On décrit deux essais effectués en vue d'améliorer l'instrumentation et la méthodologie de la mesure de l'équilibre ion–molécule. Le premier essai porte sur la dissociation des ions AB^+ dans le système d'analyse de masse du spectromètre de masse. Pour mesurer la constante d'équilibre d'association $A^+ + B = AB^+$, il faut des échantillons de A^+ et de AB^+. Les ions AB^+ s'échappant d'une source d'ions à haute pression ont une distribution d'énergie thermique. Une fraction f_{ex} a une énergie interne qui est supérieure à l'énergie de dissociation $AB^+ \rightarrow A^+ + B$. Cette fraction peut se dissocier avant d'être détectée. On a effectué une analyse théorique du $K^+(H_2O)_n$ qui se fonde sur les fréquences vibrationnelles et les géométries calculées de $K^+(H_2O)_n$. A partir de ces données on peut évaluer $f_{n,ex}$. Les calculs de RRKM fournissent également la vitesse de dissociation de AB^+_{ex}. On a trouvé qu'il peut se produire une forte dissociation pendant l'analyse de masse si on ne choisit pas convenablement les conditions expérimentales. On présente également les résultats relatifs à $H^+(H_2O)_2$ et à $(C_6H_6^+)_2$. Les mesures de l'équilibre d'association doivent être réalisées à de faibles pressions de B en présence d'une forte pression d'un gaz inerte agissant comme bain.

En reliant la plaque répulsive à une source de fréquence radio, on peut appliquer des impulsions de FR dans la source de haute pression. Ces impulsions augmentent l'énergie interne des ions. L'impulsion FR produit un déplacement de l'équilibre si le système réactionnel est à l'équilibre. Le système se détend et revient à son état initial lorsqu'on élimine la FR. Les mesures cinétiques des temps de relaxation fournissent les constantes de vitesse à partir desquelles on peut déterminer la constante d'équilibre qui n'est pas affectée par la détermination de la masse de l'ion. A l'aide de cette technique on peut également étudier la cinétique des réactions rapides.

Introduction

The measurement of ion–molecule equilibria was first initiated in this laboratory some 15 years ago (1, 2). In the intervening years many measurements of ion equilibria have been reported from this and other laboratories. The method has proven to be of extraordinary usefulness since it provides thermochemical information on inorganic and organic ions, gas phase acidities and basicities, ion–ligand binding energies and ion – solvent molecule interactions (3–5). In addition to high pressure mass spectrometry, used in this and other laboratories, flowing afterglow and particularly ion cyclotron resonance have proven to be very valuable instrumental methods (3–5).

The work on ion equilibria by high pressure mass spectrometry from this laboratory had an initial stage in which considerable effort was put into instrumental developments and experiments designed to improve the reliability of the measurements. This stage was followed by a period of extensive utilization of the method for obtaining results of interest to different areas of chemistry. Recently, we have felt that again more effort should be devoted to instrumental and methodology development. In the early measurements, when no

data whatsoever were available, we considered an accuracy of a few kcal/mol for association equilibrium [1] and a 1 kcal/mol for transfer equilibrium [2]

[1] $A^+ + B = AB^+$

[2] $CD^+ + E = C + DE^+$

as quite sufficient. However as more data accumulate, it is clearly desirable to achieve greater accuracy and reliability. In the present work we will address ourselves to a problem area in the existing technique and to an advance in technique. Part I deals with the problem of unimolecular dissociation of association products AB^+ in the vacuum of the mass analysis region. Part II describes a new ion *T*-jump relaxation method with which the kinetics of ion equilibria can be determined.

I. Unimolecular Dissociation of Ions from Association Equilibria

(a) General

The reverse reaction in the association equilibrium [1] is the thermal decompositon of the adduct AB^+. This decomposition occurs in the high pressure ion source in the course of an equilibrium measurement. At any time a fraction of AB^+ are thermally activated to the dissociation limit, $E_0 \approx -\Delta H_1$. The activation and deactivation of AB^+ is

[1] $A^+ + B \underset{k_r}{\overset{k_f}{\rightleftharpoons}} AB^+$ Lindeman

$$A^+ + B \underset{k_d}{\overset{k_c}{\rightleftharpoons}} AB^+_{ex} \underset{k_a[M]}{\overset{k_s[M]}{\rightleftharpoons}} AB^+$$

[3] Dissociation limit: $E_0 \approx -\Delta H_1$

[4] $f_{ex} = [AB^+_{ex}]/[AB^+]$

represented above through Lindeman's strong collision mechanism. The fraction of molecules AB^+ excited above the dissociation limit E_0 are defined as f_{ex} in eq. [4].

