On a effectué l'acétolyse du bromure de trianisyl[2-^{14}C]vinyle (**1**-Br-*2*-^{14}C) en présence de quantités diverses de NaOAc ou de NaOAc et de LiBr. On a observé des échanges des isotopes marqueurs du C-2 vers C-1 provenant de transpositions-1,2 des anisyles dans le cation trianisylvinyle tant dans le produit de la réaction que dans le réactif récupéré qui n'avait pas réagit. Les résultats indiquent que la contribution relative aux transpositions-1,2 diminue avec une augmentation de la quantité de NaOAc ou de LiBr; ceci est en accord avec un mécanisme impliquant la formation du cation trianisylvinyle dissocié qui subira des réactions compétitives soit de transpositions-1,2 donnant lieu à des échanges des isotopes soit des réactions où l'ion est piégé par du Br^- et donne lieu à une réaction de retour redonnant le produit de départ où il s'est produit des échanges ou des réactions où l'ion est piégé par des ions OAc^- qui fournissent des produits où il s'est effectué un échange. On compare aussi ces résultats à ceux obtenus antérieurement lors de la solvolyse du bromure de triphényl[2-^{14}C]vinyle et on discute des différences.

[Traduit par le journal]

The degenerate rearrangement arising from a 1,2-anisyl shift across the double bond in the trianisylvinyl (tris(*p*-methoxyphenyl)vinyl)) cation was first reported from this laboratory in 1975 (1). For example, in the reaction of trianisyl[2-^{13}C]vinyl bromide (**1**-Br-*2*-^{13}C) with HOAc–AgOAc, ^{13}C nmr analysis of the product showed about 20% scrambling of the label from C-2 to C-1 (1). Similarly, using D-labeling and ^{1}H nmr analysis, Rappoport and co-workers (2) found that the NaOAc buffered acetolysis of 1,2-dianisyl-2-*p*-($^2H_3$)methoxyphenylvinyl bromide (**1**-Br-methoxy-d_3) gave $35 \pm 2\%$ rearrangement[1] arising from 1,2-anisyl shifts. It was also noted that when the NaOAc buffered acetolysis was carried out in the presence of an excess of Bu_4NBr, $4 \pm 1.5\%$ rearrangement was observed in the recovered reactant (2). Earlier, Rappoport and Gal (3) had reported that the unbuffered acetolysis of **1**-Br gave irregular kinetics and extensive blackening, while in the NaOAc buffered acetolysis, the first order rate constant decreased markedly as the reaction proceeded during a given run. In the presence of added Bu_4NBr, a large common ion rate depression was observed and it was concluded that the acetolysis of **1**-Br took place via the dissociated trianisylvinyl cation, which could be captured competitively by the leaving group and by the lyate ion (3).[2] In the present work, further studies were undertaken on the acetolysis using trianisyl[2-^{14}C]vinyl bromide (**1**-Br-*2*-^{14}C). The extents of scrambling were determined in both the reaction product and unconsumed reactant at different stages of the reaction, carried out with added NaOAc or NaOAc and LiBr, in order to provide more scrambling data on the role of the trianisylvinyl cation in relation to its rearrangement and return processes.

1-Br-*2*-^{14}C was synthesized in the same way as in the preparation of **1**-Br-*2*-^{13}C (1), except that ^{14}C instead of ^{13}C was used as the label. The acetolyses of **1**-Br-*2*-^{14}C were carried out in 9:1 HOAc–Ac_2O in the presence of 2 or 20 equiv. of NaOAc, or in the

[1]With **1**-Br-methoxy-d_3, 100% rearrangement corresponds to the formation of 33.3% of the rearranged product. On this basis, the 20% scrambling observed in the work with **1**-Br-*2*-^{13}C corresponds to 40% rearrangement.

[2]A book providing a general review on vinyl cations is now in preparation (9).

0008-4042/79/111384-04$01.00/0

presence of 2 equiv. of NaOAc and various amounts of LiBr as recorded in Table 1. Since the reaction rate would decrease markedly at the later stages of the reaction because of returns and since added Br^- ions would further slow down the rate (3), for each set of experiments with a given amount of NaOAc or NaOAc and LiBr, preliminary studies were made with inactive materials to determine the time required to give about 25, 50, or 75% reaction as measured by titration of the liberated Br^- ions. In the active runs, these reaction times were utilized together with an experiment using a prolonged reaction time. Because of 1,2-anisyl shifts in the trianisylvinyl cation and returns from the ion to covalent starting material, the ^{14}C-label would be scrambled over the C-1 and C-2 positions in both the reaction product, trianisyl[1,2-^{14}C]vinyl acetate (**1**-OAc-*1,2*-^{14}C), and the unconsumed reactant, trianisyl[1,2-^{14}C]vinyl bromide (**1**-Br-*1,2*-^{14}C). Upon two successive treatments of the product and unconsumed reactant with $LiAlH_4$ as described previously (1), the **1**-OAc-*1,2*-^{14}C was converted to 1,2,2-trianisyl[1,2-^{14}C]ethanol (**2**-*1,2*-^{14}C) (1) and, at the same time, the unconsumed **1**-Br-*1,2*-^{14}C was transformed to trianisyl[1,2-^{14}C]ethene (**3**-*1,2*-^{14}C) (4). After separation through an alumina column, the **2**-*1,2*-^{14}C was oxidized (5) to give dianisyl[^{14}C]ketone (**4**-^{14}C), and the difference in activity between **4**-^{14}C and **3**-*1,2*-^{14}C gave the extent of scrambling from C-2 to C-1 in the reaction product. Degradation of the **3**-*1,2*-^{14}C was effected by ozonolysis, again giving rise to **4**-^{14}C and hence the extent of scrambling in the recovered unconsumed reactant. The results are summarized in Table 1.

The results in Table 1 can be interpreted by the mechanism shown in Scheme 1, in which RX and R′X designate, respectively, the original substrate, **1**-Br-*2*-^{14}C, and the isotopically rearranged **1**-Br-*1*-^{14}C, RY and R′Y designate the isotopically unrearranged and rearranged **1**-OAc-*2*-^{14}C and **1**-OAc-*1*-^{14}C, derived from the unrearranged and rearranged trianisyl[2-^{14}C]vinyl and trianisyl[1-^{14}C]vinyl cations, and k_r, k_{-1} and k_p, respectively, are the rate constants for the 1,2-anisyl shift, the return process, and the product formation. The rates for the return process and production formation would also be dependent on $[Br^-]$ and $[OAc^-]$, respectively. As stated in paper XLII of this series (6), a steady state treatment for the processes in Scheme 1 will give the relationship depicted in [1].

$$[1]\quad \frac{d[R'Y]/dt}{d[RY]/dt} = \frac{(k_{-1} + k_p)[R'X] + k_r([RX] + [R'X])}{(k_{-1} + k_p)[RX] + k_r([RX] + [R'X])}$$

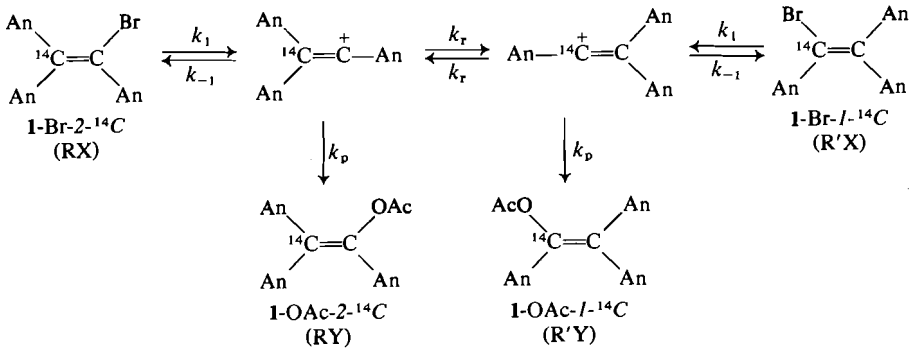

SCHEME 1

Since the ratio of the rates of formation of the rearranged and unrearranged products is dependent on [RX] and [R'X] as shown in [1], the amount of scrambling in the product is expected to increase with increasing extents of reaction. This expectation is in agreement with the observed results (Table 1) which show that for a given set of experimental conditions, the scrambling in the product does increase with an increase in reaction time. For example, when the acetolysis was carried out in the presence of 2 equiv. of NaOAc with no added LiBr (experiments 1–4), for reactions ranging from about 25 to 90%, the increasing amounts of scrambling in the product ranged from 9.6 to 24.1% (19.2 to 48.2% rearrangement). In the experiment on the NaOAc buffered acetolysis of **1**-Br-methoxy-d_3 (2), the observed 35 ± 2% rearrangement is also within this range.

The observation of scrambling in the recovered reactant indicates definitely the occurrence of returns from both the isotopically unrearranged and rearranged ions to covalent starting material. Again using experiments 1–4 as an illustration, in the earlier stages of the reaction (experiments 1 and 2), the scrambling in the recovered reactant is less than that found in the corresponding product and this is to be expected since there would be a relatively large amount of unchanged reactant remaining in the reaction mixture. In the later stages of the reaction (experiments 3 and 4), the scrambling in the recovered reactant is higher than that in the corresponding product. Most probably, the occurrence of many cycles of ionization, 1,2-shift, and return will lead to the accumulation of a greater amount of the rearranged reactant in the recovered, unconsumed substrate.

In experiments 5 and 6, an increase in the amount of NaOAc from 2 to 20 equiv. resulted in a decrease in the extent of scrambling for both the product and recovered reactant (compare experiments 5 and 6 with experiments 2 and 4). Similar effects of added OAc^- in decreasing the extent of rearrangement have been previously reported. For example, the 20% rearrangement of the 1-phenyl-2,2-di-*p*-tolylvinyl cation to the more stable 2-phenyl-1,2-di-*p*-tolylvinyl cation, observed in the decomposition in HOAc of 1-phenyl-2,2-di-*p*-tolylvinylphenyltriazene, was found to be completely suppressed by the presence of a 10 molar equiv. of KOAc (7). Similarly, in the decomposition in HOAc of trianisyl[2-^{14}C]vinylphenyltriazene, the isotopic scrambling arising from 1,2-anisyl shifts in the trianisylvinyl cation was decreased from about 38 to 17% by the presence of 1.7 equiv. of NaOAc (8). Such results from the decomposition of triazenes, which presumably took place via the diazonium ions, were interpreted as indicating that the 1,2-aryl shift occurred in the dissociated triarylvinyl cation. The presently observed decrease in rearrangement arising from an increased acetate concentration may, therefore, be regarded as a further confirmation that the acetolysis of **1**-Br proceeds via the dissociated trianisylvinyl cation which undergoes 1,2-shifts competitively with captures by nucleophiles. An increased OAc^- concentration will, therefore, enhance the rate of capture of the trianisylvinyl cation, thereby decreasing the relative amount of 1,2-anisyl shifts.

When the acetolysis was carried out in the presence of 2 equiv. of NaOAc and various amounts of LiBr (experiments 7–15), except in the cases involving prolonged reaction times, there was generally a further reduction in the extent of scrambling when compared with analogous experiments without the presence of added LiBr. This again fits the mechanism given in Scheme 1 since there would be further competition between the 1,2-shift in the dissociated trianisylvinyl cation and its capture by the additional Br^- ions. In the experiments with prolonged reaction times (experiments 10, 12, and 14), the recovered reactant showed extensive scramblings, indicative of a high rate for the return process and the repeated cycles of ionization, 1,2-shift, and return gave rise to the accumulation of a completely or nearly completely scrambled residual unconsumed reactant. In experiments 10 and 12, these cycles of ionization, 1,2-shift, and return even resulted in a higher extent of scrambling in the product than the scrambling in the

product from experiment 4, which involved the use of 2 equiv. of NaOAc and a long reaction time but without the added LiBr.

It is of interest to compare the present results with those observed from our recent study with triphenyl[2-^{14}C]vinyl bromide (**5**-Br-*2*-^{14}*C*) (6). The solvolysis of **5**-Br-*2*-^{14}*C* in HOAc–NaOAc was too slow and experiments were carried out with various combinations of HOAc and H_2O. In HOAc–H_2O, no scrambling was found in the recovered reactant. In the reaction product, the extent of scrambling remained the same regardless of the extent of reaction and was unaffected by the presence of added NaOAc or NaBr. A mechanism simpler than Scheme 1 and without involving the return process was sufficient to account for those results (6). It was also suggested that the 1,2-phenyl shift in the triphenylvinyl cation may have occurred in the ion-pair stage rather than in the dissociated ion since added OAc^- or Br^- did not affect the extent of scrambling. In the solvolysis of **5**-Br-*2*-^{14}*C* in 2,2,2-trifluoroethanol (TFE) buffered with lutidine (6), scrambling was found in both the product and recovered reactant. An interesting difference between the present results and those obtained from the trifluoroethanolysis of **5**-Br-*2*-^{14}*C* is that after about 30 or 60% reaction with **5**-Br-*2*-^{14}*C*, the scrambling in the product and in the recovered reactant was found to be the same (6). This finding suggests that in the triphenylvinyl system, k_r for the 1,2-phenyl shift is relatively unimportant when compared with k_{-1} and k_p for the return and product forming processes. Once the rearranged triphenyl[1-^{14}C]vinyl cation or ion pair is formed, the ratio of the rearranged to unrearranged ions or ion pairs will determine the ratio of their products, [R′Y]/[RY], as well as the recovered reactants, [R′X]/[RX], because interconversion between the rearranged and unrearranged ions or ion pairs, the k_r process, is relatively small. However, for the trianisylvinyl system, k_r is not unimportant when compared with k_{-1} or k_p, and from [1] the scramblings in the product and in the recovered reactant are not the same (Table 1). This interpretation of the difference between the triphenylvinyl and trianisylvinyl systems appears to be quite reasonable since the migratory aptitudes for the 1,2-shifts would be much larger for the anisyl than the phenyl group.

Experimental

*Acetolysis of Trianisyl[2-^{14}C]vinyl Bromide (***1***-Br-2-^{14}C)*

The acetolysis of **1**-Br-*2*-^{14}*C* was carried out in the presence of various amounts of NaOAc or NaOAc and LiBr as indicated in Table 1. A typical experiment is described below.

A solution of 64 mg (0.15 mmol) of **1**-Br-*2*-^{14}*C*, 26 mg (0.30 mmol) of NaOAc, and 25 mg (0.30 mmol) of LiBr in 10 mL of glacial acetic acid containing 10% acetic anhydride in a sealed tube was heated at 120 ± 2°C for the desired length of time. The tube was then cooled in ice, opened, and the contents poured into 200 mL of ether containing ordinary **1**-Br and **1**-OAc (about 100 mg each) as carriers. The ether solution was washed three times with 50 mL portions of water and then with a saturated $NaHCO_3$ solution. After drying over $MgSO_4$, the ether was removed by distillation, leaving a residue containing the reaction product, trianisyl[1,2-^{14}C]vinyl acetate (**1**-OAc-*1,2*-^{14}*C*), and any unconsumed reactant, trianisyl[1,2-^{14}C]vinyl bromide (**1**-Br-*1,2*-^{14}*C*).

Work-up Procedure

The residual mixture of **1**-OAc-*1,2*-^{14}*C* and **1**-Br-*1,2*-^{14}*C* was treated twice successively with $LiAlH_4$ as previously described (1). After one $LiAlH_4$ reduction, **1**-OAc-*1,2*-^{14}*C* gave a mixture of 1,2,2-trianisyl[1,2-^{14}C]ethanone and 1,2,2-trianisyl[1,2-^{14}C]ethanol (**2**-*1,2*-^{14}*C*) (1), while **1**-Br-*1,2*-^{14}*C* was converted to 1,2,2-trianisyl[1,2-^{14}C]ethene (**3**-*1,2*-^{14}*C*) (4). After the second reduction, a mixture of **2**-*1,2*-^{14}*C* and **3**-*1,2*-^{14}*C* was obtained. This mixture was passed through a 30 cm × 2 cm diameter column packed with adsorption alumina (Fisher Scientific Co.). The **3**-*1,2*-^{14}*C* was first eluted with 90% petroleum ether (bp 40–60°C) and 10% ether, and the **2**-*1,2*-^{14}*C* was then recovered after a change to $CHCl_3$ as eluant.

Degradation of **2**-1,2-^{14}C *and* **3**-1,2-^{14}C

After the addition of appropriate amounts of inactive carrier if needed, **2**-*1,2*-^{14}*C* was oxidized with $KMnO_4$ to give dianisyl[^{14}C]ketone (**4**-^{14}*C*) in the same way as described in earlier work (5, 8).

The **3**-*1,2*-^{14}*C*, again with added carrier if needed, was degraded by ozonolysis to give **4**-^{14}*C*. Typically, a stream of oxygen–ozone mixture, containing about 8% O_3, from an ozone generator was passed through a stirred and cooled solution of 500 mg (1.5 mmol) of **3**-*1,2*-^{14}*C* in 100 mL of ethyl acetate for 1 h. The solvent was removed in a rotary evaporator and the residual crude ozonide was heated under reflux for 2 h with a mixture of 48 mL of H_2O, 2 mL of HOAc, and 10 mg of Zn dust. After cooling, the mixture was extracted three times with ether, and the combined extract was dried over $MgSO_4$ before the ether was removed by distillation. The residue was then passed through the 15 cm × 2 cm diameter alumina column, with 90% petroleum ether(bp 40–60°C) – 10% ether as eluant. Unreacted **3**-*1,2*-^{14}*C* was eluted first, followed by a small amount of *p*-methoxybenzaldehyde. The desired ketone, **4**-^{14}*C*, was eluted last, the recovery being 200 mg (55%).

Total synthesis of δ-(L-α-aminoadipyl)-L-cysteinyl-D-valine (ACV), a biosynthetic precursor of penicillins and cephalosporins

SAUL WOLFE AND MARK GORDON JOKINEN

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received December 11, 1978

SAUL WOLFE and MARK GORDON JOKINEN. Can. J. Chem. 57, 1388 (1979).

The title compound has been synthesized as its disulfide by a classical route from the fully protected precursor *N*-BOC-*S*-trityl-δ-(L-α-aminoadipyl)-L-cysteinyl-D-valine bisbenzhydryl ester. Deprotection has been achieved by oxidative removal of the trityl group with iodine, followed by removal of BOC and benzhydryl using trifluoroacetic acid. The final product is obtained in 23% overall yield from D-valine.

SAUL WOLFE et MARK GORDON JOKINEN. Can. J. Chem. 57, 1388 (1979).

On a synthétisé le composé mentionné dans le titre sous forme de disulfure par une voie classique à partir du précurseur complètement protégé qui est l'ester bisbenzhydrylique de la *N*-BOC *S*-trityl δ-(L-α-aminoadipyl) L-cystéinyl D-valine. On a effectué la déprotection en faisant suivre l'élimination du groupe tritylе grâce à une oxydation avec de l'iode suivi par l'enlèvement des groupes BOC et benzhydryles à l'aide d'acide trifluoroacétique. On a obtenu le produit final avec un rendement global de 23% à partir de la D-valine.

[Traduit par le journal]

The biosyntheses of Penicillin N (**1***a*) by *Cephalosporium acremonium*, and of Isopenicillin N (**1***b*) by *Penicillium chrysogenum*, proceed via the common tripeptide precursor δ-(L-α-aminoadipyl)-L-cysteinyl-D-valine (**2**) (ACV) (1). Although many of the details of the biosynthesis of ACV from the amino acid precursors L-α-aminoadipic acid, L-cysteine, and L-valine have been established (1), the specific processes by which the tripeptide is transformed to the oxidation level of penicillin remain unknown. Thus it has not yet been possible to relate the stereochemical observations, that the pro-S hydrogen of cysteine is removed (2), and that the C5—N (2) and C2—S bonds (3) of penicillin are formed with retention of configuration, to proven chemical mechanisms. The principal reason for the lack of progress on this aspect of the problem is that studies of the fate of ACV and (or) the role of post-ACV intermediates require that protoplasts or protoplast lysates (4) derived from *P. chrysogenum* or *C. acremonium* be employed in the biosynthetic experiments. The required techniques have only become available in recent years, as a result of the important work of Abraham and his co-workers (5).

There are, therefore, two prerequisites for any planned investigation of the oxidative stages of penicillin biosynthesis. The first is a protoplast or protoplast lysate system that will convert ACV efficiently into penicillin; the second is a supply of labelled ACV. We wish to disclose a new total synthesis of ACV (as its disulfide), which makes this compound readily available for biosynthetic studies.

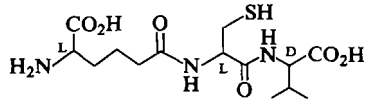
a (D-configuration at *C)
b (L-configuration at *C)



2

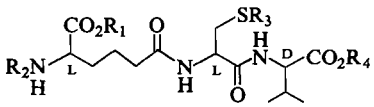
In this synthesis, the final product and most of the intermediates have been obtained in crystalline form and have been characterized fully.

Four syntheses of ACV and (or) its stereoisomers have been reported previously in the literature (6–9). Two of these (6, 7) were directed specifically towards the LLL isomer; however, the experimental details of Rudinger's synthesis (6) have not yet been presented, and spectroscopic and analytical data were not given for the peptide intermediates and the final product of Bauer's synthesis (7). Only the synthesis of Fawcett *et al.* (9) has been accompanied by full experimental details and microanalytical data for the various intermediates. In this latter work, three separate deprotecting steps were needed, and the final product was obtained in 8.5% yield from the fully protected tripeptide.

The syntheses of Adriaens *et al.* (8) and Fawcett *et al.* (9) include an alkaline hydrolysis of a protected

0008-4042/79/111388-09$01.00/0

tripeptide. In the work of Adriaens, this removes the benzyl ester of the intermediate **3**; in the work of Fawcett, the alkaline hydrolysis removes the ethyl and 4-methoxybenzyl esters from the intermediate **4**. In our hands, the removal of esters by alkaline hydrolysis led to problems.[1] Thus, exposure of **5** to ethanolic sodium hydroxide led to loss of the α-aminoadipyl residue; application of the same conditions to **6**, followed by removal of the *tert*-butoxycarbonyl (BOC) protecting groups with trifluoroacetic acid, led to a mixture of products. As a result of these failures, a successful synthesis was designed in which all carboxyl and amino protecting groups were removed in a single, acidic step. This synthesis is summarized in Scheme 1.



3 $R_1 = PhCH_2, R_2 = PhCH_2OCO, R_3 =$ disulfide, $R_4 = H$

4 $R_1 = p\text{-}CH_3OC_6H_4CH_2, R_2 = p\text{-}CH_3OC_6H_4CH_2OCO, R_3 = AcNHCH_2, R_4 = Et$

5 $R_1 = PhCH_2, R_2 = H, R_3 = PhCH_2, R_4 = H$

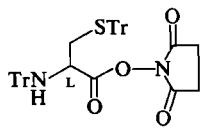
6 $R_1 = PhCH_2, R_2 = t\text{-BOC}, R_3 =$ disulfide, $R_4 = PhCH_2$

Benzhydryl and BOC protection were employed for the carboxyl and amino groups, respectively, and the trityl group for the protection of sulfur. As a test of the various procedures, D-valine was first protected and deprotected, as shown in Scheme 2, and L-cystinyl-bis-D-valine was synthesized, as shown in Scheme 3. In this latter synthesis, oxidative cleavage of the trityl group from benzhydryl-*N*-BOC-*S*-trityl-L-cysteinyl-D-valinate was accomplished in over 75% yield, using iodine in methanol containing pyridine (10).

As shown in Scheme 4, DL-α-aminoadipic acid was prepared by the amidomalonic ester procedure described by Abraham and his co-workers (11), and resolved enzymatically as the *N*-chloroacetyl derivative (12). The α-benzhydryl ester was then synthesized by treatment of the *p*-toluenesulfonic acid salt with 1 equiv. of diphenyldiazomethane (13). This reaction, based upon a literature precedent with the β-naphthalenesulfonic acid salt of glutamic acid (14), afforded a mixture of unreacted diacid and the α-benzhydryl ester, from which the ester could be isolated without difficulty. The introduction of the BOC protecting group was performed using 2-*tert*-butoxycarbonyloximino-2-phenylacetonitrile (BOC-ON) (15) in the presence of dicyclohexylamine. This minor modification of the recommended procedure (15) has been found to be generally applicable to the synthesis of BOC-amino acids.[2]

The BOC-protected cysteinylvaline peptide shown in Scheme 3 was unsuitable for an ACV synthesis because of the difficulties (16) associated with the selective removal of the BOC group from **7** (see Scheme 3) prior to coupling with the aminoadipic acid moiety. Therefore, in the ACV synthesis, the *N*,*S*-dityrityl derivative of L-cysteine (17) was coupled to the benzhydryl ester of D-valine. The *N*-trityl group of the resulting material (**8**; see Scheme 1) could be removed selectively with aqueous acetic acid, and the product isolated as the hydrochloride salt. Conversion to fully protected ACV (**9**; see Scheme 1) was achieved using EEDQ (18) as the coupling agent.

A problem with the use of the *N*-trityl group in peptide synthesis is the steric crowding which is introduced at the adjacent carboxyl group. This causes a reduction in the rate of the peptide coupling reaction (19). Nevertheless, *N*,*S*-ditritylcysteine has been coupled successfully with many amino acid esters, via the active *N*-hydroxysuccinimide ester **10** (17, 20). However, despite these literature precedents, initial experiments suggested that the direct coupling of **10** with the benzhydryl ester of D-valine was extremely slow, and did not proceed to completion.[3] The problem was overcome by addition of the active ester aminolysis catalyst 1,2,4-triazole to the reaction mixture (21), which allowed the synthesis of **8** under mild conditions.



10

Certain N,S-diprotected cysteine esters have been found to undergo racemization under the conditions required for peptide coupling (22). It was, therefore, necessary to check the stability of **10** under the conditions of its coupling to the valine moiety. No racemization was observed.

Oxidative removal of the *S*-trityl group from **9** proceeded in 64% yield, and treatment of the resulting bis-δ-(*N*-BOC-L-α-aminoadipyl)-L-cystinyl-bis-D-valine tetrabenzhydryl ester (**11**; see Scheme 1)

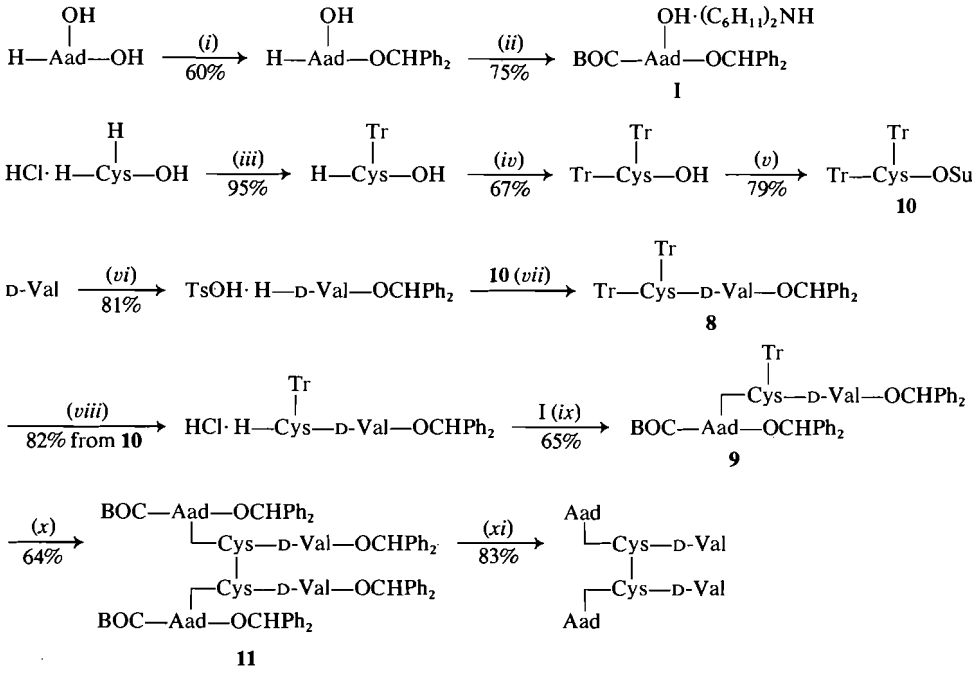
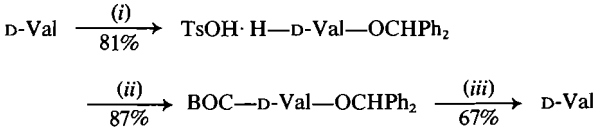


SCHEME 1. Reagents: (*i*) TsOH; Ph_2CN_2–DMF; (*ii*) BOC-ON, EtOH, dicyclohexylamine; (*iii*) TrOH, TFA; (*iv*) TrCl, Et_2NH; (*v*) *N*-hydroxysuccinimide, DCC; (*vi*) TsOH; Ph_2CN_2–DMF; (*vii*) 1,2,4-triazole, Et_3N; (*viii*) HOAc–H_2O; then HCl–EtOH; (*ix*) EEDQ; (*x*) I_2–MeOH–pyridine; (*xi*) TFA, anisole.



SCHEME 2. Reagents: (*i*) TsOH; Ph_2CN_2–DMF; (*ii*) BOC-ON–Et_3N; (*iii*) TFA.

with trifluoroacetic acid and anisole led to crystalline ACV-disulfide in 83% yield. The overall yield of this compound from D-valine is ca. 23%. As reported by Adriaens *et al.* (8), the disulfide is converted to ACV itself upon reduction with dithiothreitol (23).

Experimental

General

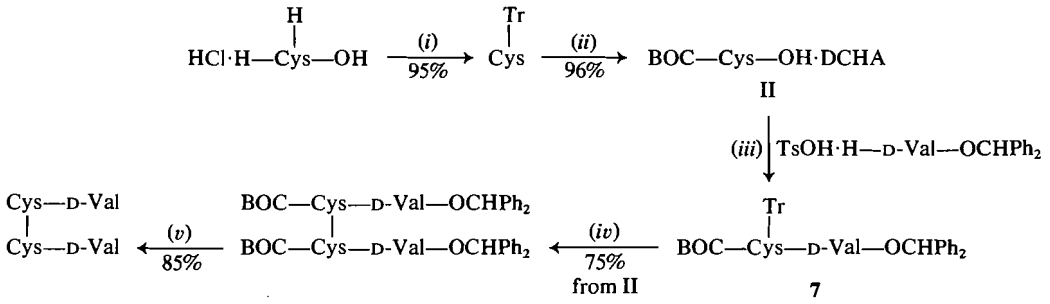
The ir spectra were taken on a Perkin-Elmer 180 spectrometer. Proton nmr spectra were recorded on a Varian Anaspect EM360, or a Varian T-60. Chemical shifts are reported in δ values relative to tetramethylsilane or 2,2-dimethyl-2-sila-pentane-5-sulfonate as internal standards, and in deuteriochloroform unless otherwise noted. Microanalyses were carried out by Galbraith Laboratories, Knoxville, Tennessee. Melting points were determined on a Meltemp apparatus. Optical rotations were obtained on a Perkin-Elmer 141 polarimeter. Thin layer chromatography was performed on pre-coated Brinkmann silica gel 60 F-254 plates with aluminum or glass backing. Spots were observed under short wave ultraviolet light, or were visualized with ninhydrin or iodine vapour. Magnesium sulfate and sodium sulfate were used as drying agents. Solvents were distilled before use, and were dried, as required, by literature procedures.

DL-α-*Aminoadipic Acid (11, 25)*

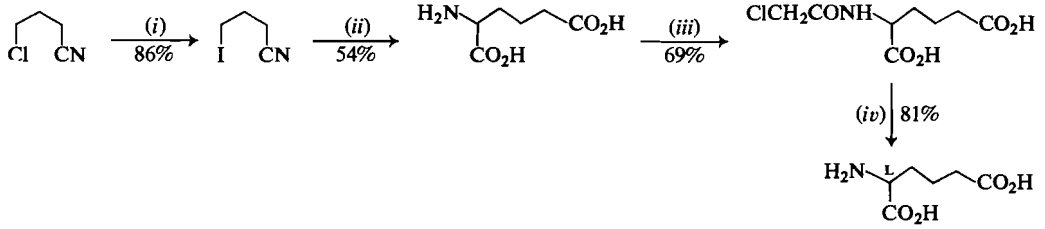
γ-Chlorobutyronitrile (Aldrich, purity 95%, 51.7 g, 0.50 mol) was added at room temperature to a solution of sodium iodide (90 g, 0.60 mol) in distilled acetone (200 mL) containing some glass boiling granules (24). A precipitate began to form within minutes. The mixture was refluxed for 24 h, cooled to room temperature, and the precipitated salt was removed by suction filtration and dried (28.4 g, 97% of theory). The filtrate was concentrated below 30°C under reduced pressure, and the residual slurry was dissolved in commercial anhydrous ether. After filtration, the ether was removed to yield crude γ-iodobutyronitrile as a clear yellow oil. This was purified by fractional distillation, bp 83–86°C/1–2 Torr, to give 83.7 g (86%) as a clear, colourless liquid; ir: 2240 cm^{-1} (—C≡N stretch); ^{1}Hmr (CCl_4): $Cl(CH_2)_3CN$: 3.64 (2H, t, 6), 1.90–2.80 (4H, m); $I(CH_2)_3CN$: 3.28 (2H, t, 6), 1.90–2.80 (4H, m).

A solution of sodium methoxide (Aldrich, 18.0 g, 0.33 mol, 1.1 equiv.) in 75 mL absolute ethanol was added dropwise and with mechanical stirring to a solution of diethylacetamidomalonate (DAM) (65.1 g, 0.30 mol) in 240 mL ethanol. The resulting mixture was extremely viscous. γ-Iodobutyronitrile (78.0 g, 0.40 mol, 1.33 equiv.), in ethanol (50 mL), was then added dropwise and with vigorous stirring. After the addition was complete, the mixture was refluxed for 6 h. The solvent was removed and the residual slurry was taken up in 100 mL of ethyl acetate, followed by water and sufficient 10% citric acid to adjust the aqueous phase to about pH 4. The aqueous phase was removed, and the organic phase was washed with water (3 × 100 mL). After drying over anhydrous magnesium sulfate, and removal of the ethyl acetate, 11.66 g of iodobutyronitrile was recovered from the residual oil by fractional distillation. The yield of crude alkylated product was 79.33 g, and its ^{1}Hmr spectrum indicated some contamination with $I(CH_2)_3CN$ and DAM.

The crude product (44.5 g) was dissolved in 480 mL of



SCHEME 3. Reagents: (*i*) TrOH, TFA; (*ii*) BOC-ON–Et_3N; (*iii*) *N*-methylmorpholine, EEDQ; (*iv*) I_2, MeOH, pyridine; (*v*) TFA.



SCHEME 4. Reagents: (*i*) NaI–Me_2CO; (*ii*) diethylacetamidomalonate–NaOEt; then 8 *N* HCl; (*iii*) *p*-nitrophenylchloroacetate; (*iv*) hog kidney acylase I.

8 *N* hydrochloric acid, and the solution was refluxed for 10 h. Removal of the solvent yielded a crystalline slurry which was dissolved in 50 mL of water. The pH was adjusted to 2.9 with aqueous sodium hydroxide and the resulting precipitate was collected, dried, and dissolved in 100 mL of water with the aid of aqueous sodium hydroxide. The clear solution (pH 6) was then acidified to pH 2.9 with concentrated hydrochloric acid, and an equal volume of ethanol was added. The DL-α-aminoadipic acid was collected after refrigeration, and dried, 14.8 g (54% from diethylacetamidomalonate). The material was positive to ninhydrin; ir (KBr): 1640, 1665 cm^{-1}; ^{1}Hmr (D_2O + Na_2CO_3 + DSS): 3.25–3.6 (1H, m), 2.4–2.1 (2H, m), 1.9–1.4 (4H, m).

p-*Nitrophenyl Chloroacetate (26)*

Monochloroacetic acid (18.8 g, 0.20 mol) and *p*-nitrophenol (27.8 g, 0.20 mol) were dissolved in 400 mL of ethyl acetate, and the solution was cooled to 0°C. Dicyclohexylcarbodiimide (43.8 g, 0.21 mol), in ethyl acetate (100 mL), was added in one portion, with stirring. Dicyclohexylurea precipitation began within a minute. After 20 min, the ice bath was removed, and the solution was stirred for another 2 h. Oxalic acid (0.5 g) was added, and the solution was stirred a further 15 min. The urea and oxalic acid were then removed by filtration and the ethyl acetate filtrate was evaporated to dryness to yield the crude product. This was recrystallized twice from absolute ethanol to yield pale brown *p*-nitrophenyl chloroacetate (36.12 g, 84%), mp 95–98°C (Meltemp); ^{1}Hmr: 8.25 (2H, d, 9), 7.31 (2H, d, 9), 4.37 (2H, s); ir: 1780–1760, 1515, 1335 cm^{-1}.

DL-α-*Chloroacetylaminoadipic Acid (26, 27)*

DL-α-Aminoadipic acid (8.06 g, 50 mmol) and sodium hydroxide (3.0 g, 75 mmol) were dissolved in 50 mL of distilled water, and the solution was cooled to room temperature (pH 9.9). Acetone (25 mL) was then added, with stirring. A solution of *p*-nitrophenyl chloroacetate (12.52 g, 61 mmol) in 25 mL of dry acetone was added dropwise with vigorous stirring during a 2 h period, with concurrent addition of 3 *N* NaOH to maintain the pH at 9.5. After the addition was complete, and the pH had ceased to fall, concentrated hydrochloric acid was added carefully to lower the pH to 7.0. The solution was concentrated to half its original volume and an orange precipitate was removed. The pH was then lowered to 5.5, and the solution was extracted with ethyl acetate (4 × 100 mL), and the organic phase was discarded. The aqueous phase was concentrated to about 50 mL, acidified to pH 1–1.5, and extracted again with ethyl acetate (2 × 50 mL, 2 × 20 mL). The combined extracts were then dried over anhydrous magnesium sulfate and evaporated. The residual yellow oil was triturated with hexane to give a pale brown solid (9.95 g). Recrystallization from ethyl acetate – hexane afforded 8.11 g (69%), mp 129–131.5°C (Meltemp) (lit. (11) mp 129–130°C); ir (KBr): 3370 (s), 1690–1750 (b), 1600–1640 cm^{-1}; ^{1}Hmr ($CDCl_3$ + 3 drops DMSO-d_6): 11.56 (2H, s), 7.53 (1H, d, 8), 4.7–4.3 (1H, m), 4.07 (2H, s), 2.30 (2H, t, 6), 2.1–1.4 (4H, m).

L-α-*Aminoadipic Acid (28)*

Racemic *N*-chloroacetylaminoadipic acid (6.02 g, 25 mmol) and potassium dihydrogen phosphate (0.68 g, 5 mmol) were suspended in 100 mL of water, and brought into solution by the addition of 3 *N* sodium hydroxide. The pH was adjusted to 7.0, 250 mg of hog kidney acylase I was added, and the solution was stirred for 22 h. The enzyme was removed by careful heating of the solution to boiling for 5 min, followed by filtration. The solution was concentrated to 50 mL, the pH adjusted to 2.9 with hydrochloric acid, and 150 mL of ethanol was then added. After refrigeration for 24 h, the crude L-α-aminoadipic acid was collected, dried, and recrystallized from water–ethanol: 1.65 g (81%); $[\alpha]_D$ + 23.5° (*c* 2, 5 *N* HCl) (lit. (28) +25°). The material was positive to ninhydrin.

The D-α-chloroacetylaminoadipic acid was recovered by removal of ethanol from the original filtrate, acidification to pH 1, and extraction with ethyl acetate. Workup in the usual manner and recrystallization from ethyl acetate – hexane gave 2.33 g (77%), mp 99–100°C.

L-α-*Aminoadipic Acid* α-*Benzhydryl Ester (14)*

L-α-Aminoadipic acid (2.65 g, 16.5 mmol) and *p*-toluene-

sulfonic acid monohydrate (3.29 g, 17.3 mmol) were dissolved in water (20 mL), with warming. The solvent was removed under reduced pressure, and the residue was recrystallized from acetone–methanol(1:1)–ether: 5.40 g (98%). The L-α-aminoadipic acid *p*-toluenesulfonate (5.32 g, 16.0 mmol) was dissolved in reagent grade dimethylformamide (8 mL) at 40°C, and diphenyldiazomethane (3.10 g, 16.0 mmol), in dimethylformamide (4 mL), was added in several portions over 5 min, with vigorous stirring. Evolution of gas occurred, and the red colour faded rapidly to a faint yellow (29). After a further 5 min of stirring, sodium acetate (4 g) in water (20 mL) was added, and the product crystallized out. After standing overnight at 4°C, the product was collected, washed thoroughly with water and ether, and dried: 2.49 g. The aqueous phase of the washings was evaporated to dryness *in vacuo*, and the residue was redissolved in water (50 mL). A second crop of product was collected and washed with aqueous potassium phosphate (pH 7) to remove traces of aminoadipic acid. The combined yield was 3.24 g (60%), mp 124–128°C. This was raised to 133–134.5°C after brief boiling in absolute ethanol. The aqueous washings of the reaction were combined, concentrated, the pH adjusted to 3, and three volumes of methanol were added to give 0.29 g (11%) of L-α-aminoadipic acid.

Analytical tlc of the aminoadipic acid benzhydryl ester (silica gel 60, ninhydrin) showed single spots in (*a*) water–methanol–pyridine (1:2:1), $R_f = 0.61$ (yellow spot); (*b*) 95% ethanol – concentrated aqueous ammonia (10:1), $R_f = 0.13$ (violet spot); (*c*) 95% ethanol – glacial acetic acid (20:1), $R_f = 0.61$ (yellow spot). Under the same conditions, α-aminoadipic acid showed R_f values of 0.52, 0.71, 0.14, respectively. $[\alpha]_D = -11°$ (*c* 2, CH_3OH, 0.1 dm cell, with 1 equiv. of *p*-toluenesulfonic acid monohydrate added); ir (KBr): 1747 cm^{-1} (ester); ^{1}Hmr (DMSO-d_6 + TMS, Fourier transform)[4]: 7.36 (10H, m), 6.79 (1H, s), 3.60–3.33 (1H, m), 2.38–2.03 (2H, m), 1.75–1.33 (4H, m). *Anal.* calcd. for $C_{19}H_{21}NO_4$: C 69.70, H 6.47; found: C 68.95, H 6.46.

N-BOC-L-α-aminoadipic acid α-Benzhydryl Ester δ-Dicyclohexylammonium Salt

L-α-Aminoadipic acid α-benzhydryl ester (1.635 g, 5.00 mmol) was suspended in methanol (10 mL). A clear solution resulted when dicyclohexylamine (1.04 mL, 5.25 mmol) was added. Then BOC-ON (1.30 g, 5.25 mmol, 1.05 equiv.) was added, and the pale yellow solution was stirred at room temperature for 24 h. The methanol was then removed *in vacuo*, diethyl ether (50 mL) was added, and, after chilling at −20°C, the precipitated product was collected, washed with ether, and dried: 2.26 g (75%), mp 153.0–155.5°C, raised to 156.5–157.5°C after one recrystallization from ethanol–ether. $[\alpha]_D = -20.5°$ (*c* 2, methanol, 0.1 dm cell); ir (KBr): 1740 (ester), 1700 cm^{-1} (urethane); ^{1}Hmr (free acid[5]): 11.3–10.9 (1H, br s, exchanges with D_2O), 7.33 (10H, s), 6.95 (1H, s), 5.20 (1H, d, 7.8, exchanges with D_2O), 4.70–4.13 (1H, m, unaltered with D_2O), 2.57-2.13 (2H, m), 1.97–1.57 (4H, m), 1.42 (9H, s).

Analytical tlc (silica gel): the free acid showed a single spot (R_f 0.74) in 95% ethanol – glacial acetic acid (20:1), visible with short wave uv, and positive to ninhydrin after treatment with one drop of concentrated hydrochloric acid. *Anal.* calcd. for $C_{36}H_{52}N_2O_6$: C 71.02, H 8.61; found: C 70.67, H 8.74.

D-*Valine Benzhydryl Ester* p-*Toluenesulfonic Acid Salt (29)*

D-Valine (1.0 equiv.) and *p*-toluenesulfonic acid monohydrate (1.05 equiv.) were dissolved in water. The solution was evaporated to dryness under reduced pressure, and the residue recrystallized from warm acetone–ether. The salt (5.83 g, 20 mmol) was dissolved in reagent grade dimethylformamide (5 mL), and the solution was warmed to approximately 50°C. Crude diphenyldiazomethane (DDM) (5.82 g, 30 mmol) was mixed with sufficient dimethylformamide to make 7.5 mL of solution and this solution was then added slowly (one drop every 4–5 s) to the vigorously stirred solution of the amino acid salt. Evolution of gas occurred, with the red colour fading immediately to faint yellow. The red colour began to persist as 1 equiv. of DDM was approached, and persisted for some minutes at slightly more than 1 equiv. The solution was then transferred to a 250 mL flask, and 150 mL of diethyl ether were added. A white solid precipitated immediately from the faintly pink solution. After chilling overnight at −20°C, the product was collected by filtration, washed with ether, and dried *in vacuo*. It was then recrystallized from absolute methanol – anhydrous diethyl ether, giving 7.43 g (81%, lit. (29) 77% with a different work-up), mp 175.5–177.0°C (lit. (26) 170–171°C, from acetonitrile); ir (KBr): 1743 cm^{-1}; ^{1}Hmr ($CDCl_3$): 7.68 (2H, d, 8.2), 7.1–7.5 (10H, m), 6.8–7.1 (3H, m), 4.0 (1H, d, 3.6), 2.05–2.50 (4H, m), 0.82 (3H, d, 6.8), 0.80 (3H, d, 7.0); $[\alpha]_D = +20.2°$ (*c* 2, CH_3OH, 0.1 dm cell).

N-*BOC-D-valine Benzhydryl Ester*

D-Valine benzhydryl ester *p*-toluenesulfonic acid salt (2.28 g, 5.0 mmol) was suspended in ethyl acetate (15 mL), and triethylamine (0.73 mL, 5.25 mmol), followed by BOC-ON (1.35 g, 5.50 mmol), were added. The mixture was stirred for 23 h at room temperature, and then extracted successively with 10% potassium hydrogen sulfate (2 × 20 mL), saturated sodium chloride (1 × 20 mL), 5% sodium carbonate (2 × 20 mL), and saturated sodium chloride (1 × 20 mL). The organic phase was dried over anhydrous magnesium sulfate and evaporated to give an oil which crystallized upon seeding and scratching. The crude product was recrystallized from methanol to give 1.39 g (72%) of white needles, mp 110–111°C. A further 0.28 g was obtained by addition of water to the methanol mother liquor, mp 109–110.5°C (total yield 87%); $[\alpha]_D = +19.5°$ (*c* 2, $CHCl_3$); ir (KBr): 3370(s), 1727(s), 1697(s); ^{1}Hmr: 7.28 (10H, s), 6.90 (1H, s), 5.03 (1H, d, J = 9 Hz, exchanges with D_2O), 4.33 (1H, q, 9,4; D_2O: d, J = 4 Hz), 2.5–1.8 (1H, m), 3.08 (9H, s), 0.92 (3H, d, 8), 0.80 (3H, d, 8). *Anal.* calcd. for $C_{23}H_{29}NO_4$: C 72.03, H 7.62; found: C 71.90, H 7.62.

Deprotection of N-*BOC-D-valine Benzhydryl Ester*

To a mixture of trifluoroacetic acid (10.5 mL, distilled from phosphorous pentoxide) and anisole (1.1 mL, distilled *in vacuo* from anhydrous calcium chloride) was added *N*-BOC-D-valine benzhydryl ester (1.34 g, 3.5 mmol). The material dissolved immediately, with evolution of gas, to give a clear yellow solution. This was stirred for 1 h at room temperature, during which time a yellow precipitate formed. The trifluoroacetic acid was removed *in vacuo*, and the residue was dissolved

[4]The compound was insufficiently stable under acidic ($CDCl_3$ + 1 drop CF_3COOH) or basic (D_2O + Na_2CO_3 + DSS) conditions for a successful nmr, and was poorly soluble under neutral conditions.

[5]The free acid was generated by partition of the salt (0.61 g, 1 mmole) between ethyl acetate (5 mL) and 10% aqueous potassium hydrogen sulfate (5 mL). The aqueous phase was removed, and the organic phase was washed a second time with aqueous acid (5 mL), once with saturated sodium chloride solution (5 mL), and dried over sodium sulfate. After removal of the solvent *in vacuo* and trituration of the residual oil with petroleum ether, the free acid solidified and was collected: 0.42 g (98%). Treatment of an ether solution of the acid with dicyclohexylamine regenerated the original salt, indicating that no ester isomerization had occurred.

in ether (75 mL). The trifluoroacetic acid salt of D-valine did not precipitate, and the ether solution was, therefore, concentrated to 20 mL and extracted with water (2 × 50 mL). The combined aqueous extracts were back-extracted once with ether (20 mL), and evaporated *in vacuo* to give about 1 mL of clear, colourless oil. This was diluted to about 5 mL with water, and pyridine was added dropwise until the pH (initially about 0) was raised to 5–6. Absolute ethanol (10 mL) was added, and the precipitated D-valine was collected after chilling at 5°C for several hours: 0.27 g (67%). The material was identical to authentic valine on thin layer chromatography (R_f 0.61 on silica gel in 2:1 isopropanol–water, ninhydrin, with the sample applied in aqueous TFA), and by ^{1}Hmr; $[\alpha]_D = -46°$ (*c* 1, glacial acetic acid, 0.1 dm cell) (lit. (30) $[\alpha]_D = +47.2°$ for the L-isomer).

N-*BOC*-S-*trityl*-L-*cysteine Dicyclohexylammonium Salt*

L-Cysteine hydrochloride hydrate (2.64 g, 15 mmol) was converted to the anhydrous form by dissolution in 15 mL of absolute methanol followed by evaporation to dryness *in vacuo*. The procedure was repeated twice with chloroform to yield cysteine hydrochloride. Trityl alcohol (3.90 g, 15 mmol) and anhydrous trifluoroacetic acid (27 mL) were added and the mixture, which had immediately turned dark red, was stirred at room temperature for 15 min. Some insoluble material was still present, and the trifluoroacetic acid was, therefore, removed under reduced pressure and the procedure repeated with a further 10 mL. After an additional 15 min, no insoluble material remained. The solvent was removed *in vacuo* at room temperature to yield a yellow foam. Anhydrous diethyl ether (25 mL) was added and the solution was evaporated. This ether addition–evaporation was repeated, and saturated aqueous sodium bicarbonate (50 mL) was then added to the foam, which was transformed into a flocculent white precipitate. After refrigeration overnight, this was collected and dried to yield crude *S*-trityl-L-cysteine, which was used without purification in the next step.

The *S*-trityl-L-cysteine was dissolved in a mixture of dioxane (10 mL) and water (5 mL) with the aid of 10 *N* sodium hydroxide. The final pH was 10.2. BOC-ON (Aldrich, 4.06 g, 16.5 mmol) in dioxane (5 mL) was added in one portion, and the pH was returned to 10.2 with sodium hydroxide. The solution was then stirred for 6 h at room temperature. The pH fell only very slowly during this period (10.2 to 9.9). No further base was added. The dioxane was then removed *in vacuo* to yield a viscous yellow solution. Water (30 mL) was added, and the mixture was extracted with diethyl ether (2 × 30 mL) and acidified to pH 3 by addition of solid citric acid. The acidified solution was extracted with ether (3 × 30 mL), and these latter extracts were combined, dried over magnesium sulfate, and dicyclohexylamine (15 mmol, 2.98 mL) in ether (5 mL) was added. A white precipitate formed immediately. After refrigeration at −20°C for 1 day, the product was collected and dried *in vacuo*: 7.83 g (84%), mp 211–212°C (dec.) (lit. (31) mp 210–211°C); $[\alpha]_D$ +23° (0.1 dm cell, *c* 1, methanol) (lit. (31) $[\alpha]_D$ +23.8°); ir (KBr): 3238, 1698, 1624 cm^{-1} (salt); ^{1}Hmr (free acid): 9.5 (1H, m), 7.5–6.9 (15H, m), 4.8 (1H, m), 4.1 (1H, m), 2.60 (2H, d, 5.5), 1.40 (9H, s).

Alternatively, *S*-tritylcysteine (1.093 g, 3 mmol) was suspended in chloroform (6 mL), and dicyclohexylamine (0.66 mL, 3.3 mmol, 99% pure) was added to yield a clear solution. BOC-ON (Aldrich, 0.81 g, 3.3 mmol) was added in one portion, and the solution was stirred at room temperature for 18 h. The chloroform was then removed under reduced pressure to yield a viscous yellow oil, to which was added diethyl ether (50 mL). After chilling at −20°C, the white precipitate was collected, washed with ether, and dried to give 1.782 g (96%) of product, mp 207–211°C; $[\alpha]_D = +23.8°$ (*c* 1, CH_3OH, 1.0 dm cell).

Bis-N-*BOC*-L-*cystinyl-bis*-D-*valine Bisbenzhydryl Ester (7)*

N-BOC-*S*-trityl-L-cysteine dicyclohexylammonium salt (3.04 g, 4.9 mmol) was converted to the free acid by partition between ethyl acetate (25 mL) and 10% aqueous potassium hydrogen sulfate (25 mL), followed by a second washing of the organic phase with aqueous potassium hydrogen sulfate, and then brine (25 mL). The organic layer was dried over anhydrous sodium sulfate, and to the solution was added D-valine benzhydryl ester *p*-toluenesulfonic acid salt (2.46 g, 5.39 mmol, 1.1 equiv.), *N*-methylmorpholine (0.55 g, 5.39 mmol), EEDQ (1.27 g, 5.15 mmol, 1.05 equiv.), and ethyl acetate (25 mL). After 2 days at room temperature, the solution was washed successively with 10% aqueous potassium bisulfate (3 × 40 mL), saturated sodium chloride (1 × 40 mL), saturated sodium bicarbonate (2 × 40 mL), and saturated sodium chloride (1 × 40 mL). It was then dried over anhydrous sodium sulfate and evaporated to yield a foam: 3.51 g (98% crude yield).

To a solution of the foam (3.29 g, 4.52 mmol) in methanol (20 mL) and pyridine (1 mL, 12 mmol) was added a solution of iodine (1.20 g, 4.73 mmol, 1.05 equiv.) in methanol (10 mL). A precipitate began to form within 2 min, and additional methanol (20 mL) was added to facilitate stirring. After 1 h of stirring at room temperature, the precipitate was collected and washed with methanol. To the filtrate was added 10% aqueous sodium bisulfite to destroy residual iodine. The filtrate was concentrated *in vacuo*, and additional sodium bisulfite was added to yield a precipitate, which was collected and combined with the first precipitate. The crude product (the dipeptide disulfide and trityl methyl ether) was dissolved in chloroform (60 mL), washed once with water (20 mL), dried over anhydrous sodium sulfate, and evaporated. Petroleum ether (30 mL) was added to the residual white solid, and the dipeptide was recovered by filtration, after grinding of the powder with the solvent: 1.90 g. Recrystallization from chloroform–methanol gave 1.66 g (75% from *N*-BOC-*S*-trityl-L-cysteine), mp 167–169°C, $[\alpha]_D = +30°$ (*c* 2, $CHCl_3$, 0.1 dm cell). The material travelled as a single spot, R_f 0.80, on aluminum-backed silica gel G plates in 1:1 ethyl acetate – petroleum ether, visible with short wave ultraviolet; not positive to ninhydrin, but became positive after heating with a drop of trifluoroacetic acid (yellow spot); ir (KBr): 3330, 3310, 1734 (ester), 1677 (urethane), 1646 cm^{-1} (amide); ^{1}Hmr: 7.44 (1H, d, J = 10 Hz, exchanges with D_2O), 7.26 (10H, s), 6.88 (1H, s), 5.54 (1H, d, J = 9 Hz, exchanges with D_2O), 4.88–4.52 (2H, m), 3.02–2.92 (2H, m), 2.45–2.00 (1H, m), 1.42 (9H, s), 0.90 (3H, d, J = 7 Hz), 0.84 (3H, d, J = 7 Hz). *Anal.* calcd. for $C_{52}H_{66}N_4S_2O_{10}$: C 64.30, H 6.85; found: C 64.25, H 7.08.

L-*Cystinyl-bis*-D-*valine*

To a mixture of trifluoroacetic acid (10 mL, distilled from phosphorus pentoxide) and anisole (1.0 mL, distilled *in vacuo* from anhydrous calcium chloride) was added 7 (1.65 g, 1.70 mmol). The material dissolved immediately, with evolution of gas, to give a clear, yellow solution. This was stirred for 1 h at room temperature, during which time a yellow precipitate formed. The trifluoroacetic acid was removed *in vacuo*, and ether (60 mL) was added to the residue. A precipitate formed, but it dissolved immediately upon the addition of water (40 mL). After agitation of the mixture, the aqueous phase was removed, and the ether phase was extracted a second time with water (40 mL). The combined aqueous extracts were evaporated *in vacuo* to yield a glassy foam. This was dissolved in water (4 mL), and pyridine was added dropwise until the pH

(initially about 0) was raised to 5–6. A white precipitate formed almost immediately. Absolute ethanol (8 mL) was added, and the precipitated L-cystinyl-bis-D-valine was collected after chilling at 5°C for several hours: 0.63 g (85%); $[\alpha]_D = +88°$ (*c* 2, 2 *N* HCl, 0.1 dm cell); ir (KBr): 1687, 1630, 1570–1510 cm^{-1}; ^{1}Hmr (trifluoroacetic acid + TMS): 8.3–7.3 (4H, m, contains d, $J = 8$ Hz; all exchange with TFA-*d*), 5.2–4.6 (2H, m, contains q, $J = 4.5$ Hz, 8 Hz: with TFA-*d*, 2H, m, contains d, $J = 4.5$ Hz), 3.50 (2H, d, 6), 2.8–2.0 (1H, m), 1.13 (6H, d, 6). Analytical tlc (silica gel): R_f 0.58 (applied as the trifluoroacetate salt; 2:1 isopropanol–water), 0.17 (applied as the free dipeptide in water; *n*-butanol – acetic acid – water, 4:1:4). The compound was visible with short wave uv, and gave a yellow spot with ninhydrin. *Anal.* calcd. for $C_{16}H_{30}N_4O_6S_2 \cdot 2H_2O$: C 40.49, H 7.22, N 11.81; found: C 40.42, H 6.96, N 11.57.

N,S-*Dityrityl*-L-*cysteine*

S-Tritylcysteine (3.63 g, 10 mmol) was suspended in methylene chloride (30 mL), and the mixture was cooled in ice. A homogeneous solution resulted when diisopropylamine (3.0 mL, 21 mmol, distilled from potassium hydroxide) was added. Solid triphenylmethyl chloride (2.93 g, 10.5 mmol, recrystallized from benzene plus acetyl chloride) was then added in five portions over 10 min, with continued cooling, and the solution was stirred for 2.5 h at room temperature. Additional methylene chloride (10 mL) was added at 90 min to facilitate the stirring. The solvent was removed under reduced pressure and the residue was triturated with water (100 mL) for 1 h. Then additional water (50 mL) and diethyl ether (50 mL) were added, whereupon the insoluble material solidified, 5.92 g. Recrystallization from hot chloroform – diethyl ether yielded 5.07 g (72%) of off-white solid, mp 169–175°C (dec.).

For conversion to the free acid, the salt (2.00 g, 2.83 mmol) was partitioned between ethyl acetate (30 mL) and 5% aqueous potassium hydrogen sulfate (20 mL). The organic phase was washed again with potassium bisulfate (20 mL), water (20 mL), and then dried over anhydrous sodium sulfate and evaporated. The residual oil was triturated with petroleum ether, to yield 1.68 g (98%) of the free acid as an amorphous solid, mp 111–119°C (dec.). This was crystallized from benzene – petroleum ether: 1.59 g (93%), mp 116–118°C (dec.) (lit. (17) mp 125–128°C); $[\alpha]_D = +71°$ (*c* 1, CH_3OH) (lit. (17) $[\alpha]_D = +70°$); ir (KBr): 1703 cm^{-1}; ^{1}Hmr (CCl_4 + TMS): 7.9–6.5 (30H, m), 3.47–3.03 (1H, m), 2.60–2.23 (2H, m).

N,S-*Dityrityl*-L-*cysteine* N-*Hydroxysuccinimide Ester (**10**)*

N,S-Dityrityl-L-cysteine (2.88 g, 4.75 mmol) and *N*-hydroxysuccinimide (0.60 g, 5.23 mmol, 1.1 equiv.) were dissolved in dimethoxyethane (4 mL). The solution was cooled in ice, and dicyclohexylcarbodiimide (1.08 g, 5.23 mmol, 1.1 equiv.) in dimethoxyethane (2 mL) was added, followed by more dimethoxyethane (2 mL). Dicyclohexylurea began to precipitate almost immediately. The solution was warmed to room temperature by allowing the ice to melt, and was stirred for a total of 19 h. The urea was then collected, washed with dimethoxyethane and dried (1.12 g, 96% of theory). Evaporation of the mother liquors afforded a golden oil which solidified, upon scratching and chilling with isopropanol (20 mL), to give, after drying *in vacuo*, 3.73 g of a pale yellow solid (20). The ^{1}Hmr spectrum of this material indicated the presence of between one and two solvated molecules of isopropanol. The crude product was recrystallized from benzene – petroleum ether (17) to give 2.94 g of white crystals (79%, lit. (17) 89%, one benzene molecule solvate), mp 119–125°C (dec.) (lit. (17) mp 130°C), $[\alpha]_D = +62°$ (*c* 2, $CHCl_3$) lit. (17) $[\alpha]_D = +64°$); ir (KBr): 1796(w), 1763(m), 1730(s); ^{1}Hmr: 7.7–6.9 (36H, m, approximately 6H removable by evaporation of the nmr sample), 4.0–3.5 (1H, m), 2.8–2.3 (7H, m, 1H exchanges with D_2O).

Rotation of N,S-*Dityrityl*-L-*cysteine* N-*Hydroxysuccinimide Ester in Ethyl Acetate Containing Triethylamine*

Two solutions of *N,S*-dityrityl-L-cysteine *N*-hydroxysuccinimide ester (50 mg/mL) in 9:1 (v:v) ethyl acetate – triethylamine were prepared. To one of these was added 1 equiv. (5 mg/mL) of 1,2,4-triazole. Each solution was kept at room temperature, and its optical rotation was measured periodically. The results are shown in Table 1.

In tetrahydrofuran in the presence of triethylamine, *N*-carbobenzoxy-*S*-benzyl-L-cysteine *N*-hydroxysuccinimide ester is reported (22) to have a second order racemization rate constant, $K_{rac} = 4.88 \times 10^{-3} M^{-1}$ s^{-1}. This would result in almost total racemization within 20 min.

S-*Trityl*-L-*cysteinyl*-D-*valine Benzhydryl Ester Hydrochloride*

D-Valine benzhydryl ester *p*-toluenesulfonic acid salt (1.51 g, 3.3 mmol, 1.2 equiv.) was partitioned between ethyl acetate (6 mL) and 5% sodium carbonate (6 mL). The aqueous phase was separated, and the organic phase was washed once with saturated sodium chloride (6 mL) and dried over anhydrous sodium sulfate. The solution was then mixed with *N,S*-dityrityl-L-cysteine *N*-hydroxysuccinimide ester (2.15 g, 2.75 mmol), and ethyl acetate (4 mL), triethylamine (0.38 mL, 2.75 mmol), and 1,2,4-triazole (0.19 g, 2.75 mmol) were added. The solution was stirred at room temperature for 36 h and then, after dilution with ethyl acetate (10 mL), was washed successively with 10% potassium hydrogen sulfate (3 × 20 mL) saturated sodium chloride (1 × 20 mL), saturated sodium bicarbonate (3 × 20 mL), and saturated sodium chloride (1 × 20 mL). It was then dried over anhydrous sodium sulfate and evaporated to give 2.50 g of a foam. Analytical chromatography on silica gel (ethyl acetate – petroleum ether – pyridine 50:40:10) showed a major uv positive spot at R_f 0.88, and minor spots at R_f 0.70, 0.15. The crude product (**8**) was detritylated without purification.

The crude dipeptide (2.50 g) was dissolved in reagent grade glacial acetic acid (16 mL), and water (4 mL) was added dropwise with stirring (32). A white gum precipitated during the course of the addition. After the addition of the water, the mixture was agitated for 1 h, and by this time the gum had partially dissolved. The clear supernatant was decanted and retained. The gum was redissolved in acetic acid (16 mL), and a clear homogeneous solution resulted when this was added dropwise to the supernatant. Water (4 mL) was added dropwise to the mixture and the resulting clear solution was stirred for an additional 30 min at room temperature. More water (28 mL) was then added slowly, and the precipitated triphenylmethanol was removed by filtration and dried (0.71 g, 99% of theory). The cloudy filtrate was evaporated *in vacuo* below 35°C to give a clear oil which was dissolved in ethyl acetate (100 mL). This solution was washed with saturated sodium bicarbonate (2 × 100 mL), saturated sodium chloride (1 × 50 mL), dried over anhydrous sodium sulfate, and concentra-

TABLE 1. Optical rotation measurements

Time (h)	$[\alpha]_D$ (no triazole) (°)	Time (h)	$[\alpha]_D$ (triazole added) (°)
0	+36.4	0	+40.6
1	+36.2	0.75	+41.8
2	+37.0	4.5	+42.0
11	+37.6	24	+41.4
35	+39.2	52	+41.2

ted *in vacuo* to about 20 mL. A solution of hydrogen chloride in absolute ethanol (2.38 *M*, 1.20 mL, 1.05 equiv.) was added dropwise with shaking, and the solvent was removed *in vacuo* to give a foam which solidified upon trituration with petroleum ether (20 mL): 1.50 g (82%) of the dipeptide ester hydrochloride, mp 80–98°C (dec.); $[\alpha]_D = +26°$ (*c* 2, $CHCl_3$); ir (KBr): 1728 (ester), 1680 cm^{-1} (amide); ^{1}Hmr: 8.8–7.6 (4H, m, exchanges with D_2O), 7.6–6.9 (25H, m), 6.82 (1H, s), 4.8–4.4 (1H, m; D_2O d, $J = 4.5$ Hz), 4.3–3.7 (1H, m; D_2O shifted to 4.0–3.6δ), 3.0–2.6 (2H, m), 2.5–1.9 (1H, m), 0.9–0.6 (6H, m).

*Fully Protected ACV (**9**)*

N-BOC-α-benzhydryl-L-α-aminoadipic acid, freed from the dicyclohexylamine salt (853 mg, 1.4 mmol) in the usual manner, was mixed with *S*-trityl-L-cysteinyl-D-valine benzhydryl ester hydrochloride (928 mg, 1.4 mmol) in ethyl acetate (5 mL). Triethylamine (0.195 mL, 1.4 mmol), and EEDQ (371 mg, 1.5 mmol) were added, and the mixture was stirred at room temperature for 30 h. It was then diluted with ethyl acetate (5 mL), and extracted successively with 10% potassium hydrogen sulfate (2 × 5 mL), saturated sodium chloride (1 × 5 mL), saturated sodium bicarbonate (2 × 5 mL), and saturated sodium chloride (1 × 5 mL). After drying of the organic phase over anhydrous sodium sulfate, evaporation yielded a foam, which solidified upon trituration with petroleum ether: 1.24 g. The crude product was recrystallized from ethyl acetate – petroleum ether to give 0.95 g (65%) of fully protected ACV, mp 97.5–101°C; $[\alpha]_D = -8°$ (*c* 2, $CHCl_3$); ir (KBr): 1736(s), 1704(w), 1680(m), 1647(s) cm^{-1}; ^{1}Hmr: 7.6–7.1 (35H, m), 6.89 (2H, s), 6.63 (1H, d, $J = 9$ Hz, exchanges with D_2O), 4.55 (1H, q, 9,4; D_2O d, $J = 4$ Hz), 4.4–3.9 (2H, m), 2.8–2.5 (2H, m), 2.2–1.1 (16H, m), 0.85 (3H, d, 7.5), 0.73 (3H, d, 7.5). Analytical tlc (silica gel): R_f 0.78 (50:50 petroleum ether – ethyl acetate), 0.63 (60:35:5 petroleum ether – ethyl acetate – diethylamine). The compound was visible with short wave uv, was negative to ninhydrin, and became positive to ninhydrin after heating with a drop of trifluoroacetic acid. *Anal.* calcd. for $C_{64}H_{67}N_3O_8S$: C 74.03, H 6.51, N 4.05, S 3.09; found: C 74.13, H 6.76, N 3.89, S 3.27.

*Detritylation of **9***

Fully protected ACV (2.08 g, 2.00 mmol) was dissolved in ethyl acetate (20 mL), and methanol (40 mL) was added with stirring. Pyridine (0.65 mL, 8 mmol), followed by iodine (0.517 g, 2.04 mmol), in methanol (5 mL), were added, and the mixture was allowed to stand for 1 h at room temperature. No precipitate had formed by this time, and analytical tlc indicated that the reaction was proceeding more slowly than expected. The solution was therefore concentrated to a volume of 10 mL, and methanol (30 mL) was added. A precipitate began to form within 2 h, and it was collected after additional stirring for 23 h. The solid was washed with methanol and then dissolved in chloroform (20 mL), and decolourized by shaking with 10% aqueous sodium bisulfite (20 mL). Evaporation of the methanol washings yielded 102 mg (5%) of unreacted **9**, mp 98–105°C. The chloroform layer was separated, and the aqueous phase was extracted with additional chloroform (10 mL). The combined chloroform extracts were dried over anhydrous sodium sulfate, filtered, and evaporated to yield a foam: 1.37 g. Trituration of the foam with petroleum ether removed trityl methyl ether and gave 1.13 g of solid, which was recrystallized from methanol to yield the product: 1.02 g (64%), mp 139–140.5°C; $[\alpha]_D = +7°$ (*c* 2, $CHCl_3$, 0.1 dm cell); ir (KBr): 1736(s), 1710(m), 1680(m), 1638(s) cm^{-1}; ^{1}Hmr: 8.46 (1H, d, $J = 9$ Hz), 7.5–7.1 (20H, m), 6.87 (2H, s), 6.53 (1H, d, 8), 5.6–5.4 (1H, br s), 5.15 (1H, d, 8, exchanges with D_2O), 4.7–4.5 (1H, m), 4.5–4.25 (1H, br s), 3.1–2.8 (2H, m), 2.4–1.3 (16H, m), 1.10–0.80 (6H, m). Analytical tlc (silica gel): R_f 0.71 (50:50 petroleum ether – ethyl acetate), 0.79 (19:1 methanol–diethylamine). The compound was revealed with short wave uv, and became ninhydrin-positive after treatment with trifluoroacetic acid. No other spots were revealed with either treatment. *Anal.* calcd. for $C_{90}H_{104}N_6O_{16}S_2$: C 68.00, H 6.59, N 5.29, S 4.03; found: C 67.46, H 6.66, N 5.19, S 4.17.

ACV Disulfide

To a mixture of trifluoroacetic acid (3.6 mL, distilled from phosphorous pentoxide) and anisole (0.36 mL, distilled *in vacuo* from anhydrous calcium chloride) was added bis-δ-(*N*-BOC-L-α-aminoadipyl)-L-cystinyl-bis-D-valine tetrabenzhydryl ester (639 mg, 0.4 mmol). The material dissolved immediately, with evolution of gas, to give a clear, yellow solution. A yellow precipitate formed within a few minutes. The mixture was stirred for 1 h at room temperature. The trifluoroacetic acid was then removed *in vacuo* below 30°C, and the residual yellow slurry was dissolved in water (10 mL) and diethyl ether (20 mL). The aqueous phase was removed, filtered to remove a small amount of solid, and the ether phase was washed again with water (5 mL). The combined aqueous fraction was concentrated *in vacuo* below 30°C to about 1 mL, and then further under high vacuum overnight to 0.5 g of a glassy foam. This was dissolved in water to give about 2 mL of solution, and the pH was adjusted to 2.9 with 10% aqueous pyridine. A precipitate formed quickly, and the mixture was diluted to 10 mL with absolute ethanol. After 6 h at 4°C, the precipitate was collected and dried *in vacuo*: 240 mg (83%) of white crystalline solid, mp 236–237°C (dec.); $[\alpha]_D = -11°$ (*c* 2, 2 *N* HCl) (lit. (8) $[\alpha]_D = -9.5°$ (*c* 2, 2 *N* HCl)); ir (KBr): 1700(m), 1630(s), 1520(s) cm^{-1}; ^{1}Hmr (TFA + TMS): 8.1–7.2 (5H, m; exchanges with TFA-*d*), 5.4–4.9 (1H, m; with TFA-*d*, vague triplet, $J = 6$ Hz), 4.9–4.2 (2H, m; with TFA-*d*: 1H, d, $J = 4$ Hz at 4.72δ, and 1H, m at 4.6–4.3δ), 3.5–3.0 (2H, d, $J = 6$ Hz), 2.9–1.75 (7H, m), 1.13 (6H, d, 7). Analytical tlc (silica gel): R_f 0.20 (applied as the trifluoroacetate salt; *n*-butanol – acetic acid – water 4:1:4). The compound was visible with short wave uv, and gave a red spot with ninhydrin. *Anal.* calcd. for $C_{28}H_{48}N_6O_{12}S_2 \cdot 1.5H_2O$: C 44.73, H 6.84, N 11.18, S 8.53; found: C 44.66, H 7.03, N 10.91, S 8.47.

Total synthesis of 14β-hydroxy-4,9(11)-androstadiene-3,17-dione

ANDRZEJ ROBERT DANIEWSKI,[1] PETER S. WHITE, AND ZDENEK VALENTA
Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received February 16, 1979

ANDRZEJ ROBERT DANIEWSKI, PETER S. WHITE, AND ZDENEK VALENTA. Can. J. Chem. **57**, 1397 (1979).

The title compound **8**, a potential intermediate in the total synthesis of cardiac-active principles and other polyfunctional steroids, is prepared in nine steps using methyl vinyl ketone and 2-methylcyclohexane-1,3-dione as starting materials and acetylene and 2-methylcyclopentane-1,3-dione as additional sources of carbon atoms. In a crucial aldol condensation leading to the closure of steroid ring *C*, an efficient asymmetric induction by one chiral center leads to the establishment of three new chiral centers.

Since the total synthesis of equilenin by Bachman, Cole, and Wilds in 1939 (1), the challenge presented by the preparation of more complex steroids has led during the past forty years to spectacular advances in synthetic methodology and in synthetic regio- and stereocontrol.[2] Interest in steroid total synthesis continues unabated because of the possibility of the discovery of new compounds with important biological activity and because of the continuing challenge in finding the simplest possible synthetic pathways.

We wish to report a synthesis of dione **8** in which known (3) intermediate **5** containing one chiral center is, after the introduction of a C(6)—C(7) double bond,[3] converted by an aldol condensation into the 14β-hydroxyandrostane derivative **7** containing four chiral centers. The chiral starting material, dione **1**, is accessible in two steps from methyl vinyl ketone and 2-methylcyclohexane-1,3-dione in an asymmetric synthesis using (*S*)-proline (6, 7). Racemic **1** was used for the synthesis reported in this communication. The previously reported (8) treatment of **1** with lithium acetylide followed by hydrogenation in pyridine solution (9) gives allyl alcohol **3**.

Treatment of **3** with thionyl chloride in methylene chloride and dimethyl formamide at −60°C to −40°C gave crude chlorocompound **4** which was not purified because of its instability. Compound **4** in dimethyl formamide was treated sequentially with sodium iodide and with the sodium salt of 2-methylcyclopentane-1,3-dione in methanol. The resulting racemic trione **5**, mp 79–81°C, was obtained in 69% yield based on **3**.[4] Dehydrogenation of **5** with DDQ in dioxane containing HCl (10) gave crude triene **6** which on treatment with sodium methoxide in anhydrous methanol for 2 h at room temperature gave tetracyclic triene **7**, mp 219–225°C (dec.), in a 30% yield based on **5**.[5] No isomeric tetracyclic compound could be isolated.[5] Finally, hydrogenation of **7** with 2% Pd on $SrCO_3$ in benzene and ethanol gave (*d,l*)-**8**, mp 170–172°C, in 85% yield.

The structure of compound **8** was established by X-ray diffraction.

A four-step sequence performed on **8** and involving Li–NH_3 reduction, reoxidation of secondary alcohols,

[1]On leave of absence from the Institute of Organic Chemistry of the Polish Academy of Sciences, Warsaw, Poland.

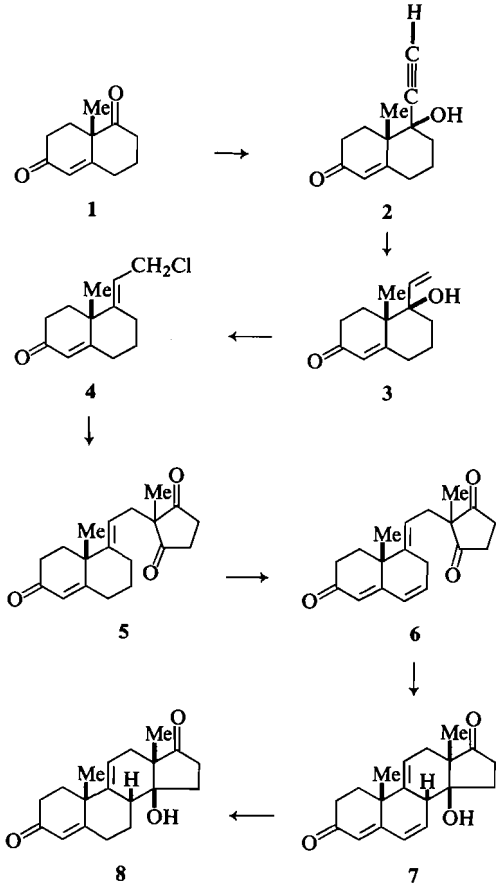
[2]For comprehensive reviews, see ref. 2.

[3]The ring *A* aromatic analogue of **5** was, following the key discovery by Ananchenko and Torgov in 1959 (4), converted in several laboratories (5) into estrone and its derivatives in a sequence so remarkably simple that we are presently able to use an adapted estrone synthesis as a one-term preparation in an introductory undergraduate laboratory (Ž. Stojanac and G. Reid, unpublished). Unfortunately, the crucial cyclization of steroid ring *C* of this sequence does not work without the activation by the aromatic ring or an equivalent (e.g. enol ether) and the method can thus not be used as such for the synthesis of C(10)-methylated steroids.

[4]Optically active **5** is known (3). Our procedure using chloride **4**, iodide exchange, and methanol improves the yield significantly.

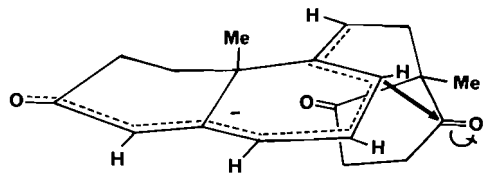
[5]Crude **6** contains ~20% of **5** from which it cannot conveniently be separated by chromatography. A maximum yield of 40% for the conversion **5** → **7** was realized in a longer sequence involving bromination and dehydrobromination of the enol-acetate of **5**. **6** was also prepared by an alternative sequence in which **3** was first converted by DDQ in 72% yield to 6,7-dehydro-**3**, mp 101–102°C.

0008-4042/79/111397-02$01.00/0



catalytic hydrogenation (Pt/HOAc), and acetylation gave racemic 3β-acetoxy-14β-hydroxyandrostan-17-one, mp 182–184°C, nmr values of which agree with those reported for the optically active compound (11).

The specificity of cyclization **6** → **7**, involving only one out of eight theoretically possible transition states, probably arises from a particularly favourable angle of attack (12) indicated in formula **9**.[6]



The presence of the 14β-hydroxyl group and additional functionality in compounds **7** and **8**, the relative efficiency and brevity of the synthetic sequence, and the ready availability of starting material **1** in chiral form (6, 7) should make the reported androstane derivatives suitable as intermediates in total syntheses of cardiac-active principles (13) and other polyfunctional steroids.

[6]Kinetic control of the reaction is probable, but not rigorously proven.

Stereocontrolled Diels–Alder reactions with a bifunctional dienophile

MASATOSHI KAKUSHIMA AND DANIEL G. SCOTT

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received February 5, 1979

MASATOSHI KAKUSHIMA and DANIEL G. SCOTT. Can. J. Chem. **57**, 1399 (1979).

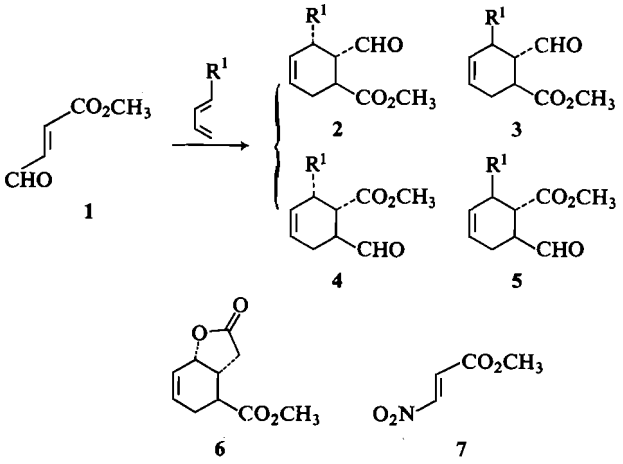
In the Diels–Alder cycloaddition of electron-rich dienes to methyl *E*-4-oxobutenoate, the formyl group controls both regio- and stereoselectivity. Secondary overlap considerations are used to explain these results.

MASATOSHI KAKUSHIMA et DANIEL G. SCOTT. Can. J. Chem. **57**, 1399 (1979).

Lors de la cycloaddition selon Diels–Alder de dièmes riches en électrons sur l'oxo-4 buténoate de méthyle (*E*), le groupe formyle contrôle la régio- ainsi que la stéréo-sélectivité. On fait appel à des considérations de recouvrements secondaires pour expliquer ces résultats.

[Traduit par le journal]

Regioselectivity of Diels–Alder reactions has been successfully predicted by frontier molecular orbital theory in the case of relatively simple systems (1). However, controversy has arisen on the subject of the importance of secondary overlap on the stereochemical outcome of the reaction (2–4). In this communication, we hope to demonstrate how secondary overlap considerations may enhance the synthetic utility of Diels–Alder reactions.



As summarized in Table 1, the addition of electron-rich dienes to methyl *E*-4-oxobutenoate (**1**) produces the isomer **2** as the major adduct.[1] It is evident that the formyl group of **1** controls regioselectivity better than the methoxycarbonyl group. Interestingly, Danishefsky *et al.* (6) have reported that the nitro group of **7** completely controls regioselectivity in such additions. The magnitudes of the LUMO coefficients at C-2 and C-3 of both **1** and **7** as listed in Table 2 agree with the observed regioselectivity. There is, however, a large difference in character between a formyl group and a nitro group: the nitro group of **7** fails to control *endo* stereoselectivity (6), while the formyl group of **1** does control it. This difference can be rationalized as follows. As shown in Table 2, the difference in the magnitudes of the LUMO coefficients at C-1 and *N* of **7** is larger than that in the magnitudes of the LUMO coefficients at C-1 and C-4 of **1**, which would normally lead to the nitro group being *endo* due to a secondary attractive

[1]The structure of **2***c* ($R^1 = OSi(CH_3)_3$) was established as follows. Hydrolysis followed by treatment with pyrrolidine gave a conjugated aldehyde: ir ($CHCl_3$) 1672, 1720, and 2720 cm^{-1}; λ_{max} (EtOH) 300 nm (log ε 4.2). Homologation of **2***c* with $(C_6H_5)_3P{=}CHOCH_3$ followed by hydrolysis gave an epimeric mixture of hemiacetals, which was then oxidized to the γ-lactone **6**: ir (CCl_4) 1730 and 1785 cm^{-1}. The overall yield of the conversion **1** → **6** is 58%. The stereochemistry of **2***b* ($R^1 = OCH_3$) and **2***c* was determined by comparison of the 220 MHz nmr spectra with the spectrum of **2***a* ($R^1 = CH_3$) (5) and both product ratios were based on the integration of the aldehydic protons. Oxidation of **2***b* with Jones' reagent followed by treatment with CH_2N_2 gave a mixture of the corresponding dimethyl esters in a ratio of 5:1.

interaction (2), but closed-shell repulsion[2] due to the large exclusion shell[3] at *N* of **7** must counteract this attraction. The experimental results (*endo*:*exo* ≃ 1:1) (6) indicate that the closed-shell repulsion should be of the same order of magnitude as the secondary attractive interaction.[4] Since the exclusion shell at C-4 of **1** is much smaller than that at *N* of **7**, the secondary attractive interaction overcomes closed-shell repulsion and the isomer **2** is therefore preferred.

As demonstrated by the formyl group of **1**, a substituent with a large LUMO coefficient and a small exclusion shell is most likely to assume *endo* geometry. A quantitative assessment of several effects (terminal (1, 3) and secondary (2) attractive interactions and closed-shell repulsion (7)) on the stereochemical outcome of Diels–Alder reactions is clearly difficult.[5] However, careful model studies with MO calculations will make it possible to advance our understanding of cycloadditions.[7]

The combination of different electron-attracting groups on the dienophile (*E* or *Z*), as indicated above, opens a way to the stereo-specific construction of synthetically useful cyclohexenes. The preparation of several types of dienes has been reported (13).

Acknowledgments

We would like to express our sincere appreciation to Professor Z. Valenta for his encouragement, suggestions, and ample financial support. Also we thank Professor F. Grein for helping us with the computations and Mr. D. J. Burnell for enlightening discussions.

2. P. V. ALSTON, R. M. OTTENBRITE, and D. D. SHILLADY. J.

[2]Salem (7) derived an expression for the total energy of interaction as a function of the total repulsive energy due to the "exclusion shell" around each atom, and the total attractive energy, due to the mixing of occupied orbitals on one molecule with unoccupied orbitals on the other. Closed-shell repulsion has also been discussed in detail by other groups (8).

[3]Since the coefficients of $2P_z$ orbitals are discussed for attractive interactions by FMO theory (1–4), the gross orbital charges of $2P_z$ orbitals should be considered for repulsive interactions.

[4]Alston (2) has also reported that the reactions with β-nitrostyrene produce almost 1:1 mixtures of the *endo* and *exo* isomers.

[5]Other effects, such as steric attraction (9), schizophrenic tendency (10), steric (11) and attractive effects on primary bond-forming termini (12), nuclear-nuclear repulsion[6] and solvent effect, may have to be considered.

[6]A point from a referee.

[7]Details on the two opposing effects in a model system will be reported shortly.

The thermal chemistry of vinyldiazo compounds as a method for the generation of vinylmethylenes

JAMES A. PINCOCK and KIM P. MURRAY
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received October 30, 1978

JAMES A. PINCOCK and KIM P. MURRAY. Can. J. Chem. **57**, 1403 (1979).

The thermal chemistry of a series of substituted 1-aryl-3-methyl-2-phenyl-1-diazobut-2-enes has been examined. These vinyldiazo compounds react in two parallel pathways: cyclization to a 3-aryl-5,5-dimethyl-4-phenyl-5*H*-pyrazole or loss of nitrogen and cyclization to a 1-aryl-2-phenyl-3,3-dimethylcyclopropene presumably by a vinylmethylene intermediate. The kinetics of these processes reveal quite different substituent effects. The relation of these results to the stability of the vinylmethylene produced and to the singlet photochemistry of cyclopropene derivatives is discussed.

JAMES A. PINCOCK et KIM P. MURRAY. Can. J. Chem. **57**, 1403 (1979).

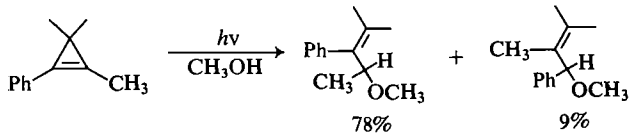
On a étudié la thermochimie d'une série d'aryl-1 méthyl-3 phényl-2 diazo-1 butènes-2 substitués. Ces composés vinyldiazo réagissent par deux voies parallèles: une cyclisation conduisant à l'aryl-3 diméthyl-5,5 phényl-4 5*H*-pyrazole ou une perte d'azote et une cyclisation en aryl-1 phényl-2 diméthyl-3,3 cyclopropène probablement par un intermédiaire vinylméthylène. Des études cinétiques de ces processus révèlent des effets de substituants importants. On discute de la relation qui existe entre ces résultats et la stabilité du vinylméthylène qui est produit ainsi que la photochimie singulet des dérivés du cyclopropène.

[Traduit par le journal]

Introduction

The photochemical reactivity of the singlet excited state of cyclopropene derivatives has generally been explained in terms of σ bond cleavage and the chemistry of the vinyl methylenes formed (1–3). However, recent results for cases with unsymmetrical substitution on the double bond (1, 2, 4, 5) have led to considerable speculation as to the effect of these substituents on ring cleavage. Some examples are summarized in reactions [1] to [4].

[1][1]



[2][2]

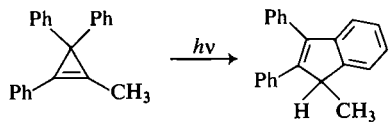
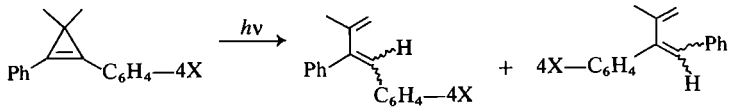
[3][3]



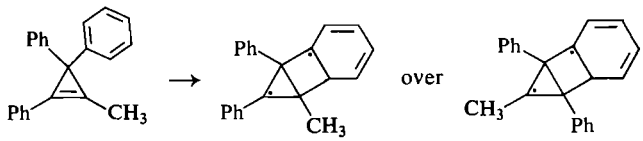
[4][4]



X = OCH_3	74%	26%
X = CN	<2%	98%

The first three cases indicate that σ bond cleavage is occurring on the methyl rather than the phenyl substituted side; the last example gives cleavage on the side that is substituted by the better electron donating aromatic ring. Zimmerman has suggested (4) that the reactions do not involve vinylmethylenes but rather housane biradicals.

[5]



Ring cleavage is then controlled by the better delocalization of odd electron density by phenyl over methyl (note reaction [5]). This mechanism cannot apply to the cases (reactions [1] and [4]) that do not have π-systems at carbon 3. Moreover, optically active cyclopropenes (reaction [2]) have been shown to racemize photochemically (2) and this is more compatible with a planar vinylmethylene intermediate than the non-planar biradical. Padwa *et al.* (1) have invoked, among several explanations, inductive destabilization by phenyl substitution at the developing biradical formed by σ bond cleavage as the controlling factor. This explanation does not hold for Arnold's results (reaction [4]) since both methoxy and cyano should be inductively electron-withdrawing and therefore cleavage at the unsubstituted phenyl side should be preferred for both substrates. Clearly a better understanding of substituent effects on vinylmethylene stability is required before these results can be interpreted.

Besides the evidence for singlet photochemistry, vinylmethylenes have attracted considerable recent interest both on theoretical grounds (6–9) and as intermediates in the thermal (10) chemistry of cyclopropenes. As has been discussed several times their properties are expected to be complicated because there should be several low-lying states of similar energy as a result of the two free valences at the methylene carbon. These are summarized in Fig. 1.

The non-planar **1***a*, a singlet biradical, is the suggested transition state for thermal σ bond cleavage of cyclopropenes (6, 10). Although a triplet **1***a* is possible, excited triplet cyclopropenes do not in general (for some exceptions, note ref. 4) react by bond cleavage but instead dimerize (12). As well, for suitably substituted cyclopropenes, polar cleavage to zwitterion **1***b*:**1***c* might be preferred. For the planar vinylmethylene, **2**, four states are again possible: a singlet and triplet corresponding to **2***a* and two singlets **2***b* (designated 2π (6) or σ^2 (9)) and **2***c* (4π or p^2). Both calculations and esr results (13, 14) give triplet **2***a* as the most stable state. Singlet **2***a* correlates with **1***a* and is the likely first-formed intermediate in the thermal reactions of cyclopropenes (10). Padwa *et al.* have observed that a 1-methyl-2-phenylcyclopropene cleaves thermally at the phenyl substituted σ bond (1) as expected based on arguments of delocalization. The most stable singlet by calculations (6) is **2***b*. The correlation between singlet excited cyclopropenes and the possible vinylmethylenes is not as yet clear.

Vinylmethylenes can also be generated by the

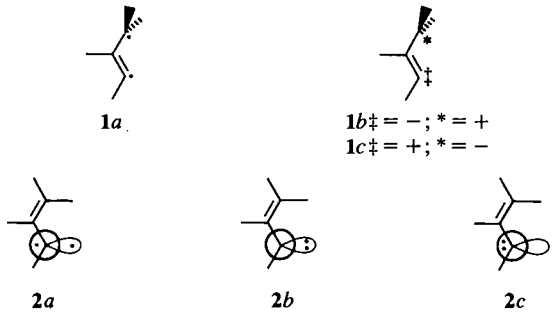


FIG. 1. Geometries and electronic configurations of vinylmethylene.

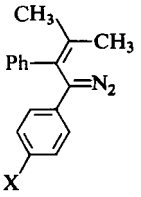
[3]Reference 4.
[4]Reference 5.

thermal decomposition of vinyldiazo compounds (3). Rate constants for this process should be directly related to vinylmethylene stabilities. This is not necessarily true for the photochemical and thermal results for cyclopropenes where the process leading to vinylmethylenes may be complicated by reversibility (2, 10). In view of this, we have examined the thermal chemistry of the vinyldiazo compounds **3***a*–**3***e* as a method of assessing substituent effects on vinylmethylene stabilities.



3*a* X = OCH_3

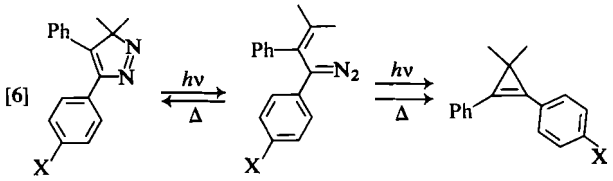
Results and Discussion

Preparation of 1-Aryl-3-methyl-2-phenyl-1-diazobut-2-enes

As has been reported previously, vinyldiazo compounds **3** can be generated by photolysis of the corresponding 5*H*-pyrazoles **4** (3, 13). This must be done with filtered light in order to avoid photochemical decomposition of the diazo compound to 1-aryl-2-phenyl-3,3-dimethylcyclopropenes, **5**. The conversion is easily monitored by ^{1}H nmr spectroscopy and the photolysis terminated when the relative amount of **3** is at a maximum (see Experimental). The 5*H*-pyrazoles were prepared by the sequence shown in Scheme 1: **4***a*, **4***c*, and **4***e* are known (3, 13); **4***b* and **4***d* are new compounds.

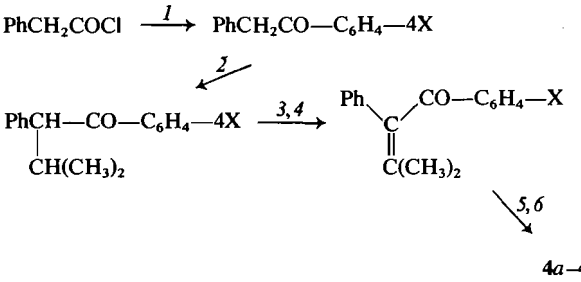
[6]



4*a*–*e* **3***a*–*e* **5***a*–*e*

Thermal Decomposition of 1-Aryl-3-methyl-2-phenyl-1-diazobut-2-enes

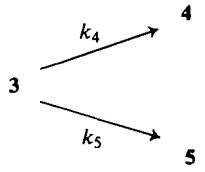
Initial attempts at obtaining rate constants for the thermal decomposition of **3***c* were by ^{1}H nmr spectroscopy. The sealed tube from the photolysis (see Experimental) was placed in a constant temperature bath, removed at suitable times and quenched in an ice bath. Integration then gave the ratio of **3***c*:**4***c*:**5***c*. However, the error of the integrations lead to considerable scatter in the rate plots. As well this method required ~10 mg per run and was somewhat wasteful of the pyrazole. We therefore switched to a spectrophotometric method which relied on the strong absorption bond of diarylcyclopropenes at ~330 nm ($\varepsilon > 10^4$). Since the rates were followed at temperatures (65–98°C) where solvent volatility would be a problem, sealed ampoules were used.



SCHEME 1. Synthesis of 1-aryl-3-methyl-2-phenyl-1-diazobut-2-enes. *1*, $AlCl_3$, C_6H_5—X; *2*, *t*-BuO^-K^+, $(CH_3)_2CHBr$; *3*, Br_2/CCl_4; *4*, LiCl/DMF; *5*, NH_2NH_2; *6*, Br_2/KOH.

The preliminary ^{1}Hmr kinetic runs indicated two facts. First from the ratio of **3***c*:**4***c*:**5***c* as a function of time, it was obvious that both **4***c* and **5***c* were products from the thermal chemistry of **3***c*. As shown in reaction [7], this is an example of the well known

[7]



(15) first-order parallel reaction where the observed rate constant is obtained from $d[5]/dt = k_{obs}[5]$ and $k_{obs} = k_4 + k_5$. At 330 nm all these species are absorbing but, since both processes are first-order, the $A - A_\infty$ method will give values proportional to the concentration of **5**. To obtain the individual rate constants, k_4 and k_5, the product ratio must be determined separately (see Experimental).

The second feature of the preliminary runs was the obvious variation in the rate constants in benzene as solvent. However, as has been reported earlier, thermal decompositions of diazo compounds are often variable because of spurious catalysis (16). In fact, from qualitative observations, **3***c* was known to be more stable in benzene if pyridine was added (3), suggesting that trace acid is the problem. The rate of decomposition of **3***c* was therefore measured spectrophotometrically at 88.9°C in benzene with 1%, 3%, and 5% pyridine. At a given concentration of pyridine the runs were quite reproducible. The rate constants were very similar for 3 and 5% pyridine but

about 30% greater with 1% pyridine. Therefore all other runs reported are in 5% pyridine/benzene.

Rate constants (k_{obs}) (at four different temperatures) for four of the five diazo compounds (**3***a*–**3***d*) are reported in Table 1. Photolysis of the *p*-cyano pyrazole **4***e* gives only very low concentrations of the corresponding diazo compound (13). Therefore the change in cyclopropene concentration during pyrolysis is quite small and the total absorbance change was only about 0.1. The deviation in the rate constants was obviously greater than that for all other substrates. Since this makes it difficult to obtain reliable activation parameters, this substrate was only studied at one temperature.

The ratio of the two products from the pyrolysis of **3** was obtained by careful ^{1}H nmr integration (see Experimental) and is reported as % cyclopropene (**4**) in Table 2. This allows k_{obs} to be separated into k_4 and k_5; these values are also in Table 2. Since the error in the product ratios is estimated at 5% (see Experimental) and the error in k_{obs} approximately 5%, the error in the individual rate constants is estimated at 10%. For **3***e* (4-cyano) no pyrazole product could be detected, so only an upper and lower limit for k_4 and k_5 respectively is available.

From the rate/temperature data activation parameters for both k_4 and k_5 can be calculated for **3***a*–**3***d* by the usual ln k/T vs. $1/T$ plot (Table 3). As has been discussed (ref. 17, p. 8), for a 30° temperature range and 10% error in rate constants, the error in $\Delta H^{\neq}$ is approximately 1.2 kcal M^{-1} and in $\Delta S^{\neq}$ 3 eu.

The most obvious feature of the rate constants reported in Table 2 is that the substituent effects are quite small for both k_4 and k_5. Since the errors in these values are about 10%, reliable quantitative interpretation of these effects may be difficult. However qualitatively, the trends in k_4 and k_5 are quite different. Thus as the substituents change from electron-donating to electron-withdrawing k_4 tends to decrease whereas the k_5 values go through a minimum for **3***b* (X = CH_3). The k_4 values will be discussed first.

As shown in reaction [6], k_4 represents the rate of thermal return of the diazo compound **3** to the 5*H*-pyrazole, **4**. Since this is a unimolecular ring closure, the transition state should have fewer degrees of freedom than the starting material leading to a negative $\Delta S_4^{\neq}$. As shown in Table 3, this is in general true except for the small positive value for **3***d* (X = Br). From an orbital viewpoint the closure of **3** to **4** might be regarded as a 6 electron 1,5-cycloaddition (ref. 18, p. 38). However, as shown in Fig. 2, this process is not the same as normal cycloadditions where out-of-plane π bonds are converted to in-plane σ bonds by rotation of the termini. In fact only a rotation at C_1 is required to give overlap with an in-plane π bond at N_5.[5] The other lobe of the N_4—N_5 π bond becomes a lone pair at N_4.

A very similar process, the conversion of vinylazide to triazole (reaction [8]), has been examined by *ab initio* MO calculations (19). The least energy path involves initial bending of the N_3—N_4—N_5 bond,

[5]These numbers refer to the Figure and are not the same as those used for nomenclature.

TABLE 3. Activation values $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for the thermal decomposition of **3***a*–**3***e*[a]

X	$\Delta H_4^{\ddagger}$ (kcal M^{-1})	$\Delta S_4^{\ddagger}$ (eu)	$\Delta H_5^{\ddagger}$ (kcal M^{-1})	$\Delta S_5^{\ddagger}$ (eu)
4-OMe	24	−8	27	+2
4-Me	24	−8	29	+5
H	25	−7	27	+2
4-Br	26	+2	27	+2

[a]Estimated errors are 1.2 kcal M^{-1} in $\Delta H^{\ddagger}$ and 3 eu in $\Delta S^{\ddagger}$ (ref. 17, p. 8).

development of the long pair on N_4 and positive charge on N_5. Very little change in the charge distribution of the out-of-plane π systems occurs during this stage. The transition state is passed as C_1 rotates and electron density is transferred from the π system to the σ bond forming.

Assuming that this reaction (reaction [8]) is a

[8] 
reasonable model for the conversion of **3** to **4**, the substituent effects can be explained. Thus, electron-withdrawing substituents on a phenyl group at C_3 (Fig. 2) stabilize negative charge and make the conversion of out-of-plane π electron density into the in-plane σ bond more difficult. Thus, k_4 decreases from **3***a* to **3***e*. According to these arguments substitution at C_1 should have the same effect. This is confirmed by the results of Brewbaker and Hart (20) on the rates for the conversion of a series of 1-aryl-3-diazopropenes, **6**, to the corresponding pyrazoles, **8** (presumably via 5*H*-pyrazoles, **7** (reaction [9])).

[9] 
6 **7** **8**

In fact Hammett plots using σ^- give $\rho^- = -0.4$ ($r = 0.998$) for cyclization of **6** and $\rho^- = -0.5$ ($r = 0.93$) for **3***a*–**3***e*. (The very poor correlation for our results is partially accounted for because only an upper limit for k_4 for 4-CN could be obtained.) The comparison between the results of Brewbaker and Hart (20) and those reported here can be extended. Thus only pyrazoles are formed from **6** whereas there is competition between pyrazole formation, **4**, and loss of nitrogen to give cyclopropene, **5**, for the case of **3**. Moreover the cyclizations of **3** occur about 10^3 times as slow. This decrease in rate probably results from steric inhibition to ring closure by dimethyl substitution at C_1 particularly if the ring closure is

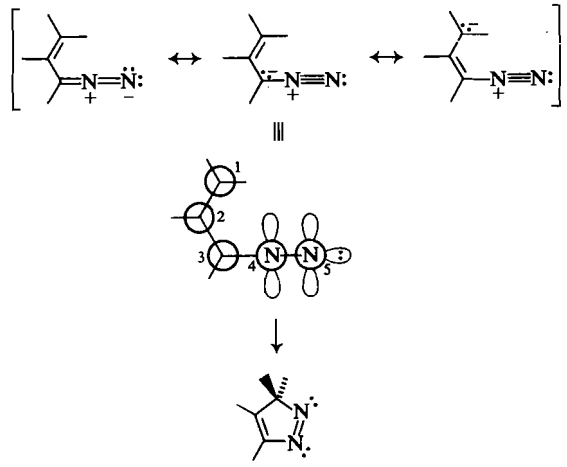

FIG. 2. Conversion of vinyldiazomethane to 5*H*-pyrazole.

initiated by bending of the C_3—N_4—N_5 bond. Since the competition between pyrazole and cyclopropene formation is quite close for **3**, not surprisingly when the pyrazole rates increase as in **6** no cyclopropene is formed.

The kinetics of the second process for **3**, loss of nitrogen to form cyclopropene **5**, presumably via a vinylmethylene intermediate will now be discussed. As shown in Table 3 this process is characterized by small positive $\Delta S^{\ddagger}$ values. Since this is a unimolecular dissociation, the entropy should be positive but a higher value might be expected (21). However, the thermal decomposition of diphenyldiazomethane has been clearly shown to be a simple unimolecular dissociation to nitrogen and diphenylmethylene and also has $\Delta S^{\ddagger}$ values close to zero (16, 22). That the reaction does not involve large charge separation for **3***c* is indicated by the observation that the rate is only 25% greater in acetonitrile:5% pyridine than in benzene:5% pyridine.

As shown in Table 2, the k_5 rate constant is a minimum for **3***b* (X = CH_3) and is faster for both electron-withdrawing and the better electron-donating substituent, OCH_3. An explanation for this order requires a more careful examination of the electronic details of the loss of nitrogen from **3**.

As discussed by Woodward and Hoffmann loss of nitrogen from a diazo compound is a cheleotropic reaction that is forbidden if it occurs in the linear mode (ref. 18, p. 152). As shown in Fig. 3*a*, this results because the electrons in the σ bond breaking correlate with the new lone pair at nitrogen and a "doubly excited" p^2 state (9) of methylene is formed. The same analysis is true for vinyldiazo compounds (Fig. 3*b*) where the vinylmethylene formed will be **2***c*.

In their recent paper on vinylmethylene, Davis, Goddard, and Bergman have stated that "extrusion

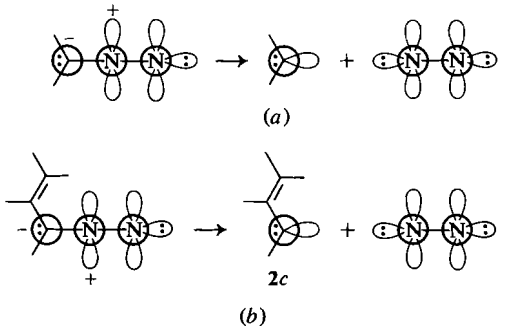

FIG. 3. (*a*) Loss of nitrogen from diazomethane, (*b*) loss of nitrogen from vinyldiazomethane.

of nitrogen from a vinyl diazo compound should lead directly to" **2***b* (6). This seems an oversimplification of the process but can be rationalized in two ways. First, the conversion of **2***c* to **2***b* will be exothermic and should have little or no activation barrier. As shown in reaction [10], this is true because

[10] 
conversion of **2***c* to **2***c* (linear) only results in decrease in *s* character for an empty orbital. The occupied *p* orbital is still of the allyl type. The rotation converting **2***c* (linear) to **2***b* (linear) should also be isothermal since the orbital system is now allyl plus non-bonded *p* and the occupancy simply changes from non-bonded allyl to non-bonded *p*. Bending **2***b* has been shown by calculation to be exothermic, as expected, by 18.1 kcal/*M* (6). Therefore, although the linear loss of nitrogen gives **2***c*, the first-formed species should be converted rapidly to **2***b*. The second possibility is that loss of nitrogen occurs in a non-linear fashion (ref. 18, p. 152) and is thus symmetry allowed. In fact, recent calculations for diazomethane (24) have shown that the barrier to loss of nitrogen disappears completely if the restriction of C_{2v} symmetry is removed. The singlet ground state of methylene is then formed directly. Regardless of whether the decomposition of **3** occurs by formation of **2***c* and then **2***b* or directly to **2***b*, the electronic distribution is such that the π-system is electron-rich and the σ-system electron-deficient (**2***c*) or *vice versa* (**2***b*).[6] It is interesting that the final product of these thermal reactions is cyclopropene **5** although **2***c* does not correlate with **5** (6). The vinylmethylene **2***b* does correlate with **5** and yet the ratio of formation of cyclopropene relative to H migration products is about 10:1 (10). For **2***b* this ratio must be at least 20:1 since no other products are observed.

The discussion above provides an explanation for the substituent effect for the thermal loss of nitrogen from **3**. The substituted phenyl group can conjugate with either an electron-deficient or an electron-rich orbital on the methylene carbon. The substituent therefore can stabilize the transition state for reaction for both electron-donating and electron-withdrawing cases.

A very similar order has been observed for the thermal decomposition of diphenyldiazomethanes where for monophenyl substitution all groups accelerate the reactions over H (23). A similar explanation was used in this case. In fact a plot of log *k* versus σ^+ for resonance electron-donating substituents and σ^- for electron-withdrawing gives very similar curves for both substrates (Fig. 4). The observation that **3** looses nitrogen about fifteen times as fast as diphenyldiazomethane means that the vinyl group is better at stabilizing the carbene center than phenyl although this may be very dependent on the conformation of the groups at the carbene carbon.

Finally, a comparison between these results for the generation of vinylmethylenes by thermolysis of **3** and those from the photochemical cleavage of cyclopropenes should be made. The closest comparison is

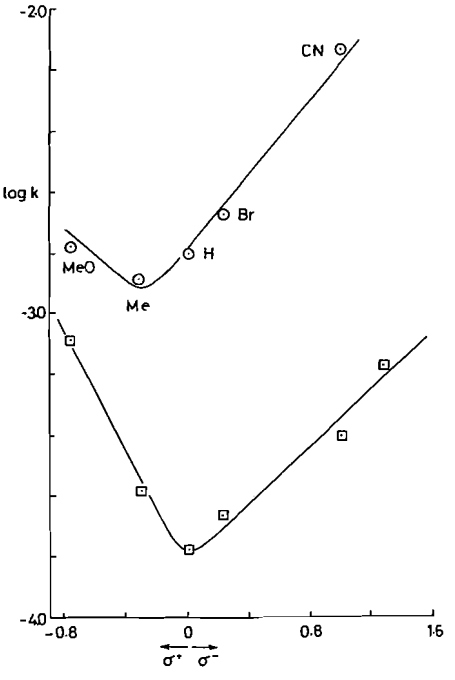

FIG. 4. Hammett plots for the conversion of **3***a*–**3***e* to **5***a*–**5***e* (○) and for the loss of nitrogen from diphenyldiazomethane (□) (25).

[6]Note that photochemical decomposition of **3** gives triplet **2** (13) but the multiplicity of the excited state involved is unknown and the intermediacy of singlet **2** is not ruled out.

with the results of Arnold (5) (reaction [4]). Obviously, the substituent effects are not the same since the photochemical results suggest that the vinylmethylene formed is more stable the better the electron-donating ability of the substituent. Perhaps the photochemical selectivity is being controlled by reversibility of vinylmethylene formation (2) in competition with the rates of hydrogen migration. A second possibility is that the substituent effects on the bond order in the excited singlet of the cyclopropene (11) are different from those on the vinylmethylene intermediate; that is, that the potential energy surfaces cross. The suggestion of Padwa *et al.* (1) that inductive destabilization by an electron-withdrawing phenyl group conjugated to the double bond of the cyclopropene and not to the developing radical center as σ bond cleavage occurs makes use of this possibility. Note that for the rate of decomposition of **3** inductively electron-withdrawing substituents (—Br, —OCH_3, —CN) are faster than H and the electron-donating CH_3 is slower.

Clearly, there is no simple explanation for all the results for both cyclopropene reactivity and vinylmethylene generation from vinyldiazo compounds. Only more extensive studies on these systems will indicate whether a single explanation exists or whether different substituent patterns and conditions lead to different mechanisms.

Experimental

Preparation of Substituted Pyrazoles

3-(4-Cyanophenyl)-5,5-dimethyl-4-phenyl-5*H*-pyrazole and 3-(4-methoxyphenyl)-5,5-dimethyl-4-phenyl-5*H*-pyrazole were prepared according to the published procedure (13). The new pyrazoles, 3-(4-bromophenyl) and 3-(4-methylphenyl), were prepared by the same six-step sequence. The physical properties for them and the precursor α,β-unsaturated ketones are given below.

1-(4-Bromophenyl)-3-methyl-2-phenyl-2-buten-1-one: bp (bulb-to-bulb distillation) 110°C/2 Torr; nmr δ1.83 (3H,s), 1.92 (3H,s), 7.37 (5H,bs), 7.77 (4H,dd). *Anal.* calcd. for $C_{17}H_{15}OBr$: C 64.77, H 4.81, Br 25.35; found: C 64.65, H 5.04, Br 25.24.

1-(4-Methylphenyl)-3-methyl-2-phenyl-2-buten-1-one: purified by sublimation: mp 106–107°C; nmr δ1.77 (3H,s), 1.86 (3H,s), 2.35 (3H,s), 7.31 (5H,bs), 7.38 (dd). *Anal.* calcd. for $C_{18}H_{18}O$: C 86.35, H 7.26; found: C 86.31, H 7.21.

3-(4-Bromophenyl)-5,5-dimethyl-4-phenyl-5*H*-pyrazole; purified by sublimation: mp 128–130°C; nmr δ1.55 (6H,s), 7.2–7.8 (9H,m); ir (CCl_4) 2970, 2930, 1460, 1330 cm^{-1}; uv (MeOH) 305 (ε, 5 700), 245 (ε, 17 700); mass spectrum (parent ion plus intensities greater than 20% of base peak), 328 (12), 326 (12), 300 (57), 298 (57), 285 (92), 283 (92), 220 (46), 204 (100), 203 (61), 202 (50), 101 (26), 100 (39). *Anal.* calcd. for $C_{17}H_{15}BrN_2$: C 62.39, H 4.63, Br 24.42, N 8.56; found: C 62.27, H 4.81, Br 24.20, N 8.39.

3-(4-Methylphenyl)-5,5-dimethyl-4-phenyl-5*H*-pyrazole; purified by sublimation: mp 106–107°C; nmr δ1.50 (6H,s), 2.35 (3H,s), 7.1–7.9 (9H,m); ir (CCl_4) 2970, 2920, 1450, 1330, 1170 cm^{-1}, uv (MeOH) 305 (ε, 4 900), 240 mm (ε, 16 900); mass spectrum 262 (4), 234 (40), 220 (20), 219 (100), 204 (21). *Anal.* calcd. for $C_{18}H_{18}N_2$: C 82.39, H 6.93, N 10.68; found: C 82.38, H 6.98, N 10.61.

Preparation of 1-Aryl-3-methyl-2-phenyl-1-diazobut-2-enes

The pyrazole (~10 mg) was dissolved in 0.4 mL of 5% pyridine in benzene-d_6 and sealed in a Pyrex nmr tube after three freeze–pump–thaw cycles. The sample was then irradiated using Filter System A (13) and a 200 W Hanovia medium-pressure mercury-arc lamp. The appearance of the diazo compound was apparent from the red colour of the sample and could be monitored quantitatively by nmr spectroscopy. As reported previously (13) the diazo compound could not be generated without some conversion to the corresponding cyclopropene. Typical compositions at the termination of irradiation were: substrate, % pyrazole, % diazo, % cyclopropene: 4-CH_3O, 10, 69, 21; 4OCH_3, 8, 78, 14; H, 20, 50, 30; 4-Br, 36, 45, 19; 4-CN, 39, 19, 42. These compositions were determined by averaging multiple integrations (five forward and five reverse) using a Varian T-60 spectrometer. The average deviation is approximately 1–2%.

Product Composition for the Thermal Decomposition of 1-Aryl-3-methyl-2-phenyl-1-diazobut-2-enes

The sealed nmr tubes containing the diazo compound solutions were placed in a constant temperature bath until the red colour of the diazo compound had disappeared. The yields of cyclopropene and pyrazole were then determined by multiple nmr integrations. The % yields as reported in Table 2 were then calculated from the difference before and after thermolysis. Since they are obtained from the difference in two nmr integrations the error is approximately 5%.

Kinetics of the Thermal Decomposition of 1-Aryl-3-methyl-2-phenyl-1-diazobut-2-enes

Solutions of $\sim 10^{-4}$ *M* in the diazo compound were prepared by diluting the nmr samples to 400 mL with 5% pyridine in benzene. Samples were then sealed in 5 mL ampoules (10 per kinetic run). (Since diazo compounds decompose in visible light, these dilute solutions could only be used reliably if the ampoules were wrapped in aluminum foil.) The ampoules were placed in a constant temperature bath for the kinetic run and quenched in ice water at appropriate times.

The absorbance of the solutions was then measured at 335 mm (355 mm for the 4-cyano compound) to monitor the appearance of the 1-aryl-2-phenyl-3,3-dimethylcyclopropene. For the 4-cyano compound the total absorbance change was only ~0.1 absorbance units and measurements were taken using a Unicam SP-800 Spectrophotometer with a scale expander. All others were taken with a Hitachi Coleman 124 Spectrophotometer. First-order rate constants were then obtained by the usual ln $(A - A_\infty)$ method with points taken for two half-lives; correlation coefficients were always greater than 0.99. A typical run for aryl = phenyl (t = 97.0°C) gave: time (abs); 0 (0.638), 120 s (0.708), 240 (0.770), 360 (0.820), 480 (0.871), 600 (0.897), 720 (0.925), 960 (0.960), ∞ (1.050): $k = 1.63 \times 10^{-3}$ s^{-1} (r = 0.999). The average values of at least two runs for each substrate at each temperature are listed in Table 1.

Acknowledgements

We would like to thank Professor D. R. Arnold for a generous gift of 4-cyano pyrazole as well as helpful discussions, and Brent Amero, Jim Hancock, and Fred Northrup for the initial ^1H nmr kinetic work. The financial support of the National Research Council of Canada is gratefully acknowledged.

Received January 3, 1979

STUART H. LAURIE, DIANA H. PRIME, and BIBUDHENDRA SARKAR. Can. J. Chem. **57**, 1411 (1979).

The complexation of nickel(II) with triethylenetetramine and D-penicillamine has been examined in 0.15 *M* NaCl solution at 25°C by a combined potentiometric–spectroscopic approach. Trien (A) forms the following complexes with Ni(II): MA, MA_2, MH_2A_2, M_2A_3, M_2HA_3, and $M_2H_2A_3$ with overall log stability constants: 14.34, 20.64, 37.28, 40.05, 49.20, and 55.02, respectively. Their concentrations as a function of pH are presented and their likely structures discussed. In contrast, D-penicillamine forms the species MA and MA_2 only. The latter species, which is the only species from pH 5.8 to 10.0, is shown to be square-planar via coordination of the N, S atoms of the ligand molecules. The overall log stability constants of MA and MA_2 are 11.22 and 22.71, respectively. The significance of these results in relation to the effectiveness of these ligands in preventing nickel toxicity in rats is discussed.

STUART H. LAURIE, DIANA H. PRIME et BIBUDHENDRA SARKAR. Can. J. Chem. **57**, 1411 (1979).

On a étudié la complexation du nickel(II) par la triéthylènetétramine et la D-pénicillamine dans des solutions 0.15 *M* en NaCl à 25°C en faisant appel à des méthodes potentiométrique et spectroscopique. Le trien (A) forme les complexes suivants avec le Ni(II): MA, MA_2, MH_2A_2, M_2A_3, M_2HA_3 et $M_2H_2A_3$ avec des constantes de stabilité logarithmiques globales respectives de 14.34, 20.64, 37.28, 40.05, 49.20 et 55.02. On présente leurs concentrations en fonction du pH et on discute de leurs structures les plus probables. Par ailleurs la D-pénicillamine ne forme que les espèces MA et MA_2. Cette dernière espèce, qui est la seule à se former à des pH de 5.8 à 10.0, est plan-carré par coordination des atomes N et S des molécules de ligand. Les constantes de stabilité logarithmiques de MA et MA_2 sont respectivement 11.22 et 22.71. On discute de la signification de ces résultats en relation avec l'efficacité de ces ligands à prévenir la toxicité du nickel dans les rats.

[Traduit par le journal]

Introduction

There is a great deal of concern regarding the health hazards caused by excessive intake of metals due to occupational exposure or environmental pollution. A study has shown that the serum nickel in the healthy inhabitants of Sudbury, Ontario, the site of the largest open-pit nickel mines in North America, was double that of healthy inhabitants of Hartford, Connecticut, a city with a relatively low environmental concentration of nickel (1). Industrial hazards of nickel workers are greatly eliminated by making better working conditions (2). However, a recent investigation of workers at a nickel refinery in Norway found that the degree of epithelial keratinization was more pronounced in the nickel exposed group than in the controls (3).

In our program of studying the biological transport of metals and its removal we have undertaken a detailed investigation with nickel(II). Recent studies have revealed that the organic ligands triethylenetetramine (trien) and D-penicillamine (Pen) were the most effective in prevention of death after a single parenteral injection of $NiCl_2$ in rats (4). Interestingly, the same two ligands have been found to be the most effective, among the many examined, for the removal of accumulated copper from patients of Wilson's disease (5). The complex equilibria of these ligands with copper(II) ions have recently been examined by us (6).

There is a general agreement on the formation of a 1:1 complex between Ni(II) and trien, but there exists some confusion over other species present, particularly above pH 7. This can be attributed partly to the use of impure trien in some instances and also to the lack of the necessary mathematical

0008-4042/79/121411-07$01.00/0

or computing facilities necessary to solve the species present, especially in the earlier work. The Ni(II)–Pen system, with no inherent redox reactions, is considerably simpler than the Cu(II)–Pen system (6), and has been studied by a number of earlier workers, some using the racemic form of the ligand, while with others the optical form used was not mentioned. The particular isomer used is important since only the D optical isomer is used medically (the L form is toxic) and the differences in the species formed in metal complexation can arise from stereoselectivity effects.

We have now re-examined the aqueous Ni(II)–trien and Ni(II)–D-Pen systems, because of their importance, by the combined analytical potentiometric–spectroscopic method (7, 8) which has been so successfully applied to other systems (9–12). In this paper we present the results of this study.

Experimental Section

Materials

AnalaR $NiCl_2 \cdot 6H_2O$ was used to prepare stock Ni(II) solutions. They were analyzed for Ni(II) content by the EDTA back-titration method employing standard $ZnSO_4 \cdot 7H_2O$ solutions. Trien–4HCl was purified as previously described (11). D-Penicillamine (Koch-Light 'Puriss' grade) was kept under vacuum at 0°C and used without further purification, tlc (*n*-butanol:acetone:water:acetic acid, 4:3:2:1) gave only a single spot. All other reagents were of 'AnalaR' or equivalent grade. All solutions were prepared from doubly-deionized CO_2-free water and kept under an oxygen-free atmosphere.

Analytical Potentiometry

Potentiometric titrations were carried out as described earlier (11) at 25 ± 0.05°C in 1.5 *M* NaCl solutions containing sufficient HCl so that the starting pH was below that of either the first deprotonation or the beginning of complexation.[2] A notable feature of the Ni(II)–trien system was the slow equilibration in the pH region 4.4–6.2.

Spectroscopic Measurements

Spectra were recorded using solutions containing 0.15 *M* NaCl thermostatted at 25 ± 0.1°C. A Cary 15 recording spectrophotometer and 5 cm cells were used to obtain the spectra of the Ni(II)–trien solutions. For the Ni(II)–Pen solutions a Unicam SP800 spectrophotometer was used with 1 cm and 3 cm cells.

Computational Procedures

The previously described programs PLOT-2, GUESS-2, and LEASK-2 (7) were substantially modified to facilitate data handling and reduce costly computer time.

PLOT-2: The polynomial fitting to obtain the $\delta H^+/\delta C_X$ curves was replaced with a numerical fitting method. This change eliminates problems found with polynomial 'over-fitting' and means the titration data can now be treated in a single computer run, considerably reducing computational time.

GUESS-2: Calculation of the species concentration factor ($p.m^p h^q a^r$) was carried out in log mode so as to avoid elimination of viable species by the computer due to the concentration factors being outside the computer's precision limits. This problem was particularly acute with the highly protonated dinuclear Ni(II)–trien species.

LEASK-2 was replaced with two programs using different minimization procedures. The first uses the Gauss–Newton minimization procedure which has the advantage of rapid convergence even with initial 'wild' guesses of the stability constants. Use of matrices in the convergence routine required this program to be written in a double-precision mode. The second program uses the Newton–Raphson minimization procedure which is more accurate than the Gauss–Newton procedure but will only converge if the initial guesses are close to the true values. These procedures have previously been used in this area and their advantages outlined (13). The advantages of using more than one minimization routine is that the chances of reading false minima (e.g. saddle points) are greatly reduced. Both programs are considerably faster to run than the earlier LEASK versions which employed a polynomial fitting procedure. The computations were carried out using a series GE400 computer (Toronto) and a Burroughs B6700 computer (Leicester).[3]

Results

Stability Constants and Species Distribution

The general equilibrium involving a metal ion M, a proton H, and a ligand A can be written in the form of reaction [1].

$$[1] \qquad pM + qH + rA \rightleftarrows M_pH_qA_r$$

The stabilities of the species formed may be expressed as their stoichiometric equilibrium constants β_{pqr} in terms of concentrations at constant ionic strength, temperature, and pressure as in eq. [2]

$$[2] \qquad \beta_{pqr} = [M_pH_qA_r]/m^p h^q a^r$$

where m, h, and a are the concentrations of free metal ion, hydrogen ion, and completely deprotonated ligand, respectively. The proton-liberation data and the amounts of unchanged reagents were determined by processing the original titration data with the computer program PLOT-2. The data so obtained were then processed by programs GUESS-2 and LEASK-2 to obtain the distribution of the species and their stability constants. A detailed account of the data processing has been previously reported (9–11).

Proton–Triethylenetetramine System

The pK values of the ligand at 25°C and in 0.15 *M* NaCl solution were obtained in an earlier study (11). The values obtained were 3.59, 6.77, 9.22, and 9.81, and these were used in this study.

[2]The concentrations used, pH titration curves, and proton displacement of pH curves can be obtained as supplementary material from Dr. B. Sarkar.

[3]The original programs and their derivations have been the subject of two recent communications (ref. 30, *a* and *b*). The former report confirms, with a few caveats, the general applicability of the analytical potentiometric method, the latter report is critical, but relates to modified versions of the computer programs. Some of the problems highlighted in these papers have been solved by the replacement of the polynomial procedures in the programs used here. These are to be published in the near future.

Proton–Triethylenetetramine–Nickel(II) System

From the metal and ligand variation titrations, using PLOT-2, pM and pA values were obtained for the concentrations Ni(II) = 2.00×10^{-4} M and trien = 8.022×10^{-4} M over the pH range 3.40–10.00 (in 0.20 steps). The input for the GUESS-2 program was $p = 1, 2; q = -2, -1, 0, +1, +2, +3$; $r = 1, 2, 3$. Of the 19 species processed, only 6 were found to give a good fit to the titration data: MA, MA_2, M_2A_3, MHA_2, M_2HA_3, and $M_2H_2A_3$. In the region pH 3.40–4.80, other protonated species (MHA, MH_2A, and MH_2A_2) were evident, but only at insignificant concentrations.

The β values obtained and the species distributions are given in Table 1 and Fig. 1 respectively.

The formation of the MA species in the pH range 4.4–6.2 corresponds to the observed slow equilibration region of the titration curves. The formation of this species is known to be relatively slow and has been studied kinetically in the pH 5.0–7.0 range (15, 16). The slow rate of formation is attributed to the rate of ring closure around the Ni(II) ion. There was no evidence for the formation of hydroxy species below pH 10.

Visible Absorption Spectroscopy of the Proton–Triethylenetetramine–Nickel(II) Systems

Solutions with Ni(II):trien = 1:4 were used to obtain the spectra as a function of pH. The measurements were made using Ni(II) concentrations of $1.2–25 \times 10^{-3}$ M. Representative spectra showing the strong pH dependence are given in Fig. 2. Resolution of these spectra into contributions from different species was achieved using the Beer–Lambert law, eq. [3], as previously described (11):

$$[3] \qquad A_l^{\lambda} = \sum^{i} \varepsilon_{\lambda,i} l [M_p H_q A_r]_i$$

The ε value was determined for each species at 20 nm intervals. Spectra were resolved at pH 5.07, 7.55, and 9.52 for all species except $M_2H_2A_3$. At pH 5.07 account was taken of the substantial amount of free Ni_{aq}^{2+}. After obtaining ε values for all species, except those for the species $M_2H_2A_3$, over the

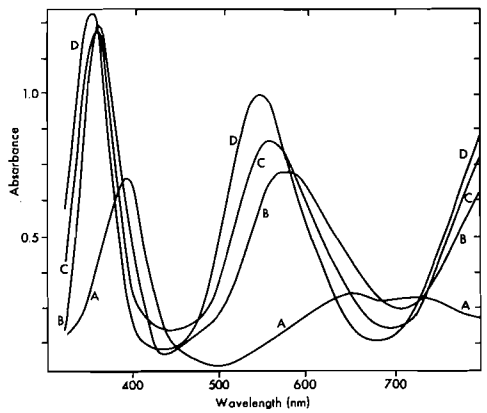

FIG. 2. Visible absorption spectra of nickel(II)–triethylenetetramine solutions as a function of pH. Ni(II), 0.025 M; trien, 0.101 M; NaCl, 0.15 M; T = 25°C, 5 cm pathlength. *A*, pH 3.98_6; *B*, pH 5.07_1; *C*, pH 7.55_3; *D*, pH 9.52_3.

300–800 nm range, the resolved spectrum of $M_2H_2A_3$ was then obtained from the observed spectrum at pH 6.70 using the ε values obtained for the other species. All six species gave an excellent fit to the observed spectra. The individual spectra are shown in Figs. 3 and 4.

For all species two peaks were evident. These are as expected for octahedrally coordinated Ni(II) ion. There is no evidence of any square-planar Ni(II) ion. The peaks in the 500–600 nm and the 340–360 nm regions can be assigned to $^3A_{2g} \rightarrow {}^3T_{1g}$ (F) and $^3A_{2g} \rightarrow {}^3T_{1g}$ (P) electronic transitions of octahedral symmetry. The corresponding transition for $Ni(H_2O)_6^{2+}$ are at 650–720 nm (doublet) and 395 nm, respectively. The occurrence of this doublet for the aquo ion and its disappearance upon replacement of H_2O with a nitrogen-donor ligand has been well documented (16), as also has the shift of λ_{max} to shorter wavelengths with increases in ε values as H_2O ligands are replaced by nitrogen-donor ligands. The resolved spectra show these expected features. A

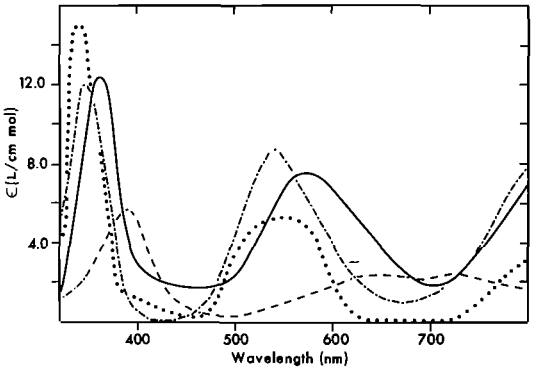

FIG. 3. Visible absorption spectra of $Ni^{2+}{}_{(aq)}$(observed), ---; and those of the species MA, —; MA_2, ·····; and MH_2A_2, ··· (computed from the spectra given in Fig. 2); NaCl, 0.15 *M*; $T = 25°C$.

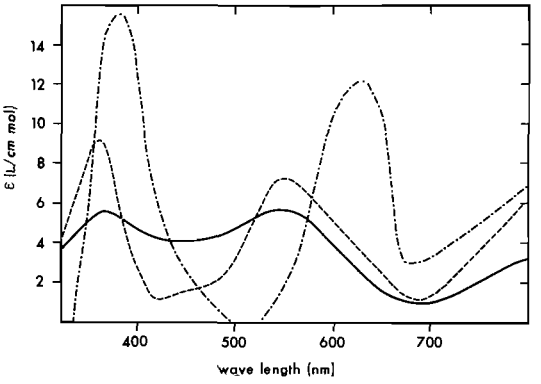

FIG. 4. Computed visible absorption spectra of the dinuclear species M_2A_3, —; M_2HA_3, ---; $M_2H_2A_3$, ·····; NaCl, 0.15 *M*; $T = 25°C$ (molar extinction coefficients based on per *M* Ni(II)).

third *d–d* transition ($^3A_{2g} \rightarrow {}^3T_{2g}$) is expected above 800 nm (~900 nm for the trien complexes). The beginning of this peak can be seen above 700 nm (the third peak for $Ni(H_2O)_6^{2+}$ is at 1100 nm).

Proton–D-Penicillamine System

Titrations were carried out over the range pH 1–12. The proton equilibrium (β_{031}) at the lower pH region was treated by the Henderson–Hasselbach equation. The two equilibria over the range pH 8–11 were solved by treating the titration data with PLOT-2 to obtain $\delta H^+/\delta C_A$, from which the average number of bound protons, $\bar{n}_H$, at each pH value was calculated, since:

$$[4] \qquad \bar{n}_H = 2 - (\delta H^+/\delta C_A)$$

The total number of bound protons in this region being two. The two equilibrium constants were then obtained via expression [5]

$$[5] \quad \bar{n}_H = \beta_{011}(1 - \bar{n}_H)[H^+] + \beta_{021}(2 - \bar{n}_H)[H^+]^2$$

Using increments of 0.20 pH units, simultaneous sets of eq. [5] were solved by program LEASK-2 to obtain the constants β_{011} and β_{021} of the species HA and H_2A respectively. The values obtained, given as pK_a values for ease of comparison with literature values, are presented in Table 2.

Proton–D-Penicillamine–Nickel(II) System

Data processing was as for trien system, using Ni(II) = 1.00×10^{-3} *M* and Pen = 4.00×10^{-3} *M* over the pH range 3.00–10.00 (in 0.20 steps), although significant metal binding only occurred above pH 4.4. The input range for GUESS-2 was $p = 1, 2$; $q = -2, -1, 0, +1, +2, +3$; $r = 1, 2, 3$. LEASK-2 reduced the number of species over the pH range 4.4–10.0 to just two, MA and MA_2. The stability constants obtained are shown in Table 2 and the species distribution in Fig. 5.

Visible Absorption Spectroscopy of the Proton–D-Penicillamine–Nickel(II) System

Consistent with the potentiometric results of a single species above pH 5.8, the visible absorption spectrum (300–800 nm) was found to be invariant over the range pH 5.8–10.0 (Fig. 6). The spectra were recorded with solutions containing a Ni:Pen ratio of 1:4, using Ni(II) concentrations over the range $1.0 \times 10^{-3} - 5.0 \times 10^{-2}$ *M*. Resolution of spectra at lower pH, in order to obtain the spectrum of the 1:1 species, was not attempted because this species is only formed to a minor extent (see Fig. 5). The red color of the Ni–Pen solutions and their spectra are in marked contrast to those of the blue Ni–trien system, and suggest a square-planar configuration for $Ni(Pen)_2$. Two electronic transitions are expected

(17) for a square planar Ni(II) system: $^1A_{1g} \rightarrow {}^1A_{2g}$ in the region 660–430 nm ($\varepsilon \sim$ 50–500 L cm^{-1} mol^{-1}), and $^1A_{1g} \rightarrow {}^1B_{1g}$ in the region of 430–370 nm (ε variable). For $Ni(Pen)_2$ three transitions are evident, a very intense band below 300 nm (presumably a ligand → metal charge transfer transition), a band with a maximum absorbance at 463 ± 2 nm (ε = 127), and from the asymmetry of the band at 463 nm a further, weaker, band is evident at approximately 560 nm. The latter band is tentatively assigned to the $^1A_{1g} \rightarrow {}^1A_{2g}$ transition and the band at 463 nm to the $^1A_{1g} \rightarrow {}^1B_{1g}$ transition.

Discussion

The results presented here show the aqueous Ni(II)–trien system to be complex. Only one other report (18) has indicated the complexity of this system. Most of the earlier work has listed the species MA and MHA as being the major species. However, our species distribution (Fig. 1) shows that MA is only a major species in the pH 5.0–6.5 region. The species MHA is only evident in our studies as a possible species below pH 5, but must be insignificant since most of the Ni(II) is in the form of the aquo complex below pH 5. In support of this, Margerum and co-workers (14), from kinetic measurements, also found only 50% of the Ni(II) to be complexed at pH 5.0. The stability constant of the MA species is in good agreement with earlier determinations (see Table 1). Reports of this species being the major one above pH 7 can be attributed to lack of consideration of species other than mononuclear ones. A survey of the literature in fact shows inconsistencies in interpretation at large trien:Ni(II) ratios (18).

Intuitively, with Ni(II) having six coordination sites and trien having only four donor atoms, one would expect bis-chelated or bridged systems to form above pH 7 in the presence of excess trien. Indeed,

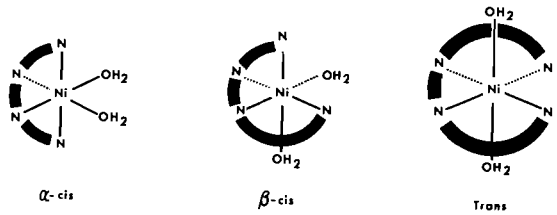

FIG. 7. Possible structures of $[Ni(trien)(H_2O)_2]^{2+}$.

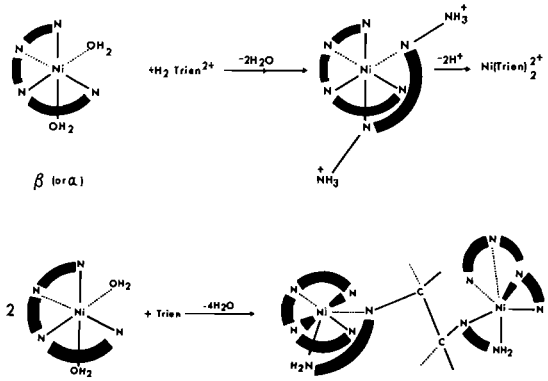

FIG. 8. Formation of MH_2A_2, MA_2, M_2A_3.

the formation of polymeric Ni(II) species in which an octahedral environment is maintained is well known and is often referred to as one of the 'anomalies' of Ni(II) chemistry (16). Earlier workers (18, 19) have reported some of these species, their stability constants given in Table 1, are in fair agreement with ours.

The resolved visible absorption spectra indicate all the species to be octahedral. The species MA must therefore have the stoichiometry $[Ni(trien)(H_2O)_2]^{2+}$, with the possible structures shown in Fig. 7.

The *cis* isomers (α and β) are likely to be the more important structures: firstly, the trien is less strained than in the planar configuration required for the *trans* isomer; secondly, two available *cis* coordination sites are necessary for the formation of the species MH_2A_2, MA_2, and M_2A_3 as depicted in Fig. 8. The species M_2A_3 makes maximum use of the available metal coordination sites and the available ligands donor atoms. Molecular models show that a trien molecule can bridge the two pairs of *cis* sites on adjacent $[Ni(trien)(H_2O)_2]^{2+}$ ions, resulting in the central

$$\diagdown N—CH_2—CH_2—N \diagup$$

moiety being elongated and the two methylene groups having a staggered conformation with respect to each other. Formation of the species M_2HA_3 from M_2A_3 must involve protonation at a coordination site with consequent breaking of the Ni—$\overset{+}{N}$ bond. This is consistent with the observed spectral differences between these species.

In contrast with the Ni(II)–trien system the Ni(II)–Pen system is exceedingly simple, only two species being formed over the pH range 4–10. The first species MA is only a minor one at lower pH (Fig. 5), while above pH 5.8 all the Ni(II) is in the form of the species MA_2. The finding of just two species is consistent with earlier reports (20–23); the stability constants are in excellent agreement (Table 2) considering the different conditions and the use of racemic penicillamine by others (22). In fact, Ritsma and Jellinek (23) have observed a small stereoselectivity effect which enhances the stability of the racemic complex, [Ni(D-Pen)(L-Pen)] over that of the optically active forms. An interesting feature of this system is the finding of $K_2 > K_1$, a reverse of the usual order.[4] The spectroscopic measurements show that this can be attributed to the enhancement of stability gained by the formation of a square-planar MA_2 species, in which the Pen ligands act as bidentate *S,N*-donor ligands rather than in the expected tridentate fashion. A similar conclusion regarding the square-planar configuration of MA_2 for both D-Pen and the much studied, L-cysteine, has been reached by others (24, 25).

L-Cysteine, which is closely related to penicillamine (penicillamine = β,β-dimethylcysteine), is a naturally occurring amino acid and an important metal-binding agent in blood serum. A comparison of the binding properties of D-penicillamine and L-cysteine with Ni(II) is therefore important. Both form MA and MA_2 species in aqueous solution, the latter in both cases being a red, square-planar complex.

The stability constants for the MA and MA_2 species are greater, by a factor of approximately 10 in each case for the D-Pen system, presumably reflecting the influence of the two methyl substituents adjacent to the thiol group in Pen. The methyl groups also exert a steric influence in that no polynuclear species are observed with D-Pen, in contrast to the finding of polynuclear species with L-cysteine, by Perrin and Sayce (22), of the type M_2A_3 and M_3A_4.

As previously indicated, both D-Pen and trien have been found to be the most effective of a number of chelating agents in preventing nickel toxicity in rats. The results presented here show that these ligands are, as was well known, very effective chelating agents of Ni(II), but a number of additional features are also shown to be of importance. Thus, at ratios

[4]The enhancement of the stability of MA_2 over MA is also evident from the species distribution curves (Fig. 5) where it is evident that the MA species exists only in a narrow band of the pH region. We are grateful to a referee for pointing this out.

of trien/Ni(II) > 1 and at the physiological pH of 7.4, trien chelates Ni(II) in a number of ways, i.e. as the species M_2HA_3, MH_2A_2, MA, plus the minor species M_2A_3, MA_2, and $M_2H_2A_3$. The efficiency of trien as a therapeutic agent therefore lies in its flexibility in being able to adopt a number of configurations. In contrast, D-penicillamine, at high Pen/Ni(II) exclusively forms $Ni(Pen)_2^{2-}$, this complex gains additional stability by adopting a square-planar configuration. Complexes of Ni(II) involving D-penicillamine are also more stable than those formed with the related, naturally occurring amino acid, L-cysteine.

Estimation of the fraction of dative structure in molecular complexes using Hammett ρ values

BO-LONG POH

School of Chemical Sciences, Universiti Sains Malaysia, Penang, Malaysia

Received August 8, 1978

BO-LONG POH. Can. J. Chem. **57**, 1418 (1979).

A simple method of estimating the fraction of dative structure in molecular complexes using Hammett ρ values is given. A physical interpretation of the parameter m in the equation, $h\nu = mI_D + n$, relating the charge-transfer energy, $h\nu$, of a molecular complex and the ionization potential, I_D, of the donor is given.

BO-LONG POH. Can. J. Chem. **57**, 1418 (1979).

On rapporte une méthode simple, basée sur des valeurs de ρ de Hammett, permettant d'évaluer la fraction de la structure dative de complexes moléculaires. On fournit une interprétation physique du paramètre m de l'équation $h\nu = mI_D + n$ permettant de relier l'énergie de transfert de charge, $h\nu$, d'un complexe moléculaire et le potentiel d'ionisation, I_D, du donneur.

[Traduit par le journal]

Introduction

A considerable amount of work has been done on molecular complexes. Several books (1–4) on this subject have been published. According to Mulliken's theory (5) a molecular complex is formed between an electron donor and an electron acceptor. In the ground state the wave function Ψ_N of a 1:1 donor–acceptor organic complex formed from neutral molecules has the form of eq. [1]. The symbols D and A denote donor and acceptor respectively, Ψ_0 is the wave function of the no-bond structure, Ψ_1 is the wave function of the dative structure in which there is a transfer of an electron from the donor to the acceptor, a and b are coefficients. The excited state wave function Ψ_V is given by eq. [2] where a^* and b^* are coefficients.

$$[1] \quad \Psi_N = a\Psi_0(D, A) + b\Psi_1(D^+—A^-)$$

$$[2] \quad \Psi_V = -b^*\Psi_0(D, A) + a^*\Psi_1(D^+—A^-)$$

Currently, there are two common methods (ref. 3, chapt. 6) of estimating the fraction of dative structure in the ground state of molecular complexes. One method is based upon infrared frequency shifts and the other method is based on dipole moment data. Both methods are quite complicated to use and they also involve some major assumptions (ref. 3, chapt. 6).

The relationship between the energy, $h\nu$, of a charge-transfer transition from the ground state, Ψ_N, to the excited state, Ψ_V, and the ionization potential, I_D, of the donor was given by Briegleb and Czekalla (7) in the form of eq. [3] where h is Planck's constant and C_1 and C_2 are constants for a given acceptor. Later, it was found that eq. [4] which expresses a

$$[3] \quad h\nu = I_D - C_1 + C_2/(I_D - C_1)$$

$$[4] \quad h\nu = mI_D + n$$

linear relationship between $h\nu$ and I_D is valid for many complexes (8, 9). There are two problems (2, 3, 7, 8) associated with the use of eq. [4]. The first one is the deviation of the slope m from unity. The deviation increases as the complex becomes stronger. In the case of amine–iodine complexes the deviation is large and various reasons have been given to account for it (10–12). The second problem is the choice of the correct set of m and n values for often more than one value each for m and n could fit the observed values of $h\nu$.

This paper is presented with two aims. The first aim is to give a simple method of estimating the fraction, F_1, of dative structure in molecular complexes using [5] where ρ_{CT} is the Hammett (13) ρ value relating the equilibrium constants of a series of molecular complexes formed from a closely related series of donors with a common acceptor and ρ_{Ref} is the Hammett ρ value of a model system which has a full positive charge developed on the donors.

$$[5] \quad F_1 = \rho_{CT}/\rho_{Ref}$$

The second aim is to give a physical interpretation to the slope m of eq. [4] to account for its deviation from unity.

Results and Discussion

Equation [5] is applied to molecular complexes formed from a series of methyl-substituted benzenes as donors with a variety of acceptors. The ρ value for the ionization potentials of benzenes is taken to be ρ_{Ref} since the cation of the substituted benzene (**1**) is a good model for the corresponding donor in the dative structure (**2**) of the molecular complex. value of ρ_{Ref} is −14.7 (14). The values of ρ_{CT} for the equilibrium constants for molecular complexes formation were calculated from the usual Hammett plots using σ_p^+ values taken from Okamoto and

1 2

Brown (15) and assuming additive substituent effects of the methyl group. On the whole the plots are good (Table 1) and the F_1 values compare well with literature values obtained from infrared frequency shifts and dipole moments. The inherent assumption in eq. [5], that molecular complexes formed from a closely related series of donors with a common acceptor have the same amount of dative structure, is supported by the few available literature results. For examples, the complexes of iodine monochloride with benzene, toluene, and *p*-xylene all have 11% dative structure (Table 1), and complexes of iodine monochloride with pyridine and 3,5-dibromopyridine have 30% dative structure (16).

Actually the ρ_{Ref} value used must be from the same solvent in which the equilibrium constants of molecular complexes were measured. However, such data are not available. The fact that the gas phase value of −14.7 works well in our method probably indicates that the ρ values in chlorinated methanes (the solvents used in molecular complex studies) are close to −14.7 (17).

The underlying principle of eq. [5] is that ρ_{CT} is essentially determined by the dative structure because the donor in the dative structure has a positive charge on it whereas the no-bond structure is expected to have a negligible effect on the magnitude of ρ_{CT} because the donor in the no-bond structure is an uncharged species. We can see an analogous situation in the large ρ values for ion producing reactions and small ρ values for free radical reactions in which no charge is developed.

We shall now derive eq. [4] from a combination of two Hammett equations. The Hammett equation correlating the charge-transfer energies of a series of molecular complexes (2) is given by eq. [6]

$$[6] \qquad (h\nu_x - h\nu_0)/(2.3RT) = \rho_{h\nu}\sigma$$

where the subscripts x and 0 denote the substituted and unsubstituted donors respectively, R is the gas constant, and T is the absolute temperature. The Hammett equation correlating the ionization potentials of the same series of donors is given by eq. [7] (I and $h\nu$ are expressed in the same unit).

$$[7] \qquad (I_x - I_0)/(2.3RT) = \rho_{IP}\sigma$$

A combination of eqs. [6] and [7] yields

$$[8] \qquad h\nu_x = (\rho_{h\nu}/\rho_{IP})I_x + h\nu_0 - (\rho_{h\nu}/\rho_{IP})I_0$$

which is analogous to eq. [4] with

$$[9] \qquad m = \rho_{h\nu}/\rho_{IP}$$

$$[10] \qquad n = h\nu_0 - (\rho_{h\nu}/\rho_{IP})I_0$$

[b]Reference 31.
[c]Calculated from data of ref. 21.
[d]Reference 18.
[e]Reference 6.
[f]Calculated from data of ref. 20.
[g]Calculated from data of ref. 12.
[h]Calculated using eq. [11]; F_1 values taken from Table 1 except No. 7 with $F_1 = 0.35$ (ref. 3, p. 68).
[i]Calculated using eq. [12] with ν_0 and I_0 values taken from the references listed under the column for n.

In eq. [5] only the ground state of the molecular complex is involved and ρ_{CT} is determined by the dative structure. In eq. [8] both the ground and excited states of the molecular complex are involved. Therefore, $\rho_{h\nu}$ is determined by the difference in the fraction of dative structures in these two states, that is, $F_1^* - F_1$ where the superscript * indicates the excited state. The factor $F_1^* - F_1$ is equivalent to $1 - 2F_1$ (ref. 3, chapt. 1). Therefore, we obtain

$$[11] \qquad m = 1 - 2F_1$$

$$[12] \qquad n = h\nu_0 - (1 - 2F_1)I_0$$

Table 2 gives the m and n values calculated from eqs. [11] and [12], respectively, for several molecular complexes. They are in good agreement with the observed values reported in the literature. Therefore, eqs. [11] and [12] provide a method of predicting the slope m and the intercept n of the commonly used eq. [4], and thereby overcome the problem of choosing the correct set of m and n values. Equation [11] further gives a physical meaning to m, in contrast to the earlier suggestion that it has no theoretical significance (2, 3). We also can see that unit m is a special case — when F_1 is zero.

In-plane and out-of-plane conformational preferences of the sulfhydryl group in some halothiophenol derivatives

TED SCHAEFER AND WILLIAM J. E. PARR
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2
Received November 10, 1978

TED SCHAEFER and WILLIAM J. E. PARR. Can. J. Chem. **57**, 1421 (1979).

Long-range spin–spin coupling constants between sulfhydryl protons and ring protons in some halothiophenol derivatives in CCl_4 solutions are reported. In contrast to the corresponding phenol derivatives, substantial amounts of out-of-plane conformers are present at 305 K for all but 2,6-dichlorothiophenol. The *cis* and *trans* conformers differ by only about 0.2 kcal/mol in free energy for 2,4-dibromothiophenol and 2,4-dichlorothiophenol, in good agreement with a recent analysis of the dipole moment observed for the latter compound. The barrier to internal rotation of the sulfhydryl group is considerably smaller than for a hydroxyl group and rough estimates are given for the barrier in a few compounds. For example, the barrier in 2,3,5,6-tetrafluorothiophenol is lower than in 2,6-dichlorothiophenol. STO-3G MO calculations overestimate the internal barrier to rotation of the sulfhydryl group, but yield charge densities for this group which indicate that a major cause of the relative weakness of its intramolecular hydrogen bonds resides in its lack of polarity.

TED SCHAEFER et WILLIAM J. E. PARR. Can. J. Chem. **57**, 1421 (1979).

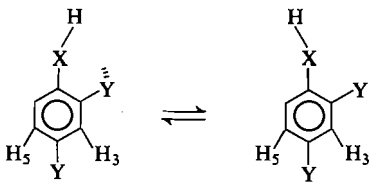
On rapporte les constantes de couplage à longue distance entre les protons sulfhydryles et ceux du cycle de quelques dérivés halothiophénols en solution dans le CCl_4. Par opposition aux résultats obtenus avec les dérivés phénoliques correspondants, il en résulte que, dans tous les cas, excepté le dichloro-2,6 thiophénol, des quantités importantes de conformères qui ne sont pas dans le plan à 305 K. L'énergie libre des conformères *cis* et *trans* ne diffère que par 0.2 kcal/mol dans le cas des dibromo-2,4 et dichloro-2,4 thiophénols; ce résultat est en bon accord avec une analyse récente du moment dipolaire observé pour ce dernier composé. La barrière à la rotation interne du groupe sulfhydryle est beaucoup plus faible que dans le cas du groupe hydroxyle et l'on donne des évaluations grossières pour cette rotation dans quelques composés. Par exemple, la barrière dans le tétrafluoro-2,3,5,6 thiophénol est plus basse que dans le dichloro-2,6 thiophénol. Des calculs de OM STO-3G donnent une évaluation trop élevée pour la barrière interne à la rotation du groupe sulfhydryle; toutefois les densités de charge qu'ils fournissent indiquent que la cause principale de la faiblesse relative de ses liaisons hydrogène intramoléculaires provient de son manque de polarité.

[Traduit par le journal]

Introduction

It has been shown (1–4) that the use of stereospecific long-range spin–spin coupling constants between hydroxyl and ring protons or ^{19}F nuclei in halophenol derivatives is perhaps one of the best ways to determine the conformational preferences of the hydroxyl group. For example, for 2,4-dihalophenols there exists little doubt that in CCl_4 or C_6H_{12} solution greater than 90% of **1** exists in the form **1***a* (*cis*) near room temperature.

For the corresponding halothiophenol derivatives,



cis **1***a* X = O, S *trans* **1***b* X = O, S

their remains some ambiguity about the conformational populations so that the existence of so-called intramolecular hydrogen bonding of the S—H group to an *ortho* halogen substituent remains in doubt.

For example, an infrared study of 2,4-dichlorothiophenol in CCl_4 solution (5) gave no evidence for an intramolecular hydrogen bond, whereas another such study (6) indicated intramolecular hydrogen bonding in *o*-chlorothiophenol. Dipole moments in benzene solution of *o*-chlorothiophenol (7) and of 2,4-dichlorothiophenol (8), respectively, indicate about 70 and 50% abundance of the *cis* form (8). Other workers (6) suggest 95 ± 5% of the intramolecularly bonded forms for *o*-chlorothiophenol in CCl_4 at 298 K. In the latter study (6) the infrared and proton chemical shift data did not prove the existence of *cis* forms for the *o*-halothiophenols (in our opinion).

CNDO/2 MO calculations predict stronger intramolecular hydrogen bonds in *o*-chloro- and *o*-bromo-

0008-4042/79/121421-05$01.00/0

thiophenol than in the corresponding phenols, whereas an STO-3G MO calculation favours the *trans* conformer of *o*-chlorothiophenol by 2.8 kcal/mol (9).

In this paper we examine the proton magnetic resonance spectra in the absence of intermolecular proton exchange of some polyhalothiophenol derivatives dissolved in CCl_4. The long-range coupling constants involving the sulfhydryl proton demonstrate that intramolecular hydrogen bonding is considerably weaker than in the corresponding phenol derivatives. *Ab initio* MO calculations on some dichlorothiophenols and on 2,4-dichlorophenol are somewhat helpful in rationalizing the differences in conformational preferences.

Experimental

The compounds came from Aldrich Chemical Co.; 5 mol% solutions in CCl_4, containing some tetramethylsilane, were degassed by the freeze–pump–thaw method. Pellets of molecular sieve were sealed into the sample tube and prevented intermolecular sulfhydryl proton exchange, although some samples were kept for several weeks before the sulfhydryl proton resonances became sharp multiplets.

Weak irradiation experiments (10) gave the relative signs of coupling constants, determining spectra which were repeatedly calibrated at sweep rates of 0.02 Hz/s and a dispersion of 1 Hz/cm on HA100 and DA60I spectrometers operating in the frequency sweep mode. Frequency markers were placed at intervals of 5 Hz or less. The proton spectra were recorded at 305 K and the ^{19}F spectra at 301 K.

The proton resonance spectra of 2,5-dichloro- and of 2,4-dichlorothiophenol were also recorded for 1 mol% solutions in CCl_4.

Molecular orbital calculations at the *ab initio* STO-3G level (11) were performed on an IBM 370/158 system.

Results and Discussion

Spectral Analysis

The calibrated ^1H and ^{19}F magnetic resonance spectra were analyzed with the computer program LAME (12, 13). The error in the spectral parameters is thought to be 0.02 Hz or less, the numerical data for a typical analysis being given in Table 1. The signs of the coupling constants are given on the basis of $^3J_o^{H,H} > 0$, $^3J_o^{HF} > 0$, and $^3J_o^{F,F} < 0$ (14). The other spectral parameters of interest in this study are presented in Table 2.

The analysis of the proton spectrum of 3,5-dichlorothiophenol was impossible because of chemical shift equivalence. A similar occurrence is known for *p*-chlorothiophenol (15). The long-range couplings to the sulfhydryl proton in 2,5-dichloro- and in 3,4-dichlorothiophenol were the same in 1 and 5 mol% solutions. The sulfhydryl proton chemical shifts were not significantly different at the two concentrations, indicating negligible self-association. The chemical shifts of the S—H proton of thiophenol at 5 mol% (16) and at infinite dilution in CCl_4 (17) differ by only 0.03 ppm.

Extent of Intramolecular Hydrogen Bonding

In 2,4-dichlorophenol, $^5J_m^{H_3,OH} = J_3$ is not observable, whereas $^5J_m^{H_5,OH} = J_5$ is 0.46 Hz (1), suggesting that the compound exists almost solely in form **1***a* as a 4.9 mol% solution in CCl_4. Now, in 2,4-dichlorothiophenol (Table 2) J_3 is 0.30 ± 0.02 Hz and J_5 is 0.24 ± 0.02 Hz. On the assumption that J_3 vanishes for **1***a*, that J_5 vanishes for **1***b*, and that $J_3 = J_5$ in **1***b* and **1***a*, respectively,[1] one has $\Delta G^0 = G^0_{1b} - G^0_{1a} = -RT \ln J_5/J_3 = -0.14 \pm 0.12$ kcal/mol. In other words, the *trans* form is slightly more stable than the *cis* form. A similar calculation for 2,4-dibromothiophenol yields $\Delta G^0 = G^0_{1b} - G^0_{1a} = -0.17 \pm 0.12$ kcal/mol.

Apparently, the *cis* conformer of 2,4-dichlorothiophenol is $45 \pm 5\%$ abundant at 305 K, in close agreement with the 50% abundance deduced from the most recent dipole moment study (8). It is also of interest that a similar abundance of the *cis* conformer occurs in 2-methoxythiophenol (18).

No comparison between J_3 and J_5 can be made for the 2,5-disubstituted derivatives in Table 2. However, it is clear that substantial amounts of the *trans* conformers of 2,5-dichloro- and 2,5-dibromothiophenol exist under the experimental conditions.

The Population of Conformers with an Out-of-plane Sulfhydryl Bond

The twofold barrier to internal rotation in phenol is 3.5 kcal/mol (19, 20). In consequence, $^6J_p^{H,OH}$ is very small at 305 K (21) because this coupling very likely displays a $\sin^2\theta$ dependence, θ being the angle by which the O—H bond twists out of the plane of the phenyl group.[2] In thiophenol, however, ^6J is -0.33 Hz (16) in CCl_4 solution. It has been used to derive a twofold barrier to rotation about the C—S bond, amounting to 1.1 ± 0.3 kcal/mol (16) and in reasonable agreement with a barrier of 0.8 kcal/mol deduced from torsional data in the gas phase (22).

[1]This assumption for $^5J_m^{H,OH}$ has led to self-consistent intramolecular equilibrium constants for a variety of phenol derivatives and to agreement with conformational preferences deduced by other methods (1–4).

[2]It could have been argued that a decrease in θ implies an increase in the conjugation of the oxygen atom with the π-electron system of the ring. A π-electron coupling mechanism operating via the partially double C···O bond would then enhance the magnitude of $^6J_p^{H,OH}$ at $\theta = 0$. However, a $\sin^2\theta$ dependence of $^6J_p^{H,OH}$ is compatible with a σ–π electron coupling mechanism in which the spin polarization of the σ electrons in the O—H bond is transferred to the π system by a 'hyperconjugative' interaction. The latter is most effective where the O—H bond occupies a plane perpendicular to the benzene plane, i.e., when $\theta = 90°$.

TABLE 1. Proton* and fluorine† chemical shift and coupling‡ parameters for 2,3,5,6-tetrafluorothiophenol in CCl_4

Parameter	Value	Parameter	Value
ν_{SH}	369.50	$^4J_m^{F_3,F_5}$	−0.427(8)

$^4J_m^{F_2,F_6}$	−1.424(8)	rms deviation	0.023§

*In Hz at 100 MHz to low field of internal tetramethylsilane at 305 K.
†In Hz to high field of internal CF_3CCl_3 at 56.4 MHz at 301 K (20 mol% in CCl_4).
‡In Hz; numbers in parentheses indicate the standard deviation in the last figure.
§For the fluorine iteration.

The value of 1.1 kcal/mol depends on the assumption that ^6J varies as $\sin^2\theta$. It was estimated that ^6J ($\theta = 90°$) is −1.05 Hz. A value of ^6J ($\theta = 90°$) of −0.97 Hz would reproduce the gas phase barrier.

The observed ^6J of −0.17 Hz in 2,5-dichlorothiophenol means that out-of-plane conformations are appreciably populated. The potential function for internal rotation of the S—H bond in this molecule must contain at least onefold and twofold terms, V_1 and V_2 (23). The former measures the energy difference between the *cis* and *trans* planar conformers and, by analogy to the 2,4-dichloroisomer, is probably less than 0.2 kcal/mol (see ^5J values in Table 2). One may write (23)

$$[1]\quad V(\theta) = V_1(1 - \cos\theta)/2 + V_2(1 - \cos 2\theta)/2$$

Here, $\theta = 0°$ for the *cis* conformer, **1***a*.

If $V_2 \gg V_1$, a treatment in terms of a twofold barrier (16) has some meaning. Writing $\langle\sin^2\theta\rangle$ as 0.17/0.97 for 2,5-dichlorothiophenol (see Table 2) yields V_2 as 2.4 ± 0.8 kcal/mol; the quoted error recognizes the approximate nature of this model.

The value of −0.12 Hz for ^6J in the corresponding bromine derivative then indicates a V_2 of 3.0 ± 1.0 kcal/mol.

Of course, it is conceivable that in the *cis* conformer the S—H bond is held mainly in-plane by electrostatic interaction with the *ortho* C–halogen bond and that the ^6J arises mainly from out-of-plane conformations in the *trans* conformer. It would then be expected, however, that V_1 be considerably larger than the value indicated by the equilibrium populations found above and by the most recent dipole moment studies (8), which surmised the existence of out-of-plane conformations of the S—H group in 2,4-dichlorothiophenol.

2,6-Dichlorothiophenol

$^6J_p^{SH,H}$ is less than 0.05 Hz in this compound, implying that the twofold barrier to internal rotation is appreciably larger than 3 kcal/mol (16), and that out-of-plane conformations are inappreciably populated at 305 K in CCl_4 solution. It is assumed, of course, that the substituents do not alter the $\sin^2\theta$ dependence of ^6J_p, a very good assumption in the corresponding toluene derivatives (24) and, apparently, in a variety of phenol derivatives (1–4).

In CCl_4 solution, the chemical shift of the S—H proton in benzenethiol is 3.23 ppm (16). In 2,6-dichlorothiophenol the S—H resonance shifts to low field by 1.28 ppm (Table 2) and such shifts have been taken as an indicator[3] of intramolecular hydrogen bonding (6, 25). On the other hand, the O—H resonance at infinite dilution of phenol in CCl_4 is 4.25 ppm at 305 K (26, 27). In 2,6-dichlorophenol (5 mol% in CCl_4 at 305 K) the O—H peak occurs at 5.66 ppm; the low-field shift is 1.41 ppm. It is accepted that a relatively strong intramolecular hydrogen bond exists in the phenol derivative (20) although no V_2 has been derived. For pentachlorophenol in solution, torsion data yield a V_2 of 6.3 kcal/mol (28), almost 3 kcal/mol higher than in phenol.

The present nmr data on 2,6-dichlorothiophenol are consistent with a V_2 of greater than 3 kcal/mol, an increase of greater than 2 kcal/mol relative to thiophenol. It is improbable that V_2 is as large as in the phenol derivative, however. Thus, our STO-3G calculations (see below) find a charge density of 0.996 electron on the S—H hydrogen atom, compared to only 0.762 electron on the O—H hydrogen atom in the *cis* conformation of 2,4-dichlorophenol. If the hydrogen bond is mainly electrostatic in nature (29, 30), these calculations suggest a weak hydrogen bond in the thiophenol derivative. The comparable magnitudes of the low-field shifts of the O—H and S—H proton resonances do not necessarily indicate similar strengths of intramolecular hydrogen bonds (31, 32).

2,3,5,6-Tetrafluorothiophenol

CNDO/2 and STO-3G calculations (9) agree that the intramolecular hydrogen bond in *o*-fluorothiophenol is about half the strength of that in *o*-fluorophenol. The CNDO/2 calculations (9) also yield a much weaker bond in *o*-fluorothiophenol than in *o*-chlorophenol. Similarly, V_2 in pentafluorophenol is 3.5 kcal/mol (33), compared to 6.3 kcal/mol in pentachlorophenol (although it should be remembered that a *para* fluoro substituent decreases the barrier in phenol by 0.3 to 0.4 kcal relative to a para *chloro* substituent (34)).

[3]The insignificant changes in the chemical shifts of the S—H protons in 2,4- and 3,4-dichlorothiophenol on dilution from 5 to 1 mol% in CCl_4 suggest negligible intermolecular association between solute molecules at these concentrations, in agreement with infrared studies of thiophenol derivatives (5).

TABLE 2. Sulfhydryl proton chemical shifts* and long-range spin–spin coupling constants† in some halothiophenol derivatives

2,5-DiBr	392.51	−0.07	0.29	—	−0.12

*In Hz at 100 MHz and 305 K for 5 mol% solutions in CCl_4; to low field of internal tetramethylsilane.
†In Hz, with an accuracy of 0.02 Hz.
‡$^4J_o^{SH,H_2}$ is −0.38 Hz and $^4J_o^{SH,H_6}$ is −0.37 Hz, i.e., the couplings are equal to within experimental error.

All these data are consistent with the ^6J_p of −0.11 Hz in the tetrafluoro derivative (Table 1). V_2 is therefore smaller than in 2,6-dichlorothiophenol, in which a ^6J_p could not be observed. An estimate of V_2 is 3.0 ± 1.0 kcal/mol in the thiophenol derivative. Note that the chemical shift of the S—H proton resonance is 3.70 ppm, considerably upfield of the 4.51 ppm in 2,6-dichlorothiophenol.

That the S—H proton approaches the *ortho* fluorine atom less closely on average in the tetrafluorothiophenol than in the analogous phenol derivative is suggested by the positive value of $^4J_o^{F,SH}$. Its magnitude is only 0.37 Hz. An approach of the S—H proton and the ^{19}F nucleus to well within a distance corresponding to the sum of the van der Waals radii of the corresponding atoms, would undoubtedly lead to a large, negative, coupling constant (2, 35). This would be a result of the so-called through-space coupling mechanism, arising from direct interaction between the orbitals in the atoms containing the ^1H and ^{19}F nuclei (35–38). Thus, $^4J_o^{F,OH}$ in *o*-fluorophenol is calculated by INDO MO FPT as −4.5 Hz when the H,F distance is in the vicinity of 2.2 Å in the *cis* conformation (35), in very good agreement with a measured $^4J_{cis}^{F,OH}$ of −4.4 Hz in an *o*-fluorophenol derivative (2) and with an average $^4J^{F,OH}$ (*cis* and *trans*) of −2.5 Hz in 2,3,5,6-tetrafluorophenol (2). An increase in the H,F distance to 2.5 Å yields a positive calculated $^4J^{F,OH}$. Furthermore, as the O—H bond twists out-of-plane the calculated $^4J^{F,OH}$ rapidly increases, not only because of the decreased H,F distance but also because the σ–π mechanism ($\sin^2\theta$ dependence) makes a positive contribution to $^4J^{F,OH}$ (the hyperfine interaction constant, Q_{CF}, is positive in contrast to Q_{CH}).

That $^4J^{F,SH}$ is +0.37 Hz in 2,3,5,6-tetrafluorothiophenol is therefore consistent with the observed, finite $^6J_p^{SH,H}$ and with the observation of a relatively small low-field shift of the S—H proton in this compound.

3,4-Dichlorothiophenol

As the barrier to internal rotation in *para*-substituted thiophenols decreases, the magnitude of $^4J_o^{SH,H}$ increases, ranging from −0.70 Hz in 4-aminothiophenol to −0.20 Hz in 4-nitrothiophenol (16). ^4J_o is −0.37 Hz in 3,4-dichlorothiophenol (Table 2), within experimental error of its values in thiophenol and 4-bromothiophenol (16), suggesting an internal barrier of 1.0 ± 0.3 kcal/mol (note that the couplings to the two *ortho* protons are equal).

The very small magnitudes of ^4J_o in the other compounds in Table 2 are consistent with appreciably larger internal barriers as suggested in previous sections. However, distortions of the S—H group and and intrinsic substituent effect on ^4J_o from an electronegative or bulky *ortho* substituent may well be present, which may alter the magnitudes of ^4J_o in an unknown way.

Molecular Orbital Calculations

The STO-3G MO calculations with a standard geometry (39) yielded an internal barrier of 2.8 kcal/mol, clearly much too high and comparable to the overestimate of 1.7 kcal/mol for phenol (34). Optimization of the geometry of the S—H bond gave a CSH bond angle of 95.8° (CNDO/2 yields 98° (9)) and a C—S bond length of 1.762 Å. The predicted barrier increased to 3.5 kcal/mol, however.

The geometry optimization consumed 1.5 h of cpu time, so that a limited number of other calculations were performed.[4] In 2,6-dichlorothiophenol, the planar conformation had an optimized CSH angle of 94.5°, indicating, by comparison with thiophenol, that intramolecular attraction (hydrogen bonding to the C—Cl dipole) decreases the CSH angle. This indication is supported by the calculated hydrogen atom charges, which are 1.029 electrons in thiophenol (optimized geometry) and 0.996 electrons in the 2,6-dichloro derivative. In other words, one has a S^+—H^- dipole in thiophenol itself.

In 2,4-dichlorothiophenol, the STO-3G calculations found the *trans* form as more stable than the *cis* form for both standard and optimized geometries, in contradiction to experiment, and reminiscent of

[4]Kollmann and co-workers (9) have compiled an extensive set of CNDO/2 and STO-3G calculations on *ortho*-substituted phenols and thiophenols.

recent calculations on *o*-chlorothiophenol (9). Further calculations were contraindicated. The calculation on the 2,4-dichlorophenol, mentioned above, assumed a standard geometry.

A CSH bond angle of 96°, C—S, S—H, and C—F bond lengths of 1.80, 1.34, and 1.35 Å, respectively, together with an otherwise standard geometry, implies a H,F distance of 2.22 Å for a planar conformation of 2,3,5,6-tetrafluorothiophenol. Therefore a large, negative $^4J^{F,SH}$ might be expected. However, a MINDO/3 optimization on thiophenol (40) gave a CSH angle of 102.3°. Such a bond angle, together with some out-of-plane motion of the S—H bond and perhaps a small increase of the CCF bond angle, might very well increase the average H,F distance to such an extent that the highly distance-sensitive through-space coupling becomes small in magnitude.

It does appear that the primary reason for the relatively weak intramolecular hydrogen bonds in thiophenol derivatives is the small polarity of the S—H bond (41). Intermolecular hydrogen bonding would therefore also be weak relative to phenol, as observed (42).

The ^{13}C chemical shifts of various methylgermanium derivatives

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI, ROBYN E. HUMPHRIES, AND ABDUL MAJID
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received November 9, 1978

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI, ROBYN E. HUMPHRIES, and ABDUL MAJID. Can. J. Chem. **57**, 1426 (1979).

This paper reports ^{13}C chemical shifts for 20 methylgermanium compounds. These shifts are correlated against (*i*) the electronegativity of halogen in the Me_3GeX compounds, (*ii*) the calculated charge on the carbon atom, (*iii*) the ^1H shifts of the methyl protons, and (*iv*) the ^{13}C shifts for the analogous carbon, silicon, and tin compounds.

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI, ROBYN E. HUMPHRIES et ABDUL MAJID. Can. J. Chem. **57**, 1426 (1979).

Dans ce travail, on rapporte les déplacements chimiques du ^{13}C de 20 composés méthylgermanium. On a établi une corrélation entre ces déplacements chimiques et (*i*) l'électronégativité de l'halogène présent dans les composés Me_3GeX, (*ii*) la charge calculée sur l'atome de carbone, (*iii*) les déplacements chimiques ^1H des protons des groupes méthyles et (*iv*) les déplacements chimiques du ^{13}C des composés analogues du carbone, du silicium et de l'étain.
[Traduit par le journal]

Introduction

Although numerous methylgermane derivatives have been described in the literature and their ^1H nmr spectra have been reported, no systematic study of their ^{13}C nmr spectra has appeared. By contrast, there have been recent ^{13}C nmr studies of organosilicon compounds (1–3) and, of course, ^{13}C nmr spectroscopy is a widely used structural tool for which many empirical correlations between ^{13}C chemical shifts and structural features have been developed (4, 5).

As an aid to understanding the chemistry of germanium compounds, we provide herein a tabulation of ^{13}C nmr chemical shifts for a variety of methylgermanium derivatives. We also include ^1H chemical shifts of the germanium compounds and the ^{13}C chemical shifts of the corresponding carbon, silicon, and tin compounds (1, 2, 4, 6–17) where available. For carbon compounds, the ^{13}C chemical shifts of the central carbon are not included in the data. These would have appropriately been correlated with ^{73}Ge chemical shifts which are not yet available.

Results and Discussion

From an inspection of the data on the halide derivatives (Table 1), it is immediately apparent that within any series of methylgermanium halides, the degree of deshielding, as represented by the value of the ^{13}C chemical shift, exhibits an inverse dependency on the electronegativity of the halogen substituent. For the series Me_3GeX (X = F, Cl, Br, I) this inverse dependency is remarkably, and probably fortuitously, linear as is shown by the insert in Fig. 1. The linearity is maintained when the plot is made using the calculated charge on the carbon atom rather than electronegativity (Fig. 1). The latter plot also serves to illustrate that, by contrast, an increase in the number of halogen, electronegative substituents does cause an increased deshielding of the remaining methyl carbon atoms. The figure also emphasizes that differences resulting from a change in the number of like substituents on germanium are much larger than differences resulting from a change in the nature of a substituent. The comparative data show that these general features are also observed for the corresponding halides in the Me_3MX, Me_2MX_2, and $MeMX_3$ species, when M = Si (1, 2) or C (4). Moreover, in the corresponding lead compounds this trend is reversed (29). but no explanation for this difference in behaviour has been presented. The ^1H chemical shifts of the methyl groups in silicon, germanium, and tin methyl halides also exhibit an inverse dependency on the electronegativity of the halogen (4, 8, 18). The trends in silicon analogues have been attributed to halogen → silicon (*p–d*) π-bonding (19). However, the same trends can be noted in germanium and tin compounds where (*p–d*) π-bonding is said to be less important (8), as well as in the carbon analogues where it must be nonexistent. It has been suggested that the trends in the ^1H chemical shifts are explainable in terms of a major contribution from diamagnetic anisotropy and (or) dispersion effects on the ligands (8, 18). It is perhaps glib to suggest that the ^{13}C chemical shifts observed herein result from the same factors because it is apparent, to quote from work on the silicon

*All ^{13}C and ^1H chemical shifts are in ppm with reference to TMS; positive values denote downfield shifts.

†The following additional ^{13}C shifts are reported: Me_3GeOCH_3 50.78; $Me_3GeSCH_2CH_3$ 19.07; $Me_3GeSCH_2CH_3$ 20.89; Me_3GeCN 125.96; $Me_3GeSC(CH_3)_3$ 43.65; $Me_3GeSC(CH_3)_3$ 35.47; Me_3GeSPh, C_m 128.95, C_p 127.05, C_o 136.22 C—S 129.9; $Me_3GeSeCH_2CH_3$ 18.77; $Me_3GeSeCH_2CH_3$ 11.43; $Me_2Ge(OCH_3)_2$ 50.95; $MeGe(OCH_3)_3$ 51.1; Me_3SiCN 126.14.

‡The numbering system is used as a key to Figs. 2–4.

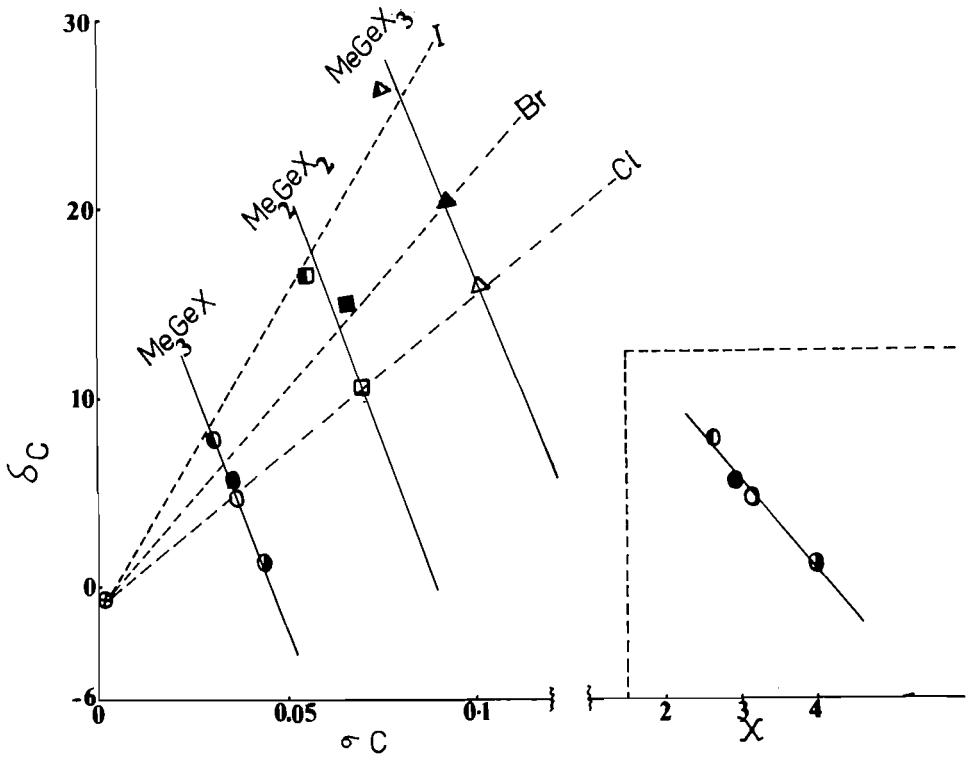

FIG. 1. ^{13}C chemical shifts, δ_C (ppm) as a function of the calculated charge on carbon, σC (and in parenthesis as a function of Pauling electronegativity, *X*) for the compounds Me_4Ge ⊗, Me_3GeF ◑, Me_3GeCl ○, Me_3GeBr ●, Me_3GeI ◐, Me_2GeCl_2 □, Me_2GeBr_2 ■, Me_2GeI_2 ◧, $MeGeCl_3$ △, $MeGeBr_3$ ▲, $MeGeI_3$ ◭.

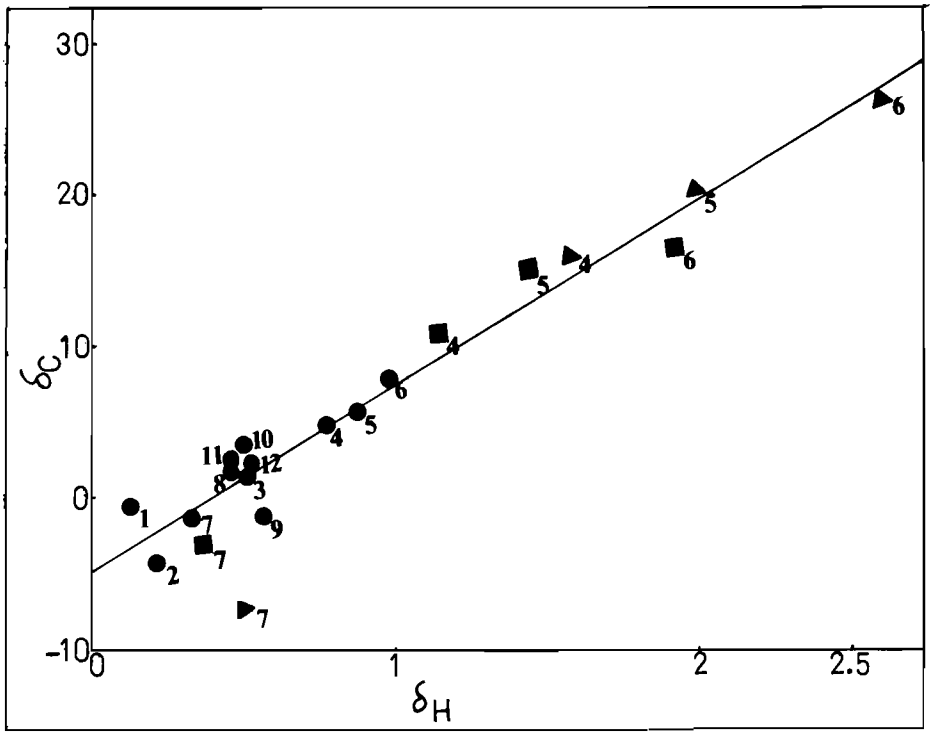

FIG. 2. ^{13}C chemical shifts (ppm) as a function of the ^{1}H chemical shifts (ppm) for various methylgermanes. The key to the numbering is in Table 1 with Me_3GeX ●, Me_2GeX_2 ■, and $MeGeX_3$ ▲. The correlation is $\delta_C = 12.7\delta_H - 5.55$.

compounds, that the reason for this β-effect is not clear (2).

However, as can be seen from Fig. 2, there is, in general, a linear relationship between the ^{13}C and ^{1}H chemical shifts within these germanium compounds which can be stated as fitting the equation $\delta_C = 12.7\delta_H - 5.55$. The linear correlation again suggests that similar factors are responsible for the observed trends in the ^{13}C and ^{1}H chemical shifts.

A correlation is presented in Fig. 3 of the ^{13}C chemical shifts of the methyl groups in germanium compounds, plotted against the corresponding shifts in similar carbon, silicon, and tin analogues. The data in two cases give slopes close to unity and may be correlated by the following linear relationships:

$$\delta_C(Ge) = 0.97\delta_C(C) - 29.68 = 0.92\delta_C(Sn) + 5.80$$

This suggests that the ^{13}C β-shifts for most of these compounds of carbon, germanium, and tin are controlled mainly by similar effects such as magnetic anisotropy or dispersion effects of ligands and hyperconjunction rather than effects such as (*p–d*) π-bonding, which if present, might be expected to differ for each group IV element. However, the silicon system, for which the latter effect is invoked most frequently, shows a significant deviation from a slope of unity, with $\delta_C(Ge) = 1.20\delta_C(Si) + 1.30$. Thus, we have yet another example of the behaviour of germanium being more like carbon than silicon.

The anomalous behaviour of successive methoxy group substitution compared with halide substitution, which was noted in discussing Fig. 2, is further illustrated by Fig. 4. The general features of this figure are remarkably similar to that recently reported for a variety of methylsilicon derivatives (1).

Experimental

Chloro- and bromomethylgermanes were obtained commercially (Alfa Inorganics) as was tetramethylgermane. The preparations of the other germanium compounds have been described in the literature (12, 13, 20–27). The purity was checked from their ir, Raman, and ^{1}H nmr spectra. Where there was sufficient quantity of material, the compounds were recorded as neat liquids (Me_3GeX and Me_2GeX_2; X = Cl, Br, I) or in deuteriochloroform (Me_3GeF) in 5 mm tubes. However, all of the other samples were sealed in capillaries which were then placed in the 5 mm nmr tubes containing deuteriochloroform (as lock) and TMS (as internal standard).

The spectra were all obtained using the Bruker CPX100 multinuclear pulsed Fourier transform NMR spectrometer operating at 22.64 MHz at a probe temperature of 35°C. All spectra were recorded under ^{1}H noise-decoupling conditions.

The charges on carbon in Fig. 1 were calculated by the EESOP method assuming varying degrees of *s*-character on fluorine (0%), chlorine (11%), bromine (16%), and iodine (19%) (28).

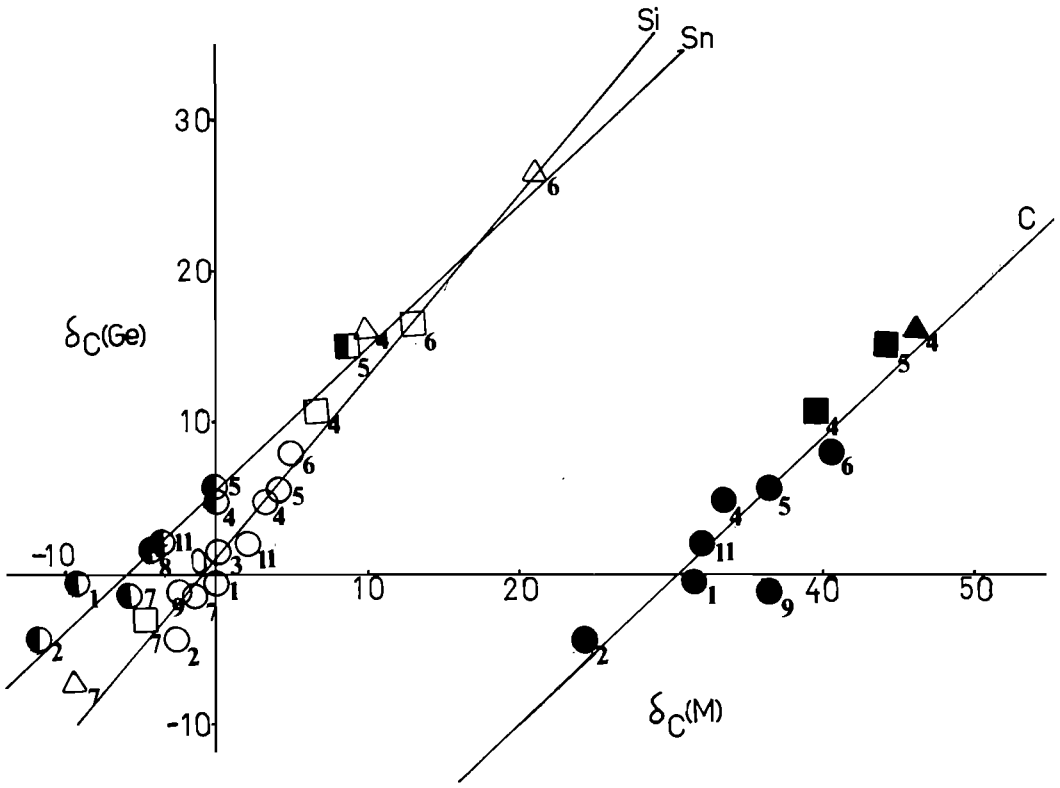

FIG. 3. The ^{13}C chemical shifts (ppm) of methylgermanium derivatives as a function of the ^{13}C chemical shifts (ppm) of the corresponding carbon, silicon, and tin analogues. The key to the numbering is shown in Table 1, with Me_3MX (M = C ●, Si ○, Sn ◐); Me_2MX_2 (M = C ■, Si □, Sn ◧); and $MeMX_3$ (M = C ▲, Si △). Correlations are given by $\delta_C(Ge) = 0.97\delta_C(C) - 29.68 = 1.20\delta_C(Si) + 1.30 = 0.92\delta_C(Sn) + 5.80$.

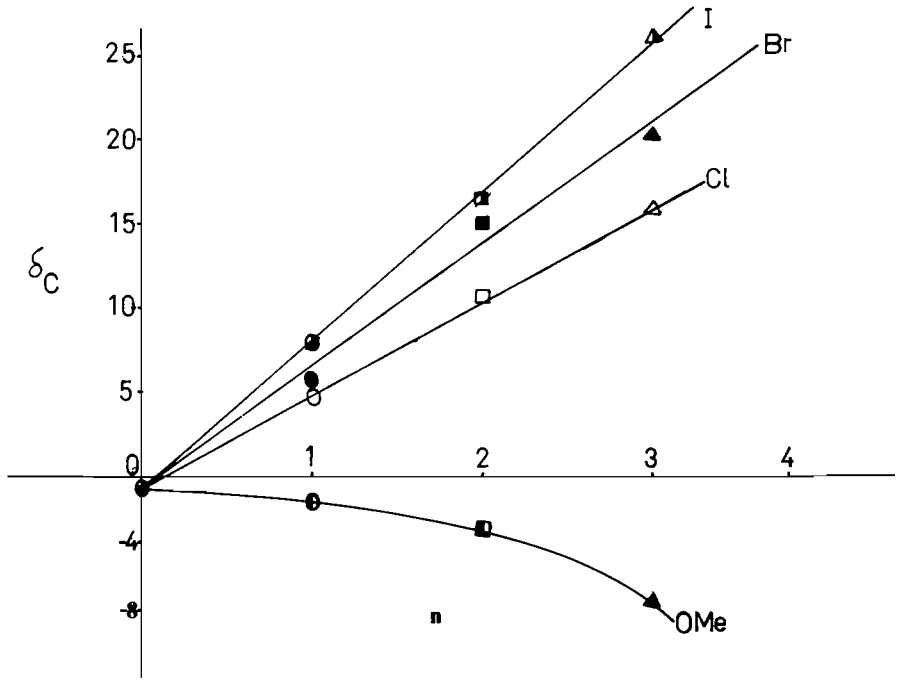

FIG. 4. Variation in ^{13}C chemical shifts of the methylgermanium resonance of $Me_{4-n}GeX_n$ as a function of the successive replacement of methyl by X = Cl ○□△, Br ●■▲, I ◑◨◭, and OMe ◐◧◮, with Me_4Ge ⊗.

Stereoselective synthesis of β-substituted α,β-unsaturated esters by dialkylcuprate coupling to the enol phosphate of β-keto esters

FUK-WAH SUM AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received November 2, 1978

FUK-WAH SUM and LARRY WEILER. Can. J. Chem. 57, 1431 (1979).

The anions from β-keto esters or β-diketones were reacted with diethyl phosphorochloridate to yield the corresponding enol phosphates. These enol phosphates were coupled with dialkylcuprates to produce the β-substituted α,β-unsaturated esters or ketones in good yield. Starting from acyclic β-keto esters this sequence was used to stereoselectively generate tri- and tetrasubstituted olefins.

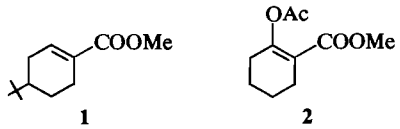
FUK-WAH SUM et LARRY WEILER. Can. J. Chem. 57, 1431 (1979).

On a fait réagir les anions de β-cétoesters ou de β-dicétones avec le phosphorochloridate de diéthyle et l'on a obtenu les phosphates énoliques correspondants. On a effectué une réaction de copulation de ces phosphates énoliques avec des cuprates de dialkyles pour conduire, avec de bons rendements, aux cétones ou aux esters α,β-non saturés substitués en β. En appliquant cette série de réactions à des esters β-cétoniques acycliques, on a obtenu stéréosélectivement des oléfines tri- et tétrasubstituées.

[Traduit par le journal]

In the past decade there has been wide interest in developing new methods to synthesize tri- and tetrasubstituted alkenes in a stereoselective fashion (1). These alkenes have been very useful in the synthesis of a range of natural products, including insect pheromones and terpenes. Recently, we have been investigating methods to utilize β-keto esters in the synthesis of these types of natural products. Dianions of β-keto esters can be trapped by a variety of electrophiles at the γ-carbon (2). These methods have been useful in the synthesis of acetogenins in which the β-keto ester moiety is directly incorporated into the final product (for some examples see ref. 3). On the other hand, conversion of the ketone of a β-keto ester into a methylated olefin as shown in [1] would then constitute a method to incorporate an isoprene unit in a synthetic scheme. The utility of this transformation would be further enhanced if any alkyl group could be used in place of the methyl group in [1].

[1] 
Casey and co-workers (4) have reported that acyclic β-keto esters can be stereoselectively converted into either the (*E*) or (*Z*) enol acetates which then undergo a stereospecific reaction with lithium dimethylcuprate. These reactions were applied in a synthesis of geraniol (4*a*) and (*Z*,*Z*)-7-methyl-3-propyl-2,6-decadien-1-ol (5). This sequence involves treating acyclic β-keto esters with isopropenyl acetate and *p*-toluenesulfonic acid at high temperature to obtain the (*Z*) enol acetates (4, 5). Unfortunately these strong acid conditions severely limit the functionality which may be incorporated in R of [1]; indeed this sequence has only been successful when R is a hydrocarbon. Recently, we have prepared the enol acetates of several cyclic β-keto esters and we find that they do not couple with dialkylcuprates. At low temperatures enol acetate is recovered, and at higher temperature or after prolonged reaction times the acetate is cleaved to yield a mixture of cyclic β-keto ester and enol acetate. House and co-workers (6) have shown that cuprate additions to α,β-unsaturated systems are governed by the ease of electron transfer to the conjugated system. This can be estimated from the reduction potential of the substrate. The reduction potential of the ester (**1**) is −2.50 V (6*a*) and House suggests that



1 **2**

a β-acetoxy substituent has about the same effect on the reduction potential as a β-hydrogen substituent (6*b*). Thus we would estimate the reduction potential of the enol acetate **2** to be −2.5 V. Since it has been found that the α,β-unsaturated carbonyl compounds will react with lithium dimethylcuprate if the reduction potential of the unsaturated carbonyl compound is in the range −1.3 to −2.3 V (6*c*), it is not totally unexpected that **2** and related enol acetates do not react with lithium dimethylcuprate.

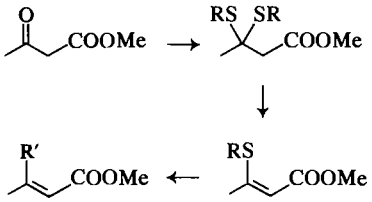
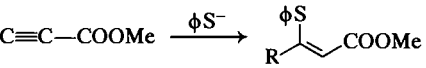
Two groups (7, 8) have reported that β-thiol α,β-unsaturated esters undergo a stereospecific coupling with dialkylcuprates. Unfortunately the β-thiol α,β-unsaturated esters are not readily available from β-keto esters as shown in [2]. In the case of methyl



[2]

acetoacetate the desired vinyl sulfide can be prepared by a base catalyzed or thermal elimination from the thioketal (see [2]). However, in the case of more complex β-keto esters, particularly cyclic β-keto esters, the β,γ-unsaturated ester was often the major product from this reaction (9). Kobayashi and Mukaiyama (8*b*) overcame this difficulty by preparing acyclic vinyl sulfides from acetylenic esters as in [3]. It is clear that this route could not be used for α-substituted or cyclic systems.



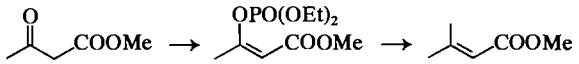
[3]

We also considered the use of β-halo α,β-unsaturated esters in a coupling reaction with dialkylcuprates. The very considerable success in the preparation of β-halo enones from β-diketones (10) and the coupling of dialkylcuprates with these systems (10*a*, 11) augured well for the β-halo α,β-unsaturated esters. However, we have been unable to efficiently convert β-keto esters into the corresponding β-halo α,β-unsaturated ester under a variety of conditions (also see ref. 10*a*). In cases where reaction did occur the product was often a mixture of *gem*-dihalo ester, desired β-halo ester, and γ-halo compound. Bryson (12) has prepared a β-iodo α,β-unsaturated ester by an internal solvolytic addition of the halide to an α,β-acetylenic ester. Again this method is not generally applicable.

Clearly there is a need for a simple, efficient, and general method to convert β-keto esters into β-substituted α,β-unsaturated esters. It is known that the enol phosphate of a ketone reacts with a dialkylcuprate to give the corresponding alkene (13). Thus we considered the synthesis and coupling of the enol phosphates of β-keto esters.

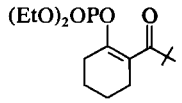
Treatment of methyl acetoacetate with sodium hydride and diethyl phosphorochloridate in ether (14) gave the enol phosphate **3** in 97% isolated yield. The vpc analysis of this material shows only one isomer and this was assigned the (*Z*) stereochemistry by comparing the proton nmr spectrum of enol phosphate **3** with that reported for the (*E*) and (*Z*) isomers of the enol dimethylphosphate of methyl acetoacetate (15). Coupling of the enol phosphate **3** with lithium dimethylcuprate gave the ester **4** in over 80% isolated yield.

This sequence was extended to include the β-keto esters in Table 1. Every β-keto ester we have investigated gave the corresponding enol phosphate in essentially quantitative yield. In the case of acyclic compounds the product was a single isomer by vpc and spectroscopic analysis, and this isomer was invariably the (*Z*) isomer using the above conditions. These enol phosphates can then be coupled with 1.5 to 3 equiv. of lithium dialkylcuprates at low temperature to produce the corresponding alkenes in good yield (Table 1).



3 **4**

Several interesting points can be seen from this data. First, the coupling of primary dialkylcuprates has been successful with *every* combination of cuprate and enol phosphate we have tried. Note, for example, that the methyl 2-cyclohexanonecarboxylate (**10**) was converted into the alkene **22** in 94% yield (Table 1, entry 12) which can be compared to the complete failure of the enol acetate route (*vide supra*) with keto ester **10**. In the coupling with lithium di-*n*-butylcuprate often it was advantageous to use 1-bromobutane to quench the reaction (Table 1, entries 11 and 15). Secondary alkylcuprates proceed in poor yield (Table 1, entry 16) and tertiary alkylcuprates do not add to these enol phosphates under the above conditions. However, with excess di-*tert*-butylcuprate and at higher temperatures the enol phosphate from **10** can be converted into the ketone **26** in 80% yield (Table 1, entry 17). There is some evidence that the ester is attacked first to give the ketone **31**,



31

which then undergoes a coupling reaction with excess dialkylcuprate to give **26**.

Second, note that the coupling proceeds in the case of highly substituted systems (Table 1, entry 18). The keto ester **11** is readily prepared according to [4]. The dianion of methyl acetoacetate (2*a*) was alkylated with 1-bromo-3-methyl-2-butene to give **32** in 85% yield and **32** was then cyclized in almost quantitative yield with stannic chloride to give the keto ester **11**. The ester **27** is an obvious terminal unit for the syn-

thesis of carotenoids and retinals. Entries 6 and 7 of Table 1 also show that the reaction can be used to synthesize acyclic tetrasubstituted alkenes.

[4] 
32 **11**

The third point to note is that the enol phosphate is prepared by a base catalyzed method and hence can be used with acid sensitive groups, for example Table 1, entry 4. In fact the dianion reactions (2) can be quenched directly with diethyl phosphorochloridate as shown in [5]. We have extended this to the multistep sequence shown in [6] in which the alkene **33** was obtained in 68% overall *without* isolation of any intermediates in a one-pot sequence in-

volving dianion generation and alkylation, followed by phosphorochloridate quench and addition to the dialkylcuprate.

Finally, we note the very high stereoselectivity in the case of acyclic enol phosphates. In no case is the stereoselectivity less than 80% and it is usually considerably higher (Table 1, entries 2–5 and 7). In all cases investigated the alkyl group of the dialkylcuprate replaces the phosphate with retention of geometry. It is not clear what the origin of the stereoselectivity is in this reaction. However, dialkylcuprates react with vinyl halides via a substitution

reaction in which the alkyl group replaces the halides with retention of geometry about the double bond (16). Although simple enol phosphates couple with dialkylcuprates (13), there is no report of any stereoselectivity in the examples cited in this work.

The stereochemistry of the alkenes **13–18** was determined from their nmr spectra. In particular, the chemical shift of β-methyl groups in α,β-unsaturated esters is δ 2.1–2.2 for a β-methyl group *cis* to a carboxymethyl group and δ 1.8–1.9 for a *trans* β-methyl group (8*a*, 12, 17, 18). The ^1H nmr spectra for the alkenes **13–18** are given in Table 5 and all of the stereochemical assignments are consistent with the above observations. In addition, the ^{13}C nmr spectrum of the tetrahydropyranyl ether **15** had a signal at δ 16.2 due to the β-methyl carbon. In the corresponding *E* alcohol the ^{13}C-resonance of the β-methyl carbon is at 19.2 whereas the isomeric *Z* alcohol from **15** has a signal at δ 25.5 due to the β-methyl group (12).

[5] 
[6] 
33

The benefits enumerated above should make this new route to α,β-unsaturated esters a very useful tool in the stereoselective synthesis of more complex compounds. Using this methodology, methyl farnesoate was prepared in over 86% yield from geranyl bromide which compares with a 38% overall yield of methyl farnesoate using the thioether sequence (8*b*). Also, compound **15** (Table 1, entry 4) has been used in a synthesis (18) of the butterfly compound **34** (19).

34

In each of these syntheses the isoprene unit **35** is stereoselectively added to a chain in an overall sense as shown in [7].

In addition we have extended this method to the β-diketones shown in Table 2. The enol phosphates of these β-diketones were formed in almost quantitative yield using the above procedure for β-keto esters. Occasionally it was advantageous to use triethylamine as base in place of sodium hydride because of

[7] 
35

insolubility of the sodium enolates in the reaction medium (Table 2, entries 4 and 5). These enol phosphates also reacted with dialkylcuprates to give the corresponding β-substituted α,β-unsaturated ketones.

This reaction appears to go with equal facility using primary and tertiary dialkylcuprates (Table 2, entry 3) unlike the above case where the tertiary dialkylcuprate could not be coupled with the enol phosphate of β-keto esters. These results (Table 2) would indicate that the enol phosphate – dialkylcuprate coupling sequence would complement the excellent methods available (10) to prepare β-halo enones and couple these compounds with dialkylcuprates (11).

Experimental

All ir spectra were recorded in $CHCl_3$ solution using a Perkin Elmer Model 700 spectrophotometer, and were calibrated with the 1601 cm^{-1} band of polystyrene. The ^1H nmr spectra were recorded in $CDCl_3$ solution on either a Varian model T-60 or HA-100 spectrometer. The signal positions are reported using the δ scale with tetramethylsilane as internal standard. The multiplicity, coupling constants, and integrated peak areas are indicated in parentheses after each signal. The mass spectra were obtained using an Atlas CH-4B mass spectrometer, and high resolution determinations were obtained using an AEI MS-9 or MS-50 mass spectrometer. Both instruments were operated at an ionizing potential of 70 eV. Elemental microanalyses were performed by Mr. Peter Borda, University of British Columbia. The silica gel used was obtained from E. Merck and that used for thin layer chromatography (tlc) was the grade PF_{254}, whilst that used for column chromatography was the 100–200 mesh ASTM (Fisher). Vapor phase chromatographic analyses were performed on a Hewlett-Packard Model 5830-A using 6 ft × $\frac{1}{8}$ in. columns of 3% OV-17 and 3% OV-101. Ether and tetrahydrofuran (THF) were freshly distilled from lithium aluminum hydride before use.

Preparation of Enol Phosphates of β-*Keto Esters*

A solution of 1.0 equiv. of the β-keto ester in dry ether was added to a suspension of 1.1 equiv. of sodium hydride in ether, all under nitrogen and at 0°C. After stirring for 15–20 min at 0°C (or 10 min at room temperature), 1.1 equiv. of diethyl phosphorochloridate (Aldrich) was introduced and stirring was continued for 1–2 h at room temperature. For reactions of less than 5 mmol scale, the reaction mixture was stirred with excess solid ammonium chloride for 20 min, filtered through Celite, and the solvent evaporated under reduced pressure. For reactions of larger than 5 mmol scale, the reaction mixture was quenched with aqueous ammonium chloride. The ether solution was then washed with saturated sodium bicarbonate solution, dried over magnesium sulfate, filtered, and the solvents removed under reduced pressure. The enol phosphate was pure by spectroscopic and chromatographic analysis, and it was used directly in the dialkylcuprate coupling reaction. The spectral data for these enol phosphates are given in Table 3.

Preparation of Enol Phosphates of β-*Diketones*

Method *A* was identical to the above procedure for β-keto esters.

Method *B* for those β-diketones which had an insoluble monosodium salt involved treating a suspension of 1.0 equiv. of the β-diketone in ether with 1.1 equiv. of triethylamine and 1.1 equiv. of diethyl phosphorochloridate for 20 h at room temperature. The reaction mixture was filtered, washed with 10% sodium bicarbonate and brine, dried over magnesium sulfate, filtered, and the solvents removed under reduced pressure. The enol phosphate was pure by spectroscopic and chromato-

graphic analysis and it was used directly in the dialkylcuprate coupling reaction. The spectral data for these enol phosphates are given in Table 4.

Coupling of Enol Phosphates with Dialkylcuprates

Preparation of Dialkylcuprates

(*i*) $LiMe_2Cu$: 2.0 equiv. of methyllithium in ether was added to a suspension of 1.0 equiv. of cuprous iodide (CuI) in ether under nitrogen and at 0°C. This solution was used directly.

(*ii*) $LiEt_2Cu$: 2.0 equiv. of ethyllithium in benzene was added to a suspension of 1.0 equiv. of CuI in ether under nitrogen and at −78°C. The resulting black mixture was stirred at −78°C for 30 min and used.

(*iii*) $Li(nBu)_2Cu$: 2.0 equiv. of *n*-butyllithium in hexane was added to a suspension of 1.0 equiv. of CuI in ether under nitrogen and at −47°C. The resulting dark brown solution was stirred at −47°C for 15 min before use.

(*iv*) $Li(sBu)_2Cu$: 2.0 equiv. of *sec*-butyllithium in cyclohexane was added to a suspension of 1.0 equiv. of CuI in ether under nitrogen and at −23°C. The dark black mixture was stirred at −23°C for 15 min before use.

(*v*) $Li(tBu)_2Cu$: 2.0 equiv. of *tert*-butyllithium in pentane was added to a suspension of 1.0 equiv. of CuI in ether under nitrogen and at −47°C. The dark black mixture was stirred at −47°C for 30 min before use.

Dialkylcuprate Coupling

One equivalent of the enol phosphate in ether was added to a cooled, −47°C to −98°C, solution of the dialkylcuprate (1.5–4 equiv.) prepared as above. The resulting mixture was stirred at low temperature for 1–4 h and worked up by pouring it into saturated ammonium chloride solution. The aqueous layer was extracted with ether. The extracts were combined, washed with dilute ammonia in brine and then brine, dried over magnesium sulfate, filtered, and the solvent removed under reduced pressure. The product was purified by chromatography or Kugelrohr distillation. The spectral data for the product esters are given in Table 5, and those for the α,β-unsaturated ketones are given in Table 6.

*Preparation of Methyl Farnesoate (**16**)*

The dianion of methyl acetoacetate (60 mmol) was generated with sodium hydride (66 mmol) and *n*-butyllithium (60 mmol) in the usual manner (2*a*). Then 50 mmol of geranyl bromide was added to the dianion solution at 0°C. After 1 h at 0°C the reaction was worked up (2*a*) to yield 12.6 g of alkylation product which was distilled at 90–92°C/0.02 Torr to give 12.0 g (95%) of **7**.

The keto ester **7** (30 mmol) was converted into 11.45 g of enol phosphate by the general procedure above. A solution of 60 mmol of lithium dimethylcuprate was prepared as above, cooled to −78°C, and treated with a solution of enol phosphate (11.45 g) in 10 mL of ether. This mixture was stirred at −78°C for 2 h and at −47°C for 1 h. The reaction mixture was worked up as described above to yield 7.4 g of crude product which was Kugelrohr distilled at 96–98°C/0.2 Torr to yield 6.83 g (91%) of methyl farnesoate (**16**).

*One-pot Preparation of Methyl (Z)-3-Methyl-2-nonenoate (**33**)*

The dianion of methyl acetoacetate (1.0 mmol) was generated (2*a*) in 3 mL of THF and treated with 1.1 mmol of 1-bromopentane at 0°C. The reaction mixture was stirred at 0°C for 10 min, warmed to room temperature for 25 min, and finally cooled to 0°C again. Diethyl phosphorochloridate (1.1 mmol) was added, and the resulting mixture was stirred at room temperature for 2 h. The enol phosphate solution was cooled to −78°C and added to 2.0 mmol of lithium dimethylcuprate in ether at −78°C. This reaction mixture was held at −78°C for 1¼ h, then at −47°C for 40 min and worked up as above. The crude product (177 mg) was purified by tlc to yield 125 mg (68%) of the unsaturated ester **33** which was characterized by ir: 1710 and 1650 cm^{-1}; nmr δ: 0.87 (b t, J = 6 Hz, 3H), 1.1–1.8 (m, 8H), 2.13 (d, J = 1.8 Hz, 3H), 1.8–2.4 (m, 2H), 3.64 (s, 3H), and 5.6 ppm (m, 1H); ms *m/e* (relative intensity): 41 (17), 55 (18), 82 (20), 83 (20), 110 (30), 114 (100), 127 (40), 153 (25), and 184 (16). *Anal.* calcd. for $C_{11}H_{20}O_2$: C 71.70, H 10.94; found: C 71.59, H 10.75.

*Methyl 6,6-Dimethyl-2-cyclohexanone Carboxylate (**11**)*

The dianion of methyl acetoacetate (2*a*) was alkylated with

3,3-dimethylallyl bromide on a 0.1 mmol scale to yield 15.7 g (85%) of alkylated β-keto ester **32**, bp 67–68°C/0.1 Torr. A solution of 9.2 g (50 mmol) of ester **32** in 10 mL of methylene chloride was added to a solution of 6.4 mL (55 mmol) of stannic chloride in about 150 mL of methylene chloride cooled in ice. The resulting solution was stirred at room temperature for 18½ h. Finally the solution was poured into ice-cold water. The aqueous phase was extracted with ether and the extracts were combined, washed with water and brine, dried over magnesium sulfate, filtered, and the solvents removed under reduced pressure. The crude product was distilled at 64–66°C/0.1 Torr to yield 8.46 g (92%) of cyclized ester **11** which was characterized by ir: 1750 (sh), 1730, and 1710 cm^{-1}; nmr δ: 1.02 (s, 3H), 1.08 (s, 3H), 1.2–2.1 (m, 4H), 2.1–2.7 (m, 2H), 3.13 (s, 1H), and 3.65 ppm (s, 3H); ms *m/e* (relative intensity): 41 (87), 43 (96), 55 (100), 69 (79), 74 (74), 83 (85), 100 (68), 111 (58), 137 (53), 141 (19), 153 (38), 169 (20), and 184 (26). *Anal.* calcd. for $C_{10}H_{16}O_3$: C 65.19, H 8.75; found: C 65.0, H 8.55.

Photoisomerization of protonated cyclohex-2-enones

RONALD F. CHILDS,[1] KENNETH E. HINE, AND FREDERICK A. HUNG
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received October 5, 1978

RONALD F. CHILDS, KENNETH E. HINE, and FREDERICK A. HUNG. Can. J. Chem. 57, 1442 (1979).

Protonated 4,4-dimethylcyclohex-2-enone, **1***H*, has been shown to isomerize on irradiation in FSO_3H at −85°C to give protonated 6,6-dimethylbicyclo[3.1.0]hexan-2-one, **5***H*, and protonated 3-isopropylcyclopent-2-enone, **4***H*. The protonated bicyclic ketone **5***H* was found to be both thermally and photochemically labile, in both instances rearranging to **4***H*. The first order rate constant for the thermal isomerization of **5***H* to **4***H* at −60°C was 1.73×10^{-4} s^{-1}. As **5***H* was shown to be photolabile in the presence of **1***H*, it was not possible to establish whether **4***H* was a primary photoproduct of **1***H*. No photoisomerizations of protonated cyclohex-2-enone and protonated 4-methylcyclohex-2-enone could be detected. The photoisomerization of protonated $\Delta^{1,9}$-10-methyl-2-octalone has been re-examined at low temperature in an attempt to detect tricyclic products.

RONALD F. CHILDS, KENNETH E. HINE et FREDERICK A. HUNG. Can. J. Chem. 57, 1442 (1979).

On a trouvé que la diméthyl-4,4 cyclohexène-2 one (**1***H*) protonée s'isomérise par irradiation dans le FSO_3H à −85°C pour fournir la diméthyl-6,6 bicyclo[3.1.0]hexanone-2 protonée (**5***H*) et de l'isopropyl-3 cyclopentène-2 one protonée (**4***H*). On a trouvé que la cétone bicyclique protonée **5***H* est labile thermiquement ainsi que photochimiquement et que chaque fois elle se transpose en **4***H*. La constante de vitesse du premier ordre de l'isomérisation thermique de **5***H* en **4***H* à −60°C est égale à 1.73×10^{-4} s^{-1}. Comme on a montré que **5***H* est photolabile en présence de **1***H*, on n'a pas pu déterminer si **4***H* est un photoproduit primaire de **1***H*. On n'a pas pu détecter de photoisomérisations de la cyclohexène-2 one protonée ou de la méthyl-4 cyclohexène-2 one. On a réétudié la photoisomérisation de la $\Delta^{1,9}$-méthyl-10 octalone-2 protonée à basse température afin d'essayer de détecter des produits tricycliques.

[Traduit par le journal]

We have recently reported that protonated acyclic α,β-unsaturated carbonyl compounds undergo photoinduced stereomutation about the carbon–carbon double bond on irradiation in super-acid media, eq. [1] (1). This photoisomerization, which takes place with protonated aldehydes, ketones, acids, and esters, eventually leads to the establishment of a photostationary state between the two stereoisomers. No other products were detected under the reaction conditions used although more recent work in our laboratories suggests that a photoinduced isomerization may also be occurring about the carbon–oxygen bond in these systems (2).

[1] 
R = H, Me, OH, OMe

With the incorporation of the chromophore of these unsaturated carbonyl compounds into a ring system, isomerism about the double bond will become more difficult to achieve and other photoreactions could become more important. For this reason we have examined and report here the photoisomerization of some protonated cyclohexenones. Cornell and Filipescu (3) have recently described the photorearrangement of protonated 10-methyloctalone, a system which incorporates a protonated cyclohexenone. However, the results reported here differ from their observations in that, working at low temperatures, a bicyclic product has been detected.

Results and Discussion

Ketones **1**, **2**, and **3** were dissolved in FSO_3H to give solutions of the corresponding hydroxy cations **1***H*, **2***H*, and **3***H* respectively. The ^1H nmr spectrum of **3***H* was very similar to that described previously (4) while those of **1***H* and **2***H* were entirely consistent with the assigned structures (Table 1). FSO_3H solutions of these cations were stable at room temperature and could be quenched with methanol–bicarbonate slurry to regenerate the original ketones. The ultraviolet spectrum of **3***H* has been reported by Zalewski and Dunn (5) and those of **1***H* and **2***H* were recorded in 96% H_2SO_4.

Samples of **1***H* in FSO_3H were irradiated at −60°C in thin walled nmr tubes with light from an unfiltered medium pressure mercury lamp. The

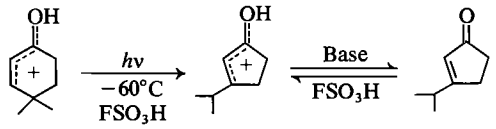
1 $R_1 = R_2 = CH_3$ — **1***H* λ_{max} 275 nm, log ε 3.96
2 $R_1 = H$; $R_2 = CH_3$ — **2***H* λ_{max} 274 nm, log ε 3.96
3 $R_1 = R_2 = H$ — **3***H* λ_{max} 271 nm, log ε 3.97

formation of a new cation was detected by ^{1}H nmr and this was identified as **4***H* (Table 1). Quenching the acid solution after irradiation gave ketone **4** with properties identical with those of an authentic sample (6). Reprotonation of **4** in FSO_3H gave **4***H*.

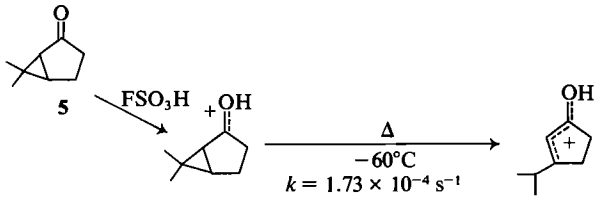


The photoisomerization of **1** in *tert*-butanol gives **4** together with bicyclic ketone **5** (6). To check whether **5***H* was also being formed on irradiation of **1***H*, it was necessary to establish that **5***H* would have been stable under the reaction conditions.

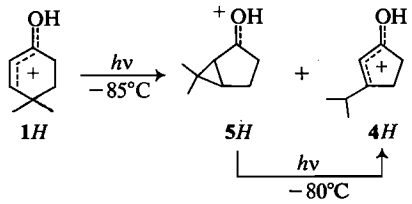
Protonation of **5** using a FSO_3H–SO_2ClF mixture (1:3) at −100°C gave a cation whose ^{1}H nmr spectrum was entirely consistent with the formation of **5***H* (Table 1). This acid solution could be quenched with a methanol–bicarbonate mixture at −78°C to give back **5** together with some **4**. Cation **5***H* was found to be thermally unstable and to isomerize quantitatively to give **4***H*. At −60°C, the first order rate constant for this process was found to be 1.73×10^{-4} s^{-1} ($\Delta G^{\ddagger}$ = 15.9 kcal/mol).

As a typical photoisomerization of **1***H* took several hours, it would not have been possible to detect **5***H* under the reaction conditions used. Accordingly, the photoisomerization of **1***H* was repeated taking care that the temperature of the sample did not rise above −85°C at any time during the irradiation or subsequent monitoring by ^{1}H nmr. After 3 h irradiation both **4***H* (25%) and **5***H* (10%) were detected in the reaction mixture. Quenching this acid solution at low temperature yielded both **4** and **5**.

Under the conditions employed in the above experiment, it would seem very unlikely that **4***H*



arises from a thermal isomerization of **5***H*. At −85°C, the half life for rearrangement of **5***H* would be of the order of 200 h, which is much longer than the 3 h used in the irradiation.

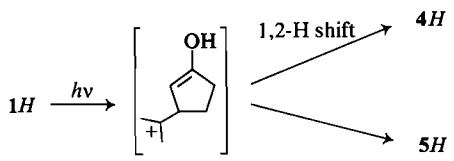


To test whether **4***H* arises by a secondary photoisomerization of **5***H*, the photochemistry of the latter cation was examined. Irradiation of a FSO_3H solution of **5***H* at −80°C caused it to isomerize to **4***H*. This photoisomerization of **5***H* to **4***H* proceeded with an efficiency comparable to that of **1***H* to **4***H* and **5***H*. Irradiation of a mixture of **1***H* and **5***H* indicated that **5***H* was photolabile *even in the presence* of **1***H*. It is not clear at this stage whether or not **4***H* is indeed a primary photoproduct of **1***H*.

In the contrast to the reactivity of **1***H* on irradiation, both **2***H* and **3***H* were remarkably unreactive. Photolysis of solutions of these cations under conditions comparable to those used for **1***H* did not induce any detectable isomerization.

The photoisomerization of **1***H* described above closely parallels the rearrangements reported for the neutral ketone (6, for recent reviews see ref. 7). This type of photoisomerization of cyclohexenones is thought to proceed via a triplet state of π,π^* character (8). The basicities of cyclohexenones are such that they are essentially completely protonated in FSO_3H (5). Consequently, with the n-electron pair being bound to a proton, the lowest excited states of the protonated enones will also most likely be of π,π^* character (10). The multiplicity of the excited state involved in the photoisomerization of **1***H* is not known.

One possible route for the photoisomerization of **1***H* to **4***H* and **5***H* involves the initial formation of **6** as an intermediate. In the ground state the orbital overlap between the p-lobe on C_3 of **1***H* and the electron in the C_4C_5 bond is poor (11). Photoexcitation of **1***H* would likely lead to a twisting about the C_2C_3 bond (1, 12) and so facilitate the 1,2-alkyl shift to give **6**. The difference in behaviour of **1***H*, **2***H*, and **3***H* could possibly be attributed to the thermodynamic differences in energy between a cation such as **6** and its twisted allyl precursor.



6

The extreme thermal lability of **5***H* raises some interesting questions regarding the photoisomerization of protonated 10-methyloctalone, **7***H*, recently reported by Cornell and Filipescu (3). The only product detected on irradiation of **6***H* at ambient temperature was **8***H* and no cyclopropyl containing products were observed, eq. [2].

[2] 
7*H* **8***H*

The photochemistry of **7** has been extensively studied. In *tert*-butanol, the principal product is the tricyclic ketone **9**, eq. [3] (13). Again, a triplet state of π,π^* character has been implicated in this isomerization.

[3] 
7 **9**

In view of the results obtained here, it would seem possible that **9***H* is also a photoproduct of **7***H* and the previous failure to detect it would stem from its thermal instability. To check this we have examined the protonation of **9** at low temperatures.

Dissolution of **9** in FSO_3H was carried out at $-78°C$ and an ^1H nmr spectrum of the solution obtained at $-80°C$. The spectrum so obtained showed no evidence for the presence of **9***H* but rather three rearrangement products were observed. These isomeric cations were **7***H* (25%), **8***H* (35%), and an unidentified cation, **10***H* (40%). This latter cation exhibited amongst other resonances signals attributable to a single vinyl proton at 6.47 δ and methyl group at 2.33 δ. All attempts to recover a pure sample of the ketone corresponding to this cation were unsuccessful.

The thermal instability of **9***H* is such that it clearly could not have been detected as a photoproduct in reactions carried out at room temperature nor indeed using our low temperature equipment (low temperature limit $-85°C$). Evidence against the intervention of **9***H* in the photoisomerization of **7***H* is suggested in that no products corresponding to **10***H* were reported. However, irradiation of the FSO_3H solution of **7***H*, **8***H*, and **10***H*, obtained by rearrangement of **9***H*, under similar conditions to those previously described (3), caused **10***H* to be converted to **8***H*. As a consequence, only a relatively low concentration of **10***H* might be expected during the photoisomerization of **7***H*. Careful examination of the ^1H nmr spectra of the partially photorearranged solution of **7***H* in fact showed reproducible but low concentrations of **10***H* ($<5\%$) to be present.

Overall, the question as to whether or not **9***H* is a photoproduct of **7***H* remains open. However, it is apparent that a close parallel exists between the photoreactions of cyclohexenones and their protonated derivatives.

Experimental

General

^1H nmr spectra were recorded on Varian HA100 or T60 spectrometers. Probe temperatures were measured using a non-spinning thermocouple inserted in a sample taken at the appropriate depth in the probe. Ultraviolet spectra were obtained on a Cary 14 instrument. Gas chromatography was carried out on a Varian A90-P3 preparative instrument using a 15% Carbowax 20 M column, and a Varian 3700 analytical instrument.

Protonations were carried out directly in nmr tubes, extracting the appropriate ketone from CH_2Cl_2 into the acid medium at low temperature ($-78°C$ with FSO_3H, $-100°C$ with FSO_3H–SO_2ClF). Tetramethyl ammonium chloride was added to the cation solutions as an internal standard.

Most irradiations were carried out using the low temperature equipment previously described (14) and a Toshiba 125 W medium pressure mercury lamp. Clear, thin wall nmr tubes were used and these transmitted light down to ca. 260 nm. Temperatures were monitored during the photoreactions with a glass encased thermocouple junction inserted into the acid

medium. The photoisomerization of **7***H* was carried out using a circular arrangement of 1.3-W, RPR 3000 A lamps (Southern New England Ultraviolet Co., Middletown, CT), surrounding a sample held at low temperature in an unsilvered Dewar.

Quenches of the acid solutions were carried out by adding the acid to a rapidly stirred slurry of methanol and sodium bicarbonate at −78°C. The resulting mixture was allowed to warm to ca. −20°C when water was added and the organic products extracted into ether. The products were identified by their ^{1}H nmr spectra and glpc retention times.

Materials

Fluorosulfuric acid (Allied Chemicals) was treated as previously described (15). The ketones **1** (9, 16), **2** (9), **4**, **5** (6), **7** (3), and **9** (13) were prepared by standard procedures.

Photoisomerization of **1**H

1 (5 mg) was dissolved in FSO_3H (0.5 mL) in an nmr tube and irradiated for 3 h using the equipment described above. The ^{1}H nmr spectrum (recorded at −85°C) of the resulting mixture indicated that **1***H* (65%), **4***H* (25%), and **5***H* (10%) were present. The reaction mixture was quenched and the organic extract analyzed by glpc. Both **4** and **5** were shown to be present in a 3:1 ratio.

Photoisomerization of **5**H

5 (5 mg) in FSO_3H (0.5 mL) was irradiated at −85°C for 2 h. The ^{1}H nmr spectrum of the resulting solution showed a mixture of **5***H* (35%) and **4***H* (65%) to be present.

Photoisomerization of **5**H *and* **1**H

A mixture of **1***H* (70%) and **5***H* (30%) was prepared in FSO_3H and assayed by ^{1}H nmr at −85°C. The solution was irradiated for 3.5 h and again subjected to ^{1}H nmr analysis. The composition found was **1***H* (12%), **5***H* (14%), and **4***H* (74%).

Photoisomerization of **7**H

A sample of **7** (5 mg) in FSO_3H was irradiated for 5 h at −65°C using the apparatus described above. The ^{1}H nmr spectrum of the resulting solution showed signals at δ 6.44 (vinyl H) and 1.22 (CH_3) attributable to **7***H*; at δ 6.67 (vinyl H) and 1.19 (CH_3) attributable to **8***H*; and δ 6.48 (shoulder, vinyl H) and 2.33 (CH_3) attributable to **10***H*. The ratio of **7***H* to **8***H* to **10***H* by integration was 55:40:5.

Protonation of **9**H

9 (5 mg) was dissolved in FSO_3H at −78°C and the ^{1}H nmr spectrum recorded at −80°C within 10 min. Only **7***H* (25%), **8***H* (35%), and **10***H* (40%) (chemical shifts given above) were detected. The reaction mixture was quenched and the products examined by analytical glpc using both Carbowax 20 M and silicone oil, SE 30, columns. Using a variety of conditions, it was not possible to separate **7** and **10** from each other.

Irradiation of a mixture of **7**H, **8**H, *and* **10**H

A solution of the above cations, prepared by protonation of **9** (5 mg) in FSO_3H, was irradiated under identical conditions to those used above for the isomerization of **7***H*. After 3 h irradiation the ratio of **7***H* to **8***H* to **10***H* had changed from 25:35:40 to 26:48:26.

Effets des substituants dans les spectres de rmn de benzhydrols substitués en présence de Eu $(dcm)_3$

JOËL CAPILLON ET LILIANE LACOMBE

Laboratoire de Chimie Organique des Hormones, G.R. n° 20 du CNRS, Collège de France, 11 Place Marcelin Berthelot, 75231 Paris Cedex 05, France

Reçu le 16 novembre 1978

JOËL CAPILLON et LILIANE LACOMBE. Can. J. Chem. **57**, 1446 (1979).

Des benzhydrols chiraux, mono ou disubstitués en *para*, ont été étudiés par rmn en présence du réactif de déplacement chiral Eu$(dcm)_3$. L'influence des constantes d'association lanthanide–substrat et des facteurs géométriques a été déterminée séparément. La non-équivalence observée ne peut être reliée à une différence des constantes d'association mais est dûe à une différence de structure des complexes lanthanide–substrat qui varie avec la nature électronique des substituants. De plus on établit une règle de détermination de configuration absolue pour ce type de composé.

JOËL CAPILLON and LILIANE LACOMBE. Can. J. Chem. **57**, 1446 (1979).

Para mono- or disubstituted chiral benzhydrols have been studied by nmr in the presence of Eu$(dcm)_3$. The influence of association constants and structural parameters has been assessed separately. The observed nonequivalence cannot be related to a difference between the association constants but is primarily due to a difference between the geometries of the lanthanide–substrate complexes, correlated with the electronic nature of the substituents. A rule for the determination of the absolute configuration of such compounds has been established.

Au cours de travaux précédents (1), nous avons été amenés à effectuer des déterminations de pureté optique d'alcools aromatiques chiraux substitués en *para*, par rmn en présence d'un réactif de déplacement chiral. Pour une série de composés voisins, nous avions envisagé de relier les sens de non-équivalence observés aux configurations absolues et nous avions remarqué que le sens de la non-équivalence dépendait du caractère électrodonneur ou électroattracteur du substituant. C'est ainsi que dans la série des benzhydrols monosubstitués en *para*, en présence[1] de Eu$(dcm)_3$ le signal du proton benzylique de l'énantiomère *R* se déplace plus rapidement que celui de l'énantiomère *S* lorsque le substituant est électrodonneur alors que l'on observe le phénomène inverse lorsque le substituant est électroattracteur. De même en présence[2] de Eu$(tfc)_3$ on observe un changement du sens de la non-équivalence opposé à celui observé avec Eu$(dcm)_3$. En ce qui concerne les signaux des protons aromatiques on ne retrouve pas le phénomène observé par Mosher *et al.* (4) dans son étude de l'action[3] de Eu$(hfbc)_3$ sur des alcools chiraux L_1CHOHL_2: lorsque le complexe chiral produit une non-équivalence sur les signaux des protons de L_1 et L_2 Mosher avait noté que le sens de la non-équivalence restait le même quels que soient L_1 et L_2 ($\Delta\delta_R - \Delta\delta_S < 0$). Cette constatation lui a permis de suggérer une règle de détermination de la configuration absolue des alcools secondaires chiraux. Dans notre cas, en présence de Eu$(dcm)_3$, $\Delta\delta_R - \Delta\delta_S > 0$ pour les signaux du noyau substitué tandis que $\Delta\delta_R - \Delta\delta_S < 0$ pour les signaux du noyau non substitué. De plus, dans la série des phényléthylcarbinols $ArCHOHCH_2CH_3$, en présence de Eu$(dcm)_3$, le sens de la non-équivalence des signaux du groupe méthyle varie selon le caractère électrodonneur ou électroattracteur du substituant porté en *para* par le noyau aromatique. Ces quelques remarques nous ont incités à étudier plus en détail ces effets de substituants.

La non-équivalence observée dépend à la fois de la différence de stabilité entre les complexes diastéréoisomères formés et de la différence de structure entre ces complexes. Il est possible d'évaluer séparément les contributions de ces deux facteurs en analysant de deux manières distinctes les déplacements induits: d'une part la méthode de Williams (6) qui permet d'apprécier les différences de constantes d'association; d'autre part la méthode de Kelsey (7) et ApSimon *et al.* (8) qui fournit des informations sur la structure des complexes lanthanide–substrat. On peut noter que ces méthodes d'analyse sont possibles quelle que soit la quantité de compétiteur qui se trouve en solution (y compris l'eau) et dans notre cas quelle que soit la pureté optique du substrat.

Cette double analyse n'est valable que si les déplacements induits sont dûs à des complexes

[1] Eu$(dcm)_3$ = tris(d,d-dicamphoylmethanato)europium III (2).

[2] Eu$(tfc)_3$ = tris(d-trifluoroacetyl-3 camphorato)europium III (3).

[3] Eu$(hfbc)_3$ = tris(d-heptafluorobutanoyl-3 camphorato)-europium III (5).

[a]Non observé.

lanthanide–substrat de stoechiométrie 1:1. Goering *et al.* (3) ont établi que le réactif chiral $Eu(tfc)_3$, donnait aussi un complexe de stoechiométrie 1:2. Une étude analogue n'a pas été effectuée au sujet du réactif $Eu(dcm)_3$. Cependant des observations qualitatives montrent que les complexes 1:2 éventuels interviennent peu dans les déplacements induits, surtout s'il y a en même temps une grande dilution du substrat et une grande concentration du lanthanide (9, 10). Ces considérations nous ont amenés à utiliser pour notre étude le réactif $Eu(dcm)_3$.

Méthode

On prépare dans CCl_4, avec le TMS comme référence interne, une solution 0.2 *M* de benzhydrol partiellement dédoublé et de configuration absolue connue (1). A cette solution on ajoute des petites quantités successives non pesées de $Eu(dcm)_3$.[4] L'enregistrement du spectre est effectué à 30°C sur un spectrographe Varian HA 100, 30 min après chaque addition de $Eu(dcm)_3$ de façon à ce que les équilibres soient atteints. On mesure au fréquencemètre les déplacements chimiques. Les déplacements initiaux et les sens de non-équivalence $\Delta\delta_R - \Delta\delta_S$ sont regroupés dans le Tableau 1.

Etude des constantes d'association

D'après les travaux de Williams (6) et Roth (12), le rapport des déplacements induits entre le signal d'un proton *i* d'un substrat A ($\Delta\delta_A{}^i$) et celui d'un proton *j* de B est

$$[1] \qquad \frac{\Delta\delta_A{}^i}{\Delta\delta_B{}^j} = \frac{K_B - K_A}{K_B \Delta_B{}^j}\Delta\delta_A{}^i + \frac{K_A \Delta_A{}^i}{K_B \Delta_B{}^j}$$

où K_A et K_B représentent les constantes d'association des complexes lanthanide–substrat et Δ_A et Δ_B les déplacements induits limites c'est-à-dire la différence entre le déplacement chimique de l'espèce totalement associé et celui de l'espèce libre.

Pour un couple d'énantiomères *R* et *S*, si on compare deux protons structuralement identiques ($i = j$), [1] peut être transformé pour faire apparaître la non-équivalence $\Delta\delta_R{}^i - \Delta\delta_S{}^i$:

$$[2] \qquad \frac{\Delta\delta_R{}^i - \Delta\delta_S{}^i}{\Delta\delta_R{}^i} = \frac{K_R - K_S}{K_R}\frac{\Delta_S{}^i - \Delta\delta_S{}^i}{\Delta_R{}^i} + \frac{\Delta_R{}^i - \Delta_S{}^i}{\Delta_R{}^i}$$

Cette équation montre que la contribution des constantes d'association au phénomène de non-équivalence diminue lorsque le degré de complexation augmente ($\Delta\delta_S{}^i \to \Delta_S{}^i$). Ce type de facteur pourrait donc être négligé si l'on pouvait atteindre un très grand degré d'association. Dans notre cas cela n'est pas possible, certainement parce que l'association benzhydrol–$Eu(dcm)_3$ est faible, et nous avons dû évaluer la différence des constantes d'association.

