slack and Baird (15) reported on some *in situ* dpp and diop systems while our work was in progress. The luminescence of the $Rh[PPh_2(CH_2)_nPPh_2]_2^+$ cations (n = 1–3) has been discussed but no other details on the complexes were given (16, 17).

Experimental

All solutions were handled under an argon atmosphere using Schlenk techniques. Spectral grade solvents were stored over molecular sieves (BDH, type 5A) and were vacuum-degassed before use for synthetic procedures. Spectra were recorded on a Perkin-Elmer 202 or Cary 14 (for uv/vis), a Perkin-Elmer 457 (for ir, solid samples being run as Nujol mulls between CsI plates), a Varian T-60 (for ^1H nmr), and a Varian XL-100 in the Fourier transform mode (for ^1H nmr, and ^{31}P nmr at 40.5 MHz using a P_4O_6 capillary as external standard). Conductivity measurements were made either in nitromethane or in *N,N'*-dimethylacetamide (DMA) at 25°C using a Thomas Serfass conductivity bridge and cell. Microanalyses were performed by Mr. P. Borda of this department.

Rhodium(III) trichloride trihydrate was obtained from Johnson, Matthey Limited, silver salts from Alfa Inorganics and Cationics Inc., and the dpm, dpe, dpp, and (+)-diop ligands were Strem products. A literature method (18) was used to prepare dpb. All the diphosphines were recrystallized from hot ethanol before use.

The rate data were measured on a constant pressure gas-uptake apparatus described previously (19). The solvents for gas-uptake experiments were distilled before use; toluene and DMA were refluxed with CaH_2, and alcohols were refluxed with magnesium metal/iodine to remove traces of water and were stored under argon.

Preparation of Complexes

The cyclooctene dimer $[RhCl(C_8H_{14})_2]_2$ was prepared by a literature procedure (20); yields of 90% are obtained on leaving the reaction mixture for 10 days.

$Rh(dpe)_2Cl$ and $Rh(dpp)_2Cl$

A benzene solution (10 mL) of the phosphine (1.1 mmol, ~0.45 g) was added to a red, benzene solution (10 mL) of $[RhCl(C_8H_{14})_2]_2$ (0.25 mmol, 0.18 g). The precipitated yellow complex was washed with warm benzene and dried *in vacuo*. The complexes have been prepared previously by other methods (5, 16).

$Rh(dpm)_2Cl$

To a benzene solution (5 mL) of $[RhCl(C_8H_{14})_2]_2$ (0.30 mmol, 0.215 g) was added dpm (1.32 mmol, 0.50 g) in benzene (5 mL), and the resulting solution was freeze-dried. The residue obtained was recrystallized from CH_2Cl_2/ether to give orange needles.

$Rh(dpb)_2Cl$ and $Rh[(+)\text{-}diop]_2Cl$

A benzene solution (15 mL) of $[RhCl(C_8H_{14})_2]_2$ (0.30 mmol, 0.215 g) and phosphine (1.32 mmol, 0.56 g dpb or 0.66 g (+)-diop) was refluxed under Ar for 3 h. Concentration to a 5 mL volume, followed by addition of *n*-hexane, gave a yellow solid that was filtered, recrystallized from CH_2Cl_2/ether [$Rh(dpb)_2Cl$] or *n*-hexane [$Rh(diob)_2Cl$], and dried *in vacuo*.

$Rh(P\frown P)_2^+BF_4^-$

The complexes were prepared in each case from the corresponding chloro complex. For example, a mixture of a CH_2Cl_2 solution (5 mL) of $Rh(dpm)_2Cl$ (0.30 mmol, 0.27 g) and a methanol solution (5 mL) of $AgBF_4$ (0.30 mmol, 0.58 g) was stirred for 30 min. Removal of the AgCl and evaporation to dryness left a residue that was recrystallized from CH_2Cl_2/ether to give red crystals of $Rh(dpm)_2^+BF_4^-$. The dpb analogue was also red, while the dpe, dpp, and diop complexes were light orange.

$HRh(P\frown P)_2$

The literature method (5), involving treatment of the chloro complexes (0.50 mmol) with a 3 mole excess of sodium borohydride in ethanol (10 mL), was used in attempts to prepare the corresponding hydrides. The red dpe (5) and orange dpp complexes were recrystallized from benzene/ethanol, while the yellow diop complex (prepared earlier by a different route (21)) was recrystallized from *n*-hexane. Use of the dpm ligand yielded a deep red precipitate but this decomposed even under Ar, and we have been unable to characterize the compound. Borohydride reduction of $Rh(dpb)_2Cl$ yielded a mixture of complexes that have not been separated; borohydride species are almost certainly present as judged by ir bands in the 2340–2390 cm^{-1} region (22). Attempts to synthesize the $HRh(dpb)_2$ complex via the routes used to synthesize the diop analogue from $RhCl_3 \cdot 3H_2O$ (10, 11, 21) were similarly unsuccessful.

The yields of all the isolated complexes described in this section were in the 75–90% range.

Results and Discussion

Cleavage of the chloride bridge in $[RhCl(diene)]_2$ complexes by a Lewis base L, including monodentate phosphines, can yield both RhCl(diene)L and $Rh(diene)L_2^+Cl^-$ species, depending on the amount of L used and the polarity of the solvent used (23). Reaction of the diene dimer with 2 mol of a chelating diphosphine is assumed to yield RhCl(diphosphine) (solvent) or Rh(diene)(diphosphine)$^+$, de-

pending on the solvent, and the cationic complexes are readily synthesized (12–15, 24–26). We have used the cyclooctene precursor $[RhCl(C_8H_{14})_2]_2$ to prepare the $Rh(P\frown P)_2Cl$ complexes (Table 1) via reaction [1].

$$[1]\quad [RhCl(C_8H_{14})_2]_2 + 4P\frown P \xrightarrow{C_6H_6} 2Rh(P\frown P)_2Cl + 4C_8H_{14}$$

While our studies were in progress, a report appeared (27) describing the synthesis of a $[RhCl(diop)(C_6H_6)]_2$ complex via a similar reaction, but using the bis(ethylene) dimer precursor with 2 mol of the diphosphine.

Reaction [1] at room temperature precipitates in analytically pure forms the dpe and dpp complexes, and probably the dpm complex but this is very hygroscopic and does not give satisfactory analytical data. The preparations are simpler than the ones reported earlier using rhodium(I) carbonyl precursors (5, 15, 28). Synthesis of the dpb and diop complexes via reaction [1] requires a refluxing procedure; the complexes are air-sensitive and this could explain the slightly low carbon analyses.

The $Rh(P\frown P)_2{}^+A^-$ complexes ($A^- = BF_4{}^-$, $PF_6{}^-$, $SbF_6{}^-$), readily prepared from the chloro complexes by treatment with Ag^+A^-, can be recrystallized from CH_2Cl_2/ether; the carbon analyses are somewhat low due to the presence of dichloromethane in the crystals (Table 1). Details are given for only the tetrafluoroborate complexes since these proved to have more convenient solubility properties for our catalytic studies (see below).

The borohydride method of Sacco and Ugo (5) was used to synthesize the $HRh(P\frown P)_2$ complexes from the chloro analogues. A presumedly dpm species decomposed spontaneously, at least at room temperature, and we were not able to isolate the dpb by this route or one developed by Robinson's group starting from rhodium trichloride (29). This latter method, in fact, proved to be unsatisfactory for all the hydrides, except $HRh(diop)_2$ (21).

Tables 1–3 report conductivity and spectroscopic data for the various complexes.

The molar conductivity data (Table 1) show that dpm, dpe, and dpp chloro complexes are 1:1 electrolytes in nitromethane, and the visible spectral data in methanol correspond also to those of the $BF_4{}^-$ salts (Table 2). The solid state spectra of the dpe and dpp chloro complexes also show absorption maxima at wavelengths similar to the solution values, indicating the same ionic structure in the solid state. These complexes have always been considered as ionic in the solid state with square planar cations (or approximately so (17)), and this appears to be based on electronic absorption and emission spectral data (16, 17, 30). The dpm complex, unlike the other two, is soluble in toluene and the visible absorption spectrum in this solvent and the solid state differs from that in methanol. We thus consider $Rh(dpm)_2Cl$ to be five-coordinate in the solid state and toluene. Detection of possible Rh—Cl stretching frequencies in the ir is prevented, due to absorption by the dpm (and dpe, dpp) ligands in the 400–280 cm^{-1} region. The dpb and diop chloro complexes also appear to be five-coordinate in the solid state and in non-polar

[a]Measured in ppm (upfield positive) from 85% H_3PO_4. Shifts (CH_2Cl_2 or $CDCl_3$) for the free ligands occur at +22.25(dpm), +12.51(dpe), +17.25(dpp), +15.95(dpb), and +22.50(diop).
[b]Measured in ppm (downfield positive) from TMS in $CDCl_3$(*b*) or C_6D_6(*b′*); s = singlet; t = triplet, m = multiplet.
[c]For phenyl region, lower shift when discernible is due to *m*- and *p*-protons, and the higher shift due to *o*-protons; for $HRh(diop)_2$, the 2 lower shifts are due to *m*-, *p*-protons, and the 2 higher shifts to *o*-protons.
[d]In CH_2Cl_2–acetone-d_6 (2:1 V/V).
[e]In C_6D_6.
[f]In CH_2Cl_2–C_6D_6 (2:1 V/V).
[g]In acetone-d_6.
[h]Corresponding values in CD_3OD were −9.12 (J_{Rh-P} 138.0), and in $CDCl_3$ −9.67 (J_{Rh-P} 140.1). In CD_3OD or acetone-d_6 at −60°C, a complex spectrum is obtained.

solvents; the conductivity data in nitromethane suggest incomplete dissociation of chloride, and their solubility in toluene (the corresponding fluoroborates being insoluble) is also consistent with coordinated chloride. Further, weak ir bands at 281 and 284 cm^{-1} for the dpb and diop complexes, respectively (not present in the BF_4^- analogues), are attributed to ν(Rh—Cl). The visible spectral data are solvent dependent and, in methanol, correspond to those of the cations, thus showing loss of ionic chloride in this medium. The absorption maximum in the cationic systems moves to higher wavelengths as *n* increases from 2 to 4. The dpm system is different in showing two maxima in the 380–450 nm region; 'anomalous' ^{31}P nmr shifts are also noted with this system (see below).

Measurement of the conductivity of the five-coordinate hydrides in nitromethane gave unexpectedly high values for the dpe and dpp complexes, while the diop species exhibited normal behaviour. All the hydrides were essentially non-conducting in polar DMA (31). Reaction of the hydrides with the nitromethane is indicated, and is being studied further, although the limited solubility of the complex and the extreme sensitivity of the solutions to oxygen present difficulties. Reaction of platinum metal hydride complexes with nitroalkanes is not unprecedented (32).

The hydride ligand of the $HRh(P\frown P)_2$ complexes is readily detected by ir, and the high field ^1H nmr, a well resolved doublet of quintets at room temperature (Table 2, Fig. 1), is consistent with four equivalent phosphorus atoms. The same nmr pattern with similar coupling constants (J_{Rh-H} 7 Hz, J_{P-H} 18 Hz) has been reported for $HRh[Ph_2P(CH_3)]_4$ at −60°C, and this was attributed to a tetragonal pyramid structure (33), although others have considered that a fluxional C_{3v} structure is more likely (34). The solid state structure of $HRh(PPh_3)_4$ with the hydrogen atom omitted is tetrahedral, and a threefold axis of symmetry implies that the hydrogen lies on this axis or must be randomly disordered in the crystal (35, 36). A recent structure determination of $HIr(dpe)_2$ shows it to be approximately trigonal bipyramidal with the hydride presumed to be at an axial site (37); the high field ^1H nmr is the quintet expected of a fluxional solution structure, and by analogy the $HRh(P\frown P)_2$ structures are likely to be similar.

The ^{31}P nmr signals (proton-decoupled for the hydrides) appear as sharp doublets at 25°C due to equivalent phosphorus atoms coupling to the rhodium (Table 3). No general trends are apparent, although the dpm ligand is different in undergoing upfield shifts on coordination to the metal. Such upfield shifts have been reported for both dpm and

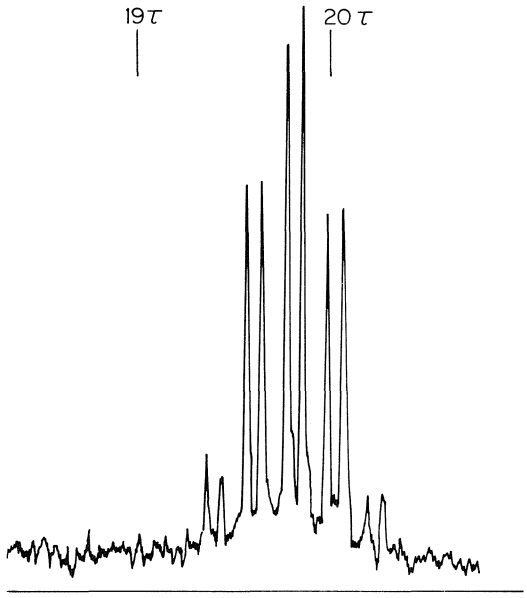

FIG. 1. High field ^1H nmr spectrum of $HRh(dpp)_2$ in C_6D_6 at 20°C.

dpp ligands in some iridium complexes (3), and the factors determining such shifts have been enunciated (38, 39). The substantially larger downfield shifts noted for the dpe complexes provide further examples of the large degree of deshielding apparent in five-membered ring systems (39). The data for the chloro and tetrafluoroborate complexes are consistent with the dpe and dpp complexes being ionic, and the variation of the ^{31}P chemical shift for $Rh(dpm)_2Cl$ with solvent is also consistent with ionic character in polar solvents and covalent character in benzene. Complex ^{31}P spectra were obtained at 25°C for the $Rh(dpb)_2Cl$ and $Rh(diop)_2Cl$ complexes in both C_6D_6 and CH_2Cl_2/acetone-d_6. Complications could arise by (*a*) partial ionization in the polar medium, (*b*) a more rigid five-coordinate structure (cf. the distorted trigonal bipyramidal structure of $HIr(dpe)_2$ (37)), since increasing chelate ring size leads to decreased fluxional behaviour (2, 3), (*c*) the occurrence of multinuclear species, which are becoming increasingly evident in rhodium–diphosphine chemistry (40, 41). The simple doublet pattern of $Rh(diop)_2{}^+BF_4{}^-$ in CD_3OD also gives way to a complex spectrum at −60°C; formation of associated species seems the most likely explanation. More detailed variable temperature nmr studies are in progress to help clarify the complications.

Data for the ^1H nmr in the phosphine region are given in Table 3. The shift of ligand protons on coordination is generally small except for the CH_2 protons of dpm which move downfield by ~0.6 and ~2.3 ppm in the $Rh(dpm)_2Cl$ and $Rh(dpm)_2{}^+BF_4{}^-$

complexes, respectively, the different shifts further confirming the non-ionic character of the chloro complex. These CH_2 resonances are somewhat solvent dependent (Table 3, footnote *g*), and appear as a sextet due to 'virtual coupling' with the rhodium (42). The *ortho* protons of the phenyl groups in the dpe and dpp complexes experience an anisotropic deshielding compared to the *meta* and *para* protons. The phenomenon is more apparent from data in benzene-d_6, since in $CDCl_3$ the phenyl absorption region is broad; for example, free dpe gives multiplets (3:2) at $\delta \sim 7.0$ (*meta,para*) and 7.3 (*ortho*), while in the $HRh(dpe)_2$ complex these absorptions appear at 7.0 and 7.6 ppm, respectively. Similar deshielding of *ortho* protons has been noted, for example (43), in some iridium alkyl complexes, $IrCl_2(CO)(PPh_3)_2$(alkyl), although a shielding of the *ortho* protons occurs in the *cis*-octahedral complexes $Ir(dpe)_2X_2^+$, X = O, S, Se (44), and in the $Rh(dpm)_2Cl$ complex reported here (Table 3).

The low field ^1H nmr of the $HRh(diop)_2$ complex is of interest (Fig. 2) in that the aromatic protons appear as four distinct multiplets of relative intensity 3:3:2:2 at δ7.0, 7.1 (*meta,para*) and δ7.5, 7.9 (*ortho*); the deshielding through coordination is again well demonstrated, and there are now two sets of phenyl groups. These very likely approximate an edge-face conformation, a geometry that has been demonstrated recently in several $Ph_2P\frown PPh_2$ complexes, including IrCl(COD)(diop) (45) and Rh(COD)(diphosphine)$^+$ species (46–48), where COD = 1,5-cyclooctadiene and diphosphine = 1,2-bis-[(anisole)(phenylphosphino)]ethane and 2,3-bis(diphenylphosphino)butane. The orientation of the phenyl groups appears critical for the high efficiency of such complexes as catalysts for asymmetric hydrogenation of prochiral olefinic substrates (13, 46, 48). All the complexes reported here are oxygen-sensitive in solution; in the solid state, only the chloride and fluoroborate complexes containing dpe and dpp are reasonably air-stable.[2]

Catalytic Hydrogenation

Some preliminary kinetic data for hydrogenation of methylenesuccinic acid to 2-methylsuccinic acid are summarized in Table 4.

In agreement with others (2, 7), we find that $Rh(dpe)_2^+Cl^-$ shows very low activity, and until our discovery of the activity of $HRh(diop)_2$ (10, 11), we and probably other workers, because of the early report (2), had not considered rhodium(I)–bis-(diphosphine) chelate complexes as likely catalysts; a

[2]The complexes $Rh(P\frown P)_2X_2$, $X_2 = O_2$ or CO, have been isolated in each case for dpm, dpe, and dpp, except for the dpe/CO system; details will be reported in a later paper.

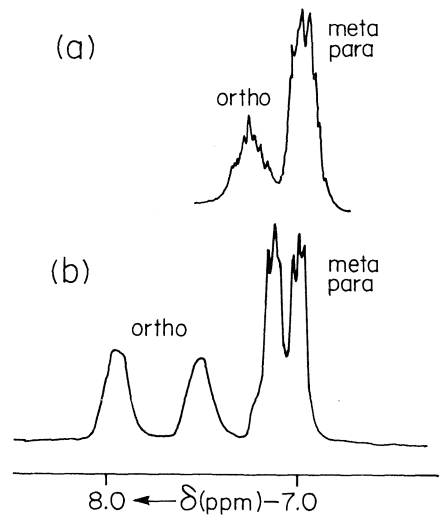

FIG. 2. ^1H nmr (phenyl region) of (*a*) diop, and (*b*) $HRh(diop)_2$ in C_6D_6 at 20°C.

reason was considered to be the difficulty in providing a vacant coordination site (49). Such complexes can clearly lead to quite high activity (Table 4), and in the case of $HRh(diop)_2$, the vacant site is thought to arise by one of the diphosphine ligands becoming monodentate (11, 50).

Initially surprising is that $Rh(dpe)_2^+BF_4^-$ shows about ten times the activity of $Rh(dpe)_2^+Cl^-$ under corresponding conditions, and a similar difference in behaviour is noted for the dpb complexes. Presumably chloride must coordinate and deactivate some intermediate (e.g. an alkyl) in the catalytic cycle. The activity of the $Rh(diop)_2^+$ cation, however, is essentially the same whether the associated anion be chloride or tetrafluoroborate. The cations generally are much less active in the polar and more strongly coordinating DMA.

The hydrides show activity comparable to that of the corresponding fluoroborate salts. The two species are interconvertible by the equilibria outlined in [2] (5, 11);

$$[2]\quad HRh(P\frown P)_2 + H^+ \rightleftharpoons H_2Rh(P\frown P)_2^+ \rightleftharpoons H_2 + Rh(P\frown P)_2^+$$

these are unimportant for the diop complex in butanol/toluene with the methylenesuccinic acid substrate used (11), but the dpe and dpp systems have not been studied in sufficient detail.

Comparison of the data for the fluoroborate salts at substrate concentrations $\geq 0.1\ M$ shows that catalytic activity increases with chain length, $n = 4$ (and diop) $> n = 3 > n = 2 > n = 1$. Kagan's group (12) reported a similar trend for rhodium(I)-*mono*diphosphine systems formed *in situ* from

$[RhCl(C_2H_4)_2]_2$ for the hydrogenation of α-acetamidocinnamic acid in benzene/ethanol at 20°C, the $n = 1$ system being inactive; however, the $n = 6$ system had activity comparable to that for $n = 3$. Although these types of data are of use in designing better catalysts (including chiral ones), rationalizations to explain such trends, based solely on rate data measured at a set of convenient conditions, should not be attempted. These systems typically show saturation behaviour in their kinetics, that is, the rates level off at higher substrate and/or H_2 concentrations (11), and the rate vs. concentration profiles will vary for different systems. The limited data in Table 4 show that the rates for the $Rh(dpe)_2^+BF_4^-$ system are close to zero order in olefinic substrate and are fractional in catalyst, while for the $Rh(dpp)_2^+BF_4^-$ system the rates are close to first order in both substrate and catalyst. Detailed kinetic studies are necessary to elucidate the mechanisms, and then comparable rate constants can possibly be extracted by suitable analysis. In this particular case, we have found that while $Rh(dpe)_2^+$ does not form a dihydride at ambient conditions (as noted by others (8)), the dpp analogue readily gives an isolable *cis*-$H_2Rh(dpp)_2$ complex (51), and the mechanisms for catalytic hydrogenation may well differ. A quite different reactivity pattern has also been found, for example, for the monodiphosphine systems referred to above, when used to hydrogenate styrene in benzene ($n = 3 > n = 1$, $5 > n = 4 >$ diop $> n = 2$) (12).

The diop systems $Rh(diop)_2X$ (X = Cl, BF_4, H) all gave rise to similar optical enrichment in the 2-methylsuccinic acid product (Table 4, footnote *i*).

Received July 10, 1978

PARAM H. TEWARI and ALLAN B. CAMPBELL. Can. J. Chem. **57**, 188 (1979).

The dissolution of iron from carbon steel in aqueous H_2S solutions has been studied as a function of time and temperature at 0.1 MPa H_2S pressure using the rotating disc technique. The iron sulfide film formed on the disc surface has been identified by X-ray diffraction analysis. The solubility and dissolution rate of synthesized mackinawite, $FeS_{(1-x)}$, have also been determined to help establish the mechanism of release of iron from carbon steel corroding in aqueous H_2S solutions.

The rate data have been analysed by an equation for a joint chemical and transport controlled process. At 22°C and 0.1 MPa H_2S, the maximum rate of release of Fe^{2+}, obtained by extrapolating the data to infinite rotation speed, is 7.4 ± 0.5 μmol/m² s. This is similar to the dissolution rate determined for synthesized mackinawite powders, but is 20 times faster than the rate of dissolution for troilite and more than 1000 times faster than the dissolution rates for pyrrhotite and pyrite. Thus, troilite and iron sulfide phases that form subsequently are not major contributors to Fe^{2+} release during the corrosion of carbon steel.

At 22°C the diffusion coefficient for the $FeSH^+$ ion is (1.4 ± 0.2) × 10^{-9} m²/s and the activation energy of the diffusion process is 25 ± 7 kJ/mol. The chemical reaction occurring at the surface has an activation energy of 77 ± 14 kJ/mol.

It is concluded that the release of iron from corroding carbon steel is governed by the dissolution rate of mackinawite, the initial corrosion product. This dissolution is controlled by the chemical reaction between mackinawite and H^+ and by the transport of the complexed $FeSH^+$ from the interface to the bulk solution.

PARAM H. TEWARI et ALLAN B. CAMPBELL. Can. J. Chem. **57**, 188 (1979).

Faisant appel à la technique du disque rotatif, on a étudié la mise en solution du fer d'aciers au carbone dans des solutions aqueuses de H_2S en fonction du temps et de la température, à une pression de 0.1 MPa de H_2S. Grâce à une analyse par diffraction de rayons-X, on a identifié le film de sulfure de fer qui se forme à la surface du disque. On a aussi déterminé la solubilité et le taux de dissolution de mackinawite de synthèse, $FeS_{(1-x)}$, afin d'aider à déterminer le mécanisme de mise en liberté du fer à partir d'aciers au carbone soumis à une corrosion dans des solutions aqueuses de H_2S.

On a étudié les données de vitesse à l'aide d'une équation exprimant les processus contrôlés conjointement d'une façon chimique et par le transport. A 22°C et à une pression de 0.1 MPa de H_2S, le taux maximal de mise en liberté du Fe^{2+} que l'on obtient en extrapolant les données jusqu'à une vitesse de rotation infinie est égal à 7.4 ± 0.5 μmol/m² s. Cette valeur est semblable au taux de dissolution déterminé pour des poudres de mackinawite mais elle est 20 fois plus rapide que celle déterminée pour la dissolution de la troilite et plus de 1000 fois plus grande que les valeurs correspondantes pour la pyrrhotite et la pyrite. Donc les phases du troilite et de sulfure de fer qui se forment subséquemment ne contribuent pas d'une façon importante à la mise en liberté du Fe^{2+} au cours de la corrosion des aciers au charbon.

A 22°C, le coefficient de diffusion de l'ion $FeSH^+$ est (1.4 ± 0.2) × 10^{-9} m²/s et l'énergie d'activation du processus de diffusion est 25 ± 7 kJ/mol. L'énergie d'activation de la réaction chimique se produisant à la surface est 77 ± 14 kJ/mol.

On en conclut que la mise en liberté du fer par un acier au charbon soumis à une corrosion est déterminée par le taux de dissolution de la mackinawite, le produit de corrosion initial. Cette dissolution est contrôlée par la réaction chimique entre la mackinawite et H^+ et par le transport du $FeSH^+$ complexé de l'interface vers la solution.

[Traduit par le journal]

Introduction

Carbon steel exposed to aqueous H_2S solutions corrodes to give ferrous ions and hydrogen (1). Subsequently, a series of iron sulfides is formed (2–8), the first such corrosion product being mackinawite (3, 5), $FeS_{(1-x)}$. Cubic FeS (3, 6–8), troilite (hexagonal FeS), pyrrhotite ($Fe_{(1-x)}S$), and pyrite, FeS_2, can then form, depending on system conditions (3). We have shown that mackinawite is the most soluble phase among the various types of iron sulfide phases

[1]AECL No. 6264.

0008-4042/79/020188-09$01.00/0

formed (9); however, it changes to other phases quite easily. It thus seems desirable to compare the rate of Fe^{2+} release from carbon steel with dissolution rates of mackinawite. Accordingly, we now report the rate of release of Fe^{2+} in aqueous H_2S solutions during the initial corrosion (1–8 h) of carbon steel under conditions of controlled area and hydrodynamics. This release rate has been investigated at several temperatures and 0.1 MPa H_2S pressure by the rotating disc (10, 11) technique.

We have also measured the solubility and dissolution rates of mackinawite at various solution pH's. Such studies should help to determine if the dissolution of mackinawite is the chief pathway for the release of Fe^{2+} from carbon steel exposed to aqueous H_2S solutions. These studies are important in several applied areas, such as in the petroleum industry and Girdler-Sulfide (G.S.) heavy water plants.

Materials and Methods

Materials

Triple-distilled water containing less than 5×10^{-8} mol/kg iron was used in the experiments. All acidic solutions were made with analytical grade H_2SO_4. NaOH solutions were CO_2-free. Analytical grade reagents were used throughout.

Mackinawite was prepared electrochemically (8) using an all glass cell fitted with a carbon steel anode and a platinum cathode. A solution of 0.1 mol/kg NaOH was introduced into the cell and purged with nitrogen for 1 h before the passage of H_2S through the solution. A current of ~ 20 mA was passed through the solution while H_2S was bubbled continuously through the cell for 3 days. Air occlusion was avoided during the reaction. The mackinawite powder formed during the process was washed with deoxygenated water under a nitrogen atmosphere. The product was vacuum dried in a desiccator.

All samples were analysed by X-ray diffraction before and after the dissolution experiments to observe changes of phase, if any, during the experiments.

Apparatus

The rotating discs used in the study were made from carbon steel rod incorporating all the features recommended by Riddiford (11). The disc was fitted into the inset of the Teflon holder (Fig. 1). Immediately before a run, the exposed surface of the disc was ground to within 0.3 mm of the surrounding Teflon surface as described earlier (12). The release of Fe^{2+} was limited to a well defined area of the exposed surface of the carbon steel disc by painting the sides and part of the surface with polyurethane paint.

The bearing for the rotating assembly was designed to ensure minimum eccentricity of rotation of the disc ($< 1\%$ of the disc radius). Rotational velocities were measured using a stroboscope. The temperature was maintained to within ± 0.1°C of the desired value using a thermostatically controlled water bath.

All dissolution work was done in vessels that were degassed and kept oxygen-free. Since mackinawite was easily oxidized in air and the oxidized material later produced other phases of iron sulfides, dissolution work with mackinawite was always performed under N_2 to prevent its oxidation and subsequent transformation to other sulfides.

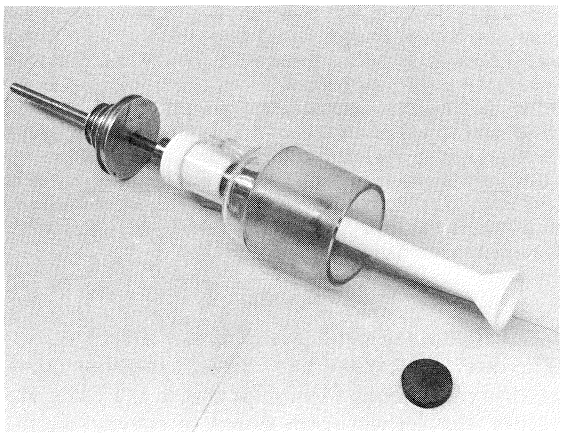

FIG. 1. Rotating disc assembly.

Method

After assembly of the reaction vessel, N_2 was bubbled through the solution for 1/2 h before introducing H_2S. The solutions were saturated with H_2S at room temperature before raising the temperature to any desired value. The temperature and H_2S pressure were allowed to reach equilibrium before the disc assembly was introduced for the start of the run.

The disc was rotated at a given speed between 10 to 85 radians/s (100–800 rpm), resulting in laminar flows with Reynolds number $\leq 10^4$. (The critical Reynolds number (11), when a transition from laminar to turbulent flow occurs, is $Re \simeq 2 \times 10^5$.)

Small aliquots of solution (< 4 g) were withdrawn at intervals from the reaction vessel for Fe^{2+} analysis without exposing the bulk solution to air. The total solution withdrawn for analysis was within 5–10% of the initial total volume. Hence the correction made in concentration change due to the withdrawn volume in samples was small and did not appreciably affect the calculation of rate of iron release.

Iron analyses were done by atomic absorption spectroscopy (detection limit $\simeq 6 \times 10^{-7}$ mol/kg) for samples containing more than 1 μg/g, and by colorimetry (Technicon Analyser) for samples containing less than 1 μg/g. In the latter (detection limit 2×10^{-8} mol/kg), iron is reduced to Fe^{2+} by hydroxylamine hydrochloride in a buffered solution of pH 5.4 before a colorimetric determination by 2,4,6-tri-2-pyridyl-*S*-triazine (TPTZ) reagent. The precision of Fe^{2+} determination was $\pm 12\%$ (2σ) in the concentration range less than 1 μg/g, and $\pm 5\%$ for concentrations > 1 μg/g.

To characterize the iron species being released from the disc, absorption spectra of dissolved iron were obtained using a Cary 17D spectrophotometer with a quartz cell. For comparison, spectra for ferrous solutions made by dissolving 99.999% pure iron in H_2SO_4 were also obtained at pH 1.0, 2.0, and 4.0 in the presence and absence of H_2S, with precautions taken to avoid oxidation of Fe^{2+} or H_2S by bubbling H_2 in the solution and by avoiding exposure to air.

The pH was measured with a Beckman research pH meter fitted with a combination pH and reference electrode. The equilibration time for the pH electrode was obtained for solutions of known acidity or basicity and, in most cases, was < 30 s except between pH 6 and 8 where it was almost 1 min. In solutions saturated with H_2S at 0.1 MPa, a prolonged and continuous exposure of the pH electrode to the H_2S environment was avoided because the performance of the electrode

deteriorated after long H_2S exposure due to silver sulfide precipitation at the tip. This presented no problem in the measurements, however, and the precision of the measured pH was always better than ± 0.01 units.

After the rate data were obtained, the disc was dismounted, washed, and stored in a vacuum desiccator. The morphology of the iron sulfide phases formed on the disc were determined by using a Cambridge Mark 2A Sterioscan electron microscope. Phase analyses of the various sulfides were performed with a Philips PW1050 X-ray diffractometer equipped with a diffracted beam monochromator.

Results

Rate of Release of Fe^{2+} from Carbon Steel

The rate of release of Fe^{2+} from a rotating carbon steel disc in aqueous H_2S solutions at 0.1 MPa H_2S pressure was derived from slopes of curves like that given in Fig. 2. At 22°C these rate data were remarkably reproducible (precision $\leq 5\%$) in contrast to the rate of dissolution data obtained from synthesized mackinawite powders (discussed later). The release rates of Fe^{2+} at 22°C at different rotation speeds are given in Table 1.

At higher temperatures, however, the rate data varied beyond the error in the analysis of iron ($\geq 10\%$). These variations were due to phase changes in mackinawite as observed by X-ray analysis, and also to peeling and rupture of the surface film and contribution from a second crystalline phase formed on the film (Figs. 3–4). Hence, interpretation of rate data at higher temperatures was not as reliable as at 22°C.

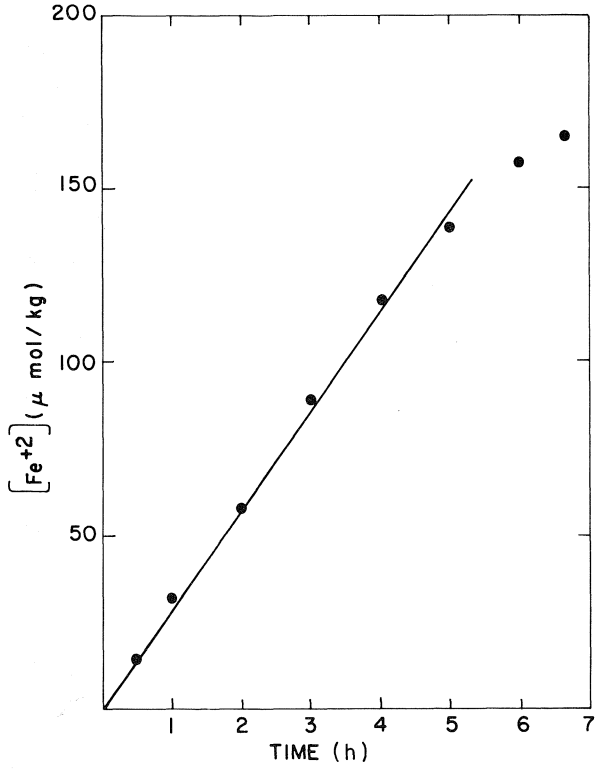

FIG. 2. Release of Fe^{2+} from rotating carbon steel discs as a function of time at 22°C and 0.01 MPa H_2S pressure.

Solubility of Mackinawite

As explained earlier, solubility data for mackinawite are necessary in the discussion of the mechanism of Fe^{2+} release from carbon steel surfaces in aqueous H_2S solutions. Although mackinawite was always handled under N_2 to prevent oxidation and its subsequent transformation to other sulfides, analysis showed that some conversion had taken place. At 25°C and 0.1 MPa H_2S pressure, only in three runs out of 24, all with fresh batches of mackinawite with no detectable impurities, did the samples remain unchanged after the dissolution experiments. The others contained various amounts of other sulfides such as marcasite, greigite (Fe_3S_4), and pyrite.

The solubility data for mackinawite (Fig. 5) show significant scatter even in the runs where the major phase of the product, after dissolution, remained mackinawite. This variation was possibly due to phase changes on the surface although these could not be detected by X-ray diffraction analysis (detection limit $\sim 2\%$). At 25°C and 0.1 MPa H_2S pressure (with no added acid or base, pH $\sim$ 3.95), the observed solubility values ranged from 0.2×10^{-3} to 2.0×10^{-3} mol/kg. The true value could be even higher than 2.0×10^{-3} mol/kg since the unconverted phase would have a higher solubility.

The solubility of mackinawite at $T > 25$°C could not be accurately determined due to its rapid transformation to other sulfides at higher temperatures. Although the extremely poor reproducibility at $T > 25$°C precluded the possibility of obtaining accurate solubility data, it was concluded that mackinawite has a negative temperature coefficient of solubility.

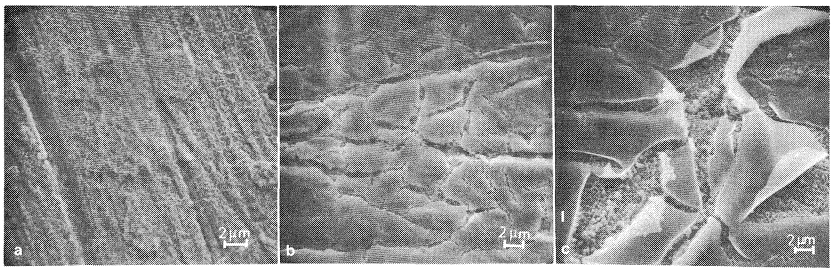

FIG. 3. Morphology of deposits on carbon steel discs exposed to aqueous H_2S solutions at 0.1 MPa H_2S pressure at 22°C. (*a*) Apparently smooth deposit of mackinawite with a preferred orientation. (*b*) Deposit with cracks which subsequently lead to peeling. (*c*) Peeling of deposits. The appearance of a fresh precipitation of cubic FeS phase is shown at location I.

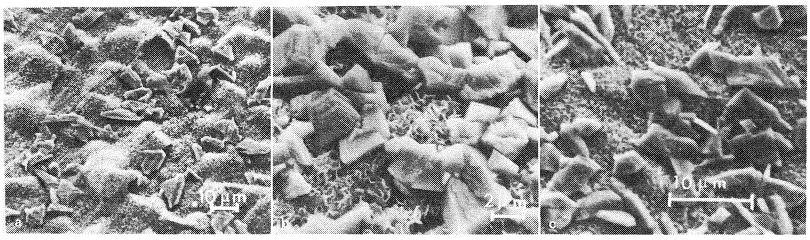

FIG. 4. Morphology of deposits on carbon steel discs exposed to aqueous H_2S solutions at 0.1 MPa H_2S pressure at 40 and 60°C. (*a*) Crystalline phase appearing on top of the first formed layer at 40°C. (*b*) Same crystals at a higher magnification. (*c*) Morphology of the disc surface at 60°C.

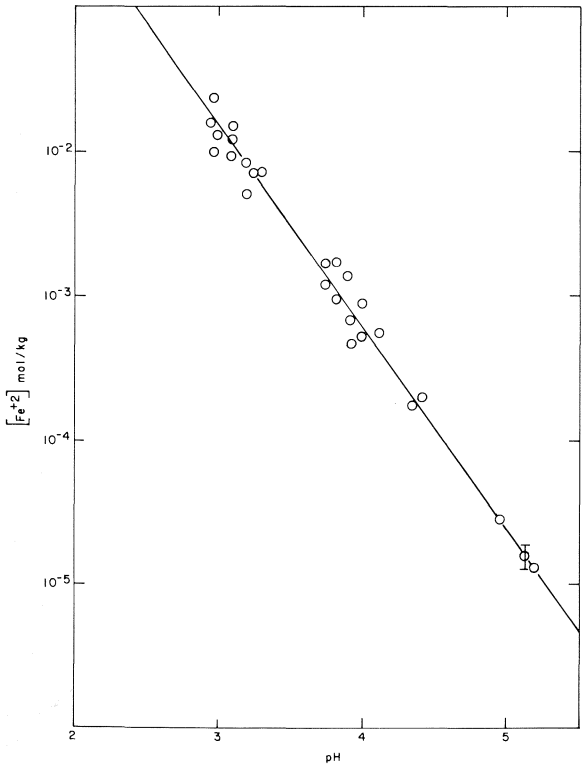

FIG. 5. Solubility of mackinawite at 25°C and 0.1 MPa H_2S pressure as a function of pH.

Stoichiometry of Reaction of Mackinawite with H^+

The kinetic order of the reaction between mackinawite and H^+ was determined by following the initial rates of dissolution at different acidities as described earlier (12) for troilite. The measurements were not accurate ($\pm 10\%$) since, in spite of precautions to avoid exposure to air, mackinawite converted to some extent to other less soluble iron sulfide phases as confirmed by X-ray analysis. From the initial slope of the curves of Fe^{2+} versus time, values of the negative logarithms of the rates were obtained and plotted against the pH of the solutions (Fig. 6). The slope of the line was 1.1 ± 0.1 showing R, the rate of dissolution of mackinawite, to be first order with respect to acid concentration. Therefore, $R = k[H^+]$, where k is the rate constant. The measured rate constant was $(1.2 \pm 0.2) \times 10^{-5}$ m/s, and this is similar to the rate constant for the release of Fe^{2+} from carbon steel discs determined at lower rotation speeds ($\sim 1.5 \times 10^{-5}$ m/s).

Morphology of Carbon Steel Surfaces Exposed to H_2S Solutions

After the kinetic studies, the products on the surface of the carbon steel discs were analysed by X-ray diffraction. At 22°C and 0.1 MPa H_2S pressure, the exposed surface of the discs had developed a black surface deposit which gave the characteristic diffraction pattern for mackinawite. Some of these deposits

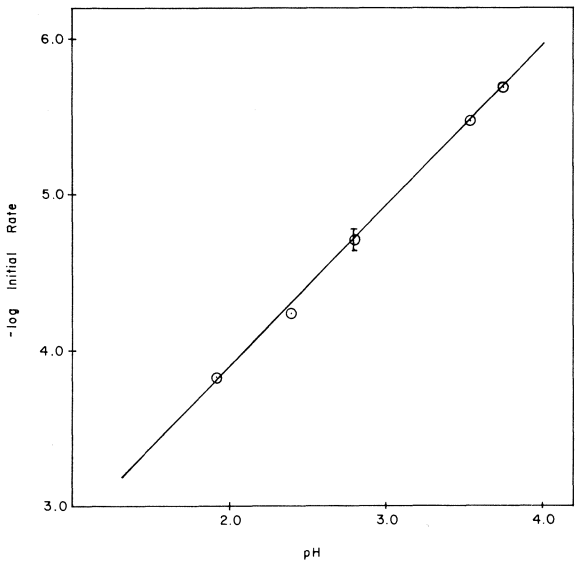

FIG. 6. Dependence of initial rate of dissolution of mackinawite on pH at 25°C.

had a preferred orientation and appeared smooth; however, the majority of these mackinawite films had cracks. Even the films which first appeared smooth developed cracks and were seen lifting and peeling off the surface as shown in Figs. 3 and 4. Peeling could be seen after exposures as short as 6 to 8 h.

The films formed on surfaces exposed to aqueous H_2S solutions at 40°C had mackinawite as the major phase, but these also contained some cubic FeS which always appeared as distinct crystals (Fig. 4). A similar crystalline appearance of cubic FeS has been observed in other studies (3, 7–8). There were fewer linear cracks in the surface film at 40°C, compared to those formed at 22°C. The large crystals appearing on top of the inner phase eventually covered the majority of the surface, but they were also observed to crack and fall off into the solution. In many cases, large numbers of these crystals appeared near an area where a hole was seen. It appeared that the raised areas in the first layer developed holes by cracks and, near the holes, crystals of cubic FeS developed by precipitation. At 60°C, the number of such crystals appearing on the top of the mackinawite phase was larger than that observed at 22 or 40°C, as is evident from Fig. 4*b* and *c*.

Absorption Spectra of Iron Solutions

Spectra of Ferrous Solutions in H_2SO_4

To characterize the iron ion being released from the carbon steel disc, spectra of ferrous solutions made by dissolving pure iron in H_2SO_4 solutions under H_2 atmosphere were obtained in the ultraviolet, visible, and infrared regions. Consistent with literature reports, a relatively intense peak (13) at 240 nm (molar extinction coefficient, $\varepsilon = 19.0$) and a weak peak (14) at 970 nm ($\varepsilon = 1.6$) are obtained for Fe^{2+} (or $[Fe_{(H_2O)_6}]^{2+}$) at pH 1.0 and 4.0 (Fig. 7).

Spectra of Ferrous Solutions in Aqueous H_2S

Since aqueous H_2S solutions have a very intense absorption at $\simeq$ 195 nm, any peak present at $\simeq$ 240 nm or lower is completely masked in the presence of H_2S. In aqueous H_2S solutions at pH 4.0 a peak at 330 nm, which is not present in solutions of iron in the absence of H_2S, is observed, suggesting the presence of species different from $[Fe_{(H_2O)_6}]^{2+}$ ($\varepsilon_{330\ nm} = 2.4$; compare curves *A* or *B* with *C* in Fig. 7).

The position of the peak at 970 nm does not change noticeably in H_2S solutions, but its intensity is very low ($\simeq 0.5$). A transient peak at 1155 nm, whose peak height is small but variable, was also sometimes observed. This peak, however, is likely due to some impurity in H_2S, since it was observed at times even in aqueous solutions of triply distilled water with no detectable iron. Since the intensity of the iron peak in the infrared region is very low, only peaks in the ultraviolet region were used for the characterization of iron species.

Spectra of Iron Ions from a Carbon Steel Disc in Aqueous H_2S

The absorption spectrum of dissolved iron from the carbon steel disc has a peak at 330 nm (Fig. 8, $\varepsilon_{330} = 2.4$), the same as that observed for iron solutions in aqueous H_2S at pH 4.0 (Fig. 7, Curve *C*).

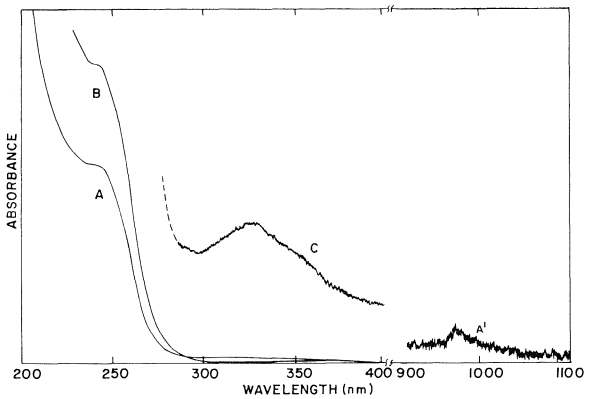

FIG. 7. Absorption spectra of ferrous solutions in H_2SO_4 acid at 25°C. *A*, Fe^{2+} in H_2SO_4, pH = 0.8, absorbance full scale 1.0, $Fe^{2+} = 1.97 \times 10^{-2}$ mol/kg, $\varepsilon_{240\ nm} = 19.0$, $\varepsilon_{970\ nm} = 1.6$. *B*, Fe^{2+} in H_2SO_4, pH = 3.9, absorbance full scale 0.5, $Fe^{2+} = 1.36 \times 10^{-2}$ mol/kg, $\varepsilon_{240\ nm} = 19.0$. *C*, dissolved iron in aqueous H_2S solution at pH = 3.95, absorbance full scale 0.02, $Fe^{2+} = 2.0 \times 10^{-3}$ mol/kg, $\varepsilon_{330\ nm} = 2.4$. *A'*, continuation of curve *A* in the infrared.

Discussion

Rate of Dissolution at Solid–Liquid Interfaces

The reaction between a solid and a solution giving dissolved species may comprise the following steps (11): (*a*) transport of the ions from the solution to the surface (in the present case H^+ or HS^-), (*b*) adsorption and chemical reaction at the solid surface, (*c*) desorption of the reaction products, and (*d*) transport of the products from the solid surface to the bulk solution. Steps (*a*) and (*d*) are transport controlled and are determined by the hydrodynamics of the system, whereas steps (*b*) and (*c*) are chemical processes at the surface and are termed chemical controlled.

According to Nernst theory (15–17), for transport controlled processes, the rate of dissolution, R, is given by

$$[1] \qquad R = \frac{DA}{V\delta}(c_s - c) = \frac{D}{\delta}(c_s - c)$$

where D = diffusion coefficient, A = area of the interface, c_s = solubility of the dissolving material at the given temperature, c = concentration of the solute at any time t, V = volume of solvent, δ = thickness of the Nernst diffusion layer.

According to Levich, for rotating discs in laminar flow (10, 11, 16),

$$\delta = 1.62D^{1/3}\gamma^{1/6}\omega^{-1/2}$$

where γ and ω are the kinematic viscosity and speed of rotation of the disc, respectively. Hence, the rate of dissolution or the flux of the ions diffusing away from the interface is

$$[2] \qquad R = 0.62D^{2/3}\gamma^{-1/6}\omega^{1/2}(c_s - c)$$

For dissolution of metals in acids with transport control, the concentration, c, is assumed to be zero (10, 18); then

$$[3] \qquad R = 0.62D^{2/3}\gamma^{-1/6}\omega^{1/2}[Fe^+]_{sat}$$

($c_s = [Fe^{2+}]_{sat}$ for the dissolving iron compound).

Equation [3] predicts that for a transport controlled process the rate of release of iron from the carbon steel disc is proportional to $\omega^{1/2}$ and that for a plot of R against $\omega^{1/2}$ the curve should pass through the origin. However, if the process of release of Fe^{2+} is not solely controlled by transport of materials to and from the disc, and the rate of surface reaction is also important, the equation for the rate under joint chemical and transport control is (10, 11)

$$[4] \qquad R^{-1} = R_\infty{}^{-1} + 1.62D^{-2/3}\gamma^{1/6}\omega^{-1/2}[Fe^{2+}]_{sat}{}^{-1}$$

where R, D, γ, and ω are the same as defined earlier, and R_∞ = the maximum dissolution rate at the interface (the chemical rate of dissolution), $[Fe^{2+}]_{sat}$ = saturation solubility of the dissolving iron sulfide formed at the interface.

Solubility data for mackinawite have been used since there is considerable evidence to show that this is the phase first formed during initial corrosion under these conditions (3), and our X-ray analysis of the disc surface has confirmed this conclusion.

The measured solubility of synthesized mackinawite powders in aqueous H_2S at 0.1 MPa pressure at 25°C is 2×10^{-3} mol/kg. The actual value may be slightly higher since the measurements are somewhat complicated by the conversion of mackinawite to other, less soluble, iron sulfide phases.

When the experimental data are analysed by eq. [4], the graph of R^{-1} vs. $\omega^{-1/2}$ is linear (Fig. 9). On the other hand, a graph of R vs. $\omega^{1/2}$ (eq. [3]) is not linear and the curve does not go through the origin. This shows that the rate of release of iron is not solely controlled by the transport of materials to and from the disc, but is controlled jointly by a chemical as well as a transport process.

Nature of the Iron Sulfide Film formed at the Interface and its Dissolution

Goeller and Rosenwald (19) have suggested that corrosion rates of iron under the influence of H_2S

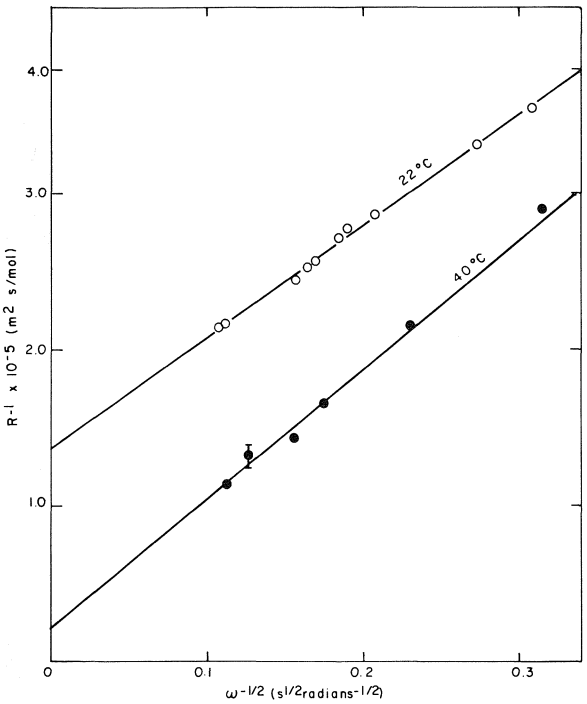

FIG. 9. A plot of R^{-1} vs. $\omega^{-1/2}$ at 22 and 40°C at 0.1 MPa H_2S pressure.

are controlled by mass transfer through an iron sulfide film, but have not specified which iron sulfide film is formed. The X-ray diffraction analyses of our corrosion films have confirmed that the initial film consists of mackinawite. Also, consistent with our postulate that mackinawite is the dissolving phase, the release rates of Fe^{2+} from carbon steel discs measured at lower rotation speeds (Table 1) are comparable to those measured from dissolving mackinawite powders at similar pH (2.8 μmol/m^2 s for carbon steel disc compared to $\simeq$ 2 μmol/m^2 s for mackinawite powder at $\simeq$ pH 3.9). At higher rotation speeds, Fe^{2+} release rates from the disc are higher than those measured from the dissolution rates of mackinawite, since the latter were severely restricted due to the low mixing speeds used in dissolving mackinawite powders.

The maximum release rate R_∞, obtained by extrapolating the release rate data for the discs to infinite rotation speed, is 7.4 $\pm$ 0.5 μmol/m^2 s at 22°C and 0.1 MPa H_2S pressure (Fig. 9). This release rate is $\simeq$ 20 times higher than that measured for troilite dissolution (9) (0.37 μmol/m^2 s), ruling out the latter as a major contributor to the Fe^{2+} release from the rotating disc. Furthermore, the rates of release of iron from the higher iron sulfides like pyrrhotite and pyrite (9) are at least 1000 times smaller ($\simeq 10^{-9}$–10^{-10} mol/m^2 s) than the observed release rates from the carbon steel disc. Thus, all higher iron sulfides can be eliminated as the cause of iron release.

Since the rate of dissolution of mackinawite is first order with respect to H^+, the rate constant k for the release of Fe^{2+} can be calculated from $k = R/[H^+]$, and at 22°C and $[H^+] = 1.23$ mol/m^3, $k = 6.0 \times 10^{-5}$ m/s.

Thermochemical Quantities and Diffusion Coefficient of Ferrous Ion

R_∞, the maximum rate of dissolution at 40°C (obtained from the intercept at $\omega^{-1/2} = 0$ in Fig. 9), is (4.8 $\pm$ 1.5) $\times 10^{-5}$ mol/m^2 s. From the two values of the intercepts at 22 and 40°C, the energy of activation of the chemical process is calculated to be 77 $\pm$ 14 kJ/mol. This value is consistent with the activation energy for the dissolution reactions of copper (20) and magnesium (21) in H_2SO_4, both of which are chemically controlled ($\simeq$ 63 kJ/mol for Cu and 55 kJ/mol for Mg).

The diffusion coefficients of the ferrous ion at 22 and 40°C have been calculated from the slope of the lines in Fig. 9 and eq. [4] by assuming that the kinematic viscosity of aqueous H_2S solutions is the same as that of water (89×10^{-6} m^2/s at 22 and 65×10^{-6} m^2/s at 40°C). This is consistent with the experimental observation of Murphy and Gaines Jr. (22) who observed little difference between the viscosity and density of water and H_2S saturated water up to 2.0 MPa pressure. The value of $[Fe^{2+}]_{sat}$ has been taken as 2×10^{-3} mol/kg at 22°C from our present results (Fig. 5) and 5×10^{-4} mol/kg at 40°C reported elsewhere (9). The values of D thus obtained are (1.4 $\pm$ 0.2) $\times 10^{-9}$ m^2/s and 2.7 $\times 10^{-9}$ m^2/s at 22 and 40°C, respectively.

The temperature dependence of the diffusion coefficient between 22 and 40°C gives E_A, the activation energy for the diffusion process, equal to 25 $\pm$ 7 kJ/mol. The reported (16) value for E_A is between 16–27 kJ/mol. Thus the thermodynamic data obtained from the results seem consistent with a joint chemical and diffusion process of iron release from carbon steel.

The derived diffusion coefficient at 22°C is higher than the literature (11, 23) values of $D_{Fe^{2+}}$ that range between 0.57×10^{-9} to 0.85×10^{-9} m^2/s. The difference between our value and the literature values for the diffusion coefficient for the iron ion is significant and is beyond the experimental error. Even if a much higher value of $[Fe^{2+}]_{sat}$ for mackinawite is chosen in calculating the diffusion coefficient (which would not be unreasonable since mackinawite changes to less soluble phases), our value of the diffusion coefficient remains significantly higher than the literature values.

The values reported in the literature for $D_{Fe^{2+}}$ are derived, however, for iron solutions containing 1.0 mol/kg perchloric acid or other more concentrated strong acids (11, 23), as compared to the aqueous H_2S solutions at 0.1 MPa pressure used in our experiments. Therefore, the reported values for the diffusion coefficient for Fe^{2+} are definitely for a different species than that observed in our experiments. As will be shown later, iron ions in aqueous H_2S solutions at pH 4.0 (the pH in our aqueous H_2S experiments) are different from the iron ions in pH 1.0 or more acidic solutions. Thus, a different diffusion coefficient is to be expected.

$FeSH^+$ species has been proposed in electrochemical studies of iron in aqueous H_2S solutions (24, 25), and by Pohl (26) for the formation of FeS troilite. Similarly $NiSH^+$ has been proposed in corrosion studies of nickel in H_2S solutions (27). Also, the existence of $PbSH^+$ and $ZnSH^+$ has been speculated in hydrothermal studies (28). No absorption spectra for such species have been reported, however, nor have their existence been confirmed experimentally by any other technique. Also, no values for the diffusion coefficients of either $NiSH^+$ or $FeSH^+$ are reported in the literature.

Kuehn and Taube (29) report the existence of $[Ru(NH_3)_5SH]^{2+}$ and $[Ru(NH_5)SH]^+$ from electrochemical evidence, but do not report absorption spectra because the species are unstable. Ramasami and Sykes (30) and Ardon and Taube (31) report the spectra of $CrSH^{2+}$ with peaks at 575 nm and 435 nm, but not the spectra for $CrSH^+$. They show that with the formation of the complex $CrSH^{2+}$, the peaks for Cr^{3+} shift to higher wavelengths; from 405 to 435 nm and from 560 to 575 nm, respectively.

Ehrenfreund and Leibenguth (13) have shown that ferrous solutions at pH $\leq$ 1.0 contain essentially Fe^{2+}, but at higher pH $FeOH^+$ species form with the appearance of a peak at $\sim$ 320 nm. In our studies, the absorption spectra for ferrous solutions contain an absorption band with a peak at 240 nm for Fe^{2+} ($\varepsilon_{240\ nm} = 19.0$) (Fig. 7), consistent with its reported spectrum (13). In aqueous H_2S solutions this 240 nm peak shifts to a higher wavelength, $\simeq$ 330 nm (Fig. 7*C*), and it is suggested that this is the absorption peak of $FeSH^+$. This is consistent with the reported shifts to higher wavelengths (13, 30, 31) in the peaks for Cr^{3+} and Fe^{2+} with the formation of $CrSH^{2+}$ and $FeOH^+$, respectively. The spectrum for the dissolved iron from the carbon steel discs in the aqueous H_2S also gives a peak at 330 nm, again suggesting $FeSH^+$ species in solution rather than Fe^{2+}. Thus, though literature confirmation for the spectrum of $FeSH^+$ is lacking, it is suggested that the dissolved iron species in H_2S solutions is $FeSH^+$.

Mechanism

According to our experimental data, formation of mackinawite on the surface of carbon steel exposed to aqueous H_2S solutions is very fast. Hence, the rate of release of iron is governed by the rate of dissolution of mackinawite formed on the carbon steel surface. The dissolution of mackinawite, in turn, is controlled by the chemical reaction between mackinawite and H^+ (adsorption reaction [5]), and by the transport of iron hydrosulfide ion ($FeSH^+$), desorbed from the mackinawite surface, into the bulk solution (eq. [7]). The kinetic data seem consistent with the following mechanism:

$$[5] \qquad FeS_{(mack)} + H^+ \overset{slow}{\rightleftharpoons} FeSH^+_{(ads)}$$

$$[6] \qquad FeSH^+_{(ads)} \overset{fast}{\rightleftharpoons} FeSH^+_{(desorb)}$$

$$[7] \qquad FeSH^+_{(desorb)} \overset{slow}{\rightleftharpoons} FeSH^+_{(soln)}$$

$$[8] \qquad FeSH^+_{(soln)} \overset{fast}{\rightleftharpoons} Fe^{2+}_{(soln)} + HS^-$$

where ads stands for adsorbed and desorb stands for desorbed. However, the following scheme with Fe^{2+} diffusing away from the interface into the bulk is also consistent with our data, i.e. kinetically indistinguishable from the first mechanism.

$$[9] \qquad FeS_{(mack)} + H^+ \overset{slow}{\rightleftharpoons} FeSH^+_{(ads)}$$

$$[10] \qquad FeSH^+_{(ads)} \overset{fast}{\rightleftharpoons} Fe^{2+}_{(ads)} + HS^-_{(ads)}$$

$$[11] \qquad Fe^{2+}_{(ads)} \overset{fast}{\rightleftharpoons} Fe^{2+}_{(desorb)}$$

$$[12] \qquad Fe^{2+}_{(desorb)} \overset{slow}{\rightleftharpoons} Fe^{2+}_{(soln)}$$

Either $FeSH^+$ or Fe^{2+} may be the diffusing species (eqs. [7] or [12]) in the transport process. We prefer eq. [7], with $FeSH^+$ diffusion, over eq. [12] because of the difference in the values of the diffusion coefficient of the diffusing species from that for Fe^{2+} given in the literature. Also, as discussed previously, absorption spectra suggest that $FeSH^+$ is the important species at pH 4.0 in aqueous H_2S solutions.

Iron release rates at higher temperatures and higher H_2S pressures are complicated by conversion of mackinawite to other phases. The morphology and erosion–corrosion behaviour of iron sulfides at 120°C and 1.6 MPa H_2S pressure, as a function of fluid velocity, will be discussed in a separate report (32).

Summary

The release rate of iron from carbon steel discs rotating in aqueous H_2S solution is governed by the

rate of dissolution of mackinawite, the first product of corrosion formed at the surface. The dissolution rate is controlled by the chemical reaction between mackinawite and hydrogen ion, and by the transport of iron hydrosulfide ions ($FeSH^+$) from the solid–liquid interface to the bulk solution. The maximum rate of release of iron at 22°C and 0.1 MPa H_2S pressure is 7.4 ± 0.5 μmol/m^2 s, which is $\simeq 20$ times higher than the measured dissolution rate of troilite and more than 1000 times higher than the dissolution rate of pyrrhotite and pyrite, ruling them out as major contributors to the iron release from carbon steel discs. At 22°C the diffusion coefficient of the complexed ferrous ion ($FeSH^+$) is $(1.4 \pm 0.2) \times 10^{-9}$ m^2/s and the activation energy for the diffusion process is 25 ± 7 kJ/mol. The chemical reaction occurring at the surface has an activation energy of 77 ± 14 kJ/mol.

The role of electron–phonon interaction and non-Gaussian transport in spectral changes of trapped electrons in glasses[1]

KOICHI FUNABASHI AND WILLIAM H. HAMILL

Department of Chemistry and Radiation Laboratory, University of Notre Dame, Notre Dame, IN 46556, U.S.A.

Received June 20, 1978

KOICHI FUNABASHI and WILLIAM H. HAMILL. Can. J. Chem. **57**, 197 (1979).

The continuous-time-random-walk (CTRW) model which was developed for electron scavenging reactions in polar glasses is extended to the phenomenon of spectral relaxation of electrons in shallow traps e_t^- in a wider range of systems. The central role of electron–phonon coupling in understanding the initial electron localization, the "pre-existing trap", and electron transfer processes are emphasized. The reactivity of e_t^- with scavengers, including protons, is discussed in terms of the theory of multi-phonon non-radiative transitions.

KOICHI FUNABASHI et WILLIAM H. HAMILL. Can. J. Chem. **57**, 197 (1979).

On a étendu le modèle de la marche aléatoire en temps continu (CTRW) qui avait été développé pour les réactions de piégeage d'électrons dans des verres polaires au phénomène de relaxation spectrale des électrons dans des pièges superficiels, e_t^-, dans un domaine plus large de systèmes On met en relief le rôle central du couplage électron–phonon pour la compréhension de la localisation initiale de l'électron, "le piège pré-existant", et les processus de transfert d'électrons. On discute de la réactivité des e_t^- avec les pièges, y compris les photons, en termes de la théorie des transitions non-radiatives multi-phonons.

[Traduit par le journal]

Introduction

The time dependence of optical absorption spectra for localized electrons in glasses involves two related problems. Since there are often at least two spectral regions (1, 2), visible and infrared, for the optical response of the localized electrons, one must first understand the physical origin of the spectral difference. Does the spectral difference represent two distinct localized states or alternatively reflect two distinguishable stages of a continuous dielectric relaxation process around the localized charge? A recent paper by Walker (3) deals with this interesting problem. For some aqueous glasses, Buxton, Gillis, and Klassen (BGK) (4) have demonstrated that the infrared (e_t^-) and visible (e_s^-) electrons belong to chemically distinguishable states because of the difference in their reactivities with electron scavengers, the fully solvated electron being more reactive.

The second problem is related to the time-dependent intensity of spectral response in each region. The decay mechanism which is commonly accepted among radiation chemists is that of electron tunneling between the acceptors and the initial trap sites, without involving any electron transport among the intermediate sites (5). We have suggested an alternative decay mode using the continuous-time-random-walk (CTRW) model (6).

The purpose of this work is to demonstrate that the CTRW model is applicable to both spectral relaxation and electron scavenging in a wider range of systems than those previously studied.

There are two objections to the tunneling mechanism. One is that the barrier-penetration model for tunneling is a "gross oversimplification" of the correct description of the two-site (i.e. a solvent trap and the acceptor) electron transfer process, according to Jortner (7). The second is that there is experimental evidence that electron scavenging is not a simple two-site electron transfer process, but requires electron transport involving both deep ("visible") and shallow ("infrared") traps (8). For the conversion $e_t^- \rightarrow e_s^-$, deep traps simulate the role of scavengers, as mentioned previously (9).

The correct description of the two-site electron transfer process has been given by the theory of non-radiative transitions (10–12). The same theory is also applicable to the electron jump process between two solvent traps in the description of electron transport. Although the relationship between the individual jump rate and the overall transport coefficient in disordered materials is quite complex (13), the magnitude and temperature dependence of the jump rate depend critically upon the nature of the electron–phonon interaction, in addition to the electronic tunneling factor. It is important to realize

[1]The research described herein was supported by the Office of Basic Energy Sciences of the Department of Energy. This is Document No. NDRL-1891 from the Notre Dame Radiation Laboratory.

0008-4042/79/020197-10$01.00/0

that, in the absence of electron–phonon interaction, electron localization itself does not take place, excluding the possibility of radiative transitions from quasi-free to localized states, and also the electron transfer between localized electron states does not take place. The electronic tunneling factor alone does not lead to physically meaningful electron transfer but gives only an oscillatory electron motion.

In polar molecular aggregates, the electron–phonon interaction may involve both long-range low-frequency medium modes and short-range high-frequency molecular modes. These interactions are operative uniformly throughout the system in the scale of intermolecular separation. Consequently, in the description of electron scavenging reactions, for example, it is difficult to accept the notion that a localized electron in the solvent is transferred (or "tunnels") directly to the scavenger molecule regardless of the separation distance.

If localized electrons are located at *special sites* of the system, such as F centers in ionic crystals or doped donors in semi-conductors (14), direct transfer to scavengers is a reasonable mechanism.

It is also important to distinguish the transient electron dynamics from that at thermal equilibrium, where the electron distribution function is given by the Boltzmann function. In the theoretical analysis of pulse-irradiated systems, we must cope initially with the electrons which are not necessarily in equilibrium with phonons, namely, with unrelaxed electrons. The transient currents of unrelaxed electrons are in general significantly large over an extended time period in amorphous solids, even though the long-time equilibrium currents are negligibly small.

In our understanding, the so-called visible and infrared electrons are not characterized simply by the difference in the degree of orientational polarization of surrounding medium, but are qualitatively different species in the sense that they could belong to different kinds of sites (e.g. alkane region and OH region in alcohols) or could be localized by different phonon modes (visible electrons by high-frequency intramolecular mode and ir electrons by low-frequency medium modes). However, both visible and ir electrons could deepen their trap depths by a small amount ($\sim$0.1 eV) by the orientational polarization at sufficiently high temperatures ($\gtrsim$77 K).

Electron hopping does not require "pre-existing traps". The electron moves concertedly with the localized deformation of the medium at low temperature. The configuration of the medium rearranges itself adiabatically by electron–phonon interaction. The electron remains localized throughout. Disorder of the medium ensures randomness among the sites and some produce much more deeply trapped electrons than most.

The notion of the pre-existing trap is a source of extensive misunderstanding in radiation chemistry. If the pre-existing trap is defined as a site at which there is no change of molecular configuration immediately before and after electron capture, then the non-radiative transition rate from the quasi-free state to the trapped state at such a site is negligibly small. When the molecular configuration of the acceptor site does not change upon electron capture there is an absence of electron–phonon interactions and there is no way to dissipate the excess electronic energy. Despite the dilemma in the definition of the pre-existing trap, our physical intuition tells us that electron localization in highly disordered materials, such as aqueous glasses, must be efficient and even activationless at low temperatures. A plausible argument for this intuition will be presented in a later section.

Finally, the diffusive motion (or hopping) of an electron in the CTRW model is not the same as classical diffusion in which the jump distance and the jump frequency are constant throughout the system. Reflecting the disordered structure of the system, the jump distance and the energy barrier fluctuate from site to site, causing a highly non-exponential decay, even under the assumption of usual first-order homogeneous kinetics (15). On a phenomenological level, this is equivalent to saying that the diffusion constant for the electron is time-dependent until all the electrons in the system settle down to the lowest levels at thermal equilibrium. The electron mobility at thermal equilibrium in aqueous glasses is expected to be negligibly small. Our model does provide for the finite *transient* mobility.

Rate Constant for Electron Scavenging

We present here a more detailed derivation for the electron scavenging rate expression according to the CTRW model from that obtained previously (6). The system of interest consists of trapped electrons and acceptor sites, e.g. scavenger molecules, whose concentration is far in excess of that of electrons. Assuming that the reaction is diffusion controlled, we are interested in calculating the number of electrons arriving at scavengers per unit time. Mathematically, this is equivalent to the problem of calculating the flux of walkers (scavengers) arriving at the origin (electron) for the first time. Since the position of the electron is fixed, diffusion motion of walkers (scavengers) corresponds practically to that of the electron itself.

Let us assume that each point of the lattice, taken arbitrarily as cubic, is initially occupied by a walker. Then the flux of the walkers arriving at the origin for the first time, $I(t)$, is related to the time-dependent

rate constant for scavenging, $k(t)$, which is defined as the same flux for unit concentration of walkers (scavengers), by

$$[1] \qquad I(t) = a^{-3}k(t)$$

where a is the lattice constant.

The number of trapped electrons at t, $n(t)$, is given by the usual first-order equation,

$$[2] \qquad n(t)/n_0 = \exp\left[-C_s \int_0^t k(t)\,dt\right]$$

where n_0 is the initial number of trapped electrons and C_s is the scavenger concentration.

The flux $I(t)$ may be calculated by the theory of random walk in the following way. If the jump time for each step is a constant τ, then [3] is obtained

$$[3] \qquad I(t) = \sum_{n,s} F_n(s)\delta(t - n\tau)$$

where $F_n(s)$ is the probability that the walker reaches the origin for the first time in n steps, starting from the lattice point s. The delta function in [3] indicates that walkers reach the origin only at times which are integral multiples of the jump time τ in this case. In order to generalize the flux calculation to the case of multiple-jump times, it is convenient to introduce the following generating functions,

$$[4] \qquad F(s,z) = \sum_{n=1}^{\infty} F_n(s)z^n$$

and

$$[5] \qquad P(s,z) = \sum_{n=0}^{\infty} P_n(s)z^n$$

where $P_n(s)$ is the probability that the walker is at the origin after n steps (not necessarily the first time), starting from the lattice point s. These generating functions satisfy the following equalities (16)

$$[6] \qquad F(s,z) = [P(s,z) - \delta_{s0}]/P(0,z)$$

and

$$[7] \qquad \sum_s P(s,z) = (1 - z)^{-1}$$

In the case of a single jump time τ, eq. [3] leads to essentially the same result (17) as that of the usual diffusion treatment, namely, $I(t)$ becomes time-independent after a few steps.

Let us now assume that at each lattice point the walker has a choice of jump time from a set of jump times, τ_1, τ_2, ..., with corresponding probabilities, C_1, C_2, ... Namely, the walker jumps to adjacent sites in jump time τ_i with probability C_i, which is normalized as

$$[8] \qquad \sum_i C_i = 1$$

In this case, the flux is given by

$$[9] \qquad I(t) = \sum_{n,s} \frac{n!\prod_i C_i^{n_i}}{\prod_i n_i!} F_n(s)\delta(t - \sum_i n_i\tau_i)$$

where

$$[10] \qquad \sum_i n_i = n$$

The summation over n in eq. [9] includes all possible combinations of n_i with the restriction [10]. Using the relationships

$$[11] \qquad \sum_{\{n_i\}} \frac{n!\prod_i C_i^{n_i}}{\prod_i n_i!} = \left(\sum_i C_i\right)^n = 1$$

and

$$[12] \qquad \delta\left(t - \sum_i n_i\tau_i\right) = \frac{1}{2\pi i} \times \int_{C-i\infty}^{C+i\infty} \exp\left[u\left(t - \sum_i n_i\tau_i\right)\right] du$$

eq. [9] can be written as

$$[13] \qquad I(t) = \frac{1}{2\pi i}\sum_{n,s} F_n(s) \times \int_{C-i\infty}^{C+i\infty} \left[\sum_i C_i\, e^{-u\tau_i}\right]^n e^{ut}\, du$$

At this point, let us assume that the jump time τ_i has a continuous spectrum so that

$$[14] \qquad \sum_i C_i\, e^{-u\tau_i} \rightarrow \int_0^{\infty} \psi(\tau)\, e^{-u\tau}\, d\tau$$

where $\psi(\tau)$ is a continuous jump – time distribution function. The rhs of [14] is the Laplace transform of $\psi(\tau)$, so that we define

$$[15] \qquad \phi(u) = \int_0^{\infty} \psi(\tau)\, e^{-u\tau}\, d\tau$$

Using eqs. [4], [13], [14], and [15],

$$[16] \qquad I(t) = \sum_{n,s} \frac{1}{2\pi i} \int F_n(s)[\phi(u)]^n e^{ut}\, du = \sum_s \frac{1}{2\pi i} \int F(s, \phi(u))\, e^{ut}\, du$$

Equation [16] is equivalent to

$$[17] \qquad I(u) = \int_0^{\infty} I(t)\, e^{-ut}\, dt = \sum_s F(s, \phi(u)) = \frac{1}{[1 - \phi(u)]P(0, \phi(u))} - 1$$

where, in the last step, eqs. [6] and [7] are used.

Since the generating function $P(s,z)$ is a property of the lattice, the effect of the disordered structure comes only from $\phi(u)$ or $\psi(t)$. By analyzing the transient photocurrents in amorphous films, Scher and Montroll (18) discovered that the following asymptotic form for $\psi(t)$ describes the experiment best,

$$[18] \quad \psi(t) \sim [At^{1+\alpha}\Gamma(1-\alpha)]^{-1} \qquad 0 < \alpha < 1$$

where Γ is the gamma function, A and α are constant parameters. The corresponding asymptotic form for $\phi(u)$ is given by

$$[19] \quad \phi(u) \sim 1 - u^{\alpha}/A \qquad z \to 1$$

Using eq. [16], one gets

$$[20] \quad P(0,z) \to 1.516 \qquad z \to 1$$

$$[21] \quad I(u) \sim \beta A u^{-\alpha} \qquad \beta = 0.659$$

The time-dependent flux has the form

$$[22] \quad I(t) \sim \frac{\beta A t^{\alpha-1}}{\Gamma(\alpha)}$$

Using eq. [1], the time-dependent scavenging rate constant is given by

$$[23] \quad k(t) \sim a^3 \beta A t^{\alpha-1}/\Gamma(\alpha) \equiv Bt^{\alpha-1}$$

Substituting eq. [20] into eq. [2], one gets

$$[24] \quad \ln \ln (n_0/n(t)) = \ln (BC_s/\alpha) + \alpha \ln t$$

Up to this point of derivation, the scavenging reaction is assumed to be diffusion-controlled. A more general model allows jumps to the reacting site which have probability p for reaction and probability $(1 - p)$ for survival to jump away from the reaction site. As far as the long-time asymptotic flux is concerned, this probability of reaction will simply scale down the magnitude of B in [24] (17). The parameter B therefore depends upon the nature of the solvent as well as that of the scavenger in general.

Equation [24] was the basis for analyzing the scavenging of trapped electrons in our previous work and will be applied to a wider class of systems and phenomena in this work.

The physical origin for the jump–time distribution [18] is the fluctuation in jump distances and trap depths. Scher and Montroll (18) neglected the latter fluctuation. Therefore, in the spirit of Scher and Montroll, the parameter α can be independent of temperature at sufficiently low temperatures because of the possibility of phonon-assisted tunneling. In general, one expects some kind of temperature dependence of α when the fluctuation in trap depth is included. It is not possible to predict the detailed form of temperature dependence without further specification of the statistical characteristics of the disordered structure itself. However, from the general structure of the continuous-time-random-walk, one can say that the temperature dependence of the decay kinetics will manifest itself on a relatively longer time scale of observation when the electrons in deeper traps begin to participate in the decay kinetics, while at earlier times the electrons can choose fast and easy passages towards the sink so that the temperature dependence is likely to be weak or even absent.

Experimentally, α is sensitive to the details of sample preparation and quantitative reproducibility from one laboratory to another is not to be expected. The preparation of glasses by plunging samples into liquid nitrogen and omission of annealing are probably responsible for much of the dispersion (small α) which has been observed.

In analyzing the decay of trapped electrons in deep traps, e_s^-, the sinks are the scavengers, while for the spectral relaxation of the electrons in shallow traps, e_t^-, the sinks are the deep traps themselves for undoped systems. As we demonstrate later, the reactivity of e_t^- with some scavengers is much less than that of e_s^-.

The preceding considerations apply to the recombination of coulombically correlated charge pairs but there is a superimposed time-dependent effect arising from the initial radial distribution. In the following section we have tried to avoid experimental results which involve this complication.

Experimental Evidence

There are many data in the early literature of trapped electrons in organic glasses which provide qualitative information for the electron transport process. Unfortunately the zero-time yield is usually unknown for γ irradiation. This problem is not serious for methyltetrahydrofuran (MTHF) at 77 K because decay of e_t^- is very slow in the undoped system. The epr data of Smith and Pieroni (19) can be fitted by eq. [24] but it is not clear whether the rate-controlling process involves trap-to-trap hopping or recombination of coulombically correlated charge pairs.

Partial but convincing support for the applicability of Scher–Montroll CTRW theory is provided by measurements of electron drift mobility in MTHF at 77 K by Huang *et al.* (20). Following 8 μs light pulses, the arrival of electrons at the anode tailed for ~250 μs after a nominal transit time of 130 μs. The basic requirement for application of S–M theory is satisfied since electrons must be trapped, detrapped, and retrapped. The initial traps are abundant and shallow and a distribution of trap depths assures a

gradual increase of trap depth. The transport is activated in the range 36–77 K with $E = 0.0035$ eV. There is little or no temperature dependence between 30 and 4 K.

Kevan (21) found that the photobleaching quantum efficiency in γ-irradiated MTHF is very small at >900 nm and maximizes at 520 nm, both at 4 K and 77 K, but the efficiency is still only ~0.2. The amplitudes of the maxima are substantially equal. This result implies that retrapping photoelectrons by the matrix is activationless in this range of temperature.

Time-dependent electron solvation in 32 mol% methanol – 68 mol% MTHF by Ogasawara *et al.* (22) following 40 ns pulses contains features of particular interest. One is that the system clearly contains a greater variety of traps than either pure component. Absorbance A is initially greatest at ~1250 nm and later is greatest at ~600 nm at 109 K. Another is that the absorbance decay is nearly first order at 116 K but deviates considerably beyond ~50% decay at 106 K. Also, there is optical evidence for intermediate solvation configurations. The authors concluded that the results did not support electron tunneling and accepted diffusive reaction of the electron with methanol clusters, involving more than one step. These features are qualitatively those needed for applying the CTRW model, although a somewhat lower temperature is certainly desirable. Data have been taken from the smooth curve reported for 106 K (22) and are presented in Fig. 1. The results suggest that after a short transition period, for which the decay seems to be nominally

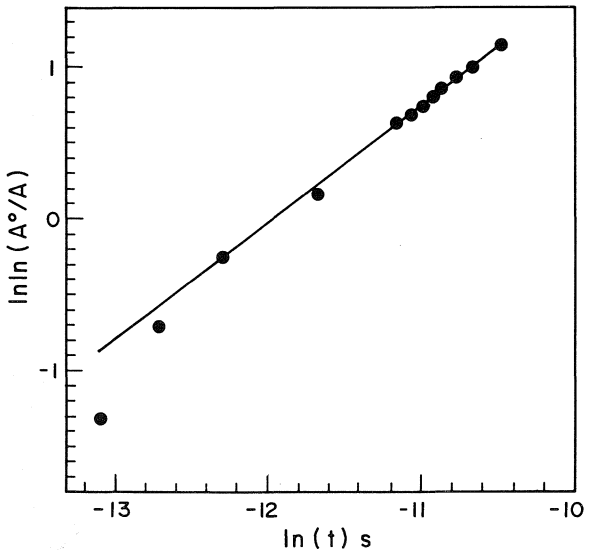

FIG. 1. The dependence of the optical absorbance A at 1250 nm on time for 32% methanol – 68% MTHF at 106 K from the data of Ogasawara *et al.* (22). The slope is 0.80.

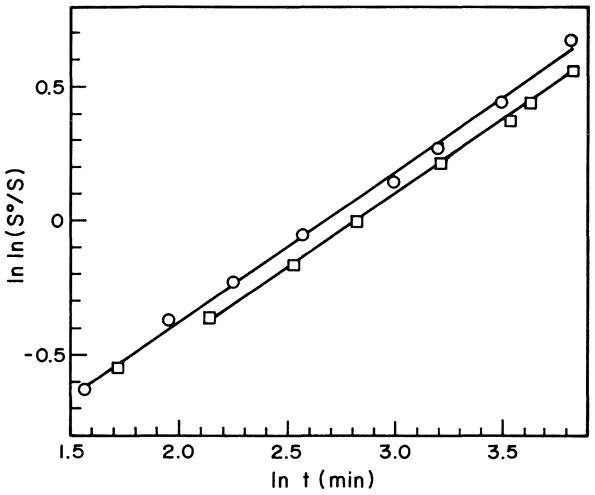

FIG. 2. The dependence of the epr signal amplitude S on time for 3MP containing 4.6 mol% trimethylamine and 2×10^{-2} mol% TMPD at 77 K following ^{60}Co-irradiation (●) and photo-ionization (■) from the work of Lin *et al.* (24). The slopes are 0.51.

first order, the decay does follow the CTRW model which is most clearly exhibited at long time.

There are few data for 3-methylpentane (3MP) in the range >1 s which are useful here but a simple qualitative demonstration of e_t^- migration is of interest. Photoionization of 2×10^{-3}% tetramethyl-*p*-phenylenediamine (TMPD) in 3MP with 0.20% biphenyl at 77 K was followed by linear increase in anion absorbance A with decrease in e_t^- absorbance. No measurable recombination occurred (23). The value of $A_0(e_t^-)$ cannot be estimated easily, but $A_\infty(\phi_2^-)$ can be. The plot of $\ln \ln A_\infty/(A_\infty - A_t)$ for ϕ_2^- vs. $\ln t$ (not shown) is adequately linear with $\alpha = 0.41$.

Lin *et al.* (24) used 3MP containing 4.6 mol% trimethylamine (to retard decay of e_t^-) with 0 and 2×10^{-2}% TMPD. After γ irradiations at 77 K, decay of e_t^- (measured by epr) is expected to arise almost entirely by impurity trapping on TMPD (23) and eq. [24] should apply. The decays of e_t^- following γ irradiation and photoionization are compared in Fig. 2. Signal amplitudes S were in arbitrary units and the zero of time used here is that reported. The decay is slower than for 3MP alone and only the comparison of the two curves is considered significant. The slope, $\alpha = 0.51$, is not affected by the mode of ionization.

Klassen, Gillis, and Teather (25) have measured spectral changes in 3MP and 3-methylhexane (3MH) at 76 K following pulsed irradiations. There was marked decay of absorbance at 2240 nm and there was no growth of absorbance at any wavelength for both systems. Since decay at 1500 nm, near the

maximum of the relaxed spectrum, was much less than that at 2240 nm, it is possible that the spectral relaxation consists of a transfer of e_t^- from shallow to deep traps. Using the data for 2240 nm, where there is little overlap from the relaxed spectrum, the results in Fig. 3 yield slopes of $\alpha = 0.11$ and 0.12 for undoped 3MP and 3MH from the curves in their Figs. 4 and 2, respectively.

In 3MP doped with 3.4 m*M* biphenyl, an electron trap, the slope for decay of 2240 nm absorption in Fig. 3 is 0.14. From the correlated growth at 410 nm due to biphenyl anion in Fig. 3, $\alpha = 0.10$. These data are taken from their Table 1, using $\text{Å} = 0.390$ at 2240 nm and $\text{Å} = 0.397$ at 410 nm. From this line and that for undoped 3MP, $\Delta \ln (BC/\alpha) = 0.42$, and $C(\text{biphenyl})/C(3\text{MP}) = 1.5$, or $C(3\text{MP}) = 5.2$ m*M*, where $C(3\text{MP})$ represents the "concentration" of self-trapping sites.

Decay of absorbance for e_t^- at 2240 nm in both doped and undoped 3MP and growth of the anion, both characterized by $\alpha = 0.11$, provides evidence that decay at 2240 nm involves migration by hopping on a rather long time scale.

Measurements of mobility in 3MP by time-of-flight correspond to a diffusion coefficient $\sim 10^{-4}$ cm^2/s (26). Consequently the states which contribute to the more mobile species are not those involved in the spectral decay just discussed. The two processes are qualitatively, but not quantitatively, similar. It must be remembered that only a quite small fraction of the electrons present contribute to the measured current. They occupy only the shallowest traps and observations are limited to events at $< 10^{-3}$ s.

After ~ 130 ns electron pulses at 76 K, Kevan observed that the absorbance at 1400 nm in C_2H_5OD decays linearly in $\ln(t)$ from $\sim 10^{-7}$ to $\sim 10^{-2}$ s (27). In C_2D_5OD + 20 mol% D_2O the decay at 1300 nm is very similar and the slopes are the same. Comparable results were obtained at 1800 nm and 1700 nm with slopes unchanged. Choosing the measurements at 1400 nm for C_2H_5OD and 1300 nm for C_2D_5OD + D_2O which are close to λ_{max}, the data are presented in Fig. 4 in terms of eq. [24] with slopes 0.28 and 0.22.

Miller *et al.* (28) have examined several undoped alcohols at 77 K in the range 10^{-7} to 10^2 s after pulsed irradiation. At the longest wavelength, 950 nm, the decay does not conform to eq. [24], suggesting that more than a single species of e_t^- is involved. The growth for ethanol at 550 nm has been chosen for examination because only one spectral component is expected, because there is an adequate range of absorbance and because there are no

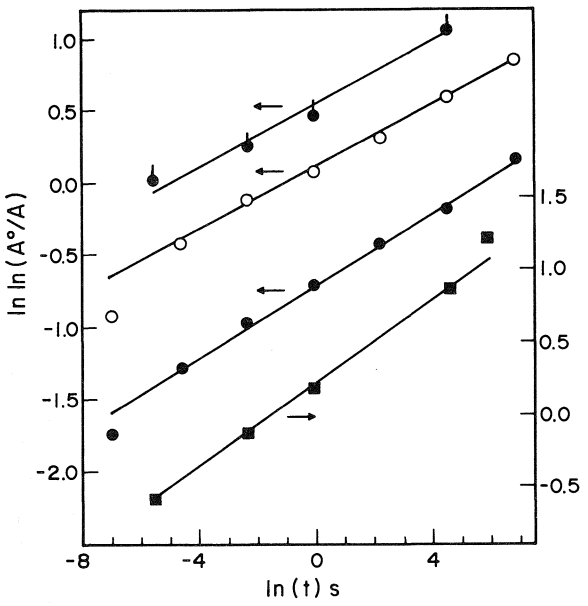

FIG. 3. The decay of absorbance in undoped 3MP (○) and 3MH (●) at 2400 nm and 76 K after pulsed irradiation. Similar data for 3MP containing 3.4 m*M* biphenyl at 2240 nm (■) and growth of biphenyl anion at 410 nm (◆), from the work of Klassen *et al.* (25). Slopes are 0.10, 0.11, 0.12, and 0.14 in order, top to bottom.

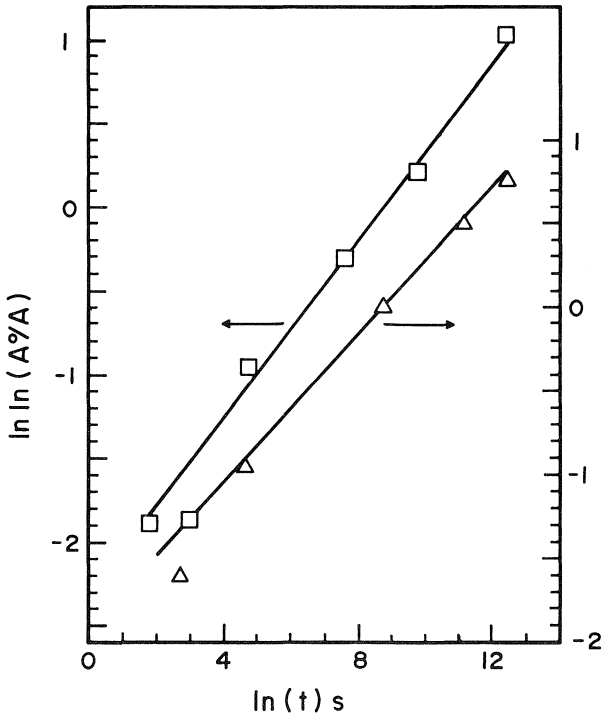

FIG. 4. The decay of absorbance of e_s^- at 1400 nm in C_2H_5OD (□) and at 1300 nm for C_2D_5OD + 20% D_2O (△), both at 76 K after ~130 ns pulsed irradiations, from the work of Kevan (27). The slopes are 0.28 and 0.22.

significant irregularities, such as appear for some of the other data. Results appear in Fig. 4.

Klassen *et al.* (29) have measured spectral shifts in ethanol at 76 K. Their results for decay of e_t^- at 1400 nm are not well described by eq. [24] when A_0 is taken as the measured value from their Fig. 3. For the yield at 200 ns after the onset of a 140 ns pulse, $G\varepsilon = 3.14 \times 10^4$ where G is the number of electrons per 100 eV and ε is the extinction coefficient in $M^{-1}\,cm^{-1}$. We find some improvement for $G\varepsilon = 4.2 \times 10^4$ at time zero. Results treated in this way, interpolated from their smooth curve, also appear in Fig. 5. The slope, 0.20, agrees adequately with the results from Miller *et al.* (27) with slope 0.18.

Data for decay of e_s^- at 750 nm in methanol/water (95/5) at 77 K, reported by Kevan (30), are included in Fig. 5.

Ogasawara and Kevan (31) have examined electron solvation kinetics in ethanol containing 0.1 M NaOH from 83 to 123 K by ruby laser photoionization of 5×10^{-4} M β-naphtholate. Decay at 123 K was simple first order. The more complicated decay at lower temperatures was attributed to a molecular reorientation mechanism. The results for growth of solvated electron absorption at 580 nm following ~20 ns ruby laser pulses appear in Fig. 6, for $A_\infty = 0.196$, at 108.0, 98.0, 92.8, 87.7, and 83.1 K (from top to bottom), the slopes being 0.134, 0.104, 0.099, 0.081, and 0.062. Although there are no data for 77 K, α is expected to be very much less than the values from Fig. 5. The difference is probably caused by the presence of 0.1 M NaOH and an increased dispersion of trap depths.

Data for decay of e_t^- in 1-propanol at 1300 nm and growth of e_s^- at 500 and 550 nm, all at 77 K, have already been published (9). For all alcoholic systems examined, $\alpha \simeq 0.2$ for both growth and decay, excepting Fig. 6.

Miller (*5a*) has measured the spontaneous decay of absorbance at 750 and 875 nm for undoped aqueous 6 M NaOH at 77 K following pulse irradiation. Some of this oscillator strength was transferred to the 400–500 nm region where there is no decay. Although A is approximately linear in ln t at both wavelengths, the slopes are not equal. These data are presented in Fig. 7 in terms of eq. [24]. The curves have the same intercept and are parallel with slope $\alpha = 0.11$. Therefore, one initial state, one final state. It has already been shown that nearly equal slopes have been obtained for decay at 550 nm and 77 K for the same matrix doped with electron acceptors (6). The value of α does not depend upon the

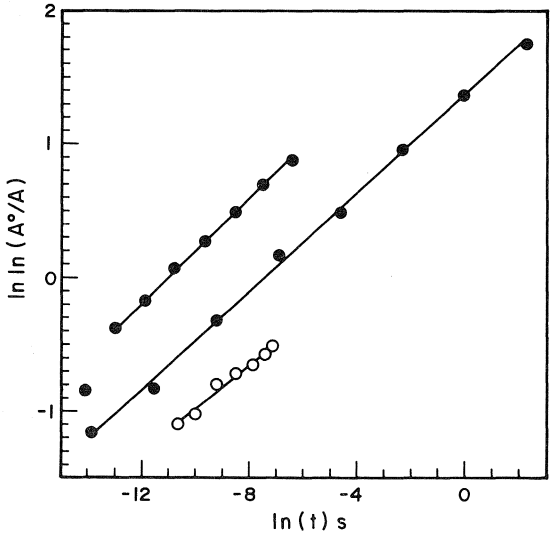

FIG. 5. The growth of optical absorbance of e_s^- in ethanol at 550 nm (●) from Miller *et al.* (28); decay of e_s^- in ethanol at 1400 nm (■) from Klassen *et al.* (29); decay of e_s^- in 95 methanol – 5 water at 750 nm (○) from Kevan (30), all at 77 K. The slopes are 0.20, 0.18, and 0.17, in order.

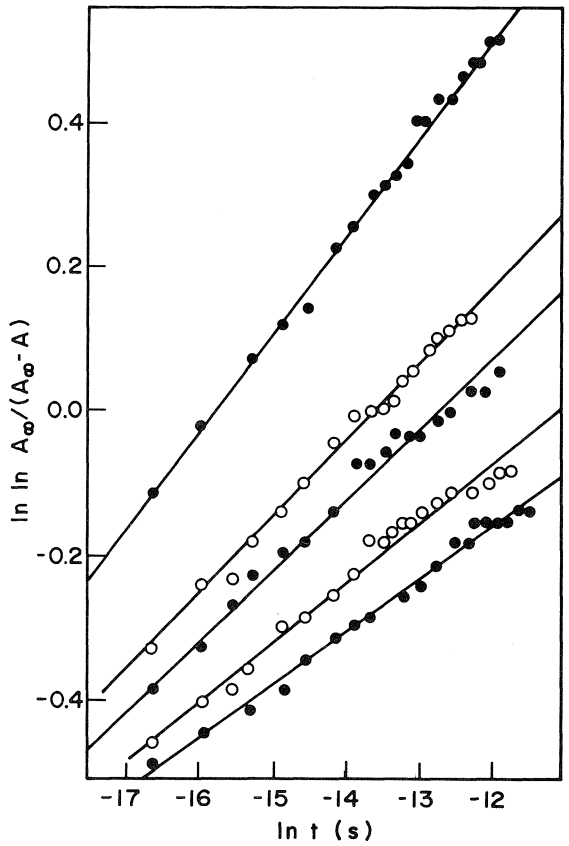

FIG. 6. The decay of e_s^- at 580 nm at 108.0, 98.0, 92.8, 87.7, and 83.1 K (top to bottom) in ethanol containing 0.1 M NaOH following ~20 ns ruby laser photoionization of 5×10^{-4} M β-naphtholate ion. The data are taken from the work of Ogasawara and Kevan (31).

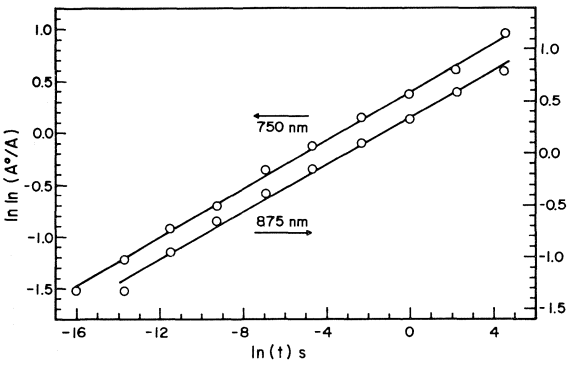

FIG. 7. The decay of e_s^- in 6 *M* NaOH at 750 nm and 875 nm at 77 K from the work of Miller (*5a*). The slopes are 0.12.

impurity or its concentration, although the rate of decay increases with increased concentration.

Pulse photoionization of γ-irradiated glassy 10 *M* NaOH has been used by Huang *et al.* (32) to measure electron mobility from transit times. Long current–time tails were attributed in part to weak trapping. The onset of this decrease was best resolved empirically on a log (time) scale. This evidence supports the dispersive hopping transport mechanism in alkaline glasses, including earlier work on trapped electron scavenging (6).

Discussion

Self-trapping Process in Disordered Media

The self-trapping process involves a radiationless transition from the quasi-free state to a localized electron state. In the Introduction, it was pointed out that the so-called static pre-existing trap cannot capture an electron non-radiatively. To elaborate in terms of a schematic diagram shown in Fig. 8*a*, the total energy of the system (i.e. an excess electron plus the medium) is plotted against the configuration coordinate which characterizes the inter- and intramolecular configurations around the trap. The pre-existing trap implies that the energy minima for the quasi-free state (curve I) and the trapped state (curve II) have the same equilibrium configuration R_0, and the same curvature. The transition rate for I → II would be zero, because the vibrational overlap is equal to zero due to the orthogonality of the vibrational wavefunctions. In order to have a finite transition rate, it is essential to destroy the orthogonality of the vibrational wavefunctions between the initial and final states. This can be achieved either by displacing the potential minimum of curve II with respect to that of I or changing the curvature (the force constant) of the curve II. In general, a finite coupling between the electron and the nuclear motion (i.e. electron–phonon coupling) causes both of these effects. For simplicity, assume that the only effect of the electron–phonon interaction is to shift the potential minimum ("displaced oscillator model"), as shown in Fig. 8*b*. Because of the non-orthogonality of vibrational wavefunctions for curves I and II, the transition rate is now non-vanishing. It can also be seen that the displaced oscillator model predicts a finite energy barrier (activation energy) for the self-trapping process. Toyozawa (33) has already pointed out the presence of a finite activation energy for self-trapping by a finite-range deformation potential. If the thermal trap depth, E_b of Fig. 8*b*, is constant throughout the system, self-trapping would be inefficient at low temperatures (~77 K) for a barrier height of ~2 kcal. When there is a fluctuation in the trap depth from site to site because of the disordered structure of the system, the crossing point of curves I and II can fall in the zero-point vibrational amplitude of curve I at certain sites, as shown by the dotted curve in Fig. 8*b*. The self-trapping process would be activationless and quite efficient. It depends upon the statistics of the energy level distribution for the localized states. Physically, this means that certain sites trap electrons much more efficiently than other sites which have a finite barrier. The essential physical feature which is required for these preferred trapping sites is provided by the disordered structure of the medium. Crystals at low temperature do not trap electrons efficiently.

The preceding discussion of non-radiative transitions to deeper traps has not included consideration of dipolar relaxation of the medium (34). Such a mechanism is quite plausible for localized electrons

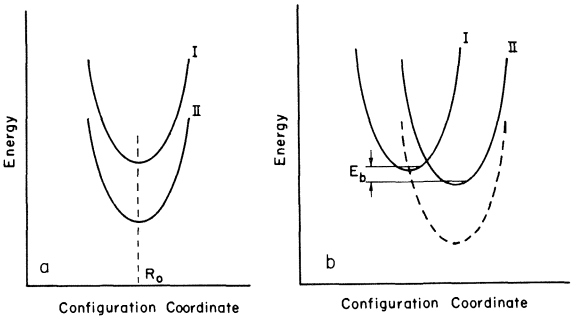

FIG. 8. (*a*) A schematic energy diagram for the quasi-free state I and the trapped state II, as a function of configuration coordinate. The transition probability for I → II is zero in this case. (*b*) A schematic energy diagram for the quasi-free state I and the trapped state II, when there is a finite electron phonon interaction at the trapping site. The transition probability for I → II is non-zero, due to the non-orthogonality of vibrational wavefunctions for I and II. Because of the energy fluctuation for the state II from site to site, there is a finite probability of finding a site where the curve crossing falls in the zero-point amplitude of curve I, as shown by the dotted curve. Such a site traps the quasi-free electron preferentially.

in liquids but it is not clear that it makes a measurable contribution in rigid glasses at low temperatures. Formation of e_s^- must be triggered by short-range electron–phonon interactions at preferred sites ("pre-existing traps") since they are observed at early time and low temperature. Relaxation of molecular configurations are expected on this time scale. The very small subsequent change in the visible spectrum, when it can be fully resolved at 77 K, requires either that dipolar relaxation is nearly complete at $\sim 10^{-8}$ s, or that it is not yet appreciable at $> 10^2$ s. Even if the former proves to be correct, our basic model for the primary localization mechanism is unaffected.

Reactivities of Localized Electrons

According to the work of BGK (4), electrons in shallow traps (the infrared electrons, e_t^-) in aqueous glasses do not react efficiently with some electron scavengers, while the solvated electrons (e_s^-) do react with the same scavengers at appreciable rates. For the same scavenger, the reaction of e_t^- is of course more exothermic than that of e_s^-. The electronic coupling matrix for e_t^- becomes smaller than that of e_s^- because of the diffuse electron wavefunction for e_t^-. Furthermore, the fact that e_t^- is weakly coupled with low-frequency medium modes ($1 \sim 10\ cm^{-1}$) and e_s^- is strongly coupled with both high-frequency molecular modes and the medium modes, in addition to the extra exothermicity for the e_t^- reaction, will make the scavenging rate for e_t^- even smaller compared to that for e_s^-.

BGK (4) also reported the similarly remarkable difference of reactivities of localized electrons with H_3O^+ in aqueous glasses. While e_t^- does not react detectably with H_3O^+, e_s^- reacts with H_3O^+ as expected. Although the same qualitative interpretation applies also for this case, one should not consider these reactions as simple electron transfer processes. Unlike other electron scavengers, the hydrated proton migrates through an efficient proton transfer from one water molecule to another. It is well-known that the reaction rate constants for proton transfer to anions are very large (35). It is tempting to suggest that the reaction mechanism for $e_s^- + H_3O^+ \rightarrow H + H_2O$ is also the proton transfer. However, the detailed nature of the reaction coordinate in the potential hypersurface for this reaction is not clear because of the limited information concerning the structural details of e_s^-. Nevertheless, it is qualitatively clear that such a possibility exists if the electron in a cavity is strongly coupled with high-frequency intramolecular vibrational modes, thereby resembling an anion, in addition to low-frequency solvent modes. On the other hand, if the electron is coupled weakly with low-frequency solvent modes only, as in the case of e_t^-, there is no effective way of dissipating the excess energy in the process of H atom formation. The details of electron–phonon coupling are also crucial in understanding some features of the absorption spectra of solvated electrons (e.g. width, temperature-dependence, isotope effect, etc.) (36).

It is to be noted that application of the barrier-penetration model to the reactions of e_s^- and e_t^- with electron scavengers or H_3O^+ would predict exactly the opposite result of what was observed by BGK (4).

The time-dependence of spectral intensity for trapped electrons can be explained quantitatively over at least several decades of time in a wide range of substances.

The apparent absence of reactivity for e_t^- with some scavengers, including protons, can be understood qualitatively in terms of the inherent inefficiency in converting a relatively large electronic energy into a large number of low-frequency phonons by radiationless transitions.

The central role of electron–phonon coupling is emphasized for understanding the initial electron localization, the meaning of the "pre-existing" trap, and electron transfer processes.

It is concluded that the so-called spectral relaxation for e_t^- in rigid glasses involves both electron transport among shallow traps and non-radiative transitions to deeper traps. Dipolar relaxation may occur subsequently but it does not affect the basic model.

The preparation and properties of some thioacylmethylenethiazolines and isothiazolines

D. M. McKINNON, M. E. HASSAN, AND M. S. CHAUHAN

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 1, 1978

D. M. McKINNON, M. E. HASSAN, and M. S. CHAUHAN. Can. J. Chem. **57**, 207 (1979).

Thiazoline-2-thiones and isothiazoline-3-thiones are converted into the 2- or 3-thiophenacylidene derivatives, respectively, by reaction with phenacyl bromide, treatment with pyridine, and thionation. The former compounds react with dimethyl acetylenedicarboxylate to form mono- and diadducts as well as some decomposition products. Attempts to demonstrate valency isomerism in the 3-thiophenacylideneisothiazoline derivatives were unsuccessful.

D. M. McKINNON, M. E. HASSAN et M. S. CHAUHAN. Can. J. Chem. **57**, 207 (1979).

On transforme les thiazolinethiones-2 et les isothiazolinethiones-3 respectivement en dérivés thio-2 (ou -3) phénacylidène par une réaction avec le bromure de phénacyle, suivie d'un traitement par la pyridine et d'une thionation. Les premiers composés réagissent avec l'acétylènedicarboxylate de méthyle pour former les mono- et les di-adduits de même que des produits de décomposition. Des essais tentés dans le but de démontrer l'existence d'une isomérie de valence conduisant à des dérivés thiophénacylidène-3 isothiazolines se sont avérés infructueux.

[Traduit par le journal]

Isothiazoline-3-thiones (**1**) are known to undergo cycloaddition reactions with dimethyl acetylenedicarboxylate to provide 2-thioacylmethylenethiazolines (**2**) (1), which react by further 1,4-cycloaddition reactions of the exocyclic thioacylmethylene group with the reagent to form thiopyranospirothiazole derivatives (**3**). Although under the conditions of this reaction none of the thiazoline intermediates **2** were isolated, two similar compounds, 2-thiophenacylidenethiazolines, were obtained via an alternative synthesis.

To provide some further information on the reaction of the 2-thioacylmethylenethiazolines (**2**) with acetylenic reagents, some other compounds have been synthesized from thiazoline-2-thiones by the procedure outlined below and allowed to react with dimethyl acetylenedicarboxylate.

A variety of thiazoline-2-thiones, mostly possessing aryl substituents (**4***a–e*), were prepared by reaction of the appropriate α-halogenated aldehydes or ketones with substituted dithiocarbamic acid salts according to known procedures (2). Some of these were new. In some cases, as described (2), the intermediate hydroxythiazolidinethiones were obtained initially but these dehydrated in sulfuric acid to the desired compounds. Another method of synthesis used in some cases (**4***d*, *e*) was the reaction of the α-halo aldehyde or ketone with methyl *N*-

0008-4042/79/020207-06$01.00/0

methyldithiocarbamate which afforded 3-methyl-2-methylthiothiazolium salts. The method is similar in concept to one for 1,3-dithiolium salts (3). The thione **4***f* was commercially available.

To allow elaboration of the thione function, these compounds were then allowed to react with phenacyl bromide to provide 2-phenacylthiothiazolium salts (**5**) which on treatment with anhydrous pyridine

were converted into 2-phenacylidenethiazolines (**6***a–f*), according to the procedure of Knott (4). Yields were rather low and the products were contaminated with starting thiones, the result of simple dealkylation reactions of the 2-alkylthio salts **5**. Treatment of the compounds **6** with phosphorus pentasulfide afforded the desired 2-thiophenacylidenethiazolines (**2***a–f*).

In an earlier study (1) the reactions of 2-methyl-5-phenylisothiazoline-3-thione (**1***a*) with phenacylidenetriphenylphosphorane was reported to give a 2-thiophenacylidenethiazoline **2** via an unexpected 1,3-dipolar reaction. Comparison of the product from this reaction with the thiones **2***d* and **2***e* prepared above showed its identity with the former. Likewise the compound **2***b* was found to be identical to the reaction product of **1***a* with *p*-methylphenacylidenetriphenylphosphorane.

Also, treatment of 2,5-diphenylisothiazoline-3-thione (**1***b*) with phenacylidenetriphenylphosphorane gave a small yield of the thione **2***a* but 2-methyl-4,5-diphenylisothiazoline-3-thione (**1***d*) failed to react, possibly because of steric hindrance.

Treatment of the above 2-thioacylmethylenethiazolines **2** with dimethyl acetylenedicarboxylate was expected to yield spiran derivatives of type **3** as was found in the earlier study (1). Thus treatment of **2***f* with 1 equiv. of the ester afforded the expected monoadduct **3***f* as a yellowish oil. When the reaction was performed with 4 equiv. of the ester, another product was obtained in addition to the monoadduct **3***f*. On the bases of its spectral data and analysis this appears to be a diadduct. Both mono- and diadducts were isolated from a reaction of the thione **2***f* with 1 equiv. of the ester in dioxane, suggesting that the formation of the diadduct is dependent on solvent polarity. Treatment of the monoadduct with excess ester failed to give any diadduct, indicating that it is not formed from the monoadduct and that it is produced by a competing reaction. Although a number of possible structures could be advanced for the diadduct, we are inclined to favor a structure of type **8***f* on the basis of similar reactions of thiazolinethiones with the ester (5). This structure is consistent with its nmr spectrum.

Although similar results were obtained from 4,5-diphenyl-3-methyl-2-thiophenacylidenethiazoline (**2***c*) and dimethyl acetylenedicarboxylate to yield **3***c* and **8***c*, treatment of **2***d* with an equimolar quantity of the ester in boiling benzene afforded three products. The first two, which were oils, appear to be the thione **7***a* and the imine **7***b*, respectively. It appears likely that these may be formed via decomposition of a spiran intermediate of type **3***d*. Such decomposition would be possible by electron release from the thiopyran ring sulfur allowing ring opening of the thiazole ring, and has many similarities to reactions of other thiopyrans and related compounds (6, 7). The exact fate of the other parts of the spiran has not been determined.

The other product, which was crystalline, had analysis and spectral data corresponding to a diadduct **8***d*. Similar results were obtained from treatment of **2***e*, which gave **7***a*, **7***b*, and the diadduct **8***e* and from **2***a* which afforded **7***a* and **8***a*. Although **7***c* would also have been expected from the reaction we were unable to identify it in the products.

Applying the above method for conversion of a heterocyclic thione function to a thiophenacylidene function to the isothiazole series, it should be possible to prepare some compounds of the type **9** which are of some interest in studies on valency isomerism. These compounds have some structural features similar to 1,6,6a-S^{IV}-trithiapentalenes and although they do not possess the central atom capable of valency shell expansion that allows the particular symmetry properties of the latter and related isosteric compounds (8–11), it appeared possible that they might be capable of acquiring some symmetry by rapid valency tautomerism, similar to some examples described (12). For this study, compound **9***a* appeared suitable. Accordingly,

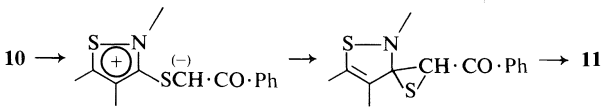
5-*p*-tolyl-1,2-dithiole-3-thione, prepared by the method of Thuillier and Vialle (13) with some modification, was converted by treatment with methyl iodide then methylamine into 2-methyl-5-*p*-tolylisothiazoline-3-thione (**1***c*), according to known methods (14, 15). Reaction of **1***c* with *p*-methylphenacyl bromide gave **10***a* which was converted into **9***a* by treatment with pyridine and thionation of the resulting ketone **11***a*. Compound **9***a* was obtained as stable red prisms. The nmr spectrum in deuteriochloroform exhibited the two *p*-tolyl methyl peaks as discrete singlets at 30°C. In 1,2,4-trichlorobenzene, over the temperature range 0 to 190°C, no coalescence of the peaks was observed, although at the higher range there was some approach of these values (to a difference of 0.3 τ). This indicates that the compound **9***a* has a rather high energy barrier to interconversion of the two identical valency tautomers, possibly because of the steric hindrance of the *N*-methyl group. The solution exhibited the original spectrum on cooling back to 0°C.

Similarly the thiones **1***a* and **1***b* were converted by reaction with phenacyl bromide, and following the above schemes, into **9***b* and **9***c*, respectively. These reactions are interesting in that although most isothiazolium salts appear to react preferentially at the ring sulfur atom with carbanions (14, 16), such a reaction is sterically impossible with the carbanions derived from the salts **10** (Scheme 1) and the subsidiary reaction site is favored.

It is obvious that compounds of the type **2**, **6**, and **8** could exist as geometrical isomers, with the thione, ketone, or the sulfide functions, respectively, being *cis* or *trans* to the thiazole ring sulfur. The involvement of *d* orbitals of this atom would certainly favor the *cis* geometry, as drawn, for the compounds of type **2** or **6** but for **8** the case is less certain.



SCHEME 1

The nmr spectrum of **6***a* showed two doublets (J = 1.5 Hz) at 2.38 and 2.62 τ whereas that of **2***a* showed one doublet (J = 1.2 Hz) at 2.35 τ. The other signal is apparently buried in the aromatic proton signals. These signals in **6***a* are assigned, respectively, to the exocyclic methine proton and to the thiazoline ring proton since **6***f* shows a singlet at 2.46 τ. In **2***a* the assignments cannot be made with certainty. The magnitude of the J values are consistent with a five-bond all *trans* proton–proton coupling which would be given by *cis* geometries of the compounds **6***a* and **2***a*. Similar results were obtained from the other members of the series. Since the formation of the diadducts **8** only involves the thione function of **2**, it therefore appears likely that these may also have a *cis* geometry.

For compound **9** also, two geometrical isomers are possible but both coulombic and electronic effects favor the *cis* geometry.

Experimental

Thin-layer chromatography was performed on Camag silica gel D.S.F. 5, supplied by Terochem Laboratories. Development of plates, unless otherwise stated, was in benzene. Nuclear magnetic resonance spectra were obtained on a Varian 56/60A model spectrometer using, unless otherwise stated, deuteriochloroform containing tetramethylsilane as an internal standard. Silylation grade pyridine was used in reactions. Melting points were obtained on a precalibrated Thermopan apparatus.

*Preparation of Thiazoline-2-thiones (**4**)*

The general procedure described for other thiones (2) was used with the modification that the initially precipitated hydroxythiazolidinethiones were dissolved in 80% sulfuric acid. After ½ h, water was added and the thiones precipitated. These were recrystallized from benzene or ethanol as pale yellow or colorless needles. Three of these were new. The results are summarized below.

3,4-Diphenyl-4-thiazoline-2-thione (**4***a*) was obtained as pale yellow needles, mp 159°C (72%). *Anal.* calcd. for $C_{15}H_{11}NS_2$: C 66.91, H 4.09, N 5.20, S 23.79; found: C 66.77, H 4.00, N 4.86, S 23.51.

3-Methyl-4-*p*-tolyl-4-thiazoline-2-thione (**4***b*) was obtained as pale yellow needles, mp 110°C (60%). *Anal.* calcd. for $C_{11}H_{11}NS_2$: C 59.72, H 4.97, N 6.33, S 28.96; found: C 59.78, H 4.63, N 6.21, S 29.04.

4,5-Diphenyl-3-methyl-4-thiazoline-2-thione (**4***c*) was obtained as colorless needles, mp 178°C (65%). *Anal.* calcd. for $C_{16}H_{13}NS_2$: C 67.84, H 4.59, N 4.95, S 22.61; found: C 67.58, H 4.89, N 4.63, S 22.48.

Other thiazoline-3-thiones (**4***d–f*) were obtained by the method described (17) or by the procedure below or were commercially available.

*Preparation of 2-Methylthio-3-methyl-4-phenylthiazolium Perchlorate (**5**a)*

Methyl *N*-methyldithiocarbamate (1.21 g, 10 mmol) and

*Identical (mixture mp and ir) with an authentic sample (1).
†Literature (4) mp 175°C.

phenacyl bromide (1.99 g, 10 mmol) in ethanol (10 mL) were refluxed 24 h. The mixture was cooled and perchloric acid (0.5 mL) added. Dilution with ether afforded a pale yellow precipitate which recrystallised from acetic acid as colorless flakes, mp 132°C (81%). *Anal.* calcd. for $C_{11}H_{12}NS_2ClO_4$: C 41.05, H 3.73, N 4.35, S 19.95, Cl 11.04; found: C 40.79, H 3.69, N 4.28, S 19.62, Cl 10.89.

*Preparation of 3-Methyl-4-phenylthiazoline-2-thione (**4**d)*

The salt **5***a* (320 mg, 1 mmol) in pyridine (10 mL) was refluxed 10 min. Dilution with water and extraction with ether afforded the thione **4***d* identical (mixture mp and ir) with an authentic sample (2) (95%).

*Preparation of 2-Methylthio-3-methyl-5-phenylthiazolium Iodide (**5**b)*

α-Bromophenylacetaldehyde (1.99 g, 10 mmol) and methyl *N*-methyldithiocarbamate (1.21 g, 10 mmol) were treated as above to afford the perchlorate (**5***b*, X = ClO_4) as colorless flakes, mp 127°C (72%). Treatment of this with saturated aqueous potassium iodide solution afforded the iodide, identical with an authentic sample (17).

*Preparation of 3-Methyl-5-phenylthiazoline-3-thione (**4**e)*

This was prepared as described (17) from the methiodide (**5***b*).

*Preparation of 2-Phenacylidenethiazolines (**6**)*

Equimolar quantities of phenacyl bromide and the thiazoline-2-thiones (**4**) were allowed to react as described (4). The initially formed thiazolium salts **5** were washed with benzene to remove non-salt-like impurities, then treated with approximately five times by weight of dry pyridine, and refluxed until homogeneous. The mixtures were diluted with water and extracted with benzene. The benzene extracts were washed with dilute hydrochloric acid, water, and dried over magnesium sulfate. Evaporation gave solid products which were mixtures of phenacylidenethiazolines and thiazolinethiones. These were separated by chromatography. The results are summarized in Table 1.

*Preparation of 2-Thiophenacylidenethiazolines (**2**)*

The ketones **6** were treated with approximately twice their weight of phosphorus pentasulfide in refluxing benzene for 4 h. The solutions were filtered, washed with dilute sodium bicarbonate solution, and dried over magnesium sulfate. Evaporation yielded the thiones as red or orange crystals which were purified by chromatography. The results are summarized in Table 2.

Reaction of 2,5-Diphenylisothiazoline-3-thione with Phenacylidenetriphenylphosphorane

The thione (269 mg, 1 mmol) (1) and the phosphorane (380 mg, 1 mmol) were fused together under nitrogen at 180°C for 1½ h. The crude mixture was examined by tlc and a red band eluted. Work-up and crystallisation from benzene afforded 3,4-diphenyl-2-thiophenacylidenethiazoline (**2***a*) as red prisms, mp 278–280°C, identical (mixture mp) with those produced by the above method.

Reaction of 2-Methyl-4,5-diphenylisothiazoline-3-thione with Phenacylidenetriphenylphosphorane

The thione (15) with an equimolar quantity of the phosphorane were fused together as above. Although starting thione and triphenylphosphine oxide were recovered, no other products could be identified.

*Reaction of 2-Thiophenacylidenethiazolines (**2**) with Dimethyl Acetylenedicarboxylate in Benzene*

Reactions were performed in dry benzene under reflux for

7 h and under a nitrogen atmosphere using either equimolar quantities, or a threefold excess of ester. Evaporation of the solvent yielded oily residues which were examined by chromatography over silica gel using a benzene–chloroform 9:1 mixture as eluent. The order of elution of bands was thione (**7***a*), imine (**7***b*), monoadduct (**3**), and diadduct (**8**). The results of individual experiments are summarized below. Reactions in dioxane were performed similarly.

3-Methyl-2-thiophenacylidenebenzothiazoline (**2***f*) treated with 1 equiv. of dimethyl acetylenedicarboxylate afforded **3***f* as a yellowish oil (66%). *Anal.* calcd. for $C_{22}H_{19}NO_4S_2$: C 62.11, H 4.47, N 3.29, S 15.06; found: C 62.33, H 4.58, N 3.01, S 14.67. The nmr spectrum, τ: 7.20 and 6.45 (two 3H singlets, ester methyls), 6.22 (3H, s, *N*-methyl), 3.65 (1H, s), 2.41–3.29 (9H bands, aromatic protons); mass spectrum, M^+ calcd.: 425; found: 425.

Repeating the reaction with a threefold excess of the ester or using dioxane as a solvent gave **3***f* (51%) and **9***f* (19%) as orange plates, mp 161°C. *Anal.* calcd. for $C_{28}H_{25}NO_8S$: C 59.23, H 4.41, N 2.47, S 11.29; found: C 58.89, H 4.63, N 2.61, S 11.09. The nmr spectrum, τ: 7.8, 7.34, 6.65, 6.31 (four 3H singlets, the ester methyls), 6.15 (3H, s, *N*-methyl), 2.25–3.10 (10H bands, aromatic protons and exocyclic methine proton).

Treatment of **3***f* with the ester yielded only unchanged material.

3-Methyl-4,5-diphenyl-2-thiophenacylidenethiazoline (**2***c*) treated as above gave only **3***c* (40%) for a 1:1 ratio of reactants and gave **3***c* (18%) and **8***c* (26%) for a 1:4 ratio of reactants. Both of these products were oils and were not analysed. The mass spectra for **3***c* M^+ calcd.: 527; found: 527. For **8***c* M^+ calcd.: 669; found: 669.

3-Methyl-4-phenyl-2-thiophenacylidenethiazoline (**2***d*) treated as above afforded **7***a* as a yellow oil (30%), **7***b* as a yellow oil (22%), and **8***e* as red plates, mp 175–176°C (18%). *Anal.* calcd. for $C_{15}H_{12}O_4S_2$ (**7***a*): C 56.25, H 3.75, S 20.00; found: C 56.55, H 3.62, S 19.81. The mass spectrum, M^+ calcd.: 320; found: 320. *Anal.* calcd. for **7***b*: C 60.57, H 4.73, N 4.42, S 10.09; found: C 60.69, H 4.81, N 4.16, S 9.73. The mass spectrum M^+ calcd.: 317; found: 317. *Anal.* calcd. for $C_{30}H_{27}NS_2O_8$ (**8***d*): C 60.70, H 4.55, N 2.36, S 10.79; found: C 60.54, H 4.92, N 2.25, S 10.98. The mass spectrum, M^+ calcd.: 593; found: 593. The nmr spectrum, τ: 7.44, 6.94, 6.37, 6.10, 6.08 (five 3H singlets, methyl protons), 4.84 (1H, s, vinyl proton), 3.58 (1H, s, thiazoline proton), 2.41–2.78 (10H bands, aromatic protons).

3-Methyl-5-phenyl-2-thiophenacylidenethiazoline (**2***e*) treated as above gave **7***a* (19%) and **7***b* (26%). A third band afforded a diadduct **8***e* (32%) as orange plates, mp 182°C. *Anal.* calcd. for $C_{30}H_{27}NS_2O_8$: C 60.70, H 4.55, N 2.36, S 10.79; found: C 61.01, H 4.96, N 2.70, S 11.11. The mass spectrum, M^+ calcd.: 593; found: 593. The nmr spectrum, τ: 7.41, 6.89, 6.37, 6.42, 6.10, 6.07 (five 3H, s's, methyl protons), 4.82 (1H, s, vinyl proton), 3.56 (1H, s, thiazoline proton), 2.38–2.79 (10H bands, aromatic protons).

3,4-Diphenyl-2-thiophenacylidenethiazoline **2***a* treated as above gave a number of bands on examination by tlc. A rapidly eluted band gave **7***a* (11%). The third band afforded the diadduct **8***a* as brown prisms (31%), mp 196°C. *Anal.* calcd. for $C_{35}H_{29}NS_2O_8$: C 64.12, H 4.42, N 7.13, S 14.07; found: C 63.85, H 4.51, N 2.40, S 14.23. The mass spectrum M^+ calcd.: 655; found: 655. The nmr spectrum, τ: 6.08, 6.25, 6.41, 6.82 (four 3H s's, methyl protons), 4.72 (1H, s, vinyl proton), 3.76 (1H, s, thiazoline proton), 1.40–1.85 (15H bands, aromatic protons).

*Preparation of 2-Methyl-5-*p*-tolylisothiazoline-3-thione* **1***c*

This was made by the procedure of Thuillier and Vialle (13) except that thionation was effected in boiling benzene for 4 h. Work-up of the solution afforded 5-*p*-tolyl-1,2-dithiole-3-thione (70%), mp 120°C (lit. (13) mp 120°C). This thione was alkylated with methyl iodide in refluxing ethyl acetate. The resulting 3-methylthio-5-*p*-tolyl-1,2-dithiolium iodide on treatment with ethanolic methylamine solution (14, 15) afforded 2-methyl-5-*p*-tolylisothiazoline-3-thione (28%) as orange-yellow needles, mp 129–130°C from benzene. *Anal.* calcd. for $C_{11}H_{11}NS_2$: C 69.84, H 5.82, N 7.40, S 16.93; found: C 69.20, H 5.81, N 7.14, S 16.57. The mass spectrum, M^+ calcd.: 221; found: 221. The nmr spectrum, τ: 7.65 (3H, s, *C*-methyl protons), 6.31 (3H, s, *N*-methyl protons), 2.90 (1H, s, isothiazoline proton), 2.49–2.71 (4H bands, aromatic protons).

*Preparation of 2-Methyl-3-*p*-methylthiophenacylidene-5-*p*-tolylisothiazoline (***9***a)*

Equimolar quantities of **1***c* and phenacyl bromide were fused together gently for 10 min. The cooled product was extracted with hot benzene then the residue crystallised from ethanol as colorless needles, mp 175°C (63%). This product on treatment with pyridine as above afforded 3-*p*-methylphenacylidene-5-*p*-tolylisothiazoline (**11**) as pale yellow needles, mp 165°C (25%). The product was purified from thione contaminant by chromatography. Thionation with phosphorus pentasulfide in boiling benzene afforded a reddish oil which on chromatography gave **9***a* as red prisms, mp 161°C (42%). *Anal.* calcd. for $C_{20}H_{19}S_2N$: C 71.21, H 5.63, N 4.15, S 18.99; found: C 71.03, H 5.46, N 4.02, S 18.73. The mass spectrum M^+ calcd.: 337; found: 337. The nmr spectrum of **9***a* in $CDCl_3$, τ: 7.61, 7.52 (two 3H, s's, *p*-methyl protons), 6.32 (3H, s, *N*-methyl protons), 2.50 (1H, s, methine proton), 2.93–2.09 (9H bands, aromatic and isothiazole protons).

In 1,2,4-trichlorobenzene at 40°C the two *p*-methyl peaks were evident as two singlets at 7.51 and 7.60 τ. At 100°C, these were separated by 0.7 τ, and at 190°C, by 0.3 τ. No further temperature rise could be attempted owing to instrumental limitations.

*2-Methyl-3-thiophenacylidene-5-phenylisothiazoline (***9***b)*

This was made by the above procedure starting from **1***a* and phenacyl bromide. It was obtained as red needles, mp 160°C (18% overall yield from thione). *Anal.* calcd. for $C_{18}H_{15}NS_2$: C 69.90, H 4.85, N 4.53, S 20.71; found: C 70.25, H 4.66, N 4.55, S 20.93. The mass spectrum, M^+ calcd.: 309; found: 309.

*2,5-Diphenyl-3-thiophenacylidenethiazoline (***9***c)*

This was made by the above procedure starting from **1***b* and phenacyl bromide. Violet needles, mp 178°C (21% overall from the thione), were obtained. *Anal.* calcd. for $C_{23}H_{17}NS_2$: C 74.39, H 4.58, N 3.77, S 17.25; found: C 74.51, H 4.38, N 4.01, S 17.06. The mass spectrum, M^+ calcd.: 371; found: 371.

Allergenic α-methylene-γ-butyrolactones. A one-carbon degradation of isoalantolactone via Pummerer rearrangement of sulfoxides

JEAN-PIERRE CORBET AND CLAUDE BENEZRA

Laboratoire de Dermato-Chimie, Associé au CNRS, Université Louis Pasteur, Clinique Dermatologique, Hôpitaux de Strasbourg, 67005 Strasbourg, France

Received June 23, 1978

JEAN-PIERRE CORBET and CLAUDE BENEZRA. Can. J. Chem. **57**, 213 (1979).

Isoalantolactone and α-methylene-γ-butyrolactone were separately treated with NaSPh, transformed into sulfoxides, and rearranged under Pummerer conditions (Ac_2O + $(CF_3CO)_2O$). The Pummerer products were hydrolyzed, oxidized, and decarboxylated resulting in the formation of 13-norisoalantolactone (with migration of the *exo*-C(4) double bond into position C(4)—C(5)) on the one hand and of γ-butyrolactone on the other. The isomeric norisoalantolactone **17** is a starting material for the synthesis of ^{14}C-labelled alantolactone, **18**.

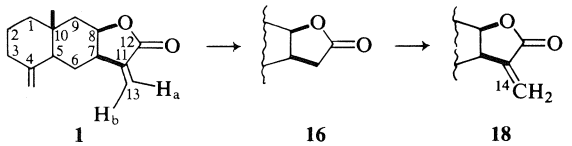
JEAN-PIERRE CORBET et CLAUDE BENEZRA. Can. J. Chem. **57**, 213 (1979).

L'isoalantolactone et l'α-méthylène-γ-butyrolactone ont été traitées séparément par NaSPh, oxydées dans les sulfoxydes correspondants et transposées dans les conditions de Pummerer (Ac_2O + $(CF_3CO)_2O$). Les produits de Pummerer ont été hydrolysés, oxydés et décarboxylés menant ainsi à la 13-norisoalantolactone (dans laquelle la double liaison en C(4) a migré en position C(4)—C(5) d'une part, à la γ-butyrolactone, d'autre part. La norisoalantolactone isomérisée **17** est un produit de départ pour la synthèse d'alantolactone marquée au ^{14}C, **18**.

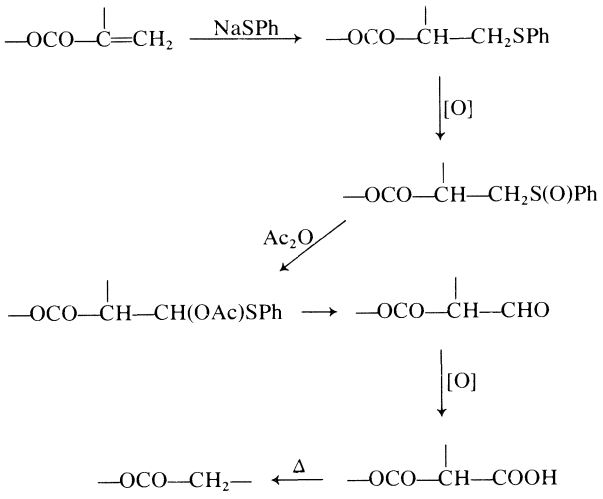
In a general approach towards the mechanism of allergic contact dermatitis (ACD), we have undertaken the synthesis of ^{14}C-labelled allergens (1). α-Methylene-γ-butyrolactones seemed attractive models, since they are widespread in nature, especially in the *Compositae* family of plants and in liverworts such as *Frullania*. Two approaches have been chosen: (*a*) the synthesis of model compounds containing the α-methylene-γ-butyrolactone moiety; (*b*) introduction, through one-carbon degradation, of ^{14}C in natural sesquiterpene lactones. This paper describes this second type of approach.

Isoalantolactone **1** is a readily available lactone (isolated from *Inula helenium* as a commercial crude extract also containing an isomer, alantolactone). The initial idea was to attack the most reactive part of the molecule, the methylene group α to the lactone, and to reintroduce it (with a ^{14}C-labelled reagent) (Scheme 1).

Among several ways which have been attempted in this laboratory with varying success,[1] one seemed attractive: the Pummerer rearrangement of sulfoxides obtained via Michael addition (2, 3) to the conjugated lactone, followed by hydrolysis, oxidation, and decarboxylation (Scheme 2).



SCHEME 1



SCHEME 2

In order to understand the results for isoalantolactone, degradation of α-methylene-γ-butyrolactone (R = H) **2** (4) was attempted simultaneously.

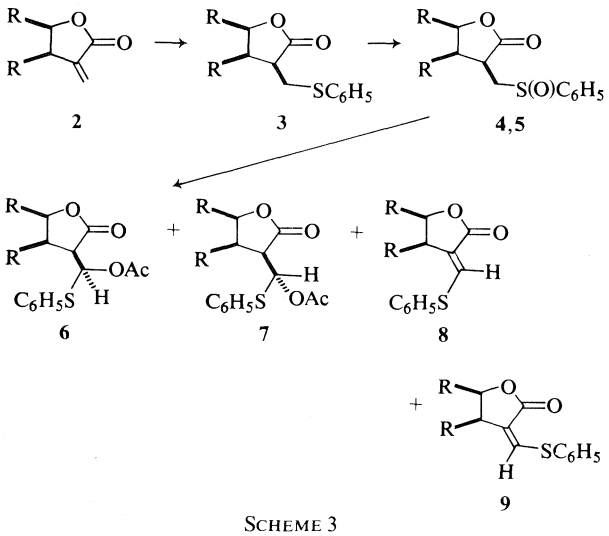
Results and Discussion

Degradation of α-Methylene-γ-butyrolactone

Addition of sodium thiophenoxide to α-methylene-γ-butyrolactone **2** (R = H) gave the sulfide **3** which was oxidized (3) into diastereomeric sulfoxides **4** and

[1] J. L. Stampf, G. Schlewer, and C. Benezra. Unpublished results.

0008-4042/79/020213-05$01.00/0



SCHEME 3

5 which were left as a mixture. Pummerer rearrangement of **4** + **5** was effected by using a mixture of Ac_2O and $(CF_3CO)_2O$ (5). This avoided heating with Ac_2O (6), which could have resulted in the thermal elimination of sulfenic acid, to give the starting α-methylene-γ-butyrolactone. This reaction gave, besides the normal Pummerer products **6** and **7**,[2] two vinyl sulfides: **8** and **9**.[3] The relative ratio of compounds **6**–**9** was approximately: 2:4:3:1. The mixture of compounds **6** and **7** was separated from **8** and **9** by column chromatography. A further separation by thin-layer chromatography gave pure **6** and **7**. Compounds **8** and **9** were analyzed as a mixture (Scheme 3).

The nmr spectra of compounds **6** and **7** (R = H) showed different coupling constants between the methine protons: —C*H*—CO— and —C*H*(OAc)SPh (3.3 Hz for isomer **6** and 6.7 Hz for isomer **7**). These results will be discussed later in the case of isoalantolactone.

Chloramine-T treatment (7) of compounds **6** and **7** gave the enol acetate **10** which was allowed to react with Ag_2O–NaOH (8), resulting in the formation of a carboxylic acid. Heating of the latter (9) gave γ-butyrolactone **11** (Scheme 4). Compound **10** was independently prepared from sodium α-hydroxymethylene-γ-butyrolactone (10) and acetyl chloride, in order to assign the configuration (*E* or *Z*) of **10**, obtained from **6** and **7**. No attempt was made to isolate the acid.

[2]For convenience of discussion, compounds **4** and **5** on the one hand, **6** and **7** on the other hand, are described with the configuration shown in the figures, even if these configurations have not been determined. In the case of α-methylene-γ-butyrolactone, compounds **4** and **5** have not been separated.

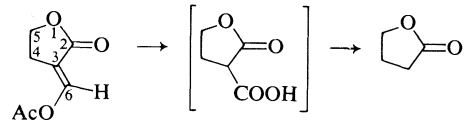
[3]Configurational assignment results from the nmr: the chemical shift of H(6) is δ 7.68 in isomer **8** (deshielding effect of the C=O group), while it is δ 7.12 in isomer **9** (no effect).

The same sequence of reactions was applied to isoalantolactone **1**. Only some differences will be noted.

Degradation of Isoalantolactone

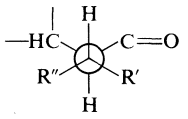
The sulfoxides **4** and **5** (R = isoalantolactone residue, see **1**) were isolated and separated. With identical ir spectra, it is quite probable that the only difference is configuration at sulfur. The $—CH_2S(O)Ph$ group is β, as will be shown further in compounds **6** and **7**. The nmr spectra of **4** and **5** show interesting differences: in particular, the broad singlets due to ethylenic hydrogens at C(4) are located at δ 4.81 and 4.51 ppm in **4** and at 4.74 and 4.37 ppm in **5**. Assignment of configuration at S cannot be made at this stage.

The Pummerer reaction was attempted on the mixture of sulfoxides and also on each sulfoxide separately, both giving the same mixture of compounds **6**–**9** in a 1:4:5:1 ratio (as shown by nmr).



SCHEME 4

The vinyl sulfides **8** and **9** have the configuration shown in Scheme 3 (R = isoalantolactone residue). As observed in the case of the degradation of α-methylene-γ-butyrolactone, the nmr spectra of compounds **6** and **7** show notable differences, such as the H(11)–H(13) coupling constant which is 6.6 Hz in compound **6** and 10.7 Hz in isomer **7**.[2] This corresponds to favored conformations. Thus, isomer **6** has probably two *trans* hydrogens, as in **12**.

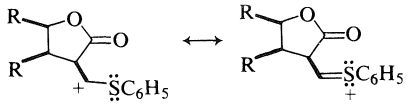


12

a R′ = SPh, R″ = OAc
b R′ = OAc, R″ = SPh

It is difficult to assess which of the *gauche* interactions C=O–SPh or C=O–OAc is the least favorable and therefore to assign configuration at C(13).

Sulfoxides **4** and **5** (R = isoalantolactone residue) separately gave the same products in the same ratio; this shows beyond any doubt that configuration at C(11) is the same in both sulfoxides and also in the sulfides, **3**. Indeed, the Pummerer intermediate **13** is achiral (11, 12).



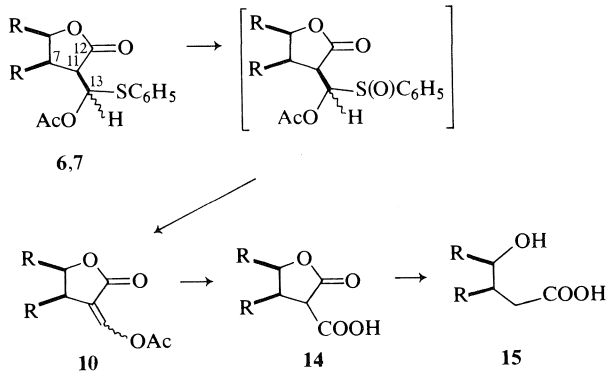
13

The H(7)–H(11) coupling constant is 6.6 Hz in compound **6** and 6.0 Hz in compound **7**. The similarity of these values implies the same configuration at C(11). They are also compatible with a β orientation of the —CH(OAc)SPh group. With an α orientation, the H(7)–H(11) dihedral angle is ~90°,[4] which would correspond to a ca 0 Hz coupling constant (13). Most Michael additions to the α-methylene group of alantolactone and isoalantolactone have been claimed to lead to the formation of β-derivatives (see for instance refs. 2 and 14).

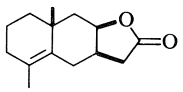
Several reactions were attempted in order to hydrolyze the Pummerer products **6** and **7**.[5] Surprisingly, chloramine-T did not react at all and the reactants were recovered unchanged. This may be due to steric effects: according to the accepted mechanism of this reaction, chloramine-T attacks the sulfur atom. The approach might not be favorable, because of steric hindrance from the sesquiterpene skeleton.

Hydrolysis and further degradation was achieved by (*a*) oxidizing the sulfide group to a sulfoxide and (*b*) thermally eliminating sulfenic acid (3). The intermediate enol acetate **10** (R = isoalantolactone residue) was not isolated but was hydrolyzed and oxidized with an Ag_2O–NaOH mixture (8) and decarboxylated by heating (Scheme 5).

The base treatment opened the lactone ring to a hydroxy acid **15**. Ring closure to the lactone was achieved by *p*-toluenesulfonic acid treatment in CCl_4. This resulted in isomerization of norisoalantolactone **16** into lactone **17**, with migration of the *exo*-methylenic double bond from C_4 into ring A. Compound **17** has already been described and its transformation into alantolactone was made in several steps (17).



SCHEME 5



17

The sequence of reaction described in this paper provides, therefore, a means to achieve the synthesis of ^{14}C-labelled alantolactone **18**.

Experimental

Melting points were observed on a 510 Büchi apparatus and are uncorrected. Infrared spectra were recorded on a Beckman Acculab 1 spectrophotometer and absorptions are expressed in cm^{-1}. ^1H nuclear magnetic resonance spectra were recorded on a R 32 Perkin-Elmer (90 MHz), except when specified, using TMS as internal standard (δ 0); chemical shifts are given in δ ppm units, coupling constants in Hz. The combustion analyses were effected by the Centre de Microanalyses du CNRS. Mass spectra were recorded on 9000S LKB apparatus.

α-Methylene-γ-butyrolactone **2** (R = H) was prepared according to the method described in ref. 4 from α-(γ-butyrolactonylidene)triphenylphosphorane.

Isoalantolactone **1** was obtained pure from Helenin® (Sigma Products) by crystallization with a heptane–methanol mixture.

Addition of Sodium Thiophenoxide to α-Methylene-γ-butyrolactone: Sulfides 3 (R = H)

To a solution of sodium thiophenoxide in absolute ethanol (prepared from sodium (379 mg, 16.5 mmol) and thiophenol (4.49 g, 40.7 mmol) in 25 ml ethanol was added α-methylene-γ-butyrolactone (1.01 g, 10.3 mmol) in 40 ml absolute ethanol. The mixture was stirred at room temperature for 1.5 h. After hydrolysis, extraction with methylene chloride and washing of the combined extracts with water, drying with $MgSO_4$, and removing the solvent *in vacuo*, a crude mixture was obtained. This was chromatographed on a silica gel column (eluent: petroleum ether – ether 1:1), leading to sulfide **3** (1.97 g, 9.47 mmol; yield 92%); mp 60°C; ir ($CHCl_3$): 1765 (CO), 1580 (C_6H_5); nmr ($CDCl_3$): 1.8–3.0 (complex m, 4H, H(6) + H(4), 3.51 (complex m, 1H, H(3)), 4.0–4.4 (complex m, 2H, H(5)), 7.0–7.6 (complex m, 5H, aromatic); ms: 208 ($M^{\ddagger}$). *Anal.* calcd. for $C_{11}H_{12}O_2S$ (208): C 63.46, H 5.77; found: C 63.46, H 5.81.

[4]A referee has commented that the *cis* relationship between H-11 and H-7 (as shown by the 6.0–6.6 Hz coupling constant) could depend on the conformation of ring B. In the most stable conformation (chair), a *cis* H(11)–H(7) relationship corresponds, according to Dreiding models, to a ca. 30° angle (i.e., a ca. 7 Hz coupling) and a *trans* one to ca. 90° (i.e., a ca. 0 Hz coupling constant). A ring B boat conformation seems excluded because of steric hindrance. A third possibility is a twist-boat conformation: in this case, H(11)–H(7) dihedral angles are, respectively, ca. 150° (for an α orientation of the PhSCH(OAc) group, i.e., a coupling constant > 10 Hz) and 30° (for a β orientation, i.e., a coupling close to the one found). In conclusion, a β orientation of the PhSCH(OAc)—group seems well established, whatever the conformation of ring B.

[5]Several hydrolysis conditions were tried on the vinyl ethers **8** and **9**, with no success. (*a*) $TiCl_4$ treatment (15) resulted only in the migration of the C(4)=CH_2 bond into the C(4)=C(5) position. (*b*) It has been shown that vinyl thioethers with a homoallylic OH group could be hydrolyzed with $HgCl_2$ (16). The lactone group in **8** and **9** was opened by alkaline treatment and the resulting compounds were reacted with a CH_3CN–$HgCl_2$–H_2O mixture: the vinyl thioethers **8** and **9** were formed again (lactone ring closure catalyzed by the Lewis acid, $HgCl_2$). (*c*) Treatment of **8** + **9** with anhydrous HCl resulted only in the migration of the C(4)=CH_2 double bond into position C(4)—C(5). (*d*) The dithiane derivative (obtained through Michael addition of PhSNa to the **8** + **9** mixture) was treated with an aqueous mixture of $HgCl_2$–CH_3CN: the thioethers **8** and **9** were obtained again.

Oxidation of Sulfide **3**: *Sulfoxides* **4** + **5** (*R* = *H*)

A solution of sulfide **3** (1.77 g, 8.51 mmol) in methanol (120 ml) was reacted with sodium metaperiodate (2.36 g, 11.1 mmol) in water (50 ml) at room temperature for 2 days. The precipitate of sodium iodate was then filtered off, methanol removed *in vacuo*, and the remaining aqueous filtrate extracted with CH_2Cl_2. After the usual work-up, the crude sulfoxides were chromatographed on a silica gel column: compounds **4** and **5** coeluted (ethyl acetate) (1.68 g, 7.48 mmol; 88% yield.) The mixture crystallized slowly at room temperature; mp ~ 65°C; ir ($CHCl_3$): 1765(CO), 1580(Ph), 1025(SO); nmr ($CDCl_3$): 1.8–2.6 (m, 2H, H(4)), 2.7–3.6 (m, 3H, H(3) + H(6)), 4.0–4.6 (m, 2H, H(5)), 7.5–7.9 (m, 5H, aromatic); ms: 224 ($M^{\ddagger}$). *Anal.* calcd. for $C_{11}H_{12}O_3S$ (224): C 58.93, H 5.35; found: C 58.87, H 5.45.