In the ion sampling process used in high pressure mass spectrometry and flowing afterglow, gas and ions effuse through an exit orifice into the evacuated mass analysis region. In our apparatus, molecular flow prevails so that there are few collisions on the vacuum side of the orifice. The initial internal energy distribution of the ions should be very close to thermal. The fraction f_{ex} which has sufficient internal energy to dissociate can do so in the vacuum. However, once these ions have been used up no other ions can dissociate since the thermal population, due to the absence of collisions, is not maintained. Therefore if f_{ex} is small, say $f_{ex} < 0.05$ no serious error will occur in the equilibrium measurements.

The possibility of sampling error due to unimolecular dissociation of AB^+_{ex} in vacuum was considered in the first paper on ion equilibria (1). However, a detailed analysis was not made. In subsequent work (3), in general, conditions were selected which keep f_{ex} as low as possible. f_{ex} is low at low temperature, where the rate of the reverse reaction [1r] is slow. If one is to observe the equilibrium, one needs also to slow down the rate of the forward reaction [1f]. This means one must use a low concentration of B. However, since the ion life-times with regard to discharge to the wall of the ion source should be relatively longer than the the equilibrium halflives, ion diffusion to the wall also must be slowed down. This is achieved by the addition of an inert major gas. Although the advantage of the third gas addition was realized early (6) and used whenever possible (3), in some cases the use of the neat gas B was continued. The ion intensity in the alkali ion clustering equilibria apparatus was low and was adversely affected by the introduction of a third gas. This condition could have been removed by improved design. However, the possible seriousness of unimolecular decomposition in vacuum was not realized and measurements were performed with neat B in this apparatus.

(b) Unimolecular decomposition in $K^+(H_2O)_n$ clusters

The present section provides an analysis of the possible problem due to unimolecular dissociation of AB^+ in the vacuum of the mass analysis system. Most of the work deals with the potassium hydrate equilibria [5]. However, the results are of significance also for any other clustering equilibria measurements.

[5] $K^+(H_2O)_{n-1} + H_2O = K^+(H_2O)_n$

The fraction f_{ex} representing molecules AB^+ excited above the dissociation limit can be calculated from statistical mechanics expressions. These provide the internal thermal energy distribution function $P(E)$ if the normal vibration frequencies and the internal rotations of AB^+ are known. These parameters were evaluated for $K^+(H_2O)_n$, $n = 1$ to 6. Potential energy surfaces for the various normal vibrations were obtained (10) from improved electrostatic calculations, similar to those performed earlier by Davidson and Kebarle (9), but incorporating the ligand–ligand dipole attractions and repulsions. The binding energies i.e. $\Delta E_{0,n}$ (see eq. [5]) for the $K^+(H_2O)_n$ clusters are also obtained with this method. A comparison of the results obtained by the electrostatic calculations (Els) with those from other methods (11) and the experimental results are given in Table 1.

For personal use only.

Third law entropies for the clusters $K^+(H_2O)_n$ can be readily obtained from Els calculated vibrational normal frequencies etc., and standard statistical mechanics expressions. The $\Delta S^0_{n-1,n}$ obtained in this manner are shown as $\Delta S^0_{n-1,n}$ (Els). These data are in substantial agreement with Mruzik's Monte Carlo entropies, ΔS(Monte) (12). The experimental (7) $-\Delta S^0_{n-1,n}$ are fairly close too, but are found to be somewhat higher, particularly for $n = 5$ and 6. As will be seen later, there is reason to believe that the $-\Delta S^0_{4,5}$ and $-\Delta S^0_{5,6}$ (exp) are too high. The general agreement between the $\Delta S^0_{n-1,n}$ Els, Monte, and Exp lends support for the Els predicted frequencies and rotational parameters.