En appliquant [2], on obtient des droites de pente $-(K_R - K_S)/K_R\Delta_R{}^i$. Cette étude a été effectuée sur les signaux des protons benzylique, α et α′, les déplacements induits des signaux des protons β et β′ étant trop faibles pour être analysés valablement (Tableau 2).

Les valeurs obtenues sont très faibles et montrent que les différences des constantes d'association ont, dans le cas des benzhydrols, une influence mineure sur le sens de la non-équivalence. Ce résultat est confirmé par la comparaison des signes des Tableaux 1 et 2. Pour les protons benzyliques et pour la moitié des protons aromatiques, les signes sont opposés ce qui démontre que, pour ces protons, les effets structuraux imposent le sens de la non-équivalence malgré l'effet contraire des effets d'association.

[b]Valeur aberrante.

[4]Nous remercions le Dr A. Schoofs et le Dr Huynh pour leur préparation du complexe $Eu(dcm)_3$.

Facteurs structuraux

Relations intermoléculaires

Puisque les effets d'association sont peu importants, [1] peut être simplifiée:

$$[3] \qquad \Delta\delta_R{}^i/\Delta\delta_S{}^j \simeq \Delta_R{}^i/\Delta_S{}^j$$

Cette nouvelle relation montre que le rapport des déplacements induits de deux signaux quelconques d'énantiomères différents est proportionnel au rapport des déplacements limites, lequel traduit les effets structuraux.

L'inversion du sens de la non-équivalence du proton benzylique quand on remplace un substituant électrodonneur par un substituant électroattracteur, nous a suggéré l'idée que les facteurs structuraux peuvent être reliés aux σ_p de Hammett des substituants. Nous avons donc porté les rapports $\Delta\delta_R/\Delta\delta_S$ pour le proton benzylique en fonction des σ_p. Pour les benzhydrols monosubstitués, nous trouvons une droite (Fig. 1). On retrouve bien que $\Delta\delta_R/\Delta\delta_S = 1$ pour $\sigma_p = 0$ c'est-à-dire pour le benzhydrol nonsubstitué. A l'aide de cette droite, on peut prédire la configuration absolue de benzhydrols monosubstitués connaissant le σ_p du substituant.

Relations intramoléculaires

La relation [3] n'est valable qu'en première approximation. L'étude de la non-équivalence nous a montré qu'il y avait des différences de structure entre les complexes L*S* et L*R*. Pour comprendre ces phénomènes, il est intéressant d'étudier les facteurs structuraux propres à chaque complexe.

Kelsey (7) et ApSimon *et al.* (8) ont montré que le déplacement observé d'un proton *i* pouvait être relié au déplacement induit d'un proton *j* de la même molécule par la relation:

$$[4] \qquad \delta_A{}^i = (\Delta_A{}^i/\Delta_A{}^j)\,\Delta\delta_A{}^j + \delta_{A_0}{}^i$$

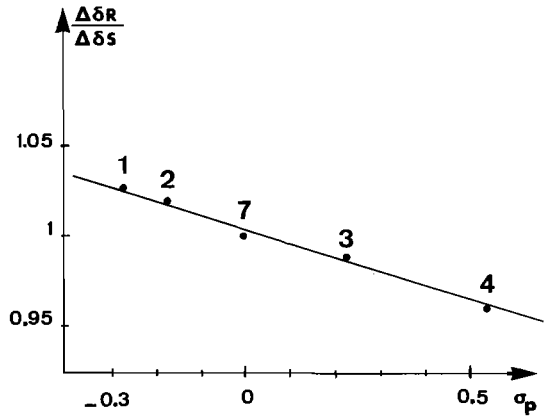

FIG. 1. Variation du rapport des déplacements induits des protons benzyliques de chaque couple d'énantiomère en fonction des σ_p.

D'après McConnell et Robertson (13) et en faisant l'hypothèse généralement admise que les facteurs angulaires sont négligeables (14), la pente de [4] est proportionnelle au rapport du cube des distances r_j^3/r_i^3. Cette simplification est particulièrement justifiée si on compare les déplacements des protons α et α′ de chaque énantiomère (Tableau 3).

Les rapports des déplacements limites sont différents de 1. Ceci indique que l'europium n'est pas à la même distance des protons α et des protons α′. D'autre part, la valeur de ces rapports varie avec la nature des substituants. Comme précédemment, on peut relier les rapports des déplacements limites aux σ_p de Hammett. Dans le cas des composés monosubstitués, on obtient une droite pour les énantiomères *S* et une autre pour les énantiomères *R* (Fig. 2). Ces droites sont à peu près parallèles et les valeurs à l'origine sont 1.142 et 0.868. Ces dernières valeurs sont inverses l'une de l'autre. Or dans le benzhydrol non substitué **7** ($\sigma_p = 0$) les protons α énantiotopes deviennent diastéréotopes (15) en présence du réactif chiral $Eu(dcm)_3$, et ils présentent une forte anisochronie. Le rapport des déplacements limites mesurés par la même méthode est 1.152 ou son inverse 0.868 selon le sens dans lequel ce rapport est calculé. On retrouve la valeur calculée à partir de la Fig. 2. Ce résultat nous a amenés à considérer que la substitution du benzhydrol **7** perturbe l'anisochronie observée en présence de $Eu(dcm)_3$ entre les protons des noyaux aromatiques Pro *R* et Pro *S* (16).

Cette perturbation peut s'exprimer uniquement en fonction de la différence d'électronégativité des substituants des noyaux. Pour cela nous avons utilisé une représentation spatiale unique de tous les composés étudiés même les composés disubstitués. Si on appelle X le substituant porté par le noyau Pro *R* et Y le substituant porté par le noyau Pro *S* (Fig. 3), on peut décrire tous les énantiomères de tous les benzhydrols étudiés à partir d'une seule repré-

6	1.040	0.807

[a]Ces valeurs sont obtenues par la méthode des moindres carrés $\rho^2 > 0.999$.

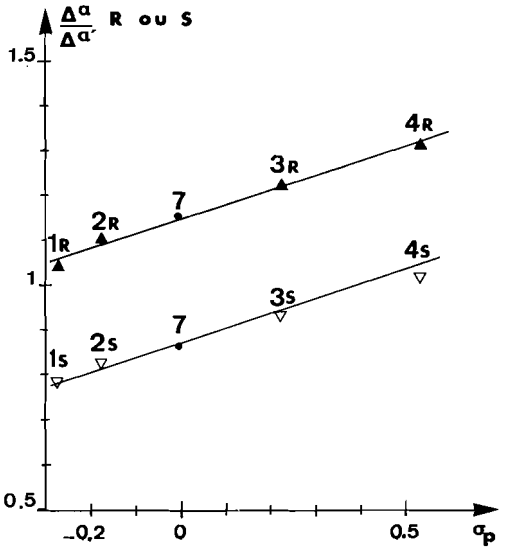

FIG. 2. Variation du rapport des déplacements induits des protons aromatiques de chaque énantiomère en fonction des σ_p.

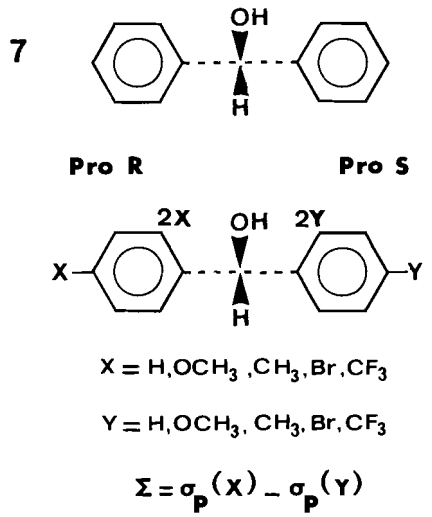

FIG. 3. Représentation spatiale des benzhydrols étudiés utilisée pour la définition de Σ.

sentation spatiale du carbone asymétrique. Par exemple, l'énantiomère *R* du composé **1** sera dans notre nouvelle représentation celui où X = OCH_3 et Y = H. Il n'est plus possible d'utiliser la nomenclature α et α′ que nous avons employé jusqu'ici. Maintenant, pour les énantiomères *R*, les protons α s'appelleront 2X et α′, 2Y et pour les énantiomères *S*, les protons α s'appelleront 2Y et α′, 2X.

On peut alors attribuer à chaque composé un paramètre Σ qui rend compte de la différence d'électronégativité entre le noyau dérivant du noyau Pro *R* et celui dérivant du noyau Pro *S*. Ce paramètre Σ peut être obtenu aisément à partir des σ_p de Hammett des substituants en faisant la différence $\Sigma = \sigma_p(X) - \sigma_p(Y)$. Cette définition entraîne que deux énantiomères ont des Σ de même grandeur mais de signes opposés.

La perturbation de l'anisochronie dûe aux substituants peut être exprimée en reliant Δ^{2X}/Δ^{2Y} au paramètre Σ. En effet $\Delta^{2X}/\Delta^{2Y} = \Delta^{\alpha}/\Delta^{\alpha'}$, pour les énantiomères *R* et $\Delta^{2X}/\Delta^{2Y} = \Delta^{\alpha'}/\Delta^{\alpha}$ pour les énantiomères *S*. On obtient à partir des données relatives aux benzhydrols **1** à **7** une droite (Fig. 4) d'origine 1.15 correspondant à X = Y, valeur proche de celle déterminée expérimentalement pour **7**. Nous avons vérifié que l'on obtenait la même valeur de ce rapport pour deux autres benzhydrols disubstitués symétriques (Σ = 0); pour X = Y = OCH_3, $\Delta^{2X}/\Delta^{2Y} = 1.145$ et pour X = Y = Cl, $\Delta^{2X}/\Delta^{2Y} = 1.148$.

Cette représentation permet aussi de déterminer la configuration absolue de benzhydrols mono- ou disubstitués en *para*: soit un énantiomère d'un benzhydrol portant deux substituants A et B: ou bien A est sur le noyau Pro *R* défini précédemment et alors Δ^{2A}/Δ^{2B} doit se placer sur la droite de la Fig. 4 à la valeur correspondant à $\Sigma = \sigma_p(A) - \sigma_p(B)$; ou bien B est sur le noyau Pro *R* et alors Δ^{2B}/Δ^{2A} doit correspondre à la valeur $\sigma_p(B) - \sigma_p(A)$. Cette méthode est applicable même si l'on ne dispose que d'un seul des énantiomères.

Puisque le rapport des déplacements induits, c'est-à-dire le rapport des distances, est supérieur à 1 lorsque X = Y, cela signifie que pour les benzhydrols symétriques, le noyau Pro *R* paraît plus proche de l'europium que le noyau Pro *S*. La distance de l'europium aux noyaux aromatiques varie selon l'électronégativité des substituants: le noyau Pro *R* devenu porteur du substituant X paraît d'autant plus proche de l'europium que ce substituant est électronégatif ou bien le noyau porteur du groupe Y paraît d'autant plus éloigné de l'europium que le substituant est électrodonneur. Tout se

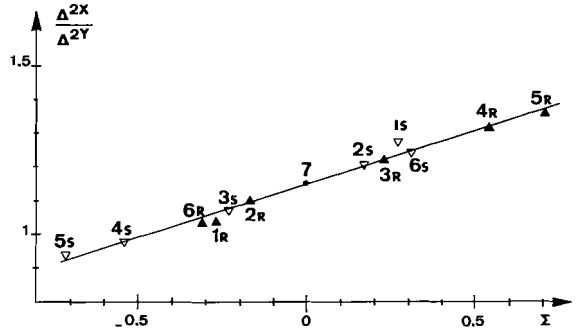

FIG. 4. Variation du rapport des déplacements induits des protons aromatiques de chaque énantiomère en fonction du paramètre Σ (voir texte).

passe comme si un substituant donneur augmentait "l'encombrement" d'un noyau aromatique tandis qu'un substituant attracteur le diminuait. Un substituant d'un noyau aromatique, du seul fait de son électronégativité peut produire des modifications notables de la structure du complexe; lorsque le substrat et le réactif sont chiraux, il en résulte que le phénomène de non-équivalence observé peut se représenter différemment selon la nature du substituant. Il devient évident que la prudence est désormais nécessaire lorsqu'on veut assimiler un composé substitué à un composé non substitué. Comme c'est déjà le cas en synthèse asymétrique (1, 11), les effets électroniques des substituants sur les manifestations de la chiralité ne peuvent plus être négligés.

GERALD ARTHUR POULTON, TERRY DONALD CYR, and ELEANOR E. MCMULLAN. Can. J. Chem. 57, 1451 (1979).

Phacidin, an antifungal antibiotic, isolated from the canker fungus *Potebniamyces balsamicola* Smerlis var. *boycei* Funk is shown to be 2-methoxy-6-nonanoyl-4*H*-pyran-4-one-3-carboxaldehyde. Carbon-13 nmr spectra of phacidin and several related γ-pyrones are discussed.

GERALD ARTHUR POULTON, TERRY DONALD CYR et ELEANOR E. MCMULLAN. Can. J. Chem. 57, 1451 (1979).

On a démontré que la structure de la phacidine, un antibiotique fongicide isolé du champignon chancre *Potébniamyces balsamicola* Smerlis var. *boycei* Funk, est le méthoxy-2 nonanoyl-6 4*H* pyrannone-4 carboxaldéhyde-3. On discute des spectres RMN du ^{13}C de la phacidine et de plusieurs γ-pyrones qui lui sont liées.

[Traduit par le journal]

Introduction

The fungus *Potebniamyces balsamicola* Smerlis var. *boycei* Funk, responsible for a bark disease in *Abies grandis* (Dougl.) Lindl. (1), produces in culture (2) a pale yellow crystalline substance, phacidin. Subsequent testing of this substance revealed (3) promising in vitro activity against a variety of dermatophytes, systemic dimorphic and opportunistic fungi, and yeasts of medical importance. The choice of 6-methoxy-5-nonanoyl-4*H*-pyran-4-one-2-carboxaldehyde (**2**) as the structure best representing phacidin was made (4) on the basis of an examination of the spectra and on the basis of reactivity analogous to that observed in the literature. The structural assignment must now be revised on the basis of more recent chemical and spectroscopic evidence.

Experimental

Nuclear magnetic resonance data were obtained on a Perkin Elmer R12A (60 MHz) or R32 (90 MHz) instrument (proton) or Nicolet TT-14 (15.1 MHz) instrument (carbon) in $CDCl_3$ solution and are referenced to TMS. Mass spectra were obtained using the Hitachi – Perkin Elmer RMU-7E, ultraviolet spectra on the Beckman SP800, and infrared spectra on Beckman IR20 and Unicam SP1000 instruments.

2-Ethoxy-, 2-methoxy-, and 3-bromo-2-ethoxy-6-methyl-4*H*-pyran-4-one (compounds **5**, **6**, **7** respectively) were prepared as described previously (5).

Phacidin (1)

Pure phacidin was isolated from cultures of *P. balsamicola* as described previously (2), as yellow needles, mp 112–113°C; ν_{max} (KBr): 3110 (w), 2975 (sh), 2040 (s), 2870 (s), 1730 (m), 1700 (s), 1690 (m), 1620 (m), 1530 (m), 1520 (s), 1480 (m), 1387 (m), 1340 (m), 1239 (m), and 1041 cm^{-1} (w); λ_{max} (EtOH) (log ε): 224 (4.20), 274 (3.43), and 342 nm (3.90); nmr δ_H: 10.17 (1H, s), 7.11 (1H, s), 4.11 (3H, s), 2.96 (2H, t, J = 6.7 Hz), 2.0–1.1 (12H, m), and 0.88 ppm (3H, t, J = 6.1 Hz); δ_C: see Table 1; ms *m/e* (relative intensity): 294.151 (3%; M^+, $^{12}C_{16}{}^1H_{22}{}^{16}O_5$ requires 294.147), 266 (3.5), 154 (9), 153.020 (100; $^{12}C_7{}^1H_5{}^{16}O_4$ requires 153.019), 141 (4), 126 (2), 125 (9), 121 (4), 93 (4), 85 (2), 71 (3), 69 (5), 59 (4), 57 (5), 55 (3), 53 (3), 43 (5), 41 (5), 39 (2), and 29 (3). *Anal.* calcd. for $C_{16}H_{22}O_5$: C 65.29, H 7.53; found: C 65.10, H 7.62.

Oxidation of Phacidin

To ruthenium tetroxide solution (from ruthenium trichloride trihydrate (3.6 mL of a 2% solution, 2.8×10^{-4} mol) and sodium hypochlorite (29 mL of a 0.5% solution) (6*a*)) were added dropwise phacidin (0.075 g, 2.55×10^{-4} mol) in dichloromethane (20 mL) and sodium hypochlorite (6%, added in quantity sufficient to maintain a yellow reaction mixture). When addition was finished, the mixture was acidified with dilute HCl, extracted with dichloromethane, the extracts dried ($MgSO_4$), filtered, and evaporated to give, after purification, *n*-nonanoic acid[3] (0.013 g, 33%), δ_H 2.33 (2H, t), 1.8–2.1 (12H, m), and 0.88 ppm (3H, t); ν_{max} 3400–2400 (br), 2950 (sh), 2920 (s), 2850 (m), 1712 (s), 1448 (m), 1410 (m), 1280 (m), 1108 (w), and 925 cm^{-1} (m); *m/e* 158.125, $^{12}C_9{}^1H_{18}{}^{16}O_2$ requires 158.131.

2-Methoxy-6-nonanoyl-4H-pyran-4-one (3)

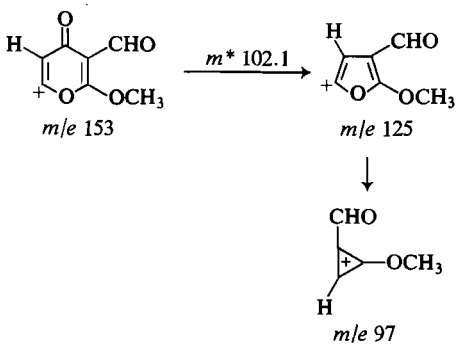
Discussion

The presence of a γ-pyrone (4*H*-pyran-4-one) nucleus in phacidin was inferred (4) from the observed infrared absorptions at 1690 (C=O), 1620, 1530, 1520 (C=C), and 1235 cm^{-1} (C—O—C) and from the ultraviolet maxima at 224 (log ε 4.20), 274 (3.43), and 342 nm (3.90). In general, γ-pyrones are found to exhibit their first carbonyl band in the 1675–1650 cm^{-1} region, the position being somewhat variable, depending upon substituent nature and solvent (7), while α-pyrones absorb in the 1740–1720 cm^{-1} range (7, 8). We felt that our data were best rationalized by a γ-pyrone structure, and this was supported by the fact that γ-pyrone ultraviolet spectra generally reveal intense absorption maxima in the 245–275 nm region (9), although differentiation between α- and γ-pyrone isomers becomes difficult unless both isomers are available. The mass spectrum of phacidin is also in agreement with that expected for γ-pyrones (10, 11), showing two successive losses of carbon monoxide:



Confirmatory evidence for the existence of the γ-pyrone nucleus in phacidin has been obtained from the carbon magnetic resonance spectra:[4] the C4 carbon resonates at 172.9 ppm (see Table 1), well within the normal range of 171–184 ppm observed for γ-pyrone carbonyl carbons (ref. 12 and references in Table 2). Similarly, the α-carbon resonances (158.5 and 160.2 ppm) and the β-carbon resonances (97.0 and 105.9 ppm) are typical of γ-pyrones (β-range normally 88–120 ppm; α-range normally 139–167 ppm (ref. 12 and Table 2)).[5]

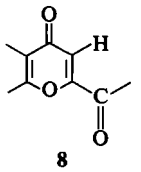
The substitution pattern of the γ-pyrone ring may be readily identified from spectral and chemical evidence. The substituents are: (*i*) a hydrogen (one-proton singlet, δ_H 7.11 ppm), (*ii*) a methoxyl group (δ_H 4.11 ppm (3H, s); δ_C 58.4 ppm ($^1J_{C-H}$ = 148.4 Hz)), (*iii*) an aldehyde, and (*iv*) a *n*-nonanoyl moiety. The aldehyde group is inferred from the infrared (2870, 1730 cm^{-1}), proton nmr (10.17 ppm, 1H, s), and carbon nmr spectra (186.3 ppm, $^1J_{C-H}$ = 186.2 Hz), and confirmed by the formation of a phenylhydrazone (4) and by ready decarbonylation with tris(triphenylphosphine)chlororhodium (6*b*) (discussed below). The nonanoyl group may be inferred from the spectra (ν_{max} 1700 cm^{-1}; δ_H 0.88 (3H, t), 1.1–2.0 (12H, m), and 2.96 ppm (2H, t); δ_C 193.5 (—CO—), plus 7 triplet resonances between 22.7 and 38.3 ppm (see Table 1 for assignments) and 14.1 ppm (q, —CH_3)), and from the isolation and identification of nonanoic acid as the sole isolable product from the oxidation of phacidin (4). The location of the unsubstituted γ-pyrone carbon can be readily made from the observed carbon–proton coupling in the gated spectrum: the resonance at 97.0 ppm exhibits a coupling constant ($^1J_{C-H}$ = 175.3 Hz), similar to those observed[6] for β-protons. This agrees with the argument which was previously advanced

[4]Obtained through the kind cooperation of Dr. John Walter, Atlantic Regional Laboratory, National Research Council of Canada, Halifax.

[5]Normal chemical shift values for α-pyrones are: α 137–165 ppm, β 87–116 ppm, and C=O 157–162 ppm (16).

[6]$^1J_{C-H}$ (β) typically 166–169 Hz, $^1J_{C-H}$ (α) 197–202 Hz (12).

(4), which identified the 7.11 ppm proton magnetic resonance absorption as being due to a β-proton deshielded by an adjacent carbonyl substituent.[7] Thus, the partial structure **8** may be assigned.

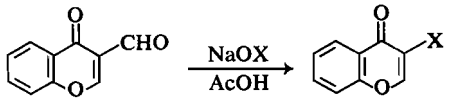


8

The nature of this carbonyl substituent may be deduced from the results of some chemical investigations with phacidin. Treatment of phacidin with tris-(triphenylphosphine)chlororhodium effects smooth decarbonylation (*6b*), producing 2-methoxy-6-nonanoyl-4*H*-pyran-4-one (**3**). Interpretation of the carbon magnetic resonance spectra of phacidin and its decarbonylated analogue can only adequately be made using the structure **1**. In phacidin, the β-carbon signal seen at 105.9 ppm appears in the gated spectrum as a double doublet, with coupling constants of 24.5 and 4.2 Hz. The latter is similar to the typical values (5.1–6.0 Hz) observed (12) for three-bond coupling between C3 and H5 in a series of simple pyrones; the former, larger coupling can then only be reasonably explained if it represents a two-bond coupling between C3 and the proton on the attached aldehyde group. This placement of the aldehyde at position 3 is confirmed by the cmr spectra of the decarbonylated compound, which show δ_C 103.7 ($^1J_{C-H}$ = 176.0 Hz, $^3J_{C-H}$ = 5.35 Hz) and 93.6 ppm ($^1J_{C-H}$ = 169.4 Hz, $^3J_{C-H}$ = 4.0 Hz) and δ_H 6.72 and 5.69 ppm (both 1H, d, J = 2.4 Hz[8]), signals characteristic of a 2,6-disubstituted γ-pyrone. This result unequivocally rules out the structure **2**, in which the deformylated compound would now have one α- and one β-proton, whose chemical shifts would be considerably different and where the coupling constant would be larger.[8] The methoxyl group must then be at position 2 and phacidin is thus 2-methoxy-6-nonanoyl-4*H*-pyran-4-one-3-carboxaldehyde (**1**).

On the basis of this structure for phacidin, the remaining spectra and chemical transformations may be rationalized. Explanation of the mass spectral behaviour is straightforward: the molecular ion undergoes predominant cleavage with loss of the side chain to yield the base peak at *m/e* 153; subsequent fragmentations of this ion have been discussed. Minor fragmentation pathways from the molecular ion involve two sequential CO losses (metastable ion peaks observed at 240.7 and 212.9). The nonanoyl side chain ion (*m/e* 141) and the ions derived from its decomposition ($C_nH_{2n+1}CO$ and $C_nH_{2n-1}CO$ series) are prevalent in the low molecular weight region of phacidin and its derivatives.

Treatment of phacidin with bromine in aqueous methanol results in the replacement of the aldehyde group by a bromine atom. This can be seen by the change in the mass spectrum (molecular weight and fragmentation pattern) and from the carbon magnetic resonance: the aldehyde signal disappears, and that due to C3 shifts upfield to 96.6 ppm (appearing now as a doublet, $^3J_{C-H}$ = 6.6 Hz). This reaction is not without precedent, as Nohara *et al.* (18) have reported the room temperature conversions of chromone-3-carboxaldehyde (**9**) to the corresponding 3-chloro- and 3-bromo-compounds (**10**).

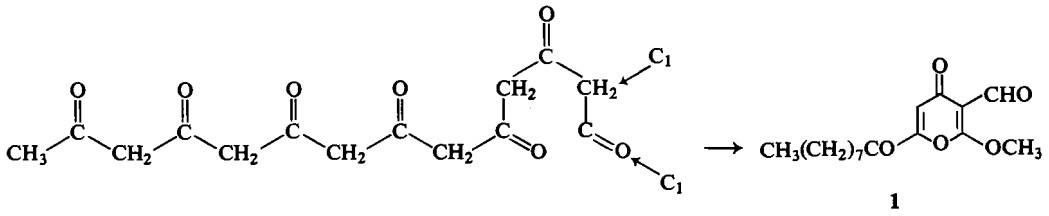


(ref. 18)

9 **10**

The biogenesis of phacidin may also be easily rationalized, since some naturally occurring α-methoxy-γ-pyrones have been shown (see, for example, refs. 13, 14) to be produced from polyketide routes.

It is therefore likely that phacidin is produced from a heptaacetate precursor which undergoes the appropriate cyclizations, alkylations, and modifications:



1

[7]The 'normal' position of a β-hydrogen (4) is in the 5.9–6.5 ppm range; a carbonyl substituent at the adjacent α-position, for example in comenaldehyde methyl ether, results in a deshielding of the proton and a shift of the resonance to 6.97 ppm.

[8]J_{H3-H5} = 2.68 Hz, J_{H2-H3} = 6.3 Hz in γ-pyrone (17).

Methylation at oxygen and ring alkylation by intermediates from the 'one-carbon' pool have been shown (13) to occur in pyrones, and a parallel biogenetic route may be assumed here.

NOTE ADDED IN PROOF: Recent synthetic evidence has shown that the decarbonylated product **3** is 6-nonanoyl-4-methoxy-2*H*-pyran-2-one. Although a rearrangement occurred (previously observed with 2-methoxy-4*H*-pyran-4-ones) and the assignment of chemical shifts (see Table 1) must necessarily be altered, this reassignment does not invalidate the arguments relating to disposition of substituents in phacidin.

GREGORIO G. TRIGO, CARMEN AVENDAÑO, EMILIA SANTOS, JOHN T. EDWARD, and SIN CHEONG WONG. Can. J. Chem. 57, 1456 (1979).

The tropane-3-spiro-5′-hydantoin (α isomer) obtained from tropinone by the Bucherer–Bergs reaction has been shown by ^{13}C nmr and X-ray diffraction studies to have the 4′-carbonyl group in the equatorial position; the β isomer, obtained via the Strecker reaction, has this group axial. The results of these two reactions on *cis*-bicyclo[3.3.0]octan-3-one and on *cis*-3,4-dimethylcyclopentanone show, on the basis of the ^1H nmr, ^{13}C nmr, and X-ray diffraction studies of the products, a stereochemical course related to the preferred conformation of the cyclopentane rings.

GREGORIO G. TRIGO, CARMEN AVENDAÑO, EMILIA SANTOS, JOHN T. EDWARD et SIN CHEONG WONG. Can. J. Chem. 57, 1456 (1979).

On a démontré, au moyen d'études de rmn ^{13}C et de diffraction de rayons-x, que la tropane-3-spiro-5′-hydantoïne (isomère α), obtenue de la tropinone au cours de la réaction Bucherer–Bergs, possède le groupe carbonyle-4′ dans la position équatoriale; l'isomère β, obtenu par la réaction Strecker, possède ce groupement en position axiale. Les structures des produits isomères fournis par le *cis*-bicyclo[3.3.0]octan-3-one et par le cyclopentanone-*cis*-3,4-diméthyle ont été établies par des études semblables. Le chemin stéréochimique des deux réactions est conditionné par la conformation préférée des anneaux cyclopentaniques.

Introduction

The Bucherer–Bergs reaction of aldehydes or ketones with ammonium carbonate and sodium cyanide to form hydantoins (1) and the alternative Strecker reaction via amino nitriles (2) can lead, with some ketones, to different (α and β) products. The stereochemistry of the α and β isomers has been studied by several workers, with conflicting conclusions (3–11). However, this conflict was resolved by the work of Edward and Jitrangsri (11) who explained, by a detailed consideration of reaction mechanisms, how the same amino nitrile could yield either the α- or the β-hydantoin, according to reaction conditions. They concluded that the Bucherer–Bergs reaction of substituted cyclohexanones yields as the major product the isomer (α) with the 4′-carbonyl group of the spiro-hydantoin ring in the less sterically hindered position, while the Strecker reaction yields as the major product the isomer (β) with this carbonyl group in the more sterically hindered position (the EJ rule).

The present work was undertaken to test this rule by establishing the configurations of the isomeric spiro-hydantoins obtained from tropinone (**1**), *cis*-bicyclo[3.3.0]octan-3-one (**4**), and *cis*-3,4-dimethylcyclopentanone (**9**). The preparation of some of these spiro-hydantoins has already been reported (12, 13).

Experimental

All melting points were taken in open capillary tubes and are uncorrected. The ^1H nmr spectra have been recorded on a Perkin Elmer R-24A (60 MHz) spectrometer. The ^{13}C nmr spectra were determined on a Bruker 22.63 MHz spectrometer. Infrared spectra were determined using a Perkin Elmer 577 spectrophotometer.

Materials

Tropinone (**1**) was synthesized by the Robinson–Schöpf method, previously modified by Findlay (14). *cis*-Bicyclo[3.3.0]octan-3-one (**4**) was obtained following the Linstead and Meade scheme (15) as modified by us (13). *cis*-3,4-Dimethylcyclopentanone (**9**) was obtained, with the *trans*-isomer, by catalyzed hydrogenation of 3,4-dimethyl-2-cyclopentenone following the Conia and Leriverend scheme (16). The *cis*- and *trans*-3,4-dimethylcyclopentanones were first separated by analytical gas chromatography on a Perkin Elmer F-20 chromatograph, using a Carbowax 1500 column (4 m length and $\frac{1}{8}$ in. diameter), Chromosorb W-80-100 as support, 130°C of column temperature, nitrogen as carrier gas and 20 mL/min flowing. Retention times (uncorrected): *trans*-isomer 8.35 min; *cis*-isomer 10.4 min. Preparative gas chromatography, using a Perkin Elmer F-21, with a Carbowax 1500 column of 5 m length, nitrogen as carrier gas, 9 s of injection time, and isothermic conditions at 145°C, yielded the two separated isomers.

Tropane-3-spiro-5′-hydantoins (2 and 3)

Bucherer and Strecker products were prepared by the methods previously described (12).

cis-*Bicyclo[3.3.0]octane-3-spiro-5′-hydantoins (5 and 6)*

Bucherer and Strecker products were prepared by the methods previously described (13).

cis-*Bicyclo[3.3.0]octane-3-spiro-5′-(1′,3′-diacetylhydantoin) (β Isomer)*

A solution of *cis*-bicyclo[3.3.0]octane-3-spiro-5′-hydantoin (β isomer; **5**) (0.7 g) in acetic anhydride (73.6 mL) was heated under reflux for 12 h. After the solvent was removed by evaporation under reduced pressure, the residue was crystallized from absolute ethanol; mp 105–110°C (50%); ν_{max} (KBr): 1815, 1785, 1760, and 1700 ($\nu_{C=O}$) cm^{-1}; $\delta(CDCl_3)$: 2.6 (s, 6H, two acetyls). *Anal.* calcd. for $C_{14}H_{18}N_2O_4$: C 60.43, H 6.47, N 10.07; found: C 60.17, H 6.55, N 9.81.

cis-*Bicyclo[3.3.0]octane-3-spiro-5′-(3′-acetylhydantoin) (α Isomer)*

A mixture (50 mg) of **5** (60%) and **6** (40%) (from the Bucherer reaction) was heated as above in acetic anhydride. The residue, recovered in poor yield after recrystallization from water, melted at 138–140°C; ν_{max} (KBr): 3220, 3110 (ν_{N-H}), 1795, 1760, 1690 ($\nu_{C=O}$) cm^{-1}. *Anal.* calcd. for $C_{12}H_{16}N_2O_3$: C 61.00, H 6.83, N 11.86; found: C 61.32, 61.53, H 7.22, 7.15, N 11.92, 11.87.

cis-*3,4-Dimethylcyclopentane-3-spiro-5′-hydantoins (10 and 11)*

(a) Bucherer Product

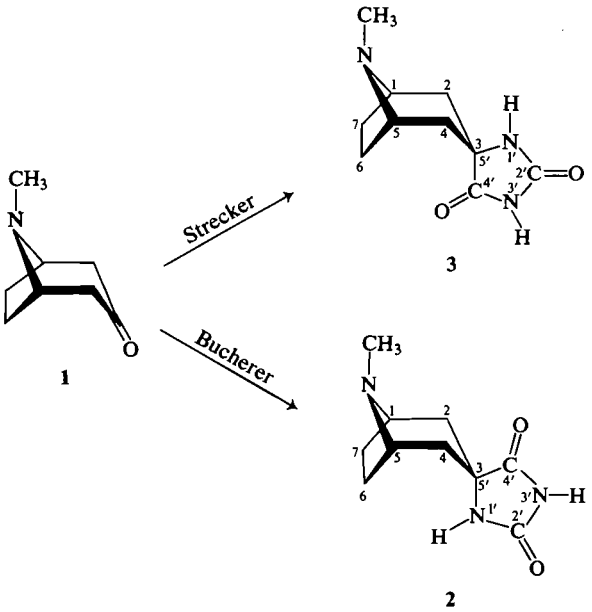
A solution of *cis*-3,4-dimethylcyclopentanone (0.6 g), potassium cyanide (0.6 g), and ammonium carbonate (7.5 g) in ethanol (20 mL) and water (20 mL) was heated under reflux at 50–55°C for 5 h. After cooling, the precipitated solid was filtered off, washed with water, and recrystallized from methanol; mp 298–299°C (31%); ν_{max} (KBr) 3200 ($\nu_{N1'-H}$), 3070 and 3120 ($\nu_{N3'-H}$), and 1745 and 1780 ($\nu_{C=O}$) cm^{-1}. *Anal.* calcd. for $C_9H_{14}N_2O_2$: C 59.34, H 7.74, N 15.37; found: C 59.50, H 7.78, N 15.09.

(b) Strecker Product

cis-3,4-Dimethylcyclopentanone (4.5 g) was stirred with potassium cyanide (3 g) and ammonium chloride (2.2 g) in water (33 mL) and ethanol (25 mL), at room temperature for 7 days. The solvents were removed under reduced pressure, the residue was extracted with ether, and the extract was dried ($MgSO_4$). Passage of dry hydrogen chloride gave 1-amino-*cis*-3,4-dimethylcyclopentanecarboxynitrile hydrochloride; mp 157–158°C (27%). A solution of this crude aminonitrile hydrochloride (1 g) and potassium cyanate (2.1 g) in acetic acid (18 mL) and water (9 mL) was heated at 100°C under reflux for 1 h. The reaction mixture was heated with concentrated hydrochloric acid (9 mL) for 30 min. The mixture was diluted with water, cooled, and the crude product was filtered off and recrystallized from methanol; mp 291–292°C (77%); ν_{max} (KBr): 3200 ($\nu_{N1'-H}$), 3080 and 3100 ($\nu_{N3'-H}$), and 1745 and 1775 ($\nu_{C=O}$) cm^{-1}. *Anal.* calcd. for $C_9H_{14}N_2O_2$: C 59.34, H 7.74, N 15.37; found: C 59.60, H 7.64, N 15.43.

Results and Discussion

We have found that the Strecker reaction with tropinone (**1**) furnished exclusively one isomer (β) and the Bucherer–Bergs reaction exclusively another isomer (α). The structures of the two isomers were established from the ^{13}C nmr data.



The isomers must differ in having the 4′-carbon atom equatorial in one (**2**) and axial in the other (**3**) isomer. In **2** the 4′-carbon will be *gauche* with respect to all four hydrogen atoms at C2 and C4, but in **3** it will be *anti* with respect to two of them. We must expect then that the vicinal coupling constant, $^3J_{^{13}C-^1H}$, should be greater, and hence the ^{13}C peak broader, in **3** than in **2**.

The ^{13}C nmr spectra of α and β isomers (Table 1) were obtained in 85% D_2SO_4 solution since solubilities in the usual solvents were too small. In this solvent the hydantoins will exist as the monoprotonated or diprotonated cations (17), so that the peaks for 2′- and 4′-carbon atoms will be at very low field. The distinction between these positions is possible from the fact that the 4′-, but not the 2′-carbon, spin couples with hydrogen atoms at positions 2 and 4 of the cycloheptane ring.

The 4′-carbon peak of the β isomer had a half-width of 17 Hz, as compared with a half-width of 10 Hz for the 4′-carbon peak of the α isomer. This indicates that the β isomer has the structure **3** and the α isomer the structure **2**.

Since these structural assignments have now been confirmed by X-ray diffraction (18), this work can be considered a confirmation both of the use of ^{13}C nmr for structural diagnosis, and of the EJ rule quoted above.

To utilize this rule to predict the stereochemistry of the Bucherer–Bergs and Strecker reactions with cyclopentanones is more difficult than with anchored cyclohexanones, since the question of which face of

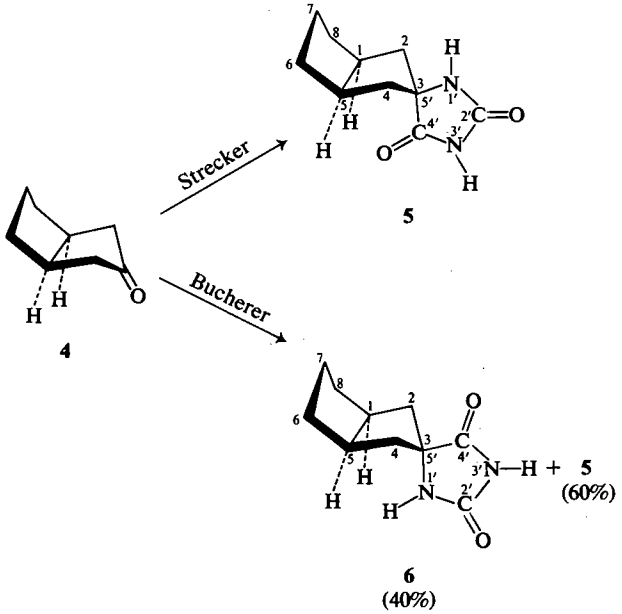
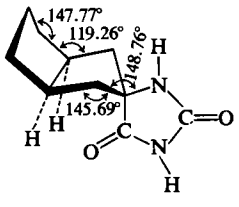
the molecule is more sterically hindered depends on the preferred conformation of the cyclopentane ring.

The only cyclopentane ketones thus far studied have been (±)-camphor and (±)-norcamphor (3, 19). Tager and Christensen (20) showed by X-ray diffraction that the amino acid formed on hydrolysis of the Bucherer hydantoin from (±)-norcamphor had the carboxyl group *exo*, sterically more accessible (21), while the amino acid formed on hydrolysis of the Strecker amino nitrile had the carboxyl *endo*, sterically less accessible, in conformity with the EJ rule.

The steric characteristics of (±)-norcamphor are unambiguous because of its rigid structure. However, *cis*-bicyclo[3.3.0]octan-3-one (**4**) is conformationally mobile, so that application of the EJ rule is difficult. If the ketone has the envelope–envelope conformation shown in **4**, then the rule would indicate the structures **5** for the Strecker product and **6** for the Bucherer product.



The ^{13}C nmr spectra (Table 2) indicate the Strecker product to be a pure compound B, but the Bucherer product, in spite of a sharp melting point, to be a mixture of 60% B + 40% of an isomeric compound A.[2] It was not necessary to separate this mixture in order to establish the structure of A, since its nmr spectrum could be obtained by comparison of the spectrum of the mixture with that of pure B. The chemical shifts and *J* values of A and B are listed in Table 2. The isomers differ in the extent to which the 4′-carbon is coupled with protons on vicinal carbon atoms, as shown by the varying half-widths of the spin-coupled systems (18 Hz for B as opposed to 6 Hz for A). This indicates the structure **5** for B and **6** for A if, indeed, *cis*-bicyclo[3.3.0]octane ring has the conformation shown in **4**–**6**. While it would be difficult to deduce this conformation a priori, it has been established by X-ray crystallography (22) for the Strecker product B. This study confirms the structure **5** for B, with the angles indicated. The plane of the hydantoin ring bisects the angle formed by the C2, C3, and C4 carbon atoms.



5

These structures accord with the results of acetylation experiments (cf. ref. 11). B reacted with acetic anhydride to give a diacetyl derivative, as would be expected of **5** (11). Under the same conditions, the 40:60 mixture of A and B from the Bucherer reaction

[2]The same composition of the Bucherer–Bergs product is indicated in its ^1H nmr spectrum, which shows two peaks for the 1′-hydrogen atom with relative intensities 6:4 (see Table 3); the spectrum of the Strecker product shows only one 1′-hydrogen peak having the same chemical shift as the peak of the major isomer from the Bucherer–Bergs reaction.

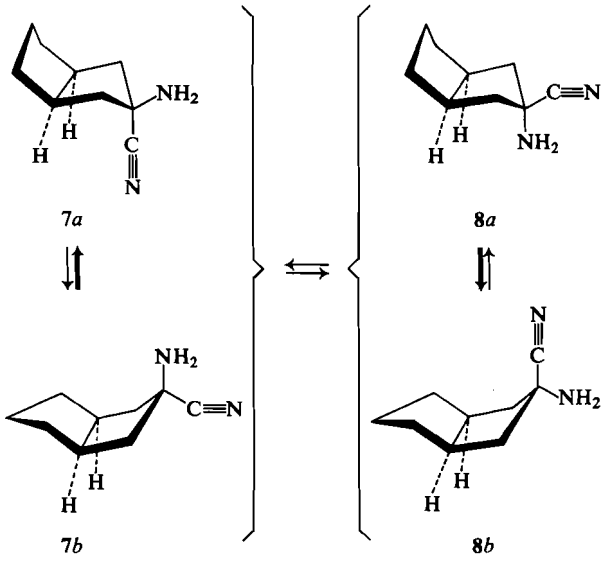
gave in low yield a monoacetyl derivative, evidently derived from **6** in which the axial N(1)—H is hindered.[3]

The results above show the limitations of the EJ rule when applied to conformationally mobile systems. Assuming for simplicity only envelope–envelope conformations for bicyclo[3.3.0]octanes, the aminonitrile progenitors of the Strecker and Bucherer products have the structures **7** or **8**; the different conformations of these isomers are shown in Scheme 1. Because of the small steric requirements of the nitrile as compared with the amino group (23), the conformation *7a* should be considerably more stable than *7b*; furthermore, the aminonitrile **7** should be considerably more stable than its isomer **8**, which in its more stable conformation (*8b*) has the nitrile group opposed by two quasi-axial methylene groups, while in *7a* it is opposed by two quasi-axial hydrogen atoms. These considerations accord with the fact that the Strecker product is derived wholly, as expected, from **7**. However, 60% of the Bucherer product is also derived from **7**, probably reacting via the conformation *7b*, and only 40% from **8**, probably reacting via the conformation *8a*, for reasons discussed earlier (11). It would be expected that the product ratio would be a complicated function of the relative proportions of *7a*, *7b*, *8a*, *8b*, and of their relative rates of reaction and of interconversion (the major product probably being formed by the route *7a* → *7b* → hydantoin).

It seems likely that the mutual repulsion of the two methyl groups in *cis*-3,4-dimethylcyclopentanone (**9**) will disfavour the envelope and favour a half-chair conformation in which the upper face will be the more sterically hindered. Consequently, the EJ rule predicts **10** as the major product of the Bucherer–Bergs reaction and **11** as that of the Strecker reaction (with the proviso that for this conformationally



SCHEME 1

[3]The hydantoins have high melting points and low solubilities because of strong hydrogen bonding (N—H···O=C) in the crystal. Melting points fall and solubilities increase dramatically with acetylation of the N—H groups. In the present instance the monoacetyl **6** (which retains one N—H group) is evidently considerably less soluble than the more abundant diacetyl **5**. Since hydantoins are readily recovered from their acetyl derivatives by hydrolysis, acetylation may prove a useful technique in separating α and β isomers.

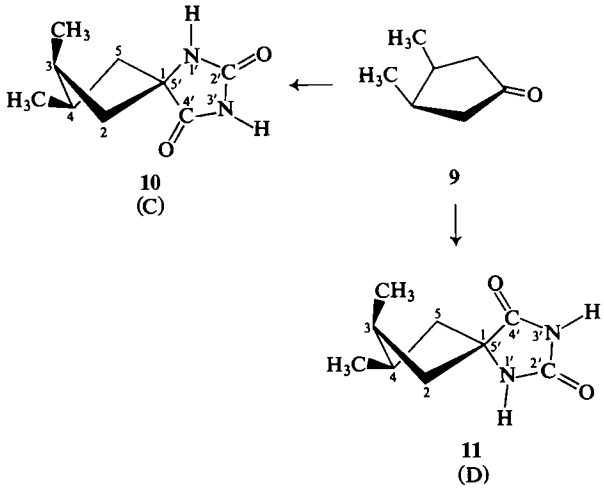
mobile system the results will not be clear-cut). In fact, the ^1H nmr spectra of both Bucherer–Bergs and Strecker products show them to be mixtures of two isomers (C and D) having chemical shift values for the 1′-hydrogen atom at 8.0 and 8.2 δ respectively. The Bucherer product was about 90%, and the Strecker product about 40% C. The ^1H chemical shifts for the other protons (N3′—H, 11 (s); CH_3, 0.9 (d); remaining protons, 1.4–2.4 δ) were identical in C and D.



10 (C) ← **9** → **11** (D)

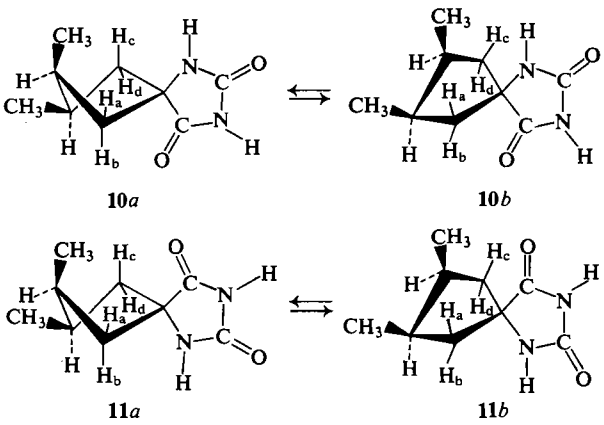
The ^{13}C nmr spectra also indicate 90% C in the Bucherer and 64% D in the Strecker product. The Bucherer product is slightly less soluble in 85% D_2SO_4 than the Strecker product, and so was dissolved in 90% D_2SO_4. This difference in acid concentration accounts for the slight differences in chemical shift values of C and D in the two products shown in Table 4. The isomers differ in the extent of coupling of the 4′-carbon atom with protons on vicinal carbon atoms, so that the half-widths of the spin-coupled systems are 9 Hz for D as opposed to 12.5 Hz for C.

We now consider arguments for identifying C with **10** and D with **11**.

Examination of Dreiding or Fieser models of **10** and **11** shows that these compounds probably exist as the conformers **10***a*/**10***b* and **11***a*/**11***b* in mobile equilibrium (Scheme 2): this would explain why only one nmr peak is observed for the two methyl groups of **10** and **11**. The models of **10***a* and **10***b* indicate the dihedral angles reported in Table 5 for the C4′C5′ bond with the C—H bonds on C2 and C5. The models (which are sensitive to Baeyer strain but not to torsional strain or nonbonded interactions) indicate the same dihedral angles for **11***a*/**11***b*; however, these structures ignore the nonbonded interaction between the 4′-carbonyl oxygen and the *quasi*-axial methyl at C3 or C4. This interaction must be very considerable (11). If one bends the oxygen away from the methyl group, the dihedral angles recorded in Table 5 for **11***a*/**11***b* can be measured on the models.[4] The curve relating the $^3J_{^{13}C-H}$ coupling constant to dihedral angle (24) is qualitatively similar to the familiar curve for $^3J_{H-H}$ (25). Using such a curve, it can be readily established that the angles reported in Table 5 require the C4′ peak of **10** to be broader than that of **11**, thus identifying C as **10** and D as **11**.

These results are in agreement with the EJ rule if one takes account of the weaker stereochemical preferences found in reactions of cyclopentanones as compared with cyclohexanones. The hydantoins **11** and **10** will be formed from the aminonitriles **12** and **13** as shown in Scheme 3. Because the amino and

[4]The angles recorded in Table 5 can be only very approximate, but almost certainly give the correct trends. The result of the argument which follows, is not affected by small variations in the dihedral angles from those reported in Table 5.



10*a* 10*b*

11*a* 11*b*

nitrile groups at the 1-position are not axial or equatorial, the preference for **12** over **13** is slight, and hence the preponderance of **11** over **10** in the Strecker product (which reflects the proportions of **12** and **13** (11)) is also slight. On the other hand, interference between the C=NH group with one axial methyl group in **14** will be much more serious than interference between this group and an axial hydrogen atom in **15**, and so the stereoselectivity of the Bucherer reaction in favour of **10** over **11** is higher.

It is evident that the stereochemical preferences of biased cyclopentanones are much less pronounced than those of biased cyclohexanones, but that the EJ rule is effective in indicating trends. Further studies of substituted cyclopentanones are needed to confirm the highly tentative conclusions reached above.

BARBARA D. GOWLAND and TONY DURST. Can. J. Chem. **57**, 1462 (1979).

Benzocyclobutyl phenyl sulfone has been converted to several 7-substituted benzocyclobutenes via reaction of its α-sulfonyl carbanion with typical electrophiles followed by desulfonylation with Na/Hg in methanol. Two benzocyclobutenes carrying remote terminal vinyl groups have been isomerized to tricyclic ring systems upon heating at 250°C. The *o*-quinodimethane obtained from thermolysis of benzocyclobutyl phenyl sulfone in toluene at 250°C is not trapped by maleic anhydride but by the solvent toluene in a Friedel–Crafts type alkylation.

BARBARA D. GOWLAND et TONY DURST. Can. J. Chem. **57**, 1462 (1979).

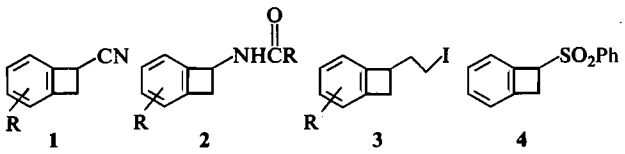
On a transformé la benzocyclobutyl phénylsulfone en plusieurs benzocyclobutènes substitués en position 7 par l'intermédiaire de la réaction de son carbanion α-sulfonyle avec des électrophiles appropriés suivie d'une désulfonylation avec Na/Hg dans le méthanol. On a isomérisé deux benzocyclobutènes, portant des groupes vinyles terminaux éloignés, en systèmes tricycliques par chauffage à 250°C. Le *o*-quinodiméthane que l'on obtient par thermolyse de la benzocyclobutyl phénylsulfone dans le toluène à 250°C ne peut pas être piégée par l'anhydride maléique; le toluène agissant comme solvant le piège toutefois par une alkylation de type Friedel–Crafts.

[Traduit par le journal]

Introduction

o-Quinodimethanes, generated thermally from benzocyclobutenes, have been used effectively, especially by groups led by Oppolzer (1) and Kametani (2) for the rapid and highly stereoselective assembly of certain steroid and alkaloid ring systems.

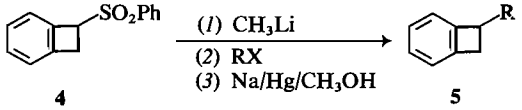
A key intermediate in these approaches is the benzocyclobutyl nitrile **1** and aryl substituted derivatives thereof. These nitriles are generally converted into the amide **2** or iodide **3** for use in the alkaloid (1) and steroid (1*b*, 2) syntheses respectively.



1 **2** **3** **4**

As part of our work on the use of sulfones in organic synthesis (3) we decided to investigate the potential of benzocyclobutyl phenyl sulfone, **4**, as a reagent in this area.

We had felt that the sulfone **4** might provide a number of key advantages over the nitrile **1** in the preparation of substituted benzocyclobutenes which could be thermolyzed to polycyclic ring systems. For example, alkylation of **4** via its anion followed by desulfonylation should yield the substituted benzocyclobutenes **5**. Similar reactions have been reported for **1** (4), but the reductive removal of the CN group requires more stringent conditions (Li or Na in amines) than that of the $PhSO_2$ group (Na/Hg in buffered methanol) (5).



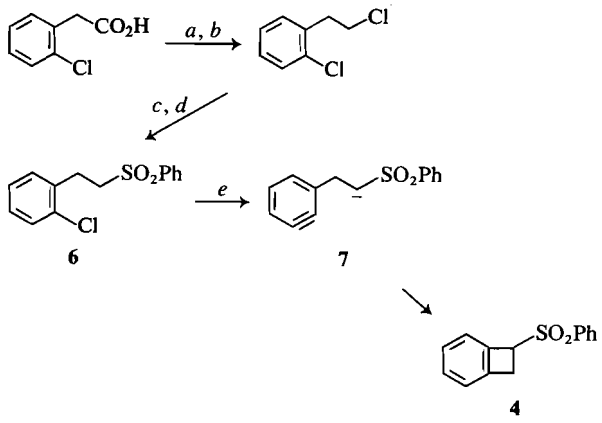
4 **5**

Synthesis of Benzocyclobutyl Phenyl Sulfone (4)

Benzocyclobutyl phenyl sulfone had previously been prepared by Bunnett and Skorcz (6) from *o*-chlorophenylacetic acid following Scheme 1. This synthesis featured an intramolecular benzyne cyclization and is thus difficult to carry out on a large scale. It was therefore decided to first investigate other potential routes to **4** which might be more suitable for a large scale synthesis. These attempts are briefly described below. Unfortunately none were successful and we had to revert, with some modifications, to the Bunnett and Skorcz synthesis.

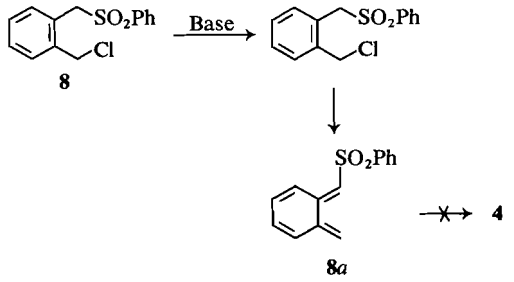
One of our approaches to **4** involved the base-catalyzed elimination of HCl from the chloro sulfone **8**. It was hoped that the intermediate **9** from such an elimination might cyclize to **4** in the same way that the debromination of α,α,α′,α′-tetrabromo-*o*-xylene with NaI afforded, via an *o*-quinodimethane intermediate, a dibromobenzocyclobutene (7). The chloro sulfone **8**, mp 75–77°C, was prepared in 42% yield by refluxing sodium benzenesulfinate with bis-1,2-

0008-4042/79/121462-06$01.00/0



SCHEME 1. Reagents: (*a*) $LiAlH_4$, (*b*) $SOCl_2$–pyridine, (*c*) PhS^-Na^+, (*d*) H_2O_2, (*e*) $NaNH_2/NH_3$.

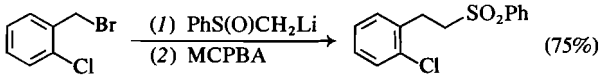
(chloromethyl)benzene in methanol for 1 day. The elimination of HCl from **8** was attempted with lithium diisopropylamide at −78°C, CH_3Li at 0°C or 25°C, and NaOH under phase-transfer conditions. In each case a yellow-coloured solution was generated but only a polymeric product was isolated. Possibly the presumed intermediate **8***a* is trapped by the α-sulfonyl carbanion of the starting material in an oligomerization reaction. Attempts to trap **8***a* with Δ-1-cyclohexenylpyrrolidine were unsuccessful.



Loudon *et al.* (8) have reported that the flash vacuum thermolysis of α-chloro-*o*-xylene at 630°C afforded 68% of benzocyclobutene. Similar treatment of **8** at 500°C/0.06 Torr gave an inseparable mixture of products containing no **4** while thermolysis at lower temperatures (400°C) yielded mixtures including some recovered starting material.

In a reinvestigation of the Bunnett and Skorcz route we attempted to prepare the benzyne precursor **6** by alkylation of α-lithiomethyl phenyl sulfone with *o*-bromobenzyl bromide. Many experimental variations of this reaction were attempted (see Experimental section); however, in all cases mixtures of mono- and dialkylation products, together with the starting materials, were recovered. In contrast, the alkylation of $PhS(O)CH_2Li$ with *o*-chlorobenzyl bromide afforded the expected sulfoxide in 82% isolated yield, oxidation of which gave 91% of **6**. The 75% overall yield of **6** in this two-step procedure can be compared with the 60% overall yield of **6** achieved in 4 steps by Bunnett and Skorcz.

The cyclization of **6** to **4** requires careful control of the stoichiometry of base to substrate. When the KNH_2/**6** ratio was 2:1 no benzocyclobutyl phenyl sulfone was obtained. Instead, the major reaction products were *o*-chlorostyrene **9** and a crystalline material, $C_6H_{14}Cl_2$, mp 51–53°C, to which we assigned the structure **10** mainly on the basis of the proton nmr spectrum (see Experimental section). A



proposal accounting for both **9** and **10** is given in Scheme 2.

The use of 4 equiv. of KNH_2 per equivalent of **6** did give **4** in an average yield of about 35% (8 runs), together with 15% of isomeric amino sulfones due to the trapping of the benzyne intermediate **7**, or its protonated equivalent with $^-NH_2$.

The different behavior of the sulfone **6** in the presence of either 2 or 4 equiv. of KNH_2 can be explained in the following manner. In the presence of one or somewhat more than 1 equiv. of KNH_2 the α-sulfonyl anion **6***a* would be expected to be formed preferentially. This anion should be stable under the reaction conditions and in equilibrium with the starting material. A slow competitive β-elimination of $PhSO_2^-$ from **6** by the action of

*Desulfonylation was carried out on nondeuterated material.
†Nuclear magnetic resonance yield. The product could not be separated from 4.

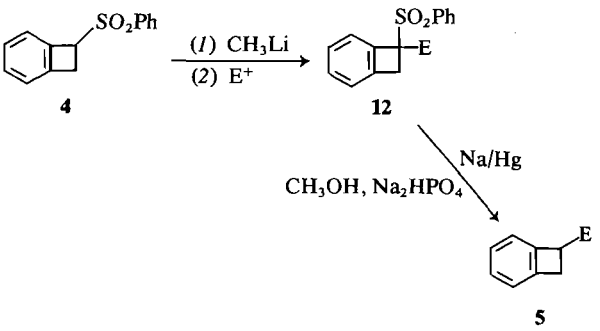
$^-NH_2$ (9) would yield *o*-chlorostyrene. Addition of the anion **6***a* to *o*-chlorostyrene should give the sulfone **11** from which **10** can be obtained via a β-elimination. Under these conditions benzyne formation would be expected to be slow.

As the amount of base is increased most of **6** would be converted to the monoanion **6***a*. Sufficient $^-NH_2$ would still be present to produce the benzyne intermediate **7** at a reasonable rate, intramolecular trapping of which yields **4**. The use of an $NaNH_2$/**4** ratio of greater than 4 was not investigated since it was felt that this would produce mainly the amination products. Reaction of **4** with either 2 or 4 equiv. of lithium 2,2,6,6-tetramethylpiperidide (11) did not generate any of the benzocyclobutene **4**.

Preparation of 7-Substituted Benzocyclobutenes

Reaction of **4** with CH_3Li at −78°C in dry tetrahydrofuran (THF) under N_2 rapidly generated a yellow-coloured solution containing the α-sulfonyl anion of **4** as evidenced by reaction with D_2O, CH_3I, and several alkyl bromides (Table 1). Typical aliphatic chlorides or epoxides did not react efficiently with this anion.[1] Each of the alkylated products was characterized by elemental analysis and infrared and ^1H nmr spectra, the latter showing a characteristic isolated AB quartet in the 3.2–3.8 ppm region. The reductive removal of the $PhSO_2$ group from the alkylated derivatives **12** was carried out using a slightly modified version of the Trost procedure (5).

[1]The anion of **4** decomposed overnight and yielded a mixture of nonpolar crystalline substances, mp 103–112°C. The nmr spectrum of this mixture showed two singlets at δ = 3.52 and 3.80 as well as aromatic protons from 7.0–7.4 ppm. The infrared indicated the absence of any sulfonyl moiety. The highest *m/e* peak in the ms of the mixture occurred at *m/e* = 204 suggestive of a possible 'dimer' of benzocyclobutadiene resulting from a β-elimination of $PhSO_2^-$ from some unionized **4**. The structure of the compounds in this mixture remain to be determined.



The yields of the desulfonylated products **5** were greater than 90% (Table 1).

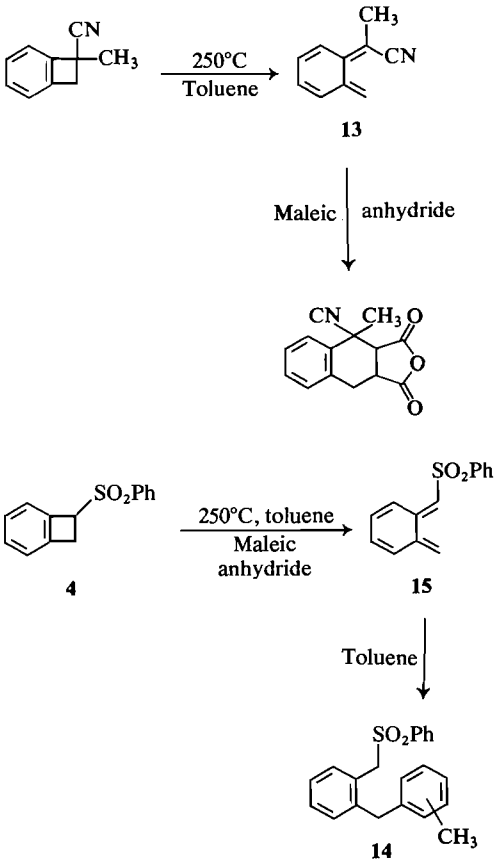
Thermolysis of Benzocyclobutyl Phenyl Sulfones

Benzocyclobutyl phenyl sulfone **4** was thermolyzed at 250°C in a sealed tube as a toluene solution containing excess maleic anhydride. The reaction conditions chosen were similar to those used by Kametani *et al.* (13) who reported the trapping of the *o*-quinodimethane intermediate **13** from 7-cyano-7-methylbenzocyclobutene with maleic anhydride in 65% yield. In contrast to the Kametani results the only isolable product from the thermolysis of **4** had not incorporated maleic anhydride, but rather toluene. The product, obtained in 25% yield after preparative thin layer chromatography, was shown to be an isomer mixture, **14**. The nmr spectrum of **14** showed peaks at 2.18 and 2.28 (2 singlets, total 3H), 3.80 (s, 2H), 4.29 (s, 2H), and 7.0–7.8 (m, 13H), while the infrared indicated sulfone bands at 1125 and 1300 cm^{-1}. A plausible route for the formation of **14** involves a rather novel Friedel–Crafts alkylation of toluene by the *o*-quinodimethane intermediate **15**. As expected, **14** was best obtained if **4** was thermolyzed in toluene at 250°C in the absence of maleic anhydride. Prolonged heating of **4** in cyclohexane at 250°C with maleic anhydride gave decomposition but none of the desired Diels–Alder product. The reason for the difference in the behavior of the intermediates **13** and **15** toward maleic anhydride is not obvious since cyano and sulfonyl groups have similar electron withdrawing character.

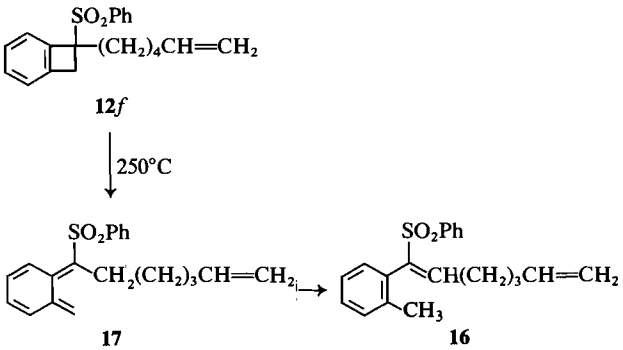
Thermolysis of the substituted benzocyclobutyl phenyl sulfone **12***f* gave only the styrene derivative **16** resulting from a 1,5-sigmatropic shift of a hydrogen in the *o*-quinodimethane intermediate **17**. No evidence of any trapping by the remote olefinic group was observed. 1,5-Hydrogen shifts in *o*-quinodimethanes are known to be facile (13).

Thermolysis of the 7-Substituted Benzocyclobutenes

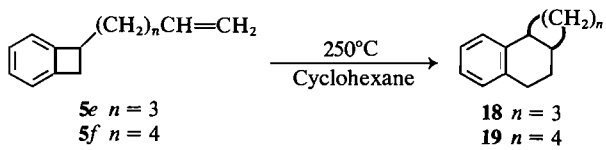
The two benzocyclobutenes (**5***e*, *f*), carrying remote vinyl groups isomerized cleanly to the tricyclic products **18** and **19** when thermolyzed in



cyclohexane. Vapor phase chromatographic analysis of the isomerized product indicated that **19** was probably formed as a single stereoisomer while **18**



was obtained as an isomeric mixture. No detailed stereochemical assignments were attempted with these products.



Conclusions

Benzocyclobutyl phenyl sulfone **4** can easily be converted into a number of substituted benzocyclobutenes via reaction of its α-sulfonyl carbanion with electrophiles followed by desulfonylation. Some of the benzocyclobutenes thus obtained are suitable for conversion into polycyclic ring systems. The method is of somewhat limited value since the present synthesis of **4** is not suitable for large scale work. The *o*-quinodimethane derived from the thermolysis of **4** does not react with a typical dienophile such as maleic anhydride; it appears to behave like a highly electron deficient diene.

Experimental

Melting points were taken on a Thomas Hoover melting point apparatus and are uncorrected. Infrared spectra were obtained on Beckman IR-20 or Unicam SP 1100 spectrophotometers. Nuclear magnetic resonance spectra were taken on Varian Associates HA-100 and T-60A spectrometers. Chemical shifts are reported in ppm downfield from internal TMS. The term 'work-up' refers to quenching a reaction mixture with excess H_2O, extraction with CH_2Cl_2, drying of the organic extracts over anhydrous $MgSO_4$, and evaporation of the solvent under reduced pressure. The silica gel used for column chromatography was 60–200 mesh Baker silica gel.

1-(Chloromethyl)-2-(phenylsulfonylmethyl)benzene (8)

Sodium benzenesulfinate (2.8 g, 17 mmol) and 1,2-bis-(chloromethyl)benzene (3.0 g 17 mmol) were refluxed in 100 mL of methanol for 1 day. The cooled reaction mixture was diluted with 100 mL of H_2O and extracted with 4 × 20 mL of CH_2Cl_2. Chromatography of the crude product on silica gel using 1:3 ethyl acetate – hexane gave 2.02 g (42%) of **8** as colourless crystals, (CH_2Cl_2–hexane), mp 75–77°C; nmr δ: 4.57 (s, 2H), 4.70 (s, 2H), 6.9–8.0 (m, 9H); ir: 1305 and 1120 cm^{-1}; ms *m/e*: M^+ 282, 280. *Anal.* calcd. for $C_{14}H_{13}ClO_2S$: C 60.00, H 4.64; found: C 59.94, H 4.70.

Reaction of 8 with Bases

The chloro sulfone **8** (0.5 g) was reacted with 1:1 equivalents of LDA in THF at −78°C. The reaction mixture turned yellow and then orange-red. After 30 min of reaction at −78°C work-up gave a product whose nmr showed very broad absorption indicative of a polymeric product.

Essentially the same results were obtained when **8** was reacted under phase-transfer conditions, or with CH_3Li either at −78°C or at +25°C.

Attempted Trapping of the Intermediate 9 with N-1-Cyclohexenylpyrrolidine

Chloro sulfone **8** (0.20 g) and the above enamine (0.12 g) were dissolved in 15 mL CH_2Cl_2 and stirred with 15 mL 50% NaOH containing benzyltriethylammonium chloride. After 24 h the reaction mixture had turned yellow and **8** was absent as shown by analytical tlc. Attempts to purify the 0.3 g of crude product were not successful.

Reaction of PhS(O)CH_2Li with o-Chlorobenzyl Chloride

To a solution of LDA (38 mmol) in THF at 0°C was added 4.74 g (34 mmol) of $PhS(O)CH_3$. The bright yellow solution was stirred for 5 min and then treated with 6.93 g (34 mmol) of *o*-chlorobenzyl chloride for 25 min. The bright purple solution was worked up in the usual manner and produced, after column chromatography, 7.3 g (82%) of chloro sulfoxide.

This chloro sulfoxide was oxidized with *meta*-chloroperbenzoic acid in refluxing CH_2Cl_2. Work-up, after the more polar sulfoxide was absent by tlc, gave 91% of the chloro sulfone **6**, mp 44–46°C (lit. (6) mp 45–47°C).

Reaction of $PhSO_2CH_2Li$ with o-Bromobenzyl Bromide

To 4.0 g (25 mmol) phenyl methyl sulfone in 80 mL of THF and 0°C was added 28 mmol of CH_3Li giving a bright yellow solution. Following 5 min of reaction time, 6.4 g (25 mmol) of *o*-bromobenzyl bromide was added which resulted in a dark brown solution. Usual work-up following 24 h of reaction time gave 8.45 g of crude product which was chromatographed on 130 g of silica with increasing proportions of ethyl acetate in hexanes. In order of elution there was obtained 0.68 g of 1,3-di(*o*-bromophenyl)-2-(phenylsulfonyl)propane (nmr δ: 2.8–3.5 (m, 4H), 4.1–4.3 (m, 1H), 6.1–8.1 (m, H)); 1.3 g (16%) of 2-(*o*-bromophenyl)ethyl phenyl sulfone (nmr δ: 2.6–3.7 (m, 4H), 6.7–8.1 (m, 9H)); and considerable amounts of recovered $PhSO_2CH_3$.

The above reaction was repeated in the presence of hexamethylphosphoramide or by adding $PhSO_2CH_2Li$ to *o*-bromobenzyl bromide in THF at −78°C. The yield of the desired monoalkylation product could not be significantly increased.

*Reaction of the Chloro Sulfone **6** with $4KNH_2$; Preparation of **4***

A solution of KNH_2 was prepared by dissolving K metal in liquid ammonia. A trace of powdered ferric nitrate was used as a catalyst. To this solution was added all at once 0.25 equiv. of the sulfone **6** giving an orange-brown solution. The reaction mixture was stirred for 10 min and then quenched with ammonium nitrate. The ammonia was allowed to evaporate and the reaction mixture was worked up. The crude reaction product was purified by silica gel column chromatography. Elution with a 1:4 ethyl acetate – hexane gave **4**, mp 102–103°C, from benzene-hexane (lit. (5) mp 103.5–104.5°C). The yields in **8** different reactions carried out on a 20 mmol scale varied from 30–40%; nmr δ: 3.52 (d, J = 4 Hz, 2H), 4.92 (t, J = 4 Hz, 1H), 6.9–8.0 (m, 9H); ir: 1120, 1290 cm^{-1}; ms *m/e*: M⁺ = 244. *Anal.* calcd. for $C_{14}H_{12}O_2S$: C 68.85, H 4.86; found: C 68.94, H 4.92.

When the above reaction was carried out using only $2KNH_2$ per mole of **6**, the nmr spectrum of the crude product showed the presence of *o*-chlorostyrene and the product **12**. Chromatography on silica gel resulted in loss of the styrene and isolation of **12**, mp 51–53°C; nmr δ: 2.4–3.0 (m, 4H), 6.0–6.4 (doublet of triplets, J = 16 and 7 Hz, 1H), 6.8 (d, J = 16 Hz, 1H), 7.0–7.6 (m, 8H); ir: 960 cm^{-1}. *Anal.* calcd. for $C_{16}H_{14}Cl_2$: C 69.32, H 5.09; found: C 69.25, H 5.04.

*Generation of the α-Lithio Derivative of **4** and Reactions with Electrophiles*

Compound **4** was dissolved in THF at −78°C and reacted with 1.1 equiv. of CH_3Li. A bright yellow solution formed immediately. This solution was treated with electrophiles at −78°C and then allowed to warm to room temperature. The products were isolated by the usual work-up and purified by chromatography on silica gel.

(*a*) D_2O. 98%; nmr δ: 3.51 (s, 2H), 6.9–8.0 (m, 9H).

(*b*) CH_3I. Reaction time 15 min (82% isolated yield); mp 61–63°C, off-white solid; nmr δ: 1.84 (s, 3H), 3.12 (d, J = 14 Hz, 1H), 3.74 (d, J = 14 Hz, 1H), 6.9–7.0 (m, 9H); ir: 1290 (s) 1120 (s) cm^{-1}; ms *m/e*: M⁺ 258. *Anal.* calcd. for $C_{15}H_{14}O_2S$: C 69.74, H 5.46; found: C 69.53, H 5.53.

(*c*) $BrCH_2CH{=}CH_2$. Reaction time 15 min, oil, 81%; nmr δ: 2.6–3.1 (m, 2H), 3.23 (d, J = 14 Hz, 1H), 3.54 (d, J = 14 Hz, 1H), 4.85–5.25 (m, 2H), 5.35–5.83 (m, 1H), 6.8–7.9 (m, 9H); ir: 1295 (s), 1130 (s), 975 (m), 905 (m); ms *m/e*: M⁺ = 284. *Anal.* calcd. for $C_{17}H_{16}O_2S$: C 71.80, H 5.67; found: C 71.82, H 5.57.

(*d*) $Br(CH_2)_2CH{=}CH_2$. Reaction time, 16 h, oil, 67%; nmr δ: 1.9–2.7 (m, 4H), 3.25 (d, J = 14 Hz, 1H), 3.58 (d, J = 14 Hz, 1H), 4.8–5.1 (m, 2H), 5.5–6.0 (m, 1H), 6.8–7.9 (m, 9H); ir: 1295 (s), 1135 (s), 985 (m), 900 (m) cm^{-1}. *Anal.* calcd. for $C_{18}H_{18}O_2S$: C 72.45, H 6.08; found: C 72.38, H 6.05.

(*e*) $I(CH_2)_3CH{=}CH_2$. Reaction time 0.5 h, oil, 79%; nmr δ: 1.1–1.6 (m, 2H), 1.9–2.5 (m, 4H), 3.22 (d, J = 15 Hz, 1H), 3.54 (d, J = 15 Hz, 1H), 4.8–5.15 (m, 2H), 5.5–6.0 (m, 1H), 6.8–7.8 (m, 9H); ir: 1290 (s), 1130 (s), 980 (m), 905 (m) cm^{-1}. *Anal.* calcd. for $C_{19}H_{20}O_2S$: C 73.04, H 6.45; found: C 73.06, H 6.50.

(*f*) $Br(CH_2)_4CH{=}CH_2$. Reaction time 0.5 h, colourless solid, mp 57–58°C, 62%; nmr δ: 1.1–1.8 (m, 4H), 1.8–2.6 (m, 4H), 3.22 (d, J = 14 Hz, 1H), 3.52 (d, J = 14 Hz, 1H), 4.80–5.1 (m, 2H), 5.5–6.0 (m, 1H), 6.8–7.9 (m, 9H); ir: 1295 (s), 1130 (s), 980 (m), 900 (m); ms *m/e*: M⁺ 326. *Anal.* calcd. for $C_{20}H_{22}O_2S$: C 73.58, H 6.79; found: C 73.13, H 6.69.

(*g*) Styrene oxide. Reaction time 24 h; the product was a mixture of the unknown nonpolar benzocyclobutene dimer (see footnote 1), unreacted **4**, and presumed product (nmr). The desired product and unreacted **4** could not be separated by chromatography.

(*h*) Acetone. Reaction time 15 min at −78°C; the remaining starting material and product (4:6 ratio) by nmr could not be separated; nmr of the product by difference: 1.37 (s, 3H), 1.67 (s, 3H), 3.55 (d, J = 14 Hz, 1H), 3.67 (d, J = 14 Hz, 1H) 6.8–7.8 (m, 9H). When the reaction was allowed to warm to room temperature prior to quenching with H_2O only unreacted **4** was obtained, presumably due to reversal of the condensation reaction.

*Reaction of **4** with CH_3Li*

To 0.2 g (0.82 mmol) of **4** at −78°C in 15 mL of THF was added 0.90 mmol of CH_3Li. The reaction mixture was allowed to stir at room temperature for 24 h. Work-up gave 0.06 g of a nonpolar product, mp 103–112°C. Vapor phase chromatographic analysis indicated the presence of two components of similar retention time; nmr (of the mixture) δ: 3.52 (s), 3.80 (s), 7.06–7.40 (m); ms *m/e*: M⁺ 204.

When **4** was reacted with about 2 equiv. of CH_3Li, starting material was recovered after a 24 h reaction period.

Desulfonylation of the α-Alkylated Benzocyclobutyl Phenyl Sulfones

All desulfonylations were carried out by treating 1 equiv. of sulfone dissolved in 10 mL of dry methanol containing Na_2HPO_4 with excess 6% Na/Hg amalgam at room temperature. Amalgam was added until tlc confirmed the absence of starting material. The reaction times were about 0.5 h. The reaction mixture was diluted with 10 mL of saturated NaCl solution and worked up in the usual manner. The products obtained are described below. All products were obtained as colorless oils.

(*a*) Benzocyclobutene, 96%; nmr δ: 2.97 (s, 4H), 6.6–7.5 (m, 4H) (14).

(*b*) 7-(2′-*n*-Propenyl)benzocyclobutene, **5***c* 95%; nmr δ: 2.45 (m, 2H) 2.80 (dd, J = 14 and 2 Hz, 1H), 3.35 (dd, J = 14 and 2 Hz, 1H), 3.35–3.8 (m, 1H), 4.95–5.25 (m, 2H), 5.7–6.2 (m, 1H) 7.0–7.3 (m, 4H); ms *m/e*: M⁺ 144.

(*c*) 7-(4′-*n*-Pentenyl)benzocyclobutene, **5***e* 93%; nmr δ: 1.4–1.9 (m, 4H), 2.0–2.30 (m, 2H), 2.74 (dd, J = 14 and 2 Hz, 1H), 3.35 (dd, J = 14 and 2 Hz, 1H) 3.3–3.6 (m, 1H), 4.8–5.2 (m, 2H), 5.5–6.1 (m, 1H), 7.0–7.3 (m, 4H). *Anal.* calcd. for $C_{13}H_{16}$: C 90.64, H 9.36; found: C 90.84, H 9.41.

(*d*) 7-(5′-*n*-Hexenyl)benzocyclobutene, **5***f* 96%; nmr δ: 1.2–1.9 (m, 6H), 1.9–2.3 (m, 2H), 2.75 (dd, J = 14 and 2 Hz, 1H), 3.25 (dd, J = 14 and 2 Hz, 1H), 3.25–3.6 (m, 1H), 4.8–5.2 (m, 2H), 5.6–6.1 (m, 1H), 7.0–7.3 (m, 4H). *Anal.* calcd. for $C_{14}H_{18}$: C 90.26, H 9.74; found: C 89.95, H 9.69.

Thermolysis of Benzocyclobutyl Phenyl Sulfone (4)

Compound **4** (0.13 g, 0.51 mmol) and maleic anhydride (0.087 g, 0.9 mmol) were heated in 3 mL of toluene in a sealed tube at 250°C for 15 h. Upon cooling 0.078 g of maleic anhydride was recovered by filtration. The remaining material was chromatographed on silica gel plates using 3:1 hexane – ethyl acetate as eluent. A major fraction was recovered which on recrystallization from CH_2Cl_2–hexane gave 0.043 g (25%) of **14**, mp 116–118°C; nmr δ: 2.18, 2.28 (2s, 3H), 3.80 (s, 2H), 4.29 (s, 2H), 6.6–7.8 (m, 13H); ir: 1300 (s), 1125 (s) cm^{-1}; ms *m/e*: M^+ 336. *Anal.* calcd. for $C_{21}H_{20}O_2S$: C 74.97, H 5.99; found: C 74.78, H 6.11.

Thermolysis of **4** in toluene in the absence of maleic anhydride gave a similar result.

Thermolysis of 0.15 g of **4** and 0.87 g of maleic anhydride in 2 mL of cyclohexane for 10 h at 250°C gave a crude product from which diphenyl disulfide was obtained as the only identifiable product.

Thermolysis of 12f

Compound **12*f*** (0.07 g) was heated in 3 mL of cyclohexane in an evacuated sealed tube at 250°C for 20 h. Purification of the crude product on silica gel plates (3:1 hexane – ethyl acetate) gave **16** in 59% yield; nmr δ: 1.5–2.1 (m, 9H), 4.8–5.0 (m, 2H), 5.2–5.9 (m, 1H), 6.7–6.9 (m, 1H), 6.9–7.7 (m, 9H). *Anal.* calcd. for $C_{20}H_{22}O_2S$: C 73.58, H 6.79; found: C 73.12, H 6.62.

Thermolysis of 7-(4′-n-Pentenyl)benzocyclobutene

This compound (0.031 g) was thermolyzed in cyclohexane at 250°C for 24 h. Purification on silica gel plates using hexane as eluent gave 74% of tricyclic material (**18**); nmr δ: 1.2–3.2 (m, 12H), 7.0–7.22 (m, 4H). *Anal.* calcd. for $C_{13}H_{16}$: C 90.64, H 9.36; found: C 91.10, H 8.96. Vapor phase chromatographic analysis on a 2.0 m SE-30 column gave a nonsymmetrical peak suggestive of two isomers.

Thermolysis of 7-(5′-n-Hexenyl)benzocyclobutene

Heating of 0.082 g of the above compound in 3 mL of cyclohexane as above resulted in the isolation of 0.063 g of tricyclic compound **19** after preparative tlc separation; nmr δ: 0.9–3.0 (m, 14H), 7.0–7.4 (m, 4H). *Anal.* calcd. for $C_{14}H_{18}$: C 90.26, H 9.74; found: C 89.96, H 9.61. Vapor phase chromatographic analysis, as for **18**, gave a single symmetrical peak suggestive of one isomer.

Determination of $\Delta H_{f298}^0(C_{12}F_{10},g)$ from studies of the combustion of decafluorobiphenyl in oxygen and calculation of $D(C_6F_5—C_6F_5)$

STANLEY JAMES W. PRICE[1] AND HENRY J. SAPIANO

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received December 22, 1978

STANLEY JAMES W. PRICE and HENRY J. SAPIANO. Can. J. Chem. 57, 1468 (1979).

The heat of formation of decafluorobiphenyl has been determined by the direct combustion method previously developed and used for hexafluorobenzene and related compounds. As in the hexafluorobenzene case the combustion of decafluorobiphenyl in oxygen yields CO_2, CF_4, and F_2. With a ten-fold excess of oxygen the CO_2 to CF_4 ratio is 5.85 ± 0.08. A full material balance was obtained. The value of $\Delta H_{f298}^0(C_{12}F_{10},g) = -1263.2 \pm 5.1$ kJ mol^{-1} may be combined with $\Delta H_{f298}^0(C_6F_5,g) = -387.4 \pm 12.0$ kJ mol^{-1} to give $D(C_6F_5—C_6F_5) = 488.4 \pm 24.5$ kJ mol^{-1}. Also with $\Delta H_{f298}^0(C_6F_6,g) = -945.6 \pm 8.0$ kJ mol^{-1} ΔH_{298}^0 for reaction [3]

[3] $$C_6F_5—C_6F_5(g) + F_2(g) \rightarrow 2C_6F_6(g)$$

is calculated to be -628.0 ± 16.8 kJ mol^{-1}.

STANLEY JAMES W. PRICE et HENRY J. SAPIANO. Can. J. Chem. 57, 1468 (1979).

On a déterminé la chaleur de formation du décafluorobiphényle par la méthode de combustion directe développée antérieurement et appliquée à l'hexafluorobenzène et à des composés apparentés. Comme dans le cas de l'hexafluorobenzène, la combustion du décafluorobiphényle dans l'oxygène fournit du CO_2, du CF_4 et du F_2. Lorsqu'on utilise un excès d'oxygène égal à dix fois les quantités requises, le rapport CO_2 à CF_4 est égal à 5.85 ± 0.08. On a établi un bilan complet des réactifs. La valeur de $\Delta H_{f298}^0(C_{12}H_{10},g) = -1263.2 \pm 5.1$ kJ mol^{-1} peut être combinée avec $\Delta H_{f298}^0(C_6H_5,g) = -387.4 \pm 12.0$ kJ mol^{-1} pour conduire à $D(C_6F_5—C_6F_5) = 488.4 \pm 24.5$ kJ mol^{-1}. Utilisant aussi la valeur de $\Delta H_{f298}^0(C_6F_6,g) = -945.6 \pm 8$ kJ mol^{-1}, on peut calculer que le ΔH_{298}^0 pour la réaction [3]

[3] $$C_6F_5—C_6F_5(g) + F_2(g) \rightarrow 2C_6F_6(g)$$

est égal à -628.0 ± 16.8 kJ mol^{-1}.

[Traduit par le journal]

Introduction

To date no thermodynamic study for the heat of formation of decafluorobiphenyl has been reported. The heat of formation of a variety of compounds containing the pentafluorophenyl group has been reported by Cox *et al.* (1, 2). To ensure complete combustion and minimize the formation of tetrafluoromethane as a product, hydrogen containing organic materials were added to the crucible.

The present paper describes the measurement of the heat of combustion of decafluorobiphenyl in a steel bomb with the compound contained in a steel crucible. The combustion was done under anhydrous conditions and without the use of any auxiliary materials. With approximately a ten-fold excess of oxygen, complete combustion is easily obtained and the only products are CO_2, CF_4, and F_2.

Experimental

Materials

(*i*) Decafluorobiphenyl was supplied by the Imperial Smelting Corporation Limited and was used without further purification. The melting point was found to be 68°C in agreement with the reported value of 68°C (3). The mass spectrum of decafluorobiphenyl was taken and found to be similar to that reported by Cotter (4). The $^{12}C^{13}C$ peak ratios at *m/e* values of 167, 167.5, 334, and 335 tend to confirm Cotter's observation that the 167 peak is due virtually exclusively to $C_{12}F_{10}^{2+}$. Cotter found no formation of the $C_6F_5^+$ ion. No mass fragments heavier than those corresponding to the molecular ion were found in the mass spectrum of the sample.

Sublimation pressure measurements (5) over the range of 24 to 49°C are adequately represented by

[1] $$\log_{10} P(\text{cm}) = 4.0777 - 4056.0/T + 2.927 \log_{10} T$$

The resulting heat of sublimation and average heat capacity differences (vapour − solid) are $\Delta H_{298}^0 = 84.9$ kJ mol^{-1} and $\langle \Delta C_p$, 25 to 49°C$\rangle = 24.33$ J deg^{-1} mol^{-1}.

(*ii*) CO_2, CF_4, and F_2 were obtained from the Matheson Chemical Company and were used without further purification.

Apparatus and Calorimetric Procedure

The apparatus and procedure used for the main combustion process were identical to those previously used for C_6F_5Br (6), C_6F_{10}, and C_6F_{12} (7). A Parr model 1004C steel bomb and steel crucible were again used for the combustion process.

Over the time interval required to place the weighed sample into the bomb no measureable loss of decafluorobiphenyl sample from the crucible in which it was weighed was observed.

Analysis of Reaction Products

The analytical procedures for CO_2, CF_4, and F_2 have been described elsewhere (8–10). Mass spectra were obtained using a Varian MAT CH5-DF Spectrometer controlled by an INCOS computer system. A Bausch and Lomb Spectronic 100 was used to determine iron with 1,10-phenanthroline (11).

Results and Discussion

The experimental results for decafluorobiphenyl are shown in Table 1. In the combustion of $C_{12}F_{10}$ in the steel bomb the formation of a green coloration was observed as in the case of C_6F_5Br (6). The amount of Fe(II) and Fe(III) fluoride after combustion was determined using a colorimetric procedure (11). Approximately 1.30 mg of iron fluorides were formed, of which roughly 80% was FeF_2. The correction to the heat of formation of $C_{12}F_{10}$ caused by the formation of FeF_2 and FeF_3 was less than 2.5 kJ mol^{-1}.

The only detectable products of combustion are CO_2, CF_4, and F_2, with the exception of the small quantities of iron fluorides. These products were identified and quantitatively determined in the same manner reported for the products of combustion of C_6F_{10} and C_6F_{12} (7).

The column used was a 6 ft × 1/4 in. od Porapak Q column (25°C, He carrier, 48 cm^3/min). Calibrations were carried out using O_2–CF_4 and O_2–CO_2 mixtures. If pure CO_2 is used the CO_2 calibration is unaffected. If pure CF_4 is used the net result is that the relative response factor for CF_4 is increased by 3.5% resulting in a value for $\Delta H_{f298}^0(C_{12}F_{10},g)$ which is about 32.6 kJ mol^{-1} too high.

Based on the observed products and the average CO_2/CF_4 molar ratio of 5.85 the combustion reaction of decafluorobiphenyl may be written

[2] $C_{12}F_{10} + 10.248O_2 \rightarrow 10.248CO_2 + 1.752CF_4 + 1.496F_2$

With the exception of $C_{12}F_{10}$ all reactants and products are in the gaseous state. The decafluorobiphenyl is present in the bomb as a solid at the time of combustion.

No detectable heat of mixing was observed when F_2, O_2, CF_4, and CO_2 were mixed under anhydrous conditions (10).

For calculation of $\Delta H_{f298}^0(C_{12}F_{10},g)$, the standard heats of formation of the combustion products were taken as $\Delta H_{f298}^0(CO_2,g) = -393.512$ kJ mol^{-1} (12) and $\Delta H_{f298}^0(CF_4,g) = -933.0$ kJ mol^{-1} (13). The heat of sublimation of $C_{12}F_{10}$ was taken as $\Delta H_{298}^0 = 84.9$ kJ mol^{-1} (5).

Based on the preceding data and an estimated correction to standard state of 5.0 kJ mol^{-1}, $\Delta H_{f298}^0(C_{12}F_{10},g) = -1263.2 \pm 5.1$ kJ mol^{-1}. Using this value and $\Delta H_{f298}^0(C_6F_5,g) = -387.4$ kJ mol^{-1} (4) the value for $D(C_6F_5—C_6F_5) = 488.4$ kJ mol^{-1}.

It is also possible to calculate the enthalpy change for reaction [3].

[3] $C_6F_5—C_6F_5(g) + F_2(g) \rightarrow 2C_6F_6(g)$

With $\Delta H_{f298}^0(C_6F_6,g) = -945.6$ kJ mol^{-1}, ΔH_{298}^0 for this reaction is −628.0 kJ. This high negative value reflects both the weakness of the F—F bond in F_2 and the high C—F bond dissociation energy in hexafluorobenzene.

For reaction [4], based on $\Delta H_{f298}^0(C_6H_5F,g) = -116.0$ kJ mol^{-1} (15)

[4] $C_6H_5—C_6H_5(g) + F_2(g) \rightarrow 2C_6H_5F(g)$

and $\Delta H_{f298}^0(C_{12}H_{10},g) = 182.3$ kJ mol^{-1} (15), $\Delta H_{rx} = -414.3$ kJ. The difference between this result and that for reaction [3], 214 kJ, is within 6 kJ of that estimated from $D(C_6F_5—F) = 637.2$ kJ mol^{-1} (8) and $D(C_6F_5—C_6F_5)$ and from $D(C_6H_5—F) =$

514.6 kJ mol^{-1} (16) and $D(C_6H_5—C_6H_5)$ = 463.7 kJ mol^{-1} (15, 16).

Effect of temperature on the fluorescence quenching by *N*-bromosuccinamide of tryptophan residues in proteins

BRANKO F. PETERMAN AND KEITH J. LAIDLER

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received January 2, 1979

BRANKO F. PETERMAN and KEITH J. LAIDLER. Can. J. Chem. 57, 1471 (1979).

The quenching of tryptophan fluorescence by *N*-bromosuccinamide was studied by the fluorescence stopped-flow technique over a temperature range of 5 to 35°C in order to compare the reactivities of tryptophan residues in various molecules. The highest rates and lowest activation energies were found with the simple molecule *N*-acetyltryptophanamide. The hormone glucagon, which contains a single tryptophan residue, showed a somewhat lower rate and higher activation energy. α-Chymotrypsin, which has three groups of tryptophan residues in different environments, gave three rate constants which were lower than those with the other compounds, and the activation energies were correspondingly higher. There was a linear relationship between enthalpy of activation and the Gibbs energy of activation, the proportionality factor being 6.7. This indicates a $\Delta H^* - \Delta S^*$ compensation, with an isokinetic temperature of 350 K. The compensation is discussed in the light of the steric effects.

BRANKO F. PETERMAN et KEITH J. LAIDLER. Can. J. Chem. 57, 1471 (1979).

On a étudié le piégeage de la fluorescence du tryptophane par la *N*-bromosuccinamide par la technique de fluorescence à flux stoppé à des températures allant de 5 à 35°C afin de comparer la réactivité de résidus de tryptophane dans diverses molécules. On a trouvé que les vitesses les plus rapides et les énergies d'activation les plus basses sont associées à la molécule simple, *N*-acétyltryptophanamide. L'hormone glucagone, qui contient un seul résidu tryptophane simple, présente une vitesse un peu plus basse et une énergie d'activation un peu plus élevée. L'α-chymotrypsine qui contient trois tryptophanes dans des environnements différents, présente trois constantes de vitesse qui sont plus faibles que celles des autres composés et les énergies d'activation sont proportionnellement plus élevées. Il existe une relation linéaire entre l'enthalpie d'activation et l'énergie libre d'activation de Gibbs; le facteur de proportionalité est de 6.7. Ceci indique que le ΔH^+ et le ΔS^+ se compensent; la température isocinétique est de 350 K. On discute de la compensation à la lumière des effets stériques.

[Traduit par le journal]

Introduction

In a previous paper (1) we have shown that kinetic studies of the quenching by *N*-bromosuccinamide (NBS) of the fluorescence of tryptophan provide valuable information about the environments of tryptophan residues in proteins. The quenching of the fluorescence of *N*-acetyl-L-tryptophanamide (*N*-AcTrpNH$_2$), the tripeptide Gly-Trp-Gly, and apocytochrome *c*, all of which contain a single tryptophan residue, was found to follow simple second-order kinetics (first-order in NBS and first-order in the tryptophan-containing compound). The enzyme α-chymotrypsin contains eight tryptophan residues per molecule, and the X-ray study (2) shows that six are at the surface and two buried in the interior of the molecule. Three of the six surface residues have the indole rings protruding out of the molecule, and the remaining three are pointing inwards. The tryptophan residues thus fall into three groups, and our quenching kinetics studies showed that there are three relaxation times which can be identified as corresponding to the three groups.

Since quenching by NBS occurs with half-lives of less than 100 ms, significant conformational changes in the protein molecules are unlikely, and the technique therefore appears to provide a valuable tool for obtaining supporting conformational evidence. Because of enthalpy–entropy compensation effects, Gibbs energies of activation, and therefore rate constants, are frequently less sensitive to structural factors than are enthalpies or energies of activation. We have therefore made a study of the temperature dependence of the rate constants for the quenching reactions, and the results are described and discussed in the present paper. The work has been done with *N*-AcTrpNH$_2$ and α-chymotrypsin, and also with the hormone glucagon. This polypeptide, which plays an important physiological role in stimulating the action of adenylate cyclase, contains a single tryptophan residue which previous fluorescence studies (3, 4) have shown to be largely exposed to the solvent. In the crystalline state glucagon has an α-helical arrangement (5) but in aqueous solution it appears to exist as a flexible chain (3, 6).

0008-4042/79/121471-04$01.00/0

Experimental

Materials

N-Bromosuccinamide was purchased from Fisher Chemical Co., *N*-acetyl-L-tryptophanamide from Sigma Chemical Co., α-chymotrypsin (3 × crystallized) from Worthington Biochemical Co., and glucagon from Research Plus Laboratories. Since glucagon suspended in HCl solution at pH ~ 2.5 did not dissolve completely, it was filtered on a Sephadex G-25 column equilibrated with sodium phosphate buffer at pH 7.0 and an ionic strength of 0.05 *M*. Undissolved material, which eluted first from the column, was followed by dissolved glucagon, as judged from the absorption spectrum. The fractions with a high A_{280}/A_{240} ratio (~1.6) were pooled and used for subsequent experiments.

Spectroscopic Measurements

Absorption measurements were carried out with a Pye-Unicam model SP 1800 spectrophotometer. The concentrations of proteins were determined spectrophotometrically using the following absorption coefficients: α-chymotrypsin, ε (282) = $5.15 \times 10^4\ M^{-1}\ cm^{-1}$ (7) and glucagon, ε (280) = $8.05 \times 10^3\ M^{-1}\ cm^{-1}$ (8).

Kinetic Measurements

Kinetic measurements were made with a Durrum stopped-flow instrument as previously described (1). All samples were excited at 296 nm and the emitted light was selected by a Corning 0-54 filter. The temperature was controlled to ±0.2°C by a Haake model KT 33 constant temperature circulator, and was measured at various positions by a Yellow Springs Instrument Co. telethermometer. Rate measurements were made at temperatures from 5 to 35°C. The records of fluorescence vs. time were captured by a Biomation recorder, displayed on an oscilloscope screen, and photographed, the records then being transferred to semilogarithmic graph paper. Analysis of the results was as explained in ref. 1. Maximum errors were estimated from a number of results obtained under identical conditions; the first-order rate coefficients were always within ±10% of the average value, and this maximum deviation is about twice the standard deviation.

Results

As in the previous studies (1) the fluorescence quenching of *N*-AcTrpNH$_2$ by NBS followed simple second-order kinetics. The Arrhenius plot for the quenching of the fluorescence of *N*-AcTrpNH$_2$ is shown in Fig. 1. The activation energy E_a is 7.3 ± 0.8 kcal mol^{-1}, and Table 1 lists other kinetic parameters at 25.0°C, calculated using the equations (9)

$$[1] \qquad \Delta H^{\ddagger} = E_a + RT$$

$$[2] \qquad \Delta G^{\ddagger} = -RT \ln [k(T)h/kT]$$

$$[3] \qquad \Delta S^{\ddagger} = (\Delta H^{\ddagger} - \Delta G^{\ddagger})/T$$

where R is the gas constant, h Planck's constant, k the Boltzmann constant, and $k(T)$ the rate constant at 25.0°C.

The fluorescence quenching of glucagon also followed simple second-order kinetics, and the Arrhenius plot is included in Fig. 1. The kinetic parameters are listed in Table 1.

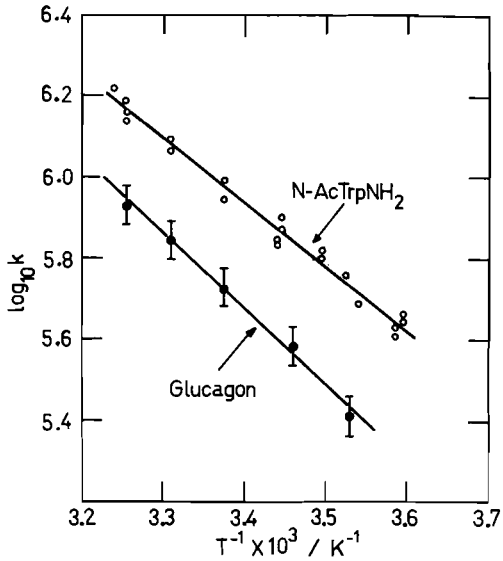

FIG. 1. Arrhenius plots for the reaction between *N*-bromosuccinamide and *N*-acetyltryptophanamide, and between *N*-bromosuccinamide and glucagon. The concentration of NBS was $5 \times 10^{-5}\ M$ for the *N*-AcTrpNH$_2$ experiments and $10 \times 10^{-5}\ M$ for the glucagon experiments. The concentrations of *N*-AcTrpNH$_2$ and glucagon were $5 \times 10^{-6}\ M$. The reactions took place in a sodium phosphate buffer, pH 7.0, at an ionic strength of 0.05 *M*.

The quenching of the fluorescence of α-chymotrypsin shows three second-order relaxations (1), and the corresponding Arrhenius plots are displayed in Fig. 2. The rate constants and other kinetic parameters are shown in Table 1.

Discussion

The order of the rate constants and the Gibbs energies of activation, $\Delta G^{\ddagger}$, can be related to the structures involved. The highest rate constant is found with *N*-AcTrpNH$_2$, where there is little steric shielding of the tryptophan residue. In glucagon there is somewhat more shielding by the rest of the protein molecule which probably forms a flexible chain (3, 6), and the rate constant is ~0.67 of the value with *N*-AcTrpNH$_2$. This ratio is consistent with the ratio of ~0.59 found with quenching by acrylamide (4).

The amplitudes for the three second-order components found in the α-chymotrypsin quenching are in the approximate ratio of 3:3:2 and, as discussed in our previous paper (1), are attributed to the three types of tryptophans in α-chymotrypsin. The fastest component presumably corresponds to reaction between NBS and the surface residues having exterior indole rings. The fact that the rate constant ($2.3 \times 10^5\ dm^3\ mol^{-1}\ s^{-1}$) is significantly less than that with glucagon suggests that even these exterior indole rings are more shielded by the protein matrix. The

TABLE 1. Kinetic parameters for the quenching of the fluorescence of tryptophan-containing compounds by NBS at 25°C*

Compound	k (25°C) ($dm^3\ mol^{-1}\ s^{-1}$)	E_a (kcal mol^{-1})	$\Delta H^{\ddagger}$ (kcal mol^{-1})	$\Delta G^{\ddagger}$ (kcal mol^{-1})	$\Delta S^{\ddagger}$ (cal $K^{-1}\ mol^{-1}$)
N-AcTrypNH$_2$	$(1.0\pm0.1)\times10^6$	7.3±0.8	7.9±0.8	9.2±0.05	−4.4±0.5
Glucagon	$(5.8\pm0.5)\times10^5$	8.4±1.2	9.0±1.3	9.5±0.1	−1.7±0.5
α-Chymotrypsin					
Fast relaxation	$(2.3\pm0.2)\times10^5$	16.7±1.4	17.3±1.5	10.1±0.1	24±3
Intermediate relaxation	$(7.6\pm0.7)\times10^4$	18.7±1.6	19.3±1.6	10.8±0.1	28±3
Slow relaxation	$(1.6\pm0.2)\times10^4$	21.0±1.8	21.6±1.8	11.7±0.1	33±3

*The errors indicated are maximum deviations, obtained from a number of duplicate experiments. The standard deviations, calculated using the method of least squares, are about one half of the maximum deviations.

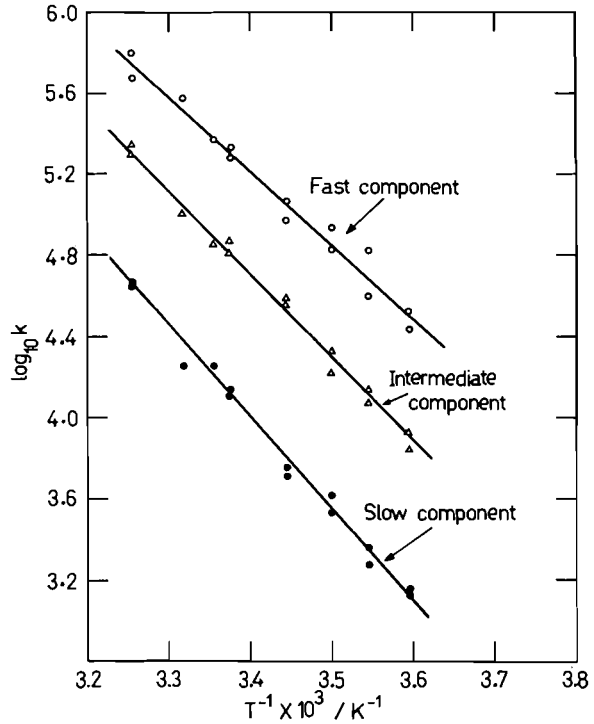

FIG. 2. Arrhenius plots for the reaction between *N*-bromosuccinamide and the tryptophan residues in α-chymotrypsin. The three plots are for the three kinetic components, as indicated. Concentrations of reactants: α-chymotrypsin, $6.2\times10^{-7}\ M$; NBS, $10\times10^{-5}\ M$. Buffer as indicated in Fig. 1.

intermediate relaxation is attributed to the three surface tryptophans whose indole rings are pointing inwards, and the slow relaxation to the two tryptophan residues which are buried inside the protein molecule.

The differences between the five reactions are greatly magnified if we consider the variations in E_a (or $\Delta H^{\ddagger}$) instead of the variations in k (or $\Delta G^{\ddagger}$). This is shown by the plot in Fig. 3*a* of $\Delta H^{\ddagger}$ against $\Delta G^{\ddagger}$. The points lie satisfactorily on a straight line, the equation for which is

[4] $$\Delta H^{\ddagger} = 6.7\Delta G^{\ddagger} + \text{constant}$$

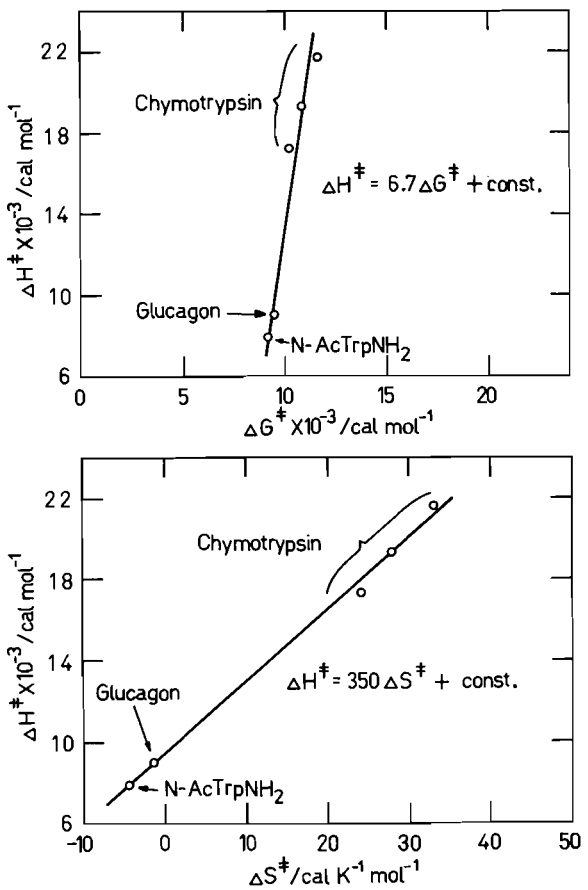

FIG. 3. (*a*), A plot of the enthalpy of activation against the Gibbs energy of activation at 25°C, for the five reactions. (*b*), A plot of the enthalpy of activation against the entropy of activation.

There is thus a magnification by 6.7 when the enthalpies (or energies) of activation are used, and the latter thus provide a much more sensitive measure of the behaviour of tryptophan groups in proteins.

Since $\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\Delta S^{\ddagger} = \Delta H^{\ddagger} - 298\Delta S^{\ddagger}$ (at 25°C) it follows from eq. [4] that

[5] $$\Delta H^{\ddagger} = 350\Delta S^{\ddagger} + \text{constant}$$

if $\Delta H^{\ddagger}$ is in the units cal mol^{-1} and $\Delta S^{\ddagger}$ in the units cal K^{-1} mol^{-1}. This relationship is shown in Fig. 3*b*. If the experiments were (hypothetically) carried out at 350 K, the compensation or isokinetic temperature, the rates would all be approximately the same, since there would then be complete compensation between $\Delta H^{\ddagger}$ and $T\Delta S^{\ddagger}$. However, the compensation temperature is of no simple significance.

Compensation effects are frequently observed (10–12), and have been interpreted (13) as due to solvent and steric effects. A change in vibrational frequency brings about parallel changes in H/T and in S, and the compensation is greater for the higher frequency. In the reactions studied in this investigation, a tryptophan residue which is sterically protected from the NBS will react with a higher activation energy. At the same time there will be a loosening of the vibrations in the activated complex, and a corresponding increase in entropy which will partly compensate for the increase in activation energy.

The present results thus provide an additional example in which measurements of activation energies provide more sensitive information than rate measurements at a single temperature.

Synthesis of *exo*- and *endo*-brevicomin and frontalin

PHAIK-ENG SUM AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received January 9, 1979

PHAIK-ENG SUM and LARRY WEILER. Can. J. Chem. **57**, 1475 (1979).

The dianion of methyl acetoacetate is alkylated at the γ-carbon with homoallylic bromides. The resulting alkenes are epoxidized and then cyclized with a Lewis acid to produce esters of 6,8-dioxabicyclo[3.2.1]octane. These esters can be hydrolyzed and decarboxylated in a novel reaction. This methodology has been applied to a stereospecific synthesis of the title compounds. In addition, one of the intermediates in the *exo*-brevicomin synthesis can be resolved to provide the natural (+)-pheromone.

PHAIK-ENG SUM et LARRY WEILER. Can. J. Chem. **57**, 1475 (1979).

Le dianion de l'acétoacétate de méthyle peut être alkylé au niveau du carbone γ par des bromures homoallyliques. Les alcènes qui en résultent peuvent être époxydés et ensuite cyclisés à l'aide d'un acide de Lewis pour fournir des esters du dioxa-6,8 bicyclo[3.2.1] octane. On peut hydrolyser ces esters et les décarboxyler dans une réaction nouvelle. On a appliqué cette méthodologie à une synthèse stéréospécifique des composés sus-mentionnés. De plus, un des intermédiaires de la synthèse de l'*exo*-brévicomine peut être résolu pour fournir la (+)-phéromone naturelle.

[Traduit par le journal]

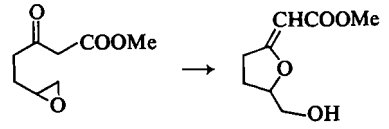
Recently we have been interested in using acyclic β-keto esters to form cyclic compounds. Five-membered carbocyclic compounds were prepared in our synthesis of jasmone (1) and a prostaglandin intermediate (2). In addition other groups have reported the cyclization of β-keto esters in prostaglandin syntheses (3). In these reactions the cyclization occurs at a sp^2 carbon as shown in [1]. We have

[1] 
also been able to generate six-membered carbocyclic rings by cyclization of an appropriately substituted β-keto ester in an approach to the synthesis of resistomycin (4). White and co-workers have found that the olefinic β-keto ester **1** undergoes the Lewis acid catalyzed cyclization shown in [2] (5). These

[2] 
1

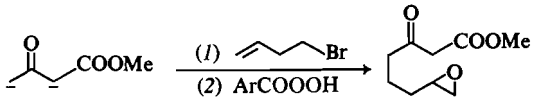
results illustrate the utility of acyclic β-keto esters to form five- and six-membered rings.

We were also interested in investigating the cyclization of epoxy β-keto esters. In the case of the epoxide **2** we found that acid or Lewis acid catalyzed reactions gave only the O-cyclized product **3**.[2] Here



2 **3**

we would like to report our results on the homologous epoxide **4** and some substituted derivatives of **4**. The epoxide **4** was readily prepared by alkylating the dianion of methyl acetoacetate (6) with 4-bromo-1-butene and epoxidizing the resulting alkene to give **4** in 60% overall yield. This same epoxide could be



4

synthesized by alkylating the dianion of methyl acetoacetate with 4-bromo-1,2-epoxybutane. However, the yields in this one-step sequence were usually lower than the above two-step sequence. The epoxide **4** underwent an isomerization on heating. Subsequently we found that this isomerization could be effected in 85% yield by treating **4** with boron trifluoride etherate. The structure of the isomerization product was readily identified from the spectral data. The salient points were the observation of a single carbonyl band in the infrared at 1740 cm^{-1}, which we assigned to an ester. The nmr spectrum of the isomerization product had a three-proton singlet at δ 3.68 due to the methyl group of an ester. The meythlene of the β-keto ester **4** was replaced by an

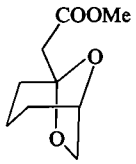
0008-4042/79/121475-06$01.00/0

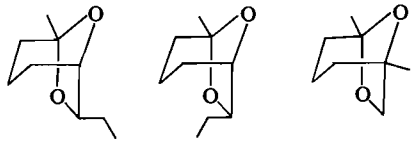
apparent singlet at δ 2.73. In addition there were two low-field signals at δ 3.8 and δ 4.5 attributed to three protons on carbon atoms attached to an oxygen atom. These structural features were combined to lead to **5** as the product of this isomerization.

Compound **5** contains the 6,8-dioxabicyclo[3.2.1]-octane skeleton (7) which is the basic framework of



5

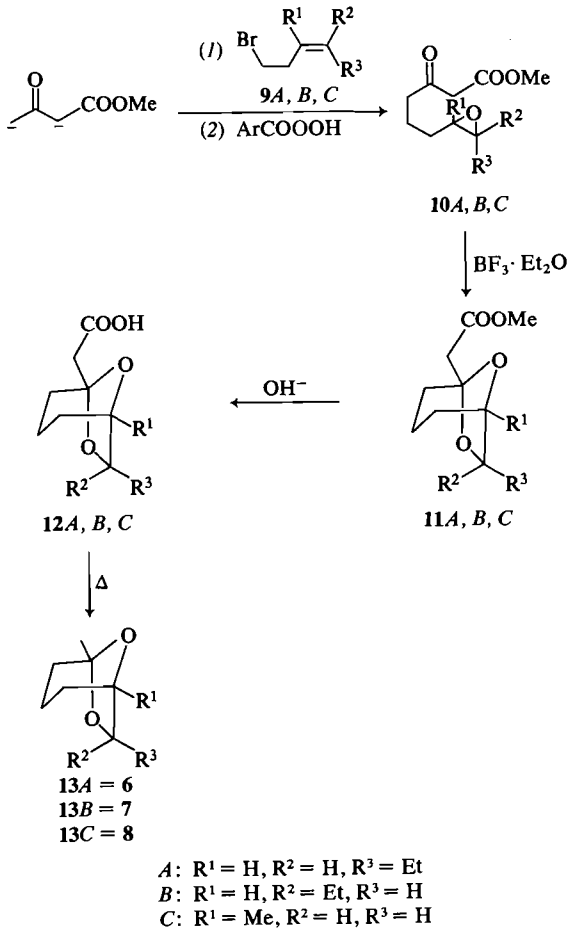
several bark beetle sex pheromones. *exo*-Brevicomin was isolated and found to have structure **6** by Silverstein and co-workers (8). This material is the aggregating pheromone of the bark beetle, *Dendroctonus brevicomis*, which attacks western pine trees. Subsequently, the *endo* isomer **7** was found to be a minor component in the natural pheromone mixture produced by *D. brevicomis*. Shortly after these reports on the brevicomin isomers frontalin, which is the sex pheromone of the bark beetle, *Dendroctonus frontalis*, that attacks southern pine trees, was found to have structure **8** (9). These three pheromones all



6 **7** **8**

have the 6,8-dioxabicyclo[3.2.1]octane skeleton and all three have been the object of several synthetic (for brevicomin, see ref. 10; for frontalin, see ref. 11) and entomological studies (12) because of their unusual structures and interesting biological properties. Hence we turned our attention to the preparation of pheromones **6**–**8** using the above β-keto ester cyclization.

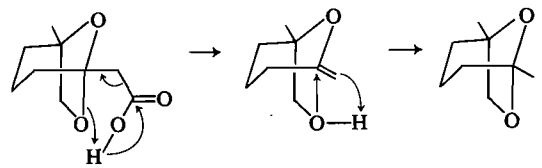
The synthesis of these pheromones is outlined in Scheme 1. In the synthesis of frontalin (**8** = **13***C*), the dianion of methyl acetoacetate was alkylated with 4-bromo-2-methyl-1-butene (**9***C*), prepared from the commercially available 2-methyl-1-buten-4-ol and phosphorus tribromide, to give an 83% yield of the γ-alkylated product which was epoxidized with *m*-chloroperbenzoic acid to produce **10***C* in 71% yield from methyl acetoacetate. The $BF_3 \cdot Et_2O$ catalyzed cyclization of **10***C* produced **11***C* in 95% yield. To convert **11***C* into frontalin we must remove the carbomethoxy group on the side chain. This was accomplished as follows. The ester **11***C* was hydro-



SCHEME 1. Syntheses of *exo*- and *endo*-brevicomin and frontalin.

lyzed in 88% yield by aqueous alkaline and the resulting carboxylic acid **12***C* underwent a smooth thermal decarboxylation (Kugelrohr oven at 220°C, 5 min) to give an 85% yield of frontalin (**13***C*). The rather facile decarboxylation of acid **12***C* may be due to participation of one of the ketal oxygens as shown below (reaction [3]). A similar mechanism was pro-

[3]



posed by Atkinson and Miller (13) for the decarboxylation of acid **14** in [4]. Hydrolysis and decarboxylation of ester **5** produced 5-methyl-6,8-dioxabicyclo[3.2.1]octane in 73% yield for the two steps.

The synthesis of *endo*-brevicomin (**13***B*) was accomplished along similar lines as that of frontalin

[4] 
14

(Scheme 1). Specifically, the dianion of methyl acetoacetate was alkylated (83% yield) with *E*-1-bromo-3-hexene (**9***B*) and the resulting alkene was epoxidized (87% yield) to give **10***B* which was cyclized to **11***B* in 91% yield. We could not detect any of the isomeric *exo*-isomer **12***A* in this cyclization. A number of earlier syntheses of *endo*- or *exo*-brevicomin have involved a thermal or acid catalyzed cyclization of a keto epoxide to generate the 6,8-dioxabicyclo[3.2.1]octane skeleton (8, 10). However, these conditions usually produced a mixture of *endo*- and *exo*-brevicomin. This Lewis acid catalyzed cyclization of the β-keto esters **10***A* (*vide infra*) and **10***B* can be effected in high yield and high stereospecificity. We suggest that the high stereospecificity in the cyclizations of **10***A* and **10***B* may be related to the significantly higher enol content of a β-keto ester relative to a simple ketone. The ketal ester **11***B* was converted into *endo*-brevicomin by hydrolysis (95%) and thermal decarboxylation (85%) as above. There was no detectable epimerization during the thermal decarboxylation which is consistent with the mechanism proposed in [3].

Finally the synthesis of *exo*-brevicomin (**13***A*) was also carried out as shown in Scheme 1. The overall yield of *exo*-brevicomin (**13***A*) from methyl acetoacetate and *Z*-1-bromo-3-hexene (**9***A*) was ca. 58%. In addition to the overall efficiency and high stereospecificity in this route we have found an added bonus. Namely, the carboxylic acid function in **12** provides a useful handle to achieve the resolution of this intermediate and hence achieve a synthesis of *both* enantiomers of **13** from a single intermediate. Often a comparison of the biological activity of the racemic attractant relative to each enantiomer can provide fascinating insight into the insect receptor sites (14). To date the lack of a useful handle has prevented the resolution of an intermediate late in the synthesis of frontalin or brevicomin. Efficiency requires that the resolution be applied as late as possible in the synthesis since we desire *both* enantiomers. Syntheses of optically active frontalin (11*c*, *e*) and brevicomin (10*d*, *i*) from a chiral precursor have been reported and the synthesis of the two enantiomers of frontalin via resolution of an intermediate has been reported (11*b*). However, we are not aware of any synthesis of (+) and (−)-*exo*-brevicomin by resolution of a synthetic intermediate; thus we investigated the possibility of resolving the carboxylic acid **12***A*. Although there are a variety of methods to resolve carboxylic acids, many of which could be applied here, we only investigated a single method to demonstrate the feasibility of this approach. We chose to resolve **12***A* via formation of the α-methylbenzylammonium salts since both enantiomers of the resolving agent are readily available (15, 16). Two recrystallizations of the (+)-α-methylbenzylammonium salt of **12***A* gave a 40% yield of a salt mp 110–115°C. This salt was hydrolyzed in aqueous acid to liberate the free acid **12***A* which was thermally decarboxylated as above to yield (+)-*exo*-brevicomin, $[\alpha]_D^{25} = +52°$ (c = 0.12 g/mL, Et_2O) which compares with the reported rotation of $[\alpha]_D^{26} = +84.1°$ (c = 2.2, Et_2O) for natural (+)-*exo*-brevicomin (10*d*). This would indicate that we have achieved a 62% resolution of **12***A*.

Experimental

All ir spectra were recorded in $CHCl_3$ solution using a Perkin Elmer model 700 spectrophotometer and were calibrated with the 1601 cm^{-1} band of polystyrene. The ^1H nmr spectra were recorded in $CDCl_3$ solution on either a Varian model T-60 or HA-100 spectrometer. The signal positions are reported using the δ scale with tetramethylsilane as internal standard. The multiplicity, coupling constants, and integrated peak areas are indicated in parentheses after each signal. The mass spectra were obtained using an Atlas CH-4B mass spectrometer and high resolution determinations were obtained using an AEI MS-9 or MS-50 mass spectrometer. Both instruments were operated at an ionizing potential of 70 eV. The silica gel used was obtained from E. Merck and that used for thin-layer chromatography (tlc) was the grade PF_{254}, whilst that used for column chromatography was the grade finer than 200 mesh ASTM. Elemental microanalyses were performed by Mr. Peter Borda, University of British Columbia.

Epoxide 4

The dianion of methyl acetoacetate (6) was alkylated with 4-bromo-1-butene to give in 79% yield methyl 3-oxo-7-octenoate, bp 60°C/0.1 Torr; ir: 1745, 1720, 1650, and 920 cm^{-1}; nmr δ: 1.5–2.3 (m, 4H), 2.51 (t, J = 7 Hz, 2H), 3.38 (s, 2H), 3.68 (s, 3H), 4.7–5.2 (m, 2H), and 5.3–6.1 (m, 1H); ms *m/e* (relative intensity): 170(29), 138(16), 129(13), 116(100), 101(54), 97(53), 84(32), 74(60), 69(43), 59(37), 55(32), 43(45), and 41(57). *Anal.* calcd. for $C_9H_{14}O_3$: C 63.51, H 8.29; found: C 63.51, H 8.37.

A sample of 1.01 g of 85% *m*-chloroperbenzoic acid (5.5 mmol) was added to a solution of 0.850 g (5.0 mmol) of the above olefinic ester in ca. 20 mL dry CH_2Cl_2 at 0°C. The reaction mixture was stirred at 0°C for ½ h and then at room temperature for an additional 20 h. The reaction was quenched with saturated aqueous $NaHSO_3$ and the aqueous layer was extracted with 2 × 50 mL Et_2O. The extracts were combined, washed with aqueous $NaHCO_3$ and brine, dried over $MgSO_4$, and the solvents removed under reduced pressure. The resulting oil was distilled (Kugelrohr) at 90°C/0.7 Torr to yield 0.696 g (75%) of epoxide **4**; ir: 1745 and 1720 cm^{-1}; nmr δ: 1.1–2.0 (m, 4H), 2.3–3 (m, 5H), 3.40 (s, 2H), and 3.68 (s, 3H); ms (*a*): high resolution calcd. for $C_9H_{14}O_4$: 186.0892

amu; found: 186.0912; (*b*) *m/e* (relative intensity): 186(15), 155(21), 124(15), 117(15), 116(21), 113(25), 101(100), 74(28), 69(50), 59(57), 55(61), 43(57), and 41(71).

*Cyclization of Epoxide **4** to Ketal **5***

A solution of 0.093 g (0.50 mmol) of ester **4** in 12 mL dry CH_2Cl_2 under N_2 was treated with 0.1 mL distilled $BF_3{\cdot}Et_2O$ and the resulting solution was stirred at room temperature for 2 h. The reaction was quenched with water and the aqueous layer was extracted several times with Et_2O. The extracts were combined, dried ($MgSO_4$), and the solvents removed under reduced pressure to yield an oil which was distilled (Kugelrohr) at 93°C/0.5 Torr to yield 0.079 g (85%) of cyclic ketal **5**; ir: 1740 cm^{-1}; nmr δ: 1.1–2.1 (m, 6H), 2.73 (s, 2H), 3.68 (s, 3H), 3.8 (m, 2H), and 4.5 (m, 1H); ms (*a*): high resolution calcd. for $C_9H_{14}O_4$: 186.0908 amu; found: 186.0889; (*b*) *m/e* (relative intensity): 186(32), 155(23), 113(13), 101(100), 87(23), 74(15), 59(16), 57(13), and 41(11).

5-Methyl-6,8-dioxabicyclo[3.2.1]octane

A solution of 0.093 g (0.50 mmol) ester **5** in 5 mL MeOH and 3 mL of 50% KOH was refluxed for 3 h. This solution was acidified with dilute HCl and extracted several times with ether. The extracts were combined and worked up as above to give 0.075 g (87%) of the acid, mp 77–79°C. The crude acid (0.026 g, 0.15 mmol) was placed in a small Kugelrohr tube which was then inserted into a preheated (220°C) Kugelrohr oven. The chromatographically pure 5-methyl-6,8-dioxabicyclo[3.2.1]octane, distilled within 8 min at that temperature and 1 atm. A total of 0.0192 g (84%) of product was obtained; ir: 2990, 1390, 1015, and 840 cm^{-1}; nmr δ: 1.41 (s, 3H), 1.3–2 (m, 6H), 3.8 (m, 2H), and 4.5 (m, 1H); ms (*a*): high resolution calcd. for $C_7H_{12}O_2$: 128.0837 amu; found: 128.0837; (*b*) *m/e* (relative intensity): 128(30), 100(15), 86(24), 68(12), 58(18), 47(14), 43(100), and 41(16).

*Z-1-Bromo-3-hexene (**9**A)*

The dianion of 3-butyn-1-ol, prepared using $LiNH_2$ in liquid NH_3, was alkylated with ethyl bromide to give 3-hexyn-1-ol in ca. 75% yield. A mixture of 4.16 g (41 mmol) of 3-hexyn-1-ol, 0.2 g of 5% Pd-on-$BaSO_4$, and 3 drops of freshly distilled quinoline in 50 mL MeOH was hydrogenated at atmospheric pressure. After 2 h the hydrogenation was stopped and the MeOH was removed under reduced pressure. The crude product was dissolved in Et_2O, washed with dilute HCl, and distilled to yield 3.4 g (82%) of *Z*-3-hexen-1-ol, bp 74°C/15 Torr.

A solution of 8.5 g of *Z*-3-hexen-1-ol in 10 mL anhydrous Et_2O was added dropwise to a cooled (−30°C) mixture of 7.6 g of PBr_3 and 0.43 g of pyridine in 40 mL of Et_2O. The reaction mixture was stirred at −30°C for 1 h, and then at room temperature for 5 h. The reaction was quenched with ice and water, and the aqueous layer was extracted several times with Et_2O. The extracts were combined, washed with 5% $NaHCO_3$, then brine, dried ($MgSO_4$), filtered, and the solvent removed under reduced pressure. This product was distilled at 65°C/15 Torr to yield 6.3 g (46%) of *Z*-1-bromo-3-hexene (**9***A*) (17); ir: 3000, 2910, and 1265 cm^{-1}; nmr δ: 0.98 (t, J = 7 Hz, 3H), 2.03 (qn, J = 7 Hz, 2H), 2.63 (q, J = 7 Hz, 2H), 3.32 (t, J = 7 Hz, 2H), and 5–5.75 (sym. m, 2H); ms *m/e* (relative intensity): 164(25), 162(25), 83(88), 82(31), 68(25), 67(33), 55(100), and 41(89).

E-*1-Bromo-3-hexene (**9**B)*

A solution of 9.8 g (0.10 mol) of 3-hexyn-1-ol, prepared as above, in 50 mL anhydrous Et_2O was added dropwise to a solution of 8.81 g of sodium in 500 mL ammonia. The reaction was stirred at −35°C for 4 h, quenched with 12 g of NH_4Cl, and the ammonia was allowed to evaporate. The residue was treated with 250 mL of ice cold water and the aqueous layer was extracted with 4 × 300 mL Et_2O. The extracts were combined and worked up to yield 8.7 g (87%) of *E*-3-hexen-1-ol which distilled at 72–74°C/15 Torr. This alcohol (6.0 g, 0.060 mol) was converted into 5.4 g (56%) of *E*-1-bromo-3-hexene (**9***B*) (18) as above; bp 78–80°C/15 Torr; ir: 3000, 2925, and 970 cm^{-1}; nmr δ: 0.98 (t, J = 7 Hz, 3H), 1.7–2.7 (m, 4H), 3.2–3.7 (m, 2H), and 5–5.8 (m, 2H); ms *m/e* (relative intensity): 164(21), 162(22), 83(77), 82(38), 69(28), 67(38), 55(81), and 41(100).

*4-Bromo-2-methyl-1-butene (**9**C)*

2-Methyl-1-buten-4-ol (1.4 g, 16 mmol) was converted into 1.0 g (42%) of bromide **9***C* (19) as above and Kugelrohr distilled at 105°C/760 Torr.

*Alkylation of the Dianion of Methyl Acetoacetate with Bromide **9***

A solution of the dianion from 0.35 g (3.0 mmol) of methyl acetoacetate was generated (6) in THF and alkylated with a solution of 0.52 g (3.2 mmol) of *Z*-1-bromo-3-hexene (**9***A*) in ½ mL THF at 0°C. The reaction mixture was stirred at 0°C for 2 h and at room temperature for an additional 3 h. It was then quenched with dilute HCl, and extracted several times with ether. The extracts were combined and worked up to yield 0.52 g (88%) of methyl *Z*-3-oxo-7-decenoate which distilled (Kugelrohr) at 70°C/0.8 Torr; ir: 1745, 1715, 1650, and 1630 cm^{-1}; nmr δ: 0.96 (t, J = 7 Hz, 3H), 1.4–2.2 (m, 6H), 2.53 (t, J = 7 Hz, 2H), 3.41 (s, 2H), 3.72 (s, 3H), and 4.9–5.5 (m, 2H); ms *m/e* (relative intensity): 198(10), 180(25), 129(22), 117(22), 116(100), 101(22), 82(84), 67(68), 55(41), and 41(46). *Anal.* calcd. for $C_{11}H_{18}O_3$: C 66.64, H 9.15; found: C 66.56, H 9.24.

In a similar manner 2.32 g (0.020 mol) of methyl acetoacetate was converted into 3.27 g (83%) of methyl *E*-3-oxo-7-decenoate which distilled (Kugelrohr) at 81°C/0.1 Torr; ir: 1745, 1720, 1660, 1630, and 970 cm^{-1}; nmr δ: 0.94 (t, J = 7 Hz, 3H), 1.2–2.1 (m, 6H), 2.48 (t, J = 7 Hz, 2H), 3.39 (s, 2H), 3.70 (s, 3H), and 5.2–5.4 (m, 2H); ms *m/e* (relative intensity): 198(32), 180(32), 125(21), 117(21), 116(100), 101(30), 82(83), 67(65), and 55(21). *Anal.* calcd. for $C_{11}H_{18}O_3$: C 66.64, H 9.15; found: C 66.65, H 9.05.

Methyl 7-methyl-3-oxo-7-octenoate was prepared as above in 83% yield. The product, bp 75°C/0.3 Torr, was characterized by ir: 1745, 1715, 1650, 1635, and 890 cm^{-1}; nmr δ: 1.69 (s, 3H), 1.6–2.1 (m, 4H), 2.49 (t, J = 7 Hz, 2H), 3.40 (s, 2H), 3.70 (s, 3H), and 4.65 (m, 2H); ms *m/e* (relative intensity): 184(24), 166(18), 129(37), 117(34), 116(75), 111(35), 101(37), 74(100), 69(58), 68(56), 59(42), 55(77), 43(87), and 41(57). *Anal.* calcd. for $C_{10}H_{16}O_3$: C 65.19, H 8.75; found: C 65.20, H 8.75.

*Epoxidation of Alkenes to Produce **10***

A solution of 0.198 g (1.0 mmol) of methyl *Z*-3-oxo-7-decenoate, from above, in 6 mL dry CH_2Cl_2 was cooled to ca. 14°C and treated with 0.236 g (1.3 mmol) of *m*-chloroperbenzoic acid and 0.213 g (1.5 mmol) of anhydrous NaH_2PO_4. The reaction mixture was stirred at room temperature for 9 h and then quenched with saturated $NaHSO_3$. The aqueous layer was extracted with 2 × 25 mL Et_2O; the extracts were combined, washed with $NaHCO_3$, and worked up to yield 0.185 g (87%) of epoxide **10***A* which was homogeneous by tlc. The epoxide **10***A* distilled (Kugelrohr) at 93°C/0.15 Torr and was characterized by the following spectral data: ir: 1745 and 1715 cm^{-1}; nmr δ: 1.02 (t, J = 7 Hz, 3H), 1.3–2 (m, 6H), 2.5–3.1 (m, 4H), 3.42 (s, 2H), and 3.70 (s, 3H); ms *m/e* (relative intensity): 214(15), 159(21), 156(57), 141(25), 139(41), 124(100),

116(37), 101(55), 97(71), 96(69), 83(55), 69(52), 59(52), 57(60), 55(72), 43(78), and 41(77). *Anal.* calcd. for $C_{11}H_{18}O_4$: C 61.66, H 8.47; found: C 61.38, H 8.25.

In a similar fashion 1.78 g (9.0 mmol) of methyl *E*-3-oxo-7-decenoate was epoxidized in 87% yield to give **10***B* which was distilled (Kugelrohr) at 96°C/0.1 Torr; ir: 1745 and 1720 cm^{-1}; nmr δ: 0.98 (t, J = 7 Hz, 3H), 1.2–2 (m, 6H), 2.35–2.7 (m, 4H), 3.43 (s, 2H), and 3.72 (s, 3H); ms *m/e* (relative intensity): 214(16), 184(20), 156(56), 141(22), 124(100), 116(59), 114(45), 113(44), 101(91), 97(68), 96(76), 59(51), 57(51), 55(67), 43(66), and 41(66). *Anal.* calcd. for $C_{11}H_{18}O_4$: C 61.66, H 8.47; found: C 61.38, H 8.57.

Epoxide **10***C* was also prepared as above in 86% yield and it was found to distill (Kugelrohr) at 95°C/0.7 Torr; ir: 1745 and 1720 cm^{-1}; nmr δ: 1.30 (s, 3H), 1.5–1.8 (m, 4H), 2.53 (s, 2H), 2.55 (t, J = 7 Hz, 2H), 3.39 (s, 2H), and 3.68 (s, 3H); ms (*a*): high resolution calcd. for $C_{10}H_{16}O_4$: 200.1042 amu; found: 200.1035; (*b*) low resolution *m/e* (relative intensity): 200(13), 170(17), 169(25), 164(20), 129(28), 127(30), 111(54), 101(65), 85(49), 81(42), 72(47), 69(40), 59(44), 55(68), 43(100), and 41(50).

*Cyclization of Epoxides **10** to Bicyclic Ketals **11***

Four drops of distilled $BF_3{\cdot}Et_2O$ were added to a solution of 0.072 g (0.33 mmol) of epoxide **10***A* in 2 mL dry CH_2Cl_2. This reaction mixture was stirred under N_2 at room temperature for 2 h, then quenched with water, and the aqueous phase was extracted with 3 × 15 mL Et_2O. The extracts were combined and worked up to yield 0.066 g (92%) of **11***A* which distilled (Kugelrohr) at 90°C/0.15 Torr for analysis. The crude material was homogeneous by tlc and had the following spectral data: ir: 1740 cm^{-1}; nmr δ: 0.89 (t, J = 7 Hz, 3H), 1.3–2.0 (m, 8H), 2.71 (s, 2H), 3.67 (s, 3H), 3.91 (t, J = 6 Hz, 1H), and 4.15 (bs, 1H); ms *m/e* (relative intensity): 214(10), 183(15), 141(9), 124(10), 115(10), 114(100), 101(31), 85(50), 68(19), 59(17), 57(15), and 41(18). *Anal.* calcd. for $C_{11}H_{18}O_4$: C 61.66, H 8.47; found: C 61.54, H 8.35.

In a similar fashion 1.28 g (6.0 mmol) of epoxide **10***B* was cyclized to 1.17 g (91%) of bicyclic ketal **11***B* which was distilled (Kugelrohr) at 96°C/0.1 Torr; ir: 1740 cm^{-1}; nmr δ: 0.97 (t, J = 7 Hz, 3H), 1.2–2 (m, 8H), 2.73 (s, 2H), 3.68 (s, 3H), 3.7–4.1 (m, 1H), and 4.1–4.3 (m, 1H); ms *m/e* (relative intensity): 214(26), 196(31), 184(47), 156(75), 141(33), 124(66), 114(61), 113(53), 101(100), 96(61), 85(55), 68(59), 59(54), and 41(51). *Anal.* calcd. for $C_{11}H_{18}O_4$: C 61.66, H 8.47; found: C 61.36, H 8.29.

Finally, 0.080 g (0.40 mmol) of epoxide **10***C* was cyclized under the above conditions to yield 0.076 g (95%) of ketal **11***C* which was Kugelrohr distilled at 90°C/0.1 Torr; ir: 1740 cm^{-1}; nmr δ: 1.32 (s, 3H), 1.5–1.9 (m, 6H), 2.72 (s, 2H), 3.40 (d, J = 7 Hz, 1H), 3.66 (s, 3H), and 3.88 (d, J = 7 Hz, 1H); ms *m/e* (relative intensity): 200(32), 169(29), 111(15), 101(59), 100(100), 72(70), and 43(59). *Anal.* calcd. for $C_{10}H_{16}O_4$: C 59.98, H 8.05; found: C 59.86, H 7.96.

*Hydrolysis of Esters **11** to Acids **12***

A solution of 0.214 g (1.0 mmol) of ester **11***A* in 5 mL MeOH and 6 mL 50% aqueous KOH was refluxed for 3 h, then cooled, acidified with aqueous HCl, and extracted several times with Et_2O. The extracts were combined and worked up to yield 0.189 g (95%) of acid **12***A*. The crude material was used directly in the decarboxylation and this acid was characterized by the following data: ir: 2400–3400, 1750, 1715 cm^{-1}; nmr δ: 0.90 (t, J = 7 Hz, 3H), 1.3–2.2 (m, 8H), 2.77 (s, 2H), 3.97 (t, J = 6 Hz, 1H), 4.18 (bs, 1H), and 9.72 (bs, 1H); ms (*a*): high resolution calcd. for $C_{10}H_{16}O_4$: 200.1049 amu; found: 200.1049; (*b*) low resolution *m/e* (relative intensity): 200(3), 124(11), 114(100), 87(26), 85(82), 68(28), 57(25), and 43(25).

The ester **11***B* (0.107 g, 0.50 mmol) was hydrolyzed in a similar fashion to yield 0.095 g (95%) of acid **12***B*; ir: 2400–3500, 1765, 1715 cm^{-1}; nmr δ: 0.98 (t, J = 7 Hz, 3H), 1.2–2.1 (m, 8H), 2.77 (s, 2H), 3.8–4.15 (m, 1H), 4.26 (bs, 1H), and 8.6 (bs, 1H); ms (*a*): high resolution calcd. for $C_{10}H_{16}O_4$: 200.1049 amu; found: 200.1045; (*b*) low resolution *m/e* (relative intensity): 200(3), 192(14), 156(21), 149(14), 142(14), 124(12), 114(36), 98(45), 71(26), 57(25), 44(47), 43(100), and 41(29).

The ester **11***C* (0.030 g, 0.15 mmol) was hydrolyzed as above to yield 0.025 g (88%) of acid **12***C*; ir: 2400–3600, 1755, 1715 cm^{-1}; nmr δ: 1.34 (s, 3H), 1.5–1.9 (m, 6H), 2.78 (s, 2H), 3.48 (d, J = 7 Hz, 1H), 3.95 (d, J = 7 Hz, 1H), and 9.52 (bs, 1H); ms (*a*): high resolution calcd. for $C_9H_{14}O_4$: 186.0892 amu; found: 186.0895; (*b*) low resolution *m/e* (relative intensity): 186(10), 156(13), 111(24), 100(100), 87(23), 72(79), and 43(42).

*Decarboxylation of Acids **12***

exo-*Brevicomin (**13**A)*

The crude acid **12***A* (0.100 g, 0.50 mmol) was placed in a Kugelrohr tube and inserted into a preheated (220°C) Kugelrohr oven. A colourless oil distilled within 8 min at atmospheric pressure to yield 0.068 g (87%) of *exo*-brevicomin (**13***A*) which had spectral data identical to that reported for **13***A* (8, 10).

endo-*Brevicomin (**13**B)*

In a similar fashion 0.060 g (0.30 mmol) of carboxylic acid **12***B* was decarboxylated to yield 0.040 g (85%) of *endo*-brevicomin (**13***B*) which had spectral data identical to that reported for **13***B* (10).

*Frontalin (**13**C)*

Finally 0.019 g (0.10 mmol) of crude acid **12***C* was decarboxylated to yield 0.012 g (85%) of frontalin (**13***C*) which had spectral data identical to that reported for **13***C* (11).

*Resolution of Carboxylic Acid **12**A*

A solution of 0.400 g (2.0 mmol) of carboxylic acid **12***A* in 10 mL dry CH_2Cl_2 was treated with 0.242 g (2.0 mmol) of (+)-α-methylbenzylamine. The mixture was stirred at room temperature and the solvent removed. The resulting solid was recrystallized from ether–hexane. After two such recrystallizations 0.180 g of salt, mp 110–115°C, was obtained. This salt was dissolved in 10% aqueous HCl and extracted several times with ether. The extracts were combined and worked up to yield 0.100 g of partially resolved **12***A*, $[\alpha]_D^{25}$ + 39.8° (0.20 g/mL, Et_2O). This acid (0.100 g) was decarboxylated as above to yield 0.060 g of (+)-*exo*-brevicomin, $[\alpha]_D^{26}$ +52° (0.12 g/mL, Et_2O).

Strong hydrogen bonding in oxime solvates of tetra-*n*-butylammonium fluoride

JAMES H. CLARK[1]

Department of Chemistry, University of Exeter, Exeter EX4 4QD, England

Received November 1, 1978

JAMES H. CLARK. Can. J. Chem. 57, 1481 (1979).

Four stable, crystalline oxime solvates of tetra-*n*-butylammonium fluoride have been prepared, characterised, and studied by ^1H, ^{13}C, and ^{19}F nmr, infrared, and ultraviolet spectroscopy. All of the complexes crystallise from solution as the disolvates, $Bu_4NF(oxime)_2$. The spectroscopic changes accompanying solvate formation are interpreted on the basis of strong hydrogen bonding between the fluoride anion and the oxime hydroxyl.

JAMES H. CLARK. Can. J. Chem. 57, 1481 (1979).

Quatre produits de solvatation stables et cristallins d'oxime par le fluorure de tétra *n*-butylammonium ont pu être préparés, caractérisés et étudiés par rmn. ^1H, ^{13}C et ^{19}F et par spectroscopies infrarouge et ultraviolette. Tous les complexes cristallisent de la solution sous forme de produits de double solvatation $Bu_4NF(oxime)_2$. On a interprété les changements spectroscopiques qui accompagnent la formation des produits de solvatation sur la base d'une liaison hydrogène importante entre l'anion fluorure et l'hydroxyle de l'oxime.

[Traduit par le journal]

In recent years, a number of complexes of the type $AH\cdots B^-$ where AH is an electron acceptor hydrogen bonded to an electron donor anion B^-, have been studied by a wide variety of spectroscopic and nonspectroscopic techniques (1–6). When AH is a strong H-bond electron acceptor such as a carboxylic acid or phenol and B a strong H-bond electron donor such as a small halide or carboxylate anion, the resulting complex is unusually stable and the spectroscopic and nonspectroscopic manifestations of H-bonding are exaggerated providing the opportunity for more detailed and more informative investigations of the H-bonding phenomenon.

This article describes the preparation and study of four novel AHB^- H-bonded complexes of the type $Bu_4N^+F^-\cdots(HON{:}CR^1R^2)_2$ (**1** to **4**). The four oximes selected represent examples of (*a*) a saturated oxime (**4**); (*b*) an aromatic oxime (**3**); (*c*) an aromatic oxime containing an additional H-bond electron acceptor site (**2**); and (*d*) a nonaromatic oxime containing a conjugated double bond system and an H-bond electron donor site (**1**). The solvates are good candidates for H-bonding investigations in that they are reasonably air-stable and may be recrystallised unchanged from aprotic solvents.

Experimental

^1H nmr spectra were recorded on JEOL MH-100 (100 MHz) and Perkin Elmer R10 (60 MHz) spectrometers. Variable temperature ^1H nmr spectra were recorded on the JEOL MH-100. ^{13}C nmr spectra were recorded on a JEOL JNM PS-100 spectrometer operating at 25.15 MHz using ca. 0.5 *m* solutions and Me_4Si as internal standard. ^{19}F nmr spectra were recorded on a JEOL JNM PS-100 spectrometer operating at 94.1 MHz using ca. 0.5 *m* solutions (MeCN). The ^{19}F nmr spectra were referenced to a separate sample of C_6F_6 and the chemical shifts quoted here are therefore, approximate. Addition of C_6F_6 to the sample solutions resulted in changes in sample colour and in the sample spectra (see later). Infrared spectra were recorded on a Perkin Elmer 357 spectrometer. Solid samples were run as Nujol and hexachlorobutadiene mulls and as evaporated thin films on NaCl discs. Ultraviolet spectra were run on Unicam SP1800 and Perkin Elmer 402 spectrophotometers; all samples were run in acetonitrile solution and those containing fluoride were prepared by vigorously shaking the oxime–MeCN solution with a labile Drifluor reagent (see later) followed by filtration. Melting points were recorded on a Mettler FP5 digital temperature read-out using a Mettler FP52 hot stage and are uncorrected.

Tetra-*n*-butylammonium fluoride was prepared by neutralisation of the commercial hydroxide (40% aqueous) with 40% hydrofluoric acid. Acetophenoxime (mp 58°C) and 2-hydroxyacetophenoxime (mp 116.5°C) were prepared from the

0008-4042/79/121481-07$01.00/0

respective ketones by reaction with hydroxylamine (from the hydrochloride + NaOH) in aqueous ethanol; the reaction mixtures were poured into cold dilute hydrochloric acid, filtered, and the solids recrystallised from benzene – petroleum ether. *dl*-Camphoroxime and 2,3-butanedionemonoxime were commercial samples recrystallised from benzene – petroleum ether before use. The purified oximes gave the following nmr characteristics. 2,3-Butanedionemonoxime: δ_H 10.20 (1H, s, OH), 2.49 (3H, s, MeCO) and 2.07 ppm (3H, s, MeCN—); δ_C 198.0 (C=O), 157.1 (C=N), 25.1 (*Me*CO), and 8.1 ppm (*Me*CN—). 2-Hydroxyacetophenoxime: δ_H 11.98 (1H, s, OH), 8.74 (1H, s, br, OH), ca. 7.1 (2H, m, ring CH), ca. 6.9 (2H, m, ring CH), and 2.29 ppm (3H, s, Me); δ_C 159.3 (C—OH), 157.1 (C=N), 130.7, 127.6, 119.4, 118.7, 117.1 (ring carbons), and 10.7 ppm (Me). Acetophenoxime: δ_H 10.04 (1H, s, OH), ca. 7.6 (2H, m, ring CH), 7.36 (3H, m, ring CH), and 2.33 ppm (3H, s, Me); δ_C 155.9 (C=N), 136.4, 129.2, 128.4, 126.0 (ring carbons), and 12.4 ppm (Me). *dl*-Camphoroxime: δ_H 9.47 (1H, s, OH), 2.55 (1H, 2 × tr, CH), ca. 1.9–1.1 (6H, m, $3CH_2$), 1.04 (3H, s, Me), 0.95 (3H, s, Me), and 0.83 ppm (3H, s, Me); δ_C 169.6 (C=N), 51.8, 48.3, 43.7, 33.1, 32.7, 27.3, 19.5, 18.6, and 11.1 ppm.

Labile Difluor reagents were prepared by treating chromatographic grade acidic alumina or commercial porous glass beads (10 g) with 20% aqueous tetra-*n*-butylammonium fluoride (20 g) followed by evaporation under reduced pressure to constant weight (14 g; 1 g ≡ 1 mmol $\overline{F}$).

All other materials were commercial products and were purified, where necessary, by normal methods.

*Preparation of Tetra-*n*-butylammonium Fluoride – 2,3-Butanedionemonoxime Disolvate (1)*

2,3-Butanedionemonoxime (0.011 mol in 20 g tetrahydrofuran) was added to a concentrated aqueous solution of tetra-*n*-butylammonium fluoride (0.01 mol) and the mixture was slowly evaporated with stirring, at ca. 50°C under reduced pressure until no further ebullition occurred. The mixture was then cooled in ice to provide a solid which was washed with cold ether and recrystallised from a little *N,N*-dimethylformamide, washed with ether, and dried at 0.1 Torr (30°C) to give fine colourless crystals of the disolvate **1** (1.95 g, 0.0042 mol, 76%), mp 80.0–80.6°C; δ_H 14.06 (2H, s, OH, concentration dependent), ca. 3.3 (8H, m, CH_2N), 2.34 (6H, s, MeCO) 1.88 (6H, s, MeCN—), ca. 1.5 (16H, m, $—(CH_2)_2—$) and 0.99 ppm (12H, tr, Me). On standing for ca. 1 week, the $CDCl_3$ solution showed the OH peak reduced to $<\frac{1}{2}$ of its original intensity and broadened; a strong peak at δ 7.3 ppm (> 2H, s, $CHCl_3$) and the peak at 2.34 weakened and overlapping with a new peak at δ 2.32 (tr, J = 2.4 Hz, CH_2D—); δ_C 198.5 (C=O), 154.5 (C=N), 58.6 (CH_2N), 24.8 (*Me*CO), 23.9 ($—CH_2—$), 19.7 (CH_2Me), 13.6 ($MeCH_2$), and 7.8 (*Me*CN—); δ_F (C_6F_6) 26.9 ppm (s, br). *Anal.* calcd. for $C_{24}H_{50}N_3O_4F$: C 62.2, H 10.8, N 9.1; found: C 61.7, H 9.9, N 9.0.

*Preparation of Tetra-*n*-butylammonium Fluoride – 2-Hydroxyacetophenoxime Disolvate (2)*

2-Hydroxyacetophenoxime (0.02 mol in 20 g tetrahydrofuran) was added to a concentrated aqueous solution of tetra-*n*-butylammonium fluoride (0.012 mol) and the mixture evaporated at ca. 70°C under reduced pressure (rotary evaporator) until no further ebullition occurred. The mixture was then cooled in an ice bath and washed with cold ether (2 × 100 cm^3) to give a white solid which was recrystallised from dimethylformamide (Et_2O), washed with ether, and dried at 0.1 Torr (30°C) to give the disolvate **2** (3.4 g, 0.006 mol, 60%); mp 92.3°C; δ_H 13.22 (4H, s, br, OH, concentration dependent), ca. 7.2 (4H, m, ring CH), ca. 6.8 (4H, m, ring CH), ca. 3.1 (8H, m, CH_2N), 2.24 (6H, s, MeCN—), 1.40 (16H, m, $—(CH_2)_2—$), and 0.86 ppm (12H, tr, Me). On standing for ca. 1 week, the $CDCl_3$ solution showed the OH peak reduced to $<\frac{1}{2}$ of its original intensity and broadened and a strong, new peak at δ 7.3 ppm (> 2H, s, $CHCl_3$). δ_C: 158.2 (C—OH), 155.3 (C=N), 129.0, 126.7, 119.9, 118.1, 116.7 (ring carbons), 58.1 (CH_2N), 23.7 (CH_2), 19.5 ($MeCH_2$), 13.5 ($MeCH_2$), and 10.4 ppm (*Me*CN—); δ_F (C_6F_6): 26.7 ppm (s, br). *Anal.* calcd. for $C_{32}H_{54}N_3O_4F$: C 68.2, H 9.6, N 7.4; found: C 66.0, H 9.2, N 7.1.

*Preparation of Tetra-*n*-butylammonium Fluoride – Acetophenoxime Disolvate (3)*

Acetophenoxime (0.01 mol in 20 g tetrahydrofuran) was added to a concentrated aqueous solution of tetra-*n*-butylammonium fluoride (0.01 mol) and the mixture evaporated with stirring, at 50–60°C under reduced pressure until no further ebullition occurred. Dimethylformamide (10 cm^3) was added and the solution evaporated at 60°C under reduced pressure for a further 15 min. The residue was washed with cold ether (2 × 50 cm^3) and the resulting solid recrystallised from dimethylformamide, washed with ether and dried at 0.1 Torr (30°C) to give crystals of the disolvate **3** (2.0 g, 0.0038 mol, 76%), mp 88.2°C (sample freezes on standing at this temperature and melts at 103.2–104°C; cooling and reheating the sample gives a mp of 103–104°C); δ_H (MeCN solvent): 11.1 (2H, s, br, OH, concentration dependent), 7.48 (4H, m, ring CH), 7.12 (6H, m, ring CH), 3.16 (8H, m, CH_2N), 2.12 (6H, s, Me), 1.32 (16H, m, $—(CH_2)_2—$), and 0.82 ppm (12H, tr, $MeCH_2$). The ^1H nmr spectrum in $CDCl_3$ shows no OH signal and a peak at δ 7.18 ppm (ca. 2H, s, $CHCl_3$); δ_C: 151.3 (C=N), 138.3, 128.0, 127.8, 125.5 (ring carbons), 58.1 (CH_2N), 23.8 (CH_2), 19.5 ($MeCH_2$), 13.6 ($MeCH_2$), and 11.6 ppm (*Me*CN—); δ_F (C_6F_6): 36.3 ppm (s). *Anal.* calcd. for $C_{32}H_{54}N_3O_2F$: C 72.3, H 10.1, N 7.9; found: C 72.0, H 9.9, N 7.9.

*Preparation of Tetra-*n*-butylammonium Fluoride –* dl*-Camphoroxime Disolvate (4)*

dl-Camphoroxime (0.01 mol in 20 g tetrahydrofuran) was added to concentrated aqueous tetra-*n*-butylammonium fluoride (0.01 mol) and the mixture evaporated with stirring, at 50–60°C, under reduced pressure until no further ebullition occurred. The resulting solid was recrystallised from dimethylformamide and then twice from dry diethyl ether followed by drying at 0.1 Torr (30°C) to give white needles of the disolvate **4** (1.8 g, 0.003 mol, 60%); mp 179–181°C; δ_H (MeCN solvent): ca. 11 (2H, s, br, OH, concentration dependent), 3.34 (8H, m, CH_2N), 2.48 (2H, 2 × tr, CH), ca. 1.8–1.1 (28H, m, CH_2), 1.01 (6H, s, Me), ca. 1.0 (12H, tr, $MeCH_2$), 0.93 (6H, s, Me), and 0.80 ppm (6H, s, Me). The ^1H nmr spectrum in $CDCl_3$ shows no OH peak and a new peak at δ 7.34 ppm (ca. 2H, s, $CHCl_3$); δ_C: 167.2 (C=N), 58.4 (CH_2N), 51.3, 48.1, 43.8, 33.2, 33.0, 27.4, 24.0 (CH_2CH_2N), 19.7 (Me?), 19.5 ($MeCH_2$), 18.6 (Me?), 13.8 ($MeCH_2$), and 11.4 ppm (Me?); δ_F (C_6F_6): 37.1 ppm (s). *Anal.* calcd. for $C_{36}H_{70}N_3O_2F$: C 72.6, H 11.7, N 7.1; found: C 71.7, H 11.4, N 7.1.

Results and Discussion

All of the solvates prepared crystallise from solution as the disolvates irrespective of the initial concentrations of fluoride and oxime. Attempts to synthesize crystalline monosolvates by using deliberate excesses of the fluoride were unsuccessful. This is not without precedent for fluorides since it has been reported that crystals of $KF(CH_3CO_2H)_2$ grow from $KF–CH_3CO_2H$ solutions (1). All of the disolvates are soluble in common polar aprotic

solvents such as dimethylformamide and acetonitrile but only **4** is soluble in diethyl ether.

Proton Magnetic Resonance Spectra

The ^1H nmr chemical shifts of the H-bonding protons of several strongly H-bonded anionic complexes have been reported (2, 4, 7). The commonly observed effect on the H-bonding proton resonance on going from the self-associated electron acceptor to the anionic complex is a deshielding (downfield shift) one which is usually assumed to reflect an increase in strength of the H-bond. The chemical shifts of the H-bonding protons of **1**–**4** along with the corresponding values for the parent oximes are summarised in Table 1. All of the hydroxyl proton signals observed (with the possible exception of the intramolecularly H-bonded phenolic proton in the parent oxime of **2**) are concentration (and temperature) dependent and although some care was taken to ensure that each pair of spectra (complex and oxime) were run at approximately the same concentration (and temperature), the results are only meant to illustrate trends and should not be considered on a strict quantitative basis.

In all cases, the H-bonding proton experiences a net deshielding effect on going to the anionic complex which presumably reflects a strengthening in the H-bond to the oxime hydroxyl. It is interesting to note that **2** shows only one hydroxyl proton signal whereas its parent oxime shows two distinct signals under the same conditions.

The most striking observation made with these spectra is that **3** and **4** do not show a hydroxyl proton signal in $CDCl_3$ but instead show a strong chloroform signal at ca. 7.2–7.3 ppm. No other changes were apparent in the spectra on going from MeCN to $CDCl_3$. This suggests that these complexes undergo rapid H–D exchange with $CDCl_3$ (eq. [1]).

[1] $$—OH\cdots\bar{F} + CDCl_3 \rightleftharpoons —OD\cdots\bar{F} + CHCl_3$$

The hydroxyl proton chemical shifts for **3** and **4** were recorded in MeCN and addition of $CDCl_3$ to these solutions was found to result in immediate loss of the OH signal and its replacement by a strong, sharp singlet at 7.2–7.3 ppm. It was also discovered that allowing **1** and **2** to stand in $CDCl_3$ over a period of several days resulted in a marked increase in intensity of the $CHCl_3$ signal while the OH signals became very weak.

Furthermore, the spectrum of **1** in $CDCl_3$, after a long period, showed a marked reduction in intensity of the *Me*CO signal and the appearance of a new triplet ($J \sim 2.4$ Hz) the central band of which is ca. 0.02 ppm upfield from the original *Me*CO signal. This is in excellent agreement with Tiers reported ^1H nmr on α-toluene-d_1 which showed a triplet ($J = 2.38$ Hz) due to $—CH_2D$ slightly upfield from that of the methyl in toluene-h_8 (8). The behaviour of **1** in $CDCl_3$ may be explained by a fluoride induced enolisation (9) of the MeCO group allowing incorporation of deuterium into the methyl group via H–D exchange at the hydroxyl group (eq. [2]).

[2] 
Variable temperature ^1H nmr studies on **1** and **2** in $CDCl_3$ showed little change[2] in δ(OH) whereas variable concentration studies showed an appreciable fall in δ(OH) with decreasing concentration of **1** and **2**. These changes may be readily interpreted in terms of dissociation of the complexes to free oxime and fluoride (eq. [3]).

[3] $$\bar{F}(oxime)_2 \rightleftharpoons \bar{F}(oxime) + oxime \rightleftharpoons \bar{F} + 2oxime$$

Fluorine-19 Magnetic Resonance Spectra

The ^{19}F nmr chemical shifts of **1**–**4** in MeCN solution are reported in Table 2. The values represent a large downfield shift (ca. 140–150 ppm) relative to

[2]δ(OH) remains constant to ±0.2 ppm for both complexes over the temperature range −24 to +28°C (0.1, 0.3, and 0.5 *m*).

the free fluoride ion (10, 11). An appreciable deshielding of the electron donor on formation of a strong H-bond is to be expected.

It is interesting to note that on addition of C_6F_6 to the sample solutions, the fluoride peak broadens and shifts to higher magnetic fields ($\Delta\delta$ = 1–5 ppm). In addition to this, several new peaks appear near the C_6F_6 signal. The position and complexity of the new peaks suggest that we may be observing nucleophilic attack by the oxime, the nucleophilicity of which will be enhanced by H-bonding to fluoride (6, 12, 13), on the C_6F_6. The results of a more detailed investigation on these and related systems will be reported elsewhere.

Carbon-13 Magnetic Resonance Spectra

Carbon-13 nmr offers the opportunity to observe long range effects of H-bonding in the solvates **1–4**. Among the relatively few reported spectroscopic investigations of long range effects of H-bonding, carbon-13 spin–lattice relaxation studies on H-bonded long chain alcohols (14) and chlorine-35 nuclear quadrupole resonance studies on H-bonded chlorocarboxylic acids (15) are outstanding, demonstrating the value of investigating electron structure modifications of nucleii that are not in the immediate vicinity of the H-bond.

The chemical shifts of the carbons closest to the H-bonds ($\rangle C{=}N{-}$) are given in Table 3 along with the differences in chemical shifts with respect to those of the corresponding parent oximes ($\delta(C{=}N)_{complex} - \delta(C{=}N)_{oxime}$). The observed shielding effect experienced on going from the oxime to its fluoride complex is relatively small but significant and is to be expected for a nucleus close to the H-bonding site of an associated electron acceptor. The methyl carbons α to the C=N group in **1–3** also experience a small shielding effect on fluoride solvation. Full details of the ^{13}C nmr spectra of **1–4** and of their parent oximes are given in the Experimental.

Infrared Spectra

The positions of the most important bands in the ir spectra of **1–4** and of the parent oximes are given in Table 4.

The most pronounced changes in the spectra on going from the oxime to the fluoride solvate occur in the 4000–1800 cm^{-1} region, that is, in the position of the ν_s(OH) bands. In all four cases, the broad bands centred at 3350–3200 cm^{-1} and due to the stretching vibrations of the self-associated oximes, disappear or are considerably reduced in intensity. The spectrum of **4** shows a new, very broad band at ca. 2700 cm^{-1} which represents a shift of some 900 cm^{-1} relative to the free oxime[3] (a $\Delta\nu_s$ consistent with strong anionic H-bonding (6)). In the spectra of **1–3** there are several new bands in the 2700–1800 cm^{-1} region as compared to the spectra of the parent oximes, although of these only **3** showed a pronounced new band at above 2300 cm^{-1}. These features are in line with type 1 H-bonds using Joesten and Schaads classification (16) having overlapping ν_s bands above 1800 cm^{-1} and being typical of the asymmetric double-minimum-potential function kind of H-bond. Thus, these H-bonds are apparently weaker than some other $\bar{F}\cdots H{-}O{-}$ H-bonds such as those in fluoride – carboxylic acid systems (1) and than the $\bar{O}\cdots H{-}O{-}$ H-bonds in some acid salts of very acidic oximes (17) which show broad bands below 1800 cm^{-1} and represent a vibration of a very strong H-bond characterised by a single potential function. It should also be emphasised that some of the bands above 1800 cm^{-1} may be due to overtones, combinations, or to proton transfer. The ir picture shows all possible H-bonds and contributions from $F{-}H\cdots\bar{O}$ cannot be ruled out although it does seem that significant contributions from $(F\cdots H\cdots F)^-$ can be discounted since some of its characteristic vibrations appear to be absent in all of the spectra recorded (18).

The relative intensities and positions of the two broad hydroxyl stretching bands in the spectrum of 2-hydroxyacetophenoxime suggest that the band at ca. 3340 cm^{-1} is due to intermolecular association (probably $\nu_s(OH\cdots O)$) while that under the strong ν_s(CH) band is due to intramolecular association ($\nu_s(OH\cdots N)$) (19). It is interesting to note that on going to **2**, the former band is absent while the latter band appears to be only slightly displaced. It would seem, therefore, that while the intermolecular association of this oxime is disrupted by the highly localised electron density of the fluoride anion, the intramolecular association remains intact (eq. [4]).

The absence of bands in the 2600–1700 cm^{-1} region of the spectrum of **4** is outstanding and suggests that this complex contains an H-bond of a quite different type from those in **1–3**. This may be due to the ability of **1–3** to delocalise their negative charges by way of their conjugated double bond systems, e.g., [5].

[3]A weak, sharp band at ca. 3600 cm^{-1} is visible in spectra of *dl*-camphoroxime dissolved in an inert (in an H-bonding sense) solvent and may be assigned to the hydroxyl stretching vibration of the monomeric oxime.

[4] 
The spectral changes in the out-of-plane torsional mode ν_t, of the H-bond electron acceptor caused by H-bond formation are often quite spectacular, though rarely as pronounced as those seen with ν_s. For each of the complexes studied, one medium-strong band below 1000 cm^{-1} is at a significantly higher frequency than in the spectra of the corresponding parent oxime ($\Delta\nu_t > 90\ cm^{-1}$) and these bands are assigned to the ν_t vibrations. The positions of these bands and their movement on increasing H-bond strength are in line with previous studies on the strongly H-bonded *N*-methylpyridinium-2-aldoxime salts (20), as are the positions and small movements of the in-plane bending modes, ν_b.

[5] 
The small but significant positive frequency shifts in the ν_s(NO) bands on going from oxime to fluoride solvate are also consistent with previous studies on oximes (20) and are consistent with increased electron density on the oxygen atom due to stronger H-bonding.

It was noted earlier that solution of **3** or **4** in $CDCl_3$ appeared, by ^1H nmr, to result in deuteration of the oxime. Infrared studies on these systems confirm this observation and suggest that in dilute solution ($CDCl_3$), the complexes are largely dissociated since the position of the most intense bands (2400 cm^{-1} for **4** and 2350 cm^{-1} for **2**) are consistent with the self-associated forms ($\nu_s(OH)_{oxime}/\nu_s(OD)_{obs}$ = 1.37 for **4** and **3**). Evaporation of these solutions restores the original spectra with only weak bands due to the deuterated forms remaining. Results of a more detailed investigation of dilution effects on the ir spectra of the solvates will be reported in a later article.

Ultraviolet Spectra

Since the very low concentrations normally re-

quired for recording electronic spectra would almost certainly result in significant dissociation of the complexes, it was necessary to consider an alternative approach to obtaining information on the effect of strong anionic H-bonding on the electronic spectra of oximes. In a recent communication, a novel source of anhydrous quaternary ammonium fluoride was described where the fluoride was supported on a porous, surface hydroxylated, polymeric support such as silica gel (21). For our purposes, we required a source of anhydrous tetra-*n*-butylammonium fluoride which would be effective in an aprotic medium such as acetonitrile. We have found that while silica supported Bu_4NF loses little, if any, of its fluoride in such media, analogous reagents involving acidic alumina and finely ground porous glass beads behave as an excellent source of fluoride in acetonitrile. We have termed these reagents 'labile drifluors' in keeping with the previous nomenclature (21).

There is a paucity of reliable electronic spectroscopic data on oximes. Orenski studied a number of saturated and unsaturated oximes and concluded that while the former usually shows a strong π–π^* band near 200 mμ, the latter show their strong π–π^* band near 240 mμ (22). The one saturated oxime we have studied here, *dl*-camphoroxime, appears to show only a weak ($\varepsilon = 1.1 \times 10^2$) band at 228 mμ which undergoes considerable enhancement in intensity but only slight change in position on addition of a large excess of available fluoride ($\varepsilon \sim 10^4$, $\lambda = 231$ mμ).

Spectacular changes occur in the ultraviolet spectra of 2,3-butanedionemonoxime and 2-hydroxyacetophenoxime on addition of fluoride. The former oxime shows a strong ($\varepsilon \sim 7 \times 10^3$) π–π^* band at 225 mμ which steadily increases in intensity and in wavelength ($\lambda_{max} = 231$ mμ) on increasing the amount of available fluoride. As the fluoride concentration increases, a new band appears at 302 mμ ($\varepsilon \sim 3 \times 10^3$).

There have been numerous reports of small changes in the wavelengths of the π–π^* bands of protic species on varying the H-bond electron donor ability of the medium (23) but dramatic changes such as that observed here are less well known. The growth of the new high wavelength band presumably reflects the formation of the anionic complex. More precisely, it may well be that the new band is due to a significant contribution from the proton transfer species [6] to the H-bonded complex since it has been reported that 2-nitrosophenol shows a strong π–π^* band at ca. 300 mμ (23).

The ultraviolet absorption spectrum of 2-hydroxyacetophenoxime shows bands at 228 mμ ($\varepsilon \sim 6 \times 10^3$) and at 305 mμ ($\varepsilon \sim 3 \times 10^3$) in addition to the

[6] 
complex pattern of bands between 240 and 260 mμ characteristic of an aromatic molecule. The low wavelength band is enhanced in intensity and shifts to higher wavelength ($\lambda_{max} \sim 231$ mμ) on addition of fluoride while the band at 305 mμ does not change significantly in position or intensity and a new, broad band appears at ca. 357 mμ. In the presence of a large excess of available fluoride, the band at 357 mμ is pronounced ($\varepsilon \sim 4 \times 10^3$) and accompanied by a very broad, complex band at 245–270 mμ with a shoulder at ca. 300 mμ. The growth of the new band at 357 mμ presumably reflects the formation of the anionic complex.

Summary

The crystalline fluoride solvates **1**–**4** show spectroscopic features characteristic of strong H-bonding. The H-bonding is between the hydroxyl group of the oxime and the fluoride anion and is probably of the asymmetric double-minimum-potential function kind although complex **4** shows somewhat different infrared and solvent-stability characteristics which may be due to an absence of conjugation in this particular species. All of the complexes will exchange with $CDCl_3$ although only very slowly in the cases of **1** and **2**. Complex **1** appears to be capable of incorporating deuterium into its MeCO group via MeCO enolisation and there is further spectroscopic evidence for this complex to support the existence of contributing structures containing a C-hydroxyl group.

Pulse radiolysis of 9.5 *M* $LiCl/D_2O$ glass at 6 K produces both types of trapped electrons, e_{vis}^- and e_{ir}^-, just as it does at 75 K. However, going from 75 K to 6 K increases the initial yield of e_{ir}^- and decreases its decay rate, while the yield of e_{vis}^- decreases and its decay rate increases. These results are attributed to fast trap-to-trap tunnelling of e_{vis}^- from unrelaxed traps at 6 K and slower tunnelling from deeper traps at 75 K while the e_{ir}^- traps seem to relax within 100 ns even at 6 K. In 12 *M* $LiCl/D_2O$ at 4–10 K the initial e_{vis}^- band with $\lambda_{max} = 625$ nm decays considerably over minutes revealing a stable band with $\lambda_{max} = 695$ nm. The stimulation spectrum and absorption spectrum of this stable band indicate a bound–free transition of 2.0 eV and a bound–bound transition of 1.8 eV. Similar measurements of e_{vis}^- at 77 K indicate a bound–free transition of 2.6 eV and a bound–bound transition of 2.1 eV. Tryptophan was photolyzed in 9.5 *M* $LiCl/D_2O$ at 2 K to produce e_{ir}^-.

NORMAN V. KLASSEN, GEORGE G. TEATHER et FERNAND KIEFFER. Can. J. Chem. **57**, 1488 (1979).

La radiolyse pulsée de verres de $LiCl/D_2O$ 9.5 *M* à 6 K produit, comme à 75 K, les deux types d'électrons piégés, e_{vis}^- et e_{ir}^-. Cependant en passant de 75 à 6 K, on voit augmenter le rendement initial de e_{ir}^- et diminuer sa vitesse de déclin, tandis que le rendement de e_{vis}^- diminue et que sa vitesse de déclin augmente. Ces résultats sont attribués à un transfert rapide de e_{vis}^- par effet tunnel de piège à piège à partir de pièges non relaxés à 6 K et à un transfer plus lent à partir de pièges plus profonds à 75 K, tandis que les pièges de e_{ir}^- semblent être déjà relaxés avant 100 ns même à 6 K. Dans $LiCl/D_2O$ 12 *M* à 4–10 K la bande initiale de e_{vis}^-, de $\lambda_{max} = 625$ nm, décroît pendant plusieurs minutes pour laisser subsister une bande stable de $\lambda_{max} = 695$ nm. Le spectre de stimulation et le spectra d'absorption correspondant à cette bande stable indiquent une transition état lié – état non lié de 2.0 eV et une transition état lié – état lié de 1.8 eV. Des mesures semblables concernant e_{vis}^- à 77 K indiquent une transition état lié – état non lié de 2.6 eV et une transition état lié – état lié de 2.1 eV. La photolyse du tryptophan dans $LiCl/D_2O$ 9.5 *M* à 2 K conduit à la formation de e_{ir}^-.

Introduction

Recently it was found by pulse radiolysis that substantial yields of two distinct types of trapped electrons, e_{vis}^- and e_{ir}^-, are formed at low temperatures in some aqueous glasses and in both pure and doped ice crystals (1–3). The species e_{vis}^- is the oft-studied species with an optical absorption band centered around 600 nm. The species e_{ir}^- has an absorption band whose maximum has not yet been measured but has been estimated to be ~ 3600 nm in aqueous glasses and ~ 2950 nm in ice. In some aqueous glasses e_{ir}^- was not found but the formation of both e_{vis}^- and e_{ir}^- in pure ice indicates that neither species requires the presence of solutes. Two very recent studies show that in $LiCl/D_2O$ (4) and in BeF_2/D_2O (5) glasses e_{vis}^- is associated with water molecules involved in the solvation shell of the Li^+ and the Be^{2+} ions whereas e_{ir}^- is associated with free water. The production of e_{ir}^-, as well as e_{vis}^-, in aqueous glasses and ice made with H_2O (6) shows that e_{ir}^- is not restricted to D_2O matrices.

The evidence for the assignment of the infrared band to a trapped electron, e_{ir}^-, is of three types: (*a*) it was found (1, 2, 4) that the electron scavengers SeO_4^{2-}, Cu^{2+}, CrO_4^{2-}, and $(CH_3)_2CO$ both reduced the initial yield and increased the decay rate of e_{ir}^-; (*b*) in ethylene glycol/D_2O (2) and BeF_2/D_2O (5) glasses at 76 K and in D_2O ice at 4 K (7) a portion of the e_{ir}^- decays to become e_{vis}^-; (*c*) in several aqueous glasses at 77 K a luminescence is found to accompany the decay of e_{ir}^- and this luminescence has also been produced by laser photolysis of e_{vis}^- at 77 K. Presumably e_{vis}^- was photoionized by laser photolysis and, in part, retrapped as e_{ir}^- which then decayed to produce the luminescence (8, 9).

In this study we have investigated e_{vis}^- and e_{ir}^-

0008-4042/79/121488-12$01.00/0

further, primarily in $LiCl/D_2O$ glasses in which both species are produced in good yield and appear to decay independently of one another. Both radiolysis of aqueous glasses and photolysis of glasses containing tryptophan were used to produce trapped electrons. Optical absorption measurements, coupled with decay kinetics, were carried out between 2 K and 90 K on both the nanoseconds to milliseconds time scale and the minutes time scale. Spectral stimulation measurements of e_{vis}^- and e_{ir}^- were carried out between 4 K and 77 K.

Experimental

All solutions were prepared with D_2O (99.7% isotopic purity) obtained from Merck, Sharp and Dohme. Solutes were reagent grade, used without purification. Samples were deaerated with argon for the absorption measurements and by the freeze–pump–thaw method for the stimulation spectra measurements. Samples were sealed off and plunged into liquid nitrogen, or otherwise rapidly cooled, to produce a glass. Radiolysis experiments were carried out with windowless samples or with 5 mm Suprasil cells, while 1 mm Suprasil cells were used for the absorption measurements following photoionization. Stimulation spectra were measured either in 3 mm id quartz tubes or in a 0.24 mm Suprasil cell. The latter was made by inserting a 0.76 mm spacer into a 1 mm cell. The $LiCl/D_2O$ and $NaOD/D_2O$ glasses were free or almost free of cracks. The ethylene glycol/D_2O (EG/D_2O) glasses were badly cracked.

Pulse radiolysis experiments were carried out as described earlier (2, 3) with the exception that the samples were irradiated in a Janis model 8DT Super Varitemp cryostat in which the samples were cooled with a flow of cold helium gas (10). The temperature was maintained within ± 0.5 K of the desired value by a Lake Shore Cryotronics model DRC-70C temperature controller and the temperature of the sample was measured with a silicon diode sensor situated very close to the sample. Pulses, 40 ns in duration, of 35 MeV electrons were used, each pulse delivering about 12 krad. Dosimetry was done by comparing each sample to 9.5 *M* $LiCl/D_2O$ irradiated at 72–73 K for which $G\varepsilon_{650} = 1.96 \times 10^4\ M^{-1}\ cm^{-1}$ at 100 ns (4).[1] It was assumed that the electron density of 9.5 *M* $LiCl/D_2O$ glass is constant from 6 K to 90 K. Variations of dose from pulse to pulse were measured with a secondary emission monitor. Absorption measurements at 450 nm $\leq \lambda \leq$ 1000 nm were made with an EG&G SHS-100 Si photodiode, at $\lambda \leq 450$ nm with a Philips XP-1003 photomultiplier and at $\lambda \geq 1000$ nm with a Barnes A-100 room temperature InAs detector. Spectra were measured by the split light beam technique. When measuring decay kinetics over more than 1 μs an interference filter restricted the analyzing light entering the sample to the wavelength being examined. It was determined that this procedure reduced photobleaching of trapped electrons by the analyzing light to negligible proportions.

The absorption measurements made on the minutes time scale were carried out with a Cary 17 spectrophotometer. In a Cary 17 the analyzing wavelength is selected before the light passes through the sample, thus avoiding the bleaching of trapped electrons by the analyzing light. Once in the spectrophotometer, the sample was not moved during the experiment. Absorption measurements were made before and after photolysis to determine the absorption spectrum produced by photolysis. Photolysis of tryptophan was carried out with an 8 W low pressure Hg lamp and bleaching was done with a tungsten halogen lamp both of which could be inserted into the sample compartment. At all other times the sample compartment was sealed from room light. The background absorbance of the matrix for radiolyzed samples at wavelengths >800 nm was measured after complete optical bleaching of the trapped electrons. At wavelengths <800 nm a residual absorbance, probably due to Cl_2^-, defied bleaching. Therefore the background below 800 nm was assumed to be that of an unirradiated solution of 12 *M* LiCl at room temperature which has a practically flat absorption spectrum between 300 nm and 800 nm. For experiments at 2 K the sample was immersed in liquid helium cooled by pumping. Experiments at 4–10 K employed the method of cooling by helium gas.

The method of measuring stimulation spectra has already been described (11, 12). The sample was held in an Oxford Instruments optical cryostat and immersed in liquid helium for studies at 4 K and immersed in liquid nitrogen for 77 K. Intermediate temperatures were obtained by cooling with cold helium gas. The phosphorescence intensity was measured with a photomultiplier using the full phosphorescence emission without any wavelength filtering.

Results and Discussion

Production of e_{vis}^- and e_{ir}^- by Tryptophan Photolysis at 2 K

We wished to find a system in which e_{ir}^- could be easily produced by methods other than radiolysis and in which e_{ir}^- could be studied on the minutes time scale. The system chosen was 9.5 *M* $LiCl/D_2O/5 \times 10^{-4}$ *M* L-tryptophan at 2 K. A 5 min uv photolysis of this glass produced spectrum *A* of Fig. 1, with an absorbance at 2500 nm typically in the range 0.1 to 0.2. Several minutes were needed to measure a complete spectrum during which time a small amount of isothermal decay occurred. Corrections were made for this decay on the basis of several consecutive spectral determinations. Spectra *A*, *B*, *C*, and *D* of Fig. 1 all represent spectra corrected to 1 min after the end of photolysis.

The uv photolysis of L-tryptophan (tryp) has been studied in several aqueous glasses at 77 K (13). When tryp was photoionized at 77 K in 9 *M* $LiCl/H_2O$ glass, both the tryptophan cation ($tryp^+$) with absorption maxima at 615, 560, and 340 nm (13) and e_{vis}^-, whose absorption maximum is known to be 590 nm (14), were produced. Our pulse radiolysis experiments with 9.5 *M* LiCl at 6 K indicate the likelihood of a very small yield of e_{vis}^- relative to that of e_{ir}^- when measured on the minutes time scale at 2 K. Thus spectrum *A* with λ_{max} at 330, 564, and 620 nm seems to be satisfactorily accounted for by $tryp^+$ and e_{vis}^-. There is no sign of the tryptophan

[1]Measurements made with a more precise instrument now lead us to believe that the temperature stated to be 76 K in refs. 1–4 was actually 72–73 K.

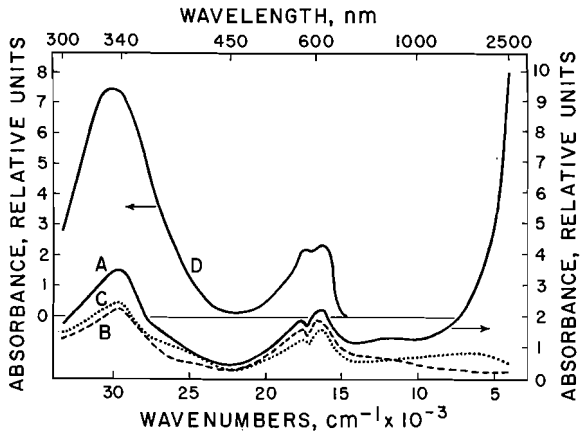

FIG. 1. Spectra *A*, *B*, and *C* were obtained at 2 K from a single sample prepared from an argon bubbled solution of 9.5 *M* LiCl/D_2O containing 5×10^{-4} *M* L-tryptophan. Spectrum *A* represents the absorption spectrum following a 5 min uv photolysis. Spectrum *B* shows the effect on *A* of partial bleaching with infrared light. Spectrum *C* shows the effect on *B* of partial bleaching with the full light of a projector lamp. Spectra *A*, *B*, and *C* are all plotted on the same relative absorbance scale and are corrected to correspond to 1 min after the end of photolysis, using kinetic data such as shown in Fig. 2. Spectrum *D*, on a different relative absorbance scale, represents the spectrum a few minutes after a 5 min photolysis of a glass prepared from a similar solution saturated with N_2O.

radical ($\lambda_{max} = 320$ and 500 nm) (15) nor the triplet state of tryptophan ($\lambda_{max} \sim 460$ nm) (16). We cannot discount the possibility of a small contribution of the tryptophan anion ($tryp^-$) ($\lambda_{max} \sim 350$ nm) (16). In addition, there is an intense infrared absorption. Above 1300 nm this absorption has a shape identical to that of e_{ir}^- as presented in ref. 2. This is further, strong evidence that the ir band is due to a trapped electron since no other species seems to be common to the uv photolysis of 9.5 *M* LiCl/D_2O/5×10^{-4} *M* tryp glass and the radiolysis of the LiCl/D_2O, $MgCl_2/D_2O$, and ethylene glycol/D_2O glasses. Ultraviolet photolysis is not expected to lead to the trapped exciton pair, $D_2O^+ \ldots e^-$.

After measuring spectrum *A*, the sample was bleached for 1 min with a 500 W projector lamp run at a dull glow and shielded from the sample with a 2 mm Chance-Pilkington filter type OX-5 which transmits mainly the infrared. The result was spectrum *B*. Thus, e_{ir}^- was completely bleached with great ease. The concomitant small decrease in the visible bands and larger decrease in the uv band are interpreted as a loss of $tryp^+$ due to reaction with bleached e_{ir}^- and some retrapping of bleached e_{ir}^- as e_{vis}^-. Finally, the sample was bleached for 1 min with the lamp at a dull glow but no OX-5 filter. The result was spectrum *C*. The result of this partial bleaching with the full light is not completely clear. The decrease in the visible band presumably represents a loss of e_{vis}^- and of $tryp^+$ with which it reacted. The small growth in the uv may be due to the production of $tryp^-$ by the reaction of bleached e_{vis}^- with tryp. The small band produced in the infrared is of unknown origin.

In another experiment, a glass made from 9.5 *M* LiCl/5×10^{-4} *M* tryp which had been saturated with N_2O at 2 atm was photolyzed for 5 min at 2 K. The result was spectrum *D* which shows that, in the presence of this electron scavenger, e_{ir}^- is not found. Neither do we believe that e_{vis}^- is present in spectrum *D*. This assumption is justified by the fact that the ratio of the visible absorbance maxima to the uv absorbance maximum is identical to that reported for the uv photolysis of tryp in 9 *M* HCl glass at 77 K (13) where e_{vis}^- would not be expected due to rapid reaction with H_3O^+.

We are now in a position to test the validity of the extinction coefficient, ε, measured previously for e_{ir}^- in ethylene glycol/D_2O glass at 1400 nm as $\varepsilon_{1400} = 5.7(\pm 0.8) \times 10^3\ M^{-1}\ cm^{-1}$ (2) which can be converted into $\varepsilon_{2500} = 3.1\ (\pm 0.5) \times 10^4$. For ε_{564}-($tryp^+$) we use $2700\ M^{-1}\ cm^{-1}$ (15). For $\varepsilon_{564}(e_{vis}^-)$ we use $1.6 \times 10^4\ M^{-1}\ cm^{-1}$ based on $\varepsilon_{max}(e_{vis}^-) = 2 \times 10^4\ M^{-1}\ cm^{-1}$ (2) and the long term spectrum of e_{vis}^- in 12 *M* LiCl at 4–10 K (see below). We assume that spectrum *D* represents $tryp^+$. We further assume that in spectrum *A* the uv band is due solely to $tryp^+$ but that the visible bands are comprised of $tryp^+$ plus e_{vis}^-. We then calculate that $\varepsilon_{2500}(e_{ir}^-) = 3.5 \times 10^4\ M^{-1}\ cm^{-1}$ if the yield of $tryp^+$ equals the sum of e_{vis}^- plus e_{ir}^- in spectrum *A*. Hence, we have determined $\varepsilon(e_{ir}^-)$ by a different method in a LiCl glass and find a value consistent with the previous determination in an ethylene glycol glass. This is further evidence that e_{ir}^- is the same species in the various glasses in which it has been produced. Several measures might be taken to make the method described here more reliable if they do not result in a significant reduction of the absorptions to be measured. The possible formation of $tryp^-$ might be countered by using a lower concentration of tryp and filtering the photolyzing light to reduce bleaching of e_{vis}^- and e_{ir}^-. The yield of e_{ir}^- relative to that of e_{vis}^- might be increased by using 6 *M* LiCl.

The isothermal changes in absorbance were measured following a 5 min photolysis of 9.5 *M* LiCl/5×10^{-4} *M* tryp at 2 K. These results are shown in Fig. 2. Photobleaching was avoided by passing the analyzing light through the sample for only a few seconds to measure each of the data points shown. A slow decay of $tryp^+$, as represented by the absorbance at 330 nm, was observed and a somewhat faster decay of e_{ir}^- was measured at 2300 nm. The growth at 580 nm and 620 nm could be due

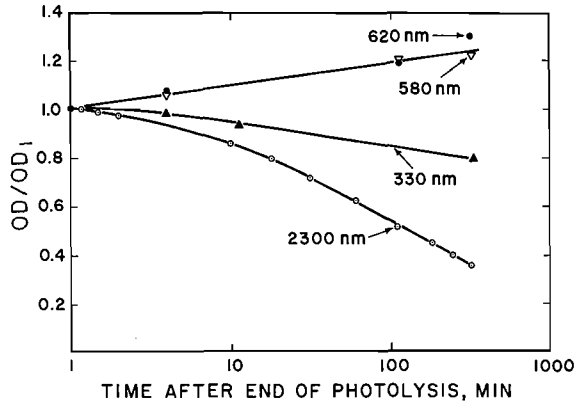

FIG. 2. The isothermal changes in absorbance with time at several wavelengths after a 5 min uv photolysis at 2 K of a glass prepared from an argon bubbled solution of 9.5 *M* $LiCl/D_2O$ containing 5×10^{-4} *M* tryptophan. OD_1 is the absorbance 1 min after photolysis.

to the reaction $e_{ir}^- \rightarrow e_{vis}^-$ and/or a spectral shift in the e_{vis}^- band. The actual growth of e_{vis}^- would be greater than the apparent growth measured at 580 and 620 nm because the absorbance changes contain both the growth of e_{vis}^- and the decay of $tryp^+$. A balance between loss of trapped electrons and $tryp^+$ cannot be made without postulating some production of $tryp^-$.

Pulse Radiolysis of 9.5 M *LiCl at 6–90 K*

The optical absorption spectra in 9.5 *M* LiCl measured at 100 ns at 6 K and 73 K are shown in Fig. 3. The ir band with $\lambda_{max} > 2400$ nm is due to e_{ir}^-, the band with $\lambda_{max} = 625$ nm to e_{vis}^-, and the band with $\lambda_{max} = 340$ nm is probably due mostly to Cl_2^-. Assuming no changes in extinction coefficients with change in temperature, the result of lowering the temperature from 73 K to 6 K is, roughly speaking, to double $G(e_{ir}^-)$ and to halve $G(e_{vis}^-)$ and $G(Cl_2^-)$. The ir band and the 625 nm band were analytically separated from one another as described in ref. 2 into a Lorentzian form for the ir band and a Gaussian form for the 625 nm band at $\lambda > 625$ nm.

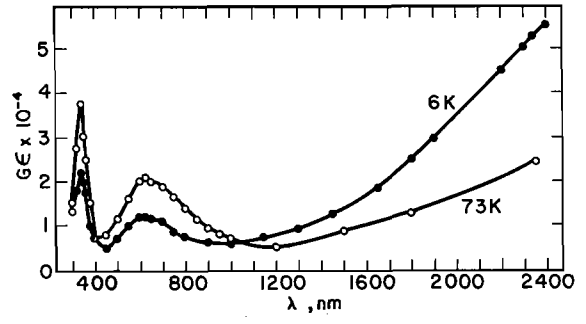

FIG. 3. Optical absorption spectra in 9.5 *M* $LiCl/D_2O$ at 6 K and 73 K measured 100 ns after the start of a 40 ns pulse.

When separated in this fashion both the e_{vis}^- and e_{ir}^- bands at 100 ns were found to have about the same shape at 6 K as at 73 K. Despite this similarity we shall show later that the visible band is probably composed of two bands (at least) which have different temperature dependent characteristics. One of the bands appears to be a relatively minor component in 9.5 *M* LiCl so we shall first discuss the results in terms of a unique visible band.

Although the absorption bands of e_{ir}^- and e_{vis}^- at 100 ns have similar shapes at 73 K and 6 K, the temporal stabilities of these two species are reversed. The decay of e_{vis}^-, represented by its absorbance at 650 nm, and of e_{ir}^-, represented by its absorbance at 2300 nm, are plotted in Fig. 4 for temperatures between 6 K and 90 K. Interference filters prevented bleaching of the trapped electrons by the analyzing light. As the temperature is lowered e_{ir}^- decays more slowly and its yield is greater. The reverse holds true for e_{vis}^- except that it decays faster at 90 K than at 75 K. In one experiment at 6 K we observed a small initial increase of 8% in the absorbance at 2300 nm. We were never able to reproduce this growth.

A detailed study of the decay of the e_{vis}^- band at 6 K and 73 K is shown in Fig. 5. The time intervals for the two temperatures are quite different, being 100 ns to 1 μs at 6 K, and 100 ns to 500 μs at 73 K. The ordinate represents the percentage of the absorbance lost over the appropriate time interval after corrections for the blank and e_{ir}^-. The decay at 73 K takes place mostly at $\lambda > \lambda_{max}$ whereas the

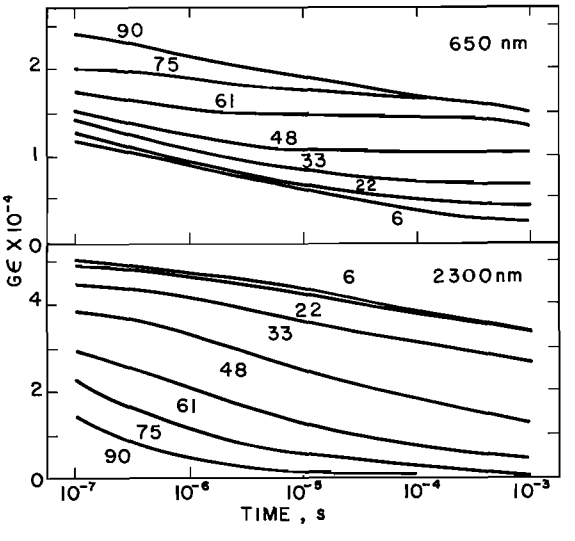

FIG. 4. Decay of e_{vis}^- (measured at 650 nm) and decay of e_{ir}^- (measured at 2300 nm) in the temperature range 6 K to 90 K. Temperatures are indicated beside each curve. No correction has been made for absorbance due to e_{ir}^- at 650 nm.

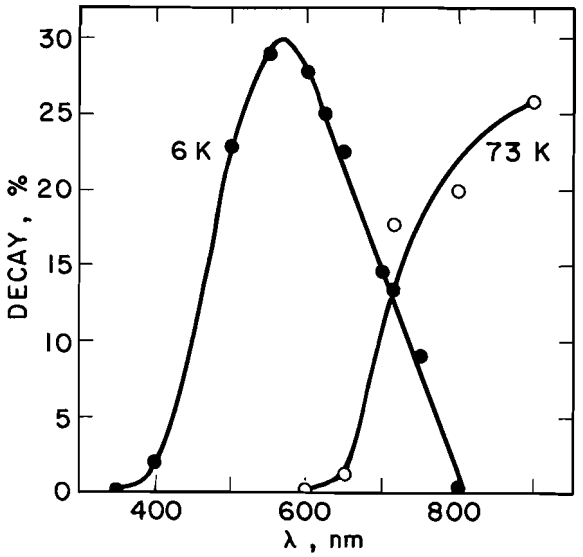

FIG. 5. Decay of the absorption band of e_{vis}^- as a function of wavelength. At 6 K the decay plotted occurred between 100 ns and 1 μs after the start of a 40 ns pulse. At 73 K the decay plotted occurred between 100 ns and 500 μs. A correction has been applied at each wavelength for the contribution of e_{ir}^-.

fractional decay at 6 K is peaked near λ_{max}. These fractional decay patterns mean that at 73 K the first spectral change in the e_{vis}^- band is a loss of intensity at $\lambda > \lambda_{max}$, perhaps due to the decay of a separate absorption band on the red side of the spectrum as suggested for BeF_2/D_2O glasses (5). At 6 K the decay observed causes the absorption band to become broader with little change in λ_{max}.

We shall consider several possible explanations for the increase in the decay rate of e_{vis}^- with decrease in temperature. One possibility is that e_{vis}^- is, on average, trapped closer to reactive species at 6 K than at 73 K. However, there is evidence in hydrocarbon glasses that the initial distributions of e_t^- are similar at 6 K and 77 K (10). Moreover, this possibility seems inconsistent with the slower decay of e_{ir}^- with decrease in temperature. Another possibility is that a reactive species such as D_3O^+, which seems to react more rapidly with e_{vis}^- than with e_{ir}^- (2), is more mobile at 6 K than at 73 K. This possibility does not explain why the absorption band decays preferentially in the vicinity of λ_{max}. Nor is it explained by the hypothesis that direct tunnelling of e_{vis}^- to reactant is faster at 6 K than at 73 K because of shallower, less relaxed, traps at 6 K. The explanation which we prefer is that e_{vis}^- at 6 K, 100 ns, exists in unrelaxed traps and that the visible absorption band is the composite of many bands representing the depth distribution of the naturally occurring traps. Apparently e_{vis}^- in the most abundant traps has λ_{max} = 625 nm (Fig. 3) and it is in the same wavelength region that decay occurs most rapidly (Fig. 5). Being in unrelaxed traps, e_{vis}^- is able to tunnel relatively freely from an occupied trap to an unoccupied trap of the same depth. The frequency of tunnelling will be greater for those e_{vis}^- absorbing near λ_{max} because they represent the most abundant traps. Increasing the movement of e_{vis}^- increases the rate at which it will disappear by reaction with a reactive species. Direct tunnelling of trapped electrons in glasses has been discussed by Miller (17). Buxton and Kemsley (14) have suggested that trap-to-trap tunnelling occurs in $LiCl/H_2O$ at low temperatures. Rice and Pilling (18) have discussed the effect of trap relaxation on trap-to-trap tunnelling. We suggest that trap relaxation for at least the first millisecond at 6 K is small enough to permit e_{vis}^- to tunnel from trap-to-trap.

Looking at Fig. 4 we can see a decrease in the 650 nm decay rate, the timing of which depends on the temperature. At 6 K we do not see any flattening of the curve, at 22 K it occurs at ~200 μs, at 33 K at ~100 μs, at 48 K at ~10 μs, at 61 K at ~2 μs, and at 75 K it presumably occurs before 100 ns. In fact, at 73 K a small sharp decay of ~3% is observed at $\lambda < \lambda_{max}$ over the period 100–200 ns. This may represent partly a flattening of the decay curve of e_{vis}^- and partly the decay of e_{ir}^- which probably makes a small contribution to the absorbance at 650 nm. We suggest that the time at which the decay curves flatten is approximately the time required for trap relaxation to substantially reduce the rate of trap-to-trap tunnelling. According to this model the 100 ns value of $G(e_{vis}^-)$ increases with increasing temperature due to the increasing rate of trap relaxation. For the same reason $G(e_{vis}^-)$ is higher at 90 K than at 75 K. At the higher temperatures we propose that thermally activated decay of e_{vis}^- also occurs as evidenced by a sudden steepening of the decay curves in Fig. 4. This sets in at ~100 μs at 61 K, ~300 ns at 75 K, and before 100 ns at 90 K. At 90 K the glass is still well below the glass transition temperature of 145 K measured for 9.5 *M* $LiCl/H_2O$ (19).

The trends of decay rates and yields of e_{ir}^- are opposite to those for e_{vis}^-. We speculate that e_{ir}^- is in relaxed traps by 100 ns at 6 K. Increased decay before 100 ns would account for the smaller values of $G(e_{ir}^-)$ at higher temperatures. We propose that the increased decay rate at higher temperatures is due to thermally assisted tunnelling. Rice and Pilling (18) have stated that phonon-assisted trap-to-trap tunnelling might be a significant factor by 10^{-2} s at 150 K for a trap relaxation energy of less than 0.2 eV. A trap relaxation energy of less than 0.2 eV for e_{ir}^-

does not seem unreasonable based on a trap depth ≤ 0.5 eV as estimated from its stimulation spectrum (below). The reason why the e_{ir}^- trap relaxes so much faster than the e_{vis}^- trap may reflect the much different environments of the two traps. It is believed that e_{ir}^- is associated with amorphous water in the glass whereas e_{vis}^- is associated with D_2O bound to Li^+ (4). It is expected that molecular motion of the water molecules in the potential field of the Li^+ ion will require more energy than will motion of the water molecules making up the e_{ir}^- traps. This effect will be particularly noticeable at low temperatures.

If e_{ir}^- was in a relaxed state during all the observations carried out it is possible to estimate very roughly an activation energy for the thermally assisted decay. Bearing in mind that tunnelling is a likely transport mechanism and that tunnelling is strongly distance dependent and removes first the e_{ir}^- trapped closest to a reactant, any meaningful calculation of activation energies must apply to the same distance distribution at all temperatures. We assume, for purposes of calculation, that the initial yield of e_{ir}^- and the initial distance distribution of e_{ir}^- with respect to species with which it may react are independent of temperature. We further assume that the distance distribution will be the same for the same value of $G\varepsilon$ regardless of temperature. We have compared the decay rates measured at $G\varepsilon = 2.2 \times 10^4$ over a range of temperatures. This value of $G\varepsilon$ is reached at 100 ns at 75 K, at 600 ns at 61 K, at 20 μs at 48 K and, by extrapolation, at ~20 ms at 33 K. Between 22 K and 6 K there seems to be an activation energy of zero indicating that simple, temperature-independent, tunnelling may predominate at these temperatures. An Arhennius plot of the decay rates above 22 K measured at $G\varepsilon = 2.2 \times 10^4$ yields an activation energy of 0.3 kcal/mol (0.01 eV). An activation energy of ~0.04 eV was estimated for the temperature dependent decay rate of e_t^- between 60 K and 77 K in methylcyclohexane glass (20), another system in which infrared absorbing trapped electrons probably decay by tunnelling.

It is not known which species react with e_{vis}^- and e_{ir}^-. Likely candidates are D_2O^+, D_3O^+, OD, and Cl_2^-. These are produced in the following reactions:

$$D_2O \rightsquigarrow D_2O^+ + e^-$$
$$D_2O^+ + D_2O \rightarrow D_3O^+ + OD$$
$$D_2O^+ + Cl^- \rightarrow D_2O + Cl$$
$$OD + Cl^- \rightarrow OD^- + Cl$$
$$Cl + Cl^- \rightarrow Cl_2^-$$

$G(Cl_2^-)$ was calculated from the absorbance at 340 nm assuming that $\varepsilon_{max} = 8.8 \times 10^3\ M^{-1}\ cm^{-1}$ (21). Corrections were made for the contribution of e_{vis}^- at 340 nm assuming that its absorption band resembles that of e_{vis}^- in an ethylene glycol/D_2O glass (2). Values calculated for $G(Cl_2^-)$ at 100 ns are 3.4 at 73 K and 2.2 at 6 K. The value of 3.4 at 73 K is in disagreement with the value of 2.57 reported previously (4).[1] The reason for this discrepancy is not known and has not yet been examined in more detail. Cl_2^- does not seem to be an important reactant in the decay of trapped electrons. For example, the absorbance at 350 nm decayed by 4% from 100 ns to 1 ms at 73 K and remained constant from 100 ns to 1 μs at 6 K. Over the same time intervals considerable decay of trapped electrons occurred (Fig. 4). It is possible that the uv band is partly due to $ClOH^-$ which has $\varepsilon_{max} = 3.7 \times 10^3\ M^{-1}\ cm^{-1}$ at 350 nm in aqueous solution (21).

Values of $G(e_{vis}^-)$, $G(e_{ir}^-)$, and $G(Cl_2^-)$ at 100 ns are tabulated in Table 1.

Radiolysis of 12 M LiCl/D_2O

Pulse radiolysis measurements on 12 *M* LiCl at 6 K led to the 100 ns spectrum shown in Fig. 6. Values of $G(e_{vis}^-)$ and $G(e_{ir}^-)$ are given in Table 1. Below the 100 ns spectrum in Fig. 6, and on the same scale of $G\varepsilon$, is shown the amount by which $G\varepsilon$ decreased between 100 ns and 1 μs. For example, a decrease in $G\varepsilon$ of 21% was measured at 600 nm. At 600 nm and 715 nm filters were used to check that bleaching by the analyzing light did not contribute to the measured decay.

The pulse radiolysis results for 12 *M* LiCl and for 9.5 *M* LiCl are similar. In both glasses the 100 ns yield of e_{vis}^- is lower at 6 K than at 73 K while the

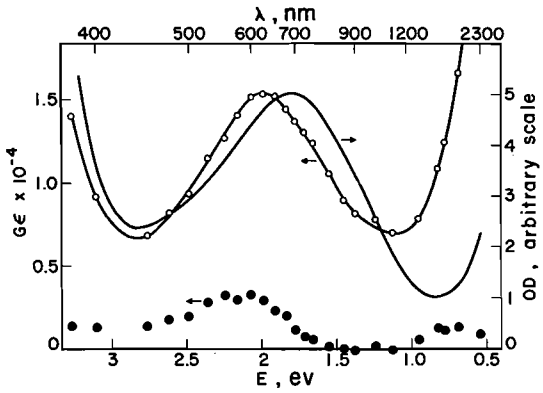

FIG. 6. Optical spectra and spectral changes in irradiated 12 *M* $LiCl/D_2O$ glass. ○ represents the absorption spectrum at 6 K measured 100 ns after the start of a 40 ns pulse. The loss (not the resultant absorption) observed to occur in this spectrum between 100 ns and 1 μs is shown by ●. The — line represents the absorption spectrum measured 50 min after irradiating a sample with 25 pulses, the sample being maintained constantly at 4–10 K.

yield of e_{ir}^- is larger. The spectral shapes of e_{vis} and e_{ir}^- are similar in both glasses. The initial decay at 6 K is faster in the visible than in the infrared. The decay was 16% at 650 nm between 100 ns and 1 μs in 12 *M* LiCl at 6 K compared to 23% in 9.5 *M* LiCl. This greater stability in 12 *M* LiCl, also evidenced by measurements to 1 ms, seems to be related to a stable underlying band in the visible at 6 K.

An experiment was carried out in which a 12 *M* LiCl sample was given 25 pulses in quick succession and kept in the dark during transfer to the Cary 17 spectrophotometer. The temperature was kept between 4–10 K at all times. The absorption spectrum was measured 50 min after irradiation and is shown in Fig. 6. A rough calculation was possible which indicated that the loss of absorbance between 100 ns and 50 min was nil in the uv, ~55% at 600 nm, ~35% at 715 nm, and ~90% at 2300 nm. At 600 nm and 715 nm these decays correspond roughly to that actually measured between 100 ns and 1 ms which leads us to believe that the decay in the visible band is largely complete by 1 ms. The stable band is similar to the 100 ns spectrum but is red shifted with $\lambda_{max} = 695$ nm. We have insufficient data to make more than a rough estimate but it seems that the stable band may represent ~40% of the visible band at 6 K, 100 ns. In 9.5 *M* LiCl this is reduced to perhaps 20% based on the decay at 650 nm over the first millisecond. After measuring the absorption spectrum for 12 *M* LiCl the sample was bleached by several exposures to 633 nm light from a 5 W He–Ne laser. The visible band appeared to bleach homogeneously. At the same time the infrared band increased presumably due to retrapping of photoionized e_{vis}^- as e_{ir}^-.

Information on the two bands making up e_{vis}^- is still very limited. Their broadness is consistent with their being trapped electrons. It is possible that the 695 nm band at 6 K may be related to the more rapid decay observed in 9.5 *M* LiCl at $\lambda > \lambda_{max}$ at 76 K, i.e., the 695 nm band may be less stable at 76 K than at 6 K in the same way that e_{ir}^- is. The 695 nm band may be similar to the "red wing" and/or "red band" in BeF_2/D_2O glasses (5). The "red wing" and "red band" have values of λ_{max} which seem to depend on the concentration of BeF_2 but which lie in the region 600 nm to 900 nm. They are believed to represent e_t^- and they form part of the larger "visible" band. The spectrum of e_{vis}^- in ethylene glycol/H_2O may also be composed of two bands. Higashimura *et al.* (22) have reported that λ_{max} for e_t^- at 77 K was 585 nm if the radiolysis was carried out at 77 K and 660 nm if carried out at 4 K.

Thus, it appears that e_{vis}^- in 12 *M* LiCl is composed mostly of the species which is predominant in 9.5 *M* LiCl but, in addition, there exists a significant fraction of another type of trapped electron. The relationship between these two components, if any exists, is not yet clear.

Stimulation Spectra of e_{vis}^- and e_{ir}^-

Stimulation spectra of e_{vis}^- and e_{ir}^- were measured in several aqueous glasses at 4 K and 77 K. The procedure followed was to photolyze a glassy sample containing 5×10^{-4} *M* tryp for 1 min with uv light from a low pressure Hg lamp. The light was first passed through a Corning 7-54 filter and a water filter to reduce bleaching of e_{ir}^- by infrared light. Photolysis ionized tryp producing $tryp^+$, e_{vis}^-, and e_{ir}^-. Beginning several minutes later, when isothermal luminescence from the sample had decreased sufficiently, the stimulation spectrum was determined by illuminating the sample with 0.3 s light pulses at wavelengths selected by a monochromator and measuring the intensity of the stimulated luminescence 0.2 s later with a photomultiplier and recording the oscilloscope trace photographically. The stimulating light came from a xenon arc, the pulse was produced with a mechanical shutter system and the timing of the sequence was exactly reproduced for each light pulse. At each wavelength the monochromator slits were set so that the same number of photons reached the sample. The correct slit widths were determined in a separate experiment with a radiation flux meter in the sample position. Each light pulse photoionized some of the trapped electrons absorbing at the wavelength used causing a very small fraction of the trapped electrons to decay by reaction with $tryp^+$. This reaction produced triplet tryptophan which phosphoresces largely in the visible (23). We measured a phosphorescence

lifetime of 6.5 ± 0.1 s in 9.5 *M* LiCl/5 × 10^{-4} *M* tryp at both 4 K and 77 K, in agreement with the reported lifetime of 6.6 s (23). This confirmed that we were measuring only the phosphorescence of triplet tryptophan when exciting at $\lambda > 500$ nm. For $\lambda < 500$ nm a small amount of more rapid decay was observed and corrections were made for this. A plot versus wavelength of the maximum phosphorescence intensity measured at each wavelength constitutes the stimulation spectrum. Barring significant changes in transmission of the stimulating light through the sample caused by absorption by the cell, the glassy matrix and the trapped species, the number of photons absorbed by trapped electrons was proportional to their absorbance at each wavelength. It was found that e_{ir}^- decayed noticeably during the measurement of a complete spectrum. A lesser decay occurred for e_{vis}^-. These decays were corrected for by measuring the spectrum several times and interpolating the results at each wavelength to construct a stimulation spectrum representing a single instant of time. This also avoids the possible problem of a change in the quantum yield of phosphorescence with change in the concentration of trapped electrons.

Stimulation spectra are akin to photobleaching spectra but instead of measuring the decrease in trapped electrons caused by photolysis one measures only the emission caused by those electrons which are photoreleased and react with $tryp^+$ to produce triplet tryptophan which phosphoresces. Absorption of light by $tryp^+$ does not result in phosphorescence. In this way we were able to study e_{vis}^- without interference from $tryp^+$ which absorbs in the same wavelength region.

For each sample a stimulation spectrum was measured on the unphotolyzed sample in order to correct for direct excitation of tryp molecules. This correction was only significant below 500 nm. The stimulation spectra and their decay characteristics were reproducible from experiment to experiment when using tubular cells but the absolute intensities were irreproducible, presumably due to variations in the output of the photolysis lamp. As usual, D_2O glasses were used to avoid the stronger near-ir absorption of light found in H_2O matrices.

(a) e_{ir}^- in LiCl Glasses

The open circles in Fig. 7 constitute the stimulation spectrum measured at 4 K for 9.5 *M* LiCl/5 × 10^{-4} *M* tryp contained in a 3 mm id tube. Beyond 1300 nm dips appear in the spectrum due to absorption of the stimulating light by the matrix. The decay of the stimulation spectrum was uniform between 1000 nm and 2300 nm indicating that, over this range at least, the decay of a single species, e_{ir}^-, was being observed. The decay rate was close to that measured by

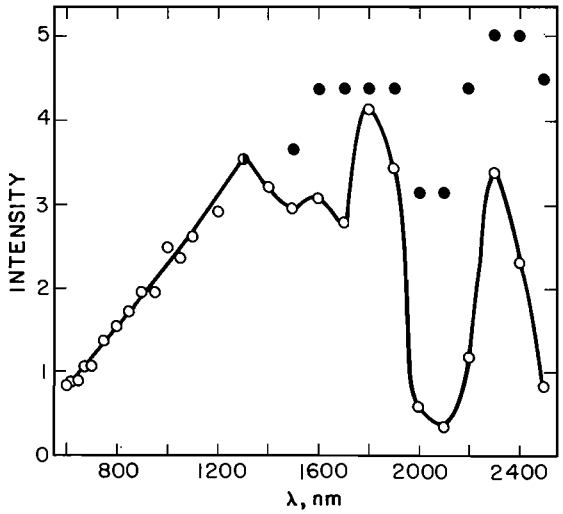

FIG. 7. Stimulation spectrum of e_{ir}^- at 4 K. ○ refers to the intensity (arbitrary units) measured in 9.5 *M* LiCl/D_2O/5 × 10^{-4} *M* tryp corrected to 30 min after the start of a 1 min photolysis. ● refers to 6 *M* LiCl/D_2O/5 × 10^{-4} *M* tryp in a 0.24 mm cell corrected to 10 min and normalized to agree with the open circles at 1300 nm.

absorption at 2300 nm at 2 K as shown in Fig. 2. Thus, those e_{ir}^- stimulated to react with $tryp^+$ and produce phosphorescence seem to represent the bulk of e_{ir}^- as measured by absorption. In other words, the stimulation method seems to sample adequately the total population of e_{ir}^-. The shape of the stimulation spectrum from 600 nm to 1300 nm, if corrected for the presence of e_{vis}^-, is very similar to the absorption spectrum of e_{ir}^-. The correction for e_{vis}^- could be made from kinetic measurements because e_{vis}^- was found to decay more slowly than e_{ir}^-. The relatively small yield of e_{vis}^- and its slower decay is consistent with the absorption measurements described above.

In order to reduce absorption of the stimulating light by the matrix we used a 0.24 mm sample of 9.5 *M* LiCl in a flat cell. The result was a stimulation spectrum with less pronounced dips but it did not prove to be an ideal sample because it always cracked badly and e_{ir}^- decayed much faster than in the cylindrical sample. The result was a spectrum dominated by e_{vis}^-. We obtained similar, but more reliable, results in the infrared with a 0.24 mm sample of 6 *M* LiCl. Gillis, Teather, and Buxton (4) have shown that the yield and stability of e_{ir}^- is increased on going from 9.5 *M* LiCl to 6 *M* LiCl at 76 K while the yield of e_{vis}^- is decreased. The stimulation spectrum in 6 *M* LiCl is shown in Fig. 7 as the closed circles which are normalized to the open circles at 1300 nm. Calculations indicate that, even in the thin sample, appreciable light absorption by the matrix took place at 2300 nm so we were still

unable to determine the true shape of the stimulation spectrum of e_{ir}^- at $\lambda > 1300$ nm. Thinner samples were not practical due to the smallness of the signal.

(b) e_{vis}^- in LiCl Glasses

The stimulation spectrum of e_{vis}^- at 4 K in 9.5 *M* LiCl, even when measured after many minutes in the 0.24 mm cell, was still difficult to disentangle from that of e_{ir}^-. However, similar and more reliable results which were obtained with a cylindrical sample of 12 *M* LiCl at 4 K are shown in Fig. 8. Gillis, Teather, and Buxton (4) have shown that, at 76 K, the yield of e_{vis}^- is increased and that of e_{ir}^- is decreased on going from 9.5 *M* LiCl to 12 *M* LiCl. Indeed, the 4 K stimulation spectrum in Fig. 8 does show a much smaller contribution of e_{ir}^- than the spectrum in Fig. 7. The λ_{max} of the stimulation spectrum at 4 K is 625 nm as compared to the absorption maximum of 695 nm at 4–10 K in Fig. 6.

The stimulation spectrum of e_{vis}^- in 9.5 *M* LiCl was also measured at 77 K. Once again, a similar but more reliable spectrum was measured in 12 *M* LiCl. This spectrum is shown, as corrected to 20 min, in Fig. 8 as open circles. This spectrum is very similar to the photoconductivity spectrum reported by Rice and Kevan (24) for 10 *M* $LiCl/H_2O$ glass at 85 K. The long term absorption spectrum at 77 K in 12 *M* $LiCl/D_2O$ has not been measured so we must compare the stimulation spectrum in Fig. 8 with its $\lambda_{max} \sim 475$ nm to the absorption spectrum in 9.5 *M* $LiCl/H_2O$ which has $\lambda_{max} = 590$ nm (14).

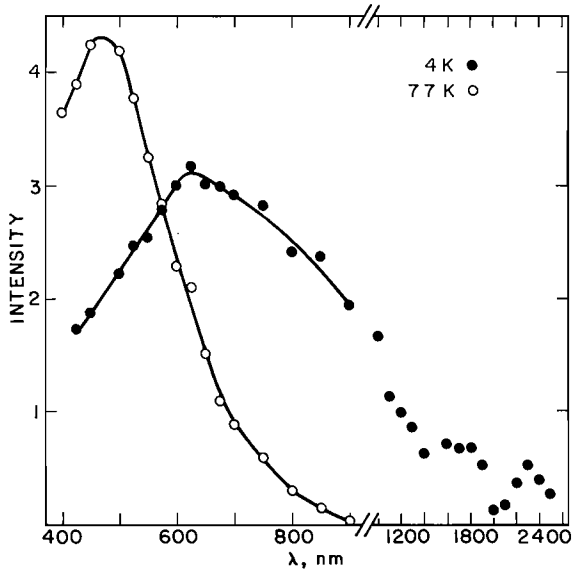

FIG. 8. Stimulation spectra in 12 *M* $LiCl/D_2O/5 \times 10^{-4}$ *M* tryp corrected to 20 min after the start of a 1 min photolysis. ● were measured at 4 K and ○ were measured at 77 K. The intensity units for each curve are arbitrary and independent of one another.

The intensity units in Fig. 8 are arbitrary and independent for each curve. The decrease in intensity on going from 450 nm to 400 nm at 77 K is believed to be real but this region of the spectrum is complicated since at $\lambda \leq 600$ nm the measured stimulation intensity grew slightly for the first 20 min and then decayed. At $\lambda > 600$ nm only decay was observed. The reason for this behaviour is not known but it might be associated with the shift in the absorption spectrum which sees λ_{max} change from a value of 625 nm at 100 ns to a long term value of 590 nm (14). A growth in the visible region, measured by absorption, has already been noted (see Fig. 2). Since e_{ir}^- decays rapidly at 77 K it is not surprising that the stimulation spectrum was zero above 1000 nm.

(c) Trap Depths and Relaxation Energies

The spectrum of the quantum yield for photoionization of e_{vis}^- in 12 *M* LiCl at 77 K can be obtained by dividing the stimulation intensity by the optical absorption. Assuming an absorption spectrum similar to that of 9.5 *M* LiCl (14), the result is a low quantum efficiency for photoionization at $\lambda > \lambda_{max}$ followed by a sharp rise from ~ 600 nm to ~ 500 nm and a broad maximum at ~ 450 nm. A similar sharp rise, setting in at λ_{max}, in the quantum efficiency of photoconductivity in 10 *M* $LiCl/H_2O$ at 85 K (24) was interpreted to mean that the optical absorption is due to bound–bound transitions above λ_{max} and to bound–free (continuum) transitions below λ_{max}.

Thus, the long term absorption band of e_{vis}^- at 77 K seems to be made up of a bound–bound transition from which photoionization is inefficient and a bound–free transition represented by the stimulation band, similar to an analysis of the e_{vis}^- band in EG/D_2O shown in ref. 2. We shall assume that these two transitions belong to the same trapped electrons. Thus, the maximum of the absorption band of e_{vis}^- at 77 K (590 nm, 2.1 eV) (14) represents the energy of the transition from the ground state to the first excited state for the most abundant trap depth. The energy of the transition from the ground state to the continuum for the most abundant trap depth is the maximum of the stimulation spectrum (475 nm, 2.6 eV). This places the first excited state 0.5 eV below the continuum. We are neglecting more refined details such as autoionization, tunnelling from a bound excited state to the continuum, and changes in λ_{max} due solely to temperature changes. Similarly, we can separate the absorption spectrum measured at 50 min, 4–10 K (Fig. 6) into a bound–bound transition with $\lambda_{max} = 695$ nm (1.8 eV) and, from its stimulation spectrum, a bound–free transition with $\lambda_{max} = 625$ nm (2.0 eV).

If we knew the energy of the bound–free transition of the unrelaxed e_{vis}^- precursor to the 77 K relaxed state we could calculate the relaxation energy. We are inclined to believe that the unrelaxed state in question is represented by the rapidly decaying component at 6 K in Fig. 5 for which the rapid decay prevents a determination of the stimulation spectrum. However, it is unlikely that the bound–free transition would correspond to an energy less than the λ_{max} of the absorption spectrum at 100 ns which is 625 nm (2.0 eV) at both 73 and 6 K. Hence we estimate that the relaxation energy of the major component of the e_{vis}^- band is ≤ 0.6 eV.

The composite picture of e_{vis}^- in $LiCl/D_2O$ glasses presented by the various techniques employed here is that the predominant species is in an unrelaxed trap at 6 K, 100 ns but in a partially relaxed trap at 77 K, 100 ns. Another band is present, at least in 12 *M* LiCl. The characteristics of this second band are ill-defined at present. We do not know whether decay of the second band at 77 K contributes to the shift of λ_{max} from 625 nm to 590 nm at long times. Both bands, under the conditions in which their stimulation spectra can be measured, show both bound–bound and bound–free transitions. The relaxation energy of the predominant species at 77 K is ≤ 0.6 eV. We recognize that we have postulated $\lambda_{max} = 625$ nm for both non-relaxed e_{vis}^- at 6 K, 100 ns and for partially relaxed e_{vis}^- at 73 K, 100 ns. Since it is not known whether the transitions at 100 ns are bound–bound or bound–free and since the maximum spectral shift on complete relaxation at 77 K is only from 625 nm to 590 nm we do not feel that any conclusions can be drawn from the similarity of λ_{max} at 6 K and 77 K at 100 ns.

We believe that the present evidence, while not conclusive, is incompatible with the idea that the energies of the ground state levels of e_{vis}^- and e_{ir}^- could be very similar. This idea was recently commented on with regard to possible tunnelling from e_{vis}^- to e_{ir}^- (4). Briefly stated, we conclude that the ground state for e_{vis}^- in relaxed traps at 77 K is 2.6 eV below the continuum. The maximum of the stimulation spectrum of e_{ir}^- could not be reliably determined because of matrix absorption but an upper energy limit is 0.5 eV (2400 nm) based on Fig. 7. The higher energy portion of the stimulation band is presumably due to transitions from the ground state to higher levels in the continuum and/or a range of trap depths. If we neglect changes in energy levels due solely to temperature changes we place the ground state of e_{ir}^- at 77 K at ~ 0.5 eV, far from the 2.6 eV level of the ground state in e_{vis}^- but, interestingly, close to the level of the first bound excited state in e_{vis}^-. A much deeper trap depth for e_{vis}^- than for e_{ir}^- has also been deduced by Rice, Dolivo, and Kevan (25).

(d) Temperature Dependent Tunnelling of e_{ir}^-

The decrease in the stimulation spectrum between 10 min and 50 min after the start of a 1 min photolysis was measured at 1800 nm at several temperatures. The percent decay was found to be relatively independent of temperature but the intensity at 10 min was clearly smaller the higher the temperature. The decay was 30% at 4 K, 28% at 20 K, 35% at 32 K, and $35(\pm 5)\%$ at 46 K. It must not be construed from this temperature independent decay that the tunnelling rate constant is temperature independent. To be valid, a comparison of tunnelling rate constants at different temperatures is best made for identical e_t^--reactant distance distributions and identical e_t^- trap depth distributions. If we assume that the initial yield and distance distribution of e_{ir}^- is independent of temperature between 4 K and 77 K, as seems to be the case for glassy hydrocarbons (10), we conclude that the higher the temperature the smaller the fraction of the original e_{ir}^- left at 10 min. Given the strong distance dependence of tunnelling, this implies that the higher the temperature, the greater is the average e_{ir}^--reactant distance at 10 min. We conclude, once again, that the tunnelling rate constant between 4 K and 46 K is temperature dependent. Phonon-assisted tunnelling of e_{ir}^- has already been mentioned.

(e) Ethylene Glycol Glass

We measured the stimulation spectra in EG/D_2O (50/50 by volume) glasses containing 5×10^{-4} *M* tryp. The EG was protiated, not deuterated. The spectra at 4 K and 77 K are shown in Fig. 9. They provide little information about e_{ir}^-. The low intensity above 1800 nm is due to a low concentration of e_{ir}^- and/or matrix absorption of the stimulating light. The stimulation spectrum of e_{vis}^- at 4 K seems to be shifted to slightly shorter wavelengths as compared to the absorption spectrum of e_{vis}^- at 4 K (26) bearing in mind the difficulty in separating the e_{vis}^- and e_{ir}^- contributions in both cases. This suggests that a considerable fraction of the absorption band is due to a bound–free transition. The stimulation spectrum of e_{vis}^- at 77 K is also shown in Fig. 9 and is consistent with the reported photoconductivity spectrum (24). From it and the absorption spectrum at 77 K (27) we calculate a relative quantum efficiency curve the same as that reported by Moan (28) for photobleaching of e_{vis}^- in EG/H_2O/tryp glass at 77 K.

(f) NaOD Glass

A cursory examination was made of the stimulation spectrum of 10 *M* $NaOD/D_2O/5 \times 10^{-4}$ *M*

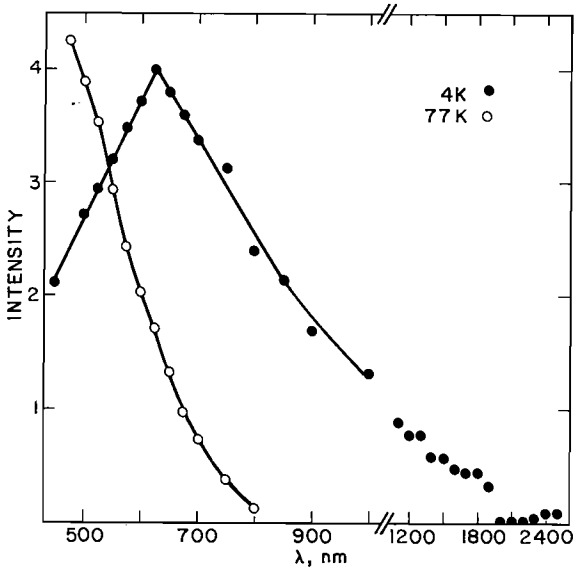

FIG. 9. Stimulation spectra measured in EG/D_2O glasses (50/50 by volume) containing 5×10^{-4} *M* tryp. ● were measured at 4 K, 25 min after the start of a 1 min photolysis. ○ were measured at 77 K, 30 min after the start of a 1 min photolysis. The intensity units for each curve are arbitrary and independent of each other.

tryp. The results at 4 K and 77 K are shown in Fig. 10. The luminescence decay in this glass was not the simple phosphorescence of triplet tryptophan. Two decays, one with lifetime ~1.4 s and another with lifetime ~4.8 s seemed to be present. In Fig. 10 we have plotted the maximum value of the total measured stimulated emission. The intensities measured in 10 *M* NaOD were weak and the measurements less reliable than in the EG and LiCl glasses but they are sufficiently interesting to warrant inclusion in this report because they demonstrate a case in which the stimulation spectrum and the absorption spectrum at 77 K (26) are very similar, indicating a bound–free transition. This conclusion has already been drawn from the similarity of the wavelength dependence of photo-current in irradiated 10 *M* NaOH to the absorption spectrum (24). The apparent differences between the stimulation spectra at 4 K and 77 K are not considered to be outside experimental error.

An indication that the absorption spectrum in 10 *M* NaOD is not due solely to one transition comes from preliminary results at both 4 K and 77 K which indicate that photobleaching with light at $\lambda > \lambda_{max}$ caused more bleaching at λ than at wavelengths $< \lambda_{max}$. This suggests that the absorption spectrum is due to at least two trap depths, one of which is more easily bleached than the other as reported for BeF_2/D_2O glasses at 76 K (5).

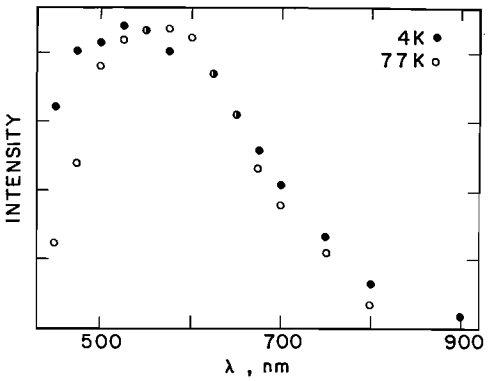

FIG. 10. Stimulation spectra measured in 10 *M* NaOD/D_2O/5×10^{-4} *M* tryp. ● were measured at 4 K between 10 and 20 min after the start of a 1 min photolysis. ○ were measured at 77 K between 20 and 30 min after the start of a 1 min photolysis. The intensity units for each curve are arbitrary and are independent of each other.

Summary of e_{ir}^- and e_{vis}^- in LiCl Glass

(a) e_{ir}^-

1. The production of the infrared band by photoionization of tryptophan further substantiates its assignment to a trapped electron, e_{ir}^-.

2. The spectrum of e_{ir}^- in LiCl/D_2O seems to be essentially the same as in EG/D_2O even to the value of its extinction coefficient ($\varepsilon_{2500} = 3.1\ (\pm 0.5) \times 10^4\ M^{-1}\ cm^{-1}$).

3. The ground state of e_{ir}^- is ≤ 0.5 eV below the continuum while the calculated value of λ_{max} is 3600 nm (0.34 eV).

4. The e_{ir}^- trap seems to be substantially relaxed by 100 ns even at 6 K.

5. The decay of e_{ir}^- is temperature independent between 6 K and 22 K and presumably occurs by tunnelling. Above 22 K the decay is temperature dependent, possibly involving phonon-assisted trap-to-trap tunnelling given the strong possibility that the relaxation energy of e_{ir}^- is small.

(b) e_{vis}^-

1. The spectrum of e_{vis}^- is probably composed of at least two distinct bands.

2. The predominant band in 9.5 *M* LiCl and 12 *M* LiCl decays faster at 6 K than at 75 K probably because it relaxes more slowly at 6 K, allowing trap-to-trap tunnelling to occur.

3. The predominant band at long times at 77 K has a bound–bound transition with maximum intensity at 2.1 eV and a bound–free transition with maximum at 2.6 eV. The relaxation energy is believed to be ≤ 0.6 eV.

4. The second band of e_{vis}^- is more prominent in 12 *M* than in 9.5 *M* LiCl. It has been isolated at 6 K where it is much more stable than the predominant

band, probably due to faster relaxation. It has a bound–bound transition maximum at 1.8 eV and a bound–free maximum at 2.0 eV.

Acknowledgements

We wish to thank J. Rolfe for the generous loan of the Cary 17 spectrophotometer and the cryostat used with it and to thank M. Buchanan for her invaluable assistance with this apparatus. We wish also to gratefully acknowledge many interesting discussions with J. Menigaux and C. Lapersonne-Meyer. The extent of the pulse radiolysis data was only made possible by the very generous assistance of C. Ross with the computer-related data collection and processing.

Electron spin resonance study of radical adducts of unsaturated dicarboxylic and tricarboxylic acids

BABATUNDE B. ADELEKE[1] AND JOSHUA A. FANIRAN
Department of Chemistry, University of Ibadan, Ibadan, Nigeria

Received October 16, 1978

BABATUNDE B. ADELEKE and JOSHUA A. FANIRAN. Can. J. Chem. 57, 1500 (1979).

An esr study of the addition reactions of $^{\bullet}OH$, $CO_2^{-\bullet}$, $SO_3^{-\bullet}$, and $^{\bullet}PO_3^{2-}$ radicals to the anions of aconitic, itaconic, and chelidonic acids is reported. There was an electron transfer reaction between $CO_2^{-\bullet}$ and chelidonic acid anion. The phosphite radical reacted with chelidonic acid to produce two types of radicals resulting from addition to C=C and the oxygen of the carbonyl group in the acid. The radical adducts of the anions of aconitic and itaconic acids exhibited extensive linebroadenings due to hindered internal rotations. The barrier to internal rotations is shown to be the repulsive forces between the negative charges on the various substituents.

BABATUNDE B. ADELEKE et JOSHUA A. FANIRAN. Can. J. Chem. 57, 1500 (1979).

On rapporte une étude rpe des réactions d'addition des radicaux $^{\bullet}OH$, $CO_2^{-\bullet}$, $SO_3^{-\bullet}$, et $^{\bullet}PO_3^{2-}$ aux anions des acides aconitique, itaconique et chélidonique. Il se produit une réaction de transfert d'électron entre le $CO_2^{-\bullet}$ et l'anion de l'acide chélidonique. Le radical phosphite réagit avec l'acide chélidonique pour conduire à deux types de radicaux provenant d'additions au niveau du C=C et de l'oxygène du groupe carbonyle de l'acide. Les adduits radicalaires des anions des acides aconitique et itaconique présentent des élargissements de raie qui sont importants et qui proviennent d'empêchement aux rotations internes. On a montré que la barrière aux rotations internes est due aux forces répulsives entre les charges négatives sur les divers substituants.

[Traduit par le journal]

Introduction

Many transient organic free radicals have been generated in aqueous flow medium for esr study by the reactions of $^{\bullet}OH$ with reactive organic substances (1–4). The hydroxyl radical is usually produced in a flow system by the reaction of Ti(III) with hydrogen peroxide. Norman *et al.* and others have extensively used this method to generate various types of radicals for esr studies (2, 5–7). Among the many systems studied by Norman and co-workers is radical addition to maleic acid (6, 7).

Chawla and Fessenden used the fumarate ion as a spin trap for a number of radicals including $SO_4^{\bullet-}$, $^{\bullet}NH_2$, and $^{\bullet}PO_4^{2-}$ radicals (8), while Neta produced radicals for esr studies by the reaction of fumarate ions with e_{aq}, $H^{\bullet}$, $^{\bullet}OH$, carboxyl radicals, and a series of alkyl radicals (8). More recently Steeken and Lyda have used fumarate and maleate ions as spin traps for acyl radicals (8). Fessenden and Neta studied the reactions of hydrated electrons with some unsaturated dicarboxylic acids including chelidonic acid (10) while Kirino and Fessenden have studied the addition of $^{\bullet}S^-$ and $^{\bullet}OH^-$ radicals to the anion of itaconic acid (10). Apart from maleic (4, 6–9) and fumaric (8) acids, few esr studies of radical addition to other unsaturated dicarboxylic and tricarboxylic acids have been reported.