Pummerer Rearrangement of Sulfoxides **4** + **5** (*R* = *H*): *Compounds* **6**–**9**

Trifluoroacetic anhydride (1.09 g, 9.3 mmol) was dissolved in acetic anhydride (6.25 ml) and kept standing for 5 hours at room temperature. The sulfoxide mixture (**4** + **5**, 1.40 g, 6.25 mmol) was then added and the resulting solution stirred for 2.5 h at room temperature. After removal of the anhydrides under reduced pressure, the residue was extracted with toluene. After usual work-up, chromatography of the residue on a silica gel column, 1.3 g of a mixture of compounds **6**–**9** was obtained. Compounds **6**, **7**, and **8** + **9** were further purified by thick-layer chromatography on silica gel coated plates. The relative ratio of compounds **6**–**9** was about 2:4:3:1, as shown by nmr.

Acetoxy sulfide **6**—ir($CHCl_3$): 1775 (CO lactone), 1755 (CO, AcO), 1580 (Ph); nmr ($CDCl_3$): 2.01 (s, 3H, CH_3CO), 2.2–2.7 (m, 2H, H(4)), 3.14 (dt, 1H, H(3), $J_{3,4}$ = 10, $J_{3,6}$ = 3.3), 4.0–4.6 (m, 2H, H(5)), 6.59 (d, 1H, H(6), $J_{6,3}$ = 3.3), 7.3–7.8 (m, 5H, aromatic).

Acetoxy sulfide **7**—ir ($CHCl_3$): 1770 (CO lactone), 1750 (CO, AcO), 1580 (Ph); nmr ($CDCl_3$): 2.11 (s, 3H, CH_3CO), 2.2–2.6 (m, 2H, H(4)), 3.0–3.3 (dt, 1H, H(3), $J_{3,6}$ = 6.7, $J_{3,4}$ = 10), 4.1–4.6 (m, 2H, H(5)), 6.41 (d, 1H, H(6), $J_{3,6}$ = 6.7), 7.3–7.8 (m, 5H, Ph).

Mixture of **6** + **7**—ms: 266 ($M^{\ddagger}$). *Anal.* calcd. for $C_{13}H_{14}O_4S$ (266): C 58.65, H 5.26; found: C 58.81, H 5.33.

Vinyl thioethers **8** + **9**— ir ($CHCl_3$): 1750 (CO lactone), 1625 (very strong, C=CSPh), 1580 (Ph); nmr ($CDCl_3$; 60 MHz): 2.84 (dt, 2H, H(3), $J_{4,6}$ = 3.0, $J_{4,5}$ = 7.5), 4.42 (t, 2H, H(5), $J_{5,4}$ = 7.7), 7.3–7.6 (m, 5H, Ph), 7.68 (t, 1H, H(6), $J_{4,6}$ = 3.0). Compound **9** showed a weak triplet at 7.12 ($J_{6,4}$ = 2.3). *Anal.* calcd. for $C_{11}H_{10}O_2S$ (206): C 64.08, H 4.85; found: C 64.22, H 4.96.

Hydrolysis of the Acetoxy Sulfides **6** + **7** (*R* = *H*): *Enol Acetate* **10**

The mixture of **6** + **7** (520 mg, 1.95 mmol) was treated with a solution of sodium *N*-chloro-*p*-toluenesulfonamide (chloramine-T, 1.1 g, 3.91 mmol) in an 85% aqueous solution of methanol (15 ml). The mixture was stirred for 5 min at room temperature and water was added. After usual work-up (with CH_2Cl_2), the residue was chromatographed on a silica gel column. The enol acetate **10** (eluent, petroleum ether – ether 25:75) was obtained in 63% yield (191 mg, 1.22 mmol). The compound crystallized slowly at 4°C; ir ($CHCl_3$): 3090 (C=C), 1780 (CO lactone), 1765 (CO, AcO), 1695 (C=C, sharp and strong); nmr ($CDCl_3$): 2.27 (s, 3H, CH_3CO), 2.99 (dt, 2H, H(4), $J_{4,5}$ = 7.3, $J_{4,6}$ = 2.8), 4.42 (t, 2H, H(5), $J_{5,6}$ = 7.3), 8.02 (t, 1H, H_a, $J_{4,a}$ = 2.8); ms: 156 ($M^{\ddagger}$).

The combustion analysis was not satisfactory, probably because the product is highly hygroscopic. To assess without ambiguity its structure and configuration, compound **10** was prepared by another route, as follows.

Preparation of Enol Acetate **10** (*R* = *H*) *from* γ-*Butyrolactone*

A solution of γ-butyrolactone (8.61 g, 100 mmol) and ethyl formate (7.41 g, 100 mmol) in anhydrous ethyl ether (25 ml) was added dropwise to a suspension of oil-free sodium hydride (2.52 g, 105 mmol) in ether (150 ml); 1 ml ethanol was added and the mixture was stirred at room temperature for 22 h. The resulting yellow-brown precipitate was filtered, washed with ether, and dried *in vacuo*. The sodium enolate was obtained in 97% yield (13.2 g, 97.0 mmol).

To a suspension of the sodium enolate (7.6 g, 55.8 mmol) in THF (100 ml) was added dropwise a solution of acetyl chloride (8.6 g, 110 mmol) in THF (150 ml). The mixture was heated under reflux for 4 h. After cooling, the NaCl precipitate was filtered off, the solvent removed *in vacuo* (this also eliminated excess acetyl chloride), and the residue chromatographed on a silica gel column, affording 3.36 g (21.5 mmol, 39% yield) of a compound whose spectra were identical with those reported for compound **10**. The nmr spectrum showed, in addition, a weak triplet centered at δ 7.46 ($J_{b,4}$ = 2.3); this corresponds to an isomer at C(6) (the *Z* isomer) and allowed us to assign configuration *E* to the major isomer.

Saponification and Oxidation of Enol Acetate **10**: *Formation of* γ-*Butyrolactone*

Enol acetate **10** (916 mg, 5.87 mmol) was treated with Ag_2O obtained from $AgNO_3$ (2.064 g, 12.1 mmol) and NaOH (6*N*, 5 ml). The mixture was stirred at room temperature for ca. 2 h and the black solid filtered off and washed with small portions of water. The aqueous layer was then refluxed for 4 h; after cooling, the solution was neutralized with HCl and water removed *in vacuo*; the resulting sodium chloride was washed several times with methylene chloride, methylene chloride was removed *in vacuo*, and the residue was chromatographed on a silica gel column. Thus, γ-butyrolactone, identical by ir and nmr spectra with an authentic sample, was obtained in an overall yield of 30% from enol acetate **10** (150 mg, 1.74 mmol).

Addition of Sodium Thiophenoxide to Isoalantolactone **1** (*R* = *isoalantolactone residue*): *Sulfide* **3**

A solution of isoalantolactone **2** (4.00 g, 17.2 mmol) in ethanol (50 ml) was added to a solution of sodium thiophenoxide in anhydrous ethanol (NaSPh was prepared from PhSH, 7.59 g, 68.9 mmol and sodium, 0.600 g, 26.1 mmol). The mixture was stirred at room temperature for 2 h and water was added. The white precipitate formed was filtered off and washed several times with small portions of heptane to eliminate the remainer of thiophenol. Pure sulfide **3** (5.47 g, 16.0 mmol) was thus obtained (93% yield); mp 138–139°C; ir ($CDCl_3$): 1770 (CO), 1645 (C(4)=CH_2), 1580 (Ph); nmr ($CDCl_3$): 0.81 (s, 3H, C(10)—CH_3), 2.9–3.1 (m, 2H, H(13)), 3.3–3.7 (m, 1H, H(11)), 4.3–4.6 (m, 1H, H(8)), 4.48 and 4.82 (2 broad s, 2H, C(4)=CH_2), 7.2–7.6 (m, 5H, Ph); ms: 342 ($M^{\ddagger}$). *Anal.* calcd. for $C_{21}H_{26}O_2S$ (342): C 73.68, H 7.60; found: C 73.54, H 7.71.

Oxidation of Sulfide **3** (*R* = *isoalantolactone residue*) *into Sulfoxides* **4** *and* **5**

A solution of sulfide **3** (2.94 g, 8.60 mmol) in 100 ml dioxane was treated with sodium metaperiodate (2.39 g, 11.2 mmol) in 50 ml water. After stirring the mixture for 2 days at 30°C, dioxane was removed *in vacuo* and the remaining aqueous phase worked up as usual with methylene chloride. The residue was chromatographed on a silica gel column, yielding a 1:1 mixture of sulfoxides **4** and **5** (2.62 g, 7.3 mmol, 85% yield). Pure compounds were obtained by thick-layer chromatography.

Sulfoxide **4**—mp 141°C; ir ($CHCl_3$): 1770 (CO), 1645 (C(4)=CH_2), 1030 (SO); nmr ($CDCl_3$): 0.78 (s, 3H,

C(10)—CH_3), 3.0–3.4 (m, 1H, H(11)), 3.16 (broad s, 2H, H(13)), 4.4–4.6 (m, 1H, H(8)), 4.51 and 4.81 (2 broad s, 2H, C(4)=CH_2), 7.5–7.8 (m, 5H, aromatic); ms: 358 ($M^{\ddagger}$).

Sulfoxide **5**—viscous oil; ir: identical with **4**; nmr ($CDCl_3$): 0.76 (s, 3H, C(10)—CH_3), 2.8–3.7 (m, 3H, H(13 + 11)), 4.56 (m, 1H, H(8)), 4.37 and 4.74 (2 broad s, 2H, C(4)=CH_2), 7.3–8.0 (m, 5H aromatic); ms: 358 ($M^{\ddagger}$).

Repeated combustion analyses gave unsatisfactory results: compounds **4** and **5** are extremely hygroscopic.

Pummerer Rearrangement of Sulfoxides ***4*** *+* ***5*** *(R = isoalantolactone residue). Compounds* ***6–9***

Trifluoroacetic anhydride (1.76 g, 8.36 mmol) was dissolved in Ac_2O (5.6 ml) and the resulting mixture was kept standing for 5 h at room temperature. This mixture was then added to sulfoxides **4** + **5** (2.01 g 5.61 mmol) and stirred for 2.5 h at room temperature. After removal of the excess anhydrides under reduced pressure, the residue was dissolved in toluene, washed with a $NaHCO_3$ solution, with water, and dried over $MgSO_4$. After removal of the solvent, a silica gel column chromatography afforded (eluent petroleum ether – ether 1:1) a mixture of compounds **6–9** (1.54 g) relative ratio as determined by nmr 1:4:5:1).

Compounds **6–9** were obtained in the same yield and with the same ratio from either **4** or **5**. Pure compounds were obtained by thick-layer chromatography.

α-Acetoxy sulfide ***6***—viscous oil; ir ($CHCl_3$): 3090 (C=C), 1770 (CO lactone), 1755 (CO, AcO), 1645 (C=C), 1580 (Ph); nmr ($CDCl_3$): 0.81 (s, 3H, C(10)—CH_3), 2.04 (s, 3H, CH_3CO), 3.22 (dd, 1H, H(11), $J_{11,13} = 6.6$, $J_{7,11} = 6.6$, this dd appears as a t), 4.48 (broad m, 1H, H(8)), 4.53 and 4.82 (2 broad s, 2H, C(4)=CH_2), 6.56 (d, 1H, H(13), $J_{11,13} = 6.6$), 7.3–7.8 (m, 5H, Ph).

α-Acetoxy sulfide ***7***—viscous oil; ir ($CHCl_3$): 3090 (C=C), 1770 (CO lactone), 1750 (CO, AcO), 1645 (C=C), 1580 (Ph); nmr ($CDCl_3$): 0.81 (s, 3H, C(10)—CH_3), 2.16 (s, 3H, CH_3CO), 3.05 (dd, 1H, H(11), $J_{11,13} = 10.7$, $J_{11,7} = 6.0$), 4.39 (m, 1H, H(8)), 4.56 and 4.86 (2 broad s, 2H, C(4)=CH_2), 6.45 (d, 1H, H(13), $J_{11,13} = 10.7$), 7.3–7.7 (m, 5H, aromatic).

Mixture of ***6*** *+* ***7***—ms: 400 ($M^{\ddagger}$). *Anal.* calcd. for $C_{23}H_{28}O_4S$ (400): C 69.00, H 7.00; found: C 69.13, H 6.95.

Vinyl sulfides ***8*** *+* ***9***—mp 178–179°C; ir ($CHCl_3$): 1740 (CO), 1645 (C=C), 1615 (very strong, C=CSPh), 1580 (Ph); nmr ($CDCl_3$): 0.78 (s, 3H, C(10)—CH_3, compound **9**), 0.84 (s, 3H, C(10)—CH_3, compound **8**), 2.9–3.3 (m, 1H, H(11)), 4.3–4.6 (m, 1H, H(8)), 4.48 and 4.77 (2 broad s, 2H C(4)=CH_2), 7.06 (d, 1H, H_b, compound **9**, $J_{b,7} = 1.0$), 7.1–7.6 (m, 5H, aromatic), 7.51 (d, 1H, H_a, $J_{a,7} = 1.2$, compound **8**); ms: 340 ($M^{\ddagger}$). *Anal.* calcd. for $C_{21}H_{24}O_2S$ (340): C 74.12, H 7.06; found: C 74.07, H 7.21.

Hydrolysis of Compounds ***6*** *+* ***7****: Formation of Compound* ***17***

A solution of α-acetoxy sulfides **6** + **7** (550 mg, 1.38 mmol) in a mixture of dioxan (20 ml) and benzene (2 ml) was treated with a solution of $NaIO_4$ (382 mg, 1.79 mmol) in water (8 ml). The mixture was heated with stirring at 40°C for 36 h. The precipitate of IO_3Na was filtered off and the solvent removed *in vacuo*. The residue was refluxed in toluene for 6 h, the solvent removed, the new residue dissolved in $CHCl_3$, and washed with water. The $CHCl_3$ extract was evaporated to dryness. Spectra showed that the major compound was the enol acetate **10** (R = isoalantolactone residue) and a hydroxymethylene lactone. This mixture was treated with Ag_2O (prepared from $AgNO_3$, 482 mg, 2.84 mmol and 2 ml of NaOH 6 *N*) with stirring at room temperature for 2 h. The black solid was filtered off and washed with small portions of ether. This was removed *in vacuo* and the remaining aqueous solution was refluxed for 4 h, neutralized with HCl 2 *N*, and extracted with $CHCl_3$ as usual. The ir spectrum of the residue thus obtained showed that the lactone had been opened in the base treatment into a hydroxy acid. The residue was therefore dissolved in CCl_4 containing catalytic amounts of *p*-toluenesulfonic acid and refluxed for 2 h. After usual work-up, the residue was chromatographed on a silica gel column yielding (eluent petroleum ether – ether 1:1) 100 mg (0.454 mmol, 33% yield from **6** + **7**) of lactone **17**. The ir and nmr spectra were identical with those reported by Marshall and Cohen (17); ir ($CHCl_3$): 1770 (CO), 1665 (C=C); nmr ($CDCl_3$): 1.13 (s, 3H, C(10)—CH_3), 1.65 (s, 3H, C(4)—CH_3), 4.56 (m, 1H, H(8)); ms: 220 ($M^{\ddagger}$).

D. BEAUPERE, P. BAUER et R. UZAN. Can. J. Chem. **57**, 218 (1979).

L'utilisation du catalyseur $RhH(P\phi_3)_4$ dans la réaction de réduction du système éthylénique de styryl cétones par le phényl-1 éthanol permet d'effectuer l'hydrogénation dès 50°C. A cette température, des effets de substituant dans les cétones α,β-éthyléniques ont pu être mis en évidence, montrant une augmentation de la vitesse initiale de réduction pour des groupes électronattracteurs et un effet inverse pour des groupes électrondonneurs. L'obtention d'une relation entre le potentiel de réduction électrochimique de ces cétones et leur vitesse d'hydrogénation suggère un transfert d'hydrogène vers la cétone par l'intermédiaire d'un ion hydrure.

D. BEAUPERE, P. BAUER, and R. UZAN. Can. J. Chem. **57**, 218 (1979).

The use of the catalyst $RhH(P\phi_3)_4$ in the reduction of the ethylenic system of styryl ketones by 1-phenylethanol permits the hydrogenation reaction to proceed at 50°C. Some substituent effects in the α,β-unsaturated ketones were demonstrated at this temperature. These showed an increase in the initial rate of reduction for electron-attracting groups and the inverse effect for electron-donating groups. The observation of a relation between the electrochemical reduction potential of these ketones and their rate of hydrogenation suggests a transfer of hydrogen to the ketone by a hydride ion intermediate.

[Journal translation]

Le transfert d'hydrogène entre un donneur tel qu'un alcool, un éther, une amine et un accepteur alcène ou une cétone, catalysé par les métaux de transition, permet de mettre en évidence l'influence électronique du donneur et du catalyseur. Dans la réduction de cétones α,β-éthyléniques à 180°C avec $RuCl_2(P\phi_3)_3$ l'étape lente est la déshydrogénation du donneur (1). Cette étape est précédée par la formation d'un complexe catalyseur–accepteur et des effets électroniques sont observés uniquement au niveau du donneur et du catalyseur. L'absence de tels effets au niveau de l'accepteur impliquerait que l'étape de transfert d'hydrogène à l'accepteur soit rapide. Ce résultat n'est pas généralisable aux observations faites lors de la réduction d'autres accepteurs (2, 3) où ces effets électroniques sont observés, il est vrai à des températures plus basses. Pour tenter de mettre en évidence de tels effets, nous avons recherché pour la réaction [1] un catalyseur

[1] $$\underset{A}{X\text{—}\phi\text{—}CH{=}CH\text{—}CO\text{—}R} + \underset{D}{\phi\text{—}CHOH\text{—}CH_3} \xrightarrow{C} X\text{—}\underset{P_{red}}{\phi\text{—}CH_2\text{—}CH_2}\text{—}CO\text{—}R + \underset{P_{ox}}{\phi\text{—}CO\text{—}CH_3}$$

permettant d'avoir des conditions expérimentales plus douces que celles utilisées précédemment (1).

Résultats

Pour la réaction de réduction de la benzalacétone en cétone saturée, le rendement et la température de la réaction dépendent du catalyseur. Si Sasson et Blum (1) réduisent en 1 h 95% de benzalacétone 0.4 *M* en solution dans l'alcool benzylique avec $RuCl_2(P\phi_3)_3$ (10^{-3} *M*) à 180°C, nous avons obtenu à une température voisine (170°C) un taux de réduction de l'ordre de 30% en 2 h de la même cétone (0.25 *M*) dans le prehnitène à l'aide du phényl-1 éthanol (0.25 *M*) en présence de $RhCl(P\phi_3)_3$ (0.01 *M*). Dès 50°C avec $RhH(P\phi_3)_4$ (10^{-2} *M*) nous sommes parvenus à réduire 71% de benzalacétone 0.25 *M* en 50 min par le phényl-1 éthanol 0.25 *M* dans le toluène.

L'évolution de cette dernière réaction est suivie par prélèvement et analyse cpv. Le taux de cétone réduite en fonction du temps est linéaire jusqu'à 50% de la réaction et la pente de cette droite permet la détermination graphique de la vitesse initiale v_i de la réaction avec une reproductibilité de l'ordre de 5%. Pour chaque cinétique les vitesses d'apparition du produit de réduction (P_{red}) et du produit d'oxydation (P_{ox}) sont les mêmes à ±5%.

Influence du donneur

Selon la nature de l'alcool D utilisé comme donneur, le produit P_{ox} peut être un aldéhyde ou une cétone, capables tous les deux de se complexer avec le catalyseur C et entrer ainsi en compétition avec l'accepteur A. Nous avons observé que cette complexation peut être suffisamment forte dans le cas d'un aldéhyde pour conduire à un empoisonnement du cata-

lyseur.[1] Cette constatation est parfaitement en accord avec les résultats de la littérature pour d'autres catalyseurs (4–6). C'est pourquoi nous avons préféré utiliser des alcools secondaires comme le phényl-1 éthanol (D) plutôt que des alcools primaires.

La vitesse de réduction de la benzalacétone augmente en fonction de la concentration de phényl-1 éthanol pour tendre, à partir d'une concentration en donneur égale à 2 *M*, vers une limite qui se situe à 75×10^{-4} *M* min^{-1}. L'allure de cette courbe est analogue à celle observée avec $RuCl_2(P\phi_3)_3$ (1); par contre, dans ce dernier cas, le palier est atteint moins rapidement.

Influence de l'accepteur

Les accepteurs étudiés sont du type X—ϕ—CH=CH—CO—R avec R = Me, ϕ, *t*Bu et X = NMe_2, OMe, H, Cl, NO_2. Pour ces composés, dont les résultats sont rassemblés tableau 1, on note une influence à la fois de X et de R sur la vitesse initiale de réduction: un substituant électronattracteur comme NO_2 dans le cas où R = ϕ multiplie approximativement par trois la vitesse initiale et un substituant électrondonneur comme NMe_2 la divise par deux.

Influence du catalyseur

Le pouvoir catalytique de C dépend fortement de la nature des ligands puisqu'à une température inférieure à 100°C seul $RhH(P\phi_3)_4$ présente une activité catalytique ce qui n'est pas le cas avec des catalyseurs chlorés tels que $RuCl_2(P\phi_3)_3$ ou $RhCl(P\phi_3)_3$. Avec $RhH(P\phi_3)_4$, la vitesse de la réaction est du premier ordre par rapport au catalyseur jusqu'à des concentrations voisines de la limite de solubilité. Ce résultat semble indiquer qu'à l'inverse de $RuCl_2(P\phi_3)_3$ (1) il n'y a pas formation de dimères ou de polymères avec $RhH(P\phi_3)_4$.

Discussion

En présence de $RhH(P\phi_3)_4$, le réduction de la double liaison des cétones éthyléniques peut donc être réalisée en catalyse homogène à des températures voisines de 50°C. Ces conditions extrêmement douces accroissent, en outre, le caractère régiosélectif de cette réaction. Ainsi la *p*-nitrobenzalacétone est réduite à plus de 90% en NO_2-4—ϕ—CH_2—CH_2—CO—CH_3 alors qu'à 180°C avec $RuCl_2(P\phi_3)_3$, au delà de 20% de réduction, le groupe nitro entre en compétition avec le système C=C. Ces conditions permettent également de mettre en évidence au niveau de l'accepteur des effets de substituant. Les résultats du tableau 1 montrent que lorsque R = Me, ϕ, *t*Bu, on observe une décroissance de la vitesse initiale et ce, quelle que soit la nature de X: c'est ainsi que la benzalacétone (R = Me) se réduit six fois plus vite que la benzalpinacolone (R = *t*Bu).

Une étude polarographique de ces mêmes cétones (7, 8) montre que le potentiel de demi-vague, caractéristique des effets polaires de substituant, diminue dans l'ordre ϕ, Me, *t*Bu. Par contre, pour la complexation de ces cétones avec le phénol (7, 9), les

[1]En effet la réduction du cinnamaldéhyde n'a pas lieu dans nos conditions expérimentales. De plus, la réduction de la benzalacétone est empêchée par l'introduction de cinnamaldéhyde.

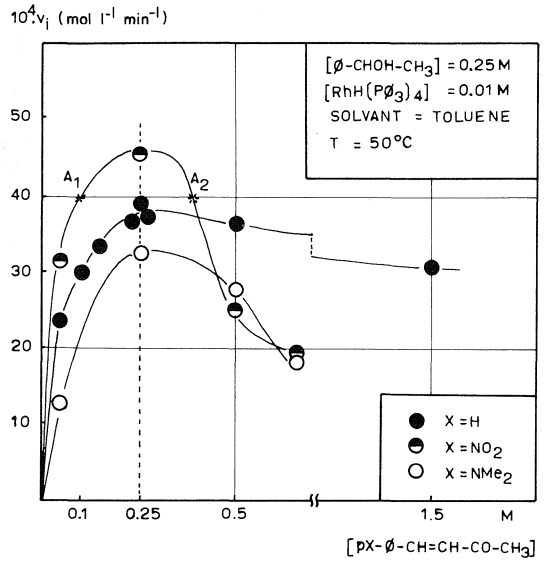

FIG. 1. Influence de la concentration en accepteur sur la vitesse de réduction de benzalacétones substituées.

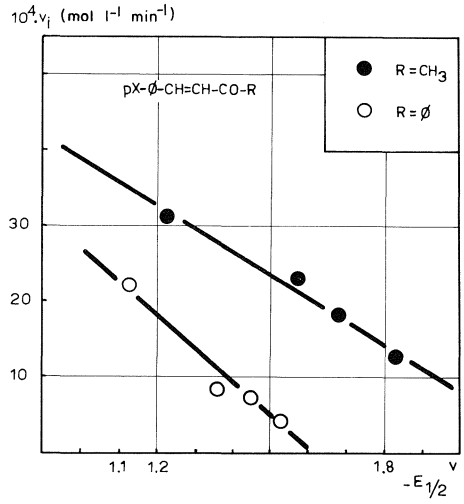

FIG. 2. Relations linéaires entre les vitesses initiales de réduction et les potentiels de réduction électrochimique pour les benzalacétones (R = Me) et les chalcones (R = ϕ).

$\Delta\nu_{OH}$, sensibles aux effets stériques, décroissent dans le même ordre que les vitesses initiales de réduction, montrant que l'influence de R est au moins partiellement d'origine stérique. Pour les composés dont le groupe R est maintenu constant, la vitesse initiale est influencée par le substituant X et par la concentration de l'accepteur (fig. 1). Pour des concentrations inférieures à 0.25 *M*, on constate qu'un groupe électrondonneur diminue la vitesse et qu'un substituant électronattracteur l'augmente. De tels effets qui n'ont jamais été mis en évidence antérieurement avec des composés analogues doivent permettre une nouvelle approche du processus de transfert d'hydrogène. En effet, il existe une tendance à la corrélation pour les benzalacétones (R = Me) et les chalcones (R = ϕ) entre les vitesses initiales de réduction et les potentiels de demi-vague (fig. 2). Comme en polarographie le potentiel de réduction correspond à l'arrivée d'un électron à la cétone, l'existence de cette corrélation implique que le transfert vers la cétone éthylénique engagé dans le complexe CDA (schéma 1) s'effectue par l'intermédiaire d'un ion hydrure. Les effets de substituant intéressent donc l'étape du transfert d'hydrogène: CDA → C + P_{red} + P_{ox}, cette hypothèse est confortée par les effets inverses observés au niveau du donneur (1, 10).

Pour des réactions de ce type trois mécanismes ont été proposés (schéma 1): la voie *1*, proposée par Imai *et al.* (13), dans laquelle la complexation du donneur D précéde celle de l'accepteur A; la voie *2* dans laquelle l'accepteur intervient avant le donneur (1, 14); enfin un mécanisme, suggéré par Sharf *et al.* (11, 12), dans lequel les deux voies sont concurrentielles. L'analyse des courbes de la fig. 1 permet de préciser la nature du mécanisme prépondérant dans la réaction envisagée ici. Pour des concentrations supérieures à 0.25 *M*, la vitesse décroît quand la concentration en accepteur augmente et cette décroissance est plus accentuée pour les dérivés nitré et aminé. Le fait d'observer, pour deux concentrations différentes de l'accepteur (points A_1 et A_2 de la fig. 1), des vitesses initiales identiques, implique l'apparition d'un nouveau phénomène intervenant au-delà de 0.25 *M* et qui vient progressivement s'opposer à l'effet normal de la concentration de l'accepteur. Comme [A_1] et [A_2] produisent au bout d'un temps *t* des concentrations égales en P_{red} et P_{ox}, ce phénomène peut être attribué au fait que [A_1] est inférieur à la concentration du donneur [D] et que [A_2] est supérieur à [D]. C'est donc qu'un accroissement de la concentration du complexe CA (schéma 1) diminue la vitesse de réduction. Ainsi dans le cas de la benzalacétone, il semble que le mécanisme passe principalement par la voie *1*, le complexe CA évoluant peu vers CAD par la voie *2*. Dans le cas des benzalacétones substituées, pour lesquelles on ob-

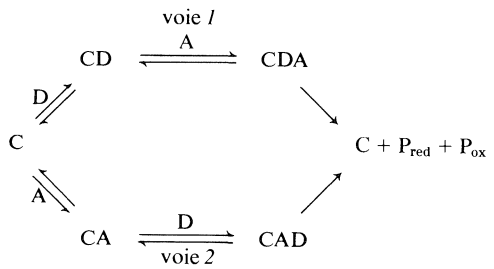

SCHÉMA 1

serve (fig. 1) une chute de la vitesse beaucoup plus importante, la voie *2* doit être pratiquement inexistante car les substituants NO_2 et NMe_2 s'associent fortement au catalyseur[2] empêchant la combinaison du donneur avec le complexe CA (2).

Conclusion

Les réactions de transfert d'hydrogène en catalyse homogène nécessitent fréquemment des conditions de température élevées, telles qu'elles restreignent fortement leur domaine d'application. L'utilisation de $RhH(P\phi_3)_4$ comme catalyseur des réactions de transfert entre le phényl-1 éthanol et les styryl cétones a permis d'opérer dans des conditions expérimentales plus douces et donc mieux adaptées à l'étude de ce type de réaction. C'est ainsi que la mise en évidence d'effets électroniques au niveau de l'accepteur suggère fortement que le transfert d'un ion hydrure constitue une étape importante de cette réaction. A 50°C, en présence de ce catalyseur, la régiosélectivité de la réaction est en outre considérablement accrue. Ces conditions permettent d'envisager l'extension de cette réaction à des structures thermiquement fragiles.

Partie expérimentale

La pureté des cétones éthyléniques préparées selon la littérature (15, 16) est vérifiée par cpv et spectroscopie rmn. Le toluène fraîchement distillé est gardé sur tamis moléculaire sous argon. Le phényl-1 éthanol Fluka, bidistillé après traitement par la dinitro-2,4 phényl hydrazine, est placé sous argon sur tamis moléculaire. $RhH(P\phi_3)_4$ est préparé selon la méthode de Levison et Robinson (17).

Exemple de cinétique

Un millilitre d'une solution dans le toluène de benzalacétone 0.25 *M* de phényl-1 éthanol 0.25 *M* et de $RhH(P\phi_3)_4$ 0.01 *M* est placé dans un tube en verre de 3 mL de contenance, rempli d'argon et fermé à l'aide d'une pastille en caoutchouc maintenue par un bouchon vissé. Ce tube est placé dans un bain thermostaté à 50°C et l'agitation est obtenue par un barreau aimanté préalablement placé à l'intérieur du tube. Des échantillons de 10 μL sont prélevés régulièrement, placés dans 40 μL d'acétone et analysés avec un chromatographe Varian 1400 muni d'un détecteur à ionisation de flamme et équipé d'une colonne DEGS 10%, 10 pieds à 160°C. La surface des pics est mesurée par un intégrateur LTT ICAP 5 et la méthode d'intégration est celle des facteurs de calibration spécifique (18).

[2]Dans la réduction des nitrobenzènes par les amines, Imai *et al.* (13) concluent que le groupe nitro se lie fortement au catalyseur ($RhCl_3$) et qu'il est alors nécessaire d'utiliser des amines qui s'associent également fortement pour réaliser la réduction.

Nuclear analogs of β-lactam antibiotics. X. Synthesis of 2-substituted desthiocephalosporins[1]

TERRENCE WILLIAM DOYLE,[2,3] TERRY THOMAS CONWAY,[2] MICHAEL CASEY, AND GARY LIM

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received April 20, 1978

TERRENCE WILLIAM DOYLE, TERRY THOMAS CONWAY, MICHAEL CASEY, and GARY LIM. Can. J. Chem. **57**, 222 (1979).

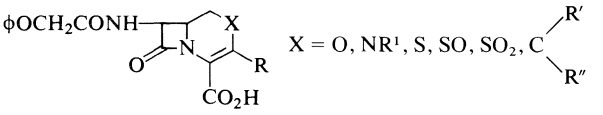
The syntheses of the desthiocephem system from the enol **2** is described. Thus conversion of **2** to its triflate **3** followed by treatment with the sodium salts of malonate esters gave the cyclized products **4***a–c*. Azide reduction followed by coupling of phenoxyacetic acid and hydrogenolysis gave the acids **7** and **8**. Compound **15** was also prepared.

TERRENCE WILLIAM DOYLE, TERRY THOMAS CONWAY, MICHAEL CASEY et GARY LIM. Can. J. Chem. **57**, 222 (1979).

On décrit les synthèses du système desthiocephem à partir de l'énol **2**. Par conversion de **2** en son triflate **3**, puis un traitement avec les sels de sodium des esters malonates, on a obtenu les produits cyclisés **4***a–c*. La réduction de l'azide, puis le couplage avec l'acide phénoxyacétique et l'hydrogénolyse ont conduit aux acides **7** et **8**. On a également préparé le composé **15**.

[Traduit par le journal]

Over the past several years a number of reports on the preparation of nuclear analogs of the cephalosporins have appeared in the literature.[4] Previously we have reported (2)[5] the syntheses of a number of analogs (Fig. 1) in which the sulfur atom at 1 has been replaced by a methylene (or substituted carbon) and a hetero atom introduced in position 2. The syntheses of these analogs proceeded via the common intermediate **2**. Direct base treatment of the enol **2** gave the *O*-2-isocephem series whereas the preparation of the 2-isocephem (X = S) and *N*-2-isocephem systems proceeded via nucleophilic attack on the triflate **3** (or the corresponding mesylate). It occurred to us that treatment of **3** with appropriate carbon nucleophiles might well provide access to the desthiocephalosporins. At the time no reports of such analogs had appeared in the literature but about the time we were completing our own work a report appeared by Christensen and co-workers (3) of the synthesis of the 1-oxacephalosporin and 1-carbacephalosporin (=desthiocephalosporin) systems. These authors reported that the carbon analog exhibited activity approximately equal to that in the natural series. In this and the accompanying papers we should like to report our own results in this area.



1

FIG. 1. Cephalosporin analogs.

Treatment of enol **2** in the presence of triethylamine with trifluoromethane sulfonic anhydride gave a high yield of the corresponding triflate **3** as a mixture of isomers (1). It proved possible to obtain one of the isomers as a crystalline solid at the expense of losing considerable amounts of product. The crude triflate was generally sufficiently pure to be used as such.

As we had anticipated, treatment of **3** with sodium dimethylmalonate in tetrahydrofuran gave the desired cyclized product **4***a* in 68% yield after chromatography. Similarly replacing the dimethyl malonate in the reaction with dibenzyl malonate or di-*tert*-butyl malonate gave the products **4***b* and **4***c* in 60 and 52% yields, respectively. The structures assigned to **4***a–c* were made on the basis of their elemental analyses and by comparison of their uv, ir, and nmr spectra with those of the earlier nuclear analogs synthesized in these laboratories. Examination of the proton nmr (Table 1) enables us to assign the conformation illustrated in Fig. 2 to these molecules.

Reduction of the azido function in **4***a* using triethylamine – hydrogen sulfide gave the amine **5***a* in 91% yield. Conversion of the amine **5***a* to the amide **6***a* proceeded in near quantitative yield using

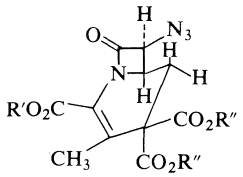

FIG. 2. Conformation of desthiocephalosporins.

2-ethoxy-*N*-ethoxycarbonyl-1,2-dihydroquinoline (EEDQ) and phenoxyacetic acid (4). Similarly **4***b* was converted to **5***b* and subsequently to **6***b*.

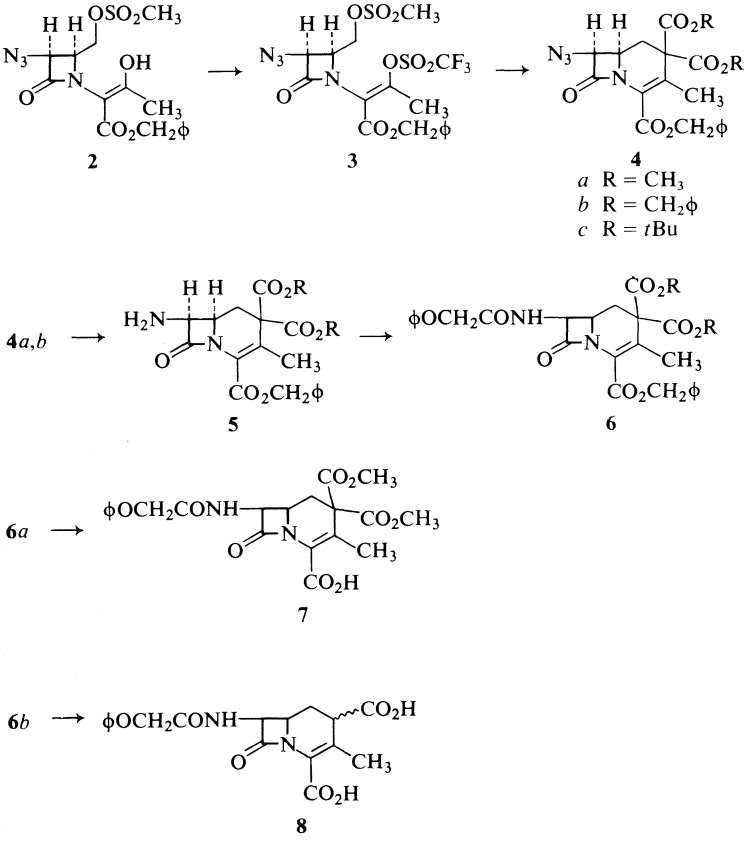
Hydrogenation of **6***a* over 10% palladium-on-carbon gave 3-methyl-2,2-biscarbomethoxy-7-β-phenoxyacetamido-Δ^3-desthiocephem-4-carboxylic acid **7** in 70% yield. Reduction of **6***b* over 10% palladium-on-carbon in acetic acid resulted in loss of all three benzyl functions and decarboxylation to give **8** in 44% yield.

To explore the synthesis of various 2-monosubstituted analogs the deesterification of **4***c* was studied next (Scheme 2). Treatment of **4***c* with trifluoroacetic acid at 60°C gave a foam the nmr spectrum of which was compatible with the diacid **9**. A solution of the foam in toluene was boiled at reflux for 10 min and evaporated to yield a mixture of the two compounds **10** and **11**, in a 3:1 ratio. Partial resolution of the mixture of acids was achieved by column chromatography on silica gel and the structural assignments made on the basis of their nmr spectra. The acid mixture was used as such in the next step. Thus treatment of the mixture with methyl chloroformate and triethylamine gave the methyl ester **12** in ~55% yield. The crude ester was reduced to the amine **13** using triethylamine – hydrogen sulfide and **13** was coupled to phenoxyacetic acid using EEDQ to give **14**. Hydrogenolysis of **14** gave the desired acid **15**. The stereochemistry of the carbomethoxy group in **14** and **15** was not determined owing to poor resolution of the nmr spectrum.

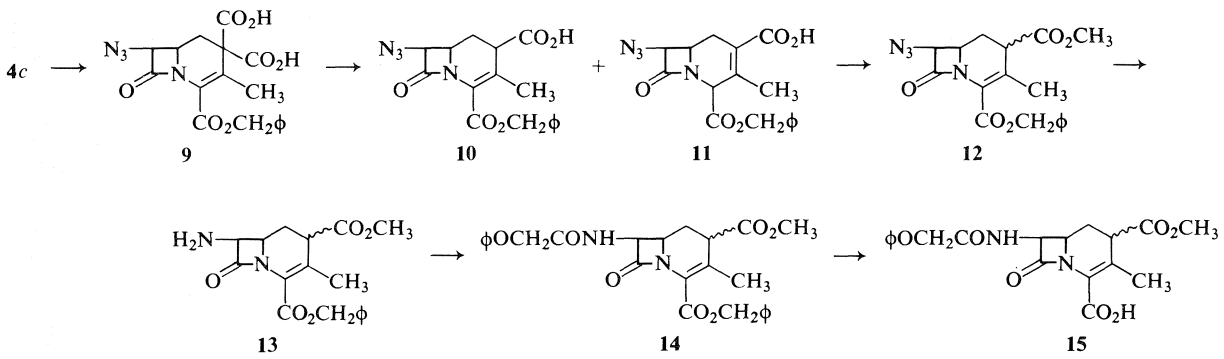
The biological activities of compounds **1**, **8**, and **15** were disappointingly low and will be discussed in full in a forthcoming structure–activity relationship paper.

Experimental

The infrared spectra were recorded on a Unicam Sp-200 G grating ir spectrophotometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected except where noted and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, IL.



SCHEME 1



SCHEME 2

Preparation of Vinyl Triflate **3**

The enol **2** (48.0 g, 0.117 mol) was dissolved in 500 ml $CaCl_2$-dried CH_2Cl_2 and then cooled in an ice bath under N_2. Triflic anhydride (33.0 g, 19.5 ml, 0.117 mol) was added in one portion. A solution of triethylamine (11.8 g, 16.3 ml, 0.117 mol) in 80 ml CH_2Cl_2 was added dropwise over a period of 40 min. When the addition was complete, the ice bath was removed and the mixture stirred at 25°C for a further 45 min.

The mixture was poured into 300 ml ice–H_2O and washed with cold H_2O until the pH was ~6 (five or six washings were necessary). The CH_2Cl_2 solution was dried (Na_2SO_4) and evaporated to give a dark red oil (54.0 g) which was dissolved in 400 ml benzene and passed through a $1\frac{1}{2}$-in. pad of silica gel (15% water, w/w) (~150 g); the pad was washed with 1 ℓ of benzene. Evaporation of the benzene gave a yellow oil (38.3 g) which contained ~20% unreacted enol. Eluting the pad with 500 ml CH_2Cl_2 gave 5.42 g of a 40:60 mixture of triflate and enol. Further elution with 500 ml Et_2O gave 5.34 g of unreacted enol.

The yellow oil which contained the two isomeric triflates was triturated with 50 ml of absolute EtOH until there were no more large gummy particles. After cooling to 0°C for a few hours, the suspension was filtered to afford 19.5 g of a white powder consisting of one triflate isomer, mp 57–59°C; ir (neat): 2110, 1790, 1730, 1656 cm^{-1}; uv (EtOH) λ_{max}: 242 (ε 6360). *Anal.* calcd. for $C_{17}H_{17}F_3N_4O_9S_2$: C 37.67, H 3.14, N 10.33, S 11.82; found: C 37.40, H 3.12, N 10.43, S 11.73.

Preparation of Compounds **4**a–c

Compound **4**a

To a suspension of 225 mg (5.34 mmol) of sodium hydride (57% mineral oil dispersion washed three times with petroleum ether) in 2 ml dry tetrahydrofuran, under nitrogen, and cooled to 0–5°C, was added 1.32 g (2.43 mmol) of **3** and 282 mg (2.43 mol) of dimethylmalonate in 3 ml of dry tetrahydrofuran over 10 min. A red color developed and hydrogen was evolved. The reaction was stirred at 25°C for 1.5 h at the end of which time the reaction was complete as determined by thin-layer chromatography.

Five percent HCl was added to the reaction (pH 3.4) and was then distributed between ether and water. The organic phase was washed with water, dried (Na_2SO_4), and concentrated *in vacuo* to give **4***a* (1.02 g, 98%) as a yellow oil. The oil was chromatographed on silica gel (15% H_2O), developed with 1 volume hexane, and eluted with benzene. Pure **4***a* was obtained (688 mg, 66%); ir (neat): 2110, 1780, 1740, 1730, 1630 cm^{-1}; uv (EtOH) λ_{max}: 270 (ε 11 200).

Compound **4**b

Similarly treatment of 504 mg (11.95 mmol) of sodium hydride with 2.95 g (5.45 mmol) of **3** and 1.54 g (5.45 mmol) of dibenzyl malonate in THF gave 1.88 g (60%) of **4***b* as an oil after chromatography; ir (neat): 2110, 1780, 1740, 1730 cm^{-1}; uv (EtOH) λ_{max}: 270 (ε 10 967). *Anal.* calcd. for $C_{32}H_{28}N_4O_7$: C 66.12, H 4.86, N 9.65; found: C 66.68, H 4.99, N 9.31.

Compound **4**c

Treatment of 2.59 g (12 mmol) of di-*tert*-butyl malonate and 6.65 g (12 mmol) of **3** with 1.05 g (24 mmol) sodium hydride in tetrahydrofuran as in the previous examples gave, after the usual work-up, **4***c* as a light brown oil. Trituration of this oil with a small volume of ethanol induced crystallization to give 3.2 g (52%) of **4***c* as a colorless solid, mp 146–147°C after recrystallization from ether; ir ($CHCl_3$): 2110, 1780, 1725(s 1738) cm^{-1}; uv (EtOH) λ_{max}: 271 (ε 11 724). *Anal.* calcd. for $C_{26}H_{32}N_4O_7$: C 60.92, H 6.29, N 10.93; found: C 61.03, H 6.38, N 11.03.

Preparation of Compounds **5**a *and* b

Compound **5**a

The azide **4***a* (588 mg, 1.37 mmol) was dissolved in 10 ml methylene chloride and triethylamine (700 mg, 0.96 ml, 6.93 mmol) was added. Hydrogen sulphide was bubbled in slowly producing an orange-red color and complete reaction to a more polar (tlc) material after 45 min. The solution was concentrated *in vacuo* and the yellow residue distributed between ether and 10% HCl. The organic phase was washed once with 10% HCl which was then combined with the previous washings and extracted once with ether. The acidic solution was brought to pH 8 with solid $NaHCO_3$ (foams!) and saturated with NaCl precipitating the amine **5***a* as a thick oil which was extracted into CH_2Cl_2. The combined extracts were washed once with brine, dried (Na_2SO_4), and evaporated *in vacuo* leaving **5***a* (500 mg, 91%), which was used as such in the following reaction. A small amount of this material was converted to the hydrochloride salt (EtOH–HCl; Et_2O), mp 178–180°C; ir (free base, neat): 3410, 3350, 1770, 1740, 1725 cm^{-1}. *Anal.* calcd. for $C_{20}H_{22}N_2O_7 \cdot HCl$: C 54.73, H 5.28, N 6.38; found: C 54.10, H 5.41, N 6.26.

Compound **5**b

Treatment of 1.88 g (3.08 mmol) of **4***b* with triethylamine (6.16 mmol) and hydrogen sulfide as in the above example gave 1.07 g (100%) of **5***b* as an oil on work-up. The amine **5***b* was used as such in the subsequent reaction.

Preparation of Compounds **6**a *and* b

Compound **6**a

Amine **5***a* (350 mg, 0.87 mmol) was stirred in methylene chloride (20 ml) with phenoxyacetic acid (132 mg, 0.86 mmol) and EEDQ (220 mg, 0.89 mmol) until CO_2 evolution had ceased (80 min). The clear solution was washed with 1% $NaHCO_3$ (2 × 15 ml), 10% HCl (2 × 10 ml), brine (2 × 20 ml), dried (Na_2SO_4), and concentrated *in vacuo* to give **6***a* (480 mg, 103%) as a white foam. The material was chroma-

tographed on 10 g silica gel (15% H_2O) in $CHCl_3$–Et_2O (9:1). Pure **6***a* was isolated (480 mg, 103%) as a glassy solid; ir (smear): 3400, 1780, 1740, 1685, 1600, 1530, 1495 cm^{-1}; uv (EtOH) λ_{max}: 269 (ε 6778). *Anal.* calcd. for $C_{28}H_{28}N_2O_9$: C 61.64, H 5.35, N 5.13; found: C 61.37, H 5.26, N 5.02.

Compound **6**b

Amine **5***b* (1.8 g, 2.13 mmol) was stirred in CH_2Cl_2 (100 ml) with phenoxyacetic acid (471 mg, 3.1 mmol) and EEDQ (765 mg, 3.1 mmol) until CO_2 evolution had ceased (1.5 h). The solution was washed with 1% $NaHCO_3$ (2 × 15 ml), 10% HCl (2 × 10 ml), brine (2 × 20 ml), dried (Na_2SO_4), and concentrated *in vacuo* to give **6***b* (2.05 g) as a red oil. This material was chromatographed on SiO_2 (35 g, 15% H_2O) eluting with $CHCl_3$ to give white crystals (1.2 g) mp 134–135°C (corrected); ir (Nujol mull): 3320, 1770, 1725, 1680, 1550, 1495 cm^{-1}; uv (EtOH) λ_{max}: 269 (ε 14 556). *Anal.* calcd. for $C_{40}H_{35}N_2O_9$: C 69.85, H 5.12, N 4.07; found: C 69.51, H 5.33, N 3.94.

*3-Methyl-2,2-biscarbomethoxy-7-β-(phenoxyacetamido)-Δ³-desthiocephem-4-carboxylic Acid (***7***)*

Amide **6***a* (410 mg, 0.76 mmol) was dissolved in 60 ml EtOH – 8 ml THF and hydrogenated at 1 atm and 25°C over 10% Pd/C (410 mg); hydrogen uptake was complete at 10 min (27 ml, 145%). The catalyst was filtered off and washed with EtOH (50 ml) and evaporation of the filtrate left **7** (306 mg, 90%) as a clear oil. It was crystallized from acetone–pentane to give 237 mg (70%) of a white powder, mp 186–188°C (corrected); ir (Nujol mull): 3315, 3340, 2500–3600, 1785, 1755, 1725(1745s), 1665, 1600, 1550, 1500 cm^{-1}; uv (EtOH) λ_{max}: 267 (ε 9580). *Anal.* calcd. for $C_{21}H_{22}N_2O_9$: C 56.50, H 4.96, N 6.27; found: C 56.47, H 4.97, N 6.24.

*3-Methyl-7-β-(phenoxyacetamido)-Δ³-desthiocephem-2,4-dicarboxylic Acid (***8***)*

A mixture of amide **6***b* (270 mg, 0.39 mmol) and 10% Pd/C (270 mg) in glacial AcOH (10 ml) was hydrogenated at 1 atm and 25°C until H_2 uptake ceased. (More than the theoretical amount of H_2 was absorbed in all cases.) The catalyst was filtered off and the AcOH was evaporated at <1 Torr, 40–50°C water bath. The glassy residue was covered with benzene and reevaporated to remove the last traces of AcOH. The residue was crystallized by warming in water. The resulting white powdery crystals were dried *in vacuo* over P_2O_5 for 18 h (64 mg, 43.5%), mp 158–159°C (corrected); ir (Nujol mull): 3410, 3370, 2500–3600, 1775, 1750, 1725, 1715, 1685, 1650, 1600, 1525, 1500 cm^{-1}; uv (EtOH) λ_{max}: 268 (ε 5180). *Anal.* calcd. for $C_{18}H_{18}N_2O_7 \cdot \frac{1}{2}H_2O$: C 56.39, H 4.99, N 7.30; found: C 56.70, H 4.83, N 7.35.

Ester Cleavage of **4**c

A solution of 555 mg (1.085 mmol) of **4***c* in 15 ml of trifluoroacetic acid was placed on a rotary evaporator at 62°C and the solvent evaporated over a period of 5–10 min to give 425 mg of a foam the nmr spectrum of which indicated the complete loss of the *tert*-butyl signals. The foam was taken up in toluene and refluxed 10 min following which the toluene was evaporated to yield 380 mg (98.5%) of a white foam. The nmr spectrum of the crude material showed two methyl signals and two benzyl signals in a ratio of 3:1 indicating that decarboxylation of the diacid had occurred. The foam was chromatographed on 10 g silica gel (15% water w/w) using chloroform as eluent. The eluting solvent was gradually changed to ether. The earlier fractions gave material greatly enriched in compound **10**, the major isomer, while the column tailings were mostly compound **11**.

Preparation of Compound **14**

To a solution of 500 mg (1.4 mmol) of crude acid (3:1 mixture of **10** and **11**) in 25 ml methylene chloride was added 150 mg (1.5 mmol) of triethylamine. The solution was cooled to −10°C (ice–methanol) and 150 mg (1.6 mmol) methyl chloroformate in 2 ml CH_2Cl_2 was added dropwise. The solution was stirred 1.5 h. The solution was evaporated to dryness at reduced pressure and the residue partitioned between water and ether. The ethereal extracts were washed with 10% hydrochloric acid and then saturated sodium bicarbonate solution. Evaporation of the organic layer gave 300 mg crude methyl ester **12** which was used as such in the subsequent step. From the basic extracts, 120 mg of starting acid was recovered (mixture).

Reduction of 300 mg of crude ester using triethylamine (100 mg) – hydrogen sulfide gave, upon work-up (see preparation of **5***a*), 200 mg of **13** as an oil; ir (film): 3420, 3360, 1770, 1750, 1740, 1640 cm^{-1}.

Treatment of 172 mg (0.5 mmol) of the amine **13** with 76 mg (0.5 mmol) phenoxyacetic acid and 124 mg (0.5 mmol) EEDQ in 10 ml methylene chloride gave 220 mg (92%) of **14** as a white foam. Chromatography of this material on silica gel (15% water, w/w) using ether as eluent gave 200 mg of pure **14**, mp 57–58°C; ir ($CHCl_3$): 3430, 1770, 1740, 1695, 1600, 1590, 1525, 1495 cm^{-1}; uv (EtOH) λ_{max}: 268 (ε 12 900). *Anal.* calcd. for $C_{26}H_{26}N_2O_2 \cdot \frac{1}{2}H_2O$: C 64.06, H 5.58, N 5.75; found: C 64.31, H 5.52, N 5.60.

*3-Methyl-2-carbomethoxy-7-β-(phenoxyacetamido)-Δ³-desthiocephem-4-carboxylic Acid (***15***)*

Reduction of 100 mg (0.208 mmol) of **14** with 100 mg 10% Pd/C in 5 ml THF and 10 ml ethanol at 1 atm and 22°C for 3 h gave, after work-up (see preparation of **7**), 75 mg of a white powder, mp 84°C (dec.); ir ($CHCl_3$): 3420, 2500–3600, 1773, 1740, 1695, 1600, 1530, 1495 cm^{-1}; uv (EtOH) λ_{max}: 265 (ε 8150). *Anal.* calcd. for $C_{19}H_{20}N_2O_2 \cdot \frac{1}{2}H_2O$: C 57.43, H 5.33, N 7.04; found: C 57.87, H 5.60, N 6.61.

Nuclear analogs of β-lactam antibiotics. XI. Synthesis of 3-methyl-7-β-(phenoxyacetamido)-Δ^3-desthiocephem-4-carboxylic acid[1]

TERRENCE WILLIAM DOYLE,[2,3] TERRY THOMAS CONWAY, GARY LIM, AND BING-YU LUH

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received April 20, 1978

TERRENCE WILLIAM DOYLE, TERRY THOMAS CONWAY, GARY LIM, and BING-YU LUH. Can. J. Chem. **57**, 227 (1979).

Treatment of the acid **3** with triethylamine in refluxing *tert*-butyl alcohol gave the decarboxylated product **4** which was isomerized to the desired Δ^3 isomer **5** using DBN. Reduction of the azido functions in **4** and **5** followed by coupling to phenoxyacetic acid and debenzylation gave the acids **11** and **8**, respectively. Attempts to prepare dienic cephalosporins failed. The halogenation of **4** and **5** was studied and is discussed.

TERRENCE WILLIAM DOYLE, TERRY THOMAS CONWAY, GARY LIM et BING-YU LUH. Can. J. Chem. **57**, 227 (1979).

Par traitement de l'acide **3** avec la triéthylamine dans l'alcool *tert*-butyle au reflux, on a obtenu le produit décarboxylé **4** qui, par isomérisation avec le DBN, a donné l'isomère Δ^3 attendu **5**. La réduction des fonctions azido dans **4** et **5**, puis le couplage subséquent à l'acide phénoxyacétique et la débenzylation ont conduit aux acides **11** et **8**, respectivement. Les tentatives pour préparer des céphalosporines diéniques ont échoué. On a étudié l'halogénation de **4** et de **5** et on discute de ces résultats.

[Traduit par le journal]

In the preceding paper of this series (1) we described the synthesis of some 2-substituted desthiocephalosporins from intermediates developed earlier for our syntheses of the *O*-2-isocephem (2*a*), *N*-2-isocephem (2*b*), and 2-isocephem (2*c*) systems (Fig. 1). In this paper we wish to report the synthesis of 7-β-phenoxyacetamido-3-methyl-Δ^3-desthiocephem-4-carboxylic acid **8**.

FIG. 1. Cephalosporin analogs.

As we reported earlier trifluoroacetic acid effected cleavage of the diester **2** to give the corresponding diacid. As had been anticipated the diacid readily underwent decarboxylation to yield the monocarboxylic acid as a mixture of isomers **3**. We had expected that **3** would readily undergo a second decarboxylation to give either **4** or **5**. To our surprise even boiling **3** at reflux in toluene in the presence of acid gave no detectable amounts of either **4** or **5**. The conversion of **3** to **4** in 78% yield occurred readily in refluxing *tert*-butyl alcohol catalysed by triethylamine. No trace of **5** could be detected in the crude product. When **4** was treated with 1,5-diazabicyclo-[4.3.0]-5-nonene (DBN) a rapid quantitative conversion to **5** occurred. The structure assignments to **4** and **5** were amply supported by their ir, nmr, and uv spectra.

The fact that only the thermodynamically less stable **4** was formed upon decarboxylation of the anion of **3** implies that the reaction occurs with concomitant loss of the carboxyl group and migration of the double bond and not via the carbanion, **ii** (Fig. 2). Two explanations may be advanced for this: either rapid kinetic protonation of an initially formed anion or the involvement of an enolized ester anion form such as **i** which can be protonated at C4 rather than C2. That the latter explanation may be valid is supported by the work of Murphy and Koehler (3) on the preparation of Δ^2-cephalosporin esters (Fig. 3) via the ketene **iv** which adds alcohols to yield exclusively the Δ^2-cephem esters. Presumably the addition of alcohols proceeds via an intermediate very similar to if not identical to **i**.

With the desired Δ^3-desthiocephem at hand the conversion of **5** to 7-β-phenoxyacetamido-3-methyl-Δ^3-desthiocephem-4-carboxylic acid **8** was carried out. Reduction of the azido function using hydrogen sulfide – triethylamine (2*a*) gave the amine **6** in 91% yield. Treatment of **6** with phenoxyacetic acid and

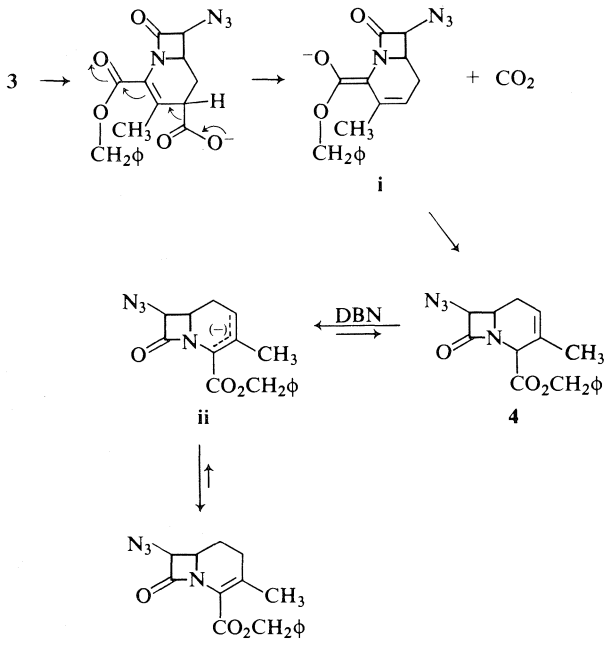

FIG. 2. Preparation of Δ^2- and Δ^3-desthiocephalosporin esters.

N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) (4) gave the amide **7** in 68% yield. Finally removal of the benzyl ester was accomplished in 59% yield via hydrogenolysis over 10% palladium-on-carbon.

Similarly reduction of the azido function in **4** gave the amine **9** (86%). The coupling of phenoxyacetic acid to **9** using EEDQ proceeded in 95% yield to give **10**.

In view of the labile double bond in **10** removal of the benzyl function via hydrogenolysis was precluded. The saponification of the ester was modeled on the more available **4**. Thus treatment of **4** with 1 equiv. of 10% sodium hydroxide gave the acid **12** in 69% yield. We were unable to detect any **5** in the reaction thus indicating saponification to proceed more rapidly than isomerization. Similarly compound **10** was treated with 1% sodium hydroxide to give 7-β-phenoxyacetamido-3-methyl-Δ^2-desthiocephem-4-carboxylic acid **11** in 60% yield. These reactions are outlined in Scheme 1.

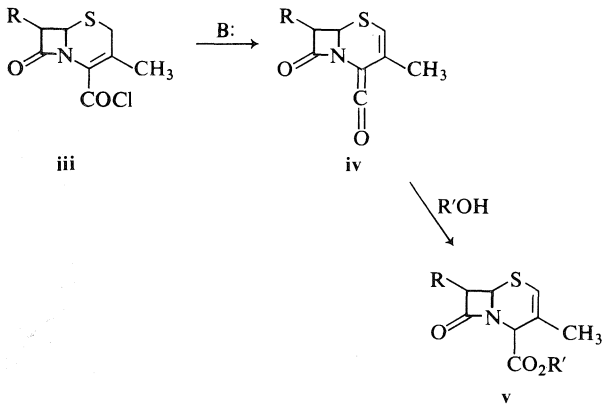

FIG. 3. Preparation of Δ^2-cephalosporin esters.

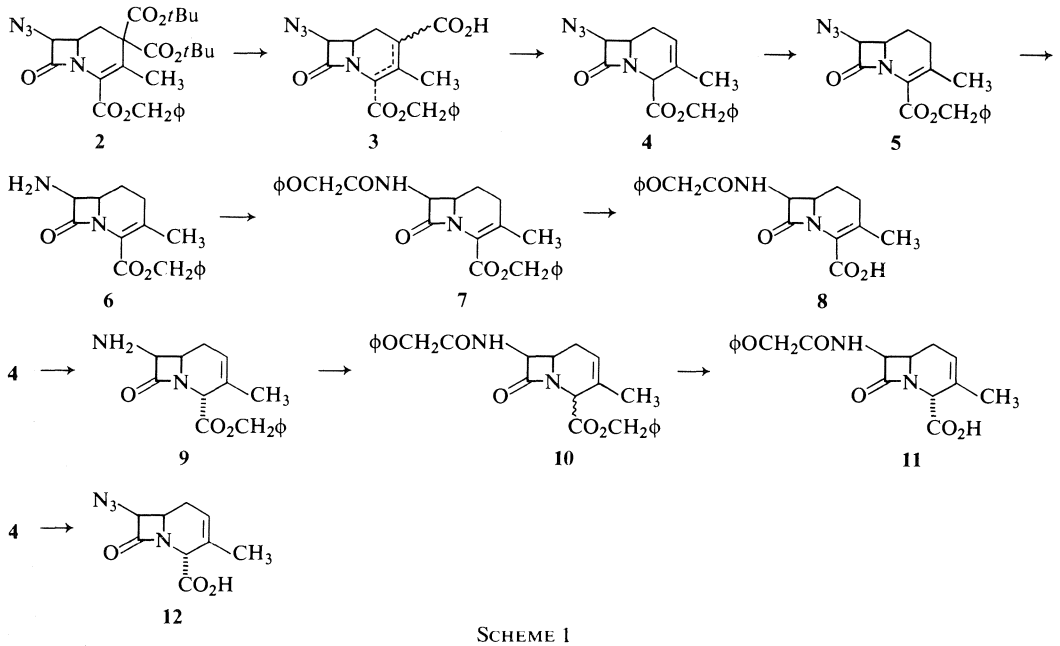
The ready access to compounds **4** and **5** led us to attempt the preparation of a desthiocephalosporin doubly unsaturated in the six membered ring or substituted with functionality other than carboxy groups at C2. The results obtained are outlined in Scheme 2.

Our first attempts involved treatment of **4** with NBS followed by treatment of the product with base to effect elimination to the diene. Thus upon treatment of **4** with NBS there was obtained a mixture of products. The nmr spectrum of the crude bromination mixture showed the presence of some starting material and at least two bromination products. The signals for the C3 methyl group and C4 protons was largely intact indicating bromination to have occurred at C1. Treatment of this crude mixture with triethylamine gave a mixture the nmr spectrum of which showed a singlet at 5.98 δ. Chromatography of the mixture led to recovery of **14** as an impure oil. Compound **14** proved to be relatively unstable and underwent rapid decomposition at ~25°C. The assignment of structure was made on the basis of the spectral data and the subsequent transformation of **14** to **5**. The nmr spectrum of **14** showed the proton α to the azide as a doublet at 5.05 δ (J = 5 Hz) and the C6 proton also as a doublet (J = 5 Hz) at 4.39 δ. The signals for the olefinic protons at C1 and C2 appeared together as a singlet at 5.98 δ integrating for two protons. The failure of the C1 proton to couple to the C6 proton is probably due to the fact that these protons are at ~75–80° dihedral angle to one another. The uv spectrum of **14** gave evidence of extended conjugation having a maxima at 322 nm (compared to 268 nm in **5**). All attempts to reduce the azido function in **14** to an amine failed. The use of hydrogen sulfide-triethylamine led to polymerization. When **14** was hydrogenated over 10% Pd/C the only characterizable product was **5** obtained in ~60% yield. All attempts to carry out formation of the dienic system via NBS bromination of **10** (or other suitable ester) and base treatment failed to give any detectable product.

Bromination of **4** proceeded readily to yield a dibromide **15** in quantitative yield. The nmr spectrum of **15** was compatible with a single product. The conversion of **15** to the desired **16** upon treatment with triethylamine was facile. The stereochemistry of the bromo group is that indicated in the scheme and is readily deduced from the nmr coupling constants to



SCHEME 1

the C1 protons of the protons at C2 and C6. In our earlier work we have demonstrated that as in the natural series the molecule assumes the conformation shown in Fig. 4 (*2a–d*). The coupling constants of ~10.5 and 5 Hz between the C1-H_β and C6-H and between the C1-H_α and C6-H, respectively, confirm that as in the earlier work the desthiocephalosporins

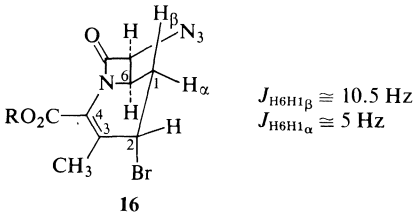


FIG. 4. Conformation of desthiocephalosporins.

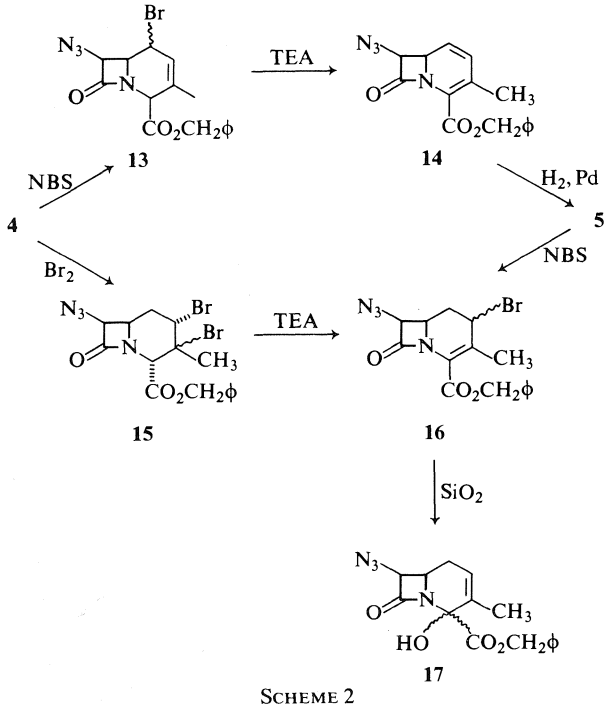

SCHEME 2

adopt the conformation shown. The appearance of the signal for the proton α to the bromine atom at 4.67 δ as a doublet of doublets with $J_1 = 3.5$, $J_2 = 2.5$ Hz is only compatible with the α configuration for the bromide. This also establishes the stereochemistry of the 2-bromo group in **15** as α. Compound **16** could also be prepared from **5** in near quantitative yield via treatment of **5** with NBS. The stereochemistry of **16** prepared from **5** was identical to that prepared via **15**.

Recently Macchia (5) and co-workers have reported the result of bromination of 2-cephems. As in our case they observed bromination to occur from the α face of the molecule. In their case however the entering bromide ended up at the C3 position owing to greater stabilization of charge in the bromonium ion by sulfur. Both *cis* and *trans* dibromides were obtained in their case (Fig. 5). In the case of the bromination of **4** only a single dibromide was formed. On mechanistic grounds the product might well be expected to be one of *trans* addition.

Attempts to displace the bromide **16** with various nucleophiles did not give well defined products so our

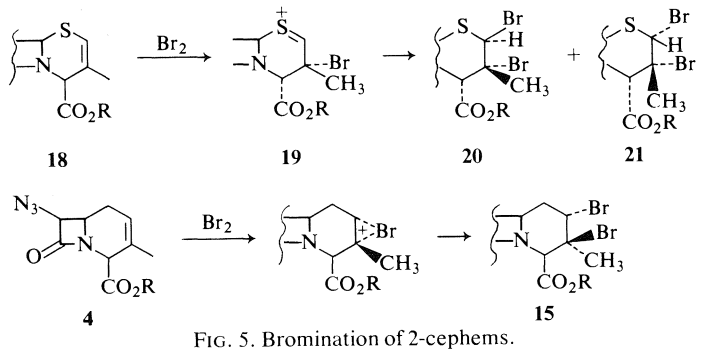

FIG. 5. Bromination of 2-cephems.

efforts along this line were abandoned. In one experiment attempted silica gel chromatography of **16** led to the rearranged alcohol **17** the structure of which was readily apparent from its spectral characteristics.

Compound **8** had antibiotic activity comparable to, although a bit weaker than the corresponding *O*-2-isocephem reported earlier (*2a*). A full discussion of the biological activities of **8** is reserved to a forthcoming structure activity paper.

Experimental

The infrared spectra were recorded on a Unicam SP-200G grating, ir spectrometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, IL, U.S.A.

*Benzyl 3-Methyl-7-β-azido-Δ²-desthiocephem-4-carboxylate (**4**)*

A solution of 10.24 g (20 mmol) of **2** in 150 ml trifluoroacetic acid was evaporated at 50–60°C on a rotary evaporator at reduced pressure followed by pumping on a high vacuum pump (1 Torr). The residue was taken up in 100 ml chloroform and boiled at reflux for 20 min, following which the solution was washed three times with brine, dried over Na_2SO_4, filtered, and evaporated to dryness. The residual oil was taken up in 75 ml dry *tert*-butyl alcohol and 3 ml triethylamine was added. The solution was boiled at reflux for 30 min following which it was evaporated to dryness at reduced pressure. The residual oil was partitioned between ether (100 ml) and 1% NaOH (25 ml). The organic layer was washed with brine, 10% HCl, brine, and dried over Na_2SO_4. Filtration and evaporation of the filtrate yielded 4.84 g (77.5%) almost pure **4**. The oil was decolorized by passage through a pad of silica gel (Woelm) (15% water, w/w) with benzene. A small sample of the oil was sent for analysis; ir (film): 2110, 1770, 1750 cm^{-1}. *Anal.* calcd. for $C_{16}H_{16}N_4O_3$: C 61.53, H 5.16, N 17.94; found: C 61.69, H 5.27, N 17.96.

*Benzyl 3-Methyl-7-β-azido-Δ³-desthiocephem-4-carboxylate (**5**)*

To a solution of 480 mg (1.54 mmol) **4** in 25 ml CH_2Cl_2 was added 3 drops 1,5-diazabicyclo[4.3.0]-5-nonene (DBN). The solution was let stand 10 min at ambient temperature and washed with 10% HCl followed by brine. The solution was dried over Na_2SO_4, filtered, and evaporated to give 450 mg pure **5** which crystallized on trituration with a few drops of ether, mp 70.5–71.5°C (recrystallized from benzene – petroleum ether); ir ($CHCl_3$): 2110, 1770, 1725, 1635 cm^{-1}; uv (EtOH): λ_{max} 268 (ε 9250). *Anal.* calcd. for $C_{16}H_{16}N_4O_3$: C 61.53, H 5.16, N 17.94; found: C 61.39, H 5.17, N 18.19.

*Benzyl 3-Methyl-7-β-(phenoxyacetamido)-Δ³-desthiocephem-4-carboxylate (**7**)*

*Preparation of **6***

To a solution of 312 mg (1 mmol) **5** and 0.150 ml TEA in 20 ml CH_2Cl_2 was added a stream of H_2S gas over 2 min. The solution was observed to evolve N_2 and was let stand at 20°C until N_2 evolution ceased (30 min). The orange solution was evaporated to dryness at reduced pressure and the residue partitioned between ether and 10% HCl. The acidic layer was made basic with Na_2CO_3 and extracted into ether. The ethereal extracts were dried over Na_2SO_4, filtered, and evaporated to yield 260 mg (91%) pure amine **6**.

Side-chain Coupling

The oil from the above procedure 260 mg (0.91 mmol) was taken up in 20 ml CH_2Cl_2. To this was added 138 mg (0.91 mmol) phenoxyacetic acid followed by 225 mg (0.91 mmol) EEDQ. The solution was let stand 1.0 h at 25°C, washed with 10% HCl, dried over Na_2SO_4, filtered, and evaporated to give an oil. The oil was taken up in 5 ml ether and petroleum ether (30–60°C) was added to the cloud point. The solution was allowed to slowly evaporate over 18 h. The remaining solvent was decanted and the partially crystalline residue was triturated with ether (2 ml) and scratched. The crystals were isolated by filtration, mp 96–97°C (recrystallized from ether – petroleum ether). A total of 260 mg (68%) pure **7** were obtained; ir ($CHCl_3$): 3400, 3320, 1770, 1720, 1690, 1600, 1590, 1530, 1495 cm^{-1}; uv (EtOH): λ_{max} 269 (ε 12 750). *Anal.* calcd. for $C_{24}H_{24}N_2O_5$: C 68.56, H 5.75, N 6.66; found: C 68.28, H 5.80, N 6.57.

*3-Methyl-7-β-(phenoxyacetamido)-Δ³-desthiocephem-4-carboxylic Acid (**8**)*

A suspension of 200 mg (0.475 mmol) ester **7** and 100 mg 10% Pd/C in 25 ml ethylacetate was shaken 1.25 h at 45 psi under H_2. The suspension was filtered through Celite and evaporated to yield a semisolid glass which was triturated with 20 ml ether to induce crystallization. The solid was recrystallized from acetonitrile–ether to yield 92 mg (59%) pure acid, mp 184–185°C with decomposition (placed in melting point apparatus at 177°C, heating rate, 2°C/min); ir (Nujol mull): 3300, 2500–3600, 1770, 1685, 1620, 1600 cm^{-1}; uv (EtOH): λ_{max} 264 (ε 9050) shifts to λ_{max} 259 on addition of **1***d* TEA. *Anal.* calcd. for $C_{17}H_{18}N_2O_5$: C 61.81, H 5.49, N 8.48; found: C 61.63, H 5.52, N 8.61.

*Benzyl 3-Methyl-7-β-(phenoxyacetamido)-Δ²-desthiocephem-4-carboxylate (**10**)*

Reduction of 936 mg (3 mmol) of **4** using triethylamine (0.5 ml) – hydrogen sulfide in methylene chloride gave 712 mg (86%) of pure **9** after the usual work-up, mp 79–80°C (crystallized from ether); ir ($CHCl_3$): 3400, 1755, 1745 cm^{-1}. *Anal.* calcd. for $C_{16}H_{18}N_2O_3$: C 67.12, H 6.34, N 9.78; found: C 66.77, H 6.30, N 9.67.

[a]Recorded at 60 MHz in $CDCl_3$ unless otherwise noted. Coupling constants are in Hz.
[b]DMSO-d_6–$CDCl_3$.
[c]Arms of AB quartet.

The amine **9**, 712 mg (2.58 mmol) was treated with 378 mg (2.58 mmol) phenoxyacetic acid and 620 mg (2.58 mmol) EEDQ in 50 ml methylene chloride as in the previous example to yield 1.002 g (95%) of **10**, mp 95°C (corrected); ir ($CHCl_3$): 3430, 1775, 1750, 1695, 1600, 1595, 1525, 1495 cm^{-1}. *Anal.* calcd. for $C_{24}H_{24}N_2O_5$: C 68.56, H 5.75, N 6.66; found: C 68.49, H 5.82, N 6.47.

*3-Methyl-7-β-(phenoxyacetamido)-Δ²-desthiocephem-4-carboxylic Acid (**11**)*

To a solution of 210 mg (0.5 mmol) of **10** in 8 ml tetrahydrofuran was added 2 ml of 1% sodium hydroxide. The solution was stirred 30 min and diluted with 20 ml ether. The layers were separated and the organic layer washed three times with 10-ml aliquots of water. The combined aqueous layers were acidified with 10% HCl, saturated with sodium chloride, and extracted three times with methylene chloride. The extracts were dried over sodium sulfate and evaporated to yield 100 mg (60%) of the desired acid **11**, mp 157°C (corrected) with decomposition (recrystallized from ethanol–ether); ir (Nujol mull): 3300, 2500–3600, 1760, 1735, 1680, 1600, 1540, 1500 cm^{-1}. *Anal.* calcd. for $C_{17}H_{18}N_2O_5 \cdot \frac{3}{4}H_2O$: C 59.38, H 5.72, N 8.15; found: C 59.66, H 5.36, N 8.13.

*3-Methyl-7-β-azido-Δ²-desthiocephem-4-carboxylic Acid (**12**)*

Treatment of 1.75 g (5.6 mmol) of **4** in 30 ml tetrahydro-

furan with 22.5 ml of 1% sodium hydroxide as in the above example gave 857 mg (69%) of pure **12** after the usual work-up, mp 144–144.5°C (recrystallized from acetone – methylene chloride); ir ($CHCl_3$): 2500–3500, 2110, 1765, 1725(sh) cm^{-1}; *Anal.* calcd. for $C_9H_{10}N_4O_3$: C 48.64, H 4.54, N 25.22; found: C 48.65, H 4.59, N 25.33.

*Preparation of Compound **14***

A suspension of 624 mg (2 mmol) of **4** and 460 mg (2.58 mmol) *N*-bromosuccinimide in 20 ml carbon tetrachloride was boiled at reflux with irradiation from a sun lamp. After 30 min an aliquot was removed and checked by nmr for the presence of **4**. The reaction was continued an additional 15 min. The solution was cooled, washed with water, dried over sodium sulfate, and evaporated. The nmr spectrum showed traces of **4** and the presence of **13** in the reaction mixture. The sample was taken up in 25 ml methylene chloride and treated with 0.22 g of triethylamine. The solution was washed with 20 ml of water, dried over sodium sulfate, and evaporated. The oil was chromatographed on 50 g silica gel (15% water, w/w) with chloroform. The earlier fractions from the column yielded a material (~70 mg) the nmr spectrum of which was compatible with benzyl 3-bromomethyl-7-β-azido-Δ^2-desthiocephem-4-carboxylate. After a number of mixed fractions there was eluted 273 mg of impure **14** as an oil. Compound **14** was unstable being completely decomposed in a week. The assignment of structure is based on the ir, nmr, and uv spectra of **14**; ir ($CHCl_3$): 2110, 1780, 1770, 1720, 1600, 1585 cm^{-1}; uv (EtOH): λ_{max} 322 (ε 3550).

*Reduction of **14***

A solution of 250 mg of crude **14** in 20 ml ethyl acetate was hydrogenated over 10% Pd/C at atmospheric pressure and 25°C for 1 h. The solution was filtered and evaporated to yield an oil which was taken up in methylene chloride and chromatographed on 15 g silica gel (15% water, w/w) to give 145 mg of **5** identical in all respects with that obtained earlier.

*Benzyl 3-Methyl-2-α-bromo-7-β-azido-Δ^3-desthiocephem-4-carboxylate (**16**)*

*From **4***

To a solution of 1.78 g (5.7 mmol) of **4** in 50 ml methylene chloride was added an excess of bromine (3.2 g, 20 mmol). The solution was refluxed 20 minutes. A small aliquot was evaporated to dryness. The nmr spectrum of the residual oil was compatible with a single dibromide (see Table 1). To the solution was added 1.01 g (10 mmol) triethylamine. The solution was let stand 30 min, washed with water, 10% hydrochloric acid, and brine. After drying over sodium sulfate the solution was evaporated to dryness and the residual oil was triturated with ether. A total of 500 mg of pure **16** was obtained on filtration, mp 95.5–96°C; uv (EtOH): λ_{max} 284 nm (ε 6600). *Anal.* calcd. for $C_{16}H_{15}BrN_4O_3$: C 49.12, H 3.86, N 14.32, Br 20.42; found: C 49.01, H 3.91, N 14.43, Br 20.32.

*From **5***

To a solution of 106 mg of **5** in 10 ml carbon tetrachloride was added 60 mg *N*-bromosuccinimide and 2 mg benzoyl peroxide. The solution was brought to reflux for 30 min, cooled, washed with water, brine, and dried over sodium sulfate. The suspension was filtered and the filtrate evaporated to yield 137 mg (95%) of **16** identical in all respects with that obtained from **4**.

*Benzyl 3-Methyl-4-hydroxy-7-β-azido-Δ^2-desthiocephem-4-carboxylate (**17**)*

The mother liquors from the crystallization of **16** in the above experiment were chromatographed on 20 g silica gel (Woelm activity III) using methylene chloride as eluent. In addition to some **16** (450 mg) which eluted early a second material eluted from the column as an oil. The nmr spectrum (Table 1) was consistent for the material being **17**. *Anal.* calcd. for $C_{16}H_{16}N_4O_4$: C 58.53, H 4.91, N 17.07; found: C 58.41, H 5.02, N 16.93.

Facile syntheses of the enantiomers of sulcatol

BLAIR D. JOHNSTON AND KEITH N. SLESSOR[1]

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received August 4, 1978

BLAIR D. JOHNSTON and KEITH N. SLESSOR. Can. J. Chem. **57**, 233 (1979).

The synthesis of *R*-(−)- and *S*-(+)-6-methyl-5-hepten-2-ol (sulcatol) from commercially available ethyl *S*-(−)-lactate via chiral methyloxiranes is reported. Both substances have crystalline intermediates in their synthetic routes insuring high optical purity. The necessity for a simple route to *S*-(+)-sulcatol results from the identification of this chiral substance in the pheromone complement of *Gnathotricus retusus*, a northwestern American timber pest.

BLAIR D. JOHNSTON et KEITH N. SLESSOR. Can. J. Chem. **57**, 233 (1979).

On rapporte la synthèse des *R*-(−)- et *S*(+)-méthyl-6 heptène-5 ols-2 (sulcatol) à partir du *S*(−)-lactate d'éthyle disponible commercialement et par l'intermédiaire de méthyloxirannes chirales. La synthèse de ces deux substances implique des intermédiaires cristallins qui assurent des puretés optiques élevées. La nécessité de trouver une voie simple permettant d'accéder au *S*(+)-sulcatol provient du fait que cette substance chirale a été identifiée dans le complément de la phéromone du *Gnathotricus retusus*, un insecte des bois du nord-ouest de l'Amérique.

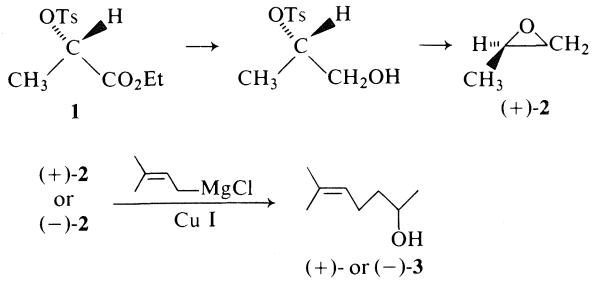
[Traduit par le journal]

Introduction

Recent investigations[2] have shown that *S*-(+)-6-methyl-5-hepten-2-ol, *S*-(+)-sulcatol ((+)-**3**), is the aggregation pheromone of *Gnathotricus retusus*, a wood boring ambrosia beetle which attacks fallen and cut timber. The syntheses of sulcatol enantiomers (1, 2) devised for the elucidation of the role of the chiral pheromone complement in *G. sulcatus* (3) were clearly not applicable to the amounts necessary for *G. retusus* lab–field bioassays and future control programs. *R*-(+)- and *S*-(−)-Methyloxirane **2** appeared to be ideal synthons for the sulcatol enantiomers.

Seuring and Seebach (4) have identified the chiral pool as a convenient source of *S*-(−)-methyloxirane from the commercial ethyl *S*-(−)-lactate. A low melting crystalline intermediate enhances chiral purity but the crystallization is difficult. *R*-(+)-Methyloxirane, *R*-(+)-**2**, has been prepared by a fermentation method (5) with good results, although no crystalline intermediates provided the necessary insurance of optical purity. Diborane reduction of the carboxylate ester in the readily prepared, crystalline ethyl 2-*O*-*p*-toluenesulphonyl *S*-(−)-lactate **1** provided ideal access to *R*-(+)-**2**. With pure enantiomers of methyloxirane, prenylation provided the desired sulcatols **3**.

Stereospecific opening of methyloxiranes is well established (6) and recently regioselective alkylation



SCHEME 1

by allylic Grignard reagents has been achieved using copper(I) iodide catalysis (7). Recent syntheses of (+)-α-bisabolol (8) and *R*-(+)-recifeiolide (9) are examples of alkylation of chiral epoxides with no apparent racemization.

To insure the optical purity of the enantiomeric sulcatols, the crystalline *p*-nitrobenzoates **4** were prepared and recrystallized to constant melting point and optical rotation. Base hydrolysis of the esters regenerated the enantiomers of *S*-(+)- and *R*-(−)-**3**. The optical purity of the sulcatols was evident from the strong optical rotations of gc pure final products. To obtain optical rotations of sufficient accuracy, temperature control of the samples was necessary.

The utility of this work rests not only in the facile syntheses of chiral insect pheromones for pest

management but also in the availability of *R*-(+)-methyloxirane. The convenient synthesis of this synthon from a commercial product expands the usefulness of the chiral pool as a source of optically active reagents.

Experimental

General procedures and instrumentation were as described earlier (2). Melting and boiling points are uncorrected. The ethyl *S*-(−)-lactate was purchased from The Aldrich Chemical Co. and the cuprous iodide (purified grade) was obtained from Fisher Scientific.

S-*(−)-Methyloxirane* (S-*(−)*-**2**)

This compound was prepared by the method of Seuring and Seebach (4) via the crystalline *S*-(−)-1-*p*-toluenesulphonyl-2-propanol; $[\alpha]_D^{24}$ −14.2° (neat), bp 34°C/750 Torr. A linear dependence of $[\alpha]_D$ with temperature over the range α_{obs}^{14} −6.20° to α_{obs}^{32} −5.60° (0.4999-dm cell) was observed (lit. (4) $[\alpha]_D$ −12.5° (neat), bp 34°C/760 Torr. Nuclear magnetic resonance and ir spectra were identical with those of racemic propylene oxide (Aldrich ρ 0.83 g/mL).

S-*(+)-6-Methyl-5-hepten-2-ol* (S-*(+)*-**3**)

Magnesium (7.2 g, 300 mmol) was stirred with dry tetrahydrofuran (50 mL) under an N_2 atmosphere with ice-bath cooling. A solution of 1-chloro-3-methyl-2-butene (20.8 g, 200 mmol) in dry tetrahydrofuran (100 mL) was slowly added dropwise over a period of 1.5 h. After stirring for a further 1 h at ice-bath temperature the black suspension was filtered through a plug of glass wool into a clean, dry flask and again cooled in an ice-bath. Cuprous iodide (3.8 g, 20 mmol) was then added and a solution of *S*-(−)-**2** (5.8 g, 100 mmol) in dry tetrahydrofuran (50 mL) was dripped in over a period of 3 h with vigorous stirring. After a further 1 h the black suspension was poured into saturated aqueous ammonium chloride solution (300 mL) and extracted with ether (3 × 200 mL). The combined ether extracts were washed with water (75 mL) and saturated aqueous sodium chloride (75 mL), dried over anhydrous sodium sulphate, and evaporated to ~25 ml. After two vacuum distillations the yield of *S*-(+)-**3** was 9.4 g (75%), bp 85–86°C/20 Torr, $[\alpha]_D^{23}$ +17.4° (neat).

S-*(+)-6-Methyl-5-hepten-2-ol* p-*Nitrobenzoate* (S-*(+)*-**4**)

p-Nitrobenzoyl chloride (27.8 g, 150 mmol) was added to a solution of *S*-(+)-sulcatol (16.8 g, 131 mmol) in pyridine (200 mL). After stirring for 4 h at room temperature the solution was poured into water (500 mL) and extracted with ether (3 × 250 mL). The combined ether extracts were washed with 5% aqueous sodium bicarbonate (2 × 150 mL) and saturated aqueous sodium chloride (150 mL) solutions, dried over magnesium sulphate, filtered, and evaporated to a syrup which was co-evaporated twice with toluene (75 mL) to remove pyridine. The residue partially crystallized on cooling and was recrystallized from methanol (150 mL) to yield 32 g (88%) of light yellow needle-like crystals, mp 53–55°C. After two recrystallizations from methanol the derivative had mp 54–55°C, $[\alpha]_D^{22}$ +61.4° (*c* 5.01, $CHCl_3$). *Anal.* calcd. for $C_{15}H_{19}NO_4$: C 64.96, H 6.89, N 5.02; found: C 64.92, H 6.99, N 5.02.

Regeneration of S-*(+)-Sulcatol from the* p-*Nitrobenzoate* (*(+)*-**4**)

S-(+)-Sulcatol *p*-nitrobenzoate (29.5 g, 106 mmol) was dissolved in 2 *N* alcoholic sodium hydroxide (500 mL) and the solution stirred 20 h at room temperature, poured into water (1000 mL), and extracted with chloroform (3 × 250 mL). The chloroform extracts were dried over magnesium sulphate and evaporated to ~30 mL. Distillation, bp 74–75°C/12 Torr, yielded *S*-(+)-sulcatol (13 g, 95%), $[\alpha]_D^{24}$ +18.6° (neat), ρ^{24} 0.841 g/mL (observed), with a linear dependence of $[\alpha]_D$ with temperature over the range α_{obs}^{14} +8.07° to α_{obs}^{32} +7.58° (0.4999-dm cell), $[\alpha]_D^{23}$ +14.8° (*c* 4.96, EtOH) (lit. (1) $[\alpha]_D^{23}$ +14.4° (*c* 0.998, EtOH), lit. (2) $[\alpha]_D^{20}$ +13.96° (*c* 4.56, EtOH)).

*Ethyl 2-*p*-Toluenesulphonyl-*S*-(−)-lactate* (**1**)

Ethyl *S*-(−)-lactate (40 g, 0.34 mol) was dissolved in pyridine (400 mL) and cooled in an ice-bath to < 5°C. *p*-Toluenesulphonyl chloride (80 g, 0.42 mol) was added in small portions over a period of 10 min and the resulting yellow solution was kept for 24 h at −5°C. Small portions of ice (~1, ~5, and ~10 g) were then added, with a period of 15 min between additions, insuring that the temperature remained near 0°C. The solution was then poured into ice water (1 L) and extracted with chloroform (3 × 250 mL). The chloroform extracts were dried over anhydrous sodium sulphate and evaporated. The syrupy residue was taken up in petroleum ether (30–60°C) – $CHCl_3$ 10:1 (500 mL) and crystallized by rapid cooling in a Dry Ice – acetone bath to yield 66 g (71%) of the tosylate. Recrystallization from petroleum ether – $CHCl_3$ gave 60 g of pure tosylate **1**, mp 31°C, $[\alpha]_D^{23}$ −33.2° (*c* 5.05, $CHCl_3$). *Anal.* calcd. for $C_{12}H_{16}SO_5$: C 52.94, H 5.92; found: C 53.18, H 5.95.

R-*(+)-Methyloxirane* (R-*(+)*-**2**)

To 82 g (300 mmol) of **1** was added 1 *M* BH_3 in tetrahydrofuran (600 mL) and the solution stirred for 5 days at room temperature and 3 days at 40°C under N_2. The resulting cloudy solution was poured into water (1 L) and sodium carbonate (~5 g) was added to break the emulsion. The aqueous phase was extracted with ether (2 × 300 mL) and the combined ether extracts were washed with saturated aqueous sodium chloride (300 mL) and dried over magnesium sulphate. Filtration and evaporation at 0.01 Torr yielded 71 g of crude syrupy 2-*O*-*p*-toluenesulphonyl-1-propanol. This material was dripped into 100 mL of 50% KOH at 55°C. The *R*-(+)-methyloxirane which distilled out of the reaction flask was collected in a Dry Ice – acetone trap. Weak vacuum (200 Torr) was applied for 1/2 h to assist in collection of the product. A further distillation over KOH, bp 34–35°C/760 Torr, yielded 8.7 g of (+)-**2**, 50% based on **1**, $[\alpha]_D^{24}$ +13.9° (neat).

R-*(−)-6-Methyl-5-hepten-2-ol* (R-*(−)*-**3**)

This was prepared in exactly the same manner as *S*-(+)-**3** in 73% yield from *R*-(+)-**2**. Doubly distilled *R*-(−)-**3**, bp 85–86°C/20 Torr, exhibited a rotation of $[\alpha]_D^{24}$ −18.0° (neat). Purified via the *p*-nitrobenzoate, in the same way as the (+) enantiomer, *R*-(−)-**3** exhibited a rotation of $[\alpha]_D^{24}$ −18.5° (neat) and $[\alpha]_D^{23}$ −14.7° (*c* 5.02, EtOH) (lit. (1) $[\alpha]_D^{23}$ −14.5° (*c* 0.74, EtOH), lit. (2) $[\alpha]_D^{20}$ −13.89° (*c* 4.76, EtOH)).

R-*(−)-6-Methyl-5-hepten-2-ol* p-*Nitrobenzoate* (R-*(−)*-**4**)

This was prepared as described for *S*-(+)-**4**. Two recrystallizations yielded material of mp 54–55°C, $[\alpha]_D^{22}$ −61.2° (*c* 5.02, $CHCl_3$). *Anal.* calcd. for $C_{15}H_{19}NO_4$: C 64.96, H 6.89, N 5.02; found: C 64.95, H 6.88, N 5.06.

Tautomerization equilibria for phosphorous acid and its ethyl esters, free energies of formation of phosphorous and phosphonic acids and their ethyl esters, and pK_a values for ionization of the P—H bond in phosphonic acid and phosphonic esters

J. Peter Guthrie[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 2, 1978

J. Peter Guthrie. Can. J. Chem. **57**, 236 (1979).

From data in the literature the free energies of formation in aqueous solution of triethyl phosphite and diethyl phosphonate can be calculated as -138.4 ± 1.7 and -165.1 ± 2.0 kcal mol^{-1}, respectively. From these values, by application of free energy relations which we have published, the free energies of formation of the corresponding hydroxy compounds can be calculated and thence the equilibrium constants for tautomerization, which are $10^{7.2}$, $10^{8.7}$, and $10^{10.3}$ in favor of the tetracoordinate phosphonate tautomer for $P(OEt)_2OH$, $P(OEt)(OH)_2$, and $P(OH)_3$, respectively. Using estimated pK_a values for the tricoordinate phosphite species the tautomerization equilibria for the anions could also be calculated, as could the pK_a values from the P—H bonds: 13, 26, and 38 for $H—PO(OEt)_2$, $H—PO_2(OEt)^-$, and $H—PO_3^{2-}$, respectively.

J. Peter Guthrie. Can. J. Chem. **57**, 236 (1979).

En se basant sur des données de la littérature, on a calculé que les énergies libres de formation, en solution aqueuse, du phosphite de triéthyle et du phosphonate de diéthyle sont respectivement -138.4 ± 1.7 et -165.1 ± 2.0 kcal mol^{-1}. Utilisant ces valeurs et les relations d'énergie libre que nous avons publiées, on peut calculer les énergies libres de formation des composés hydroxylés correspondants ainsi que les constantes d'équilibre de la tautomérisation qui sont respectivement $10^{7.2}$, $10^{8.7}$ et $10^{10.3}$ en faveur du tautomère phosphonate tétracoordonné du $P(OEt)_2OH$, $P(OEt)(OH)_2$ et $P(OH)_3$. Faisant appel à des évaluations des valeurs de pK_a pour les espèces phosphites tricoordonnées, on peut aussi calculer l'équilibre de tautomérisation des anions de même que les valeurs de pK_a des liaisons P—H qui sont respectivement 13, 26 et 38 pour $H—PO(OEt)_2$, $H—PO_2(OEt)^-$ et $H—PO_3^{2-}$.

Introduction

Phosphorous acid was one of the anomalous cases confusing the pattern of acidities shown by the inorganic oxy acids (1). The anomaly was removed by the recognition that phosphorous acid was not $P(OH)_3$, but rather $H—PO(OH)_2$, which normally acts as a dibasic acid (2).[2] Nevertheless, the tautomer $P(OH)_3$ must have some reality (although it may be much less stable than $HPO(OH)_2$) since its esters are well known. Furthermore, oxidation of phosphonate derivatives, $H—PO(OR)_2$ to phosphate derivatives demonstrably involves initial removal of the H bonded to P (4). Although the rate of exchange of this proton in dialkyl phosphonates has been measured (5), neither the pK_a of H directly bonded to phosphite P nor the equilibrium constant for the tautomerization is known.

Recently methods have been developed in this laboratory (6, 7) which permit these equilibrium constants to be evaluated. This paper reports a complete elucidation of the tautomeric equilibria for phosphorous acid and its mono and diethyl esters.

Results and Discussion

Thermodynamic Data

In Table 1 are found the thermodynamic quantities required for the compounds discussed in this paper. In some cases it was necessary to estimate quantities using accepted methods from the literature; these calculations are detailed under Calculations.

The heat of formation of diethyl phosphonate was calculated starting from results of Neale and Williams (8) who reported the difference in heats of formation for diethyl phosphonate and diethyl phosphate, both as the liquids. The heat of formation of diethyl phosphate in aqueous solution has recently been reported (7) and so it is possible to complete the calculation. The heat of solution of diethyl phosphate in aqueous KOH solution is known (8),

[1]Alfred P. Sloan Fellow, 1975–1979.

[2]This situation is recognized by an elaboration of nomenclature, not always followed for the parent acid: $P(OH)_3$ is phosphorous acid and its esters are alkyl phosphites; $HPO(OH)_2$ is phosphonic acid and its esters are alkyl phosphonates (3). Thus, on most of the occasions when one speaks of phosphorous acid, one should in fact refer to phosphonic acid; ordinarily there is no confusion but in the present paper the terms will be used only in the strict sense.

0008-4042/79/020236-04$01.00/0

TABLE 1. Thermodynamic quantities for compounds discussed in this paper[a]

(*a*) Compounds for which ΔG_f^0(aq) has not been reported

Compound	ΔH_f^0(g)[b]	S^0(g)[c]	ΔG_f^0(g)[b]	ΔH_v[b,d]	ΔH_f^0(l)[b]	ΔG_t[b,e]	ΔG_f^0(aq)[b]
$(EtO)_3P$	−195.9(1.3)[f]	127.62(2.0)[g]	−136.7(1.4)[h]	10.0 (1.0)[f]	−205.9 (1.0)[f]	−1.74(1.0)[i]	−138.4(1.7)[h]
$(EtO)_2PHO$	−206.4(1.9)[h]	108.13(2.0)[g]	−160.7(2.0)[h]	11.78(1.0)[i]	−218.14(1.61)[j]	−4.40(1.0)[i]	−165.1(2.0)[h]

(*b*) Compounds for which ΔG_f^0(aq) has been reported

Compound	ΔG_f^0(aq)[b]
H_2O	−56.69[k,l]
HPO_3H_2	−202.04(1.0)[j]
EtOH	−43.31[k]

(*c*) Compounds for which ΔG_f^0(aq) only was calculated in this work

Compound	ΔG_f^0(aq)
$P(OH)(OEt)_2$	−155.3(1.7)
$P(OH)_2(OEt)$	−171.8(1.8)
$P(OH)_3$	−187.8(1.8)
HPO(OH)(OEt)	−183.7(2.0)
$HPO(OH)_2$	−201.9(2.0)[m]

[a]At 25°C, standard states are ideal gas at 1 atm, pure liquid, and 1 *M* aqueous solution with an infinitely dilute reference state, unless otherwise noted; estimated standard deviations in parentheses. [b]In kcal mol^{-1}. [c]In cal deg^{-1} mol^{-1}. [d]Heat of vaporization. [e]Free energy of transfer, from gas at 1 atm to 1 *M* aqueous solution with an infinitely dilute reference state. [f]Reference 21. [g]Calculated by the method of atomic contributions; ref. 15; see Calculations. [h]Calculated from other values in this table. [i]Calculated as described in Calculations. [j]Calculated as described in the text. [k]Reference 22. [l]Standard state is the pure liquid. [m]This value is derived from ΔG_f^0 for $HPO(OEt)_2$ as described in the text; compare with the literature value in part *b* of this table.

the heat of ionization of diethyl phosphate is known (7), and the heat of ionization of water is known (9); by combining these quantities the heat of solution of diethyl phosphate in water to give a solution of the free acid can be calculated and so the heat of formation of the pure liquid can be obtained from the heat of formation of the ester in solution. Finally, the value of the heat of formation of liquid diethyl phosphonate can be calculated, giving the value in Table 1.

The free energy of formation of aqueous phosphonic acid was recalculated from the heat of formation given in the CATCH tables (10) and the entropy value given by Latimer (11).

Acidities

For the calculations reported below, it was necessary to have both the apparent pK_a values for phosphonic acid (i.e., for $HPO(OH)_2$) and the unobservable pK_a values for its tricoordinate tautomer $P(OH)_3$. For the latter, the values estimated by Kossiakoff and Harker (12) were employed. These authors used a simple electrostatic model which proved quite accurate for those acids where resonance is *not* important either in the acid or the anion. Their values for the first and second pK_a values for $P(OH)_3$ are used; the third pK_a (which they did not report) was estimated assuming that the electrostatic effect of going from the monoanion to the dianion is the same as that of going from the neutral acid to the monoanion with suitable allowance for symmetry effect. The pK_a values for the mono and diesters were estimated assuming that the effect of replacing OH by OEt is the same as the average value observed for phosphate esters (7) with suitable allowance for symmetry effects (13). These values may be found in Table 2.

Equilibria for Ester Hydrolysis

We have discovered (6, 7) and tested (13) a linear free energy relationship between free energies of hydrolysis of esters and the pK_a values of the corresponding acids which appears to work very well for those acids where resonance does not play an important role in determining the pK_a. This relationship states that for the reaction:

[1] $$X—OR + H—O—H \rightleftharpoons X—OH + H—OR$$

[2] $$\Delta G'' = -4.78(0.28) + 0.336(0.024)pK_a$$

where $\Delta G''$ is the standard free energy change in kcal mol^{-1} (with the standard state for water being the pure liquid) corrected for any steric or symmetry effects.[3] Using this relationship the free energies for the hydrolysis equilibria found in Table 3 were calculated. Steric effects should be very small for these equilibria; they were assumed to be the same as in the analogous orthoformate.

Tautomeric Equilibria

The free energy changes in Table 3, together with the free energies of formation in Table 1, permit the calculation of the free energy changes for the tautomeric equilibria, as shown in Table 4. The magnitude of the equilibrium constants is such that direct measurement is unlikely to be possible.

[3]$\Delta G''$ is used to indicate that what is calculated is the free energy change in the absence of steric or symmetry effects. These must now be added to get ΔG^0.

TABLE 2. pK_a values for the acids discussed in this paper[a]

Compound	pK_1	pK_2	pK_3
$P(EtO)_2OH$	6.1(0.9)[b]	—	—
$P(OEt)(OH)_2$	6.7(0.9)[b]	11.3(0.9)[b]	—
$P(OH)_3$	7.4(0.9)[c]	11.9(0.9)[c]	16.4(0.9)[b]
$HPO(OEt)OH$	0.9[b]	—	—
$HPO(OH)_2$	1.5[d]	6.79[d]	—
HPO_3^{2-}	38(2)[b]		
$HPO_2(OEt)^-$	26(2)[b]		
$HPO(OEt)_2$	13(2)[b]		

[a]In water at 25°C; estimated uncertainties in parentheses.
[b]Estimated as described in the text.
[c]Reference 12.
[d]Reference 23.

TABLE 3. Free energy changes for the hydrolysis reactions calculated using [2][a]

Reaction	ΔG^{0b}
$P(OEt)_3 + H_2O = HO—P(OEt)_2 + EtOH$	−3.53(0.35)
$P(OEt)_2(OH) + H_2O = (HO)_2POEt + EtOH$	−3.09(0.36)
$P(OEt)(OH)_2 + H_2O = (HO)_3P + EtOH$	−2.61(0.37)
$HPO(OEt)_2 + H_2O = HPO(OH)(OEt) + EtOH$	−5.14(0.33)
$HPO(OEt)(OH) + H_2O = HPO(OH)_2 + EtOH$	−4.84(0.28)

[a]In aqueous solution at 25°C.
[b]In kcal mol^{-1}; estimated uncertainties in parentheses.

TABLE 4. Tautomerization equilibria[a]

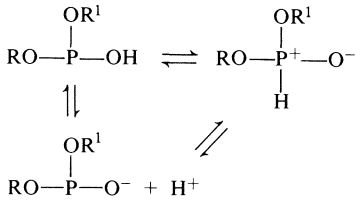
Equilibrium	ΔG^{0b}	log K
$P(OEt)_2OH = HPO(OEt)_2$	−9.8(2.6)	7.2(1.9)
$P(OEt)(OH)_2 = HPO(OEt)OH$	−11.9(2.6)	8.7(1.9)
$P(OH)_3 = HPO(OH)_2$	−14.1(2.1)	10.3(1.5)
$P(OEt)(OH)(O^-) = HP(O)_2OEt^-$	−19.8(2.9)	14.5(2.1)
$P(OH)_2(O^-) = HP(O)_2(OH)^-$	−22.1(2.3)	16.2(1.7)
$P(OH)(O^-)_2 = HP(O)_3^{2-}$	−29.1(2.5)	21.3(1.8)

[a]In aqueous solution at 25°C; estimated uncertainties in parentheses.
[b]In kcal mol^{-1}.

The only previous evaluation of a tautomeric equilibrium constant for phosphorous was the calculation of the equilibrium constant for tautomerism of hypophosphorous acid by Van Wazer (14), based on kinetic data, leading to a value of 10^{-12} for $K = [H—P(OH)_2]/[H_2PO(OH)]$. This value is rather similar to the value which we obtain for phosphorous acid.

pK_a for P—H Bonds

From the equilibrium constants for tautomerization and the pK_a values for O—H ionization found in Table 2, it is possible to calculate the pK_a values for P—H ionization. These values are also found in Table 2. The calculation is based upon Scheme 1 and was carried out for the cases where OR and OR′ are OEt and O^-. With a pK_a for $H—PO(OEt)_2$ in hand, it is possible to calculate a rate constant for the protonation of $:PO(OEt)_2^-$ from the published rate constant for proton abstraction by water (5); the value so calculated is $1.9 \times 10^8\ M^{-1}\ s^{-1}$.



SCHEME 1

Calculations

Entropies of the gaseous esters were estimated by the method of atomic additivity of Benson and Buss (15); the only new parameter required was that for tetracoordinate phosphorous which was calculated, starting from the standard entropies of POF_3 and $POCl_3$ (16), as $-31.2(0.5)$ cal deg^{-1} mol^{-1}.

Solubilities of the esters were estimated from the parachors by the method of Deno and Berkheimer (17); for $P(OEt)_3$ the correction for hydrogen bonding (17) was assumed to be the same as for $HC(OEt)_3$, i.e., 3.34; the solubility of $P(OEt)_3$ is estimated as 0.149 M. The hydrogen bonding contribution for a PO group was taken as the difference in E_A between the value observed for $PO(OEt)_3$ and the value expected using $HC(OEt)_3$ as a model; this contribution amounted to 1.02. The value used for the solubility of $PO(OEt)_3$ was for ideal solutions derived from the free energy of transfer reported recently (2). Then for $HPO(OEt)_2$ the value for E_A was taken as that for PO plus two thirds of the value for $HC(OEt)_3$. This indirect procedure is necessary because of the high solubility of phosphate and phosphonate esters with small alkyl groups. The value obtained for the ideal solubility of diethyl phosphonate was 1.55 M.

The heat of vaporization of diethyl phosphonate was calculated from the slope of a plot of log p vs. $1/T$, using the vapor pressure data from Beilstein (18). The data are described by the line $\log p = 8.457 - 2571.4/T$, from which $\Delta H_v = 11.78$, kcal mol^{-1} in reasonable agreement with the value expected from the Wadsö equation (19), namely 12.7 kcal/mol. Page and Purnell (20) have reported a study of the vapor pressures of several phosphite esters, and give $\log p = 7.174 - 1988.5/T$ for diethyl phosphonate;[4] although this equation gives the boiling point at atmospheric pressure correctly, it is consistent with none of the data reported at lower pressures and leads to a heat of vaporization of 9.11 kcal mol^{-1}, which is far from the expected value.

The vapor pressure of diethyl phosphonate at 25°C was calculated from the equation reported above. The vapor pressure of triethyl phosphite was calculated from the boiling point using the heat of

[4]In the reference the slope was given as 1.9885 but this was assumed to be a typographical error.

vaporization (Table 1) and a value of -12 cal deg^{-1} mol^{-1} for the heat capacity of vaporization (24).

Free energies of transfer from the gas phase at one atmosphere to aqueous solution (standard state 1 *M* with an infinitely dilute reference state) were then calculated from the vapor pressures and the molar solubilities.

Experimental

The solubility of triethyl orthoformate (Aldrich; purity, 98% checked by nmr analysis) was determined in aqueous 0.1 *N* NaOH. The ortho ester was added to the solvent, the mixture was shaken vigorously to saturate the aqueous layer, centrifuged briefly, and then the organic layer was discarded. A known amount of dimethylformamide was added (Hamilton syringe) to serve as internal standard, and the concentration was determined by nmr analysis. The solubility was 0.225 ± 0.010 *M*.

The enol content of simple carbonyl compounds: a thermochemical approach

J. Peter Guthrie[1] and Patricia A. Cullimore

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 16, 1978

J. Peter Guthrie and Patricia A. Cullimore. Can. J. Chem. **57**, 240 (1979).

From the heats of hydrolysis of enol ethers, the heats of formation of the enol ethers, and thence the free energies of formation of the enol ethers in aqueous solution can be calculated. For this calculation it was necessary to determine the free energies of transfer from the gas phase to aqueous solution. By methods previously published it was possible to estimate the free energy change for the hypothetical hydrolysis reaction leading from the enol ether to the enol, which in turn made possible calculation of the free energy of formation of the enol. Finally the free energy change for enolization in aqueous solution could be calculated using the known free energy of formation of the corresponding keto tautomer. In this way the following were determined: carbonyl compound, $pK_{enol} = -\log([enol]/[keto])$: acetaldehyde, 5.3; propionaldehyde, 3.9; isobutyraldehyde, 2.8; acetone, 7.2; 2-butanone, 8.3; 3-pentanone, 7.8; cyclopentanone, 7.2; cyclohexanone, 5.7; acetophenone, 6.7.

J. Peter Guthrie et Patricia A. Cullimore. Can. J. Chem. **57**, 240 (1979).

Utilisant des chaleurs d'hydrolyse d'éthers énoliques, on a calculé les chaleurs de formation d'éthers énoliques ainsi que les énergies libres de formation d'éthers énoliques en solution aqueuse. Pour ces calculs, il est nécessaire de déterminer les énergies de transfert de la phase gazeuse à la solution aqueuse. Utilisant des méthodes décrites antérieurement, on a pu évaluer le changement d'énergie libre de la réaction d'hydrolyse hypothétique conduisant de l'éther énolique à l'énol; à partir de cette valeur, on a pu calculer l'énergie libre de formation de l'énol. Finalement on a pu calculer la variation d'énergie libre associée à l'énolisation en solution aqueuse en faisant appel à la valeur connue de l'énergie libre de formation du tautomère cétonique correspondant. De cette façon, on a pu déterminer les valeurs suivantes: composé carbonyle, $pK_{enol} = -\log([enol]/[cétol])$; acétaldéhyde, 5.3; propionaldéhyde, 3.9; isobutyraldéhyde, 2.8; acétone, 7.2; butanone-2, 8.3; pentanone-3, 7.8; cyclopentanone, 7.2; cyclohexanone, 5.7; acétophénone, 6.7.

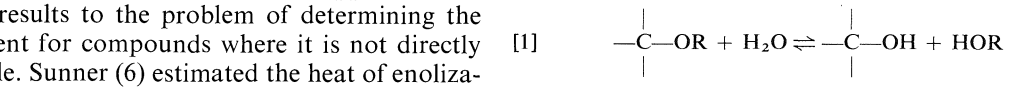
[Traduit par le journal]

Introduction

Simple carbonyl compounds have a very small enol content; methods which work well for multifunctional compounds, such as halogen titration (1, 2), become very difficult to apply when the enol content falls to less than 1 ppm. The early literature contains reports of the enol content of simple compounds such as acetone (2, 3) but more recent work has shown the nature of the problems associated with the measurements (4, 5) and has led to the conclusion that for acetone in aqueous solution the amount of enol is too small to be measured by the halogen titration method, even in its most sensitive form (5).

There have been several attempts to apply thermochemical results to the problem of determining the enol content for compounds where it is not directly measurable. Sunner (6) estimated the heat of enolization of liquid acetone from the heat of hydrolysis of isopropenyl acetate, using *m*-cresyl acetate as a model. More recently Hine and Arata (7, 8) measured the heats of hydrolysis of three enol ethers and estimated the heat of enolization of the liquid ketones, using the enthalpy of hydrolysis of simple ethers as a model. These approaches suffer from the fact that they give only the enthalpy for the hypothetical pure liquid reaction, rather than the more useful free energy change for reaction in solution in a standard solvent. Furthermore they ignore the influence of the electronic nature of the ether upon the free energy or enthalpy change for the hydrolysis (9).

In this paper a new and general approach to the problem of determining the free energies of enolization will be presented. This approach is based upon previous studies of the effect of structure upon the free energy change in reaction [1] (9–13). Provided



[1] $$-\overset{|}{\underset{|}{C}}-OR + H_2O \rightleftharpoons -\overset{|}{\underset{|}{C}}-OH + HOR$$

that the free energy of formation of the enol ether in aqueous solution can be determined and an estimate made of the pK_a of the enol, the free energy of formation of the enol can be calculated and so the free energy of enolization. The generality of the method comes not just from the possibility of

[1]Alfred P. Sloan Fellow, 1975–1979.

0008-4042/79/020240-09$01.00/0

preparing any enol ether and performing appropriate measurements but also from the possibility (once appropriate parameters have been evaluated) of calculating the free energy of formation by the methods of group additivity pioneered by Benson (14, 15).

Results

Thermodynamics of Enol Ethers

Heats of formation for several enol ethers were available in the literature; these values are found in Table 1, along with other thermodynamic quantities measured or calculated in this work. The heat of formation of α-methoxystyrene was determined by measuring its heat of hydrolysis. The experimental enthalpy data are found in Table 2, as are our data for 1-methoxycyclohexene and 2-methoxypropene which may be compared with the results of Hine and Arata (7, 8). These authors used quite different reaction conditions (aqueous tetrahydrofuran at 0°C) so that comparison is made for the ideal process involving pure liquid reagents and products at 25°C. Our results are seen to be in good agreement for 1-methoxycyclohexene and in fair agreement for 2-methoxypropene; since the latter compound is extremely volatile, we could easily have been subject to systematic errors from loss of substrate. In any case, the discrepancy is less than two standard deviations.

Heats of vaporization were estimated where necessary using the equation proposed by Wadsö (16); estimated values were checked for consistency with the available boiling point data at various pressures. Standard entropies for the gaseous compounds were calculated after Benson (14, 15), permitting calculation of free energies of formation in the gas phase. Free energies of transfer were calculated either from the solubilities and vapor pressures, using data derived as described in the Experimental or in the Calculations, and summarised in Table 3, or else were estimated by a modified version of the 'group additivity' method of Hine and Mookerjee (17) (corrected to give free energies in kcal mol^{-1} rather than dimensionless activity coefficients, with suitable allowance for both the change in units and the change in standard states). The results in Table 3 permit the determination of several new group contributions to the free energy of transfer suitable for enol ethers which should be useful for future applications of our method; these values are given in Table 4.

Equilibrium Constants for the Enol Ether – Enol Interconversion

Free energies for reaction [1] were initially shown to depend upon the electronic properties (as measured by the sum of the σ* values) of the substituents on the carbon bearing the OH or OR group (9). This

approach cannot be applied to enol ethers in the absence of σ* values for alkylidene groups. More recently, in an extension of the method to phosphate derivatives it was shown that the free energy change for reaction [1] is linearly related to the pK_a of the OH species, provided that resonance does not make an important contribution to the acidity (13). Since it is intuitively clear that of the two contributing forms:

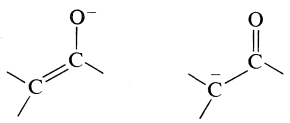

TABLE 4. New group contributions for enol ethers

Group	Contribution to ΔG_t[a] (kcal mol^{-1})
$[C_dH(O)] + [O(C)(C_d)]$	-2.28
$[C_d(C)(O)] + [O(C)(C_d)]$	-3.03 ± 0.12
$[C_d(C_B)(O)] + [O(C)(C_d)]$	-2.58

[a]Free energy of transfer from gas, 1 atm, to 1 *M* aqueous solution with an infinitely dilute reference state.

that with the negative charge on oxygen makes overwhelmingly the more important contribution to the resonance hybrid for an enolate ion, this latter relationship should be useful for reaction [1] applied to enol ethers, provided that the pK_a values of the enols can be estimated. Although it is clear that the pK_a for an enol must lie between that of an alcohol, ca. 16 and a phenol, ca. 10, no direct measurement is possible for any simple enol. Fortunately Novak and Loudon (18) have recently published an indirect evaluation of the pK_a for the enol of acetophenone as 11.0 ± 1.1. Since the free energy change for reaction [1] is rather insensitive to the pK_a value (13), estimated pK_a values need not be of high accuracy to be useful. For other enols, the pK_a values were estimated making the following two assumptions: for substituents on the β carbon of the enol the effect of the substituent is the same as for substitution at the *ortho* position of a phenol; for substituents at the α position of an enol the effect of the substituent is the same as for a saturated alcohol. Substituent effects were calculated from the observed pK_a values for *ortho*-substituted phenols (19) and from the linear free energy relationship shown to hold for alcohol pK_a values (20).

Using pK_a values estimated in this way and [1] the free energies of formation of the enols were calculated; these are found in Table 1. The pK_a values are found in Table 5, as are the equilibrium constants for enolization calculated from the free energies of formation of the enol and keto tautomers from Table 1.

Discussion

Our results for the enol content of a number of simple carbonyl compounds as well as results for the same compounds derived in a forthcoming paper by a completely independent method are found in Table 5, as are recent literature values for determinations of these equilibrium constants either by direct titration or by indirect kinetic arguments. For convenience in dealing with these very unfavorable equilibria, the equilibrium constants are expressed in terms of pK_{enol}, which is the negative logarithm of the equilibrium constant for formation of the enol tautomer from the keto tautomer.

Acetone and 3-pentanone are the two cases where enolization constants derived by our thermochemical method can be compared with unambiguous experimental values. The agreement is fairly good although the discrepancy for acetone is somewhat larger than is desirable. The value derived from the data of Dubois and Toullec (21, 22) is based upon the rate constants for halogenation (identical for chlorine, bromine, and iodine) under conditions where the rate determining step is reaction of enol with halogen, and a calculated value for the diffusion controlled rate constant. This calculated value should be close to $10^{10}\ M^{-1}\ s^{-1}$ on the basis of the Smolouchowski equation (23) but could vary as much as threefold from this value depending upon the probability of reaction occurring upon each collision (24). Any such effect would tend to make the true enol content larger than the calculated value.

The experimental values for the enolization constant derived from halogen titrations using extremely low halogen concentrations are in several cases in poor agreement with our thermochemical estimates. For acetone, no enol could be detected (5), so that pK_{enol} was necessarily greater than 6, which is consistent with our value of 7.2. For cyclohexanone the two methods are in good agreement. However, for cyclopentanone there is a serious disagreement. Hine and Arata (7, 8), reasoning from calculated enthalpies of enolization based upon their thermochemical results, also noted such a disagreement and argued that the results of Bell and Smith (5) appear to contradict various features of cycloalkanone chemistry. Our kinetic method (25) gives good agreement with the thermochemical method for both cycloalkanones. Two groups have measured the enol content of cyclopentanone using the same very sensitive technique and reported closely similar results (5, 18). To disregard such careful experimental work is disturbing to say the least, yet we are led to conclude that there is some systematic error in the method which leads at least part of the time to anomalously high enol contents being measured. The advantage of our methods, although they are less precise, is that they are based upon behavior of entire samples and not upon detection of the behavior of a tiny fraction of the sample.

The same difficulty arises in the case of acetophenone, where halogenation experiments (18) lead to a much larger enolization constant than our thermochemical method. On the other hand it must be pointed out that the value reported by Novak and Loudon (18) implies, as they stated, that the pK_a (keto) for acetophenone must be quite different from the normally accepted value of 19, whereas our value is in good agreement with this value.

TABLE 5. Comparison of various methods for determining the equilibrium constant for enolization[a]

Carbonyl compound	pK_a(enol)[b]	pK_{enol}[c]			
		Thermochemical[d]	Kinetic[e]	Equilibrium	Other
$CH_3—C(=O)—H$	11.1(1.0)	5.3(0.6)	4.7		
$CH_3CH_2—C(=O)—H$	11.4(1.0)	3.9(1.0)	3.9		
$(CH_3)_2CH—C(=O)—H$	11.7(1.0)	2.8(1.1)	2.7		
$CH_3—CO—CH_3$	11.8(1.0)	7.2(0.9)	7.0	>6[f,h]	8.84(0.9)[g]
$CH_3CH_2COCH_3$	12.1(1.0)	8.3(1.0)			
$CH_3CH_2COCH_2CH_3$	12.1(1.0)	7.8(1.0)			8.02(0.9)[g]
	12.1(1.0)	7.2(1.2)	6.7	4.9[f,h]	
	12.1(1.0)	5.7(1.1)	5.3	5.4[f,h]	
$Ph—CO—CH_3$	11.0(1.1)[i]	6.7(1.0)	6.6	4.7[j]

[j]Reference 18.

For the aldehydes, acetaldehyde, propionaldehyde, and isobutyraldehyde the thermochemical and the kinetic methods give very satisfactory agreement, although the high enol content predicted for isobutyraldehyde is somewhat surprising. This surprise is probably not justified, since for the aldehyde where one of the methyls in isobutyraldehyde is replaced by a phenyl the enol content in DMSO-d_6 at 60°C is 8.7% (26); phenyl stabilizes a double bond more than methyl but not dramatically more so. A measure of the greater stabilization by phenyl than by methyl is the ratio of equilibrium constants for dehydration of the aldol adducts of acetaldehyde and benzaldehyde, for the same carbon nucleophile (27). The average value for four such cases is 220, which may be compared with the ratio of the enolization constants for isobutyraldehyde (Table 5) and 2-phenylpropanal (26) which is 50.

Initially it had been hoped that the kinetics results of Salomaa and co-workers (28) could lead to an evaluation of the effect of halogen substituents upon enol stability. The published data do permit calculation of equilibrium constants for the acetal to enol ether conversion; unfortunately the equilibrium constant so calculated for acetaldehyde (which applies to solutions in ethanol) does not agree with the value calculated for aqueous solutions from the available thermochemical data. Either there are substantial free energy of transfer effects (which is not impossible since Abraham and Grellier (29) have shown that there are sizable free energies of transfer from water to ethanol for neutral organic compounds, (although no data are available for acetals or enol ethers) or else there is some systematic error in the procedure leading to the equilibrium constants. Since the discrepancies amount to several powers of 10 in enolization constant we have not reported any enolization constants for chloroacetaldehydes; the results of Salomaa and co-workers (28) clearly show a large enol stabilizing effect of chlorine.

Although the method which we use to derive enol free energies from the free energies of formation of the enol ethers is novel, the free energies of the enol ethers themselves and of the analogous ketones are based upon experimental enthalpies and well tested procedures for estimating standard entropies. Using the values from Table 1, the equilibrium constants for enol ether formation from the cycloalkanone and methanol are 9×10^{-9} M for cyclopentanone and 3×10^{-7} M for cyclohexanone. These equilibrium constants clearly reflect the relationship between the enolization constants which we derived from either

TABLE 6. Equilibrium constants for enol ether formation[a]

Carbonyl compound	Hydration[b]	Equilibrium constant: Acetal formation[c] (M^{-2})	Acetal to enol ether[c] (M)	Enol ether formation[d] (M^{-1})	Enol ether formation[e] (M^{-1})

the thermochemical method or the kinetic method and are not consistent with the relative enol contents reported by Bell and Smith (5).

The thermochemical method for determining enolization constants has the disadvantage of being inherently imprecise but the advantage of being tied to experimental numbers of high reliability, by extrathermodynamic relations involving estimation of small free energy changes. It is confirmed by the close agreement observed with the kinetic method (25) which makes very different but also very plausible assumptions. This method also is subject to an inherent uncertainty based upon the imperfections of the model used; since methyl enol ethers and ethyl enol ethers do not hydrolyze at identical rates, they can not both be ideal models for the enol and in fact one expects that neither is much more than an approximate mode. Although both of our methods are subject to inherent imprecision, they seem to be in satisfactory agreement; this means that the problem of determining the enol content of carbonyl compounds can be considered as solved, since there are now a variety of unambiguous methods which can be employed: the kinetic method of Dubois and Toulec (21, 22); the kinetic method based upon Lienhard's observations (30), or our thermodynamic method (25). On the other hand, we are led to conclude that the halogen titration method, even in its most refined form, is not suitable for determining very small enol contents.

Calculations

Calculation of Vapor Pressures

For all but cyclohexanone (for which vapor pressure data were available in the Handbook of Chemistry and Physics (35), so that the vapor pressure at 25°C could be estimated by interpolation), vapor pressures at 25°C were estimated from the boiling point and the heat of vaporization (taken from Table 1), using a constant value for the heat capacity of vaporization of -12 cal/deg^{-1} mol^{-1} (36). The boiling points used were ethyl vinyl ether, 35.8°C (37*a*); 2-methoxypropene, 35.5°C (8); isobutyraldehyde, 64.2°C (37*b*); cyclopentanone, 131°C (35); 1-methoxycyclohexene, 140°C (8); and α-methoxystyrene, 193°C, corrected from a boiling point at 745 Torr (33). In all cases the predicted vapor pressures were checked by comparison with the rather sparse data on boiling points at reduced pressures in Beilstein.

Calculation of Thermodynamic Quantities

Entropies were estimated where necessary by the group equivalents method of Benson (15). It was necessary to estimate a few contributions not contained in the tables in ref. 15. The contribution for the group $[C_d(C)(O)]$ was assumed to be equal to that for $[C_d(C)_2]$; this approximation has been justified by Benson (15). Similarly the contribution for $[C_d(C_B)(O)]$ was taken as equal to that for $[C_d(C_B)(C)]$. For cyclopentanone and cyclohexanone the ring correction to S^0 was taken as that for the corresponding cycloalkane. For 1-methoxycyclopentene and 1-methoxycyclohexene the ring corrections were taken as those for the corresponding cycloalkenes.

There has been no experimental determination of the heat of formation of an enol ether of 3-pentanone. It was desirable to estimate this quantity in order to compare the thermochemical estimate of the enol content with the value reported by Dubois and Toullec (21, 22). In principle this should be straightforward, by Benson's method of group additivity (14, 15). However the values for the group contribu-

tions for enol ethers proposed by Eigenmann *et al.* (38) do not fit the experimental heats of formation (for 2-methoxypropene and 2-methoxy-2-butene) very well. Either the experimental values are in error or there is a destabilizing interaction in 2-methoxy-2-butene.[2] The latter explanation appears to be preferable. The reported heats of formation of 2-ethoxypropene and 2-methoxypropene are self consistent, differing by approximately the amount expected for an extra CH_2 group. If the free energy of formation of 2-methoxy-2-butene is estimated from that of 2-methoxypropene by taking the difference in group contributions between C_dH_2 and $C_dH(C)$ and $CH_3(C_d)$, the value so obtained is -13.16 and differs by 3.51 kcal mol^{-1} from the value based upon the experimental heat of formation. Furthermore this estimated value leads to a calculated $pK_{enol} = 5.98$, in poor agreement with the value of 7.96 derived from the results of Dubois and Toullec (21, 22) for 3-pentanone. The experimental heat of formation of 2-methoxy-2-butene leads to a calculated $pK_{enol} = 8.55$, in distinctly better agreement. Thus it seems plausible to conclude that there is a destabilizing interaction amounting to 3.51 kcal mol^{-1}. Taskinen (39) has shown that in 2-methoxy-2-butene, the preferred geometrical isomer has the methyl groups *cis*. The destabilizing interaction of 3.51 kcal mol^{-1} is considerably larger than the usual value of 1.0 kcal mol^{-1} for *cis* methyl groups (15) but there may be a buttressing effect of the methoxy group. If the free energy of formation of 3-methoxy-2-pentene is estimated starting from the free energy of formation of 2-methoxy-2-butene (using the value derived from the experimental heat of formation (38)), then a value of $pK_{enol} = 8.13$ is obtained which agrees very well with the observed value of 7.96. The assumption of no destabilizing effect leads to very poor agreement.

Experimental

Materials

2-Methoxypropene was prepared from the corresponding acetal by the procedure of Newman and Vanderzwan (31), bp 36–41°C (lit. (31) bp 37°C). 1-Methoxycyclohexene was prepared by heating cyclohexanone dimethyl acetal with a catalytic amount of *p*-toluenesulfonic acid in benzene and distilling out the methanol formed, bp 131°C (lit. (32) bp 137–142°C). α-Methoxystyrene was similarly prepared, using chlorobenzene as the solvent for the cracking (33), bp 90–93°C/17 Torr (lit. (33) bp 85–87°C/13 Torr). In all cases the enol ethers were purified by preparative gc using a Carbowax 20M column.

Calorimetry

Heats of reaction and solution were measured using an improved version of the simple Dewar calorimeter employed previously (34). Temperature changes were measured using a thermistor (Sargent Welch S-81670) with a Sargent Welch S-81601 bridge and a Heath SR 205 recorder. Electrical calibration was achieved using a Hewlett-Packard 6213A power supply to supply constant voltage across heater of ca. 10.1 Ω. The voltage drop across the heater was measured using a Simpson model C464 digital multimeter with a $3\frac{1}{2}$ figure display. The meter was also used to check the heater resistance. The heater consisted of a length of nichrome wire spot welded to copper leads; shrinkable polypropylene tubing was used to provide insulation; the leads extended below the surface of the liquid in the calorimeter.

The calorimeter was charged with 400 mL of solvent and brought to 25°C. The sample, usually 100 μL, was injected using a Hamilton syringe; the amount of the sample was determined by weighing before and after injection. Several electrical calibrations were performed for each run.

Solubility

The solubility of 2-methoxypropene was determined by nmr analysis of a saturated solution in 0.1 *N* NaOH, with 0.03 *M* *tert*-butyl alcohol as internal standard. The solubility of 1-methoxycyclohexene was too low for this method to be applicable. A saturated solution, 200 mL, in 0.1 *N* NaOH (purged with argon before adding the solute) separated from all undissolved solute was extracted four times using 5 mL portions of $CHCl_3$. The extracts were combined and made up to 25 mL with $CHCl_3$; a weighed amount of methyl benzoate was added as internal standard and the concentration of 1-methoxycyclohexene was determined by nmr analysis. This procedure permits an approximately 10-fold amplification before analysis and permits the use of nmr to determine solubility down to lower concentrations than would otherwise be practical. The solubility of α-methoxystyrene was too low even for this technique, and was determined by uv analysis. A sample (300 μL, measured using a 500 μL Hamilton syringe) of a saturated solution in 0.1 *N* NaOH was diluted to 10 mL using 0.1 *N* NaOH and the absorbance at 250 nm was measured. The extinction coefficient was determined to be 6680 ± 450.

[2]Although the heat of formation of 2-methoxy-2-butene probably refers to the *E* isomer, there is unfortunately some ambiguity. Dolliver *et al.* (40), who determined the heat of hydrogenation of 2-methoxy-2-butene, prepared it by what should be a stereospecific route from 2-butene, but identify the olefin only as 'purified butene-2,' with no comments concerning geometrical isomerism. Taskinen (39) found that *E*-2-methoxy-2-butene is 2.35 kcal mol^{-1} more stable than the *Z* isomer. Although it is most probable that the species studied by Dolliver *et al.* (40) is the *E* isomer or else a mixture, the possibility must exist that they studied the *Z* isomer, in which case there would be a systematic error of 2.35 kcal mol^{-1} in the free energies for 2-methoxy-2-butene and 3-methoxy-2-pentene.

JOHN L. HOLMES and F. P. LOSSING. Can. J. Chem. **57**, 249 (1979).

The loss of halogen atom from the molecular ions of compounds of formulae C_3H_3Cl and C_3H_3Br produces the cyclopropenium cation as daughter ion. Each reaction takes place with appreciable reverse activation energy, most of which is partitioned into translational degrees of freedom of the products. In marked contrast, the iodo-analogues generate [propargyl]$^+$ as daughter ions at the thermochemical threshold (i.e. E_{rev} for these fragmentations is ~ 0). It is proposed that the reason for this behaviour lies in a large activation energy for the reaction [*cyclo*-$C_3H_3]^+ + I^\cdot \rightarrow [C_3H_3I]^{+\cdot}$.

JOHN L. HOLMES et F. P. LOSSING. Can. J. Chem. **57**, 249 (1979).

La perte de l'atome d'halogène par les ions moléculaires des composés de formule C_3H_3Cl et C_3H_3Br conduit au cation cyclopropénium comme ion-fille. Chaque réaction se produit avec une énergie d'activation inverse importante; on en attribue le maximum à des degrés de liberté de translation des produits. En opposition marquée, les analogues iodés donnent lieu au [propargyle]$^+$ comme ion-fille au seuil thermochimique (à savoir E_{rev} pour ces fragmentations est ~ 0). On croit que la raison de ce comportement est attribuable à une énergie d'activation élevée pour la réaction [*cycle* $C_3H_3]^+ + I^\cdot \rightarrow [C_3H_3I]^{+\cdot}$.

[Traduit par le journal]

Introduction

The simplest aromatic cation, cyclopropenium $[C_3H_3]^+$, has attracted considerable interest in recent years and its heat of formation now is well established. The appearance potentials (A.P.) for $[C_3H_3]^+$ fragment ions from a number of C_3H_4 and C_4H_6 hydrocarbons lead to ΔH_f values of 11.21 eV and 11.08 eV, respectively (1). These results, obtained by impact of monoenergetic electrons, are in good agreement with results from photoionisation studies (2–5) and photoelectron–photoion coincidence techniques (6). The slightly higher values for $\Delta H_f[C_3H_3]^+$ derived from C_3H_4 isomers arise from the small, common reverse activation energy of 0.1 eV (7) for the reaction $[C_3H_4]^{+\cdot} \rightarrow [C_3H_3]^+ + H^\cdot$. The mean $\Delta H_f = 11.1 \pm 0.1$ eV almost certainly corresponds to the cyclopropenium structure, because the isomeric propargyl cation, $[CH{\equiv}CCH_2]^+$, has been shown by experiment to have an appreciably higher $\Delta H_f = 12.2 \pm 0.1$ eV (1). Recent *ab initio* calculations using LCAO-SCF molecular orbital theory (8) are in agreement as to the greater stability of cyclopropenium, giving ΔH_f[*cyclo*-$C_3H_3]^+ = 10.98$ eV, with ΔH_f[propargyl]$^+$ 1.5 eV higher. These authors also calculated ΔH_f for six other $[C_3H_3]^+$ structures, all of which were much less stable than the propargyl cation and therefore were considered less likely to be encountered in experiment.

Metastable ion studies have shown that the formation of $[C_3H_3]^+$ from a variety of precursors frequently generates a metastable peak of composite shape (7, 9–12). For example, the reaction $[C_3H_5]^+ \rightarrow [C_3H_3]^+ + H_2$, yields a composite metastable peak comprising two dish-topped components. The broad component corresponds to the formation of cyclopropenium with a reverse activation energy of 1.2 eV and the other (narrow) component results from the formation of the propargyl cation, $[HC{\equiv}CCH_2]^+$, with a reverse activation energy of $\sim$0.5 eV (11). Formation of these two daughter ions has also been reported in a photoion–photoelectron coincidence study of the fragmentations of propargyl bromide and chloride (13).

In the present work we have measured the appearance potentials (A.P.) of $[C_3H_3]^+$ from C_3H_3X precursor molecules (where X = Cl, Br, I, and $[C_3H_3] = CH_3C{\equiv}C-$ or $HC{\equiv}C{-}CH_2-$). The translational energies released in the corresponding metastable fragmentations and the fraction of the reverse activation energy, E_{rev}, partitioned into translational degrees of freedom have been determined.

Results and Discussion

The ionisation potentials (I.P.) of C_3H_3X mole-

[a] $\Delta H_f[cyclo\text{-}C_3H_3]^+ = 11.07$ eV, $\Delta H_f[HC{\equiv}CCH_2]^+ = 12.2$ eV; all values ± 0.05 eV. ΔH_f of neutral pairs are taken as equal.
[b] A.P.(obs) − A.P.(calcd).
[c] Minimum energy partitioned into product translation.
[d] Contains ~ 2% iodoallene (see Experimental).
[e] Gaussian metastable peaks; $T_{0.5}(CH_3CCl) = 0.063$ eV, $T_{0.5}(HCCCH_2I) = 0.005$ eV.

cules and A.P. values for the $C_3H_3^+$ ions produced therefrom are presented in Table 1, together with the metastable peak measurements. The metastable peaks are shown in Fig. 1.

The observed I.P.'s are characteristic of electron removal from an acetylenic triple bond (14) for propargyl compounds (e.g. I.P.($CH_3C{\equiv}CH$) = 10.36 eV, I.P.($CH_3CH_2C{\equiv}CH$) = 10.18 eV) and for halogen ionisation in the case of the 1-halopropynes. For the apparent exception, propargyl iodide, the observed I.P. is no doubt too low because of the difficulty of preparing a sample of this compound completely free of its isomer, iodoallene (see Experimental); this impurity would certainly be expected to have an I.P. of ca. 9.1 eV.

The A.P. results for propargyl chloride agree well with previous data (13); it is the same for both chlorocompounds and lies well below that calculated for the propargyl ion and 0.32 eV above the calculated threshold for generation of $[cyclo\text{-}C_3H_3]^+$, see Fig. 2. The metastable peak for Cl$^\cdot$ loss is basically the same for both compounds and that for propargyl chloride is shown in Fig. 1. It should be noted that the metastable peak for 1-chloropropyne is of lower intensity than the above and also *appears* to contain a second (Gaussian) component situated in the centres of each 'dish'. However, this additional peak arises from a contribution from $[M—H]^+$—Cl from

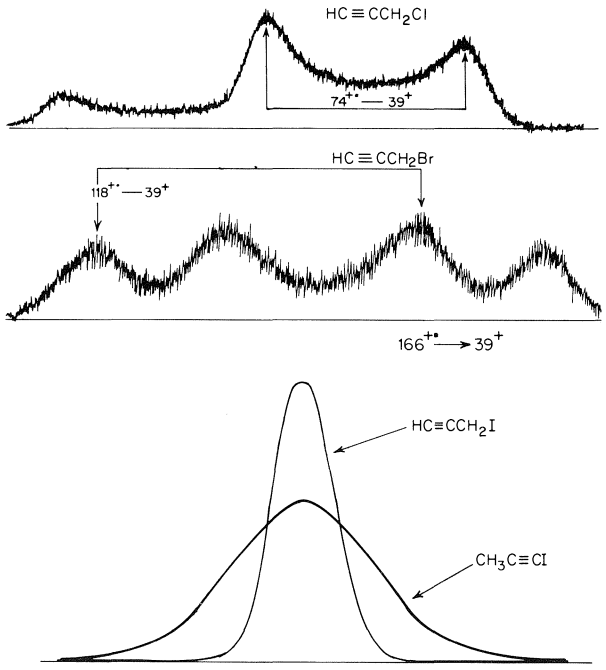

FIG. 1. Metastable peak shapes for the reaction $[C_3H_3X]^+ \rightarrow C_3H_3^+ + X^\cdot$. The *x*-axes do not have a common scale.

$[^{13}CC_2H_2Cl]^+$. The normal mass spectrum of 1-chloropropyne has an ion of appreciable abundance at *m/e* 73, $[C_3H_2Cl]^+$, and an intense metastable peak arises from the fragmentation $[C_3H_2Cl]^+ \rightarrow [C_3H_2]^{+\cdot} + Cl^{\cdot}$. The apparent second component described above also has a higher A.P. than the dished chlorine-atom-loss peak. The above observations may also account for the composite metastable peak reported by Sen-Sharma *et al.* (12) in their observations on propargyl chloride, although under our experimental conditions none was observable. The minimum energy released in the metastable fragmentation, 0.28 eV, was evaluated from the distribution of released energies (as described elsewhere (15)). It can be seen from the energy levels shown in Fig. 2 that the threshold daughter ion must be the cyclopropenium cation, and furthermore that the fragmentation has a reverse activation energy, E_{rev}, of 0.32 eV, about 90% of which is partitioned into translational energy of the products.

The bromo compounds also behaved similarly, generating a common dish-topped metastable peak and having a common A.P. for $[C_3H_3]^+$. Here, $E_{rev} = 0.83$ eV and a smaller fraction (~45%) is partitioned into product translational energy. Cyclopropenium again must be the threshold daughter ion (see Figs. 1 and 2).

In marked contrast, the A.P. for $[C_3H_3]^+$ from the iodo compounds corresponds very closely to the calculated threshold for [propargyl]$^+$. Furthermore, both metastable peaks are of Gaussian type (Fig. 2) and are associated with small energy releases; characteristic indeed, of fragmentations having zero E_{rev}. An explanation for the fragmentation behaviour of these molecules which fits all the observations is as follows.

Note from Table 1 that the activation energy for the reaction

$$[\text{halogen}]^{\cdot} + [cyclo\text{-}C_3H_3]^+ \rightarrow [C_3H_3X]^{+\cdot}$$

increases in the order $E_{iodo} > E_{bromo} > E_{chloro}$. It is suggested that E_{iodo} is *so large* that the fragmentation pathway of lowest energy for the C_3H_3I isomers becomes that leading to the propargyl cation, rather than that producing the more stable [cyclopropenium]$^+$.

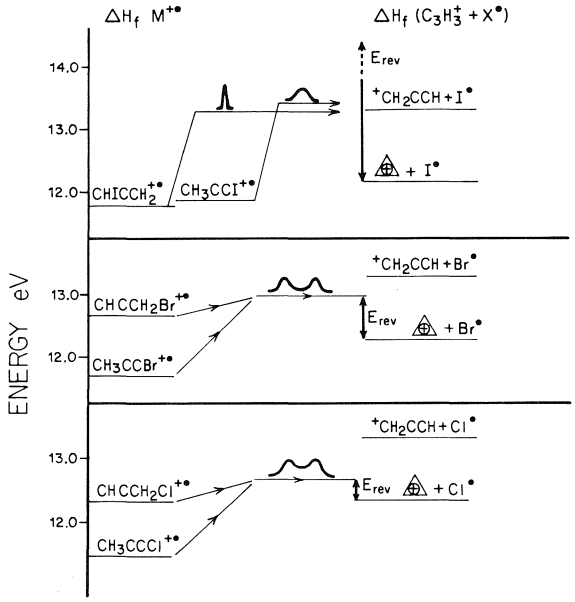

FIG. 2. Energy diagram for the reactions $[C_3H_3X]^{+\cdot} \rightarrow C_3H_3^+ + X^{\cdot}$. Metastable peak shapes are as illustrated above the transition arrows.

Experimental

Ionisation and appearance energies were measured using energy selected electrons in an apparatus which has previously been described (16, 17). Metastable peaks were measured on a Kratos-AEI MS902S Mass Spectrometer under conditions of good energy resolution (7). Propargyl chloride and bromide were obtained from Aldrich Co. Propargyl iodide was prepared by treating propargyl chloride with NaI in acetone (18), the Finkelstein reaction. This reaction was carried out at 0°C and purification was performed at the same temperature. In spite of these precautions a small amount of iodoallene (2–3%) was always produced. Any attempts to distill the product led to polymerisation and/or production of larger proportions of iodoallene. The halopropynes were prepared by the method of Smith and McLeod (19) (chloride), Cleveland and Murray (20) (bromide), and Grignard and Perichon (21) (iodide).

The electron spin resonance spectrum of $(CH_3)_3{}^{13}COO^{\cdot}$[1]

J. A. HOWARD
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received August 12, 1978

J. A. HOWARD. Can. J. Chem. **57**, 253 (1979).

The esr spectrum of $(CH_3)_3{}^{13}COO^{\cdot}$ has been observed in solution and the hyperfine interaction with the carbon-13 nucleus is 3.92 G.