The vibrational frequencies obtained from the electrostatic calculations for the clusters $K^+(H_2O)_n$ ($n = 1$ to 6) were used for the evaluation of the thermal distribution function $P(E)$. From this, f_{ex} was calculated by eq. [6]. The calculated f_{ex} for

$$[6] \qquad f_{n,ex} = \int_{E_0}^{\infty} P_n(E)\, dE$$

$K^+(H_2O)_n$ are shown in Fig. 1 as a function of the temperature. The temperature interval given for each $K^+(H_2O)_n$ corresponds to the range accessible to measurement with the high pressure mass spectrometer. The corresponding equilibrium constants $K_{n-1,n}$ for reaction [5] are also given in the figure. It is evident from Fig. 1 that f_{ex} is less than 10^{-1} for $n = 2$ and $n = 3$, but for higher n, f_{ex} is generally larger than 0.1. The best conditions for measurement, i.e. lowest f_{ex}, are at low temperature. This corresponds to high values of $K_{n-1,n}$. For example if conditions were used to measure $K_{n-1,n}$ where they are larger than 100 $Torr^{-1}$, f_{ex} would have been less than 10^{-1} even for $n = 6$. Conditions for $K_{n-1,n} = 100\ Torr^{-1}$ are generally easily obtained. One uses a third gas as diffusion barrier while the pressure of the clustering gas B (H_2O in the present case) is kept in the 1 to 10 mTorr range. With ions n and $n - 1$ at similar concentrations, this leads to $K_{n-1,n} \approx 1000$ to 100 $Torr^{-1}$.

The fraction of molecules excited above the dissociation limit f_{ex} give the ions AB^+ that have enough energy to dissociate in the vacuum of the analysis system. Whether they will dissociate during the time of flight to the ion detector ($\sim$15 μs) depends on the actual unimolecular decomposition rates. The rate constants for unimolecular decomposition $k_n(E)$ of the $K^+(H_2O)_n$ ions were calculated using RRKM theory (10). The required frequencies were obtained from the electrostatic calculations mentioned earlier. The intensity I_n of an

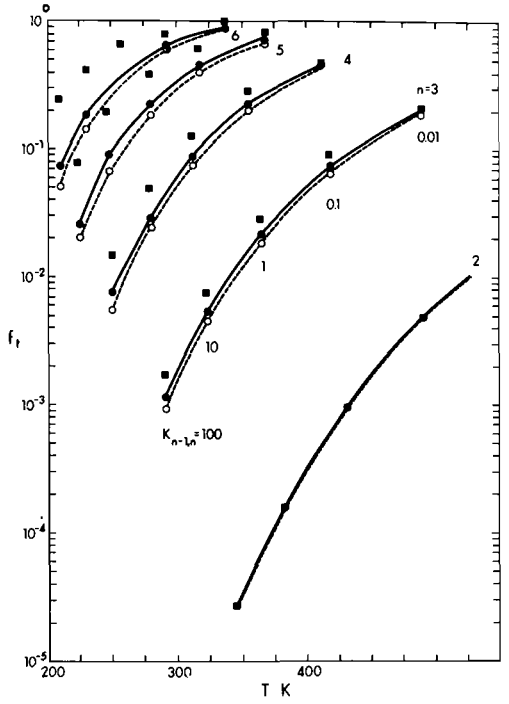

FIG. 1. Results of calculations for system $K^+(H_2O)_{n-1} + H_2O = K^+(H_2O)_n$; ■ $f_{n,ex}$ = fraction of clusters n excited above critical energy $E_0 = -\Delta H_{n-1,n}$, i.e. fraction of clusters n that have sufficient internal energy to dissociate in the vacuum of the mass analysis system; ● $f_{n,b}$ = fraction of clusters n that dissociate before leaving magnetic sector. ○ $f_{n,a}$ = fraction of clusters n that dissociate within 2 μs after entering the vacuum system. For each n, the value of the equilibrium constant $K_{n-1,n}$ in $Torr^{-1}$ is shown on the curves. That value changes from 100 to 0.01 $Torr^{-1}$.