In this article we report an esr study of addition reactions of $^{\bullet}OH$, $SO_3^{-\bullet}$, $CO_2^{-\bullet}$ and $^{\bullet}PO_3^{2-}$ radicals to the anions of aconitic, itaconic, and chelidonic acids. The radicals generated in alkaline medium were very persistent. This is presumably because of the high negative charges on the radicals. As a result of this high persistency, enough concentration of some radicals was obtained to observe, at natural abundance ratio, ^{13}C splittings.

Results and Discussion

Itaconic Acid

When $^{\bullet}OH$ radical was generated in the presence of itaconic acid, the observed esr spectrum depended on both the concentration of the acid and the pH of the medium. It was obvious that more than one radical type was present. A similar observation was made by Fischer *et al.* (1) in their esr study of hydrogen abstraction from succinic acid. They showed that rapid and reversible proton transfer reactions between the radicals and the acid molecules was responsible for the observation.

At a pH of 9.5 and itaconic acid concentration of 0.5 g/L, a spectrum attributable to radical **I** was observed. The *g*-value and splitting constants

TABLE 1. Radical structures and their esr parameters

Number	Radical structure	a_α^H (G)	a_β^H (G)	a^{others}	g
I	$CH_2(CO_2^-)\dot{C}(CO_2^-)CH_2OH$		21.45 (2H) 14.21 (2H)	$a_{OH}^H = 0.40$	2.0032
II	$(^-O_2CCH_2)_2\dot{C}CO_2^-$		14.02 (4H)	$a_\gamma^{13}C(2) = 17.94$ $a_\beta^{13}C(2) = 10.81$ $a_\beta^{13}C(1) = 12.42$	2.0032
III	$(HO_2CCH_2)_2\dot{C}CO_2H$		14.71 (4H)		2.0032
IV	$^-O_2CCH_2\dot{C}(CO_2^-)CH_2SO_3^-$		12.01*(2H) 13.92*(2H)	$a_\beta^{13}C(1) = 12.46$ $a_\beta^{13}C(1) = 11.66$ $a_\beta^{13}C(1) = 10.75$ $a_\gamma^{13}C(1) = 18.41$	2.0030
V	$^-O_2CCH_2\dot{C}(CO_2^-)CH_2PO_3^{2-}$		14.8*(2H) 12.1 (2H)	$a^P = 71.6$	2.0032
VI	$^-O_2CCH_2COH(CO_2^-)\dot{C}HCO_2^-$	20.06 (1H)		$a_\gamma^H = 0.54$ (1H) $a_{OH}^H = 0.22$	2.0032
VII	$^-O_2CCH_2\dot{C}(CO_2^-)CHOH(CO_2^-)$		12.31 (1H) 5.35 (1H) 0.84 (1H)		2.0032
VIII	$HO_2CCH_2\dot{C}(CO_2H)CHOH(CO_2H)$		14.77 (1H) 4.69 (1H) 1.39 (1H)		2.0032
IX	$^-O_2CCH_2\dot{C}(CO_2^-)CH(CO_2^-)_2$		13.80*(2H) 9.57 (1H)		2.0033
X			1.26 (2H)		2.0038
XI		9.6 (1H)		$a_\gamma^H = 1.8$ (1H) $a^P = 81.6$	2.0035
XII			5.8 (2H)	$a^P = 62.4$	2.0031

*The value given is one-half the observed line separation.

(Table 1) are in good agreement with the values reported by Kirino and Fessenden (10), however, they did not observe the —OH proton splitting constant. The lines corresponding to $M_I = 0$ of both triplets were broadened with respect to the other lines.

The inclusion of sodium formate in the system resulted in the observation of the spectrum shown in Fig. 1*a*. The spectrum conforms to that of four equivalent protons in which the lines corresponding to $M_I = \pm 1$ are broadened. The spectrum is assigned to radical **II**, Table 1. Laroff and Fessenden (11) obtained a spectrum similar to that of Fig. 1*a*, except that the $M_I = \pm 1$ lines were broadened beyond detection. They assigned the spectrum to radical **II**, which they obtained during the continuous in situ radiolysis of the anion of 1,2,3-propane tricarboxylic acid. Our values of both the proton and ^{13}C splitting constants are in good agreement with theirs. The broadened lines became sharper with increasing temperature, but at 50°C the expected 1:4:6:4:1 ratio was not attained. However, at pH of 3, the spectrum in Fig. 1*b* was obtained. The intensity ratio approximates closely to that expected from four equivalent protons. The spectrum is that of radical **III** in Table 1.

The spectrum recorded when the sulphite anion radical was generated in the presence of itaconate anion consisted of four lines of equal intensity and one broader and less intense line at $g = 2.0030$. This

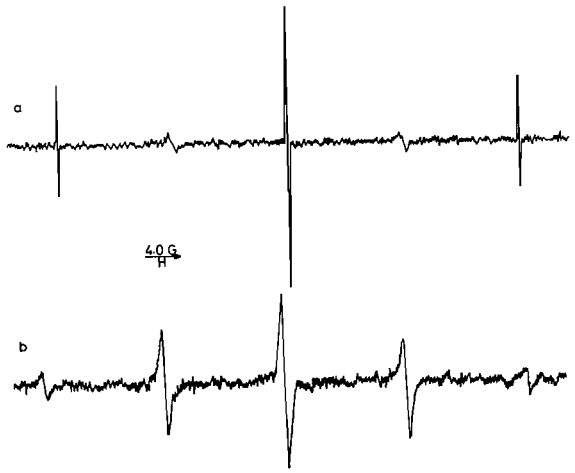

FIG. 1. Electron spin resonance spectrum of (*a*) $(^{-}O_2C\text{-}CH_2)_2\dot{C}CO_2^{-}$; (*b*) $(HO_2CCH_2)_2\dot{C}CO_2H$.

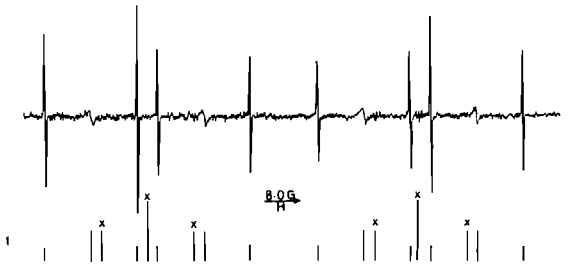

FIG. 2. Electron spin resonance spectrum and stick plot of $^{-}O_2CCH_2\dot{C}(CO_2^{-})CH_2PO_3^{2-}$. The asterisked lines are broadened beyond detection.

one line is due to the sulphite anion radical (6). The four lines spectrum is analysed in terms of a pair of two equivalent protons, in which the centre line of each triplet was broadened beyond detection. The parameters and the suggested structure of radical **IV** are shown in Table 1.

Figure 2 is the spectrum recorded for the adduct of $^{\bullet}PO_3^{2-}$ with itaconic acid at pH of 9.5. The large doublet is associated with phosphorus. Here again, the centre line of each triplet is broadened but the centre line of the triplet with larger splitting constant is broadened beyond detection. The spectrum is assigned to radical **V**.

From the values of a_β^H in $(^{-}O_2CCH_2)_2\dot{C}CO_2^{-}$, the hyperfine splitting constants which are much different from 14 G are assigned to the methylene protons of $—CH_2X$ in $^{-}O_2\dot{C}CH_2\dot{C}(CO_2^{-})CH_2X$ where X is OH, SO_3^{-}, or PO_3^{2-}. We note that the values of a_β^H in all the radicals reported above are less than the value expected for a freely rotating β methyl group (12).

Aconitic Acid

Three radicals **VI, VII,** and **VII**(*b*) can be identified from the reaction of $^{\bullet}OH$ with aconitic acid at pH of 9.8 (Fig. 3). The determined parameters and the structures of radicals **VI** and **VII** are recorded in Table 1.

Radical **VI** was generated previously during the photolysis of sodium citrate (13) and in situ radiolysis of the anion of 1,2,3-propane tricarboxylic acid (11). It is interesting to note that the two γ methylene protons of radical **VI** are non-equivalent. This agrees with the observation of Norman *et al.* that methylene protons which are adjacent to a chiral centre are magnetically non-equivalent (14).

Radical **VII** is the major $^{\bullet}OH$ adduct of the anion of aconitic acid (Fig. 3*a*). The smallest splitting did not decrease either in deuterium oxide or in the presence of a mineral acid. This suggests that all the splitting constants in this radical can be assigned to the three β-protons of the radical. It is not clear why the methylene protons of the $—CH_2CO_2^{-}$ group in this radical unlike in the OH adduct of itaconate are not equivalent. It is observed that the two outermost lines are broadened compared to the inner lines.

We are unable to suggest a structure for radical **VII**(*b*) which has a large doublet of 34.74 G and a smaller doublet of 1.01 G.

At pH of 2, radical **VIII** and the unknown radical with $a^H = 38.35$ G were observed (Fig. 3*b*).

The spectrum observed when carbon dioxide

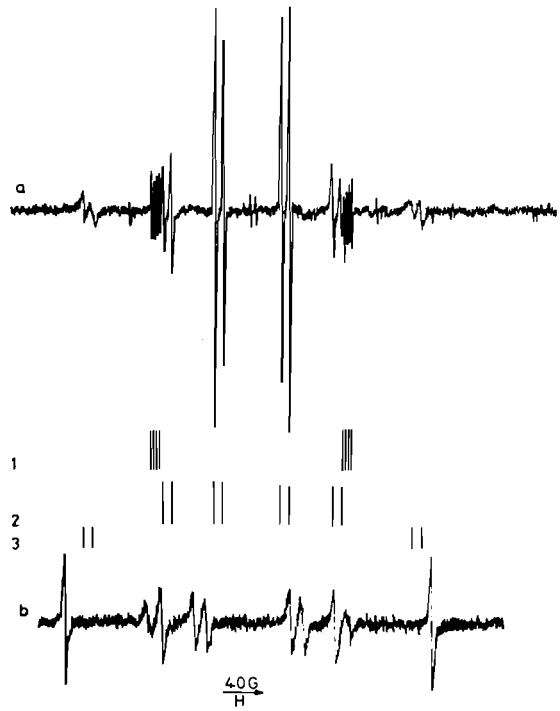

FIG. 3. Electron spin resonance spectrum of $^{\bullet}OH$ adduct of aconitic acid at (*a*) pH of 9.8; (*b*) pH of 2.0. (*1*) Stick plot for $^{-}O_2CCH_2COH(CO_2^{-})\dot{C}HCO_2^{-}$; (*2*) stick plot for $^{-}O_2CCH_2\text{-}\dot{C}(CO_2^{-})CHOH(CO_2^{-})$; (*3*) stick plot for radical **VII**(*b*).

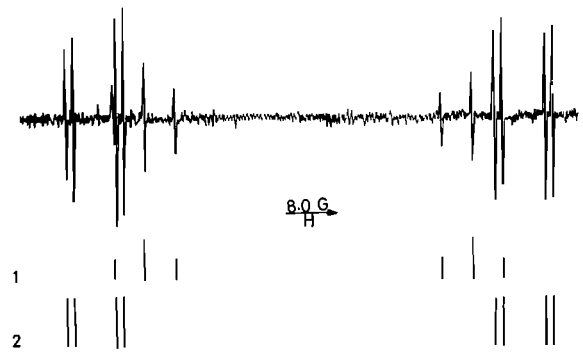

FIG. 4. Electron spin resonance spectrum of $\cdot PO_3^{2-}$ adducts of chelidonic acid in alkaline medium; (*1*) stick plot for radical **XII**; (*2*) stick plot for radical **XI**.

radical anion reacted with the anion of aconitic acid consisted of four lines. The parameters and the suggested structure for radical **IX** are given in Table 1.

The sulphite radical anion was generated in the presence of aconitic acid anion. No other esr spectrum was observed besides those of the sulphite radical anion and radical **VII**. Apparently $SO_3^{\cdot -}$ did not add to aconitic acid. A similar observation was made by Norman and Storey (6).

The spectrum obtained when $\cdot PO_3^{2-}$ reacted with aconitic acid could not be unambiguously analysed, though the large doublet characteristic of phosphorus was obvious.

Chelidonic Acid

No esr spectrum was observed when either ·OH or $SO_3^{-\cdot}$ was generated in the presence of the anion of chelidonic acid.

A three line spectrum with intensity ratio of 1:2:1 was obtained by the reaction of $CO_2^{-\cdot}$ with chelidonic acid. The radical is identified as **X** in Table 1.

Neta and Fessenden (10) produced radical **X** by the addition of hydrated electrons to the anion of chelidonic acid. Our values of a_β^H and g are in good agreement with theirs. In the present study radical **X** must have been produced by an electron transfer from $CO_2^{-\cdot}$ to the acid. The carbon dioxide radical anion has been shown to be an effective one-electron reducing agent for carbonyl-containing compounds (18).

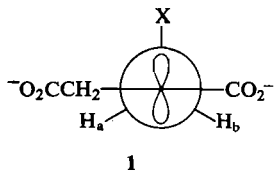
Two radicals (Fig. 4) identified as **XI** and **XII** were produced by the addition of $\cdot PO_3^{2-}$ to chelidonic acid at pH of 9.5.

Structure **XI** is suggested by the observation of the hyperfine constant of the γ-proton. The appearance of a 1:2:1 triplet in the spectrum of radical **XII** suggests that the radical possesses a C_2 axis and the structure of the radical must be similar to that of radical **X**. The value of ^{31}P splitting constant in radical **XII** appears to be large compared with a^P of straight chain aliphatic radicals (15), which possess similar $\cdot COPO_3^{2-}$ structure. The relatively large value of a^P in radical **XII** indicates the existence of hyperconjugation interaction between the unpaired electron and the phosphorus atom. Such hyperconjugation interaction has been used to explain the increase in the splitting due to the ^{31}P nucleus from 1.3 G in the *p*-benzosemiquinone-1-phosphate radical to 20 G in 2,3,5,6-tetrachloro-1,4-benzosemiquinone-1-phosphate radical (16). Phosphorus splitting constants of 57.79 G, 56.58 G, and 46.6 G have been observed by Ingold *et al.* in radicals possessing the $\cdot CN[(EtO)_2PO]$ structure (17). In the two instances cited above steric hindrance forces the P—O and P—N bonds into a plane in which the phosphorus atom is optimally positioned for hyperconjugation interaction with the unpaired electron. In the present study the repulsive forces between PO_3^{2-} and the two CO_3^{2-} groups in radical **XII** might serve the same purpose as the steric hindrance in the substituted benzosemiquinone 1-phosphate (16) and the substituted α-aminoalkyl radicals (17). Previously we have observed the addition of diphenyl phosphino radical to the carbonyl oxygen of 2,6-di-*tert*-butyl-*p*-benzoquinone (18).

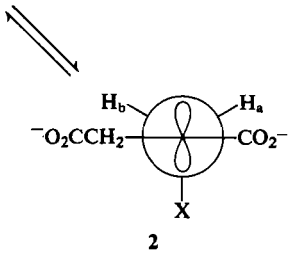
Generally the dependence of a_β^H upon the dihedral angle θ, between the β-C—H bond and the *p*-orbital containing the unpaired electron is given by

$$a_\beta^H = A + B\cos^2\theta$$

where A and B are constants. The minimum value (13–15 G) of a_β^H occurs when the radical is fixed in a conformation with $\theta = 60°$ (12, 19). Thus the values of a_β^H for the $SO_3^{-\cdot}$, $CO_2^{-\cdot}$, and $\cdot PO_3^{2-}$ radical adducts of itaconate and $CO_2^{-\cdot}$ radical adduct of aconitic acid suggest that the radicals exist in the preferred conformation **1** or **2**.



1



2

This is supported by the increase of a_β^H with increasing temperature (Table 2).

It is noteworthy to observe that the values of 12 G for a_β^H when X is SO_3^- or PO_3^{2-} are less than the

TABLE 2. Variation of a_β^H with temperature

(*a*) $^-O_2CCH_2\dot{C}(CO_2^-)CH(CO_2^-)_2$

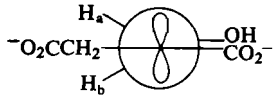
Temperature (°C)	a_β^H $CH_2CO_2^-$	a_β^H $CH(CO_2^-)_2$
24	13.90	9.58
43	14.04	9.77

(*b*) $^-O_2CCH_2\dot{C}(CO_2^-)CH_2SO_3^-$

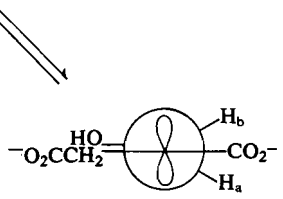
Temperature (°C)	a_β^H $CH_2CO_2^-$	a_β^H $CH_2SO_3^-$
13	13.88	11.96
36	13.97	12.04
44	14.02	12.06

predicted minimum. Similar observation was made in the study of β-mercapto alkyl radicals (12). The unusually low values of a_β^H were explained by a model in which the β-sulfur atom is displaced from its tetrahedral position toward the *p*-orbital. Possibly the same type of distortion might be responsible for the very low values of a_β^H of $-CH_2PO_3^{2-}$ and $-CH_2SO_3^-$ methylene protons.

The value (21.45 G) of a_β^H of the $-CH_2OH$ methylene protons in radical **I** and its decrease with increasing temperature suggest that the $-CH_2OH$ group assumes conformation **3** or **4** in the radical.



3



4

The line broadenings observed in the radicals reported here are not unique. Kochi and Krusic (12) and Norman *et al.* (7) have observed similar effects. Such line broadenings result from hindered internal rotation. Exchanges between conformations **1** and **2** or **3** and **4** as shown above at a rate comparable to the difference in the a_β^H splitting constants in the two corresponding conformations would lead to the broadening of the lines associated with $M_I = 0$ of the triplets. These line broadenings are virtually absent in the protonated radicals (Figs. 1*b*, 3*b*). This shows that the barrier to internal rotation in these radicals is mainly the repulsive forces between the negatively charged substituents.

Experimental

Electron spin resonance spectra were recorded on Varian E-4 spectrometer with 100 kHz modulation. The mixing chamber was the Varian E-249 liquid flow mixing chamber which allows the mixing of two reactants. The instrument was calibrated using the $^\cdot PO_3^{2-}$ radical adduct of maleate ion (7). The *g*-values were measured by comparison with DPPH (20) and are corrected for second order effect (21). The temperature of the solutions was varied by the appropriate use of ice or heater. The temperature of the solution as it left the mixing chamber was recorded. The pH of the effluent solution is reported.

For the generation of the $^\cdot OH$ adduct in alkaline medium, the two solutions which were mixed contained (*a*) 12.5 mL/L of 12.5% (w/v) titanium trichloride solution, 9 g/L of disodium ethylenediamine tetraacetate, EDTA, and the pH of solution adjusted to 8.5 with concentrated ammonia solution. (*b*) 0.5–3 g/L of an unsaturated acid, 2 mL/L of 30% hydrogen peroxide, and pH of solution adjusted to 9–11 with ammonia.

In the study of $SO_3^{-\cdot}$ or $CO_2^{-\cdot}$ reactions 30 g/L of sodium sulphite or sodium formate respectively was included in solution (*a*). For $^\cdot PO_3^{2-}$ radical, 10 g/L of phosphorus acid was included in solution (*b*).

The reactions in acid medium were carried out without EDTA in solution (*a*) and the pH of both solutions were adjusted to values of 2–3 with sulphuric acid.

Itaconic acid (L. Light and Co.) and chelidonic acid (L. Light and Co.) were used as supplied. Aconitic acid was prepared from citric acid using the literature method (22). All other chemicals were from BDH company.

Reactions at the nitrogen atoms in azafluorene systems

KRYSTIAN KLOC, JACEK MŁOCHOWSKI, AND ZDZISŁAW SZULC

Institute of Organic and Physical Chemistry, Technical University, 50-370 Wrocław, Poland

Received August 30, 1978

KRYSTIAN KLOC, JACEK MŁOCHOWSKI, and ZDZISŁAW SZULC. Can. J. Chem. **57**, 1506 (1979).

Isomeric azafluorenones have been oxidized to *N*-oxides with H_2O_2 in acetic acid or in the presence of Na_2WO_4.

In the same manner monoazafluorenes have been converted into azafluorene *N*-oxides, but oxidation of diazafluorenes led first to diazafluorenones which then formed diazafluorenone *N*-oxides. Azafluorenones and azafluorenes are readily *N*-methylated with CH_3I to give methiodides. The relations between the rate constants of *N*-methylation and structural factors have been discussed.

KRYSTIAN KLOC, JACEK MŁOCHOWSKI et ZDZISŁAW SZULC. Can. J. Chem. **57**, 1506 (1979).

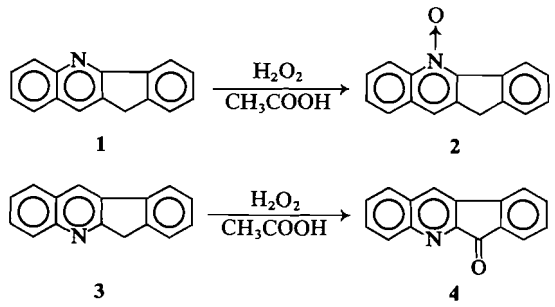
Les azafluorénones isomères sont oxydées en *N*-oxydes par H_2O_2 en présence d'acide acétique ou en présence de Na_2WO_4. De la même façon on a converti les monoazafluorènes en azafluorène *N*-oxydes, alors que l'oxydation de diazafluorènes conduit à la formation de diazafluorènones qui fournissent ensuite les diazafluorénones *N*-oxydes. Les azafluorénones et azafluorènes sont aisément méthylés avec CH_3I. On discute des vitesses de la *N*-méthylation en fonction de la structure.

Introduction

The chemistry of nitrogen analogues of fluorene and fluorenone is of interest because of the high biological activity and the possibility of pharmaceutical application, as well as the synthetic significance of this little known class of compounds (1, 2). In connection with a general study of the chemistry of polycyclic azines we have previously reported a convenient synthesis of unsubstituted azafluorenones starting from mono- and diazaphenanthrenes (3). Azafluorenones were simply converted into azafluorenes by adopting the Wolff–Kishner reduction procedure (4).

The aim of the present work has been to investigate oxidation and alkylation at nitrogen azafluorenes and azafluorenones, and to obtain hitherto unknown *N*-oxides as well as *N*-methiodides.

There are only a few reported examples of *N*-alkylation of azafluorenes and azafluorenones (5–8). The *N*-oxidation of this class of compounds has been reported only for the cases of 4-azafluorene to 4-azafluorene *N*-oxide (9) and of 3-methyl-2-azafluorene to 3-methyl-2-azafluorene *N*-oxide (10). Analogously, 11*H*-indene[1,2-b]quinoline **1** gives 85% of the corresponding *N*-oxide **2**, but its isomer, 11*H*-indene[2,1-b]quinoline **3**, is oxidized to the corresponding oxo-compound **4** (11).



1 **2** **3** **4**

Results and Discussion

We have examined the reactions of 1- and 4-monoazafluorenones **5** and **6** with hydrogen peroxide in benzene – acetic acid medium and found that they gave corresponding *N*-oxides **7** and **8**.

Under similar conditions, after 18 h, 1,8-diazafluorenone **9** gave 1,8-diazafluorenone 1,8-dioxide **10** in 47% yield, and 2,5-diazafluorenone **11** gave 2,5-diazafluorenone 2,5-dioxide **12** in 9% yield only. Oxidation of 1,5- and 4,5-diazafluorenones **13** and **14** led to tarry unidentified products in which no *N*-oxides were detected.

Adopting the procedure reported by Hamada and Takeuchi (12) and oxidizing the studied compounds with H_2O_2 in the presence of Na_2WO_4 we obtained 2,5-diazafluorenone 2,5-dioxide **12** (30%), 4,5-diazafluorenone 4-oxide **15** (22%), as well as 1,5-diazafluorenone 5-oxide **16** (37%).

The structure of **16** was confirmed by its ^1H nmr spectrum and comparison with the starting base **13**. The H-4 proton is deshielded by the *N*-oxide group and its signal is shifted to lower field by about

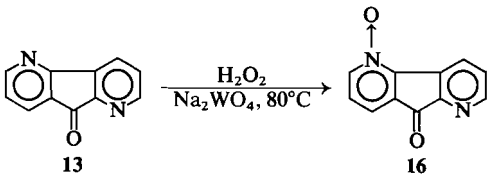
8 4-*N*

0008-4042/79/121506-05$01.00/0

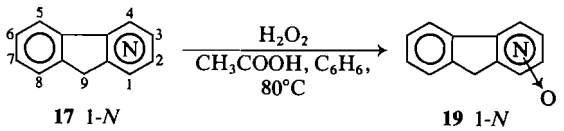


13 16

0.55 ppm. Similar effects were observed in other *N*-oxides (13).

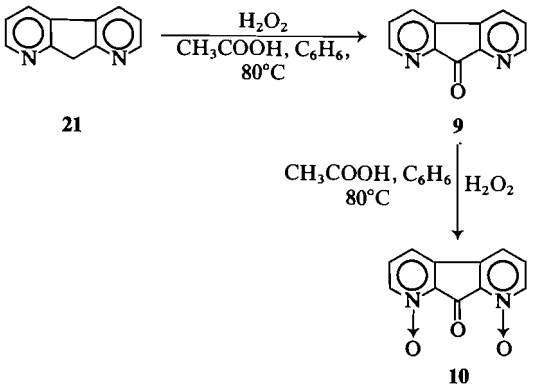
The presence of N→O groups was confirmed by the ir spectra in which the position of stretching bands occurring at 1200–1300 cm^{-1} in accord with the data obtained for other *N*-oxides (14).

By oxidizing 4-azafluorene **18** with hydrogen peroxide in acetic acid – benzene mixture, we obtained 4-oxide **20** as reported in the literature (9). 1-Azafluorene **17** was oxidized to 1-oxide **19** and neither azafluorenone nor its *N*-oxide was detected, although in the case of the similar compound **3** the active methylene group was oxidized to give **4** (11).



17 1-*N* **19** 1-*N*
18 4-*N* **20** 4-*N*

Nevertheless, 1,8-diazafluorene **21** was oxidized in the first step to 1,8-diazafluorenone **9** which was simultaneously converted to 1,8-diazafluorenone 1,8-dioxide **10**.



21 **9** **10**

Analogously, 1,5-, 2,5-, and 4,5-diazafluorenes **22**, **23**, and **24** were oxidized to the corresponding azafluorenones and then to their *N*-oxides which immediately underwent decomposition in acetic acid medium.

When reaction was carried out with H_2O_2 in the presence of Na_2WO_4, the diazafluorenone *N*-oxides **12** (9%), **15** (7%), and **16** (16%) were isolated. The above experiments are evidence that in diazafluorenes, where two pyridine rings exert a strong electron withdrawing effect on the methylene group; this group is more active than are nitrogen atoms. No significant steric effects were observed in contrast to nitrogen analogues of phenanthrene (14). We carried out the *N*-methylation of azafluorenes **17**, **18**, **21**, **22**, **23**, and **24** as well as azafluorenones **5**, **6**, **9**, **11**, **13**, and **14**. The reaction was performed with methyl iodide in benzene solution under reflux. The results of *N*-methylation and the properties of the products are listed in Table 1.

The structure of the synthesized products was confirmed by ^1H nmr spectroscopy and comparison of the spectra with those of starting bases (3, 4), although the structure of *N*-methyl derivatives of monoazafluorenes, monoazafluorenones, and symmetrical diazacompounds are unequivocal.

In the case of 1,5-diazafluorene **22** only 1-methiodide **30** was formed and in the ^1H nmr spectrum the downfield signals were similar to **26**, and not to **28**. The product could not be a mixture of two monomethiodides because the $-CH_3$ protons would not be equivalent, and two singlets would be seen in the spectrum. On the other hand, 1,5-diazafluorenone formed mainly 1-methiodide **29**, admixture with about 20% of the 5-isomer. In the ^1H nmr spectrum two upfield singlets of $-CH_3$ groups (δ = 4.86 and 4.72 ppm, 1:4) occurred. The 4.86 ppm signal was similar to **27** and the 4.72 ppm to **25**. The downfield signals were more similar to **25** than to **27**.

In the same manner we found that 2,5-diazafluorene **23** and 2,5-diazafluorenone **11** were methylated at the 2-position to give **33** and **34**.

The rate constants were also established for the *N*-methylation of monoaza- and symmetric diazafluorenones and azafluorenes, and are listed in Table 2.

The data obtained show that the azafluorenes are more reactive as compared to azafluorenones, this fact being probably due to the electron withdrawing effect of the carbonyl group decreasing nucleophilicity of the nitrogen atoms. The second nitrogen atom in diazacompounds **9**, **14**, **21**, and **24** also decreases the electron density on the other one and reactivities of **9** or **21** are similar to that of **5** or **17**. Otherwise one would have expected that double the number of nitrogen atoms in the molecule would have doubled the rate constants.

4-Azacompounds **6** and **18** are less reactive than 1-isomers **5** and **17** because the H-5 atom could cause steric hindrance. When the ≡C—H group in the 5-position is replaced by a nitrogen atom (compounds **14** and **24**) reactivity increases, and this fact can probably be assigned to the high electron density at the reaction center, which is due to the proximity of the nonbonding orbitals of both N atoms and to

TABLE 1. Results of the syntheses of azafluorene and azafluorenone *N*-methiodides

Compound	Yield (%)	mp (°C)	^{1}H nmr†	Elemental analysis (% I) Calcd.	Found

*After 60 h.

†The spectra of azafluorenone *N*-methiodides were measured in DMSO. The spectra of azafluorene *N*-methiodides except compound **28** were measured in D_2O and the spectrum of **28** in CF_3COOD–$CDCl_3$ (1:1).

the absence of the H-5 atom. Nevertheless, the influence of these factors is smaller than in the analogous azaphenanthrenes (15) because azafluorene molecules are more linear.

The synthesized *N*-oxides and *N*-methiodides of the azafluorenones were subjected to preliminary screening against bacteria and fungi in the same manner as was described for phenanthrolines (16). We have found that in all cases the *N*-derivatives exhibited higher activity than the free bases. Activity most similar to that of 1,10-phenanthroline and the widest antibacterial spectra were shown by 2,5-diazafluorenone 2,5-dioxide **12**, and *N*-methiodides of 1-azafluorenone **25**, 1-azafluorene **26**, and 1,8-diazafluorene **32** *N*-methiodides. Further investigations of the activity of azafluorenones, azafluorenes, and their derivatives are in progress.

Experimental

All melting points were taken with a Kofler apparatus and are uncorrected. The ir spectra (in KBr) were recorded with a Perkin Elmer 621 spectrophotometer, and nmr spectra with a Tesla BS-478/80 MHz spectrometer in D_2O, DMSO, $(CF_3)_2CO$, or $CDCl_3$–CF_3COOD solution, using HMDS as an external standard.

The reaction course, and their products were checked by tlc on silica gel using chloroform or ethyl acetate as eluents. The spots were visualized with Dragendorff reagent.

The starting azafluorenones and azafluorenes were synthesized from the appropriate azaphenanthrenes as described earlier (3, 4). The biological tests were performed in the Microbiology Department of the Medicinal Academy in Lublin. The screening method involved testing synthetic compounds against bacteria and fungi; the results are available from the Depository of Unpublished Data.[1]

1-Azafluorenone 1-Oxide (7)

To a solution of **5** (1.81 g, 10 mmol) in glacial acetic acid (10 mL) and benzene (10 mL), 30% hydrogen peroxide (3 mL) was added and the mixture was heated to gentle boiling. After 8 h, the second portion of 30% hydrogen peroxide (3 mL) was added and the reaction mixture was heated for an additional 6 h. After oxidation the reaction mixture was concentrated under reduced pressure to about 5 mL, water (20 mL) added, and the resulting mixture concentrated again. This procedure was repeated, and then the residue was evaporated to dryness. The crude product was recrystallized from ethanol–water yellow needles 69% yield, mp 221–223°C (dec.); ir (KBr) ν_{max}: 1720 (s, CO), 1285 cm^{-1} (s, NO). *Anal.* calcd. for $C_{12}H_7O_2N$: C 73.10, H 3.55, N 7.10; found: C 73.45, H 3.50, N 7.11.

4-Azafluorenone 4-Oxide (8)

This compound was obtained from **6** in the same manner as **7**, oxidation time being 8 h; orange needles, 68% yield, mp 257–259°C; ir (KBr) ν_{max}: 1720 (s, CO), 1285, and 1275 cm^{-1} (s, NO). *Anal.* calcd. for $C_{12}H_7O_2N$: C 73.10, H 3.55, N 7.10; found: C 73.40, H 3.45, N 6.79.

1,8-Diazafluorenone 1,8-Dioxide (10)

10 was obtained from **9** in the same manner as for **7**. After 10 h, the second portion of 30% hydrogen peroxide (3 mL) was added and reaction mixture was heated for an additional 6 h. The insoluble product was filtered and washed with hot ethanol; orange needles, 47% yield, mp 274–276°C (dec.); ir (KBr) ν_{max}: 1712 (s, CO), 1290, and 1270 cm^{-1} (s, NO). *Anal.* calcd. for $C_{11}H_6N_2O_3$: C 61.69, H 2.82, N 13.08; found: C 61.76, H 3.02, N 12.78.

2,5-Diazafluorenone-2,5-dioxide (12)

12 was obtained from **11** in the same manner as for **7**. The reaction was complete after 30 min and the product was isolated in 9% yield only. The following modification was also used. **11** (1.82 g, 10 mmol) was stirred at 50°C with the solution of $Na_2WO_4 \cdot 2H_2O$ (0.2 g) in 5% hydrogen peroxide (40 mL) until the starting material was dissolved completely. The reaction mixture was then allowed to stand for 12 h at room temperature and the insoluble product filtered off and recrystallized from water. Small red prisms decomposed in a range of 220–240°C; 30% yield; ir (KBr) ν_{max}: 1728 (s, CO), 1272, and 1245 cm^{-1} (s, NO). *Anal.* calcd. for $C_{11}H_6N_2O_3$: C 61.69, H 2.82, N 13.08; found: C 61.99, H 2.93, N 13.13.

4,5-Diazafluorenone 4-Oxide (15)

A suspension of **14** (1.82 g, 10 mmol) in 30% hydrogen peroxide (40 mL) with $Na_2WO_4 \cdot 2H_2O$ (0.1 g) was heated at 80°C with vigorous stirring for 1 h. The insoluble excess of the starting material was removed by filtration and the filtrate was extracted several times with chloroform and the extracts were checked chromatographically. The previous extracts containing a mixture of substrate and **15** were evaporated, the residue collected and added to unreacted substrate, and the oxidation repeated. The latter extracts containing solely *N*-oxide were collected and dried ($MgSO_4$). This compound **15** underwent decomposition on a column filled with silica gel or alumina and could be purified or separated chromatographically. Purification was effected by recrystallization from water; yellow needles decomposed above 230°C, 22% yield; ir (KBr) ν_{max}: 1725 (s, CO), 1294, and 1262 cm^{-1} (s, NO). *Anal.* calcd. for $C_{11}H_6N_2O_2$: C 66.66, H 3.05, N 14.14; found: C 66.40, H 2.91, N 13.76.

1,5-Diazafluorenone 5-Oxide (16)

16 was obtained from **13** similarly to **15**. The reaction was complete after 3 h, and the reaction mixture was extracted with chloroform. The extracts were dried ($MgSO_4$) and evaporated, and the residue separated chromatographically on a column filled with silica gel, using the mixture: ethyl acetate – methanol – chloroform (5:3:1) as eluent. The crude **16** was obtained from the former fractions and recrystallized from water; yellow needles, 37% yield, mp 240–242°C (dec.); ir (KBr) ν_{max}: 1732 (s, CO), 1270, and 1251 cm^{-1} (s, NO). *Anal.* calcd. for $C_{11}H_6N_2O_2$: C 66.66, H 3.05, N 14.14; found: C 66.36, H 3.06, N 14.17; ^1H nmr ($(CF_3)_2CO$) δ: 9.08 (dd, J = 8 Hz and 1.5 Hz, 1H, H-4), 8.94 (dd, J = 5 Hz and 1.5 Hz, 1H, H-2), 8.62 (dd, J = 5 and 1.5 Hz, 1H, H-6), 8.17 (dd, J = 8 Hz and 1.5 Hz, 1H, H-8), and 7.65–7.97 (m, 2H, H-3 and H-7).

1-Azafluorene 1-Oxide (19)

To a solution of **17** (1.0 g, 6 mmol) in glacial acetic acid (12 mL) and benzene (12 mL), 30% hydrogen peroxide (3 mL) was added and the mixture was refluxed for 2 h. Then the second portion of 30% hydrogen peroxide (1 mL) was added and the reaction mixture was heated for an additional 6 h, concentrated under reduced pressure to about 3 mL, water (15 mL) added, and the solution concentrated again. This procedure was repeated for the complete removal of acetic acid. The residue was evaporated to dryness and extracted with chloroform. The extracts were dried ($MgSO_4$) and evap-

orated. The crude product was recrystallized from methanol–water (5:1); yellow prisms, 54% yield, mp 142–143°C (dec.); ir (KBr) ν_{max}: 1255 and 1240 cm^{-1} (s, NO). *Anal.* calcd. for $C_{12}H_9NO$: C 78.66, H 4.95, N 7.64; found: C 78.31, H 4.80, N 7.52.

4-Azafluorene 4-Oxide (20)

20 was obtained from **18** in a similar manner as for **19** by oxidation for 10 h. The crude product was recrystallized twice from ethyl acetate; yellow needles, 45% yield, mp 164–165°C (lit. (9) mp 163–164°C); ir (KBr) ν_{max}: 1291 (s, NO), 1270 cm^{-1} (s, NO). *Anal.* calcd. for $C_{12}H_9NO$: C 78.66, H 4.95, N 7.64; found: C 78.51, H 5.08, N 7.54.

Oxidation of Diazafluorenones

Oxidation of 1,8-diazafluorenone **21** was carried out in a similar manner as for **9**, with 30% H_2O_2 in acetic acid – benzene solution. The product (19% yield) was identical with **10**.

Oxidation of 1,5-, 2,5-, and 4,5-diazafluorenes **22**, **23**, and **24** was performed in a similar manner as for the oxidation of diazafluorenones, with H_2O_2 in the presence of Na_2WO_4, and the corresponding *N*-oxides **12** (9% yield), **15** (7% yield), and **16** (16% yield) isolated.

General Procedure of N-*Methylation*

Azafluorene or azafluorenone (5 mmol) and methyl iodide (22.7 g, 160 mmol) were dissolved in 50 mL of benzene, refluxed for 6 h, and allowed to stand for an additional 12 h at room temperature. The precipitated *N*-methiodide was isolated by filtration and washed three times with small amounts of benzene. The crude **29** was recrystallized from water. Reaction yields and the characteristics of the products are given in Table 1.

In order to determine the rate constants, two series of measurements were run for each experiment, reacting the solution of 2.5 mmol of the starting base in benzene (25 mL) with 80 mmol of CH_3I for four short reaction times at the boiling point of the mixture. Amounts of the methiodides formed were established gravimetrically. The particular rate constants k were calculated using the formula for a second order reaction

$$kb(t_1 - t_2) = \ln [(a - x_1)/(a - x_2)] \qquad \text{when } b \gg a$$

where b = the methyl iodide concentration, a = the initial concentration of the substrate, x_1 = the loss of the substrate in time t_1, and x_2 = the loss of the substrate in time t_2. The average k values obtained with the accuracy ±2% are listed in Table 2.

M. H. BACK and R. A. BACK. Can. J. Chem. **57**, 1511 (1979).

The decomposition of cyclobutanone vapor by infrared radiation from a pulsed CO_2 TEA laser at 9.552 μm has been studied at pressures from about 0.1 to 10 Torr. The main decomposition path was

[1] 
while the reaction

[2] 
was much less important. Very minor amounts of propylene and acetylene were also observed. From the ratio of reaction [2] to reaction [1], information was obtained about the effective temperature of the decomposition and the energy of the decomposing molecules. With the laser beam unfocussed, the decomposition at pressures above about 3 Torr is adequately described as a thermal decomposition, controlled by the initial temperature attained and the rate of cooling of the irradiated gas. At lower pressures, and when the laser beam was focussed, direct excitation and decomposition of individual molecules by multiphoton absorption appears to be involved.

M. H. BACK et R. A. BACK. Can. J. Chem. **57**, 1511 (1979).

Opérant à des pressions de 0.1 à 10 Torr, on a étudié la décomposition de la vapeur de cyclobutanone par une radiation infrarouge émise par un laser TEA à CO_2 déclenché à 9.552 μm. La voie principale de décomposition est

[1] 
alors que la réaction

[2] 
est moins importante. On a aussi observé la formation de quantités mineures de propylène et d'acétylène. En se basant sur le rapport de la réaction 2 à la réaction 1, on a obtenu des informations concernant la température effective de la décomposition et l'énergie des molécules qui se décomposent. Lorsque le rayon laser n'est pas bien focalisé, on peut décrire adéquatement la décomposition à des pressions supérieures à 3 Torr par une décomposition thermique qui est contrôlée par la température initiale obtenue et le taux de refroidissement des gaz irradiés. A des pressions inférieures et lorsque le rayon laser est bien focalisé, il semble que l'excitation et la décomposition directe de molécules individuelles par une absorbtion multiphoton soient impliquées.

[Traduit par le journal]

Introduction

The decomposition of gases by intense infrared radiation from pulsed lasers is the subject of widespread interest and investigation (1, 2). It is clear that many molecules can be excited beyond their dissociation limits, both at high pressures where collisional energy transfer dominates, and at low pressures where excitation of isolated molecules occurs essentially free of collisions. One of the more interesting questions in these systems is the energy distribution of the molecules that have been excited, particularly those that have been excited beyond their dissociation limits and decompose (1–6). Such energy distributions are obviously complex functions of radiation intensity, absorption coefficients, energy transfer (both inter- and intramolecular), and the rate of decomposition of molecules from various states of excitation above the dissociation energy.

One experimental approach to an estimate of energy distributions in such systems is the study of a

[1]NRCC No. 17348.

0008-4042/79/121511-07$01.00/0

molecule with two well-defined modes of decomposition with different threshold energies. A molecule that appears well suited to such a study is cyclobutanone. It is well established (7–10) from conventional thermal decomposition studies that there are two clean, nonradical unimolecular modes of decomposition:

[1]  $\rightarrow C_2H_4 + CH_2CO$

[2]  $\rightarrow \triangle + CO$

with rates given by the Arrhenius expressions[2]

$$k_1 = 3.60 \times 10^{14} \exp(-52\,000/RT)\ s^{-1}$$

and

$$k_2 = 2.34 \times 10^{14} \exp(-58\,000/RT)\ s^{-1}$$

The present paper describes a study of the decomposition of cyclobutanone vapor over a range of pressures and in both the focussed and unfocussed beams of a pulsed CO_2 TEA laser.

Experimental

Experiments were done in a cylindrical Pyrex reaction vessel, 10 cm long and 5 cm in diameter, fitted with plane salt windows attached with black wax. Infrared radiation was obtained from a Lumonics Model 203 pulsed CO_2 TEA laser, operating at about 0.5 Hz, with a $He/CO_2/N_2$ mix of 10/3/1.1, with the beam stopped down to a diameter of 1.3 cm. Incident and transmitted fluence were monitored with calibrated pyroelectric detectors and suitable beam splitters. Incident fluence was varied by inserting germanium flats in the laser beam. For experiments with a focussed beam, a NaCl lens with 5 cm focal length was placed immediately before the front window of the cell. All irradiations were done using the P(20) line at 9.552 μm, selected by an intracavity grating, which represented an optimum combination of laser intensity and absorption coefficient to give a maximum energy deposition in the cyclobutanone vapor. Maximum pulse energy was about 2 J.

Cyclobutanone was purchased from Aldrich Chemical Co. and used after simple degassing at −78°C on a conventional vacuum line. Blank experiments showed residual traces of ethylene and cyclopropane for which small corrections were made. The reaction vessel was attached to the vacuum line by a standard-taper joint, filled to the desired pressure, and removed for irradiation. After irradiation it was attached again to the vacuum line for analysis. Gases noncondensable at −210°C were removed through a solid-nitrogen trap, after which products volatile at −78°C were condensed and sealed into glass ampoules for gc analysis. The products ethylene, cyclopropane, propylene, and acetylene were analysed on a 6 m column of phenylisocyanate on Porasil at 40°C. Ketene, which is a probable product, was not detected by this analysis.

[2]These expressions are based on the measurements of k_1 by Das *et al.* (7) and on values of k_1/k_2 obtained by Blades (8). The later study by McGee and Schleifer (9) gave almost identical values of k_1, while their relative rate data when replotted with those of Blades show no significant differences and cover a much narrower range of temperature.

Results

Infrared Absorption Spectrum

The absorption spectrum of cyclobutanone vapor in the 10-μm region is shown in Fig. 1. The band at 1070 cm^{-1} has been assigned to ν_{24}, a B_2 rocking mode of the αCH_2 groups (11). All experiments were done using the P_{20} line of the CO_2 laser at 1059 cm^{-1} which lies on the low frequency shoulder of the absorption band (Fig. 1). The absorption at this frequency, based on measurements of incident and transmitted fluence of the unfocussed beam, showed a Beer's Law behaviour, i.e., log (incident fluence/transmitted fluence) varied linearly with cyclobutanone pressure corresponding to an effective decadic molar extinction coefficient of 23 $M^{-1}\ cm^{-1}$. Addition of inert gas (air or xenon) had no effect on the absorption.

Decomposition in the Unfocussed Beam

Products observed and measured were ethylene, cyclopropane, propylene, and acetylene, the latter two of very minor importance. Yields per pulse were independent of the number of pulses, showing that all products were of primary origin and that their secondary decomposition was not important. The fraction of the cyclobutanone decomposed was never more than 5% and usually much less.

Figure 2 shows a log–log plot of the dependence of the yield of ethylene on pressure of cyclobutanone,

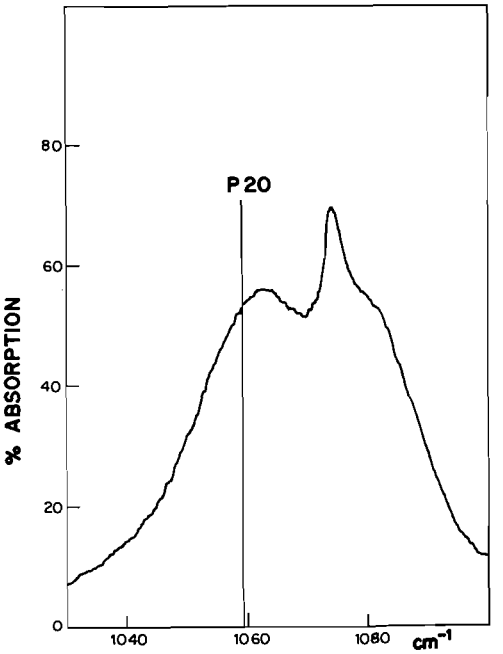

FIG. 1. Absorption spectrum of cyclobutanone vapor at 10 Torr pressure, in the 9–10 μm region.

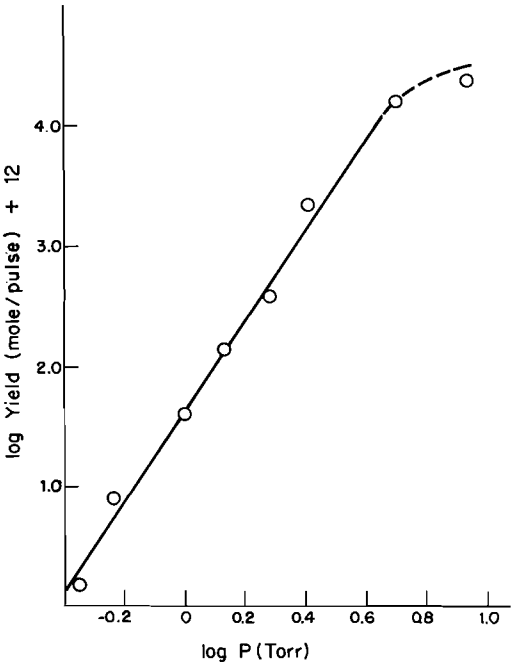

FIG. 2. Yield of ethylene per pulse vs. pressure of cyclobutanone from the unfocussed beam.

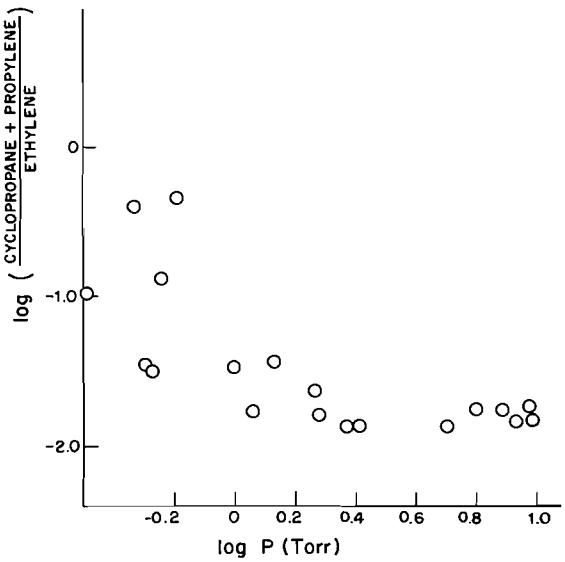

FIG. 3. Product ratio (cyclopropane + propylene)/ethylene vs. pressure of cyclobutanone from the unfocussed beam.

while Fig. 3 shows the variation of the (cyclopropane + propylene)/ethylene ratio. Yields of propylene varied from about 1% of the cyclopropane at pressures above 5 Torr to as high as 20% at the lowest pressures, with considerable scatter in the data. Acetylene formation was somewhat irregular, but usually less than 0.5% of the ethylene.

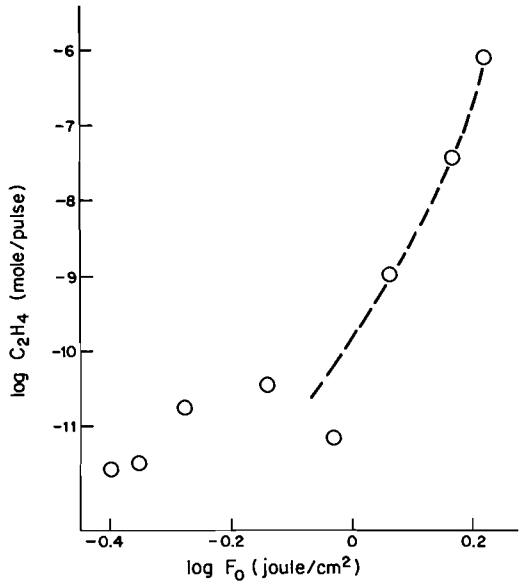

FIG. 4. Yield of ethylene per pulse vs. incident fluence; unfocussed beam, 9.5 Torr cyclobutanone.

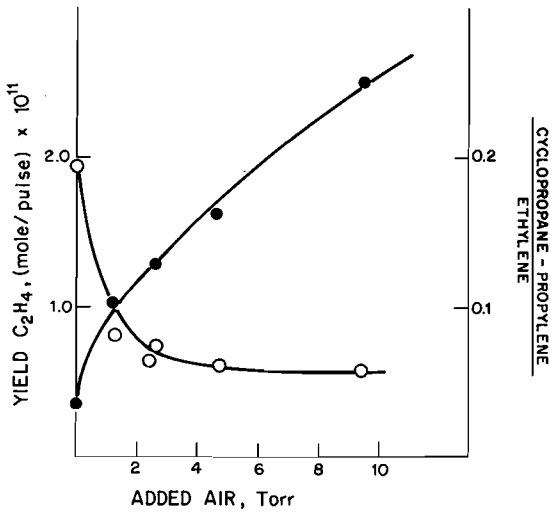

FIG. 5. Effect of added air on the product yields; unfocussed beam, 0.5 Torr cyclobutanone. ○ = ethylene; ● = (cyclopropane + propylene)/ethylene.

Figure 4 shows the dependence of the yield of ethylene on fluence at a constant pressure (9.5 Torr) of cyclobutanone. Figure 5 shows the effect of the addition of a nonabsorbing gas (air) on the yield of ethylene from 0.5 Torr of cyclobutanone, and the effect on the ratio (cyclopropane + propylene)/ethylene.

Decomposition in the Focussed Beam

Ethylene was again the major product of the decomposition detected and measured. The minor

products increased in importance in the focussed beam. The sum of cyclopropane + propylene increased to about 3.5% of the ethylene, while the propylene rose sharply to about 40% of the cyclopropane, with both these product ratios approximately independent of cyclobutanone pressure and incident fluence. The yield of acetylene increased markedly to about 4% of the ethylene at the maximum fluence employed. The ratio acetylene/ethylene was approximately independent of pressure, but varied almost linearly with incident fluence. Figure 6 shows the dependence of the ethylene yield on cyclobutanone pressure, while Fig. 7 shows its variation with fluence incident on the lens at a pressure of 0.14 Torr.

Discussion

It is useful to discuss the present results in terms of two limiting mechanisms. The first, which will predominate at high pressure and low fluence, can be described as a thermal decomposition of a hot gas approaching thermal equilibrium through collisional redistribution of energy. The second mechanism involves multiphoton absorption and dissociation of individual molecules essentially free of collisions, which can be expected to operate at low pressures and high fluence. Under conditions between these two extreme limits, some mixture of the two mechanisms will occur.

The results with the unfocussed laser at pressures above about 3 Torr of cyclobutanone point clearly to a system tending towards the first mechanism, a thermal decomposition, rather than a multiphoton dissociation. At the highest fluence employed, an average of about 4 photons per molecule were absorbed during the ~250 ns pulse, while at 3 Torr pressure each molecule would suffer on the average about 25 collisions during the same period. Collisional energy transfer would obviously compete effectively with excitation, and the direct accumulation in a single molecule of the 17 quanta necessary for dissociation would become very improbable. At lower fluence and higher pressure collisional processes would become even more dominant. To test the plausibility of a thermal decomposition model under such conditions, a simple calculation can be made of the maximum temperature to be expected in the irradiated gas. At a pressure of 9.5 Torr the average total energy absorbed in a single pulse at the highest fluence was 17.9 kcal/mol. The heat capacity of cyclobutanone was calculated by the group additivity method outlined by Benson and O'Neal (10) at intervals of 100°, and a graphical integration performed to estimate a temperature of 880 K at the end of the pulse, assuming thermal equilibration in the irradiated zone and negligible cooling. Temperatures estimated in this way are shown in Table 1 for all the experiments plotted in Fig. 4, and yields of ethylene are then plotted in Arrhenius form in Fig. 8, in which the linear portion corresponds to an activation energy of about 50 kcal/mol. The deviation from linearity at the lowest fluences may be genuine or may simply reflect the uncertainty in measurement

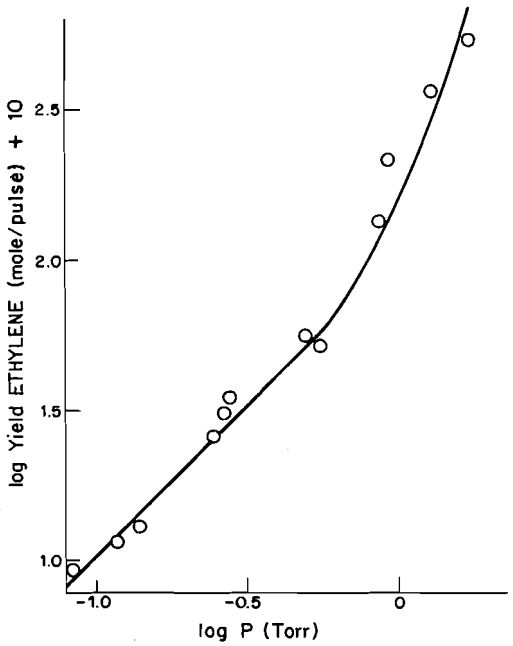

FIG. 6. Yield of ethylene per pulse vs. pressure of cyclobutanone in the focussed beam.

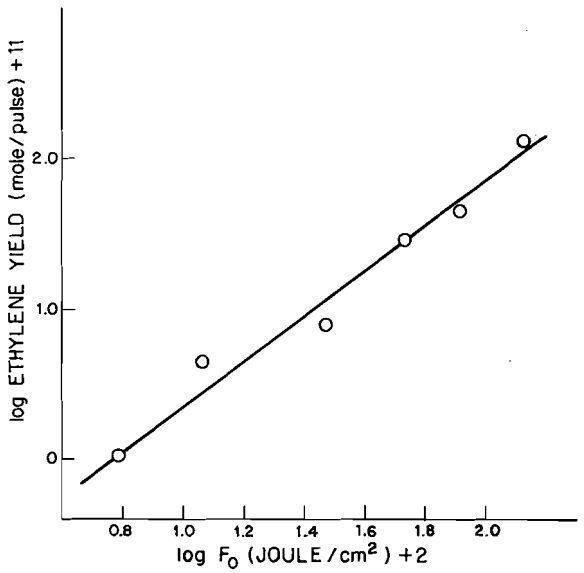

FIG. 7. Yield of ethylene per pulse vs. fluence incident on the lens; focussed beam, 0.13 Torr cyclobutanone.

TABLE 1. Thermal decomposition model for unfocussed beam

Expt. No.	F_0 (J/cm²)	C_2H_4 (mol/pulse)	T (K)	Reaction time (ms)
52	1.47	3.89×10^{-8}	816	1
53	1.65	1.30×10^{-7}	880	0.5
54	0.53	1.77×10^{-11}	486

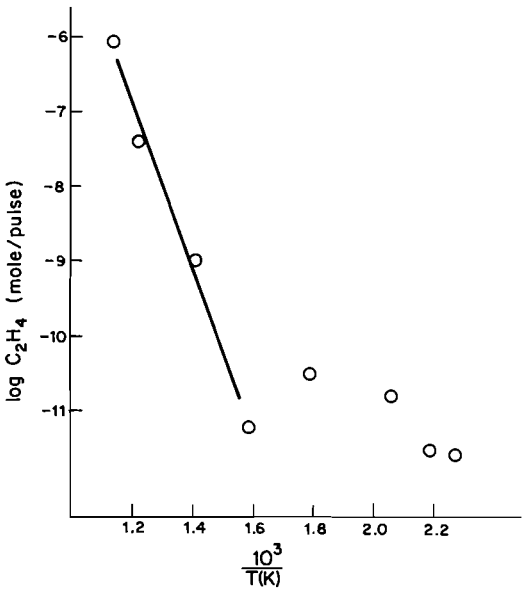

FIG. 8. Yield of ethylene per pulse as a function of estimated temperature in irradiated zone. The straight line corresponds to an activation energy of about 50 kcal/mol. Unfocussed beam, 9.5 Torr cyclobutanone.

of the very small yields. In the thermal decomposition model, the reaction time will be determined by the rate of cooling of the hot gas after the pulse. Effective reaction times required to account for the extent of decomposition observed can be estimated from the known Arrhenius parameters for k_1 and are shown in Table 1. A precise treatment of the system would require a complex integration of k_1 over time, temperature, and space. The magnitude of the activation energy, however, will dictate that most of the decomposition will occur within a few degrees of the maximum temperature achieved, so that the estimates of the latter in Table 1 may be a fair approximation to the temperature of the decomposition. The activation energy obtained from Fig. 8 is close to that established for reaction [1], and the effective times estimated are in reasonable accord with rough approximations of the rate of cooling by conduction of the hot gas. Thus the decomposition of cyclobutanone observed in the unfocussed beam at 9.5 Torr can be reasonably accounted for by a thermal decomposition model, although the limitations of such a simple treatment are obvious (3–6) and should be stressed.

The ratio of cyclopropane to ethylene can also be used to estimate the effective temperature of the decomposition. This ratio was approximately constant above 3 Torr (Fig. 3) with a value of 0.017 ± 0.002. From the Arrhenius relation reported by Blades (8) that $k_2/k_1 = 0.65 \exp(-6000/RT)$, this corresponds to a temperature of 830 ± 30 K. Uncertainty in the measurement of the rather small yields of cyclopropane make this an inaccurate estimate of temperature, but within these limitations the agreement with the data in Table 1 is reasonable. The same uncertainty in the measurement of cyclopropane obscured any systematic variation in the cyclopropane/ethylene ratio with fluence.

The strong pressure dependence of the reaction (Fig. 2) is also explicable by the thermal decomposition model. For the present weakly absorbing system, the energy absorbed per molecule and hence the temperature achieved at the end of the pulse should be roughly independent of pressure. The rate of cooling then becomes an important parameter and in cylindrical geometry with cooling by conduction, the integrated decomposition of the hot gas during the cooling period should be very roughly proportional to p^2. Blades observed that the decomposition of cyclobutanone was pressure dependent below 10 Torr at about 630 K (8), and at the higher temperatures achieved in the present study this effect would be enhanced and the decomposition would approach second order. A total pressure dependence of about p^3 or p^4 might therefore be expected, as was observed.

The effect of adding a nonabsorbing gas (air or xenon) to the system is also compatible with the thermal decomposition model. Interpretation of these experiments is not simple, as three different effects will be superimposed; (*i*), reduction in temperature through increased heat capacity of the system; (*ii*), slower cooling by conduction, just as in cyclobutanone itself; and (*iii*), enhancement of rates of reactions [1] and [2] if they are pressure dependent as suggested. The first effect should predominate, and indeed the rate of decomposition decreased as expected (Fig. 5), although the decrease was probably reduced by the latter two effects which act in the opposite direction. Surprisingly, formation of cyclopropane was reduced less than that of ethylene, so that the ratio cyclopropane/ethylene increased with

added gas (Fig. 5), the reverse of the effect expected from a reduction in temperature. The same effect was observed on the addition of xenon. A possible explanation lies in the greater pressure dependence of reaction [2] reported by Blades (8), which might outweigh the effect of reduced temperature.

At pressures below 3 Torr of cyclobutane in the unfocussed beam, the ratio (cyclopropane + propylene)/ethylene increased notably (Fig. 3), and a similar increase in the propylene/cyclopropane ratio was also observed. The thermal decomposition model does not predict a rise in temperature at low pressure, and it seems probable that these changes in the product ratios arise from the onset of some multiphoton dissociation as the pressure was reduced. If the decomposition of a cyclobutanone molecule energized by multiphoton absorption is a statistical process dependent only on the total energy content, as seems probable for a polyatomic molecule of this complexity (1–6), the change in product ratios at low pressure implies that the dissociating molecules have a much higher average energy content than those decomposing in the thermally equilibrated system at the same fluence. This could come about through a more efficient absorption of radiation, either an overall higher average absorption coefficient, or perhaps a stronger absorption at the higher energy levels which could lead to relatively higher populations at energies above the dissociation energy than found in a Boltzmann distribution. An alternative explanation is that only a fraction of the molecules (those in appropriate rotational levels) absorb radiation, and the absorbed energy remains more or less in this selected assembly of molecules which is thereby raised to a higher average energy content or 'temperature'. From an average value of cyclopropane/ethylene of about 0.1 at 0.5 Torr, an effective temperature of the dissociating molecules of about 1600 K can be estimated, which would require that the absorbed energy was effectively restricted to about half the molecules in the irradiated zone. The present level of understanding of multiphoton absorption does not permit a clear decision between the two suggested explanations.

The decomposition of cyclobutanone in the focussed beam showed a behaviour quite different from that found with unfocussed radiation. The dependence on pressure and fluence was much less sharp (Figs. 6 and 7), and the minor products, propylene, and acetylene, became much more important. All these features point to a decomposition occurring largely through multiphoton absorption by individual molecules, as might be expected at the high fluence and relatively low pressures in these experiments (pressure was limited by electrical breakdown at the focus). The 3/2 dependence on fluence (Fig. 7) has been attributed in other systems to a simple geometric effect arising when complete decomposition occurs within a reaction zone around the focus which is sharply defined by a threshold fluence (1, 2, 12). The very high dependence on fluence observed in the unfocussed beam (Fig. 4) will give rise to such a threshold behaviour, and there is no reason to doubt that this model applies to the present system. From the absolute yield of decomposition per pulse, a reaction zone of 0.09 cm^3 volume can be estimated at the maximum fluence employed, which corresponds to a double cone 3.4 cm long and 0.44 cm end diameter, and a threshold fluence of ~ 11 J/cm^2.

The first-order pressure dependence of the decomposition at low pressures is also indicative of a multiphoton dissociation, simply reflecting the number of molecules present in the reaction zone. The increasing pressure dependence above about 0.5 Torr suggests that a thermal decomposition mechanism is beginning to contribute to the reaction.

The source of the increased yields of the minor products in the focussed beam is not entirely clear. It was concluded that in the unfocussed beam, cyclopropane and propylene were primary in origin, arising from excitation of cyclobutanone to levels capable of yielding these products. For cyclopropane, Blades found an activation energy 6 kcal/mol higher than that for ethylene formation (8), and suggested that from theoretical estimates of its heat of formation (9), the C_3H_6 biradical (which could give rise to propylene) would require an additional 5 to 10 kcal/mol. The relative yields of ethylene, cyclopropane, and propylene in the unfocussed system are compatible with these activation energy differences operating in a thermal decomposition, with some contribution from direct multiphoton excitation at low pressure. The marked increase in yields of cyclopropane and propylene in the focussed beam could be explained by primary excitation of cyclobutanone to higher energy levels in the multiphoton process, operating at the much higher fluences of the focussed beam. However, secondary decomposition of cyclopropane or ethylene cannot be ruled out as sources of propylene and acetylene in the focussed beam, since cyclobutanone was almost completely decomposed in the reaction zone so that product concentrations became comparable to that of starting material. Both ethylene and cyclopropane absorb the 9.552 μm laser radiation, the former weakly, the latter strongly, and their decomposition by multiphoton absorption (13, 14) or perhaps by thermal processes following the pulse might be possible. In particular, formation of acetylene, which

was barely detectable in the unfocussed beam, and which would probably require a large additional excitation of cyclobutanone above the threshold for ethylene formation, is best explained in the focussed beam by a secondary decomposition of ethylene. The relatively small enhancement of the sum of the yields of cyclopropane + propylene on focussing the beam suggests that the energy content of the decomposing cyclobutanone molecules was not enormously higher than in the unfocussed beam, perhaps implying an energy distribution limited by rapid decomposition via reactions [1] and [2]. It is not clear whether propylene is primary or secondary in origin in the focussed beam.

Rate constants measured with the flowing afterglow technique at 298 ± 2 K are reported for the proton-transfer reactions of H_3O^+ with CH_2O, CH_3CHO, $(CH_3)_2CO$, HCOOH, CH_3COOH, $HCOOCH_3$, CH_3OH, C_2H_5OH, $(CH_3)_2O$, and CH_2CO. Dissociative proton-transfer was observed only with CH_3COOH. The rate constants are compared with the predictions of various theories for ion–molecule collisions. The protonation is discussed in terms of the energetics and mechanisms of various modes of dissociation.

GERVASE I. MACKAY, SCOTT D. TANNER, ALAN C. HOPKINSON et DIETHARD K. BOHME. Can. J. Chem. 57, 1518 (1979).

On rapporte les constantes de vitesse à 298 ± 2 K, mesurées grâce à la technique de lueur d'écoulement, pour les réactions de transfert de proton de H_3O^+ avec CH_2O, CH_3CHO, $(CH_3)_2CO$, HCOOH, CH_3COOH, $HCOOCH_3$, CH_3OH, C_2H_5OH, $(CH_3)_2O$ et CH_2CO. On a observé la réaction de transfert dissociatif de proton que dans le cas du CH_3COOH. On compare les constantes de vitesse avec les valeurs prédites par diverses théories pour les collisions ion–molécule. On discute de la protonation en termes des énergies et des mécanismes de divers modes de dissociation.

[Traduit par le journal]

Introduction

Experimental studies of the gas-phase chemistry of the hydronium ion have not been extensive since its first observation in 1940 (1). This is somewhat surprising, particularly in view of the history of this ubiquitous ion in solution chemistry. The gas-phase measurements have generally been restricted to the kinetics and equilibria of three-body association reactions of the hydronium ion with H_2O molecules (2, 3). They were undertaken primarily to provide insight into fundamental aspects of the step-wise hydration of this ion, particularly as it is believed to proceed in and below the D-region of the earth's ionosphere (4, 5). The few measurements concerned with two-body reactions of H_3O^+ which have been reported were largely incidental to investigations directed towards the determination of the gas-phase proton affinity of H_2O (6), the systematic assessment of classical theories of ion–molecule collisions (7–9), and the identification of ion–molecule reactions which represent a sink for chlorofluoromethanes in the troposphere and stratosphere (10). We report here an extensive flowing afterglow study of the room-temperature kinetics and energetics of proton-transfer reactions of H_3O^+ which was undertaken primarily to provide a 'benchmark' for the solution chemistry of the hydronium ion and to set the stage for further gas-phase measurements designed to elucidate the influence of step-wise hydration on the chemical behaviour of H_3O^+ (11). Proton-transfer reactions of H_3O^+ are also of interest in several other diverse areas of chemistry including chemical ionization mass spectrometry (12), flame ion chemistry (13), and the ion chemistry of moist atmospheres (5).

Experimental

The majority of the measurements was carried out in a conventional flowing plasma mass-spectrometer (flowing afterglow) system which has been described previously (14). The reactant H_3O^+ ions were established in either a flowing helium or a flowing hydrogen plasma. Distilled water vapor was added to the helium upstream of the ion production region. In this mode the H_2O^+, OH^+, and H^+ ions produced, either directly by electron impact, or indirectly by reactions of helium ions and excited neutral atoms, undergo further reactions with H_2O to eventually produce H_3O^+. In a flowing hydrogen plasma H_3O^+ is established primarily by the fast proton-transfer reaction

$$[1] \qquad H_3^+ + H_2O \rightarrow H_3O^+ + H_2$$

with $k = (4.3 \pm 1) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} (15). In this case the distilled water vapor was added downstream of the ionizer in amounts sufficient to ensure the completion of reaction [1] prior to the reaction region further downstream.

A few of the measurements were carried out with the apparatus in the Selected Ion Flow Tube (SIFT) configuration modelled after the original design reported by Adams and Smith (16). In this configuration a differentially pumped quadrupole mass filter was interposed between the ion production and ion reaction regions. The H_3O^+ ions, after being produced in the conventional manner described above, were extracted from the ion production region through a 1 mm diameter orifice into the quadrupole mass filter which communicated

with the flow tube through a 5 mm diameter gas entrainment orifice. After injection into the flow tube at ca. 40 eV, the H_3O^+ ions were allowed to thermalize by collision before they entered the reaction region 106 cm further downstream. In this way we could avoid the introduction of ion types other than H_3O^+ into the reaction region. This procedure also eliminated H_2O, the parent gas of H_3O^+, from the reaction region.

The reactant neutrals were added into the reaction region as vapors either in their pure form or diluted with helium. The determination of their flows required separate viscosity measurements as has been described (17). Rate constants were determined in the usual manner from measurements of the $m/e = 19$ signal as a function of addition of vapor into the reaction region (14). Product ion signals were measured concomitantly. The operating conditions in these experiments encompassed total gas pressures, P, in the range 0.258 to 0.509 Torr, average gas velocities, $\bar{v}$, in the range 6.7 to 8.2 × 10^3 cm s^{-1}, effective reaction lengths, L, of the order of 60 and 85 cm and a gas temperature, $T = 298 \pm 2$ K.

The vapors were derived from the following liquids: CH_3OH, HCOOH, and $(CH_3)_2CO$ (BDH chemicals, Analytical Reagent Grade), C_2H_5OH (Consolidated Alcohols, Absolute), CH_3CHO (BDH chemicals, Laboratory Reagent Grade, 99.0% min.), $HCOOCH_3$ (BDH chemicals, 98%), CH_3COOH (Anachemia Chemicals, Glacial, 99.7%), and $(CH_3)_2O$ (Matheson, 99.8% (typical)). CH_2O was prepared by the low pressure distillation of paraformaldehyde (Fisher Scientific, Purified Grade) by an adaptation of the method of Spence and Wild (18). Ketene was prepared by the pyrolysis of acetone at ca. 800 K. The monomeric gas was purified by passing it through a cold trap at 250 K (CCl_4 slush) and collecting it as a liquid at 144 K (pentane slush).

The flows of formic acid and acetic acid were corrected for dimerization using the dissociation equilibrium constants K_p (Torr) = 2.704 and 0.5458 respectively, at 299 K (19, 20). This correction was based on the reasonable assumption that the dimers were present in their equilibrium amounts both in the storage bulbs and prior to their entry into the reaction region. A separate experiment was performed to determine the extent of dimerization in ketene vapor. The infrared spectrum of a sample of ketene vapor was recorded over a period of several days and was compared to those of the ketene monomer (21, 22) and dimer (23). Over the range of pressure and storage time of our experimental gas samples, the mole fraction of dimer in the vapor phase appeared to be negligible.

Results and Discussion

Kinetics of Proton Transfer

The rate constants measured in this study for the reactions of H_3O^+ with oxygen bases are given in Table 1 along with several others which have been determined previously in this laboratory. The majority of these reactions appeared to proceed simply by the transfer of a proton without concomitant decomposition of the protonated product but followed by its solvation, primarily with the parent base. For example, as is evident from Fig. 1, the reaction of H_3O^+ with HCOOH produced $HCOOH_2^+$ as the only primary product ion which then reacted further by solvation to form the proton-bound formic acid dimer, $HCOOH_2^+ \cdot HCOOH$, presumably via three-body association according to the reaction

$$[2]\quad HCOOH_2^+ + HCOOH + M \rightarrow HCOOH_2^+ \cdot HCOOH + M$$

where M is a stabilizing third body which is primarily H_2 in these experiments. The rise in the hydrated ion $HCOOH_2^+ \cdot H_2O$ may be attributed primarily to the reaction of the hydrated H_3O^+ with HCOOH (11).

Proton transfer was observed to proceed in all cases with the rate constants spanning a range in

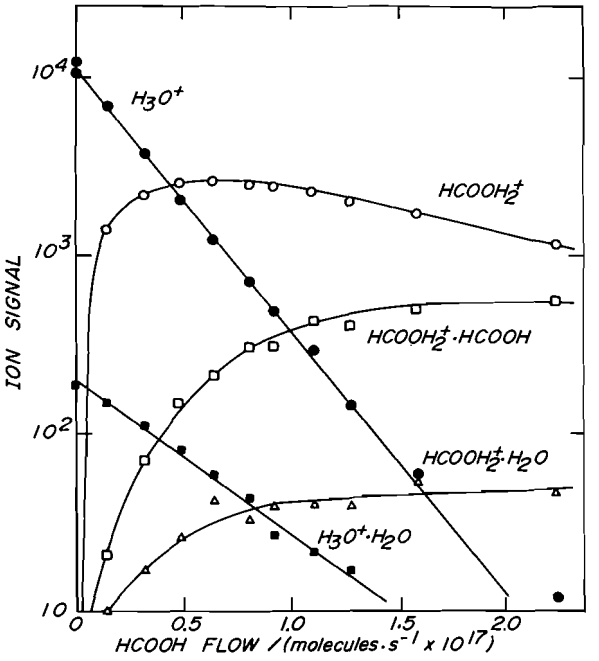

FIG. 1. The variation of the major positive ions observed upon the addition of formic acid vapor into a flowing H_2O–H_2 plasma in which H_3O^+ is initially a dominant ion. This decay of the H_3O^+ signal provides a rate constant of 2.4×10^{-9} cm^3 molecule^{-1} s^{-1}. $T = 298$ K, $P = 0.414$ Torr, $\bar{v} = 8.0 \times 10^3$ cm s^{-1}, and $L = 85$ cm.

values from 1.5 to 4.1×10^{-9} cm^3 molecule^{-1} s^{-1}. Surprisingly few other measurements are available for comparison. Interest in tropospheric and stratospheric ion chemistry prompted Fehsenfeld and co-workers to determine and report rate constants for the reaction of H_3O^+ with NH_3 for which (27) $k = (2.1 \pm 0.6) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} at 296 K, and with CH_2O and CH_3OH for both of which (28) $k = (2.2 \pm 0.9) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} at room temperature. These values are systematically lower than the corresponding values in Table 1, albeit there is agreement within the overall uncertainties reported for the two sets of measurements. The larger uncertainties associated with the reactions involving CH_2O and CH_3OH are attributed by these authors to the uncertainties associated with the measurement of the flow of these substances as vapors when derived from the liquid phase. The reaction of H_3O^+ with NH_3 has also been investigated with the ion cyclotron resonance technique by Huntress who reported (29) a value of $(2.20 \pm 0.12) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. The remaining rate constants in Table 1 appear not to have been determined previously by other workers.

Figure 2 compares the proton-transfer rate constants listed in Table 1 with the capture rate constants predicted by various ion–molecule collision theories: the Langevin theory which ignores the influence of the permanent dipole moment of the molecule (30), the average-dipole-orientation (ADO) theory (the $\overline{\cos\theta}$ model) (31), the theory of Barker and Ridge (32), and the locked-dipole limit (33). The permanent dipole moments, μ_D, were all taken from the compilation of Nelson *et al.* (34). The polarizabilities, α, for H_2S, CH_2O, HCN, CH_3CHCH_2, CH_3OH, $(CH_3)_2CO$, and NH_3 were taken from existing compilations (35–37). The mean polarizabilities of the remaining molecules were calculated from bond and group polarizabilities (36) to be 3.09, 5.2, 4.40, 5.17, 5.03, 4.56, 5.90, 6.04, and 4.12 Å^3 for HCOOH, CH_3NO_2, CH_3CHO, C_2H_5OH, CH_3COOH, CH_3CN, $HCOOCH_3$, $(CH_3)_2O$, and CH_2CO, respectively. It is apparent from Fig. 2 that proton transfer to these molecules from H_3O^+ proceeds with essentially unit probability, in concert with the behaviour reported previously for other analogous systems (38). The small deviation of the measured proton-transfer rate constants from the calculated capture rate constants which is evident from Fig. 2 is reminiscent of similar deviations observed previously in our laboratory for other proton-transfer reactions. Barker and Ridge (32) have also discussed the implications of these deviations. No new substantial insight is evident from the comparison reported here, but the results do provide an additional useful data base for the assessment of any future developments in theories of ion–molecule collision and reaction.

Dissociative Proton Transfer

Most of the reactions of H_3O^+ listed in Table 1 appeared to proceed simply by proton transfer to form predominantly (>99%) MH^+. Only with CH_3COOH did the primary product spectrum include substantial amounts of ions other than MH^+ with lower values of *m/e*, evidently because of the dissociation of MH^+ according to

$$[3] \qquad H_3O^+ + M \rightarrow [MH^+]^* + H_2O$$

$$[3a] \qquad [MH^+]^* \rightarrow \text{products}$$

where the internal energy required for the unimolecular decomposition of $[MH^+]^*$ is provided by the deposition of a substantial fraction of the excess energy which is in the form of reaction exothermicity. The extent to which this decomposition may be moderated under our experimental conditions by collisional stabilization of $[MH^+]^*$ is uncertain; the influence of the H_2 bath pressure on the primary product spectrum was not investigated systematically. The excess energy available in the form of reaction exothermicity is given by the difference in the proton affinity of H_2O and M which is included in Table 1. It is possible, therefore, using thermo-

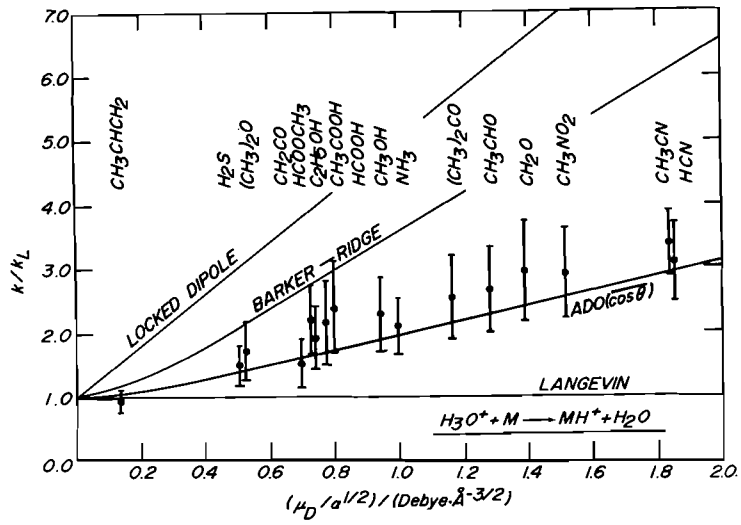

FIG. 2. A comparison of measured rate constants with capture rate constants predicted by various theories of collision for proton transfer reactions of H_3O^+ with polar molecules. The solid bars represent the estimated accuracy of the measurements. k_L is the collision rate constant determined from the Langevin expression.

TABLE 2. Energies (in kcal/mol) and energetically possible dissociative pathways

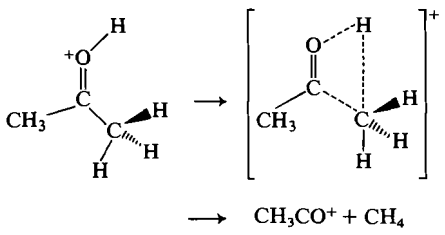
Molecule	Maximum excess energy available on protonation by H_3O^+	Possible dissociation reaction		
C_2H_5OH	20±4	$C_2H_5OH_2^+$	$\rightarrow C_2H_4OH^+ + H_2$	−18
$(CH_3)_2O$	24±5	$(CH_3)_2O^+H$	$\rightarrow CH_3CHOH^+ + H_2$	−9
			$\rightarrow CH_2OH^+ + CH_4$	−19
			$\rightarrow H_3O^+ + C_2H_4$	−23
$(CH_3)_2CO$	27±4	$(CH_3)_2C^+OH$	$\rightarrow CH_3CO^+ + CH_4$	−22
CH_3COOH	21±5	$CH_3COOH_2^+$	$\rightarrow CH_3CO^+ + H_2O$	0
HCOOH	12±5	$HCOOH_2^+$	$\rightarrow HCO^+ + H_2O$	−41
			$\rightarrow CO + H_3O^+$	−18
$HCOOCH_3$	22±5	$HCOO(CH_3)H^+$	$\rightarrow HCO^+ + CH_3OH$	−54
			$\rightarrow CH_3OH_2^+ + CO$	−16
			$\rightarrow CH_3CO^+ + H_2O$	−8

chemical data from the recent compilation of Rosenstock *et al.* (39), to calculate what dissociation reactions are feasible for each protonated base. The energetically possible dissociation pathways are listed in Table 2.

H_2 elimination from $C_2H_5OH_2^+$ to yield $C_2H_4OH^+$ (assumed to be protonated acetaldehyde) is, by analogy with vicinal elimination of H_2 from $CH_3OH_2^+$ (40), likely to have a kinetic barrier of approximately 20 kcal/mol and would therefore not be expected to occur. Furthermore, this mode of decomposition is not observed with the stronger acid HCO^+ (41).

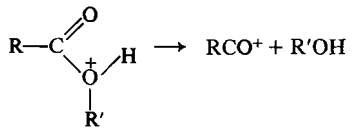
The only thermodynamically possible dissociation products of $(CH_3)_2OH^+$ require generation of carbon bonds. These can only be achieved by large skeletal rearrangements and the large barriers normally accompanying such rearrangements would not be expected to be overcome by the relatively low exothermicity of the initial proton transfer reaction.

Dissociation of protonated acetone to form methane and the acetyl ion is possible thermodynamically but is mechanistically unlikely as it requires protonation at the methyl carbon (calculation of the exothermicity of the proton-transfer reaction is for protonation at the most basic site, in this case the oxygen atom). Protonation at a saturated carbon is a high energy process, while the alternative process, a 1,3-shift of the proton from the oxygen to the carbon accompanied by synchronous fission of the carbon–carbon bond will also have a high barrier.

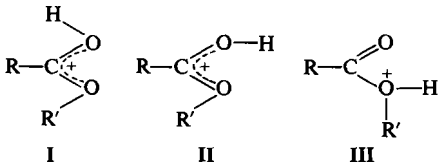


$\longrightarrow$ $CH_3CO^+ + CH_4$

Dissociative proton transfer to formic acid, acetic acid, and methyl formate should result in acylium ions and water or methanol via the $A_{Ac}1$ mechanism.



In the case of formyl derivatives subsequent proton transfer between HCO^+ and R'OH (R' = CH_3 or H) produces $R'OH_2^+$ and CO. However, this mechanism requires protonation at the energetically less accessible ether or hydroxy-oxygen. In solution two



I II III

tautomers of $HCOOH_2^+$ (42) have been detected by proton nmr but these have been assigned structures **I** and **II**, both rotamers of carbonyl protonated formic acid. Benoit and Harrison (43), using ionization energy correlations, predict that the proton affinities of the hydroxy-oxygens of formic acid and acetic acid will be 26 ± 3 and 27 ± 3 kcal/mol respectively lower than those of the corresponding carbonyl oxygens. *Ab initio* molecular orbital calculations (44) similarly predict hydroxy-protonation of formic acid (**III**, R = R' = H) to be 25 kcal/mol less stable than the carbonyl-protonated tautomer (structure **I**). The exothermicities listed in Table 2 are for formation of the most stable carbonyl-protonated rotamer and the hydroxy-protonated tautomers, required as intermediates in the $A_{Ac}1$ fission mechanism, can only be attained if the exothermicities of the initial proton transfer are at least 25 kcal/mol. Clearly, then, when the protonating acid is H_3O^+ the $A_{Ac}1$ mechanism is not accessible to formic acid and is barely possible, within the error limits, for acetic acid. The observed 5% dissociation of acetic acid and the total lack of dissociation for formic acid are then entirely consistent with this mechanism. Protonation by the stronger acid HCO^+ is sufficient to increase the dissociation of acetic acid to 20% but does not cause formic acid dissociation (45). The even stronger acid, H_3^+, results in complete dissociation of both acetic and formic acids.

Protonation of the methoxy-oxygen of methyl formate, using the ionization energy correlation method (43), only requires ca. 22 kcal/mol more energy than that of the carbonyl group. Hence, in the unlikely event of all the exothermicity appearing as internal energy in the protonated ester, gas-phase protonation by H_3O^+ may occur at either oxygen. However, dissociation by the $A_{Ac}1$ mechanism would formally produce HCO^+ and CH_3OH, a process requiring 54 kcal/mol, and is therefore not possible. The final products from this mode of fission, CO and $CH_3OH_2^+$, are within the exothermicity of the initial proton transfer and it is possible to envisage a second proton transfer reaction occurring synchronously with the cleavage of the C—O bond, thereby lowering the overall barrier to the reaction. There is little evidence (46) of such a lowering as the stronger acids HCO^+ and CH_5^+ (reaction exothermicities 45 and 57 kcal/mol, respectively) also do not produce dissociation.

Kinetics and mechanisms of some reactions of aqueous sodium bromite

C. L. LEE AND M. W. LISTER

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A7

Received September 7, 1978

C. L. LEE and M. W. LISTER. Can. J. Chem. **57**, 1524 (1979).

The kinetics of the reactions of aqueous bromite ions with basic aqueous solutions of iodide, sulphite, formate, and thiosulphate ions have been investigated. The products are, respectively, iodate, sulphate, and carbonate ions, and with thiosulphate either tetrathionate or sulphate depending on the conditions. The reaction with formate is autocatalytic, being catalysed by carbonate ions. All the reactions show some dependence on hydroxide concentration, and in general k(apparent) $= k_1 + k_2[OH^-]^{-1}$. The various rate constants have been obtained, as have the associated kinetic parameters. The relative rates of the reactions of bromite ions parallel those of the corresponding reactions of hypochlorite ions, but at 25°C K is smaller by a factor of roughtly 10^5.

C. L. LEE et M. W. LISTER. Can. J. Chem. **57**, 1524 (1979).

On a étudié la cinétique des réactions des ions bromites avec des solutions aqueuses basiques d'ions iodure, sulfite, formate et thiosulfate. Les produits sont respectivement les ions iodate, sulfate et carbonate; dans le cas du thiosulfate, on obtient soit du tétrathionate ou du sulfate suivant les conditions. La réaction avec le formate est autocatalytique puisqu'elle est catalysée par les ions carbonates. Toutes les réactions dépendent un peu de la concentration en ions hydroxyde et, d'une façon générale, k(apparent) $= k_1 + k_2[OH^-]^{-1}$. On a obtenu les diverses constantes de vitesse de même que les paramètres cinétiques qui leur sont associés. Les vitesses relatives des réactions des ions bromites sont parallèles à celles des réactions correspondantes des ions hypochlorites; toutefois, à 25°C, les vitesses sont plus faibles par un facteur de 10^5.

[Traduit par le journal]

Many investigations of the kinetics of groups of similar reactions have been made with the intention of relating the rate constants to other properties of the reagents, and thereby throwing some light on the details of the mechanisms of the reactions. Edwards (1, 2) applied this technique some time ago to the reactions of peroxides and it has, of course, been applied to many other reactions, both inorganic and organic. In particular, investigations of oxyhalogen ions have been made, in an attempt to discover whether the regularity of behaviour found for peroxides, and summarised in ref. 3, was duplicated elsewhere. Reactions of hypochlorous acid and hypochlorite ions (4, 5) with a series of reducing agents, and of hypobromous acid or hypobromite ions (6), have been investigated. There is evidently some similarity between the reactions of peroxides and of hypochlorites, and the same holds to a smaller degree with hypobromites.

The behaviour of the bromite ion is evidently of interest, both as a continuation of the above series, and also in itself, since it is an ion of which the chemistry has been studied relatively little. Its decomposition has been examined (7), and goes in several steps to bromate and bromide ions. The present paper deals with its reaction with various reducing ions, and as might be expected these reactions were all found to require at least two stages for completion. Comparisons with the reactions of other oxyhalogen ions will be made.

Experimental

Chemicals

Sodium Bromite

This was prepared as described in the earlier paper (7).

The following were all Fisher Scientific Co. certified reagent grade, with further treatment as noted.

Sodium Iodide

This was recrystallized once, and stock solutions were standardised by titration with silver nitrate.

Sodium Formate

This was recrystallized once, and stock solutions were standardised by titration with potassium permanganate.

Sodium Sulphite

To avoid the effect of any air oxidation, stock solutions were standardised just before use by adding excess iodine to an aliquot and titrating the excess with As_2O_3.

Sodium Thiosulphate

This was standardised by titration with iodine.

Sodium Hydroxide

The 50% solution was diluted as required.

Sodium Perchlorate

The Anachemia Chemical Company product was recrystallized, and dried to constant weight. Weighed amounts were added as required to control the ionic strength.

0008-4042/79/121524-07$01.00/0

Apparatus

In the experiments with iodide or formate ions, the appropriate solutions were mixed, and sealed in Pyrex glass ampoules. These were immersed in a silicone oil bath with the temperature controlled to ±0.02°C. At known times the ampoules were removed, rapidly cooled, and analysed as outlined below.

In experiments with sulphite or thiosulphate ions, a Durrum Stopped-Flow Spectrophotometer Model D110 was used. The wavelength drum was usually set to 296 nm, which is the absorption peak for bromite ions. The decay of the absorbance was followed on the oscilloscope. The final absorbance was also recorded by reactivating the oscilloscope after a sufficient interval of time. The time base was calibrated at intervals by pulses generated by a Tektronix, Type 184, Mark Time Generator. The temperature was controlled to ±0.05°C by a water bath surrounding the drive syringes.

Results

1. Reaction of Bromite and Iodide Ions

Preliminary experiments showed that the overall reaction in alkaline solution is

$$3BrO_2^- + 2I^- \rightarrow 3Br^- + 2IO_3^-$$

In the kinetic runs, solutions containing sodium bromite, iodide, hydroxide, and perchlorate were made up, kept at constant temperature, and at intervals the absorbances of the solutions were measured at wavelengths from 296 to 380 nm. The resulting spectra could not be explained on the assumption that only bromite and iodate ions were present as light absorbing species (the contribution of IO_3^- ions is very small). Various possible combinations of other absorbing species were examined, and it was found that good agreement with the observed spectra could be obtained, if it was assumed that absorbing species were bromite, hypoiodite, and triiodide ions. Previously published (8, 9) extinction coefficients were used. The concentration of hypobromite ions seemed to be negligibly small, presumably because, as was already known, they react rapidly with iodide ions.

During a typical run at 25°C with initial concentrations approximately: bromite 6.5×10^{-3} *M*, iodide 1.0×10^{-1} *M*, and hydroxide ions 5.0×10^{-2} *M*, the concentration of hypoiodite ions built up slowly to about 10^{-3} *M*, and triiodide ions (with a large extinction coefficient) to about 10^{-5} *M*. Triiodide ions are presumably formed by

$$IO^- + 2I^- + H_2O \rightleftharpoons I_3^- + 2OH^-$$

and the observed concentrations in the later stages of a run at 25°C, ionic strength 0.25 *M*, gave a roughly constant value for $[I_3^-][OH^-]^2/[IO^-][I^-]^2$ of 1.5×10^{-3}. It cannot be claimed that this is the equilibrium constant, since the concentrations are altering; however, it may be noted that Chia (ref. 10, see also ref. 14, p. 348) gave a value of 5×10^{-3} for this equilibrium constant at 25°C and zero ionic strength.

The concentrations of bromite ions were calculated from the absorbances on the assumption that hypoiodite and triiodide ions were the only other species contributing appreciably to the absorption. It was found that the concentrations fitted a rate law which was first order in both reagents, and if k is defined by

$$-\tfrac{1}{3}\frac{d[BrO_2^-]}{dt} = k[BrO_2^-][I^-]$$

this leads to

$$kt = \frac{1}{A}\ln\left(\frac{2x}{2x - A}\right) - \frac{1}{A}\ln\left(\frac{2x_0}{2x_0 - A}\right)$$

where $x = [BrO_2^-]$, initially x_0,

$$A = 2x_0 - 3[I^-]_0$$

k was obtained as the slope of the least mean squares line through the points in a plot of $(1/A)\ln(2x/(2x - A))$ against t.

The results are given in Table 1. The initial bromite concentrations ranged from 5 to 8×10^{-3}, in different runs, and runs were continued until about 50% of the original bromite remained. The initial iodide concentration varied from 8 to 12×10^{-2} *M*. In every case the ionic strength was 0.50 within 0.02. Values of k are given in Table 1, together with the standard deviation, σ_k, calculated in the usual way (11). These deviations are almost all in the range of 1 to 3%.

The value of k varies with hydroxide concentration, and a plot of k against $[OH^-]^{-1}$ was linear. If

16	44.4	0.1694	26.98	0.64

we write

$$k = k_1 + k_2[OH^-]^{-1}$$

the derived values of k_1, k_2 are given in Table 2. These lead to the following activation parameters, calculated for 35°C. k_1, $\Delta H_1^{\ddagger} = 48.5$ kJ mol^{-1}, $\Delta S_1^{\ddagger} = -169$ J K^{-1} mol^{-1}. The part of the reaction that depends on $[OH^-]^{-1}$ is probably a reaction of bromous acid. However, as thermodynamic data on the ionisation of bromous acid are not available, only an apparent $\Delta H^{\ddagger}$ can be calculated. Since the first reaction (k_1) is between two similarly charged ions, a negative $\Delta S_1^{\ddagger}$ might be expected, but the value found is surprisingly large, and suggests that other factors, such as orientation, must contribute to it.

The first step in the reaction is probably

$$BrO_2^- + I^- \rightarrow BrO^- + IO^-$$

for which ΔG^0 can be calculated from earlier data (7, 12) to be -44.6 kJ mol^{-1}; followed by the known reaction

$$BrO^- + I^- \rightarrow Br^- + IO^- \qquad \Delta G^0 = -53.3 \text{ kJ mol}^{-1}$$

Hypoiodite ions are known to decompose readily to iodate and iodide; although the direct reaction

$$BrO_2^- + IO^- \rightarrow Br^- + IO_3^-$$

is possible so far as ΔG^0 (-230 kJ mol^{-1}) is concerned.

2. Reaction of Bromite and Sulphite Ions

The overall reaction was (as might be expected):

$$BrO_2^- + 2SO_3^{2-} \rightarrow Br^- + 2SO_4^{2-}$$

The reaction was found to be first order in both reagents, which leads to the equation

$$kt = \frac{1}{B}\ln\left(\frac{2x}{2x - B}\right) - \frac{1}{B}\ln\left(\frac{2x_0}{2x_0 - B}\right)$$

where $x = [BrO_2^-]$, initially x_0

$$B = [2x_0] - [SO_3^{2-}]_0$$

k was obtained as the slope of the least mean squares line through the points on a plot of $(1/B)\ln(2x/(2x - B))$ against t.

The results are given in Table 3. The plots from which k was obtained were always good straight lines, as shown by the fairly small values of σ_k. It can be seen that k varies with $[OH^-]$, and it was found that k plotted against $[OH^-]^{-1}$ also gives a straight line. If we write $k = k_1 + k_2[OH^-]$, and take the slope and intercept to get k_2 and k_1, we obtain the results in Table 4. This table also gives the standard deviations of these constants.

These values make the activation parameters for k_1, $\Delta H_1^{\ddagger} = 44.3$ kJ mol^{-1}, $\Delta S_1^{\ddagger} = -85$ J K^{-1} mol^{-1}. As before, the part in k_2 is probably a reaction of bromous acid, and hence only an apparent rate constant and activation enthalpy can be calculated. The part in k_1 has a negative $\Delta S^{\ddagger}$ of a size that is reasonable for a reaction of ions of charge -1 and -2. The fairly small $\Delta H^{\ddagger}$ is also not sur-

prising, since the reaction

$$BrO_2^- + SO_3^{2-} \rightarrow BrO^- + SO_4^{2-}$$

which is presumably the first stage, has ΔH^0 equal to -326 kJ mol^{-1}, and $\Delta G^0 = -317$ kJ mol^{-1}, so it is a very exothermic reaction. It was already known (6) that the proposed second stage:

$$BrO^- + SO_3^{2-} \rightarrow Br^- + SO_4^{2-}$$

is rapid.

3. Reaction of Bromite and Formate Ions

Preliminary experiments showed that formate was oxidized to carbonate by the overall reaction:

$$BrO_2^- + 2HCO_2^- + 2OH^- \rightarrow Br^- + 2CO_3^{2-} + 2H_2O$$

It was also found that the rate of reaction accelerated at first before slowing down; see Fig. 1. This behaviour presumably arose from catalysis by the products, and experiment showed that carbonate, but not bromide, ions caused this acceleration. As will be seen later, the reduction in $[OH^-]$ would also speed up the reaction, but this would be a small effect. Accordingly a series of experiments was made in the virtual absence of carbonate, by adding barium nitrate which precipitated $BaCO_3$. The remaining solution was analysed for bromite.

The following mechanism is proposed for the reaction:

[*i*] $$2BrO_2^- \xrightarrow{k_1} BrO^- + BrO_3^-$$

[*ii*] $$BrO^- + BrO_2^- \xrightarrow{k_2} BrO_3^- + Br^-$$

[*iii*] $$BrO_2^- + HCO_2^- \xrightarrow{k_3} BrO^- + HCO_3^-$$

[*iv*] $$BrO^- + HCO_2^- \xrightarrow{k_4} Br_2^- + HCO_3^-$$

[*v*] $$HCO_3^- + OH^- \xrightarrow{k_5} CO_3^{2-} + H_2O$$

Reactions [*i*] and [*ii*] allow for the spontaneous decomposition of bromite ions, and the corresponding rate constants, k_1 and k_2 above, were already known (7). The rate constant for reaction [*iv*], k_4, was also known (6), and reaction [*v*], of course, is rapid. To apply this mechanism, if

$$x = [BrO_2^-] \quad y = [HCO_2^-] \quad z = [BrO^-]$$

then

$$-dx/dt = 2k_1x^2 + k_2xz + k_3xy$$

$$-dy/dt = k_3xy + k_4yz$$

$$-dz/dt = -k_1x^2 + k_2xz - k_3xy + k_4yz$$

Since our experiments indicated that hypobromite ions reacted considerably faster than bromite ions,

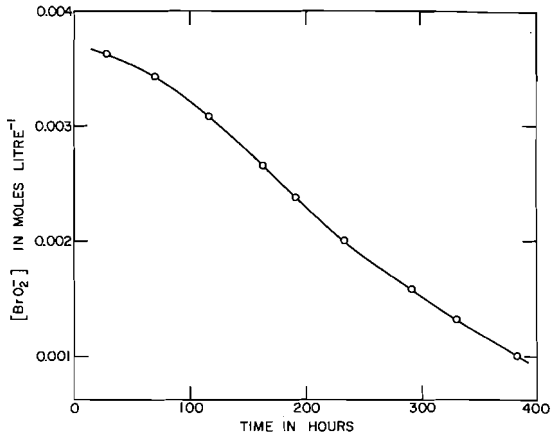

FIG. 1. $[BrO_2^-]$ plotted against time in a reaction of bromite and formate ions, without added carbonate or barium ions.

it was assumed that a steady state treatment could be applied to them; that is, $dz/dt = 0$. With this assumption these equations can be solved to give

$$q \ln \frac{x}{x_0} = -3\alpha\beta \ln \frac{\mu}{\mu_0} + \frac{n}{2\sqrt{m}} \times \ln \left\{ \frac{\mu\mu_0 + (\alpha+\beta-1)(\mu+\mu_0) + \sqrt{m}(\mu-\mu_0) + q}{\mu_0 + (\alpha+\beta-1)(\mu+\mu_0) - \sqrt{m}(\mu-\mu_0) + q} \right\} + \frac{\alpha+\beta}{2} \ln \left\{ \frac{\mu^2 + 2(\alpha+\beta-1)\mu + q}{\mu_0^2 + 2(\alpha+\beta-1)\mu_0 + q} \right\}$$

where $\mu = y/x$, initially μ_0; $\alpha = k_1/k_3$; $\beta = k_2/k_4$; $q = 3\alpha\beta - \alpha - \beta$; $n = \alpha^2 + \beta^2 - 4\alpha\beta + \alpha + \beta$; $m = \alpha^2 + \beta^2 - \alpha\beta - \alpha - \beta + 1$. In effect an iterative method was used in applying this equation, as follows. Since k_1, k_2, and k_4 were known from earlier work, only k_3 remained to be found. A value of k_3 was guessed, and hence x/x_0 could be calculated for any value of μ. The ratio of the changes in formate and bromite concentrations:

$$\frac{\Delta y}{\Delta x} = \frac{y_0 - y}{x_0 - x} = a$$

could thus be calculated. This quantity, the effective stoichiometry arising from all reactions, was found to be nearly constant in any one run; details are given in Table 5. If this quantity is constant, the differential equations can be solved to give

$$k_3t = \frac{1}{2ps} \left[(s+\alpha) \ln \left\{ \frac{r+s+p/x}{r+s+p/x_0} \right\} + (s-\alpha) \ln \left\{ \frac{r-s+p/x}{r-s+p/x_0} \right\} \right]$$

where

$$p = y_0 - ax_0$$
$$r = \alpha + \beta + a$$
$$s^2 = \alpha^2 + \beta^2 - \alpha\beta$$

If we define

$$g(x) = (1/2ps)[(s + \alpha)\ln(r + s + p/x) + (s - \alpha)\ln(r - s + p/x)]$$

the equation above is: $k_3t = g(x) - g(x_0)$. Consequently $g(x)$ was plotted against t. These plots were found to be linear, and the slope of the best line through the points, which equals k_3, was found by the usual method of least squares. The k_3 so obtained was in general somewhat different from the originally assumed k_3. The calculations were therefore repeated until k_3 did not change appreciably on further repetition. It was checked that the change in the effective stoichiometry, a, during a run did not appreciably alter k_3; in fact, use of the initial or final values of a during any one run was found to give values of k_3 differing by 0.1% or less. Hence a value of a corresponding to the middle of each run was used.

Table 5 gives details of the initial conditions of each run, and the calculated values of a and k_3. The ionic strength throughout was close to 0.26 ($\pm$0.02). The other rate constants used in the calculations were: for 85.7°C, $k_1 = 7.81 \times 10^{-6}$, $k_2 = 2.30 \times 10^{-3}$, $k_4 = 9.09 \times 10^{-4}/[OH^-]$; for 96.7°C, $k_1 = 2.53 \times 10^{-5}$, $k_2 = 5.34 \times 10^{-3}$, $k_4 = 1.74 \times 10^{-3}/[OH^-]$. Average values of k_3 are $(1.97 \pm 0.04) \times 10^{-6}$ at 85.7°C and $(4.00 \pm 0.17) \times 10^{-6}\ M^{-1}\ s^{-1}$ at 96.7°C. The precision is only moderate, in part because of the considerable spontaneous decomposition of sodium bromite. These constants, though only for two temperatures, make $\Delta H^{\ddagger} = 68 \pm 9$ kJ mol^{-1}, $\Delta S^{\ddagger} = -166 \pm 20$ J K^{-1} mol^{-1}.

A similar series of runs was carried out with a fairly high concentration (0.05 M) of sodium carbonate present. This did not increase much during a run, since the initial bromite concentrations were about ten times smaller. The same method was applied in analysing the results, and the initial concentrations, and calculated values of a and k_3 are given in Table 6. The ionic strength was the same as before. It is evident that these values of k_3 depend on $[OH^-]$. A plot of k_3 against $[OH^-]^{-1}$ was approximately linear. If we write

$$k_3 = k_5 + k_6[OH^-]^{-1}$$

and use the average $[OH^-]$ during the period of measurement then the usual least-squares method gives values of k_5 and k_6 as in Table 7.

The part of the reaction contributed by k_6 presumably arises from the reaction of $HBrO_2 + HCO_2^-$, or $BrO_2^- + HCO_2H$. As before, it is impossible to go further in terms of bromous acid, but data are available on formic acid (13) for its ionisation over the temperature range 0 to 60°C at 5°C intervals. From these ΔG^0 of ionisation can be calculated, and ΔS^0 from $-\partial\Delta G^0/\partial T$. ΔS^0 varies quite considerably, and approximately linearly, with temperature; the same is true of ΔH^0. The values of ΔS^0 and ΔH^0 were extrapolated to the temperatures of the kinetic measurements. Similar data on the ionisation of water (ref. 14, p. 39) are available for a wide range of temperature, and hence the equilibrium constant, K_{eq}, for

$$HCO_2^- + H_2O \rightleftharpoons HCO_2H + OH^-$$

was calculated at each of the temperatures used in the kinetic measurements with the results: T = 85.7°C, $K_{eq} = 3.70 \times 10^{-9}$; 91.0°C, 5.20×10^{-9}; 96.7°C, 7.46×10^{-9}. If we write this part of the overall rate as $k_7[BrO_2^-][HCO_2H]$, then $k_7 = k_6/K_{eq}$, and resulting values of k_7 are given in the last column of Table 7. The activation parameters obtained are: k_5: $\Delta H^{\ddagger} = 167(\pm 4)$ kJ mol^{-1}; $\Delta S^{\ddagger} = 120(\pm 12)$ J K^{-1} mol^{-1}; k_7: $\Delta H^{\ddagger} = 63(\pm 11)$ kJ mol^{-1}; $\Delta S^{\ddagger} = 36(\pm 30)$ J K^{-1} mol^{-1}. The relative large positive values of $\Delta S^{\ddagger}$ are perhaps unexpected, but the mechanism of the catalysis by carbonate is unknown. In deducing k_7 above it was assumed that

all this part of reaction came from formic acid; apart from the possibility of a reaction of bromous acid, it should be mentioned that catalysis by bicarbonate, as well as carbonate ions, might be considered.

4. Reaction of Bromite and Thiosulphate Ions

Preliminary experiments showed that at least two overall reactions were possible between bromite and thiosulphate ions. If the initial concentration of thiosulphate ions was about ten times that of bromite ions, the ratio of thiosulphate to bromite ions consumed was close to, though always a little less than, four. This corresponds to the reaction

[1] $BrO_2^- + 4S_2O_3^{2-} + 2H_2O \rightarrow Br^- + 2S_4O_6^{2-} + 4OH^-$

Moreover this value of the ratio was only approached at low hydroxide concentration (0.05 *M* or less). The hydroxide produced in the reaction was an amount corresponding to reaction [1] only if it was rapidly titrated with acid; on standing less hydroxide was found, and after roughly an hour or more, the ratio of hydroxide produced to bromite consumed was close to 1.0. Probably the cause of these effects was the alkaline hydrolysis of tetrathionate ions, reported (15) to occur by

$$4S_4O_6^{2-} + 6OH^- \rightarrow 5S_2O_3^{2-} + 2S_3O_6^{3-} + 3H_2O$$

At lower ratios (2.5 or less) of thiosulphate to bromite ions, and roughly 0.1 *M* sodium hydroxide, the ratio of thiosulphate to bromite consumed was 0.5. Tests showed that sulphate had been produced, and one OH^- had reacted for each BrO_2^- reacting. This agrees with the reaction:

[2] $2BrO_2^- + S_2O_3^{2-} + 2OH^- \rightarrow Br^- + 2SO_4^{2-} + H_2O$

Preliminary kinetic experiments were made on the stopped flow spectrophotometer, with concentrations such that reaction [1] would greatly preponderate. With initial concentrations approximately: $[BrO_2^-] = 0.007\ M$, $[S_2O_3^{2-}] = 0.09\ M$, and $[OH^-] = 0.05\ M$, and 25°C, the bromite concentration had fallen virtually to zero in 10 s. At this instant the spectrum of the remaining solution agreed with that of sodium tetrathionate; sodium thiosulphate has extinction coefficients about 100 times smaller at the wavelengths used, which ranged from 296 to 380 nm, and so it contributes very little to the total absorbance. The absorbance was followed at intervals for about 3 min after mixing, and over the period from 20 to 180 s, the tetrathionate concentration decreased by an apparently first order reaction with a rate constant of 0.0082 s^{-1}. Thus, over the period of measurement in the kinetic runs (10 s or less), only a very small amount of thiosulphate could have been regenerated by hydrolysis of tetrathionate, and this was therefore ignored.

In the main series of runs, the absorbance at 350

1.5	0.74	0.0798		

nm was followed. It was assumed that BrO_2^-, $S_2O_3^{2-}$, and $S_4O_6^{2-}$ contributed to the absorbance, and that the overall reaction was [1] above. Hence $[BrO_2^-]$ could be calculated for various time intervals. With thiosulphate in considerable excess, a plot of ln $[BrO_2^-]$ against t was found to be linear. The slopes of such plots were found by the usual method of least squares; the standard deviations in these slopes were always about 1%. By plotting these slopes against thiosulphate concentration (the concentration at the midpoint of the run was used), the rate was found to depend on the first power of the thiosulphate concentration. There was also a small spontaneous decomposition of bromite ions. The slope of the plots of $-\mathrm{d} \ln [BrO_2^-]/dt$ against mean $[S_2O_3^{2-}]$ are given in Table 8, as are also the mean $[OH^-]$ during each series of runs. These mean $[OH^-]$ values are averages of $[OH^-]$ at the midpoint of a series of runs with closely similar hydroxide concentration (the initial $[OH^-]$ were the same). There seems to be some dependence of rate on $[OH^-]$, but the differences are sufficiently small that, after allowing for the scatter in the points, the exact form of the dependence of rate on $[OH^-]$ cannot be deduced. If it is assumed that, as in other reactions, k(apparent) $= k_1 + k_2[OH^-]^{-1}$, then the values of k_1 and k_2 so obtained are also shown in Table 8. In obtaining k_1 and k_2 in Table 8, the points are weighted in proportion to the number of runs contributing to each point. The activation parameters are (for 25°C) k_1, $\Delta H_1^{\ddagger} = 33$ kJ mol^{-1}; $\Delta S_1^{\ddagger} = -120$ J K^{-1} mol^{-1}. The accuracy of these is not very high; perhaps for k_1, $\Delta H_1^{\ddagger} \pm 5$ kJ, $\Delta S_1^{\ddagger} \pm 20$ J K^{-1} mol^{-1}. However the general pattern of the reaction seems to be similar to other reactions of bromite ions.

Discussion

It is evident that bromite ions behave somewhat like the hypohalite ions as an oxidising agent, though they have the peculiarity that the reaction independent of $[OH^-]$ and that proportional to $[OH^-]^{-1}$ both contribute appreciably to the rate at ordinary hydroxide concentrations. This makes a detailed comparison difficult, but the following are all apparent rate k, for the rate proportional to $[OH^-]^{-1}$, for reactions at 25°C (extrapolated where necessary). Values of log k are given:

Oxidiser/reducer	SO_3^{2-}	I^-	HCO_2^-
ClO^-	3.93	1.96	−6.12
BrO_2^-	−0.92	−5.23	−10.73

The rates fall in the same order, with the bromite reactions about 10^5 slower. $\Delta H^{\ddagger}$ are also roughly parallel.

The reactions of bromite ions so far investigated were all first order in both reagents, and in the cases above are probably simple oxygen transfer reactions, followed by a similar reaction with hypobromite ions (or hypobromous acid). The reaction with thiosulphate is evidently complicated, and though it may also be an oxygen transfer reaction, at present this would simply be speculation.

Kinetic investigations of the hydrolysis of the 2-phenyl-4,4,5,5-tetramethyl-1,3-dioxolenium ion and 2-phenyl-2-methoxy-4,4,5,5-tetramethyl-1,3-dioxolane furnish rate constants for all three reaction stages of the ortho ester hydrolysis: (*1*) generation of the dioxolenium ion, (*2*) hydration of this ion to form hydrogen ortho ester, and (*3*) breakdown of this species to pinacol monobenzoate. The equilibrium constant for stage (*2*) can also be obtained. This study complements a previous investigation of 2-phenyl-2-alkoxy-1,3-dioxolanes where similar information was obtained.

The rate constants for carbonyl oxygen exchange of the ester products of these reactions, pinacol monobenzoate and ethylene glycol monobenzoate, have been measured. This reaction is shown to proceed by a different mechanism to that normally associated with exchange of carboxylic acid derivatives: cyclization of the glycol monoester to form hydrogen ortho ester, followed by loss of the labelled exocyclic OH group to give 1,3-dioxolenium ion. Reversal of these steps, initiated by an unlabelled water molecule, results in exchange. The relationship of this mechanism with that of the ortho ester hydrolysis is obvious; it is shown that the exchange provides rate constants for the reverse of stage (*3*). This means that both the forward and reverse rates of this process have been obtained, and this provides the equilibrium constant.

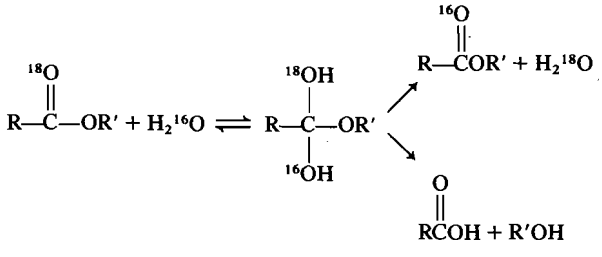
Des études cinétiques de l'hydrolyse de l'ion phényl-2 tétraméthyl-4,4,5,5 dioxolénium-1,3 et du phényl-2 méthoxy-2 tétraméthyl-4,4,5,5 dioxolanne-1,3 ont permis d'établir les constantes de vitesse pour chacune des trois étapes de l'hydrolyse des ortho esters: (*1*) formation de l'ion dioxolénium, (*2*) hydratation de cet ion conduisant à l'ortho ester acide et (*3*) décomposition de cette espèce en monobenzoate de pinacol. On a pu aussi obtenir la constante d'équilibre pour l'étape (*2*). Cette étude complète un travail antérieur sur les phényl-2 alkoxy-2 dioxolannes-1,3 qui a fourni des informations semblables.

On a mesuré les constantes de vitesse d'échange d'oxygène du carbonyle des esters produits au cours de ces réactions, soit le monobenzoate de pinacol et le monobenzoate de l'éthylène glycol. On montre que cette réaction se produit par un mécanisme différent de celui qui est normalement associé avec l'échange de dérivés d'acides carboxyliques: cyclisation du monoester du glycol avec formation d'une ortho ester acide, suivie par la perte du groupe OH exocyclique marqué conduisant à un ion dioxolénium-1,3. Les étapes inverses, provoquées par l'addition d'eau ne contenant pas de marqueur, conduisent à l'échange. La relation entre ce mécanisme et celui de l'hydrolyse des ortho esters est évidente; on montre que l'échange fournit les constantes de vitesse pour l'inverse de l'étape (*3*). Ceci signifie que l'on a déterminé les vitesses dans les deux sens de la réaction et que l'on peut évaluer la constante d'équilibre.

[Traduit par le journal]

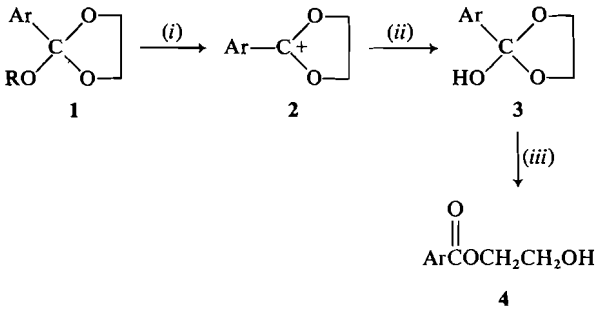
It has been established for some time now that the hydrolysis of carboxylic acid esters is accompanied by exchange of the carbonyl oxygen atom with solvent (1). This exchange occurs when the tetrahedral intermediate of this reaction returns to starting ester, rather than proceeds to product. The demonstration that hydrolysis is accompanied by such exchange is one of the principal pieces of evidence that there is a discrete tetrahedral addition intermediate in acyl transfer reactions (2).



In experiments involving the hydrolysis of 2-aryl-2-alkoxy-1,3-dioxolane ortho esters we have found that it is possible to observe all three reaction stages (3, 4), thus verifying the general mechanism commonly proposed for such reactions.

The ultimate product of this reaction, an ethylene glycol monobenzoate ester, has in principle an additional route available for carbonyl oxygen exchange, namely **4** → **3** → **2** → **3** → **4**, where a solvent water molecule comes in at the **2** → **3** reaction stage. This sequence is of course intimately related to

0008-4042/79/121531-10$01.00/0



1 2 3 4

the last two reaction stages of the ortho ester hydrolysis. Our results on this latter system lead to the prediction that this exchange reaction is a reasonable one. This paper presents that argument and experimental results obtained with ethylene glycol monobenzoate and pinacol monobenzoate.

Experimental

Materials

Oxygen-18 water (83.1% ^{18}O or 92.2% ^{18}O) was obtained from Miles Research. Sulfuric acid solutions were prepared as previously described (5). 2-Phenyl-2-methoxy-1,3-dioxolane (**1***a*) (6), 2-phenyl-1,3-dioxolenium borofluorate (**2***a*) (7), and 2-phenyl-4,4,5,5-tetramethyl-1,3-dioxolenium borofluorate (**2***b*) (8) have been described.

2-Phenyl-2-methoxy-4,4,5,5-tetramethyl-1,3-dioxolane (**1***b*) was obtained by addition of the dioxolenium salt **2***b* to a sodium methoxide solution in methanol, as described for other ortho esters (7). Compound **1***b* had bp 75°C (0.2 Torr); nmr($CDCl_3$, TMS) δ: 7.2–7.7 (m, 5H), 3.03 (s, 3H), 1.38 (s, 6H), 1.13 (s, 6H). *Anal.* calcd. for $C_{14}H_{20}O_3$: C 71.16, H 8.53; found: C 71.17, H 8.59.

Ethylene glycol monobenzoate, **4***a*, and pinacol monobenzoate **4***b*, were prepared by stirring the ortho esters **1***a* and **1***b* in 0.1 *M* HCl for 30 min. The acid was neutralized with $NaHCO_3$, and the resultant suspension was extracted with ether. This was dried ($MgSO_4$), filtered, and the ester obtained by distillation. Ethylene glycol monobenzoate had bp 100°C (0.2 Torr). Pinacol monobenzoate had bp 85°C (0.1 Torr); nmr ($CDCl_3$, TMS) δ: 8–8.2 (m, 2H), 7.5–7.6 (m, 3H), 3.7 (s, 1H), 1.70 (s, 6H), 1.35 (s, 6H). *Anal.* calcd. for $C_{13}H_{18}O_3$: C 70.25, H 8.16; found: C 70.13, H, 8.37.

Ethylene glycol monobenzoate-carbonyl-^{18}O (92.2%) and pinacol monobenzoate-carbonyl-^{18}O (83.1%) were prepared by mixing ortho ester **1***a* or **1***b* (0.01 mol) with ^{18}O-water (0.011 mol), and adding *p*-toluene sulfonic acid (10 mg). The two phase system was stirred until it became homogeneous. Work-up followed the procedure outlined above for the unlabelled glycol monoester.

Kinetics of Exchange

Labelled glycol monoester (0.2 g) was dissolved in unlabelled aqueous solution (100 mL for **4***a*, 500 mL for **4***b*), and the solution placed in a thermostatted water bath (25°C). After an appropriate time this solution was extracted with ether, the ether extract washed with aqueous $NaHCO_3$, dried ($MgSO_4$), filtered, and the ether removed.

This sample was analyzed directly on an AEI model MS 902 mass spectrometer, equipped with a Vacuumetrics ratiometer. The relative intensity of two peaks in the mass spectrum of the glycol monoester was determined as the average of 40–50 measurements. For ethylene glycol monobenzoate the ratio of the peaks at *m/e* 125/123 was taken; for pinacol monobenzoate, 166/164. Neither ester shows a molecular ion in its mass spectrum; both exhibited strong signals at 107/105, but the ratio of these was found to vary with time. This was not the case with the peaks chosen for analysis.

The excess ^{18}O in a given sample was calculated using the formula (9)

$$\text{Excess } ^{18}O = 99.8\left(\frac{R - R_0}{1.002 + R - R_0}\right)$$

where R is the ratio of the two peaks of the sample in question, and R_0 is the ratio of the same two peaks in unlabelled material. This equation corrects relative peak intensities for natural isotopic variation, but it applies to a sample where one atom only is enriched, a point which will be addressed later. Rate constants for oxygen exchange were evaluated as slopes of plots of ln (excess ^{18}O) versus time. Table 1 shows the results of a representative run.

Hydrolysis of Ethylene Glycol Monobenzoate

The ester was dissolved in aqueous sulfuric acid, and the solution placed in a thermostatted water bath (25°C). At appropriate times a sample was withdrawn and its nmr spectrum immediately recorded on a Varian T60 nmr spectrophotometer. The quantities measured were the (integrated) area of the set of signals of the methylene protons of the ester (A_E) relative to the area of the sharp singlet of the ethylene glycol product (A_p). Rate constants were calculated as the slopes of plots of ln ($A_E/(A_p + A_E)$) versus time.

Hydroxy Ester – Dioxolenium Ion Equilibrium

Ultraviolet Method

A stock solution containing 2-phenyl-1,3-dioxolenium borofluorate (4×10^{-5} mol L^{-1}) in rigorously dry acetonitrile was prepared. This solution (3.0 μL) was added directly to a thermostatted uv cell containing exactly 3 mL of various sulfuric acid solutions, and the spectral change recorded at 265 nm, the wavelength corresponding to λ_{max} for the ion. A first-order decrease in absorbance is observed (below 80% H_2SO_4); first-order rate constants were evaluated as the slopes of plots of ln ($A - A_\infty$) vs. time. A plot of the A_∞ values vs. % H_2SO_4 was found to take the form of a titration curve. Above 80% H_2SO_4 the 2-phenyl-1,3-dioxolenium ion is in fact stable, and undergoes no hydrolysis. This is caused by the fact that the dioxolenium ion (**2***a*) and glycol monoester (**4***a*) equilibrate. Their ratio at equilibrium [**2**]/[**4**] was determined as $(A_\infty - A^4)/(A^2 - A_\infty)$, where A^4 is the absorbance of ester at 265 nm as determined from the A_∞ value in dilute acid (below 50% H_2SO_4) and A^2 is the absorbance of ion at 265 nm as determined in concentrated acid (above 85% H_2SO_4).

The approach to equilibrium was also followed starting with ester, for which an increase in absorbance is observed at 265 nm in solutions more concentrated than 67% H_2SO_4. Rate constants for this process, obtained as the slopes of plots of ln ($A_\infty - A$) versus time were found to be identical to rate

TABLE 1. Oxygen exchange of pinacol monobenzoate-^{18}O in 0.100 *M* HCl (25°C)

[a]Labelled ester, before solution.

constants in the same acids obtained starting with dioxolenium ion.

Nuclear Magnetic Resonance Method

Ethylene glycol monobenzoate was dissolved in acids where the uv spectra suggest an appreciable concentration of ion at equilibrium. The formation of this ion could be easily seen from the appearance of a downfield singlet corresponding to the methylene protons of the ion. (This signal is not due to ethylene glycol, whose C—H protons are upfield from the methylene protons of the ester.) The ratio of ion to ester after attainment of equilibrium was calculated from the relative areas of the signals of the methylene protons in the two species. This ratio was within experimental error identical to the ratio obtained using uv spectroscopy.

Hydrolysis of Ortho Ester **1**b *and Ion* **2**b

In the pH region these species hydrolyze to pinacol monobenzoate. The kinetics for this hydrolysis were followed spectroscopically, using either a Unicam Sp 1800 spectrophotometer or a Durrum-Gibson stopped-flow apparatus. Studies involving the former were carried out by adding 3 μL of an acetonitrile solution of the substrate directly to a pre-equilibrated uv cell containing the aqueous solution. Studies with the latter were carried out by dissolving the substrate (ortho ester only in this case) in 0.002 *M* NaOH, and mixing this with an equal volume of the appropriate aqueous acid. In both cases changes in optical density as a function of time were monitored; wavelengths of 265 nm, λ_{max} for the dioxolenium ion, or 232 nm, λ_{max} for the ester product, were employed. First-order rate constants were evaluated as the slopes of plots of ln $(A - A_\infty)$ ($\lambda = 265$) or ln $(A_\infty - A)$ ($\lambda = 232$) versus time. All studies were carried out at 25°C, and ionic strength 0.1.

Results

2-Phenyl-4,4,5,5-tetramethyl-1,3-dioxolenium Ion

The above ion, as its borofluorate salt, was added in a very small amount of acetonitrile to aqueous solutions with pH 1.0–5.5, and the conversion to pinacol monobenzoate monitored by conventional uv spectroscopy. First-order rate constants for this process were obtained throughout this pH region following the absorbance increase due to the product ester at $\lambda = 232$ nm. In the more acidic solutions a signal due to the ion could also be seen at $\lambda = 265$ nm. First-order rate constants for the disappearance of this signal were also determined; these were found to be identical to the rate constants obtained following product appearance. The variation with pH of the observed rate constants will be described later. Buffer catalysis is also found; standard analysis reveals that both the acid and base component are catalytically active.

2-Phenyl-2-methoxy-4,4,5,5-tetramethyl-1,3-dioxolane

First-order rate constants for the hydrolysis of the above ortho ester were obtained following product appearance in solutions with pH > 6, and follow the rate law

$$k_{obs} = k_{H^+}{}^1[H^+] + k_0{}^1 + k_{HA}{}^1[HA]$$

with $k_{H^+}{}^1 = 3.1 \times 10^4\ M^{-1}\ s^{-1}$ and $k_0{}^1 \approx 1 \times 10^{-6}\ s^{-1}$. At pH 5–6, the first-order rate plots based on product appearance show marked deviations from linearity. At pH 1–5 the rate behaviour becomes identical in every respect to that observed with the 1,3-dioxolenium ion. This includes the fact that the ion itself can be detected in the more acidic solutions. Stopped-flow experiments, starting with the ortho ester in very dilute base and mixing with excess acid, show that this ion disappears in two phases (Fig. 1). The absorbance decrease which is observed in the experiments using conventional uv spectroscopy is preceded by a much faster decrease. This initial phase is also first order; rate constants follow the empirical equation $k_{obs} = a + b[H^+]$, with $a = 6 \times 10^2\ s^{-1}$ and $b = 2 \times 10^4\ M^{-1}\ s^{-1}$. The stopped-flow experiments also permit accurate measurement of the amount of dioxolenium ion which disappears in the two kinetic phases. A plot versus acidity of the absorbance change of the slow second phase divided by the total absorbance change takes the form of a titration curve for an acid with a pK value of 1.4, with the slow phase accounting for a greater proportion at high acid concentrations.

Hydroxy Ester – Dioxolenium Ion Equilibrium

The equilibrium between the 2-phenyl-1,3-dioxo-

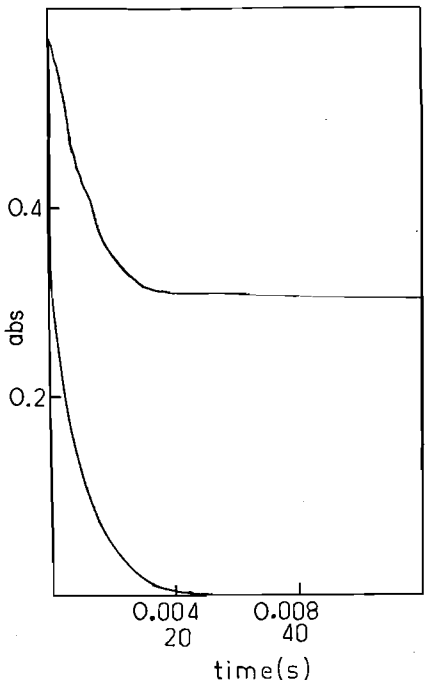

FIG. 1. Biphasic nature of the disappearance of dioxolenium ion ($\lambda = 265$) in the hydrolysis of 2-phenyl-2-methoxy-4,4,5,5-tetramethyl-1,3-dioxolane in 0.02 *M* HCl. The two traces were obtained in consecutive runs on the stopped-flow apparatus. The top and bottom timescales refer to the top and bottom traces respectively.

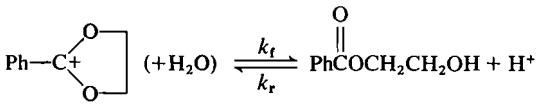
lenium ion and ethylene glycol monobenzoate was studied in 67–77% H_2SO_4 by determining



2 4

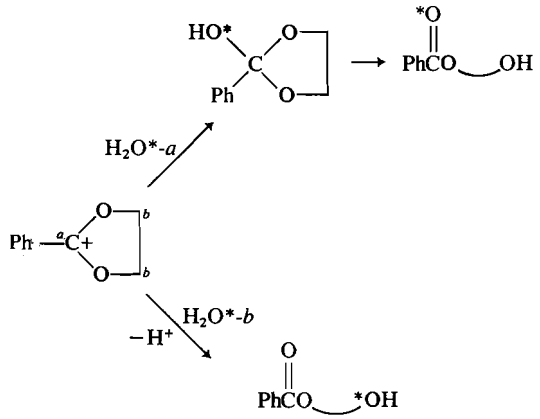
using uv and nmr spectroscopy, the ratio [**2**]/[**4**] as a function of acidity. A plot of the logarithm of this ratio versus the H_R acidity function was linear (correlation coefficient = 0.998), with a slope = −0.71 and an intercept of −8.68.

First-order rate constants could also be obtained for the approach to equilibrium, and are the same regardless of the direction of approach. These rate constants are given by $k_{obs} = k_f + k_r$; the ratio [**2**]/[**4**] = k_f/k_r, so that the individual rate constants k_f and k_r can be obtained. These are depicted in Fig. 5 (see Discussion).

Oxygen Exchange

Samples of the two glycol monoesters enriched with ^{18}O were prepared by hydrolyzing the corresponding ortho ester with ^{18}O enriched water, in the presence of a small amount of acid. It is important to establish that this reaction has produced only carbonyl labelled ester. This is obviously required if we are going to follow carbonyl exchange, and not some other process. We also require in the equation used to calculate ^{18}O content that any excess ^{18}O be present in only one oxygen. Finally and perhaps most importantly, our mechanistic interpretation of these ortho ester hydrolyses demands this result.

In principle the label could end up in two different oxygens.



The peaks analyzed in the mass spectrum of each ester were fragments arising from loss of a group containing the hydroxyl oxygen. The analysis shows that all of the label of the reagent ^{18}O water is still present in these peaks, and therefore could not have gone into the β-hydroxy oxygen. For example 83.1% ^{18}O-water was used to prepare the labelled pinacol monobenzoate; the 166/164 fragment peaks analyzed show 83.0% label (see Table 1).

A second piece of evidence, perhaps less rigorous, is the observation that the label can be completely exchanged out with a large excess of unlabelled solvent (see, for example, Table 1). As we will show, there is a mechanism by which this can occur if the label is in the carbonyl oxygen. It is more difficult to account for this exchange if the label is in the hydroxy oxygen, since alcohol exchange is far too slow (10).

The labelled esters do exchange this oxygen when treated with unlabelled aqueous acid. Unlike ordinary esters, this exchange process occurs more rapidly than the ester undergoes hydrolysis and it is in fact possible to observe essentially complete exchange before the ester is completely destroyed. A typical exchange run is presented in Table 1. Excellent first-order plots for the exchange were obtained in all cases. The acid dependency of these rate constants is described in the Discussion.

Discussion

Ortho Ester Hydrolysis

We will discuss initially how it is possible to obtain kinetic information for the three reaction stages for the hydrolysis of the tetramethyl substituted ortho ester. Our results, and analysis, for the unsubstituted system are presented elsewhere (3, 4). Although the same kinetic information is eventually obtained in each case, experimentally slightly different approaches are used. This happens simply because in the tetramethyl system the rate of the last reaction stage is in the range of conventional uv spectroscopy. This means that it is possible to add the 1,3-dioxolenium ion directly to a uv cell, and observe the kinetics associated with the last reaction stage, in essentially a pure aqueous medium. With the unsubstituted ortho esters the later reaction stages are too fast for conventional uv spectroscopy, although they are in the range of stopped-flow instruments. However, because of the nature of our apparatus which mixes only in a 50:50 proportion, experiments starting directly with dioxolenium ion result in rate constants in a solvent which is 50% organic. To obtain rate data in water alone we were forced to rely on the fact that appropriate precursors which are stable in aqueous base hydrolyze at some acidity with rate-determining decomposition of the hydrogen ortho ester (3, 4).

First-order rate constants obtained in the hydrolysis of the 2-phenyl-4,4,5,5-tetramethyl-1,3-dioxolenium ion are depicted in Fig. 2. These, along with

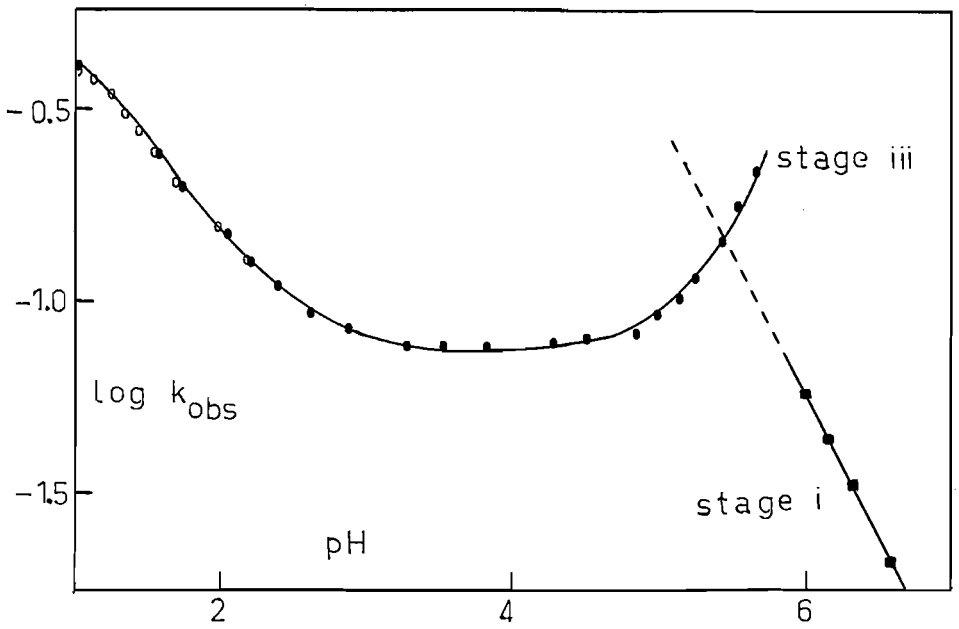


FIG. 2. First-order rate constants (μ = 0.1, 25°C) in the hydrolysis of 2-phenyl-4,4,5,5-tetramethyl-1,3-dioxolenium borofluorate ((●) λ = 232 nm; (○) λ = 265 nm, slow phase) and 2-phenyl-2-methoxy-4,4,5,5-tetramethyl-1,3-dioxolane ((■) λ = 232 nm). Rate constants for experiments starting with the ortho ester in solutions with pH < 5 are not shown but are identical, within experimental error, to those of the dioxolenium ion. All rate constants for solutions with pH > 3 are based on extrapolation to zero buffer concentration.

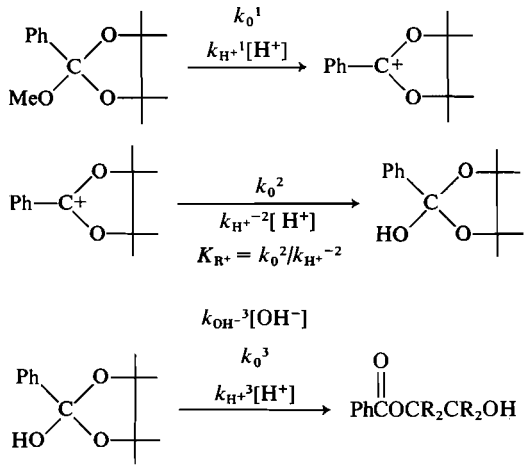
other observations, can be explained by postulating a rapid and reversible hydration of the ion followed by a slower decomposition of the hydrogen ortho ester to pinacol monobenzoate. This latter process is catalyzed by hydronium ion, water (no catalysis), and hydroxide ion, as well as general acids and general bases. We will define the rate constants for the three stages of a dioxolane ortho ester hydrolysis as indicated below.



For the last two stages, the following rate law can be derived, assuming a rapid equilibrium between dioxolenium ion and hydrogen ortho ester. The

$$k_{obs} = \frac{k_{H^+}{}^3[H^+] + k_0{}^3 + k_{OH^-}{}^3[OH^-]}{1 + [H^+]/K_{R+}}$$

observed first-order rate constant k_{obs} refers to formation of pinacol monobenzoate, and the disappearance of the ion present after the equilibrium between ion and hydrogen ortho ester is established. Values of the four constants of this equation which best fit the experimental data of Fig. 2 are given in Table 2. The agreement of our kinetic analysis with

the experimental observations can be seen by comparing in Fig. 2 the curve, which is calculated, with the experimental points. In simple terms the rate–pH profile exhibits regions corresponding to the hydronium ion catalysis, water catalysis, and hydroxide ion catalysis of the hydrogen ortho ester decomposition. Also a levelling off in rate at high acid concentration is apparent. This occurs because of a shift in the position of the equilibrium between the hydrogen ortho ester and dioxolenium ion, the latter species becoming favored in this equilibrium as the acidity is increased. In the solutions where significant amounts of dioxolenium ion and hydrogen ortho ester are present at equilibrium, the ion disappearance is biphasic. The initial kinetic phase corresponds to the rapid equilibration of the two species. This is followed by a considerably slower second phase as the ion in equilibrium with hydrogen ortho ester is siphoned off as the latter is converted to pinacol monobenzoate. In the experiments starting with the borofluorate salt of the ion, only the second phase is seen. These experiments are necessarily carried out on a conventional uv spectrophotometer, and are incapable of showing the much more rapid initial phase. In less acidic solutions, no uv signal due to the ion can be observed in these conventional uv experiments. Now the equilibrium favors hydrogen ortho ester, and the ion completely disappears in the rapid phase. However, although the ion does disappear rapidly, the appearance of product is much slower. This can only mean that there is some intermediate being formed and this must be the hydrogen ortho ester.

Considering now the situation starting one stage further back at the ortho ester, it can be concluded that only in solutions with pH > 6 is the first reaction stage the slow step in the overall hydrolysis. In more acidic solutions this stage becomes faster than the third stage, and what is observed (following product appearance) are the kinetics associated with this later stage. In other words, there is a change in the rate-limiting step in the overall hydrolysis, just as there is in the unsubstituted case (3, 4). Here, however, the evidence is very simple. In the more acidic solutions the kinetic behavior observed starting with ortho ester is identical to that observed starting with dioxolenium ion, one of the intermediates in its hydrolysis. Above pH 6 this is no longer the case, and the dioxolenium ion decomposes more rapidly than the ortho ester hydrolyses. The crossover in behavior is seen very clearly in Fig. 2, in the intersection of the two curves, the curve obtained at high pH representing the first stage, and the curve obtained at low pH representing the third stage. The reason for the changeover is also apparent; the first stage remains hydronium ion catalyzed throughout this pH region, whereas the third stage is catalyzed by water and hydroxide ion as well. It can also be noted that in the vicinity of the crossover point, first-order kinetics in product appearance are not obtained. The system is properly described here by the equations for two consecutive first-order reactions (see ref. 4 for a more detailed discussion of this point).

Stopped-flow experiments starting with ortho ester (Fig. 1) reveal the two step nature associated with the disappearance of the dioxolenium ion in the more acidic solutions. First-order rate constants for the initial phase must follow the rate law

$$k_{obs} = k_0^2 + k_{H^+}{}^{-2}[H^+]$$

so that the empirically determined constants $a = k_0^2$ and $b = k_{H^+}{}^{-2}$. The ratio $k_0^2/k_{H^+}{}^{-2}$ should also give pK_R and, in fact, the value so determined agrees well with that obtained in the kinetic analysis (Table 2).

A third measure of the value of pK_R, also in agreement, is produced by the titration curve representing the variation in the absorbance in the two kinetic phases. This is essentially a standard

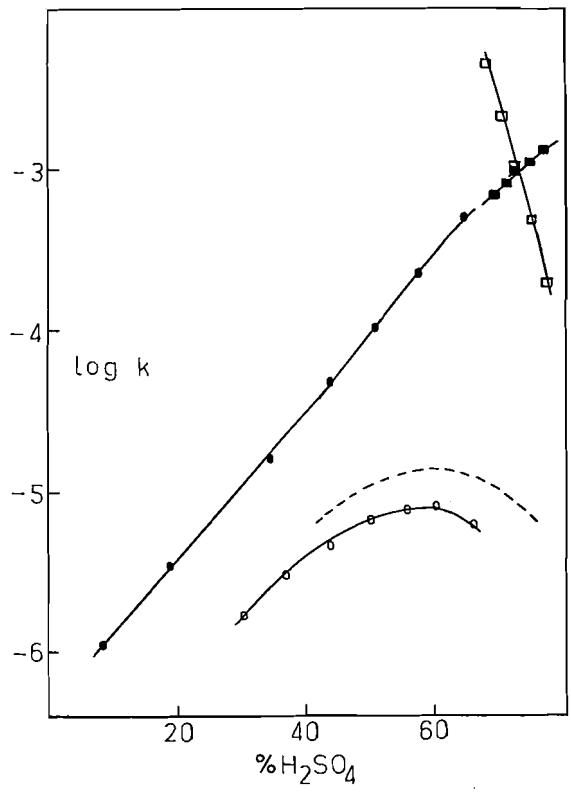

FIG 3. Rate constants for ethylene glycol monobenzoate. (●) Carbonyl oxygen exchange, (○) hydrolysis, (■) and (□) forward and reverse rate constants for the reversible cyclization to the 2-phenyl-1,3-dioxolenium ion, (--) rate constants for methyl benzoate hydrolysis (13).

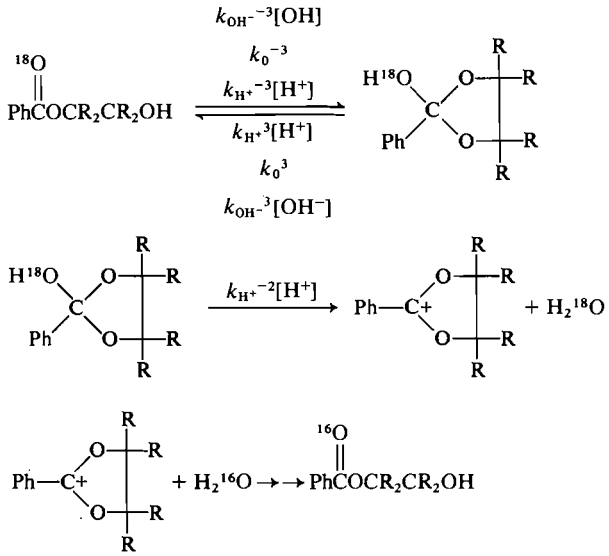
spectroscopic approach, and is described in detail elsewhere (4).

Table 2 also contains values of the rate and equilibrium constants obtained for the unsubstituted system. The introduction of the four methyl substituents results in a 5–6-fold increase in the rate of the first reaction stage, as well as the reverse of stage 2. This is probably due to increased steric strain in the ortho ester (or hydrogen ortho ester), relative to the dioxolenium ion, brought about by the presence of the four methyl groups. This substitution also results, undoubtedly for the same reason, in a decrease by a factor of 28 in the rate constant for hydration of the ion. The combined effects result in a change in pK_R by 1.9 log units. That the steric effect is manifested more in the hydration direction (k_0^{-2}) than the dehydration direction ($k_{H^+}^{-2}$) implies that the transition state lies closer to the hydrogen ortho ester. This suggestion is consistent with previous observations of ortho ester hydrolysis, which imply an 'early' transition state in the reaction proceeding to the oxocarbonium ion (11, 12).

Carbonyl Oxygen Exchange

The cyclization mechanism for carbonyl oxygen exchange of a labelled glycol monoester is shown below, where for consistency we have maintained the same formulism for the rate constants.



Under our experimental conditions, which involve the use of a large excess of unlabelled solvent, any dioxolenium ion that forms is trapped by unlabelled water. Thus we can assume that exchange occurs via the above mechanism whenever β-hydroxy ester is converted to dioxolenium ion. To observe this exchange there are two requirements: (*a*) hydrogen ortho ester formed on cyclization of the β-hydroxy ester must have some tendency to proceed on to dioxolenium ion, rather than revert immediately back, and (*b*) the cyclization reaction, which involves intramolecular addition of an OH group, must be able to compete with normal hydrolysis, i.e., the intermolecular addition of an OH group. It can immediately be predicted that in acid solutions, where the reversion of the hydrogen ortho ester to hydroxy ester occurs with acid catalysis, requirement (*a*) is met. As seen in our results on the ortho ester hydrolysis, acid-catalyzed ring opening of the hydrogen ortho ester is considerably slower than the acid-catalyzed cleavage of the exocyclic OH group ($k_{H^+}^{-2} > k_{H^+}^{3}$, Table 2).

Ethylene Glycol Monobenzoate

Figure 3 plots first-order rate constants for the carbonyl oxygen exchange of ethylene glycol monobenzoate as a function of sulfuric acid concentration. We suggest that these rate constants do represent the cyclization mechanism for exchange. The most convincing argument for this proposal comes from our observation that in acids more concentrated than 67% H_2SO_4 there is a detectable amount of the 2-phenyl-1,3-dioxolenium ion present in equilibrium with the hydroxy ester, and we have been able to measure the forward and reverse first-order rate constants associated with this equilibration. One of these rate constants refers specifically to the rate of formation of the 1,3-dioxolenium ion from the ester. We have pointed out that the cyclization exchange involves this very reaction. As can be seen in Fig. 3 there are two curves, one obtained in dilute acids for carbonyl oxygen exchange, and the other obtained in more concentrated acids where the cyclization is actually observed. Within experimental error these two curves are continuous functions of one another.

Another observation of significance is that the rate constants for exchange are greater than the rate constants for the hydrolysis. In all other examples of acid-catalyzed ester hydrolysis thus far investigated the reverse has been true (1, 2, 10, 13–17). Ethyl benzoate, for example, in 0.1 *M* HCl (33% dioxane:H_2O) exchanges its carbonyl oxygen one-fifth as fast as it hydrolyzes (1, 14). As can be seen in Fig. 3 the hydrolysis of ethylene glycol monobenzoate is in fact normal; its kinetic behavior is very similar to that shown in the hydrolysis of methyl benzoate (13). It is the exchange reaction of ethylene glycol monobenzoate which is abnormally rapid, and this occurs because of the different mechanism.

Also significant is a comparison of the rate profiles for hydrolysis and exchange. For the simple esters investigated in detail thus far (ethyl acetate (13) and isopropyl acetate (16)), the ratio of the rates of

hydrolysis and exchange has been found to be essentially constant as the sulfuric acid concentration is changed. For ethylene glycol monobenzoate, however, this is not the case, the ratio of exchange to hydrolysis increasing by a factor of about 10 over the range of acidities for which both processes were investigated. This can be accounted for in terms of two different mechanisms for the two processes.

The comparison can in fact be put on quantitative terms based on the following expressions for the first-order rate constants.

$$k_{ex} = \frac{k_{ex}^{0}}{K_{SH^+}} \frac{f_s a_{H^+}}{f_{s^*}^{ex}}$$

$$k_{hyd} = \frac{k_{hyd}^{0}}{K_{SH^+}} \frac{f_s a_{H_2O} a_{H^+}}{f_{s^*}^{hyd}}$$

These equations are obtained by assuming that the reactions occur by way of the protonated ester; all of the terms are defined in the normal way (17, 18). We have explicitly included in the expression for the hydrolysis rate constant the activity of water, this term representing the external water molecule which must be involved in this reaction. Dividing these equations, and taking logarithms, there is obtained the equation

$$\log k_{ex} - \log k_{hyd} = \log k_{ex}^{0} - \log k_{hyd}^{0} - \log a_{H_2O} + \log (f_{s^*}^{ex}/f_{s^*}^{hyd})$$

In fact, a plot of $\log k_{ex} - \log k_{hyd}$ versus $-\log a_{H_2O}$ is linear, with a slope of 1.05 (Fig. 4). This implies that $\log (f_{s^*}^{ex}/f_{s^*}^{hyd}) \approx 0$, or, in other words, that the activity coefficients for the two transition states vary with acidity in the same way. As will be shown in a later section, the rate of exchange in acid solutions is essentially equal to the rate of cyclization, so that $f_{s^*}^{ex}$ refers to the reaction of protonated carbonyl with the β-hydroxy group. Since in normal esters hydrolysis occurs more rapidly than exchange, the rate of formation of the hydrolysis tetrahedral intermediate is rate determining in that reaction, so that $f_{s^*}^{hyd}$ can be taken to refer to the reaction of the protonated carbonyl with a water molecule. Therefore, the two transition states are in fact very similar, the only difference being that one involves reaction with an internal nucleophile, while the other involves reaction with an external nucleophile. It is only necessary in considering the latter case to account explicitly for the activity of this nucleophile.

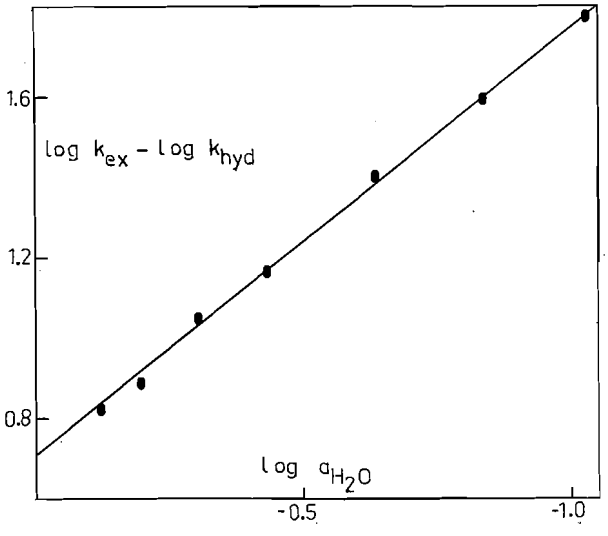


FIG. 4. Log k_{ex} − log k_{hyd} for ethylene glycol monobenzoate plotted as a function of log a_{H_2O}.

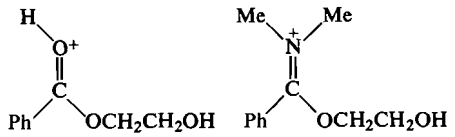
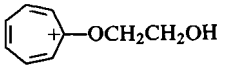
The intercept of Fig. 4 provides the relative rates in water of the intramolecular and intermolecular reactions. This is compared below with the same ratio for two related systems recently studied in our laboratories.



$\frac{k_{intra}}{k_{inter}}$ 5 ≈40 (ref. 19)



4.5 (ref. 20)

In all three cases the intramolecular reaction is favored, but the preference for it is not that great.

Pinacol Monobenzoate

With this ester, the exchange reaction is sufficiently rapid in the pH region that an extensive rate–pH profile could be obtained (see Fig. 5). Rates of hydrolysis were not determined; using data for *tert*-butyl benzoate (21), we estimate that in 0.1 *M* HCl the exchange of pinacol monobenzoate occurs 10 times more rapidly than its hydrolysis. Moreover, even if hydrolysis did occur, the normal carbonyl oxygen mechanism would still not be in operation, since this ester, being a tertiary ester, would probably hydrolyze by an $A_{A1}1$ mechanism (21). There can be little doubt then that the exchange observed arises via cyclization.

To account for the rate–pH profile we note that the rate of exchange can be set equal to the rate of formation of dioxolenium ion, and calculate this rate making a steady-state assumption in hydrogen ortho ester.

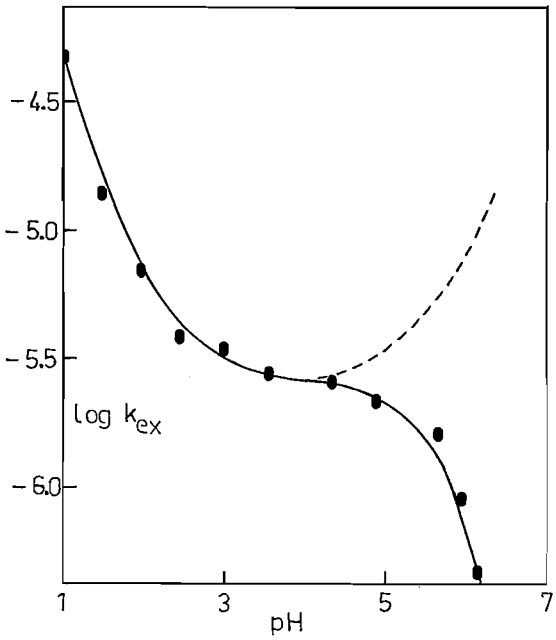


FIG. 5. Rate constants for the carbonyl oxygen exchange of pinacol monobenzoate (25°C, $\mu = 0.1$). The points are experimental, while the solid curve is calculated (see text). The dashed curve, which merges with the solid curve below pH 3.5, represents the variation in the rate constant for the cyclization step as a function of pH.

[1] $$k_{ex} = \frac{k_{H^+}{}^{-2}[H^+](k_{OH^-}{}^{-3}[OH^-] + k_0{}^{-3} + k_{H^+}{}^{-3}[H^+])}{k_{OH^-}{}^{3}[OH^-] + k_0{}^{3} + (k_{H^+}{}^{3} + k_{H^+}{}^{-2})[H^+]}$$

Although several rate constants not already obtained appear in this expression, there is in fact only one new unknown, since

$$k_{OH^-}{}^{-3}/k_{OH^-}{}^{3} = k_0{}^{-3}/k_0{}^{3} = k_{H^+}{}^{-3}/k_{H^+}{}^{3} = K^{-3}$$

Taking this into account, and rearranging

[2] $$K^{-3} = \frac{k_{ex}((k_{OH^-}{}^{3}[OH^-] + k_0{}^{3} + (k_{H^+}{}^{3} + k_{H^+}{}^{-2})[H^+])}{k_{H^+}{}^{-2}[H^+](k_{OH^-}{}^{3}[OH^-] + k_0{}^{3} + k_{H^+}{}^{3}[H^+])}$$

Values of K^{-3} obtained from this equation, using the rate constants of Table 2 are indeed constant, with a value of $K^{-3} = 3.7 \pm 0.5 \times 10^{-5}$. This can be used to calculate values for the three constants of the form k^{-3} (Table 2). The consistency of our analysis is seen in Fig. 5 from the agreement of the experimental data with the solid curve which has been calculated using [1].

In simple terms, this kinetic analysis can be broken down, showing that at pH 1–3.5 the carbonyl exchange is occurring with rate-determining cyclization, and $k_{ex} \approx k_{H^+}{}^{-3}[H^+] + k_0{}^{-3}$. The rate–pH profile contains an acid-catalyzed region giving way to a pH independent region. In these acidic solutions the hydrogen ortho ester has a large preference for cleavage of the exocyclic hydroxyl group over ring-opening to return to glycol monoester. Exchange therefore results on virtually every act of cyclization. In the pH region 3.5–4.5 there is, however, a change in rate-determining step. This occurs because the conversion of hydrogen ortho ester to glycol monoester becomes water catalyzed, and then hydroxide ion catalyzed, while its conversion to dioxolenium ion remains hydronium ion catalyzed. By about pH 5.0 the hydrogen ortho ester reverts to ester more readily, and the rate-limiting step in the exchange is the conversion to the dioxolenium ion. The rate constant for exchange is now given by $k_{ex} = K^{-3}k_{H^+}{}^{-2}[H^+]$ and the reaction now becomes acid-catalyzed again. It is interesting to note that the cyclization stage has, in fact, become hydroxide ion catalyzed by this point. This is seen by the dashed line in Fig. 5 which represents $k_{OH^-}{}^{-3}[OH^-] + k_0{}^{-3} + k_{H^+}{}^{-3}[H^+]$, and gives therefore the rate constant for cyclization. We can also point out that the exchange reaction should become pH independent at high pH, where the loss of the exocyclic OH group becomes non-catalyzed ($k_{ex} = K^{-3}k_0{}^{-2}$, where $k_0{}^{-2}$ = pH independent rate constant). That this process should occur can be predicted on the basis that a very similar reaction, the loss of the exocyclic OMe group from the ortho ester, becomes pH independent at high pH.

Glycol Monoester–Hydrogen Ortho Ester Equilibrium

For ethylene glycol monobenzoate, carbonyl oxygen exchange in dilute acids is very slow. We did obtain one rate constant in 0.1 *M* HCl (8.0×10^{-8} s^{-1}); using [2] this provides a value of $K^{-3} = 2.7 \times 10^{-9}$. This then allows the determination of the values for the constants k^{-3} (Table 2).

For both monobenzoates, the calculation of K^{-3} in acids as concentrated as 0.1 *M* HCl is, in fact, simpler than it seems on the basis of [2], since the terms in hydronium ion dominate, and $k_{H^+}{}^{3} < k_{H^+}{}^{-2}$. This means that essentially we are obtaining K^{-3} in this solution as the ratio of forward and reverse rate constants. This is possible despite the instability of the hydrogen ortho ester, since this species can be observed, starting with an appropriate precursor, and its rate of decomposition measured (the reverse rate). The forward process cannot be observed; we can, however, measure its rate using ^{18}O exchange.

The hydrogen ortho ester can be regarded as a tetrahedral intermediate, being the intermediate of a

degenerate intramolecular acyl transfer reaction. Although the equilibrium between the hydrogen ortho ester and the glycol monoester considerably favors the latter, our values of the equilibrium constant for their interconversion are actually measured quantities, with no assumptions or approximations. This represents the first direct measurement for such equilibrium constants. The numbers obtained, particularly that for the unsubstituted compound, reflect the expected instability of the tetrahedral intermediate relative to the carbonyl compound.

Recently, Guthrie has used a thermochemical method for calculating equilibrium constants for the formation of several types of tetrahedral intermediates (22, 23). The basic premise of his method involves the evaluation of the free energy change for the replacement of the OR group of a stable ortho acid derivative by an OH group, using a correlation based on cases where both species are stable. Although the actual compounds of our study have not been considered, the cyclization of several glycol monoesters was investigated. In Table 3 we compare Guthrie's results for formate derivatives with our numbers. Considering that the effect of replacing hydrogen by phenyl will disfavor the hydrogen ortho ester relative to the carbonyl, there is excellent consistency between the two sets of methods, since the formate esters are indeed predicted to cyclize considerably more readily. Both sets of data also show the much greater tendency for the pinacol monoester to cyclize. This has been attributed by Guthrie (23) to relief of steric compression on cyclization.

COMMUNICATION

An interesting azirine induced reaction of the cyclopentadienyliron dicarbonyl dimer

HOWARD ALPER[1] AND TSUTOMU SAKAKIBARA

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received March 22, 1979

HOWARD ALPER and TSUTOMU SAKAKIBARA. Can. J. Chem. **57**, 1541 (1979).

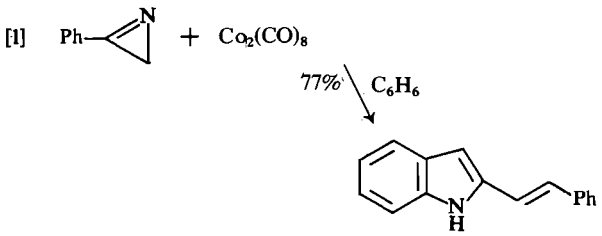
Reaction of cyclopentadienyliron dicarbonyl dimer with a series of 2-arylazirines in anhydrous benzene (room temperature or 40°C, 41–96 h) affords cycloaddition products (pyrazines, isoxazoles) and the dimer of cyclopentadienone (1,8-diketo-4,7-methano-3a,4,7,7a-tetrahydroindene). The formation of the latter product is proposed to occur via a complex in which each cyclopentadienyl ring is π-complexed to one iron atom and σ-bound to another.

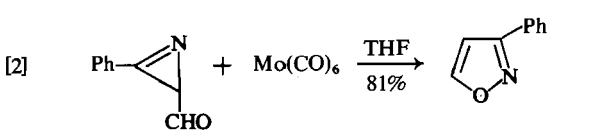
HOWARD ALPER et TSUTOMU SAKAKIBARA. Can. J. Chem. **57**, 1541 (1979).

La réaction du dimère du cyclopentadiénylferdicarbonyle avec une série d'aryl-2 azirines dans le benzène anhydre (t.a. ou 40°C, 41–96 h) conduit aux produits de cycloaddition (pyrazines, isoxazoles) et au dimère de la cyclopentadiènone (dicéto-1,8 méthano-4,7 tétrahydro-3a,4,7,7a indène). On croit que ce dernier produit se forme par l'intermédiaire d'un complexe dans lequel chaque cycle cyclopentadiènyle forme un complexe π avec un atome de fer et un complexe σ avec l'autre.

[Traduit par le journal]

Recent investigations have shown cobalt (eq. [1]) and Group VI (eq. [2]) metal carbonyls to be effective reagents for converting azirines to useful heterocycles via cycloaddition processes (1, 2). Several interesting complexes were obtained by the use of diiron enneacarbonyl as the reagent (3). In continuation of our exploration of azirine – metal carbonyl chemistry, we studied the reaction of the three-membered ring heterocycles with the cyclopentadienyliron dicarbonyl dimer (**1**). We now wish to report that the latter reaction results not only in cycloaddition of the azirine, but in an unusual reaction of the iron dimer.





Treatment of 2-arylazirines (**2***a–c*) with half the molar amount of **1** in *dry* benzene (N_2 or Ar atmosphere) for 41–96 h at room temperature, or higher, followed by work-up in air, gave pyrazines (**3***a–c*) in modest yields (Table 1). A similar reaction, using **2***d* as the substrate, afforded 3-phenylisoxazole (see [2]) in 84% yield. These results indicate that the iron dimer is behaving in an analogous manner towards azirines as Group VI metal carbonyls (2).

A surprising product of most of these reactions, formed in as high as 38% yield, was the cyclopentadienone dimer **4**[2], identified on the basis of melting

TABLE 1. Products obtained from reaction of azirines with **1**[a]

Azirine	Reaction temperature (°C)	Reaction time (h)	Product yields[f] (%)		
			3[b]	**4**[c]	Other
2*a*	r.t.[g]	41	39	tr[g]	17[d]
	40	41	6	28	
2*b*	r.t.	72	16	8	
	40	72	15	5	
2*c*	r.t.	96	17	26	
2*d*	r.t.	41		38	84[e]

[a]The ratio of **2**:**1** used was 10:5 or 5:2.5 mmol.
[b]Yield is based on azirine reacted. Products were identified by comparison of melting points and spectral properties with those for authentic materials (2).
[c]Yield is based on $(C_5H_5Fe(CO)_2)_2$ reacted.
[d]A tetramer of the azirine. Its structure is not known, and it is not formed from reaction of **3** with **1**.
[e]3-Phenylisoxazole.
[f]Polymeric materials were also formed.
[g]Abbreviations: r.t. = room temperature; tr = trace.

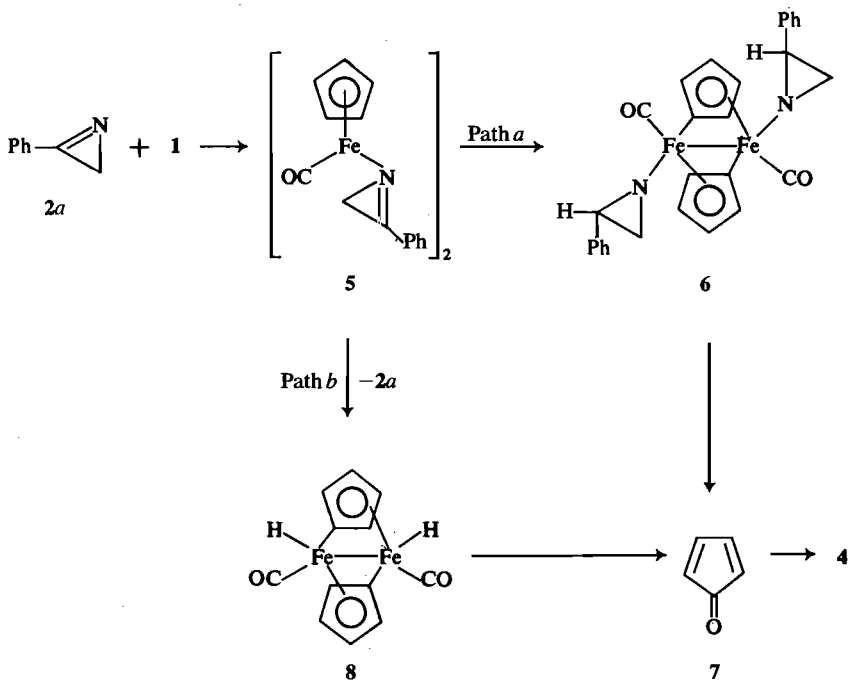
point (101–102°C, lit. (5) mp 102.0–102.5°C), elemental analysis (*anal.* calcd. for $C_{10}H_8O_2$: C 74.99, H 5.03; found: C 75.50, H 5.04), and spectral data ir γ_{CO} (KBr): 1788, 1720 cm^{-1} (5); ^{1}Hmr ($CDCl_3$) δ: 2.88t, 3.16m, 3.41m, 6.25m, 7.30m (5); uv λ_{max} (CH_3OH): 228, 328 nm (6); ms *m/e*: 160 $(M)^+$, 132 $(M - CO)^+$, 104 $(M - 2CO)^+$, 78 $(M - 2CO - C_2H_2)^+$ (7). The cyclopentadienone dimer was not formed in the absence of azirine, and use of a 10:1 ratio of **1**:**2***d* gave **4** in less than 2% yield.

The formation of the cyclopentadienone dimer may occur via initial azirine displacement of carbon monoxide from **1** to give **5** (Scheme 1, illustrated for **2***a*). Metalation with hydrogen transfer to the azirine (possibly by an iron hydride intermediate) would afford **6**, in which each iron atom is π-complexed to one cyclopentadienyl ring and σ-bonded to another. Oxidative cleavage of **6** (work-up) would give cyclopentadienone (7), which readily dimerizes (path *a*). It is also conceivable that loss of azirine would accompany metalation of **5** to give **8**, which could then collapse to **7** (path *b*).

Precedence exists for intermediates of type **6** and **8**, from the work by Tebbe and Parshall (8) on niobium and tantalum complexes and by Baker *et al.* (9) on a thorium(IV) complex. Cyclopentadienone is not formed prior to work-up of the above reactions since (*i*) no organometallic complexes of the dienone ligand were detected (10, 11) and (*ii*) cycloaddition



SCHEME 1

of any azirine with **7** would produce azepines, which were not isolated either (4).

The following general procedure was used. A mixture of the azirine (**2**) and cyclopentadienyliron dicarbonyl dimer (**1**) in *dry* benzene was stirred at room temperature until none of the azirine remained (by thin-layer chromatography, see Table 1 for reaction times). The solvent was then rotary evaporated to remove benzene. The residue was chromatographed on silica gel or Florisil. The pyrazine (**3***a*) or 3-phenylisoxazole was eluted with benzene–hexane, and the dimer of cyclopentadienone (**4**) was eluted with chloroform–ether.

B. C. NALLIAH, D. B. MACLEAN, H. L. HOLLAND, and R. RODRIGO. Can. J. Chem. **57**, 1545 (1979).

Eight spirobenzylisoquinolines and four phthalideisoquinolines have been synthesized through 1,9-dehydrophthalideisoquinoline intermediates. The latter are reduced and rearranged in one step to spirobenzylisoquinolines of the corydaine–sibiricine type. The phthalideisoquinoline alkaloid hydrastine has been converted by *in vitro* methods to a spirobenzylisoquinoline in two steps.

B. C. NALLIAH, D. B. MACLEAN, H. L. HOLLAND et R. RODRIGO. Can. J. Chem. **57**, 1545 (1979).

On a synthétisé huit spirobenzylisoquinoléines et quatre phtalideisoquinoléines par l'intermédiaire de déhydro-1,9 phtalideisoquinoléines. Ces dernières se réduisent et se transposent en spirobenzylisoquinoléines du type corydaine–sibiricine en une étape. On a transformé l'alcaloïde phtalidéisoquinoléine, hydrastine, en une spirobenzylquinoléine par des méthodes *in vitro* impliquant deux étapes.

[Traduit par le journal]

The last decade has seen the isolation of a new group of benzylisoquinoline alkaloids whose structures are characterised by the presence of an indane moiety spiro fused at C1 of the isoquinoline system. Approximately 20 such spirobenzylisoquinoline alkaloids have been isolated and characterised (1) and all of them possess 'unsymmetrical' methylenedioxy substitution in the indane benzene ring (ring D). The five-membered ring of the indane moiety is often oxygenated at the benzylic positions with one or two substituents. In the latter case they may be identical hydroxyl groups in a *trans* disposition as in ochrobirine (**1**) and yenhusomine (**2**) (or *cis* as in raddeamine (**3**)) or nonidentical substituents as in corydaine (**4**), sibiricine (**5**), yenhusomidine (**6**), and raddeanone (**7**).

Many syntheses of these alkaloids have been developed (2) but variations of the indanedione and indanetrione approaches have hitherto been the most popular. Such methods, however, are in the main long and tedious, often beset with poor yields and are not especially suited to the preparation of alkaloids of the corydaine–sibiricine type because some differentiation of the two oxygenated positions of the five-membered ring C would have to be tailored into the C/D synthon. Recently these difficulties have in fact been overcome in a synthesis of corydaine (13).

Nevertheless, it still seemed desirable to develop a route to alkaloids such as **4**–**7** by devising a strategy

that would avoid this problem. The intramolecular aldol condensation of an intermediate such as **10** appeared to be an attractive solution to the problem. The epimeric mixture (e.g., **4** and **5** or **6** and **7**) that would result from such a process might be expected to be richer in **4** or **6**, thermodynamically more stable in view of their capacity (3, 4) for intramolecular hydrogen bonding.

This scheme was first investigated (5) with easily available model compounds. Meconin-α-carboxylic acid **11** (6) was converted to the amide **12** and cyclised to yield dehydrocordrastine **13** (7). Reduction of the latter with diisobutylaluminum hydride resulted in the production of an epimeric mixture of **8** and **9** in the ratio 6:7 presumably through an enolate such as **10**. This result confirmed the viability of the route but surprisingly provided the nonhydrogen bonded **9** in slightly larger quantities than the more stable epimer **8**.

Application (8) of this procedure to the synthesis of alkaloids **4**–**7** required the preparation of the phthalide-α-carboxylic acid **14**. Piperonal was carboxylated (9) and the resulting 2-carboxylic acid converted through the amide **15** to the required phthalide-α-carboxylic acid **14** in 31% overall yield. This acid was used as before to obtain the dehydrophthalideisoquinolines **16** and **17** through the amides **18** and **19**, respectively. The detection of a substantial nuclear Overhauser effect between the *N*-methyl group and the C6′ aromatic proton in **16** and **17** established the *E*-configuration of the double bond as shown. Catalytic hydrogenation of **16** and **17** provided the phthalideisoquinolines (±)-adlumidine (**20**), (±)-bicuculline (**21**) and (±)-adlumine (**22**),

(±)-corlumine (**23**), respectively. The individual components of each mixture were separated by chromatography and characterised by comparison with authentic samples.

The dehydrophthalides **16** and **17** upon treatment with diisobutylaluminum hydride in tetrahydrofuran at −10°C for 1 h underwent reduction and rearrangement as expected to yield mixtures of corydaine (**4**) – sibiricine (**5**) and yenhusomidine (**6**) – raddeanone (**7**), respectively, in total yields of approximately 65% in each case. The individual components of each pair were again separated by chromatography.

We have observed that the proportions of the individual diastereomers produced in each mixture varies with the time spent in the work-up procedure upon completion of the reaction. Thus the proportion of corydaine–yenhusomidine is increased if the treatment of the reaction mixture with methanol and saturated aqueous sodium sulfate, routinely done at completion of the reaction, is extended. Indeed it has been possible to equilibrate pure samples of sibiricine and raddeanone with corydaine and yenhusomidine, respectively, by exposure to methanolic potassium hydroxide. These mixtures were analysed by ^{1}Hmr spectroscopy; furthermore, the process is not a clean and entirely reproducible one, since other reactions presumably supervene. These results however, clearly point to the existence of a retro-aldol realdolisation sequence which is responsible for the generation of at least a part of the corydaine–yenhusomidine components of the mixtures.

The formation of the sibiricine–raddeanone components may result from the transition states in these instances possessing oxygen and nitrogen atoms *anti* to each other (they will have to be *syn* for the formation of corydaine–yenhusomidine) or from aluminum coordination to both negative oxygen atoms in the transition states or from both of these considerations. Such an aluminum coordinate complex, if it arises from the *E*-enolate could be a seven-membered cyclic species which must lead to the *anti* arrangement of the nitrogen and hydroxyl groups in the product. Indeed precedents do exist for such aluminum coordination in the aldol condensation (10).

Reduction of corydaine and yenhusomidine with sodium borohydride provided the *trans*-diols ochrobirine **1** and yenhusomine **2** in satisfactory yield.

The successful completion of this synthesis prompted us to investigate the possibility of applying the strategy for the conversion of a natural phthalide-isoquinoline to a spirobenzylisoquinoline. Thus hydrastine **24** was converted to its *N*-oxide with *m*-chloroperbenzoic acid and then treated with trifluoroacetic anhydride to provide dehydrohydrastine **25** which was similarly reduced and rearranged with diisobutylaluminum hydride to yield the spirobenzylisoquinolines **26** and **27**.

Alternatively, hydrastine diol **28** was oxidised with dimethyl sulfoxide – trifluoroacetic acid (12) and the product rearranged without isolation into the same epimeric mixture of **26** and **27** though now in different proportions. In the latter instance the more stable (H-bonded) isomer **26** predominated 5:4 whereas in the previous case **26** and **27** were isolated in 2:3 proportions. Such a result although not absolutely unambiguous, lends some credibility to the idea of aluminum coordination expressed above.

Experimental

Melting points were determined on a Fischer Mel-Temp apparatus and are uncorrected. The ^{1}Hmr spectra were recorded on a Varian HA-100 spectrometer in $CDCl_3$ with added TMS as the internal lock. Chemical shifts are reported in ppm (δ) from TMS. A Beckmann IR10 spectrometer was used to record the ir spectra.

*Dehydrocordrastine (**13**)*

The amide **12** (7) (4 g) was dissolved in a mixture of phosphorus oxychloride (24 mL) and acetonitrile (8 mL) and the resulting solution refluxed for 3 h. The red solution was cooled and evaporated to dryness. The residue was dissolved in methanol (10 mL), basified with 10% aqueous ammonia, and extracted with chloroform. The extract was washed, dried, and evaporated to dryness and the residue crystallised twice from methanol to afford pale yellow crystals (2.8 g), mp 140–142°C (lit. (7) mp 136–136.5°C); ir ν_{max} ($CHCl_3$): 1760 cm^{-1}; ^{1}Hmr: 8.02 (s, 1H), 7.86 and 7.22 (q, 2H, J_{AB} = 8.0 Hz), 6.56 (s, 1H), 4.08 (s, 3H), 3.92 (s, 3H), 3.88 (s, 3H), 3.84 (s, 3H), 3.20 (t, 2H), 2.80 (t, 2H), and 2.68 (s, 3H). *Anal.* calcd. for $C_{22}H_{23}NO_6$: C 66.49, H 5.83, N 3.52; found: C 66.65, H 5.72, N 3.61.

*Spirobenzylisoquinolines **8** and **9***

A solution of diisobutylaluminum hydride in hexane (1.5 mL, 15%) was added to a stirred solution of dehydrocordrastine (0.15 g) in dry toluene (30 mL) under an atmosphere of argon at −78°C. The resulting red solution was stirred at this temperature for 10 min. Acetone (0.5 mL) was then added and the solution allowed to come to room temperature. The reaction mixture was diluted with ether, water added, and the ether phase washed with water, dried and evaporated. Chromatography of the residue on silica gel in chloroform gave the two compounds which were crystallised from ether: **8**, mp 118–120°C (47 mg); **9**, mp 149–151°C (54 mg). Spectral data have been previously reported (5). *Anal.* calcd. for $C_{22}H_{25}NO_6$: C 66.15, H 6.31, N 3.50; found for **8**: C 66.08, H 6.49, N 3.48; found for **9**: C 65.93, H 6.30, N 3.38.

*3,4-Methylenedioxyphthalide-α-carboxamide (**15**)*

An aqueous solution (20 mL) of potassium cyanide (1.6 g) was added dropwise to a stirred suspension of 2-formyl-5,6-methylenedioxybenzoic acid (4 g) in water (20 mL) and a clear solution was obtained. On continued stirring (1 h) a white precipitate separated. The mixture on acidification (15% HCl, 10 mL) yielded a clear solution and on continued stirring another white precipitate separated. The mixture was heated to obtain a clear solution and the solution maintained at this

temperature for ten minutes until another precipitate begins to separate. The mixture was cooled, the solid separated by filtration and crystallized from aqueous methanol as white needles (3.84 g), mp 239–240°C; ir ν_{max} (Nujol): 3460, 3220, 1770, and 1650 cm^{-1}; ^{1}Hmr (DMSO-d_6): 7.89 (s, 1H), 7.60 (s, 1H), 7.32 and 7.12 (AB_q, 2H, J_{AB} = 8.0 Hz), 6.27 (s, 2H), 5.83 (s, 1H). *Anal.* calcd. for $C_{10}H_7O_5N$: C 54.28, H 3.19, N 6.36; found: C 54.26, H 3.24, N 6.31.

*3,4-Methylenedioxyphthalide-α-carboxylic Acid (**14**)*

A stirred suspension of the amide **15** (2 g) in concentrated hydrochloric acid (20 mL) was heated until a clear solution was obtained (ca. 75°C) and the solution maintained at this temperature for 5 min. The pale yellow crystals which separated on cooling were filtered and crystallized from aqueous acetone yielding white needles (1.35 g), mp 210°C; ir ν_{max} (Nujol): 1733 and 1790 cm^{-1}; ^{1}Hmr (DMSO-d_6): 7.31 and 7.11 (AB_q, 2H, J_{AB} = 8.0 Hz), 6.27 (s, 2H), 6.04 (s, 1H). *Anal.* calcd. for $C_{10}H_6O_6$: C 53.80, H 2.71; found: C 53.64, H 2.91.

N-*Methyl*-N-*[2′-(3″,4″-methylenedioxyphenyl)ethyl]-3,4-methylenedioxyphthalide-α-carboxamide (**18**)*

Oxalyl chloride (3 mL) was added to a solution of the acid **14** (2 g) in dry tetrahydrofuran (50 mL) and refluxed for 0.5 h. The solution was cooled, the solvent removed under reduced pressure, and the residue dried under vacuum for 1 h. The dried residue was dissolved in methylene chloride (30 mL) and added dropwise to a stirred solution of *N*-methylhomopiperonylamine (2 g) in methylene chloride (20 mL) and 10% sodium hydroxide (5 mL). Stirring was continued for 2 h, the mixture was acidified (10% hydrochloric acid), and the organic layer separated. The organic phase was successively washed with aqueous potassium carbonate, water, and dried (Na_2SO_4). The solvent was removed and the residue crystallized from methanol as colorless prisms (2.5 g), mp 155°C; ir ν_{max} ($CHCl_3$): 1665 and 1780 cm^{-1}; ^{1}Hmr: 7.10 and 6.90 (q, 2H, J_{AB} = 8.0 Hz), 6.67 (br s, 2H), 6.17 (s, 2H), 5.91 (s, 2H), 6.03 and 5.67 (s, 1H), 3.4–3.8 (m, 2H), 3.0 and 3.1 (s, 3H), 2.67–3.0 (m, 2H). *Anal.* calcd. for $C_{20}H_{17}O_7N$: C 62.66, H 4.44, N 3.66; found: C 62.45, H 4.25, N 3.58.

N-*Methyl*-N-*[2′-(3″,4″-dimethoxyphenyl)ethyl]-3,4-methylenedioxyphthalide-α-carboxamide (**19**)*

The experiment was carried out using the same reaction conditions and quantities as above with *N*-methyl-3,4-dimethoxyphenethylamine and the amide **19** was obtained as colorless prisms (2.3 g), mp 145–146°C; ir ν_{max} ($CHCl_3$): 1668 and 1780 cm^{-1}; ^{1}Hmr: 7.07 and 6.83 (q, 2H, J_{AB} = 8.0 Hz), 6.77 (br s, 2H), 6.13 (s, 2H), 6.03 and 5.57 (s, 1H), 3.83 (s, 6H), 3.5–3.8 (m, 2H), 3.10 and 3.0 (s, 3H), 3.10–2.7 (m, 2H); *Anal.* calcd. for $C_{21}H_{21}O_7N$: C 63.16, H 5.26, N 3.51; found: C 63.01, H 5.08, N 3.36.

*Dehydrobicuculline (**16**)*

Phosphorus oxychloride (10 mL) was added dropwise to a stirred refluxing solution of the amide **18** (1 g) in acetonitrile (30 mL) over a period of 30 min and the mixture was refluxed for 4 h. The solvent was removed under reduced pressure, the residue washed with petroleum ether and dissolved in the minimum quantity of cold methanol. The solution was basified (NH_4OH) and extracted with methylene chloride. The organic phase was washed with water and dried (Na_2SO_4). Upon removal of the solvent under reduced pressure a yellow residue remained which was crystallized from benzene–methanol as yellow needles (710 mg), mp 259°C; ir ν_{max} ($CHCl_3$): 1760 cm^{-1}; ^{1}Hmr: 7.90 (s, 1H), 7.71 and 7.24 (q, 2H, J_{AB} = 8.0 Hz), 6.62 (s, 1H), 6.18 (s, 2H), 5.96 (s, 2H), 3.18 (t, 2H), 2.83 (t, 2H), 2.72 (s, 3H). A 25% nOe was observed for the resonance at 7.71 ppm upon irradiation of the *N*-methyl signal at 2.72 ppm. *Anal.* calcd. for $C_{20}H_{15}O_6N$: C 65.75, H 4.11, N 3.84; found: C 65.93, H 4.29, N 3.68.

*Dehydrocorlumine (**17**)*

The experiment was carried out using the same conditions and quantities as above with the amide **19**. The residue crystallized from methanol – methylene chloride as golden flakes (750 mg), mp 218–219°C; ir ν_{max} ($CHCl_3$): 1765 cm^{-1}; ^{1}Hmr: 8.02 (s, 1H), 7.77 and 7.13 (q, 2H, J_{AB} = 8 Hz), 6.63 (s, 1H), 6.17 (s, 2H), 3.98 (s, 3H), 3.90 (s, 3H), 3.23 (t, 2H), 2.83 (t, 2H), 2.75 (s, 3H). *Anal.* calcd. for $C_{21}H_{19}O_6N$: C 66.14, H 4.99, N 3.67; found: C 66.36, H 5.02, N 3.58.

*(±)-Adlumidine (**20**) and (±)-Bicuculline (**21**)*

Platinum oxide (15 mg) was added to a solution of dehydrobicuculline **16** (100 mg) in acetic acid (30 mL) and shaken in a Parr apparatus under hydrogen at 30 psi. After hydrogen uptake had ceased the catalyst was removed by filtration and the filtrate evaporated to dryness. The residue was basified (NH_4OH), extracted with ether and the organic phase dried (Na_2SO_4). The ether was removed under reduced pressure and the residue chromatographed (silica gel, benzene–acetone (70:30)) yielding (±)-adlumidine (31 mg), mp 198–199°C, and (±)-bicuculline (32 mg), mp 215–216°C, identical with authentic samples.

*(±)-Adlumine (**22**) and (±)-Corlumine (**23**)*

The experiment was carried out using the same conditions and quantities as described previously and (±)-corlumine (28 mg), mp 175–176°C, (±)-adlumine (38 mg), mp 189–190°C, were isolated. They were identical with authentic samples.

*(±)-Sibiricine (**5**) and (±)-Corydaine (**4**)*

A solution of diisobutylaluminum hydride in hexane (1.5 mL, 20%) was added to a stirred solution of dehydrobicuculline **16** (0.15 g) in dry tetrahydrofuran (70 mL) under an atmosphere of nitrogen at −10°C and the stirring continued at this temperature for 1 h. Methanol (3 mL) was added and the solution was allowed to come to room temperature. A saturated solution of sodium sulfate (1 mL) was added to the solution and the stirring continued for 10 min. The precipitated salts were removed by filtration and the filtrate evaporated to dryness under reduced pressure. The residue was chromatographed (silica gel, benzene–acetone (7:3)) and the two components isolated and crystallized from methanol were corydaine (39 mg), mp 127–129°C, and sibiricine (62 mg), mp 223–225°C, whose ir and ^{1}Hmr spectra were identical with those of authentic samples.

*(±)-Raddeanone (**7**) and (±)-Yenhusomidine (**6**)*

The experiment was repeated using similar conditions as above and (±)-raddeanone (15 mg), mp 181–182°C, and (±)-yenhusomidine (83 mg), mp 239–240°C, were separated by chromatography. It was found that (±)-raddeanone was very unstable and rearranged to the more stable yenhusomidine making its isolation difficult. The ir and ^{1}Hmr spectra of the two compounds were identical with the spectra of the authentic materials (4).

*(±)-Ochrobirine (**1**)*

Sodium borohydride (150 mg) was added to a solution of corydaine **4** (60 mg) in methanol (20 mL) and the stirring continued for 24 h. The solution was acidified with acetic acid and the solvent removed under reduced pressure. The residue was basified (ammonia) and extracted with ether. The ether extract was dried ($MgSO_4$), evaporated to dryness, and the residue crystallized from methanol (24 mg), mp 235°C. The ir and

^{1}Hmr spectra were identical with the spectra of the authentic material.

(±)-Yenhusomine (2)

Sodium borohydride (150 mg) was added to a solution of yenhusomidine **6** (60 mg) in tetrahydrofuran (15 mL) and methanol (5 mL) and stirred for 24 h. The solution was acidified and the solvent removed under reduced pressure. The residue was basified (NH_4OH) and extracted with ether. The ether extract was dried ($MgSO_4$), evaporated to dryness, and the residue crystallized from methanol (28 mg), mp 223–225°C. The ir and ^{1}Hmr properties were identical with published (4) data.

Preparation of Dehydrohydrastine (25)

m-Chloroperbenzoic acid was added to a solution of hydrastine (800 mg) in dry tetrahydrofuran (50 mL) and stirred at ambient temperature for 24 h. The solution was cooled in ice, trifluoroacetic anhydride (2 mL) was added, and the mixture was stirred at this temperature for 0.5 h. Ammonium hydroxide (5 mL) was added and stirring was continued for another 15 min whereupon the solution turned deep orange. Water (50 mL) was added and the solution was extracted twice with methylene chloride (100 mL). The extract was dried (Na_2SO_4), evaporated under reduced pressure, and the residue crystallised from methanol as yellow needles (325 mg), mp 203°C (dec.); ir ν_{max} ($CHCl_3$): 1755 cm^{-1}; ^{1}Hmr: 7.98 (s, 1H), 7.93 and 7.33 (q, 2H, J_{AB} = 8 Hz), 6.64 (s, 1H), 5.96 (s, 2H), 4.13 (s, 3H), 3.94 (s, 3H), 3.21 (t, 2H), 2.82 (t, 2H), 2.71 (s, 3H). *Anal.* calcd. for $C_{21}H_{21}O_6N$: C 66.14, H 4.99, N 3.67; found: C 66.23, H 4.97, N 3.58.

Reduction of Dehydrohydrastine with Dibal-H

Dibal-H (1.5 mL, 20% in hexane) was added to a solution of dehydrohydrastine (150 mg) in dry tetrahydrofuran under a nitrogen atmosphere at −30°C and the mixture stirred for 1 h. Methanol (3 mL) was added to decompose the excess reducing agent and the mixture allowed to warm up to room temperature. A saturated solution of sodium sulfate (2 mL) was added and the mixture stirred for 0.5 h and filtered. The filtrate was evaporated to dryness under reduced pressure and the residue chromatographed (silica gel, benzene–acetone (7:3)). Two compounds were isolated and crystallised from methanol: **26** (42 mg), mp 164–165°C, and **27** (60 mg), mp 191–192°C; ^{1}Hmr compound **26**: 7.67 and 7.17 (q, 2H, J_{AB} = 8.0 Hz), 6.61 (s, 1H), 6.07 (s, 1H), 5.87 (br s, 2H), 5.07 (s, 1H), 4.07 (s, 3H), 4.00 (s, 3H), 3.5–2.5 (m, 4H), 2.33 (s, 3H); ^{1}Hmr compound **27**: 7.67 and 7.17 (q, 2H, J_{AB} = 8.0 Hz), 6.63 (s, 1H), 6.07 (s, 1H), 5.87 (s, 2H), 5.63 (br s, 1H), 4.08 (s, 6H), 3.5–2.7 (m, 4H), 2.40 (s, 3H). *Anal.* calcd. for $C_{21}H_{21}O_6N$: C 65.79, H 5.48, N 3.66; found for **26**: C 65.57, H 5.71, N 3.48; found for **27**: C 65.57, H 5.36, N 3.41.

Oxidation of Hydrastine Diol with Dimethyl Sulfoxide and Trifluoroacetic Anhydride

A solution of trifluoroacetic anhydride (630 mg, 30 mmol) in dry methylene chloride (5 mL) was added dropwise to a solution of dry dimethyl sulfoxide (312 mg, 4 mmol) in methylene chloride (5 mL) at −60°C (Dry Ice – acetone) and the mixture stirred at this temperature for 10 min. A solution of the diol **28** (387 mg, 1 mmol) in methylene chloride (10 mL) was added dropwise to the cold mixture and the stirring was continued for another 30 min. Triethylamine (4 mL) was added dropwise over a period of 10 min to the cold solution, then the cooling bath was removed and the reaction was allowed to warm up to room temperature (ca. 1 h). The solution was poured into water and extracted with methylene chloride (50 mL). The extract was dried (Na_2SO_4) was evaporated and the residue was chromatographed on silica gel (benzene–acetone–methanol, (7:2:1)) and the two epimeric spirobenzylisoquinolines were isolated and crystallised from methanol. The faster moving component (52 mg) and the slower moving component (41 mg) were identical with the two compounds **26** and **27**, respectively, obtained from the reduction of dehydrohydrastine with Dibal-H (*vide supra*).

Acknowledgments

We thank the National Research Council of Canada for support of this work. We are grateful to Professor Stewart McLean for informing us of his synthetic route to these alkaloids before publication (13).

^{13}C nuclear magnetic resonance studies. 85. ^{13}C spectra of several ring-contracted and -expanded steroids[1,2]

VINOD DAVE AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 27, 1978

VINOD DAVE and J. B. STOTHERS. Can. J. Chem. 57, 1550 (1979).

The ^{13}Cmr spectra of several cholestanes including 13 *A*-homo-*B*-nor derivatives, 11 *A*-homo derivatives, and 8 *B*-nor examples have been examined. In addition the ^{13}C data for a few of the corresponding androstanes and 16 precursors in the cholestane series are reported. Examples in both the 5α- and 5β-cholestane families were included. These results represent the first systematic examination of the ^{13}C spectra of *A*-homo-*B*-nor steroids and should be useful for the characterization of other members in each series. These data also permit some tentative conclusions regarding the favored conformation for the seven-membered ring in the *A*-homo derivatives.

VINOD DAVE et J. B. STOTHERS. Can. J. Chem. 57, 1550 (1979).

On a étudié les spectres rmn du ^{13}C de plusieurs cholestanes dont 13 dérivés *A*-homo *B*-nor, 11 dérivés *A*-homo et 8 dérivés *B*-nor. On rapporte de plus des données rmn du ^{13}C de quelques androstanes correspondants et de 16 précurseurs de la série cholestane. On a inclu des exemples des familles 5α- aussi bien que 5β-cholestanes. Ces résultats représentent le premier examen systématique de spectres rmn du ^{13}C de stéroïdes *A*-homo *B*-nor et ils devraient s'avérer utiles pour caractériser d'autres composés de chacune de ces séries. Ces données permettent aussi de tirer des conclusions provisoires concernant la conformation favorisée des cycles à sept chaînons des dérivés *A*-homo.

[Traduit par le journal]

Since the appearance of the original report describing the ^{13}C spectra of several steroids by Roberts' group in 1969 (1), literally dozens of papers have been published extending the examination to a wide variety of compounds within the family. For example, two recent reviews (2) include the complete shielding data for nearly 500 steroids. Within this body of data, however, there is a dearth of examples having the *A*-homo-*B*-nor, *A*-homo, or *B*-nor steroid skeleton. The ^{13}C spectra of a few members of the first of these three series were recorded as an aid to their characterization in connection with another study (3) and these results established that the ^{13}C spectra of *A*-homo-*B*-norcholestanes could be readily utilized to identify these derivatives in the presence of cholestanes. This finding led to a reexamination of several ring expansion processes to exploit the use of ^{13}C spectra for the determination of the true product compositions. Previously, the analyses of these products by other physical methods had led to conflicting results and, in some cases, rather startling conclusions. The reexamination with ^{13}Cmr analysis, however, gave a consistent, readily interpretable set of results (4). In the course of this project several additional compounds were required as synthetic intermediates and, thus, derivatives in each of the three series noted above became available. The ^{13}C spectrum of each sample was recorded and these results are presented in this paper. These data form the basis for the specific assignments noted in the accompanying paper for the signals which were employed for the product analyses. The results for the carbons in the A and B rings of the *A*-homo derivatives allow one to consider probable favored conformations for the seven-membered ring.

Experimental

Materials

With two exceptions, the compounds examined in this study have been described in the literature and the specific method of preparation employed for each compound is cited in the tables of shielding data. In a few cases, hydrogen–deuterium exchange at positions α to carbonyl groups was carried out to aid the spectral analysis (3). A sample of 6β-acetyloxy-5α-cholestan-3-one (**39**) was prepared from 3β-benzoyloxy-5α-cholestan-6-one by interchange of the carbonyl and ester functions using standard methods.[3]

A-*Homo-5β-cholestane (**15**)*

A mixture of *A*-homo-5β-cholestan-3-one and -4-one (**16** and **19**) was treated under Wolff–Kishner conditions. The crude product was chromatographed on a 10-g plate (SiO_2, hexanes) and the band at the solvent front gave **15** as a colorless oil (13 mg) whose ir spectrum exhibited no carbonyl absorption. ^{1}Hmr ($CDCl_3$) δ: 0.65, 0.81, 0.90 (3 methyl signals). *Exact mass* calcd. for $C_{28}H_{50}$: 386.3912; found (high resolution ms): 386.3908.

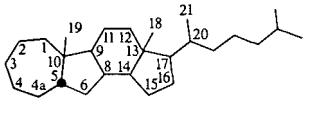
Spectra

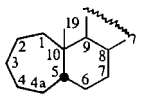
All ^{13}C spectra were obtained at 25.2 MHz with a Varian XL-100-15 system operating in the Fourier transform mode with square wave modulated proton decoupling at 100 MHz. Completely decoupled and off-resonance decoupled spectra were recorded for each compound in $CDCl_3$ solutions (10–20 mg in 0.2–0.3 mL of solution). In several cases, the shift dispersions produced by the sequential addition of 0.1–0.5 equiv. of $Eu(fod)_3$ were determined to aid the asssignment of specific signals. In most cases the operating conditions gave digital resolution of 0.02 ppm and the precision of the tabulated data is judged to be ± 0.05 ppm.

Results and Discussion

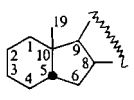
Most of the compounds included in this study are cholestane derivatives with substitution restricted to the A and B rings; consequently, the shieldings of the side chain carbons are the same in each case, while the shieldings of C-15, -16, and -17 fall into two groups depending on the size of the B ring. Thus the signals for C-15–C-27, with the exception of C-18 and -19, were readily identified for each of these compounds, and the assignments confirmed by the fact that these signals were least sensitive to the addition of $Eu(fod)_3$. These results are summarized in Table 1. For the four androstan-17β-ol derivatives, C-15, -16, and -17 were similarly easily identified with these signals appearing at 23.4, 30.6, and 81.9 ppm, respectively. Significant variations were observed for each of the remaining shieldings and these data are tabulated in the following groups: *A*-homo-*B*-norcholestanes **1–14**, Table 2; *A*-homo derivatives **15–27**, Table 3; *B*-norcholestanes **28–35**, Table 4; the cholestanes **36–51** and androstanes **52** and **53** which were encountered in the preparations and for which ^{13}C data have not been published are collected in Table 5. The numbering scheme for the *A*-homo and *B*-nor derivatives are given for the parent hydrocarbons **1**, **15**, and **28** below. The assignments listed



1



15



28

in these tables were based on the following considerations.

For C-11, -12, -13, and -14, the variations throughout the series could be expected to be small (2) and the line positions should be less affected by the addition of $Eu(fod)_3$ than those for the A- and B-ring carbons. The latter feature rendered the distinction between C-10 and C-13 straightforward. Of the methine carbons, C-5, -8, and -9, the shift reagent experiments permitted a ready distinction in addition to the expected pronounced shielding difference between C-8 and -9. In the *B*-nor derivatives the C-6 methylene signal was identified by its lesser sensitivity to added $Eu(fod)_3$ relative to the shifts exhibited by the A-ring methylene carbons. In most cases the C-18 and -19 methyl carbons were readily distinguished both by comparisons within each series and with the data for other related compounds; in many instances, this was confirmed by the difference in shift reagent effects. Thus the major assignment problem concerned the methylene signals arising from the A ring carbons.

TABLE 1. ^{13}C shieldings[a] in cholestane derivatives **1–51**

Compounds	C-15	C-16	C-17
1–14, 28–35	24.5	28.5	55.8
15–25, 36–51	24.2	28.3	56.3

[a]In ppm from internal TMS for $CDCl_3$ solutions; in all cases C-20 to C-27 absorb at 35.7, 18.7, 36.2, 23.9, 39.5, 28.0, 22.6, and 22.8 ppm, respectively.

The ^{13}C spectra of several methyl-substituted cycloheptanes, cycloheptanols, and cycloheptanones were examined by Christl and Roberts (21) who found that the results are in good agreement with predictions based on the twist-chair (TC) conformation for the ring. Since the conformational features revealed by earlier molecular mechanics calculations were presented by these authors, there seems no need to review the details here. Their shielding results led to a set of shielding effects for the various substituents on the ring carbons and these data provide a starting point for the present analysis. Although the TC form of cycloheptane is flexible and undergoes rapid pseudorotation between equivalent forms, the A ring in these *A*-homo steroids may be expected to favor a particular conformation. Having an angular C-19 methyl and ring fusion to the B ring, hydrocarbon **1**, the parent of the *A*-homo-*B*-nor-5β series, can be viewed as a '1,1,2-trialkylcycloheptane' and on the basis of the earlier work (21) probably adopts TC **54** preferentially with C-9 and -19 in isoclinal positions and C-6 in a pseudoequatorial orientation. In which case the shieldings of C-2, -3, and -4 would be expected to approximate those for C-6, -5, and -4, respectively, in 1,1,2-trimethylcycloheptane (**55**). The latter values are 22.8, 30.7, and 29.7 ppm, in reasonable agreement with the data for **1** as the two sets were obtained in different media.

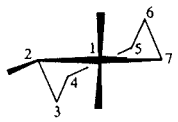
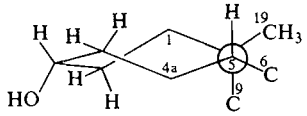
54



55

In addition C-1 in **1** which is *gauche* with respect to C-11 should be shielded relative to C-7 in **55** and an upfield shift of -3.6 ppm is indeed found. On the other hand, C-4a is deshielded by 2.6 ppm relative to C-3 in **55** but there is no obvious prediction for the change at C-4a, whereas the downfield shifts for C-5 and -10 in **1** vs. the C-2 and -1 shieldings (43.2 and 35.6) in **55** are as expected because of the β-effects of C-8 and -11. Even better correspondence is found between the A-ring methylene shieldings of **15** and those of **55** indicating that **15** probably adopts a TC form analogous to **54** with a six-membered ring.

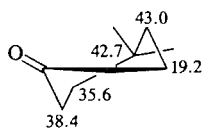
Introduction of the 3α-hydroxyl as in **2** appears to require a conformational change for the A ring since in **54** the 3α-OH is axial and the observed shielding differences from those of **1** do not fit well for such substitution. For example, C-4 shifts downfield by only 2.2 ppm, and C-1 and -4a exhibit distinctly different upfield shifts. Inspection of molecular models indicates that the latter carbons should be shielded to comparable extents with 3α-OH substitution in **54**. On the other hand, TC **56** may be a major contributing form. Three methylene signals at 26.5, 30.5, and 31.8 ppm are much more strongly affected by $Eu(fod)_3$ than the others which is consistent with **56**



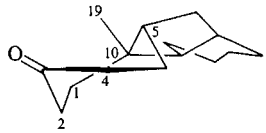
56

whereas the symmetry of **54** suggests that four signals should shift appreciably.

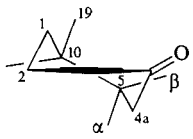
A recent analysis of the cycloheptanone system by St-Jacques *et al.* (22) led to the conclusion that these ketones favor twist-chair forms with the carbonyl group at position TC-2. Thus, **57** should be the favored arrangement for 4,4-dimethylcycloheptanone, the methylene shielding results (21) for which are indicated. A comparison of the results for **3** with the latter suggests that **58** is a major conformer for **3** as is 5β-**59** for **4**. The same comparison of **16** and **19** with **57** shows even better agreement indicating that the differences of 1–2 ppm between model **57** and the *B*-nor derivatives may arise, in part, from constraint owing to the presence of the five-membered ring. It may be noted that C-9 is shielded by -5.8 ppm in **16** relative to **15** but is little changed from **1** to **3**. From molecular models this difference in the two hydrocarbon–ketone pairs can be attributed to the change in B-ring size. With a six-membered B ring, the TC analogous to **58** places C-9 *gauche* with respect to C-2 and C-4a, whereas the TC form analogous to **54** has only one such interaction, C-9 with C-4a. This accounts nicely for the observed shift for C-9 between **16** and **15**. With five-membered B rings, however, C-9 is not *gauche* to any A-ring carbon in either **54** or **58** and its shielding would be expected to be similar in **1** and **3**, as observed. In any event, the methylene shieldings in **3**, **4**, **16**, and **19** seem consistent with forms **58** and 5β-**59**. The analogous comparison for the 5α-*A*-homoketones **11**, **21**, and **26** suggests **60** as a major contributing form with 5α-**59** important for **24** and **27**.



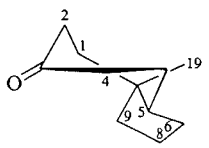
57



58



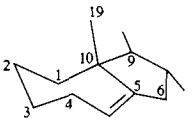
59



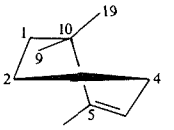
60

Apart from **12** and **13** which lack flexibility,[4] the remaining *A*-homo derivatives contain olefinic bonds. Compounds **5**, **6**, and **7** could exist preferentially in chair **61** or a more flexible twist-boat arrangement such as **62**. Although a clear distinction between these two possibilities cannot be made on the basis of the present results, it may be noted that a comparison of **6** with **5**, to assess the differences produced upon introduction of the 3α-OH group, indicates a significant upfield shift for both γ-carbons (C-1 and -4a) suggesting an axial disposition of the hydroxyl group in **6**. Furthermore, the carbinyl proton absorption in **6** exhibited a half width of

[4]A referee suggests that C-1 in these oxides has sufficient freedom of movement to alter the conformation of the A ring and produce the shielding differences found for C-9 and -19.



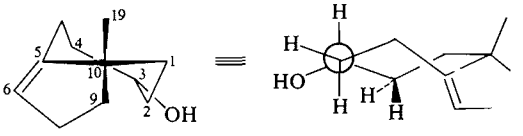
61



62

~9 Hz (3) which seems more compatible with **61** than **62**. A comparison of the carbonyl shieldings for **7** vs. **3** and **18** vs. **16** reveals upfield shifts of −5 ppm ascribable to homoconjugation in the unsaturated systems (23) and is consistent with **61** as the favored conformer.

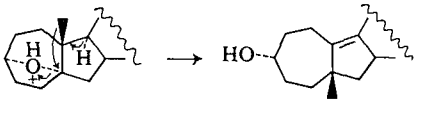
Compounds **8–10** contain double bonds exocyclic to the *A*-homo ring and can be considered in the light of the results for substituted cycloheptanones cited above (22). On this basis **8** should favor TC **63**



63

having C-9 and -19 at the isoclinal positions and the olefinic bond at the TC-2 position. In contrast to **54** this form places the hydroxyl group in an equatorial orientation with the carbinyl proton antiperiplanar with respect to a proton on each of C-2 and -4. However, this proton absorption has a half-width of ~11 Hz (3) which suggests that other conformations make significant contributions to the actual equilibrium mixture of conformers.

In the earlier study (3) concerning the chemistry of the *A*-homo-*B*-nor derivatives included in Table 2 it had been found that cleavage of **12** with $BF_3 \cdot Et_2O$–Ac_2O at room temperature afforded a single acetate which contained a fully substituted double bond rather than the desired acetate of **6**. Clearly a backbone rearrangement had occurred. Hydrolysis of the product to the alcohol whose ^{13}C spectrum was recorded established that the rearrangement was relatively simple. The ^{13}C signals included a series corresponding to those for C-13 to C-27 in many cholestanes (2) with one methyl (C-18) at 11.0 ppm. Furthermore, in the presence of $Eu(fod)_3$, the olefinic signals were more strongly affected than any of the methine signals apart from that for the carbinyl carbon. These findings show the alcohol to have structure **9** arising from a Westphalen-type of rearrangement as indicated in **64** (24). Alcohol **9**

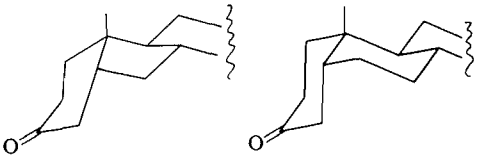


64 9

would be expected to exist preferentially in the conformation corresponding to the mirror image of **63** and it may be noted that the half width of the carbinyl proton absorption of ~20 Hz (3) fits nicely with this prediction. The ^{13}C shieldings for **10**, obtained by oxidation of **9**, indicate that the ketone favors a similar conformation.

The remaining *A*-homo derivatives lack suitable models for consideration of favored conformations but the signal assignments as listed seem the most probable. The results for the single bis-*A*-homo ketone **14** may be viewed similarly.

The *B*-nor compounds listed in Table 4 include the precursors, or derivatives, employed for the preparation of the several *A*-homo steroids discussed above. It is interesting to compare the shieldings for A- and B-ring carbons with those for the normal analogs. For example, a comparison of the data for *B*-nor-5β-cholestan-3-one (**29**) with those for 5β-cholestan-3-one (2) reveals that, in **29**, C-1 and -2 are more shielded whereas C-3 and -4 are deshielded. Presumably this reflects an enhancement of the *gauche* interaction between C-1 and -11 (and, perhaps, C-2 and -9) and the absence of a *gauche* interaction corresponding to that between C-4 and -7 in 5β-cholestan-3-one (see projections **65** and **66**). The



65 66

carbons of the *B*-nor ring appear at significantly lower fields than the corresponding centres in the normal B ring which is consistent with the somewhat enhanced deshielding effects found for some simple methyl substituted cyclopentanes (25) relative to results for the corresponding cyclohexanes (26). The assignments listed for the parent hydrocarbon **28** were obtained using the data for 5β-cholestane (2) and the differences observed between 5β-cholestan-3-one and **29**; thus, these assignments are tentative. The analogous comparison of **31–33** with the cholest-4-en-3-one, cholesterol and its acetate indicates that the shieldings of C-1, -2, and -3 are comparable in both systems while C-4 is somewhat shielded in the *B*-nor derivatives; each of the carbons in the B ring are significantly deshielded in the *B*-nor derivatives relative to the cholestane analogs which is the usual trend for cyclopentenes versus cyclohexenes. Finally, the data for aldol **34** and acid **35**, the parent derivatives for each of the *B*-nor compounds, are included in Table 4.

The stereochemistry of the A/B ring junction in each of these modified steroid skeletons is clearly revealed by the C-19 shieldings, as had been expected by analogy with the results for the natural steroids (2). A comparison of the data for 5α and 5β isomers such as **3** and **11**, **16** and **21**, **19** and **24** (**27**) shows that C-19 is deshielded by 10–12 ppm in the 5β structures, which is comparable to the findings for cholestane, coprostane and several of their derivatives (27).

The ^{13}C shieldings for 16 cholestanes and 2 androstanes are collected in Table 5 since these results provide information on the shielding effects of some substituents and substitution patterns which had not been reported previously.[5] These data should be helpful for the examination of related systems.

From the body of data for the *A*-homo derivatives included in this study, it is apparent that tentative conclusions can be drawn regarding the favored conformations of the seven-membered ring which are consistent with expectations based on the results for simpler systems for which definitive data are available. It may be noted that in each case there are characteristic signals which can be utilized to identify these derivatives in mixtures with other steroids. This can be helpful, both qualitatively and quantitatively, in monitoring the course of reactions involving these species as illustrated in the accompanying paper (4).

Ring expansion of cyclic ketones: The reliable determination of migration ratios for 3-keto steroids by ^{13}C nuclear magnetic resonance and the general implications thereof[1,2]

VINOD DAVE, J. B. STOTHERS, AND E. W. WARNHOFF

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received November 27, 1978

VINOD DAVE, J. B. STOTHERS, and E. W. WARNHOFF. Can. J. Chem. 57, 1557 (1979).

Several ring-expansion reactions (diazomethane, diazoacetic ester, Tiffeneau–Demjanov, Baeyer–Villiger, and Schmidt) of 3-keto steroids have been reexamined to determine the true migration ratios for C-2 and C-4 in these unsymmetrical cyclohexanones. Migration ratios were measured to $\pm 3\%$ accuracy by integration of baseline-separated signals in the proton-decoupled ^{13}Cmr spectra of total reaction products. This underexploited method provides for the first time a way to get accurate migration ratios without loss of components during separation and without interference from excess starting material under conditions minimizing side reactions. In contrast to numerous literature reports, all but one of the 16 reactions studied were found to give nearly the same amount of both possible *A*-homo products. (The single exception was the only reaction in which the *A*-homo product reacts markedly faster than the starting material.) This simple, consistent $\sim 1:1$ pattern is that expected if migration is governed mainly by the electronic effect of the α- and α′-carbon atoms and not by any conformational or near-by-to-remote substituent effect.

VINOD DAVE, J. B. STOTHERS et E. W. WARNHOFF. Can. J. Chem. 57, 1557 (1979).

On a réétudié plusieurs réactions d'extension de cycles (diazométhane, esterdiazoacétique, Tiffeneau–Demjanov, Baeyer–Villiger et Schmidt) de céto-3 stéroïdes afin de déterminer les rapports réels de migration de C-2 et de C-4 dans ces cyclohexanones qui ne sont pas symétriques. On a mesuré ces rapports d'aptitudes à la migration avec une exactitude de $\pm 3\%$ en intégrant les signaux séparés à la base, des spectres rmn du ^{13}C découplés pour le proton, des produits totaux de réaction. Cette méthode sous-exploitée fournit pour la première fois une façon d'obtenir des rapports précis d'aptitudes à la migration sans perte de composants au cours de la séparation et sans interférence de la part du produit qui n'a pas réagi dans des conditions minimisant les réactions secondaires. Par opposition à de nombreux rapports publiés dans la littérature, on a trouvé, dans tous les 16 cas étudiés, à l'exception d'un, qu'il se forme des quantités égales des deux produits *A*-homo possibles. (La seule exception est notée dans la seule réaction dans laquelle le produit *A*-homo réagit beaucoup plus rapidement que le produit de départ). Ce résultat, $\sim 1:1$, obtenu d'une façon systématique est celui que l'on peut prévoir si la migration n'est gouvernée que par l'effet électronique des atomes de carbone α et α′ et non pas par un effet conformationnel ou d'un substituant proche ou éloigné.

[Traduit par le journal]

The ring expansion of cyclic ketones is a useful synthetic reaction, but it is frequently complicated by the problem of similar α- and α′-migratory aptitudes leading to two isomeric ring-expanded products which can be difficult to separate or analyze. This problem has been of most concern with unsymmetrical cyclohexanones, and a conspicuous example is the ring homologation of 3-keto steroids **1**. The conflicting reports (2–15) of varying product composition from this series of compounds has led to the postulation of remarkable differential migratory aptitudes and their equally remarkable rationalizations (4, 7, 13, 16). It has now become apparent, through the work of Jones and Price (15) and Levisalles *et al.* (10) on the homologation reactions, that most of the complexities are the result of analytical techniques inadequate for the task.

For example, initial reports of the formation of a majority (≥ 50–60%) of *A*-homo-4-ketone **4***a* (Scheme 1) from ring expansion of 5α-cholestan-3-one (**2***a*) by either diazomethane (CH_2N_2) (3) or by the Tif-

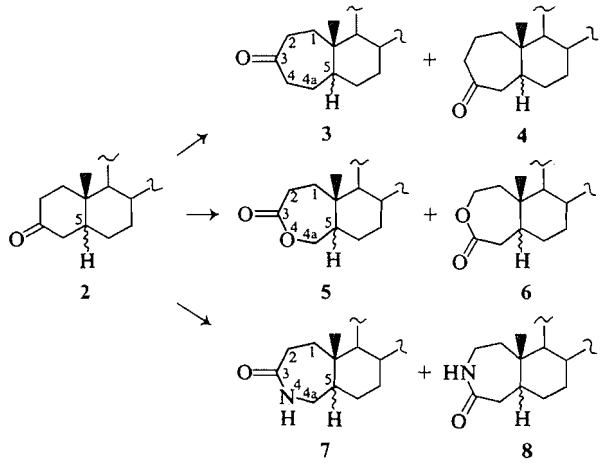
feneau–Demjanov method (amino alcohol diazotization) (2, 3) were based on analysis by alumina chromatography and infrared spectroscopy. Later, the additional use of ord was introduced by Jones and co-workers (4, 7) to determine the ratio of *A*-homo ketones in product mixtures from 3-keto steroids by comparison with the ord curves for the pure products. With the nearly inseparable products from 5α-cholestan-3-one, the ratio of 3-ketone **3***a* to 4-ketone **4***a* determined by this method was 21:79 ±3% (7). However, further investigation revealed that one or both of the reference samples **3***a* or **4***a* was apparently contaminated. Thus, Levisalles *et al.* (10) prepared these two ketones by methods leading unambiguously to pure specimens, and both they and Jones and Price (15) used these samples to recheck the ring-expansion ratio for **2***a* + CH_2N_2. Both groups found a new **3***a*:**4***a* ratio of 57:43 ±5% (10) ≈ 58.5:41.5 ±3% (15) in good agreement with ratios for other 3-keto steroids whose homologation products were more readily separated (see entries from ref. 7 in Table 1). The Tiffeneau–Demjanov expansion of 5α-cholestan-3-one was also checked by Levisalles *et al.* (10) who found the **3***a*:**4***a* product ratio to be 50:50 (Table 1, entry 7) comparable to the value found for CH_2N_2. In complete disagreement, Sykes and co-workers (13) reported concurrently that the 4-ketone **4***a* was the only *A*-homo ketone formed from either epimer of the amino alcohol **9**; the absence of *A*-homo-3-ketone **3***a* was judged by glpc comparison with authentic specimens of **3***a* and **4***a*. In a more recent repetition of the reaction, Jones and Price (15) have reaffirmed that both *A*-homo ketones are formed in slightly different proportions from each epimer of the amino alcohol **9** (Table 1, entries 8 and 9). It was desirable to have an independent check both on these conflicting accounts of the Tiffeneau–Demjanov reaction and on the CH_2N_2 reaction.

As can be appreciated from the foregoing, the analytical methods employed had inherent shortcomings. The use of ord requires both optical activity and the availability of both ring-expansion products in pure form; it also requires that *only* the two compounds of interest be present in the mixture to be analyzed. However, CH_2N_2 ring expansion usually produces small amounts of epoxides and polyhomologation products difficult to separate from the homo ketones. With CH_2N_2 another drawback of the chromatography–ord method of analysis is that the 3-keto starting material should be completely used up to simplify the product separation. In this way is introduced the additional complication of possible differential ring expansion of the initial *A*-homo ketones. Should the 3- and 4-ketones react



a 5α-Cholestane skeleton

c 17β-Hydroxy-5α-androstane skeleton
d 6β-Acetoxy-5α-cholestane skeleton

SCHEME 1

at different rates, the final **3**:**4** ratio would not reflect the true migration ratio for the reaction of **2**. On the other hand, the use of glpc requires sufficiently different retention times for the two expansion products, a requirement not easily met for such closely similar high molecular weight compounds (15). Although the application of ^{1}Hmr spectra to the analysis of these product mixtures should be more successful, it depends on there being well-separated signals for the two isomers, and for 3-keto steroids very high magnetic fields may be needed to achieve separation (17).

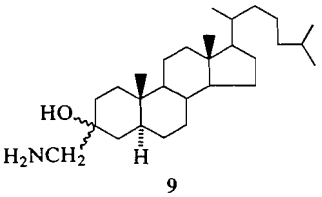
A convenient, more recently available analytical method which does overcome all of the aforementioned difficulties is integration of appropriate peaks in the proton-decoupled ^{13}Cmr spectra of product mixtures. Although for smaller molecules peak areas are not necessarily proportional to numbers of nuclei, Wehrli (18, 19) has shown that for molecules as large and rigid as **2***a*, under non-saturating conditions the nuclear Overhauser effect in proton-decoupled spectra is complete and equal for all skeletal carbon atoms (including quaternary), and therefore signal integration can be used for quantitative analysis. Moreover, unlike the ord or glpc methods, the nature of ^{13}Cmr spectra reflects the structural identity of a mixture's components. We have found, in the course of examining the ^{13}Cmr spectra of some *A*-homo steroids (1, 20), that several of the lower-field signals in the 40–60 ppm region were well separated in isomeric *A*-homo compounds and their precursor. Fortunately, integration of these separated peaks in mixtures was not only reproducible in duplicate reactions, but with test mixtures

it was found to give reliable isomer ratios accurate to ±3%.[3] Hence, there were no complications from potentially unequal Overhauser effects (21). The absence of interfering absorptions from starting material meant that it was now possible to perform the CH_2N_2 ring expansions with a large excess of starting material remaining in order to minimize the likelihood of further reaction of initially formed *A*-homo ketones, a bothersome problem in some instances. Furthermore, if any side products such as epoxides and bishomo ketones should be formed to any significant (≥5%) extent, they would be readily detected by extra peaks in the low-field end (40–70 ppm) of the ^{13}Cmr spectrum, but they would not cause any difficulties with integration of carefully selected signals. The extent of mono- and polyhomologation could be estimated from the mass spectrum of the reaction product.[4] The advantages of the method were well demonstrated in examining the reactions of 3-keto steroids.

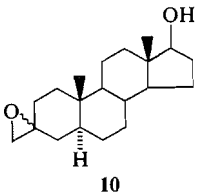
The first compound studied was 5α-cholestan-3-one (**2***a*) whose ^{13}Cmr spectrum has a region devoid of signals between 46 and 54 ppm (22). Authentic samples of **4***a* and **3***a* prepared by known methods (10, 23) (see Experimental) were used for ^{13}C peak assignments (1). Each of the *A*-homo ketones absorbed in the region free of **2***a* absorption, **3***a* at 50.6 (C-5) and 53.3 ppm (C-9), and **4***a* at 47.9 (C-4a) and 54.1 ppm (C-9). The accuracy of integration of these peaks was verified with three known mixtures of **3***a* and **4***a* (see Experimental). Limited ring expansion of the 3-ketone **2***a* with CH_2N_2 by both the *in situ* and *ex situ* procedures (see Experimental) gave a product containing 20–28% of *A*-homo ketones. Integration of the ^{13}C signal at 53.3 ppm relative to that at 54.1 ppm and of the peak at 47.9 ppm relative to that at 50.6 ppm gave the same **3***a*:**4***a* ratio of 58:42 ±3% (Table 1, entries 1, 2, and 5) in excellent agreement with the ord derived value of Levisalles *et al.* (10) and Jones and Price (15) (Table 1, entries 3 and 4), which therefore did represent the true kinetic migration ratio in spite of consumption of most of the starting ketone **2***a* in their reactions.

To test whether the initial *A*-homo ketones would show selectivity in the event of their reaction, a synthetic 50:50 mixture of **3***a* + **4***a* was treated to the extent of 15% reaction with CH_2N_2 generated *in situ*. ^{13}Cmr examination of the remaining *A*-homo ketones gave an altered **3***a*:**4***a* ratio of 57:43 ±3%, and consequently the 4-ketone is more reactive. The probable reason that this selectivity was not reflected in Levisalles's and Jones's ratios is that the reaction of CH_2N_2 with both **3***a* and **4***a* is slower than with **2***a*, and any excess CH_2N_2 may have been used up in polymerization.[5]

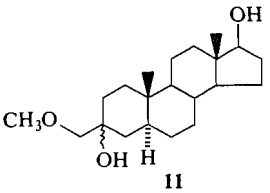
As independent confirmation that the Tiffeneau–Demjanov expansion of 5α-cholestan-3-one does indeed give both *A*-homo ketones, this reaction too was reexamined. Diazotization of a 30% α – 70% β mixture of hydroxyl epimers of amino alcohol **9** gave a product whose ^{13}Cmr spectrum revealed the presence of both **3***a* and **4***a* in the ratio of 43:57 (Table 1, entry 6) in reasonable agreement with the ord-derived values of Levisalles *et al.* (10) and Jones and Price (15) (Table 1, entries 7, 8, and 9). Apparently, as pointed out by Jones and Price (15), the very close glpc retention times for **3***a* and **4***a* used by Sykes and co-workers (13) did not permit resolution of mixtures of the two isomers.



9



10



11

The next migration ratio determined was for a reported (7, 9, 15) ring expansion giving products more easily separated by chromatography, and for which the migration ratio determined by a combination of separation and ord should therefore be accurate provided that no by-products contaminated the ord samples. Ring expansion of an excess of 17β-hydroxy-5α-androstan-3-one (**2***c*) afforded a product containing 35–43% of *A*-homo ketones. The ^{13}C peaks were assigned (1) with the aid of authentic specimens of both products (7) separated by chromatography from a reaction in which all starting material had been consumed. In the spectrum of the mixture, the best separated peaks for integration were the signals at δ 27.8 in homo ketone **3***c* and at δ 18.9 in **4***c*. Values of the **3***c*:**4***c* ratio of 56:44 and

[3]The accuracy is probably better than that (±3–5%) estimated for the ord method (7, 10). Note also that integration of two or more peaks for each component provides an internal check.

[4]The extra CH_2 group or two would have a negligible effect on the vapour pressure of these large molecules.

[5]Note that the selectivity found (**4***a* reacts faster than **3***a*) is in the wrong sense to account for the originally reported **3***a*:**4***a* ratio of 21:79 (7) by further preferential reaction of initial *A*-homo products.

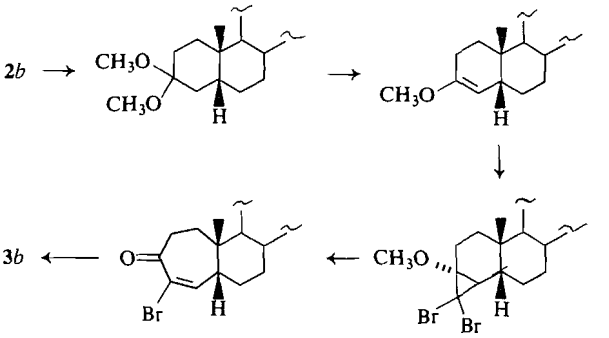
57:43 were obtained in this way from two reactions. Four lower-field signals at δ 47.8, 50.5, 53.4, and 54.2 were not sufficiently separated from starting material peaks for confident integration unless most of the **2***c* had been consumed. Therefore, a homologation carried to >90% consumption of **2***c* was chromatographed to separate the *A*-homo ketone mixture which was integrated over all six peaks to give a **3***c*:**4***c* ratio of 55:45, identical with the two-peak integration ratio within experimental error. The validity of the integrations was also checked with a known mixture. The **3***c*:**4***c* migration ratio of 56:44 (Table 1, entry 14) obtained by averaging the above results agrees within experimental error with the earlier reported value of 59:41 (7, 15).

For 5β-cholestan-3-one, the only reported (7) value of 78:22 (ord derived) for the **3***b*:**4***b* ring-expansion ratio was suspect because the almost 4:1 preference for C-4 migration deviated from the negligible preference now established for other 3-keto steroids. Accordingly, the reaction was re-examined. The ^{13}C absorption-free region was slightly shifted to 44–56 ppm for **2***b* (22). Limited ring expansion by the *in situ* method gave a product with 39–53% of starting material remaining.[6] Its ^{13}C signals were assigned by comparison with those of starting ketone **2***b* and of an authentic specimen of *A*-homo-5β-cholestan-3-one (**3***b*) prepared as shown in Scheme 2 (also see Experimental). The true **3***b*:**4***b* product ratio found by integration of baseline separated peaks at 46.6 ppm (C-5 of **3***b*) and 45.9 ppm (C-5 of **4***b*) was 52:48 in good agreement with the values of other 3-ketones.

There are two other reports in the literature which are at variance with the present findings. In ref. 6, only the *A*-homo 4-ketone[7] was isolated from the reaction of *B*-nor-5β-cholestan-3-one with CH_2N_2. Actually, both *A*-homo ketones were undoubtedly formed since the Tiffeneau–Demjanov expansion of the same *B*-nor ketone gave both *A*-homo-3- and -4-ketones (14), and since diazoacetic ester expansion gave a 42:58 ratio of *A*-homo-3- to -4-ketone after decarbethoxylation (20). Repetition of the reaction with CH_2N_2 to a limited extent gave a product containing 83.4% of unreacted *B*-nor ketone, 11.2% of *A*-homo ketone mixture, and surprisingly 5.3% of



SCHEME 2

bis-*A*-homo ketones. Therefore, one or both of the *A*-homo ketones reacts considerably faster with CH_2N_2 than does the starting material. Consequently, the *A*-homo-3- to -4-ketone ratio found of ~70:30[7] probably does not represent the true migration ratio which should be closer to the 42:58 figure from the diazoacetic ester reaction (Table 1, entry 35).

The second anomalous case is that of 6β-acetoxy-5α-cholestan-3-one (**2***d*) from whose reaction with a large excess of CH_2N_2 + $AlCl_3$ only bis- and tris-homo products were isolated (12). However, from reaction with a limited amount of CH_2N_2 such that 69% of starting material remained, we find that both *A*-homo ketones are formed in a ratio not experimentally different from 50:50 by comparison of the integral of the ^{13}C signal at δ 75.3, which contains the absorption from C-6 of both *A*-homo ketones, with peaks at δ 30.0, 30.5, 51.9, and 53.0, each of which arises from only one of the *A*-homo ketones.

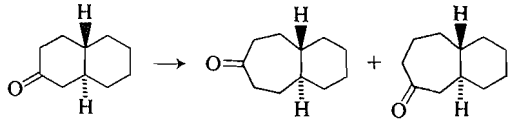
Therefore, for all of the 15 steroids whose ring homologation has been studied with care (see Table 1) there is either no preference or else a negligible preference for migration of C-4 over C-2, and the **3**:**4** ratio does not exceed 6:4 (or *vice versa*) in any case.[8] This is as would be expected in consideration of both C-2 and C-4 being secondary and there being no conformational migratory preference discernible from Dreiding models. It should also be noted that the C-19 methyl group and the steroid C- and substituted D-ring do not play a detectable role in determining the migration ratio since CH_2N_2 ring expansion of *trans*-2-decalone (**12**), a bicyclic model for 5α-3-keto steroids, also gave the same value of 56:44 for the **13**:**14** ratio (24). Likewise, the Tiffeneau–Demjanov rearrangement of each of the

[6]If ring expansion of the 5β-ketone **2***b* is carried to near completion, a much more complex mixture of products is apparent from the ^{13}Cmr spectrum than is the case with the 5α-ketone **2***a* under similar conditions.

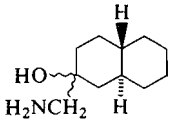
[7]It is not clear which ketone isomer is meant in ref. 6; the structural formula is that of the *A*-homo-3-ketone but the name given in the Experimental is for the *A*-homo-4-ketone. Since excess CH_2N_2 was used and since the $[\alpha]_D$ was +21°, the product was probably the *A*-homo-3-ketone (20) in view of the present findings, even though its melting point was low.

[8]Strictly speaking, the homologations of the compounds listed in entries 23–31 of Table 1 should also be reexamined by the ^{13}Cmr method but the 1:1 pattern from all five different reactions examined by this technique in the present work now leaves no real doubt that the earlier ord results for these compounds (7) are substantially correct.

epimeric bicyclic amino alcohols **15** gave the same ratios as did the Tiffeneau-Demjanov rearrangement of the corresponding amino alcohols from 5α-cholestan-3-one and 17β-hydroxy-5α-androstan-3-one (compare entries 8, 9, 16, and 17 with 37 and 38 in Table 1).



12 **13** **14**

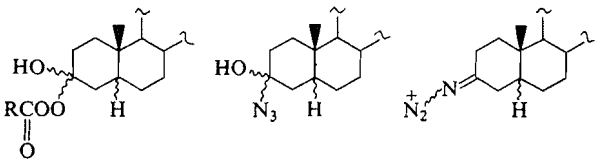


15

The consistency of the results emerging from these experiments prompted the scrutiny of related ring expansion reactions to see how widely the generalization held.

Homologation of ketones with diazoacetic ester (DAE) has become a useful alternative to the use of CH_2N_2 (25, 26). When both 5α- and 5β-cholestan-3-one were partially homologated with DAE–$Et_3O^+BF_4^-$ and decarbethoxylated,[9] the ratios of *A*-homo products were the same for both (Table 1, entries 10 and 20) and were changed slightly in favor of more 4-ketone relative to the CH_2N_2 reactions, but for all practical purposes the change is negligible.

The ring expansion of ketones to lactones by migration to oxygen in the Baeyer–Villiger reaction involves an intermediate **16** that is of the same type as in the diazoalkane reaction, and the simplest view would lead one to expect the same migration ratio for both reactions. Unfortunately, the Baeyer–Villiger cleavage of 3-keto steroids has been beset by the same difficulties found with the CH_2N_2 reactions. Most investigators report only the isolation of the 3-oxolactone **5** in yields as high as 76% (27–35) from peracid oxidation, but on reinvestigation some of these reactions have been shown to produce both lactones **5** and **6** (36). In other cases both lactones were found initially (37, 38). However, no accurate values for product ratios have been reported. Therefore, we have carried out the cleavage by *m*-chloroperbenzoic acid – $CHCl_3$ of 5α- and 5β-cholestan-3-one as well as 17β-hydroxy-5α-androstan-3-one. In each case both lactones were formed in a nearly 1:1 ratio. The different location of the introduced oxygen atom in the two lactones made unambiguous the assignment by chemical shift of the lowest-field sp^3-^{13}C signals in the ^{13}Cmr spectrum without the necessity of authentic samples of the lactones. For example, the lowest field sp^3-^{13}C peak in the spectrum of the 5α-cholestan-3-one product at 70.0 ppm can only be C-4a (O—CH_2—CH) of lactone **5***a*, while the next lowest sp^3-^{13}C peak at 64.7 ppm must be C-2 (O—CH_2—CH_2) of lactone **6***a* (39). These assignments were confirmed for the **2***a* reaction by preparation of pure lactone **5***a* (40) as described in the Experimental. Integration of the spectrum of the lactone mixture gave a **5***a*:**6***a* migration ratio of 55:45 (Table 1, entry 11), very nearly the same as the CH_2N_2 migration ratio with this ketone (Table 1, entries 1–5). The product ratios for the lactones from **2***b* and **2***c* (Table 1, entries 18 and 21) were likewise as easily determined[10] and were close to those for the corresponding CH_2N_2 reactions.



16 **17** **18**

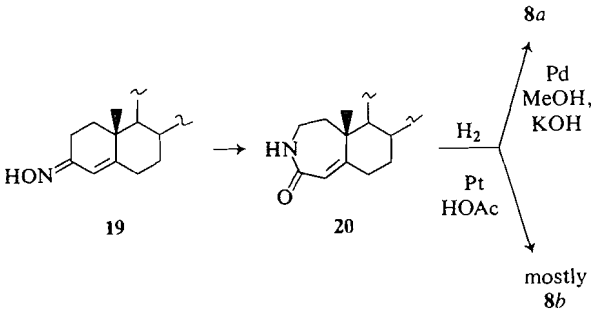
Because different peracid oxidation conditions have been known to influence the proportion of cleavage products from some ketones, the oxidation of **2***a* was also done with CF_3CO_3H–$CHCl_3$, a much stronger peracid. Contrary to a previous report for this reagent (34), the migration ratio (Table 1, entry 12) was found to be essentially the same as for the *m*-chloroperbenzoic acid – $CHCl_3$ cleavage.