J. A. HOWARD. Can. J. Chem. **57**, 253 (1979).

On a étudié le spectre rpe du radical $(CH_3)_3{}^{13}COO^{\cdot}$ en solution; on a évalué que l'interaction hyperfine avec le noyau du ^{13}C est égale à 3.92 G.

[Traduit par le journal]

Introduction

Alkylperoxy radicals have been extensively studied by electron spin resonance spectroscopy and *g*-factors, oxygen-17 and γ-hydrogen hyperfine coupling constants are well characterized (1–6). There has, however, been only one report of a carbon-13 hyperfine coupling constant (7) although central atom hyperfine coupling constants have been reported for vanadium (8), cobalt (9), manganese (9), and phosphorus (10–12) centred peroxy radicals while fluorine and hydrogen hyperfine couplings have been observed for $FOO^{\cdot}$ and $HOO^{\cdot}$ (13).

In this article we report the preparation of $(CH_3)_3{}^{13}COO^{\cdot}$ and the observation of its esr spectrum at low temperature.

Experimental

$(CH_3)_3{}^{13}COOH$ was prepared in about 40% yield from $(CH_3)_3{}^{13}CCl$, silver trifluoroacetate, and hydrogen peroxide by the method of Cookson *et al.* (14). $(CH_3)_3{}^{13}CCl$ (90% isotopic enrichment) was obtained from Merck, Sharpe and Dohme Canada Ltd.

Electron spin resonance spectra were recorded on a Varian E-4 spectrometer equipped with a variable temperature accessory. The microwave frequency was measured with a Systron-Donner Model 6016 frequency counter which also monitored the frequency of a proton magnetometer used to measure the magnetic field.

[1]NRCC No. 17093.

Results and Discussion

The esr spectrum shown in Fig. 1 was observed during photolysis of $(CH_3)_3{}^{13}COOH$ (0.2 *M*) and di-*tert*-butyl peroxide (0.2 *M*) in cyclopropane at low temperature (123 to 173 K) and consists of two lines 1.8 G wide, separated by 3.92 G and centred at $g = 2.0151$. At temperatures below 123 K the signal intensity did not decrease when the initiating light was switched off. Spectrum resolution was not as good above 173 K and the spectrum consists of a broad singlet ($\Delta H_{ms} = 7.5$ G) at 167 K. This spectrum can definitely be attributed to $(CH_3)_3{}^{13}COO^{\cdot}$ with the doublet arising because of interaction of the unpaired electron with the carbon-13 nucleus ($I = 1/2$) because *tert*-butylperoxy is the only radical that can be detected during low temperature photolysis of *tert*-butyl hydroperoxide (15).

Now it has been established that the unpaired electron on an alkylperoxy radical is confined almost entirely to a π orbital located on the two oxygen atoms with approximately 60% on the terminal oxygen and 40% on the inner oxygen (2). Since there is no direct mixing between the inner oxygen $2p_z$ orbital and the carbon 2*s* orbital the ^{13}C hyperfine interaction should be small. Negative spin density can, however, be induced onto the carbon atom via spin-polarization while hyperconjugation would produce positive spin density on this atom. The

0008-4042/79/030253-02$01.00/0

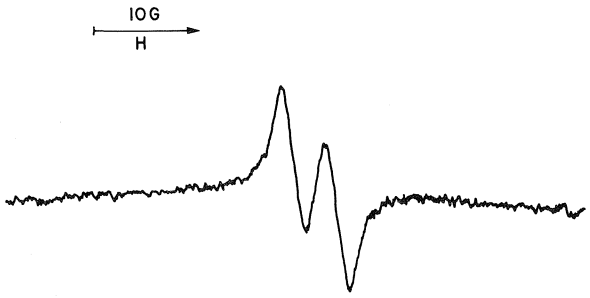

FIG. 1. Electron spin resonance spectrum of $(CH_3)_3{}^{13}COO^{\bullet}$ at 118 K in cyclopropane.

magnitude of the ^{13}C hyperfine splitting constant ($a_{^{13}C}$ = 3.92 G) divided by the value of A_0 (1339 G) for this atom (16) indicates that the 2*s* spin density at carbon is ca 0.003.

The value of $a_{^{13}C}$ for $(CH_3)_3{}^{13}COO^{\bullet}$ is smaller than $a_{^{13}C}$ = 6.15 G for $Cl_3{}^{13}COO^{\bullet}$ (7) which suggests a lower spin density at the central carbon atom in the former radical. This difference is consistent with the difference in electronegativity between the methyl and chlorine substituents. Thus the more electronegative chlorine will withdraw bonding electrons by an inductive mechanism leaving more unpaired spin density on the central carbon atom because of the essentially anti-bonding nature of the orbital occupied by the unpaired electron.

The value of the proton hyperfine coupling in $HOO^{\bullet}$ (13) is about 4 times larger than $a_{^{13}C}$ for $(CH_3)_3{}^{13}COO^{\bullet}$ even though $A_0(^{13}C)/A_0(^1H) \sim 2.63$. This implies that the *s* spin density on hydrogen is about 10 times larger than the 2*s* spin density on carbon which may reflect the difference in the polarizability of the electrons in the H—O and C—O bonds in these peroxy radicals.

Semi-empirical SCF-INDO calculations have proved useful for calculating the sign and magnitude of the spin density on the various atoms of free radicals. This method has in fact been applied to several alkylperoxy radicals by Biskupič and Valko (17). Not unexpectedly they calculate that the unpaired spin is almost entirely concentrated in a π orbital built from $2p_z$ orbitals on the terminal and inner oxygens. In addition they calculate that the total spin density on the central carbon atom is -0.0051 for $CH_3OO^{\bullet}$, -0.0053 for $C_2H_5OO^{\bullet}$, and -0.0052 for n-$C_4H_7OO^{\bullet}$. The INDO method would, therefore, be expected to give a value of -0.0052 for $(CH_3)_3COO^{\bullet}$ which is close to our estimated value of 0.003. The negative sign of the spin density does imply that spin-polarization overshadows hyperconjugation as a mechanism for inducing unpaired spin on the central atom in alkylperoxy radicals.

The INDO method also predicts a larger spin density on the proton in $HOO^{\bullet}$ (-0.0070) than on the carbon in $CH_3OO^{\bullet}$ although the ratio is much smaller than the ratio of the experimental spin densities. Values of a_H for $HOO^{\bullet}$ have, however, all been obtained in a powder or single crystal (13) and may not be directly comparable with $a_{^{13}C}$ for $(CH_3)_3COO^{\bullet}$ obtained in solution.

ρ as a quantitative measure of transition state structure

BO-LONG POH

School of Chemical Sciences, Universiti Sains Malaysia, Penang, Malaysia

Received August 25, 1977[1]

BO-LONG POH. Can. J. Chem. **57**, 255 (1979).

The values of the Brønsted exponent for several examples of nucleophilic substitution reactions, aromatic electrophilic substitution reactions, and hydrogen atom abstraction from toluene by free radicals have been calculated from the ρ values of the corresponding reactions. The magnitude of the Brønsted exponent is shown to indicate the degree of charge developed in the transition state structure.

BO-LONG POH. Can. J. Chem. **57**, 255 (1979).

En se basant sur les valeurs de ρ des réactions correspondantes, on a calculé les valeurs des exposants de Brønsted représentant plusieurs cas de réactions de substitutions nucléophiles, de réactions de substitutions aromatiques électrophiles et de réactions d'enlèvement d'atomes d'hydrogène du toluène par des radicaux libres. On a démontré que l'amplitude de l'exposant de Brønsted est une indication du développement de la charge dans la structure de l'état de transition.

[Traduit par le journal]

Introduction

We have been interested in understanding the success and failure of the common linear free energy correlations. In two earlier papers (1, 2) we have put forward a modified MacInnes equation and discussed its relationships with Taft (3), Brønsted (4), and Kirkwood–Westheimer (5) equations. In this paper we discuss the use of the ρ parameter as a quantitative measure of the charge developed in the transition state structure of a chemical reaction. Up to the present time only the Brønsted exponent (4, 6) has been used as a quantitative measure of transition state structure and the ρ parameter is commonly believed to give only a rough idea of the degree of charge developed in the transition state structure (7).

Results and Discussion

The Brønsted equation (4), which correlates the ionization constants of a given series of acids (or bases) with the rate constants of a reaction that is catalyzed by the same series of acids (or bases), is actually composed of two Hammett equations (1, 8, 9), one correlating ionization constants in reaction [1] and the other correlating rate constants in reaction [2].

$$[1] \qquad HA \underset{}{\overset{K}{\rightleftharpoons}} H^+ + A^-$$

$$[2] \qquad HA + S \xrightarrow[\text{slow}]{k} [S\text{---}H\text{---}A]^{\ddagger} \xrightarrow{\text{fast}} \text{Products}$$

The symbols HA and S denote acid and substrate respectively. The usual method of obtaining the value of the Brønsted exponent, α, is equivalent to calculating the ratio of the ρ values of reactions [1] and [2] for α is related to ρ_e (for the equilibrium process in reaction [1]) and ρ_r (for the rate process in reaction [2]) in the form of eq. [3] where *m* is the parameter defined earlier (1). For reactions in which the charge is located on the same atom in both the equilibrium and rate processes *m* is unity, eq. [3] reduces to eq. [4] (8).

$$[3] \qquad m\alpha = \rho_r/\rho_e$$

$$[4] \qquad \alpha = \rho_r/\rho_e$$

Since nucleophilic substitution reactions, aromatic electrophilic substitution reactions, and hydrogen abstraction from toluenes by free radicals are analogous to the reaction scheme shown in reaction [2] we can compute the values of α for these reactions from their ρ_r values if the ρ_e values of suitable reference series are available. We apply eq. [4] to several reactions and the reference series which provide the ρ_e values are given in Table 1. The values of α calculated are given in Table 2. These values have not been corrected for any temperature and solvent effects.[2] The α values of reactions [1], [2], and eq. [4]

[1]Revision received June 14, 1978.

[2]Solvent effects on ρ_e values are probably small because the reference equilibrium processes (Table 1) have their positive charge delocalised in the aromatic ring. Therefore, the values of α calculated without solvent corrections (Table 2) probably do not differ significantly from the corresponding true values. This view is supported by (*i*), the close agreement of the α values with Abraham's *z* values in Table 1 although the solvents differ and (*ii*), the large α value of reaction [13] in Table 2 (the value of 0.82 is close to the upper limit of 1) though ρ_r value is for aqueous medium and ρ_e for gas phase. Even when assuming that the true α value of reaction [13] is unity the ρ_e value for aqueous medium then differs from that for the gas phase by a maximum of 18% only.

0008-4042/79/030255-03$01.00/0

TABLE 1. Rate and reference equilibrium processes

Rate process	Reference equilibrium process	ρ_e	Reference
[1] Pyridines + EtI	Protonation of pyridines in water, 25°C	−6.01	8
[2] Solvolysis of $ArC(R)_2Cl$, R = alkyl, H [3] Hydrogen abstraction from $ArCH_3$	$ArCH(C_6H_5)OH + H^+ \rightleftharpoons Ar\overset{+}{C}H(C_6H_5) + H_2O$	−5.6	12[a]
[4] Electrophilic substitution in $ArCH_3$		−14.7	13[b]
[5] Electrophilic substitution in thiophenes		−16.5	13[c]

[a]The more appropriate reference equilibria should be the corresponding arylalkyl carbonium ion equilibria. But such data are lacking. However, their ρ_e values are estimated to be close to those of the arylmonophenyl carbonium ion equilibria given above (12).
[b]Data on the more appropriate reference equilibrium process (protonation of benzenes) are lacking. However, the above given equilibrium is a suitable reference series (13) since the aryl cation is a good model for the Wheland intermediate in aromatic electrophilic substitution reactions.
[c]Data on the more appropriate reference equilibrium process (ring protonation of thiophenes) are lacking. However, the above given equilibrium is a suitable reference series (13) for the same reason given in footnote *b*.

[a]Charge developed on the nitrogen atom in the transition state of the reaction: pyridine + CH_3I; value taken from ref. 14.
[b]Charge developed on the methylene carbon atom in the transition state of solvolysis of benzyl chloride; value taken from ref. 14.
[c]Charge developed on the carbon atom in the transition state of solvolysis of *tert*-butyl chloride, value taken from ref. 14.

are in good agreement with the degree of charge developed in the transition state structures of the corresponding reactions. Therefore, the magnitude of α seems to give a quantitative measure of the degree of charge developed in the transition state structure, as we have suggested earlier (1). It is unfortunate that no data on the degree of charge developed in the transition state structures of the remaining reactions are available for comparison. It is worth noting that the α values of hydrogen abstraction reactions (reactions [5]–[8]) are small but, nevertheless, indicate polar character (10, 11). It must be cautioned that the above interpretation of α is not applicable to reactions in which ρ_r is a composite term (for example, acid-catalyzed hydrolysis of esters).

A number of α,β-epoxy sulfoxides and epoxy sulfones have been prepared via cyclization of α-chloro-β-hydroxy sulfoxides or phase-transfer catalyzed reaction between α-chloroalkyl sulfones and carbonyl compounds. Thermal and acid-catalyzed rearrangement of these epoxides resulted in migration of sulfinyl or sulfonyl groups to form β-carbonyl sulfoxides or sulfones. Upon treatment of the epoxy sulfones with $MgBr_2$ in ether, α-bromocarbonyl compounds were obtained in excellent yield. The reaction of epoxy sulfones with nucleophiles was also briefly investigated.

TONY DURST, KAM-CHUNG TIN, FRANCOIS DE REINACH-HIRTZBACH, JOHN M. DECESARE et M. DOMINIC RYAN. Can. J. Chem. **57**, 258 (1979).

On a préparé un certain nombre d'α,β-époxy sulfoxydes et d'époxy sulfones par cyclisation d'α-chloro β-hydroxy sulfoxydes ou par une réaction catalysée par transfert de phase entre des α-chloroalkyl sulfones et des composés carbonylés. Une transposition thermique ou acido-catalysée de ces époxydes provoque une migration des groupes sulfinyle ou sulfonyle avec formation de sulfoxydes ou de sulfones β-carbonylés. La réaction des époxysulfones avec du $MgBr_2$ dans l'éther fournit des composés α-bromo carbonylés avec d'excellents rendements. On a aussi étudié brièvement la réaction des époxy sulfones avec des nucléophiles.

[Traduit par le journal]

Synthesis

α,β-Epoxy sulfones have been prepared by two general routes: (*i*) epoxidation of α,β-unsaturated sulfones (1, 2), eq. [1], and, (*ii*) cyclization of halohydrin sulfones (3–7), eq. [2]. Several versions of the latter route have been described including Darzens-type (3) and phase-transfer-catalyzed reactions (4, 5) between α-halo sulfones and ketones or aldehydes, in which the halohydrin sulfones are intermediates converted *in situ* to the epoxy sulfones, and base-induced cyclizations of previously isolated halohydrin sulfones (6, 7).

Epoxy sulfoxides cannot be prepared by oxidation of α,β-unsaturated sulfoxides since all epoxidizing agents cause oxidation of the sulfur atom to the sulfone stage before epoxidation. These epoxides have been prepared by reaction of α-chloro sulfoxides with carbonyl compounds in the presence of K*t*OBu (8, 9) and by KOH-mediated cyclization of α-chloro-β-hydroxy sulfoxides (7).

Zwanenburg and ter Wiel (1) reported that the epoxidation of the α,β-unsaturated sulfone **1** (R = R^2 = Ph, R^1 = R^3 = H) with basic hydrogen peroxide led only to the *trans*-epoxide **2**, irrespective of the stereochemistry of the starting olefin. More recently, Curci and Difuria (2) found that the stereoselectivity observed in the epoxidation of *cis*-**1** was dependent on the nature of the epoxidizing nucleophile. Thus *cis*-**1** and ClO^- gave exclusively *cis*-**2**, *m*-chloroperbenzoate gave a *cis–trans* ratio of 95:5, whereas basic H_2O_2 or basic *t*BuOOH yielded a 1:9 *cis–trans* mixture; the latter results essentially confirm the earlier report (1).

Vogt and Tavares (3) prepared several epoxy sulfones in good to excellent yield by reacting chloromethyl *p*-tolyl sulfone with aldehydes or ketones in the presence of KO*t*Bu. When benzaldehyde was used as the carbonyl component, the resulting epoxide had the *trans* geometry. Independently Bohlmann and Haffer (6) described the KOH induced cyclization of an α-chloro-β-hydroxy sulfone, having produced the intermediate **3** by oxidation of an α-chloro-β-hydroxy sulfide. Recently Makosza and co-workers (4) showed that α,β-epoxy sulfones are very simply prepared from α-chloro sulfones and carbonyl compounds under phase-transfer conditions with yields of 60–90% being obtained from chloromethyl *p*-tolyl sulfone and a variety of carbonyl components. Although we had developed a route to

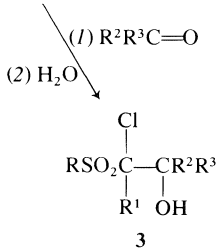
epoxy sulfones (see below) we have, in our recent work (5), used only the phase-transfer route and feel that it is the most practical and versatile approach to these compounds.

We had initially prepared a number of epoxy sulfones by cyclization of the chlorohydrin sulfones **3** with 5% KOH in methanol. The halohydrin sulfones were obtained via condensation of α-lithio-α-chloro sulfones with ketones or aldehydes at −70°C followed by quenching with H_2O at low temperature (eq. [3]). In some instances, Table 1, entries *g* and *l*, epoxy sulfones were formed directly by this procedure. One difficulty with this approach was that cleavage of **3** to its carbonyl and chloromethyl sulfone components competed, often to a major extent, with cyclization to the epoxide (see also ref. 6). This competing reaction is apparently more serious when R = Ph in **3** compared to when R = CH_3, probably because of the greater stability of **5** when R = Ph compared to R = CH_3.[1] The reversibility of **3** into its components is immaterial under the phase-transfer conditions.

An interesting aspect of the route outlined by [3] involved the preparation and trapping of the lithio derivative of chloromethyl methyl sulfone, i.e., **5** (R—CH_3, R^1 = H), without serious competition from the familiar Ramberg–Bäcklund reaction. In contrast to the behavior of chloromethyl methyl sulfone,

[3] 
4 **5**



3

it was not possible to intercept a metallated derivative of 2-chlorothiane 1,1-dioxide. We did not attempt to isolate the possible by-products, 2-thia[2.1.0]bicyclohexane 2,2-dioxide or its decomposition product, cyclopentene. These results are summarized in Tables 1 and 2.

The phase-transfer technique (4) is also capable of providing epoxy sulfones starting from α-chloro sulfones, such as chloromethyl methyl sulfone, which have α′ hydrogens and are thus susceptible to the Ramberg–Bäcklund rearrangement. α-Chlorobenzyl benzyl sulfone, however, yielded only *trans*-stilbene and no condensation product upon attempted reaction with benzaldehyde under phase-transfer conditions (see Table 2).

The α-chloro-β-hydroxy sulfoxides **6**, prepared from the reaction of the α-chloro sulfoxides **7** with aldehydes and ketones (10), could be cyclized in very

[1]Bordwell *et al.* (25) have shown that $PHSO_2CH_3$ is more acidic by 2pK_a units than $CH_3SO_2CH_3$. One would expect a similar trend, for $PhSO_2CH_2Cl$ vs. $CH_3SO_2CH_2Cl$ and thus a greater stability for **5** when R = Ph than CH_3.

high yield to α,β-epoxy sulfoxides **9** (eq. [4]). These substances were in several instances oxidized with *m*-chloroperbenzoic acid (MCPBA) to epoxy sulfones. Of considerable interest was the observation that the reactions of the α-lithio derivatives **7** derived from chloromethyl phenyl, chloromethyl methyl, and α-chlorobutyl sulfoxides yielded only one of the two diastereomeric products upon condensation with symmetrical ketones. The stereochemistry of these adducts has not been determined. The high stereoselectivity observed in the chloromethyl phenyl sulfoxide series initiated our investigations (11) into the nature and the reactions of α-sulfinyl carbanions (α-lithio sulfoxides).

The reaction of both chloromethyl methyl (9) and chloromethyl *p*-tolyl sulfoxides (8) with aldehydes in the presence of potassium *tert*-butoxide resulted in preferential formation of the *cis*-substituted epoxy sulfoxide (**9**, $R^1 = R^2 = H$), whereas similar preparations of epoxy sulfones normally gave *trans* epoxides (3).

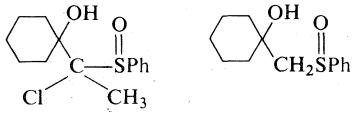
The chlorohydrin sulfoxides **6** (Table 1) were prepared using *n*BuLi or CH_3Li to generate the lithio derivative **7**. In such a reaction displacement of the chloroalkyl function by the alkyl group of the RLi competes with α-metallation (11) thereby lowering the yield of the desired product. For example, treatment of α-chloroethyl phenyl sulfoxide with methyllithium followed by cyclohexanone gave the adducts **6***f* and **10** in a 45:55 ratio.

The interference from the displacement reaction

[4] 
can be avoided if a nonnucleophilic base such as lithium diisopropyl amide (LDA) is employed. Thus the yields of the adducts **6***e* and **6***f* were raised from 34 and 45% to 72 and 70%, respectively, when the anion generating base was changed from CH_3Li to LDA.

BF_3-catalyzed and Thermal Rearrangements

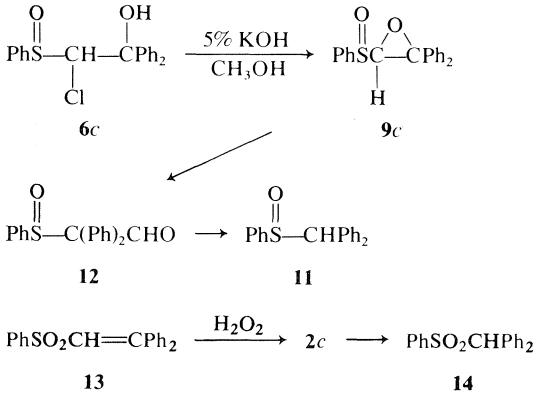
The acid-catalyzed rearrangement of negatively substituted epoxides such as **2** and **9** to carbonyl compounds with concomitant migration of the



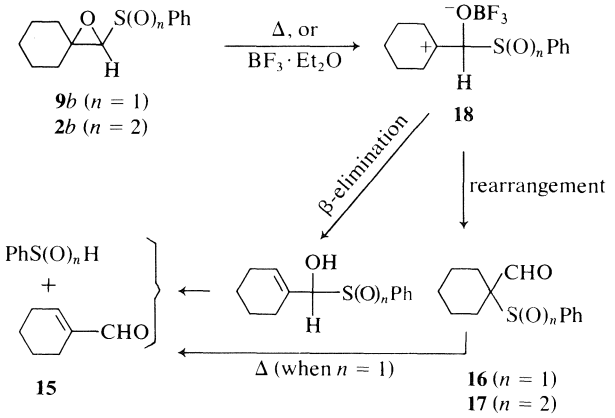
electronegative substituent (eq. [5]) has been well studied (see ref. 13*a* for X = Cl, *b* for X = COR, *c* for X = COOR, and *d* for X = P(O)(OCH$_3$)$_2$).

[5] 
X = Cl, OAc, C(O)R, CO_2R, P(O)(OR)$_2$, S(O)R, SO_2R

In our hands, both the epoxy sulfoxides and sulfones when subjected to either $BF_3{\cdot}Et_2O$ treatment or heating in an inert solvent underwent the above rearrangement (7). In all cases studied phenylsulfonyl or phenylsulfinyl migration occurred with high preference over hydrogen migration in agreement with group migratory aptitudes observed in related systems (13). The temperature required for thermal rearrangement varied from less than 25°C in **2** or **9** ($R^2 = R^3 = Ph$) to greater than 130°C when $R^2 = R^3 =$ alkyl, as expected on the basis of the relative stability of the intermediate, e.g. **18**. For example, we were unable to isolate the epoxy sulfoxide **9***c*, the expected product from the reaction of **6***c* with methanolic KOH. Instead, benzhydryl phenyl sulfoxide **11**, the result of rearrangement of **9***c* to the aldehyde sulfoxide **12** and subsequent decarbonylation, was obtained in near quantitative yield. In agreement with this observation, attempted preparation of the epoxy sulfone **2***c* by the reaction of the unsaturated sulfone **13** with hot basic H_2O_2 resulted in the formation of benzhydryl phenyl sulfone **14**, presumably via a pathway analogous to that discussed for **11**. Tavares *et al.* (8) have succeeded in isolating the *p*-tolyl analogue of **2***c* and found that exposure of this substance to $BF_3{\cdot}Et_2O$ yielded the expected aldehyde sulfone.



In the rearrangement of the epoxides **9***b* and **2***b* two products were isolated. The α,β-unsaturated aldehyde **15** was obtained from both starting materials and the α-formyl sulfoxide **16** and sulfone **17** from **9***b* and **2***b*, respectively. The formation of both types of products is easy to rationalize as shown below. In the thermolysis of **9***b*, the cyclohexencarboxaldehyde could also have arisen via the sulfenic acid elimination from **16** (14). Recently Reutrakul and Kanghae (15) have reported the thermolysis in refluxing toluene of a number of epoxy sulfoxides of the type **9***b* in which the carbocyclic ring varied in size from C_4 to C_8. α,β-Unsaturated aldehydes such as **15** were obtained 40–90% yield (15).

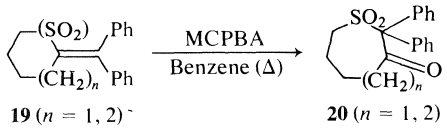


The above rearrangement of epoxy sulfones suggested a possible route to medium-size sulphur-containing rings via a one-carbon ring enlargement. Thus, the unsaturated sulfones **19** which are readily prepared from the corresponding parent cyclic sulfones, alkyllithiums, and benzophenone followed by dehydration, gave directly the expanded β-keto sulfones **20** in greater than 90% yield upon refluxing in $CHCl_3$ containing *m*-chloroperbenzoic acid. The spectroscopic properties of these compounds are in complete agreement with the structure assignments.

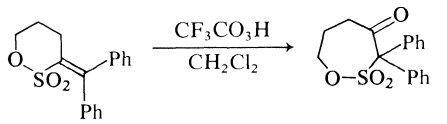
The six-membered ring sultone **21** likewise could be converted into the seven-membered β-keto sultone **22** (mp 150–151°C; ir: 1725, 1373, 1185, and 995 cm^{-1}; nmr: 1.8–2.6 (m, 2H), 3.02–3.35 (m, 2H), 4.62 (t, J = 5 Hz, 2H), and 7.2–7.6 (m, 10H)) in 24% isolated yield upon heating with trifluoroperacetic acid in CH_2Cl_2 for 30 min. The γ-sultone analogue of **21** could not be epoxidized and therefore not ring-expanded under identical conditions. Similarly, the α,β-unsaturated sulfonate ester $Ph_2C{=}CHSO_2OCH_3$ and sulfonamide $Ph_2C{=}CHSO_2N(CH_3)_2$ were unreactive toward pertrifluoroacetic acid.

Reaction with $MgBr_2$ and Grignard Reagents

Several electronegatively substituted epoxides (**23**) have been reported (16–18) to react with $MgBr_2$ according to [6]. It was expected that epoxy sulfones should behave in a similar manner and indeed they



19 (n = 1, 2) **20** (n = 1, 2)



21 **22**

do. Thus seven different epoxy sulfones when reacted with $MgBr_2$ in ether at room temperature or below gave the expected α-bromocarbonyl compounds **24** in 80–90% isolated yields. These reactions were found to be exceptionally clean and the nmr spectra of the crude products which were obtained in almost quantitative yield were essentially identical with those of the purified materials. The results are shown in Table 3.

[6] 
23 **24**

a X = CN (ref. 16)
b X = Cl (ref. 17)
c X = OAc (refs. 17, 18)
d X = SO_2Ph

Since the epoxy sulfones are conveniently prepared from α-chloro sulfones and ketones or aldehydes under phase-transfer conditions the overall synthetic transformation as represented by [7] represents a useful procedure for the introduction of both an acyl group and a Br atom at the original carbonyl carbon. The α carbon in the chlorosulfone thus serves as a masked nucleophilic acyl carbon.

[7] 
The epoxy sulfone route offers a number of advantages when compared to epoxy nitriles (16*a*) and chloro epoxides (see ref. 16*b* for the reactions of **23***a* with HCl) which can also be used to effect the overall transformation outlined in [7]. As mentioned above the epoxy sulfones are conveniently prepared using phase-transfer conditions whereas the synthesis of the chloro epoxides requires the generation of dichloromethyllithium in THF at −95°C. In addition, the epoxy sulfones are generally stable, easily purified, crystalline substances whereas the chloro epoxides are often not stable enough to be purified by distillation. Finally, the epoxy sulfone route is

TABLE 3. Preparation of α-bromo ketones and α-bromo aldehydes

Entry	α-Bromo derivative	Isolated yield (%)
a		85

f		89
m		80
n		90
o		95

quite general and can quite easily be applied to the synthesis of both α-bromo ketones and α-bromo aldehydes since the required α-chloroalkyl phenyl sulfones are available by a number of simple routes.[2] Exposure of the epoxide **23** ($R^1 = R^3 = H$, $R^2 = Ph$, $X = SO_2PH$) to $FeCl_3$ in ether (20) resulted in an approximately equal mixture of α-chlorophenyl acetaldehyde and the α-formyl sulfone $PhCH(CHO)SO_2Ph$.

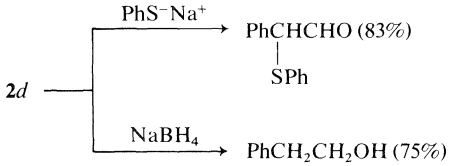
The reaction of several epoxy sulfones with Grignard reagents was also briefly investigated. Analysis of the crude products obtained from such reactions by infrared spectroscopy indicated the absence of carbonyl groups but showed strong O—H absorption. Thin-layer chromatography indicated the presence of a number of products presumably formed by reaction of several possible initial carbonyl-group containing intermediates with remaining Grignard reagents. These reactions were not further investigated.

Reactions with Nucleophilic Reagents

The ring opening of epoxy sulfones with nucleophiles would be expected to occur with complete regiospecificity at the carbon β to the sulfone group since S_N2 reactions α to a sulfonyl group are known to be extremely slow (21). The initial product of such a reaction, an α-hydroxy sulfone, is unstable and should fragment to a sulfinic acid and carbonyl compound (22). Up to the present only a few nucleophiles were found to be sufficiently reactive. For example PhS^- reacted with several epoxy sulfones to give α-phenylthio ketones and aldehydes

[2]Among the possible routes are (*i*) $PhSCH_2R$ + chlorinating agents followed by oxidation (19*a*); (*ii*) PhSH + RCHO + HCl (19*b*); and (*iii*) alkylation of $PhSO_2CH_2Cl$ with RX (4).

in good yield; no attempt was made to isolate phenyl sulfinic acid from these reactions. Azide and cyanide ion on the other hand were unreactive toward the epoxy sulfones on hand in solvents such as methanol or dimethylformamide. Reduction of the epoxide **2***d* with sodium borohydride furnished 2-phenylethanol, presumably by reduction of the initially formed carbonyl intermediate.



Experimental

General Comments

The organization of this section is as follows. All experiments pertaining to a particular epoxy sulfoxide or sulfone are gathered together. General descriptions are given for each of the major types of reaction and these are usually not repeated unless considered appropriate.

Nuclear magnetic resonance spectra were recorded as $CDCl_3$ solutions using Varian T-60 and HA-100 spectrometers; peak positions are given in δ units relative to TMS. Infrared spectra were obtained as films if liquid, or in $CHCl_3$ solution if solid, on a Beckman IR-20A spectrophotometer. Melting points and boiling points are uncorrected. Usual work-up involved partitioning the products between water and an organic solvent, generally CH_2Cl_2, drying the organic extracts, and evaporating the solvent under reduced pressure.

General Procedures

(I) Preparation of α-Chloro-β-hydroxy Sulfoxides or Sulfones

To a rapidly stirred solution of the α-chloro sulfoxide or sulfone in THF at −70°C under nitrogen atmosphere was added dropwise 1.1 equiv. of *n*BuLi in hexane or CH_3Li in ether. (As mentioned in the text the use of lithium diisopropylamide (LDA) is preferred (12).) The clear bright yellow or greenish-yellow solution was stirred for about 5 min at −70°C and then treated with the carbonyl component, neat if liquid or as a tetrahydrofuran solution if solid. The colour of the reaction mixture was generally discharged during this step. The reaction was then allowed to stir for a further 15–30 min at −70°C, poured into water, and worked up in the usual manner. The crude products were purified by recrystallization or column chromatography (Table 1).

The condensation reaction was carried out on a 1–25 mmol scale. The THF solutions were 0.1–0.25 *M* in carbanion solution.

(II) Conversion of Chlorohydrin Sulfoxides or Chlorohydrin Sulfones into the Corresponding Epoxides

The chlorohydrin sulfoxides or sulfones were dissolved in 10% methanolic KOH, about 1 mmol of substrate per 10 millilitres of solution, and stirred for 30–60 min at room temperature. The reaction mixture was then diluted with H_2O, extracted with CH_2Cl_2, and further worked up in the usual manner.

(III) Oxidation of Epoxy Sulfoxides to Epoxy Sulfones

This was carried out by allowing equimolar amounts of *m*-chloroperbenzoic acid and epoxy sulfoxide to react in a methylene chloride solution overnight. The reaction mixture was then washed with 5% NaOH, the organic layer dried with $MgSO_4$, and the solvent evaporated.

(IV) Preparation of Epoxy Sulfones using the Phase-transfer Technique

The following is a slight modification of the published procedure (5). The α-chloro sulfone and aldehyde, or ketone, were stirred at 0°C with 50% NaOH containing a few mol-% of benzyltriethylammonium chloride as catalyst until tlc showed the disappearance of either the α-chloro sulfone or the carbonyl component. If reaction periods of greater than 4 h were required then the reaction was carried out at room temperature. The epoxy sulfones were purified by silica gel chromatography or recrystallization.

(V) Reactions of Epoxy Sulfones with $MgBr_2$

An ethereal solution of $MgBr_2$ was prepared by reacting Mg with ethylene dibromide. To such a solution cooled to 5°C was added the epoxy sulfone. After completion of the reaction as judged by tlc (approximately 15–30 min), the ether layer was washed with ice water and the solvent dried and evaporated. The crude α-bromo ketone or α-bromo aldehyde was purified by chromatography on a short silica gel column using first hexane, which eluted any residual $BrCH_2CH_2Br$, and then 1:1 CH_2Cl_2–hexane to obtain the desired product.

Series a

Chloromethyl Phenyl Sulfone and Acetone

The chlorohydrin sulfone **3***a*, mp 82–83°C (CH_2Cl_2–pentane), was obtained in 71% yield according to method I. *Anal.* calcd. for $C_{10}H_{13}ClO_3S$: C 48.29, H 5.23, Cl 14.25, S 12.86; found: C 48.29, H 5.23, Cl 14.23, S 12.81.

Reaction of **3***a* (355 mg) with 0.5 g KOH in 10 mL of methanol for 10 min gave, after the usual work-up, 228 mg of a solid whose nmr indicated a 9:1 mixture of chloromethyl phenyl sulfone and the epoxy sulfone **2***a* (see below).

The epoxy sulfone **2***a* was also prepared in 94% yield starting with 1.25 g of $PhCH_2SO_2Cl$, 1.7 mL of acetone, 15 mL of 50% NaOH, 15 mL CH_2Cl_2, and 0.3 g of $PhCH_2\overset{+}{N}(CH_2CH_3)_3Cl^-$. These reagents were stirred first at 0°C for about 2 h, then overnight at room temperature. The yield of colorless granules, after chromatography, was 1.3 g, mp 72–74°C (ether–pentane); ir: 1305, 1145 cm^{-1}; nmr: 1.42 (s, 3H), 1.84 (s, 3H), 3.82 (s, 1H), 7.4–8.15 (m, 5H). *Anal.* calcd. for $C_{10}H_{12}O_3S$: C 56.60, H 5.70; found: C 56.83, H 5.56.

Compound **3***a* was also obtained upon oxidation of **9***a* (5.06 g) with 5.24 g of 85% MCPBA in 100 mL of CH_2Cl_2. The yield of **3***a* was 5.29 g (95%).

The chlorohydrin sulfoxide **6***a* was obtained in 75% yield via procedure I as colorless needles from CH_2Cl_2–pentane, mp 134–137°C; nmr: 1.58 (s, 6H), 2.87 (OH), 4.32 (s, 1H), 7.4–7.6 (m, 5H). *Anal.* calcd. for $C_{10}H_{13}ClO_2S$: C 51.61, H 5.63, Cl 15.24, S 13.77; found: C 51.16, H 5.59, Cl 15.87, S 13.60.

Reaction of 127 mg of **6***a* with 10 mL of 5% methanolic KOH for 15 min at room temperature yielded 96 mg (91%) of **9***a* as a colorless oil which was homogeneous on tlc; nmr: 1.41 (s, 3H), 1.72 (s, 3H), 3.66 (s, 1H), 7.4–7.8 (m, 5H). *Anal.* calcd. for $C_{10}H_{12}O_2S$: C 61.21, H 6.17; found: C 61.40, H 6.06.

Epoxy sulfone **2***a* (700 mg) was added to a twofold excess of $MgBr_2$ in 10 mL of ether, kept overnight, and then worked up. The nmr of the crude product showed only peaks for 2-bromo-2-methylpropanal (1.77 (s, 6H), 9.90 (s, 1H)) and the residual 1,2-dibromoethane used to generate $MgBr_2$. The estimated yield of α-bromo aldehyde was >85%.

Series b

Chloromethyl Phenyl Sulfone and Cyclohexanone

The chlorohydrin sulfone **3***b* was obtained in 94% yield

according to procedure I as colorless needles, mp 150–151°C (CH_2Cl_2–pentane). *Anal.* calcd. for $C_{13}H_{17}ClO_2S$: C 54.06, H 5.94, S 11.10, Cl 12.28; found: C 54.02, H 5.94, S 11.10, Cl 12.28.

Reaction of 206 mg of **3***b* with 0.5 g of KOH in 10 mL of methanol for 15 min gave 152 mg of a crude solid material whose nmr spectrum showed it to be a 4:6 mixture of the epoxy sulfone **2***b*, mp 56°C, and chloromethyl phenyl sulfone. Compound **2***b* had nmr peaks at 1.4–2.4 (m, 10H), 3.8 (s, 1H), 7.4–8.2 (m, 5H); ir: 1325, 1152 cm^{-1}. *Anal.* calcd. for $C_{13}H_{16}O_3S$: C 61.89, H 6.39; found: C 62.21, H 6.53. This compound was better prepared by MCPBA oxidation of the corresponding epoxy sulfoxide (see below).

Chloromethyl Phenyl Sulfoxide and Cyclohexanone

Addition of 3.80 mg (3.9 mmol) of cyclohexanone to 3.9 mmol of the α-lithio derivative of chloromethyl phenyl sulfoxide in 20 ml of THF gave, after work-up and recrystallization of the crude product, 844 mg (79%) of **6***b* as fluffy white needles, mp 169–171°C; ir: 3450, 1050 cm^{-1}; nmr: 1.5–2.2 (m, 10H), 2.7 (1H, OH), 4.31 (s, 1H), 7.4–7.7 (m, 5H). *Anal.* calcd. for $C_{13}H_{17}ClO_2S$: C 57.24, H 6.28, Cl 13.00, S 11.75; found: C 57.16, H 6.25, Cl 13.16, S 11.75.

Chlorohydrin sulfoxide **6***b* (90 mg, 0.33 mmol) was cyclized in 91% yield according to procedure II to **9***b*, colorless granules, mp 64–66°C (ether–pentane); ir: 1090, 1030 cm^{-1}; nmr: 1.4–2.3 (m, 10H), 3.6 (s, 1H), 7.4–7.8 (m, 5H). *Anal.* calcd. for $C_{13}H_{16}O_2S$: C 66.08, H 6.83, S 13.65; found: C 66.03, H 6.94, S 13.61.

MCPBA oxidation of **9***b* (200 mg) according to procedure III gave 202 mg of epoxy sulfone **2***b* (see above).

Thermal decomposition of **9**b—The epoxy sulfoxide **9***b* (822 mg) was heated in a micro distillation apparatus. The sulfoxide decomposed at about 190°C and 260 mg (62%) of Δ^1-cyclohexenecarboxaldehyde (ir: 2970, 1685, 1645 cm^{-1}; nmr: aldehyde proton, 9.48) distilled as a colorless liquid; mp of DNP 213–216°C (lit. (21) mp 213–214°C).

Acid-catalyzed rearrangement of **9**b—$BF_3{\cdot}Et_2O$ (0.45 mL) was added to a solution of 416 mg of epoxy sulfoxide in 20 mL of ether. The usual work-up after a 2-h reaction period gave a crude product which was separated on preparative tlc using 1:1 ether–pentane as eluent. Aldehyde sulfoxide **16** was obtained as a colorless oil, 149 mg, 36%. MCPBA oxidation afforded **17** (see below). In addition a 60% yield of Δ^1-cyclohexene carboxaldehyde was obtained.

Acid-catalyzed rearrangement of **2**b—To a solution of 300 mg of **2***b* in 25 mL of ether was added 0.4 mL of $BF_3{\cdot}Et_2O$. The reaction was refluxed for 1 h. The crude product showed a mixture of Δ^1-cyclohexenecarboxaldehyde and the aldehyde sulfone **17**. The sulfone **17** was obtained pure by preparative tlc (1:1 ether–pentane) as colorless plates, mp 66–67.5°C; ir: 1717, 1310, 1142 cm^{-1}; nmr: 0.7–2.5 (m, 10H), 7.3–7.9 (m, 5H), 9.67 (m, 1H). *Anal.* calcd. for $C_{13}H_{16}O_3S$: C 61.89, H 6.39, S 12.68; found: C 61.82, H 6.40, S 12.68.

Series c

Chloromethyl Phenyl Sulfoxide and Benzophenone

Using procedure I, the chlorhydrin sulfoxide **6***c* was obtained in 68% yield as colorless needles, mp 128–130°C (CH_2Cl_2–pentane); ir: 1060 cm^{-1}; nmr: 4.75 (OH), 5.36 (s, 1H), 7.2–7.8 (m, 15H). *Anal.* calcd. for $C_{20}H_{17}ClO_2S$: C 67.31, H 4.77, S 8.97, Cl 9.99; found: C 67.09, H 4.82, S 9.16, Cl 10.23.

The chlorohydrin sulfoxide **6***c* (180 mg) was heated in a mixture of 15 mL of H_2O, 5 mL of methanol, and 1 g of KOH until dissolution took place. On cooling 159 mg (99%) of colorless needles precipitated, mp 132–133°C (CH_2Cl_2–pentane); ir: 1045 cm^{-1}; nmr: 4.81 (s, 1H), together with an aromatic multiplet, 15H. The compound was identified as benzhydryl phenyl sulfoxide on the basis of its analysis (found: C 77.63, H 5.52, S 10.80) and oxidation to benzhydryl phenyl sulfone.

When the unsaturated sulfone **13** was refluxed overnight in a 1:1 CH_3OH – 30% H_2O_2–Na_2CO_3 mixture, benzhydryl phenyl sulfone was obtained in 83% isolated yield.

Series d

Chloromethyl Phenyl Sulfone and Benzaldehyde

Reaction of equimolar amounts of the lithio salt of chloromethyl phenyl sulfone in THF with benzaldehyde at −78°C according to procedure I furnished, in 94% yield, the chlorohydrin sulfone **3***d*. Recrystallization from CH_2Cl_2–pentane gave a single diastereoisomer, mp 129–130°C; *Anal.* calcd. for $C_{14}H_{13}ClO_3S$: C 56.66, H 4.41, S 10.80, Cl 11.9; found: C 56.45, H 4.16, S 10.79, Cl 12.15.

Attempted conversion of **3***d* to **2***d* by procedure II failed. Only the two components, $PhSO_2CH_2Cl$ and PhCHO, were obtained.

The epoxy sulfone **2***d* was prepared in 92% yield using the phase-transfer technique and stirring the reaction mixture for 1 h at ice-bath temperature; nmr: 4.18 (d, J = 1.5 Hz, 1H), 4.62 (d, J = 1.5 Hz, 11H), 7.2–8.2 (m, 10H). *Anal.* calcd. for $C_{14}H_{12}O_3S$: C 64.59, H 4.65, S 12.32; found: C 64.40, H 4.81, S 12.48.

To 25 mL of a $MgBr_2$ in ether solution prepared from 690 mg of Mg and 2.5 mL of $BrCH_2CH_2Br$ was added 1.10 g of the epoxide **2***d*. The reaction mixture was kept overnight and then worked up. Chromatography on silica gel yielded 642 mg (78%) of α-bromo aldehyde, **24***d*.

When **2***d* was stirred with an equimolar mixture of $FeCl_3$ in ether for 10 min (20) a 1:1 mixture of α-chlorophenylacetaldehyde and α-phenylsulfonylphenylacetaldehyde were obtained.

Reduction of **2***d* with $NaBH_4$ in ethanol at room temperature for 10 min gave, after work-up, 2-phenylethanol (75%) whereas reaction with PhS^-K^+ in methanol for 4 h afforded, after usual work-up and column chromatography, 83% of α-phenylthiophenylacetaldehyde; ir: 1685 cm^{-1}; nmr: 1.53–2.23 (m, 7H), 3.23–3.56 (m, 1H), 5.50–5.83 (m, 2H), 7.1–7.5 (m, 10H), 9.8 (d, J = 2 Hz, 1H).

Series e

α-Chloroethyl Phenyl Sulfoxide and Acetone

The crude products (2.67 g) obtained from 3.1 g of chloro sulfoxide and excess acetone (procedure I) were separated by chromatography. The less polar fraction, 1.36 g (34%), mp 105–107°C, was identified as **6***e*; ir: 3440, 1025 cm^{-1}; nmr: 1.48 (s, 3H), 4.18 (OH), 7.4–7.9 (m, 5H); $M^{\pm}$ 244 and 246 in 3:1 ratio. The more polar component, mp 116°C, was identical to the product obtained from the reaction of $PhS(O)CH_2Li$ and acetone (23).

Chlorohydrin sulfoxide **6***e* was better prepared using the following procedure. To a solution of 5 mmol of LDA, prepared from diisopropylamine and methyllithium, in 30 mL of dry THF at −70°C was added 955 mg, (5.0 mmol) of α-chloroethyl phenyl sulfoxide dissolved in 5 mL of THF. The reaction mixture was stirred for 5 min and then 490 mg of cyclohexanone was added. After a further 10 min, water was added and the reaction was worked up. The yield of **6***e* was 1.03 g (72%).

Reaction of **6***e* (630 mg) with 50 mL 10% methanolic KOH at 25°C for 30 min gave 514 mg (96%) of **9***e* as a colorless oil; ir: 1040 cm^{-1}; nmr: 1.52 (s, 3H), 1.63 (s, 3H), 1.81 (s, 3H),

7.4–7.9 (m, 5H). *Anal.* calcd. for $C_{11}H_{14}O_2S$: C 62.79, H 6.71; found: C 63.00, H 6.58.

Series f

α-Chloroethyl Phenyl Sulfone and Cyclohexanone

The epoxy sulfone **2***f* was obtained in 76% yield using phase-transfer conditions and a reaction time of 3 days, mp 79–80.5°C (ether–hexane). *Anal.* calcd. for $C_{14}H_{18}O_3S$: C 63.12, H 6.81, S 12.04; found: C 62.78, H 6.86, S 12.34. The CH_3 group occurred at 1.26 ppm.

The epoxy sulfone **2***f* (280 mg) was treated with $MgBr_2$ in ether at −30°C for 3 h. The yield of 1-bromo-1-acetylcyclohexane was 250 mg (89%).

Reaction of the α-chloroethyl phenyl sulfoxide (2.22 g) with 1.1 equiv. of CH_3Li followed by 1.77 g of cyclohexanone gave two components which were separated by fractional crystallization. From CH_2Cl_2–pentane was obtained 1.53 g (45%) of **6***f* as colorless plates, mp 163–164°C; ir: 3400, 1082, 1038 cm^{-1}; nmr: 0.8–2.4 (m, 10H), 1.46 (s, 3H), 3.4 (OH), 7.4–7.9 (m, 5H). *Anal.* calcd. for $C_{14}H_{19}ClO_2S$: C 58.64, H 6.63; found: C 58.52, H 6.79.

Recrystallization of the mother liquors from ether–pentane gave 1.55 g (55%) of **10**, identical with that produced from the reaction of $PhS(O)CH_2Li$ and cyclohexanone (23).

When LDA was used to generate the anion of α-chloroethyl phenyl sulfoxide rather than methyllithium, the yield of **6***f* was 70%. (See also the similar preparation of **6***e* above.)

The chlorohydrin sulfoxide **6***f* was converted in near quantitative yield into the epoxy sulfoxide **9***f*, mp 60–62°C (CH_2Cl_2–pentane); nmr: 1.31 (s, 3H), 1.4–2.5 (m, 10H), 7.4–7.8 (m, 5H); ir: 1045 cm^{-1}. *Anal.* calcd. for $C_{14}H_{18}O_2S$: C 67.18, H 7.25; found: C 67.05, H 7.32.

Series g

α-Chloroethyl Phenyl Sulfoxide and Benzophenone

Reaction of the lithio salt obtained from 2.47 g of the above sulfoxide with benzophenone (2.35 g) gave directly 2.73 g (68%) of the epoxide **9***g* after purification on basic Al_2O_3. The epoxide was obtained as a colorless oil having its parent ion at *m/e* 334; ir: 1078 and 1098 cm^{-1}; nmr: 1.2 (s, 3HO), 7.2–7.8 (m, 15H). In addition to **9***g*, 1.33 g of the hydroxy sulfoxide obtainable also from benzophenone and $PhS(O)CH_2Li$ was formed (23).

Series h

Chloromethyl Methyl Sulfone and Cyclohexanone

The chlorohydrin sulfone **6***h*, mp 73–74°C (ether–pentane), was obtained in 78% yield using procedure I; ir: 3520, 1315, 1126 cm^{-1}; nmr: 1.3–2.1 (m, 10H), 3.08 (s, 3H), 3.20 (OH), 4.67 (s, 1H); $M^{\ddagger}$ 226 and 228 (3:1).

The above chlorohydrin was converted in 94% yield to the epoxy sulfone **2***h*, colorless liquid; ir: 1320, 1145 cm^{-1}; nmr: 1.38–2.32 (m, 10H), 3.02 (s, 1H), 3.86 (s, 1H). *Anal.* calcd. for $C_8H_{14}O_2S$: C 55.14, H 8.10; found: C 55.01, H 7.99.

The chlorohydrin sulfoxide (**6***h*) was obtained in 15% isolated yield by reaction of cyclohexanone (830 mg) to the anion of chlormethyl methyl sulfoxide generated from 867 mg of sulfoxide and *n*BuLi, mp 144–146°C (ether–pentane); nmr: 1.4–2.1 (m, 10H), 2.65 (s, 3H), 2.94 (OH), 4.36 (s, 1H); ir: 3450, 1065 cm^{-1}. *Anal.* calcd. for $C_8H_{15}ClO_2S$: C 45.60, H 7.18, Cl 16.83, S 15.22; found: C 45.73, H 7.23, Cl 16.80, S 15.05.

The chlorohydrin sulfoxide **6***h* was converted in 94% yield to the epoxy sulfoxide (**9***h*); colorless oil having an ir band at 1035 cm^{-1}; nmr: 1.4–2.1 (m, 10H), 2.68 (s, 3H), 3.65 (1H). Oxidation with MCPBA afforded the sulfone **2***h*, identical with the one described above.

Series i

Chloromethyl Methyl Sulfoxide and Benzophenone

Benzophenone (1.31 g) was added to a solution of the lithio sulfoxide obtained by reacting 8.3 mmol of *n*BuLi with 807 mg of chloromethyl methyl sulfoxide. Usual work-up followed by recrystallization from ether–pentane gave 345 mg (17%) of the epoxy sulfoxide (**9***i*) resulting from cyclization of the intermediate chlorohydrin sulfoxide, mp 102.5–104°C; ir: 1160, 1135 cm^{-1}; nmr: 2.58 (s, 3H), 4.6 (s, 1H), 7.4–7.5 (m, 10H); ms *m/e* 258.

Series j, k, l

*Reactions of α-Lithio-*n*-butyl* n*-Butyl Sulfoxide with Ketones*

The above α-lithio salt was reacted according to procedure I with acetone, cyclohexanone, and benzophenone. The results were (*i*) chlorohydrin sulfoxide **6***j* (66%), colorless oil; nmr: 0.8–1.2 (m, 6H), 1.47 (s, 3H), 2.01 (s, 3H), 1.2–2.2 (m, 8H), 2.4–3.2 (m, 2H), 4.4 (OH); (*ii*) chlorohydrin sulfoxide **6***k* (71%), mp 88–90°C (ether–pentane); nmr: 0.8–2.4 (m, 18H), 2.6–3.3 (m, 2H), 3.08 (OH). *Anal.* calcd. for $C_{14}H_{27}ClO_2S$: C 57.06, H 9.17; found: C 57.21, H 9.25. The chlorohydrin sulfoxide **6***l* was not isolated, instead the epoxy sulfoxide **1** was obtained in 34% yield as a colorless powder, mp 74–75°C, after Al_2O_3 chromatography; nmr: 0.6–2.4 (m, 14H), 2.6–2.9 (m, 2H), 7.2–7.7 (m, 10H). *Anal.* calcd. for $C_{21}H_{26}O_2S$: C 73.66, H 7.66; found: C 73.63, H 7.46.

In the condensations involving cyclohexanone and benzophenone a 14 and 11% yield, respectively, of the condensation products expected from the reaction of $nBuS(O)CH_2^-Li^+$ and the ketones were obtained (12).

The chlorohydrin sulfoxide **6***j* was converted using method II into epoxy sulfoxide **9***j* in 92% yield, colorless oil; nmr: 0.8–1.2 (m, 6H), 1.2–2.2 (m, 8H), 1.50 (s, 3H), 1.62 (s, 3H), 2.5–2.8 (m, 2H). *Anal.* calcd. for $C_{11}H_{22}O_2S$: C 60.45, H 10.15; found: C 60.62, H 10.27.

Series m–p

The epoxy sulfones **2***m–p* were all prepared using the phase-transfer technique.

Compound **2**m—colorless oil; nmr: 1.2–2.3 (m, 7H), 3.5–3.7 (m, 1H), 4.01 (d, J = 2 Hz, 1H), 5.6 (s, 2H), 7.4–8.1 (m, 5H).

Reaction of **2***m* with $MgBr_2$ in ether furnished **24***m* as a colorless oil; ir: 1720 cm^{-1}; nmr: 1.3–2.5 (m, 7H), 3.14 (d of d, J = 7 and 4 Hz, 1H), 4.6 and 4.8 (m, 2H), and 9.41 (d, J = 4 Hz, 1H); ms *m/e*: 204 and 202 ($M^{\ddagger}$), 175 and 173 ($M^{\ddagger}$ − CHO), 150 and 148 ($M^{\ddagger}$ − C_4H_6), 123 ($M^{\ddagger}$ − Br).

Compound **2**n—mp 123–125°C; ir: 1145 (s), 1300 (s), 1310 (s) cm^{-1}; nmr: 1.60 (s, 3H), 1.4–2.4 (m, 7H), 3.6–3.8 (m, 1H), 5.7–5.8 (m, 1H), 7.5–8.0 (m, 5H). *Anal.* calcd. for $C_{15}H_{18}O_3S$: C 64.72, H 6.49; found: C 64.70, H 6.33.

Rearrangement of **2***n* with $MgBr_2$ gave **24***n* as a clear oil after chromatography; nmr: 1.2–2.6 (m, 7H), 2.19 (s, 3H), 3.12 (d, J = 7 Hz, 1H), 5.6–5.9 (m, 2H); ms *m/e*: 214 and 216 ($M^{\ddagger}$), 201 and 199 ($M^{\ddagger}$ − 15).

Compound **2**o—mp 98.5–99.5°C; ir: 1140 (s), 1300 (s), 1320 (s) cm^{-1}; nmr: 1.39 (s, 3H), 4.90 (s, 1H), 7.2–8.1 (m, 10H). *Anal.* calcd. for $C_{15}H_{14}O_3S$: C 65.63, H 5.14, S 11.69; found: C 65.71, H 5.06, S 11.87.

Rearrangement of **2***o* with $MgBr_2$ gave 1-bromo-1-phenyl-2-propanone; nmr: 2.12 (s, 3H), 5.43 (s, 1H), and 7.2–7.6 (m, 5H); $M^{\ddagger}$ at *m/e* 212 and 214.

Compound **2**p—colorless solid, mp 94–95°C; nmr: 3.00 (s, 3H), 4.22 (d, J = 2 Hz, 1H), 4.50 (d, J = 2 Hz, 1H), and

7.2–7.5 (m, 5H). *Anal.* calcd. for $C_9H_{10}O_3S$: C 54.54, H 5.05; found: C 54.42, H 5.17.

Preparation of ***22***

The unsaturated sultone **21** was prepared as described (24). To a solution of ~500 mg of per-trifluoroacetic acid in 25 mL of CH_2Cl_2 was added with stirring 882 mg of sultone **21** in 25 mL of CH_2Cl_2. The reaction mixture, which became yellow and cloudy, was refluxed for 30 min, then worked up by washing with 10% Na_2CO_3 and saturated NaCl solution. The crude black oil obtained upon evaporation of the organic solvents was chromatographed on Al_2O_3. β-Keto sultone **22**, mp 150–151°C was obtained in 24% yield, 34% based on recovered starting material; ir: 1725, 1375, 1185, 995 cm^{-1}; nmr: 1.8–2.3 (quintet, 2H), 3.0–3.3 (m, 2H), 4.64 (t, J = 6 Hz, 2H), 7.2–7.5 (m, 10H). *Anal.* calcd. for $C_{17}H_{16}O_4S$: C 64.55, H 5.10; found: C 64.38, H 3.58.

Preparation of ***19*** *(*n = *1,2)*

Thiane 1,1-dioxide or thiepane 1,1-dioxide were converted into the α-lithio derivative in the usual manner in THF at −70°C and reacted with benzophenone. The product was isolated and dehydrated to **19** by refluxing in benzene containing a trace of toluene sulfonic acid for 1 h. The overall yield in both instances approached 90%. Compound **19**, n = 1, showed peaks at δ 1.8–2.5 (m, 4H), 7.0–7.6 (m, 10H), and 2.6–3.0 (m, 2H), whereas that of **19**, n = 2, had peaks at 1.6–2.2 (m, 6H), 2.4–2.7 (m, 2H), 3.0–3.3 (m, 2H), and 7.0–7.4 (m, 10H).

The epoxidation rearrangement was carried out by refluxing the unsaturated sulfones with a four-fold excess in MCPBA in benzene overnight. The yield of **19***a* was 91% after column chromatography, mp 108°C (CH_2Cl_2–pentane); nmr: 1.1–3.2 (m, 8H), 7.0–7.7 (m, 10H); ir: 1725, 1315, 1123 cm^{-1} *Anal.* calcd. for $C_{18}H_{18}O_3S$: C 68.78, H 5.77; found: C 68.70, H 5.90.

Received May 29, 1978

SANDRA L. KIELLAND, PONNAMPALAM MATHIAPARANAM, LEWIS A. SLOTIN, and ROSS E. WILLIAMS. Can. J. Chem. **57**, 267 (1979).

Two peptides, H-Gly Ser Phe Lys-NH_2 and H-Gly Ser Phe Lys Leu-NH_2, whose sequence may be found in a conserved and phosphorylated site in histone H-1 have been synthesized. Their ability to act as substrates for several protein kinase preparations have been examined. In addition, their ability to inhibit the action of several protein kinases of muscle origin was also tested.

SANDRA L. KIELLAND, PONNAMPALAM MATHIAPARANAM, LEWIS A. SLOTIN et ROSS E. WILLIAMS. Can. J. Chem. **57**, 267 (1979).

On a synthétisé un tétrapeptide et un pentapeptide, H-Gly Ser Phe Lys-NH_2 et H-Gly Ser Phe Lys Leu-NH_2, ayant la séquence d'un site totalement conservé dans les histones H-1 et H-5. Il a été antérieurement démontré que ce site acceptait du phosphate pendant le fonctionnement de la cellule. On a examiné l'introduction du phosphate dans les peptides par quelques kinases de protéine, ainsi que l'inhibition par les peptides de l'activité enzymatique des kinases de protéines d'origine musculaire.

[Traduit par le journal]

Introduction

The lysine-rich histones H-1 and H-5[5] are believed to play an important role in the regulation of nuclear DNA transcription and condensation (1–5). Histone H-1 and H-5 fractions have been isolated from many different sources. The partial amino acid sequences of histone H-1 fractions from calf (6), rabbit (5, 7), sea urchin (8), and trout (9) have been reported. Partial amino acid sequences of the functionally-related histone H-5 found in chicken (10, 11), goose (12), duck (11), and pigeon (12) have also been reported.

The amino acid sequences of each of the histones may be subdivided into three regions: (*i*) the N-terminal region, composed of about 35–45 amino acid residues; (*ii*) the central region, composed of about 60–70 amino acid residues; (*iii*) the C-terminal region, composed of the remainder of the 190–225 amino acid residues. Although histone amino acid sequences tend to be highly conserved, only the central region of both these histones has been found to exhibit a high degree of homology (Fig. 1). In addition to being highly conserved this region has also been implicated in the observed salt-induced aggregation of histone H-1 in solution (13, 14), in the observed effect of histone H-1 phosphorylation on histone H-1 aggregation (15, 16), and in the observed phosphorylation of histone H-1 by a crude preparation of protein kinase from calf liver (17). The amino acid sequence of the phosphorylated peptide was reported to be (Thr, Ser, Gly_2, Ala)-Gly-Ser(PO_4)-Phe-Lys (18). This sequence is found in a very highly conserved section of the central region of both histones H-1 and H-5 (Fig. 1).

Bearing in mind the highly conserved nature of this section, its phosphorylation, its implication in chromosome condensation, and the observation that the phosphorylation by intracellular protein kinases may be controlled, in part, by the amino acid sequence surrounding the phosphorylated serine or threonine (19, 20) and, in part, by the secondary structure surrounding the site (21), we have prepared two peptide fragments related to this highly conserved and phosphorylated section of the central region of the histones H-1 and H-5. In this report we wish to describe the synthesis of these two fragments, their ability to act as substrates for four exogenous protein kinase preparations and their effect on the phosphorylation of purified calf thymus histone H-1 by three exogenous protein kinases from muscle.

FIG. 1. A highly conserved sequence in histones H-1 and H-5. Areas of sequence homology are boxed in and include functionally conserved residues, i.e., Lys → Arg. Where known, numbers are inserted to indicate the position of the -Gly Ser Phe Lys Leu- sequence in the histone.

reagent grade and were used as received unless otherwise noted. Solvents were purified as follows: Dimethylformamide (DMF) by distillation under reduced pressure from barium oxide (nitrogen purged system); 1,2-dimethoxyethane (DME) by distillation from lithium aluminum hydride (LAH); triethylamine (TEA) by distillation from barium oxide (nitrogen purged system); pyridine by distillation from *p*-toluenesulfonyl chloride and redistillation from LAH; water by resin deionization and distillation from glass; trifluoroacetic acid (TFA) by distillation from phosphorous pentoxide.

tert-Butyloxycarbonyl (Boc) amino acids and other amino acid derivatives were purchased from Beckman Instruments (Spinco Division) Toronto, Ont., Canada and Bachem Inc., Torrance CA, U.S.A. Disodium adenosine triphosphate, disodium glycerophosphoric acid, theophylline, ethyleneglycolbis(β-aminoethyl ether)-*N*,*N*′-tetraacetic acid (EGTA), 3′,5′-cyclic adenosine monophosphate (cAMP), crude calf thymus histone (lysine-rich histone fraction 1), and salmon protamine were purchased from Sigma Chemical Co., St. Louis MO, U.S.A. Protein kinases from rabbit skeletal muscle (peak I and peak II) and bovine cardiac muscle (peak II), isolated as crude fractions after DEAE-cellulose chromatography (22), were also purchased from Sigma Chemical Co. Biogel P-60 was purchased from Bio-Rad Inc., Mississauga, Ont., Canada. Cellulose chromatographic plates (MN300, 0.5 mm) were purchased from Analtech Inc., Newark, DE, U.S.A. Stoppered polypropylene vials, Whatman chromatographic paper (3 MM), Gelman Instant Thin-layer Chromatographic sheets (ITLC-SG) were purchased from either Fisher Scientific Ottawa, Ont., Canada or Canlab, Montreal, P.Q., Canada. Kemptide (Leu-Arg-Arg-Ala-Ser-Leu-Gly) was purchased from Peninsula Laboratories, San Carlos, CA, U.S.A. Amino acid analysis: Leu:Arg:Ala:Ser:Gly (2.15:2.04:1.08:1.00:1.00).

Calf thymus histone H-1 was purified by gel filtration on Biogel P-60 according to the published procedure of Böhm *et al.* (23, 24).

^{32}P-ATP(γ^{32}P adenosine triphosphate, tetra(triethylammonium) salt) (2–10 Ci/mmol) was purchased from New England Nuclear, Montreal, P.Q., Canada. Stock ^{32}P-ATP solutions were prepared as follows: the solution of labelled ATP (approximately 1 mCi) was diluted to 2.0 ml with incubation buffer. An aliquot (500 μl) was mixed before use with 2.5 ml of incubation buffer (^{32}P-ATP approximately 0.1 mCi/ml).

Elemental analyses were done on a Perkin-Elmer CHN analyzer, model 240. Amino acid analyses were done on a Beckman analyzer, model 120C equipped with a multisample inlet and automatic integrator. Samples for amino acid analysis were prepared by hydrolysis in 6 *N* HCl at 110°C for 24 h. Optical rotations were taken on a Perkin-Elmer polarimeter, model 141. Melting points were determined in an open capillary on a Gallenkamp melting point apparatus. Liquid scintillation counting was done on a Beckman counter LSC-250. Samples were prepared for counting in low potassium vials using 10 ml of a scintillation cocktail (8 g Omnifluor in 2 ℓ toluene–2-methoxyethanol (1:1, v/v)). A ^{14}C-^{32}P window was used in all cases in order to overcome energy profile shifts caused by quenching. Enzyme incubations were done in a Fisher-Versabath at 37.0 ± 0.5°C. High voltage electrophoresis was done in an apparatus equipped with a 20-cm water-cooled platen (10–15°C). Power for the apparatus was supplied by a Buchler high voltage supply. A 30 V/cm gradient was applied for 1–1.5 h to strips of paper (Whatman 3 MM) which had been equilibrated with citrate buffer (sodium citrate 0.05 *M*, citric acid 0.05 *M*, pH 3.5). After electrophoresis the strips were dried and cut into pieces (1 cm × 3 cm). The pieces were placed into vials and the radioactivity levels were determined.

Bovine Liver Protein Kinase Isolation

A crude fraction of protein kinase activity from an acetone powder of beef liver (animal weight less than 200 kg) was prepared by the procedures outlined by Langan (25). The crude fraction referred to here is that which was eluted at the calcium phosphate gel step. The protein kinase activity was eluted from the gel as described with 0.5 *M* phosphate buffer, pH 7.5, precipitated with $(NH_4)_2SO_4$ (75% saturation), collected and redissolved in 0.05 *M* phosphate buffer, pH 7.5. The preparation was dialyzed overnight at 4°C against several changes of 0.05 *M* phosphate buffer, pH 7.5. Protein concentration was determined spectrophotometrically (280 nm) to be 1.5 mg/ml (26, 27). Protein kinase activity was determined in the presence of cAMP and was found to be 12 ± 2 pmol ^{32}P incorporated per minute per milligram of protein (60 min assay, calf thymus histone H-1 (40 μg) as substrate).

Enzyme Assays

Substrate Activity

The peptide to be tested for substrate activity was incubated with either the bovine cardiac muscle or rabbit skeletal muscle enzyme preparations as in the following procedure: 50 μl γ-^{32}P ATP stock solution (0.1 mCi/ml), 5 μl c-AMP (from a 10 m*M* stock solution), 20 μl protein kinase enzyme preparation (bovine cardiac enzyme, 1 mg/ml stock solution; rabbit skeletal muscle, 2 mg/ml stock solution; bovine liver preparation, 1.5 mg/ml stock solution), and 5 μl of the peptide stock solution were incubated at 37°C for 1 h. Kemptide stock solutions used were approximately 30 m*M*. The other peptide stock solutions were approximately 30 m*M*. All solutions, save that of the peptide which was in water, contained the following buffer; buffer *A*: 50 m*M* β-glycerophosphoric acid disodium, 10 m*M* magnesium acetate tetrahydrate, 10 m*M* sodium

[a]Molar rotation (based on lysine concentration) $[M_D]$ −26.5 (c, 30.8 m*M*, H_2O).
[b]Molar rotation (based on lysine concentration) $[M_D]$ −341.9 (c, 43.8 m*M*, H_2O).

fluoride, 2 m*M* theophylline, and 0.3 m*M* EGTA, pH 7.0 (adjusted with 10% v/v HCl). Controls excluding the peptide and enzyme were run simultaneously. After the incubation period an aliquot (10 µl) was removed and applied to a strip of Whatman 3 MM chromatographic paper in preparation for high voltage electrophoresis as described above.

Inhibition Assays

The ability of the peptide to interfere with the phosphorylation of pure histone H-1 by protein kinase preparations was assessed as follows: 50 µl γ-^{32}P ATP stock solution (0.1 mCi/ml), 10 µl cAMP (from a 10 m*M* stock solution), 10 µl pure histone H-1 (from an 8 mg/ml stock solution), and either 10 µl of bovine cardiac muscle protein kinase preparation (from a 0.1 mg/ml stock solution) or 20 µl of rabbit skeletal muscle protein kinase preparation (from a 0.1 mg/ml stock solution). The total volume was made up to 200 µl with buffer. All stock solutions, save that of the histone which was made up in water, contained buffer *A*. The reaction mixture was incubated at 37°C and aliquots (10 µl) were removed at 5-min time intervals in order to determine the rate of incorporation of phosphorous into the histone H-1. Under all circumstances linear rates of incorporation were observed during the initial stages of the reaction. Phosphorous incorporation into protein was assayed using Gelman ITLC-SG strips and 20% trichloroacetic acid in 0.4 *M* KCl as irrigant (28). After irrigation, strips were heat-dried, the origins removed and deposited into vials in preparation for counting.

Peptide Syntheses

The elemental analysis of intermediate compounds are reported in Table 1.[6,7] The physical constants of the intermediate compounds are given in Table 2. Compounds were synthesized as given below.

[6]All analyses were within acceptable limits C ± 0.2%, H ± 0.2%, N ± 0.3%.

[7]Table 1 may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Cbz
Boc Phe Lys-NH_2
Cbz

Boc Phe Lys OMe (20 g, 37 mmol, prepared as described previously (29)) was dissolved in cold (0°C) methanol (500 ml) and NH_3 bubbled in over a period of 1.5 h. The solution was then stoppered and placed in the refrigerator for 18 h. The solution was concentrated to dryness *in vacuo* and the residue recrystallized from ethyl acetate; yield 13.8 g (71%).

OBz Cbz
Boc Ser Phe Lys-NH_2
OBz

Boc Ser (4.43 g, 15 mmol) was dissolved in 100 ml DME–pyridine (95:5) and cooled to 0°C. *N*-Hydroxysuccinimide (15 mmol, 1.71 g) and DCC (15 mmol, 3.08 g) were added and the mixture stirred at 0°C for 6 h. The mixture was filtered and

Cbz

the filtrate concentrated *in vacuo*. Boc Phe Lys NH_2 (15 mmol, 7.9 g) was treated with trifluoroacetic acid–methylene chloride (1:1, 30 ml) and allowed to stand at room temperature for 2 h. The solution was then concentrated and the residue triturated with ether. The residue was dissolved in DME–DMF (1:1, 30 ml) and cooled to 0°C. Triethylamine (30 mmol, 4.2 ml) was

OBz

added followed by Boc Ser OSu in DME–DMF (1:1, 30 ml). The mixture was stirred overnight at 0°C and then concentrated. Water (100 ml) was added and the solution extracted with ethyl acetate (3 × 300 ml). The ethyl acetate was then washed with cold 0.1 *N* HCl (300 ml), 5% $NaHCO_3$ (cold, 300 ml), and cold water (300 ml). The ethyl acetate was dried over sodium sulfate, filtered and concentrated. The residue was recrystallized from ethyl acetate to yield 5.88 g (56%).

OBz Cbz
Boc Gly Ser Phe Lys-NH_2
OBz Cbz

Boc Ser Phe Lys NH_2 (0.35 g, 0.5 mmol) was treated with TFA–CH_2Cl_2 (3 mmol, 1:1) at room temperature for 2 h. The solution was concentrated and the residue triturated with

ether. The residue was dissolved in DME (5 ml) and cooled to 0°C. Triethylamine (0.5 mmol, 75 μl) was added followed by Boc Gly (0.5 mmol, 0.088 g) and EEDQ (0.5 mmol, 0.123 g) and the reaction stirred at 0°C overnight. After 20 min the mixture became a gummy paste. After 18 h the reaction was concentrated *in vacuo* and the residue washed with ether (3 × 50 ml), water (100 ml), and isopropanol (100 ml). The residue was then crystallized from methanol to yield 0.18 g (48%).

H-Gly Ser Phe Lys-NH_2
OBz Cbz

Boc Gly Ser Phe Lys NH_2 (0.1 g, 0.13 mmol) was treated with TFA–CH_2Cl_2 (2 ml, 1:1) at room temperature for 1 h. The reaction mixture was concentrated *in vacuo* and the residue triturated with ether. The residue was dissolved in methanol – acetic acid (10:1, 11 ml) and hydrogenated at room temperature and atmospheric pressure for 4 h over palladium oxide (Pd oxide). Analysis by tlc on cellulose in butanol – pyridine – acetic acid – water (15:10:3:12) and in butanol – acetic acid – water (5:2:3) showed a major ninhydrin positive spot at R_f 0.67 and 0.31, respectively. Preparative chromatography in the former solvent followed by elution with water gave, after filtration (Millipore, 0.45 μ), the required tetrapeptide (R_f 0.31); yield 0.062 mmol (42%). Amino acid analysis: Gly:Ser:Phe:Lys (0.97:0.97:1.01:1.00).

Cbz
Boc Lys Leu-NH_2
Cbz

Boc Lys DCHA (5.6 g, 10 mmol scale), HCl Leu OMe (1.8 g) were mixed in DME (50 ml). *N*-Hydroxysuccinimide (1.2 g) was added and the mixture was cooled to ice temperature, and stirred for 60 min. DCC (2.2 g) was added and the mixture stirred overnight during which time the ice coolant melted. Glacial acetic acid (2 drops) was added and the solution stirred for 5 min. CH_2Cl_2 (50 ml) was added and the precipitated dicyclohexylurea (DCU) was removed by filtration. The filtrate was evaporated, taken up in EtOAc, and washed with chilled acid (HCl), base ($NaHCO_3$), and water. The washed EtOAc was dried (Na_2SO_4) and evaporated (4.5 g). The residue was taken up in MeOH (200 ml), chilled to ice temperature, and NH_3 (gas) was blown in until the solution was saturated (15–20 min). The stoppered flask was kept 48 h at 4°C and the contents evaporated. The residue was crystallized from EtOAc–petroleum ether (bp 30–60°C); yield 3.85 g (88%).

Cbz
Boc Phe Lys Leu-NH_2
Cbz

Boc Lys Leu NH_2 (9.85 g, 20 mmol scale) was deblocked by treating with TFA–CH_2Cl_2 (1:1, v/v) (50 ml) for 30 min. The product was precipitated with ether (300 ml), washed with ether twice, and dried overnight under high vacuum. DMF–pyridine (9:1, v/v) (20 ml) and Boc Phe (4.94 g) were added to the residue and chilled to ice temperature. *N*-Hydroxysuccinimide (2.3 g), triethylamine (2.1 g), and DCC (4.3 g) were added and the solution stirred overnight during which time the ice coolant melted. Glacial acetic acid (2 drops) was added and the solution stirred for 5 min. The DCU precipitate was removed by filtration and the filtrate evaporated to dryness. The residue was taken up in EtOAc (4 ℓ) and washed with chilled acid (HCl), base ($NaHCO_3$), and water. The washed EtOAc was dried (Na_2SO_4) and evaporated. The residue was crystallized from EtOAc; yield 8.1 g (62%).

OBzl Cbz
Boc Ser Phe Lys Leu-NH_2
CBz

Boc Phe Lys Leu NH_2 (7.05 g, 10 mmol scale) was deblocked with TFA–CH_2Cl_2 (1:1, v/v) (50 ml) and the ether-insoluble product isolated as described above. DMF–pyridine
OBzl
(9:1, v/v) (100 ml), Boc Ser (3.2 g), and *N*-hydroxysuccinimide (1.3 g) were combined and the solution chilled in ice. DCC (2.3 g) was added and the solution stirred overnight during which time the ice coolant melted. The precipitated DCU was removed by filtration and the filtrate was added to a chilled solution of the above ether-soluble product in DMF–pyridine (9:1, v/v) (20 ml). Triethylamine (1.1 g) was added and the solution stirred for 48 h during which time the ice coolant melted. The solution was evaporated to dryness, taken up in cold EtOAc (10 ℓ), and washed with chilled acid (HCl), base ($NaHCO_3$), and water. The washed EtOAc was dried (Na_2SO_4), evaporated to 100 ml, filtered, and then evaporated to dryness. The residue was crystallized from MeOH–ether (1:40, v/v); yield 4.9 g (60%).

OBzl Cbz
Boc Gly Ser Phe Lys Leu-NH_2
OBzl Cbz

Boc Ser Phe Lys Leu NH_2 (2 g, 2 mmol scale) was deblocked with TFA–CH_2Cl_2 (1:1, v/v) (20 ml) and the ether-insoluble product isolated as described above. Boc Gly (1.8 g) was dissolved in chilled CH_2Cl_2 or DMF (10 ml) and DCC (1.01 g) was added. After stirring at ice temperature for 4 h the solution was filtered and added to the above ether-insoluble product dissolved in cold DMF (15 ml) containing pyridine (1 ml) and triethylamine (250 mg). The mixture was stirred for 4 days during which time the ice coolant melted. The solution was filtered and evaporated to dryness. The residue was crystallized from hot EtOAc (approximately 2 ℓ); yield 1.31 g (62%).

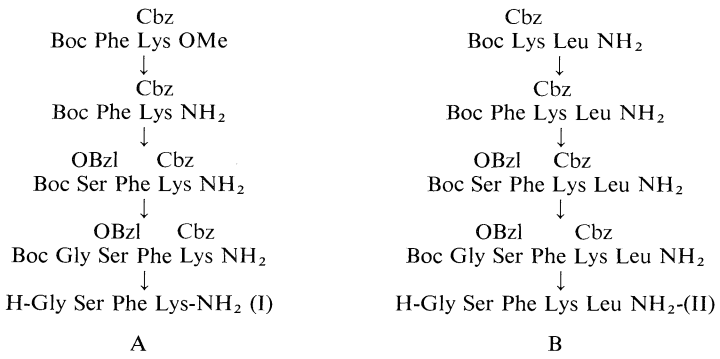
H-Gly Ser Phe Lys Leu-NH_2
OBzl Cbz

Boc Gly Ser Phe Lys Leu NH_2 (50 mg) was suspended in a stirred solution of trifluoroacetic acid (7.0 ml) containing a small amount of water (100 μl). The mixture was chilled in an ice bath and hydrogen bromide, which had been scrubbed with pure tetralin, was passed through the solution for 60 min. The reaction mixture was concentrated under reduced pressure (40°C) and anhydrous diethyl ether (approximately 150 ml) was added to the residue. The white solid which formed was collected by centrifugation, washed with diethyl ether (five times), and dried under high vacuum; yield 42.6 mg. Thin-layer chromatography on cellulose in ethyl acetate – pyridine – acetic acid – H_2O (20:10:3:5), v/v/v/v) showed one ninhydrin positive spot R_f 0.13; amino acid analysis: Gly:Ser:Phe:Lys:Leu (1.09:0.78 (0.96):0.96:1.00:1.05 (72 h)) (1.12:0.99(1.11):1.01:1.00:1.09 (48 h)). Figures in parentheses after serine are the ratios corrected for destruction of serine at the rate of 6% per 24-hour period. Paper electrophoretic mobility (citrate buffer pH 3.4, 30 V/cm, 5–10°C), R_{rel} 0.90 (relative to arginine).

Results and Discussion

Synthesis

Two peptides, related to the highly conserved sequence found in the central region of the H-1 and H-5 (Fig. 1), have been synthesized. They are I-H-Gly Ser Phe Lys-NH_2 and II-H-Gly Ser Phe Lys Leu-NH_2. They were synthesized by conventional methods according to Scheme 1A and 1B. Analyses and physical constants of the intermediates are given in Tables 1 and 2 respectively. Benzyloxycarbonyl (Cbz) blocking of the lysine ε-amino group, *tert*-butyloxycarbonyl (Boc) blocking of α-amino groups,



SCHEME 1

and *O*-benzyl (Bzl) group blocking of serine was used. Final deblockings of the fully blocked peptides were carried out either by catalytic hydrogenation or by treatment with HBr – trifluoroacetic acid – H_2O (30, 31). The tetrapeptide (I) was separated by thin-layer chromatography (tlc) on cellulose plates and isolated by extraction, filtration, and lyphilization. The pentapeptide product (II) was isolated by washing the fully deblocked material with ether. Homogeneity of the final products was assured by tlc and amino acid analyses.

Protein Kinase Substrate Activity

The two peptides which have been synthesized come from an area of histone H-1 which has been found to be phosphorylated by a crude preparation of calf liver protein kinase (17, 18). Both peptides were tested for their ability to act as substrates for the crude preparations of the peak II enzyme[8] activity from bovine cardiac muscle and the peak I and peak II enzyme activities from rabbit skeletal muscle. A peptide known to be a substrate of the enzymes was used as a control. This peptide, known as Kemptide (Leu-Arg-Arg-Ala-Ser-Leu-Gly), has been found to be a substrate of protein kinases (32). Peptides with similar structures have also been found in substrates of protein kinases (33–38). Work with these peptides and other substrates has suggested that a specific pattern of amino acids will be required in the peptide before it acquires the ability to act as a protein kinase substrate (19, 20, 33–38).

The two peptides and Kemptide were incubated separately with each of the crude muscle protein kinase preparations and the reaction products separated by electrophoresis. Phosphorous was incorporated readily into Kemptide by all protein kinase preparations. None of the muscle protein kinase preparations were able to incorporate measurable amounts of phosphorous into the tetrapeptide. Measurable amounts of phosphorous were, however, incorporated into the pentapeptide by the bovine cardiac muscle enzyme preparation. The results obtained with the crude peak II enzyme activity from bovine cardiac muscle are shown in Fig. 2*a*. Smaller, but still measurable, amounts of phosphorous were incorporated when the crude peak I and peak II enzyme activities from rabbit skeletal muscle were used.

The known structural requirements of the endogenous protein kinases (19, 20) and the ability of the pentapeptide to act as a phosphate acceptor suggest that there may have been a histone H-1 specific kinase present in calf liver, the tissue from which the phosphorylated peptide was originally isolated.

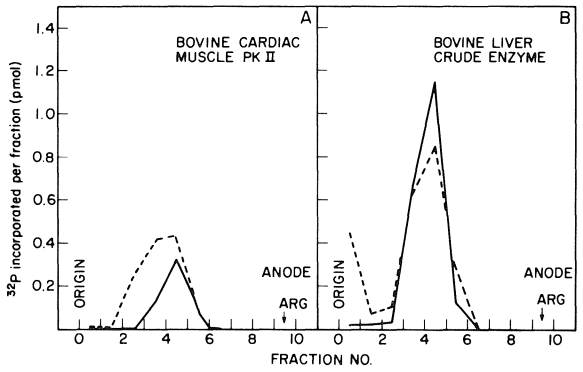


FIG. 2. The electrophoretic separation of the peptides after incubation with crude peak II protein kinase from bovine cardiac muscle and the crude protein kinase from beef liver. Radioactivity incorporated into the pentapeptide (II) (—) and Kemptide (---) by the crude peak II protein kinase from bovine cardiac muscle (Fig. 2*A*). Radioactivity incorporated into the pentapeptide (II) (—) and Kemptide (---) by the crude protein kinase from beef liver (Fig. 2*B*). Experimental conditions: incubation mixtures (180 μl) were 2.13×10^{-3} *M* in pentapeptide or 1.78×10^{-6} *M* in Kemptide. Incubations were carried out in buffer *A* at 37.5°C for 1 h with either crude bovine cardiac peak II protein kinase (20 μg) (Fig. 2*A*) or crude bovine liver protein kinase (30 μg) (Fig. 2*B*). An aliquot (10 μl) was electrophoresed in sodium citrate 0.05 *M*; citric acid 0.05 *M*, pH 3.5; voltage gradient, 30 V/cm; temperature, 10–15°C. Arg (=arginine) indicates the position of arginine after electrophoresis. Fraction number is equivalent to the distance migrated in centimetres.

[8]Peak numbers refer to the order of elution from a DEAE-cellulose column.

TABLE 3. Peptide inhibition of protein kinase phosphorylation of histone H-1

Peptide	Concentration[b] (*M*)	% inhibition of phosphate addition[a]		
		Bovine cardiac protein kinase, peak II[c]	Rabbit skeletal muscle protein kinase, peak I[d]	Rabbit skeletal muscle protein kinase, peak II[d]
H-Gly Ser Phe Lys-NH_2	1.50×10^{-3}	22±2	20±2	12±2
H-Gly Ser Phe Lys Leu-NH_2	2.13×10^{-3}	13±2	20±2	0
H-Leu Arg Arg Ala Ser Leu Gly-OH	2.28×10^{-3}	95	83	90
H-Leu Arg Arg Ala Ser Leu Gly-OH	1.78×10^{-6}	12±2	21±3	18±2

[a]Experimental conditions: buffer supplemented with cyclic AMP (10^{-6} *M*); incubation volume, 200 µl; temperature, 37°C; protein substrate, calf thymus histone H-1 (80 µg per assay); % inhibition is calculated as follows: $100\,(C_0 - C_p)/C_0\,100$ where $C_p = {}^{32}P$ counts incorporated in the presence of peptide and $C_0 = {}^{32}P$ counts incorporated in the absence of peptide. Errors (sd) indicated were determined from three or more experiments.
[b]Peptide concentrations are based on amino acid analyses and represent the final concentration in the assay.
[c]Incubation time, 10 min. Enzyme concentration, approximately 2 units per assay (approximately 1 µg per assay).
[d]Incubation time, 20 min. Enzyme concentration, approximately 4 units per assay (approximately 2 µg per assay).

Indeed, a histone H-1 specific kinase has been isolated from soyabean hypocotyls, but no indication of the distribution of the label within the histone was given (39). In addition, the distribution of Ser/Thr phosphorylated sites in rabbit thymus histone H-1 was recently shown to be influenced by the origin of the protein kinase preparation used for labelling (40).

When a crude preparation of protein kinase activity, isolated from bovine liver, was incubated with the pentapeptide substantial amounts of phosphate were incorporated into the peptide (Fig. 2*b*). This would suggest that this highly metabolically- and divisionally-active tissue may contain a highly site-specific histone H-1 kinase.

Inhibition Activity

Even though both peptides had very small or no substrate activity with the endogenous protein kinase preparations from muscle it is conceivable that they might be able to prevent the addition of phosphate to protein by binding at or near the substrate site. The ability of both peptides and Kemptide to inhibit the incorporation of phosphate into purified calf thymus histone H-1 by the exogenous enzymes was tested. Conditions were set up such that 2–3 phosphate groups of a total of 5–7 (41, 42) were incorporated into the histone during the time of the assay. The ability of the peptides to interfere with this incorporation was then tested. The results are given in Table 3. Kemptide was very effective at inhibiting the phosphorylation of histone H-1 by all the exogenous protein kinases. At 10^{-3} *M* it reduced incorporation by 80–90%. The tetra- and pentapeptides were also effective in inhibiting the reaction though not nearly to the same degree. Assays done with Kemptide showed that a 10–25% inhibition level could be achieved at 10^{-6} *M*, a concentration about a 1000-fold less than that of the two peptides. Some small differences between the tetra- and pentapeptides was noted. In general the pentapeptide was slightly less effective at inhibiting the enzymes. It also was unable to cause any inhibition of the rabbit skeletal muscle peak II protein kinase.

Although it is evident from the above results that the two peptides which have been synthesized are able to act as inhibitors of the endogenous enzymes studied, further work will be necessary before a full description of the actual mode of action of these peptides can be given.

Finally, two recent reports must be mentioned. It has recently been reported that several sequences surrounding serine-38 in calf thymus histone H-1 have been synthesized (43) and that this same serine-containing sequence, which is found only in the N-terminal section of calf thymus histone H-1, is able to act as a substrate for an endogenous protein kinase isolated from calf thymus nuclei (44). This peptide, Arg-Arg-Lys-Ala-Ser-Gly-Pro, has the same relationship of charged groups to the serine as in Kemptide and thus, fulfils not only the general requirements but also the specific requirements of protein kinases for recognition of primary amino acid sequences.

Nucleic acid related compounds. 29. Thionyl chloride reactions with adenine nucleosides. Course of nucleophilic displacements and a preferential route to the 2′-chloro-*arabino* isomer[1,2]

MORRIS J. ROBINS, PETER SPORNS, AND WOLFGANG H. MUHS[3]

Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 14, 1978

MORRIS J. ROBINS, PETER SPORNS, and WOLFGANG H. MUHS. Can. J. Chem. **57**, 274 (1979).

A multistage sequence gave 5′-*O*-pivalyl-3′-*O*-methyladenosine (**2***e*) which was treated with thionyl chloride in hot pyridine to give the corresponding 2′-chloro-*arabino* product **3***a*. Hydrogenolysis using tri-*n*-butyltin hydride and deblocking gave 2′-deoxy-3′-*O*-methyladenosine (**3***b*). Analogous treatment of a mixture of 3′(2′),5′-di-*O*-acetyladenosines (**5***a*,*b*) with $SOCl_2$–pyridine gave the 3′-*O*-acetyl-2′-chloro-*arabino* (**6***a*) and 2′-*O*-acetyl-3′-chloro-*xylo* (**7***a*) derivatives in a ratio of ~3:2, respectively. Hydrogenolysis and deprotection gave 2′-deoxyadenosine (**6***c*) and 3′-deoxyadenosine (**7***c*) (~3:2) in ~45% overall yield from adenosine (based on recovered starting materials). This represents the first example of preferential external nucleophilic displacement at C-2′ (vs. C-3′) in an equilibrating purine ribonucleoside system. Treatment of 9-β-D-xylofuranosyladenine (**9**) with $SOCl_2$–HMPA gave the 5′-chloro-5′-deoxy product **10***a* rather than the previously suggested 2′-chloro-2′-deoxy derivative.

MORRIS J. ROBINS, PETER SPORNS et WOLFGANG H. MUHS. Can. J. Chem. **57**, 274 (1979).

Une longue série de réaction conduit à la *O*-pivalyl-5′ *O*-méthyl-3′ adénosine (**2***e*) qui par traitement avec du $SOCl_2$ dans la pyridine à chaud fournit le produit chloro-2 *arabino* correspondant **3***a*. Une hydrogénolyse à l'aide de l'hydrure de tri-*n*-butylétain suivie d'un déblocage donne la désoxy-2′ *O*-méthyl-3′ adénosine (**3***b*). Si l'on traite de la même manière un mélange de di-*O*-acétyl-3′(2′),5′ adénosine (**5***a*,*b*) avec du $SOCl_2$–pyridine, on obtient les dérivés *O*-acétyl-3′ chloro-2′ *arabino* (**6***a*) et *O*-acétyl-2′ chloro-3′ *xylo* (**7***a*) dans des rapports respectifs de ~3:2. Une hydrogénolyse suivie d'une déprotection conduit à un mélange de la désoxy-2′ adénosine (**6***c*) et de la désoxy-3′ adénosine (**7***c*) (dans un rapport de 3:2) avec un rendement global de 45% à partir de l'adénosine (et en se basant sur les produits récupérés). Ce sont les premiers exemples d'une substitution nucléophile externe préférentielle au niveau de C-2′ (vs. C-3′) dans une purine en équilibre d'un système ribonucléoside. La réaction de la β-D-xylofurannosyl-9 adénine (**9**) avec le $SOCl_2$–HMPA fournit le produit chloro-5′ désoxy-5′ (**10***a*) plutôt que le dérivé chloro-2 désoxy-2 suggéré antérieurement.

[Traduit par le journal]

Nucleophilic displacements at C-2′ of purine-type ribonucleosides using external nucleophiles have proven to be very difficult (1). Attempted substitutions of 2′-sulfonate esters have failed[4] (2). Reactions involving 'symmetrical' C-2′,C-3′ species such as 2′,3′-acyloxonium cation intermediates (3, 4) 2′,3′-anhydro (epoxide) structures (1, 3*d*, *h*, 4*d*), and 2′,3′-thiiranium (episulfonium) ions (1) in the *ribo* series have resulted in highly predominant or sometimes exclusive (1, 3*b*,*d*,*g*,*h*, 4*b*,*c*) formation of the 3′-substituted *xylo* products. This can be seen to result from the sterically (base at C-1′ *cis*-vicinal to the site of S_N2 attack at C-2′) and electronically (5) (C-2′ bonded to the electronegative *N*,*O*-acetal anomeric carbon) favored attack at C-3′.

We have explored some reactions of adenine nucleosides with thionyl chloride and now wish to report that replacement of the 2′-hydroxyl function by chlorine with inversion of configuration occurs, albeit in low to moderate yields with significant accompanying decomposition. The known favorable O-2′ ⇄ O-3′ equilibrium of adenosine acetate esters (6*a*) has been employed to provide the first noted preferential functionalization at C-2′ with an *external nucleophile*[5] by treatment of the equilibrium mixture with thionyl chloride – pyridine.

The 3′-*O*-methyl ether function was first chosen to provide a 'fixed' model compound for reaction at C-2′ since it exerts minimal steric and electronic

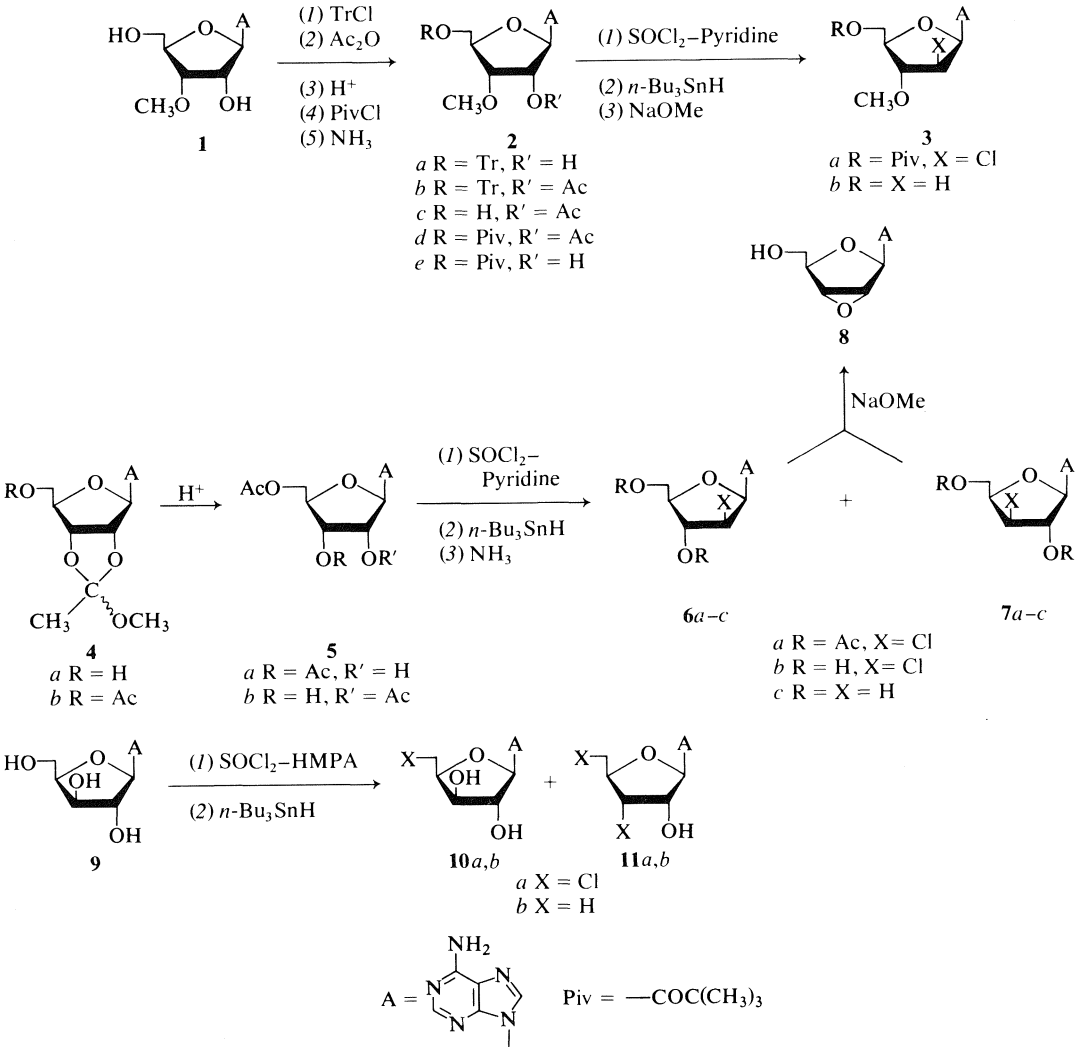
[3]Postdoctoral Research Associate.

[4]M. J. Robins and J. R. McCarthy, Jr. Unpublished observations. Treatment of 2′-*O*-tosyl- (or *p*-nitrobenzenesulfonyl-) tubercidin with ethanethiolate in ethanol or dry DMF under various conditions resulted in formation of tubercidin by presumed nucleophilic attack on sulfonate sulfur.

[5]Formation of purine X-8 → C-2′ cyclonucleosides occurs readily by intramolecular nucleophilic attack of 8-*N*, *O*, or *S* substituents at C-2′ (7).

0008-4042/79/030274-09$01.00/0



SCHEME 1

effects and is stable against migration or cleavage. Previous work in this laboratory has made 3′-*O*-methyladenosine (**1**) (and its 2′-*O*-methyl isomer) readily available (8). Selective blocking of **1** at O-5′ in high yield using pivalyl chloride was unsuccessful under several conditions as was selective deblocking of the 2′,5′-di-*O*-pivalyl derivative. Therefore, a multistage route was employed to prepare the desired O-5′ blocked model system.

Treatment of **1** (see Scheme 1) with triphenylmethyl chloride – pyridine gave 3′-*O*-methyl-5′-*O*-trityladenosine (**2***a*) in 66% yield (based on recovered **1**). Acetylation of **2***a* gave the 2′-*O*-acetyl derivative **2***b* which was detritylated in aqueous acetic acid to give 2′-*O*-acetyl-3′-*O*-methyladenosine (**2***c*) in 81% overall yield from **2***a*. Pivalylation of **2***c* gave the 2′-*O*-acetyl-5′-*O*-pivalyl derivative **2***d* plus some *N*-6,*O*-5′-dipivalylated material. Selective deacetylation (and *N*-6 depivalylation) occurred as expected using aqueous ethanolic ammonia to give the desired 3′-*O*-methyl-5′-*O*-pivalyladenosine (**2***e*) in 78% overall yield from **2***c*.

Treatment of **2***e* with thionyl chloride–pyridine under a variety of conditions (involving temperature, solvents, other tertiary organic bases, etc.) resulted in black mixtures from which ~20% maximum yields of 9-(2-chloro-2-deoxy-3-*O*-methyl-5-*O*-pivalyl-β-D-arabinofuranosyl)adenine (**3***a*) were isolated. The *arabino* configuration is suggested by the small coupling of H-2′ and H-3′ ($J_{2'-3'}$ ~ 1.6 Hz) which is indicative of *trans* orientation ($\phi_{H\text{-}2'\text{-}H\text{-}3'}$ ~ 115°) (9) on a five-membered ring (10). The

[a]Chemical shifts in δ ppm from internal Me_4Si; 'apparent' coupling constants in (Hz).
[b]Solvent: A, Me_2SO-d_6; B, $CDCl_3$.
[c]Sharp singlets.
[d]Broad singlets.
[e]Doublets.
[f]See 'Other resonance peaks.'
[g]Overlapping multiplets.
[h]Doublet of doublets, $J_{1'-2''}$ = 6.5 Hz, $J_{2'-2''}$ = −14 Hz.
[i]$J_{4'-5'}$ = 5.1 Hz, $J_{4'-5''}$ = 7.4 Hz, $J_{5'-5''}$ = −11.3 Hz.
[j]$J_{4'-5'}$ = 4.7 Hz, $J_{4'-5''}$ = 6 Hz, $J_{5'-5''}$ = −11.7 Hz.

anomeric proton coupling constant ($J_{1'-2'} = 4.2$ Hz) is in agreement with a *cis* orientation of H-1′ and H-2′ with $\phi_{H\text{-}1'\text{-}H\text{-}2'} \sim 46°$ (9). These coupling–dihedral angle parameters are compatible with the indicated *arabino* structure **3***a* in an *S*-type furanose conformation (11). Replacement of hydroxyl by chloro with net inversion was determined chemically in the corresponding reactions with 3′(2′),5′-di-*O*-acetyladenosines (*vide infra*).

Hydrogenolysis of the chloro function from **3***a* proceeded smoothly using tri-*n*-butyltin hydride under free radical conditions (12). Deprotection of the resulting deoxy compound gave 3′-*O*-methyl-2′-deoxyadenosine (**3***b*) in ~19% overall yield from **2***e* without isolation of intermediate products. The structure of **3***b* was conclusively confirmed by elemental analyses, ^{1}H nmr (see Table 1) and mass spectral data.

With conversion of hydroxyl to chloro at C-2′ successfully demonstrated in the above 'fixed' model, we sought a blocked precursor which could be deprotected to give a free deoxynucleoside after functionalization and hydrogenolysis. Equilibration of O-2′- and O-3′-acyl nucleoside esters is known to favor the 3′-isomer substantially (6*a*). Since rapid equilibration in the $SOCl_2$–pyridine reaction mixture would occur, no advantage in the use of esterifying acids which give higher 3′:2′ ratios during selective crystallizations (6*b*) was anticipated. Therefore the easily accessible di-*O*-acetyl derivative mixture was employed.

Treatment of the mixed ortho ester 2′,3′-*O*-methoxyethylideneadenosine (**4***a*) (3*e*) with acetic anhydride and a catalytic amount of 4-*N*,*N*-dimethylaminopyridine (13) gave the corresponding 5′-*O*-acetyl derivative **4***b*. This diastereomeric product was treated with acetic acid (6*a*) to provide 3′,5′-di-*O*-acetyladenosine (**5***a*) and 2′,5′-di-*O*-acetyladenosine (**5***b*) in a ratio of ~63:37, respectively (by ^{1}H nmr).

The isomeric mixture **5***a*,*b* was heated with $SOCl_2$–pyridine. A black mixture resulted from which 38% of **5***a*,*b* was recovered and a 29% combined yield (by uv) of the 2′-chloro-*arabino*- (**6***a*) and 3′-chloro-*xylo*- (**7***a*) di-*O*-acetyl isomers was obtained in a ratio of ~3:2 (by nmr). Longer reaction times at elevated temperatures resulted in disappearance of starting material (**5***a*,*b*) without significant increases in the isolated yields of chloro isomers (**6***a*,**7***a*). A black insoluble polymeric material, which did *not* release uv absorbing materials (adenine chromophore) upon treatment with acid or base at reflux, separated from the reaction solution. Therefore, heating was terminated after 30 min and a conversion (**5***a*,*b* → **6***a*,**7***a*) of ~47% based on recovered starting material was obtained. The structures of **6***a*,**7***a* were confirmed by exact mass measurement of the molecular ions and the ~3:2 ratio by integration of the respective anomeric proton resonance peaks.

Treatment of **6***a*,**7***a* with aqueous ethanolic ammonia gave 9-(2-chloro-2-deoxy-β-D-arabinofuranosyl)adenine (**6***b*) and 9-(3-chloro-3-deoxy-β-D-xylofuranosyl)adenine (**7***b*) which were separated by column chromatography and identified by comparison with known samples (3*e*). Treatment of **6***a*,**7***a* with methanolic sodium methoxide gave 2′,3′-anhydroadenosine (**8**) (3*d*), which confirmed the exclusive formation of *trans*-2′,3′-chloro and -acetoxy products as demanded by an S_N2 process.

The possibility of 2′,3′-acetoxonium ion formation followed by attack at C-2′ or C-3′ by chloride ion exists in the conversion of **5***a*,*b* to **6***a*,**7***a*. However, significant intervention of such dioxolenium ion intermediacy is precluded by the observed 3′- to 2′-chloro isomer ratio (~2:3) since it is known that markedly predominant attack at C-3′ by chloride (>6:1) occurs in such reactions (3, 4). It may also be noted that the ratio of chloro isomers (**6***a*:**7***a*) obtained closely approximates the isomeric ratio of the corresponding precursor diacetates (**5***a*:**5***b*). Secondary alkyl chlorosulfite esters are known to undergo S_N2 or S_N1 (S_Ni ion pair collapse) processes with inversion or retention of configuration in the resulting chloro compound (see for example ref. 14 and references therein). The mechanism is affected by solvent changes and by heating in the absence of solvent. The inversion reaction (S_N2) would be expected to be favored using pyridine as solvent (14*c*) and, additionally, S_Ni ion pair collapse (S_N1) (14*b*) would be strongly inhibited in the nucleoside system (i.e., generation of carbonium ion character at C-2′ bonded to the electronegative *N*,*O*-acetal anomeric C-1′).

Hydrogenolysis of **6***a*,**7***a* gave the expected di-*O*-acetyl deoxynucleoside mixture as indicated by exact mass measurement of the molecular ions. Deprotection and anion exchange chromatography (15) gave 2′-deoxyadenosine (**6***c*) and 3′-deoxyadenosine (cordycepin) (**7***c*) in 25 and 17% overall yields (by uv, based on recovered starting material) from **5***a*,*b* without isolation of intermediates. Corresponding crystallized product yields were 17 and 11%.

A final aspect of the present work involved clarification of a previously reported study. Chlorination at C-5′ of nucleosides using neat thionyl chloride has been reported (16). The Vilsmeier–Haack reagent (SOX_2–DMF) (17) and the related (18) SOX_2–hexamethylphosphoric triamide (HMPA) reagent

(19, 20) have been employed to effect halogenation at C-5′ of nucleosides, with concomitant C-3′ (di)halogenation having been observed with 2′-deoxy nucleosides (20)

Hogenkamp noted that the product of treatment of 9-β-D-xylofuranosyladenine (**9**) with $SOCl_2$–HMPA failed to react with the reduced vitamin B_{12} product, cob(I)alamin (20*a*). This cobalt species was known to be nucleophilically unreactive with secondary alkyl halides. Therefore, Hogenkamp postulated the formation of a neutral cyclic 3′,5′-*O*-phosphorotriamidate intermediate from the HMPA reagent. This would be inert to replacement with chloride at C-5′ and allow formation of the 2′-chloro-2′-deoxynucleoside upon collapse of the cyclic pentacovalent phosphorus intermediate during aqueous processing. The absence of secondary hydroxyl replacement upon analogous treatment of ribonucleosides was rationalized on the basis of a 2′,3′-*O*-phosphorotriamidate protective intermediate. Since the 2′-deoxy nucleosides were not expected to form such a cyclic structure (i.e., no *cis*-diol system), accompanying onium activation and replacement at C-3′ could proceed. Steric effects were invoked to rationalize the selective primary (C-5′) chlorination of 9-β-D-arabinofuranosyladenine (20*a*).

The experimental conditions noted (20*a*) were applied by us to 9-β-D-xylofuranosyladenine (**9**). A 71% yield of a monochloro product (**10***a*) was obtained which had mass spectral peaks consistent with loss of CH_2Cl from the molecular ion and with formation of the BHCH=CHOH ion (2′-hydroxyl group present) (21). The ^1H nmr spectrum of this compound had downfield shifts of H-5′, H-5″, and H-4′ and had nmr properties consistent with N-3 → C-5′ cyclonucleoside formation upon heating the spectral sample at 100°C. The monochloro product also failed to exhibit complexing with borate (as evidenced by electrophoresis and paper chromatography) in contrast to the large effects of borate on the migrations of the 3′,5′-*cis*-diol starting material **9**. The structure of **10***a* was conclusively demonstrated by hydrogenolysis of the 5′-chloro group to provide a compound with melting point, ^1H nmr, and mass spectral properties in harmony with the known (22) 5′-deoxy-9-β-D-xylofuranosyladenine (**10***b*).[6] This raises an interesting question with respect to the observed lack of reactivity of this primary C-5′-alkyl chloride (with a sterically butressing *cis*-3′-hydroxyl group) with cob(I)alamin (20*a*).

An alternative explanation for the observed selectivity of replacement of hydroxyl by chloride in reactions of ribonucleosides with $SOCl_2$–HMPA (19, 20) is that only the activated primary 5′-onium group is readily subject to nucleophilic displacement by chloride ion at the ambient temperatures employed. Secondary (C-3′) substitution is known to proceed much more easily with 2′-deoxy nucleosides than with ribonucleosides (1). Sufficient energy is apparently available at room temperature to smoothly effect 3′,5′-dichloro-2′,3′,5′-trideoxynucleoside formation in the 2′-deoxy series (20*a*, *c*). In harmony with this interpretation is the observation that a small quantity (~4%) of a 3′,5′-dichloro product (**11***a*) was produced along with 71% of the 5′-chloro-*xylo* compound (**10***a*) under the standard conditions. Treatment of **9** at elevated temperatures or at ambient temperature for extended times with freshly distilled $SOCl_2$–HMPA reagents resulted in yields of greater than 50% of the 3′,5′-dichloro derivative[6] (presumed to be the inverted *ribo* diastereomer, **11***a*) along with reduced quantities of **10***a*. Compound **11***a* was considerably less stable than **10***a* and was obtained in only ~20% yield at 60°C. Hydrogenolysis of **11***a* gave a product whose ^1H nmr and mass spectral properties were compatible with its assignment as the known (23) 3′,5′-dideoxyadenosine (**11***b*).

The present study has demonstrated that external nucleophilic displacement reactions can be effected at C-2′ in purine ribonucleosides. Although the replacement yields are low to moderate, the facile free radical mediated hydrogenolysis of the chloro function results in overall C-2′ deoxygenation in yields which compare favorably with prior intramolecular (24) and acyloxonium (3*e*) routes as well as with 2-deoxy sugar, base coupling syntheses (25). Preferential displacement at C-2′ over C-3′ by an external nucleophile was observed for the first time in a 2′ ⇄ 3′ equilibrating adenosine system (resulting from the 3′-ester blocking function equilibrium predominance). Although deoxygenation of nucleosides at C-2′ can be effected more conveniently by direct free radical mediated routes[7] (26), nucleophilic displacement is necessary for the introduction of substituents required for modified structures presently under investigation. The selectivity for primary alcohol replacement at C-5′ appears now to be uniform for reactions of the diastereomeric pentofuranosyladenine nucleosides with $SOCl_2$–HMPA, although secondary (3′) replacement can occur upon extended treatment at ambient temperature or upon heating.

Experimental

Melting points were determined on a Reichert microstage apparatus and are uncorrected. Nuclear magnetic resonance spectra were recorded on Varian HA-100 and Bruker 90 spec-

[6]We have been informed by Dr. R. Mengel that they have independently made the same observations regarding the hydroxyl → chloro transformations of compound **9**.

[7]M. J. Robins and J. S. Wilson. Unpublished experiments.

trometers with Me_4Si as reference. Ultraviolet spectra were recorded on Cary 15 or Pye Unicam SP 1700 spectrophotometers. Optical rotations were determined with a Perkin Elmer Model 141 polarimeter using a 10-cm, 1-mL microcell. Mass spectra (ms) were determined by the mass spectrometry laboratory of this department on AEI MS-2, MS-9, or MS-50 instruments at 70 eV using a direct probe and are quoted as percentage relative intensity of the most intense ion at $m/e > 134$. Elemental analyses were determined by the microanalytical laboratory of this department or by Schwarzkopf Microanalytical Laboratory, Woodside, New York. Water of hydration when indicated was verified in the nmr spectrum. Thin-layer chromatography was performed on Eastman Chromatogram sheets (silica gel No. 13181, indicator No. 6060). Developed chromatograms were evaluated under 2537 Å light. Preparative scale tlc was performed on ~1-mm thick Merck silica gel GF 254 (20 × 20 cm) plates. Solvent system E (SSE) is the separated upper phase of EtOAc–*n*-propanol–H_2O 4:1:2 (by volume). Column chromatography was performed using J. T. Baker No. 3405 silica gel. Evaporations were carried out using a rotating evaporator with aspirator or oil pump vacuum at <40°C. Coevaporations were effected by adding the specified solvent and re-evaporating. 'Diffusion crystallization,' which has been modified in this laboratory (*3e, g*), was effected by allowing a concentrated solution of the nucleoside in the first mentioned (dissolving) solvent to stand in a desiccator containing a large volume of the second (diffusing) solvent in which the material is insoluble at room temperature and the resulting crystals were collected by filtration. Compounds reacted in dry pyridine as solvent were dried by repeated dissolution in and evaporation of dry pyridine. Pyridine was refluxed over and distilled from calcium hydride before use. HMPA was distilled and stored over 4 Å molecular sieves. Toluene was dried using sodium wire. DMF used for optical rotations was distilled from calcium hydride under reduced pressure at <40°C and stored over Linde 4A molecular sieves. Other solvents, pivalyl chloride, and $SOCl_2$ were of reagent purity and were distilled before use. Tri-*n*-butyltin hydride solution (~1 *M*) was prepared by the Holý modification (27) of the original procedure (28). The 3′-*O*-methyladenosine (**1**) (8) and 9-β-D-xylofuranosyladenosine (**9**) (*3d*) were prepared as described. Adenosine was purchased from Terochem Laboratories Ltd., Edmonton, Alberta.

*3′-O-Methyl-5′-O-triphenylmethyladenosine (**2**a)*

To a stirred solution of 6.36 g (22.6 mmol) of **1** in ~100 mL of dry pyridine was added 5.70 g (20.4 mmol) of triphenylmethyl chloride. The solution was heated, with exclusion of moisture, for 2 h at 100°C and then cooled. The solution was concentrated to ~50 mL and poured into 150 mL of cold saturated $NaHCO_3$–H_2O. The resulting mixture was extracted with $CHCl_3$. The organic phase was washed with saturated $NaHCO_3$–H_2O, dried (Na_2SO_4), evaporated, and coevaporated with dry toluene. The resulting yellow glass was treated with $CHCl_3$ and applied to a silica gel column (5.5 × 40 cm, 300 g) packed in $CHCl_3$. The column was washed with 4.2 L of $CHCl_3$ and eluted with MeOH–$CHCl_3$ (1:24). The first 1.5 L was discarded and the following 1.8 L was pooled and evaporated. Crystallization of the residue from acetone gave 5.92 g (50%) of **2***a*. The original aqueous $NaHCO_3$ layer and extracts were combined and continuously extracted with CH_2Cl_2 to recover 1.51 g of starting material, giving a 65.6% yield of **2***a* based upon recovered starting material. Pure **2***a* had mp 120–122°C; uv (MeOH) max 259 nm (ε 16 300), min 240 nm (ε 9000); ms (200°C) *m/e*: 523 (0.1, M), 280 (100, M − CPh_3), 243 (56, CPh_3), 165 (66, CPh_3 − Ph), 164 (21, BHCHO), 148 (7.5, BCH_2), 136 (55, B + 2H), 135 (16, B + H). *Anal.* calcd. for $C_{30}H_{29}N_5O_4$: C 68.82, H 5.58, N 13.38; found: C 68.79, H 5.78, N 13.61.

*2′-O-Acetyl-3′-O-methyladenosine (**2**c)*

To an ice-cold stirred solution of 8.1 g (15.5 mmol) of **2***a* in ~80 mL of dry pyridine was added 1.72 mL (15.5 mmol) of Ac_2O dropwise with exclusion of moisture. This solution was stirred for 18 h at 5°C and a further 0.15 mL of Ac_2O was added. After 2 h stirring at 5°C, the reaction was allowed to warm to 19°C and 0.5 mL of Ac_2O was added. After 1.5 h at 19°C, the reaction mixture was poured with stirring into 200 mL of ice water and extracted with $CHCl_3$. The combined organic phase was washed with cold 10% $NaHCO_3$–H_2O, H_2O, evaporated, and coevaporated with dry toluene to leave 8.45 g of 2′-*O*-acetyl-3′-*O*-methyl-5′-*O*-triphenylmethyladenosine (**2***b*) as a white amorphous solid; ms (200°C) *m/e*: 322 (37, M − CPh_3), 306 (2.5, M − $OCPh_3$), 243 (23, CPh_3), 220 (3, BHCH=CHOAc), 178 (7, BHCH=CHOH), 165 (100, CPh_3 − Ph), 164 (11, BHCHO), 148 (7.5, BCH_2), 136 (43, B + 2H), 135 (24, B + H).

The solid **2***b* (less 0.1 g) was dissolved in 100 ml of 80% aqueous HOAc and heated at 100°C for 15 min with stirring. The pale yellow solution was poured into 300 mL of cold H_2O and extracted with Et_2O. The combined organic phase was back-extracted with 10% HOAc. The combined aqueous layers were evaporated to dryness and the residue was crystallized from 98% EtOH to give 4.09 g (83%) of **2***c*, mp 214.5–215.5°C; uv (MeOH) max 259 nm (ε 14 300), min 227 nm (ε 1600); ms (200°C) *m/e*: 323 (2, M), 293 (6.5, MH − $CH_2O(5')$), 280 (0.3, M − Ac), 264 (5, M − OAc), 220 (24, BHCH=CHOAc), 189 (6.0, sugar), 178 (16.5, BHCH=CHOH), 164 (32, BHCHO), 148 (16, BCH_2), 146 (5, sugar − Ac), 136 (100, B + 2H), 135 (65, B + H). *Anal.* calcd. for $C_{13}H_{17}N_5O_5$: C 48.29, H 5.30, N 21.66; found: C 48.02, H 5.38, N 21.70.

*3′-O-Methyl-5′-O-pivalyladenosine (**2**e)*

To an ice-cold stirred solution of 3.9 g (12 mmol) of **2***c* in 125 mL of dry pyridine was added 2.3 mL (18 mmol) of pivalyl chloride dropwise with exclusion of moisture. The solution was stirred for 18 h at 5°C and poured into 300 mL of ice-water. The aqueous solution was extracted with $CHCl_3$. The combined organic extract was washed with cold 10% $NaHCO_3$–H_2O, H_2O, evaporated, and coevaporated with dry toluene and then 98% EtOH to give 5.09 g of 2′-*O*-acetyl-3′-*O*-methyl-5′-*O*-pivalyladenosine (**2***d*) as a white solid containing about 20% of 6-*N*-pivalyl-9-(2-*O*-acetyl-3-*O*-methyl-5-*O*-pivalyl-β-D-ribofuranosyl)adenine (by nmr). The major compound showed ms calcd. for $C_{18}H_{25}N_5O_6$: 407.1805; found: *m/e* 407.1816.

The solid residue (less 0.1 g) was then dissolved in 125 mL of 95% EtOH and 100 mL of concentrated NH_3–H_2O was added. This solution was stirred at 24°C for 1.5 h, evaporated to a small volume and partitioned between 150 mL of H_2O and 300 mL of $CHCl_3$. The $CHCl_3$ extract was washed with cold 10% $NaHCO_3$–H_2O, H_2O, and evaporated. The resulting oil was 'diffusion crystallized' from acetone (*n*-pentane, desiccator) and the resulting solid was recrystallized in the same manner to give 2.42 g of pure **2***e*. The mother liquors were treated with concentrated NH_3–H_2O as above and after analogous workup and crystallization yielded a further 0.87 g of **2***e*. The mother liquors from this crystallization were again processed to give a further 0.18 g for a total yield of 3.47 g (79%) of **2***e*. The pure material had mp 138–139°C; uv (MeOH) max 259 nm (ε 13 400), min 227 nm (ε 1800); ms (200°C) *m/e* 365 (0.5, M), 350 (8.5, M − CH_3), 280 (0.5, M − Piv), 264 (3, M − OPiv), 178 (5.5, BHCH=CHOH), 164 (100, BHCHO), 148 (9, BCH_2), 136 (89, B + 2H), 135 (51, B + H). *Anal.*

calcd. for $C_{16}H_{23}N_5O_5 \cdot 0.25\ H_2O$: C 51.95, H 6.40, N 18.94; found: C 51.80, H 6.66, N 19.09.

*9-(2-Chloro-2-deoxy-3-O-methyl-5-O-pivalyl-β-D-arabinofuranosyl)adenine (**3**a)*

To an ice-cold stirred solution of 0.5 g (1.35 mmol) of **2***e* in ~30 mL of dry pyridine was injected (through a septum) 0.5 mL (6.95 mmol) of $SOCl_2$ with exclusion of moisture. The resulting red solution was stirred for 30 min and after warming to room temperature was placed in a 120°C oil bath for 1 h. The cooled black mixture was poured into 150 mL of ice water and extracted with Et_2O. The combined organic phase was washed with cold 10% $NaHCO_3$–H_2O, H_2O, evaporated, and coevaporated with toluene. The dark brown residue was treated with hot 98% EtOH and filtered. On cooling a brown nonnucleoside precipitate separated and was filtered. The resulting solution was evaporated, the residue was dissolved in $CHCl_3$, and applied to a silica gel column (30 g) packed in and washed with $CHCl_3$. Elution was then begun with MeOAc. The first 165 mL was discarded and the following 130 mL was evaporated to give 109 mg (21%) of crude **3***a* which gave 86 mg (16.6%) of pure product in two crops upon 'diffusion crystallization' from acetone (*n*-pentane, desiccator). Pure **3***a* had mp 185–187°C; uv (MeOH) max 258 nm (ε 14 300), min 226 nm (ε 2500); ms (210°C) *m/e*: 383 (2.5, M), 368 (1.5, M − CH_3), 352 (1.5, M − OCH_3), 298 (12, M − Piv), 282 (25, M − OPiv), 220 (2, B + H + Piv), 214 (3.5, sugar − Cl), 196 (2.5, BHCH=CHCl), 164 (35, BHCHO), 136 (100, B + 2H), 135 (51, B + H). *Anal.* calcd. for $C_{16}H_{22}ClN_5O_4$: C 50.06, H 5.78, Cl 9.24, N 18.25; found: C 49.77, H 5.90, Cl 9.40, N 18.49.

*3′-O-Methyl-2′-deoxyadenosine (**3**b)*

To a solution of 75 mL of dry pyridine and 0.57 mL (7.92 mmol) of $SOCl_2$ in a 500-mL three-necked round bottomed flask, fitted with a mechanical stirrer, dropping funnel, dry N_2 flow and in an ice bath, was added dropwise over 15 min, 0.58 g (1.57 mol) of **2***e* in 100 mL of dry pyridine. The solution was stirred for 10 min and then was heated at 120°C for 1 h. The resulting black mixture was poured into 75 mL of ice water and extracted with $CHCl_3$. The combined organic phase was filtered, evaporated, and coevaporated with toluene. The black residue was treated with $CHCl_3$ and adsorbed on 3 g of silica gel which was applied to a dry-packed silica gel column (1.6 × 36 cm, 25 g). The column was developed with MeOH–$CHCl_3$ (1:19). The initial 25 mL of eluate was discarded and the next 50 mL was evaporated.

The resulting oil was mixed with 25 mL of dry benzene, 10 mg (6.1 mmol) of AIBN (α,α′-azobisisobutyronitrile), and 5 mL of tri-*n*-butyltin hydride solution in benzene (~5 mmol) (27). This orange mixture was heated at reflux for 1 h and another 10 mg of AIBN was added. After a further 2.75 h at reflux the pale yellow reaction mixture was cooled, concentrated to about one third volume and slowly added to 200 ml of *n*-pentane. The precipitate formed was filtered, dissolved in $CHCl_3$, and evaporated.

The resulting glass was dissolved in 25 mL of MeOH containing 1.25 g (54 mmol) of sodium. After stirring for 0.5 h, H_2O was added and the reaction was neutralized with HOAc. The MeOH was evaporated and the aqueous solution was extracted with MeOAc. The combined organic extract was evaporated and the residue partitioned between 50 mL of H_2O and 50 mL of *n*-pentane. The aqueous layer was washed with *n*-pentane, concentrated , and applied to a column (2.5 × 53 cm) of Dowex 1-X2(OH^-) resin packed in and eluted with H_2O. The first 460 mL of eluate was discarded. The following 490 mL contained 0.29 mmol (18.5% overall yield from **2***e*) of **3***b* by uv analysis. This solution was evaporated and the residue was 'diffusion crystallized' from 98% EtOH (*n*-pentane, desiccator) to give 59 mg (14%) of **3***b*, mp ~160–170°C (with resolidification and decomposition); $[\alpha]_D^{24}$ −25.4° (*c* 0.5, DMF); uv (H_2O) max 260 nm (ε 15 600), min 226 nm (ε 2600); ms (calcd. for $C_{11}H_{15}N_5O_3$: 265.1175; found *m/e*: 265.1172); ms (150°C) *m/e*: 265 (5, M), 250 (9, M − CH_3), 235 (11.5, MH − OCH_2(5′)), 235 (3.5, M − OCH_3), 164 (4.5, BHCHO), 162 (38, BHCH=CH_2), 136 (37, B + 2H), 135 (100, B + H), 131 (6, sugar). *Anal.* calcd. for $C_{11}H_{15}N_5O_3 \cdot 0.25\ H_2O$: C 48.97, H 5.79, N 25.97; found: C 48.89, H 5.85, N 25.88.

*Preparation of 2′-Deoxyadenosine (**6**c) and 3′-Deoxyadenosine (Cordycepin) (**7**c)*

To a stirred solution of 19.3 g (59.7 mmol) of **4***a* in 100 mL of dry pyridine cooled in a salt–ice bath was added 50 mg of 4-*N*,*N*-dimethylaminopyridine and 8 mL (85 mmol) of Ac_2O with exclusion of moisture. After stirring for 50 min, MeOH was added and the reaction was stirred for an additional 30 min, evaporated, and coevaporated with toluene, 98% EtOH, and CH_2Cl_2. An nmr spectrum of the residual amorphous solid (20.6 g) confirmed formation of the 5′-*O*-acetyl derivative (**4***b*) in a diastereomeric ratio (because of the methoxyethylidene moiety) of 3:2. Its mass spectrum contained the expected molecular ion, calcd. for $C_{15}H_{19}N_5O_3$: 365.1335; found: 365.1331.

This crude material was dissolved in 5% HOAc–H_2O (200 mL) and 98% EtOH (10 mL) and stirred at 24°C for 1 h. The reaction mixture was then evaporated and coevaporated with 98% EtOH and toluene. The solid glass (22.4 g) was a mixture of ~63% **5***a* and ~37% **5***b* (by nmr). Its mass spectrum contained the expected molecular ions, calcd. for $C_{14}H_{17}N_5O_6$: 351.1179; found: 351.1176.

A 0.93 g (2.6 mmol) sample of this mixture was dissolved in ~100 mL of dry pyridine. This solution was cooled to 4°C and added dropwise to a solution of 1.1 mL (15.3 mmol) of $SOCl_2$ in 75 mL of dry pyridine which was mechanically stirred in an ice bath under a flow of dry N_2 and exclusion of moisture. Stirring was continued for 20 min. The solution was then stirred vigorously in an oil bath for 30 min at 120°C. The resulting black mixture was poured into 50 mL of ice water and extracted with CH_2Cl_2. The combined organic phase was evaporated and coevaporated with toluene. The residue was adsorbed on 3 g of silica gel and applied to a silica gel column (1.8 × 20 cm, 25 g). The column was eluted with MeOH–CH_2Cl_2 (1:19). The first 40 mL of eluate was discarded and the next 70 mL contained product slightly contaminated with starting material. A further 480 mL of eluate contained starting material. Ultraviolet analysis indicated that 0.75 mmol of **6***a*,**7***a* and 1 mmol of starting **5***a*,*b* had been collected. The **5***a*,*b* was dissolved in CH_2Cl_2 and precipitated into *n*-pentane to yield 0.35 g of solid material. The yield of **6***a*,**7***a* less recovered starting material was 47%. An nmr spectrum ($CDCl_3$–D_2O) of the product indicated a ratio of **6***a* to **7***a* of ~3:2 (integration of δ 6.52 (d, $J_{1'-2'}$ = 3.9 Hz, 1, H-1′) to 6.24 (d, $J_{1'-2'}$ = 2.2 Hz, 1, H-1′), respectively). A mass spectrum of this mixture contained the expected molecular ions, calcd. for $C_{14}H_{16}{}^{35}ClN_5O_5$: 369.0841; found: 369.0841.

Mixed **6***a*,**7***a* (0.75 mmol) was dissolved in dry benzene (10 mL) and 25 mg (1.5 mmol) of AIBN and 12.5 mL of tri-*n*-butyltin hydride solution in benzene (~12.5 mmol) was added with stirring and exclusion of moisture. This mixture was heated at reflux for 4 h, concentrated to ~5 mL, and precipitated by slow addition to *n*-pentane (400 mL). A mass spectrum of the precipitate contained the expected molecular ions, calcd. for $C_{14}H_{17}N_5O_5$: 335.1230; found: 335.1227.

The precipitate was dissolved in 98% EtOH (25 mL) and

concentrated NH_3–H_2O (10 mL) and stirred for 23 h at room temperature. The solution was evaporated, dissolved in H_2O, and applied to a Dowex 1-X2(OH^-) column (72 × 2.2 cm). The column was eluted with 4 L of H_2O, 2 L of 10%, 1.6 L of 30%, 1.5 L of 60%, and 2 L of 90% MeOH–H_2O. The first 3.5 L of eluate was discarded and then 1.5 L of eluate containing pure **6***c* was collected. The continuing 1.1 L of uv transparent eluate was discarded and then 750 mL of eluate containing pure **7***c* was obtained. A further 2.5 L of uv transparent eluate was discarded and then 700 mL of eluate containing adenosine was collected. Analysis by uv showed 0.4 mmol (25%) of **6***c* plus 0.27 mmol (17%) of **7***c* (based on recovered **5***a,b*) and 0.047 mmol of adenosine. The solution containing pure **6***c* was evaporated and the residue was 'diffusion crystallized' from MeOH (Et_2O, desiccator) to give 67 mg (16.7%) of **6***c* (*3e*), mp 193.5–194°C; $[\alpha]_D^{24}$ −27.3° (*c* 0.7, H_2O); uv (H_2O) max 260 nm (ε 15 200), min 226.5 nm (ε 2200); ms (200°C) *m/e*: 251 (2.5, M). *Anal.* calcd. for $C_{10}H_{13}N_5O_3$: C 47.80, H 5.21, N 27.87; found: C 47.78, H 5.29, N 27.94.

The eluate containing **7***c* was evaporated and 'diffusion crystallized' from 98% EtOH (Et_2O, desiccator) to give 43 mg (11%) of **7***c* (*3e*), mp 210–211.5°C; $[\alpha]_D^{24}$ −46.5° (*c* 0.75, H_2O); uv (H_2O) max 260 nm (ε 14 600), min 227 nm (ε 2100); ms (185°C) *m/e*: 251 (4.5, M). *Anal.* calcd. for $C_{10}H_{13}N_5O_3$: C 47.80, H 5.21, N 27.87; found: C 47.57, H 5.26, N 27.89.

Evidence for the arabino *Configuration of* **6**a *and* xylo *Configuration of* **7**a

To a crude mixture of ~75 mg (0.2 mmol) of **6***a*,**7***a* (~3:2, prepared as given in the above procedure) was added 98% EtOH (10 mL) and concentrated NH_3–H_2O (5 mL). This solution was stirred for 3 h and the reaction mixture evaporated. EtOH (98%) was added and coevaporated to give a yellow glass which was applied to a silica gel column (1.4 × 17 cm, 35 g) wet packed in $CHCl_3$. The column was eluted with MeOH–$CHCl_3$ (1:9). The first 25 mL of eluate was discarded and the next 15 mL was collected. The following 12 mL was discarded and the next 20 mL was collected. The first 15 mL fraction contained **7***b* contaminated with a small amount of 2′,3′-anhydroadenosine (**8**) (*3d*) (epoxide formation was prevented by deblocking at 0°C or lower with MeOH saturated with NH_3). This material had an nmr spectrum (Me_2SO-d_6) identical to that of an authentic sample (*3e*).

The second fraction collected (20 mL) contained **6***b*. Some of this material crystallized directly from the eluate and had mp 242.5–243°C which was not depressed when mixed with an authentic sample of **6***b* (*3e*). This material also had nmr (Me_2SO-d_6) and ms (200°C) *m/e* 285 (1.5, M) identical to those of the authentic sample.

Both chloro samples **6***b* and **7***b* were converted to the epoxide **8** (*3d*) by treatment with NaOMe–MeOH. This further confirms the trans 'up' chloro and 'down' hydroxy configurations at the 2′ and 3′ positions.

*9-(5-Chloro-5-deoxy-β-D-xylofuranosyl)adenine (**10**a)*

To a solution of 0.1 mL of $SOCl_2$ in 1 mL of HMPA was added 100 mg (0.37 mmol) of **9** and stirring was continued for 12 h at room temperature. Ice water (1 mL) was added and the mixture was applied to a column (2 × 9 cm) of Amberlite IR-120(H^+) resin. The column was washed with 200 mL of H_2O and then eluted with 0.2 *N* NH_3–H_2O. Fractions (15 mL) 27–70 were pooled and evaporated. The residue was dissolved in MeOH, applied to two preparative tlc plates, and developed in SSE. The major band contained 77 mg (71%) of **10***a*. A faster migrating zone contained 4 mg (4%) of the dichloro derivative (**11***a*) and a slower migrating zone contained 3 mg (3%) of unreacted **9**. The major product was recrystallized from MeOH–Et_2O to give 55 mg of **10***a* as colorless crystals of mp 155–156°C; uv (H_2O) max 258 nm (ε 14 900) min 227 nm (ε 2100); ms *m/e*: 287 (2.5, M^+ [^{37}Cl]), 285.0628 (7.5, calcd. for M^+ [$C_{10}H_{12}{}^{35}ClN_5O_3$]: 285.0628), 250 (50, M − Cl), 236 (1.3, M − CH_2Cl), 194 (5, BCHOHCHOH), 178 (19, BHCH=CHOH), 164 (62, BHCHO), 148 (6.5, BCH_2), 136 (91, B + 2H), 135 (100, B + H). *Anal.* calcd. for $C_{10}H_{12}ClN_5O_3$: C 42.04, H 4.23, N 24.51; found: C 42.03, H 4.50, N 24.25.

Heating an nmr sample (Me_2SO-d_6–D_2O) of **10***a* in a boiling water bath resulted in the appearance of new peaks at δ 6.30 (s, 1, H-1′) and 8.47 & 8.70 (s & s, 1 & 1, H-8 & H-2). These resonances are indicative of formation of the corresponding N-3 → C-5′ cyclonucleoside (29).

*9-(3,5-Dichloro-3,5-dideoxy-β-D-ribofuranosyl)adenine (**11**a)*

To a solution of 53 mg (0.2 mmol) of **9** in 1 mL of freshly distilled HMPA was added 0.12 mL of freshly distilled $SOCl_2$ and stirring was continued for 9 days at room temperature. Ice water (2 mL) was added and the mixture was applied to a column (2 × 15 cm) of Amberlite IR-120(H^+) resin. The column was washed with 500 mL of 30% MeOH–H_2O, 300 mL of 50% MeOH–H_2O, and eluted with 1000 mL of 0.5 *N* NH_3 in 50% MeOH–H_2O. Fractions (20 mL) 40–70 were pooled and evaporated. The oily residue was diluted with 3 mL of MeOH, applied to two preparative tlc plates and developed in SSE. The major band contained 32 mg (54% by uv) of **11***a* and the minor slower migrating zone contained 15 mg (26% by uv) of **10***a*. Recrystallization of the major product from MeOH gave 26 mg (43%) of colorless crystals of **11***a* with mp ~200°C (dec.); uv (MeOH) max 258 nm (ε 15 300) min 226 nm (ε 1800); ms (150°C) *m/e*: 305.0258 (3.6, calcd. for M^+ ($C_{10}H_{11}{}^{35}Cl{}^{37}ClN_5O_2$): 305.0256), 303.0287 (7, calcd. for M^+ ($C_{10}H_{11}{}^{35}Cl_2N_5O_2$): 303.0290), 268 (16, M − Cl), 254 (1.4, M − CH_2Cl), 164 (62, BHCHO), 148 (2.7, BCH_2), 136 (95, B + 2H), 135 (100, B + H).

*9-(5-Deoxy-β-D-xylofuranosyl)adenine (**10**b)*

To a solution of 28 mg (0.1 mmol) of **10***a* in 1 mL of dry pyridine was added 0.15 mL of *N*,*O*-bis(trimethylsilyl)acetamide and stirring was continued for 1 h.

The solution was evaporated and the residue was dissolved in 2 mL of benzene. Several crystals of AIBN were added followed by 0.5 ml of *n*-Bu_3SnH in benzene (~0.5 mmol) and the mixture was heated for 4 h at reflux. After stirring overnight at room temperature, the mixture was evaporated. The oily residue was stirred for 1 h with 4 mL of 0.1 *N* NaOMe–MeOH, extracted with pentane, and applied to a column (2.5 × 7 cm) of Dowex 1-X2(OH^-) resin. The column was developed with 500 mL of H_2O, 1800 mL of 20% MeOH–H_2O, and 600 mL of 50% MeOH–H_2O. Fractions (15 mL) 111–180 contained 20 mg (80%) of **10***b*. Recrystallization of this product from MeOH gave **10***b* with mp 229–232°C (lit. (22) mp 229–231°C and 232–232.5°C); ms *m/e*: 251.1020 (calcd. for M^+ ($C_{10}H_{13}N_5O_3$): 251.1018).

*9-(3,5-Dideoxy-β-D-erythro-pentofuranosyl)adenine (3′,5′-Dideoxyadenosine) (**11**b)*

A solution of 20 mg of **11***a* in 10 mL of dry pyridine was treated with 0.4 mL of *N*,*O*-bis(trimethylsilyl)acetamide for 1 h at room temperature, evaporated, dissolved in 10 mL of dry benzene, and heated at reflux for 4.5 h with AIBN and 1 mL of *n*-Bu_3SnH solution. The solution was evaporated and the oily residue was processed as described above for the conversion **10***a* → **10***b*, using H_2O and then 25% MeOH–H_2O to develop the anion exchange column. Evaporation of appropriately pooled fractions gave 12 mg (77% by uv) of **11***b*; ms (200°C) *m/e*: 235.1069 (7.7, calcd. for M^+ ($C_{10}H_{13}N_5O_2$):

235.1069), 178 (21, BHCH=CHOH), 164 (100, BHCHO), 136 (68, B + 2H), 135 (93, B + H).

Acknowledgments

Generous financial support from the National Research Council of Canada (A5890), the National Cancer Institute of Canada, and The University of Alberta is gratefully acknowledged. We thank Dr. Y. Fouron for helpful discussions and for a sample of 9-β-D-xylofuranosyladenine.

Yields of excited states from thermolysis of some 1,2-dioxetanes[1]

KARL R. KOPECKY AND JOHN E. FILBY[2]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2E1

Received April 7, 1978

KARL R. KOPECKY and JOHN E. FILBY. Can. J. Chem. **57**, 283 (1979).

The singlet $^1\Phi$ and triplet $^3\Phi$ excited state product yields produced on thermolysis in toluene of trimethyl- (**1**), tetramethyl- (**2**), *cis*-3, 4-butano-3,4-dimethyl- (**3**), and 3,4:3,4-dibutano-1,2-dioxetane (**4**) were determined to be as follows (dioxetane, °C, $^1\Phi$, $^3\Phi$): **1**, 40, 1.1×10^{-3}, 0.15; **2**, 45, 4.4×10^{-4}, 0.31; **3**, 26, 8.5×10^{-4}, 0.23; **4**, 24, 4.8×10^{-6}, 0.011. The reason for the low yield of excited states obtained from **4** is not known. Thermochemical calculation indicate that as much energy is available from thermolysis of **4** as is available from **2**.

Dioxetane-energized dimerization of acenaphthylene, accompanied by an intense yellow luminescence, produced mainly the *trans* dimer in 1–3% yield. Dioxetane-energized cyclization of 1-(2,4-dimethylphenyl)-1,2-propanedione produced 2-hydroxy-2,5-dimethylindan-1-one in 0.5–6% yields.

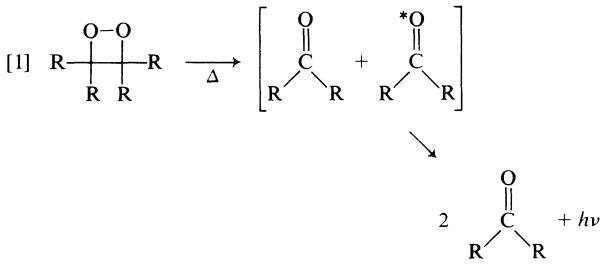
On a déterminé que les rendements des produits des états excités singulet $^1\Phi$ et triplet $^3\Phi$ obtenus lors de la thermolyse dans le toluène du triméthyl- (**1**), du tétraméthyl- (**2**), du *cis*-butano-3,4 diméthyl-3,4- (**3**) et du dibutano-3,4:3,4 dioxétanne-1,2 (**4**) sont les suivants: (dioxétanne, °C, $^1\Phi$, $^3\Phi$): **1**, 40, 1.1×10^{-3}, 0.15; **2**, 45, 4.4×10^{-4}, 0.31; **3**, 26, 8.5×10^{-4}, 0.23; **4**, 24, 4.8×10^{-6}, 0.011. On ne connait pas la raison des faibles rendements d'états excités obtenus dans le cas de **4**. Des calculs thermochimiques indiquent qu'il y a autant d'énergie disponible pour la thermolyse de **4** que de **2**.

La dimérisation de l'acénaphtylène activée par un dioxétanne est accompagnée par une luminescence jaune intense et conduit principalement au dimère *trans* avec un rendement de 1 à 3%. La cyclisation de la (diméthyl-2,4 phényl)-1 propanedione-2,5 conduit à l'hydroxy-2 diméthyl-2,5 indanone-1 avec des rendements de 0.5–6%.

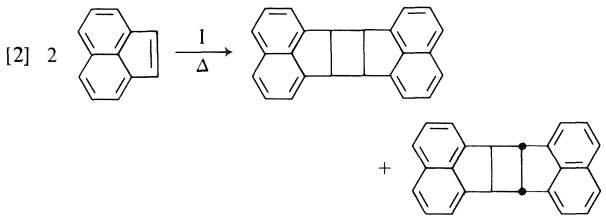
[Traduit par le journal]

Introduction

Thermolysis of 1,2-dioxetanes yields carbonyl compounds in quantitative yield and is accompanied by luminescence, eq. [1] (1). The luminescence



observed in aerated solutions of trimethyl-1,2-dioxetane **1** (1*a*) is evidence that a carbonyl product is formed in the excited singlet state. It was first thought that the singlet was the exclusive initial excited state product formed. However, it was soon shown that the triplet is by far the predominant initial excited state product by observing that thermolysis of **1** in the presence of acenaphthylene produces mainly the *trans* dimer of acenaphthylene, eq. [2] (2), the result of dimerization via the triplet state (3).



The luminescence from thermolysis of dioxetanes is enhanced by the presence of fluorescers, particularly by 9,10-dibromoanthracene DBA (4), which produces a much brighter luminescence than does 9,10-diphenylanthracene DPA even though the fluorescence efficiency of DBA, Φ_f(DBA) ~ 0.1, is much less than that of DPA, Φ_f(DPA) ~ 1. Energy transfer from triplet carbonyl to DBA produces excited singlet DBA fairly efficiently (5) whereas the same transfer to DPA produces only triplet DPA which does not fluoresce in solution. Thus, the more efficient luminescence with DBA is further evidence that the triplet is the predominant initial excited state product. This has been demonstrated in other

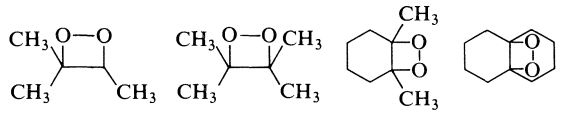
0008-4042/79/030283-06$01.00/0

ways (6) and most dioxetanes produce initially the triplet carbonyl product in far greater amount; for a review see ref. 7.