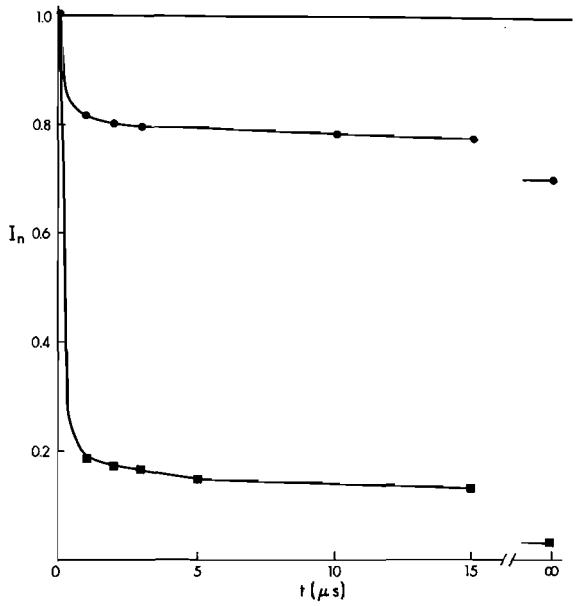

FIG. 2. Calculated unimolecular decay of a thermal population of ions exposed to vacuum. ● $K^+(H_2O)_4$ initially at 354 K ($K_{3,4} \approx 0.1$ $Torr^{-1}$); ■ $K^+(H_2O)_6$ initially at 337 K ($K_{5,6} \approx 0.01$ $Torr^{-1}$). These are examples of severe change of ion intensities due to unimolecular dissociation of the cluster ions.

ion in function of the flight time t (in vacuum) is given by [7].

$$[7] \quad I_n(t) = \int_0^\infty P_n(E)\{\exp[-k_n(E)t]\}\,dE$$

The intensity time dependence for two ions $K^+(H_2O)_4$ and $K^+(H_2O)_6$ calculated with eq. [7] for conditions where quite severe dissociation occurs is shown in Fig. 2. From [7] one can also evaluate $f_{n,a}$ the fraction of ions dissociating within 2 μs and $f_{n,b}$, those dissociating before having left the magnetic sector of the mass analysis system. $f_{n,a}$ gives the fraction of ions n that will be detected as $n - 1$, while $1 - f_{n,b}$ gives the fraction of ions n that will be detected as n. The fractions $f_{n,a}$ and $f_{n,b}$ are shown in Fig. 1. For small n i.e. $n = 2$ and 3, $f_{ex} \approx f_b \approx f_a$ i.e. all ions with energy above the dissociation limit E_0 dissociate rapidly. This is expected for systems that have a small number of degrees of freedom. For higher n the difference between f_{ex}, f_b, and f_a increases. For these systems there are many vibrations which can obtain energy quanta. Therefore considerable time elapses before sufficient energy can collect in the critical mode. It is also observed in Fig. 1 that for a cluster with a given n, the difference between f_{ex}, f_a, and f_b increases as the temperature is decreased. This behavior reflects the different energy distribution in the cluster for different temperatures. At low temperatures the energy distribution above E_0 falls off rapidly with E, therefore it takes a longer average time for this energy poor population of excited clusters to decompose.

Considering that the predicted decomposition (see Figs. 1 and 2) can be so severe for higher n, the question immediately arises: why is there no indication in the experimental results of something being wrong? As will be shown below a cancellation which reduces the error occurs.

The relationship between the true equilibrium constant for the $n - 1,n$ equilibrium $K_{n,tr}$, and the observed equilibrium constant $K_{n,obs}$ is given in eq. [8].

$$[8] \quad \frac{K_{n,obs}}{K_{n,tr}} = \frac{(1 - f_{n,b}) + (f_{n+1,a})(K_{n+1,tr})\,P}{(1 - f_{n-1,b}) + (K_{n,tr})(f_{n,a})\,P}$$

P is the pressure of the clustering gas, i.e. H_2O in the present case. Equation [8] expresses the fact that a fraction $(1 - f_{n,b})$ of clusters n are detected as clusters n and a fraction $f_{n+1,a}$ of clusters $(n + 1)$ are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

also detected as clusters n. Furthermore a fraction $(1 - f_{n-1,b})$ of clusters $(n - 1)$ are detected as $(n - 1)$ and a fraction $f_{n,a}$ of clusters n are detected as clusters $(n - 1)$. An example of the changes due to unimolecular decomposition is given in Fig. 3 for the ions, $n = 5$ and $n = 4$. The value of the observed equilibrium constant $K_{5,obs}$ is not too far from the true value, because both the ion $n = 5$ and $n = 4$ receive a somewhat proportional contribution from fast dissociating ions $n = 6$ and $n = 5$ respectively.