Finally, ring expansion to nitrogen was examined by means of the Schmidt reaction. The mechanistic evidence (41, 42) allows for the reaction to proceed to amide through either the tetrahedral intermediate **17**, analogous to those of the already mentioned ring expansion reactions, or else through *anti* rearrangement of the geometrical isomers of the diazoimonium ion **18**. Since the proportion of *syn* and *anti* isomers is determined by steric factors, and since the steric situation is the same for both isomers with these 3-keto steroids, either mechanism would be expected to lead to an approximately 1:1 ratio of products **7** and **8**. However, the Schmidt reaction with both 5α- and 5β-cholestan-3-one has been

[9]The crude β-keto esters were decarbethoxylated with water in sealed tubes at 150°C (26). Under these conditions the ketonic components underwent condensation reactions to some extent. Possibly these side reactions were acid catalyzed (by traces of boron compounds remaining?) because they were minimized by the addition of a small amount of $NaHCO_3$ to the water (see Experimental).

[10]With the 17β-hydroxy compound **2***c* care had to be taken to avoid an excess of peracid which oxidized the 17β-OH to a carbonyl group.

reported by Doorenbos and Wu (43) to yield only isomer **8**. Repetition of the reaction of the 5α- and 5β-ketones **2***a* and **2***b* according to their procedure gave products each of whose ^{13}Cmr spectra clearly showed the presence of both lactams **7** and **8** in similar amount. The assignment of ^{13}C peaks in each lactam mixture was made with the aid of spectra of pure **8***a* and **8***b* prepared as described below.



Beckmann rearrangement of the mixture of cholest-4-en-3-one oximes **19** at room temperature with $SOCl_2$ in dioxane results only in migration of the sp^3 C-2 to produce the unsaturated lactam **20** (44, 45). Hydrogenation over Pd/C in methanol–KOH gave the 5α-lactam **8***a* (44) whose *trans* A/B fusion was verified by its ^{13}C-19 methyl signal at 12.0 ppm (46). Hydrogenation of **20** over Pt in HOAc gave mostly the 5β-lactam **8***b* which was purified by thick-layer chromatography; the *cis* A/B fusion was confirmed by its ^{13}C-19 methyl peak at 23.3 ppm (46). With the ^{13}C signals identified in the Schmidt reaction mixtures, the 1:1 ratios given in entries 13 and 22 of Table 1 were calculated.[11]

In conclusion, we see that the supposedly widely differing results of various 3-keto steroid ring-expansion reactions actually fit a consistent pattern. Thus, for 16 of these similar unsymmetrical cyclohexanones (including 2-decalone) and five different reactions, ring expansion to C, N, and O gives a migration ratio of ~1:1. This simple outcome is to be expected if migration in all of these reactions is governed *mainly* by the electronic effect of the α- and α′-methylene groups and not by any conformational or long range effects. As a corollary, in each of the many cases in which the lactones and lactams from Baeyer–Villiger or Schmidt or even Beckmann reactions on 3-keto steroids have been prepared or used (on the assumption that pure compounds were involved) in structure assignments to other compounds or as starting materials for synthesis (*inter alia* 32, 34, 40, 47, 48), the conclusion or purity of product is dubious, and this implication of the present work will be considered in a subsequent paper.

[11]Although the ratios turned out to be exactly 50:50, assignment of signals to individual lactams gave assurance that the integrated peaks were not all from a single lactam.

Experimental

General

Reagents, instruments, and procedures are the same as in ref. 20 except for the following. Camag DSF-O silica gel was used for some tlc plates. Some ir spectra were recorded on a Perkin Elmer model 621 instrument. The samples of **2***a*, **2***b*, **2***c*, and **2***d* used were shown to be pure by ^{13}Cmr spectroscopy. Complete ^{13}Cmr assignments for the steroids in this work are given in ref. 1. The mass spectra for quantitative analysis of product mixtures were run at 25 eV to minimize fragmentation and maximize molecular ions. The figures in parentheses after the ion masses are the percentages of starting material and homo and bishomo products calculated from the ion intensities and estimated to be accurate to ±3%.

^{13}C Nuclear Magnetic Resonance Spectra

Spectra were obtained at 25.2 MHz with a Varian XL-100-15 system operating in the Fourier transform mode with square-wave modulated proton decoupling. Solutions were usually ~0.25 *M* in $CDCl_3$ and in no case exceeded 1.25 *M*; TMS was used as an internal reference. Wehrli has shown (18) that all carbons of the steroid ring system exhibit maximum and equal nOe's under appropriate operating conditions. With 2 or 2.5 kHz sweep widths, flip angles ≤45°, and pulse acquisition times of 0.8–1.0 s, our conditions insured that the protonated skeletal carbons gave full nOe's although the quaternary carbons were probably partially saturated. To achieve suitable signal-to-noise levels the number of scans varied from 10–50 K and 8 K transforms were used. Integrations were done both by the usual electronic means and by comparing the products of peak height × peak width at half-height for the best-separated signals in expanded traces of the region of interest. If peak separation permitted, two or more signals per component were integrated, and the results were averaged to obtain the reported composition data. Integrals were found to be reproducible to ±2% and, from control experiments, the composition of known mixtures of **3***a* and **4***a* was found to a precision of ±2%; in these controls the following signal areas were measured: **3***a*, 50.6 (C-5) and 53.3 ppm (C-9); **4***a*, 47.9 (C-4a) and 54.1 ppm (C-9). This led to the following results.

Mixture (mg)		3a		
3a	4a	By weight %	By integration	Average
12.0	36.0	25	26, 25, 27, 26	26
24.0	24.0	50	49, 49, 50, 49	49
36.0	12.0	75	76, 74, 76, 75, 74	75

On this basis, the compositions of the product mixtures are judged by the 4d rule to have precisions of 3%. Whenever possible, the crude mixtures of ring expansion products were not chromatographed before ^{13}Cmr spectroscopy to avoid any possibly unequal irreversible adsorption. Each CH_2N_2 and DAE ring expansion was done at least in duplicate, but only one experiment per ring expansion is described in the sequel.

General Procedure for In Situ *CH_2N_2 Reactions*

To a stirred (magnetic bar) solution of 100 mg of steroid, 30 mg of powdered KOH, 1 mL of MeOH, and 2 mL of ether at 0–5°C was added a known amount of CH_2N_2 precursor. When less than 100 mg was used, the amounts of MeOH and ether were reduced proportionately. Throughout the reaction

solid was present, initially the partially soluble CH_2N_2 precursor and later presumably potassium salts. After the two-phase mixture had been stirred at 5–8°C for 6 h, the solvents were evaporated in a stream of N_2. Water and 10% aqueous HCl were added, and the product was extracted with ether. The organic layer was washed with water, dried, and evaporated to leave the crude product which was examined by ^{13}Cmr and mass spectroscopy. The amount of CH_2N_2 precursor required to achieve partial homologation varied because of the limited solubility of the CH_2N_2 precursor and the competing polymerization side reaction of CH_2N_2. For the same reasons, a given level of homologation was difficult to reproduce in duplicate reactions.

(a) 5α-Cholestan-3-one + N-Methyl-N-nitrosourea (NMU)

From 100 mg (0.26 mmol) of **2***a* and 15 mg (0.15 mmol) of NMU was obtained 92 mg of colorless solid product, *m/e* 386 (72% of **2***a*) and 400 (28% of **2***a* + CH_2) with no detectable bis homologation at 414. ^{13}C peaks integrated: δ 47.9 (C-4a of **4***a*), 50.6 (C-5 of **3***a*), 53.3 (C-9 of **3***a*), and 54.1 ppm (C-9 of **4***a*) (Table 1, entry 1).

(b) 5α-Cholestan-3-one + Diazald

From 100 mg (0.26 mmol) of **2***a* and 94 mg (0.44 mmol) of Diazald was obtained 88 mg of colorless solid, *m/e* 386 (20.5% of **2***a*), 400 (78.7% of **2***a* + CH_2), and 414 (0.7% of **2***a* + 2 CH_2). ^{13}C peaks integrated: same as in (*a*) (Table 1, entry 5).

(c) A-Homo-5α-cholestan-3- and -4-ones (1:1) + NMU

From 20 mg (0.05 mmol) of **3***a* plus 20 mg (0.05 mmol) of **4***a* and 21 mg (0.20 mmol) of NMU was obtained 40 mg of colorless solid, *m/e* 400 (84% of **3***a* + **4***a*) and 414 (16% of **3***a* and **4***a* + CH_2) with no detectable amount of bis homologation product. ^{13}C peaks integrated: same as in (*a*); **3***a*:**4***a* ratio, 57:43 ± 3%.

(d) 5β-Cholestan-3-one + NMU

From 50 mg (0.13 mmol) of **2***b* and 15 mg (0.15 mmol) of NMU was obtained 47 mg of colorless solid, *m/e* 386 (53% of **2***b*), 382 and 400 (47% of **2***b* + CH_2 and its $M^+ - 18$ ion) with less than 0.5% of bis homologation. ^{13}C peaks integrated: δ 45.9 (C-5 of **4***b*) and 46.6 ppm (C-5 of **3***b*) (Table 1, entry 19).

(e) 17β-Hydroxy-5α-androstan-3-one + NMU

From 50 mg (0.17 mmol) of **2***c* and 12 mg (0.12 mmol) of NMU was obtained 44 mg of colorless solid, *m/e* 290 (65% of **2***c*) and 304 (35% of **2***c* + CH_2) with no more than 0.2% of bis homologation. ^{13}C peaks integrated (see Discussion): δ 18.9 (C-2 of **4***c*), 27.8 (C-4a of **3***c*), 47.8 (C-4a of **4***c*), 50.5 (C-5 of **3***c*), 53.4 (C-9 of **3***c*), and 54.2 ppm (C-9 of **4***c*). Duplicate reactions gave **3***c*:**4***c* ratios of 56:44 and 55:45 (Table 1, entry 14).

A synthetic mixture of 17.0 mg of **3***c* and 13.0 mg of **4***c* (ratio 56.6:43.4) was analyzed by integration of the same set of signals, and it gave a **3***c*:**4***c* ratio of 56:44.

(f) B-Nor-5β-cholestan-3-one + NMU

From 48 mg (0.13 mmol) of *B*-nor-5β-cholestan-3-one and 13 mg (0.13 mmol) of NMU was obtained 48 mg of colorless noncrystalline product, *m/e* 372 (83.4% starting material), 386 (11.2% of monohomo product), and 400 (5.3% of bishomo product). ^{13}C peaksi ntegrated: δ 47.8 (C-4a of the *A*-homo-4-ketone) and 50.0 ppm (C-5 of the *A*-homo-3-ketone) (Table 1, entry 34).

Ex Situ *Diazomethane Reactions*

(a) 5α-Cholestan-3-one

A solution of 100 mg of **2***a* in 1.5 mL of ether, 1.5 mL of MeOH, and 0.1 mL of water was treated with excess distilled ethereal CH_2N_2 at 5–8°C for 2 days. After evaporation of solvent, the residue was dissolved in ether, washed with water, dried, and concentrated to give 90 mg of colorless solid, *m/e* 400 (93% of **2***a* + CH_2) and 414 (7% of **2***a* + 2 CH_2) with no **2***a* remaining. ^{13}C peaks integrated: same as in (*a*) of the *in situ* reactions (Table 1, entry 2).

(b) 6β-Acetoxy-5α-cholestan-3-one

To a solution of 44 mg (0.10 mmol) of 6β-acetoxy-5α-cholestan-3-one in 0.75 mL of ether plus 0.75 mL of MeOH was added 0.3 mL of 0.33 *N* CH_2N_2 in ether and 1 drop of water. After 2 days at 5–8°C, solvent was evaporated to leave 44 mg of solid which gave two tlc spots. Since the ^{13}Cmr spectrum of the crude product was not suitable for integration, it was chromatographed on a 10-g preparative plate developed (2×) in benzene–ether (90:10). Extraction of the band at R_f 0.54 gave 32 mg of the major, more polar material, *m/e* 444 (79% of starting material) and 458 (21% of starting material + CH_2) with no detectable amount of bis homologation product. ^{13}C peaks integrated [relative peak area] δ: 30.0[177], 30.5[177], 51.9[163], 53.0[165], and 75.3 ppm [350] (Table 1, entry 33).

Preparative Reaction with 17β-Hydroxy-5α-androstan-3-one (2c)

To a stirred (magnetic bar) solution of 200 mg of **2***c* (Sigma Chemical Co.), 980 mg of powdered KOH, 3 mL of ether, and 3 mL of MeOH at 0–5°C was added 750 mg of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide during 10 min; the two-phase mixture was then stirred at 5°C for 6 h. After evaporation of most of the solvent in a stream of nitrogen, the residue was dissolved in ether, washed with water, dried, and concentrated to leave 186 mg of oily solid which was chromatographed on four preparative plates developed (3×) with benzene–ether (50:50).

Extraction of the band at R_f 0.76 gave 12 mg of a colorless oily mixture of oxides, probably **10**, ir: no C=O absorption. M^+ calcd. for $C_{20}H_{32}O_2$: 304.2402; found: 304.2405.

Extraction of the band at R_f 0.73 gave 25 mg of colorless solid. Recrystallization (2×) from EtOAc gave 8 mg of 17β-hydroxy-*A*-homo-5α-androstan-4-one (**4***c*), mp 196–199°C (lit. (7) mp 193.5–194.5°C); ^{1}Hmr ($CDCl_3$) δ: 0.74 (3H, s, CH_3), 0.88 (3H, s, CH_3), 2.41 (2H, m, band w = 16 Hz, ketone α-CH_2), 2.82 (1H, dd, J_{AX+BX} = 25 Hz, ketone α-H), and 3.64 ppm (1H, bt, J_{AX+BX} = 18 Hz, C*H*OH).

Extraction of the band at R_f 0.67 gave 44 mg of colorless solid. Recrystallization from MeOH (1×) and from EtOAc (1×) gave 13 mg of colorless plates of 17β-hydroxy-*A*-homo-5α-androstan-3-one (**3***c*), mp 207–210°C (lit. (4) mp 212–213°C). M^+ calcd. for $C_{20}H_{32}O_2$: 304.2402; found: 304.2404.

Extraction of the most polar band at R_f 0.52 gave 17 mg of colorless solid, *m/e* 336 (M^+) and 291 ($M - CH_3OCH_2$); ir ($CHCl_3$): 3700–3300 cm^{-1} (broad OH) and no C=O absorption; ^{1}Hmr ($CDCl_3$) δ: 0.73 (3H, s, CH_3), 0.76 (3H, s, CH_3), 3.18 (2H, s, —OCH_2—), 3.39 (3H, s, OCH_3), and 3.64 ppm (1H, bt, J_{AX+BX} = 18 Hz, C*H*OH). M^+ calcd. for $C_{21}H_{36}O_3$: 336.2664; found: 336.2665. The ^{13}Cmr spectrum was in agreement with structure **11**. The compound did not react with $NaIO_4$ or $Pb(OAc)_4$.

Tiffeneau–Demjanov Expansion of 5α-Cholestan-3-one

A mixture of epimeric amino alcohols **9** was made from **2***a* by the method of ref. 13 without purification of intermediates. Integration of the —CH_2N protons at δ 2.75 for the 3β-OH epimer and δ 2.55 for the 3α-OH epimer gave 70% β-OH and 30% α-OH. To a stirred (magnetic bar) solution of 110 mg (0.26 mmol) of the amino alcohol mixture in 2 mL of HOAc and 2 mL of ether at 0–5°C was added a solution of 400 mg (5.8 mmol) of $NaNO_2$ in 1 mL of water during 10 min. The reaction mixture was stirred at ~8°C for 1 h and at room temperature for 17 h. After dilution with water and extraction with ether, the organic layer was washed with water and 5%

aqueous $NaHCO_3$. Evaporation of the dried organic solution left 90 mg (86%) of oily solid, ir ($CHCl_3$): 1695 cm^{-1} (C=O); *m/e* 400 (M^+). ^{13}C peaks integrated: same as in (*a*) of the *in situ* CH_2N_2 reactions (Table 1, entry 6).

Diazoacetic Ester Reactions

*(a) 5α-Cholestan-3-one (***2a***)*

To a stirred (magnetic bar) solution of 100 mg (0.26 mmol) of **2***a* and 99 mg (0.52 mmol) of $Et_3O^+BF_4^-$ in 1 mL of CH_2Cl_2 at 0–5°C was added a solution of 59 mg (0.52 mmol) of DAE in 0.5 mL of CH_2Cl_2. The cooling bath was allowed to warm to room temperature, and the reaction mixture which slowly darkened was stirred for 7 h. After addition of 5% aqueous $NaHCO_3$, stirring was continued for 15 min. Evaporation of CH_2Cl_2 and partition of the residue between ether and water yielded a dark brown oil which was heated in a sealed glass tube at 150°C with 1 mL of water and 5 mg of $NaHCO_3$ for 1 h.[9] There was obtained 83 mg (83%) of amber oily ketone mixture, ir ($CHCl_3$): 1695 and 1705 cm^{-1} (C=O); *m/e* 386 (46% of **2***a*), 400 (51% of **2***a* + CH_2), 414 (1% of **2***a* + 2 CH_2), and 416 (2% of **2***a* + ?) (Table 1, entry 10).

*(b) 5β-Cholestan-3-one (***2b***)*

A reaction was carried out as in (a) on 50 mg of **2***b* and half quantities of the other reagents. There was obtained 46 mg (92%) of amber oily ketone mixture after decarbethoxylation, *m/e* 386 (31% of **2***b*), 382 and 400 (69% of **2***b* + CH_2 and its $M^+ - 18$ fragmentation ion). ^{13}C peaks integrated: same as (*d*) of the *in situ* reaction (Table 1, entry 20).

Synthesis of Authentic A-*Homo-5α-cholestan-4-one (***4a***)*

(a) 3,3-Dimethoxy-5α-cholestane

This dimethyl ketal was prepared by the method of Levisalles *et al.* (10). From 500 mg of **2***a* was obtained after recrystallization (4×) from ether–MeOH 228 mg (40%) of colorless granules, mp 77–79°C, $[\alpha]_D^{19}$ +35° (*c* 1.06, $CHCl_3$) (lit. (10) mp 78–80°C, $[\alpha]_D$ +24°); ir, no C=O absorption; ^{1}Hmr ($CDCl_3$) δ: 3.15 (3H, s, OCH_3) and 3.20 ppm (3H, s, OCH_3); *m/e* 432.4 (M^+).

(b) 3-Methoxy-5α-cholest-2-ene

The procedure of Levisalles *et al.* (10) was modified. The dimethyl ketal (125 mg) from (*a*) was evaporatively distilled in a tube at 200°C/1 Torr over a period of ~7 h. The solidified distillate was recrystallized (4×) from ether–methanol to give 35 mg (30%) of colorless plates of the enol ether, mp 98–100°C, $[\alpha]_D^{19}$ +69° (*c* 1.04, $CHCl_3$) (lit. (10) mp 100–101°C, $[\alpha]_D$ +61°); ir ($CHCl_3$): 1680 cm^{-1} (C=C of enol ether); ^{1}Hmr ($CDCl_3$) δ: 3.50 (3H, s, OCH_3) and 4.50 ppm (1H, bd, C=CH) M^+ calcd. for $C_{28}H_{48}O$: 400.3705; found: 400.3708.

On a larger scale (500 mg) the reaction was conducted by heating the ketal in a sealed tube at 200°C for 10–20 h.

(c) 2α,3α-Dibromomethylene-3β-methoxy-5α-cholestane

The procedure of Levisalles *et al.* (10) was used. The reaction of 92 mg of enol ether from (*b*) with dibromocarbene gave 50 mg (38%) of adduct, mp 128–130°C, $[\alpha]_D^{19}$ +51.5° (*c* 1.10, $CHCl_3$) (lit. (10) mp 137–138°C, $[\alpha]_D$ +44°); ir, no C=C absorption; ^{1}Hmr ($CDCl_3$) δ: 3.51 ppm (3H, s, OCH_3). M^+ calcd. for $C_{29}H_{48}Br_2O$: 572.2051; found: 572.2037.

*(d) 3-Bromo-*A*-homo-5α-cholest-2-en-4-one*

The AgOAc-catalyzed solvolysis of the dibromocarbene adduct (50 mg) from (*c*) was carried out according to the published procedure (10) to yield 20 mg (47%) of bromo enone, mp 108–110°C (lit. (10) mp 112–112.5°C); ir ($CHCl_3$): 1680 cm^{-1} (conjugated C=O); ^{1}Hmr ($CDCl_3$) δ: 4.79 ppm (1H, t, $|J_{AX} + J_{BX}| = 15$ Hz, C=CH). M^+ calcd. for $C_{28}H_{45}BrO$: 478.2633; found: 478.2639.

(e) A-*Homo-5α-cholestan-4-one (***4a***)*

The bromo enone (200 mg) from (*d*) and a larger scale run was hydrogenated in benzene over 10% Pd/C and Na_2CO_3 according to ref. 10 to yield 166 mg (99%) of colorless plates of **4***a* after recrystallization from MeOH, mp 96–99°C, $[\alpha]_D^{20}$ +107° (*c* 1.02, $CHCl_3$) (lit. (10) mp 96–97.5°C, $[\alpha]_D$ +103°); ir ($CHCl_3$): 1695 cm^{-1} (7-ring C=O). M^+ calcd. for $C_{28}H_{48}O$: 400.3705; found: 400.3701.

Synthesis of Authentic A-*Homo-5α-cholestan-3-one (***3a***)*

*(a) 4-Chloro-*A*-homocholesta-4,5-dien-3-one*

This compound was prepared in 13% yield from 1.0 g of cholest-4-en-3-one without purification of the pyrrolidine dienamine or dichlorocarbene adduct according to the procedure of ref. 23. The 148 mg of colorless plates had mp 138–140°C, $[\alpha]_D^{19.5}$ −147°C (*c* 1.04, $CHCl_3$) (lit. (23) mp 137.5–140°C); ir ($CHCl_3$): 1660 (conjugated C=O) and 1610 cm^{-1} (conjugated C=C); ^{1}Hmr ($CDCl_3$) δ: 6.04 (1H, bs, C=CH) and 7.10 ppm (1H, s, C=CH—C=C). M^+ calcd. for $C_{28}H_{43}ClO$: 430.3002; found: 430.3005.

(b) A-*Homo-5α-cholestan-3-one (***3a***)*

The chlorodienone (148 mg) from (*a*) was hydrogenated by the procedure of ref. 23 to give, after thick-layer chromatography and recrystallization from ether–MeOH, 72 mg of colorless needles of **3***a*, mp 83–84°C, $[\alpha]_D^{19}$ −21.6° (*c* 1.00, $CHCl_3$) (lit. (23) mp 81–82.5°C, lit. (14) $[\alpha]_D$ −21°); ir ($CHCl_3$): 1698 cm^{-1} (7-ring C=O). M^+ calcd. for $C_{28}H_{48}O$: 400.3705; found: 400.3708.

Synthesis of Authentic A-*Homo-5β-cholestan-3-one (***3b***)*

(a) 3,3-Dimethoxy-5β-cholestane

A solution of 50 mg of **2***b* and 2 mg of *p*-TsOH in 2.5 mL of MeOH was refluxed for 5 h. After basification with NaOMe–MeOH the reaction mixture was diluted with ether, washed with water, dried, and concentrated to leave 50 mg of a colorless oil (49); ir ($CHCl_3$): faint C=O at 1710 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.14 (3H, s, OCH_3) and 3.21 ppm (3H, s, OCH_3). M^+ calcd. for $C_{29}H_{52}O_2$: 432.3967; found: 432.3957.

Analysis by tlc showed ~5% of **2***b* remaining; the ketal was used without further purification.

(b) 3-Methoxy-5β-cholest-3-ene

The dimethyl ketal (50 mg) from (*a*) was evaporatively distilled in a tube at 200°C/1 Torr over a period of 3 h to give 35 mg of viscous oily enol ether containing ~5% of **2***b* (49); ir ($CHCl_3$): 1667 (C=C of enol ether) and faint C=O at 1710 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.53 (3H, s, OCH_3) and 4.24 ppm (1H, bs, C=CH). M^+ calcd. for $C_{28}H_{48}O$: 400.3705; found: 400.3697.

(c) 3β,4β-Dibromomethylene-3α-methoxy-5β-cholestane

To a stirred (magnetic bar) solution of 92 mg of enol ether from (*b*) in 2.5 mL of cyclohexane at 0–5°C was added 272 mg of KO *t*Bu followed by addition of a solution of 540 mg of $CHBr_3$ in 1.5 mL of cyclohexane during 3 min. The reaction mixture was allowed to warm to room temperature and was stirred for 1 h. Dilution with ether, washing with water, drying, and concentration left a viscous oil which was chromatographed on a preparative plate developed twice with hexanes. Extraction of the band at R_f 0.38 gave 82 mg (62%) of colorless solid. Recrystallization from ether–MeOH (1×) and from $CHCl_3$–MeOH (2×) gave glistening colorless plates of the dibromocyclopropyl steroid, mp 140–143°C (dec.), $[\alpha]_D^{20}$ +66° (*c* 0.90, $CHCl_3$); ir, no C=C absorption; ^{1}Hmr ($CDCl_3$) δ: 3.51 ppm (3H, s, OCH_3). M^+ calcd. for $C_{29}H_{48}Br_2O$: 572.2051; found: 572.2026. *Anal.* calcd. for $C_{29}H_{48}Br_2O$: C 60.83, H 8.45; found: C 60.98, H 8.46.

*(d) 4-Bromo-*A*-homo-5β-cholest-4-en-3-one*

A mixture of 59 mg of dibromocyclopropyl compound from (*c*), 30 mg of AgOAc, 2 mL of HOAc, and 2 drops of water was stirred (magnetic bar) and refluxed for 2 h. After evaporation

of HOAc and water, the $CHCl_3$-soluble material was chromatographed on a preparative plate developed in benzene–hexanes (75:25). Extraction of the band at R_f 0.40 gave 33 mg (67%) of colorless solid. Recrystallization from ether–MeOH (3×) afforded 23 mg of colorless needles of the bromo enone, mp 108–110°C, $[\alpha]_D^{19.5}$ −124° (*c* 0.80, $CHCl_3$); ir ($CHCl_3$): 1680 cm^{-1} (conjugated C=O); ^{1}Hmr ($CDCl_3$) δ: 7.07 (1H, d, J = 6.5 Hz, C=CH) ppm. M^+ calcd. for $C_{28}H_{45}BrO$: 476.2654; found: 476.2663. *Anal.* calcd. for $C_{28}H_{45}BrO$: C 70.41, H 9.50; found: C 70.58, H 9.45.

(e) A-Homo-5β-cholestan-3-one (3b)

A mixture of 98 mg of bromo enone from (*d*), 50 mg of 10% Pd/C, 50 mg of K_2CO_3, and 6 mL of benzene was hydrogenated with stirring (magnetic bar) at room temperature and atmospheric pressure for 17 h. The filtered solution was concentrated and chromatographed on a preparative plate developed with benzene–ether (95:5). Extraction of the band at R_f 0.44 gave 80 mg of colorless viscous oil which crystallized on standing. Recrystallization (2×) of a 68-mg portion from ether–MeOH gave 26 mg of colorless needles of pure **3***b*, mp 55.5–56°C, $[\alpha]_D^{19}$ +89° (*c* 0.88, $CHCl_3$); ir ($CHCl_3$): 1695 cm^{-1} (7-ring C=O). M^+ calcd. for $C_{28}H_{48}O$: 400.3705; found: 400.3697. *Anal.* calcd. for $C_{28}H_{48}O$: C 83.93, H 12.07; found: C 84.15, H 11.87.

Baeyer–Villiger Reactions

(a) 5α-Cholestan-3-one

A solution of 100 mg (0.26 mmol) of **2***a*, 100 mg (75%, 0.43 mmol) of *m*-chloroperbenzoic acid, and 3 mL of $CHCl_3$ was allowed to stand at room temperature for 36 h. The solution was washed with 10% aqueous Na_2SO_3, 5% aqueous $NaHCO_3$, water, and dried. Concentration left 94 mg (90%) of colorless solid lactone mixture **5***a* + **6***a* which gave a single tlc spot more polar than **2***a*, ir ($CHCl_3$): 1725 cm^{-1} (lactone C=O), *m/e* 402 (M^+). ^{13}C peaks integrated: δ 64.7 (C-2 of **6***a*) and 70.0 ppm (C-4a of **5***a*).

(b) 5β-Cholestan-3-one

A 100-mg sample of **2***b* oxidized as in (*a*) yielded 92 mg (88%) of colorless solid lactone mixture **5***b* + **6***b*; ir ($CHCl_3$): 1720 cm^{-1} (lactone C=O); *m/e* 402 (M^+). ^{13}C peaks integrated: δ 63.3 (C-2 of **6***b*) and 70.5 ppm (C-4a of **5***b*).

(c) 17β-Hydroxy-5α-androstan-3-one

A 50-mg sample (0.19 mmol) of **2***c* was oxidized with 48 mg (0.21 mmol) of *m*-chloroperbenzoic acid in 3 mL of $CHCl_3$ for 24 h to yield 48 mg (92%) of colorless solid lactone mixture **5***c* + **6***c* which contained ~20% of **2***c*; ir ($CHCl_3$) 1730 cm^{-1} (lactone C=O); *m/e* 306 (M^+). ^{13}C peaks integrated: δ 64.7 (C-2 of **6***c*) and 70.0 ppm (C-4a of **5***c*).

When 50 mg (0.19 mmol) of **2***c* was oxidized with 100 mg (0.43 mmol) of *m*-chloroperbenzoic acid for 2.5 days, the product was ~85% 17-oxo-A-ring lactones; *m/e* 304 (85%) and 306 (15%) (M^+).

(d) 5α-Cholestan-3-one + CF_3CO_3H

A solution of CF_3CO_3H made by stirring 0.1 mL of 63% H_2O_2 and 0.4 mL of $(CF_3C{=}O)_2O$ in 1 mL of CH_2Cl_2 at 5°C for 10 min was added to a solution of 125 mg of **2***a* in 2 mL of CH_2Cl_2 containing 250 mg of suspended Na_2HPO_4. The reaction was stirred (magnetic bar) at room temperature for 2 h. The organic solution was washed with 10% aqueous Na_2CO_3 and water, dried, and concentrated to leave 123 mg (95%) of oily solid lactone mixture **5***a* + **6***a* which was used for ^{13}C integration of the isolated peaks at δ 64.7 (C-2 of **6***a*) and 70.0 ppm (C-4a of **5***a*).

Authentic 4-Oxa-A-homo-5α-cholestan-3-one (5a)

(a) 2α-Bromo-A-homo-4-oxa-5α-cholestan-3-one

A solution of 200 mg (0.43 mmol) of 2α-bromo-5α-cholestan-3-one and 500 mg (~2 mmol) of *m*-chloroperbenzoic acid (Aldrich, 75%) in 5 mL of $CHCl_3$ was allowed to stand at room temperature. At the end of 4 h, tlc showed considerable starting material remaining, and two more 500-mg portions of the peracid were added during the next 4 h to increase the reaction rate. The $CHCl_3$ solution was washed thoroughly with 10% aqueous Na_2SO_3, saturated aqueous $NaHCO_3$ and water. Evaporation of the dried solution left 207 mg (100%) of colorless solid which gave a single tlc spot more polar than starting material. A 125-mg portion dissolved in 1 mL of CCl_4 was chromatographed on a column of 3 g of silica gel. Elution with hexanes–benzene (45:55) gave 79 mg of colorless solid. Recrystallization from acetone–hexanes (1×) and from ether – petroleum ether (1×) gave 34 mg of colorless needles of *bromo lactone*, mp 186–189°C, $[\alpha]_D^{20}$ −5.4° (*c* 1.60, $CHCl_3$) (lit. (40), mp 192–193°C, $[\alpha]_D$ −4.5°); ir ($CHCl_3$): 1750 cm^{-1} (lactone C=O); ^{1}Hmr ($CDCl_3$) δ: 3.82 (1H, d, 4a-H), 4.34 (1H, dd, 4a-H), and 4.96 ppm (1H, dd, 2β-H). The bromo lactone was a single pure isomer according to its ^{13}Cmr spectrum.

(b) Reductive Debromination

The method of Bolliger *et al.* (40) was used. A solution of $CrCl_2$ was made from 1.0 g of $CrCl_3{\cdot}6H_2O$, 2.0 g of Zn, and 1.6 g of $HgCl_2$ (50). To this stirred solution under N_2 was added a solution of 100 mg of the bromo lactone from (*a*) in 4 mL of HOAc, and the reaction mixture was stirred for 12 h. The product was isolated by ether extraction, and the ether solution was washed with aqueous $NaHCO_3$ and water. Evaporation of the dried solution left 64 mg (77%) of colorless solid. Recrystallization (3×) from $CHCl_3$–CH_3OH gave 23 mg of colorless needles of lactone **5***a*, mp 192–195°C (lit. (40), mp 199–200°C); ir ($CHCl_3$): 1725 cm^{-1} (lactone C=O); ^{1}Hmr ($CDCl_3$) δ: 3.68 (1H, d, 4a-H) and 4.29 ppm (1H, dd, 4a-H). M^+ calcd. for $C_{27}H_{46}O_2$: 402.3498; found: 402.3501. The ^{13}Cmr spectrum was that of a single lactone.

Schmidt Reactions

(a) 5α-Cholestan-3-one

The procedure of Doorenbos and Wu (43) was used. To a mixture of 1.25 g of polyphosphoric acid and 50 mg (0.13 mmol) of **2***a* at 65°C was added 10 mg (0.15 mmol) of NaN_3; the 65°C temperature was maintained for 12 h. After addition of ice, the mixture was basified with 50% aqueous NaOH and extracted with $CHCl_3$. The organic layer was washed with water, dried and concentrated. Since tlc examination of the product revealed some unreacted **2***a*, it was recycled through a second treatment with HN_3 as above to give 35 mg (67%) of colorless solid lactam mixture **7***a* + **8***a* (free of **2***a*), mp 262–264°C with a phase change ~230°C; ir ($CHCl_3$): 3430 (NH) and 1660 cm^{-1} (amide C=O); *m/e* 401 (M^+). ^{13}C peaks for integration: δ 21.0, 35.3, 44.4, 49.6, and 53.8 ppm from **7***a*; δ 21.3, 34.7, 42.0, 43.3, and 54.1 ppm from **8***a* (Table 1, entry 13).

(b) 5β-Cholestan-3-one

A 50-mg sample of **2***b* under the reaction conditions in (*a*) gave complete reaction after one treatment and yielded 45 mg (86%) of colorless solid lactam mixture **7***b* + **8***b* (free of **2***b*); ir ($CHCl_3$): 3430 (NH) and 1660 cm^{-1} (amide C=O); *m/e* 401 (M^+). ^{13}C peaks for integration: δ 27.0, 38.8, 42.2, 44.1, and 45.5 ppm from **7***b*; δ 26.0, 36.8, and 43.0 ppm from **8***b* (Table 1, entry 22).

Authentic Lactams 8a and 8b

(a) 3-Aza-A-homo-4a-cholesten-4-one (Part Structure 20)

The Beckmann rearrangement procedure of Mazur (51) was adapted. To a stirred (magnetic bar) solution of 300 mg of the oxime of 4-cholesten-3-one (~30% *syn*, ~70% *anti* OH:C=C)

in 4.5 mL of dry dioxane at 10°C was added 0.9 mL of freshly distilled $SOCl_2$. The cooling bath was allowed to warm to room temperature, and the dark yellow solution was stirred for 2 h. After addition of excess 5% aqueous $NaHCO_3$, the product was extracted with ether. Evaporation of the washed and dried organic solution left 285 mg of tan oily solid which was chromatographed on two preparative plates developed in EtOAc. Extraction of the band visible under uv on the lower half of the plate gave 160 mg of off-white solid. Recrystallization (2×) from benzene–acetone gave colorless granules of the *lactam* **20**, mp 245–247°C with a phase change ~220°C, $[\alpha]_D^{20}$ +24° (*c* 1.40, $CHCl_3$) (lit. (44, 52), mp 252–256°C, 255–260°C, $[\alpha]_D$ +20°); uv (MeOH): 222 (22 000) and 247 nm (20 000); ir ($CHCl_3$): 3440 (NH), 1660 (C=O), and 1625 cm^{-1} (conjugated C=C); ^{1}Hmr ($CDCl_3$) δ: 3.18 (2H, bm, O=$CNCH_2$), 5.75 (1H, bs, C=CH), and 6.55 ppm (1H, bs, NH). M^+ calcd. for $C_{27}H_{45}NO$: 399.3501; found: 399.3498.

*(b) 3-Aza-*A*-homo-5α-cholestan-4-one (**8**a)*

To a mixture of 100 mg of 10% Pd/C catalyst and 100 mg of powdered KOH in 5 mL of MeOH stirred (magnetic bar) under H_2 was added a solution of 100 mg of unsaturated lactam **20** in 25 mL of MeOH. After 12 h the catalyst was removed by filtration and the solvent evaporated. The residual solid was dissolved in $CHCl_3$, and the solution was washed with water, dried, and concentrated. Recrystallization (2×) from MeOH–$CHCl_3$ gave 42 mg of colorless granules of pure *lactam* **8***a*, mp 260–280°C (dec. and subl.) with a phase change to needles at ~210°C; when the melting point was taken in a sealed capillary, a narrower range, mp 280–282°C (dec.), was observed; $[\alpha]_D^{20}$ +35° (*c* 1.60, $CHCl_3$) (lit. (44) mp 294–296°C, $[\alpha]_D$ +41°); uv (MeOH) rising end absorption only; ir ($CHCl_3$): 3420 (NH) and 1660 cm^{-1} (amide C=O); ^{1}Hmr ($CDCl_3$) δ: 2.6–3.5 (2H, bm, O=$CNCH_2$) and 6.47 ppm (1H, bs, NH). M^+ calcd. for $C_{27}H_{47}NO$: 401.3658; found: 401.3655.

*(c) 3-Aza-*A*-homo-5β-cholestan-4-one (**8**b)*

To a mixture of 50 mg of PtO_2 in 1.5 mL of HOAc stirred (magnetic bar) under H_2 was added a solution of 140 mg of unsaturated lactam **20** in 4 mL of HOAc. After 18 h the catalyst was removed by filtration, and the product was isolated by partition between ether and water. The semi solid product was chromatographed on two preparative plates developed (3×) in EtOAc–MeOH (97:3). Extraction of the band at R_f 0.82 produced 78 mg of colorless solid which was recrystallized (2×) from MeOH to give 49 mg of colorless plates of pure *lactam* **8***b*, mp 230–232°C, $[\alpha]_D^{20}$ + 56.4° (*c* 1.00, $CHCl_3$); uv (MeOH) rising end absorption only; ir ($CHCl_3$): 3420 (NH) and 1655 cm^{-1} (amide C=O); ^{1}Hmr ($CDCl_3$) δ: 3.08 (2H, m, O=$CNCH_2$) and 6.18 ppm (1H, bs, NH). M^+ calcd. for $C_{27}H_{47}NO$: 401.3658; found: 401.3663.

Both **8***a* and **8***b* gave only 27 signals each in their ^{13}Cmr spectra.

Acknowledgements

We would like to thank the National Research Council of Canada for financial support, Cheryl DuCharme for the ^{13}Cmr spectra, Heather Schroeder for the 100 MHz ^{1}Hmr spectra, and Doug Hairsine for the mass spectra.

DAVID DIME and STEWART MCLEAN. Can. J. Chem. 57, 1569 (1979).

The strategy outlined previously has been developed to provide, in principle, routes to any known spirobenzylisoquinoline alkaloid. The generality has been demonstrated by the synthesis of the racemic forms of corydaine, yenhusomidine, corpaine, sibiricine, and raddeanone.

DAVID DIME et STEWART MCLEAN. Can. J. Chem. 57, 1569 (1979).

On a développé la stratégie décrite antérieurement afin de proposer en principe des voies permettant d'atteindre tous les alcaloïdes connus derivés de la spirobenzylisoquinoléine. On a démontré la généralité de la méthode par la synthèse des formes racémiques de la corydaïne de la yenhusomidine, de la corpaïne, de la sibiricine et de la raddéanone.

[Traduit par le journal]

It has been our goal to develop a synthetic strategy which could, with appropriate tactical modifications, provide a totally synthetic route to any possible spirobenzylisoquinoline alkaloid. We have previously outlined the strategy and described its application to the successful syntheses of (±)-ochotensimine (**1**) (1) and (±)-ochrobirine (**2**) (2). Alkaloids such as corydaine (**3**), yenhusomidine (**4**), sibiricine (**5**), and raddeanone (**6**) present a more challenging target since control of both functionality and stereochemistry at C-9 and C-14 is required in the synthesis. We have recently made a preliminary report (3) of our partial success in reaching this target with the syntheses of (±)-corydaine and (±)-yenhusomidine. We report now a more detailed account of these syntheses and an account of further developments that have allowed us to complete the generalization of the synthetic approach.

The synthetic strategy was based on the formation of the spirobenzylisoquinoline skeleton (**7**) by a Pictet–Spengler reaction of a suitably substituted indanedione (**8**) with an appropriate phenylethylamine derivative (**9**). This, in principle, maintains the functional differentiation between C-9 and C-14 and allows the development of the required functional groups with control of stereochemistry. For the synthesis of the alkaloids with two oxygen functions on the five-membered ring we chose to use the bromoindanedione **8** (X = Br), and 3,4-dihydroxyphenylethylamine **9** (R′ = R″ = H); the latter was used since our earlier work with this series of compounds indicated that, without the hydroxyl group *para* to the site of ring closure, yields in the Pictet–Spengler reaction were unsatisfactory. The bromoindanedione was unstable and was used as soon as it had been prepared. The product of the Pictet–Spengler reaction was amorphous and could not be characterized completely but on the basis of the eventual successful outcome of the synthetic sequence, it was assumed to be **7** (R = R′ = R″ = H; X = Br). Various spectroscopic data were in accord with this proposal and, furthermore, the nmr evidence indicated that the product was a single epimer but no conclusion could be reached from this evidence about its configuration. Displacement of the halogen by an external nucleophile was unsuccessful under a wide variety of conditions and a plan was then devised in which the nitrogen atom was acylated, with the intention that this would provide a nucleophile capable of partaking in an intramolecular displacement. It was recognized that this should be successful only if the intermediate were the correct epimer with the halogen *trans* to the nitrogen. The *N*-formyl derivative was treated with silver acetate in aqueous acetic acid and the desired transformation to an alcohol with the hydroxyl group *cis* to the nitrogen did indeed take place. This successful outcome led us to propose that the reaction had followed the anticipated path (Scheme 1).

Our present study was concerned first with probing further the apparent high degree of stereoselectivity in the Pictet–Spengler reaction that seemed to lead to a single epimer. Unfortunately, we have not made significant progress regarding this question but we have made a number of surprising discoveries that force us to revise our account (2) of the course of the

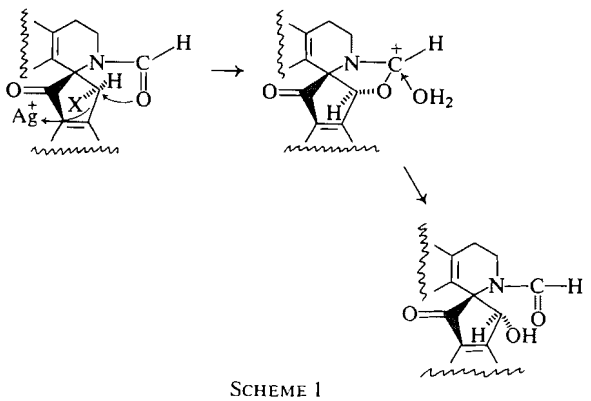
reactions we have described. Most of the compounds at this stage of the synthesis have been amorphous, and often unstable and difficult to characterize adequately. In a modification of the procedure we used to protect the phenolic hydroxyl groups, the Pictet–Spengler product was treated with methyl chloroformate under conditions that also carbomethoxylated the nitrogen. For the first time a beautifully crystalline product was obtained and presumed to be **7** (R = R′ = R″ = COOMe; X = Br). This was considered to be ideal for an investigation of its stereochemistry by X-ray crystal analysis. During this analysis (4) several disturbing features unfolded, not the least of which was the discovery that the molecule contained chlorine, not bromine. The final structure determination by the X-ray method showed further that the compound was not a ketone and not a simple urethane but had the more complex bridged structure **10**. This compound and its mode of formation are interesting in their own right, but the most significant feature for our present concern is that the configuration at C-9 (with a Cl substituent) is opposite to that we had assigned to related compounds in the original *N*-formyl series where we believed that C-9 carried a Br substituent. Furthermore, the chlorine was displaced by the treatment of **10** with silver fluoroborate in aqueous acetone. The product could not be properly characterized but it appears to be a mixture, possibly of epimers; the nmr spectrum, for example, shows signals appropriate for two kinds of C-9 protons (τ 4.47, 4.76) with a combined area of one proton. Nevertheless, when this intermediate was subjected to the sequence of reactions used in the *N*-formyl series (described below), the alkaloids corydaine (**3**) and yenhusomidine (**4**) were isolated. The most important observation for the present is that the displacement reaction took place on a molecule with the C-9 configuration of **10** and at

[3]The absolute configurations of natural (+)-ochotensimine (**1**) and (+)-ochrobirine (**2**) have been determined (12). Other configurations depicted in this paper are arbitrarily chosen for convenience and uniformity of presentation. All synthetic compounds are racemic.



SCHEME 1

least a substantial part of the product was formed with retention of configuration.

These disconcerting results led us to examine more closely our intermediates in the original sequence (including a series of model compounds (2)), particularly with respect to the question of how and when chlorine had replaced bromine in the molecule. It became apparent that our original observation that compounds of form **7** are not susceptible to simple S_N2 displacement of the halogen was indeed correct and that replacement of bromine by chlorine had not taken place at this stage. The precursor **8** (X = Br) is, however, extremely susceptible to displacement of bromine by chlorine when treated with hydrochloric acid; the extreme ease of this reaction leads us to assume that it takes place by addition of HCl to the enol form of **8** followed by elimination of HBr from the adduct. It follows that the replacement of bromine by chlorine in the synthetic sequence took place through the action of the HCl used in the Pictet–Spengler reaction. As we have already pointed out, the products could not be adequately purified and were deemed unsuitable for microanalysis; no molecular ions were observed in the high resolution mass spectra and the ions of highest mass appeared to correspond to M − Br. Subsequently, differential Br/Cl analyses were carried out by standard procedures and it became clear that all of the Pictet–Spengler products were mixtures of bromo and chloro compounds, usually containing a substantial excess of the chloro compound; since replacement took place before the spiro product had formed and not after, the Br/Cl ratio in a given run depended on how long **8** had been in contact with HCl during the Pictet–Spengler reaction.

It follows that where we have previously described intermediates of form **7** (X = Br) we should replace this description by **7** (X = Cl/Br). It also follows that we can not come to a firm conclusion about the configuration of these compounds. It is still true that the nmr spectra suggest that only one epimer is present but the previous argument that led to the conclusion that this was the epimer sterically suitable for internal displacement is no longer valid. The X-ray crystal structure analysis of **10** provides the only firm evidence for the stereochemistry of any halo compound in this series, and this compound has the configuration opposite to that proposed previously (2), yet it still undergoes replacement of Cl by OH under the conditions described previously. A more satisfactory explanation for the success of this reaction must therefore be found.

The key reagent in the displacement reaction is the silver salt, which undoubtedly serves to 'pull off' the halogen from C-9. However, the 'push' from the *N*-formyl group shown in Scheme 1 is not obligatory. Compound **10** at least has the wrong configuration for this and still undergoes the reaction. Nevertheless, the presence of the *N*-acyl group is necessary for a successful completion of the desired reaction but we believe now that it serves rather a different function: the amide resonance makes the lone pair of electrons on nitrogen unavailable for direct attack at the carbonium centre (incipient or otherwise); when the amine is not acylated, this attack does take place and the aziridinium ion formed can subsequently reopen in a direction that leads to rearranged products. We also believe that the stereospecific formation of the hydroxyl group *cis* to the nitrogen shows that, once the halogen has been removed far enough, the ionic intermediate in Scheme 1 is indeed formed by internal attack of the electrons on the *N*-acyl oxygen atom, and that the remainder of the sequence proceeds as originally proposed. (It is possible that the bridged intermediate derived from 10 is not susceptible to this internal attack and a mixture of epimers results.) Our original synthetic sequence thus remains an experimentally viable route to intermediates with the stereochemistry of **11**, albeit for reasons different in detail from those originally postulated.

The continuation of the synthetic sequence required at this stage the deprotection of the catechol system and its conversion to the derivative present in the target alkaloid; the example of the formation of the methylenedioxybenzene **12** required for ochrobirine (**2**) has already been described (2). The dimethoxy analog **13** is available by methylation of the catechol with diazomethane. It is worth noting here that it is desirable to protect the sensitive β-hydroxy ketone during hydrolysis of the protecting groups under basic conditions, and that it is undesirable to hydrolyze the *N*-formyl group before methylation of the phenolic hydroxyl groups since the free amine in these compounds is especially susceptible to *N*-methylation by diazomethane.

In our earlier work (2), a difficulty arose at this stage and severely limited the generality of the synthesis: the Eschweiler–Clarke reaction, which had worked well in the ochotensimine synthesis (1), failed to convert **14**, the hydrolysis product of **12**, to corydaine (**3**). Direct reduction of the *N*-formyl group of **12** to *N*-methyl was accomplished with lithium aluminium hydride but inevitably the ketone was reduced at the same time. This provided a successful synthesis of ochrobirine (**2**) but unhappily removed the functional differentiation at C-9 and C-14 that we had carefully preserved through the synthesis, and syntheses by this route of alkaloids having one ketone and one alcohol function at these sites became impossible. It was presumed that the failure of the Eschweiler–Clarke reaction could be attributed to the interaction of the C-14 hydroxyl group with the moiety formed by reaction of formaldehyde with the adjacent amine centre. Confirmation of this proposal was forthcoming when a crystalline oxazolidine (**15**) was isolated when the amine **14** was treated with formaldehyde in the absence of formic acid. A variant of the Eschweiler–Clarke reductive methylation could now be designed: sodium cyanoborohydride reduced the oxazolidine in an acidic solution, where it presumably exists in equilibrium with the open hydroxy imminium intermediate, and the desired *N*-methylated product was obtained, with regeneration of the C-9 alcohol *cis* to the nitrogen and without reduction of the C-14 ketone. A general route to alkaloids of this substitution pattern was thus available and it was applied successfully to the synthesis of (±)-corydaine (**3**) and (±)-yenhusomidine (**4**).

One step in the route to yenhusomidine was the hydrolysis of the *N*-formyl intermediate **13** under acidic conditions. This normally proceeded without difficulty and in high yield, but on one occasion about half of the product had suffered hydrolysis of a methoxyl group as well as hydrolysis of the amide. The nmr spectrum showed that it was the higher field methoxyl group that had disappeared and that it was probably the phenol **16** that had been produced. This was the only occasion when the mild hydrolysis conditions normally used gave significant amounts of phenol but careful examination of the spectra of other batches of hydrolyzed material showed that small amounts had been produced in other runs. However, the production of a significant amount of this phenol on one occasion led us to seek and find more vigorous hydrolysis conditions under which significant amounts of the phenol could be obtained reproducibly. We are unable to advance a convincing argument based on either electronic or steric features to account for the observed selective hydrolysis of one methoxyl group; we would certainly not have been able to predict it. Compounds of form **7** (R′ = H; R″ = Me) are available from the Pictet–Spengler reaction (see above) whereas those of form **7** (R′ = Me; R″ = H) are not. The result we have observed serendipitously opens a route to the alkaloids with the latter substitution pattern. Thus when the phenol **16** was carried through the modified reductive methylation sequence described above, the alkaloid (±)-corpaine (**17**) was obtained.

Once we had shown that our synthetic strategy could provide routes to the alkaloids corydaine, yenhusomidine, and corpaine, we had to face an important stereochemical question, one which had been apparent to us from the start. These alkaloids are β-hydroxy ketones and epimers are possibly susceptible to equilibration by a sequence of retro-aldol and aldol condensations. If equilibration did take place, our earlier efforts to maintain steric control of reactions would have been wasted and the stereospecificity of our synthesis would be an illusion since the stereochemistry of the final products would simply be under the control of thermodynamics. A report from the laboratories of MacLean and Manske (5) indicated that our worst fears were justified: in the course of an imaginative and elegant synthesis of the spirobenzylisoquinoline alkaloids, they showed that the aldol–retro-aldol equilibration does take place under basic conditions and, even worse from our point of view, the more stable epimers are those such as **3** which we had synthesized. At this point we were pleased to receive a sample of natural corydaine (**3**) from the laboratory of M. E. Perel'son and to find that this material was optically active; this allowed us to dispose of the suggestion that all alkaloids of this group would probably be found to have racemized by equilibration during the isolation process. We were also able to follow semiquantitatively the rate of racemization of the alkaloid under a number of conditions. Racemization took place rapidly, as expected, in alkaline methanol, but in neutral or acidic solution the rate was very much lower. We were also pleased to find that racemized alkaloid showed mp 126–130°C, thus removing the apparent discrepancy between natural and synthetic material in this physical constant. The main value of this study was, however, the demonstration that the alkaloid could survive the conditions of the final steps of our synthetic sequence without equilibrating.

A way of testing more searchingly the stereospecificity of the final steps of our synthesis now presented itself and, at the same time, pointed to a procedure that could complete the generalization of

our synthesis and make available the epimers, such as **5** and **6**, that had initially appeared unavailable by our route. The model compound **18** was prepared from precursors described previously (2) in order to investigate the proposed procedure.

The ir spectrum of **18** in chloroform shows a broad peak at 2.84 μ, indicating that the hydroxyl group is hydrogen bonded. However, as the solution is progressively diluted, this band is replaced by a sharp peak at 2.76 μ and at high dilution the replacement is complete; as this change occurs, an amide peak at 6.07 μ grows at the expense of a peak at 6.24 μ and at high dilution the 6.24 μ peak is absent. It follows that the hydrogen bonding is not intramolecular and the factor that is believed to stabilize the *cis*-hydroxy amines such as **3** (5) is absent. When **18** was heated with anhydrous potassium carbonate in dry dimethylformamide, a mixture of the epimers **18** and **19** (the ratio varied with reaction conditions and was not optimized; a typical value is 40:60) was obtained. Partial separation of the mixture was possible by fractional crystallization; a crystalline sample of **18** was recovered but even the best sample of **19** was not completely pure and failed to crystallize, and in accord with previous observations (5), **19** readily underwent epimerization during crystallization attempts. The original mixture was, therefore, subjected to the sequence of reactions described for converting the *N*-formyl group to *N*-methyl. Hydrolysis of the amides in acidic methanol solution required a longer reflux time than in previous cases, probably because the *trans* isomer was not so readily hydrolyzed. The epimeric ratio remained constant, as judged by nmr spectroscopy, during this process. The mixture of amines was treated with formaldehyde in methanol, the pH was brought to 3, and reduction with sodium cyanoborohydride was carried out. A mixture of the required *N*-methyl compounds was obtained and no appreciable change in the epimeric ratio was observed.

Epimerization of the intermediates **12** and **13**, required for the synthesis of the actual alkaloids, proved to be more difficult than in the model series and it was necessary to modify the conditions used. The *N*-formyl compound was treated with lithium diisopropylamide and hexamethylphosphoramide in tetrahydrofuran at −78°C; the reaction mixture was then allowed to warm to room temperature and was stirred overnight. The mixture of epimers produced was then converted to the *N*-methyl analogs by the same reaction sequence as that used in the model series. The dimethoxy compound **13**, under the epimerizing conditions described, was converted to a mixture of epimers which contained 30% of the *trans* isomer **22**. This mixture afforded, after hydrolysis and methylation, the alkaloids (±)-yenhusomidine (**4**) and (±)-raddeanone (**6**), still in the ratio 70:30. Separation was again difficult because of the ease with which epimerization took place; a pure sample of the more stable epimer, yenhusomidine, could be obtained by fractional crystallization but only spectroscopic evidence could be obtained that the mother liquors were enriched in raddeanone and separation was effected only at an analytical level by hplc. In the same way **12** was converted through a mixture (70:30) of the starting compound and its epimer **23** to a mixture of (±)-corydaine (**3**) and (±)-sibiricine (**5**) in the same ratio. Pure corydaine could be isolated by fractional crystallization but, once again, sibiricine could be separated only at an analytical level by hplc of the mother liquors.

The success of the strategy has thus been established. It is capable, in principle, of providing rational synthetic routes to spirobenzylisoquinoline alkaloids of any substitution pattern or stereochemistry and it has been reduced to practice with the syntheses of the racemic modifications of ochotensimine (1), ochrobirine (2), corydaine, yenhusomidine, sibiricine, raddeanone, and corpaine by us and of ochotensine (6, 7), fumaricine, fumaritine, and fumariline (8) by others using the same approach.

Experimental

Melting points were determined on a Thomas-Kofler micro hot stage. Spectrometers used were a Perkin-Elmer 137 for ir spectra, a Unicam SP800A for uv spectra, a Varian T-60, Bruker WP-80, or Varian HA-100 for proton nmr spectra, a CEC 21-490 for mass spectra, an AEI MS-902 for accurate mass measurements, and a Roussel-Jouan Dichrographe II for cd spectra. Unless otherwise indicated, chloroform solutions were used to obtain ir spectra and the wavelengths (μ) of selected absorptions are reported, methanol solutions were used to obtain uv spectra and the wavelengths (λ_{max}, nm) of significant peaks are reported followed in parentheses by the extinction coefficient (ε), and chloroform-*d* solutions (with tetramethylsilane as internal standard) were used to obtain proton nmr spectra and chemical shifts are reported on the τ scale (60 MHz spectra are routinely reported) followed in parentheses by an indication of the multiplicity (initial letter) and the number of protons associated with it. The ms data reported are the *m/e* values of significant ions followed in parentheses by an indication of their abundance relative to the base peak (100%).[4]

The Model Series

3-Bromo-1,2-indanedione; Reaction with Hydrochloric Acid

When the bromoindanedione (209 mg), prepared as described previously (1, 2), was dissolved in 50 mL of ethanol containing 0.25 mL of concentrated hydrochloric acid and heated at 65°C under nitrogen for 13 h, and the reaction mixture was then diluted with 200 mL of water and extracted with

[4]Carbon-13 nmr spectra of pure compounds were recorded. Copies of these data may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, The National Research Council of Canada, Ottawa, Ont., K1A 0S2.

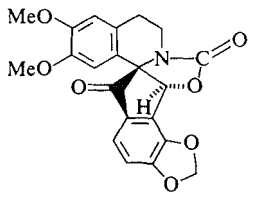
25



26

methylene chloride, an oil (122 mg) was obtained from the extract. No starting material remained and the product appeared to be 3-chloro-1,2-indanedione; ms: 182 (15), 180 (45).

Compound ***18***

The preparation of the unstable intermediate **24** (R = R′ = R″ = H; X = Cl/Br) from 3-bromo-1,2-indanedione and **9** (R′ = R″ = H) has been described previously (2). A solution of this compound in methanol was treated at 0°C with an excess of diazomethane dissolved in ether. The solution was allowed to come to room temperature and was stirred overnight in the absence of light. Excess diazomethane was destroyed with acetic acid and the solvent was removed under reduced pressure. (This method sometimes produced a considerable amount of *N*-methylated product.) The crude product was treated with acetic anhydride – formic anhydride in the manner described previously (2). A brown foam was isolated; recrystallization from methanol afforded white crystals, mp 181–182°C. This was a mixture of the halo compounds **24** (R = CHO; R′ = R″ = Me; X = Cl/Br); ir: 5.79, 5.99. *Anal.* calcd. for $C_{20}H_{18}NBrO_4$: C 57.70, H 4.36, N 3.36, Br 19.20; calcd. for $C_{20}H_{18}NClO_4$: C 64.60, H 4.88, N 3.77, Cl 9.54; found: C 64.06, H 4.63, N 3.77, Br 2.84, Cl 8.06.

This formamide (357 mg) was dissolved in 20 mL of nitromethane and stirred overnight with silver fluoroborate (700 mg) under a nitrogen atmosphere and with the exclusion of light. The reaction mixture was stirred for 10 min with aqueous sodium chloride and then filtered through Celite. The organic layer afforded **18** as a crystalline solid (311 mg) which, on recrystallization from methanol, formed white crystals, mp 202–206°C; ir: 2.76 (sharp), 2.84 (broad, absent at high dilution), 5.81, 6.07 (increases on dilution), 6.24 (absent at high dilution); uv; 212 (17 300), 238 (13 400), 288 (3300); nmr: 1.73 (s, 1), 2.0–2.7 (complex, 4), 3.33 (s, 1), 4.08 (s, 1), 4.78 (d, J = 12 Hz, D_2O addition produces s, 1), 5.8–7.5 (complex, 4), 6.13 (s, 3), 6.55 (s, 3), 6.87 (d, J = 12 Hz, 1, removed by D_2O addition); ms 354 (22), 353 (95), 335 (27), 325 (19), 324 (60), 308 (56), 307 (30), 280 (60), 279 (20), 248 (20), 221 (18), 220 (100). *Anal.* calcd. for $C_{20}H_{19}NO_5$: C 67.98, H 5.42, N 3.96; found: C 67.83, H 5.45, N 3.89.

The Oxazolidine ***25***

A solution of the formamide **18** (443 mg, 1.25 mmol) in 50 mL of 9:1 methanol – concentrated hydrochloric acid was refluxed under nitrogen for 5 h. The amine (420 mg, 1.25 mmol) was isolated from the reaction mixture after it had been cooled, diluted with 200 mL of water, made basic with solid sodium bicarbonate, and extracted with methylene chloride. Recrystallization from methanol of the product obtained from the extract gave white crystals, mp 182–183°C; ir: 3.10 (broad), 5.80; uv: 214 (15 200), 239 (16 800), 285 (5650), 343 (450); nmr: 2.0–2.6 (complex, 4), 3.67 (s, 1), 4.05 (s, 1), 5.00 (s, 1), 6.0–7.5 (complex, 4), 6.17 (s, 3), 6.40 (broad signal, removed by D_2O addition, 2), 6.57 (s, 3); ms: 326 (12), 325 (63), 324 (10), 323 (44), 322 (41), 321 (33), 320 (100), 308 (34), 307 (83), 306 (23), 305 (31), 292 (63), 276 (29), 266 (24), 264 (16), 262 (20), 248 (27), 220 (20), 192 (15), 190 (15), 105 (17), 89 (16), 79 (29), 77 (23), 76 (26), 52 (22), 51 (23), 44 (62). *Anal.* calcd. for $C_{19}H_{19}NO_4 \cdot \frac{1}{2}H_2O$: C 68.25, H 6.03, N 4.19; found: C 68.18, H 6.03, N 4.14.

A solution of this amine (321 mg, 0.96 mmol) in 200 mL of acetonitrile containing 2 mL of 37% aqueous formaldehyde was stirred at room temperature under nitrogen for 2 h. The solution was evaporated under reduced pressure, and the residue was dissolved in methylene chloride and washed with water. The organic layer yielded the oxazolidine **25** (306 mg, 91 mmol), which was recrystallized from methanol and obtained as white crystals, mp 160–163°C; ir: 5.82; uv: 214 (18 000), 242 (18 000), 286 (5500); nmr: 2.0–2.6 (complex, 4), 3.30 (s, 1), 4.00 (s, 1), 4.63 (s, 1), 5.59 (ABq; J = 7 Hz, internal (int.) chemical shift 21 Hz, 2), 6.5–7.5 (complex, 4), 6.12 (s, 3), 6.45 (s, 3); ms: 338 (22), 337 (100), 309 (24), 308 (84), 307 (45), 294 (45), 280 (90), 278 (37). *Anal.* calcd. for $C_{20}H_{19}NO_4$: C 71.20, H 5.68, N 4.15; found: C 71.15, H 5.77, N 4.08.

Compound ***20***

A solution of the oxazolidine **25** (208 mg, 0.62 mmol) and sodium cyanoborohydride (60 mg, 0.95 mmol) in 30 mL of methanol containing enough concentrated hydrochloric acid to bring it to pH 3 was stirred at room temperature under nitrogen for 1 h. The solution was diluted with 200 mL of water, made basic with solid sodium bicarbonate, and then thoroughly extracted with methylene chloride. The organic extract was washed with dilute sodium hydroxide and then with water, dried, and evaporated to dryness under reduced pressure. The product, **20** (209 mg, 0.62 mmol), was obtained as a crystalline solid which, after recrystallization from hexane–acetone, had mp 199–200°C; ir: 3.08 (broad), 5.82; uv: 213 (13 400), 243 (12 800), 286 (4750); nmr: 2.0–2.9 (complex, 4), 3.37 (s, 1), 3.92 (s, 1), 4.92 (s, 1), 5.62 (broad, 1), 6.4–7.5 (complex, 4), 6.13 (s, 3), 6.37 (s, 3), 7.81 (s, 3); ms: 340 (24), 339 (100), 324 (31), 296 (25), 294 (39), 280 (30). *Exact mass* calcd. for $C_{20}H_{21}NO_4$: 339.1462; found: 339.1470. *Anal.* calcd. for $C_{20}H_{21}NO_4$: C 70.77, H 6.24, N 4.13; found: C 70.53, H 6.16, N 4.22.

Epimerization Experiments

A mixture of compound **18** (118 mg) and anhydrous potassium carbonate (200 mg) in 15 mL of dry dimethylformamide was heated to 120–125°C with vigorous stirring under nitrogen for 1.3 h. The reaction mixture was poured into 200 mL of ice water and extracted with methylene chloride. The extract was washed with water, dried, and evaporated under reduced pressure. A yellow solid was obtained which was judged to consist of 40% of **18** and 60% of **19** on the basis of its nmr spectrum.

The mixture was hydrolyzed by refluxing in methanol – hydrochloric acid in the manner described above for pure **18** (see oxazolidine **25**), except that reflux was continued for 18 h. The product, a pale foam (78 mg) was judged, from its nmr spectrum, to contain the amine derived from **18** (described above) and its epimer in the ratio 40:60. Fractional crystallization of this material afforded a crystalline sample of the former amine, but the epimer was recovered from the mother liquor

as a noncrystalline residue; ir: 2.86 (sharp), 2.97 (sharp), 3.03 (broad), 5.83; nmr: 2.0–2.7 (complex, 4), 3.35 (s, 1), 4.42 (s, 1), 4.75 (s, 1), 6.3–7.5 (complex, 4), 6.33 (s, 3), 6.58 (s, 3), 7.62 (broad signal, removed by D_2O addition, 2). *Exact mass* calcd. for $C_{19}H_{19}NO_4$: 325.1317; found: 325.1320.

The 40:60 mixture of epimeric amines (27 mg) was dissolved in 6 mL of methanol, 0.2 mL of 37% aqueous formaldehyde was added, and the solution was stirred for 1 h at room temperature under nitrogen. The solution was brought to pH 3.5 by the addition of concentrated hydrochloric acid, sodium cyanoborohydride (6 mg) was added, and the stirring under nitrogen was continued for 1 h further. During this period the pH was maintained by the addition of hydrochloric acid as required. The reaction mixture was worked up in the manner previously described and the product was obtained as an oil (23 mg) which was judged on the basis of its nmr spectrum to contain compounds **20** and **21** in the ratio 40:60.

The 10,11-Methylenedioxyspirobenzylisoquinolines

*3-Bromo-4,5-methylenedioxy-1,2-indanedione (**8**; X = Br)*

This was prepared from *o*-vanillin by the method described previously (1, 2) with the following improvements. The 2,3-methylenedioxycinnamic acid intermediate was dissolved in aqueous sodium hydroxide and reduced quantitatively to the dihydro compound with hydrogen (40 psi) in the presence of 10% palladium–charcoal catalyst; the method of Kelly and Beckett (7) was used to convert the indanone to the indanedione.

Pictet–Spengler Reaction

The bromoindanedione **8** (X = Br) (1.847 g, 6.87 mmol) and β-(3,4-dihydroxyphenyl)ethylamine hydrochloride (2.38 g, 13.6 mmol) in 150 mL of dry ethanol were heated to 70°C under nitrogen for 24 h. The reaction mixture was cooled, poured into 150 mL of 3% hydrochloric acid, and extracted with methylene chloride. (The organic extract provided 650 mg of uncharacterizable material.) The aqueous solution was freeze-dried, the solid (3.52 g) obtained was dissolved in the minimum volume of boiling methanol, and the solution was then diluted with twice that volume of benzene. The excess starting amine hydrochloride precipitated as white crystals (1.074 g, 6.14 mmol). The spirobenzylisoquinoline hydrochloride product was obtained from the mother liquor as a brown oil (2.45 g) after evaporation of the solvent. A solution of this material in 40 mL of dry pyridine under nitrogen was cooled to −78°C and methyl chloroformate (1.50 mL, 19.3 mmol) was added dropwise to the solution. The reaction mixture was allowed to warm to room temperature and was stirred vigorously under nitrogen for 22 h. The solvent was removed under high vacuum and the residue was dissolved in 200 mL of methylene chloride, washed with brine, dried, and evaporated to dryness. The residue (2.46 g) was dissolved in 50 mL of dry methylene chloride and stirred under nitrogen with 10 mL of acetic-formic anhydride for 26 h. The solvent was removed under reduced pressure and the residue was dissolved in 200 mL of methylene chloride and washed with brine. The organic layer afforded, as a brown foam (2.52 g), **7** (R = CHO, R′ = R″ = COOMe, X = Cl/Br) which had the same spectroscopic characteristics as those reported previously (2).

*Displacement of Halogen: Compound **11***

Undried silver fluoroborate (5 g) was added to a solution of the above halo product (2.52 g) in 50 mL of nitromethane and the mixture was stirred under nitrogen with exclusion of light for 18 h. An excess of aqueous sodium chloride solution was added, stirring was continued for 5 min, and the mixture was filtered through Celite. The filter pad was washed with methylene chloride and water, and the combined organic layers were washed with water, dried, and evaporated to dryness under reduced pressure. The product (**11**) was obtained as a brown solid (2.29 g, 4.73 mmol) which, after recrystallization from acetone–ether, formed white crystals, mp 205–210°C; ir: 2.80 (sharp), 3.05 (shoulder), 5.62, 5.77, 6.00, 6.05, (shoulder); uv: 214 (21 200), 238 (22 400), 295 (8150), 313 (9400); nmr: 1.70 (s, 1), 2.77 (ABq, J = 8 Hz, int. chemical shift 27 Hz, 2), 2.80 (s, 1), 3.50 (s, 1), 3.78(s, 2), 4.72 (broadened d, J = 5 Hz, s after D_2O addition, 1), 5.8–7.5 (complex, 5, 4 after D_2O addition), 6.08 (s, 3), 6.14 (s, 3); ms: 467 (3), 453 (28), 377 (25), 350 (41), 349 (24), 334 (18), 323 (20), 322 (100), 59 (66). *Anal.* calcd. for $C_{23}H_{19}NO_{11}$: C 56.91, H 3.95, N 2.89; found: C 56.65, H 4.28, N 3.14.

*Compound **12***

The procedure used has been described previously (2). Compound **11** (1.000 g, 2.06 mmol) was converted to its tetrahydropyranyl ether (epimeric mixture) by treatment with 0.32 mL of dihydropyran in 60 mL of dry methylene chloride containing a trace of *p*-toluenesulfonic acid and the ester protecting groups were removed by hydrolysis with sodium bicarbonate in aqueous methanol, with care being taken to deoxygenate all solutions by continuous flushing with nitrogen. The catechol produced was dried in a 500-mL flask under high vacuum, anhydrous potassium carbonate (3.6 g), cupric oxide (1.8 g), and a stirring bar were added to the flask and the contents were dried under vacuum for a further 30 mins. Deoxygenated dimethylformamide (200 mL) and dry methylene iodide (2.0 mL) were then added and the mixture was heated at 120–125°C for 1.5 h. After it had cooled, the reaction mixture was filtered through Celite, the filter cake was washed with 200 mL of water and 200 mL of methylene chloride, and 500 mL of brine was added to the filtrate. The organic layer was separated, the aqueous layer was extracted with additional methylene chloride, and the combined organic extracts were worked up in the usual manner. The tetrahydropyranyl derivative of **12** was obtained as a light brown foam, which was dissolved in 100 mL of methanol containing 80 mL of 0.5 *N* hydrochloric acid and hydrolyzed in the manner described before (2). Compound **12** was obtained as white crystals (775 mg, 2.03 mmol) which, after recrystallization from acetone–methanol, had mp 190–193°C; ir: 2.86 (sharp), 5.78, 6.01; uv: 212 (13 000), 236 (14 900), 293 (7500), 308 (inflection 5350); nmr: 1.72 (s, 1), 2.76 (ABq, J = 8 Hz, int. chemical shift 27 Hz, 2), 3.37 (s, 1), 3.82 (s, 2), 3.98 (s, 1), 4.16 (ABq, J = 1.5 Hz, int. chemical shift 3 Hz, 2), 4.78 (d, J = 12 Hz, s after D_2O addition, 1), 5.6–7.5 (complex, 5, 4 after D_2O addition); ms: 381 (23), 364 (23), 363 (100), 352 (15), 336 (35), 335 (42), 334 (23), 320 (29), 308 (27), 307 (44), 278 (21), 277 (57), 249 (22), 163 (19). *Exact mass* calcd. for $C_{20}H_{15}NO_7$: 381.0847; found: 381.0846; calcd. for $C_{20}H_{13}NO_6$: 363.0757; found: 363.0771; calcd. for: $C_{19}H_{14}NO_6$: 352.0846); found: 352.0871; calcd. for $C_{19}H_{13}NO_5$: 335.0744; found: 335.0724; calcd. for $C_{19}H_{12}NO_5$: 334.0707; found: 334.0699; calcd. for $C_{18}H_{10}NO_5$: 320.0572; found: 320.0585; calcd. for $C_{11}H_{10}NO_3$: 204.0671; found: 204.0682. *Anal.* calcd. for $C_{20}H_{15}NO_7$: C 62.99, H 3.97, N 3.67; found: C 62.79, H 4.38, N 3.96.

*Compound **14***

A solution of the formamide **12** (120 mg, 0.315 mmol) in 20 mL of a 9:1 mixture of methanol and concentrated hydrochloric acid was refluxed for 5 h. The reaction mixture was poured into 100 mL of water, the solution was made basic with solid sodium bicarbonate, extracted with methylene chloride, and the extract was worked up in the usual manner. The amine

14 was obtained as crystals (112 mg, 0.314 mmol) which, after recrystallization from methanol, had mp 191–193°C; ir: 3.16 (broad), 5.85; uv: 212 (18 400), 237 (23 800), 294 (10 700), 308 (inflection 8400); nmr: 2.82 (ABq, J = 8 Hz, int. chemical shift 28 Hz, 2), 3.44 (s, 1), 3.83 (s, 2), 3.99 (s, 1), 4.20 (s, 2), 5.04 (s, 1), 5.9–7.7 (complex, 6, 4 after D_2O addition); ms: 353 (50), 336 (34), 335 (100), 334 (30), 320 (22), 306 (20). *Exact Mass* calcd. for $C_{19}H_{15}NO_6$: 353.0901; found: 353.0903. *Anal.* calcd. for $C_{19}H_{15}NO_6$: C 64.58, H 4.28, N 3.96; found: C 64.19, H 4.23, N 3.87.

The Oxazolidine 15

A solution of compound **14** (103 mg, 0.292 mmol) and 1.0 mL of 37% aqueous formaldehyde in 10 mL of methanol was stirred at room temperature under nitrogen for 1 h. The solvent was removed under reduced pressure and the residue was dissolved in 100 mL of methylene chloride, washed with water, and worked up in the usual way. Oxazolidine **15** was obtained as crystals (104 mg, 0.285 mmol) which, after recrystallization from acetone–ether had mp 240–247°C; ir: 5.80; uv: 212 (23 200), 237 (31 400), 295 (14 300), 314 (11 800); nmr: 2.74 (ABq, J = 8 Hz, int. chemical shift 27 Hz, 2), 3.35 (s, 1), 3.78 (narrow m, 2), 3.95 (s, 1), 4.72 (narrow m, 2), 4.66 (s, 1), 5.56 (ABq, J = 7 Hz, int. chemical shift 21 Hz, 2), 6.5–7.8 (complex, 4); ms: 365 (59), 337 (24,) 336 (100), 335 (79), 320 (27), 308 (66), 307 (19), 306 (31), 279 (20), 278 (40). *Exact Mass* calcd. for $C_{20}H_{15}NO_6$: 365.0897; found: 365.0895. *Anal.* calcd. for $C_{20}H_{15}NO_6$: C 65.75, H 4.14, N 3.83; found: C 65.48, H 4.34, N 3.57.

(±)-Corydaine 3

A solution of the oxazolidine **15** (16 mg; 0.044 mmol) and sodium cyanoborohydride (4 mg, 0.063 mmol) in 3 mL of methanol containing sufficient concentrated hydrochloric acid to bring it to pH 3 was stirred at room temperature under nitrogen for 1 h. The reaction mixture was diluted with 100 mL of water, made basic with solid sodium bicarbonate, and thoroughly extracted with methylene chloride. The extract afforded (±)-corydaine (**3**) as a solid (11 mg, 0.030 mmol) which, on recrystallization from ethanol, had mp 127–128°C. The spectroscopic (nmr, ir, ms) and tlc (four systems) characteristics of the synthetic material and of natural (+)-corydaine were identical. A sample of racemized natural corydaine (see below) was identical in every respect and the melting point was not depressed on admixture. A sample of (±)-corydaine synthesized by a different route (5) was also identical.

Compound 13

Compound **11** (500 mg, 1.03 mmol) was converted to its tetrahydropyranyl derivative and the ester groups were hydrolyzed as before (see under Compound **12**) but the catechol was not isolated; instead the methylene chloride extract was concentrated and then added to a solution of diazomethane (prepared from 7.5 g of *N,N'*-dimethyl-*N,N'*-dinitrosoterephthalamide (70% in mineral oil)) in ether at 0°C. The solution was allowed to warm to room temperature and was stirred overnight with exclusion of light. Sufficient glacial acetic acid was added to destroy the excess diazomethane, and the solution was evaporated to dryness under reduced pressure. The oil obtained was stirred under nitrogen with 50 mL of methanol and 40 mL of 0.5 *N* hydrochloric acid for 2.5 h; 200 mL of water was added and the mixture was extracted with methylene chloride. The extract afforded **13** as a solid product (390 mg, 0.982 mmol), which had mp 166–176°C after recrystallization from acetone–ether. The microanalyses of this material were unsatisfactory, the erratic values suggesting that samples were hydrated to varying degrees. Spectroscopic characteristics: ir: 2.87 (sharp), 5.80, 6.04, 6.20; uv: 212 (23 200), 235 (23 200), 290 (9850), 310 (7400); nmr: 1.77 (s, 1), 2.81 (ABq, J = 8 Hz, int. chemical shift 28 Hz, 2), 3.40 (s, 1), 3.87 (s, 2), 4.04 (s, 1), 4.79 (broad, 1), 5.6–7.5 (complex, 4), 6.17 (s, 3), 6.50 (s, 3); ms: 397 (25), 383 (30), 381 (20), 379 (75), 366 (25), 365 (100), 354 (10), 352 (27), 351 (76), 338 (47), 337 (70), 336 (55), 335 (30), 324 (26), 323 (46), 322 (40), 310 (33), 309 (32), 308 (20), 307 (25), 294 (30), 293 (20), 292 (30), 278 (21), 277 (55), 220 (25), 206 (27), 106 (34). *Exact Mass* calcd. for $C_{21}H_{19}NO_7$: 397.1155; found: 397.1149; calcd. for $C_{20}H_{17}NO_7$: 383.1007; found: 383.1009; calcd. for $C_{21}H_{17}NO_6$: 379.1010; found: 379.0965; calcd. for $C_{19}H_{16}NO_6$: 354.0932; found: 354.0887; calcd. for $C_{20}H_{17}NO_5$: 351.1132; found: 351.1158; calcd. for $C_{19}H_{15}NO_5$: 337.0943; found: 337.0935; calcd. for $C_{19}H_{14}NO_5$: 336.0868; found: 336.0864.

Yenhusomidine 4

The formamide **13** (200 mg, 0.504 mmol) was hydrolyzed in the manner described above in the preparation of **14**. The amine (186 mg, 0.504 mmol) isolated, after recrystallization from methanol–ether, had mp 183–184°C; ir: 3.18 (broad), 5.85; uv: 212 (20 300), 236 (28 800), 289 (10 800), 310 (8450); nmr: 2.78 (ABq, J = 8 Hz, int. chemical shift 28 Hz, 2), 3.39 (s, 1), 3.81 (s, 2), 3.97 (s, 1), 4.98 (s, 1), 5.9–7.7 (complex, 4), 6.18 (s, 3), 6.49 (s, 3); ms: 370 (23), 369 (100), 352 (33), 351 (85), 340 (20), 336 (40), 310 (28), 292 (23). *Exact Mass* calcd. for $C_{20}H_{19}NO_6$: 369.1208; found: 369.1204. *Anal.* calcd. for $C_{20}H_{19}NO_6$: C 65.03, H 5.19, N 3.79; found: C 64.73, H 5.35, N 3.69.

(On one occasion (see below) the hydrolysis gave a 50:50 mixture of the normal amine and the phenolic amine **16**.)

The amine (87 mg, 0.235 mmol) was stirred with 1 mL of 37% aqueous formaldehyde in 5 mL of acetonitrile at room temperature under nitrogen for 50 min. The oxazolidine (90 mg, 0.235 mmol), isolated in the manner described for **15**, was recrystallized from methanol and obtained as white crystals, mp 262–267°C; ir: 5.80; uv: 211 (15 800), 236 (22 200), 290 (8100), 314 (7350); nmr: 2.73 (ABq, J = 8 Hz, int. chemical shift 28 Hz, 2), 3.32 (s, 1), 3.77 (s, 2), 3.95 (s, 1), 4.63 (s, 1), 5.57 (ABq, J = 7 Hz, int. chemical shift 20 Hz, 2), 6.5–7.6 (complex, 4), 6.14 (s, 3), 6.40 (s, 3); ms: 381 (20), 352 (19), 351 (15), 324 (17), 86 (27), 85 (67), 84 (41), 83 (100). *Exact Mass* calcd. for $C_{21}H_{19}NO_6$: 381.1207; found: 381.1202. *Anal.* calcd. for $C_{21}H_{19}NO_6$: C 66.13, H 5.02, N 3.67; found: C 66.38, H 5.27, N 3.52.

The oxazolidine (100 mg, 0.262 mmol) was reduced with sodium cyanoborohydride (20 mg, 0.313 mmol) in 10 mL of methanol in the manner described above for the preparation of **3**. (±)-Yenhusomidine (**4**) was obtained as a solid (95 mg, 0.248 mmol) which, after recrystallization from methanol, had mp 239–241°C. Its spectroscopic characteristics (ir, uv, nmr, ms) were identical with those of natural yenhusomidine (9). The material was identical in all respects with (±)-yenhusomidine synthesized by a different route (5), and the melting point of a mixture of the two was not depressed.

Compound 16

In one run, the hydrolysis of formamide **13** (198 mg) in methanolic hydrochloric acid (see Yenhusomidine **4**, above) led to the isolation of a mixture of products (163 mg) which was separated by tlc on alumina with chloroform that had been treated with ammonia. This provided the previous dimethoxy amine (66 mg) and the phenolic amine **16** (51 mg) as a foam with the following characteristics: ir: 2.88 (sharp), 3.03 (sharp), 3.15 (broad), 5.83; nmr: 2.79 (ABq, J = 8 Hz, int. chemical shift 28 Hz, 2), 3.39 (s, 1), 3.80 (s, 2), 3.87 (s, 1), 5.01 (s, 1), 5.80 (broad signal, removed by D_2O addition, 3), 6.2–7.8 (complex, 4), 6.17 (s, 1); ms: 355 (45), 338 (35), 337 (100), 336 (42), 294 (28), 107 (25), 106 (40), 105 (27). *Exact Mass* calcd. for $C_{19}H_{17}NO_6$: 355.1062; found: 355.1056.

The formation of **16** in significant amounts under these conditions occurred only once. Reproducible results were obtained with the following hydrolysis conditions: a solution of the formamide **13** (25 mg) in 2 mL of acetic acid saturated with hydrogen bromide was refluxed under nitrogen for 1.5 h. The reaction mixture was cooled, diluted with 25 mL of water, made basic with solid sodium bicarbonate, and extracted thoroughly with methylene chloride. The extract afforded a 50:50 mixture of the two amines (13 mg).

Corpaine ***17***

A solution of the amine **16** (23 mg, 0.065 mmol) in 5 mL of acetonitrile containing 0.2 mL of acetonitrile was stirred at room temperature under nitrogen for 1.25 h. The oxazolidine (21 mg, 0.059 mmol) was isolated in the manner described for **15** and obtained as a white solid; ir: 2.86 (sharp), 5.79; nmr: 2.25 (ABq, J = 8 Hz, int. chemical shift 28 Hz, 2), 3.35 (s, 1), 3.77 (narrow m, 2), 3.83 (s, 1), 4.43 (broad, 1, removed by D_2O addition), 4.68 (s, 1), 5.58 (ABq, J = 7 Hz, int. chemical shift 20 Hz, 2), 6.2–7.6 (complex, 4), 6.12 (s, 3); ms: 368 (23), 367 (82), 339 (27), 338 (100), 337 (84), 324 (30), 323 (21), 322 (48), 310 (74), 308 (27), 294 (27), 292 (26), 281 (21), 280 (42). *Exact Mass* calcd. for $C_{20}H_{17}NO_6$: 367.1062; found: 367.1056.

The oxazolidine (20 mg, 0.054 mmol) was reduced with sodium cyanoborohydride (10 mg) in 10 mL of methanol in the manner described for the preparation of **3**. (±)-Corpaine (**17**) was obtained as a solid (20 mg, 0.053 mmol) which, after recrystallization from methanol, had mp 252–255°C. Its spectroscopic characteristics (ir, nmr, ms) were identical with those of natural corpaine (10). *Exact Mass* calcd. for $C_{20}H_{19}NO_6$: 369.1227; found: 369.1241; calcd. for $C_{20}H_{17}NO_5$: 351.1116; found: 351.1125; calcd. for $C_{19}H_{18}NO_5$: 340.1181; found: 340.1177; calcd. for $C_{19}H_{15}NO_5$: 337.0939; found: 337.0928; calcd. for $C_{19}H_{18}NO_4$: 324.1235; found: 324.1235; calcd. for $C_{11}H_{12}NO_3$: 206.0849; found: 206.0881.

Compound ***10***

The bromoindanedione **8** (X = Br) (1.134 g) and β-(3,4-dihydroxyphenyl)ethylamine hydrochloride (1.00 g) in 90 mL of dry ethanol were heated to 70°C under nitrogen for 24 h. The unstable product was isolated in the manner described above (see Pictet–Spengler Reaction), dissolved in 25 mL of dry pyridine, and treated as before with methyl chloroformate, except that excess methyl chloroformate (5.0 g) was employed and the treatment with methyl chloroformate was repeated twice (or until no free amine remained). The product (1.025 g) was a foam which formed crystals after it had been dissolved in methanol and treated with activated charcoal. Recrystallization from methanol afforded **10** as white crystals, mp 215–216°C; ir: 5.78; uv: 216 (28 600), 252 (3900), 297 (2800); nmr: 2.82 (s, 1), 2.91 (ABq, J = 8.5 Hz; int. chemical shift 8.5 Hz, 2), 3.33 (s, 1), 3.85 (s, 2), 4.43 (s, 1), 5.3–7.6 (complex, 4), 6.08 (s, 3), 6.15 (s, 3), 6.54 (s, 3); ms: 579 (5), 577 (15), 395 (23), 96 (99), 94 (100), 93 (20), 59 (29). *Anal.* calcd. for $C_{25}H_{20}NClO_{13}$: C 51.96, H 3.49, N 2.42, Cl 6.14; found: C 51.87, H 3.30, N 2.42, Cl 6.24.

Conversion of ***10*** *to Corydaine and Yenhusomidine*

A solution of **10** (527 mg) and silver fluoroborate (1.2 g) in 30 mL of acetone containing 2 mL of water was stirred at room temperature under nitrogen with the exclusion of light for 40 h. The solvent was removed under reduced pressure and the product was isolated in the standard way. This solid (467 mg), mp 199–201°C, appeared to be a mixture but it could not be characterized satisfactorily.

This material (175 mg) was converted to its tetrahydropyranyl derivative in the manner described above. The product (210 mg) was hydrolyzed to the catechol and this was converted to the methylenedioxybenzene in the manner described above (see Compound **12**). Hydrolysis of both the tetrahydropyranyl group and the amide were carried out at the same time under the conditions described above for the conversion of **12** to **14**. The product (166 mg) obtained was impure **14** and could be converted to (±)-corydaine by the sequence described above.

The above dehalogenated intermediate, mp 199–201°C, (188 mg) was converted to the catechol just described. This was treated with diazomethane as described previously (see Compound **13**) and the product was hydrolyzed under the conditions described for the conversion of **12** to **14** except that reflux was carried out for 10 h. The product (149 mg) was subjected to tlc on silica gel (with 96:4 methylene chloride – methanol) and separated into two components: the amine (67 mg) derived from **13**, which was converted to (±)-yenhusomidine, and a compound (67 mg) tentatively identified as the urethane **26** from its spectroscopic characteristics; ir: 5.77, 5.87; nmr: 2.72 (ABq, J = 8 Hz, int. chemical shift 25 Hz, 2), 3.35 (s, 1), 3.81 (s, 2), 3.91 (s, 1), 4.23 (s, 1), 5.6–7.4 (complex, 4), 6.15 (s, 3), 6.33 (s, 3); ms: 395 (24), 352 (25), 351 (100), 350 (15), 336 (50), 308 (15), 293 (19), 292 (50).

Sibiricine ***5***

A solution of the amide **12** (65 mg) in 20 mL of dry tetrahydrofuran was added dropwise to a solution of lithium diisopropylamide (prepared from 0.10 mL of dry diisopropylamine and 0.18 mL of 1.6 M n-butyllithium in hexane) in 10 mL of dry tetrahydrofuran at −78°C under nitrogen and 0.2 mL of hexamethylphosphoramide (freshly distilled from calcium hydride) was then added. The solution was stirred and allowed to warm to room temperature. After 20 h, the solution was poured into 100 mL of ice water, salt was added, and the mixture was thoroughly extracted with methylene chloride. The extract afforded a solid (65 mg) which was judged, from its nmr spectrum, to be a 70:30 mixture of **12** and **23**. This mixture was hydrolyzed under the conditions used to convert **12** to **14** (except that reflux was carried out for 17 h) and the solid product (53 mg) obtained was judged, from its nmr spectrum, to be a 70:30 mixture of **14** and its epimer. A solution of this material and 0.4 mL of 37% aqueous formaldehyde in 10 mL of acetonitrile was stirred at room temperature under nitrogen for 15 min. Sodium cyanoborohydride (20 mg) and 10 drops of glacial acetic acid were added, and stirring was continued for a further 1 h; 100 mL of water was added, the solution was made basic with solid sodium bicarbonate, and thoroughly extracted with methylene chloride. The product contained some unchanged amine, so it was subjected to another cycle of the methylation sequence. After this, the product was a solid (46 mg) which, from its nmr spectrum, was judged to be a 70:30 mixture of **3** and **5** (11). Recrystallization from methanol afforded crystalline **3** and the mother liquors were evaporated to provide a 55:45 mixture of **3** and **5**. This mixture was separated into its components by reversed phase hplc (Corasil C-18 in 90:10 water–methanol) at an analytical level.

Raddeanone ***6***

A solution of the amide **13** (40 mg) in 20 mL of dry tetrahydrofuran was treated with lithium diisopropylamide in the manner described above (see Sibiricine). The product was a mixture of **13** and **22** in the ratio 70:30, as judged from the nmr spectrum. The mixture was hydrolyzed as described above and the hydroxy amines were obtained as a 70:30 mixture. A solution of the mixture in 20 mL of methanol was treated with 0.2 mL of aqueous formaldehyde and reduced with sodium cyanoborohydride (10 mg) in the manner described for the model series (see Epimerization Experiments). The methylated

product (35 mg) consisted of a 70:30 mixture of (±)-yenhusomidine (**4**) and (±)-raddeanone (**6**), as judged from the nmr spectrum. Trituration of the mixture with acetone left a sample of yenhusomidine undissolved, and the solution contained raddeanone and yenhusomidine in the ratio 70:30. This mixture could be separated under the hplc conditions described above (see Sibiricine).

Racemization of Natural Corydaine

Corydaine, isolated by Perel'son *et al.* (ref. 10 and personal communication) by a procedure that avoided prolonged contact of the extract with a base, formed crystals, mp 189–189.5°C, $[\alpha]_D^{32}$ +145° (*c* 1.3, chloroform). We were provided with a sample of this material; as received, it had mp 175–186°C. A sample (1.3 mg) was dissolved in pure methanol at room temperature and its optical activity, measured by its circular dichroism between 360 and 450 nm, was plotted as a function of time. The decay in optical activity followed first-order kinetics and showed a half-life of about 500 h. A similar sample showed no measurable loss of optical activity when refluxed with 9:1 methanol – concentrated hydrochloric acid under nitrogen for 5 h.

A solution of natural corydaine (8 mg) in 10 mL of methanol containing a little potassium hydroxide was refluxed under nitrogen for 20 h. The recovered alkaloid (7.3 mg) was optically inactive and had mp 126–130°C.

Acknowledgements

Reference samples and spectra were received from the following: Drs. M. E. Perel'son and N. Margvelashvily (natural corydaine and corpaine), Professor T. Kametani (natural yenhusomidine and raddeanone), and Professor D. B. MacLean (synthetic corydaine and yenhusomidine). We are grateful to them for their generous cooperation. We thank the National Research Council of Canada for financial support of this work and for a scholarship (to D.D.), and the University of Toronto for an Open Fellowship (to D.D.).

A new synthesis of spirovetivanes via the spiro acyloin intermediate[1]

TOSHIRO IBUKA, KENJI HAYASHI, HIROYUKI MINAKATA,
YOSHIKUNI ITO, AND YASUO INUBUSHI

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606, Japan

Received November 28, 1978

TOSHIRO IBUKA, KENJI HAYASHI, HIROYUKI MINAKATA, YOSHIKUNI ITO, and YASUO INUBUSHI. Can. J. Chem. 57, 1579 (1979).

Ethyl-3-(1-ethoxycarbonyl-2,6-dimethylcyclohex-2-enyl)propionate **5** was stereoselectively synthesized. The diester **5** was spiroannulated by the acyloin condensation to give the bis(trimethylsiloxy) ether **11**. The ether **11** was hydrolyzed to provide the acyloins **6** and **12**. The acyloins **6** and **12** were elaborated into (±)-hinesol **1**, (±)-agarospirol **2**, (±)-β-vetivone **3**, and (±)-α-vetispirene **4**.

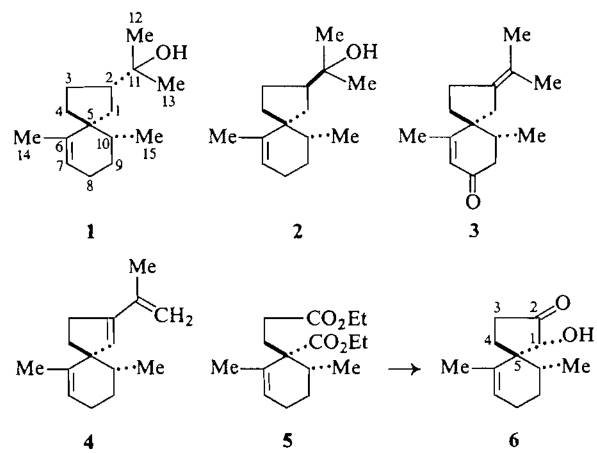
TOSHIRO IBUKA, KENJI HAYASHI, HIROYUKI MINAKATA, YOSHIKUNI ITO et YASUO INUBUSHI. Can. J. Chem. 57, 1579 (1979).

On a synthétisé le (éthoxycarbonyl-1 diméthyl-2,6 cyclohexène-2 yl)-3 propionate d'éthyle (**5**) d'une façon stéréosélective. On a provoqué une spirocyclosation de **5** par une condensation aux acyloïnes qui a conduit au bis(triméthylsiloxy) éther (**11**). L'hydrolyse de l'éther **11** fournit les acyloïnes **6** et **12**. On a pu transformer les acyloïnes **6** et **12** en (+)-hinésol (**1**), en (+)-agarospirol (**2**), en (+)-β-vétivone (**3**) et en (+)-α-vétispirène (**4**).

[Traduit par le journal]

The spirovetivanes possessing a spiro[4.5]decane framework (1) have been isolated from a variety of sources such as vetiver oil (2), the stress metabolites from infected potato tubers (3), the flue-cured Virginia tobacco (4), and the stress metabolites of *Datura stramonium* (5). Since Marshall and coworkers (6) reported that β-vetivone was a member of spirovetivanes rather than a hydroazulenone derivative, much attention, by many groups (1, 7–10), has been directed towards the efficient syntheses of these types of sesquiterpenes, owing to their unique structures and the increasing occurrence of spirovetivanes with interesting biological activity (3).

We have been interested in constructing stereoselectively the properly functionalized spiro[4.5]decane system which is generally suited for synthesis of spirovetivanes. The efficient synthesis of such sesquiterpenes as (±)-hinesol **1**, (±)-agarospirol **2**, (±)-β-vetivone **3**, and (±)-α-vetispirene **4** depends upon the stereoselective construction of the spirocycle and the regioselective introduction of the unsaturated bond into the spirocyclic compound (Scheme 1). The diester **5** is suitably substituted for the annulation to a functionalized spiro[4.5]decane key intermediate **6**, which may subsequently be elaborated to the natural spirovetivanes. We now detail the synthesis of racemic hinesol **1**, agarospirol **2**, β-vetivone **3**, and α-vetispirene **4**.



SCHEME 1

The keto ester **8**, prepared by the Diels–Alder reaction of 2,4-bis(trimethylsiloxy)-1,3-pentadiene (**7**) with ethyl crotonate followed by hydrolysis (11), was treated with ethanedithiol to afford the dithioacetal **9** which was subsequently reduced with Raney nickel to give the β,γ-unsaturated ester **10** (Scheme 2). Treatment of **10** with lithium diisopropylamide, and subsequent alkylation of the lithium enolate with ethyl β-bromopropionate provided the diester **5**. The high stereoselectivity of the alkylation reaction is probably a result of axial alkylation in which the bromide approaches the face of the molecule opposite to the pseudo axial C-10 methyl group. This high stereoselectivity was ascertained finally by the conversion of diester **5** to racemic hinesol **1**, which was identified by comparison with an authentic sample.[2]

[1]Dedicated to the memory of Professor R. H. F. Manske.

[2]We are grateful to Prof. I. Kitagawa, Osaka University, for his gift of an authentic natural hinesol.

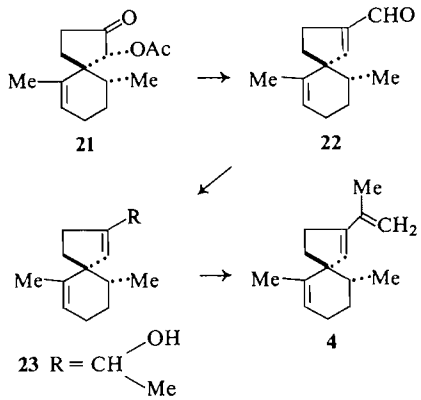
SCHEME 2

Acyloin condensation of the diester **5** was carried out at reflux in toluene employing sodium and trimethylchlorosilane to afford the bis(trimethylsiloxy) ether **11** in a 79% yield. The condition for hydrolysis of the bis(trimethylsiloxy) ether **11** was critical. Thus, hydrolysis of **11** in dry methanol under the conditions recommended (12) led to a mixture consisting of many inseparable products, but in tetrahydrofuran containing 10% hydrochloric acid at 0°C, a mixture of the crystalline spiro acyloin **6** and the unisolable isomeric acyloin **12** was obtained in ca. 100% yield. Although the isomeric acyloin **12** itself could not be isolated by chromatographic procedure on silica gel owing to its instability, the presence of **12** was easily detected by ^{1}H nmr analysis of the hydrolyzed product of **11**. The mother liquor removed from the crystalline **6** by filtration was concentrated and acetylated to give the stable acetyl derivative **13** of the acyloin **12**. The β-configuration of the C-1 hydrogen of **6** was confirmed by the observation of a nuclear Overhauser effect: irradiation at the frequency of the C-10 methyl group (δ 1.12) resulted in ca. 20% enhancement of the C-1 hydrogen signal at δ 4.05.

With the key spiro acyloin intermediate **6** in hand, we focused our efforts on the synthesis of the spirovetivane sesquiterpenes. Mesylation of **6**, followed by zinc – ammonium chloride reduction of the mesylate **14** in tetrahydrofuran afforded the spiro ketone **15** in a 99% yield. Spiro ketone **15** is a constituent of vetiver oil (13) and was recently synthesized in racemic form by Büchi *et al.* (8), Caine *et al.* (9), and Piers and Lau (10). The structure of **15** was confirmed by comparison of its ir and ^{1}H nmr spectra with those of an authentic sample (9).[3] The ketone **15** (19% yield), accompanied with the isomeric ketone **16** (38% yield), was also prepared from the keto acetate **13** by a known three-step sequence (14) involving reduction with sodium borohydride, mesylation, and elimination with potassium hydroxide.

To prepare (±)-hinesol (**1**) and (±)-agarospirol (**2**) from ketone **15**, it was necessary to introduce a three-carbon unit at the C-2 position. A Wittig reaction of **15** with methoxymethylenetriphenylphosphorane (59% yield) followed by hydrolysis of the enol methyl ether **17** with 10% hydrochloric acid gave the aldehyde **18** as an epimeric mixture. Without separation at this stage, **18** was converted into a 3:2 mixture of (±)-hinesol (**1**) and (±)-agarospirol (**2**)

[3]The authors express their thanks to Prof. D. Caine, Georgia Institute of Technology, U.S.A., for authentic ir and nmr spectra.



SCHEME 3

by the conventional method via the alcohol **19** and the methyl ketone **20**. Separation of the mixture of **1** and **2** is known to be troublesome and was achieved by repeated preparative thin-layer chromatography on silica gel. Synthetic (±)-hinesol (**1**) was identical with an authentic sample of natural hinesol (15)[2] by ir and ^{1}H nmr spectral comparison and by gas chromatographic analysis. The epimeric mixture of **1** and **2** was readily converted to (±)-β-vetivone (**3**), mp 44–46°C, according to the method of Marshall and Johnson (6). The spectral properties of synthesized (±)-β-vetivone (**3**) were completely in accord with the assigned structure.

To prepare (±)-α-vetispirene (**4**) from the key intermediate **6** (Scheme 3), it was necessary to introduce an isopropenyl group at C-2 and a double bond between C-1 and C-2. The acetate **21** derived from the spiro acyloin **6** was treated with methoxymethylenetriphenylphosphorane and then hydrolyzed with 10% hydrochloric acid in tetrahydrofuran to provide the α,β-unsaturated aldehyde **22**. (±)-α-Vetispirene **4** was prepared from **22** by a conventional four-step sequence (**22** → **23** → **24** → **25** → **4**) involving reaction with methyllithium, oxidation with Jones' reagent, treatment with methyllithium, and finally dehydration with 10-camphorsulfonic acid. The identity of the synthesized (±)-α-vetispirene **4** with an authentic sample was shown by comparison of their ir and ^{1}H nmr spectra.[3]

Experimental

All melting points were determined on a Yanagimoto micro-melting point apparatus and were uncorrected. The nmr spectra were obtained, unless otherwise specified, in deuteriochloroform containing tetramethylsilane as an internal standard with either a Varian A-60 or a JOEL JNM-FX-100 spectrometer, and chemical shifts were reported in δ values relative to tetramethylsilane. The abbreviations, s, d, t, q, and m in the nmr spectra signify singlet, doublet, triplet, quartet, and multiplet and the coupling constant (J) was measured in Hz. The nominal and the high resolution mass spectra were taken on a JOEL JMS-01SG-2 spectrometer equipped with a computer; M^+ signifies the molecular ion. Unless otherwise specified, the ir spectra were taken on a Shimadzu IR-400 spectrometer in chloroform. Gas chromatography was carried out on a 1.5% SE-30 or 10% FFAP on Chromosorb W (glass column, 1 or 3 m × 3 mm) with a Hitachi gas chromatograph model 063 and nitrogen as carrier gas (30 mL/min). Column chromatography was performed on silica gel (Mallinckrodt silicic acid, 100 mesh). Bulb-to-bulb distillation was carried out using a Büchi Kugelrohr distillation apparatus (type KR) and the temperatures recorded were oven temperatures. Unless otherwise stated, all the extracts were dried over anhydrous magnesium sulfate.

2,4-Bis(trimethylsiloxy)-1,3-pentadiene (7)

To a stirred mixture of triethylamine (61 g, 0.6 mol) and zinc chloride (2 g) was added a solution of acetylacetone (20 g, 0.2 mol) in a mixture of ether (100 mL) and benzene (100 mL) at 0°C. To the above mixture was added trimethylchlorosilane (64 g, 0.6 mol) under stirring and the mixture was stirred at room temperature for 48 h. Ether (500 mL) was added to the mixture and the filtrate of the mixture was concentrated under reduced pressure below 40°C. The resultant residue was distilled to give **7** (42 g, 86%) as a 1:1 mixture of 4*E* and 4*Z*; bp 73°C/3 Torr; nmr δ: 0.20 (36H, s, $Si(CH_3)_3$), 1.84 (3H, s, vinylic CH_3), 2.00 (3H, s, vinylic CH_3), 4.11 (2H, d, J = 3 Hz, olefinic protons), 4.31 (1H, m, olefinic proton), 4.71 (1H, s, olefinic proton), 4.76 (1H, m, olefinic proton), and 5.20 (1H, s, olefinic proton); ms *m/e*: 244 (M^+). *Anal.* calcd. for $C_{11}H_{24}O_2Si_2$: C 54.04, H 9.90; found: C 53.78, H 9.85.

The Keto Ester 8

A mixture of the diene **7** (4.9 g, 20 mmol), ethyl crotonate (3.42 g, 30 mmol), and xylene (6 mL) was heated at 180°C in a sealed glass tube for 5 days. After cooling, the mixture was mixed with 5% hydrochloric acid (3 mL) and tetrahydrofuran (10 mL) at 5°C for 1 h, and then extracted with ether. The extract was washed, dried, and evaporated *in vacuo* to leave a yellowish residue. Distillation of the residue gave the keto ester **8** (2.45 g); bp 133–135°C/3 Torr; nmr δ: 1.07 (3H, d, J = 6 Hz, secondary CH_3), 1.28 (3H, t, J = 7 Hz, $CO_2CH_2CH_3$), 1.95 (3H, m, vinylic CH_3), 4.23 (2H, q, J = 7 Hz, $CO_2CH_2CH_3$), and 5.93 (1H, m, olefinic proton); ir ν_{max}: 1729 and 1666 cm^{-1}; ms *m/e*: 196 (M^+). *Anal.* calcd. for $C_{11}H_{16}O_3$: C 67.32, H 8.22; found: C 67.18, H 8.38.

The Ethylene Dithioacetal 9

To the keto ester **8** (10 g) in methylene chloride (40 mL) were added ethanedithiol (5.76 g), boron trifluoride etherate (2 mL), and molecular sieves (3 g). The mixture was allowed to stand at room temperature for 5 days and then filtered. The filtrate was made alkaline with 3% ammonia and the methylene chloride layer was separated. The organic layer was washed, dried, and evaporated to leave the dithioacetal **9** (13 g, 94%). This product was used for the next step without purification. An analytical sample of **9** was obtained by silica gel column chromatography with chloroform; Kugelrohr distillation at 160–161°C/3 Torr; nmr δ: 1.02 (3H, d, J = 6 Hz, secondary CH_3), 1.27 (3H, t, J = 7 Hz, $CO_2CH_2CH_3$), 1.67 (3H, m, vinylic CH_3), 3.34 (4H, m, $S(CH_2)_2S$), 4.20 (2H, q, J = 7 Hz, $CO_2CH_2CH_3$), and 5.75 (1H, m, olefinic proton); ir ν_{max}: 1728 cm^{-1}. *Anal.* calcd. for $C_{13}H_{20}O_2S_2$: C 57.32, H 7.40; found: C 57.06, H 7.54.

The β,γ-Unsaturated Ester 10

To a solution of **9** (23 g) in dry tetrahydrofuran (200 mL) was added Raney W2 nickel (115 g) and the mixture was stirred at room temperature for 7 days. The mixture was

filtered and the solvent of the filtrate was evaporated *in vacuo* to leave an oily residue. The residue was extracted with ether, and the extract was washed, dried, and evaporated to leave an oil, which was distilled to give the β,γ-unsaturated ester **10** (9.44 g, 61%); bp 98–101°C/28 Torr; ir ν_{max}: 1720 cm^{-1}; nmr δ: 0.97 (3H, d, J = 6 Hz, secondary CH_3), 1.27 (3H, t, J = 7 Hz, $CO_2CH_2CH_3$), 1.64 (3H, m, vinylic CH_3), 4.18 (2H, q, J = 7 Hz, $CO_2CH_2CH_3$), and 5.59 (1H, m, olefinic H). *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.96; found: C 72.72, H 10.11.

The Diester **5**

To a solution of lithium diisopropylamide prepared from diisopropylamine (2.4 mL) and *n*-butyllithium (11 mL of 1.6 *M* *n*-hexane solution) in tetrahydrofuran (3 mL) was added a solution of **10** (1.82 g, 0.01 mol) in tetrahydrofuran (3 mL) at −70°C and the mixture was stirred at −70°C for 2 h. To the mixture were added hexamethylphosphoric triamide (1 mL) and ethyl β-bromopropionate (2.72 g, 0.015 mol), and the mixture was stirred at −30°C for 1 h and then at 0°C for 11 h. The mixture was acidified with 6% hydrochloric acid, concentrated *in vacuo* at room temperature and extracted with ether. The extract was successively washed with 2% sodium bicarbonate, 5% hydrochloric acid, and water. The solution was dried and concentrated to leave a yellow oil (1.5 g). Chromatography over silica gel with chloroform gave the starting material **10** (900 mg) and the diester **5** (570 mg, 40% based on the starting material consumed); Kugelrohr distillation at 128°C/5 Torr; ir ν_{max}: 1721 and 1715 cm^{-1}; nmr δ: 0.92 (3H, m, secondary CH_3), 1.25 (6H, t, J = 7 Hz, $CO_2CH_2CH_3$), 1.55 (3H, m, vinylic CH_3), 4.14 (2H, q, J = 7 Hz, $CO_2CH_2CH_3$), 4.16 (2H, q, J = 7 Hz, $CO_2CH_2CH_3$), and 5.73 (1H, m, olefinic H). *Anal.* calcd. for $C_{16}H_{26}O_4$: C 68.05, H 9.28; found: C 67.82, H 9.02.

The Bis(trimethylsiloxy) Ether **11**

To a refluxing mixture of dry toluene (200 mL) and sodium (11.3 g, 0.5 mol) was added a mixture of **5** (28.2 g, 0.1 mol) and trimethylchlorosilane (70 mL, 0.5 mol) with vigorous stirring under argon and the mixture was continuously stirred under reflux for 2 h. After cooling, the mixture was filtered and the residue was washed with dry ether. The filtrate and the washing were combined and concentrated *in vacuo*. Distillation of the residue under reduced pressure gave **11** (26.6 g, 79%) as a colorless oil; bp 123°C/5 Torr; ir ν_{max}: 1694, 869, and 850 cm^{-1}; nmr δ: 0.17 (9H, s, $Si(CH_3)_3$), 0.22 (9H, s, $Si(CH_3)_3$), 0.98 (3H, d, J = 6 Hz, CH_3 at C-10), 1.67 (3H, m, CH_3 at C-6), and 5.52 (1H, m, H at C-7); ms *m/e* (M^+), calcd. for $C_{18}H_{34}O_2Si_2$: 338.2096; found: 338.2084.

The Spiro Acyloin **6** *and the Keto Acetates* **13** *and* **21**

A mixture of **11** (26.6 g, 79 mmol), 10% hydrochloric acid (10 mL), and tetrahydrofuran (80 mL) was stirred at 0°C for 1 h and then concentrated at room temperature *in vacuo*. The residual oil was extracted with chloroform and the extract was washed, dried, and concentrated *in vacuo* to provide a semisolid (15.6 g). Recrystallization of the solid from chloroform gave the acyloin **6** as colorless needles (5.6 g, 34%); mp 115–118°C; ir ν_{max}: 3500 and 1742 cm^{-1}; nmr δ: 1.12 (3H, d, J = 6 Hz, CH_3 at C-10), 1.52 (3H, m, CH_3 at C-6), 2.75 (1H, d, J = 3.5 Hz, OH at C-1, disappeared by addition of deuterium oxide), 4.05 (1H, d, J = 3.5 Hz, H at C-1, this signal was changed to a singlet by addition of deuterium oxide), 5.53 (1H, m, H at C-7). *Anal.* calcd. for $C_{12}H_{18}O_2$: C 74.19, H 9.34; found: C 73.89, H 9.46.

The solvent of the mother liquor removed from the crystalline acyloin **6** by filtration was evaporated *in vacuo* to leave an oil (10 g) which was treated with pyridine (10 mL) and acetic anhydride (10 mL) in chloroform (30 mL) at 0°C for 48 h. The mixture was concentrated *in vacuo* and the residue was made alkaline with 3% ammonia, and then extracted with ether. The extract was washed, dried, and concentrated to leave an oil (11.7 g) which was chromatographed over silica gel (column 6 × 22 cm) with a 3:7 mixture of *n*-pentane and chloroform to yield the colorless oily keto acetate **13** in the first eluate (5.3 g, 43.6% based on the oil obtained from the mother liquor) and the colorless oily keto acetate **21** in the later eluate (1.9 g, 15.6% based on the oil obtained from the mother liquor).

The acetate **13**: Kugelrohr distillation at 110°C/5 Torr; ir ν_{max}: 1754 and 1737 cm^{-1}; nmr δ: 0.93 (3H, d, J = 6 Hz, CH_3 at C-10), 1.58 (3H, m, CH_3 at C-6), 2.12 (3H, s, $OCOCH_3$), 5.28 (1H, t, J = 10 Hz, H at C-1), and 5.63 (1H, m, H at C-7); M^+ calcd. for $C_{14}H_{20}O_3$: 236.1411; found (ms): 236.1364.

The acetate **21**: mp 64–68°C (**21** forms colorless prisms on standing in a refrigerator after Kugelrohr distillation): ir ν_{max}: 1757 and 1742 cm^{-1}; nmr δ: 1.00 (3H, d, J = 6 Hz, CH_3 at C-10), 1.59 (3H, m, CH_3 at C-7), 2.13 (3H, s, $OCOCH_3$), 5.38 (1H, s, H at C-1), and 5.48 (1H, m, H at C-7). *Anal.* calcd. for $C_{14}H_{20}O_3$: C 71.16, H 8.53; found: C 70.96, H 8.56.

The Keto Mesylate **14**

To the acyloin **6** (300 mg, 1.55 mmol) in chloroform (5 mL) were added pyridine (3 mL) and methanesulfonyl chloride (1.4 mL) at 0°C and the mixture was allowed to stand at 0°C for 48 h. The mixture was made alkaline with 3% ammonia and extracted with ether. The extract was washed with 5% hydrochloric acid, dried, and evaporated to leave a crystalline mass. Recrystallization of the mass from a 4:1 mixture of ether and chloroform gave **14** (405 mg, 96%) as colorless needles; mp 126–127°C; ir ν_{max}: 1759 cm^{-1}; nmr δ: 1.15 (3H, d, J = 6 Hz, CH_3 at C-10), 1.57 (3H, m, CH_3 at C-6), 3.27 (3H, s, SO_2CH_3), 5.09 (1H, s, H at C-1), and 5.48 (1H, m, H at C-6). *Anal.* calcd. for $C_{13}H_{20}O_4$: C 57.33, H 7.40; found: C 57.56, H 7.58.

The Spiro Ketone **15**

To a mixture of **14** (230 mg, 0.85 mmol) in methanol (9 mL) and tetrahydrofuran (1 mL) were added ammonium chloride (1 g) and zinc powder (3 g) with stirring. The mixture was stirred at room temperature for 2 h and then at 60°C for 6 h. The mixture was added to tetrahydrofuran (20 mL) and filtered and the residue was washed with ether. The filtrate and the washing were combined and concentrated *in vacuo* to leave an oil. The oil was extracted with ether and the extract was washed, dried, and evaporated to leave an oil. Chromatography of the oil on silica gel (column 2.5 × 17 cm) with methylene chloride gave **15** (150 mg, 99%). The spiro ketone **15**: Kugelrohr distillation at 128°C/15 Torr; ir ν_{max} (film): 1740 cm^{-1}; nmr δ (CCl_4): 0.90 (3H, d, J = 6 Hz, CH_3 at C-10), 1.64 (3H, m, CH_3 at C-6), and 5.37 (1H, m, H at C-7). *Anal.* calcd. for $C_{12}H_{18}O$: C 80.85, H 10.18; found: C 81.14, H 10.48.

The Spiro Ketones **15** *and* **16**

To the keto acetate **13** (700 mg) in a 9:1 mixture of methanol and water was added sodium borohydride (150 mg) with stirring at −10°C and the mixture was stirred for 30 min. After evaporation of the solvent *in vacuo*, the residue was made acidic with 5% hydrochloric acid and extracted with chloroform. The extract was washed, dried, and evaporated to leave a colorless oil (710 mg). To the above oil (710 mg) in chloroform (4 mL) were added pyridine (2 mL) and methanesulfonyl chloride (2 mL) at 0°C with stirring, and the mixture was kept

at 0°C for 24 h. The mixture was made alkaline with 3% ammonia and extracted with ether. The extract was successively washed with 5% hydrochloric acid and water, dried, and evaporated to leave a colorless oil (800 mg). The above oil (800 mg) in ethanol (10 mL) was added to 25% potassium hydroxide (2 mL), and the mixture was heated under reflux for 3 h under an atmosphere of argon. After evaporation of the solvent *in vacuo*, the residue was extracted with ether and the extract was washed, dried, and concentrated *in vacuo* to leave an oil. The oil was chromatographed on silica gel (column 10 × 30 cm) with methylene chloride to afford the spiro ketone **15** (100 mg, 19% based on the keto acetate **13**) and the isomeric spiro ketone **16** (200 mg, 38% based on **13**). The spiro ketone **15** was identified by ir, nmr, and gas chromatographic comparisons with those of an authentic sample prepared from **14**. The spiro ketone **16**: ir ν_{max}: 1719 cm^{-1}; nmr δ: 0.89 (3H, d, J = 6 Hz, CH_3 at C-10), 1.57 (3H, m, CH_3 at C-6), and 5.62 (1H, m, H at C-7). *Anal.* calcd. for $C_{12}H_{18}O$: C 80.85, H 10.18; found: C 80.92, H 10.42.

The Enol Methyl Ether ***17***

To a solution of the Wittig reagent prepared from methoxymethylenetriphenylphosphonium chloride (1.7 g, 5 mmol) and sodium hydride (120 mg, 5 mmol) in dimethyl sulfoxide (12 mL) was added **15** (176 mg, 1 mmol) in tetrahydrofuran (2 mL) at 0°C with stirring under an atmosphere of argon, and the mixture was stirred at 0°C for 17 h. The mixture was added to water (10 mL) and extracted with ether. The extract was successively washed with 2% hydrochloric acid, 3% ammonia, and water, dried and evaporated to leave an oily residue, which was purified by preparative thin-layer chromatography on silica gel developed with a 3:7 mixture of *n*-hexane and chloroform to yield **17** (120 mg, 59%) as a colorless oil; ir ν_{max}: 1690 cm^{-1}. M^+ calcd. for $C_{14}H_{22}O$: 206.1670; found (ms): 206.1660.

The Aldehyde ***18***

To a solution of **17** (140 mg, 0.68 mmol) in tetrahydrofuran (2 mL) was added 10% hydrochloric acid (2 mL) and the mixture was heated under reflux for 2 h. After evaporation of the solvent, the residue was extracted with ether. The extract was washed, dried, and evaporated to leave a yellow oily residue which was purified by preparative thin-layer chromatography on silica gel developed with a 4:1 mixture of chloroform and *n*-hexane to provide **18** (110 mg, 84%) as an epimeric mixture; Kugelrohr distillation at 95°C/5 Torr; ir ν_{max}: 2680 and 1718 cm^{-1}; nmr δ: 0.90 and 0.93 (3H, d, J= 6 Hz, CH_3 at C-10), 1.67 (3H, m, CH_3 at C-6), 2.75 (1H, m, H at C-1), 5.37 (1H, m, H at C-7), and 9.63 (1H, d, J = 3 Hz, CHO). M^+ calcd. for $C_{13}H_{20}O$: 192.1512; found (ms): 192.1495.

The Methyl Ketone ***20***

To an ethereal solution (3 mL) of 1.25 mol methyllithium in ether was added a solution of **18** (100 mg, 0.52 mol) in dry ether (2 mL) and the mixture was stirred at room temperature for 30 min. To the mixture was added water and then the solution was extracted with a 4:1 mixture of ether and chloroform. The extract was successively washed with 2% sodium bisulfite and water, dried, and evaporated to leave a yellow oil (100 mg). The above oil (100 mg) in acetone (5 mL) was oxidized with the Jones' reagent (0.3 mL) under stirring at room temperature. After evaporation of the solvent *in vacuo*, the residual oil was extracted with ether. The extract was washed, dried, and evaporated to provide a yellow oil which was purified by preparative thin-layer chromatography on silica gel developed with a 10:1 mixture of chloroform and *n*-hexane to provide **20** (33 mg, 31% based on **18**) as an epimeric mixture due to the C-2 chiral center. The methyl ketone **20**: Kugelrohr distillation at 145°C/8 Torr; ir ν_{max}: 1703 cm^{-1}; nmr δ: 0.89 and 0.93 (3H, d, J = 6 Hz, CH_3 at C-10), 1.68 (3H, m, CH_3 at C-6), 2.15 (3H, s, $COCH_3$), 2.92 (1H, m, H at C-2), and 5.33 (1H, m, H at C-7). M^+ calcd. for $C_{14}H_{22}O$: 206.1669; found (ms): 206.1669.

*(±)-Hinesol (**1**) and (±)-Agarospirol (**2**)*

To an ethereal solution (3 mL) of 1.25 mol methyllithium in ether was added a solution of **20** (370 mg, 1.8 mmol) in dry ether (3 mL) with stirring at −30°C. The solution was allowed to stand at room temperature for 5 min. To the mixture was added water, and the solution was extracted with a 4:1 mixture of ether and chloroform. The extract was washed with 2% sodium bisulfite and water, dried, and evaporated to leave an oily residue (330 mg, 83%) which was a 3:2 mixture of (±)-hinesol **1** and (±)-agarospirol **2** judging from gas chromatography on 10% FFAP on chromosorb W (3 mm × 3 m, column temperature 190°C, (±)-hinesol 12.4 min, (±)-agarospirol 12.0 min). The mixture was separated by repeated preparative thin-layer chromatography on silica gel (silica gel 60 F_{254}, Merck) developed with a 3:1 mixture of chloroform and *n*-hexane to give (±)-hinesol (**1**) and (±)-agarospirol (**2**).

(±)-Hinesol (**1**): Kugelrohr distillation at 99°C/5 Torr; ir ν_{max} (CCl_4): 3620, 3025, 2965, 2920, 2870, 2830, 1660, 1468, 1455, 1380, 1367, 947, and 915 cm^{-1}; nmr δ: 0.93 (3H, d, J = 6 Hz, CH_3 at C-10), 1.21 (6H, s, CH_3 at C-12 and C-13), 1.69 (3H, m, CH_3 at C-6), and 5.28 (1H, m, H at C-7). M^+ calcd. for $C_{15}H_{26}O$: 222.1983; found (ms): 222.2058. The ir and nmr spectra of (±)-hinesol **1** were indistinguishable from those of natural hinesol.

(±)-Agarospirol (**2**): Kugelrohr distillation at 99°C/5 Torr; ir ν_{max} (CCl_4): 3620, 3025, 2960, 2930, 2875, 2845, 1460, 1437, 1379, 1368, 931, and 910 cm^{-1}; nmr δ: 0.90 (3H, d, J = 6 Hz, CH_3 at C-10), 1.20 (6H, s, CH_3 at C-12 and C-13), 1.68 (3H, m, CH_3 at C-6), and 5.22 (1H, m, H at C-7). M^+ calcd. for $C_{15}H_{26}O$: 222.1982; found: 222.1979.

The Keto Acetates ***13*** *and* ***21***

To a stirred solution of **6** (500 mg, 2.6 mmol) in chloroform (2 mL) pyridine (2 mL) and acetic anhydride (2 mL) were added and the mixture was allowed to stand at room temperature for 18 h. The solvent and the excess reagents were evaporated *in vacuo*, and the residual oil was, after made alkaline with 3% ammonia, extracted with ether. The extract was successively washed with 5% hydrochloric acid, 3% ammonia, and water. The solution was dried and evaporated *in vacuo* to leave an oily residue (600 mg, 99%) which was a 10:24 mixture of **13** and **21**. The mixture was chromatographed on silica gel (column 3.8 × 21 cm) with chloroform to provide **13** in the first eluate and **21** in a later eluate. The keto acetates **13** and **21** were identified by ir and nmr spectral comparisons with those of authentic samples (*vide supra*).

The α,β-Unsaturated Aldehyde ***22***

To a solution of sodium methylsulfinylmethide prepared from sodium hydride (120 mg, 5 mmol) and dimethyl sulfoxide (4 mL) were added tetrahydrofuran (5 mL) and methoxymethylenetriphenylphosphonium chloride (1.7 g, 5 mmol) in dimethyl sulfoxide (6 mL). To the above reagent was added **21** (236 mg, 1 mmol) in tetrahydrofuran (3 mL) with stirring at 0°C and stirring was continued for 15 h. To the mixture was added ice water and the solution was extracted with ether. The extract was washed, dried, and evaporated *in vacuo* to provide an oily residue which was heated under reflux in a mixture of tetrahydrofuran (20 mL) and 10% hydrochloric acid (5 mL) for 1 h. After evaporating the solvent *in vacuo*, the residual oil was extracted with ether and

the extract was washed, dried, and evaporated to give an oily residue. Purification by preparative thin-layer chromatography over silica gel developed with a 1:1 mixture of *n*-hexane and chloroform gave **22** (13 mg, 7%); ir ν_{max}: 1678 and 1620 cm^{-1}; nmr δ: 0.90 (3H, d, J = 6 Hz, CH_3 at C-10), 1.57 (3H, m, CH_3 at C-6), 5.50 (1H, m, H at C-7), 6.62 (1H, t, J = 1.5 Hz, H at C-1), and 9.82 (1H, s, CHO). M^+ calcd. for $C_{13}H_{18}O$: 190.1356; found (ms): 190.1348.

The Methyl Ketone ***24***

Following the experimental procedure of the synthesis of the ketone **20**, the aldehyde **22** (55 mg, 0.29 mmol) was converted into the methyl ketone **24** (25 mg, 42%) by the conventional two-step sequence involving reaction with methyllithium and subsequent treatment with Jones' reagent. The methyl ketone **24**: ir ν_{max}: 1657 and 1610 cm^{-1}; nmr δ: 0.88 (3H, d, J = 6 Hz, CH_3 at C-10), 1.58 (3H, m, CH_3 at C-6), 2.31 (3H, s, $COCH_3$), 5.48 (1H, m, H at C-7), and 6.47 (1H, t, J = 1.5 Hz, H at C-1). M^+ calcd. for $C_{14}H_{20}O$: 204.1512; found (ms): 204.1497.

*(±)-α-Vetispirene (****4****)*

To a stirred ethereal solution of methyllithium (4 mL, 5 mmol) was added a solution of **24** (25 mg, 0.12 mmol) in dry ether (2 mL) at −30°C and the solution was stirred for 30 min. Water was added to the mixture and the solution was extracted with ether. The extract was washed with 5% sodium bisulfite and then with water, dried, and evaporated to leave **25** (27 mg, 95%) as a rather labile oil which was warmed at 50°C with 10-camphorsulfonic acid (5 mg) in dry benzene (1 mL) for 1 h. The mixture was extracted with ether and the extract was washed, dried, and evaporated to leave an oil which was purified by preparative thin layer chromatography on silica gel developed with *n*-hexane to provide (±)-α-vetispirene **4** (11 mg, 44%). The ir and nmr spectra of synthesized product were identical with those of an authentic sample.[3] (±)-α-Vetispirene **4**: ir ν_{max} (CCl_4): 3085, 3045, 3018, 1774, 1673, 1630, 1596, 1374, 1199, 1073, 1056, 880, and 840 cm^{-1}; nmr δ (CCl_4): 0.86 (3H, d, J = 6 Hz, CH_3 at C-10), 1.53 (3H, m, CH_3 at C-6), 1.90 (3H, d, J = 1.0 Hz, CH_3 at C-12) 4.83 (2H, d, J = 1.0 Hz, CH_2 at C-13), 5.30 (1H, m, H at C-7), and 5.44 (1H, m, H at C-1). M^+ calcd. for $C_{15}H_{22}$: 202.1719; found (ms): 202.1651.

Microbial hydroxylation of steroids. 6. Hydroxylation of C-6-substituted androst-4-ene-3,17-diones by *Rhizopus arrhizus* ATCC 11145[1]

HERBERT L. HOLLAND AND PETER R. P. DIAKOW

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received November 1, 1978

HERBERT L. HOLLAND and PETER R. P. DIAKOW. Can. J. Chem. **57**, 1585 (1979).

The products arising from the incubations of C-6α and C-6β chloro-, fluoro-, and methyl-substituted Δ^4-3-keto steroids with the C-6β hydroxylating fungus *Rhizopus arrhizus* ATCC 11145 have been identified, and their formation rationalised in terms of $\Delta^{3,5}$ enolic intermediates. The incubations of C-6 chloro and methyl $\Delta^{3,5}$ enol acetates with *R. arrhizus*, and the oxidations by *m*-chloroperoxybenzoic acid of the corresponding enol ethyl ethers have also been described. The relevance of the results so obtained to the mechanism of C-6β hydroxylation of Δ^4-3-keto steroids by *R. arrhizus* is discussed.

HERBERT L. HOLLAND et PETER R. P. DIAKOW. Can. J. Chem. **57**, 1585 (1979).

On a identifié les produits qui se forment par incubation de Δ^4 céto-3 stéroïdes (substitués en C-6α et C-6β par des chlore, fluor ou méthyle) avec les champignons hydroxylant en C-6β, *Rhizopus arrhizus* ATCC 11145 et l'on a rationalisé leur formation en termes d'intermédiaires énoliques $\Delta^{3,5}$. On décrit aussi les incubations des acétates énoliques $\Delta^{3,5}$ substitués en C-6 par un chlore ou un méthyle ainsi que les oxydations par l'acide *m*-chloroperbenzoïque des éthers énoliques éthyliques correspondants. On discute de la relation entre ces résultats et le mécanisme de l'hydroxylation en C-6β des Δ^4 céto-3 stéroïdes par le *R arrhizus*.

[Traduit par le journal]

Introduction

The microbial hydroxylation of the medicinally important 9-halo steroids at positions remote from the site of halogen substitution has been investigated (1, 2) and the C-11α hydroxylation of 6-halo steroids documented (1, 2) but there have been no reports concerning the incubation of *n*-halo steroids with fungi known to hydroxylate C-*n* of the corresponding unsubstituted steroid.

As part of our investigation into the mechanism of the C-6β hydroxylation of androst-4-ene-3,17-dione (**1***a*) (3, 4) by *Rhizopus arrhizus* ATCC 11145, we have incubated C-6-chloro- (**1***b*, **2***a*), C-6-fluoro- (**1***d*, **2***b*), and C-6-methyl- (**1***e*, **2***c*) substituted androst-4-ene-3,17-diones with this fungus. We have also studied the metabolism of the $\Delta^{3,5}$ enol acetates **4***a* and **4***b*, and the oxidation of the corresponding enol ethers **4***c* and **4***d* by *m*-chloroperoxybenzoic acid.

Results and Discussion

The results of the incubations with *R. arrhizus* are summarised in Table 1 (see also Experimental). The identification of known steroids was confirmed by a comparison of physical and spectral data with those of authentic samples. New steroids arising from C-11α hydroxylation (**1***c*, **1***f*, **1***g*, and **2***d*) were identified by spectral analysis (see Experimental), ^{1}Hmr data being typically diagnostic (5).

4*b*	150	104	**1***e* (40), **2***d* (16), **3***b* (14)

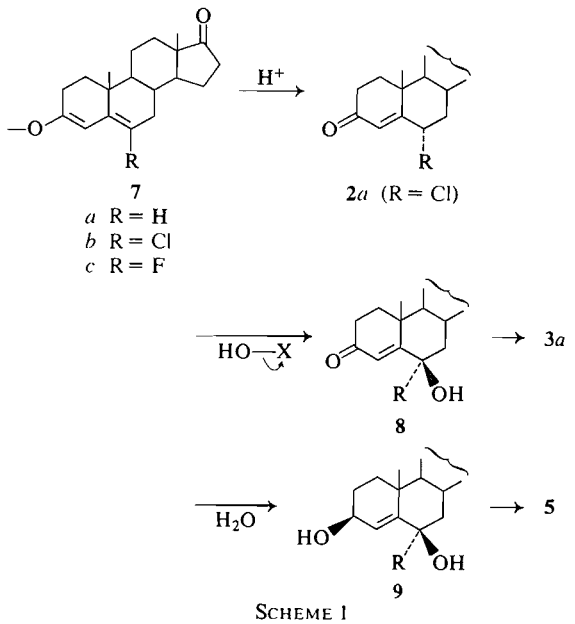
*Control incubations in the absence of fungus resulted in the recovery of starting material only.

The C-6β chloride **1***b* gave, along with some recovered starting material, small amounts of the corresponding C-6α chloride **2***a* and the product of C-11α hydroxylation, **1***c*, only. In contrast, the C-6β fluoride **1***d* gave, in addition to the C-11α-hydroxy steroid **1***g*, the Δ^4-3,6-dione **3***a*, the 3β-hydroxy-Δ^4-6-ketone **5**, and the product of reduction of the C-17 carbonyl, **6**; the reduction at C-17 of androst-4-ene-3,17-dione (**1***a*) by *R. arrhizus* has been reported (3). The corresponding C-6α-halo steroids **2***a* and **2***b* were recovered largely unchanged from incubation with *R. arrhizus*, although small amounts of **3***a* were formed in each case and the chloride **2***a* also gave the 3β-hydroxy Δ^4-6-ketone **5**.

The hydroxylation at C-6β of androst-4-ene-3,17-dione (**1***a*) by *R. arrhizus* is thought to proceed via the $\Delta^{3,5}$ enol intermediate (**7***a*) (3, 4, 6) and the results presented above may also be interpreted as involving the corresponding chloro and fluoro enols, **7***b* and **7***c*, respectively (Scheme 1). Protonation of an intermediate such as **7** would be expected to give the thermodynamically stable C-6α derivative; electrophilic oxidation will lead, via the halo hydrin **8** to **3***a*; and hydration, via **9**, will lead to **5**. The extent of protonation versus oxidation and/or hydration is presumably controlled by enzymic factors, which are unknown at the present time.

Support for the existence of the intermediate **7** is provided by the results of the incubation of the 6-chloro enol acetate **4***a*; the products of protonation (**2***a*), oxidation (**3***a*), and hydration (**5**) were isolated. Chemical analogy for the protonation and oxidation processes are provided by the *m*-chloroperoxybenzoic acid oxidation of the 6-chloro enol ether **4***c* (see refs. 3 and 6 for discussion of this reaction as a model for the C-6β hydroxylation process), where both **2***a* and **3***a* were formed.

The C-6-methyl substituted steroids **1***e* and **2***c* gave only the products of the C-11α hydroxylation (**1***f* and **2***d*, respectively), on incubation with *R. arrhizus*,



7
a R = H
b R = Cl
c R = F

2*a* (R = Cl)

8

9

SCHEME 1

although incubation of the corresponding enol acetate **4***b* did lead to the formation of a C-6β-hydroxylated steroid (**3***b*), in addition to C-11α hydroxylation. This observation has been interpreted as follows (7): C-6β hydroxylation occurs via the $\Delta^{3,5}$ enol and the fungus is able to hydrolyse and oxidise **4***b* to **3***b* but it lacks the ability to enolise either **1***e* or **2***c*. Chemical analogy for the enzymic oxidation of **4***b* is again provided by peracid oxidation of the corresponding enol ether (**4***d*), leading to **3***b* in moderate yield.

The results presented and discussed herein therefore support our earlier conclusion (3, 4) that the C-6β hydroxylation of androst-4-ene-3,17-dione by the fungus *R. arrhizus* involves an enolic intermediate. Studies with more sophisticated chemical model systems for this reaction are currently in progress.

Experimental

Apparatus, Materials, and Methods

The apparatus and techniques used were as previously described (3). Analytical samples were purified and final separation of **1***g*, **5**, and **6** performed by chromatography on a column of Whatman Partisil 20 silica gel (800 × 7.8 mm, eluent 0.5% methanolic chloroform) using a Perkin-Elmer series 3 high pressure liquid chromatograph. Incubations with *R. arrhizus* were performed as described (6).

Preparation of Substrates

The following were prepared by published procedures and gave satisfactory spectral and analytical data. 6β-Chloroandrost-4-ene-3,17-dione (**1***b*) (8), 6α-chloroandrost-4-ene-3,17-dione (**2***a*) (8), 6β-fluoroandrost-4-ene-3,17-dione (**1***d*) (9), 6α-fluoroandrost-4-ene-3,17-dione (**2***b*) (9), 6β-methylandrost-4-ene-3,17-dione (**1***e*) (10), 6α-methylandrost-4-ene-3,17-dione (**2***c*) (10), 3-acetoxy-6-methylandrosta-3,5-diene-17-

one (**4***b*) (11), 6-chloro-3-ethoxyandrosta-3,5-diene-17-one (**4***c*) (12), and 3-ethoxy-6-methylandrosta-3,5-diene-17-one (**4***d*) (13).

*3-Acetoxy-6-chloroandrosta-3,5-diene-17-one (**4**a)*

6α-Chloroandrost-4-ene-3,17-dione (5 g) was dissolved in a mixture of absolute ethyl acetate (800 mL), chloroform (100 mL), and acetic anhydride (100 mL), and then 70% aqueous perchloric acid (0.4 mL) added to the solution. The resulting dark green mixture was stirred at room temperature for 2 h and then washed (sodium bicarbonate, followed by water) and dried (sodium sulphate). After treatment of the solution with decolourising carbon and filtration, it was concentrated on a rotary evaporator at 40°C and then diluted with hexane (500 mL). The crystals which deposited after the resulting solution was cooled overnight at −20°C were collected by filtration and recrystallized from ethyl acetate – hexane to give 2.5 g of the title compound, mp 170–172°C; ir (KBr) ν_{max}: 1735, 1760 cm^{-1}; ^{1}Hmr (δ): 0.92 (3H, s, C-18H), 1.08 (3H, s, C-19H), 2.17 (3H, s, CH_3CO—), 6.33 (1H, s, C-4H); ms *m/e* (%): 322 (32), 320 (100), 307 (1.5), 305 (3.5), 285 (9). *Anal.* calcd. for $C_{21}H_{27}ClO_3$: C 69.51, H 7.50, Cl 9.77; found: C 69.31, H 7.47, Cl 9.63.

Incubations with R. arrhizus

Results of the incubations of **1**, **2**, and **4** are presented in Table 1. In all cases, products were isolated by chromatography as previously described (4). Physical and spectral data for hitherto unreported compounds are listed (*vide infra*); all other products were identified by comparison of physical and spectral data with those of authentic samples.

*6β-Chloro-11α-hydroxyandrost-4-ene-3,17-dione (**1**c)*—mp 189–192°C (dec.); ^{1}Hmr (δ): 1.01 (3H, s, C-18H), 1.62 (3H, s, C-19H), 4.20 (1H, sex., J = 10 and 5 Hz, C-11βH), 4.82 (1H, t, J = 3 Hz, C-6αH), 5.90 (1H, s, C-4H); ms *m/e* (%): 338 (6), 336 (15), 302 (100), 300 (39), 287 (36), 282 (50). *Anal.* calcd. for $C_{19}H_{25}ClO_3$ (M^+ 336.149 (^{35}Cl)): C 67.75, H 7.48, Cl 10.52; found (M^+ 336.155): C 67.72, H 7.37, Cl 10.39.

M^+ calcd. for $C_{19}H_{25}FO_3$: 320.179; found: 320.181.

Oxidations with m-*Chloroperoxybenzoic Acid*

The following were oxidised using the procedure described previously (6) and gave the products indicated.

*6-Chloro-3-ethoxyandrosta-3,5-diene-17-one (**4**c)*

Oxidation of 0.696 g of **4***c* gave 6α-chloroandrost-4-ene-3,17-dione (**2***a*) (0.31 g, 50%), mp 215–217°C (lit. (8) mp 216–218°C); ^{1}Hmr (δ): 0.93 (3H, s, C-18H), 1.27 (3H, s, C-19H), 4.6–5.0 (1H, m, C-6βH), 6.43 (1H, d, J = 2 Hz, C-4H); ms M^+ 320/322; and androst-4-ene-3,6-17, trione (**3***a*) (0.107 g, 19%), mp 222–224°C (lit. (14) mp 217–219°C); ^{1}Hmr (δ): 0.94 (3H, s, C-18H), 1.21 (3H, s, C-19H), 6.21 (1H, s, C-4H); ms M^+ 320.

*3-Ethoxy-6-methylandrosta-3,5-diene-17-one (**4**d)*

Oxidation of 0.9 g of **4***d* gave 6α-methylandrost-4-ene-3,17-dione (**2***c*) (0.1 g, 12%), mp 165–166°C (lit. (10) mp 164–167°C); ^{1}Hmr (δ): 0.93 (3H, s, C-18H), 1.12 (3H, d, J = 6.5 Hz, C-6αCH_3), 1.23 (3H, s, C-19H), 5.86 (1H, d, J = 2 Hz, C-4H); ms M^+ 300; and 6β-hydroxy-6α-methylandrost-4-ene-3,17-dione (**3***b*) (0.48 g, 42%), mp 235–238°C (lit. (11) mp 237–239°C); ^{1}Hmr (δ): 0.95 (3H, s, C-18H), 1.42, 1.45 (each 3H, s, C-19 and C-6CH_3 H's), 6.06 (1H, s, C-4H); ms M^+ 316.

Received December 15, 1978

HERBERT L. HOLLAND, PETER W. JEFFS, THOMAS M. CAPPS, and DAVID B. MACLEAN. Can. J. Chem. 57, 1588 (1979).

The biosynthesis of berberine and hydrastine (in *Hydrastis canadensis*), corydaline and protopine (in *Corydalis solida*), and ochotensimine and protopine (in *C. ochotensis*), has been investigated by the administration of [3-^{14}C]-3′,4′-dihydroxyphenylalanine ([3-^{14}C]DOPA). In all cases, incorporation of label was predominantly into the isoquinoline portion of the alkaloid. The role of DOPA in the early stages of isoquinoline alkaloid biosynthesis in these plants is discussed in the light of this and other relevant data. In addition, the later stages of corydaline biosynthesis have been studied by the administration of [9-*methoxy*-^{14}C]palmatine and -tetrahydropalmatine to *C. solida*, and the origin of the exocyclic carbons of ochotensimine further verified by feeding [*methyl*-^{14}C,^{3}H]methionine to *C. ochotensis*.

HERBERT L. HOLLAND, PETER W. JEFFS, THOMAS M. CAPPS et DAVID B. MACLEAN. Can. J. Chem. 57, 1588 (1979).

On a étudié la biosynthèse de la berbérine et de l'hydrastine (dans *Hydrastis canadensis*), de la corydaline et de la protopine (dans *Corydalis solida*) et de l'ochotensimine et de la protopine (dans *C. ochotensis*) en administrant de la [3-^{14}C]dihydroxy-3′,4′ phénylalanine ([3-^{14}C]DOPA). Dans tous les cas, l'incorporation du marqueur se fait principalement dans la portion isoquinoléine de l'alcaloïde. On discute du rôle de la DOPA dans les stades préliminaires de la biosynthèse des alcaloïdes de l'isoquinoléine dans ces plantes à la lumière de ces données et d'autres qui leur sont reliées. De plus, on a étudié les derniers stades de la biosynthèse de la corydaline en administrant des [*méthoxy*-9 ^{14}C]palmatine et -tétrahydropalmatine dans du *C. solida* et on a de plus vérifié l'origine des carbones exocycliques de l'ochotensimine en administrant de la [*méthyl*-^{14}C,^{3}H]méthionine au *C. ochotensis*.

[Traduit par le journal]

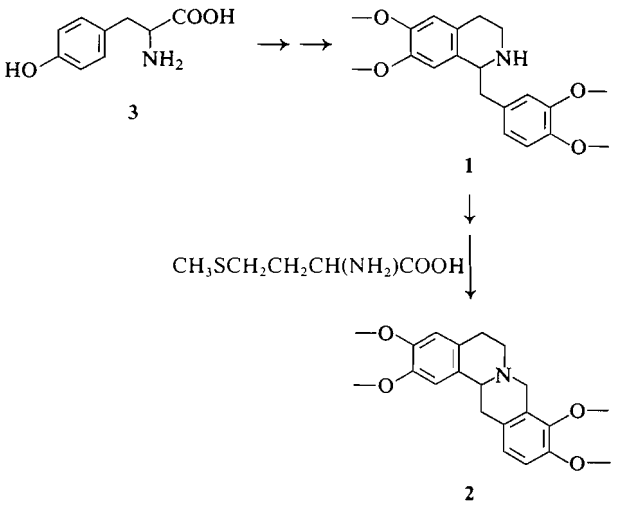
The biosynthesis of alkaloids of the benzylisoquinoline group (**1**) and of related alkaloids such as the protoberberines (**2**) has been extensively investigated (1). As shown in Scheme 1 two molecules of tyrosine (**3**) form the isoquinoline 'upper' and benzyl 'lower' portions of **1** whereas the protoberberines are derived from **1** and methionine. In the many isoquinoline systems that have been studied tyrosine has been shown to be incorporated almost equally into both the 'upper' and 'lower' portions of the molecule (1, 2).

The nature of the intermediates resulting from tyrosine during the biosynthesis of the benzylisoquinoline system has not, however, been fully established. It has been proposed that norlaudanosoline (**8***a*) may be derived from two molecules of tyrosine by either of the routes shown in Scheme 2 (1, 3) and that norlaudanosoline in turn serves as a precursor of other classes of isoquinoline alkaloids. It is well known that dopamine (**5**) is incorporated only into the upper portion of the alkaloids (1). Tyramine (**4**) can also serve as a precursor but it has been less extensively examined (4). DOPA (3,4-dihydroxyphenylalanine) **6** is a key intermediate in this scheme since it may lead both to dopamine, by decarboxylation, and to 3,4-dihydroxyphenylpyruvic acid (**7**) by transamination. The combination of **5** and **7** followed by decarboxylation provides the benzylisoquinoline **8***a* (3, 5, 6).

Although the incorporation of DOPA into isoquinoline alkaloids has been known for some time (7), its role in their formation is only now being clarified. Battersby *et al.* (8) reported that 96% of

[1]This paper is dedicated to the memory of our former coworker, R. H. F. Manske, who contributed so much to the chemistry of the isoquinoline alkaloids.

0008-4042/79/131588-10$01.00/0

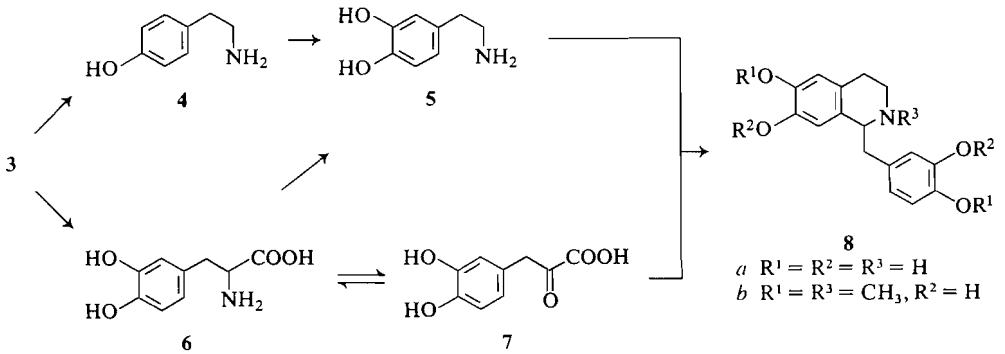


SCHEME 1. Biogenesis of the protoberberine skeleton

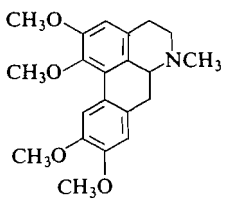
the radioactive label from [2-^{14}C]DOPA was located in the 'upper' portion of the aporphine alkaloid glaucine (**9**) and that similar incorporation into the alkaloids hasubanonine (**10**), protostephanine (**11**) (98 and 92%, respectively) (4), and into morphine (5) was observed. Similarly, Bhakuni and co-workers (3, 9) observed that 97% of the radioactivity of intact reticuline (**8***b*) isolated from *Litsea glutinosa* fed with [2-^{14}C]DOPA was located in the 'upper' half of the molecule. These results are consistent with a mechanism of benzylisoquinoline biosynthesis in which the predominant route of DOPA metabolism is via decarboxylation to dopamine. Wilson and Coscia (6) have recently reported that DOPA is incorporated into the 'lower' portion of norlaudanosoline carboxylic acid (**12**) and propose that the latter is an intermediate in the pathway for norlaudanosoline. This would indicate that although DOPA may be predominantly incorporated into benzylisoquinoline and derived alkaloids via dopamine, this mode of incorporation is not the unique pathway of DOPA metabolism and that, in all the cases quoted above, a small but significant proportion of DOPA may be incorporated into the 'lower' portion of the intact alkaloid.

In the present study, [3-^{14}C]DOPA was administered to plants which elaborate protoberberine, protoberberine-derived bases, and spirobenzylisoquinolines as major alkaloid components. The alkaloids examined were berberine (**13**) (10, 11) and hydrastine (**16**) (10, 11) in *Hydrastis canadensis*, corydaline (**19**) (2) and protopine (**21**) (7) in *Corydalis solida*, and ochotensimine (**24**) (2) and protopine in *Corydalis ochotensis*. The feeding experiments are summarized in Table 1. The intact alkaloids were degraded by established procedures (see refs. 2, 10, 11 and Experimental). These degradations are outlined in Schemes 3–7, and the results summarized in Tables 2–6.

In all cases examined, incorporation of DOPA was predominantly into the upper portion of the molecule. Since all the alkaloids examined have been shown to be derived from tyrosine, which is incorporated with approximately equal efficiency into both portions of the molecule, tyrosine cannot be metabolised *solely* via DOPA in its incorporation into the benzylisoquinoline system (see Scheme 2). The distribution of DOPA-derived label in the alkaloids is consistent with a pathway in which DOPA is metabolised predominantly by decarboxylation to **5** (9). The observation of Wilson and Coscia (6) that DOPA contributes to the lower portion of norlaudanosoline carboxylic acid (**12**) in *P. orientale* may mean that oxidation of DOPA to a keto acid such as **7** occurs to an appreciable extent in that plant. However, the specific function of the intermediate **7** in the formation of a benzyl isoquinoline or benzyl isoquinoline-derived alkaloid remains to be demonstrated: Bhakuni *et al.* (3) report the



SCHEME 2. Biogenesis of the benzylisoquinoline skeleton



9

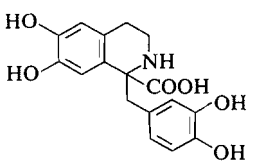
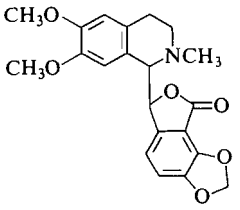
11



12



33

incorporation of [^{3}H]-**7** into reticuline but note that significant label (32%), presumably via transamination, appears in the upper portion. The interpretation of the results of experiments with DOPA must therefore necessarily be regarded as tentative until the roles of **7** and *p*-hydroxyphenylpyruvic acid in the production of benzyl isoquinolines are clarified.

We have also investigated the later stages of the biosynthesis of corydaline (**19**) in *C. solida* by the administration of (*RS*)-[9-*methoxy*-^{14}C]tetrahydropalmatine ([9-OCH_3-^{14}C]-**26**) and [9-*methoxy*-^{14}C]-palmatine ([9-OCH_3-^{14}C]-**27**). The synthesis of these alkaloids via palmatrubine (**28**) is outlined in Scheme 8. The corydaline fraction isolated from three separate feedings of [9-OCH_3-^{14}C]-**26** showed only slight activity, and radiochromatoscan analysis failed to detect significant activity associated with corydaline. Feeding of [9-OCH_3-^{14}C]-**27** as the hydroxide, however, yielded corydaline (**19**) which was labelled at the C-9 methoxyl carbon. Specific incorporation was demonstrated by degradation (Scheme 9, Table 7) of the resulting corydaline, via the tetradehydro salt (**29**), to corydalubine (**30**) and methyl iodide (isolated as methyl triethyl ammonium chloride), the latter accounting for 94% of the activity of the corydaline from which it was derived.

The incorporation of labelled **27**, but not **26**, into corydaline is explained in Scheme 10 on the basis of our earlier assumption (2) that the one carbon unit comprising C-13′ (derived from the *S*-methyl group of methionine (2)) is added to a didehydro protoberberine precursor such as **31**. The inability of *C. solida* to convert **26** into **31** is in accord with our demonstration (2) that extensive reversible oxidation and reduction of corydaline in *C. solida* does not occur (viz. retention of tritium from [*methyl*-^{3}H]-methionine at C-8 of corydaline); presumably the same is true of tetrahydropalmatine. We therefore regard **27** as functioning to provide **31** following reduction but not necessarily as an obligatory intermediate in the corydaline pathway. The stage in the pathway from **8***a* to **19** (see Schemes 2 and 10) at which the enamine functionality of **31** is introduced is unknown, and experiments to clarify this are currently under way.

As an extension of our earlier work on the biosynthesis of ochotensimine (**24**) in *C. ochotensis* (2),

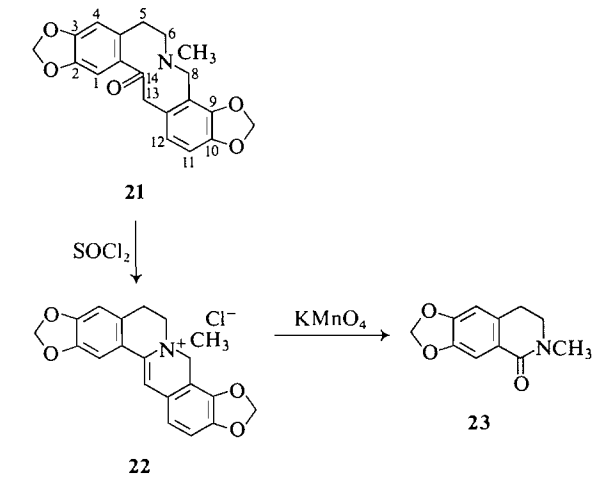

SCHEME 6. The degradation of protopine (**21**)

we have administered L-[*methyl*-^{3}H,^{14}C]methionine to this plant (Table 8): degradation of the resulting ochotensimine (Scheme 11, Table 9) followed established procedures (2, 12), and confirmed the intact derivation of the *O*-methyls, *N*-methyl, and C-13′-methylene from the *S*-methyl of methionine. The results also suggest, although do not confirm, the intact derivation of the C-8 methylene group from the same source. The ^{3}H/^{14}C ratio of **25**, which contains all the carbon and hydrogen atoms of ochotensimine, is identical with that of the precursor amino acid (cf. Table 8), whereas the ratio observed for the Hoffmann product **32** (6.5) is only 83% of that of **25**. Since the ^{3}H/^{14}C ratio of the *N*-methyl lost in this transformation is close to that of the precursor (7.4 ± 0.2 vs. 7.8 ± 0.1), this reduction in ^{3}H/^{14}C ratio can only be explained by an additional loss of ^{3}H relative to ^{14}C. The observed loss of 17% ^{3}H relative to ^{14}C is close to that which would result from the loss of two labelled hydrogen atoms in the conversion of **25** to **32** (10:12 = 83.3%). The reaction of the C-3 benzylic hydrogens of 1-indenes with base (the conditions for this transformation) is well known (e.g. ref. 13) so that loss of tritium from C-8 by base catalysed exchange during the production of **32** from **25** methiodide may well account for the observed ratios. The retention of tritium from L-[*methyl*-^{3}H]methionine at C-8 of ochotensimine would preclude a pathway of ochotensimine biosynthesis which involves a ring C oxygenated intermediate such as adlumine (**33**) but is consistent with other proposals for the derivation of ochotensimine (and related alkaloids) from the protoberberine system (2, and references therein).

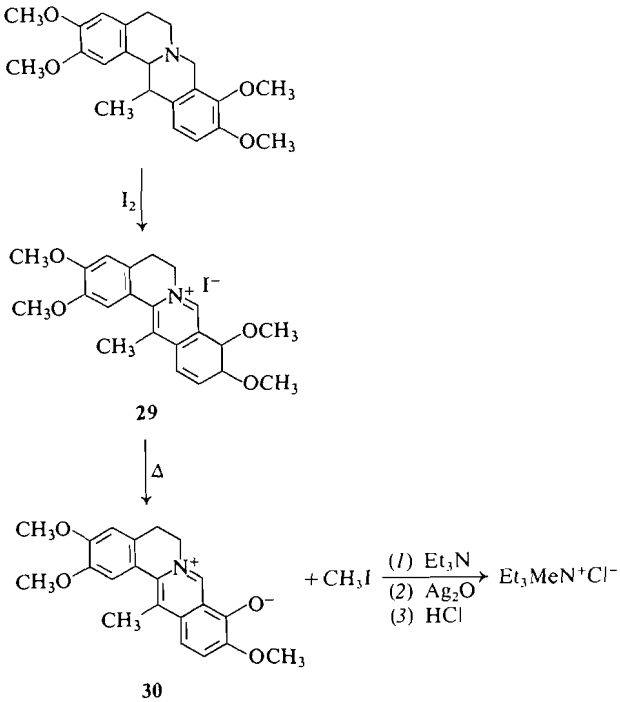

SCHEME 9. Degradation of corydaline derived from [9-OCH_3-^{14}C]palmatine

Experimental

Plants

Corydalis solida (2), *Corydalis ochotensis* (2), and *Hydrastis canadensis* (10) plants were propagated as described.

Synthesis of Labelled Alkaloids

(RS)-[9-methoxy-^{14}*C*]*Tetrahydropalmatine from* (±)-*Tetrahydropalmatine* (**26**)

Palmatine iodide (**27**)—(±)-Tetrahydropalmatine (3.55 g, 10 mmol) was dissolved in 95% ethanol (250 mL) containing iodine (3.81 g, 30 mmol) and refluxed for 3 h. The dark brown mixture was then treated with 5% sodium bisulphite (ca. 2 mL) and the mixture turned bright yellow within 30 s. The mixture was cooled in an ice bath to induce crystallization and the palmatine iodide removed by filtration. Recrystallization from MeOH–EtOAc yielded 4.60 g (96%) of the palmatine iodide as yellow needles; mp 240–242°C (lit. (14) 241°C).

Palmatrubine (**28**)—Palmatine iodide (1.0 g, 2.1 mmol) was mixed with urea (2 g) and ground into a fine powder. This powdered mixture was heated at 200°C in an oil bath for 30 min. Upon heating the mixture turned from bright yellow to a brilliant red colour. The resulting dark red solid was then poured into water (100 mL) and extracted into chloroform (4 × 50 mL). The combined organic extracts were washed with water (1 × 100 mL), dried over magnesium sulphate, and the solvent removed *in vacuo* to give a dark reddish solid. Recrystallization from absolute ethanol gave 650 mg (92%) of the palmatrubine (**28**) as red flakes; mp 288–292°C (lit. (15) 290–295°C).

(RS)-[9-methoxy-^{14}*C*]*Tetrahydropalmatine* (**26**)

The phenol betaine, palmatrubine (**28**) (35 mg, 0.1 mmol),

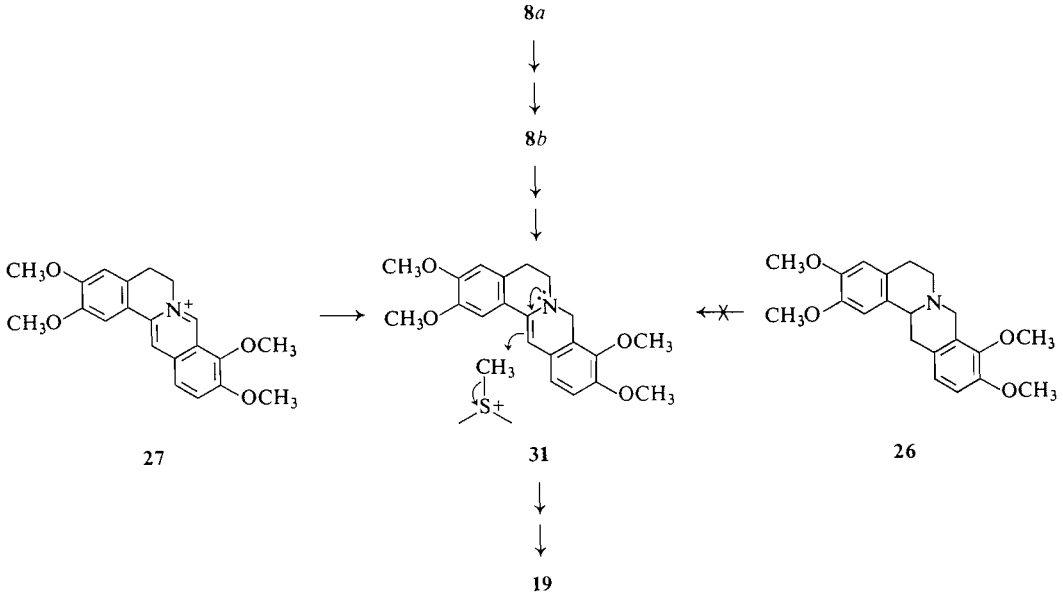
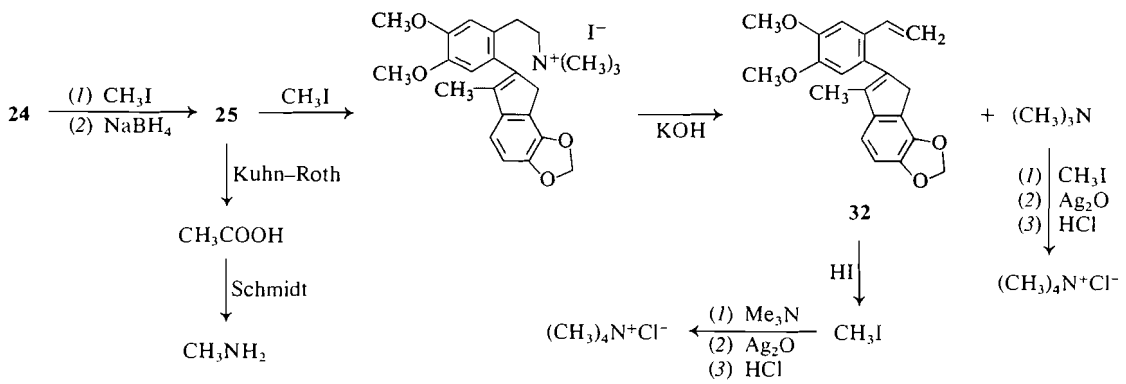


SCHEME 10. Introduction of the C-13 methyl of corydaline

was dissolved in dry DMF (3 mL) and placed on a high vacuum manifold. A break-seal ampule containing ^{14}C-labelled methyl iodide (1 mCi, 20 mCi/mmol) was also placed on the vacuum manifold. The reaction vessel containing the DMF solution was thoroughly cooled in Dry Ice – acetone and the system was evacuated to a pressure of 0.03 Torr with a rough pump. At this time liquid nitrogen was substituted for the Dry Ice – acetone bath and the break-seal container of methyl iodide was also cooled in liquid nitrogen. With the aid of an oil diffusion pump the system was further evacuated to a



SCHEME 11. Degradation of ochotensimine derived from L-[*methyl*-^{3}H,^{14}C]methionine (Table 9).

pressure of ca. 10^{-5} Torr. At this time the break-seal was cracked, the liquid nitrogen removed from the break-seal ampule, and the radio-labelled methyl iodide was allowed to distill into the reaction mixture which was kept at liquid nitrogen temperature. The reaction flask was then sealed under vacuum and kept at room temperature for 6 days. At the end of this period the mixture was cooled in Dry Ice – acetone and an additional aliquot (2 mL) of inactive methyl iodide was added. The mixture was again sealed and kept at room temperature for 2 days during which time a yellow solid had precipitated. The DMF was removed *in vacuo* and this residue taken up in methanol–water (3:1, v/v 30 mL). The mixture was treated with excess sodium borohydride and stirred at room temperature overnight. The excess borohydride was quenched by slow addition of 10% hydrochloric acid and the mixture was concentrated *in vacuo* to remove the methanol. The resultant solution was diluted with water (75 mL), basified with solid potassium carbonate and extracted with chloroform (3 × 60 mL). The combined extracts were washed with water (50 mL) and dried over sodium sulphate. The solvent was removed *in vacuo* to yield a white powder which was radiochemically pure by tlc and radioscan. Recrystallization from methanol yielded 25 mg (70%) of 9-[OCH_3-^{14}C]-(±)-tetrahydropalmatine as white needles; specific activity 21.26 μCi/mg, 7.54 mCi/mmol.

[*9*-methoxy-^{14}*C*]*Palmatine (27) from* (RS)-[*9*-methoxy-^{14}*C*]-*Tetrahydropalmatine (26)*

(RS)-[*9-methoxy*-^{14}C]Tetrahydropalmatine (4.8 mg, 102 μC) was converted into [*9-methoxy*-^{14}C]palmatine iodide by the method described above. The salt so obtained was dissolved in distilled water (5 mL) and stirred with an excess of freshly prepared silver oxide with exclusion of light for a period of 1 h. The resulting yellow solution was decanted, combined with aqueous washings of the insoluble material, and used directly.

Administration of DL-[*3*-^{14}*C*]*DOPA (Table 1)*

The labelled material was administered by infusion into the stem as described (2, 10). Ascorbic acid (1 mg/mL) was added to the feeding solutions to prevent aerial oxidation.

Extraction of the Alkaloids

Corydalis solida

Six plants were exposed to the radioactive amino acid for 3 days. The total plant material was then harvested (fresh weight 130 g) and dried at 40°C for 72 h, yielding 34 g of dry plant material. The extraction then followed the procedure of Manske (16). Corydaline (300 mg) was added to fractions BC + EC of the extract and crystallization of the extract from methanol gave 270 mg of radioactive corydaline, which was purified by recrystallization from methanol followed by sublimation (140°C, 1 × 10^{-2} Torr). Protopine (150 mg) was added to fractions BS + ES and the resulting extract crystallized from methanol to give 94 mg of radioactive protopine. A further 200 mg of protopine was added to 50 mg of the radioactive sample, and this mixture was recrystallized from chloroform–methanol to give material for degradation.

Corydalis ochotensis

Five plants (fresh weight 203 g) were exposed to the labelled amino acid for 4 days, and harvested and dried as described above to give 46 g of dry plant material. This was extracted by the procedure of Manske (17) and ochotensimine isolated from fractions BC + EC and converted to the methiodide (124 mg) as described previously (2). The radioactive methiodide (50 mg) was diluted with carrier methiodide (200 mg) prior to degradation. Protopine (24 mg) was crystallized directly from fractions BS + ES. A further 230 mg of protopine was added to 20 mg of the labelled sample and the whole crystallized from chloroform–methanol to give material for degradation purposes.

Hydrastis canadensis

Three plants were exposed to radioactive tracer for 3 days and harvested to give a total of 626 g of fresh material. The dried roots (205 g) and aerial portion (32 g) were extracted as described (10) to give berberine chloride (3.76 g) and hydrastine (1.8 g).

Administration of (RS)-[*9*-methoxy-^{14}*C*]*Tetrahydropalmatine (26) and* [*9*-methoxy-^{14}*C*]*Palmatine (27) to* C. solida *(Table 7)*

In separate feeding experiments [9-OCH_3-^{14}C]-(**26**) and -(**27**) were each administered to three plants for a period of 4 days by the cotton wick method. Corydaline was extracted and purified by the procedure described above with the modification that only 30 mg of carrier corydaline was added to the extract. It was then further purified by preparative layer chromatography (silica gel, 2% methanolic chloroform).

Administration of [methyl-^{14}*C*,^{3}*H*]-*Methionine to* C. ochotensis *(Table 8)*

Following administration by the method used previously (2), *C. ochotensis* (fresh weight 230 g, dry weight 45 g) was extracted as described (2) to give ochotensimine (**24**) (88 mg).

Degradation of the Alkaloids

Degradation of Berberine Chloride Derived from DL-[*3*-^{14}*C*]*DOPA (Table 2)*

Conversion to (±)-*canadine*—Reduction of berberine chloride (1 g) with sodium borohydride in ethanol gave (±)-canadine (746 mg), mp 170–172°C from ethanol (lit. (18) mp 171°C).

Carbons 1–6, nitrogen, and carbon-14; oxidation of canadine to **15**—Oxidation of (±)-canadine (0.5 g) with potassium permanganate, by the method described below for the oxidation of corydaline to corydaldine, gave 6,7-methylenedioxy-1,2,3,4-tetrahydro-1-isoquinolinone. Sublimation at 70–80°C, 1.1×10^{-3} Torr, and crystallization from ether gave 32 mg, mp 180–182°C (lit. (19) mp 181–182°C).

Degradation of Hydrastine Derived from DL-[*3*-^{14}*C*]*DOPA (Scheme 4, Table 3)*

Hydrastine (400 mg) was converted to hydrastinine, 162 mg, mp 116–117°C (lit. (7) mp 116–117°C) and opianic acid, 23 mg, mp 143–145°C (lit. (10) mp 146°C) by the described procedure (10).

Degradation of Corydaline Derived from DL-[*3*-^{14}*C*]*DOPA (Scheme 5, Table 4)*

Carbon-13 and the C-methyl by oxidation—The Kuhn–Roth oxidation of corydaline and the conversion of the resulting acetic acid to *N*-acetyl-α-naphthylamide were performed as described (2).

Carbon 1–6, nitrogen, and carbon-14; oxidation of corydaline to corydaldine—Sodium hydroxide solution (15%) was added dropwise to a stirred solution of corydaline (100 mg) in 50 mL of aqueous sulfuric acid at 0°C until the mixture reached pH 5. A solution of potassium permanganate (180 mg) in water (10 mL) was then added and the resulting solution stirred at 0°C. After 2 h had elapsed the solution was heated to 50°C, adjusted to pH 10 (15% NaOH) and then filtered. The filtrate was extracted with chloroform and the extract washed with 5% HCl, dried and evaporated. The residue was purified first by preparative layer chromatography (Merck silica 60 F-254, 10% methanolic chloroform, R_f 0.5) and then by sublimation at 100°C, 2×10^{-2} Torr. Crystallization from ether gave 8.4 mg of corydaldine, mp 173–175°C (lit. (20) mp 175°C).

Degradation of Corydaline Derived from [*9*-methoxy-^{14}*C*]-*Palmatine (Table 7)*

9-O-Methyl by conversion to methyltriethylammonium chloride and corydalubine—Corydaline isolated from *C. solida* after administration of [*9-methoxy*-^{14}C]palmatine (10 mg) was diluted with unlabelled corydaline (400 mg) and the mixture so obtained treated as described for the preparation of palmatrubine (above), with the addition of nitrogen inlet and outlet tubes to the reaction flask. During the reaction a slow stream of nitrogen was passed through the flask and then through three traps each containing a solution of 0.5 mL triethylamine in 5 mL methanol at −78°C. When the reaction was complete, the material from the traps was combined, allowed to stand overnight at room temperature, and then evaporated in a stream of dry nitrogen. The residue was then converted to methyltriethylammonium chloride by reaction with silver oxide and HCl as described (2). The residue in the reaction flask was treated as described above and afforded corydalubine (230 mg).

Degradation of Protopine Derived from DL-[*3*-^{14}*C*]*DOPA (Scheme 6, Table 5)*

Conversion of protopine to N-methyldihydrocoptisinium chloride—This was performed by the method described (21). In a typical transformation 200 mg of protopine gave 136 mg of the desired salt, mp 210–213°C (dec.) (lit. (21) mp 215°C (dec.)).

Carbons 1–6, nitrogen, and carbon-14; oxidation of **22** *to oxyhydrastinine*—Potassium permanganate (100 mg) was added to a stirred suspension of **22** (100 mg) in water (50 mL) at 0°C. The solution was stirred for 2 h at 0°C and then heated to 50°C, basified to pH 10 (15% NaOH), and extracted with chloroform. The extract was washed with 5% HCl, dried and evaporated to give a residue which was purified first by preparative layer chromatography (Merck silica 60 F-254, 5% methanolic chloroform, R_f 0.6) and then by sublimation at 120°C, 5×10^{-2} Torr. Crystallization from ether gave oxyhydrastinine (11.2 mg), mp 96–98°C (lit. (22) mp 97–98°C).

Degradation of Ochotensimine (Schemes 7 and 11, Tables 6 and 9)

Carbon-13 and the exocyclic methylene—The degradation of ochotensimine methiodide to isolate C-13 and C-13′ as acetic acid and transformation of the latter into *N*-acetyl-α-naphthylamide was performed as described (2).

N-Methyl as tetramethylammonium chloride—The indene derivative **25** (150 mg), obtained from ochotensimine as described (2), was dissolved in a solution of ether (1 mL) and methanol (0.2 mL) containing methyl iodide (0.5 mL). The resulting solution was allowed to remain at room temperature for 24 h, and then at −20°C for a further 24 h. The crystals which deposited (220 mg) were then removed by filtration. A solution of **25** methiodide so obtained (200 mg) in 50% aqueous ethanol (30 mL) containing potassium hydroxide (1 g) was heated at 80°C for 4 h. A slow stream of nitrogen passed through the reaction flask into a series of three traps each containing 1 mL of 10% methyl iodide – ether (v/v). The material from the traps was combined and allowed to stand at room temperature for 24 h. The precipitate of tetramethylammonium iodide so obtained was converted to tetramethylammonium chloride (2) for counting.

1-Methyl-2(2′-vinyl-4′,5′-dimethoxyphenyl)-4,5-methylene dioxy-1-indene (32)—The aqueous ethanol solution from the Hoffmann degradation described above was poured onto water (20 mL) and extracted with chloroform. The extract was washed with 5% HCl, dried, and then evaporated. The residue was dissolved in chloroform and filtered through a column of silica gel to remove polar impurities. It was then evaporated and recrystallized from acetone–hexane to give **32** (120 mg), mp 140–142°C (lit. (12) mp 142–144°C). The sample was further purified for counting by sublimation at 100°C and 0.05 Torr.

Methoxyl methyls as tetramethylammonium chloride—Treatment of **32** (100 mg) with HI by the procedure described previously (2) gave tetramethylammonium iodide (18 mg) which was converted to tetramethylammonium chloride (2) for counting.

Determination of Radioactivity

Radioactivity was assayed by liquid scintillation counting (Mark 1 liquid scintillation computer, Model 6860, Nuclear Chicago). Samples were dissolved in methanol or water and the solution dispersed in a solution of Aquasol (New England Nuclear). Triplicate samples of each compound were counted under comparable conditions of quenching. For highly quenched samples the confidence limits of the quench correction curves were ±5%. Confidence limits shown in the tables are standard deviations of the mean.

Acknowledgements

We are greatly indebted to the late Dr. R. H. F. Manske of the University of Waterloo for providing generous samples of alkaloids and plant material, and for the provision of live plants of *Corydalis solida* and *Corydalis ochotensis* from his private garden in Guelph, Ontario. We are also grateful to the Royal Botanical Gardens, Hamilton, Ont., for the propagation of *Hydrastis canadensis*. This work was supported by the National Research Council of Canada.

A convergent route to phthalideisoquinoline alkaloids via directed metalation of tertiary benzamides[1,2]

S. O. DE SILVA, I. AHMAD,[3] AND V. SNIECKUS

Guelph–Waterloo Center for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received January 2, 1979

S. O. DE SILVA, I. AHMAD, and V. SNIECKUS. Can. J. Chem. **57**, 1598 (1979).

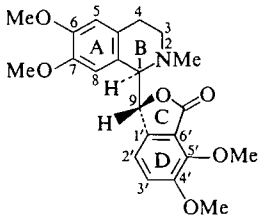
Diastereomeric phthalideisoquinolines **8** and **9** have been synthesized by a route involving an amine-induced bromohomophthalic anhydride – phthalide-α-carboxamide rearrangement, **3** + **4** → **6**, as the key step. This rearrangement has been applied to the synthesis of the methoxylated phthalide-α-carboxamide **18** which has been converted into the dehydrophthalide **19** thereby achieving a formal synthesis of the phthalideisoquinoline alkaloids cordrastine I (**1***a*) and cordrastine II (**1***b*). The key intermediate in this sequence, 3,4-dimethoxyhomophthalic acid (**15**), has been efficiently prepared in two steps via directed lithiation of 2,3-dimethoxy-*N*,*N*-diethylbenzamide (**13**).

S. O. DE SILVA, I. AHMAD et V. SNIECKUS. Can. J. Chem. **57**, 1598 (1979).

On a synthétisé les phtalideisoquinoléines diastéréoisomères **8** et **9** en faisant appel, comme étape-clé, à une transposition induite par une amine d'un anhydride bromohomophtalique en phtalide α-carboxamide **3** + **4** → **6**. On a utilisé cette transposition pour la synthèse du phtalide α-carboxamide méthoxylé (**18**) qui peut être transformé en déhydrophtalide **19**; ces réactions complètent la synthèse formelle des alcaloïdes de la phtalideisoquinoléine, cordrastine I (**1***a*) et cordrastine II (**1***b*). On a préparé l'intermédiaire de cette série de réactions, l'acide diméthoxy-3,4 homophtalique (**15**), d'une manière efficace en deux étapes par une lithiation directe du diméthoxy-2,3 *N*,*N*-diéthylbenzamide (**13**).

[Traduit par le journal]

Cordrastine I (**1***a*) and cordrastine II (**1***b*) constitute early discoveries of the phthalideisoquinoline class of alkaloids which currently number about 15 bases elaborated by Berberidaceae, Fumariaceae, Papaveraceae, and Ranunculaceae plant families (2–5). Recent interest in this group derives from the discovery of biogenetically related B/C ring-opened alkaloids (4) the interconversion of representative members into other classes of alkaloids (3, 4), elucidation of biosynthetic pathways (6), and the finding that several alkaloids act as effective γ-aminobutyric acid (GABA) antagonists (4).



1*a*
Cordrastine I

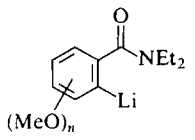
Cordrastine II



2

The isolation and structural elucidation of the cordrastines (**1**) was carried out by Manske (7) in a historical period when "new alkaloids were discovered at a rate that would make the discoverer of islands in the St. Lawrence envious" (8). Forty years later, Manske and co-workers also contributed to the development of a total synthesis of phthalideisoquinoline alkaloids (9), based on the classical Haworth–Pinder route (10), which constitutes one of the most efficient of the available routes reported to date (3, 4). Herein we describe a new synthesis[2,3] of phthalideisoquinolines which also proceeds via Haworth–Pinder intermediates but which involves the principle of directed metalation of substituted benzamides (**2**) (11) for the construction of the C/D ring fragment. An additional feature of our synthesis is a bromohomophthalic anhydride – phthalide-α-carboxamide rearrangement for the convergent assemblage of a skeleton embodying all the requisite atoms of cordrastine I (**1***a*) and cordrastine II (**1***b*) (Scheme 2).

Model Study (Scheme 1)

In connection with synthetic efforts towards the

[1]Dedicated to R. H. F. Manske, an early force and a continuing influence in Canadian Chemistry.

[2]Part of this work has been published in preliminary form; see ref. 1.

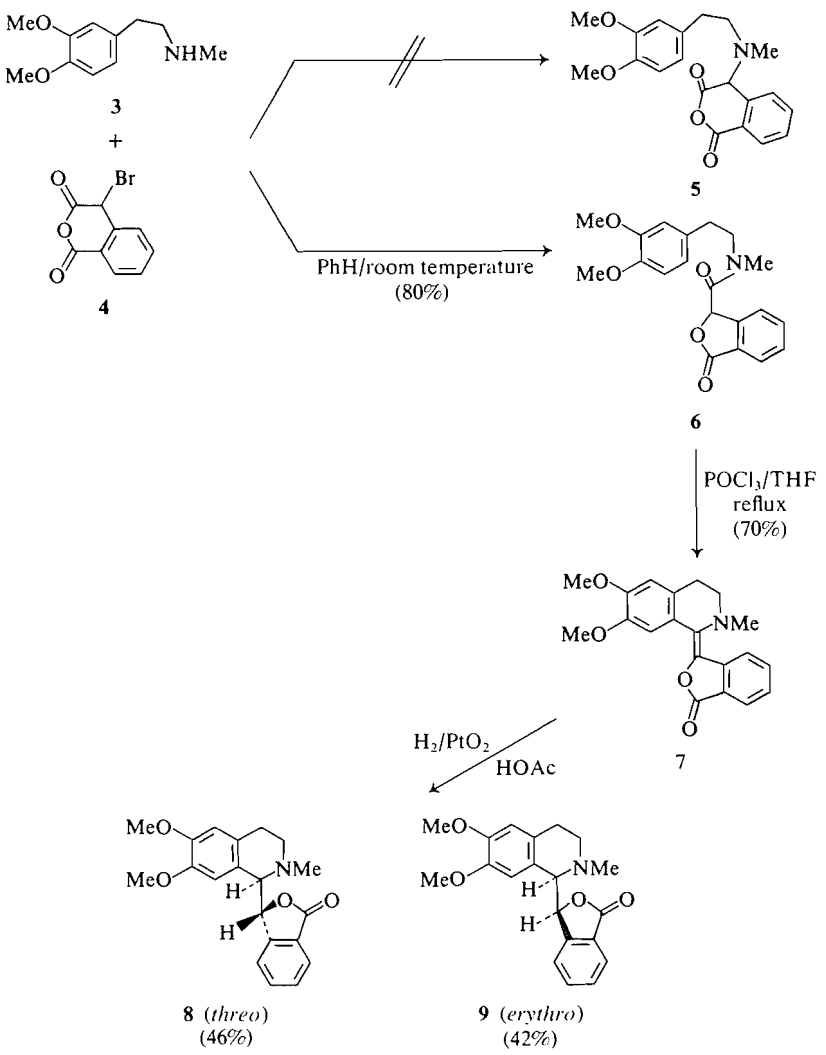
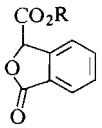


SCHEME I

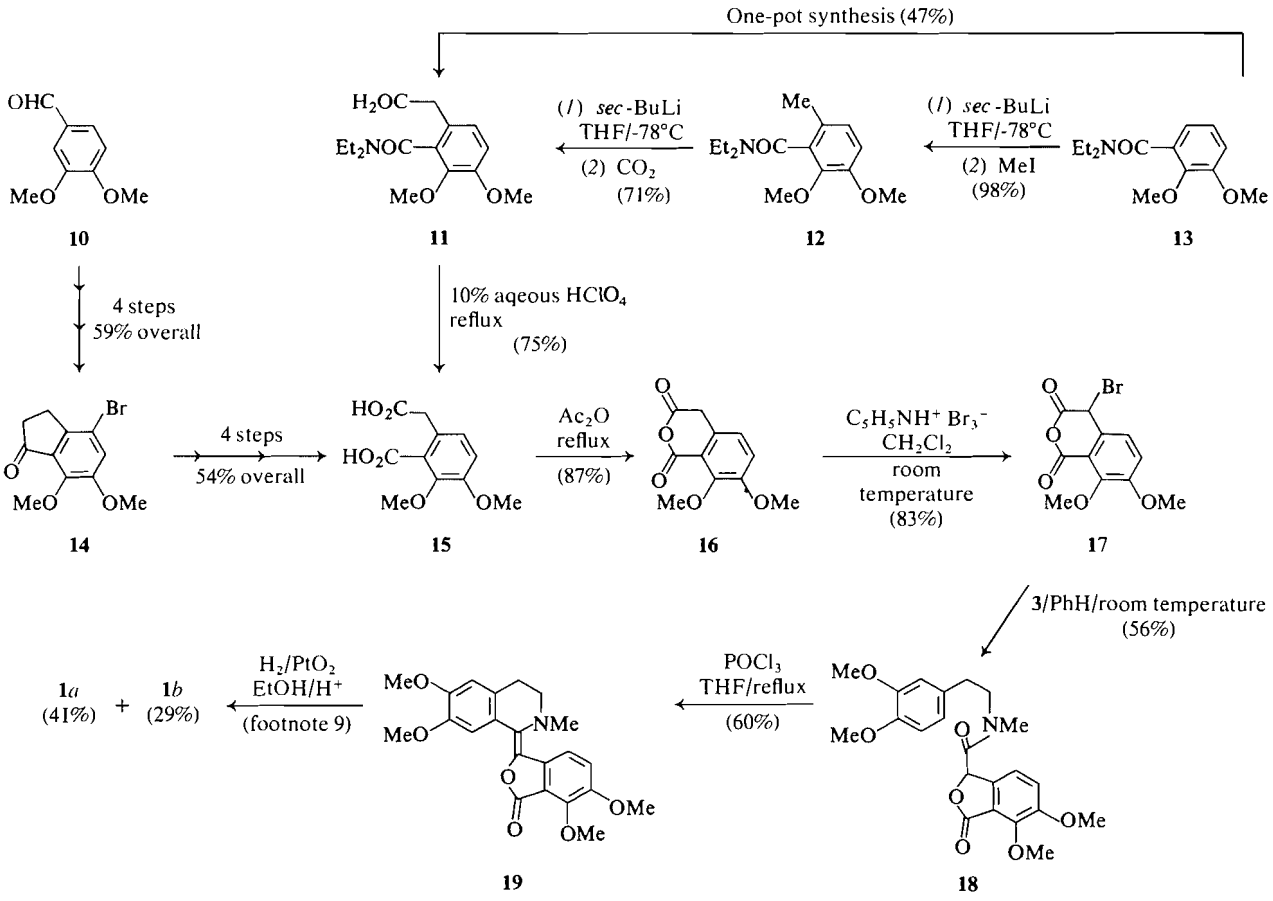
rhoeadine alkaloids,[3] we observed that condensation of the phenethylamine **3** with bromohomophthalic anhydride (**4**), both readily available compounds (see Experimental), did not yield the required anhydride **5** but provided the rearranged phthalide-α-carboxamide **6** in good yield.[4] The structure of **6** was assigned by comparison of its spectral data[5] with those of the ring D dimethoxylated analogue **18**. Modified Bischler–Napieralski cyclization afforded the yellow dehydrophthalide **7** which upon catalytic hydrogenation gave a mixture of the phthalideisoquinolines **8** and **9**. These were easily separated by preparative tlc into the pure *threo* (**8**) (46%) and *erythro* (**9**) (42%) diastereomers. Stereochemical assignments were made by comparison of tlc behavior and ^{1}Hmr spectra of **8** and **9** with those of

[4]This rearrangement was foreshadowed by the observations that bromination of homophthalic anhydride in acetic acid gave **i**[3] and distillation of dimethyl α-bromohomophthalate produced the corresponding methyl ester **ii** (28).



i R = H
ii R = Me

[5]An interesting feature of the ^{1}Hmr spectrum of **6** is the presence of two sets of doublets at δ 3.02, 3.13 and δ 5.64, 6.12 assigned to the NCH_3 and C-3 protons respectively of the two conformational isomers arising from restricted rotation about the amide bond. These signals were shown to collapse at + 69°C (sharp singlet) and + 74°C (broad peak, incomplete averaging).



SCHEME 2

the corresponding diastereomeric cordrastines **1***a* and **1***b* (12). The faster moving diastereomer **8**, R_f = 0.7 (silica gel, $CHCl_3$–MeOH, 97:3), showed absorptions at δ 4.15 (d, J = 4 Hz), 5.76 (d, J = 4 Hz), and 6.38 (s) assigned to the C-1, C-9, and C-8 protons, respectively, whereas the other diastereomer **9**, R_f = 0.35, displayed corresponding signals at δ 4.08 (d, J = 4 Hz), 5.7 (d, J = 4 Hz), and 6.3 (s). The differences in R_f values and chemical shifts of **8** and **9** are mirrored in the corresponding tlc and ^{1}Hmr data of the diastereomeric cordrastine I (**1***a*) (R_f = 0.6) and cordrastine II (**1***b*) (R_f = 0.3) whose stereochemistry has been established (12). In particular, the highly characteristic C-8 proton which reflects the favored conformations of phthalideisoquinoline diastereoisomeric pairs (4) appears at lower field in the ^{1}Hmr spectrum of the *threo* isomer **8** (δ 6.38) compared to the *erythro* isomer **9** (δ 6.3) thus paralleling the values recorded for the cordrastine isomers **1***a* (δ 6.62) and **1***b* (δ 6.19) (12). The correspondence of the R_f values and ^{1}Hmr data for the pairs **8**,**1***a* and **9**,**1***b* supports the *threo* and *erythro* stereochemical assignments to **8** and **9**, respectively.

Cordrastines I and II (Scheme 2)

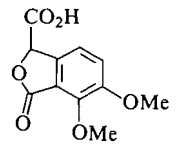
The applicability of the model bromohomophthalic anhydride – phthalide-α-carboxamide rearrangement, **3** + **4** → **6**, to the synthesis of the cordrastines I (**1***a*) and II (**1***b*) critically depended on the availability of 3,4-dimethoxyhomophthalic acid (**15**). This compound could be prepared by a tedious, multistep route from 3,4-dimethoxybenzaldehyde (**10**) via the bromoindanone intermediate **14** (Scheme 3).[6] Simplification and abbreviation of this classical route was achieved as a consequence of our work with *ortho*-lithiated *N*,*N*-diethylbenzamides (**2**) as useful intermediates for the synthesis of contiguously tri- and tetrasubstituted aromatic systems (11).

Directed lithiation of 2,3-dimethoxy-*N*,*N*-diethylbenzamide (**13**) with *sec*-butyllithium in THF provided a yellow homogeneous solution which upon treatment with methyl iodide afforded a quantitative

[6]This route consists of reactions from unrelated literature sources some of which have been improved to provide a higher overall yield of **15**. *Only* the significantly improved procedures are given in the Experimental (Scheme 3). For similar results, see ref. 13.

yield of the toluamide **12**. The ^{1}Hmr spectrum of compound **12** showed, *inter alia*, a collapsed AB pattern centered at δ 6.93 (2H) due to the aromatic protons and broad absorption at δ 0.87–1.42 (2 × t, 6H) and δ 2.87–3.83 (2 × q, 4H) due to the CH_2 and CH_3 protons, respectively, of the diethylamide function. The nonequivalency of the two sets of CH_2 and CH_3 protons is due to the amide restricted rotation phenomenon and strongly suggests that methylation has occurred *ortho* to the diethylamide function. Lithiation of **12** under similar conditions resulted in the formation of a deep purple solution of the *o*-toluoyl anion[7] which upon quenching with dry carbon dioxide gave the homophthalic acid amide **11**. The conversion of **13** into **11** was also achieved in a one-pot operation with attendant gain in convenience but some loss in overall efficacy. In this sequence, the second lithiation was carried out with *sec*-BuLi (1 equiv.) in the presence of $(i\text{Pr})_2\text{NH}$ (0.1 equiv.) as it was found that the use of *sec*-BuLi alone resulted in partial lithiation of the aromatic ring (presumably *ortho* to the 3-OMe group). The abbreviated synthesis of the homophthalic acid **15** was completed by perchloric acid hydrolysis of **11**.

Conversion of **15** into the C/D ring precursor (**17**) of the target alkaloids was readily effected by treatment with acetic anhydride to give the homophthalic anhydride **16** followed by bromination of the latter with pyridinium bromide perbromide. The unstable bromoanhydride **17** (ir ν_{max}: 1810, 1755 cm^{-1}; nmr δ: 6.10 (s, 1H, C-4 H))[8] was not purified but immediately treated with the phenethylamine **3** to give the phthalide-α-carboxamide **18**. Compound **18** was shown to be identical (mp, mixture mp, tlc, ir, and ^{1}Hmr) with an authentic sample[9] prepared by the Haworth–Pinder synthesis (10). The phenomenon of restricted rotation about the amide bond, already encountered in the model compound **6**, was again evident from the examination of the ^{1}Hmr spectrum of **18** (see Experimental). Bischler–Napieralski cyclization of **18** furnished the orange-yellow dehydrocordrastine (**19**) whose identity was established by comparison (mp, mixture mp, tlc, and ir) with an authentic sample.[9] Since **19** has been previously converted[9] (10) into cordrastine I (**1***a*) and cordrastine II (**1***b*), our work formally represents a new synthesis of these phthalideisoquinoline alkaloids.



20

As demonstrated here and elsewhere (9, 11), oxygenated homophthalic anhydrides, e.g., **16**, and phthalide-α-carboxylic acids (**20**) are now readily available by directed metalation reactions. These developments elevate the original Haworth–Pinder route (10) to the stature of a general method for phthalideisoquinoline alkaloid synthesis.

Experimental

General Methods

Microanalyses were performed by A. G. Gygli, Toronto, Ont., and Baron Consulting Co., Orange, CT. Melting points were measured on Fisher-Johns and Büchi SMP-20 apparatus and are uncorrected. Infrared spectra were determined on a Beckmann IR-10 spectrometer. Ultraviolet spectra were recorded on an SP-800E ultraviolet spectrophotometer in methanol solution. Nuclear magnetic resonance spectra were obtained with a Varian T-60 spectrometer using tetramethylsilane as internal standard in deuteriochloroform unless otherwise indicated. Mass spectra were determined on an A.E.I. MS-30 double beam, double focussing mass spectrometer. For column chromatography, silica gel 60 (70-230 mesh) and aluminum oxide (neutral, activity 1) obtained from Brinkmann (Canada), and Florisil (60–100 mesh) purchased from Fisher Scientific Co. (Canada) were used. Silica gel GF-254 and aluminum oxide G (type E) adsorbents were used for thick-layer chromatography. *sec*-Butyllithium, as a solution in hexane, and tetramethylethylenediamine (TMEDA) were purchased from Aldrich Chemical Co. When used below, the phrase 'standard work-up' signifies that a given organic solution was dried (Na_2SO_4) and evaporated to dryness *in vacuo*.

4-Bromoisochroman-1,3-dione (4)

To a stirred solution of isochroman-1,3-dione (15) (0.8 g, 5 mmol) in anhydrous methylene chloride (7 mL) was added pyridinium bromide perbromide (1.6 g, 5 mmol) in one portion. The mixture which became homogeneous in a few minutes was further stirred for 1 h. The solvent was removed under reduced pressure at room temperature and the residue was stirred with anhydrous benzene (25 mL) for 0.5 h after which time the benzene solution was decanted. This process was repeated. The combined benzene solution was subjected to filtration to remove the suspension of pyridinium hydrobromide. The filtrate was concentrated *in vacuo* at room temperature to give 0.8 g (67%) of compound **4** as a pale yellow oil; ir (C_6D_6) ν_{max}: 1800 and 1765 cm^{-1} (anhydride); nmr (C_6D_6) δ: 6.20 (s, 1H, C-4 H), 7.7–8.13 (m, 4H, aromatic H). This compound was found to be unstable and rearranged to phthalide-α-carboxylic acid, mp 154–156°C (lit. (16) mp 151°C) when water was used in the work-up or when it was stored for 1 week. Owing to its instability, compound **4** was used in the next reaction on the same day.

N-Methyl-N-(β-3,4-dimethoxyphenylethyl)phthalide-α-carboxamide (6)

A solution of freshly prepared 4-bromoisochroman-1,3-

[7]Related, synthetically useful species may be derived from secondary *o*-toluamides (14*a* and references therein) and *o*-toluic acids (14*b*).

[8]The possibility that these data correspond to the rearranged 6,7-dimethoxyphthalide-α-carboxylic acid bromide (see footnote 4) was eliminated by synthesis of this compound and comparison of its spectral data with those of the isomeric **17** (see Experimental).

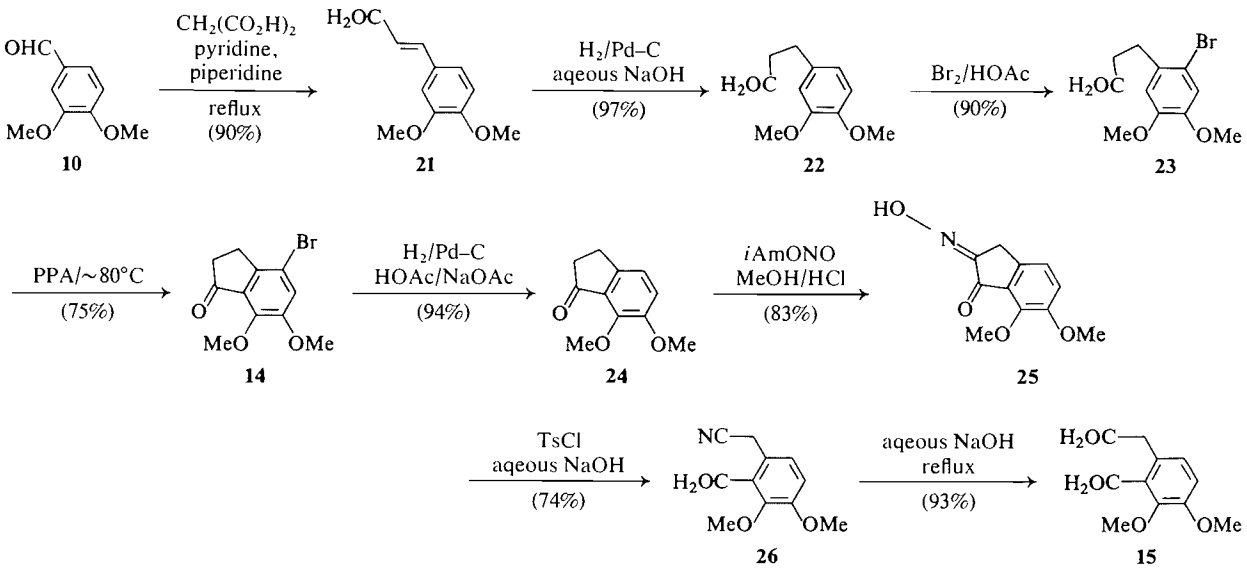

SCHEME 3

dione (**4**) (0.72 g, 3 mmol) in anhydrous benzene (10 mL) was added dropwise under nitrogen to a stirred solution of *N*-methyl-β-3,4-dimethoxyphenylethylamine (**3**) (17) (1.17 g, 6 mmol) in anhydrous benzene (18 mL). The mixture was stirred at room temperature for 1 h and the precipitated hydrobromide of **3** was removed by filtration. The filtrate was concentrated under reduced pressure to give a thick pale yellow oil which was purified by column chromatography (silica gel, $CHCl_3$–MeOH, 100:0.7). Initial fractions were combined and evaporated to dryness to give 0.85 g (80%) of compound **6** as a colourless syrup; ir ($CHCl_3$) ν_{max}: 1775 (γ-lactone), 1660 cm^{-1} (amide); nmr δ: 2.60–2.95 (m, 2H, —CH_2), 3.02, 3.13 (2 × s, 3H, NCH_3), 3.4–3.75 (m, 2H, —CH_2N), 3.8, 3.83, 3.88 (3 × s, 6H, 2 × OCH_3), 5.64 and 6.12 (2 × s, 1H, C-9 H), 6.8 (s, 3H, A ring aromatic H), 7.4–8.0 (m, 4H, D ring aromatic H); ms *m/e* (% relative intensity): 355 (41, M^+), 222 (26), 165 (78), 164 (100), 151 (100), 134 (24), 133 (100), 104 (28), 79 (41), 78 (41). *Anal.* calcd. for $C_{20}H_{21}NO_5$: C 67.60, H 5.90, N 3.94; found: C 67.38, H 6.16, N 3.80.

3-(3,4-Dihydro-6,7-dimethoxy-2-methyl-1(2H)isoquinolylidene)phthalide (7)

To a solution of *N*-methyl-*N*-(β-3,4-dimethoxyphenylethyl)phthalide-α-carboxamide (**6**) (0.5 g, 1.41 mmol) in dry THF (1 mL) was added freshly distilled phosphorous oxychloride (2.5 mL) and the mixture was refluxed on a steam bath for 3.5 h. The resulting dark red solution was cooled in an ice bath and treated by dropwise addition of a mixture of ammonium hydroxide and methanol (1:1) (2 mL). Water (4 mL) was added and the mixture was extracted with chloroform (3 × 25 mL). The organic extract was washed with water and treated by standard work up to give a dark red gum which when dissolved in methanol and allowed to stand overnight deposited 0.33 g (70%) of yellow crystals of compound **7**, mp 167–168.5°C; ir (KBr) ν_{max}: 1758 (lactone), 1594 cm^{-1} (C=C); uv λ_{max}: 219 (23 300), 307 (9600), 342 (11 600), 400 nm (16 000); nmr δ: 2.9 (s, 3H, NCH_3), 3.0–3.85 (m, 4H, —CH_2CH_2—), 4.05 (s, 3H, OCH_3), 4.15 (s, 3H, OCH_3), 6.9 (s) and 7.58–8.58 (m, 6H, aromatic H); ms *m/e* (% relative intensity): 338 (23), 337 (100, M^+), 280 (42), 278 (65). *Anal.* calcd. for $C_{20}H_{19}NO_4 \cdot \frac{1}{2}CH_3OH$: C 69.67, H 5.99, N 3.96; found: C 69.82, H 5.70, N 3.70.

(±)-threo- and -erythro-2-Methyl-6,7-dimethoxy-1-(phthalidyl)-1,2,3,4-tetrahydroisoquinolines (8 and 9)

To a suspension of powdered dehydrophthalide **7** (0.25 g, 0.74 mmol) in glacial acetic acid (25 mL) was added platinum oxide (10 mg) and the mixture was hydrogenated at room temperature and atmospheric pressure until hydrogen uptake ceased. The catalyst was removed by filtration and the colourless filtrate was evaporated to dryness under reduced pressure. The residual gum was neutralized with aqueous ammonium hydroxide and the resulting mixture was extracted with chloroform (3 × 25 mL). Standard work-up gave 0.25 g (96%) of a colourless syrup which was subjected to preparative tlc (silica gel, $CHCl_3$–MeOH, 97:3) to give the following two components.

Band 1

(±)-*threo*-2-Methyl-6,7-dimethoxy-1-(phthalidyl)-1,2,3,4-tetrahydroisoquinoline (**8**), 0.12 g (46%); R_f 0.7 (silica gel, $CHCl_3$–MeOH, 97:3); mp 168–170°C; ir (KBr) ν_{max}: 1760 cm^{-1} (γ-lactone); nmr δ: 2.66 (s, 3H, NCH_3), 2.2–3.4 (m, 4H, —CH_2CH_2—), 3.71 (s, 3H, OCH_3), 3.79 (s, 3H, OCH_3), 4.15 (d, J = 4 Hz, 1H, C-1 H), 5.76 (d, J = 4 Hz, 1H, C-9 H), 6.38 (s, 1H, C-8 H), 6.7 (s, 1H, C-5 H), 7.3–7.9 (m, 4H, D aromatic ring H); ms *m/e* (% relative intensity): 206 (100), 58 (67).

Picrate—Compound **8** (67.8 mg, 0.2 mmol) was dissolved in methanol (0.5 mL) and treated with a solution of picric acid (45.8 mg, 0.2 mmol) in methanol (0.5 mL). The mixture was refluxed on a steam bath for 15 min and cooled to give 105 mg (92%) of the picrate of **8** as yellow prisms, mp 198–200°C. *Anal.* calcd. for $C_{26}H_{24}N_4O_{11}$: C 54.93, H 4.26, N 9.86; found: C 54.87, H 4.41, N 9.77.

Band 2

(±)-*erythro*-2-Methyl-6,7-dimethoxy-1-(phthalidyl)-1,2,3,4-tetrahydroisoquinoline (**9**), 0.11 g (42%); R_f 0.35 (silica gel, $CHCl_3$–MeOH, 97:3); amorphous solid; ir ($CHCl_3$) ν_{max}: 1765 cm^{-1} (γ-lactone); nmr δ: 2.57 (s, 3H, NCH_3), 2.35–3.2 (m, 4H, —CH_2CH_2—), 3.63 (s, 3H, OCH_3), 3.85 (s, 3H, OCH_3), 4.08 (d, J = 4 Hz, 1H, C-1 H), 5.7 (d, J = 4 Hz, 1H, C-9 H), 6.3 (s, 1H, C-8 H), 6.6 (s, 1H, C-5 H), 6.8–7.05, 7.4–8.0 (m, 4H, D aromatic ring H); ms *m/e* (% relative intensity): 206 (100), 58 (67).

Picrate—Using the procedure described above, the picrate of **9** was prepared in 92% yield: yellow prisms, mp 208–210°C. *Anal.* calcd. for $C_{26}H_{24}N_4O_{11}$: C 54.93, H 4.26, N 9.86; found: C 55.10, H 4.26, N 9.78.

The mixture melting point of the two picrates was depressed (mp 176–188°C).

*Synthesis of 3,4-Dimethoxyhomophthalic Acid (**15**)*

(a) By a Classical Route (Scheme 3)

*3,4-Dimethoxycinnamic acid (**21**)*—A high yield (92%) procedure has been claimed (18) which apparently could not be reproduced (60%) (19). Following the Doebner reaction between 3,4-dimethoxybenzaldehyde and malonic acid as described by Koo *et al.* (20) furnished a 90% yield of compound **21**. A sample recrystallized from aqueous ethanol gave colourless needles, mp 180–181.5°C (lit. (19) mp 181–181.5°C); ir (KBr) ν_{max}: 3440 (br, OH) and 1682 cm^{-1} (C=O); nmr δ: 3.95 (s, 6H, 2× OCH_3), 6.3 (d, J = 16 Hz, 1H, —CH=C*H*CO_2H), 6.75–7.15 (m, 3H, aromatic H), 7.78 (d, J = 16 Hz, 1H, —C*H*=$CHCO_2H$).

*3,4-Dimethoxyphenylpropionic acid (**22**)*—Compound **22** has been previously obtained in 85% yield by reduction of **21** using sodium amalgam (21, 22). The hydrogenation procedure of McCorkindale *et al.* (23) was followed. From 5 g (24 mmol) of **21** there was obtained 4.9 g (97%) of compound **22**. A sample recrystallized from aqueous ethanol showed mp 95–96°C (lit. (21) mp 97°C); ir (KBr) ν_{max}: 2900 (br, OH), 1700 cm^{-1} (C=O); nmr δ: 2.40–3.20 (m, 4H, —CH_2CH_2—), 3.88 (s, 6H, 2× OCH_3), 6.80 (s, 3H, aromatic H), 8.90 (br s, 1H, OH).

*3-(2-Bromo-4,5-dimethoxyphenyl)propionic acid (**23**)*—Compound **23** was obtained in 90% yield by bromination of **22** according to a literature procedure (24). A sample recrystallized from aqueous ethanol showed mp 118–119°C (lit. (24) mp 118–119°C); ir (KBr) ν_{max}: 2930–2832 (br, OH), 1710 cm^{-1} (C=O); nmr δ: 2.45–3.15 (m, 4H, —CH_2CH_2—), 3.83 (s, 6H, 2× OCH_3), 6.78 (s, 1H, C-6 H), 7.0 (s, 1H, C-3 H), OH absorption was not detected.

*4-Bromo-6,7-dimethoxyindan-1-one (**14**)*—Friedel–Crafts cyclization of **23** using concentrated sulfuric acid (24) gave **14** in only 25% yield. We obtained **14** in 75% yield by using polyphosphoric acid under conditions which are essentially those recently described by Cushman and Dekow (13). A sample recrystallized from methanol showed mp 120–121°C (lit. (13) 118–120°C; lit. (24) mp 120–121°C); ir and nmr spectra identical with those reported (13).

*6,7-Dimethoxyindan-1-one (**24**)*—Compound **24** has been previously obtained from 2-carboxy-3,4-dimethoxybenzaldehyde (opianic acid) in four steps and unknown overall yield (25). A mixture of compound **14** (2 g, 7.4 mmol) and anhydrous sodium acetate (1 g) in glacial acetic acid (100 mL) was hydrogenated in the presence of 10% palladium-on-carbon (0.2 g) at room temperature and 50 psi until hydrogen uptake ceased. The catalyst was removed by filtration and the filtrate was evaporated to dryness under reduced pressure. The resulting residue was dissolved in water (25 mL) and extracted with ethyl acetate (2 × 50 mL). Standard work up gave an oil. Vacuum distillation afforded 1.33 g (94%) of compound **24** as a colourless oil, bp 188–190°C/20 Torr which crystallized, mp 40–42°C (lit. (25) mp 40–43°C); ir ($CHCl_3$) ν_{max}: 1703 cm^{-1} (C=O); nmr δ: 2.48–2.78 (m, 2H, —CH_2—), 2.86–3.2 (m, 2H, CH_2CO), 3.9 (s, 3H, OCH_3), 4.0 (s, 3H, OCH_3), 7.04 (d, J = 8 Hz, C-5 H), 7.24 (d, J = 8 Hz, C-4 H).

*2-Hydroxyimino-6,7-dimethoxyindan-1-one (**25**)*—The method of Schöpf *et al.* (25), also recently adopted by Cushman and Dekow (13), was employed using *iso*-amylnitrite as the nitrosating reagent. In this manner, compound **24** gave **25** in 83% yield, mp 208–209.5°C. (lit. (25) mp 208–210°C); ir (KBr): 1722 (C=O), 1650 cm^{-1} (C=N). This material was used in the next step without purification.

*2-Carboxy-3,4-dimethoxyphenylacetonitrile (**26**)*—The second-order Beckmann rearrangement of **25** was carried out according to the method of Gensler *et al.* (26) (see also ref. 13) to give compound **26** in 74% yield, mp 116–118°C (lit. (25) mp 97–99°C; lit. (26) mp 104–108°C); ir ($CHCl_3$) ν_{max}: 2320 (CN), 1745 cm^{-1} (C=O); nmr δ: 3.93 (s, 2H, —CH_2—), 4.0 (s, 6H, 2 × OCH_3), 7.0 (d, J = 8.5 Hz, C-5 H), 7.25 (d, J = 8.5 Hz, C-6 H).

*3,4-Dimethoxyhomophthalic acid (**15**)*—Base-catalyzed hydrolysis of **26** was carried out according to a literature method (25) (see also ref. 13) to give **15** in 93% yield, mp 117–118°C (lit. (25) mp 115–117°C); ir and nmr spectra in agreement with those reported (13).

*(b) By Directed Metalation of **13** (Scheme 2)*

*2,3-Dimethoxy-6-methyl-*N,N*-diethylbenzamide (**12**)*—A stirred solution of 2,3-dimethoxy-*N,N*-diethylbenzamide (bp 140°C/0.2 Torr) (27) (2.37 g, 10 mmol) and TMEDA (1.5 mL, 10 mmol) in dry tetrahydrofuran (200 mL) contained in a two-necked flask equipped with a gas inlet tube and a septum inlet and maintained under an atmosphere of dry nitrogen, was cooled to −78°C (Dry Ice – acetone bath). A solution (0.9 *M*) of *sec*-butyllithium in hexane (11.1 mL, 10 mmol) was slowly introduced through the septum inlet using a hypodermic syringe. The light yellow solution was stirred for 1 h at −78°C and dry methyl iodide (1.24 mL, 20 mmol) was injected into the flask. Stirring was continued for 6 h during which time the cooling bath warmed to room temperature. Evaporation of the reaction mixture under reduced pressure gave a gummy product which was suspended in water (200 mL) and extracted with methylene chloride (2 × 100 mL). Standard work up yielded an oil which upon vacuum distillation gave 2.4 g (98%) of compound **12**, bp 130°C/0.4 Torr; ir ($CHCl_3$) ν_{max}: 1625 cm^{-1} (amide); nmr δ: 0.87–1.42 (2 × overlapping t, 6H, $N(CH_2CH_3)_2$), 2.23 (s, 3H, $ArCH_3$), 2.87–3.83 (2 × overlapping q, 4H, $N(CH_2CH_3)_2$), 3.87 (s, 6H, 2× OCH_3), 6.93 (s, 2H, collapsed AB pattern, aromatic H). *Anal.* calcd. for $C_{14}H_{21}NO_3$: C 66.91, H 8.42, N 5.57; found: C 66.61, H 8.39, N 5.23.

*2-(*N,N*-Diethylcarboxamido)-3,4-dimethoxyphenylacetic acid (**11**)*—A solution of **12** (0.5 g, 2 mmol) in dry THF (200 mL) at −78°C prepared as for the synthesis of **11**, was treated with a solution (0.9 *M*) of *sec*-butyllithium in hexane (2.22 mL, 2 mmol) by slow injection through a septum cap using a hypodermic syringe. The resulting purple solution was stirred at −78°C for 0.5 h and allowed to warm to −60°C. The solution was blanketed with a stream of dry carbon dioxide passed through a syringe needle inserted into the septum cap. The purple color was discharged (3 min) to give a yellow solution but the carbon dioxide supply was maintained for 15 min. The solution was allowed to warm to room temperature and evaporated to yield a gum which was suspended in water (200 mL). The resulting mixture was extracted with methylene chloride (100 mL) and the aqueous layer was acidified (6 *N* HCl, 50 mL) and continuously extracted (24 h) with diethyl ether. Standard work up yielded 0.498 g of a semisolid which was recrystallized from benzene – petroleum ether (60–80°C) (1:1) to afford 0.42 g (71% of compound **11**), mp 107°C; ir ($CHCl_3$) ν_{max}: 1740 (CO_2H), 1580 cm^{-1} (amide); nmr δ: 0.87–1.42 (2 × overlapping t, 6H, $N(CH_2CH_3)_2$), 3.02–3.75 (m, 6H, CH_2CO_2H, $N(CH_2CH_3)_2$), 3.75 (s, 3H, OCH_3), 3.91 (s, 3H, OCH_3), 6.98 (d, 1H, J = 8 Hz, C-6 H), 7.2 (d, 1H, J = 8 Hz, C-5 H). *Anal.* calcd. for $C_{15}H_{21}NO_5$: C 61.00, H 7.17, N 4.74; found: C 60.91, H 7.02, N 4.42.

*One-pot synthesis of compound **11***—The procedure described for the preparation of **12** was followed up to and including the

methyl iodide addition step using the following quantities of reagents: compound **13** (237 mg, 1 mmol), dry THF (100 mL), *sec*-butyllithium (0.9 *M* solution in hexane, 1.12 mL, 1 mmol), methyl iodide (0.09 mL, 1.5 mmol). The mixture was allowed to warm to room temperature over 1 h and then heated at 60°C for 0.5 h in the presence of a continuous stream of dry nitrogen. The mixture was cooled to −60°C (gradual addition of Dry Ice to an acetone bath) and sequentially injected with freshly distilled diisopropyl amine (0.14 mL, 0.1 mmol) and a solution of *sec*-butyllithium in hexane (1.12 mL, 1 mmol). The resulting deep purple solution was stirred for 0.5 h and subjected to treatment with carbon dioxide and standard work up according to the description above for the conversion **12** → **11**. The crude product was chromatographed (silica gel, benzene–methanol–acetone, 9:1:1) to give 0.140 g (47%) of compound **11** which was shown to be identical (mp, tlc, nmr) with a sample prepared above by the two-step procedure.

*Hydrolysis of Compound **12**: 3,4-Dimethoxyhomophthalic acid (**15**)*—A suspension of the homophthalic acid amide **11** (120 mg) in 10% aqueous perchloric acid (40 mL) was refluxed for 40 h, cooled, and continuously extracted with diethyl ether. The ether layer was dried by azeotropic removal of water using benzene and evaporated to dryness yielding a gum which was recrystallized from benzene to give 74 mg (75%) of compound **15**, mp 117°C which was shown to be identical (mixture mp, ir, nmr) with a sample prepared by the classical method. decribed above.

*7,8-Dimethoxyisochroman-1,3-dione (**16**)*

A mixture of dry 3,4-dimethoxyhomophthalic acid (**15**) (0.5 g, 2.1 mmol) and acetic anhydride (4.5 mL) was refluxed for 3 h and evaporated to dryness under reduced pressure to give a pale yellow solid. Recrystallization from anhydrous benzene afforded 0.4 g (87%) of 7,8-dimethoxyisochroman-1,4-dione (**16**) as colourless plates, mp 103–105°C (lit. (24) mp 104–105°C); ir (KBr) ν_{max}: 1790, 1750 cm^{-1} (anhydride); nmr (acetone-d_6) δ: 3.87 (s, 3H, OCH_3), 3.9 (s, 3H, OCH_3), 4.14 (s, 2H, —CH_2—), 7.17, 7.47 (2 × d, J = 8.5 Hz, 2H, aromatic H).

*4-Bromo-7,8-dimethoxyisochroman-1,3-dione (**17**)*

To a solution of 7,8-dimethoxyisochroman-1,3-dione (**16**) (0.44 g, 2 mmol) in anhydrous methylene chloride (4 mL) was added pyridinium bromide perbromide (0.638 g, 2 mmol). Dissolution occurred in a few minutes. The mixture was stirred at room temperature for 1.5 h and then evaporated to dryness at reduced pressure and room temperature. The residue was stirred with anhydrous benzene (10 mL) for 15 min and the benzene solution was decanted. This process was repeated. The combined benzene extracts were subjected to filtration in order to remove remaining pyridinium hydrobromide. The filtrate was concentrated *in vacuo* at room temperature to give 0.58 g (83%) of compound **17** as an unstable oil (ir ($CHCl_3$) ν_{max}: 1810, 1755 cm^{-1} (anhydride); nmr (acetone-d_6) δ: 3.93 (s, 3H, OCH_3), 3.99 (s, 3H, OCH_3), 6.10 (s, 1H, C-4 H), 7.55 (s, 2H, aromatic H)) which was used without further purification in the next reaction.

That the above data correspond to structure **17** and are not due to the acid bromide of 6,7-dimethoxyphthalide-α-carboxylic acid (**20**) was shown by an unambiguous synthesis of the latter as follows.

Thionyl bromide (1 mL) was added to 6,7-dimethoxyphthalide-α-carboxylic acid (**20**) (20 mg) (11) placed in a flask equipped with a magnetic stirring bar and a drying tube, and the flask immersed in an ice bath. The mixture was stirred and allowed to warm to room temperature over 3 h. The excess thionyl bromide was removed under high vacuum to give the acid bromide of compound **20** as a gummy, highly moisture-sensitive material (22 mg, 87%); ir ($CHCl_3$) ν_{max}: 1780, 1770 cm^{-1} (γ-lactone); nmr (acetone-d_6) δ: 3.96 (s, 3H, OCH_3), 4.05 (s, 3H, OCH_3), 6.0 (s, 1H, C-3 H), 7.5 (collapsed AB pattern, 2H, aromatic H); mass spectrum *m/e* (% relative intensity) 301 (M^+, 3), 193 (—COBr, 72), 85 (97), 83 (97).

N-*Methyl*-N-*(β-3,4,-dimethoxyphenylethyl)meconine-α-carboxamide (**18**)*

A solution of freshly prepared **17** (0.58 g, 1.92 mmol) in anhydrous benzene (5 mL) was added dropwise under dry nitrogen to a stirred solution of *N*-methyl-β-3,4-dimethoxyphenylethylamine (**3**) (0.749 g, 3.84 mmol) in anhydrous benzene (8 mL). The mixture was stirred at room temperature for 1.5 h. The resulting precipitate of the hydrobromide of **3** was removed by filtration and the filtrate was diluted with benzene (25 mL) and washed with successive portions of dilute hydrochloric acid and water. The organic layer was dried (Na_2SO_4) and concentrated under reduced pressure to give a pale yellow syrup. Purification by preparative tlc (silica gel, $CHCl_3$–MeOH, 100:3) gave 0.45 g (56%) of compound **18** as an oil which crystallized from methyl alcohol in glistening white prisms, mp 123–125°C (lit. (10) mp 123–124°C); ir ($CHCl_3$) ν_{max}: 1780 (lactone), 1650 cm^{-1} (amide); nmr δ: 2.65–2.98 (m, 2H, —CH_2—), 3.07, 3.15 (2 × s, ~2:1, 3H, NCH_3), 3.51–4.2 (m, 14H, —CH_2N, 4 × OCH_3), 5.58, 6.03 (2 × s, ~2:1, 1H, phthalide-α-H), 6.67–7.25 (m, 5H, aromatic H). This compound was shown to be identical (mixture mp, tlc (silica gel, $CHCl_3$–MeOH, 100:3), and nmr) with an authentic sample provided by Professors D. B. MacLean and H. L. Holland.

*3-(3,4-Dihydro-6,7-dimethoxy-2-methyl-1(2H)-isoquinolylidene)-6,7-dimethoxyphthalide (Dehydrocordrastine) (**19**)*

To a solution of compound **18** (200 mg, 0.48 mmol) in anhydrous THF (0.5 mL) was added freshly distilled phosphorous oxychloride (1.2 mL) and the mixture was refluxed on a steam bath for 3.5 h. The resulting deep red solution was evaporated to dryness *in vacuo* to give a dark red syrup which was cooled in an ice bath and treated dropwise with a mixture of ammonium hydroxide and methanol (1:1) (1.2 mL). Water (2 mL) was added and the mixture was extracted with chloroform (3 × 30 mL). Standard work up gave a dark red gum which was crystallized from methanol to afford 120 mg (60%) of compound **19** as orange-yellow prisms, mp 139–141°C (lit. (10) mp 136–136.5°C); ir (KBr) ν_{max}: 1764 (lactone), 1600 cm^{-1} (C=C); uv λ_{max}: 225 (24 800), 307 (14 950), 330 (14 400), 404 nm (18 900); nmr δ: 2.65 (s, 3H, NCH_3), 2.76 (t, 2H, —CH_2—), 3.17 (t, 2H, —CH_2N), 3.8, 3.85, 3.89, 4.04 (4 × s, 12H, 4 × OCH_3), 6.54 (s, 1H, C-8 H), 7.18, 7.84 (2 × s, 2H, C-2′, C-3′ H), 7.97 (s, 1H, C-5 H); ms *m/e* (% relative intensity): 398 (28), 397 (M^+, 100), 382 (32), 364 (32), 341 (32), 339 (50), 309 (25), 199 (67). This compound was shown to be identical (mixture mp, ir, tlc (silica gel, $CHCl_3$–MeOH, 100:3), nmr) with an authentic sample provided by Professors D. B. MacLean and H. L. Holland.

The biosynthesis of the Lythraceae alkaloids.[1,2] I. The lysine-derived fragment

RAM NATH GUPTA, PETER HORSEWOOD, SWE HOO KOO, and IAN D. SPENSER

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 30, 1978

RAM NATH GUPTA, PETER HORSEWOOD, SWE HOO KOO, and IAN D. SPENSER. Can. J. Chem. **57**, 1606 (1979).

The biosynthesis of decodine (**7**) and decinine (**9**), Lythraceae alkaloids containing a *trans*-fused quinolizidine nucleus, was studied in intact plants of *Decodon verticillatus* (L.) Ell. Nonrandom incorporation of radioactivity from ^{14}C-labelled samples of lysine, cadaverine, and Δ^1-piperideine was demonstrated by partial degradation. Pelletierine did not serve as a precursor of the alkaloids. It was also shown, by means of ^{3}H,^{14}C-labelled tracers, that the alkaloids are derived from L-lysine whereas pipecolic acid, which is present in the plant, is derived from D-lysine.

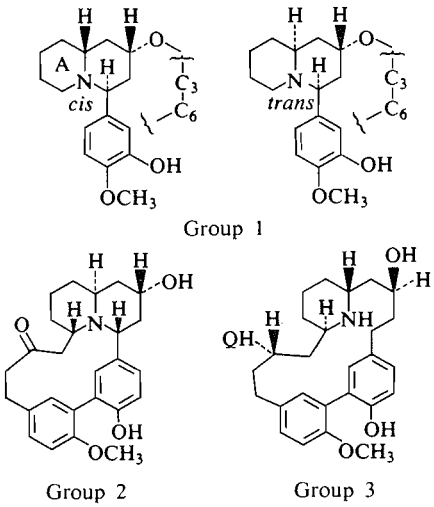
RAM NATH GUPTA, PETER HORSEWOOD, SWE HOO KOO et IAN D. SPENSER. Can. J. Chem. **57**, 1606 (1979).

On a étudié la biosynthèse, dans des plantes complètes de *Decodon verticillatus* (L.) Ell, de la décodine (**7**) et de la décinine (**9**), des alcaloïdes lythraceae contenant un noyau quinolizidine avec fusion *trans*. Faisant appel à une dégradation partielle, on a démontré que l'incorporation de la radioactivité provenant d'échantillons de lysine, de cadavérine et de Δ^1-pipéridéine se fait d'une façon qui ne relève pas du hasard. On n'a pas observé que la pelletierine puisse servir de précurseur pour ces alcaloïdes. On a aussi montré, en faisant appel à des marqueurs ^{3}H et ^{14}C que les alcaloïdes dérivent de la L-lysine alors que l'acide pipécolique qui est présent dans la plante provient de la D-lysine.

[Traduit par le journal]

Introduction

Several structural variants are known among the alkaloids of the family Lythraceae (Scheme 1) (for a review, see ref. 2). One major group comprises *cis*- and *trans*-fused phenylquinolizidinols, derivatized by esterification and phenol coupling (either C—C or O—C) with a C_6–C_3 phenylpropanoid acid. A second group are *cis*-fused phenylquinolizidinols which are further substituted by a C_6–C_4 unit. Thirdly, there are piperidine derivatives, disubstituted, at the two α-carbons, by C_6–C_4 units. The different groups are further characterized by stereochemical distinctions.



SCHEME 1. Alkaloids of the Family Lythraceae: group 1: *Decodon*-type alkaloids; group 2: *Lythrum*-type alkaloids; group 3: piperidine-type alkaloids.

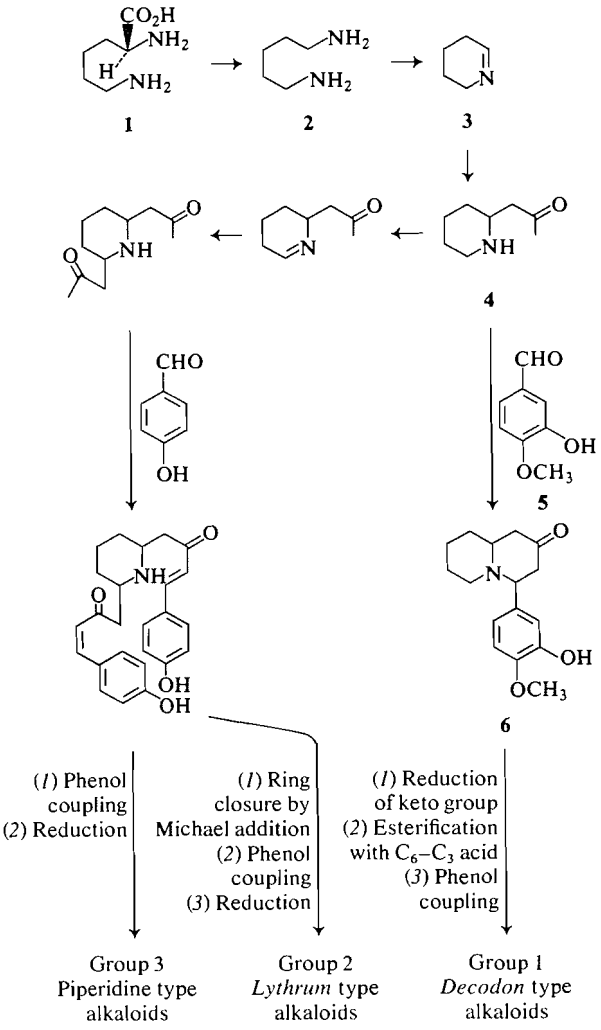
The ring systems of the three structural types are biogenetically derivable (3, 4) (Scheme 2) from pelletierine (**4**) whose nucleus, in turn, has been shown to be generated from L-lysine (5), via cadaverine (6) and, presumably, Δ^1-piperideine (cf. refs. 7–10), and whose side chain originates from acetate (11–13). Biogenetically modelled syntheses of pelletierine have been reported (14). Mannich condensation of pelletierine with a C_6–C_1 unit, isovanillin, a reaction which has been employed in biomimetic synthesis (15–17), yields the phenylquinolizidinone (**6**). This compound, together with the corresponding alcohol, has been detected in *Heimia salicifolia* (16, 17). It represents the structural core of the first group of Lythraceae alkaloids. Introduction of a second α-side chain into pelletierine (cf. ref. 18), followed by condensation with two C_6–C_1 units, yields an intermediate from which alkaloids of the second and third groups may plausibly be derived.

We have tested the validity of the pelletierine hypothesis of the origin of the Lythraceae alkaloids of *Decodon verticillatus* by tracer experiments. Radioactivity from ^{14}C-labelled samples of lysine, cadaverine, and Δ^1-piperideine is indeed incorporated

[1]This paper is dedicated to the memory of R. H. F. Manske.

[2]A preliminary report of part of this work has been published (1).

0008-4042/79/131606-09$01.00/0



SCHEME 2. Biogenesis from pelletierine of the skeletons of the Lythraceae alkaloids (ignoring stereochemistry).

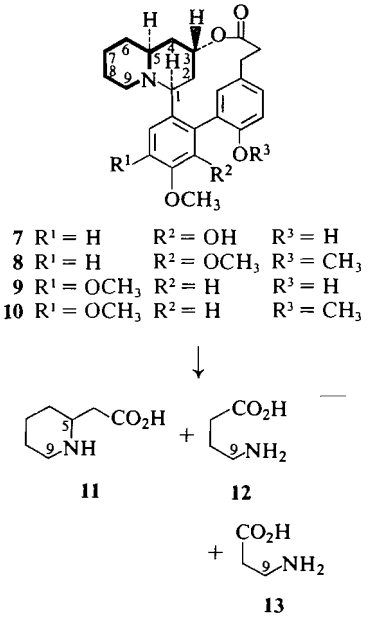
in predicted fashion into decodine and decinine. Contrary to prediction, however, pelletierine does not serve as a precursor.

Methods and Results

The plant species used in this investigation was *Decodon verticillatus* (L.) Ell. (water oleander). This is the species of the family Lythraceae from which alkaloids were first isolated by J. P. Ferris (19, 20). A voucher specimen is deposited in the herbarium of the Royal Botanical Gardens, Hamilton. For feeding experiments, stocks of the plant were transferred to the greenhouse from their native habitat in swampy areas of the botanical gardens. Tracers were administered to intact plants through wicks inserted into the stems of the plants. Two, three, or four stocks were used in each experiment. All feeding experiments were carried out in late June or early July, 3 or 4 weeks after fresh growth appeared. Biosynthesis of the major alkaloids does not appear to take place later in the season.

Specifically labelled samples of lysine (experiments 1–4), cadaverine (experiment 5), Δ^1-piperideine (experiment 6), and pelletierine (experiments 7 and 8) were administered, the plants were kept in contact with tracer for 3 days, and the aerial parts of the plants were harvested, dried, and ground. The underwater parts of the plant, which do not appear to contain alkaloids, were discarded. Alkaloids were extracted from the powdered leaves and stems. Decodine, and in most cases also decinine, was isolated by dilution with inactive carrier and purified to constant radioactivity. A summary of these experiments is presented in Table 1.

Decodine obtained from the experiments with labelled lysine, cadaverine, and Δ^1-piperideine was radioactive, as was the decinine which was also isolated from the experiments with lysine. To determine the distribution of ^{14}C, the labelled samples were degraded by chromic acid oxidation into the partial degradation products, β-alanine, γ-aminobutyric acid, and 2-piperidylacetic acid (Scheme 3).



SCHEME 3. Degradation of decodine (**7**) and decinine (**9**). (For reasons which will be discussed in the second paper of this series, the numbering of the quinolizidine carbon atoms employed here is that used by Schöpf *et al.* (21) rather than that recommended by the Ring Index (22, RR1 1687) and used previously for the *Decodon* alkaloids.)

[c]Assayed as dimethyldecodine.
[d]Amersham/Searle.

The specific activities of these degradation products, obtained from the samples of decodine and decinine from individual feeding experiments, are listed in Tables 2 and 3.

The samples of β-alanine and of γ-aminobutyric acid (isolated as their *N*-dinitrophenyl derivatives) obtained by oxidation of decodine and decinine, derived from [2-^{14}C]lysine (experiment 1) and [6-^{14}C]lysine (experiment 2), and of decodine from [1,5-^{14}C]cadaverine (experiment 5) in each case accounted for approximately one-half of the activity of the intact alkaloid from which they were derived. The sample of 2-piperidylacetic acid from the same experiments contained the entire activity of the intact alkaloid. Decodine, derived from [6-^{14}C]-Δ^1-piperideine (experiment 6), on the other hand, yielded γ-aminobutyric acid which, like the 2-piperidylacetic acid, maintained the total activity of the intact alkaloid.