The quantitative determination of luminescence from dioxetane solutions containing DBA and DPA has been used to measure the yields of the initially formed triplet and singlet excited states, respectively (7, 8). The present paper reports our determination of the yields of excited states formed on thermolysis of **1**, tetramethyl-1,2-dioxetane **2**, *cis*-3,4-butano-3,4-dimethyl-1,2-dioxetane **3**, and 3,4:3,4-dibutano-1,2-dioxetane **4** by this method,

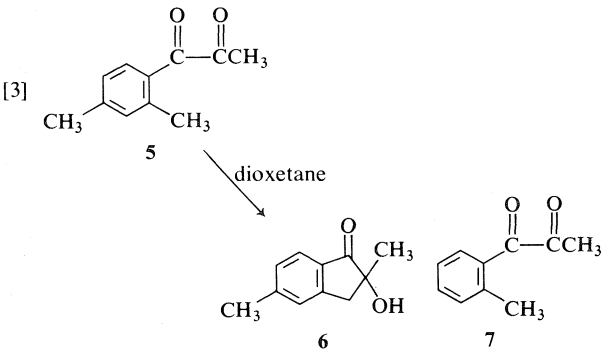


1 **2** **3** **4**

as well as the results of some energy transfer experiments to acenaphthylene and to 1-(2,4-dimethylphenyl)propane-1,2-dione **5**. This series of dioxetanes, containing mono-, di-, and tricyclic members, was chosen to study the effect of structure on the yield of excited state products formed.

Results

Our initial attempts to estimate excited state yields from the above dioxetanes involved energy transfer experiments to the photoreactive acceptors acenaphthylene and **5**. The dioxetane-energized cyclization of **5** to 2-hydroxy-2,5-dimethylindan-1-one **6**, eq. [3], was patterned after a similar reaction of



5 **6** **7**

1-(2-methylphenyl)propane-1,2-dione **7** (9). Since the preparation of **5** is much simpler than that of **7**, **5** was chosen for the present study.

Degassed benzene solutions 1 *M* in **2**, **3**, or **4** containing 1 *M* acenaphthylene or **5** were heated to ~90°C. The yield of acenaphthylene dimer, based on dioxetane used, was 2–3% from **2** and **3** and 1% from **4**. In all these reactions the *cis* to *trans* dimer ratio was ~0.1, indicating that mainly triplet energy transfer to acenaphthalene was occurring (2). The yields of **6** formed from **2**, **3**, and **4** were 6, 1, and 0.5%, respectively. Shortly after heating began all the reactions luminesced so brightly that the luminescence was clearly visible in ordinary room light for 5–10 s. It was not surprising to observe the greenish-yellow luminescence from **5** as 1,2-diketones are known to luminesce efficiently. However, the bright yellow luminescence from solutions containing acenaphthylene was completely unexpected since this compound fluoresces very weakly, if at all (10). This luminescence was not observed when the initial dioxetane concentration was less than 0.1 *M*.

The yields of acenaphthalene dimer obtained in the present study are about double those obtained previously using **1** under similar conditions (2) and the *cis* to *trans* dimer ratios of ~0.1 are lower than the value of ~0.3 obtained previously. It is not clear what the reasons for these discrepancies may be. The higher initial concentration of **1** used before, ~2 *M*, may have resulted in more wastage of dioxetane than in the present work (see below). At 25°C the triplet dimerization of acenaphthylene results in a *cis* to *trans* dimer ratio of ~0.25 in nonpolar solvents (3). The effect of temperature on this ratio is not known.

The yields of products formed in the above reactions are quite low. The quantum yield for the dimerization of triplet acenaphthylene is not known but that for cyclization of **5** must be ~0.8 (9). The low yield of **6** may be due to low yields of excited states formed from the dioxetanes and/or induced decomposition of the dioxetanes at the high concentration used by the excited state of **5** or of the initial carbonyl products (8, 11). Such a wastage of dioxetane does not occur in aerated solutions of DBA and DPA (8). Measurement of the light emitted from such solutions should be a more reliable method for determining the excited state yields (7).

The yields of excited singlet $^1\Phi$ and triplet $^3\Phi$ products from the dioxetanes **1**–**4**, Table 1, were determined from plots of the reciprocal of the light

TABLE 1. Yields of excited states formed on thermolysis of 1,2-dioxetanes[a]

Dioxetane	$^3\Phi$[b]	$^1\Phi \times 10^4$[c]
1	0.15	11
2	0.31	4.4
3	0.23	8.5
4	0.011	0.048

[a]The values given here differ somewhat from those previously published (8) because the spectrofluorimeter has been recalibrated and the luminescence intensities from solutions of some of the dioxetanes have been redetermined.
[b]Molecules of excited triplet ketone formed per molecule of dioxetane decomposed. Estimated errors ±25%.
[c]Molecules of excited singlet ketone formed per molecule of dioxetane decomposed. Estimated errors ±25%.

intensity vs. the reciprocal of the DBA and DPA concentrations, respectively (7, 8). The spectrofluorimeter used was calibrated with the luminol light standard (12). Use of this standard results in apparent excited state yields that are smaller by a factor of ~2.5 than those obtained on the basis of the radioactive light standard which is often used (7, 13). In fact, the yield of triplet acetone formed from **2** as determined in the present work is in the low end of the range of values, $^3\Phi \geq 0.2$–0.5, reported by others (7). The yield of singlet acetone is smaller by a factor of about 10 than most other determinations (7) but it is in very good agreement with recently reported values, $^1\Phi = 9 \times 10^{-4}$ at 72°C and 5×10^{-4} at 22°C (14).

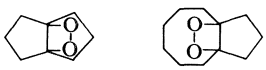
Although the exact values of the excited state yields are uncertain the relative yields given in Table 1, using **2** as a reference point, should be meaningful. The yields of excited states formed from **1**, **2**, and **3** vary at most by a factor of about 2 but the tricyclic dioxetane **4** is only about 10^{-2} as efficient at forming the excited singlet and about a 30th as effective at forming triplet products as are the other dioxetanes. It can clearly be seen visually that the luminescence from solutions of **4** is much weaker than that from solutions of the other dioxetanes.

However, based on the sensitized dimerization of acenaphthylene and cyclization of **7** the efficiency of excited state formation from **4** is not so greatly different from those from the other dioxetanes. It is not obvious why the different methods of measurement should result in different relative excited state efficiencies. The yields determined by luminescence measurements using DPA and DBA should be the most accurate and the discussion will be based on these.

Discussion

Incorporation of the dioxetane ring into a bicyclic system as in **3** has little effect on the efficiency of excited state formation as compared with **2**. This has been observed already for the dioxetanes derived from 3,6-dioxacyclohexene (7) and 1,2-dimethylcyclopentene (15). But there certainly is an effect when the dioxetane ring is incorporated into the tricyclic system of **4**. It was thought initially that there might not be enough energy available (equal to the difference in the heats of formation of **4** and the ground state product plus the energy of activation for the thermolysis) on thermolysis of **4** to populate the excited singlet state of the product as a 10-membered ring is formed which might have considerable strain. However, cyclodecanone has been calculated to have only 3.6 kcal/mol of strain energy (16) and force-field calculations indicate that introduction of a second sp^2 center in cyclic molecules reduces the strain energy even further (17). Thus, 1,6-cyclodecanedione must be nearly strain free and thermochemical calculations (18) give a value of 93 kcal/mol for the energy available from **4**. This is essentially the same as is available from **2**. It was assumed that 1,6-cyclodecanedione was strain free and that the dioxetane ring of **4** had the same strain energy as does **2**.

Nor does the inefficiency of **4** appear to be due to its rigid structure which must restrict considerably the motions available during decomposition as compared to **1**, **2**, and **3**, for two other tricyclic dioxetanes, **8** and **9**, which also have rigid structures, are almost



8 **9**

as efficient as **2** in the formation of excited states (19) Thus, the reason for the inefficiency of **4** must lie elsewhere and we are unable to offer an explanation.

It was suggested recently that the entropy of the overall reaction instead of the energy of activation should be considered in addition to the enthalpy of the reaction for calculating the energy available for population of excited states on thermolysis of dioxetanes (20). Monocyclic dioxetanes produce two molecules and the energy available as calculated in this way (20) is sufficient to produce excited singlet state products. However, the entropy of the reaction on thermolysis of the bicyclic **3** and especially the tricyclic dioxetanes is much less and the free energy of these reactions is not great enough to produce the excited singlet state of the product. The formation of excited singlet state from **3**, **8**, and **9** with the same efficiency as from **2** is experimental evidence that the original method (18) for the calculation of the energy available is correct. The original method also has been justified on thermodynamic grounds (21).

Experimental

The dioxetanes **1**–**4** were prepared as described (1*e*) and all had at least 99% of the theoretical active oxygen content.

1-(2,4-Dimethylphenyl)-1-(hydroxyazylene)propane

Treatment (22) of 2,4-dimethylpropiophenone (23) with 3-methyl-1-butyl nitrite gave an 87% yield of product, recrystallized from toluene, mp 104–105°C. *Anal.* calcd. for $C_{11}H_{13}NO_2$: C 69.09, H 6.85, N 7.33; found: C 69.31, H 6.96, N 7.49.

*1-(2,4-Dimethylphenyl)propane-1,2-dione (**5**)*

A mixture of 16 g sodium bisulfite and 1.9 g 1-(2,4-dimethylphenyl)-1-(hydroxyazylene) propane in 25 mL 50% aqueous ethanol was heated under reflux for 2 h. The solvent was evaporated and 25 mL water and 50 mL 6 *N* hydrochloric acid were added to the residue. The resulting mixture was extracted with 3 × 10 mL methylene chloride. The combined extracts were dried, concentrated, and the residue distilled to give

1.0 g (57%) of a yellow oil, bp 85–89°C/0.2 Torr, n_D^{21} 1.5382, which was crystallized from isopentane to give yellow needles, mp 16.5–17.5°C. *Anal.* calcd. for $C_{11}H_{12}O_2$: C 74.97, H 6.86; found: C 75.20, H 6.95.

*2-Hydroxy-2,5-dimethylindan-1-one (**6**)*

A stirred solution of 0.5 g of the above dione in 500 mL hexane was irradiated under a nitrogen atmosphere with a General Electric 'Sunlamp' until the yellow color had faded. The solvent was removed to leave a yellow oil which slowly deposited crystals at −10°C. These were crystallized from heptane to give white cubes, mp 84–85°C; ^{1}Hmr ($CDCl_3$): τ 2.29 (d, J = 8 Hz, 1H), 2.70 (s, 1H), 2.80 (d, J = 8 Hz, 1H), 6.8 (m, 2H), 7.66 (s, 1H), and 8.57 (s, 3H). *Anal.* calcd. for $C_{11}H_{12}O_2$: C 74.97, H 6.96; found: C 74.98, H 6.84.

cis- *and* trans-*Acenaphthylene Dimers*

These were formed by photolysis (3*b*) of purified (3*a*) acenaphthalene in cyclohexane and separated (3*b*) into the crude *cis*- and *trans* isomers. The *cis* dimer was dissolved in benzene and an equivalent amount of picric acid in a saturated benzene solution was added. After several hours splendid, deep red crystals of the picrate formed which were recrystallized from benzene and then decomposed with ammonia. The *cis* dimer was recrystallized from cyclohexane (activated charcoal) to yield white prisms, mp 231–232°C (lit. (3*b*) mp 231–233.5°C). The crude *trans* dimer was recrystallized several times from benzene until the melting point remained constant to give fine white needles, mp 320–321°C (lit. (3) mp 305–307°C). The extinction coefficients in cyclohexane used for analysis of the product mixtures were *cis* dimer, ε^{219} 1.44 × 10^5, ε^{225} 7.75 × 10^4 (lit. (3*b*) ε^{219} 1.27 × 10^5, ε^{225} 6.60 × 10^4); *trans* dimer, ε^{219} 7.50 × 10^4, ε^{225} 1.22 × 10^5 (lit. (3*b*) ε^{219} 7.38 × 10^4, ε^{225} 1.19 × 10^5).

Dioxetane Sensitized Dimerization of Acenaphthylene

Solutions of dioxetane and acenaphthylene in benzene were degassed by six freeze–thaw cycles at 0.005 Torr in clean Pyrex ampoules and sealed. The ampoules were then heated at 95°C in a water bath for 15 min. Bright yellow luminescence clearly visible in daylight was observed for about 10 s during thermolysis of solutions ~1 *M* in dioxetane. The ampoules were stored at 8°C for several days and opened. The crystals which had deposited were collected and washed with cold (0°C) pentane. The filtrate and washings were applied to a silica gel preparative tlc plate which was eluted twice in the dark with cyclohexane. The dimers, visualized under uv light as a purple line near the bottom of the plate, were isolated by extracting the silica gel for 8 h in a Soxhlet thimble with boiling benzene. The extract was evaporated to dryness and the residue repeatedly treated with 10 mL cyclohexane and evaporated. The residue was combined with the precipitated dimers and the product composition determined by uv analysis (3*b*). Blank solutions containing only acenaphthalene were handled in exactly the same way. The optical densities of solutions made up from the blank samples were negligible.

The *cis* dimer was shown to be stable to the isolation conditions. A solution of the *cis* dimer in C_6D_6 containing 1,4-dimethoxybenzene as internal standard was heated at 80°C for 4 h. Examination of the ^{1}H nmr spectra taken before and after heating revealed that no detectable decomposition had occurred.

*Dioxetane Sensitized Cyclization of 1-(2,5-Dimethylphenyl)-propane-1,2-dione (**5**)*

About 0.5 mL of benzene solutions 1 *M* in dioxetane and 1 *M* in **5** in clean test tubes were degassed with three freeze–thaw cycles under 0.005 Torr. The tubes were sealed and placed in a 95°C bath. After 1–2 min a bright green fluorescence lasting 10–15 s appeared. The samples were then cooled and some (4-methoxyphenyl)methanol was added as internal standard. The solutions were analyzed by gc at 190°C on a 5 ft × ¼ in. stainless steel column packed with 15% FFAP on 60–80 Chromosorb W. The gc instrument was calibrated by injecting solutions of internal standard and cyclized product **6** at known concentrations.

*Calibration of the Spectrofluorimeter and of a Solution of **2** Containing DBA*

Luminescence intensities from dioxetane solutions were measured using a Turner Model 430 spectrofluorimeter with the xenon lamp source turned off and using the 60 nm emission monochrometer band width. Solutions were placed in a 10 cm jacketed polarimeter type cell of 11 mL capacity with one end silvered. It was mounted in a specially made compartment with the unsilvered end ~2 cm from the entrance slit. Water from a constant temperature bath was circulated through the jacket and the internal temperature of the solution was measured with a calibrated thermometer.

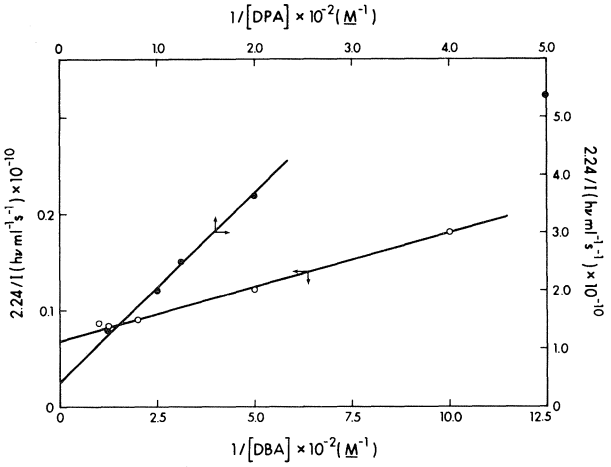

FIG. 3. Effect of DBA (○) and DPA(●) concentration on the initial intensity of chemiluminescence from 8.9×10^{-4} *M* **3** in toluene at 26°C.

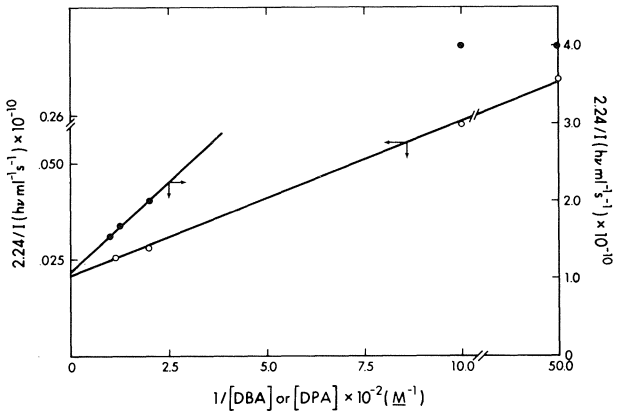

FIG. 4. Effect of DBA (○) and DPA(●) concentration on the initial intensity of chemiluminescence from 8.5×10^{-3} *M* **4** at 24°C.

The spectrofluorimeter was calibrated with the luminol light standard (12). Ten millilitres of a dry dimethyl sulfoxide solution of freshly prepared luminol (24) which had an optical density of 0.00163 at 360 nm and 1.0 mL of a solution of 0.1 *M* potassium *tert*-butoxide in *tert*-butyl alcohol were injected simultaneously into the cell through a light-tight septum. Injections could be completed within 3 s. The output from the spectrofluorimeter, with the emission wavelength setting at 484 nm, was recorded on a strip chart recorder. With a ×3 setting on the spectrofluorimeter and the recorder setting at 1 V and operating at 5 in./min the areas under the curves, measured with a planimeter, for four runs were 11.47, 11.15, 13.49, and 11.91 in.^{2}, average = 12.00 ± 0.49 in.^{2}. When 0.03 *M* potassium *tert*-butoxide was used the area was 12.01 in.^{2}. Two further determinations were made using 0.01 potassium *tert*-butoxide solution as base and the areas were measured to be 10.50 and 12.10 in.^{2}. The light intensity decreased much more slowly when the more dilute base was used, falling to 0.5% of the maximum intensity after 22 min with 0.01 *M* base as compared to six m with the 0.1 *M* base. The results indicate that all the light that was produced was detected even when 0.1 *M* base was used. The correct area under the curve was taken to be 12.00 ± 0.49 in.^{2}. With the emission wavelength setting at 450 nm (for maximum light intensity) and all other settings the same a toluene solution 6.87×10^{-4} *M* in **2** and 5×10^{-3} *M* in DBA at 44.8°C required 94.7 s to generate 12.00 in.^{2} under the output curve, a straight line. Using the light yield of $(9.75 \pm 0.7) \times 10^{14}$ photons per millilitre of luminol solution with optical density 1.00 (12) this dioxetane solution was emitting an apparent $(1.68 \pm 0.18) \times 10^{10}$ photons mL^{-1} s^{-1}. Correction factors (13*a*) to be applied to this value were obtained by graphical integration for the variable wavelength response of the photomultiplier tube (S-4 response), a factor of 0.84 for both DBA and DPA and for the relative amounts of light that passed through the slit from the solutions containing luminol, DBA and DPA, factors of 1.15 for DBA and 1.18 for DPA. The errors in the graphical integrations were estimated to be 5%. Applying the corrections for DBA to the apparent emission of the DBA solution above indicated that it was emitting $(1.63 \pm 0.26 \times 10^{10})$ photons mL^{-1} s^{-1}.

Excited State Yields from Dioxetanes

Plots of the reciprocal of the light intensity vs. the reciprocal of fluorescer concentration for dioxetane solutions in toluene are given in Figs. 1–4. The light intensities at infinite fluorescer concentration were obtained from the intercepts of the plots.

$$[4] \qquad {}^1\Phi = \frac{I_\infty(\mathrm{DPA})}{([\mathrm{D}] \times 10^{-3}) \times k_d \times (6.02 \times 10^{23}) \times 0.8}$$

$$[5] \qquad {}^3\Phi = \frac{I_\infty(\mathrm{DBA})}{\Phi_{T \to S} \times \Phi_f(\mathrm{DBA}) \times ([\mathrm{D}] \times 10^{-3}) \times k_d \times (6.02 \times 10^{23})}$$

The yields of excited singlet and triplet states formed on thermolysis of the 1,2-dioxetanes were calculated using [4] and [5], respectively. The parameters used in the calculations are listed and defined in Table 2 except for [D], the concentration of dioxetane and $\Phi_{T\rightarrow S}$, the efficiency with which triplet carbonyl compounds produces singlet DBA. This efficiency was assumed to be the same for all the carbonyl compounds produced from dioxetanes **1**–**4** and the value 0.2 determined for acetophenone (7) was used. The factor of 0.8 in [4] was used to correct for the fact that 20% of excited DPA molecules are quenched by oxygen in aerated solutions (8). The excited state yields are presented in Table 1 and the total error of each value is estimated to be ~25%. The errors consist of ~16% in the calibration of the spectrofluorimeter, ~5% in k_d and ~5% in the determination of the values of the intercepts of the plots of Figs. 1–4.

Received July 31, 1978

JAMES P. KUTNEY, RODNEY A. BADGER, JOHN F. BECK, HERBERT BOSSHARDT, FATHY S. MATOUGH, VICENTE E. RIDAURA-SANZ, YING HUNG SO, RATTAN S. SOOD, and BRIAN R. WORTH. Can. J. Chem. **57**, 289 (1979).

A synthesis of 16,17-dihydrosecodin-17-ol and of secodine is described. Various indole derivatives were elaborated to a series of pyridinium salts, potential precursors for 1,2- and 1,6-dihydropyridine compounds exemplifying the proposed biointermediate 'dehydrosecodine.'

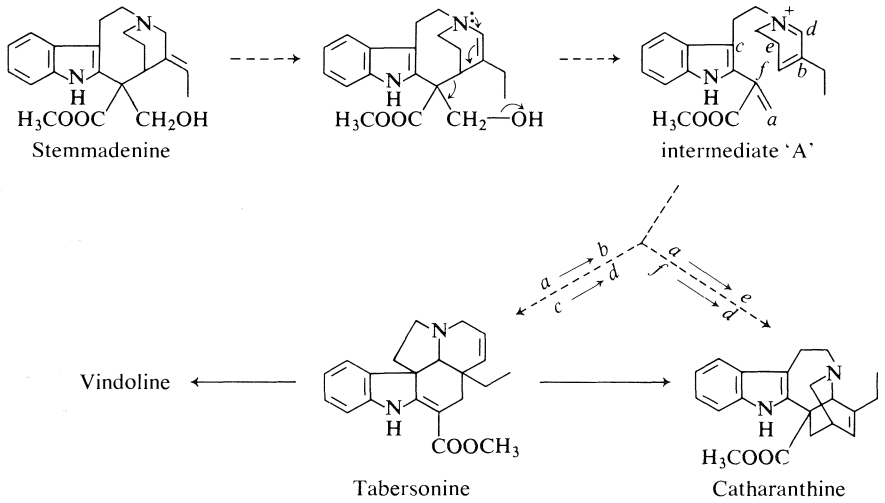
JAMES P. KUTNEY, RODNEY A. BADGER, JOHN F. BECK, HERBERT BOSSHARDT, FATHY S. MATOUGH, VICENTE E. RIDAURA-SANZ, YING HUNG SO, RATTAN S. SOOD et BRIAN R. WORTH. Can. J. Chem. **57**, 289 (1979).

On décrit une synthèse du dihydro-16,17 sécodinol-17 et de la sécodine. On a transformé divers dérivés de l'indole en une série de sels de pyridinium qui sont des précurseurs possibles de composés dihydro-1,2 (et -1,6) pyridine et qui servent d'exemples pour les biointermédiaires suggérés pour la "déhydrosécodine."

[Traduit par le journal]

The possible role of dihydropyridines as late stage intermediates in indole alkaloid biosynthesis has been discussed for some years (see ref. 1 for a recent review). Wenkert (2) first speculated that such intermediates could be involved in the later stages of *Aspidosperma* and *Iboga* alkaloid biosynthesis and experimental evidence supporting such a proposal came forth from various investigations in different laboratories. Scott's experiments with germinated *Catharanthus roseus* seedlings (3–5) and our own studies with *C. roseus* plants (6) brought forward a rationale (Scheme 1) which invoked such systems (e.g., 'intermediate A'). Clearly such studies suggested, but did not prove, the role of dihydropyridines in these biosynthetic pathways. To provide more direct evidence in this direction a synthetic program was initiated in the hope that dihydropyridine systems could be made available

The expected instability of dihydropyridines led initially to the consideration of the more stable yet closely related tetrahydropyridines as model systems. To this end the synthesis of 16,17-dihydrosecodin-



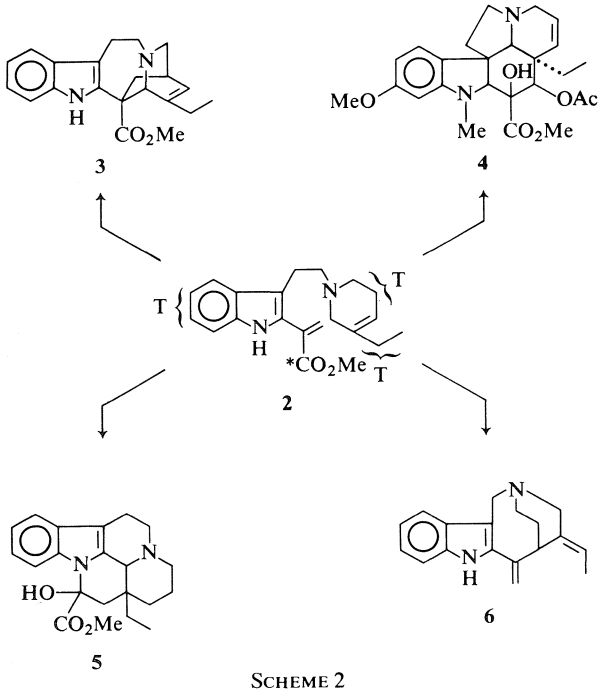
SCHEME 1. A possible rationale for the implication of intermediate 'A' in the biosynthesis of *Aspidosperma* and *Iboga* alkaloids.

0008-4042/79/030289-11$01.00/0

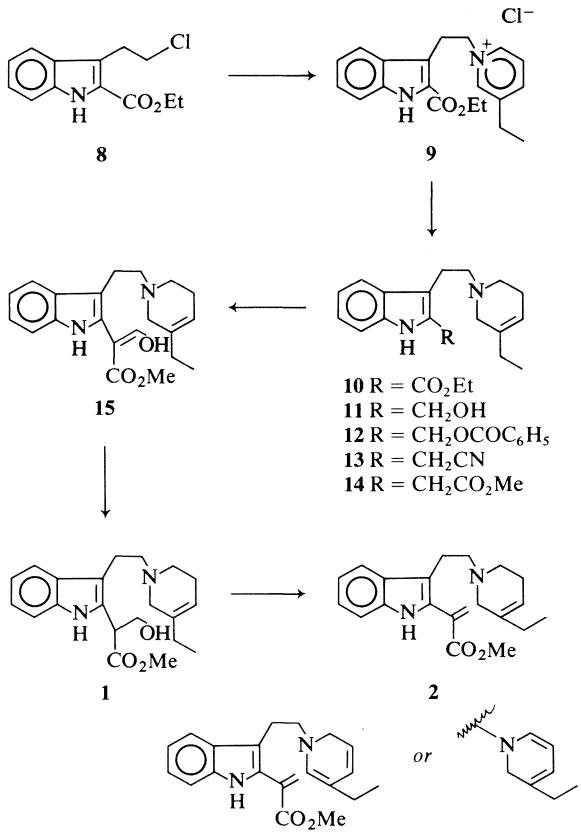
17-ol (**1**) and secodine (**2**) was finally completed and a large number of experiments, with radioactive-labelled forms of **1** and **2**, in various alkaloid bearing plants, carried out. Two recent reviews (7) provide a detailed account of these investigations and Scheme 2 summarises the most important features pertaining to the present discussion. Thus it was established that in three different plant species, containing very different alkaloids, *C. roseus* (catharanthine (**3**) and vindoline (**4**)), *Vinca minor* (vincamine (**5**)), and *Aspidosperma pyricollum* (apparicine (**6**)), secodine was incorporated *intact* with ^{14}C or ^{3}H labels retained except when tritium was located in the piperideine unit. In those cases significant loss (catharanthine, 61.5%; vindoline, 60%; apparicine, 50%) of the label was observed thereby suggesting a higher oxidised form of (**2**) as a more accurate representation of the biointermediate.

The importance of secodine and related dihydropyridines as possible intermediates in the biosynthesis of various indole alkaloid families necessitated considerable development of the chemistry of these systems. This report discusses our experiments in this area with reference to both biosynthetic and synthetic applications (8).

With a 'dehydrosecodine' (**7**) as an eventual goal it was necessary to evaluate methods for preparation and stabilisation of both the acrylic ester and dihydropyridine functions. The synthesis of secodine (9) (Scheme 3) provided the necessary experience



SCHEME 2



SCHEME 3

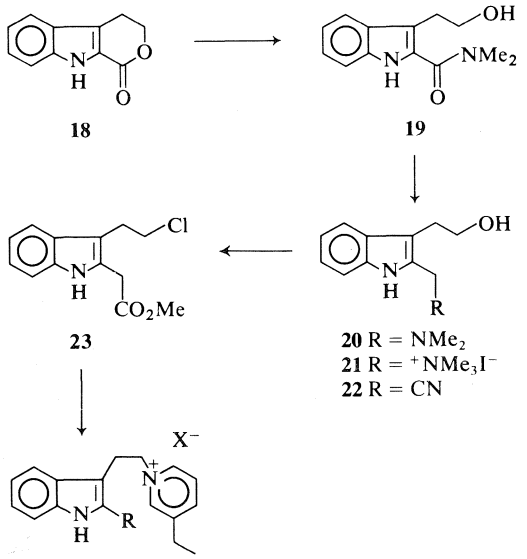
regarding generation of the labile indole acrylic ester moiety. The chloro ester **8** was available in large quantities by Japp–Klingemann reaction between diethyl γ-chloropropylmalonate (10) and benzenediazonium fluoroborate[1] and subsequent Fischer indole cyclisation. Condensation with 3-ethylpyridine afforded the salt **9** which on reduction with sodium borohydride gave the tetrahydropyridine **10**. Reduction of **10** with lithium aluminum hydride in tetrahydrofuran gave the primary alcohol **11** in 70% overall yield from **8**. Reaction of the corresponding benzoate with potassium cyanide in dimethylformamide provided the nitrile **13** which was solvolysed directly to the ester **14**. The conversion to 16,17-dihydrosecodin-17-ol (**1**) was similar to that reported by Battersby and Bhatnagar (11) and here formylation and careful reduction with sodium borohydride gave a 40% yield of **1**. At this point Smith and co-workers (12–14) had commented on the lability of secodine and in fact our initial attempts at dehydration of **1** met only with frustration.

[1]Alternative use of benzenediazonium chloride in large scale preparations proved quite hazardous.

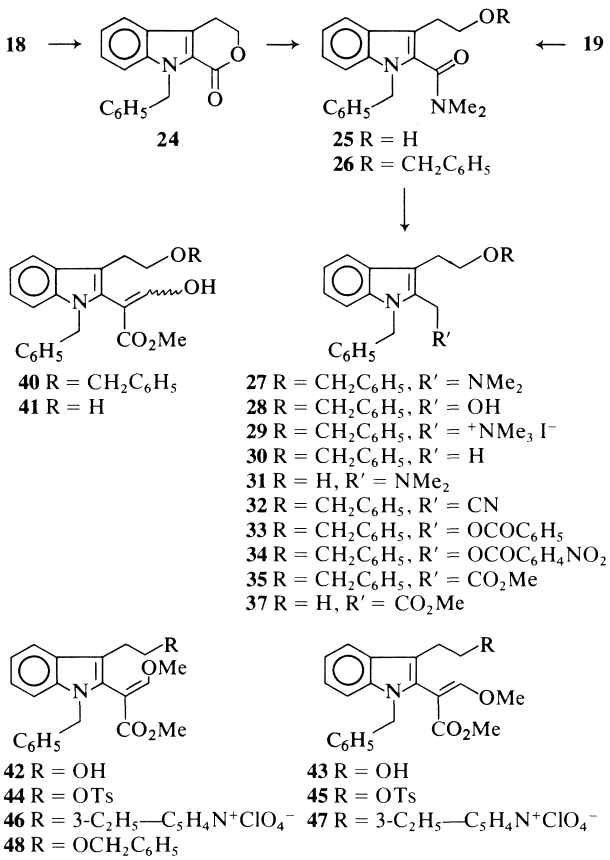
Surprisingly, however, reaction with sodium hydride in benzene followed by *careful* work-up enabled a 61% isolation of the unstable secodine **2**. Studies with radiolabelled secodine revealed that 35% of the latter was transformed to presecamine and secamine (12–14) in 2 h at ambient temperature.

In view of the instability of secodine, the approach to 'dehydrosecodine' (**7**) necessitated either protection/stabilisation of the acrylic ester function and subsequent generation and trapping of the dihydropyridine moiety or alternatively, formation of the trapped dihydropyridine and then elaboration of the unsaturated ester. To adequately develop the chemistry of dihydropyridine units it was necessary to evaluate methods of their formation and trapping (15, 16) in the presence of a variety of functional groups (8). Thus pyridinium salts were chosen as the logical precursors of the corresponding dihydropyridines. Here we describe the preparation of simple pyridinium salts together with more complex alkaloid precursors containing this system.

The simplest model system (**16**) relevant to the present work was obtained by condensation between tryptophyl bromide and 3-ethylpyridine. The analogous product (**17**), now incorporating the acetic ester side chain, was available as outlined in Scheme 4. Exploitation of work reported by Plieninger (17) facilitated large scale preparations of the indole lactone (**18**) efficiently from butyrolactone. The action of dimethylamine readily afforded **19** which was reduced with lithium aluminum hydride to the corresponding tertiary amine. Reaction of the



SCHEME 4



SCHEME 5

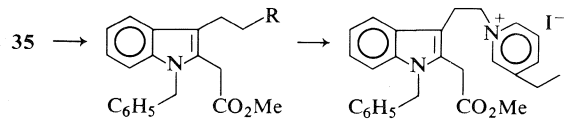
derived methiodide **21** with potassium cyanide in refluxing acetonitrile gave a high yield of the nitrile **22** which was solvolysed to the known (18) chloro ester **23**. Condensation with 3-ethylpyridine gave the salt, isolated as its perchlorate (**17**).

The salts **9**, **16**, and **17** now provided means of determining the formation and stability of trapped dihydropyridines in the presence of ester and indole groups and, via **17**, the possibility of elaborating an acrylic ester function in the presence of a preformed dihydropyridine. Subsequent investigations directed at the conversion of the ester side chain in **17** to the required acrylic ester met with difficulties. The instability of the latter system made isolation of intermediates virtually impossible, and it now appeared mandatory to provide stabilisation of the indole system before further elaboration.

N-Benzylation of the indole nucleus appeared to offer an appropriate means of stabilising the indole acrylic esters. Scheme 5 summarises the route employed. Ring opening of the protected indole lactone **24** and subsequent *O*-benzylation of the product provided **26** also available by dibenzylation of **19**. Reduction of **26** with lithium aluminum

hydride in tetrahydrofuran gave the required amine **27** as the minor component of a mixture with the primary alcohol **28**. Direct methylation, of the mixture, with methyl iodide in ethyl acetate gave a 48% yield of the methiodide salt **29**. Alternatively, borane reduction of **26** gave **27** in 58% yield together with the cleavage product **30**. At this point it was found that the hydroxy amide **25** was reduced cleanly, with lithium aluminum hydride, to the amine **31** without the complication of side products. Thus it was reasoned that an alkoxyaluminum hydride agent might provide similar improvements in the *O*-benzyl series. Indeed reduction of **26** with lithium *n*-butoxyaluminum hydride in tetrahydrofuran gave a 6.5:1 ratio of **27** and **28**. Direct methylation of this mixture gave an 82% yield of the salt **29**. As in the earlier sequence, displacement of triethylamine using potassium cyanide in acetonitrile proceeded efficiently to the corresponding nitrile **32**. Attempts to form **32** from the benzoate (**33**) or *p*-nitrobenzoate (**34**) were unsuccessful. Solvolysis of **32** with hydrogen chloride – moist methanol at reflux provided the debenzylated, chloro ester (**23**), whereas the use of acetyl chloride – methanol gave the ester (**35**) in 67% yield.

At this point elaboration to the model system (**36**) was readily accomplished by debenzylation to **37**, tosylation, iodination, and finally condensation of **39** with 3-ethylpyridine.



37 R = OH
38 R = OTs
39 R = I

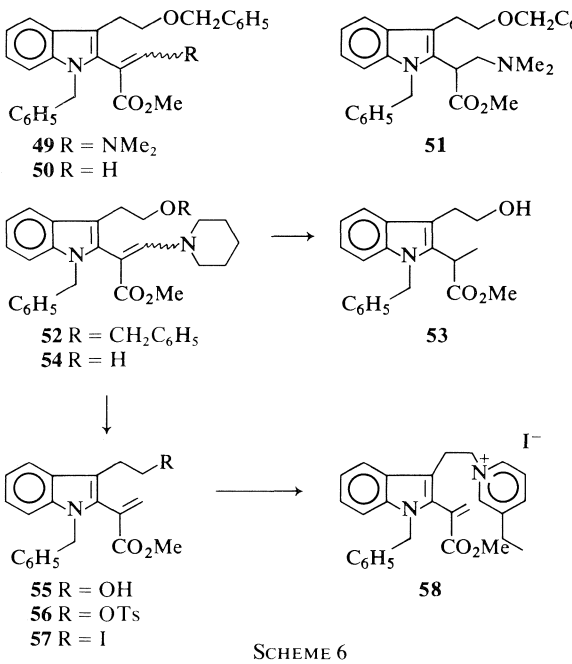
36

Various methods of formation and protection of the acrylic ester function were investigated. The anion prepared from **35** and potassium diisopropylamide was allowed to react with methyl formate at ambient temperature to furnish the enol **40**, which on hydrogenolysis gave **41**. Methylation of **41** with diazomethane produced the *E*- and *Z*- enol ethers **42** and **43**, respectively. These ethers were more efficiently available from **35** by condensation with methyl formate, hydrogenolysis, and methylation without purification of the intermediates. In this manner a 58% yield of **42** and **43** was obtained. Each isomer formed a tosylate for eventual elaboration to the pyridinium systems **46** and **47**.

Analogous methylation of **40** did not yield the expected enol ether but gave instead two 'dimeric-type' products ($m/e \geq 838$) which were stable to quite vigorous acid conditions and were not affected by treatment with sodium borohydride. Furthermore these products were formed almost quantitatively on storage of **40** for several months, in the dark. Each of these dimers underwent apparent hydrogenolysis over Pd/C catalyst, to give in each case two products (m/e 658.3034, $C_{41}H_{42}N_2O_6$; m/e 700.3134, $C_{43}H_{44}N_2O_7$). Subsequently it was observed that the yield of the vinyl ethers **42** and **43** from the methylation of **41** was by no means reproducible and that the four desbenzyl 'dimers' mentioned above constituted up to 65% of the product mixture. The vinyl ether **42** was also available, although in poor yield, by acid-catalysed reaction of **41** in methanol for prolonged time periods at ambient temperature. Here, the major product (**37**) was presumably formed by Michael addition of methanol and subsequent retro-Aldol cleavage of the intermediate hemiacetal. Similarly **40** provided **48** and **35**. The consistent formation of 'dimeric' products, which were not further investigated, from the 3-hydroxyacrylic ester derivatives precluded this route as an efficient means of producing precursors containing the acrylic ester function. Moreover the expected enol ether hydrolysis was not observed when **42** was kept in dilute sulphuric acid for 18 h. Also the mild reduction process used earlier in the preparation of secodinol was ineffectual, even at ambient temperature, when applied to **40**.

Retrograde Michael reaction of β-amino lactones had proved efficient in the formation of α-methylene-γ-butyrolactone functions in certain sesquiterpenoids (19) and provided here a potential alternative for the generation of acrylic esters. In the event, condensation between the anion of **35** and the 1:1 adduct of dimethylformamide and dimethylsulphate gave the enamine **49**. Reduction of **49** with sodium cyanoborohydride gave directly the acrylic ester **50** together with the amine **51** which rapidly decomposed to **50** even below 0°C.

Alternatively, the stable enamine **52** was formed by heating **40** with piperidinium acetate in refluxing benzene. The use of piperidine in place of its salt gave variable ratios of **52** and **35**. Reduction of **52** with sodium cyanoborohydride and prolonged reflux in methanol afforded the required acrylic ester **50**. However, de-*O*-benzylation by hydrogenation over Pd/C catalyst was accompanied by saturation of the α,β-unsaturated ester to give **53**. Thus the enamine was hydrogenolysed to give the primary alcohol **54** which on reduction with sodium borohydride and subsequent base treatment produced the acrylic ester **55**. More efficiently, hydrogenation of **52** for prolonged periods followed by base treatment gave **55** directly. Reaction with *p*-toluenesulphonyl chloride and triethylamine in dichloromethane gave **56** which



SCHEME 6

was converted to the primary iodide by the action of lithium iodide in refluxing acetone. Condensation of **57** with 3-ethylpyridine in the usual manner gave the required salt **58**. This final product, with the acrylic ester function stabilised by the *N*-benzyl group and containing the pyridinium progenitor of the dihydropyridine, appeared an ideal precursor of a dehydrosecodine (**7**).

Thus, in addition to the synthesis of secodine (**2**), a series of compounds, particularly **58**, of fundamental importance in the investigation of dihydropyridine systems such as **7**, was now in hand. Methods of generation and stabilisation of such systems are discussed in the accompanying publication.

Experimental

Melting points were determined on a Kofler block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in ethanol solution. The wavelengths of absorption maxima are reported in nanometers (nm) with log ε values in parentheses. Infrared (ir) spectra were measured on a Perkin Elmer model 710 or 457 spectrophotometer in chloroform solution. The absorption maxima are reported in wavenumbers (cm^{-1}), calibrated with respect to the absorption band of polystyrene at 1601 cm^{-1}. Proton magnetic resonance (^{1}Hmr) spectra were measured in deuteriochloroform ($CDCl_3$) solution at ambient temperature on either a Varian HA-100 or XL-100 spectrometer. Chemical shift values are given in the δ (ppm) scale relative to tetramethylsilane (TMS) used as internal standard. The integrated peak areas, signal multiplicities and proton assignments are given in parentheses. Low resolution mass spectra (ms) were determined on either an AEI-MS-902 or an Atlas CH-4B spectrometer. High resolution mass spectra were measured on an AEI-MS-902 instrument. Microanalyses were carried out by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia.

Thin-layer chromatography (tlc) utilized Merck silica gel G (according to Stahl) containing 2% fluorescent indicator. For preparative layer chromatography (plc), plates (20 × 20 or 20 × 60 cm) of 1-mm thickness were used. Visualization was effected by viewing under ultraviolet light and/or by colour reaction with ceric sulphate spray reagent. Column chromatography utilized Merck silica gel 60 (70–230 mesh) or Merck aluminum oxide 90 (neutral).

As a matter of routine, all reagents and solvents were recrystallised or distilled before use.

The Chloro Ester ***8***

Diethyl γ-chloropropylmalonate (10) (120 g) was added to a solution of sodium ethoxide (from 12 g of sodium) in dry ethanol and the mixture stirred at ambient temperature for 30 min in an atmosphere of nitrogen. Benzenediazonium fluoroborate (105 g) was added in small portions to the cooled solution such that the reaction mixture was kept below −2°C. Stirring was maintained at 0°C for 2 h and then at −10°C for 12 h. The mixture was poured into water (1 L) and extracted with ether. The extract was washed with water, brine, dried (Na_2SO_4), and concentrated *in vacuo*.

The crude product (190 g) and concentrated sulphuric acid (200 mL) were heated in refluxing dry ethanol (1 L) for 12 h. The cooled mixture was concentrated to ca. 500 mL *in vacuo*, poured onto crushed ice, and extracted with chloroform. The extract was washed successively with water, sodium carbonate solution, water, dried (Na_2SO_4), and concentrated *in vacuo*. The crude, semicrystalline material was chromatographed over alumina (grade III) with benzene–chloroform (1:1) to give the chloro ester **8** (yield 13–20%) as white plates from chloroform – petroleum ether; mp 131–132°C; uv λ_{max}: 296 (4.27), 229 (4.40); ir ν_{max}: 3250, 1670; ^{1}Hmr δ: 9.25 (1H, bs, —N*H*), 7.40 (4H, m), 4.46 (2H, q, J = 7 Hz, —$CO_2CH_2CH_3$), 3.50 (4H, m —CH_2CH_2Cl), 1.40 (3H, t, J = 7 Hz, —$CO_2CH_2CH_3$). *Anal.* calcd. for $C_{13}H_{14}NO_2Cl$: C 62.03, H 5.57, N 5.57, Cl 14.12; found: C 62.07, H 5.53, N 5.60, Cl 14.08.

The Salt ***9***

The chloro ester **8** (6.43 g) and 3-ethylpyridine (22 mL) were heated in a sealed tube at 120°C for 24 h. The mixture was poured into ether and the precipitate collected by filtration to give the pyridinium salt **9** (8.34 g, 91%); mp 87–89°C (methanol–ether); uv λ_{max}: 296 (4.20), 276 (3.90), 226 (4.35), 220 (4.30); ir ν_{max}: 3120–2880, 1701, 1250; ^{1}Hmr (CD_3OD) δ: 8.6–7.66 (4H, m, pyridinium-*H*), 7.44–6.82 (4H, m, indole-*H*), 4.26 (2H, q, J = 7 Hz, —$CO_2CH_2CH_3$), 2.60 (2H, q, J = 7 Hz, —CH_2CH_3), 1.37 (3H, t, J = 7 Hz, —$CO_2CH_2CH_3$), 1.02 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 358, 215, 187, 169, 129. This compound was hygroscopic and analysis was difficult.

The Tetrahydropyridine ***10***

A solution of sodium borohydride (25 g) in methanol (400 mL) was added slowly to the salt **9** (7.67 g) in methanol (275 mL) and triethylamine (8 mL). The mixture was stirred at ambient temperature for 2.5 h, diluted with water (100 mL), and the methanol removed *in vacuo*. The aqueous solution was adjusted to pH 2 with 6 *N* HCl, stirred at ambient temperature for 20 min, and then diluted with excess 10% sodium carbonate solution. The aqueous solution was extracted with dichloromethane, the extract washed with water, dried (Na_2SO_4), and concentrated *in vacuo* to give a thick gum (7 g); ^{1}Hmr ($CDCl_3$) δ: 5.5 (1H, bs, olefinic-*H*), 4.4 (2H, q, J = 7 Hz,

—$CO_2CH_2CH_3$). The crude product was homogeneous on tlc and was used as such for the next reaction.

The Alcohol ***11***

A solution of **10** (7 g) in dry tetrahydrofuran (70 mL) was added during 40 min to a suspension of lithium aluminum hydride (9 g) in dry tetrahydrofuran (350 mL) under a nitrogen atmosphere. The mixture was stirred at ambient temperature for 20 min then at reflux for 2 h. Normal work-up provided a light yellow gum (5.4 g) which was chromatographed on alumina to give the alcohol **11** (4.4 g, 70% from **8**); mp (methanol and sublimation) 108–110°C; uv λ_{max}: 292 (3.73), 284 (3.81), 274 (3.76), 223 (4.45); ir ν_{max}: 3340, 3180; ^{1}Hmr (CD_3OD) δ: 7.6–6.91 (4H, m, indole-*H*), 5.55 (1H, m, olefinic-*H*), 4.83 (2H, s, —CH_2OH), 1.00 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 284 (M^+), 174, 160, 142, 124. High resolution molecular weight determination, calcd. for $C_{18}H_{24}N_2O$: 284.188; found: 284.184. *Anal.* calcd. for $C_{18}H_{24}N_2O{\cdot}CH_3OH$: C 72.09, H 8.93, N 8.85; found: C 72.05, H 9.13, N 8.22.

The Benzoate ***12***

Benzoylation of **11** with benzoyl chloride in pyridine at 0°C gave **12**; mp (dichloromethane – petroleum ether) 110.5–112.5°C; uv λ_{max}: 293 (3.80), 284 (3.96), 274 (3.94), 224 (4.61); ir ν_{max}: 3000, 1715, 1455, 1260; ^{1}Hmr δ: 8.64 (1H, s, —N*H*), 8.0–7.0 (9H, m, aromatic-*H*), 5.42 (3H, bs, olefinic-*H* plus —$CH_2OCOC_6H_5$), 1.00 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 388 (M^+), 266, 170, 143, 124, 122. High resolution molecular weight determination, calcd. for $C_{25}H_{28}N_2O_2$: 388.216; found: 388.215. *Anal.* calcd. for $C_{25}H_{28}N_2O_2$: C 77.27, H 7.28, N 7.21; found: C 77.05, H 7.29, N 7.05.

The benzoate was also available (99% yield) by reaction of **11** with benzoyl chloride in tetrahydrofuran in the presence of anhydrous potassium carbonate, followed by chromatography on alumina.

The Nitrile ***13***

The benzoate **12** (2.0 g) and potassium cyanide (3.3 g) were stirred in dimethylformamide (60 mL) for 1 h under nitrogen. The temperature was raised gradually to 105–110°C over a period of 45 min, maintained at that temperature for 1 h, cooled, diluted with water (100 mL), and extracted with dichloromethane. The extract was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on alumina afforded **13** (0.95 g, 65%); mp (dichloromethane – petroleum ether) 135–137°C; uv λ_{max}: 291 (3.77), 281 (3.85), 274 (3.84), 221 (4.69); ir ν_{max}: 3160, 2900, 2256; ^{1}Hmr δ: 8.37 (1H, s, —N*H*), 7.54–7.00 (4H, m, indole-*H*), 5.42 (1H, m, olefinic-*H*), 3.8 (2H, s, —CH_2CN), 1.01 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 293 (M^+), 267, 169, 156, 124. High resolution molecular weight determination, calcd. for $C_{19}H_{23}N_3$: 293.189; found: 293.186. *Anal.* calcd. for $C_{19}H_{23}N_3$: C 77.75, H 7.92, N 14.32; found: C 77.65, H 7.86, N 14.16.

The Ester ***14***

A solution of the nitrile **13** (746 mg) and water (0.2 mL) in dry methanol (20 mL) was saturated, at 0°C, with HCl gas and then kept at ambient temperature for 60 h. The mixture was concentrated *in vacuo*, diluted with sodium bicarbonate solution, and extracted with dichloromethane. The extract was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on alumina gave the ester **14** (574 mg, 70%); mp (dichloromethane – petroleum ether) 85–87.5°C; uv λ_{max}: 292 (3.83), 283 (3.92), 274 (3.87), 223 (4.43); ir ν_{max}: 3000, 1728, 1460, 1245; ^{1}Hmr δ: 8.54 (1H, bs, —N*H*), 7.58–7.00 (4H, m, indole-*H*), 5.42 (1H, m, olefinic-*H*), 3.73 (2H, s, —$CH_2CO_2CH_3$), 3.66 (3H, s, —CO_2CH_3), 1.00 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 326 (M^+), 267, 202, 156, 144, 124. High resolution molecular weight determination, calcd. for $C_{20}H_{26}N_2O_2$: 326.199; found: 326.202. *Anal.* calcd. for $C_{20}H_{26}N_2O_2$: C 73.50, H 8.04, N 8.58; found: C 73.47, H 8.05, N 8.71.

The Enol ***15***

The ester **14** (50 mg) in dry benzene (3 mL) was added slowly to a suspension of excess sodium hydride (ca. 25 mg) in dry benzene (2 mL) and redistilled methyl formate (2 mL) under an atmosphere of dry nitrogen. The mixture was stirred at ambient temperature for 15 min and then at 35°C for 2 h. The mixture was cooled to ca. 0°C, diluted with methanol (3 drops), and crushed ice. The solution was adjusted to pH 2 with 2 *N* hydrochloric acid, diluted with sodium bicarbonate solution, and extracted with dichloromethane. The extract was washed with water, dried (Na_2SO_4), and concentrated *in vacuo* to afford the crude enol **15** as a white foam. This product was not purified but used directly for the next reaction.

16,17-Dihydrosecodin-17-ol ***1***

Sodium borohydride (50 mg) was added in small portions to a solution of the crude enol **15** (ca. 60 mg) in methanol (3 mL) at −30°C. The mixture was stirred at this temperature for 40 min. The excess hydride was destroyed by careful addition of 2 *N* HCl (2–3 drops). The mixture was diluted with water and the methanol removed *in vacuo*. The aqueous solution was acidified with 2 *N* HCl, then diluted with sodium bicarbonate solution, and extracted with chloroform. The extract afforded 68 mg of white foam. Chromatography on alumina gave **1** (22 mg, 40% from (**14**)); mp (dichloromethane) 131.5–132°C; uv λ_{max}: 292 (3.86), 284 (3.93), 274 (3.87), 222 (4.49); ir ν_{max}: 3400, 3050, 2900, 1718, 1465, 1235; ^{1}Hmr δ: 8.84 (1H, s, —N*H*), 7.52–7.00 (4H, m, indole-*H*), 5.39 (1H, bs, C(15)-*H*), 4.00 (4H, m, —$CHCH_2OH$), 3.63 (3H, s, —CO_2CH_3), 0.96 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 356 (M^+), 338, 326, 214, 202, 124. High resolution molecular weight determination, calcd. for $C_{21}H_{28}N_2O_3$: 356.209; found: 356.207. *Anal.* calcd. for $C_{21}H_{28}N_2O_3$: C 70.24, H 7.93, N 7.86; found: C 70.20, H 7.83, N 7.35.

Secodine ***2***

A solution of the alcohol **1** (20 mg) in dry benzene (2.5 mL) was added, all at once, to a suspension of sodium hydride (16 mg) in dry benzene (0.5 mL). The mixture was stirred at 40°C for 15 min, cooled, and quickly flushed through alumina (2 g, activity IV) with benzene. The eluate was quickly freeze dried to give secodine (**2**) (9.1 mg, 50%) as a light yellow gum; ^{1}Hmr δ: 9.11 (1H, bs, —N*H*), 7.60–7.00 (4H, m, indole-*H*), 6.45 (1H, d, J = 1 Hz, C(17)-*H*), 6.09 (1H, d, J = 1 Hz, C(17)-*H*), 5.42 (1H, m, C(15)-*H*), 3.80 (3H, s, —CO_2CH_3), 1.00 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 338 (M^+), 307, 251, 214, 154, 124.

The Amide ***19***

The indole lactone **18** and excess dimethylamine were stirred in dry methanol at ambient temperature for 48 h. The solvent was removed *in vacuo* and the residue crystallised from acetone–hexane to give the amide (**19**) (87.5%), mp 125–126°C; uv λ_{max}: 289 (4.31), 218 (4.75); ir ν_{max}: 3460, 3200, 1600; ^{1}Hmr δ: 5.92 (1H, s, D_2O exchangeable, —CH_2CH_2OH), 4.0 (2H, t, J = 6 Hz, —CH_2OH), 3.11 (2H, t, J = 6 Hz, —CH_2CH_2OH), 3.04 (6H, s, —$N(CH_3)_2$); ms *m/e*: 232 (M^+), 202 (100%), 158, 128. High resolution molecular weight determination, calcd. for $C_{13}H_{16}N_2O_2$: 232.1211; found: 232.1214.

The Amine ***20***

A solution of the amide **19** (32 g) in dry tetrahydrofuran

(200 mL) was added slowly to a suspension of lithium aluminum hydride (30 g) in dry tetrahydrofuran (750 mL) at 0°C under a nitrogen atmosphere. The mixture was heated under reflux for ca. 5 h, cooled, and quenched with saturated sodium sulphate solution. The mixture was filtered and the solids washed with hot ethyl acetate (ca. 2 L). The filtrate was evaporated and the residue recrystallised from ethyl acetate to give **20** (24.3 g, 84%); mp 140–142°C; uv λ_{max}: 290 (3.88), 281 (3.95), 274 (3.91), 222 (4.61); ir ν_{max}: 3470, 3400–3000; ^{1}Hmr δ: 8.70 (1H, bs, —N*H*), 4.29 (1H, bs, —O*H*), 3.84 (2H, t, J = 6 Hz, —CH_2OH), 3.49 (2H, s, —CH_2N(CH$_3$)$_2$), 3.01 (2H, t, J = 6 Hz, —CH_2CH$_2$OH), 2.20 (6H, s, —N(CH_3)$_2$); ms *m/e*: 218 (M^+), 174, 173, 144 (100%), 143, 132, 130, 115. *Anal.* calcd. for $C_{13}H_{18}N_2O$: C 71.53, H 8.31, N 12.83; found: C 71.39, H 8.15, N 12.79.

*The Methiodide **21***

A solution of iodomethane (27.2 g) in ethyl acetate (40 mL) was added to the amine **20** (24 g) in ethyl acetate (700 mL). The mixture was stirred at ambient temperature for 45 min then at 50°C for 1 h. The mixture was cooled and the precipitate collected by filtration. Recrystallisation from ethanol yielded **21** (35.7 g, 90%); mp 162–165°C; uv λ_{max}: 296 (3.68), 286 (3.93), 273 (4.02), 218 (4.72); ir ν_{max}: 3410, 3280; ^{1}Hmr ($CDCl_3$ + DMSO-d_6) δ: 10.84 (1H, s, —N*H*), 4.96 (2H, s, —CH_2N$^+$), 4.20 (2H, t, J = 6 Hz, —CH_2OH), 3.28 (9H, s, —$^+$N(CH$_3$)$_3$), 3.13 (2H, t, J = 6 Hz, —CH_2CH$_2$OH).

*The Nitrile **22***

The methiodide **21** (40 g) and potassium cyanide (30 g) were heated in refluxing acetonitrile (1 L) under nitrogen for 20 h. The mixture was cooled and filtered. The filtrate was evaporated and the residue filtered through alumina (grade III) with dichloromethane and then with ethyl acetate to give **22** (18.5 g, 87%) mp (benzene) 106–107°C; uv λ_{max}: 289 (3.79), 279 (3.90), 272 (3.89), 220 (4.58); ir ν_{max}: 3680, 3620, 3460, 2400; ^{1}Hmr δ: 8.29 (1H, bs, —N*H*), 3.84 (2H, s, —CH_2CN), 3.81 (2H, t, J = 6 Hz, —CH_2OH), 2.90 (2H, t, J = 6 Hz, —CH_2CH$_2$OH), 1.66 (1H, s, —OH); ms *m/e*: 200 (M^+), 182, 169, 142, 115, 77, 64. *Anal.* calcd. for $C_{12}H_{12}N_2O$: C 71.98, H 6.04, N 13.99; found: C 72.10, H 6.20, N 13.74.

*The Salt **17***

The chloro ester **23** (5.14 g) and freshly distilled 3-ethylpyridine (15 mL) were heated at 82°C for 18 h. The solution was cooled and diluted with ether. The ether was decanted and the residual oil chromatographed on alumina (grade V) with ethyl acetate. Evaporation of the eluate gave a thick oil which was dissolved in water (100 mL). A saturated solution of sodium perchlorate (25 mL) was added and the formed precipitate collected by filtration. Recrystallisation from methanol gave the perchlorate **17** (3.85 g, 44%), mp 140–141.5°C; uv λ_{max}: 289 (3.83), 280 (3.91), 271 (3.98), 265 (4.01), 219 (4.56); ir ν_{max}: 3350, 1740; ^{1}Hmr ($CDCl_3$ + DMSO-d_6) δ: 10.77 (1H, bs, —N*H*), 8.70 (1H, d, J = 6 Hz, C(6′)-*H*), 8.46 (1H, s, C(2′)-*H*), 8.19 (1H, d, J = 8 Hz, C(4′)-*H*), 7.79 (1H, dd, J = 8, 6 Hz, C(5′)-*H*), 4.81 (2H, t, J = 6.5 Hz, —CH$_2$C$H_2$$^+$N—), 3.83 (2H, s, —C$H_2CO_2CH_3$), 3.74 (3H, s, —OC$H_3$), 3.40 (2H, t, J = 6.5 Hz, —CH_2CH$_2$—$^+$N—), 2.60 (2H, q, J = 8 Hz, —CH_2CH$_3$), 1.01 (3H, t, J = 8 Hz, —CH$_2$CH_3). *Anal.* calcd. for $C_{20}H_{23}N_2ClO_6$: C 56.81, H 5.48, N 6.62; found: C 56.61, H 5.30, N 6.63.

*The Lactone **24***

A solution of the lactone **18** (18.7 g) in HMPA (40 mL) and tetrahydrofuran (30 mL) was added slowly to a suspension of potassium hydride (40 mL of 23% suspension) in HMPA (40 mL) and tetrahydrofuran (500 mL) at 0–5°C. Benzyl bromide (35 mL) was added at 0–5°C and stirring maintained at this temperature for 30 min then at ambient temperature for 2 h. The mixture was cooled in ice and excess hydride destroyed by the addition of alumina (grade III, 200 g) and the mixture stirred for 45 min. The solids were removed by filtration and the filtrate concentrated *in vacuo*. Chromatography on silica gel gave **24** (19.9 g, 67%) mp (ethyl acetate – hexane) 109–109.5°C; uv λ_{max}: 297 (4.55), 232 (4.64); ir ν_{max}: 1710; ^{1}Hmr δ: 7.7–7.0 (9H, m, aromatic-*H*), 5.76 (2H, s, —N—CH_2C$_6$H$_5$), 4.56 (2H, t, J = 6 Hz, —CH_2O—), 3.07 (2H, t, J = 6 Hz, —CH_2CH$_2$O—); ms *m/e*: 277 (M^+), 91 (100%). *Anal.* calcd. for $C_{18}H_{15}NO_2$: C 77.96, H 5.45, N 5.05; found: C 77.92, H 5.56, N 5.00.

*The Amide **25***

As described above for the preparation of **19**, **24** gave a 97% yield of **25**; mp (methanol–hexane) 93.5–94°C; uv λ_{max}: 287 (4.31), 215 (4.91); ir ν_{max}: 3280, 1630, 740–710; ^{1}Hmr δ: 6.8–7.8 (9H, m, aromatic-*H*), 5.28 (2H, s, —NCH_2C$_6$H$_5$), 3.78 (2H, t, J = 6 Hz, —CH$_2$CH_2OH), 2.93 (3H, bs, —CONCH_3), 2.95 (2H, m, —CH_2CH$_2$OH), 2.53 (3H, bs, —CONCH_3); ms *m/e*: 322 (M^+), 292 (100%), 291, 278, 277, 248, 247, 91. High resolution molecular weight determination, calcd. for $C_{20}H_{24}N_2O_2$: 322.168; found: 322.165. *Anal.* calcd. for $C_{20}H_{24}N_2O_2$: C 74.51, H 6.88, N 8.69; found: C 74.35, H 6.79, N 8.52.

*The Amide **26***

(*a*) As described for the preparation of **24**, **25** gave a 91% yield of **26** as a thick gum; uv λ_{max}: 287 (3.97), 215 (4.55); ir ν_{max}: 1630, 745, 700; ^{1}Hmr δ: 6.9–7.7 (14H, m, aromatic-*H*), 5.28 (2H, s, —NCH_2C$_6$H$_5$), 4.47 (2H, s, —OCH_2C$_6$H$_5$), 3.69 (2H, t, J = 7 Hz, —CH_2OCH$_2$C$_6$H$_5$), 3.04 (2H, t, J = 7 Hz, —CH_2CH$_2$O—), 2.89 (3H, bs, —CONCH_3), 2.44 (3H, bs, —CONCH_3); ms *m/e*: 412 (M^+), 291, 149, 91 (100%). High resolution molecular weight determination, calcd. for $C_{27}H_{28}N_2O_2$: 412.2151; found: 412.2159.

(*b*) A mixture of **19** (4.64 g), benzyl bromide (20 mL), and tetra-*n*-butylammonium iodide (7.2 g) was heated under reflux in 2 *N* KOH (40 mL) and toluene (65 mL) for 5 h. The mixture was cooled and extracted with ether. The extract was washed with brine, dried (Na_2SO_4), and evaporated. Chromatography on silica gel gave **26** (7.8 g, 95%) identical with that obtained above.

*Reductions of the Amide **26***

(*a*) A solution of the amide (**26**) (1.65 g) in dry tetrahydrofuran (10 mL) was added slowly to a suspension of lithium aluminum hydride (230 mg) in dry tetrahydrofuran (10 mL) at 0°C under nitrogen. The mixture was stirred at ambient temperature for 4 h, cooled, and excess hydride destroyed with $Na_2SO_4 \cdot 10H_2O$. The solids were removed by filtration and the filtrate concentrated *in vacuo*. Chromatography on silica gel afforded:

*The amine **27***—(150 mg, 9.5%); uv λ_{max}: 296, 285, 277, 225; ir ν_{max}: 1470, 1450, 1360, 740, 700; ^{1}Hmr δ: 6.8–7.7 (14H, m, aromatic-*H*), 5.50 (2H, s, —NCH_2C$_6$H$_5$), 4.48 (2H, s, —OCH_2C$_6$H$_5$), 3.67 (2H, t, J = 8 Hz, —CH$_2$CH_2O—), 3.19 (2H, s, —CH_2N(CH$_3$)$_2$), 3.09 (2H, t, J = 8 Hz, —CH_2CH$_2$O—), 2.11 (6H, s, —N(CH_3)$_2$); ms *m/e*: 398 (M^+), 354, 353, 352, 262, 232, 91 (100%). High resolution molecular weight determination, calcd. for $C_{27}H_{30}N_2O$: 398.2358; found: 398.2387.

*The alcohol **28***—(850 mg, 67%); uv λ_{max}: 297 (3.81), 286 (3.88), 279 (3.87), 225 (4.52); ir ν_{max}: 3400, 740, 700; ^{1}Hmr δ: 6.8–7.6 (14H, m, aromatic-*H*), 5.35 (2H, s, —NCH_2C$_6$H$_5$), 4.54 (2H, s, —CH_2OH), 4.38 (2H, s, —OCH_2C$_6$H$_5$), 3.66 (2H, t, J = 6 Hz, —CH$_2$CH_2O—), 3.06 (2H, t, J = 6 Hz, —CH_2CH$_2$O—), 2.82 (1H, bs, —O*H*); ms *m/e*: 371 (M^+),

250 (100%), 91. High resolution molecular weight determination, calcd. for $C_{24}H_{25}NO_2$: 371.1885; found: 371.1906.

(*b*) A solution of the amide **26** (3.0 g) in dry tetrahydrofuran (25 mL) was added slowly to a suspension of lithium aluminum hydride (928 mg) in dry tetrahydrofuran (20 mL) at 0–5°C under nitrogen. The mixture was stirred at ambient temperature for 18 h. Work-up as described above gave a thick oil (3.127 g) which was stirred with iodomethane (6 mL) in ethyl acetate (50 mL) for 40 h at ambient temperature. The solid material was collected by filtration and the filtrate evaporated to give **28** (1.26 g, 46%) identical with that obtained above. The solid was recrystallised from methanol – ethyl acetate to yield the methiodide **29** (2.12 g, 48%); mp 143–145.5°C (dec.); uv λ_{max}: 304 (3.71), 292 (3.89), 276 (4.01), 220 (4.68); ir ν_{max}: 1400, 1200, 1100, 1030, 860, 730, 690; ^{1}Hmr ($CDCl_3$ + DMSO-d_6) δ: 6.7–7.8 (14H, m, aromatic-*H*), 5.67 (2H, s, —N$CH_2C_6H_5$), 5.01 (2H, s, —$CH_2N(CH_3)_3$), 4.46 (2H, s, —O$CH_2C_6H_5$), 3.81 (2H, t, J = 6.5 Hz, —CH_2CH_2O—), 3.24 (11H, envelope, —N(CH_3)$_3$ and —CH_2CH_2O—). *Anal.* calcd. for $C_{28}H_{33}N_2OI$: C 62.22, H 6.15, N 5.18; found: C 62.21, H 6.30, N 5.12.

(*c*) A solution of borane–tetrahydrofuran (1.5 mL of 1 *N* solution) was added to the amide **26** (250 mg) in dry tetrahydrofuran (50 mL) at 0–5°C under a nitrogen atmosphere. The solution was refluxed for 1 h, diluted with triethylamine (1 mL), and reflux continued for 2 h. The mixture was cooled and concentrated *in vacuo*. The residue was dissolved in ethyl acetate, washed with 1 *N* ammonium hydroxide solution, water, brine, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on silica gel gave the amine **27** (140 mg, 58%) identical with that prepared above.

(*d*) *n*-Butanol (8.4 mL) was added, over a period of 15 min, to a suspension of lithium aluminum hydride (3.5 g) in dry tetrahydrofuran (60 mL) at 0–5°C under nitrogen and the mixture stirred at ambient temperature for 1 h. A solution of the amide **26** (7.4 g) in dry tetrahydrofuran (100 mL) was added and the mixture stirred at ambient temperature for 4 h. Work-up as described above gave a mixture of **27** and **28** (6.5 g, ratio 6.5:1 by ^{1}Hmr).

This crude product was stirred in ethyl acetate (200 mL) with iodomethane (20 mL) for 18 h. The solid was collected by filtration and the filtrate evaporated to give **28** (0.91 g). Recrystallisation of the solid material from methanol – ethyl acetate gave the salt **29** (8.1 g, 82%).

The Nitrile 32

The salt **29** (18.5 g) and potassium cyanide (10 g) were stirred in refluxing acetonitrile (500 mL) for ca. 40 h. The mixture was cooled and filtered. The filtrate was washed with water (2×), brine (2×), dried, and concentrated *in vacuo*. Chromatography of the residue provided the nitrile **32** (10.6 g, 82%) as a thick gum; uv λ_{max}: 295 (3.84), 283 (3.93), 275 (3.93), 222 (4.59), ir ν_{max}: 2250, 740, 700; ^{1}Hmr δ: 6.8–7.7 (14H, m, aromatic-*H*), 5.40 (2H, s, —N$CH_2C_6H_5$), 4.44 (2H, s, —O$CH_2C_6H_5$), 3.69 (2H, s, —CH_2CN), 3.66 (2H, t, J = 6.5 Hz, —$CH_2OCH_2C_6H_5$), 3.04 (2H, t, J = 6.5 Hz, —CH_2CH_2O—); ms *m/e*: 380 (M^+), 289, 91 (100%). High resolution molecular weight determination, calcd. for $C_{26}H_{24}N_2O$: 380.1887; found: 380.1909.

Excess cyanide in the solid and aqueous washings was destroyed with a saturated solution of ferrous sulphate containing some ferric sulphate.

The Benzoate 33

Benzoyl chloride (3.5 mL) was added to a solution of the alcohol (**28**) (5.6 g) and triethylamine (10 mL) in tetrahydrofuran (200 mL) at 0–5°C and the mixture stirred at ambient temperature for 6 h. The mixture was partitioned between ether and saturated potassium bicarbonate solution. The organic layer was washed with water, brine, dried (Na_2SO_4), and evaporated. Recrystallisation of the residue from ethyl acetate – petroleum ether gave **33** (4.6 g, 64%); mp 90.5–92°C; uv λ_{max}: 300 (3.86), 275 (4.16), 225 (4.66); ir ν_{max}: 1710; ^{1}Hmr δ: 6.8–7.8 (19H, m, aromatic-*H*), 5.45 (2H, s, —$CH_2OCOC_6H_5$), 5.42 (2H, s, —N$CH_2C_6H_5$), 4.16 (2H, s, —O$CH_2C_6H_5$), 3.70 (2H, t, J = 7 Hz, —CH_2CH_2O—), 3.22 (2H, t, J = 7 Hz, —CH_2CH_2O—); ms *m/e*: 475 (M^+), 354 (100%), 232, 91. *Anal.* calcd. for $C_{32}H_{29}NO_3$: C 80.82, H 6.15, N 2.95; found: C 80.62, H 6.19, N 2.92.

The p*-Nitrobenzoate 34*

Similarly the use of *p*-nitrobenzoyl chloride gave **34** (54%); mp (ethyl acetate – hexane) 89–91°C; uv λ_{max}: 300 (3.96), 268 (4.30), 224 (4.63); ir ν_{max}: 1720, 1530, 1350; ^{1}Hmr δ: 8.07 (2H, d, J = 10 Hz, aromatic-*H*), 7.73 (2H, d, J = 10 Hz, aromatic-*H*), 6.8–7.7 (14H, m, aromatic-*H*), 5.57 (2H, s, —CH_2OCOAr), 5.46 (2H, s, —N$CH_2C_6H_5$), 4.50 (2H, s, —O$CH_2C_6H_5$), 3.75 (2H, t, J = 7 Hz, —CH_2CH_2O—), 3.26 (2H, t, J = 7 Hz, —CH_2CH_2O—); ms *m/e*: 520 (M^+), 399, 234, 167, 121, 91 (100%). *Anal.* calcd. for $C_{32}H_{28}N_2O_5$: C 73.83, H 5.42, N 5.38; found: C 73.91, H 5.63, N 5.23.

Solvolysis of the Nitrile 32

(*a*) A solution of the nitrile **32** (20 g) in dry methanol (400 mL) and water (4 mL), cooled to ca. 0°C was saturated with hydrogen chloride. The mixture was heated to reflux for 1 h, cooled, and concentrated *in vacuo*. The residue was partitioned between saturated sodium bicarbonate solution and dichloromethane. The organic layer was washed with water, brine, dried (Na_2SO_4 and K_2CO_3), and evaporated. Chromatography on silica gel afforded the ester (**23**) (8.8 g, 32%) identical with a sample prepared earlier.

(*b*) Reaction of the nitrile **32**, as described above in *a*, at ambient temperature for 72 h, gave after chromatography the ester **35** (67%) as a gum; uv λ_{max}: 295 (3.81), 287 (3.90), 277 (3.87), 224 (4.53); ir ν_{max}: 1735, 740, 700; ^{1}Hmr δ: 6.8–7.7 (14H, m, aromatic-*H*), 5.38 (2H, s, —N$CH_2C_6H_5$), 4.48 (2H, s, —O$CH_2C_6H_5$), 3.71 (2H, s, —$CH_2CO_2CH_3$), 3.68 (2H, t, J = 7 Hz, —CH_2CH_2O—), 3.43 (3H, s, —OCH_3), 3.08 (2H, t, J = 7 Hz, —CH_2CH_2O—); ms *m/e*: 413 (M^+), 312, 292, 91 (100%). High resolution molecular weight determination, calcd. for $C_{27}H_{27}NO_3$: 413.1989; found: 413.1950.

(*c*) Reaction as in *b* above, using acetyl chloride to generate hydrogen chloride in methanol also gave **35** in 67% yield.

The Ester 37

The ester **35** (2.0 g) was hydrogenated over 10% Pd/C (150 mg) in ethyl acetate (40 mL), methanol (40 mL), and 60% perchloric acid (1.6 mL) for 3 h. The mixture was filtered through Celite. The filtrate was diluted with ethyl acetate, washed with 5% sodium bicarbonate solution, dried (Na_2SO_4), and evaporated. Chromatography on silica gel gave the ester **37** (1.44 g, 92%); uv λ_{max}: 274 (3.40); ir ν_{max}: 3600, 1730; ^{1}Hmr δ: 6.9–7.7 (9H, m, aromatic-*H*), 5.37 (2H, s, —N$CH_2C_6H_5$), 3.90 (2H, t, J = 7 Hz, —CH_2CH_2OH), 3.78 (2H, s, —$CH_2CO_2CH_3$), 3.53 (3H, s, —OCH_3), 3.05 (3H, t, J = 7 Hz, —CH_2CH_2OH); ms *m/e*: 323 (M^+), 292, 131. High resolution molecular weight determination, calcd. for $C_{20}H_{21}NO_3$: 323.1516; found: 323.1543.

The Tosylate 38

The alcohol **37** (1.44 g), *p*-toluenesulphonic acid (2 g), and triethylamine (1 mL) were stirred in dichloromethane (50 mL) at ambient temperature for 24 h. The solvent was removed under reduced pressure and the residue chromatographed on silica gel to give starting material **37** (290 mg) and the tosylate **38** (1.5 g, 70%).

The Iodide ***39***

The crude tosylate **38** (1.5 g) and lithium iodide (400 mg) were heated in refluxing acetone (50 mL) for 19 h. The solvent was removed *in vacuo* and the residue chromatographed on silica gel to yield the iodide **39** (1.22 g, 90%).

The Pyridinium Salt ***36***

The crude iodide **39** (1.22 g) was heated at 45–50°C in 3-ethylpyridine (10 mL) for 17 h. The solvent was removed by aezeotropic distillation with water. The residue was partitioned between water and ethyl acetate. Evaporation of the aqueous layer gave the salt **36** (1.3 g, 85%); mp (acetone) 143–144°C; uv λ_{max}: 265 (4.0); ir ν_{max}: 1710; ^{1}Hmr δ: 9.12 (1H, d, J = 5 Hz, C(6′)-*H*), 8.74 (1H, s, C(2′)-*H*), 8.00 (1H, d, J = 7 Hz, C(4′)-*H*), 7.70 (1H, dd, J = 7, 5 Hz, C(5′)-*H*), 6.76–7.30 (9H, m, aromatic-*H*), 5.25 (2H, s, —NC*H*$_2$C$_6$H$_5$), 5.08 (2H, t, J = 6 Hz, —CH$_2$C*H*$_2$N—), 3.82 (2H, s, —C*H*$_2$CO$_2$CH$_3$), 3.48 (2H, t, J = 6 Hz, —C*H*$_2$CH$_2$N—), 3.49 (3H, s, —OC*H*$_3$), 2.56 (2H, q, J = 6 Hz, —C*H*$_2$CH$_3$), 0.90 (3H, t, J = 6 Hz, —CH$_2$C*H*$_3$). *Anal.* calcd. for C$_{27}$H$_{29}$N$_2$O$_2$I: C 60.00, H 5.37, N 5.19, I 23.52; found: C 59.64, H 5.40, N 5.13, I 23.40.

The Enol ***40***

Potassium diisopropylamide was prepared at −30 to 0°C from potassium hydride (5.5 mL of 20% dispersion in oil) and diisopropylamine (10 mL) in dry tetrahydrofuran (50 mL) and dry HMPA (5 mL). A solution of **35** (3.0 g) in dry tetrahydrofuran (10 mL) was added at −30°C. The mixture was stirred at this temperature for 15 min, at ambient temperature for 1 h, then cooled to −30°C. Dry methyl formate (50 mL) was added and the mixture stirred at ambient temperature for 18 h and diluted with water (100 mL), ethyl acetate (250 mL), and 1 *N* HCl (100 mL). The organic layer was washed with water, saturated sodium bicarbonate solution, brine, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on silica gel gave the crude enol **40** (2.6 g) as a pale yellow crystalline solid satisfactory for use in further reactions. Recrystallisation from methanol gave pure **40** (2.1 g, 65%); mp 88–90°C; uv λ_{max}: 295 (4.01), 286 (4.12), 275 (4.17), 225 (4.45); ir ν_{max}: 3500–3000, 1665, 1605; ^{1}Hmr δ: 6.8–7.8 (16H, m, aromatic-*H*, olefinic-*H*, —O*H*), 5.11 (2H, s, —NC*H*$_2$C$_6$H$_5$), 4.46 (2H, s, —OC*H*$_2$C$_6$H$_5$), 3.64 (2H, t, J = 7 Hz, —CH$_2$C*H*$_2$O—), 3.35 (3H, s, —OC*H*$_3$), 2.95 (2H, t, J = 7 Hz, —C*H*$_2$CH$_2$O—); ms *m/e*: 441 (M$^+$), 320, 290, 289, 288, 91 (100%). *Anal.* calcd. for C$_{28}$H$_{27}$NO$_4$: C 76.17, H 6.16, N 3.17; found: C 76.16, H 6.00, N 3.35.

The Enol ***41***

The enol **40** (52 mg) and 10% Pd/C catalyst (11 mg) were stirred in methanol (5 mL) under one atmosphere of hydrogen at ambient temperature for 9 h. The mixture was filtered through Celite and the filtrate concentrated *in vacuo*. Chromatography on silica gel gave **40** (12 mg) and **41** (28 mg, 67%) as a clear gum; uv λ_{max}: 276, 225; ir ν_{max}: 3700–3200, 1665, 1610; ^{1}Hmr δ: 6.4–7.7 (12H, m, aromatic-*H*, olefinic-*H*, 2 × —O*H*), 5.11 (2H, bs, —NC*H*$_2$C$_6$H$_5$), 3.72 (2H, poorly resolved t, —CH$_2$C*H*$_2$OH), 3.36 (3H, bs, —OC*H*$_3$), 2.88 (2H, poorly resolved t, —C*H*$_2$CH$_2$OH); ms *m/e*: 351 (M$^+$), 320, 319, 292, 289, 288, 91 (100%).

The Ethers ***42*** *and* ***43***

Excess ethereal diazomethane was added at 0–5°C to a solution of **41** (55 mg) in ethyl acetate (2 mL). The solution was kept at this temperature for 12 h. Excess reagent and solvent were removed by passage of nitrogen. Chromatography of the residue provided **41** (16 mg) together with ethers **42** and **43**.

Ether ***42***—(12 mg, 21%); uv λ_{max}: 288 (3.86), 226 (4.56); ir ν_{max}: 3660, 3600, 3560, 1700, 1630; ^{1}Hmr δ: 7.69 (1H, s, olefinic-*H*), 7.0–7.6 (9H, m, aromatic-*H*), 5.16 (2H, s, —NC*H*$_2$C$_6$H$_5$), 4.86 (2H, t, J = 6 Hz, —CH$_2$C*H*$_2$OH), 3.69 (3H, s, —OC*H*$_3$), 3.57 (3H, s, —CO$_2$C*H*$_3$), 2.93 (2H, t, J = 6 Hz, —C*H*$_2$CH$_2$OH), 1.83 (1H, bs, —O*H*); ms *m/e*: 365 (M$^+$), 334 (100%), 91. High resolution molecular weight determination, calcd. for C$_{22}$H$_{23}$NO$_4$: 365.1627; found: 365.1627.

Ether ***43***—(6 mg, 11%); uv λ_{max}: 289 (3.89), 226 (4.56); ir ν_{max}: 3550, 1710, 1630; ^{1}Hmr δ: 6.9–7.8 (9H, m, aromatic-*H*), 6.52 (1H, s, olefinic-*H*), 5.24 (2H, s, —NC*H*$_2$C$_6$H$_5$), 3.88 (2H, t, J = 6 Hz, —CH$_2$C*H*$_2$OH), 3.79 (3H, s, —OC*H*$_3$), 3.51 (3H, s, —CO$_2$C*H*$_3$), 3.05 (2H, t, J = 6 Hz, —C*H*$_2$CH$_2$OH), 1.7 (1H, bs, —O*H*); ms *m/e*: 365 (M$^+$), 334 (100%), 91. High resolution molecular weight determination, calcd. for C$_{22}$H$_{23}$NO$_4$: 365.1627; found: 365.1628.

The Tosylates ***44*** *and* ***45***

The ether **42** (25 mg), *p*-toluenesulphonyl chloride (120 mg), and pyridine (150 μL) were stirred in chloroform (2 mL) initially at 0°C then at ambient temperature for 12 h. The mixture was diluted with chloroform, washed with water, sodium bicarbonate solution, brine, dried (Na_2SO_4), and concentrated. Chromatography on silica gel gave **44** (14 mg, 40%) as a clear oil; ir ν_{max}: 1705, 1630, 1360, 1190, 1175; ^{1}Hmr δ: 7.69 (1H, s, olefinic-*H*), 6.8–7.8 (13H, m, aromatic-*H*), 5.14 (2H, s, —NC*H*$_2$C$_6$H$_5$), 4.19 (2H, t, J = 8 Hz, —CH$_2$C*H*$_2$O—), 3.71 (3H, s, —OC*H*$_3$), 3.54 (3H, s, —CO$_2$C*H*$_3$), 3.01 (2H, t, J = 8 Hz, —C*H*$_2$CH$_2$O—), 2.40 (3H, s, —C$_6$H$_4$C*H*$_3$); ms *m/e*: 519 (M$^+$), 334, 155, 91 (100%). High resolution molecular weight determination, calcd. for C$_{29}$H$_{29}$NO$_6$S: 519.1893; found: 519.1891.

Similarly, **43** gave a 39% yield of **45**; uv λ_{max}: 285, 222; ir ν_{max}: 1710, 1630, 1360, 1190, 1175; ^{1}Hmr δ: 6.9–7.8 (13H, m, aromatic-*H*), 6.65 (1H, s, olefinic-*H*), 5.14 (2H, s, —NC*H*$_2$C$_6$H$_5$), 4.14 (2H, t, J = 7 Hz, —CH$_2$C*H*$_2$O—), 3.78 (3H, s, —OC*H*$_3$), 3.38 (3H, s, —CO$_2$C*H*$_3$), 3.01 (2H, t, J = 7 Hz, —C*H*$_2$CH$_2$O—), 2.30 (3H, s, —C$_6$H$_4$C*H*$_3$).

The Salts ***46*** *and* ***47***

The crude tosylates **44** and **45** obtained as described above from a mixture of **42** and **43** (1.98 g) were heated at 80°C in dry 3-ethylpyridine (4 mL) for 100 h. The excess solvent was removed *in vacuo* and the residue chromatographed on alumina (acidic, activity V) with ethyl acetate – methanol (95:5) to give the pure *E* isomer (300 mg) plus a mixture of *E* and *Z* isomers (400 mg). The *E* isomer was converted to the perchlorate (**46**) as described for the preparation of **17**; uv λ_{max}: 285 (3.90), 262 (4.03), 216 (4.59); ir ν_{max}: 1700, 1630; ^{1}Hmr δ: 8.67 (1H, d, J = 5 Hz, C(6′)-*H*), 8.24 (1H, bs, C(2′)-*H*), 8.06 (1H, bd, J = 7 Hz, C(4′)-*H*), 7.85 (1H, s, olefinic-*H*), 7.75 (1H, dd, J = 7, 5 Hz, C(5′)-*H*), 6.8–7.4 (9H, m, aromatic-*H*), 5.22 (2H, bs, —NC*H*$_2$C$_6$H$_5$), 4.86 (2H, 8 line m, —CH$_2$C*H*$_2$N$^+$—), 3.88 (3H, s, —OC*H*$_3$), 3.76 (3H, s, —CO$_2$C*H*$_3$), 3.42 (2H, bt, J = 6 Hz, —C*H*$_2$CH$_2$N$^+$), 2.56 (2H, q, J = 7 Hz, —C*H*$_2$CH$_3$), 0.95 (3H, t, J = 7 Hz, —CH$_2$C*H*$_3$). *Anal.* calcd. for C$_{29}$H$_{31}$N$_2$O$_7$Cl: C 62.76, H 5.63, N 5.05; found: C 62.37, H 5.93, N 4.60.

Methylation of ***40*** *and* ***41***

The crude enol **40** (44 mg) was dissolved in benzene (0.5 mL) and methanol (3 mL) saturated with hydrogen chloride. The mixture was kept in the dark at ambient temperature for 5 days. The solvent was removed *in vacuo* and the residue chromatographed on silica gel to give **35** (20 mg) together with **48** (8 mg); ir ν_{max}: 1700, 1630; ^{1}Hmr δ: 7.66 (1H, s, olefinic-*H*), 7.0–7.6 (14H, m, aromatic-*H*), 5.14 (2H, bs, —NC*H*$_2$C$_6$H$_5$), 4.56 (2H, s, —OC*H*$_2$C$_6$H$_5$), 3.62 (3H, s, —OC*H*$_3$), 4.50 (3H, s, —OC*H*$_3$), 3.02 (2H, dd, J = 8, 6 Hz,

—CH_2CH$_2$O—); ms *m/e*: 455 (M^+), 334, 163, 121, 105, 91 (100%).

Similarly, **41** gave **37** (40%) together with **42** (20%), identical with respective authentic samples.

The Enamine 49

A solution of the ester **35** (160 mg) in dry tetrahydrofuran (2 mL) was added to a solution of lithium diisopropylamide (0.84 mmol) in tetrahydrofuran (10 mL) and HMPA (0.13 mL) at −78°C under a nitrogen atmosphere. The solution was stirred at −78°C for 15 min then allowed to attain 0°C. The adduct of dimethylformamide and dimethyl sulphate (1:1, 1 g) was added and the mixture stirred at 0°C for 2 h. The mixture was diluted with water and extracted with ethyl acetate. The extract was washed with water, brine, dried (Na_2SO_4), and evaporated. Chromatography on silica gel gave **35** (68 mg) together with the enamine (**49**) (30%); mp (methanol) 112–113°C; ir ν_{max}: 1665, 1600; ^{1}Hmr δ: 7.71 (1H, s, olefinic-*H*), 7.0–7.7 (14H, m, aromatic-*H*), 5.12 (2H, q, J_{AB} = 16 Hz, N—CH_2C$_6$H$_5$), 4.48 (2H, s, —OCH_2C$_6$H$_5$), 3.64 (2H, m, —CH$_2$CH_2O—), 3.33 (3H, s, —CO$_2$CH_3), 2.92 (2H, m, —CH_2CH$_2$O—), 2.42 (6H, bs, —N(CH_3)$_2$); ms *m/e*: 468 (M^+, 100%), 347, 316, 256, 91. *Anal.* calcd. for $C_{30}H_{32}N_2O_3$: C 76.90, H 6.88, N 5.98; found: C 76.69, H 6.97, N 6.25.

The Acrylic Ester 50

Glacial acetic acid (8 drops) was added to a solution of the enamine **49** (50 mg) and sodium cyanoborohydride (50 mg) in methanol and tetrahydrofuran (1:1, 8 mL) and the mixture stirred under a nitrogen atmosphere for 18 h. The mixture was evaporated and the residue partitioned between saturated sodium bicarbonate solution and ethyl acetate. The extract was washed with water, brine, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed on silica gel to give the following compounds.

The acrylic ester 50—(16 mg, 35%); mp 87–89°C; uv λ_{max}: 276, 223; ir ν_{max}: 1720, 1615; ^{1}Hmr δ: 7.0–7.8 (14H, m, aromatic-*H*), 6.75 (1H, d, *J* = 2 Hz, olefinic-*H*), 5.89 (1H, d, *J* = 2 Hz, olefinic-*H*), 5.20 (2H, s, —NCH_2C$_6$H$_5$), 4.53 (2H, s, —OCH_2C$_6$H$_5$), 3.72 (2H, t, *J* = 7.5 Hz, —CH$_2$CH_2O—), 3.52 (3H, s, —CO$_2$CH_3), 3.05 (2H, t, *J* = 7.5 Hz, —CH_2CH$_2$O—); ms *m/e*: 425 (M^+), 304 (100%), 91. *Anal.* calcd. for $C_{28}H_{27}NO_3$: C 79.03, H 6.40, N 3.29; found: C 78.71, H 6.50, N 3.21.

The unstable amine 51—(8 mg); ^{1}Hmr δ: 6.8–7.6 (aromatic-*H*), 5.38 (2H, s, —NCH_2C$_6$H$_5$), 4.52 (2H, s, —OCH_2C$_6$H$_5$), 3.41 (3H, s, —CO$_2$CH_3), 2.03 (6H, s, —N(CH_3)$_2$).

The Enamine 52

The crude enol **40** (from 1.32 g of **35**) and piperidinium acetate (4 g) were heated in refluxing benzene (150 mL) for 17 h. The solution was cooled, washed with 5% sodium bicarbonate solution, water, brine, dried (Na_2CO_3), and concentrated. Chromatography on silica gel gave the enamine **52** (657 mg, 41% from **35**); uv λ_{max}: 283 (4.30); ir ν_{max}: 1670, 1590; ^{1}Hmr δ: 7.77 (1H, s, olefinic-*H*), 7.0–7.7 (14H, m, aromatic-*H*), 5.14 (2H, q, J_{AB} = 16 Hz, —NCH_2C$_6$H$_5$), 4.52 (2H, s, —OCH_2C$_6$H$_5$), 3.36 (3H, s, —OCH_3); ms *m/e*: 508 (M^+), 477, 449, 387, 296, 277, 224, 154, 91. High resolution molecular weight determination, calcd. for $C_{33}H_{36}N_2O_3$: 508.2716; found: 508.2727.

The Alcohol 53

Sodium cyanoborohydride (39 mg) was added to the enamine **52** (110 mg) in a 0.1 *M* solution of citric acid in methanol (10 mL). The pH of the solution was adjusted to 3.0 with 0.1 *M* aqueous disodium citrate, and the mixture stirred at ambient temperature for 16 h. The solution was then heated to reflux for 24 h, concentrated *in vacuo*, and the residue chromatographed on silica gel to give the acrylic ester **50** (10 mg). Hydrogenation of this product in methanol (10 mL) over 10% Pd/C (9 mg) as described for the preparation of **41**, gave **53** (10 mg); ^{1}Hmr δ: 6.8–7.7 (9H, m, aromatic-*H*), 5.30 (2H, bs, —NCH_2C$_6$H$_5$), 4.14 (1H, q, *J* = 7 Hz, —C*H*CH$_3$), 3.83 (2H, bt, *J* = 6 Hz, —CH$_2$CH_2OH), 3.34 (3H, s, —OCH_3), 1.40 (3H, d, *J* = 7 Hz, —CHCH_3); ms *m/e*: 337 (M^+), 319, 305, 278, 246, 156, 91.

The Alcohol 54

The enamine (**52**) (281 mg) was hydrogenated in methanol (30 mL) over 10% Pd/C (89 mg) for 3 h to give **54** (137 mg, 59%); ^{1}Hmr δ: 7.76 (1H, s, olefinic-*H*), 7.0–7.7 (9H, m, aromatic-*H*), 5.16 (2H, q, J_{AB} = 16 Hz, —NCH_2C$_6$H$_5$), 3.47 (3H, s, —OCH_3); ms *m/e*: 418 (M^+), 387.

The Acrylic Ester 55

(*a*) Sodium cyanoborohydride (41.5 mg) was added to a solution of crude **54** (135 mg) in methanol (76.5 mL) and 1 *M* citric acid in methanol (8.5 mL). The pH of the solution was adjusted to 3.0 with 0.1 *M* aqueous disodium citrate and stirring continued for 18 h. The solvents were removed *in vacuo* and the residue partitioned between sodium carbonate solution and ethyl acetate. The organic layer was dried (Na_2CO_3) and evaporated. The residue was heated in refluxing benzene for 18 h and chromatographed on silica gel to give **55** (104 mg, 96%); uv λ_{max}: 275 (3.30); ir ν_{max}: 3600, 1720; ^{1}Hmr δ: 6.9–7.7 (9H, m, aromatic-*H*), 6.75 (1H, d, *J* = 2 Hz, olefinic-*H*), 5.91 (1H, d, *J* = 2 Hz, olefinic-*H*), 5.20 (2H, s, —NCH_2C$_6$H$_5$), 3.88 (2H, t, *J* = 6 Hz, —CH$_2$CH_2OH), 3.58 (3H, s, —OCH_3), 3.00 (2H, t, *J* = 6 Hz, —CH_2CH$_2$OH), 1.62 (1H, bs, —O*H*); ms *m/e*: 335 (M^+), 304, 175, 143, 101, 91. High resolution molecular weight determination, calcd. for $C_{21}H_{21}NO_3$: 335.1516; found: 335.1541.

(*b*) As described above, the enamine **52** (657 mg) was hydrogenated in methanol (55 mL), ethyl acetate (55 mL), and perchloric acid (4 mL) over 10% Pd/C catalyst (378 mg) for 30 h. The mixture was filtered through Celite and the filtrate stirred vigorously with saturated sodium bicarbonate solution for 30 min. The aqueous layer was extracted with ethyl acetate and the combined organic layers washed with brine, dried (K_2CO_3), and evaporated. Chromatography on silica gel gave **55** (299 mg, 69%).

The Tosylate 56

Triethylamine (16 drops) was added to a solution of the crude alcohol (**55**) (65 mg) and *p*-toluenesulphonic acid (111 mg) in dichloromethane (8 mL) and the mixture stirred for 19 h. The solvent was removed *in vacuo* and the residue chromatographed on silica gel to give **55** (12 mg) together with the tosylate **56** (41 mg); ^{1}Hmr δ: 7.0–7.7 (13H, m, aromatic-*H*), 6.74 (1H, d, *J* = 2 Hz, olefinic-*H*), 5.84 (1H, d, *J* = 2 Hz, olefinic-*H*), 5.16 (2H, s, —NCH_2C$_6$H$_5$), 4.18 (2H, t, *J* = 7 Hz —CH$_2$CH_2O—), 3.56 (3H, s, —OCH_3), 3.04 (2H, t, *J* = 7 Hz, —CH_2CH$_2$O—), 2.36 (3H, bs, ArCH_3).

The Iodide 57

The crude tosylate **56** (41 mg) and lithium iodide (158 mg) were heated in refluxing, dry acetone (15 mL) for 19 h. The solvent was evaporated and the residue chromatographed on silica gel to yield **57** (35 mg, 94%); ^{1}Hmr δ: 6.9–7.7 (9H, m, aromatic-*H*), 6.80 (1H, d, *J* = 2 Hz, olefinic-*H*), 5.90 (1H, d, *J* = 2 Hz, olefinic-*H*), 5.22 (2H, bs, —NCH_2C$_6$H$_5$), 3.52 (3H, s, —OCH_3), 3.34 (4H, bs, —CH_2CH_2—); ms *m/e*: 445 (M^+), 318, 304, 149, 91.

The Pyridinium Salt 58

The crude iodide **57** (25 mg) was heated at 40°C in 3-ethylpyridine (4 mL) for 21 h. The solvent was removed by

azeotropic distillation with water, under reduced pressure. The residue was partitioned between water and benzene (vigorous stirring) and the layers separated. The organic layer gave a mixture (ca. 1:1) of **57** and **58** (9 mg). The aqueous layer afforded pure **58** (26 mg); mp 130–132°C; uv λ_{max}: 285 (3.70), 265 (3.85); ir ν_{max}: 1700; ^{1}Hmr δ: 9.15 (1H, d, J = 6 Hz, C(6′)-*H*), 8.61 (1H, s, C(2′)-*H*), 7.97 (1H, d, J = 8 Hz, C(4′)-*H*), 7.71 (1H, dd, J = 8, 6 Hz, C(5′)-*H*), 6.8–7.4 (9H, m, aromatic-*H*), 6.76 (1H, d, J = 2 Hz, olefinic-*H*), 6.00 (1H, d, J = 2 Hz, olefinic-*H*), 5.17 (2H, s, —N$CH_2C_6H_5$), 5.10 (2H, t, J = 6 Hz, —CH_2CH_2N—), 3.73 (3H, s, —OCH_3), 3.49 (2H, t, J = 6 Hz, —CH_2CH_2N—), 2.53 (2H, q, J = 7 Hz, —CH_2CH_3), 0.93 (3H, t, J = 7 Hz, —CH_2CH_3). *Anal.* calcd. for $C_{28}H_{29}N_2O_5I$: C 60.87, H 5.25, N 5.09, I 23.01; found: C 60.49, H 5.23, N 4.79, I 23.11.

Received July 31, 1978

JAMES P. KUTNEY, RODNEY A. BADGER, WILLIAM R. CULLEN, ROBERT GREENHOUSE, MASAKI NODA, VICENTE E. RIDAURA-SANZ, YING HUNG SO, ANTONIO ZANAROTTI, and BRIAN R. WORTH. Can. J. Chem. **57**, 300 (1979).

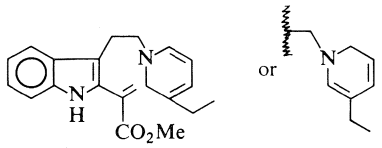
Controlled reduction of *N*-methyl-3-ethylpyridinium iodide afforded the corresponding 1,2-dihydropyridine which was stabilised by complexation to give 1,2- and 1,6-dihydro-3-ethyl-*N*-methylpyridinetricarbonylchromium(0). These stable, isomeric complexes were interrelated by thermal equilibration. Analogous sequences with more complex, alkaloid derivatives enabled formation, and stabilisation by complexation, of 1,2- and 1,6-dihydropyridines in the presence of other functions such as the indole unit and ester groups.

JAMES P. KUTNEY, RODNEY A. BADGER, WILLIAM R. CULLEN, ROBERT GREENHOUSE, MASAKI NODA, VICENTE E. RIDAURA-SANZ, YING HUNG SO, ANTONIO ZANAROTTI et BRIAN R. WORTH. Can. J. Chem. **57**, 300 (1979).

La réduction contrôlée de l'iodure du *N*-méthyléthyl-3 pyridinium conduit à la dihydro-1,2 pyridine correspondante que l'on a stabilisée par complexation pour isoler les dihydro-1,2 (et -1,6) éthyl-3 *N*-méthylpyridines tricarbonylchrome(0). On a pu relier ces complexes stables et isomères par l'équilibration thermique. Des séries de réactions analogues avec des dérivés d'alcaloïdes plus complexes ont permis de former et de stabiliser par complexation des dihydro-1,2 (et -1,6) pyridines en présence d'autres fonctions comme des groupes indole et ester.

[Traduit par le journal]

The important role of 1,4-dihydropyridines in various biological systems is well known and the chemistry of such compounds has received considerable attention (2). On the other hand, although 1,2-dihydropyridines have been implicated in alkaloid biosynthesis with certain plant species (3), comparatively little is known in this area. Electron withdrawing substituents have been shown to stabilize dihydropyridine systems (2) and the relative stabilities of units lacking such stabilisation have been examined for a few simple cases (4, 5). These nonstabilised dihydropyridines are generally quite reactive and readily undergo Diels–Alder and enamine-type reactions. Our interest in intermediates such as dehydrosecodine (**1**) (1, 3) dictated that the 1,2-dihydro- and/or isomeric 1,6-dihydropyridines be formed, protected/stabilised, and regenerated under mild conditions.



1

Metal carbonyls had found extensive application in the stabilisation of reactive π-electron systems (for extensive reviews see ref. 6) but, with the exception of one preliminary report (7), little information was available on such complexes in which a nitrogen hetero atom provided one of the chelating sites. Nevertheless a tricarbonylchromium(0) complex seemed a potential means of stabilising dihydropyridines. To develop the required methodology a simple model system was chosen. In this regard, inspection of dehydrosecodine (**1**) (1) suggested a 1,3-dialkylpyridine derivative, ideally 3-ethyl-*N*-methyldihydropyridine. This choice, through lack of symmetry in the molecule, also provided potential formation of isomeric 1,2- and 1,6-dihydropyridine derivatives.

Sodium borohydride reduction of pyridinium salts was known to yield the corresponding tetrahydro systems and as expected, reduction of 3-ethyl-*N*-methylpyridinium iodide (**2**) in this manner gave **3** in high yield. Consideration of the mechanism of this reduction suggested that suppression of the protonation of the initially formed dihydropyridine **4** (or its 1,6-dihydro isomer **5**) would prevent further reduction (8) to **3** and enable isolation of the target compound(s). In the event, sodium borohydride reduction of **2** in a vigorously stirred, two-phase

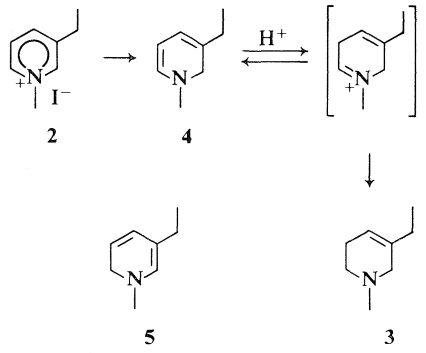
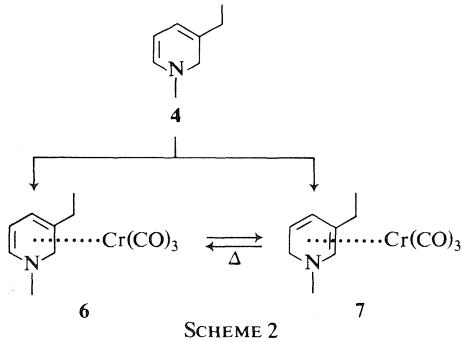
0008-4042/79/030300-04$01.00/0



SCHEME 1

medium (ether, 2 *N* sodium hydroxide) gave the 1,2-dihydropyridine **4** in high yield. The product dimerised on standing at ambient temperature but the ^{1}Hmr spectrum of a freshly prepared sample indicated the structure **4** without observable contamination by the 1,6-dihydro isomer **5**. The ultraviolet spectrum showed the characteristic absorption maximum at 327 nm. Reaction of the crude product with trisacetonitriletricarbonylchromium(0) (9, 10) in ether solution at 0 to 20°C under an *oxygen free* atmosphere of dry nitrogen gave a deep red solution which was filtered through degassed Florisil to give a 67% yield of a mixture of two complexes together with ca. 8% yield of a complex of a dimeric unit (M^+ 382). This latter product was not identified unambiguously but was presumed formed by complexation of an already dimerised dihydropyridine. The major fraction was chromatographed on degassed silica gel, under a nitrogen atmosphere to give 1,2-dihydro-3-ethyl-*N*-methylpyridinetricarbonylchromium(0) (**6**) and 1,6-dihydro-3-ethyl-*N*-methylpyridinetricarbonylchromium(0) (**7**) in the ratio 65:35, respectively. Each complex exhibited the characteristic carbonyl absorption in the infrared region, and electron impact studies gave in each case a weak molecular ion at *m/e* 259, a fragment ion at 123 for the loss of the elements of $Cr(CO)_3$, a base peak at 122 ($C_8H_{12}N$), and significant ions at 107 (C_7H_9N) and 94 (C_6H_8N). The ^{1}Hmr spectra were sufficiently informative to characterise **6** and **7**. In deuteriobenzene, the 1,6-dihydro isomer (**7**) gave singlet absorbance at δ 4.58 for C(2)-*H* and a doublet (J = 7 Hz) at 4.83 for C(4)-*H*. The signal for C(5)-*H* appeared as an octet (J = 7, 5.5, and 1.5 Hz) centred at δ 3.09. Isomer **6** gave, also in deuteriobenzene, the following signals: δ 2.34 (2H, q, J_{AB} = 10 Hz, C(2)-H_2); 4.50 (2H, bd, $J \simeq$ 5 Hz, C(4)-*H* and C(6)-*H*); 5.00 (1H, dd, J = 5.5 and 4.5 Hz). The exact chemical shifts of all signals were significantly dependent on concentration and solvent. Unambiguous confirmation of these structural assignments was possible by X-ray crystal analysis (9).



SCHEME 2

The curious formation of significant amounts of the 1,6-dihydro isomer **7** from **4** required some consideration. Careful ^{1}Hmr analysis of the borohydride reduction product indicated the presence of ca. 5% of the tetrahydro derivative **3** together with **4** (≥95%). Thus formation of **7** was presumed to occur via double bond isomerisation during complexation or by isomerisation of the formed 1,2-dihydropyridine complex **6**. That the latter explanation was unlikely was demonstrated by almost quantitative recovery of **6** after stirring in ether at ambient temperature for 18 h. Thermal isomerisation between **6** and **7** was, however, possible by heating in refluxing cyclohexane. At equilibrium, a 1:1 ratio of **6** and **7** was obtained. The pure complexes were stable in solid form if protected from oxygen and were stable in solution at or below ambient temperature provided that rigorous exclusion of oxygen was ensured.

Thus our initial objectives had been realised and attention turned to the stabilisation of alkaloid precursors bearing the dihydropyridine unit. The preceding report (1) described the preparation of several pyridinium salts, designed specifically for determining the generality of methodology outlined above.

TABLE 1. Thermal equilibration of the complexes **6** and **7**

Time (h)	Ratio **7**:**6** from **7***	Ratio **7**:**6** from **6***
1	76:24	31:69
2	66:34	—
3	63:37	45:55
4	57:43	—
5.5	55:45	50:50
8	50:50	50:50
14	50:50	50:50

*As determined by ^{1}Hmr ($CDCl_3$) integrals of the N—CH_3 signals at δ 2.42 for **6** and δ 2.39 for **7**.

Application of the procedure to the indole derivative **8** gave, after the usual work-up and chromatography, a red oil, assigned the structure **9** on the basis of spectral data. A small amount of a second complex was also isolated and identified as the 1,6-dihydropyridine derivative **10**. This simple experiment had demonstrated that the required complexes could be formed, although only in low yield, in the presence of the electron rich indole nucleus. To further test the method, the salt **11** was reduced and treated with trisacetonitriletricarbonylchromium(0) as before, to give the expected product **12** together with the descarbomethoxy derivative **13** and, surprisingly, **6**. These latter products were presumed formed via cleavages in the strongly basic medium during the reduction step. In each case spectral analysis indicated 1,2-dihydropyridinetricarbonylchromium(0) isomers and here the corresponding 1,6-dihydro products were not detected. The *N*-benzyl derivative **14** did not appear to undergo such fragmentation and here a single product **15** was isolated. The corresponding acrylic ester **16** also formed a single, stable complex but spectral analysis indicated that the reduction of the pyridinium system had occurred with concomitant conjugate reduction of the acrylic ester function leading to **17** in 35% yield.

These experiments indicated that the generally unstable dihydropyridine system could be generated and trapped to form stable complexes without interference from indole and ester functions. Specific

formation of the complex of a dehydrosecodine (**1**), regeneration of the diene and its reactions will be described at a later date. The complexes described here are interesting entities in themselves and investigations of their chemistry are presently underway in these laboratories.

Experimental

General experimental details are given in the accompanying report (1). *All* procedures involving the preparation, separation and purification of chromium complexes were carried out under a liberal flow of oxygen free, dry nitrogen.

3-Ethyl-N-*methyl-1,2,5,6-tetrahydropyridine (3)*

Sodium borohydride (100 mg) was added in portions to a solution of 3-ethyl-*N*-methylpyridinium iodide (250 mg) in methanol (15 mL). After 30 min, the solution was diluted with 3 *N* HCl and washed with ether. The aqueous layer was adjusted to pH 8 and extracted with dichloromethane. The extract was dried (Na_2SO_4) and carefully evaporated to give **3** (98 mg, 79%) as a colourless oil; ^{1}Hmr δ: 5.33 (1H, m, C(4)-H), 2.65 (2H, bs, C(2)-H_2), 2.20 (3H, s, —NCH_3), 0.95 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 125 (M^+), 124, 110, 96 (100%), 94, 82, 81, 67, 44, 43, 42, 39. High resolution molecular weight determination, calcd. for $C_8H_{15}N$: 125.1204; found: 125.1225.

1,2-Dihydro-3-ethyl-N-*methylpyridine (4)*

The salt **2** (3.0 g) was added, all at once, to a vigorously stirred mixture of 2.1 *N* NaOH (9 mL), methanol (9 mL), ether (36 mL), and sodium borohydride (547 mg), under a nitrogen atmosphere. The two-phase system was stirred at ambient temperature for exactly 5 min, the aqueous layer was removed, and the ether layer washed *briefly* with 2.1 *N* NaOH (9 mL), dried by passage through basic alumina (grade I), and evaporated to give **4** (1.294 g, 86%); uv λ_{max}: 327; ^{1}Hmr δ (C_6D_6): 5.73 (2H, m, superimposed doublets, one with J = 7 Hz, C(6)-*H* and C(4)-*H*), 4.74 (1H, dd, J = 7, ca. 7 Hz, C(5)-*H*), 3.58 (2H, s, C(2)-H_2), 2.27 (3H, s, —NCH_3), 1.88 (2H, q, J = 7 Hz, —CH_2CH_3), 1.00 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 123 (M^+), 122 (100%), 108, 107, 96, 94, 67. High resolution molecular weight determination, calcd. for $C_8H_{13}N$: 123.1047; found: 123.1041.

The Tricarbonylchromium(0) Complexes 6 and 7

The pyridinium salt **2** (10 g) was reduced as described above. The washed and dried ether solution of **4** was added under nitrogen to a solution of trisacetonitriletricarbonylchromium (1 equiv.) in dry ether at 0°C and the mixture stirred at

ambient temperature for ca. 20 h. The resulting red solution was filtered through previously degassed Florisil with degassed dichloromethane under a nitrogen atmosphere to afford a mixture of **6** and **7** (6.97 g, 67%; ratio ca. 65:35 by ^{1}Hmr spectroscopy). Elution with oxygen free tetrahydrofuran gave a third red complex (1.2 g, 8%; *m/e* 382). The major fraction was purified by chromatography on silica gel, again with rigorous exclusion of oxygen, to give the following.

*The complex (**6**)*—orange prisms, mp (benzene–hexane) 97–99°C; uv λ_{max}: 403 (3.64); ir ν_{max}: 1830, 1860, 1942; ^{1}Hmr (C_6D_6) δ: 5.00 (1H, dd, J = 5.5 and 4.5 Hz, C(5)-*H*), 4.50 (2H, bd, $J \simeq$ 5 Hz, C(4)-*H* and C(6)-*H*), 2.34 (2H, q, J_{AB} = 10 Hz, C(2)-H_2), 1.60 (2H, q, J = 7 Hz, —CH_2CH_3), 1.45 (3H, s, —NCH_3), 0.70 (3H, t, J = 7 Hz, —CH_2CH_3); ($CDCl_3$) δ: 5.66 (1H, dd, J = 5.5 and 4.5 Hz, C(5)-*H*), 5.41 (1H, d, J = 4.5 Hz, C(6)-*H*), 4.96 (1H, bd, J = 5.5 Hz, C(4)-*H*), 3.24 (2H, bs, C(2)-H_2), 2.42 (3H, s, —NCH_3), 2.10 (2H, bq, J = 7 Hz, —CH_2CH_3), 0.94 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 259 (M^+), 123, 122 (100%), 107, 94. *Anal.* calcd. for $C_{11}H_{13}NO_3Cr$: C 50.90, H 5.05, N 5.40; found: C 51.04, H 4.95, N 5.46.

*The complex (**7**)*—red prisms, mp (benzene–hexane) 68°C; uv λ_{max}: 399 (3.67); ir ν_{max}: 1825, 1860, 1942; ^{1}Hmr (C_6D_6) δ: 4.83 (1H, bd, J = 7 Hz, C(4)-*H*), 4.58 (1H, s, C(2)-*H*), 3.09 (1H, octet, J = 7, 5.5, 1.5 Hz, C(5)-*H*), 2.54 (1H, m, C(6)-*H*), 2.21 (1H, m, C(6)-*H*), 2.30 (2H, m, —CH_2CH_3), 1.45 (3H, s, —NCH_3), 1.12 (3H, t, J = 7 Hz, —CH_2CH_3); ($CDCl_3$) δ: 5.40 (1H, bs, C(2)-*H*), 5.29 (1H, bd, J = 7 Hz, C(4)-*H*), 3.69 (1H, octet, J = 7, 5.5, 1.5 Hz, C(5)-*H*), 3.42 (1H, m, C(6)-*H*), 3.15 (1H, m, C(6)-*H*), 2.73 (2H, m, —CH_2CH_3), 2.39 (3H, s, —NCH_3), 1.40 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 259 (M^+), 123, 122 (100%), 107, 94. *Anal.* calcd. for $C_{11}H_{13}NO_3Cr$: C 50.90, H 5.05, N 5.40; found: C 50.81, H 5.26, N 5.16.

*The Complexes **9** and **10***

Using the procedure described above, the salt **8** gave a 27% yield of the complex **9**; uv λ_{max}: 400 (3.60), 290 (4.02), 285 (4.11), 220 (4.96); ir ν_{max}: 1945, 1855, 1830; ^{1}Hmr (C_6D_6) δ: 7.0–7.6 (4H, m, aromatic-*H*) 6.29 (1H, bs, —indole C(2)-*H*), 4.97 (1H, dd, J = 5.5, 4.5 Hz, C(5)-*H*), 4.70 (1H, d, J = 4.5 Hz, C(6)-*H*), 4.65 (1H, bd, J = 5.5 Hz, C(4)-*H*), 2.69 (2H, bs, C(2)-H_2), 2.45 (4H, bs, —CH_2CH_2—), 1.90 (2H, q, J = 7 Hz, —CH_2CH_3), 0.84 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 388 (M^+), 304, 252, 144, 130, 122, 52.

A small amount (ca. 7%) of the isomeric complex **10** was also isolated; uv λ_{max}: 397, 288, 278, 272, 219; ir ν_{max}: 1950, 1870, 1835; ^{1}Hmr (C_6D_6) δ: 7.1–7.6 (4H, m, aromatic-*H*), 6.31 (1H, bs, —indole C(2)-*H*), 4.96 (1H, d, J = 7 Hz, C(4)-*H*), 4.80 (1H, bs, C(2)-*H*), 3.19 (1H, bdt, J = 7, 2 Hz, C(5)-*H*), 1.12 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 388 (M^+), 304, 252, 144, 130, 122, 52.

*The Complexes **12** and **13***

Reduction of the salt **11** and complexation of the intermediate dihydropyridines in the usual manner gave the following.

*The complex **6***—12% yield.

*The complex **12***—(15%); uv λ_{max}: 400 (3.3); ir ν_{max}: 1950, 1860, 1825, 1730; ^{1}Hmr δ: 8.50 (1H, bs, —N*H*), 7.0–7.6 (4H, m, aromatic-*H*), 5.65 (1H, dd, J = 5.5, 4.5 Hz, C(5)-*H*), 5.43 (1H, d, J = 4.5 Hz, C(6)-*H*), 5.03 (1H, d, J = 5.5 Hz, C(4)-*H*), 3.76 (3H, s, —OCH_3), 3.74 (2H, s, C(2)-H_2), 3.39 (2H, q, J_{AB} = 14 Hz, —CH_2CO_2Me), 2.82 (4H, m, —CH_2CH_2—), 2.19 (2H, q, J = 6 Hz, —CH_2CH_3), 1.02 (3H, t, J = 6 Hz, —CH_2CH_3); ms *m/e*: 460 (M^+), 376, 344, 324, 220, 202, 122, 52. High resolution molecular weight determination, calcd. for $C_{23}H_{24}N_2O_5Cr$: 460.1089; found: 460.1090.

*The complex **13***—(10%); uv λ_{max}: 400 (3.3); ir ν_{max}: 1930, 1840, 1815; ^{1}Hmr δ: 7.83 (1H, bs, —N*H*), 7.05–7.45 (4H, m, aromatic-*H*), 5.61 (1H, dd, J = 5.5, 4.5 Hz, C(5)-*H*), 5.39 (1H, d, J = 4.5 Hz, C(6)-*H*), 5.30 (1H, d, J = 5.5 Hz, C(4)-*H*), 3.38 (2H, s, —C(2)-H_2), 2.82 (4H, m, —CH_2CH_2—), 2.36 (3H, s, —indole C(2)-CH_3), 2.19 (2H, q, J = 6 Hz, —CH_2CH_3), 1.02 (3H, t, J = 6 Hz, —CH_2CH_3); ms *m/e*: 402 (M^+), 318, 266, 158, 144. High resolution molecular weight determination, calcd. for $C_{21}H_{22}N_2O_3Cr$: 402.1030; found: 402.1011.

*The Complex (**15**)*

Stereochemical equilibration of the lithium derivatives of 1,2-diols

CLARKE E. SLEMON[1] AND PETER YATES

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received August 9, 1978

CLARKE E. SLEMON and PETER YATES. Can. J. Chem. **57**, 304 (1979).

The dilithium derivatives of the ditertiary 1,2-diols, *cis*- and *trans*-1,2-dimethyl-1,2-cyclohexanediol, fail to undergo base-induced stereochemical equilibration under conditions that lead to such equilibration with the dilithium derivatives of the disecondary 1,2-diols, *cis*- and *trans*-1,2-cyclohexanediol. This casts doubt on the proposal that the latter equilibration proceeds by carbon–carbon bond cleavage of the dialkoxide to give a diketyl intermediate. It is highly probable that it involves oxidation–reduction as established by Doering in the case of monohydric alcohols. Examination of steroidal secondary-tertiary 1,2-diols under similar conditions shows that such systems can epimerize at both carbinol centres; this is interpreted in terms of sequential oxidation, α-ketol rearrangement, and reduction.

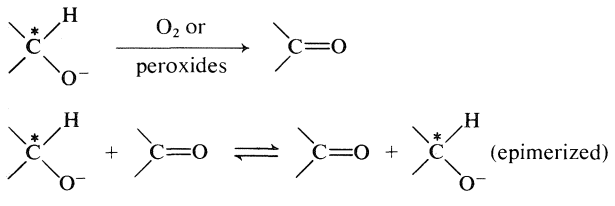
CLARKE E. SLEMON et PETER YATES. Can. J. Chem. **57**, 304 (1979).

Les dérivés dilithiés des diols-1,2 ditertiaires, *cis*- et *trans*-diméthyl-1,2 cyclohexanediols-1,2 ne subissent pas d'équilibrations stéréochimiques induites par les bases dans des conditions qui permettent de telles équilibrations avec les dérivés dilithiés des diols-1,2 disecondaires, *cis*- et *trans*-cyclohexanediols-1,2. Ces résultats jettent un doute sur la proposition à l'effet que la dernière équilibration se produit par l'intermédiaire de la rupture de la liaison carbone–carbone du dialcoolate conduisant à un intermédiaire dicétyle. Il est très probable que cette réaction implique une oxydo-réduction du type proposé par Doering dans le cas des monoalcools. Un examen de diols-1,2 stéroïdaux secondaire–tertiaire dans des conditions semblables montre que de tels systèmes s'épimérisent au niveau des deux centres carbinoliques; on interprète ces résultats en termes d'une oxydation séquentielle, d'une transposition α-cétolique et d'une réduction.

[Traduit par le journal]

Introduction

The mechanism by which secondary alkali metal alkoxides epimerize has been thoroughly examined (1, 2). The results are well accounted for by a reaction sequence (Scheme 1) wherein the substrate is



SCHEME 1

slowly oxidized by solvent impurities or atmospheric oxygen to form a catalytic quantity of the corresponding carbonyl compound. Small amounts of this hydride acceptor are sufficient to prime a chain of hydride transfers between substrate molecules that eventually results in complete stereochemical equilibration.

In agreement with this mechanism, the reaction shows a variable induction period depending upon the extent of exclusion of oxidizing impurities. Moreover, it has been observed that heating alkoxides racemizes asymmetric centres α to the carbinol carbon if they bear a hydrogen atom. Such data conform with the proposed mechanisms in which the alkoxide is converted to a carbonyl group thereby making the α-hydrogen exchangeable in the alkaline medium.

In a piece of elegant experimentation, Doering and Aschner (2) were able to demonstrate that by diligent exclusion of oxygen, alkali peroxides, and carbonyl compounds these epimerizations could be entirely arrested. Alternatively, by the addition of a mixture of fluorenone and fluorenol, one a facile hydride acceptor and the other a facile hydride donor, such stereochemically hindered substrates as α- and β-fenchol, which were inert under other conditions, could be epimerized.

In 1970 Schlosser and Weiss (3) reported the stereochemical equilibration of the dilithium derivatives of 1,2-diols in diglyme at 155°C. These derivatives were formed by treatment of the diols with butyllithium in diglyme, e.g., **1** or **2** gives an equilibrium mixture of **1** and **2** via their dilithium derivatives:

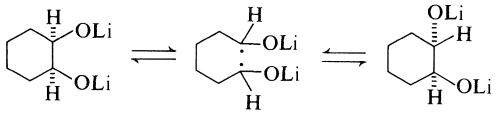
1 2

They proposed that the reaction proceeds by cleavage of the carbon–carbon bond to produce a diketyl **3** which subsequently rebonds[2] (Scheme 2).



3

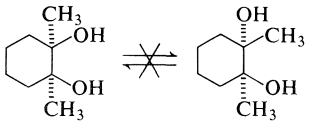
SCHEME 2

However, all of their substrates possessed the requisite hydrogen atoms for the operation of the transfer mechanism of Scheme 1.

Because of the intrinsic interest of the postulated carbon–carbon bond cleavage to give a diketyl, we have undertaken a further study of the reaction of 1,2-diols with butyllithium in diglyme followed by thermolysis. To avoid the mechanistic ambiguity of the earlier work we chose first to investigate a ditertiary 1,2-diol, where hydride transfer processes analogous to those of Scheme 1 could not be operative, whereas cleavage to a diketyl would be expected to be unimpeded and probably enhanced. This investigation has led us to conclude that the stereochemical equilibration of the dilithium derivatives of 1,2-diols is unlikely to proceed via diketyl intermediates. Furthermore, we have found that the diglyme solvent is extensively decomposed under the reaction conditions, giving rise to doubts as to whether the method actually produces the intermediate dialkoxide quantitatively. Nevertheless we have confirmed that the procedure is experimentally effective for secondary-secondary 1,2-diols and have extended it by showing that secondary-tertiary 1,2-diols can be converted to diastereoisomeric mixtures with epimerization at *both* carbinol centres.

Results and Discussion

cis- and *trans*-1,2-Dimethyl-1,2-cyclohexanediol (**4** and **5**) were treated with butyllithium in diglyme in the presence of a trace of triphenylmethane.[3] A large excess of butyllithium was used in an attempt to ensure that all the hydroxyl protons reacted. The resulting mixture was heated in a sealed tube at 200°C for 17 h. Neither **4** nor **5** showed any epimerization by gc and gc–ms analysis under conditions where 1% of either isomer could be detected in authentic mixtures of the two.



4 5

Since **1** and **2** and the other secondary-secondary 1,2-diols examined by Schlosser and Weiss (3), all undergo equilibration even at the lower temperature of 155°C, these experiments provide strong evidence that the equilibration requires at least one non-tertiary alcohol group. This is in complete accord with a route of the type of Scheme 1 but not readily explicable in terms of the diketyl intermediate **3** of Scheme 2. Furthermore, it cannot be argued that the methyl groups inhibit the reaction to give a diketyl, since it has been concluded that in aliphatic ketyls most of the radical character is associated with carbon and most of the anionic character with oxygen (4). Thus it would be expected that if **3** were an intermediate in the equilibration of **1** and **2**, the formation of the corresponding diketyl intermediate would probably be facilitated in the cases of **4** and **5**.[4]

To ensure that *cis*- and *trans*-1,2-cyclohexanediols (**1** and **2**) undergo equilibration under the exact conditions that we employed for **4** and **5** we subjected **1** and **2** to these conditions (200°C, 17 h, triphenylmethane present) and also to the conditions of Schlosser and Weiss (155°C, 17 h, no triphenylmethane). In the latter case we obtained from **1** a 3:97 mixture of **1** and **2** and from **2** a 2:98 mixture of **1** and **2**, in excellent accord with the results reported by the earlier workers. In the former case only the *trans* isomer **2** was detectable in the equilibrated system formed from either **1** or **2**. Although this is a

[2]In the single case examined involving an acyclic 1,2-diol, **3** would correspond to two ketyls.

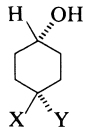
[3]Triphenylmethane was added in the expectation that it would serve as an indicator of excess butyllithium and thus of complete conversion of the diol to its dilithium derivative. In fact we have found that butyllithium reacts with diglyme even at 0°C and no permanent colour ever develops.

[4]The possibility that such a diketyl is formed but does not undergo reclosure because of steric effects may be discounted because of the good recoveries of **4** and **5** after attempted equilibration.

noteworthy difference (and one for which we are currently unable to account) it in no way vitiates our conclusion above concerning the structural requirements for equilibration, since in the case of **4** and **5**, *neither* underwent conversion to the other.

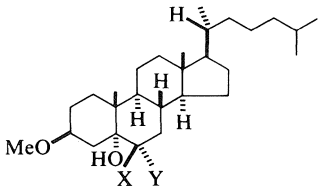
We have observed that the epimerization reaction of **1** and **2** has a variable induction period as expected in terms of Scheme 1. This can be shortened with such additives as triphenylmethane, di-*tert*-butyl peroxide, fluorenone, and fluorenol or lengthened by the addition of lithium hydride. Unfortunately, in spite of considerable effort, it was not possible to bring all the factors affecting the induction period under experimental control and rate measurements were unreproducible.

If the equilibration of secondary-secondary 1,2-diols involves processes of the type of Scheme 1 there appears to be no reason why these epimerization conditions should not also be applicable to the lithium derivatives of simple secondary alcohols and we have in fact applied them successfully to *cis*- and *trans*-4-methylcyclohexanol (**6** and **7**).[5]



6 X = CH_3, Y = H
7 X = H, Y = CH_3

Having established the failure of tertiary-tertiary 1,2-diols to epimerize and confirmed the epimerization of secondary-secondary 1,2-diols we turned to the examination of secondary-tertiary 1,2-diols. To detect the stereochemical changes in the secondary-tertiary case it is necessary that the diol have at least one fixed chiral centre in relationship to which the retention or inversion of configuration of each carbinol carbon can be observed separately. The steroids 3β-methoxy-5α-cholestane-5,6β-diol (**8**) and 3β-methoxy-5α-cholestane-5,6α -diol (**9**) were selected as suitable for this purpose.



8 X = OH, Y = H
9 X = H, Y = OH

Treatment of **8** in diglyme with butyllithium in the presence and absence of triphenylmethane followed by heating at 200°C, for 17 h gave mixtures of compounds **10–13** in different relative amounts together with a little unconsumed **8** (see Table 1).[6] Similar treatment of **9** in the presence of triphenylmethane gave compounds **10** and **11** together with a considerable amount of unconsumed **9** (Table 1).

TABLE 1. Products from thermolysis of lithium derivatives of 3β-methoxy-5α-cholestane-5α,6β-diol (**8**) and -5α,6α-diol (**9**)[a]

Products	From 5α,6β-diol (**8**)		From 5α,6α-diol (**9**)
	No Ph_3CH	$+Ph_3CH$	$+Ph_3CH$
5α,6β-diol (**8**)	7	7	0

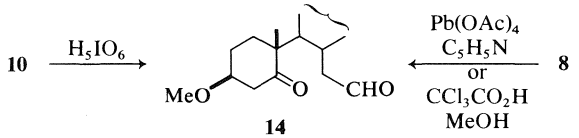
15 R = Ac

11

12

13

In each case the previously unknown 3β-methoxy-5β-cholestane-5,6α-diol (**10**) was a major component of the reaction mixture. The structure of this product was established as follows. It was shown to be stereoisomeric with **8** (and **9**) by oxidation with periodic acid to give the keto aldehyde **14**, which was



14

identical with the product formed on oxidation of **8** with lead tetraacetate in pyridine or trichloroacetic acid – methanol.[7] The ir spectrum (CS_2) of **10** shows two hydroxyl stretching bands: a weak but sharp

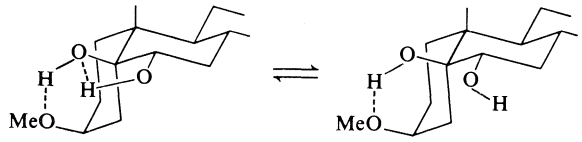
[5]Another, unidentified alcohol was also formed in the reaction.

[6]It cannot be assumed that the differences are due solely to the presence of triphenylmethane since, as we have already noted, there is some uncontrolled variation in the induction period for these reactions.

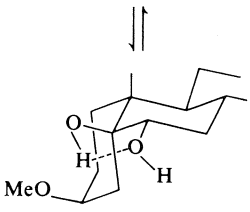
[7]Compare with refs. 5 and 6; the *trans*-diaxial diol **8** is inert to periodic acid and reacts only slowly with lead tetraacetate.

band at 3571 cm^{-1}, comparable with the single absorption band for free hydroxyl in the spectrum of *trans*-diaxial **8**, and a stronger and broader signal at 3497 cm^{-1}, characteristic of a hydrogen-bonded hydroxyl group. The most compelling evidence for the stereochemical assignment comes from the ^1H nmr spectrum of **10**. In the spectrum of **8** the C-19 methyl signal appears at δ 1.20, shifted downfield because of its rigid 1,3-diaxial orientation with respect to the C-6 hydroxyl group. In the spectrum of **10** no methyl signal appears at lower field than δ 0.93 and it can thus be concluded that the C-6 hydroxyl group is now equatorial. Corroboration comes from the coupling constants (J = 12, 5 Hz) for the C-6 proton in the ^1H nmr spectrum of **15**, the monoacetate of **10**, and from the single band at 1242 cm^{-1} in its ir spectrum (7, 8). Since **10** is stereoisomeric with **8** and **9** and has an equatorial secondary hydroxyl group it must have the 5β,6α-diol stereochemistry as assigned.[8]

The ^1H nmr spectrum of **10** shows two separate signals for the hydroxyl protons; these and the ir data (*vide supra*) are consistent with the existence of **10** in solution as a mixture of the hydrogen-bonded species **16***a–c* (9).

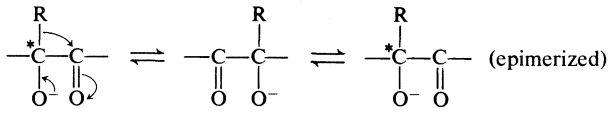


16*a* **16***b*



16*c*

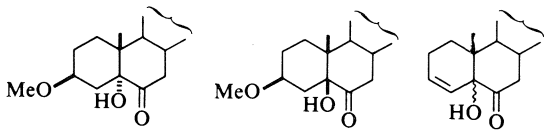
The formation of **10** and **9** involves epimerization at the secondary carbinol carbon C-6 but its formation from **8** requires equilibration at both the tertiary and secondary carbinol carbons C-5 and C-6. At first sight this might appear to be explicable in terms of the C—C cleavage mechanism of Scheme 2 and not in terms of the oxidation–reduction mechanism of Scheme 1. However it is well documented (9, 10) that tertiary α-hydroxy ketones can be epimerized under basic conditions at the tertiary carbinol carbon via a reversible rearrangement of



SCHEME 3

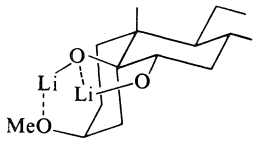
the type shown in Scheme 3. Such a process together with processes of the type of Scheme 1 can then account for the conversion of **8** to **10**. Because of our earlier discussed reservations regarding the diketyl mechanism of Scheme 2, we propose the reaction pathways for the conversion of **8** and **9** to **10** that are shown in Scheme 4.

The feasibility of the postulated equilibration of **18** and **19** in Scheme 4 was established by the demonstration that treatment of the hydroxy ketone **20** with methanolic potassium hydroxide gives a mixture of **20** and its C-5 epimer **21**.[9] The reaction mixture also contained a minor component that is tentatively assigned structure **22**.



20 **21** **22**

It remains for us to discuss in terms of Scheme 4 the positions of the equilibria. Although we have not investigated these in detail our results indicate that the lithium derivative of **10** is greatly favoured over those of **8** and **9** and also over that of 3-methoxy-5β-cholestane-5,6β-diol (**23**), the fourth C-5,6 stereoisomer in the series. The preponderance of the lithium derivative of **10** is attributed to the relief of 1,3-diaxial interaction with the C-19 methyl group and the stabilization conferred by coordination of the methoxyl oxygen atom with the lithium cation associated with the C-5 oxygen atom (cf. **24**). It is considered that this stabilization, which is related to the hydrogen bonding equilibria in the case of **10** itself (*vide supra*), more than offsets the destabilization owing to the assumption of the *cis* A–B ring fusion.

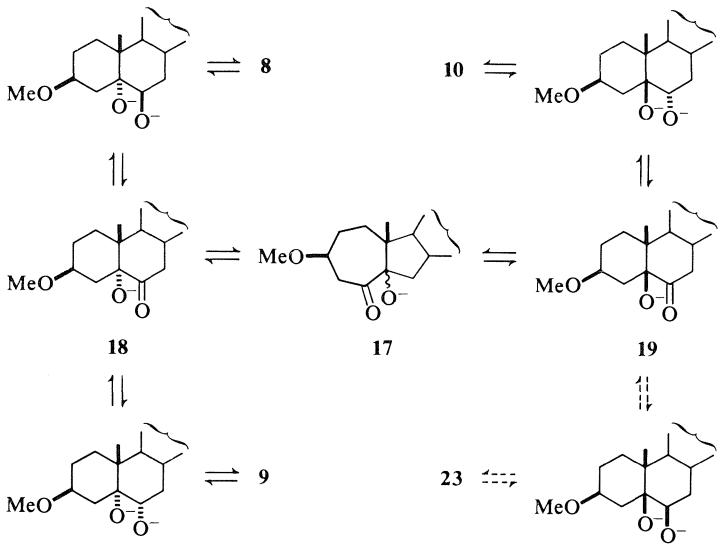


24

Next we discuss the other products formed together with **10** on the thermolysis of the lithium derivatives of **8** and **9** in diglyme (see Table 1). The

[8]Since the completion of this work, the preparation of **10** by reduction of 5-hydroxy-3β-methoxy-5β-cholestan-6-one (**20**) with sodium and ethanol has been reported (9).

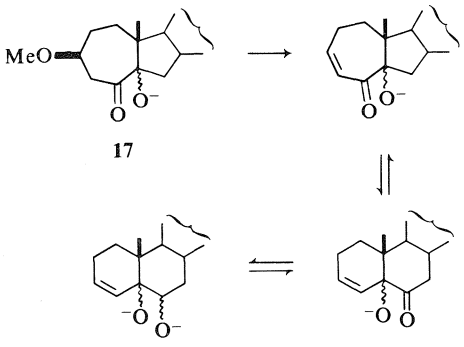
[9]This epimerization has also been carried out recently by Campion *et al.* (9).



SCHEME 4

products were separated by preparative-layer chromatography and in the case of both **8** and **9** one band contained a mixture of similar compounds whose mass and ^{1}H nmr spectra showed that they had been formed by elimination of methanol. These fractions were not further investigated but are tentatively assigned structures of type **11**. These might arise by base-catalysed elimination of methanol from **8**–**10** but their formation is best interpreted in terms of elimination of methanol from the β-methoxy ketone **17** that is postulated as an intermediate in Scheme 4 (Scheme 5).

A major product from **8** was the epoxide **12**, which was not formed from **9**. This epoxide is a known compound (11, 12) and was identified on the basis of its elemental composition, physical constants, and spectra (see Experimental). A work-up of the reaction mixture after addition of butyllithium, but before heating, returned **8**, showing that **12** was formed by thermolysis. Variation in the procedure for quenching and working up the reaction

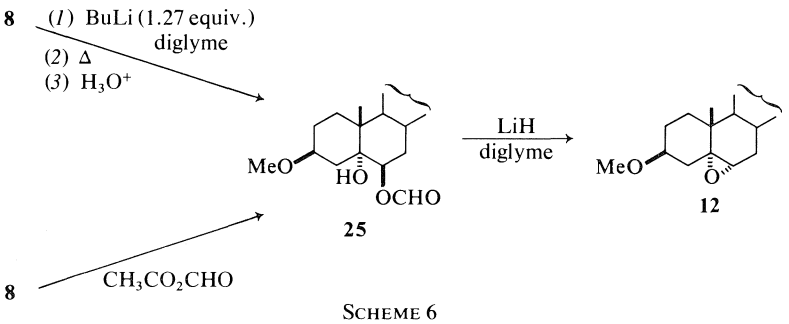


SCHEME 5

mixture after thermolysis did not appear to alter significantly the extent of its formation. The epoxide was also shown to be stable in the presence of lithium oxide under the conditions of the thermolysis, contraindicating its involvement as an intermediate in the interconversion of the stereoisomeric diols. It seemed most likely that the unexpected formation of this epoxide was associated with the decomposition of the solvent diglyme (*vide supra*) and in particular that **8** underwent conversion to an intermediate in which the C-6 oxygen function was converted to a better leaving group followed by *trans* diaxial displacement by the C-5 alkoxide to give **12**.

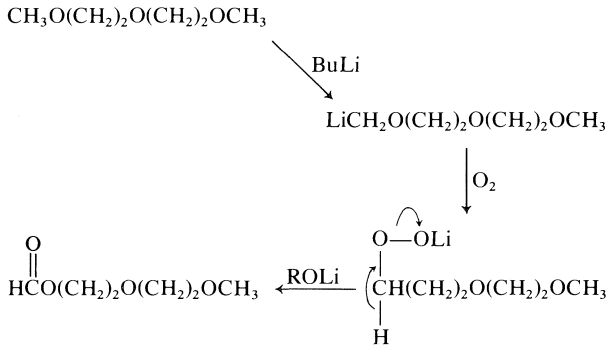
Evidence on this score was obtained by treatment of **8** in diglyme with 1.27 equiv. of butyllithium followed by thermolysis under the usual conditions. This gave a mixture containing 59% of **8** and 28% of a novel product **25**, a monoformate of **8**. This was identified by its spectral characteristics and by direct comparison with an authentic sample prepared by formylation of **8** with acetic formic anhydride. On hydrolysis it returned **8**. Treatment of **25** with lithium hydride in diglyme at reflux gave the epoxide **12** as the only product (Scheme 6).

These observations provide excellent support for the general pathway proposed for the formation of **12** on treatment of **8** with excess butyllithium in diglyme followed by thermolysis. They also confirm that decomposition of the solvent is involved in that considerations of mass balance alone in the reaction of **8** with 1 equiv. of butyllithium dictate that the formyl carbon of **25** is, at least in part, solvent derived. A possible route to the formate precursor is shown in Scheme 7. This involves lithiation of a terminal carbon atom of diglyme (facilitated by coordination



SCHEME 6

of the lithium with the two remote oxygen atoms) and autoxidation[10] of this to give **26**, which is converted by base to the formate **27**. The latter could then give rise to **25** via transesterification.[11]

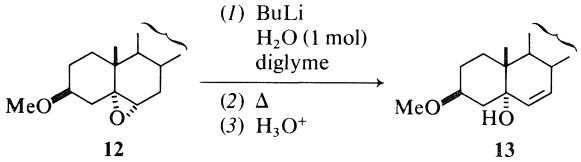


SCHEME 7

The remaining product from the thermolysis of the lithium derivative of **8** is the unsaturated alcohol **13**. Like **12**, this was not formed from **9**. The structural assignment was initially based on spectroscopic data (see Experimental) and the formation of **13** in association with that of **12**. In particular the ir spectrum shows a nonhydrogen-bonded hydroxyl group, favouring the 5α configuration since the hydroxyl group in the 5β isomer would be expected to hydrogen bond with the 3β-methoxyl group.[12]

An unusual feature in the ^{1}H nmr spectrum of **13** is the accidental equivalence of the two olefinic protons in deuteriochloroform, hexadeuterioacetone, and hexadeuteriobenzene solutions, This was unexpected and led us to consider the possibility that the double bond had migrated to the Δ^{11} position. This could be excluded, however, since an sp^3 C-11 signal is clearly evident at δ 21.1 (t) in the partially decoupled ^{13}C nmr spectrum of the product: in a 3-substituted cholestane derivative such a high-field methylene carbon signal can only be associated with a C-11 carbon.[13] Although the equivalence of the C-6 and C-7 protons in the ^{1}H nmr spectrum is unusual, it may be noted that a similar equivalence is observed in the spectrum of 1,5,5-trimethyl-2-cyclohexen-1-ol (15).

Corroboration for the structural assignment **13** and an indication of the origin of this product was provided by the observation that treatment of the epoxide **12** in diglyme with excess butyllithium and one molar equivalent of water followed by thermolysis gave **13** in high yield. Thus, it may be suggested that the formation of **13** in the thermolysis of the lithium derivative of **8** involved the intermediacy of **12**.[14] This interpretation accounts for the observation that although both **12** and **13** are formed from **8** neither type of product is formed from **9** or **10**. Neither **9** nor **10** has the favourable *trans*-diaxial orientation of the oxygen functions for epoxide formation, and in the absence of such an intermediate, formation of an unsaturated alcohol of type **13** does not occur.



It may finally be noted that if, as proposed, the complexity of the reaction of **8** in diglyme with butyllithium stems from decomposition of the sol-

[10]Although the reaction with butyllithium was conducted under nitrogen, air could have been introduced during the transfer to the freeze–thaw degassing cycle.

[11]An alternative route involving fragmentation of the lithiation product to give formaldehyde, ethylene, and $LiO(CH_2)_2OCH_3$ followed by conversion of the formaldehyde to formate by a Cannizzaro reaction is considered to be less likely because of our failure to observe gas formation on treatment of diglyme with butyllithium in ether.

[12]*trans*-5-*tert*-Butyl-*cis*-1,3-cyclohexanediol which has both hydroxyl groups axial shows in its ir spectrum both free and intramolecularly hydrogen-bonded hydroxyl bands (13).

[13]The ^{13}C nmr spectra of compounds **8**–**10**, **13**, and **20** are given in Table 2; the signal assignments are based on comparison with the large body of literature data on the ^{13}C nmr spectra of steroids (14).

[14]An additional source of **13** could be the postulated precursor of **12**, the formate **25**.

[a]Individual assignments cannot be made to pairs of close-lying signals marked with asterisks; signals considered to be superimposed are marked with a dagger or double dagger.

vent, cleaner and more efficient stereochemical equilibration should be achievable by the use of lithium hydride in diglyme or other high boiling solvents.[15]

Experimental

Melting points were determined on a Kofler block and are corrected. Infrared spectra were recorded in CS_2 solution on a Perkin Elmer model 327 or 237B spectrophotometer; the absorption maxima are reported in wavenumbers (cm^{-1}) calibrated with respect to the absorption band of polystyrene at 1602 cm^{-1}. Proton magnetic resonance (^1H nmr) spectra were recorded in deuteriochloroform solution at ambient temperature on a Varian T-60 instrument unless otherwise specified. The ^{13}C magnetic resonance (^{13}C nmr) spectra were recorded on a Bruker WP-80 instrument in deuteriochloroform solution unless otherwise specified. Chemical shift values are given on the δ scale downfield from tetramethylsilane as internal standard. Low resolution mass spectra were determined with a Bell and Howell CEC 21-490 spectrometer and high resolution mass spectra on an AEI MS-902 instrument.

Analytical thin-layer chromatography (tlc) was carried out on Brinkmann analytical silica gel plates with fluorescent indicator. Preparative-layer chromatography (plc) was carried out on 20 cm × 20 cm silica plates of 2-mm thickness from Brinkmann or Quantum Industries. Visualization was effected by spraying either the entire plate or a single edge of the plate with 0.5% vanillin in 80% v/v ethanol – sulfuric acid followed by heating the sprayed area.

Oxygen-free nitrogen was obtained by bubbling commercial nitrogen through one or two traps filled with a mixture of sodium and benzophenone in diglyme. The gas was then bubbled through concentrated sulfuric acid and passed up a drying tower filled with solid sodium hydroxide pellets. The rate of flow was monitored with a mercury bubbler.