The calculated $K_{n,obs}$ obtained from eq. [8] are compared with the $K_{n,tr}$ in Fig. 4. These results show that the effect of unimolecular dissociation is to introduce some curvature and steepen the experimental van't Hoff plots. The curvature will not be noticed in experimental work unless the measurements extend over a wide range of temperatures. The steeper slopes lead to $-\Delta H_{n-1,n}$(obs) that are larger than the true values. This effect increases with n. A set of corrected $\Delta H^0_{n-1,n}$ and $\Delta S^0_{n-1,n}$ based on this analysis is given in Table 1, where these corrected experimental results are identified as Expc. The largest difference observed for $-\Delta H^0_{5,6}$ is: Exp 10.0 kcal/mol, Expc 8.4 kcal/mol.

An experimental verification for the occurrence of unimolecular decomposition can be obtained by

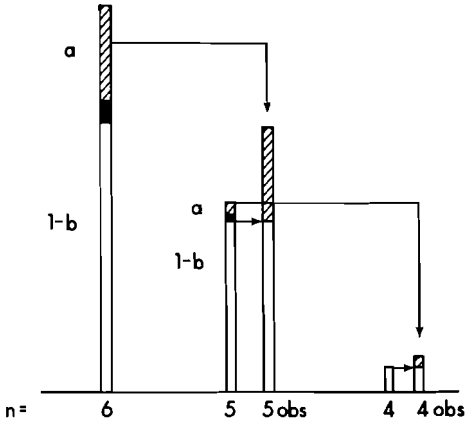

FIG. 3. Illustration of partial cancellation of errors caused by unimolecular decomposition of ion clusters in vacuum. Ion source temperature 250 K. 1 Torr H_2O pressure. Shaded part of ion intensity designated as a, represents clusters n that dissociate rapidly to $n - 1$ and are detected as $n - 1$. Clear part of ion intensity designated $(1 - b)$ represents clusters n which do not decompose until after mass separation and are therefore detected as clusters n. The observed equilibrium constant $K_{4,5}$(obs) = 8.5 (Torr^{-1}) while the true constant is $K_{4,5}$(true) = 10 (Torr^{-1}). Error is reduced because *both observed* ions $n = 5$ and $n = 4$ receive a contribution from the respective rapidly dissociating $n + 1$ ion. Black part of ion intensity are ions that dissociate during acceleration and mass analysis and are not detected.

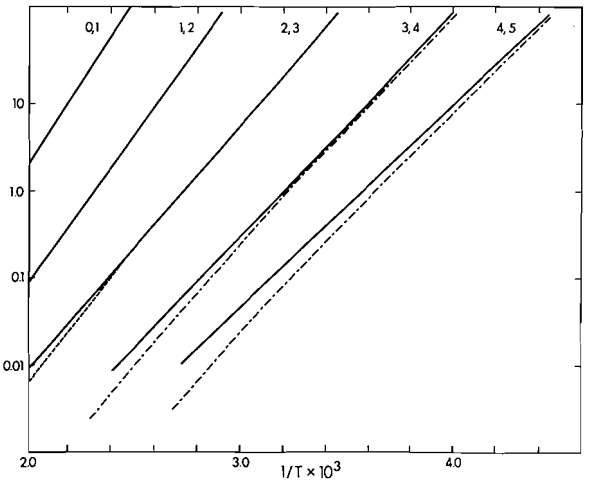

FIG. 4. Effect of unimolecular dissociation of $K^+(H_2O)_n$ to $K^+(H_2O)_{n-1}$ in vacuum, on van't Hoff plots. — $K_{n-1,n} = K_{n,tr}$ = (assumed) true equilibrium constants; -·-·- observed equilibrium constants $K_{n,obs}$ as predicted by eq. [7]. Calculations are for $p(H_2O) = 1$ Torr. The effect of the unimolecular decomposition is to introduce some curvature and steepen the plots. This leads to somewhat larger enthalpies: $-\Delta H_{n-1,n}$.

measurement of metastable ions resulting from dissociations $K^+(H_2O)_n \rightarrow K^+(H_2O)_{n-1}$ in the field-free region before the magnetic field. These experiments are somewhat difficult for two reasons. The abundance of unimolecular decomposition metastables is quite low. For example, an ion like $K^+(H_2O)_4$ of mass 112 enters the metastable region after 8 μs and leaves it after 12 μs. An inspection of the unimolecular decay curves in Fig. 2 shows that most of the decomposition occurs much earlier, and that very little decomposition occurs in the metastable region. On the other hand there is some collision-induced decomposition, with residual gas in the vacuum system, which also produces metastables. Results from experimental measurements of the metastables are shown in Fig. 5. The ratio R_n is defined in the equation below.