The alkaloids, obtained from plants which had been kept in contact with labelled pelletierine (experiments 7 and 8), were not radioactive.

The ^{3}H/^{14}C ratio of the lysine administered in experiments 3 and 4 is compared with that of the samples of decodine and decinine as well as that of the pipecolic acid isolated from the plants (Table 4). The alkaloids and pipecolic acid maintained the ^{3}H/^{14}C ratio of the tracer in the experiment with DL-[^{3}H]lysine/DL-[^{14}C]lysine. In the experiment with L-[^{3}H]lysine/DL-[^{14}C]lysine, the pipecolic acid was rich in ^{14}C but had lost 97% of the ^{3}H relative to ^{14}C. The alkaloids, on the other hand, were found to have a ^{3}H/^{14}C ratio which was double that of the precursor.

Discussion

Biosynthesis of decodine and decinine from pelletierine and pelletierine precursors demands a predictable pattern of radioactivity from ^{14}C-labelled samples of lysine, cadaverine, Δ^1-piperideine and ring-labelled pelletierine, in ring A (i.e., C-5 to C-9,*N*) of the alkaloids. A degradation of the alkaloids was therefore required which generates fragments recognizably derived from that portion of the molecules. Chromic acid oxidation of the alkaloids yields such fragments (Scheme 3). They are 2-piperidylacetic acid (**11**) (C-3 to -9), γ-aminobutyric acid (**12**) (C-6 to -9), and β-alanine (**13**) (C-7 to -9). Pipecolic acid or δ-aminovaleric acid were not detected among the degradation products. The yield of the oxidation products was too low (1–2%) to permit the further chemical manipulation which is required to separate individual carbon atoms. It was not possible, therefore, to isolate C-5 and C-9, the

[a]See ref. 5. In an experiment with L-[^{3}H]substrate/DL-[^{14}C]substrate, % product derived from L-substrate = 50 (^{3}H/^{14}C in product)/(^{3}H/^{14}C in substrate).

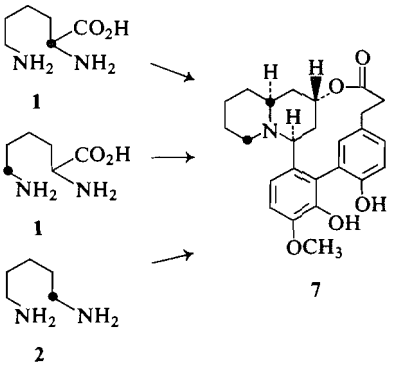
sites within the alkaloids predicted to carry label derived from the chosen precursors, for individual radioactive assay. However, since β-alanine and γ-aminobutyric acid contain only one of these two carbon atoms (C-9), whereas 2-piperidylacetic acid contains both (C-5 and C-9), and since it can be assumed (cf. ref. 10) that none of the other carbon atoms of the isolated degradation products are likely to be sites of activity from the radiomers of lysine, cadaverine and Δ^1-piperideine which were tested as precursors, definite conclusions can nevertheless be drawn on the basis of this degradation, incomplete though it is.

The results of experiments 1 and 2 show that lysine is incorporated into decodine (Table 2) and decinine (Table 3) in a specific manner. When either [2-^{14}C]-lysine or [6-^{14}C]lysine served as the precursor, the entire radioactivity of the alkaloids was recovered in 2-piperidylacetic acid and was, therefore, located at C-5 or at C-9, or at both sites. One-half of the label was found in β-alanine and in γ-aminobutyric acid, and was therefore located at C-9. The other half must then be present at C-5. It can thus be inferred that a C_5 fragment comprising C-2 to C-6 of lysine is incorporated into ring A. Since distribution of activity within the alkaloids was the same when either [2-^{14}C]- or [6-^{14}C]lysine serves as substrate, the C_5 fragment must originate from lysine by way of a symmetrical intermediate.

The symmetrical mode of entry into the alkaloids of label from lysine (Scheme 4) is similar to that observed in the case of the lycopodium (9, 23) and lupine (24, 25) alkaloids.

It is known that the lysine-derived units of lycopodine (26), lupanine (27), and several piperidine alkaloids (5) originate from L-lysine, whereas pipecolic acid, isolated from the same sources, is derived from D-lysine (5, 26, 27). This is demonstrated by a tracer technique whereby the chirality of a precursor–product relationship is determined by the use of doubly labelled substrate. Provided intact incorporation of ^{3}H,^{14}C-labelled racemate of a substrate into a product has been shown to take place with maintenance of the ^{3}H/^{14}C ratio, it is possible to determine, by use of a multiply-labelled substrate in which one enantiomer is labelled with tritium, while the other is labelled not only with tritium but also with ^{14}C, which one of the enantiomers of the substrate is incorporated into the product (5).

The incorporation into decodine and decinine of an intact C_5 fragment (C-2 to C-6 of lysine) derived from lysine by decarboxylation, may be inferred from the results of the experiments with [2-^{14}C]- and [6-^{14}C]lysine (experiments 1 and 2). Experiment 3 (Table 4) shows that when DL-[4,5-$^3H_2$]lysine/DL-[6-^{14}C]lysine serves as the substrate, the ^{3}H/^{14}C ratio of the precursor is maintained in the alkaloids, as well as in the pipecolic acid which is isolated. The



SCHEME 4. Incorporation of lysine (**1**) (experiments 1 and 2) and cadaverine (**2**) (experiment 5) into decodine (**7**).

necessary conditions for the determination of the chirality of the precursor-product relationship are thus met. The experiment with L-[4-^{3}H]lysine/DL-[6-^{14}C]lysine (experiment 4) then gives the required information.

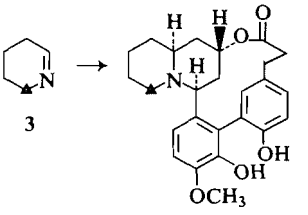
Comparison of the $^3H/^{14}C$ ratios of substrate and products (experiment 4, Table 4) clearly indicates that decodine and decinine are derived from L-lysine, since their $^3H/^{14}C$ ratio was twice that of the administered lysine. Pipecolic acid, on the other hand, is derived largely, if not exclusively, from D-lysine, since it was rich in ^{14}C but contained little ^3H. These results are entirely analogous to those obtained with other plant species in which alkaloids are derived from L-lysine whereas L-pipecolic acid is generated from D-lysine (5, 26, 27).

Two other substrates whose incorporation into decodine was tested were [1,5-^{14}C]cadaverine (experiment 5) and [6-^{14}C]-Δ^1-piperideine (experiment 6). These compounds are regarded as intermediates on the route from lysine into pelletierine (6, 8, 9, 23), anabasine (6, 7), and other piperidine alkaloids. Both served as specific precursors of decodine.

Decodine derived from [1,5-^{14}C]cadaverine showed a distribution of label identical with that of the lysine-derived samples. Activity was equally divided among C-9 (β-alanine) and C-5 (2-piperidylacetic acid minus β-alanine) (experiment 5, Table 2). Since cadaverine is a symmetrical molecule, no other incorporation pattern is possible.

The distribution of activity in decodine derived from [6-^{14}C]-Δ^1-piperideine was entirely different. Label was confined to C-9 (γ-aminobutyric acid) (experiment 6, Table 2) (Scheme 5). This is consistent with the established evidence (7, 14) that the double bond in Δ^1-piperideine does not migrate from one side of the nitrogen to the other.

The fact that the individuality of C-6 of labelled Δ^1-piperideine is maintained within the product, whereas that of the corresponding carbon atom of lysine (C-6) and of cadaverine (C-1) are not, is not inconsistent with a route into the alkaloids from lysine via cadaverine and Δ^1-piperideine. It simply indicates that randomization of C-6 and C-2 of lysine takes place before the formation of Δ^1-piperideine, since, once the latter is formed, equilibration of the corresponding centres does not occur. The Δ^1-piperideine which is formed *in situ* from [2-^{14}C]- or [6-^{14}C]lysine and from [1,5-^{14}C]cadaverine is an equimolar mixture of [2-^{14}C]- and [6-^{14}C]-Δ^1-piperideine, incorporation of which into the alkaloids yields a different labelling pattern from that obtained when either [2-^{14}C]-Δ^1-piperideine or [6-^{14}C]-Δ^1-piperideine is supplied exogenously.



SCHEME 5. Incorporation of Δ^1-piperideine (**3**) into decodine (**7**) (experiment 6).

The specific incorporation, into predicted sites of ring A of the alkaloids, of radioactivity from labelled samples of L-lysine, cadaverine, and Δ^1-piperideine, compounds known or inferred to be precursors of pelletierine, is consistent with the pelletierine hypothesis of their origin (3). The ultimate test of the hypothesis is the specific incorporation into the alkaloids of labelled samples of pelletierine. Decodine and decinine, isolated from plants which had been treated with *RS*-[6,2′-$^{14}C_2$]pelletierine and *RS*-[6-^{3}H,2′-^{14}C]pelletierine (experiments 7 and 8, Table 1) were not radioactive, however.

The two negative experiments with pelletierine were carried out concurrently with experiments in which labelled alkaloids were obtained from other substrates (cadaverine (experiment 5) and lysine (experiment 3), respectively).[3] The conclusion was, therefore, unavoidable that the pelletierine hypothesis of the biosynthesis of decodine and decinine might have to be abandoned. Conclusive evidence against the pelletierine hypothesis, and in support of an alternative biogenetic hypothesis, will be presented in the second paper of this series.

[3]It can, of course, be argued that the alkaloids are formed from pelletierine which is synthesized endogenously from the substrates whose incorporation has been demonstrated, but that exogenously administered pelletierine does not reach the site of alkaloid biosynthesis in *Decodon verticillatus*. Such a contention can be neither proved nor disproved on the basis of tracer experiments with intact plants.

Experimental

Labelled Compounds

The samples of DL-[2-^{14}C]-, [6-^{14}C]-, [4,5-$^{3}H_2$]-, and [6-^{3}H]lysine, L-[4-^{3}H]lysine, [1,5-^{14}C]cadaverine, and ethyl [3-^{14}C]acetoacetate were obtained from commercial suppliers (see Table 1).

[6-^{14}C]-Δ^1-Piperideine (experiment 6) was prepared from DL-[6-^{14}C]lysine (8). *RS*-[6-^{14}C]- and [6-^{3}H]Pelletierine were synthesised by condensation of labelled Δ^1-piperideine, prepared, respectively, from DL-[6-^{14}C]- and [6-^{3}H]lysine, with inactive acetoacetic acid (14). *RS*-[2′-^{14}C]Pelletierine was obtained by condensation of [3-^{14}C]acetoacetic acid (prepared by hydrolysis of ethyl [3-^{14}C]acetoacetate) with Δ^1-piperideine, obtained from inactive DL-lysine (cf. ref. 8). The location of the label in the latter sample of pelletierine was confirmed by subjecting a small amount of the product ($\sim$0.5 μCi) to Kuhn–Roth oxidation, followed by Schmidt reaction of the resulting acetate.

Administration of Labelled Compounds to Decodon verticillatus *(Water Oleander)*

Decodon verticillatus plants were found in two colonies in swampy areas of Hendrie Valley and of Coote's Paradise, Royal Botanical Gardens, Hamilton. Plants from the colony in Hendrie Valley were used in the experiments from 1968–1972. The plants in this location were rooted in the muddy bottom of the swamp, generally in 3–4 ft of water. In the spring of 1973, the water level in this location was above 6 ft and the colony was wiped out. In later experiments, plants from Coote's Paradise were used. This colony is growing on a floating mat of roots and survived the high water. Plants used in feeding experiments were transported intact to the greenhouse where they were acclimatized for 1–2 weeks before administration of tracers.

All feeding experiments were performed in late June or early July, about 3 or 4 weeks after appearance of foliage, when shoots were approximately 1–1½ ft tall. Experiments later in the season yielded inactive decinine and decodine.

Preliminary experiments showed that administration of tracer solution to intact stocks by the wick method led to incorporation of label into decodine and decinine, whereas no incorporation was observed when cuttings from the same stocks were immersed in tracer solution, even though the tracer was readily absorbed by the cuttings.

In each tracer experiment, threads were inserted into 20 stems on 2–4 stocks. The ends of each thread were placed into a specimen tube attached to the stem by Scotch tape. A solution (10 mL) of the labelled compound was distributed among the specimen tubes, and was absorbed by the plants within 24 h. The plants were kept in contact with tracer for 3–5 days and were then harvested. The green stems and leaves were cut, dried for 2 days, and extracted as described below, to yield radioactive alkaloids. The roots were discarded since it was found in preliminary work that they contained little, if any, alkaloidal material.

The details of the feeding experiments are summarized in Table 1.

Radioactivity Measurements

In early experiments (before 1971, experiments 1, 2, 5) radioactivity was determined on samples of finite thickness on aluminum planchettes with a gas-flow system (model 4342, Nuclear Chicago). For plating, a 1% solution of collodion in dimethylformamide was used as a solvent. The usual corrections for background and selfabsorption were applied. The efficiency of the system for ^{14}C ($\sim$30%) was determined using sodium benzoate of known activity as a standard. Since 1971, radioactivity was assayed by liquid scintillation counting (Mark I liquid scintillation computer, model 6860, Nuclear Chicago Corporation). The efficiency of counting for ^{14}C and ^{3}H was determined by external standardization counting with ^{133}Ba. Samples for counting were dissolved in dioxane or methanol and dispersed in Aquasol (New England Nuclear) (10 mL). To determine the activity of the yellow DNP derivatives of the degradation products of the alkaloids (*vide infra*), the samples were decolorized before counting. Weighed samples (ca. 1 mg) of the DNP derivatives were dissolved in methanol (2 drops) in the liquid scintillation vial and aqueous sodium borohydride (1 *M*, 2 drops) was added. The solution decolorized within 5 min. Aquasol (10 mL) was then added. The confidence limits shown in the results (Tables 1–4) are standard deviation of the mean.

Isolation of Decodine (7), Decinine (9), and Pipecolic Acid

For large-scale isolation of inactive alkaloids, the procedure of Ferris *et al.* (20) was employed. In small-scale work with radioactive plants, several modified procedures were used.

In a typical experiment, the dried aerial parts (14 g) of the plants which had been kept in contact with tracer solution were ground to a fine powder in a blender (Osterizer Galaxie 10). The powder was moistened with aqueous ammonia (3% w/v, 10 mL) and was continuously extracted with chloroform for two days in a Soxhlet extractor. In the experiments in which pipecolic acid was to be isolated, the chloroform extract was washed once with dilute ammonia solution and this was used in the isolation of the amino acid (*vide infra*). The chloroform solution was evaporated *in vacuo* to a small volume (20 mL) and 2 *M* hydrochloric acid (20 mL) was added. The mixture was heated on a steam bath 15 min to boil off residual chloroform and the aqueous solution was decanted from the coagulated solids. Chloroform (10 mL) and 2 *M* hydrochloric acid was again added and the procedure repeated. After yet another extraction with 2 *M* hydrochloric acid, the combined acid extract (ca. 60 mL) was washed with ether (2 × 25 mL) and the ether layer was discarded. The aqueous layer was carefully basified with solid sodium bicarbonate (foaming) and extracted with chloroform (3 × 20 mL). The chloroform extract was dried (anhydrous Na_2SO_4) and evaporated *in vacuo*, leaving the crude alkaloids as a foam (155 mg).

The crude alkaloid extract (155 mg) was fractionated on a column (10-mm diameter) of neutral alumina (activity IV, 10 g). The following solvent sequence was used for elution of the alkaloids: petroleum ether (30–60°C); petroleum ether – benzene (1:4); benzene; benzene–chloroform (1:4); chloroform; 5% methanol in chloroform; and methanol. Twenty-five fractions, each containing 25 mL solvent, were collected. A small sample (ca. 5 μL) of each fraction was checked for radioactivity by liquid scintillation counting. The fractions were concentrated and chromatographed (silica gel GF 254 containing 4% KOH, developed with chloroform–methanol–diethylamine (10:1:1)). The fractions containing the same compounds were combined. In general, decinine was eluted from the column by petroleum ether – bezene (1:4) whereas decodine was found mostly in the benzene–chloroform (1:4) fractions. However, the elution sequence of these alkaloids from the column varied somewhat from experiment to experiment and depended on the activity and amount of alumina used and the size of the column. To conserve radioactive materials, inactive decodine, mp 195–197°C, and decinine, mp 223–225°C, obtained by extraction of *D. verticillatus* plants, was added to their respective fractions and the diluted product crystallized from methanol to constant radioactivity.

In further simplification of the separation method, the

crude alkaloid mixture was applied to several alumina plates (20 cm × 20 cm × 1.5 mm thickness, Merck F_{254} type T) using chloroform – 2% methanol as developing solvent. Four well-defined bands were observed under uv light. The corresponding bands from the several plates were combined and stirred overnight with chloroform–methanol (4:1) solution. Filtration and evaporation gave the alkaloids. The least polar band (R_f 0.65) gave crude decinine which crystallized as colourless needles from methanol. This was diluted with inactive decinine and crystallized to constant activity. Repeated chromatography was, in some cases, necessary to remove contaminating decamine from the decinine fraction.

The third least polar band (R_f 0.4) gave decodine as a nearly colourless residue. This crystallized from methanol and after dilution with inactive material, was crystallized to constant activity.

The specific activity of the samples of decodine and decinine so obtained in each experiment is shown in Table 1.

Isolation of Pipecolic Acid

The chloroform extracted plant material from experiments 3 and 4 was mixed with inactive dried ground plant material (8 g). Inactive DL-pipecolic acid (100 mg) was added as carrier and the mixture was placed in a large column. Hot water (400 mL) was percolated through the column and to this was added the ammonia solution obtained by washing the chloroform alkaloid extract (*vide supra*). The combined aqueous solution was evaporated to small volume and then taken to dryness under reduced pressure. Methanol (30 mL) was added to the dark residue and the solution left for 20 h with occasional shaking. Charcoal was added and the mixture was then filtered. The solution was evaporated, the residue dissolved in a little water (1 mL), and the solution applied to a column of Dowex 50W × 4 (H^+ form) (12 cm × 2.5 cm). The column was washed with water (120 mL). Amino acids were then eluted with 1 *M* ammonia until no further activity emerged (ca. 200 mL). The eluate was evaporated to dryness under reduced pressure and the residue dissolved in 6 *M* hydrochloric acid (4 mL). Sodium nitrite (0.5 g) was added in small portions and the solution left for 25 min when a further batch (0.3 g) of sodium nitrite was added in small portions. The solution was left at room temperature for 40 min and was then extracted with ether (3 × 10 mL). The ether extracts were evaporated and the yellow, oily residue dissolved in concentrated hydrochloric acid. The acid solution was heated on a steam bath for 15 min and finally taken to dryness under reduced pressure and the residue crystallized from methanol–ether. A solution of the purified pipecolic acid was applied to a column of Dowex 50W × 4 (H^+ form) (10 cm × 1.5 cm). The column was washed with water–methanol (9:1) and the column was then eluted with *M* ammonia until all activity had emerged. Evaporation of the solvent gave pipecolic acid which sublimed at 190°C and 10^{-1} Torr and was crystallized from methanol–ether, mp 266–268°C (lit. (28) mp 264°C (DL-pipecolic acid); lit. (29) mp 270°C (L-pipecolic acid)).

Degradation of Decodine (7) and Decinine (9)

Conversion of Decodine (7) to Dimethyldecodine (8)

Decodine (**7**) (300 mg) was dissolved in methanol (15 mL) and excess ethereal diazomethane (75 mL) was added. The mixture was kept in a cold room (0–4°C) for 2 days. The solvent was then removed. Methanol (10 mL) was added to the residue and the mixture was warmed on a steam bath and filtered. The methanolic filtrate was concentrated and dimethyldecodine (**8**) (308 mg) crystallized out. Repeated recrystallization from methanol yielded dimethyldecodine, mp 207–208°C (lit. (30) mp 206–207°C).

Chromic Acid Oxidation of Dimethyldecodine (8) and Decinine (9)

Dimethyldecodine (300 mg) was dissolved in hot sulfuric acid (30% v/v, 3 mL) and chromium trioxide (1.5 g) in water (3 mL) was added in several portions. The resulting mixture was heated under reflux with stirring for 48 h. The mixture was cooled and extracted with ether (3 × 10 mL). The ether layer was rejected. The aqueous layer was diluted with water (10 mL) and heated on the steam bath. Hot aqueous barium hydroxide solution was then added until the solution was neutral (pH 7). After 1 h, the mixture was filtered, the precipitate was washed with hot water (3 × 10 mL) and the combined filtrate and washings were concentrated *in vacuo*. Sodium carbonate (35 mg) and methanolic 2,4-dinitrofluorobenzene (10%, 1.5 mL) was added and the resultant mixture was allowed to stand for 2 h at room temperature with occasional stirring. The pH of the solution was maintained at 8–9 with additional sodium carbonate. At the end of 2 h, the solution was extracted with ether (3 × 8 mL) and the ether extract was discarded. The solution was then acidified by addition of 6 *M* hydrochloric acid and extracted with ether (3 × 10 mL). The dried (anhydrous Na_2SO_4) ether extract was evaporated to dryness. The deep yellow residue, containing the 2,4-dinitrophenyl (DNP) amino acids, was dissolved in methanol (0.5 mL) and applied to a silica gel plate (GF_{254}, 20 cm × 20 cm × 0.5 mm). Development with benzene – pyridine – acetic acid (40:10:1) led to the appearance of four well-separated bands. The major band (R_f 0.50) was identical with that of an authentic sample of *N*-2,4-dinitrophenyl-β-alanine. The band with an R_f value of 0.65 was identical with that of an authentic sample of *N*-2,4-dinitrophenyl-γ-aminobutyric acid while the top band (R_f 0.76) corresponded to *N*-2,4-dinitrophenyl-2-piperidylacetic acid. The minor band (R_f 0.22) was 2,4-dinitrophenol. The amino acid DNP derivatives were scraped off the plates separately and eluted from the absorbant with methanol. The methanolic extract (60 mL) of the DNP-β-alanine band (R_f 0.50) which was the most abundant, was evaporated to dryness. The residue was dissolved in dilute hydrochloric acid (6 *M*, 5 mL) and water (2 mL) was then added. The mixture was extracted with ether (3 × 10 mL). The ether layer was washed with water (8 mL), dried (anhydrous Na_2SO_4), and evaporated. The yellow residue was distilled at 160–170°C and 1×10^{-3} Torr when the DNP-β-alanine was obtained as a yellow crystalline solid, mp 140–142°C (lit. (31) mp 145–146°C), yield, 6 mg. The bands corresponding to DNP derivatives of γ-aminobutyric acid and 2-piperidylacetic acid were worked up separately in the same way to give pure DNP-γ-aminobutyric acid, mp 144–145°C (lit. (31) mp 145–146°C), yield, 3.5 mg; and DNP-2-piperidylacetic acid (presumably *S*), mp 139–143°C, rising to 148–151°C after repeated recrystallization from benzene, yield, 3.5 mg. *Anal.* calcd. for $C_{13}H_{15}N_3O_6$: C 50.48, H 4.89, N 13.59; found: C 50.70, H 4.96, N 13.56.

Direct oxidation of decodine by the same method yielded the same products, except that β-alanine was a minor and 2-piperidylacetic acid the major oxidation product.

Decinine was oxidized similarly to give the same amino acid derivatives.

Acknowledgements

We are indebted to Dr. J. P. Ferris, Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York, for authentic specimens from his collection of *D. verticillatus* alkaloids and for informing us of an improved isolation procedure (20), before publication. We are grateful to Mr. L. Laking,

Director, Royal Botanical Gardens, Hamilton, for permission to use plants from the colonies of *Decodon verticillatus* growing in his gardens, and to Dr. J. S. Pringle, taxonomist of the Royal Botanical Gardens, Hamilton, for authenticating the plant species. We thank Dr. A. I. Meyers, Department of Chemistry, Colorado State University, Fort Collins, Colorado, for a generous sample of 2-piperidylacetic acid. Label from [1-^{14}C]-, [2-^{14}C]-, [3-^{14}C]-, and [1,3-^{14}C$_2$]phenylalanine is incorporated non-randomly into the Lythraceae alkaloids, decodine and decinine, in *Decodon verticillatus*. The incorporation pattern, determined by chemical degradation of the alkaloids, demonstrates incorporation of two intact C_6—C_3 units.

PETER HORSEWOOD, W. MAREK GOLEBIEWSKI, JERZY T. WROBEL, IAN D. SPENSER, JONATHAN F. COHEN et FRED COMER. Can. J. Chem. **57**, 1615 (1979).

Des marqueurs provenant de phénylalanines [1-^{14}C], [2-^{14}C], [3-^{14}C] et [1,3-^{14}C$_2$] s'incorporent d'un façon qui n'est pas au hasard dans les alcaloïdes lythracée, décodine et décinine, dans le *Decodon verticillatus*. Le schéma général de l'incorporation, tel que déterminé par la dégradation chimique des alcaloides, démontre qu'il y a incorporation de deux unités C_6—C_3 intactes.

[Traduit par le journal]

Introduction

Several biogenetic proposals (1–4) have been advanced to account for the origin of the phenylquinolizidine lactone alkaloids (e.g., decodine (**5**) and decinine (**6**)) found in several genera of the family Lythraceae (e.g., *Decodon verticillatus* (5, 6), *Heimia salicifolia* and *H. myrtifolia* (7–11), *Lagerstroemia indica* (12), and *Lythrum lanceolatum* (13)) (Scheme 1). Steps common to all the proposals are the reduction of a phenylquinolizidinone (**1**, or the corresponding *cis*-ring-fused isomer) to the corresponding phenylquinolizidinol (**2**), followed by insertion into the latter, by ester formation and phenol coupling, of a phenylpropanoid (C_6–C_3) unit (e.g., *p*-coumaric acid (**3**)) derived from phenylalanine via cinnamic acid.

Indeed, compounds corresponding in structure to the phenylquinolizidinone (**1**) (14), the phenylquinolizidinols (**2**, and its *cis*-fused isomer) (14, 15) and to phenylpropanoid esters of the latter (e.g. **4**) (16, 17) have been found in *H. salicifolia*.

The proposals differ in the suggested mode of biogenesis of the skeleton of the phenylquinolizidinone (**1**).

The skeleton is derivable, *inter alia*, from a polyketide chain (4 × C_2) and a C_6–C_1 unit (route A); or from a polyketide chain (3 × C_2) and a phenylpropanoid C_6–C_3 unit (route B). It is also derivable from pelletierine (itself generated from lysine and acetate (18, 19)) and a C_6—C_1 unit (route C); from pipecolic acid (derived from lysine (19, 20)) and a phenylpropanoid C_6—C_3 unit (route D); or from Δ^1-piperideine (derived from lysine (cf. refs. 21–24)) and a C_6—C_5 unit which is generated from a phenylpropanoid C_6—C_3 unit by chain extension with acetyl or malonyl CoA (route E) (Scheme 1).

The first paper of this series (25) dealt with the status of lysine and its metabolites in the biosynthesis of decodine (**5**) and decinine (**6**), phenylquinolizidine lactone alkaloids from *Decodon verticillatus*. In the present investigation, the question is examined whether it is a C_6—C_1 unit, or a C_6—C_3 unit, derived from phenylalanine, which is implicated in the biosynthesis of the phenylquinolizidinol system of the *Decodon* alkaloids.

It is shown that two intact C_6—C_3 units are incorporated into decodine and into decinine. One of these units supplies the phenylpropanoid C_6—C_3 unit of the lactone ring. The other supplies the phenyl ring and C-1, C-2, and C-3 of the phenylquinolizidinol system.

Methods and Results

Administration of tracers to plants of *Decodon verticillatus* (water oleander) and isolation of decodine (**5**) and decinine (**6**) was carried out by the methods described in the preceding paper (25).

Radioactive samples of the alkaloids were obtained from plants which had been kept in contact with [^{14}C]-labelled phenylalanine (experiments 9–12) and

[d]The total activity due to each component of the intermolecularly doubly labelled material was determined prior to mixing. The activity due to [1-^{14}C]-phenylalanine accounted for 45.4(± 1.4)%, and due to [3-^{14}C]phenylalanine for 54.6(± 1.3%) of the total activity of the doubly labelled sample.
[e]Assayed as dimethyldecodine.

malonic acid (experiment 13). The details of the tracer experiments are presented in Table 1.

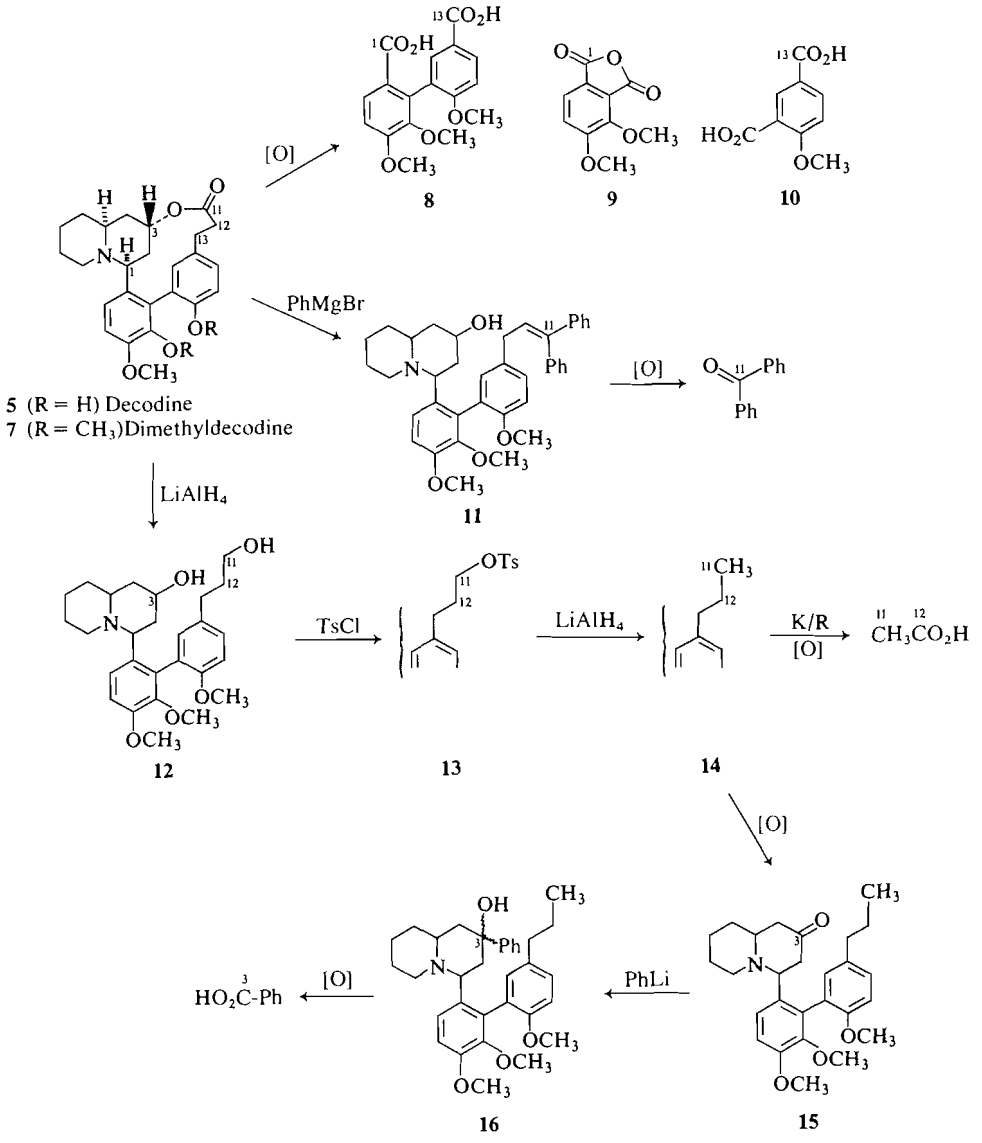
The distribution of radioactivity within the labelled alkaloids was determined by a series of partial degradation sequences designed to separate predicted sites of labelling. The reactions employed in the degradation of the labelled samples of decodine (Scheme 2) and decinine (Scheme 3) are fully described in the Experimental. The segments of the alkaloids demanding attention in tracer experiments with labelled phenylalanine are the two C_6—C_3 moieties, C-14 to C-19, C-13 to C-11 and C-20 to C-25, C-1 to C-3.[3]

The carbon atoms predicted as the sites of label when [3-^{14}C]phenylalanine served as the substrate (C-1, C-13) were secured by oxidative cleavage (3, 26). Permanganate oxidation of dimethyldecodine (**7**), obtained by methylation of decodine (**5**) (27), gave 4-methoxyisophthalic acid (**10**) (C-13 to C-20) (containing C-13 as the only carbon atom not originating from an aromatic nucleus) and hemipinic anhydride (**9**) (C-1, C-18, C-20 to C-25, OCH_3) (containing C-1 as the only 'nonaromatic' or nonmethoxy carbon) (27). Similarly, methyldecinine (**17**), obtained from decinine (**6**) (cf. ref. 7), gave 4-methoxyisophthalic acid (**10**) (C-13) (cf. ref. 26). The yield of the other desired oxidation product, 4,5-dimethoxyphthalic acid (**18**) (C-1) was too low to permit assay of radioactivity. In the course of the oxidative degradation of one sample of labelled decodine (experiment 11), a new dicarboxylic acid was isolated. The accurate mass of its dimethyl ester was found by high resolution mass spectrometry to be 360.119. This corresponds to that of the dimethyl ester of the expected biphenyldicarboxylic acid (**8**) (mass calcd. for $C_{19}H_{20}O_7$: 360.121) (cf. refs. 26, 28, 29).

The carbonyl carbon atom of the lactone ring (C-11) of each of the two alkaloids was obtained by phenylation of dimethyldecodine (**7**) and methyldecinine (**17**), respectively, with phenyl Grignard reagent (29). The diphenylcarbinols so obtained were dehydrated to the diphenylolefins (**11**) and (**19**), respectively, and these were subjected to chromic acid oxidation, yielding C-11 as benzophenone, which was isolated as the oxime.

Several steps were required to gain access to the carbinol carbon of the quinolizidine system (C-3) and the carbon (C-12) adjacent to the lactone carbonyl group. Lithium aluminium hydride reduction of dimethyldecodine (**7**) (27) and of methyldecinine (**17**) gave the corresponding diols **12** and **20**, respectively. Tosylation of the primary alcohol group, followed by lithium aluminium hydride reduction of the resulting tosylates **13** and **21**, respectively, yielded the corresponding desoxy derivatives, **14** and **22**. These were the key intermediates of the degradation sequences. Kuhn–Roth oxidation gave acetic acid isolated as the α-naphthylamide, derived from the ethyl group, C-11, C-12. Since C-11 is obtainable

[3]For a justification of the new numbering system for the phenylquinolizidine lactone alkaloids, employed here, see the Appendix.



SCHEME 2. Degradation of decodine.

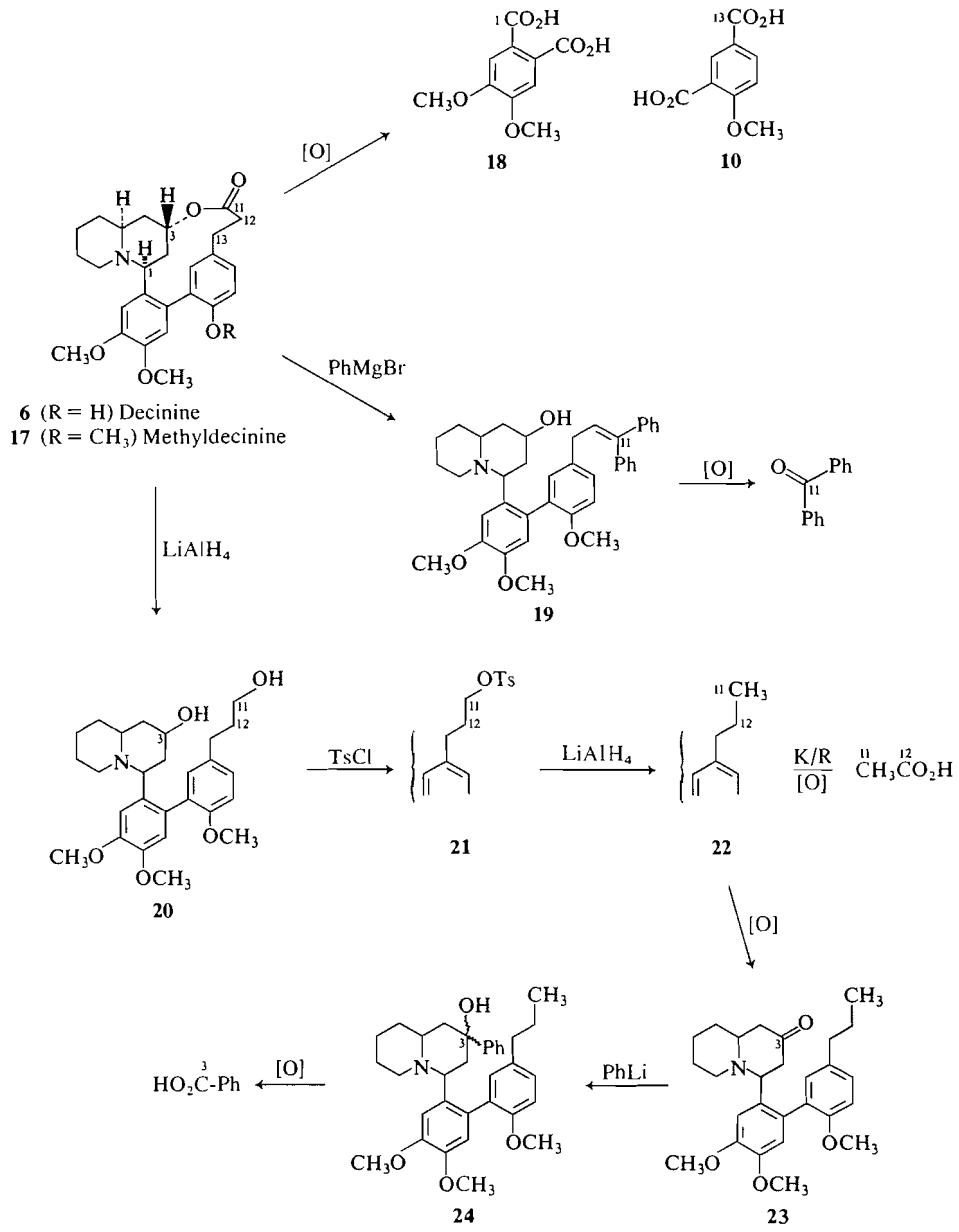
separately as benzophenone (see above), C-12 is thus accessible.

Mild oxidation of the desoxy derivatives **14** and **22**. yielded the corresponding ketones, **15** and **23**, respectively. Phenylation with phenyl lithium gave, in each case, a mixture of epimeric phenyl carbinols, **16** and **24**, respectively. Permanganate oxidation then yielded benzoic acid, i.e. C-3 of the alkaloids.

The results of the degradation of the labelled samples of decodine and of decinine derived from the experiments with radiomers of [^{14}C]phenylalanine are presented in Tables 2 and 3.

Decodine and decinine, isolated from plants kept in contact with DL-[1-^{14}C]phenylalanine (experiment 9) yielded benzophenone oxime (C-11) which contained approximately three-quarters and benzoic acid (C-3) which contained approximately one-quarter of the activity of the intact alkaloid from which they were derived. These two degradation products accounted for 99 ± 2 and $96\pm2\%$, respectively, of the total activity of the original alkaloids.

Decodine and decinine, isolated from plants to which DL-[2-^{14}C]phenylalanine (experiment 10) had been administered, yielded *N*-acetyl-α-naphthylamine (C-11, C-12) containing ca. two-thirds of the activity of the intact alkaloids. Since C-11 was shown, above, to be derived from the carboxyl carbon of phenylalanine, the activity derived from [2-^{14}C]phenyl-



SCHEME 3. Degradation of decinine.

alanine must be present at C-12. The remaining one-third of the activity of the alkaloids was not accounted for, as attempts to develop a practicable degradation sequence yielding C-2 of the quinolizidine system were unsuccessful.

Decodine, from the experiment with DL-[3-^{14}C]-phenylalanine (experiment 11) gave the biphenyl derivative (**8**) (C-1 plus C-13, together with C-14 to C-25 and *O*-methyl) containing all the activity of the alkaloid (98±7%). Of this activity, approximately one-third was recovered in hemipinic anhydride (**9**), representing C-1, and the rest in 4-methoxyisophthalic acid (**10**), representing C-13.

Decodine from a doubly labelled sample of phenylalanine, DL-[1,3-$^{14}C_2$]phenylalanine (experiment 12), gave labelled benzophenone oxime (C-11) (25(±1)% of the activity of the original decodine), benzoic acid (C-3) (19(±2)%), 4-methoxyisophthalic acid (C-13) (30(±1)%), and hemipinic anhydride (C-1) (23(±2)%). The four degradation products account for the total activity of the intact decodine. Decinine, from the same feeding experiment, gave benzophenone oxime

γ-Aminobutyric acid	C-6 to C-9	1.28±0.03	44±1

[a]Specific activity (dpm mmol^{-1}) × 10^{-4}.
[b]Relative specific activity (%) (decodine = 100).

(C-11) (17(±1)%), benzoic acid (C-3) (28(±4)%), and 4-methoxyisophthalic acid (C-13) (21(±1)%).

A further experiment was performed with [2-^{14}C]-malonic acid as the tracer (experiment 13). Decodine which was isolated, was radioactive and was degraded by chromic acid oxidation and the partial degradation products, β-alanine (C-7 to C-9), γ-aminobutyric acid (C-6 to C-9) and 2-piperidylacetic acid (C-3 to C-9), were isolated as described in the preceding paper (25). The 2-piperidylacetic acid accounted for the entire activity of the intact alkaloid. The β-alanine and the γ-aminobutyric acid each contained approximately 40% of the total activity (Table 4).

Discussion

It has been known for almost 10 years that radioactivity from [3-^{14}C]phenylalanine is incorporated into cryogenine (**25**), a *Decodon*-type alkaloid, in *Heimia salicifolia* (3, 26). Partial degradation placed most of this activity into one or more of the carbon atoms of the two C_6—C_1 units, C-13 to C-19 and C-1, C-20 to C-25. In particular, it was shown that label was localized at C-13 (ca. 50%) and very probably at C-1 (ca. 33%). From these results it is reasonable to infer that phenylalanine supplies the two aromatic nuclei of cryogenine (**25**) together with one carbon atom adjacent to each, a conclusion which is consistent with any one of the five biogenetic schemes outlined in Scheme 1. To distinguish among the schemes the question must be answered whether the phenylalanine derived fragment which enters the quinolizidine nucleus is indeed a C_6—C_1 unit (routes A, C) or whether it is an intact C_6—C_3 unit (routes B, D, E).

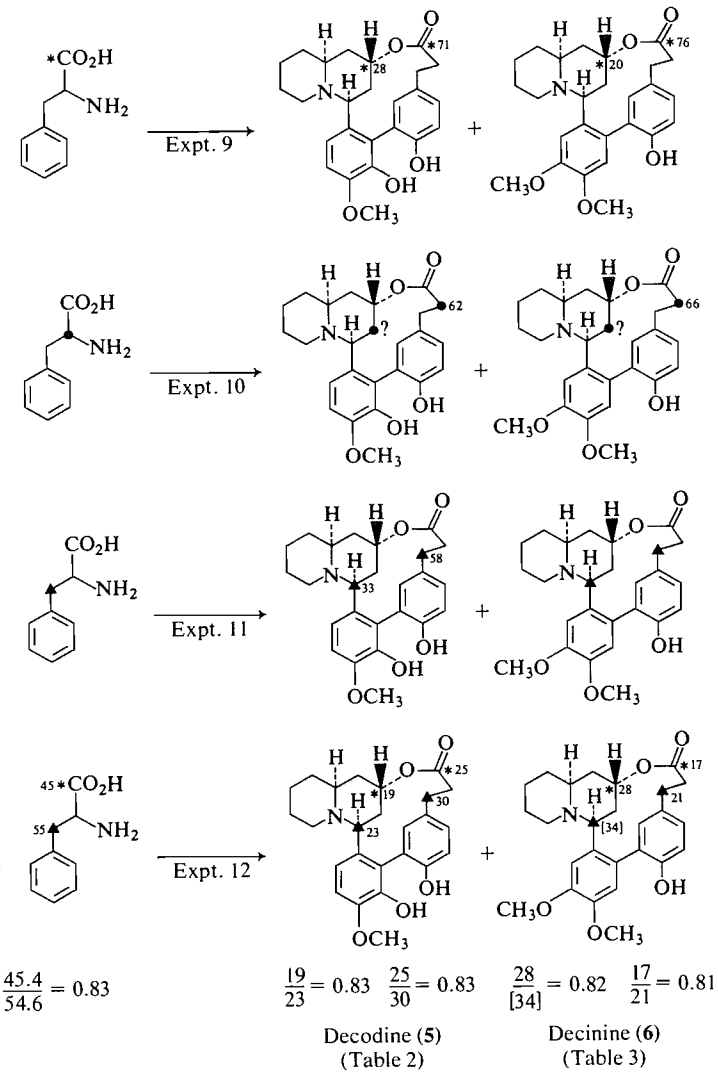
The key to the solution of this problem is a controlled degradation of the carbon skeleton, capable of yielding products recognizably derived from C-2, C-3, C-11, and C-12 of the skeleton of the *Decodon* alkaloids. The reaction sequences discussed in the preceding section, which were devised for the degradation of decodine (**5**) (Scheme 2) and decinine (**6**) (Scheme 3), account for three of these four carbon atoms. Application of these reaction sequences to labelled samples of decodine and decinine, derived from feeding experiments with [1-^{14}C]- , [2-^{14}C]- , [3-^{14}C]- , and [1,3-$^{14}C_2$]phenylalanine yielded data (Tables 2 and 3 and preceding section) from which the desired information was deduced (Scheme 4).

The experiment with [3-^{14}C]phenylalanine (experiment 11) showed that the distribution of label within decodine (**5**) in *D. verticillatus* (C-13 58%, C-1 33%) was very similar to that found earlier in cryogenine (**25**) derived from the same precursor in *H. salicifolia* (C-13 61%, C-1 31%(3), C-13 46%, C-1 33% (26)), indicating a close correspondence in the origin of two alkaloids of different ring stereochemistry in two different plant species.

The experiment with [1-^{14}C]phenylalanine as the substrate (experiment 9) showed that even though the major fraction of activity within decodine (**5**) (71%) and within decinine (**6**) (76%) was located at C-11, i.e., at the carbonyl carbon of the lactone ring, label was not confined to this position. The remaining activity (28 and 20%, respectively) was present at C-3, i.e., at the carbinol carbon of the quinolizidine ring. In each case, these two carbon atoms, C-11 and C-3, accounted for the entire activity of the intact alkaloid. It can be inferred from this result that, in all probability, phenylalanine supplies two C_6—C_3 units to the skeleton of the *Decodon* alkaloids.

The result of the experiment with [2-^{14}C]phenylalanine (experiment 10) was consistent with this inference. Label was not confined to C-12 of the phenylpropanoid unit of decodine and of decinine. Only 62 and 66% of the total activity, respectively, was recovered from this site. The rest of the activity is presumably located at C-2 of the quinolizidine nucleus. It is a plausible supposition that this site is derived from the α-carbon of phenylalanine, since the adjacent carbon atoms, C-3 and C-1, have been shown (experiments 9 and 11) to be derived from the carboxyl carbon and from the β-carbon of phenylalanine, respectively. However, a degradation sequence capable of extracting C-2 of the quinolizidine system has not yet been realized and this assumption remains to be confirmed.

The fourth experiment with labelled phenylalanine (experiment 12) was intended to strengthen the evidence that 2 three-carbon chains, each representing an entire phenylalanine side-chain, enter the *Decodon* skeleton as intact units. The substrate was a sample of phenylalanine, intermolecularly doubly labelled at the carboxyl carbon and at the β-carbon of the side chain, with 45.4% activity at the carboxyl and 54.6% at the β-carbon (radioactivity ratio —CO_2H-β-CH_2 = (45.4±1.4)/(54.6±1.3) = 0.83±0.03) (see Table 1). Incorporation into decodine and decinine of the intact side chain from this doubly labelled phenylalanine would be demonstrated by the isolation of labelled alkaloids containing radioactivity at each of the four carbon atoms C-3, C-1, C-11, and

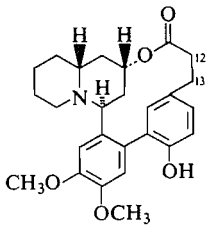


SCHEME 4. Incorporation pattern within decodine and decinine of radioactivity derived from [1-^{14}C]-, [2-^{14}C]-, [3-^{14}C]-, and [1,3-$^{14}C_2$]phenylalanine.

C-13 and at no other site, with a distribution such that the ratios of activities, C-3/C-1, and C-11/C-13, each equalled the ratio of activities —CO_2H/β-CH_2 within the doubly labelled phenylalanine serving as their precursor.

This was indeed observed:[4] each of the four predicted sites of labelling within the decodine obtained from this experiment (experiment 12) were isolated, and assayed for radioactivity (Table 2). The ratios of relative specific activities, calculated from these data (C-11/C-13 = $(25\pm1)/(30\pm1) = 0.83\pm0.04$; C-3/C-1 = $(19\pm2)/(23\pm2) = 0.83\pm0.11$), are in good agreement with the activity ratio of the substrate (0.83 ± 0.03, see above). As predicted, the activities

[4]A different result of this experiment was recorded in a preliminary communication (30). It was reported that the hemipinic anhydride obtained by degradation of decodine derived from the experiment with [1,3-$^{14}C_2$]phenylalanine (now referred to as experiment 12) accounted for 46% of the activity of the alkaloid. When, at a later date, degradation sequences were devised which made C-3 of decodine and decinine accessible, and it was found that radioactivity from [1-^{14}C]phenylalanine entered C-3 (experiment 9), the earlier result became suspect. Further doubt was cast on its validity when it was shown that the sample of decinine derived from [1,3-$^{14}C_2$]-phenylalanine also contained activity at C-3. It was fortunate that a sample, large enough to permit a complete reinvestigation, of the original decodine from the experiment with [1,3-$^{14}C_2$]phenylalanine remained in our possession. The data reported in the present paper (experiment 12, Table 2) are based on an entirely new set of degradation experiments. Since it is now evident that the earlier result was in error, the inference drawn from it (30) is untenable. Careful reexamination of the relevant laboratory records failed to disclose the origin of the erroneous result.



25 Cryogenine = Vertine
26 Decamine = 12,13-Dihydrovertine

at these four carbon atoms of decodine account for the total activity of the alkaloid (C-3 + C-1 + C-11 + C-13 = $(19\pm2) + (23\pm2) + (25\pm1) + (30\pm1) = 97\pm3\%$).[3]

In the case of decinine, only three of the four crucial carbon atoms were assayed directly (Table 3). Activity at the fourth site, C-1, could not be determined because of the low yield of the degradation product representing this carbon atom (4,5-dimethoxyphthalic acid (**18**)) (see Experimental) (cf. ref. 26). For the present calculation, activity at C-1 must be obtained by difference. Even so, the calculated ratios (C-11/C-13 = $(17\pm1)/(21\pm1) = 0.81\pm0.06$; C-3/C-1 = $(28\pm4)/\{100 - [(28\pm4) + (17\pm1) + (21\pm1)]\} = 0.82\pm0.16$), are in reasonable agreement with the $-CO_2H/\beta\text{-}CH_2$ ratio of the substrate (0.83 ± 0.03).

The results of the experiments with [1-^{14}C]-, [2-^{14}C]-, and [1,3-$^{14}C_2$]phenylalanine (experiments 9, 10, and 12) lead to the inference that two intact C_6—C_3 units are implicated in the biosynthesis of decodine and decinine. One of these gives rise to the phenylpropanoid moiety of the lactone ring, C-11 to C-19, the other to the segment C-3 to C-1, C-20 to C-25, of the phenylquinolizidine system of the alkaloids.

Since it thus appears that an intact C_6—C_3 unit is implicated in the biosynthesis of the phenylquinolizidine ring system (**1**), those biogenetic hypotheses which demand participation of a C_6—C_1 unit in its construction (routes A and C, Scheme 1) must be rejected. One of the hypotheses which is thus eliminated is the hitherto favoured route based on pelletierine (route C). Each of the remaining routes, B, D, and E, involves an intact phenylpropanoid moiety. They differ from each other in the postulated origin of the rest of the quinolizidine system.

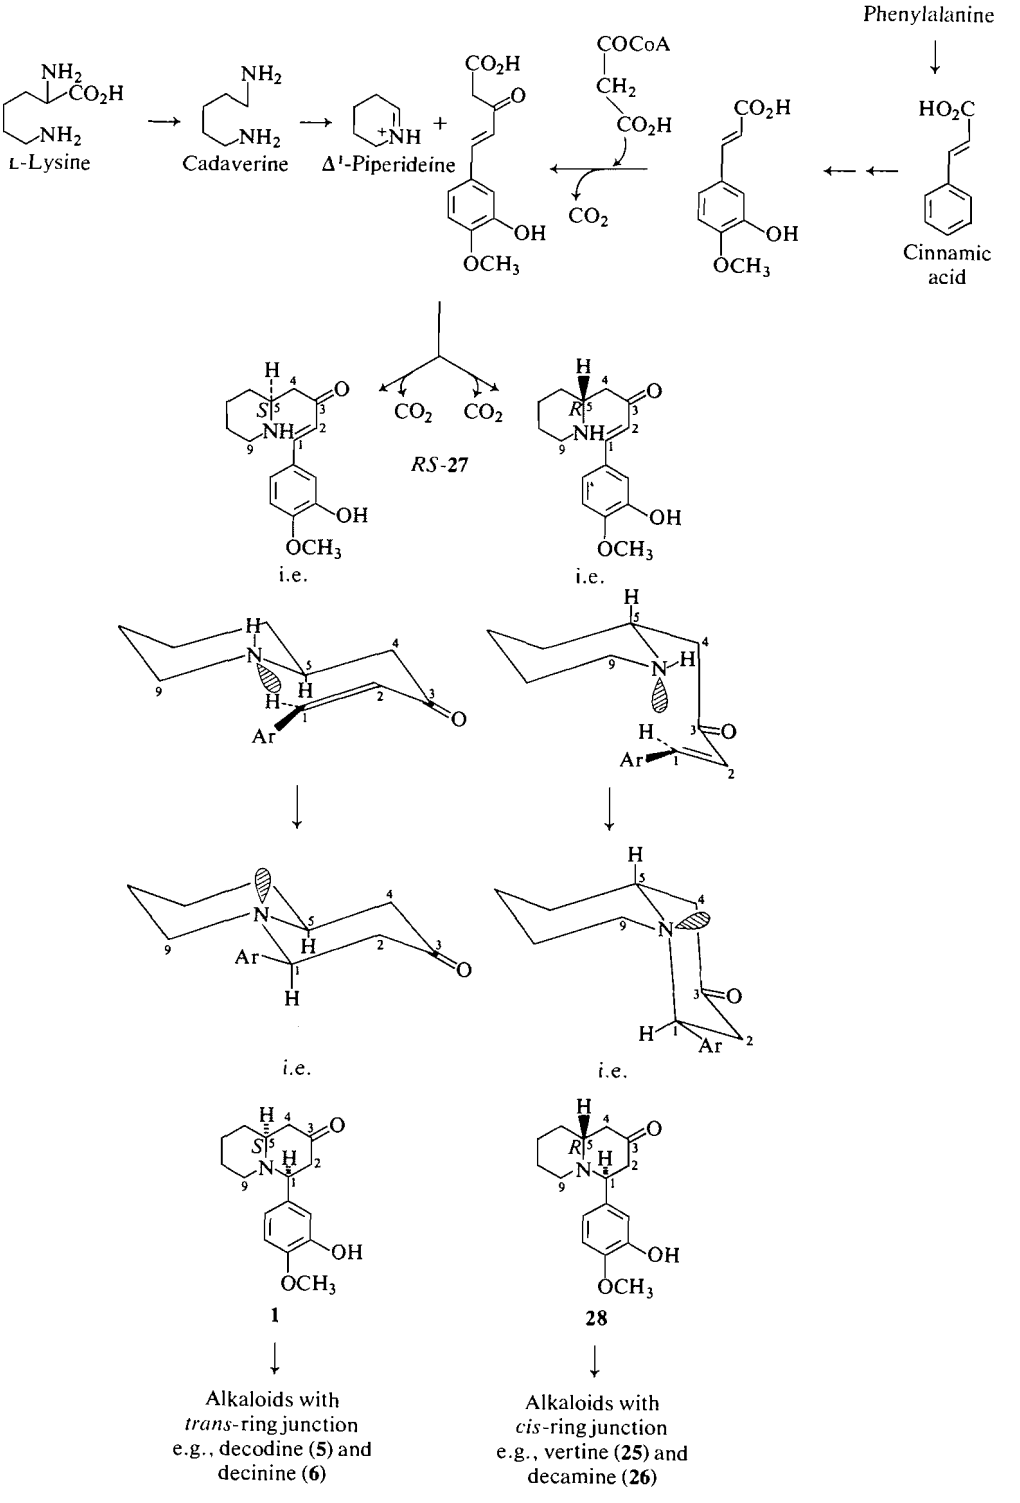
In the preceding paper of this series (25), we showed that the C_5N unit, C-5 to C-9, N, of the quinolizidine system is derived from L-lysine, which is incorporated after loss of its carboxyl group, via cadaverine and Δ^1-piperideine. This earlier evidence eliminates route B, which invokes a polyketide precursor. It also disposes of route D which demands participation of pipecolic acid or of some other lysine metabolite containing the intact C_6 chain of lysine, since pipecolic acid in *D. verticillatus* was shown to be derived from D-lysine whereas the alkaloids incorporate a C_5N unit derived from L-lysine.

The remaining hypothesis, route E (Scheme 1) (2, 4) is the only one that is consistent with all the evidence now available on the mode of incorporation of phenylalanine, and of L-lysine and its metabolites. A more detailed outline of this route is shown in Scheme 5.

The scheme demands an extension of the side chain of the phenylpropanoid precursor by a two-carbon unit, supplied by a donor such as acetyl or malonyl CoA. A final experiment (experiment 13) with [2-^{14}C]malonic acid was performed in an attempt to test this prediction. Label from this substrate should enter C-4 of the quinolizidine system. The results of this experiment (Table 4), even though consistent with route E (Scheme 5), were inconclusive. As predicted, all activity of the decodine which was isolated was located within the fragment, C-3 to C-9, recovered as 2-piperidylacetic acid. Since C-3 has been shown to be derived from the carboxyl group of phenylalanine (experiment 9) and C-5 to C-9 from lysine (25), it might have been anticipated that all activity derived from [2-^{14}C]malonate might be confined to C-4, the predicted site. This was not so, however. Two other degradation products, β-alanine (C-7 to C-9) and γ-aminobutyric acid (C-6 to C-9), representing fragments of the lysine derived portion of the ring system, contained a significant fraction of the total activity (~40%). As lysine in plants originates by the diaminopimelic pathway (31) which delivers label from the methyl group of acetate into every carbon atom of its C_6 chain, but not with equal efficiency, and as malonate serves as an acetate donor, incorporation of label into the lysine-derived fragment of the molecule was not unexpected. What was unexpected was the high level of labelling within this moiety. As a consequence and since C-4, the carbon atom at issue, was not directly accessible, the results of this experiment are indicative rather than conclusive, and the origin of C-4 remains to be confirmed by direct experiment.

Several other aspects of the biosynthesis of the Lythraceae alkaloids which remain to be clarified deserve mention.

The first of these emerges from the present results. It concerns the variation in the distribution of label among the two phenylpropanoid units of each of the alkaloid samples obtained from experiments 9–12. In three of the four experiments (experiments 9–11), the lactone C_6—C_3 unit (C-11 to C-19) of each alkaloid sample contains approximately twice as much label as the phenylquinolizidine C_6—C_3 unit (C-1 to C-3, C-20 to C-25). A similar distribution was



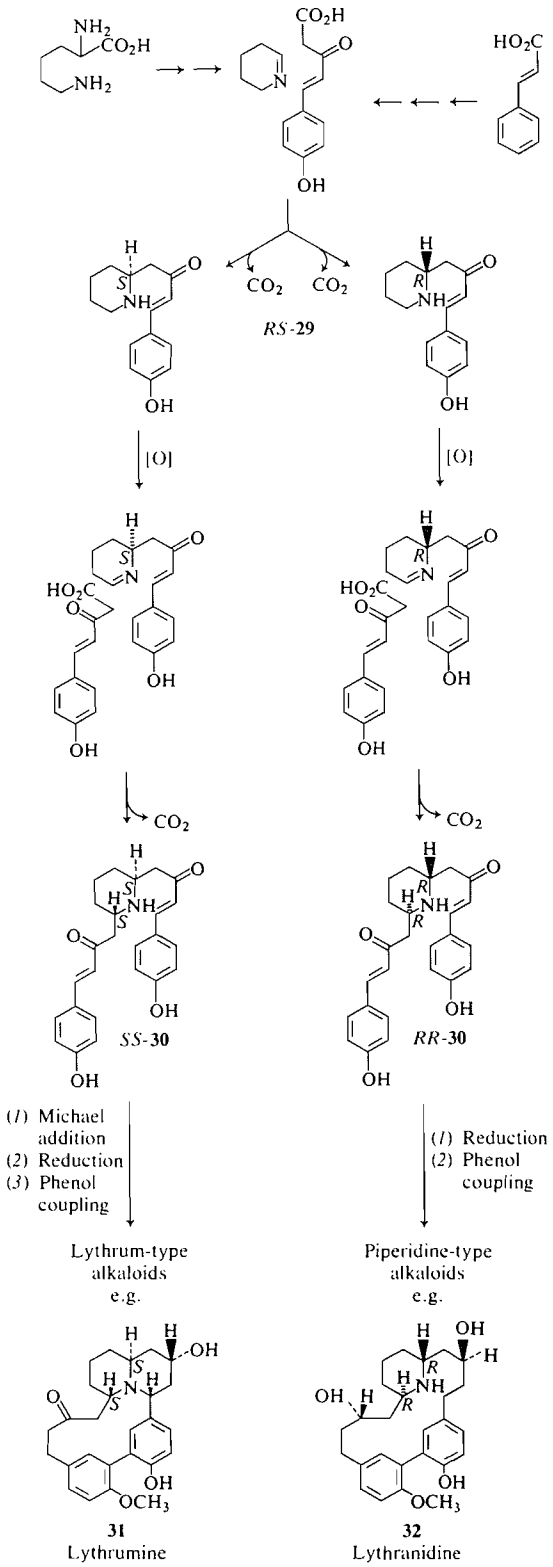
SCHEME 5. Biosynthesis of the phenylquinolizidine system.

found in cryogenine (**25**) in *H. salicifolia* (3, 26). The distribution of label in the alkaloids obtained in experiment 12 is entirely different. In the decodine from this experiment, activity is almost equally divided between the two C_6—C_3 units, the lactone phenylpropanoid unit being favoured to a slight extent. In the decinine, on the other hand, the distribution of activity is reversed, with the phenylquinolizidine unit containing almost twice as much label as the lactone C_6—C_3 unit.

Since the two C_6—C_3 units in each of the samples contain a different fraction of the total activity, the units, even though derived from the same substrate, must have entered the product by different routes (cf. ref. 32). Since the two alkaloids, isolated from the same experiment, show different distributions of label, a systematic study of the variation of this distribution with time over the seasonal growth period of the plant may throw light on the timing of the competing biosynthetic events which lead from the phenylquinolizidine intermediate (**1**) to the two alkaloids with common ring stereochemistry, decodine and decinine.

A second problem concerns the competing routes which lead, in the same plant, from the same substrate, to alkaloids with isomeric ring stereochemistry (e.g., decinine (**6**) and decamine (**26**) in *D. verticillatus* (5)). A possible derivation of diastereomeric phenylquinolizidines from common precursors is illustrated in Scheme 5. It is suggested that the stereochemistry at the ring junction (5-*S*-*trans*, e.g., decodine (**5**) or 5-*R*-*cis*, e.g., decamine (**26**)) is determined by the conformation of the lone pair (axial or equatorial) within the requisite enantiomer of the key intermediate, **27**. Intramolecular Michael addition yields the *S*-*trans*-phenylquinolizidinone (**1**) and the *R*-*cis*-phenylquinolizidinone (**28**), respectively. This model cannot explain the stereospecific utilization of the two conformers, i.e., conversion into alkaloids of the conformer with equatorial lone pair in the *S*-series but not in the *R*-series, and of the conformer with axial lone pair in the *R*-series but not in the *S*-series.

Finally, the origin of the Lythraceae alkaloids of the *Lythrum* and piperidine groups requires consideration. The only published proposal (13) concerning their biogenesis is based on pelletierine. In the light of the present evidence which eliminates pelletierine as a precursor of the *Decodon* group of Lythraceae alkaloids, it is tempting to seek a new model for the biogenesis of the other alkaloid groups, from precursors analogous to those now shown to yield the *Decodon* group. Such a model is shown in Scheme 6. It invokes intermediacy of a 2-substituted piperidine (**29**), analogous in structure to the *Decodon* intermediate **27**, and of a 2,6-disubstituted piperidine (**30**). The latter is analogous in structure (33) and, pre-



SCHEME 6. Biogenesis of the Lythrum and piperidine-type Lythraceae alkaloids.

sumably, in origin (34) to the lobelia alkaloids (e.g., lobeline (**33**)) and bears the same relationship to the intermediate **29** that lobeline (**33**) bears to sedamine (**34**) (35).

Experimental

Administration of Labelled Compounds to Decodon verticillatus *and Isolation of Decodine and Decinine*

These experiments were performed as described in the preceding paper (25). The details of the feeding experiments and the specific activities of the samples of decodine and decinine isolated from individual experiments are summarized in Table 1.

Determination of Radioactivity

Before 1971 (experiment 12) radioactivity was measured on samples of finite thickness on aluminum planchettes with a gas-flow Geiger system (Model 4342, Nuclear Chicago). For plating, a 1% solution of collodion in dimethylformamide was used as a solvent. The usual corrections for background and self-absorption were applied. The efficiency of the system for ^{14}C (~30%) was determined using sodium benzoate of known activity as a standard. Since 1971, radioactivity has been assayed by liquid scintillation counting (Mark 1 liquid scintillation computer, model 6860, Nuclear Chicago Corporation). The efficiency of counting was determined using ^{133}Ba as the external standard. Samples were dissolved in methanol and dispersed in Aquasol (New England Nuclear) (10 mL). The confidence limits shown in the results (Tables 1–4) are standard deviation of the mean.

Degradation of Labelled Samples

Degradation of Decodine Derived from [1-^{14}C]Phenylalanine

The Lactone Carbonyl Carbon (C-11) as Benzophenone Oxime

*Dimethyldecodine (**7**) (27)*—Decodine (300 mg) was methylated with diazomethane or with dimethyl sulfate. Dimethyldecodine was recrystallized from methanol; mp 206–207°C (lit. (27) mp 206–207°C); ^1H nmr ($CDCl_3$) δ: 3.70 (s, 3H, OCH_3), 3.72 (s, 3H, OCH_3), 3.88 ppm (s, 3H, OCH_3). To prepare dimethyldecodine hydrochloride the base was dissolved in ether, ethereal hydrogen chloride was added until precipitation was complete. The product was recrystallized from methanol, mp 256–262°C (dec.)

*Diphenylolefin (**11**) from dimethyldecodine (**7**)* (cf. ref. 29)—To a solution of phenylmagnesium bromide prepared from magnesium turnings (200 mg) and bromobenzene (0.85 mL, 1.27 g) in dry tetrahydrofuran, was added a solution of dimethyldecodine (180 mg) in dry tetrahydrofuran (8 mL). The mixture was heated 6 h under reflux. Water was added to destroy excess Grignard reagent, the magnesium salts were dissolved by adding ammonium sulfate and enough 1 *M* sulfuric acid to give pH 8. The mixture was extracted with ether (3 × 10 mL). Formic acid (5 mL, 90%) was added to the ether extract and the solution was heated 1 h on a steam bath. The cooled solution was washed with carbon tetrachloride (15 mL) and the organic layer discarded. The aqueous phase was concentrated to a small volume (ca. 2 mL) and basified with dilute sodium hydroxide solution. Extraction with ether (4 × 20 mL) followed by drying (anhydrous Na_2SO_4) and evaporation gave a foam (200 mg) whose tlc showed two spots. The two components were separated by chromatography on silica plates (20 × 20 cm × 2 mm thickness) using ether as developing solvent. The less polar product was recovered from the plates as a white foam (95 mg) which could not be obtained crystalline; ^1H nmr ($CDCl_3$) δ: 6.28 (t, J = 7 Hz, 1H, olefin), 7.25 ppm (m, 10H, 2 × phenyl).

*Oxidation of the diphenylolefin (**11**)*—Glacial acetic acid (4.5 mL) was added to a solution of the diphenylolefin (90 mg) in chloroform (0.8 mL). A solution of chromium trioxide (75 mg) in 85% aqueous acetic acid (4 mL) was added dropwise over 10 min to the stirred solution and stirring was continued for a further 1 h at room temperature. Methanol (1 mL) and, after a further 15 min, water (40 mL) was added and the solution extracted with ether (3 × 15 mL). The combined extracts were washed with water, dried (anhydrous Na_2SO_4) and evaporated, the remaining trace of acetic acid being removed by azeotropic distillation with benzene. The crystalline yellow residue (29 mg) showed a single spot on tlc which had the same R_f value as benzophenone. The residue was dissolved in ethanol (5 mL), pyridine (0.5 mL) and hydroxylamine hydrochloride (30 mg) were added, and this solution was heated under reflux for 2 h. The solvent was removed and the residue dissolved in a little methanol and filtered. Removal of the methanol gave benzophenone oxime as pale yellow needles (21 mg), mp 135–137°C (from methanol–water). The solid was dissolved in ether, the solution filtered, the ether removed, and the residue sublimed at 90°C and 10^{-1} Torr giving benzophenone oxime as colourless prisms, mp 142–143°C, (lit. (36) mp 144°C).

The Lactone Carbinol Carbon (C-3) as Benzoic Acid

*Tetrahydrodimethyldecodine (**12**) (27)*—Dimethyldecodine (260 mg) obtained by methylation of decodine (250 mg) was dissolved in dry ether (25 mL) and lithium aluminium hydride (200 mg) added in small portions over 15 min. The mixture was stirred at room temperature overnight, a little Celite was then added and excess lithium aluminium hydride destroyed by addition of water. The mixture was filtered, washed with ether and the residue heated with tetrahydrofuran and again filtered and washed. The combined filtrates were evaporated leaving a white foam (210 mg) which showed one spot on tlc. *Anal.* calcd. for $C_{27}H_{37}NO_5$: C 71.18, H 8.19, N 3.07; found: C 71.05, H 8.13, N 2.99; ms *m/e*: 455 (molecular ion), 454, 425.

O-*Tosyltetrahydrodimethyldecodine (**13**)*[5]—*p*-Toluenesulfonyl chloride (200 mg) was added to an ice cold solution of tetrahydrodimethyldecodine (210 mg) in freshly distilled dry pyridine (5 mL). The yellow solution was kept 16 h at 4°C when tlc showed one major product. The pyridine solution was poured into a cold, stirred saturated solution of sodium bicarbonate (40 mL) and stirred for 15 min. This solution was extracted with chloroform (3 × 20 mL) and the dried (anhydrous Na_2SO_4) extracts evaporated at room temperature under reduced pressure. The residual pyridine was removed at room temperature *in vacuo* to leave a pale yellow foam (280 mg); ^1H nmr ($CDCl_3$) δ: 2.43 ppm (s, 3H, aromatic methyl).

[5]The conditions employed here for the selective tosylation of a primary in the presence of a secondary alcohol are similar to those described by Johnson *et al.* (37).

Reduction of O-*tosyltetrahydrodimethyldecodine (**13**) to desoxytetrahydrodimethyldecodine (**14**)*—The above tosylate (275 mg) was dissolved in dry distilled tetrahydrofuran (20 mL) and lithium aluminium hydride (100 mg) was added in four portions over a 10 min period. The mixture was heated under reflux for 1 h when tlc showed three spots (one major) none of which corresponded to starting material. A little Celite was added to the cold mixture and the excess lithium aluminium hydride destroyed by the careful addition of water. The mixture was filtered and the solids stirred with hot tetrahydrofuran and again filtered. The combined filtrates were evaporated leaving a pale yellow oil (210 mg) which was dissolved in a little chloroform and applied to a neutral alumina column (12 × 1.5 cm, Activity 1). Fractions (20 mL) were eluted with ether. After elution of a small amount of a minor component, the major product emerged. Combination and evaporation of the fractions gave a colourless gum (154 mg) which was pure by ^{1}H nmr and on three tlc systems but could not be obtained crystalline; ^{1}H nmr ($CDCl_3$) δ: 0.93 (t, J = 7 Hz, 3H, CH_2CH_3) 2.58 (broad t, J = 7 Hz, 2H, Ar—CH_2), 3.57 (s, 3H, OCH_3), 3.71 (s, 3H, OCH_3), 3.89 ppm (s, 3H, OCH_3). *Anal.* calcd. for $C_{27}H_{37}NO_4$: C 73.77, H 8.49, N 3.19; found: C 73.82, H 8.20, N 3.30.

*Oxidation of desoxytetrahydrodimethyldecodine (**14**) to the corresponding ketone, dehydrodesoxytetrahydrodimethyldecodine (**15**)*—Standard Jones' reagent (0.9 mL) was added dropwise to an ice cold solution of the alcohol (**14**) (150 mg) in acetone. The cooled mixture was stirred 10 min, excess reagent was destroyed by addition of 2-propanol (1 mL), and the solution poured into 0.01 *M* hydrochloric acid (30 mL). The acid solution was washed with ether, basified with solid sodium bicarbonate, and extracted with ether (4 × 40 mL). The ether solution was dried ($MgSO_4$) and evaporated to yield a light yellow oil (83 mg). The residue which on tlc showed a trace of starting material and one major product, was purified by preparative thick layer chromatography on alumina with ether as the solvent. The major band (R_f 0.8) was eluted from the absorbant with ether, and the product (80 mg) was obtained as an almost colourless oil; ir 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.92 (t, J = 7 Hz, 3H, CH_2CH_3), 3.56, 3.68, 3.90 ppm (3 × s, 3H, 3 × OCH_3). *Anal.* calcd. for $C_{27}H_{35}NO_4$: mol. wt. 437.257; C 74.11, H 8.06, N 3.20; found: *m/e* 437.256; C 74.02, H 8.28, N 2.93.

If the reaction time is increased, a by-product showing a second carbonyl band at 1680 cm^{-1}, in addition to the band at 1730 cm^{-1} is obtained.

*Phenylation of the ketone, dehydrodesoxytetrahydrodimethyldecodine (**15**)*—The above ketone (77 mg) was carefully dried and dissolved in anhydrous ether in a 5 mL flask under nitrogen. Phenyllithium (1.9 *M*, 1 mL) was added to the stirred solution. After 1 h stirring at room temperature no starting material was detectable by tlc. The reaction was quenched with ice and the product extracted into chloroform. The chloroform solution was evaporated to yield a pale yellow oily residue (80 mg) which did not crystallize. *Anal.* calcd. for $C_{33}H_{41}NO_4$: C 76.86, H 8.01, N 2.72; found: C 76.65, H 8.20, N 2.59. Mass spectrum *m/e*: 515 (M^+), 499, 485, 454, 347. Thin-layer chromatography of the product on alumina revealed two bands, presumably due to the epimeric, equatorial and axial, phenylcarbinols (**16**).

*Oxidation of the phenylcarbinol (**16**)*—The phenylation product (75 mg) was dissolved in acetone and dispersed in water (15 mL). Acetone was removed at 80°C and potassium carbonate (1 g) was added to the stirred solution. Finely powdered potassium permanganate (2.5 g) was added in small portions over 6 h and the mixture refluxed 8 h with vigorous stirring and then kept overnight. Manganese dioxide was filtered off, washed with water (3 × 2 mL), the filtrate extracted with ether (3 × 10 mL), and the extracts discarded. The aqueous solution was acidified with 1 *M* sulfuric acid and decolourized with sodium bisulfite. Ether extraction and evaporation of solvent gave benzoic acid which was purified by sublimation at 40°C and 10^{-2} Torr. The yield of benzoic acid (10 mg) was 14% overall from decodine.

Degradation of Decodine Derived from [2-^{14}C]Phenylalanine

The α-Methylene Carbon (C-12) (Together with the Carbonyl Carbon (C-11)) of the Lactone Ring

*Kuhn–Roth oxidation of desoxytetrahydrodimethyldecodine (**14**)*—This derivative was prepared from dimethyldecodine via tetrahydrodimethyldecodine and *O*-tosyltetrahydrodimethyldecodine as described above in the sequence to separate the lactone carbinol carbon.

Desoxytetrahydrodimethyldecodine (142 mg) was dissolved in dilute sulfuric acid (4 *M*, 8 mL), in a small flask fitted with a condenser. A solution of chromium trioxide (2.5 g) in water (2 mL) was added by pipette down the condenser into the magnetically stirred mixture, which was then slowly heated to boiling under reflux for 2 h. The flask was cooled in ice and water washed down the condenser. The flask was fitted with a steam distillation head such that nitrogen could be bubbled through the solution and water added at the same rate as it distilled off. A total of 60 mL distillate was collected in 3 h and this was titrated with 0.1 *N* sodium hydroxide to pH 8 (2.0 mL). The titrated solution was then evaporated at 60°C overnight and the residue dissolved in water (1.5 mL). To this solution was added a solution of α-naphthylamine hydrochloride (25 mg) in water (1.5 mL) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (50 mg). The mixture was kept for 2 h and the resulting pink precipitate was extracted with chloroform (3 × 5 mL) and the concentrated extracts applied to a silica plate (20 × 5 cm, 2 mm thickness). The plate was developed with ether and showed three bands under uv. The band corresponding to *N*-acetyl-α-naphthylamine was removed and extracted with chloroform–methanol. The product (8 mg) was obtained as a white crystalline solid, which was further purified by sublimation at 130°C and 10^{-2} Torr. Yield 7 mg, mp 159–160°C (lit. (36) mp 160°C; (38) mp 159–160°C).

Degradation of Decodine Derived from [3-^{14}C]Phenylalanine

*4-Methoxyisophthalic Acid (**10**) and Hemipinic Anhydride (**9**) by Permanganate Oxidation of Dimethyldecodine (**7**) (26–28)*

Dimethyldecodine (200 mg) was dissolved in dilute sulfuric acid (1 *M*, 8 mL) and dilute sodium carbonate (1 *M*, 10 mL) was added (final pH 8.5) yielding a fine white precipitate of dimethyldecodine. Potassium permanganate (1.1 g) was added to the stirred suspension in small portions over a 4-h period and stirring was continued for a further 18 h. The solution was carefully (frothing!!) acidified with 2 *M* sulfuric acid and the excess potassium permanganate and precipitated manganese dioxide destroyed by the addition of sodium bisulfite. The resulting solution was extracted with ethyl acetate (4 × 20 mL). The dried extracts (anhydrous Na_2SO_4) were evaporated leaving a pale yellow residue (160 mg).

The above oxidation was repeated on a second sample of dimethyldecodine (200 mg) and a similar residue (170 mg) was obtained.

Thin-layer chromatography (silica, ethanol–water–ammonia (100:12:10)) showed each of the two oxidation residues to be a complex mixture of at least nine components. Preparative chromatography (silica, 20 × 20 cm × 2 mm plates) using the

above solvent system resolved the components into nine bands. Numbering from the solvent front, the sixth and seventh bands, containing the major components which in a preliminary run had been shown to correspond to 4-methoxyisophthalic acid and hemipinic acid, respectively, by comparison with authentic specimens, were eluted separately from the inert support with water. The extract was acidified and the product extracted into ethyl acetate (5 × 25 mL). Corresponding eluates from the two oxidations were combined.

The crude product from band six (41 mg) was sublimed at 155°C and 10^{-1} Torr to give 4-methoxyisophthalic acid (**10**) as a pale yellow solid which was crystallized from aqueous methanol and sublimed. Yield 3.5 mg, mp 260–265°C, undepressed by admixture with an authentic sample; (lit. (27) mp 258–263°C).

The crude hemipinic acid from band seven (21 mg) was sublimed at 130°C and 10^{-1} Torr to give hemipinic anhydride (9) as a white crystalline sublimate. This was crystallized from a very small amount of acetone to give colourless crystals (3 mg) mp 159–161°C, undepressed on admixture with authentic hemipinic anhydride; (lit. (27) mp 158–160°C; (36) 166–167°C).

During one of the radioactive runs (experiment 11) a third component of the mixture was obtained in larger quantity. This was presumably 2′,2,3-trimethoxybiphenyl-5′,6-dicarboxylic acid (**8**), mp 236–239°C after sublimation at 195°C and 5 × 10^{-2} Torr. Accurate mass measurement (CEC 21-110B) of the molecular ion of the corresponding dimethyl ester; *m/e* calcd. for $C_{19}H_{20}O_7$: 360.121; found: 360.119.

Degradation of Decodine from [1,3-$^{14}C_2$]Phenylalanine

Decodine (**5**) was converted into dimethyldecodine (**7**) which was degraded to benzophenone oxime (C-11) and to benzoic acid (C-3) as described for the degradation of the sample from [1-^{14}C]phenylalanine, and to 4-methoxyisophthalic acid (**10**) and hemipinic anhydride (**9**), as described for the degradation of the sample from [3-^{14}C]phenylalanine.

Degradation of Decinine Derived from [1-^{14}C]Phenylalanine

The Lactone Carbonyl Carbon (C-11) as Benzophenone Oxime

Methyldecinine (17) (cf. ref. 7)—Decinine (300 mg) was dissolved in methanol (15 mL) and excess diazomethane in ether (75 mL) was added. The mixture was kept in a cold room (4°C) for 2 days. Solvent was removed, methanol (10 mL) was added to the residue, and the mixture was warmed on a steam bath and filtered. The filtrate was concentrated and the product crystallized. Repeated recrystallization from methanol yielded methyldecinine (305 mg), mp 169–170°C (lit. (7) mp for methylated reduced lythrine, i.e., methyldihydrolythrine, i.e. methyldecinine (**17**) 173–175°C); ^{1}H nmr ($CDCl_3$) δ: 3.72, 3.83, 3.92 ppm (3 × s, 3H, 3 × OCH_3).

Benzophenone oxime from methyldecinine—Methyldecinine was converted to the diphenylcarbinol by treatment with phenylmagnesium bromide, and the diphenylcarbinol dehydrated to the corresponding diphenylolefin (**19**) (29) as described for decodine. The product was obtained as a frothy solid which was directly oxidized to benzophenone. The latter was converted into the oxime. The procedure and yields were similar to those reported in the corresponding decodine degradation.

The Lactone Carbinol Carbon (C-3) as Benzoic Acid

Tetrahydromethyldecinine (20) (cf. ref. 29)—Methyldecinine (140 mg) obtained by methylation of decinine (140 mg) was dissolved in dry ether (18 mL), and lithium aluminium hydride (130 mg) was added in small portions and the mixture stirred at room temperature overnight. Subsequent work-up followed that for the corresponding decodine derivative (*vide supra*). The product (135 mg) was obtained as a white foam; ^{1}H nmr ($CDCl_3$) δ: 2.68 (broad, t, J = 7 Hz, 2H, Ar—CH_2), 3.55 (t, J = 6 Hz, —CH_2OH), 3.70, 3.80, 3.92 ppm (3 × s, 3H, 3 × OCH_3).

O-*Tosyltetrahydromethyldecinine (21)*[5]—The above tetrahydromethyldecinine (135 mg) was tosylated with *p*-toluenesulfonylchloride (125 mg) in anhydrous pyridine (4 mL) in the manner described for the corresponding reaction in the decodine series. The product (167 mg) was a brown foam, which showed a single spot on tlc (alumina, chloroform).

Reduction of O-*tosyltetrahydromethyldecinine (21) to desoxytetrahydromethyldecinine (22)*—The above tosylate (165 mg) in anhydrous tetrahydrofuran (12 mL) was reduced with lithium aluminium hydride (70 mg) in the manner described for the corresponding reaction in the decodine series. The product was obtained as a yellow oil (133 mg) which was purified by chromatography on neutral alumina to yield a colourless foam (94 mg) which did not crystallize; ^{1}H nmr ($CDCl_3$) δ: 0.95 (t, J = 7 Hz, 3H, —CH_2CH_3), 2.60 (broad t, $J \sim$ 7 Hz, 2H, Ar—CH_2), 3.72, 3.83, 3.92 ppm (3 × s, 3H, 3 × OCH_3).

Oxidation of desoxytetrahydromethyldecinine (22) to the corresponding ketone, dehydrodesoxytetrahydromethyldecinine (23)—Standard Jones' reagent (0.55 mL) was added dropwise to a stirred, cooled solution of the above derivative (94 mg) in acetone (30 mL). Stirring was continued 10 min, excess Jones' reagent was destroyed with 2-propanol (1 mL), and hydrochloric acid (0.025 *M*, 90 mL) was added. Subsequent work-up was similar to that for the corresponding experiment in the decodine series, yield 49 mg; ir 1730 cm^{-1}; ms *m/e*: 437 (molecular ion) 422, 406; ^{1}H nmr ($CDCl_3$) δ: 0.92 (t, J = 7 Hz, 3H, —CH_2CH_3), 3.75, 3.84, 3.94 ppm (3 × s, 3H, 3 × OCH_3).

Phenylation of dehydrodesoxytetrahydromethyldecinine (23)—The ketone (49 mg) was phenylated with phenyllithium following the procedure described for the corresponding reaction in the decodine series. The product (45 mg), a mixture of epimeric phenylcarbinols (**24**), was not separated into components. Mass spectrum *m/e*: 515 (molecular ion), 485, 454.

Oxidation of the phenylcarbinol (24)—The phenylation product (43 mg) was oxidized with permanganate (1.5 g) in the presence of potassium carbonate in the manner described for the corresponding reaction in the decodine series. On work-up, benzoic acid was obtained and purified by sublimation, yield 5 mg.

Degradation of Decinine Derived from [2-^{14}C]Phenylalanine

The α-Methylene Carbon (C-12) (Together with the Carbonyl Carbon (C-11)) of the Lactone Ring

Kuhn–Roth oxidation of desoxytetrahydromethyldecinine (22)—Desoxytetrahydromethyldecinine was prepared from methyldecinine (**17**) via tetrahydromethyldecinine (**20**) and *O*-tosyltetrahydromethyldecinine (**21**), as described above. The Kuhn-Roth oxidation was carried out by the same procedure that was used in the corresponding degradation of desoxytetrahydrodimethyldecodine; yield of *N*-acetyl-α-naphthylamine 8 mg (from 300 mg decinine); mp 157–158°C.

Degradation of Decinine Derived from [1,3-$^{14}C_2$]Phenylalanine

4,5-Dimethoxyphthalic acid (18) and 4-Methoxyisophthalic Acid (10) from Methyldecinine (17) (26–28)

A suspension of methyldecinine (*17*) (200 mg) in dilute sulfuric acid (1 *M*, 8 mL) was made alkaline by adding 1 *M* sodium carbonate solution (10 mL) so that the pH of the solution was 8–8.5. Potassium permanganate (1.1 g) was added with stirring over a period of 4 h and stirring was continued for 20 h at room temperature. The solution was then acidified with 2 *M* sulfuric acid and the excess potassium permanganate and the precipitated manganese dioxide were decomposed

with sodium bisulfite. The resulting colourless solution was extracted with ethyl acetate (4 × 40 mL) and the organic layer washed, dried (anhydrous Na_2SO_4), and evaporated.

The residue (70 mg) was separated by preparative thin layer chromatography (silica, benzene–methanol–acetic acid 45:8:4). The major product, R_f 0.43, was eluted with water, the solution acidified with sulfuric acid (1 *M*) and extracted with ethyl acetate (3 × 25 mL). The organic layer was washed with water, dried (anhydrous Na_2SO_4) and evaporated and the crude product sublimed (160°C, 1 × 10^{-3} Torr) to yield 4-methoxyisophthalic acid (**10**); yield 6 mg; mp 260–265°C.

The other product which was detected on the tlc plate (R_f 0.25) was eluted similarly. This product had chromatographic properties corresponding to those of authentic 4,5-dimethoxyphthalic acid (**18**). The low yield (< 1 mg) precluded the use of this compound in radioactive determinations.

Degradation of Decodine Derived from [2-^{14}C]Malonic Acid

Chromic acid oxidation of decodine, and isolation of the resulting degradation products, 2-piperidylacetic acid, γ-aminobutyric acid and β-alanine, was carried out as described in the preceding paper (25).

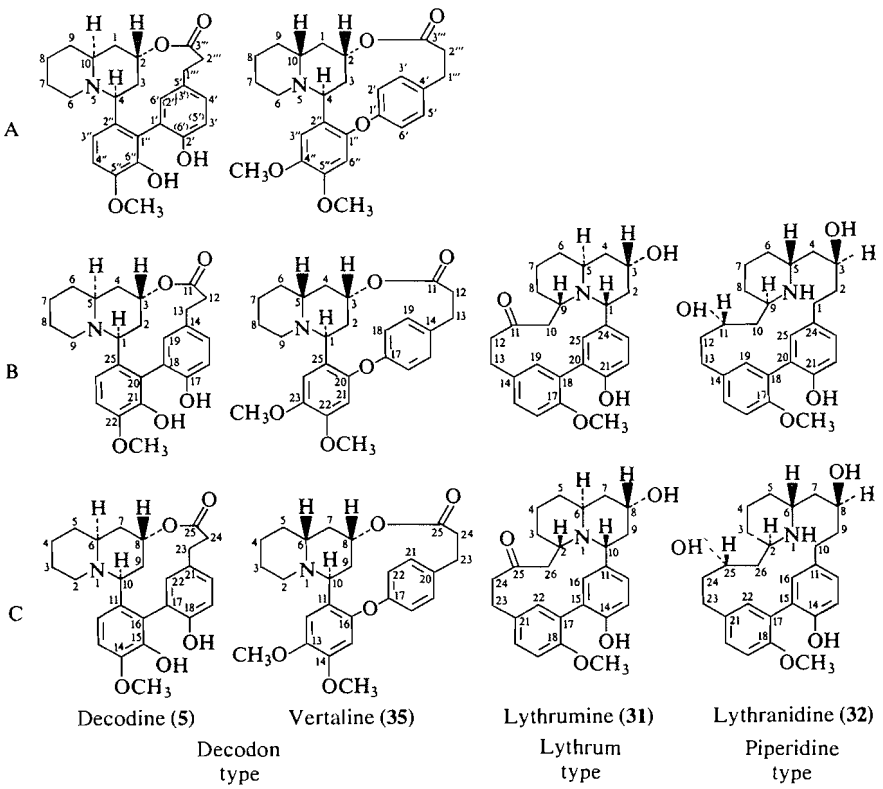
Appendix

Numbering of the Lythraceae Alkaloids

In view of the probable common biogenetic origin of the three structural groups of the Lythraceae alkaloids, a numbering system is desirable which is applicable to the *Decodon*-type alkaloids (group 1) (e.g., decodine (**5**) and vertaline (**35**)), as well as the *Lythrum*-type (group 2) (e.g., lythrumine (**31**)), and



SCHEME 7. Numbering of the Lythraceae alkaloids.

the piperidine-type alkaloids (group 3) (e.g., lythranidine (**32**)).

The numbering system A, in common use for the *Decodon*-type alkaloids, was introduced by Ferris and co-workers (29, 39, 40) and adopted and extended by Rother and Schwarting (3). The quinolizidine nucleus is numbered as recommended by *The Ring Index* (ref. 41, RRI 1687) but primed and multiply primed numbers are employed for other C-atoms and the system is thus not rationally adaptable to use with the alkaloid skeletons of groups 2 and 3.

Numbering system B for the latter two groups of alkaloids was introduced by Fujita and co-workers (42, 43) and is generally used for these alkaloids. This system is readily adaptable to the alkaloids of group 1. Extrusion of C-10 of the group 2 skeleton, and union of C-11 with the O-atom at C-3, formally yields a group 1 skeleton.

The numbering system of the group 1 alkaloids which is generated in this manner is attractive for several reasons: (i) carbon atoms which correspond in biogenetic origin in the three structural groups maintain corresponding numbers; (ii) the numbering of the quinolizidine ring system, even though different from that recommended by *The Ring Index* (41) which, with a minor change is also used by Chemical Abstracts, is not new but corresponds to that originally employed by Schöpf *et al.* (44); and (iii) the numbering of only one of the three structural groups of alkaloids is changed, while currently used numbering is maintained for the other two groups.

An entirely new numbering system[6] for all three groups of alkaloids which is chemically as well as biogenetically rational, is system C, in which the quinolizidine ring is numbered as in the lupine alkaloids.

We have employed system B, since it shows common biogenetic origin while minimizing changes in current practice.

[6]We are indebted to Dr. V. Snieckus, University of Waterloo, for this suggestion.

The total synthesis of (±)-luciduline[1]

JERZY SZYCHOWSKI[2] AND DAVID B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 14, 1978

JERZY SZYCHOWSKI and DAVID B. MACLEAN. Can. J. Chem. 57, 1631 (1979).

(±)-Luciduline has been synthesised in seven steps from 2-(2-cyanoethyl)-5-methylcyclohex-2-en-1-one. The synthetic approach is adaptable to the synthesis of intermediates of interest in biosynthetic studies of the Lycopodium alkaloids.

JERZY SZYCHOWSKI et DAVID B. MACLEAN. Can. J. Chem. 57, 1631 (1979).

On a synthétisé la (±)-luciduline en sept étapes à partir de la (cyano-2 éthyl)-2 méthyl-5 cyclohexène-2 one-1. On pourrait adapter cette approche à la synthèse d'intermédiaires intéressants dans des études biosynthétiques des alcaloïdes du lycopodium.

[Traduit par le journal]

Luciduline (**1**) (originally designated L21) was first described by Manske and Marion (1) who isolated the alkaloid from *Lycopodium lucidulum* Michx. Its structure was elucidated by Ayer *et al.* (2) by chemical degradation and by an X-ray study. Luciduline is the only representative of this ring system that has been isolated from the Lycopodiaceae.

Two syntheses of luciduline have already been reported, the first by Scott and Evans (3) and the second by Oppolzer and Petrzilka (4). Both syntheses lead in straightforward steps to the stereochemically desired intermediates and eventually to the product. Neither however is related to the biosynthesis of the alkaloid in the plant. The synthetic approach reported here is not biomimetic but leads to an intermediate that may however be involved in the biosynthesis, not only of luciduline itself but also of other ring systems in this family of alkaloids (5).

In a recent paper Nyembo *et al.* (6) have proposed that the amino acid **2** and compounds of general structure **3**, the phlegmarines, both of unspecified stereochemistry, may be biosynthetic intermediates on the pathway to many of the Lycopodium alkaloids. It was the purpose of the present study, not only to develop a general method for the synthesis of compounds of type **2** and **3** so that they might be eventually tested as biosynthetic precursors but also to develop a synthesis of (±)-luciduline and of the phlegmarines. A part of this work has been completed and we report here a synthesis of **4**, the ethyl ester of the lactam of **2**, and its conversion to luciduline.

The compound used as starting material in the synthesis was 2-(2-cyanoethyl)-5-methylcyclohex-2-en-1-one (**5**). This compound has recently been used by Heathcock *et al.*[3] in their synthesis of lycopodine. We have prepared it from 5-methyl-1,3-cyclohexanedione (6) using Clark and Heathcock's procedure (7) with slight modification.

The dione **6** was prepared by the method of Crossley and Renouf (8), a method that has been used with varying success by others (9, 10). We have found that the key to acceptable and reproducible results in this procedure rests in the manner of hydrolysis of the intermediate keto ester. The dione **6** was treated with acrylonitrile yielding 2-(2-cyanoethyl)-5-methyl-1,3-cyclohexanedione (**7**) according to the method of Reinshagen (11). Compound **7** was converted to 2-(2-cyanoethyl)-5-methyl-3-chlorocyclohex-2-en-1-one (**8**) by treatment with oxalyl chloride and that in turn to **5** by reduction with Zn activated by Ag (7). We found that our product was contaminated with variable quantities of some fully reduced material contrary to the earlier study (7).

Compound **5** was converted to a mixture of bicyclic keto lactams making use of a little known annelation reaction. Some years ago it was reported that compound **9** cyclized to the lactam **10** upon treatment with alkali (12). We found that a similar cyclization occurred when **5** was treated with methanolic NaOH. Two lactams, **11** and **12**, were separated from the reaction mixture by chromatography on alumina and separated from one another for analytical purposes by careful chromatography on silica gel. They were assigned the structures shown on the basis of nmr examination. The spectra were remarkably different, especially in the signals at H-9 which are clearly separated from the other signals in the two spectra. In isomer **11**, in which the bridgehead protons were deduced to be *cis*, the signal for H-9 was a nearly regular quartet, δ 4.12, J = 3.5 Hz, whereas in isomer **12**, in which the bridgehead protons are considered *trans*, this signal appeared as a triplet, split into doublets, δ 3.30, J = 11.0 and 4.0 Hz. In the *cis*-isomer **11** this implies coupling with three protons with nearly equivalent dihedral angles to H-9, namely H-10, H-8a, and H-8e, while for the *trans*-isomer **12** there are probably two equal *trans*-diaxial couplings of H-9, with H-10 and H-8a, and one axial–equatorial coupling between H-9 and H-8e. On these grounds isomer **11** was assigned conformation **11***a* (it may exist in equilibrium with a small amount of **11***b*) and compound **12** was assigned stereostructure **12***a*. The dihedral angles observed from molecular models of the *cis*- and *trans*-isomers conform with these deductions.

A detailed examination of the spectrum of **11** was carried out at 220 MHz in chloroform and benzene and in mixtures of the two. Through these studies it was possible to assign tentatively all the protons of **11** and to confirm some of the assignments by decoupling studies as reported in the experimental section. The change in chemical shift in changing solvent from chloroform to benzene was in the same direction (upfield) and of the same magnitude for H-9, H-10, H-8a, and H-6a, namely 0.75, 0.96, 0.62, and 0.75 ppm, respectively. The *C*-methyl group was shifted upfield by 0.3 ppm but H-7a by only 0.2 ppm. These results imply a *cis* relationship among H-9, H-10, H-8a, H-6a, and the *C*-methyl group since benzene might be expected to coordinate with only one face of the molecule.

Both broadband and off-resonance ^{13}C spectra of **11** were also recorded. The assignments that were made are shown in Fig. 1 where they are compared with those of 3-methylcyclohexanone (13) chosen as a model in this study. The upfield shift of C-7 relative to the model is ascribed to the γ-gauche interaction with the axial substituent at C-9. The ^{13}C spectrum is compatible with the structure deduced from the ^{1}H nmr data.

The relative stereochemistry, especially at the *C*-methyl group, deduced from nmr, was not definitely established however until the synthesis of luciduline was complete.

The mechanism of cyclization of **5** seems to involve the attack of OH^- on the carbon atom of the C≡N group with subsequent attack of the negatively charged nitrogen on the enone system (12). Protonation of the resulting enol then leads to the amides **11** and **12** (Fig. 2).

The predominance of **11** in the reaction product shows that nitrogen attack occurs mainly on the side of the enone system *trans* to the methyl group. A similar directive influence of a methyl group in a conjugate addition to a cyclohexenone was observed by Stork (14) in his synthesis of lycopodine. Allinger and Riew (15) have provided an analysis of the stereochemistry of the copper-catalysed Michael additions of Grignard reagents to methylcyclohexenone which is in accord with the present observations. The enol resulting from attack of negatively charged nitrogen on the side opposite to the methyl group protonates to give **11***a* in which the carbon–carbon bonds at C-7 and C-10 are equatorial in the carbocyclic ring. This isomer seems relatively stable to isomerization and none of its epimer at C-10 has been detected. The ratio, **11**–**12**, usually greater than 5:1, does however vary with

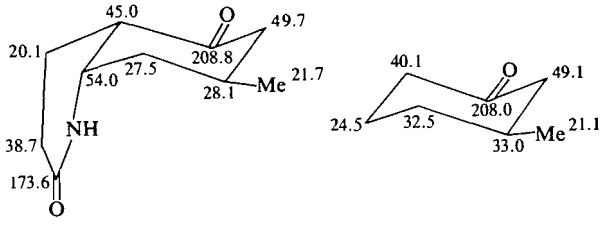

FIG. 1. ^{13}C nmr spectra of **11** and 3-methylcyclohexanone.

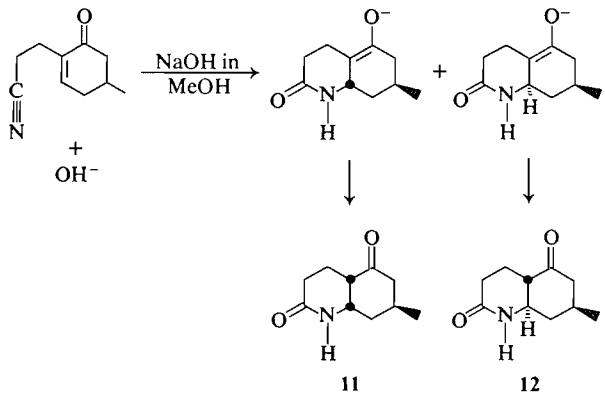

FIG. 2. The cyclization of 2-(2-cyanoethyl)-5-methylcyclohex-2-en-1-one (**5**).

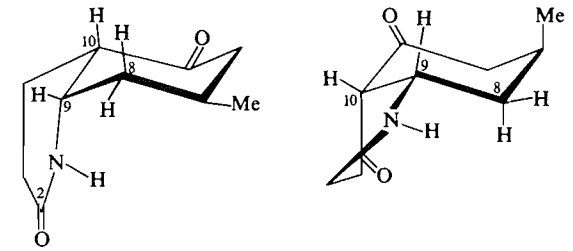
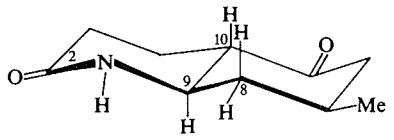
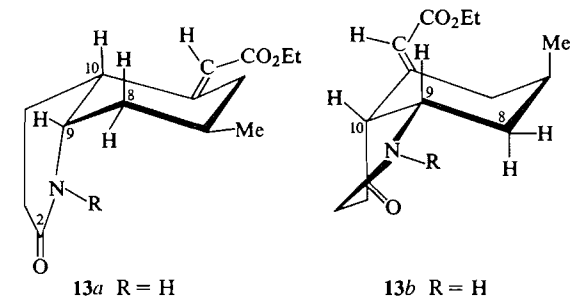
reaction time and this suggests that isomerization may occur but it must take place at C-9 rather than at C-10, for an interconversion of **11** to **12**. Isomerization at C-9 may result from a reverse Michael reaction followed by ring closure but that has not been established. Nevertheless it is apparent that the isomerization of **11** to its epimer at C-10 is by no means facile, contrary to the generally held belief that compounds with a ketone α to a bridgehead isomerize readily from the *cis* to the *trans* configuration.



11*a* **11***b*



12*a*



13*a* R = H
17*a* R = Me

13*b* R = H
17*b* R = Me

Compound **12** is derived from an enol resulting from attack by nitrogen on the enone system *cis* to the methyl group. This enol also protonates to give an equatorial bond at C-10 resulting in an all equatorial array of substituents in the carbocyclic ring as shown in stereo formula **12***a*.

It was now necessary to add to C-5 the two carbon atoms required to complete the skeleton of luciduline. Initial studies in which **11** was treated with ethyl triethylphosphonoacetate in base did not give satisfactory results. Although some of the desired **13** was present, the product proved to be a mixture of isomers in which those isomers with an endocyclic double bond predominated. However **13** was obtained in good yield in the Peterson reaction (16) with ethyl trimethylsilyl acetate (17). The reaction was normally carried out on the mixture of *cis*- and *trans*-lactams obtained from the cyclization step. The *trans*-isomer was found to react faster than the *cis* and to give a mixture of isomers about the newly formed double bond, one of which, **14**, was obtained crystalline. The *cis*-isomer **11** gave however only a single isomer **13** to which the *E* configuration has been assigned on the following grounds. In the nmr spectrum of **13** there is a signal at 3.18 δ that is absent in the dihydro compounds **15** and **16** (*vide infra*). Accordingly this signal can be assigned only to H-10 or to one of the two protons at C-6. Its low field position is attributed not only to its allylic position but also to deshielding by the ester function. Because the signal at 3.18 δ is a doublet of doublets (J = 15.0 and 4.0 Hz) it has been assigned to H-6e. The 15 Hz coupling is attributed to a geminal coupling to H-6a and the 4.0 Hz coupling to a vicinal coupling to H-7a. The signal for H-10 would be expected to be more complex and was excluded from consideration on these grounds. The conformation of the product represented in formula **13***a*, is favoured because the signal at H-9 still appears as a near quartet at 3.83 δ. The conformation **13***b* is also shown and a small amount of it may exist in equilibrium with **13***a*.

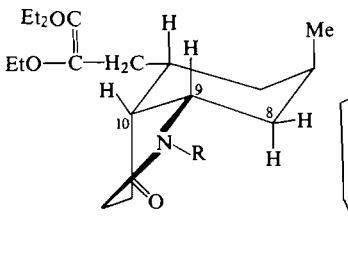
Hydrogenation of **13***a* might have been expected to yield only a single isomer. Instead, two products **15** and **16** (in a ratio of 2:1) that are epimeric at C-5 were isolated from reaction of **13** with hydrogen over an Adams' catalyst. The isomers **15** and **16** have been assigned the configurations and conformations shown from examination of the signal at H-9. In **15**, the desired isomer, this signal appears at 3.62 δ as a quintet formed by overlap of two triplets. In this conformation the protons at H-10 and H-8e will have approximately the same coupling constant, J = 6 Hz, to H-9 forming the triplet and this will be split by coupling with H-8a, J = 12 Hz. The methyl group at C-7 is axial and the carboethoxymethyl group at

C-5 is equatorial under these circumstances. On the other hand isomer **16** appears to have a conformation similar to **13***a* because the signal at H-9 appears as a quartet at 3.71 δ. Both the methyl and carboethoxymethyl groups will therefore adopt equatorial positions in the carbocyclic ring of **16**. The chemical shifts of the methyl groups in the two isomers reflect their axial–equatorial relationship.

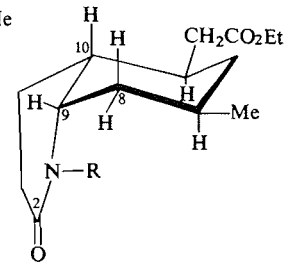
The *N*-methylation of **15** was not attempted because we considered that cyclization at nitrogen might occur under the conditions required to introduce the *N*-methyl group. We therefore decided to introduce the *N*-methyl before hydrogenation and accordingly treated **13** with dimethyl sulfate in the presence of base; the reaction proceeded normally yielding **17**. Examination of **17** by nmr showed that conformation **17***b* was favoured over **17***a*. The signal for H-9 now appeared at 3.55 δ as a doublet of triplets in a manner similar to **15**. The *C*-methyl group of **17***b* must adopt an axial position but the *N*-methyl group occupies a position where its interactions with the carbocyclic ring are minimized relative to **17***a*.

Examination of models indicated that hydrogenation of **17** might now be less favoured from the top face of the molecule. This indeed proved to be the case and when **17** was treated with hydrogen over Adams' catalyst it yielded a 1 : 1 mixture of **18** and **19**. The conformations of **18** and **19** follow from examination of the signal at H-9 in the two compounds. In **18** this signal appears as a doublet of triplets centred at 3.44 δ, J = 5 and 12 Hz, and the molecule is assigned conformation **18***a* while in **19** it appears as a near quartet at 3.58 δ, J = 3 Hz, and the molecule assumes the conformation shown. The difference in chemical shift of the methyl group in the two isomers also reflects the difference in configuration and conformation.

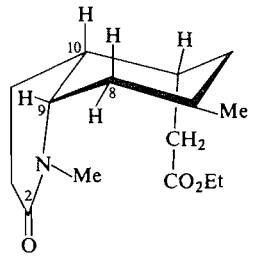
Cyclization of **18** to luciduline lactam requires that it adopt conformation **18***b* with the methyl group equatorial at C-7 and the carboethoxymethyl axial at C-5. It is apparent that the barrier to interconversion is not high because **18** was successfully converted to **20**, (±)-luciduline lactam, in good yield on treatment with base. The spectroscopic properties in solution of (±)-luciduline lactam were identical within experimental error with those reported previously (2). It seems likely however that the assignments of H-3 and H-6 should be reversed. The chemical shift and coupling constant for H-6 are very similar to those of the corresponding proton in the bicyclic intermediates of similar conformation discussed previously. Moreover H-3 might be expected to be a multiplet with long range 'W' couplings to H-1 and H-5.



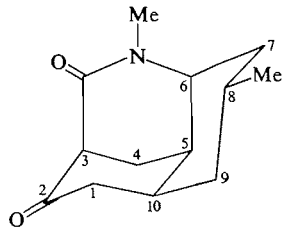
15*a* R = H
18*a* R = Me



16 R = H
19 R = Me



18*b*



20
(±)-Luciduline lactam

The reduction of **20** with lithium aluminum hydride gave (±)-dihydroluciduline with spectroscopic properties in solution identical with a sample of dihydroluciduline **21** prepared by reduction of natural luciduline with sodium borohydride. (±)-Luciduline, with spectroscopic properties in solution identical with those of natural luciduline, was obtained on Jones' oxidation of **21**.

The completion of the synthesis places on a firm foundation the configurational assignments made for the intermediates on the basis of nmr examination. In particular we can now proceed to prepare labelled **15** and **18** for biosynthetic studies knowing that their stereochemistry is secure. Moreover it is now possible to proceed from **11** and **12** to prepare compounds of the phlegmarine structure and in this way arrive at the stereochemistry of the naturally occurring bases.

Experimental

Apparatus, Methods, and Materials

The infrared spectra were determined on a Perkin Elmer 383 spectrophotometer in chloroform solution. The nmr spectra were run at 90 MHz on a Varian EM 390 spectrometer or Bruker WH 90 spectrometer. The 220 MHz proton spectra were obtained at the Canadian 220 MHz NMR Centre, University of Toronto, Toronto, Ont. Chemical shifts are reported in ppm (δ) from tetramethylsilane. The symbols s (singlet), d (doublet), t (triplet), q (quartet), and m (multiplet) are used to report the multiplicity of signals. Coupling constants are accurate within ±0.5 Hz. Mass spectra were recorded on a CEC 21-110B mass spectrometer at an ionizing voltage of 80 eV and a source temperature of 150–200°C. High resolution measurements were performed by the method already de-

scribed (18). Natural abundance ^{13}C nuclear magnetic resonance spectra were recorded on a Bruker WH-90 Fourier transform spectrometer at 22.62 MHz and a probe temperature of +35.0°C. Samples were 0.08–0.15 *M* in $CDCl_3$; TMS was used as an internal reference.

Melting points and boiling points are uncorrected. Microanalyses were performed by Microanalysis Laboratories Ltd., Toronto, Ont.

The purity of all samples was checked by thin-layer chromatography in several solvent systems. Silica gel 60F-254 (Merck) was used for tlc and for column chromatography. Mixtures of methanol (3–10%) in ether were used in most cases to develop tlc silica plates. Tetrahydrofuran was always distilled before use over lithium aluminum hydride.

*5-Methyl-1,3-cyclohexanedione (**6**)*

Sodium (20.2 g) was dissolved in absolute ethanol (240 mL) and ethyl acetoacetate (120 g) and ethyl crotonate (100 g, 96%) were added. The mixture was heated on a steam bath for 6–7 h (after 0.5 h the mixture partly solidified) and the alcohol was then removed under reduced pressure. The residue was dissolved in H_2O (1 L) and treated with aqueous KOH (100 g in 400 mL) in two portions, the second portion being added at room temperature after 2 h. The reaction mixture was maintained at room temperature for a further 4 h and then boiled for 0.5 h to remove the remaining alcohol. The mixture was cooled to 60°C and acidified with aqueous sulfuric acid. It was then slowly heated and finally boiled for 15–20 min to complete the decarboxylation. 5-Methyl-1,3-cyclohexanedione crystallized from the mixture upon cooling. The crystals were separated by filtration, dried and recrystallized from ethyl acetate. The product melted at 126–127°C, yield 58–68%.

*2-(2-Cyanoethyl)-5-methyl-1,3-cyclohexanedione (**7**)*

This compound was prepared from **6** by the method of Reinshagen (11) in a yield of 50%. It melted at 148–152°C after one recrystallization from ethyl acetate and was used as such in the next step.

*2-(2-Cyanoethyl)-3-chloro-5-methylcyclohex-2-en-1-one (**8**)*

This compound was obtained by the method of Clark and Heathcock (7) from **7** as a colorless liquid in 77% yield. It boiled at 123–125°C/0.2 Torr.

*2-(2-Cyanoethyl)-5-methylcyclohex-2-en-1-one (**5**)*

This compound was prepared by the method of Clark and Heathcock (7) from the chloro derivative above in 77% yield as a colorless oil boiling at 95–97°C/0.6 Torr. The oil solidified on standing in the refrigerator and melted at 22–23°C. This product always contained variable amounts of 2-(2-cyanoethyl)-5-methylcyclohexanone which could be removed by allowing compound **5** to crystallize from methanol at −78°C. Optimum yields of **5** (ca. 95%) were obtained if the progress of the reaction was monitored by gc (3% OV-17, 110–120 mesh Anakrom ABS, 4 mm id × 2 m, 170°C) and stopped when all the starting material was consumed.

*Preparation of the Lactams (**11** and **12**)*

2-(2-Cyanoethyl)-5-methylcyclohex-2-en-1-one **5** (5 g), was dissolved in a mixture of methanol (100 mL) and sodium hydroxide (2.4 g). The solution was heated under reflux for 44 h under an atmosphere of argon. The solution was then cooled, neutralized with glacial acetic acid (3.6 mL), and the solvent removed on a rotary evaporator. The residue was dissolved in chloroform (100 mL) and washed with water (20 mL). Evaporation of the chloroform yielded a residue that showed two major spots on tlc on alumina, one of which was the starting material. By column chromatography on alumina (Al_2O_3 neutral, Fischer Scientific Company, 250 g, activity III) the starting material (1.4 g) was eluted with benzene and the product (2.4 g) with chloroform. The solid residue from the chloroform (mp 153–166°C) showed two components of very similar R_f value on tlc on silica. A portion was separated on a silica column (20 g) with ether–methanol, 10:1 on a 200 mg scale into the *trans*- and *cis*-isomers in a ratio of 1:5, respectively.

The *trans*-isomer **12** after recrystallization from ether–benzene melted at 225–227°C (with sublimation); ir ν_{max} ($CHCl_3$): 3400 (NH), 1720 (carbonyl), 1670, 1660 cm^{-1} (lactam); ^1H nmr, 90 MHz ($CDCl_3$) δ: 1.10 (3H, d, J = 6 Hz, —CH—CH_3), 3.30 (1H, t, split into doublets, J = 11.0 and 4 Hz, H-9), ~ 7.0 (1H, br s, —NH, disappears after D_2O exchange). *Mol. Wt.* calcd. for $C_{10}H_{15}NO_2$: 181.110; found (ms): 181.114.

The *cis*-isomer **11** was recrystallized from benzene and melted at 168–169°C; ir ν_{max}($CHCl_3$): 3400 (NH), 1720 (carbonyl), 1660 cm^{-1} (lactam); ^1H nmr, 220 MHz ($CDCl_3$) δ: 1.05 (3H, d, J = 6 Hz, CH—CH_3), 4.12 (1H, q, J = 3.5 Hz, H-9); *Mol. Wt.* calcd. for $C_{10}H_{15}NO_2$: 181.110; found (ms): 181.111.

The ^1H nmr spectrum measured in $CHCl_3$–benzene 4:3 (data given below) gave the best separation of signals. From an examination of this spectrum and comparison of it with the spectra from pure chloroform, pure benzene, and $CHCl_3$–C_6H_6 4:1 and 2:1 it was possible to make the following assignments of chemical shift and coupling constant for each proton. An asterisk indicates a decoupling experiment was performed; δ: 2.49 (H-3a, $J_{3a,3e}$ = 18.5 Hz, $J_{3a,4a}$ = 12 Hz, $J_{3a,4e}$ = 7 Hz), 2.13 (H-3e, $J_{3e,4a} = J_{3e,4e}$ = 7 Hz), 1.25 (H-4a), 2.1 (H-4e), 1.65 (H-6a, $J_{6e,6a}$ = 13 Hz, $J_{6a,7}$ = 13 Hz), 2.24 (H-6e, $J_{6e,7}$ = 3 Hz), 1.87 (H-7a), 0.85 (CH_3, $^*J_{CH_3,7a}$ = 6.0 Hz), 1.24 (H-8a, $J_{8a,7}$ = 14 Hz, $J_{8a,8e}$ = 14 Hz, $^*J_{8a,9}$ = 3.5 Hz), 1.72 (H-8e, $J_{8e,7}$ = 3 Hz, $^*J_{8e,9}$ = 3.5 Hz), 3.66 (H-9, $^*J_{9,10}$ = 3.5 Hz), 2.01 ppm (H-10, $J_{10,4a} = J_{10,4e}$ ~ 3–4 Hz).

*Reaction of the Lactams (**11** and **12**) with Ethyl Trimethylsilyl Acetate*

N-Isopropylcyclohexylamine (5.6 g, 40 mmol) was treated with 2.42 *M n*-butyllithium (16 mL, 39 mmol) at −60°C under an atmosphere of argon. To this solution after 1 h there was added dropwise ethyl trimethylsilylacetate (6.4 g, 40 mmol) prepared according to the method of Fessenden and Fessenden (17). The mixture was kept at −60°C during the addition and for 20 min thereafter and then the epimeric lactams (*trans–cis* 3:7), 3.26 g (18 mmol) were added. The solution was maintained at −60°C for 1 h, then at −20°C for 2 h, and finally at 0°C for 0.75 h. The whole mixture was then quenched with 160 mL of 0.5 *M* HCl and extracted once with benzene (200 mL) and twice with chloroform (2 × 50 mL). The extracts were worked up separately. The chloroform solution contained a mixture of *N*-isopropylcyclohexylamine and starting lactam (2.05 g) while the benzene extract contained a mixture of starting lactam, silyl ester, and product (5.2 g). A portion of the mixture derived from benzene (4.2 g) was separated by column chromatography on silica (100 g, SiO_2 for tlc) using ether–ethanol 9:1. The reaction product of the ester with the *trans*-lactam (1.1 g) was eluted first. Spectroscopic examination revealed that this was a mixture probably consisting of isomers about the newly generated double bond.

One isomer **14** was separated by crystallization from ether and melted at 193–195°C; ^1H nmr, 90 MHz ($CDCl_3$) δ: 1.06 (3H, d, J = 6 Hz, CHCH_3), 1.30 (3H, t, J = 7 Hz,O—CH_2—CH_3), 3.12 (1H, d of t, J = 3 and 11 Hz, H-9), 4.00 (1H, d with

additional small coupling, J = 11 Hz, probably C-6_{eq}), 4.23 (2H, q, J = 7 Hz, OCH_2—CH_3), 5.65 (1H, s, =CH), 6.95 (1H, br s, disappears after exchange in D_2O, N*H*); *Mol. Wt.* calcd. for $C_{14}H_{21}NO_3$: 251.152; found (ms): 251.149.

The second isomer was not investigated further.

The *cis*-isomer **13** (0.8 g), eluted next, was crystallized from ether and melted at 158–159°C; ir ν_{max}($CHCl_3$): 3400 (NH), 1715 (ester), 1660 cm^{-1} (lactam); ^1H nmr, 90 MHz ($CDCl_3$) δ: 0.97 (3H, d, J = 6 Hz, CH—CH_3), 1.30 (3H, t, J = 7 Hz, —OCH_2—CH_3), 3.18 (1H, d of d, J = 4 and 15 Hz, probably H-6_{eq}), 3.83 (1H, q, better defined after D_2O exchange, J = 5 Hz, H-9), 4.20 (2H, q, J = 7 Hz, O$CH_2$$CH_3$), 5.82 (1H, s, =C*H*), 6.57 (1H, br s, disappeared after D_2O exchange, —N*H*); *Mol. Wt.* calcd. for $C_{14}H_{21}NO_3$: 251.152; found (ms): 251.153. *Anal.* calcd. for $C_{14}H_{21}NO_3$: C 66.91, H 8.42, N 5.57; found: C 66.81, H 8.44, N 5.39.

*Preparation of the 7-Methyl-5-carboethoxymethyloctahydro-2-quinolones (**15** and **16**)*

A solution of 7-methyl-5-carboethoxymethyleneoctahydro-2-quinolone (**13**) (232 mg, 0.92 mmol) in ethanol (15 mL) was treated with hydrogen at atmospheric pressure over Adams' catalyst (50 mg). The reaction was complete in 40 min, (H_2 absorbed: 22.0 mL; calcd: 20.7 mL). The catalyst was separated by decantation and the solvent removed by distillation. The product showed two spots on tlc on silica. Separation of the two components was achieved by column chromatography on silica (silica for tlc, 25 g). The first component (77 mg), designated **16**, was eluted from the column with ether–ethanol 9:1. After recrystallization from hexane it melted at 147–149°C; ir ν_{max}($CHCl_3$): 3400 (NH), 1730 (ester), 1660 cm^{-1} (lactam); ^1H nmr, 90 MHz ($CDCl_3$) δ: 0.90 (3H, d, J = 6 Hz, CHCH_3), 1.26 (3H, t, J = 7 Hz, —O$CH_2$$CH_3$), 3.71 (1H, q (better defined after D_2O exchange), J = 3 Hz, H-9), 4.14 (2H, q, J = 7 Hz, —O$CH_2$$CH_3$), 5.59 (1H, br s, disappears on D_2O exchange, N*H*); *Mol. Wt.* calcd. for $C_{14}H_{23}NO_3$: 253.168; found (ms): 253.168.

The second component (150 mg) designated **15**, melted at 112–113°C after recrystallization from hexane: ir $\nu_{max}CHCl_3$: 3400 (NH), 1730 (ester), 1660 (lactam); ^1H nmr, 90 MHz ($CDCl_3$) δ: 1.04 (3H, d, J = 7 Hz, CH—CH_3), 1.26 (3H, t, J = 7 Hz, —O$CH_2$$CH_3$), 3.62 (1H, m, changes to quintet after D_2O exchange; caused by superposition of two triplets, J = 6 and 12 Hz, H-9), 4.16 (2H, q, J = 7 Hz, O$CH_2$$CH_3$), 6.00 (1H, disappears on D_2O exchange, NH); *Mol. Wt.* calcd. for $C_{16}H_{23}NO_3$: 253.168; found (ms): 253.167.

*Preparation of 1,7-Dimethyl-5-carboethoxymethyleneoctahydro-2-quinolone (**17**)*

N-Isopropylcyclohexylamine (0.423 g, 3 mmol) in THF (50 mL) was treated with butyllithium (2.6 mmol) at −60°C under an atmosphere of argon. The mixture was stirred for 1 h and 7-methyl-5-carboethoxymethyleneoctahydro-2-quinolone (**13**) (625 mg, 2.5 mmol) was added and after another 0.5 h at −40°C, dimethyl sulfate (378 mg, 3 mmol) was added. The mixture was then allowed to warm to room temperature (it became cloudy but cleared again) and was kept at this temperature for an additional 3 h. Water (5 mL) and benzene (50 mL) were then added. The aqueous layer was separated and extracted again with benzene (10 mL). The combined benzene extract was dried, the benzene removed, and the residue subjected to column chromatography on silica with ether–ethanol 9:1 to separate *N*-isopropylcyclohexylamine and starting material from the methylation product. 1,7-Dimethyl-5-carbomethoxymethyleneoctahydro-2-quinolone (**17**) (410 mg, 62%), recrystallized from hexane, melts at 93–94°C; ir ν_{max} ($CHCl_3$): 1715 (unsaturated ester), 1630 cm^{-1} (lactam); ^1H nmr, 90 MHz ($CDCl_3$) δ: 0.94 (3H, d, J = 7 Hz, CHCH_3), 1.28 (3H, t, J = 7 Hz, —O$CH_2$$CH_3$), 2.92 (3H, s, N—$CH_3$), 3.55 (2H, d of t, J = 4 and 12 Hz, H-9 superimposed on another proton, probably H-10), 4.16 (2H, q, J = 7 Hz, O$CH_2$$CH_3$), 5.90 (1H, s, =C*H*); *Mol. Wt.* calcd. for $C_{15}H_{23}NO_3$: 265.168; found (ms): 265.169; *Anal.* calcd. for $C_{15}H_{23}NO_3$: C 67.90, H 8.74, N 5.28; found: C 68.41, H 8.49, N 5.13.

*Preparation of 1,7-Dimethyl-5-carboethoxymethyloctahydro-2-quinolones (**18** and **19**)*

A solution of 1,7-dimethyl-5-carboethoxymethyleneoctahydro-2-quinolone **17** (330 mg, 1.25 mmol) in ethanol (15 mL) was treated with hydrogen at atmospheric pressure over Adams' catalyst (75 mg). The reaction was complete in 0.5 h as judged by the completion of the uptake of hydrogen. The product obtained after removal of catalyst and solvent showed two spots on tlc on silica. The mixture was separated by column chromatography on silica (35 g, SiO_2 for tlc) using first ether and then ether with 5% ethanol as eluants. The first compound to be eluted, designated **19** (157 mg), melted at 61–62°C after recrystallization from hexane; ir ν_{max}($CHCl_3$): 1730 (ester), 1620 cm^{-1} (lactam); ^1H nmr, 90 MHz ($CDCl_3$) δ: 0.91 (3H, d, J = 6 Hz, CHCH_3), 1.26 (3H, t, J = 7 Hz, O$CH_2$$CH_3$), 2.93 (3H, s, N—$CH_3$), 3.58 (1H, apparent q, J = 3 Hz, H-9), 4.14 (2H, q, J = 7 Hz, O$CH_2$$CH_3$); *Mol. Wt.* calcd. for $C_{15}H_{25}NO_3$: 267.183; found (ms): 267.184.

The second isomer, **18** (154 mg) was a colorless oil; ir ν_{max}($CHCl_3$): 1730 (ester), 1620 cm^{-1} (lactam); ^1H nmr, 90 MHz ($CDCl_3$) δ: 1.07 (3H, d, J = 7 Hz, CHCH_3), 1.26 (3H, t, J = 7 Hz, —O$CH_2$$CH_3$), 2.92 (3H, s, N—$CH_3$), 3.44 (1H, d of t, J = 5 and 12 Hz, H-9), 4.15 (2H, q, J = 7 Hz, O$CH_2$$CH_3$); *Mol. Wt.* calcd. for $C_{15}H_{25}NO_3$: 267.183; found (ms): 267.181.

*(±)-Luciduline Lactam (**20**)*

N-Isopropylcyclohexylamine (71 mg, 0.5 mmol) in THF (20 mL) was treated with *n*-butyllithium (0.5 mmol) at −60°C in an atmosphere of argon and the mixture stirred for 0.5 h. 1,7-Dimethyl-5-carboethoxyethyloctahydro-2-quinolone **18** (135 mg, 0.5 mmol) in THF (10 mL) was then added. The solution was stirred for 0.5 h at −60°C, then allowed to warm to room temperature, and stirred for an additional 3 h. A few drops of acetic acid were then added and the solvent removed on the rotary evaporator. The residue was dissolved in benzene (50 mL) and washed with 5% hydrochloric acid (5 mL). The benzene extract was evaporated yielding luciduline lactam (100 mg, 90%) which melted at 97–99°C after crystallization from hexane; ir ν_{max}($CHCl_3$): 1730 (ketone), 1640 cm^{-1} (lactam); ^1H nmr, 90 MHz ($CDCl_3$) δ: 0.97 (3H, d, J = 6 Hz, CHCH_3), 2.99 (3H, s, N—CH_3), 3.33 (1H, m, H-3), 3.67 (1H, q, J = 3 Hz, H-6). *Mol. Wt.* calcd. for $C_{13}H_{19}NO_2$: 221.142; found (ms): 221.142.

(±)-Dihydroluciduline

Luciduline lactam (57 mg) was added to a suspension of lithium aluminum hydride (50 mg) in ether (20 mL) and the mixture boiled for 1 h. The excess lithium aluminum hydride was then decomposed with wet ether, the ether layer separated, and the residue extracted with benzene (5 mL). The combined organic extract was taken to dryness leaving a colorless oil that slowly solidified (49 mg). The crude solid residue was dissolved in ether and purified by filtration through alumina (5 g, activity III). Evaporation of the ether gave (±)-dihydroluciduline (30 mg, 63%) melting at 70–73°C. The ir (in $CHCl_3$), nmr (in benzene), the mass spectra of the synthetic sample and the tlc behaviour were identical with those of an authentic sample of dihydroluciduline prepared from luciduline by reduction with $NaBH_4$ (2).

(±)-Luciduline (1)

(±)-Dihydroluciduline (17 mg) in acetone (0.5 mL) was added to Jones' reagent (0.8 mL). The latter was prepared by dissolving CrO_3 (0.7 g) in 5 mL of H_2O and 1.2 mL 98% H_2SO_4 and adding this solution to 100 mL of acetone just before use. The reaction mixture was quenched with water (10 mL) after a period of 10 min, the solution was basified with sodium hydroxide and extracted with benzene (3 × 5 mL). The extract was taken to dryness and showed on tlc examination two spots corresponding to starting material and luciduline. Separation by chromatography on alumina yielded 13.6 mg of (±)-luciduline which had spectroscopic properties (ir in $CHCl_3$, nmr in benzene, and ms) and tlc behaviour identical with those of natural luciduline.

The hydrochloride of (±)-luciduline was prepared in acetone and after recrystallization melted at 238–239°C in a sealed capillary. Scott and Evans (3) report a melting point of 171–172°C and Oppolzer and Petrzilka (4) a melting point of 238–240°C.

Isolation of ergovaline, ergoptine, and ergonine, new alkaloids of the peptide type, from ergot sclerotia[1,2]

RUDOLF BRUNNER, PETER LEOPOLD STÜTZ, HANS TSCHERTER, AND PAUL ALBERT STADLER

Chemical Research, Pharmaceutical Department, SANDOZ Ltd., CH-4002 Basle, Switzerland

Received December 6, 1978

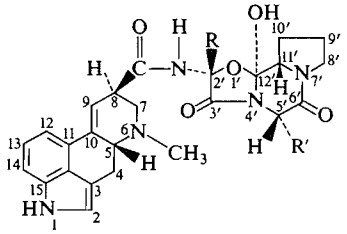
RUDOLF BRUNNER, PETER LEOPOLD STÜTZ, HANS TSCHERTER, and PAUL ALBERT STADLER. Can. J. Chem. 57, 1638 (1979).

The isolation of three new ergot alkaloids of the peptide type from sclerotia of *Claviceps purpurea* and from mother liquors of rye ergot alkaloid extraction processes is described. The constitution of the new alkaloids ergovaline, ergoptine, and ergonine has been established by comparison with compounds previously obtained by total synthesis.

RUDOLF BRUNNER, PETER LEOPOLD STÜTZ, HANS TSCHERTER et PAUL ALBERT STADLER. Can. J. Chem. 57, 1638 (1979).

Trois nouveaux alcaloides de l'ergot de type peptidique ont pu être isolés à partir de sclérotes de *Claviceps purpurea* et à partir d'eaux mères accumulées après l'extraction d'autres alcaloides de l'ergot. La structure de ces nouveaux alcaloides ergovaline, ergoptine et ergonine a été etablie par comparaison à des produits obtenus auparavant par synthèse totale.

Genuine ergot alkaloids of the peptide type are found as pairs of diastereomers in nature. Their relative amounts depend strongly on the method of isolation, owing to an easy and reversible isomerization in position 8 of the lysergic acid moiety (1). Up to now seven pairs of alkaloids of the peptide type have been isolated from ergot sclerotia and also partly from mycelia of *Claviceps purpurea* fermentations (2–7). Systematically, ergot peptide alkaloids can be divided into three natural groups by their differing substituents (R) at position 2′ of the peptide moiety (Table 1) (see general structure **1**).



1

Of the ergotoxine group, with an isopropyl group at C-2′, four natural alkaloid pairs have been isolated from natural sources: ergocristine–ergocristinine (4), α-ergokryptine–α-ergokryptinine (5), β-ergokryptine–β-ergokryptinine (7), and ergocornine–ergocorninine (5).

Hitherto, in the ergotamine group only two alkaloid pairs have been isolated, ergotamine–ergotaminine (2) and ergosine–ergosinine (3). The ergoxine group has as yet been represented only by the pair ergostine–ergostinine (6).

The total synthesis of ergotamine, achieved some 15 years ago (8), may be regarded as a breakthrough for the total synthesis of new ergot alkaloids of the peptide type. All 12 alkaloid pairs listed in Table 1 have been synthesized following more or less the successful approach employed in the ergotamine total synthesis (6, 9–12).

The availability of synthetic samples of ergot peptide alkaloids also expected to occur in nature somewhat simplified the hunt for the missing links. In a systematic search crude alkaloid extracts of field harvests of new *Claviceps* strains, on the one hand, and mother liquors of the current peptide alkaloid extraction processes, on the other, were tested by paper chromatography for new alkaloids.

Ergovaline **2**

In 1967, an experimental field harvest of our *Claviceps purpurea* strain 235, grown on Swiss rye, produced a mixture of α- and β-ergokryptine, ergocornine, ergosine, and ergometrine as the main alkaloids; the presence of ergovaline in an amount of about 4% of the total alkaloid content was verified by chromatography.

Following the usual procedure, a combined crude alkaloid yield of 0.85% was obtained by extraction of the sclerotia. The main alkaloids mentioned above were separated by chromatography on alumina; some middle fractions probably contained ergovaline: analysis by paper chromatography revealed the presence of about 70% of ergosine and about 20%

[2]88th communication on ergot alkaloids. For part 87, see ref. 14.

0008-4042/79/131638-04$01.00/0

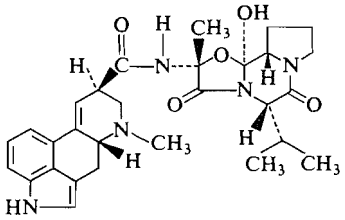
TABLE 1. Natural groups of ergot peptide alkaloids

R′	Ergotamine group R = CH_3	Ergoxine group R = C_2H_5	Ergotoxine group R = $CH(CH_3)_2$
$CH_2—C_6H_5$	Ergotamine	Ergostine	Ergocristine
$CH_2—CH(CH_3)_2$	Ergosine	Ergoptine†	α-Ergokryptine
$CHCH_3—C_2H_5$	β-Ergosine*	β-Ergoptine*	β-Ergokryptine
$CH(CH_3)_2$	Ergovaline†	Ergonine†	Ergocornine

NOTE: All names listed above correspond to those isomers with an equatorial carboxylic acid amide function at C-8 of the lysergic acid moiety; the 8-epimeric isomers derived from isolysergic acid, characterized by the ending -inine, are omitted here for the sake of simplicity.
*Not yet found in nature.
†Isolation reported in this paper.

of a new alkaloid with the same R_f values as synthetic ergovaline.

The isolation of ergovaline **2** on a preparative scale from this fraction proved to be a tedious task owing to its structural similarity to ergosine. Comparison of all chemical and physical properties of synthetic ergovaline with ergosine revealed practically no differences in solubilities, pK values, partition coefficients, and chromatographic behavior on silica gel thin-layer plates.



Ergovaline, **2**

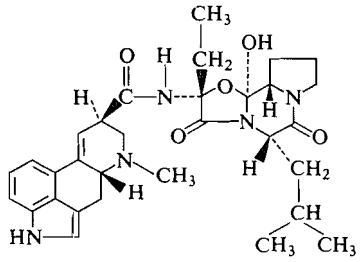
After testing several chromatographic systems on alumina thin-layer plates, it was found that the two alkaloids showed a slight R_f difference of 0.06 in a solvent mixture of ethyl acetate – n-butanol 9:1. Column chromatography on alumina using this mixture permitted sufficient enrichment of the new alkaloid for further purification to be effected by crystallization.

Natural ergovaline **2** melted at 207–208°C (dec.) in contrast to the reported (9) melting point of synthetic ergovaline (177–178°C, dec.). Yet after a few recrystallizations of an original sample of synthetic ergovaline from ethyl acetate, its melting point could be raised to a constant 209–210°C (dec.). This phenomenon can be attributed to dimorphism, often observed with ergot alkaloids. Otherwise the specimen of ergovaline isolated from *Claviceps purpurea* sclerotia was completely identical with a sample originating from total synthesis.

Ergoptine 3, Ergonine 4

Ergoptine **3** and ergonine **4** are members of the ergoxine group of ergot peptide alkaloids, hitherto represented only by ergostine, sometimes accompanying ergotamine as a minor constituent (≦0.5%) in nature (6). As a working hypothesis it was therefore assumed that these alkaloids might occur in ergokryptine–ergocornine-producing strains. Indeed, after thorough analysis of all types of mother liquors derived from technical ergokryptine–ergocornine extraction plants, a few revealed the presence of ergoptine and ergonine, previously obtained by synthesis (11), in the alkaloid mixture.

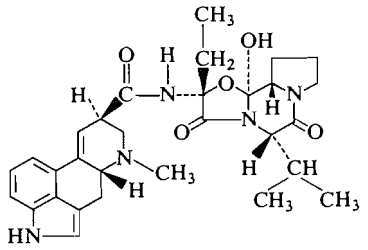
For example, in the isolation of ergoptine **3** a



Ergoptine, **3**

mother liquor with an estimated content of about 10% served as starting material. Its main constituent, about 40%, was ergocornine which could be partially separated by two consecutive chromatographic steps. Synthetic ergoptine gives a well crystallizing and more sparingly soluble salt with di-*p*-toluyl-L-tartaric acid than ergocornine. Thus, a fraction containing about 80% ergoptine, could be further purified as the above mentioned salt. Subsequent chromatography of the base on a silica gel column followed by crystallization from acetone–water gave pure natural ergoptine **3**, identical in all respects with a synthetic specimen.

For the isolation of ergonine **4** a mother liquor consisting of almost 90% ergosine and about 10% ergonine was at hand. Again, the different solubilities of the di-*p*-toluyl-L-tartrates of ergosine and ergonine in methanol could be exploited for their separation,



Ergonine, **4**

the salt of the latter being more soluble. Therefore, most of the ergosine present could be removed in pure form. The mother liquors, enriched in ergonine, were subjected to further purification as free base by column chromatography on alumina. Crystallization from ethanol – diisopropyl ether finally led, with great losses, to pure, natural ergonine **4**, identical with a synthetic specimen.

The separatory procedures described above do not, of course, provide a basis for accurate estimation of the relative amounts of **3** and **4** occurring in raw alkaloid extracts obtained from ergokryptine–ergocornine-producing strains. Very approximately, the concentration of ergoptine may be assumed not to exceed 0.5% of the total alkaloids present, whereas the ergonine concentration is even lower, probably in the region of 0.1%. The occurrence of ergovaline **2** in certain strains of *Claviceps purpurea* appears to be only sporadic.

Experimental

Owing to decomposition, melting points of ergot alkaloids were determined on a Tottoli apparatus in high vacuum and are uncorrected. Ultraviolet (uv) spectra were recorded on a Beckman spectrophotometer, model DK 2, in dichloromethane solution. The wavelengths of absorption maxima are reported in nanometers (nm) with log ε values in parentheses. Infrared (ir) spectra were measured on a Perkin Elmer model 21 spectrophotometer. The absorption maxima are reported in wavenumbers (cm^{-1}). Proton magnetic resonance (^{1}Hmr) spectra were measured on a Varian high resolution spectrometer. Chemical shift values are given in the δ (ppm) scale relative to tetramethylsilane (TMS) used as internal standard. The integrated peak areas, signal multiplicities, and eventual proton assignments are given in parentheses. Low resolution mass spectra (ms) were determined on an AEI-MS-30 spectrometer, high resolution ms on a CEC-21-110B apparatus.

Ergovaline **2**

Sclerotia (1.4 kg) of *Claviceps purpurea* (strain No. 235, grown in the summer of 1967 on rye in an experimental field in the outskirts of Basle were ground and consequently defatted by extraction with petrol ether (2 × 5 L). The dark violet residue was extracted with a mixture of 70% acetone and 30% water containing 5% tartaric acid (4 × 5 L). The extracts were concentrated *in vacuo* at 50°C to a volume of 5 L, removing practically all acetone. The acidic solution was rendered alkaline by addition of Na_2CO_3, extracted with ethyl acetate (3 × 5 L), washed with water, dried (Na_2SO_4), and evaporated at 50°C *in vacuo*. The raw residue (12 g) showed a total alkaloid content of 40% on colorimetric determination (reagent of Van Urk (15)); semiquantitative determination of the alkaloids by paper chromatography gave ergometrine (7%), ergometrinine (1%), ergosine (14%), ergosinine (3%), ergocristine (5%), α- and β-ergokryptine (26%), ergocornine (26%), mixture of ergotoxinine (12%), and a new alkaloid (4%) with the same R_f values as synthetic ergovaline.

Chromatography of the raw extract (12 g) on alumina (600 g, activity II) afforded fraction 1 (chloroform – 0.5% methanol, 5 g, ergotoxine alkaloids, discarded), fraction 2 (chloroform – 1.5% methanol, 1.5 g, ergosine and new alkaloid), and fraction 3 (chloroform – 3% methanol, 0.6 g, ergometrine, discarded). Chromatography of fraction 2 (1.5 g) on alumina (100 g) gave a purified fraction 2 (chloroform – 1.5% methanol, 0.7 g, colorimetric alkaloid content 80%, paper chromatography: ergosine, 70%, and the new alkaloid, 30%). Chromatography of purified fraction 2 (0.7 g) on alumina (420 g, DS-O Camag, activity I, elution with ethyl acetate – *n*-butanol 9:1, fractions of 20 mL) gave the following fractions. Fraction 6 (15 mg), rest of ergokryptine and ergocornine, discarded. Fractions 7–10 (382 mg) primarily ergosine, discarded. Fractions 11–13 (199 mg), containing the new alkaloid, were combined and purified by crystallization: natural ergovaline **2** (60 mg); mp 207–208°C (ethyl acetate), mixture mp 207–208°C (synthetic ergovaline mp 207–208°C (ethyl acetate)); $[\alpha]_D^{20}$ −172° (*c* 0.5, chloroform); uv λ_{max}: 237 (4.3), 307 (3.95); ir (dichloromethane) ν_{max}: 3466, 1727, 1666 (sh), 1650; ^{1}Hmr (DMSO) δ: 10.8 (1H, s, N1-H), 9.37 (1H, s, CONH), 7.0–7.3 (4H, m, aromatic H), 6.75 (1H, d, J = 2 Hz, OH), 6.33 (1H, s, C9-H), 4.31 (1H, d, J = 5 Hz, C5′-H), 2.53 (3H, s, N6-CH_3), 1.7–3.9 (~14H, m), 1.58 (3H, s, C2′-CH_3), 1.08 (6H, d, J = 7 Hz, $CH(CH_3)_2$). *Exact Mass* calcd. for $C_{29}H_{35}N_5O_5$: 533.2638; found (ms): 533.2602.

Ergoptine **3**

A mother liquor (251 g) of the ergokryptine–ergocornine production with a total alkaloid content of about 80% (determined colorimetrically with the reagent of Van Urk) was chromatographed on alumina (8 kg, activity II). Elution with chloroform and 0.3% methanol led to a first fraction (110 g) which consisted primarily of ergokryptine and ergocornine and was not further considered. A second fraction (95 g) was obtained on elution with chloroform and 0.6% methanol which contained on analysis by paper chromatography about 25% ergoptine. This fraction was chromatographed again on alumina (3 kg, activity II). A first fraction obtained on elution with chloroform and 0.3% methanol again contained ergokryptine and ergocornine and was discarded. Elution with chloroform and 0.6% methanol gave a second fraction (23 g). Its analysis by paper chromatography revealed a content of about 80% ergoptine **3**, 5% ergonine **4**, and 15% ergotoxine alkaloids. For the isolation of ergoptine this fraction was converted into the salt with di-*p*-toluyl-L-tartaric acid. The fraction (23 g, ~40 mmol) was dissolved in methanol (230 mL), a solution of di-*p*-toluyl-L-tartaric acid (17 g, 44 mmol) in methanol (170 mL) was added whereupon the salt (30 g, 31.6 mmol) crystallized. Being too poorly soluble to be recrystallized in a reasonable amount of solvent, the salt (30 g) was cleaved by partition between chloroform – 2 *N* Na_2CO_3 giving an amorphous resin (17.2 g, 30.6 mmol) which was again converted into the salt with di-*p*-toluyl-L-tartaric acid by the same procedure. The salt (27.3 g, 28.8 mmol) thus obtained, mp 177–178°C, was cleaved by partition in chloroform – 2 *N* Na_2CO_3 and afforded 15.2 g (27 mmol) base, purity about 95%. Further purification of that base by chromatography on a column of silica gel (700 g, Merck, 70–230 mesh, ASTM) followed by crystallization from acetone–water 7:3 yielded homogeneous ergoptine **3** (7.8 g); mp 198–199°C, mixture mp 199–200°C (synthetic ergoptine mp 199–200°C);

$[\alpha]_D^{20}$ −188° (*c* 0.8, chloroform); uv λ_{max}: 238 (4.34), 308 (3.98); ir (dichloromethane) ν_{max}: 3470, 3150–3300, 1732, 1671 (sh), 1653; ^{1}Hmr ($CDCl_3$) δ: 9.58 (1H, s, N1-H), 8.17 (1H, s, CONH), 7.1–7.3 (3 + 1H, m aromatic H, OH), 6.99 (1H, s, C2-H), 6.34–6.5 (1H, m, C9-H), 4.58 (1H, t, J = 6 Hz, C5′-H), 2.8–4 (~9H, m, C4-H, C5-H, C7-H, C8-H, C8′-H, C11′-H), 2.68 (3H, s, C6-CH_3), 1.7–2.4 (~9H, m, C2′-CH_2, C5′-CH_2, C9′-CH_2, C10′-CH_2, side-chain CH), 1.9–2.2 (9H, m, side-chain CH_3). *Exact Mass* calcd. for $C_{31}H_{39}N_5O_5$: 561.2951; found (ms): 561.2875.

Ergonine 4

A mother liquor (2.9 g, ~5.3 mmol) of an ergokryptine–ergocornine-producing strain of *Claviceps purpurea* was shown by paper chromatography to consist of almost 90% ergosine and 10% ergonine. For the removal of ergosine the mother liquor was dissolved in a mixture of dichloromethane (15 mL) and methanol (15 mL) and a solution of di-*p*-toluyl-L-tartaric acid (1.87 g, 4.84 mmol) in methanol (20 mL) was added. The resulting salt of di-*p*-toluyl-L-tartaric acid with ergosine crystallized on concentration of the solution *in vacuo*. Recrystallization of the salt from dichloromethane–methanol yielded ergosine di-*p*-toluyl-L-tartrate (2.47 g, 2.65 mmol), mp 184–185°C, chromatographic purity 99%. The mother liquors were recrystallized several times from dichloromethane–methanol giving additional ergosine di-*p*-toluyl-L-tartrate (0.94 g, 1 mmol), mp 181–182°C. The combined mother liquors of the salt were cleaved by partition between dichloromethane and 2 *N* Na_2CO_3 and the resulting base (670 mg) chromatographed on alumina (67 g, activity II). With dichloromethane and 0.3% methanol the ergonine containing fractions were eluted from the column. Further purification was performed by crystallization from a little ethanol and diisopropylether and yielded natural ergonine **4** (20 mg), chromatographic purity 99%; mp 206–207°C, mixture mp 206–207°C (synthetic ergonine mp 207–208°C); uv λ_{max}: 238 (4.31), 307.5 (3.95); ir (dichloromethane) ν_{max}: 3460, 1728, 1668 (sh), 1649; ^{1}Hmr ($CDCl_3$) δ: 9.05 (1H, s, N1-H), 8.2 (1H, s, CONH), 7.0–7.3 (3 + 1H, m, aromatic H, OH), 6.9 (1H, s, C2-H), 6.2–6.5 (1H, m, C9-H), 4.4 (1H, d, J = 5 Hz, C5′-H), 1.5–4.0 (~16H, m), 2.6 (3H, s, N6-CH_3), 1.15 (3 + 3H, d, J = 7 Hz, $CH(CH_3)_2$), 0.91 (3H, t, J = 7 Hz, CH_2—CH_3). *Mol. wt.* calcd. for $C_{30}H_{37}N_5O_5$: 547; found (field desorption): 547.

Splendidine, a new oxoaporphine alkaloid from *Abuta rufescens* Aublet[1]

JERRY W. SKILES, JOSE M. SAA, AND MICHAEL P. CAVA
Department of Chemistry, University of Pennsylvania, Philadelphia, PA 19104, U.S.A.

Received October 30, 1978

JERRY W. SKILES, JOSE M. SAA, and MICHAEL P. CAVA. Can. J. Chem. 57, 1642 (1979).

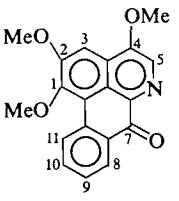
The oxoaporphine alkaloids lysicamine, homomoschatoline, imenine, and splendidine have been isolated from *Abuta rufescens* Aublet (=*Abuta splendida* Krukoff and Moldenke). Splendidine has been shown to be 1,2,4-trimethoxy-7*H*-dibenzo[*de*,*g*]quinolin-7-one (**1**) by total synthesis.

JERRY W. SKILES, JOSE M. SAA et MICHAEL P. CAVA. Can. J. Chem. 57, 1642 (1979).

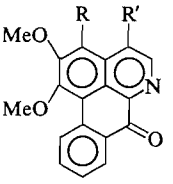
On a isolé les alcaloïdes oxoaporphines, lysicamine, homomoschatoline, imenine et splendidine à partir du *Abuta rufescens* Aublet (=*Abuta splendida* Krukoff et Moldenke). On a démontré, par synthèse, que la structure de la splendidine est la triméthoxy-1,2,4 7*H*-dibenzo-[*de*,*g*]quinoléinone-7 (**1**).

[Traduit par le journal]

As part of a broad search for anticancer agents in the South American *Menispermaceae*, we recently described the isolation of several bisbenzylisoquinoline alkaloids from the Amazonian species, *Abuta rufescens* (=*Abuta splendida* (1))[2]. We now report the isolation of several oxoaporphines from this plant, including the new alkaloid splendidine, and the proof of structure **1** for splendidine by total synthesis.



1



2 R = R′ = H
3 R = OMe; R′ = H
4 R = R′ = OMe

Isolation of Splendidine

The most weakly basic alkaloidal fraction from *Abuta rufescens* (=*A. splendida*) contained a complex mixture of highly colored compounds, the four major components of which were separated by dry-column silica chromatography. Three of these compounds proved to be the known oxoaporphine alkaloids lysicamine (**2**), homomoschatoline (**3**), and imenine (**4**) (3). The fourth compound was the new yellow crystalline alkaloid splendidine, mp 235°C, for which structure **1** was proposed on the basis of spectroscopic data (*vide infra*).

The high-resolution mass spectrum of splendidine established its composition as $C_{19}H_{15}NO_4$. Its ultraviolet spectrum in ethanol (λ_{max} 237, 270, 290sh, and 415 nm), which showed no alkaline bathochromic shift, was characteristic of a typical nonphenolic 7-oxoaporphine (4), as was its infrared carbonyl band at 1665 cm^{-1}.

The nmr spectrum of splendidine showed its three noncarbonyl oxygens to be present in the form of well-resolved methoxyls at δ 4.01, 4.10, and 4.21. Of the six aromatic protons present, only the two at δ 7.56 and 8.47 were singlets; the remaining four formed a multiplet characteristic of an oxoaporphine unsubstituted on the lower ring (i.e., compounds **2**–**4**). Significantly, the typical AB quartet (J = 5.5–6.0 Hz) due to the C(4)—C(5) protons of an oxoaporphine was not present, suggesting that splendidine might be the second example (after imenine) of a 4-oxygenated 7-oxoaporphine. Since all naturally-occurring aporphines are oxygenated at C(1) and C(2), structure **1** seemed appropriate for splendidine and its confirmation was sought by total synthesis.

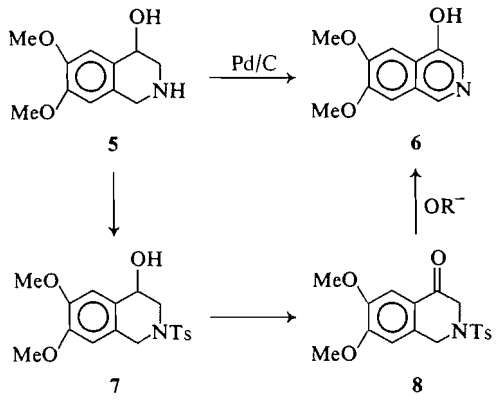
Synthesis of Splendidine

The key intermediate for the synthesis of splendidine was the hitherto unreported 4-hydroxy-6,7-dimethoxyisoquinoline (**6**), which was prepared in two fundamentally different ways from the readily available 4-hydroxy-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (**5**) (5). The first method illustrates a basically new synthesis of 4-hydroxyisoquinolines. Thus, amino alcohol **5** was selectively tosylated by 1 equiv. of tosyl chloride in pyridine solution to give,

[1]Dedicated to the memory of Dr. R. H. F. Manske.

[2]*Abuta splendida* has been very recently reduced to synonymy of *Abuta rufescens* (2). According to B. A. Krukoff (private communication), the identification of the plant previously examined by us phytochemically and cited as *A. rufescens* (3) cannot be verified as apparently no voucher was deposited by a Brazilian collector anywhere.

0008-4042/79/131642-05$01.00/0

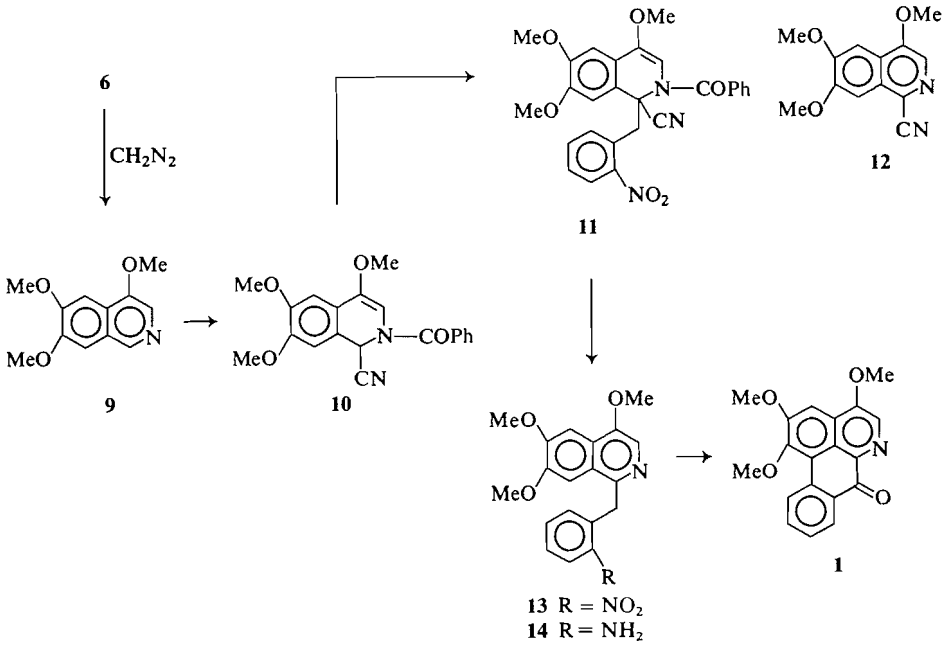


in high yield (92%), the *N*-tosyl alcohol **7**. Oxidation of the latter by Collins' reagent gave (63%) the *N*-tosyl ketone **8**, which underwent elimination of *p*-toluenesulfinic acid on treatment with potassium *tert*-butoxide to give the desired phenol **6** in 76% yield. The second method of converting alcohol **5** to phenol **6** involved direct catalytic dehydrogenation, using 10% palladium-on-charcoal catalyst. When this reaction was carried out under conditions reported earlier for a closely related alcohol (*p*-cymene at 140–145°C) (6), the yield of phenol **6** was poor (10–12%); when dimethylformamide was used as the solvent, however, the yield of **6** rose to 57%.

Reaction of phenol **6** with diazomethane afforded 4,6,7-trimethoxyisoquinoline (**9**), which was converted by potassium cyanide and benzoyl chloride into 2-benzoyl-1,2-dihydro-4,6,7-trimethoxyisoquinaldonitrile (**10**). Alkylation of Reissert compound **10** by *o*-nitrobenzyl chloride under phase-transfer conditions (7) gave 2-benzoyl-1,2-dihydro-1-(*o*-nitrobenzyl)-4,6,7-trimethoxyisoquinaldonitrile (**11**) in good yield (61%), in addition to a lesser amount (20%) of the difficultly separated 1-cyano-4,6,7-trimethoxyisoquinoline (**12**). Reaction of the alkylated Reissert compound **11** with Triton B in dimethylformamide (8) gave a mixture of nitrile **12** (>33%) and 1-(*o*-nitrobenzyl)-4,6,7-trimethoxyisoquinoline (**13**, ca. 58%). The latter nitro compound, which could not be separated completely from nitrile **12**, was reduced by Adams' catalyst in methanol. The resulting oily amine (**14**) was directly diazotized and subjected to Pschorr cyclization under conditions favorable to 7-oxoaporphine formation (3). Chromatographic purification gave, in 19% yield, yellow needles of 1,2,4-trimethoxy-7*H*-dibenzo[*de*,*g*]quinolin-7-one (**1**), which proved to be identical with splendidine from *Abuta rufescens* (=*Abuta splendida*).

Experimental

Melting points are uncorrected. Elemental analyses were carried out by Midwest Microlabs, Indianapolis, IN. Nuclear magnetic resonance spectra were determined in $CDCl_3$ solution with Me_4Si as internal standard using Varian A-60A, HA-100D, and HA-220 instruments. Infrared (KBr), ultraviolet (ethanol), and low-resolution mass spectra were determined using Perkin-Elmer Models 137, 202, and 270B instruments, respectively. *Abuta rufescens* (=*Abuta splendida*) (*Schunke 1971/38*) was collected by J. Schunke in Mariscal



Caceres, Tocache Nuevo, Department of San Martin, Peru, and identified by B. A. Krukoff. A voucher specimen has been deposited at the New York Botanical Garden and other institutions.

Isolation of Lysicamine (2), Homomoschatoline (3), Imenine (4), and Splendidine (1) from Abuta rufescens *(=*Abuta splendida*)*

The extraction and countercurrent distribution (200 transfers) of the total alkaloidal material used here has been described earlier. In the presently reported study, the highly colored and weakly basic alkaloids of tube fractions 171 and 175 were combined and 2.4 g of the mixture was subjected to dry-column silica chromatography, using ethyl acetate as the developer solvent. Good band separation resulted only after running the developer through the column for several hours. The column was then cut into bands A–E, which were individually extracted with chloroform–methanol.

Bands A and B contained the same major constituent, homomoschatoline (**3**, 1.0 g), which crystallized from ethyl acetate as orange prisms, mp 181–182°C, identical (mp, ir, nmr) with synthetic material (3).

Band C afforded an orange mixture of bases (0.130 g) which were not identified.

Band D was a mixture (0.780 g) of two components which could not be separated by repeated chromatography. The components were separated readily, however, by partitioning the mixture between chloroform and 5% aqueous sulfuric acid. The chloroform phase, on evaporation and crystallization of the residue from acetone, gave yellow needles of imenine (**4**), mp 205–206°C, identical (mp, ir, uv, nmr) with authentic material (3, 6). The aqueous acid phase was made basic and extracted with chloroform. Evaporation of the solvent and crystallization from acetone–chloroform gave yellow crystals of lysicamine (**2**), mp 207–208°C, identical (mp, ir, uv, mass spectrum) with authentic material (9).

Band E formed the purple-green segment at the top of the silica column. The extract of this band was rechromatographed (silica, ethyl acetate developer) to give, after crystallization from methanol–chloroform, bright yellow needles of splendidine (**1**, 0.100 g), mp 235°C; ir (KBr) 1665 cm^{-1}; uv (EtOH) λ_{max} (log ε): 237 (4.36), 270 (4.34), 290sh (4.15), 415 nm (4.05); nmr δ: 4.01 (s, 3H, OCH_3), 4.10 (s, 3H, OCH_3), 4.21 (s, 3H, OCH_3), 7.51 (t, 1H, $J_{8,9} = J_{9,10} = 8.75$ Hz, C(9)-H), 7.56 (s, 1H, C(3)-H), 7.69 (t, 1H, $J_{9,10} = J_{10,11} = 8.75$ Hz, C(10)-H), 8.47 (s, 1H, C(5)-H), 8.54 (d, 1H, $J_{8,9} = 8.75$ Hz, C(8)-H), 9.13 (d, 1H, $J_{10,11} = 8.75$ Hz, C(11)-H); ms *m/e* (relative intensity): 321 (M^+, 100), 306 (14), 291 (6), 278 (65), 263 (29), 248 (8), 235 (14), 220 (28), 207 (11), 192 (11), 164 (22), 160.5 (5), 150 (10); high-resolution mass spectrum *m/e* calcd. for $C_{19}H_{15}NO_4$: 321.1001; found: 321.1021.

1,2,3,4-Tetrahydro-6,7-dimethoxy-2-(p-*toluenesulfonyl)-4-isoquinolinol (7)*

4-Hydroxy-6,7-dimethoxyisoquinoline (**5**, 3.28 g, 15.6 mmol) was dissolved in dry pyridine (25 mL) and the resulting solution was cooled in an ice bath. Freshly recrystallized tosyl chloride (3.43 g, 18.0 mmol) was added portionwise and the mixture was stirred at 5 to 10°C for 2 h and then placed in a refrigerator overnight. Most of the solvent was evaporated and the residue was diluted with water. The product was extracted several times into chloroform. The extract was washed with 5% HCl, 5% $NaHCO_3$, and water. The solvent was dried ($MgSO_4$) and evaporated to yield a colorless solid which was recrystallized from ether to afford colorless needles of **7** (5.2 g, 92%), mp 132–134°C; nmr δ: 2.39 (s, 3H, CH_3), 2.96–3.55 (m, 3H), 3.77 (s, 6H, 2 × OCH_3), 4.05 (br s, 1H), 4.24 (br s, 1H), 4.69 (br s, 1H, OH), 6.53 (s, 1H), 6.93 (s, 1H), 7.32 (d, 2H, $J = 8.5$ Hz), 7.74 (d, 2H, $J = 8.5$ Hz). *Anal.* calcd. for $C_{18}H_{21}NO_5S$: C 59.50, H 5.79, N 3.86, S 8.82; found: C 59.74, H 5.65, N 3.85, S 8.74.

2,3-Dihydro-6,7-dimethoxy-2-(p-*toluenesulfonyl)-4(1H)-isoquinolone (8)*

Chromium trioxide (9.42 g, 0.0942 mol) was added to a magnetically stirred solution of freshly distilled dry pyridine (14.7 mL, 0.188 mol) in pure methylene chloride (240 mL). The flask was stoppered with a drying tube containing Drierite and the deep burgundy solution was stirred for 15 min at room temperature. At the end of this period a solution of alcohol **7** (4.351 g, 0.012 mol) in a small volume of methylene chloride was added in one portion. A black deposit separated immediately. After stirring an additional 15 to 20 min at room temperature, the solution was decanted from the residue and the residue was washed with methylene chloride (200 mL). The combined organic solution was washed with 100 mL of 5% aqueous NaOH, 100 mL of 5% aqueous HCl, 100 mL of 5% aqueous $NaHCO_3$, 100 mL of saturated NaCl, and dried ($MgSO_4$). Evaporation of the solvent gave a colorless solid which was recrystallized from methanol to afford colorless cubes of **8** (2.7 g, 62.4%), mp 153–154°C; ir (KBr): 1686 (C=O), 1342 (SO_2), 1167 cm^{-1} (SO_2); nmr δ: 2.39 (s, 3H, CH_3), 3.88 (s, 3H, OCH_3), 3.96 (s, 5H, OCH_3 and CH_2), 4.51 (s, 2H, CH_2), 6.79 (s, 1H), 7.33 (d, 2H, $J = 8.0$ Hz), 7.38 (s, 1H), 7.74 (d, 1H, $J = 8.0$ Hz). *Anal.* calcd. for $C_{18}H_{19}NO_5S$: C 59.81, H 5.31, N 3.88, S 8.87; found: C 59.88, H 5.66, N 3.72, S 8.76.

4-Hydroxy-6,7-dimethoxyisoquinoline (6)

Ketone **8** (477 mg, 1.30 mmol) was dissolved in dry *tert*-butyl alcohol (25 mL). The solution was heated to reflux and potassium *tert*-butoxide (0.310 g) was added in one portion. The resulting mixture was placed under nitrogen and heated at reflux for 4 h. The solution was cooled, water (10 mL) was added, the organic solvent was evaporated, and additional water (25 mL) was added. The solution was neutralized (NH_4Cl) and the product was extracted into chloroform. The extract was washed (water), dried ($MgSO_4$), and evaporated to give a residue which crystallized from methanol to give prisms of **6** (206 mg, 76%), 243–245°C; nmr δ: 4.01 (s, 3H, OCH_3), 4.03 (s, 3H, OCH_3), 7.52 (s, 1H), 7.60 (s, 1H), 8.16 (s, 1H, C(1)-H), 8.79 (s, 1H, C(3)-H). *Anal.* calcd. for $C_{11}H_{11}NO_3$: C 64.39, H 5.37, N 6.83; found: C 64.45, H 5.40, N 6.75.

The phenol **6** was also prepared directly from the tetrahydroisoquinoline **5**. Alcohol **5** (10.0 g, 0.0478 mol) was dissolved in dimethylformamide (200 mL) and 10% palladium-on-carbon (2.0 g) was added. The mixture was heated for 5 h at reflux under argon. The catalyst was filtered off and the solvent was evaporated to give a dark gummy residue. On scratching under methanol the product crystallized as slightly green prisms, which were recrystallized from methanol (Soxhlet) to give light colored prisms (5.12 g, 52%), mp 243–245°C.

4,6,7-Trimethoxyisoquinoline (9)

A distilled solution of diazomethane in ether (85 mL) was prepared in the usual way from *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (Diazald, 8.0 g, 0.0372 mol) and added to a cold solution of phenol **6** (2.05 g, 0.010 mol) in 1:1 methanol–dioxane (50 mL).

The resulting mixture was lightly corked and allowed to stand overnight in the dark at room temperature. Excess diazomethane was destroyed with a few drops of glacial acetic acid and the solvent was evaporated. The residue was basified to pH 8 to 9 with 10% ammonium hydroxide and the product was extracted into chloroform. The extract was washed

successively with 10% NaOH and water. The solvent was dried over magnesium sulfate, filtered, and evaporated to give light colored needles which were filtered and washed with a small amount of cold ether to give **9** (2.14 g, 98%). The product was recrystallized from methanol to give needles, mp 166–167°C; nmr δ: 3.98 (s, 3H, OCH_3), 4.01 (s, 3H, OCH_3), 4.03 (s, 3H, OCH_3), 7.17 (s, 1H), 7.43 (s, 1H), 8.77 (s, 1H). *Anal.* calcd. for $C_{12}H_{13}NO_3$: C 65.75, H 5.94, N 6.39; found: C 65.80, H 5.93, N 6.34.

*2-Benzoyl-1,2-dihydro-4,6,7-trimethoxyisoquinaldonitrile (**10**)*

To 4,6,7-trimethoxyisoquinoline (**9**, 2.204 g, 0.010 mol) in methylene chloride (25 mL) was added potassium cyanide (1.95 g, 0.030 mol) in water (10 mL). The resulting mixture was cooled in an ice bath and benzoyl chloride (2.82 g, 0.020 mol) in methylene chloride (15 mL) was added dropwise over 15 min. The resulting mixture was stirred at ice temperature for 1 h and then at room temperature for an additional 4 h. Water (50 mL) was added and the layers were separated. The organic layer was washed with water, 10% HCl, 10% NaOH, again with water, and dried (Na_2SO_4). Filtration followed by removal of the solvent gave a brown gum which on scratching under methanol afforded the Reissert compound **10** as colorless needles (1.84 g, 52.1%). The analytical sample was crystallized from ethanol to give colorless needles, mp 150–151°C; nmr δ: 3.72 (s, 3H, C(4)-OCH_3), 3.92 (s, 3H, OCH_3), 3.95 (s, 3H, OCH_3), 6.14 (br s, 1H, C(3)-H), 6.63 (br s, 1H, C(1)-H), 6.98 (s, 1H), 7.22 (s, 1H), 7.38–7.86 (m, 5H, OCOPh). *Anal.* calcd. for $C_{20}H_{18}N_2O_4$: C 68.57, H 5.14, N 8.00; found: C 68.53, H 5.11, N 7.71.

*2-Benzoyl-1,2-dihydro-4,6,7-trimethoxy-1-(o-nitrobenzyl)isoquinaldonitrile (**11**)*

In a 100-mL three-necked flask, fitted with a serum cap and a gas inlet adapter extending to the bottom of the flask, were placed 2-benzoyl-1,2-dihydro-4,6,7-trimethoxyisoquinaldonitrile (**10**, 1.203 g, 3.44 mmol), *o*-nitrobenzyl chloride (0.600 g, 3.50 mmol), and 50 mg of phase-transfer catalyst (cetrimonium bromide). Benzene (50 mL) was added and argon was bubbled through the solvent for 10 min. Sodium hydroxide (10 mL of a 50% by weight aqueous solution) was added in one portion and the resulting mixture was stirred at room temperature for 1.5 h. Argon was bubbled through the solvent throughout the reaction period. The contents of the flask were cooled in an ice bath and acidified to pH 6 with 5% sulfuric acid. The product was extracted several times into benzene and the extract was washed with water and dried (Na_2SO_4). Evaporation of the solvent gave a gum which was chromatographed on silica, eluting with benzene. Two components were isolated. Fraction A, the least polar fraction, crystallized from ether to give 1-cyano-4,6,7-trimethoxyisoquinoline (**12**, 160 mg, 20%) as colorless needles, mp 196–197°C; ir (KBr): 2237 cm^{-1} (CN); nmr δ: 4.04 (s, 6H, 2 × OCH_3), 4.13 (s, 3H, OCH_3), 7.29 (s, 1H), 7.38 (s, 1H), 8.04 (s, 1H, C(3)-H). *Anal.* calcd. for $C_{13}H_{12}N_2O_3$: C 63.92, H 4.96, N 11.47; found: C 63.66, H 5.14, N 11.76.

Fraction B, the more polar fraction, crystallized from ethanol to give 2-benzoyl-1,2-dihydro-4,6,7-trimethoxy-1-(*o*-nitrobenzyl)isoquinaldonitrile (**11**, 1.017 g, 61%) as bright yellow prisms, mp 170–171°C; ir (KBr): 1681 (amide carbonyl), 1658 (amide carbonyl), 1527 (NO_2), 1325 cm^{-1} (NO_2). The ion corresponding to M − HCN was the species observed at highest mass in its high resolution mass spectrum; high-resolution mass spectrum *m/e* calcd. for M − HCN, $C_{26}H_{22}N_2O_6$: 458.14778; found: 458.14541; nmr δ: 3.47 (s, 3H, OCH_3), 3.65 (s, 3H, OCH_3), 3.88 (s, 3H, OCH_3), 4.14 (dd, 2H, J_{gem} = 13.0 Hz, $\Delta_{A,B}$ = 29 Hz, δ_A = 3.90, δ_B = 4.38, benzylic protons), 5.76 (s, 1H, C(3)-H), 6.58 (s, 1H), 6.97 (s, 1H), 7.17–7.92 (m, 9H).

*1-(o-Nitrobenzyl)-4,6,7-trimethoxyisoquinoline (**13**)*

2-Benzoyl-1,2-dihydro-4,6,7-trimethoxy-1-(*o*-nitrobenzyl)-isoquinaldonitrile (**11**, 400 mg, 0.825 mmol) was dissolved in dry dimethylformamide (20 mL) and the system was flushed with argon for 10 min. Triton B (0.20 mL, 40% methanolic benzyltrimethylammonium hydroxide) was syringed in, when an intense blue color resulted. The system was stirred at room temperature under argon for 45 min. The reaction flask contents were diluted with water, the product was extracted into chloroform, and the extract was washed with water and dried (Na_2SO_4). Evaporation of the solvent gave a gum which was chromatographed on silica, eluting with benzene. Fraction A, the less polar fraction, crystallized from ether to give 1-cyano-4,6,7-trimethoxyisoquinoline (**12**, 66 mg, 33%) as colorless needles, mp 196–197°C. Fraction B, obtained from the polar zone, gave 1-(*o*-nitrobenzyl)-4,6,7-trimethoxyisoquinoline (**13**) as a pale yellow oil which by nmr analysis proved to be contaminated with approximately 10% of nitrile **12**. All attempts to remove the contaminant failed. The yield of **13**, after compensation for contaminant **12**, was 58% (169 mg); nmr δ: 3.92 (s, 3H, OCH_3), 4.00 (s, 6H, 2 × OCH_3), 4.81 (s, 2H, CH_2), 7.17–7.50 (m, 6H), 7.90 (s, 1H, C(3)-H).

*1-(o-Aminobenzyl)-4,6,7-trimethoxyisoquinoline (**14**)*

Crude **13** (125 mg, 0.353 mmol) was dissolved in methanol (50 mL) and potassium carbonate (50 mg) was added. Adams' catalyst (50 mg) in methanol (25 mL) was added. The resulting mixture was hydrogenated at an initial pressure of 45 psi for 4 h. The catalyst was filtered off and the solvent was evaporated. Water (50 mL) was added to the residue and the product was extracted into chloroform. The extract was washed with water, dried (Na_2SO_4), and evaporated to give a gum which was chromatographed over silica, eluting initially with benzene followed by chloroform–methanol, to give two components. Fraction A, the less polar fraction, afforded nitrile **12** (8 mg, 6.5%), mp 195–197°C. Fraction B, the more polar fraction, afforded 1-(*o*-aminobenzyl)-4,6,7-trimethoxyisoquinoline (**14**) as a pale yellow oil (93 mg, 82%) which was used in the Pschorr reaction without further purification; nmr δ: 3.95 (s, 3H, OCH_3), 3.98 (s, 6H, 2 × OCH_3), 4.37 (br s, 2H, concentration-dependent NH_2), 4.38 (s, 2H, CH_2), 6.67–7.55 (m, 6H), 7.86 (s, 1H, C(3)-H).

*1,2,4-Trimethoxy-7H-dibenzo[de,g]quinolin-7-one (**1**)*

1-(*o*-Aminobenzyl)-4,6,7-trimethoxyisoquinoline (**14**, 70 mg, 0.216 mmol) was dissolved in 30 ml of methanol and 2 *N* sulfuric acid (2 mL) was added. The resulting solution was cooled to 0 to 5°C and a solution of $NaNO_2$ (83 mg, 1.203 mmol) in a small amount of water was added dropwise. The resulting mixture was stirred for 30 min at 0 to 10°C. Sulfamic acid (83 mg) dissolved in a small amount of water, was added to destroy excess nitrous acid. One minute after adding the sulfamic acid, excess copper–bronze was added. A rapid evolution of nitrogen resulted. The reaction was stirred for 30 min at room temperature followed by 1.5 h at 45 to 50°C. Copper was filtered off and most of the solvent was evaporated. Water was added to the residue and the solution was basified to pH 8 to 9 with concentrated ammonium hydroxide. The precipitate was extracted several times into chloroform and the extract was washed with water, twice with 5% NaOH, again with water, and dried (Na_2SO_4). Evaporation of the solvent gave dark gum which was chromatographed on silica plc plates, developing with chloroform–methanol. A yellow band was isolated from the polar zone which was rechromatographed on silica by dry column chromatography, eluting with purified ethyl acetate. A

bright yellow polar band appeared which was isolated and crystallized from acetone to afford **1** as bright yellow needles (13 mg, 19%), mp 231–235°C. Its tlc, nmr spectrum, mass spectrum, and infrared spectrum were all identical to those of natural splendidine, and a mixture melting point determination of the two samples showed no melting point depression.

Acknowledgments

We thank the National Institutes of Health for a grant (CA-22337-01) in partial support of this work, and also the Fundación Juan March for the supporting fellowship to one of us (J. M. Saá). We also thank the following individuals for their invaluable assistance: B. A. Krukoff (Honorary Curator of the New York Botanical Garden and Consulting Botanist of the Merck Sharp and Dohme Research Laboratories) for the supply of plant material, identification of the vouchers, and botanical consultation; Dr. C. Costello (Massachusetts Institute of Technology) for the determination of high-resolution mass spectra.

Berberidic acid[1]

P. CHINNASAMY AND M. SHAMMA

Department of Chemistry, The Pennsylvania State University, University Park, PA 16802, U.S.A.

Received September 15, 1978

P. CHINNASAMY and M. SHAMMA. Can. J. Chem. 57, 1647 (1979).

Berberidic acid (**2**), obtained by nitric acid oxidation of berberine (**1**), can be esterified to diester **3**, or to monoesters **4** and **5**. Sodium borohydride reduction of **4** provides γ-lactone **6** which can be oxidized with iodine to pyridinium salt **7**. In like fashion, monoester **5** leads to γ-lactone **8** which is oxidized by mercuric acetate to salt **9**. Berberidic acid dimethyl ester (**3**) is hydrogenated to *allo* hexahydro diester **10** from which normal diester **11** can be derived by base isomerization. Hydrogenation of lactone **6** produces *allo* lactone **14** whose further reduction with lithium aluminum hydride gives diol **15**. This same diol can also be obtained from the lithium aluminum hydride reduction of hexahydro diester **10**. Alternatively, lithium aluminum hydride reduction of diester **11** gives rise to diol **16**, diastereomeric with **15**. Catalytic hydrogenation of lactone **8** provides normal lactone **18** which is transformed to diol **16** by lithium aluminum hydride.

P. CHINNASAMY et M. SHAMMA. Can. J. Chem. 57, 1647 (1979).

L'acide berbéridique (**2**), que l'on obtient par oxydation avec de l'acide nitrique de la berbérine (**1**), peut être estérifié en diester **3** ou en monoester **4** et **5**. La réduction de **4** par le borohydrure de sodium fournit la γ-lactone **6** qui peut être oxydée par l'iode pour donner le sel de pyridinium **7**. De la même manière, le monoester **5** conduit à la γ-lactone **8** qui peut être oxydée par l'acétate mercurique pour donner le sel **9**. L'hydrogénation de l'ester diméthylique de l'acide berbéridique (**3**) conduit à l'hexahydro diester *allo* (**10**) à partir duquel on peut obtenir l'isomère normal (**11**) par isomérisation en milieu basique. L'hydrogénation de la lactone **6** fournit la lactone *allo* (**14**) qui par réduction subséquente par l'hydrure de lithium et d'aluminium fournit le diol **15**. On peut aussi obtenir le même diol par réduction de l'hexahydro diester **10** par $LiAlH_4$. Par ailleurs, la réduction de **11** par $LiAlH_4$ fournit le diol **16** diastéréoisomère de **15**. L'hydrogénation catalytique de la lactone **8** fournit la lactone normale **18** qui peut être transformée en diol **16** sous l'influence de $LiAlH_4$.

[Traduit par le journal]

In a short communication in 1958, Resplandy reported (1) the oxidation of berberine (**1**) using hot dilute nitric acid to the betaine berberidic acid, which was assigned structure **2**. However, the exact experimental conditions as well as the yield and the full details of the structural elucidation were not described.

As part of an effort to study the varied aspects of the chemistry of berberine, it was decided to re-investigate this transformation and also to explore the chemistry of berberidic acid.

In our hands, the optimum conditions for the oxidation of berberine chloride were found to involve the use of 15% nitric acid together with gentle heating on a steam bath for 16 h. The maximum yield obtained was 53%. The Resplandy structure for berberidic acid (**2**) was confirmed by a study of the ^{1}Hmr spectrum of this product in TFA as described in expression **2**.

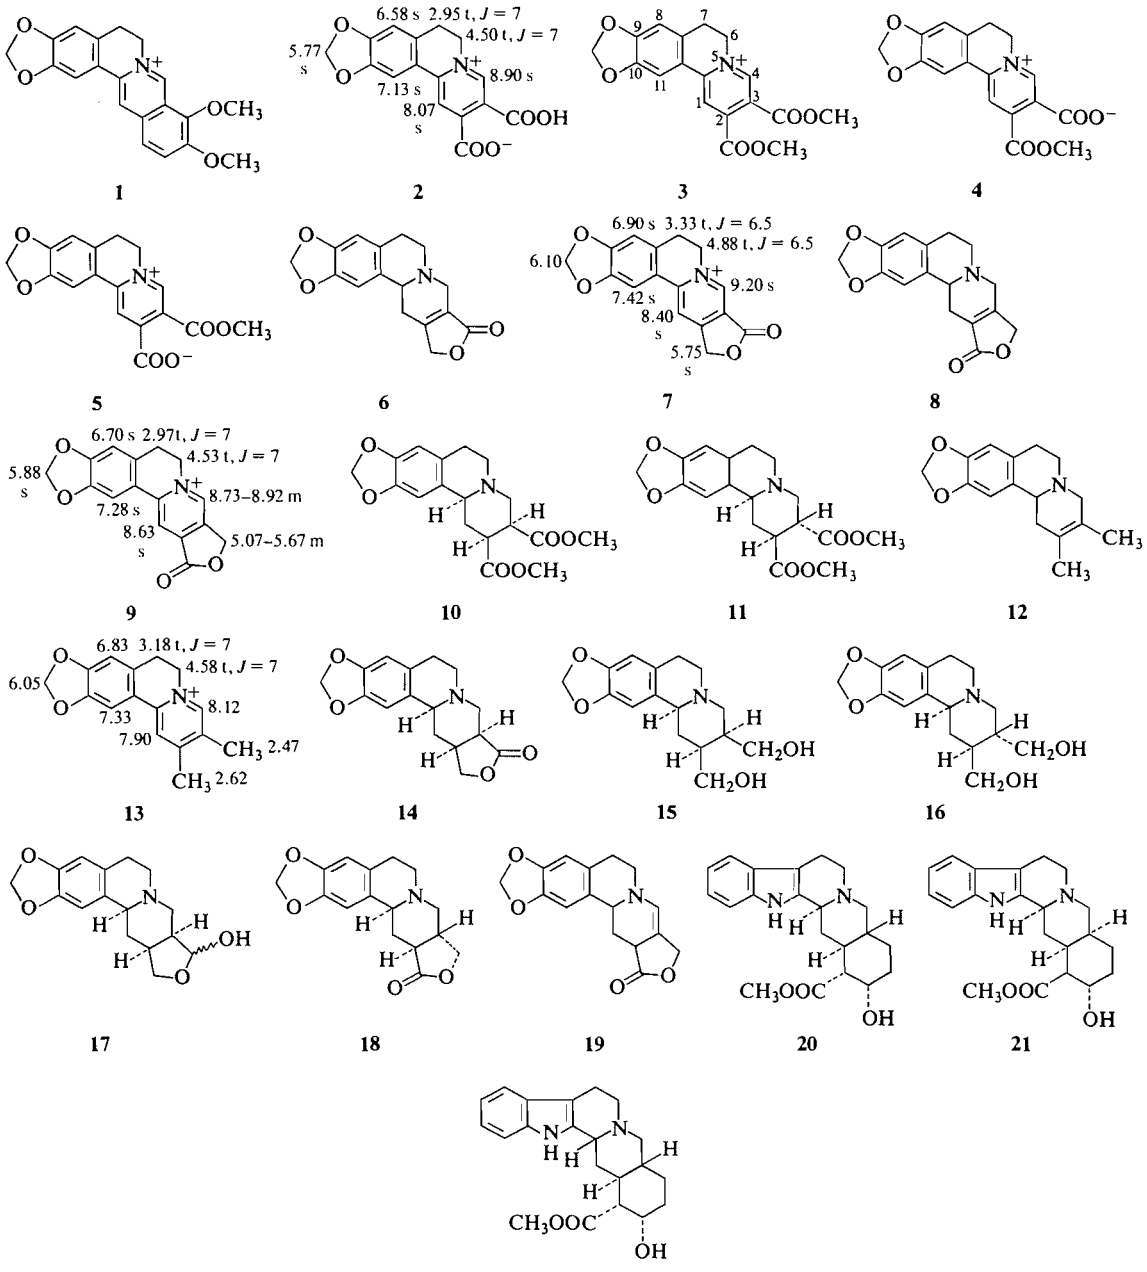
Esterification of berberidic acid (**2**) with methanol in the presence of hydrogen chloride gave berberidic acid dimethyl ester (**3**). On the other hand, the use of concentrated sulfuric acid as a catalyst during esterification yielded a mixture of diester **3** and monoesters **4** and **5** in 10, 65, and 15% yields, respectively.

The relative positions of the carbomethoxyl groups in **4** and **5** were established as follows. On reduction with excess sodium borohydride in ethanol, **4** provided the unsaturated lactone **6** which upon iodine oxidation generated the pyridinium salt **7**. The ^{1}Hmr spectrum of **7** in TFA is summarized in expression **7**. Noteworthy is the downfield aromatic singlet at δ 9.20 assigned to H-4 which is in a *peri* relationship to the carbonyl oxygen. In like fashion, sodium borohydride reduction of monoester **5** led to the γ-lactone **8**. Since iodine oxidation of **8** proved to be unsuccessful, mercuric acetate in acetic acid was used to furnish the pyridinium salt **9**. The ^{1}Hmr spectrum of **9** in TFA is summarized in expression **9**. Significantly, the lactone methylene protons appear as multiplets, whereas H-4 is also a multiplet between δ 8.73 and 8.92.

Berberidic acid dimethyl ester (**3**) could be hydrogenated quantitatively to the hexahydro diester **10** using Adams' catalyst. Even though three asymmetric centers are formed in this reduction, only one racemate, assigned the all-*cis allo* stereochemistry, was

[1]This paper is dedicated to the memory of R. H. F. Manske.

0008-4042/79/131647-05$01.00/0



obtained. Compound **10** could be isomerized to its normal diastereomer **11** using sodium methoxide in methanol, indicating that **10** is the thermodynamically less stable isomer.

Reduction of berberidic acid dimethyl ester (**3**) with zinc in hot concentrated hydrochloric acid took an unexpected course to supply the dimethyl compound **12**, albeit in low yield. Oxidation of this piperidine derivative with mercuric acetate in acetic acid furnished the pyridinium salt **13** whose ^{1}Hmr spectrum (TFA) exhibits two aromatic methyls, one methylenedioxy group, and four aromatic protons. Significantly, H-4 appeared relatively upfield at δ 8.12. Reduction of salt **13** with sodium borohydride in methanol regenerated the dimethyl compound **12**.

Hydrogenation of the unsaturated lactone **6** over Adams' catalyst produced the saturated *allo* γ-lactone **14** which could be further reduced with lithium aluminum hydride to the diol **15**. The same diol was also obtained upon lithium aluminum

hydride reduction of the hexahydro diester **10**. Alternatively, lithium aluminum hydride reduction of the normal diester **11** supplied the diol **16** which is diastereomeric with **15**.

Turning again to the α,β-unsaturated lactone **6**, its lithium aluminum hydride reduction gave rise to the hemiacetal **17** and the *allo* diol **15** in 28 and 30% yields, respectively.

Finally, catalytic hydrogenation of the unsaturated lactone **8** gave the normal lactone **18**. In turn, lithium aluminum hydride reduction of this lactone led to the normal diol **16** rather than to the *allo* diol **15**.

Stereochemical Considerations

The Wenkert–Bohlmann bands and the rates of methiodide formation were the primary tools used in solving the stereochemical problems. All the tertiary bases prepared in the present study were found to contain Wenkert–Bohlmann bands in their infrared spectra between 2650 and 2800 cm^{-1}, thus suggesting the ubiquitous presence of a *trans*-quinolizidine system (2).

The small amounts (≈3 mg) of alkaloids or nitrogenous bases required for following the pseudo-first-order kinetics of quaternization of tertiary amines in acetonitrile make this method a particularly attractive one (3). The pseudo-first-order rate constants observed are listed in Table 1.

To interpret the data in Table 1, it is necessary to consider first the particularly apposite examples of the rates of methiodide formation for yohimbine (**20**), α-yohimbine (**21**), and pseudoyohimbine (**22**). Yohimbine (**20**), which possesses the normal configuration, shows a moderate rate of *N*-methylation, 48×10^{-4} s^{-1}. α-Yohimbine (**21**), which is *allo* and has a hindered nitrogen, exhibits an appreciably slower rate of 1×10^{-4} s^{-1}. Pseudoyohimbine (**22**) has a very fast rate of quaternization, 7×10^{-2} s^{-1}, reflecting the presence of an unhindered nitrogen.

All the bases in the present study assigned the *allo* configuration, namely species **10**, **14**, **15**, and **17**, were found to have slow rates between 5 and 10×10^{-4} s^{-1}, whereas those compounds of the normal configuration such as **11**, **16**, and **18**, understandably exhibited faster rates between 19 and 21×10^{-4} s^{-1}.

TABLE 1. Pseudo-first-order rates of methiodide formation

Compound	Rate × 10^{-4} (s^{-1})
6	9
8	14
10	5
11	21
12	125
14	5
15	10
16	19
17	9
18	19

The dimethyl compound **12** which possesses a 2,3-double bond and is thus unhindered to attack by methyl iodide showed a very fast rate, 125×10^{-4} s^{-1}. However, similar unsaturation in γ-lactones **6** and **8** resulted in slower rates of 9 and 14×10^{-4} s^{-1}, respectively, owing to the presence of the carbonyl electron withdrawing group.

The stereochemical results of the catalytic hydrogenation studies are interesting and worthy of note. Reduction of pyridinium salt **3** leads to the all-*cis* diester **10**. In like fashion, reduction of unsaturated γ-lactone **6** produces *allo* γ-lactone **14**. In contrast, the structurally isomeric unsaturated γ-lactone **8** furnishes upon catalytic reduction the normal γ-lactone **18**. A possible rationalization for these results is that it may be relatively easy for compound **8** to isomerize during the reductive process to the enamine **19** which could then suffer reduction to generate the product **18**.

Experimental

General Procedures

Melting points are uncorrected. ^1H nuclear magnetic resonance spectra were recorded on a Varian A-60A spectrometer. Where elemental analyses indicated that solvent (methanol) was present, the sample was dissolved in TFA, the solvent evaporated, and fresh TFA added by which time ^1Hmr spectroscopy indicated that the original solvent (methanol) had completely evaporated. The pseudo-first-order rates of methiodide formation in acetonitrile were followed by conductivity measurements using a conductivity cell with black platinized electrodes, an audiooscillator to generate a 1000 Hz current, a Leeds and Northrup Maxwell bridge No. 1553, a condenser to balance the capacitance, and an oscilloscope as a galvanometer to measure the null point (3). Thin layer chromatography was done on Merck 254 silica gel plates. Spots were visualized under short and long uv light and spraying was with chloroplatinate or chromatropic acid reagent.

The numbering system adopted for berberidic acid and its derivatives is analogous with that used in the emetine series.

Berberidic Acid (2)

A mixture of berberine chloride (5 g, 0.013 mmol) in 5 mL concentrated HNO_3 and 18 mL water was heated gently on a steam bath for 16 h. The precipitate was filtered and washed with water and then triturated with MeOH to provide yellow crystals of **2** (2.2 g, 53%); mp 230–235°C (dec.) (MeOH); λ_{max} (EtOH): 230sh, 295, and 385 nm (log ε 3.64, 3.61, and 3.56).

Berberidic Acid Dimethyl Ester Chloride (3)

Berberidic acid (**2**) (1 g, 3.2 mmol) was mixed with dry MeOH (25 mL) and the mixture saturated with dry HCl gas. The solution was refluxed for 16 h. Work-up provided diester **3** (1.1 g, 90%); mp 195–198°C (dec.) (MeOH); λ_{max} (EtOH): 277, 303, and 405 nm (log ε 4.28, 4.43, and 4.47); ^1Hmr (TFA) δ: 3.40 (2H, m, H-7), 4.20 (3H, s, $COOCH_3$), 4.25 (3H, s,

$COOCH_3$), 4.90 (2H, m, H-6), 6.23 (2H, s, OCH_2O), 7.03 (1H, s, H-8), 7.57 (1H, s, H-11), 8.47 (1H, s, H-1), and 9.27 (1H, s, H-4). *Anal.* calcd. for $C_{18}H_{16}NO_6Cl{\cdot}CH_3OH$: C 55.68, H 4.88, N 3.42; found: C 55.77, H 4.89, N 3.55.

*Berberidic Acid Monomethyl Esters **4** and **5***

Berberidic acid (1 g, 3.2 mmol) was refluxed for 16 h in 25 mL MeOH and 10 drops concentrated H_2SO_4. The products were separated by tlc using 40% MeOH in $CHCl_3$ as eluent. The band with R_f 0.56 was the diester **3** (120 mg, 10%). The band with R_f 0.23 furnished monoester **5** (157 mg, 15%); mp 203–206°C (MeOH); λ_{max} (EtOH): 232, 252, 271, 292, and 380 nm (log ε 4.03, 3.99, 4.02, 4.05 and 4.12); ^{1}Hmr (TFA) δ: 3.33 (2H, m, H-7), 4.13 (3H, s, $COOCH_3$), 4.87 (2H, m, H-6), 6.12 (2H, s, OCH_2O), 6.90 (1H, s, H-8), 7.43 (1H, s, H-11), 8.28 (1H, s, H-1), and 9.22 (1H, s, H-4). *Anal.* calcd. for $C_{17}H_{13}NO_6{\cdot}\frac{1}{2}CH_3OH$: C 61.22, H 4.37, N 4.08; found: C 61.49, H 4.08, N 4.28.

The band with R_f 0.19 gave monoester **4** (680 mg, 65%); mp 210–215°C (dec.) (MeOH); λ_{max} (EtOH): 290 and 373 nm (log ε 3.49 and 3.38); ^{1}Hmr (TFA) δ: 3.30 (2H, m, H-7), 4.10 (3H, s, $COOCH_3$), 4.83 (2H, m, H-6), 6.08 (2H, s, OCH_2O), 6.88 (1H, s, H-8), 7.40 (1H, s, H-11), 8.23 (1H, s, H-1), and 9.13 (1H, s, H-4). *Anal.* calcd. for $C_{17}H_{13}NO_6{\cdot}\frac{1}{2}CH_3OH$: C 61.22, H 4.37, N 4.08; found: C 61.27, H 4.23, N 4.16.

*Lactone **6***

Monoester **4** (400 mg, 1.2 mmol) was dissolved in 200 mL EtOH and $NaBH_4$ (2 g, 53 mmol) was added with stirring. Work-up gave colorless needles of **6** (280 mg, 81%); mp 224–226°C (MeOH); λ_{max} (EtOH): 292 nm (log ε 3.70); ^{1}Hmr ($CDCl_3$) δ: 4.77 (2H, br s, CH_2OCO), 5.92 (2H, s, OCH_2O), 6.60 (1H, s, H-8), and 6.62 (1H, s, H-11). *Exact mass* calcd. for $C_{16}H_{15}NO_4$: 285.1001; found (high resolution ms): 285.1001.

*Lactone **7***

Lactone **6** (100 mg, 0.4 mmol), I_2 (270 mg, 1.1 mmol), and EtOH (25 mL) were refluxed for 4 h. Excess I_2 was destroyed with $NaHSO_3$ solution. The EtOH was removed and the aqueous solution extracted with $CHCl_3$. Drying and evaporation of the solvent left a residue which was purified by tlc using 40% MeOH in $CHCl_3$. The major yellow band, R_f 0.21, consisted of **7** as the iodide (57 mg, 40%); λ_{max} (EtOH): 280 and 375 nm (log ε 3.97 and 3.91).

*Lactone **8***

Monoester **5** was reduced with $NaBH_4$ in the manner described above for **4**. When 400 mg (1.2 mmol) of **5** was used, 280 mg (81%) of **8** was obtained; mp 211–215°C (MeOH); λ_{max} (EtOH): 290 nm (log ε 3.53); ^{1}Hmr ($CDCl_3$) δ: 4.85 (2H, m, CH_2OCO), 5.97 (2H, s, OCH_2O), 6.62 (1H, s, H-8), and 6.72 (1H, s, H-11). *Exact Mass* calcd. for $C_{16}H_{15}NO_4$: 285.1001; found (high resolution ms): 285.0992.

*Lactone **9***

Lactone **8** (50 mg, 0.2 mmol) was mixed with 20% HOAc and $Hg(OAc)_2$ (270 mg, 0.8 mmol) and the mixture heated for 16 h on a steam bath. The product was filtered and the filtrate treated with $(NH_4)_2S$ solution. The resulting black suspension was heated on a steam bath for 1 h and the precipitate filtered through Celite. The resulting solution was mixed with a saturated KI solution and extracted with $CHCl_3$. The organic layer was dried and evaporated. The residue was purified by tlc (40% MeOH in $CHCl_3$). The major band, R_f 0.18, was collected and proved to be salt **9** as the iodide (29 mg, 40%); λ_{max} (EtOH): 235, 283, and 375 nm (log ε 3.95, 4.00, and 3.79).

*Hexahydro Diester **10***

Berberidic acid dimethyl ester chloride (**3**) (100 mg, 0.26 mmol) in 25 mL EtOH was hydrogenated over Adams' catalyst for 8 h. Work-up furnished 91 mg (100%); mp 200–202°C (MeOH); λ_{max} (EtOH): 292 nm (log ε 3.62); ^{1}Hmr ($CDCl_3$) δ: 3.67 (3H, s, $COOCH_3$), 3.72 (3H, s, $COOCH_3$), 5.88 (2H, s, OCH_2O), 6.52 (1H, s, H-8) and 6.73 (1H, s, H-11). *Anal.* calcd. for $C_{18}H_{21}NO_6$: 347.1368, C 62.25, H 6.05; found (high resolution ms): 347.1366, C 62.43, H 6.09.

*Hexahydro Diester **11***

Freshly cut Na (0.5 g) was added to dry MeOH (25 mL) under N_2. Diester **10** (100 mg) was added to the cooled solution and the mixture stirred for 1 h at room temperature under N_2. Two millilitres of water was added and the solvent evaporated. The residue was taken up in water and $CHCl_3$. Evaporation of the organic layer provided **11**, ν_{max} ($CHCl_3$): 1740 and 2760 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.72 (6H, s, $COOCH_3$), 5.87 (2H, s, OCH_2O), 6.53 (1H, s, H-8), and 6.63 (1H, s, H-11). *Exact Mass* calcd. for $C_{18}H_{21}NO_6$: 347.1368; found (high resolution ms): 347.1382.

Zinc Reduction of Berberidic Acid Dimethyl Ester

Diester chloride **3** (500 mg, 1.3 mmol) was dissolved in concentrated HCl (10 mL) and warmed to 60°C. Zinc dust (2 g) was added slowly and the mixture stirred for 2 h around 60°C. The product was cooled and basified with cold NH_4OH. Extraction with $CHCl_3$ left a dark residue which was purified by tlc using 4% MeOH in $CHCl_3$, R_f 0.37, to provide **12** as an oil; λ_{max} (EtOH): 292 nm (log ε 3.51); ^{1}Hmr ($CDCl_3$) δ: 1.62 (6H, s, CH_3), 5.75 (2H, s, OCH_2O), 6.42 (1H, s, H-8) and 6.53 (1H, s, H-11). *Exact Mass* calcd. for $C_{16}H_{19}NO_2$: 257.1415; found (high resolution ms): 257.1415.

*Salt **13***

A mixture of amine **12** (50 mg, 0.2 mmol), 20% HOAc (10 mL), and $Hg(OAc)_2$ (270 mg, 0.8 mmol) was heated for 16 h on a steam bath. The mixture was filtered while hot and then treated with $(NH_4)_2S$ solution. The suspension was heated on a steam bath for 1 h and the precipitate filtered off through Celite. The resulting solution was treated with KI solution and extracted with $CHCl_3$. Evaporation of the solvent and tlc using 40% MeOH in $CHCl_3$ provided a major band, R_f 0.41, which furnished amorphous salt **13** as the iodide (30 mg, 40%); λ_{max} (EtOH): 267 and 355 nm (log ε 3.54 and 3.42).

Three milligrams of **13** was reduced with excess $NaBH_4$ in MeOH to afford **12** in near quantitative yield.

*Lactone **14***

Lactone **6** (500 mg, 1.8 mmol) was dissolved in methanolic HCl and the solution evaporated to dryness. The residue was dissolved in EtOH and hydrogenated over Adams' catalyst for 8 h. Work-up supplied lactone **14** (500 mg, ≈100%); mp 216°C (MeOH); λ_{max} (EtOH): 290 nm (log ε 3.61); ^{1}Hmr ($CDCl_3$) δ: 3.88–4.37 (2H, m, CH_2OCO), 5.87 (2H, s, OCH_2O), 6.52 (1H, s, H-8) and 6.60 (1H, s, H-11). *Exact Mass* calcd. for $C_{16}H_{17}NO_4$: 287.1157; found (high resolution ms): 287.1149.

*$LiAlH_4$ Reduction of **6***

Lactone **6** (150 mg, 0.5 mmol) was refluxed in dry THF (30 mL) containing $LiAlH_4$ (40 mg, 1.1 mmol) for 1 h under N_2. Thin-layer chromatography of the product mixture showed two major spots (10% MeOH in $CHCl_3$). The band with R_f 0.58 furnished hemiacetal **17** (43 mg, 28%); mp 156–158°C (MeOH); λ_{max} (EtOH): 290 nm (log ε 3.72); ^{1}Hmr

($CDCl_3$) δ: 3.82 (2H, m, CH_2OCHOH), 5.42 (1H, d, J = 6 Hz, $OCHOH$), 5.87 (2H, s, OCH_2O), 6.50 (1H, s, H-8), and 6.60 (1H, s, H-11). *Exact Mass* calcd. for $C_{16}H_{19}NO_4$: 289.1313; found (high resolution ms): 289.1319.

The band with R_f 0.33 yielded diol **15** (46 mg, 30%), mp 173–176°C (MeOH); λ_{max} (EtOH): 290 nm (log ε 3.85); ν_{max} ($CHCl_3$): 2775, 2820 and 3330 cm^{-1}. *Exact Mass* calcd. for $C_{16}H_{21}NO_4$: 291.1470; found (high resolution ms): 291.1450.

*$LiAlH_4$ Reduction of Lactone **14***

Compound **14** (100 mg, 0.35 mmol) was reduced with $LiAlH_4$ (26 mg, 0.7 mmol) in THF. Work-up supplied diol **15** (61 mg, 60%).

*$LiAlH_4$ Reduction of Diester **10***

Compound **10** (100 mg, 0.29 mmol) was reduced with $LiAlH_4$ (22 mg, 0.58 mmol) in THF to supply diol **15** (65 mg, 77%).

*Diol **16***

A few milligrams of diester **11** were reduced with excess $LiAlH_4$ in THF. Work-up provided colorless crystals of **16**, R_f 0.1 (10% MeOH in $CHCl_3$); mp 248–251°C (MeOH); ms *m/e*: 291 (30) $(M)^+$, 290 (60) $(M - H)^+$, 260 (50), 232 (30), and 175 (base). *Exact Mass* calcd. for $C_{16}H_{21}NO_4$: 291.1470; found (high resolution ms): 291.1461.

*Lactone **18***

Unsaturated lactone **8** (100 mg, 0.35 mmol) was hydrogenated with Adams' catalyst in EtOH. Work-up provided **18** (100 mg, ≈100%); mp 217–218°C (MeOH); λ_{max} (EtOH): 292 (log ε 3.53); ^{1}Hmr ($CDCl_3$) δ 3.88–4.38 (2H, m, CH_2OCO), 5.90 (2H, s, OCH_2O), 6.54 (1H, s, H-8), and 6.77 (1H, s, H-11). *Exact Mass* calcd. for $C_{16}H_{17}NO_4$: 287.1156; found (high resolution ms): 287.1108.

*$LiAlH_4$ Reduction of Lactones **8** and **18***

Ten milligrams of each of lactones **8** and **18** were reduced separately using excess $LiAlH_4$ in THF. The product was purified by tlc using 10% MeOH in $CHCl_3$ to provide in each case a major band (R_f 0.1) which proved to be diol **16**.

^{13}C nuclear magnetic resonance spectra of some C_{19}-diterpenoid alkaloids and their derivatives[1]

S. William Pelletier, Naresh V. Mody, and Rajinder S. Sawhney

Institute for Natural Products Research and the Department of Chemistry, University of Georgia, Athens, GA 30602, U.S.A.

Received December 15, 1978

S. William Pelletier, Naresh V. Mody, and Rajinder S. Sawhney. Can. J. Chem. **57**, 1652 (1979).

The natural abundance carbon-13 nuclear magnetic resonance spectra of some C_{19}-diterpenoid alkaloids and their alkamines (lappaconitine, lappaconine, lapaconidine, ranaconine, 14-dehydrobrowniine, aconine, pseudoaconine, deoxyaconine, and hypaconine) have been determined at 15.03 MHz. With the aid of proton decoupling techniques, additivity relationships, and comparison with spectra of related alkaloids, self-consistent and unambiguous assignments of nearly all carbon resonances for these alkaloids have been made. Some important chemical shift trends have been observed, which are useful for identifying the basic C_{19}-diterpenoid alkaloid skeleton and the hydroxy and methoxy group substitution patterns in these alkaloids. On the basis of ^{13}C nmr spectra of lappaconitine and lappaconine, the anthranoyl ester moiety is assigned to the C-4 position in lappaconitine. The ^{13}C nmr spectra of lapaconidine, aconine, and pseudoaconine taken in pyridine and chloroform have been compared to determine the conformational changes of the ring A hydroxy groups in these alkaloids.

S. William Pelletier, Naresh V. Mody et Rajinder S. Sawhney. Can. J. Chem. **57**, 1652 (1979).

Opérant à 15.03 MHz, on a déterminé les spectres rmn du ^{13}C en abondance naturelle de quelques alcaloïdes diterpènoïdes en C_{19} et de leurs alkylamines (lappaconitine, lappaconine, lapaconidine, ranaconine, déhydro-14 browniine, aconine, pseudoaconine, déoxyaconine et hypaconine). Faisant appel aux techniques de découplage des protons, à des règles d'addition et à des comparaisons avec les spectres d'alcaloïdes apparentés, on a pu proposer des attributions autocohérentes et non ambigües de pratiquement toutes les résonances de carbones de ces alcaloïdes. On a observé quelques tendances importantes des déplacements chimiques qui sont utiles pour identifier le squelette fondamental des alcaloïdes diterpénoïdes en C_{19} ainsi que la disposition des groupes hydroxyles et méthoxyles attachés à ce squelette. En se basant sur les spectres rmn du ^{13}C de la lappaconitine et de la lappaconine, on attribue la position ester anthranoyle à la position C-4 de la lappaconitine. On a comparé les spectres rmn du ^{13}C de la lapaconidine, de l'aconine et de la pseudoaconine, déterminées en solution dans la pyridine et le chloroforme, pour évaluer les changements conformationnels du groupe hydroxyle attaché au cycle A de ces alcaloïdes.

[Traduit par le journal]

Introduction

During the last 10 years, investigators have made extensive use of carbon-13 nmr spectroscopy in the structure elucidation of natural products. This technique has played an important role in solving problems which otherwise would be very difficult, e.g., determination of the existence of C-20 epimers in atisine and related alkaloids (1). Carbon-13 nmr spectra provide detailed information about the degree and sites of oxygen substitution in the basic skeleton of diterpenoid alkaloids.

Jones and Benn (2) were the first to apply carbon-13 nmr spectroscopy to a study of the C_{19}-diterpenoid alkaloids. Later we reported a comprehensive ^{13}C nmr study of more than 50 aconitine- and lycoctonine-type alkaloids and their derivatives (3, 4). Using these data, we have revised and elucidated the structures of several complex C_{19}-diterpenoid alkaloids (3–5). We present here an analysis of the ^{13}C nmr spectra of additional alkaloids and alkamines. We anticipate that these data will be of use in the structure elucidation of newly isolated alkaloids from various *Aconitum*, *Consolida*, and *Delphinium* species.

Results and Discussion

The general procedure for ^{13}C nmr data acquisition and assignment of the carbon resonances for the compounds reported here involved determination of the noise-decoupled and the single-frequency off-resonance decoupled (SFORD) spectra. The carbon resonances were assigned with the aid of the single-frequency proton off-resonance decoupling techniques, direct analysis of nonprotonated carbon centers, application of known chemical shift rules

[a]Chemical shifts in ppm downfield from TMS; solvent is deuteriochloroform unless otherwise mentioned.
[b]The ^{13}C chemical shifts and assignments of the anthranoyl ester group in lappaconitine are shown separately on structure **1**.
[c]Spectra were taken in pyridine-d_5.
[d]Values given for primed carbons refer to chemical shifts for methoxyls.

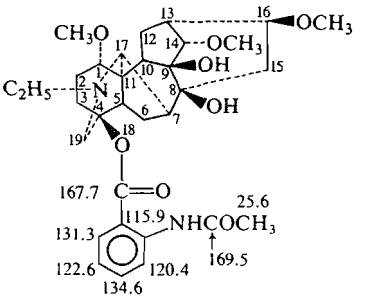
for hydroxyl substitution, esterification shifts, steric effects, and from comparisons of spectra from compound to compound (6).

Assignments for Lappaconitine (1), Lappaconine (2), Lapaconidine (3), and Ranaconine (4)

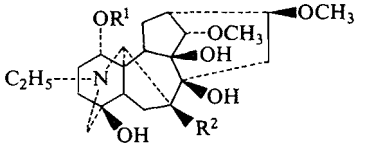
During a reinvestigation of the alkaloids present in the roots of *Aconitum septentrionale* Koelle, we isolated the previously reported alkaloids lappaconitine (**1**) and lapaconidine (**3**). Basic hydrolysis of lappaconitine afforded the parent alkamine, lappaconine (**2**), and *N*-acetylanthranilic acid. On the basis of extensive chemical studies, Marion and co-workers (7) assigned structure **2** for lappaconine, which was confirmed by an X-ray analysis of lappaconine hydrobromide (8). Subsequently Soviet workers assigned the *N*-acetylanthranilic ester moiety to the C-4 position in lappaconitine (9). We have confirmed this assignment by the ^{13}C nmr spectral analyses of lappaconitine and lappaconine as discussed below.

The ^{13}C chemical shifts and assignments for lappaconitine (**1**), lappaconine (**2**), lapaconidine (**3**), and ranaconine (**4**) are reported in Table 1. The chemical shift assignments for these alkaloids were made by correlation with previously published ^{13}C nmr spectra of a variety of model *Aconitum* and *Delphinium* alkaloids (3, 4). The presence of the *N*-acetylanthranilic acid moiety in lappaconitine was confirmed by a comparison of observed resonances in **1** with the values observed for methyl anthranilate. The chemical shifts of compounds **1** and **2** are in agreement with their respective structures. Comparison of the spectrum of lappaconine (**2**) with that of lappaconitine (**1**) revealed the absence in lappaconine of chemical shifts due to the *N*-acetylanthranoyl ester group, a major change in the chemical shift of C-4, and some minor changes in the chemical shifts of C-3, C-5, and C-19. These results lead to the conclusion that the ester group is present at the C-4 position in lappaconitine. The spectrum of lapaconidine (**3**), when compared with lappaconine (**2**), reveals the presence of a hydroxyl group at C-1 in the α-configuration (see discussion on conformation of ring A). The ^{13}C chemical shifts of lapaconidine are in agreement with the structure (**3**) reported by Yunusov and his co-workers (10).

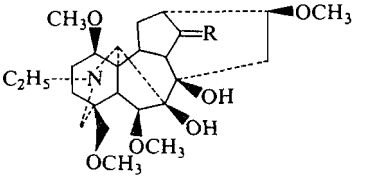
Recently, we have elucidated the structure of the highly oxygenated alkaloid, ranaconitine, by the help of ^{13}C nmr spectroscopy (11). We report here the



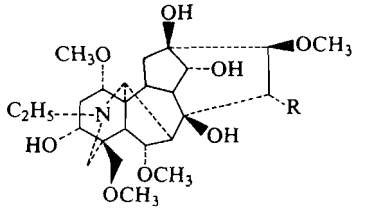
1 Lappaconitine



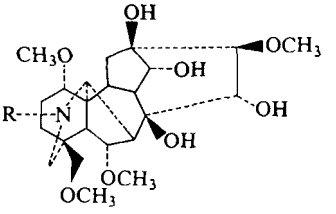
2 $R^1 = CH_3$; $R^2 = H$ Lappaconine
3 $R^1 = R^2 = H$ Lapaconidine
4 $R^1 = CH_3$; $R^2 = OH$ Ranaconine



5 R = O 14-Dehydrobrowniine
6 R =  Browniine



7 R = OH Aconine
8 R = H Pseudoaconine



9 $R = C_2H_5$ Deoxyaconine
10 $R = CH_3$ Hypaconine

chemical shifts of ranaconine (**4**), the parent alkamine of ranaconitine. Comparison of the spectrum of ranaconine with that of lappaconine (**2**) revealed the presence of an additional quaternary carbon singlet at 78 ppm and the absence of a methine carbon doublet, results which indicate the presence of an extra tertiary hydroxyl group in ranaconine. The downfield shift of the C-6, C-8, and C-17 carbon resonances in ranaconine in comparison with lappaconine indicated the presence of an extra tertiary hydroxyl group at C-7. The ^{13}C nmr data of bases **1–4** indicate the structural similarity within this group of alkaloids. These examples demonstrate the usefulness of ^{13}C nmr spectroscopy in determining the structures of newly isolated alkaloids without tedious chemical work.

Assignments for 14-Dehydrobrowniine (5)

In 1966 Benn (12) isolated a known derivative of browniine, 14-dehydrobrowniine (**5**), as a natural product from *Delphinium cardinale*. We have prepared alkaloid **5** from browniine (**6**) to examine its ^{13}C nmr spectrum and to make a comparison with browniine. A downfield singlet at 216.3 ppm in alkaloid **5** indicates the presence of the carbonyl group at the C-14 position. The presence of the C-14 carbonyl group in **5** moved the chemical shifts of C-8, C-9, C-10, C-11, C-12, C-13, and C-16 significantly downfield in comparison with browniine. These shifts are a result of the disappearance of the 1,3-diaxial interactions of the C-14 α-hydroxyl with the C-16 β-methoxyl and the C-8 hydroxyl when browniine is transformed to ketone **5**.

Assignments for Aconine (7), Pseudoaconine (8), Deoxyaconine (9), and Hypaconine (10)

Alkamines **7** to **10** were prepared by published procedures (13). The chemical shift assignments for alkamines **7** to **10** were made by correlation with previously published ^{13}C nmr spectra of the corresponding naturally occurring alkaloids (3). The absence of C-3 and C-15 secondary hydroxyl groups in deoxyaconine (**9**) and pseudoaconine (**8**), respectively, greatly facilitated the unambiguous assignments of ^{13}C chemical shifts in aconine (**7**). The patterns of ^{13}C chemical shifts in these alkamines are very similar. Comparison of the spectra of the alkamines revealed precise information for identifying the basic C_{19}-diterpenoid alkaloid skeleton and the hydroxy and methoxy groups substitution pattern in these alkaloids.

Thus, the presence of a hydroxyl group at C-15 in

aconine (**7**) deoxyaconine (**9**), and hypaconine (**10**) was detected by observing the downfield shift of the C-8 (~3.5 ppm) and C-16 (~8 ppm) resonances in comparison with pseudoaconine (**8**). A doublet at ~91 ppm in the SFORD spectra of the alkamines of the aconitine-type alkaloids is characteristic of the presence of a hydroxy group in the α-configuration at the C-15 position when the methoxyl group is present at C-16 in the β-configuration. A secondary hydroxy group at C-3 can be easily detected in aconine (**7**) and pseudoaconine (**8**) by observing the presence of a doublet at ~72 ppm and a downfield singlet of C-4 at ~43 ppm in comparison with alkamines without a C-3 hydroxy group, e.g., deoxyaconine (**9**) and hypaconine (**10**). Alkaloids with a $-CH_2OCH_3$ group at C-4 and with H at C-3, are characterized by a singlet between 38–39 ppm, e.g., 14-dehydrobrowniine (**5**), browniine (**6**), and deoxyaconine (**9**).

Conformation of Ring A in Lapaconidine, Aconine, and Pseudoaconine

It is known that in C_{19}-diterpenoid alkaloids containing $-CH_2OCH_3$ at C-4, ring A bearing a C-1 α-hydroxy *or* a C-3 α-hydroxy group exists in a boat conformation (3). Ring A is in the chair conformation in the cases where the C-1 α-substituent is acetoxyl *or* methoxyl, *or* in the case where the C-1 substituent is in the β-configuration (3). On the basis of ^{13}C nmr data from several alkaloids containing C-1 α- and β-hydroxyl groups, we observed that the resonance of C-1 bearing an α-hydroxyl group appears at ~72 ppm (e.g., neoline, neoline 8-acetate, delphisine, condelphine, isotalatizidine), whereas the resonance of C-1 bearing a β-hydroxyl group appears at ~69 ppm (1-*epi*-delphisine, 1-*epi*-neoline). The orientation of the C-1 hydroxyl also affected the chemical shifts of other carbons in ring A.

From these observations, we postulated that the C-1 α-hydroxyl group forms a hydrogen bond with the lone-pair electrons of the nitrogen and thus stabilizes ring A in a boat form (3). However, when the C-1 hydroxyl is in the β-configuration, the hydroxyl group is not available to form a hydrogen bond with the lone-pair electrons of nitrogen and thus ring A remains in a chair conformation. This idea prompted us to investigate the behavior in chloroform and pyridine of ring A in lapaconidine (**3**), aconine (**7**), and pseudoaconine (**8**), bases which contain the C-1 or C-3 α-hydroxyl group.

The spectra of lapaconidine (**3**) taken in chloroform and pyridine were almost identical. No significant differences in their chemical shifts other than normal solvent effects were observed. But it is interesting to note that the ^{13}C nmr spectra of aconine (**7**) and pseudoaconine (**8**) taken in chloroform and pyridine were significantly different in the chemical shifts at C-2, C-3, and C-4 (Table 1). This observation suggests that in pyridine the C-3 α-hydroxyl group forms a hydrogen bond with the solvent instead of with the lone-pair electrons of nitrogen and thus hydrogen bond formation between the C-3 α-hydroxyl group and pyridine stabilizes ring A in a chair conformation. In contrast, in chloroform solution, ring A exists in the boat conformation.

Experimental

Carbon-13 nmr spectra were determined at 15.03 MHz in the Fourier mode using an FX-60 spectrometer in conjunction with a JEC-980 computer. The spectra were determined at 30°C in deuteriochloroform solutions (which also provided the lock signal) with 5% tetramethylsilane as internal reference. Samples were contained in precision ground 5 mm o.d. tubes. The spectrometer was used in the crosscoil configuration. On the average a 5μs pulse, corresponding to an approximate tilt angle of 45°, was employed. For the average spectral width of 4000 Hz, the delay between pulses was 2 s. Acquisition times averaged 1–2 h over 8 K data points for concentrations of the order of 0.4–1.0 *M*. For off-resonance spectra this time was 5–10 h.

The alkaloids and their derivatives used here were isolated and/or synthesized by procedures given in the literature cited.

Aliphatic diazo compounds. XII. The synthesis of 5-*endo*-hetero-atom-substituted 3-diazo-2-norbornanones and the proton magnetic resonance spectra of these diazo ketones and their precursors[1,2]

PETER YATES AND GORDON F. HAMBLY[3]

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 30, 1978

PETER YATES and GORDON F. HAMBLY. Can. J. Chem. 57, 1656 (1979).

Treatment of 6-*endo*-acetoxy-5,5-dimethyl-2,3-norbornanedione (**6**) with tosylhydrazine gives the 2-tosylhydrazone (**7**), which is converted to 5-*endo*-acetoxy-3-diazo-6,6-dimethyl-2-norbornanone (**1**) by basic alumina; the exclusive formation of the 2-tosylhydrazone is ascribed to the smaller steric effect of the *endo* C-6 acetoxyl relative to the *endo* C-5 methyl group. The 6-*endo*-methoxy analogue of **6**, **17**, and the related 6-*endo*-chloro- and 6-*endo*-bromo-1,5,5-trimethyl-2,3-norbornanediones (**23** and **26**) are similarly converted to the corresponding α-diazo ketones **2–4**. The ^{1}H nmr spectra of the diazo ketones **1–4** have their C-1 bridgehead proton signals shifted to higher field relative to the corresponding bridgehead proton signals of the related α-diketones, whereas the C-4 bridgehead proton signals of **1** and **2** are shifted to lower field in relation to the corresponding α-diketone signals. The ^{1}H nmr spectra of the α-diketones show an unusual long range coupling ($^4J \geq 1$ Hz) between the C-4 bridgehead protons and the *exo* C-6 protons that is significantly smaller or absent in the spectra of the related diazo ketones and monoketones. In all of these types of compound an *endo*-methoxyl or -acetoxyl group at C-5(6) shifts the *exo* and *endo* C-6(5) methyl signals to lower and higher field, respectively, whereas an *endo*-halo substituent at C-5(6) shifts both the *exo* and *endo* C-6(5) methyl signals to lower field.

PETER YATES et GORDON F. HAMBLY. Can. J. Chem. 57, 1656 (1979).

La réaction de l'acétoxy-6-*endo* diméthyl-5,5 norbornanedione-2,3 (**6**) avec de la tosylhydrazine conduit à la tosylhydrazone-2 (**7**) qui est transformée en acétoxy-5-*endo* diazo-3 diméthyl-6,6 norbornanone-2 (**1**) par de l'alumine basique; la formation exclusive de la tosylhydrazone-2 est attribuée à l'effet stérique plus faible de l'acétoxyle *endo* en C-6 par rapport au groupe méthyle *endo* en C-5. L'analogue méthoxy-6-*endo* de **6**, **17**, et les chloro-6-*endo* et bromo-6-*endo* triméthyl-1,5,5 norbornanediones-2,3 (**23** et **26**) qui leur sont apparentées sont transformées d'une manière semblable en α-diazo cétones correspondantes (**2–4**). Dans les spectres rmn du ^{1}H, les signaux des protons portés par le carbone de pont C-1 des diazo cétones **1–4** sont déplacés à des champs plus élevés par rapport aux signaux des protons correspondants des α-dicétones auxquelles elles sont reliées; toutefois les signaux des protons portés par le carbone de pont C-4 de **1** et de **2** sont déplacés vers un champ plus bas par rapport aux signaux des α-dicétones correspondantes. Dans le spectre rmn du ^{1}H des α-dicétones, on observe une constante de couplage à longue distance ($^4J \geq 1$ Hz) entre les protons portés par l'atome de pont C-4 et les protons *exo* en C-6 qui est inhabituelle et qui est beaucoup plus faible ou absente dans le spectre des diazo cétones et monocétones apparentées. Dans tous ces types de composés les groupes méthoxyle ou acétoxyle *endo* en C-5(6) déplacent les signaux des groupes méthyles *exo* et *endo* en C-6(5) respectivement vers des champs plus faibles et plus élevés alors qu'un halogène *endo* en C-5(6) déplace les signaux des méthyles *exo* et *endo* en C-6(5) vers des champs plus faibles.

[Traduit par le journal]

In connection with our studies on the copper-catalyzed decomposition of α-diazo ketones (1–5), we wished to examine the copper-catalyzed decomposition of 3-diazo-2-norbornanones that possess an *endo* carbon – hetero atom bond at C-5. We describe here the synthesis of the diazo ketones **1–4**, prepared for this purpose, and discuss the ^{1}H nmr spectra of the diazo ketones and their precursors, which showed features of intrinsic interest in addition to providing evidence for the structural assignments. The investigation of the copper-catalyzed decomposition of the diazo ketones is described in the following paper (6).

Synthesis of the α-Diazo Ketones

Some years ago Meinwald *et al.* (7) reported the synthesis by the route shown in Scheme 1 of an α-diazo ketone that was either **1** or **5**. For their

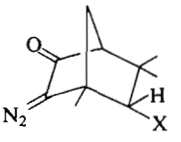
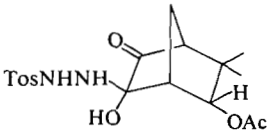
1 X = OAc
2 X = OMe



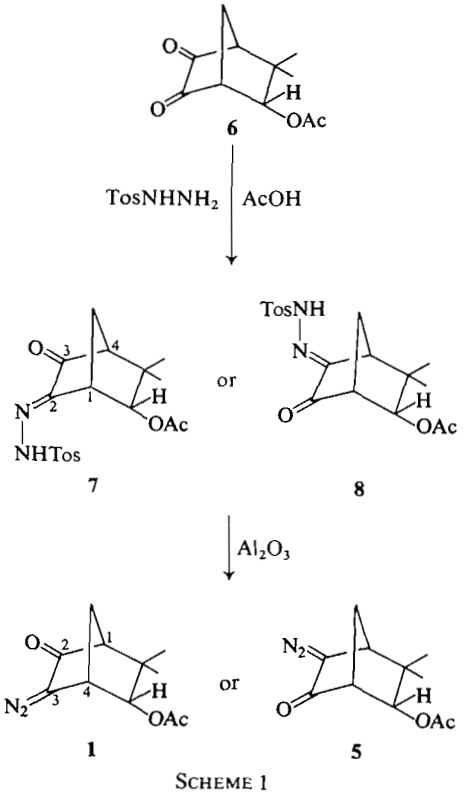
3 X = Cl
4 X = Br

purpose, which was its photochemical Wolff rearrangement, it was immaterial which of these two structures the diazo ketone possessed. For our purpose it was necessary that it be **1**, which seemed to us to be the more likely structure, and we have now established this to be the case. The basis of our optimism was the knowledge that the conformational free energy difference for an axial and an equatorial methyl group on a cyclohexane ring is ca. 1.0 kcal/mol greater than that in the case of an acetoxyl group (8). Thus the steric crowding between the *endo*-hydroxyl group and the *endo*-methyl group in **10** should be appreciably more severe than that between the *endo*-hydroxyl group and the *endo* acetoxyl group in **9**. The known high propensity for 2-norbornanones lacking a 7-*syn*-methyl substituent to undergo *exo* nucleophilic attack at the carbonyl group (9) and the circumstance that the rate-determining step in hydrazone formation under acidic conditions is the formation of the intermediate adduct (10) makes it likely that **9** and **10** will be the intermediates for the formation of **7** and **8**, respectively, and that their relative rates of formation will determine the relative rates of formation of the latter. Thus the single monotosylhydrazone reported to be formed from **6** may be anticipated to be **7** and the derived diazo ketone to be **1**.[4,5]

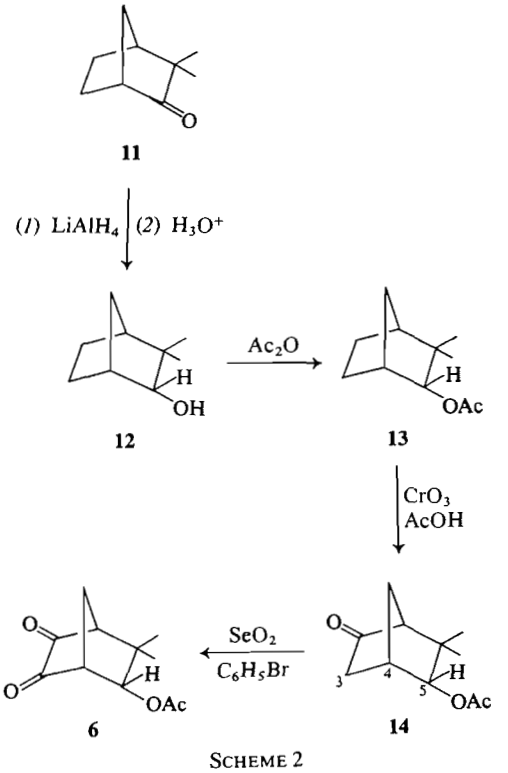


9 10

The dione **6** was prepared from *dl*-camphenilone (**11**) as previously reported (7) (Scheme 2). The product isolated from the chromic acid oxidation of **13** was earlier tentatively formulated as the 5-acetoxy-2-norbornanone **14** on the reasonable grounds of analogy with the similar oxidation of bornyl acetate to the corresponding acetoxy ketone (12). The fact that the oxidation product of **13** shows in its ^{1}H nmr



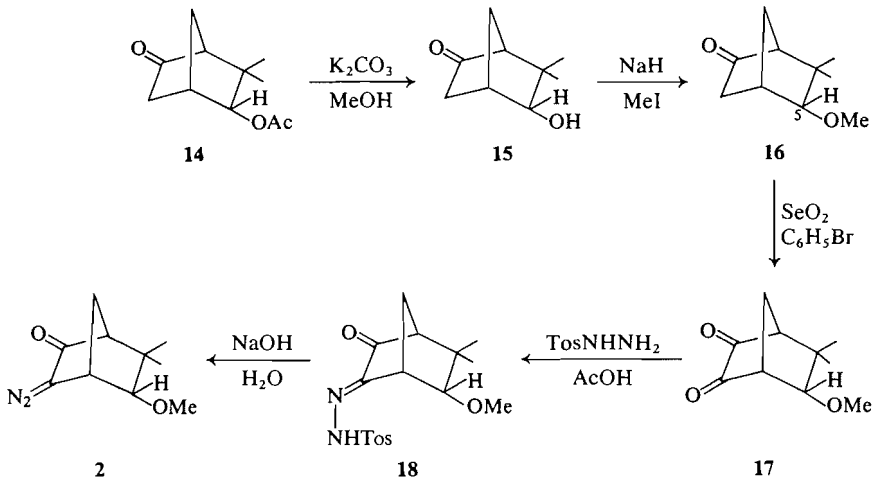
SCHEME 1



SCHEME 2

[4]For a related difference in reactivity, see ref. 11.

[5]Polar and hydrogen-bonding effects, to the extent that they are operative, would also be expected to favor formation of **7**.



SCHEME 3

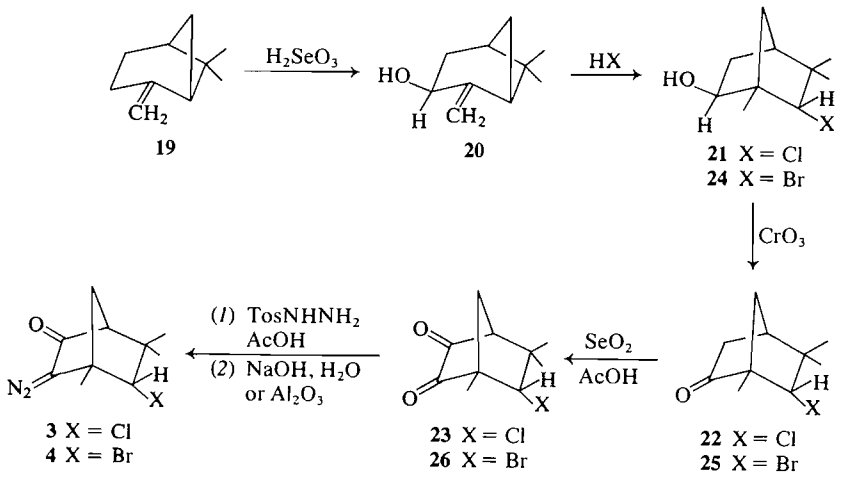
spectrum a doublet of doublets at δ 4.89 (J = 4.2, 1.0 Hz), demonstrating that the *exo* C-5 proton is coupled both with the C-4 proton and the *exo* C-3 proton (*vide infra*), excludes the alternative 6-acetoxy-2-norbornanone structure and confirms the assignment to it of structure **14**. Selenium dioxide oxidation of **14** to **6** was found to give considerably better yields when carried out in bromobenzene rather than the acetic anhydride used as solvent previously.

Treatment of **6** with slightly more than 1 equiv. of tosylhydrazine in acetic acid gave a single monotosylhydrazone that is assigned structure **7** rather than **8**, on the following grounds. Although the acetoxyl methyl proton chemical shifts in the ^{1}H nmr spectra of **6**, **13**, and **14** are normal (δ 2.02–2.07), that of the monotosylhydrazone is at abnormally high field (δ 1.79). This can be attributed to shielding of the acetoxyl methyl group by the aromatic ring of the tosylhydrazone residue, which must therefore be located at C-2 as in **7**. This assignment was confirmed and also the structure of the diazo ketone formed by chromatography of the monotosylhydrazone on basic alumina was established as **1** rather than **5** by the observation that in the ^{1}H nmr spectrum of the diazo ketone the signal of the bridgehead proton adjacent to the diazo group is shifted downfield by 0.3 ppm relative to the corresponding signal in the spectrum of the dione **6**, whereas the signal of the bridgehead proton adjacent to the carbonyl group is shifted upfield by 0.4 ppm relative to the corresponding signal for **6**. We have found that in the spectra of 3-diazo-2-norbornanones in general the signal due to the bridgehead proton at C-4 is shifted downfield and that of the bridgehead proton at C-1 upfield relative to their respective chemical shifts in the corresponding 2,3-norbornanediones (*vide infra*). The bridgehead protons adjacent to the acetoxyl group and the *gem*-dimethyl group in the diazo ketone derived from **6** must therefore be adjacent to the diazo and carbonyl groups, respectively, establishing its structure as **1**.

The diazo ketone **2** was also prepared from the acetoxy ketone **14** by the route shown in Scheme 3. Hydrolysis with methanolic aqueous potassium carbonate gave the hydroxy ketone **15**. Methylation of **15** gave the methyl ether **16**, which like **14** and **15** showed the C-5 proton signal in its ^{1}H nmr spectrum as a doublet of doublets with $J \sim 4$ and 1 Hz.