Diglyme (BDH Chemicals) was purified by distillation at atmospheric pressure and dried just before use by refluxing over calcium hydride followed by redistillation under nitrogen. It was injected into the reaction vessel with a syringe.

Gas Chromatographic Analyses

The gc analyses were conducted either on an Aerograph A-170 instrument with a thermal conductivity detector and helium as the carrier gas or on a Perkin-Elmer F-11 instrument with a hydrogen flame detector and nitrogen as the carrier gas. The following columns were used: (*1*) 13 ft × $\frac{1}{4}$ in. aluminum, 5% UCON HB-2000 on 80–100 Chromosorb G-DMCS-AW; (*2*) 10 ft × $\frac{1}{8}$ in. stainless steel, 20% Carbowax 20M (SPA-64) on 80–100 Chromosorb W-HMDS-AW; (*3*) 10 ft × $\frac{1}{8}$ in. stainless steel, 10% DEGS on 80–100 Chromosorb P-DMCS-AW. Column *1* was used with the Aerograph instrument and columns *2* and *3* with the Perkin Elmer instrument.

Substrates

The following compounds were prepared by previously reported methods: *cis*-1,2-cyclohexanediol (**1**) (16), *trans*-1,2-cyclohexanediol (**2**) (17), *cis*-1,2-dimethyl-1,2-cyclohexanediol (**4**) (16), and *trans*-1,2-dimethyl-1,2-cyclohexanediol (**5**) (18). *cis*-4-Methylcyclohexanol (**6**) and *trans*-4-methylcyclohexanol (**7**) were obtained from Aldrich Chemical Co. It was determined by glc analysis that none of these substances was contaminated with a detectable amount of its epimer.

3β-Methoxy-5α-cholestane-5,6β-diol (**8**) was prepared by methylation of cholesterol to give cholesteryl methyl ether (19) and treatment of this with hydrogen peroxide and formic acid followed by hydrolysis with base (12).

3β-Methoxy-5α-cholestane-5,6α-diol (**9**) was prepared from cholesteryl methyl ether by an adaptation of the procedure for the *cis* hydroxylation of 5-cholestene (20). Cholesteryl methyl ether (794 mg, 1.25 mmol) was dissolved in dry ether (140 mL) containing dry pyridine (4 mL) with magnetic stirring. A capsule containing osmium tetroxide (0.5 g, 1.97 mmol) was broken and the two parts were dropped immediately into the solution. The flask walls were washed down with ether (5 mL), the flask was stoppered, and its contents were stirred for 123 h at ambient temperature. A stream of hydrogen sulfide was passed through the solution, and the precipitate was filtered. This was repeated until no more precipitate formed. The solution was extracted with saturated aqueous sodium bicarbonate and then with 3 *N* aqueous sodium hydroxide containing some mannitol. The organic layer was dried over sodium sulfate and filtered through a plug of Florisil. The solvent was evaporated and any pyridine still present was removed on the rotary evaporator by co-distillation several times with isopropyl alcohol. The crude solid product was chromatographed on a small column of silica gel. Elution with 4:1 v/v chloroform–ether gave cholesteryl methyl ether, and elution with ether gave **9**; yield 50% (75% based on unrecovered starting material). Compound **9** was recrystallized from acetonitrile (10 mL/100 mg) giving needles (87% recovery), mp 175–178°C, $[\alpha]_D^{28.5}$ +12° (*c* 1.0, $CHCl_3$) (lit. (7) mp 172°C (uncorrected), $[\alpha]_D$ +18°); λ_{max}: 3636, 3597 cm^{-1}; $^H\delta$: 0.66 (s, 3H, 18-Me), 0.90 (s, 3H, 19-Me), 3.32 (s,

[15]NOTE ADDED IN PROOF: For a related study that came to our attention after submission of this manuscript, see ref. 22.

3H, OMe) 3.6 (br m, 2H, 3-H and 5-H); *m/e*: 416 (49) ($M - H_2O$).

Thermolyses at Atmospheric Pressure

The following is a typical procedure for thermolyses at atmospheric pressure, which were carried out in the apparatus shown in Fig. 1. *cis*-1,2-Cyclohexanediol (237 mg) was dissolved with a few milligrams of triphenylmethane in distilled diglyme (15 mL). The solution was cooled under nitrogen to −21°C in a liquid nitrogen – carbon tetrachloride slush; ~2 *N* butyllithium in hexane (6.4 mL) was added until a transient red colour developed. The cold bath was removed and replaced with a heating mantle. A timer was started simultaneously with the heating. Hexane and solvent decomposition products distilled out, and then the diglyme was boiled under reflux for 3 h. The heating was stopped and the warm mixture was poured into saturated aqueous ammonium sulfate. The further work-up was identical with the procedure for thermolyses in sealed tubes below.

Thermolyses in Sealed Tubes

The following is a typical procedure. *cis*-1,2-Cyclohexanediol (233 mg, 2.01 mmol) was placed in a 60-cm Carius tube with triphenylmethane (10 mg). The tube was closed with a septum and purged with nitrogen, and purified diglyme (15.0 mL) was added by syringe. The solution was cooled to 0°C in ice and ~2 *N* butyllithium in hexane (6 mL, ~12 mmol) was added slowly by syringe with intermittent agitation of the tube. Towards the end of the addition the red colour of lithium triphenylmethide appeared in the upper part of the tube. The septum was quickly removed and replaced by the vacuum attachment shown in Fig. 2. The tube was cooled in dry ice and degassed at ~0.25 Torr to remove volatile substances. After two freeze–thaw cycles the tube was sealed and heated at ca. 200°C for 17 h in an electrically heated furnace. The tube was cooled, and the gelatinous contents were poured into a flask containing saturated aqueous ammonium sulfate (25 mL). The transfer was completed by washing the tube with 1:1 v/v benzene–ether, saturated aqueous ammonium sulfate, and distilled water. The organic layer was separated, and the aqueous phase was extracted with ether (2 × 25 mL). The total extracts were dried over sodium sulfate and evaporated. The diglyme was removed by short-path distillation at reduced pressure (0.25 Torr, ambient temperature) into a reservoir cooled with Dry Ice. The residue (222 mg) was analyzed by gc and gc–ms by means of the procedure below.

Analysis for cis- *and* trans-*1,2-Dimethyl-1,2-cyclohexanediol (**4**, **5**)*

Thermolysates were analyzed either on column *1* with injector 225°C, detector 208°C, column 124°C; or column *2* with injector setting 6, column 200°C, pressure 30 psi. Compounds **4** and **5** did not epimerize since in no case did the thermolysate from one isomer give rise to a peak of the correct retention time for the other. The identity of reisolated starting material was proven by gc–ms in each case on column *2* with injector 225°C, detector 230°C, column 200°C, carrier gas helium, solvent methanol, 13–18 mg/mL, 1.5 μL injection, 5 mV attenuation, giving a retention time for **4** of 9.75 min and for **5** of 11.75 min.

Analysis for cis- *and* trans-*1,2-Cyclohexanediols (**1**, **2**)*

Compounds **1** and **2** are separable on both columns *1* and *2*. Quantitative estimation of the ratio by integration of the peak areas from crude thermolysates was not justified in this case; however, because gc–ms of the mixtures showed that although the peak eluting with retention time corresponding to **2** was

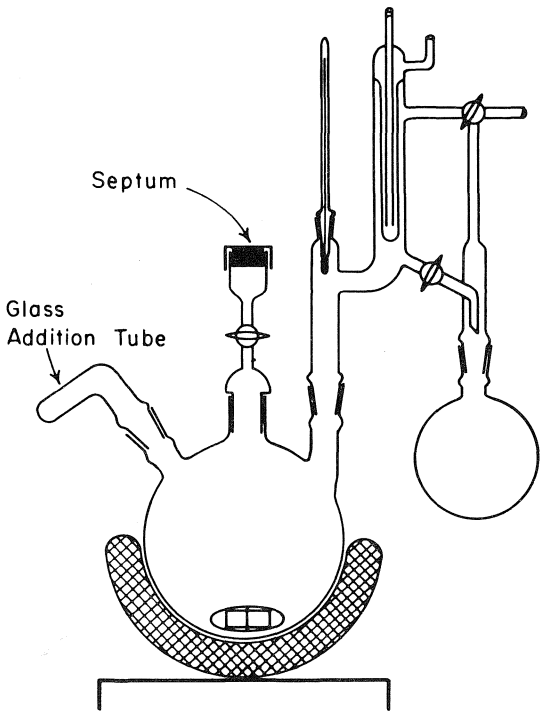

FIG. 1. Apparatus for atmospheric pressure reactions.

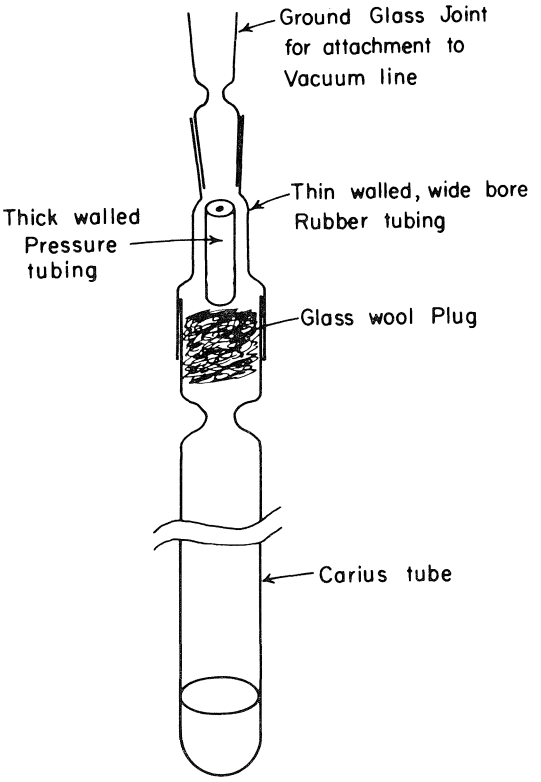

FIG. 2. Apparatus for sealed tube reactions.

pure **2**, the peak eluting with retention time corresponding to **1** was a mixture of **1** and an unknown impurity. Estimation of the ratio **1**:**2** was effected by first placing the crude thermolysate in 1% methanol–dichloromethane onto a short column of 80–200 mesh Brockmann neutral alumina and eluting with the same solvent mixture (fraction A) and then with methanol (fraction B). Fractions A and B both showed a gc peak with retention time corresponding to **1**, whereas only the latter showed a peak with retention time corresponding to **2**. Each of these fractions was acetylated (acetic anhydride, pyridine, ambient temperature, overnight) under conditions previously shown to give quantitative and complete derivatization of **1** and **2**. No peak in the gc on column *2* of acetylated fraction A had the same retention time as diacetylated **1** or **2**, showing that fraction A contains impurities only. The acetylated fraction B had only two peaks in its gc on column *2*, corresponding to diacetylated **1** and **2**. Acetylated fraction B also showed only two peaks, now better resolved, on column *3*. On this column with injection setting 5, column 170°C, pressure 30 psi, *cis*-1,2-diacetoxycyclohexane had a retention time of 21.05 ± 0.1 min and *trans*-1,2-diacetoxycyclohexane had 23.25 ± 0.1 min.

*Thermolysis of the Lithium Derivative of 3β-Methoxy-5α-cholestane-5,6β-diol (**8**)*

The thermolysis was conducted in a sealed tube for 17 h at 200°C according to the general procedure. The product mixture was separated by plc by multiple elution with 4:1 v/v chloroform–ether giving the following products in decreasing order of R_f.

*3β-Methoxy-5,6α-epoxy-5α-cholestane (**12**)*—mp 80–81°C; $[\alpha]_D^{28}$ −53.2° (*c* 1.2, $CHCl_3$) (lit. (11) mp 81°C, $[\alpha]_D^{20}$ −52.0 ± 1°; lit. (12) mp 81–81.5°C, $[\alpha]_D^{28}$ −51.5°); ν_{max}: no OH; $^H\delta$ (CCl_4): 0.60 (s, 3H, 18-Me), 1.03 (s, 3H, 19-Me), 2.72 (d, J = 4 Hz, 1H, 6-H), 3.25 (s, 3H, OMe), 3.25 (br m, 1H, 3-H); *m/e*: 416 (49). *Anal.* calcd. for $C_{28}H_{48}O_2$: C 80.71, H 11.61; found: C 80.43, H 11.46.

*3β-Methoxy-5α-cholest-6-en-5-ol (**13**)*—mp 133–134°C (from acetonitrile); $[\alpha]_D^{29}$ −44.5° (*c* 1.0, $CHCl_3$); ν_{max}: 3610 cm^{-1}; $^H\delta$: 0.68 (s, 3H, 18-Me), 0.92 (s, 3H, 19-Me), 3.36 (s, 3H, OMe), 3.6 (br m, 1H, 3-H), 5.60 (s, 2H, 6- and 7-H); $^H\delta$ (acetone-d_6, 80 MHz); 0.75 (s, 3H), 0.91 (s, 3H), 3.26 (s, 3H), 3.6 (br m, 1H), 5.53 (s, 2H); $^H\delta$ (benzene-d_6, 80 MHz): 0.62 (s, 3H), 0.87 (s, 3H), 3.28 (s, 3H), 3.9 (br m, 1H), 5.49 (s, 2H); *m/e*: 416 (1.5). *Anal.* calcd. for $C_{28}H_{48}O_2$: C 80.71, H 11.61; found: C 80.51, H 11.47.

*3β-Methoxy-5β-cholestane-5,6α-diol (**10**)*—mp 91–93°C; $[\alpha]_D^{28.5}$ +30.8° (*c* 1.0 $CHCl_3$) (lit. (9) mp 91–92°C, $[\alpha]_D$ +27.9°); ν_{max}: 3571, 3497 cm^{-1}; $^H\delta$: 0.67 (s, 3H, 18-Me), 0.93 (s, 3H, 19-Me), 2.54 (br s, 1H, exchangeable with D_2O, 6-OH), 3.37 (s, 3H, OMe), 3.70 (br m, 1H, 3-H), 3.78 (dd, J = 11, 4 Hz, 6-H), 4.35 (s, 1H, exchangeable with D_2O, 5-OH); *m/e*: 434 (18). *Anal.* calcd. for $C_{28}H_{50}O_3$: C 77.36, H 11.59; found: C 77.24, H 11.58. The *6-monoacetate **15*** was prepared by treatment of **10** with acetic anhydride in pyridine at room temperature overnight; mp 128–130°C (from acetonitrile); ν_{max}: 3484, 1736, 1242 cm^{-1}; $^H\delta$: 0.69 (s, 3H, 18-Me), 0.99 (s, 3H, 19-Me), 2.08 (s, 3H, OAc), 3.34 (s, 3H, OMe), 3.62 (br s, 1H, 3-H), 4.03 (br s, 1H, 5-OH), 4.95 (dd, J = 12, 5 Hz, 1H, 6-H); *m/e*: 476 (2).

*Cholest-3-ene-5,6-diols (**11**)*—gum; ν_{max}: 3590 cm^{-1}; $^H\delta$: 0.67 (s, 3H, 18-Me), 0.95 (s, 3H, 19-Me), 3.3–4.0 (m, 3H, 6-H and 5- and 6-OH), 5.95 (br s, 2H, 3- and 4-H); *m/e*: 402 (36).

*Cleavage of Diol **10** with Periodic Acid. Formation of Keto Aldehyde **14***

To a solution of diol **10** (24 mg, 0.054 mmol) in 95% ethanol (2.0 mL) was added all at once periodic acid (12 mg, 0.051 mmol) in water (0.5 mL). The solution was maintained at 40°C for 2.5 h. It was diluted with water (10 mL) and the resulting opaque suspension was extracted with ether (3 × 5 mL). Drying (Na_2SO_4) and evaporation of the solvent gave the keto aldehyde **14** as a gum that could not be crystallized; ν_{max}: 2775 (w), 1721, 1698 cm^{-1}. This was shown to be identical with the product obtained by oxidation of diol **8** with lead tetraacetate in either pyridine (5) or trichloroacetic acid – methanol (6) by ir spectral comparison and tlc with the following solvent systems: 4:1 v/v chloroform/ether (R_f 0.52), 9:1 v/v chloroform – ethyl acetate (R_f 0.41), and 5:7:1 v/v cyclohexane–benzene–methanol (R_f 0.58).

*Epimerization of 5α-Hydroxy-3β-methoxy-5α-cholestan-6-one **20**. Formation of **21** and **22***[9]

A 10% w/w solution of potassium hydroxide in anhydrous methanol (100 mL) was added to 5α-hydroxy-3β-methoxy-5α-cholestan-6-one (**20**; 334 mg) (12). The mixture was boiled at reflux under dry nitrogen for 48 h, added to ice water (500 mL) and extracted with ether (1 × 50, 2 × 100 mL). To the extract was added phenolphthalein solution (1 drop) in water (100 mL) and then 2 *N* sulfuric acid until the red colour was discharged. The ethereal solution was washed with saturated aqueous sodium bicarbonate (20 mL), dried ($MgSO_4$), and evaporated. The yield of crude product was 307 mg. Preparative-layer chromatography yielded in order of decreasing R_f a substance tentatively identified as **22**, the epimerized product **21**, and the starting material **20**, in the relative proportions 1:5:8.

*5-Hydroxy-5-cholest-3-en-6-one (**22**)*—gum; ν_{max}: 3436, 1706 cm^{-1}; $^H\delta$: 0.60 (s, 3H, 18-Me), 0.72 (s, 3H, 19-Me), 4.10 (s, 1H, exchangeable, OH), 5.32 (d, J = 10 Hz, 1H, 4-H), 5.95 (br d, 1H, J = 10 Hz, 3-H); *m/e*: 400 (92).

*5-Hydroxy-3β-methoxy-5β-cholestan-6-one (**21**)*—gum; ν_{max}: 3390, 1698 cm^{-1}: $^H\delta$: 0.68 (s, 3H, 18-Me), 0.80 (s, 3H, 19-Me), 3.35 (s, 3H, OMe), 3.60 (br s, $w_{1/2}$ = 8 Hz, 1H, 3H), 4.25 (s, 1H, exchangeable, OH); *m/e*: 432 (16).

*5-Hydroxy-3β-methoxy-5α-cholestan-6-one (**20**)*—mp 145–147°C; ν_{max}: 3571 (sh), 3401, 1712 cm^{-1}; $^H\delta$: 0.65 (s, 3H, 18-Me), 0.80 (s, 3H, 19-Me), 2.65 (s, 1H, exchangeable, OH), 3.37 (s, 3H, OMe), 3.6 (br m, $w_{1/2}$ = 20 Hz, 1H, 3-H); *m/e*: 432 (100).

*Thermolysis of the Monolithium Derivative of Diol **8**. Formation of 3β-Methoxy-5α-cholestane-5,6β-diol 6-Formate (**25**)*

Diol **8** (277 mg, 0.66 mmol) was placed into a dry, nitrogen-filled Carius tube and dissolved in diglyme (20 mL). The solution was cooled to 0°C and stirred by means of a small magnetic stirring bar within the tube and was treated with 2.11 *N* butyllithium in hexane (0.40 mL, 0.84 mmol, 1.27 equiv.). While the nitrogen atmosphere was retained the tube's inner walls were washed with additional solvent (10 mL) and the tube was quickly attached to a vacuum line and evacuated with stirring to remove hexane. It was then cooled in a liquid nitrogen – carbon tetrachloride slush and sealed under vacuum. The tube was heated in a furnace at 195–200°C for 18 h, cooled, and opened, and the contents were poured into saturated aqueous ammonium sulfate. The solution was extracted with ether, and the extract was washed with water, aqueous sodium bicarbonate, and brine, dried over sodium sulfate, and evaporated. The high boiling solvent was removed under high vacuum leaving a yellowish foam (312 mg). Preparative-layer chromatography with elution with 4:1 v/v chloroform–ether gave three fractions: recovered **8** (167 mg, 60%), an unidentified product (15 mg), and **25** (81 mg, 28%) as a gum that could not be crystallized; ν_{max}: 3636, 3610, 1730, 1175 cm^{-1}; $^H\delta$: 0.68 (s, 3H, 18-Me), 1.13 (s, 3H, 19-Me), 3.33 (s, 3H, OMe), 3.6 (br m, 1H, 3-H), 4.85 (m, $w_{1/2}$ = 6 Hz, 1H, 6-H), 8.10 (s, 1H, CHO); *m/e*: 462. *Mol. wt.* calcd. for

$C_{29}H_{48}O_3$ ($M - H_2O$): 444.3603; found (high resolution ms): 444.3597.

Hydrolysis of Monoformate ***25****. Formation of Diol* ***8***

The monoformate **25** (69 mg) was dissolved in benzene (4 mL) and 6 mL of a solution of potassium carbonate (317 mg) in water (5 mL) and methanol (80 mL) was added to give a homogeneous solution. After 21.5 h at room temperature tlc showed complete hydrolysis to a single product. The solution was diluted with brine and extracted once with chloroform and once with ether. The extract was dried ($MgSO_4$) and evaporated to give a solid (42 mg), which was recrystallized from benzene to give **8**, mp 153–154°C, with ir and ^1H nmr spectra identical with those of authentic material.

Monoformylation of Diol ***8****. Formation of Monoformate* ***25***

Acetic–formic anhydride was prepared by the method of Maramatsu *et al.* (21). The ^1H nmr spectrum of the product showed that it was 92% pure and contained 8% acetic anhydride. In a stoppered flask was placed diol **8** (104 mg), acetic–formic anhydride (92%; 60 drops from a disposable pipette) and benzene (40 drops). The stoppered flask was allowed to stand at room temperature with occasional agitation for 36 h. The contents were poured into saturated aqueous sodium bicarbonate and the mixture was extracted with ether. The extract was dried and evaporated to a foam (81 mg) whose ^1H nmr spectrum was identical with that of the product from **8** and butyllithium–diglyme except that the formate was accompanied by 8% of acetate. Attempted crystallization was unsuccessful but gave **25** as a gum that was free of acetate.

Treatment of Monoformate ***25*** *with Lithium Hydride. Formation of Epoxide* ***12***

The monoformate **25** (containing 8% monoacetate; 187 mg, 0.40 mmol) was dissolved in diglyme (7 mL) and lithium hydride (11.6 mg, 1.5 mmol) was added. The solution was stirred at reflux under nitrogen for 17 h and then worked up in the usual way. The ir and ^1H nmr spectra of the product were identical with those of the epoxide **12**. Crystallization gave **12** (99 mg), mp 80–81°C.

Conversion of Epoxide ***12*** *to Enol* ***13***

In a 60-cm Carius tube was placed triphenylmethane (8 mg). A septum was placed on the tube, which was purged with a slow stream of oxygen-free nitrogen. The length of the tube was heated to displace air and moisture. A 0.149 *M* solution of water in diglyme (5.0 mL, 0.745 mmol) was added by syringe and then butyllithium in hexane (7 mL, ~11 mmol) was added by syringe at 0°C. After ~3.5 mL of the latter solution had been added the mixture had become persistently red. A solution of the epoxide **12** (261 mg, 0.745 mmol) in diglyme (10.0 mL) was added by syringe all at once to the ice-cold solution of base. The red colour faded immediately to yellow but reappeared on standing. The tube was transferred to the vacuum line, given two freeze–thaw cycles, and then sealed. It was heated for 18 h at 200°C. The usual work-up gave a reddish oil that immediately showed signs of solidifying. This gave on tlc one predominant spot, which gave with sulfuric acid spray and heat the deep blue colour characteristic of the allylic alcohol **13**. The impure solid was triturated with cold methanol and then with cold acetonitrile to give an off-white solid. This was recrystallized from acetonitrile to give **13** (134 mg) as long white needles, mp 133–134°C, which was shown by ir and ^1H nmr spectroscopy to be identical with the enol obtained by thermolysis of the lithium derivative of **8**.

Acknowledgements

We gratefully acknowledge the help of Dr. Renuka Misra who performed the gc–ms measurements and Dr. J. E. McCloskey and Mr. J. D. Kronis for recording and discussing the ^{13}C nmr spectra. We thank the National Research Council of Canada for support of the work.

Reactions of *N*-3′-furylbenzamide with some dienophiles

JOHN N. BRIDSON

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received July 11, 1978

JOHN N. BRIDSON. Can. J. Chem. **57**, 314 (1979).

N-3′-Furylbenzamide gives a conventional Diels–Alder adduct with maleic anhydride but with dimethyl maleate and methyl acrylate further reactions take place at the enamide grouping of the initially formed adducts. Compounds have been isolated in which molecules of an alcohol, used as solvent, or the starting furan have added to the double bond of the 1:1 adducts. In the first case unstable alkoxyamides are formed; in the second stable 2:1 adducts result from a novel uncatalysed addition to the double bond of the enamide. The stereochemistry of these and related compounds is discussed.

JOHN N. BRIDSON. Can. J. Chem. **57**, 314 (1979).

Avec l'anhydride maléique, le *N*-furyl-3′ benzamide fournit un adduit de Diels–Alder normal; toutefois le maléate ou l'acrylate d'éthyle conduisent à des réactions subséquentes au niveau du groupement ènamide des adduits qui se forment initialement. On a isolé des composés dans lesquels des molécules d'un alcool, utilisé comme solvant, ou le furanne de départ se sont additionnés à la double liaison des adduits 1:1. Dans le premier cas, il y a formation d'alkoxyamides instables; dans le deuxième cas, il en résulte des adduits 2:1 stables provenant d'une addition qui n'est pas catalysée à la double liaison de l'ènamide. On discute de la stéréochimie de ces composés et d'autres qui leur sont apparentés.

[Traduit par le journal]

Introduction

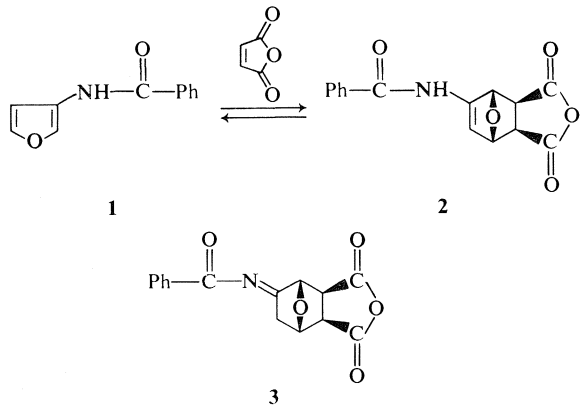
There has recently been considerable interest shown in the properties of derivatives of the 7-oxabicyclo[2.2.1]heptane system and the related alkene and diene. Papers and patents have been published referring to cytotoxic (1), antidiabetic (2), and the well known fungicidal and herbicidal activities of these compounds; structurally related molecules synthesized from these bicyclic systems have shown promise as analgesics and antiinflammatory drugs (3). Research into chemical and biological properties is however hampered by the difficulties encountered while constructing the bridged system by Diels–Alder reactions of furan and its derivatives. Such reactions are frequently easily reversible and in consequence lack endo selectivity, variable mixtures of *exo* and *endo* adducts resulting. The reactions often proceed slowly and in poor yield, e.g., furan and acrylonitrile are reported to form 7-oxabicyclo[2.2.1]hept-5-ene-2-nitrile in 39% yield after 5 weeks (4). Dauben and Krabbenhoft (5) have found that under extremely high pressure the reactions proceed more rapidly in satisfactory yield but nevertheless the synthetic utility of Diels–Alder reactions of furan and its more common derivatives seems to be limited.

In this laboratory a study of the diene reactivity of furan rings bonded to oxygen and nitrogen has been undertaken, anticipating that the enhanced availability of electrons in this group of compounds, to date relatively neglected by synthetic chemists, might facilitate their reactions with a variety of electron deficient dienophiles. This paper reports the results of experiments on *N*-3′-furylbenzamide (**1**), a particularly interesting potential diene, the adducts of which might easily be converted into muscarine analogs similar to those prepared by Nelson and Allen (6), in which the nitrogen atom was introduced *after* generation of the bicyclic ring system.

Results and Discussion

When maleic anhydride was added to a saturated ethereal solution of **1**, the colorless, analytically pure Diels–Alder adduct **2** separated in reasonable yield. In other solvents, no adduct crystallised and it seems that the equilibrium expressed in Scheme 1 is unfavourable with respect to product. A similar isolation taking advantage of the limited solubility of *endo,cis*-7-oxabicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic acid is reported (7). The ^{1}Hmr spectrum of **2** indicated an *exo* configuration for the anhydride group, the bridgehead protons appearing as a singlet (1-H) and doublet (4-H), the latter coupled with the vinyl proton. Couplings with the 2-H and 3-H were undetectably small as observed in many similar compounds (see, for example, ref. 8). The amide proton resonance at δ 10.22 in DMSO-d_6 disappeared slowly after addition of D_2O, but the remaining absorptions were unchanged after several hours including the vinyl-H doublet at δ 6.03. Thus tautomerism to the *N*-benzoylimine **3** does not take place under these

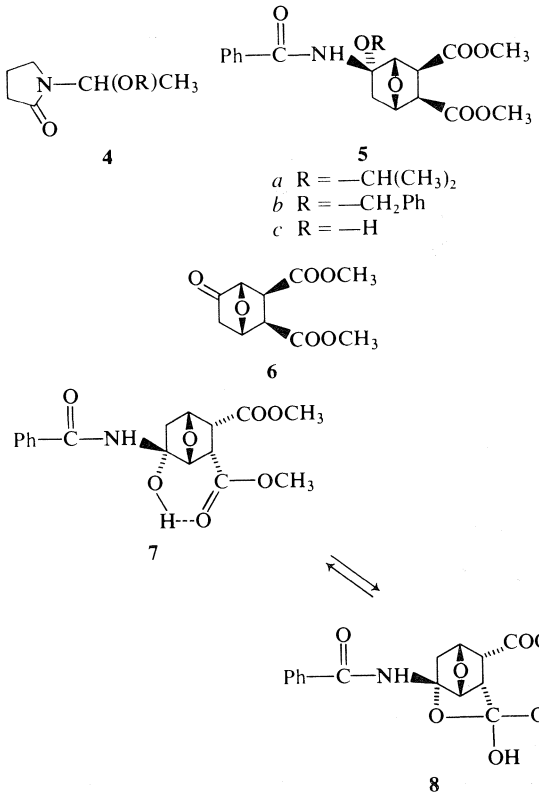
0008-4042/79/030314-04$01.00/0



SCHEME 1

conditions and, despite their almost complete absence from the literature (see, however, ref. 9) enamides with a free N—H appear to be stable compounds, in contrast to the corresponding enamines (10).

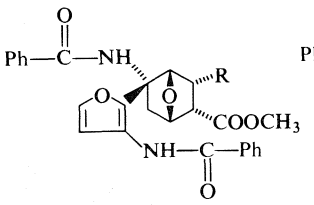
Efforts to obtain Diels–Alder adducts with other dienophiles failed in a variety of solvents and under a variety of conditions, presumably because of reversion to starting materials. It is significant that **2** decomposed on attempted recrystallisation from hot solvents and that its mass spectrum showed no molecular ion but was simply a sum of the mass spectra of the component diene and dienophile. Similarly dimethyl maleate – furan adducts were not isolable directly from a Diels–Alder reaction (11) and when prepared by other means reverted to components very readily (7). In an effort to bypass the problem, advantage was taken of the ready addition of alcohols to enamides which, in the case of *N*-vinyl-2-pyrrolidinone in the presence of acid catalysts, proceeded in almost quantitative yield (12) giving **4**. At higher temperatures the reverse reaction of a closely related alkoxyamide has been observed (13). It was found that acidic catalysts caused extensive decomposition but that the reactions of dimethyl maleate and *N*-3′-furylbenzamide in alcoholic solvents gave the unstable alkoxyamides, in the absence of catalysts, quite cleanly, but reversibly. It proved impossible to isolate these sensitive compounds but their existence was clearly demonstrated by ^{1}Hmr spectra recorded on the crude reaction mixtures. Structures **5***a* and **5***b* have been assigned to the adducts formed in isopropanol and benzyl alcohol respectively. The bridgehead protons' resonances appear as doublets (1-H) and singlets (4-H) confirming the *exo* orientation of the ester groups. The 1-H couples with the *exo*-6-H but not the *endo* protons as anticipated from the respective dihedral angles. Stereochemistry at the 5-position is less certain but assuming that the *exo* position is less sterically hindered and that the reaction is reversible, it would seem that the bulky amide group should be *exo* when in competition with an isopropyloxy group, and possibly also in the benzyloxy case, particularly if the planar conformation of the amide group is dominant. This is supported by the 2-H and 3-H absorption appearing as an AB system in **5***b* but as a singlet in **5***a* and **2**. An *endo* benzyloxy group could cause selective shielding in certain conformations in which the aromatic group lies directly beneath the bicyclic system. The alkoxyamides were easily hydrolysed by traces of water in solvents and on silica columns and when sufficient water was deliberately added to the reaction mixture a quantitative yield of **6** mixed with an equimolar



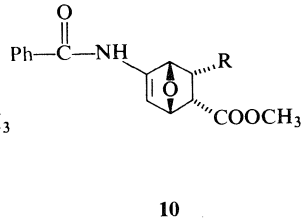
amount of benzamide was obtained after evaporation of excess alcohol. The keto diester **6** was identified by its ^{1}Hmr spectrum and by comparison of its melting point and that of its 2,4-dinitrophenylhydrazone with literature values. A possible intermediate in the formation of **6** is the hydroxyamide **5***c* and although this compound was never isolated, its stereoisomer **7** was obtained in very poor yield on one occasion when dimethyl maleate, furanamide, and methanol were heated together and subsequently chromatographed on silica. Surprisingly, **7** is reasonably stable and

could be recrystallised to give an analytically pure sample. The bridgehead protons appear in the ^{1}Hmr spectrum as partially overlapping multiplets suggesting the *endo* disposition of the two ester groups and the hydroxyl group is also tentatively assigned the *endo* configuration. The ir spectrum shows two clear C=O absorptions, a normal ester peak at 1738 cm^{-1} and a second peak at 1713 cm^{-1} which is assigned to the intramolecularly H-bonded 3-ester group. The —O—H stretching absorption appears, as expected, as a broad peak at 3400 cm^{-1}. The methyl group proton resonances appear at the normal position of δ 3.80 and at unexpectedly high field δ 3.33. It is possible that in solution **7** is rapidly equilibrating with **8** which might cause such an upfield shift. Attempts are being made to isolate more of this compound and further investigate its structure. The reluctance of **8** to lose methanol and form the lactone under the mild isolation conditions may be due to the increased strain in the tricyclic system which would result. Such lactones, although well known, are generally formed by internal quenching of a carbonium ion by a carboxylate group (14) rather than by an internal acyl substitution (transesterification). The difficulties associated with the latter route to the lactones are discussed in Zefirov's paper (15).

In refluxing toluene, 2:1 mixtures of *N*-3′-furylbenzamide and dimethyl maleate or methyl acrylate gave compounds **9***a* and **9***b*, respectively, presumably via the Diels–Alder adduct **10**. There is no precedent



9



10

a R = —$COOCH_3$
b R = —H

for the uncatalysed addition of the second molecule of furanamide to the enamide and this interesting reaction is being further investigated. The ^{1}Hmr spectra of **9** again clearly demonstrate the geometry of the system, the bridgehead proton resonances showing couplings consistent with the *endo* configuration of the ester groups. The stability of these 2:1 adducts with respect to elimination and subsequent reverse Diels–Alder reaction would favor the isolation of *endo* isomers and would also lead one to suppose that the second furanamide molecule adds irreversibly from the least hindered *exo* side of the adduct **10**. The regioselectivity displayed in the acrylate reaction is the first indication of adherence to the '*para* rule' in a Diels–Alder reaction of a furanoid diene.

Experimental

Elemental analyses were performed by Atlantic Microlabs, GA, U.S.A. or by Memorial University Water Analysis Facility. ^{1}Hmr spectra were recorded on a Varian EM 360 instrument and ir spectra (Nujol mulls) on a Perkin-Elmer 237B grating spectrophotometer. Mass spectra showing the molecular ion and a base peak at *m/e* 105 (Ph—C≡O^+) were recorded for all new compounds, on an Hitachi-Perkin-Elmer RMU-6E spectrometer with direct inlet system. Melting points are uncorrected.

N-*3′-Furylbenzamide (**1**)*

3-Furoic acid was converted by standard methods into the hydrazide, mp 126–127.5°C, in 71% yield. 3-Furoylhydrazide (12.6 g, 0.1 mol) in water (300 mL) and 2 *N* H_2SO_4 (75 mL) was swirled at 0–5°C for 15 min whilst $NaNO_2$ (7 g in 30 mL H_2O) was added dropwise. After standing for 1 h at 0°C, the resulting white suspension was extracted with ether (2 × 250 mL), the ethereal solution of the azide separated, dried (Na_2SO_4 anhydrous), filtered, and cautiously distilled until approximately 300 mL of ether had been collected. Dry benzene (60 mL) was added and distillation continued until nitrogen evolution commenced (distillation temperature 75°C). The heating rate was adjusted until distillation almost ceased and continued for 5 h until nitrogen evolution was complete. The resulting solution was added dropwise to a cooled ethereal solution of phenylmagnesium bromide (0.1 mol) over 10 min. Aqueous acidic work up gave *N*-3′-furylbenzamide, mp 145–147°C (lit. (16) mp 142°C), 12.1 g, 64.7% from the hydrazide.

exo-N-*Benzoyl-5-amino-7-oxabicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic Acid Anhydride (**2**)*

The furan (**1**) (0.25 g, 1.3 mmol) in dry ether (15 mL) was stirred with maleic anhydride (0.14 g, 1.4 mmol) at room temperature for 24 h. Filtration gave colorless crystals of **2**, 0.29 g, 75.9%; ir ν cm^{-1}: 3370, 1865, 1836 (shoulder), 1773, 1671, 1630; ^{1}Hmr (DMSO-d_6) δ: 3.24 (s, 2H), 5.07 (d, 1H), 5.21 (s, 1H), 6.03 (d, 1H), 7.1–7.7 (m, 5H), 10.22 (s, 1H), $J_{1,6}$ = 1.7 Hz. *Anal.* calcd. for $C_{15}H_{11}NO_5$: C 63.16, H 3.89, N 4.90; found: C 63.01, H 3.97, N 4.90.

Dimethyl endo,exo,exo,cis-N-*Benzoyl-5-isopropoxy-5-amino-7-oxabicyclo[2.2.1]heptane-2,3-dicarboxylate (**5**a)*

The furan (**1**) (0.28 g, 1.5 mmol) and dimethyl maleate (0.22 g, 1.53 mmol) were refluxed in isopropanol (5 mL) for 2 days. Evaporation gave a pale yellow oil estimated to contain ~85% of **5***a* plus unidentified by-products; ^{1}Hmr ($CDCl_3$) δ: 1.15 (d, 6H), 2.01 (d, 1H), 2.42 (dd, 1H), 3.5 (m, 2H), 3.61 (s, 3H), 3.63 (s, 3H), 3.93 (septet, 1H), 4.96 (d, 1H), 5.69 (s, 1H), 7.2–7.9 (m, 6H), $J_{(CH_3)_2CH}$ = 5.8, $J_{1,6}$ = 4.8, $J_{6,6}$ = 15.8 Hz.

Dimethyl exo-*5-Oxo-7-oxabicyclo[2.2.1]heptane-2,3-dicarboxylate (**6**)*

The furan (**1**) (0.56 g, 3.0 mmol) and dimethyl maleate (0.44 g, 3.1 mmol) were refluxed in isopropanol (7 mL) containing 0.5 mL water for 2 days. Evaporation gave in quantitative yield, pale yellow crystals of an equimolar mixture of benzamide and **6**, from which the latter could be separated by repeated recrystallisations from benzene or by preparative thin layer chromatography on silica; mp 128–129°C (lit. (17) mp 123–124°C); ir ν cm^{-1}: 1760, 1735, 1720 (shoulder); ^{1}Hmr ($CDCl_3$) δ: 2.07 (d, 1H), 2.60 (dd, 1H), 3.21 (s, 2H), 3.68 (s, 6H), 4.66 (s, 1H), 5.17 (d, 1H), $J_{1,6}$ = 5.6, $J_{6,6}$ = 17.8 Hz. *Anal.* calcd. for $C_{10}H_{12}O_6$: C 52.63, H 5.30; found: C 52.56,

H 5.30. 2,4-Dinitrophenylhydrazone mp 234–236 (lit. (17) mp 230°C).

Dimethyl endo,exo,exo,cis-N-*Benzoyl-5-benzyloxy-5-amino-7-oxabicyclo[2.2.1]heptane-2,3-dicarboxylate (5b)*

Prepared in crude form as for **5***a*, the unstable alkoxyamide **5***b* had mp 138–142°C; ^{1}Hmr ($CDCl_3$) δ: 1.91 (d, 1H), 2.38 (dd, 1H), 3.04 (d, 1H), 3.32 (d, 1H), 3.62 (s, 6H), 4.45 (d, 1H), 4.65 (d, 1H), 4.78 (d, 1H), 5.64 (s, 1H), 7.0–7.9 (m, 11 H), $J_{1,6}$ = 5.2, $J_{2,3}$ = 9.6, $J_{6,6}$ = 14.0, $J_{gem(benzyl)}$ = 16.4 Hz. Attempted purification by tlc failed, only benzamide and **6** being isolated.

Dimethyl endo,exo,endo,cis-N-*Benzoyl-5-hydroxy-5-amino-7-oxabicyclo[2.2.1]heptane-2,3-dicarboxylate (7)*

The furan (**1**) (0.28 g, 1.5 mmol) and dimethyl maleate (0.22 g, 1.53 mmol) were refluxed in absolute methanol (5 mL) for 4 days. Evaporation gave a yellow oil which was chromatographed on silica gel. Elution with toluene–ether (1:1) gave **7**, recrystallised from benzene as colorless needles (0.03 g, 5.7%), mp 142–144°C; ir ν cm^{-1}: 3380 (very broad), 1738, 1713, 1650; ^{1}Hmr ($CDCl_3$) δ: 2.35 (dd, 1H), 2.74 (d, 1H), 3.33 (s, 3H), 3.48 (narrow m, 2H), 3.80 (s, 3H), 5.0 (m, 1H), 5.1 (m, 1H), 7.3–7.9 (m, 5H), 8.60 (s, 1H), $J_{1,6}$ = 5.0, $J_{6,6}$ = 13.0 Hz. *Anal.* calcd. for $C_{17}H_{19}NO_7$: C 58.45, H 5.48, N 4.01; found: C 58.35, H 5.50, N 4.00.

Dimethyl exo,endo,endo,cis-N-*benzoyl-5-(N′-benzoyl-3′-aminofur-2′-yl)-5-amino-7-oxabicyclo[2.2.1]heptane-2,3-dicarboxylate (9a)*

The furan (**1**) (0.16 g, 0.86 mmol) and dimethyl maleate (0.06 g, 0.42 mmol) were refluxed in toluene (4 mL) for 10 h, cooled in an ice bath, and filtered to separate the tan crystals. Recrystallisation from toluene gave colorless plates (0.12 g, 55.1%), mp 214–216°C; ir ν cm^{-1}: 3270, 3200, 1735, 1725 (shoulder), 1658, 1622; ^{1}Hmr ($CDCl_3$) δ: 2.46 (d, 1H), 3.02 (dd, 1H), 3.5 (m, 2H), 3.57 (s, 3H), 3.71 (s, 3H), 4.84 (broad t, 1H), 5.65 (broad d, 1H), 6.96 (d, 1H), 7.27 (d, 1H), 7.2–8.2 (m, 10H), 9.28 (s, 1H), 10.47 (s, 1H), $J_{1,2} \approx$ 4.8, $J_{1,6}$ = 5.6, $J_{3,4}$ = 4.1, $J_{6,6}$ = 14.2, $J_{4',5'}$ = 1.9 Hz. *Anal.* calcd. for $C_{28}H_{26}N_2O_8$: C 64.86, H 5.05, N 5.40; found: C 64.92, H 5.09, N 5.35.

Methyl exo,endo,endo-N-*benzoyl-5-(N′-benzoyl-3′-aminofur-2′-yl)-5-amino-7-oxabicyclo[2.2.1]heptane-2-carboxylate (9b)*

In a manner similar to the preparation of **9***a*, the monoester (**9***b*) was isolated as colorless crystals (41%), mp 188–189°C; ir ν cm^{-1}: 3310 (shoulder), 3255, 1735, 1649, 1624; ^{1}Hmr ($CDCl_3$) δ: 2.10 (d, 1H), 2.0–3.3 (m, 4H), 3.64 (s, 3H), 4.72 (t, 1H), 5.58 (d, 1H), 7.0–8.1 (m, 13H), 10.44 (s, 1H), $J_{1,2} \approx J_{1,6} \approx$ 5.5, $J_{3,4}$ = 4.6, $J_{6,6}$ = 15.0 Hz. *Anal.* calcd. for $C_{26}H_{24}N_2O_6$: C 67.82, H 5.25, N 6.08; found: C 67.92, H 5.26, N 5.94.

A correction in the published nuclear magnetic resonance spectra of *trans*-camphane-2,3-diols

MARK A. JOHNSON AND MICHAEL P. FLEMING
Thimann Laboratories, University of California, Santa Cruz, CA 95064, U.S.A.

Received April 12, 1978

MARK A. JOHNSON and MICHAEL P. FLEMING. Can. J. Chem. **57**, 318 (1979).

It is unequivocally shown that the published nmr spectra assigned to 2-*endo*,3-*exo*-camphanediol and 2-*exo*-3-*endo*-camphanediol should be reversed. The 2-*exo*,3-*endo* isomer is prepared unambiguously by hydroboration–oxidation of camphor enol silyl ether.

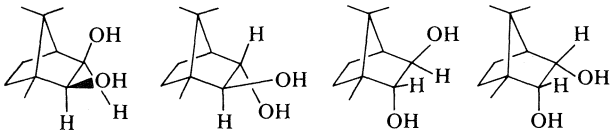
MARK A. JOHNSON et MICHAEL P. FLEMING. Can. J. Chem. **57**, 318 (1979).

On démontre sans équivoque que les spectres rmn publiés et attribués aux *endo*-2 *exo*-3 camphanediol et *exo*-2 *endo*-3 camphanediol devraient être inversés. On a préparé l'isomère *exo*-2 *endo*-3 sans ambiguité par hydroboration–oxydation de l'éther énolique silylé du camphre.

[Traduit par le journal]

During the course of our mechanistic investigations on the titanium-induced deoxygenation of 1,2-diols to olefins (1, 2), we found it necessary to prepare *cis* and *trans* (+)-camphane-2,3-diols. There are four possible (+)-camphane-2,3-diols, and all have been prepared, purified, and characterized (3, 4). In addition, the nmr spectra of the four have been recorded and analyzed in detail (5).

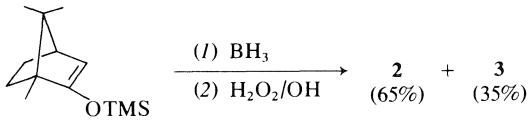
The 2-*exo*,3-*exo* isomer **1** is readily prepared by



1 2-*exo*,3-*exo* **2** 2-*exo*,3-*endo* **3** 2-*endo*,3-*exo* **4** 2-*endo*,3-*endo*

$LiAlH_4$ reduction of camphorquinone (6). Hydride attack occurs almost exclusively from the less hindered *endo* face of the camphorquinone and we have verified the details of the synthesis as well as the reported (5) nmr spectrum (nmr (pyridine–D_2O) δ: 0.77 (s, 3 H), 1.03 (s, 3 H), 1.30 (s, 3 H), 3.70 (d, 1 H, J = 7 Hz), 3.95 (d, 1 H, J = 7 Hz)).

The *cis* diol **1** was thus readily available but we also needed a *trans* diol for our work. Rather than follow the rather tedious literature procedure, however, it occurred to us that 2-*exo*,3-*endo* diol **2** might be readily obtained by hydroboration–oxidation of (+)-camphor enol silyl ether. Hydroboration of the known (7) silyl ether **4** with BH_3 followed by basic hydrogen peroxide oxidation occurred without incident and yielded a 65:35 mixture of the two possible *trans*-camphane-2,3-diols. The major isomer had nmr (pyridine–D_2O) δ: 0.83 (s, 3 H), 0.99 (s, 3 H), 1.25 (s, 3 H), 3.90 (d, 1 H, J = 3 Hz), 4.29 (broad, 1 H) while the minor isomer had nmr (pyridine–D_2O) δ: 0.83 (s, 3 H), 0.99 (s, 3 H), 1.19 (s, 3 H), 3.70 (d, 1 H, J = 3 Hz), 4.66 (broad, 1 H). According to published spectral data (5), these results show that our major hydroboration product is the 2-*endo*,3-*exo* diol **3**, whereas the minor product is the 2-*exo*,3-*endo* diol **2**. This is most surprising since it indicates that hydroboration has occurred from the more hindered *exo* face of the enol silyl ether. We believe that this is unlikely and that there is in fact an error in the published spectral data (5) transposing the correct values for isomers **2** and **3**. Since nmr spectroscopy is the only convenient method for distinguishing between the isomers, we believe that this error should be corrected.



5

Confirmation of our structural assignments, and therefore of the literature error, was obtained by two further experiments. In the first of these, hydroboration with the hindered reagent thexylborane, followed by oxidation, gave a 90:10 mixture of **2** and **3**. One would expect this reaction to be quite selective for *endo* attack.

In the second experiment, we prepared a mixture of di-*p*-nitrobenzoates derived from the **2** + **3** mixture and measured the optical rotation. Angyal has reported (3) that the di-*p*-nitrobenzoate of **2** has $[\alpha]_D$ +134.5° whereas the di-*p*-nitrobenzoate of **3** has $[\alpha]_D$ −113°. The value of our **2** + **3** mixture was $[\alpha]_D$ +30°, corresponding to 60% **2** and 40% **3** (vs.

0008-4042/79/030318-02$01.00/0

65:35 by nmr integration). Both chemical and physical evidence is therefore in agreement that the published nmr data (5) for **2** and **3** should be reversed.

Experimental

A solution of (+)-camphor enol silyl ether (7) (11.220 g, 50.0 mmol) in 50 mL dry tetrahydrofuran (THF) was prepared and a solution of borane in THF (50 mL of 1 *M* solution) was slowly added over 30 min at room temperature. After stirring 2 h at room temperature and a further 2 h at 35°C, the solution was cooled to 0°C. Hydrogen peroxide (16 mL of 30% aqueous solution) and sodium hydroxide (16 mL of 3 *N* aqueous solution) were added and the mixture was heated to 35°C for 2 h. After cooling, the aqueous layer was separated and extracted with ether. The combined organic solutions were washed with 10% HCl and with brine, then dried ($MgSO_4$) and concentrated at the rotary evaporator. Recrystallization from benzene gave the 65:35 mixture of diols **2** and **3**; mp 251–252°C (lit. (3) **2** mp 250.5–252°C; **3** mp 254–256°C).

The carbon monoxide/nitrous oxide reaction. Kinetics of catalysis on TiO_2 (anatase) and ZnO and activity correlations for the first-row transition metal oxides

BORDAN WALTER KRUPAY[1] AND ROBERT ANDERSON ROSS

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received June 23, 1978

BORDAN WALTER KRUPAY and ROBERT ANDERSON ROSS. Can. J. Chem. **57**, 320 (1979).

The catalytic reaction between carbon monoxide and nitrous oxide on titanium dioxide (anatase) and zinc oxide has been examined in a continuous flow reactor at atmospheric pressure. The experimental activation energy was 144 ± 4 kJ mol^{-1} from 723 to 793 K on TiO_2 and 121 ± 4 kJ mol^{-1} from 543 to 653 K on ZnO. Analyses of kinetic results indicated that a transient carbonate-like species may be involved in catalysis on both oxides. Relationships between the experimental activation energies for the CO/N_2O reaction on first-row transition metal oxides and (*i*) activation energies for isotopic oxygen exchange, (*ii*) heats of carbonate formation, and (*iii*) the charge/radius ratio of the cation are interpreted in terms of the influence on catalysis of the cohesive properties of the metal/oxygen bonds in the oxide surfaces.

BORDAN WALTER KRUPAY et ROBERT ANDERSON ROSS. Can. J. Chem. **57**, 320 (1979).

Opérant dans un réacteur à écoulement continue à pression atmosphérique, on a étudié la réaction catalytique du monoxyde de carbone et de l'oxyde nitreux sur le dioxyde de titane (anatase). L'énergie d'activation expérimentale est de 144 ± 4 kJ mol^{-1} de 723 à 793 K sur le TiO_2 et de 121 ± 4 kJ mol^{-1} de 543 à 653 K sur le ZnO. L'analyse des données cinétiques indique qu'une espèce transitoire ressemblant à un carbonate peut être impliquée dans la catalyse sur les deux oxydes. On a interprété les relations qui existent entre les énergies d'activations expérimentales pour la réaction du CO/N_2O sur des oxydes de métaux de transition de la première période et (*i*) les énergies d'activation des échanges isotopiques de l'oxygène, (*ii*) les chaleurs de formation du cabonate et (*iii*) le rapport charge/rayon du cation en termes de l'influence, sur la catalyse, des propriétés cohésives des liaisons métal/oxygène sur les surfaces des oxydes.

[Traduit par le journal]

Introduction

Kinetic results and mechanistic proposals for the catalytic reaction between carbon monoxide and nitrous oxide over several first-row transition metal oxides have been communicated recently (1–3). Although the oxides exhibited some differences in kinetic behaviour which could be ascribed to individual surface chemical factors, the overall course of catalysis could be generally related to (*i*) the reaction of carbon monoxide with surface oxygen via a cyclic transition state, (*ii*) the destabilization of an intermediate surface carbonate species, and (*iii*) the desorption of carbon dioxide which could occupy two surface sites.

The proposals have been further explored through kinetic measurements of the reaction on titanium dioxide, anatase, and zinc oxide and also by comparisons of catalytic activation energies for the 3*d* series of oxides with (*i*) oxygen isotope exchange energies, (*ii*) heats of carbonate formation, and (*iii*) charge/radius ratios of the oxide cations.

Experimental

The reaction was examined in a differential flow-reactor at atmospheric pressure with high-purity helium as the carrier gas. A thermal conductivity detector with stainless steel columns, 183 × 0.32 cm o.d., packed with 61 cm 'Carbosieve B' and the remainder with 'Poropak Q' at a column temperature of 353 K was sufficient to resolve nitrogen, carbon monoxide, carbon dioxide, and nitrous oxide in the Beckman GC-5 gas chromatograph.

The standard reacting gas mixture consisted of carbon monoxide and nitrous oxide each at a partial pressure of 5.33 kN m^{-2} (40 Torr). 'Blank' runs confirmed that reaction on the quartz wool and reactor walls reached 1% at 853 K which was 130 K above the highest temperature of catalysis. Preliminary experiments on titanium dioxide and zinc oxide established that diffusion phenomena (4, 5) did not influence the rate measurements at a total gas flow rate of 350 ml min^{-1} (NTP) for both catalysts.

Titanium dioxide (100% anatase), supplied by British Drug Houses Ltd., and zinc oxide, 99.99% pure, from Alfa Inorganics Inc., were heated at 873 K in air for 10 h and stored in desiccators over P_2O_5 prior to use. Carbon monoxide (C.P.; 99.5% minimum), carbon dioxide (Coleman; 99.99%), nitrogen (super-pure; 99.99%), nitrous oxide (99.9% minimum), and helium (high purity; 99.995%) were used as supplied.

Prior to the kinetic experiments, titanium dioxide was heated in helium for 5 h at 773 K and exposed to the standard gas mixture at 793 K. Catalyst activities reached steady levels after 1 h. The surface area (krypton; B.E.T.) and catalyst volume of

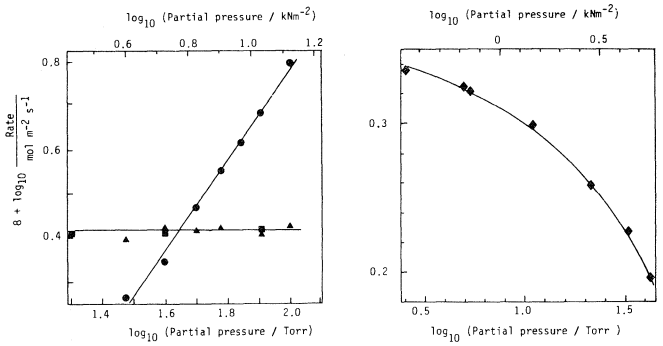

FIG. 1. Effects of variations in the partial pressures of carbon monoxide (●), nitrous oxide (▲), nitrogen (■), and carbon dioxide (◆) on the catalytic CO/N_2O reaction on titanium dioxide at 763 K.

the oxide after catalysis were 9.0 m^2 g^{-1} and 1.64 cm^3 g^{-1}, respectively. The largest conversion, 5.45%, was recorded at 793 K, the maximum temperature for the study. X-ray powder diffraction photographs revealed no structural changes in the oxide after catalysis.

The reaction was examined on zinc oxide from 653 to 543 K in the standard gas mixture. Steady catalyst activity, corresponding to a conversion level of 13.2%, was established at 653 K after 5 h and X-ray powder diffraction photographs of samples taken before and after catalysis were identical. The surface area (krypton; B.E.T.) of the oxide, 12.0 m^2 g^{-1}, and the catalyst volume, 1.36 cm^3 g^{-1}, were determined after the kinetic experiments were completed.

Results

Titanium Dioxide

With the nitrous oxide partial pressure fixed at 5.33 kN m^{-2}, the rate order with respect to carbon monoxide partial pressure was examined at 763 K from 4.00 to 13.3 kN m^{-2} (Fig. 1). This figure also shows the rate results for nitrous oxide in the partial pressure range 4.00 to 13.3 kN m^{-2} at 763 K with carbon monoxide maintained at 5.33 kN m^{-2}.

With both carbon monoxide and nitrous oxide fixed at 5.33 kN m^{-2}, the effect of variations in nitrogen partial pressure was examined from 2.67 to 10.7 kN m^{-2} at 763 K (Fig. 1). For the range of carbon dioxide partial pressures studied to determine kinetics, a rate order of -0.1 was approximated.

Thus for titanium dioxide, the experimental rate of reaction, r (mol m^{-2} s^{-1}), was expressed as:

$$[1] \qquad r = kP_{CO}{}^{0.9}/P_{CO_2}{}^{0.1}$$

Zinc Oxide

The partial pressure of carbon monoxide was varied from 1.33 to 16.0 kN m^{-2} at 593 K while nitrous oxide was maintained constant at 5.33 kN m^{-2} (Fig. 2). The rate order was 0.8 from 16.0 to 2.67 kN m^{-2} and 0.2 below this range. The effect of nitrous oxide partial pressure was examined at 593 K from 1.33 to 16.0 kN m^{-2} with carbon monoxide fixed at 5.33 kN m^{-2}. Between 1.33 and 4.00 kN m^{-2} the rate order of 0.2 changed to zero at higher partial pressures (Fig. 2).

With the carbon monoxide and nitrous oxide partial pressures both fixed at 5.33 kN m^{-2}, 1.45 kN m^{-2} carbon dioxide was continuously introduced to the gas stream. When the effluent was sampled 3 min later, the reaction rate with respect to nitrous oxide had increased to 15.5×10^{-8} mol m^{-2} s^{-1} which, when compared to an initial value of 1.51×10^{-8} mol m^{-2} s^{-1}, represented a 10-fold increase in the reaction rate. The reaction rate decreased continuously with time until a steady value of 0.30×10^{-8} mol m^{-2} s^{-1} was reached 2 h later. This rate did not change when the carbon dioxide partial pressure was subsequently increased step-wise to 5.79 kN m^{-2}. During the initial 2 h period, the measured carbon monoxide level in the gas stream remained constant while the nitrous oxide level gradually rose from zero to 5.31 kN m^{-2}. Thus, steady state conditions did not prevail and the surface reaction was

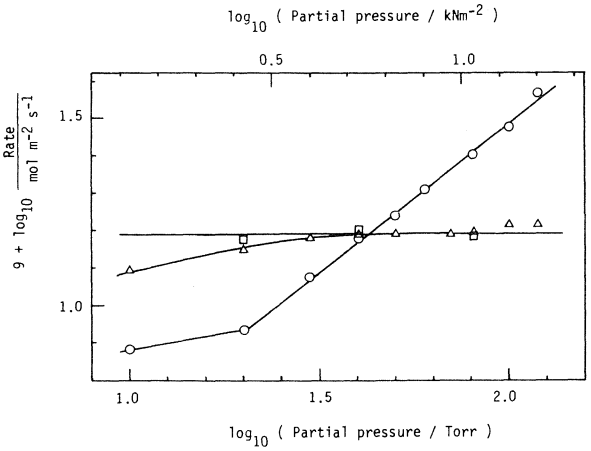

FIG. 2. Reaction rate order measurements for the CO/N_2O reaction on zinc oxide at 593 K with variations in the partial pressures of carbon monoxide (○), nitrous oxide (△), and nitrogen (□).

assumed to be proceeding mainly by reaction of nitrous oxide with carbon dioxide in a manner similar to that observed with cobalto-cobaltic oxide (3). Since a numerical value for the rate order with respect to carbon dioxide could not be established, subsequent determinations of rate constants were made on the assumption of zero order kinetics.

A reaction rate order of zero with respect to nitrogen in the partial pressure range 2.67 to 10.7 kN m^{-2} was determined.

The experimental reaction rate on zinc oxide, r (mol m^{-2} s^{-1}), at 593 K was expressed as:

$$[2] \qquad r = kP_{CO}{}^{0.8}$$

Temperature Effects

After pretreatment in the standard reaction mixture to establish steady catalytic activity at 793 K, the variation in the rate of catalysis with temperature on titanium dioxide was examined from 793 to 723 K at 6 K intervals. The Arrhenius plot was linear throughout the range and an experimental activation energy of 144 $\pm$ 4 kJ mol^{-1} was calculated using rate constants obtained by integrating eq. [1] (Fig. 3).

On zinc oxide, reaction rates were measured from 653 to 543 K at 10 K intervals once steady activity levels were established at 653 K using the standard reaction mixture. Rate constants calculated by integrating eq. [2] are shown in the Arrhenius plot (inset Fig. 3) from which an experimental activation energy of 121 $\pm$ 4 kJ mol^{-1} was calculated.

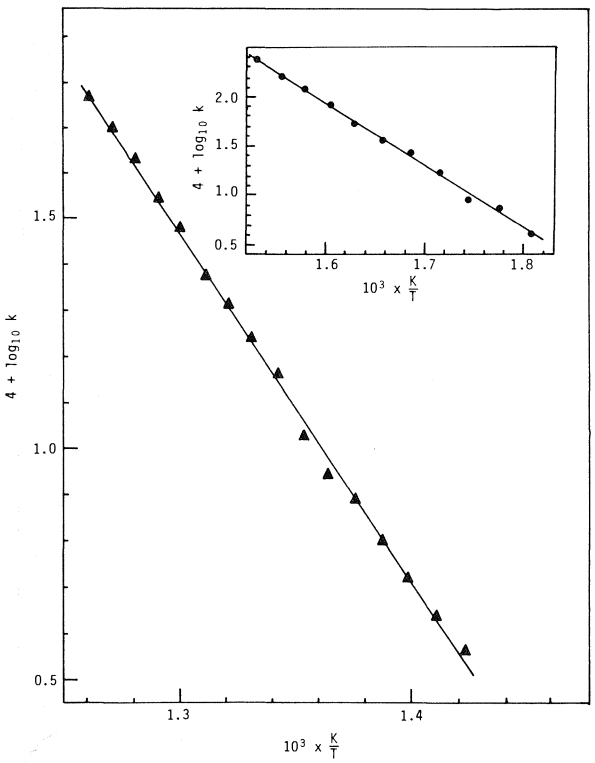

FIG. 3. Arrhenius plot of experimental reaction rate constants for the CO/N_2O reaction on titanium dioxide. Inset: Arrhenius plot for the CO/N_2O reaction on zinc oxide.

Discussion

Both stoichiometric zinc oxide and titanium dioxide may be regarded as semi-conductors with intrinsic energy gaps of 3.3 and 3.2 eV, respectively (6). Their surface properties may be influenced considerably by the presence of both adsorbed paramagnetic species and surface defects (7, 8) which can be related to the conditions of preparation. The defect structure of zinc oxide is associated with interstitial zinc ions (7) while that of anatase is explained by either the presence of oxygen vacancies or interstitial titanium ions (7).

The decomposition of nitrous oxide on TiO_2 has been shown to be insensitive to adsorbed oxygen (9), decomposition being restricted to special small areas of the surface where adjacent anion vacancies contain trapped electrons (type: R_2-centers). Their formation was attributed to O_2 desorption and rapid conversion to F-centers by surface migration making these inaccessible to gaseous oxygen. For ZnO prepared with different levels of interstitial zinc ions (10), the rate and extent of nitrous oxide decomposition did not substantially depend upon the zinc excess content of the oxide and rate control was associated with the diffusion of oxygen in the solid phase.

Titanium Dioxide

In the analysis of the present experimental results for anatase, a variety of kinetic expressions were examined with respect to the carbon monoxide and carbon dioxide rate order data and the best correlations were obtained with the equation:

$$[3] \qquad r = kP_{CO}\theta_{CO}$$

where

$$[4] \qquad \theta_{CO} = \frac{aP_{CO}}{1 + aP_{CO} + bP_{CO_2}{}^{1/2}}$$

The reduced plots are shown in Figs. 4 and 5. (The limitations inherent in the use of Langmuir–Hinshelwood type expressions in deriving mechanistic models have been documented (11, 12) and these equations are thus adopted as general guides to the nature of the surface reaction although, recently, further support regarding the specificity of such considerations has been presented (13) in the case of organic polymer ion-exchange catalysts.)

The zero order dependence of the catalytic reaction rate upon nitrous oxide partial pressure is indicative

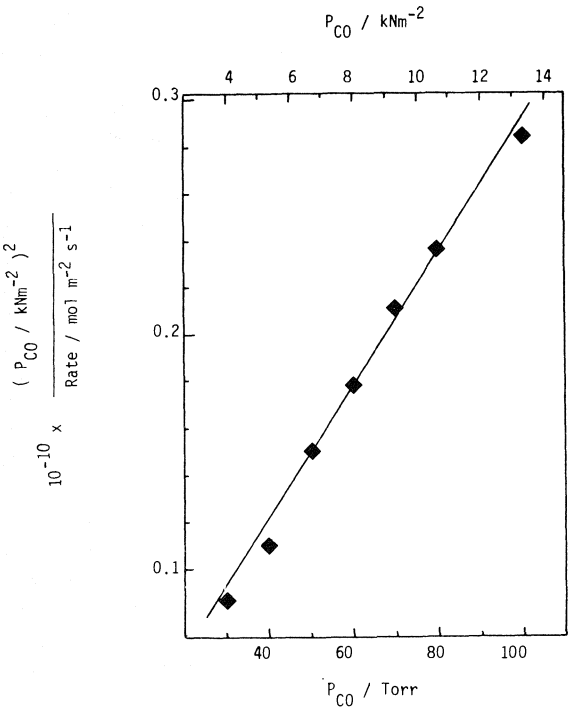

FIG. 4. Carbon monoxide rate order measurements plotted according to eq. [3] on titanium dioxide at 763 K.

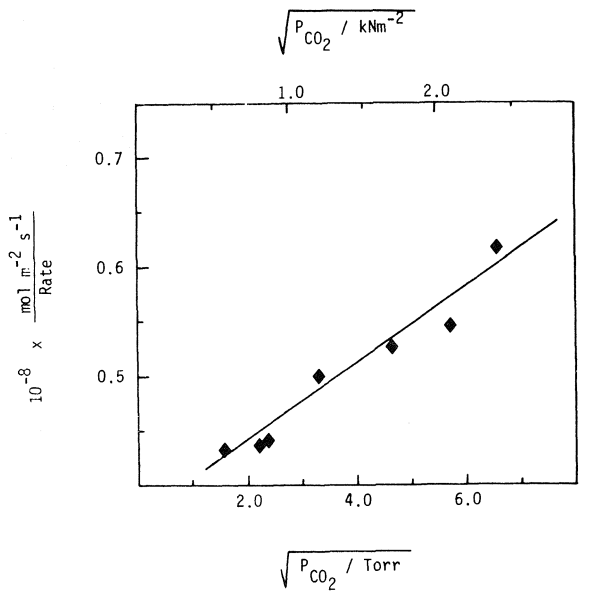

FIG. 5. Carbon dioxide rate order results plotted according to eq. [3] on titanium dioxide at 763 K.

of rapid chemisorption relative to that for carbon monoxide and thus the N_2O reaction may proceed at active defect regions of the oxide. There is some indication from the form of eq. [3] that a transient carbonate-like structure may be involved possibly arising from the reaction of CO with surface oxygen (from the rapid decomposition of N_2O) and a lattice oxygen in view of the high temperature range of catalysis (14).

Zinc Oxide

The apparent activation energy for the catalytic reaction between carbon monoxide and nitrous oxide was 121 ± 4 kJ mol^{-1} while the corresponding value of 172 kJ mol^{-1} for nitrous oxide decomposition (15) suggests that rate control of the CO/N_2O reaction is not exercised through N_2O decomposition. This is supported by the reaction rate order of 0.2 with respect to nitrous oxide at low partial pressures compared to 0.8 for carbon monoxide.

The carbon monoxide and nitrous oxide rate order results were analyzed in the same manner as that for anatase and the best fit was obtained with:

[5] $$r = kP_{CO}\theta_{CO}\theta_{N_2O}$$

where

[6] $$\theta_{CO} = \frac{aP_{CO}}{1 + aP_{CO}}$$

and

[7] $$\theta_{N_2O} = \frac{bP_{N_2O}}{1 + bP_{N_2O}}$$

The plots for these data are shown in Fig. 6. The expression accounts for only one N_2O molecule but two such molecules are necessary to preserve the stoichiometry of the reaction under steady-state catalysis and thus rapid adsorption and decomposition of a second N_2O molecule would be indicated. If the surface coverage for this molecule is given by $\theta = mP/(1 + mP)$, then relatively rapid chemisorption would result in $mP \gg 1$ and hence $\theta \simeq 1$ in accord with the form of eq. [5].

With the continuous addition of carbon dioxide

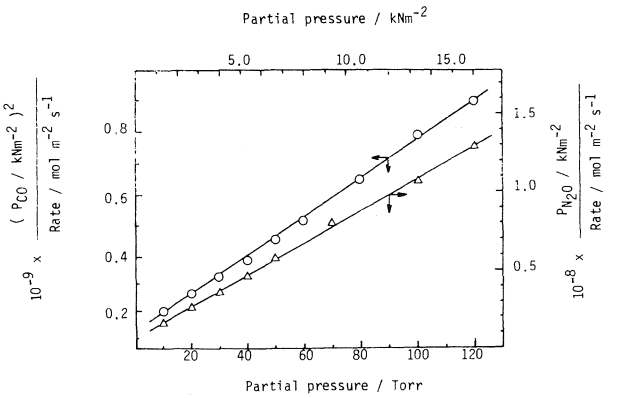

FIG. 6. Reduced plot of the carbon monoxide (○) and nitrous oxide (△) rate order results for the CO/N_2O reaction on zinc oxide at 593 K according to eq. [5].

to the reaction mixture an initial period of enhanced nitrogen production was noted while the level of unreacted carbon monoxide remained steady. Thus a precursor such as $CO_2^*(a)$, proposed for catalysis on Co_3O_4 (3), may be involved and if its formation was rate-controlling relative to the reaction involving the first N_2O molecule, and the reaction of the second N_2O was rapid, then this effect of carbon dioxide on catalysis may be rationalized. Thus, the adsorption of CO_2 would give rise to the $CO_2^*(a)$ species; the subsequent reaction of a second N_2O molecule to form the carbonate-like intermediate would be rapid and the enhanced production of nitrogen would be associated with a facile decomposition of nitrous oxide. Also, since the level of unreacted CO in the gas stream remained fixed, the formation of a surface carbonate-like intermediate is not likely to control the rate. Rather, the adsorption of the second CO involved in the reaction with the latter species may be rate-controlling.

This proposal is consistent with the form of eq. [5] where the P_{CO} term corresponds to low CO surface coverage, $1 \gg aP_{CO}$ such that $\theta_{CO} \simeq P_{CO}$. The eventual appearance of a retarding effect by carbon dioxide may arise after the most reactive sites with respect to $CO_2^*(a)$ formation are occupied with consequent inhibition on the adsorption of reactants.

Catalytic Activity Patterns

Some measure of independent support for the mechanistic proposals may be adduced from Fig. 7. The heats of carbonate formation from the corresponding oxide were calculated from available data (16) and revealed little variation for the oxides except for the formation of $Fe_2(CO_3)_3$. The basis for such a correlation would be that the metal cation and lattice oxygen participate in the formation of the carbonate. At high catalytic temperatures (>600 K) this proposal would be consistent for MgO and ZnO (14), however, lattice oxygen has not been implicated during the course of carbon monoxide oxidations below this temperature range (17–20). Generally, an associative mechanism involving the reactants has been proposed and, on this basis, the correlation between E_A and the heats of carbonate formation *from the elements* would seem more appropriate. The actual state may be intermediate to the two extremes.

All of the 'E_A' values have been calculated directly from experimental data with no a priori assumptions involved regarding the nature of the kinetics. A clear trend was also found in the variation of 'E_A' with the activation energy for isotopic oxygen exchange (21) determined on many of the same oxide samples (Fig. 8), thereby suggesting a dependence of catalysis on the strength of the labile metal/oxygen bond in the oxide surface.

A contribution of polarization effects to catalysis would be expected if carbon monoxide adsorption and reaction contributed significantly to the overall process. The simplest representation of bond polarization, the charge/radius ratio with respect to the cation (8, 21), can be refined but for the present purpose it does provide a useful indicator of the importance of polarization trends in the series of metal oxides (Fig. 9). The data indicate two series with only

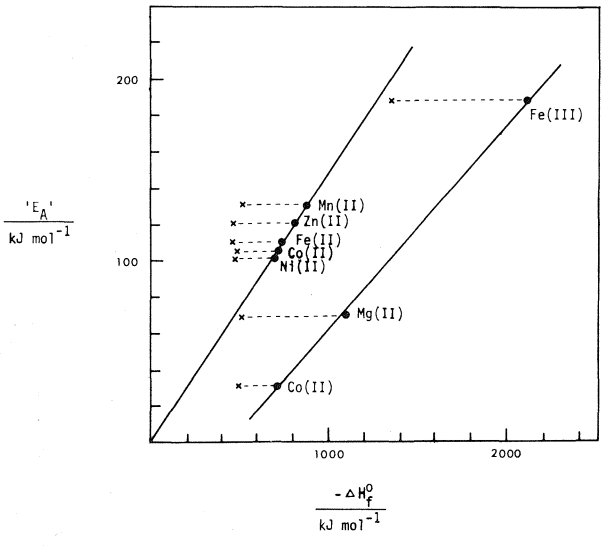

FIG. 7. Relationship between the experimental activation energy for the catalytic CO/N_2O reaction and the heats of carbonate formation from the corresponding 3*d* oxide (×) and from the elements (●).

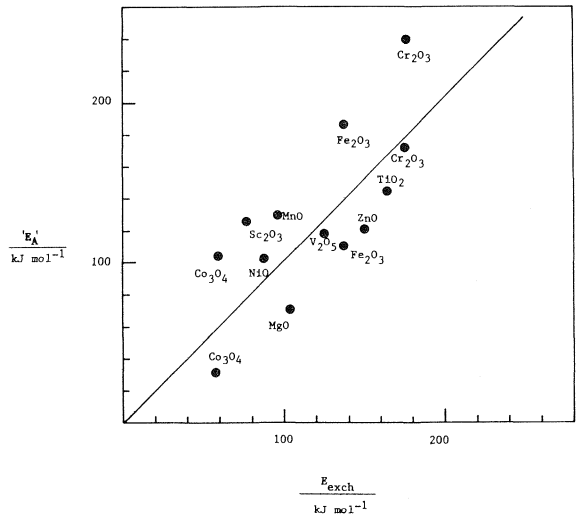

FIG. 8. Relationship between the experimental activation energy for catalysis, 'E_A', and isotopic oxygen exchange energy, E_{exch}.

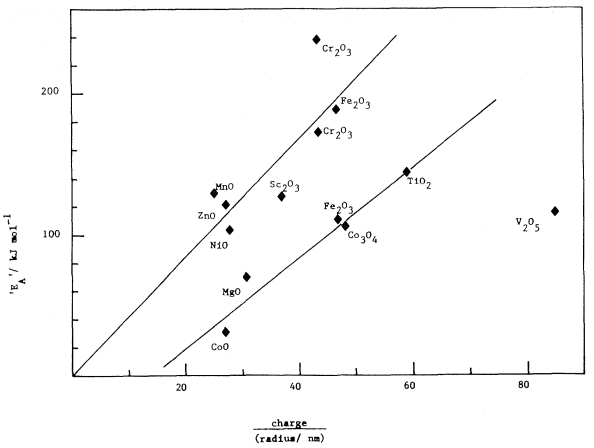

FIG. 9. Relationship between the experimental activation energy for catalysis, 'E_A', and the charge/radius ratio of the cation in the metal oxides.

V_2O_5 departing from linearity. The surface vanadium oxidation state during steady catalysis cannot be specified with certainty (8). The charge/radius ratios for the 4+ and 3+ states were 66.7 and 40.5 nm^{-1} respectively, but, for consistency, only the value corresponding to the 5+ oxidation state has been used.

Titanium dioxide possesses a larger metal/oxygen bond polarization than zinc oxide and this may, in part, account for the differences in the surface reactions on these oxides. In the case of anatase, the greater bond polarization would be expected to enhance the reactivity of adsorbed carbon monoxide with nitrous oxide. Thus, the zero order dependence of nitrous oxide partial pressure on anatase can be rationalized while the behaviour on zinc oxide would be associated with the lower polarization of the adsorbed carbon monoxide and a reduced reactivity with nitrous oxide. It is not clear whether this interaction proceeds through an associative surface complex or on adjacent sites through a redox type process, although in view of the high temperatures involved, the latter proposal seems more likely.

The synthesis and characterisation of the trifluoromethylsulfates of silver(II) and gold(III)

PATRICK C. LEUNG, KEITH C. LEE, AND FRIEDHELM AUBKE[1]

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received August 23, 1978

PATRICK C. LEUNG, KEITH C. LEE, and FRIEDHELM AUBKE. Can. J. Chem. **57**, 326 (1979).

The new trifluoromethylsulfates $Ag(SO_3CF_3)_2$ and $Au(SO_3CF_3)_3$, as well as the compound $Cs[Au(SO_3CF_3)_4]$, are synthesised by the solvolysis of the corresponding fluorosulfates in an excess of trifluoromethyl sulfuric acid. The resulting compounds are characterised by their vibrational spectra and, in the case of $Ag(SO_3CF_3)_2$, also by esr.

PATRICK C. LEUNG, KEITH C. LEE et FRIEDHELM AUBKE. Can. J. Chem. **57**, 326 (1979).

On a synthétisé les nouveaux trifluorométhylsulfates, $Ag(SO_3CF_3)_2$, $Au(SO_3CF_3)_3$ ainsi que $Cs[Au(SO_3CF_3)_4]$, en procédant à la solvolyse des fluorosulfates correspondants dans un excès d'acide trifluorométhylsulfurique. On a caractérisé les composés obtenus à l'aide de leurs spectres vibrationnels et, dans le cas du $Ag(SO_3CF_3)_2$, grâce à la rpe.

[Traduit par le journal]

Introduction

Trifluoromethylsulfuric acid, CF_3SO_3H, has, since its discovery in 1954, attracted much attention (1). The acid is one of the strongest, simple protonic acids, exceeded only by fluorosulfuric acid in this respect (1–3). Many of its derivatives, both organic and inorganic in nature, have been reported (1). It is therefore somewhat surprising that only a rather small number of binary transition metal trifluoromethylsulfates seem to have been synthesized and characterized to date (1), whereas a relatively large number of corresponding fluorosulfates are known (4). This discrepancy is primarily due to the lack of suitable synthetic routes to transition metal trifluoromethylsulfates. The very limited thermal stabilities of oxidising agents such as bis(trifluoromethylsulfuryl)peroxide, $(CF_3SO_3)_2$ (5), and chlorine(I) trifluoromethylsulfate, CF_3SO_3Cl (6), restrict the available preparative methods to solvolysis reactions in CF_3SO_3H with metal-halides, -carboxylates, -oxides, and -carbonates as solutes. Hence the availability and the reactivity of these solutes become the limiting factors. The previously reported transition metal trifluoromethylsulfates $Cu^{I}(SO_3CF_3)$ (7), $Cu^{II}(SO_3CF_3)_2$ (7, 8), and $Co^{II}(SO_3CF_3)_2$ (8) have the metals in rather common oxidation states. $Mo_2(SO_3CF_3)_4$ (9) contains the quadruply bonded Mo_2^{4+} ion. All are prepared by solvolysis reactions.

The conversion of fluorosulfates into trifluoromethylsulfates, illustrated by the synthesis of $Ag(SO_3CF_3)_2$, $Au(SO_3CF_3)_3$, and $Cs[Au(SO_3CF_3)_4]$, widens the scope of the available routes to trifluoromethylsulfates and allows the synthesis of compounds with the metal in an unusual oxidation state.

[1]To whom all correspondence should be addressed.

Silver(II) fluorosulfate (10) is besides AgF_2 the only binary Ag^{2+} compound. Gold(III) fluorosulfate (11) was found recently (12) to act as a SO_3F^- ion acceptor and to behave as an acid in HSO_3F. It appears to be the only stable binary oxyacid derivative of tervalent gold.

Experimental Section

Chemicals

Gold powder, 100 mesh, 99.995% pure and silver powder, 100 mesh, 99.999% pure were obtained from the Ventron Corporation. Trifluoromethylsulfuric acid (Minnesota Mining and Manufacturing Co.) was distilled from concentrated H_2SO_4 under reduced pressure. Technical grade fluorosulfuric acid (Allied Chem. Corp.) was purified by double distillation. Bis(fluorosulfuryl)peroxide was prepared according to Cady and Shreeve (13). $Ag(SO_3F)_2$ (10) and $Au(SO_3F)_3$ (12) were obtained by the oxidation of Ag and Au, respectively, by a roughly equimolar mixture of HSO_3F and $S_2O_6F_2$. $Cs[Au(SO_3F)_4]$ (12) resulted from the reaction of 1:1 stoichiometric mixture of CsCl and Au with $HSO_3F/S_2O_6F_2$. All other chemicals were obtained from commercial sources in the highest grade of purity available.

Instrumentation

Infrared spectra were obtained on a Perkin-Elmer 457 grating spectrophotometer or on a Pye Unicam SP 1100 instrument. KRS-5, silver chloride, and bromide were used as window materials (all from Harshaw Chemicals). Due to the reactivity of the materials, no mulling agent was used. Spectra were obtained on thin films of solid materials pressed between the windows. Raman spectra were obtained with a Spex Ramalog 5 Spectrometer equipped with an argon ion laser using the line at 514.5 nm for excitation. The samples were contained in melting point capillaries. Electron spin resonance spectra were recorded on a Varian Associates E-3 spectrometer equipped with 100 kHz field modulation at room temperature and at liquid nitrogen temperature.

Magnetic susceptibilities were determined using a Gouy apparatus described before (14). Measurements were made at constant field strengths of approximately 4500 and 8000 G. All susceptibilities measured were found to be independant of field strength. Calibrations were carried out using $HgCo(CNS)_4$

0008-4042/79/030326-04$01.00/0

(15). Diamagnetic corrections were obtained from the literature (16).

All reactions were performed in Pyrex reaction vials of about 40 ml contents, fitted with Kontes Teflon stem valves. Volatile materials were handled using vacuum line techniques. Solids were handled in a Vacuum Atmosphere Corp. "Dri Lab" Model No. HE-43-2, filled with purified dry nitrogen and equipped with a "Dri-Train" Model No. HE-93-B circulating unit. Filtrations of moisture sensitive compounds outside the drybox were carried out in an apparatus described by Shriver (17).

Synthetic Reactions

$Ag(SO_3CF_3)_2$

An excess of distilled trifluoromethylsulfuric acid (~5 mL) was added to 1.012 g (3.31 mmol) of $Ag(SO_3F)_2$. The resulting suspension was magnetically stirred for 48 h at room temperature, subsequently filtered, and repeatedly washed with distilled HSO_3CF_3. Traces of volatile materials were removed in a dynamic vacuum. A dark brown solid (740 mg) was obtained. This extremely hygroscopic solid melted at 140°C under decomposition and analysed as $Ag(SO_3CF_3)_2$.

$Au(SO_3CF_3)_3$

$Au(SO_3F)_3$ (198 mg, 0.40 mmol) was dissolved in about 3 mL of HSO_3CF_3 by heating the mixture to 100°C. The red solution was kept at this temperature overnight. When allowed to cool to room temperature, yellow-brown crystals precipitated out, and removal of all volatiles yielded 250 mg (0.39 mmol) of $Au(SO_3CF_3)_3$. Gold(III) trifluoromethylsulfate is hygroscopic and thermally stable to +160°C.

$Cs[Au(SO_3CF_3)_4]$

$Cs[Au(SO_3F)_4]$ (478 mg, 0.66 mmol) was dissolved in ~3 mL of HSO_3CF_3 by heating the mixture to +50°C. The yellow-brown solution was kept at this temperature overnight. After all volatiles were removed *in vacuo*, 576 mg (0.63 mmol) of yellow $Cs[Au(SO_3CF_3)_4]$ were obtained. The compound is diamagnetic and melts at +190°C to a brown liquid.

Analysis

Chemical analysis was performed by Analytische Laboratorien (formerly A. Bernhardt), Gummersbach, West Germany. The carbon contents was determined by Mr. P. Borda of this department. The found and expected values for all three compounds are listed below.

Anal. calcd. for $Ag(SO_3CF_3)_2$: Ag 26.57, S 15.79, F 28.08, C 5.92; found: Ag 26.81, S 15.92, F 28.04, C 5.82.

Anal. calcd. for $Au(SO_3CF_3)_3$: Au 30.58, S 14.93, F 26.55, C 5.59; found: Au 30.83, S 15.11, F 26.32, C 5.90.

Anal. calcd. for $Cs[Au(SO_3CF_3)_4]$: Cs 14.35, Au 21.27, S 13.85, F 24.61; found: Cs 14.50, Au 21.40, S 14.04, F 24.57.

Results and Discussion

Synthesis

The successful quantitative conversion of a transition metal fluorosulfate into a trifluoromethylsulfate seems to follow the same general pattern of previously reported solvolysis reactions in HSO_3CF_3 with metal chlorides or carboxylates as reactants (7, 9). The general overall reaction may be formulated as:

$$[1] \qquad MX_n + n HSO_3CF_3 \rightarrow M(SO_3CF_3)_n + n HX$$

with X = Cl, O_2CR, or SO_3F. In order to achieve complete conversion and to avoid mixed products HX must be removed from the acid mixture, either as a volatile byproduct, like HCl in the solvolysis of metal chlorides, or as a soluble protonated species, as in the solvolysis of carboxylates. The solvolysis of a metal fluorosulfate in HSO_3CF_3 departs from these precedents in two important respects: (*a*) HSO_3F and HSO_3CF_3 have virtually identical boiling points at 760 Torr (162.7°C for HSO_3F (18) vs. 163°C for HSO_3CF_3 (19)), and similar volatilities in a vacuum of 10^{-2} Torr at room temperature; and (*b*) a stronger protonic acid (HSO_3F) appears to be generated by a weaker protonic acid (HSO_3CF_3) from its salts ($M(SO_3F)_n$). Hence, removal of HSO_3F by virtue of its volatility or by forming a protonated ion, such as $H_2SO_3F^+$, is rather improbable.

The possibility that HSO_3F is removed by a chemical reaction with HSO_3CF_3 appears to be more likely. Recently Olah and Ohyama (20) have obtained both the trifluoromethyl ester $CF_3OSO_2CF_3$, and trifluoromethylsulfuryl fluoride, CF_3SO_2F, in yields of 19 and 5.5%, respectively, when HSO_3CF_3 and HSO_3F at a molar ratio of 2:1 are refluxed. No other reaction products were reported and the overall reaction is not completely understood.

Because our solvolysis reactions are carried out with HSO_3CF_3 in excess, further involvement of HSO_3F in reactions is very likely. In all reactions described here a slight pressure increase is noted when the solvolysis is completed and a gas phase ininfrared spectrum, obtained on volatile byproducts from the reaction of $Cs[Au(SO_3F)_4]$ with HSO_3CF_3, shows bands attributable to CF_3SO_2F, CF_3OSO_2-CF_3, F_2CO, SO_2, and SiF_4 (21).

It must be concluded that HSO_3F, formed in the solvolysis according to [1], or the metal fluorosulfates directly, interact with trifluoromethylsulfuric acid to form volatile products, which do not interact with the metal trifluoromethylsulfates.

A number of alternative routes to the silver(II) and the gold(III) trifluoromethylsulfates were tried, but found to be either unsatisfactory or less useful: gold(III) chloride did not react with HSO_3CF_3 even at elevated temperatures. The attempted solvolysis of AgF_2 in HSO_3CF_3 (in a Kel-F reaction vessel) resulted in a rather impure product. The oxidation of silver or gold by $S_2O_6F_2$ in HSO_3CF_3 solution, a method previously used to synthesize $I(SO_3CF_3)_3$ (22), proceeded far too slowly to avoid the slow oxidative cleavage of the S—C bond in HSO_3CF_3 by $S_2O_6F_2$. This side reaction is rather exothermic and occasional explosions may result. A similar risk is encountered when $S_2O_6F_2$ is added to a solution of $AgSO_3CF_3$ in HSO_3CF_3, but if the resulting dark

brown solid is filtered immediately, reasonably pure $Ag(SO_3CF_3)_2$ is obtained. In summary it seems that none of the alternative methods tested has the same general applicability as the solvolysis of metal fluorosulfates in HSO_3CF_3.

Both $Ag(SO_3CF_3)_2$ and $Au(SO_3CF_3)_3$ are similar in colour to the corresponding fluorosulfates, but unlike these, they are virtually insoluble in the parent acid. The formation of $Cs[Au(SO_3CF_3)_4]$ indicates $Au(SO_3CF_3)_3$ may act as a trifluoromethylsulfate ion acceptor and may behave as an acid in HSO_3CF_3; however, the lack of any appreciable solubility precludes more detailed solution studies.

Like $Ag(SO_3F)_2$, silver(II) trifluoromethylsulfate is converted to the complex $[Ag(byp)_2](SO_3CF_3)_2$ by direct combination of α,α'-bipyridine (bpy) with $Ag(SO_3CF_3)_2$ in a manner described in detail (10) for $Ag(SO_3F)_2$. The resulting complex $[Ag(bpy)_2](SO_3CF_3)_2$ had been obtained previously via a different method (23), the oxidation of $[Ag(bpy)_2]SO_3CF_3$, and its vibrational spectrum and the esr parameter (10) are known.

Vibrational Spectra

Infrared spectra are obtained on all three compounds down to 300 cm^{-1}, while only the Raman spectrum of $Cs[Au(SO_3CF_3)_4]$ is reported. Gold(III) trifluoromethylsulfate shows strong fluorescence while the dark colour of $Ag(SO_3CF_3)_2$ prevents Raman scattering.

Tentative vibrational assignments for SO_3CF_3 derivatives have been reported for both a bidentate bridging group (9, 24) and for a monodentate group in an anionic complex (22), and will not be discussed here. In addition, the complexity of the molecules, the unavailability of Raman data for all compounds, and the coincidence and vibrational mixing of SO_3 and CF_3 vibrational modes prevent a more detailed assignment. The observed ir frequencies and Raman shifts are listed in Table 1 in order of decreasing frequencies. Except for occasional band splittings, good agreement between ir and Raman data for $Cs[Au(SO_3CF_3)_4]$ is observed.

The band positions for $Ag(SO_3CF_3)_2$ suggest strongly a bidentate SO_3CF_3 group when compared to the precedents (9, 24). A similar conclusion had been reached for $Ag(SO_3F)_2$ (10) and it is not surprising that both silver(II) compounds should show strong structural similarities. The lack of volatility and solubility in HSO_3CF_3 is also more consistent with the presence of bridging groups and hence a polymeric structure. The strong involvement of two

*Reference 10.

oxygens from the SO_3CF_3 groups would imply a square planar or a distorted (tetragonally elongated) environment for Ag^{2+}, not unreasonable for a metal ion with a d^9 electronic configuration.

For $Cs[Au(SO_3CF_3)_4]$, the presence of monodentate OSO_2CF_3 groups seems to be indicated. The observed band positions in particular in the stretching range are in reasonable agreement with reported data for $Rb[I(SO_3CF_3)_4]$ (22). Intense Raman bands at ~650, ~450, and ~270 cm^{-1} are also observed in the Raman spectrum of $Cs[Au(SO_3F)_4]$ (12). The corresponding vibrations seem to involve AuO_4 skeletal vibrations in a square planar environment. Such a structure for gold (consistent with the observed diamagnetism) is suggested for both the fluorosulfato and the trifluoromethylsulfato complexes.

Finally, the infrared data for $Au(SO_3CF_3)_3$ with numerous bands in the stretching frequency range (1500 to 800 cm^{-1}) suggest the presence of both mono and bidentate trifluoromethylsulfate groups. In addition, strong vibrational coupling (evident also for $Cs[Au(SO_3CF_3)_4]$) seems to cause further proliferation of bands. Even though a clear distinction between bands due to mono and bidentate SO_3CF_3 groups is not possible, a polymeric structure is indicated. Thus, the strong structural parallels between the corresponding fluorosulfates and trifluoromethylsulfates seem to extend to the gold(III) derivatives as well.

Electron Spin Resonance and Magnetic Susceptibilities of $Ag(SO_3CF_3)_2$

As for the silver(II) fluorosulfate (10), a broad, isotropic esr signal is obtained for solid $Ag(SO_3CF_3)_2$, both at room temperature and at liquid N_2 temperature. Comparable g_0 values for both compounds suggest similar magnetic properties as reflected in the magnetic moment values calculated by using the spin-only formula for one unpaired electron. The data are presented in Table 2.

Preliminary bulk magnetic susceptibilities on $Ag(SO_3CF_3)_2$ suggest a slightly lower μ_{eff} value of approximately 1.60 BM at room temperature. Further work is required, extending the measurements down to 80 K or even lower, to decide whether antiferromagnetic coupling is the cause for the low magnetic moment.

There is, however, no doubt that silver(II) trifluoromethylsulfate, like the corresponding bisfluorosulfate, is a true divalent silver compound with one unpaired electron.

Conclusions

The conversion of transition metal fluorosulfates into trifluoromethylsulfates by solvolysis in HSO_3CF_3, demonstrated here by the syntheses of $Ag(SO_3CF_3)_2$, $Au(SO_3CF_3)_3$, and the complex $Cs[Au(SO_3CF_3)_4]$, should have rather wide applications. Extension to other main group and transition metal fluorosulfates should be possible. Judging by the wide use other metal trifluoromethylsulfates have found in organic synthesis (1), the new compounds should find some use as reagents as well.

Adsorption of Et_4NBr at the mercury/electrolyte interface from water and heavy water solutions

FRANK M. KIMMERLE AND HUGUES MENARD

Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received June 16, 1977[1]

FRANK M. KIMMERLE and HUGUES MENARD. Can. J. Chem. **57**, 330 (1979).

Droptime measurements of aqueous and deuterated Et_4NBr solutions indicate that the mercury/electrolyte interfacial tension differs by less than 1 mJ m^{-2} (dyn cm^{-1}). Et_4NBr is slightly more adsorbed from heavy water in dilute solutions, but the difference becomes relatively less important in concentrated electrolytes. This behaviour is interpreted in terms of interfacial transfer parameters and attributed to the nature of the solvent–solute interactions.

FRANK M. KIMMERLE et HUGUES MENARD. Can. J. Chem. **57**, 330 (1979).

Des mesures de temps de chute d'une goutte de mercure dans des solutions aqueuses et des solutions deuterées de Et_4NBr, indiquent un écart de la tension interfaciale de moins de 1 mJ m^{-2} (dyn cm^{-1}). Et_4NBr est adsorbé légèrement plus des solutions diluées d'eau lourde, mais les différences disparaissent en solution concentrée. Ce comportement est interprété à l'aide des fonctions de transfert à l'interface et peut être attribué à la nature des intéractions solvant–soluté.

Introduction

It has long been recognized (1) that water and deuterium oxide have very similar properties, but that small differences in the magnitude of several physical properties exist. Not the least important difference is the fact that more structural order exists in liquid D_2O than in H_2O. One way of detecting structural effects is to study the properties of solutions of the same solutes in two solvents (2). Another is to examine the electrode/electrolyte interface where it is now established that hydration entropy plays a predominant role in the case of the adsorption of the quaternary ammonium salts (3, 4).

The treatment follows directly from the general electrocapillary given by Mohilner (cf. eq. [52] of ref. 5) which can be simplified for a pure mercury electrode in contact with a three component aqueous solution containing one electrolyte $C_{\nu+}A_{\nu-}$ and one neutral organic compound H at constant temperature and pressure:

$$[1] \quad d\gamma = -\sigma^M dE^{\mp} - \Gamma_{H,S} d\mu_H - \frac{\Gamma_{\pm,S} d\mu_{C_{\nu+}A_{\nu-}}}{\nu\pm}$$

where γ is the interfacial tension of the mercury/electrolyte interface, σ^M is the excess charge density of the metal surface, $E^{\pm}$ is the potential of the polarized electrode with respect to an indicator electrode reversible to the anion (E^-) or (E^+), $\Gamma_{H,S}$ is the relative surface excess of neutral species H with respect to the solvent S, $\Gamma_{\pm,S}$, the relative excess of the anion or cation with respect to solvent S, μ_H and $\mu_{C\nu+C\nu-}$, the chemical potentials of the neutral and ionic solutes respectively, and $\nu\pm$ the stoichiometric coefficient of the cation or anion.

In order to compare bulk thermodynamic properties in two solvents, transfer parameters have been defined as the difference between observed quantities (e.g. the enthalpy, free energy, heat capacities, etc.) in the two solvents. Similarly, it is possible to define interfacial transfer properties. Thus we consider the interfacial energy of transfer, γ_{tr}, as the difference of the surface tensions of two interfacial regions: phase 0 (the electrode) in contact with phase 1 containing solvent 1 and phase 0 in contact with phase 2 containing solvent 2.

$$[2] \quad \gamma_{tr} = \gamma(\mu,E^{\pm},S_2) - \gamma(\mu,E^{\pm},S_1)$$

Transfer parameters involving the first and second derivatives are also readily defined, for example.

$$[3] \quad \sigma_{tr}{}^M = -\left\{\left(\frac{\partial\gamma}{\partial E^{\pm}}\right)_{T,p,\mu,S_2} - \left(\frac{\partial\gamma}{\partial E^{\pm}}\right)_{T,p,\mu,S_1}\right\}$$

Clearly the solution composition and thus μ_i must be held constant while performing the mathematical differentiation. However, some ambiguity exists as to the concentrations in solvents S_1 and S_2 that should be compared, since it is impossible to keep constant all of the chemical potentials including that of the solvent itself. Historically one might be inclined to keep the molality or the molarity constant and compare absorption in two solvents or solvent mixtures (6, 7). It may be more meaningful, however, to compare solutions at fixed mole fractions. Since $\sigma_{tr}{}^M$ refers to the variation in charge necessary to maintain a fixed electrode potential with respect to

[1]Revision received.

0008-4042/79/030330-05$01.00/0

an indicator electrode, it would furthermore be useful to employ a hypothetical indicator electrode whose response does not vary with the nature of the solvent. Alternately, it may be necessary to take into account the free energy of transfer of the solute, and thus compare the potential scale in one solvent to that in the other.

The subtraction and differentiation implicit in eq. [3] can be carried out in reverse order and we can write (at constant temperature and pressure):

$$[4] \qquad \sigma_{tr}{}^{M} = -\left(\frac{\partial \gamma_{tr}}{\partial E^{\pm}}\right)_{\mu'}$$

The relative surface excess of transfer for a neutral species can similarly be defined as:

$$[5] \quad \Gamma_{H,tr} = -\left\{\left(\frac{\partial \gamma}{\partial \mu_H}\right)_{\mu',E^{\pm},S_2} - \left(\frac{\partial \gamma}{\partial \mu_H}\right)_{\mu',E^{\pm},S_1}\right\}$$

where the subscript μ' indicates that the chemical potentials of all the components are held constant except that one with respect to which the differentiation is performed, and that of the solvent itself. For solvents having similar properties and hence where $\gamma(S_1) \sim \gamma(S_2)$ it is probably easier to calculate $\Gamma_{H,tr}$ according to:

$$[6] \qquad \Gamma_{H,tr} = -\left(\frac{\partial \gamma_{tr}}{\partial \mu_H}\right)_{\mu',E^{\pm}}$$

The relative surface excess may be expressed in terms of the absolute surface excess values and the mole fractions of solute X_H and solvent X_S in solution.

$$[7] \quad \Gamma_{H,tr} = \left\{\left(\Gamma_H{}^{S_2} - \frac{X_H}{X_{S_2}}\Gamma_{S_2}\right)_{S_2} - \left(\Gamma_H{}^{S_1} - \frac{X_H}{X_{S_1}}\Gamma_{S_1}\right)_{S_1}\right\}$$

If we compare solutions at fixed mole fraction ratio $X_H/X_{S_1} = X_H/X_{S_2}$, which can also be expressed as the molality divided by the number of moles of solvent/kg (m/55.5 for water), eq. [7] becomes

$$[8] \quad \Gamma_{H,tr} = (\Gamma_H{}^{S_2} - \Gamma_H{}^{S_1}) - \frac{m}{55.5}(\Gamma_{S_2} - \Gamma_{S_1})$$

A positive value, $\Gamma_{H,tr} > 0$, therefore implies that

$$[9] \qquad (\Gamma_H{}^{S_2} - \Gamma_H{}^{S_1}) > (m/55.5)(\Gamma_{S_2} - \Gamma_{S_1})$$

For dilute solutions, where $m/55.5 \ll 1$, it may be assumed that the neutral component H is more strongly adsorbed at the interface in solvent 2 than in solvent 1. In concentrated solutions a positive value, $\Gamma_{H,tr} > 0$ might conceivably imply that $\Gamma_{S_1} > \Gamma_{S_2}$ without necessarily dictating that $\Gamma_H{}^{S_2} > \Gamma_H{}^{S_1}$. Similarly a negative value, $\Gamma_{H,tr} < 0$, does not necessarily imply the desorption of the neutral component in solvent S_2, it could also reflect the fact that the interfacial region is relatively richer in solvent molecules S_1 than solvent molecules S_2 at equivalent concentration of the neutral component H.

In the case of electrolyte solutions, similar expressions arise. The ionic relative surface excess of transfer is given as

$$[10] \quad \Gamma_{\pm,tr} = (\Gamma_{\pm}{}^{S_2} - \Gamma_{\pm}{}^{S_1}) - \nu_{\pm}\frac{m}{55.5}(\Gamma_{S_2} - \Gamma_{S_1})$$

$\Gamma_{\pm,tr}$ can be calculated from the expressions analogous to eqs. [5] or [6] or again using Parson's function (8).

$$[11] \quad \Gamma_{\pm,tr} = -\nu_{\pm}\left\{\frac{\partial[\xi(\mu, S_2, \sigma_M) - \xi(\mu, S_1, \sigma_M)]}{RT\partial \ln a_{(C\nu_+ A\nu_-)}}\right\}_{\sigma^M}$$

The latter expression might prove particularly useful at the potential of zero charge, since the electrode potential with respect to a given reference electrode does not have to be known in order to calculate the relative surface excess nor the relative surface excess of transfer.

Because water and deuterium oxide have almost the same molar volumes (1) (18.069 and 18.134 cm^3/mol at 25°C) dilute solutions of equal molarity contain practically the same number of solvent molecules. Even for 1 *M* Et_4NBr the difference in concentration on a mole fraction basis is less than 3% so that either scale should prove satisfactory. The distinction becomes significant, however, when comparing solvents having significantly different volumes or higher solute concentrations in heavy water solutions.

Experimental

Surface tension data were calculated from droptime measurement recordings using the apparatus described previously (9). The time interval between successive drops was defined by the interruption of a light beam by the falling drop. The resulting signal from a Systron Donner frequency meter caused the time interval together with the drop potential controlled by a Tacussel PRT 30-0.1 potentiostat to be printed out by a HP 5150A printer. Although the electrode potential was actually recorded with respect to a saturated calomel electrode, conversion to a reversible indicator potential scale was later accomplished using the activity data of Lindenbaum and Boyd. All aqueous solutions were prepared from water distilled from alkaline-permanganate and twice recrystallized Et_4NBr (Baker reagent grade). D_2O (Stohler Isotope Chemicals) was used without further purification.

Results

The interfacial tension for tetraethylammonium bromide solution in contact with the mercury elec-

trode is plotted in Fig. 1 as a function of potential with respect to a reversible Br electrode in aqueous or deuterated solutions. Although γ_{D_2O} is consistently greater than γ_{H_2O}, the difference is usually less than 1 mJ m^{-2}, i.e. only ten times the experimental uncertainty near the E_{pzc} and about three times the experimental error at the extremities of the electrocapillary curves. Any interpretation of these results will therefore be limited by the experimental scatter of the data and could be distorted by even relatively minor systematic errors in the data treatment.

The interfacial energy of transfer, Fig. 2, decreases with increasing electrolyte concentration but seems to be relatively potential independent. Perhaps not unsurprisingly, in view of the reported negligible difference in dipole moments, dielectric constant, crystallographic parameters, and molar volumes of water and deuterium oxide (1), the electrode charge – potential relationship is also virtually identical in H_2O and D_2O Et_4NBr solutions, and any differences fall within the experimental uncertainty of the measurements.

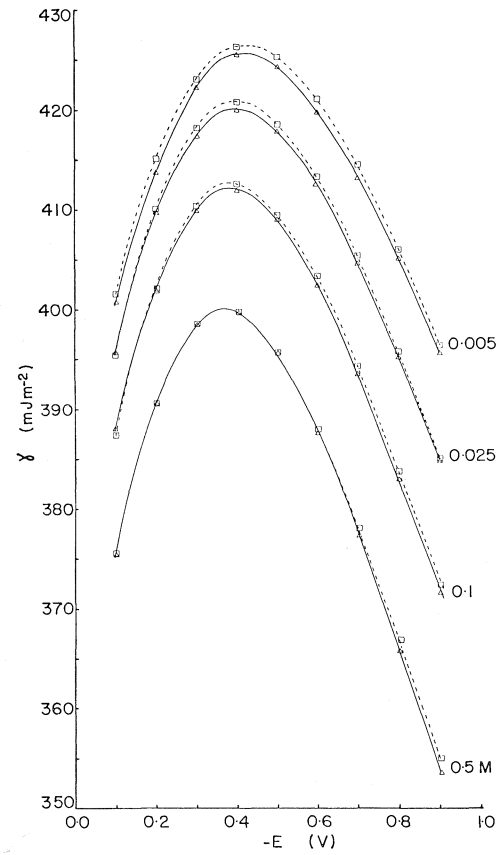

FIG. 1. Interfacial tension for tetraethylammonium bromide electrolytes: □, D_2O solutions; △, H_2O solutions. Electrode potentials refer to a reversible Br indicator electrode.

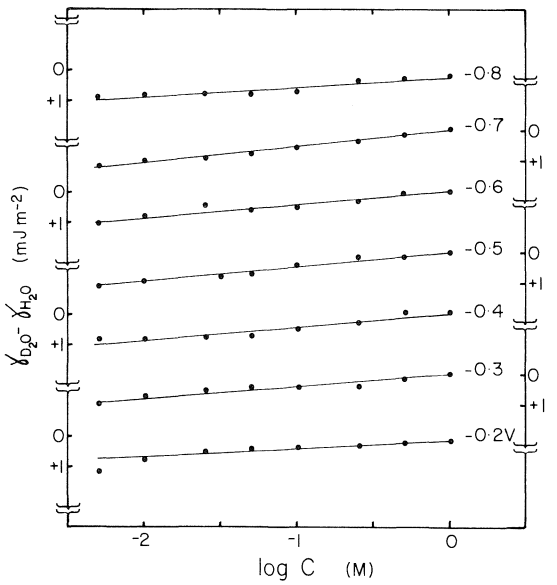

FIG. 2. Interfacial energy of transfer for Et_4NBr electrolytes. $\gamma_{tr} = \gamma_{D_2O} - \gamma_{H_2O}$.

The relative surface excess of transfer of the cation, $\Gamma_{+,tr}$ can be calculated according to eq. [6] from Fig. 2 provided that the activity coefficients are available. We have not found any measurements of Et_4NBr activity coefficients in the literature but have assumed that $\gamma^{\pm}(D_2O) = \gamma^{\pm}(H_2O)$. This assumption is justified by the fact that Wen and Chen reported (Tables III and V of ref. 10) ratios of activity coefficients $\gamma^{\pm}(D_2O)/\gamma^{\pm}(H_2O) > 1.0$ for $(CH_3)_4NBr$ and $\gamma^{\pm}(D_2O)/\gamma^{\pm}(H_2O) < 1.0$ for $(C_4H_9)_4NBr$ and $-15 < \Delta\bar{G}_{tr} < +15$ cal/mol. Levine and Wood (11) reported almost identical values of the excess enthalpy of dilution of Et_4NBr in H_2O and D_2O. Any differences in activity coefficients are probably less than 2% and approach the reliability $\gamma^{\pm}(H_2O)$ (12) itself.

The surface excess of transfer obtained by assuming that single ion activities can be replaced by mean ionic activities (and thus that the potential scale in D_2O is identical to that in H_2O) is found to be $\Gamma_{+,tr} = 8 \pm 1 \times 10^{-8}$ mol m^{-2}. This value does not depend on the electrode charge (+0.15 to −0.12 C m^{-2}), the electrolyte concentration (5×10^{-3} to 1.0 M), nor the relative surface excess ($\Gamma_{+,S} = 0.3$ to 3×10^{-6} mol m^{-2}) (13).

According to eq. [10] $\Gamma_{+,tr}$ could be explained by differences in the surface excess Γ_S, or in the surface excess of the solute Γ_+^S. In the former case we would expect $\Gamma_{+,tr}$ to vary with electrolyte concentration ($X_{\pm}/X_S$) and to become negligible at infinite dilution. The opposite behaviour is observed and we are forced to conclude that $\Gamma_{+,tr}$ must be attributed to

differences in the absolute amounts of Et_4NBr absorbed in the two solvents. Since the excess charge of transfer $\sigma_{M,tr} \simeq 0$, and

$$\sigma_{M,tr} = (\nu_+ F\Gamma_{+,tr} - \nu_- F\Gamma_{-,tr})$$

we must further conclude that $\Gamma_{Et_4N^+,tr} \sim \Gamma_{Br^-,tr}$ i.e. that the adsorption of the cation and anion are perturbed to approximately equal extent.

We can interpret $\Gamma_{\pm,tr}$ in view of the relationship between the hydration entropy and $\Gamma_{+,S}$ found by Ikeda *et al.* (3) and the relationship between the ion size and the free energy of adsorption of the tetraalkylammonium salts (15). When Et_4NBr is absorbed beyond the $\Gamma_{+,S}$ or $\Gamma_{-,S}$ values predicted from simple diffuse layer theory, the salt is said to be specifically or contact adsorbed. In deuterated solutions from 2 to 20% more Et_4NBr species are found in the interfacial region than in aqueous solutions. For aqueous and aqueous urea solutions we have previously found that contact adsorbed Et_4NBr seems to involve an equal number of anions and cations in the immediate neighbourhood of the electrode in a configuration not unlike Fig. 3. Such contact absorption can be described (14) by a general hangview isotherm:

$$[12] \qquad f(\theta) = \frac{X_H}{X_S} \exp -\frac{\Delta\bar{G}_H - n\Delta\bar{G}_S}{RT}$$

where $f(\theta) \simeq \theta/n(1-\theta)^n$ tends to θ at low surface coverages ($1 \gg \theta$). $\Delta\bar{G}_H$ and $\Delta\bar{G}_S$ are the standard free energies of adsorption of solute H and solvent S and n is the number of solvent molecules necessary to occupy the same surface area as the absorbed species H (here the anion–cation pair).

In aqueous Et_4NBr solutions we have already noted no significant charge dependence for the contact adsorbed anion or cation. It is therefore significant that in deuterated solutions the absorption of Br^- also is not favored over that of Et_4N^+ or vice versa. If only cations were contact adsorbed at $\sigma^M < 0$ and only anions contact adsorbed at $\sigma^M > 0$ then the solute–solvent interactions should show a strong charge dependence. As is obvious from Figs. 1 and 2 γ_{tr} varies in a monotone fashion. It thus follows, as indicated in Fig. 3*A* for intermediate positive σ^M values, that the number of anion–cation or solute–electrode interactions does not vary significantly from those found at intermediate negative σ^M values (Fig. 3*C*). We would further conclude that the interfacial properties of equimolar or constant mole fraction deuterated and aqueous solutions are very similar. With the possible exceptions of the quaternary ammonium salts of very hydrophillic anions they almost lie within the experimental limits (± 0.1 mJ m^{-2}) of present measuring techniques. The differential data acquisition via the transfer functions aids considerably in the interpretation but does not encourage us to undertake a major project on solvents as similar as H_2O and D_2O.

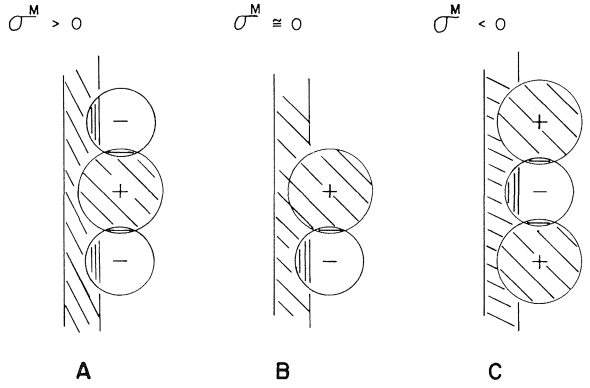

FIG. 3. Model of the structure of the electrode/electrolyte region for Et_4NBr electrolytes. (*A*) $\sigma^M > 0$, (*B*) $\sigma^M \sim 0$, (*C*) $\sigma^M < 0$.

According to eq. [12] or equivalent expressions it is to be expected that a difference in the free energy of adsorption of two solvents $\Delta\bar{G}_S$ results in difference of surface coverage or a $\Gamma_{H,tr}$ value proportional to the solute concentration. Such is not the case here. The concentration and charge independence of $\Gamma_{H,tr}$ could arise if $\Delta\bar{G}_H$ or $\Delta\bar{G}_S$ or both depend on the number of solute–solvent interactions and thus the surface coverage and solute concentration.

A part of the hydration structure, the electrode and a part of the hydration shell of the ions are detroyed or highly modified. In D_2O solutions for all values of σ^M (Fig. 3), a somewhat greater gain in free energy seems to result when water molecules in the interfacial region are returned to the bulk solution. As the solute concentration increases, the bulk structure differs less and less from that of the interfacial region and γ_{tr} and Γ_{tr} tend towards zero.

1 **2**

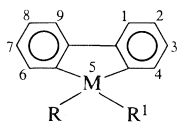
positions ioniques. Il est particulièrement intéressant de noter, au cours de la fragmentation, la migration des atomes de fluor des cycles, vers l'atome central. On discute des principes de liaisons impliquées dans les intermédiaires postulés.

[Traduit par le journal]

Introduction

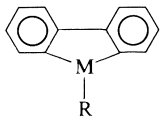
Compounds of the general structure (**3**) are known for a variety of main group elements (1–10) and a number of transition metals (11–13).



3

Nomenclature is based on the corresponding dibenzophospholes (M = P) or dibenzometalloles (M = metal, e.g., titanole for M = Ti). All the compounds referred to in this paper are of the perfluorinated moieties, i.e., 1,2,3,4,6,7,8,9-octafluorodibenzo species.

To the present time there has only been one detailed mass spectral study of these compounds. Hellwinkel *et al.* (14) reported the mass spectra of the Group VA derivatives with the structure **4**.



M = P, As, Sb, Bi
R = CH_3, C_6H_5, 2-$C_{12}H_9$

4

The basic trend was a decrease in molecular ion abundance as the size of the central atom increased. Along these same lines, an increase in the net abundance of hydrocarbon ions was noted. There was also evidence for proton abstraction by the

0008-4042/79/030335-07$01.00/0

central atom, a tendency which increased with atomic size.

Interest in the mass spectra of phospholes has been influenced by studies (15, 16) in the aromaticity of these compounds as compared to the related pyrroles and carbazoles. Mass spectral evidence is in support of at least partial aromatic character while other chemical and spectroscopic evidence is contradictory. It is therefore of interest to compare the behaviour of such phosphorus heterocycles to the triaryl phosphines with regard to the stability of related P-containing fragments.

Little data are currently available on the mass spectral fragmentation of perfluorinated metalloles, the only reported results being simple molecular weight determinations, except for our earlier work on perfluoroaromatic heterocyclic derivatives of Group IV (17*a*) of the type $(C_{12}F_8)_2M$. These heterocyclic complexes have provided some interesting additions to previous studies of perfluoroaromatics with regard to fluorine abstraction processes.

Experimental

The transition metal derivatives were prepared by Gardner *et al.* (13). The phospholes were prepared using the method of Chambers and Spring (7*b*). The 5-phenyl derivative has been prepared previously. 5-*tert*-Butyloctafluorodibenzophosphole and 5-pentafluorophenyloctafluorodibenzophosphole were synthesized in a similar manner, and isolated in yields of 68% and 5%, respectively. See Table 1 for elemental analysis.

Mass spectra were recorded on an AEI-MS30 double beam mass spectrometer at 70 eV with a 4 kV accelerating voltage, resolution 1000, and a source temperature of 180°C. Samples were admitted to beam I using the direct probe and concentric sample cups. High boiling PFK was admitted in beam II via a gas liquid probe to serve as a chemical mass marker, simultaneously recorded but not interfering with the spectrum under study. Metastable transitions were assigned with the aid of a Fortran computer program BMETAST, while isotopic patterns were calculated and overlapping species deconvoluted using the Fortran programs BMASROS and BMASABD, respectively.

All intensities are reported as a percentage of the total positive ion current and polyisotopic species have been summed over all isotopic contributions.

Transition Metal Derivatives

The partial mass spectra of these compounds are summarised in Table 2. A general metastable ion supported fragmentation scheme is given for the Group VIII complexes in Scheme 1 and for the titanole in Scheme 2 although metastable ions were not abundant for the titanole.

(*i*) The Group VIII metalloles all exhibit relatively strong parent ions, that of the rhodole being of lower abundance than either the cobaltole or iridole. A significant trend develops for the ion resulting from loss of carbonyl. As the size of the metal atom increases the abundance of this ion also increases. This pattern is probably a reflection of the increased polarizability and 'soft' character associated with the larger atoms.

When one considers the overall fragmentation, it is the rhodole which exhibits an inconsistent behaviour. The iridole gives rise to a large variety of iridium-containing ions resulting from sequential F and HF losses from the (M—CO) ion. A similar pattern is observed for the cobaltole although the abundance of the resulting ions is much lower. These ions are almost completely absent from the rhodole spectrum as one can see from the abundance of the species listed as $C_xF_yH_zM$ where Ir > Co > Rh.

This 'different' rhodole behaviour is consistent with other parameters determined for these com-

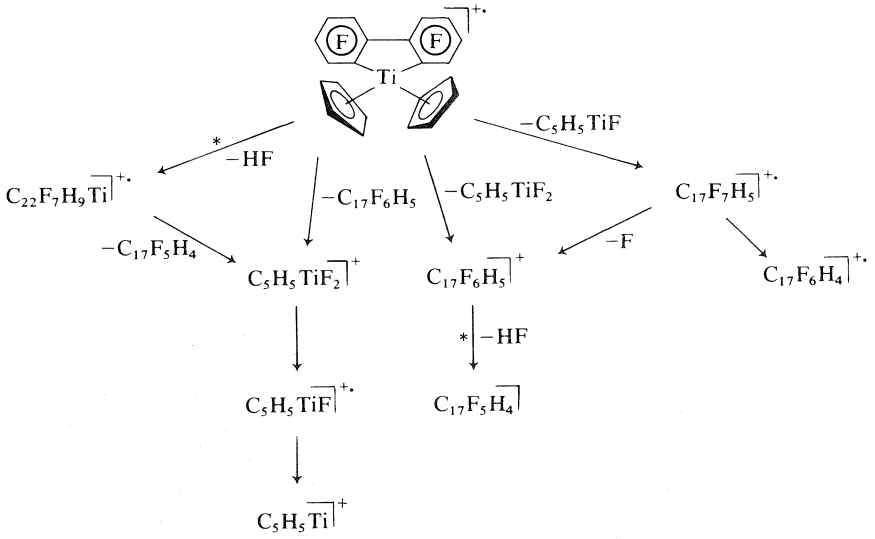
pounds by Rausch and co-workers (13). They found the rhodole exhibits a ν(CO) at higher frequency than either the cobalt or iridium derivative. The proton shifts for the cyclopentadienyl ring also indicated a decreased shielding in the rhodole with respect to either the cobaltole or iridole. This seems to suggest a preference for π-bonded ligands by rhodium with the cobalt and iridium showing progressively lower tendencies for such behaviour. Indeed, the abundance of the $C_5H_5M^+$ species adds further weight to this argument where M = Rh > Co ≫ Ir.

There is no metastable ion evidence for fluorine abstraction rearrangements by the central atom during fragmentation nor any MF^+ ions, and yet the formation of many of the coupled fragments such as $C_{17}F_7H_5^{+\cdot}$, $C_{17}F_6H_5^+$, etc. may have arisen by a neutral metal-fluoride elimination as has been observed in many other cases (17–30).

(*ii*) 5,5-Bis(η-cyclopentadienyl)-1,2,3,4,6,7,8,9-octafluorodibenzotitanole. The partial mass spectrum of this compound, shown in Table 2, reveals a significant difference in its fragmentation as compared to the Group VIII complexes. Most notable is the presence of the ions $C_5H_5TiF_2^+$ and $C_5H_5TiF^{+\cdot}$ which must arise by fluorine abstraction from the octafluorodibenzo substituent. Though no metastable ion sup-



SCHEME 2

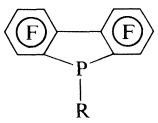
port is available, the formation of these ions should involve residues as were observed for the Group VIII compounds, i.e., $C_{17}F_7H_5^+$, $C_{17}F_6H_5^+$, etc.

The behaviour of the parent molecular ion for the titanole is quite different from the Group VIII complexes. The π-bonded cyclopentadienyl does not cleave readily to give a species similar to the (M—CO) fragment observed for the cobaltole, rhodole, and iridole. A $C_{12}F_8Ti(C_5H_5)$ fragment is detected in the spectrum, but at very low abundance. The titanole exhibits preferential loss of HF to give an intense ion formulated as $C_{22}F_7H_9Ti^{+\bullet}$. Such a species could have formed only via an interaction between the cyclopentadienyl and dibenzo substituents, which would seem to indicate the possibility of bond-forming rearrangements between the substituents, a fact which has been well-documented in many cases (17–23). Though somewhat speculative, this type of breakdown process helps to account for the formation of many of the fragments, especially $C_5H_5TiF_n$ (n = 1, 2) and $C_{19}F_xH_5$ (x = 6, 7), for which there is no metastable evidence.

There was little evidence for straightforward Ti—C cleavage of the heterocyclic system to form the titanocene ion. The latter was detected (*m/e* 178) in very low abundance (~0.08%). Alt and Rausch (31) reported the photochemical cleavage of dimethyl titanocene, zirconocene, and hafnocene. In all cases the methyl groups underwent homolytic cleavage giving rise to methane and a metallocene-type product. Since we do not observe an analogous Ti—C bond cleavage in the case of the titanole which would have resulted in the formation of either $(C_5H_5)_2Ti^+$ or $C_{12}F_8^+$ ions, there must be other stabilizing factors in this system. These may involve Ti-*d*-orbital interaction with the octafluorodibenzo π-system, an increase in ionic resonance energy of the fluorinated titanole, or other factors resulting in an enhanced stabilization (32, 33) (this is supported by the strong parent and parent–HF species observed in the spectrum).

Phosphole Derivatives

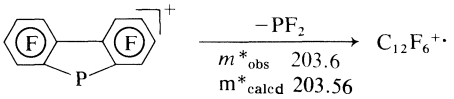
All of these compounds have the structure given below (**7**).



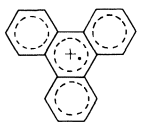
7, R = *t*-C_4H_9, C_6H_5, C_6F_5

The partial mass spectra of these phospholes is given in Table 3 and a general fragmentation scheme is also presented (Scheme 3).

The spectrum of the *tert*-butyl analogue is dominated largely by the stability of the *tert*-butyl cation. As a result, cleavage of the P—C alkyl bond is the major fragmentation mode leaving only a small number of ions of any interest. Despite this, there is still evidence for the operation of fluorine and proton abstraction processes. Proton abstraction from an alkyl substituent is a well-characterized process in the mass spectra of phosphorus compounds (34, 35) and it is seen in the expulsion of butene from the parent ion. The lone example of fluorine abstraction is also common to a number of perfluoroaromatic phosphorus compounds (18, 23).



The 5-phenyl- and 5-pentafluorophenyloctafluorodibenzophospholes give rise to a large variety of fluoroaromatic fragments, many of which result from PF_n losses (n = 1, 2, 3). The most obvious of these species are the C_{18} fluoroaromatics which have been detected in a number of other systems including compounds of phosphorus (17–23). These probably have the triphenylene structure indicated below and are a good indication that PF, PF_2, and PF_3 or PHF_2 losses are being experienced by the parent ion. Such transitions can be rationalized in terms of intermediate species which may or may not involve higher coordination by phosphorus.



$C_{18}F_{12}$ or $C_{18}F_8H_4$ structure

The influence of the substituent R on parent ion stability is well illustrated in Table 3, reflecting the resonance stabilization for C_6H_5— and C_6F_5— versus the less effective inductive stabilization afforded by the *tert*-butyl group. There seems to be no indication of increased stabilization of the parent through participation of phosphorus in an aromatic π-system. If we compare the 5-phenyl and 5-pentafluorophenyl derivatives with their 'open' analogues, bis(pentafluorophenyl)phenylphosphine and tris(pentafluorophenyl)phosphine, one can see that any conclusions based on dibenzophosphole aromaticity (in particular, increased parent ion stability) are ambiguous (Table 4).

The mass spectrum of 5-phenyloctafluorodibenzophosphole-5-oxide is inconsistent with that of trispentafluorophenylphosphine oxide which only reluctantly shows loss of oxygen (17*b*). The partial mass spectrum, as given in Table 5, indicates a surprisingly large abundance for loss of oxygen, suggesting a

strong resonance stability of phosphorus capable of compensating for cleavage of the normally strong phosphorus–oxygen bond. However, the second most abundant species in the spectrum is $C_{18}F_8H_5^+$ which results from expulsion of a PO fragment from the parent ion. This latter behaviour suggests that there could be little, if any, special stabilization of phosphorus in the ring system of the parent species. The fact that P—O cleavage is highly restricted in the fragmentation of many other phosphorus compounds (23, 34, 35) while easily lost in this case is not readily explained.

The anomalous behaviour of the phosphole oxide is not a result of thermal decomposition since it is quite volatile at source temperatures (180°C) below its melting point (189–190°C) (*7b*), using an unheated direct probe.

Summary

We have described previously a large number of cases of rearrangement involving fluorine transfer to the central atom in the mass spectra of perfluoroaromatic compounds, and have attributed this to the possibility of intermediate formation involving expanded co-ordination about a central atom with empty, available *p*- or *d*-orbitals capable of accepting fluorine *p*-electron density. Because the metalloles described in this report already had π-donor ligands (η-C_5H_5) it is highly unlikely that fluorine abstraction could proceed via π-bonded fluoroaromatic intermediates in consideration of the present concepts of bonding orbitals in these systems (36) and the resultant steric restrictions.

Though the mass spectra of the cobalt, rhodium, and iridium compounds give no direct evidence for fluorine transfer, many of the fragmentation products indicate possible neutral atom fluorine losses (see Scheme 1). The titanole, with its greater availability of empty frontier orbitals, shows ample evidence for the operation of fluorine abstraction processes. Since the titanium atom represents a d^0 configuration, one would predict a more favourable situation for overlap and subsequent rearrangement involving empty $(\eta\text{-}C_5H_5)_2Ti$ frontier orbitals than could be attained in the Group VIII complexes where cobalt, rhodium, and iridium have a d^6 configuration.

The obvious presence of suitable orbitals on phosphorus creates a situation where halogen transfer should be facile. This, combined with the fact that phosphorus can expand its co-ordination sphere to accommodate up to six ligands, can rationalize elimination of neutral PF, PF_2, and PF_3 species.

There is no convincing mass spectral evidence for delocalization of the phosphorus lone pair in the dibenzophosphole system, although some results can be explained only in terms of an increased stability of phosphorus in such heterocyclic systems.

The general behaviour for the phosphorus and titanium heterocycles is reminiscent of the Group IV compounds described earlier (*17a*). These all showed loss of MF_n (n = 1–4) species rather than expulsion of the metal atom and as a result gave rise to a variety of tetra-, tri-, and biphenylene species. A further example of comparable behaviour, which is common to the Group VIII metalloles as well, involves the consecutive losses of HF or F· from the basic heterocyclic species[1] to give a whole series of metal containing ions, again in preference to expulsion of the central atom.

In light of these considerations it is reasonable to suggest the operation of mechanisms involving expanded co-ordination about the central atom which is consistent with the rearrangement ions described previously for the Group IV compounds (*17a*).

The quenching of triplet acetone in degassed acetonitrile solution by electron-rich and electron-deficient olefins has been measured by flash emission technique. With the exception of fumaronitrile, the efficiency of quenching of triplet ketones by olefins is not determined by the triplet energy of the ketone, but by the ability of the excited ketone to donate or accept electrons. The results are consistent with the assumption that back dissociation of the triplet exciplex is an important process in the overall reaction and accounts for quenching rate constants which are less than those for diffusion-controlled reactions. Lifetimes and binding energies of the triplet exciplexes have been estimated.

RAFIK O. LOUTFY, S. K. DOGRA et R. W. YIP. Can. J. Chem. **57**, 342 (1979).

Faisant appel à la technique de l'émission éclair, on a mesuré le piégeage de l'acétone à l'état triplet, en solution dans de l'acétone dégazée, par des oléfines riches et déficitaires en électrons. A l'exception du furamonitrile, l'efficacité du piégeage de cétones à l'état triplet par des oléfines n'est pas déterminée par l'énergie triplet de l'acétone mais plutôt par la capacité de la cétone excitée à donner ou à accepter des électrons. Les résultats sont en accord avec l'hypothèse que la redissociation de l'exciplex triplet est un processus important de la réaction globale et qu'il tient compte des constantes de vitesse de piégeage qui sont plus faibles que celles de réactions contrôlées par diffusion. On a évalué les temps de vie et les énergies de liaison des exciplex triplets.

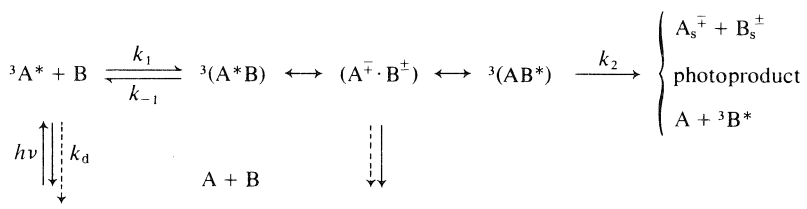
Introduction

The interaction of electronically excited ketone triplet states with ground state amines (1), olefins (2), aromatic and aliphatic hydrocarbons (3) in a process not involving electronic energy transfer has attracted considerable interest in the past decade. Consequences of such interaction are enhanced radiationless decay, chemical reactions, and electron transfer resulting in ion formation. These processes can be represented by the following general scheme.



The interaction between triplet ketones and (electron-rich) olefins proceeds via a complex (exciplex) with weak charge-transfer character (2*a*, 2*c*) in which the ketone acts as an acceptor. In the case of triplet benzophenone interacting with 2-butene and isobutylene, isotopic and kinetic results suggest that the complexes are formed irreversibly (2*c*, 3*d*). Whether the conclusion applies to other or all triplet exciplexes has not yet been established. With electron-deficient olefins, such as chloroethylenes, the major quenching process has been suggested to be triplet energy transfer (2*a*, 2*c*) rather than charge transfer from ketone to the electron-deficient quencher, such as has been postulated to account for the quenching of ketones by substituted benzenes (3*b*). Thus, in terms of the above scheme, k_{-1} is considered to be negligible, as is the con-

tribution of A^+B^- and the formation of $A + {}^3B^*$ via an exciplex. At present, owing to the absence of reported exciplex phosphorescence in solution, no information is available on the binding energy or lifetime of ketone–olefin triplet exciplexes.

We report here the results of the quenching of triplet acetone by olefins which are pertinent to the question of involvement of charge transfer complexation in the quenching of electron-deficient olefins, and the reversibility of ketone–olefin exciplex formation. In addition, we put forward calculations to provide a semi-quantitative estimation of the binding energies and lifetimes of ketone–olefin exciplexes.

Results and Discussion

The luminescent decay of triplet acetone in degassed acetonitrile solutions was measured by flash emission technique described earlier (4). The rate constants for quenching triplet acetone by a series of substituted olefins and the relevant values for quenching triplet butyrophenone (2*b*) and benzophenone (2*c*) are recorded in Table 1. Table 2 lists the dependence on temperature and the rate constants for quenching of triplet acetone by norbornene.

Quenching of triplet acetone by the formation of an intermediate π-type complex (exciplex) with partial charge transfer from electron-rich quenchers (1-ethoxy-1-butene and alkyl substituted olefins) is indicated by (*1*) the high rate constants, (*2*) the good correlation of log k_q with $IP_{quencher}$, and (*3*), the value of the slope of the plot of log k_q vs. $IP_{quencher}$ relative to that for a full electron-transfer reaction (5). The value of the slope, -0.072 kcal^{-1} mol (1.7 eV^{-1}), is ~10% of that for full electron transfer ($(2.303RT)^{-1} = 0.74$ kcal^{-1} mol (17 eV^{-1})) (5), and is in excellent agreement with the values reported by Schore and Turro (2*d*) for the quenching of singlet and triplet acetone by alkoxyethylenes.

273	3.63
291	3.87
297	4.16

[a]Determined from three points; errors estimated to be ±10%.

In a previous study on the quenching of triplet butyrophenone by chloroethylenes, Kochevar and Wagner (2*a*) observed that triplet butyrophenone (E_T 74.5 kcal mol^{-1}) was more rapidly quenched by *cis*-dichloroethylene than was triplet benzophenone (E_T 68.5 kcal mol^{-1}), and that the rate of triplet quenching by *cis*-dichloroethylene (IP 9.66 eV) was significantly higher than that by the alkylethylenes (IP ≤ 9.11 eV). On the basis of these results, it was concluded that energy transfer was the major quenching process, since both charge transfer complexing and radical addition would be slowed by

TABLE 3. Dependence of quenching rate constant on ($E_{1/2}^{ox} - E_T$) of ketone and $E_{1/2}^{red}$ of chloroethylenes

Ketone	E_T[a] (eV)	$E_{1/2}^{ox}$ (V)	$E_{1/2}^{ox} - E_T$ (eV)	$k_q \times 10^{-7}$ (M^{-1} s^{-1}) $Cl_2C{=}CCl_2$ (1.38)[b,c]	$Cl_2C{=}CHCl$ (1.64)[b,c]	*trans*-ClCH=CHCl (1.90)[b,c]

[e]Rate constants, ref. 3*d*.

increasing chloro substitution (2*a*). A similar conclusion was reached for the quenching of triplet benzophenone by dichloroethylene (2*c*). In the present work, the rate constants obtained for the quenching of triplet acetone (E_T 76 kcal mol^{-1}) by the chloroethylenes (Table 1) are lower than that for butyrophenone. These results are clearly incompatible with a triplet energy transfer mechanism. We believe that the quenching of triplet ketones by the chloroethylenes is best explained by means of a complex with charge transfer character in which the direction of electron transfer is opposite that for the electron-rich olefins: i.e., in which the ketone is the donor and the chloroethylene is the acceptor.

The consideration of CT interaction obviously necessitates that the direction of transfer be determined. Based on arguments used previously to determine the relative energies of two possible donor–acceptor pairs (3*b*), we have as a condition for the pair with the lowest energy, in solution, the inequality,

$$(E^{ox} + E^{red})_{acceptor} > (E^{ox} + E^{red})_{donor}$$

Calculations based on the above inequality using the data recorded in Tables 1 and 3 show that the donor–acceptor pair with the lowest energy is that in which acetone is the donor and the chloroethylene is the acceptor. The conclusion that A^+B^- is important in the description of the exciplex formed between acetone (A) and the chloroethylene (B) provides a rationale for two features exhibited by the quenching results: (*1*) the absence of a correlation between log k_q and IP of the chloroethylenes, and (*2*) the correlation of log k_q with reduction potentials of the chloroethylenes (2*e*). The importance of 'reverse' electron transfer in the quenching of triplet ketones by the chloroethylenes is further emphasized by the correlation between log k_q and the excited ketone electron donating ability ($E^{ox} - E_T$) rather than with ketone triplet energy (see Table 2). For two triplet ketones, the relative magnitude of the rate constants for quenching by a given chloroethylene is

$$\frac{k_{q_1}}{k_{q_2}} = \frac{\exp -(E_{1/2}^{ox} - E_T)_1/RT}{\exp -(E_{1/2}^{ox} - E_T)_2/RT}$$

For example, the calculated value for acetone and butyrophenone is $k_{q(acetone)}/k_{q(butyrophenone)} = 0.46$ which falls within the experimental values of 0.45–0.58.

The rapid quenching of ketone triplets by fumaronitrile can be attributed to direct energy transfer. Consistent with this conclusion, k_q decreases from acetone to benzophenone, that is, with decreasing ketone triplet energy.

The quenching rate constants of triplet ketones by olefins are slower than those of diffusion-controlled processes. This could be due to the occurrence of reversible exciplex formation. In the case of α-cyanonaphthalene–olefin exciplexes, Ware *et al.* (6) have shown that reversible exciplex formation can lead to an observed quenching rate constant, k_q, significantly slower than the rate of exciplex formation, k_1.

In terms of the reaction scheme which we have put forward, the question is how important is k_{-1} relative to k_2. The experimental quenching rate constant k_q is given by

$$[1] \qquad k_q = \frac{k_1 k_2}{k_{-1} + k_2}$$

and therefore the experimental activation energy can be expressed in terms of the activation energies corresponding to k_{-1}, k_1, and k_2. In the event that $k_{-1} \geq k_2$, the presence of the term $-\Delta H_C$ (where ΔH_C is the binding energy of the complex) will tend to give a lower experimental activation energy than if it were absent. This is most readily seen in the case of $k_{-1} \gg k_2$, and $k_q = (k_1/k_{-1})k_2 = K_c k_2$ where $K_c = k_1/k_{-1}$. We have $E_q = -\Delta H_C + E_2$. In the extreme, where $\Delta H_C > E_2$, the observed activation energy, E_q, can even be negative (3*c*, 7, 8). There is one other case to be considered, that is the situation

[c] Calculated from eq. [2*a*].
[d] The triplet exciplex energy calculated according to $E_{EX} = b^2E_{CT}{}^0 + (1 - b^2)E_T$, where $b^2 = 0.1$.
[e] The free energy change for exciplex formation = $E_{EX} - E_T$.
[f] $K = \exp(-G^0/RT)$.

where $k_2 \gg k_{-1}$, and $k_q = k_1 < k_D$, where k_D is the diffusion-controlled rate constant. In this case, $E_q \geq E_D$ (~2–4 kcal mol^{-1} (9)) unless the Arrhenius factor associated with k_1 is low. The activation energy which we have obtained from the temperature-dependent quenching of triplet acetone by norbornene is 0.8 kcal mol^{-1}. In this instance, back dissociation of the exciplex is probably an important process.

For full charge transfer involving the reaction of an excited molecule, the free energy for the reaction is given by (5)

$$[2] \qquad \Delta G^0 = E_{CT}{}^0 - E^* \qquad \text{where}$$

$$[2a] \qquad E_{CT}{}^0 = E_D{}^{ox} - E_A{}^{red} - e^2/\varepsilon r$$

E^* is the excited (triplet) state energy, and ε is the dielectric constant of the solvent. The solvation energy of the CT complex is small compared with the terms in eq. [2*a*] (or implicit in eq. [2*a*]), and has been neglected. In acetonitrile (ε = 36), the term $e^2/\varepsilon r$ assumes a value of 0.1 eV for r = 3.4 Å. Although the value of $e^2/\varepsilon r$ changes with the ε of the solvent, this change is offset by an equal change in the values of E^{ox} and E^{red} with the ε of the solvent. In essence, this means that the total coulomb energy comprised of the 'mutual solvation energy' $e^2/\varepsilon r$ (that is, the coulomb energy arising from A^- and D^+ separated by a slab of dielectric, ε, at a distance r), and the solvation energies of D^+ and A^- (incorporated in E^{ox} and E^{red}) is constant. In a high dielectric solvent such as water, the coulomb energy between D^+ and A^- is negligibly small compared with the solvation energies of the ions D^+ and A^- in water. The converse applies in the case of a low dielectric constant solvent.

Similarly, the ΔG^0 for exciplex formation, in which partial charge transfer is involved, is given by

$$[3] \qquad \Delta G^0 = b^2(E_{CT}{}^0 - E^*)$$

where b^2 is the fraction of the electron transferred from donor to acceptor molecule, and can be obtained from the slope of log k_q vs. IP of the donor (2*d*, 3*d*). Values of b^2, ΔG^0, ΔH, and K are listed in Tables 4 and 5. The enthalpy of formation of the exciplex, ΔH ($\Delta H = \Delta G^0 + T\Delta S$) was calculated taking $\Delta S = -18.2$ eu (5*b*).

Triplet exciplex lifetimes and binding energies can be deduced from the quenching data if a number of assumptions are made. One of these is the assumption that exciplex reversal is important.

Since the values of ΔG^0 listed in Table 6 are all positive, with the exception of quenching with 1-ethoxy-1-butane, it is expected that the rate of exciplex reversal, k_{-1}, will be large. Assuming that $k_{-1} \gg k_2$, k_q reduces to

$$[4] \qquad k_q = (k_1/k_{-1})k_2 = Kk_2$$

The equilibrium constant K can be calculated from the free energy change for exciplex formation. Knowing K, we can calculate k_2 from the measured values of k_q using eq. [4].

To obtain the rate constant for exciplex reversal, k_{-1}, the rate constant for exciplex formation (k_1) is calculated and then substituted into the equation $k_1/k_{-1} = K$. The rate constant for exciplex formation can be written as

$$[5] \qquad k_1 = A_1 \exp(-\Delta G^{\ddagger}/RT)$$

where A_1 ($\sim 10^{11}\ M^{-1}\ s^{-1}$) (10) is the collision frequency between neutral molecules in solution. For reactions between unchanged species, the free energy of activation, $\Delta G^{\ddagger}$, for outer-sphere electron transfer can be expressed in terms of the standard free energy of the reaction, ΔG^0, according to (10)

$$[6] \qquad \Delta G^{\ddagger} = \frac{\lambda}{4}\left(1 + \frac{\Delta G^0}{\lambda}\right)^2$$

where λ is the solvent reorganization energy. For weak complexes with only partial charge transfer, the solvent reorganization parameter can be estimated to be 7.5 kcal/mol from the equation (11):

$$[7] \qquad \lambda = \frac{e^2}{2a}\left(\frac{1}{\varepsilon_o} - \frac{1}{\varepsilon_s}\right)$$

In eq. [7], e is the unit electron charge, $2a$ is the internuclear separation between the reactants, assumed to be 11 Å (11) for the acetone complexes, ε_o and ε_s are the optical and static dielectric constants of the solvent, respectively. The rates of exciplex formation, k_1, were calculated using eqs. [5] and [6], and found to approach the rate of diffusion-limited processes, while the rate of reversal, k_{-1}, were obtained from the ratio $k_1/k_{-1} = K$. Values of k_1, k_{-1}, and k_2 are recorded in Table 6. The values of k_{-1} are an order of magnitude greater than k_1 in most cases, in spite of the fact that ΔH is negative. This is due to the positive ΔS for the reversal. The values of k_1 and k_{-1} for the system are dependent on the accuracy of the term λ used in eq. [5], and A_1 used in eq. [6], and thus are by no means absolute. For example, in Fig. 1 plots of log k_1 against ΔG^0 correspond to (*a*), λ = 7.5 kcal/mol and (*b*), λ = 11.8 kcal/mol. A small change in λ had a significant effect on the calculated rate constant k_1. Nonetheless, the results allow us to estimate that the triplet exciplex lifetimes $\tau_{EX} = 1/(k_{-1} + k_2)$ is less than a nanosecond, in most cases. The extremely short exciplex lifetime is consistent with the lack of emission from these complexes. Similar analysis could be carried out for triplet ketones quenching by electron-deficient olefins.