$$R_n = \frac{\text{Detected metastables from transition } n \rightarrow n-1}{\text{Ions detected as } n}$$

R_n(RRKM) is the ratio predicted by the calculations, while R_n(exp) is the experimentally observed ratio. Fair agreement is observed in Fig. 5 for the calculated and observed R_5 and R_4. Experiments in which known gas pressures were admitted into the ion flight tube permitted the study of collision induced dissociation. Extrapolation of these data to low tube pressures showed that the R_3(Exp) observed at low temperatures is due to collision induced metastables. The unimolecular decomposition metastables, from the $n = 3$ ion, at that

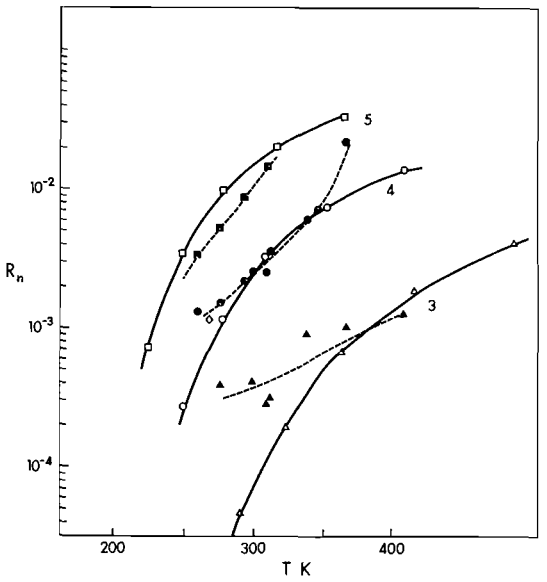

FIG. 5. R_n is ratio of metastables due to decomposition $K^+(H_2O)_n \rightarrow K^+(H_2O)_{n-1}$, over ions detected as $K^+(H_2O)_n$. □, ○, △ experimentally measured R_n; ■, ●, ▲ R_n predicted by calculation, for equilibrium measurement at 1 Torr H_2O ion source pressure. Mass analysis region at 3×10^{-7} Torr. Abscissa gives ion source temperature.

temperature are of such low intensity that they are overshadowed by the collision induced metastables. On the other hand, the R_4(Exp) and R_5(Exp) correspond almost completely to unimolecular metastables.

(c) *Unimolecular decomposition of $H^+(H_2O)_2$ and $(C_6H_6)_2^+$*

Calculations also were performed for the equilibria [9] and [10].

[9] $H_3O^+ + H_2O = H_3O^+ \cdot H_2O$

[10] $C_6H_6^+ + C_6H_6 = (C_6H_6)_2^+$

For these systems use was made of the parameters for internal motion given by Brauman and coworkers (13). The calculated fraction of complexes excited over the threshold energy f_{ex} is given in Table 2. The experimental measurements for the equilibrium constant K_9 were made (14) with K_9 ranging from 100 to 10. Examination of Table 2 shows that even for $K_9 = 1$ Torr^{-1}, f_{ex} is only 1.1×10^{-3}. This means that no error due to unimolecular decomposition in vacuum was present in the K_9 measurements.

Measurements of the equilibrium [10] were made by Field *et al.* (15) in the temperature range 330 to 475 K at 0.5 Torr constant benzene pressure. The upper experimental temperature falls in the region where appreciable dissociation of the dimers is

predicted (Table 2), however most of the van't Hoff plots fall in a region where f_{ex} is small. The experimental $\Delta H^0{}_{10}$ and $\Delta S^0{}_{10}$ probably are affected only little by unimolecular decomposition.

(d) *How to Determine if Unimolecular Decomposition Occurs*

Calculations to determine the extent of unimolecular decomposition such as those described above may be very time consuming. The experimental test consisting of measurements of metastables can be unreliable, because of the collision induced metastables. It is clearly desirable to have some simple rules or experimental tests with which to determine whether danger from unimolecular decomposition does or does not exist. Such a test is presented below. The Lindeman treatment of the reaction [1] leads to eqs. [11]–[13].

$$[11] \quad k_f = \frac{k_c k_s[M]}{k_d + k_s[M]} \qquad k_r = \frac{k_a k_d[M]}{k_d + k_s[M]}$$

$$[12] \quad \frac{[AB^+*]}{[AB^+]} = \frac{k_a}{k_s}$$

$$[13] \quad K_{eq} = \frac{k_c k_s}{k_d k_a}$$

Under conditions where the forward reaction is third order

$$k_d \gg k_s[M],$$

such that

$$[14] \quad k_f = \frac{k_c k_s[M]}{k_d} = k_{to}[M]$$

where $k_{to} = k_c k_s / k_d$ is the third order rate constant for the forward direction. Substituting [13] and [14] into [12] one obtains [15].