The selenium dioxide oxidation of **16** to **17** proved to be unexpectedly difficult. Initial experiments were carried out with crude methoxy ketone **16** that contained hydroxy ketone **15** as the major impurity. When treatment with selenium dioxide was carried out in boiling acetic anhydride, no reaction other than acetylation of **15** to **14** occurred. But subsequent treatment of the reaction mixture, after removal of the acetic anhydride, in bromobenzene with selenium dioxide gave **17** in 70% yield based on the amount of **16** in the mixture. However, repetition of the oxidation with pure **16** in bromobenzene failed to give **17**. Deliberate addition of **14** did result in oxidation of **16** to **17** by selenium dioxide in bromobenzene, albeit in low yield. It is possible that the active species responsible for the oxidation of **16** is a Se(II) compound generated in the oxidation of **14**.

Conversion of **17** to the monotosylhydrazone **18**, followed by treatment with 0.3 N aqueous sodium hydroxide (13) gave the diazo ketone **2**. The structure of **2** was established by the correspondence in the relationship between its ^{1}H nmr spectrum and that of its α-diketone precursor **17** with that between the spectra of **1** and **6** (*vide supra*). Corroboration for the



SCHEME 4

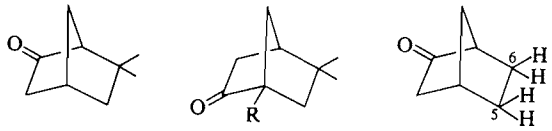
structural assignment derives from an alternative, but less efficient, synthesis of **2** from **16** via hydroxymethylenation followed by treatment with *p*-carboxybenzenesulfonyl azide and triethylamine (14, 15). It was expected that the monotosylhydrazone formed from **17** would be **18**, and thus that the diazo ketone would be **2**, on the basis of the considerations discussed earlier and the fact that the conformational free energy difference between an axial and an equatorial methoxyl group on a cyclohexane ring is, like that of an acetoxyl group, ca. 1 kcal/mol less than that of a methyl group (8).

The chloro diazo ketone **3** was prepared from (−)-β-pinene (**19**) by the route shown in Scheme 4. Oxidation of **19** with selenous acid gave *trans*-pinocarveol (**20**) (16), which on treatment with hydrogen chloride gave **21**. Although a different structure was originally assigned to this product (16), it is clear from subsequent work on the action of hydrogen bromide on **20** (17, 18) that the hydrogen chloride adduct has structure **21**. This structural assignment is confirmed by the ^{1}H nmr spectra of the hydrogen chloride adduct and its chromic acid oxidation product **22** and by the ir spectrum of the latter (see Experimental). Selenium dioxide oxidation of **22** in acetic acid gave **23** in modest yield, which could probably be improved by the use of bromobenzene as solvent. Conversion of **23** to a monotosylhydrazone followed by treatment with aqueous sodium hydroxide gave the diazo ketone **3**, whose structure was again established by the correspondence in the relationship between its ^{1}H nmr spectrum and that of its α-diketone precursor **23** with that between the spectra of **1** and **6**.

The bromo diazo ketone **4** was prepared from (−)-β-pinene (**19**) via **24**–**26** in analogous fashion. Treatment of the monotosylhydrazone with aqueous sodium hydroxide gave impure **4** in low yield, perhaps because bromide ion is a better leaving group than chloride ion in S_N2 reactions. Under the milder conditions of chromatography of the tosylhydrazone on basic alumina (7), **4** was produced in good yield.

Spectra of the α-Diazo Ketones and their Precursors

Salient ir bands and the ^{1}H nmr signals of the 5- and 6-hetero-atom-substituted 2-norbornanones are given in Tables 1 and 2, together with corresponding data (19) for the parent 6,6-dimethyl-2-norbornanone (**27**) and isofenchone (**28**).



27 **28** R = Me, **30** R = H **29**

It is well known that in the ^{1}H nmr spectra of both norbornane and norbornene the *endo* protons are shielded relative to the *exo* protons (20, 21), and in an exhaustive study of the ^{1}H nmr spectrum of 2-norbornanone (**29**) Marshall and Walter (22) have shown that the same is true of the *endo* and *exo* protons at each of C-5 and C-6. Furthermore, the methyl signals of 6-*endo*-methyl-2-norbornanone and 6-*exo*-methyl-2-norbornanone occur at δ 0.93 (23) and 1.04 (24), respectively. It is thus reasonable to assign the methyl signals at δ 1.02 and 1.12 in the spectrum of **27** to the *endo* and *exo* methyl groups, respectively. Introduction of an *endo* C-5 oxygen substituent in **15**, **16**, and **14** leads to a greater separation of the methyl signals, which can be interpreted as resulting from an upfield shift of the *endo* methyl signals in all cases and a downfield shift of

the *exo* methyl signals in the case of the methoxy and acetoxy compounds. Related effects of hydroxy (25) and acetoxy (26) substitution in the norbornane series have been observed previously; the effect of hydroxy substitution has been attributed to the anisotropic effect of the C—O bond (25). The methyl signals at δ 1.03, 1.12, and 1.17 in the spectrum of **28** can be assigned to the *endo* C-5, *exo* C-5, and C-1 methyl groups, respectively, on the basis of comparison with the methyl signals at δ 1.03 and 1.12 in the spectrum of 5,5-dimethyl-2-norbornanone (**30**) (19) and of the relationship of the *endo* and *exo* C-5 proton signals in the spectrum of **29** referred to above. Introduction of the C-6 chlorine atom in **22** shifts the methyl signals to δ 1.12, 1.20, and 1.30. Comparison of the chemical shifts of the methyl protons in the spectra of the four stereoisomeric 5-chloro-6-methylnorbornenes (27) with those of the methyl protons in the spectra of 5-*exo*-methyl- and 5-*endo*-methylnorbornene (28) shows that the introduction of either a *cis* or *trans* chlorine atom adjacent to the methyl groups of the latter compounds results in a downfield shift, which is greater in the *trans* case. On this basis the signals of **22** at δ 1.12, 1.20, and 1.30 are assigned to the *endo* C-5, C-1, and *exo* C-5 methyl groups, respectively. The methyl signals of the corresponding bromo compound **25**, are assigned as in Table 2 by analogy.

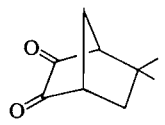
[a]The relative intensities of the ^1H nmr signals are in accord with the assignments.
[b]Also includes H-6 signals.
[c]Overlapping signals.

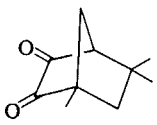
The interesting observation has been made (22, 29) that the C-4 proton signal of **29** (δ 2.61) appears at lower field than the C-1 signal (δ 2.41). The spectra of compounds **27**, **15**, **16**, and **14** all show a one-proton multiplet in the region δ 2.6–2.8 and this is therefore assigned to the C-4 proton in each case. The downfield shift of this signal in the spectra of the last three compounds relative to its position in the spectra of **27** and **29** is attributable to the presence of the electron-withdrawing *endo* C-5 oxygen substituents. No individual signals could be assigned to the C-1 protons of compounds **27**, **15**, **16**, and **14** because of overlap with signals arising from the C-3 and/or C-7 protons (and C-5 protons in the case of **27**).

It remains to discuss the signals of the *exo* C-5 and *exo* C-6 protons in the spectra of **15**, **16**, and **14** and of **22** and **25**, respectively. As expected these are the lowest-field signals in each spectrum, occurring at δ 3.4–4.9. In the former group of compounds these signals appear as doublets of doublets. First-order analysis in terms of an AMX system gives values of $J \sim 4$ and 1 Hz for the coupling constants.[6] These can be ascribed to coupling of the C-5 proton with the C-4 and *exo* C-3 protons, respectively (25, 30–34). As expected in terms of this interpretation of the coupling of the C-5 protons in **15**, **16**, and **14**, the *exo* C-6 proton signals of **22** and **25** appear as singlets.

The strong ir bands and the ^1H nmr signals of the C-6 hetero-atom-substituted 2,3-norbornanediones are given in Tables 3 and 4, together with corresponding data (19) for the parent 5,5-dimethyl-2,3-norbornanedione (**31**) and isofenchoquinone (**32**).



31



32

The methyl signals in the ^1H nmr spectrum of **31** at δ 1.07 and 1.27 can be assigned to the *endo* and *exo* methyl groups, respectively, on the basis of considerations similar to those invoked in the assignment of the methyl signals for **27**. As in the case of the latter, introduction of an *endo* methoxy or *endo* acetoxy substituent on the methylene carbon adjacent to the carbon bearing the geminal methyl groups, as in **17** and **6**, leads to an increase in the chemical shift difference between the geminal-methyl protons that can be interpreted as resulting from an upfield shift of the *endo* methyl signal and a downfield shift of the *exo* methyl signal. Similarly, the signals of **32**, at δ 1.03 (3H) and 1.28 (6H) can be assigned to the *endo* C-5 methyl group and a combination of the *exo* C-5 and the C-1 methyl groups, respectively, and again in analogy with the monoketone series, the effect of *endo* halogen substitution as in **23** and **26** can be interpreted in terms of down-

[6]The justification of the applicability of such a first-order analysis derives from the observation in analogous systems that none of the *exo* C-3, C-4, and *exo* C-5 protons are strongly coupled with one another and from the fact that in the present cases the lack of further splitting of the *exo* C-5 proton signal indicates that this proton is not virtually coupled with other protons; cf. refs. 30 and 31.

[c]Also includes H-6 signals.

field shifts of the signals of both the adjacent *exo* and *endo* methyl protons, with the former effect having the greater magnitude.

The signals of the C-7 protons of **17** and **6** each appear as doublets of triplets with approximate values of $J_{7s,7a}$ of 12–13 Hz and $J_{1,7s}$ ($\sim J_{1,7a} J_{4,7s} \sim J_{4,7a}$) of 1.5 Hz. The lower-field signal in each case (δ 2.40 and 2.60, respectively) is assigned to the *syn* proton and the higher-field signal (δ 1.93 and 2.03, respectively) to the *anti* proton, in analogy with the relationship between the chemical shifts of the *syn* and *anti* C-7 proton signals of **29** (22). The assignment is corroborated by the observation that the signal of the *anti* C-7 proton of the α-dione **33** appears at δ 2.26;[7] it would be expected that this would be downfield from the signal of the *anti* C-7 protons of **17** and **6** because of deshielding by the C-7 methyl group in **33**. The C-7 proton signals of **23** and **26** each appear as doublets of doublets with $J \approx 13$ and 1.5 Hz, and again the lower-field signals are assigned to the *syn* proton and the higher-field signals to the *anti*-protons.

Multiplets at δ 3.4 and 3.33 in the spectra of **17** and **6**, respectively, are assigned to the C-1 protons; the latter has $w_{1/2} \sim 10$ Hz as expected to result from coupling J = 1–2 Hz with *syn* and *anti* C-7 and C-4 protons and $J \sim 5$ Hz with the *exo* C-6 proton (*vide infra*); in the case of **17** the multiplet is partially obscured by the methoxyl signal at δ 3.38. The chemical shifts of these multiplets may be compared with the chemical shift of the signal assigned to the C-1 proton (δ 3.05) in the parent compound **31**. This assignment is made in the expectation that, of the two bridgehead protons, the C-1 proton will give rise to a signal at lower field because of shielding of the C-4 proton by the C—C bond of the *exo* C-5 methyl group (35). The downfield bridgehead proton multiplet has a considerably greater band width, reflecting the additional coupling of the C-1 proton with the *exo* C-6 proton. The downfield shift of this signal in the spectra of **17** and **6** is attributable to the electron-withdrawing effect of the *endo* C-6 oxygen substituents. In accord with these interpretations, no signals appear in the δ 3.0–3.5 region of the spectra of compounds **32**, **23**, and **26**.

The *exo* C-6 signals in the spectra of **17** and **6** appear as doublets of doublets with $J \sim 5$ and 1 Hz. The larger splitting is expected as a result of coupling with the C-1 proton but the smaller is unusual in that it does not correspond to any of the common 'W pattern' long-range proton couplings in the norbornane system (33). That it involves long-range coupling with the C-4 proton was demonstrated by irradiation at the frequency of the C-4 proton signal (*vide infra*) in each case, which led to the collapse of the C-6 proton signals to doublets with J = 4.8 and 5 Hz, respectively. Analogous long-range coupling is also observed in the spectra of **23** and **26**, where the *exo* C-6 protons give rise to doublets with J = 1.2 and 1.25 Hz, respectively. Similar, unusual long-range couplings have been observed in the spectra of the α-diketones **34** and **35**

[a]The relative intensities of the ^{1}H nmr signals are in accord with the assignments.

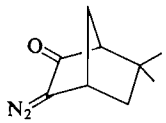
(36), and we have discussed the origin of such couplings elsewhere (37). Although such couplings with $J \geq 1$ Hz have only been observed for α-diketones, it should be pointed out, that analogous, albeit smaller, couplings have been observed in the case of 2-norbornanone (**29**), where $J_{1,5x} = 0.15$ Hz and $J_{4,6x} = 0.65$ Hz, although $J_{1,3x} = 0.0$ Hz (22).

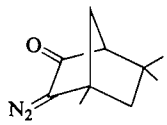
Multiplets at δ 2.6–2.8 in the spectra of all the compounds in Tables 3 and 4 are assigned to the C-4 protons, as discussed earlier for the case of **31**. In the case of **17** and **6** these signals have a considerably narrower bandwidth than the signals assigned to the C-1 protons, as for **31**, and appear as quintuplets with peak separations of ~1.5 Hz, in accord with previously assigned couplings of this order of magnitude between the C-4 and C-1, *exo* C-6, C-7_a, and C-7_s protons.

The strong bands in the ir spectra and the ^{1}H nmr signals of the *endo* C-5 hetero-atom-substituted 3-diazo-2-norbornanones are given in Tables 5 and 6, together with corresponding data (19) for the parent 3-diazo-6,6-dimethyl-2-norbornanone (**36**) and 3-diazoepiisofenchone (**37**).

Assignments of the ^{1}H nmr signals to the methyl protons are made on the basis of considerations analogous to those discussed previously. The effects



36

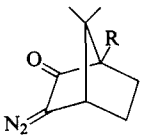


37

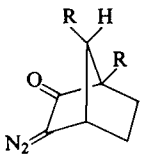
of the introduction of the *endo* C-5 hetero-atom substituents on the positions of the methyl signals are entirely analogous to those found for the corresponding mono- and α-diketones. It is noteworthy that in the cases of all pairs of similarly substituted α-diazo ketones and diketones, the *endo* C-6 methyl signal is shifted downfield in the diazo ketone spectrum whereas the *exo* C-6 methyl signal is shifted upfield. Comparison of the chemical shifts of the bridgehead methyl protons in **3**, **4**, and **37** with those in the corresponding diketones shows that replacement of the 3-keto group with a 3-diazo group leads to a downfield shift of this signal (Δδ 0.15–0.2).

The *syn* and *anti* C-7 protons in the spectra of the diazo ketones **1–4** are approximately chemically equivalent, unlike the C-7 protons in the corresponding diketones, and give rise to signals whose chemical shifts are similar to those of the *anti* C-7 protons in these diketones but appreciably upfield of the *syn* C-7 proton signals.

The signals of the bridgehead protons of diazo compounds **1**, **2**, and **36** appear as multiplets in the ranges δ 2.2–2.3 and 3.5–3.65. The former are assigned to the C-1 and the latter to the C-4 protons on the basis of comparison with the C-1 proton signals of the diazo ketones **3**, **4**, and **37**, which appear in the range δ 2.2–2.3 and of comparisons of the chemical shifts of the bridgehead protons of 3-diazoapocamphor (**38**) (δ 2.06, 2.92) with that of the bridgehead proton of 3-diazocamphor (**39**) (δ 2.92) (38) and those of the bridgehead protons of 3-diazo-2-norbornanone (**40**) (δ 2.62, 3.50) (39) with that of 3-diazo-β-santenone (**41**) (δ 3.15).[7] When account is taken of anisotropic shielding (Δδ ~ 0.3 per methyl group) of the bridgehead protons in **38**, **39**, and **41** by the C—CH_3 bonds of the C-7 methyl



38 R = H
39 R = Me



40 R = H
41 R = Me

groups, it can be seen that the C-4 proton signals of 3-diazo-2-norbornanones occur at considerably lower field than the C-1 proton signals. Comparison with the corresponding α-diketones shows that the C-4 proton signals are shifted downfield whereas the C-1 proton signals are shifted upfield. In accord with the above differentiation between the chemical shifts of the C-1 and C-4 protons the single C-1 bridgehead proton signals of **3**, **4**, and **37** occur in the range δ 2.2–2.3. The bandwidths and multiplicities of the signals assigned to the bridgehead protons of the diazo ketones are in accord with the attributions. Thus in the spectra of **1** and **2** the multiplets at δ 2.27 and 2.18, respectively, assigned to the C-1 protons are much narrower than the multiplets at δ 3.63 and 3.65, respectively, assigned to the C-4 protons. In each case the bridgehead proton is coupled with the other bridgehead proton and the C-7 protons but the C-4 protons are in addition coupled with the *exo* C-5 protons, accounting for the greater width of their signals. The multiplicities of the C-5 proton signals of **1–4** are of particular interest. In the case of **1** the signal is a doublet with $J = 3.6$ Hz, arising from coupling with the C-4 proton; in that of **2**, an analogous doublet can be discerned although here it overlaps with the signal due to the C-4 proton. In the cases of **3** and **4** the C-5 proton signals appear as singlets. These observations show that the coupling in these diazo ketones between the *exo* C-5 and C-1 protons, if any, is significantly less than in the case of the corresponding diketones. Possible interpretations of the enhanced coupling of this type in the diketone spectra have been discussed previously (37).

Experimental

Melting points and boiling points are uncorrected. Infrared spectra were recorded with carbon tetrachloride as solvent unless otherwise specified. Proton magnetic resonance spectra were recorded with deuteriochloroform as solvent. Solutions in organic solvents were dried over anhydrous magnesium sulfate and evaporated with a rotary evaporator unless otherwise specified.

*Camphenilone (**11**)*

Camphenilone was prepared by ozonolysis of *dl*-camphene (Aldrich; 80%, remainder tricyclene) (40) or by conversion of camphene to ω-nitrocamphene with nitrogen dioxide followed by treatment of this with aqueous sodium hydroxide (41); bp 78–83°C/18 Torr (lit. (42) bp 70–80°C/11 Torr); λ_{max}: 5.75 μm; δ_H: 1.2–2.6 (m, 8H), 1.02 (s), and 1.00 (s) (6H).

endo-*Camphenilol (**12**)*

A solution of camphenilone (**11**, 55.3 g) in anhydrous ether (100 mL) was added dropwise with stirring at a rate that maintained gentle refluxing to lithium aluminum hydride (9.0 g) in anhydrous ether (100 mL). After the addition was complete, the reaction mixture was stirred and boiled under reflux for 1 h. The excess lithium aluminum hydride was decomposed by cautious dropwise addition of water to the ice-cooled, stirred slurry. The aqueous layer was made homogeneous by addition of 5% sulfuric acid and the ethereal layer was separated. The aqueous layer was extracted with ether (4 × 100 mL) and the combined ethereal extracts were dried and filtered. The ether was removed and the residue was recrystallized from hexane to give **12** (34.5 g). Slow evaporation of hexane from the filtrate gave further **12** (16.0 g; total

yield, 50.5 g, 90%), mp 71–73°C (lit. (7) mp 66–69°C); λ_{max}: 2.75 μm; δ_H: 3.66 (br d, J = 4 Hz, 1H), 2.2 (m, 1H), 2.0 (s, shifts on dilution, 1H), 1.2–1.9 (m, 7H), 0.99 (s, 3H), 0.85 (s, 3H).

endo-*Camphenilyl Acetate (**13**)*

A solution of *endo*-camphenilol (**12**, 78.7 g) in acetic anhydride (280 mL) and pyridine (400 mL) was boiled under reflux with stirring for 3 h, cooled, and poured into a large amount of ice water. The mixture was extracted four times with ether. The combined ethereal extracts were washed with 10% hydrochloric acid, aqueous sodium bicarbonate, and water and dried. Distillation gave **13** (91.3 g, 89%), bp 98–99°C/17 Torr (lit. (7) bp 97–99°C/14 Torr); λ_{max}: 5.80, 8.09 μm; δ_H: 4.58 (br d, J = 4.0 Hz, 1H), 2.2 (m, 1H), 2.02 (s, 3H), 1.2–1.9 (m, 7H), 1.06 (s, 3H), 0.82 (s, 3H).

5-endo-*Acetoxy-6,6-dimethylbicyclo[2.2.1]heptan-2-one (**14**)*

A slurry of pulverized chromium trioxide (50 g) in glacial acetic acid (100 mL) was carefully added in small portions over 1 h to a stirred solution of *endo*-camphenilyl acetate (**13**, 25.0 g) in glacial acetic acid (35 mL) at a rate such that the reaction mixture temperature was maintained below 100°C. After the addition was complete, the solution was boiled under reflux and stirred for 30 min, cooled, and transferred to a separatory funnel with water (1200 mL). The green solution was extracted with ether (7 × 100 mL), and the combined ethereal extracts were washed with water (3 × 200 mL) and with saturated aqueous sodium bicarbonate (100 mL) and were dried. Distillation gave **13** (7.2 g), bp 42–50°C/25 × 10^{-3} Torr, and **14** (6.76 g, 35%), bp 70–71°C/25 × 10^{-3} Torr (lit. (7) bp 91–100°C/1.2 Torr); the product solidified slowly on standing at −20°C. One recrystallization from hexane gave a white solid, mp 61.0–63.0°C (lit. (7) mp 65.0–65.5°C); λ_{max}: 5.74, 7.10, 8.10 μm; δ_H: 4.89 (dd, J = 4.2 and 1.0 Hz, 1H), 2.83 (m, 1H), 2.07 (s, 3H), 2.1–2.3 and 1.6–2.0 (m, 5H), 1.23 (s, 3H), 0.83 (s, 3H).

6-endo-*Acetoxy-5,5-dimethylbicyclo[2.2.1]heptane-2,3-dione (**6**)*

A mixture of **14** (1.0 g), selenium dioxide (Alfa, 1.0 g), and bromobenzene (15 mL) was boiled under reflux with stirring for 9 h. The reaction was conveniently followed by examining the ^{1}H nmr spectra of aliquots that showed, when the reaction was complete, signal patterns identical with those in the ^{1}H nmr spectrum of **6** in benzene. The yellow solution was cooled and chromatographed on Florisil (100 g). Elution with benzene (750 mL) gave bromobenzene. Elution with 50% ether–benzene (450 mL) gave **6** as a yellow solid (0.75 g, 70%), mp 120.5–122.0°C (lit. (7) mp 121–122°C); λ_{max}: 5.61, 5.68, 5.72, 8.12 μm; δ_H: 5.14 (dd, J = 5.2 and 1.0 Hz, 1H), 3.33 (m, 1H), 2.71 (m, 1H), 2.60 (dt, J = 12 and 1.5 Hz, 1H), 2.03 (dt, J = 12 and 1.5 Hz, 1H), 2.06 (s, 3H), 1.41 (s, 3H), 0.91 (s, 3H).

6-endo-*Acetoxy-5,5-dimethylbicyclo[2.2.1]heptane-2,3-dione 2*-p-*Toluenesulfonylhydrazone (**7**)*

A warm solution of tosylhydrazine (0.96 g, 5.15 mmol) in glacial acetic acid (2.7 mL) was added to a warm solution of **6** (1.00 g, 4.75 mmol) in glacial acetic acid (1.6 mL). After standing at room temperature for 0.5 h the yellow solution was added dropwise to ice (100 g), forming a white precipitate that was filtered, washed thoroughly with water, and air dried overnight to give **7** (1.60 g, 88%), mp 159.5–162.0°C (lit. (7) mp 161–162°C); λ_{max}: ($CHCl_3$) 5.78, 6.11, 6.26 μm; δ_H: 7.7–8.0 (m, 2H), 7.2–7.5 (m, 2H), 4.90 (d, J = 4 Hz, 1H), 3.25 (m, 1H), 1.7–2.6 (m, 10H) with singlets at 2.40 (3H) and 1.79 (3H), 1.28 (s, 3H), 0.78 (s, 3H).

5-endo-*Acetoxy-3-diazo-6,6-dimethylbicyclo[2.2.1]heptan-2-one (**1**)*

A slurry of tosylhydrazone **7** (0.72 g) in benzene was placed on a 2.5 × 0.5 in. column of basic alumina (Merck 71707, 2.5 × 0.5 in.) packed in benzene. The reaction mixture was eluted with benzene. The first 600 mL of eluate contained most of the product. Any solid tosylhydrazone that remained on top of the column was mixed with the alumina by means of a long rod and elution with benzene was continued. Evaporation of the benzene from the eluate, and recrystallization of the residual solid from a small amount of hexane afforded **1** as yellow crystals (0.295 g, 70%), mp 69.0–71.0°C (lit. (7) mp 70–71°C); λ_{max}: 4.82, 5.77, 5.90, 7.32, 8.09 μm; δ_H: 5.03 (d, J = 3.6 Hz, 1H), 3.63 (m, 1H), 2.27 (m, 1H), 2.06 (s, 3H), 1.91 (m, 2H), 1.27 (s, 3H), 0.94 (s, 3H).

5-endo-*Hydroxy-6,6-dimethylbicyclo[2.2.1]heptan-2-one (**15**)*

A solution of **14** (2.0 g) in 50% methanol–water (24 mL) and potassium carbonate (5.0 g) was boiled under reflux with stirring for 2.5 h. After cooling the red solution was extracted with ether (70 and 35 mL) and the combined ethereal extracts were dried and filtered. Evaporation of the ether afforded the hygroscopic keto alcohol **15** (1.25 g, 80%), which was a semi-solid at room temperature; λ_{max}: 2.82, 2.95, 5.74, 7.11 μm; δ_H: 3.98 (dd, J = 4.0 and 1.0 Hz, 1H), 3.02 (s, shifts on dilution, 1H), 2.7 (m, 1H), 1.3–2.4 (m, 5H), 1.12 (s, 3H), 0.88 (s, 3H).

5-endo-*Methoxy-6,6-dimethylbicyclo[2.2.1]heptane-2-one (**16**)*

To a stirred mixture of **15** (1.25 g), methyl iodide (1.4 mL), 1,2-dimethoxyethane (10 mL), and anhydrous sodium sulfate (ca. 0.2 g) was added over 0.5 h pure sodium hydride obtained by washing a 53% dispersion of sodium hydride (0.440 g) in oil three times with ether and drying under a stream of nitrogen. After an additional 0.5 h of stirring, further methyl iodide (0.5 mL) was added and the mixture was stirred overnight. The mixture was filtered, and the ether and excess methyl iodide were evaporated. The product was treated with warm hexane (40 mL) and the hexane-soluble fraction was decanted. Evaporation of the hexane gave **16** (88% pure as determined by vpc; 0.95 g, 69%). The impure **16** (100 mg) was chromatographed on Florisil (10 g). After elution with benzene (175 mL) and 5% ether–benzene (40 mL), pure **16** (24 mg) was obtained from the next 20 mL of 5% ether–benzene eluate; bp 56°C/50 × 10^{-3} Torr); λ_{max}: 3.53, 5.74, 7.11, 9.00 μm; δ_H: 3.44 (dd, J = 4.0 and 1.1 Hz, 1H), 3.34 (s, 3H), 2.8 (m, 1H), 1.3–2.2 (m, 5H), 1.14 (s, 3H), 0.88 (s, 3H). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.39, H 9.59; found: C 71.65, H 9.55.

6-endo-*Methoxy-5,5-dimethylbicyclo[2.2.1]heptane-2,3-dione (**17**)*

A mixture of **16** (0.99 g), **14** (0.20 g), selenium dioxide (Alfa, 0.99 g), and bromobenzene (6.6 mL) was stirred and heated in an oil bath at 150°C for ca. 4 h. As the reaction proceeded, the ^{1}H nmr spectra of aliquots showed a new signal, assigned to the methoxyl protons of **17**, at slightly lower field than the signal attributed to the methoxyl protons of **16**. The red solution was cooled and chromatographed on Florisil (150 g). Elution with benzene (600 mL) gave bromobenzene and elution with a further 50 mL of benzene gave **14**. Elution with a further 250 mL of benzene gave crude **17** (193 mg), which was recrystallized from hexane to give **17** (148 mg, 14%) as yellow crystals, mp 54.5–55.5°C; λ_{max}: 5.64, 5.70, 9.08 μm; δ_H: 3.72 (dd, J = 4.8 and 1.0 Hz, 1H), 3.4 (m) and 3.38 (s) (4H), 2.65 (m, 1H), 2.40 (dt, J = 13 and 1.5 Hz, 1H), 1.93 (dt,

J = 13 and 1.5 Hz, 1H), 1.32 (s, 3H), 0.94 (s, 3H). *Anal.* calcd. for $C_{10}H_{14}O_3$: C 65.91, H 7.74; found: C 65.81, H 7.89.

*3-Diazo-5-*endo*-methoxy-6,6-dimethylbicyclo[2.2.1]heptan-2-one (2)*

A warm solution of tosylhydrazine (75 mg, 0.40 mmol) in glacial acetic acid (0.2 mL) was added to a warm solution of **17** (65 mg, 0.36 mmol) in glacial acetic acid (0.2 mL). After standing for 2.5 h at room temperature the yellow solution was added dropwise to ice (10 g), forming a light yellow precipitate of tosylhydrazone **18** that was collected and washed thoroughly with water. Five millilitres of 0.3 *M* aqueous sodium hydroxide was added to the tosylhydrazone and the yellow solution that formed after a few minutes of stirring was stirred vigorously with hexane (20 mL) for 0.5 h. The hexane layer was removed, ether (25 mL) was added, and the mixture was stirred vigorously for 2 h. The ethereal layer was removed, fresh ether (25 mL) was added, and the mixture was again stirred vigorously for 2 h. This process was repeated until the ethereal layer was colorless (ca. 8 h). The combined organic extracts were dried over anhydrous sodium sulfate for 4 h and filtered. Evaporation of the solvent gave **2** (39 mg, 57%) as a yellow oil that solidified on standing, mp 57–59°C; λ_{max}: 4.82, 5.90, 7.35, 9.05 μm; δ_H: 3.65 (m, 1H), 3.60 (d, J = 3.4 Hz, 1H), 3.36 (s, 3H), 2.18 (m, 1H), 1.79 (t, J = 1.8 Hz, 2H), 1.19 (s, 3H), 0.99 (s, 3H). *Mol. Wt.* calcd. for $C_{10}H_{14}N_2O_2$: 194.1055; found (ms): 194.1050.

*6-*endo*-Chloro-1,5,5-trimethylbicyclo[2.2.1]heptan-2-*exo*-ol (21)*

An ice-cooled solution of *trans*-pinocarveol (**20**, 5.0 g) (42) in anhydrous ether (25 mL) was saturated with hydrogen chloride. The light brown solution was kept at 0°C for 20 h and poured onto ice (80 g). Ether (50 mL) was added and the ethereal extract was washed with water (4 × 50 mL), dried, and filtered. Evaporation of the ether afforded **21** (5.89 g, 92%) as a volatile solid, mp 84–91°C (lit. (16) mp 99.5°C); δ_H: 4.02 (ddd, J = 7.0, 3.5, and 1.3 Hz, 1H), 3.69 (s, 1H), 1.3–2.8 (m, including a singlet at 2.2 that shifts on dilution, 6H), 1.15 (s, 3H), 1.06 (s, 3H), 0.95 (s, 3H).

*6-*endo*-Chloro-1,5,5-trimethylbicyclo[2.2.1]heptan-2-one (22)*

To an ice-cooled, stirred solution of **21** (4.9 g) in glacial acetic acid (12 mL) was added dropwise a solution of chromium trioxide (4.0 g) in a small amount of water and glacial acetic acid (18 mL). After 22 h standing the dark green solution was poured into water (100 mL) and extracted with ether (2 × 75 mL). The ethereal extracts were washed with saturated aqueous sodium bicarbonate and dried. Distillation afforded **22** (1.77 g, 37%), bp 93–97°C/2 Torr (lit. (15) bp 132–122°C/15 Torr); λ_{max}: 5.71, 7.10 μm; δ_H: 3.81 (s, 1H), 1.3–2.9 (m, 5H), 1.30 (s, 3H), 1.20 (s, 3H). 1.12 (s, 3H).

*6-*endo*-Chloro-1,5,5-trimethylbicyclo[2.2.1]heptane-2,3-dione (23)*

A mixture of **22** (100 mg), glacial acetic acid (2 mL), and selenium dioxide (150 mg) was boiled under reflux with stirring for 19 h, cooled, poured into water, and extracted with ether (2 × 20 mL). The ethereal extracts were washed with saturated aqueous sodium bicarbonate, dried, and filtered. Evaporation of the ether and recrystallization of the residue from hexane afforded **23** (33 mg, 31%) as yellow needles, mp 108–114°C; further recrystallizations gave yellow needles, mp 115.0–116.2°C; λ_{max}: 5.64, 5.71 μm; δ_H: 3.96 (d, J = 1.2 Hz, 1H), 2.73 (m, 1H), 2.43 (dd, J = 13 and 1.5 Hz, 1H), 1.91 (dd, J = 13 and 1.5 Hz, 1H), 1.36 (s) and 1.33 (s) (6H), 1.07 (s, 3H). *Anal.* calcd. for $C_{10}H_{13}O_2Cl$: C 59.87, H 6.53, Cl 17.67; found: C 59.69, H 6.40, Cl 17.44.

*5-*endo*-Chloro-3-diazo-4,6,6-trimethylbicyclo[2.2.1]heptan-2-one (3)*

A warm solution of tosylhydrazine (152 mg, 0.82 mmol) in glacial acetic acid (1.4 mL) was added to a warm solution of **23** (148 mg, 0.74 mmol) in glacial acetic acid (0.7 mL). After standing for 1.25 h at room temperature the yellow solution was added dropwise to ice (14 g) forming a light yellow precipitate, which was collected and washed with water. Five millilitres of 0.3 *M* aqueous sodium hydroxide was added to the solid and the mixture was stirred for a few minutes until a yellow solution formed. Hexane (5 mL) was added, and the mixture was stirred vigorously for 1 h. The yellow hexane layer was removed, further hexane (5 mL) was added, the mixture was stirred vigorously for a further 2.5 h, and the faintly yellow hexane layer was removed. The combined hexane extracts were dried and filtered. Evaporation of the ether and recrystallization of the residue from hexane afforded **3** (95 mg, 62%) as yellow needles, mp 77–79°C; λ_{max}: 4.82, 5.90, 7.41, 7.51 μm; δ_H: 3.92 (s, 1H), 2.30 (t, J = 1.7 Hz, 1H), 1.90 (d, J = 1.7 Hz, 2H), 1.51 (s, 3H), 1.25 (s, 3H), 1.12 (s, 3H). *Anal.* calcd. for $C_{10}H_{13}N_2OCl$: C 56.48, H 6.16, Cl 16.67; found: C 56.32, H 6.19, Cl 16.28.

*6-*endo*-Bromo-1,5,5-trimethylbicyclo[2.2.1]heptan-2-*exo*-ol (24)*

An ice-cooled solution of *trans*-pinocarveol (**20**, 19.3 g) (46) in anhydrous ether (90 mL) was saturated with hydrogen bromide and kept at 0°C for 20 h. Evaporation of the ether and excess hydrogen bromide followed by air drying for 0.5 h gave **24** (26.0 g, 88%). After one recrystallization from petroleum ether (bp 60–70°C) **24** was obtained as fluffy white needles, mp 111–114°C (lit. (17) 118–119°C); λ_{max}: 2.79, 9.45 μm; δ_H: 3.97 (ddd, J = 7.4, 3.5, and 0.8 Hz, 1H), 3.85 (s, 1H), 1.3–2.8 (m, including a singlet at 2.2 that shifts on dilution, 6H), 1.18 (s, 3H), 1.08 (s, 3H), 1.02 (s, 3H).

*6-*endo*-Bromo-1,5,5-trimethylbicyclo[2.2.1]heptan-2-one (25)*

The method used was similar to that previously described (17). To the complex formed from chromium trioxide (8.3 g) and pyridine (125 mL) was added a solution of **24** (5.0 g) in pyridine (8 mL), and the mixture was stirred at room temperature for 44 h. The reaction mixture was poured into a separatory funnel, and ether (400 mL) and a solution of concentrated hydrochloric acid (137 mL) in water (250 mL) was added. The emulsion that formed on shaking this mixture was filtered to separate a brown sludge. The ethereal layer from the filtrate was washed with 10% hydrochloric acid (2 × 50 mL) and saturated aqueous sodium bicarbonate (2 × 50 mL), dried, and filtered. Evaporation of the ether afforded **25** (3.73 g, 75%); λ_{max}: 5.71, 7.12 μm; δ_H: 3.93 (s, 1H), 1.3–2.7 (m, 5H), 1.28 (s, 3H), 1.15 (s, 6H).

*6-*endo*-Bromo-1,5,5-trimethylbicyclo[2.2.1]heptane-2,3-dione (26)*

A mixture of **25** (0.50 g), selenium dioxide (0.75 g), and acetic acid (10 mL) was boiled under reflux with stirring for 3.5 h. The mixture was cooled and ether (150 mL) was added. The ethereal solution was washed with saturated aqueous sodium bicarbonate until the evolution of carbon dioxide ceased, dried, and filtered. Evaporation of the ether afforded a red oil. Hexane (20 mL) was added to the oil, the mixture was heated, and the hexane-soluble fraction was decanted and cooled to −20°C, affording orange crystals (190 mg). Sublimation at 80°C/50 × 10^{-3} Torr gave **26** (161 mg, 31%) as a yellow solid, mp 120–123°C; recrystallizations from hexane raised the melting point to 131.5–132.5°C; λ_{max}: 5.63, 5.69 μm; δ_H: 4.07 (d, J = 1.25 Hz, 1H), 2.78 (m, 1H), 2.54 (dd, J = 12.5 and 1.5 Hz, 1H), 2.01 (dd, J = 12.5 and 1.5 Hz, 1H), 1.37 (s,

3H), 1.30 (s, 3H), 1.11 (s, 3H). *Anal.* calcd. for $C_{10}H_{13}O_2Br$: C 49.00, H 5.35, Br 32.60; found: C 48.97, H 5.49, Br 32.48.

5-endo-Bromo-3-diazo-4,6,6-trimethylbicyclo[2.2.1]heptan-2-one (4)

A warm solution of tosylhydrazine (250 mg, 1.34 mmol) in glacial acetic acid (2.4 mL) was added to a warm solution of **26** (290 mg, 1.18 mmol) in glacial acetic acid (1.2 mL). After standing for 2.0 h in an oil bath at 50°C the yellow solution was added dropwise to ice (15 g) forming a light yellow precipitate that was collected on a sintered glass funnel, washed thoroughly with water, and dried in a desiccator *in vacuo* overnight. The tosylhydrazone (mp 136–139°C; 510 mg, 86%) was dissolved in benzene and placed on a column of basic alumina (Merck 71707, 3.0 × 0.5 in.), and the product was eluted with benzene (200 mL). Evaporation of the benzene, and recrystallization of the residual yellow solid from hexane afforded **4** (194 mg, 64% based on **26**) as yellow needles, mp 95.0–96.5°C; further recrystallizations raised the melting point to 99.0–100.0°C; λ_{max}: 4.82, 5.90, 7.42, 7.62 μm; δ_H: 4.08 (s, 1H), 2.33 (t, J = 1.5 Hz, 1H), 1.98 (d, J = 1.5 Hz, 2H), 1.50 (s, 3H), 1.22 (s) and 1.18 (s) (6H). *Anal.* calcd. for $C_{10}H_{13}N_2OBr$: C 46.71, H 5.10, N 10.89, Br 31.08; found: C 46.85, H 5.23, N 10.52, Br 30.81.

Aliphatic diazo compounds. XIII. The copper-catalyzed decomposition of 5-*endo*-hetero-atom-substituted 3-diazo-2-norbornanones[1,2]

PETER YATES AND GORDON F. HAMBLY[3]

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 29, 1978

PETER YATES and GORDON F. HAMBLY. Can. J. Chem. 57, 1668 (1979).

The copper-catalyzed decomposition of 5-*endo*-acetoxy-3-diazo-6,6-dimethyl-2-norbornanone (**4**) in dilute solution in benzene gives as the major product 2-acetoxy-5,5-dimethyltricyclo[2.2.1.$0^{2,6}$]heptan-3-one (**12**) together with 5-*endo*-acetoxy-6,6-dimethyl-2-norbornanone (**8**), 6-*endo*-acetoxy-5,5-dimethyl-2,3-norbornanedione (**9**), and 5-*endo*-acetoxy-3-*endo*-hydroxy-6,6-dimethyl-2-norbornanone (**10**). The structure of **12** was established by its independent synthesis from 5-*endo*-bromo-7,7-dimethyl-2,3-norbornanedione (**19**) by treatment with lithium followed by acetic anhydride. Copper-catalyzed decomposition of **4** labelled with ^{18}O in the acetoxyl carbonyl shows that the major pathway for the formation of **12** involves bonding of the carbenoid center at C-3 to the carbonyl oxygen of the acetoxyl group and not insertion into the *endo* C-5–oxygen bond. Similar copper-catalyzed decomposition of **5**, the methoxy analogue of **4**, gives only 9,9-dimethyl-5-oxatricyclo[4.2.1.$0^{3,7}$]nonan-2-one (**31**), the product of carbenoid insertion into a C—H bond of the methoxyl methyl group. Copper-catalyzed decomposition of 5-*endo*-chloro-3-diazo-4,6,6-trimethyl-2-norbornanone (**6**) and of **7**, its bromo analogue, gives as major products the corresponding α-diketones and azines; if insertion into the *endo* C-5–halogen bond occurs at all it can only represent a minor pathway. Thus although very ready carbenoid insertion into an *endo* C-5–hydrogen bond occurs in the copper-catalyzed decomposition of 3-diazo-2-norbornanones, such insertion into an *endo* C-5 – hetero atom bond occurs with difficulty, if at all.

PETER YATES et GORDON F. HAMBLY. Can. J. Chem. 57, 1668 (1979).

La décomposition catalysée par le cuivre de l'acétoxy-5-*endo* diazo-3 diméthyl-6,6 norbornanone-2 (**4**) en solution diluée dans le benzène fournit l'acétoxy-2 diméthyl-5,5 tricyclo-[2.2.1.$0^{2,6}$]heptanone-3 (**12**) comme produit principal aux côtés d'acétoxy-5-*endo* diméthyl-6,6 norbornanone-2 (**8**), d'acétoxy-6-*endo* diméthyl-5,5 norbornanedione-2,3 (**9**) et d'acétoxy-5-*endo* hydroxy-3-*endo* diméthyl-6,6 norbornanone-2 (**10**). On a déterminé la structure de **12** en effectuant sa synthèse à partir de la bromo-5-*endo* diméthyl-7,7 norbornanedione-2,3 (**19**) par une réaction avec du lithium suivie par de l'anhydride acétique. La décomposition catalysée par le cuivre de **4** dont le carbonyle de l'acétoxyle est marqué au ^{18}O démontre que la voie principale conduisant à la formation de **12** implique la liaison du centre carbénoïde en C-3 à l'oxygène du carbonyle du groupe acétoxyle et non pas l'insertion dans la liaison C-5–oxygène *endo*. Une décomposition semblable, catalysée par le cuivre, de **5**, l'analogue méthoxylé de **4**, ne fournit que la diméthyl-9,9 oxa-5 tricyclo[4.2.1.$0^{3,7}$]nonanone-2 (**31**), le produit provenant de l'insertion d'un carbénoïde dans une liaison C—H du groupe méthyle du méthoxyle. Les compositions catalysées par le cuivre de la chloro-5-*endo* diazo-3 triméthyl-4,6,6 norbornanone (**6**) et de **7**, son analogue bromé, conduisent aux α-dicétones et aux azines correspondants comme produits principaux; s'il se produit la moindre insertion dans la liaison C-5–halogène *endo* elle ne représente qu'une voie de réaction mineure. Donc, même s'il se produit des insertions faciles de carbénoïdes dans une liaison C-5–hydrogène lors de la décomposition catalysée par le cuivre de diazo-3 norbornanones-2, de telles insertions dans une liaison C-5 – hétéro atome *endo* ne se produisent, au mieux, qu'avec difficulté.

[Traduit par le journal]

It has long been known that thermal or copper-catalyzed decomposition of 3-diazocamphor (**1**) gives cyclocamphanone (**2**) (2). Several other 3-diazobicyclo[2.2.1]heptan-2-ones (3-diazo-2-norbornanones) have been found to undergo analogous reactions (3, 4) and it has become generally accepted (5) that such reactions involve loss of nitrogen from the α-diazo ketone to give an α-oxocarbene (e.g., **3**) or α-oxocarbene–copper complex that undergoes intramolecular C—H insertion to give the tricyclic

ketone.[4] In accord with such a mechanism, all of the 3-diazo-2-norbornanones that have been reported to undergo the reaction possess an *endo* C—H bond at C-5. We thought it of interest to study the course of the copper-catalyzed decomposition of 3-diazo-2 norbornanones, that possess an *endo* carbon–hetero atom bond at C-5 and to this end have examined the copper-catalyzed decomposition of the α-diazo ketones **4**–**7** (1).

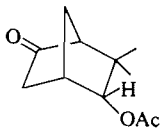
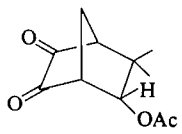
Products from the Copper-catalyzed Decomposition of the Diazo Ketones

The diazo ketone **4** was decomposed in the presence of an excess of copper in benzene under high dilution conditions to minimize the occurrence of bimolecular reactions. The product distribution from such decomposition of **4** was found to be remarkably dependent on the provenance of the copper used as catalyst. In general four products were obtained. Two of these were **8** and **9**, compounds which were



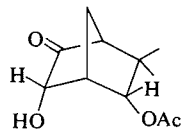
8



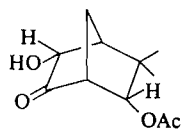
9

readily identified since they had been prepared as intermediates in the synthesis of **4** (1).

Another product is assigned structure **10** on the following basis. Its mass spectrum showed that it is a compound $C_{11}H_{16}O_4$ and its ir spectrum (λ_{max} 2.95, 5.74 μm) indicated that it is a hydroxy ketone. Its ^{1}H nmr spectrum indicated that it retains the CHOAc grouping (δ 2.08 (s, 3H), 5.07 (br d, J = 4 Hz, 1H)) and has another proton on a carbon bearing an oxygen atom (δ 4.03 (br d, J = 4 Hz)). This structural assignment was confirmed by hydrogenation of the dione **9**, which gave a mixture whose major component is identical with the hydroxy ketone obtained from the copper-induced decomposition of **4**, as indicated by its vpc retention time and ^{1}H nmr spectrum. The minor product is considered to be **11** on the basis of its ^{1}H nmr spectrum (δ 2.04 (s), 4.22 (d, J = 4 Hz), 4.92 (d, J = 4 Hz)). The formation of the *endo* hydroxy isomers **10** and **11** on



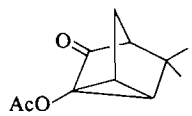
10



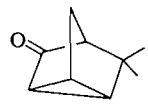
11

hydrogenation of **9** is expected since it involves addition of hydrogen from the least hindered *exo* face (7).

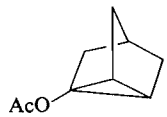
The fourth product from the copper-induced decomposition of **4** was the most volatile product and was the major product (74%) when the most active copper catalysts were used. Its elemental composition and mass spectrum showed that it corresponds in composition to loss of nitrogen from **4**. Its ir spectrum includes strong bands of equal intensity at 5.60 and 5.65 μm suggesting the retention of two carbonyl groups. Its ^{1}H nmr spectrum shows a sharp three-proton singlet at δ 2.11 and no signals at lower field than δ 2.35, indicating the presence of a tertiary acetate and the absence of vinylic protons; it also shows two three-proton singlets at δ 1.05 and 1.27, indicating the retention of the geminal methyl groups, and an apparent one-proton quintuplet (J = 1.5 Hz) at δ 1.65 (*vide infra*). On the basis of these data and its origin, it was concluded that this product has structure **12**. Thus the position of its ir



12

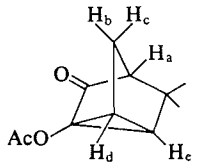


13



14

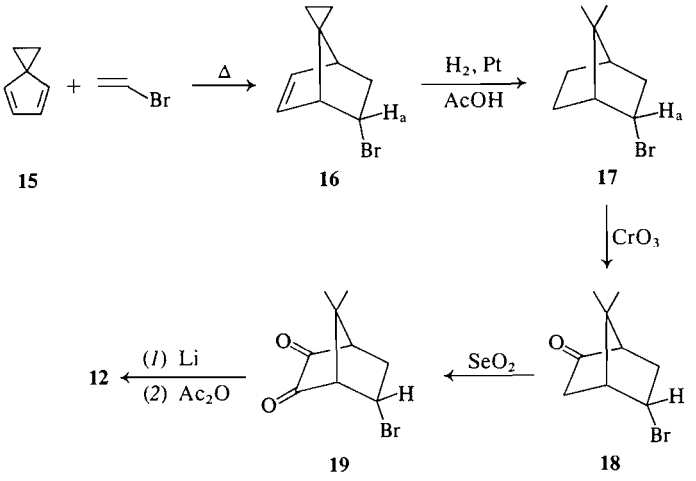
carbonyl stretching bands relative to those of cyclocamphanone (**2**) and cycloapocamphanone (**13**) (5.70 μm)[5] and of 1-acetoxynortricyclene (**14**) (5.68 μm (8)) can be interpreted in terms of the well-known shift to lower wavelength of both carbonyl stretching bands of α-acetoxy ketones relative to the bands in the corresponding ketones and acetates (9*a*). It is noteworthy that the C—O stretching band of the acetate group in **12** is at unusually long wavelength (8.28 μm) relative to simple acetates (8.0–8.1 μm (9*b*)), in accord with the observation of Jones and Herling (10) that the wavelengths of the C—O bands of a number of steroid acetates are inversely related



12′

[4]In the case of **1** and its 4-methyl derivative, the reaction has also been shown to be catalyzed by silver salts (6).

[5]Cycloapocamphanone (**13**) was prepared by the copper-catalyzed decomposition of 3-diazoapocamphor (4).



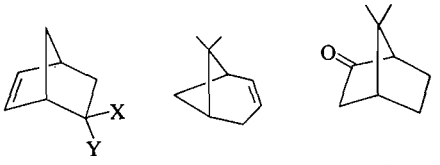
SCHEME 1

to the wavelengths of their C=O bands. The geminal methyl signals in the ^{1}H nmr spectrum of **12** are more widely separated ($\Delta\delta$ 0.22) than they are in the spectrum of **13** (δ 1.04 and 1.08 (4)), a circumstance that can be attributed to deshielding of one of the methyl groups in **12** by the acetoxyl group. The one-proton quintuplet at δ 1.65 is assigned to H_a (see **12'**); its high-field position is attributed to shielding by the cyclopropane ring and its multiplicity to approximately equivalent vicinal coupling with H_b and H_c and long range (^4J) coupling with H_d and H_e ($J \sim 1.5$ Hz). Analogous long-range coupling has been observed in the spectrum of **13** (4) and corresponds to the well-known 'W-pattern' couplings of the C-1 and C-4 protons in 2-norbornanones (11).

The assignment of structure **12** to the major product from the copper-catalyzed decomposition of **4** was confirmed by an independent synthesis of **12** by the route shown in Scheme 1.

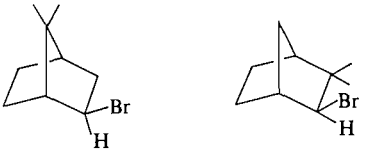
The spiro diene **15** (12)[6] and vinyl bromide at 170°C gave the Diels–Alder adduct **16** in good yield. The ^{1}H nmr spectrum of **16** shows a doublet of triplets at δ 4.47 (J = 8.0, 3.5 Hz, 1H), assigned to H_a; comparison with the spectra of *endo*- and *exo*-5-bromonorbornene (**20** and **21**, respectively) (13) leaves no doubt that the adduct has the *endo* configuration as in **16**. Hydrogenation of **16** proceeded with the uptake of 2 molar equiv. of hydrogen (14) to give apobornyl bromide (**17**) in high yield; this shows a very broad multiplet in its ^{1}H nmr spectrum at δ 4.62 ($w_{1/2}$ = 21 Hz), assigned to H_a, again demonstrating the *endo* configuration (1, 15).

An alternative route to **17** was investigated, based on the report that addition of hydrogen bromide to apopinene (**22**) in chloroform gave a mixture of bromides that upon treatment with silver acetate in acetic acid, hydride reduction, and oxidation gave apocamphor (**23**) (16), since it appeared likely that this mixture of bromides contained **17**. Apopinene (**22**) on treatment as described gave in high yield a



20 X = H, Y = Br
21 X = Br, Y = H
22
23

mixture of three compounds; ^{1}H nmr spectroscopy showed that the major product was **17** (~53%) and that this was accompanied by its *exo* isomer **24**



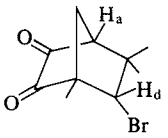
24 **25**

(~39%) (δ 4.00 (dd, J = 8.5, 5.0 Hz)) and compound **25** (8%) (δ 3.71 (d, J = 2.0 Hz)) (1.15). It was anticipated that in the next step of the synthesis of **12** from **17**, which involves the chromic acid oxidation of the latter, the *exo* bromides **24** and **25** would undergo solvolysis and therefore **17** would not have to be separated from the mixture of bromides. Although this proved to be the case, it was found to be preferable to synthesize **17** by the route of Scheme 1.

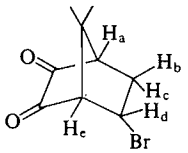
Chromic acid oxidation of apobornyl bromide (**17**) gave the ketone **18** in analogy with the similar oxidation of other bornyl derivatives (17). Its ir spectrum shows a strong band at 5.71 μm and its ^{1}H nmr spectrum shows a very broad multiplet

[6]We thank Dr. John D. Fenwick for providing us with a sample of **15**.

($w_{1/2}$ = 21 Hz) at δ 4.78 analogous to that due to H_a in the spectrum of **17**. Selenium dioxide oxidation of **15** in bromobenzene gave the α-diketone **19**, whose ir spectrum exhibits bands at 5.61 and 5.70 μm assigned to the coupled C=O stretching vibrations (18), similar to those at 5.63 and 5.69 μm in the spectrum of compound **26**, an intermediate in the preparation of the diazo ketone **7** (1). The ^{1}H nmr spectrum of **19** shows two methyl-proton singlets at δ 1.15 and 1.21 and five one-proton signals at 2.13, 2.75, 2.94, 3.18, and 4.75, assigned, respectively, to H_c, H_e, H_a, H_b, and H_d (see **19′**). The multiplicities



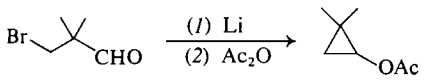
26



19′

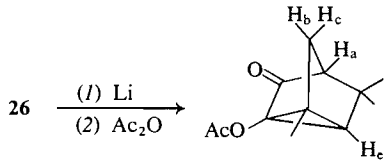
of these signals could readily be interpreted in a first-order manner in terms of the following coupling constants: J_{ab} = 5.0 Hz, J_{ad} = 1.5 Hz, J_{bc} = 15 Hz, J_{bd} = 10 Hz, J_{be} = 0.8 Hz, J_{cd} = 4.0 Hz, J_{de} = 5 Hz. These values are in general in accord with expectation (11, 15), with the exception of the unusually large long range J_{ad}. However, several other examples of such unusually large J_{ad} values have been observed in the case of closely related 2,3-norbornanediones (1, 19), e.g., in the case of **26**, J_{ad} = 1.25 Hz.

The final step in Scheme 1, the conversion of **19** to **12** by treatment with lithium followed by acetic anhydride was conceived on the basis of the report by Hamon and Sinclair (20) that **27** is converted to

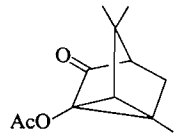


27 **28**

28 by similar treatment. Because of the crucial nature of this final step in the synthetic scheme and the considerable difference between the substrates **19** and **17**, its feasibility was tested on the α-diketone **26**, which is much more closely related to **19**, before the synthetic scheme was embarked upon. Compound **26** in ether was stirred with lithium for 2 days and the resulting solution was treated with acetic anhydride to give a product in 52% yield that is assigned structure **29**. The close relationship of this structure to **12** is most readily seen from its representation as its enantiomorph, **29*a***. Its ir spectrum is very similar to that of **12**, exhibiting strong bands at 5.61, 5.65, and 8.30 μm. Its ^{1}H nmr spectrum shows four three-proton signals at δ 1.05, 1.21, 1.33, and 2.13 (cf. the three three-proton signals of **12** at δ 1.05, 1.27, and



29



29*a*

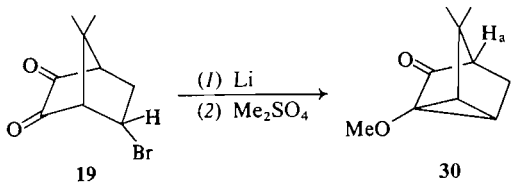
2.11). A one-proton signal at δ 1.66 appears as a distorted quartet ($J \sim$ 1.5 Hz) and is assigned to H_a (cf. the quintuplet ($J \sim$ 1.5 Hz) at δ 1.65 assigned to H_a of **12**). A doublet (J = 1.7 Hz) at δ 1.82 is assigned to H_e, coupled with H_a. The acetoxyl methyl singlet at δ 2.13 is superimposed on a doublet at δ 2.10 (J = 1.5 Hz), the total intensity corresponding to five protons; this doublet is considered to arise from H_b and H_c, which are accidentally chemically equivalent and coupled with H_a.

The successful conversion of **26** to **29** encouraged us to pursue the synthesis of **12** via **19**. Treatment of **19** in ether with lithium followed by acetic anhydride gave a product in 50% yield that is identical with the most volatile product obtained in the copper-catalyzed decomposition of **4**, thus firmly establishing its structure as **12**.

Preparatory to examining the copper-catalyzed decomposition of diazo ketone **5**, the methoxy analogue of the acetoxy diazo ketone **4**, we sought to synthesize **30**, the analogue of **12**, so that it could be readily recognized if it were a product from the decomposition of **5**. Treatment of the bromo α-diketone **19** with lithium, followed by methyl iodide, gave no **30**, but treatment with lithium followed by dimethyl sulfate afforded the volatile methoxy ketone in low yield.[7] The ir spectrum of **30** shows a strong C=O stretching band at 5.68 μm. Its ^{1}H nmr spectrum is closely related to that of **12**, exhibiting two C—CH_3 singlets at δ 1.00 and 1.17, a quintuplet at δ 1.51 ($J \sim$ 1.5 Hz) assigned to H_a, a multiplet at δ 2.0–2.3 assigned to the other ring protons, and a methoxyl singlet at δ 3.47.

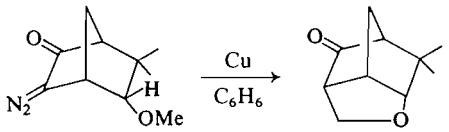
Copper-catalyzed decomposition of **5** in benzene in the same manner as for **4** gave a single volatile product in 90% yield: this is considerably less volatile than **30**. It was shown by high resolution mass spectrometry to have an elemental composition corresponding to the loss of nitrogen from **5**, i.e., to be isomeric with **30**. It is assigned structure **31** on the

[7]These results presumably reflect the greater reactivity of dimethyl sulfate as an alkylating agent (21).



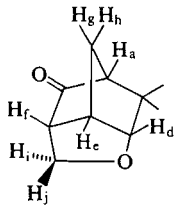
19 30

basis of the following considerations. Its ir spectrum possesses a strong C=O stretching band at 5.73 μm. Its ^1H nmr spectrum lacks a three-proton singlet in the δ 3–4 region, demonstrating that the methoxyl group is no longer present. Three-proton singlets at δ 0.84 and 1.02 indicated the retention of the geminal methyl groups. A broad doublet (J = 4.8 Hz, 1H) at δ 4.04 is assigned to H_d, coupled with H_e (see **31***a*);

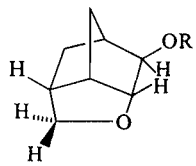


5 31

a two-proton multiplet at δ 3.75–3.95 is assigned to H_i and H_j, which form the AB part of an ABX system, with H_f acting as X. A doublet of triplets (J = 12, 1.5 Hz, 1H) at δ 1.82 is assigned to one of H_g and H_h; the other of these gives rise to a signal at δ 2.03 that is a doublet (J ~ 12 Hz) with further small splittings but is partially obscured by a multiplet at δ 2.09, assigned to H_a. Broad multiplets at δ 2.5 (1H) and 3.0 (1H) are assigned to H_e and H_f. The pattern of the multiplet assigned to H_i and H_j is very similar to that reported for the corresponding protons in **32** and **33** (22); in addition, the chemical shifts of H_d, H_i, and H_j in **31***a* relate well with those reported for the corresponding protons in **32** and **33**.

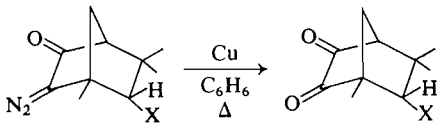


31*a*



32 R = Ac
33 R = Tos

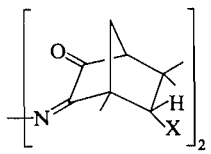
A preliminary investigation of the copper-catalyzed decomposition of **6** in benzene in the same manner as for **4** and **5** gave two major products. One of these (48%) was readily identified as the α-diketone **34**, which had been prepared as an intermediate in the synthesis of **6** (1). The other (32%) is considered to be a mixture of stereoisomeric azines **35**, as indicated by its mass, ir, and ^1H nmr spectra. In an attempt to eliminate azine formation the copper-catalyzed decomposition of **6** was carried out at very high dilution (0.02% in benzene). The reaction required 10 days for completion and still gave **35** (24%); **34** was again the major product (40%). There was only one minor component (~5%) that was sufficiently volatile to be **36**, the analogue of **12**. Fractions enriched in this product showed an ir band at 5.67 μm, but insufficient material was available for purification and



6 X = Cl
7 X = Br

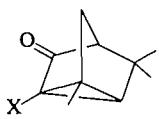
34 X = Cl
37 X = Br

+

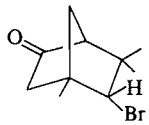


35 X = Cl
38 X = Br

identification. Decomposition of **7** under similar high dilution conditions required 4 days and gave the α-diketone **37** (42%) and the azine **38** (28%). A third product (22%) that was considerably more volatile

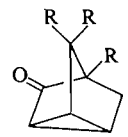


36 X = Cl
39 X = Br

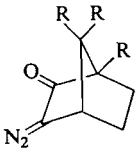


40

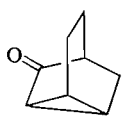
than **37** was formed. It had a band in its ir spectrum at 5.67 μm, and included peaks in its mass spectrum at *m/e* 228 (9) and 230 (11), corresponding to the elemental composition of **39**. But again insufficient material was available for purification and identification. A minor product (ir bands at 5.72 and 7.12 (w) μm) is considered to be **40**, the analogue of **8**. Although we have not firmly established that the



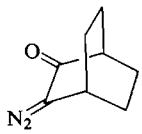
2 R = Me
41 R = H



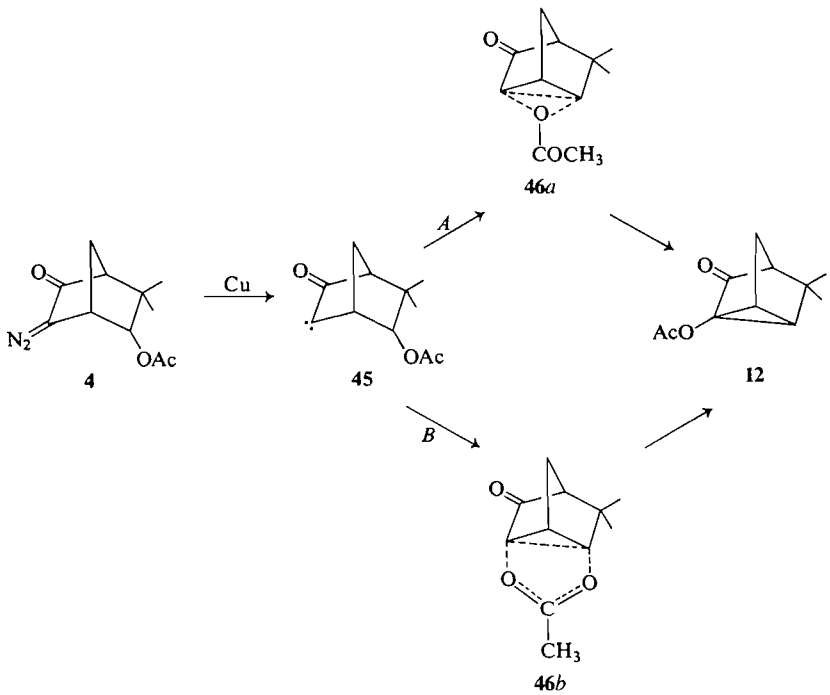
1 R = Me
42 R = H



43



44



SCHEME 2

tricyclic compounds **36** and **39** are formed from **6** and **7**, respectively, our preliminary investigation has clearly shown that if these compounds are in fact formed it is with considerable reluctance.

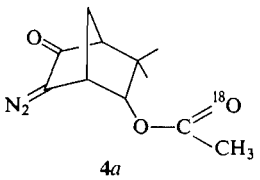
Mechanisms of the Decomposition Reactions of the Diazo Ketones

The high yields of cyclocamphanone (**2**) and nortricyclanone (**41**) obtained in the copper-catalyzed decomposition of 3-diazocamphor (**1**) and 3-diazo-2-norbornanone (**42**), respectively, in benzene (2, 3) contrast sharply with the very low yield of the tricyclic ketone **43** obtained in the similar decomposition of 3-diazobicyclo[2.2.2]octan-2-one (**44**) (3). This suggests that the geometry of the 2-norbornanone system is particularly favorable for the insertion of a carbenoid center at C-3 into the *endo* C—H bond at C-5 and that *endo* carbon – hetero atom bonds might undergo such insertion. The formation of the acetoxynortricyclanone derivative **12** from the diazo ketone **4** could be accounted for in this way (route *A* in Scheme 2). However, there is an alternative pathway that must be considered, wherein the carbonyl oxygen of the original acetoxyl group bonds with the carbenoid center (route *B* in Scheme 2). Two qualifications apply to each of the routes depicted in Scheme 2. First, the representation of the common intermediate as the free oxocarbene **45** may be an oversimplification; the copper-catalyzed decomposition of α-diazo ketones most probably gives an oxocarbene–copper complex (5, 23) which could be the species in which acetoxyl migration occurs (although it is not excluded that the reactive species is the free oxocarbene **45**, which is in equilibrium with its copper complex). Second, although the representation of the transition states as **46***a* and **46***b* implies that the acetoxyl migration is concerted with carbon–carbon bond formation, this need not be the case.

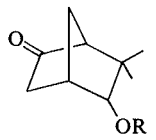
In order to distinguish between routes of type *A* and *B* the synthesis of **4***a*, labelled in the acetoxyl carbonyl with oxygen-18 was undertaken. The label was introduced by acetylation of the hydroxy ketone **47**, which had previously been prepared in the synthesis of **5** (1), with ^{18}O-labelled acetic anhydride to give **8***a*.[8] The ir spectrum of **8***a* shows bands at 5.74 and 5.86 μm in contrast to the single band at 5.74 μm in the ir spectrum of unlabelled **8**. The band at 5.86 μm is ascribed to the acetoxyl C=^{18}O stretching vibration.[9] Oxidation of **8***a* with selenium dioxide in bromobenzene as in the preparation of **1** (1) gave the labelled α-diketone **9***a*. The ir spectrum of **9***a* shows,

[8] ^{18}O-labelled acetic anhydride was prepared by the method of Gerrard and Thrush (24). Although two-thirds of the ^{18}O label is lost with this acetylating agent, it was found to be preferable to acetyl chloride because of losses in the preparation of the latter due to its high volatility.

[9] Substitution of ^{16}O by ^{18}O in ketones has been reported to cause an increase of ~0.10 μm (calcd. 0.13 μm) in the wavelength of the C=O stretching vibration (25).



4*a*



47 R = H
8*a* R = C(=^{18}O)CH$_3$

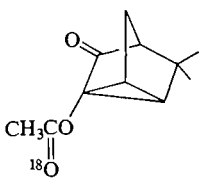
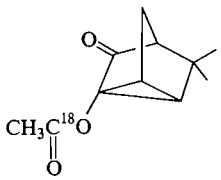
48 X = NNHTos

in addition to bands associated with unlabelled **9**, a broad band at 5.82 μm ascribed to the acetoxyl C=^{18}O stretching vibration (cf. the corresponding C=^{16}O band at 5.72 μm). Mass spectral analysis of **9***a* showed that it contained ~32% of ^{18}O label (see Experimental). The tosylhydrazone of **9***a*, **48**, was prepared in the usual way (1) and was shown by mass spectrometry to contain ~32% of ^{18}O label. It was converted to the diazo ketone **4***a* by chromatography on basic alumina (1, 26). The ir spectrum of **4***a* shows a close similarity to that of unlabelled **4** with the exception that the band at 5.90 μm is much stronger than the 5.77 μm band. The former band in the spectrum of **4***a* is ascribed to overlap of the diazo ketone C=^{16}O and acetoxyl C=^{18}O bands. Mass spectral analysis again indicated the presence of ~32% of ^{18}O label. The copper-catalyzed decomposition of **4***a* in the usual manner afforded a mixture (1.9 mg) of labelled tricyclic acetoxy ketone **12** (70%) and **8** (30%), as determined by vpc. The latter must be labelled as in **8***a*. The ir spectrum of the mixture included bands due to labelled **12** of equal intensity at 5.60 and 5.65 μm. This indicates that the labelled tricyclic acetoxy ketone consists largely of **12***b* rather than **12***a*, since if the latter had been present in major amount the diminution of the band due to the CH$_3$C=^{16}O carbonyl stretching vibration would have been expected to result in a significant difference in the intensities of the 5.60 and 5.65 μm bands. The mass spectrum of the mixture included peaks at *m/e* 43 (100) and 45 (18), indicating that 15% of the components of the mixture contained an acetoxyl group labelled with C=^{18}O. Clearly much of the peak at *m/e* 45 arises from the ~30% of **8***a* present in the mixture, and the ratio of **12***b* to **12***a* is calculated to be ~4:1 (see Experimental); thus it can be concluded that the major pathway for formation of **12** from **4** involves route *B* in Scheme 2.



12*a*



12*b*

The failure of **4** to follow route *A* as a major pathway is matched by the results with diazo ketones **5–7**. In these cases no equivalent to route *B* is available and the formation of tricyclanyl derivatives occurs not at all or at most as a minor pathway. Thus in the case of **5** the formation of the carbon–hydrogen insertion product **31** is the sole process observed, although insertion into the C—O bond would have been expected to be more facile in this case than in that of **4**. The preliminary results with **6** and **7** also show that insertion into the carbon–halogen bond is not a facile reaction and indeed is so slow that bimolecular reaction occurs more readily, even at high dilution. Thus in spite of the presumed favorable geometry C-3 carbenoid insertion into an *endo* C-5 carbon – hetero atom bond occurs with difficulty, if at all.[10]

We conclude by discussing briefly the putative origin of the other types of products formed from **4**, **6**, and **7**. The formation of the reduction products **8** and **40** is considered to involve hydrogen atom abstraction by the oxocarbene or carbenoid intermediate, perhaps after intersystem crossing from the singlet to triplet state. The oxidation products **9**, **34**, and **37** are thought to result from reaction of the same intermediate with adventitious oxygen, perhaps again after intersystem crossing. The hydroxy ketone **10** is considered to arise from **4** via the intervention of adventitious water. The formation of the azines **35** and **38**, which finds precedent in the copper-catalyzed decomposition of other α-diazo ketones (see for example refs. 3 and 27), can be interpreted in terms of reaction of the oxocarbene or carbenoid intermediate with undecomposed diazo ketone. The formation of these various other types of product again reflects the reluctance of the oxocarbene or carbenoid intermediate to insert into a carbon – hetero atom bond; only in the case of the formation of the carbon–hydrogen insertion product **31** from **5** is there no appreciable competition from intermolecular reactions.

Experimental

Melting points and boiling points are uncorrected. Infrared

[10]This result is in striking contrast to the report by one of us that such insertion can occur into a carbon–carbon bond (27); see, however, ref. 5.

spectra were recorded with carbon tetrachloride as solvent unless otherwise specified. Proton magnetic resonance spectra were recorded with deuteriochloroform as solvent. Solutions in organic solvents were dried over anhydrous magnesium sulfate and evaporated with a rotary evaporator, unless otherwise specified. Vapor phase chromatography was carried out on 10% SE 30 on Chromosorb P columns with a Perkin Elmer model 11 chromatograph.

Copper-catalyzed Decomposition of 5-endo-*Acetoxy-3-diazo-6,6-dimethyl-bicyclo[2.2.1]heptan-2-one (**4**). Formation of **8**, **9**, **10**, and **12***

Anhydrous benzene (dried by boiling under reflux for several days over lithium aluminum hydride and distillation immediately before use; ca. 500 mL); copper powder (Fisher, electrolytic metal, washed with ether and hexane, and vacuum dried prior to use; 6 g), and **4** (100 mg) were placed in a flame-dried, two-necked, 1-L flask containing a magnetic stirring bar and fitted with a nitrogen inlet tube, a double-surface condenser, and an outlet tube that directed the exit gases through a pool of mercury (a nitrogen bubbler with the inlet tube stoppered was used). Oxygen-free nitrogen[11] was passed through the solution for 0.5 h. The mixture was boiled under reflux with vigorous stirring under a stream of nitrogen for 40 h, cooled, and filtered. Evaporation of the light yellow solution afforded a viscous oil (104 mg). The volatile products in the residue were **12** (74%), **8** (5.5%), **9** (13%), and **10** (7.5%), as determined by vpc. The residue was digested for a short time with boiling hexane (ca. 10 mL). The hexane solution was cooled to −20°C, and the hexane soluble fraction was decanted from the precipitated **9** and **10**. Evaporation of the hexane soluble fraction afforded a viscous oil (62 mg) containing **12** (89.5%), **8** (7.5%), and **9** (3%). The isolated yield of **12** was 64%; it was purified by preparative vpc or chromatography on Florisil with elution with benzene (some decomposition was observed); it slowly solidified on standing. Recrystallization from hexane afforded chunky crystals of **12**, mp 47.5–48.5°C; λ_{max}: 5.60, 5.65, 8.28 μm; δ_H: 2.0–2.4 (m, with a sharp singlet at δ 2.11, 7H), 1.65 (m, 1H), 1.27 (s, 3H), 1.05 (s, 3H). *Anal.* calcd. for $C_{11}H_{14}O_3$: C 68.02, H 7.27; found: C 68.00, H 7.33.

The keto acetate **8** was identified by comparison of its vpc retention time, ir spectrum, and mass spectrum with those of authentic **8** (1).

The dione **9** and the ketol **10** were separated by preparative vpc or fractional recrystallization from hexane at 2°C. The dione **9** was identified by a mixture melting point determination and comparison of its vpc retention time and ir spectrum with those of authentic **9** (1). The ketol **10** is a white solid, mp 60–63°C; λ_{max}: 2.95, 5.74 μm; δ_H: 5.07, (br d, J = 4 Hz), 4.0 (m), 3.0 (m), 2.08 (s), 1.27 (s), 0.89 (s); *m/e* 212. It was identified by independent synthesis (*vide infra*).

5-endo-*Acetoxy-3-*endo-*hydroxy-6,6-dimethylbicyclo[2.2.1]-heptan-2-one (**10**) and* 6-endo-*Acetoxy-3-*endo-*hydroxy-5,5-dimethylbicyclo[2.2.1]heptan-2-one (**11**)*

A mixture of **9** (91.5 mg), anhydrous ether (10 mL), and platinum (10 mg) was stirred vigorously under a hydrogen atmosphere until the ethereal solution was colorless (ca. 45 min). Filtration of the mixture and evaporation of the ether afforded a mixture of the ketols **10** and **11** (92 mg, 100%); λ_{max}: 2.95, 5.74 μm; δ_H: 5.07 (br d, J = 4 Hz), 4.03 (br d, J = 4 Hz), 3.0 (m), 2.3 (m), 1.5–2.0 (m), 2.08 (s), 1.27 (s), 0.89 (s), 4.92 (br d, J = 4 Hz), 4.22 (br d, J = 4 Hz), 2.04 (s), 1.06 (s).

*2-Acetoxy-1,5,5-trimethyltricyclo[2.2.1.0^{2,6}]heptan-3-one (**29**)*

A mixture of **26** (49 mg) (1), anhydrous ether (6 mL), and lithium (washed twice with hexane, once with ether, and cut into small pieces; 40 mg) was vigorously stirred under nitrogen for 40 h. A grey precipitate of lithium bromide formed. The excess lithium was removed and destroyed in methanol. Addition of acetic anhydride (0.4 mL) to the stirred reaction mixture produced an immediate white precipitate of lithium acetate. Ether (15 mL) was added to the mixture and the ethereal layer was washed with water (5 × 20 mL), dried, and filtered. Distillation afforded **29** (22 mg, 52%), bp 80°C/18 Torr; λ_{max}: 5.61, 5.65 μm; δ_H: 2.13 (s) and 2.10 (d, J = 1.5 Hz) (5H), 1.82 (d, J = 1.7 Hz, 1H), 1.66 (m, J = 1.5 Hz, 1H), 1.33 (s, 3H), 1.21 (s, 3H), 1.05 (s, 3H). *Mol. Wt.* calcd. for $C_{12}H_{16}O_3$: 208.1099; found (ms): 208.1105.

5′-endo-*Bromospiro(cyclopropane-1,7′-norborn-2′-ene) (**16**)*

Vinyl bromide (4.30 g), a small amount of hydroquinone, and a mixture (3.34 g) of 60% of the diene **15**[6] and 40% of 1,2-dibromoethane (12) were heated in a sealed glass tube at ca. 170°C for 13.5 h. After cooling to room temperature the sealed tube was further cooled in a Dry Ice – acetone bath and opened. Distillation of the orange solution afforded 1,2-dibromoethane, bp 37–42°C/22 Torr, and **16** (2.66 g, 62%), bp 95–98°C/22 Torr; λ_{max}: 3.30, 6.08 μm; δ_H: 6.38 (m, 1H), 6.18 (m, 1H), 4.47 (dt, J = 8.0, 3.5 Hz, 1H), 2.0–2.7 (m, 3H), 1.39 (dd, J = 12.5, 3.5 Hz, 1H), 0.42 (m, 4H). *Anal.* calcd. for $C_9H_{11}Br$: C 54.30, H 5.57, Br 40.14; found: C 54.08, H 5.72, Br 39.90.

*Apobornyl Bromide (**17**)*

A mixture of **16** (1.99 g, 10.0 mmol), glacial acetic acid (15 mL), and a small amount of platinum catalyst was stirred at 80°C under an atmosphere of hydrogen until the absorption of hydrogen ceased (18.4 mmol was absorbed); 8.5 h reaction time was required. To the cooled reaction mixture was added ether (300 mL), and the ethereal solution was decanted from the platinum, washed with water (5 × 100 mL), and saturated aqueous sodium bicarbonate (2 × 100 mL), dried, and filtered. Evaporation of ether afforded apobornyl bromide (**17**; 1.80 g, 89%), bp 83–86°C/10 Torr; δ_H: 4.62 (m, 1H), 1.15–2.9 (m, 8H), 1.11 (s) and 1.06 (s) (6H). *Anal.* calcd. for $C_9H_{15}Br$: C 53.22, H 7.44, Br 39.34; found: C 53.29, H 7.54, Br 39.34.

6-endo-*Bromoapocamphor (**18**)*

A slurry of pulverized chromium trioxide (35 g) in glacial acetic acid (100 mL) was added in small portions over 0.6 h to a stirred solution of apobornyl bromide (**17**, 11.86 g) in glacial acetic acid (10 mL) at a rate such that the reaction mixture temperature was maintained near 75°C. After the addition was complete, the green solution was stirred at 75°C for 1 h, cooled, and diluted with water (350 mL). The solution was extracted with ether (10 × 50 mL), and the combined ethereal extracts were washed with water (2 × 300 mL) and saturated aqueous sodium bicarbonate (100 mL), dried, and filtered. Distillation afforded **18** (5.40 g, 43%) as an unstable colorless oil, bp 73–80°C (50 μm); λ_{max}: 5.71, 7.09 μm; δ_H: 4.78 (m, 1H), 1.3–3.0 (m, 6H), 1.14 (s, 6H). *Anal.* calcd. for $C_9H_{13}BrO$: C 49.79, H 6.04, Br 36.81; found: C 50.52, H 6.03, Br 36.16. *Mol. Wt.* calcd. for $C_9H_{13}BrO$: 216.0134, 218.0110; found (ms): 216.0150, 218.0130.

5-endo-*Bromoapocamphorquinone (**19**)*

A mixture of **18** (5.31 g), selenium dioxide (7.0 g), and bromobenzene (35 mL) was stirred at 150°C for 24 h and then cooled. The red bromobenzene solution was decanted from the

[11]Nitrogen was passed twice through Fieser's solution (28), and once through acid, sodium hydroxide, and silica gel desiccant, to remove oxygen and water.

selenium. The selenium was washed with small amounts of ether until the ethereal extracts were colorless. Distillation of the combined bromobenzene and ether solutions afforded an orange oil, bp 50°C/15 Torr, which was mainly bromobenzene. The undistilled residue was chromatographed on Florisil (120 g) with elution with benzene. After a light yellow forerun, **19** was eluted with 10% ether–benzene. Recrystallization from hexane (100 mL) afforded **19** (1.89 g, 33.5%) as a very unstable yellow solid, mp 86–89°C. Sublimation and recrystallization raised the melting point to 92.0–93.5°C; λ_{max}: 5.61, 5.70 μm; δ_H: 4.75 (m, 1H), 3.18 (m, 1H), 2.94 (dd, J = 5.0, 1.5 Hz, 1H), 2.75 (br d, J = 5 Hz, 1H), 2.13 (dd, J = 15, 4.0 Hz), 1.21 (s, 3H), 1.15 (s, 3H). *Mol. Wt.* calcd. for $C_9H_{11}BrO_2$: 229.9942, 231.9915; found (ms): 229.9943, 231.9923.

*Treatment of **19** with Lithium and Acetic Anhydride. Formation of **12***

A mixture of **19** (freshly recrystallized; 50 mg) anhydrous ether (7 mL), and lithium (washed twice with hexane, once with ether, and cut into small pieces; 100 mg) was vigorously stirred under nitrogen for 24 h. A grey precipitate of lithium bromide formed. The excess lithium was removed. Acetic anhydride (100 mg) was added to the stirred reaction mixture and produced an immediate white precipitate of lithium acetate. Ether (20 mL) was added to the mixture and the ethereal layer was washed with water (5 × 10 mL), dried, and filtered. The ether was evaporated, and the residue was digested in boiling hexane (2 mL) for a short time; the mixture was then cooled to −20°C, and the hexane-soluble fraction was decanted. Evaporation of the hexane afforded **12** (21 mg, 50%) as a colorless oil that crystallized slowly on standing. Preparative vpc gave material with a melting point of 45.0–48.0°C. A mixture of this material with pure **12**, mp 47.5–48.5°C, obtained in the copper-catalyzed decomposition of **4**, had mp 46.0–48.0°C.

*Apopinene (**22**)*

Apopinene (**22**) was prepared by the method of Eschinazi and Pines (29) by oxidation of α-pinene to myrtenal with selenium dioxide (30) and decarbonylation of this with palladium hydroxide on barium sulfate (31); bp 84–88°C/118 Torr (lit. (30) 47–48°C/30 Torr); λ_{max}: 3.32, 6.15 μm; δ_H: 6.12 (m, 1H), 5.55 (m, 1H), 1.9–2.7 (m, 6H), 1.29 (s, 3H), 0.90 (s, 3H).

*Addition of Hydrogen Bromide to Apopinene (**22**). Formation of **17**, **24**, and **25***

Hydrogen bromide was bubbled into an ice-cold solution of **22** (13.95 g, 0.115 mol) in chloroform (16 mL) until at least 9.3 g (0.115 mmol) of hydrogen bromide had been absorbed. After standing at 2°C overnight the purple solution was distilled, producing a mixture of bromides (18.50 g, 80%); bp 68–72°C/1.2 Torr (lit. (16) bp 43°C/0.15 Torr). The mixture contained **17** (53%), **24** (39%), and **25** (8%), as determined by ^{1}H nmr spectroscopy; δ_H: 4.62 (m), 4.00 (dd, J = 8.5, 5.0 Hz), 3.71 (d, J = 2.0 Hz).

*2-Methoxy-5,5-dimethyltricyclo[2.2.1.0^{2,6}]heptan-3-one (**30**)*

A mixture of **19** (321 mg), lithium (washed twice with hexane, once with ether, and cut into small pieces; 400 mg), and anhydrous ether (16 mL) was vigorously stirred under nitrogen for 44 h. The excess lithium was removed with tweezers from the brown mixture, washed with ether, and destroyed in methanol; the ethereal washings were combined with the reaction mixture. Dimethyl sulfate (0.2 mL) was added to the stirred mixture. The white solid that formed was filtered, and the ether in the filtrate was evaporated. The residue was digested in boiling hexane (30 mL) and the solution was cooled to −20°C; the hexane-soluble layer was separated from the hexane-insoluble layer by decantation and heated with water (20 mL) on a steam bath for 0.5 h to destroy the remaining dimethyl sulfate. The solution was cooled and extracted three times with ether. The ethereal extracts were dried and filtered. Distillation gave **30** (26 mg, 15% based on unrecovered **19**), bp ca. 75°C/15 Torr. Preparative vpc afforded a sample, mp 41.8–43.0°C; λ_{max}: 5.68 μm; δ_H: 3.47 (s, 3H), 2.0–2.3 (m, 4H), 1.51 (m, 1H), 1.17 (s, 3H), 1.00 (s, 3H). *Mol. Wt.* calcd. for $C_{10}H_{14}O_2$: 166.0994; found (ms): 166.0995.

The hexane-insoluble layer was worked up in the same way as the hexane-soluble layer. Recrystallization of the residue from hexane (20 mL) afforded **19** (86 mg).

*Copper-catalyzed Decomposition of the Methoxy Diazo Ketone (**5**). Formation of 9,9-Dimethyl-5-oxatricyclo[4.2.1.0^{3,7}]nonan-2-one (**31**)*

The conditions described for the copper-catalyzed decomposition of **4** were employed. A mixture of **5** (38 mg), benzene (distilled from lithium aluminum hydride; 190 mL) and copper (Pfaltz and Bauer; washed twice with hexane, once with ether, and dried at water-aspirator pressure; 1.6 g), was boiled under reflux with vigorous stirring under a stream of oxygen-free nitrogen. After 16 h the solution was almost colorless. The mixture was cooled and filtered; evaporation of the filtrate left an orange oil (39 mg). Distillation afforded **31** (29 mg, 90%) as a semisolid (decomposes on standing at room temperature), bp ca. 80°C/20 Torr; λ_{max}: 5.73 μm; δ_H: 4.04 (br d, J = 4.8 Hz, 1H), 3.75–3.95 (m, 2H), 3.0 (m, 1H), 2.5 (m, 1H), 2.09 (m, 1H), 2.03 (d, J ~ 12 Hz, 1H), 1.82 (dt, J = 12, 1.5 Hz, 1H), 1.02 (s, 3H), 0.84 (s, 3H). *Mol. Wt.* calcd. for $C_{10}H_{14}O_2$: 166.0994; found (ms): 166.0993.

*Copper-catalyzed Decomposition of the Chloro Diazo Ketone **6**. Formation of **34** and **35***

All the precautions described for the copper-catalyzed decomposition of **4** were employed. A mixture of **6** (49 mg), benzene (distilled from lithium aluminum hydride; 250 mL) and copper powder (Fisher electrolytic metal powder, washed with ether and hexane, and dried at water-aspirator pressure; 1.0 g) was boiled under reflux with vigorous stirring under a stream of oxygen-free nitrogen for 10 days. The mixture was cooled and filtered. Evaporation of the filtrate afforded a brown semisolid (46 mg), which was digested in boiling hexane (1 mL) for a few min. The hexane solution was decanted from the yellow residue of the azine **35** (11 mg, 24%), mp ca. 310°C (dec.); λ_{max}: ($CHCl_3$): 5.76, 6.19 μm; δ_H: 3.92 (br s), 0.8–2.4 (m); ms m/e: 396 (16), 398 (10), 400 (3).

The dione **34**, which precipitated on cooling the hexane solution was identified by comparison of its ir spectrum and vpc retention time with those of an authentic sample and accounted for 40% of the products, as determined by vpc. The remaining solution was evaporated and the residue was chromatographed on a column of Florisil (1.0 g) with elution with 2% ether–benzene. The first fraction (8 mL) contained a product with an ir band at 5.67 μm; its vpc retention time was compatible with its being **36**, but insufficient material was available for purification and identification. It composed ~5% of the total product mixture. Subsequent fractions contained **34** and **6**.

*Copper-catalyzed Decomposition of the Bromo Diazo Ketone (**7**)*

All the precautions described for the copper catalyzed decomposition of **4** were employed. A mixture of **7** (40 mg), benzene (distilled from lithium aluminum hydride; 200 mL), and

copper (Pfaltz and Bauer, washed twice with hexane, once with ether and dried at water-aspirator pressure; 0.90 g) was boiled under reflux with vigorous stirring under a stream of oxygen-free nitrogen. After 96 h the decomposition was almost complete as determined by the ir spectrum of an aliquot. The mixture was cooled and filtered; evaporation of the filtrate left an orange semisolid (34 mg). This residue was digested in boiling hexane (13 mL) for a few min; the yellow hexane solution was separated by decantation from **38** which was obtained as a yellow solid (9.8 mg, 28%), mp ca. 310°C (dec.); λ_{max} ($CHCl_3$): 5.76, 6.19 μm; ms *m/e*: 406 (M − HBr).

The hexane solution contained three other products in yields of greater than 3%. The hexane was evaporated, and the residue was chromatographed (preparative thin layer) on silica gel with elution with ethyl acetate followed by extraction of the yellow band with an R_f of 0.72 with methanol. The methanol was evaporated and the residue was dissolved in hexane, and the solution was cooled to −20°C; the hexane solution was decanted from the yellow precipitate of dione **37**, identified by comparison of its ir spectrum and vpc retention time with those of an authentic sample. The dione accounted for 42% of the products as determined by vpc of the crude reaction residue. Evaporation of the hexane-soluble layer decanted from **37** afforded a volatile product mixture, containing a single major product (70%, as estimated by vpc) which is tentatively considered to be **39**. This compound accounted for 22% of the products as determined by vpc; λ_{max}: 5.67 μm; ms *m/e* 228 (9), 230 (11).

Preparative vpc of a sample of the crude reaction residue, after removal of **38**, afforded a small amount of a compound assigned structure **40**; λ_{max}: 5.72, 7.12 μm; ms *m/e*: 230 (11), 232 (11).

6-endo-*(Acetoxycarbonyl-^{18}O)-5,5-dimethylbicyclo*[*2.2.1*.]-*heptane-2,3-dione (**9**a)*

Acetyl chloride was added dropwise to $H_2{}^{18}O$ (136 mg, 6.80 mmol)[12] until the weight increased to 424 mg (6.80 mmol of acetic acid-^{18}O). The acetic acid was allowed to stand at room temperature for *ca.* 16 h to scramble the label; λ_{max}: 5.86, 5.91 μm. To a stirred solution of this (202 mg, 3.26 mmol) and pyridine (259 mg, 3.26 mmol) in anhydrous ether (2 mL), cooled in an ice–salt bath, was added thionyl chloride (195 mg, 1.63 mmol) in anhydrous ether (1 mL). The mixture was stirred for 10 min and the precipitate was filtered and washed with anhydrous ether (5 mL). The filtrate and washings were concentrated on a water bath at ca. 40°C, giving a yellow liquid (401 mg) that was 75% ether and 25% by weight of labelled acetic anhydride (58% yield), as determined by ^{1}H nmr spectroscopy; λ_{max}: 5.50, 5.58, 5.70, 5.79 μm.

A mixture of this labelled acetic anhydride, **47** (220 mg, 1.42 mmol), and pyridine (5 mL) was boiled under reflux with stirring for 3.5 h. The solution was cooled, and ether (60 mL) was added. The ethereal solution was washed with saturated aqueous sodium bicarbonate (20 mL) and aqueous 10% hydrochloric acid (3 × 20 mL), dried, and filtered. Evaporation of the ether afforded **8***a* (220 mg, 63%) of 80% purity, as determined by ^{1}H nmr spectroscopy, as an oil; λ_{max}: 5.74, 5.86, 7.10, 8.10 μm.

A mixture of **8***a* (80%; 220 mg), selenium dioxide (220 mg), and bromobenzene (3 mL) was heated at 150°C with stirring for 5 h. The mixture was cooled and chromatographed on Florisil (50 g). Elution with benzene gave bromobenzene. Elution with 50% ether–benzene (250 mL) gave **9***a* as a yellow solid (95 mg, 50%); λ_{max}: 5.61, 5.68, 5.72, 5.82 (br), 8.12 μm; ms *m/e*: 43 (100), 45 (44), indicating ca. 32% labelling when account is taken of the fact that 4% of the *m/e* 43 peak in the spectrum of **9** arises from $C_3H_7^+$, as determined by high resolution mass spectrometry.[13]

5-endo-*(Acetoxycarbonyl-^{18}O)-3-diazo-6,6-dimethylbicyclo-*[*2.2.1*]*heptan-2-one (**4**a)*

A warm solution of tosylhydrazine (90 mg, 0.48 mmol) in glacial acetic acid (0.4 mL) was added to a warm solution of **9***a* (93 mg, 0.44 mmol) in glacial acetic acid (0.2 mL). After standing at room temperature for 1 h the yellow solution was added to ice (ca. 25 g), forming a white precipitate that was collected, washed thoroughly with water, and air dried to give **48** (145 mg, 88%); ms *m/e* 43 (100), 45 (54), indicating ca. 32% labelling when account is taken of a small peak at *m/e* 45 in the spectrum of the unlabelled tosylhydrazone.[13]

Tosylhydrazone **48** (140 mg) was placed on a column of basic alumina (Merck: 1.5 × 0.3 in.). Elution with benzene (100 mL) and ether (100 mL) followed by evaporation of the eluate and recrystallization from hexane afforded **4***a* (45 mg, 55%) as a chunky yellow solid; λ_{max}: 4.82, 5.77, 5.90, 7.32, 8.02 μm; ms *m/e*: 43 (100), 45 (47), indicating ca. 32% labelling.[13]

*Copper-catalyzed Decomposition of **4**a. Formation of 2-(Acetoxyalkoxyl-^{18}O)-5,5-dimethyltricyclo*[*2.2.1.0^{2,6}*]-*heptan-3-one (**12**b)*

All the precautions described for the copper-catalyzed decomposition of **4** were employed. A mixture of the labelled diazo ketone **4***a* (5.0 mg), benzene (distilled from lithium aluminum hydride), and copper (Pfaltz and Bauer, washed twice with hexane, once with ether, and dried at water-aspirator pressure: 0.50 g) was boiled under reflux with vigorous stirring under a stream of oxygen-free nitrogen for 40 h. The mixture was cooled and filtered. The filtrate was evaporated and the residue was dissolved in warm hexane (1 mL), and the solution was cooled to −20°C. The hexane-soluble layer was separated by decantation and evaporated affording an oil (1.9 mg) consisting of labelled **12** (70%) and **8** (30%) as determined by vpc; 5.60, 5.65, 5.7–5.85 (sh) μm; *m/e* 43 (100), 45 (18), indicating that when account is taken of the presence of **8***a* the ratio **12***b*–**12***a* is ~4:1.[13]

Studies on the syntheses of heterocyclic compounds. Part 782. Another total synthesis of (±)-tubulosine and (±)-deoxytubulosine[1,2]

TETSUJI KAMETANI, YUKIO SUZUKI, AND MASATAKA IHARA
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980, Japan

Received December 13, 1978

TETSUJI KAMETANI, YUKIO SUZUKI, and MASATAKA IHARA. Can. J. Chem. 57, 1679 (1979).

(±)-Tubulosine (**1**) and (±)-deoxytubulosine (**3**) were totally synthesized by the Pictet–Spengler reaction of (±)-4-oxoprotoemetine (**7**) with serotonin (**8**) or tryptamine (**9**) followed by reduction with sodium bis(2-methoxyethoxy)aluminum hydride in pyridine.

TETSUJI KAMETANI, YUKIO SUZUKI et MASATAKA IHARA. Can. J. Chem. 57, 1679 (1979).

On a effectué des synthèses totales de la (±)-tubulosine (**1**) et de la (±)-désoxytubulosine (**3**) par la réaction de Pictet–Spengler de la (±)-oxo-4 protoemétine (**7**) avec la sérotonine (**8**) ou la tryptamine (**9**) suivie par une réduction à l'aide du $Na(CH_3OCH_2CH_2O)_2AlH_2$.

[Traduit par le journal]

Tubulosine (**1**), isotubulosine (**2**), and deoxytubulosine (**3**) were isolated as levorotatory forms from the same plant, *Alangium lamarckii* (2). Tubulosine derivatives are known to inhibit the protein synthesis and expected to be potential antineoplastic agents (3). Recently we have developed a short synthetic route to emetine through (±)-4-oxoprotoemetine (**7**) which was stereoselectively prepared by the condensation of 3,4-dihydro-6,7-dimethoxy-1-methylisoquinoline (**4**) with dimethyl 3-methoxyallylidenemalonate (**5**) in several steps via the intermediate enamide **6** (Scheme 1). The total yield from **4** was 60% (4). Thus, we have examined the synthesis of tubulosine and related compounds from aldehyde **7**, and we wish to report here the total synthesis of the above alkaloids, during whose reaction a new method of reducing the amide group was also revealed.

Serotonin (**8**) is commercially available as a complex with creatinine sulfate and was liberated from the complex using Amberlite XAD-4 column chromatography. Condensation of **8** with (±)-4-oxoprotoemetine (**7**) was carried out by stirring an equimolecular mixture in acetic acid at room temperature for 2 days. The Mannich base, *m/e* 489 (M^+), obtained in high yield, consisted of (±)-4-oxotubulosine (**10**) and its C-1′ epimer (**11**) in a 4:1 ratio; the identities of **10** and **11** were verified by tlc and nmr (DMSO-d_6) analysis. The ratio did not change appreciably even when the reaction was carried out under more acidic conditions or at a higher temperature. The product was very insoluble in ordinary solvents and a separation of the diastereoisomeric mixture could not be achieved. Mainly because of its slight solubility, reduction of a mixture of **10** and **11** with lithium aluminum hydride in hot dioxane gave none of the desired product. Eventually the reduction was carried out by treatment of a mixture of **10** and **11** with sodium bis(2-methoxyethoxy)aluminum hydride in pyridine at room temperature for 1 h. The reduction product was purified by column chromatography and recrystallization from methanol to afford (±)-tubulosine (**1**), mp 249–250°C, whose nmr (DMSO-d_6) and mass spectra and chromatographic behavior (tlc and hplc) were identical with those of natural tubulosine donated by Prof. Szántay (4). (±)-Isotubulosine (**2**) was obtained as a minor product but could not be separated from **1** completely. However the structure of **2** was supported by the nmr spectrum (DMSO-d_6), which exhibited one of the methoxyl groups at high field (3.49 ppm) (**6**), and tlc behavior on silica gel, which showed the compound to have a lower R_f value than that of tubulosine (5–7). The preferential formation of tubulosine (**1**) over isotubulosine (**2**) in the Pictet–Spengler reaction using (−)-protoemetine and serotonin (**8**) was also observed by Szántay and Kalaus (5).

Stirring a mixture of aldehyde **7** and tryptamine (**9**) hydrochloride in acetic acid at room temperature for 2 days yielded a mixture of (±)-4-oxodeoxytubulosine (**12**) and its epimer (**13**) in a 4:1 ratio. The former (**12**) was obtained in pure form after preparative thin-layer chromatography and was reduced with sodium bis(2-methoxyethoxy)aluminum hydride in pyridine under the same condition as above to furnish (±)-deoxytubulosine (**3**), mp 156–158°C. The nmr spectrum ($CDCl_3$) of this product was superimposable upon that of an authentic sample of compound **3** given to us by Prof. Battersby. Since lactam **12** was soluble in hot dioxane, reduction with

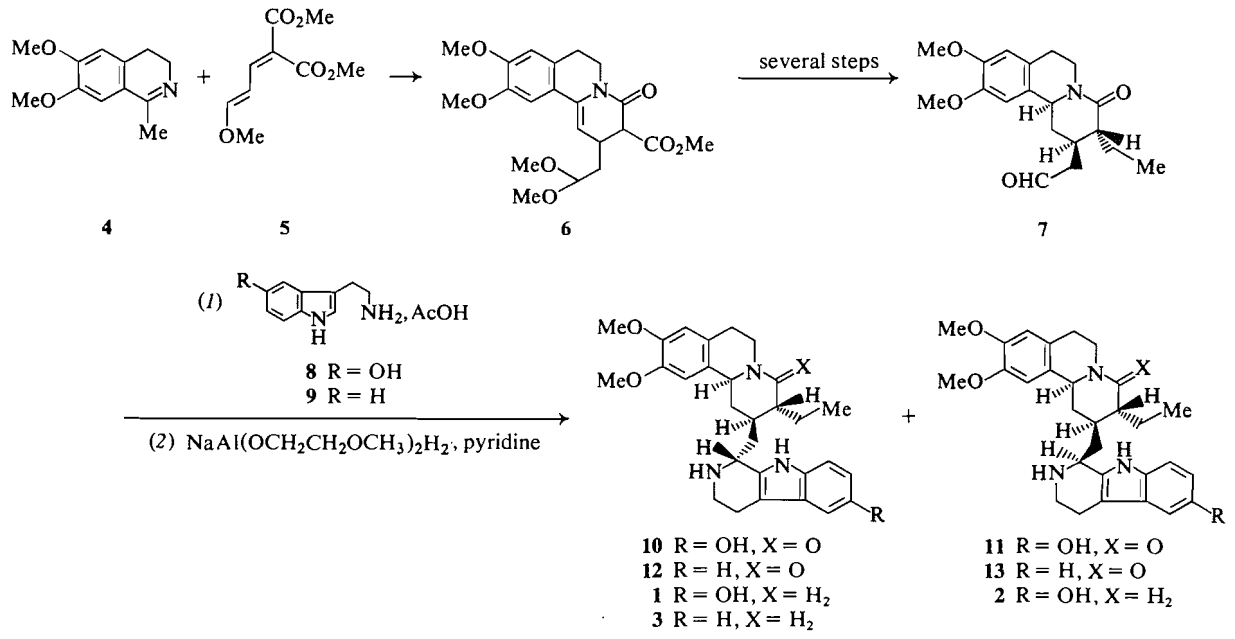
0008-4042/79/131679-03$01.00/0



SCHEME 1[3]

lithium aluminum hydride under reflux was examined but **3** was obtained in very poor yield. Sodium bis(2-methoxyethoxy)aluminum hydride reduced the tertiary amides under mild condition in pyridine and the limit and the scope of this reduction is under investigation.

Experimental

Melting points were determined with a Yanaco micro-melting point apparatus and are uncorrected. Infrared spectra were taken with a Hitachi 215 spectrophotometer. Nuclear magnetic resonance spectra were measured with a JNM-PMX-60 instrument with tetramethylsilane as an internal standard. Mass spectra were taken with Hitachi M-52 spectrometer.

(±)-Tubulosine (1)

A solution of serotonin (**8**) – creatinine sulfate complex (300 mg) in water (50 mL) was subjected to Amberlite XAD-4 (80 mL) column chromatography. After elution with water (100 mL), an eluate of methanol–water (1:1 v/v) gave serotonin (124 mg), which was judged free from creatinine sulfate on the basis of its nmr analysis.

A mixture of serotonin (**8**) (124 mg) and (±)-4-oxoprotoemetine (**7**) (217 mg) in AcOH (30 mL) was stirred for 2 days at room temperature. The solvent was evaporated to give a caramel which was dried under reduced pressure. To a stirred 70% solution of $NaAl(OCH_2CH_2OCH_3)_2H_2$ in toluene (2 mL) was added a solution of the above material in pyridine (2 mL) and the resulting solution was stirred for 1 h at room temperature. The solvents were evaporated and excess reagent was decomposed and neutralized by the addition, under ice-cooling, of a saturated NH_4Cl solution. The resulting mixture was extracted several times with $CHCl_3$. The $CHCl_3$ extract was washed with a saturated NaCl solution, dried (Na_2SO_4), and evaporated to give a reddish viscous material which was purified by column chromatography on silica gel. Elution with $CHCl_3$–MeOH (20:1 v/v), followed by concentration of the solvent, gave a solid, which was recrystallized from MeOH to afford (±)-tubulosine (**1**) (65 mg, 21%) as fine colorless needles, mp 249–250°C, the mass and nmr (DMSO-d_6) spectra and hplc and tlc behavior of which were identical with those of natural tubulosine. *Anal.* calcd. for $C_{29}H_{37}N_3O_3 \cdot 2H_2O$: C 68.08, H 8.08; found: C 67.86, H 7.79.

Further elution with the same solvent gave a fraction which mainly consisted of (±)-isotubulosine (**2**) and a small amount of (±)-tubulosine which were not separable by recrystallization.

(±)-4-Oxodeoxytubulosine (12)

A mixture of (±)-4-oxoprotoemetine (**7**) (150 mg) and tryptamine (**9**) hydrochloride (90 mg) in AcOH (5 mL) was stirred for 2 days at room temperature. After evaporation of the solvent, the residue was basified with a saturated $NaHCO_3$ solution and extracted with $CHCl_3$. The $CHCl_3$ extract was washed with a saturated NaCl solution, dried (Na_2SO_4), and evaporated to give a syrup, which was purified by ptlc on silica gel to afford (±)-4-oxodeoxytubulosine (**12**) (128 mg, 59.8%) as a syrup; ir ν_{max} ($CHCl_3$): 1620 cm^{-1} (C=O); nmr ($CDCl_3$) δ: 1.00 (3H, m, CH_2CH_3), 3.93 (6H, s, 2 × OMe), 6.67 and 6.87 (2H, each s, 2 × ArH); ms *m/e* 473 (M^+).

(±)-Deoxytubulosine (3)

To a stirred 70% solution of $NaAl(OCH_2CH_2OCH_3)_2H_2$ in toluene (2 mL) was added (±)-4-oxodeoxytubulosine (**12**) (128 mg) in pyridine (2 mL) and the solution was stirred for 1 h at room temperature. The solvents were removed and excess reagent was decomposed and neutralized by the addition, with ice cooling, of a saturated NH_4Cl solution. The resulting mixture was extracted with $CHCl_3$. The extract was washed with a saturated NaCl solution, dried (Na_2SO_4), and evaporated to give a reddish viscous material which was dissolved in 2% HCl (5 mL). The resulting solution was washed with Et_2O. The aqueous layer was basified with solid $NaHCO_3$ and extracted with $CHCl_3$. The extract was washed with a

[3]All compounds having chiral centers are racemates.

saturated NaCl solution, dried (Na_2SO_4), and evaporated to give a reddish solid. Recrystallization from $CHCl_3$–MeOH gave (±)-deoxytubulosine (**3**) (51 mg, 41%) as colorless needles, mp 156–158°C; the nmr spectrum ($CDCl_3$) was identical with that of the authentic sample (**3**); ms *m/e* 459 (M^+). *Anal.* calcd. for $C_{29}H_{37}N_3O_2 \cdot H_2O$: C 72.86, H 8.23, N 8.80; found: C 72.65, H 8.18, N 8.75.

Acknowledgments

We thank Prof. C. Szántay and Prof. A. R. Battersby for their kind gifts of (−)-tubulosine and of an nmr spectrum of deoxytubulosine, respectively. We also thank Mr. K. Kawamura, Mrs. C. Koyanagi, Miss K. Mushiake, Mrs. R. Kobayashi, Miss M. Tanno, Miss K. Katsuma, Miss K. Kikuchi, Miss. Y. Katoh, and Miss J. Okazaki for microanalyses and spectral measurements and for the preparation of this manuscript.

Total synthesis of indole and dihydroindole alkaloids. XVII. The total synthesis of catharine and vinamidine (catharinine)[1–3]

JAMES P. KUTNEY, JOHN BALSEVICH, AND BRIAN R. WORTH

Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, B.C., Canada V6T 1W5

Received December 8, 1978

JAMES P. KUTNEY, JOHN BALSEVICH, and BRIAN R. WORTH. Can. J. Chem. 57, 1682 (1979).

Oxidation of 16,18-dicarbomethoxycleavamine gave the epoxide (**6**) and the enamide (**9**). Similar oxidation of 3′,4′-dehydrovinblastine (**8**) or leurosine (**7**) gave the natural product catharine (**3**). Potassium permanganate oxidation of **7** or **8** gave 3*R*-hydroxyvinamidine (**19**) whereas similar oxidation of 4′-deoxyleurosidine (**29**) gave the alkaloid vinamidine (**4**).

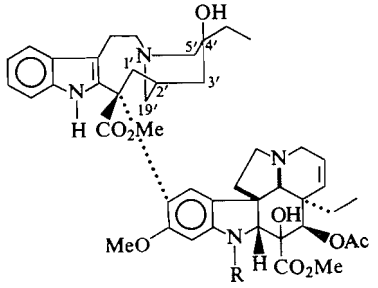
JAMES P. KUTNEY, JOHN BALSEVICH et BRIAN R. WORTH. Can. J. Chem. 57, 1682 (1979).

L'oxydation de la dicarbométhoxy-16,18 cléavamine conduit à l'époxyde (**6**) et à l'énamide (**9**). Une oxydation semblable de la déhydro-3′,4′ vinblastine (**8**) ou de la leurosine (**7**) fournit le produit naturel catharine (**3**). L'oxydation de **7** ou **8** par le permanganate de potassium fournit l'hydroxy-3*R* vinamidine (**19**) alors qu'une oxydation semblable de la déoxy-4′ leurosidine (**29**) conduit à l'alcaloïde vinamidine (**4**).

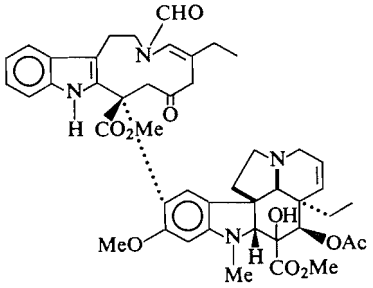
[Traduit par le journal]

The important oncolytic action of many of the members of the vinblastine (**1**) – vincristine (**2**) family initiated innumerable investigations into the chemistry and biochemistry of these 'dimeric' alkaloids. Indeed efforts from several laboratories led to syntheses of some of the natural products as well as many derivatives while more recent work enabled unambiguous structure identification of two interesting ring cleaved compounds catharine (**3**) (4) and vinamidine (catharinine) (**4**) (5, 6). This report describes total syntheses of both **3** and **4**, and several related compounds.

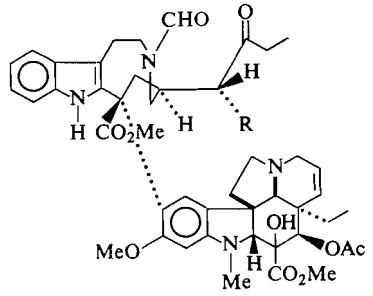
In the early stages of our investigation of totally synthetic routes to 'bisindole' alkaloids, considerable emphasis was placed on selective functionalisation of model systems of the cleavamine type, particularly the protected indole derivative (**5**) (8). In this regard, aerial or hydroperoxide oxidation of (**5**) (7, 8) provided the 3*R*,4*S*-epoxide (**6**) and later adaption of this transformation allowed the first of several syntheses of the natural product leurosine (**7**) from synthetic 3′,4′-dehydrovinblastine (**8**) (7, 8).



1 R = CH_3
2 R = CHO



3



4 R = H **20** R = OAc
19 R = OH **28** R = $OCSC_6H_5$

In an attempt to optimise conditions for the formation of the epoxide **6**, the aerial oxidation of **5** in peroxide-free tetrahydrofuran (THF) containing a small amount of aqueous trifluoroacetic acid (TFA) was studied, the course of the reaction being monitored by thin-layer chromatography (tlc) after 3, 5,

[3]For preliminary reports on this work see refs. 2 and 3.

0008-4042/79/131682-09$01.00/0

and 8 days. At ambient temperature, no reaction was apparent after 3 days, whereas both **5** and **6** were detected after 5 days. The starting material (**5**) had been consumed after 8 days but the epoxide **6** (isolated in only 10% yield) had undergone further transformation to **9** which was isolated in 52% yield. Based on an assumption that the cleavamine skeleton was intact, this latter product was originally assigned as the 5-oxo derivative **10** (8). The revised assignment (**9**) followed further analysis of spectral properties and results of a chemical transformation. Thus the ^{1}Hmr spectrum of **9** exhibited absorbances at δ 8.13 (N_b-CHO), 5.23 (C5-H), and 1.90 ppm (—CH_2CH_3) in accord with the proposed structure. The duplication of various resonances as observed in this spectrum has also been noted in a number of alkaloids exhibiting rotomers of a formamide group (9). The infrared spectrum showed strong absorbance at 1680 and 1650 cm^{-1} in support of the enamide assignment. The presence of a ketone carbonyl function was substantiated by sodium borohydride reduction to the corresponding secondary alcohol

14

(**11**), thus ruling out structure **10**. Infrared absorption at 1669 and 1651 cm^{-1} for **11** corroborated the enamide assignment (**9**) and eliminated the alternate cleavage possibilities **12** and **13**. The alternative enamide structure (**14**) was incompatible with the ^{1}Hmr quartet resonance at δ 1.90 ppm due to the methylene of the ethyl group.

Subsequently, the apparent existence of an induction period for the oxidation led to an observation that when THF, which had already undergone some aerial oxidation, was used the alkene **5** was converted to **6** in 4 h and that after 22-h work up afforded **6** (32%) and **9** (25%). Reproducible conditions were found using peroxide-free THF containing a small amount of 1% TFA and added *tert*-butylhydroperoxide. In this manner, a 76% yield of **6** was attained and in fact these conditions were later used for the synthesis of the alkaloid leurosine (**7**). In this regard, similar protection of the indole nitrogen of **8** was neither possible nor necessary and leurosine was obtained directly from **8** without observable oxidation at the β-position of the indole system. Examination of the reaction mixture by tlc indicated that on prolonged treatment leurosine also underwent further oxidation to yield a product readily detected on tlc by its distinct green colouration after spraying with ceric sulphate reagent. Again this product was initially assigned the 5′-oxo structure **15** (8, 10). Later comparison of this product with naturally occurring catharine (**3**)[4], a structure derived

[4]The authors are very grateful to Dr. Gordon Svoboda, Eli Lilly and Company, Indianapolis, IN, for providing samples of catharine and vinamidine.

TABLE 1. Aerial and *tert*-butyl hydroperoxide oxidations

Entry	Substrate	Reaction conditions	Products

*The radical inhibitor used was 3-*tert*-butyl-4-hydroxy-5-methylphenyl sulphide.

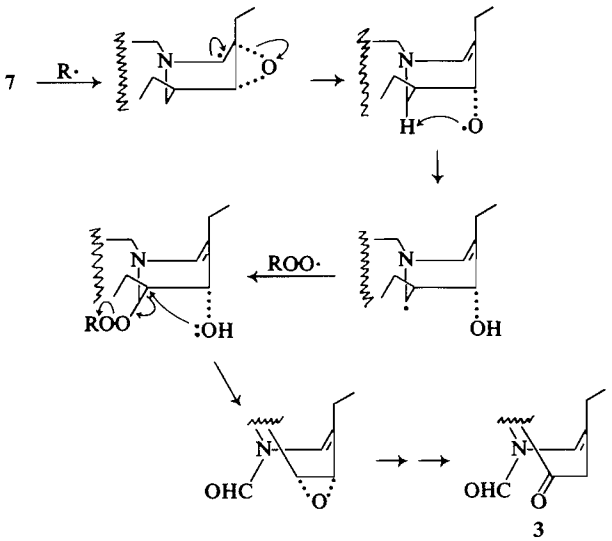
by X-ray analysis (4), showed its identity; mp (acetone) 213–215°C (lit. (4) mp 213–215°C); mp (ethanol) 162–166°C (lit. (11) mp 171–175°C),[5] undepressed on admixture with an authentic sample; $[\alpha]_D$ −49° (*c* 0.7, $CHCl_3$), (lit. (11) $[\alpha]_D$ −51°). Again duplication of ^{1}Hmr signals was consistent with a formamide function (9) and the spectrum of **3** was superimposable on that of authentic catharine.

Under the conditions employed for the formation of **3**, an acid-catalysed or radical mechanism was possible and a further examination of the reaction was needed to distinguish the pathway involved. Aerial or *tert*-butylhydroperoxide oxidation of **8** in THF containing a small amount of 1% aqueous TFA gave catharine (**3**) (ca. 30% yield) after 11 or 5 days, respectively, and monitoring the course of the reaction by tlc implicated leurosine (**7**) as a precursor of **3**. Accordingly aerial or *tert*-butylhydroperoxide oxidation of leurosine (**7**) also afforded catharine (Table 1, entries 10, 11). Alternatively, reaction of **7** or **8** with *tert*-butylhydroperoxide could be inhibited or the course of reaction changed on addition of a radical inhibitor (entries 6, 14, 15). The role of aqueous acid in the transformation of **8** to **7** was obscure, since although leurosine was formed in small amounts in the absence of acid, the product mixture was very complex. On the other hand, formation of catharine did not require acid or water (entries 4, 13). Indeed optimum conditions for the transformation of **7** to **3** (48% yield) were found using *tert*-butylhydroperoxide in dichloromethane. Finally, the possible intermediacy of the corresponding N_b-oxides **16** and **17** was eliminated since these substrates did not react under the original experimental conditions (entries 7, 16).

[5]In our hands, an authentic sample had mp 164–168°C.

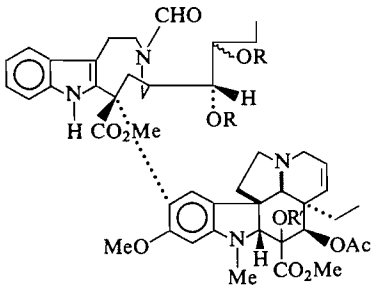
Thus the alkene **8** could be converted to the alkaloid leurosine (**7**), via a radical mechanism. Aqueous acid was necessary for a synthetically useful transformation possibly owing to inhibition of unwanted side reactions at N_b. Catharine (**3**) was in turn formed from leurosine via a radical pathway possibly as shown in Scheme 1. Notably, recent work from these laboratories has shown the biosynthetic intermediacy of leurosine in the natural formation of catharine (12).

Although hydroperoxide oxidation of cleavamine systems led to C19′—C2′ cleavage products, potassium permanganate oxidation allowed an alternative mode of ring cleavage. Here oxidation of **8** with $KMnO_4$ in acetone gave two products (3). The minor component of the mixture was identical with the known 19′-oxo derivative (**18**) (8). The major product

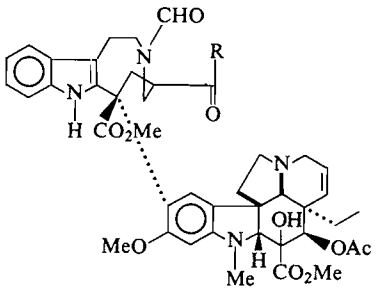


SCHEME 1

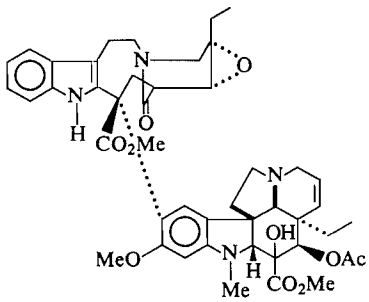
was identified, *ex post facto*, as 3*R*-hydroxyvinamidine (**19**). The identity of this product was established by spectral analysis and by chemical transformations. High resolution mass spectrometry gave the molecular formula $C_{46}H_{56}N_4O_{11}$ while infrared absorbance at 1660 cm^{-1} suggested the presence of an



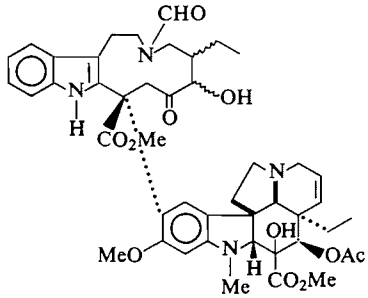
21 R = R′ = H
22 R = R′ = Ac
23 R = Ac, R′ = H



24 R = $COCH_2CH_3$
26 R = H



27



25

N_b-formyl function, further evidenced by ^{1}Hmr singlet resonance at δ 7.30 ppm. Acetylation in the usual manner gave the keto acetate **20** with ^{1}Hmr signals at δ 4.80 (bs, C3′-H) and 2.10 (s, —$OCOCH_3$) indicating a secondary alcohol group in **19**. Alternatively reduction of **19** with sodium borohydride gave the triol **21** which on acetylation gave a mixture of the tetraacetate **22** and the triacetate **23**. Oxidation of **19** with cupric acetate (14) in hot methanol gave the α-diketone (ν_{max} 1713 cm^{-1}) **24** thus confirming the α-ketol function in **19**. The possible cleavage structure **25** was eliminated as periodate cleavage of either **19** or **21** gave only the aldehyde **26** exhibiting singlet absorbances at δ 7.61 (N_b-CHO) and 9.20 ppm (—CHO). High resolution mass spectrometry gave the molecular formula $C_{43}H_{50}N_4O_{10}$ thus confirming the loss of a three-carbon fragment. The formation of an aldehyde by periodate cleavage of **19** also supported the ketol orientation as shown. The stereochemistry at C3′ in **19** was assigned *R* on the basis of the permanganate cleavage of leurosine (**7**) to **19** (27% yield) with the assumption that the stereochemical integrity at C3′ had been maintained. The lactam **27** was also isolated from this oxidation.

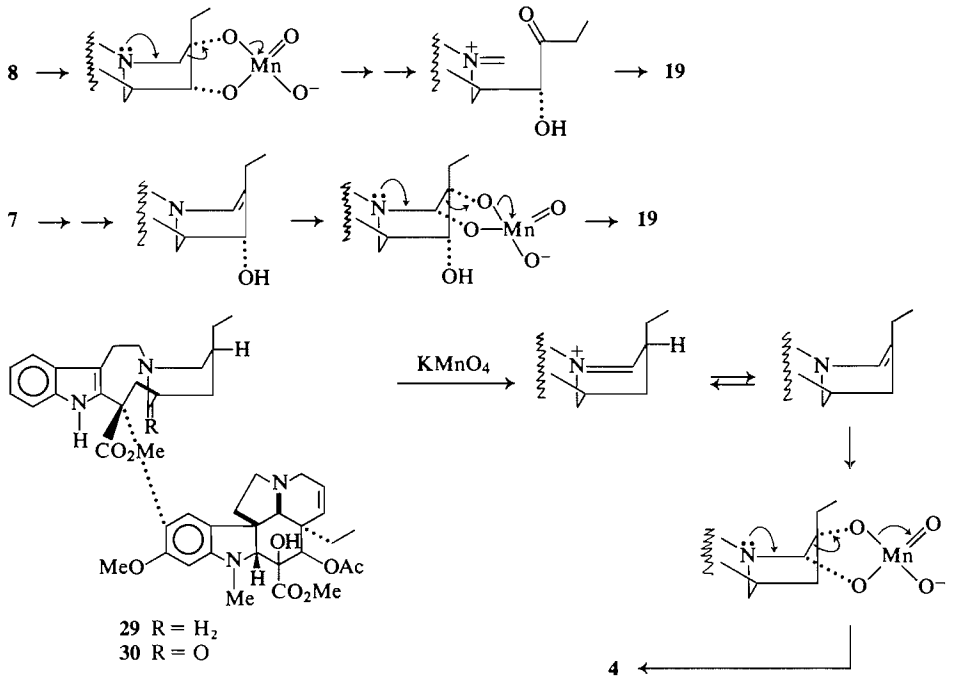
At this time the structure of the alkaloid vinamidine (catharinine) (**4**) was reported (5) and we sought a method to convert the hydroxy derivative **19** to the natural product. However attempted reductive cleavage of the derived acetate **20** was unsuccessful under a variety of conditions as were efforts to form the corresponding thionobenzoate **28**.

Therefore an alternative route to **4** was considered. The plausible mechanism (outlined in Scheme 2) for the oxidative cleavage of **7** or **8** to give **19** suggested that a substrate of lower oxidation state might similarly lead to vinamidine (**4**). In the event oxidation of 4′-deoxyleurosidine (**29**) with $KMnO_4$ in acetone gave the lactam **30** together with vinamidine (**4**). The cleavage product was identical with an authentic sample[4] of the alkaloid and the specific rotation of the sodium borohydride reduction product was in agreement with the literature value (5).

Thus propitious use of potassium permanganate oxidant enabled preparation of several unusual seco-4′,5′ derivatives including the natural product vinamidine (catharinine) (**4**). Alternatively, hydroperoxide oxidation of leurosine **7** or **8** afforded the seco-2′,19′ compound catharine (**3**).

Experimental

Melting points were determined on a Kofler block and are uncorrected. Ultraviolet (uv) spectra were recorded on a Cary 15 spectrophotometer in ethanol solution. The wavelengths of absorption maxima are reported in nanometers (nm) with log ε values in parentheses. Infrared (ir) spectra were measured on a Perkin Elmer model 710 or 457 spectrophotometer in chloroform solution. The absorption maxima are reported in



SCHEME 2

wavenumbers (cm^{-1}), calibrated with respect to the absorption band of polystyrene at 1601 cm^{-1}. Proton magnetic resonance (^{1}Hmr) spectra were measured in deuteriochloroform ($CDCl_3$) solution at ambient temperature on either a Varian HA-100 or XL-100 spectrometer. Chemical shift values are given in the δ (ppm) scale relative to tetramethylsilane (TMS) used as internal standard. The integrated peak areas, signal multiplicities, and proton assignments are given in parentheses. Low resolution mass spectra (ms) were determined on either an AEI-MS-902 or an Atlas CH-4B spectrometer. High resolution mass spectra were measured on an AEI-MS-902 instrument. Microanalyses were carried out by Mr. P. Borda of the Microanalytical Laboratory, University of British Columbia.

Thin-layer chromatography (tlc) utilized Merck silica gel G (according to Stahl) containing 2% fluorescent indicator. For preparative-layer chromatography (plc), plates (20 × 20 or 20 × 60 cm) of 1-mm thickness were used. Visualization was effected by viewing under ultraviolet light and/or by colour reaction with ceric sulphate spray reagent. Column chromatography utilized Merck silica gel 60 (70–230 mesh) or Merck aluminum oxide 90 (neutral).

As a matter of routine, all reagents and solvents were recrystallized or distilled before use.

Autoxidation of 16,18-Dicarbomethoxycleavamine

A solution of 16,18-dicarbomethoxycleavamine (**5**) (400 mg, 1 mmol) in peroxide-free tetrahydrofuran (10 mL) containing aqueous 1% trifluoroacetic acid (1 mL) was stirred at ambient temperature in the presence of air for a period of 8 days. After drying (K_2CO_3), the solvent was removed *in vacuo*. Chromatography of the residue on alumina (activity III, benzene) afforded the epoxide **6** (40 mg, 10%) and the keto enamide **9** (230 mg, 54%).

Oxidation of 16,18-Dicarbomethoxycleavamine (5) in 'Preoxidized' Tetrahydrofuran[6]

A solution of **5** (900 mg, 2.27 mmol) in 'preoxidized' tetrahydrofuran (20 mL) containing aqueous 1% trifluoroacetic acid (2 mL) was stirred at ambient temperature for 20 h. The

[6]'Preoxidized' tetrahydrofuran refers to tetrahydrofuran which had undergone aerial oxidation and contained an unspecified amount of peroxides.

reaction mixture was poured into a saturated solution of sodium bicarbonate (20 mL) and extracted with ethyl acetate (2 × 40 mL). The combined organic portion was washed with water (3 × 15 mL) and brine (1 × 20 mL). After drying (Na_2SO_4) the solvent was removed *in vacuo* and the residue was chromatographed on alumina (activity III, benzene) to afford the epoxide **6** (306 mg, 33%) and the keto enamide **9** (250 mg, 26%). These compounds were identical with the respective products obtained above.

Oxidation of 16,18-Dicarbomethoxycleavamine (5) using tert-*Butyl Hydroperoxide*

A solution of **5** (1.76 g, 4.4 mmol) in freshly distilled tetrahydrofuran (50 mL) containing aqueous 1% trifluoroacetic acid (10 mL) and *tert*-butyl hydroperoxide (9 mL) was stirred at ambient temperature for 21 h. The reaction mixture was poured into a saturated solution of sodium bicarbonate (40 mL) and extracted with ethyl acetate (2 × 30 mL). The combined organic portion was washed with 5% sodium hydroxide solution (1 × 20 mL), water (1 × 20 mL), and brine (1 × 20 mL). After drying (Na_2SO_4) the solvent was removed *in vacuo* to give a viscous oil. Chromatography on alumina (activity III, benzene) afforded the epoxide **6** (1.22 g, 67%) identical with that obtained above.

Hydroxy Enamide (11)

A solution of the keto enamide (**9**) (10 mg, 0.023 mmol) in 95% ethanol (2 mL) was treated with sodium borohydride (4 mg, 0.1 mmol). The reaction mixture was stirred at ambient temperature for 20 min, taken up in water (10 mL), and extracted with methylene chloride (3 × 5 mL). After drying (Na_2SO_4), the solvent was removed *in vacuo* and the residue chromatographed on silica gel (ether) to afford the hydroxy enamide **11** (6 mg, 60%) as a film; uv λ_{max}: 293 (3.50), 281 sh (3.68), 262 (4.03), 224 (4.32); ir ν_{max}: 3530, 3420, 1730, 1669, 1651; ^{1}Hmr δ: 8.05 (1H, m, C14-H), 8.02 (1H, s, N_b-C*H*O), 7.6–7.2 (3H, m, C11–C13-H's), 5.48 (1H, bs, C5-H), 4.00 (3H, s, —OCH_3), 3.66 (3H, s, —OCH_3), 0.98 (3H, t, J = 7.5 Hz, —CH_2CH_3); ms *m/e*: 428 (M^+), 315, 201, 126 (base peak). *Mol. Wt.* calcd. for $C_{23}H_{28}N_2O_6$: 428.1947; found (high resolution ms): 428.1928.

Leurosine (7)

This compound was prepared as described earlier (8).

Catharine (3)

(*A*) A solution of leurosine (7) (30 mg, 0.037 mmol) in tetrahydrofuran (2 mL) containing aqueous 1% trifluoroacetic acid (0.2 mL) was stirred in the presence of air for 11 days. The reaction mixture was diluted with a saturated solution of sodium bicarbonate (5 mL) and extracted with methylene chloride (3 × 5 mL). The combined organic portion was dried (Na_2SO_4) and the solvent was removed *in vacuo*. Chromatography of the residue on silica gel (ethyl acetate – 12% methanol) afforded leurosine (7) (4 mg) and catharine (**3**) (4 mg, 15%). The synthetic catharine had mp 213–215°C (acetone) (lit. (4) mp 213–215°C); mp 162–166°C (ethanol) (lit. (11) mp 171–175°C),[5] undepressed on admixture with an authentic sample; $[\alpha]_D$ −49° (*c* 0.7, $CHCl_3$) (lit. (11) $[\alpha]_D$ −51°). The ^{1}Hmr, uv, ir, and mass spectra were superimposable with those of authentic material.

(*B*) Oxidation of 3′,4′-dehydrovinblastine (**8**) as above afforded catharine in 34% yield.

(*C*) A solution of leurosine (**7**) (45 mg, 0.56 mmol) in methylene chloride containing *tert*-butyl hydroperoxide (0.06 mL) was stirred at ambient temperature for 24 h. The solvent was removed *in vacuo* and the residue chromatographed on silica gel (methylene chloride – 5% methanol) to afford catharine (22 mg, 48%).

Comparative Oxidations of 3′,4′-Dehydrovinblastine (8), Leurosine (7), and Derivatives, Utilizing tert-*Butyl Hydroperoxide*

All reactions were carried out utilizing 10 mg of substrate dissolved in 0.5 mL tetrahydrofuran containing 0.05 mL of *tert*-butyl hydroperoxide. To these solutions were added any further reagents used. The product composition of the reactions was ascertained via tlc. Authentic samples of 3′,4′-dehydrovinblastine (**8**), leurosine (**7**), catharine (**3**), pleurosine (**17**) (14), and 3′,4′-dehydrovinblastine N_b-oxide (**16**) (8) were used for comparison purposes. The solvent systems used for the chromatographic analysis were ethyl acetate – 20% methanol and methylene chloride – 6% methanol. Visualization was achieved by spraying with ceric sulfate spray reagent and heating at 100°C for 1 h. The relative amounts of products formed were *estimated* from the visualized chromatograms.

Reaction of 3′,4′-Dehydrovinblastine (8) with Potassium Permanganate

A solution of 3′,4′-dehydrovinblastine (**8**) (250 mg, 0.316 mmol) in methylene chloride (2 mL) and acetone (5 mL) was treated at 0°C with a solution of potassium permanganate (105 mg, 0.665 mmol) in acetone (5 mL). The reaction mixture was stirred at 0°C for 5 min and the solvent was removed *in vacuo*. The residue was triturated with methylene chloride (5 mL) and filtered through silica gel (ethyl acetate – 25% methanol). Removal of the solvent *in vacuo* followed by chromatography of the residue on silica gel (ethyl acetate – 15% methanol) afforded the ketol **19** (111 mg, 42%) as the major product (R_f 0.4). 19′-Oxo-3′,4′-dehydrovinblastine (**18**) (25 mg, 9.8%) identical with an authentic sample (8) (tlc, ms, ^{1}Hmr) was obtained as the minor product (R_f 0.75).

Ketol **19**, mp 198–202°C (ethanol); uv λ_{max}: 310 (3.80), 294 (4.08), 284 (4.14), 268 (4.19), 212 (4.72); ir ν_{max}: 3475, 1734, 1660, 1612; ^{1}Hmr δ: 7.88 (1H, bs, N*H*), 7.51 (1H, m, C14′-H), 7.32 (1H, s, NC*H*O), 7.14 (3H, m, C11′–C13′-H's), 6.71 (1H, s, C14-H), 6.00 (1H, s, C17-H), 5.86 (1H, dd, J = 10 and 4 Hz, C7-H), 5.49 (1H, s, C4-H), 5.30 (1H, d, J = 10 Hz, C6-H), 3.97 (1H, bs, C3′-H), 3.79 (3H, s, —OCH_3), 3.73 (3H, s, —OCH_3), 3.51 (3H, s, —OCH_3), 2.69 (3H, s, —NCH_3), 2.12 (3H, s, —OCOCH_3), 0.79 (3H, t, J = 7 Hz, —CH_2CH_3), 0.70 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 840 (M^+), 781, 680, 573, 135 (base peak). *Mol. Wt.* calcd. for $C_{46}H_{56}N_4O_{11}$: 840.3945; found (high resolution ms): 840.3966.

Reaction of Leurosine (7) with Potassium Permanganate

A solution of leurosine (**7**) (105 mg, 0.13 mmol) in acetone (1 mL) and methylene chloride (0.5 mL) was treated with a solution of potassium permanganate (40 mg, 0.25 mmol) in acetone (4 mL). The reaction mixture was stirred at ambient temperature for 3 min and the solvent was removed *in vacuo*. The residue was treated as above to afford the ketol **19** (30 mg, 27%), identical with that obtained above, and 19′-oxoleurosine (**27**) (20 mg, 19%) as a colorless film.

19′-Oxoleurosine (**27**); uv λ_{max}: 309 sh (3.74), 294 (4.00), 284 (4.05), 262 (4.13), 214 (4.66); ir ν_{max}: 3470, 1738, 1644; ^{1}Hmr δ: 8.06 (1H, bs, N*H*), 7.57 (1H, m, C14′-H), 7.18 (3H, m, C11′–C13′-H's), 6.65 (1H, s, C14-H), 6.19 (1H, s, C17-H), 5.90 (1H, dd, J = 10.5 and 3.5 Hz, C7-H), 5.51 (1H, s, C4-H), 5.33 (1H, d, J = 10.5 Hz, C6-H), 4.76 (1H, m, C2′-H), 3.85 (3H, s, —OCH_3), 3.83 (3H, s, —OCH_3), 3,63 (3H, s, —OCH_3), 2.76 (3H, s, NCH_3), 2.12 (3H, s, —OCOCH_3), 1.01 (3H, t, J = 7.5 Hz, —CH_2CH_3), 0.84 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 822 (M^+), 763, 282, 135 (base peak); ^{13}Cmr δ: 163.0 (C19′), 61.6 (C3′), 59.8 (C4′), 8.9 (—CH_2CH_3), 8.5 (—CH_2CH_3). *Mol. *3-*tert*-Butyl-4-hydroxy-5-methylphenyl sulphide.

*Keto Acetate **20***

A solution of the ketol **19** (22 mg, 0.026 mmol) in pyridine (2 mL) at ambient temperature under a nitrogen atmosphere was treated with acetic anhydride (4 drops). The reaction mixture was stirred for 30 h. Methanol (1 mL) and toluene (10 mL) were added and the solvent was removed *in vacuo*. Chromatography of the residue on silica gel (ethyl acetate – 10% methanol) afforded the keto acetate **20** (15 mg, 65%) as a white amorphous solid; uv λ_{max}: 310 (3.81), 294 (4.10), 285 (4.17), 270 (4.21), 213 (4.73); ir ν_{max}: 3470, 1738, 1660, 1612; ^{1}Hmr δ: 7.90 (1H, bs, N*H*), 7.51 (1H, m, C14′-H), 7.32 (1H, s, NC*H*O), 7.12 (3H, m, C11′–C13′-H's), 6.64 (1H, s, C14-H), 6.00 (1H, s, C17-H), 5.86 (1H, dd, J = 10 and 4 Hz, C7-H), 5.48 (1H, s, C4-H), 5.31 (1H, d, J = 10 Hz, C6-H), 4.80 (1H, bs, C3′-H), 3.79 (3H, s, —OC*H*$_3$), 3.76 (3H, s, —OC*H*$_3$), 3.72 (1H, s, C2-H), 3.62 (3H, s, —OC*H*$_3$), 2.69 (3H, s, NC*H*$_3$), 2.14 (3H, s, —OCOC*H*$_3$), 2.10 (3H, s, —OCOC*H*$_3$), 0.77 (3H, t, J = 7 Hz, —CH$_2$C*H*$_3$), 0.70 (3H, t, J = 7 Hz, —CH$_2$C*H*$_3$); ms *m/e*: 882 (M^+), 822, 762, 720, 613, 555, 354, 181, 169, 135, 131, 119 (base peak). *Mol. *Triol **21***

A solution of the ketol **19** (50 mg, 0.06 mmol) in 95% ethanol (3 mL) was treated with sodium borohydride (6 mg, 0.16 mmol). The reaction mixture was stirred at ambient temperature for 30 min and treated with acetone (1 mL). The solvent was removed *in vacuo* and the residue was triturated with methylene chloride (20 mL) and filtered through Celite. Removal of the solvent *in vacuo* followed by chromatography of the residue on silica gel (methylene chloride – 5% methanol) afforded the triol **21** (33 mg, 66%) as a colorless film; uv λ_{max}: 310 (3.65), 295 (4.00), 284 (4.06), 267 (4.11), 212 (4.65); ir ν_{max}: 3585, 3472, 1738, 1660, 1613; ^{1}Hmr δ: 7.98 (1H, s, N*H*), 7.53 (1H, m, C14′-H), 7.45 (1H, s, NC*H*O), 7.15 (3H, m, C11′–C13′-H's), 6.76 (1H, s, C14-H), 6.12 (1H, s, C17-H), 5.90 (1H, dd, J = 10 and 4 Hz, C7-H), 5.46 (1H, s, C4-H), 5.35 (1H, d, J = 10 Hz, C6-H), 3.82 (3H, s, —OC*H*$_3$), 3.80 (3H, s, —OC*H*$_3$), 3.76 (1H, s, C2-H), 3.55 (3H, s, —OC*H*$_3$), 2.71 (3H, s, NC*H*$_3$), 2.10 (3H, s, —OCOC*H*$_3$), 0.84 (3H, t, J = 7.5 Hz, —CH$_2$CH$_3$), 0.79 (3H, t, J = 7 Hz, —CH$_2$C*H*$_3$); ms *m/e*: 842 (M^+), 783, 681, 574, 516, 135 (base peak). *Mol. Wt.* calcd. for $C_{46}H_{58}N_4O_{11}$: 842.4102; found (high resolution ms): 842.4060.

*Acetylation of Triol **21***

A solution of the triol **21** (32 mg, 0.38 mmol) in pyridine (2 mL) at ambient temperature under a nitrogen atmosphere

was treated with acetic anhydride (0.1 mL). The reaction mixture was stirred for 22 h at which point methanol (0.5 mL) and toluene (10 mL) were added. The solvent was removed *in vacuo* and the residue was chromatographed on silica gel (methylene chloride – 5% methanol) to yield the tetraacetate **22** (9 mg, 24%, R_f 0.4) and the triacetate **23** (9 mg, 26%, R_f 0.35). Both compounds were obtained as colorless films.

Tetraacetate **22**; uv λ_{max}: 310 (3.73), 294 (4.06), 284 (4.11), 267 (4.15), 212 (4.70); ir ν_{max}: 3468, 1732, 1666, 1618; ^{1}Hmr δ: 8.06 (1H, bs, N*H*), 7.50 (H, m, C14′-H), 7.36 (1H, s, NC*H*O), 7.14 (3H, m, C11′–C13′-H's), 6.53 (1H, s, C14-H), 6.13 (1H, s, C17-H), 5.89 (1H, dd, J = 10 and 5 Hz, C7-H), 5.52 (1H, s, C4-H), 5.30 (1H, d, J = 10 Hz, C6-H), 4.90 (1H, m, C4′-H), 4.54 (1H, t, J = 6 Hz, C3′-H), 4.03 (1H, s, C2-H), 4.82 (3H, s, —OCH_3), 4.77 (3H, s, —OCH_3), 4.59 (3H, s, —OCH_3), 2.85 (3H, s, NCH_3), 2.08 (6H, s, 2 × —OCOCH_3), 1.98 (6H, s, 2 × —OCOCH_3), 0.75 (3H, t, J = 7 Hz, —CH_2CH_3), 0.48 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 968 (M^+), 765, 659, 600, 135 (base peak). *Mol. Wt.* calcd. for $C_{52}H_{64}N_4O_{14}$: 968.4419; found (high resolution ms): 968.4395.

Triacetate **23**; uv λ_{max}: 309 (3.70), 294 (4.03), 284 (4.08), 269 (4.10), 212 (4.67); ir ν_{max}: 3480, 1732, 1664, 1617; ^{1}Hmr δ: 7.95 (1H, bs, N*H*), 7.54 (1H, m, C14′-H), 7.38 (1H, s, NC*H*O), 7.15 (3H, m, C11′–C13′-H's), 6.54 (1H, s, C14-H), 6.17 (1H, s, C17-H), 5.88 (1H, dd, J = 10 and 4 Hz, C7-H), 5.55 (1H, s, C4-H), 5.30 (1H, d, J = 10 Hz, C6-H), 4.89 (1H, m, C4′-H), 4.41 (1H, t, J = 6 Hz, C3′-H), 3.84 (3H, s, —OCH_3), 3.82 (3H, s, —OCH_3), 3.75 (1H, s, C2-H), 3.58 (3H, s, —OCH_3), 2.73 (3H, s, NCH_3), 2.12 (3H, s, —OCOCH_3), 2.08 (3H, s, —OCOCH_3), 1.97 (3H, s, —OCOCH_3), 0.76 (6H, t, J = 7 Hz, 2 × —CH_2CH_3); ms *m/e*: 926 (M^+), 867, 765, 659, 600, 135 (base peak). *Mol. Wt.* calcd. for $C_{50}H_{62}N_4O_{13}$: 926.4313; found (high resolution ms): 926.4331.

*Diketone **24***

A solution of the ketol **19** (30 mg, 0.036 mmol) and cupric acetate (monohydrate) (20 mg, 0.11 mmol) in methanol (3 mL) was heated at reflux for 25 min. The solvent was removed *in vacuo* and the residue was triturated with methylene chloride (2 mL) and filtered through Celite. Removal of the solvent *in vacuo* followed by chromatography of the residue on silica gel (methylene chloride – 5% methanol) afforded the diketone **24** (16 mg, 53%) as a pale yellow film; uv λ_{max}: 308 (3.70), 293 (4.03), 277 (4.11), 260 (4.20), 207 (4.70); ir ν_{max}: 3450, 1739, 1713, 1662, 1615; ^{1}Hmr δ: 7.94 (2H, bs, N*H*, NC*H*O), 7.52 (1H, m, C14′-H), 7.18 (3H, m, C11′–C13′-H's), 6.77 (1H, s, C14-H), 6.10 (1H, s, C17-H), 5.91 (1H, dd, J = 10 and 4 Hz, C7-H), 5.51 (1H, s, C4-H), 5.34 (1H, d, J = 10 Hz, C6-H), 3.82 (3H, s, —OCH_3), 3.74 (3H, bs, —OCH_3), 3.62 (3H, s, —OCH_3), 2.74 (3H, s, NCH_3), 2.12 (3H, s, —OCOCH_3), 1.04 (3H, t, J = 7.5 Hz, —CH_2CH_3), 0.79 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 838 (M^+), 779, 678 (base peak), 570, 135. *Mol. Wt.* calcd. for $C_{46}H_{54}N_4O_{11}$: 838.3789; found (high resolution ms): 838.3770.

*Periodic Acid Cleavage of **21***

A solution of **21** (25 mg, 0.030 mmol) in tetrahydrofuran (2 mL) at ambient temperature under a nitrogen atmosphere was treated with a solution of periodic acid (8.5 mg, 0.066 mmol) in tetrahydrofuran (0.5 mL). The reaction mixture was stirred for 2 min and concentrated *in vacuo*. Chromatography of the residue on silica gel (methylene chloride – 5% methanol – 0.1% ammonium hydroxide) afforded the N_b-formyl aldehyde **26** (15 mg, 65%) as a colorless film; uv λ_{max}: 310 (3.67), 294 (4.00), 284 (4.08), 268 (4.15), 213 (4.66); ir ν_{max}: 3464, 1732, 1661, 1612; ^{1}Hmr δ: 9.20 (1H, s, —C*H*O), 7.96 (1H, bs, N*H*), 7.61 (1H, s, NC*H*O), 7.56 (1H, m, C14′-H), 7.18 (3H, m, C11′–C13′-H's), 6.64 (1H, s, C14-H), 6.11 (1H, s, C17-H), 5.88 (1H, dd, J = 10 and 4 Hz, C7-H), 5.49 (1H, s, C4-H), 5.29 (1H, d, J = 10 Hz, C6-H), 3.80 (6H, s, 2 × —OCH_3), 3.62 (3H, s, —OCH_3), 3.50 (1H, s, C2-H), 2.71 (3H, s, NCH_3), 2.11 (3H, s, —OCOCH_3), 0.74 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 782 (M^+), 723, 621, 514, 135 (base peak). *Mol. Wt.* calcd. for $C_{43}H_{50}N_4O_{10}$: 782.3515; found (high resolution ms): 782.3484.

*Periodic Acid Cleavage of the Ketol **19***

A solution of the ketol **19** (40 mg, 0.048 mmol) in tetrahydrofuran (2 mL) at ambient temperature under a nitrogen atmosphere was treated with a solution of periodic acid (15 mg, 0.117 mmol) in tetrahydrofuran (1 mL). The reaction mixture was stirred for 4 h and the solvent was removed *in vacuo*. Chromatography of the residue on silica gel (methylene chloride – 5% methanol – 0.1% ammonium hydroxide) afforded the N_b-formyl aldehyde **26** (20 mg, 54%) identical with that obtained above.

*Reaction of 4′-Deoxyleurosidine (**29**) with Potassium Permanganate*

A solution of 4′-deoxyleurosidine (**29**) (260 mg, 0.33 mmol) in acetone (5 mL) and methylene chloride (2 mL) at ambient temperature under a nitrogen atmosphere was treated with a solution of potassium permanganate (158 mg, 1 mmol) in acetone (3 mL). The reaction mixture was stirred for 20 min and the solvent was removed *in vacuo*. The residue was triturated with methylene chloride (10 mL) and filtered through silica gel (ethyl acetate – 25% methylene chloride – 15% methanol). Removal of the solvent *in vacuo* followed by chromatography of the residue on silica gel (ethyl acetate – 13% methanol) afforded vinamidine (**4**) (60 mg, 22%) and 19′-oxo-4′-deoxyleurosidine (**30**) (30 mg, 11%). The synthetic vinamidine had $[\alpha]_D$ −35° (*c* 1.1, $CHCl_3$) (lit. (5) $[\alpha]_D$ −33°). The ^{1}Hmr and mass spectra as well as the tlc properties of the synthetic material were in accord with those exhibited by an authentic sample.

19′-Oxo-4′-deoxyleurosidine (**30**); uv λ_{max}: 311 (3.92), 294 (4.03), 284 (4.08), 263 (4.13), 212 (4.72); ir ν_{max}: 3476, 1736, 1640, 1615; ^{1}Hmr δ: 8.05 (1H, bs, N*H*), 7.58 (1H, m, C14′-H), 7.17 (3H, m, C11′–C13′-H's), 6.65 (1H, s, C14-H), 6.16 (1H, s, C17-H), 5.88 (1H, dd, J = 10.5 and 4 Hz, C7-H), 5.51 (1H, s, C4-H), 5.31 (1H, d, J = 10 Hz, C6-H), 4.84 (1H, m, C2′-H), 3.82 (6H, s, 2 × —OCH_3), 3.78 (1H, s, C2-H), 3.61 (3H, s, —OCH_3), 2.74 (3H, s, NCH_3), 2.12 (3H, s, —OCOCH_3), 0.92 (3H, t, J = 7 Hz, —CH_2CH_3), 0.84 (3H, t, J = 7 Hz, —CH_2CH_3); ms *m/e*: 808 (M^+), 749, 690, 646 (base peak), 589, 540, 135. *Mol. Wt.* calcd. for $C_{46}H_{56}N_4O_9$: 808.4079; found (high resolution ms): 808.4046.

Catharininol

Catharininol was prepared from the synthetic vinamidine (catharinine) via the literature procedure (5). This material had $[\alpha]_D$ −78° (*c* 0.42, $CHCl_3$) (lit. (5) $[\alpha]_D$ −80°).

The isolation of the novel pentacyclic base megastachine (**1**), representative of a new type of *Lycopodium* alkaloid, is reported. Its structure has been determined by X-ray diffraction analysis.

JEAN-CLAUDE BRAEKMAN, CLAUDE HOOTELE, NOAH MILLER, JEAN-PAUL DECLERCQ, GABRIEL GERMAIN et MAURICE VAN MEERSSCHE. Can. J. Chem. **57**, 1691 (1979).

Dans le présent travail, nous décrivons l'isolement d'une base pentacyclique nouvelle, la megastachine (**1**), représentative d'un type nouveau d'alcaloïdes des *Lycopodium*. Sa structure est établie par l'analyse du diagramme de diffraction des rayons-X.

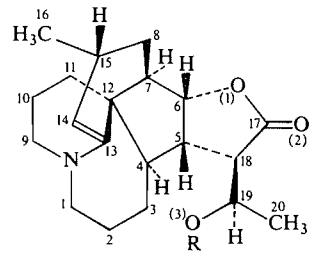
In the course of our systematic search for new *Lycopodium* alkaloids of possible biogenetic significance (1), we have examined the basic extract of the African species *Lycopodium megastachyum* Baker (syn. *Huperzia megastachia* (Bak.) Tard) collected in the Ifody forest (Madagascar). This species is actively sought by the natives as a substitute for hashish.

In a previous communication, we reported the isolation from the light petroleum extract of this plant of eight triterpenes of the serratane type (2). We wish to describe now the isolation and the structure determination of megastachine, a new base isolated from the methanol extract.

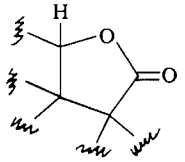
The molecular formula of megastachine (**1**, $C_{20}H_{29}NO_3$) was established through high resolution mass spectrometry on the free base. One of the oxygen atoms is clearly involved in a secondary alcohol function (ν_{OH} at 3140 cm^{-1}; broad signal of 1H at δ 2.54, disappearing on treatment with D_2O; double quartet of 1H (J = 6.5 and 3 Hz) at δ 4.28). Acetylation of (**1**) afforded a monoacetate (**2**) confirming the presence of only one hydroxyl group and implying that the nitrogen atom of the molecule is tertiary.

The ^1H nmr spectrum of megastachine shows a 1H doublet (J = 4 Hz) at δ 5.63 and two 3H doublets (J = 7 Hz) at δ 1.29 and 1.02, attributed to a trisubstituted double bond and to two CH—CH_3 groups respectively. Moreover, the slightly deshielded signal observed for one of these doublets suggests that one of the methyl groups is geminal to an oxygen atom.

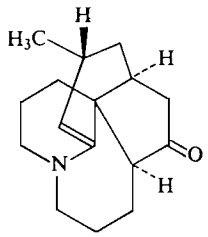
Mass spectra of both **1** and **2** show a base peak at



1 R = H
2 R = $COCH_3$



3



4

m/e 286 ($C_{18}H_{24}NO_2$ by high resolution ms) corresponding to the loss from the molecular ion of 45 and 87 mass units, respectively (metastable ions at *m/e* 247 for **1** and at *m/e* 220 for **2**). This suggests the presence in the molecule of a CH_3—CHOH group. Moreover, the multiplicity of the proton geminal to the hydroxyl group led us to extend this part structure to CH_3—CH(OH)—CH—.

The presence of only one double bond in megastachine was substantiated by the obtention of a dihydro derivative on catalytic hydrogenation.

The two last oxygen atoms of **1** are probably involved in a γ-lactone ring such as **3** ($\nu_{C=O}$ at 1760 cm^{-1}; double doublet of 1H at δ 4.65). On lithium aluminium hydride reduction, megastachine afforded a diol (arising, most probably, from the partial reduction of the γ-lactone to the corresponding hemiacetal) which could be converted to the corresponding diacetate.

None of the known *Lycopodium* alkaloid skeletons (3, 4) fits the data obtained for **1** and, consequently, megastachine must have an original structure. As the available quantities of **1** were insufficient to permit a complete structure determination by chemical methods, the problem was solved using X-ray diffraction performed on the methiodide. The computer drawing of this salt is reproduced in Fig. 1 and the atomic parameters are given in Table 1.

Thus megastachine represents a new structural type amongst the *Lycopodium* alkaloids. Its formal relationship to the other *Lycopodium* alkaloids is implicit in the numbering system shown in formula **1**. It is closely related to fawcettidine (**4**) and its congeners (4).

Biogenetically, megastachine can formally be obtained by substitution, from the less hindered side of the molecule, of the C-5 hydroxyl group of a precursor such as **5**, by an acetoacetic unit (see Scheme 1).

Experimental

The plant material was collected in the Ifody forest near Sabotsy-Anjiro (Madagascar) by P. Boiteau.

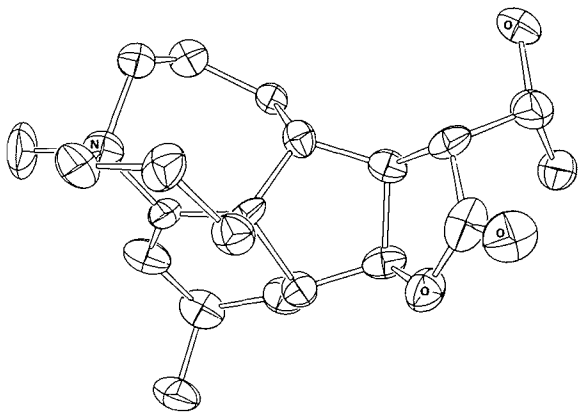

FIG. 1. Computer drawing of megastachine methiodide.

The defatted dry powder of *Lycopodium megastachyum* (4.5 kg) was continuously extracted in glass Soxhlets with MeOH. The extract was evaporated to dryness under reduced pressure and the residue was treated several times with an aqueous solution of 2% HCl. After filtration the aqueous acid solution was made basic by addition of ammonia and extracted with $CHCl_3$. The chloroform phases were combined and evaporated to dryness under reduced pressure, yielding 2.84 g of crude alkaloids. This fraction was then submitted to a countercurrent distribution ($CHCl_3$ – McIlvaine buffer pH 5.8, 23 transferts) and fractionized into three subfractions: A (0.3 g, $K = 0$), B (0.22 g, $K = 1$), and C (1.99 g, $K = 20$). Fraction A gave negative Aebisch and Reichstein tests and was discarded. Fraction C was found to be a complex mixture of high molecular weight basic compounds. Fraction B was chromatographed on alumina (eluent: (*i*) C_6H_6; (*ii*) AcOEt); this led to the isolation of 34 mg of megastachine homogeneous on tlc,

O-*Acetylmegastachine*

Treatment of megastachine (4 mg) with the mixture (1 mL) pyridine – acetic anhydride (2:1) at room temperature for 12 h yielded, after the usual work up, crude *O*-acetylmegastachine (4 mg) which was purified by filtration on alumina, mp 140–142°C; ir (KBr): $\nu_{C=O}$ at 1760 and 1740 cm^{-1}, $\nu_{C=C}$ at 1660 and 1237 cm^{-1}; ms intense ions *m/e*: 373 (M^+, 25), 372 (95), 358 ($M^+ - 15$, 55), 286 ($M^+ - 87$, 100), 270 (25), 242 (37), 176 (66).

H_4LiAl Reduction of Megastachyne

To 50 mg of H_4LiAl dissolved in 3 mL of anhydrous THF was added 5 mg of megastachyne dissolved in 10 mL of THF. The mixture was stirred at room temperature for 24 h. After the usual work-up, 4 mg of an oil was obtained; ir: ν_{OH} at 3400 cm^{-1} and $\nu_{C=C}$ at 1660 cm^{-1}; ms: M^+ at *m/e* 333 (95), 318 (42), 290 (80), 246 (50), 176 (100), 163 (77); the spectrum also showed the presence of a small quantity of a triol (M^+ at 335). After acetylation a diacetate was obtained ir ($CHCl_3$): $\nu_{C=O}$ at 1735 cm^{-1} and $\nu_{C=C}$ at 1660 cm^{-1}; ms: M^+ at *m/e* 417 (64), 402 (52), 186 (100), 168 (90), 148 (67); the spectrum also showed the presence of a small quantiy of a triacetate (M^+ at 461).

Dihydromegastachine

Catalytic hydrogenation of megastachine (6 mg) in MeOH (8 mL) at atmospheric pressure for 120 h yielded, after filtration and evaporation of the solvent under reduced pressure, 5 mg of dihydromegastachine which could not be induced to crystallize; ir (KBr): ν_{OH} at 3350 cm^{-1}, $\nu_{C=O}$ at 1760, 1460, and 1180 cm^{-1}; ms: intense ions at *m/e* 333 (M^+, 100), 318 ($M^+ - 15$, 22), 290 (16), 288 (19), 286 (17), 164 (90), 158 (27), 149 (35).

X-ray Diffraction Data

The X-ray diffraction analysis was performed on the methiodide of megastachine (mp 215–220°C (dec.); $C_{21}H_{32}INO_3$) using a Syntex diffractometer. Space group $P2_12_12_1$ with a = 16.708, b = 14.967, c = 9.150 Å, Z = 4. Radiation MoKα; $2\theta_{max}$ = 47°; number of independent reflections measured, 1493; number of reflections observed, 1493. The structure was solved by direct methods, using the random approach described by Baggio *et al.* (5). The refinements were realized using the XRAY 72 programs (6). R final: 0.048.

An approach to the synthesis of quadrigemine-A[1]

P. K. BATTEY, D. L. CROOKES, AND G. F. SMITH
Department of Chemistry, The University, Manchester, England M13 9PL

Received December 28, 1978

P. K. BATTEY, D. L. CROOKES, and G. F. SMITH. Can. J. Chem. 57, 1694 (1979).

Two syntheses of *N*-{2-[1′-benzyl-3′-(indole-7′′-yl)oxindol-3′-yl]ethyl}-*N*-methylacetamide (**6**), a possible intermediate in a synthesis of quadrigemine-A, are described. The more efficient of the two syntheses gives an overall yield of 12% in 11 steps from tryptamine.

P. K. BATTEY, D. L. CROOKES et G. F. SMITH. Can. J. Chem. 57, 1694 (1979).

On décrit deux synthèse du *N*-{benzyl-1′ (indolyl-7′′)-3′ oxindolyl-3′]-2 éthyl} *N*-méthyl-acétamide (**6**), un intermédiaire possible dans la synthèse de la quadrigémine-A. La meilleure des deux synthèses conduit au produit désiré en 11 étapes à partir de la tryptamine avec un rendement global de 12%.

[Traduit par le journal]

The alkaloid quadrigemine-A is a minor constituent of the leaves of the East Australian shrub *Hodgkinsonia frutescens* F. Muell. (Rubiaceae). The alkaloids of this species were first investigated by Anet *et al.* (1) who isolated the main crystalline alkaloid, hodgkinsine (**1**), the structure of which was elucidated by degradation (2) and was confirmed by X-ray structure determination (3). The minor alkaloids, quadrigemine-A (**2**) and quadrigemine-B (**3**) were more recently isolated by a long countercurrent separation process and the gross structures, excluding stereochemistry, elucidated by degradation (4). These two alkaloids were obtained in small quantity and are as yet inseparable mixtures of diastereoisomers. Synthesis will, we hope, open the way to the preparation of the set of diastereoisomers and to a complete solution of the stereochemical problem.

These alkaloids belong to the small calycanthaceous group, of which the prototypes are (−)- and *meso*-chimonanthine (**4** and **5**). The chimonanthines have been synthesized by four distinct routes by three different groups of workers, Hendrickson *et al.* (5), Scott *et al.* (6), and Hino *et al.* (7, 8), all involving a β–β′ dimerisation of indole or oxindole units. This approach can in principle be applied to a synthesis of quadrigemine-A and our work in this direction has had as objective a synthesis of the 3-(7′-indolyl)-oxindole system, for which there is no precedent.

This paper describes the synthesis of *N*-{2-[1′-benzyl-3′-(indole-7′′-yl)oxindol-3′-yl]ethyl}-*N*-methylacetamide (**6**).

The first approach started with *N*-benzyloxindole and involved the introduction at C3 of a hydroxycyclohexyl group and a cyanomethyl group: the former was then converted into the 7′-indolyl substituent and the latter into the ethanamine side chain.

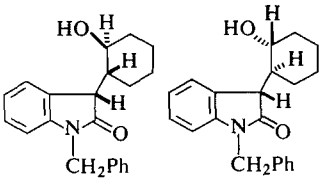
6



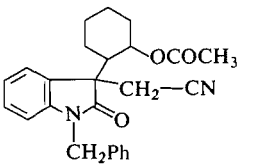
7

The introduction of a β-hydroxyalkyl function at the oxindole C3 position has a precedent in the reaction of 1,3-dimethyl-5-methoxyoxindole sodium enolate with ethylene oxide (9) to give 3-(2′-hydroxyethyl)-1,3-dimethyl-5-methoxyoxindole in 21% yield: in our hands, repetition of this reaction with 1,3-dimethyloxindole in the absence of air yielded 3-(2′-hydroxyethyl)-1,3-dimethyloxindole in 42% yield. The reaction of the lithium enolate of *N*-benzyloxindole with cyclohexene oxide in anisole under nitrogen proceeded very much more efficiently and gave a 90% yield of an approximately 1:1 mixture of the two diastereoisomers **7**. This makes the plausible assumption that the reaction leads to *trans*-disubstituted cyclohexanes. Column chromatography allowed the isolation of the diastereoisomers as pure compounds but unfortunately spectral and other data in this case, and in all subsequent cases of diastereoisomerism in this series, did not allow a clear assignment of relative stereochemistry. This failure however is not very serious, since the diastereoisomerism disappears in the product **6**.

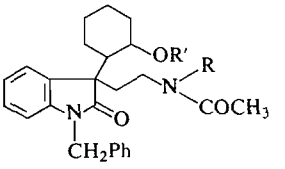
The introduction of a cyanomethyl group at C3 was effected at this point. The hydroxyl group in **7** was protected by acetylation and the corresponding sodium oxindole enolate treated with chloroacetonitrile in THF, which gave an excellent yield of 3-(2′-acetoxycyclohexyl)-1-benzyl-3-cyanomethyloxindole (**8**) as a mixture of diastereoisomers. These were isolated, one as a pure compound and the other contaminated with a small percentage of a product of further cyanomethylation.

The next step was the reduction of the nitrile function which had to be effected without reduction of the oxindole carbonyl or hydrogenolysis of the *N*-benzyl group. Catalytic hydrogenation proved to be surprisingly difficult, but was eventually achieved with W5 Raney nickel in acetic anhydride – NaOH at 85°C and 6.5 atm (10). This led to *N*-{2-[1′-benzyl-3′-(2″-acetoxycyclohexyl)oxindol-3′-yl]ethyl}acetamide (**9**), in almost quantitative yield as a mixture consisting mainly of two easily separable diastereoisomers. However, even these hydrogenation conditions led to problems of reproducibility and of scaling up, and eventually to the search for an alternative approach.

Direct *N*-methylation of the secondary acetamide **9** under a range of conditions led to mixtures, the major by-product being that derived from *O*-deacetylation and subsequent *O*-methylation, so protection of the hydroxyl function as a THP ether had to be resorted to. This was achieved in high overall yield by hydrolysis with aqueous alcoholic Na_2CO_3 followed by treatment with dihydropyran-HCl in

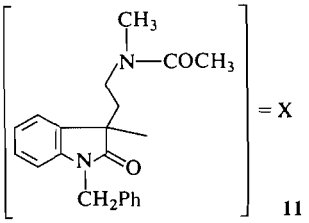


8

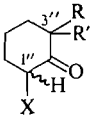


9 (R = H, R′ = $COCH_3$)
10 (R = CH_3, R′ = H)

DMF (significantly lower yields of THP ether were obtained in THF or HMPA as solvents). *N*-Methylation by KOBu*t*–THF–MeI then led to a quantitative yield of pure mixed diastereoisomers moving as one spot on tlc, smoothly hydrolysed by dilute HCl to *N*-{2-[1′-benzyl-3′-(2″-hydroxycyclohexyl)oxindol-3′-yl]ethyl}-*N*-methylacetamide **10**. The two diastereoisomers in this case were separable by preparative tlc, and spectral data, which only differed slightly between the two compounds, were entirely compatible with the gross structure **10**. The nmr spectra (at 25°C) show doubling of *N*-methyl and acetyl methyl signals due to hindered rotation of the ethanamine side chain: single signals were, however, observed at 85°C. Similar effects were observed with most of the following compounds and will not be discussed again. Oxidation of the mixture of alcohols with chromic acid in acetone led to a 70% yield of two separable diastereoisomeric ketones (**11**) each of



= X



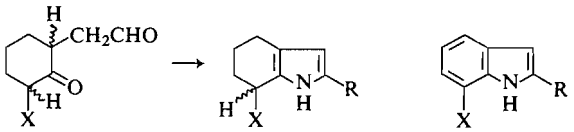
11 R = R′ = H
12 R = H, R′ = CHO
13 R = $CH_2CH{=}CH_2$, R′ = CHO
14 R = $CH_2CH{=}CH_2$, R′ = H

which was the sole product of analogous oxidation of the separated diastereoisomeric alcohols **7**.

The plan now was to build up a pyrrole ring by the introduction of —CH_2CHO at C3″, then dehydrogenate to the indole system. To ensure specific alkylation at C3″, and not at the alternative C1″

position, formylation at C3'' followed by alkylation and deformylation was undertaken.

Formylation was achieved in nearly 90% yield by the action of a large excess of ethyl formate and NaOEt in dry C_6H_6 (20): the formyl compound (**12**) was then allylated with allyl iodide in the presence of lithium carbonate in aqueous acetone to give a high yield of **13**, nearly quantitative deformylation of which to *N*-{2-[1'-benzyl-3'-(2''-keto-3''-allylcyclohexyl)oxindol-3'-yl]ethyl}-*N*-methylacetamide (**14**) occurred in 2.5% aqueous alcoholic KOH at room temperature. It may be noted that allylation of **12** with allyl bromide in the presence of sodium carbonate in aqueous acetone gave a 3:2 mixture of **13** and the corresponding *O*-allyl compound.[2] Ozonolysis in dry methanol at −30°C and reductive work-up with Me_2S (21) gave the keto aldehyde **15** in up to 91% yield. The reproducibility of this step was poor and the factors leading to failure were not discovered. Compounds **12–15** all ran on tlc as oval



15

16 R = H
17 R = $COCCl_3$
18 R = CO_2CH_3
19 R = $CO_2CH_2CH_3$

20 R = CO_2CH_3
21 R = CO_2H
43 R = $CO_2CH_2CH_3$

spots, probably indicative of diastereoisomeric mixtures; in no case, however, was a mixture resolved.

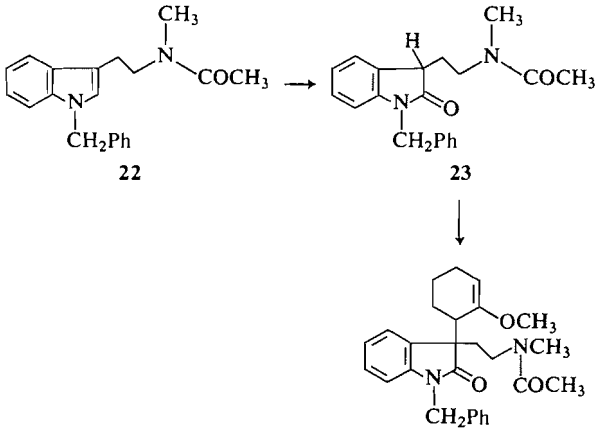
Keto aldehyde **15** was most satisfactorily converted into the pyrrole **16** on treatment with $(NH_4)_2CO_3$ in dry ethanol (cf. ref. 22). The yield was somewhat variable, generally around 50% of product being obtained by preparative tlc which allowed partial resolution of the two diastereoisomers, produced in about equal amounts. This pyrrole is very susceptible to autoxidation and has to be stored under N_2 at low temperatures. All attempts to dehydrogenate **16** to the indole **6** either failed or gave unacceptably low yields. The best results, which gave about 20% of a mixture of **16** and **6**, were obtained with palladium-on-charcoal. Also tried were other Pd catalysts under a wide range of conditions, DDQ, chloranil, MnO_2, Raney nickel, potassium hexacyanoferrate(III), and tristriphenylphosphine rhodium(I) chloride.

It was eventually decided to reduce the reactivity of the pyrrole ring by the introduction of an ester function at the α-position. This was achieved in the low overall yield of 30% by trichloroacetylation followed by treatment of the intermediate trichloroacetyl derivative with sodium methoxide in methanol (17). Dehydrogenation in this case proceeded satisfactorily, DDQ in refluxing benzene affording a 69% yield of the indole ester **20**. Now that the molecule contains only one asymmetric atom, it runs cleanly as a round spot on tlc. Saponification of this ester under mild conditions yielded the corresponding acid, which was decarboxylated smoothly in refluxing quinoline in the presence of copper(II) acetate (17) to give a 71% yield of *N*-{2-[1'-benzyl-3'-(indol-7''-yl)oxindol-3'-yl]ethyl}-*N*-methylacetamide (**6**).

The weak points in this synthesis are the difficulties in reproducing the high yield hydrogenation of the nitrile **8** and the ozonolysis of the allyl compound **14**. Furthermore, the aromatisation of the pyrrole **16** to the indole **6** contains too many unsatisfactory reactions, the overall yield of 14% in five steps being poor.

The reduction of a nitrile function half-way through the synthesis could be avoided by starting with a tryptamine derivative. The very convenient and high yield oxidation of indoles to oxindoles by DMSO and HCl (18), which appeared at about this point in our deliberations, made this approach viable. *N*-[2-(1'-Benzylindol-3'-yl)ethyl]-*N*-methylacetamide (**22**) was oxidised by DMSO concentrated HCl in AcOH to the corresponding oxindole **23** in 84% yield. Numerous attempts to introduce the 2-hydroxycyclohexyl group at C3 in oxindole **23** by the interaction of epoxycyclohexane with the enolate anion failed. This may be due to steric hindrance by the ethanamine side chain to approach of the epoxycyclohexane, cyclohexane compounds being well known as being sterically more demanding in S_N2 type reactions.

It was then found that, in complete contrast, the oxindole enolate anion derived from **23** reacted very smoothly with 6-bromo-1-methoxycyclohexene (19) to give a 78% yield of *N*-{2-[1'-benzyl-3'-(1''-me-

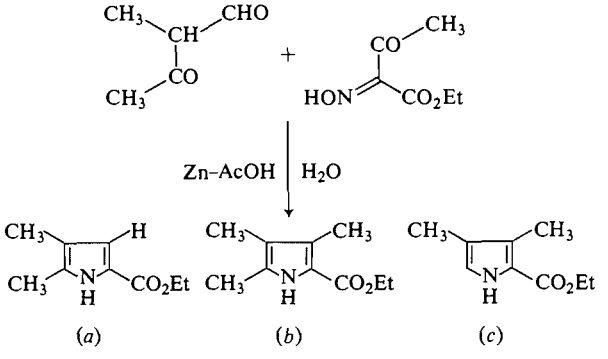


22 **23** **24**

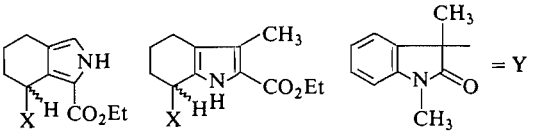
[2]See ref. 16, Chapt. 9, pp. 521–530, for an excellent review of the question of *C* vs. *O* alkylation.

thoxycyclohex-1''-en-6''-yl)oxindol-3'-yl]ethyl}-*N*-methylacetamide (**24**). This great ease of reaction may well reflect the allyl halide nature of the reactant which gives a greater S_N1 character to the displacement reaction. Two aspects of the spectral properties of this compound are not satisfactory: the first concerns the mass spectrum, in which three significant peaks at *m/e*: 269, 267, and 254 cannot be rationalised and the second concerns the nmr spectrum, in which the signal intensities in the enol ether CH and CH_3 are too low. The latter anomaly may be due to large upfield shifts into the general CH envelope above τ7 caused by shielding effects of the oxindole benzene ring in certain conformations. That the structure **24** must be correct, however, is indicated by mild acidic hydrolysis, which gave an 89% yield of the mixed diastereoisomers of ketone **11**. This represents an overall yield of 37% in six steps from tryptamine, a considerable improvement over the earlier approach from isatin, which gave a 28% yield in 10 steps.

When it was found that the simple pyrrole **16** could not be satisfactorily dehydrogenated and had to be converted into the ester **18**, the exploration of the Fischer–Fink synthesis, which leads directly from the keto aldehyde **12** to the ester **18**, was undertaken. The low yields reported for simple cases of this synthesis, together with the possible formation of isomeric or other pyrrole esters as by-products, had deterred us from exploring this route in the first instance. As it turns out, it affords a satisfactory route to the indole ester **20**, giving a 47% yield in two steps but the isolation necessitated preparative tlc. However, by saponifying the total crude dehydrogenation product and isolating the acid fraction, the pure acid **21** could be obtained in 41% overall yield from the keto aldehyde **12** in three steps without the isolation of intermediates, which is a great improvement on the earlier route, which gave 8% overall yield in eight steps.



The Fischer–Fink synthesis involves the condensation of a β-ketoaldehyde with 2-aminoacetoacetic ester and might be expected to yield three pyrroles; thus 3-formylbutan-2-one and aminoacetoacetic ester (produced *in situ*) gave the pyrrole esters shown in a 10:2:1 (*a*:*b*:*c*) ratio (11). This was not promising for our purposes. In the event, however, when this reaction was applied to our keto aldehyde **12**, the desired ester **19** was produced in 70% nonisolated yield completely free from the isomer **25** and containing about 1% of the homologue **26**, as far as could be judged from spectral and chromatographic observations. It is noteworthy that at the stage of indole **6**, the +14 homologue peak is totally absent. The absence of the isomer **25** is easily explained in steric terms, since the ester function would interact very strongly with the very bulky oxindole residue X. The fortunately very low percentage production of homologue **26** is not obviously rationalisable.



25 **26**

In the course of this work, the exploration of most of the reactions involved was carried out on model compounds based on the 1,3-dimethyloxindole system Y. The synthesis and spectral properties of the following are described in the Experimental section: the Y analogues of **6**, **9**, **11**, **12**, **13**, **14**, **15**, **16**, **18**, and **20** (i.e., **27**, **28**, **29**, **30**, **31**, **32**, **33**, **34**, **36**, and **37**, respectively). Also described in the Experimental section are Y – Z, where Z = CH_2CH_2OH (**39**), **40**, **41**, **42**, and **45**.

1-Benzyl-3-(2'-hydroxycyclohexyl)oxindole (7)

A solution of 1-benzyloxindole (4.46 g, 0.02 mol) in dry anisole (25 mL) was purged with N_2 for 30 min, then *n*-butyllithium in hexane (10.25 mL, 0.024 mol) was added from a

syringe through a septum cap to the well stirred solution. After 10 min, 1,2-epoxycyclohexane (2.94 g, 0.03 mol) was added with stirring from a syringe and the reaction solution heated to 90°C for 2 h. Glacial acetic acid (1.23 g, 0.024 mol) was then added to the cooled reaction, the anisole distilled off at the water pump, and the residue partitioned between ether and water. The ether-soluble product (6.5 g) (shown by tlc to be made up mainly of the two diastereoisomers of **7**) was chromatographed on silica gel (500 g): elution with ethyl acetate – 60–80 petrol – ether, 3:7:7 with gradually increasing proportions of Et_2O. The eluates were monitored by tlc and combined into four fractions: (*i*) 40 mg unidentified material; (*ii*) 225 mg of pure diastereoisomer A: (*iii*) 6.15 g of mixed diastereoisomers A and B; (*iv*) 25 mg of pure diastereoisomer B. The overall yield was 90%.

Diastereoisomer A—R_f 0.45 (S/*B*) was a white crystalline solid, mp 126.5–128°C, and crystallised well from petrol – ethyl acetate; ν_{max} ($CHCl_3$): 3540 (w), 3450–3200 (w), 1700 cm^{-1} (s); λ_{max} (EtOH): 253 (τ 8150); λ_{infl} 280 nm (ε 1650); τ ($CDCl_3$): 2.70–3.50 (m, 9H), 5.05 (d, 1H, J = 15.6 Hz), 5.23 (d, 1H, J = 15.6 Hz), 5.80–6.30 (m, 2H), 7.34 (br s, 1H, exchange with D_2O), 7.50–9.20 (br m, 9H); *m/e*: 321 (M^+, 29), 304 (7), 303 (46), 249 (6), 237 (6), 236 (27), 235 (18), 224 (18), 223 (100), 158 (7), 145 (17), 132 (7), 118 (5), 91 (100). *Anal.* calcd. for $C_{21}H_{23}NO_2$: C 78.50, H 7.17, N 4.36; found: C 78.6, H 7.5, N 4.4.

Diastereoisomer B—R_f 0.36 (S/*B*) recrystallized from petrol – ethyl acetate, mp 129–132°C; ν_{max} ($CHCl_3$): 3510 (w), 3450–3150 (w), 1700 cm^{-1} (s); λ_{max} (EtOH): 253 (ε 8100), λ_{infl} 280 nm (ε 1030); τ ($CDCl_3$): 2.50–3.52 (m, 9H), 5.00 (d, J = 15.6 Hz, 1H), 5.21 (d, J = 15.6 Hz, 1H), 5.85 (d, J = 3.0 Hz, 1H), 6.00–6.40 (br m, 1H), 7.50–9.00 (br m, 10H); *m/e*: 321(M^+, 29), 304 (8), 303 (32), 237 (5), 236 (20), 235 (12), 224 (18), 223 (100), 158 (5), 145 (16), 132 (6), 91 (87). *Anal.* calcd. for $C_{21}H_{23}NO_2$: C 78.50, H 7.17, N 4.36; found: C 78.0, H 7.1, N 4.8.

3-(2′-Acetoxycyclohexyl)-1-benzyloxindole

A solution of **7** (1.0 g) in acetic anhydride (2.5 mL) was refluxed under N_2 for 10 min. The reaction mixture was poured into water and stirred with addition of small quantities of Na_2CO_3 until the excess Ac_2O had been hydrolysed. Ether extraction yielded a pale brown viscous liquid (1.005 g, 89%) which crystallised on standing. Thin-layer chromatography (S/*B*) showed one spot only, at R_f 0.79. Even after three recrystallisations from petrol the melting point had the wide range of 105–125°C, thus indicating that the product is a mixture of the two diastereoisomers of 3-(2′-acetoxycyclohexyl)-1-benzyloxindole; ν_{max} ($CHCl_3$): 1720(s), 1705 cm^{-1} (s); λ_{max} (EtOH): 252.5 (ε 8060), λ_{infl} 279 nm (ε 1370); τ ($CDCl_3$): 2.25–3.50 (m, 9H), 4.60–5.50 (m, 3H), 6.27 (d, J = 3 Hz) and 6.37 (d, J = 3 Hz) together 1H, 8.00 (s) and 8.12 (s) together 3H, 7.20–9.00 (br m, 9H); *m/e*: 363 (M^+, 24), 304 (25), 303 (100), 262 (6), 260 (5), 249 (9), 237 (6), 236 (30), 235 (23), 223 (13), 212 (8), 158 (6), 132 (6), 91 (55). *Anal.* calcd. for $C_{23}H_{25}NO_3$: C 76.03, H 6.89, N 3.86; found: C 75.8, H 6.9, N 4.2.

*3-(2′-Acetoxycyclohexyl)-1-benzyl-3-cyanomethyloxindole (**8**)*

A solution of 3-(2′-acetoxycyclohexyl)-1-benzyloxindole (12 g, 0.033 mol) in dry THF (20 mL) was added to mineral oil free sodium hydride (1.68 g, 0.07 mol) under N_2, when vigorous evolution of H_2 occurred over 15 min. Freshly distilled chloroacetonitrile (3.02 g, 0.04 mol) was added with stirring. After standing for 10 min, water (10 mL) was added, the THF boiled off at room temperature at the water pump, and the residue partitioned between ether and water. This yielded a pale yellow foam (13.2 g, 99%), tlc analysis of which showed it to consist exclusively of the two diastereoisomers described below. An earlier procedure which used anisole as solvent yielded a less pure product, 3.6 g of which was chromatographed on a column of silica gel (300 g). Elution with ethyl acetate – 60–80°C petrol – ether (3:7:1) yielded (after combining the appropriate fractions) diastereoisomer A (0.836 g) contaminated with a small amount of dicyanomethylated product, mixed diastereoisomers A and B likewise contaminated (0.412 g), pure mixed A and B (1.146 g), and pure diastereoisomer B (0.567 g).

Diastereoisomer A—A colourless glass, R_f 0.41 (S/*C*); ν_{max} ($CHCl_3$): 2240 (w), 1720 (s), 1710 cm^{-1} (s); λ_{max} (EtOH): 254, λ_{infl} 283 nm; τ ($CDCl_3$): 2.05–3.45 (m, 9H), 4.98 (d, J = 15.6 Hz), 5.21 (d, J = 15.6 Hz) both superimposed on 4.60–5.40 (broad absorption) together 3H, 6.94 (d, 1H, J = 15.0 Hz), 7.28 (d, 1H, J = 15.0 Hz), 7.35–9.20 (broad absorption, 13H) including 8.31 (s, 3H); *m/e*: 441 (M^+ + CHCN, 3), 402 (M^+, 13.5), 342 (5), 303 (5), 302 (8), 263 (9), 262 (35), 261 (6), 260 (10), 236 (5), 235 (13.5), 184 (6), 171 (6), 141 (6), 99 (6), 92 (11), 91 (100), 81 (21), 65 (11), 43 (44). *Exact Mass* calcd. for $C_{25}H_{26}N_2O_3$: 402.194340; found: 402.190315.

Diastereoisomer B—A white crystalline solid, mp 139–140°C; R_f 0.34 (S/*C*); ν_{max} ($CHCl_3$): 2240 (w), 1720 (s), 1710 cm^{-1} (s); λ_{max}: 254 (ε 7210), λ_{infl} 283 nm (ε 780); τ ($CDCl_3$): 2.40–3.30 (m, 9H), 4.78 (d, J = 15.6 Hz), 5.39 (d, J = 15.6 Hz) both superimposed on 5.00–5.60 (broad absorption) together 3H, 7.03 (d, 1H, J = 15.0 Hz), 7.38 (d, 1H, J = 15.0 Hz), 7.50–9.00 (broad absorption, 13.5H) including 8.09 (s, 3H); *m/e* 402 (M^+, 19), 342 (2), 302 (5), 263 (10), 262 (57), 261 (7), 260 (21), 235 (14), 184 (4), 171 (3), 141 (3), 99 (4), 91 (100), 81 (16), 65 (6), 43 (36). *Anal.* calcd. for $C_{25}H_{26}N_2O_3$: C 74.63, H 6.47, N 6.97; found: C 74.8, H 6.8, N 6.8.

N-{2-[*1′-Benzyl-3′-(2″-acetoxycyclohexyl)oxindol-3′-yl*]-*ethyl*}*acetamide (**9**)*

A solution of the diastereoisomers **8** (760 mg) in acetic anhydride (50 mL) was hydrogenated in a Parr hydrogenator in the presence of W5 Raney nickel (1 g) and powdered A.R. sodium hydroxide (2.5 g) for 6 h at 85°C and 6.5 atm. The catalyst was filtered off and the acetic anhydride was boiled off at the water pump. The residue was suspended in water and treated with Na_2CO_3 until permanent neutrality was reached. Shaking with ether dissolved some of the product, but left a white powder suspended in the aqueous phase, which was extracted by chloroform. The ether soluble fraction (545 mg) was a mixture of diastereoisomers running as one spot on tlc, R_f 0.72 (S/*A*); the chloroform soluble fraction (279 mg) was pure diastereoisomer A, R_f 0.72 (S/*A*). The combined yield was almost quantitative. It is noteworthy that this very high yield was obtained in several runs (P.K.B), where two years later it could not be reproduced at all, H_2 uptake being very slow and reduction incomplete (D.L.C.).

Diastereoisomer A (low ether solubility)—This crystallised from 80–100 petrol as white crystals, mp 190.5–192°C; ν_{max} ($CHCl_3$): 3375 (w), 1720 (s), 1702 (s), 1665 (s); λ_{max} (EtOH): 253.5 (ε 7000), λ_{infl} 281 nm (ε 1300); τ ($CDCl_3$): 2.50–3.30 (m, 9H), 4.67 (d, J = 15.6 Hz), 5.63 (d, J = 15.6 Hz), 4.40–4.90 (broad hump), 5.40–6.05 (broad hump) last four signals adding up to 4H, 6.75–7.25 (br m, 2H), 7.30–9.00 (broad absorption, about 18H) including sharp 3H singlets at 8.18 and 8.40; *m/e*: 448 (M^+, 20), 389 (7), 388 (14), 364 (6), 363 (16), 345 (5), 316 (5), 309 (8), 308 (22), 307 (17), 306 (23), 305 (5), 304 (17), 303 (57), 302 (9), 250 (6), 249 (20), 248 (20), 247 (18), 238 (5), 237 (12), 236 (46), 235 (14), 234 (10), 223 (6), 158 (17), 141 (7), 92 (11), 91 (100), 81 (16). *Anal.* calcd. for $C_{27}H_{32}N_2O_4$: C 72.32, H 7.15, N 6.25; found: C 72.1, H 7.0, N 6.0.

Diastereoisomer B (high ether solubility)—Repeated ether extraction from the solid mixture gave the pure compound as white crystals from 60–80 petrol – ethyl acetate, mp 163–164°C; ν_{max} identical with A; λ_{max} (EtOH): 255 (ε 6850), λ_{infl} 282 nm (ε 1350); τ ($CDCl_3$): 2.70–3.50 (m, 9H), 4.25–4.70 (br s, 1H), 5.05 (d, J = 15.6 Hz), 5.27 (d, J = 15.6 Hz), 5.0–5.3 (br s), the last three signals adding up to 3H, 6.75–7.25 (br m, 2H), 7.40–9.00 (broad absorption, about 18H) including sharp 3H singlets at 8.20 and 8.30; *m/e*: 448 (M^+, 33), 389 (6), 388 (12), 376 (7), 364 (11), 363 (34), 316 (7), 309 (8), 308 (26), 307 (16), 306 (18), 305 (6), 304 (26), 303 (100), 302 (11), 260 (6), 259 (22), 258 (24), 257 (16), 237 (14), 236 (59), 235 (16), 234 (10), 223 (8), 158 (19), 141 (8), 99 (7), 92 (10), 91 (100), 81 (18). *Anal.* calcd. for $C_{27}H_{32}N_2O_4$: C 72.32, H 7.15, N 6.25; found: C 71.9, H 7.1, N 6.1.

N-{2-[*1′-Benzyl-3′-(2′′-hydroxycyclohexyl)oxindol-3′-yl*]-*ethyl*}*acetamide*

A solution of **9** (115 mg) in a mixture of ethanol (5 mL) and 10% aqueous sodium carbonate (10 mL) was refluxed for 17 h. The reaction mixture was then boiled down to dryness at the water pump and the residue partitioned between ether and water to yield a colourless foam (97 mg, 93%). Preparative tlc (S/*A*) of this product (70 mg) cleanly separated the two diastereoisomers.

Diastereoisomer A—R_f 0.57 (31.2 mg), crystallised from 60–80 petrol – ethyl acetate as white crystals, mp 197–198°C; ν_{max}: 3520 (w), 3400 (m), 3480–3200 (m), 1700 (s), 1665 cm^{-1} (m); λ_{max} (EtOH): 253 (ε 7700), λ_{infl} 281 nm (ε 890); τ ($CDCl_3$): 2.00–3.40 (m, 9H), 4.20–4.60 (br s, 1H, exchanges slowly with D_2O), 5.02 (d, 1H, J = 15.6 Hz), 5.27 (d, 1H, J = 15.6 Hz), 6.89 (d, J = 5.4 Hz), 7.09 (d, J = 5.4 Hz) overlying ~6.8 (m) together 3H, 7.50–9.05 (broad absorption, 17H) including 8.32 (s, 3H) and ~8.50 (br s exchanges with D_2O); *m/e*: 406 (M^+, 21), 334 (5), 322 (16), 321 (66), 320 (5), 319 (5), 309 (14), 308 (47), 307 (7), 306 (7), 304 (11), 303 (28), 302 (5), 266 (6), 263 (5), 262 (13), 250 (7), 249 (26), 248 (13), 247 (11), 238 (16), 237 (7), 236 (14), 235 (7), 225 (9), 220 (5), 217 (6), 159 (6), 158 (25), 146 (7), 130 (7), 92 (11), 91 (100), 81 (8). *Anal.* calcd. for $C_{25}H_{30}N_2O_3$: C 73.90, H 7.39, N 6.90; found: C 73.8, H 7.4, N 7.0.

Diastereoisomer B—R_f 0.44, crystallised from 60–80 petrol – ethyl acetate, mp 176–179°C; ν_{max} identical with A; λ_{max} (EtOH): 253.5 (ε 6900), λ_{infl} 280 nm (ε 1040); τ ($CDCl_3$): 2.00–3.40 (m, 9H), 3.87–4.23 (br s, 1H), 5.01 (d, 1H, J = 15.6 Hz), 5.25 (d, 1H, J = 15.6 Hz), 6.05–6.60 (br m, 1H), 6.60–9.00 (broad absorption, ~17H) including 8.25 (s, 3H); *m/e*: 406 (M^+, 12), 388 (3), 334 (5), 322 (14), 321 (47), 310 (5), 309 (16), 304 (10), 303 (35), 262 (7), 249 (16), 248 (10), 237 (10), 236 (48), 235 (10), 223 (5), 158 (17), 146 (5), 130 (5), 92 (10), 91 (100), 78 (50). *Anal.* calcd. for $C_{25}H_{30}N_2O_3$: C 73.90, H 7.39, N 6.90; found: C 73.5, H 7.3, N 7.2.

N-[2-{*1′-Benzyl-3′-[2″-(2‴-tetrahydropyranyloxy)cyclohexyl*]-*oxindol-3′-yl*}*ethyl*]*acetamide*

A solution of the above alcohol, as the mixture of diastereoisomers (4.2 g), 2,3-dihydropyran (20 mL), freshly purified DMF (30 mL), and concentrated HCl (1 drop) was left at room temperature for 40 h. The reaction solution was dissolved in ether (200 mL) and washed several times with 10% aqueous sodium carbonate. Removal of volatiles under reduced pressure yielded an orange liquid from an ether solution of which the product was precipitated with 40–60 petrol. It was obtained as a foam which eventually crystallised (4.77 g, 94%). This was homogeneous on tlc (S/*A*, R_f 0.63). Four recrystallisations from 60–80°C petrol – ethyl acetate yielded a product with mp 163.5–165°C; ν_{max} ($CHCl_3$): 3440 (w), 1680 cm^{-1} (s); λ_{max}: 254.5 (ε 9540), λ_{infl} 280 nm (ε 2190); τ ($CDCl_3$): 2.50–3.50 (m, 9H), 3.85–4.45 (broad signal, 1H), 4.45–5.72 (m, 3H), 5.80–8.80 (broad absorption, ~27H) including sharp 3H singlets at 8.26 and 8.35; *m/e*: 490 (M^+, 1), 407 (3), 406 (11), 389 (8), 387 (4), 347 (3), 345 (6), 322 (8), 321 (42), 309 (12), 308 (64), 303 (16), 249 (18), 248 (6), 237 (8), 236 (50), 235 (5), 223 (3), 158 (10), 92 (6), 91 (100). *Anal.* calcd. for $C_{30}H_{38}N_2O_4$ (490.2831): C 73.50, H 7.75, N 5.73; found (490.2846): C 73.7, H 7.8, N 5.3.

N-[2-{*1′-Benzyl-3′-[2″-(2‴-tetrahydropyranyloxy)-cyclohexyl*]*oxindol-3′-yl*}*ethyl*]-N-*methylacetamide*

A solution of the above acetylethanamino compound (4.7 g of unrecrystallised material) in dry THF (50 mL) was added to a solution of freshly sublimed potassium tertiary butoxide (4.7 g) in THF (100 mL) and the resultant solution left at room temperature for 30 min. A solution of methyl iodide (20 mL) in THF (25 mL) was then added dropwise over about 20 min. The reaction mixture was then boiled down to a thick slurry under water pump vacuum, and the residue partitioned between ether and water to give the product as a pale yellow foam (4.85 g, 99%) running as a single oval spot on tlc (S/*A*, R_f 0.68); ν_{max} ($CHCl_3$): 1710 cm^{-1} (s); λ_{max} (EtOH): 254 (ε 6350), λ_{infl} 280 nm (ε 1370); τ ($CDCl_3$): 2.00–3.30 (m, 9H), 4.30–8.75 (broad complex absorption, ~32H) including N—CH_3 at 7.22 and 7.26 (restricted rotation); *m/e*: 504 (M^+, 1), 421 (3), 420 (9), 419 (4), 403 (7), 346 (3), 335 (8), 323 (8), 322 (58), 321 (100), 304 (6), 303 (25), 286 (4), 262 (3), 250 (3), 249 (14), 248 (4), 237 (7), 236 (24), 235 (6), 223 (4), 158 (5), 100 (4), 92 (6), 91 (92), 86 (12), 85 (32). *Anal.* calcd. for $C_{31}H_{40}N_2O_4$ (504.2988): C 73.79, H 7.95, N 5.56; found (504.2998): C 73.9, H 8.2, N 5.2.

N-{2-[*1′-Benzyl-3′-(2′′-hydroxycyclohexyl)oxindol-3′-yl*]*ethyl*}-N-*methylacetamide* (***10***)

A solution of the above tetrahydropyranyl ether (4.7 g) in ether (60 mL) was stirred vigorously with 2.5 *M* hydrochloric acid (60 mL) at room temperature for 2 h. The ether soluble product, **10**, was obtained as a foam (3.64 g, 93%) pure by tlc, running as two clean spots (R_f 0.65, 0.54; S/A) corresponding to the two diastereoisomers A and B respectively. These were separated by preparative tlc.

Diastereoisomer A—This compound did not crystallise; ν_{max} ($CHCl_3$): 3570 (m), 3400 (broad, w), 1700 cm^{-1} (s); λ_{max} (EtOH): 253.5 (ε 10 000), λ_{infl} 280 nm (ε 1630); τ ($CDCl_3$) 2.60–3.40 (m, 9H), two overlapping AB systems, together = 2H, 5.11 (d, J = 16 Hz), 5.38 (d, J = 16 Hz), 5.12 (d, J = 15 Hz), 5.32 (d, J = 15 Hz), changing at 85°C to 5.12 (d, J = 15 Hz, 1H) and 5.32 (d, J = 15 Hz, 1H), 6.60–9.10 (broad complex absorption, 21H) including sharp singlets at 7.28, 7.33, 8.15, and 8.23, changing at 85°C to a sharp singlet at 7.30 and a broad singlet at 8.23; *m/e*: 420 (M^+, 2), 335 (7), 322 (9), 321 (17), 304 (9), 303 (24), 264 (6), 249 (11), 236 (17), 223 (7), 91 (100). *Exact Mass* calcd. for $C_{26}H_{32}N_2O_3$: 420.2413; found: 420.2410.

Diastereoisomer B—This compound likewise did not crystallise; ν_{max} ($CHCl_3$): 3570 (w), 3400 (m), 1700 cm^{-1} (s); λ_{max} (EtOH): 253.5 (ε 8250), λ_{infl} 280 nm (ε 1615); τ ($CDCl_3$): 2.50–3.40 (m, 9H), overlapping singlet and AB system, together = 2H, 5.18 (s), 5.09 (d, J = 16 Hz), 5.30 (d, J = 16 Hz), changing at 85°C to a broad singlet at 5.17 (2H), 6.10–9.00 (broad complex absorption, 21H) including sharp singlets at 7.23, 7.30, 8.12, and 8.24 changing at 85°C to a sharp singlet at 7.28, and a broad singlet at 8.20; *m/e*: 420 (M^+, 6), 335 (8), 322 (12), 321 (36), 304 (12), 303 (40), 264 (6), 249 (12), 248 (6), 237 (8), 236 (24), 235 (12), 223 (8), 91 (100). *Exact Mass* calcd. for $C_{26}H_{32}N_2O_3$: 420.2413; found: 420.2410.

N-{2-[1′-*Benzyl-3′-(2″-ketocyclohexyl)oxindol-3′-yl]ethyl*}-N-*methylacetamide* (**11**)

A solution of the mixed diastereoisomers of alcohol **10** (3.0 g) in pure acetone (45 mL) was treated with a solution of sodium dichromate (3.0 g) and concentrated H_2SO_4 (4.5 g) in water (30 mL). After 30 min at room temperature the reaction solution was neutralised with solid $NaHCO_3$, the acetone distilled off at the water pump and the aqueous residue extracted with ethyl acetate (4 × 50 mL). The extracts were washed with aqueous 1*M* HCl, water, and dried. The solvent was boiled off, and the product obtained as a yellow foam (2.1 g, 70%) which gave one spot at R_f 0.66 (S/*A*) and was thus pure mixed diastereoisomers of the ketone. Similar oxidation of the separated diastereoisomers of alcohol **10** gave the corresponding pure diastereoisomers of ketone **11**.

Diastereoisomer A—This was obtained as a colourless gum; ν_{max} ($CHCl_3$): 1710 (s), 1640 cm^{-1} (s); λ_{max} (EtOH): 254 (ε 9530), λ_{infl} 280 nm (ε 1830); τ ($CDCl_3$): 2.50–3.40 (m, 9H), 5.01 (br s, 2H), 6.20–8.50 (complex absorption, 19H) including sharp singlets at 7.22, 7.26, 8.06, and 8.24 changing at 60°C to a broad singlet at 7.26 and broad humps at 8.06 and 8.24; *m/e*: 418 (M^+, 5), 320 (8), 319 (35), 291 (22), 262 (6), 248 (7), 223 (5), 158 (5), 154 (12), 126 (10), 100 (5), 98 (12), 97 (5), 95 (7), 91 (100). *Exact Mass* calcd. for $C_{26}H_{30}N_2O_3$: 418.2256; found: 418.2266.

Diastereoisomer B—This was likewise obtained as a colourless gum; ν_{max}: same as A; λ_{max} (EtOH): 254 (ε 9530), λ_{infl} 280 nm (ε 1820); τ ($CDCl_3$): 2.20–3.40 (m, 9H), 5.08 (br s, 2H), 6.70–9.00 (complex absorption, 19H) including sharp singlets at 7.27, 8.15, and 8.22; the last two coalesce at 60°C to a broad singlet at 8.19; *m/e*: 418 (M^+, 9), 320 (12), 319 (55), 318 (5), 292 (5), 291 (22), 262 (5), 248 (10), 100 (8), 92 (8), 91 (100). *Exact Mass* calcd. for $C_{26}H_{30}N_2O_3$: 418.2256; found: 418.2261.

N-{2-[1′-*Benzyl-3′-(2″-keto-3″-formylcyclohexyl)oxindol-3′-yl]ethyl*}-N-*methylacetamide* (**12**)

A mixture of sodium ethoxide (1.73 g, 25 mmol) and freshly purified ethyl formate (2.81 g, 38 mmol) in dry benzene (25 mL) was left at room temperature under N_2 for 2.5 h. A solution of the ketone **11** (418 mg, 1 mmol) in dry benzene (20 mL) was then added, the mixture left for 10 h at room temperature, acidified with dilute aqueous HCl, and extracted with ethyl acetate (3 × 25 mL). The combined extracts were then extracted with 10% aqueous sodium carbonate (3 × 30 mL). The combined carbonate extracts were washed with ether (2 × 20 mL), acidified with 6 *M* aqueous HCl, keeping the temperature below 10°C, and then extracted with ethyl acetate (3 × 50 mL). This yielded a pale brown foam (403 mg) which after charcoaling in benzene became a very pale yellow foam of the formyl compound **9** (390 mg, 87%). The product runs as a streaking spot on tlc at R_f 0.65 (S/*A*); ν_{max}: 3400 (w), 1710 (s), 1640 cm^{-1} (s); λ_{max} (EtOH): 258 (ε 13 390), 285 nm (ε 11 550); λ_{max} (EtOH–NaOH): 253.5 (ε 11 000), 322 nm (ε 19 500); τ ($CDCl_3$): −4.95 (br s) and −4.21 (br s) together = 1H and exchange with D_2O, 1.58 (br s) and 2.01 (br s) together = 1H, sharpen on addition of D_2O, 2.20–3.50 (m, 9H), 5.10 (compact m, 2H), 6.30–8.50 (complex absorption, 17H) including close-packed sharp signals centred at 7.18, and sharp singlets at 8.06, 8.09, 8.12, and 8.22; *m/e*: 446 (M^+, 3), 347 (6), 322 (6), 249 (4), 248 (6), 223 (9), 91 (100). *Anal.* calcd. for $C_{27}H_{30}N_2O_4$ (446.2204): C 72.67, H 6.73, N 6.28; found (446.2206): C 72.4, H 6.8, N 6.0.

N-{2-[1′-*Benzyl-3′-(2″-keto-3″-allyl-3″-formylcyclohexyl)-oxindol-3′-yl]ethyl*}-N-*methylacetamide* (**13**)

This allylation was carried out in a darkroom because of the high light sensitivity of allyl iodide. A large excess of allyl iodide (8 mL) was added to a stirred solution of the lithium salt of formyl ketone **12**, prepared by stirring a suspension of **12** (835 mg, 1.87 mmol) and lithium carbonate (244 mg, 3.3 mmol) in water (12 mL). Pure acetone (100 mL) was added to render the reaction mixture homogeneous and the solution was left at room temperature for 1 h. The acetone and allyl iodide were then removed under water pump vacuum at 30°C and the residue partitioned between 5% aqueous Na_2CO_3 (25 mL) and ethyl acetate (25 mL). The aqueous phase was further extracted with ethyl acetate (3 × 25 mL) and the combined organic extracts washed with aqueous Na_2CO_3, then with water. Removal of the solvent yielded a pale yellow foam of essentially pure allyl formyl compound **13** (758 mg, 83%) which ran as a slightly elongated spot at R_f 0.70 (S/*A*). (The acidic (Na_2CO_3 soluble) portion of the reaction mixture (109 mg) contained at least seven components.) ν_{max}: 3000 (m), 1710 (s), 1640 cm^{-1} (s); λ_{max} (EtOH): 255 (ε 8220), λ_{infl} 280 (ε 2100); τ ($CDCl_3$): 0.22 (s), 0.45 (s) together = 1H, 2.20–3.50 (m, 9H), 4.10–5.90 (complex absorption, 5H), 6.30–8.60 (complex absorption, 20H) including sharp singlets at 7.26, 7.27, 8.09, 8.17, 8.25, 8.26; *m/e*: 486 (M^+, 1), 458 (0.3), 445 (2), 387 (9), 346 (9), 322 (5), 263 (4), 236 (9), 223 (2), 176 (8), 158 (5), 134 (5), 117 (5), 105 (5), 104 (4), 91 (100). *Anal.* calcd. for $C_{30}H_{34}N_2O_4$ (486.2518): C 74.06, H 7.00, N 5.76; found (486.2493): C 71.8, H 6.9, N 5.4.

N-{2-[1′-*Benzyl-3′-(2″-keto-3″-allylcyclohexyl)oxindol-3′-yl]ethyl*}-N-*methylacetamide* (**14**)

A solution of the allyl formyl compound **13** in 2.5% aqueous alcoholic KOH (40 mL) was left at room temperature under N_2 for 1 h. The solvent was nearly completely removed by distillation under reduced pressure. Partition of the residue between water (10 mL) and ethyl acetate (25 mL), followed by further extraction of the aqueous phase with ethyl acetate (3 × 30 mL) gave the allyl compound **14** as a pale yellow foam (700 mg, 98%) which ran as a single oval spot on tlc (R_f 0.70, S/*A*); ν_{max} ($CHCl_3$): 3400 (w), 1705 (s), 1640 cm^{-1} (s); λ_{max} (EtOH): 255 (ε 7150), λ_{infl} 280 nm (ε 1790); τ ($CDCl_3$): 2.10–3.33 (m, 9H), 3.40–5.30 (complex absorption, 5H), 6.60–9.10 (complex absorption, 20H) including sharp singlets at 7.28, 8.10, 8.18, 8.23, 8.39; *m/e*: 458 (M^+, 21), 360 (13), 359 (49), 358 (9), 322 (7), 318 (10), 278 (6), 262 (6), 250 (6), 249 (13), 248 (16), 235 (24), 234 (6), 223 (25), 158 (7), 100 (18), 91 (100). *Exact Mass* calcd. for $C_{29}H_{34}N_2O_3$: 458.2569; found: 458.2577.

N-{2-[1′-*Benzyl-3′-(2″-keto-3″-ethanalylcyclohexyl)oxindol-3′-yl]ethyl*}-N-*methylacetamide* (**15**)

A stream of ozonised oxygen was passed through a solution of the allyl compound **14** (350 mg) in dry methanol (8 mL) at −30°C for 45 min. The solution was then cooled to −60°C, purged with nitrogen for 15 min, and treated with dimethyl sulphide (3 mL). After 1 h at room temperature, the reaction solution was boiled down at the water pump, and the residual colourless oil partitioned between ethyl acetate (25 mL) and 5% aqueous Na_2CO_3 (25 mL). The aqueous phase was extracted with ethyl acetate (3 × 30 mL) and normal work-up of the nonacidic and acidic organic products gave the aldehyde **15** (318 mg, 91%) as an off-white foam and the corresponding carboxylic acid (30 mg, 8%) as a colourless gum. This good experimental result was reproduced several times, but on a number of occasions was not. These failures could not be accounted for.

The aldehyde **15** ran as a single elongated spot on tlc (R_f 0.57, S/*A*); ν_{max} ($CHCl_3$): 2740 (w), 1710 (s), 1640 cm^{-1} (s); λ_{max} (EtOH); 253.5 (ε 8080), λ_{infl} 280 nm (ε 1840); τ ($CDCl_3$): 0.20 (br s), 0.34 (br s) together = 1H, 2.10–3.35 (m, 9H), 5.06 (br s) overlapping 5.0–5.40 (br m) together = 2H, 6.50–8.70

(complex absorption, 21H) including 7.24 (br s) and sharp singlets at 8.06, 8.14, 8.20, 8.25; *m/e*: 460 (M^+, 7), 361 (27), 343 (36), 333 (14), 322 (18), 249 (14), 248 (14), 236 (20), 223 (27), 168 (14), 150 (11), 149 (14), 106 (23), 105 (18), 91 (100). *Exact Mass* calcd. for $C_{28}H_{32}N_2O_4$: 460.2362; found: 460.2382.

N-{2-[*1'-Benzyl-3'-(2''-keto-3''-carboxycyclohexyl)oxindol-3'-yl]ethyl*}-N-*methylacetamide*

The acidic fraction from the above ozonolysis gave analytical and spectral data consistent with the structure proposed. It ran on tlc as a streaking spot at variable R_f around 0.27 (S/*A*); ν_{max} ($CHCl_3$): 3300–2600 (broad, w), 1715 (s), 1640 cm^{-1} (s); λ_{max} (EtOH): 254 (ε 8500), λ_{infl} 280 nm (ε 1730); τ ($CDCl_3$): 0.80–1.80 (very broad s, 1H, exchange with D_2O), 2.20–3.50 (m, 9H), 5.08 (br s) overlying a broad hump 4.75–5.50, together = 2H, 6.20–9.20 (complex absorption, 22H), including broad singlet at 7.24; *m/e*: 476 (M^+, 2), 377 (4), 361 (5), 359 (5), 322 (17), 249 (17), 237 (9), 236 (22), 223 (17), 165 (7), 158 (20), 149 (17), 91 (100). *Exact Mass* calcd. for $C_{28}H_{32}N_2O_5$: 476.2311; found: 476.2307.

N-{2-[*1'-Benzyl-3'-(4'',5'',6'',7''-tetrahydroindol-7''-yl)-oxindol-3'-yl]ethyl*}-N-*methylacetamide* (***16***)

The keto aldehyde **15** (180 mg) was added to a suspension of ammonium carbonate (0.5 g) in absolute ethanol (15 mL) under nitrogen. After a further 2 g of ammonium carbonate had been added, the stirred mixture was refluxed for 2 h, during which time further ammonium carbonate was added (5 × ~0.5 g). The ethanol was then boiled off under reduced pressure and the pale brown solid residue partitioned between ethyl acetate (10 mL) and water (10 mL); the aqueous phase was reextracted with ethyl acetate (3 × 10 mL). The combined organic extracts yielded an orange-brown foam (180 mg). This product ran as two main spots on tlc, at R_f 0.70 and 0.64, together with three faint lower-running components and much baseline material. Preparative tlc (S′/*A*) of 25 mg on four plates (S′/*A*) under a N_2 atmosphere gave diastereoisomer A (3.3 mg), mixed diastereoisomers A and B (7.0 mg), and diastereoisomer B (3.5 mg) as colourless oils. The yield of A + B is thus 54%.

Diastereoisomer A—This ran as a round spot on tlc at R_f 0.70 (S/*A*); ν_{max} ($CHCl_3$): 3280 (m), 1700 (s), 1640 cm^{-1} (s); λ_{max} (EtOH): 257, λ_{infl} 281 nm; τ ($CDCl_3$): −0.80 to −0.30 (broad hump, 1H, did not exchange with D_2O), 2.60–3.60 (m, 9H), 3.66 (m, 1H), 4.04 (m, 1H), 4.98 (d, 1H, *J* = 14 Hz), 5.21 (d, 1H, *J* = 14 Hz), 5.70–8.50 (complex absorption, ~17H) including sharp singlets at 7.04 and 7.93; *m/e*: 441 (M^+, 1), 322 (6), 236 (5), 121 (20), 120 (100), 119 (5), 118 (13), 103 (5), 91 (64). *Exact Mass* calcd. for $C_{28}H_{31}N_3O_2$: 441.2416; found: 441.2399.

Diastereoisomer B—This ran as a round spot on tlc at R_f 0.64 (S/*A*); ν_{max} ($CHCl_3$): 3430 (m), 1700 (s), 1640 cm^{-1} (s); λ_{max} (EtOH): 257, λ_{infl} 281 nm; nmr spectrum not satisfactory (sample too small) but pyrrole CH's and benzyl CH_2 visible, and NMe and $COCH_3$ each split into two signals (sharp singlets 7.18, 7.23, and 8.04, 8.22) by restricted rotation; *m/e*: 441 (M^+, 1), 342 (6), 322 (4), 249 (4), 236 (8), 167 (4), 158 (4), 121 (9), 120 (98), 118 (16), 103 (4), 92 (6), 91 (100). *Exact Mass* calcd. for $C_{28}H_{31}N_3O_2$: 441.2416; found: 441.2420.

Palladium-on-charcoal Dehydrogenation of ***16***

A solution of **16** (6.5 mg) in decalin (1.5 mL) containing suspended 10% Pd/C (2 mg) was heated for 1 h at 165°C under N_2. Thin-layer chromatographic assay showed total consumption of the diastereoisomer B of **16** and just one main running spot at R_f 0.70 (S/*A*) coincident with diastereoisomer A of **16**. The mass spectrum of this fraction (1.3 mg after preparative tlc) showed it to be a mixture of the diastereoisomer A of **16** and the desired indole **6**; *m/e*: 441 (M^+), 437 (M^+), 338, 247, 120, 100, 91. *Exact Mass* calcd. for $C_{28}H_{31}N_3O_2$: 441.2416; found: 441.2402. *Exact Mass* calcd. for $C_{28}H_{27}N_3O_2$: 437.2103; found: 437.2107.

N-{2-[*1'-Benzyl-3'-(2''-methoxycarbonyl-4'',5'',6'',7''-tetrahydroindol-7''-yl)oxindol-3'-yl]ethyl*}-N-*methylacetamide* (***18***)

A solution of the tetrahydroindole **16** (88.2 mg, 0.2 mmol) in dry, ethanol-free chloroform (2 mL) was added over a period of 20 min to a solution of trichloroacetyl chloride (91 mg, 0.5 mmol) in pure chloroform (3 mL) containing a suspension of anhydrous potassium carbonate (276 mg, 2 mmol). After a further 25 min, the solids were filtered off and washed with chloroform (2 × 5 mL). The combined chloroform solutions were washed with saturated aqueous $NaHCO_3$ solution (2 × 5 mL) and then with water (2 × 10 mL) to give an orange yellow solution. This yielded a brown foam (104 mg) which ran as one major spot (R_f 0.7, S/*A*) together with baseline material. This crude product (100 mg) was dissolved in methanol (2 mL) and treated with a solution of sodium methoxide in methanol (made from Na, 11.5 mg, and MeOH, 3 mL). After 5 min, the methanol was boiled off at the water pump and the residue partitioned between ethyl acetate (10 mL) and water (10 mL). The aqueous phase was further extracted with ethyl acetate (2 × 5 mL) and the combined extracts boiled down to yield a brown liquid (70 mg) which ran as several spots on tlc (S/*A*), one of which, at R_f 0.6, was dominant. Preparative tlc (S′/*A*, six plates) of 60 mg of the product mixture gave the ester **18** as a pale orange foam (22 mg, 30% yield from **16**), which ran as a round spot on tlc at R_f 0.6 (S/*A*); ν_{max} ($CHCl_3$): 3430 (m), 3240 (m), 1700 (s), 1635 cm^{-1} (s); λ_{max} (EtOH): 284.5 nm (ε 16 480); *m/e*: 499 (M^+, 2), 468 (2), 323 (7), 322 (23), 249 (8), 236 (11), 223 (3), 178 (100), 146 (48), 91 (71); τ ($CDCl_3$): −0.95 (br s) and −0.15 (br s) neither is exchangeable with D_2O and both together = 1H, 2.30–3.70 (m, 10H), 4.50–5.40 (m, 2H), 6.25 (s) and 6.31 (s) together = 3H, 6.40–8.70 (complex absorption, 18H) including sharp singlets at 7.11, 7.22, 8.00, and 8.22. *Exact Mass* calcd. for $C_{30}H_{33}N_3O_4$: 499.2471; found: 499.2492.

N-{2-[*1'-Benzyl-3'-(2''-methoxycarbonylindol-7''-yl)oxindol-3'-yl]ethyl*}-N-*methylacetamide* (***20***)

A solution of the tetrahydroindole **18** (17 mg, 0.034 mmol) and DDQ (15.5 mg, 0.068 mmol) in benzene (5 mL) was refluxed for 1.25 h. Ethyl acetate (10 mL) was added to the cooled reaction mixture and the solution extracted with aqueous sodium bicarbonate (3 × 5 mL) and water (2 × 5 mL). The ethyl acetate solution yielded the indole **20** as a pale greenish brown viscous liquid (11.7 mg, 69%), which ran as a single round spot on tlc at R_f 0.62 (S/*A*); ν_{max} ($CHCl_3$) 3300 (m), 1705 (s), 1690 (s), 1640 cm^{-1} (s); λ_{max} (EtOH): 258 (ε 11 180), 293 (ε 18 500), λ_{infl} 230 nm (ε 27 850); τ ($CDCl_3$): −1.1 (br s, 1H, not exchangeable with D_2O), 2.00–3.20 (m, 11.5H, 1.5H too high), 5.05 (br s, 2H), 6.04 (s, 3H), 6.50–8.90 (complex absorption, 11H, 1.0H too high) including broad singlets at 7.20 and 8.15; *m/e*: 495 (M^+, 7), 409 (4), 397 (7), 396 (23), 365 (4), 364 (17), 363 (4), 305 (4), 273 (6), 207 (7), 178 (9), 149 (17), 100 (44), 91 (100). *Exact Mass* calcd. for $C_{30}H_{29}N_3O_4$: 495.2157; found: 495.2163.

N-{2-[*1'-Benzyl-3'-(2''-carboxyindol-7''-yl)oxindol-3'-yl]ethyl*}-N-*methylacetamide* (***21***)

A solution of the above ester **20** (7 mg) in a mixture of 95% ethanol (1.5 mL) and 0.1 *M* aqueous NaOH (1.5 mL) was left at room temperature for 18 h, then boiled down at 20°C at the water pump to remove the ethanol, and the aqueous residue

partitioned between 5% aqueous Na_2CO_3 (5 mL) and ethyl acetate (5 mL). The aqueous phase was then acidified with concentrated HCl and extracted with ethyl acetate (3 × 5 mL). This yielded the indole carboxylic acid **21** as a pale brown foam (6.3 mg, 93%) running as a streaking spot on tlc with a variable R_f (S/*A*). This product crystallised; recrystallisation from ethyl acetate gave colourless crystals, mp 139.5–141°C: ν_{max} ($CHCl_3$): 3550–2600 (broad m), 3300 (m), 1690 (s), 1640 cm^{-1} (s); λ_{max} (EtOH): 258 (ε 12 000), 269 (ε 12 000), 292 nm (ε 16 250); τ ($CDCl_3$): −1.15 (s) and −1.10 (s) not exchangeable with D_2O, together = 1H, changing at 85°C to 0.9 (br s, 1H); 1.25 (broad hump, 1H) exchange with D_2O, shifting at 85°C to 0.68; 2.30–3.40 (m, 13H), 5.10 (s, 2H), 5.60–7.75 (m, 7H) including sharp singlets at 7.20 and 7.24 (changing at 85°C to 7.24); 8.12 (s) and 8.15 (s) together = 3H (changing at 85°C to 8.15); *m/e*: 481 (M^+, 9), 438 (8), 437 (18), 395 (1), 383 (15), 382 (44), 381 (8), 364 (14), 363 (8), 351 (8), 339 (13), 338 (38), 337 (15), 291 (11), 273 (11), 248 (8), 247 (25), 245 (10), 218 (9), 203 (8), 130 (8), 100 (93), 91 (100). *Exact Mass* calcd. for $C_{29}H_{25}N_3O_4$: 481.2002; found: 481.2003.

N-{2-[*1′-Benzyl-3′-(indol-7″-yl)oxindol-3′-yl*]*ethyl*}-N-*methylacetamide* (**6**)

A solution of the indolecarboxylic acid **21** (594 mg) in pure quinoline (30 mL) containing cupric acetate monohydrate (120 mg) was heated at 200°C for 8 h under nitrogen, the cooled reaction mixture poured into ethyl acetate (100 mL) and extracted with aqueous 1 *M* hydrochloric acid (5 × 40 mL) and water (2 × 10 mL). The ethyl acetate soluble product, which produced one major spot at R_f 0.7 and a small spot of less polar compound, in addition to baseline material (S/*A*), was dissolved in the minimum volume of chloroform and transferred onto an alumina column (8 × 2 cm). Elution with carbon tetrachloride removed the less polar impurity; elution with methanol then gave the pure indole **6** as a pale orange foam (380 mg, 70.5%), which ran as a round spot at R_f 0.7 (S/*A*) and 0.65 (S/*E*); ν_{max} ($CHCl_3$); 3470 (w), 3350 (m), 1700 (s), 1680 cm^{-1} (s); λ_{max} (EtOH): 259 (ε 11 990), 285 (ε 9680), 290 nm (ε 8290); τ ($CDCl_3$): —0.52 (broad hump) and −0.41 (broad hump) together = 1H, not exchangeable with D_2O, changing at 85°C to −0.24 (broad hump, 1H); 2.40–3.40 (m, 13H); 5.18 (s, 2H); 6.70–8.00 (complex absorption, 7H) including sharp singlets at 7.31 and 7.36 (changing at 85°C to a sharp singlet at 7.36, ~3H); 8.21 (s) and 8.30 (s) together = 3H (changing at 85°C to a singlet at 8.26, 3H); *m/e*: 437 (M^+, 60), 364 (5), 351 (18), 339 (32), 338 (100), 337 (41), 310 (5), 273 (14), 260 (5), 248 (14), 247 (50), 246 (9), 245 (14), 231 (14), 230 (9), 218 (18), 204 (14), 130 (14), 100 (95), 91 (91). *Exact Mass* calcd. for $C_{28}H_{27}N_3O_2$: 437.2104; found: 437.2103.

N-[2-(*1′-Benzylindol-3′-yl*)*ethyl*]-N-*methylacetamide* (**22**)

(1-Benzyltryptamine was prepared for the first time by *N*-benzylation of tryptamine. Of the several methods available for the specific 1-alkylation of tryptamine, that reported by Potts and Saxton (12) for 1-methylation gave by far the best results; the *N*-methylacetamide **22** had been previously prepared from 1-benzylindole-3-carboxaldehyde (13) and also by a Fischer synthesis from 1-phenyl-1-benzylhydrazine (14).)

A solution of *N*-[2-(1′-benzylindol-3-yl)ethyl]acetamide (960 mg, 3.2 mmol) in dry THF (5 mL) was added to a stirred solution of freshly sublimed potassium *tert*-butoxide (1.08 g, 9.6 mmol) in dry THF (20 mL) under N_2. After 30 min at room temperature a solution of methyl iodide (4.6 g, 32 mmol) in dry THF (5 mL) was added dropwise with stirring. After a further period of 30 min at room temperature, the reaction mixture was boiled down at the water pump and partitioned between water (50 mL) and ether (50 mL). The aqueous phase was further extracted with ether (2 × 50 mL). The combined dried ether extracts then yielded the *N*-methyl compound **22** as a white crystalline product (980 mg). Crystallisation from toluene gave pure **22**, mp 98–98.5°C (821 mg, 82%); moves as a round spot at R_f 0.63 (S/*A*) and at 0.40 (S/*D*); ν_{max} ($CHCl_3$): 1635 cm^{-1} (s); λ_{max} (EtOH): 289 (ε 5450), λ_{infl} 281 (ε 5000), 299 nm (ε 4900); τ ($CDCl_3$): 2.90–3.05 (m, 9H), 3.12 (d, *J* = 2.5 Hz, 1H), 4.82 (s, 2H), 6.39–6.58 (m, 2H), 6.95–7.21 (m, 5H) including sharp singlets at 7.08 and 7.19, 8.00 (s, 1.5H), 8.16 (s, 1.5H); *m/e*: 306 (M^+, 5), 289 (1), 288 (1), 233 (45), 220 (17), 129 (3), 91 (100). *Anal.* calcd. for $C_{20}H_{22}N_2O$ (306.1732): C 78.43, H 7.19, N 9.15; found (306.1736): C 78.9, H 7.2, N 9.2.

N-[2-(*1′-Benzyloxindol-3′-yl*)*ethyl*]-N-*methylacetamide* (**23**)

A solution of the indole **22** (5 g) in glacial acetic acid (50 mL) containing dimethyl sulphoxide (5 mL) and concentrated HCl (2.5 mL) was left overnight at room temperature under nitrogen. The reaction solution was added to water (200 mL) and extracted with ether (4 × 75 mL). The combined ether extracts were carefully neutralised with solid $NaHCO_3$ at 0°C, washed with saturated aqueous $NaHCO_3$ (2 × 100 mL), then with water. The extracts yielded a colourless viscous liquid (4.9 g) part of which (61.7 mg) yielded the pure oxindole (55.4 mg, 90%) by preparative tlc (S/*D*). The yield for the reaction is 84%, allowing for the 90% purity of the isolated product. The *purified* compound failed to crystallise and was used in the following analytical and spectral measurements; moves as a round spot at R_f 0.58 (S/*A*) and 0.32 (S/*D*); ν_{max} ($CHCl_3$): 1706 (s), 1635 cm^{-1} (s); λ_{max} (EtOH): 256 (ε 7150), λ_{infl} 280 (ε 1380); τ ($CDCl_3$): 2.5–3.5 (m, 9H), 5.13 (s, 2H), 6.09–6.85 (m, 3H), 7.05 (s, 1.6H), 7.10 (s, 1.4H), 7.55–8.10 (m, 5H), including a sharp singlet at 8.0 (~3H); *m/e*: 322 (M^+, 17), 280 (0.5), 279 (0.5), 249 (6), 236 (18), 223 (2), 158 (5), 130 (4), 117 (4), 103 (2), 91 (100). *Exact Mass* calcd. for $C_{20}H_{22}N_2O_2$: 322.1681; found: 322.1684.

N-{2-[*1′-Benzyl-3′-(1″-methoxycyclohex-1″-en-6″-yl)oxindol-3′-yl*]*ethyl*}-N-*methylacetamide* (**24**)

A solution of the crude oxindole (**23**) (1.29 g, 4 mmol) in dry THF (5 mL) was added dropwise under N_2 to a stirred solution of freshly sublimed potassium *tert*-butoxide (492 mg, 4.4 mmol) in dry THF (5 mL). After 30 min at room temperature, a solution of 6-bromo-1-methoxycyclohex-1-ene (840 mg, 4.4 mmol) in THF (5 mL) was added dropwise with stirring. After a further period of 30 min at room temperature, water (25 mL) and then saturated aqueous NaCl (150 mL) were added, and the whole extracted with ethyl acetate (3 × 50 mL). The extracts yielded a colourless liquid (1.60 g). Preparative tlc of 61.1 mg of this product (S/*E*) yielded the pure product (**24**) as mixed diastereoisomers (45.6 mg, corresponding to a 78% yield, allowing for the 90% purity of crude **20** used); the mixed diastereoisomers ran as one spot on tlc at R_f 0.38 (S/*D*) and at 0.54 (S/*E*); ν_{max} ($CHCl_3$): 1702 (s), 1630 cm^{-1} (s); λ_{max} (EtOH): 257 (ε 7450), λ_{infl} 280 nm (ε 2420); τ ($CDCl_3$): 2.50–3.40 (m, 9H), 5.08 (m, 0.75H), 5.12 (s, 0.5H), 5.21 (m, 0.75H), 5.60 (m, 0.6H), 6.41 (s, 0.7H), 6.44 (s, 0.3H), 6.60–8.40 (m, 19H), including sharp singlets at 7.21, 7.25, 7.30, 7.34, 8.07, 8.13, and 8.22; *m/e*: 432 (M^+, 0.4), 417 (1.8), 357 (0.8), 340 (2), 332 (1), 322 (18), 318 (5), 305 (1), 291 (2), 269 (8), 267 (22), 254 (10), 249 (10), 236 (12), 223 (2), 158 (3), 129 (3), 111 (10), 91 (100), 87 (14). *Exact Mass* calcd. for $C_{27}H_{32}N_2O_3$: 432.2413; found: 432.2406.

Hydrolysis of **24** *to the Ketone* **11** *and Formylation to the Formylketone* (**12**)

A solution of the crude enol ether **24** as obtained above, in aqueous methanolic HCl (from 27 mL MeOH and 3 mL 3 *M*

aqueous HCl) was left at room temperature under N_2 for 2.5 h; solid $NaHCO_3$ (3 g) was then added and the methanol boiled off at the water pump. The residue was partitioned between ethyl acetate (100 mL) and water (50 mL). The organic phase yielded a yellow viscous liquid (1.33 g) shown to contain 72.5% of ketone **11** by preparative tlc. This corresponds to a yield of 89% for the hydrolysis step and an overall 58% in three steps based on the indole **22**. The purified ketone **11** was found to run as two spots corresponding to the two diastereoisomers at R_f 0.36 and 0.26 (S/*D*), and at 0.52 and 0.47 (S/*E*); ketone prepared by the earlier method (oxidation of the corresponding alcohol) showed identical behaviour.

The crude product (containing 72.5% of **11**) was used directly in the formylation step, which was carried out as described earlier in this experimental (toluene was used instead of benzene): the acidic fraction of the reaction proved to be pure **12** and was formed in 83% yield (overall 48% yield in the four steps from the indole **22**).

N-{2-[*1′-Benzyl-3′-[2″-ethoxycarbonyl-4″,5″,6″,7″-tetrahydroindol-7″-yl)oxindol-3-yl*]*ethyl*}-N-*methylacetamide (**19**)*

A solution of the formyl ketone **12** (3.6 g, 8 mmol) in THF (4 mL) was added to a refluxing solution of sodium acetate (1.45 g, 17.8 mmol) in water (24 mL) and glacial acetic acid (25 mL) under N_2. A solution of ethyl 2-amino-3-oxobutanoate hydrochloride (15) (the literature procedure was simplified by the use of concentrated HCl instead of dry HCl and by the use of a 10:1 ratio of oxime to catalyst; 1.46 g, 8.1 mmol) in aqueous acetic acid (4 mL) was then added dropwise with stirring and refluxing. After about 15 min, a second equivalent of the amine hydrochloride was gradually added, and the refluxing continued for a further 15 min. After cooling in an ice–salt bath, a cold solution of 10% aqueous Na_2CO_3 (200 mL) was added and the whole extracted with ethyl acetate (4 × 100 mL). The combined extracts were then washed with 5% aqueous Na_2CO_3 (4 × 100 mL), dried, and boiled down to yield a brown product, which after charcoal treatment was obtained as a pale red oil (3.89 g). Preparative tlc showed this to contain 70% of the ethyl ester (**19**) as a mixture of two diastereoisomers. The purified **19** runs as two spots at R_f 0.39 and 0.35 (S/*D*), and as one spot at 0.52 (S/*E*); ν_{max} ($CHCl_3$): 3440 (w), 3250 (w), 1697 (s), 1635 cm^{-1} (s); λ_{max} (EtOH): 286 nm (ε 19 700); τ($CDCl_3$): 0.25 (hump, 0.5H), 1.01 (hump), and 1.35 (hump) together = 0.5H, 2.55–3.62 (m, 10H), 4.92 (d, J = 13.8 Hz), 5.26 (d, J = 13.8 Hz), 4.91 (d, J = 10.8 Hz), 5.43 (d, J = 10.8 Hz) all four doublets = 2H, 5.7–6.1 (two sharp closely overlapping quartets, 2H), 6.4–6.9 (m, 2H), 7.05–8.95 (complex absorption, 20H) including sharp singlets at 7.13, 7.21, 7.23, 8.01, 8.05, 8.22, and two sharp closely overlapping triplets 8.68–8.86; *m/e*: 513 (M^+, 0.2), 468 (1), 322 (20), 249 (9), 236(14), 192 (100), 146 (35), 91 (35). *Exact Mass* calcd. for $C_{31}H_{35}N_3O_4$: 513.2627; found: 513.2627.

N-{2-[*1′-Benzyl-3′-(2″-ethoxycarbonylindol-7″-yl)oxindol-3′-yl*]*ethyl*}-N-*methylacetamide (**43**)*

A solution of DDQ (3.04 g, 13.4 mmol) in dry toluene was added under nitrogen over 5 min to a solution of the crude pyrrole ester **19** (3.416 g, 6.7 mmol) in dry toluene (40 mL) at 80°C and the reaction solution kept at that temperature for 75 min. Ethyl acetate (100 mL) was then added and the whole extracted with 0.5 *M* $NaHCO_3$ (4 × 75 mL). The dried organic phase yielded, after charcoaling, a dark brown oil (3.125 g) preparative tlc of which (56.5 mg, S/*E*) gave 29.8 mg of pure indole ester **43** (53%). This compound moves as a single spot at R_f 0.50 (S/*D*) and at 0.58 (S/*E*); ν_{max} ($CHCl_3$): 3440 (w), 3310 (m), 1705 (s), 1639 cm^{-1} (s); λ_{max} (EtOH): 293.5 nm (ε 18 300); τ ($CDCl_3$): −0.83 (broad s, 1H, no exchange with D_2O), 2.26–3.40 (m, 14H), 5.08 (s, 2H), 5.63 (q, J = 7.5 Hz, 2H), 6.60–7.15 (multiplet, 8H) including a sharp singlet at 7.21, 8.13 (s), and 8.15 (s) together = 3H, 8.60 (t, J = 7.5 Hz, 3H); *m/e*: 509 (M^+, 7), 464 (1), 423 (3), 410 (30), 364 (25), 273 (6), 100 (65), 91 (100). *Exact Mass* calcd. for $C_{31}H_{31}N_3O_4$: 509.2314; found: 509.2323.