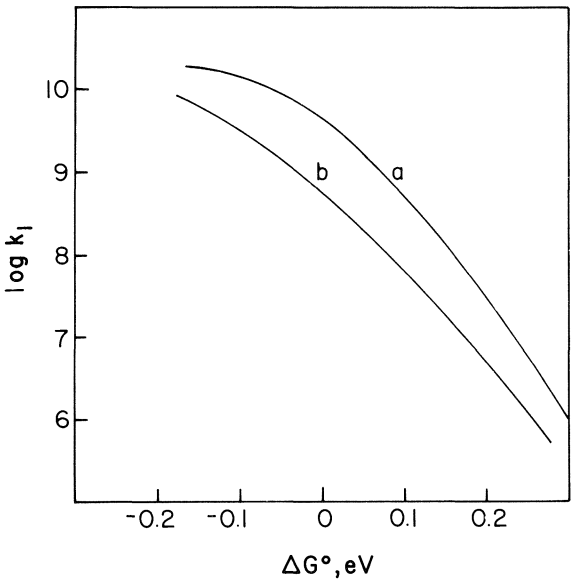

FIG. 1. Plot of log k_1 against ΔG^0; $Z = 10^{11}\ M^{-1}\ s^{-1}$. (*a*) λ = 7.5 kcal mol^{-1}, (*b*) λ = 11.8 kcal mol^{-1}.

TABLE 6. Calculated rate constants of: formation (k_1), reversal (k_{-1}), reaction (k_2), and lifetime for triplet acetone/olefin exciplexes

Quencher	$k_1(10^8)$ ($M^{-1}\ s^{-1}$)	$k_{-1}(10^9)$ (s^{-1})	$k_2(10^7)$ (s^{-1})	τ_{EX} (ns)
1-Ethoxy-1-butene	85.7	2.08	2.67	0.47
2,3-Dimethyl-2-butene	43.8	4.47	5.23	0.22
2-Methyl-2-butene	16.3	10.2	17.55	0.1

Cyclopentene	6.26	18.4	55.96	0.05
cis-2-Pentene	4.5	21.6	50.0	0.045

In summary, this study indicates that triplet acetone quenching by olefins involves the formation of a partial charge transfer complex or exciplex. With the exception of fumaronitrile, the efficiency of quenching of triplet ketones by olefins is not determined by the triplet energy of the ketone, but by the ability of the excited ketone to donate or accept electrons. The data are consistent with the assumption that back dissociation of the triplet exciplex is an important process in the overall reaction and accounts for quenching rate constants which are less than those for diffusion-controlled reactions. Life-

times and binding energies of the triplet exciplexes have been estimated.

Isomeric cyclic $[C_6H_{10}]^{+\cdot}$ ions. The energy barrier to ring opening

PEDER WOLKOFF AND JOHN L. HOLMES
Chemistry Department, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received August 21, 1978

PEDER WOLKOFF and JOHN L. HOLMES. Can. J. Chem. **57**, 348 (1979).

Appearance energies and metastable peak shapes for methyl loss from the molecular ions of cyclohexene, methylcyclopentenes, methylenecyclopentane, bicyclo[3.1.0]hexane, and 2-methyl-1,4-pentadiene indicate that they have a common reaction pathway which produces [cyclopentenium]$^+$ as the daughter ion at threshold.

From measurements of appearance energies and from relative peak abundances and kinetic energy releases for the metastable losses of $CH_3^\cdot$ and labelled methyl from the deuterium labelled cyclic $[C_6H_{10}]^{+\cdot}$ molecular ions it was concluded that: (*a*) H/D mixing in [cyclohexene]$^{+\cdot}$ occurs in the intact ring prior to a concerted methyl extrusion; (*b*) [methylcyclopentenes]$^{+\cdot}$ loses methyl without *any* H/D mixing at or near to threshold by a straight C—C cleavage, possibly via the 3-isomer. Methyl losses involving H/D mixing are preceded by ring opening which has an activation energy of ca. 1 eV. However, [cyclopentenium]$^{+\cdot}$ is again the daughter ion; (*c*) methylenecyclopentane and bicyclo[3.1.0]hexane molecular ions isomerize to methylcyclopentenes prior to methyl loss.

H/D mixing (prior to methyl loss) in the molecular ion 1,1-$^2H_2$-2-methyl-1,4-pentadiene takes place before cyclisation to methylcyclopentene.

PEDER WOLKOFF et JOHN L. HOLMES. Can. J. Chem. **57**, 348 (1979).

Les énergies d'apparition et les formes des pics métastables dus à la perte de méthyles par les ions moléculaires du cyclohexène, de méthylcyclopentènes, du méthylènecyclopentane, du bicyclo[3.1.0]hexane et du méthyl-2 pentadiène-1,4 indiquent qu'elles procèdent par un chemin réactionnel commun qui fournit le [cyclopentènium]$^+$ comme ion-fille au seuil.

A partir des mesures des énergies d'apparition, des abondances relatives des pics et des énergies cinétiques émises lors des pertes de $CH_3^\cdot$ et de méthyles marqués provenant d'ions moléculaires $[C_6H_{10}]^{+\cdot}$ cycliques marqués au deutérium, on a conclu que: (*a*) le mélange H/D dans le [cyclohexène]$^{+\cdot}$ se produit dans le cycle intact avant l'expulsion concertée d'un groupe méthyle; (*b*) les [méthylcyclopentènes]$^{+\cdot}$ perdent un méthyle sans mélange H/D au niveau ou près du seuil par une rupture C—C simple possiblement par l'isomère-3. Des pertes de méthyles impliquant des mélanges H/D sont précédées par une ouverture de cycle accompagnée d'une énergie d'activation d'environ 1 eV. Toutefois le [cyclopenténium]$^{+\cdot}$ est à nouveau l'ion-fille; (*c*) les ions moléculaires du méthylène cyclopentane et du bicyclo[3.1.0]-hexane s'isomérisent en méthylcyclopentènes avant de perdre un méthyle.

Le mélange H/D (précédant une perte de méthyle) dans l'ion moléculaire $^2H_2$-1,1 méthyl-2 pentadiène-1,4 se produit avant la cyclisation en méthylcyclopentène.

Introduction

Eight years ago (1) it was written that "the mass spectra of the alkenes is one of the most obscure chapters of mass spectrometry". Since then the picture has become less obscure, largely due to the development of experimental methods for studying ion fragmentations in well defined time frames (2) (e.g. metastable ion studies (3) and field ionisation kinetics (4) (F.I.K.)) and the introduction of collisional activation (C.A.) (5) as a method for inducing ion fragmentation. These techniques, combined with isotopic labelling (6), have led to the identification of reacting configurations of fragmenting ions, daughter ion structures, and, in some cases, where good thermochemical data are available, to the identification of the neutral fragment's structure as well (7).

Experiments on isomers of the hydrocarbons C_3H_6 (8), C_4H_8 (9–12), C_5H_8 (13), C_5H_{10} (11, 14, 15), and C_6H_{12} (11, 14, 15) have employed the above methods and although much has been learned concerning possible mechanisms for the interconversion of isomers prior to fragmentation and daughter ion structures, the complete loss of positional identity of C and H atoms among molecular ions of lifetimes greater than about 10^{-9} s often makes it difficult to draw unequivocal conclusions.

In a recent study of the isomeric octenes (16), it was concluded that the molecular ions had isomerised to a common structure (or structures) in less than 10^{-9} s. However, at times shorter than 10^{-10} s, the decomposing molecular ions retained their structural integrity and decomposed by specific mechanisms.

A F.I.K. study (17) of methylcyclopentane-α-^{13}C revealed that on the picosecond time scale, loss of

0008-4042/79/030348-07$01.00/0

methyl involved only the labelled group. At longer times (10^{-6} s) loss of $CH_3^{\bullet}$ and C_2H_4 was preceded by ring opening and randomisation of C atoms. Levsen *et al.* (18) have also investigated the behavior of cyclo-alkane molecular ions. 3-, 4-, and 5-membered rings were shown to open within 10^{-9} s to yield the corresponding 1-alkene molecular ions. 6-, 7-, and 8-membered rings were, however, found to remain intact prior to fragmentation from the pico- to micro-second time frames.

Comparatively little work has been reported on the isomeric C_6H_{10} hydrocarbons, with the exception of cyclohexene. The latter was thoroughly investigated by Derrick *et al.* in a F.I.K. study (19) of 3,3,6,6-$^2H_4$-cyclohexene. The methyl loss was envisaged as a ring contraction leading to a methylenecyclopentane-like ion which readily lost $CH_3^{\bullet}$ yielding [cyclopentenium]$^+$. Rapid 1,3-allylic H atom shifts were proposed to take place around the cyclohexene ring, leading to the loss of positional identity of H atoms; this was found to begin within 10^{-11} s and was complete by 10^{-9} s. Ausloos and co-workers (20) studied some ion–molecule reactions of molecular ions of cyclohexene, and 1-, 3-, and 4-methylcyclopentene produced by 10 eV photons and explained their results on the basis that these molecular ions of low internal energy content did not undergo appreciable rearrangement. However, Levsen and Hilt (21) concluded from their study of the C.A. mass spectra of cyclohexene, 1-methylcyclopentene, 3-methyl-1,2-pentadiene, 2-methyl-2,3-pentadiene, and 1-hexyne that the non-fragmenting molecular ions of these isomers have partially isomerised (but to different extents) in the first μs after ionisation.

The thermochemistry of C_6H_{10} isomers has been investigated by Winters and Collins (22) and more recently by Lossing and Traeger (14). The latter authors conclusively showed that at threshold, the $[C_5H_7]^+$ daughter ion from cyclohexene has the [cyclopentenium]$^+$ structure; this they showed to be the most stable $[C_5H_7]^+$ ion, (ΔH_f = 199 kcal mol^{-1}) with [dimethylcyclopropenium]$^+$ as the probable nearest $[C_5H_7]^+$ isomer (ΔH_f(estimated) = 217 kcal mol^{-1}). The very low ΔH_f for [cyclopentenium]$^+$ makes methyl loss the fragmentation of lowest activation energy, and so can account for m/z = 67 being the base peak in the compiled mass spectra of almost all C_6H_{10} isomers (23).

In this paper we report an investigation of the energetics and metastable ion characteristics of deuterium labelled cyclohexene, the methylcyclopentenes, methylenecyclopentane, and bicyclo[3.1.0]-hexane. The aim of the present work was to re-examine the behaviors of these cyclic C_6H_{10} isomers with respect to their fragmentation of lowest energy requirement, namely the loss of $CH_3^{\bullet}$, in order to understand better the earlier conclusions of Derrick *et al.* (19) and Levsen and Hilt (21).

Results

(1) Thermochemistry and Kinetic Energy Release for Metastable Fragmentations

The heats of formation, ΔH_f, of the molecular ions of cyclohexene, 1- and 3-methylcyclopentene, methylenecyclopentane, bicyclo[3.1.0]hexane, and 2-methyl-1,4-pentadiene and their corresponding $[C_5H_7]^+$ (methyl radical loss) daughter ions are presented in Table 1. Ionization (IE) and appearance energies (AE) were measured for us by Lossing using energy selected electrons (14, 24). The kinetic energy releases measured from the half-height widths of the metastable peaks, ($T_{0.5}$) for the fragmentations taking place in the first field-free region of a Kratos AEI MS 902S Mass Spectrometer, are also given in Table 1. The ΔH_f values for the molecular ions show that 1-methylcyclopentene is the most stable species. (This is to be expected, cf. $[CH_3—CH{=}CH—CH_2CH_3]^{+\bullet}$, ΔH_f = 198 kcal mol^{-1} and $[CH_3CH{=}C(CH_3)_2]^{+\bullet}$, ΔH_f = 190 kcal mol^{-1}) (25). The daughter ions $[C_5H_7]^+$ all have ΔH_f values corresponding to the cyclopentenium cation, the most stable $[C_5H_7]^+$ ion. The slightly higher value for bicyclo[3.1.0]hexane could be ascribed to a kinetic shift. Within experimental error, the $T_{0.5}$ values are considered to be essentially the same for all compounds and indeed the normalized metastable peaks (which are of Gaussian shape) are almost superimposable. From these data it is concluded that the six isomers fragment via a common transition state to yield [cyclopentenium]$^+$ as daughter ion.

(2) Deuterium Labelling Experiments

The metastable peak abundances and $T_{0.5}$ values for the losses of $CH_3^{\bullet}$ and deuterated methyl radicals from variously labelled cyclic C_6H_{10} molecular ions are shown in Table 2.

1-Deuterio and 1,3,3-Trideuterio Cyclohexenes

The metastable peak abundances for these deuterated cyclohexenes are close but not equal to those for random statistical positional mixing of H and D prior to fragmentation. It is, however, noteworthy that the relative daughter ion abundances (i.e. for ions generated at short times (<0.1 μs) in the ion source from high energy molecular ions) are in the exact random statistical ratio. These metastable peak observations are in agreement with those of Derrick *et al.* (19) on 3,3,6,6-$^2H_4$-cyclohexene. These authors found, in a field ionization kinetics experiment, that

*Values in parentheses are for random distribution of H and D. $T_{0.5}$ values ± 1.0 meV or less, except where indicated.

on the picosecond time scale the $^2H_4$ molecular ion predominantly lost CD_2H.

The $T_{0.5}$ values (Table 2) for the various methyl radical losses are, within experimental error, the same as that for the unlabelled molecule. Furthermore, the AE values for *m/z* 67 and 68 from the monodeuterio species were the same, 10.30 and 10.32 ± 0.05 eV, respectively.

1-Trideuteriomethylcyclopentene

The metastable peak abundance ratios for the various methyl losses from this compound are clearly far from statistical (Table 2).

The major loss is $CD_3^\cdot$, 57% (random statistical proportion 0.8%), but the metastable peaks for the losses of $CH_3^\cdot$, $CH_2D^\cdot$, and $CD_2H^\cdot$ have relative abundances quite close to the random ratios. At a nominal ionising electron energy of 20 eV the metastable peak for $CD_3^\cdot$ loss comprises 71% of the methyl loss and for the ion-source generated daughter ions (normal mass spectrum) this proportion rises to 80%.

The kinetic energy releases ($T_{0.5}$) for the metastable peaks are substantially different. For $CD_3^\cdot$ loss the $T_{0.5}$ value (15.5 meV) is slightly lower than that for the unlabelled compound (17.2 meV) while the other methyl loss peaks have $T_{0.5}$ values about twice as large (31 meV). The appearance energies of the daughter ions *m/z* 67, 69, and 70 (corresponding to losses of $CD_3^\cdot$, $CH_2D^\cdot$, and $CH_3^\cdot$) were measured using energy selected electrons (24) and were found to be 10.27, 11.18, and 11.18 eV (all ±0.05 eV), respectively. Thus the apparent heats of formation of the daughter ions were 200, 223, and 223 kcal mol^{-1}, respectively. A measurement of AE *m/z* 68 was not attempted because of interference from the ^{13}C contribution from *m/z* 67.

1-Deuterio-3-methylcyclopentene and 2-Deuterio-4-methylcyclopentene

The metastable peak abundances for losses of $CH_3^\cdot$ and $CH_2D^\cdot$ from these two labelled molecular ions are significantly different and neither is close to the ratio for random loss (Table 2). The 3-methyl compound (methyl at allylic position) shows a greater relative loss of $CH_3^\cdot$ than the 4-methyl isomer. Loss of $CH_3^\cdot$:$CH_2D^\cdot$ from the former increases from 8:1 (metastable peaks) to 12:1 (daughter ions, normal mass spectrum) and for the latter from 4.3:1 to 7:1, respectively. The kinetic energy releases for these two compounds show a behavior very similar to that of the trideuteriomethyl analogue. The difference in appearance energies (AE *m/z* 68 − AE *m/z* 67) was not accurately measured with energy selected electrons but was estimated to be not less than 1.0 eV from the AE values for the metastable peaks (semi-log plots, MS 902S Mass Spectrometer). This is essentially in agreement with the observations on the trideuteriomethyl compound.

α,α-*Dideuteriomethylenecyclopentane*

The metastable peak characteristics for this compound are similar to those for 3-trideuteriomethylcyclopentene, with loss of $CHD_2^\cdot$ predominant and having a low $T_{0.5}$, and with $CH_2D^\cdot$ and $CH_3^\cdot$ losses having larger $T_{0.5}$ values and relative abundances close to the random ratio.

1,1-Dideuterio-2-methyl-1,4-pentadiene

Metastable loss of $CH_3^\cdot$ is the major process here and the overall results ($T_{0.5}$ values and relative abundances) show similar trends to those of the 5-membered ring isomers.

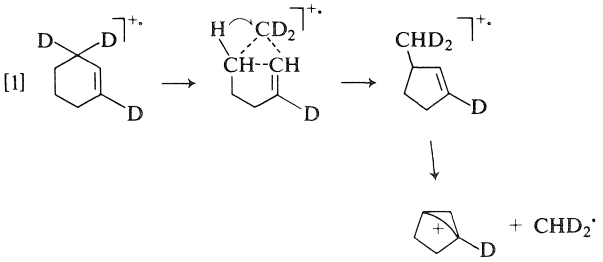
Discussion

Cyclohexene

We propose that prior to fragmentation at or close to the thermochemical threshold for methyl loss, the cyclohexene molecular ion *irreversibly* isomerises to that of a methylcyclopentene (possibly the 3-isomer). (The intermediacy of alkadiene molecular ions can be ruled out on energetic grounds (26).) The above rearrangement is unlikely to be reversible for the following reasons: (*a*) whereas loss of C_2H_4 generates an important peak at *m/z* 54 and also gives rise to an intense metastable peak in the mass spectrum of cyclohexene (via a retro-Diels Alder reaction), it is of negligible intensity in the mass spectra of 1- or 3-methylcyclopentenes; (*b*) direct cleavage of the methyl group from methyl substituted cyclopentenes, *without loss of positional identity of labelled atoms*, is clearly the predominant threshold process (Table 2).

The atom mixing observed in labelled cyclohexene molecular ions must therefore take place in the six-membered ring prior to the loss of a methyl group. This H/D atom mixing in labelled cyclohexenes has adequately been explained by Derrick *et al.* (19) who proposed a series of 1,3-allylic hydrogen atom shifts. The same authors found that at the shortest times investigated ($\sim 10^{-11}$ s) the major methyl loss from —3,3,6,6-$^2H_4$-cyclohexene was $CHD_2^\cdot$. Ring *opening* by breaking a vinylic C—C bond is an energetically unfavourable process (27) and so a concerted extrusion similar to that proposed by Derrick *et al.* (19) is illustrated below.

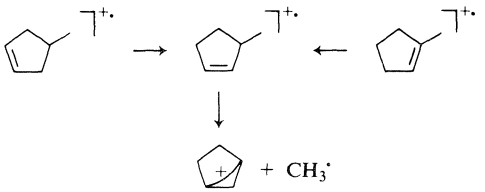
[1]



It is worthwhile to emphasize that neutral cyclohexene, under a variety of experimental conditions, readily isomerises to 1-methylcyclopentene (28).

Methylcyclopentenes

The AE and metastable peak measurements (Table 2) clearly demonstrate that at or near to threshold the methyl substituent is lost without any appreciable prior mixing of H/D between the ring and the methyl group. The results also indicate that 3-methylcyclopentene may well be the favoured reacting configuration, i.e. in which the methyl group occupies the allylic position.[1] This is seen by comparing the losses of $CH_3^{\cdot}$ from the monodeuterated 3- and 4-methylcyclopentenes with $CD_3^{\cdot}$ loss from the 1-trideuteriomethyl analogue (Table 2).



[2]

The methyl losses associated with the mixing of H/D have an AE 1.0 eV higher than that for the threshold methyl loss from the unlabelled molecule. However, these fragmentations are accompanied by a much larger kinetic energy release (31 meV) than that for the simple methyl cleavage reaction (15.5 meV). The apparent ΔH_f for the (labelled) $[C_5H_7]^+$ daughter ion, 223 kcal mol^{-1} is equal to that for the 3-vinylallyl cation (14), but the large kinetic energy release for that metastable decomposition leads us to suggest that this daughter ion is not being generated. We propose that the daughter ion is again [cyclopentenium]$^+$ and that the excess energy, 1.0 eV, represents that required to open the cyclopentene ring. The *acyclic* ion then undergoes rapid H/D randomisation and fragments to yield [cyclopentenium]$^+$ with the excess internal energy (required for ring opening) being partitioned into translational energy of the products. The only other feasible daughter ion (on thermochemical grounds) is the dimethylcyclopropenyl cation, whose ΔH_f has been estimated (14) to be $\sim$217 kcal mol^{-1}. We would argue that this is an improbable reaction product on the following grounds. We suggest that the partitioning of the excess internal energy of these various decomposing ions can adequately be evaluated for comparative purposes, by the semi-empirical equation of Haney and Franklin (29).

$$\varepsilon^{\ddagger} \simeq 0.44(3n - 6)T_{ave}$$

where $\varepsilon^{\ddagger}$ is the excess internal energy of a fragmenting ion available for partitioning among $(3n - 6)$ degrees of freedom (non-linear ion consisting of n atoms) and T_{ave} is the average translational energy acquired by the daughter ion. The average translational energies for the ions generated by the high and low AE methyl losses were evaluated from their respective kinetic energy release distributions obtained by analysis of the metastable peak shapes (30) and were 110 and 55 meV respectively. The difference in these values, 55 meV, substituted in the above equation yields the difference in average internal energies of the fragmenting metastable ions ($\Delta\varepsilon^{\ddagger} = 0.44 \times 42 \times 0.055 = 1.0$ eV) and is equal to the measured difference in AE values for the two processes. It is not possible specifically to identify the proposed ring-opened ion with any of the isomeric methylpentadiene or hexadiene molecular ions because (with the exception of 2-methyl-1,4-pentadiene) they all display different ΔH_f and $T_{0.5}$ values for $[C_5H_7]^+$ formation (26). The present results do not indicate whether the proposed ring closure takes place before or during the methyl radical loss.

Methylenecyclopentane and Bicyclo[3.1.0]hexane

The results shown in Table 2 indicate that the major loss of $CHD_2^{\cdot}$ from the molecular ion of the α,α-$^2H_2$ compound takes place from ionized (dideuteriomethyl)-cyclopentene, perhaps following a simple 1,3 hydrogen shift. This isomerisation also cannot be a reversible process, by analogy with the behavior of the methylcyclopentenes.

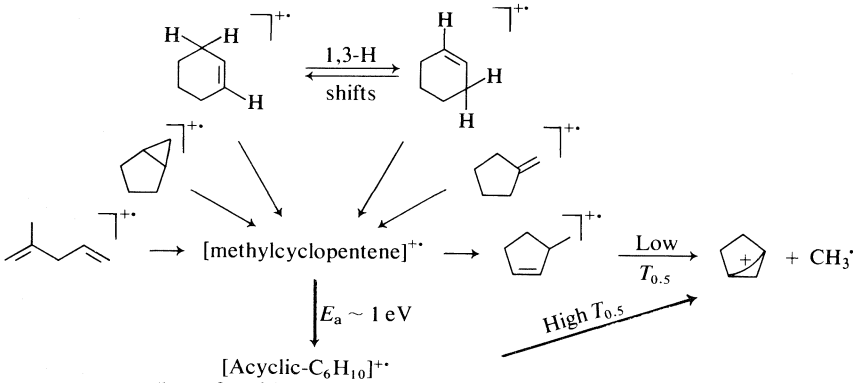
We propose that the bicyclic isomer also fragments via a methylcyclopentene molecular ion.[2]

2-Methyl-1,4-pentadiene

The daughter ion for loss of $CH_3^{\cdot}$ from the 1,1-$^2H_2$ compound clearly results in the main from the generation of [cyclopentenium]$^+$ (Tables 1 and 2). We propose that prior to this loss of methyl, ring closure to a methylcyclopentene molecular ion takes place rapidly (an exothermic reaction) without an activation energy. Molecular ions having greater than 1 eV excess internal energy (above the threshold for cyclopentenium plus methyl) do not ring close prior to methyl loss but yield cyclopentenium as daughter ion with positional randomisation of label atoms. These high energy ions decompose over the same potential surface as that for the ring opened cyclic molecular ions, hence the high T values for $CH_2D^{\cdot}$ and $CHD_2^{\cdot}$ losses. Nevertheless, there must be some positional mixing of H and D in the low energy process because the AE for m/z 67, 68, and 69 are the same (within experimental error) as that for $[C_5H_7]^+$ generated

[1]Methylenecyclopentane, 1-, 3-, and 4-methylcyclopentenes equilibrate in the presence of acidic alumina (250°C) to a mixture having proportions 1:80:13:6 respectively (37).

[2]Thermolysis of this compound yields 1-methylcyclopentene (38).



SCHEME 1

from the unlabelled molecule. A possible mechanism (which does not incorporate H/D mixing prior to ring closure) is shown below:

[3] 
The general behavior of acyclic C_6H_{10} molecular ions will be discussed in detail elsewhere (26).

Summary

The mechanistic conclusions drawn from the above results are shown in Scheme 1 which illustrates the processes leading to loss of $CH_3^{\bullet}$ from various $[C_6H_{10}]^{+\bullet}$ isomers. All fragmenting cyclic molecular ions of low internal energy lose methyl without ring opening and yield the cyclopentenium cation; H/D mixing in labelled cyclohexenes occurs prior to the extrusion reaction [1]. Methylcyclopentenes lose methyl from low internal energy molecular ions by direct cleavage *without* prior mixing of H/D between the ring and the methyl group. A second methyl loss process, having an AE ~1 eV above the minimum energy for methyl loss, leads to almost complete loss of positional identity among H/D atoms prior to this higher energy fragmentation. For this process it is suggested that ring opening imposes the energy barrier but the $[C_5H_7]^+$ daughter ion is again proposed to be the cyclopentenium cation.

The above energy requirement for ring opening may usefully be compared with that for cycloalkanes. The energy required to open a cycloalkane ring has been estimated to be 0.1 eV or less (14, 31). Levsen *et al.*, from a recent collisional activation study of cycloalkanes, agreed that the energy barrier to ring opening was certainly below the lowest decomposition threshold and could not exceed 0.1 eV. It should also be noted that many of the isomeric acyclic $[C_6H_{12}]^{+\bullet}$ ions have lower heats of formation (14) than [cyclohexane]$^{+\bullet}$ or [methylcyclopentane]$^{+\bullet}$, ring opening and rearrangement for the latter are then exothermic processes. In contrast, the methylcyclopentenes and cyclohexene molecular ions have lower ΔH_f values than almost all their acyclic isomers (14, 26), and so analogous rearrangements would be endothermic.

Experimental Section

Metastable peak measurements were performed on a Kratos AEI MS 902S mass spectrometer operating under conditions of good energy resolution, as described previously (8). Sample pressures were 3–5 × 10^{-7} Torr. Energy releases ($T_{0.5}$) values were calculated in the usual way (3) with appropriate corrections for the width of the main beam and overlapping contributions from (natural abundance) ^{13}C processes.

Unlabelled compounds were purchased from Chem. Samples Co., isomeric purity better than 99%. Bicyclo[3.1.0]-hexane was prepared by a Simmon–Smith reaction (32), and purified by glc.

All labelled compounds were purified by pglc, columns were either silver nitrate – ethylene glycol on Chromosorb PAW (60–80 mesh) (33) or 20% carbowax 20M on Chromosorb WAW (60–80 mesh); structures and position of deuterium were confirmed by 100 MHz ^1H nmr.

Cyclohexene-1-$^2H_1$ was prepared by reduction of cyclohexanone with $LiAlD_4$, followed by dehydration of the alcohol in hexamethylphosphoric triamide (34) (98% $^2H_1$).

Cyclohexene-1,3,3-$^2H_3$ was made similarly starting with cyclohexanone-2,2,4,4-$^2H_4$ (97% $^2H_3$ and 3% $^2H_2$).

3-Methylcyclopentene-1-$^2H_1$ and 4-methylcyclopentene-2-$^2H_1$ were prepared by reduction of 3-methylcyclopentanone, followed by dehydration of the alcohol (34) (98% $^2H_1$).

1-Trideuteriomethylcyclopentene was prepared according to Bailey and Hale (35) using CD_3MgI (> 96% $^2H_3$).

Methylenecyclopentane-α,α-$^2H_2$ was made by a Wittig reaction using Ph_3PCD_3I and butyl lithium (~41% $^2H_2$, 43% $^2H_1$).

2-Methyl-1-4-pentadiene-1,1-$^2H_2$ (36) was a gift from Professor R. G. Miller (96% $^2H_2$).

Acknowledgements

This work was supported by the National Research Council of Canada. One of us (P.W.) acknowledges the receipt of a travel grant from the Danish National Science Research Council. We are

grateful to Professor R. G. Miller for a donation of 2-methyl-1,4-pentadiene-1,1-$^2H_2$. We also thank Dr. D. Tong for the preparations of cyclohexene-1-$^2H_1$ and cyclohexene-1,3,3-$^2H_3$. We thank Dr. J. Krause for assistance with the metastable peak measurements.

Finally, we especially wish to acknowledge our gratitude to Dr. F. P. Lossing for providing us with the thermochemical measurements which were so vital to the successful completion of this study, and for many stimulating discussions.

Received July 28, 1978

TED SCHAEFER, WALTER NIEMCZURA, and WERNER DANCHURA. Can. J. Chem. **57**, 355 (1979).

We report the preparation and the analysis of the phenyl ring proton magnetic resonance spectra of 3,5-dichlorophenylcyclohexane and of the 2-(3,5-dichlorophenyl) derivatives of 1,3-dioxane, 1,3-dithiane, and 1,3-dioxolane. With the exception of the dioxolanes these compounds exist predominantly as the equatorial isomers. The *J* method is used to show that the phenyl moiety prefers the conformation in which the α C—H bond lies in the phenyl plane. The predominantly twofold barriers to rotation about the carbon–carbon bond between the two ring systems are 2.0 ± 0.3, 0.4 ± 0.2, 2.2 ± 0.3, 0.85 ± 0.3 kcal/mol for these compounds, in the order given above. The low value for the barrier in the 1,3-dioxane derivative agrees reasonably well with molecular mechanics calculations and with the results of calorimetric and X-ray studies on equatorial 2-phenyl-1,3-dioxane.

TED SCHAEFER, WALTER NIEMCZURA et WERNER DANCHURA. Can. J. Chem. **57**, 355 (1979).

On rapporte la préparation et l'analyse des spectres de résonance magnétique nucléaire des protons des noyaux phényles du dichloro-3,5 phénylcyclohexane et des dérivés (dichloro-3,5 phényl)-2 du dioxanne-1,3 du dithianne-1,3 et du dioxolanne-1,3. A l'exception des dioxolannes, ces composés existent préférentiellement sous la forme d'isomères équatoriaux. On a utilisé la méthode *J* pour montrer que la portion phényle préfère la conformation dans laquelle la liaison C—H α se trouve dans le plan du phényle. Les barrières, principalement binaires, à la rotation autour de la liaison carbone–carbone entre les deux systèmes cycliques sont de 2.0 ± 0.3, 0.4 ± 0.2, 2.2 ± 0.3 et 0.85 ± 0.3 kcal/mol pour ces composés dans l'ordre cité. La faible valeur pour la barrière, dans le dérivé dioxanne-1,3, est en bon accord avec des calculs de mécanique moléculaire et avec les résultats d'études calorimétriques et de diffraction de rayons-X sur le phényl-2 dioxanne-1,3 équatorial.

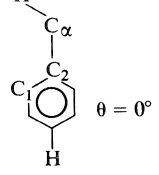
[Traduit par le journal]

Introduction

The free energy difference between axial and equatorial conformers has been tabulated for many derivatives of cyclohexane, 1,3-dithiane, and of 1,3-dioxane (1, 2). Again, activation parameters for the inversion of the parent compounds, and some of their derivatives, have been measured by a variety of methods (2, 3). The classical nmr line-shape study of the inversion in cyclohexane (4) depended on the dephasing of magnetization as spin magnetic moments are transferred between sites of different Larmor frequencies (T_2 effects).

More recently, molecular mechanics calculations (5) and calorimetric techniques (6) have been used to tackle the determination of the stable conformers of, and of the barrier to internal rotation in, 2-phenyl-1,3-dioxane and lead to the conclusion that the rotation is essentially free in the equatorial isomer. Even if the barrier magnitude is not zero but comparable to kT, it is evident that the nmr line-shape methods will not be applicable. The lowest energy of activation ascertained by these methods stands at 4.2 kcal/mol (7).

However, another nmr technique may apply here. We have recently shown that reasonable values of small barriers to internal rotation can be derived from long-range spin–spin coupling constants over six formal bonds. This approach recognizes that ${}^6J_p^{H,CH}$, the coupling between a *para* proton in the benzene ring and a proton bound to the alpha carbon, varies as $\sin^2\theta$. The dihedral angle θ is defined by the $C_1C_2C_\alpha H$ fragment in **1**. One may write an equation



1

somewhat analogous to that of Heller and McConnell (8)

0008-4042/79/030355-05$01.00/0

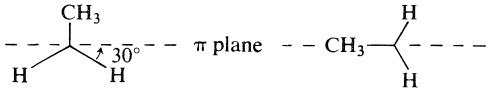
[1] $$^6J_{obs} = {}^6J_o + {}^6J_{90}\langle\sin^2\theta\rangle$$

where $^6J_{90}$ is the value of ^6J at $\theta = 90°$ and $\langle\sin^2\theta\rangle$ is the expectation value of $\sin^2\theta$, an average over the populated rotational states. The maximum magnitude of ^6J occurs at $\theta = 90°$, as expected for a σ–π spin–spin coupling mechanism (sometimes called a hyperconjugative interaction) in which information about the unpaired electron density, induced in the σ C—H bond by the proton magnetic moment, is transmitted via the π electrons to the site of the *para* carbon atom and then to the *para* proton by spin polarization.

Such a mechanism implies $^6J < 0$. In toluene, $^6J_p^{H,CH}$ is -0.62 Hz (9) and, if the σ–π mechanism is operative, $^7J_p^{CH_3,CH_3}$ in *p*-xylene should equal $-{}^6J_p^{H,CH_3}$ in toluene, as it does (10, 11). The $\sin^2\theta$ dependence is supported by INDO MO FPT calculations (12). The barrier in toluene is only 0.014 kcal/mol (13), so that $\langle\sin^2\theta\rangle$ is 0.5 (essentially free rotation) and $^6J_{90}$ is therefore -1.24 Hz.

One test of the $\sin^2\theta$ dependence involves 2,6-dichloroethylbenzene where **2** is favored by at least 5 kcal/mol. Therefore $\langle\sin^2\theta\rangle$ must be close to 0.25 because θ lies near 30°. Hence $^6J_p^{H,CH_2}$ is predicted to be $-1.24/4$, or -0.31 Hz. Indeed, it is observed as -0.29 ± 0.02 Hz in benzene solution (14). The ring substituents and the methyl group apparently do not greatly perturb the $\sin^2\theta$ dependence of ^6J.

The rotation about the bond between the phenyl ring and the ethyl group can be treated as a hindered rotor problem in a manner similar to that employed by McClung and co-workers (15). Assuming a twofold hindering potential, e.g., in ethylbenzene V_2 is the energy difference between **2** and **3**, and an

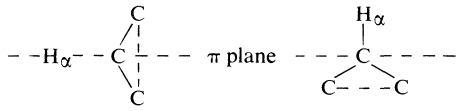


2 **3**

unperturbed basis set of 11 lowest free rotor functions eventually yields $\langle\sin^2\theta\rangle$ as a function of V_2 and of the reduced moment of inertia at a given temperature.

Application to 3,5-dibromoethylbenzene, chosen because a precise analysis of a very tightly coupled ring proton spectrum is unobtainable, gave $V_2 =$ 1.2 kcal/mol (16), in excellent agreement with a recent thermodynamic value of 1.16 kcal/mol (17). Conformer **2** is the most stable according to the ^6J method, in line with low resolution microwave data (18).

Some other examples, particularly appropriate to this paper, include isopropylbenzene, phenylcyclopropane, and styrene. The *J* method finds the 'bisected' conformation **4** as stable for the first two compounds (19, 20) and, assuming **5** as the high



4 **5**

energy form and a twofold barrier, a V_2 of 2.0 kcal/mol for both. The *J* method yields 1.6 kcal/mol for V_2 in styrene (21), assuming a planar ground state, in reasonable agreement with a Raman value of 1.78 kcal/mol (22).

All these results assume a negligibly small ^6J_o in [1]. A test of this assumption for toluene is the result above, viz. $^6J_p^{H,CH_3} = -{}^7J_p^{CH_3,CH_3}$. Another test is that $^6J_p^{H,CH_2} = -{}^7J_p^{CH_2,CH_3}$ in 2,6-dichlorobenzyl bromide and its 4-methyl derivative.[1] Furthermore, the recent measurement of the internal barrier to rotation in benzyl cyanide derivatives (23) implies that $^6J_p^{H,CH}$ in 3,5-dibromoisopropylbenzene should be 0.03 Hz larger in magnitude than $^7J_p^{CH,CH_2}$ in *p*-isopropylbenzyl cyanide, as it is,[1] if the $\sin^2\theta$ mechanism is operative to the exclusion of a J_o component. These tests encompass a number of preferred θ values and strongly suggest that the J_o term in [1] is negligibly small.

In this paper, the *J* method is applied to the determination of the low energy conformations and of the barrier to internal rotation about the carbon–carbon bond between the two rings in R-cyclohexane, **6**; 2-R-1,3-dithiane, **7**; 2-R-1,3-dioxane, **8**; and 2-R-1,3-dioxolane, **9**; where R is the 3,5-dichlorophenyl substituent. The chlorine substituents at the *meta* positions allow an accurate determination of the relevant spectral parameters. There is no evidence that these substituents are significant perturbers of the ^6J values or of the conformational preferences to be discussed below.

Results and Discussion

Spectral Analysis

The ring proton spectra are the AB_2 subspectra of AB_2X spectra, where X is the proton on the carbon atom bonded to the aromatic group. The X proton in these compounds resonates at a frequency sufficiently different from the other alkyl protons, such that an AB_2X analysis represents an accurate approach. Figure 1 displays the observed *para* proton resonance of the dioxolane derivative, illustrating the spectral quality. Table 1 reports the results of the analyses,

[1]T. Schaefer, R. Sebastian, and L. Shengwai. Unpublished results.

TABLE 1. Chemical shifts and coupling constants for the 3,5-dichlorophenyl group in **6–9**

Parameter	Value			
	6[a]	**7**[b]	**8**[a]	**9**[a]
$\nu_2 = \nu_6$[c]	687.586(5)	729.792(3)	739.270(8)	729.053(4)

[e]The coupling was the same in a CS_2 solution. In C_6D_6 solution the 10 other cyclohexyl protons resonated to high field of $\delta = 1.3$ ppm.

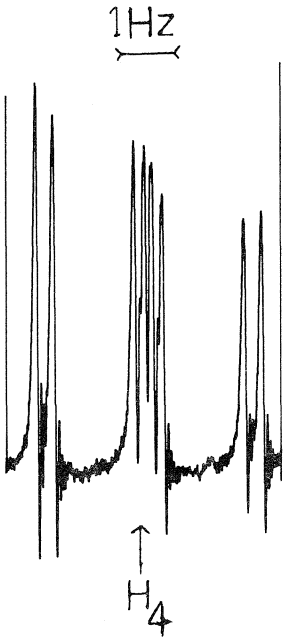

FIG. 1. The ^{1}H nmr spectrum at 100 MHz and 305 K of the *para* proton in a 10 mol% solution in benzene-d_6 of 2-(3,5-dichlorophenyl)-1,3-dioxolane. The spectrum was recorded at a sweep rate of 0.01 Hz/s and displays linewidths at half height of 0.10 ± 0.01 Hz. The outer doublets are split by 0.33 ± 0.01 Hz (repeated runs).

performed with the computer program LAME (24, 25).

Of course, it would have been preferable to analyze the spectra of compounds not containing chlorine substituents in the ring. Unlike phenylcyclopropane, however, in which the magnetic anisotropy of the cyclopropyl group causes dispersion of the phenyl proton resonances sufficient to allow an analysis (20), the phenyl derivatives of the alicyclic systems in this paper display very small internal shifts for the aromatic protons, vitiating attempts at a confident extraction of coupling constants below 0.5 Hz in magnitude.

Calculational Procedure

Plots of $\langle \sin^2 \theta \rangle$ were constructed as a function of temperature, reduced moments of inertia, and of V_2. Conformation **4** (bisected) was assumed to be of lowest energy for **6–9**, implying that $\langle \sin^2 \theta \rangle$ ranges from 0.5 for a vanishing twofold barrier to zero at an infinite barrier. The reduced moments of inertia of **6–9** were calculated for various conformations, including **4** and **5**. For these, the dithiane derivative, as an extreme example, had moments of 2.5 and 3.5×10^{-38} g cm^2, respectively. Fortunately, at 305 K the values of $\langle \sin^2 \theta \rangle$ are insensitive to differences of this magnitude, varying only in the third significant figure. This fact obviates the consideration of variations in the moments of inertia caused by changes in θ during the internal rotation and by the assumption of regular geometries. In the calculations, 11 basis functions were employed, quite sufficient for temperatures below 400 K.

3,5-Dichlorophenylcyclohexane (6)

The free energy of the equatorial isomer is 3.1 kcal/mol lower than that of the axial isomer in phenylcyclohexane, so that more than 99% of **6** likely exists in the equatorial form at 305 K, the temperature of the experiment. Inversion of the cyclohexyl moiety is many orders of magnitude slower than the rate of rotation about the bond between the two cyclic systems. The following discussion is couched in terms of the properties of a noninverting equatorial form. It is also assumed that the chlorine substituents do not materially alter the conclusions above.

A $^6J_{90}$ of −1.24 Hz, as for toluene, implies a $\langle \sin^2 \theta \rangle$ of 0.188 because the observed value of $^6J^{H,CH}$ for **6** is −0.233 Hz (Table 1). A reduced moment of inertia for conformation **4** of 1.72 ×

10^{-38} g cm^2 (it is 1.80×10^{-38} g cm^2 for **5**) then yields a V_2 of 2.1 kcal/mol.

However, $^6J_{90}$ in **6** need not be the same as in toluene. If the $C_{ring} \ldots C_\alpha \ldots H$ angle becomes greater than 109.5°, the overlap of the C_α—H bond with the π orbitals of the ring will decrease, leading to a lower magnitude of $^6J_{90}$. For example, when this angle in styrene is taken as 120°, the calculated $^6J_{90}$ is -1.05 Hz (21). In cyclohexane the H—C—H angle is $107.5 \pm 1.5°$ (26*a*) or perhaps 110.0° (26*b*) and the assumption will here be made that the $C_{ring} \ldots C_\alpha \ldots H$ angle is within 2° of tetrahedral, suggesting a possible difference of 0.04 Hz between $^6J_{90}$ in toluene and in **6**. If $^6J_{90}$ in **6** were as low in magnitude as -1.14 Hz, then V_2 would become 1.95 kcal/mol.

Allowing for an error of 0.02 Hz in the measured $^6J^{H,CH}$ and in $^6J_{90}$, it appears reasonable that V_2 in **6** is 2.0 ± 0.3 kcal/mol, with the bisected conformation **4** as the ground state. If **5** were the low energy conformer, $^6J^{H,CH}$ would have a magnitude of over 0.5 Hz for a finite V_2.

Conformation **4** minimizes steric hindrance between the C—H bonds and, if such interactions account for V_2, it appears possible that V_2 has similar values in **6**, in phenylcyclopropane, and in isopropylbenzene. As argued for phenylcyclopropane (20), V_2 should be the dominant component in the actual internal barrier for **6**.

Molecular mechanics calculations (26*c*) on phenylcyclohexane suggest that **4** is 3.9 kcal/mol more stable than **5**.

2-(3,5-Dichlorophenyl)-1,3-dithiane (7)

In the crystal (27*a*), 2-phenyl-1,3-dithiane exists in a conformation in which the phenyl plane is approximately perpendicular to the 'plane' of the 1,3-dithiane ring (bisected conformation, **4**). In gaseous 1,3-dithiane, nonchair forms have not been detected (27*b*). In CS_2 solution, the *p*-chlorophenyl derivative favours the equatorial form by a free energy of 1.7 ± 0.3 kcal/mol (28), suggesting that $94 \pm 3\%$ of **7** exists in this form at 305 K. The discussion below assumes an equatorial form.

If $^6J_{90}$ is -1.24 Hz, the usual procedure yields 2.25 kcal/mol for V_2, using the observed $^6J^{H,CH}$ in Table 1. Again, if $^6J_{90}$ is -1.14 Hz, V_2 becomes 2.1 kcal/mol. A V_2 of 2.2 ± 0.3 kcal/mol should easily encompass errors in measurement of ^6J and in $^6J_{90}$. If steric interactions between *ortho* C—H bonds of the phenyl group and bonds at the 1,3 positions in the saturated ring cause the barrier, then it seems that CH_2 moieties and sulfur atoms are very similar in their steric requirements in **6** and **7**.

2-(3,5-Dichlorophenyl)-1,3-dioxane (8)

Extensive X-ray (29) and calorimetric investigations (6), as well as molecular mechanics calculations (5), imply at most a very small barrier to internal rotation in equatorial 2-phenyl-1,3-dioxane, this isomer being favoured by a free energy of 3.1 kcal/mol (6).

In previous work (30), we have argued that highly electronegative substituents at the α carbon atom appreciably reduce $^6J_{90}$. Two fluorine substituents reduce the magnitude of $^6J_{90}$ to about -0.9 Hz (30). The reduction can be understood as a consequence of the polarization of the C—H bond, reducing the overlap of its orbitals with the neighbouring π electron system. A linear relationship between $^6J_{90}$ and the electronegativity of the substituents implies that $^6J_{90}$ is -0.96 Hz in **8**. Allowing for an error of 0.05 Hz in this number and for an error of 0.02 Hz in $^6J^{H,CH}$ in **8**, yields a V_2 of 0.4 ± 0.2 kcal/mol. We take this result as a confirmation of the conclusions (5, 6) described above. It is difficult to reconcile our observed couplings with entirely free rotation about the central carbon–carbon bond in **8**. Free rotation implies that $^6J_{90} = -0.89$ Hz (2×-0.40) in **8**, which we think is rather too low in magnitude.

2-(3,5-Dichlorophenyl)-1,3-dioxolane (9)

In the gas phase, 1,3-dioxolane is almost a free pseudorotor (31), whereas in solution the envelope form is apparently rather more stable (5, 32, 33). Detailed equilibration (34) and ^{13}C chemical shift (35) studies of various 1,3-dioxolane derivatives suggest to us that there exists very little preferred equatorial or axial character in **9**, the ring being highly flexible.

On the other hand, the observed $^6J^{H,CH}$ of -0.33 Hz means that the C—H_α bond prefers to lie in the plane of the benzene ring. Otherwise, its magnitude would be rather larger than 0.4 Hz (see discussion of **8** above). This conclusion is supported by the chemical shifts of the α proton in the isomers of 2,4,5-trimethyl-1,3-dioxolane and 2-phenyl-4,5-dimethyl-1,3-dioxolane (34). Substitution of methyl by phenyl causes a shift to low field of 0.8 ppm, best explained as arising from the magnetic anisotropy of the phenyl ring. The anisotropy causes marked downfield shifts for proton sites near the plane of the phenyl ring.

If, then, the small-amplitude ring puckering motion is rapid compared to rotation about the connecting carbon–carbon bond and the ground state conformation of the phenyl group is best represented by the bisected conformation, **4**, a treatment in terms of a twofold barrier is feasible. If $^6J_{90}$ is the same as for **8**, one has $\langle \sin^2 \theta \rangle$ as 0.33/0.96, or 0.34, then V_2 is 0.85 ± 0.3 kcal/mol; the quoted error allows for large errors in $^6J_{90}$. It

would be interesting if other methods were to confirm that the barrier in **9** is higher than in **8**.

Conclusions

The *J* method implies that the bisected conformations, **4**, are the most stable for **6**–**9**; further, that the twofold barrier to internal rotation in **6** and **7** is very similar in magnitude to those in phenylcyclopropane and isopropylbenzene; finally, that in **8** the barrier is finite but similar to kT at ambient temperatures, in rough agreement with other experimental and with theoretical approaches.

Experimental

Compounds **6**–**9** were prepared by standard procedures (34, 36–42) and gave satisfactory mass and ^{1}H nmr spectra (28, 43–47). These were repeatedly calibrated at 5-Hz intervals in the frequency sweep mode of an HA100 spectrometer at a probe temperature of 305 ± 1 K. The spectral dispersion was 1 Hz/cm and sweep rates were 0.02 and 0.01 Hz/s. The spectrum in Fig. 1 has linewidths at half height of 0.10 ± 0.01 Hz and illustrates that peaks separated by 0.3 Hz (outer doublets) were cleanly resolved.

Optically active 2-pyrazolines were synthesized and their optical properties were studied using various spectroscopic techniques to investigate the effects of substituents at the 3 and 5 positions of the 2-pyrazoline ring on their optical activity. It was found that in the case of 5-substituted-1,3-diphenyl-2-pyrazoline derivatives, the substituent at the 5 position has considerable influence on the optical activity, whereas in 3-substituted-1,5-diphenyl-2-pyrazoline derivatives, the substituent at the 3 position has no such influence.

MAKOTO MUKAI, TAKASHI MIURA, MASAHIRO NANBU, TOSHINOBU YONEDA et YOHJI SHINDO. Can. J. Chem. **57**, 360 (1979).

On a synthétisé certaines pyrazolines-2 optiquement actives et l'on en a étudié les propriétés optiques par différentes méthodes spectroscopiques, dans le but de déterminer l'influence qu'exerce sur l'activité optique les substituants aux positions 3 et 5 du noyau pyrazoline-2. Dans le cas des dérivés de la diphényl-1,3 pyrazoline-2 portant un substituant en position 5, on a observé que ce substituant exerce une influence importante sur l'activité optique; par contre, pour les diphényl-1,5 pyrazolines-2 possédant un substituant en position 3, ce substituant est sans effet.

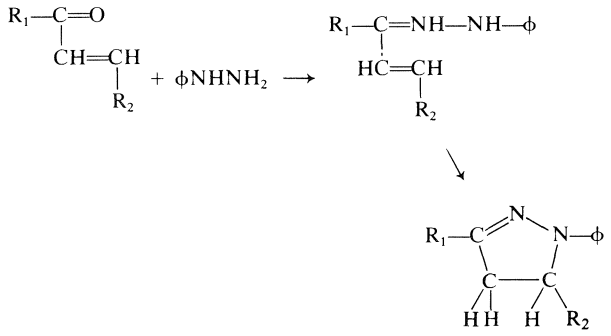
[Traduit par le journal]

Introduction

A number of studies on 2-pyrazoline compounds have been carried out for the purpose of using them as optical brighteners (1, 2), scintillators (3–8), and photoconductive materials (9). As a result, some of their optical properties are well documented. However, no study on the optical activity of these compounds has been reported except that by Neunhoeffer and Ulrich (10) on sodium (+)-4-(3,5-diphenyl-2-pyrazolin-1-yl)benzenesulfonate, (+)-**1**. Furthermore, there are only a few studies (11, 12) on the optical activity of the pyrazoline derivatives. Thus, we decided to prepare some 2-pyrazolines in optically pure form and to investigate the effect of substituents at the 3 and 5 position of the 2-pyrazoline ring on their optical activity.

Results and Discussion

Among the many methods of synthesizing 2-pyrazolines (1, 8, 13–16) that outlined in Scheme 1 is most widely used owing to its ease and high efficiency (1). All our 2-pyrazoline compounds except sodium *dl*-4-(5-*tert*-butyl-3-phenyl-2-pyrazolin-1-yl)benzenesulfonate, *dl*-**6**, were readily obtained by this method, although *p*-hydrazinobenzenesulfonic acid, instead of phenylhydrazine, was used to resolve the compounds by the formation of separable diastereoisomers. An attempt to synthesize compound *dl*-**6** by the methods outlined in Scheme 2 (8, 14, 15) was unsuccessful. Thus, it was necessary to develop a completely new approach to synthesize compound *dl*-**6**.

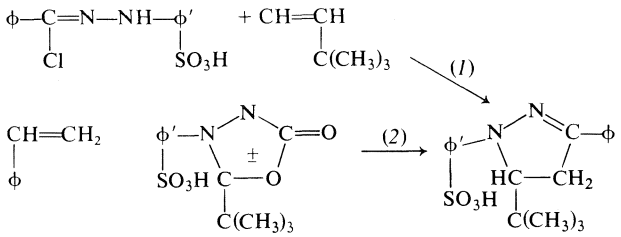


$R_1, R_2 = CH_3, C(CH_3)_3, C_6H_5$

SCHEME 1

Cinchonidine was found to be a good resolving agent for a series of 3- but not 5-substituted-1,5-diphenyl-2-pyrazoline derivatives and *dl*-**1** was successfully resolved using brucine. After several unsuccessful attempts to use alkaloids such as brucine, cinchonidine, strychnine, and quinine, the resolution of sodium *dl*-4-(5-methyl-3-phenyl-2-pyrazolin-1-yl)benzenesulfonate, *dl*-**2**, was achieved using (−)-α-methylbenzylamine. Our preliminary experiments also show that (−)-α-methylbenzylamine seems to be effective in the resolution of all the 2-pyrazoline compounds obtained, though its resolving power is not particularly good.

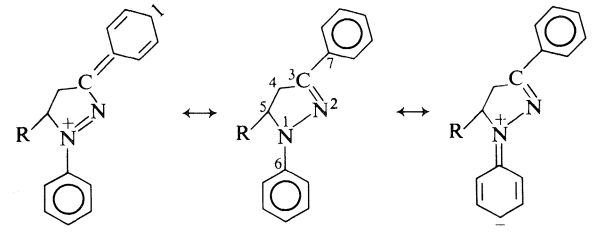
0008-4042/79/030360-07$01.00/0



SCHEME 2

It is known from previous studies (17) on the uv spectra of 2-pyrazoline compounds that the spectrum has one maximum at about 240 nm when there is no substituent at the 1 position of the pyrazoline ring and that a second maximum at about 280 nm appears when the 1 position is substituted by a benzene ring. This long-wavelength band is not affected by a second substituent at the 3 position except when the substituent is a phenyl group. In such a case, the pyrazoline compounds exhibit a band shift to 354 nm and show a blue fluorescence whose maximum appears around 455 nm. The introduction of a third substituent at the 5 position of the pyrazoline ring causes no alteration in the established spectral pattern and such substituted pyrazoline compounds also show the same fluorescence as 1,3-diphenyl-2-pyrazoline (5). From an X-ray study of the crystal structure of 1,3-diphenyl-2-pyrazoline (18) it is evident that the N(1)—N(2), N(2)—C(3)—C(7), and N(1)—C(6) bonds are significantly shorter than a single bond. Those factors suggest that conjugation between the phenyl rings occurs via atom N(1), N(2), and C(3) (19) as shown in Scheme 3. This conjugated chromophore is common to a series of 1,3-diphenyl-2-pyrazoline derivatives and is responsible for the strong absorption and fluorescence bands at about 355 and 455 nm, respectively (20), which are due to the π–π^* transition (3).

As illustrated in Figs. 1 and 2, there is little difference in the uv and fluorescence spectra between compounds (+)-**1** and (−)-**2**. However, the ord and cd spectra, shown in Fig. 3, indicate that the two compounds are very different. In the case of compound (+)-**1**, the cd maximum peak, which corresponds to the uv maximum peak at 357 nm, appears at 349 nm, whereas in compound (−)-**2** both the cd and uv maximum peaks are observed at 358 nm. However, the molar ellipticity of the conjugated chromophore is about 3.0×10^4 in the both cases, indicating that the conjugated chromophores of those two have almost the same optical activity. Furthermore, in the 240–280 nm wavelength region there are more differences in the cd spectra between these two compounds. In (+)-**1**, two cd peaks at 275 and 250 nm, which have the same sign as the main cd peak at 349 nm, are found to appear at longer wavelengths than the two corresponding uv absorption peaks. On the other hand, in (−)-**2**, only one peak, whose sign is opposite to that of the strong



R = H, CH_3, C_6H_5

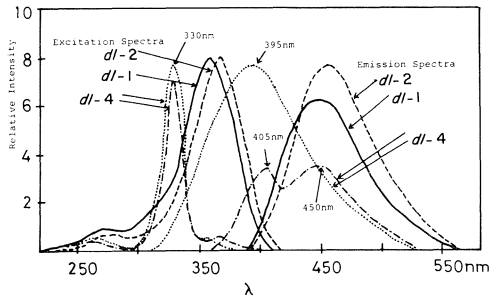

FIG. 2. The fluorescence excitation and emission spectra of sodium *dl*-4-(3,5-diphenyl-2-pyrazolin-1-yl)benzenesulfonate, *dl*-**1** (——), at 2.5×10^{-7} mol/L in methanol (excitation: 358 nm; emission: 450 nm); sodium *dl*-4-(5-methyl-3-phenyl-2-pyrazolin-1-yl)benzenesulfonate, *dl*-**2** (---), at 2.95×10^{-7} mol/L in methanol (excitation: 365 nm; emission: 450 nm); and sodium *dl*-4-(3-methyl-5-phenyl-2-pyrazolin-1-yl)benzenesulfonate, *dl*-**4**, at 2.95×10^{-4} mol/L in methanol: (---), excitation: 330 nm, emission: 395 nm; (—·—·—), excitation: 358 nm, emission: 450 nm.

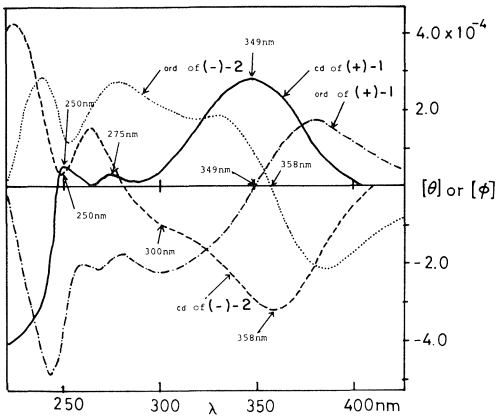

FIG. 3. The ord and cd spectra of sodium (+)-4-(3,5-diphenyl-2-pyrazolin-1-yl)benzenesulfonate, (+)-**1**, and sodium (−)-4-(5-methyl-3-phenyl-2-pyrazolin-1-yl)benzenesulfonate, (−)-**2**, in methanol.

cd peak at 358 nm, appears at 250 nm and a shoulder is observed at 300 nm in the main cd band. It is reported (6, 14) that the uv band at 265 nm arises from the phenyl ring whereas that at 234 nm is due to the pyrazoline ring. However, they are probably all strongly coupled and result, more or less, from the entire composite system. The same is also true for the cd and ord bands around 250 nm.

In the case of (+)-**1**, the phenyl group at the 5 position not only serves as a chromophore itself but also contributes greatly to the optical activity of the whole system by producing an asymmetric perturbation. On the other hand, the methyl group of (−)-**2** cannot act as a chromophore but it does induce an asymmetric environment such as to make other chromophores optically active. This factor certainly results in the considerable difference between the two compounds as seen in their cd and ord spectra. X-ray analysis (18) of 1,3-diphenyl-2-pyrazoline reveals that the two phenyl rings are not completely coplanar; that is, the dihedral angle between the planes of the phenyl rings is 11.0° and rotation about the C(6)—N(1) and C(3)—C(7) bonds gives the molecule a slight propeller shape. In other words, the conjugated chromophore is distorted slightly. The difference in the position of the maximum peaks between the cd and the uv spectra of (+)-**1** may, in some way, relate to the additional distortion (21, 22) of the conjugated chromophore due to the steric effect of the phenyl group at the 5 position of the pyrazoline ring or to the coupling between those two chromophores. On the other hand, the fact that both the uv and cd maxima occur at 358 nm in compound (−)-**2** may indicate that the methyl group at the 5 position causes almost no additional distortion to the conjugated chromophore.

It was considered worthwhile preparing compound *dl*-**6** to investigate more clearly the effect of a substituent at the 5 position on the optical properties of 1,3-diphenyl-2-pyrazoline derivatives.

Sodium (+)-4-(5-phenyl-2-pyrazolin-1-yl)benzenesulfonate, (+)-**3**, sodium (−)-4-(3-methyl-5-phenyl-2-pyrazolin-1-yl)benzenesulfonate, (−)-**4**, and sodium (−)-4-(3-*tert*-butyl-5-phenyl-2-pyrazolin-1-yl)benzenesulfonate, (−)-**5**, all exhibit similar patterns in their uv, cd and ord spectra. As shown in Fig. 1, only one maximum is observed at 290–294 nm for each of these compounds. The band at 290-294 nm is attributed to the chromophore through C(6), N(1), N(2), and C(3), —C=N—N—Ar, because, as mentioned earlier (5), this band is also observed in the uv spectrum of 1-phenyl-2-pyrazoline. This absorption band corresponds to the maximum peak in the cd curves and to the Cotton effect in the ord curves of the above three compounds as shown in Fig. 4. This means that the introduction of a methyl or a *tert*-butyl group at the 3 position of the pyrazoline ring has no effect on the optical activity of *dl*-**3**. As expected, the cd and ord spectra of compound (+)-**3** and (−)-**3** are mirror images as shown in Fig. 4.

There has been considerable discussion about the origin of the weak fluorescence observed in 3-methyl-1,5-diphenyl-2-pyrazoline (4, 7, 19). Neunhoeffer *et al.* (19) attribute it to the hyperconjugation of the methyl group and this is supported by Sandler and Tsuo (4). If the fluorescence is a consequence of such hyperconjugation, 3-methyl-1-phenyl-2-pyrazoline should show similar fluorescence because the presence and nature of a substituent at the 5 position is

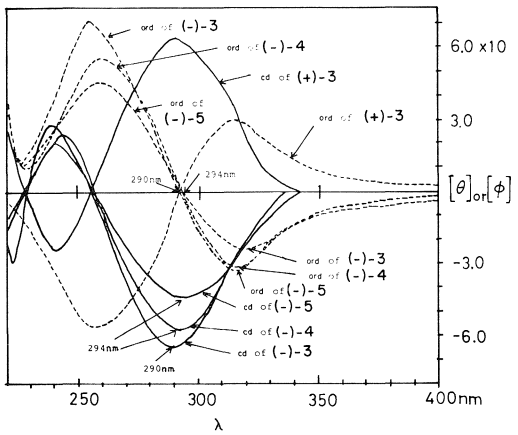

FIG. 4. The ord and cd spectra of sodium (+)-4-(5-phenyl-2-pyrazolin-1-yl)benzenesulfonate, (+)-**3**; sodium (−)-4-(5-phenyl-2-pyrazolin-1-yl)benzenesulfonate, (−)-**3**; sodium (−)-4-(3-methyl-5-phenyl-2-pyrazolin-1-yl)benzenesulfonate, (−)-**4**; sodium (−)-4-(3-*tert*-butyl-5-phenyl-2-pyrazolin-1-yl)benzenesulfonate, (−)-**5** in methanol.

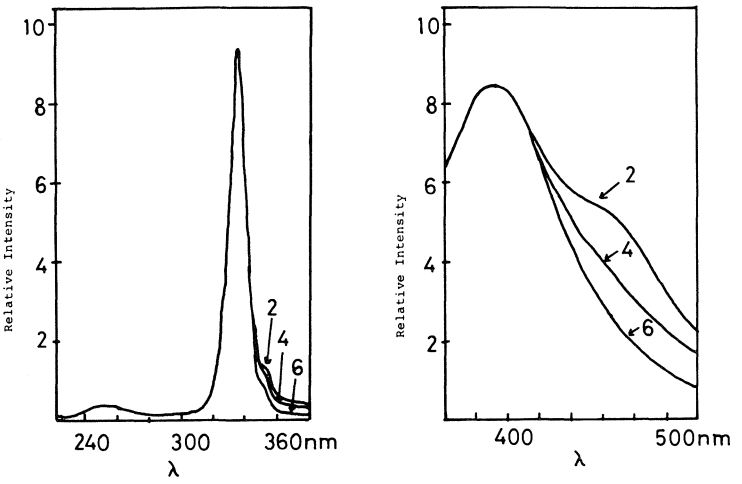

FIG. 5. The change in the fluorescence excitation and emission spectra of sodium *dl*-4-(3-methyl-5-phenyl-2-pyrazolin-1-yl)benzenesulfonate with purification: **2**, after two recrystallizations; **4**, after four recrystallizations; **6**, after six recrystallizations; (*a*) the excitation spectra at a concentration of 0.2 g/L in methanol (emission: 390 nm); (*b*) the emission spectra at a concentration of 0.29 g/L in methanol (excitation: 330 nm).

found to have little effect on the excitation process (20, 23). However, 3-methyl-1-phenyl-2-pyrazoline has been reported to be nonfluorescent (24). Furthermore, if hyperconjugation of the methyl group is related to the excited state of compound (−)-**4**, then the chromophore for compound (−)-**4**, CH_3—C=N—N—Ar, is different from that for compound (−)-**5**, $(CH_3)_3C$—C=N—N—Ar, and the ord and cd spectra of these two are expected to be different. However, as shown in Fig. 4, the optical properties of those two are almost identical. These facts indicate that the fluorescence of compound *dl*-**4** is not due to hyperconjugation of the methyl group. Owing to the possibility that the fluorescence was produced by trace impurities, compound *dl*-**4** was examined by thin-layer chromatography but no impurities were detected.

As seen in Fig. 2, the 330 nm excited emission spectrum has one peak at about 400 nm, whereas the one excited at 358 nm has two peaks, one at 400 and the other at 450 nm. The intensity of the fluorescence at 400 nm did not vary as the purity of *dl*-**4** was increased, whereas that at 450 nm gradually decreased as shown in Fig. 5. This fact indicates that the fluorescence at 400 nm is an inherent property of the compound and that the fluorescence observed at 450 nm is due to impurities. From a comparison of Figs. 1 and 2, it is noted that the excitation spectrum of compound *dl*-**4** is very different in shape from the absorption spectrum and that the wavelength of its excitation maximum is 40 nm longer than that of its absorption maximum. The other interesting observation is that fluorescence was hardly detected when compound *dl*-**4** was excited at 290 nm, i.e., at its absorption maximum. As shown in Fig. 6, the excitation spectrum of *dl*-**4** at a concentration of 0.1 g/L has two peaks, one at 330 and the other at 260 nm but at 0.005 g/L these two peaks disappear and one new peak appears at 310 nm. These facts indicate that the origin of the observed weak fluorescence may be due to the associated species.

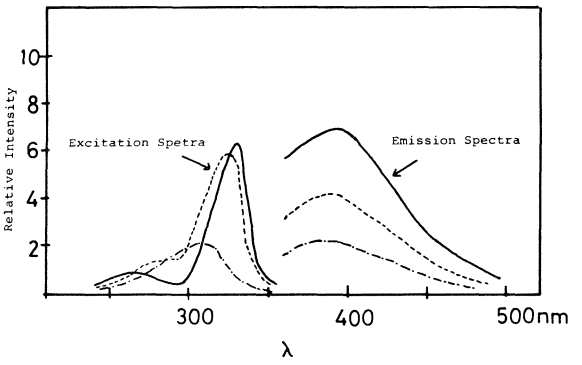

FIG. 6. The fluorescence excitation and emission spectra of sodium *dl*-4-(3-methyl-5-phenyl-2-pyrazolin-1-yl)benzenesulfonate at various concentrations in methanol; (——), 0.1 g/L; (---), 0.05 g/L; (—·—·—), 0.005 g/L (excitation: 330 nm; emission: 395 nm).

Experimental

Materials

Special grade benzylideneacetophenone (BDH Ltd.), benzylideneacetone (Wako Chemicals), pinacolone (Wako), cinnamaldehyde (Wako), brucine (Wako), cinchonidine

(Nakarai Chemical Ltd.), acetic anhydride (Wako), and tartaric acid (Kanto Chemical Ltd.) were used without further purification. Special grade 1-phenyl-2-buten-1-one (Tokyo Kasei Kogyo Ltd.) was purified by vacuum distillation before use. Crude *p*-hydrazinobenzenesulfonic acid (Wako) was recrystallized from water. Reagent grade benzaldehyde (Nakarai) was purified by steam distillation before use. Reagent grade *dl*-α-methylbenzylamine (Nakarai) was distilled under reduced pressure before use. Double distilled methanol, ethanol, and acetone were used throughout the experiments. For thin-layer chromatography, special grade Kieselgel nach Stahl (Merck), 1-butanol (Wako), and reagent grade soluble starch (Wako) were used without further treatment.

Instruments

A Shimadzu UV-20 spectrophotometer, a Shimadzu IR-27C spectrometer, an Hitachi 204 fluorescence spectrophotometer, and a JASCO J-20 spectropolarimeter were used for the measurement of uv, ir, fluorescence, cd, and ord, respectively. A JASCO DIPSL polarimeter was used for the determination of the optical purity of diastereomers.

Syntheses and Resolution of 2-Pyrazoline Compounds

Sodium dl-*4-(3,5-Diphenyl-2-pyrazolin-1-yl)benzenesulfonate (*dl-***1***)*

Preparation

A solution of benzylideneacetophenone (5 g) in 25 mL of ethanol and *p*-hydrazinobenzenesulfonic acid (4.5 g) in 8 mL of water was refluxed at 123–125°C for 7 h and then cooled. On the addition of 15 mL of 2 *N* sodium hydroxide, a yellow product precipitated immediately. The precipitate was filtered and recrystallized (seven times) from a mixture of methanol and water (2:1) to give 2.1 g of white plates, mp 198–201°C; uv and visible (100% CH_3OH, 23°C) λ_{max} (log ε): 234 (4.16), 276 (4.15), 357 (4.49) nm; ir (KBr pressed disc) ν_{max}: 1605 (s, C=N), 1505 (s, aromatic C=C), 1405 (s, CH_2), 1326 (m, Ar—N), 1200 (s, SO_3^-), 1130 (s, CH—N), 1040 (s, SO_3^-), 820 (m, aromatic CH *p*-substituted), 750 (s, aromatic CH 5-adjacent H atoms), 700 (s, aromatic CH) cm^{-1}. *Anal.* calcd. for $C_{21}H_{17}O_3SNa{\cdot}2.5H_2O$: C 56.62, H 4.98, N 6.29; found: C 56.59, H 4.96, N 6.18.

Resolution

A solution of the racemic compound (5 g) and brucine (5 g) in 50 mL of acetic anhydride was concentrated under reduced pressure giving an oily residue. To the residue, 50 mL of water was added under continuous stirring and the pale yellow brucine salt began to precipitate as a mixture of diastereoisomers. The precipitate was filtered and recrystallized (seven times) from a mixture of methanol and water (2:1). Ethanol (150 mL), water (50 mL), and 2 *N* sodium hydroxide (10 mL) were added sequentially to 2 g of the resolved brucine salt. After the addition of a large amount of water, the solution was kept cool overnight, and white crystals precipitated in the form of plates. The crystals were filtered and dried *in vacuo* to give compound (+)-**1**, mp 205–210°C, $[\alpha]_D^{25}$ +300° (*c* 0.06, CH_3OH); ord (*c* 0.0033(450–220 nm), *c* 0.06(700–400 nm), CH_3OH) 25°C: $[\phi]_{700}$ +760°, $[\phi]_{589}$ +1240°, $[\phi]_{380}$ +17 570° (peak), $[\phi]_{349}$ 0° (intersects), $[\phi]_{305}$ −23 030° (trough), $[\phi]_{282}$ −16 970° (peak), $[\phi]_{244}$ −50 300° (trough); cd (*c* 0.00011 *M*, CH_3OH) 25°C: $[\theta]_{410}$ 0, $[\theta]_{349}$ +28 000, $[\theta]_{285}$ 720, $[\theta]_{275}$ +2900, $[\theta]_{265}$ 0, $[\theta]_{250}$ +5440, $[\theta]_{246}$ 0, $[\theta]_{223}$ −41 800.

Sodium dl-*4-(5-Methyl-3-phenyl-2-pyrazolin-1-yl)benzenesulfonate (*dl-***2***)*

Preparation

A mixture of *p*-hydrazinobenzenesulfonic acid (3.7 g) in 30 mL of water and 1-phenyl-2-buten-1-one (3 g) in 15 mL of ethanol was refluxed at 130°C for 4 h and then concentrated to about one-third of its original volume. The concentrate was refluxed for an additional 3 h and then cooled. The yellow product began to precipitate on the addition of 2 mL of 10 *N* sodium hydroxide. The precipitate was filtered and washed with ethanol. Nine recrystallizations from a mixture of ethanol and water (16:1) gave 0.4 g of white needles, mp 257°C; uv and visible (100% CH_3OH, 23°C) λ_{max} (log ε): 234 (4.11), 267 (4.11), 358 (4.46) nm: ir (KBr pressed disc) ν_{max}: 1610 (s, C=N), 1515 (s, aromatic C=C), 1405 (s, CH_2), 1345 (m, Ar—N), 1190 (s, SO_3^-), 1140 (s, CH—N), 1055 (s, SO_3^-), 830 (m, aromatic CH *p*-substituted), 740 (s, aromatic CH 5-adjacent **H** atoms), 700 (s, aromatic CH) cm^{-1}. *Anal.* calcd. for $C_{16}H_{15}N_2O_3SNa{\cdot}0.5H_2O$: C 55.33, H 4.61, N 8.06; found: C 55.54, H 4.35, N 8.02.

Resolution

The racemic compound (4 g) and (−)-α-methylbenzylamine (1.8 g), prepared according to the procedure of Theilacker and Winkler (25), were added to 12 mL of 1 *N* hydrochloric acid under vigorous stirring. After the addition of 120 mL of water, the solution was heated until the product had dissolved completely. The solution was kept in a refrigerator overnight to precipitate yellow needles. The yellow crystals were filtered and dried *in vacuo* to give 5 g of the amine salt as diastereoisomers. The amine salt (5 g) dissolved in 40 mL of ethanol was carefully poured into 200 mL of ether and allowed to stand 60 min. Pale yellow crystals precipitated in the form of well developed plates. The precipitate was filtered and dried *in vacuo*. The amine salt was treated eight times in the above manner and was further recrystallized four times from ethanol to give 0.4 g of the resolved amine salt. The resolved amine salt (0.4 g) was treated with 0.9 mL of 1 *N* sodium hydroxide. The addition of a large amount of ether precipitated white crystals. After filtration, the crystals were recrystallized once more from a mixture of ethanol and water (30:4) to give 0.16 g of compound (−)-**2**, mp 254°C, $[\alpha]_D^{25}$ −360° (*c* 0.06, CH_3OH); ord (*c* 0.0021 (450–220 nm), *c* 0.06 (700–400 nm), CH_3OH) 25°C: $[\phi]_{700}$ −640°, $[\phi]_{589}$ −1280°, $[\phi]_{386}$ −21 870° (trough), $[\phi]_{356}$ 0° (intersects), $[\phi]_{330}$ +18 630° (shoulder), $[\phi]_{278}$ +27 540° (peak), $[\phi]_{253}$ +11 340° (trough), $[\phi]_{240}$ +28 350° (peak); cd (*c* 0.00003 *M*, CH_3OH) 25°C: $[\theta]_{410}$ 0, $[\theta]_{358}$ −25 270, $[\theta]_{315}$ −12 960 (shoulder), $[\theta]_{282}$ 0, $[\theta]_{265}$ +15 550, $[\theta]_{250}$ +3240, $[\theta]_{228}$ +40 820.

Sodium dl-*4-(5-Phenyl-2-pyrazolin-1-yl)benzenesulfonate (*dl-***3***)*

Preparation

A solution of *p*-hydrazinobenzenesulfonic acid (14 g) in 150 mL of water was stirred with 10 g of cinnamaldehyde for 7 h at 60°C. After the addition of 3.0 g of sodium hydroxide, the solvent was evaporated completely on a water bath. The yellow residue was recrystallized three times from water and twice from methanol to give 9.2 g of yellow needles, mp 244–245°C; uv and visible (100% CH_3OH, 23°C) λ_{max} (log ε): 290 (4.25) nm; ir (KBr pressed disc) ν_{max}: 1605 (s, C=N), 1510 (s, aromatic C=C), 1385 (s, CH_2), 1195 (s, SO_3^-), 1130 (s, CH—N), 1035 (s, SO_3^-), 830 (m, aromatic CH *p*-substituted), 750 (s, aromatic CH 5-adjacent H atoms), 705 (m, aromatic CH) cm^{-1}. *Anal.* calcd. for $C_{15}H_{14}N_2O_3Na{\cdot}2H_2O$: C 49.97, H 4.78, N 7.78; found: C 50.29, H 4.76, N 8.08.

Resolution

The racemic compound (10 g) and cinchonidine (9 g) were added to 30 mL of 1 *N* hydrochloric acid and warmed under continuous stirring. On filtration, 16.7 g of the crude cinchonidine salt was obtained as diastereoisomers. The cinchonidine salt was recrystallized once from methanol. The pure cinchonidine salt (10 g) dissolved in 300 mL of methanol was allowed to stand in a refrigerator for 90 min. White

crystals were filtered and dried *in vacuo*. The yield after the first recrystallization should be kept to about 30% to achieve good resolution. The same procedure was repeated five times.

The resolved cinchonidine salt (0.5 g) was treated with 1 mL of 1 *N* sodium hydroxide. After the addition of 10 mL of water, the reaction mixture was heated and insoluble cinchonidine was removed by filtration. The filtrate was evaporated to dryness on a water bath. The residue was recrystallized once from methanol to give 0.12 g of compound (+)-**3**, mp 244–245°C, $[\alpha]_D^{25}$ +320° (*c* 0.1, CH_3OH); ord (*c* 0.0045 (400–220 nm), *c* 0.1 (700–400 nm), CH_3OH) 25°C: $[\phi]_{700}$ +710°, $[\phi]_{589}$ +1040°, $[\phi]_{318}$ +31 100° (peak), $[\phi]_{292}$ 0° (intersects), $[\phi]_{255}$ −60 030° (trough), $[\phi]_{228}$ −12 290° (peak); cd (*c* 0.000028 *M*, CH_3OH) 25°C: $[\theta]_{340}$ 0, $[\theta]_{292}$ +63 640, $[\theta]_{254}$ 0, $[\theta]_{240}$ −26 030, $[\theta]_{228}$ 0, $[\theta]_{223}$ +33 990, $[\theta]_{217}$ 0.

Compound (−)-**3** is also obtained as follows; after the first filtrate of the 300 ml of methanol solution was allowed to stand in a refrigerator overnight, the precipitate was filtered and dissolved in warm methanol. The solution was then cooled in a refrigerator for 90 min and the resulting white crystals were filtered and dried *in vacuo*. The same procedure was repeated four times. The resolved cinchonidine salt was converted into the sodium salt by the above procedure, mp 244–245°C, $[\alpha]_D^{25}$ −320° (*c* 0.1, CH_3OH); ord (*c* 0.0044 (400–220 nm), *c* 0.1 (700–400 nm), CH_3OH) 25°C: $[\phi]_{700}$ −710°, $[\phi]_{589}$ −1040°, $[\phi]_{318}$ −32 030° (trough), $[\phi]_{292}$ 0° (intersects), $[\phi]_{255}$ +58 840° (peak), $[\phi]_{288}$ +14 150° (trough) cd (*c* 0.000027 *M*, CH_3OH) 25°C: $[\theta]_{340}$ 0, $[\theta]_{292}$ −66 290, $[\theta]_{254}$ 0, $[\theta]_{240}$ +26 810, $[\theta]_{228}$ 0, $[\theta]_{223}$ −29 040, $[\theta]_{218}$ 0.

Sodium dl-*4-(3-Methyl-5-phenyl-2-pyrazolin-1-yl)benzenesulfonate (*dl-***4***)*

Preparation

Benzylideneacetone (3 g) in 3 mL of ethanol and sodium *p*-hydrazinobenzenesulfonate (3.7 g) in 5 mL of water and 5 mL of acetic acid were mixed and heated at about 130°C for 4 h. The reaction mixture was concentrated to about one-third its original volume, refluxed for additional 3 h, and then cooled. On the addition of a large amount of ethanol, the product began to precipitate. The precipitate was filtered and washed with ethanol. Nine recrystallizations from ethanol containing a trace of water gave 0.7 g of pale yellow needles, mp 219–221 °C; uv and visible (100% CH_3OH, 23°C) λ_{max} (log ε): 294 (4.31) nm; ir (KBr pressed disc) ν_{max}: 2950 (m, CH_3), 1590 (s, C=N), 1500 (s, aromatic C=C), 1400 (m, CH_2), 1360 (m, CH_3), 1180 (s, SO_3^-), 1120 (s, CH—N), 1030 (s, SO_3^-), 830 (m, aromatic CH *p*-substituted), 740 (m, aromatic CH 5-adjacent H atoms), 700 (m, aromatic CH) cm^{-1}. *Anal.* calcd. for $C_{16}H_{15}N_2O_3SNa{\cdot}0.5H_2O$: C 55.33, H 4.61, N 8.08; found: C 55.48, H 4.60, N 7.99.

Resolution

The racemic compound (4 g) dissolved in 50 mL of glacial acetic acid and cinchonidine (3.5 g) in 50 mL of ethanol were mixed and the solvent was evaporated under reduced pressure. The residue was washed with water and dried *in vacuo*. The crude cinchonidine salt obtained as diastereoisomers was recrystallized once from a mixture of ethanol and water (2:1). The pure cinchonidine salt (5 g) dissolved in 100 mL of the above mixture of solvents was allowed to stand for 90 min in a refrigerator and the precipitate was filtered and dried *in vacuo*. This procedure was repeated four times. To the resolved cinchonidine salt (1.2 g) in 20 mL of water was added 1.2 mL of 2 *N* sodium hydroxide and the mixture was warmed slightly. White crystalline cinchonidine precipitated upon cooling. After filtration, the filtrate was concentrated to one-third of its original volume and cooled to precipitate any remaining cinchonidine. After the precipitate was removed, the filtrate was evaporated completely on an oil bath. The residue was recrystallized once from a mixture of ethanol and water (10:1) to give 0.7 g of compound (−)-**4**, mp 219°C, $[\alpha]_D^{25}$ −315° (*c* 0.1, CH_3OH); ord (*c* 0.0037 (400–220 nm), *c* 0.1 (700–400 nm), CH_3OH) 25°C: $[\phi]_{700}$ −940°, $[\phi]_{589}$ −1060°, $[\phi]_{316}$ −32 050° (trough), $[\phi]_{294}$ 0° (intersects), $[\theta]_{260}$ +55 860° (peak), $[\theta]_{227}$ +10 980° (trough); cd (*c* 0.000033 *M*, CH_3OH) 25°C: $[\theta]_{340}$ 0, $[\theta]_{294}$ −57 590, $[\theta]_{257}$ 0, $[\theta]_{245}$ +23 280, $[\theta]_{228}$ 0.

Sodium dl-*4-(3-*tert*-Butyl-5-phenyl-2-pyrazolin-1-yl)benzenesulfonate (*dl-***5***)*

Preparation

Sodium *p*-hydrazinobenzenesulfonate (3.8 g) in 10 mL of water, 4,4-dimethyl-1-phenyl-penten-3-one (3.8 g), synthesized according to the procedure of Bramen (26), in 5 mL of ethanol and 3 mL of acetic acid were mixed and refluxed at 123–125°C for 7 h. The reaction mixture was concentrated to one-third of its original volume, refluxed for additional 3 h, and then cooled. On the addition of a large amount of ethanol, the product began to precipitate as white needles. The crystalline precipitate was filtered, washed with ethanol, and then with acetone. Six recrystallizations from acetone containing a trace of water gave 3.2 g of white needles, mp 220–222°C; uv and visible (100% CH_3OH, 23°C) λ_{max} (log ε): 295 (4.10) nm; ir (KBr pressed disc) ν_{max}: 2900 (s, CH_3), 1590 (s, C=N), 1495 (s, aromatic C=C), 1360 (m, —$C(CH_3)_3$), 1260 (m —$C(CH_3)_3$), 1190 (s, SO_3^-), 1120 (s, CH—N), 1040 (s, SO_3^-), 830 (s, aromatic CH *p*-substituted), 750 (m, aromatic CH 5-adjacent H atoms), 700 (m, aromatic CH) cm^{-1}. *Anal.* calcd. for $C_{19}H_{21}N_2O_3SNa{\cdot}H_2O$: C 57.29, H 5.79, N 7.03; found: C 57.08, H 6.08, N 7.09.

Resolution

Cinchonidine (3 g) was added to the racemic mixture (4 g) and 10.2 mL of 1 *N* hydrochloric acid was added with continuous stirring. After the addition of 90 mL of water, the mixture was heated until the cinchonidine salt had dissolved completely. The solution was allowed to stand in a refrigerator overnight and white crystals precipitated as needles. On filtration, the crude cinchonidine salt was obtained as diastereoisomers. The cinchonidine salt was recrystallized once from a mixture of methanol and water (7:10). The pure cinchonidine salt (5 g) was dissolved in 300 mL of the above mixture of solvents and allowed to stand for 90 min in a refrigerator and the precipitate was filtered and dried *in vacuo*. The same procedure was repeated five times. The resolved cinchonidine salt was added to 14 mL of 0.1 *N* sodium hydroxide. To this solution a small amount of ethanol was added until the cinchonidine salt was completely dissolved. The solution was kept in a refrigerator overnight to precipitate white crystalline cinchonidine. After filtration, the filtrate was concentrated to one-third of its original volume and cooled to precipitate cinchonidine completely. After the removal of cinchonidine, the filtrate was evaporated to dryness on an oil bath. The residue was recrystallized once from a mixture of methanol and acetone to give 0.36 g of compound (−)-**5**, mp 222°C, $[\alpha]_D^{25}$ −275° (*c* 0.1, CH_3OH); ord (*c* 0.0028 (400–220 nm), *c* 0.1 (700–400 nm), CH_3OH) 25°C: $[\phi]_{700}$ −750°, $[\phi]_{589}$ −1080°, $[\phi]_{318}$ −48 500° (trough), $[\phi]_{294}$ 0° (intersects), $[\phi]_{260}$ +89 900° (peak), $[\phi]_{228}$ +22 800° (trough); cd (*c* 0.000014 *M*, CH_3OH) 25°C: $[\theta]_{340}$ 0, $[\theta]_{294}$ −85 960, $[\theta]_{258}$ 0, $[\theta]_{242}$ +40 110, $[\theta]_{228}$ 0.

Alkanes with multiple asymmetric centers: synthesis, identification, and ^{13}C nuclear magnetic resonance spectra[1]

PIERRE LACHANCE, S. BROWNSTEIN, AND ARTHUR M. EASTHAM
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received January 16, 1978[2]

PIERRE LACHANCE, S. BROWNSTEIN, and ARTHUR M. EASTHAM. Can. J. Chem. **57**, 367 (1979).

The identification of aliphatic hydrocarbons containing multiple asymmetric centers can be difficult because of the complexity of the nmr spectra and because in capillary chromatography the diastereomers may be resolved to varying degrees. We suggest that the most effective method for identifying such hydrocarbons is through the pattern of retention times developed by the mixture of diastereomers on a suitable capillary glc column.

This paper presents the results of some studies of a series of alkanes having the general form C_2H_5—(CH—CH_3)$_n$—R, where n = 1 to 4, and includes the syntheses and ^{13}C nmr spectra of the compounds.

PIERRE LACHANCE, S. BROWNSTEIN et ARTHUR M. EASTHAM. Can. J. Chem. **57**, 367 (1979).

L'identification d'hydrocarbures aliphatiques possédant plusieurs centres asymétriques est parfois très difficile. La difficulté vient de la complexité de leur spectre rmn et du fait que la chromatographie en phase vapeur avec colonne capillaire peut résoudre, jusqu'à un certain point, les mélanges de diastéréoisomères. Nous proposons cependant que cette dernière méthode, grace aux temps de retention à motif obtenus par passage d'un mélange de diastéréoisomères sur une colonne capillaire appropriée, demeure la plus efficace pour l'identification de tels produits.

Dans cet article on décrit les résultats d'études portant sur une série d'alcanes de formule générale C_2H_5—(CH—CH_3)$_n$—R, où n = 1 à 4. On trouvera aussi les synthèses et les spectres de rmn du ^{13}C de ces composés.

We wish to report here the characterization of a series of alkanes of the general form,

$$CH_3CH_2-\left[\begin{array}{l}CH_3\\|\\-CH-\end{array}\right]_n-R \quad n = 1, 2, 3, \text{ or } 4;\ R = Me, Et, nPr$$

obtained from the oligomerization of 2-butene (1). Nuclear magnetic resonance spectroscopy can often be used to resolve such structural problems but is not effective for these compounds because the multiple asymmetric centers produce numerous diastereomers and consequently some very complex resonance spectra. (When n = 4, the ^{13}C spectrum shows more than 40 lines.) It thus becomes necessary to revert to traditional methods of identification which in practice means that the unknown is assigned tentative structures and is then compared with authentic samples, prepared when necessary by unequivocal synthesis.

Effective comparison of known with unknown is essential and major difficulties arise when, as in the present case, the unknown is a liquid yielding no solid derivative. In these circumstances a mixture melting point determination is not possible and various physical measurements such as infrared absorption, nmr spectra, glc retention time, etc., may not be sufficiently discriminatory.

For the alkanes under study the problem is especially acute. The presence of stereoisomers, which are resolved to varying degrees in capillary chromatography, makes it necessary to determine whether the compounds are 'pure,' i.e., whether the observed inhomogeneity is in fact due to stereoisomers, whether it arises from contamination of the

0008-4042/79/040367-10$01.00/0

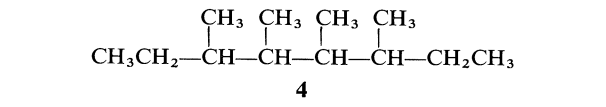
sample by closely related structural isomers, or both. The simplest way to handle the problem is by careful synthesis of the alkane, followed by comparison of the synthetic product with the unknown in the same capillary chromatograph which revealed the composite character of the unknown in the first place. We are aware that glc identifications are not generally acceptable in the chemical journals but we wish to suggest that in the present circumstances capillary chromatography is not only the most suitable technique available for comparing two compounds but may even be definitive when, as here, a compound gives rise to a group of peaks having a well-defined pattern of retention times.

The basic procedure adopted for the synthesis was as follows: the 1,4-addition of an appropriate Grignard reagent to an α,β-unsaturated ketone yields a ketone which can then be treated with an organometallic reagent to give an alcohol corresponding to the desired alkane. The alcohol is dehydrated and the resulting olefin(s) hydrogenated. The chief concern with this series of reactions lies in the possibility that some unexpected product might arise, most probably by rearrangement during the dehydration step, and escape detection because of inadequate control methods. Most of the ketone intermediates in the syntheses did not yield solid derivatives suitable for analysis, presumably because of the presence of diastereomers (see below) but in any event, elemental analysis would not detect the presence of isomers. To minimize such dangers we have carried out the syntheses by at least two independent pathways on the assumption that if the two routes give mixtures of alkanes with identical retention times, then the products are most probably mixtures of stereoisomers and not mixtures of structurally different alkanes. The results seem to be consistent with this assumption.

Discussion

The alkanes to be identified were obtained from the oligomerization of 2-butene by careful fractional distillation of the olefin mixture followed by hydrogenation of the fractions. It was found that most of the lower molecular weight olefins (up to C_{10}) consisted of a single carbon skeleton with the double bond in various positions, giving rise to a single alkane on hydrogenation. These lower alkanes were readily identified since their nmr spectra were simple and good reference material was commercially available; from them it was therefore possible to make good predictions about the structures of the higher members, an important prerequisite to synthesis.

As a typical case of a higher alkane consider the dodecane obtained from the butene oligomers by hydrogenation of a close-boiling distillation fraction. The olefin, in ordinary chromatography (OV-101; 1/8 in. × 6 ft), appeared as a doublet which, when passed into the mass spectrometer, showed a parent mass of 168 only, corresponding to a butene trimer. Capillary glc (Squalane or OV-101; 0.01 in. × 150 ft) further resolved the doublet into about a dozen components which on hydrogenation took up roughly 1 mol equiv. of hydrogen and gave at least five new compounds (Fig. 1*C*). (Complete hydrogenation was difficult so a small amount of unchanged olefin is evident in the chromatogram.) Since from these results it seemed probable that the olefin consisted of a group of *cis–trans* pairs having the carbon skeleton of the normal butene trimer but with the double bond in various positions, it was decided to synthesize the corresponding alkane (**4**) in order to compare it with the group of alkanes obtained by hydrogenating the unknown.



4

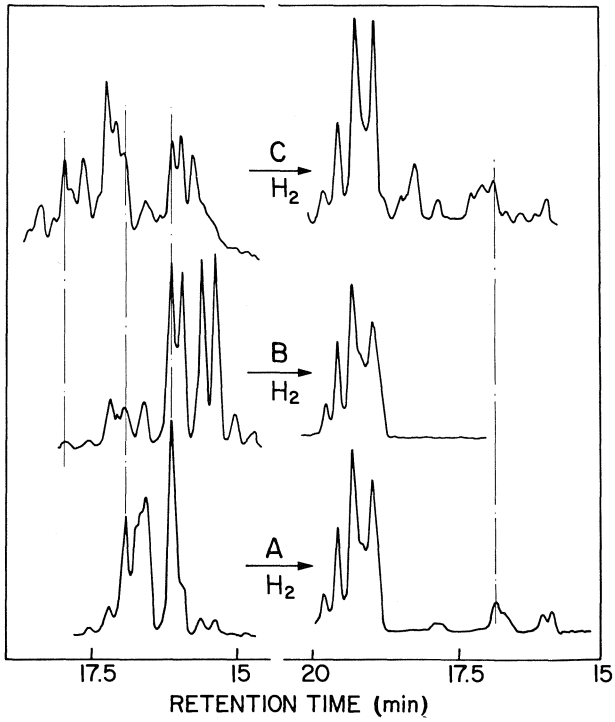


FIG. 1. Chromatograms for 3,4,5,6-tetramethyloctane (**4**) and the corresponding olefins: (*A*) olefins (**3**) prepared from 3,4-dimethylhexanone-2 and *sec*-butyl Li; (*B*) olefins (**8**) prepared from 4,5,6-trimethyloctanone-3 (**6**); (*C*) olefins obtained from the oligomerization of 2-butene. Hydrogenations over Pd/C; chromatograms WCOT squalane, 0.01 in. × 150 ft, 120°C.

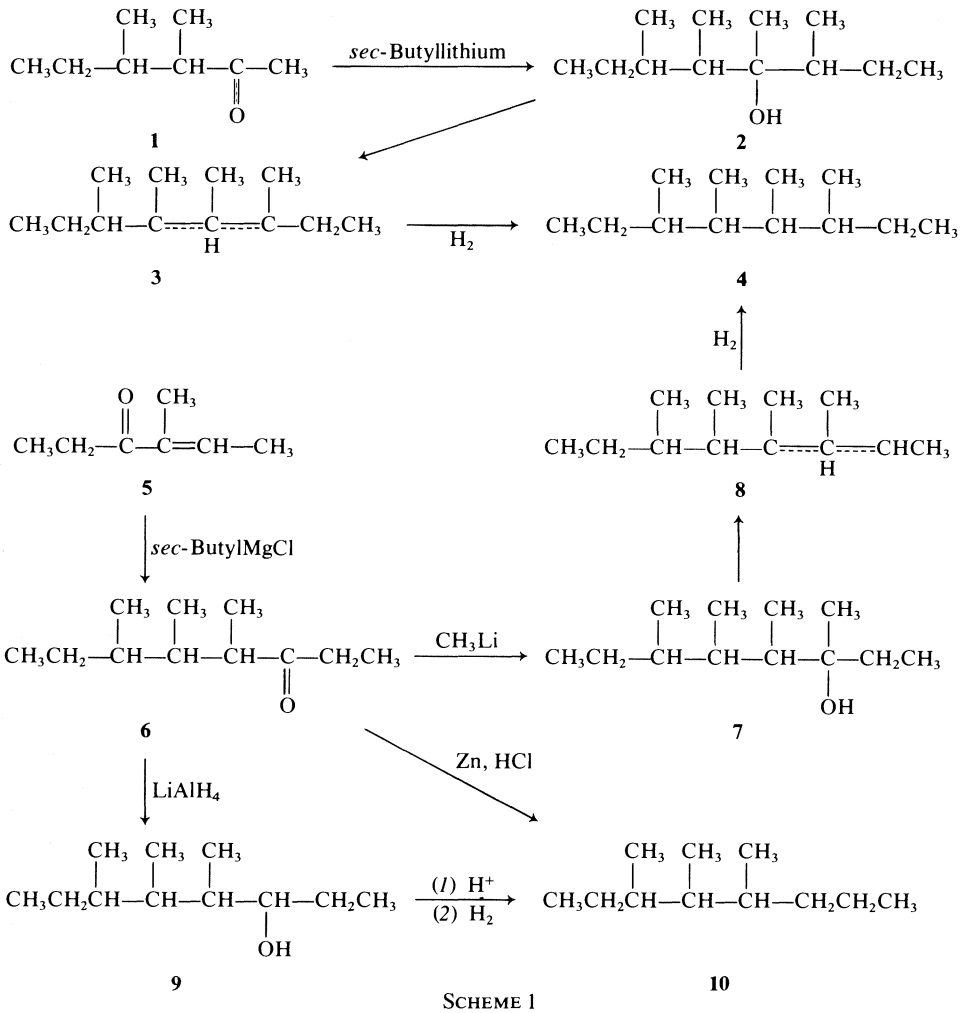


SCHEME 1

Two separate syntheses were carried out as shown in Scheme 1. In the first, 3,4-dimethyl-2-hexanone (**1**) was allowed to react with *sec*-butyllithium to give a dodecanol (**2**). In the other, 3-methyl-2-hexene-4-one (**5**) was treated with *sec*-butylmagnesium chloride to obtain, by 1,4-addition, the undecanone 4,5,6-trimethyl-3-octanone (**6**). Yield was good but the identity of the product could not be confirmed either by proton resonance or through preparation and analysis of a solid derivative. Capillary glc (UCON LB550X) showed the presence of two components of very similar retention times, assumed to be diastereomers. The presumed undecanone was treated with methyllithium to obtain the dodecanol **7**.

The two dodecanols **2** and **7** were dehydrated with acid and, as expected, gave different mixtures of olefins. However these, on hydrogenation, gave identical mixtures of alkanes (Fig. 1*A* and *B*) which in turn were identical with the major part of the product from hydrogenation of the unknown (Fig. 1*C*). We conclude therefore, perhaps somewhat tentatively, that the unknown alkanes and olefins have the carbon skeleton of 3,4,5,6-tetramethyloctane (4).

In the chromatogram of the unknown there is one peak (retention time about 18.5 min) which is not found in the synthetic product and which does not seem to correspond to unchanged olefin; we can only suppose that this material was an impurity, perhaps an isomeric dodecene, in the original olefin.

A comment should be made here about the use of the gas chromatograph – mass spectrometer combination (glc–ms). Throughout most of this work we have been restricted to the use of macro (1/8 in.) columns and electron impact ionization and have therefore used the instrument primarily for determining molecular weight and molecular weight homogeneity of olefin samples; olefins generally give easily observable parent ions. It would have been most helpful to have been able to make similar

measurements on the alkanes and alkanols but the former tend to fragment completely and the latter dehydrate in the electron beam to give the olefin spectra. Chemical ionization might get around this problem and permit better control over the syntheses. Very recently we have had access to capillary glc–ms and have used it to examine the groups of stereoisomers which make up some of the alkanes. By using a long (300 ft × 0.01 in.) squalane WCOT column it proved possible to obtain complete separation of five isomers of 3,4,5,6-tetramethyloctane[3] and of four isomers of 2,3,4,5-tetramethylheptane, and to obtain their individual cracking patterns. Within experimental error all of the stereoisomers for each compound had the same mass spectrum but we are unable to assess the usefulness of this observation in recognizing a group of stereoisomers. We have not found the mass spectrometer to be helpful in defining structures.

The undecane 2,3,4,5-tetramethylheptane (**14**) was prepared in much the same way as the 3,4,5,6-tetramethyloctane, by dehydration of two different undecanols and hydrogenation of the resulting olefins. The undecanols (**12** and **17**) were derived from the reaction of methyllithium with two different trimethylheptanones (**11** and **16**), one of which was obtained by 1,4-addition of isopropylmagnesium bromide to 3-methyl-2-hexene-4-one (**5**) and the other by addition of *sec*-butylmagnesium bromide to 3-methyl-3-hexene-1-one (**15**). A third quite independent synthesis of one of the undecanols (**17**) was based on the Favorskii rearrangement of the bromo ketone **21** and is outlined in Scheme 2.

The 2,3,4,5-tetramethylheptane system is particularly useful for studying these reactions because of the good isomer separation obtained in the capillary chromatogram. The undecanols were therefore dehydrated in different ways, naphthalenesulfonic acid, $SOCl_2$ in pyridine, $POCl_3$ in pyridine, to see if any rearrangement could be detected. Some of the results are shown in Fig. 2. As would be expected, the two alcohols give quite different mixtures of olefins but these can be equilibrated by acid catalysis to identical composition. However, irrespective of the olefin composition, the same group of four alkanes is obtained on hydrogenation. The ratio of the four isomers in the alkane mixture varies considerably with variations in the olefin mixture, presumably because the hydrogenation is stereospecific; also, because of differences in rates of hydrogenation it is sometimes possible to relate the disappearance of particular olefin peaks to the appearance of specific alkane peaks in the chromatogram. It seems clear from these results that no rearrangements are occurring during the reactions and that the mixture of alkanes obtained is a group of diastereomers having the desired skeletal structure.

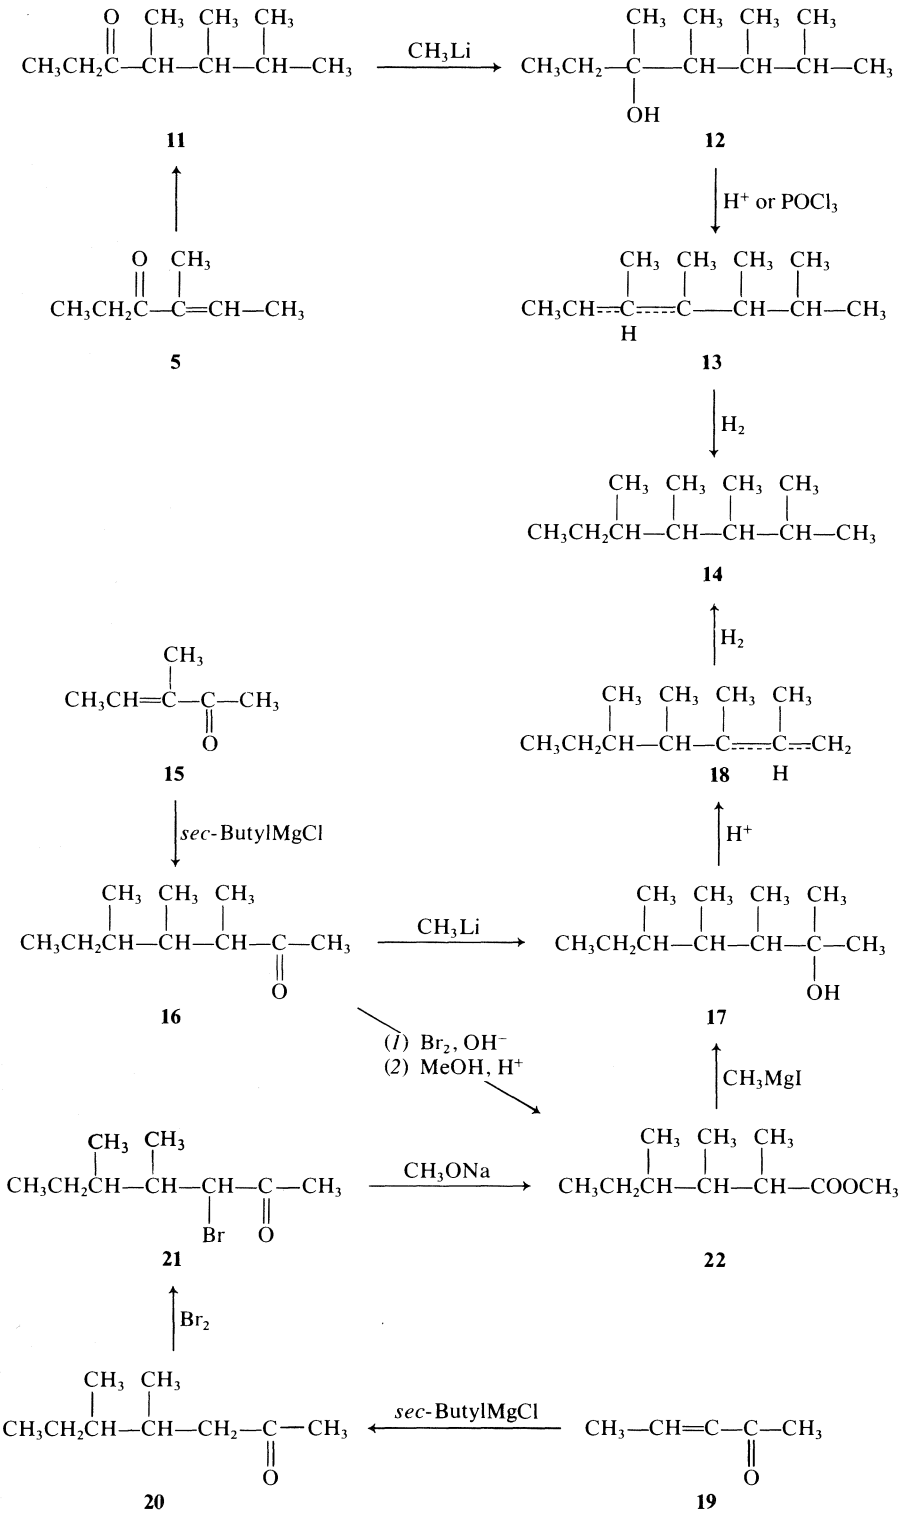
One other point is perhaps worth noting. The synthetic trimethylheptanone **11** appears as a broad peak (unresolved doublet ?) in capillary chromatography but becomes a clear doublet on treatment with acid. If the synthetic product is allowed to react with methylmagnesium iodide to about 60% completion, the unreacted ketone then appears in the glc as a sharp singlet. The olefin mixture obtained from the ketone (via the alcohol) is essentially the same from either partial or complete reaction, and the unreacted ketone is converted back to a glc doublet by treatment with acid. The doublet has the same retention times as the unreacted ketone. We interpret these observations to mean that the ketone is 'pure' but a mixture of stereoisomers which react at different rates with the Grignard reagent.

The alkane 3,4,5-trimethyloctane (**10**) was prepared in two different ways but the diastereomers were unresolved in the capillary chromatograph. The single peak showed a slight shoulder near the apex, thus resembling the closely-related 3,4,5-trimethylheptane which is also largely unresolved. Since the starting materials, and the reactions used to synthesize this undecane, were the same as those used for the other syntheses we are confident of the preparation but the chromatogram is certainly not definitive.

^{13}C Nuclear Magnetic Resonance Results and Discussion

Chemical shifts and longitudinal relaxation times (T_1) for seven methyl branched hydrocarbons are listed in Table 1. Chemical shifts and assignments for the first two of these hydrocarbons have already been reported (2). They are included here to facilitate comparison with the other sets of data and because T_1 values were not previously measured. The assignment of lines to particular carbon atoms was done on the basis of calculated chemical shifts and the differences in relaxation time expected for primary, secondary, and tertiary carbon atoms. Chemical shifts were calculated for the different carbon atoms of the compounds listed in Table 1 by the methods given in refs. 2 and 3. An average deviation from the experimental results of 0.9 ppm was observed for the method of Lindeman and Adams and 1.2 ppm for the modified Grant and Paul approach.

[3]There was no sign of the sixth diastereomer for 3,4,5,6-tetramethyloctane; either it was not formed in the synthesis or was not resolved at all in the capillary chromatogram.



11 **12** **5** **13** **14** **15** **18** **16** **17** **21** **22** **20** **19**

SCHEME 2

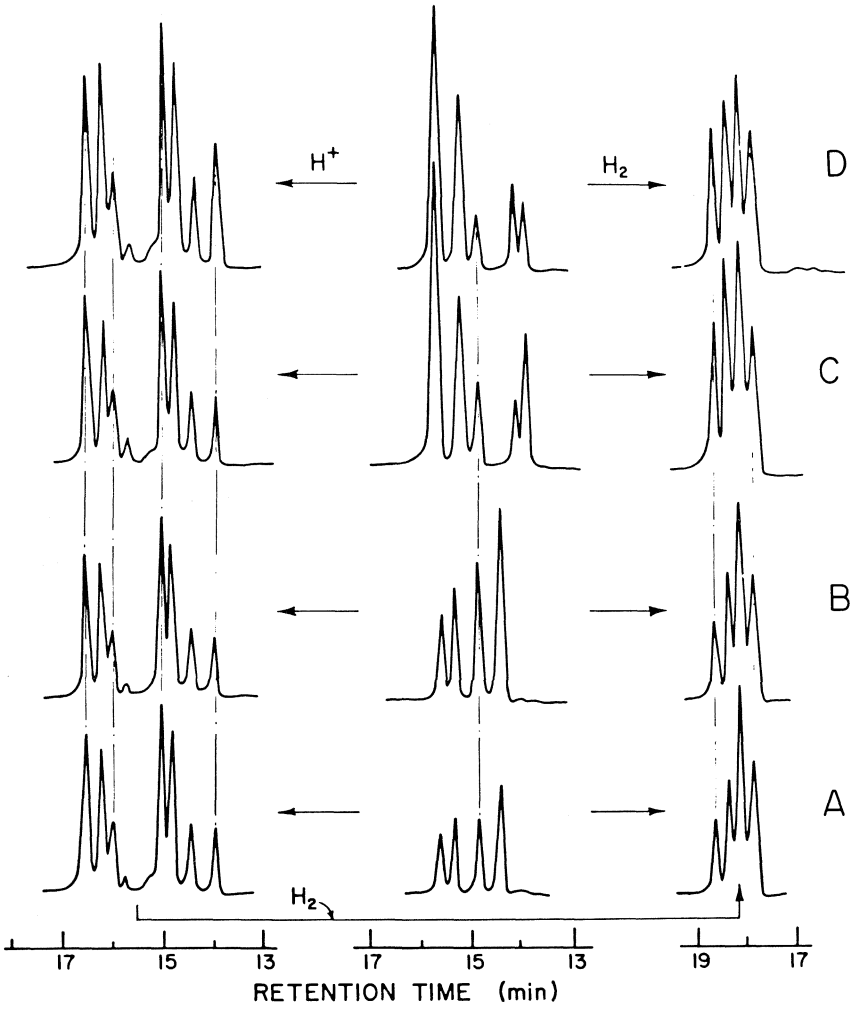


FIG. 2. 2,3,4,5-Tetramethylheptene (**13**) and (**18**) conversion to olefins and alkanes. The center column shows the chromatogram of the olefins as synthesized, the column on the left the olefins after isomerization by acid, and the column on the right the alkanes obtained by hydrogenation of the synthetic olefins or (*A*) of the equilibrium mixture. The synthetic products were obtained as follows: *A* and *B*, from undecanol **17** by dehydration with naphthalenesulfonic acid or with $POCl_3$ respectively; *C* and *D* from undecanol **12** with acid or $POCl_3$, respectively.

The assignment of peaks for 3,4-dimethylhexane and 3,5-dimethylheptane is that of Lindeman and Adams (2). The assignment of lines to particular carbon atoms in 2,3,4-trimethylhexane follows directly from the calculated values. There is excellent agreement between the number of lines observed and those theoretically expected for these compounds. 3,4,5-Trimethylheptane has three diastereomers. For the two *meso* forms there is magnetic equivalence about the center of the carbon chain, so that six lines from carbon atoms 1, 2, 3, 4, 8, and 9 are observed for each isomer. For the last, the *dl* diastereomer, there is a single line from each of the carbon atoms. This magnetic nonequivalence is similar to that observed for the isopropyl methyl carbons in 2,4,6-trimethylheptane and 2,5,8-trimethylnonane (2) and to that observed in triad and pentad sequences in isotactic polypropylene (4).

There are three chiral centers in 3,4,5-trimethyloctane (**10**) so four stereoisomeric pairs are possible. Since there are no equivalent carbon atoms in the molecule, 12 lines are expected from each of the methine and methylene carbons and 20 lines from the methyl carbons. The 24 lines of the secondary and tertiary carbons are clearly separated but because of extensive overlap not all the methyl lines are (separately) observed.

The compound 2,3,4,5-tetramethylheptane (**14**) has three chiral centers and therefore four pairs of optical isomers. All 11 carbon atoms will be mag-

netically nonequivalent in each of these four isomer pairs so a total of 44 lines should be found in the carbon resonance spectrum. At least 41 lines can be distinguished. The only ones which can be identified with any certainty are those from the CH_2 group in each of the four isomers. This was done by a combination of chemical shift, T_1 relaxation, and difference spectroscopy between samples with different isomeric composition (Fig. 2).

For 3,4,5,6-tetramethyloctane (**4**) there are six possible diastereomers, two of which have *meso* configurations. Two of the *dl* diastereomers have complete magnetic equivalence about the central 4–5 bond, the other two like 3,4,5-trimethylheptane have only nonequivalent carbons. From the glc data it is known that the compound contains at least five diastereomers, one of them in rather small concentration. If it is assumed that the least abundant isomer is one of those with no magnetic equivalence, it becomes possible to assign lines from the carbon resonance spectrum to C_2, C_3, and C_4 for five isomers (but see footnote 3).

Experimental

Melting points (evacuated capillaries) and boiling points are uncorrected. Reference alkanes were obtained when available, from Chemical Sample Co., Columbus, OH. Microanalyses were performed by C. Daesslé of Montreal or H. Seguin of these laboratories. Gas–liquid chromatographic comparisons were done by mixing the two components and examining the chromatogram for any sign of separation.

Reactions with organometallic reagents including Grignards were carried out under argon and were worked up by treating the reaction mixtures with NH_4Cl solution and extracting with ether. Olefin hydrogenations were accomplished at atmospheric pressure over 5% palladium-on-carbon as catalyst.

^{13}C resonance spectra with proton noise decoupling at ambient temperature were obtained with a Varian XL-100 spectrometer operating at 25.2 MHz and coupled to a Nicolet TT100A Fourier transform system. T_1 values were obtained by an inversion recovery sequence using the software of the manufacturer or by a saturation recovery sequence (5) using our own programme. Samples were prepared in CS_2 solvent without removal of oxygen, and referenced to internal tetramethylsilane. Chemical shifts are reported in ppm to low field of TMS and relaxation times are in seconds. Free induction decays of 16K were accumulated for spectral widths of 5000 Hz. This gives nominal resolution of 0.75 Hz which is broadened to 1.0 Hz by sensitivity enhancement.

*3,4,5,6-Tetramethyloctane (**4**)*

Method A

A 25.0 g sample of *3-methyl-2,4-pentanedione*, obtained by methylation of 2,4-pentanedione with methyl iodide and sodium *tert*-butylate, was refluxed for 2 h with a Grignard solution prepared from 13.0 g Mg and 40 mL ethyl bromide, to give 29.3 g of crude hydroxyketone. Distillation of the product with 2.0 g oxalic acid gave 20.7 g of unsaturated ketone, hydrogenated to 20.2 g of *3,4-dimethyl-2-hexanone* (**1**), bp 156–157°C (lit. (6) bp 153–154°C).

Compound **1** (5.0 g) was allowed to react at 0°C for 3 h with 50 mL of 11.6% *sec*-butyllithium (Foote Mineral Co.) in hexane to give 6.3 g of crude dodecanol (**2**). The alcohol dehydrates on heating so, without further purification, was treated with naphthalenesulfonic acid to give 1.7 g of olefin. The olefin was then hydrogenated to 1.5 g *3,4,5,6-tetramethyloctane* (**4**), bp 84°C/12 Torr; *n*, 1.4356.

Method B

A 15.0 g portion of *3-methyl-2-hexene-4-one* (**5**) (7) was added at 0°C to a Grignard reagent prepared from 4.0 g Mg and 18 mL *sec*-butyl chloride and the mixture then refluxed for 3 h to give 21.7 g of crude *4,5,6-octanone-3* (**6**). This ketone was fractionally distilled and the material distilling at 106°C/15–18 Torr collected. Yield, 9.2 g; *n*, 1.4342; ir ν_{max} 1710 cm^{-1} (carbonyl).

Ketone **6** (8.0 g) was added at 0°C to 75 mL of 3.5% methyllithium solution in ether and refluxed for 2 h, yielding 8.4 g of crude dodecanol (**7**). Dehydration with 2.0 g naphthalenesulfonic acid at 75°C gave 7.1 g of crude olefins which were fractionally distilled and the fraction passing over at 96–97°C/15–18 Torr retained (5.3 g). A small amount of residual starting ketone was removed by spinning band distillation. Hydrogenation then gave 3.1 g of *3,4,5,6-tetramethyloctane* (**4**), bp 85°C/12 Torr; *n*, 1.4353. The two alkanes prepared by methods *A* and *B* had identical infrared spectra and capillary chromatograms. *Anal.* calcd. for $C_{12}H_{26}$: C 84.60, H 15.39; found: C 84.79, H 15.09.

*3,4,5-Trimethyloctane (**10**)*

4,5,6-Trimethyl-3-octanone (**6**; 2.0 g) was refluxed in ether for 1 h with 0.25 g $LiAlH_4$ to give 1.3 g of undecanol **9**. The alcohol was then dehydrated with 0.5 g naphthalenesulfonic acid in ethanol to give 1.1 g of olefins which on hydrogenation gave 1.0 g *3,4,5-trimethyloctane* (**10**), bp 71°C/12 Torr; *n*, 1.4260; *Anal.* calcd. for $C_{11}H_{24}$: C 84.52, H 15.48; found: C 84.34, H 15.60.

Conversion of the ketone **6** to the alkane **10** can be accomplished by Clemmensen reduction; 1.0 g ketone in 15 mL 35% ethanol was refluxed 1 h with 35 g of zinc, 1.7 g of $HgCl_2$, and 25 mL concentrated HCl. More HCl (20 mL) was added over a further 2 h. A yellow oil (0.8 g) was recovered which, in capillary chromatography on squalane, showed only unchanged ketone and the 3,4,5-trimethyloctane described above. Yield, 30–40% with no indication of other products.

The undecanol **9** and alkane **10** were also prepared from the octanone **1** and *n*-propylmagnesium chloride.

*2,3,4,5-Tetramethylheptane (**14**)*

Method A

Aldol condensation (1% KOH) of 2-butanone with acetaldehyde yields a mixture of 2-hexene-4-one and 3-methyl-2-pentene-4-one (**15**). To obtain the latter in pure form the mixture was partially hydrogenated and then carefully distilled to remove the 2-hexene-4-one. The *3-methyl-2-pentene-4-one* thus obtained was allowed to react with *sec*-butylmagnesium chloride to give, in good yield, the ketone *3,4,5-trimethyl-2-heptanone* (**16**), bp 80–82°C/14 Torr; *n*, 1.4334; mol. wt. (ms) 156. A portion (5.0 g) of this ketone (**16**) was added at 0°C to 35 mL of 3.5% methyllithium solution, then refluxed for 2 h, to give 4.7 g of crude alcohol (**17**). The alcohol was dehydrated at 75°C with 1.0 g naphthalenesulfonic acid to give 2.3 g of olefins which were then hydrogenated to the alkane *2,3,4,5-tetramethylheptane* (**14**).

Method B

3-Methyl-2-hexene-4-one (**5**) (15.5 g; 8) was allowed to react with a Grignard reagent prepared from 4.0 g Mg and 13.8 g 2-chloropropane to give 20.4 g of crude ketone **11**. Fractionation of the product gave 16.8 g of *4,5,6-trimethyl-3-heptanone* (**11**), bp 81–82°C/14 Torr; *n*, 1.4301; mol. wt. (ms)

*Chemical shifts are reported in ppm to low field of TMS in CS_2 and relaxation times are in seconds.
†Particular lines assigned to carbons 1 and 7 could be reversed.
‡Four lines were observed for each carbon atom 1, 2, 3, and 8. Since there are three possible diastereomers, three lines were assigned arbitrarily to carbons 1, 2, 3, 8 and one to carbons 7, 6, 5, and 10 (see text).
§Six lines were found for each carbon atom 2, 3, and 4. Since the gas chromatograph shows five peaks, five lines were assigned arbitrarily to each of carbons 2, 3, and 4 and one to carbons 7, 6, and 5.

156; ir (carbonyl) ν_{max} 1705 cm^{-1}. On treatment with methyllithium, 16.8 g of ketone gave 18.1 g crude alcohol (**12**) which was dehydrated immediately with naphthalenesulfonic acid. The crude olefin product thus obtained was twice fractionally distilled to remove some unreacted ketone and yield a highly pure sample of olefin. Hydrogenation gave *2,3,4,5-tetramethylheptane* (**14**), bp 69°C/12 Torr; *n*, 1.4286. *Anal.* calcd. for $C_{11}H_{24}$: C 84.51, H 15.48; found: C 84.58, H 15.23.

Method C

A 15.0 g portion of *3-pentene-2-one* (**19**) (8) was added at 0°C to a Grignard solution prepared from 5.5 g Mg, 0.35 g CuCl, and 21.2 g 2-chlorobutane and the mixture was refluxed for 2 h and allowed to stand overnight. The 22.7 g of crude product on fractionation gave 12.7 g of *4,5-dimethyl-2-heptanone* (**20**), bp 107–108°C/23 Torr; *n*, 1.4279; ir ν_{max} (carbonyl) 1715 cm^{-1}, (CO—CH_3) 1165 cm^{-1} (lit. (9) 1720, 1162). The semicarbazone had mp 132–133°C (lit. (9) mp 121°C). *Anal.* calcd. for $C_{10}H_{21}N_3O$: C 60.26, H 10.53, N 21.08; found: C 59.76, H 10.78, N 21.22.

4,5-Dimethyl-2-heptanone (**20**; 13.0 g) was brominated with 14.7 g Br_2 in 50 mL dichloromethane and 10 drops acetic acid at 0°C. The crude bromo ketone **21** was added dropwise to 7.0 g sodium methoxide in ether and then refluxed for 3 h. Water was added and the product extracted with ether. Yield, 12.1 g crude, 10.9 g purified *methyl 2,3,4-trimethylhexanoate* (**22**), bp 92°C/15 Torr; *n*, 1.4293; ir ν_{max} ($COOCH_3$) 1735 cm^{-1}, (OCH_3) 1185 cm^{-1}.

An alternative synthesis of *2,3,4-trimethylhexanoic acid* was based on the haloform reaction (10). The methyl ester of the acid obtained in this way had the same pattern of retention times in the capillary glc as that prepared above.

When 5.0 g of the ester **22** was treated with 2 equiv. of methylmagnesium iodide, 5.3 g of oil having strong ir absorption at 3460 cm^{-1} was formed. Dehydration occurred on distillation under reduced pressure; spinning band distillation of the product gave 1.6 g of olefin which hydrogenated to *2,3,4,5-tetramethylheptane* (**14**).

Dehydration of the alcohols **12** and **17** by $POCl_3$ was accomplished by dissolving 1.5 g of alcohol in 12 mL dry pyridine and adding 3 mL $POCl_3$ dropwise at 0°C. The mixture was stirred at room temperature for 5 h, diluted with water, and extracted with ether to give about 1.2 g crude olefins. Hydrogenation then gave 2,3,4,5-tetramethylheptane.

Violation of the '*para*' rule in the boron trifluoride catalyzed cycloaddition of 4,4-dimethyl-2,5-cyclohexadien-1-one to isoprene. Total synthesis of ionene

HSING-JANG LIU AND ERIC N. C. BROWNE

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 18, 1978

HSING-JANG LIU and ERIC N. C. BROWNE. Can. J. Chem. **57**, 377 (1979).

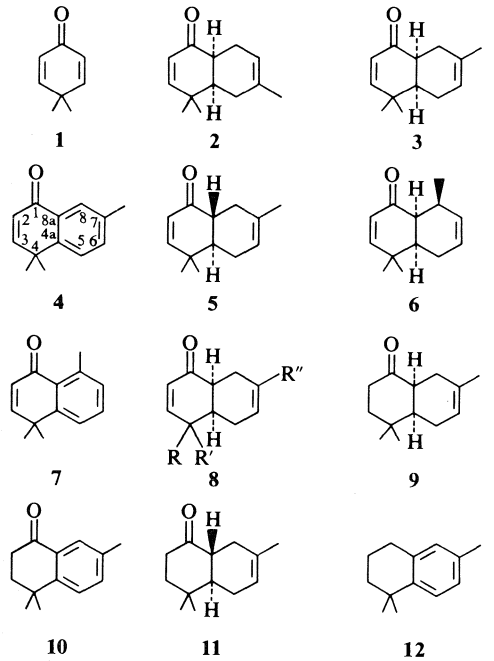
In violation of the '*para*' rule, the boron trifluoride catalyzed addition of 4,4-dimethyl-2,5-cyclohexadien-1-one (**1**) to isoprene gave rise to the unexpected enone **3** as the only adduct. Under similar conditions, the addition of *trans*-piperylene proceeded as predicted by the '*ortho*' rule to give the single adduct **6**. Enone **3** was converted in three steps to the naturally occurring hydrocarbon ionene (**12**).

HSING-JANG LIU et ERIC N. C. BROWNE. Can. J. Chem. **57**, 377 (1979).

Contrairement à la "règle *para*", l'addition catalysée par le trifluorure de bore de la diméthyl-4,4 cyclohexadiène-2,5 one-1 (**1**) à l'isoprène conduit uniquement à la formation de l'énone **3** inattendue. Dans des conditions semblables, l'addition du *trans*-pipérylène conduit, tel que prévu par la "règle *ortho*", à un seul adduit, **6**. On peut transformer l'énone **3** en trois étapes à l'hydrocarbure ionène (**12**) que l'on retrouve dans la nature.

[Traduit par le journal]

In connection with a project directed towards the total synthesis of terpenoids, we have investigated the Diels–Alder reaction of 4,4-dimethyl-2,5-cyclohexadien-1-one (**1**) (1, 2) with isoprene. It has been well established both experimentally (3–6) and theoretically (7, 8, and references therein) that dienophiles in which the double bond is conjugated with an electron-withdrawing group undergo Diels–Alder reaction with 1- and 2-substituted dienes to give '*ortho*' and '*para*' adducts, respectively, as the predominant products. Equally well known is the pronounced enhancement of regioselectivity[1] when the reaction is carried out in the presence of a Lewis acid (8, 11–17). The production of adduct **2** is thus expected to predominate from the cycloaddition of dienone **1** to isoprene, particularly when catalyzed by a Lewis acid.



Treatment of dienone **1** with an excess of isoprene in ether at ambient temperature for 22 days using boron trifluoride as a catalyst resulted in the formation, in 61% yield, of a single 1:1 adduct as clearly indicated by examination of its spectral data.[2] To establish its orientation, the adduct was dehydrogenated with *N*-bromosuccinimide (18) in carbon tetrachloride. The principal product[3] so obtained was shown spectroscopically to possess structure **4**. In its nmr spectrum, the C-8 hydrogen atom, which lies within the deshielding zone of the carbonyl, appeared at a significantly lower field (δ 7.90) as a narrowly split multiplet (<1 Hz) whereas the two remaining aromatic protons appeared at δ 7.27 and 7.37 each with a large coupling constant of 8 Hz. These observations were in agreement only with the assigned structure **4**. It follows that the precursor of

[1]Except in the case of certain dienophiles of type XRC=CHY or XHC=CHY where X and Y are both conjugating and electron withdrawing. In such cases, the reversal of the orientation under thermal conditions could be achieved using the 'guidance-by-catalysis' approach illustrated by the elegant work of Valenta and co-workers (9, 10).

[2]See Experimental for details.

[3]The aromatic compound corresponding to structure **2** was not detected. The balance of the material consisted of bromo derivatives of **3** and **4** as shown by the nmr and mass spectra.

0008-4042/79/040377-04$01.00/0

4 must also possess a methyl group at C-7, as represented by structure **3**,[4] in violation of the '*para*' rule (3, 5, 6) for Diels–Alder addition.

The exclusive formation of such an '*anti-para*'[5] adduct from the addition of isoprene to dienone **1** is, to our knowledge, unprecedented. The unusual orientational effect could well be steric. The exclusion of the otherwise favoured formation of the '*para*' product could be attributed to the interference of the methyl groups of the two counterparts in development of the *endo* transition state (3, 5, 6) when approached in accordance with the '*para*' rule. In agreement with this postulate was the finding that the addition of *trans*-piperylene to dienone **1** under similar conditions proceeded normally to give enone **6**[6] as the only adduct.

From a synthetic viewpoint, the one-step formation of enone **3**, and possibly adducts of type **8** by suitable choice of the reactants, offers an efficient route for the construction of synthetically useful 1-decalone systems. To demonstrate the synthetic utility as well as to further confirm the structure of **3**, we have completed a simple total synthesis of ionene (**12**), a naturally occurring hydrocarbon (20, 21). Reduction of enone **3** with lithium in ammonia (22) afforded a 78% yield of *cis*-ketone **9** which, on treatment with *N*-bromosuccinimide, underwent dehydrogenation giving rise to aryl ketone **10** in 35% yield. The same compound could be prepared in a better yield of 45% from the *trans*-ketone **11** which was obtained in 91% yield by epimerization of **9** with aqueous sodium hydroxide in methanol. Wolff–Kishner reduction (23) of aryl ketone **10** resulted in the formation of ionene (**12**) in 64% yield. The ir, nmr, and mass spectra of the synthetic material were shown to be identical with those of an authentic sample prepared from β-ionone (24).

Experimental

General

Mass spectra were recorded on an AEI MS-50 spectrometer. Infrared spectra were obtained using a Perkin-Elmer Model 457 or a Nicolet 7-199 FT-IR spectrophotometer. Nuclear magnetic resonance spectra were recorded on an HR-100 spectrometer using tetramethylsilane as internal standard. Elemental analyses were performed by the microanalytical laboratory of this department.

cis-*4,4,7-Trimethyl-1,4,4a,5,8,8a-hexahydronaphthalen-1-one (3)*

To a solution of 4,4-dimethyl-2,5-cyclohexadien-1-one (**1**) (4.887 g, 40 mmol) in ether (100 mL) were added, 30 min apart, boron trifluoride etherate (2.46 mL, 20 mmol) and then freshly distilled isoprene (12 mL, 0.12 mol). The resulting solution was stirred at room temperature under a nitrogen atmosphere for 22 days during which time additional isoprene was added (12 mL after each 24-h period for 6 days and a further 40 mL each after 13 and 17 days). The reaction mixture was cooled to 0°C, made basic by dropwise addition of saturated aqueous sodium bicarbonate solution, and extracted with chloroform. The organic solution was washed with water, dried (Na_2SO_4), filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with a solution of 80% ether in Skelly B, gave a mixture consisting of enone **3** and a small amount of polymer. This mixture was subjected to bulb-to-bulb distillation at 90°C/0.5 Torr. The pure enone **3** (4.624 g; 61% yield) thus obtained showed the following spectral data: ir (neat): 3010 (C=CH), 1685 (C=O), 1378, 1365 (CH_3), and 827 cm^{-1} (C=CH); nmr (CCl_4) δ: 1.09 (s, 3H, CH_3), 1.30 (s, 3H, CH_3), 1.66 (s, 3H, $=CCH_3$), 5.18 (br s, 1H, —CH=), 5.68 (d, 1H, J = 10 Hz, —CH=C*H*CO—), and 6.28 (dd, 1H, J = 10, $J' \simeq$ 1 Hz, —C*H*=CHCO—); ms M^+ 190.1354 (calcd. for $C_{13}H_{18}O$: 190.1358). *Anal.* calcd. for $C_{13}H_{18}O$: C 82.06, H 9.54; found: C 81.81, H 9.56.

4,4,7-Trimethyl-1,4-dihydronaphthalen-1-one (4)

Enone **3** (292 mg, 1.49 mmol) was dissolved in carbon tetrachloride (20 mL). *N*-Bromosuccinimide (530 mg, 2.98 mmol) and benzoyl peroxide (10 mg, 0.04 mmol) were added. The mixture was refluxed using a preheated oil bath for 45 min. After cooling to room temperature, it was filtered and concentrated to give an oil which was purified by column chromatography twice on silica gel eluting with a solution of 5–7% ether in petroleum ether. The aryl enone **4** (106 mg; 38% yield) thus obtained showed the following spectral data: ir (neat): 1665 (C=O), 1618, 1500 (C=C), 1383, 1374, 1364 (CH_3), 828, and 891 (aromatic CH); nmr (CCl_4) δ: 1.47 (s, 6H, 2 × CH_3), 2.43 (s, 3H, benzylic CH_3), 6.25 (d, J = 10 Hz, —CH=C*H*CO—), 6.78 (d, J = 10 Hz, —C*H*=CHCO—), 7.27 (md, 1H, J = 8, $J' <$ 1 Hz, C-6 H), 7.37 (d, 1H, J = 8 Hz, C-5 H), and 7.90 (m, 1H, $J <$ 1 Hz, C-8 H); ms M^+ 186.1053 (calcd. for $C_{13}H_{14}O$: 186.1044).

trans-*4,4,7-Trimethyl-1,4,4a,5,8,8a-hexahydronaphthalen-1-one (5)*

A solution of 1 *N* aqueous sodium hydroxide (10 mL) was added to a solution of *cis*-enone **3** (459 mg, 2.42 mmol) in 20 mL of methanol and stirred for 1 h. The mixture was then extracted with methylene chloride. The extracts were washed with water, dried ($MgSO_4$), filtered, and concentrated. Column chromatography on silica gel eluting with 3% ether in petroleum ether gave 400 mg (87% yield) of a mixture of enones **3** and **5** in a ratio of 30:70 as determined by glc analysis on a 8 ft × $\frac{1}{8}$ in. column of 10% diethyleneglycol succinate on 80–100 mesh Chromosorb W (DMCS treated, acid washed).

Recrystallization from ether gave 120 mg of pure **5**, mp 56–60°C, and 279 mg of recovered *cis–trans* mixture. The *trans*-enone **5** showed the following spectral data: ir ($CHCl_3$): 1673 (C=O), 1390, 1383 (CH_3), and 790 cm^{-1} (C=CH); nmr

[4]The stereochemistry of **3** follows from the *cis* principle (3, 5, 6) and its successful epimerization with aqueous sodium hydroxide in methanol to the *trans*-isomer **5**.

[5]This term is used to distinguish this effect from the '*meta*' addition observed by Fleming *et al.* (19), in cases where the substituents of both reactants are electron donating, an effect which was predicted by Houk (7). We wish to emphasize that, although the methyl substituent is '*meta*' to the directing group, the important feature is the violation of the rule which is expected to apply and not the application of a different rule.

[6]The structure of **6** was verified by dehydrogenation with *N*-bromosuccinimide to aryl ketone **7**. Its stereochemistry which is not of crucial importance for the present studies, was tentatively assigned on the basis of the *cis* principle and the *endo* rule (3, 5, 6).

(CCl_4) δ: 1.03, 1.13 (both s, 3H each, —$C(CH_3)_2$—), 1.67 (br s, 3H, =CCH_3), 5.31 (m, 1H, =CH—), 5.69 (d, 1H, J = 10 Hz, —COC*H*=CH—), and 6.55 (d, 1H, J = 10 Hz, —COCH=C*H*—); ms M^+ 190.1359 (calcd. for $C_{13}H_{18}O$: 190.1358). *Anal.* calcd. for $C_{13}H_{18}O$: C 82.06, H 9.54; found: C 81.94, H 9.78.

cis,syn-*4,4,8-Trimethyl-1,4,4a,5,8,8a-hexahydronaphthalen-1-one (**6**)*

To a solution of dienone (**1**) (116 mg, 0.935 mmol) in ether (10 mL), were added, 15 min apart, boron trifluoride etherate (66 mg, 0.468 mmol) and then *trans*-piperylene (1.87 mL, 18.7 mmol). The solution was stirred at room temperature under a nitrogen atmosphere for 6 days after which a solution of *trans*-piperylene (0.94 mL, 9.4 mmol) in ether (5 mL) was added. After further stirring for 3 days, the reaction mixture was made basic with saturated aqueous sodium bicarbonate and extracted with methylene chloride. The extracts were washed with water, dried over magnesium sulfate, and filtered. Concentration of the filtrate followed by column chromatography of residue on silica gel with ether – petroleum ether (1:50) elution gave enone **6** (123 mg; 69% yield); ir ($CHCl_3$): 1686 (C=O), 1397, 1386 (CH_3), and 716 cm^{-1} (HC=CH); nmr (CCl_4) δ: 1.10 (s, 3H, CH_3), 1.33 (s, 3H, CH_3), 1.38 (d, 3H, J = 8 Hz, CH_3), 5.46 (complex, 2H, —CH=CH—), 5.58 (d, 1H, J = 10 Hz, —CH=C*H*CO—), and 6.15 (dd, 1H, J = 10, J' = 1.5 Hz, —C*H*=CHCO—); ms M^+ 190.1359 (calcd. for $C_{13}H_{18}O$: 190.1358). *Anal.* calcd. for $C_{13}H_{18}O$: C 82.06, H 9.54; found: C 81.68, H 9.56.

*4,4,8-Trimethyl-1,4-dihydronaphthalen-1-one (**7**)*

To a solution of enone **6** (85 mg, 0.45 mmol) in carbon tetrachloride (10 mL), were added *N*-bromosuccinimide (159 mg, 0.89 mmol) and benzoyl peroxide (5 mg, 0.02 mmol). The mixture, after refluxing for 30 min, was cooled to room temperature and filtered. Concentration followed by column chromatography of the residue twice on silica gel using a solution of 1% ether in petroleum ether as eluent gave aryl enone **7** (10 mg; 12% yield); ir ($CHCl_3$): 1663 (C=O), 1592 (aromatic), 1395, 1377, and 1364 cm^{-1} (CH_3); nmr (CCl_4) δ: 1.45 (s, 6H, 2 × CH_3), 2.70 (s, 3H, benzylic CH_3), 6.15 (d, 1H, J = 10 Hz, —CH=C*H*CO—), 6.64 (d, 1H, J = 10 Hz, —C*H*=CHCO—), 7.05 (dd, 1H, $J = J'$ = 4 Hz, C-6 H), and 7.30 (d, 2H, J = 4 Hz, C-5 and C-7 H); ms M^+ 186.1039 (calcd. for $C_{13}H_{18}O$: 186.1044).

cis-*4,4,7-Trimethyl-1,2,3,4,4a,5,8,8a-octahydronaphthalen-1-one (**9**)*

Lithium ribbon (480 mg, 69 g-at.) was added over a 10-min period to 360 mL of liquid ammonia (freshly distilled from sodium) at −78°C under a nitrogen atmosphere. After 5 min, a solution of enone **3** (1 g, 5.26 mmol) in ether (60 mL) was added dropwise over 40 min and stirring was continued for an additional 90 min. Solid NH_4Cl was then added to discharge the blue color and ammonia was allowed to evaporate. Addition of water was followed by extraction with chloroform. After washing sequentially with water, 5% hydrochloric acid, and saturated aqueous sodium chloride, the chloroform solution was dried (Na_2SO_4), filtered, and concentrated. Column chromatography of the residue on silica gel eluting with ether – Skelly B (1:20) gave ketone **9** (791 mg; 78% yield); ir (neat): 3010 (C=CH), 1712 (C=O), 1390, 1379, 1366 (CH_3), and 808 cm^{-1} (C=CH); nmr (CCl_4) δ: 0.98 (s, 3H, CH_3), 1.32 (s, 3H, CH_3), 1.65 (br s, 3H, =CCH_3), and 5.17 (br s, 1H, —CH=); ms M^+ 192.1520 (calcd. for $C_{13}H_{20}O$: 192.1514). *Anal.* calcd. for $C_{13}H_{20}O$: C 81.20, H 10.48; found: C 81.44, H 10.59.

trans-*4,4,7-Trimethyl-1,2,3,4,4a,5,8,8a-octahydronaphthalen-1-one (**11**)*

To a solution of ketone **9** (91 mg, 0.47 mmol) in methanol (5 mL) was added 1 *N* aqueous NaOH (5 mL). After stirring at room temperature under a nitrogen atmosphere for 15 h, the reaction mixture was extracted with ether. The organic solution was washed with water and dried ($MgSO_4$). Filtration and concentration gave an oil which was purified by silica gel column chromatography. Elution with ether – petroleum ether (1:25) gave ketone **11** (83 mg; 93% yield); ir (neat): 3005 (C=CH), 1708 (C=O), 1372, 1392 (CH_3), and 793 cm^{-1} (C=CH); nmr (CCl_4) δ: 0.99 (s, 3H, CH_3), 1.07 (s, 3H, CH_3), 1.65 (br s, 3H, =CCH_3), and 5.24 (br s, 1H, —CH=); ms M^+ 192.1517 (calcd. for $C_{13}H_{20}O$: 192.1520). *Anal.* calcd. for $C_{13}H_{20}O$: C 81.20, H 10.48; found: C 81.06, H 10.31.

*4,4,7-Trimethyl-1,2,3,4-tetrahydronaphthalen-1-one (**10**)*

From trans-*Ketone **11***

Ketone **11** (63 mg, 0.32 mmol) was dissolved in carbon tetrachloride (10 mL) and *N*-bromosuccinimide (117 mg, 0.64 mmol) was added. The mixture was heated under reflux for 1 h. After cooling to room temperature, it was filtered. Concentration of the filtrate gave an oil which was purified by column chromatography on silica gel. Elution with a solution of 1.5% ether in petroleum ether gave aryl ketone **10** (28 mg; 45% yield); ir ($CHCl_3$): 1686 (C=O), 1611, 1498 (aromatic), 1390 and 1366 cm^{-1} (CH_3); nmr (CCl_4) δ: 1.34 (s, 6H, 2 × CH_3), 1.92 (complex, 2H, —C*H*$_2$CH$_2$CO—), 2.32 (s, 3H, benzylic CH_3), 2.57 (complex, 2H, —CH_2CO—), 7.18 (s, 1H, —C*H*=CH—) 7.19 (s, 1H, —CH=C*H*—), and 7.69 (s, 1H, C-8 H); ms M^+ 188.1195 (calcd. for $C_{13}H_{16}O$: 188.1201).

From cis-*Ketone **9***

Under similar conditions, oxidation of ketone **9** (99 mg, 0.52 mmol) with *N*-bromosuccinimide (148 mg, 1.04 mmol) in carbon tetrachloride (5 mL) gave aryl ketone **10** (34 mg; 35% yield).

*Ionene (**12**)*

Aryl ketone **10** (34 mg, 0.18 mmol) was dissolved in triethylene glycol (1.8 mL). Hydrazine hydrochloride (199 mg, 2.89 mmol) and anhydrous hydrazine (1.15 mL, 36.2 mmol) were added. The mixture was heated at 130°C (bath temperature) for 3 h. Powdered KOH (408 mg; 12.7 mmol based on 87% KOH) was added and the resulting mixture was heated at 190–200°C for 1 h and 230°C for 2 h; during that period condensers were exchanged and rinsed to remove volatile materials. The reaction mixture, after cooling to room temperature, was combined with rinsings and extracted with ether. The extracts were washed with 5% hydrochloric acid and water, dried ($MgSO_4$), filtered, and concentrated. Column chromatography of the residue on neutral alumina (Woelm II) with petroleum ether elution gave ionene (**12**) (20 mg; 64% yield); ir (neat; KBr window): 1885, 1745 (ArH), 1616, 1500 (C=C), 1386, 1365 (CH_3), 881 and 821 cm^{-1} (ArH); nmr (CCl_4) δ: 1.24 (s, 6H, 2 × CH_3), 1.66 (complex, 4H, —CH_2CH_2—), 2.21 (s, 3H, benzylic CH_3), 2.66 (t, 2H, J = 6 Hz, benzylic CH_2), 6.71 (s, 1H, CH_3—C=C*H*C=), 6.78 and 7.06 (both d, 1H each, J = 8 Hz, —CH=CH—); ms M^+ 174.1410 (calcd. for $C_{13}H_{18}$: 174.1408). The compound was found to be identical in spectral properties with an authentic sample prepared from β-ionone (24).

Branched-chain sugars. Reaction of furanoses with formaldehyde: A simple synthesis of D- and L-apiose[1]

PAK-TSUN HO

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received July 20, 1978

PAK-TSUN HO. Can. J. Chem. **57**, 381 (1979).

A simple synthesis of D- and L-apiose using the aldol condensation of furanose with formaldehyde under alkaline conditions as a key reaction is described.

PAK-TSUN HO. Can. J. Chem. **57**, 381 (1979).

On décrit une synthèse simple du D- et du L-apiose faisant appel à une condensation aldolique du furannose avec le formaldéhyde en milieu alcalin comme étape clé.

[Traduit par le journal]

Introduction

D-Apiose which is a naturally occurring branched-chain sugar is widely distributed in the plant kingdom. The chemistry and biochemistry of apiose continue to be of interest. Several groups have reported the synthesis of D- or L-apiose (1).

In the previous paper (2), the author reported an efficient and stereospecific method for the preparation of 2-*C*-hydroxymethyl branched sugar by way of condensation of a furanose with formaldehyde under alkaline conditions. To demonstrate further the potential and generality of this type of condensation in the branched carbohydrate field, a simple synthesis of D- and L-apiose, using the aldol condensation as a key reaction, is described.