$$[15] \quad f_{ex} = \frac{[AB^+*]}{[AB]} = \frac{k_{to}}{k_s K_{eq}} \approx \frac{3 \times 10^{25} k_{to}\,(\text{molecule}^{-2}\,\text{cm}^6\,\text{s}^{-1})}{K_{eq}\,(\text{Torr}^{-1})}$$

The numerical factor on the right side of [15] was obtained by assuming: $k_s = 10^{-9}$ cm^3 molecule^{-1} s^{-1}, which is the Langevin rate constant for orbiting collisions, and introducing the proper convervsion factors. f_{ex} calculated from [15] for reaction [9] are given in Table 2. The k_{to} and K_{eq} required for [15] are experimental values taken from our earlier publication (14). The agreement between f_{ex} (eq. [15]) and f_{ex} obtained from vibrational frequencies and statistical mechanics equations is extremely close. The close agreement is obviously fortuitous, however the result supports both [15] and the frequencies used by Brauman and co-workers (13) which enter the calculation of f_{ex}.

Equation [15] can be used when one wishes to examine whether unimolecular decomposition is occurring. Having measured K_{eq} at a given T_{eq} one substitutes K_{eq} and k_{to} (T_{eq}) into [15]. If $f_{ex} < 0.05$ the experiment should not be significantly affected by sampling error due to unimolecular decomposition. The k_{to} will have to be determined in separate kinetic measurements at temperatures below T_{eq}. Plots of log k_{to} versus log T are common practice in ion molecule kinetic measurements and almost always lead to straight lines. Such plots should be used to obtain an extrapolated k_{to} at T_{eq}.

An even simpler condition not requiring the knowledge of k_{to} can be obtained. Combining [12] and [13] one obtains [16].

$$[16] \quad f_{ex} = \frac{[AB^+*]}{[AB]} = \frac{k_c}{k_d K_{eq}}$$

substituting the third order condition $k_s[M] < k_d$ one obtains [17].

$$[17] \quad f_{ex} < \frac{k_c}{k_s[M]K_{eq}} \approx \frac{1}{[M]K_{eq}}$$

The approximate expression on the right is obtained with the assumption $k_c \approx k_s$ (both probably Langevin rate constants). Equation [17] shows that if f_{ex} is to be small, say 10^{-2}, then for a pressure of M in the 1 to 10 Torr range, measured K_{eq} should be in the 100 to 10 (Torr^{-1}) range. It should be noted that [17] is valid also for reactions in which the forward rate is second order but the unequal sign must be reversed. Evidently an even larger K_{eq} should be selected in this case if f_{ex} is to be kept small.

The problem arising from unimolecular decomposition could be solved by instrumental changes. One method eliminating ion sampling errors is the ion T-jump technique discussed in section II. However, this technique will eliminate the problems only if all ions detected as n originate from ions n in the ion source. Another approach is to use controlled adiabatic expansion in the ion exit leak to cool the clusters down before their passage through vacuum. Experiments along these lines are tried presently in our laboratory.

(e) Conclusions

Unimolecular decomposition of ion clusters n or adducts AB^+ can occur in the vacuum region of the mass analysis system. The effect of the decomposition is to increase somewhat $-\Delta H^0_{n-1,n}$ and $-\Delta S^0_{n-1,n}$. The problem occurs for $n > 4$ and is aggravated by ligand molecules which have a large number of internal degrees of freedom.

The problem can be avoided by proper choice of experimental conditions. One must measure equilibrium constants $K_{n-1,n}$ at the lowest experimentally accessible temperature, i.e. the values of the equilibrium constants should be in the range $K = 10^3$ to 10 Torr^{-1}. Such values can be measured with present apparatus by using pressures of the clustering gas in the 1–100 mTorr range and a third gas in the Torr range.