*Hydrolysis of Crude Ethyl Ester **43** to Pure Indole Carboxylic Acid **21***

The total reaction product mixture as obtained above (2.8 g) was saponified as described for the methyl ester (**20**). The total acidic fraction was obtained as a pale brown crystalline solid (1.49 g) recrystallisation of which from ethyl acetate gave the pure indole carboxylic acid **21** as colourless crystals, mp 139.5–141°C (1.21 g, which represents an 86% yield based on the 53% content of ester in the crude starting material).

*3-(2′-Hydroxyethyl)-1,3-dimethyloxindole (**39**)*

A 15% solution of *n*-butyl lithium in hexane (4.3 mL, 0.01 mol) was added dropwise over 5 min to a stirred solution of 1,3-dimethyloxindole (1.61 g, 0.01 mol) in dry anisole (25 mL) under N_2 at 0°C. The solution was left at 10°C for 15 min, then cooled to 0°C and treated dropwise with stirring over 2 min with a solution of ethylene oxide (0.88 g, 0.02 mol) in dry anisole (4 mL). The reaction solution was left under N_2 at room temperature for 19 h. Glacial acetic acid (0.6 g, 0.01 mol) was then added and, after a period of 15 min, the anisole distilled off at the water pump. The residue was thoroughly extracted with ether. Distillation of the product yielded a viscous yellow liquid (1.2 g, bp 160°C/0.6 Torr). Preparative tlc (S/*B*) of 86 mg gave two products: (*a*) at R_f 0.28 3-(2′-hydroxyethyl)-1,3-dimethyloxindole (**39**) as white crystals, mp 75.5–77.5°C (60.2 mg, 42% yield); ν_{max} ($CHCl_3$): 3570 (m), 3500–3150 (m), 1700 (s); λ_{max} (EtOH): 252.5 (ε 8630), λ_{infl} 281 (ε 1670); τ ($CDCl_3$): 2.50–3.20 (m, 4H), 6.10–6.60 (m, 2H), 6.78 (s, 3H), 7.50–7.70 (br s, 1H), exchange with D_2O), 7.60–8.30 (m, 2H), 8.60 (s, 3H); *m/e*: 205 (M^+, 30), 175 (5), 174 (17), 162 (13), 161 (100), 160 (72), 159 (9), 130 (13), 117 (10), 103 (5), 91 (10), 77 (10). *Anal.* calcd. for $C_{12}H_{15}NO_2$: C 70.22, H 7.37, N 6.83; found: C 70.0; H 7.3, N 6.7. (*b*) at R_f 0.40: 1,3-dimethyldioxindole as a white solid, mp 151–153°C (lit. (23) mp 148–149°C) (17 mg, 13% yield); *m/e*: 177 (M^+, 100); τ ($CDCl_3$): 2.45–3.25 (m, 4H), 6.10–6.50 (br s, 1H), exchange with D_2O) 6.79 (s, 3H), 8.39 (s, 3H).

*1,3-Dimethyl-3-(2′-hydroxycyclohexyl)oxindole (**28**)*

A 15% solution of *n*-butyl lithium in hexane (4.7 mL, 11 mmol) was added dropwise over 5 min under N_2 to a well stirred solution of 1,3-dimethyloxindole (1.61 g, 10 mmol) in anisole (20 mL) at 0°C. The solution was warmed to room temperature and a solution of 1,2-epoxycyclohexane (1.47 g, 15 mmol) in anisole (4 mL) was added dropwise over 5 min. The reaction solution was then left at room temperature for 20 h under N_2, then 2 h at 100°C. Glacial acetic acid (0.66 g, 11 mmol) was then added to the cooled mixture, the solvents boiled off at the water pump, and the residue partitioned between ethyl acetate (100 mL) and water (50 mL). The organic phase gave a white crystalline product (2.36 g), recrystallisation of which from 60–80 petrol – ethyl acetate yielded pure **28**, mp 169.5–170.5°C, R_f 0.1 (S/*B*) (1.51 g, 58%); ν_{max} ($CHCl_3$): 3520 (m), 3500–3250 (broad, w), 1698 cm^{-1} (s); λ_{max} (EtOH): 252.5 (ε 8580), λ_{infl} 280.5 nm (ε 1650); τ ($CDCl_3$): 2.60–3.25 (m, 4H), 6.83 (s, 3H), 6.95–9.00 (complex absorption, 14.5 H) including a sharp doublet 8.57 (J = 10 Hz, exchange with D_2O, about 1H) and a sharp singlet at 8.72, ~3H; *m/e*: 259 (M^+, 18), 175 (4), 174 (30), 162 (15), 161 (100), 160 (25), 159 (5), 158 (4), 146 (4), 144 (4), 130 (5), 118 (4), 117 (4), 91 (4),

81 (6). *Anal.* calcd. for $C_{16}H_{21}NO_2$: C 74.10, H 8.16, N 5.40; found: C 74.5, H 8.1, N 5.2.

*1,3-Dimethyl-3-(2'-ketocyclohexyl)oxindole (**29**)*

A solution of sodium dichromate dihydrate (77.6 mg, 0.26 mmol) and 98% H_2SO_4 (101.4 mg, 1.1 mmol) in water (0.7 mL) was added dropwise over 15 min at room temperature to a vigorously stirred suspension of the alcohol **28** (100 mg, 0.39 mmol) in ether (10 mL). After being stirred for 5 h the aqueous phase was separated and extracted with ether (5 × 5 mL), the combined extracts were washed with 10% aqueous Na_2CO_3 (3 × 5 mL) and then water. The dried solution yielded a pale yellow solid (67 mg). Preparative tlc (S/*B*) of the product (48.5 mg) led to the isolation of the pure ketone **29** as a mixture of diastereoisomers, mp 137–140°C (80–100 petrol – ether acetate) (35.9 mg, 50% yield); ν_{max} ($CHCl_3$): 1705 (s), 1695 cm^{-1} (s); λ_{max} (EtOH): 252 (ε 9050), λ_{infl} 280 nm (ε 1730); τ ($CDCl_3$): 2.30–3.30 (m, 4H), 6.75 (s) and 6.79 (s) together = 3H, 6.80–8.90 (complex absorption 12H) including sharp singlets at 8.57 and at 8.72 together ~3H; *m/e*: 257 (M^+, 14), 223 (4), 205 (3), 180 (3), 174 (4), 161 (20), 160 (32), 149 (4), 130 (4), 128 (4), 117 (4), 91 (4), 75 (5), 74 (75), 73 (11), 71 (6), 59 (100), 45 (62). *Anal.* calcd. for $C_{16}H_{19}NO_2$: C 74.70, H 7.46, N 5.45; found: C 74.4, H 7.5, N 5.5.

*1,3-Dimethyl-3(1',2',3',4'-tetrahydrocarbazol-1'-yl)oxindole (**40**)*

A solution of the ketone **29** (139 mg, 0.54 mmol) in glacial acetic acid (1.5 mL) was heated to 100°C. Pure phenylhydrazine (58.4 mg, 0.54 mmol) in glacial acetic acid (1 mL) was added dropwise with stirring to the solution at 100°C. After 30 min the acetic acid was boiled off at the water pump and the residue partitioned between ether and water. The aqueous phase was further extracted with ether (3 × 10 mL), the combined extracts washed with saturated aqueous $NaHCO_3$ (3 × 10 mL), then with water. This yielded a yellow solid (161.3 mg) which crystallised from 80–100 petrol – ethyl acetate and gave the tetrahydrocarbazole **40** as colourless crystals, mp 192–194°C; the compound moves as one spot on tlc at R_f 0.52 (S/*B*); ν_{max} ($CHCl_3$): 3380 (m), 1690 cm^{-1}(s); λ_{max} (EtOH): 228 (ε 34 950), 256 (ε 10 390), 286 (ε 9770), 293 (ε 7880); τ ($CDCl_3$): 2.10 (br s, 1H, no exchange with D_2O), 2.50–3.40 (m, 8H), 6.10–6.60 (m, 1H), 6.72 (s, 3H), 7.10–8.40 (complex absorption, 6H), 8.48 (s, 3H); *m/e*: 330 (M^+, 3), 171 (20), 170 (100), 169 (16), 168 (41), 167 (30), 166 (7), 161 (9), 160 (9), 154 (9), 143 (25), 130 (20), 128 (11), 118 (20), 117 (16), 115 (16), 81 (16), 77 (16). *Anal.* calcd. for $C_{22}H_{22}N_2O_2$: C 80.00, H 6.66, N 8.49; found: C 79.8, H 6.7, N 8.1.

*3-(1'-Carbazolyl)-1,3-dimethyloxindole (**41**)*

o-Chloranil (37.5 mg, 0.15 mmol) was added portionwise to a stirred solution of the tetrahydrocarbazole **40** in decalin (3 mL) at 120°C. After completion of the addition, the reaction was left at 120°C for 10 min, the decalin then distilled off under reduced pressure and the residue subjected to preparative tlc (S/*B*). The main band at R_f 0.68 was the carbazole **41** (18 mg) which after three crystallisations from 60–80 petrol – ethyl acetate was obtained as colourless crystals, mp 171–173°C; ν_{max} ($CHCl_3$): 3280 (m), 1690 cm^{-1} (s); λ_{max} (EtOH): 236 (ε 36 200), 245 (ε 26 620), 258.5 (ε 15 100), 282.5 (ε 10 210), 292.5 (ε 13 350), 323.5 (ε 3560), 336.5 nm (ε 3080); τ ($CDCl_3$): −0.35 (br s, 1H), no exchange with D_2O), 1.80–2.20 (m, 2H), 2.30–3.20 (m, 10H), 6.80 (s, 3H), 8.02 (s, 3H); *m/e*: 326 (M^+, 84), 325 (6), 312 (26), 311 (100), 309 (5), 295 (6), 294 (8), 283 (15), 282 (8), 281 (8), 280 (6), 279 (5), 268 (15), 267 (9), 266 (8), 265 (5), 255 (5), 254 (13), 253 (6), 252 (5), 241 (5), 167 (8), 163 (8), 155 (11), 149 (9), 116 (7), 110 (6). *Anal.* calcd. for $C_{22}H_{18}N_2O$ (326.1419): C 80.98, H 5.52, N 8.59; found (326.1427): C 79.8, 79.6; H 5.9, 5.7; N 7.9, 8.2.

*1,3-Dimethyl-3-(3'-formyl-2'-ketocyclohexyl)oxindole (**30**)*

Ethanol-free sodium ethoxide (from sodium, 0.67 g, 0.029 g-at.) was treated with pure ethyl formate (3.2 g, 44 mmol) in benzene (30 mL) under N_2. After 2 h at room temperature, the ketone **29** (3.5 g, 14 mmol) was added and the reaction solution left for a further 2.5 h. The benzene was then boiled off at the water pump and the orange solid residue partitioned between 10% aqueous Na_2CO_3 (50 mL) and ether (50 mL). Further extraction of the ether phase with aqueous Na_2CO_3 (2 × 25 mL) and washing of the combined aqueous phases with ether was followed by careful acidification with concentrated HCl, the temperature being kept at 0°C. The acidified mixture was extracted with ether (3 × 50 mL) which yielded a white solid (3.32 g, 84%). Four recrystallisations from 60–80 petrol – ethyl acetate gave pure formyl ketone **30** as colourless crystals, mp 122–123°C. It ran as an elongated spot on tlc, R_f 0.37 (S/*B*); ν_{max} ($CHCl_3$): 3600–2600 (w), 1705 (s), 1640 cm^{-1} (m); λ_{max} (EtOH): 253.5 (ε 11 170), 282 nm (ε 8330); τ ($CDCl_3$): −4.20 (br d, J = 5.4 Hz, 1H, exchange with D_2O), 1.95 (d, J = 5.4 Hz, 1H) changing to singlet with D_2O, 2.50–3.27 (m, 4H), 6.40–8.90 (complex absorption, 13H) including sharp singlets ~3H at 6.75 and 8.67; *m/e*: 285 (M^+, 21), 174 (9), 162 (17), 161 (93), 160 (100), 159 (9), 158 (7), 145 (9), 144 (10), 132 (21), 131 (10), 130 (19), 128 (7), 118 (10), 117 (21), 115 (7), 103 (9), 91 (12), 77 (12). *Anal.* calcd. for $C_{17}H_{19}NO_3$: C 71.57, H 6.67, N 4.91; found: C 72.0, H 7.0, N 5.1.

*3-(3'-Allyl-3'-formyl-2'-ketocyclohexyl)-1,3-dimethyloxindole (**31**) and 3-(3'-Allyloxymethylene-2'-ketocyclohexyl)-1,3-dimethyloxindole (**42**)*

The formyl ketone **30** (2.5 g, 8.8 mmol) was dissolved in sodium carbonate (1.06 g, 10 mmol) and water (1 mL) and allyl bromide (60 g, 500 mmol) were then added, followed by sufficient acetone to form a homogeneous solution (100 mL). After 12 h at room temperature, the acetone and excess allyl bromide were distilled off at the water pump and the residue partitioned between ether (50 mL) and aqueous Na_2CO_3 (50 mL). The aqueous phase was further extracted with ether (3 × 20 mL). The combined extracts yielded a colourless liquid (3 g) which was chromatographed on silica gel (300 g). Elution was started with a 7:3 mixture of 60–80 petrol – ethyl acetate, proceeding with an increasing proportion of ether: the *C*-allyl compound **31** was eluted with 5–10% ether (2.42 g, 85% yield), and the *O*-allyl compound **42** came off as a quite distinct band with 15–60% ether (0.38 g, 13.5%).

*The C-allyl compound (**31**)*—This formed colourless crystals, mp 117.5–119°C, after three recrystallisations from 60–80 petrol – ethyl acetate. It runs as a round spot on tlc at R_f 0.47 (S/*B*); ν_{max} ($CHCl_3$): 1710 (s), 1645 cm^{-1} (w); λ_{max} (EtOH): 252.5 (ε 9000), λ_{infl} 280 (ε 1980); τ ($CDCl_3$): 0.44 (s, 0.4H), 2.50–3.30 (m, 4H), 4.00–5.10 (m, 3H), 6.50–8.90 (complex absorption, 13H) including sharp singlets ~3H each at 6.74 and 8.71; *m/e*: 325 (M^+, 73), 187 (24), 186 (16), 174 (30), 162 (48), 161 (100), 160 (98), 137 (46), 132 (20), 130 (26), 117 (28), 109 (13), 91 (24), 77 (25), 67 (22). *Anal.* calcd. for $C_{20}H_{23}NO_3$: C 73.85, H 7.09, N 4.31; found: C 74.1, H 7.25, N 4.3.

*The O-allyl compound (**42**)*—This could not be induced to crystallise. It runs at R_f 0.33 (S/*B*); ν_{max} ($CHCl_3$): 1705 (s), 1685 cm^{-1} (sh, s); λ_{max} (EtOH): 253.5 (ε 12 530), 280 nm (ε 4900); τ ($CDCl_3$): 2.45–3.25 (m, 5H), 3.90–5.10 (m, 3H), 5.65 (d, J = 6 Hz, 2H), 5.95–8.90 (complex absorption, 16H) including sharp singlets, each ~3H at 6.70 and at 8.71; *m/e*: 325 (M^+, 13), 285 (9), 284 (36), 257 (10), 176 (6), 162 (32), 161 (43), 160 (100), 145 (5), 144 (6), 132 (9), 130 (9), 117 (10),

109 (5), 108 (6), 91 (5), 77 (5). *Exact Mass* calcd. for $C_{20}H_{23}NO_3$: 325.1678; found: 325.1668.

3-(3'-Allyl-2'-ketocyclohexyl)-1,3-dimethyloxindole (32)

A solution of the formyl compound **31** (500 mg) in 2.5% aqueous alcoholic potassium hydroxide was heated to 50°C for 6 h under nitrogen. The aqueous alcohol was boiled off at the pump and the residue neutralised with dilute hydrochloric acid before being extracted with ether (3 × 25 mL). This yielded a diastereoisomeric mixture of **32** in the form of a colourless oil (480 mg), running as two round spots on tlc (S/*B*). Separation by preparative tlc (55 mg, S/*B*) gave diastereoisomers A and B.

Diastereoisomer A—R_f 0.5 (24.9 mg) colourless crystals, mp 83.5–84.5°C, after recrystallisation twice from 60–80°C petrol and twice from cyclohexane; ν_{max} ($CHCl_3$): 1710 (s), 1700 (s), 1645 cm^{-1} (m); λ_{max} (EtOH): 253 (ε 8390); λ_{infl} 279 (ε 1925); τ ($CDCl_3$): 2.30–3.40 (m, 4H), 3.82–5.75 (m, 3H), 6.60–9.00 (complex absorption, 16H) including sharp singlets, each 3H, at 6.77 and 8.58; *m/e*: 297 (M^+), 48), 187 (5), 174 (17), 173 (5), 162 (12), 161 (80), 160 (100), 159 (6), 158 (5), 146 (23), 145 (10), 144 (12), 137 (6), 132 (8), 131 (6), 130 (12), 129 (6), 128 (7), 118 (7), 117 (13), 116 (7), 115 (12), 103 (7), 91 (13), 77 (10). *Anal.* calcd. for $C_{19}H_{23}NO_2$: C 76.76, H 7.74, N 4.71; found: C 76.8, H 7.8, N 4.7.

Diastereoisomer B—R_f 0.47 (24.7 mg) a colourless oil which failed to crystallise; ν_{max} ($CHCl_3$): identical with A; λ_{max} (EtOH): 253; λ_{infl} 280; τ ($CDCl_3$): 2.50–3.60 (m, 4H), 3.88–5.67 (m, 3H), 6.60–9.00 (complex absorption, 16H) including sharp singlets, each 3H at 6.74 and 8.73; *m/e*: 297 (M^+, 14), 174 (20), 173 (3), 162 (8), 161 (88), 160 (100), 144 (9), 132 (7), 130 (11), 117 (13), 91 (9), 77 (13). *Exact Mass* calcd. for $C_{19}H_{23}NO_2$: 297.1729; found: 297.1728.

1,3-Dimethyl-3-(2'-keto-3'-ethanalylcyclohexyl)oxindole (33)

The diastereoisomeric mixture of compound **32** (1.2 g) was dissolved in dry methanol (15 mL) and an ozone–oxygen mixture bubbled through the solution at −30°C for 40 min. The reaction mixture was cooled to −60°C and the system purged with nitrogen for 15 min before addition of dimethyl sulphide (6 mL). The colourless solution was allowed to warm to room temperature gradually over a period of 2 h before distillation of the solvent at the pump. The residual yellow oil was partitioned between water (25 mL) and ether (4 × 25 mL). The combined ethereal solutions were extracted first with water (10 mL) and then with 5% sodium bicarbonate solution (3 × 10 mL). The basic extracts were acidified with concentrated hydrochloric acid at 0°C and ether extracted (3 × 25 mL). The two ethereal solutions gave *a* and *b* respectively.

(*a*) Nonacidic material (898 mg) identified as being a diastereoisomeric mixture of **33** (75%). Preparative tlc (S/*B*) on the mixture (105 mg) gave the following.

Diastereoisomer A—R_f 0.30 (49.6 mg), a pale yellow oil; ν_{max} ($CHCl_3$): 3410 (w), 2730 (m), 1720 (s), 1705 (s), 1695 cm^{-1} (s); λ_{max} (EtOH); 253.5, λ_{infl} 279; τ ($CDCl_3$): 0.25 (s, 0.85H) 2.35–3.30 (m, 4H), 6.60–8.70 (complex absorption, 18H) including sharp singlets, each 3H, at 6.76 and 8.58; *m/e*: 299 (M^+, 21), 271 (<1), 174 (12), 162 (12), 161 (100), 160 (99), 146 (5), 132 (8), 130 (7), 121 (23), 118 (5), 117 (8), 111 (7), 91 (8), 77 (8). *Exact Mass* calcd. for $C_{18}H_{21}NO_3$: 299.1521; found: 299.1554.

Diastereoisomer B—R_f 0.17 (42.5 mg) a pale yellow foam; ν_{max} ($CHCl_3$) identical with A with the exception of 3410 (m), 2730 cm^{-1} (w); λ_{max} (EtOH): 252.5 (ε 9310), λ_{infl} 278.5 (ε 1830); τ ($CDCl_3$): 0.39 (br s, 0.6H), 2.60–3.30 (m, 4H), 6.65–8.90 (complex absorption, 18H) including sharp singlets, each 3H, at 6.78 and 8.72; *m/e*: 299 (M^+, 25), 271 (<1), 174 (15), 162 (7), 161 (68), 160 (100), 117 (5), 85 (5), 83 (8). *Exact Mass* calcd. for $C_{18}H_{21}NO_3$: 299.1521; found: 299.1557.

(*b*) The carboxylic acid corresponding to **33** (136.7 mg, 11%) and running as two spots on tlc R_f 0.21 and 0.32, S/*B*); *m/e*: 315 (M^+, 8), 300 (4), 299 (8), 177 (12), 174 (17), 162 (12), 161 (83), 160 (100), 132 (21), 130(17), 118 (12), 117 (21), 91 (38), 77 (29). *Exact Mass* calcd. for $C_{18}H_{21}NO_4$: 315.1521; found: 315.1522.

1,3-Dimethyl-3-(4',5',6',7'-tetrahydroindol-7'-yl)oxindole (34)

The keto aldehyde **33** (105 mg) was dissolved in 95% ethanol (5 mL) and saturated aqueous ammonium carbonate solution (5 mL) added. The mixture was refluxed under nitrogen with periodic addition of solid ammonium carbonate (200 mg) over 1 h. The aqueous ethanol was distilled off at the pump and the residue partitioned between water (10 mL) and ethyl acetate (4 × 10 mL). The combined organic extracts gave a pale yellow foam which was identified as being predominantly a diastereoisomeric mixture of **34** (91% yield). Preparative tlc (S/*B*) of 25 mg of the mixture under nitrogen atmosphere gave diastereoisomers A and B.

Diastereoisomer A—R_f 0.5 (1.7 mg), colourless crystals, mp 157.5–158.5°C; ν_{max} ($CHCl_3$): 3440 (w), 3300 (m), 1690 cm^{-1} (s); λ_{max} (EtOH): 253 (ε 7010), λ_{infl} 279 (ε 1590); τ ($CDCl_3$): 0.25–0.85 (br s, 1H) fails to exchange with D_2O, 2.50–3.35 (m, 4H), 3.34 (t, J = 2.4 Hz, 1H), 4.02 (t, J = 2.4 Hz, 1H), 6.60–7.40 (m, 4H) including 3H singlet at 6.79, 7.40–7.90 (6m, 2H), 7.90–8.80 (6m, 7H) including a 3H singlet at 8.65; *m/e*: 280 (M^+, 4), 161 (14), 160 (5), 146 (7), 121 (11), 120 (100), 119 (5), 118 (20), 117 (5), 103 (8), 91 (7), 77 (5). *Anal.* calcd. for $C_{18}H_{20}N_2O$ (280.1576): C 77.2, H 7.2, N 10.0; found (280.1574): C 77.7, H 7.2, N 9.7.

Diastereoisomer B—R_f 0.45 (4.0 mg), a colourless oil; ν_{max} ($CHCl_3$) identical with that of A, with the exception of 3440 cm^{-1} (m) and the absence of 3300 cm^{-1}; λ_{max} (EtOH): 254: λ_{infl}: 280; τ ($CDCl_3$): 1.91–2.41 (br s, 1H) fails to exchange with D_2O, 2.00–3.35 (m, 4H), 3.55 (t, J = 2.4 Hz,1H), 4.20 (t, J = 2.4 Hz, 1H), 6.78 (s, 3H), 7.35–8.40 (complex absorption, 6H), 8.52 (s, 3H); *m/e*: 280 (M^+, 4) 161 (3), 160 (6), 121 (11), 120(100), 119 (3), 118 (10), 117 (4), 105 (3), 103 (6), 93 (3), 91 (4), 77 (4). *Exact Mass* calcd. for $C_{18}H_{20}N_2O$: 280.1576; found: 280.1560.

1,3-Dimethyl-3-(2'-carbomethoxy-4',5',6',7'-tetrahydro-7'-indolyl)oxindole (36)

The tetrahydroindole **34** (56 mg, 0.2 mmol) was dissolved in dry ethanol-free chloroform (2 mL) and added to a mixture of trichloroacetyl chloride (46 mg, 0.25 mmol) and anhydrous potassium carbonate (138 mg, 1.0 mmol) in similarly purified chloroform (2 mL) over 20 min. After stirring for a further 25 min, the solid was filtered from the deep red suspension and the filter cake washed with chloroform (2 × 5 mL) and water (2 × 10 mL) and the solvent removed at the pump to give an orange brown foam (72.4 mg). This was dissolved in methanol (5 mL) and added to a methanolic solution of sodium methoxide (from sodium (5.5 mg) and methanol (1.2 mL)) and stirred for 5 min. The methanol was removed at the pump and the orange-red residual oil partitioned between water (10 mL) and ethyl acetate (1 × 10 mL, 2 × 5 mL). The organic phase gave an orange-red oil (57.6 mg) which after dissolving in benzene and treating with charcoal to remove polar material resulted in an orange oil (44.4 mg). Isolation of the material running at R_f 0.4 (S/*B*) by preparative tlc afforded the ester **36** as a white foam (21.8 mg, 38% yield); λ_{max} (EtOH): 255, 282,5; τ ($CDCl_3$): −0.20 (br s, 0.5H), 2.40–3.5 (m, 5H), 6.18 (s, 3H), 6.30–8.75 (complex absorption, 10H) including 3H singlets at 6.80 and 8.60; *m/e*: 338 (M^+, 2) 307 (2), 279 (2), 178 (100), 160 (11), 146 (49), 130 (7), 118 (20), 117 (14), 91 (38).

1,3-Dimethyl-3-(2′-carbomethoxy-7′-indolyl)oxindole (37)

The tetrahydroindole ester **36** (3.1 mg, 9.2×10^{-3} mmol) was dissolved in benzene (1 mL) and heated to reflux under nitrogen. A solution of DDQ (4.2 mg, 1.84×10^{-2} mmol) in benzene was added dropwise over 5 min and the yellow solution refluxed for 1.5 h during which time a brown precipitate formed and the solution became virtually colourless. Ethyl acetate (10 mL) was added to the cooled reaction mixture and the solution extracted with dilute aqueous sodium bicarbonate solution (3×5 mL) and water (2×5 mL). The organic phase (an orange oil) (4.6 mg), on charcoal treatment in benzene solution, afforded a colourless oil (2.7 mg). Isolation of the material running at R_f 0.58 (S/*B*) by preparative tlc gave the pure indole ester **37** (2.5 mg, 81% yield) as a colourless oil; λ_{max} (EtOH): 232, 252.5, 292; *m/e*: 334 (M^+, 100), 320 (20), 319 (84), 288 (11), 287 (50), 259 (29), 160 (13), 91 (18). *Anal.* calcd. for $C_{20}H_{18}N_2O_3$: 334.1317; found: 334.1308.

Methylation of 3-(2′-Hydroxycyclohexyl)-1-benzyloxindole (7)

A solution of **7** (100 mg, 0.031 mmol) in anisole (0.75 mL) under N_2 was treated with a solution of *n*BuLi (40 mg, 0.0625 mmol) in hexane (0.55 mL). After stirring at 20°C for 10 min, a large excess of methyl iodide (3 mL) was added and the mixture refluxed for 30 min and left at 20°C for 62 h. The anisole was distilled off under reduced pressure and the residue partitioned between ether and water. The extract gave a yellowish brown viscous liquid (83 mg). Preparative-layer chromatography of 75 mg (S′/*B*) gave two products.

(a) 3-(2′-Methoxycyclohexyl)-1-benzyl-3-methyloxindole (45, R = R′ = CH_3)

This compound, R_f 0.61 (22 mg), was isolated as white crystals, mp 120.5–122.5°C after three crystallisations from 60–80°C petrol; τ ($CDCl_3$): 2.5–3.5 (m, 9H), 4.89 (d, J = 15 Hz, 0.9H), 5.48 (d, J = 15 Hz, 0.9H), 7.55 (s, 3H, the high-field shift for this methoxyl is due to shielding by the oxindole benzene ring), 7.5–9.2 (complex absorption, 16H) including a 3H singlet at 8.75; *m/e* 349 (M^+, 3), 237 (77), 113 (14), 91 (100).

(b) 3-(2′-Hydroxycyclohexyl)-1-benzyl-3-methyloxindole (45, R = H, R′ = CH_3)

This compound, R_f 0.37 (24 mg), was isolated as white crystals, mp 146–149°C after crystallisation from 60–80 petrol; τ ($CDCl_3$): 2.5–3.5 (m, 9H), 5.02 (d, J = 16 Hz, 1H), 5.24 (d, J = 16 Hz, 1H), 6.7–9.0 (complex absorption, 26H) including a 3H singlet at 8.65; *m/e*: 335 (M^+, 43), 250 (30), 237 (100), 159 (13), 146 (10), 91 (100). *Anal.* calcd. for $C_{22}H_{25}NO_2$: C 78.82, H 7.45, N 4.18; found: C 79.0, H 7.6, N 4.1.

Received December 28, 1978

ROBERT E. SCHWARTZ, MARK B. YUNKER, PAUL J. SCHEUER, and TOR OTTERSEN. Can. J. Chem. **57**, 1707 (1979).

From a deep water Pacific zoanthid, *Gerardia* sp., we have isolated two new fluorescent nitrogenous pigments, derivatives of tetrazacyclopentazulene. The first was characterized by uv, ^1H and ^{13}C nmr data, and by X-ray diffraction; the second by interconversion.

ROBERT E. SCHWARTZ, MARK B. YUNKER, PAUL J. SCHEUER et TOR OTTERSEN. Can. J. Chem. **57**, 1707 (1979).

On a isolé, d'un zoanthide provenant des profondeurs du Pacifique, *Gerardia* sp., deux nouveaux pigments fluorescents contenant de l'azote et dérivés du tétrazacyclopentazulène. On en a caractérisé un par uv, par rmn du ^1H et du ^{13}C et par diffraction de rayon-x; la structure du second a été établie par interconversion.

[Traduit par le journal]

A spectacular feature of tropical coral reefs is the brilliant coloration of its fauna. Yet surprisingly, aside from a number of novel carotenoids (1) and quinones (2, 3), and the unconventional chlorin bonellin (4), so far only one group of pigments belonging to an entirely new structural type has been reported. These pigments are tetrazacyclopentazulenes or zoanthoxanthins which were first isolated in 1973 from Mediterranean zoanthids (Coelenterata, Anthozoa, Zoantharia ≡ Hexacorallia) by Prota and co-workers (*5a–e*), and subsequently by a Japanese group from the Sagami Bay coelenterate *Parazoanthus gracilis* (6). Discovery of the linear zoanthoxanthin (**1**) and the angular pseudozoanthoxanthin (**2**) skeletons led Prota and co-workers to speculate (*5d*) that the biogenesis of these pigments might involve dimerization of two arginine-derived C_5N_3 units. Büchi and co-workers (*7a, b*) based their ingenious biomimetic synthesis of the two ring systems (**1**, **2**, R,R′ = H) on an oxidative coupling reaction of two suitably functionalized C_5N_3 moieties.

Inspection of formulas **1** and **2** shows that the angular skeleton may lead to a third structural type, **3**. In a preliminary communication (8) we reported isolation of the first member of this new series from gold coral, which is a deep water (−350 m) *Gerardia* sp.[3] The structure of this metabolite is entirely consistent with the suggested C_5N_3 biogenetic building blocks of these pigments. In this paper we present the details of this investigation, including the structure of a second member having skeletal type **3**.

sp., trivially named gold coral, because of the golden luster of its polished endoskeleton, since this coral was causing adverse reactions to the skin and mucous membranes of the workers who handled the freshly harvested coral with bare hands. We did not succeed in finding a suitable laboratory bioassay which would trace the bioactive constituent(s). We were, however, prompted by the strong fluorescence of the ethanolic extract of the animals to pursue research into the nature of the fluorescent compounds.

Purification of the fluorescent ethanolic extract by ion exchange, adsorption, and gel permeation chromatography yielded as the major constituent (**4**) an amorphous yellow powder, $C_{13}H_{16}N_6$, which decomposed at approximately 200°C, characterized further as an orange monoacetate (**5**), $C_{15}H_{18}N_6O$, mp 125–129°C. The minor component (**6**), also an amorphous yellow solid, $C_{12}H_{14}N_6$, decomposing at approximately 180°C could be converted into the major constituent (**4**) by reaction with methyl iodide in sodium – liquid ammonia.

The strong fluorescence and the biological origin of these compounds from *Gerardia* sp. led us to suspect that we might be dealing with zoanthoxanthin pigments (*vide supra*). Comparison of the uv spectra of our compounds (Table 1) with those reported for zoanthoxanthin (**1**) and pseudozoanthoxanthin (**2**) derivatives (8) convinced us that we were dealing with a new skeletal type.[4] The complexity of the spectra suggested that our compounds belonged to the angular (pseudo) series. The composition of the major constituent (**4**), $C_{13}H_{16}N_6$, indicated the presence of three additional carbons, shown by ^1H nmr data (Table 2) to be present as a

[4]The trivial nomenclature of these pigments has become unnecessarily complex. We should like to suggest simplification by omitting prefixes (*para*, *epi*) which denote methylation patterns and/or biological origin. Instead, we propose to call the linear system zoanthoxanthin (**1**) and the angular system pseudozoanthoxanthin (**2**) with numbering as shown. The position number of saturated nuclear nitrogen followed by *H* will distinguish among the major groups of zoanthoxanthins. Zoanthoxanthin (**1**, R, R′ = Me) becomes a 3*H* zoanthoxanthin, norpseudozoanthoxanthin (**2**, R = H, R′ = Me) becomes a 4*H* pseudozoanthoxanthin, and compounds of structural type **3** become 3*H* pseudozoanthoxanthins.

nuclear *N*-methyl singlet at δ 4.63 and two side-chain *N*-methyls appearing as a broad six-proton singlet at δ 3.55. A three-proton singlet at δ 2.96 and AB quartet for two aromatic protons, plus the ^{13}C nmr data (see Experimental) were equally compatible for a number of structures. X-ray diffraction of crystalline **4** monohydrate defined the structure as 2-amino-3,9-dimethyl-5-dimethylamino-3*H*-1,3,4,6-tetrazacyclopent[*e*]azulene and confirmed that we were dealing with a new series of angular zoanthoxanthins, i.e. pseudozoanthoxanthins.

The minor component (**6**), $C_{12}H_{14}N_6$, differed from **4** by a methyl group. ^1H nmr data, chiefly a three proton singlet at δ 3.42, were evidence for a methylamino substituent at C-2 or C-5. Methylation of **6** yielded three products. The major component was identical with **4** thereby proving unequivocally structure **6**, 2-amino-3,9-dimethyl-5-methylamino-3*H*-1,3,4,6-tetrazacyclopent[*e*]azulene. A second component was isolated as a yellow solid, $C_{15}H_{20}N_6$, decomposing at approximately 155°C, which was a trimethyl-**6** and is formulated as **7**, 2,5-bisdimethylamino-3,9-dimethyl-3*H*-1,3,4,6-tetracyclopent[*e*]azulene. A small amount of a third compound was not characterized.

An interesting aspect of this work relates to the longstanding question whether organic metabolites of marine coelenterates are synthesized by the animals or by the symbiotic zooxanthellae (9). Clearly, in our case, these nitrogenous pigments must be the products of the animals which live at a depth of −350 m, where no photosynthesis takes place.

Experimental

Apparatus, Methods, and Materials

Natural abundance ^{13}C nmr spectra were recorded on a Varian XL-100 Fourier transform spectrometer at 25.2 MHz. Field–frequency locking was provided by the deuterium signals of CF_3CO_2D and D_2O. ^1H nmr spectra were recorded on a Varian XL-100 nmr spectrometer at 100 MHz; TMS was used as an internal reference. Mass spectra were determined on a MAT 311 mass spectrometer at an ionizing voltage of 70 eV. A Beckman ACTA CIII spectrophotometer was used for the uv spectra. Melting points were taken on a Fisher-Johns apparatus. New England Nuclear silica gel OF 250 μ plates were used for all tlc examinations.

Isolation

Fresh animals (320 g) were soaked in 95% ethanol overnight and concentrated to a water layer of about 100 mL, which was diluted to approximately 350 mL, acidified to pH 1, and continuously extracted with CH_2Cl_2 overnight. This CH_2Cl_2 extract was discarded.

The resulting aqueous acidic layer was again diluted, to 1.5 L and passed through a Dowex 50W-4X cation exchange column. The column was then washed with 7 L of 1*N* HCl, followed by water until the eluant reached pH 6.

The top quarter of the column was removed and slurried with aqueous NH_3, to about 2 *N*. This suspension was then extracted twice with *n*BuOH and four times with $CHCl_3$–MeOH (4:3). All six extracts were combined and concentrated to yield 1.2 g dry residue.

This solid was chromatographed on silica gel with $CHCl_3$–MeOH – 25% aqueous NH_3 (80:20:2), which was followed by chromatography on Sephadex LH-20 with $CHCl_3$–MeOH (4:3) yielding about 900 mg of **4** and 60 mg of **6**.

2-Amino-3,9-dimethyl-5-dimethylamino-3H-1,3,4,6-tetraza-cyclopent[e]azulene (**4**)

Compound **4** was isolated as an amorphous yellow powder decomposing at ~200°C, R_f 0.61, $CHCl_3$–MeOH – 25% aqueous NH_3 (80:20:2); ^{13}C nmr (CF_3CO_2D): 153.67 (s), 150.68 (s), 149.09 (s), 139.06 (s), 137.47 (d), 136.85 (s), 130.16 (s), 121.88 (d), 39.37 (2q), 35.14 (q), and 23.51 (q) ppm. The ninth sp^2 carbon, which was obscured by the solvent absorbances in the CF_3CO_2D spectrum, was found at 160.57 (s) ppm in the D_2O spectrum of the dihydrochloride salt of **4**. Mass spectrum *m/e* 256 (67%, M^+), 241 (100%, $M^+ - CH_3$), 227 (70%, $M^+ - NCH_3$), 212 (17%, $M^+ - NMe_2$). *Exact Mass* calcd. for $C_{13}H_{16}N_6$: 256.143647; found: 256.14353. Compound **4** was crystallized from EtOH–H_2O (80:20) by adding a minimum amount of hot solvent and allowing it to stand overnight. Crystalline **4** also decomposed at approximately 200°C.

2-Acetylamino-3,9-dimethyl-5-dimethylamino-3H-1,3,4,6-tetrazacyclopent[e]azulene (**5**)

Acetylation of 20 mg of **4** with Ac_2O–pyridine yielded 10 mg of cyclopent[*e*]azulene (**5**) as an orange amorphous solid, mp 125–129°C, R_f 0.81, $CHCl_3$–MeOH – 25% aqueous NH_3 (80:20:2); *m/e*: 298 (58%, M^+), 283 (39%, $M^+ - CH_3$), 269 (36%, $M^+ - NCH_3$), 255 (22%, $M^+ - COCH_3$), 241 (100%), 227 (44%). *Exact Mass* calcd. for $C_{15}H_{18}N_6O$: 298.15423; found: 298.1523.

2-Amino-3,9-dimethyl-5-methylamino-3H-1,3,4,6-tetraza-cyclopent[e]azulene (**6**)

Compound **6** was isolated as an amorphous yellow solid decomposing at ~180°C, R_f 0.30, $CHCl_3$–MeOH – 25% aqueous NH_3 (80:20:2); *m/e* 242 (100%, M^+), 214 (43%, $M^+ - CNH_2$), 186 (36%). *Exact Mass* calcd. for $C_{12}H_{14}N_6$: 242.127997; found: 242.127770.

Methylation of 6

In 20 mL of liquid NH_3 and 45 mg of Na, 15.4 mg **6** was reacted with 1.5 mL of MeI to give 4.8 mg of a compound identical with **4** (uv, ms, nmr), 4.0 mg of **7**, and 2.6 mg of a compound not further characterized.

2,5-Bisdimethylamino-3,9-dimethyl-3H-1,3,4,6-tetraza-cyclopent[e]azulene (**7**)

Compound **7** was isolated as an oily yellow solid decomposing at ~115°C, R_f 0.71, $CHCl_3$–MeOH – 25% aqueous NH_3 (80:20:2); *m/e* 284 (100%, M^+), 269 (78%, $M^+ - CH_3$), 255 (42%, $M^+ - NCH_3$). *Exact Mass* calcd. for $C_{15}H_{20}N_6$: 284.174948; found: 284.17469.

X-ray Diffraction

Oscillation and Weissenberg diagrams indicated monoclinic symmetry, and the systematic absences were those characteristic of the space group $P2_1/c$. (Most of the crystals were twinned leading to a doubling of the *c* axis and orthorhombic symmetry.) A crystal of approximate dimensions 0.2 × 0.1 × 0.05 mm was used for the crystallographic work. A computer controlled Syntex $P\bar{1}$ diffractometer with graphite-monochromatized Mo K_α radiation was utilized in the determination of cell parameters and the collection of intensity data. Cell dimensions were determined by a least-squares treatment of the angular coordinates of 15 reflections with 2θ-values between 14° and 32°.

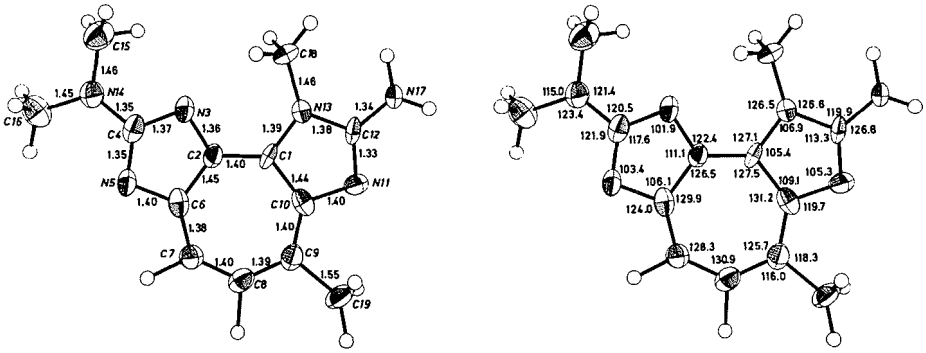

FIG. 1. Bond lengths (Å) and bond angles (°). The estimated standard deviations in bond lengths are 0.01 Å and in angles 0.8–0.10°. The ellipsoids are given for 50% probability, the hydrogens are drawn artificially small.

Three-dimensional intensity data were recorded using the θ-2θ scanning mode with scan speed (2θ) variable from 2 to 8° min^{-1} depending on the intensity of the reflection. Background counting time was equal to 0.35 × scan time on each side of the scan range, which was from $2\theta(\alpha_1) - 0.9°$ to $2\theta(\alpha_2) + 0.9°$. The temperature was maintained within 1° at 19°C. The intensities of three standard reflections which were remeasured regularly showed no significant variations.

The estimated standard deviations in the net intensities, I, were calculated as:

$$\sigma(I) = \left(I_{scan} + (B_1 + B_2)\left(\frac{\text{scan time}}{2 \times \text{background time}}\right)^2 + (0.02 \times I)^2\right)^{1/2}$$

where

$$I = I_s - (B_1 + B_2)\frac{\text{scan time}}{2 \times \text{background time}}$$

The factor 0.02 × I is an addition for experimental uncertainties. Of the 1271 reflections measured ($2\theta_{max} = 40°$) 757 had intensities larger than twice their standard deviations. These were regarded as observed, and the remaining were excluded from the refinements. The intensities were corrected for Lorentz and polarization effects. The computer program used, as well as programs subsequently employed, is part of a local assembly of programs for CYBER-77 which is described in ref. 10.

Atomic scattering factors used were those of Doyle and Turner (11) for carbon, nitrogen, and oxygen and of Stewart *et al.* (12) for hydrogen. The phase problem was solved by the MULTAN 77 program package (13). The structure model was refined to a conventional R of 0.24. Owing to this relatively high R-factor a difference Fourier synthesis was calculated and this revealed the position of an oxygen atom (H_2O). The water molecule was situated such that it participated in three hydrogen bonds. The introduction of anisotropic temperature factors for all 20 nonhydrogen atoms and least-squares refinements lowered R to 0.096. The positions of the 18 hydrogens were found in a difference Fourier synthesis. These were included with estimated isotropic thermal parameters in the structure factor calculations. Full-matrix least-squares refinement of all nonhydrogen parameters converged to an R of 0.075 and an R_w of 0.058. Final atomic parameters are given in Table 3.[5] A list of observed and calculated structure factors may be obtained from the authors upon request.

Crystal Data for 2-amino-3,9-dimethyl-5-dimethylamino-3*H*-1,3,4,6-tetracyclopent[*e*]azulene monohydrate.

$C_{13}H_{16}N_6 \cdot H_2O$ $M = 274.33$ amu

Space group $P2_1/c$, $a = 11.111(5)$ Å, $b = 16.567(12)$ Å, $c = 7.368(2)$ Å, $\beta = 98.32°(3)$, $V = 1342.0(12)$ Å^3, $Z = 4$, $D_{calcd} = 1.357$ g cm^{-3}, $F(000) = 584$.

Description of the Structure

The molecular structure and atomic numbering is shown in Fig. 1, where bond lengths and bond angles are also listed. The molecule is planar; deviations from a least-squares plane through all nonhydrogen atoms are given in Table 4.[5] The maximum deviation is only 0.1 Å for N17. The bond lengths and the planarity of the system imply a totally aromatic molecule. The double bond character varies from 0.33(6) to 0.76(6). (Double bond character is calculated in the standard way as p from bond length = single bond length − 0.18 p.)

The water molecule participates in three hydrogen bonds, which leads to a three-dimensional net of hydrogen bonding in the crystal. Hydrogen bond parameters are as follows: 020-H202-N5 (in position: $1 - x$, $0.5 + y$, $1.5 - z$), 020-N5: 2.89(1) Å; 020-H201-N5 ($1 - x$, $1 - y$, $1 - z$), 020-N5: 3.01(1) Å; N17-H172-020 ($1 + x$, $0.5 - y$, $0.5 + z$), N17-020: 2.99(1) Å.

The formation and interconversion of oxazines and dioxazines from the reaction of nitrosocarbonyl compounds with cyclopentadienes[1]

LÊ H. DAO,[2] JULIAN M. DUST,[3] DONALD MACKAY, AND KENNETH N. WATSON

The Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received October 5, 1978

LÊ H. DAO, JULIAN M. DUST, DONALD MACKAY, and KENNETH N. WATSON. Can. J. Chem. **57**, 1712 (1979).

The nitrosocarbonyl arenes or -alkanes, obtained by oxidation of hydroxamic acids, behave as dienophiles towards cyclopentadiene to give the bridged oxazines **1**. In the case of pivalohydroxamic acid, however, the nitrosocarbonyl compound also reacts as a heterodiene, giving, as well as the oxazine **1***d*, the 1,4,2-dioxazine **2***d*; **1***d* is not converted into **2***d* under the conditions of the oxidation reaction.

Extended heating of compounds **1** slowly converts them into **2** and other more complex reaction products. This contrasts with the rapid and quantitative isomerization of the analogous azodicarbonyl adducts, and probably reflects the lesser crowding of the reacting NCOR group by an adjacent oxygen than by an adjacent NCOR group.

1,4-Dimethyl-2,3-diphenylcyclopentadiene traps the nitroso compounds to form the labile oxazines **8**, which rapidly isomerize to the dioxazines **9** on brief heating or in polar solvents. In the case of the benzoyl compound **8***a* the isomerization to **9***a* is reversible in benzene at 80°C, favouring the latter isomer by a factor of about 9:1.

LÊ H. DAO, JULIAN M. DUST, DONALD MACKAY et KENNETH N. WATSON. Can. J. Chem. **57**, 1712 (1979).

Les nitrosocarbonyl-arènes ou -alcanes, obtenus par oxydation d'acides hydroxamiques, se comportent comme des diénophiles vis-à-vis le cyclopentadiène et conduisent aux oxazines pontées **1**. Toutefois dans le cas de l'acide pivalohydroxamique, le composé nitrosocarbonyle réagit aussi comme une hétérodiène fournissant en plus de l'oxazine **1***d*, l'oxadiazine-1,4,2 (**2***d*); on ne peut pas transformer **1***d* en **2***d* dans les conditions utilisées pour la réaction d'oxydation.

Par chauffage prolongé, **1** se transforme lentement en **2** et d'autres produits de réaction plus complexes. Ceci est en opposition avec l'isomérisation rapide et quantitative des adduits azidocarbonyle analogues et reflète probablement un encombrement moindre du groupe NCOR qui réagit par un oxygène voisin plutôt que par un groupe NCOR.

Le diméthyl-1,4 diphényl-2,3 cyclopentadiène piège les composés nitroso pour former des oxazine labiles **8** qui s'isomérisent rapidement en dioxazines **9** lorsqu'on les chauffe brièvement ou lorsqu'on les place dans des solvants polaires. Dans le cas du composé benzoyle **8***a*, l'isomérisation en **9***a* est reversible dans le benzène à 80°C favorisant le dernier isomère par un facteur d'envirion 9:1.

[Traduit par le journal]

The formation of *C*-nitrosocarbonyl compounds (RCONO) as intermediates in the oxidation of hydroxamic acids (RCONHOH) has for some time been suspected (1) and has now been confirmed (2, 3) by their addition reactions with thebaine and other dienes. The analogous *O*-nitrosocarbonyl compounds (ROCONO) can also be produced, by oxidation of *N*-hydroxyurethanes (ROCONHOH), and behave similarly (4). These intermediates form in part the subject of a recent review by Kirby (5).

In principle two kinds of Diels–Alder adducts with a diene are possible, as illustrated for cyclopentadiene and a *C*-nitrosocarbonyl compound. In path *i*, RCONO acts as a heterodienophile to give a bridged bicyclic 1,2-oxazine **1** (4 + 2 mode) and in path *ii* it acts as a heterodiene to give a fused bicyclic 1,4,2-dioxazine **2** (2 + 4 mode); in the latter reaction a regioisomer is of course possible. Normally only the product of path *i* is produced. However from the reaction of nitrosocarbonylbenzene with ergosteryl acetate both types of B-ring adduct were isolated but it was shown that the dioxazine arose, not by path *ii* but by partial isomerization of the oxazine formed in path *i* (3).

The isomerization of the oxazine to the dioxazine, formally a [3,3]-sigmatropic rearrangement, has analogies in other heterocyclic systems. A clear general example is the conversion of the adducts **3** of

azodicarbonyl compounds into the 1,3,4-oxadiazines **4**, which we have studied in some detail (6). This process is especially favourable with the adducts of cyclopentadiene, **5** → **6**, and prompted us to prepare and to examine the stability of a number of adducts of nitrosocarbonyl arenes and -alkanes with cyclopentadiene and with 1,4-dimethyl-2,3-diphenylcyclopentadiene.

In a preliminary report we showed that generally oxazines only are formed from cyclopentadiene and dioxazines only from dimethyldiphenylcyclopentadiene (7). A notable exception was the oxidation of pivalohydroxamic acid in the presence of cyclopentadiene from which reaction both types of adduct were isolated and we concluded that in this case *both* paths were being utilized.

The synthesis and properties of these and related adducts are now described in more detail. Firm proof is provided of the independent occurrence of path *ii* in the oxidation of pivalohydroxamic acid in the presence of cyclopentadiene. It is confirmed that the thermal isomerization of the oxazine to the dioxazine (3) does occur, in general, for the adducts of cyclo-

*The kinetic analysis on compounds **1***a–d* was carried out by integration of appropriate peaks in the ^{1}Hmr spectrum in C_6D_6. The probable limits of error are ± 15%. The values for **5***a–d* are from refs. 6 and 12, and were obtained spectrophotometrically, with a probable error of ± 5%.

pentadiene; however, it does so slowly and only in competition with pathways to much more complex products. It is also shown that the dioxazines isolated from the reaction with dimethyldiphenylcyclopentadiene are probably formed exclusively by isomerization of a labile oxazine.

In the hydroxamic acid oxidations silver oxide or lead dioxide were found to be excellent alternatives to the more common reagents tetraethylammonium periodate (8) and *N*-bromosuccinimide (6).

With cyclopentadiene as substrate, the yields of isolated adducts (Table 1), all crystalline solids, varied from 40 to 70%. Their identity as compounds **1** followed from their spectra. The ^{1}Hmr spectra resembled those of adducts from cyclopentadiene and unsymmetrical azodicarbonyl derivatives, both in chemical shifts and in couplings (9). The carbonyl stretching frequencies (1640–1660 cm^{-1}) were in the range expected for *O,N*-dialkyl-*N*-acylhydroxylamines (10).

The purification of compounds **1***a–c* was readily achieved by crystallization techniques but the low melting pivaloyl adduct **1***d* required column chromatography. The elution of **1***d* was always preceded by fractions containing small amounts of an oil. This was readily recognized as the isomer **2***d* by the absence of OH, NH, and C=O stretching frequencies in the ir spectrum, in which a medium intensity band at 1621 cm^{-1}, attributable to C=N, was the most significant feature. The ^{1}Hmr spectrum supported structure **2***d*, showing a large downfield shift of its methylene protons and an upfield shift of one tertiary proton relative to those of **1***d* (parallel changes are observed in the spectra of **6** relative to **5** (9)).

On the basis of the known lability of the azodipivaloyl adduct **5***d* (9) it was first assumed that **2***d* was a secondary reaction product, generated by the isomerization of **1***d* under the reaction conditions or during work-up. To monitor small amounts of **2***d* we used ^{1}Hmr spectroscopy in benzene-d_6, taking particular advantage of the coincidence of its vinylic peaks as a sharp singlet at 4.73 τ, unobscured by peaks from **1***d* or other reaction products. This enabled **2***d* to be detected in the presence of **1***d* in amounts as small as 1%. A wide range of gas–liquid chromatography columns failed to give a clean separation.

It was confirmed that **2***d* was present before chromatography by directly analyzing the hexane extracts from the crude reaction product. The measured yields varied from 2 to 10% of the total isomeric mixture, depending on the oxidizing agent. It was also shown not to be an artifact of the reaction conditions, since **1***d* did not isomerize in the presence of *N*-bromosuccinimide–pyridine in methylene chloride. Compound **1***d*, and presumably all the adducts **1**, showed considerable stability to polar solvents, to bases, and in marked contrast with the azodicarbonyl adducts **3** (11), to strong acids.

The occurrence of path *ii* is thus established. Nitrosocarbonylisobutane at least can function as a heterodiene as well as a heterodienophile. Whether this is true for most nitrosocarbonyl compounds in their reaction with cyclopentadiene has not been established. In the case of benzohydroxamic acid a rigorous search was made for the dioxazine by chromatography of the total oxidation products but it could not be conclusively detected.

We have now reexamined the effect of heat on the oxazines **1**. On prolonged refluxing in benzene the solutions darkened and the adducts slowly decomposed. The ^{1}Hmr spectra became complex but the dioxazines **2** could be detected among the products. Analysis of the relative amounts of **1**, **2**, and by-products, by integration of the spectra, led to approximate values for the yields of **2** and the first-order rate constants of decomposition of **1**. These are shown in Table 2, along with the first-order rate

constants of the (quantitative) isomerization of the azodicarbonyl adducts **5***a–d* taken from earlier work (6, 12).

Work-up of the benzene solutions led to the isolation of the *p*-bromo and *p*-nitro adducts, **2***b* and **2***c*, which were crystalline (Table 3). Efforts to purify **2***a* failed and the isolation of the small amount of the product **2***d* (10% yield) was not attempted. The isomerization to **2***d* is highly unfavourable relative to other pathways; the complex by-products are derived solely from **1***d* and not from **2***d*, since the latter was unaffected after 4 days in refluxing benzene.

^{1}Hmr and ir spectra of compounds **2***a–c* were in line with those of **2***d*, described above. The *p*-nitrobenzimidoyl group in **2***c* absorbs at 307 nm, compared with 264 nm for the *p*-nitrobenzoyl group in **1***c*; a similar red shift was noted in the product of isomerization of **5***c*.

There are two features of note in Table 2: (*a*) The nitrosocarbonyl adducts **1** are much more stable than the azodicarbonyl adducts **5**. In particular the pivaloyl adduct **5***d* isomerizes 3000 times faster than **1***d* (a difference in free energy of activation, $\Delta\Delta G^{\ddagger}$, of 5.7 kcal mol^{-1} at 80°C) and the rate of formation of **6***d* is 30 000 times faster than that of **2***d* ($\Delta\Delta G^{\ddagger} = 7.3$ kcal mol^{-1}). (*b*) The nitrosocarbonyl adducts show little substituent steric effect compared with the azodicarbonyl adducts. The small spread in *k* values for **1***a–d* is in marked contrast with the large value for **5***d*, relative to those for **5***a–c*.

The lesser reactivity of **1** compared with **5** is itself probably steric in origin, reflecting the more severe crowding of the reacting NCOR group by the adjacent NCOR group in **5** than by the adjacent oxygen atom in **1**. Such crowding is relieved if the reacting nitrogen adopts a pyramidal geometry, which is also the geometry necessary for the transition state to product, if the reaction is concerted. This is known to be the case for the isomerization **5** → **6** but it has not been established for **1** → **2**.

One factor militating against a pyramidal geometry at nitrogen for the adduct **1** is that the conformational arrangement then produced around the N—O bond is likely one of very high energy. In this conformation the N—C and O—C ring bonds are eclipsed, or nearly so, and the nitrogen atom is pyramidal, with a localized electron pair and an electron-withdrawing substituent (RCO). Theoretical calculations predict that this geometry is very near the potential energy maximum for the internal rotation of the N—O bond (13, 14) and this seems to be supported by spectroscopic evidence (15–17).

An alternative nonconcerted route from **1** to **2**, which avoids this interaction, involves the open dipole **7**, stabilized by local resonance in each of its charged moieties. The intermediate **7** is consistent

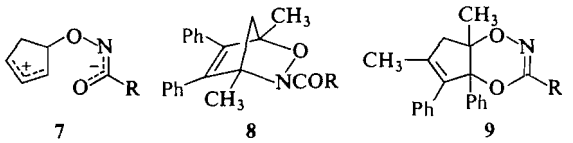
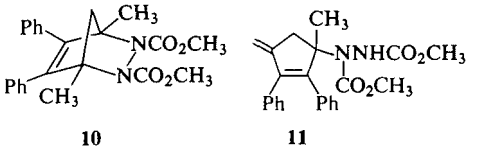
with the higher rate and yield observed in the formation of **2***c*, since a *p*-nitro group would further stabilize the negative charge in **7** (R = $pC_6H_4NO_2$).

In our first experiments (7) using 1,4-dimethyl-2,3-diphenylcyclopentadiene as a trapping agent, the oxidation of benzo-, *p*-bromobenzo-, and *p*-nitrobenzohydroxamic acids in ethyl acetate at room temperature proceeded smoothly to give, not the oxazines **8***a–c*, but the crystalline dioxazines **9***a–c* (Table 3). They were isolated in yields of 45–70% by treatment of the crude reaction residues[4] with cold methanol. The structures were inferred from their spectra. Typically **9***c* had widely separated methyl singlets at 7.92 and 8.98, and a broad allylic methylene absorption at 7.28 τ in its ^{1}Hmr spectrum ($CDCl_3$); its ir spectrum (CCl_4) had a low intensity absorption at 1620 cm^{-1} (C=N) and no carbonyl absorption.

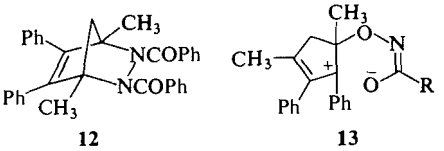


7 **8** **9**

a R = Ph *c* R = $pNO_2C_6H_4$
b R = $pBrC_6H_4$ *d* R = $C(CH_3)_3$



10 **11**



12 **13**

Compounds **9** were extremely sensitive to acids. The ^{1}Hmr spectrum of **9***b* in $CDCl_3$ containing trifluoroacetic acid was degraded completely in less than 1 min, becoming very complex. The rapid disappearance of the methyl peaks suggests that protonation of the heterocyclic ring is followed by deprotonation of a methyl group, similarly to the acid catalyzed isomerization of the corresponding azo ester adduct **10** in which the isomer **11** was produced (18). If the analogous diene is formed here it is evidently unstable.

The failure to isolate **8** was surprising since the known (9) accelerating effect on isomerization of the ring substituents would not have been predicted to prevent its survival at room temperature. Thus **12** is only 70–80 times as labile as **5***a* at 25°C in isooctane, with a half life of ca. 12 h.[5] The stability of **8** should be at least that great in view of the retarding effect found for the ring oxygen in **1**.

It was thought that the isomerization of **8** might have been promoted by the use of the polar solvent ethyl acetate in the oxidation reaction, since the azo adduct **12** had been shown to be rather sensitive to solvent polarity in its isomerization (thus $k_{aq\ EtOH}/k_{isooctane} = 25$ at 25°C).[5]

Accordingly, the oxidations were repeated in benzene. Direct ^{1}Hmr analysis of the filtered and concentrated solution from the oxidation with benzohydroxamic acid showed a new product, recognizable by a pair of methyl singlets at 7.99 and 8.30 τ. Its yield could be brought to 80% by carrying out the oxidation at 4°C. The methyl singlets slowly diminished at the expense of those of **9***a*. The new product was clearly **8***a*. Careful work-up in the cold led to the isolation of the crystalline adduct, which was fully characterized. It melted at 96.5–97°C and immediately solidified to crystals which then had the melting point of pure **9***a*.

The half-life of **8***a* at 25°C was about 9 h in chloroform-*d* and 28 h in benzene-d_6. At 80°C in the latter solvent it was 7 min but continued heating led to a levelling off in the production of **9***a* to an equilibrium concentration of 11% of **8***a* (ΔG = 1.5 kcal mol^{-1} at 80°C). This was identical with the value reached when a similar solution of pure **9***a* was heated at 80°C. At 110°C in benzene the equilibrium value was 14%. The formal [3,3]-sigmatropic rearrangement of **8***a* to **9***a* is thus detectably reversible, a feature which has been observed in at least one example in the related isomerization of an *N*-acylpyridazine to a 1,3,4-oxadiazine (19). A dipolar species, analogous to **7**, seems a particularly likely intermediate between **8** and **9**; thus the resonance form **13** is highly stabilised by the positive charge at benzylic carbon.

Formation of a benzene solution rich in **8***b* could be achieved similarly; the *p*-nitro compound **8***c* was at best only a minor product. The ^{1}Hmr spectrum of **8***b* was analogous to that of **8***a*. No effort was made to isolate it.

The amounts of dioxazine **9***a* (~20%), detected in the oxidation in benzene at 4°C, must be reconciled with the observation that pure **8***a* is <2% isomerized (the detection limit) in benzene at the same temperature. This might suggest the possibility that some **9***a* is formed directly (path *ii*). It is more likely, however, that other ingredients in the oxidation reaction catalyze the isomerization of **8***a*, e.g., H_2O, $PhCO_2H$

[4]Retrospective examination of the spectra of these residues showed small amounts of Me singlets due to unisomerized oxazines.

[5]By extrapolation of rate data from ref. 6.

(a common trace product in the oxidation of the hydroxamic acid), colloidal Ag, or Ag^+ (perhaps complexed with the alkene bond in **8***a*).

The mode of regioisomeric fusion and the *cis* stereochemistry in the dioxazines **2** and **9** have been tacitly assumed. In fact their spectroscopic properties do not unequivocally justify these choices. Either a concerted mechanism or a dipolar intermediate like **7** or **13** requires the regioisomers given (the alternative dipole formed on opening the oxazine would lead to a fused 2-acyloxazetidine). Only the concerted mechanism requires the *cis* stereochemistry.[6]

Experimental

The following spectrometers were used: for ir, a Beckman IR 10; for uv, a Unicam SP .800 B; for ^{1}Hmr, a Varian T-60 or Perkin Elmer R12B. Melting points are uncorrected.

Reagents

Benzo-, *p*-bromobenzo-, and *p*-nitrobenzohydroxamic acids were prepared from their methyl or ethyl esters by the standard method (20). Pivalohydroxamic acid was best prepared by dropwise addition at room temperature of the acid chloride to a threefold excess of hydroxylamine hydrochloride in an eightfold excess of pyridine, followed by evaporation to dryness and leaching out of the product with hot ethyl acetate. Recrystallization from ethyl acetate gave needles (45%), mp 170–171°C (lit. (21*a*) mp 163.6–164.1°C (dec.) lit. (21*b*) mp 169°C).

The following oxidizing agents were used in the hydroxamic acid reactions: silver oxide, lead dioxide, tetraethylammonium periodate (8), *N*-bromosuccinimide–pyridine; the potassium salts of the hydroxamic acids could also be oxidized directly with *N*-bromosuccinimide.

*3-Acyl-2,3-oxazabicyclo[2.2.1]hept-5-enes (**1**) (Table 1)*

*The Benzoyl Compound **1**a*

To a stirred suspension of benzohydroxamic acid (2.74 g, 0.02 mol) in methylene chloride (40 mL), containing pyridine (1.58 g, 0.02 mol) and cyclopentadiene (7 mL), was added, in portions, *N*-bromosuccinimide (3.56 g, 0.02 mol). When the reaction mixture had become clear the solution was washed once with water, twice with saturated aqueous sodium hydrogen carbonate, then with water again and dried. Evaporation gave an oil which was extracted thoroughly with several portions of hot hexane. The hexane solution gave a crystalline residue (2.8 g, 70%) whose ^{1}Hmr spectrum showed it to be substantially pure **1***a*. Recrystallization from hexane gave prisms, mp 73–75.5°C.

*Alternative Syntheses of **1**a*

Yields of at least 50% were consistently obtained when the oxidation was carried out by oxidizing (*a*) the benzohydroxamic acid in ethyl acetate with aqueous acetic acid containing sodium acetate and tetraethylammonium periodate or (*b*) the potassium salt of the hydroxamic acid in methylene chloride with *N*-bromosuccinimide.

The p*-Bromobenzoyl Compound **1**b*

A suspension of *p*-bromobenzohydroxamic acid (1.08 g, 5.0 mmol), silver oxide (2.0 g, 8.6 mmol), and sodium sulfate (2 g) was stirred for 1 h at room temperature in ethanol (50 mL) containing cyclopentadiene (1 mL). The mixture was filtered, evaporated to dryness, and the residue treated with ether (50 mL). Filtration from traces of silver followed by evaporation gave an oily residue (0.61 g) whose ^{1}Hmr spectrum showed it to be about 80% **1***b* (about 45% yield). This oil was extracted with hot hexane (100 mL) which was allowed to evaporate at room temperature and deposited crystals of the product. A recrystallization from acetone–isooctane gave **1***b* as large prisms, mp 83–83.5°C.

The p*-Nitrobenzoyl Compound **1**c*

The potassium salt of *p*-nitrobenzohydroxamic acid (2.20 g, 10 mmol), *N*-bromosuccinimide (1.6 g, 9 mmol), and anhydrous sodium sulfate (1 g) were added to a stirred solution of cyclopentadiene (5 mL) in methylene chloride (50 mL). The reaction was at first exothermic. Stirring was continued for 20 h, the solution was filtered from potassium and sodium salts, and then shaken out with water (100 mL). It was dried and evaporated to a semisolid residue which on trituration with pentane containing a little ether gave crystalline **1***c* (1.40 g, 63%). It was recrystallized from benzene–isooctane as small yellow prisms, mp 119.5–121°C.

The synthesis of **1***c* could also be achieved using *N*-bromosuccinimide and pyridine, as described for **1***a*.

*The Pivaloyl Compound **1**d*

Silver oxide or lead dioxide (7.9 or 8.2 g, 0.034 mol) was added to a stirred solution of pivalohydroxamic acid (4.0 g, 0.034 mol) and cyclopentadiene (8 mL) in ethyl acetate (100 mL) containing suspended sodium sulfate (1 g). After 4 h the solution was filtered and washed with water, aqueous sodium hydrogen carbonate and water again. It was then dried and evaporated to an orange-brown gum, which was refluxed for 1 h with hexane (100 mL). The hexane solution furnished a pale yellow syrup (3.7 g) whose ^{1}Hmr spectrum showed it to contain about 85% (51% yield, routinely 50–55%) of the expected adduct.

(*N*-Bromosuccinimide and pyridine in methylene chloride gave overall yields of 40–45%.)

Column chromatography of the hexane extract was done on neutral alumina (1 g/100 g) from benzene solution, using increasing amounts of ether as eluant. In a typical run from 3.3 g of extract from the above reaction 1% ether caused the elution of 0.078 g of the isomer **2***d*, followed by 0.520 g of a mixture of **2***d* and **1***d*; 2% ether gave 0.408 g of **1***d*. The separation was somewhat more efficient on Florisil. ^{1}Hmr analysis of the mixed fractions showed that a total of 0.235 g of **2***d* and 0.771 g of **1***d* were recovered from the column.

The total of 1.0 g compared with the expected amount of 2.8 g reflects the considerable loss of these volatile adducts during the evaporation of chromatographic fractions. Furthermore the proportions of the adducts are at variance, being biased towards **2***d*, with the true values obtained directly from the extracts before chromatography (see below).

Repeated crystallization from pentane gave **1***d* as prisms, mp 37–38°C (earlier value (7) 36–37.5°C).

*Control Experiment: Exposure of **1**d to Reaction Conditions of its Synthesis*

The adduct (150 mg), *N*-bromosuccinimide (148 mg), and pyridine (66 mg) (8.3 mmol in each case) were stirred for 0.5 h in methylene chloride (25 mL). The work-up was as described in the synthesis of **1***a*. The ^{1}Hmr spectrum of the reisolated adduct showed none of the isomer **2***d*.

*Stability of **1**d*

Polar Solvent

The adduct **1***d* (100 mg) was completely unchanged on refluxing in methanol (10 mL) for 2 h.

[6]NOTE ADDED IN PROOF: An X-ray analysis has confirmed the structure of the bromo compound **9***b*. It has the *cis* stereochemistry.

Acid Catalyzed

The adduct (70 mg, 0.39 mmol) and trifluoracetic acid (4.5 mg 0.04 mmol) were heated at the boiling point in benzene-d_6 (0.3 mL). After 26 h the solution had darkened considerably. The ^{1}Hmr spectrum showed that only about 30% of the starting material had decomposed, but there was no evidence of the presence of **2***d*.

Base Catalyzed

A solution of **1***d* (150 mg) in pyridine-d_5 (0.5 mL) was heated at 80°C; there was little change after 20 h.

The adduct (100 mg) was likewise unaffected by refluxing it for 3 h in 0.2 *M* NaOMe in MeOH (10 mL); the solution was evaporated and the residue extracted with carbon tetrachloride for ^{1}Hmr analysis.

Analysis of Product Ratio in Oxidation Reactions of Pivalohydroxamic Acid with Cyclopentadiene

Gas–liquid chromatography gave poor separations of **1***d* and **2***d* using a wide range of columns.

^{1}Hmr analysis in CCl_4 or $CDCl_3$ was unsuitable for the determination of small amounts of **2***d* which had no peak that was clearly distinguishable from peaks of **1***d* or of by-products. With C_6D_6 as solvent an excellent analytical technique was available using the intensity of the broad singlet of the two vinylic hydrogens of **2***d* at 4.73 τ, which was unobscured by any other absorptions. A detection limit of 0.6% of **2***d* in 50 mg of mixture was determined using authentic samples of the purified isomers.

Measurements of the proportions of each isomer originally produced in the oxidation, involved removing the hexane from the extracts (see synthesis of **1***d*) through a fractionating column to minimize losses of the volatile isomers. Analysis of the residue in C_6D_6 revealed the percentages of **2***d* in the total isomeric mixture for the following oxidizing agent to be: silver oxide, 4%; lead dioxide, 2%; *N*-bromosuccinimide, 7–10% (several runs).

cis-*3-Aryl(or Alkyl)-4a,7a-dihydro-*7H-*cyclopenta-1,4,2-dioxazine (2) (Table 3)*

Solutions of the adducts **1** were refluxed in benzene (ca. 1%). Aliquots were periodically removed, evaporated, and the residue analyzed by ^{1}Hmr spectroscopy in $CDCl_3$. Integration of all peaks in the aliphatic region (> 3 τ) allowed the proportions of **1**, **2**, and by-products to be determined. The yields of **2** are shown in Table 2. When the reaction was nearly complete, the solution was cooled, filtered from the dark precipitate (< 5%) present, and evaporated to a dark sticky residue which was worked up as described.

For the adduct **1***d* the isomerization was monitored directly by ^{1}Hmr analysis using a solution containing 0.1 g in 0.5 mL C_6D_6. No effort was made to scale up the reaction to isolate **2***d*. Its isolation as a co-product with **1***d* is described above.

In a control reaction the pure isomer **2***d* was heated under identical conditions for 80 h without any change in its spectrum.

Approximate rate constants of decomposition of compounds **1** are shown in Table 2.

The phenyl and the *tert*-butyl compounds, **2***a* and **2***d*, were oils; the purification of **2***d* is described above; the *p*-bromo- and *p*-nitrophenyl compounds, **2***b* and **2***c*, had melting points of 144–146 and 151–152°C.

3-Acyl-1,4-dimethyl-5,6-diphenyl-2,3-oxazabicyclo[2.2.1]hept-5-enes (8) (Table 1)

The Benzoyl Compound **8**a

To a solution of 1,4-dimethyl-2,3-diphenylcyclopentadiene (1.04 g, 4.1 mmol) in benzene (50 mL, spectroscopic grade from J. T. Baker Chemical Co.), kept at 4°C by a benzene – solid carbon dioxide bath, were added benzohydroxamic acid (0.56 g, 4.1 mmol), silver oxide (2.0 g, 8.6 mmol), and sodium sulfate (2 g). The whole was stirred for 4 h, filtered through Celite, and evaporated below room temperature. The ^{1}Hmr spectrum of the concentrated residue showed about 80% of the isomeric mixture to be **8***a*. Evaporation to dryness and addition of ether caused the precipitation of further silver residues. Filtration, concentration to a small volume, and dropwise addition of hexane caused precipitation of **8***a*. The whole was chilled to −10°C and filtered giving product of high purity (0.48 g, 31%). Recrystallization was effected by dissolving it at room temperature in ether, adding hexane till crystallization just began, filtering, and storing at −10°C for 1 h. It formed prisms which melted sharply at 96.5–97°C. The melt solidified almost immediately to give pure **9***a*, the crystals melting again at 144–146°C.

At 25°C a 0.3 *M* solution of **8***a* had a half-life of 9 h in chloroform-*d* and 28 h in benzene-d_6. At 4°C no isomerization could be detected after 20 h in a 0.3 *M* solution in benzene-d_6 (the detection limit is ca. 2% of **9***a*).

Reversible Isomerization of **8**a

A sample of **8***a* (50 mg) in benzene-d_6 (0.5 mL, 0.26 *M*) was heated in an nmr tube at 80°C and periodically monitored by measuring peak heights of the upfield Me group in **8***a* and **9***a* (a control reaction on a freshly prepared equimolar mixture of the two isomers showed the heights of the peaks to be identical). The half-life of **8***a* was 7 min but in the later stages of the reaction the kinetics drifted from first order, the decay of **8***a* becoming increasingly slow. An equilibrium value of 11% **8***a* remained. The identical value was reached when a solution of **9***a* was similarly heated. At 110°C the equilibrium concentration of **8***a* was 14%. In the reaction at 80°C no compounds were detected other than **8***a* and **9***a* but at 110°C there was slight decomposition.

Other Oxazines **9**

Similar oxidation at room temperature of *p*-bromobenzohydroxamic acid gave a benzene solution of **8***b* and **9***b*, in a ratio of 1.6:1. The former was easily characterized by its Me absorptions at 8.19 and 8.87 τ.

The oxidation of *p*-nitrobenzohydroxamic acid was more complex and peaks due to **8***c* could not be recognized with certainty in the spectrum.

cis-*3-Aryl-4a,5-diphenyl-6,7a-dimethyl-4a,7a-dihydro-*7H-*cyclopenta-1,4,2-dioxazine (9) (Table 3)*

Typically a solution of the diene (1.0 g, 4.1 mmol) was stirred for 12 h with the hydroxamic acid (4.6 mmol), silver oxide (1.6 g, 7.0 mmol), and sodium sulfate (2 g) in ethyl acetate (40 mL, washed with aqueous sodium bicarbonate and dried). The solution was filtered through Celite and evaporated to dryness. Methanol (5 mL) was added to the stickly residue which crystallized. The isolated yields were: **9***a*, 46%; **9***b*, 67%; **9***c*, 65%.

Instability of Dioxazine **9**b *to Acid*

A solution of **9***b* (50 mg, 0.11 *M*) in $CDCl_3$ (0.5 mL) in an nmr sample tube was treated with 5 μL (0.13 *M*) of trifluoracetic acid. The solution became deep yellow at once, then darkened, and finally became purple. In less than 1 min the methyl peaks of **9***b* had completely disappeared in the ^{1}Hmr spectrum. The spectrum of the purple solution was complex. An ether – aqueous sodium hydrogen carbonate work-up led only to an intractable solid.

Selective *O*-demethylation of isoquinoline alkaloids: Preparation of hydrocotarnoline from hydrocotarnine and conversion of *S*-(+)-laureline into *S*-(+)-roemerine via *S*-(+)-mecambroline[1]

JUN-ICHI MINAMIKAWA AND ARNOLD BROSSI

Medicinal Chemistry Section, Laboratory of Chemistry, NIAMDD, National Institutes of Health, Bethesda, MD 20014, U.S.A.

Received December 13, 1978

JUN-ICHI MINAMIKAWA and ARNOLD BROSSI. Can. J. Chem. 57, 1720 (1979).

The methoxy group in the simple isoquinoline alkaloid hydrocotarnine and in the aporphine alkaloid *S*-(+)-laureline can be cleaved selectively with trimethylsilyl iodide in boiling *o*-dichlorobenzene in the presence of DABCO, affording hydrocotarnoline and *S*-(+)-mecambroline, respectively. Deoxygenation of *S*-(+)-mecambroline afforded *S*-(+)-roemerine.

JUN-ICHI MINAMIKAWA et ARNOLD BROSSI. Can. J. Chem. 57, 1720 (1979).

On peut éliminer sélectivement le groupe méthoxy d'un alcaloïde simple de l'isoquinoléine, l'hydrocotarnine et d'un alcaloïde de l'aporphine, la *S*-(+)-lauréline, en faisant appel à l'iodure de triméthylsilyle dans le *o*-dichlorobenzène au reflux en présence de DABCO; il y a formation d'hydrocotarnoline et de *S*-(+)-mécambroline. La désoxygénation de la *S*-(+)-mécambroline fournit la *S*-(+)-roemérine.

[Traduit par le journal]

The selective cleavage of an aromatic methoxy group in the presence of an aromatic methylenedioxy group (1) has now been studied with isoquinolines. Hydrocotarnine (**1**), readily prepared from cotarnine (2), afforded a rather complex mixture of reaction products when heated with trimethylsilyl iodide (Me_3SiI) in quinoline (1).

Quaternization of **1** and initially formed hydrocotarnoline trimethylsilyl ether (**2**, $OSiMe_3$ instead of OH) with simultaneously generated methyl iodide offered a reasonable explanation for the formation of by-products. Replacement of quinoline with a much stronger base therefore seemed to be indicated and supported by the following observations: Ether cleavage took place when hydrocotarnine (**1**) was heated with Me_3SiI in *o*-dichlorobenzene in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO), or similarly, when **1** was heated in *o*-dichlorobenzene with a preformed DABCO–Me_3SiI complex (1:1) and excess DABCO. Heating of a hydrocotarnine–Me_3SiI complex (1:1) to 190°C for 2.5 h gave no reaction and heating this complex with excess amounts of DABCO in *o*-dichlorobenzene gave only very little hydrocotarnoline (**2**).

Cleavage of the methyl ether function in **1**, affording **2**, is probably initiated by the iodide anion of a DABCO–Me_3SiI complex. Methyl iodide formed simultaneously, is trapped by DABCO. Thus it was possible to obtain by either of the two variations (heating **1** with Me_3SiI and DABCO or heating **1** with a preformed DABCO–Me_3SiI complex (1:1) and DABCO) after methanolysis and the usual work-up, about 30% of chemically pure hydrocotarnoline (**2**) taking recovered starting material into account.

Simple conversion of abundantly available polyoxygenated alkaloids into less oxygenated congeners is important for chemical correlation, for determining absolute structures and for biological evaluation (3, 4). With the methodology elaborated with the isoquinoline **1**, the conversion of more complicated methoxymethylenedioxy-substituted aporphines into hydroxymethylenedioxy- and demethoxymethylenedioxy-substituted congeners seemed feasible. *S*-(+)-Laureline (**4**), prepared from *S*-(+)-bulbocapnine (**3**) by catalytic deoxygenation of its phenyltetrazolyl ether derivative (4), was for this purpose an attractive alkaloid to study. Heating *S*-(+)-laureline (**4**) with Me_3SiI and DABCO in *o*-dichlorobenzene afforded chemically and optically pure *S*-(+)-mecambroline (**5**) in 60% overall yield. The physical data of **5** are in good agreement with those reported for mecambroline (**5**) from *Meconopsis cambrica* species (5, 6) and *O*-methylation of **5** with diazomethane afforded optically pure *S*-(+)-laureline (**4**). Conversion of **5** into *S*-(+)-roemerine (**7**) (7) by catalytic deoxygenation of the phenyltetrazolyl ether derivative **6** was accompanied by partial racemization, as **7** was obtained as an oil and with a specific rotation about 20% lower than that reported for crystalline *S*-(+)-roemerine (**7**) (7). Purification was possible by converting optically impure material into the sparingly soluble (ethanol) tartrate with (−)-tartaric acid. From the tartrate crystalline and optically pure **7** could readily be obtained, thus chemically corre-

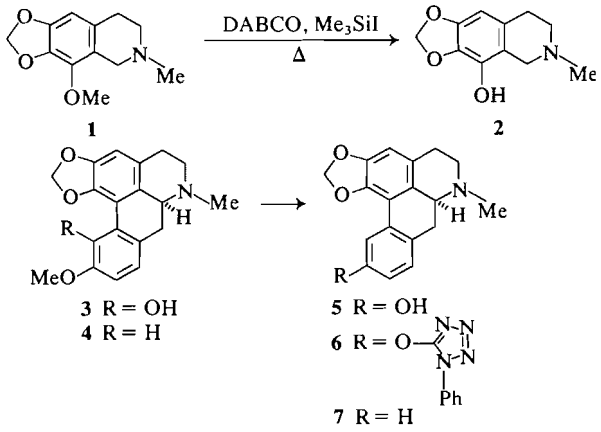
0008-4042/79/131720-03$01.00/0



SCHEME 1

lating the following aporphine alkaloids directly with each other: *S*-(+)-bulbocapnine (**3**), *S*-(+)-laureline (**4**), *S*-(+)-mercambroline (**5**), *S*-(+)-roemerine (**7**). Accumulated data show that racemization during catalytic deoxygenation of phenyltetrazolyl ether derivatives probably occurs with the deoxygenated aporphines and is more likely with compounds lacking oxygen functions in one or both aromatic rings: *R*-(−)-aporphine (4), *S*-(+)-10,11-dimethoxyaporphine (3), and *S*-(+)-roemerine. To avoid racemization it seems at this time prudent to perform the catalytic deoxygenation of optically active phenyltetrazolyl ether derivatives under conditions which are as mild as possible (room temperature, same amount of active catalyst as substrate).

Experimental

Melting points were determined in open capillary tubes on a Thomas-Hoover melting point apparatus and are corrected. Elemental analyses were performed by the Section on Microanalytical Services and Instrumentation of this laboratory. Infrared (ir) spectra were obtained on a Beckman IR 4230 (absorption maxima ν_{max} in cm^{-1}), ultraviolet (uv) spectra on Beckman DB-G (wavelength of λ_{max} reported in nm with ε values) and mass spectra on a Hitachi Perkin-Elmer RMU-6E (70 eV) spectrometer. Optical rotations were measured with a Perkin-Elmer model 141. Thin-layer chromatography (tlc) utilized silica gel plates from Analtech (Newark, Delaware). Organic extracts were dried using Na_2SO_4.

Purification of Hydrocotarnine (1)

Cotarnine, prepared from narcotine (2) by published procedures, was reduced with sodium borohydride in methanol and crude **1**, after evaporation of solvent, extracted with ether and converted with 48% hydrobromic acid into the crystalline hydrobromide salt. Crystallization from 25% aqueous sodium bromide solution afforded **1**·HBr of mp 237–238°C (lit. (8) mp 237°C); methiodide mp 205–206°C (lit. (8) mp 206°C).

Hydrocotarnoline (2) from 1

Hydrocotarnine (**1**) (1.7 g) prepared from the HBr salt in the usual way and 2.5 g DABCO in 10 mL *o*-dichlorobenzene were mixed with 2.0 mL Me_3SiI. This reaction mixture was heated for 2 h at 170–180°C (bath) in a sealed system. The reaction mixture was cooled, acidified with 20% HCl, and the aqueous solution washed with ether, basified with $NaHCO_3$, and extracted with chloroform (4 × 100 mL). The combined chloroform extracts were evaporated and the residue obtained chromatographed on silica gel with ether–methanol (9:1). The first eluates (monitored with tlc), afforded 827 mg (49.8%) of hydrocotarnine (**1**) (HBr salt mp 233–235°C). Further elution afforded 334 mg of hydrocotarnoline (**2**) which was purified by sublimation (180–190°C/1 Torr) and crystallization from ether to give 252 mg (16.2%) hydrocotarnoline (**2**); mp 196–198°C (lit. (9) mp 198°C); ir ($CHCl_3$): 3590; ms *m/e*: 207 M^+. *Anal.* calcd. for $C_{11}H_{13}NO_3$: C 63.75, H 6.32, N 6.72; found: C 63.34, H 6.42, N 7.01.

Methylation of hydrocotarnoline (**2**) with ethereal diazomethane solution in methanol afforded hydrocotarnine (**1**) (tlc, HBr salt mp 237°C).

S-(+)-Mecambroline (5) from S-(+)-Laureline (4)

Me_3SiI (2.0 mL) was added to a solution of *S*-(+)-laureline (1.1 g) and DABCO (1.2 g) in 10 mL *o*-dichlorobenzene. The reaction mixture was treated as above. The cooled solution was diluted with methanol (30 mL), acidified with concentrated HCl, and after standing for 1.5 h, diluted with ether (100 mL) and extracted with 1 *N* NaOH (5 × 50 mL). From the organic phase 167 mg (15.1%) of starting material **4** (tlc, mp 113–115°C) was recovered.

The combined NaOH extracts afforded after acidification with concentrated HCl, filtration, basification with NH_4OH, and extraction with chloroform (5 × 50 mL) an oil, which was chromatographed on silica gel (ether; ether–methanol (9:1) and (7:3)). The material obtained was crystallized from ether to afford 559 mg (54.1%) of pure *S*-(+)-mecambroline (**5**); mp 254–255°C (lit. (5) mp 252–253°C); $[\alpha]_D^{23}$ +74° (*c* 0.5, $CHCl_3$) (lit. (5) $[\alpha]_D^{23}$ +76° (*c* 0.48, $CHCl_3$)); uv (95% EtOH): 266 (15 800), 276 (17 000), and 312 (10 000); after addition of 0.1 *N* NaOH: 236, 255 (sh), and 318 (ref. 10); ms *m/e*: 295 M^+. *Anal.* calcd. for $C_{18}H_{17}NO_3$ (295.30): C 73.20, H 5.80, N 4.74; found: C 72.84, H 5.77, N 4.62.

S-(+)-Mecambroline O-Phenyltetrazolyl Ether (6)

Mecambroline (**5**) (561 mg) was reacted with 5-chloro-1-phenyl-1*H*-tetrazole (1.03 g) and sodium hydride (250 mg of 50% oily dispersion) in dry DMF (20 mL) under nitrogen for 1 h at 100°C. The cooled reaction mixture was diluted with water (50 mL) and extracted with chloroform (5 × 50 mL). The oily residue obtained from the combined extracts was purified by filtration through silica gel (1.5 g, ether–methanol (9:1)) and the crude product crystallized from hexane–methylene chloride (10:1) to afford 709 mg (84.7%) of the ether derivative **6**; mp 187–188°C; $[\alpha]_D^{20}$ +35.9° (*c* 0.55, $CHCl_3$); ir ($CHCl_3$): 1600; ms *m/e*: 439 M^+. *Anal.* calcd. for $C_{25}H_{21}N_5O_3$ (439.49): N 15.94; found: N 15.71.

S-(+)-Roemerine (7) from 6

Mecambroline tetrazolyl ether (180 mg) was hydrogenated in acetic acid (30 mL) over 10% Pd/C catalyst (200 mg) at 50 psi for 22 h at room temperature. Usual work-up afforded an oily base which was filtered through a 10-fold amount of silica gel (ether–methanol (9:1)) to afford 81 mg of roemerine (**7**, 71%); oil; $[\alpha]_D^{20}$ +62.4° (*c* 0.54, EtOH). For further purification this oil was dissolved in ethanol (25 mL) and combined with a hot solution of (−)-tartaric acid in ethanol (50 mg, 10 mL). The precipitate was crystallized from ethanol to give 112 mg of roemerine tartrate; mp 263–264°C (lit. (7) mp 264.5°C). Optically pure roemerine (**7**) was prepared from the

tartrate (80 mg) by treatment with NH_4OH, extraction with ether, and crystallization from ether (40 mg, 77%); mp 87–88°C (lit. (7) mp 87 and 102°C); $[\alpha]_D^{21}$ +81.3° (*c* 0.6, EtOH), (lit. (7) $[\alpha]_D$ +80.2° (*c* 0.18, EtOH)); uv (95% EtOH): 272 (22 400), 292 (sh, 9100), and 315 (5000); ms *m/e*: 279 M^+. Roemerine methiodide mp 225–226°C (lit. (7) mp 224.5°C). Methylation of **5** with ethereal diazomethane in methanol afforded after 48 h *S*-(+)-laureline (**4**), mp 115–117°C, $[\alpha]_D^{22}$ +97.3 (*c* 1, EtOH), identical with an authentic sample.

Acknowledgement

We would like to thank Dr. Max Gerecke, Pharmaforschung C, F. Hoffmann-La Roche & Co., AG., Basle, Switzerland, for a most valuable gift of *S*-(+)-laureline.

Perturbed normal-mode analysis of induction times, relaxation times, and reaction rates in unimolecular reactions

ANDREW W. YAU[1] AND HUW O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received October 16, 1978

ANDREW W. YAU and HUW O. PRITCHARD. Can. J. Chem. 57, 1723 (1979).

A perturbed normal-mode analysis is presented of the induction (or incubation) time, the relaxation rate, and the reaction rate of a diluted unimolecular system. At high temperature, the unimolecular rate approaches the Lindemann behaviour and the low-pressure rate is related to the normal modes of relaxation of the reactive states in a simple manner. In a step-ladder model system, the network relationship between the normal modes and the microscopic transition probabilities leads to explicit theoretical correlations between the respective experimental quantities. Illustrative calculations of such correlations are presented for the decomposition reactions of N_2O and CO_2 diluted in Ar at shock wave temperatures, and are compared with experiment.

ANDREW W. YAU et HUW O. PRITCHARD. Can. J. Chem. 57, 1723 (1979).

On présente une analyse en mode normal perturbé pour le temps d'induction (ou d'incubation), le taux de relaxation et la vitesse de réaction d'un système unimoléculaire dilué. A température élevée, la vitesse unimoléculaire approche le comportement de Lindemann et la vitesse à basse pression est reliée aux modes normaux de relaxation des états réactifs d'une manière simple. Dans un système modèle à échelons, la relation de réseau entre les modes normaux et les probabilités de transition microscopique conduit à des corrélations théoriques explicitées entre les quantités expérimentales respectives. On présente des calculs illustrant de telles corrélations pour les réactions de décomposition du N_2O et du CO_2 dilués dans Ar à des températures d'onde de choc et on les compare avec les résultats expérimentaux.

[Traduit par le journal]

I. Introduction

A master-equation formulation is required for a realistic treatment of thermal unimolecular reactions in the low and fall-off pressure regions (1–3). At the low pressure limit where collisional energy transfer is rate-determining, analytic solutions of the master equation have been obtained (2, 4) for several collisional transition probability models, and the possibility of extracting information on collisional energy transfer from these solutions has been the subject of much discussion (2, 5). In the fall-off pressure region where the intermolecular energy transfer and intramolecular reaction rates are comparable, the master equation is less amenable to analytic solutions, and little attention has so far been directed to the implications of the master-equation solution in this pressure region for collisional energy transfer studies.

Using the perturbed normal-mode approach (6–9), we have recently presented a master-equation formulation of thermal unimolecular reactions (3): the microscopic reaction processes were treated explicitly as dissipative perturbations to the normal modes of collisional relaxation of the reactant; and the solution for the unimolecular reaction rate was derived analytically at all pressures in terms of the relevant microscopic reaction probabilities and relaxation elements (8). The solution relates the various experimental quantities (the unimolecular reaction rate, the relaxation rate, etc.) directly to the collisional transition probability functions of the reactant system. Where sufficient experimental data are available, it is possible to undertake a semi-quantitative analysis of the experimental data using the analytic properties of the solution, and to study the energy transfer properties of the reactant molecule. Such analyses are useful in small polyatomic systems where reliable theoretical information on collisional energy transfer properties in the reactive energy range is virtually non-existent (10). The aim of this paper is to present such analyses for the decomposition reactions of N_2O and CO_2 diluted in Ar at high temperature.

II. The Relaxation and Unimolecular Reaction Rates

Following earlier works (3, 9), we envisage the reactant molecule to possess a set of n discrete states, and define $\eta_i(t)$ as the population of state i at time t, $\tilde{n}_i$ the equilibrium population of state i *in the absence*

[1]Present address: Herzberg Institute of Astrophysics, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6.

0008-4042/79/131723-08$01.00/0

of reaction, k_i the microscopic reaction probability of state i, and q_{ij} the transition rate constant from state i to state j via collisions with heat-bath molecules M. The master equation for the evolution of the population vector $\boldsymbol{\eta}(t)$ is

$$[1] \qquad \mathrm{d}\boldsymbol{\eta}(t)/\mathrm{d}t = \mathbf{J}\cdot\boldsymbol{\eta}(t) = (\mathbf{A} + \mathbf{D})\cdot\boldsymbol{\eta}(t)$$

where $a_{ij} = q_{ji}[\mathrm{M}]$, $a_{ii} = -\sum_{j\neq i} a_{ji}$, and $\mathrm{d}_{ij} = \delta_{ij}\mathrm{d}_i = -\delta_{ij}k_i$. The evolution eq. [1] may be transformed (3) to

$$[2] \qquad \mathrm{d}\boldsymbol{\chi}(t)/\mathrm{d}t = \mathbf{R}\cdot\boldsymbol{\chi}(t)$$

where

$$[3] \qquad \boldsymbol{\chi}(t) = \mathbf{E}^{-1/2}\cdot\boldsymbol{\eta}(t)$$

and

$$[4] \qquad \mathbf{R} = \mathbf{E}^{-1/2}\cdot\mathbf{J}\cdot\mathbf{E}^{1/2} = \mathbf{B} + \mathbf{D}$$

with

$$[5] \qquad \mathbf{B} = \mathbf{E}^{-1/2}\cdot\mathbf{A}\cdot\mathbf{E}^{1/2}$$

and $e_{ij} = \tilde{n}_i\delta_{ij}$. Both **B** and **R** are symmetric, and may be diagonalised (3) to

$$[6] \qquad \mathbf{B} = \mathbf{S}\cdot\boldsymbol{\Lambda}\cdot\mathbf{S}^{t}$$

and

$$[7] \qquad \mathbf{R} = \boldsymbol{\Psi}\cdot\boldsymbol{\Gamma}\cdot\boldsymbol{\Psi}^{t}$$

with the respective eigenvalues λ_j and γ_j being non-positive, as follows

$$[8] \qquad 0 = \lambda_{n-1} > \lambda_{n-2} \geq \lambda_{n-3} \geq \ldots \geq \lambda_0$$

and

$$[9] \qquad 0 > \gamma_{n-1} \gg \gamma_{n-2} \geq \gamma_{n-3} \geq \ldots \geq \gamma_0$$

Formally, the solution for the population evolution eq. [1] is

$$[10] \qquad \boldsymbol{\eta}(t) = \mathbf{E}^{1/2}\cdot\boldsymbol{\Psi}\cdot\exp(\boldsymbol{\Gamma}t)\cdot\boldsymbol{\Psi}^{t}\cdot\mathbf{E}^{-1/2}\cdot\boldsymbol{\eta}(0)$$

or equivalently,

$$[10a] \qquad \eta_i(t) = \tilde{n}_i^{1/2}\sum_j \exp(\gamma_j t)\psi_{ij}\sum_k \psi_{kj}\eta_k(0)\tilde{n}_k^{-1/2}$$

At short time ($t \ll |\gamma_{n-1}|^{-1}$), the system goes through a transient phase during which the initial distribution of the reactant molecules relaxes to a new distribution via collision (VR-T) energy transfer with the heat-bath molecules; it is convenient to treat this "vibrational relaxation" phase using the approach of normal modes of relaxation (refs. 11, 12; see, however, ref. 4*b* for the implications at very high temperature), and relate the experimental energy relaxation rate to the characteristic time constant of the slowest relaxation mode. Explicitly (12),

$$[11] \qquad k_{\mathrm{rel}} = \lim_{t\to\infty} -\mathrm{d}\ln[E(t) - \tilde{E}]/\mathrm{d}t \simeq -\lambda_{n-2}$$

$E(t)$ and $\tilde{E}$ being the average internal energy of the reactant at time t and at equilibrium, respectively.

At long time ($t > |\gamma_{n-1}|^{-1}$), the term associated with γ_{n-1} in the j-summation of eq. [10*a*] will dominate, and the total population of the reactant molecule becomes

$$[12] \qquad \eta(t) = \sum_i \eta_i(t) \rightarrow \left(\sum_i \tilde{n}_i^{1/2}\psi_{i,n-1}\right) \times \left[\sum_k \psi_{k,n-1}\eta_k(0)\tilde{n}_k^{1/2}\right]\exp(\gamma_{n-1}t)$$

This compares with

$$[13] \qquad \eta(t) = \eta(0)\exp[-k_{\mathrm{uni}}(t - \tau_{\mathrm{ind}})]$$

whence the unimolecular reaction rate and the induction (or incubation) time are respectively

$$[14] \qquad k_{\mathrm{uni}} = -\gamma_{n-1}$$

and

$$[15] \qquad \tau_{\mathrm{ind}} = -\gamma_{n-1}^{-1}\left[\ln\left(\sum_i \tilde{n}_i^{1/2}\psi_{i,n-1}\right) + \ln\left(\sum_i \psi_{i,n-1}\eta_i(0)\tilde{n}_i^{-1/2}/\eta(0)\right)\right]$$

The induction time τ_{ind} comprises two parts: the first depends only upon the transition probabilities at the temperature of the reaction; the second, as shown by Brau, Keck, and Carrier (13), depends on the initial population also.

The solution of the master equation predicts (9) that, at least for weak-collision systems, the unimolecular rate expression approaches the simple Lindemann form at high temperature; viz.

$$[16] \qquad k_{\mathrm{uni}} = k_\infty/\{1 + k_\infty/k_0[\mathrm{M}]\}$$

where k_∞ and k_0 are respectively the infinite-pressure unimolecular and low-pressure bimolecular rate constants. This prediction has indeed been confirmed for the decomposition reactions of diluted N_2O, CO_2, NO_2, and N_2H_4 at shock-wave temperatures (9).

The conformity of a reaction to the Lindemann behaviour has the interesting implication that the bimolecular rate constant k_0 is related to the relaxation elements associated with the reactive states (9), which, for a step-ladder model system ($q_{ij} = 0$ for $|i - j| > 1$), are related to the detailed transition rate constants $q_{i,i+1}$ in a network-like manner (7, 8). Explicitly,

[17] $$k_0 = \left(\sum_{j=0}^{n-2} t_j\right)^{-1}$$

where

$$t_j = \left(\sum_{i=0}^{j} \tilde{n}_i\right)^2 \Big/ \tilde{n}_j q_{j,j+1}$$

Notice that the bimolecular rate constant k_0 is independent of the microscopic reaction probabilities k_i, since collisional energy transfer is rate-determining at the low pressure limit.

III. Calculations

Under these conditions, the overall reaction rate depends principally on the average energy transfer $\langle \Delta E \rangle$ and is only weakly dependent on the detailed functional form of the collisional transition probabilities (2, 5, 7, 8, 14); moreover, it has been shown (5, 8), particularly when the relevant energy states are grouped into pseudo-levels in the actual calculation, that the step-ladder model gives a reasonable (but coarsely averaged) description of the collisional energy-transfer properties of the reactant system. Hence, it is a simple matter to calculate the bimolecular rate constant k_0 using eq. [17] given the transition rate constants $q_{i,i+1}$; also, once k_0 is determined, the eigenvector Ψ_{n-1} and hence the induction time τ_{ind} in eq. [15] may be calculated non-iteratively. Our method of calculation is then to (*i*) grain the energy states of the reactant molecule into pseudo-levels; (*ii*) characterise the transition rate constants in the form of

[18] $$q_{i,i+1} = q_{01} f_i$$

with q_{01} so chosen that the relaxation eigenvalue λ_{n-2} coincides with (minus) the experimental relaxation rate (cf. eqs. [5], [6], and [11]); and (*iii*) examine the dependence of the calculated bimolecular reaction rate and induction time on the respective functional forms f_i.

A. Graining of Energy States

The colossal number of vibration–rotation states in the interesting energy region ($\sim 10^7$ and $\sim 10^8$ for N_2O and CO_2, respectively, below the bond dissociation energy) necessitates the grouping of near-degenerate states into pseudo-levels — an approximation justified by the relatively large collisional energy transfer rates between levels of similar energies. The grained system then contains $\bar{n}$ pseudo-levels, with energies $\bar{\varepsilon}_i$ and degeneracies $\bar{g}_i$ ($i = 0, 1, 2, \ldots, \bar{n}-1$) where

[19] $$\bar{\varepsilon}_i = i\bar{\varepsilon}$$

and

[20] $$\bar{g}_i = G\left(\frac{2i+1}{2}\bar{\varepsilon}\right) - G\left(\frac{2i-1}{2}\bar{\varepsilon}\right)$$

the sum of states $G(\varepsilon)$ up to energy ε being computed by direct count (15) for $\varepsilon \leq 4000$ cm^{-1} and by steepest-descent (16) for $\varepsilon > 4000$ cm^{-1}. Notice that the graining scheme covers energy states from $\varepsilon_{min} = 0$ to $\varepsilon_{max} = (\bar{n} + \frac{1}{2})\bar{\varepsilon}$.

The state sum $G(\varepsilon)$ depends upon the chosen model for the reactant molecule. Both in diatomic and in polyatomic systems, rotation has often been ignored altogether in the enumeration of the state-sum. Yet, as we have shown (8), rotational effects are important in diatomic dissociation; rotational dissociation is believed to be important in polyatomic molecules also. In addition, there are no arbitrary reasons to exclude rotation in collisional energy transfer. Hence, we examine the effect of inclusion of rotation in the state-sum using two series of calculations: one including both vibration and rotation (VR) in the state-count and the other including vibration only (V), with the vibrations treated as independent oscillators in both cases.

In N_2O, the two stretching modes are well represented by two independent Morse oscillators (17); the two degenerate bending modes are treated as harmonic. For CO_2, all four vibrations are treated as harmonic. The relevant spectroscopic parameters are listed in Table 1.

The grain size $\bar{\varepsilon}$ is chosen to be one vibrational quantum for the bending mode (600 and 700 cm^{-1} for N_2O and CO_2, respectively); other grain sizes have also been used in test calculations to examine the sensitivities of the calculated quantities with variations in $\bar{\varepsilon}$, see below. The topmost pseudo-level, $\bar{n}$, is chosen so that $\bar{\varepsilon}_{\bar{n}}$ lies above the critical energy of reaction, ε_{crit}. The latter quantity is actually uncertain; it corresponds to the crossing point of the singlet and triplet adiabatic potentials, and is placed at ~ 64 and ~ 125 kcal/mol for N_2O and CO_2 respectively, by experiments (18, 19) and by theoretical calculations (20). Thus, we set $\bar{n} = 39$ for N_2O, corresponding to $\bar{\varepsilon}_{\bar{n}-1} = 63.5$ and $\bar{\varepsilon}_{\bar{n}} = 65.2$ kcal/mol. (For CO_2, $\bar{n} = 64$, $\bar{\varepsilon}_{\bar{n}-1} = 124.1$, and $\bar{\varepsilon}_{\bar{n}} = 126.1$ kcal/mol.) Again, the value of $\bar{\varepsilon}_{\bar{n}}$ was varied in test calculations; the calculated rates are not sensitive to the uncertainties in $\bar{\varepsilon}_{\bar{n}}$ since they depend primarily on the transition probabilities associated with levels below the reactive energy region.

B. Transition Probability Models

Within the framework of the step-ladder model, two functional forms of f_i (cf. eq. [18]) were examined: the constant f_i model (CF), with

TABLE 1. Spectroscopic parameters in reactant molecule

Molecule	$\omega_e(x_e)^a$				B_x (cm^{-1})	Reference
N_2O	1298.4 (0.0048)	599.4	599.4	2283.1 (0.0066)	0.41901	35, 36
CO_2	1388.2	667.4	667.4	2349.2	0.39021	36

$^a\varepsilon_v = \omega_e[(1 - x_e)v - v^2x_e]$, ω_e in cm^{-1}.

[21a] $$q_{i,i+1} = q_{01}$$

for all i; and the Landau–Teller model (LT), with

[21b] $$q_{i,i+1} = (i + 1)q_{01}$$

For each model, q_{01} is related through eqs. [5], [6], and [11] to the experimental relaxation time,[2] the latter being given by

[22] $$\log_{10} p\tau_{rel}\,(\text{atm}\ \mu\text{s}) = -1.36 + 13.6T^{-1/3} \qquad (800 < T < 2370\ \text{K})$$

for N_2O in Ar (21) and

[23] $$\log_{10} p\tau_{rel}\,(\text{atm}\ \mu\text{s}) = -1.56 + 21.3T^{-1/3} \qquad (450 < T < 3000\ \text{K})$$

for CO_2 in Ar (22, 23).

C. The Reaction Rate

It should be reiterated that eq. [17] is valid only when the unimolecular fall-off is Lindemann-like, i.e., when eq. [16] is obeyed. Hence, we shall restrict our calculations in this Section to $T > 2000$ K for N_2O and $T > 3000$ K for CO_2, where the experimental rates have been found to conform to eq. [16] (9).

N_2O

The low-pressure dissociation rates of N_2O diluted in Ar have been measured by several authors. The high temperature data (2160–3590 K) of Dove *et al.* (21) are in good agreement with those of Olschewski *et al.* (25) at lower temperatures (1400–2500 K); the data of Gutman *et al.* (26) are in good agreement with both Dove *et al.* (21) and Olschewski *et al.* (25) near 2000 K, but are systematically lower at higher temperatures. Figure 1 compares these experiments with three calculations. The first one, labelled VR-LT, includes rotation in the state-count and assumes the LT transition probability model for the transition rates between the *grained* levels (eq. [21b]).

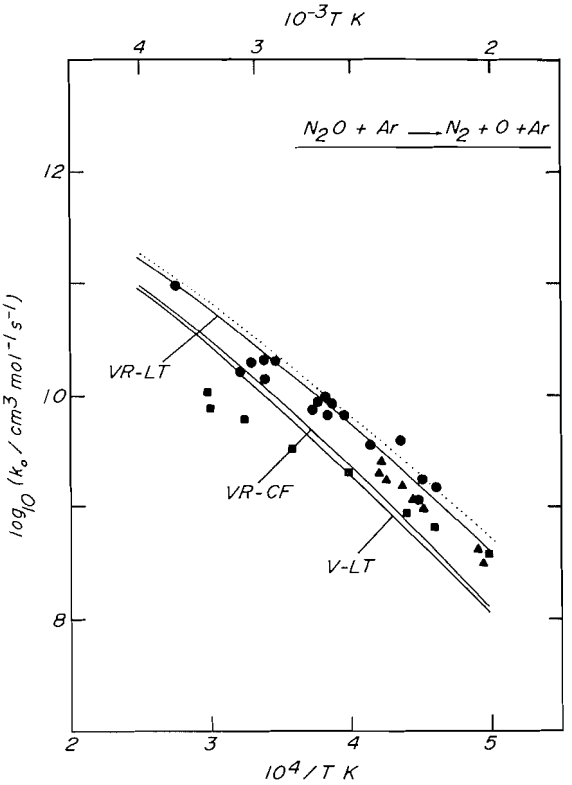

FIG. 1. Low-pressure rate constant for dissociation of N_2O diluted in Ar. Experiments: ●, Dove *et al.* (21); ▲, Olschewski *et al.* (25) with 0.2% N_2O in argon; ■, representative data points of Gutman *et al.* (26). Calculations — solid curves: VR-LT, vibration-rotational state-count and Landau–Teller transition probability model, eq. [21b]; VR-CF, vibration-rotational state-count and constant f_i model, eq. [21a]; V-LT, vibrational state-count, and Landau–Teller model. Calculations — dotted curve: VR-LT calculation with a step-size of 1200 cm^{-1} in LT model (see text).

The second, labelled VR-CF, differs from the first one in that it assumes the constant f_i model (eq. [21a]) instead. The third calculation, labelled V-LT, excludes rotation in the state-count and assumes the LT model. Notice that the absolute magnitude of the transition probabilities in the three models are chosen to yield the same (experimental) relaxation rate (see previous subsection). Yet, they predict appreciably different reaction rates. This is not unexpected since relaxation and reaction rates are in general related to the collisional energy transfer

[2]The expression $q_{01} = k_{rel}/[\exp((\varepsilon_1 - \varepsilon_0)/kT) - 1]$, which is used extensively (8, 24) to relate q_{01} to the experimental relaxation rate in diatomic systems, is not applicable to polyatomic systems. Hence, we compute the eigenvalue λ_{n-2}' for the reduced transition matrix A′ (A′ being constructed with $q_{i,i+1}' = f_i$) and relate q_{01} to the experimental relaxation rate using the relationship $q_{01} = -k_{rel}/\lambda_{n-2}'$. For the transition probability patterns that we examined, this latter expression can differ from the former one by as much as a factor of ten.

properties of the reactant molecule at different energy regions. It is now well recognized (14) that they are the consequences of a network of microscopic processes, and it is generally not possible to associate them with a particular transition (27). The energy region of importance to the reaction rate is characterised by the bottleneck (7, 8), which shifts to lower energy as temperature increases. The corresponding region for the relaxation rate is associated with levels carrying the largest energy fluxes; it is more subtle and a normal-mode analysis is needed for a detailed understanding (11).

That the VR-CF rates are smaller than the experimental rates (of Dove *et al.* (21) and Olschewski *et al.* (25)) by a factor of two to three is not surprising, since the transition rates are expected to increase at higher energy, rather than being constant at all energies. Hence, eq. [21*a*] represents an underestimate for the transition rates in the reactive energy region; and this underestimate is reflected in the calculated reaction rates.

Likewise, the V-LT rates are expected to be smaller than the experimental data, since the exclusion of rotation in the state-count underestimates the state-density (and population) of the reactive energy levels.

Note, however, that the VR calculations are likely to be (slight) overestimates, since in the graining procedure, we have grouped all energy states above the critical energy for reaction into reactive pseudo-levels, whereas in reality some of these states (those in very high rotational states) are non-reactive. We believe it is this overestimate that compensates for the underestimate in the LT transition rate constants, yielding the good agreement between the VR-LT rates and experiment; while the present calculations suggest the LT model to be much more realistic than the CF model, we would hesitate to attach any physical interpretation or justification to the model.

The activation energies of the three calculated rates are compared in Table 2. (*i*) The inclusion of rotation in the state-count lowers the activation energy (difference between VR-LT and V-LT) by 5 kcal/mol at 2100 K and more at higher temperatures; the reasons for this lowering have been discussed earlier in diatomic dissociation (8). (*ii*) The lower activation energies of the VR-LT rates, compared with the corresponding VR-CF data, arise from the faster energy transfer rates at high energy in the LT model and hence more drastic population disequilibrium at high temperature: the reasons for this have also been discussed before (8).

To examine the effect of the grain size $\bar{\varepsilon}$ on the calculated reaction rate, the VR-LT calculation was repeated using $\bar{\varepsilon} = 1200\ cm^{-1}$ (instead of $600\ cm^{-1}$); the calculated rates increase by less than 30% (dotted curve in Fig. 1), showing that the calculation is indeed not sensitive to the grain size chosen.

TABLE 2. Activation energy for the dissociation of N_2O in Ar at low pressure

		$\varepsilon_{act,0}$[a]		
T_1	T_2	VR-LT	V-LT	VR-CF
4000	3500	42.1	48.0	45.4
3500	3250	43.5	49.6	47.4
3250	3000	44.9	50.9	49.2
3000	2750	46.5	52.5	51.2
2750	2500	48.5	54.3	53.5
2500	2300	50.5	56.0	55.7
2300	2100	52.4	57.5	57.6

[a] $\varepsilon_{act,0} = -k \ln [k_0(T_1)/k_0(T_2)]/[1/T_1 - 1/T_2]$, in kcal/mol.

CO_2

The dissociation of diluted CO_2 at shock wave temperatures has received much experimental attention in the last two decades; nevertheless, data of various workers were not always concordant, see ref. 28. The experimental activation energy at low pressure is significantly lower than the bond dissociation energy ($\varepsilon_{act,0} \sim 105$ kcal/mol at 3300 K (29) compared with D(O—CO): 125.75 kcal/mol). Theoretically, Gilbert (30) obtained from model calculations an activation energy of 98 kcal/mol at 4000 K. However, his calculations assume energy-independent collision cross sections, and it is not clear if these cross sections are in fact consistent with the temperature dependence of the relaxation rate. Since the activation energy for reaction is related to that of the relaxation rate, it is not possible to assess the calculated activation energies with respect to experiment. More recently, Tardy (31) obtained $\varepsilon_{act,0} \simeq 100$ kcal/mol at 3500 K by applying corrections to the strong-collision rate constants and using his "universal function" for collision efficiency. Again, the consistency between the experimental relaxation rate and the transition probabilities assumed in this calculation is not at all clear. Both of these calculations ignore rotation; inclusion of rotation would lower the calculated activation energies substantially.

In this section, we calculate the reaction rate by synthesising the transition probabilites from eq. [21] (*a* and *b*) and experimental relaxation rate data. Figure 2 compares our calculations with the experimental data of Dean (32), Vasatko (33), Davies (34), and Wagner and Zabel (29). The data of Dean and Vasatko are in good agreement; those of Wagner and Zabel (29) are systematically lower. Again, the

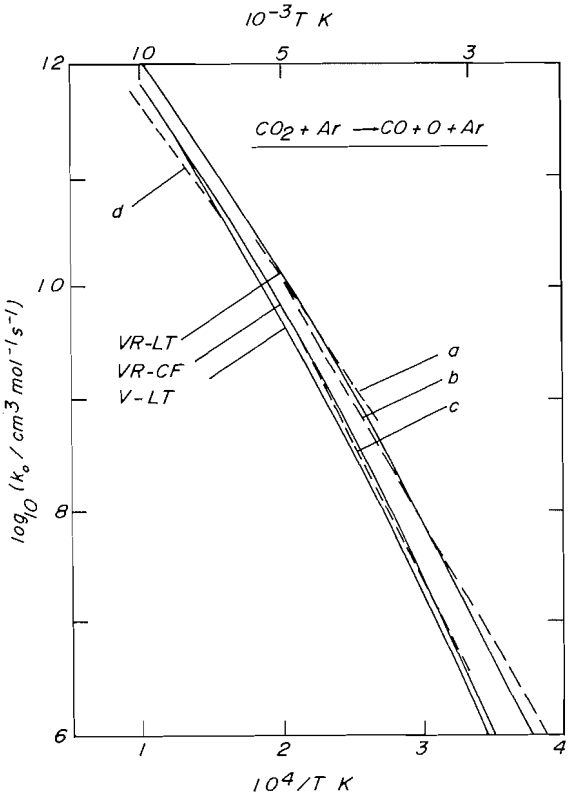

FIG. 2. Low-pressure rate constant for dissociation of CO_2 diluted in Ar. Experiments: *a*, Dean (32); *b*, Vasatko (33); *c*, Wagner and Zabel (29); *d*, Davies (34). Calculations: see caption in Fig. 1 for details.

VR-LT rates, which are in good agreement with the experiments of Dean (32) and Vasatko (33), are a factor of 2–4 larger than the V-LT and VR-CF rates.

Table 3 compares the activation energies of the respective rates. (*i*) Again, rotation leads to a noticeable reduction in the activation energy: from 7 kcal/mol at 3500 K to 10 kcal/mol at 10 000 K. (*ii*) Note also the dependence of the activation energy on the transition probability model, which becomes more appreciable at high temperature; cf. the VR-LT vs. VR-CF data. (*iii*) The activation energies of the VR-LT rates are in good accord with experimental estimates: the calculated value of $\varepsilon_{act,0} = 109.3$ kcal/mol between 3000 and 3500 K compares favourably with the experimental value (29) of 105 kcal/mol at 3300 K. Clearly, the low activation energies at very high temperatures are not anomalous at all.

D. The Induction Time

In the relaxation experiment of Dove *et al.* (21), the induction time for the N_2O reaction was measured and reported in terms of its ratio to the vibrational relaxation time, τ_{ind}/τ_{rel}. The ratio ranges between 4 and 7 at 2160–3590 K. To our knowledge, no measurements exist for the CO_2 reaction.

TABLE 3. Activation energy for the dissociation of CO_2 in Ar at low pressure

		$\varepsilon_{act,0}$[a]		
T_1	T_2	VR-LT	V-LT	VR-CF
10000	7500	79.1	89.4	82.9
7500	6000	83.2	94.6	89.2
6000	5000	89.8	101.2	97.3
5000	4500	98.1	108.2	106.6
4000	3500	104.9	113.2	113.4
3500	3000	109.3	116.3	117.4

[a]See footnote in Table 2.

TABLE 4. Induction to relaxation time ratio of the N_2O–Ar system

	τ_{ind}/τ_{rel}		
T(K)	VR-LT	V-LT	VR-CF
4000	2.13	2.05	1.47
3000	2.37	2.31	1.78
2500	2.56	2.48	2.10
2100	2.72	2.58	2.58

TABLE 5. Induction to relaxation time ratio of the CO_2–Ar system

	τ_{ind}/τ_{rel}		
T(K)	VR-LT	V-LT	VR-CF
10000	2.08	2.00	1.33
6000	2.42	2.43	1.73
4000	2.94	2.83	2.42
3500	3.03	2.71	1.74

From eq. [15], τ_{ind} is proportional to the reaction time $\tau_{react}(= -1/\gamma_{n-1})$. Hence, it is in general more convenient to characterise the induction time in terms of the ratio τ_{ind}/τ_{react}. Nevertheless, in the low-pressure limit, τ_{react} is directly proportional to τ_{rel}, and it is equally convenient to characterise τ_{ind} in terms of τ_{ind}/τ_{rel}; to facilitate comparison with experiment, we present our results in this section in this form.

Tables 4 and 5 list the ratios τ_{ind}/τ_{rel} for the N_2O and CO_2 reactions, respectively, for the three sets of calculations.[3] Notice that τ_{ind} is dependent upon the initial population distribution, $\eta(0)$; nevertheless, as for relaxation time, the dependence is not significant

[3]Kiefer and Hajduk (24) have recently cautioned against the numerical difficulties associated with the use of eq. [15]. We did not encounter any difficulties in our calculations. However, the alleged difficulties may well arise in calculations at lower temperatures.

for polyatomic systems in experimental shock conditions: in all calculations, an initial temperature of 300 K was assumed to mimic the experiment. For both reactions, the ratio decreases slightly with increasing temperature, in accord with the experiment of Dove *et al.* (21); the calculated ratios of 2–3 are in reasonable agreement with the experimental ratios of 4–7, considering the simplicity of the theoretical model and the difficulty of the experiment. Note the similar patterns between the corresponding data in the two reactions: the VR-LT and V-LT induction times are very similar; on the other hand, the difference between the VR-LT and VR-CF induction times is quite appreciable, especially at high temperature. This is because the induction time is related predominantly to the transition probability pattern, and less so to the energy level structure of the reactant molecule.

IV. Discussions

The present master-equation analysis of the relaxation and reaction behaviour of the N_2O–Ar and CO_2–Ar systems provides interesting insights into the energy transfer properties of small polyatomics ("weak collision systems") at high temperature.

In the master-equation formulation, the reaction rate at low pressure is explicitly related to the internal (collisional) relaxation behaviour of the reactant. It is important to note that the relaxation rate has, in general, no direct connection with the "strong" collision rate. (Indeed, the transition rate constant q_{01} is not related to the Lennard–Jones collision number at all!) Nor is there any similar relationship between the (non-equilibrium) reaction rate and the strong collision number. Thus, to relate these last two quantities using a collisional efficiency parameter has, at best, operational meaning only.[4] For meaningful interpretations of a reaction at high temperature and the energy transfer properties of the reactant, the collisional relaxation behaviour of the molecular system must be explicitly considered. Note also that it is in general not possible to relate the reaction rate to the collision (or energy transfer) rate from a particular energy state or group of states in the reactant molecule; rather, the overall rate represents a co-operative effect of a network of microscopic transition processes.

The treatment of the microscopic reaction processes in unimolecular systems as dissipative perturbations to the internal (collisional) relaxation of the reactant molecule is attractive for several reasons. The algebra involved in the treatment bears close resemblance to perturbation formalisms in quantum mechanics; this facilitates not only the analytic solution for the unimolecular reaction rate at all pressures, but also the physical interpretations of the relevant theoretical results. Thus, the theoretical origin of the Lindemann behaviour is now well understood: it occurs *either* when the molecule has only one reactive state, in which case the internal relaxation amongst its various states has the overall effect of grouping all the non-reactive states into one (3); *or* when the relaxation modes associated with the respective reaction states (as characterised by the respective relaxation elements (8)) are identical, in which case the reaction-relaxation behaviour of all the reactive states is similar. The latter follows from the fact that the reaction bottleneck lies in the non-reactive energy region, and that the reaction behaviour does not depend at all on the microscopic processes associated with the reactive states (9).

This latter point is important since it leads to the prediction of the Lindemann fall-off behaviour at high temperature and, in turn, the direct association of the low-pressure reaction rate at high temperature with the relaxation elements of the reactive states. Within the step-ladder model, the justification of which for a grained system we have discussed earlier, this direct identification facilitates a straightforward semiquantitative analysis of the collisional energy transfer properties of a reactant system, from the experimental relaxation and reaction rate data.

The present master-equation analysis of the various experimental data (the relaxation rate, the reaction rate, and the induction time) of the N_2O and CO_2 systems demonstrates that (*i*) rotation should be taken into account in rate calculations; (*ii*) both "vibrational" population disequilibrium and rotation are important contributors to the lowering of the low pressure activation energy at high temperature; and (*iii*) an (initial-) state-independent energy transfer model is inadequate, even for the description of thermal systems; in the model we have used, the initial state is characterised only by its total energy (and not by its rotational and vibrational components), but within this framework of coarsely-grained pseudo-levels, a Landau–Teller transition probability model seems to give semi-quantitatively reasonable results. As we have noted before (8) it is not rotational energy transfer nor rotational disequilibrium that are of vital importance in determining the reaction rate at these temperatures, or its Arrhenius temperature coefficient: it is simply the proper accounting for the rotational states taken

[4]The "strong collision" rate constants for the two reactions have recently been calculated by Troe (2), using slightly different spectroscopic data. For N_2O, the collisional efficiency decreases from 0.09 at 900 K to 0.02 at 2500 K; for CO_2 it increases from 0.005 at 1000 K to 0.03 at 3000 K.

together with the fact that at high temperatures, rotational energy and vibrational energy seem to be roughly equally effective in promoting dissociation (8).

Unimolecular reactions of N_2O and CO_2 at high pressure

ANDREW W. YAU[1] AND HUW O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received December 6, 1978

ANDREW W. YAU and HUW O. PRITCHARD. Can. J. Chem. 57, 1731 (1979).

An *a priori* calculation in the framework of the theory of radiationless transitions is presented for the non-adiabatic spin-forbidden reactions of N_2O and CO_2. The calculation is two-dimensional, incorporating the two stretching degrees of freedom, and the microscopic reaction process is formulated using the relative coordinate system of Rosen as modified by Beswick and Jortner. All microscopic parameters required for the calculation are derived from spectroscopic data; no adjustable parameter is included. For each reaction, a purely theoretical reaction probability function $k(E)$ is synthesised and used to derive a theoretical Arrhenius expression for the infinite-pressure reaction rate. The calculated high-pressure unimolecular dissociation rates for both reactions are in reasonable agreement with experiment. High-pressure recombination rate coefficients are also presented for CO_2; they exhibit positive activation energies which increase from 0.5 kcal/mol at room temperature to 8 kcal/mol at 5000 K.

ANDREW W. YAU et HUW O. PRITCHARD. Can. J. Chem. 57, 1731 (1979).

On présente un calcul *a priori*, dans le cadre de la théorie des transitions sans radiation, pour les réactions non adiabatiques interdites d'après les spin, du N_2O et du CO_2. On présente le calcul bidimensionnel incorporant les deux degrés de liberté d'élongation et le procédé de réaction microscopique en faisant appel au système de coordonnées relatives de Rosen, modifié par Beswick et Jortner. On a déduit tous les paramètres microscopiques requis pour les calculs à partir de données spectroscopiques; on n'a ajouté aucun paramètre ajustable. Pour chaque réaction, on a synthétisé une fonction de probabilité de réaction purement théorique $k(E)$ et on l'a utilisée pour déduire une expression d'Arrhénius théorique pour des vitesses de réaction à pression infinie. Les vitesses de dissociation unimoléculaires à haute pression, calculées pour les deux réactions, sont en bon accord avec les valeurs expérimentales. On rapporte aussi, pour le CO_2, les coefficients de vitesse de recombinaison à haute pression; ils comportent des énergies d'activation positives qui augmentent de 0.5 kcal/mol à température ambiante à 8 kcal/mol à 5000 K.

I. Introduction

Since the pioneering paper of Rice on the quantal treatment of radiationless transitions in 1929 (1), time-dependent perturbation theory has found itself applied to various types of physical/chemical processes in the last 50 years — autoionisation (2), diatomic predissociation (3), radiationless electronic relaxation (4), and unimolecular reaction (5) — in the framework of the theory of configuration interactions (2, 6, 7). Indeed, time-dependent perturbation treatments of unimolecular reaction kinetics date back to the remarkable model calculations of Rosen (8) in 1933 on the predissociation of a vibrationally excited metastable molecule. To the extent that the distinction between vibrational predissociation (involving nuclear motion along only one potential surface) and electronic predissociation (involving two electronic configurations) is not well defined, and that the theoretical frameworks of the two kinds of reactions are not dissimilar within the configuration-interaction approach, the calculations of Stearn and Eyring (9), Olschewski *et al.* (10), and Gilbert and Ross (11) for the non-adiabatic spin-forbidden reaction of N_2O represent natural developments from the work of Rosen (8).

These practical calculations were not without inherent difficulties. Required spectroscopic information was often approximate and incomplete, and had to be supplemented by informed guesswork. The required numerical computations were not trivial, even with drastic simplifications and analytic approximations. In the calculation of Stearn and Eyring (9), an empirical potential surface was constructed for the ground electronic state from experimental vibrational frequencies; an inverted Morse function with arbitrarily chosen range parameters was assumed for the repulsive upper-state potential. The semi-classical expression of Zener (12) for the non-adiabatic crossing of energy levels was used for calculating the microscopic decomposition probabilities. The Zener expression is inadequate (13); also, the value adopted in the calculation (50 kcal/

[1]Present address: Herzberg Institute of Astrophysics, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6.

0008-4042/79/131731-12$01.00/0

mol) for the energy of curve crossing is a gross underestimate and the calculated infinite-pressure activation energy (52 kcal/mol) differs substantially from the experimental value (60 kcal/mol) (10). Nevertheless, some of the empirical estimates for the relevant molecular parameters in the calculation are remarkably realistic; indeed, the theoretical implications of these estimates have served as useful guides for the later works (10, 11).

A different approach was adopted in Olschewski *et al.* (10): a theoretical analysis was undertaken for the infinite-pressure rate constant in terms of spectroscopic parameters of the two electronic states; the theoretical results were then compared with experimental rate data, and "experimental" values were deduced for the relevant molecular parameters. The calculation was similar to that of Stearn and Eyring (9) in some regards: as in Stearn and Eyring (9), the overlap integral in the microscopic reaction probability term was evaluated one-dimensionally (along the N—O coordinate), and was related to the potential surfaces only through their slope along the coordinate at the curve-crossing point; also, the values for the two slopes were chosen empirically. Unlike Stearn and Eyring (9), however, the semi-classical expression of Rice (14), which is more accurate (3) than that of Zener near the curve-crossing region, was used for the overlap integral. Three calculations were performed to examine semi-quantitatively the consequence of allowing energy from other vibrational modes for reaction (within the one-dimensional formalism). By comparison between computational and experimental data, the energy of curve crossing was placed at 63 ± 1 kcal/mol — 3.5 kcal/mol above the experimental activation energy. Also, a value of 39 cm^{-1} was obtained for the spin–orbit coupling constant, with an uncertainty of a factor of two.

The calculation of Gilbert and Ross (11) is different from the two earlier works (9, 10) in two regards: it was two dimensional; also, the relevant wavefunction overlaps were evaluated numerically, rather than being approximated by semi-classical expressions. The incorporation of the second degree of freedom (N—N stretch) and the evaluation of the two-dimensional overlap integrals substantially compounded the required computational elaboration, even with drastic approximations such as the neglect of anharmonicity in the ground-state potential. The calculation was exploratory in nature: the upper-state potential was defined in terms of adjustable parameters, which were chosen to effect agreement between the calculated and experimental activation energies; a factor of four agreement was obtained between the calculated and experimental rates. Comparable agreement was also obtained in another rather similar calculation by Gebelein and Jortner (15); they employed instead an anharmonic (Morse) function for the ground-state N—O potential and adjusted the upper-state repulsive potential, assuming it to obey an inverse power dependence.

These reasonable agreements between the calculated and experimental rates point to a purely theoretical calculation which allows no arbitrarily adjustable parameters. Comparison between such a calculation and experiment would then provide realistic assessment of the validity of the various simplifications in the theoretical framework. The aim of this paper is to present such a calculation for the spin-forbidden reactions of N_2O and CO_2:

[1] $$N_2O(\tilde{X}^1\Sigma^+) \rightarrow N_2(X^1\Sigma_g^+) + O(^3P)$$

[2a] $$CO_2(\tilde{X}^1\Sigma_g^+) \rightarrow CO(X^1\Sigma^+) + O(^3P)$$

Our objectives are three-fold. First, we synthesize a purely theoretical $k(E)$ function from the microscopic reaction probabilities for the two reactions: the calculation is two-dimensional; however, our theoretical approach obviates the formidable amount of numerical computation involved in the work of Gilbert and Ross (11). Second, we derive from the $k(E)$ function a 'theoretical' Arrhenius rate expression for the high-pressure reaction rates of both reactions; in a future publication, we will use the latter to examine the sensitivity of the Slater–Forst inversion procedure (16, 17) of high-pressure rate laws — a question of some interest in thermal unimolecular reaction theory. Third, we study the low-temperature behaviour of the reverse (recombination) reaction of [2a];

[2b] $$CO(X^1\Sigma^+) + O(^3P) \rightarrow CO_2(\tilde{X}^1\Sigma_g^+)$$

in the high-pressure region. The current knowledge, both experimental and theoretical, of the kinetics of [2b] is uncertain (18); our aim here is to examine the theoretical temperature dependence of the reaction in the high-pressure limit.

II. Formulation

The microscopic dissociation process is described by a bound vibrational state of a Born–Oppenheimer electronic state $|b\rangle$ coupled by intramolecular non-adiabatic coupling H_{int} to a set of vibrational continua belonging to another Born–Oppenheimer unbound electronic state $|u\rangle$. For a linear triatomic molecule ABX restricted to linear motion, the total wavefunctions for the two electronic states are

[3a] $$|b\rangle = |\Psi_b\rangle|b,v_{b1},v_{b2}\rangle$$

[3b] $$|u\rangle = |\Psi_u\rangle|u,\varepsilon_{u1},v_{u2}\rangle$$

where $|\Psi_s\rangle$, $s \equiv b, u$, are the electronic wavefunctions, v_{b1},v_{b2} the vibrational quantum numbers in the bound electronic state, v_{u2} the vibrational quantum number of the diatomic fragment AB, and ε_{u1} the relative kinetic energy of the AB—X pair.

Following the Beswick–Jortner modification (19) of Rosen's relative coordinate system (8), we characterise the nuclear dynamics in terms of the centre of mass coordinate of the entire system, the separation r_1 between X and the centre of mass of AB, and the internuclear separation r_2 of AB. Note that

$$[4] \qquad r_1 = \theta r_2 + r_{BX}$$

where $\theta = m_A/(m_A + m_B)$. In this representation, the motion of the centre of mass of the entire system is factored out, and the nuclear Hamiltonian for the internal motion assumes the form

$$[5] \quad H = -(\hbar^2/2\mu_1)(\partial^2/\partial r_1^2) - (\hbar^2/2\mu_2)(\partial^2/\partial r_2^2) + V_s$$

where μ_1 is the reduced mass of AB and X ($\mu_1 = (m_A + m_B)m_X/(m_A + m_B + m_X)$) and μ_2 the reduced mass of AB ($\mu_2 = m_A m_B/(m_A + m_B)$); V_s denotes the potential of electronic state s.

We now assume that the potentials in both electronic states can each be written as the sum of component potentials between neighbouring nuclei, viz.

$$[6] \qquad V_s = V_{s1}(r_{BX}) + V_{s2}(r_{AB})$$

$s \equiv b, u$, and partition the nuclear Hamiltonian H into the zero-order Hamiltonian H^0 and the residual perturbation H^1, with

$$[7a] \quad H^0 = -(\hbar^2/2\mu_1)(\partial^2/\partial r_1^2) + V_{s1}(r_1 - \theta\bar{r}_{AB,s}) - (\hbar^2/2\mu_2)(\partial^2/\partial r_2^2) + V_{s2}(r_2)$$

and

$$[7b] \quad H^1 = V_{s1}(r_1 - \theta r_2) - V_{s1}(r_1 - \theta\bar{r}_{AB,s})$$

The zero-order Hamiltonian then corresponds to the motion of the diatomic fragment AB and the motion of X relative to the centre of mass of AB which is 'frozen' at its equilibrium separation $\bar{r}_{AB,s}$. Its 'diabatic' wavefunctions are[2]

$$[8a] \qquad |b,v_{b1},v_{b2}\rangle = \phi_{v_{b1}}(r_1)\,\chi_{v_{b2}}(r_2)$$

for the bound state $|b\rangle$ and

$$[8b] \qquad |u,\varepsilon_{u1},v_{u2}\rangle = \phi_{\varepsilon_{u1}}(r_1)\chi_{v_{u2}}(r_2)$$

for the unbound state $|u\rangle$.

[2]Notice that the diabatic states $|b\rangle$ are *not* separable in the conventional normal-mode coordinates; the use of the latter is valid only for low-lying vibrational levels and is inadequate for the dissociating states.

These zero-order nuclear-diabatic states are coupled: the intrastate (discrete–discrete and continuum–continuum) couplings by the residual perturbation H^1 have been discussed by Atabek *et al.* (20) and by Beswick and Jortner (19);[3] our interest here is the interstate coupling by the intramolecular non-adiabatic terms in the Hamiltonian between the discrete levels in $|b\rangle$ and the continuum states in $|u\rangle$:

$$[9] \qquad H^{u,\varepsilon_{u1},v_{u2}}_{b,v_{b1},v_{b2}} = \langle u|H_{int}|b\rangle$$

which, invoking the Condon approximation, reduces to

$$[10] \quad H^{u,\varepsilon_{u1},v_{u2}}_{b,v_{b1},v_{b2}} = \langle\Psi_u|H_{int}|\Psi_b\rangle\langle u,\varepsilon_{u1},v_{u2}|b,v_{b1},v_{b2}\rangle$$

The synthesis of the microscopic reaction probability k_{i-j} from level i ($i \equiv v_{b1},v_{b2}$) in the 'reactant' to level j ($j \equiv \varepsilon_{u1},v_{u2}$) in the 'product' centres upon the nuclear factor $\langle u,\varepsilon_{u1},v_{u2}|b,v_{b1},v_{b2}\rangle$ and the electronic factor $\langle\Psi_u|H_{int}|\Psi_b\rangle$ in eq. [10]. Explicitly,

$$[11] \quad k_{i-j} \equiv k^{u,\varepsilon_{u1},v_{u2}}_{b,v_{b1},v_{b2}} = (2\pi/\hbar)|H^{u,\varepsilon_{u1},v_{u2}}_{b,v_{b1},v_{b2}}|^2 = (2\pi/\hbar)R_{ub}{}^2 q_{\varepsilon_{u1}v_{u2}v_{b1}v_{b2}}$$

where $R_{ub} = \langle\Psi_u|H_{int}|\Psi_b\rangle$ is the electronic transition moment between $|u\rangle$ and $|b\rangle$;

$$q_{\varepsilon_{u1}v_{u2}v_{b1}v_{b2}} = |\langle u,\varepsilon_{u1},v_{u2}|b,v_{b1},v_{b2}\rangle|^2$$

is the Franck–Condon density of the ($\varepsilon_{u1},v_{u2} - v_{b1},v_{b2}$) transition, and factorises into

$$[12] \qquad q_{\varepsilon_{u1}v_{u2}v_{b1}v_{b2}} = q_{\varepsilon_{u1}v_{b1}}q_{v_{u2}v_{b2}}$$

with

$$q_{\varepsilon_{u1}v_{b1}} = |\langle\phi_{\varepsilon_{u1}}|\phi_{v_{b1}}\rangle|^2$$

and

$$q_{v_{u2}v_{b2}} = |\langle\chi_{v_{u2}}|\chi_{v_{b2}}\rangle|^2$$

For the bound state $|b\rangle$, we assume a harmonic potential for the AB bond and a Morse potential for the BX bond,

$$[13a] \quad V_{b1}(r_{BX}) = D_e\{1 - \exp[-\alpha(r_{BX} - \bar{r}_{BX,b})]\}^2$$

$$[13b] \qquad V_{b2}(r_{AB}) = \tfrac{1}{2}k_b(r_{AB} - \bar{r}_{AB})^2$$

For the unbound state $|u\rangle$, we assume a harmonic potential for the diatomic fragment AB,

$$[14a] \qquad V_{u2}(r_{AB}) = \tfrac{1}{2}k_u(r_{AB} - \bar{r}_{AB,u})^2$$

and an exponential repulsive potential along the BX

[3]The discrete–discrete couplings in van der Waals molecules have been shown (19) to be negligible; the couplings between the high-lying states in conventional molecules are likely to be similar. The continuum–continuum couplings are important in modifying the final product state distribution.

coordinate,

$$[14b] \quad V_{u1}(r_{BX}) = A \exp(-a\bar{r}_{BX}) = \tilde{A} \exp[-a(r_{BX} - \bar{r}_{BX,b})]$$

The eigenfunctions corresponding to these potentials are (21–23):

$$[15] \quad \phi_{v_{b1}}(r_1) = [(2\kappa - 2v_{b1} - 1)\alpha/(v_{b1}!\Gamma(2\kappa - v_{b1}))]^{1/2} z^{-1/2} W_{\kappa,\kappa-v_{b2}-1/2}(z)$$

$$[16] \quad \phi_{\varepsilon_{u1}}(r_1) = 2/\pi[\mu_1/a \sinh(2\pi k/a)]^{1/2} K_{2ik/a}(\eta)$$

$$[17] \quad \chi_{v_{s2}}(r_2) = (\alpha_{s2}/\pi)^{1/4}(2^{v_{s2}}v_{s2}!)^{-1/2} \times \exp(-\alpha_{s2}x_s^2) H_{v_{s2}}(\alpha_{s2}^{1/2}x_s)$$

where

$$\kappa = (2\mu_1 D_e)^{1/2}/(\alpha\hbar)$$

$$z = (8\mu_1)^{1/2}/(\alpha\hbar) \exp[-\alpha(r_1 - \bar{r}_{BX,b} - \theta\bar{r}_{AB,b})]$$

$$k = (2\mu_1\varepsilon)^{1/2}/\hbar$$

$$\eta = (8\mu_1 A)^{1/2} \exp[-\tfrac{1}{2}a(r_1 - \theta\bar{r}_{AB,u})]/(a\hbar)$$

$$x_s = r_2 - \bar{r}_{AB,s}$$

$$\alpha_{s2} = (\mu_2 k_s/\hbar^2)^{1/2}$$

$$s \equiv b \text{ or } u$$

$W_{\lambda,\mu}(x)$ is the Whittaker function, $K_\lambda(x)$ the Bessel function, $H_n(x)$ the Hermite polynomial, and $\Gamma(x)$ the Gamma function (24). Notice that $\phi_{\varepsilon_{u1}}$ is normalised to the delta-function with respect to energy. The bound states are characterised by energies

$$E(b,v_{b1},v_{b2}) = E_{b0} + E_{v_{b1}} + E_{v_{b2}}$$

where E_{b0} is the electronic origin of $|b\rangle$,

$$E_{v_{b1}} = \omega_{b1}(v_{b1} + \tfrac{1}{2}) - \omega_{b1}x_{b1}(v_{b1} + \tfrac{1}{2})^2$$

$$E_{v_{b2}} = \omega_{b2}(v_{b2} + \tfrac{1}{2})$$

Likewise, the continuum states have energies

$$E(u,\varepsilon_{u1},v_{u2}) = E_{u0} + \varepsilon_{u1} + E_{v_{b2}}$$

with

$$E_{v_{u2}} = \omega_{u2}(v_{u2} + \tfrac{1}{2})$$

Note that

$$\omega_{b1} = \hbar\alpha(2D_e/\mu_1)^{1/2}$$

$$\omega_{b1}x_{b1} = \hbar^2\alpha^2/(2\mu_1)$$

$$\omega_{s2} = \hbar(k_s/\mu_2)^{1/2} \qquad (s \equiv u, b)$$

The overlap of the wavefunctions $\chi_{v_{u2}}$ and $\chi_{v_{b2}}$ is approximated by the analytic expression

$$[18] \quad q_{v_{u2}v_{b2}} = |\langle\chi_{v_{u2}}|\chi_{v_{b2}}\rangle|^2 \simeq (m!/n!)\eta^{n-m}[L_m^{n-m}(\eta)]^2 \exp(-\eta)$$

where

$$m = \min(v_{u2}, v_{b2})$$

$$n = \max(v_{u2}, v_{b2})$$

$$\eta = \tfrac{1}{2}(\alpha_{u2}\alpha_{b2})^{1/2}(\bar{r}_{AB,u} - \bar{r}_{AB,b})^2$$

and $L_m^n(x)$ is the generalised Laguerre polynomial (24). The expression [18] is exact when $\alpha_{u2} = \alpha_{b2}$, and is an excellent approximation in real physical systems where α_{u2} is close to α_{b2}; the derivation of [18] is straightforward by approximating α_{u2} and α_{b2} by $(\alpha_{u2}\alpha_{b2})^{1/2}$ in [17].

For the overlap of the wavefunctions $\phi_{\varepsilon_{u1}}$ and $\phi_{v_{b1}}$, the dominant contribution is localised in the curve-crossing region. Hence, one may employ the semi-classical approximation by linearising the respective potentials at their turning points and approximating the wavefunctions by Airy functions. One then obtains

$$[19] \quad q_{\varepsilon_{u1}v_{b1}} = |\langle\phi_{\varepsilon_{u1}}|\phi_{v_{b1}}\rangle|^2 \simeq \{4\mu^2/[\hbar^4 F_u F_b(F_u - F_b)^2]\}^{1/3}\alpha \times [(2D_e/\mu_1)^{1/2} - (2v_{b1} + 1)\alpha/(2\mu_1)] \times \mathrm{Ai}^2[(2\mu_1 F_u F_b/(\hbar^2(F_u - F_b)))]^{1/3}\Delta r]$$

where

$$\Delta r = r_{tu} - t_{tb} = \alpha^{-1} \ln[1 - (E_{v_{b1}}/D_e)^{1/2}] - a^{-1} \ln(\varepsilon/\tilde{A}) + \theta(\bar{r}_{AB,u} - \bar{r}_{AB,b})$$

$$F_u = -\partial V_{u1}/\partial r_1|_{r_{tu}} = \varepsilon b$$

$$F_b = -\partial V_{b1}/\partial r_1|_{r_{tb}} = -2\alpha E_{v_{b1}}^{1/2}(D_e^{1/2} - E_{v_{b1}}^{1/2})$$

The derivation of [19] is given in the Appendix.

In spin-forbidden reactions, the intramolecular non-adiabatic coupling H_{int} is the spin–orbit coupling between states of different spin. Hence, one may identify the electronic transition moment R_{ub} with the spin–orbit coupling constant between the two spin states, H_{ub}^{so},

$$[20] \quad R_{ub} = \langle\Psi_u|H_{int}|\Psi_b\rangle = H_{ub}^{so}$$

Given the relevant spectroscopic parameters, the microscopic reaction probabilities $k_{i\to j}$ may be computed using eqs. [11], [12], [18], [19], and [20].

III. Spectroscopic Data

The relevant parameters in the model potentials are derived from spectroscopic data: they are summarised in Table 1.

For the harmonic potential in the dissociative state, V_{u2}, the force constant k_u is related to the vibrational frequency of the diatomic molecule by

$$k_u = \mu_2\omega_{AB,u}^2/\hbar^2$$

TABLE 1. Spectroscopic parameters for model potentials[a]

Potential	Parameter (AB—X)	Value N$_2$—O	Value OC—O
V_{b1}	α (Å^{-1})	2.8510(25)	2.5583[b]
	$\bar{r}_{BX,b}$ (Å)	1.1856(25)	1.1621(26)
	D_e (cm^{-1})[c]	30560.2[d]	61447.0[d]
	$zpe_{BX,b}$ (cm^{-1})	648.4 (27)	994.3[e]
V_{b2}	$\omega_{AB,b}$ (cm^{-1})	2252.8(27)	1988.6[f]
	$\bar{r}_{AB,b}$ (Å)	1.1266(25)	1.1621(26)
	k_b (au)	1.3447[g]	1.0261(28)
	$zpe_{AB,b}$ (cm^{-1})	1137.8(27)	994.3[e]
V_{u1}	$\tilde{A}$ (cm^{-1})[h]	20400.2[i]	21797.1[j]
	a (au)	0.65[k]	6.0[k]
V_{u2}	$\omega_{AB,u}$ (cm^{-1})	2330.7(29)	2143.3(29)
	$\bar{r}_{AB,u}$ (Å)	1.0975(25)	1.1282(29)
	k_u (au)[l]	1.4393	1.2016
	$zpe_{AB,u}$ (cm^{-1})	1176.2(29)	1071.6(29)
	Additional parameters		
	ω_{bend} (cm^{-1})	599.4(27)	677.2(28)
	B_e (cm^{-1})	0.41901(26)	0.39021(26)
	D_0(AB—X) (kcal/mol)	38.55(30)	125.75(30)
	$E_{u0} - E_{b0}$ (cm^{-1})[m]	14692.5	45576.3
	zpe_{ABX} (cm^{-1})[n]	2385.5	2665.9
	μ_1 (amu)	10.1806	10.1791
	μ_2 (amu)	7.0015	6.8562

[a]Conversion factor for energy: 1 au = 219 474.7 cm^{-1}; 1 kcal/mol = 349.758 cm^{-1}; for mass: 1 amu = 1822.853 au; for length: 1 au = 0.529177 Å.
[b]$\alpha = (k_b/2D_e)^{1/2}$.
[c]$D_e = D_0$(AB—X) + $zpe_{ABX} - zpe_{AB,u} + E(X^*)$; $E(X^*)$ being the energy of X in the excited product state.
[d]$E(X^*) = E(O^1D) = 15\,867.7$ cm^{-1} (31).
[e]Approximated by $\frac{1}{2}\hbar(k_b/\mu_2)^{1/2}$.
[f]$\omega_{AB,b} = \hbar(k_b/\mu_2)^{1/2}$.
[g]$k_b = \mu_2\omega_{AB,b}^2/\hbar^2$.
[h]See eq. [21] in text.
[i]$\Delta E_{vert} = 34\,482.8$ cm^{-1} from Sponer and Bonner (32).
[j]$\Delta E_{vert} = 66\,459.4$ cm^{-1} from Winter *et al.* (33).
[k]See text.
[l]$k_u = \mu_2\omega_{AB,u}^2/\hbar^2$.
[m]$E_{u0} - E_{b0} = D_0$(AB—X) + $zpe_{ABX} - zpe_{AB,u}$.
[n]$zpe_{ABX} = zpe_{AB,b} + zpe_{BX,b} + \omega_{bend}$.

ω_{AB} being the vibrational frequency of the diatomic molecule AB; $\bar{r}_{AB,u}$ is simply the equilibrium separation of the diatomic AB.

The potentials V_{b1} and V_{b2} are derived from the ground-state potential surface of the triatomic. For N_2O, Morse type functions have been found (25) to be very good approximations in describing the stretching potentials for the two bonds. Following Suzuki (25), V_{b1} is identified with the stretching potential in the NO bond, and V_{b2} with that in the N_2 bond: the use of a harmonic potential for the latter is justified here since the dissociation energy is higher (for the N_2 bond) and the important reactive states are associated with low excitation in this bond. For CO_2, the model potential surfaces assumed here do not, in fact, have the proper symmetry in the Franck–Condon region, where either oxygen atom may dissociate: to circumvent this deficiency, a symmetry number of 2 is incorporated into the microscopic dissociation probability. The bound state potentials V_{b1} and V_{b2} are constructed from the potential energy function of Cihla and Chedin (28) along the CO coordinate: for V_{b2}, $k_b = 1.0261$ au ($=2f_1r_{12}^{0\,2}$, in the notation of ref. 28) and $\bar{r}_{AB,b} = 1.1621$ Å; for V_{b1}, the range parameter α is obtained using the relationship $\alpha = (k_b/2D_e)^{1/2}$.

Spectroscopic data for the repulsive potential V_{u1} are less complete. Indeed, there is no a priori justification for representing the potential by a pure exponential repulsive form, aside from its associated analytic tractability, and the fact that only two parameters are necessary to characterise the geometry of the potential. The strength parameter $\tilde{A}$ may be deduced from the vertical transition energy between the two electronic states at the ground-state equilibrium nuclear configuration. Explicitly,

$$[21]\quad \tilde{A} \equiv Ae^{-a\bar{r}_{BX,b}} = \Delta E_{vert} + zpe_{ABX} - zpe_{AB,u} - \omega_{bend} - (E_{u0} - E_{b0})$$

where $(E_{u0} - E_{b0}) = D_0(\text{AB—X}) + zpe_{\text{ABX}} - zpe_{\text{AB},u}$ is the difference of the two electronic origins; D_0(AB—X) the thermochemical dissociation energy of ABX; zpe_x the zero-point-energy of species x, and ω_{bend} the bending frequency. The spectroscopic values of the vertical transition energies for both N_2O and CO_2 are in fact uncertain. Nor are the state assignments unambiguous. Two dissociative triplet states correlate with the ground dissociation limit: $^3\Sigma^-$ and $^3\Pi$. The two states lie close to one another. In CO_2, the $^3\Sigma^-$ state is 1 eV below the $^3\Pi$ state; the corresponding separation in N_2O is unknown. We assume for the purpose of this work the $^3\Sigma^-$ state to be the upper repulsive state; it is clear that insofar as the present rate calculation is concerned, the state assignment is not important. For N_2O, Hall *et al.* (34) concluded from their electron loss spectrum that the $^3\Sigma^-$ state lies within 6.2 eV above the ground $^1\Sigma^+$ state. This conclusion is not inconsistent with the weak absorption maximum at 2900 Å in the continuous N_2O spectrum of Sponer and Bonner (32), which corresponds to a vertical energy of 4.27 eV, and, using eq. [21], a value of 20 400.2 cm^{-1} for $\tilde{A}$. For CO_2, Winter *et al.* obtained a value of 8.24 eV for the vertical energy of the $^3\Sigma_u^-$ state from configuration interaction calculations. No experimental data exist for this state to assess the accuracy of the theoretical value. Nevertheless, the theoretical results for the higher states compare favourably with the experimental data of Hall *et al.* (35). Using $\Delta E_{\text{vert}} = 8.24$ eV and eq. [21], we obtain $\tilde{A} = 21\,797.1$ cm^{-1}.

Spectroscopic data relevant for the shape parameter a in V_{u1} are not available for the N_2O $^3\Sigma^-$ and CO_2 $^3\Sigma_u^-$ states; the corresponding data for their neighbouring states do, however, exist. Thus, for the N_2O $^1\Sigma$ state (that correlates with $N_2(X^1\Sigma_g^+) + O(^1S)$) Shapiro (36) obtained from photodissociation data a fit to the repulsive potential in the bi-exponential form, viz. $V = A_1 \exp(-a_1 r) + A_2 \exp(-a_2 r)$, with $a_1 = 0.62$ au and $a_2 = 0.68$ au. Now, there is no a priori reason for the shape parameter of different repulsive electronic states of a molecule to be the same, but they are not expected to be appreciably different. For lack of precise data, it is reasonable to assume for the purpose of our calculation the same value of a for the $^3\Sigma^-$ state, whence we have $a = 0.65$ au for N_2O. Likewise, for CO_2, the value of 6.0 au for the dissociative state correlated with $CO(a'^3\Sigma^+) + O(^3P)$ (37) (obtained from photodissociation data (38)) is used in the present calculation.

No theoretical calculations have yet been reported for the spin–orbit interactions in the N_2O and CO_2 systems, although procedures are available for relating the values in the two molecular systems to those of the component atoms. The spin–orbit interaction between $O(^1D_2)$ and $O(^3P_2)$ is 106 cm^{-1}; the values for both N_2O and CO_2 may be expected to be similar (9).[4] We assume $H_{ub}^{so} = 106$ cm^{-1} in our calculations.

IV. Microscopic Reaction Probability

Using the spectroscopic data in Table 1 and the theoretical results in Section II, we have computed the microscopic reaction probabilities k_{i-j} for reactive states i up to 100 and 180 kcal/mol (relative to the electronic origin) for N_2O and CO_2, respectively.

The potential surface geometries (in the important energy region) for the two reactions are qualitatively different, and this is reflected in the behaviour of the respective probabilities. Figure 1 *a* and *b* shows the assumed model potentials for N_2O and CO_2 respectively, along their 'reaction co-ordinates'. In N_2O, the repulsive potential spans a relatively wide range (the range parameter $a = 0.65$ is small) and the curve-crossing point lies about 24 kcal/mol above the dissociation limit. In contrast, the repulsive potential in CO_2 is much steeper (the range parameter $a = 6.0$ is large) and the curve crossing lies only barely above the dissociation limit. Now for reactive channels below the curve-crossing point [i.e. $\Delta = \varepsilon_{u1} - (E_c - E_0) < 0$], the Franck–Condon density $q_{\varepsilon_{u1} v_{b1}}$ in eq. [19] decreases exponentially with $|\Delta|$. The implication of this is that in N_2O, k_{i-j} is extremely small (compared with the maximum value of $\sim 10^{12}$ s^{-1}) for states lying within 20 kcal/mol above the reaction threshold E_0. In CO_2 on the other hand, where the curve-crossing point lies close to the threshold, the first maximum of k_{i-j} is reached within 5 kcal/mol above the threshold.

Note that in the present collinear model, the reaction probability k_{i-j} is a function of three quantities: v_{b1}, v_{b2}, and one of ε_{u1} and v_{u2} (the four being related to one another by $E_{b0} + E_{v_{b1}} + E_{v_{b2}} = E_{u0} + \varepsilon_{u1} + E_{v_{u2}}$) and it is not feasible to discuss in detail the results for all of the thousands of reaction channels. Rather, it is more instructive to highlight the qualitative features of the k_{i-j} function in terms of the calculated results for representative groups of reaction channels. Figure 2 gives the logarithmic plots of k_{i-j} versus the energy of the reactive states for four groups of reaction channels in the N_2O reaction: ($v_{b2} = 0 \rightarrow v_{u2} = 0$), ($v_{b2} = 0 \rightarrow v_{u2} = 1$), ($v_{b2} = 4 \rightarrow v_{u2} = 3$), and ($v_{b2} = 4 \rightarrow v_{u2} = 2$): only reactive channels for which $k_{i-j} > 10^7$ s^{-1} are shown.

[4] $H_{ub}^{so} \simeq 100$ cm^{-1} for O_2 $B^3\Sigma_u^-$ and $^3\Pi_u$ (39), and $\simeq 70$ cm^{-1} for NO $^4\Sigma^-$ and $^2\Pi$ (29). Also, the coupling constants for N_2O^+ $X^2\Pi_g$ and CO_2^+ $X^2\Pi_g$ are 133 cm^{-1} and 160 cm^{-1}, respectively (40).

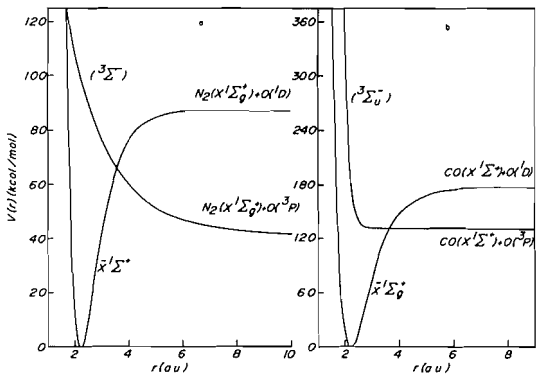

FIG. 1. (*a*) Potential energy curve for N_2O along the N_2—O coordinate; r is the internuclear separation between N and O. The triplet state assignment is uncertain. The two curves cross at 66.2 kcal/mol (64.3 kcal/mol above the zero point energy). (*b*) Potential energy curve for CO_2 along the OC—O coordinate; r is the internuclear separation between C and O. The triplet state assignment is uncertain. The two curves cross at 130.3 kcal/mol (127.5 kcal/mol above the zero point energy).

Note that the energy is relative to the zero point energy *zpe* ($= \frac{1}{2}\omega_{b1} - \frac{1}{4}\omega_{b1}x_{b1} + \frac{1}{2}\omega_{b2}$) and the reaction threshold corresponds to $D_0(N_2—O) =$ 38.55 kcal/mol in the scale of the diagram. (*i*) Above the curve-crossing point, the reaction probability k_{i-j} exhibits quasi-periodic fluctuations within each (v_{b2},v_{u2}) series; the increase in fluctuation frequency with energy is related in part to the increased steepness of the repulsive potential at high energy. (*ii*) Between the two $v_{b2} = 0$ series, the first one ($v_{u2} = 0$) has larger reaction probabilities than the second ($v_{u2} = 1$); this is not surprising in view of the respective wavefunction overlaps $q_{v_{u2}v_{b2}}$ (eq. [18]). Indeed, the corresponding probabilities for the ($v_{b2} = 0 \rightarrow v_{u2} = 2$) series are even smaller. (*iii*) On the other hand, between the two $v_{b2} = 4$ series, the one corresponding to $\Delta v = v_{b2} - v_{u2} = 2$ has *larger* reaction probabilities than the other ($\Delta v = 1$) near 80 kcal/mol. This is because the wavefunction overlap $q_{\varepsilon_{u1}v_{b1}}$ is now overwhelmingly more favourable for the former series. (*iv*) The reaction probabilities in these two series are much smaller than the $v_{b2} = 0$ series in magnitude. Nevertheless, these reactive channels become important above 85 kcal/mol where there are fewer and fewer bound states belonging to the low v_{b2} groups. (*v*) The maximum value of k_{i-j} is about 10^{12} s^{-1}; this compares with the classical vibrational frequency of the order 10^{14} s^{-1} along the v_{b1} (NO) coordinate, and corresponds to a curve-crossing probability of the order of 0.01. (*vi*) The successive maxima in the $v_{b2} = v_{u2} = 0$ series are similar in magnitude. This contrasts the corresponding behaviour in CO_2.

Figure 3 gives the k_{i-j} versus energy plots for the

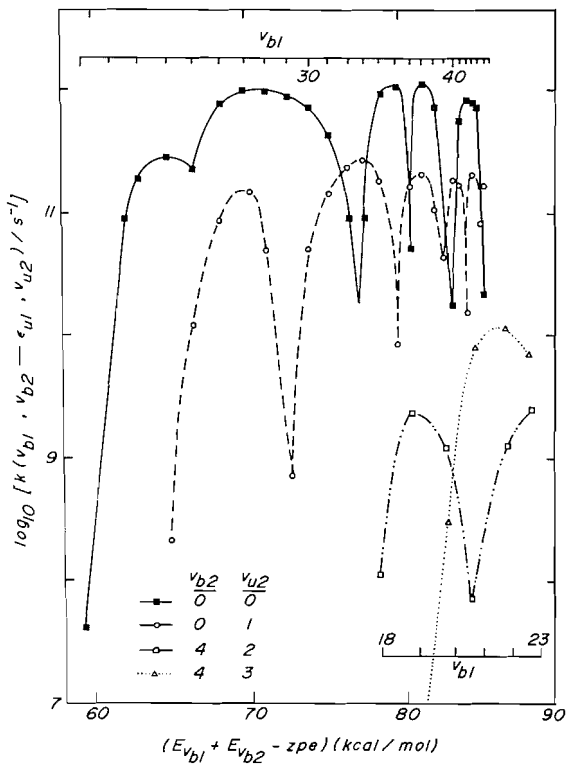

FIG. 2. Microscopic reaction probability for the dissociation of N_2O. $k(v_{b1},v_{b2} - \varepsilon_{u1},v_{u2})$ is the probability between discrete state (v_{b1},v_{b2}) in electronic state $|b\rangle$ and continuum state $(\varepsilon_{u1},v_{u2})$ in electronic state $|u\rangle$. The energy is relative to the zero point energy; the reaction threshold is 38.55 kcal/mol in the scale of the diagram.

($v_{b2} = v_{u2} = 0$) and the ($v_{b2} = 0 \rightarrow v_{u2} = 1$) series in CO_2. (*i*) There is now a systematic decrease in the magnitude of the k_{i-j} maxima with increasing energy. (*ii*) The fluctuation of the magnitude of k_{i-j} with energy is more frequent. (*iii*) The solid triangles correspond to reactive channels above 150 kcal/mol, in which $v_{b2} > 0$ and for which $k_{i-j} > 2 \times 10^{11}$ s^{-1}. These triangles indicate that in this energy region reaction channels in excited v_{b2} states are more important than those in the ground v_{b2} states. (*iv*) The first maximum of k_{i-j} is at 131 kcal/mol, only 4 kcal/mol above the reaction threshold. These features, compared with those in N_2O, are the direct consequences of the relative steepness of the repulsive potential and the closeness between the curve crossing and the reaction threshold energies.

Within the framework of the collinear model, one may in principle determine from k_{i-j} the product distribution of a reaction, given the reactant state distribution; of course, it should be kept in mind that the continuum–continuum (intrastate) coupling by

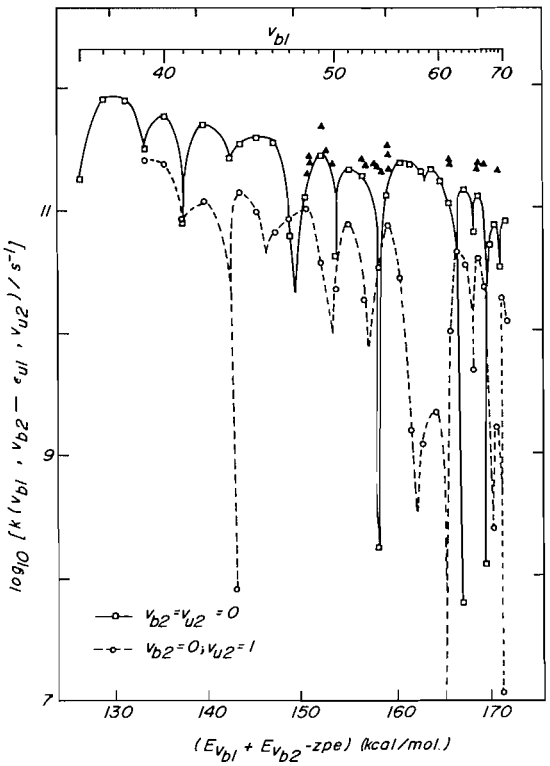

FIG. 3. Microscopic reaction probability for the dissociation of CO_2. $k(v_{b1},v_{b2} - \varepsilon_{u1},v_{u2})$ is the probability between discrete state (v_{b1},v_{b2}) in $|b\rangle$ and continuum state $(\varepsilon_{u1},v_{u2})$ in $|u\rangle$. The energy is relative to the zero point energy; the reaction threshold is 125.75 kcal/mol in the scale of the diagram. The solid triangles refer to reactive states above 150 kcal/mol relative to the zero point energy and with reaction probabilities greater than 2×10^{11} s^{-1}; see text.

the residual perturbation may modify the "nascent" product distribution.[3]

V. High-pressure Unimolecular Reaction Rate

In the high-pressure limit, the unimolecular reaction rate is (17)

$$[22] \qquad k_\infty = \sum \tilde{n}_i k_i$$

where $\tilde{n}_i$ is the equilibrium fractional population, k_i is the reaction probability from reactive state i, and the summation is over all reactive states. Explicitly

$$[23] \qquad \tilde{n}_i = g_i \exp(-\beta E_i)/Q(\beta)$$

and

$$[24] \qquad k_i = \sum_j k_{i-j}$$

where $\beta = 1/kT$ is the inverse temperature, $Q(\beta)$ is the partition function, g_i is the state-degeneracy of i, and the j-summation in eq. [24] is over all accessible product channels.

A full *ab-initio* calculation of the microscopic reaction probability for linear triatomics should incorporate not only the two stretching modes, but also the two bending modes and the rotation of the reactant molecule. However, the increase of elaboration in incorporating the bending and rotational motions into the theoretical treatment is formidable (41) and the current knowledge of the potential surfaces does not justify any such calculations. In the present work, we make the assumption that the microscopic reaction probability from a state $(v_{b1}, v_{b2}, v_{\text{bend}}, J, M_J)$ is independent of v_{bend}, J, and M_J, where v_{bend}, J, and M_J are respectively the bending and rotational quantum numbers. Explicitly, we have

$$[25] \qquad k_{v_{b1},v_{b2},v_{\text{bend}},J,M_J} = k_{v_{b1},v_{b2},0,0,0}$$

where

$$[25a] \qquad k_{v_{b1},v_{b2},0,0,0} \equiv k_{v_{b1}v_{b2}} = \sum_{v_{u2}} k^{u,\varepsilon_{u1},v_{u2}}_{b,v_{b1},v_{b2}}$$

$$[26] \qquad E_{v_{b1},v_{b2},v_{\text{bend}},J,M_J} = E_{v_{b1},v_{b2},0,0,0} + (v_{\text{bend}} + 1)\omega_{\text{bend}} + J(J+1)B_e$$

where

$$[26a] \qquad E_{v_{b1},v_{b2},0,0,0} \equiv E_{v_{b1},v_{b2}} = E_{v_{b1}} + E_{v_{b2}}$$

The high-pressure rate expression [22] then reduces to

$$[27] \qquad k_\infty = \frac{\sum_{v_{b1}} \sum_{v_{b2}} k_{v_{b1},v_{b2}} \exp(-\beta E_{v_{b1},v_{b2}})}{\sum_{v_{b1}} \sum_{v_{b2}} \exp(-\beta E_{v_{b1},v_{b2}})}$$

The activation energy E_∞ and pre-exponential factor A_∞ in the Arrhenius expression are respectively

$$[28] \qquad E_\infty = \frac{\left\{\sum_{v_{b1}} \sum_{v_{b2}} k_{v_{b1},v_{b2}} E_{v_{b1},v_{b2}} \exp(-\beta E_{v_{b1},v_{b2}})\right\}}{\left\{\sum_{v_{b1}} \sum_{v_{b2}} k_{v_{b1},v_{b2}} \exp(-\beta E_{v_{b1},v_{b2}})\right\}} - \frac{\sum_{v_{b1}} \sum_{v_{b2}} E_{v_{b1},v_{b2}} \exp(-\beta E_{v_{b1},v_{b2}})}{\sum_{v_{b1}} \sum_{v_{b2}} \exp(-\beta E_{v_{b1},v_{b2}})}$$

and

$$[29] \qquad A_\infty = k_\infty \exp(\beta E_\infty)$$

Given the reaction probabilities $k_{v_{b1},v_{b2}}$ and the energy levels $E_{v_{b1},v_{b2}}$, it is straightforward to calculate k_∞, E_∞, and A_∞ using eqs. [27]–[29]. In the following calculations, we have excluded reactive states for which the reaction probabilities are less than 10^5 s^{-1} since their contributions to k_∞ are negligible (except for temperatures below 200 K in N_2O). There are 527 (v_{b1},v_{b2}) states in N_2O for which $k_{v_{b1},v_{b2}}$ exceeds 10^5 s^{-1}; 949 states in CO_2.

A. N_2O Dissociation

The decomposition of N_2O represents one of the most extensively studied unimolecular reactions; a thorough evaluation of the relevant kinetic data has recently been presented by Baulch *et al.* (42). Nevertheless, data at high pressure (first order region) are limited. Figure 4 compares the data of Olschewski *et al.* (10) between 1400 and 2100 K and those of Johnston (43) at 888 K with calculation above 800 K. The calculated curve is in good agreement with experiments, both in the activation energy and actual magnitude, except above 1700 K, where there is a gradual departure. The departure is more apparent in the inset, where the actual experimental data points of Olschewski *et al.* (10) are shown. The origin of this seemingly divergent departure is not clear, though it could well be due to the inadequacy of the theoretical model; for example, rotation might lower the activation energy at high temperature, as is the case in diatomic dissociation (44, 45). The assumed potential surface is fairly realistic, possessing the various qualitative features that are important to the reaction process, and it is unlikely that within the framework of the present collinear model, improved spectroscopic data will significantly modify the calculated rates.

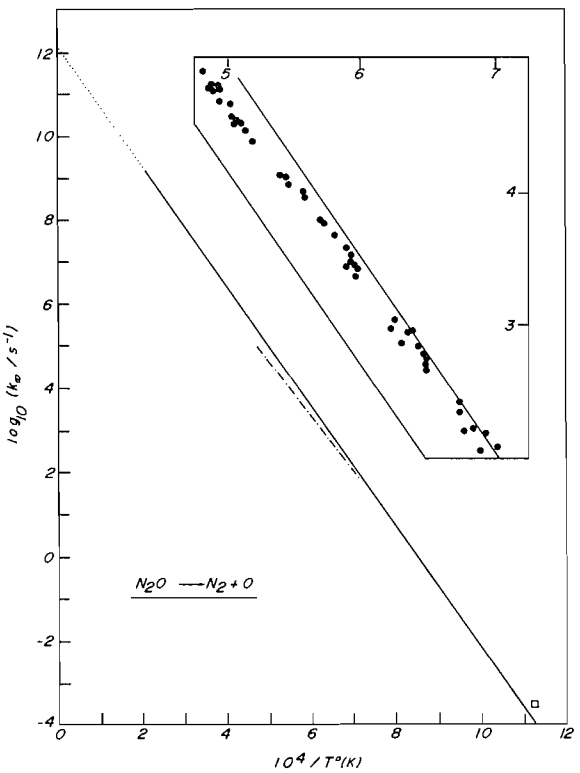

FIG. 4. Arrhenius plot for the infinite-pressure rate constant for the dissociation of N_2O. Experiments: ·····, Olschewski *et al.* (10), □, Johnston (43). Theory: —, eq. [27]; · · ·, Arrhenius rate law with $A_{\infty,\text{calcd}} = 1.41 \times 10^{12}\ s^{-1}$, and $E_{\infty,\text{calcd}} = 65.1$ kcal/mol. Inset: ●, data of Olschewski *et al.* (10); —, calculated rates from eq. [27].

Table 2 lists the Arrhenius parameters A_∞ and E_∞ between 5000 and 300 K. Despite the strong variation of the reaction probabilities with energy near the threshold in N_2O, the activation energy E_∞ varies only by about 10% over the temperature range covered in the table, and by about 5% in the temperature range of experimental interest (1000–2500 K). The pre-exponential factor A_∞ varies by less than a factor of two above 1000 K, and it is only below 750 K that it falls rapidly with temperature. The moderate variations in both A_∞ and E_∞ with temperature mean that the calculated rates may be *very well approximated* by a strict Arrhenius rate expression, viz. $k_\infty = A_{\infty,\text{calcd}} \exp(-E_{\infty,\text{calcd}}/RT)$, with $A_{\infty,\text{calcd}} = 1.41 \times 10^{12}\ s^{-1}$ and $E_{\infty,\text{calcd}} = 65.1$ kcal/mol, as is shown by the dotted line in Fig. 2. The implications of this on the Slater–Forst inversion procedure (16–17) of high-pressure experimental rate data will be examined in detail in a future publication.

B. CO_2 Dissociation

Compared with the N_2O reaction, the decomposition of CO_2 is less well understood. A variety of explanatory mechanisms have been proposed to account for the observed behaviour of the reaction rate (see ref. 18). In particular, an attractive triplet state ($^3B_2$) that correlates with ground state $CO(^1\Sigma^+)$ and $O(^3P)$ has been proposed by Lin and Bauer (46) and by Clyne and Thrush (47) to account for the "anomalous" activation energy of the reaction rate at low pressure. We have shown in the accompanying paper (48) that the low activation energy of the low-pressure reaction rate at high temperature is due, in fact, to the severe population disequilibrium in the reactant; the postulation of an attractive triplet potential does not seem necessary for the interpretation of rate data at low pressure and high temperature. The high-pressure reaction rate is not influenced

TABLE 2. Arrhenius parameters for the dissociation of N_2O

[a]Equation [29].
[b]Equation [30].
[c]$E_{\infty,rec} = -R \ln [k_{\infty,rec}(T_1)/k_{\infty,rec}(T_2)]/(T_1^{-1} - T_2^{-1})$.
[d]1.07(12) = 1.07×10^{12}.

by the collisional energy transfer (and non-equilibrium effects) of the reactant; rather, it is related to the $k(E)$ function which depends on the reactant potential surface. The present calculation assumes a purely repulsive rather than attractive triplet state potential and comparison with experimental data should throw further light on this point.

The high-pressure decomposition rate has been measured by Olschewski *et al.* (49) to be

$$k_{\infty,expt} = 2.5 \times 10^{11} \exp(-110/RT)\ s^{-1} \quad (2800\text{–}3700\ K)$$

and by Wagner and Zabel (50) to be

$$k_{\infty,expt} = 9.0 \times 10^{12} \exp(-129.7/RT)\ s^{-1} \quad (3000\text{–}3700\ K)$$

The two experiments are in good mutual agreement, despite the apparently large discrepancy between the two activation energies. Figure 5 compares these data with the calculated rates, and Table 3 lists the Arrhenius parameters A_∞ and E_∞ for the reaction from 6000 to 200 K. As discussed in Section III, a symmetry number of two has been incorporated into the calculation of $k(E)$ to take into account the symmetry of the potential surface. The good accord between the theoretical and experimental activation energies indicates that a purely repulsive triplet state is not inconsistent with experimental observations at high temperature and pressure. Notice that the variation of the activation energy with temperature is more moderate in this reaction (than in the N_2O reaction), being 5% between 200 and 6000 K and 1% in the experimental temperature range of 2000–4000 K. This smaller variation here is attributed to the less drastic variation of the $k(E)$ function with energy near the reaction threshold (cf. Fig. 3).

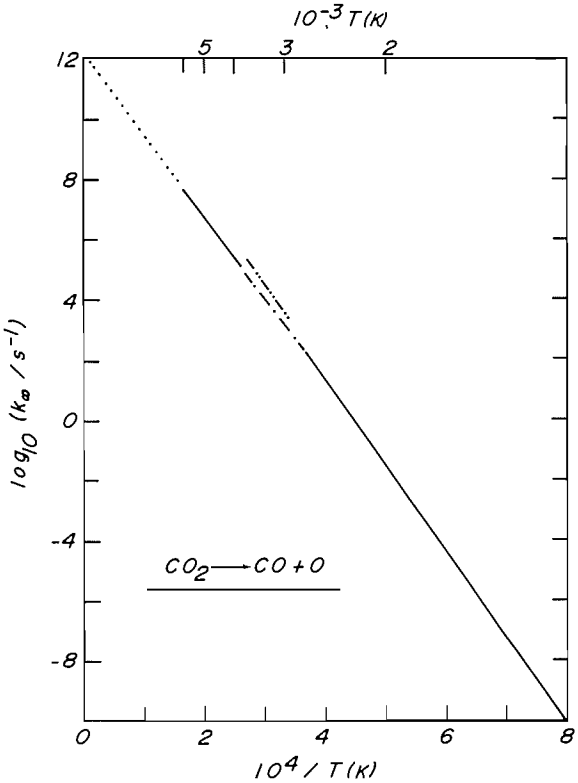

FIG. 5. Arrhenius plot for the infinite-pressure rate constant for the dissociation of CO_2. Experiments: ·····, Olschewski *et al.* (49); –·–·–, Wagner and Zabel (50). Theory: —, eq. [27]; · · ·, Arrhenius rate law with $A_{\infty,calcd} = 1.80 \times 10^{12}\ s^{-1}$ and $E_{\infty,calcd} = 127.3$ kcal/mol. The theoretical (solid) curve overlaps with the experimental (dash-dot) curve of Olschewski *et al.* (49).

Likewise, the pre-exponential factor varies only moderately, by about a factor of two between 1000 and 6000 K. Also, the dramatic drop at low temperature in N_2O is absent here. Again, the calculated

rates are well approximated by a strict Arrhenius rate expression, with $A_{\infty,\text{calcd}} = 1.80 \times 10^{12}\ \text{s}^{-1}$ and $E_{\infty,\text{calcd}} = 127.3$ kcal/mol.

C. CO_2 Recombination

The room temperature recombination rate of CO and O in the second order region has been determined on two occasions. Gaedtke *et al.* (51) studied the photolysis of NO_2 in the presence of CO and obtained an upper limit of 3×10^8 cm^3/mol s for the recombination rate coefficient $k_{\infty,\text{rec}}$. Their value is to be compared with the work of DeMore (52), who measured the relative recombination rates of CO + O and O_2 + O, and obtained (using the O_2 + O recombination rate data of Sauer (53) and of Hippler and Troe (54)) $k_{\infty,\text{rec}} \simeq 5 \times 10^8$ cm^3/mol s. The calculation of the recombination rate coefficient k_{rec} is straightforward from eq. [27] and the rate quotient law:

$$[30] \qquad k_{\infty,\text{rec}} = k_{\infty,\text{diss}}/K_c$$

Table 3 lists the recombination rate coefficient and activation energy, as well as the equilibrium constant K_c for the reaction between 200 and 6000 K. The calculated value of 7.6×10^8 cm^3/mol s at 300 K is in satisfactory agreement with the experimental values.

The temperature dependence of the high-pressure reaction rate is of some interest, even though no experimental data yet exist. Table 3 shows that the recombination reaction has a positive activation energy at high pressure. This activation energy actually varies moderately with temperature: it increases from 0.4 kcal/mol at 250 K to 9 kcal/mol at 6000 K. Experimental studies of the activation energy for the reaction should provide a stringent test on the quality of the calculated rates.

Appendix

The wavefunction $|\phi_{v_{b1}}\rangle$ is approximated by (3)

[A1] $$\phi_{v_{b1}}(r_1) \simeq N_b \,\mathrm{Ai}\,[-c_b(r_1 - r_{tb})]$$

where

$$N_b = [2\mu_1/(F_b^{1/2}\hbar^2)]^{1/3}\rho_b^{1/2}$$
$$c_b = (2\mu_1 F_b/\hbar^2)^{1/3}$$
$$F_b = -\partial V_{b1}/\partial r_1|_{r_{tb}}$$

ρ_b the state density and r_{tb} the outer turning point. Explicitly,

$$r_{tb} = \bar{r}_{\mathrm{BX},b} + \theta\bar{r}_{\mathrm{AB},b} - \alpha^{-1}\ln(1 - E_{v_{b1}}^{1/2}/D_e^{1/2})$$

$$\rho_b = \alpha[(2D_e/\mu_1)^{1/2} - (2v_{b1} + 1)\alpha/(2\mu_1)]$$

and

$$F_b = -2\alpha\, E_{v_{b1}}^{1/2}(D_e^{1/2} - E_{v_{b1}}^{1/2})$$

Likewise, the wavefunction $|\phi_{\varepsilon_{u1}}\rangle$ is approximated by

[A2] $$\phi_{\varepsilon_{u1}}(r_1) = N_u \,\mathrm{Ai}\,[-c_u(r_1 - r_{tu})]$$

where

$$N_u = [2\mu_1/(F_u^{1/2}\hbar^2)]^{1/3}$$
$$c_u = (2\mu_1 F_u/\hbar^2)^{1/3}$$
$$F_u = -\partial V_{u1}/\partial r_1|_{r_{tu}}$$

and

$$r_{tu} = \bar{r}_{\mathrm{BX},b} + \theta\bar{r}_{\mathrm{AB},u} - a^{-1}\ln(\varepsilon/\tilde{A})$$
$$F_u = b\varepsilon$$

Substitution of the respective expressions into [A1] and [A2] and integration of the two Airy functions lead to [19].

The generation of *C*-glycosides through the enolate Claisen rearrangement[1]

ROBERT E. IRELAND, CRAIG S. WILCOX, SUVIT THAISRIVONGS, AND NOEL R. VANIER
Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasedena, CA 91125, U.S.A.

Received January 25, 1979

ROBERT E. IRELAND, CRAIG S. WILCOX, SUVIT THAISRIVONGS, and NOEL R. VANIER. Can. J. Chem. **57**, 1743 (1979).

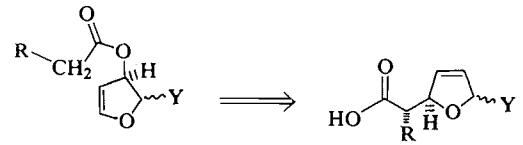
The [3,3]-sigmatropic rearrangements of silyl ketene acetals obtained from aliphatic esters of furanoid and pyranoid glycals is described. The heterocyclic γ,δ-unsaturated carboxylic acids **II** are produced in good yields. A new preparation of furanoid and pyranoid glycals is described.

ROBERT E. IRELAND, CRAIG S. WILCOX, SUVIT THAISRIVONGS et NOEL R. VANIER. Can. J. Chem. **57**, 1743 (1979).

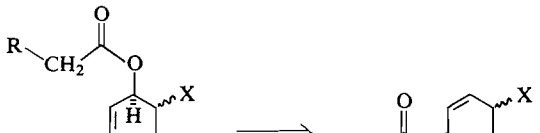
On décrit les transpositions sigmatropiques [3,3] de silylcétènes acétals obtenus à partir d'esters aliphatiques de glycals furannoïdes et pyrannoïdes. On obtient les acides carbocycliques γ,δ non saturés hétérocycliques II avec de bons rendements. On décrit une nouvelle préparation des glycals furannoïdes et pyrannoïdes.

[Traduit par le journal]

The application of the ester enolate Claisen rearrangement (1, 2) to aliphatic esters derived from β-hydroxy enol ethers was recently reported from this laboratory (3). This rearrangement provides a means for the stereoselective synthesis of either of two diasteromeric α-alkyl-β-alkoxycarboxylic acids without regard to their relative thermodynamic stabilities. Application of this procedure to furanoid and pyranoid enol ethers of type **I***a* or **I***b* provides a valuable route to oxygen heterocycles of type **II***a,b*



I*a* **II***a*



I*b* **II***b*

in which the chirality of the side chain may be preselected. Such an approach was envisioned as a key component of a convergent, general approach to the polyether class of ionophoric antibiotics, and the initial investigation that demonstrates the viability of this concept is presented here.

The preparation of the glycals **1** (Y = H), **2**, and **3***a* by an efficient new technique developed in this laboratory has already been described (4). For the synthesis of the glycal **3***b*, the lactol **6***a* (evaporative distillation 80–90°C/0.005 Torr; $[\alpha]_D^{25} = +0.9°$ (*c* 0.89, $HCCl_3$))[2] was prepared in 95% overall yield from 2,3-*O*-isopropylidene-D-(+)-ribonicacid γ-lactone by 5-*O*-methoxymethylation ($[(CH_3)_2CH]_2NC_2H_5$, CH_2Cl_2, $ClCH_2OCH_3$), and then partial reduction (DIBAL, Et_2O, −78°C). Treatment of the lactol **6***a* with CCl_4–$P(NMe_2)_3$ in tetrahydrofuran solution, and then reduction of the crude chloride with lithium in liquid ammonia (4) afforded the glycal **3***b* (evaporative distillation, 70–80°C/0.005 Torr; $[\alpha]_D^{24}$ +259° (*c* 0.91, $HCCl_3$)) in 80% overall yield,

[1]Dedicated to the memory of R. H. F. Manske.

[2]Satisfactory combustion analyses were obtained on all new substances.

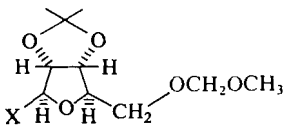
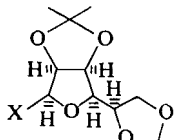
[a]Intermediate ester not isolated.
[b]Solvent employed during enolization.
[c]Ratio of diastereomers obtained as determined by nmr or gc analysis.
[d]Approximate half-life for the rearrangement of silyl ketene acetal to silyl ester at 35°C.
[e]The low stereocontrol in this experiment can be attributed to an unfavorable interaction of the intermediate ketene acetal with the dioxolane side chain.

together with 13% of the simple reduction product **6***b*.[2] The glycal **4** (evaporative distillation 70–110°C/0.06 Torr; $[\alpha]_D^{23}$ −100° (*c* 1.0, $HCCl_3$)), previously prepared in 11% yield by reduction of the bromide **7***c* with sodium sand in toluene (5), was available in 75% yield, together with a 9% yield of the bisacetonide **7***b*,[3] by lithium – liquid ammonia reduction of the chloride **7***a* (6), followed by chromatography of the reduction product on silica gel. The glycal acetate **5** was generously provided by Professor B. Fraser-Reid (University of Waterloo, Ontario).



6*a* (X = —OH)
6*b* (X = —H)



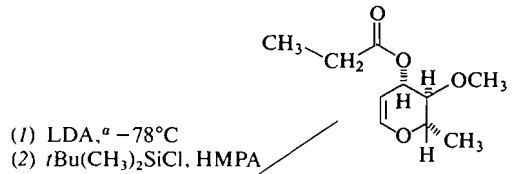
7*a* (X = —Cl)
7*b* (X = —H)
7*c* (X = —Br)

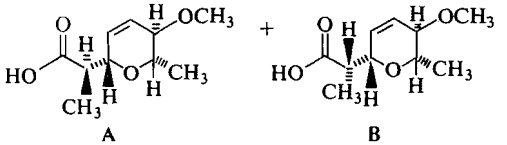
Acylation of the pyranoid glycal **1** (Y = H) with propionyl chloride and pyridine in dichloromethane solution at 0°C provided the propionate **1** (Y = $COCH_2CH_3$) (evaporative distillation 90–95°C/0.7 Torr; $[\alpha]_D^{22}$ +125° (*c* 1.1, $HCCl_3$)). Treatment of this ester under the standard conditions for ester enolate Claisen rearrangement afforded a mixture of diastereomeric acids **A** and **B** in good yield. As expected, the relative ratios of these two products was dependent upon the solvent used in the enolization step (1–3). The stereochemistry proposed for the side chain in this example and in the examples below is based upon (*i*) the control of enolate geometry previously demonstrated (2) for propionate esters and (*ii*) the assumption of a boat-like transition state for the [3,3]-sigmatropic rearrangement.

The esters derived from the pyranoid glycal **2** and especially the esters of the furanoid glycals **3***a*, **3***b*, and **4** were too unstable to allow isolation in acceptable yields. Therefore, with these substrates the technique described earlier (3) for direct acylation and rearrangement without isolation of the intermediate esters was used. Table 1 presents these results.

The enolate of the acetate **5** was best prepared with potassium hexamethyldisilazide in tetrahydrofuran at −78°C and in contrast to the ketene acetals of the monocyclic esters described above, this ketene acetal rearranged very slowly at 35°C. The half-life for the rearrangement was 8 ± 1 h at 80°C and the best yield (61%) of the rearranged product **8** (mp 95–95.5°C, $[\alpha]_D^{23}$ +67.1° (*c* 1.24, $HCCl_3$)) was obtained

[3]The production of small amounts of **6***b* and **7***b* in these reactions is in accordance with our previous experience with furanosyl chloride reductions. (See ref. 4.)





A **B**

Stereoselective routes to some unsaturated α- and β-*C*-glycopyranosides[1]

BERT FRASER-REID, ROBERT DAVID DAWE,[2] AND DEEN BHANDU TULSHIAN
Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

BERT FRASER-REID, ROBERT DAVID DAWE, and DEEN BHANDU TULSHIAN. Can. J. Chem. **57**, 1746 (1979).

4,6-*O*-Benzylidene-D-allal, **1***a*, undergoes the Eschenmoser–Claisen rearrangement giving the unsaturated α-*C*-hex-2-enopyranoside, **4** (3,7-anhydro-6,7-*O*-benzylidene-4,5-dideoxy-D-*lyxo*-oct-4-*N*,*N*-dimethyl amide) in 85% yield. The corresponding β-anomer **13***a* (methyl 3,7-anhydro-6,7-*O*-benzylidene-4,5-dideoxy-D-*ribo*-oct-4-enonate) is prepared by reductive elimination of the β-*C*-glucopyranoside **11**. The latter is obtained as the sole product from 4,6-*O*-ethylidene-D-glucose in two steps involving Wittig addition of carboxymethylene followed by cyclization of the resulting α,β-unsaturated ester under thermodynamic conditions.

BERT FRASER-REID, ROBERT DAVID DAWE et DEEN BHANDU TULSHIAN. Can. J. Chem. **57**, 1746 (1979).

Le *O*-benzylidène-4,6 D-allal, **1***a*, subit une transposition de Eschenmoser–Claisen conduisant à l'α-*C*-hexèno-2 pyrannoside insaturé, **4** (anhydro-3,7 *O*-benzylidène-6,7 didéoxy-4,5 D-*lyxo*-octéno-4 *N*,*N*-diméthylamide), avec un rendement de 85%. On a préparé l'anomère β correspondant, **13***a* (anhydro-3,7 *O*-benzylidène-6,7 didéoxy-4,5 D-*ribo*-octène-4 onate de méthyle), par une élimination réductrice du β-*C*-glucopyrannoside **11**. On a obtenu ce dernier comme seul produit, à partir du *O*-éthylidène-4,6 D-glucose, en deux étapes impliquant une addition de Wittig de carboxyméthylène suivie d'une cyclisation de l'ester α,β non saturé qui en résulte à l'aide de conditions thermodynamiques.

Tetrahydropyranoid rings bearing alkyl substituents at positions 2 and 6 are frequently encountered as components of natural products. Chiral representations of these segments are readily conceived from carbohydrate *C*-glycopyranoses, a class of compounds which are of interest in their own right in view of their relationship to the *C*-nucleosides (1). Some of the latter display pronounced antitumor and antiviral activity (2) but in all of these instances the sugar rings are furanoid and synthetic developments reflect this circumstance (1*a*, 3–7). Thus *C*-glycofuranoses bearing the C-1 and C-4 substituents in either *cis* or *trans* relationship may be prepared with a high degree of stereoselectivity (7). However the same does not hold for the pyranose analogues (8–10), routes to the 1,5-*trans*- (e.g. α-D) *C*-glycopyranoses being particularly elusive (11). The latter are required by us for certain synthetic projects and in the course of our investigations we have developed stereospecific routes to both α-D- and β-D-*C*-glycopyranoses. We report on these studies in this communication.

The most incontrovertible approach to the desired α-*C*-glycoside envisages a Claisen rearrangement[3] on the glycal **1***a* (12) (Scheme 1). Attempts to apply the classical procedure to the vinyl ether **1***b* were plagued by incompleteness of the conversion **1***a* → **1***b* (cf. refs. 13–15), an obstacle which made it unacceptable for our purposes.[4] Of the recently modified versions of the Claisen rearrangement, the Johnson process is experimentally the simplest but when applied to **1***a* a quantitative 1:1 mixture of the propionate esters **2** and **3**[5] was obtained. On the other hand, the Eschenmoser modification (17) was found to afford an 85% yield of the amide **4**.[6,7] The Ireland variation as applied to the propionate of **1***c* is described in the adjoining communication (18).

With regard to a functionalized one-carbon substituent at the anomeric centre, the [2,3]-sigmatropic rearrangement developed recently by Still and Mitra (19) seemed promising particularly since the intermediate stanylmethyl ether **5***a* could be prepared in 80% yield. Unfortunately metalation of **5***a* (−78°C → room temperature, 12 h) afforded only 25% yields of

the Eschenmoser–Claisen product **4**. In the ^{13}Cmr spectra, carbon-5 of **4** was found to resonate at 65.824 ppm while with the new alkene, the signal occurred at 70.912 ppm. This trend, in accordance with the γ-effect (22), indicated β-D-orientation for the alkene **13***a*[6,8] and pointed to **11** as the product of the Wittig–Michael sequence.

However, to eliminate the possibility that epimerisation at carbon-1 was occurring during the reductive elimination of **11** to give **13**, it was decided to monitor the ring closure of **9** by a technique more discriminating than tlc. Since *C*-glycopyranosides usually obey Hudson's rule of isorotation[9] (8*a*, 10, 11, 20) polarimetry was the technique of choice and our study is recorded in Fig. 1. The substance at equilibrium, isolated in 70% yield, and examined by 220 MHz ^{1}Hmr, was entirely consistent with the pure β-D-ester **11**.[5] On the other hand, the substance at maximum rotation was isolated in 80% yield as an inseparable 1:1 mixture of **10** and **11**.

In an attempt to bias the cyclization in favour of the α-*C*-glycoside, compound **9** was treated with an aqueous solution of imidazole. Our objective was in fact realized since the product proved to be a 3:2 mixture of the β-ester **11** and the α-lactone **12**. On the other hand the stability of the β-D-anomer could be gauged by the fact that the optical rotation of a solution of **13***a* in potassium hydroxide remained constant over a 5-h period. Consistent with this observation, the product isolated in quantitative yield was the carboxylic acid **13***b*.[6]

[8]Methyl 3,7-anhydro-6,7-*O*-benzylidene-4,5-dideoxy-D-*ribo*-oct-4-enonate.

[9]Briefly, the rule states that the α-D-anomer is more dextrorotatory than the corresponding β-D-anomer.

C. E. DOIRON, F. GREIN, T. B. MCMAHON, and K. VASUDEVAN. Can. J. Chem. **57**, 1751, (1979).

The gas phase ion–molecule reactions and proton affinity of borazine have been investigated by both theoretical *ab initio* and ion cyclotron resonance techniques. The experimental proton affinity has been determined from competitive proton transfer equilibria with standard reference bases and found to be 196.4 ± 0.2 kcal/mol. Ion–molecule reaction schemes for reaction of borazine molecular ions have been proposed. *Ab initio* calculations find the proton affinity of borazine to be 203.4 kcal/mol and the most energetically favorable structure of the borazinium ion is one in which very little structural change occurs relative to neutral borazine with the exception of the geometry about the protonated nitrogen atom. Charge distributions and bond lengths are used to explain bonding changes upon protonation.

C. E. DOIRON, F. GREIN, T. B. MCMAHON et K. VASUDEVAN. Can. J. Chem. **57**, 1751 (1979).

On a étudié les réactions ion–molécule en phase gazeuse et l'affinité protonique du borazine par des calculs théoriques *ab initio* et des techniques de résonance ionique dans des cyclotrons. On a déterminé l'affinité protonique expérimentale à partir d'équilibres compétitifs de transferts de proton avec des bases de référence et on l'évalue à 196.4 ± 0.2 kcal/mol. On propose des schémas de réaction ion–molécule pour la réaction d'ions moléculaires du borazine. Par calculs *ab initio*, on trouve que l'affinité protonique du borazine est de 203.4 kcal/mol et on trouve que la structure de l'ion borazinium qui est la plus favorisée sur une base énergétique est celle dans laquelle il ne se produit que de faibles changements structuraux par rapport au borazine neutre à l'exception de la géométrie autour de l'atome d'azote protoné. On utilise les distributions de charge et les longueurs de liaisons pour expliquer les changements de liaison lors de la protonation.

[Traduit par le journal]

Introduction

The similarity of borazine in structure and physical properties to its important organic analogue, benzene, has engendered considerable experimental and theoretical interest in the electronic structure of this boron–nitrogen heterocycle (1–14). Since protonated benzenes and borazines are frequently implicated in reactions in acidic media (15) and under radiolysis conditions (16) an accurate determination of the energetics and structure of these species becomes highly desirable. A knowledge of geometry changes which occur upon protonation provides valuable clues to the mechanisms of reactions of protonated species and offers insight into the nature of bonding in both neutral and protonated molecules.

Very recently highly accurate determinations of the proton affinity of benzene have been made by both high pressure mass spectrometry (17) and ion cyclotron resonance spectroscopy (18). In addition Hehre and Pople have carried out *ab initio* calculations to examine the energetics and geometry of protonated benzene (19). The agreement between theoretically calculated and experimentally determined proton affinities is found to be very good and the optimized geometry is in good agreement with spectroscopic, nmr, and X-ray crystallographic studies of other protonated benzenoid aromatics (20).

Study of the gas phase protonation of borazine has been considerably less extensive, however. Porter has conducted several photo-ionization high pressure

0008-4042/79/141751-07$01.00/0

mass spectrometric studies of borazine and substituted borazines and suggested limits for the proton affinity of borazine of 203 ± 7 kcal/mol. Semi-empirical CNDO calculations (11) to determine the approximate structure of protonated borazine were also carried out leading to the conclusion that the most favorable site of protonation is either at nitrogen or above the boron–nitrogen bond at a point near the nitrogen atom. No experimental determination of the structure of protonated borazine is available for comparison.

In the present work we wish to report an accurate determination of the proton affinity of borazine using the ion cyclotron resonance (ICR) trapped-ion equilibrium technique (22, 23). In addition several ion–molecule reactions of borazine ions with borazine and other molecules are reported. In conjunction with the experimental work an *ab initio* study of the energetics and structure of protonated borazine has also been done. The experimental and theoretical results have been found to be complementary, giving proton affinity values in good agreement.

Experimental

The ion cyclotron resonance spectrometer used in the present work was of basic Varian design but extensively modified to permit trapped-ion experiments according to the method of McMahon and Beauchamp (24). Switching of cell voltages from trapping to detect modes was accomplished using timing circuitry similar to that described previously (25), interfaced to an analog dual DPST switch (26). The transient output of the marginal oscillator was amplified with a PAR Model 113 Low Noise Pre Amp and this signal subsequently integrated using a PAR Model CW-1 Boxcar Integrator (26). All other techniques of ICR used were identical to those described in detail elsewhere. Pressures were monitored by ion pump current and ionization gauge readings calibrated against a MKS Model 170 M Baratron Capacitance Manometer.

Borazine was synthesized according to the method of Hohnstedt and Haworth (27) by reaction of B-trichloroborazine (Alfa Inorganics) with sodium borohydride in triethylene glycol dimethyl ether solvent at 0°C. Impurities of diborane and hydrogen were removed by flowing the gaseous products of reaction through a series of cold traps of decreasing temperature. The final borazine product was routinely degassed by several freeze, pump, thaw cycles before use.

Ammonia was obtained from Matheson of Canada, Ltd. All other chemicals from commercial sources were reagent grade purity and were used without further purification.

All equilibrium constant and rate constant determinations are the average of at least three independent determinations. In the case of proton affinity experiments relative pressures of borazine and reference bases were varied by at least a factor of 10.

Quantum Mechanical Method

Ab initio molecular orbital calculations were carried out on borazine and protonated borazine using the Gaussian 70 (27) program system on the UNB IBM 370/158 computer. Geometry optimizations were performed with the STO-3G basis set while final total energies and proton affinity values were determined from the 4-31G basis.

Results

(a) Experimental

At 12 eV electron energy the only ion observed in the low pressure borazine mass spectrum is the borazine molecule ion. The observed intensities of *m/e* 78–81 in the low pressure ICR spectrum are in excellent agreement with those calculated from the natural abundances of boron isotopes for a species containing three boron atoms. The variation of relative ionic abundances with time in pure borazine at 12 eV and 1.0×10^{-6} Torr is shown in Fig. 1. The only ion–molecule reaction products observed are protonated borazine (reaction [1]) and a dimer species containing six borons and six nitrogens (reaction [2]).

[1] $B_3N_3H_6^+ + B_3N_3H_6 \rightarrow B_3N_3H_7^+ + B_3N_3H_5$

[2] $B_3N_3H_6^+ + B_3N_3H_6 \rightarrow B_6N_6H_{11}^+ + H$

[3] $B_6N_6H_{11}^+ + B_3N_3H_6 \rightarrow B_3N_3H_7^+ + B_6N_6H_{10}$

The dimeric species, $B_6N_6H_{11}^+$, is observed to subsequently react via proton transfer (reaction [3]) to

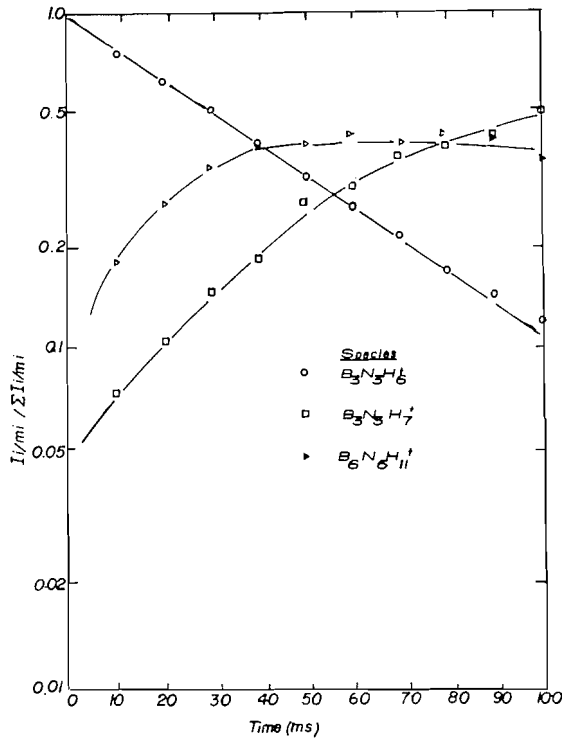

FIG. 1. Variation of relative ionic abundances with reaction time in borazine at 1.6×10^{-6} Torr and an electron energy of 12 eV.

produce the borazinium ion. The identity of $B_6N_6H_{11}^+$ was confirmed by the correct distribution of intensities in the mass range *m/e* 155–161 for a species containing six boron atoms.

Porter has previously suggested that $B_6N_6H_{11}^+$ results exclusively from reaction of protonated borazine (reaction [4]). However, the fact that the

[4] $$B_3N_3H_7^+ + B_3N_3H_6 \rightarrow B_6N_6H_{11}^+ + H_2$$

$B_6N_6H_{11}^+$ abundance is greater than that of $B_3N_3H_{11}^+$ at short reaction times in the present study and at low pressures in Porter's study preclude this possibility. In addition, in proton affinity experiments where the borazinium ion was produced in the absence of the borazine molecule ion no dimeric $B_6N_6H_{11}^+$ was observed.

The rate constants for reactions [1] and [2] obtained from the overall rate of disappearance of $B_3N_3H_6^+$ and the ratio of $B_3N_3H_7^+$ to $B_6N_6H_{11}^+$ at short times are $k_1 = 1.2 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} and $k_2 = 3.0 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. The overall disappearance rate constant for $B_3N_3H_6^+$ is in poor agreement with Porter's value of 1.3×10^{-9} cm^3 molecule^{-1} s^{-1}.

The proton affinity of borazine was experimentally determined using a series of bimolecular proton transfer equilibria (17, 18). Porter previously assigned a proton affinity of 203 ± 7 kcal/mol to borazine based on occurrence of proton transfer from $B_3N_3H_7^+$ to ammonia and failure to observe proton transfer to 2-butyne (21). Initial ICR trapped-ion experiments involving borazine–ammonia mixtures revealed the proton affinity of borazine to be sufficiently less than that of ammonia to prevent establishment of equilibrium. Reaction [5] was observed to occur which is analogous to reaction [2] for the pure borazine system.

[5] $$NH_3^+ + B_3N_3H_6 \rightarrow B_3N_3H_6{-}NH_2^+ + H$$

Mixtures of borazine and compounds of successively lower proton affinity were examined until bases were found for which equilibrium could be attained. The variation of intensities of protonated borazine and a protonated ethyl formate with reaction time is shown in Fig. 2 and that for protonated borazine and protonated 1,4-dioxane is shown in Fig. 3. The equilibrium constant data and thermochemical information derived are summarized in Table 1. The results obtained for the two proton transfer equilibria show excellent agreement, allowing an assignment of 196.4 ± 0.2 kcal/mol for the proton affinity of borazine.[1] The heat of formation of the borazinium

[1]The proton affinity scale summarized in ref. 28 has been used, corrected to a proton affinity for ammonia of 207 kcal/mol.

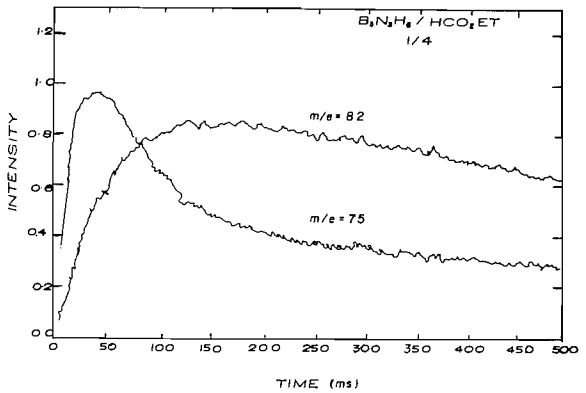

FIG. 2. Experimental temporal variation of intensities of protonated ethyl formate and protonated borazine ions in a 4:1 borazine:ethyl formate mixture at a total pressure of 2.6×10^{-6} Torr and an electron energy of 70 eV.

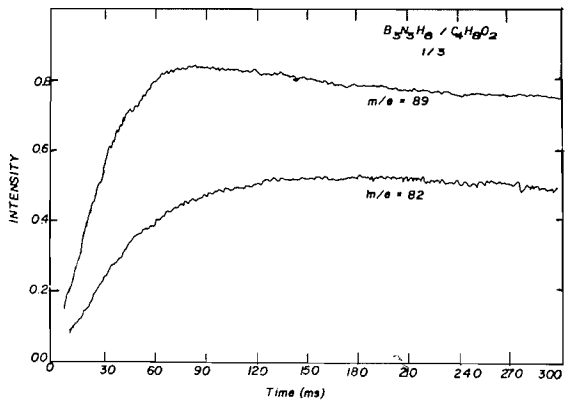

FIG. 3. Experimental temporal variation of intensities of protonated dioxane and protonated borazine in a 3:1 borazine:dioxane mixture at a total pressure of 2.0×10^{-6} Torr and an electron energy of 70 eV.

cation may then be calculated as 46 ± 3 kcal/mol using $\Delta H_f^0(B_3N_3H_6) = -124 \pm 3$ kcal/mol.

(b) Theoretical

A preliminary CNDO study of protonated borazine established the most energetically favorable site of protonation as a nitrogen lone pair rather than face protonation of the ring or B—N bond protonation. A more detailed study of the geometry of the protonated species was then undertaken by *ab initio* molecular orbital calculations using a STO-3G basis set. For protonated borazine two separate approaches to the geometry optimization were used. The first of these, resulting in structure I, was modelled on the study of Hehre and Pople (19), in which the geometry of the ring other than about the protonated site is held fixed while the distance from the center of the ring to N_1 is varied. Varying this distance causes a simultaneous change in the N_1B_2 and N_1B_6 dis-

TABLE 1. Equilibrium and thermodynamic data relevant to the proton affinity of borazine

Reaction	K_{eq}[a]	ΔG^0 (kcal/mol)	ΔS^{0}[b] (cal/K)	ΔH^0 (kcal/mol)	PA(borazine)[c] (kcal/mol)

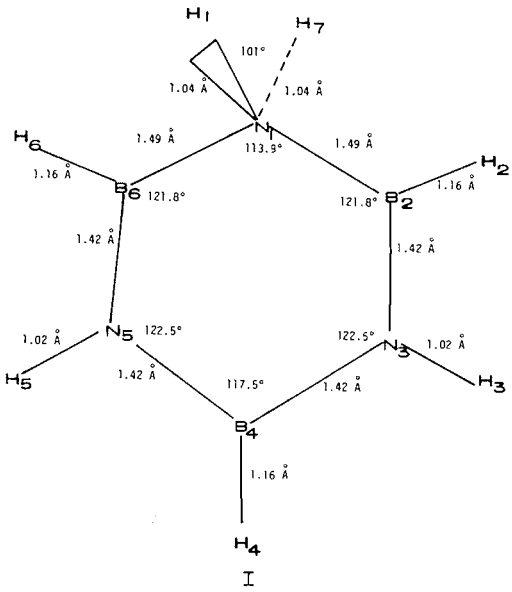
$c(C_4H_8O_2)H^+ + B_3N_6H_6 \rightleftharpoons B_3N_3H_7^+ + cC_4H_8O_2$	3.3	−0.7	0.8	−0.5	196.5

[a]Average of at least three independent determinations.
[b]Entropy changes are estimated simply on the basis of changes in symmetry of products and reactants.
[c]All data relative to $PA(NH_3) = 207$ kcal/mol.[1] Relative proton affinities of reference bases are well established by work of Yamdagni and Kebarle (17) and Wolf *et al.* (18).

tances and the $N_5B_6N_1$, $B_6N_1B_2$, and $N_1B_2N_3$ bond angles. In addition the H_7N_1 and H_1N_1 bond distances and $H_1N_1H_7$ bond angles were then optimized.



I

A second more complete geometry optimization was also carried out in which the structure of the entire ring system is relaxed. Beginning with a ring geometry identical to that of neutral borazine and N_1H_1 and N_1H_7 bond distances and an $H_1N_1H_7$ bond angle equal to those of structure I the final geometry shown in structure II was arrived at by the sequence of coordinate variations described below.

1. Optimize all N—H and B—H bond distances and the $N_1N_1H_7$ bond angle.

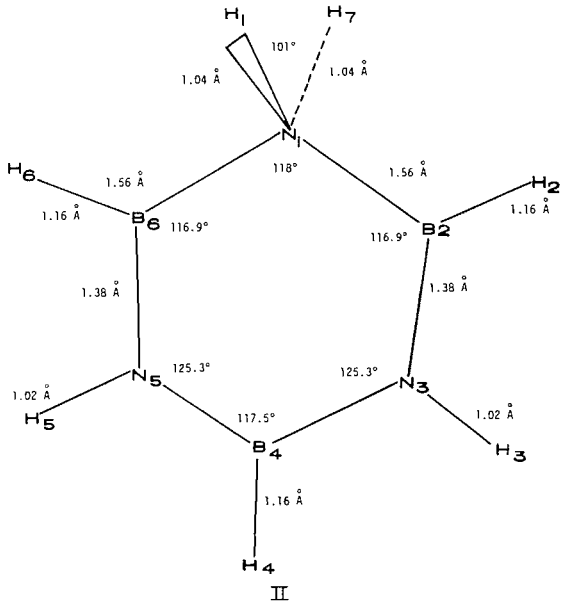
2. Optimize the B_6N_1 and B_2N_1 bond distances while holding the N_3, B_4, and N_5 coordinates fixed. As this variation takes place the $N_5B_6N_1$, $N_1B_2N_3$, $B_2N_3B_4$, and $B_6N_5B_4$ bond angles also vary.

3. Optimize the B_2N_3 and B_6N_5 bond distances while holding the $N_5B_4N_3$ angle fixed. During this optimization the $B_2N_3B_4$, $B_6N_5B_4$, $N_1B_2N_3$, and $N_1B_6N_5$ bond angles vary.

4. Optimize the B_4N_5 and N_3B_4 bond distances holding the $N_5B_4N_3$ angle fixed. The same four ring angles again vary.

5. Optimize the $B_6N_1B_2$ bond angle by moving N_1 along the ring C_2 axis holding the N_1B_6 and N_1B_2 distances fixed. The same four ring angles again vary.

6. Optimize the $N_5B_4N_3$ bond angle by moving B_4 along the ring C_2 axis. The same four ring angles again vary.



II

Effects of ring puckering were separately examined by moving N_1 out of the ring plane. All such structures led to an increase in total energy.

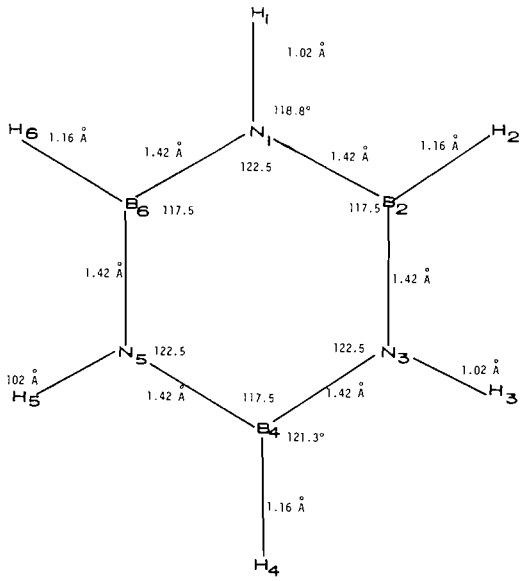
In addition to the borazinium ion the geometry of the neutral borazine molecule was also optimized. Experimental studies (29) and previous semi-empirical calculations (30) support a structure of D_{3h} symmetry with unequal BNB and NBN angles. The STO-3G optimization of BN bond distances, NBN and BNB bond angles, and NH and BH bond distances lead to structure III.

Proton affinities for borazine were calculated by taking the differences in STO-3G total energies of structures II and III and I and III. In addition calculations using the 4-31G basis were also carried out on I, II, and III and the corresponding proton affinities also calculated. Total energies and derived proton

TABLE 2. Total energies of borazine and borazinium ions

Species	Total energy (au)		Proton affinity (kcal/mol)	
	STO-3G	4-31G	STO-3G	4-31G
$B_3N_3H_7^+$ (I)	−238.521493	−241.127126	234.3	193.9
$B_3N_3H_7^+$ (II)	−238.545125	−241.14225	249.0	203.4
$B_3N_3H_6$ (III)	−238.147696	−240.818175		

affinities are summarized in Table 2. These data show a significant lowering of the proton affinity using the 4-31G basis and also reveal structure II as the more stable borazinium ion.



III

Changes in charge density for protonation of borazine may be seen from the Mulliken population analyses for II and III shown in Table 3. Most evident from these total electron population analyses is the rather small change in charge density at individual atoms with total loss of 0.05 to 0.1 electron occurring at each site. More dramatic, however, is the

TABLE 3. STO-3G total atom charges

B_4	−0.393	−0.285

shift in π electron density which may be seen from the comparison of ring π charges summarized in Table 4. The large increase in positive charge at N_1 due to donation of the lone pair to the approaching proton is accompanied by a decrease in π electron density throughout the ring giving rise to the several bond length changes described below.

Discussion

The magnitude of the proton affinity of borazine is of interest relative to that for other amino compounds. Unlike ordinary alkyl amines the nitrogen lone pair in borazine participates in partial π bond formation with the adjacent electron deficient borons. From the π ring charges given by the Mulliken population analysis donation of approximately 0.4 electron from a nitrogen lone pair to an empty boron $2p$ orbital occurs. This partial π bond formation thus lowers the availability of the nitrogen lone pair for coordination with the approaching proton and upon protonation the partial π bond is broken. This thus results in an overall lowering of the proton affinity of borazine relative to ammonia. Also, as a consequence of the electron deficient nature of boron, the borons in the ring system may be expected to exert an electron withdrawing inductive effect thus destabilizing the positive charge center. Inductive effects of boron substituents have not been extensively characterized to date for comparison purposes. In this light the borazine proton affinity of 196.4 kcal/mol is quite reasonable compared to an ammonia proton affinity of 207 kcal/mol.[1]

Bond lengths obtained for the borazinium ion are quite similar to those found in analogous boron–nitrogen compounds. For example the N_1B_2 and N_1B_6 bond distances of 1.56 Å are quite close to those of other boron–nitrogen single bonds such as

in $B_2H_5NH_2$ (1.56 Å) (31) and $B_2H_5N(CH_3)_2$ (1.54 Å) (32). They are also seen to be slightly shorter than bond lengths representative of boron–nitrogen coordination compounds such as $(CH_3)_3NBH_3$ (1.64 Å) (33), $NH_3B(CH_3)_3$ (1.61 Å) (30), and NH_3BH_3 (1.59 Å) (30) and somewhat longer than B—N bond lengths where partial π bond formation may occur such as $B_3N_3H_6$ (1.44 Å) (9); $B(N(CH_3)_2)_3$ (1.45 Å) (30); $(CH_3)_2NB(CH_3)_2$ (1.42 Å) (30). The slight decrease in B_2N_3 and B_6N_5 bond distances in the borazinium ion (1.38 Å relative to 1.42 Å) is a reflection of the increased electron demand of B_2 and B_6 caused by the protonation of N_1 which increases π electron density in these two B—N bonds relative to neutral borazine. Similarly the slight increase in the N_3B_4 and N_5B_4 distances is caused by the overall shift in electron density toward N_1 to compensate for the effect of addition of the positively charged proton.

The ring bond angles are observed to remain relatively invariant upon protonation, with the largest changes being the $B_6N_1B_2$ angle which contracts by 4.5° and the $B_2N_3B_4$ and $B_6N_5B_4$ angles which expand by 2.8°. All of the remaining ring angles change by less than 1° from their corresponding values in the neutral borazine molecule. Hehre and Pople (19) have found that upon protonation of benzene the benzenium ion achieves a nearly tetrahedral geometry at the protonated site, although only an incomplete geometry optimization was carried out. Similarly in borazine it might be expected that the protonated nitrogen of the borazinium ion would achieve a tetrahedral geometry analogously to ammonium ions. This expectation is not borne out as can be seen from the final borazinium ion geometry which bears close resemblance to the borazine structure (9). This rigidity of the ring structure is due to the π system which maintains the ring structure close to its most energetically favored geometry for sp^2 nitrogen and boron atoms.

This argument leads to the suggestion that a complete geometry optimization for benzene might yield a more energetically favorable structure with less drastic changes in ring angles. This possibility is currently under investigation by us.

Conclusions

We have determined the proton affinity of borazine both by experimental and theoretical *ab initio* techniques and found the two methods to be in good agreement. In addition, the theoretical calculations have provided a geometry for the borazinium ion which is not available from any previous experimental determination. The proton affinity values for borazine and calculated geometry of the borazinium ion are seen to be reasonable when compared to analogous data for model compounds. Studies such as the present one in which both experimental gas phase measurements and *ab initio* calculations are used to provide complementary data for ionic systems can thus be seen to be a valuable means for providing energetic and structural information for chemically interesting species. Further studies of this nature are currently in progress in these laboratories.

Partial deconvolution of the absorption spectrum of trapped electrons in 15 *M* LiCl aqueous glasses at 77 K

TUAN QUOC NGUYEN

Chemistry Department, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 6, 1978

TUAN QUOC NGUYEN. Can. J. Chem. 57, 1758 (1979).

Evidence is presented for the composite nature of the solvated (or trapped) electron absorption band in LiCl aqueous glass at 77 K. It is shown that the overall visible absorption spectrum can be deconvoluted into a homogeneously-bleachable 'green' band and a heterogeneously-bleachable 'red' band, whose relative magnitude and absorption band-maxima change with the concentration of electrolyte. From the combined results of time-resolved and steady-state photobleaching experiments, it is concluded that at least two unstable bands are formed during photobleaching (with smaller lifetimes for the band lying further towards the infrared) which then reconverted into the 'green' band with over 40% efficiency.

TUAN QUOC NGUYEN. Can. J. Chem. 57, 1758 (1979).

Les résultats montrent que le spectre d'absorption de l'électron solvaté (ou piégé) dans les verres aqueux contenant du LiCl à 77 K est la résultante de plusieurs bandes d'absorption distinctes. Par photoblanchiment fractionné, il a été possible de déconvolutionner partiellement cette bande d'absorption en deux composants: une bande "verte" qui se comporte de manière homogène sous photoblanchiment, et une bande "rouge" non-homogène. Le rapport des intensités et la position de chacun des deux pics d'absorption changent avec la concentration en électrolyte. Les résultats obtenus par photoblanchiment résolu dans le temps et ceux par photoblanchiment stationnaire ont permis de conclure qu'au moins deux bandes instables sont ainsi formées par photoblanchiment (avec une durée de vie d'autant plus courte que leur absorption se trouve loin dans l'infrarouge), qui se retransforment ensuite en bande "verte" avec un rendement supérieur à 40%.

Introduction

It seems to be well documented that the optical absorption spectrum of the equilibrated solvated electron (e_{vis}^-) in aqueous glasses at 77 K is the result of overlapping of narrower bands, each of which may originate from a distinct species of electron traps (1–4). The problem remains unsettled, however, whether there is a continuous distribution of substructures or only a small number of discrete overlapping bands contributing to the overall absorption band (5, 6). A related question concerns itself with how much narrower is each individual band than the overall band (7, 8).

Many of the conclusions reached so far rely solely upon the results of steady-state bleaching (2, 9) and this has been shown to introduce ambiguities (10). In the hope of resolving these issues more conclusively, both steady-state and time-resolved photobleaching experiments have been conducted on the same system, and this is the topic of this paper.

Frozen aqueous LiCl glass was chosen as the medium for this study because its radiation chemistry has been thoroughly investigated (11), it accommodates the infrared-absorbing electron state (e_{ir}^-) (12, 13), a range of electrolyte concentrations can be used (10, 12), and its steady-state (14) and time-resolved (10, 15) bleaching has been examined previously.

Experimental

The experimental set-up for time-resolved photobleaching experiments is a modified version of the one used previously (10, 13) and is indicated in Fig. 1. One particular improvement is the use of a metallic Dewar (D) provided with four Suprasil windows. The liquid nitrogen is contained in a separate compartment in good thermal contact with the sample but without interfering with the optical path. This solves the problem of bubbling and the consequent scattering of laser light by liquid nitrogen. L_1 and L_2 are two Q-switched lasers which provide single 15 ns pulses at 530 nm and 694 nm. Optical attenuators A_1 and A_2 are used to limit the energy of the laser pulse reaching the sample, they are made from solutions of $CoSO_4$ for 530 nm and $CuSO_4$ for 694 nm laser light. W_1 is a 150 W tungsten lamp powered with a regulated power-supply (Sorensen DCR40-20A), and used conjointly with 10 nm bandwidth interference filter combinations F_1 and F_2. It was used either as a bleaching or as a monitoring light source. To get the baseline for absorbance measurements, the irradiated sample was bleached with a white light source (W_2). E_1 is a mechanical shutter employed to prevent bleaching by the monitoring light and to trigger the laser and the oscilloscope through pulse delay units (C). V is a digital voltmeter connected in parallel with the oscilloscope (O) to measure the change in absorbance during steady-state experiments. P is a photomultiplier (1P28, R213, or R446) which was replaced by an InAs photodiode for measurements in the infrared at 970 nm and 1850 nm. Various interference filters, Corning color glass cut-off filters, and neutral density filters (placed at

0008-4042/79/141758-07$01.00/0

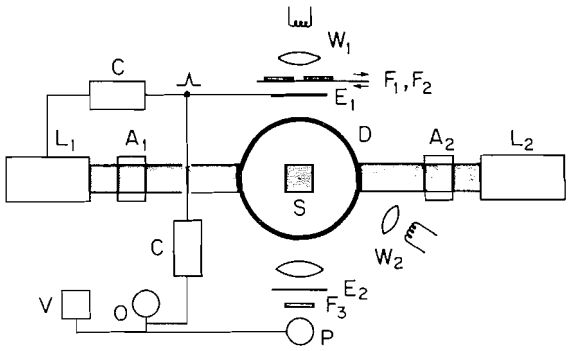

FIG. 1. Schematic representation of the apparatus used to measure the steady-state and time-resolved photobleaching. S is the sample γ-irradiated at 77 K; D the liquid N_2 Dewar vessel with four windows; L_1 and L_2, a frequency-doubled neodynium laser and a ruby laser with the corresponding light attenuators A_1 and A_2; E_1 and E_2 are mechanical shutters; F_1 to F_3 light filters; W_1 is the monitoring and bleaching light source; W_2 an auxiliary bleaching lamp; O an oscilloscope; V a digital voltmeter; P either a photomultiplier or a photodiode.

F_3) were used to block scattered laser-light, and to reduce the light level reaching the photomultiplier so that the drain current was always less than 1 mA. Even so, non-linearity corrections from a calibration curve were necessary to ensure good accuracy. To prevent fatigue of the photomultiplier during steady-state bleaching, the shutter E_2 was opened only for < 2 s during the time of the measurement.

The incident flux from the tungsten lamp was measured with a Spectra Physics power meter (Model 402B) and calibrated at 420 nm, 450 nm, and 480 nm with 0.15 *M* solutions of ferrioxalate, for which Φ_{Fe3+} was taken as 1.05 at 420 nm, 1.00 at 450 nm, and 0.94 at 480 nm (16). The incident intensity was typically 1×10^{15} to 9×10^{15} photons s^{-1} cm^{-2} depending on the wavelength. Each experiment lasted up to 30 min. For laser pulses, a Korad power meter (Model 102C) was used to determine the intensity and the number of absorbed photons. The equilibrated trapped electron state (e_t^-) was produced at the desired absorbance by γ-irradiation in the dark at 77 K at a dose-rate of 35 rad s^{-1}. The anhydrous LiCl used was of the highest purity available (99.999%) from Spex and recrystallized once from D_2O. D_2O was from Merck, Sharp and Dohme with a quoted isotopic purity of 99.7%.

Results and Discussion

Steady-state Bleaching

A γ-irradiated sample of 15 *M* $LiCl/D_2O$ glass when bleached with light at longer wavelength than the absorption band maximum (i.e. with $\lambda > 580$ nm) selectively lost the red component (the 'red' band) of its absorption spectrum. Subsequent bleaching with red light (>620 nm) did not change the position and shape of the remaining part of the absorption band which will be referred to as the 'green' band. However, when light of wavelength shorter than λ_{max} was used, the band shifted to the red, in accord with the previous findings of photoshuffling in other aqueous glasses (2, 17).

In Fig. 2, the change in absorbance due to bleaching is shown as a function of the monitoring wavelength for various extents of bleaching. This kind of plot clearly indicates the heterogeneous nature of the absorption band.

Bleaching with light at 646 nm initially removes mainly the 'red' band but also some of the 'green' band. Extended bleaching depletes the 'red' band so that only the 'green' band is available for bleaching at the end.

Bleaching with 750 nm light revealed that the 'red' band is itself a composite spectrum consisting of at least two overlapping absorbing species, as shown by the initial removal of its red edge (Fig. 2).

After the entire 'red' band and about 20% of the 'green' band were removed with light at 646 nm, the remaining 'green' band was bleached at different wavelengths and the results are given in Fig. 3. It is possible to see from this figure that if the monitoring wavelength is on the blue side of the bleaching wavelength, the observed rate of bleaching was identical to that at the bleaching wavelength itself, whereas it was always less from the red side. This behaviour can be understood if the 'red' band is reformed by photoshuffling during bleaching of the 'green' band. At any wavelength, the net observed rate of steady-state bleaching is equal to the rate of bleaching of the 'green' band minus the rate of formation of the 'red' band, where the last term itself is the difference between the rate of photoshuffling and the rate of

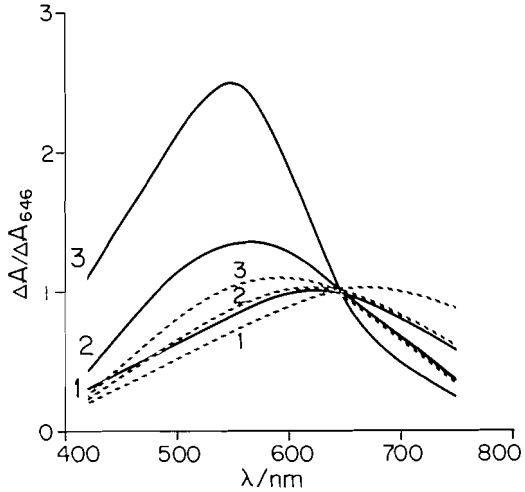

FIG. 2. Differential bleaching spectra normalized to 646 nm. The ordinates represent the loss of absorbance, normalized to the loss at 646 nm, between two different bleaching times. The dotted lines are for bleaching with 750 nm light and the full lines at 646 nm. The extent of bleaching is used as a parameter: curves (*1*) from 0–15% of bleaching, curves (*2*) from 45–55%, and curves (*3*) from 75–80%.

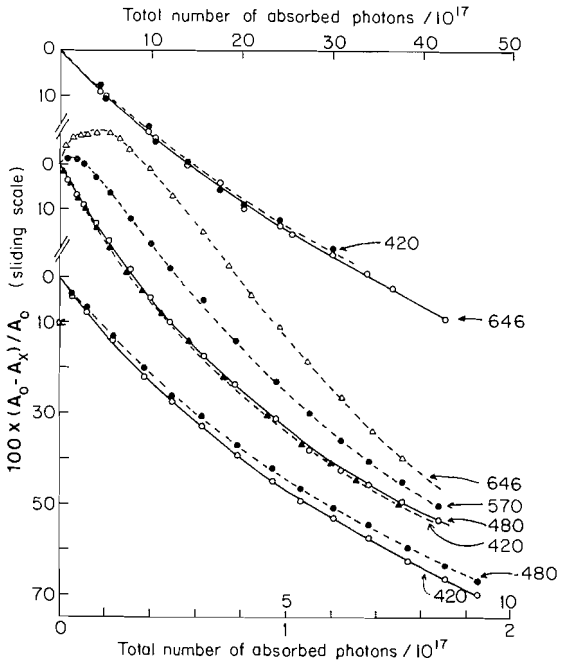

FIG. 3. Bleaching of the 'green' band as a function of accumulated number of absorbed photons. A_0: initial absorbance of the γ-irradiated sample. A_x: absorbance after the sample was bleached with x absorbed photons (x being the number on the abscissa). The monitoring wavelengths are given next to each line. The bleaching wavelength was 420 nm for the bottom two curves, 480 nm for the middle four curves, and 646 nm for the top two. A solid line is drawn when the monitoring and bleaching wavelengths are the same. The horizontal scales, starting from the bottom, refer respectively to the curves with λ_b = 420 nm, λ_b = 480 nm, and λ_b = 646 nm.

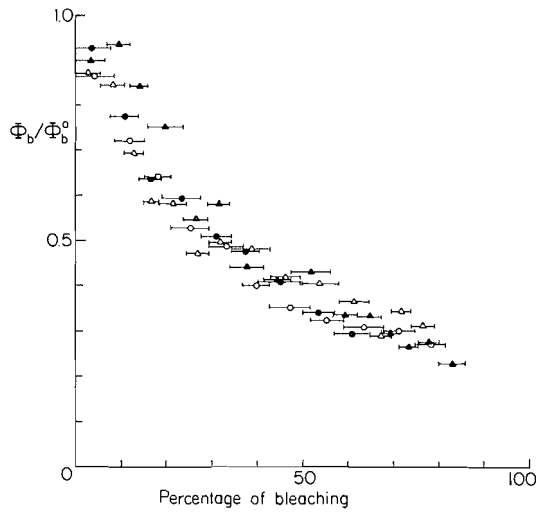

FIG. 4. Variation of the quantum yield for bleaching of the 'green' band with the extent of bleaching (Φ_b^0 is the initial value). The horizontal bars denote the range of bleaching over which the quantum yield was computed. △ is for λ_b = 420 nm, ▲ for λ_b = 450 nm, ○ for λ_b = 480 nm, and ● for λ_b = 521 nm.

bleaching of the 'red' band. With the gradual decrease in the contribution of the 'red' band when one goes towards shorter wavelengths, the rate of formation of the 'red' band relative to the rate of bleaching of the 'green' band diminishes appropriately. In any case, the rate of bleaching on the blue side of the bleaching wavelength was smaller than the rate at the bleaching wavelength itself, even when both were far apart (for example: λ_b at 646 nm and λ_m = 420 nm in Fig. 3), and this again supports the homogeneous nature of the 'green' band over more than 1 eV. If the quantum yield for bleaching is independent of the percentage of bleaching of the band, then the plots of Fig. 3 should give straight lines. Actually, the quantum yield decreases with the fraction of bleaching as observed in other aqueous glasses (2, 18) and this fact is emphasized by the use of Fig. 4 for four bleaching wavelengths, 521, 480, 450, and 420 nm. (Contrary to Fig. 3, only the 'red' band was bleached with light at 750 nm and the 'green' band remained untouched on Fig. 4.) The dependence of Φ_b on the percentage of bleaching is identical for the four wavelengths within experimental errors; this shows that the quasi-free electron (e_{qf}^-) formed has the same fate even if it may have different kinetic energy upon being released from the trap.