Results and Discussion

Treatment of 2,3:5,6-di-*O*-isopropylidene-D-mannofuranose (**1**) (3) with excess 37% aqueous solution of formaldehyde and potassium carbonate (at pH 10) in methanol at 80°C yielded exclusively the 2-*C*-hydroxymethyl derivative **2** in 86% yield (2). The product **2** was a chromatographically homogeneous syrup and exhibited a specific rotation of +11° (*c* 1.2, methanol). Its corresponding diacetate **3** was obtained under standard acetylation conditions in excellent yield, $[\alpha]_D$ +31.5° (*c* 1.4, chloroform). Interestingly, its ^{1}H nmr spectrum showed a sharp singlet at 6.30 ppm for the C-1 proton and suggested that one anomer was formed. Further, oxidation of **2** with bromine containing barium carbonate in water provided the lactone **4** in almost quantitative yield, mp 106°, $[\alpha]_D$ +34° (*c* 2.6, chloroform).

Now transformation of compound **2** to 2,3-*O*-isopropylidene-D-apiose (**6**) could be accomplished in a simple one-pot operation. Selective hydrolysis of compound **2** in aqueous methanol containing concentrated sulfuric acid at room temperature overnight resulted in removal of the 5,6-*O*-isopropylidene group and afforded exclusively 2-*C*-(hydroxymethyl)-2,3-*O*-isopropylidene-D-mannofuranose (**5**), which for the purpose of characterization could be isolated quantitatively as a homogeneous syrup, $[\alpha]_D$ +16.3° (*c* 3.2, acetone). In practice, however, the reaction mixture was neutralized to pH 7 and compound **5** was reduced readily with excess sodium borohydride at room temperature. After neutralization of the aqueous reaction mixture, oxidation of the resulting reduction product with sodium metaperiodate gave crystalline 2,3-*O*-isopropylidene-D-apiose (**6**), mp 72°C, $[\alpha]_D$ −40° (*c* 1.5, chloroform).[2] Using this one-pot reaction, crystalline compound **6** could be produced in 79% yield from compound **2**. Sharp singlets at 5.34 and 4.29 ppm for C-1 and C-2 protons in its ^{1}H nmr spectrum indicate that these protons have to be in *trans* configuration and that it is a β-D-anomer (5). Compound **6** after hydrolysis with Dowex 50W (H^+) in water at 70°C and removal of the 2,3-*O*-isopropylidene group yielded D-apiose (**7**) in almost quantitative yield, $[\alpha]_D$ +5.2° (*c* 1.1, water). Its *N*-benzyl-*N*-phenylhydrazone was identical with a sample prepared from natural apiose (4).

Treatment of 2,3-*O*-isopropylidene-D-hamamelose (**8**) (2) with excess sodium borohydride in water at room temperature afforded the corresponding reduction product, which, after neutralization of the aqueous reaction mixture with acetic acid, was oxidized subsequently with sodium metaperiodate to give crystalline 2,3-*O*-isopropylidene-L-apiose (**9**) in 82% yield, mp 74°C, $[\alpha]_D$ +39° (*c* 1.7, chloroform). Its ^{1}H nmr spectrum was completely identical with the spectrum of D-isomer **6**. On treatment of compound **9** under

[1]NRCC No. 17060.

[2]Williams and Jones (4) obtained compound **6** as a syrup, $[\alpha]_D$ −35° (*c* 0.87, methanol).

similar conditions described for the preparation of compound **6**, L-apiose (**10**) was obtained in excellent yield, $[\alpha]_D$ −5.0° (*c* 1.1, water), and was characterized as its *N*-benzyl-*N*-phenylhydrazone prepared by Schaffer's method, mp 136°C, $[\alpha]_D$ −76.5° (*c* 1.8, pyridine) (6).

Experimental

Melting points were determined on a Reichert hot stage apparatus and are uncorrected. Optical rotations were measured with a Perkin-Elmer Model 141 automatic polarimeter at room temperature. Infrared spectra were of chloroform solutions and ^{1}H nmr spectra were of deuteriochloroform solutions with TMS as internal reference. Thin-layer and preparative-layer chromatography was done using silica gel containing a fluorescent indicator (G_{254}).

2-C-(Hydroxymethyl)-2,3:5,6-di-O-isopropylidene-D-mannofuranose (2)

2,3:5,6-di-*O*-isopropylidene-D-mannofuranose (1) (4) (3.86 g) and potassium carbonate (2.8 g) were dissolved in methanol (50 mL) and 37% aqueous solution of formaldehyde (30 mL). The solution was heated at 85°C (oil bath temperature) under argon for 2 days, after which time it was neutralized with 10% aqueous sulfuric acid. Evaporation of the solvent to dryness gave a residue which was extracted with chloroform and the extracts were concentrated to a syrup. Chromatography of the crude product on silica gel using 4% methanol in chloroform as the eluant gave **2** as a chromatographically homogeneous syrup (3.84 g, 86%); $[\alpha]_D$ +11° (*c* 1.2, methanol); ir ($CHCl_3$): 3550 and 3380 cm^{-1} (hydroxyl); ^{1}H nmr ($CDCl_3$) δ: 5.43 (s, 1H, C-1 proton), 4.70 (d, 1H, C-3 proton), 3.92 (m, 2H, C-2′ protons), and 1.50 ppm (broad s, 12H, four methyls). *Anal.* calcd. for $C_{13}H_{22}O_7$: C 53.78, H 7.64; found: C 53.46, H 7.52.

1-O-Acetyl-2-C-(acetoxymethyl)-2,3:5,6-di-O-isopropylidene-D-mannofuranose (3)

2-*C*-(Hydroxymethyl)-2,3:5,6-di-*O*-isopropylidene-D-mannofuranose (**2**) (50 mg) was acetylated with acetic anhydride (10 drops) in dry pyridine (1 mL) at room temperature overnight. The reaction mixture was isolated in the usual manner and yielded compound **3** as a syrup (54 mg, 85%); $[\alpha]_D$ + 31.5° (*c* 1.4, chloroform); ir ($CHCl_3$): 1750 cm^{-1} (acetate); ^{1}H nmr ($CDCl_3$) δ: 6.30 (s, 1H, C-1 proton), 4.73 (d, 1H, C-3 proton), 4.46 (s, 2H, C-2′ protons), and 2.13 ppm (s, 6H, two acetoxyls). *Anal.* calcd. for $C_{17}H_{26}O_9$: C 54.54, H 7.00; found: C 54.68, H 7.12.

Oxidation of Compound 2 to the Corresponding Lactone 4

Barium carbonate (800 mg) was suspended in an aqueous solution of compound **2** (189 mg) in distilled water (10 mL). Bromine (0.6 mL) was added dropwise with stirring, after which time the reaction mixture was filtered and the filtrate was evaporated to dryness. The residue was extracted with chloroform. The extracts were concentrated to a syrup which was crystallized from ether–hexane to yield the pure lactone **4** (170 mg, 90%) and the product had melting point 106°C; $[\alpha]_D$ +34° (*c* 2.6, chloroform); ir ($CHCl_3$): 3500 (hydroxyl), 1785 cm^{-1} (lactone); ^{1}H nmr ($CDCl_3$) δ: 4.92 (d, 1H, C-3 proton), 4.58 (q, 1H, C-4 proton), 4.06 (q, 2H, C-2′ protons), and 1.50 ppm (broad s, 12H, four methyls). *Anal.* calcd. for $C_{13}H_{20}O_7$: C 54.16, H 6.99; found: C 54.21, H 6.97.

2-C-(Hydroxymethyl)-2,3-O-isopropylidene-D-mannofuranose (5)

A solution of compound **2** (280 mg) in 20% aqueous methanol (8 mL) containing small amount of concentrated

sulfuric acid (0.05 mL) was stirred at room temperature overnight and tlc showed the starting material had been completely consumed with the formation of a new component. The solution was neutralized with sodium bicarbonate and evaporated to dryness. The residue was then extracted with ethyl acetate. Evaporation of the solvent afforded the product **5** as a homogeneous syrup (237 mg, 98%). $[\alpha]_D$ +16.3° (*c* 3.2, acetone); ^{1}H nmr (acetone-d_6) δ: 5.29 (broad s, 1H, C-1 proton), 4.65 (d, 1H, C-3 proton), and 1.43 ppm (s, 6H, two methyls). *Mol. wt.* calcd. for $C_{10}H_{18}O_7$: 250; found (mass spectroscopy): 250.

*2,3-*O*-Isopropylidene-*β*-*D*-apiose (**6**)*

A solution of compound **2** (459 mg) in 20% aqueous methanol (12 mL) containing 1 drop of concentrated sulfuric acid was stirred at room temperature overnight, after which it was neutralized to pH 7 and an excess of sodium borohydride (180 mg) was added in portions with stirring. After 4 h at room temperature acetic acid was then added until the pH of the solution was at 7. To the stirred solution at 0°C, sodium metaperiodate (580 mg, 2 equiv.) was added in portions and the stirring was continued at room temperature for a further 1 h. Evaporation of the solvent to dryness gave a residue which was extracted with chloroform three times. Removal of the solvent yielded a solid material. Pure D-apiose derivative **6** (265 mg, 79%) was obtained by recrystallization from ether–hexane and melted at 72°C; $[\alpha]_D$ −40° (*c* 1.5, chloroform); ir ($CHCl_3$): 3500 cm^{-1} (hydroxyl); ^{1}H nmr ($CDCl_3$): δ 5.34 (d, J = 4 Hz, 1H, C-1 proton, singlet when D_2O added), 4.29 (s, 1H, C-2 proton), 4.10 (d, J = 4 Hz, OH, disappearing when D_2O added), 3.93 (s, 2H, C-4 protons) 3.74 (d, J = 5 Hz, 2H, C-3′ protons, singlet when D_2O added), 2.93 (t, J = 5 Hz, OH, disappearing when D_2O added), 1.40 and 1.30 ppm (25, 6H, two methyls). *Anal.* calcd. for $C_8H_{14}O_5$: C 50.52, H 7.42; found: C 50.58, H 7.56.

*D-Apiose (**7**) and its* N*-Benzyl-*N*-phenylhydrazone*

2,3-*O*-Isopropylidene-D-apiose **6** (250 mg) was hydrolyzed with Dowex 50W (H^+) resin (300 mg) at 70°C (oil bath temperature) for 5 h. The resin was removed by filtration and the filtrate was evaporated to dryness to afford D-apiose (**7**) as a syrup (198 mg, 96%), $[\alpha]_D$ +5.2° (*c* 1.1, water). D-Apiose (**7**) was treated with a solution of *N*-benzyl-*N*-phenylhydrazine (1.2 equiv.) in ethanol at room temperature for 3 h. Evaporation of the solvent gave a solid material. Recrystallization of the crude product from chloroform–methanol yielded pure *N*-benzyl-*N*-phenylhydrazone of **7**, $[\alpha]_D$ −75° (*c* 1.7, pyridine), mp 137°C. This was found to be identical in all respects (mp specific rotation, nmr) with a sample prepared from natural apiose. *Anal.* calcd. for $C_{18}H_{22}O_4N_2$: C 65.40, H 6.70, N 8.50; found: C 65.38, H 6.52, N 8.38.

*2,3-*O*-Isopropylidene-L-apiose (**9**)*

To a stirred solution of 2,3-*O*-isopropylidene-D-hamamelose (**8**) (3) (425 mg) in distilled water (20 mL) was added an excess of sodium borohydride (152 mg). The reaction mixture was stirred at room temperature for 1 h, after which time the reaction mixture was neutralized to pH 7 with acetic acid. Sodium metaperiodate (420 mg, 1 equiv.) was added with stirring. After 1 h at room temperature, the solution was taken to dryness and the residue was then extracted with chloroform. Evaporation of the solvent and recrystallization of the crude product from ether–hexane yielded the pure product **9** (302 mg, 82%), mp 74°C; $[\alpha]_D$ +39° (*c* 1.7, chloroform); its ^{1}H nmr spectrum was completely identical with the spectrum of compound **6**. *Anal.* calcd. for $C_8H_{14}O_5$: C 50.52, H 7.42; found: C 50.63, H 7.56.

*L-Apiose (**10**) and its* N*-Benzyl-*N*-phenylhydrazone*

2,3-*O*-Isopropylidene-L-apiose (**9**) (190 mg) was hydrolyzed under the same conditions used for the preparation of D-apiose (**7**), and L-apiose (**10**) (140 mg) was obtained as a syrup in 91% yield, $[\alpha]_D$ −5.0° (*c* 1.1, water). Its *N*-benzyl-*N*-phenylhydrazone was prepared by the same procedure described above for the *N*-benzyl-*N*-phenylhydrazone of **7**. It had melting point 136°C and $[\alpha]_D$ −76.5° (*c* 1.8, pyridine) and was identical in all respects with a sample prepared by Schaffer's method. *Anal.* calcd. for $C_{18}H_{22}O_4N_2$: C 65.40, H 6.70, N 8.50; found: C 65.41, H 6.65, N 8.42.

A simple conversion of 2,3-*O*-isopropylidene-D-hamamelose, prepared by reaction of 2,3-*O*-isopropylidene-D-ribose with formaldehyde, into L-dendroketose is described.

PAK-TSUN HO. Can. J. Chem. **57**, 384 (1979).

On décrit une transformation simple du *O*-isopropylidène-2,3 D-hamamelose, obtenu par réaction du *O*-isopropylidène-2,3 D-ribose avec le formaldéhyde, en L-dendrocétose.

[Traduit par le journal]

Introduction

Reaction of 1,3-dihydroxy-2-propanone under alkaline conditions provided a biosynthetically interesting and unnatural branched-chain hexose, which was named dendroketose (1). It was also observed by the same investigator that the L-isomer is preferentially fermented by a mold and the D-isomer, 4-*C*-(hydroxymethyl)-D-*glycero*-pentulose, could then be isolated.

An effort to synthesize L-dendroketose from 2,3:4,5-di-*O*-isopropylidene-*aldehydo*-D-arabinose failed because the intermediate racemized when treated with base (2). However, very recently, the same group reported a successful synthesis of this sugar (3).

In the previous communication (4), a general and stereospecific method for the synthesis of branched sugar by way of condensation of furanoses with formaldehyde and the utilization of this facile technique in synthesis have been described. The present paper reports the further use of our method in a simple synthesis of L-dendroketose.

Results and Discussion

On treatment of 2,3-*O*-isopropylidene-D-hamamelose **1**, prepared by reaction of 2,3-*O*-isopropylidene-D-ribose with formaldehyde (4), with 2.2 equiv. of benzoyl chloride in pyridine and benzene at 0°C, the dibenzoate **2** after work-up and crystallization was obtained in 89% yield, mp 116°C, $[\alpha]_D$ −2.5° (*c* 2.2, chloroform). Compound **2** was reduced readily with excess sodium borohydride in aqueous tetrahydrofuran and yielded 5-*O*-benzoyl-2-*C*-(benzoyloxymethyl)-2,3-*O*-isopropylidene-D-*erythro*-pentitol **3** in 91% yield as a chromatographically homogeneous syrup $[\alpha]_D$ +24° (*c* 1.5, chloroform). Tritylation of compound **3** with 4,4′-dimethoxytrityl chloride in pyridine at room temperature provided quantitatively the 4,4′-dimethoxytrityl ether **4**, $[\alpha]_D$ −6.4° (*c* 1.1, chloroform).

It is noteworthy that compound **4** could be prepared by an alternative route with complete selectivity as follows. Reduction of compound **1** with sodium borohydride in water afforded the corresponding reduction product, which after work-up was treated carefully with 2.1 equiv. of benzoyl chloride in pyridine and benzene (1:1) at −5°C overnight and then treated subsequently with 4,4′-dimethoxytrityl chloride in the same reaction mixture at room temperature to give a homogeneous material in 60% yield from the starting compound **1**. This material was completely identical with compound **4** in all respects.

Now compound **4** could be oxidized to 1-*O*-benzoyl-4-*C*-(benzoyloxymethyl)-5-*O*-(4,4′-dimethoxytrityl)-3,4-*O*-isopropylidene-L-*glycero*-pentulose **5** in 80% yield by way of chromium trioxide–pyridine complex in anhydrous methylene dichloride, $[\alpha]_D$ −24° (*c* 1.5, chloroform). When the ketone **5** was treated with 80% aqueous acetic acid at room temperature overnight, crystalline 1-*O*-benzoyl-4-*C*-(benzoyloxymethyl)-3,4-*O*-isopropylidene-L-dendroketose **6** was obtained in 94% yield and exhibited a specific rotation of +47.2° (*c* 1.1, chloroform). It seemed unlikely that racemization at C-3 would take place under such mild acidic treatment. Finally alkaline hydrolysis of **6** in methanolic sodium hydroxide at room temperature gave crystalline 3,4-*O*-isopropylidene-L-dendroketose **7** in quantitative yield, mp 98°C, $[\alpha]_D$ +48.6° (*c* 1.4, chloroform). To establish the structure and configurational purity of our synthetic material, 1,2:3,4-di-*O*-isopropylidene-L-dendroketose **8** was prepared. When compound **7** was dissolved in anhydrous acetone containing a

[1]NRCC No. 17102.

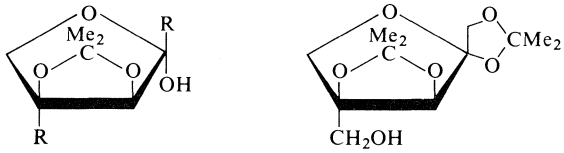
5



6 R = CH_2OCph
7 R = CH_2OH **8**

small amount of *p*-toluenesulfonic acid at room temperature, the desired compound **8** was obtained as the sole product, mp 87°C, $[\alpha]_D$ +122° (*c* 0.7, acetone), and it was identical with an authentic sample. The overall yield from **1** was 60%.

Experimental

Melting points were determined on a Reichert hot stage apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer Model 141 automatic polarimeter at room temperature. ^{1}H nmr spectra were taken on a Varian E360 spectrometer using tetramethylsilane as an internal reference. Infrared spectra were of chloroform solutions. Thin-layer and preparative-layer chromatography was done using silica gel containing a fluorescent indicator (G_{254}).

*2-C-(Benzoyloxymethyl)-5-O-benzoyl-2,3-O-isopropylidene-*D*-hamamelose (2)*

To a stirred solution of 2,3-*O*-isopropylidene-D-hamamelose **1** (4) (764 mg) in dry pyridine (6 mL) and benzene (3 mL) was added dropwise a solution of benzoyl chloride (1.1 g, 2.2 equiv.) in benzene (6 mL) at 0°C and the reaction mixture was stirred at 0°C overnight. The reaction mixture was diluted with chloroform and washed with cold 10% aqueous sulfuric acid, then with aqueous sodium bicarbonate solution and finally with water. After drying over magnesium sulfate, evaporation of the solvent gave a syrup which crystallized on standing. Recrystallization from ether yielded compound **2** (1.3 g, 89%), mp 116°C; $[\alpha]_D$ −2.5° (*c* 2.2, chloroform); infrared ($CHCl_3$): 3500 (OH), 1720 cm^{-1} (benzoate); ^{1}H nmr ($CDCl_3$) δ: 5.55 (d, J = 4 Hz, 1H, C-1 proton, singlet when D_2O added), 4.83 (d, 2H, C-5 protons), 4.75 (s, 1H, C-3 proton), 4.60 (s, 2H, C-2′ protons), 4.33 (d, J = 4 Hz, OH, disappearing when D_2O added), 1.55 (s, 3H, methyl), and 1.46 ppm (s, 3H, methyl). *Anal.* calcd. for $C_{23}H_{24}O_8$: C 64.48, H 5.65; found: C 64.45, H 5.44.

*2-C-(Benzoyloxymethyl)-5-O-benzoyl-2,3-O-isopropylidene-*D*-erythro-pentitol (3)*

A solution of compound **2** (720 mg) in 10% aqueous tetrahydrofuran (40 mL) was cooled to 0°C and sodium borohydride (300 mg) was added with stirring. After 1 h, acetic acid was added dropwise until the solution became slightly acidic (pH 6). Sodium chloride was then added and the solution was extracted with chloroform several times. Drying over magnesium sulfate and evaporation of the chloroform solvent yielded the product **3** (660 mg) as a homogeneous syrup in 90% yield; $[\alpha]_D$ +24° (*c* 1.5, chloroform); infrared ($CHCl_3$): 3500 ~ 3400 (OH), 1720 cm^{-1} (benzoate); ^{1}H nmr ($CDCl_3$) δ: 4.70 (m, 2H, C-5 protons), 4.63 (s, 2H, C-2′ protons), 3.84 (s, 2H, C-1 protons), and 1.42 ppm (s, 6H, two methyls). *Mol. wt.* calcd. for $C_{23}H_{26}O_8$: 430; found (mass spectroscopy): 430.

Tritylation of Compound 3

Method A

A mixture of compound **3** (430 mg) and 4,4′-dimethoxytrityl chloride (410 mg, 1.2 equiv.) in pyridine (6 mL) was stirred at room temperature overnight. The solvent was evaporated *in vacuo* and the crude product was purified by preparative tlc on silica gel; 702 mg of the pure compound **4** was obtained as a foam and the yield was 95%; $[\alpha]_D$ −6.4° (*c* 1.1, chloroform); infrared ($CHCl_3$): 3470 (OH), 1720 cm^{-1} (benzoate); ^{1}H nmr ($CDCl_3$) δ: 4.87 (q, 2H, C-2′ protons), 4.34 (m, 2H, C-5 protons), 3.75 (s, 6H, two methoxyls), 3.50 (q, 2H, C-1 protons), 1.35 and 1.30 ppm (two s, 6H, two methyls). *Anal.* calcd. for $C_{45}H_{44}O_{10}$: C 72.56, H 5.95; found: C 72.62, H 6.01.

Method B

To a stirred solution of compound **1** (140 mg) in 90% aqueous tetrahydrofuran (6 mL) was added sodium borohydride (50 mg). The reaction mixture was stirred at room temperature for 2 h, neutralized with acetic acid, and then evaporated to complete dryness *in vacuo*. The crude product was treated with benzoyl chloride (196 mg, 2.1 equiv.) in pyridine (6 ml) at 0°C overnight, after which time 4,4′-dimethoxytrityl chloride (256 mg, 1.2 equiv.) was added and the reaction mixture was stirred at room temperature for 4 h. The yellow solution was then diluted with chloroform. The chloroform solution was washed with aqueous sulfuric acid and then with water, dried over anhydrous magnesium sulfate, and evaporated to dryness. The crude product **4** was purified by preparative tlc on silica gel. The pure **4** was obtained as a foamed material (156 mg, 60%) which was identical with the material prepared by method A.

1-O-*Benzoyl*-*4*-C-*(benzoyloxymethyl)*-*5*-O-*(4,4′-dimethoxytrityl)*-*3,4*-O-*isopropylidene*-L-glycero-*pentulose (**5**)*

A solution of the alcohol **4** (900 mg) in anhydrous methylene dichloride (10 mL) was added dropwise to a stirred solution of chromium trioxide – pyridine complex (3 g) in the same solvent (20 mL) and the mixture was stirred at room temperature for 5 h. The reaction mixture was diluted with ether (150 mL) and the dark precipitate was then removed by filtration. The filtrate was washed with water, dried over anhydrous magnesium sulfate, and concentrated to a syrup. Purification of the syrup by preparative tlc on silica gel yielded 720 mg (80%) of the ketone **5** as a homogeneous syrup; $[\alpha]_D$ −24° (*c* 1.5, chloroform); infrared ($CHCl_3$): 1720 cm^{-1} (benzoate and ketone); ^1H nmr ($CDCl_3$) δ: 5.16 (q, 2H, C-5 protons), 4.75 (s, 1H, C-3 protons), 4.60 (q, 2H, C-2′ protons), 3.75 (s, 6H, two methoxyls), 3.33 (q, 2H, C-1 protons), 1.73 and 1.45 ppm (two s, 2H, two methyls). *Anal.* calcd. for $C_{45}H_{42}O_{10}$: C 72.76, H 5.70; found: C 72.71, H 5.62.

1-O-*Benzoyl*-*4*-C-*(benzoyloxymethyl)*-*3,4*-O-*isopropylidene*-L-*dendroketose (**6**)*

A solution of the ketone **5** (440 mg) in 80% aqueous acetic acid (4 mL) was stirred at room temperature overnight, at which time the solution was evaporated to dryness *in vacuo*. Pure L-dendroketose derivative **6** was isolated by preparative tlc on silica gel and recrystallization from ether–hexane afforded 252 mg (94%) of **6**, mp 101°C; $[\alpha]_D$ +47.2° (*c* 1.1, chloroform); infrared ($CHCl_3$): 3560 and 3480 (OH), 1720 cm^{-1} (benzoate); ^1H nmr ($CDCl_3$) δ: 4.70 and 4.61 (2q, 4H, C-1 and C-4′ protons), 4.65 (s, 1H, C-3 proton), 4.19 (s, 2H, C-5 protons), 3.62 (s, OH, exchanged with D_2O), 1.56 and 1.47 ppm (two s, 6H, two methyls). *Anal.* calcd. for $C_{23}H_{24}O_8$: C 64.48, H 5.65; found: C 64.46, H 5.62.

3,4-O-*Isopropylidene*-L-*dendroketose (7)*

A solution of compound **6** (209 mg) and sodium hydroxide (40 mg) in methanol (7 mL) was stirred at room temperature for 1 h. The solution was neutralized with 5% aqueous sulfuric acid and evaporated to dryness. The residue was extracted several times with chloroform. Evaporation and crystallization from ether–hexane gave pure **7** (106 mg, 98%), mp 98°C; $[\alpha]_D$ +48.6° (*c* 1.4, chloroform); infrared ($CHCl_3$): 3500 and 3350 cm^{-1} (OH); ^1H nmr ($CDCl_3$ + D_2O) δ: 4.36 (s, 1H, C-3 protons), 4.04 (s, 2H, C-5 protons), 3.85 (broad s, 4H, C-1 and C-4′ protons), 1.52 and 1.43 ppm (two s, 6H, two methyls). *Anal.* calcd. for $C_9H_{16}O_6$: C 49.08, H 7.33; found: C 49.07, H 7.34.

1,2:*3,4*-*Di*-O-*isopropylidene*-L-*dendroketose (**8**)*

3,4-*O*-Isopropylidene-L-dendroketose **7** (100 mg) was stirred with anhydrous acetone (5 mL) containing a small amount of *p*-toluenesulfonic acid (1 mg) at room temperature for 1 h. The solution was neutralized with pyridine and compound **8** was isolated as crystalline material (102 mg). After recrystallization from hexane it melted at 87°C and was identical with an authentic sample in all respects, $[\alpha]_D$ +122° (*c* 0.7, acetone); infrared ($CHCl_3$): 3500 and 3350 cm^{-1} (OH); ^1H nmr ($CDCl_3$ + D_2O) δ: 4.33 (s, 1H, C-3 proton), 4.22 (q, 2H, C-1 protons), 3.90 (s, 2H, C-5 protons), 3.82 (broad s, 2H, C-4′ protons), 1.50 ppm (broad s, 12H, 4 methyls). *Anal.* calcd. for $C_{12}H_{20}O_6$: C 55.37, H 7.75; found: C 55.39, H 7.74.

Heats of mixing and vapour pressures of chloroform (A)+ methanol (B_n) as a function of concentration have been determined at 303.15 K. The excess Gibbs free energy of mixing, G^E values, have been obtained from the measured vapour pressure data. The heats of mixing values are negative for solutions rich in methanol but they become positive for solutions rich in chloroform. On the other hand, G^E values are positive for all the methanol mole fractions and $G^E > H^E$. The results have been analysed in terms of Barker and ideal associated model theory of non-electrolyte solutions. The analysis has revealed that only the ideal associated model approach (which here assumes the presence of A_mB ($m = 1, 2$), AB_k ($k = 2$) and B_l ($l = 1$) molecular species) well describes the general behaviour of H^E with x_A over the entire chloroform concentration range for this mixture. The equilibrium constants for the various association reactions along with the enthalpy of formation of the various molecular species have also been calculated.

On a déterminé à 303.15 K la chaleur de mélange et la pression de vapeur de mélanges chloroforme (A) + méthanol (B_n) en fonction de la concentration. A l'aide des mesures de pression de vapeur, on a calculé les valeurs de l'énergie libre de Gibbs d'excès G^E pour le mélange. Les chaleurs de mélange sont négatives si les solutions sont riches en méthanol, mais elles deviennent positives si les solutions sont riches en chloroforme. D'autre part, la valeur de G^E est positive pour toutes les fractions molaires de méthanol et $G^E > H^E$. On a analysé les résultats en rapport avec la théorie de Barker et celle du modèle de l'association idéale pour les solutions de non-électrolytes. Cette analyse a révélé que seule le modèle de l'association idéale (en admettant l'existence des espèces moléculaires A_mB ($m = 1, 2$), AB_k ($k = 2$) et B_l ($l = 1$)) décrit bien la variation générale de H^E en fonction de x_A sur tout le domaine de concentrations de chloroforme. On a également calculé les constantes d'équilibre des réactions d'association, ainsi que l'enthalpie de formation des différentes espèces moléculaires.

[Traduit par le journal]

Introduction

Following Frank and Wen's model (1) of liquid water, it was believed that lower alcohols should also possess a similar type of cooperativity in the formation of hydrogen bonded polymers. However, there is considerable disagreement as to the identity of the predominant associated species (2–6). Again while the solution hetero-association data (7, 8) have been limited to calculation of equilibrium constants for 1:1 and 2:1 complexes only, Tucker and Christian (9) have interpreted the results of their distribution studies to indicate that methanol contains monomers, dimers, and higher *r*-mers. The present work describes interactions in methanol and chloroform mixtures.

Experimental

Materials

Reagent grade methanol (B.D.H.) was treated in the manner suggested by Vogel (10). Methanol (50–75 ml), 5 g Mg, and 0.5 g iodine were placed in a round bottomed flask. The mixture was warmed on a water bath until iodine disappeared and methoxide formed. Methanol (900 ml) was added, the mixture was boiled under reflux and then finally distilled. Chloroform B.D.H. (A.R.) was shaken as suggested by Vogel (10) several times with about half of its volume of water, dried over anhydrous calcium chloride, and finally distilled. The purity of the final samples was checked by density determinations at 295.15 ± 0.01 K which agreed to within 0.00005 g ml^{-1} with the literature values (11, 12).

Heats of mixing measurements at 303.15 ± 0.01 K were made in an adiabatic calorimeter similar in design to Fernandez-Garcia and Boissonas (13) and has been described

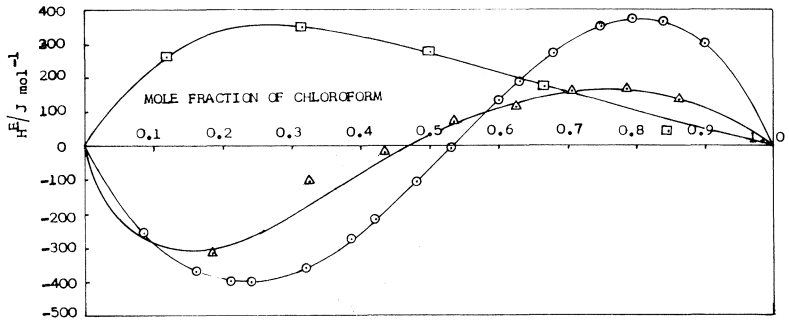

FIG. 1. Enthalpies of mixing H^E for chloroform (A) + methanol (B) at 303.15 K: ○, experimental H^E; △, calculated H^E according to ideal associated model that assumes the presence of AB, AB_2, A_2B, and B molecular species; □, calculated H^E according to ideal associated model that assumes the presence of AB, AB_2, AB_3, and B molecular species ($K_{1,0.5} = 0.4$, $\Delta H_{AB} = -1.0$ kJ mol^{-1}; $K_{0.5} = 0.04$, $\Delta H_B = 2.5$ kJ mol^{-1}; $K_{1.1} = 0.6$, $\Delta H_{AB_2} = -2.0$ kJ mol^{-1}; $K_{1,1.5} = 0.1$, $\Delta H_{AB_3} = -1.0$ kJ mol^{-1}).

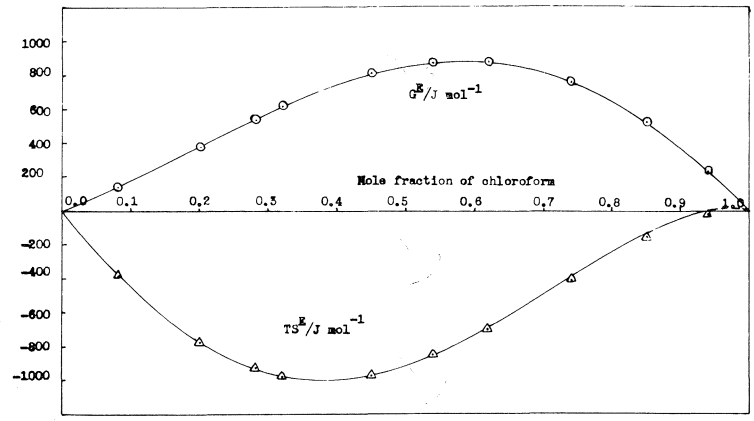

FIG. 2. Excess functions for chloroform (A) + methanol (B) at 303.15 K: ○, G^E and △, TS^E.

elsewhere (14). The performance of the calorimeter was tested by determining the heats of mixing of benzene and cyclohexane at 298.15 ± 0.01 K and these agreed to within 0.3% (over central range of concentration) with the corresponding literature values (15).

Vapour pressures of the methanol + chloroform mixtures were determined by a static method described previously (16). The apparatus (excluding the manometric part) was placed in a water thermostat which in turn was placed in another thermostat. The temperature of the outer thermostat was controlled to better than ±0.01 K and the temperature drift in the inner thermostat was of the order of ±0.002 K. The mercury heights in the manometer were read by a cathetometer which could read to ±0.001 cm. All vapour pressure measurements were reproducible to better than ±0.02 Torr.

The measured vapour pressure (155.49 Torr) of methanol at 303.15 K agreed within 0.3% with that (156.00 Torr) at 303.15 K obtained from the vapour pressure data (17, 18) reported for this compound at different temperatures. The measured vapour pressure of chloroform (241.15 Torr) also compares well with that (239.00 Torr) reported in the literature (19).

The H^E, G^E, and TS^E data are plotted in Figs. 1 and 2.

Results

The molar heats of mixing, H^E, and the measured vapour pressure data at 303.15 K for methanol and chloroform are recorded in Tables 1 and 2 respectively.[2]

The H^E data (Table 1) were fitted to the expression

$$[1] \quad H^E/x_A(1 - x_A) = h_0 + h_1(2x_A - 1) + h_2(2x_A - 1)^2$$

where x_A is the mole fraction of chloroform. The parameters h_0, h_1, and h_2 evaluated by fitting $H^E/x_A(1 - x_A)$ to expression [1] by the method of least-squares are given together with the standard deviation of the molar heats of mixing, $\sigma(H^E)$, in Table 1.

The vapour pressure data were used to evaluate the molar excess Gibbs free energy, G^E, by Barker's method (20). The form of the function used for G^E, following Redlich-Kister (21) is

$$[2] \quad G^E/RT = x_A(1 - x_A)[G_0 + G_1(2x_A - 1) + G_2(2x_A - 1)^2 + G_3(2x_A - 1)^3]$$

[2]Complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TABLE 1. Parameters X_m ($X = h$ or G) of eqs. [1] and [2], standard deviation of pressure $\sigma(P)$ along with the standard deviation of H^E, $\sigma(H^E)$ for chloroform (A) + methanol (B) mixture at 303.15 K

	Value for m =					
Parameter	0	1	2	3	$\sigma(H^E)$/(J mol^{-1})	$\sigma(P)$/Torr
h_m	−264.30	4049.22	531.87	—	2.47	—
G_m	1.3559	0.5744	−0.2320	−0.0560	—	7.64

TABLE 2. Comparison of H^E values calculated according to Barker's theory with values interpolated from the measured values at three mole fractions of the component A and the interaction energies of chloroform (A) + methanol (B) at 303.15 K

Property	Values for mole fraction of the component A =			
(J mol^{-1})	0.3	0.5	0.7	Interaction energies/(J mol^{-1})
H^E_{exp}	−370.00	−67.0	302.00	
$H^{E(1)}$	65.40	41.62	39.26	$U_1^{(1)} = 25.53$, $U_2^{(1)} = -2099.35$, $U_3^{(1)} = -2408.72$
$H^{E(2)}$	−6.44	−19.02	−260.32	$U_1^{(2)} = 25.53$, $U_2^{(2)} = -2099.35$, $U_3^{(2)} = -2503.91$
$H^{E(3)}$	−76.45	−91.10	−63.92	$U_1^{(3)} = 25.53$, $U_2^{(3)} = -1618.18$, $U_3^{(3)} = -1618.18$, $U_4^{(3)} = -1481.81$

where G_0, G_1, G_2, and G_3 are adjustable parameters. These parameters are recorded in Table 1. The second virial coefficients of methanol and chloroform were evaluated from the Berthelot relation (22) using critical constant data (23, 24). The cross virial coefficients were taken as $(B_{11} + B_{22})/2$. The thermodynamic consistency of the data was tested (21) by plotting ln γ_A/γ_B vs. x_A. The positive and negative areas bounded by the curve ln γ_A/γ_B vs. x_A and the X-axis agreed to better than 0.2%.

Discussion

We are unaware of any H^E or G^E data for the chloroform and methanol system with which to compare our results.

Heats of mixing for chloroform (A) + methanol (B) are negative for solutions rich in methanol but they become positive for solutions rich in chloroform. The S-shaped H^E curve attains a maximum negative value of 400 J mol^{-1} at $x_{methanol} = 0.75$ and maximum positive value of 375 J mol^{-1} at $x_{methanol} = 0.19$. Further TS^E is negative at all the methanol mole fractions for which the experimental data are available and the curve of TS^E against $x_{methanol}$ is highly unsymmetrical about $x_{methanol}$.

At the simplest qualitative level the observed H^E data for this mixture may be accounted for if we assume that (*i*), methanol is self-associated and there is a change (decrease) in its self-association when it is mixed with chloroform, (*ii*), there is a hydrogen-bonded interaction between the hydroxyl oxygen of methanol and the chloroform hydrogen, and (*iii*), there is specific interaction between the hydroxyl hydrogen of methanol with the chlorine of chloroform. The negative values of H^E for high methanol concentrations are then due essentially to the factor (*ii*). This is because while interactions due to the factor (*ii*) can occur without breaking the alcohol–alcohol hydrogen bond, the same is not true of interactions due to factor (*iii*). Again the hydrogen-bonded interaction due to factor (*ii*) limits the orientational freedom of the chloroform molecules, thus making TS^E strongly negative so that G^E should be (as indeed is) positive. The positive values of H^E at high chloroform concentrations are due to the rupture of alcohol–alcohol hydrogen bonds followed by their subsequent hydrogen-bonded interaction with chloroform molecules. This in turn would require the TS^E at high chloroform concentrations to be considerably more positive than that at low chloroform concentrations and thus explains the unsymmetrical nature of TS^E vs. $x_{methanol}$ curve.

We examined our results using Barker's theory (25). It was assumed that chloroform (A) and methanol (B) have the following geometrical parameters:

Lattice

$$Z = 4$$

Chloroform molecules (A)

$$r_A = 4,\ Q_{H'}{}^A = 1,\ Q_{R'}{}^A = 9$$

Methanol molecules (B)

$$r_B = 2,\ Q_O{}^B = 2,\ Q_H{}^B = 1,\ Q_R{}^B = 3$$

where O, H, and R represent, respectively, hydroxyl oxygen, hydrogen, and hydrocarbon surface of methanol, and H′ and R′ represent the hydrogen and chlorine surface of chloroform. The interactions first considered were a specific (O...H′) interaction of

strength U_3 between the hydroxyl oxygen of methanol and the hydrogen of chloroform, a specific (O...H) interaction of strength U_2 between the hydroxyl oxygen and hydroxyl hydrogen of methanol, and a non-specific interaction for all the remaining contact points. For the sake of simplicity these non-specific interactions for all the remaining contact points were considered to have the same strength U_1. Excess energy of mixing at constant volume U_V^E, values at $x_A = 0.3$, 0.5, and 0.7 were then calculated (25) from this theory and they did not reproduce the corresponding experimental H^E values. (It is customary while testing a lattice theory to convert U_V^E values to measurements at constant pressure, H^E, using the relation $H_V^E = H^E - TV^E\alpha_m/(K_T)_m$ where α_m, $(K_T)_m$, and V^E are respectively the expansivity, isothermal compressibility, and excess volume of the mixture. However, since V^E is small (V^E for an equimolar mixture is -0.143 cm^3 mol^{-1}), contribution of the $TV^E\alpha_m/(K_T)_m$ term would be negligibly small and for the present analysis we have assumed $U_V^E \approx H^E$.) The best value of U_1, U_2, U_3 (designated as $U_i^{(1)}$ (i = 1 to 3)) and the corresponding H^E values designated as $H^{E(1)}$ are recorded in Table 2.

We next considered a slightly different model where, in addition to the above interactions, one of the chlorines of chloroform was assumed to be involved in a specific (H...Cl) interaction of strength U_4 with the hydroxyl of methanol. The chloroform was considered to have the following geometrical parameters

$$r_A = 4,\ Q_H{}^A = 1,\ Q_{Cl}{}^A = 1, \text{ and } Q_R{}^A = 8$$

The theoretical H^E values are now negative throughout the entire chloroform concentration range. The experimental H^E values for this mixture, on the other hand, are negative for $x_A \leq 0.53$ only. (The values of U_i (i = 1 to 4) and H^E are designated as $U_i^{(2)}$ and $H^{E(2)}$ in Table 2.) Models of chloroform molecules with two and higher hydrogen contact points were also considered but they failed to explain the overall behaviour of H^E with x_A for this mixture. The reason for the failure of the theory may be due to the simplicity of the models. Perhaps associated complexes of the general formula A_iB_j and B_n are present in these mixtures. H^E and G^E data for this mixture were next analysed in terms of the ideal associated model (26, 27).

TABLE 3. The equilibrium constants (mole fraction scale) for the various complexing reactions together with the enthalpies of formation of various molecular species and the variance of the fit $\sigma_D{}^2$ at 303.15 K

Equilibrium constant	Reaction of chloroform with methanol	Parameter	Mixtures of methanol (B_n) with chloroform (A)
$K_{1,0.5}$	0.40	ΔH_{AB}/(kJ mol^{-1})	−1.01
$K_{2,0.5}$	0.05	ΔH_{A_2B}/(kJ mol^{-1})	−1.00
$K_{1,1}$	0.80	ΔH_{AB} /(kJ mol^{-1})	−2.00
$K_{0.5}$	0.04	ΔH_B/(kJ mol^{-1})	2.50
		$\sigma_{D[10]}{}^2$	0.058
		$\sigma_{D[11]}{}^2$	0.060

It is assumed that in a binary solution of chloroform (A) and methanol (designated as B_n since methanol is self-associated) mutual equilibrium of the species A_mB, AB_k, and B_l (l = 1, 2, 3, ..., l; k = 1, 2, 3, ..., k; n = 1, 2, 3, ..., n; m = 2, 3, ..., m) exist according to the reactions

$$[3] \qquad (1+m)A + B_n \rightleftharpoons A_mB + AB_k + B_l$$

so that the equilibrium constants for the various association reactions represented by reaction [3] are

$$[4] \qquad K_{m,1/n} = a_{A_mB}/a_A{}^m a_{B_n}{}^{1/n}$$

$$[5] \qquad K_{1,k} = a_{AB_k}/a_A a_{B_n}{}^{k/n}$$

and

$$[6] \qquad K_{1/n} = a_{B_l}/a_{B_n}{}^{1/n}$$

where a denotes activities. If the activity coefficients of the various species represented in reaction [3] are assumed to be unity (26–29), the material balance equation for the system can be written as

$$[7] \qquad a_A + a_{B_n} + \sum_m K_{m,1/n} a_A{}^m a_{B_n}{}^{1/n} + \sum_k K_{1,k/n} a_A a_{B_n}{}^{k/n} + \sum_l K_{l/n} a_{B_n}{}^{1/n} = 1$$

Two simple cases were next considered.

Case (i), m = 1, 2, ..., m; n = 2; k = 2, 3, ..., k; l = 1, so that eq. [7] reduces to

$$[8] \qquad a_A + a_{B_2} + \sum_m K_{m,0.5} a_A{}^m a_{B_2}{}^{1/2} + \sum_k K_{1,k/2} a_A a_{B_2}{}^{k/2} + K_{0.5} a_{B_2}{}^{1/2} = 1$$

Case (ii), m = 1; n = 2; k = 2, 3, ..., k; l = 1, so that eq. [7] becomes

$$[9] \qquad a_A + a_{B_2} + K_{1,0.5} a_A a_{B_2}{}^{1/2} + \sum_k K_{1,k/2} a_A a_{B_2}{}^{k/2} + K_{0.5} a_{B_2}{}^{1/2} = 1$$

Algebraic manipulation of eqs. [8] and [9] yields

[10] $$\sum_m K_{m,0.5} a_A{}^m + \sum_k K_{1,k/2} a_A a_{B_2}{}^{(k-1)/2} + K_{0.5} = \frac{1 - a_A - a_{B_2}}{a_{B_2}{}^{1/2}}$$

and

[11] $$K_{1,0.5} a_A + \sum_k K_{1,k/2} a_A a_{B_2}{}^{(k-1)/2} + K_{0.5} = \frac{1 - a_A - a_{B_2}}{a_{B_2}{}^{1/2}}$$

respectively.

In order to evaluate the various K's in eqs. [10] and [11], the observed activities of the components of these binary mixtures were first corrected (30–32) for dispersion contributions by expressing

$$a_A = \gamma_A x_A / \gamma_A{}^*$$

$$a_{B_2} = \gamma_{B_2} x_{B_2} / \gamma_{B_2}{}^*$$

where $\gamma_A{}^*$ and $\gamma_{B_2}{}^*$ are the activity coefficients of a reference mixture. Since cyclohexane has nearly the same molar volume as chloroform, cyclohexane (A) + methanol (B_n) was taken as a reference system for the present analysis. Further, as the G^E data (33) for cyclohexane + methanol are available at 304.15 K, we assumed $G^E{}_{304.15K} \approx G^E{}_{303.15K}$ in order to evaluate the activity coefficient data for the components of this reference mixture at the various experimental mole fractions of methanol. A series of values were next assumed for the various K in eqs. [10] and [11] and the process was repeated till a set of K values was obtained which yielded

$$(1 - a_A - a_{B_2})/a_{B_2}{}^{1/2} = D$$

values that corresponded very closely to those obtained from the experimental a_A and a_{B_2} values. It was observed that eq. [10] with a set of K values ($K_{1,0.5}$, $K_{2,0.5}$, $K_{1,1}$, $K_{0.5}$) and eq. [11] with a set of K values ($K_{1,0.5}$, $K_{1,1}$, $K_{1,1.5}$, $K_{0.5}$) yield D values that reproduce equally well the corresponding values obtained from experimental values for this system.

The criterion of effectiveness was the variance of the fit $\sigma_D{}^2$ defined by

[12] $$\sigma_D{}^2 = \sum_i (D_{calcd} - D_{exp})^2/(q - p)$$

where q is the number of points used in the fit and p is the number of adjustable parameters. The various K and $\sigma_D{}^2$ for eqs. [10] and [11] are recorded in Table 3. $\sigma_{D[10]}{}^2$ and $\sigma_{D[11]}{}^2$ in Table 3 represent $\sigma_D{}^2$ for the activity data analysed in terms of eqs. [10] and [11], respectively. Since both eqs. [10] and [11] represent the corresponding D values obtained from experimental data equally well, the analysis of the activity coefficient data described above suggests that these mixtures may be assumed to have either AB, A_2B, AB_2, and B or AB, AB_2, AB_3, and B molecular species in solution. We next considered our H^E data.

Examination of the H^E data of this mixture involved consideration of (*i*), AB, A_2B, AB_2, and B and (*ii*), AB, AB_2, AB_3, and B molecular species. Consequently H^E was expressed as

[13] $$H^E = \left(\sum_{m=1}^{2} n_{AB_m} \Delta H_{AB_m} + n_{A_2B} \Delta H_{A_2B} + n_B \Delta H_B \right) \Big/ (N_A + N_{B_2})$$

and

[14] $$H^E = \left(\sum_{m=1}^{3} n_{AB_m} \Delta H_{AB_m} + n_B \Delta H_B \right) \Big/ (N_A + N_{B_2})$$

where n_{AB_m} represents the amount of species AB_m at equilibrium in the solution and N_A and N_{B_2} the stoichiometric amounts of A and B_2. If the equilibrium mole fractions of A, B_2, B, AB_m ($m = 1, 2$), and A_2B are represented by Z_A, Z_{B_2}, Z_B, Z_{AB_m}, and Z_{A_2B}, then for an ideal associated mixture A + B_2, containing AB, A_2B, AB_2, and B molecular species

[15] $$Z_A + Z_{B_2} + \sum_{m=1}^{2} Z_{A_mB} + Z_{AB_2} + Z_B = 1$$

where

$$Z_{A_mB} = K_{m,0.5} Z_A{}^m Z_{B_2}{}^{1/2}$$

$$Z_{AB_2} = K_{1,1} Z_A Z_{B_2}$$

$$Z_B = K_{0.5} Z_{B_2}{}^{1/2}$$

The experimental H^E values were again corrected for dispersion contributions by subtracting from H^E_{exp} the H^E values (34) at 298.15 K for cyclohexane + methanol. Consequently in eqs. [13] and [14]

$$H^E = H^E_{exp} - H^E_{cyclohexane+methanol} \quad [15a]$$

Algebraic manipulation of eqs. [13] and [14] and the material balance equations

$$N_A = n_A + \sum_{m=1}^{2} n_{AB_m} + 2n_{A_2B} \quad [16]$$

$$N_{B_2} = n_{B_2} + \tfrac{1}{2}\sum_{m=1}^{2} n_{A_mB} + n_{AB_2} + \tfrac{1}{2}n_B \quad [17]$$

leads to

$$jH^E = \sum_{m=1}^{2} K_{m,0.5} Z_{A_m}{}^m \Delta H_{A_mB} + Z_{B_2}{}^{1/2} K_{1,1} \Delta H_{AB_2} + K_{0.5}\Delta H_B \quad [18]$$

where

$$j = (Z_{B_2}{}^{1/2} + 0.5K_{1,0.5}Z_A + K_{1,1}Z_{B_2}{}^{1/2}Z_A + 0.5K_{2,0.5}Z_A{}^2 + 0.5K_{0.5})/x_{B_2}$$

Further combination of eqs. [15]–[17] gives

$$x_{B_2} = \frac{0.5K_{1,0.5}Z_AZ_{B_2}{}^{1/2} + K_{1,1}Z_AZ_{B_2} + 0.5K_{0.5}Z_{B_2}{}^{1/2} + 0.5K_{2,0.5}Z_A{}^2Z_{B_2}{}^{1/2} + Z_{B_2}}{Z_A + Z_{B_2} + 1.5K_{1,0.5}Z_AZ_{B_2}{}^{1/2} + 2K_{1,1}Z_AZ_{B_2} + 2.5K_{2,0.5}Z_A{}^2Z_{B_2}{}^{1/2} + 0.5K_{0.5}Z_{B_2}{}^{1/2}} \quad [19]$$

where

$$Z_{B_2}{}^{1/2} = \frac{-Y \pm \sqrt{Y^2 - 4(Z_A - 1)(1 + K_{1,1}Z_A)}}{2(1 + K_{1,1}Z_A)}$$

$$Y = (K_{1,0.5}Z_A + K_{2,0.5}Z_A{}^2 + K_{0.5})$$

Using the various K values described above for a solution containing AB, A_2B, AB_2, and B species, we calculated x_{B_2} from eq. [19] for various values of Z_A and assigned various values to ΔH_{A_mB}, ΔH_{AB_2}, and ΔH_B till they gave H^E values (from eqs. [15a] and [18]) that compared well with the corresponding experimental values. The various ΔH values are recorded in Table 3 and the calculated H^E values are plotted in Fig. 1. It is evident from Fig. 1 that the theoretical H^E values well describe the general behaviour of H^E with x_A for chloroform (A) + methanol (B) mixture.

A similar process was applied to the case when the mixture contain AB_m (m = 1 to 3) and B molecular species. The final expressions were

$$j'H^E = K_{1,0.5}Z_A\Delta H_{AB} + K_{1,1}Z_A\Delta H_{AB_2} + K_{1,1.5}Z_AZ_{B_2}{}^{3/2}\Delta H_{AB_3} + K_{0.5}\Delta H_B \quad [20]$$

where

$$j' = (Z_{B_2}{}^{1/2} + 0.5K_{1,0.5}Z_A + K_{1,1}Z_AZ_{B_2}{}^{1/2} + 1.5K_{1,1.5}Z_AZ_{B_2}{}^2 + K_{0.5}Z_{B_2}{}^{1/2})/x_{B_2}$$

$$x_{B_2} = \frac{Z_{B_2} + 0.5K_{0.5}Z_{B_2}{}^{1/2} + 0.5K_{1,0.5}Z_AZ_{B_2}{}^{1/2} + K_{1,1}Z_AZ_{B_2} + 1.5K_{1,1.5}Z_AZ_{B_2}{}^{3/2}}{Z_A + Z_{B_2} + 0.5K_{0.5}Z_{B_2}{}^{1/2} + 1.5K_{1,0.5}Z_AZ_{B_2}{}^{1/2} + 2K_{1,1}Z_AZ_{B_2} + 2.5K_{1,1.5}Z_AZ_{B_2}{}^{3/2}}$$

and

$$Z_A = (1 - K_{0.5}Z_{B_2}{}^{1/2} - Z_{B_2})/(1 + K_{1,0.5}Z_{B_2}{}^{1/2} + K_{1,1}Z_{B_2} + K_{1,1.5}Z_{B_2}{}^{3/2})$$

where

$$Z_{AB_m} = K_{1,m/2}Z_AZ_{B_2}{}^{m/2} \qquad m = 1, 2, 3$$

$$Z_B = K_{0.5}Z_{B_2}{}^{1/2}$$

However, no values of ΔH_{AB_m}(m = 1 to 3) and ΔH_B could yield H^E values that described the experimental behaviour of H^E with x_A for this mixture. The calculated H^E values are either positive or negative throughout the entire chloroform concentration range. Further the quantitative agreement is also not good (see Fig. 1 where only those ΔH_{AB_m} and ΔH_B values are considered that render H^E_{calcd} positive throughout the entire chloroform concentration range).

The analysis of H^E and activity coefficient data for chloroform + methanol mixtures thus suggests that this mixture is characterized by the presence of AB, AB_2, A_2B, and B molecular species in solution.

P. P. SINGH and S. P. YADAV. Can. J. Chem. **57**, 394 (1979).

Binuclear mixed-metal mixed-ligand monomeric bridged complexes of the type $(XCN)_2(L)_2M(NCX)_2Hg(PPh_3)_2$ (M = Co(II), Ni(II), Cu(II), Zn(II); L = pyridine, nicotinamide; PPh_3 = triphenylphosphine; X = S, Se) have been synthesized and characterized by elemental analysis, molar conductance, magnetic moment, and infrared and electronic spectral studies. In all the complexes, the most likely structure involves pyridine or nicotinamide linked to M and PPh_3 to Hg. Total softness calculations have also been made to extend support to the structure of the complexes.

P. P. SINGH et S. P. YADAV. Can. J. Chem. **57**, 394 (1979).

On a synthétisé les complexes pontés, monomères ligand-mixte, métal-mixte et binucléaires du type $(XCN)_2(L)_2M(NCX)_2Hg(PPh_3)_2$ (M = Co(II), Ni(II), Cu(II), Zn(II); L = pyridine, nicotinamide; PPh_3 = triphénylphosphine; X = S, Se); on les a caractérisés par analyse centésimale, conductivité molaire, moment magnétique et des études spectrales infrarouge et électronique. Dans tous les complexes, la structure la plus probable implique une pyridine ou une nicotinamide liée au M et une PPh_3 liée au Hg. On a effectué des calculs de mollesse totale afin d'étendre le support pour les structures des complexes.

[Traduit par le journal]

Introduction

Pyridine or its derivatives reacts with $MHg(XCN)_4$ (M = Co(II), Ni(II), Cu(II), Zn(II); X = S, Se), to yield polymeric bridged complexes (1–4) of the type $\rangle(XCN)_2(py)_2M(NCX)_2Hg\langle$ in which the ligand is coordinated to M. On account of this, the maximum coordination of M is achieved, but the coordination number of Hg(II) remains four against the maximum of six. This paves the way to further coordination at this site. It is at this site the triphenylphosphine has been introduced and an entirely new series of mixed-ligand complexes synthesized and studied.

Experimental

Materials and Manipulations

Nicotinamide (nia) (B.D.H.) was used after recrystallization from methanol. Pyridine (py) (B.D.H.) was purified by the known methods. Other materials were used as described earlier (5).

Preparation of the Complexes

These complexes were prepared by either of the following two methods.

First Method

$\rangle(XCN)_2(L)_2M(NCX)_2Hg\langle$ (M = Co, Ni, Cu, Zn; L = py, nia; X = S, Se) were first prepared by the methods described elsewhere (1–4). To the suspensions of these complexes in methanol, solutions of PPh_3 in the same solvent were added in 1:2 molar ratio and stirred for 30 h. In each case a solid was formed and was filtered off, washed with the solvent, and dried in vacuum at room temperature.

Second Method

$(L)_2M(NCX)_2$ was first prepared by stirring the solution of $M(NCX)_2$ in methanol with the excess of the solution of the ligand (py or nia) in the same solvent for 6 h. To the suspension of $Hg(XCN)_2$ in methanol, a solution of PPh_3 in the same solvent was added in 1:2 molar ratio and stirred for 10 h to get $(Ph_3P)_2Hg(XCN)_2$. In each reaction a solid mass was separated which was filtered, washed with the solvent, and dried *in vacuo*.

$(L)_2M(NCX)_2$ was dissolved in a mixture of methanol and pyridine or nicotinamide. This solution was added to the suspension of $(Ph_3P)_2Hg(XCN)_2$ in methanol in 1:1 molar ratio and the reaction mixture was stirred. After about 32 h a solid mass separated in each case which was isolated by filtration, washed with the solvent, and dried *in vacuo* at room temperature.

All the complexes are insoluble in most organic solvents, except for dimethylformamide.

Analysis and Physical Measurements

Analysis of the complexes and all other physical measurements were made as described earlier (5). Analytical data are included in Table 1.

Results and Discussion

On account of the insolubility of these complexes in suitable organic solvents, we could not find the molecular weight, and could not grow the single crystals. The structure of the complexes, therefore, have been proposed on the basis of analytical data, magnetic moments, chemical reactions, HSAB consideration, and ir and electronic spectral studies.

The analytical data as presented in Table 1 show that two molecules of PPh_3 react with one molecule of $\rangle(XCN)_2(L)_2M(NCX)_2Hg\langle$.

0008-4042/79/040394-06$01.00/0

The ligands show features of coordination. Pyridine and nicotinamide are coordinated through their ring nitrogen as is evidenced by the positive shift in the ring vibrations. Similarly, the X-sensitive *q*, *r*, *t*, and *y* (Whiffen's) bands of triphenylphosphine experience positive shift; this indicates that the ligand is coordinated (6, 7).

The incoming PPh_3 may either rupture the NCX bridge to form a cationic–anionic complex or may retain it to yield a bridging complex.

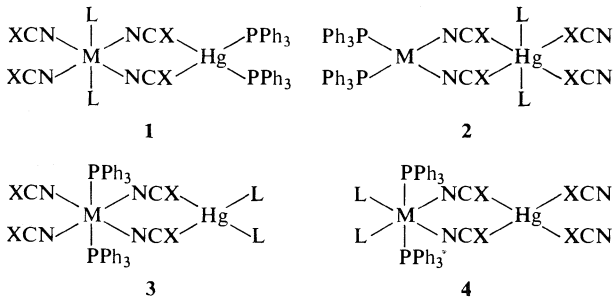
These complexes are only slightly soluble in dimethylformamide, and conductance values of the dilute solutions as presented in Table 1 show them to be nonconducting in nature. Thus the cationic–anionic structure may be set aside in favour of the bridge structure.

Bridged structure may be either polymeric or monomeric (2–4). In the absence of molecular weight data it is difficult to distinguish between the two. However, on the basis of the number and position of ir bands due to thio or selenocyanate fundamental vibrations and other qualitative considerations as presented below, the possibility for a monomeric bridged structure is more.

(*i*) The essential requirement of a monomeric bridged compex is the presence of both bridging and terminal thio or selenocyanate groups (2–5). The ir spectra of these complexes as presented in Tables 2 and 3 demonstrate the presence of three to four absorption bands in the CN stretching region. These bands possibly indicate the presence of both bridging and terminal NCX groups (8–12).

(*ii*) PPh_3 is a bulky ligand and obstructs the formation of a polymeric bridged complex, and it is on this account all the reported complexes of PPh_3 with $MM'(XCN)_4$ are monomeric bridged (1, 5, 13).

On the basis of the above considerations, the polymeric bridged structure is disclaimed. The monomeric bridged structure, which is the most likely species present, may have either of the following four structure **1**, **2**, **3**, and **4**.



M = Co(II), Ni(II), Cu(II), Zn(II); L = pyridine, nicotinamide; X = S, Se

values as discussed later reveal that Co(II) or Ni(II) is in octahedral coordination geometry which disagrees with structure **2**, since in it M is tetracoordinated. On this ground the structure **2** is unacceptable. Since in all three other possible structures, the configuration of Co(II) or Ni(II) remains octahedral, the distinction cannot be made with the help of electronic spectra and magnetic moment values. The balance of evidence has, therefore, been derived on the other considerations which are as follows:

Triphenylphosphine never forms an octahedral complex with cobalt thiocyanate. In all the reported complexes of $CoM'(XCN)_4$ with PPh_3, the coordination number of Co(II) is four (1, 5, 13). Similarly, when PPh_3 is coordinated to $Ni(NCS)_2$ or $NiHg(XCN)_4$, Ni(II) acquires square planar configuration (5, 13, 14). It is, therefore, very unlikely that PPh_3 is linked to cobalt or nickel when they are in their octahedral coordination geometry. Furthermore, the blue complex $(Ph_3P)_2Co(NCX)_2Hg(XCN)_2$ does not become pink when reacted with pyridine (5) which indicates that pyridine cannot link to cobalt if the latter is already coordinated to PPh_3. On the basis of these observations, structures **3** and **4** can be disowned and structure **1** can be taken as the possible structure of these complexes. The evidences as mentioned below also lend support to the structure **1**.

(*i*) The formation of the complexes by the reaction between $(L)_4M(NCX)_2$ and $(Ph_3P)_2Hg(XCN)_2$ in methanol

$$(XCN)_2M(L)_4 + (NCX)_2Hg(PPh_3)_2 \rightarrow (XCN)_2(L)_2M(NCX)_2Hg(PPh_3)_2$$

also indirectly supports the structure **1**.

(*ii*) The difference in total softness values $[(\Delta TE_n{}^*(M—Hg)]$ of M and Hg is the highest in case of the structure **1**, hence it is the more probable out of the four. The description of total softness values and its application to the determination of the structure is discussed later.

(*iii*) The steric hindrance which plays an important role in the determination of the structure of PPh_3 complexes (5) is least in the case of the structure **1**.

(*iv*) Structure **1** possesses C_{2v} symmetry. Assuming this symmetry, we have calculated the number of ir active normal vibrations which are found to be in good agreement with the observed ones (see Tables 2 and 3).

Electronic Spectra of $(XCN)_2M(L)_2(NCX)_2Hg(PPh_3)_2$ (M = Co(II), Ni(II); X = S, Se)

In order to ascertain the coordination geometry around Co(II) or Ni(II) in these complexes, we have studied their electronic spectra. The assignment of the electronic spectral bands, their positions, and the spectral parameters are included in Table 4. The values of Dq and B' have been calculated from the values of ν_3 and ν_2 bands using the matrices of Tanabe and Sugano (15).

The positions of electronic spectral bands indicate that Co(II) and Ni(II) possess octahedral configuration in these complexes. Being formally a two electron transition the ν_2 band is weak in intensity

TABLE 3. Infrared spectral assignments for the selenocyanate fundamental vibrations of $(SeCN)_2(L)_2M(NCSe)_2Hg(PPh_3)_2$

and in some cases not observed in the cobalt complexes. In these cases, the *Dq* values are derived from the position of ν_1 bands.

The *Dq* values of these complexes are in the range prescribed for the octahedral complexes of Co(II) and Ni(II), and are nearly the same as that of $\rangle(XCN)_2(L)_2M(NCX)_2Hg\langle$ (M = Co(II), Ni(II)) (1–4) which is, possibly, due to the presence of the same octahedron L_2MN_4 in the two. The *Dq* values of the selenocyanate complexes are higher than that of the corresponding thiocyanate complexes which reveals that the ligand field strength of the former is higher than that of the latter (16–18). The metal–ligand bond in selenocyanates is more covalent than in thiocyanates as is evidenced by the values of *B'*.

Magnetic moment values of these complexes as presented in Table 4 also suggest octahedral environment around cobalt and nickel. All the zinc complexes are diamagnetic and copper complexes possess the magnetic moment values in the range 1.8–2.0.

Description of Total Softness ($TE_n^{\ddagger}$) and its Application

The stability of thio and selenocyanate bridge in the complexes of mixed dithio-diselenocyanate complexes has recently been related (19) to the difference in total softness $[\Delta TE_n^{\ddagger}(M—M')]$ of M and M'. A higher value of $\Delta TE_n^{\ddagger}(M—M')$ suggests greater stability. In order to extend support to the proposed structure of the complexes of the present series, the total softness ($TE_n^{\ddagger}$) of M (Co, Ni, Cu, Zn) and Hg have been calculated in respect of the different structures of the complexes and the difference $\Delta TE_n^{\ddagger}(M—Hg)$ evaluated by adopting the pro-

TABLE 5. $\Delta TE_n^{\ddagger}$ values for probable and alternative structures of the complexes

Complex	Type	$TE_n^{\ddagger}$(M)	$TE_n^{\ddagger}$(Hg)	$\Delta TE_n^{\ddagger}$(M—Hg)

$(SeCN)_2(py)_2Zn(NCSe)_2Hg(PPh_3)_2$	A	59.89	27.24	32.65
$(SeCN)_2(Ph_3P)_2Zn(NCSe)_2Hg(py)_2$	B	50.57	36.56	14.01

cedure as outlined below:

(i) $(SCN)_2(py)_2Co(NCS)_2Hg(PPh_3)_2$, *Structure* **1**

$$TE_n^{\ddagger}(Co) = E_n^{\ddagger}(Co) + 2E_m^{\ddagger}(py) + 4E_m^{\ddagger}(NCS)$$
$$= -0.22 + 2 \times (-11.44) + 4 \times (-8.10)$$
$$= -55.50$$

$$TE_n^{\ddagger}(Hg) = E_n^{\ddagger}(Hg) + 2E_m^{\ddagger}(SCN) + 2E_m^{\ddagger}(PPh_3)$$
$$= -4.86 + 2 \times (-5.20) + 2 \times (-6.78)$$
$$= -28.82$$

Here $E_n^{\ddagger}$ and $E_m^{\ddagger}$ are the softness values of the metal ions and the ligands, respectively. These values have been calculated by using the Klopman's equation (20).

Now

$$\Delta TE_n^{\ddagger}(Co—Hg) = TE_n^{\ddagger}(Hg) - TE_n^{\ddagger}(Co)$$
$$= -28.82 - \cdots -(-55.50)$$
$$= 26.68$$

(ii) $(SCN)_2(Ph_3P)_2Co(NCS)_2Hg(py)_2$, *Structure* **3**

$$TE_n^{\ddagger}(Co) = E_n^{\ddagger}(Co) + 2E_m^{\ddagger}(PPh_3) + 4E_m^{\ddagger}(NCS)$$
$$= -0.22 + 2 \times (-6.78) + 4 \times (-8.10)$$
$$= -46.18$$

$$TE_n^{\ddagger}(Hg) = E_n^{\ddagger}(Hg) + 2E_m^{\ddagger}(py) + 2E_m^{\ddagger}(SCN)$$
$$= -4.86 + 2 \times (-11.44) + 2 \times (-5.20)$$
$$= -38.14$$

So

$$\Delta TE_n^{\ddagger}(Co—Hg) = TE_n^{\ddagger}(Hg) - TE_n^{\ddagger}(Co)$$
$$= (-38.14) - (-46.18)$$
$$= 8.04$$

The above calculations show that the $\Delta TE_n^{\ddagger}$(Co—Hg) value is higher for structure **1**, hence it is the most likely structure. Since the other factors also favour the same structure, this should be adopted for the complexes of the present series. The total softness values of the metal ions and the difference derived from them in respect of all the complexes are presented in Table 5, along with the $\Delta TE_n^{\ddagger}$(M—Hg) values of the alternative structures. The possible structures are marked with A and the alternative ones with B. The $\Delta TE_n^{\ddagger}$(M—Hg) values for the adopted structures marked with A are higher than those marked with B.

Conclusions

(*i*) Most likely the triphenylphosphine coordinates to M (Co, Ni, Cu, Zn) in preference to Hg, when reacted with $MHg(SCN)_4$ or $MHg(SeCN)_4$ to yield monomeric bridged complexes of the type $(Ph_3P)_2M(NCX)_2Hg(XCN)_2$ (X = S, Se).

(*ii*) When pyridine or nicotinamide is already linked to M as in $>(XCN)_2(L)_2M(NCX)_2Hg<$, the incoming triphenylphosphine most likely coordinates to Hg, to yield monomeric bridged complexes of the type $(XCN)_2(L)_2M(NCX)_2Hg(PPh_3)_2$.

Etude par spectrométrie infrarouge de l'action de solvants aprotiques sur l'association ester–eau et ester–Ba^{2+}. Discussion du rôle catalytique du solvant et de l'ion Ba^{2+} dans l'hydrolyse alcaline du propionate de methyle

ANNE LE NARVOR ET PIERRE SAUMAGNE

Laboratoire de Spectrochimie Moléculaire, Faculté des Sciences et Techniques, 6, Avenue Le Gorgeu, 29283 Brest, Cedex, France

Reçu le 19 juillet 1978

ANNE LE NARVOR et PIERRE SAUMAGNE. Can. J. Chem. **57**, 400 (1979).

Les spectres ir de mélanges propionate de méthyle–eau et propionate de méthyle–Ba^{2+} dans le diméthylsulfoxyde et l'acétonitrile ont été enregistrés dans la région des vibrations νC═O de l'ester. On met en évidence la présence de différents types de complexes, et on suit l'évolution de leur concentration avec la composition du milieu. Les résultats spectroscopiques sont comparés à ceux de la cinétique d'hydrolyse alcaline obtenus dans les mêmes conditions. On montre que le contrôle orbitalaire rend mieux compte des résultats expérimentaux que la densité de charge portée par l'atome de carbone du carbonyle.

ANNE LE NARVOR and PIERRE SAUMAGNE. Can. J. Chem. **57**, 400 (1979).

The ir spectra of mixtures of methyl propionate/water and methyl propionate/Ba^{2+} in dimethylsulfoxide and in acetonitrile have been recorded in the region of the ν_{CO} mode of the ester. Evidence is presented to indicate the presence of different types of complexes; their concentration was determined as a function of the composition of the medium. The spectroscopic results are compared to those from the kinetics of the alkaline hydrolysis in the same conditions. It is demonstrated that the orbital control explains the experimental results better than does the charge density on the carbon of the carbonyl group.

[Journal translation]

Introduction

Une récente étude par spectrométrie infrarouge des interactions ester – solvant protique et ester–cation (1) a permis de montrer le rôle de la formation de complexes entre l'ester et le solvant ou le cation dans la cinétique de l'hydrolyse alcaline de l'ester. Nous avons entrepris l'analyse des spectres infrarouges montrant l'association propionate de méthyle–eau dans l'acétonitrile et le diméthylsulfoxyde (DMSO) en l'absence ou en présence d'un sel alcalino-terreux, afin de préciser l'influence de ces solvants basiques sur les associations ester–eau ou ester–cation.

Partie expérimentale

Le propionate de méthyle est un produit commercial qui a été purifié par distillation. Les solvants étudiés sont des produits pour spectroscopie et ont été desséchés sur tamis moléculaire 4 Å. L'eau lourde titre 99.7% en D_2O et provient du Commissariat à l'Energie Atomique.

Les spectres ont été enregistrés à la température ambiante sur un spectromètre Perkin-Elmer 225. La précision de lecture sur les fréquences et les demi-largeurs est de ± 1 cm^{-1}. Les cellules utilisées d'épaisseur 0.05 mm sont équipées de faces en CaF_2.

I. Interaction eau – propionate de méthyle – solvant basique

Résultats

On a représenté l'évolution du massif νC═O du propionate de méthyle en fonction des concentrations en eau et en acétonitrile sur la fig. 1, en eau et en DMSO sur la fig. 2.

La bande fine correspondant à la vibration νC═O de l'ester libre dans le solvant est située à 1739 cm^{-1} pour l'acétonitrile et à 1735 cm^{-1} pour le DMSO.

Aux faibles concentrations en eau dans l'acétonitrile, nous observons un léger déplacement du maximum à 1739 cm^{-1} vers les basses fréquences et surtout un élargissement très notable de la bande d'absorption dans le même sens. ($\Delta\nu_{\frac{1}{2}} = 15$ cm^{-1} pour $[D_2O] = 0$; $\Delta\nu_{\frac{1}{2}} = 21$ cm^{-1} pour $[D_2O] = 2.2\,M$.) Par contre, la bande νC═O située à 1735 cm^{-1} ne présente aucune évolution pour les faibles concentrations en eau dans le DMSO.

Quand $[D_2O] = 10\,M$, on note pour l'acétonitrile une bande au maximum aplati vers 1735 cm^{-1}; l'absorption dans le DMSO est plus fine et centrée à 1732 cm^{-1}.

Dans les solutions plus concentrées en eau (20 M), le profil du massif νCO centré à 1724 cm^{-1} est sensiblement le même avec les deux solvants.

Dans l'eau pure, la bande νCO vers 1709 cm^{-1} est dissymétrique et très élargie vers les hautes fréquences.

Interprétation

L'addition de quantités croissantes d'eau produit un déplacement accompagné d'un élargissement de la bande νCO avec apparition successive de deux maximums à 1724 puis 1709 cm^{-1}. On a montré (2) que ces deux maximums correspondent respectivement aux deux associations:

[1] $\mathrm{R{-}C(=O){-}OR'} + H_2O \rightleftarrows \mathrm{R{-}C(=O\cdots H{-}OH){-}OR'}$

1 ("complexe I-1")

0008-4042/79/040400-04$01.00/0

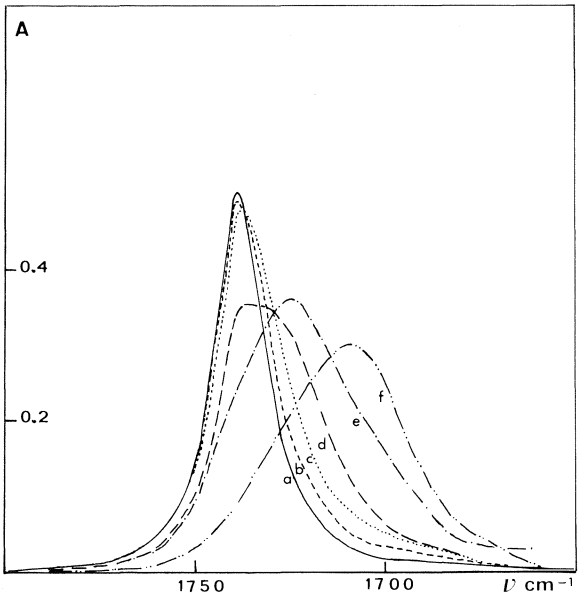

FIG. 1. Spectres d'absorption dans la région des vibrations νC=O du propionate de méthyle en solution dans des mélanges d'acétonitrile et d'eau (D_2O). Concentration en D_2O: a = 0, b = 0.5 M, c = 2.2 M, d = 10 M, e = 20 M, f = eau pure. Concentration en ester 0.2 M.

[2] 
2 ("complexe 1-2")

Dans les solutions concentrées en eau (20 M et 10 M), le rôle du solvant organique est peu important, comme nous l'avons signalé dans un autre travail (3). N'existent donc en solution que les complexes 1-1 (**1**) et 1-2 (**2**).

Lorsque la concentration en eau est faible ($\leq$2.2 M), on peut attribuer l'absence de modification de la bande νC=O à 1735 cm^{-1} dans le DMSO au fait que l'eau s'associe préférentiellement au DMSO selon [3]:

[3] $$\text{Solv.} + \text{HOH} \rightleftarrows \text{Solv....HOH}$$

les complexes **1** et **2** sont vraisemblablement en concentration infime. En effet, les valeurs de la constante de complexation mesurée pour l'équilibre [3] établi dans le tétrachlorure de carbone sont:

$$K(\text{DMSO/eau}) = 200\ \text{L mol}^{-1}\ (4)$$

$$K(\text{propionate de méthyle/eau}) = 50\ \text{L mol}^{-1}$$

Au contraire, l'évolution de la bande νC=O du propionate dans l'acétonitrile à faible concentration en eau nous paraît traduire une compétition entre les trois équilibres [1], [2] et [3]. En effet, le pouvoir accepteur de proton de l'acétonitrile est inférieur à celui du propionate {K(acétonitrile/eau) = 25 L mol^{-1} (4)}.

II. Interaction propionate de méthyle – eau – solvant basique – perchlorate de baryum

Résultats

A l'addition de perchlorate de Ba à une solution de propionate de méthyle (0.2 M) et d'eau (2.2 M) dans l'acétonitrile, correspond l'apparition d'une nouvelle absorption à 1710 cm^{-1} et une diminution d'intensité de la bande à 1739 cm^{-1} (fig. 3).[1]

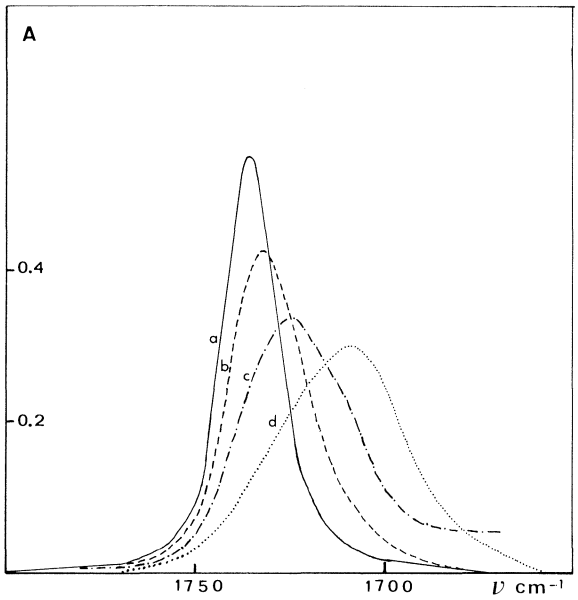

FIG. 2. Spectres d'absorption dans la région des vibrations νC=O du propionate de méthyle en solution dans des mélanges de DMSO et d'eau (D_2O). Concentration en D_2O: a = 0, b = 10 M, c = 20 M, d = eau pure. Concentration en ester 0.2 M.

Quand l'acétonitrile est remplacé par le DMSO, l'addition de perchlorate ne produit aucune modification de la bande νCO à 1735 cm^{-1} (fig. 2, courbe a).

Interprétation

On a montré (1) que la complexation du propionate de méthyle par l'ion Ba^{2+} s'établit par l'intermédiaire de l'oxygène du C=O de l'ester, plus basique que l'oxygène de l'eau, selon l'équilibre:

[4] 
4

Le pouvoir donneur d'électrons de l'oxygène du carbonyle dépendra du solvant polaire par suite de compétition entre l'équilibre [4] et les équilibres [3] et [5]:

[5] 
Dans l'équilibre [5] le caractère donneur d'électrons de l'oxygène de l'eau augmente avec l'interaction entre l'eau et le solvant.

Lorsque le solvant utilisé est l'acétonitrile, l'absorption à

[1]Il a été observé par ailleurs que l'abaissement de la fréquence CO par complexation de type **4** est plus grand avec l'ion Ba^{2+} qu'avec un ion alcalin M^+ (1).

1710 cm^{-1} correspond à la vibration νC=O perturbée par l'ion Ba^{2+} selon [4]. Avec le DMSO au contraire, l'absence de modification spectrale par addition de Ba^{2+} indique que, sans doute, l'équilibre [5] prédomine.

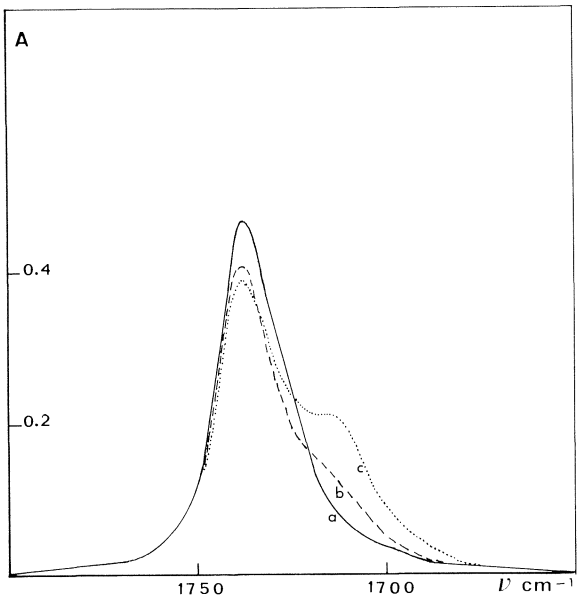

FIG. 3. Spectres d'absorption dans la région des vibrations νC=O du propionate de méthyle en solution dans un mélange eau–acétonitrile en l'absence (*a*) et en présence du perchlorate de baryum. Concentration en Ba^{2+}: $a = 0$, $b = 0.25$ *M*, $c = 0.50$ *M*. Concentration en eau: 2.2 *M*, concentration en ester: 0.2 *M*.

Discussion

Tommila et coll. (5, 6) ont étudié la vitesse d'hydrolyse alcaline de l'acétate d'éthyle dans divers mélanges eau–solvants. Ils ont montré que le rapport des constantes de vitesse k/k_{eau} en présence ou en absence de solvant, diminue habituellement quand la concentration en solvant augmente, mais qu'il augmente d'un facteur 4 à 5 dans le seul cas où le solvant est le DMSO. Pour ces auteurs, la réactivité de l'ion OH^- vis-à-vis de l'ester dépend de son degré d'hydratation ou de solvatation, qui est accru dans l'eau, le méthanol, l'acétone, le dioxanne mais au contraire, diminué dans le DMSO: ce dernier solvant accélère donc la réaction.

Nos résultats confirment ce point de vue. En effet, dans l'eau pure et jusqu'à des concentrations en eau de 10 à 20 *M*, seuls existent les complexes 1-1 et 1-2. Dans ce même domaine de concentration, le DMSO accélère la vitesse d'hydrolyse de 20% environ, alors que les autres solvants l'inhibent légèrement. Or l'évolution des spectres infrarouges est la même quel que soit le solvant. L'effet catalytique du DMSO s'exerce donc, non pas sur le carbone du carbonyle de l'ester, mais très vraisemblablement sur l'ion OH^-.

Cet ion OH^- est hydraté selon le schéma:

$$[6] \qquad OH^- + H_2O \rightleftarrows (H_2O...OH^-)$$

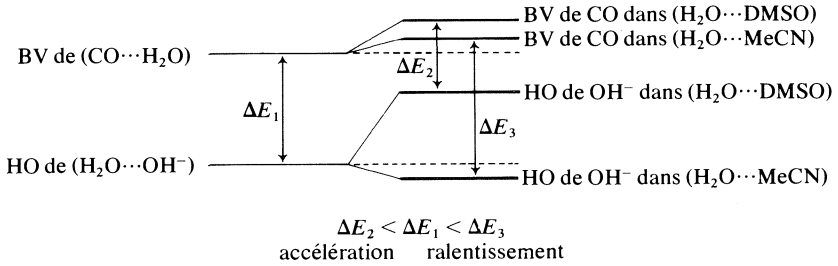
Le calcul de l'énergie de stabilisation de l'ion hydraté (7) donne la valeur $E = 1.265$ eV.

Dans le cas du DMSO, l'équilibre [3] est fortement déplacé vers la droite, ce qui a pour effet de faire rétrograder l'équilibre [6] dans le sens donnant des ions OH^- non hydratés. Cette action du DMSO, sensible dès les premières additions de ce solvant, est amplifiée avec la concentration. La dissociation de l'ion $(H_2O...OH^-)$ entraîne la remontée de l'orbitale haute occupée (HO) de l'ion OH^- qui tend à se rapprocher de l'orbitale basse vacante (BV) du carbonyle de l'ester, bien que cette dernière remonte également par destruction progressive et simultanée des complexes 1-1 et 1-2 (équilibres [1] et [2] (8)).

L'acétonitrile, au contraire, est un accepteur de proton trop faible pour perturber l'équilibre [6] autrement que par solvatation de l'ion $(H_2O...OH^-)$. Cette solvatation expliquerait l'effet inhibiteur de l'acétonitrile.[2]

Cette hypothèse semble confirmée si l'on se place dans le domaine des très fortes concentrations en solvant. L'addition des petites quantités d'eau à l'acétonitrile (jusqu'à 2 *M* en eau) provoque un déplacement visible de la bande νCO de l'ester par formation de complexe 1-1. On n'observe rien de semblable avec le DMSO.

On peut représenter schématiquement l'évolution des orbitales BV de l'ester et HO de l'ion OH^- sous l'action des solvants telle qu'elle vient d'être expliquée:



$\Delta E_2 < \Delta E_1 < \Delta E_3$
accélération ralentissement

[2]En fait les expériences de Tommila et coll. ont été réalisées avec l'acétone et le dioxanne. Mais nous avons montré que l'acétone, le dioxanne et l'acétonitrile ont un comportement semblable par rapport à l'eau (3, 4).

Le calcul théorique des énergies des orbitales et des valeurs des ΔE devrait permettre de confirmer ce schéma.

Quant à l'analyse de l'action de l'ion Ba^{2+}, faute de données cinétiques, nous sommes réduits à des hypothèses concernant l'effet catalytique du sel.

Lors d'études d'effet de sel, Corset et coll. (8) ont montré le rôle important de la formation du complexe $C{=}O...M^{+}$ dans le contrôle orbitalaire de la réaction d'hydrolyse de l'ester.

En nous inspirant de leurs conclusions, nous pouvons postuler que l'ion Ba^{2+} aura un effet accélérateur de la cinétique en abaissant le niveau d'énergie de l'orbitale BV du carbonyle dans l'acétonitrile à faible concentration en eau. Ceci est en accord avec l'apparition de l'absorption à 1710 cm^{-1} (fig. 3).

On a déjà signalé l'effet catalytique positif du DMSO. L'addition d'ions Ba^{2+} dans le milieu ne modifiant pas le spectre de vibration, on peut conclure, que vraisemblablement, les ions Ba^{2+} n'ont pas d'effet catalytique sur l'hydrolyse alcaline d'un ester dissous dans le DMSO.

Conclusion

Nos résultats expérimentaux font donc apparaître que l'effet du solvant ne s'exerce pas sur le carbonyle de l'ester mais plutôt sur le réactif OH^{-}. La charge portée par le carbone du carbonyle ne doit pas dépendre du solvant. La réaction d'hydrolyse d'un ester dans un solvant aprotique est donc sous contrôle orbitalaire.

Remerciements

Nous remercions Monsieur J. Corset, Maître de Recherches au Laboratoire de Spectrométrie Infrarouge et Raman du C.N.R.S. de THIAIS, pour l'intérêt qu'il a porté à ce travail et pour les discussions dont il nous a fait bénéficier.

The ν_1 and ν_{4bc} infrared absorptions of the NH_3D^+ probe ion dispersed at low concentration in polycrystalline ammonium halides were used to investigate possible correlations between the frequencies of these absorptions and various structural and other parameters of the ammonium compounds. The most important among these parameters are the H...X distance, the acceptor strength of the halogen atom X for hydrogen bonding, and the coordination number C.N. and activation energy E_a for reorientation of the ammonium ion. It is found that the ν_1 and ν_{4bc} frequencies are affected by the acceptor strength and by the degree of 'compression' of the ammonium ion in the crystal, the volume effect. These two factors affect ν_{4bc} in the same direction but ν_1 in opposite directions. As a consequence, in a ν_{4bc} vs. ν_1 plot the halides are separated according to X, C.N., and certain other parameters. The effective radius of the ammonium ion in cubic $(NH_4)_2MX_6$ is shown to increase with the strength of hydrogen bonding.

The E_a vs. ν_1 plot contains two branches. The low-frequency branch is dominated principally by the strength of the hydrogen bonding and corresponds to C.N. 4 and 8 and to *normal* hydrogen bonds. The high-frequency branch is dominated principally by the volume effect and corresponds to C.N. 12 and to hydrogen bonds of highly dynamic character (*fluxional* hydrogen bonds). Ammonium ions with C.N. 6 may correspond to either branch, depending on the formal charge on X. Existence of the so-called symmetrically trifurcated hydrogen bond that has been proposed for the ammonium ion in certain coordinations is not supported by the present evidence.

The problem of the fundamental vibrational frequencies of the 'free' ammonium ion is discussed and values are proposed for the 'limiting' ν_1 and ν_{4bc} frequencies in ammonium halides. Criteria of hydrogen bonding in ammonium halides are reviewed and comment is offered on symmetry aspects of crystallographic transformations in cubic hexahalometallates(IV), A_2MX_6.

OSVALD KNOP, IAN A. OXTON et MICHAEL FALK. Can. J. Chem. **57**, 404 (1979).

Les absorptions infrarouge ν_1 et ν_{4bc} de l'ion sonde NH_3D^+ dispersé en faible concentration dans des halogénures d'ammonium polycristallins ont été utilisées afin d'établir d'éventuelles relations entre les fréquences de ces absorptions et des paramètres relatifs à la structure et à d'autres propriétés des composés de l'ammonium. Parmi ces paramètres, les plus importants sont la distance H...X, l'importance de l'affinité de l'atome halogène X pour la liaison hydrogène, la coordinence C.N. et l'énergie d'activation E_a nécessaire à la réorientation de l'ion ammonium. Il apparait que les facteurs qui ont une influence sur les fréquences ν_1 et ν_{4bc} sont l'importance de l'affinité pour la liaison hydrogène et le degré de "compression" de l'ion ammonium dans le cristal, c'est-à-dire l'effet de volume. Chacun de ces deux facteurs déplace la fréquence ν_{4bc} dans la même direction, mais leurs effets respectifs sur ν_1 ont lieu dans des directions opposées. Par conséquent, les halogénures sont différenciés selon X, C.N., et certains autres paramètres dans le graphique donnant ν_{4bc} en fonction de ν_1. On montre que le rayon effectif de l'ion ammonium dans les phases cubiques $(NH_4)_2MX_6$ s'accroît avec la force de la liaison hydrogène.

Le graphique donnant la variation de E_a avec ν_1 présente deux parties. La partie basse-fréquence est dominée principalement par la force de la liaison hydrogène et correspond à des coordinences 4 et 8 et à des liaisons hydrogène *normales*. La partie haute-fréquence est, elle, dominée principalement par l'effet de volume et correspond à une coordinence 12 et à des liaisons hydrogène de caractère dynamique très prononcé (liaisons hydrogène de type "*fluxional*"). Les ions ammonium en coordinence 6 peuvent correspondre à l'une ou l'autre des deux parties du graphique, selon la charge formelle sur X. Ces faits ne laissent pas supposer

[1]For Part V, see ref. 5.

0008-4042/79/040404-20$01.00/0

l'existence de la liaison hydrogène symétriquement trifurquée qui a été proposée pour l'ion ammonium dans certaines situations.

Le problème des fréquences vibrationnelles fondamentales de l'ion ammonium "libre" est traité, et des valeurs sont proposées pour les fréquences "limite" ν_1 et ν_{4bc} dans les halogénures d'ammonium. Les différents critères relatifs à la liaison hydrogène dans les halogénures d'ammonium sont présentés, ainsi qu'un apperçu sur les aspects de symétrie des transformations cristallographiques dans les hexahalométallates(IV) cubiques A_2MX_6.

Previous papers in this series (1–5) have dealt with the usefulness of the ir spectra of polycrystalline ammonium compounds at low deuteration for diagnosing the site symmetry and obtaining information on hydrogen bonding and motions of the ammonium ion. To avoid, or at least to reduce, spectroscopic complications encountered with the NH_4^+ and ND_4^+ ions (6), we studied the spectra of NH_3D^+ introduced into the crystals as an isotopic impurity by low-level (0.5–2%) deuteration. At these deuterium concentrations the frequencies of the $\nu_1(NH_3D^+)$ and $\nu_{4bc}(NH_3D^+)$ absorptions, which correspond essentially to the ND stretching and HND bending modes, respectively, of isotopically isolated NH_3D^+ ions, are not subject to vibrational coupling. Since they have also been shown (6) to be free from Fermi resonance, they are well suited for investigating the existence of correlations between vibrational frequency and crystallographic and other parameters. The NH_3D^+ probe is representative of the ammonium ion save for those properties that depend critically on the difference in the inertial character of NH_3D^+ (symmetric top) and NH_4^+ (spherical top).

In the present investigation we have attempted to see to what extent the use of the NH_3D^+ probe can contribute toward elucidation of certain poorly known aspects of the behaviour of the ammonium ion. By virtue of its charge and dimensional similarity to the Rb^+ ion, the ammonium ion occurs frequently in crystal environments in which formation of a hydrogen bond simultaneously involving more than one acceptor, typically a trifurcated hydrogen bond, appears possible. However, while the existence of a trifurcated bond has been suggested (7, 8), it has never been demonstrated. The fact that the ammonium ion cannot exist, under any practical conditions, as an isolated entity presents a further complication: it precludes the possibility of obtaining the fundamental vibration frequencies of the 'free' ion, i.e., convergence limits of the effect of hydrogen bonding on vibrational frequency and hence a standard for assessing the strength of individual hydrogen bonds. With these problems in mind we have studied the spectra of the NH_3D^+ probe ion in a number of additional ammonium compounds, most importantly in the cubic and trigonal hexahalometallates(IV), $(NH_4)_2MX_6$, and in ammonium halide and alkali halide matrices, both of the simple cubic (sc, CsCl) and face-centred cubic (fcc, NaCl) types.

To facilitate presentation of our results and conclusions, we deal with details of experimental evidence, and with matters outside the main line of argument, at the end of the paper. Consistent with the previous usage (cf. ref. 2), the term hydrogen bonding, as applied in the following to the ammonium ion, shall include all factors which restrict rotation of the ion to torsional oscillations.

Discussion

The isotopically isolated ND stretching frequencies $\nu_1(NH_3D^+)$ in simple and complex ammonium halides are plotted in Fig. 1 against the best estimates of the corresponding H...X distances. This figure summarizes all such frequencies available at this time. The positions of the H atoms have been determined only in NH_4F (9, 10), with some reservations in the other simple NH_4X halides and, approximately, in $(NH_4)_2SiF_6$ (11) and $(NH_4)_2SnCl_6$ (12) at room temperature. In all the other cases they had to be inferred from geometrical considerations; the estimated H...X distances refer to 'normal' (i.e., essentially straight) N—H...X bonds[3] and the H...X* distances to assumed symmetrically trifurcated bonds. The estimates are based on an assumed N—H distance of 1.03(2) Å and are probably no better than ±0.05 Å and in some cases much worse.

In the following, all the frequencies quoted are those of the NH_3D^+ probe ion at 77 K unless stated otherwise. The site symmetry of the ammonium N atom is denoted, as in ref. 6, by *S* and the effective symmetry of the NH_3D^+ probe ion by *E'*. The coordination number, C.N., is the number of atoms in the immediate environment of an ammonium ion.

NH_3D^+ in Ammonium and Alkali Halide Matrices: Expected Behaviour

NH_4F occupies a unique place in the plot of Fig. 1 in that it appears to be the only ammonium halide in which the immediate environment of the NH_4^+ ion consists of only four acceptors. Although the N atom is located on a polar axis, the axial and non-axial N—H...F distances have been found to be

[3]Where orientation of the NH_4^+ ion is unknown or indeterminate H...X represents the minimum N...X distance less 1.03 Å.

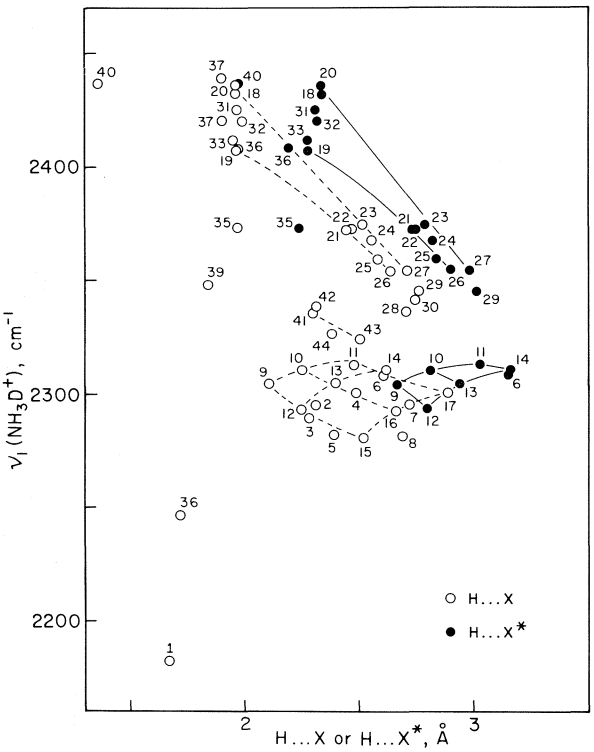

FIG. 1. Variation of $\nu_1(NH_3D^+)$ with H...X (or H...X*) distance in simple and complex ammonium halides. For key numbers refer to Tables 1–4 and text.

equal, within a small experimental error, and so the symmetry of the immediate environment of the N atom is effectively T_d. The single, narrow ν_1 band in the spectrum of NH_4F at 77 K is consistent with the crystallographic evidence. The frequency of this band is the lowest of all ND stretching frequencies reported to date.

The situation in the other simple ammonium halides is complicated by the occurrence of phase transitions. It is best exemplified by the iodide. In the ordered phase *III* each NH_4^+ ion is coordinated by eight I atoms at the corners of a tetragonally distorted cube ($S = D_{2d}$) and simultaneous formation of four normal N—H...I bonds is possible. All the iodine atoms are equivalent and only one type of hydrogen bond occurs. Hence a single, unbroadened ν_1 band is expected and found (Table 1). In the disordered sc phase *II* NH_4^+ is also surrounded by eight I atoms and the diffraction symmetry gives $S = O_h$. However, an iodine atom in this structure may be the recipient of zero to eight hydrogen bonds pointing at random in the eight possible directions, and so a distribution of acceptor strengths and I...H configurations will exist. As a result most of the coordination cubes will be slightly distorted, $S \neq O_h$, and the absorptions corresponding to the distribution of closely-spaced frequencies will appear as ν_1 and ν_{4bc} envelopes. Thus single ν_1 and ν_{4bc} bands will be expected, but this time broadened by the disorder as well as thermally. Single bands are in fact observed; for ν_1, $\Delta\nu_{1/2} \sim 50\ cm^{-1}$ at 250 K compared with $9\ cm^{-1}$ for $NH_4I(III)$ at 77 K. In phase *I*, the NH_4^+ ion is at the centre of an octahedron of iodine atoms and simultaneous formation of four normal N—H...I bonds is not possible. The *S* from diffraction evidence is O_h, and so one might again expect single ν_1 and ν_{4bc} bands but with additional broadening. The actual halfwidth of the single, symmetric ν_1 band was $\sim 65\ cm^{-1}$ at 290 K, and only one ν_{4bc} band was observed.

In the other NH_4X halides the situation is similar (Table 1). Phases *I* of NH_4Cl and NH_4Br occur at temperatures well above ambient and were not investigated, but there is no reason to suppose that the behaviour of the ammonium ion in $NH_4Cl(I)$ and $NH_4Br(I)$ is fundamentally different from that in $NH_4I(I)$. The sc $NH_4Br(IV)$ is the phase stable below 108 K but no spectral differences could be attributed in this work to the *III–IV* transition.

The range of ν_1 frequencies in the chloride, bromide, and iodide spans only about $30\ cm^{-1}$ (Fig. 2). The variation of the ν_1 frequencies between these halides is not clear-cut. While the ν_1 values of $NH_4Br(III)$ and $NH_4I(III)$ are practically the same, that of $NH_4Cl(III)$ is slightly higher. This is possibly related to the X...4H configuration, which is different in the cubic $NH_4Cl(III)$ and the tetragonal $NH_4Br(III)$ and $NH_4I(III)$: in the tetragonal phases each X atom is at the apex of a C_{4v} pyramid, with the four H atoms forming the base, while in $NH_4Cl(III)$ each Cl is *tetrahedrally* (T_d) coordinated by H atoms (7, 13). If the hydrogen bonding in the T_d configuration indeed *is* weaker than in the C_{4v} configuration, resulting in a higher ν_1 frequency in $NH_4Cl(III)$, a similar explanation could be applied to the observed increase in ν_1 associated with the $III \rightarrow II$ transition in the bromide and iodide: in a completely random phase *II* the C_{4v} configuration would account for only 6/70 ~ 8.5% of the X...4H and 6/256 ~ 2.3% of all the hydrogen-bonding geometries at the X atoms. It should be emphasized that the differences in ν_1 in the chloride, bromide, and iodide are very small compared to the difference of over $100\ cm^{-1}$ between ν_1 of NH_4F and NH_4Cl.

In the sc matrices **15–17** single narrow ν_1 bands are observed, consistent with $S = O_h$ and $E' = C_{3v}$ (6). Also observed is the anticipated increase in the ν_1 frequency from **15** to **17**. Single ν_1 and ν_{4bc} bands are also present in the spectra of the NH_3D^+ ion in

[c] See text.
[d] The possibility that the actual symmetry of NH_4Cl(*III*) is $P4_2/mcm$ (No. 132) (cf. ref. 64) does not affect the discussion of NH_4Cl(*III*) and NH_4Br(*III*) in the text, which is based on the distinction between the parallel (in the chloride) and the antiparallel (in the bromide and iodide) alignment of the ammonium ions.

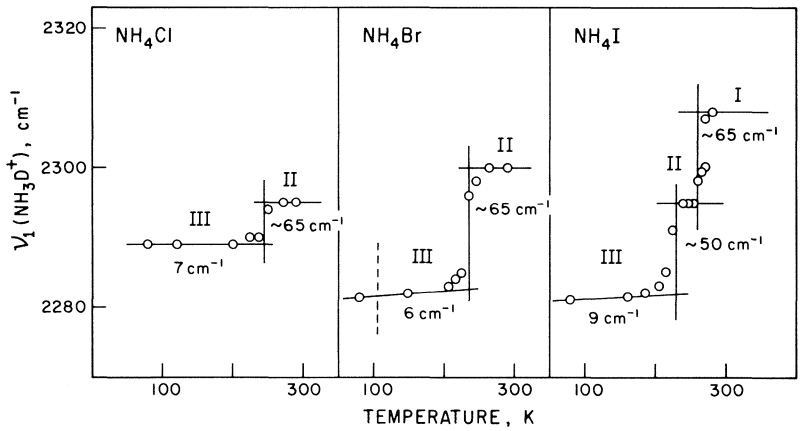

FIG. 2. Variation of $\nu_1(NH_3D^+)$ in simple ammonium halides with temperature. The halfwidths of the ν_1 absorptions are indicated.

the fcc matrices **9–14** ($S = O_h$) but the absorptions are significantly broader. The implications of these differences in bandwidth are discussed below.

Compared with the corresponding NH_4X halides, the acceptor strength of the X atoms in the CsX matrices is little affected by hydrogen bonding to neighbouring NH_4^+ ions because of the dilution, and an increase in hydrogen-bond strength and therefore lower ν_1 frequencies would be expected. This decrease is by no means evident. This means that it is masked by other effects of at least equal order of magnitude and possibly opposite direction (see below).

NH_3D^+ in Cubic and Trigonal $(NH_4)_2MX_6$: Unexpected Behaviour

In the cubic hexahalo compounds (Table 2) the ammonium ion is coordinated by 12 equidistant X atoms at the corners of four tetrahedrally disposed equilateral 3X triangles (= cuboctahedron of symmetry T_d) (Fig. 1 of ref. 1). A single ν_1 band is observed in the spectra of these crystals, consistent with $S = T_d$. The frequencies of this band show an unexpected trend: they *decrease* from F to Br and with increasing H...X (or H...X*) distance.

The trigonal $(NH_4)_2MX_6$ in this investigation are restricted to the fluorides (Table 3). Because of

$\nu_{4b}(n)$	1278.2	1272.9	1268.0	1274.7
$\nu_{4c}(n)$	1256.8	1258.9	1263.2	1256.2

$S = C_{3v}$, $E' = C_{3v} + C_s$ (3), there are *two* ν_1 components, $\nu_1(a)$ and $\nu_1(n)$, in an intensity ratio of 1:3 (2). The $\nu_1(a)$ frequency is the higher of the two and corresponds to a symmetrically trifurcated situation. The values for the Si, Ge, Ti, and Sn fluorides fall between those of **18** and **19**.

The cubic $(NH_4)_2SnBr_6$ and $(NH_4)_2TeBr_6$ on cooling transform to phases of lower symmetry.[4] The symmetry reduction causes the ν_1 absorption in the cubic phases to split into four components at 77 K, but, more importantly, the frequency corresponding to the centroid of the composite absorption bands is lower than the ν_1 of the corresponding cubic phase. This implies that the strength of the hydrogen bonding has increased when the immediate environment of the ammonium ion has changed from one in which the 12 nearest Br atoms are distributed very uniformly (at the corners of an almost regular cuboctahedron) to a less symmetric (unknown) environment, presumably favouring formation of a preferred hydrogen bond.

[4]The spectra of NH_3D^+ in these low-symmetry phases are described more fully in the Experimental section. Certain symmetry aspects of transitions in A_2MX_6 are examined in the Appendix.

Acceptor Strength vs. Volume Effect

To account for the unexpected direction of variation of ν_1 with H...X let us first consider NH_3D^+ in the alkali halide matrices and in the cubic $(NH_4)_2MX_6$. In Fig. 1 the ν_1 vs. H...X points for the KX and RbX matrices form a net which joins smoothly with the corresponding points for CsX. Leaving aside for the moment the difference between the fcc and sc structures, we see that ν_1 increases, for a given cation, from Cl to I and decreases, for a given X, from K to Cs. The points for NH_4Cl, $NH_4Br(II)$, and $NH_4I(I)$ fall close to the corresponding points for RbX.

These trends demonstrate that ν_1 is affected by two factors acting in opposite directions: acceptor strength for hydrogen bonding and a volume effect.

The acceptor strength decreases from Cl to I, so that, for a given cation, the hydrogen bond weakens and ν_1 increases. On the other hand, for a given acceptor, decreasing the size of the matrix cation compresses the three-dimensional potential well of the H atoms in the probe and raises ν_1. Thus ν_1 in KI has the highest and in CsCl the lowest value of the nine. In NH_4F, in which the energy of the hydrogen bonds has been estimated to be about 3.5 kcal/mol (cf. ref. 9), the acceptor strength is clearly the dominant factor.

The cubic $(NH_4)_2MX_6$ set is not as complete. For some M,X combinations the chemistry or crystal chemistry are unfavourable, and spectra of NH_3D^+ in the iodides could not be obtained because of sample absorption. However, in the two series for which three points are available, Pt,X and Sn,X, ν_1 decreases with increasing H...X, i.e., from F to Br.

In the KX, RbX, and CsX series the ν_1 vs. H...X curves are concave while in the MCl, MBr, and MI series they are convex, tending to level off as H...X increases. In the $(NH_4)_2SnX_6$ series, however, the curve appears to be a straight line and in the $(NH_4)_2PtX_6$ series it is convex and tends to level off with *decreasing* H...X. This must mean that in the alkali halide matrices hydrogen bonding and the volume effect are almost equally significant and largely compensate each other as H...X increases,[5] while in the $(NH_4)_2MX_6$ compounds the volume effect dominates the variation of ν_1 with H...X. As H...X decreases, the hydrogen-bonding interaction, which is very weak for X = Br, becomes stronger and is significant in $(NH_4)_2SiF_6$. The progressive strengthening of the hydrogen bonding is sufficient to alter the concave curve expected for the pure volume effect to the observed straight line and moderately convex curve, respectively.

The presence of the volume effect in $(NH_4)_2MX_6$ would be demonstrated most directly if an increase in ν_1 of the NH_3D^+ probe was observed from Cs_2PtCl_6 to K_2PtCl_6. In these matrices the acceptor strength and geometry are practically the same, and replacing one alkali ion by another would be expected to affect NH_3D^+ (at a shortest distance of 5–5.2 Å from an alkali neighbour) merely through the changing volume of the matrix. Unfortunately, we did not succeed in our attempts to incorporate ammonium ion into A_2PtCl_6, A_2SnCl_6, or A_2SiF_6 in amounts sufficiently large to observe the NH_3D^+ spectrum. However, in the presence of significant hydrogen bonding the ND stretching frequency ν_1 would be expected to decrease, and the HND bending frequency ν_{4bc} to increase, with the strength of the bonding. This expectation is verified in the fcc alkali halide matrices, but in the $(NH_4)_2MX_6$ the trend is reversed (Fig. 3), showing that in these crystals the increase in ν_{4bc} is, but that in ν_1 is not, due to an increase in hydrogen-bonding strength. Figure 3 also shows that the positions of the points for the non-cubic low-temperature phases of $(NH_4)_2SnBr_6$ and $(NH_4)_2TeBr_6$ differ enough from those for the corresponding cubic phases (above T_{tr}) again to indicate that the strength of the hydrogen-bonding interaction has increased from the cubic to the less symmetric low-temperature phase.

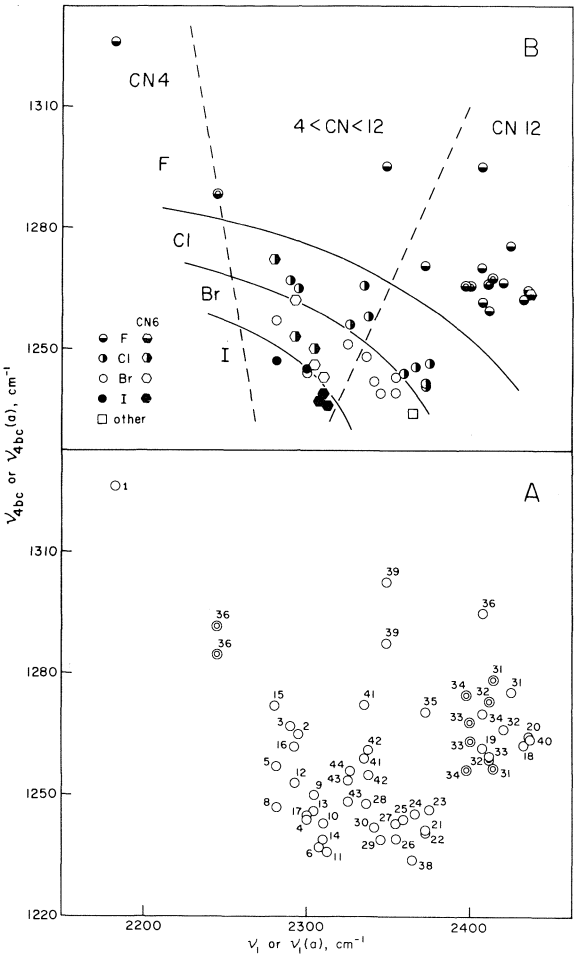

FIG. 3. Correlation of the ν_1 and ν_{4bc} frequencies of the NH_3D^+ probe ion in simple and complex ammonium halides. (*A*) All available values. The non-axial $\nu_{4b}(n)$ and $\nu_{4c}(n)$ values of **31–34** and **36** are shown as double circles. (*B*) Display of acceptor and C.N. For the alkali halide matrices (**9–17**), in which the NH_3D^+ ion is in a constrained situation, the separation by acceptor is not completely clean. Mean values are plotted where more than one component of the ND bending absorption occurs (**36, 39, 41–43**); $\nu_{4b}(n)$ and $\nu_{4c}(n)$ values of **31–34** have been averaged.

[5]The ν_1 for KCl, RbBr, and CsI are almost identical; so are the ν_1 for KBr and RbI and the ν_1 for RbCl and CsBr.

A clear demonstration of the existence of the volume effect as a general factor affecting the stretching frequency of a hydrogen bond is presented, for a *strong* bond, in Fig. 4: the antisymmetric stretching frequency ν_3 at room temperature, of the linear $(FHF)^-$ ion dispersed in alkali halide matrices increases with the decreasing linear dimension $\bar{a} = (V/Z)^{1/3}$ of the matrix (data taken from Fig. 1 of ref. 14). While each of the NaX, KX, and RbX series forms a separate correlation, Ketelaar and van der Elsken (14) showed that, on applying the Bauer–Magat correction, all the points in a ν_3(corr.) vs. $1/a$ plot fall on a smooth curve. In our presentation, $\nu_3(\text{corr.}) = c_1 + (c_2/\bar{a})^4$, with $r^2 = 0.999$ and $\sigma = 2.2\ \text{cm}^{-1}$.[6] The ν_3 values in pure $NaHF_2$ (at 5 and 35 kbar) and KHF_2 (at 1 atm and 40 kbar) (15) fall below the respective curves for NaX and KX, but their line segments have slopes comparable to those of the NaX and KX curves. When the $NaHF_2$(5 kbar) and KHF_2(1 atm) points are brought, by vertical displacement, in coincidence with the ν_3(corr.) vs. $\bar{a}$ curve, the points for $NaHF_2$(35 kbar) and KHF_2(40 kbar), on corresponding displacement, fall on its extension. Although the high-pressure compressibility data for the two acid fluorides are not available,[7] and leaving open the question of validity of the Bauer–Magat correction, it is clear that the effect on ν_3 of the variation of the dimensions of the potential field to which the *internally* hydrogen-bonded $(FHF)^-$ ion is subject in the matrix, is the same, be the variation of $\bar{a}$ produced by mechanical compression or by manipulating the volume of the host structure chemically. In $(FHF)^-$ a hydrogen bond of maximum strength already exists, and on compression the stretching frequency will be affected by a closer approach of ionic charges external to the $(FHF)^-$ ion, of atoms not participating in the hydrogen bonding, hence an essentially pure volume effect. By contrast, the strength of hydrogen bonding of the ammonium ion in $(NH_4)_2MX_6$ will depend on the extent of effective compression, and as the nearest-neighbour anions participate in the hydrogen bonding, further compression will tend to strengthen the hydrogen bond at the same time as it raises the stretching frequency through the stronger factor, the volume effect.

Another consequence of the volume effect in crystals in which it dominates is the direction of variation of the vibrational frequencies on cooling. In the absence of crystallographic transitions, cooling a crystal in which S is cubic[8] will raise all the internal frequencies because of the uniform, symmetry-preserving contraction of the charge field acting on the ammonium ion. The increase may be expected to be more pronounced in crystals containing less compressible (polarizable) counterions and, in general, when the contraction is imposed on a guest ion by the matrix. Taking the mean linear coefficient of thermal expansion α of KX and RbX to be, typically, $3.5 \times 10^{-5}\ \text{deg}^{-1}$ (16), and estimating from Fig. 1 the mean variation $\partial\nu_1/\partial(\text{H}\ldots\text{X})$ in the fcc matrices as $50\ \text{cm}^{-1}/\text{Å}$, leads to an expected increase in ν_1 of only about $3\ \text{cm}^{-1}$ on going from room temperature to 77 K.[9] The actual increase is no greater than $2\ \text{cm}^{-1}$ where the room-temperature frequency can be determined accurately. In **22** and **25** (1) the variation did not exceed $3\ \text{cm}^{-1}$, but the direction of the shift could not be determined because the ν_1 absorption in the room-temperature spectra was poorly defined (cf. Fig. 2 of ref. 1). The observed increases include the compensating effect of the strengthened hydrogen bonding attendant on the temperature reduction.

The conclusion that the strength of the hydrogen-bonding interaction in cubic $(NH_4)_2MX_6$ increases

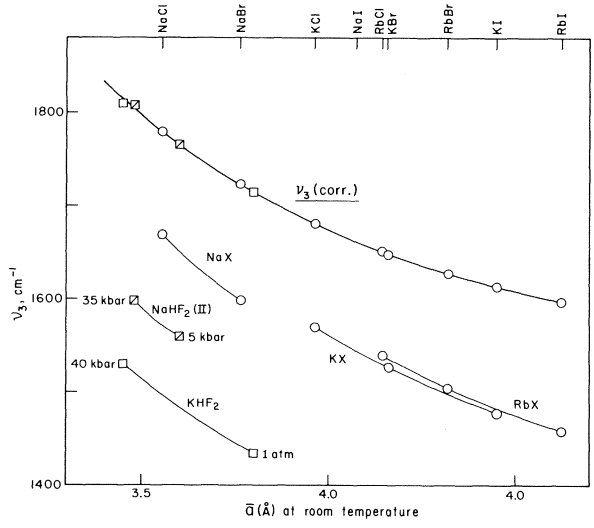

FIG. 4. Variation of the antisymmetric stretching frequency ν_3 of the $(FHF)^-$ ion with the linear dimension $\bar{a}$ of the host matrix.

[6]The coefficient of determination r^2 is the square of the correlation coefficient.

[7]The compressibilities of $NaHF_2$ and KHF_2 were assumed to be similar to those of NaBr and KBr, respectively.

[8]Sites of cubic symmetry occur in all 36 cubic space groups but nine: *Nos.* 198, 199, 205, 206, 212–214, 220, and 230.

[9]Similar considerations predict an increase of about 1.5 cm^{-1} for the ν_4 and about $4\ \text{cm}^{-1}$ for the $\nu_2 + \nu_4$ absorptions of the $^{11}BH_4^-$ ion in alkali halide matrices, with the expected increases in ν_3 and $2\nu_4$ intermediate and about equal. The observed increases on cooling, as estimated from Figs. 1 and 2 of ref. 17 (allowing for a misprint in the captions) and Fig. 11 of ref. 18, are of this order.

from Br to F is supported by the variation of the effective radius of the ammonium ion in these compounds, by consideration of the activation energies for reorientation of the ion and by the progressive increase in the temperature at which combination bands involving librations begin to appear in the spectra of the NH_4^+ ion. Some support comes also from diffraction experiments bearing on the whereabouts of the H atoms. This evidence, in turn, will be considered next.

Effective Radius of the Ammonium Ion

The existence of the large family of isostructural cubic A_2MX_6 halides affords an opportunity to examine in some detail the vexatious problem of the effective radius of the ammonium ion. Shannon (19), in his comprehensive compilation, remarks that "the nature of NH_4^+ made it impossible to define its ionic radius...Khan and Baur (8) derived an apparent radius of the NH_4^+ ion by analyzing the N—O distances in a large number of ammonium salts. They concluded that NH_4^+ has an octahedral radius of 1.61 Å, between that of Rb^+ (1.52 Å) and Cs^+ (1.67 Å). Alternatively, cell volumes of NH_4^+ and Rb^+ fluorides, chlorides, bromides, iodides, and oxides may be compared. This leads to the conclusion that

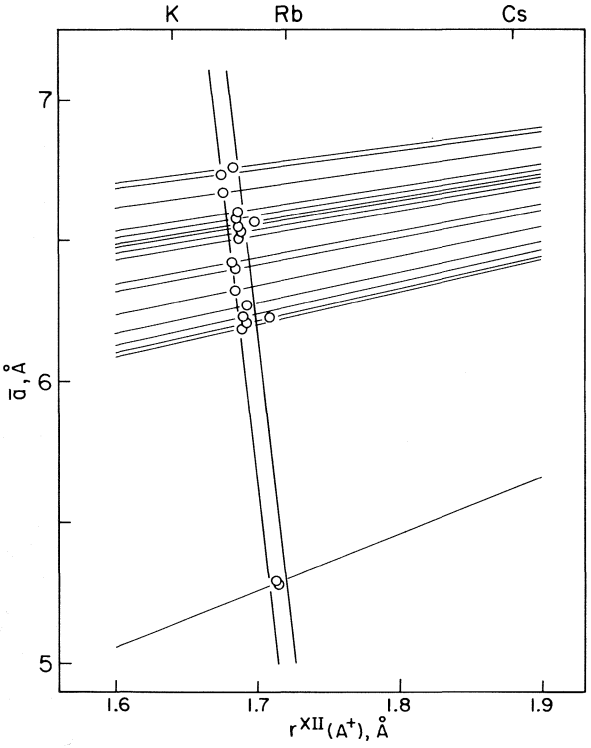

FIG. 5. Variation with $\bar{a}$ of the effective radius r^{xii} of the ammonium ion in cubic $(NH_4)_2MX_6$.

NH_4^+ is not significantly different in size from Rb^+. No explanation is offered for this inconsistency and therefore the radius of NH_4^+ is not included". Brown (20) used an empirical value of 1.56 Å for C.N. 12, compared with 1.60 Å for Rb^+. Agarwal and Shanker (21) attempted to estimate the 'crystal' radius of NH_4^+ (C.N. 8?) from a polarizability–radius relation; their value, 1.58 Å, is contrasted with Pauling's 1.48 Å and Slater's 1.90 Å.

When the room-temperature values of $\bar{a} = a/\sqrt[3]{4}$ for the cubic A_2MX_6 (A = K, Rb, Cs) are plotted against Shannon's ionic radii $r^{xii}(A^+)$ (K, 1.64; Rb, 1.72; Cs, 1.88 Å), the three points in each M,X series are linearly correlated, with $r^2 > 0.98$ and $\sigma < 0.04$ Å. In fact, for the chlorides of Ti, Pd, Pt, Mo, Sn, Pb, Te and bromides of Pd, Pt, Re, Sn, and Te, $r^2 \geq 0.998$ and $\sigma < 0.008$ Å. The fit was worse only for the fluorides, **18** ($r^2 = 0.993$, $\sigma = 0.029$ Å) and **20** ($r^2 = 0.988$, $\sigma = 0.037$ Å), probably owing to a genuine slight departure from linearity. Moreover, the $\bar{a}$ vs. $r^{xii}(A^+)$ straight lines are seen to converge with increasing values of the radius (Fig. 5). When they are treated as a pencil of lines, the point of intersection is at $r^{xii} = 2.805$ Å and $\bar{a} = 7.473$ Å. Constraining the correlation lines for the individual series by least squares to pass through this fictitious point[10] results in an overall σ of 0.010 Å (**18**, $\sigma = 0.021$ Å; **20**, $\sigma = 0.027$ Å). This is about twice the realistic estimate of a typical error on the reported a values. M,X series for which only two of the three points are available can now be included with some confidence.

When the observed room-temperature values of $\bar{a}$ for the NH_4^+ members of the series are used to calculate the respective $r^{xii}(NH_4^+)$ values from the smoothed correlation equations, $r^{xii}(NH_4^+)$ is seen to decrease with increasing $\bar{a}$, i.e. from F to Br (Fig. 5). A straight line fitted to the ammonium points, $r^{xii}(NH_4^+) = 1.836 - 0.023\bar{a}$, has $r^2 = 0.72$ and $\sigma = 0.006$ Å, while the total range of $r^{xii}(NH_4^+)$ is from about 1.714 to about 1.675 Å, *relative to the fixed* r^{xii} *values for* K^+, Rb^+, *and* Cs^+. This increase from Br to F is small but real and must be attributed to the increased hydrogen-bonding interaction in the hexafluoro compounds, which tends to expand the charge cloud of the ion. Thus the effective radius of the ammonium ion relative to Rb^+, which is similar in size, is not constant even in this one isostructural series of high crystallographic symmetry. In general, the radius will vary, for a given C.N., with the extent

[10]This procedure is merely an artificial smoothing device whose use is justified by the overall goodness of fit. It does not apply to composite cations like Me_4N^+; in $(Me_4N)_2SnCl_6$ a is determined by Cl...Me...Cl contacts (25).

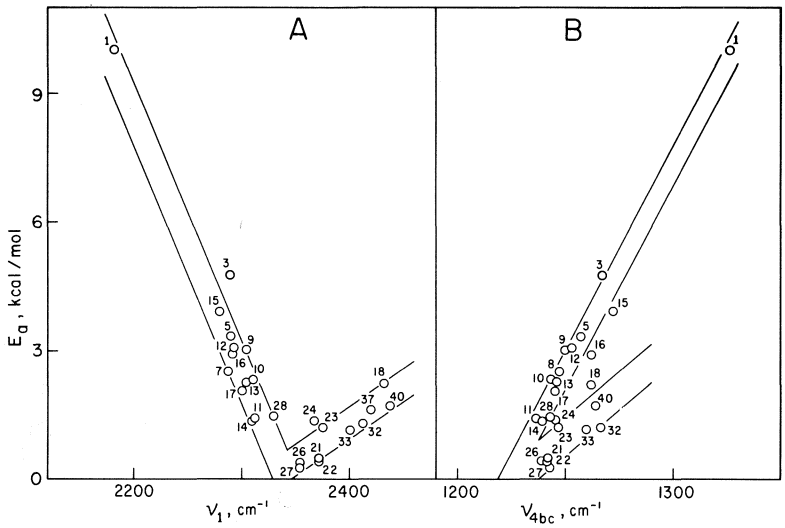

FIG. 6. Activation energy E_a for reorientation of the NH_4^+ ion plotted against $\nu_1(NH_3D^+)$ (*A*) and ν_{4bc} (*B*) frequencies. The vertical widths of the bands represent the $\pm 1\sigma$ limits of goodness of fit. The $\nu_1(n)$ frequencies have been used for **32**, **33**, and **37**, and weighted means of ν_4 for **32** and **33**.

of hydrogen bonding and no single fixed value can be given.

Activation Energy for Reorientation of the Ammonium Ion

This energy, E_a, would be expected to decrease with the strength of the hydrogen-bonding interaction, tending to zero as the barriers to reorientation are progressively reduced and the corresponding potential function becomes smoother, i.e., with increasing H...X and C.N. On the reasonable assumption that $E_a(NH_3D^+) \sim E_a(NH_4^+)$, for those compounds in which hydrogen bonding is significant the E_a value ought to correlate with ν_1. That this is the case can be seen in Fig. 6*A*. Although the functional nature of the E_a,ν_1 association is not known, for **1**–**17** and **28** a linear regression of E_a on ν_1 yields $r^2 = 0.90$ ($\sigma = 0.72$ kcal/mol), indicating that even a linear correlation is highly significant. On the other hand, the E_a,ν_1 points for cubic and trigonal[11] $(NH_4)_2MX_6$ (including **27**), NH_4BF_4, and NH_4PF_6 fall in a different correlation region: linear regression of E_a on ν_1 gives $r^2 = 0.69$ ($\sigma = 0.38$ kcal/mol), hence even this, separate, linear correlation is significant. This implies that as the volume effect, imposed on the ammonium ion by the electrostatic energy requirements of the matrix crystal (as compared with the corresponding Rb compound), becomes more significant the height of the barrier to reorientation increases and so does E_a. This increase in barrier height may be viewed as an increase in hydrogen-bonding interaction, in support of our above contention that this interaction increases from Br to F.[12] The strength of the hydrogen bonding therefore increases both to the left and to the right of the region of minimum E_a in Fig. 6*A*.

The E_a,ν_1 correlation would be represented more properly by a curve within the two $\pm 1\sigma$ bands of Fig. 6*A* and having a minimum corresponding to a very low E_a value in the vicinity of $\nu_1 = 2340$ cm^{-1}. Several such functions could be proposed, but the final choice will have to await the availability of further E_a data. No E_a values appear to exist for $(NH_4)_2MX_4$ or NH_4MF_3 salts but would clearly be of use; **41**, **36**, and the perovskite NH_4ZnF_3 (isostructural with **35**) would be obvious candidates for nmr studies.

A similar plot for ν_{4bc} (Fig. 6*B*) shows that E_a decreases with the frequency of the bending vibration. This is not unreasonable to expect, considering that the bending and librational modes involve motions perpendicular to the N—H...X bond and, if the reorientational motion is seen as a libration executed from one local minimum to another, across the hindering potential barrier. A linear regression of E_a on ν_{4bc} gave $r^2 = 0.75$ ($\sigma = 1.02$ kcal/mol) when all the available points were included; $r^2 = 0.48$ ($\sigma = 0.84$ kcal/mol) for all the points less

[11]The $\nu_1(n)$ values were used for **32** and **33**, and the lower of the two ν_1 values for **37**, on the view that at least three hydrogen bonds must be 'broken' in the reorientation, at least one of which being of necessity that corresponding to the stronger interaction and hence to lower stretching frequency.

[12]Bonori and Terenzi (22) remark that in some cubic $(NH_4)_2MX_6$ salts, E_a *increased* with decreasing lattice constant. This obviously corresponds to the high-frequency branch of our E_a vs. ν_1 plot of Fig. 6*A*.

NH_4F; $r^2 = 0.96$ ($\sigma = 0.44$ kcal/mol) for the points of the low-frequency branch of Fig. 6*A*; and $r^2 = 0.57$ ($\sigma = 0.45$ kcal/mol) for the high-frequency branch. All four regressions indicate that the correlation is significant. The regression lines intersect $E_a = 0$ at ν_{4bc} between 1225 and 1230 cm^{-1}; this range of values may be regarded as an upper-bound estimate of the 'limiting' ν_{4bc} frequency (= the 'free ion' value) in crystals of ammonium halogen compounds.

Combination Bands Involving the $\nu_6(NH_4^+)$ Librational Mode

In general, the $\nu_2 + \nu_6$ and $\nu_4 + \nu_6$ bands of NH_4^+ are observed in the room-temperature spectra of ammonium salts in which *normal* hydrogen bonds are present but not of those where the ammonium ion occurs in a trifurcated situation. However, in such cases they may appear when the temperature of the sample is lowered.

Gardner *et al.* (23), who studied the inelastic neutron scattering spectra of NH_4^+ in alkali halide matrices, found that in CsX peaks corresponding to the librational (torsional) fundamental ν_6 itself were quite well resolved even at room temperature. However, in the fcc matrices under comparable conditions, the corresponding peaks were so broad that for the iodides they could not be located with the instrument used; the torsional peaks remained much sharper in the CsX matrices down to liquid-helium temperature. Similar differences were observed, for the combination bands, in the ir spectra of NH_4^+ in such matrices. In the room-temperature ir spectra of $(NH_4)_2MX_6$ the combination bands occur only in **18–20** and in **31** and **32** (2). They were absent in the spectrum of **23** at 77 K, reflecting the weakness of the hydrogen bonding in the chloride **23** compared with the fluorides **18–20**, but the $\nu_4 + \nu_6$ band emerged on cooling the sample to 22 K (Fig. 7).[13] Its relative sharpness strongly suggests that a considerable change in the motions of the ammonium ion has occurred as a result of cooling.

Effect of Acceptor Atom on ν_1: Coordination Number, NHX Angle, and Formal Charge*

Returning to Fig. 1, we now can make certain observations concerning the effect of the acceptor atom X on ν_1. When the ν_1 values of a number of additional ammonium halides (Table 4) are introduced, trends associated with C.N., the NHX* angle, and the formal charge on X begin to emerge (Fig. 8).

NH_4F is the only ammonium halide in which C.N. equals the number of normal hydrogen bonds

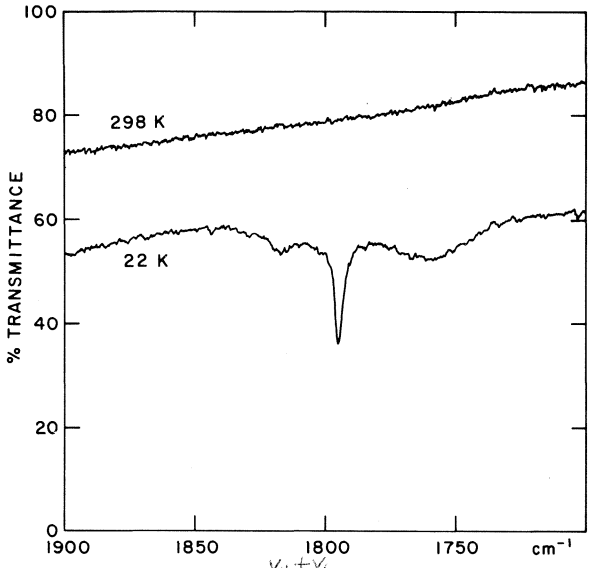

FIG. 7. The $\nu_2+\nu_6$ and $\nu_4+\nu_6$ region of the spectrum of NH_4^+ in $(NH_4)_2SnCl_6$ (**23**) at 298 and 22 K.

formed. NH_4SnF_3 is an intermediate case: C.N. is 6, but three of the ammonium hydrogens form normal N—H...F bonds with the three F atoms of an SnF_3^- ion (tetrahedral bonds similar to those in NH_4F) and the fourth point, along a C_3 axis, at the centre of a triangle of F atoms belonging to different SnF_3^- ions. This constitutes a symmetrically trifurcated situation and the C.N. is more properly 3 + 3. The $\nu_1 = 2246$ cm^{-1} frequency in **36** is the second lowest in Fig. 1. See errata, p. 423

The next compound encountered in the approximate direction of a straight line drawn through the **1** and **36** points in Fig. 2 is **39**, C.N. 8, followed by **35**, **37**, and $(NH_4)_2MF_6$, all of which have C.N. 12. In the perovskite NH_4MnF_3, which is cubic at 200 K and above, the coordination figure is an undistorted cuboctahedron ($S = O_h$), while in the cubic $(NH_4)_2MF_6$ the coordination cuboctahedron is of symmetry T_d.[14] In NH_4BF_4 the coordination figure is irregular, $S = C_s$. Since the H...X distance along this straight line does not vary greatly, the increase in ν_1 in the fluorides is attributed to the increase in C.N., even though C.N. is not the only factor (see below). A similar trend is observed for the chlorides and bromides.

The case of C.N. 6 is somewhat different in that there is no clear separation of the ν_1 frequencies for C.N. 6 from those for C.N. 8 (**2–5** and **7–17**). This point will be discussed in more detail later. NH_4PF_6 (C.N. 6) is close to **37** (C.N. 12), but here the low formal charge on the F atom is probably the domi-

[13]Although the possibility of a phase transition below 77 K has been raised (24) our NH_3D^+ spectra between 22 and 80 K showed no evidence of it.

[14]It approaches a metrically regular cuboctahedron as $x(X) \rightarrow \frac{1}{4}$, i.e. from F to Br.

nant factor. With this exception, the periphery of the plot in Fig. 8, as seen from the NH_4F point, consists of points corresponding to C.N. 12.

The NHX* angle, in compounds where symmetric trifurcation (i.e. $S \supset C_3$) is obtained, is defined as the obtuse angle formed by the XH vector and the NH vector pointing at the centre of the equilateral triangle of X atoms. It cannot be divorced from C.N. In compounds with C.N. 6, NHX* = 100–110°; in those with C.N. 12, NHX* = 120–135°. For C.N. 12 a trend is discernible not only for ν_1 (Fig. 8) but also for ν_{4bc} (Fig. 9). In both cases the frequency decreases as NHX* increases, i.e., as the H atom moves away from the plane of the 3X triangle. There also appears to be a moderately strong ($r^2 = 0.54$) correlation between NHX* and E_a: the closer NHX* is to 90°, the higher is E_a.

In ammonium halides containing isolated or linked complex anions MX_n the acceptor strength does not depend only on the nature of the halogen atom but also on its formal charge. The latter is defined as $(pc/n) - 1$, where c is the formal charge on M and p is the C.N. of X relative to M. In addition, X may be a simultaneous recipient of a total of q hydrogen bonds from ammonium ions. These quantities are listed, for compounds of interest, in Table 5.

It is evident that the formal charge affects the variation of ν_1 but not independently of C.N. and NHX*; the effect of p and q is not clear. For example, the increase in ν_1 in the fluoride sequence **39**, **35**, **40** is associated with a decrease in the formal charge but also with a simultaneous increase in C.N. The ν_1 of **18** is about the same as that of **40**, in spite of the formal charge in **18** being $-1/3$ compared with $-1/6$ in **40**. However, q(**18**) = 4q(**40**) and this, together with the decrease in H...X and NHX* from **18** to **40**, appears to outweigh the doubling of the formal charge.

The 'Free Ion' ν_1 and ν_{4bc} Frequencies

The ν_1 frequencies of the several families of halides

TABLE 5. Formal charges on acceptor atoms in complex ammonium halides

	Compound	Structural arrangement	p	Formal charge	q

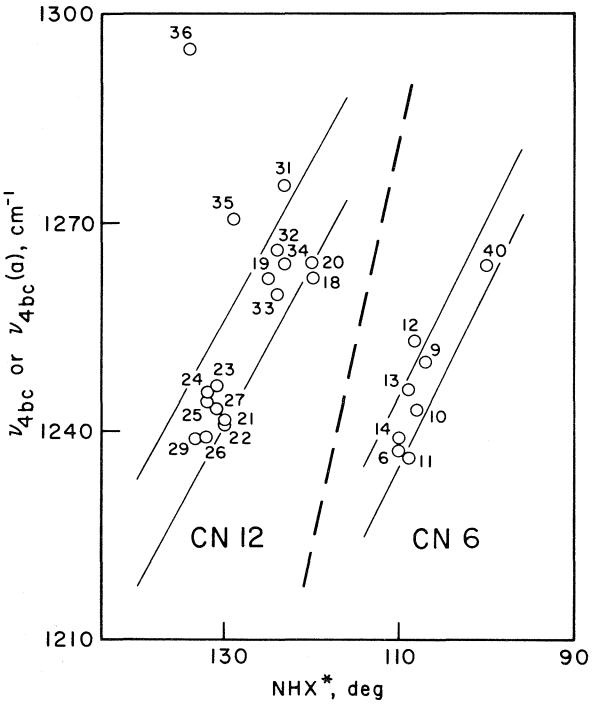

FIG. 9. Variation of $\nu_{4bc}(NH_3D^+)$ with the NHX* angle in simple and complex ammonium halides. The point for **36** was not included in the regression.

in the ν_1 vs. H...X plot of Fig. 1 are seen to converge, with increasing H...X, to a 'limiting' value somewhere in the region of 2320–2340 cm^{-1}. A similar convergence is observed in the ν_{4bc} vs. ν_1 plot of Fig. 3, to ν_{4bc} values in the vicinity of 1220 cm^{-1}, and also in Fig. 6. All these trends are manifestations of the same basic fact, viz. the division of the ammonium halides into two main groups, one in which ν_1 is dominated principally by hydrogen bonding and another, in which the dominant factor is the volume effect. The two frequencies, $\nu_{1,\infty}$ = 2330–2340 and $\nu_{4bc,\infty}$ = 1220–1230 cm^{-1}, may thus be regarded as corresponding to 'zero' hydrogen bonding and a minimum volume effect, i.e., to the 'free ion' state in halide crystals. The $\nu_{1,\infty}$ value is to be compared with that proposed recently (5) for the ν_1 vs. N...O correlation in the ammonium Tutton salts, 2450–2500 cm^{-1}. The cut-off H...X value corresponding to this hypothetical state of the ion is difficult to estimate but it would seem to be at least 3.4 Å.

In this connection it is of interest to observe that in NH_4BPh_4 (**38**), in which the ammonium ion has been regarded as non-hydrogen-bonded (26), the ν_1 is 2364 cm^{-1}, i.e., above the estimated $\nu_{1,\infty}$, but the ν_{4bc}, 1234 cm^{-1}, is the lowest in Tables 1–4 and Fig. 3. The only conceivable hydrogen bonding, to the π systems of the benzene rings, would be expected to lower ν_1, so we conclude that the ammonium ion in this crystal is in a state of compression imposed by electrostatic interactions similar to those existing in the presumably isostructural Rb salt. Thus the idea (27) that one should take the highest observed $\nu_3(NH_4^+)$ as representing the frequency of the 'free' ammonium ion must be considered dubious.

It should be noted that, as the volume effect cannot be evaluated *absolutely* but only along an isostructural series, the contribution of the 'compression' of the ammonium ion to ν_1 in an isolated compound can be estimated only with reference to the aggregate of available results for NH_3D^+, such as presented for the halides in Fig. 3.

Does a Symmetrically Trifurcated Hydrogen Bond Exist?

The answer to this question must be compatible with the evidence from the ir spectra of the NH_3D^+ probe ion: (*1*) Where favourable geometry for the possible existence of a trifurcated bond is obtained, only *one* ν_1 absorption is observed when *S* is cubic, and this absorption at 77 K is narrow. (*2*) The difference between the ν_1 value in $NH_4I(I)$ and those in $NH_4I(II)$ and $NH_4I(III)$ is small compared with the total ν_1 range of ca. 250 cm^{-1} in Fig. 1, about 13 cm^{-1} between phases *I* and *II* and about 27 cm^{-1} between *I* and *III*. (*3*) The difference between the ν_1 values in the fcc RbX and the corresponding sc CsX matrices amounts to only about 10 cm^{-1} if one allows for the volume effect (by comparison between the KX and RbX salts).

Comparison of the halfwidths of ν_1 at 77 K shows that $\Delta\nu_{1/2}$ is 3–9 cm^{-1} in cases where normal hydro-

gen bonds are expected (phases *III* of NH_4X and CsX matrices) but 17–28 cm^{-1} in the fcc matrices (Table 1). This striking difference is undoubtedly real and seems to be indicative of enhanced motions of the NH_3D^+ ion (and by implication the NH_4^+ ion) in the fcc environments. The extra breadth does not result from stronger hydrogen bonding, for the ν_1 frequencies are much the same in the sc and the fcc crystals. Its most likely origins are rapid reorientation and large librational amplitude. Gardner *et al.* (23) failed to observe, in their inelastic neutron scattering studies, any quasielastic broadening of the elastic peak and hence they ruled out the former. The origin of the extra breadth then appears to lie in large-amplitude librations of the ammonium ions.

The transition from the ordered phase *III* to the disordered phase *II* in simple ammonium halides is associated with a large increase in the halfwidth of ν_1 (Table 1): $\Delta\nu_{1/2}$ increases from 6–9 cm^{-1} to 50 cm^{-1} or more. A portion of the extra breadth must be due to the distribution of acceptor strengths attendant on disordering. When the already disordered sc $NH_4I(II)$ transforms to the fcc phase *I*, an additional increase in $\Delta\nu_{1/2}$ of about 15 cm^{-1} is observed. This is of the same order as the difference between the sc and fcc matrices at 77 K, though a fraction of this increase will come from the thermal broadening owing to the difference of about 40 deg between the temperatures of measurement. It thus seems that the change-over from the 'normal' to the 'trifurcated' regime is associated with an increase in $\Delta\nu_{1/2}$ of the order of 15 cm^{-1}, and that this increase corresponds to an enhanced librational motion of the ammonium ions.

Another kind of evidence which must be reconciled comes from diffraction studies. When the librational amplitude is large, interpretation of the results of such studies becomes difficult and ambiguous. Of the three available, room-temperature studies bearing on trifurcation in ammonium halides, one concerns **6**, another deals with **18**, and the third is an X-ray study of **23**. The conclusion from the detailed neutron-diffraction study of $NH_4I(I)$ is that there are six equivalent maxima in the proton-density distribution round the N atom; they are associated with the corners of the octahedron of iodine atoms (28). In $(NH_4)_2SiF_6$, according to the neutron-diffraction study of Schlemper and co-workers (7, 11), three local proton-density maxima are associated with each threefold axis of the ammonium ion in the directions pointing away from the Si atoms. In the view of those authors these maxima are to be looked upon as a manifestation of a dynamic rather than static disorder. The data of Schlemper *et al.* were re-analyzed, at our request, by Press using cubic harmonics (29) and the existence of the four triple maxima was confirmed.[15] The broad 0.9 e $Å^{-3}$ peaks at the 32(*f*) ($x = 0.30$) positions of *Fm*3*m* in a difference Fourier map of $(NH_4)_2SnCl_6$ (12), which were considered as probably corresponding to the H atoms, may be regarded as the (unresolved) electron-density counterparts of the local maxima in the proton-density distribution in $(NH_4)_2SiF_6$.

The picture that emerges is then as follows. In $NH_4I(I)$ (and we assume also in phases *I* of the chloride and bromide), the fcc matrices and cubic $(NH_4)_2MX_6$ the site symmetry at the ammonium ion is cubic and all conceivable orientations of the ion, consistent with *S*, are equivalent. Thus only one ν_1 absorption is observed. The ion undergoes librational motions of large amplitude, as witnessed by the breadth of the ν_1 absorption. The H atoms spend a considerable portion of their time near the acceptor atoms, away from the symmetrically 'trifurcated' equilibrium positions. This is evident from the positions of the local maxima in the electron and proton-density distributions and would be even clearer if low-temperature neutron diffraction studies of **18** and **23** were available. Hence the ν_1 values are not very different from the ν_1 values that would be expected for normal bonds of comparable length,[16] and similarly only small differences are observed on comparing the ν_{4bc} values. Analogous situations are likely to occur in **35**, **40**, and **45**, for which the relevant structural information does not exist.

In describing hydrogen bonding in such compounds, distinction must be made between symmetrically trifurcated *situations*, i.e. coordination geometry, and symmetrically trifurcated *bonds*. The hydrogen bond in these cases may be regarded as symmetrically trifurcated only in the sense that the coordination geometry of the acceptor atoms round each H atom of the ammonium ion provides positions of symmetry C_3 or C_{3v}, and these may be thought of as the equilibrium positions toward which the N—H vectors are directed. Because they are strongly influenced by the dynamics of the ammonium ion, the actual whereabouts of the H atoms cannot be specified beyond indicating diffuse regions between the equilibrium positions of the N atom and the acceptors, such as those suggested by the broad local maxima in the proton and electron-density distributions.

Hydrogen bonds encountered in symmetrically trifurcated situations are only a special case of hy-

[15]Personal communication.

[16]This accounts for the consistency of the trends in Fig. 1 when H...X rather than H...X* is used for the trifurcated situations.

drogen bonds lacking definite spatial relationship, between reorientations, to the acceptor atom(s). Such bonds may generally be expected to exist in crystals with C.N. > 8; the greatest librational freedom is likely to exist in situations where *S* is cubic. A more appropriate generic description of such bonds might be *fluxional* hydrogen bonds.

An exceptionally favourable situation for a study of the hydrogen bond in a symmetrically trifurcated but noncubic coordination appears to exist in **36**. Because three of the H atoms of the ammonium ion are engaged in strong normal hydrogen bonds to the F atoms of a single SnF_3^- ion, the fourth H atom can only point into a triangle of F atoms related by the unique threefold axis of the ammonium ion, and so an opportunity seems to exist for examining a single bond of this type in a relatively stationary ammonium ion. The trifurcated situation in this compound is, however, not quite similar to that in **18** or **6**. In **18** a hydrogen atom has three nearest H neighbours at 3.01 Å (laterally) and one next-nearest at 5.21 Å (along C_3); in **6** the nearest H neighbours of a hydrogen atom are at 3.45 Å (laterally), always assuming that the H atoms are at their equilibrium positions required by the space-group symmetry. In **36**, however, the nearest H neighbours, which occur in centrosymmetric pairs on C_3, are separated by only 1.66 Å. The H–H repulsion in **36** must thus be much more significant than in **18** and **6** and can be expected to raise the frequency of the axial ND stretching vibration over and above the increase due to the overall volume effect. This is indeed observed. The low $\nu_1(n)$ frequency, 2246 cm^{-1}, indicates that the three normal N—H...F bonds are strong, and the large values of the three components of the HND bending, 1284.7–1295.2 cm^{-1} (Table 4), and their small spread can be taken as evidence of the nonaxial bonds and the axial bond both being strong and of similar strength. However, the $\nu_1(a)$ value is 162 cm^{-1} above the $\nu_1(n)$, which is by far the largest difference between two ν_1 component frequencies of the NH_3D^+ probe observed to date in an ammonium compound. See errata, p. 423.

The strong H–H repulsion, which may also be regarded as an anisotropic volume effect, probably also accounts for the misfit of the NHF* angle of **36** in Figs. 8*B* and 9. A point corresponding to NHX* = 134° would be expected to fall appreciably below those of $(NH_4)_2MF_6$ in Fig. 8*B*. In Fig. 3*B* the point for the axial bond falls among the fluorides with C.N. 12, which is not in contradiction with the type of bond encountered here, although the region in which the point would have been expected to fall is 4 < C.N. < 12. Since the axial N—H bond in **36** probably comes closest to the notion of a symmetrically trifurcated *bond*, a neutron diffraction study of the crystal at two temperatures would be of considerable interest.

Criteria of Hydrogen Bonding of the Ammonium Ion in Crystals

Various criteria have been previously proposed in attempts to determine whether hydrogen bonding plays an important role in ammonium salts. They have been recently summarized by Hamann (30). Those pertinent to the present work are: (*i*) Hydrogen bonding is present if combination modes $\nu_i + \nu_6$ (i = 2 and 4) involving the librational mode ν_6 are observed in the ir spectra of NH_4^+, and (*ii*) if the frequency of the antisymmetric bending mode $\nu_4(NH_4^+)$ is higher than 1400 cm^{-1}.

Criterion *i* refers actually more to the *type* of the hydrogen-bonding interaction than to its strength. The most important single factor governing the presence of the NH_4^+ combination modes seems to be the C.N. and the attendant NHX* angle. We have seen that the hydrogen bonds in ammonium halides with C.N. 6 or 12 are most probably highly dynamic in nature and that motion of H atoms on a portion of a spherical surface in the regions between acceptor atoms is relatively free. In this situation, especially at room temperature (the temperature at which most studies have been conducted), there is reason to believe that no $\nu_i + \nu_6$ absorption would be observed because of the strong temperature dependence of the breadth of the $\nu_6(NH_4^+)$ fundamental (cf. ref. 23). Dunsmuir and Lane (31) only cite one salt of the cubic K_2PtCl_6 type, **18**, in which both combination modes were present. The sharp contrast between NH_4^+ in fcc alkali halide matrices (C.N. 6), in whose spectra $\nu_i + \nu_6$ are apparently absent, and the CsX matrices (C.N. 8), in whose spectra these bands were observed (18, 23), provides further support for this view, in that the *strength* of the hydrogen bonding, as measured by the ν_1 frequency of the NH_3D^+ probe, is much the same in both cases. It may be noted that the combination bands appear in the room-temperature spectra of the fluorides $(NH_4)_3MF_6$ (M = Fe, Al, Ga, In, Sc) (31, 32), which are structurally closely related to $(NH_4)_2MF_6$ and contain ammonium ions in both 6- and 12-coordination. It is likely that the increased formal charge on the F atoms in the triammonium compounds (Table 5) causes the combination bands in these salts to emerge more readily than in $(NH_4)_2MF_6$, even though direct evidence for this is lacking.

The suggestion that, for a hydrogen-bonded ammonium salt, $\nu_4(NH_4^+)$ will occur above 1400 cm^{-1}

(31) is not beyond doubt (cf. ref. 33). The volume effect applies equally to pure NH_4^+ spectra, and in those halides where it predominates over hydrogen-bonding effects it will tend to increase this frequency.

The commonly-held view that crystallographic dissimilarity of an ammonium salt and its K and Rb analogues should be attributed to the effects of hydrogen bonding also bears closer examination. It is undoubtedly correct in some cases, notably in NH_4F, but in many instances the stability of one phase relative to a second is only marginal, and the dissimilarity of the ammonium compound and the K and Rb compounds, *at a particular temperature*, may be the result of different lattice dynamics, without significant involvement of hydrogen-bonding interactions. Thus **18** is isostructural with K_2SiF_6 and Rb_2SiF_6 at room temperature, yet we have seen that hydrogen-bonding interactions are present in the ammonium compound. Similarly, $(NH_4)_2TeBr_6$ and Rb_2TeBr_6 are cubic at room temperature while K_2TeBr_6 is not; at 180 K the ammonium compound is noncubic while the Rb compound remains cubic, but below 77 K all three compounds are noncubic (24), even though the transformation in the Rb compound cannot be attributed to hydrogen bonding. As a *general* criterion, crystallographic comparisons of this kind must therefore be used with due caution.

A more reliable criterion than most, for ammonium halogen compounds, appears to be the position of the ν_1, ν_{4bc} point in Fig. 3. It is based entirely on internal, of necessity selfconsistent, evidence from the ir spectra, and it has the advantage of relating the *strength* of the hydrogen-bonding interaction to parameters associated with the *type* of hydrogen bonding. To what extent this criterion is applicable to ammonium salts of oxyacids cannot be determined at present because of the paucity of spectral data for the NH_3D^+ probe in such crystals.

Conclusions

This study is concerned with the problem of determining the extent of hydrogen bonding and the type of environment and motions of an ammonium ion in a crystal from ir spectra of polycrystalline simple and complex ammonium halides. Our results show that unambiguous information bearing on this problem can be obtained from spectra of the isotopically isolated NH_3D^+ probe ion but not from spectra of the NH_4^+ or ND_4^+ ions.

Contrary to what might be expected, the ν_1-(NH_3D^+) stretching frequency is not a monotonic indicator of the strength of the N—D...X bond. As Figs. 1, 3, 6, and 8 show, the frequency of the ν_1 vibration in a crystal is affected by two factors acting in opposite directions, the acceptor strength and a volume effect. The effect of each factor levels off with increasing D...X distance. As a result, the ν_1 frequencies converge to a value near 2330–2340 cm^{-1}; this value may be regarded as the 'free ion' value in ammonium halogen compounds. Observed ν_1 values significantly below this limit, say below 2310 cm^{-1}, correspond to C.N. between four and eight and to strong or moderately strong normal (i.e. 'straight') N—D...X bonds, while those significantly above, say 2350 cm^{-1} or higher, are most likely to correspond to C.N. 12 (possibly 8, rarely 6) and to weak or very weak hydrogen-bonding interactions (Fig. 8). However, formal charge on the acceptor atom also plays a part and must be considered when making an estimate of the hydrogen-bond strength.

When both the ν_1 stretching and ν_{4bc} bending frequencies of the NH_3D^+ probe are known, the situation in which the ammonium ion finds itself in the crystal can be determined with considerable confidence with reference to Fig. 3. This is possible because the acceptor strength and the volume effect act in the same direction on ν_{4bc} but in opposite directions on ν_1. Thus the ν_{4bc} frequency decreases steadily with the strength of hydrogen bonding, while the ν_1 frequencies separate into two limiting groups, a low-frequency, normal-hydrogen-bond one, dominated essentially by the acceptor strength, and a high-frequency one, dominated essentially by the volume effect and corresponding to hydrogen-bonding interactions pronouncedly dynamic in character. The points of the ν_{4bc} vs. ν_1 plot fall into well-separated regions according to the acceptor and C.N., which leads to assignment of NH_3D^+ spectra not studied previously to particular structural situations and makes predictions possible.

The factors that are responsible for the trends evident in the ν_{4bc} vs. ν_1 and ν_1 vs. H...X plots manifest themselves also in other ways. Thus when the activation energy E_a for reorientation of the ammonium ion in a crystal is plotted against ν_1 (Fig. 6), the correlation curve has a low-frequency and a high-frequency branch, the former corresponding to normal hydrogen bonds and C.N. < 12, the latter to hydrogen bonds of a highly dynamic character and C.N. 12. However, ammonium ions of C.N. 6 may fall on either branch, depending on the formal charge on the acceptor atom: on the low-frequency branch when the formal charge is high (e.g., $NH_4I(I)$), and on the high-frequency branch when the formal charge is low (e.g., NH_4PF_6). In either case the bonds for C.N. 6 are similar in character to those for C.N. 12.

The conclusions drawn from the combined evidence obtained from our ir spectra of the NH_3D^+ probe and from the results of published diffraction

studies do not support the view that in situations where C.N. is 6 or 12, e.g., in **6** or **18**, the ammonium ion is attached, between reorientations, by *normal* (i.e. essentially straight) hydrogen bonds to one or simultaneously to two or three acceptor atoms, for only *one*, symmetric ν_1 band is observed. The so-called 'trifurcated' hydrogen bond, which had been suggested to occur in such situations, is most likely a highly non-directional hydrogen-bonding interaction of a strength not much different from that of a normal hydrogen bond of comparable N...X length. For $\nu_1(NH_3D^+)$ in the alkali halide matrices the increase in $\Delta\nu_{1/2}$ on going from C.N. 8 to C.N. 6 is of the order of 15 cm^{-1}.

The desirability of comparing the vibrational frequencies of the isotopically isolated NH_3D^+ probe ion rather than those of NH_4^+ or ND_4^+ must be emphasized. Thus Dunsmuir and Lane (31), who obtained ir spectra of the NH_4^+ ion in a number of undeuterated complex ammonium halides, were not as successful as they might have been in establishing correlations between vibrational frequency and C.N. or what in our terms amounts to formal charge on the acceptor atom, even though their compounds were well selected for the purpose. This was in part due to the unreliable nature of the NH_4^+ frequencies, which becomes evident when the $\nu_4(NH_4^+)$ frequencies of Dunsmuir and Lane are plotted against their $\nu_3(NH_4^+)$ frequencies. The plot resembles in a general way the high-ν_1 region of our Fig. 3, but the separation of the points according to X and C.N. is much less obvious.

Experimental

Sample Preparation and Apparatus

The ammonium salts were either obtained commercially or prepared by literature methods. In most cases the salts were recrystallized from moderately concentrated solutions of the appropriate HX acid. A further recrystallization was then used to introduce a small proportion of deuterium into the samples, typically at a level of 0.5–2%. The sample of **19** was prepared at our request by Dr J. H. Holloway in a manner analogous to the K salt, followed by a cation exchange procedure. Ammonium fluoride containing 1% D was obtained by recrystallization from MeOH (1% D).

The spectra of NH_3D^+ in **18**, **22**, **23**, **25**, **31**–**33**, **37**, **38**, **40**, **41**, and **44** have been described elsewhere (1–4, 6). The spectra of the isotopically isolated NH_3D^+ ion in the rest of the salts are reported here for the first time. Details of the ir apparatus and technique will be found in previous papers of this series (1–5).

The KX, RbX, and CsX crystals containing low concentrations of ammonium ion were prepared by slow evaporation of aqueous solutions of the alkali halide and appropriate ammonium halide in the desired proportion; attempts to incorporate in this manner NH_3D^+ into NaX crystals were unsuccessful. Typically the alkali halide contained 5% NH_4^+ and the sample was crystallized hot from water containing 5% D. This rather high level was necessitated by the need to obtain a reasonable absorption in samples in these 'double-dilution' experiments. Samples suitable for our purposes were pressed into pellets which could be held in the low-temperature sample holder using indium gaskets.

Structural Information

In spite of our efforts we failed to find in the literature crystal-structure determinations for a few of the compounds, and in a number of cases we have had to accept determinations of inferior quality. A further difficulty was encountered where transitions occurred, or were suspected to occur, on cooling. Practically no detailed crystallography has been done on the low-temperature phases, so we had to assume that the H...X distances did not change drastically on lowering the temperature. Where no reference is given, particulars of the crystal structure will be found in ref. 13.

*Ammonium and Alkali Halides, **1–17** (Table 1)*

1, NH_4F (9, 10). $P6_3mc$ (No. 186), $Z = 2$, $S = C_{3v}$. Although *two* ν_1 bands, in a 3:1 intensity ratio, would be expected for $S = C_{3v}$, only a single band was observed. The band appeared to be symmetric when visual allowance was made for a slight distortion due to the Christiansen effect. The displacement between the N and F hcp sublattices is such that each ion is equidistant, at 2.708(3) Å, from its four nearest neighbours (9).

2, **3**, NH_4Cl. Phase *II* (242–457 K), $Pm3m$ (No. 221), $Z = 1$, S(diffraction) $= O_h$, S(local) $\neq O_h$ (see Discussion). Phase *III* (< 242 K), $P\bar{4}3m$ (No. 215), $Z = 1$, $S = T_d$.

4, **5**, NH_4Br (28, 34). Phase *II* (235–411 K), as in **2**. Phase *III* (< 235 K), $P4/nmm$ (No. 129), $Z = 2$, $S = D_{2d}$.

6, **7**, **8**, NH_4I (28). Phase *I* (> 259 K), $Fm3m$ (No. 225), $Z = 4$, $S = O_h$. Phases *II* (231–259 K) and *III* (< 231 K) as in NH_4Br.

Single ν_1 bands were observed for all three halides. In NH_4I the halfwidth was 9 cm^{-1} in phase *III* and increased to ~50 cm^{-1} in phase *II*. In $NH_4I(I)$ the band was very broad, ~65 cm^{-1} at 290 K. The variation of ν_1 with temperature is shown in Fig. 2.

In the KX and RbX matrices $S = O_h$, C.N. 6; in the CsX matrices, $S = O_h$, C.N. 8. The H...X values in Table 1 are those for the pure halides at 80 K; no account was taken of the size disparity of the guest and the host ions. The lattice parameters of the fcc alkali halides at 80 K were taken from ref. 16. Those of CsX were estimated on the assumption that the contraction percentage on cooling is the same as for the corresponding RbX.

*Cubic $(NH_4)_2MX_6$, **18–30** (Table 2)*

$Fm3m$ (No. 225), $Z = 4$, $S = T_d$, C.N. 12 (cf. Fig. 1 of ref. 1). The positional parameter x(X) has been determined accurately only for **18** (11), **19** (personal communication from J. H. Holloway), **23** (12, 25), and **29** (35). In all the other compounds in Table 2 it had to be estimated. To do this, the structures of all the cubic A_2MX_6 compounds in the NBS collection of X-ray powder diffractometer patterns (36) were refined by least-squares from the intensity data listed there, using X-ray scattering factors for neutral atoms and an overall temperature factor. Unfortunately many of the x(X), K, B refinements did not converge properly owing to the insufficient accuracy, and at times the small volume, of usable intensity data. Those of the refined x(X) values that were judged satisfactory were combined with the available literature values of x(X) (room temperature), and the entire set was regressed, separately for x(Cl) and x(Br), on the values of the effective radii $r^{xii}(A^+)$ and $r^{vi}(M^{4+})$. The x(F) values presented a problem because of their small range and poor accuracy; refinements from the NBS powder intensities gave 0.212 for K_2SiF_6, 0.208 for **18**, 0.217 for Rb_2SiF_6, and 0.211 for Cs_2GeF_6.

The radii used in the double regressions were those of ref. 19 except for Si, Ge, Pt, Hf, Zr, Pb, Pu, U, Th, and Po, for which the values from ref. 37 were employed. For Se and Te the values were 0.650 and 0.785 Å, respectively. The radius of NH_4^+ was calculated from the equation given in Discussion. The regressions are represented by the equations

$$x(\mathrm{Cl}) = 0.2493 - 0.0276r^{\mathrm{xii}}(\mathrm{A}^+) + 0.0548r^{\mathrm{vi}}(\mathrm{M}^{4+})$$

(28 compounds, $r^2 = 0.85$, $\sigma = 0.002$) and

$$x(\mathrm{Br}) = 0.2190 - 0.0158r^{\mathrm{xii}}(\mathrm{A}^+) + 0.0733r^{\mathrm{vi}}(\mathrm{M}^{4+})$$

(based on four compounds for which x(Br) had been determined accurately from single-crystal data; for a total of eight compounds, $r^2 = 0.87$, $\sigma = 0.002$).

The x(F) value of **20** was taken to be the same as that of **18**. No structural data are available for the low-temperature phases **28** and **30** except as noted in Table 2.

With the exception of **28** and **30**, single, sharp ($\Delta\nu_{1/2}$ = 5–9 cm^{-1}) ν_1 and ν_{4bc} absorptions were observed for all the compounds listed in Table 2. None of the bands was completely free from the Christiansen effect; the effect was very large in the spectra of **24**. No evidence of Fermi resonance between the $2\nu_{4bc}$ and ν_1 levels was found.

*Trigonal $(NH_4)_2MF_6$, **31–34** (Table 3)*

$P\bar{3}m1$ (No. 164), $Z = 1$, $S = C_{3v}$, C.N. 12 (cf. Fig. 1 of ref. 2). The three positional parameters, z(N), x(X), and z(X), have been determined only for **31** (38). The H...X values for **32–34** are estimates based on similarity to other compounds of this type (13, 36). The NH_3D^+ frequencies of **31** and **32** were reported in ref. 2; those of **33**, in ref. 6; those of **34** are new. Both the axial (a) and the non-axial (n) ν_1, in an intensity ratio of 1:3, correspond to H atoms in trifurcated situations: $\nu_1(a)$ to an equilateral and $\nu_1(n)$ to three isosceles triangles of fluorine atoms.

The $\nu_1(a)$ and $\nu_1(n)$ values for the four compounds show a strong correlation ($r^2 = 0.94$).

*Other Compounds, **35–45** (Table 4)*

35, NH_4MnF_3. Cubic perovskite. At ≥200 K, $Pm3m$ (No. 221), $Z = 1$. The spectrum of NH_3D^+ in the hitherto unreported low-temperature phase will be described elsewhere.

36, NH_4SnF_3 (39). $R\bar{3}$ (No. 148), $Z = 2$. The expectation for three normal N—H...F bonds and one in a trifurcated situation (on C_3, H...F* ~ 2.19 Å, NHF* ~ 134°) would be a 3:1 ν_1 doublet. Two components, with a separation of 162 cm^{-1}, are in fact observed. The 1295.2 cm^{-1} absorption is assigned to $\nu_{4bc}(a)$. No indication of transitions between room temperature and 77 K was found in the spectra. The strong hydrogen bonding inferred from the low $\nu_1(n)$ frequency is reflected in the very intense, sharp $\nu_2 + \nu_6$ and $\nu_4 + \nu_6$ combination bands of the NH_4^+ ion.

37, NH_4BF_4 (40). *Pnma* (No. 62), $Z = 4$.

38, NH_4BPh_4. The crystal structure does not appear to have been determined. For the corresponding K (41) and Rb (42) compounds, $I\bar{4}2m$ (No. 121), $Z = 2$, $S = D_{2d}$. If the ammonium compound is isostructural, which appears likely (4), the NH_4^+ ion is surrounded by four benzene rings belonging to two BPh_4^- ions.

39, NH_4AlF_4. $P4/mmm$ (No. 123), $Z = 1$.

40, NH_4PF_6. A structure determination is not available. While **40** has been presumed (46) isostructural with α-KPF_6 ($Pa3$ (No. 205), $Z = 4$, $S = C_{3i}$), the previously reported spectrum of NH_3D^+ in this compound (4) was consistent with *cubic* site symmetry down to 77 K. To estimate the H...X and NHF* values, **40** was assumed to be isostructural with $NaSbF_6$(*I*) ($Fm3m$ (No. 225), $Z = 4$) and P—F was taken as 1.58 Å.

41, $(NH_4)_2PdCl_4$. $P4/mmm$ (No. 123), $Z = 1$. At 125 K and above the ammonium ions are disordered between the two possible orientations at each N site. Krebs Larsen and Berg (43) could not see any evidence of phase change in the X-ray pattern of a crystal cooled to 90 K. The spectra of **42** $(NH_4)_2PtCl_4$ and **43** $(NH_4)_2PdBr_4$ were very similar and these compounds are presumed isostructural with **41**.

44, $(NH_4)_2[CuCl_4(H_2O)_2]$. At room temperature the space group is $P4_2/mnm$ (No. 136), $Z = 2$ (neutron diffraction, ref. 44), but on cooling transitions take place in the crystal; their nature has not yet been determined (45).

Transitions in Cubic $(NH_4)_2MX_6$

The existence of numerous thermally induced transitions in A_2MX_6 is well documented (cf. ref. 24). The transition temperature may be above (e.g., in K_2PbCl_6 (48) or K_2SnBr_6 (13)) or below room temperature. In the present study evidence of low-temperature transitions was detected in the spectra of $(NH_4)_2SnBr_6$ and $(NH_4)_2TeBr_6$, consistent with the DTA results on the stannate (T_{tr} = 124 and 145 K) and with nqr (49) and X-ray (35) results on the tellurate (T_{tr} = 194 and 214 K), but not in $(NH_4)_2SnCl_6$ and $(NH_4)_2PbCl_6$, for which T_{tr} of < 77 and 240 K, respectively, have been reported (24).

Above ~150 K a single broad ν_1 band and a single broad ν_{4bc} band were observed in the spectra of the stannate. These absorptions are consistent with $S = T_d$, but the breadth of the bands calls for caution in drawing definite conclusions about the site symmetry in this, the room-temperature, phase from the ir results alone. Between 124 and 145 K a multiple absorption was observed in the ν_1 region. Again the bands were broad and we are only able to say with any certainty that at least two components were present. Below 124 K *four* sharp bands were present in the ND stretching region.[17] Assuming that NH_4^+ in this phase occupies a single equipoint, the occurrence of four bands is consistent with $S = C_1$; the absence of diffraction data for the lowest-temperature phase precludes a more detailed conclusion.

The much greater breadth of the ν_1 components in the phase stable above 125 K is an indication that considerable reorientational motion of the ammonium ion occurs in this phase (cf. ref. 4). The halfwidth of each ν_1 component at 77 K was 6 cm^{-1}. It seems likely that a correlation time of less than about 10^{-11} s would be required to account for the broadening observed on passage through the 124 K transition point. This conclusion agrees well with the nmr results of Strange and Terenzi (50) which suggest a correlation time, for reorientation of the NH_4^+ ion at 130 K, of about 8×10^{-12} s. The activation energy of reorientation changes, at the 145 K transition, from 0.26 for the upper phase to 1.44 kcal/mol for the lower phase.

The quality of the $(NH_4)_2TeBr_6$ spectra was inferior by comparison. The ν_1 absorption of the room-temperature phase was again compatible with $S = T_d$. Below 214 K the NH_3D^+ absorptions were too broad to be of diagnostic value for S. At 77 K, in a third phase, the observed NH_3D^+ absorptions were very similar to those in the corresponding stannate phase, hence probably $S = C_1$.

The space group of the phase existing below 214 K was deduced by Das and Brown (35) from Weissenberg photographs as $P4/mnc$ (No. 128), $Z = 2$, hence $S = D_2$. An NH_3D^+ probe ion at such a site would be expected to give rise to a single ν_1 and two ν_{4bc} absorptions (6). In view of the implied rapid reorientational motion in this phase we were unable to verify the expected site symmetry from our spectra.

It is interesting to note that in both salts combination modes

[17]The NH_3D^+ frequencies of **28** and **30** and similar data for other low-temperature phases of ammonium halides will be published elsewhere.

involving librations are observed in the lowest phase. Their occurrence, together with an overall lowering of ν_1 by about 15 cm^{-1}, leaves little doubt that hydrogen bonding is implicated in the formation of this phase. One notes further that the observed combination modes $\nu_4 + \nu_6$ are broad ($\Delta\nu_{1/2} \sim 50\ cm^{-1}$), which is in agreement with the earlier discussion of the dependence of band breadth on C.N.

The hexabromostannate and tellurate provide an interesting illustration of the hydrogen-bonding behaviour of the ammonium ion in crystals. It is apparent that the ion itself is not responsible for the phase transitions, analogous transitions occur in the K and Rb salts, but whatever the specific cause of the transition, in the ammonium salts the consequence is stronger hydrogen bonding.

An observation concerning the crystallographic relationship of the lower-symmetry phases to the parent *Fm3m* phase will be found in the Appendix.

Estimation of the Activation Energies

Activation energies E_a for reorientation of the NH_4^+ ion have been estimated, mostly from nmr experiments, in a variety of ammonium halides. References for the compounds included in Fig. 6 are as follows: **1** (51), **2–8** (52), **18** (50), **21** (22), **22** (22, 53), **23** (50, 54, 55), **24** (cited in ref. 56), **26** (22, 53), **27** (50), **32** (57), **33** (58), **37** (59), **40** (60). In addition, estimates of E_a for **9–17** were obtained from the barrier heights (23) by subtracting the zero-point energies.

Acknowledgments

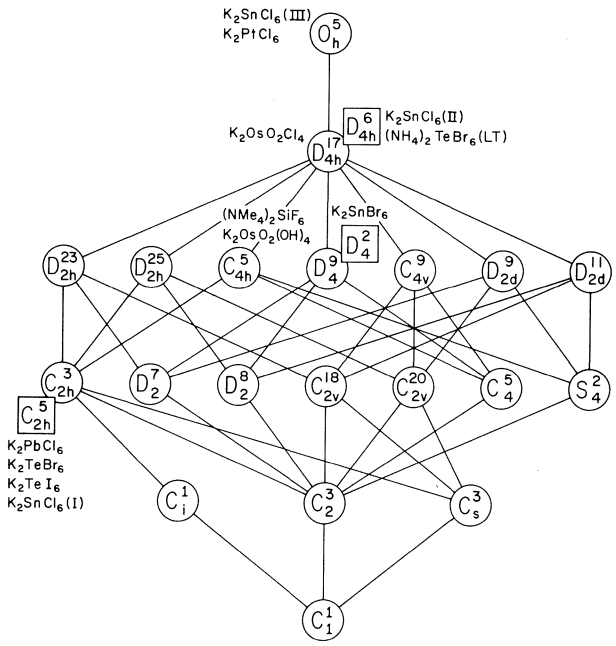

FIG. 10. Crystallographic transformations in A_2MX_6 via tetragonal distortions. The space groups framed in squares are not subgroups of O_h^5-$Fm3m$.

Appendix

A remark is in order concerning the crystallographic relationship of the lower-symmetry A_2MX_6 phases to the parent O_h^5 phase.[18] In none of the cases in which the space group H of the phase immediately below cubic has been reported — D_{4h}^6 in K_2SnCl_6 (61) and $(NH_4)_2TeBr_6$ (35) at low temperature, D_4^2 in K_2SnBr_6 at room temperature (13), and C_{2h}^5 in K_2TeBr_6 (20), K_2TeI_6 (62), and K_2PbCl_6 (48) at room temperature (and also in $K_2SnCl_6(I)$ (61), below the D_{4h}^6 phase II) — is H a subgroup of O_h^5, even though the structural similarity is evident (cf. ref. 20). However, each of the three space groups is a monochromatic subgroup of index two of a Shubnikov group Ш which corresponds to one of the subgroups G of O_h^5: $D_{4h}^6 \subset Ш_{128}^{410}(=P_I4/mnc)$, $D_4^2 \subset Ш_{90}^{102}$ $(=P_I42_12)$, $C_{2h}^5 \subset Ш_{14}^{83}$ $(=P_A2_1/b)$. When the colour-changing symmetry operations are retained but their chromatic nature is disregarded, $Ш_{128}^{410}$, $Ш_{90}^{102}$, and $Ш_{14}^{83}$ become, respectively, D_{4h}^{17}, D_4^9, and C_{2h}^3. The symmetry reduction *outside* the composition series of O_h^5 (cf. Fig. 10) can then be represented as $D_{4h}^{17}|D_{4h}^6$, $D_4^9|D_4^2$ and $C_{2h}^3|C_{2h}^5$, i.e. $(G \subset O_h^5)|(H \not\subset O_h^5)$: H is derived from O_h^5 by descent in symmetry along the composition series $O_h^5 \supset G_1 \supset G_2 \ldots \supset C_1^1$ to a subgroup G which generates a Ш having the requisite $G|H$ relationship. Omission of the chromatic symmetry operations from Ш then yields H. This loss of symmetry operations results in a reduction of symmetry-imposed restrictions in both the equilibrium positional parameters of the atoms affected and the dynamic freedom of the composite ions (e.g. with respect to 'rigid' rotation). For example, in K_2SnCl_6 the subgroup and chromatic-symmetry reductions produce the changes in positional coordinates and site symmetries shown in Table 6. The tetragonal (subgroup) distortion may manifest itself metrically but leaves the symmetry constraints on the individual atoms unchanged. The removal of reflections from the Sn site by the 'chromatic' distortion, however, not only makes possible rotation of the square of Cl atoms in the $z = 0$ plane from its $x,x,0$ etc. position, but also removes a symmetry restriction on the freedom of rotational and reorientation motions of the $SnCl_6$ octahedron in the 002 planes. The second transition, $II \rightarrow I$, corresponds to the subgroup symmetry reduction $D_{4h}^6 \supset D_{2h}^{12} \supset C_{2h}^5$ and carries a step further the distortion initiated by the 'chromatic' symmetry reduction $D_{4h}^{17}|D_{4h}^6$.

The above three Shubnikov groups are all of the so-called type IV (cf. for example, ref. 63), i.e. based on *dichromatic* Bravais lattices.[19] The 'chromatic' translation corresponds in this case to an *antiphase* rotation of the MX_6 octahedron, resulting in an

[18] To avoid explanations concerning changes in the setting of the unit cell, the Schönfliess symbols will be used for convenience.

[19] All $G \subset O_h^5$ are symmorphic; D_{4h}^6, D_4^2, and C_{2h}^5 are non-symmorphic.

TABLE 6. Changes produced in positional coordinates[a] and site symmetries on subgroup and chromatic symmetry reductions in a K_2SnCl_6 crystal

Phase[b]	S.G.[c]	Sn	K	Cl
III	$O_h^{5\,d}$	0,0,0 (O_h)	$0,\frac{1}{2},\frac{1}{4}$ (T_d)	$x,x,0$ (C_{4v})
	$D_{4h}^{17} \subset O_h^5$:			
	$[D_{4h}^{17}]^e$	0,0,0 (D_{4h})	$0,\frac{1}{2},\frac{1}{4}$ (D_{2d})	$x,x,0$ (C_{2v}); $0,0,z$ (C_{4v})
	$(D_{4h}^{17} \subset O_h^5) \mid (D_{4h}^6 \not\subset O_h^5)$:			
II	D_{4h}^6	0,0,0 (C_{4h})	$0,\frac{1}{2},\frac{1}{4}$ (D_2)	$x,y,0$ (C_s); $0,0,z$ (C_4)
	$D_{2h}^{12} \subset D_{4h}^6$:			
	$[D_{2h}^{12}]^e$	0,0,0 (C_{2h})	$0,\frac{1}{2},z$ (C_2)	$x,y,0$ (C_s); $x,y,0$ (C_s); $0,0,z$ (C_2)
	$C_{2h}^5 \subset D_{2h}^{12} \subset D_{4h}^6$:			
I	C_{2h}^5	0,0,0 (C_i)	x,y,z (C_1)	x,y,z (C_1); x,y,z (C_1); x,y,z (C_1)

[e]Formal step.

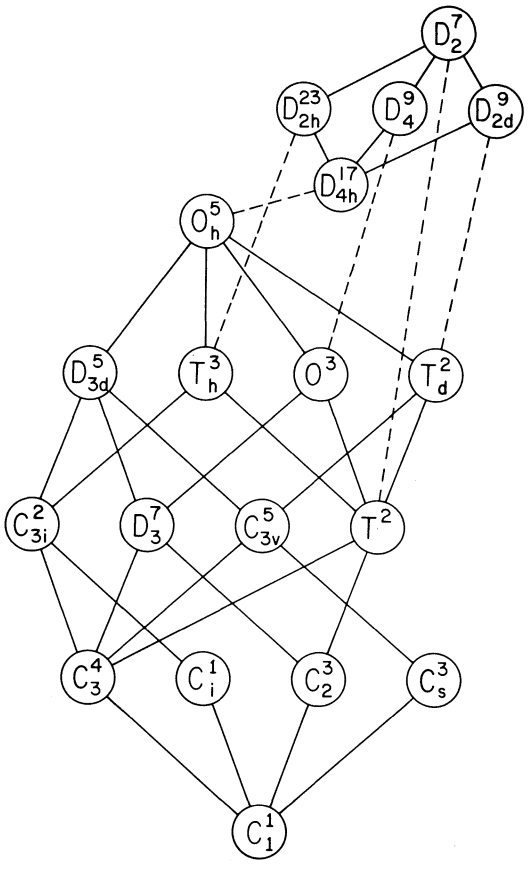

FIG. 11. Same as Fig. 10 but via cubic and trigonal distortions.

'antiferro' arrangement of the rotational displacements.

Symmetry changes similar to those in A_2MX_6 are also observed in the structurally closely related A_3MF_6 on cooling (47): $O_h^5 \rightarrow D_{4h}^6$ in $(NH_4)_3AlF_6$ and $(NH_4)_3FeF_6$, $O_h^5 \rightarrow C_{2h}^5$ in Na_3AlF_6, and $O_h^5 \rightarrow D_{4h}^{17}$ in K_3AlF_6. The involvement of soft modes (64) in these transitions remains to be determined.

Apparently the transitions in A_2MX_6 need not be of the 'antiferro' type. The space group of the low-temperature phase of K_2OsCl_6 has not been stated, but on evidence from limited neutron-diffraction data (65) the transition $K_2OsCl_6(O_h^5) \rightarrow K_2OsCl_6$-(LT) is continuous, showing no metric departures from cubic symmetry, and 'ferrorotative', characterized by a collective in-phase rotation of the $OsCl_6$ octahedra. In K_2ReCl_6 no fewer than four transitions have been detected (24, 66). The most probable chemical space group of the phase existing below 76 K, based on limited neutron-diffraction data, has been stated to be T_h^2, with the possibility of a disordered arrangement in O_h^4 (66, 67); an attempt has been made (66) to understand the nature of the transitions involving the other phases, using a combination of theory and experiment, of lattice dynamics and the Landau theory of second-order transitions. There is *no* $G|T_h^2$ pair. Here the only way to visualize the symmetry parentage of the phase would be via the common subgroup C_{3i}^2 (cf. Fig. 11): $O_h^5 \rightarrow (D_{3d}^5$ or $T_h^3) \rightarrow C_{3i}^2 \rightarrow T_h^2$. To what extent the various formal symmetry paths reflect actual transformation mechanisms remains to be seen.

In the first paragraph of the right-hand column on p. 413 and in the second paragraph of the left-hand column on p. 417 the discussion of NH_4SnF_3 is based, erroneously, on the assumption that the axial N—H vector points away from the Sn atom of the nearest SnF_3^- ion on the threefold axis and consequently, that the three equivalent nonaxial hydrogen bonds are to the F atoms of that SnF_3^- ion. In fact, even though the H atoms have not been located, the conclusion from the evidence presented in ref. 39 must be that the axial N—H vector points in the *opposite* direction, i.e., to the Sn atom. H–H repulsion cannot therefore be the cause of the high value of $\nu_1(a)$. This matter will be discussed more fully, together with additional ir results for NH_4SnF_3, in Part VIII of this series. The H...X and NHX* entries for **36** in Table 4 are correct.

Lone pair interactions in dimethoxymethane and anomeric effect

IGOR TVAROŠKA

Received January 12, 1977[1]

IGOR TVAROŠKA and TOMAŠ BLEHA. Can. J. Chem. **57**, 424 (1979).

Perturbation molecular orbital analysis has been used for a computation of the through-bond and through-space orbital interactions of oxygen lone pairs in dimethoxymethane (DMM). The analysis predicts the symmetrical combination of *p*-type lone pairs as a highest occupied orbital in an antiperiplanar conformation. The conformational dependence of through-bond orbital interactions has the character of the V_2 term in the Fourier expansion of the rotation potential function about the C—O bond. Contrary to the recent theoretical interpretation that the anomeric effect (preference of *gauche* conformation) is caused by superjacent orbital control, the orbital interactions in DMM are not dominant terms with respect to the anomeric or exoanomeric effect. The dipole–dipole interactions of the C—O bonds stabilizing the *gauche* conformation should thus be considered as the primary cause of the anomeric effect in DMM. The frontier orbital energies and geometric parameters in DMM are strongly influenced by a variation of orbital interaction with rotation. Results obtained for DMM are used to explain the conformational behaviour of other molecules containing the acetal moiety, such as pyrane heterocycles, sugars, and polyoxymethylene.

IGOR TVAROŠKA et TOMAŠ BLEHA. Can. J. Chem. **57**, 424 (1979).

On a utilisé une analyse de perturbation d'orbitale moléculaire pour calculer les interactions orbitalaires à travers les liaisons et à travers l'espace des paires libres d'oxygène du diméthoxyméthane (DMM). L'analyse prédit que la combinaison symétrique de la paire libre de type *p* sera l'orbitale haute occupée dans la conformation antipériplanaire. La dépendance sur la conformation des interactions orbitalaires à travers la liaison possède un caractère d'un terme V_2 dans une expansion de Fourier de la fonction de potentiel de rotation autour de la liaison C—O. Contrairement à l'interprétation récente de l'effet anomérique (préférence de la conformation gauche) par un contrôle orbitalaire superjacent, les interactions orbitalaires de DMM ne sont pas des termes dominants par rapport à l'effet anomérique ou exoanomérique. Les interactions dipôle–dipôle des liaisons C—O stabilisant la conformation gauche doivent donc être considérées comme la principale cause de l'effet anomérique dans le DMM. L'énergie des orbitales frontières et les paramètres géométriques du DMM sont fortement influencés par une variation de l'interaction orbitalaire avec la rotation. On a utilisé les résultats obtenus avec le DMM pour expliquer le comportement conformationnel d'autres molécules contenant une portion acétal, comme les hétérocycles du pyranne, les sucres et le polyoxyméthylène.

[Traduit par le journal]

Introduction

The influence of lone-pair electrons is often discussed in the explanation of conformational properties of molecules containing a segment of the type R—X—C—Y, where X denotes O, N, or S and Y denotes O, N, or another element having unshared electron pairs. The preference of the synclinal (*gauche*) position to the antiperiplanar one is characteristic of such a segment and has been called a generalized anomeric effect (1–3). This phenomenon, originally described in carbohydrate chemistry, also appears generally valid for a number of heterocyclic and acyclic compounds.

Probably the most familiar interpretation of the anomeric effect is that based on the dipole–dipole interaction between polar bonds (4). This type of interaction is frequently visualised as a repulsion of sp^3-hybridized lone pairs ('rabbit-ears effect'), especially if both X and Y are oxygen atoms (1–3, 5). However, other explanations for the anomeric effect have also been suggested. For example, an *ab initio* SCF calculation of fluoromethanol led Wolfe *et al.* (6) to conclude that the lone pairs are not oriented directionally and that their mutual interactions are consequently independent of molecular conformation. These authors interpret the generalized anomeric effect as being the result of the fine balance within the molecule between an electron–electron repulsion and a core–electron type attraction. On the other hand, Radom *et al.* (7) provide an explanation

[1]Revision received July 6, 1978.

0008-4042/79/040424-12$01.00/0

of the conformational properties of fluoromethanol calculated by the *ab initio* SCF method, based on the idea of directional orientation of lone pairs within the molecule. The 'rabbit-ears effect' concept has also been criticized by Zhdanov *et al.* (8, 9) who assume that the anomeric effect is not a consequence of steric, or lone-pair, or polar-bond interactions.

Apart from the 'rabbit-ears effect,' the delocalization of an unshared electron pair of oxygen (= X) into a suitably oriented antibonding σ^* orbital of the C—Y bond (3, 10–12) is frequently used to explain the anomeric effect. According to this latter idea, the highest delocalization occurs at a conformation which has unshared *p*-type electron pairs in an antiperiplanar arrangement with respect to the C—Y bond; the synclinal conformation in acyclic compounds and the axial one in heterocycles are therefore preferred. David *et al.* (13) have analyzed the nature of the synclinal stabilization in more detail and stress the significance of the two energetically nonequivalent oxygen lone pairs interacting with antibonding orbitals σ_{C-Y}^* and σ_{C-H}^*. The delocalization interaction has been used as a qualitative explanation of the geometrical changes in the simplest diols containing an H—O—C—O—H segment (14, 15) and for methoxymethanol (16). This interpretation of the anomeric effect has recently also been reconciled (17) with the apparently contradictory interpretation of Wolfe *et al.* (6) which effectively ignores lone pairs.

The aim of the present paper is to investigate to what extent the interactions between lone pairs are responsible for the anomeric effect in molecules containing a C—O—C—O—C segment and to estimate their significance in comparison with dipole–dipole interactions of polar bonds. Dimethoxymethane (DMM) represents the simplest model for this purpose, with the synclinal–synclinal conformation being the most stable in this compound (18). A similar conformational preference was found in some carbohydrates as well as in polyoxymethylene, a polymeric analogue of DMM. Both proposals to rationalize the anomeric effect in DMM are shown in Fig. 1. The electrostatic dipole–dipole repulsion of lone pairs in the conventional sp^3 hybridization (Fig. 1*b*) leads to the destabilization of the antiperiplanar conformation. According to the delocalization theory, donation from oxygen lone pairs to antibonding orbitals in DMM is most efficient in the coplanar arrangement of orbitals formed by a 90° rotation from the antiperiplanar conformation. This rotation simulates a *gauche* position and is shown in Fig. 1*c* on the left.

In this paper we present a theoretical analysis of

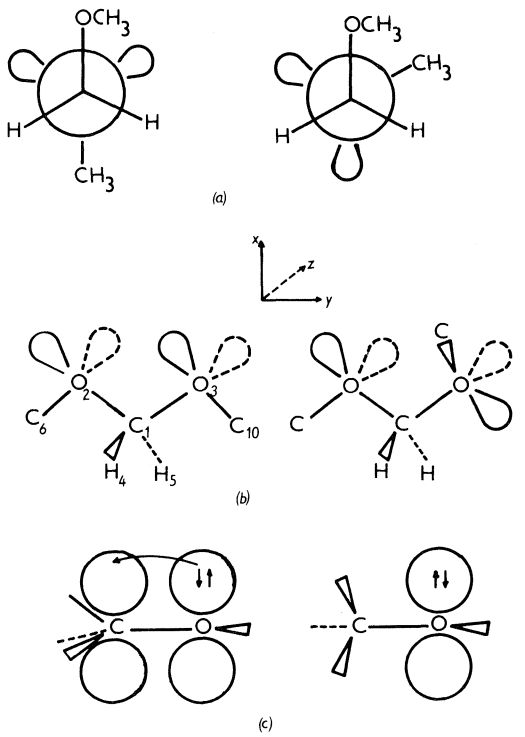

FIG. 1. (*a*) Newman projection of DMM in *ap* (left) and *sc* (right) conformations; (*b*) DMM with sp^3 hybridization of lone pairs on oxygens; (*c*) delocalization of *p*-type lone pair into antibonding orbital in *ap* and *og* conformation.

two distinct symmetry-controlled mechanisms for the interaction of oxygen lone pairs: (*i*) through-space overlap and (*ii*) through-bond or hyperconjugation interaction. We will show how a change in these interactions with rotation influences the geometric and conformational properties of the acetal segment. This procedure has been extensively used in the theoretical analysis of the interaction of nonbonding orbitals in different kinds of molecules along with EHT and CNDO/2 semiempirical methods (19, 20). Through-space and through-bond orbital interactions of lone pairs in an antiperiplanar conformation are analyzed using a simple perturbation molecular orbital (PMO) method (21) in the first part of the paper. The second part is devoted to a study of the conformational dependence of the above interactions and its significance in the anomeric effect in molecules with a C—O—C—O—C bond sequence is discussed.

Theory

Orbital Interaction Analysis

The antiperiplanar (*trans*) conformation (*ap*, $\varphi_1 = \varphi_2 = 180°$) of DMM is shown on the left-hand side of Fig. 1*b*. Conformations formed by rotation

about the O3—C1 bond are denoted as orthogonal (*og*) when $\varphi_1 = 90°$, synclinal (*sc*) when $\varphi_1 = 60°$ (*gauche*), and synperiplanar (*sp*) when $\varphi_1 = 0°$ (*cis*). Hydrogen atoms in methyl groups are assumed to be fixed in a staggered (*ap*) conformation with respect to the central C—O bonds.

An oxygen atom situated in an isolated —C—O—C— group is characterized by two lone pairs having different energies (22). According to the description of this group by means of molecular orbitals (MO), the lone pair having higher energy is of the *p* type, whereas that with lower energy is formed by a combination of *s* and *p* atomic orbitals (AO). A DMM molecule in the *ap* conformation contains two equivalent oxygen atoms. The individual lone pairs, degenerate in the absence of any interaction, may differ in energy as a result of through-bond and through-space interactions between the individual nonbonding orbitals. The energy splitting between these MO's is a prime operational measure of the extent of orbital interaction.

When the coordinate system for DMM in the *ap* conformation is oriented according to Fig. 1*b*, the *p*-type lone pair is in the direction of the p_z AO of oxygen and the *sp*-type lone pair is situated mainly in the p_x AO direction. The hyperconjugation of the p_z lone electron pair with the $\pi_z(CH_3)$ bonding and $\pi_z^*(CH_3)$ antibonding orbitals of the methyl groups (23) (Fig. 2) leads to the formation of the three doubly degenerate orbitals P_z, L_z, P_z^*. The P_z and P_z^* orbitals are predominantly localized at the methyl groups. The L_z orbital is, on the contrary,

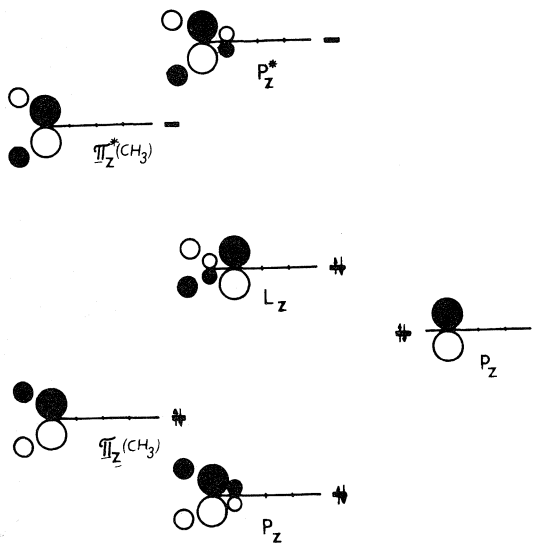

FIG. 2. Interaction of the *p*-type lone pair of oxygen with orbitals of the methyl group in *ap* conformation.

localized mainly at the p_z AO of the oxygen atoms and characterizes a *p*-type lone pair. The *sp* type lone pair interacts in an analogous way. In this case, however, $\pi_x(CH_3)$ and $\pi_x^*(CH_3)$ represent the symmetrically suitable orbitals and interaction leads to the creation of P_x, L_x, and P_x^* orbitals. For the through-bond and through-space interaction of oxygen atom lone pairs, the L_z and L_x will be mainly discussed in the present paper and the subscripts *z* and *x* will be omitted wherever possible.

Through-space and through-bond interactions of lone electron pairs can be expressed using the PMO theory (19, 21). Since we do not know the detailed form of the perturbational Hamiltonian *P*, we assume that the matrix element of $P_{\mu\nu}$ is proportional to the overlap integral as is customary in semiempirical MO theory (24) when expressing resonance integrals. The resulting expression for the orbital energy change (21) is

$$[1a] \quad E_i = E_i - E_i^0 = \sum_{j \neq i} \sum E(i,j) = \sum_{i \neq j} \sum_{\mu,\nu} c_{i\mu}^2 c_{j\nu}^2 \beta_{AB}^2 S_{\mu\nu}^2 / (E_i^0 - E_j^0)$$

$$[1b] \quad E(i,j) = E_i - E_i^0 = \pm \sum_{\mu,\nu} \sum c_{i\mu} c_{j\nu} \beta_{AB} S_{\mu\nu}$$

where E_i^0 and E_j^0 are the energies of the orbitals before interaction, $c_{i\mu}$, $c_{j\nu}$ are the coefficients of an LCAO expansion, and $S_{\mu\nu}$ refers to an overlap integral between μ and ν AO, and β_{AB} denotes a bonding parameter for the atom pair (24).

It should be pointed out that although these formulae do not contain the overlap explicitly, they possess an implicit dependence on overlap through the selected expression for the perturbational Hamiltonian. Obviously we could use the complete expression for the off-diagonal elements of the Hartree–Fock matrix for the perturbational Hamiltonian and, in this way, include the electron repulsion term in eq. [1]. However, in our approach this term depends only on the distance between two atoms and therefore does not change during rotation. These two equations allow for the expression of through-bond and through-space interactions, respectively, and for their dependence on conformation.

Through-space or direct interaction of lone pairs leads to the formation of a symmetrical combination, depicted as *L*(S), and an antisymmetrical one, *L*(A), of lone-pair orbitals. This process is illustrated schematically in the *xy* projection for an L_z-type of lone pair in the *ap*,*ap* conformation of DMM as shown in Fig. 3.

The order of the final MO levels also depends on whether *L*(S) and *L*(A) orbitals can interact with orbitals of the same symmetry. In the case of DMM,

hyperconjugating π_z,π_x, and π_z*,π_x* orbitals of the central methylene group may take part in this through-bond interaction but for symmetry reasons, only L(S) orbitals may interact, while the energy of the antisymmetric L(A) remains unchanged.

In Fig. 4 we again illustrate the through-bond interaction for L(A) and L(S) combinations of L_z lone pairs with π_z and π_z* orbitals of the central methylene group in the xy projection. The resulting orbitals are depicted as N(S) and N(A), respectively. In an analogous way we could describe through-bond and through-space interaction of the *sp* lone pairs.

Results and Discussion

Orbital Interaction in the Antiperiplanar Conformation

We have chosen MO's and energies of dimethyl ether (DME) calculated by the CNDO/2 method as unperturbed orbital values in calculating the through-bond and the through-space interactions in DMM according to eq. [1]. The LCAO expansion coefficients and the energies calculated for the most stable conformation of DME are listed in Table 1. For this purpose geometric parameters similar to DMM were used: 1.403 and 1.108 Å for the C—O and C—H lengths, 114.2 and 109.46° for the C—O—C and O—C—H angles, respectively, and a staggered position for the methyl group hydrogen atoms.

It is clear that the results of our analysis depend on the selection of the CNDO/2 method for a calculation of unperturbed orbitals. There have been several reports that the CNDO/2 method does not properly predict conformational properties of the rotation around the bond formed by two hetero atoms with lone pairs (25). However, there are only a few CNDO/2 calculations for molecules having atoms with lone pairs in the 1,3 position (26–30). The results of our calculations (26–28) on CH_3—O—CH_2—X, (where X = CH_3, OCH_3, F, Cl, NH_2, and NH_3^+) and those of Truax *et al.* (29) on fluoro alcohols and of Gorenstein *et al.* (30) on DMM and dimethylphosphate show that the CNDO/2 method describes fairly well the rotational barriers and conformational equilibria for molecules with hetero atoms in the 1,3 position. Moreover DME, which is the starting molecule for our PMO calculation, belongs to a group of molecules which does not suffer from the above problems (31, 32). On the basis of foregoing arguments we feel that the application of the CNDO/2 approach to the PMO analysis of the conformational dependence of lone-pair interactions in molecules of the DMM type is sound.

The through-space and through-bond interaction energies of lone pairs for DMM in an *ap* conformation, calculated from DME unperturbed values using eq. [1], are given in Table 2.

	x			−0.2091
	y			−0.1087

It follows from the PMO analysis that the resulting order of the N(S) and N(A) levels, and also the difference in their energies, depends upon a mutual equilibrium between both kinds of interaction. As the distance between oxygen atoms in the DMM molecule is relatively large (ca. 2.35 Å), overlap between orbitals is low ($S = 0.0049$) and the through-space interaction comparatively weak. It is substantially less than a through-bond interaction (Table 2) and consequently, the highest occupied MO in DMM should be a symmetrical combination of lone electron pairs of the *p* type, i.e., N(S).

In applications of the simple PMO method (neglecting overlap), only interactions of occupied orbitals with unoccupied ones are relevant for the estimation of energy changes and electron density transfer in DMM. The mutual interaction of occupied orbitals is irrelevant in this respect, as its absolute value is much higher. The stabilization energy of DMM resulting from delocalization is given as a double sum of the interaction energy changes of the *p* and *sp* type lone pairs Lp(*p*) and Lp(*sp*) (in *ap* conformations this corresponds to L_z and L_x, respectively) with the π_{CH_2}* orbital. It follows from Table 2 that the value calculated by the PMO method for an *ap* conformation is $E_{stab} = -8.634$ kcal/mol. As evident from Fig. 4, two electrons originally localized in L(S) occupy, after interaction, an MO involving also a small contribution from the π_{CH_2}* orbital. The relative stabilization of DMM with respect to DME may be considered to be a consequence of delocalization of electrons originally localized on L(S).

The order of levels obtained by an analysis of the interaction between the lone pairs by means of the

NOTE: Z denotes the $2p_z$ orbitals of oxygens and carbons; S, $1s$ orbital of hydrogens. The upper sign refers to an orbital introduced at first. Number of atoms is according to Fig. 1*b*, methyl group hydrogens on C6 are denoted as 8, 9, 10; those on C10 as 11, 12, 13.

PMO method may be compared with the order of DMM MO's calculated by the CNDO/2 method. In the CNDO/2 calculation, the DMM molecule consists of 32 valence electrons represented by 28 AO's leading to 28 MO's in the LCAO approximation. Sixteen of these are occupied by two electrons. Set B of geometrical parameters from ref. 26 was used in the calculation. All the LCAO expansion coefficients of the eight selected MO's which differ from the zero value for DMM in the *ap* conformation are summarized in Table 3. MO levels calculated by the CNDO/2 method may be assigned to PMO orbitals resulting from through-space and through-bond interactions of lone pairs by using LCAO expansion coefficients. Comparison of Table 3 with Figs. 3 and 4 confirms the results of the orbital interaction analysis obtained by the PMO theory. The symmetric combination of nonbonding orbitals N(S) is indeed the highest occupied orbital.

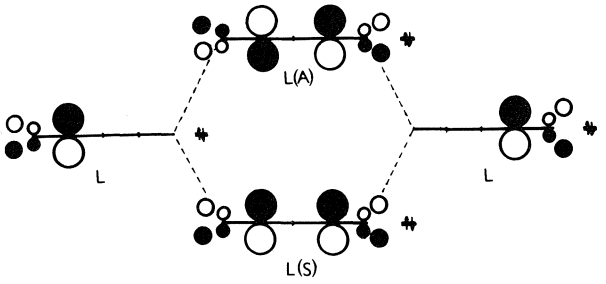

FIG. 3. Through-space interaction of the p-type lone pairs in *ap* conformation.

Conformational Dependence of Orbital Interactions

To estimate the role of the interaction between the lone pair orbitals for the anomeric effect in DMM we have investigated the conformational dependence of these interactions on the rotation about the C1—O3 bond. For the sake of simplicity we have fixed the torsional angle (φ) about the C1—O2 bond at $\varphi = 180°$, although it does not correspond to the value in the most stable conformation of DMM, (*sc*,*sc*). We believe that the effects responsible for the stabilization of the *sc*,*sc* conformation in comparison with the *ap*,*sc* one are the same as those for the stabilization of *sc*,*ap* over *ap*,*ap*, although the effects may not be additive. This choice of the φ_2 agrees at least with the model for rotation about a glycosidic bond in β-glycosides (so-called exoanomeric effect (2) i.e., preference of the *ap*,*sc* conformation in comparison with the *ap*,*ap* one). The variation of the interacting orbital orientation is described by θ, which is related to φ_1 by $\theta = 180° - \varphi_1$. To determine the conformational dependence of the interactions studied, it is necessary to evaluate the conformational dependence of the overlap integral on rotation about the C1—O3 bond. Since the axis of rotation does not lie in any of the coordinate axes (Fig. 1*b*) we have to express dependence of the overlap integral between the atomic orbitals on rotation. The usual means for solving this problem is to use an Euler transformation (33). Doing so, we get the overlap integrals as a function of θ (see Appendix). Substituting these functions in eq. [1] one obtains the dependence of the energy of orbital interactions on rotation about the C1—O3 bond (Appendix,

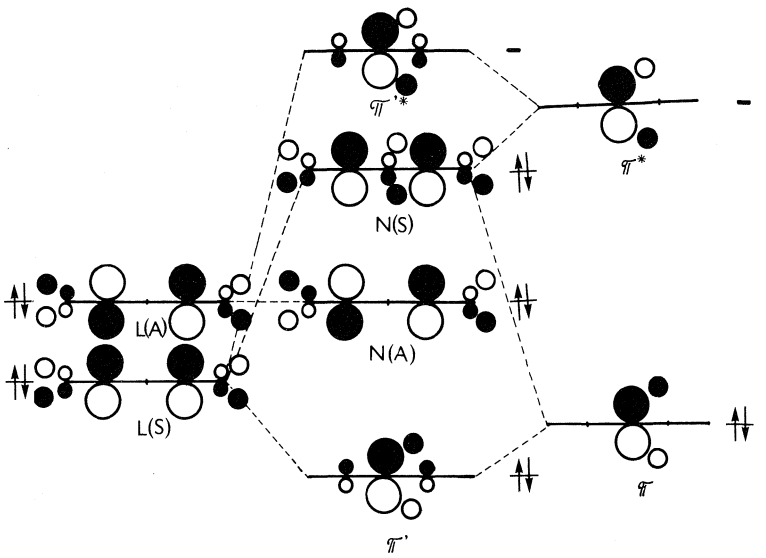

FIG. 4. Through-bond interaction of the *p*-type lone pairs in *ap* conformation.

eqs. [A1]–[A11]). Except for *sp* lone pair interaction with π_x orbitals, variation of the through-bond interactions with rotation may be described by the simple function $\cos^2\theta$.

Rotation about the C1—O3 bond causes the interactions of the *p* lone pair with π_z and π_z^* and of the *sp* lone pair with π_x and π_x^* to decrease, and the 'crossed' interactions of the *p* lone pair with π_x and π_x^* and the *sp* lone pair with π_z and π_z^* to increase. These interactions are demonstrated schematically for two extreme conformations, *ap* and *og*, in Fig. 5 and the values of the interactions for the *og* conformation are given in Table 2.

Conformational Dependence of HO

At first we shall study only the conformational dependence of orbital interactions for the highest occupied molecular orbital (HO) which is the most important MO from the viewpoint of the spectral behaviour and reactivity. The curve of the HO orbital energy may be expressed using the energy dependence of the *p* lone-pair interaction on rotation (see eq. [A1]–[A4], [A9], [A11] in the Appendix, and Fig. 5).

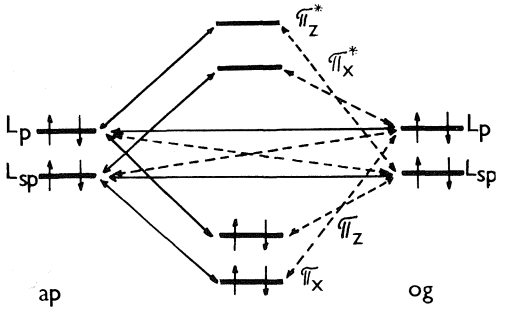

FIG. 5. Schematical representation of orbital interaction of the *p*- and *sp*-type lone pairs in *ap* and *og* conformations.

$$[2]\quad E_{HO}(\theta) = -E[Lp(p), Lp(p)]\cos\theta + \{E[Lp(p), \pi_z] - E[Lp(p), \pi_z^*]\}(1 + \cos 2\theta) + \{E[Lp(p), \pi_x] - E[Lp(p), \pi_x^*] - E[Lp(p), Lp(sp)]\}(1 - \cos 2\theta)$$

Substituting the values from Table 2 we get an expression for the variation of the HO energy with regard to the energy of the *ap* conformation:

$$[3]\quad E_{OH}(\theta) = 3.0620\cos 2\theta - 2.2949\cos\theta - 0.7671$$

Conformational dependences of individual interactions contributing to the energy of HO, calculated by the PMO method and listed in the Appendix, as well as their sum, which determines the resulting conformational dependence of HO (eq. [3]), are shown in Fig. 6. The variation of the HO energy with rotation, obtained by the usual CNDO/2 approach, is shown in the same figure for comparison. The HO energy profiles produced by both methods are similar; both show minima near 90° and maxima at 0° or 180°. The pronounced minimum at the *og* conformation is primarily due to the through-bond interaction of the Lp(*p*) orbital with π_z and π_x^*, (curves A1, A4) and by through-space interaction of Lp(*p*) orbitals (curve A9). The latter interaction is also responsible for the higher maximum of the HO energy at the *sp* conformation in comparison with the maximum at the *ap* conformation.

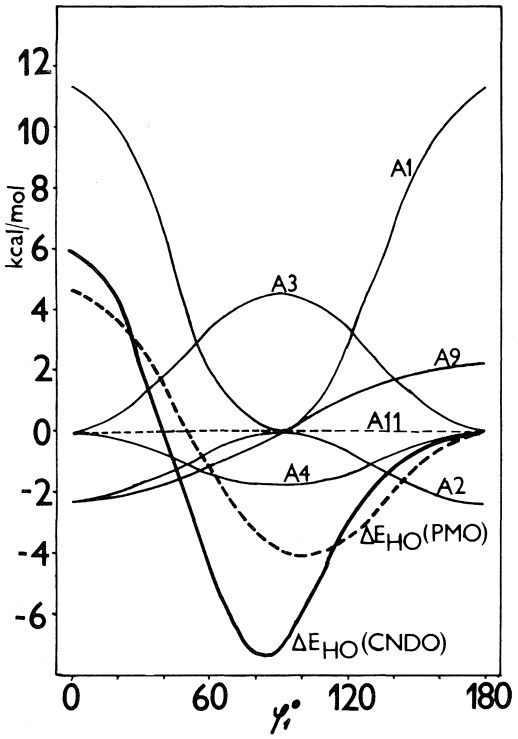

FIG. 6. Conformational dependence of orbital interactions at rotation about C1—O3 bond and the variation of HO energy calculated by PMO and CNDO/2 methods. Specification of orbital interaction curves according to the Appendix.

The close conformational dependence of the HO energy calculated by both PMO and CNDO/2 methods indicates that all important, conformationally dependent contributions to the energy of HO are included in our PMO treatment (eq. [2]).

According to the frontier orbital theory (34), the energy and symmetry of HO and the lowest unoccupied MO are the decisive factors in determining molecular reactivity. The torsional dependence of the HO level shown in Fig. 6 and given by eq. [3] may parallel the conformational dependence of the reactivity of DMM and the more complex molecules in which configuration of the segment —C—O—C—O—C— is fixed at various angles (φ_1). The acid-catalyzed hydrolysis of sugars, for which the first step involves the addition of a proton to oxygen, is an example.

It follows from Fig. 6 that the interaction of a proton with an acetal group in the *ap* position should be greater than the corresponding interaction in the *sc* position. This is in agreement with the higher rate of hydrolysis of β-D-glucopyranosides (corresponding to the *ap* conformation) in comparison with α-D-glucopyranosides (corresponding to the *sc* conformation) (35). Our preliminary results of the CNDO/2 study of the hypersurface of this proton transfer reaction support this explanation. The conformational dependence of the frontier orbitals may also be used to explain the stereoelectronic control mechanism in the cleavage of tetrahedral intermediate in the hydrolysis of esters and amides (36).

Stabilization Energy

From the conformational dependence of the interaction between lone pairs there follows the conformational dependence of the stabilization energy of DMM. Except for interactions of the Lp(*p*) orbital with π_{CH_2} orbitals (Fig. 6), inclusion of analogical interactions of the Lp(*sp*) orbital appears to be satisfactory for obtaining sufficiently representative conformational dependence of the DMM stabilization energy. The course of all through-bond orbital interactions is shown in Fig. 7 (curves A2, A4, A6, A8). In addition, combinations of these contributions are depicted in Fig. 7. The double value of an algebraic sum of curves A2 and A8 determines the total interaction of lone pairs with the π_z^* orbital (curve *a*) and similarly, with the π_x^* orbital (*b*, double sum of A4 and A6). Also shown is the con-

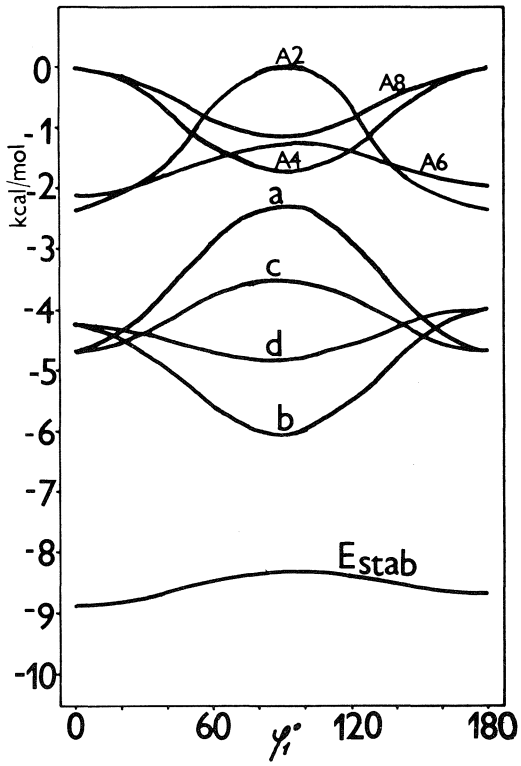

FIG. 7. Variation of orbital interactions, delocalization energies (*a–d*) and stabilization energy (E_{stab}) with rotation about C1—O3 bond in DMM.

formational dependence of interactions of the *p* lone pair (*c*, A2 + A6) and the *sp* lone pair (*d*, A4 + A8). An algebraic summation of the curves *a* and *b* or *c* and *d*, respectively, determines the total stabilization energy dependence (E_{stab}). It follows from Fig. 7 that orbital interactions have the form of the function cos 2θ. The stabilization energy of DMM resulting from the interaction of lone electron pairs is lowest in the *og* conformation and represents the net result of two conformationally opposite effects. For example, the stabilization energy obtained by delocalization into the π_z^* orbital exhibits maxima at *sp* and *ap* conformations and a minimum at *og*. In the case of interactions with π_x^*, the *og* conformation is the most stable. We suppose that the conformational dependence of the stabilization energy in Fig. 7 is negligibly influenced by consideration of the interactions with all remaining orbitals in DMM.

Geometrical Consequences

The energetic stabilization of DMM resulting from the interactions of occupied and unoccupied orbitals is accompanied by a transfer of charge. Owing to the interaction of lone pairs with the $\pi_{CH_2}^*$ orbital, transfer of electron density occurs from the oxygen atom to the methylene group and the electron density on the $\pi_{CH_2}^*$ orbital increases. The comparison of LCAO coefficients in Tables 1 and 3 for the *p*-type lone pair (−0.7934 and 0.543) and for the $2p_z$ orbital on carbon (−0.4990 and 0.521) confirms this transfer. The electron redistribution gives rise to several interesting structural consequences. Since the π_z^* orbital is antibonding along two methylene C—H bonds, we expect these bonds to lengthen. This orbital is also antibonding between the two C—H bonds so that the bond angle H—C—H should increase and the O—C—O angle should decrease.

The resulting geometry of an *ap* conformation should reflect a balance between the above influences. In the other conformations, electron transfer will decrease (increase) as a consequence of the conformational dependence of lone-pair interactions with the π_z^* (π_x^*) orbital. Therefore, more pronounced geometrical changes should occur. From the torsional dependence of orbital interactions in DMM (Fig. 7) one may obtain the following idea about the influence of through-bond interactions upon the geometry of the DMM molecule. Rotation about the C1—C3 bond should lead to its contraction as well as to an increase in the O2—C1—O3 bond angle and a decrease in the H4—C1—H5 angle.

The variation of bond lengths with rotation in simple diols and methoxymethanol has previously been rationalized in terms of qualitative PMO theory without quantitative estimation of various orbital interactions (14–16). That variation was also compared with the crystal structure data for carbohydrate systems and oligosaccharides (15, 16). The present more exact PMO treatment explains all changes, found previously by *ab initio* SCF computations, of bond lengths for simple model compounds (Table 4) including the shortening of bonds in *ap,ap* conformations. This effect is difficult to interpret with the simple concept of 'back donation' (15, 16) resulting in partial double-bond character of the C—O moiety. The experimental data for the C5—O5—C1—O1 bond sequence of α- and β-glycosides, for which DMM is a close model, are also listed in Table 4. This table shows that C—O bond lengths in the —O—C—O— moiety (37) are shorter than those for methanol. In agreement with the theoretical predictions in the foregoing paragraph it follows from the data in Table 4 that each rotation about the C—O bond produces its shortening and the elongation of the vicinal C—O bond. Similarly, the O—C—O bond angle is greater in an *sc,sc* conformation and lower in an *ap,ap* conformation than the tetrahedral angle. Recently several *ab initio* calculations of the geometry of DMM have been carried out (38, 39) within a 'restricted minimization frame.' The results of these calculations are shown in Table 4. We have carried out full optimization of the geometry of DMM in different conformations using the CNDO/2 method (28). The final geometries of the equilibrium conformers are shown in Table 4. Though the C—O bond lengths for the *ap,ap* and *sc,sc* conformers seem to be shorter in comparison with the results of *ab initio* restricted minimization (38, 39), the bond angle and bond lengths are in very good agreement with the experimental data (18) for the *sc,sc* conformation. The results show the great dependence of the O—C—O bond angle on conformation and confirm the PMO prediction of an increase in the O—C—O bond angle on going from the *ap,ap* to the *sc,sc* conformation. The results also show the ability of the CNDO/2 method to describe the conformational properties of molecules of this kind. A full account of these results together with a discussion of relaxational effects on conformational equilibrium will be published elsewhere (28). In conclusion, we wish to point out that contrary to stabilization energy there exists a strong conformational dependence of bond lengths and bond angles on torsional angles in DMM. Recently the similar strong coupling between polar methoxy rotors in

the acyclic phosphate ester has been demonstrated (38). Since the structure of this compound is very similar to DMM we may speculate that in this case the origin of the coupling can also be ascribed to lone-pair orbital interactions.

Orbital Interactions and Anomeric or Exoanomeric Effects

It follows from our analysis that the through-space and through-bond interactions of lone pairs are not responsible for the anomeric or exoanomeric effect in molecules with a C—O—C—O—C segment.

Delocalization of lone pairs into an antibonding $\sigma_{C—Y}$* orbital has often been invoked to explain the anomeric effect for molecules containing a segment of the —C—O—C—Y kind (where Y = O, N, Cl, F, etc.), though originally this conception was designed mainly for molecules with a —C—O—C—Cl segment (10, 11). The substantially greater interaction between a *p*-type lone pair and a $\sigma_{C—Cl}$* orbital in the *ap* conformation compared with the interaction in the *sc* conformation also confirms the C—Cl bonds lengths in α-chloroethers or heterocycles corresponding to them (11), as well as nuclear quadrupole resonance frequency values (40, 41). For this reason we have calculated in the same way the conformational dependence of the interaction between the oxygen lone pair with the antibonding orbital of the C—O bond (Table 1), which is situated in the *xy* plane. The conformational dependence of these interactions follows.

$$E[\mathrm{Lp}(p), \sigma^*] = -0.3376(1 - \cos^2\theta)$$

$$E[\mathrm{Lp}(sp), \sigma^*] = -3.6655 + 0.0656\cos\theta - 0.1218\cos^2\theta$$

and their sum

$$E(L, \sigma^*) = -3.7833 + 0.0656\cos\theta - 0.2158(1 - \cos^2\theta)$$

The last expression shows that the conformational dependence of the interaction of lone pairs with σ* in the case of DMM is not very important; for example, the change of their interaction energy in going from an *ap*,*ap* to an *ap*,*sc* conformation is only 0.2509 kcal/mol. Therefore, for both the through-space and through-bond interactions, more complete treatment including the interaction of lone pairs with σ* does not result in an appreciable stabilization of the *gauche* conformation in molecules with a C—O—C—O—C segment.

The total potential curve of the rotation about the C—O bond may be conveniently analyzed by means of the Fourier expansion

$$V(\varphi_1) = \sum_{i=1}^{3} 0.5V_i(1 - \cos i\varphi_1)$$

The coefficient V_1 describes the dipole–dipole interaction between dipoles of both C—O—C groups. The conformational dependence of the through-bond orbital interactions has the shape of the cos $2\varphi_1$ function so that the lone-pair orbital interactions should determine the V_2 term. In DMM the positive sign for this term follows from Fig. 7 (curve E_{stab}).

From the Fourier expansion it follows that the anomeric effect may be expressed as an energy difference between the *ap* and the *sc* conformations (equatorial and axial conformations, respectively, for heterocycles): $E = V(180°) - V(60°) = 0.75(V_1 - V_2)$ (27). The anomeric or exoanomeric effect may therefore be generally interpreted as a result of the mutual balance between dipole–dipole interaction of the polar bonds and delocalization interactions of the lone pairs. Through an analysis of a potential energy curve of the rotation about the C1—O3 bond in DMM calculated by the CNDO/2 method we obtained the following values for coefficients in kcal/mol: $V_1 = 3.499$, $V_2 = 0.346$, and $V_3 = -0.899$ (27).

It follows from a comparison of these values, that the $V_1 - V_2$ balance in DMM is considerably shifted toward electrostatic dipole–dipole interactions. We suggest that dipole–dipole interaction of the polar bonds is the primary cause of the anomeric effect in DMM and the results of a previous analysis support this. The 'rabbit ears' scheme, in which an interaction between sp^3 hybridized oxygen atom lone pairs is used to depict electrostatic interactions, represents an alternative model for this interaction (Fig. 1*b*). The dipole interaction favours an *sp* conformation, whereas the net result of through-space and through-bond interactions is to favour both the *sp* and the *ap* conformations. The resulting effect of both these contributions leads to a stabilization of the *sp* conformation. Van der Waals' repulsion between nonbonding atoms and other interactions contributing to the value of the V_3 term, which were not considered in our analysis, shift the equilibrium to the nearest staggered conformation, *sc*. The sum of all three contributions determines the value of φ_1 corresponding to a rotational minimum in the total energy ($\varphi_1 = 35°$) (26, 42). That sum also determines the rotation barrier for a transition through the *sp* conformation.

Usually only one cause (either electrostatic, or delocalization, etc.) of the anomeric effect in the C—O—C—Y segment has been emphasized in the literature regardless of the character of the Y substituent. Comparison of the potential energy curves for rotation in DMM and chloromethoxymethylene (CMM) led us recently to the conclusion (27) that either electrostatic or delocalization effects can prevail according to the character of the Y substituent. For example, electronic delocalization effects (V_2 term) are more pronounced for molecules with Y = Cl than with Y = OCH_3 from the point of view of the anomeric effect. Thus, in contrast to molecules with a 1,3-dioxa group it indicates that, in the case of the C—O—C—Cl segment, the nature of the anomeric effect is determined by delocalization interactions between oxygen lone pairs and antibonding orbitals of the C—Cl and C—H bond, respectively, in agreement with the 'superjacent orbital control' proposal (13). The absolute value of the delocalization interaction leading to the stabilization in the C—O—C—Y bond sequence is probably higher for O—CH_3 than for Cl. However, from the point of view of the anomeric effect, only the conformational dependence of the delocalization interaction is important and that is more pronounced for Cl. The high stabilization energy of the C—O—C—O—C segment has been explained as a consequence of electron delocalization through double bond – no bond resonance (43). It follows from the experimental results that linear diethers containing two oxygen atoms separated by a methylene group are stabilized by about 4 kcal/mol, compared with aliphatic monoethers (44). The value of the stabilization owing to orbital interaction, which we have calculated by the PMO method for DMM, is in the range 8.2–8.9 kcal/mol (Fig. 7).

No account is taken of an electrostatic lone-electron pair repulsion in the simple PMO theory, which we used for the calculation of the through-space and through-bond interactions and their conformational dependences in DMM. Such repulsion of the lone pairs has not been considered in the present analysis because of the uncertainty in the distribution of the nuclear repulsion energy between the bonding and antibonding pairs (45). Van Catledge (46) attempted to express the conformational dependence of an electrostatic lone electron pair repulsion by means of the double-electron elements of the Hartree–Fock matrix. From the calculation of a repulsion between two lone pairs on neighbouring atoms there follows a conformational dependence of the cos φ type (46). Repulsion in the *sp* conformation prevails over the *ap* one.

Conclusions about the prevailing electrostatic interaction origin of the anomeric effect in DMM may be extended to other types of molecules containing an R—O—C—O—R segment. Alkoxysubstituted heterocycles of the pyrane type, and especially sugars, has been most frequently studied with respect to the anomeric effect. In fact, the dependence of the anomeric effect on solvent polarity, observed for 2-alkoxytetrahydropyrane (2, 3), has been used

as an argument favouring the electrostatic origin of the anomeric effect (1).

The preference of the *sc* (*gauche*) conformation to the *ap* (*trans*) one is also observed in the DMM polymer analogue polyoxymethane (POM) and is the cause of right- and left-handed helix formation in the polymer chain. This behaviour should be considered to be the result of the anomeric effect in polymer chemistry. This fact seems to have been omitted in the discussion of the anomalous conformational behaviour of POM (47). From the combustion heat measurement one obtains the constant stabilization energy of POM oligomers per CH_2O segment (44). This suggests that the nature of the anomeric effect is the same for both DMM and POM and so information obtained for DMM might be quantitatively transferred to POM.

Conclusions

The PMO calculation for DMM does not support the suggestion that the anomeric effect in a C—O—C—O—C bond sequence originates from lone pair interactions. The importance of dipole–dipole interactions in the conformational behaviour of this moiety is reconfirmed. On the other hand, through-bond orbital interactions are responsible for the relative stabilization of molecules with 1,3 dioxa groups compared with linear monoethers. Although lone pair interactions are not dominant with respect to conformational stability, they appear to be the most important factors in describing the strong coupling between the geometrical parameters and torsional angles in DMM and related molecules.

Calculation of the Conformational Dependence of the Energy of Orbital Interactions

We denoted cos α and sin α as A and B, respec-

tively, where α (56.
(bisector of the O-
system (Fig. 1*b*) a
and S_3 denote the
(5.172, 0.165), $S(2$
(10.074, 0.0), and
tively. The overla
overlapping AO's
a and *b* obtained
(33) are given by

$S(XC1,XC$
$S(YC1,XC$
$S(ZC1,XC$
$S(YC1,YC$
$S(ZC1,YC$
$S(ZC1,ZC$
$S(XO2,XC$
$S(YO2,XC$
$S(ZO2,XC$
$S(YO2,YC$
$S(ZO2,YC$
$S(ZO2,ZC$

tively, where α (56.3°) is the angle between the x axis (bisector of the O—C—O angle) of the coordinate system (Fig. 1*b*) and the C1—O3 bond. S_2, S_1, S_4, and S_3 denote the pure overlap integrals $S(2p_\pi,2p_\pi)$ (5.172, 0.165), $S(2p_\sigma,2p_\sigma)$ (5.172, 0.165), $S(2p_\pi,2p_\pi)$ (10.074, 0.0), and $S(2p_\sigma,2p_\sigma)$ (10.074, 0.0), respectively. The overlap integrals $S(\phi_a,\phi_b)$ for a pair of overlapping AO's ϕ_a and ϕ_b corresponding to atoms a and b obtained by applying Euler transformation (33) are given by

$$S(XC1,XO3) = A^2S_1 + B^2S_2\cos\theta$$
$$S(YC1,XO3) = ABS_1 - ABS_2\cos\theta$$
$$S(ZC1,XO3) = -BS_2\sin\theta$$
$$S(YC1,YO3) = B^2S_1 + A^2S_2\cos\theta$$
$$S(ZC1,YO3) = BS_2\sin\theta$$
$$S(ZC1,ZO_3) = S_2\cos\theta$$
$$S(XO2,XO3) = S_4(B^2\cos\theta + A^2)$$
$$S(YO2,XO3) = ABS_3(\cos\theta - 1)$$
$$S(ZO2,XO3) = BS_4\sin\theta$$
$$S(YO2,YO3) = S_3(A^2\cos\theta + B^2)$$
$$S(ZO2,YO3) = AS_4\sin\theta$$
$$S(ZO2,ZO3) = S_4\cos\theta$$

where X, Y, and Z are the $2p_x$, $2p_y$, and $2p_z$ AO's of the oxygen atoms 2 and 3 and carbon 1.

Substitution of $S(\phi_a, \phi_b)$ into eq. [1] provides the following expressions for the conformational dependence of the through-bond and through-space interactions of the lone pairs (in kcal/mol):

Through bond

[A1] $E[\mathrm{Lp}(p), \pi_z] = 11.3298\cos^2\theta$

[A2] $E[\mathrm{Lp}(p), \pi_z^*] = -2.3340\cos^2\theta$

[A3] $E[\mathrm{Lp}(p), \pi_x] = 4.5368(1 - \cos^2\theta)$

[A4] $E[\mathrm{Lp}(p), \pi_x^*] = -1.7377(1 - \cos^2\theta)$

[A5] $E[\mathrm{Lp}(sp), \pi_x] = 4.3722 - 0.1786\cos\theta + 2.3918\cos^2\theta$

[A6] $E[\mathrm{Lp}(sp), \pi_x^*] = -1.2790 + 0.0587\cos\theta - 0.7625\cos^2\theta$

[A7] $E[\mathrm{Lp}(sp), \pi_z] = 7.1488(1 - \cos^2\theta)$

[A8] $E[\mathrm{Lp}(sp), \pi_z^*] = -1.1368(1 - \cos^2\theta)$

Through space

[A9] $E[\mathrm{Lp}(p), \mathrm{Lp}(p)] = \pm 2.2949\cos\theta$

[A10] $E[\mathrm{Lp}(sp), \mathrm{Lp}(sp)] = \mp 0.1890 \mp 1.2839\cos\theta$

[A11] $E[\mathrm{Lp}(p), \mathrm{Lp}(sp)] = 0.0727(1 - \cos^2\theta)$

Microbial hydroxylation of steroids. 5. Metabolism of androst-5-ene-3,17-dione and related compounds by *Rhizopus arrhizus* ATCC 11145

HERBERT L. HOLLAND AND PETER R. P. DIAKOW

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received August 10, 1978

HERBERT L. HOLLAND and PETER R. P. DIAKOW. Can. J. Chem. **57**, 436 (1979).

The products of the incubation of androst-5-ene-3,17-dione (**2***a*), 3β-hydroxyandrost-5-ene-17-one (**2***b*), and androsta-3,5-diene-17-one (**3**) with *Rhizopus arrhizus* ATCC 11145 under a variety of conditions have been identified and the mechanisms of their formation discussed. In addition, several C-(4,5)- and C-(5,6)-epoxyandrostanes have been incubated with *R. arrhizus*, the products identified and possible pathways for their formation presented.

HERBERT L. HOLLAND et PETER R. P. DIAKOW. Can. J. Chem. **57**, 436 (1979).

On a identifié les produits obtenus par l'incubation de l'androstène-5 dione-3,17 (**2***a*), de l'hydroxy-3β androstène-5 one-17 (**2***b*) et de l'androstadiène-3,5 one-17 (**3**) avec le *Rhizopus arrhizus* ATCC 11145 sous diverses conditions; on discute de leurs mécanismes de formation. De plus, on a incubé plusieurs C-(4,5) et C-(5,6)-époxyandrostanes avec le *R. arrhizus*; on a identifié les produits et on présente des voies possibles pour leur formation.

[Traduit par le journal]

The C-6β hydroxylation of androst-4-ene-3,17-dione (**1***a*) by *R. arrhizus* ATCC 11145 proceeds via the $\Delta^{3,5}$-enol form of the ketone (1). In an attempt to gain further insight into this enzymic process, we have studied the metabolism of androst-5-ene-3,17-dione (**2***a*), the corresponding 3β-alcohol (**2***b*), and the $\Delta^{3,5}$-enol analogue **3**, by *R. arrhizus* under a variety of conditions. In addition we have incubated a series of epoxy steroids and related compounds, **4**–**9**.

Results

The results of the incubations of **2**–**9** are tabulated in the Experimental. The alcohol **2***b* gave predominantly the C-11α-hydroxy derivative **2***c*, while incubation of **2***a* involved changes in rings A and B. In the presence of oxygen, **2***a* gave the *C*-6β- and *C*-6α-Δ^4-3-keto alcohols, **1***b* and **1***c*, respectively, together with the Δ^4-3,6-dione, **1***e*; with live fungus C-11α hydroxylation was also observed. In the absence of oxygen, **2***b* was rearranged nonenzymically to the conjugated isomer **1***a*. The $\Delta^{3,5}$-diene **3** gave, along with some recovered starting material, small amounts of the isomeric 3α- and 3β-hydroxy-Δ^4-6β-alcohols **10***a* and **10***b*, respectively; no C-11α hydroxylation of **3** was observed. The structure of the major product, **10***a*, followed from an analysis of its ^{1}Hmr spectral data (2) (see Experimental) and oxidation to the known Δ^4-3,6-dione **1***e*. The structure of **10***b* was confirmed by a comparison of observed physical and spectral data with those published (3). For both **10***a* and **10***b*, the chemical shift of the C-19 hydrogens was diagnostic of the presence of a C-6β-hydroxyl function (2) and agreed well with that predicted from additivity parameters (2) (**10***a*, calcd.: 1.22; found: 1.20 δ; **10***b*, calcd.: 1.30; found: 1.28 δ).

The keto epoxide **4***a* gave, with both live and autoclaved fungus, the C-6α-alcohol **1***c*; some starting material was recovered under the latter conditions. In contrast, both the C-(5,6)α- and C-(5,6)β-epoxides, **4***b* and **5***a*, gave a complex mixture of products. The α-oxide **4***b* under normal incubation conditions gave the C-7α-hydroxy derivative **4***c* as the major product together with the 3β,5α-dihydroxy-6-ketone **9***b* and the triol **9***a*. The structure of **4***c* was deduced from its ^{1}Hmr spectrum (*q.v.*). The location of oxygen at C-7 was suggested by the downfield shift of the doublet assigned to the C-6β hydrogen (0.34 ppm with respect to starting material) (4) and confirmed by spin decoupling of the C-7β and C-6β hydrogens; irradiation at δ 4.15 (C-7βH) caused collapse of the doublet at δ 3.26. The chemical shift of the C-19 hydrogens of **4***c* (−0.01 ppm with respect to **4***b*) is also consistent with C-7α hydroxylation (2). The keto diol **9***b* was characterized by the upfield resonance of the C-19 hydrogens, a feature diagnostic of 6-keto-5α-steroids (2), and identified by comparison with authentic material. The triol **4***c* was formed in the presence of both live and autoclaved fungus.

An analogous series of products was obtained from the β-epoxide **5***a*. The structure of the 7α-hydroxy derivative **5***b* again followed from ^{1}Hmr data, the signal assigned to the C-6α hydrogen now appearing as a singlet at δ 3.20, and that of the C-7β hydrogen as a doublet (coupled only to the C-8 hydrogen) at δ 3.67. The absence of coupling between

0008-4042/79/040436-05$01.00/0

the C-6α and C-7β hydrogens is a consequence of the dihedral angle, estimated from models to be close to 90°. This interpretation is strengthened by the observation that the C-6α hydrogen of **5***a* appears as a well-resolved doublet (J = 3 Hz) at δ 3.10, coupled only to the C-7α hydrogen.

The (4,5)-epoxy steroids **6** and **7**, the 5α-hydroxy ketone **8**, the triol **9***a* and keto diol **9***b* were all recovered unchanged after incubation with *R. arrhizus*.

Discussion

The hydroxylation of **2***b* at 11α without extensive oxidation at C-3 is a feature of 11α-hydroxylating fungi such as *R. nigricans* (5) and *Aspergillus ochraceus* (6), a feature which is apparently shared by *R. arrhizus*.

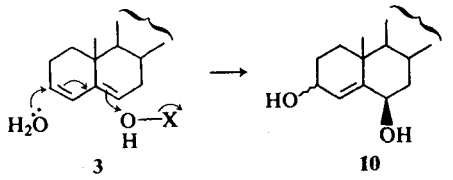
The microbial oxidation of Δ^5-3-ketones has not been thoroughly examined but their nonenzymic oxidation, in the presence (7–9) or absence (10, 11) of fungus, to 6α- and 6β-oxygenated Δ^4-3-keto steroids is documented. The initial products are the 6α- and 6β-hydroperoxides, **1***f* and **1***g*. When produced nonenzymically in the presence of the fungus *Actinoplanes missouriensis*, these are reduced to the corresponding alcohols **1***c* and **1***b*, respectively (7–9).

The results obtained by incubation of **2***a* with *R. arrhizus* confirm that nonenzymic oxidation of **2***a* occurs. The 6α- and 6β-alcohols **1***c* and **1***b* are formed at both pH 5.3 and 6.8 in the presence of either living or autoclaved fungus. The formation of **1***b* and **1***c* with autoclaved fungus implies that, if the autoxidation follows the normal course and the hydroperoxides are the initial products (10, 11), then the alcohols **1***b* and **1***c* are formed in a secondary step. A mechanism has been proposed and discussed (11) for the autoxidation of cholest-5-ene-3-one to analogous products. The 6-ketone **1***e* also produced under a variety of incubation conditions may be readily formed by the dehydration of a peroxide intermediate.

The formation of the 6α-alcohol **1***c* and the 6-ketone **1***e* from **2***a* militates against the intermediacy of the Δ^5-3-ketone **2***a* in the normal C-6β hydroxylation of **1***a*: in our experience (1) neither C-6α-hydroxylated nor-C-6-keto steroids are produced during the C-6β-hydroxylation reaction. The possibility of a Δ^5-3-ketone is produced as a transient enzyme bound species, protected from aerial oxidation during the C-6β-hydroxylation process cannot be eliminated (12) but chemical analogies (1) indicate a direct conversion of $\Delta^{3,5}$-enol to 6β-hydroxy-Δ^4-3-ketone and thus support the present conclusions.

The isomerization of **2***a* to **1***a* during all the incubations performed indicates that, even at pH 6.8, **2***a* may be rapidly and nonenzymically isomerized in the presence of the incubation medium and either live or autoclaved fungus. The catalysis of the Δ^5-3-keto-Δ^4-3-keto steroid isomerization by amino acids has been reported (13) and may be operative under the conditions reported herein.

Further evidence for the direct oxidation of an enolic intermediate is provided by the products obtained from the $\Delta^{3,5}$-diene **3**. The formation of **10***a* and **10***b* may be rationalized by a mechanism involving electrophilic oxidation of the Δ^5 bond, with rearrangement and attack of water at C-3, as shown in Fig. 1. The stereochemistry of the products at C-6 is a result of stereoelectronic factors (1 and references therein) and a similar preference for axial attack at C-3 leads to the observed predominance of the C-3α-alcohol **10***a*.



3 10

FIG. 1.

Microbial transformations of epoxy steroids have not been extensively studied, although dehydrogenation (14), C-11 hydroxylation (15, 16) and ring opening (17) have been reported. In analogy with earlier work (17), we found that **4***a* is opened nonenzymically to the 6α-hydroxy-Δ^4-3-ketone **1***c*. This facile conversion has been studied in the cholestane series (18) and demonstrates the possibility that an unstable (18) (5,6)β-epoxy-3-ketone (or its Δ^3-enol equivalent) may be an intermediate in the microbial C-6β hydroxylation, although no direct evidence for such an intermediate species exists.

The hydroxylation of **4***b* and **5***a* at C-7α is not a known reaction of the *Rhizopus* genus, although both C-7α and C-7β hydroxylation have been reported with its members (19). The production of the 3β,5α,6β-triol **9***a* from both **4***b* and **5***a* may be the result of nonenzymic hydrolysis, since both are produced with autoclaved fungus. The formation of the corresponding keto diol **9***b*, however, may be the result of enzymic oxidation of the epoxide; its formation by oxidation of **9***a* is precluded by the observation that **9***a* is recovered unchanged after incubation with *R. arrhizus* (*vide infra*) and its formation by autoxidation, although possible (20), unlikely in view of the fact that it is not formed in the absence of live fungus. Chemical analogy for the formation of **9***b* is

provided by the conversion of other 5,6α-oxides into 6-keto derivatives under oxidative conditions (21–23), although the mechanism of this reaction has not been defined.

Although *R. arrhizus* is an efficient C-11α hydroxylator (24), no C-11α hydroxylation of epoxides **4***a*, **4***b*, **5***a*, **6**, or **7** was observed, **6** and **7** being recovered unchanged from the incubation medium: the closely related fungus *R. nigricans* is reported to hydroxylate C-(4,5)-epoxides of the pregnane series at C-11α (16). Control incubations of compounds **8**, **9***a*, and **9***b* also failed to show detectable metabolism by *R. arrhizus*.

Experimental

Apparatus, Materials, and Methods

The apparatus and techniques used were as previously described (1). Incubations with *R. arrhizus* were performed as described (25); incubations under nitrogen were performed after the flasks were autoclaved, cooled, degassed, flushed with nitrogen, and sealed.

Preparation of Substrates

The following steroids were prepared by published procedures: Androst-5-ene-3,17-dione (**2***a*) (26), androsta-3,5-diene-17-one (**3**) (27, 28), (5,6α)-epoxy-5α-androstane-3,17-dione (**4***a*) (29), (5,6α)-epoxy-3β-hydroxy-5α-androstan-17-one (**4***b*) (1), (5,6β)-epoxy-3β-hydroxy-5β-androstan-17-one (**5***a*) (1), (4,5β)-epoxy-5β-androstane-3,17-dione (**6**) (16), (4,5α)-epoxy-5α-androstane-3,17-dione (**7**) (16), and 5-hydroxy-5α-androstane-3,17-dione (**8**) (1). 3β-Hydroxyandrost-5-ene-17-one (**2***b*) was a commercial sample.

3β,5,6β-Trihydroxy-5α-androstan-17-one (9a)

Perchloric acid (5.5 mL, 6.5% w/v) was added to a refluxing solution of (5,6α)-epoxy-3β-hydroxy-5α-androstan-17-one (2 g) in acetone (35 mL). After a further 10 min at reflux, the reaction mixture was cooled and the product collected by filtration, washed with ether, and dried, to give 1.9 g, mp 292–297°C (dec.). The product showed physical and spectral data identical with those published (3).

3β,5-Dihydroxy-5α-androstane-6,17-dione (9b)

This was prepared by a modification of the method of Fieser and Rajagopalan (30). 3β,5,6β-Trihydroxy-5α-androstan-17-one (3.2 g) was dissolved in a mixture of dioxan (50 mL) and water (5 mL). *N*-Bromosuccinimide (2 g) was then added and the resulting solution placed 2 ft from a G.E. sunlamp and maintained at 20–25°C by ice cooling. After 1 h, water (400 mL) was added and the solution extracted with chloroform. The chloroform extract was washed (water, 2 *N* sodium metabisulphite), dried, and evaporated. The residue was crystallized from ethyl acetate – hexane. Recrystallization from the same solvent gave the desired compound, 0.37 g, mp 281–283°C (dec.); ir (ν_{max}, KBr): 3450, 3300, 1740, 1700 cm^{-1}; nmr (δ, DMSO-d_6): 0.70 (3H, s, C-19H), 0.77 (3H, s, C-18H), 3.6–3.9 (1H, m, C-3αH), 4.47 (1H, d, J = 5 Hz, C-3βOH), 5.37 (1H, s, C-5αOH); ms (*m/e*, %): 320 (50), 302 (11), 287 (6), 220 (100). *Anal.* calcd. for $C_{19}H_{28}O_4$: C 71.22, H 8.81; found: C 71.02, H 8.87.

Incubations with Rhizopus arrhizus

The results of the incubations of **2** to **9** are presented in the table. In all cases, products were isolated following column chromatography on silica gel. The standard chromatographic procedure involved stepwise elution from benzene to ether (increments of 10% ether) followed by stepwise elution to 10% methanol (increments of 1% methanol). Physical and spectral data for hitherto unreported compounds are listed below. All other products were identified by comparison of physical and spectral data with those of authentic samples.

Received June 14, 1978

SEBASTIÃO F. FONSECA, LAURO E. S. BARATA, EDMUNDO A. RÚVEDA, and PAUL M. BAKER. Can. J. Chem. 57, 441 (1979).

The ^{13}C nmr spectra of the naturally occurring stereoisomers of the tetrahydrofuran lignans were recorded and the signals assigned. Based on these assignments, on the observed sensitivity of the benzylic carbon shifts to the orientation of the aryl groups, and on the comparison with previously reported ^{1}H nmr data, the most probable conformations for the mentioned stereoisomers are suggested.

SEBASTIÃO F. FONSECA, LAURO E. S. BARATA, EDMUNDO A. RÚVEDA et PAUL M. BAKER. Can. J. Chem. 57, 441 (1979).

On a enregistré les spectres rmn du ^{13}C de stéréoisomères naturels de lignanes tétrahydrofuranniques et on a attribué les signaux. En se basant sur ces attributions, sur la sensibilité observée pour les déplacements des carbones benzyliques sur l'orientation des groupes aryles et sur une comparaison avec les données de rmn de ^{1}H rapportées antérieurement, on fait des suggestions concernant les conformations les plus probables pour les stéréoisomères mentionnés.
[Traduit par le journal]

Of the six possible stereoisomers of the tetrahydrofuran lignans, **2**–**7**, only four, **2**–**5**, with a variety of oxygenated substituents in the aryl groups (1), have so far been isolated from plants.

By phenol oxidation, Sarkanen and Wallis (2) obtained four isomers of 2,5-bis-(3′,4′,5′-trimethoxyphenyl)-3,4-dimethyltetrahydrofuran, **2***a*, **3***a*, **5***a*, and **6**, which were analyzed by ^{1}H nmr spectroscopy to establish their most probable conformations. The availability of galbacin (**2***b*) and veraguensin (**5***b*), isolated from *V. surinamensis* (3) and di-*O*-methyltetrahydrofuroguaiacin B (**4**) and galgravin (**3***b*), obtained by simple synthetic procedures (4, 5), prompted us to study these stereoisomers by ^{13}C nmr spectroscopy, in order to extract as much conformational information as possible, and in continuation with our project on ^{13}C nmr spectral analysis of lignans and related families of natural products (6).

From ^{1}H nmr spectral analysis, it was shown that the segment of the cycle of pseudorotation (CYCLOPS) representing the most populated conformations of **2***a* are $^{2}T_{3}$–$^{4}T_{5}$, with torsion angles for $H_{2\beta}$–$H_{3\alpha}$ and $H_{4\beta}$–$H_{5\alpha}$ protons of approximately 150°, and with all the substituents pseudoequatorially oriented (2).[1] This is in agreement with the ^{13}C nmr spectrum of galbacin (**2***b*), which shows 10 signals readily assigned by standard chemical shift theory.

The similarity between the H_2–H_3 coupling constant of licarin B (**8**) and the corresponding ones of $H_{2\beta}$–$H_{3\alpha}$ and $H_{4\beta}$–$H_{5\alpha}$ of **2***b*, indicates that the dihedral angles for the methyl and piperonyl groups should be approximately the same in both compounds (7). Since the 3-Me group of **8** is considered to be free of steric interactions from the piperonyl group of C-2 (7), it can be suggested that the shielding of both methyls of **2***b*, at 13.7 ppm, is a consequence of a reciprocal γ effect, owing to the puckering of C-3 and C-4, confirming their pseudoequatorial orientation. The shift of C-1′ and C-1″ of **2***b* at 136.1 ppm, deshielded 2.1 ppm in comparison with C-1′ of **8** and with a δ value similar to the reported ones for C-1′ and C-1″ of the 'equatorially' oriented piperonyl units of the 2,6-diaryl-3,7-dioxabicyclo[3.3.0]octane lignans type (8), confirms the pseudoequatorial orientation of the piperonyl groups of **2***b* and also that the methyl groups are free of their steric interactions.

It was suggested, based on the *J* values of $H_{2\beta}$–$H_{3\alpha}$ and $H_{4\alpha}$–$H_{5\beta}$ protons, that the most probable conformations of **3***a* are the ones represented by the $^{3}T_{2}$–$^{5}T_{4}$ and $^{2}T_{3}$–$^{4}T_{5}$ segments of the CYCLOPS (2). The shift of C-1′ and C-1″ at 134.6 ppm, in the ^{13}C

[1]See **1** for numbering. The designations α and β are given to the substituents oriented below and above the plane of the paper, respectively.

nmr spectrum of galgravin **3***b*, similar to the ones for C-1′ and C-1″ of 'equatorial' veratryl groups of lignans of the 2,6-diaryl-3,7-dioxabicyclo[3.3.0]octane type (8), suggests that in **3***b*, both aryl groups are pseudoequatorially oriented and free of steric interactions. The signal at 12.9 ppm, assigned to the *cis*-methyl groups, shows that in **3***b* the reciprocal γ effect between them is stronger than in the all-*trans* isomer **2***b*. The forms V_4, $^5T_4$, $^2T_3$, and V_3 with torsion angles averaging 120° for $H_{2\beta}$–$H_{3\alpha}$ and $H_{4\alpha}$–$H_{5\beta}$ protons, allowing partial release of the *C*-methyl groups steric interactions and keeping the aryl groups pseudoequatorially oriented, probably represent the most populated conformations of galgravin **3***b*.

The reported $H_{2\alpha}$–$H_{3\alpha}$ and $H_{4\alpha}$–$H_{5\alpha}$ coupling constants of 6.5 Hz for the all-*cis* isomer di-*O*-methyltetrahydrofuroguaiacin B (**4**) (4), indicate a torsion angle for the mentioned protons of approximately 30°. Two groups of conformations ^3V,$^3T_4$,V_4 and V_3,$^4T_3$,^4V satisfy this requirement. Analysis of the ^{13}C nmr spectrum of **4**, shows that the methyl groups resonate at higher field, 11.6 ppm, compared with related groups of galgravin (**3***b*), 12.9 ppm. This difference can be attributed to the nonbonded interactions between the methyl groups and the pseudoaxially oriented veratryl groups of **4**, since the dihedral angles between the methyls are approximately the same in the proposed conformations of both stereoisomers and consequently, a similar γ effect could be expected. In view of the reciprocity of the γ effect, C-1′ and C-1″ of **4** are shielded by 1.8 ppm in comparison with similar sites of the stereoisomer **3***b*, confirming the above observations.

It has been observed that C-2,C-6; C-1,C-5; and C-4,C-8 shifts of the 2,6-diaryl-3,7-dioxabicyclo-[3.3.0]octane system are sensitive to the orientation of the aryl groups but not to the nature of their oxygenated substituents (8). The benzylic carbons, for example, show shifts at ca. 82 and 88 ppm, whereas the remaining methines resonate at ca. 50 and 54 ppm, according to the 'axial' or 'equatorial' orientation of the aryl groups, respectively. C-2,C-5 and C-3,C-4 of galbacin (**2***b*), with all pseudoequatorial substituents, show shifts at 88.1 and 50.9 ppm, respectively, whereas similar sites of di-*O*-methyltetrahydrofuroguaiacin B (**4**), with all pseudoaxial substituents, resonate at 82.4 and 41.2 ppm, respectively. In galgravin (**3***b*), the benzylic carbons have a shift of 87.1 ppm, in good agreement with the pseudoequatorial orientation of the veratryl groups, whereas C-3 and C-4 show shielding with an intermediate value, 44.3 ppm. These observations strongly suggest that in tetrahydrofuran lignans, the benzylic carbons are clearly sensitive to the orientation of the aryl groups and their chemical shifts could be of diagnostic importance for the conformational analysis of this system.

The ^1H nmr spectrum of **5***a*, very similar to that of veraguensin (**5***b*), suggested torsion angles for the $H_{2\beta}$–$H_{3\alpha}$ and $H_{4\beta}$–$H_{5\beta}$ protons of approximately 150 and 0°, respectively. All conformations of the ^5T_O–$^4T_5$ segment of the CYCLOPS satisfy these requirements but two of them, forms ^4V and $^4T_5$, were

discarded owing to steric interactions between both aryl groups. It is interesting to consider, however, that the latter conformations, together with the form $^4T_3$, in spite of having the aryl group on C-5 pseudoaxially oriented, minimize the eclipsing strain of the *cis* substituents carried by C-4 and C-5, while the oxygen is one of the in-plane atoms. The ^{13}C nmr spectrum analysis of **5***b* confirms these observations. The shifts of C-2 and C-5 at 87.1 and 82.8 ppm, respectively, are in good agreement with the pseudoequatorial and pseudoaxial orientations of their corresponding veratryl groups; further C-1′ and C-1″ are slightly shielded, 133.6 and 133.2 ppm, respectively, compared with related carbons of galgravin **3***b*, considered free of steric interactions. The shift of the methyl groups of **5***b* at 14.9 ppm suggests weaker steric interactions between both groups, probably owing to a larger torsion angle, than in the all-*trans* isomer **2***b* and further shows lower sensitivity of carbon shifts to anisotropic effects.[2] In the ^1H nmr spectrum of veraguensin (**5***b*) the methyl hydrogens show signals at δ 1.07 and 0.66, assigned to C-3 and C-4 methyl groups, respectively (2, 3).

[2]In the series of α-acylindole alkaloids however, the anisotropic shielding of the methoxy hydrogens of vobasine in comparison with 16-epivobasine, induced by the indole ring is reflected on the shifts of the CO and OMe carbons and they are diagnostic of the stereochemistry of C-16 (9).

Considering the δ value of C-3 (or C-4) of the all-*trans* isomer galbacin (**2***b*) at 50.9 ppm as standard for a pseudoequatorial orientation of its Me group, it can be concluded that the shift of C-4 of **5***b* at 47.8 ppm indicates that its Me group approximates this orientation, confirming the puckering on C-4 and C-5, while C-3 shows a shift similar to the one observed for related carbons of **3***b*.

The shifts of the fully aromatic di-*O*-methylfuroguaiacin (**9**), assigned by standard chemical shift theory and by analysis of its SFORD spectrum, together with the shifts of compounds **2***b*, **3***b*, **4**, and **5***b* are listed in Table 1.

Experimental

The ^{13}C nmr spectra were obtained in a 10-mm spinning tube from solutions of approximately 0.3 mmol in 1 mL of $CDCl_3$ at ambient temperature. The ^{13}C resonance of $CDCl_3$ was used as internal reference and converted to Me_4Si scale by the following correction: δ (Me_4Si) = δ ($CDCl_3$) + 76.9. The instrument employed was a Varian XL-100 nmr spectrometer operating at 25.2 MHz, interfaced with a Varian 620/L Fourier transform computer with 16K memory. The chemical shifts (±0.05 ppm) were measured at 5-kHz spectral width, with an acquisition time of 0.8 s, and a 15-μs pulse width, using an internal deuterium lock.

Reactions of phenyl(trichloromethyl)carbinol with substituted thioureas, thiobenzhydrazide, and amino thiols to form heterocyclic compounds[1]

WILKINS REEVE AND W. ROBERT COLEY III

Chemistry Department, University of Maryland, College Park, MD 20742, U.S.A.

Received March 10, 1978[2]

WILKINS REEVE and W. ROBERT COLEY III. Can. J. Chem. 57, 444 (1979).

Phenyl(trichloromethyl)carbinol reacts with bifunctional reagents containing nucleophilic sulfur such as thioureas, thiobenzhydrazide, *o*-aminothiophenol, etc., in a series of steps involving an initial attack of the sulfur anion on the intermediate epoxide **2** followed by ring closure to a heterocyclic compound. Thiazolidinones, thiadiazinones, benzothiazinones, and thiomorpholinones are easily obtained in yields ranging from 57–20%. Monosubstituted ureas react to give exclusively the 2-substituted iminothiazolidinones. Evidence is presented that these are actually in the aminothiazolone form with considerable zwitterionic character. 1,3-Disubstituted ureas do not give heterocyclic products. The reaction works particularly well with those nucleophiles which are stable to base, contain a sulfur nucleophilic center for the initial step of the reaction (**2** to **3**) and an amino or imino group properly positioned for the final ring closure to the heterocyclic compound.

Hydroxylamine forms α-oximinophenylacetohydroxamic acid, an oxidation–reduction reaction having occurred. Thiophenol forms phenyl(phenylthio)acetic acid in nearly quantitative yield.

WILKINS REEVE et W. ROBERT COLEY III. Can. J. Chem. 57, 444 (1979).

Le phényl (trichlorométhyl) carbinol réagit avec des réactifs bifonctionnels incorporant un soufre nucléophile, tels les thiourées, thiobenzhydrazide, *o*-aminothiophénol, etc. par une série d'étapes impliquant une attaque initiale de l'anion sulfuré sur l'époxyde intermédiaire **2** suivie d'une cyclisation en un composé hétérocyclique. On obtient facilement, avec des rendements de 57–20%, des thiazolidinones, des thiadiazinones, des benzothiazinones et des thiomorpholinones. Les urées monosubstituées réagissent pour fournir exclusivement des iminothiazolidinones substituées en position 2. On présente des données à l'effet que ces composés existent de fait sous la forme d'aminothiazolones avec un fort caractère zwitterionique. Les urées disubstituées en 1,3 ne fournissent pas de produits hétérocycliques. La réaction fonctionne particulièrement bien avec les nucléophiles stables en milieu basique qui contiennent un centre sulfuré nucléophile pour l'étape initiale de la réaction (**2** à **3**) et un groupe amino ou imino dans une position appropriée pour la cyclisation finale en composé hétérocyclique.

L'hydroxylamine forme un acide α-oximinophénylacétohydroxamique; il s'est produit une autre réaction d'oxydo–réduction. Le thiophénol forme de l'acide phényl(phénylthio) acétique avec un rendement pratiquement quantitatif.

[Traduit par le journal]

Introduction

It has previously been shown that nucleophiles with a thioamide function react readily with phenyl(trichloromethyl)carbinol to form heterocyclic compounds (1, 2; for a general review, see ref. 3). This new reaction sequence has provided a useful and novel synthesis of substituted thiazolidinones, thiadiazinones, and 4-hydroxythiazoles. The purpose of this research was to study the reaction of phenyl(trichloromethyl)carbinol with other bifunctional nucleophiles including mono- and disubstituted thioureas. Fifteen nucleophiles have been studied.

Substituted Thioureas

Methylthiourea was allowed to react with phenyl(trichloromethyl)carbinol under the same conditions as used before with thiourea (1), namely in a methanolic potassium hydroxide solution at 50°C for a few hours. The epoxide, **2**, forms *in situ* and reacts with the thioenolate anion of methylthiourea to form successively, **3** and **4**. Compound **4** (R = Me) was isolated in 20% yield. None of the isomeric 2-imino-3-methyl-5-phenyl-4-thiazolidinone could be isolated. Both isomers have been previously synthesized by other routes. The chemistry of **4** (R = Me) has been studied by Najer *et al.* (4–6) who assigned structure **4***c* to the material on the basis of its uv spectra and pK_a value. Proof of any of these structures by chemical means is difficult because of the

tendency of the heterocyclic ring to open at the amide linkage on treatment with acid or base. Thus, we found that refluxing **4** (R = Me) with 10% aqueous sulfuric acid gave a 20:1 mixture of 3-methyl-5-phenyl-2,4-thiazolidinedione and **5**, respectively. On refluxing with 3 *N* hydrochloric acid in ethanol, only the former is obtained (4). That **4** (R = Me), rather than 2-imino-3-methyl-5-phenyl-4-thiazolidinone, is the correct structure follows from the solubility of the material in 1 *N* sodium hydroxide and from its

6

^{1}H nmr spectrum. This spectrum provided evidence that **4** (R = Me) is a mixture of **4***a* and the resonance hybrid **4***b* ↔ **4***c*. Compound **4***a* theoretically can exhibit *E* and *Z* isomerism but we have no evidence for the existence of such isomers. At δ 5.47, the customary benzylic proton signal showed a small shoulder on the upfield side which was reproducible in every spectrum. The methyl signal, instead of being a sharp singlet, consisted of a doublet at δ 3.07 with J = 4.6 Hz (due to **4***b* ↔ **4***c*) and a singlet with δ 2.95 (due to **4***a*). The N—H proton gave two signals, one a broad singlet at δ 9.75 (due to **4***a*) and the other a broad quartet at δ 9.32 (due to the resonance hybrid **4***b* ↔ **4***c*) with J = 4.6 Hz. The combined N—H signals integrated for one proton, the phenyl signal for five, the benzyl signal for one, and the combined methyl signals for three. The integration data suggest the ratio of **4***a* to the resonance hybrid **4***b* ↔ **4***c* to be 25:75. Decoupling experiments establish that the methyl group and the proton are both on the same nitrogen. Saturation of the N—H quartet at δ 9.32 caused the doublet at δ 3.07 to collapse to a singlet.

A high temperature nmr study established that **4** (R = Me) was composed only of **4***a* in equilibrium with the resonance hybrid **4***b* ↔ **4***c* and that the observed spectra could not be explained by the unsuspected presence of 2-imino-3-methyl-5-phenyl-4-thiazolidinone. Raising the temperature to 98°C caused the doublet and singlet of the methyl region to coalesce to a broad based singlet. Further heating to 138°C gave a sharp methyl singlet. Upon cooling to 35°C the spectrum was identical to the one obtained before heating, indicating no thermal isomerization had occurred. These changes in the observed spectra on heating would not have been observed if the 3-methyl isomer were one of the major components of the mixture.

Structures **4***b* and **4***c* are contributing forms to a resonance hybrid. The argument for the zwitterionic structure as the major contributing form to this resonance hybrid rests upon the high value of the chemical shift of the N—H resonance, by analogy to the unalkylated compound **4***g* for which nmr and crystal structure data support the zwitterionic structure in both solution (1) and the crystalline state (7), and the solubility behavior of compounds **4***b* and **4***g*, both of which have the same solubility characteristics as amino acids. The N—H resonance of the neutral structure **4***c* should be approximately the same as in methylaniline (δ in DMSO-d_6 = 5.4) whereas the resonance for the zwitterionic form should be more like that of the —NH_2— in methylaniline hydrochloride (δ in DMSO-d_6 = 10.5). The observed

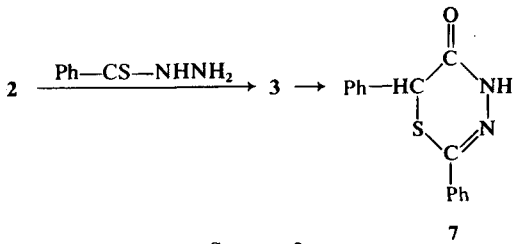
chemical shift of δ = 9.32 for **4** (R = Me), and 8.85 and 9.18 (due to *cis–trans* isomerism of the iminonium ion) for **4***g* (1) argues strongly for the zwitterionic forms. Compound **4** (R = Me) is insoluble in water, easily soluble in 1 *M* sodium hydroxide (1 mequiv. in 50 mL), 1 *N* hydrochloric acid (1 mequiv. in 16 mL), insoluble in ether (1 part in 600), and of limited solubility in acetone (1 part in 160). In contrast, **5** is quite soluble in acetone and ether as is also 2-(methylimino)-3-methyl-5-phenyl-4(5*H*)-thiazolidinone (**6**). The latter cannot exist as a zwitterion like structure **4***b* and this accounts for the 60-fold increase in solubility in ether (1 part in 10) and acetone (1 part in 2). All of the above evidence suggest a structure consisting of around 25% **4***a* and 75% of the resonance hybrid **4***b* ↔ **4***c*, with the neutral structure **4***c* making less of a contribution to the resonance hybrid than the zwitterionic form **4***b*. Accordingly, 2-(methylamino)-5-phenyl-4(5*H*)-thiazolone is a better name for the product than 2-methylimino-5-phenyl-4-thiazolidinone.

Phenylthiourea was allowed to react with phenyl(trichloromethyl)carbinol under the same conditions as with methylthiourea and the known compound **4** (R = Ph) (4, 8–11) was isolated in 49% yield. It is soluble in 1 *N* sodium hydroxide and hydrolysis with 40% sulfuric acid gives mostly the dione **5** with only traces of the 3-phenyl-2,4-thiazolidinone being formed by rearrangement (8). There has been considerable discussion among previous investigators over the merits of **4***d* vs. **4***f* as possible structures for the product with **4***d* being favored by Najer *et al.* (5) and Ramsh *et al.* (12). Mornon *et al.* (13) carried out an X-ray crystallographic study which established the presence of a hydrogen on the exocyclic nitrogen but he did not consider the possible existence of the zwitterionic structure **4***e*. The zwitterionic form should be less likely in the case of **4***e* (vs. **4***b*) because the anilino function of **4** (R = Ph) would be expected to be 10^6 times less basic than the methylamino function of **4** (R = Me); on the other hand the zwitterionic form would be favored by delocalization of the positive charge by the adjacent phenyl ring. Our evidence strongly suggests that the zwitterionic structure (**4***e*) does make a contribution to the **4***e* ↔ **4***f* resonance hybrid; exactly how much is difficult to determine. In the ^{1}H nmr spectra, the sharp singlet for the CH resonance at δ 5.55 suggests that only one tautomeric form is present and Mornon's X-ray crystallographic data eliminate structure **4***d*. The NH resonance at δ 7.77 corresponds to the iminonium NH of **4***e* (vs. δ 9.32 for **4***b*). The NH signal for the neutral form **4***f* should occur near δ 5.4 (diphenylamine has δ ($CDCl_3$) of 5.4). Like diphenylamine the compound is insoluble in dilute hydrochloric acid. It is also insoluble in ether (approximately 1 part in 500) and this suggests some contribution by the zwitterionic form. Mornon's X-ray crystallographic data fit structure **4***e* as well as **4***f*. The bond distances between C-2 and N-3, and between C-2 and the exocyclic nitrogen were 1.32 and 1.34 Å, respectively, suggesting that the bond orders are more nearly alike than would be expected for either structure **4***d* or **4***f*. In summary, we believe **4***e* as well as **4***f* contributes to the structure of **4** (R = Ph).

The reaction of three disubstituted thioureas (1,3-dimethylthiourea, 1,3-diethylthiourea, and 1,3-diphenylthiourea) with phenyl(trichloromethyl)carbinol under the same conditions as before was studied but no heterocyclic compounds could be obtained. α-Mercaptophenylacetic acid (isolated as dithiobis-(phenylacetic acid)) appeared to be a major constituent of the complex mixture of acids formed. The expected heterocyclic compounds can be prepared by the sodium acetate catalyzed reaction of α-halo esters with 1,3-disubstituted ureas (5). Accordingly, 2-(methylimino)-3-methyl-5-phenyl-4(5*H*)-thiazolidinone (**6**) was prepared and treated with methanolic potassium hydroxide to see if the 3-substituted thiazolidinone was decomposed by potassium hydroxide under the conditions used in the reaction of the carbinol with the thioureas at 50°C. An immediate nitroprusside test for the thiol function was obtained. Titration of aliquots showed that no base was consumed; the thiobenzyloxy–carbon bond was cleaved. None of the thiazolidinone could be recovered after a reaction time of 1 h. It should be noted that **4***b* ↔ **4***c* is an imino thioester with resonance stabilization whereas **6** has no resonance stabilization.

Thiobenzhydrazide

This nucleophile reacted with phenyl(trichloromethyl)carbinol in an ethanolic potassium hydroxide solution at 55°C to form 2,6-diphenyl-4*H*-1,3,4-thiadiazin-5(6*H*)-one (**7**) in 57% yield (Scheme 2). Proof of the assigned structure follows from elemental analyses, the insolubility of **7** in dilute 6 *N* hydrochloric acid and its ir and nmr spectra. Absence of isomeric enolic forms is demonstrated by the presence of the carbon six proton signal at δ 5.2 as expected, a strong amide carbonyl band at 1660 cm^{-1} and a secondary amide NH stretching bond at 3220



7

*All are known compounds.

cm^{-1}. The material is insoluble in 3 *N* sodium hydroxide solution. Methylation of **7** with dimethyl sulfate gave the 4-methyl derivative. Compound **7** was also prepared from methyl α-bromophenylacetate and thiobenzhydrazide and the two products found to be identical.

Hydroxylamine

Three moles of this nucleophile reacted with phenyl(trichloromethyl)carbinol in an oxidation–reduction sequence reminiscent of osazone formation with sugars. The known *Z* form of α-oximinophenylacetohydroxamic acid was formed in 23% yield. The other products of the reaction were a mixture of eight carboxylic acids; the methyl esters were prepared using diazomethane and the two major components shown by glpc and nmr to be methyl benzoate and methyl α-ethoxyphenylacetate.

Other Nucleophiles

Two nucleophiles, sulfamide and acetamidine, failed to give any heterocyclic products. Both hydrolyze easily in potassium hydroxide solution, and they may have been largely destroyed before they could react with the phenyl(trichloromethyl)carbinol. Ammonium dithiocarbamate (Table 1) also hydrolyzes easily.

General Conclusions

The condensation of phenyl(trichloromethyl)carbinol with bifunctional nucleophiles provides an excellent method for the formation of heterocyclic compounds provided that two conditions are met: first, the nucleophile, besides being a good nucleophile, must be stable in strongly alkaline solution. Nucleophiles which decompose before they can react with the phenyl(trichloromethyl)carbinol are obviously of little use. Second, the heterocyclics to be prepared should be at least somewhat stable to base. For these reasons the best bifunctional reagents for reaction with phenyl(trichloromethyl)carbinol are those with sulfur and nitrogen nucleophilic centers. The sulfur will attack the epoxide intermediate (**2**) to form an acid chloride intermediate (**3**) which then reacts with the nucleophilic nitrogen to close the heterocyclic ring. The heterocycle formed in this case is an amide which is relatively stable to base.

Experimental

Melting points and boiling points are corrected. The infrared spectra were determined with a Perkin-Elmer Model 337; the nmr spectra were obtained with a Varian A-60-A instrument. Chemical shift values are expressed as δ values (ppm) downfield from tetramethylsilane internal standard. ^{1}Hmr spectra obtained using hexadeuteriodimethyl sulfoxide as the solvent had as an internal standard the pentadeuteriodimethyl sulfoxide peak at δ 2.53. The mass spectrum was recorded on a Du Pont 492 double focusing, magnetic scanning mass spectrometer run at 70 eV. Elemental microanalyses were performed by Dr. Franz J. Kasler. The 100 MHz ^{1}Hmr spectrum of **4** (R = Me) was run by Mr. Mark Mattingly.

2-(Phenylamino)-5-phenyl-4(5H)-thiazolone (4, R = Ph)

The general procedure for the reaction for phenyl(trichloromethyl)carbinol with the substituted thioureas follows. To a solution of 11.2 g (0.05 mol) of phenyl(trichloromethyl)carbinol and 12.2 g (0.08 mol) of phenylthiourea in 75 mL of methanol at 50°C was added with stirring 19.8 g (0.3 mol) of 85% potassium hydroxide pellets in 50 mL of methanol over a 30 min period. The reaction mixture was heated to 50–60°C with an oil bath for 1 h, after which time it was allowed to cool to room temperature and was stirred for 24 h. The precipitated potassium chloride was filtered off, the filtrate diluted with an equal volume of water, and the alkaline solution extracted with three 75-mL portions of ether to remove neutral material. Acidification to pH 5 yielded 6.5 g of **4** (R = Ph) (49%), mp 180–185°C. The material was washed with water to remove inorganic impurities and recrystallized from absolute ethanol to give pure 2-(phenylamino)-5-phenyl-4(5*H*)-thiazolone: mp 188–189°C (lit. (4) mp 188–189°C, (10, 11) mp 191–191.5°C); ir (KBr): 3255, 3195, 3130, 3010, 1675, 1625, 1560, 1480, 1445, 1315, 1265, 1235, 1225, 1175, 740, 725, 680, and 645 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 7.77 (broad s, 1, N*H*), 7.50–7.12, (m, 10, aromatic *H*), 5.55 (s, 1, Ph—C*H*<).

2-(Methylamino)-5-phenyl-4(5H)-thiazolone (4, R = Me)

This was prepared by the same procedure as above starting with a solution of 11.2 g (0.05 mol) of phenyl(trichloromethyl)-carbinol and 6.3 g (0.07 mol) of methylthiourea in 50 mL of methanol, and 19.8 g (0.3 mol) of potassium hydroxide pellets in 50 mL of methanol. After filtering off the potassium chloride the reaction mixture, acidified successively to pH values of 9, 7, and 1.2, was extracted with ether and the final aqueous layer was then adjusted to pH 7. From the second ether extract and from the final aqueous solution there was obtained on evaporation a total of 2.1 g of **4** (R = Me), mp 178–181°C. One recrystallization from acetone and five recrystallizations from absolute ethanol gave pure 2-(methylamino)-5-phenyl-4(5*H*)-

thiazolone (**4**, R = Me); mp 185–185.5°C (lit. (4) mp 181–182°C); ir (KBr): 3220–2950, 1680, 1605, 1395, 1280, 1250, 1150, 735, 690, 645, 625, and 520 cm^{-1}; ^{1}Hmr (DMSO-d_6 at 35°) δ: 9.75 (broad s, >N*H* of **4***a*) and 9.32 (broad q, J = 4.6 Hz, —N*H*CH_3 of **4***b*) with combined area 1, 7.35 (s, 5, Ph), 5.47 (s, 1, PhC*H*<), 3.07 (d, J = 4.6 Hz, CH_3NH— of **4***b*) and 2.95 (s, CH_3N= of **4***a*) with combined area 3. At 138°C the δ 0 to 8 spectrum was δ: 7.35 (s, 5, Ph), 5.37 (s, 1 Ph—C*H*<), 3.07 (s, 3, NC*H*$_3$). The ^{1}Hmr spectrum at 100 MHz was unchanged.

Refluxing 1 g (0.005 mol) of **4** (R = Me) with 10 mL of 10% sulfuric acid for 3 h gave a semisolid mass which crystallized to a white solid (0.8 g) after being leached with cyclohexane. After two recrystallizations from ethanol the mixture of 5-phenyl-2,4-thiazolidinedione and 3-methyl-5-phenyl-2,4-thiazolidinedione melted at 81–85°C. These were separated by stirring with 6 mL of ice-cold 1 *N* sodium hydroxide for 10 s and then filtering. The filtrate was acidified to give 0.03 g of 5-phenyl-2,4-thiazolidinedione, mp 124–126°C; a mixture mp with an authentic sample was 125–129°C (1). The solid which did not dissolve in the alkaline solution was 3-methyl-5-phenyl-2,4-thiazolidinedione, mp 92–94°C (lit. (4) mp 96°C).

Nuclear Magnetic Resonance Spectra of Methylaniline and its Hydrochloride

Methylaniline ^{1}Hmr (DMSO-d_6) δ: 7.4–6.5 (m, 5, Ph), 5.4 (broad s, 1, NH), and 2.65 (s, 3, CH_3).

The methylaniline hydrochloride was recrystallized twice from acetonitrile (14), mp 123.5–125°C (lit. (14) mp 124°C); ^{1}Hmr (DMSO-d_6) δ: 10.4 (s, 2, NH_2), 8.1–7.5 (m, 5, Ph), and 3.2 (s, 3, CH_3).

*2-(Methylimino)-3-methyl-5-phenyl-4-(5*H*)-thiazolidinone (6)*

This was prepared by Najer's method (5), mp 94–96°C (lit. (5) mp 93–94°C); ir (KBr): 2925, 1715, 1640, 1420, 1365, 1305, 1200, 1105, 1042, 1020, 898, 855, 767, 732, 695, and 640 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 7.4 (s, 5, Ph), 5.74 (s, 1, CH), 3.1 (two singlets three cycles apart, 6, two N—CH_3).

*2,6-Diphenyl-4*H*-1,3,4-thiadiazin-5(6*H*)-one (7)*

Thiobenzhydrazide was prepared from thiobenzoylthioglycolic acid (from 50 g benzotrichloride, 126 g sodium sulfide nonahydrate, and 32 g chloroacetic acid) and excess hydrazine, all by the procedure of Holmberg (15) who gives no spectral data for the following compounds. The crude thiobenzoylthioglycolic acid (61% yield) was recrystallized twice from benzene and aqueous ethanol; mp 126°C (lit. (15) mp 127–128°C); ir (KBr): 3100–2500 (COOH), 1680 (CO), 1350, 1300, 1240, 1220, 1170, 1040, 885, 770, 680, and 670 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 10.9–10.0 (broad s, 1, —COO*H*), 8.23–7.87 (m, 2, *o*-protons of Ph), 7.77–7.33 (m, 3, *m*- and *p*-protons of Ph), 4.37 (s, 2, —CH_2—). The thiobenzhydrazide (87% yield) was recrystallized twice from benzene; mp 70.5–71°C (lit. (15) mp 70–71°C); ir (KBr): 3250–3000, 1590, 1555, 1445, 1320, 1215, 1120, 960, 910, 765, and 690 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 7.83–7.50 (m, 2, *o*-protons of Ph), 7.45–7.10 (m, 3, *m*- and *p*-protons of Ph), 6.65 (broad s, 3, —N*H*N*H*$_2$). A higher melting form, mp 81–82°C, is also sometimes obtained as noted by Holmberg (15); both work equally well in the following reaction.

2,6-Diphenyl-4*H*-1,3,4-thiadiazin-5(6*H*)-one (**7**) was prepared using the same procedure as in the preparation of **4**, starting with 11.2 g (0.05 mol) of phenyl(trichloromethyl)carbinol and 10.6 g (0.05 mol) of thiobenzhydrazide dissolved in 50 mL of absolute alcohol, and 19.8 g (0.3 mol) of potassium hydroxide pellets in 60 mL of absolute ethanol. The filtrate from the reaction mixture was acidified to pH 3 and 7.1 g of crude **7** precipitated. Another 0.5 g was obtained from an ether extraction of the initial alkaline, aqueous reaction mixture. Two recrystallizations from absolute ethanol gave white needles of **7**; mp 182–182.5°C; ir (KBr): 3220 (NH), 1670 (CO), 1320, 1235, 1145, 1070, 1030, 970, 860, 760, 740, 695, and 685 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 11.7 (broad s, 1, NH), 8.0–7.7 (m, 2, *o*-protons of 2-Ph), 7.62–7.37 (m, 8, other Ph and *m*- and *p*-protons of 2-Ph), 5.20 (s, 1, Ph—CH<); ms (70 eV) *m/e* (relative intensity): 270(6.8), 269(18.2), 268(100), 122(19.7), 121(34.9), 119(16.5), 118(28.6). *Anal.* calcd. for $C_{15}H_{12}N_2OS$: C 67.14, H 4.51, N 10.44, S 11.95; found: C 66.95, H 4.63, N 10.48, S 11.74.

Compound **7** was also prepared in 90% yield by refluxing for 2 h a mixture of 1.5 g (0.0066 mol) of methyl α-bromophenylacetate, 1.0 g (0.0066 mol) of thiobenzhydrazide and 0.5 g of anhydrous sodium acetate. The material was identical with that prepared above.

*2,6-Diphenyl-4-methyl-4*H*-1,3,4-thiadiazin-5-(6*H*)-one*

This was prepared in 81% yield by heating at 62°C for 2 h, a mixture of 1.0 g (0.0037 mol) of **7**, 25 mL of 1.5 *N* sodium hydroxide solution, enough acetone to dissolve all of the solid, and 5 mL of freshly distilled dimethyl sulfate. Two recrystallizations from ethanol gave the pure material; mp 135–135.5°C (lit. (16) mp 137–138°C); ir (KBr): 1655 (CO), 1360, 1325, 1270, 1220, 1090, 1075, 1010, 840, 765, 740, 720, 710, and 690 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 8.00–7.73 (m, 2, *o*-protons of 2-Ph), 7.57–7.17 (m, 8, 6-Ph and *m*- and *p*-protons of 2-Ph), 4.77 (s, 1, Ph—C*H*<), 3.63 (s, 3, N—CH_3). *Anal.* calcd. for $C_{16}H_{14}N_2OS$: C 68.06, H 5.00, N 9.92, S 11.36; found: C 67.94, H 5.07, N 10.20, S 11.40.

*2-Phenyl-2*H*-1,4-benzothiazin-3(4*H*)-one*

This was prepared, using the same procedure as in the preparation of **4** except the reaction mixture was not heated, starting with 11.2 g (0.05 mol) of phenyl(trichloromethyl)carbinol and 6.9 g (0.05 mol) of *o*-aminothiophenol dissolved in 50 mL of absolute methanol, and 19.8 g (0.3 mol) of potassium hydroxide pellets in 75 mL of absolute methanol. After filtering off the precipitated potassium chloride and diluting the reaction mixture with an equal volume of water, a light brown solid precipitated and was recrystallized from absolute ethanol to yield 3.8 g of **7**. Additional material was obtained on acidifying the reaction mixture to pH 2. The combined material (6 g after recrystallization (50% yield)) melted at 205–206°C (lit. (17) mp 205–206°C); ir (KBr): 3180, 3100, 3040, 2960, 2890, 1680 (C=O), 1480, 1370, 1235, 1160, 1075, 1025, 940, 820, 760, 740, and 695 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 10.95 (broad s, 1, N*H*), 7.5–6.8 (m, 9, aromatic protons), 5.0 (s, 1, Ph—C*H*<).

2-Phenyl-3-thiomorpholinone

This was prepared by the general procedure, except the reaction mixture was not heated and the reaction period was reduced to 12 h, from 11.2 g (0.05 mol) of phenyl(trichloromethyl)carbinol and 6.7 g (0.06 mol) of 2-aminoethanethiol hydrochloride in 75 mL of absolute ethanol, and 23 g (0.35 mol) of potassium hydroxide pellets in 100 mL of absolute ethanol. The shorter reaction time was used because the amide linkage undergoes hydrolysis in the strongly alkaline reaction mixture. This has been previously observed with other thiomorpholinones (18). The hydrolysis product was also synthesized independently as described below. An ether extract of the alkaline mixture gave 3.5 g of gummy material. One recrystallization from 30 mL of benzene gave 2 g (21% yield)

α-(2-Aminoethylthio)phenylacetic Acid Hydrochloride

This was prepared by refluxing for 1 h a solution of 2.1 g (0.01 mol) of α-bromophenylacetic acid, 1.1 g (0.01 mol) of 2-aminoethanethiol hydrochloride, and 1.6 g (0.02 mol) of anhydrous sodium acetate in 50 mL of absolute ethanol, and allowing the reaction mixture to stand for 2 days. The solid which formed was washed with 10 mL of water, filtered, and dried. It weighed 0.3 g, mp 207–208°C dec. The solid was dissolved in an excess of 6 *N* hydrochloric acid and allowed to evaporate to dryness. It then melted at 171–173°C. Washing with a little 6 *N* hydrochloric acid, in which it was insoluble, raised the melting point of the α-(2-aminoethylthio)phenylacetic acid hydrochloride to 175–177°C; ir (KBr): 3200–2500, 1715 (C=O), 1480, 1245, 1210, 1160, 720, and 635 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 8.86 (broad s, 4, —N*H*$_3$ + COO*H*), 7.70–7.27 (m, 5, Ph), 4.95 (s, 1, Ph—C*H*<), 3.22–2.70 (m, 4, —C*H*$_2$C*H*$_2$—). *Anal.* calcd. for $C_{10}H_{14}NO_2SCl$: C 48.48, H 5.70, N 5.66, S 12.94; found: C 48.11, H 5.49, N 5.82, S 12.76.

Z-α-Oximinophenylacetohydroxamic Acid

This was prepared by the general procedure, except the reaction mixture was not heated, starting with 11.2 g (0.05 mol) of phenyl(trichloromethyl)carbinol and 10.4 g (0.15 mol) of hydroxylamine hydrochloride in 50 mL of absolute ethanol, and a solution of 26.4 g (0.4 mol) of potassium hydroxide pellets in 100 mL of absolute ethanol. After filtering off the potassium chloride, the filtrate was diluted with an equal volume of water, acidified to pH 4.5 with 6 *N* hydrochloric acid, and allowed to evaporate to dryness. An acetone extract of the residue was concentrated to an orange oil which contained a small amount of solid; the mixture was allowed to stand for 18 h. The oil was taken up in cold chloroform, leaving behind 2.2 g of cream-colored crystals, mp 164–166°C. One recrystallization from 30 ml of water gave 2.1 g (23% yield) of *Z*-α-oximinophenylacetohydroxamic acid; mp 176–176.5°C dec. (lit. (20, 21) mp 177°C, 173.5–175.5°C); ir (KBr): 3400–2600, 1680–1650 (C=O), 1610, 1500, 1430, 1300, 1230, 1095, 1020–1000, 850, 840, 760, 725, and 690 cm^{-1} (similar to that of ref. 21); ^{1}Hmr (DMSO-d_6) identical with that of ref. 21. *Anal.* calcd. for $C_8H_8N_2O_3$: C 53.33, H 4.48, N 15.55; found: C 53.40, H 4.17, N 15.75.

Phenyl(phenylthio)acetic Acid

This was prepared by the general procedure, except the reaction mixture was not heated, starting with 11.2 g (0.05 mol) of phenyl(trichloromethyl)carbinol and 5.5 g (0.05 mol) of thiophenol in 50 mL of absolute ethanol, and 19.8 g (0.3 mol) of potassium hydroxide pellets in 100 mL of absolute ethanol. After filtering off the potassium chloride, the neutral fraction was extracted with ether and 1.3 g of crude phenyl(trichloromethyl)carbinol was obtained. Acidification yielded 10.5 g (86% yield) of phenyl(phenylthio)acetic acid, mp 92–95°C. One recrystallization from a benzene–cyclohexane mixture gave crystals of pure phenyl(phenylthio)acetic acid; mp 101.5–102.5°C (lit. (22) mp 101–102°C, lit. (23) mp 102–103°C); ir (KBr): 3200–2400, 1690 (C=O), 1580, 1480, 1410, 1280, 950, 735, 725, 695, 690, and 675 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 10.35 (broad s, 1, —COO*H*), 7.58–7.13 (m, 10, Ph), 4.90 (s, 1, Ph—C*H*<).

Comparison of the intramolecular hydrogen bonds and of the internal barrier to rotation of the hydroxyl and sulfhydryl groups in 2-methoxyphenol and 2-methoxythiophenol

TED SCHAEFER AND TIMOTHY A. WILDMAN

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received August 15, 1978

TED SCHAEFER and TIMOTHY A. WILDMAN. Can. J. Chem. **57**, 450 (1979).

The long-range spin–spin coupling constants involving the hydroxyl proton in 2-methoxyphenol are consistent with a potential function for rotation of the hydroxyl group derived from far infrared torsion data. The internally hydrogen bonded *cis* conformer is the only one detected by nmr. In contrast, the long-range couplings of the sulfhydryl group in 2-methoxythiophenol indicate that the *trans* conformer is favored over the *cis* conformer by a free energy difference of 0.2 ± 0.2 kcal/mol. Furthermore, the barrier to internal rotation of the sulfhydryl group is much smaller than that of the hydroxyl group in these two compounds. It is suggested that the barrier in the thiophenol derivative is 2.7 ± 0.6 kcal/mol, to be compared with a twofold component of 6 kcal/mol in the rotational potential function of the phenol analog.

TED SCHAEFER et TIMOTHY A. WILDMAN. Can. J. Chem. **57**, 450 (1979).

Les constantes de couplage spin–spin à longue distance impliquant le groupe hydroxyle du méthoxy-2 phénol sont en accord avec une fonction de potentiel établie, pour la rotation du groupe hydroxyle, à partir de données de torsion provenant de l'infrarouge lointoin. En rmn, on ne détecte que la présence du conformère *cis* impliqué dans une liaison hydrogène interne. Par ailleurs, les constantes de couplage à longue distance impliquant le groupe sulfhydryle de méthoxy-2 thiophénol indiquent que le conformère *trans* est plus favorisé que le conformère *cis*; la différence d'énergie libre est de 0.2 ± 2.0 kcal/mol. De plus, la barrière à la rotation interne du groupe sulfhydryle est beaucoup plus faible que celle du groupe hydroxyle dans ces deux composés. On suggère que la barrière dans le dérivé thiophénol est 2.7 ± 0.6 kcal/mol; on doit comparer cette valeur avec une composante binaire de 6 kcal/mol dans la fonction de potentiel de rotation de l'analogue oxygéné.

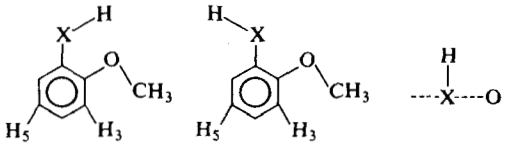
Introduction

The intramolecular hydrogen bond in 2-methoxyphenol apparently is of intermediate strength. There occurs only one hydroxyl stretching band in the infrared. It is assigned to the intramolecularly hydrogen bonded *cis* conformer, **1** (1). In cyclo-



cis, θ = 0° (**1**) *trans*, θ = 180° (**2**) θ = 90° (**3**)

hexane solution, those far infrared bands assigned to the hydroxyl torsions are consistent with an equilibrium in which **1** is 2.00 kcal/mol more stable than **2** (1). Furthermore, conformation **3**, in which the OH bond is situated in a plane perpendicular to the benzene plane, lies 6.94 kcal/mol above **1**.

Carlson and Fateley (1) write:

$$[1] \quad V(\theta) = 2.00(1 - \cos\theta)/2 + 5.94(1 - \cos 2\theta)/2$$

in which $V_1 = 2.00$ kcal/mol is the onefold component (maximum at θ = 180°); whereas $V_2 = 5.94$ kcal/mol is the twofold component (maximum at θ = 90°) describing the torsional potential of the hydroxyl group about the C—O bond. In phenol, V_2 is 3.4 ± 0.2 kcal/mol (1–4).

If V_1 is identified as the enthalpy difference between **1** and **2** and if the entropy difference between **1** and **2** is small enough, then at 305 K the equilibrium constant is 0.036 (assuming equal activities for the isomers in a dilute solution). It follows that 3.5% exists as the *trans* conformer, **2**, at 305 K.

CNDO/2 MO calculations predict **1** as 1.32 kcal/mol more stable than **2** (5). Both conformers are reasonably assumed to have the CH_3 group staggered about the C—O bond. An empirical relationship (6) between hydroxyl torsional frequencies and the strength of the intramolecular hydrogen bond, suggests **1** as 1.7 ± 0.2 kcal/mol more stable than **2**. Apparently (5, 6) the intramolecular hydrogen bond is considerably weaker in 2-methoxyphenol than in 2-nitrophenol or in salicylaldehyde.

Infrared band intensities and dipole moment data were interpreted (7) as indicating preferred *cis* conformations, **1**, for 2-nitro- and 2-methoxythiophenol; although it was clear that intramolecular hydrogen bonding was less marked than in the corresponding

0008-4042/79/040450-04$01.00/0

phenol derivatives. A different set of dipole moment data (8) indicated roughly equal populations for **1** and **2** (X = S) for 2-methoxythiophenol in cyclohexane, benzene and dioxane solutions.

An extensive set of calculations, at the CNDO/2 and STO-3G levels of molecular orbital theory (5), on intramolecular hydrogen bonding in *ortho* substituted phenols and thiophenols successfully reproduces the stronger hydrogen bonds in the phenol derivatives. In particular, the *cis* form of 2-hydroxythiophenol, analogous to **1**, is calculated as more stable than the *trans* form, analogous to **2**. Furthermore, the lower values of V_2 in the thiophenol derivatives are also predicted (see below).

On the other hand, long-range spin–spin coupling constants over five bonds between the thiol proton and ring protons in 2-nitrothiophenol dissolved in chloroform or benzene imply that the conformer in which the SH bond lies *trans* to the nitro group is favoured over the *cis* conformer by a free energy difference of 0.5 ± 0.2 kcal/mol at 305 K (9). This implication depends on the stereospecificity of the five-bond coupling, $^5J_m^{H,XH}$ (X = O, S). References 9–14 give a discussion of this method of determining intramolecular equilibria in phenol and thiophenol derivatives.

In this paper, $^5J_m^{H,XH}$ measurements are used to compare strengths of the intramolecular hydrogen bonds in 2-methoxythiophenol and in 2-methoxyphenol. It turns out that a rough value for the barrier to rotation of the S—H group can also be deduced.