The dependence of Φ_b on the bleaching wavelength is depicted in Fig. 5. All the values refer to the initial quantum yield, when less than 10% of the band was bleached. (The same wavelength was used for bleaching and for monitoring the absorbance.) The most interesting feature of Fig. 5 is the sharp increase in Φ_b by going from 480 nm to 420 nm. This is common to most aqueous glasses (19, 20) except that the sharp rise occurs at shorter wavelengths and is sharper than previously reported. For example, Rice and Kevan (21) found the threshold for conductivity at ~600 nm in 10 *M* LiCl glass at 85 K, right at the maximum of the absorption band, compared to our value of ~500 nm which is 40 nm to the blue of λ_{max} for the 'green' band in 15 *M* LiCl at 77 K. This discrepancy, however, arises from the heterogeneous nature of the overall e_t^- absorption band which was not previously taken into account. (In the extreme case, if there is a broad distribution of overlapping bands, one may expect to obtain a flat or smooth curve like the one observed in 10 *M* NaOH glass (3, 21), even though each individual band may have a sharp threshold for bleaching or for photoconductivity.)

In Table 1 are reported the position of the λ_{max} and the *G* values for the overall, 'green' and 'red' band

TABLE 1. Position of the band maximum and G values for the overall, 'green' and 'red' bands in $LiCl/D_2O$ glasses at 77 K

	Overall band			'Green' band			'Red' band		
[LiCl]/M	λ_{max}/nm	G	$W_{1/2}$/eV	λ_{max}/nm	G	$W_{1/2}$/eV	λ_{max}/nm	G	$W_{1/2}$/eV
6.5	600	0.10	1.04	590	0.065	1.01	680	0.036	0.80

15	580	1.65	1.13	540	0.86	1.03	640	0.79	0.77

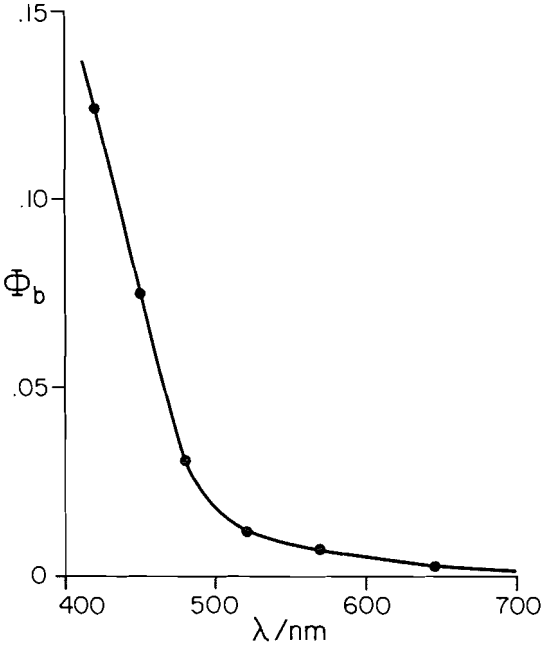

FIG. 5. Dependence of the initial quantum yield for bleaching of the 'green' band on the bleaching wavelength (the dose used was 15 krads for all samples).

(by taking $\varepsilon_{max} = 1.8 \times 10^4\ M^{-1}\ cm^{-1}$ (22) for the overall band) at different concentrations of LiCl. There is a gradual blue shift of both bands with increasing content of electrolyte as observed in the liquid state (22) and in BeF_2 glasses (23), and an enhancement of the ratio of intensities of 'red' band/'green' band which may be peculiar to LiCl glasses since this ratio was found to be constant in BeF_2 glasses (23).

Time-resolved Bleaching

The heterogeneity of the e_t^- absorption band in 15 M $LiCl/D_2O$ glass is best illustrated with pulsed-photobleaching experiments. The 'green' band has a small absorbance and a very low bleaching quantum yield at 694 nm. Therefore, only the 'red' band is bleached significantly with ruby laser light. With the doubled frequency of the Nd laser (530 nm), both bands are bleached. However, by selectively bleaching-off the 'red' band first, the 'green' band can be studied independently.

Figure 6(*a*) depicts schematically the observed behaviour of the absorbance at several monitoring wavelengths when the solvated electron band is bleached with 694 nm light. At 480 nm, after a sharp decrease immediately after the laser pulse, the absorbance is almost independent of time. The spike (during and just after the pulse) is due to luminescence stemming from e_{ir}^- (13, 24), as shown by firing the laser without the monitoring light. At 646 nm, in addition to the initial bleaching, some post-pulse bleaching occurred between 10^{-3} and 1 s, as mentioned previously by Walker and May (15). In lower concentrations of LiCl (7.5 M and 9.5 M), partial recovery of the original absorbance was observed as well (10). At 750 nm, there was a slight increase in absorbance immediately after the pulse followed by post-pulse bleaching which happened on the same time-scale as at 646 nm. At 1850 nm, some immediate increase in absorbance was observed which then decayed on a microsecond time-scale. The species responsible for the infrared absorption at >1500 nm was identified before as a second type of trapped electron (11, 13) and its yield and decay rate depend strongly on the concentration of LiCl (10, 20). The loss of absorbance at 480 nm, compared to the immediate loss at 646 nm, is entirely consistent with the 'red' band being bleached by 694 nm light and with there being no photoshuffling, even transiently, from the 'red' band to the 'green' band. By contrast, the reverse takes place readily in accord with the results of steady-state photobleaching experiments.

Figure 6(*b*) is analogous to Fig. 6(*a*), except that the bleaching wavelength is 530 nm. At 480 nm (and 570 nm), an immediate bleaching was observed followed by a post-pulse recovery. The sharp spike during the pulse was both scattered light from the laser and luminescence of the aqueous glass. When the absorbance was monitored at 646 nm, no bleaching was seen during the pulse but a post-pulse decay

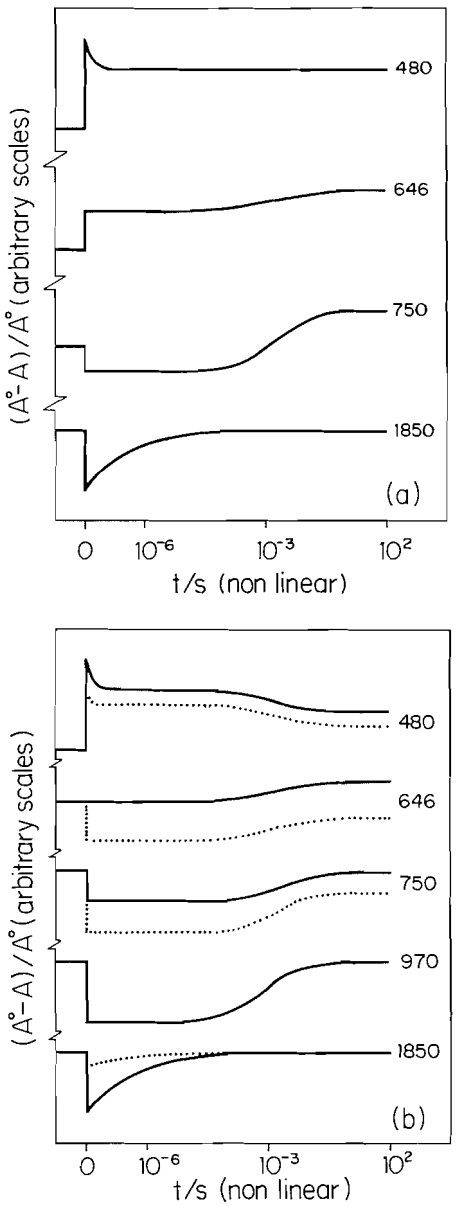

FIG. 6. Schematic representation of the approximate time scales involved for various types of bleaching observed in 15 *M* $LiCl/D_2O$ glass at different wavelengths: (*a*) is for bleaching with laser light at 694 nm and (*b*), at 530 nm. The full curves are for fresh samples, and the dotted curves for samples previously bleached with red light at 750 nm. *A* is the absorbance at times after a laser pulse and A^0 the initial absorbance.

occurred on the millisecond time-scale. In contrast, an irradiated sample pre-bleached with red light at 750 nm showed an immediate increase in absorbance. This was followed by a post-pulse bleaching which is identical to the temporal behaviour observed at 750 nm (dotted line in Fig. 6(*b*)). Pre-bleaching with red light again increased the absorbance at 750 nm without affecting the general shape of the decay.

Experimental evidence indicates the formation of unstable species during photobleaching which absorb in the near infrared, in addition to the infrared electron. This is analogous to the 'red wing' found in pulse-radiolysis (23, 25). The decay of the 'red wing' is linear over five decades of time when the absorbance is plotted against log (time) as in Fig. 7. This is in accord with a geminate tunnelling mechanism (26) for the decay of the 'red wing'. Therefore, it resembles the disappearance of e_{ir}^-, except it occurs on a much longer time-scale (initial half-life ~ 8 ms for the $e^-_{\text{red wing}}$ compared to < 1 μs for the e_{ir}^-). Moreover, the fractional decay is identical whether monitored at 646 nm or 750 nm, consistent with the possibility that it is homogeneous over this entire range of wavelengths. At 970 nm, the decay curve can be broken down into two components: one with a fast decay (5–8 μs for the half-lifetime) and accounts for 30–35% of the initial absorbance; the other 65–70% has a half-lifetime of ~ 8 ms and is identical with the decay observed at 646 nm and 750 nm. The recovery at 480 nm was also found to be

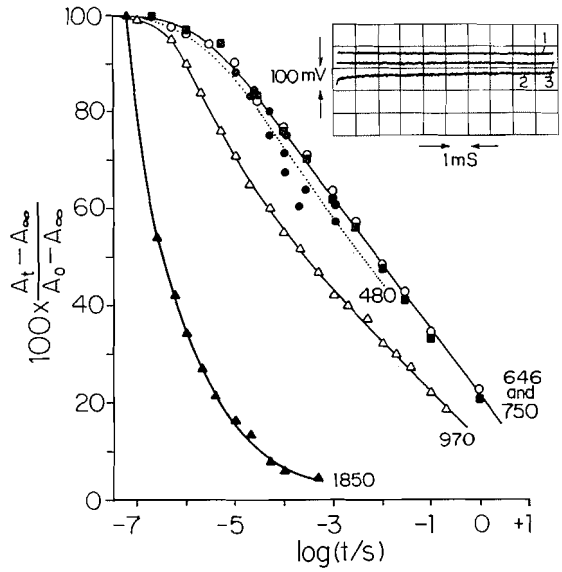

FIG. 7. Decay kinetics of the 'red wing' at 646 nm, 750 nm, and 970 nm and the recovery of the 'green' band at 480 nm on a log (time) scale, after bleaching with a 530 nm laser pulse. The decay of the 'infrared' band at 1850 nm is for the unbleached sample. Insert shows a typical oscilloscope trace as observed at 750 nm: (*1*) is the baseline, (*2*) the trace following the laser pulse, and (*3*) some 100 s later (I_0 = 1000 mV). A_0 on the ordinates is the absorbance at time zero (immediately after the pulse) limited by the response-time of the detectors used: ~ 60 ns for the InAs detector (11) and ~ 100 ns for the photomultiplier (load resistance 1 kΩ). A_∞ is the absorbance measured 100 s after the laser pulse.

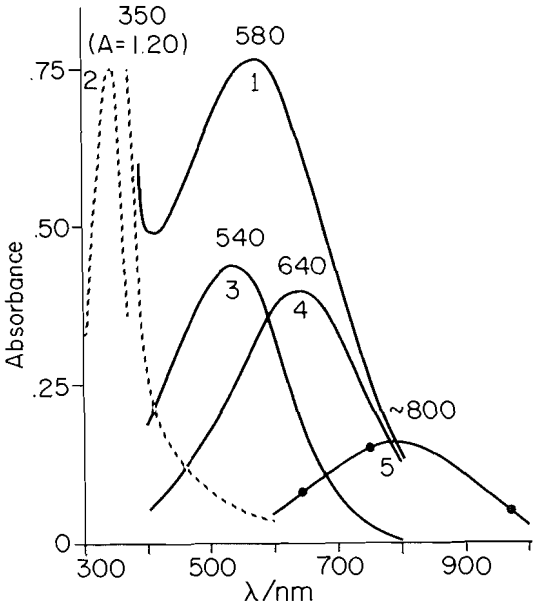

FIG. 8. Partial deconvolution of the absorption spectrum of e_{vis}^- in 15 *M* $LiCl/D_2O$ glass at 77 K into different bands: (*1*) is the overall equilibrated e_{vis}^- absorption spectrum, (*2*) the Cl_2^- band, (*3*) the 'green' band, (*4*) the 'red' band, and (*5*) the 'red wing'. The numbers indicate the position of the absorption maxima.

linear on a log (time) plot, as shown in Fig. 7 and has a half-lifetime of 2–5 ms (a precise determination is rendered difficult by the luminescence from the aqueous glass at that wavelength). The similarity between the decay rate of the 'red wing' and the recovery of absorbance at 480 nm suggests that photoshuffled electrons from the 'red wing' can tunnel back to the 'green' band. The observed recovery of the 'red' band in 7.5 *M* and 9.5 *M* LiCl glasses (10, 15) may have the same origin. If this is true, then this reversed photoshuffling provides a direct observation of a trap-to-trap tunnelling proposed previously by Buxton and Kemsley (27) (although they excluded 10 *M* LiCl glasses in their conclusions).

By comparing the amounts of bleaching and recovery, and assuming the same oscillator strength for the different bands, it is found that ~70% of the bleached electrons from the 'green' band photoshuffled to the 'red wing' and some 40–50% of the decay of the 'red wing' gave back the 'green' band; the overall recovery is one third of the initial bleaching of the 'green' band.

The shape of the 'red wing' is sketched in Fig. 8 (not on scale with the other bands), together with the Cl_2^-, the 'green' and the 'red' bands. It is obtained by plotting the absorbance due to the 'red wing' at 646, 750, and 970 nm (subtracted from the fast component at this later wavelength) and normalized for the same number of absorbed photons of the laser.

The maximum γ-irradiation dose used was 17 krads. This is far from the e_t^--saturation dose which is >100 krads for 15 *M* $LiCl/D_2O$ glass and should be of the order of several Mrads as found in high concentration alkaline glasses (28).[1] Even so, prebleaching with 750 nm light increased the amount of photoshuffling to the 'red' band by more than a factor of two, without influencing the photoshuffling to the 'red wing' (Fig. 6(*b*)). This has two important implications: (*i*) a substantial fraction of the occupied 'green' and 'red' traps are close together, probably within the same spur; (*ii*) the quasi-free electrons ejected from the 'green' trap have limited travelling distances and disappear by chemical reactions if no empty sites are immediately available for retrapping.

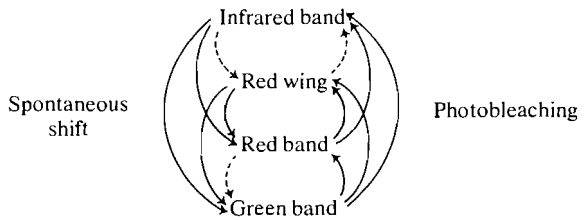
Another inference from Fig. 6(*b*) is the difference in fate of the photo-released electron, depending on if it came from the 'green' band or the 'red' band: the main process for a bleached electron from the 'green' band is photoshuffling with a very small yield for formation of the e_{ir}^-, whereas the contrary is true for an electron photobleached from the 'red' band.

Conclusions

These observations can be rationalized if the 'red' traps are closer to the positive charge than are the 'green' traps, and if photo-released electrons from the 'green' or 'red' traps have to move towards this positive charge and can only get retrapped along this path. The 'red wing' and the 'infrared' traps should be even closer to the positive hole and this may explain why these bands are unstable. This is reminiscent of the coulombic distortion model proposed by Albrecht (29). The absence of photoshuffling from 'red' to 'green' fits satisfactorily this coulombic picture as each e_{qf}^- can only move 'downhill'. Spontaneous shift from 'red' to 'green', however, is possible and indeed observed (this paper and ref. 23) if the trapped electron can tunnel to a site of lower energy or digs its own hole. In these situations it is not mobile enough to drift to a positive charge. It is worth noting at this point the recent model of ion pairs formation, proposed by Kroh and Polevoi (5), as the origin of the 'red' band in concentrated aqueous alkaline glasses. It is not clear at the present if the results from alkaline glasses can be extrapolated to other neutral aqueous glasses.

The different processes mentioned above are summarized in Scheme 1.

[1]T. Q. Nguyen and D. C. Walker. Unpublished results.



SCHEME 1

Spontaneous shifts from 'infrared' to 'red' band and/or 'red wing' are observed in BeF_2 aqueous glasses (23) but not in 15 *M* $LiCl/D_2O$ glass; also shifts from 'red wing' to 'red' band seemed to occur in low concentration LiCl glasses (10, 15). The broken arrows are processes not observed so far; however, there is no experimental evidence to exclude them. The relative importance of the different mechanisms changes, depending on which part of the spectrum one is looking at. In fact, it is possible to reproduce the five types of bleaching observed by Walker and May (15) in a variety of glasses simply by using 15 *M* $LiCl/D_2O$ and changing the monitoring wavelength (Fig. 6). The processes involved are complex and the fact that bleaching is observed at 570 nm and not at 646 nm does not necessarily imply that the absorption band is narrower than this spectral range. The 'red wing' and the 'infrared band' are not without similarity. Both can be formed either by pulse-radiolysis or by photobleaching. Both are unstable and decay with the same kinetics, albeit with more than four orders of magnitude difference in the lifetimes. There are some indications that the yield and lifetime of the 'red wing' change with the amount of electrolyte added to the glass (23) and a study of this dependence, as was done with the 'infrared band' (12, 23), should provide some insight into the nature of this trap.

Acknowledgements

I would like to thank Dr. Josh van Houten for providing the actinometry solutions and the Physics Division of the National Research Council of Canada in Ottawa for loan of the InAs detector.

I would also like to thank Professor David C. Walker for his suggestions and his contributions in effort and time to this paper which could never have been completed otherwise.

Received December 28, 1978

ROBERT J. BALAHURA and NITA A. LEWIS. Can. J. Chem. **57**, 1765 (1979).

The chromium(II) reduction of the complexes en_2Co(3-acetyl-ptdn)$^{2+}$ (**1**) and en_2Co(2-acetyl-btdn)$^{2+}$ (**2**) has been studied. Both complexes obey the rate law

$$-\mathrm{d}\ln[\mathrm{Co(III)}]/\mathrm{d}t = k[\mathrm{Cr(II)}]$$

At 25°C, $I = 1.0\ M$ ($LiClO_4$), $k = (4.5 \pm 0.2) \times 10^{-4}\ M^{-1}\ s^{-1}$, $\Delta H^{\ddagger} = 13.0 \pm 0.7$ kcal mol^{-1}, $\Delta S^{\ddagger} = -30 \pm 2$ eu for complex **1** and $k = (5.6 \pm 0.4) \times 10^{-3}\ M^{-1}\ s^{-1}$, $\Delta H^{\ddagger} = 11 \pm 1$ kcal mol^{-1}, $\Delta S^{\ddagger} = -30 \pm 4$ eu for complex **2**. Product studies indicate attack at the uncoordinated acetyl functions in both complexes. The results are compared to those obtained for reduction of en_2Co(3-formyl-ptdn)$^{2+}$ and en_2Co(ptdn)$^{2+}$ by chromium(II).

ROBERT J. BALAHURA et NITA A. LEWIS. Can. J. Chem. **57**, 1765 (1979).

On a étudié la réduction du chrome(II) des complexes en_2Co(acétyl-3 ptdn)$^{2+}$ (**1**) et en_2Co(acétyl-2 btdn)$^{2+}$ (**2**). Les lois de vitesse pour chacun des complexes sont exprimées par l'équation

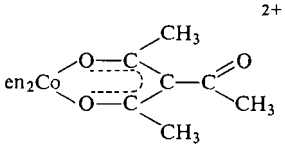
$$-\mathrm{d}\ln[\mathrm{Co(III)}]/\mathrm{d}t = k[\mathrm{Cr(II)}]$$

A 25°C $I = 1.0\ M$ ($LiClO_4$), $k = (4.5 \pm 0.2) \times 10^{-4}\ M^{-1}\ s^{-1}$, $\Delta H^{\ddagger} = 13.0 \pm 0.7$ kcal mol^{-1} et $\Delta S^{\ddagger} = -30 \pm 2$ eu pour le complexe **1** et $k = (5.6 \pm 0.4) \times 10^{-3}\ M^{-1}\ s^{-1}$, $\Delta H^{\ddagger} = 11 \pm 1$ kcal mol^{-1} et $\Delta S^{\ddagger} = -30 \pm 4$ eu pour le complexe **2**. Une étude des produits indique que l'attaque est initiée dans chacun des complexes, au niveau des fonctions acétyles qui ne sont pas coordonnées. On compare ces résultats à ceux obtenus lors de la réduction des complexes en_2Co(formyl-3 ptdn)$^{2+}$ et en_2Co(ptdn)$^{2+}$ par le chrome(II).

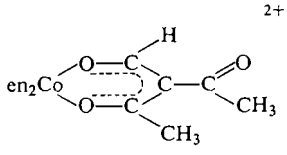
[Traduit par le journal]

Introduction

As part of our continuing studies (1) on electron transfer through the pseudo-aromatic chelate ring pentane-2,4-dione (ptdn)[3] and its analogues, we would like to report the Cr(II) reduction studies on en_2Co(3-acetyl-ptdn)$^{2+}$ (**1**) and en_2Co(2-acetyl-btdn)$^{2+}$ (**2**).[4] We have previously reported the details

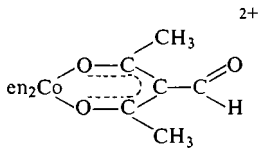


1

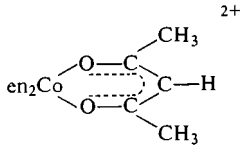


2

of the chromium(II) reduction of the linkage isomer of **2**, that is, en_2Co(3-formyl-ptdn)$^{2+}$ (**3**) (1), and of the parent compound $en_2Co(ptdn)^{2+}$ (**4**) (2). Our



3



4

interest lies in determining the effect of changes in substituent at the C-3 position of the ptdn ring on the electron transfer rate and mechanism. It was anticipated that ptdn may have unusual electron mediating ability due to its pseudo-aromatic character. Furthermore, we hoped to determine the effect of small structural changes in the chelate skeleton.

In this paper we explore the result of substitution of the acetyl function at C-3 in complex **1** and the effect of replacing the coordinated acetyl function in **1** with a formyl group in the ring skeleton in complex **2**.

Experimental

Reagents

All reagent solutions were prepared in water which was deionised, distilled, and then redistilled from alkaline perman-

ganate in an all-glass apparatus. Lithium perchlorate solutions were made as previously described (3). Chromium(II) perchlorate solutions were prepared by reduction of chromium(III) perchlorate (G. Frederick Smith Chemical Co.) in aqueous perchloric acid solution using zinc–mercury amalgam. The solutions were standardised as reported earlier (3) and were stored and handled using standard syringe techniques, in an atmosphere of high purity argon.

Complexes

The preparation of $[en_2Co(2\text{-acetyl-btdn})](PF_6)_2$ has been described (1).

Preparation of $[en_2Co(3\text{-acetyl-ptdn})](PF_6)_2$

Triethylphosphate (150 mL, BDH Chemicals Ltd.) was dried over molecular sieves before adding $NOBF_4$ (4.11 g, Alfa Products). The resulting solution was allowed to stir over molecular sieves for a further 2 h.

The complex *cis*-$[en_2Co(N_3)_2]ClO_4$ (4) (7.76 g) was added in several portions and after further stirring to allow for evolution of gases, the ligand triacetylmethane (3-acetylpentane-2,4-dione, 2.50 mL, Aldrich Chemical Company, Inc.) was introduced into the reaction mixture. The solution was stirred for two weeks at room temperature and the complex was then precipitated by adding the reaction mixture slowly to diethyl ether. The resulting precipitate was dissolved in water and ion-exchanged on Rexyn 102 (H) weak acid cation exchange resin (Fisher Scientific Co.) in the sodium ion form (5). The desired red band was physically removed from the column and was placed on a smaller column. The complex was then removed from the resin by passing a saturated solution of NaCl through the small column and the red product was precipitated by the addition of solid NH_4PF_6. *Anal.* calcd. for $[Co(C_2H_8N_2)_2(C_7H_9O_3)](PF_6)_2$: C 24.37, H 4.65, N 10.33; found: C 24.70, H 4.59, N 10.85.

Kinetic Measurements

The rate of reduction of the $[en_2Co(3\text{-acetyl-ptdn})]^{2+}$ and $[en_2Co(2\text{-acetyl-btdn})]^{2+}$ compounds was followed by observing the change in absorbance of the longest wavelength maximum of the cobalt(III) complex. The kinetic runs were performed on a Beckman Acta CIII spectrophotometer with the temperature controls described previously (6). All reactions were carried out in cylindrical cells sealed with rubber serum caps in the absence of oxygen. The reactions were run under pseudo first-order conditions (reductant in a 20–160 fold excess over oxidant).

Product Analyses

Reactions were carried out at Cr(II):Co(III) ratios between 1:1 and 4:1 and subjected to cation exchange chromatography on Dowex 50W-X8, 200 mesh resin. Elution was carried out using a standard 0.5 *M* $NaClO_4$, 0.1 *M* $HClO_4$ solution. The eluting solution was added in one-quarter strength and the concentration gradually increased as separation was achieved. Generally the 2+ ions were removed from higher charged species with the one-quarter strength solution and eluted from the column with half-strength solution. The total time spent on the ion exchange column was about 2 h. The products were characterized by their uv–visible spectra. The extinction coefficients were calculated on the basis of the chromium concentration which was determined spectrophotometrically as chromate ($\varepsilon_{372\,nm} = 4.815 \times 10^3\ M^{-1}\ cm^{-1}$).

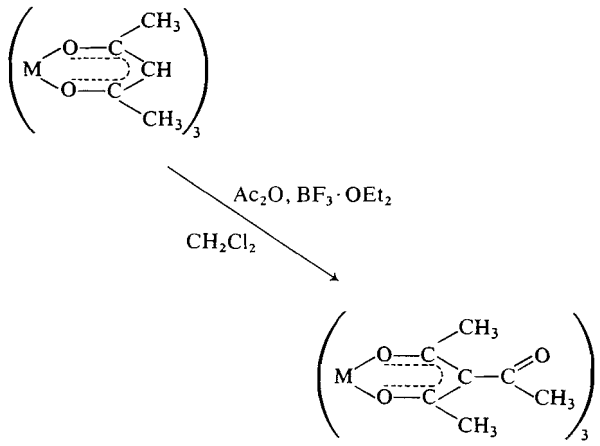
Physical Measurements

The proton magnetic resonance spectra were obtained on a Varian A60 spectrometer. The ultraviolet and visible spectra were measured on a Beckman Acta CIII spectrophotometer. The infrared spectra were recorded on a Beckman IR 12 spectrophotometer.

Results and Discussion

Preparation of $[Co(en)_2(3\text{-acetyl-ptdn})](PF_6)_2$

Friedel–Crafts acetylations of tris(pentane-2,4-dionato) complexes were found by earlier investigators (7) to proceed much more slowly than other electrophilic substitutions such as nitrations, halogenations, and thiocyanogenations. This was thought to be the result of the considerable steric bulk at the reaction site for the acetylation reaction. Nevertheless, for the chelates of chromium, cobalt, and rhodium, it was possible to acetylate all three rings in dichloromethane using acetic anhydride and boron trifluoride etherate (8).



M = Co(III), Cr(III), Rh(III)

We were not able to use this technique to acetylate $[Co(en)_2(acac)]^{2+}$, which is a charged species, since it was not sufficiently soluble in CH_2Cl_2 or other slightly polar solvents. Attempts to perform this reaction in more polar solvents were unsuccessful.

The complex $[Co(en)_2(3\text{-acetyl-ptdn})](PF_6)_2$ was prepared by adaptation of a technique developed by Taube and co-workers (9) for preparation of pentaamminecobalt(III) complexes. The starting material, *cis*-$[Co(en)_2(N_3)_2]^+$, was dissolved in the weakly coordinating solvent triethylphosphate (TEP). The azide ligands were liberated as gaseous products by the addition of nitrosyl tetrafluoroborate. The desired ligand, in this case 3-acetylpentane-2,4-dione, was then added to replace the weakly bound solvent molecules. By optimising the temperature, reaction time, and amount of free ligand used, the substituted complex could be obtained as the sole product.

Physical Studies

There is a large body of literature on the infrared spectra of β-diketone complexes (10, 11). Two bands appear in the region $1515 \pm 10\ cm^{-1}$ (*B* band) and $1575 \pm 30\ cm^{-1}$ (*A* band) for unsubstituted chelate rings (e.g. structure **4**). Although the two modes are coupled slightly to each other, the *A* band is pre-

dominantly a C=C stretching mode and the *B* band is mostly a C=O stretch.

Dryden and Winston (12) developed an empirical rule for chelates of pentane-2,4-dione which are substituted at the 3-position. The rule states that metal complexes of pentane-2,4-dione possessing a hydrogen on the central carbon of the chelate ring exhibit two strong infrared bands in the 1500–1600 cm^{-1} region, whereas complexes with a group other than hydrogen in this position show a singlet in this region. The rule appears to be valid for single atom substituents such as halogen but, as pointed out earlier, for double-bonded species such as formyl or acetyl functions the rule may be violated. It also appears that the medium used to run the spectrum is important since the number and position of the peaks in the 1500–1600 cm^{-1} region may be different depending on whether the spectrum is run in Nujol or as a KBr disc. The $[Co(en)_2(3\text{-acetyl-ptdn})](PF_6)_2$ complex (**1**), however, showed only a singlet in this region, at 1576 cm^{-1} as a KBr disc and at 1566 cm^{-1} in Nujol. This complex apparently obeys Dryden's rule, in sharp contrast to complexes **2** and **3**, both of which showed two peaks in the 1500–1600 cm^{-1} region when run as Nujol mulls. Thus, it appears that the number of peaks exhibited by substituted β-diketones is not subject to prediction.

The ^1H nmr spectrum (Fig. 1) shows two methyl peaks in a 2:1 ratio as predicted for $[Co(en)_2(3\text{-acetyl-ptdn})]^{2+}$. The peak at 2.14 δ corresponds to the methyl groups of the cobalt substituted acetyl functions. That this peak is a singlet implies that rotation about the $C_3—C_{acetyl}$ bond is fast. The peak for the free acetyl protons occurs at 2.50 δ and $—CH_2—$ protons of the ethylenediamine appear at 2.74 δ.

The positions of the absorption bands in the visible and ultraviolet regions of the spectrum for various substituted pentane-2,4-dione complexes are given in Table 1. The lowest energy band in the visible spectrum can be assigned to the $d \rightarrow d$ transition $^1A_{1g} \rightarrow {}^1T_{1g}$ (based on pseudo-octahedral symmetry). The expected $^1A_{1g} \rightarrow {}^1T_{2g}$ transition is observed as a shoulder at 376 nm in $[Co(en)_2(ptdn)]^{2+}$ but is obscured by ligand transitions in the substituted complexes. The bonds in the ultraviolet spectrum are due to ligand and charge transfer transitions and are assigned following Boucher and Bailar (13).

Collman (14) suggested that the lowest energy $\pi \rightarrow \pi^*$ ligand transition would provide evidence for steric inhibition of resonance for substituted β-diketones. A shift of the band at 237 nm in the parent complex $[Co(en)_2(ptdn)]^{2+}$ to lower energy upon substitution at the 3-position would imply that the substituent was conjugated with the pseudo-aromatic chelate ring. For $[Co(en)_2(3\text{-formyl-ptdn}]^{2+}$ and

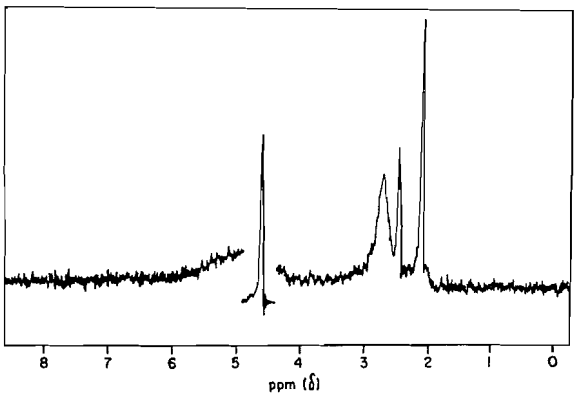


FIG. 1. Proton magnetic resonance spectrum of 3-acetylpentane-2,4-dionatobis(ethylenediamine)cobalt(III) in D_2O. Peaks are relative to DOH peak at 4.61 δ.

$[Co(en)_2(2\text{-acetyl-btdn})]^{2+}$, a shift of 15 and 10 nm, respectively, to lower energy was observed (Table 1). This implies that the formyl and acetyl functions are conjugated with the ring in complexes **3** and **2**, respectively, and hence are coplanar with the pseudo-aromatic chelate. For $[Co(en)_2(3\text{-acetyl-ptdn})]^{2+}$, however, the band is shifted only 2 nm to lower energy, suggesting that there may be some interference of the 'flanking' methyl groups with the methyl of the free acetyl group. Thus, it may be more difficult for the free acetyl function to become coplanar with the ring and this might be expected to influence the rate of electron transfer through the ligand.

Kinetic Studies

Reductions of $[Co(en)_2(2\text{-acetyl-btdn})]^{2+}$ and $[Co(en)_2(3\text{-acetyl-ptdn})]^{2+}$ by Cr(II) both follow the rate law

$$-d[[Co(III)\ complex]/dt = k[Cr(II)][Co(III)\ complex]$$

Summaries of the kinetic data for these reactions are given in Tables 2 and 3. The progress of the reaction of the complex $[Co(en)_2(2\text{-acetyl-btdn})]^{2+}$ with Cr(II) was also followed by scanning the range 300–700 nm with varying ratios of Cr(II) and Co(III) and with different hydrogen ion concentrations. A typical scan is shown in Fig. 2. Good isosbestic behaviour was observed in all cases with isosbestic points at 397, 423, 544, and 646 nm. The final spectrum in each reaction indicated that the product of the reduction was not $Cr(OH_2)_6^{3+}$ and that, therefore, an inner-sphere pathway was implicated.

Product studies on the reaction of Cr(II) with $[Co(en)_2(2\text{-acetyl-btdn})]^{2+}$ showed that a single product was formed, with 78 ± 3% of the ligand being transferred. It was the symmetrical linkage isomer of Cr(III) and was identical to the product formed by

[a]The errors shown on the extinction coefficients are actual deviations from the average value obtained from at least three separate determinations using different samples.

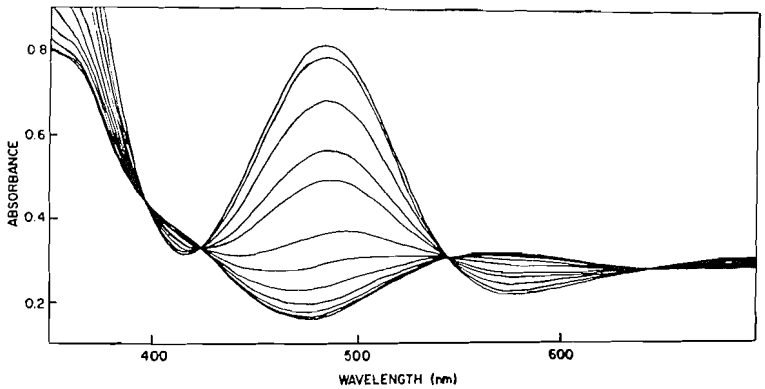

FIG. 2. Typical scan run for the chromium(II) reduction of 2 - acetylbutane - 1,3 - dionatobis(ethylenediamine)cobalt(III). Initial concentrations of reacting species were $[en_2Co(2\text{-acetyl-btdn})^{2+}] = 1.26 \times 10^{-3}$, $[Cr^{2+}] = 1.00 \times 10^{-2}$, $[H^+] = 0.10$. Temperature = 25°C, $I = 1.0$ M ($LiClO_4$). The spectral scans were started at 5, 15, 65, 145, 205, 355, 495, 679, 850, 1022, 1193, and 1365 min after mixing. The last two show essentially no change. (The peak at 489 nm decreases with increasing time while an increase in absorbance with increasing time is observed at 410 and 570 nm.)

substitution of the free ligand on $[Cr(OH_2)_6]^{3+}$ (1) (see Scheme 1 and Table 4). As noted earlier (1), these products adhere fairly strongly to the ion-exchange resin used in separating the reaction mixtures and it is difficult to effect complete removal. Also, our scan runs imply quantitative ligand transfer.

Substitution on $Cr(OH_2)_6^{3+}$ by 3-formyl-ptdn gives an equilibrium mixture of mono-, di-, and trisubstituted products which are readily separated by cation exchange chromatography (1). If substitution is allowed to continue for more than 10 h some 3-formyl-ptdn decomposes to ptdn which also substitutes on $Cr(OH_2)_6^{3+}$. The fact that only a single product is obtained from the electron transfer reaction (reaction time 20 h) thus tends to rule out an outer-sphere pathway followed by substitution on $Cr(OH_2)_6^{3+}$. These results and those discussed above are consistent with an inner-sphere mechanism for the electron transfer as outlined in Scheme 1.

We infer from these results that the Cr(II) attacked at the oxygen of the free acetyl function of $[Co(en)_2(2\text{-acetyl-btdn})]^{2+}$ followed by rapid ring closure over the other acetyl group. It seems clear that the Cr(II) did *not* attack at the co-ordinated aldehyde function since the expected product of this reaction (**5**) is known to be stable (1). If attack occurred at the co-ordinated acetyl function, the reaction would be expected to be at least 100 times slower, i.e. it should occur on the same time scale as the reduction of the

unsubstituted (parent) complex, $[Co(en)_2(ptdn)]^{2+}$. We have argued elsewhere (2) that at least part of the reduction of the parent complex goes by the inner-sphere pathway with $k(50°C) = 5.7 \times 10^{-5}$ M^{-1} s^{-1}. Thus, the results are more consistent with reductant attack at the free acetyl group of the complex $[Co(en)_2(2\text{-acetyl-btdn})]^{2+}$.

Reduction of the acetyl-substituted complex $[Co(en)_2(3\text{-acetyl-ptdn})]^{2+}$ was surprisingly slow, but it was still 1–2 orders of magnitude faster than the parent compound (see Table 5). The slowness of this reaction precluded doing scan runs or product studies to determine the mechanism of reduction since substitution reactions interfere with electron transfer before the latter reaction is complete. Therefore, although an outer-sphere reaction cannot be ruled out, it seems unlikely to predominate in view of the number of potential bridging groups present. Since there was a definite rate enhancement over the parent compound, it seems likely that attack again occurred at the remote acetyl function.

It is interesting to note that linkage isomer **2** is reduced some 15 times more slowly than isomer **3** (Table 5). This rate ratio for attack of Cr(II) at a free aldehyde function over a free acetyl function is typical; the rate of reduction in the former case is usually 10 to 270 times faster than in the latter case (15–17). This may be due to the presence of lower energy empty π-antibonding orbitals on the formyl substituent relative to the acetyl group (18). The ability of the formyl group to achieve coplanarity with the aromatic ring more readily than does the acetyl group (19) may also contribute to the increased rate.

The twelve-fold difference in rates observed for reduction of complexes **1** and **2** may be due to a steric effect. The only difference between these two species is that complex **2** has an aldehyde function coordinated to cobalt(III) whereas complex **1** has an acetyl group in this position. We have argued, in both cases, that reduction occurs by attack of the reductant at the uncoordinated acetyl group at C-3 of the chelate skeleton. Thus it may be more difficult to form the precursor complex in the case of complex **1** and this could account for the decreased rate with respect to the 2-acetyl-btdn complex (**2**). It is also possible that the activation step for electron transfer is less favourable for the chelate skeleton of the 3-acetyl-ptdn complex than for that of the 2-acetyl-btdn complex due to the weaker ordination of the aldehyde oxygen. Effects of this type have been referred to before (20) but no systematic data are available.

Acknowledgements

The authors wish to thank the National Research Council of Canada for financial support and for a post-graduate scholarship to N.A.L. We are also grateful to Professor H. Taube for allowing one of us (N.A.L.) to prepare a sample of $[Co(en)_2(2\text{-acetyl-btdn})](PF_6)_2$ in his laboratories.

Charge distributions and chemical effects. XIX. Analysis of 'bonded' and 'non-bonded' energy contributions in saturated hydrocarbons

SÁNDOR FLISZÁR AND MARIE-THÉRÈSE BÉRALDIN

Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received December 21, 1978

SÁNDOR FLISZÁR and MARIE-THÉRÈSE BÉRALDIN. Can. J. Chem. **57**, 1772 (1979).

Total Coulomb interactions between non-bonded atoms behave in general in a 'quasi-additive' fashion, not only in simple linear and branched paraffins, but also in polycyclic hydrocarbons constructed from chair and boat cyclohexane rings. Because of their relative insensitivity to structural features, they cannot be regarded as being the leading terms in the explanation of energetic effects related to structural changes. The prime factors governing molecular stabilities, as well as the explanation of the structural effects which are at their origin, are found in the behavior of the charge dependent energy contributions associated with bonded atoms, i.e., in the chemical bonds themselves.

SÁNDOR FLISZÁR et MARIE-THÉRÈSE BÉRALDIN. Can. J. Chem. **57**, 1772 (1979).

Les sommes des interactions Coulombiennes entre atomes non liés se comportent en général de manière "quasi additive", tout aussi bien dans les paraffines linéaires et ramifiées que dans les hydrocarbures polycycliques constitués d'anneaux cyclohexaniques en forme chaise ou bateau. En raison de leur faible sensibilité aux modifications structurales, ces interactions ne peuvent jouer de rôle prépondérant dans leur interprétation. Les principaux facteurs déterminant les stabilités moléculaires, ainsi que l'explication des effets structuraux qui sont à leur origine, se retrouvent dans le comportement des contributions énergétiques associées aux charges des atomes liés, c'est-à-dire dans les liaisons chimiques elles-mêmes.

The molecular energy of isolated molecules in their hypothetical vibrationless state is the quantity of choice for the study of energy partitioning. This is particularly true if one wishes to extract information about possible additive contributions. Indeed, at this level the problem is not obscured by other forms of molecular energies, namely zero-point (ZPE) and thermal ($H_T - H_0$) energies, which cannot be regarded as truly additive properties (1).

This particular choice is not restrictive because atomization energies (ΔE_a*) of vibrationless molecules can be derived from the corresponding standard enthalpies of formation ΔH_f^0 (gas, 298.16 K) and appropriate spectroscopic data (eq. [1]; $\sum n_i$ = total number of atoms in the molecule, T = 298.16 K).

$$[1]\quad \Delta E_a^* = \sum \Delta H_f^0(\text{atoms}) - \Delta H_f^0 + \text{ZPE} + H_T - H_0 - 5\sum n_i RT/2$$

Here we investigate saturated hydrocarbons $C_nH_{2n+2-2m}$ considering both simple paraffins and six-membered cyclic compounds, including polycyclic hydrocarbons (m = number of cycles) such as adamantane, bicyclo[2.2.2]octane, iceane, etc. Attention is focussed on energy partitioning and additivity rules involving ΔE_a*.

Formulation of Additivity

Because of our central interest in additivity, a few preliminary remarks about its formulation are in order. Let X be a molecular property and $X(2)$, $X(1)$ the corresponding values for ethane and methane. If X is exactly additive, then

$$[2]\quad X = (1 - m)X(2) + (n - 2 + 2m) \times [X(2) - X(1)]$$

where $X(2) - X(1)$ is the change in X going from methane to ethane, i.e., the contribution of one CH_2 group. The meaning of eq. [2] is obvious for noncyclic compounds (m = 0). For cyclohexane (m = 1), which consists of $n - 2 + 2m = 6$ CH_2 groups, the $(1 - m)X(2)$ term of eq. [2] cancels. Decalin is constructed from two cyclohexane units. In this case $n - 2 + 2m$ accounts for 12 CH_2 groups, but one additional ethane $X(2)$ contribution (i.e., that of two CH_2 and two H atoms) is subtracted with respect to cyclohexane, i.e., a total of $2X(2)$ contributions with respect to noncyclic alkanes. Similar arguments applied to other polycyclic saturated hydrocarbons

Bicyclo[3.3.1]nonane

verify the validity of eq. [2] as a test for exact additivity.

Energy Partitioning

The ΔE_a^* energy is the amount of energy which must be given to vibrationless molecules (1 mol) at 0 K in order to break them up entirely. If a molecule is viewed as an assembly of 'chemical bonds' possessing energies of their own and, moreover, if it is also considered that non-bonded atoms do interact, then ΔE_a^* is clearly made up from that part required to break all bonds, ΔE_a^*(bonds), plus the contribution required to annihilate all non-bonded interaction energies, E_{nb}^*, i.e.,[1]

$$[3] \qquad \Delta E_a^* = \Delta E_a^*(\text{bonds}) - E_{nb}^*$$

Molecular quantum mechanics, of course, does not allow for such a distinction since the chemical bonds themselves are not defined quantum mechanically. The concept of chemical bond can, however, be translated into a wave-mechanical language. Indeed, the energy of a Slater determinant for a closed-shell ground state consisting of doubly occupied molecular orbitals is invariant under a unitary transformation of the spin orbitals with which the corresponding Slater determinant has been constructed. Therefore, we can always assume that the σ molecules under study consist only of localized bonds which are described by orthogonal two-centre bonding molecular orbitals. In this type of analysis, Del Re (2) has shown that a valid approximation for non-bonded interactions in σ systems is Coulombic in nature, i.e.,

$$[4] \qquad E_{nb}^* = \tfrac{1}{2} \sum_{k,l}^{n.b.} \frac{q_k q_l}{r_{kl}}$$

where q_k, q_l are the net (= nuclear minus total electronic) atomic charges of non-bonded atom pairs, at a distance r_{kl}.

Equation [4] may represent a severe simplification. To begin with, let us proceed with the calculation of the Coulombic term of eq. [4] for a number of molecules. The validity of this approach for describing E_{nb}^*, at least as a first approximation, is a point to be dealt with after examination of the results derived in this manner, in comparison with experiment.

Coulomb Interactions

Interatomic distances were derived from standard geometries, with all angles set at 109.47°, r_{CC} = 1.54 Å and r_{CH} = 1.09 Å and/or from optimized geometries given by the STO-3G *ab initio* method (3). The results do not differ significantly.

Atomic net charges are of STO-3G quality, involving full optimization of all variational parameters (*3b*), and correspond to a population analysis which does not imply halving of all overlap population terms, as is the case in the familiar Mulliken scheme (4). They are recalculated from the latter using eqs. [5] and [6],

$$[5] \qquad q_C = q_C(\text{Mulliken}) + Np$$

$$[6] \qquad q_H = q_H(\text{Mulliken}) - p$$

where N = number of H atoms attached to C and $p = 30.12 \times 10^{-3}$ electron is the departure from the usual halving of the CH overlap population, for one C—H bond. (The reasons leading to this type of analysis are given in detail elsewhere (5, 6).) The same carbon atomic charges are also obtained from C-13 nmr shifts (6) (eq. [7]), in ppm from TMS

$$[7] \qquad \delta_C = -237.1 q_C / 69.40 \times 10^{-3} + 242.64$$

where the q_C's are expressed in electron units and 69.40×10^{-3} e is the net charge of the carbon atoms in ethane. Of course, one can do without eq. [7] and use only optimized STO-3G results. There is, however, no real point in not taking advantage of this relationship, just for the sake of 'theoretical purity', since the charges obtained from the two methods agree within ~0.15% for the class of compounds investigated here.

The total Coulomb interactions between non-bonded centers calculated under these premises are presented in Table 1.

Attractive (i.e., stabilizing) interactions are negative. Butane appears to be 0.14 kcal/mol more stable than isobutane in Coulombic energy. Now, the corresponding *experimental* atomization energies (7) ΔE_a^* are 1298.15 and 1299.70 kcal/mol respectively, which makes isobutane 1.55 kcal/mol more stable than its normal isomer. Similarly, the *experimental* ΔE_a^*'s of neopentane and normal pentane are (7) in that order, 1595.94 and 1592.20 kcal/mol, thus indicating that the branched isomer is 3.74 kcal/mol more stable. In non-bonded Coulombic energy, however, the reverse order is found, by 0.44 kcal/mol. Clearly, Coulombic interaction energies between non-bonded atoms cannot be invoked to explain the major differences between isomers.

Of course, it is not surprising that branching increases repulsive contributions, but the effect does not appear to be large. Let us examine the situation

[1]Energy differences (Δ) are defined as 'sum of atomic values less the molecular value'. For non-bonded interaction energies, it follows that $\Delta E_{nb}^* = -E_{nb}^*$, hence the negative sign in eq. [3].

TABLE 1. Non-bonded Coulomb interaction energies

18 Adamantane	−5.08
19 Iceane	−6.30

[a]Calculated for the statistical average (8) of one *anti* (−1.55) and two *gauche* (−1.52) forms.

which would result from a neglect of non-bonded Coulomb energy differences between isomers.

In this approximation, we can ask whether Coulomb interactions behave, at least to some extent, as if they were additive. This is simply done with the aid of eq. [2] which expresses exact additivity. This equation, applied to the energies given in Table 1, yields the result presented in Fig. 1.

This result is self-explanatory. Coulomb interactions behave in general in a 'quasi-additive' manner if we agree upon accepting an uncertainty of ~0.2 kcal/mol due to the neglect of differences between isomers. Branching causes a systematic trend toward higher energies (repulsive destabilization) but situations of extreme steric crowding are required, such as those encountered in 2,2,3,3-tetramethylbutane and, to a lesser extent, in 2,2,3-trimethylbutane, in order to produce sizeable departures from 'quasi-additivity'. This result strongly suggests that non-bonded Coulomb interactions cannot be primely responsible for the bulk of the energy differences between isomers. Let us now examine the energy associated with the bonded atoms.

Analysis of the Atomization Energy ΔE_a^*

The partitioning of ΔE_a^* into energy terms ε_{ij} referring to the individual bonds ij, i.e.,

$$[8] \qquad \Delta E_a^* = \sum \varepsilon_{ij}$$

has been studied recently (7) without explicit consideration of non-bonded interactions, thus including

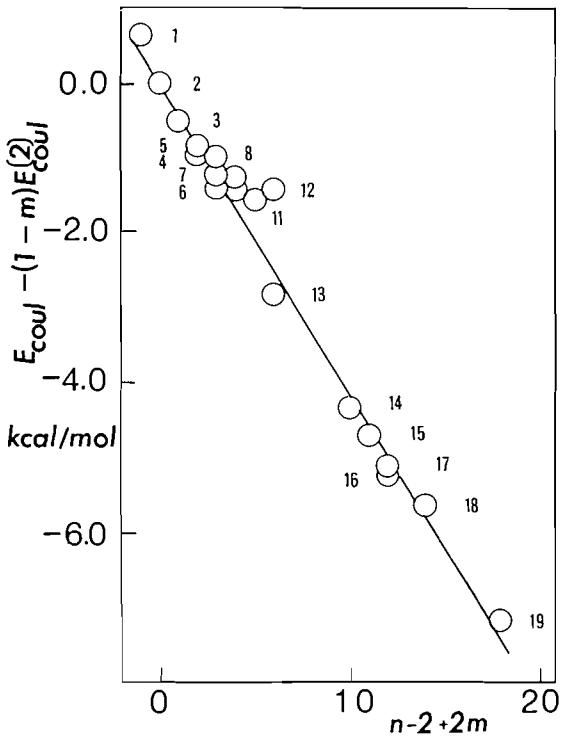

FIG. 1. Additivity test for Coulomb energies by means of eq. [2]. The radii of the circles represent an uncertainty of 0.125 kcal/mol.

them as 'quasi-additive' contributions in the ε_{ij} terms. Postulating that the individual bond-energy terms are some function

$$[9] \qquad \varepsilon_{ij} = \varepsilon_{ij}(Q_i, Q_j)$$

of the total electron populations Q_i and Q_j of the bond-forming atoms, the following expression was derived for saturated hydrocarbons (7).

$$[10] \quad \Delta E_a^* = (1 - m)\Delta E_a^*(2) + (n - 2 + 2m) \times [\Delta E_a^*(2) - \Delta E_a^*(1)] + \lambda_1 \sum N_{CC}\delta + \lambda_2[(n - 2 + 2m)\delta(1) + \sum\delta]$$

Comparing eq. [10] with eq. [2] one recognizes the first two terms of eq. [10] as an additive part, in which $\Delta E_a^*(2)$ and $\Delta E_a^*(1)$ are the ΔE_a^*'s of ethane and methane, i.e., a description of the result corresponding to invariant CC and CH bond contributions. The last two terms of eq. [10] measure the departure from simple additivity attributed to the fact that the charges of the bond-forming atoms are not exactly the same in the various environments because of some charge transfer from neighboring bonds. Here, this charge dependence is expressed conveniently in terms of C-13 nmr shifts, δ, relative to ethane (δ(1) ≡ methane-C shift), using eq. [7].

[a]The ^{13}C nmr shifts are extracted from literature: C_1–C_6 (10), 2,2,3-Me_3C_4 (11), cyclohexane (12), bicyclo[2.2.2]octane (13), *trans*-decalin (14), adamantane (15). Zero-point energies were derived (7) from experimental and calculated frequencies (16), except those of methane (1), 2-methylbutane (17), 2,3-dimethylbutane (17), and bicyclo[2.2.2]octane (18). Heat-content ($H_T - H_0$) values are from ref. 19, except for *trans*-decalin, adamantane (7), and bicyclo[2.2.2]octane (18). Enthalpies of formation are from ref. 19, except for ethane, propane, butane, isobutane (20), neopentane (21), cyclohexane, *trans*-decalin (22), bicyclo[2.2.2]octane, and adamantane (18).

The parameters λ_1 and λ_2, constructed from the derivatives $\partial\varepsilon_{ij}/\partial Q_i$ of Taylor expansions of eq. [9] for the CC and CH bonds, are empirically adjusted. N_{CC} is the number of CC bonds formed by the C atom whose shift is δ.

Dividing now the total ΔE_a^* energy of the molecule into intra-bond and non-bonded contribution (eq. [3]), the inclusion of the effects of the environment on any specific bond term ε_{ij}^{bond} is evaluated in terms of charges allocated to the bond-forming atoms, i.e.,

$$\varepsilon_{ij}^{bond} = \varepsilon_{ij}^{bond}(Q_i, Q_j) \quad [11]$$

The sum

$$\Delta E_a^{*bond} = \sum\varepsilon_{ij}^{bond} \quad [12]$$

is obtained by following the same sequence of calculations (7) which led to eq. [10] from eqs. [8] and [9], with the result

$$\Delta E_a^{*bond} = (1 - m)\Delta E_a^{*bond}(2) + (n - 2 + 2m)[\Delta E_a^{*bond}(2) - \Delta E_a^{*bond}(1)] + \lambda_1\sum N_{CC}\delta + \lambda_2[(n - 2 + 2m)\delta(1) + \sum\delta] \quad [13]$$

To the extent that non-bonded interactions behave, at least approximately, in an additive manner, i.e.,

$$E_{nb}^* \simeq (1 - m)E_{nb}^*(2) + (n - 2 + 2m) \times [E_{nb}^*(2) - E_{nb}^*(1)] \quad [14]$$

it is clear that the total atomization energies obtained from eqs. [3], [13], and [14] equal those given by eq. [10]. The quality of this approximation is best discussed by comparing with experimental results.

Experimental Verifications

The ΔE_a^{*bond} energies (eq. [13]) were calculated with $\lambda_1 = 0.0380$ and $\lambda_2 = 0.0526$, as determined by least-squares analysis. Then, assuming that eq. [4] is approximately valid, we have deduced the corresponding ΔE_a^* energies by means of eq. [3] and the results given in Table 1. Finally, using experimental ZPE + $H_T - H_0$ energies, as well as (9) $\Delta H_f^0(C) = 170.89$ and $\Delta H_f^0(H) = 52.09$ kcal/mol at $T = 298.16$ K, we have calculated the enthalpies of formation (eq. [1]) indicated in Table 2. On the other hand, similar calculations were performed using instead ΔE_a^* values derived directly from eq. [10], implying exact additivity of non-bonded interactions. Not surprisingly, in this model the parameters ($\lambda_1 = 0.03244$ and $\lambda_2 = 0.05728$) differ slightly from the previous ones.

The results obtained from eq. [10] are in general good agreement with their experimental counterparts, virtually within experimental uncertainty. While this is not a new aspect of this type of analysis (7), the point made here is that such an agreement points to a quasi-additive behavior of non-bonded interaction energies. The obvious exception, 2,2,3,3-tetramethylbutane, is discussed further below.

It is difficult to evaluate how well Coulomb energies represent total interactions between non-

bonded pairs. Present results indicate that, individually, both E_{nb}* and $\frac{1}{2}\sum q_k q_l / r_{kl}$ energies behave, within narrow limits, essentially in an additive manner. Consequently, to the extent that eq. [4] can be regarded as a reasonable first approximation, we find here a justification for the observed approximate validity of eq. [10].

It also appears that ΔH_f^0 calculations involving explicitly non-bonded contributions described by eq. [4] are no better, in a statistical sense, than those using simply eq. [10]. Indeed, the average deviations from the experimental values are in both cases 0.18 kcal/mol,[2] excluding 2,2,3,3-tetramethylbutane. This means that, within experimental precision, eq. [10] largely recovers the error introduced in assuming exact additivity of non-bonded contributions as long as the latter behave in a quasi-additive manner. As an important corollary, the prime factors governing molecular stabilities, as well as the explanation of the structural effects which are at their origin, are found in the behavior of the charge dependent bonded contributions. For example, neopentane appears to be more stable than *n*-pentane in $\Delta E_a{}^{*bond}$ energy by 4.39 kcal/mol (Table 2), but also 0.44 kcal/mol less stable in Coulomb energy (Table 1), for a net difference in atomization energy ΔE_a* of 3.95 kcal/mol (experimental, from eq. [1], 3.74 kcal/mol). The dominant role of the energy terms associated with the chemical bonds can be expressed as a rule of thumb 'in comparisons between isomers, the more stable compound is that whose carbon skeleton best approaches electroneutrality, which is reflected in eq. [10] by larger (downfield) δ values'. Again, it should be stressed that these considerations apply to molecules in their hypothetical vibrationless state. The enthalpy values given in Table 2 indicate, however, that the same general trends are followed by molecules in their real states at $T = 298.16$ K.

These results should not be used to minimize the importance of non-bonded interactions, which is particularly well revealed by the properties of 2,2,3,3-tetramethylbutane. For this alkane, the error in ΔH_f^0 accompanying its calculation using eq. [10] is exceptionally large, and there seems to be little doubt concerning the experimental value (25). Moreover, the difficulties associated with the evaluation of its ZPE energy[3] can hardly be invoked to justify such a large discrepancy. The published ^{13}C nmr spectrum (11) has also been duplicated. Turning now to the detailed calculation of ΔH_f^0 by means of eqs. [3], [4], and [13], the Coulomb term is seen to significantly reduce the error. While the residual discrepancy remains important, possibly pointing to an imperfection when assimilating Coulomb with total non-bonded interactions, it would also be difficult to draw definite conclusions in that matter. It is important, however, to recognize that in cases involving extreme steric crowding any significant deviation from 'quasi-additivity' is a warning against the straightforward use of eq. [10].

Conclusions

In saturated hydrocarbons, total Coulomb interaction energies between non-bonded atoms behave in general in a 'quasi-additive' fashion as they are little affected by structural features, even major ones, except for situations of extreme steric crowding. As a consequence, they cannot be primarily responsible for the bulk of the energy differences between isomers or conformers.

The atomization energies of molecules in their hypothetical vibrationless state are, on the contrary, not simply additive, the departures being attributed to the charges of the bond-forming atoms which are not exactly the same in the various environments because of some transfer from (or to) neighboring bonds. The prime factors governing molecular stabilities are found in the behavior of the charge dependent bonded contributions. The corresponding eq. [10] can be used with confidence in a wide variety of cases, unless non-bonded Coulomb terms depart markedly from 'quasi-additivity'.

[2]We have also examined the possibility of describing E_{nb}* by the Coulomb energies of Table 1 multiplied by k^2, on the grounds that the net charges are perhaps in error by a factor k. This is a definite possibility. Indeed, the C and H charges derived from optimized STO-3G, Hoylands' bond-order (23), 7*s*3*p*/3*s* (24), and 6-31G *ab initio* calculations are in all cases in a ratio (k) of 1: 1.3: 0.86: 0.84, after readjustment through eqs. [5] and [6], evidently without any change in their relative ordering (5). Here, the search for the best k yields $k = 0.7$–0.95 (depending upon whether or not one or another compound is left out of the correlation), with an insignificant improvement in the calculations of the ΔH_f^0's, the average deviation being now 0.15 kcal/mol. Hence, within the precision of this type of analysis, there is no point in trying to improve the description of the E_{nb}* interactions simply by taking some multiple of the Coulomb energies given in Table 1. There is an indication, however, that Coulomb terms are even closer to 'quasi-additivity' than is shown in Fig. 1. Indeed, because of this 'shrinking' of the Coulomb term, the differences (e.g., those between isomers) must now also be multiplied by k^2, which is less than 1.

[3]Because of the significantly larger than usual deviations (1.83%) between calculated and observed frequencies (16) and the fact that only 17 of the 48 fundamentals were observed, our present estimate of the ZPE enegy of 2,2,3,3-Me_4C_4 (147.60 kcal/mol) is based on the regular progression of the increments in ZPE in going from 2-MeC_3 to 2,2-Me_2C_3 (16.66), from 2-MeC_4 to 2,2-Me_2C_4 (16.76), and from 2,3-Me_2C_4 to 2,2,3-Me_3C_4 (16.88) and on the value (130.61 kcal/mol) for 2,2,3-Me_3C_4. Though open to criticism, this estimate is more consistent in comparisons with other molecules than the sum $h\Sigma\nu_l/2 = 146.97$ kcal/mol derived from calculated frequencies (16), which represents an increment of only 16.36 kcal/mol with respect to 2,2,3-Me_3C_4, rather than the 16.99 increment suggested by the progression.

Of course, under usual working conditions one also has to take into account the zero-point and thermal energies for evaluating the various aspects of molecular energies at, say, 298.16 K in a realistic manner. This now seems to be the real problem arising in the discussion of molecular energies.

Acknowledgments

The most generous support by the Centre de Calcul de l'Université de Montréal and the financial aid from the National Research Council of Canada are gratefully acknowledged. We also thank Dr. P. Ausloos and the National Bureau of Standards, Washington, DC, for a sample of pure 2,2,3,3-tetramethylbutane.

Appendix

The atomic charges of methane, ethane, propane, butane, isobutane, and neopentane were extracted from the literature (3*b*, 5), as well as those of cyclohexane (26) and adamantane (27), and correspond to the population analysis described by eqs. [5] and [6]. For the other molecules, carbon atomic charges were derived from ^{13}C nmr shifts, using eq. [7].

The appropriateness of the population analysis employed here has been verified in the following manner. Equation [10] was written in its original form (7) in terms of atomic charges instead of ^{13}C nmr shifts, whereby the charge dependent part takes the form $\lambda_1'\sum N_{CC}\Delta q_C + \lambda_2'\sum\Delta q_C$. The Δq_C's are the differences in C charges with respect to the ethane-C atom, i.e., $\Delta q_C = q_C - q_C(\text{ethane})$. The q_C's were then expressed as in eq. [5] using Mulliken populations as input and leaving p as the unknown to be determined. The $\Delta E_a{}^*$'s constructed in this fashion were compared with their experimental counterparts calculated from eq. [1] and p was determined by least-squares analysis. This procedure amounts to an experimental partitioning of Mulliken overlap populations. The result, $p = (30.3 \pm 0.3) \times 10^{-3}$ electron equals, within experimental uncertainty, that found by similar procedures for ^{13}C resonance shifts (6, 26, 27) and adiabatic ionization potentials (28), i.e., $p = 30.12 \times 10^{-3}$ electron. Consequently, the charges derived from eqs. [5] and [6] are appropriate for the problem at hand and are adequately represented by ^{13}C resonance shifts, through eq. [7], as was done in eqs. [10] and [13].

When fully optimized STO-3G calculations were not feasible, we have deduced the H net charges from the C charges derived from chemical shifts by carrying out a renormalization reflecting the detailed trends revealed by standard STO-3G results. In the case of 2-methylbutane, 2,2-dimethylbutane, and 2,2,3-trimethylbutane, additional verifications were made by means of the "inductive" approach (5) which has been shown to be in excellent agreement with fully optimized STO-3G results. In R—CH_3 compounds the net charge of the CH_3 group is given by the equation $q(CH_3) = a\sigma_R{}^*$ in which $\sigma_R{}^*$ is the Taft polar constant (29) of R and for R—R′ structures we have calculated $q(R') = a(\sigma_R{}^* - \sigma_{R'}{}^*)$,

TABLE 3. Atomic charges, 10^{-3} electron units[a]

Molecule	Atomic charge							
	C_1	C_2	C_3	C_4	$H(C_1)$	$H(C_2)$	$H(C_3)$	$H(C_4)$
C_2H_6	69.40				−23.13			
C_5H_{12}	66.95	64.41	60.92		−26.05	−27.00	−29.69	
2-MeC_4H_9	64.69	62.35	61.85	67.74	−25.23	−35.61	−29.91	−24.83
2,2-$Me_2C_4H_8$	62.59	62.12	60.31	68.50	−26.60		−31.44	−25.47
2,3-$Me_2C_4H_8$	65.40	61.07			−29.50	−36.50		
2,2,3-$Me_3C_4H_7$	63.12	61.45	59.93	65.84	−28.48		−37.0	−26.69
2,2,3,3-$Me_4C_4H_6$	63.63	60.88			−27.97			
Bicyclo[2.2.2]octane	63.79	63.17			−36.19	−36.19		
Bicyclo[3.3.1]nonane	62.86	61.77	64.44	60.75	−41.16	−39.09	−52.89	−38.21 (e)
						−37.00	+3.19	(a)
trans-Decalin	60.85	63.07		58.08	−33.21	−31.42		−40.95 (e)
					−34.75	−33.12		(a)
cis-Decalin	62.30	63.82		60.21	−34.72	−33.17		−43.37 (e)
					−35.77	−30.71		(a)
Iceane	62.63		61.75		−48.87		−34.76	(e)
							−40.75	(a)

[a]The conventional atom numbering is used, except for the decalins and bicyclo[3.3.1]nonane, where C-4 corresponds to the position 9. For *cis*-decali one also finds the following H charges (in the usual atom numbering): −32.32 (e), −33.21 (a) at C-3 and −37.22 (e), −31.96 (a) at C-4.

where the constant a takes the value 52.43×10^{-3} e appropriate for reproducing the fully optimized STO-3G results. Taking 2-methylbutane as an example, which can be considered as isoC_3H_7—C_2H_5, isoC_4H_9—CH_3, and s-C_4H_9—CH_3, we find (in 10^{-3} electron units) $q(C_2H_5) = -4.72$, $q(CH_3) = -6.76$ (C-4 atom), and $q(CH_3) = -11.01$ (C-1). The charges of the various molecular fragments being determined in this way, those of the H atoms are deduced using the carbon charges derived from eq. [7]. The hydrogen atomic charges were required only for deriving Coulomb energies. It has been verified that possible minor uncertainties associated with these charges do not affect the calculated Coulomb energies to any significant extent. The results are given in Table 3.

On the planarity of the NSi_3 skeleton in the trisilylamine molecule. A normal coordinate analysis involving complex symmetry coordinates

Normal coordinate calculations have been carried out for the $N(SiH_3)_3$ molecule. A model with C_{3h} symmetry was used, which is based on a planar NSi_3 skeleton. The presence of complex numbers for the characters of degenerate irreducible representations of the point group C_{3h} leads to an unusual problem when factoring the **G** and **F** matrices. A set of real degenerate symmetry coordinates for the E' and E'' species can be constructed, but these are not true symmetry coordinates under the C_{3h} point group. However, they can be obtained from the genuine (complex) symmetry coordinates by a unitary transformation. For a degenerate species, this procedure leads to *a* and *b* blocks of the factored **G** and **F** matrices, which contain interaction terms. Consequently both blocks must be taken together when forming the secular equation, and subsequently the calculated frequencies appear as pairs of identical numbers.

A valence force field that includes all reasonable interactions has been obtained and used to predict the wavenumbers of the ^{15}N and d_9 isotopic molecules. Details of the normal vibrations in the three molecules have been obtained from potential energy distributions. The results show reasonable agreement with the limited experimental data available for the isotopic molecules.

H. F. SHURVELL, A. DUNHAM, S. J. CYVIN et J. BRUNVOLL. Can. J. Chem. **57**, 1779 (1979).

On a effectué des calculs de coordonnées normales pour la molécule de $N(SiH_3)_3$. On a utilisé un modèle avec une symétrie C_{3h} qui est basée sur un squelette NSi_3 plan. La présence de nombres complexes pour les caractères de représentations irréductibles dégénérées du groupe ponctuel C_{3h} conduit à un problème exceptionnel lorsqu'on veut factoriser les matrices **G** et **F**. On a construit un ensemble de coordonnées de symétrie dégénérées réelles pour les espèces E' et E'', mais elles ne sont pas des coordonnées de symétrie vraies pour le groupe ponctuel C_{3h}. Toutefois, on peut les obtenir à partir de coordonnées de symétrie véritables (complexes) par une transformation unitaire. Dans le cas des espèces dégénérées, cette façon d'agir conduit à des chocs *a* et *b* des matrices **G** et **F** factorisées qui contiennent des termes d'interaction. Il en résulte que l'on doit considérer les deux blocs comme un ensemble lorsque l'on forme l'équation séculaire et les fréquences calculées apparaissent donc sous forme de paires de nombres identiques.

On a obtenu un champ de force de valence qui comprend toutes les interactions vraisemblables et on l'a utilisé pour prédire les nombres d'onde de molécules contenant des isotopes ^{15}N et d_9. On a obtenu les détails des vibrations normales de trois molécules à partir de distributions d'énergies potentielles. Les résultats présentent un bon accord avec les valeurs expérimentales restreintes disponibles pour des molécules marquées.

[Traduit par le journal]

Introduction

On the basis of infrared and Raman spectra of trisilylamine $N(SiH_3)_3$, Ebsworth *et al.* (1) and Robinson (2) concluded that the NSi_3 skeleton was planar in this compound and that the point group of the molecule was C_{3h}. Electron diffraction studies (3, 4) support these conclusions. A later paper (5) reported infrared spectra of trisilylamine in gas and solid states and in an argon matrix. It was concluded that the infrared spectra of the matrix isolated sample fits C_{3v} selection rules better than C_{3h}. Miller *et al.* (6) recently reported careful measurements of Raman wavenumbers of the totally symmetric NSi_3 stretching modes of $^{14}N(SiH_3)_3$ and $^{15}N(SiH_3)_3$. In the gas phase the isotopic shift was found to be zero within experimental error, indicating that the NSi_3 skeleton is planar.

Previous vibrational calculations (1, 6) were based on planar or pyramidal XY_3 models for $N(SiH_3)_3$ and made use of the valence force field equations from Herzberg's book (7). Ebsworth *et al.* (1) obtained a value of 4.1 mdyn $Å^{-1}$ for the N—Si

0008-4042/79/141779-06$01.00/0

stretching force constant and 0.2 mdyn $Å^{-1}$ for the stretch–stretch interaction constant of the planar C_{3h} structure. Miller *et al.* (6) in considering the possible ^{14}N–^{15}N isotopic shift of the NSi_3 symmetric stretching mode in a pyramidal C_{3v} structure used the force constants reported by Ebsworth *et al.* (1) together with bending and bend–bend interaction constants. Neither group of workers made calculations of isotopic shifts of vibrational modes of the C_{3h} model, although wavenumbers for some bands in ^{15}N and ^{2}H isotopic molecules were reported.

In this article we report a normal coordinate calculation on the $^{14}N(SiH_3)_3$ molecule using a general valence force field. It was intended that the refined force field could be used to predict the wavenumbers of the $^{15}N(SiH_3)_3$ and $^{14}N(SiD_3)_3$ molecules for comparison with observed wavenumbers. Potential energy distributions (P.E.D.) have also been obtained. The P.E.D. gives the contribution of every force constant of the refined force field to each calculated normal frequency and, from this, qualitative descriptions of the fundamentals can be given.

Structure and Calculations

The structure of trisilylamine (Fig. 1) was taken from the electron diffraction study of ref. 4 where the Si—N and Si—H bond lengths were reported as 1.734 Å and 1.485 Å respectively. The SiNSi angle was reported as $119.7 \pm 0.1°$. However, this apparent slight deviation from planarity is associated with a shrinkage effect (8) on the Si—Si distance. We have used 120.0° for the SiNSi angle and the SiH_3 groups were assumed to be tetrahedral with HSiN and HSiH angles of 109.5°. The electron diffraction results [4] indicate that the HSiN angle is in fact slightly less and the HSiH angle slightly greater than the exact tetrahedral value.

The normal vibrations of the $N(SiH_3)_3$ molecule can be divided into $6A' + 5A'' + 7E' + 4E''$ modes according to the point group C_{3h}. The A' and E'' modes are Raman active, the A'' modes are infrared active, and the E' modes are both infrared and Raman active. From the recorded spectra, wavenumbers can be assigned to 31 of the 33 fundamentals. Only the N—(SiH_3) torsions have not been observed.

The Wilson **FG** matrix method (9) was used for the calculations. An iterative procedure for refining an initial set of force constants was employed. A modified (10) version of the Fortran program written by Schachtschneider (11) was used for these calculations, which were carried out on a Burroughs 6700 computer.

Internal Coordinates and Symmetry Coordinates

A set of 37 internal coordinates was chosen. These

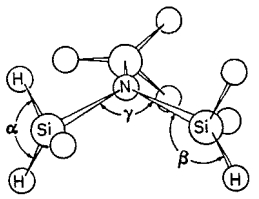

FIG. 1. The structure of the $N(SiH_3)_3$ molecule showing typical internal coordinates.

comprise three N—Si stretches (R_1–R_3), nine Si—H stretches (R_4–R_{12}), three Si—N—Si bends (γ_1–γ_3), nine H—Si—H bends (α_1–α_9), nine N—Si—H bends (β_1–β_9), one NSi_2 out-of-plane wag (ω_1), and three N—SiH_3 torsions (τ_1–τ_3). This set of internal coordinates, which contains four redundancies, involving bending of the angles around the N and Si atoms, was used to calculate the **G** matrix. The corresponding **F** matrix was set up algebraically using the usual **Z** matrix formulation (10, 11). The valence force field contains seven diagonal force constants corresponding to N—Si and Si—H stretching, Si—N—Si, H—Si—H, and N—Si—H bending, NSi_2 wagging, and N—SiH_3 torsion. To take account of all reasonable interactions, 21 independent interaction constants were added. Interactions involving N—SiH_3 torsion and NSi_2 wagging with stretching or bending were omitted, but a wag–torsion interaction was included. These force constants with their final refined values are listed in Table 1.

Non-degenerate symmetry coordinates for the A' and A'' species can be obtained by the usual methods (9, 12). However, these methods cannot be applied to the degenerate species E' and E'', because the character table of the C_{3h} point group contains complex numbers for the degenerate irreducible representations. A similar situation was encountered previously for the cyclic $(HF)_6$ molecule (point group C_{6h}) (13) and for boric acid $B(OH)_3$ (point group C_{3h}) (14). The solution to the problem has been given by Cyvin *et al.* (13). It was noted that the character table for the point group C_{3h} contains two rows for each degenerate species and that these rows contain complex numbers. If the corresponding characters in the two rows are added, one obtains a set of real numbers. Using an analogous procedure, pairs of complex symmetry coordinates can be combined by addition or subtraction to give real degenerate pairs of symmetry coordinates. Although these are not true symmetry coordinates under the C_{3h} point group, they can be used to factor the secular equation in the usual way. As an example, consider the degenerate N—Si_3 stretching mode (E'). The genuine (complex) degenerate symmetry coordinates are:

$$S_{1a} = (1/\sqrt{3})(R_1 + \varepsilon R_2 + \varepsilon^* R_3)$$

$$\varepsilon = \exp(2\pi i/3)$$

$$S_{1b} = (1/\sqrt{3})(R_1 + \varepsilon^* R_2 + \varepsilon R_3)$$

These can be combined to give the pair of real degenerate symmetry coordinates:

$$\mathfrak{S}_{1a}(E') = (1/\sqrt{6})(2R_1 - R_2 - R_3)$$

$$\mathfrak{S}_{1b}(E') = (1/\sqrt{2})(-R_2 + R_3)$$

In this way, the set of real degenerate symmetry coordinates listed in Table 2 was obtained. Table 2 also contains the non-degenerate symmetry coordinates and the four redundant coordinates ($2A' + E'$). A group theoretical justification for this treatment has been given in ref. 13, where it is shown that real degenerate symmetry coordinates such as those of Table 2 are connected with the genuine complex degenerate symmetry coordinates through a unitary transformation.

It should be emphasized that because these real coordinates are not true symmetry coordinates they do not give the usual complete factoring of the **G** and **F** matrices. These normally appear as block diagonalized matrices with pairs of identical blocks for doubly degenerate species. In the present case a single block of twice the normal dimensions is obtained for each degenerate species. The form of these blocks has been discussed in ref. 13. Both **F** and **G** matrices obtained using the $\mathfrak{S}$ coordinates of Table 2 have the same form. These double sized blocks must be used in the solution of the secular equation $(\mathbf{FG} - \mathbf{I}\lambda) = 0$. This leads to calculated frequencies which appear as pairs of identical numbers for each degenerate mode.

TABLE 1. Valence force constants for trisilylamine

Number	Description*	Final refined value†
1	N—Si stretch	3.04
2	Si—H stretch	2.67
3	Si—N—Si bend	0.57731
4	H—Si—H bend	0.42375
5	N—Si—H bend	0.69
6	N—Si_2 wag	0.32

8	N—Si stretch/N—Si stretch	0.71
9	N—Si stretch/Si—H stretch	0.0
10	N—Si stretch/Si—N—Si bend[a]	0.0
11	N—Si stretch/Si—N—Si bend[b]	−0.298
12	N—Si stretch/H—Si—H bend	0.1741
13	N—Si stretch/N—Si—H bend	0.2947
14	Si—H stretch/Si—H stretch	0.04
15	Si—H stretch/Si—N—Si bend	0.0
16	Si—H stretch/H—Si—H bend[a]	0.0
17	Si—H stretch/H—Si—H bend[b]	0.05444
18	Si—H stretch/N—Si—H bend[b]	−0.02386
19	Si—H stretch/N—Si—H bend[a]	0.0
20	Si—N—Si bend/Si—N—Si bend	−0.08489
21	Si—N—Si bend/H—Si—H bend	0.0
22	Si—N—Si bend/N—Si—H bend[a]	0.0
23	Si—N—Si bend/N—Si—H bend[b]	0.07281
24	H—Si—H bend/H—Si—H bend	0.031
25	H—Si—H bend/N—Si—H bend[a]	0.0
26	H—Si—H bend/N—Si—H bend[b]	0.006
27	N—Si—H bend/N—Si—H bend	0.04
28	Wag/torsion interaction	0.001

*a and b refer to interactions between stretches and bends having no common bond and a common bond respectively.

†Units for force constants are: stretches and stretch/stretch interactions, mdyn Å^{-1}; bends and bend/bend interactions, mdyn Å; stretch-bend interactions, mdyn.

Results and Discussion

Initial values for the diagonal force constants were obtained from previous calculations on the NSi_3 skeleton (1, 6, 15) and SiH_3 groups (16, 17). Refinement of the force field was made by the introduction of various interaction constants and eventually an acceptable fit between observed and calculated wavenumbers was obtained for the $N(SiH_3)_3$ molecule. These wavenumbers are listed in the first two columns of Tables 3 and 4. The set of force constants that give the calculated values is listed in Table 1. Of course no claim for uniqueness is made for this force field and the large number of significant figures associated with some force constants are shown only because they produce the wavenumbers given in Tables 3 and 4.

G matrices were calculated for the $N(SiD_3)_3$ and $^{15}N(SiH_3)_3$ isotopic molecules. After factorization using the symmetry coordinates of Table 2, wavenumbers were calculated for these molecules using the force field of Table 1. Calculated values for $N(SiD_3)_3$ are listed in Tables 3 and 4 and values for $^{15}N(SiH_3)_3$ are given in column 3 of Table 4 for the A'' and E' modes. These are the only vibrations of C_{3h} structure which involve motion of the nitrogen atom. For several of these fundamentals, significant wavenumber shifts are predicted for the ^{15}N isotopic molecule. The largest shifts are for the two E' fundamentals ν_{15} and ν_{16}, both of which involve N—Si—H bending and N—Si stretching. These modes also involve H—Si—H bending and undergo large shifts in the deuterated molecule.

Assignments

Several previous workers (1, 2, 5, 6) have made assignments of the observed infrared and Raman bands to the fundamentals of trisilylamine. These assignments will be discussed in the light of the present calculations. Two different numbering sequences have been employed previously for the E' and A'' modes. If the latter are numbered ν_7–ν_{11}, then the E' modes will be ν_{12}–ν_{18}. This was the scheme used in refs. 1, 5, 6 and it has been adopted

TABLE 2. Symmetry coordinates for an $X(YZ_3)_3$ molecule of symmetry C_{3h}

Species	Symmetry coordinate	Description

here. Robinson (2) used the alternative notation with the E' modes numbered ν_7–ν_{13} and the A'' modes ν_{14}–ν_{18}. The A' modes (ν_1–ν_6) and E'' modes (ν_{19}–ν_{22}) are the same in both systems of numbering.

SiH Stretching Modes

For the normal molecule the calculations indicate two groups of SiH stretching frequencies with $\nu_1(A')$ and $\nu_{12}(E')$ near 2160 cm^{-1} and $\nu_2(A')$, $\nu_{13}(E')$, $\nu_7(A'')$, and $\nu_{19}(E'')$ about 8 cm^{-1} lower. No separation is observed in gas or liquid phase spectra. However, Miller *et al.* (6) reported eight frequencies between 2180 and 2138 cm^{-1} in the Raman spectrum of the solid. This is the number of components that would be expected, for the Raman active modes, if the E' and E'' degeneracies were removed by a low site symmetry. Five features were also reported in the infrared spectrum of the solid between 2185 and 2146 cm^{-1} (6). Again this is the expected number if the E' degeneracies are lifted by the site symmetry. The predicted Si—D stretching frequencies in the d_9 isotopic molecule are very close to the values reported by Robinson (2) and Ebsworth *et al.* (1).

N—Si Stretching Modes

These two vibrations $\nu_6(A')$ and $\nu_{14}(E')$ are characterized by small deuterium isotope shifts and in the case of ν_{14} an ^{15}N isotope shift. The observed wavenumber for the A' mode in $N(SiD_3)_3$ is very close to the calculated value (Table 3). However, the

[a]Based on the potential energy distribution.

agreement is not so good for the E' mode (Table 4). In the latter case it is noted that the potential energy distribution indicates a much greater contribution from the N—Si stretching force constant in the heavy isotopic molecule than in the light molecule.

Other Modes

The modes usually described as SiH_3 deformation and SiH_3 rocking are found between 1000 and 650 cm^{-1}. The P.E.D. shows that these modes all involve N—Si—H and H—Si—H bending and in the case of the E' vibrations, there is a considerable contribution from the N—Si stretching force constant.

The out-of-plane NSi_2 wagging mode $\nu_{10}(A'')$ can also be described as an NSi_3 deformation. A small ^{15}N isotopic shift (3.5 cm^{-1}) is predicted for this mode. The two torsional modes $\nu_{11}(A'')$ and $\nu_{22}(E'')$ have not been observed experimentally, although complete Raman spectra and infrared spectra as low as 35 cm^{-1} have been recorded (6). The SiH_3 groups are expected to rotate almost freely if the NSi_3 skeleton is planar and the calculated wavenumbers for the torsions in Tables 3 and 4 are not unreasonable.

Comments on Previous Assignments

A Raman line at 1011 cm^{-1} was assigned to $\nu_3(A')$ by Ebsworth *et al.* (1), while Robinson (2) assigned an infrared band at 944 cm^{-1} to this mode, as well as to $\nu_8(A'')$, $\nu_{15}(E')$, and $\nu_{20}(E'')$. The present calculation supports the former assignment and in any case ν_3 is not infrared active. Robinson (2) also

assigned an infrared band at 748 cm^{-1} to $\nu_5(A')$, $\nu_9(A'')$, $\nu_{17}(E')$, and $\nu_{21}(E'')$. Again the A' assignment is unlikely to be correct on symmetry grounds, but the A'' assignment is supported by the calculation. The assignment of Ebsworth *et al.* of a Raman line at 697 cm^{-1} to ν_5 is in agreement with the calculation. However, these authors, like Robinson, also assigned this band to ν_{17} and ν_{21}. The more recent work of Miller *et al.* (6) has provided a separate wavenumber (661 cm^{-1}) for ν_{17}. The calculation supports this, but confirms the accidental degeneracy between ν_5 and ν_{21}.

It is suggested, on the basis of our calculations, that $\nu_4(A')$ and $\nu_{20}(E'')$ be assigned to the very strong doublet 919/921 cm^{-1} reported in ref. 6 from the Raman spectrum of solid trisilylamine. The calculated wavenumber is 924 cm^{-1} for both modes again confirming the expected accidental degeneracy.

Conclusions

A reasonable valence force field has been obtained for trisilylamine and this has been used to predict wavenumbers for the normal modes of the fully deuterated and the ^{15}N isotopic molecules. The results are in reasonable agreement with the limited experimental data available. It is unfortunate that more complete spectra of $^{15}N(SiH_3)_3$ and $N(SiD_3)_3$ are not available for comparison with the present predictions.

Potential energy distributions indicate that the qualitative assignments made by previous workers (1, 2, 5) are essentially correct. A few changes suggested by the present calculations have been noted in the discussion.

While the present calculation does little to support the planar structure of the NSi_3 skeleton, it does provide predicted sets of vibrational wavenumbers for isotopic species with structures based on the C_{3h} model. The calculation has also provided a further example of a method for dealing with complex symmetry coordinates.

Reactions of triethylenetetramine with protons and bivalent zinc, cadmium, and lead in aqueous solution and aqueous dioxane (50% v/v)

W. A. E. McBRYDE AND H. K. J. POWELL[1]

Guelph–Waterloo Centre for Graduate Work, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received November 17, 1978

W. A. E. McBRYDE and H. K. J. POWELL. Can. J. Chem. 57, 1785 (1979).

The reactions of triethylenetetramine with protons and with bivalent Zn, Cd, and Pb have been studied in aqueous solution and in 50% (v/v) aqueous 1,4-dioxane, 25°C, $I = 0.10$ M KNO_3. log K (potentiometric) and ΔH (calorimetric) data are interpreted in terms of electrostatic effects and solvation effects operative in the two solvents.

Protonation constants are higher by 0.2–0.6 log units in aqueous solution. Stepwise enthalpies of protonation $-\Delta H_n$ ($n = 2, 3, 4$) are significantly higher, and the corresponding entropies lower, in aqueous solution. The complexes $[ML]^{2+}$ are of similar stability in the two solvents but $-\Delta H$ is ca. 10–20% lower in aqueous dioxane.

W. A. E. McBRYDE et H. K. J. POWELL. Can. J. Chem. 57, 1785 (1979).

On a étudié les réactions de la triéthylènetétramine avec des protons et des ions Zn, Cd et Pb bivalents en solutions aqueuses et en solutions dioxanne–eau (50% v/v), à 25°C et $I = 0.10$ M KNO_3. On a interprété les données de log K (potentiométrique) et de ΔH (calorimétrique) en termes des effets électrostatique et de solvatation présents dans les deux solvants.

Les constantes de protonation sont de 0.2 à 0.6 unités logarithmiques plus élevées en solution aqueuse. En solution aqueuse, les enthalpies progressives de protonation, $-\Delta H_n$ ($n = 2, 3, 4$) sont beaucoup plus élevées et les entropies correspondantes sont plus faibles. Les stabilités des complexes $[ML]^{2+}$ dans les deux solvants sont semblables mais le $-\Delta H$ est environ 10 à 20% plus faible dans le dioxanne–eau.

Introduction

The stabilities of metal complexes are determined by an interplay of many factors including metal ion size and electronic configuration, ligand basicity and ring size, and donor atom orbital energies. The distinctive patterns of affinity which class A and class B metal ions have for different types of donor atoms relate to the factors which enhance either ionic or covalent (σ and π) bond formation, and to the contribution which metal ion and ligand solvation make to the enthalpy and entropy changes.

Some understanding of the role of solvation can be achieved by comparing series of reactions in water and in a non-aqueous solvent. Ahrland *et al.* (1, 2) have studied the reactions of bivalent Zn and Cd with Cl^-, Br^-, and I^- in dimethylsulfoxide and in water. The class A character of the metal ion is enhanced in the solvent of lower dielectric constant, i.e. there is an enhanced relative affinity for the smallest anion. The effect of solvent dielectric on electrostatic interactions was not emphasized, but from ΔH and ΔS values it was deduced that (*i*) the stronger solvation of small (hydrogen bonding) anions such as Cl^- in water, and (*ii*) the larger gain in entropy associated with desolvating a metal ion in the less structured solvent DMSO made important contributions to the change in stability.

This work describes a thermodynamic study of the reactions of triethylenetetramine with protons and with bivalent Zn, Cd, and Pb in water and in 50% (v/v) aqueous dioxane. The choice of a non-ionic ligand minimizes the effect of electrostatic contributions to ΔH and ΔS for metal complex formation, avoids the complication of ion-pairing in a solvent of low dielectric constant, and focuses attention on solvation effects. Aqueous dioxane is less structured than water, the density being greater than that for an ideal mixture at all compositions (3, 4). The basicities of amines are lower in aqueous dioxane than in water and for ethylenediamine basicity is at a minimum at compositions close to 50% (v/v) (5, 6). Free energies and enthalpies of transfer from water into aqueous dioxane establish that cations (and the proton) are more strongly solvated in the mixed solvent. Parker and co-workers (6, 7) noted the effect which the structure of solvent water has in reducing hydration energies. Bennetto and Feakins (8) have emphasized the enhanced basicity of aqueous dioxane over water; this results from the transfer of negative charge from the dioxane oxygen to water oxygen via a hydrogen bond.

Aqueous dioxane (50% (v/v)) has a dielectric constant of 35.7 at 25°C (6) and is 17.3 mol% dioxane.

$LH_3^{3+} + H^+ \rightleftharpoons LH_4^{4+}$	4	3.40±0.01 (2.80±0.05)	19.4 (15.9)	31.3±0.6 (16.4±9)	−40.0±2.0 (−2±7)

[a]Values for aqueous 0.1 M KCl: $\log k_n = 9.78, 9.06, 6.55$, and 3.24, and $-\Delta H_n = 46.1, 47.1, 39.9$, and 28.6 kJ mol^{-1} for $n = 1$ to 4 respectively, ref. 16. Values for aqueous 0.1 M $NaClO_4$: $\log k_n = 9.80, 9.08, 6.55, 3.25$, ref. 17.
[b]Values for aqueous 0.1 M $NaNO_3$: $\log k_n = 9.89, 9.21, 6.71, 3.45$, $n = 1$ to 4 respectively (T. B. Field and W. A. E. McBryde, to be published).

The dioxane molecule has a gas phase dipole moment of zero, while the low dielectric constant of liquid dioxane (2.2) is consistent with a dominant chair conformation. However, Grunwald *et al.*'s (9) evidence for specific dioxane interactions with univalent cations in aqueous dioxane and the anomalous dependence of K_A for ion pairing upon the bulk dielectric constant for aqueous dioxane solvents (10) have led to postulates that existence of the boat conformation is enhanced by the electrostatic fields about cations.

Experimental and Results

Triethylenetetramine Tetrahydronitrate

Triethylenetetramine (Baker Analyzed Reagent, 15 cm^3) was stirred in ethanol (150 cm^3) in an ice bath. Nitric acid (25 cm^3) in ethanol (100 cm^3) was added dropwise, and the precipitated salt was collected and washed with ethanol. The product was recrystallized as colorless platelets from hot water, washed on the filter crucible with absolute ethanol and ether, then dried at 85°C for 60 min. Molar mass by pH titration (end points determined by Gran's analysis) was 395.5; calculated 398.2 g mol^{-1}.

Solvents and Solutions

All aqueous solutions were prepared with CO_2-free distilled water. The preparation and analysis of the metal salt solutions have been described (11). Dioxane (Baker Analyzed Reagent) was refluxed with sodium and distilled through a 35 cm Vigreaux column in a nitrogen atmosphere; distillation was essential to remove the preservative sodium diethyldithiocarbamate (0.001%). Solvent purity was checked by ultraviolet spectroscopy and by pH titration to determine dissolved CO_2.

pH Measurements

For work in aqueous solution pH^+ measurements were made with the equipment and procedure described previously (11). In aqueous dioxane pH measurements were made with a Beckman E-2 glass electrode and EIL calomel electrode (utilizing a filling solution of 0.1 M KCl in 1.25 M KNO_3) coupled with a Radiometer PHM52 Digital pH meter. The electrode pair was calibrated as a hydrogen-ion concentration probe by titration of (*i*) HNO_3 into KNO_3 solution and into KNO_3/HNO_3 solution (pH^+ 1.6–2.7), and (*ii*) KOH into KNO_3 solution (pOH^- 2.9–2.0), all solutions and titrants being in 50% (v/v) aqueous dioxane, 25°C, $I = 0.10$ M (KNO_3).

Ligand protonation was studied by titration of standard KOH from a Gilmont micrometer syringe into solutions (40 cm^3) of ligand salt (ca. 2×10^{-3} M) and KNO_3 ($I = 0.10\ M$) in the appropriate solvent. The stepwise (amino) protonation constants in Table 1 were computed from derived $\bar{n}_H$(obsd) – pH data by use of the least-squares procedures detailed elsewhere (12) ($\bar{n}_H$ average number of protons bound per ligand molecule). A typical titration involved 50 data points in the range $\bar{n}_H$ = 0.2–3.6 (aqueous solution) or 0.4–3.35 (aqueous dioxan). R factors (13) of 0.3% (1% for aqueous dioxan) were achieved and there were no systematic trends in the residuals $\bar{n}_H$(obsd) − $\bar{n}_H$(calcd).

The formation of complexes $[ML]^{2+}$ and $[M(HL)]^{3+}$ was studied by titration of KOH into solutions of metal nitrate (ca. 1×10^{-3} M), ligand salt (ca. $1.2–1.6 \times 10^{-3}$ M), and KNO_3 ($I = 0.10\ M$) in the appropriate solvent. The titration curves for Zn, Cd, and Pb showed an end point at pH^+ 3.9–4.9 (after addition of 1 mol of OH^- per mole of ligand) followed by a buffer region (at pH^+ 4.8–5.6, 5.0–6.1, and 5.2–6.1, respectively) and a second end point corresponding to completion of the reaction

$$M(aq)^{2+} + LH_3^{3+} + 3OH^- \rightarrow [ML]^{2+} + 3H_2O$$

TABLE 2. Thermodynamic data for the formation of triethylenetetramine complexes $[ML]^{2+}$ and $[M(HL)]^{3+}$, (M = Mn, Zn, Cd, Pb) in aqueous solution and 50% (v/v) aqueous dioxane, 25°C, I = 0.10 M KNO_3 (values in parentheses for aqueous dioxane)

[b]0.10 M KNO_3.

plus one mole of OH^- per mole of excess ligand. (The end point for the reaction $LH_3^{3+} + OH^- \rightarrow LH_2^{2+} + H_2O$ is at ca. pH^+ 8.0.) For Zn, Cd, and Pb the data in the buffer region were analysed in terms of the equilibria [1] and [2] by use of the computer program SCOGS (14).

$$[1] \qquad M(aq)^{2+} + L \overset{K_1}{\rightleftharpoons} [ML]^{2+}$$

$$[2] \qquad M(aq)^{2+} + HL^+ \overset{K_2}{\rightleftharpoons} [M(HL)]^{3+}$$

The standard deviation in titer ($V_{calcd} - V_{obsd}$) was typically 3.5 × 10^{-4} cm^3 and there were no systematic trends in the residuals. For Mn the titration curve showed much less distinct inflections and a poorly defined buffer region at pH^+ 7.7–8.7; these solutions were very oxygen-sensitive. The data in the buffer region were best analysed in terms of the single equilibrium reaction [1]. All solutions were swept with N_2 during titration; this was essential for Mn solutions (both solvents) and for aqueous dioxane which rapidly absorbs atmospheric CO_2.

Calorimetric Measurements

The calorimeter has been described (11). For the protonation of triethylenetetramine in aqueous solution buffered solutions of the ligand (C_L ca. 3 × 10^{-3} M, $\bar{n}_H$ 0.4, I = 0.10 M KNO_3) were titrated in the calorimeter with HNO_3 (1 M). ΔH_i values were determined from the measured heat changes (2–8 J) as outlined previously (11). The least-squares fit gave an R factor of 1.2% and a standard deviation of 0.08 J in $Q_{obsd} - Q_{calcd}$. The ΔH_i values in Table 1 result from 14 data points (2 titrations). For the protonation of triethylenetetramine in aqueous dioxane buffered solutions of the ligand (C_L 1.7 × 10^{-3} M, $\bar{n}_H$ 0.35) were titrated with HNO_3 (0.5 M; 50% aqueous dioxane). The measured heat changes were corrected for the heat of dilution of the titrant acid (determined from the average of 8 measurements as 1.4 ± 2 kJ mol^{-1} for a 625-fold dilution of titrant), and for the neutralization of OH^- produced by the reaction $L + H_2O \rightleftharpoons LH^+ + OH^-$ (ΔH = −57.82 kJ mol^{-1}) (15). The ΔH_i values in Table 1 result from 17 data points (3 titrations); R factor 3.0%, standard deviation 0.12 J.

For the complexes $[M(HL)]^{3+}$ and $[ML]^{2+}$ calorimetric measurements involved titration of HNO_3 into solutions of metal nitrate (1 × 10^{-3} M) and ligand salt (1.6 × 10^{-3} M), starting at pH^+ ca. 5.9 (Pb) or 5.4 (Zn) (cf. titration curves); i.e. the enthalpy changes for dissociation of the complex and protonation of the ligand were determined:

$$[ML]^{2+} + nH^+ \rightarrow M(aq)^{2+} + LH_n^{n+}$$

$$[M(HL)]^{3+} + (n-1)H^+ \rightarrow M(aq)^{2+} + LH_n^{n+}$$

The composition of the calorimeter solution at each titration point was calculated as described previously (11). The enthalpy changes for reactions [1] and [2] (ΔH_1 and ΔH_2) were calculated from a least-squares fit to the equation $Q_{corr} = a_1\Delta H_1 + a_2\Delta H_2$ where a_1 and a_2 are the changes in the number of moles of $[ML]^{2+}$ and $[M(HL)]^{3+}$ respectively between successive titration points. Q_{corr} is the observed heat change corrected as above and for protonation of ligand displaced from the metal. The ΔH_2 values (Table 2) carry significant uncertainties. The distribution curves for $[ML]^{2+}$ and $[M(HL)]^{3+}$ as a function of pH^+ show that the concentration of $[M(HL)]^{3+}$ varies less with pH than does the concentration of $[ML]^{2+}$; e.g. for a 1 × 10^{-3} M zinc solution (C_L = 1.18 × 10^{-3} M) the concentration of $[ML]^{2+}$ increases from 3.2 × 10^{-4} to 6.6 × 10^{-4} M between pH^+ 5.12 and 5.44, whereas in this pH range the concentration of $[M(HL)]^{3+}$ increases from 6.4 × 10^{-5} to 6.9 × 10^{-5} M at pH^+ 5.27 then decreases to 6.3 × 10^{-5} M. Thus in the calorimetric titration $a_2 \ll a_1$ for each data point and ΔH_2 carries a larger error than ΔH_1.

Discussion

Ligand Protonation in Aqueous Solution

The log k_n and ΔH_n data reported here for protonation of triethylenetetramine (L) in 0.1 *M* KNO_3 are in satisfactory agreement with those reported for 0.1 *M* KCl (16) and 0.1 *M* $NaClO_4$ (17). The observed trend $-\Delta H_1 < -\Delta H_2 > \Delta H_3 > \Delta H_4$ is typical for protonation of linear polyamines in aqueous solution. It has been postulated that the first protonation of a polyamine gives a tautomeric mixture in which the proton has added predominantly to the slightly more basic secondary amino center(s) (18). For a secondary alkylamine $-\Delta H$ is smaller and ΔS is larger (typically ca. 43 J K^{-1} mol^{-1}) (19) than for protonation of a primary amine. The second step involves predominantly the (more exothermic) protonation of primary amino groups and is characterized by a larger $-\Delta H$ value (when the protonation sites are sufficiently separated) and a smaller ΔS value (typically ca. 23 J K^{-1} mol^{-1}) for a primary alkylamine. The dominant tautomeric form of the dication LH_2^{2+} is postulated to be that having both terminal amino groups protonated.

The enthalpy changes ΔH_n result from several effects: (*i*) the difference in solvation enthalpy for a polar amino group, an alkylammonium group, and a hydronium ion, (*ii*) the relative donor strengths of the amino group and the solvent towards the proton, and (*iii*) intramolecular electrostatic interactions between an ammonium group and adjacent ionic or polar sites. Solvation effects encompass hydrogen bonding, formation of primary and secondary spheres of ion- or dipole-oriented solvent molecules (interactions which relate to the polarity, polarizability, and dielectric constant of the solvent), and charging effects associated with placing a charge site in a medium of given dielectric. It is only when some of these effects are approximately constant for a series of structurally related ligands in a given solvent, or for a given ligand in a series of solvents, that clear deductions can be made from series of thermodynamic values.

Ligand Protonation in Aqueous Dioxane

The data in Table 1 indicate that for each protonation step the free energy change is more negative in water (ΔG_n) than in aqueous dioxane (ΔG_n^*). This is in accord with the results for ethylenediamine (5). As expected on the basis of intramolecular inductive effects and electrostatic interactions between ionic sites, ΔG_n becomes less negative with increasing n. Further, the difference $-(\Delta G_n - \Delta G_n^*)$ increases from 0.25 for $n = 1$ to 0.62 for $n = 4$. This trend indicates a contribution from 'through solvent' intra-ionic interactions.

The sites of addition for the first two protons might be inferred if ΔH and ΔS data were available for model compounds in this solvent, as is discussed above for aqueous solution. The order of alkylamine basicities, secondary > primary > tertiary, has been established for aqueous solution (20) and for 1,4-dioxane (21), and it could be assumed for the mixed solvents. For both solvents it is expected that the dominant tautomeric form for the diammonium cation LH_2^{2+} will have both terminal groups protonated; it follows that in both solvents the addition of the third (and fourth) proton will be predominantly to secondary amino groups.

The stepwise protonations can be divided into two groups. The addition of the first proton to give LH^+ is characterized by $-\Delta H_1^* > -\Delta H_1$ and $\Delta S_1 > \Delta S_1^*$. These relationships may indicate a difference in solvation energies for reactants and product in the two solvents. For addition of the second, third, and fourth protons, reactions in which intramolecular electrostatic interactions will also contribute, $-\Delta H_n$ is greater than $-\Delta H_n^*$, and $\Delta S_n^* > \Delta S_n$. ΔH_n^* values are significantly less exothermic (by 5.0, 9.3, and 14.9 kJ mol^{-1}) and ΔS_n^* values significantly more favorable (by 9, 21, and 38 J K^{-1} mol^{-1}, $n =$ 2, 3, 4 respectively) than the corresponding values for reaction in aqueous solution.

Effect of Dielectric on Ion–Ion Interactions

The more positive values for ΔH_n^* and ΔS_n^* ($n =$ 2, 3, 4) are consistent with the effects of ion–ion interactions in media with different dielectric properties. For the approach of spherical ions of charge ν and γ to separation a_n in a structureless homogeneous medium of fixed macroscopic dielectric constant ε, the free energy, enthalpy, and entropy changes are given by eqs. [3]–[5]

$$\Delta G = -T\Delta S_t - A \qquad [3]$$

$$\Delta H = -A\left(1 + \frac{T}{\varepsilon}\cdot\frac{\partial E}{\partial T}\right) \qquad [4]$$

$$\Delta S = \Delta S_t - A\left(\frac{1}{\varepsilon}\cdot\frac{\partial \varepsilon}{\partial T}\right) \qquad [5]$$

where ΔS_t is the difference in translational entropy of product and reactants and A is the electrostatic work involved in the process, $A = Ne^2\lambda\nu/a_n\varepsilon$ (22). The partition of ΔG between ΔH and ΔS depends on the solvent, viz. on $\partial\varepsilon/\partial T$, this term being non-zero for both solvents. The polar H_2O molecules in solvent water ($\partial\varepsilon/\partial T = -0.36$ at 25°C) (22) have a larger capacity to release (or absorb) enthalpy in a solvent orientation (or release) process than do dioxane molecules ($\partial\varepsilon/\partial T = -0.21$ for 45% w/w

dioxane–water) (23); $\partial\varepsilon/\partial T$ measures the extent to which thermal motion can offset the alignment of solvent dipoles. Substituting macroscopic values of ε and $\partial\varepsilon/\partial T$ into eqs. [3]–[5] we obtain

$$\Delta H_n - \Delta H_n^* = -A_n'\,(0.016)$$

and

$$\Delta S_n - \Delta S_n^* = -A_n'\,(0.001)$$

where A_n' ($= Ne^2\lambda v/a_n$) is positive. Thus ΔS_n^* will be greater than ΔS_n and $-\Delta H_n > -\Delta H_n^*$. These predictions are consistent with the experimental data. They indicate that formation of multiple cationic center in LH_n^{n+} ions causes greater net solvent orientation in water than in aqueous dioxane.

It can be approximated that for addition of the second proton, $LH^+ + H^+ \rightarrow LH_2^{2+}$, $a_n = 3d$ where d is the mean distance between adjacent amino groups in triethylenetetramine. For the third proton the new ammonium site is at distances d and $2d$ from charge centers, while for the fourth proton the distances are d, d, and $2d$. One can write

$$\Delta H_n = -A''\cdot f(d)\cdot f(\varepsilon)$$

or

$$\Delta H_n - \Delta H_n^* = -A''\cdot f(d)\cdot f(\varepsilon,\varepsilon^*)$$

where $A'' = Ne^2v$ and $f(d) = 1/3$, $3/2$, and $5/2$ for $n = 2$, 3, 4 respectively. Plots of $\Delta H_n - \Delta H_n^*$, ΔH_n, and $\Delta S_n - \Delta S_n^*$ against $f(d)$ are linear within experimental error (Fig. 1). These plots support the model assumed for stepwise protonation.

The reaction $L + H^+ \rightarrow LH^+$ differs from those discussed above in that no ion–ion repulsions are involved. Desolvation of an amino group and a proton, and solvation of a newly formed ammonium group will contribute to the solvation enthalpy and entropy. The reaction involves a larger net increase in entropy in aqueous solution than in aqueous dioxane. The polar amino group will contribute to the observed trend: an amino group can hydrogen bond to a water molecule via the nitrogen lone pair, and we infer that it will have a lower partial molal entropy in water than in aqueous dioxane in which hydrogen bonding between dioxane and water is considered to decrease the charge density on the hydrogen atoms in the water molecules (8). The positive transfer enthalpies for halide ions from water to aqueous dioxane are consistent with this concept (24).

The proton is more strongly solvated than an alkylammonium group ($-\Delta H_{soln} = 1129$ kJ mol^{-1}; cf. $C_2H_5NH_3^+$ 314 kJ mol^{-1} in water) (20) and desolvation of a proton and solvation of an ammonium ion is expected to involve a net release of solvent. At 25°C the density of 50% (v/v) aqueous dioxane is greater than that of an ideal solution (3)

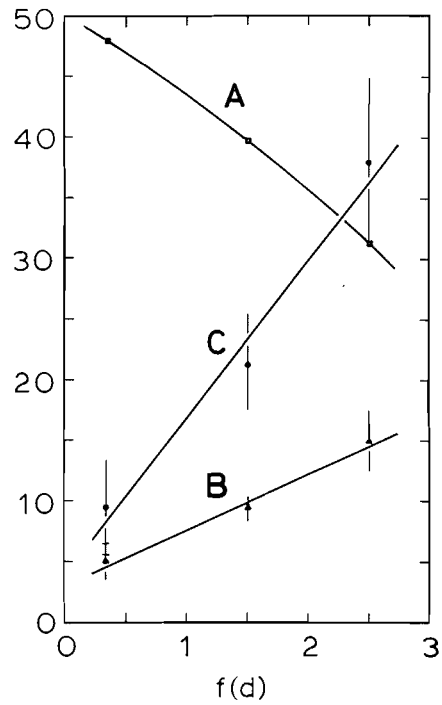

FIG. 1. Plots of thermodynamic functions vs. $f(d)$. Curve A, $-\Delta H_n$/kJ mol^{-1}; curve B, $(\Delta H_n^* - \Delta H_n)$/kJ mol^{-1}; curve C, $(\Delta S_n^* - \Delta S_n)$/J K^{-1} mol^{-1}.

implying a less ordered solvent structure than in water, as also indicated by X-ray diffraction (25). Thus release of solvent molecules from cations and their incorporation in the bulk solvent is expected to involve a more positive entropy change in aqueous dioxane. Thus solvation reactions of the polar amino group and the cations are expected to make opposing contributions to the entropy change. From the observed ΔS_1 values it is inferred that solvation of the polar amino group is the dominant factor in determining relative basicity in the two solvents.

Metal–Triethylenetetramine Complexes

Schwarzenbach (26) reported log K values for the formation of complexes $[MnL]^{2+}$, $[FeL]^{2+}$, and $[ML]^{2+}$, $[M(HL)]^{3+}$ ($M = Co^{2+}$, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, Ag^+) at 20°C. Sacconi *et al.* (27) corrected the values for Mn, Fe, Co, Ni, Cu, Zn to 25°C by use of their calorimetrically determined ΔH values. Values of log K for the Pb^{2+} complex (25°C) have been reported from polarographic studies (9.9, 1 M KNO_3) (28) and pH measurement (10.4, 0.1 M) (29).

Sacconi *et al.* (27) measured ΔH for formation of $[ML]^{2+}$ complexes by titrating metal ion solution into a buffered solution of the ligand. Under the conditions used the concentration of $[M(HL)]^{3+}$ in

solution was immeasurably small and only ΔH_1 (reaction [1]) was determined. A similar approach was used by Wright *et al.* (30) for divalent Ni, Cu, Zn, and Cd. In the present work enthalpy changes have been determined by titration of HNO_3 into a buffered solution of the metal and ligand, i.e. the decomposition reactions of $[ML]^{2+}$ and $[M(HL)]^{3+}$ have been studied. However, for reasons noted under Experimental, the ΔH_2 values (reaction [2]) are subject to a very large uncertainty; values are reported in Table 2 but are not discussed further.

The entropy change for formation of $[ZnL]^{2+}$ in aqueous solution is ca. 42 J K^{-1} mol^{-1} greater than that for formation of complexes $[ML]^{2+}$, M = Mn, Co, Fe, Ni (27). It was deduced that the zinc complex has a lower coordination number (probably 4) than do the other complexes (probably $[ML(H_2O)_2]^{2+}$). No ΔH or ΔS data have been reported previously for the Pb–triethylenetetramine system in aqueous solution.

The data in Table 2 establish that the stability of each complex is similar in the two solvent systems. This result is consistent with those observed for many metal-ion hydrolysis reactions in water and aqueous dioxane (31). The similar log K values conceal significant differences in ΔH and ΔS values. For Zn^{2+} and Pb^{2+}, $-\Delta H_1$ is greater than $-\Delta H_1$* (by 7.5 and 5 kJ mol^{-1} respectively) and ΔS_1 is less than ΔS_1* (by 26 and 14 J K^{-1} mol^{-1}). These compensating ΔH and ΔS values indicate that solvation effects are different in the two solvents.

From Raman studies on zinc nitrate solutions (32) it has been deduced that there is no significant solvation of zinc ions by dioxane molecules in aqueous dioxane. Aqueous dioxane is a less structured solvent (fewer hydrogen bonds) than water. Thus for a given metal ion, if n' (reaction [6])

$$[6] \quad M(H_2O)_6^{2+} + L(nH_2O) \rightarrow [ML]^{2+} + n'H_2O$$

is the same in both solvents, the binding properties of the bulk solvent toward the released water molecules will lead to a higher $-\Delta H$ and lower ΔS in solvent water. This is consistent with the results recorded in Table 2.

It has been postulated (*loc. cit.*) that the polar amino centers of the ligand will be more strongly solvated in aqueous solution. Thus desolvation of L will be more endothermic in water but this apparently does not offset the effect of n' water molecules binding into the water lattice.

Although there is no evidence for specific Zn^{2+}–dioxane interactions in aqueous dioxane, such interactions (involving the boat conformation of dioxane) have been postulated for solutions of alkali metal ions (9) and tetraalkylammonium ions (10). These results are not contradictory if it is noted that the average binding energy of a water molecule to a bivalent cation is strongly dependent on the polarizability of the water molecule. For example, for $Fe(H_2O)_6^{2+}$ the permanent and induced dipoles in the water molecule contribute 217 and 138 kJ mol^{-1} respectively to the average bond energy (33). In contrast, for $K(aq)^+$ the figures are 71 and 17 kJ mol^{-1} and under these circumstances the less polarizable dioxane molecule can compete with the water molecule in the metal-ion coordination sphere.

Flash photolysis of K^-, Rb^-, and Cs^- in tetrahydrofuran (THF) produces the corresponding ion-pairs (K^+, e_s^-), (Rb^+, e_s^-), and (Cs^+, e_s^-), followed by the regeneration of the parent metal anion, M^-. In mixed-metal solutions containing Na and M where M is K, Rb, or Cs, photolysis of Na^- also forms the (M^+, e_s^-) ion-pair and M^-, but with the latter then reforming Na^- on an extended time scale. Similar results were obtained in dimethoxyethane (DME) at 213 K, but in this case with the initial formation of a loose ion-pair, $(M^+, e_s^-)_{loose}$.

Based on a Gaussian–Lorenztian shape function, the 'best-fit' optical bands for the (M^+, e_s^-) and M^- species were used to simulate the experimental spectra and deduce the corresponding extinction coefficients in both solvents.

The overall mechanism is complex but is in good agreement with previous interpretations deduced by pulse radiolysis.

W. A. SEDDON, J. W. FLETCHER, F. C. SOPCHYSHYN et E. B. SELKIRK. Can. J. Chem. **57,** 1792 (1979).

La photolyse éclair de K^-, Rb^- et Cs^- dans le tétrahydrofuranne (THF) conduit aux paires d'ions correspondantes (K^+, e_s^-), (Rb^+, e_s^-) et (Cs^+, e_s^-) qui sont suivies par une regénération de l'anion métallique apparenté, M^-. Dans des solutions de métaux mixtes contenant du Na et du M où M est égal à K, Rb et Cs, la photolyse de Na^- conduit aussi à la formation de la paire d'ions (M^+, e_s^-) et de M^-; ce dernier conduit à la reformation de Na^- sur une échelle de temps prolongée. On a obtenu des résultats semblables dans le diméthoxyéthane (DME) à 213 K; toutefois, dans ce cas, il y a une formation initiale d'une paire d'ions lâche, $(M^+, e_s^-)_{lâche}$.

Sur la base d'une fonction de forme Gaussienne–Lorenztienne, on a utilisé les bandes optiques qui concordent le mieux pour les espèces (M^+, e_s^-) et M^- pour simuler le spectre expérimental et pour en déduire les coefficients d'extinction correspondants dans les deux solvants.

Le mécanisme global est complexe mais il est en bon accord avec les interprétations antérieures déduites d'études par radiolyse pulsée.

[Traduit par le journal]

Introduction

Steady state photolysis and flash photolysis of alkali metal anions, M^-, in ethers have been investigated previously (1–3). The primary photolysis step is considered to be reaction [1] involving the formation of solvated electrons, e_s^-, and a species of stoichiometry M, best regarded as an ion-pair (M^+, e_s^-) (4, 5).

$$[1] \qquad M^- \xrightarrow{h\nu} (M^+, e_s^-) + e_s^-$$

However, because of Na^+ contamination and, what are now known to be incorrect spectral assignments, the early work (1) on the flash photolysis of potassium in tetrahydrofuran (THF) and dimethoxyethane (DME) requires reinterpretation. Furthermore, a more recent study (4) has indicated a basic inconsistency in the spectra attributed to the species (Na^+, e_s^-), as generated by flash photolysis (3), and pulse radiolysis (4).

This paper describes the flash photolysis of potassium rubidium, and cesium solutions in THF and DME together with similar studies on mixed metal solutions containing sodium/potassium, sodium/rubidium, and sodium/cesium. The results clearly substantiate the conclusions reached earlier by pulse radiolysis (4, 6).

Experimental

A detailed description of the flash photolysis apparatus has been given elsewhere (7). Briefly, solutions were photolyzed with a 60 J, 1 μs flash from two quartz arc lamps (iLC Sunnyvale Inc., California, #L378-008) connected in series. The flash was filtered by surrounding each lamp with the solvent under investigation. The analyzing light was filtered at the source with a Corning glass filter #2-62 and at the monochromator with either a 7-56 or a 1400 nm "cut-on" interference filter at the appropriate wavelengths. Quartz flow systems containing 2 cm × 1 cm diameter reaction cells were otherwise identical to those described previously (8, 9). Methods of sample preparation, solvent purification, and optical detection are also well documented (8, 10). However, it is worth noting that dissolution of the alkali metals to form

[1]AECL No. 6550.

0008-4042/79/141792-09$01.00/0

M^- is greatly facilitated by immersion of the container in an ultrasonic bath. Initial M^- spectra were measured on a Cary 17 Recording Spectrophotometer. Simulation of the experimental spectra was accomplished using a Hewlett Packard 9830 calculator, 9864A digitizer, and 9862 plotter, to store and compute the ratio of component species produced after the flash.

Results and Discussion

In THF (and DME) alkali metal solutions the equilibrium optical spectra are predominantly due to the formation of M^- (11), with only small concentrations of (M^+, e_s^-) and e_s^- detectable by electron spin resonance (12). The reported optical spectra (13–16) show good agreement in the position of the band maxima but often significant differences in band width and intensity, particularly on the high energy side of the spectrum. Utilizing the most reliable data (free of Na^+ contamination) (15, 16) in comparison with our own initial spectra, the overall band envelope for each M^- species was established by a Gaussian–Lorenztian (G–L) shape function analogous to the method used for e_s^- (17–19). Since sodium is insoluble in THF (and DME) our Na^- spectra were obtained either by the addition of dicyclohexano-18-crown-6 (16) or from Na/Cs solutions in which the final equilibrium spectrum is due to Na^-.

Figure 1 shows the best-fit G–L spectra for the species Na^-, K^-, Rb^-, and Cs^- in THF observed by conventional steady state techniques. The experimental data only begin to diverge from these curves at a point corresponding to about half the peak intensity on the high energy Lorenztian tail of the spectrum. This may be due to light scattering by finely distributed metal particles or, in the absence of added sodium, due to contamination by Na^-. Representative experimental points are shown for Na^- and K^- to illustrate the region of discrepancy.

A similar fitting procedure was adopted for the ion-pair species (Na^+, e_s^-), (K^+, e_s^-), and (Cs^+, e_s^-) (10, 20). The (Rb^+, e_s^-) spectrum was deduced by the flash photolysis of Rb^- solutions (see Fig. 4 and discussion below). In general the G–L fits are even better than observed for the M^- species and are given in Fig. 2 along with a few representative experimental points where differences occur.

Although empirical the G–L band shapes, particularly with respect to M^-, were chosen for the purposes of simulation (see below) because these gave the closest fit to the bleached M^- photolysis bands. For the purposes of this paper the precise shape in this region is of relatively minor importance. However, because they are observed as a difference in optical properties before and after the flash, the photolysis spectra do suggest that the high energy "wing" is adequately described by the Lorenztian function. The alternative involves a somewhat arbitrary choice between the broader (15, 16) or narrower (3, 13) bands reported previously. In all other respects equally good fits to the data were obtained using the experimentally observed equilibrium spectra. This simply reflects how

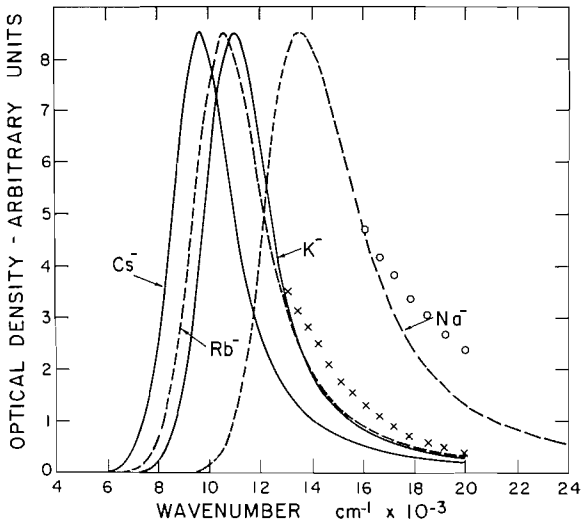

FIG. 1. Gaussian–Lorenztian shape functions describing the optical absorption spectra of alkali metal anions in THF. ○, ×, representative experimental points for Na^- and K^- to illustrate divergences on the high energy sides of the spectra.

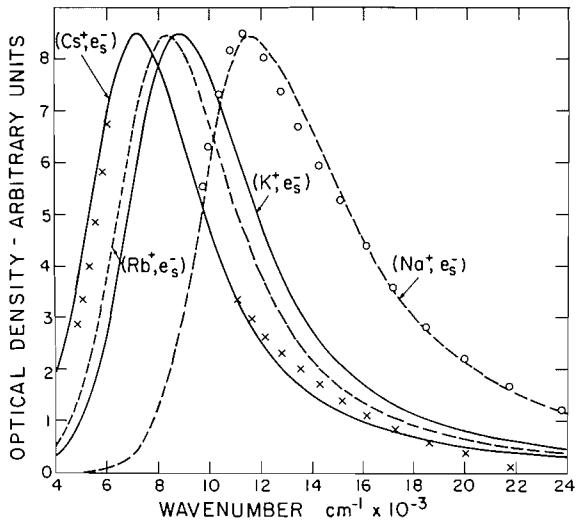

FIG. 2. Gaussian–Lorenztian shape functions describing the optical absorption spectra of alkali metal ion-pairs in THF. ○, ×, representative experimental points for (Na^+, e_s^-) and (Cs^+, e_s^-) to illustrate agreement with G–L spectra.

well the G–L shapes otherwise describe the overall (M^+, e_s^-) and M^- absorption bands.

Flash Photolysis of M^- Solutions in THF-spectra

Figures 3, 4, and 5 (open circles) show the spectra observed at the end of the flash (~6 μs) in ~2.5 μ*M* K^-, ~8 μ*M* Rb^- (saturated solutions) and ~10 μ*M* Cs^- solutions in THF at 294 K. In essence each spectrum represents the bleaching of the respective M^- species together with the concurrent formation of an infrared absorption band which shifts to longer wavelengths on progressing from K^- to Cs^- solutions. For K^- and Cs^- solutions such absorption bands correspond to those expected for the appropriate ion-pairs (K^+, e_s^-) and (Cs^+, e_s^-), respectively (10). Likewise we suggest that the corresponding band observed from Rb^- solutions represents the formation of (Rb^+, e_s^-). Its band maximum is intermediate to that of (K^+, e_s^-) and (Cs^+, e_s^-) and entirely consistent with established trends for the M^- and (M^+, e_s^-) series from Na to Cs (21).

However, the experimental spectra in Figs. 3–5 cannot be duplicated entirely on the basis of the spectra given in Figs. 1 and 2. In each case the bleached band contains a small, but significant, contribution from Na^-, presumably formed from spurious Na^+ contamination. Furthermore, the infrared absorption observed from the photolysis of K^- is, at wavelengths >1300 nm, significantly greater than anticipated from (K^+, e_s^-) alone suggesting, in addition, a small contribution from e_s^-.

Assuming $[K^+] \sim [K^-] = 2.5$ μ*M*, the presence

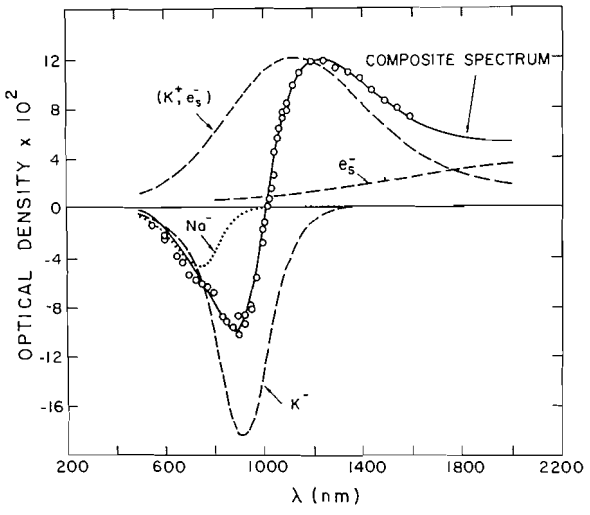

FIG. 3. Optical spectrum (open circles) observed at the end of the flash in ~2.5 μ*M* K^- solutions in THF. The solid line represents the composite spectrum simulated from the component species, Na^-, K^-, (K^+, e_s^-), and e_s^-.

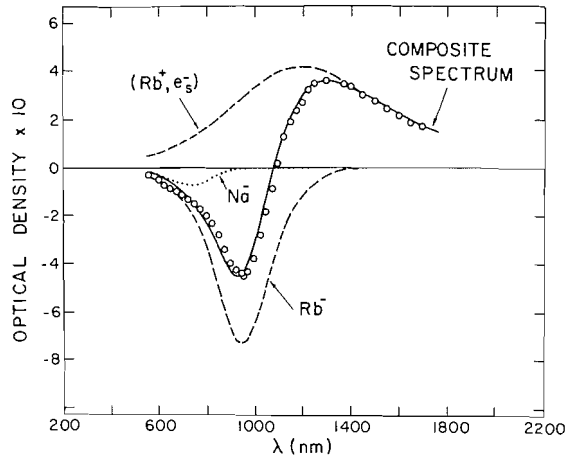

FIG. 4. Optical spectrum (open circles) observed at the end of the flash in ~8 μ*M* Rb^- solutions in THF. The solid line represents the composite spectrum simulated from the component species Na^-, Rb^-, and (Rb^+, e_s^-).

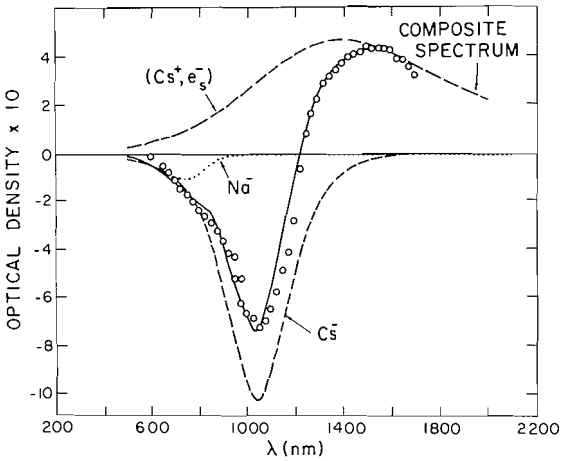

FIG. 5. Optical spectrum (open circles) observed at the end of the flash in ~10 μ*M* Cs^- solutions in THF. The solid line represents the composite spectrum simulated from the component species Na^-, Cs^-, and (Cs^+, e_s^-).

of e_s^- is consistent with the dissociation constant $1/K_2 = 4 \pm 2 \times 10^{-7}$ *M* (10).

[2] $$K^+ + e_s^- \rightleftharpoons (K^+, e_s^-)$$

Since $k_2 = 4.6 \pm 0.6 \times 10^{11}$ L mol^{-1} s^{-1} (10) reaction [2] will be essentially complete at the end of the flash and hence $[e_s^-]/[(K^+, e_s^-)] = 0.16 \pm 0.08$. The solid line drawn through the experimental points in Fig. 3 represents the simulated spectrum deduced by adding the appropriate optical densities for the component species Na^-, K^-, and (K^+, e_s^-) (Figs. 1 and 2) and e_s^- (10). Taking the extinction coefficients $\varepsilon_{e_s^-}$ and $\varepsilon_{(K^+, e_s^-)} = 5 \pm 0.5 \times 10^4$ and $2.9 \pm 0.2 \times 10^4$ L mol^{-1} cm^{-1}, respectively (10),

TABLE 1. Optical parameters for alkali metal anions and ion-pairs in THF

Species	ν_{max}	$\omega_{1/2}{}^{G}$*	$\omega_{1/2}{}^{L}$*	$\varepsilon_{max} \times 10^{-4}$ L mol^{-1} cm^{-1}

*In $cm^{-1} \times 10^{-3}$.
†Reference 24 and this work (see later).
‡Reference 10.

then $[e_s^-]/[(K^+, e_s^-)] = 0.17 \pm 0.02$, in excellent agreement with the above $1/K_2$.

It is worth noting that using the experimentally observed component spectra to simulate the composite spectrum in Fig. 3 gives, within experimental error, the same result.

Interpretation of the Rb^- and Cs^- photolysis spectra was accomplished in a similar manner. However, in both cases the infrared band appears to be due entirely to (Rb^+, e_s^-) or (Cs^+, e_s^-), respectively. Hence, the dissociation constant for both ion-pairs must be $< 1/K_2$. Again this is consistent with recognized trends for equilibrium constants in alkali metal solutions (22) and with the decreasing dissociation constants, from Na to Cs, for alkali metal salts of tetraphenylboron in THF (23).

Extinction Coefficients

Having established that the flash photolysis spectra are essentially composed of M^- (bleached) and (M^+, e_s^-) then, based on the material balance inherent in [1] and [2], one can deduce their relative extinction coefficients. Taking ε_{Na^-}, $\varepsilon_{(K^+, e_s^-)}$, and $\varepsilon_{(Cs^+, e_s^-)} = 8.2 \pm 0.3$, 2.9 ± 0.2, and $2.5 \pm 0.2 \times 10^4$ L mol^{-1} cm^{-1}, respectively (10, 24), the absolute values for ε_{K^-} and ε_{Cs^-} can be determined experimentally. Furthermore, the oscillator strength, f, for a Gaussian–Lorenztian absorption band is given by [3] (18).

$$[3] \quad f = 4.32 \times 10^{-9} (1.065\omega_{1/2}{}^{G} + 1.571\omega_{1/2}{}^{L})\varepsilon$$

where $\omega_{1/2}{}^{G}$ and $\omega_{1/2}{}^{L}$ represent the width at half height on the Gaussian and Lorenztian sides, respectively. Since $f = 1$ for (M^+, e_s^-) (20) and $f = 2$ for M^- (24), it is also possible to calculate $\varepsilon_{(M^+, e_s^-)}$ and ε_{M^-} from the spectra given in Figs. 1 and 2. In this way both the experimental and calculated values can be compared for self-consistency.

With respect to the experimental value for ε_{Na^-} (24) it should be noted that this was determined in ethylenediamine (EDA). Although the absorption maximum in EDA occurs at higher energy (15 000 cm^{-1}) the overall band shape is very close to that given for THF in Fig. 1 ($\nu_{max} = 13\,500\ cm^{-1}$). Consequently, it seems reasonable to assume the same extinction coefficient in THF.

Table 1 summarizes the optical parameters and extinction coefficients deduced by experiment and calculation from the results given in Figs. 1–5. The calculated value for ε_{Rb^-} was used to deduce $\varepsilon_{(Rb^+, e_s^-)}$ from Fig. 4. It can be seen that the agreement between both sets of data is well within experimental error and hence substantiates the overall mass balance and validity of the G–L spectra in Figs. 1 and 2.

Kinetics

The decay of the infrared absorption and concomitant recovery of the bleached M^- band follow neither good first nor second order kinetics. In potassium solutions the decay at 1450 nm appears to be a better second order process with $k/\varepsilon = 4.3 \times 10^5$ cm s^{-1} at 1450 nm. From the known spectrum and $\varepsilon_{(K^+, e_s^-)}$ we calculate $\varepsilon_{1450} = 1.8 \times 10^4$ L mol^{-1} cm^{-1} and hence $k = 7.7 \times 10^9$ L mol^{-1} s^{-1} at 294 K. Similar kinetic analysis between 213 and 270 K gives for the decay process, an energy of activation, $E_a = 20 - 30$ kJ mol^{-1}. This is consistent with the reformation of M^- by either reaction [4f] or [5f] or, some combination of both.

$$[4] \quad (M^+, e_s^-) + e_s^- \overset{f}{\rightleftharpoons} M^-$$

$$[5] \quad (M^+, e_s^-) + (M^+, e_s^-) \overset{f}{\rightleftharpoons} M^- + M^+$$

However, we are unable to differentiate between these alternatives because of the equilibrium nature of the overall system.

In cesium solutions and rubidium solutions a much better first order fit is obtained. This is not under-

stood and a detailed study of the overall kinetics is in progress.

Pure Metals in DME

Compared to THF the M^- solutions are considerably less stable and require low temperatures to minimize autodecomposition. Because of this inherent difficulty we were unable to obtain reliable spectra from the photolysis of Rb^- or Cs^- in DME.

Figure 6 shows the spectrum observed after the flash in $\sim 5\ \mu M\ K^-$ solutions in DME at 213 K. Whereas the bleached band is similar to that obtained in THF the infrared absorption is significantly different. Previous investigators (3) have assigned this band to e_s^-. However, attempts to simulate the experimental spectra using the known spectrum for e_s^- at 213 K (4) were not entirely satisfactory (see Fig. 6) and gave a very poor material balance. On the other hand good agreement is obtained when the infrared band is assigned to the formation of a loose ion-pair $(K^+, e_s^-)_{loose}$. The absorption spectrum of the latter (shown in Fig. 6) was obtained from the pulse radiolysis of 10^{-2} *M* potassium tetraphenylboron in DME at 213 K. Its spectrum is very similar to that reported previously for $(Na^+, e_s^-)_{loose}$ (4) and is significantly narrower than e_s^- at wavelengths below the band maximum.

The solid line drawn through the experimental points in Fig. 6 represents the composite spectrum produced by the bleaching of K^-, and a small amount of Na^-, together with the formation of $(K^+, e_s^-)_{loose}$. The band shapes taken for Na^- and K^- were as shown in Fig. 1 but with the maxima

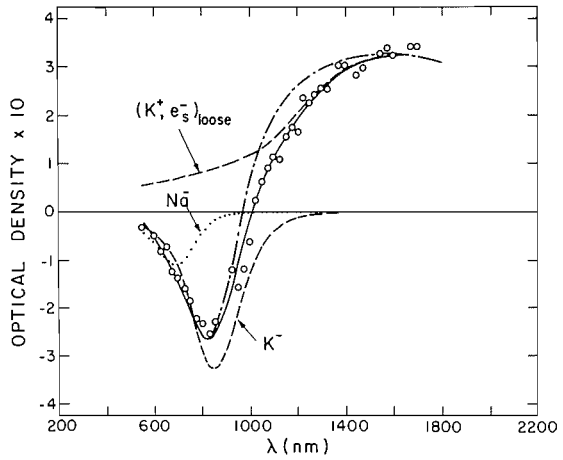

FIG. 6. Optical spectrum (open circles) observed at the end of the flash in $\sim 5\ \mu M\ K^-$ solutions in DME at 213 K. The solid line represents the composite spectrum simulated from the component species, Na^-, K^-, and $(K^+, e_s^-)_{loose}$. The broken line ----- shows a corresponding simulation using e_s^- instead of $(K^+, e_s^-)_{loose}$.

shifted to 14 280 cm^{-1} and 11 575 cm^{-1}, respectively, to compensate for effects of temperature (15, 16). As in the case of K/THF solutions the Na^- must arise from inadvertent Na^+ contamination. Excluding Na^- from the simulation gives a narrower bleached band and a significant absorption at wavelengths <600 nm. The latter is not observed experimentally.

Extinction Coefficients

Taking the experimental extinction coefficients in Table 1 for ε_{Na^-} and ε_{K^-}, and the component optical densities in Fig. 6, then $\varepsilon_{(K^+, e_s^-)_{loose}}$ at 213 K = $3.6 \pm 0.5 \times 10^4$ L mol^{-1} cm^{-1}. This is in reasonable agreement with the value of $2.8 \pm 0.4 \times 10^4$ L mol^{-1} cm^{-1} estimated by pulse radiolysis (4).

Kinetics

Both the decay of the infrared band and concomitant recovery of K^- appear to follow second order kinetics. Taking $\varepsilon_{(K^+, e_s^-)_{loose}} = 3.6 \times 10^4$ L mol^{-1} cm^{-1} to be independent of temperature, then k/ε_{1600} ranges from 3.8×10^9 L mol^{-1} s^{-1} at 270 K to 3.7×10^8 L mol^{-1} s^{-1} at 213 K with $E_a = 20$ kJ mol^{-1}.

Mixed Metal Solutions in THF-spectra

Figures 7, 8, and 9 show the spectra obtained as a function of time in Na/K, Na/Rb, and Na/Cs solutions, respectively. In each case two distinct time resolved processes can be observed. The decay of the infrared absorption, and partial recovery of the bleached band, occurs on a μs time scale to produce a long-lived intermediate absorption which then decays over a period of ~ 50 ms to re-establish the pre-photolysis equilibrium. These observations parallel those reported previously in both amine and ether solutions. A variety of explanations have been offered (1, 3, 25), the most recent of which (3) attributes the intermediate absorption to the formation of the (Na^+, e_s^-) ion-pair. As the ensuing discussion will show, the former interpretations are incorrect, but instead reflect a complexity, namely, the formation of Na^- in a mixed-metal solution.

From the earlier discussion concerning 'pure' M^- solutions it is evident from Figs. 7–9 that, qualitatively, the spectra observed immediately after the flash correspond to the bleaching of Na^- with the associated formation of (K^+, e_s^-), (Rb^+, e_s^-), and (Cs^+, e_s^-), respectively. The long-lived spectra clearly show a remaining contribution from Na^- along with the production of K^-, Rb^-, and Cs^-, respectively.

Quantitatively, the situation is more complex. In Na/K alloy solutions we have noted (10) that the M^- band is in fact composed of both Na^- and K^-.

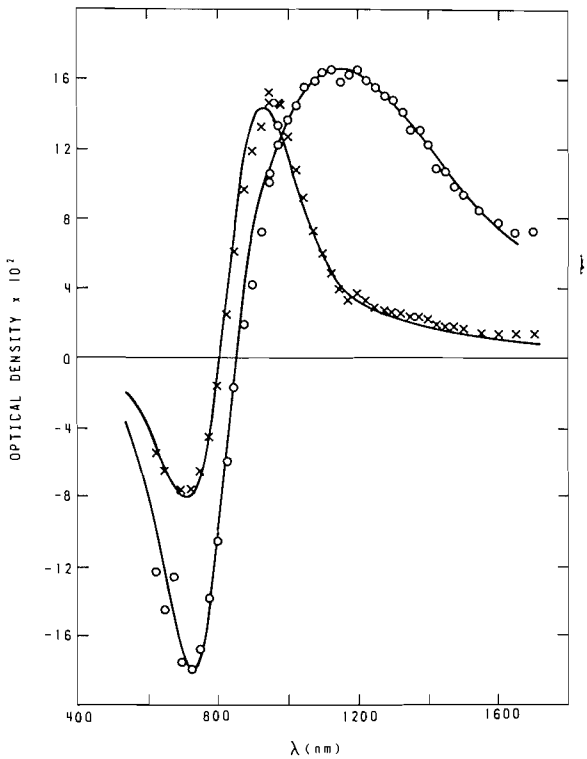

FIG. 7. Optical spectra observed following the flash photolysis of Na/K alloy solutions in THF: ○, immediately after the flash; ×, ~80 μs after the flash. The solid lines represent the composite spectra simulated from the component species with the following peak optical densities; ○, Na^-, −0.233; K^-, −0.023; e_s^-, 0.017; (K^+, e_s^-), 0.163; ×, Na^-, −0.124; K^-, 0.136; (K^+, e_s^-), 0.025.

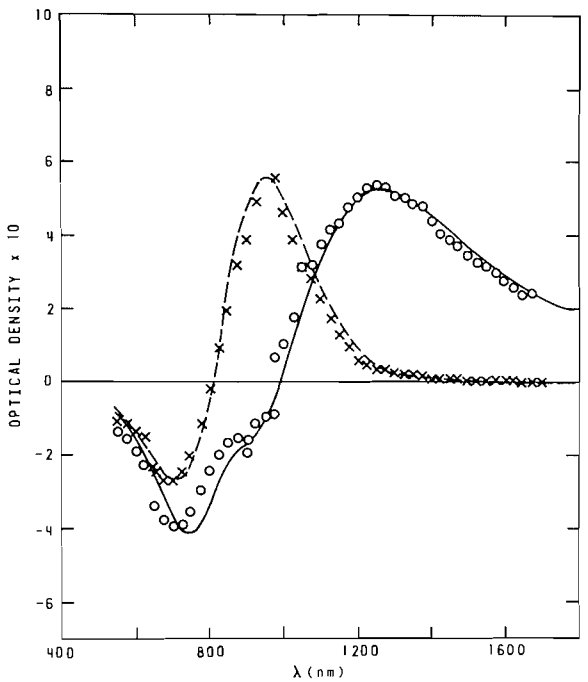

FIG. 8. Optical spectra observed following the flash photolysis of Na/Rb solutions in THF: ○, immediately after the flash; ×, ~180 μs after the flash. The solid and dashed lines represent the composite spectra simulated from the component species with the following peak optical densities; ○, Na^-, −0.45; Rb^-, −0.47; (Rb^+, e_s^-), 0.564; ×, Na^-, −0.404; Rb^-, 0.572.

Utilizing the spectra in Fig. 1, and the experimental extinction coefficients in Table 1, the relative concentrations correspond to 3.3×10^{-6} and 0.67×10^{-6} *M*, for Na^- and K^-, respectively. Consequently, the photolysis of both species is involved in the overall mechanism. This can be demonstrated more graphically for Na/Rb and Na/Cs solutions. In both cases the ultimate formation of Na^- occurs over a period of a week or more such that photolysis of a mixed M^- solution can be investigated. Representative examples are shown in Figs. 8 and 10, illustrating the simultaneous bleaching of both Na^-/Rb^- and Na^-/Cs^- solutions.

Extinction Coefficients

The solid line drawn through the experimental points represents, in all cases, the composite spectrum simulated from the individual species in Figs. 1 and 2. Relative optical densities of the latter are given in the caption. Taking $\varepsilon_{Na^-} = 8.2 \times 10^4$ L mol^{-1} cm^{-1}, the extinction coefficients for both M^- and (M^+, e_s^-) can then be determined. Based on a series of independent experiments we find $\varepsilon_{(K^+, e_s^-)}$, $\varepsilon_{(Rb^+, e_s^-)}$, and $\varepsilon_{(Cs^+, e_s^-)} = 2.8 \pm 0.2$, $\varepsilon_{K^-} = 12.3 \pm 1.0$, $\varepsilon_{Rb^-} = 11.1 \pm 1.0$, and $\varepsilon_{Cs^-} = 13.5 \pm 1.5$ all $\times 10^4$ L mol^{-1} cm^{-1}. All are in excellent agreement with the values deduced earlier and at the same time the material balance in the Na/K solution (Fig. 7) confirms the value for $\varepsilon_{Na^-} = 8.4 \pm 0.8 \times 10^4$ L mol^{-1} cm^{-1}. Further evidence of their self-consistency is illustrated by the fact that the disappearance of the (M^+, e_s^-) absorption corresponds in concentration to the intermediate M^- formation and partial recovery of Na^-.

Kinetics

The overall kinetics are complex and will be discussed in detail elsewhere. Qualitatively the results are consistent with the following mechanism

[1] $M^- \xrightarrow{h\nu} (M^+, e_s^-) + e_s^-$

[4] $(M^+, e_s^-) + e_s^- \rightleftharpoons M^-$

[5] $(M^+, e_s^-) + (M^+, e_s^-) \rightleftharpoons M^- + M^+$

[6] $M^+ + e_s^- \rightleftharpoons (M^+, e_s^-)$

[7] $Na^- \xrightarrow{h\nu} (Na^+, e_s^-) + e_s^-$

[8] $(Na^+, e_s^-) + e_s^- \rightleftharpoons Na^-$

[9] $(Na^+, e_s^-) + (Na^+, e_s^-) \rightleftharpoons Na^- + Na^+$

[10] $Na^+ + e_s^- \rightleftharpoons (Na^+, e_s^-)$

[11] $(Na^+, e_s^-) + M^+ \rightleftharpoons (M^+, e_s^-) + Na^+$

[12] $(Na^+, e_s^-) + (M^+, e_s^-) \rightleftharpoons Na^- + M^+$

[13] $M^- + Na^+ \rightleftharpoons (Na^+, e_s^-) + (M^+, e_s^-)$

At the end of the flash reactions [1] and [7], followed by [6], [10], and [11], are essentially complete to form (M^+, e_s^-). Some Na^- is reformed on a μs time scale by a combination of reactions [8], [9], and [12] with [9] predominating. As mentioned earlier, reactions [4] and [5] produce M^- also on a μs time scale. The slow rate determining step for the regeneration of Na^- is considered to be reaction [13]. This process appears to be pseudo first order with, for the three Na/M solutions investigated, $k_{13} \sim 50\ s^{-1}$.

These observations are entirely consistent with the mechanism deduced by pulse radiolysis for solutions in ethylamine (6). Regardless of the detailed kinetics it is clear that dominant reactions are [11] and [13] with the long-lived intermediate species being M^-.

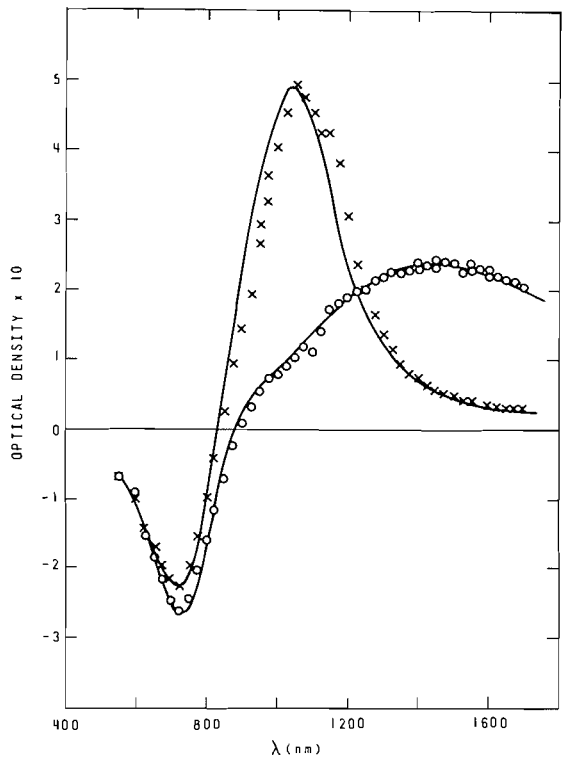

FIG. 9. Optical spectra observed following the flash photolysis of Na/Cs solutions in THF: ○, immediately after the flash; ×, ~90 μs after the flash. The solid lines represent the composite spectra simulated from the component species with the following peak optical densities: ○, Na^-, −0.302; Cs^-, −0.046; (Cs^+, e_s^-), 0.225; e_s^-, 0.033; ×, Na^-, −0.299; Cs^-, 0.468; (Cs^+, e_s^-), 0.034.

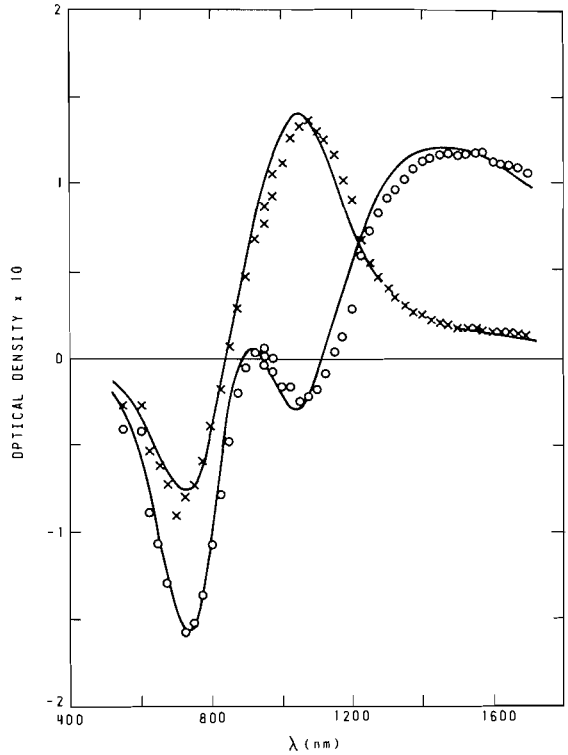

FIG. 10. Optical spectra observed following the flash photolysis of Na/Cs solutions in THF containing appreciable concentrations of both Na^- and Cs^-. ○, Immediately after the flash; ×, ~85 μs after the flash. The solid lines represent the composite spectra simulated from the component species with the following peak optical densities: ○, Na^-, −0.213; Cs^-, −0.144; (Cs^+, e_s^-), 0.128; (Na^+, e_s^-), 0.063; ×, Na^-, −0.098; Cs^-, 0.132; (Cs^+, e_s^-), 0.014.

It is interesting to note that in the original work (1), the absorption spectrum of potassium in THF, is significantly broader on the high energy side than is the long-lived photolysis intermediate which has the same absorption maximum. The latter very closely corresponds to the K^- spectrum given in Fig. 1 whereas the former clearly indicates the presence of Na^-, presumably due to the leaching of Na^+ from the Pyrex containers. Inadvertently, the results stem not from the photolysis of K^- but rather from a mixed metal solution.

Mixed Metal Solutions in DME-spectra

Figures 11 and 12 show the spectra observed from Na/K and Na/Cs alloy solutions in DME at 213 K. Although there is more scatter in the experimental points it is clear that the infrared absorption is distinctly different from that observed in comparable THF solutions. As in K/DME solutions, we attribute this absorption to the formation of $(K^+, e_s^-)_{loose}$ or

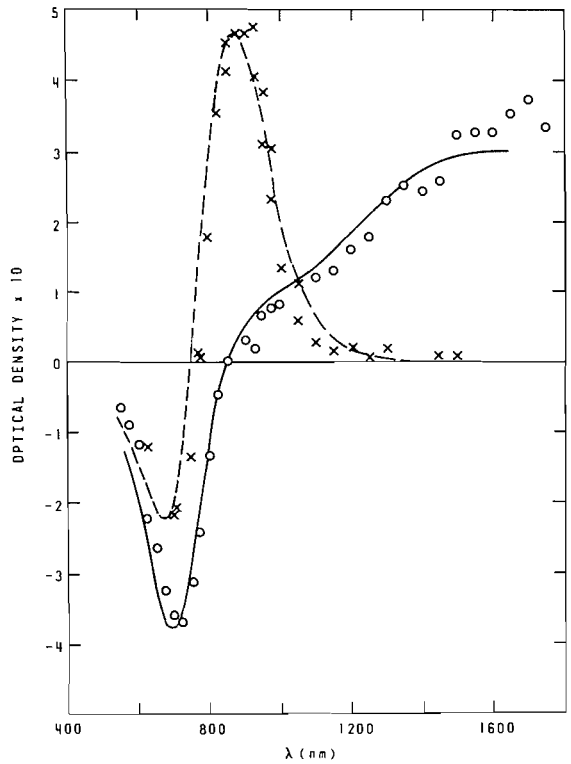

FIG. 11. Optical spectra observed immediately following the flash photolysis of Na/K solutions in DME at 213 K. ○, Immediately after the flash; ×, ~1.8 ms after the flash. The solid and dashed lines represent the composite spectra simulated from the component spceies with the following peak optical densities: ○, Na^-, −0.437; $(K^+, e_s^-)_{loose}$, 0.301; ×, Na^-, −0.369; K^-, 0.522.

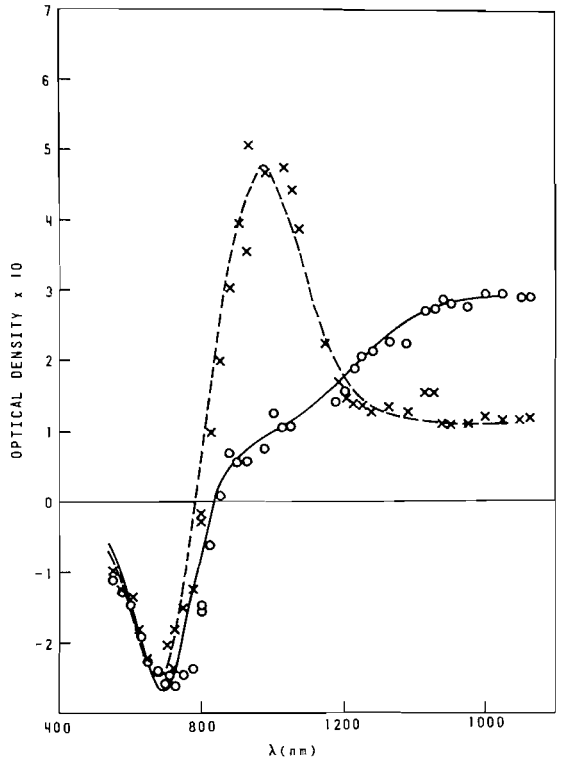

FIG. 12. Optical spectra observed immediately following the flash photolysis of Na/Cs solutions in DME at 213 K. ○, Immediately after the flash; ×, ~1.0 ms after the flash. The solid and dashed lines represent the composite spectra simulated from the component species with the following peak optical densities. ○, Na^-, −0.328; $(Cs^+, e_s^-)_{loose}$, 0.294; ×, Na^-, −0.349; $(Cs^+, e_s^-)_{loose}$, 0.111; Cs^-, 0.444. It is assumed that the $(Cs^+, e_s^-)_{loose}$ spectrum is the same as $(K^+, e_s^-)_{loose}$.

$(Cs^+, e_s^-)_{loose}$, respectively. However, since the absorption spectra of the $(K^+, e_s^-)_{loose}$ and $(Na^+, e_s^-)_{loose}$ are virtually the same at 213 K the distinction between the potassium and cesium ion-pairs is made by analogy with THF solutions.

The long-lived absorption spectra correspond to those expected for K^- and Cs^- after correcting the band maxima to slightly higher energies, 11 575 and 10 350 cm^{-1}, respectively, at 213 K. The solid and dashed lines in both figures represent the simulated spectra derived from the appropriate M^- species and $(K^+, e_s^-)_{loose}$. The corresponding optical densities are given in the caption.

Allowing therefore for the effect of temperature and solvent (4), the results in DME are entirely analogous to those observed in THF. The long-lived intermediate absorption is due to M^-, and not (Na^+, e_s^-), as originally suggested (3).

Extinction Coefficients

Quantitatively the results in DME are not as reproducible as in THF mainly because of experimental difficulties associated with the low temperature experiments, instability of the initial solutions, and photolysis of the much longer lived M^- intermediate by the analyzing light. Taking $\varepsilon_{(K^+, e_s^-)_{loose}} = 2.8 \pm 0.4 \times 10^4$ L mol^{-1} cm^{-1} (4), then from the results in Fig. 11 we obtain $\varepsilon_{Na^-} = 8.1 \pm 1.1 \times 10^4$ L mol^{-1} cm^{-1}, a value in very good agreement with that deduced earlier in THF and measured in EDA (24). Based on this value then $\varepsilon_{K^-} = 11.5 \pm 1.0$, again in good agreement with that given in Table 1 for THF. Similarly from the results in Fig. 2 we find $\varepsilon_{(Cs^+, e_s^-)_{loose}} = 3.7 \pm 0.3$ and $\varepsilon_{Cs^-} = 16.0 \pm 1.0 \times 10^4$ L mol^{-1} cm^{-1}, in reasonable agreement with the values obtained in THF.

Kinetics

The overall kinetics are explicable on the same basis as proposed for THF. However, the conversion of M^- to Na^- is significantly slower at 213 K, requiring ≥0.1 s to return to the pre-flash equili-

brium condition. This could not be measured with any precision on our apparatus but is consistent with previous observations (3).

Summary

The flash photolysis of alkali metal anions M^- proceeds via the formation of the intermediate ion-pair species (M^+, e_s^-) which, in turn, ultimately decays to reform M^-. In mixed-metal solutions containing Na^- and M^+ the photolysis again proceeds via (M^+, e_s^-) and M^- with, in this case, regeneration of Na^- occurring via M^-. Extinction coefficients deduced by experiment for both (M^+, e_s^-) and M^- are in good agreement with those calculated on the basis of Gaussian–Lorenztian shape functions for the individual optical spectra.

Electrochemical studies of the $Pb^{2+}/Pb(Hg)$ system in aqueous and aqueous ethylene glycol solutions

TIBOR RABOCKAI

Instituto de Química, Universidade de São Paulo, Caixa Postal 20.780, São Paulo, SP, Brasil

Received November 23, 1978

TIBOR RABOCKAI. Can. J. Chem. 57, 1801 (1979).

The electrochemical behavior of the $Pb^{2+}/Pb(Hg)$ system in aqueous and aqueous ethylene glycol solutions is studied in the temperature range of 20.0 to 50.0°C by means of current reversal chronopotentiometry. It is shown that the reduction of Pb^{2+} ion is reversible and that kinetic or catalytic complications are not present. The value of $dE_{1/2}/dT$ is -0.6 mV/deg in the aqueous solution and -0.5 mV/deg in the solution with 56% (w/w) or higher concentrations of the organic solvent. In the above concentration range of ethylene glycol the activation energies of diffusion and viscosity vary from 4.3×10^3 to 7.2×10^3 cal mol^{-1} and from 3.7×10^3 to 6.7×10^3 cal mol^{-1}, respectively. For all solutions the solvodynamic mean radius of the diffusing species remains constant within the experimental error, suggesting that the diffusing species is always the hydrated Pb^{2+} ion.

TIBOR RABOCKAI. Can. J. Chem. 57, 1801 (1979).

On a étudié le comportement électrochimique du système $Pb^{2+}/Pb(Hg)$ en solutions aqueuses et en solutions eau–éthylèneglycol à des températures de 20.0 à 50.0°C à l'aide de la technique de chronopotentiométrie de renversement de courant. On montre que la réduction de l'ion Pb^{2+} et réversible et qu'il n'y a pas de complications cinétique ou catalytique. En solution aqueuse, la valeur de $dE_{1/2}/dT$ est de -0.6 mV/deg alors qu'elle est de -0.5 mV/deg dans des solutions contenant au moins 56% (p/p) de solvant organique. Aux concentrations d'éthylène glycol mentionnées plus haut, les énergies d'activation de diffusion et de viscosité varient respectivement de 4.3×10^3 à 7.2×10^3 cal mol^{-1} et de 3.7×10^3 à 6.7×10^3 cal mol^{-1}. Pour toutes les solutions, le rayon solvodynamique moyen des espèces qui diffusent reste constant à l'intérieur des erreurs expérimentales. Ceci suggère que l'espèce qui diffuse est toujours un ion Pb^{2+} hydraté.

[Traduit par le journal]

Introduction

Ethylene glycol, hereafter called EG, is a good solvent for inorganic and organic substances. In comparison with water, EG has a lower freezing point, a higher boiling point, and a higher viscosity. In electrochemistry, EG has been used in reference electrodes for low temperature pH measurements (1); in polarographic studies of various inorganic substances (2, 3); in some practical applications, such as the electrochemical refining of germanium (4) and the electrodeposition of silver (5). Mn(II) ion (6) and Tl_2SO_4 (7) were studied in EG–water mixtures.

In this paper we describe the study of the $Pb^{2+}/Pb(Hg)$ system in aqueous and aqueous ethylene glycol solutions using chronopotentiometry with current reversal in the temperature range of 20.0 to 50.0°C. Since the organic solvent can affect the charge transfer reaction as well as the transport properties of the species in solution, information on these properties was, therefore, included in our study.

Experimental

The electrochemical cell employed has been described previously (8). The working electrode was a shielded mercury pool with an area of 3.51 cm^2. A commercial sce was used as reference electrode. The junction potentials between the sce and the mixed-solvent electrolyte were negligible. The temperature of the cell was maintained within 0.1°C. Dissolved oxygen was removed from the electrolyte by bubbling purified nitrogen. An Electroscan™ 30 was used as both constant current source and recorder for potential/time curves. Solutions of $Pb(NO_3)_2$ (10^{-3} to 10^{-2} *M*) containing the appropriate amount of ethylene glycol were investigated and 0.1 *M* KNO_3 was used as supporting electrolyte. All solutions were prepared from stock solutions of analytical grade $Pb(NO_3)_2$ and KNO_3. Ethylene glycol (Carlo Erba, p.a) was purified according to the procedure described by Dzaparidze *et al.* (9). The water content of the purified ethylene glycol was determined by the Karl Fisher method. The viscosity of the solutions was measured with an Ostwald viscosimeter, and the density of the solutions with a 5 mL picnometer.

The constant current was within the range of 0.05 mA to 2 mA. Chronopotentiometric transition times were measured according to the procedure described by Adams (10). The potentials at time $t = \tau/4$ (τ = transition time) were measured by the empirical method shown in Fig. 1.

Results and Discussion

(a) Diffusion Coefficients

The current reversal chronopotentiometry of the solutions containing Pb^{2+} displays well defined cathodic and anodic transition times (τ_c and τ_a,

0008-4042/79/141801-03$01.00/0

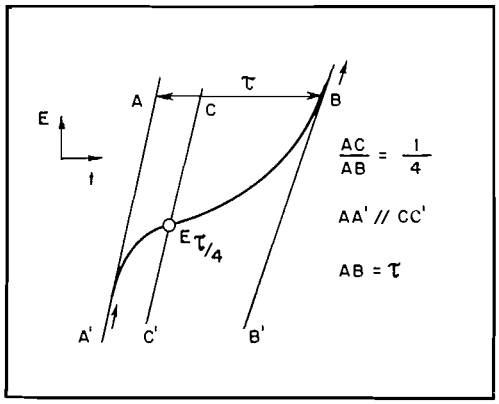

FIG. 1. Determination of transition times and $E_{\tau/4}$ potentials.

respectively). Within the investigated concentration and current ranges the $i\tau_c^{1/2}/C_0^0$ ratio (i = current density, $C_0^0 = Pb^{2+}$ concentration) is independent of C_0^0 and i, for a given ethylene glycol concentration and temperature. Thus, for each ethylene glycol concentration and temperature, the average value of the $i\tau_c^{1/2}/C_0^0$ ratio was calculated. From the average values, the diffusion coefficients D_0 of Pb^{2+} were calculated by means of the well-known Sand's equation. The diffusion coefficients are shown in Table 1. Assuming that the solvated electroactive species is a spherical particle with an average radius r, the latter was estimated from D_0 and viscosity data by means of the Stokes–Einstein equation, $D_0 = RT/(6\pi\eta rN)$. The experimental value of r was 2.7 ± 0.1 Å, independently of temperature and EG content. Thus the increase of diffusion coefficient with increasing temperature and water content, as shown in Table 1, is due to changes of viscosity. Taking into account that the mean ionic radius of Pb^{2+}, water, and ethylene glycol are, respectively, 1.32 (11), 1.9 (8), and 4 Å (this latter estimate is based on a molecular model from Framework Molecular Model, Prentice-Hall, NJ), one may conclude, from the value of solvodynamic radius, that the diffusing species is always the hydrated Pb^{2+} ion.

(b) Variation of Potential with the Electrolysis Time

For all the investigated temperature range and ethylene glycol concentration range the plots of the potential vs. log $[(\tau^{1/2} - t^{1/2})/t^{1/2}]$ are linear. The slopes calculated are in good agreement with the theoretical value of $2.303(RT/nF)$, which is observed in the case of a reversible charge transfer (12).

TABLE 1. Diffusion coefficient data of Pb^{2+} in ethylene glycol aqueous solutions

Temperature (°C)	$D_0 \times 10^6$ (cm² s⁻¹) for % ethylene glycol w/w = 0	20	39	56	73	94
20.0	8.1	5.4	3.0	1.7	1.0	0.5
30.0	10.4	6.5	4.0	2.5	1.6	0.7
40.0	13.0	8.7	5.3	3.4	2.2	1.0
50.0	16.1	10.8	6.8	4.5	2.9	1.1

(c) Ratio between Direct and Reverse Transition Times

The ratios between direct and reverse transition times present a value of 0.33, which is independent of EG content, temperature, and the values of direct transition times. The constancy of τ_a/τ_c and $i\tau_c^{1/2}/C_0^0$ indicates the absence of any kinetic or catalytic process interfering with the electrode reaction, according to the criteria already reported in the literature (12, 13).

(d) Half-wave Potentials

The observed $E_{\tau/4}$ values are independent of the electroactive species concentration and current density. It was found that direct and reverse chronopotentiograms exhibit the same values for $E_{\tau/4}$ after correction for the ohmic drop. The equality of direct and reverse $E_{\tau/4}$ values and their independence relative to electroactive species concentration and current density agrees with the previous conclusion that the reaction

$$Pb(II) + 2e = Pb(Hg)$$

is reversible in ethylene glycol–water mixtures (12). It is known that in the case of a reversible charge transfer which takes place on a mercury electrode we have $E_{\tau/4} = E_{1/2}$ where $E_{1/2}$ is the same as the corresponding polarographic half-wave potential (12). The change of the sce potential with temperature is given by (14)

$$[1] \qquad E = 0.2415 - 7.6 \times 10^{-4}(t - 25)$$

so that, the half-wave potentials may be referred to the value of E at 25.0°C. The results are illustrated in Fig. 2, for solutions containing 0% and 56% (w/w) of EG. From the straight lines of Fig. 2, the values of $dE_{1/2}/dT$ are −0.6 mV/deg and −0.5 mV/deg, respectively. The latter value does not change with increasing EG concentration.

(e) Diffusion and Viscosity Activation Energies

According to Eyring and co-workers (15) the phenomena of diffusion and viscosity may be described by the absolute rate theory. Thus the influence of temperature on diffusion coefficient and on viscosity is given by an equation of the form

$$[2] \qquad Z = A \exp[-E^*/(RT)]$$

where Z means either diffusion coefficient or viscosity, and E^* is the diffusion or viscosity activation energy, respectively.

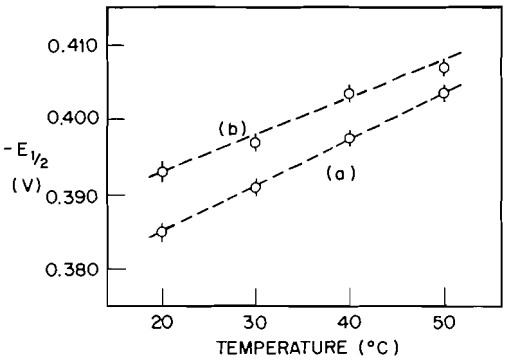

FIG. 2. Variation of half-wave potentials with temperature in solutions with (*a*) 0% (w/w) and (*b*) 56% (w/w) of ethylene glycol.

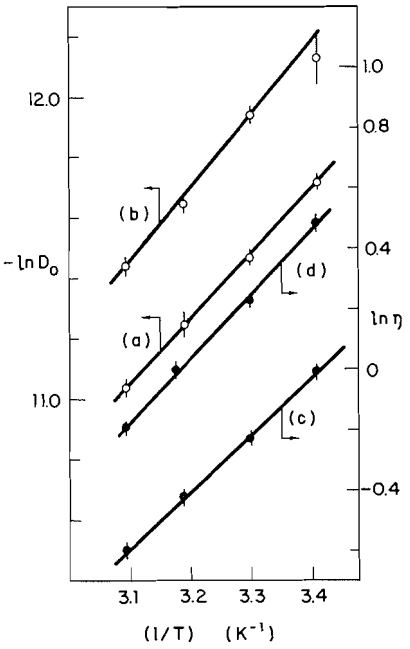

FIG. 3. Plot of ln D_0 and ln η vs. $1/T$ for the calculation of the activation energies; lines (*a*), (*c*) refer to 0% (w/w) and lines (*b*), (*d*) to 20% (w/w) of ethylene glycol.

As eq. [2] shows, the activation energies may be calculated from the slope of the straight line representing ln Z vs. $(1/T)$. These plots are illustrated in Fig. 3. Table 2 assembles the activation energies obtained. These data reveal that diffusion and viscosity are affected to the same extent by ethylene glycol: an increase of the order of 50% in the value of the activation energies when going from zero to about 80% of non-aqueous solvent is observed. The values of the diffusion activation energy, E_D*, are slightly higher than those of the viscosity energy of activation, E_V*.

TABLE 2. Activation energies for diffusion and viscosity

Received November 28, 1978

MICHEL MOMENTEAU, BERNARD LOOCK, EMILE BISAGNI, and MICHEL ROUGEE. Can. J. Chem. **57**, 1804 (1979).

Meso-α,β,γ,δ,tetraphenylporphin derivatives bearing acrylic (*cis* and *trans* isomers) and propionic side chains with a terminal imidazole group have been synthesized. Intermediate compounds obtained during their preparation were characterized by visible spectroscopy and nmr. In non-coordinating solvents (benzene or toluene), the iron(III) complexes of these compounds do not show intramolecular coordination of the terminal base on the metal ion. The reduced forms of the compounds have been obtained from ferric forms by heterogeneous reduction with aqueous dithionite and exhibit optical spectra characteristic of five-coordinate ferrous complexes. The nitrogenous bases and carbon monoxide affinities of the latter have been measured and the results indicate that the '*trans influence*' exerted by the terminal imidazole does not depend greatly on the nature and the structure of the covalent side chain. In contrast the stability of the five-coordinate compounds depends on the side chain (*trans* acrylic < propionic < *cis* acrylic) as suggested by the values reported for the replacement constants of the terminal imidazole by 4-cyanopyridine in unsymmetrical six-coordinate derivatives. The stability of these compounds towards oxidation is also reported.

MICHEL MOMENTEAU, BERNARD LOOCK, EMILE BISAGNI et MICHEL ROUGEE. Can. J. Chem. **57**, 1804 (1979).

La synthèse de composés dérivés de la *meso*-α,β,γ,δ,tétraphenylporphine possédant une chaîne acrylique (isomères *cis* et *trans*) ou une chaîne propionique et substituée par un groupe imidazole terminal est décrite. Les composés intermédiaires obtenus au cours de cette synthèse sont caractérisés par spectrophotométrie visible et par rmn. Dans les solvants non-coordinants (benzène ou toluène), les complexes ferriques de ces composés ne montrent pas de coordination intramoléculaire de la base terminale sur l'ion métallique. Les formes réduites obtenues par réduction hétérogène des complexes ferriques présentent des spectres d'absorption caractéristiques des complexes ferreux pentacoordonnés. Les constantes d'affinité de ces composés pour les bases azotées et le monoxyde de carbone ont été mesurées. Elles indiquent que l'"*effet trans*" exercé par l'imidazole terminal ne dépend ni de la nature ni de la structure de la chaîne. Au contraire, la stabilité des composés pentacoordonnés en dépend (*trans* acrylique < propionique < *cis* acrylique) comme le suggèrent les valeurs des constantes de remplacement de l'imidazole par la 4-cyanopyridine dans les dérivés hexacoordonnés. La stabilité de ces composés vis-à-vis de l'oxydation est également décrite.

Introduction

For some years, several studies have been made in order to understand the factors controlling the binding of oxygen in oxygen carriers, such as hemoglobin and myoglobin, or in oxygen activating hemoproteins. Synthesis of models for the active sites in these proteins has demonstrated the role of the hydrophobic environment and of the *trans* coordinating base upon the fixation of oxygen and the stabilization of the resulting oxygen complexes. In these models, the pentacoordination of iron(II) arises from an axial ligand covalently linked either to the vinyl side chains of protoheme via a thioether linkage (1–3) or to the propionic acid side chain of the heme IX molecules (4–7). More recently, Molinaro *et al.* (8) developed a synthetic route to monosubstituted tetraarylporphyrins in which the axial base is covalently linked to one of the four mesoaryl substituents.

As a part of our continuing study of the preparation and reactivity of new synthetic five-coordinate iron porphyrins, we wish to report in this paper the synthesis of new derivatives of *meso*-α,β,γ,δ,tetraphenylporphin (TPP) functionalized by either an acrylic acid side chain (*cis* or *trans* substituted isomers) or a propionic one on which a ligand group (imidazole or pyridine) was linked. The synthesis of

0008-4042/79/141804-10$01.00/0

porphyrins carrying a peptide acrylic side chain has been reported recently by Callot *et al.* (9) in an independent work. We have followed the same route to prepare our models, but used other metallo TPP compounds as starting materials. Thus, aside from better yields of intermediate derivatives, we have isolated several new compounds which have been characterized by their spectroscopic properties. We also describe comparative chemical properties of their iron(II) derivatives towards external ligands such as nitrogenous bases or neutral small molecules (carbon monoxide or oxygen).

Results and Discussion

1. Preparation of Substituted meso-α,β,γ,δ,*Tetraphenylporphins*[2]

The synthesis of porphyrins bearing an acrylic acid side chain was performed following the method described by Callot (10, 11) from Cu-TPP (**1***b*). In a first step, a formyl group was introduced into a pyrrolic position using Vilsmeier formylation; after hydrolysis, the Cu-monoformyl compound **2***b* was obtained in a good yield (>95%), but demetallation of **2***b* under various sulfuric acid conditions did not yield the corresponding free-base. Thin layer chromatography on silica gel showed that several compounds were formed, suggesting direct attack of the formyl group and/or sulfonation of the porphyrin ring. These results are different from those obtained in the sulfuric acid treatment required for the demetallation of formylated Cu-etioporphyrin I and Cu-octaethylporphyrin (12).

An alternative route to the formylporphyrin free-base was then considered using the iron(III)TPP as starting material, but under the same formylating conditions as for Cu-TPP, iron(III)TPP appeared considerably less reactive (10% yield). This difference in reactivity probably lies in the electronegativity of the central metal ion. The presence of electron donor metals leads to a greater reactivity of the porphyrin ring by increasing the electron density especially on the pyrrolic carbon (13). Despite the low yield of formylated iron(III)TPP, this method allowed us to obtain the formyl-TPP free-base since, in this case, removal of iron is easily performed by treatment with iron(II) sulfate in dilute acids at room temperature (14). Silica gel column chromatography afforded two compounds: TPP starting material **1***a* and formyl-TPP **2***a*. The latter showed a

[2]Abbreviations: TPP: *meso*-α,β,γ,δ,tetraphenylporphin; Im: imidazole; Py: pyridine; *N*MeIm: *N*-methylimidazole; *N*buIm: *N*-butylimidazole; 4-PyCN: 4-cyanopyridine; nmr: nuclear magnetic resonance.

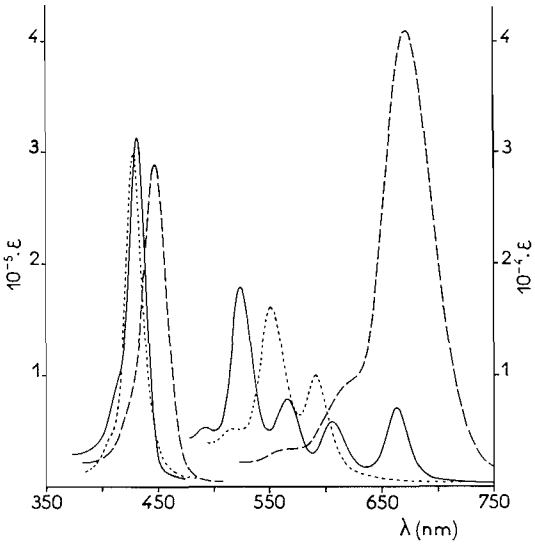

FIG. 1. Optical absorption spectra (optical path, visible 1 cm, Soret 1 mm) of formyl-*meso*-tetraphenylporphin **2***a* (—); formyl-*meso*-tetraphenylporphin dicationic form (– – –); copperformyl-*meso*-tetraphenylporphin **2***b* (---) in benzene.

typical porphyrin spectrum (Fig. 1) in which a bathochromic shift of the absorption maxima was caused by the aldehyde group substitution. Furthermore some noticeable differences were observed: the visible spectrum was of a type which had not been observed previously in the porphyrins bearing a single carbonyl group in the β or *meso* position (15). These strongly electron-withdrawing groups caused a 'Rhodo' type spectrum. The extinction coefficient of band I (663 nm) in the formyl-TPP spectrum is more intense than that of band II (605 nm). The new type of spectrum (band IV > III > I > II) could result from the strong asymmetric delocalization of the π electron cloud, due to the formyl substituent group.

As in Callot's work, the acrylic derivatives were directly obtained by condensation of carbethoxyethyl-methenyl-triphenylphosphorane with Cu-formyl-TPP according to the Wittig reaction (12). *Cis–trans* isomers (**3***b* and **4***b* respectively) were isolated as red crystals in 28.9 and 47.1% yields respectively. These compounds were rapidly transformed into free-base derivatives **3***a* and **4***a* under mild conditions with gaseous hydrogen-chloride and identified by their nmr spectra. The preparation of the propionic derivative **5***a* was achieved in good yield by catalytic hydrogenation of compounds **3***a* or **4***a* on palladium charcoal in formic acid.

Reaction of triethylphosphonoacetate with Cu-formyl-TPP was an alternative method (16) for the

preparation of acrylic derivatives **3***b* and **4***b* in yields of 4.5 and 85.5%, respectively. This method appeared more suitable for the preparation of **5***a* because isolation of the mixed *cis–trans* isomers was easier and hydrogenation could then be performed directly, without purification of acrylic acid intermediates.

When **3***a*, **4***a*, and **5***a* were saponified with alcoholic potassium hydroxide, acidification afforded free acid compounds in 95% yield. After treatment with oxalyl chloride (17), acid chloride derivatives were then condensed with 1-(3-aminopropyl)imidazole (18) giving compounds **6***a*, **7***a*, and **8***a* in 70% yield. Their iron(III) complexes have been prepared by treatment of free-bases with an excess of ferrous acetate in hot acetic acid under argon (19). In the same way, acylation of 3-(3-pyridyl)-1-propanol with the acid chloride of compound **5***a* in methylene chloride gave the derivative **9***a* which was converted into the iron complex **9***c*.

All acrylic and propionic TPP derivatives **3***a*, **4***a*, **5***a*, **6***a*, **7***a*, **8***a*, and **9***a* showed 'etio' type absorption spectra but the presence of a double bond in the side chain of the acrylic compounds caused a bathochromic shift of the absorption bands in comparison with the spectrum of propionic acid derivatives. This shift is greater in the *trans* isomer (10 nm) than in the *cis* one (5 nm).

All nmr spectra are characterized by the non-equivalence of the seven pyrrolic protons in contrast to *meso*-tetraphenylporphin (20) (Table 3). In the *cis* derivatives, the α and β vinyl protons are shifted upfield relative to the equivalent *trans* ones. The coupling constants $J_{\alpha\beta}$ = 12 Hz and 16 Hz for the *cis* and *trans* ethylenic configurations respectively are similar to those observed by Callot in Ni-vinyl-TPP (10). A more important effect is observed in the resonance of the ethyl ester protons of compounds **3***a*, **4***a*, and **5***a* and the imidazole ring protons of compounds **6***a*, **7***a*, and **8***a*. In the *cis* acrylic derivatives **3***a* and **6***a*, the proton resonances of the ethyl ester group and imidazole ring appear upfield. Those in the *trans* acrylic isomers **4***a* and **7***a* are shifted downfield relative to the normal values for the ethyl ester and imidazole protons, as a result of the ring current of the macrocycle. These resonances may be due to different stereochemical configurations of *cis* and *trans* acrylic isomers, in which the ethyl ester groups and imidazole rings are positioned over the conjugated macrocycle in the former compounds and outside the macrocycle plane in the latter.

2. Physico-chemical Properties of Iron(II) Derivatives

The porphyrins **6***a*, **7***a*, **8***a* and their related iron(III) and iron(II) derivatives have side chains of different geometry. Molecular models show that the terminal imidazole lies close to the center of the porphyrin ring in the *cis* acrylic isomer and in the saturated propionic derivatives **6***a* and **8***a*, but far from this center in the case of the *trans* acrylic isomer **7***a*, in agreement with the nmr results. In this connection, Fuhrhop *et al.* (21) have noted an observation on sterically fixed porphyrins having rigid axial ligands through the central ion. The phenyl group of the benzyl ester of [2,2-bis(benzyloxycarbonyl)vinyl]porphyrin lying '*cis*' to the porphyrin occurs in position exactly above the center of the macrocycle. Such a conformation is also observed in our '*cis*' compounds.

In toluene solution, the optical spectra of the ferric derivatives **6***c*, **7***c*, and **8***c* are quite similar to that of Fe(III)Cl-TPP **1***c*, except for a bathochromic shift observed with the two '*cis* and *trans*' acrylic compounds as observed for the related free-bases. This similarity indicates that the imidazole group is not coordinated to the sixth coordination position of the iron ion, even in the '*cis*' acrylic derivative. Also, the similarity between the spectra of the same isomer in which the side chain bears ethyl ester or imidazole shows that in the imidazole compounds the ferric complexes are in the high spin state, without an

imidazole on the iron ion. The low affinity constant of Fe(III)Cl-TPP for the first imidazole derivative as reported by Walker *et al.* (22) is in good agreement with the coordination state of iron(III) in our compounds suggested from the absorption spectra. A similar observation has been found with deuterohemin 6(7) methyl ester, 7(6) histidine methyl ester, in which the histidine methyl ester attached to the side chain was not firmly bound to the iron(III) (7).

The reduction of hemins **6***c*, **7***c*, and **8***c* with aqueous sodium dithionite, under anaerobic conditions, in a two-phased system ($C_6H_5CH_3/H_2O$) (23) gives orange compounds **6***d*, **7***d*, and **8***d* which are stable in the absence of oxygen. Their absorption spectra are characterized by one broad visible band (near 540 nm) with two shoulders (615 and 570 nm) and a Soret band at 440 nm (Fig. 2). These spectra are clearly distinct from both that of bare Fe(II)TPP (24) and four-coordinate iron(II) compounds **3***d*, **4***d*, and **5***d* and that of typical six-coordinate TPP (24). However, they are quite similar to that obtained with the well-identified five-coordinate species, mono(2-methylimidazole) TPP, except for the increase of absorbance at 540 nm (25, 26). These results unambiguously show that in non-coordinating solvents at room temperature, typical five-coordinate complexes with imidazole bound in the fifth axial coordination position of iron(II) are obtained. However the Soret band of the *trans* acrylic isomer is less sharpened than those of the *cis* acrylic isomer and propionic derivative. This could reflect the constraint exerted by the side chain in the coordination of the terminal imidazole.

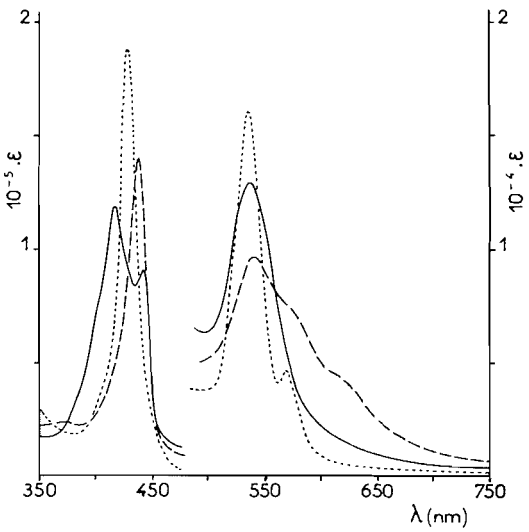

FIG. 2. Optical absorption spectra (optical path, visible 1 cm, Soret 1 mm) of Fe(II) *meso*-tetraphenylporphin **1***d* (—), Fe(II) *meso*-tetraphenyl-1-[3-(*N*-imidazolyl propyl)propionamido]porphin **8***d* (– – –), *N*-methylimidazole-Fe(II) *meso*-tetraphenyl-1-[3-(*N*-imidazolyl propyl)propionamido]porphin (---) in benzene.

Progressive addition of *N*-methylimidazole to the five-coordinate compounds **6***d*, **7***d*, and **8***d* in benzene at 20°C progressively leads to species whose absorption spectra are similar to that of the symmetrical six-coordinate complexes (hemochromes) resulting from the binding of two imidazole or *N*-methylimidazole molecules to Fe(II)TPP **1***d* and to the four-coordinate species **3***d*, **4***d*, **5***d*. The bathochromic shift of the absorption maxima noted for the bare *cis* and *trans* acrylic isomers **3***d*, **4***d*, compared to the propionic related compound **5***d*, is also observed for the corresponding symmetrical (**3***d*, **4***d* + 2 *N*-methylimidazole) and unsymmetrical (**6***d*, **7***d* + *N*-methylimidazole) complexes.

Titrations of ca. 2×10^{-5} *M* (= $[P_0]$) of all three five-coordinate species by L = *N*-methylimidazole appears almost quantitative. Full hemochrome spectra are obtained for $[P_0] < L_t \ll 2[P_0]$ (L_t standing for the total added ligand concentration) thus indicating that only one external L ligand is required to get the unsymmetrical six-coordinate hemochrome. As noted by Antonini and Brunori (27) this means that $K_{Im}^{L}[P_0] \gg 1$. The values reported in Table 5 obtained assuming $K_{Im}^{L}[P_0] > 10$, are probably slightly higher than the second affinity constant K_L^L measured in the case of Fe(II)TPP ($1.4 \times 10^5\ M^{-1}$). Unfortunately, because of these very high values, it has not been possible to detect experimentally any influence of the structure of the covalent chain upon the *trans influence* exerted by the terminal imidazole. Moreover, attempts to determine the exchange constants $K_L^{Im,L}$ by increasing the *N*-methylimidazole concentration have been unsuccessful either because this constant is too low or because of the great similarity of the symmetrical and unsymmetrical hemochrome spectra (further complications arise upon dilution when adding an excess of *N*-methylimidazole to the initial solution).

On the contrary, titrations of the five-coordinate species **6***d*, **7***d*, **8***d* by L′ = 4-cyanopyridine occurs in two distinct steps. In the first, one 4-cyanopyridine molecule binds to the sixth coordination site with a high affinity, $K_{Im}^{L'} = \sim 2.5 \times 10^5\ M^{-1}$, which is rather insensitive to the structure of the side chain linking the terminal imidazole and comparable to, but slightly lower, than other K_{Im}^{L} values. Hemochrome type spectra are obtained at the end of this step. Further modifications of these intermediate spectra are observed in the red when the 4-cyanopyridine concentration is greatly increased, and the spectra obtained at the end of this second step (Fig.

3) are almost identical to those of the symmetrical hemochromes resulting from the coordination of two 4-cyanopyridine molecules to the corresponding four-coordinate species **3***d*, **4***d*, **5***d* (the slight differences observed can be related to the fact that a very high 4-cyanopyridine concentration is needed to get the pure symmetrical hemochromes). The measured affinity constants, $K_{L'}^{Im,L'} = 1$, 30, and 1.2 M^{-1} for **6***d*, **7***d*, **8***d* respectively, show that the terminal imidazole is more easily replaced by a 4-cyanopyridine molecule in the case of the *trans* acrylic isomer **7***d*, than in the case of the *cis* isomer **6***d* and the saturated propionic derivative **8***d*.

In order to get further information about the role of the covalent attachment of the axial chain upon the affinities for externally added ligands, we have also studied the coordination of Fe(II)TPP **1***d* and of the four-coordinate compounds **3***d*, **4***d* and **5***d*.

1*d* and **5***d* bind L = *N*-methylimidazole in two overlapping steps, as previously observed for the titration of Fe(II)TPP by imidazole and pyridine (24, 26). (The values reported in Table 5 have been redetermined at 20°C.) However, the affinity constants for *N*-methylimidazole are significantly higher than the values obtained for imidazole, in agreement with the more basic character of *N*-methylimidazole ($pK_a = 7.33$) with respect to Im ($pK_a = 6.65$). Only the overall affinity constant $K^L K_L^L$ can be estimated for **3***d* and **4***d*. Comparison of the values reported in Table 5 shows that the reactivity at the iron center is not greatly influenced by the nature of the noncoordinating side chain.

Spectrophotometric titrations of **1***d*, **3***d*, **4***d*, and **5***d* by L′ = 4-cyanopyridine indicate a two-base fixation in a single step, with affinity constants $K^{L'} K_{L'}^{L'} = 5$, 2.9, 2.5, and 1.3×10^8 M^{-2}, respectively, which are again little affected by the presence of the side chain.

Defining Im-P ⇄ P(Im), (K = [P(Im)]/[Im-P]) the equilibrium between the four and five-coordinate forms of species **6***d*, **7***d*, **8***d* and assuming that the affinities of the former for L′ are the same as that of species **3***d*, **4***d*, **5***d* respectively, we obtain $K^{L'} K_{L'}^{L'}$ (for **3***d*, **4***d*, **5***d*) = $K\, K_{Im}^{L'}\, K_{L'}^{Im,L'}$ (for **6***d*, **7***d*, **8***d*). From the values reported in Table 5, we obtain K = 950, 65, and 430 for **6***d*, **7***d*, **8***d* respectively, which corroborates the strong predominance of the five-coordinate versus the four-coordinate form of these three models. A significant decrease of the equilibrium constant is observed for the *trans* acrylic isomer **7***d*, whereas the values for models **6***d* and **8***d* are comparable to the value K = 800 obtained by Geibel *et al.* (28) for their five-coordinate model derived from mesoporphyrin IX.

The particular features of the hemochrome spectra obtained with L′ = 4-cyanopyridine together with

the great difference of the affinity constants of Fe(II)TPP **1***d* for L′ and L = *N*-methylimidazole allowed us to study the stepwise replacement of L by L′ (and vice-versa) in the case of Fe(II)TPP. Values of $K_L^{L,L'} = 1$ and $K_{L'}^{L,L'} = 0.06$ agree with the overall affinity constants $K^L K_L^L = 0.85 \times 10^{10}\ M^{-2}$ and $K^{L'} K_{L'}^{L'} = 5 \times 10^8\ M^{-2}$ measured in separate experiments (see Experimental section). Besides, knowledge of $K_L^L = 1.4 \times 10^5\ M^{-1}$ gives $K_L^{L'} = 1.4 \times 10^5\ M^{-1}$, which compares well with the affinity constant of the five-coordinate models **6***d*, **7***d*, **8***d* for 4-cyanopyridine, $K_{Im}^{L'} \sim 2.5 \times 10^5\ M^{-1}$. In other words, the *trans influence* exerted by the covalently linked imidazole, irrespective of the nature of the covalent chain, is not very different from that exerted by the free base *N*-methylimidazole in solution.

Compounds **6***d*, **7***d*, **8***d* strongly bind CO, leading to the well characterized monocarbonyl hemochromes. Affinity constants $K_{Im}^{CO} \sim 1 \times 10^8\ M^{-1}$ are obtained which are comparable to the value obtained by Geibel *et al.* (28) on their mesoheme derivative (**1**, $K = 6 \times 10^8\ M^{-1}$, determined by kinetic methods).

Replacement of L = *N*-methylimidazole by CO in the symmetrical hemochromes of **3***d*, **4***d*, **5***d* gives constants $K_L^{L,CO} = 1.05$, 1.2, and 1.6×10^3, respectively. Knowledge of $K_L^L = 1.3 \times 10^5\ M^{-1}$ for **5***d* gives $K_L^{CO} = 2.1 \times 10^8\ M^{-1}$, which is again comparable with the above K_{Im}^{CO} value.

On exposure to oxygen at room temperature, compounds **6***d*, **7***d*, and **8***d* are immediately and irreversibly oxidized to iron(III) complexes. However admission of oxygen to a toluene solution of these compounds at low temperature (−45°C) immediately gives new species which are characterized by a visible band near 545 nm with a shoulder at 583 nm, and a Soret band at 432 nm. These oxygenations at low temperature are fully reversible, and bubbling argon restores the initial spectra.

Conclusions

In non-coordinating solvents such as benzene or toluene, the physico-chemical properties of iron substituted *meso*-tetraphenylporphins with imidazole covalently attached to either an acrylic (*cis–trans* isomers) or a propionic side chain show that the internal coordination is only observed in the reduced form.

Quantitative titration of the three iron(II) compounds by 4-cyanopyridine shows that internal fifth coordination is much less favourable in the *trans* acrylic derivative than in the *cis* propionic derivatives. This conclusion may be related to the stereochemistry of their free-bases observed in nmr studies.

However, the '*trans influence*' exerted by imidazole upon external fifth ligands is not particularly marked either by the nature or by the structure of the side chain.

The affinity of these compounds derived from the synthetic H_2TPP porphyrin ring is comparable to that of other five-coordinate models derived from meso- (5) and deuteroporphyrin IX rings (7), and related hemoproteins such as isolated α and β chains of human hemoglobin containing protoporphyrin IX as prosthetic group, indicating that porphyrin substituent effects are weak. As quoted by James *et al.* (29), porphyrin substituent effects with 2,4 substituted deuteroporphyrins (proto, meso) and H_2TPP

seem small compared with those observed on changing to octamethyltetrabenzoporphyrin and phthalocyanine. On the contrary, the reactivity of iron(II) model compounds seems more dependent on the length of the chain bearing the terminal base and on the nature of the base (28).

Our own results show that iron(II) derivatives of TPP are as valuable as those derived from naturally occurring porphyrins to mimic the active site of hemoproteins.

Experimental

meso-α,β,γ,δ,Tetraphenylporphin (H_2TPP) and its metal complexes (Cu and Fe) were synthesized as described by Adler *et al.* (30) and Rothemund and Menotti (31) respectively. All chemicals used were of reagent grade. Silica gel was purchased from Merck Company. *N*-Methylimidazole, 4-cyanopyridin, and 3-(3 pyridyl)-1-propanol were purchased from Aldrich. Prediluted CO in nitrogen, grade U (1.08×10^{-4} *M* in volume) was especially supplied by Air Liquide.

Optical spectra in the Soret and visible regions were recorded using a Beckman DKU or a Varian-Techtron 635 spectrophotometer. Proton magnetic resonance spectra in deuterochloroform (CEA, France) were recorded at 100 MHz in the Fourier transform mode using 4K data points in the frequency domain. Chemical shifts were referenced to internal tetramethylsilane (TMS).

The spectrophotometric titrations of the four- and five-coordinate Fe(II) compounds by externally added ligands (including CO) have been performed as previously described (23, 24, 32). The solubility of CO in benzene at 20°C is assumed to be 6.7×10^{-3} *M* atm^{-1} (19). The abbreviations and notations used throughout are the same as in ref. 32 for the four-coordinate species, and are derived from them for the five-coordinate species, as briefly summarized below.

Titration of four-coordinate species, P = **1***d*, **3***d*, **4***d*, **5***d*, by ligands L, L′:

$$P + L \rightleftharpoons PL \qquad (K^L, M^{-1})$$

$$PL + L \rightleftharpoons PL_2 \qquad (K_L^L, M^{-1})$$

$$PL + L' \rightleftharpoons PLL' \qquad (K_L^{L'}, M^{-1})$$

$$PL_2 + L' \rightleftharpoons PLL' + L$$

$$K_L^{L,L'} = [PLL'][L]/[PL_2][L']$$

$$PLL' + L' \rightleftharpoons PL'_2 + L$$

$$K_{L'}^{L,L'} = [PL'_2][L]/[PLL'][L']$$

leading to the obvious relationship

$$K_L^{L'} = K_L^L \times K_L^{L,L'}$$

$$K^L K_L^L \times K_L^{L,L'} \times K_{L'}^{L,L'} = K^{L'} K_{L'}^{L'}$$

and any combination between them.

Titration of five-coordinate species P(Im) = **6***d*, **7***d*, **8***d*, by a ligand L:

$$P(Im) + L \rightleftarrows P(Im)L \qquad (K_{Im}^L, M^{-1})$$

$$P(Im)L + L \rightleftarrows Im—PL_2 \qquad (K_L^{Im,L}, M^{-1})$$

All the constants were obtained at 20°C ± 0.1°C in benzene. Each value was calculated as an average of at least three determinations, with an estimated error of ±30%.

Formylation of Transition Metal Complexes of meso-α,β,γ,δ,-*Tetraphenylporphin*

(1) Cu-TPP. To a mixture of phosphoryl chloride (40 mL) in dimethylformamide (40 mL) was added a solution of metal complex (5 g) in 1,2-dichloroethane (550 mL). The mixture was heated under reflux for 18 h. Saturated sodium acetate solution (600 mL) was added and the mixture was warmed under stirring for a further 2 h. The product was extracted with chloroform. The chloroformic solution was washed with water (× 3), dried over sodium sulfate, and evaporated to dryness. The desired product was crystallized from methylene chloride:methanol (1:5) giving Cu-*meso*-tetraphenyl-1(formyl)porphin **2***b* (4.8 g; 92%). *Anal.* calcd. for $C_{45}H_{28}N_4OCu$: C 76.74, H 4.01, N 7.96; found: C 76.22, H 4.19, N 7.85.

(2) Fe-TPP. Phosphoryl chloride (17 mL) was added to dry dimethylformamide (17 mL) cooled in an ice-bath and the solution was kept at room temperature for 1 h with vigorous stirring. A solution of Fe(III)Cl·TPP (2 g) in 1,2-dichloroethane (100 mL) was added and heated under reflux for 24 h. Following the foregoing treatment, we obtained a residue which was then dissolved in a mixture of pyridine (15 mL), acetic acid (600 mL), and chloroform (250 mL). A saturated solution of iron(II) sulfate in hydrochloric acid (12 *N*, 40 mL) was added under nitrogen. After 5 min, the mixture was poured into a saturated sodium acetate solution. The products were extracted with chloroform. The chloroformic solution was washed with water (× 3) and dried over sodium sulfate. The organic solvent was removed under reduced pressure and the residue dissolved in benzene–cyclohexane (4:1) and chromatographed on a silica gel column. The first compound eluted with the same solvent corresponded to *meso*-tetraphenylporphin **1***a* (1.432 g, 82%). The second one eluted with pure benzene was identified by nmr as formyl-*meso*-tetraphenylporphin **2***a* (231 mg, 12.7%). *Anal.* calcd. for $C_{45}H_{30}N_4O$: C 84.09, H 4.70, N 8.72; found: C 83.79, H 4.80, N 8.64.

Cu-meso-*Tetraphenyl-1-[2-ethoxycarbonylvinyl]porphin (*Cis *and* Trans *Isomers)* **3**b *and* **4**b

Method 1

To a toluene solution of Cu-*meso*-tetraphenyl-1(formyl)porphin **2***b* (2.11 g) was added carbethoxyethyl-methenyl-triphenylphosphorane (15 g). The mixture was refluxed overnight. The solution was evaporated under reduced pressure, and the residue was chromatographed on a silica gel column (3.5 × 100 cm). Elution with toluene gave two successive bands. The first band contained *cis*-Cu-*meso*-tetraphenyl-1-[2-ethoxycarbonylvinyl]porphin **3***b* (0.670 g from chloroform–methanol, 2:7; 28.9%). *Anal.* calcd. for $C_{49}H_{34}N_4O_2Cu$: C 76.00, H 4.43, N 7.24; found: C 75.77, H 4.42, N 7.48. The second one yielded *trans*-Cu-*meso*-tetraphenyl-1-[2-ethoxycarbonylvinyl]porphin **4***b* (1.093 g from chloroform–methanol, 2:7; 47.1%). *Anal.* calcd. for $C_{49}H_{34}N_4O_2Cu$: C 76.00, H 4.43, N 7.24; found: C 75.08, H 4.40, N 7.57.

Method 2

Triethyl phosphonoacetate (10.08 g) was added dropwise under stirring to a slurry of sodium hydride (2.16 g of 50% dispersion in mineral oil) in 90 mL of dry 1,2-dimethoxyethane at 10°C. The solution was then stirred until gas evolution had ceased. Cu-formyl-TPP **2***b* (2.11 g) in 1,2-dimethoxyethane (25 mL) was added and the mixture stirred for 4 h. The reaction mixture was poured in water (500 mL) and the compounds were extracted with chloroform. The organic layer was washed with water (× 2), dried over sodium sulfate, and evaporated under reduced pressure. The residue was dissolved in toluene and chromatographed on a silica gel column in the same solvent to give two isomers as described above.

TABLE 5. Absorption maxima of hemochromes and affinity constants in benzene at 20°C

Cis-Cu-*meso*-tetraphenyl-1-[2-ethoxycarbonylvinyl]porphin, **3***b* (0.104 g; 4.5%).

Trans-Cu-*meso*-tetraphenyl-1-[2-ethoxycarbonylvinyl]porphin, **4***b* (1.980 g; 85.5%).

meso-*Tetraphenyl-1-[2-ethoxycarbonylvinyl]porphin (*Cis *and* Trans *Isomers)* **3**a *and* **4**a

To a solution of Cu-porphin **3***b* (or **4***b*) (1.35 g) in chloroform (250 mL), containing 1% water, gaseous hydrochloric acid was bubbled. Demetallation of metalloporphins was followed by changes in the absorption spectra of the reaction mixture. After completion of the reaction, the solution was successively washed with water, aqueous 0.2 *N* ammonium hydroxide and water, then dried over sodium sulfate and evaporated to dryness. The residue crystallized from methylene chloride–methanol (2:7).

Cis-isomer **3***a*; 1.038 g, 83.5%. *Anal.* calcd. for $C_{49}H_{36}N_4O_2$: C 82.56, H 5.09, N 7.86; found: C 82.79, H 4.98, N 7.64.

Trans-isomer **4***a*; 1.056 g, 85%. *Anal.* calcd. for $C_{49}H_{36}N_4O_2$: C 82.56, H 5.09, N 7.86; found: C 82.98, H 5.05, N 7.72.

meso-*Tetraphenyl-1-[2-ethoxycarbonylethyl]porphin* **5**a

Porphin-*trans*-isomer **4***a* (0.932 g) was dissolved in formic acid (100 mL) and hydrogenated over 30% palladium on charcoal (250 mg) at 40–50°C. Hydrogenation was followed by spectrophotometry. At the end of the reaction the catalyst was removed by filtration and the filtrate evaporated to dryness under reduced pressure. The residue was dissolved in chloroform. The chloroformic solution was successively washed with water, aqueous sodium bicarbonate and water, then dried over sodium sulfate. The crude compound was chromatographed on a silica gel column (3.5 × 45 cm) with benzene as eluting solvent. The porphin fraction was evaporated to dryness and crystallized from methylene chloride–methanol (1:6) to give *meso*-tetraphenyl-1-[2-ethoxycarbonylethyl]porphin **5***a* (735 mg, 80%).

Anal. calcd. for $C_{49}H_{38}N_4O_2$: C 82.33, H 5.36, N 7.84; found: C 82.09, H 5.48, N 7.96.

meso-*Tetraphenyl-1-[3-acrylic acid]porphin (*Cis *and* Trans *Isomers)*

A solution of *meso*-tetraphenyl-1-[2-ethoxycarbonylvinyl] porphin **3***a* (or **4***a*) (1.038 g) dissolved in a mixture of tetrahydrofuran (150 mL) and 80% hydroalcoholic solution of potassium hydroxyde (2 *N*, 75 mL) was shaken for 2 h. The formation of

acid porphin was controlled by analytical thin layer chromatography. The solution was evaporated to dryness. The residue was dissolved in water and acidified by hydrochloric acid giving a compound which was extracted with chloroform (100 mL). The organic solvent was washed with water (× 3) and dried over sodium sulfate. The product was precipitated from methylene chloride by addition of light petroleum.

Cis-isomer: 956 mg, 96%.

Trans-isomer: 936 mg, 94%.

meso-*Tetraphenyl-1-[3-propionic acid]porphin*

This compound was obtained from *meso*-tetraphenyl-1-[2-ethoxycarbonylethyl]porphin **5***a* (735 mg) by the foregoing procedure (671 mg, 95%).

meso-*Tetraphenyl-1-[3-(*N-*imidazolyl propyl)acrylamido]porphin (*Cis *and* Trans *Isomers)* **6**a *and* **7**a

The free acid compounds (154 mg) in benzene (50 mL) were treated with an excess of oxalyl chloride (120 μL) at 50°C until gas evolution has ceased. The solvent was evaporated to dryness. The residue is taken up in methylene chloride and mixed with a solution of *N*-(3-aminopropyl)imidazole in the same solvent. The mixture was stirred for 2 h, then washed successively with water, aqueous sodium bicarbonate, and water, then dried over sodium sulfate. After evaporation, the residue was chromatographed on a silica gel column (1 × 20 cm) (eluting solvent: methylene chloride – methanol, 100:5) and was precipitated with heptane.

Cis-isomer **6***a*: 120 mg, 67%. *Anal.* calcd. for $C_{53}H_{41}N_7O$: C 80.37, H 5.22, N 12.38; found: C 79.98, H 5.26, N 12.43.

Trans-isomer **7***a*: 118 mg, 66%. *Anal.* calcd. for $C_{53}H_{41}N_7O$: C 80.37, H 5.22, N 12.38; found: C 80.03, H 5.31, N 12.41.

meso-*Tetraphenyl-1-[3-(*N-*imidazolyl propyl)propionamido]porphin* **8**a

The foregoing procedure was used. 128 mg, 71%. *Anal.* calcd. for $C_{53}H_{43}N_7O$: C 80.18, H 5.46, N 12.35; found: C 80.36, H 5.29, N 12.31.

meso-*Tetraphenyl-1-[2-(3'pyridyl-*n *propyloxy)carbonylethyl]porphin* **9**a

The acid chloride obtained from 160 mg of free acid of **5***a* by the foregoing procedure and an excess of 3-(3-pyridyl)-1-propanol at 0°C in methylene chloride were stirred for 3 h, and washed successively with water, aqueous sodium bicarbonate, and water, then dried over sodium sulfate. The solvent was removed under reduced pressure and the residue purified by chromatography on a silica gel column (1 × 20 cm) (eluting solvent, chloroform–methanol, 100:2) and precipitated with heptane (112 mg, 60%).

Anal. calcd. for $C_{55}H_{43}N_5O_2$: C 81.96, H 5.38, N 8.69; found: C 81.58, H 5.24, N 8.61.

Iron Complexes

The insertion of iron in the substituted nitrogenous base porphyrins **6***a*, **7***a*, **8***a*, and **9***a* was carried out in a solution of ferrous acetate in acetic acid according to the method of Alben *et al.* (19).

The iron(III) complexes were chromatographed on a silica gel column (1 × 20 cm), eluted with methylene chloride – methanol (100:10), washed with saturated aqueous sodium chloride, and then precipitated with heptane as chloro derivatives (**6***c*, **7***c*, **8***c*, and **9***c*).

Reçu le 2 janvier 1979

J. SERRIER, F. BREHAT, B. WYNCKE et A. HADNI. Can. J. Chem. 57, 1814 (1979).

Les modes de vibration de réseau actifs en absorption infrarouge sont mis en évidence dans le cas des *p*-$C_6H_4X_2$ (X = Cl, Br, I), *m*-$C_6H_4I_2$ et *o*-$C_6H_4I_2$. Le spectre de diffusion Raman est également présenté dans le cas du *m*-$C_6H_4I_2$. Dans le cas des *p*-$C_6H_4X_2$, la position des atomes dans la maille cristalline est connue et les fréquences de vibration externes sont calculées par la méthode de la matrice **GF**. La comparaison avec les valeurs obtenues par les spectres d'absorption infrarouge est acceptable bien qu'on ait négligé toutes les forces multipolaires à grand rayon d'action.

J. SERRIER, F. BREHAT, B. WYNCKE, and A. HADNI. Can. J. Chem. 57, 1814 (1979).

Low frequency lattice modes of *p*-$C_6H_4X_2$ (X = Cl, Br, I), *m*-$C_6H_4I_2$, and *o*-$C_6H_4I_2$ were observed by infrared absorption. Raman scattering spectra were recorded in the case of *m*-$C_6H_4I_2$.

When atomic positions were known in the unit cell (*p*-$C_6H_4X_2$), the lattice mode frequencies were computed by the **GF** matrix method.

The agreement between calculated and experimental values is reasonable although we did not consider the multipole–multipole long range interactions.

I. Introduction

Ce travail fait suite à celui que nous avons publié (1) sur les dérivés dihalogénés du benzène qui sont liquides à température ambiante. A 300 K les composés étudiés ici se présentent sous forme de cristaux moléculaires dont la formule brute est $C_6H_4X_2$ (X = Cl, Br, I). Les halogènes sont substitués aux hydrogènes en position *ortho*, *méta* et *para*. A cette étude nous avons ajouté celle des spectres infrarouge lointain des *p*-chloroiodo- et *p*-bromoiodobenzène.

II. Expérimentation

Les monocristaux utilisés sont fabriqués au laboratoire par la méthode de Bridgmann. Nous les avons taillés et orientés suivant les axes cristallographiques. Les lingots sont orientés à l'aide des rayons X par la méthode de Laue en retour. La tête goniométrique, sur laquelle sont disposés les cristaux, est placée sur une scie à fil. Les lames obtenues ont une épaisseur variant entre 0.5 et 1 mm. Pour obtenir des lames de 100 μm d'épaisseur nous avons collé les plaquettes de 16 × 16 mm^2 sur des cales de verre à l'aide de paraffine. L'épaisseur désirée est obtenue par usure des lames sur du papier abrasif (Norton 600 A). Suivant le domaine spectral étudié l'épaisseur des échantillons est comprise entre 100 μm et 1 mm. Les échantillons sont facilement sublimables et il est nécessaire de les enfermer dans une cuve étanche à fenêtres de quartz.

Les spectres d'absorption dans l'infrarouge lointain (15–250 cm^{-1}) sont enregistrés en lumière polarisée à 80 et 300 K, à l'aide d'un spectromètre Cameca SI 36 équipé d'un cryostat et d'un polariseur. La limite de résolution est de l'ordre de 1 à 2 cm^{-1}.

Nous avons vérifié le spectre de diffusion Raman de ces composés, en particulier celui du *m*-diiodobenzène. Le spectrophotomètre utilisé est un appareil Coderg T 800 équipé d'un laser Spectra Physics 165 à argon (488 nm). La limite de résolution spectrale est de l'ordre de 1 cm^{-1}.

III. Résultats expérimentaux

Le *p*-dichlorobenzène (PDC) dans la phase α cristallise dans le système monoclinique et possède le groupe d'espace $C_{2h}^5(P_{2_1/a})$ et deux molécules par maille. Il suffit donc pour l'étude de l'absorption infrarouge d'orienter le champ électrique ***E*** de l'onde excitatrice suivant l'axe binaire ***b*** et normalement à celui-ci. Il en est de même pour le *p*-dibromobenzène (PDB) dont la structure est isomorphe à celle du PDC α. Sur la fig. 1 nous avons représenté la variation de l'indice d'absorption *k* du PDB en fonction de la fréquence spatiale $\bar{\nu}$ (cm^{-1}). Le spectre du PDC a déjà été publié antérieurement (2). La structure des *p*-chloroiodo- (PCI) et *p*-bromoiodobenzène (PBI) n'est pas connue avec exactitude mais nous supposerons avec Prasad et coll. (3) qu'ils cristallisent dans le système monoclinique. L'axe binaire étant désigné par ***b***, nous présentons sur la fig. 1 le spectre d'absorption dans l'infrarouge lointain de ces deux composés.

Selon Hendricks et coll. (4) l'*o*-diiodobenzène (ODI) possède une structure monoclinique et très probablement le groupe d'espace $C_{2h}^1(P_{2/m})$ ou $C_{2h}^2(P_{2_1/m})$, il y aurait quatre molécules par maille. Sur la fig. 1, nous avons porté la variation de l'indice d'absorption *k* d'une lame polycristalline d'ODI. Il ne nous a pas été possible de faire une étude en lumière polarisée d'un monocristal d'ODI par suite de son point de fusion peu élevé (pf = 23°C). Nous avons dû nous contenter de solidifier le liquide entre

0008-4042/79/141814-09$01.00/0

deux lames de quartz. Il peut y avoir une orientation partielle des cristallites. Toutefois nous avons enregistré le spectre infrarouge lointain plusieurs fois dans des conditions de cristallisation différentes. Nous observons toujours huit maximums d'absorption sur les neuf possibles et il est probable que deux ou plusieurs maximums de types différents soient superposés.

Les *m*- et *p*-diiodobenzène (MDI et PDI) cristallisent dans le système orthorhombique (4). Sur la fig. 2 nous présentons les variations de l'indice d'absorption $k = f(\dot{\nu})$ lorsque le champ électrique $\boldsymbol{E}$ de l'onde excitatrice est orienté suivant chacun des axes cristallographiques. Les résultats de cette étude sont rassemblés dans les tableaux 1 à 7.

IV. Discussion

IV.1. Attribution des maximums d'absorption observés

Les structures monocliniques de PDC, PDB, PCI et PBI possèdent le groupe d'espace $C_{2h}^5(P_{2_1/a})$. Les deux molécules de la cellule élémentaire occupent le site C_i. En conséquence l'analyse du groupe facteur C_{2h} permet de prévoir la répartition des modes de réseau: trois modes de translation de type $u(2a_u + 1b_u)$ actifs en absorption infrarouge et six modes de type $g(3a_g + 3b_g)$ qui correspondent aux librations actives en diffusion Raman.

Dans le cas de l'ODI les quatre molécules de la maille sont en position générale et il n'est plus possible de distinguer les translations des rotations. Les modes de réseau se répartissent en $6a_g + 6b_g + 5a_u + 4b_u$. La maille à faces *C* centrées du MDI est multiple, et peut être réduite en une maille élémentaire contenant seulement deux molécules. Dans le groupe facteur C_{2v}, les neuf modes de réseau du MDI se répartissent en $2a_1 + 3a_2 + 2b_1 + 2b_2$. Ces modes sont actifs en absorption et en diffusion à l'exception des modes a_2 qui ne se manifestent qu'en Raman. Les modes de réseau du PDI se séparent en translations actives en infrarouge $(2b_{1u} + 2b_{2u} + 2b_{3u})$ et en librations $(3a_g + 3b_{1g} + 3b_{2g} + 3b_{3g})$ actives en diffusion puisque le groupe d'espace est D_{2h}^{15} et que la maille élémentaire comporte quatre molécules occupant des sites C_i. Le PDI présente une transition de phase à 326 K (12). Nous n'avons pas observé de modifications importantes dans le spectre. Il y a seulement un élargissement des bandes ce qui réduit considérablement la précision de la position des maximums d'absorption.

Récemment Clayman et coll. (13) ont publié le spectre infrarouge lointain du PDI. Nos résultats sont en bon accord avec les leurs. Toutefois nous avons observé un maximum d'absorption supplémentaire à 15.5 cm^{-1} qui passe à 16 cm^{-1} lorsqu'on abaisse la température à 80 K. Ce mode est attribué à une vibration de réseau (tableau 7).

Ces quelques remarques nous permettent de proposer une attribution pour les maximums d'absorption que nous avons observés. Nous avons rassemblé tous ces résultats dans les tableaux 1 à 7. Dans le tableau 6 nous avons porté les modes que nous avons observés en diffusion Raman dans le cas du MDI. Pour les autres composés les résultats obtenus (5–7) sont identiques à ceux publiés par d'autres auteurs.

Le spectre de ces composés dissous dans le tétrachlorure de carbone nous permet de séparer les vibrations internes des molécules des vibrations de réseau. Les résultats que nous obtenons sont en bon accord avec ceux publiés par Green (8). Dans les tableaux nous avons indiqué l'attribution proposée par cet auteur.

Seul l'ODI présente un maximum d'absorption dans les basses fréquences lorsqu'il est dissout dans le tétrachlorure de carbone. Ce maximum d'intensité s'explique par le caractère fortement polaire de la molécule d'ODI.

Afin d'étayer l'attribution précédente des modes de réseau à tel ou tel mouvement de translation ou de pivotement, nous avons calculé la valeur des fréquences des vibrations de réseau en utilisant la méthode de la matrice **GF** (14) (**G** représente l'inverse de l'énergie cinétique dans le système des coordonnées internes et **F** l'énergie potentielle).

IV.2. Calcul des fréquences de vibration du réseau

Le calcul des fréquences de vibration de réseau par la méthode de la matrice **GF** nécessite la connaissance exacte de la position des atomes dans la maille élémentaire.

Les données structurales du PDC (15), du PDB (16) et du PDI (4) sont connues et nous avons effectué le calcul des fréquences des modes de réseau de ces trois composés. La cohésion de la structure de ces cristaux moléculaires est assurée par des liaisons de type Van der Waals et nous considérons en première approximation que les molécules sont rigides. Lors des mouvements de réseau la distance r_{ij} qui sépare deux atomes de molécules différentes varie. Si k_{ij} désigne la constante de force correspondante nous pouvons évaluer l'expression du potentiel. Nous choisirons un potentiel transférable comme celui de Buckingham:

$$V_{ij}(r_{ij}) = A_{ij} \exp(-B_{ij}r_{ij}) - C_{ij}r_{ij}^{-6}$$

La constante de force de la liaison *i–j* est donnée par la dérivée seconde par rapport à r_{ij} de l'expres-

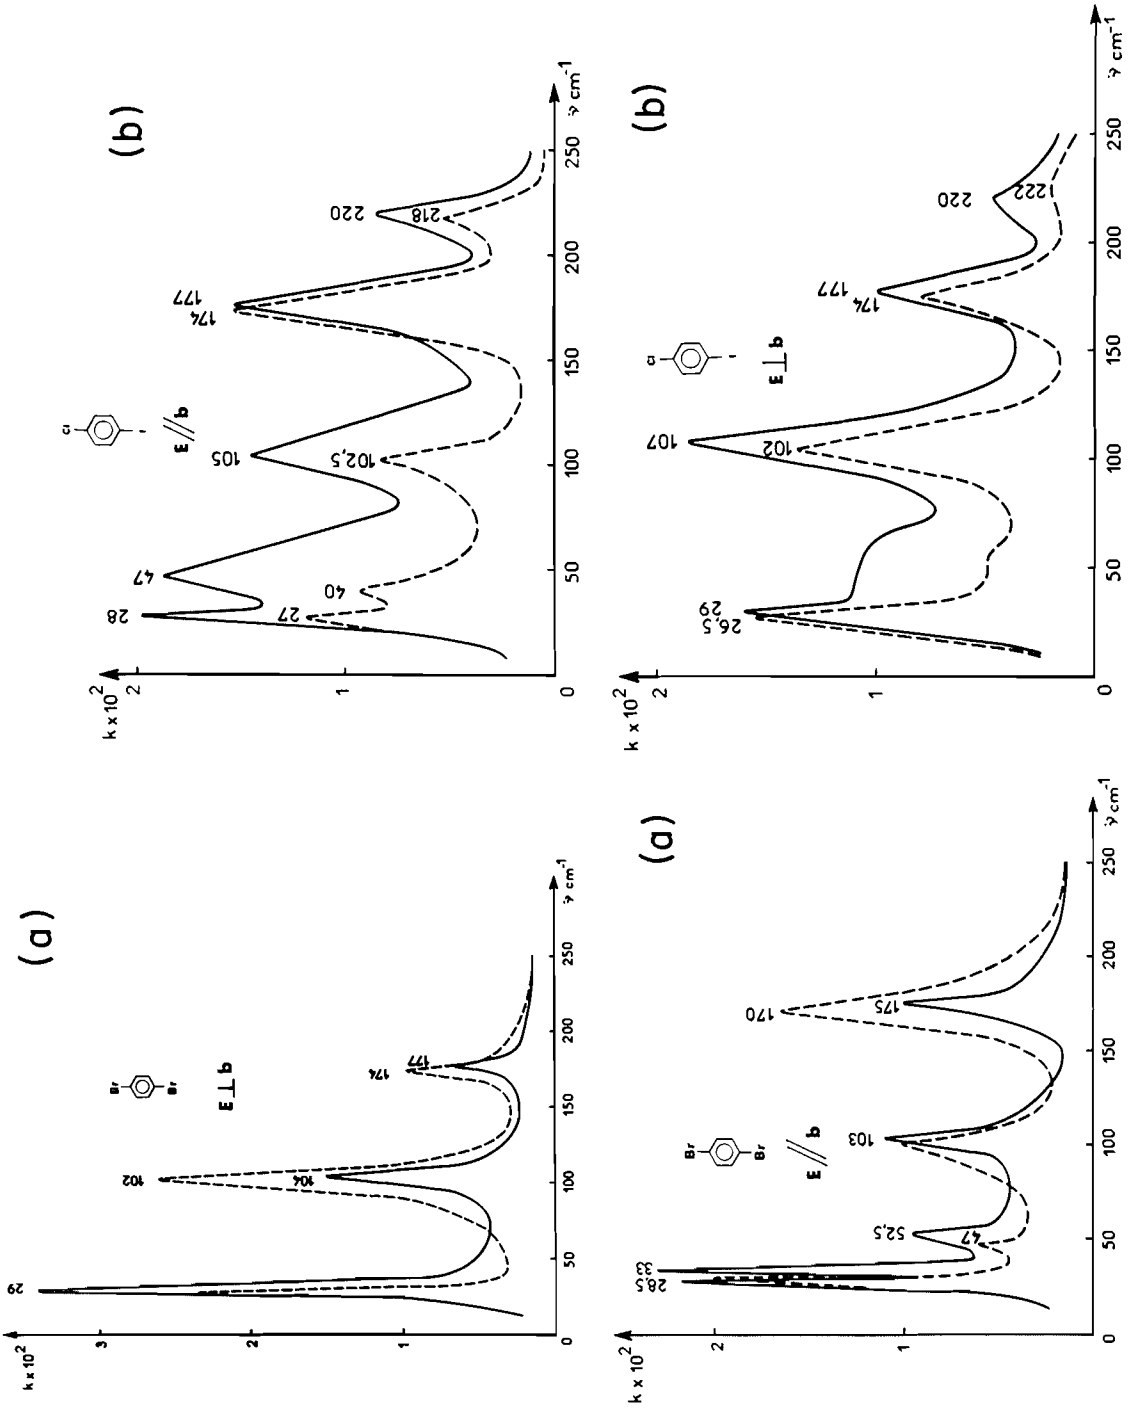

FIG. 1 (Part 1).

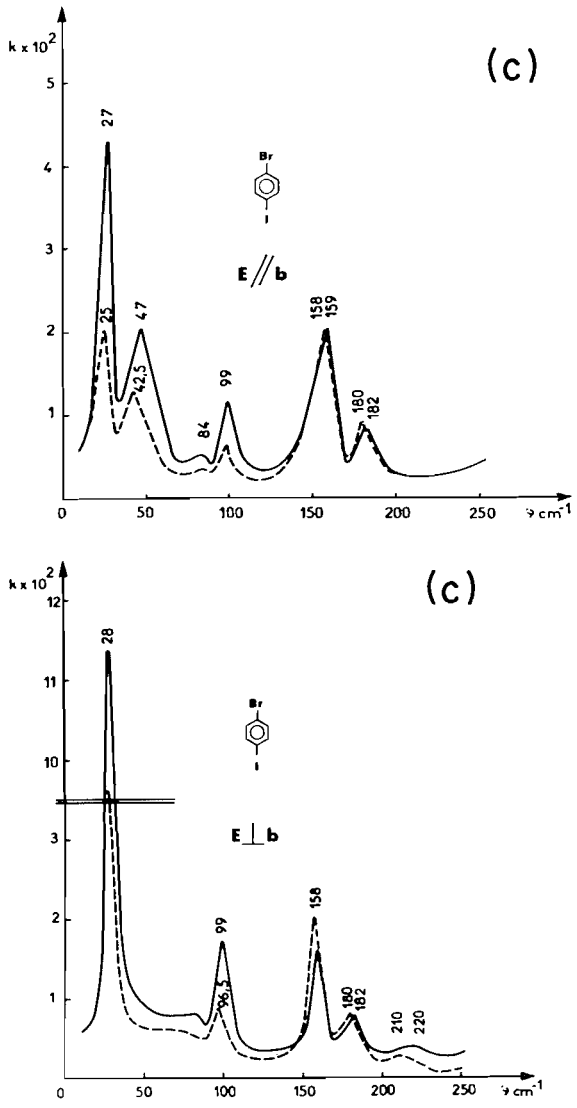

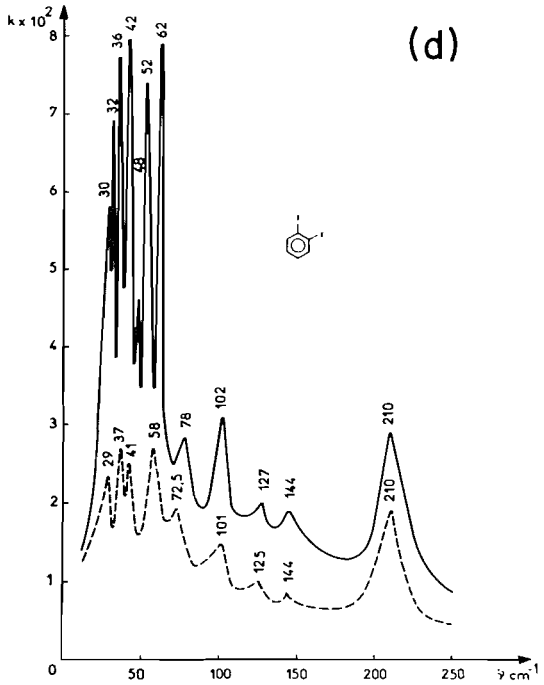

FIG. 1 (Part 2) (*Concluded*). Variation de l'indice d'absorption k en fonction de la fréquence spatiale $\bar{\nu}$ (cm^{-1}) à 80 (—) et 300 K(---): (*a*) du *p*-dibromobenzène; (*b*) du *p*-chloroiodobenzène; (*c*) du *p*-bromoiodobenzène; le champ électrique ***E*** est orienté suivant l'axe binaire ***b*** et normalement à celui-ci; (*d*) de l'*o*-diiodobenzène polycristallin.

sion du potentiel:

$$k_{ij}(r_{ij}) = A_{ij}B_{ij}^{2} \exp(-B_{ij}r_{ij}) - 42C_{ij}r_{ij}^{-8}$$

Les coefficients empiriques A_{ij}, B_{ij} et C_{ij} dépendent uniquement de la nature des atomes i et j. L'interaction moléculaire totale s'obtient par sommation sur chacune des paires d'atomes présentes dans le cristal. L'énergie du réseau est égale à la somme de tous ces potentiels s'il n'y a pas d'interactions dipolaires ou quadrupolaires électriques et si les liaisons sont purement covalentes:

$$E = \tfrac{1}{2}\sum_{ij}\{A_{ij}\exp(-B_{ij}r_{ij}) - C_{ij}r_{ij}^{-6}\}$$

Les coefficients A, B, C doivent être choisis de façon à retrouver l'énergie de sublimation, les paramètres de la maille, la vitesse du son et les fréquences de vibration du réseau. Dashevsky et coll. (17) proposent une sérié de valeurs obtenue à partir d'une étude structurale de dérivés aromatiques. Il en est de même de Williams (18) qui considère une série de composés aromatiques (benzène, naphtalène, ... ovalène). Kitaigorodskii et coll. (19) proposent une autre série de valeurs obtenue en évaluant l'énergie de réseau du benzène cristallisé. Nous avons également utilisé une autre série due à Bartell-Crowell cité par Ozora et coll. (20). Pour les liaisons entre atomes d'halogènes identiques nous avons suivi les indications de Hill (21) pour calculer la valeur des coefficients A, B, C. Il faut reconnaître que les valeurs empiriques des coefficients A, B et C du même potentiel de Buckingham varient beaucoup suivant les auteurs. Par exemple, $A_{CC} = 26.19$ (Dashevsky) et $A_{CC} = 51.76$ (Kitaigorodskii); $A_{CH} = 11.17$ (Bartell-Crowell) et $A_{CH} = 28.19$ (Kitaigorodskii). Pour des liaisons entre atomes différents (C—H, C—Cl, H—Cl) nous avons appliqué les relations:

$$A_{ij} = (A_{ii}B_{jj})^{1/2}$$

$$B_{ij} = \tfrac{1}{2}(B_{ii} + B_{jj})$$

$$C_{ij} = (C_{ii}C_{jj})^{1/2}$$

Dans le calcul des modes de réseau du PDC, du

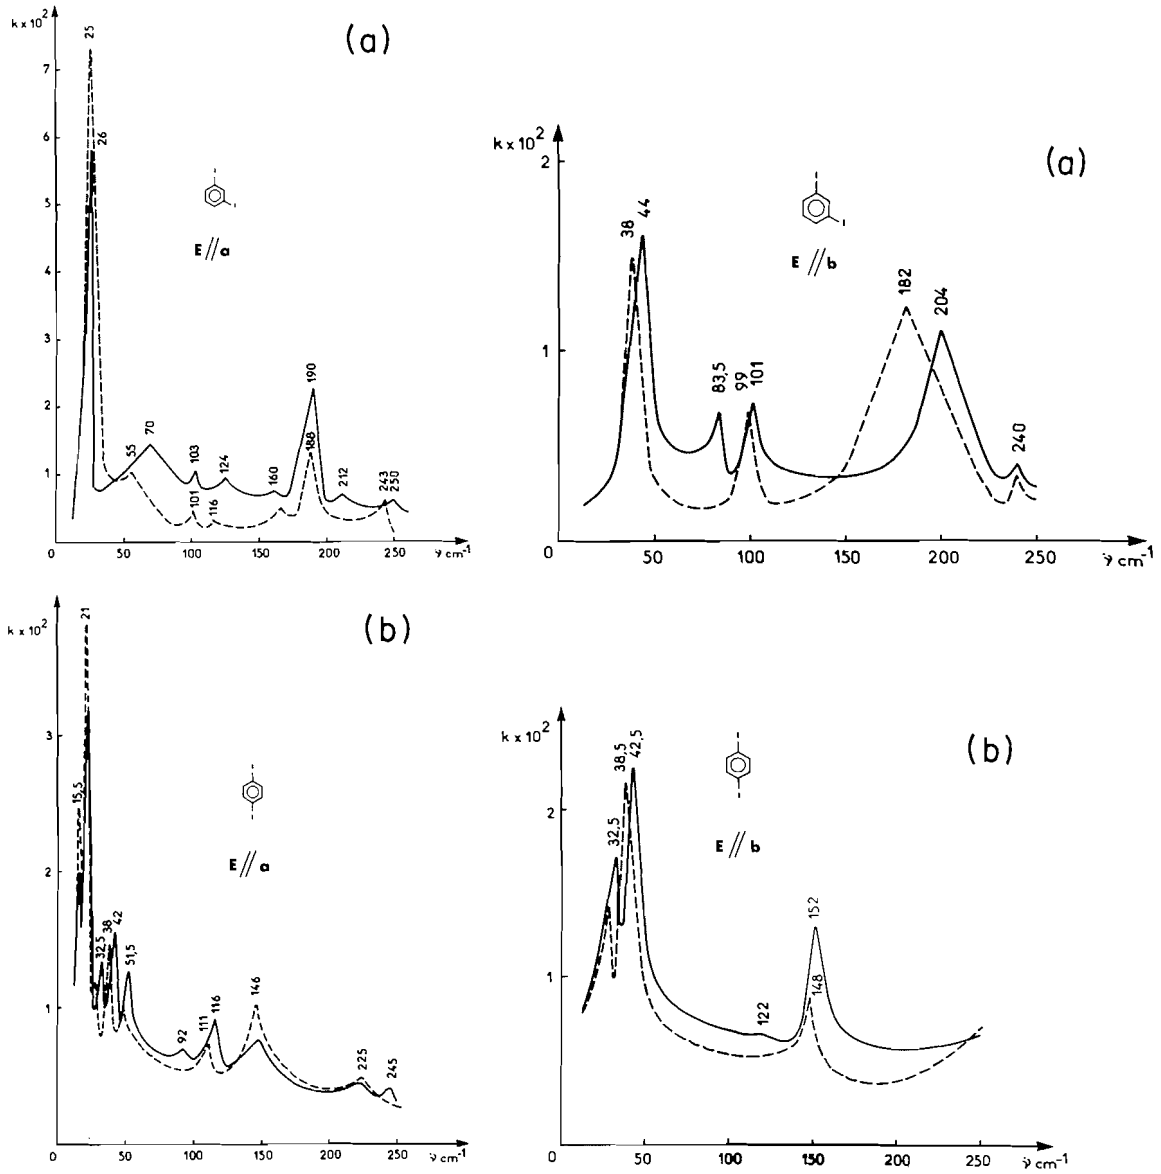

FIG. 2 (Part 1).

PDB et du PDI nous n'avons retenu que les liaisons dont les constantes de force sont supérieures à 8×10^{-3} mdyn/Å. Les constantes de force k_{ij} sont les éléments diagonaux de la matrice **F** représentative de l'énergie potentielle d'interaction rapportée à la maille élémentaire et exprimée dans un système de coordonnées internes.

On montre (22) que la matrice **G** représentative de l'énergie cinétique, exprimée dans un système de coordonnées normales, est égale à la matrice identité **E**. L'équation séculaire $|\mathbf{GF} - \mathbf{E}\Lambda| = 0$, se simplifie suivant $|\mathbf{F} - \mathbf{E}\Lambda| = 0$, où **Λ** est la matrice diagonale des valeurs propres λ de la matrice **F**. L'équation séculaire est résolue simplement dans le système des coordonnées de symétrie (23).

IV.3. Comparaison des fréquences calculées aux fréquences observées expérimentalement

Le calcul des fréquences a été effectué avec les séries de paramètres proposés par les auteurs cités ci-dessus (17–20).

Nous remarquons que le meilleur accord entre les fréquences calculées et observées est obtenu avec le système des coefficients proposés par Williams.

Dans ce cas, le calcul de PED (potential energy distribution) permet d'évaluer le pourcentage des