II. An Ion T-jump Technique

The high pressure ion sources used in our laboratory have a repeller which is placed some 5 mm above the ion exit slit. In normal operation this repeller is kept at the same potential as the ion source. The ion T-jump technique consists of applying a radiofrequency (RF) field pulse to the repeller. The normal operating pressure of the ion source is 0.5–4 Torr. At these pressures, the ions accelerated by the RF field suffer collisions with the (nonreacting) major gas. These collisions increase the internal energy of the ions. If the ions are participating in an ion–molecule equilibrium a shift of the equilibrium towards a higher "temperature"

occurs. An experiment illustrating the effect is shown in Fig. 6. The reaction system is the equilibrium between Cl^- and Cl^-(DMSO) as shown in [18].

$$[18] \quad Cl^- + DMSO \underset{r}{\overset{f}{\rightleftharpoons}} Cl^-(DMSO)$$

The results in Fig. 6 were obtained with a mixture having the following ion source pressures: isobutane 0.7 Torr, DMSO 0.8 mTorr, CCl_4 ~ a few mTorr. The chloride ion is produced from dissociative electron capture by CCl_4. The Cl^- then reacts with DMSO according to [18]. The normalized ion intensities shown in Fig. 6 are observed after an electron pulse of some 20 μs duration. The system rapidly approaches equilibrium with Cl^- decreasing and Cl^-(DMSO) increasing in intensity. In the absence of an RF field pulse the system would have followed the dashed lines (see Fig. 6). The application of the RF (700 kHz) 40 V peak-to-peak pulse of duration ~500 μs displaces the system from equilibrium. The reaction reaches a new steady state towards the end of the RF pulse. The reactants relax back to equilibrium after the RF pulse is terminated.

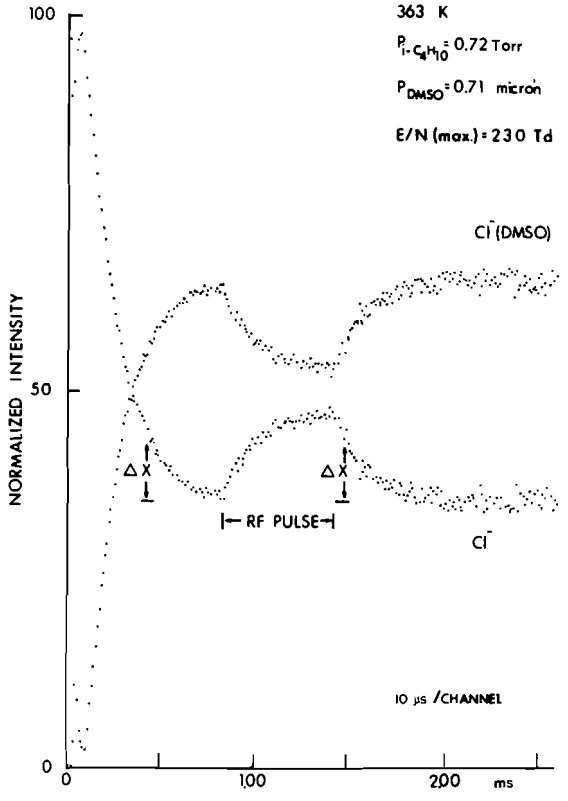

FIG. 6. Time resolved ion intensities obtained with 0.7 Torr *i*-butane, 0.7 mTorr DMSO, and traces of CCl_4. Ion source temperature 363 K. Electron pulse duration 20 μs. The reaction: Cl^- + DMSO = Cl^-(DMSO) rapidly reaches equilibrium. Application of an RF burst displaces the equilibrium to higher temperature. After the RF is terminated, relaxation to the equilibrium occurs.

The "temperature" with the RF field on can be estimated as follows. In separate experiments which are to be published elsewhere (16) the equilibrium constant for [18] was determined by measuring the equilibrium concentration of the ions. Measurements of K_{eq} at different temperatures provided a van't Hoff plot of the equilibrium [18]. The maximum displacement from the equilibrium during the RF pulse in Fig. 6 may be considered as a new position of equilibrium at a higher "temperature". Evaluating an equilibrium constant from the ion concentrations with the RF on, and reading off the temperature from the van't Hoff plot corresponding to the new equilibrium constant gives a "temperature" in the presence of the RF field which is about 10° higher, than the ion source temperature (363 K) in the absence of the field.

The clustering of DMSO to Cl^-, reaction [18], is pseudo first order in the forward and reverse direction. To make the treatment more general we replace [18] with reaction [19]. Calling a displacement from equilibrium, ΔX as defined in [20], it is easy to show that the variation of ΔX with time is given by [21]. The relaxation time τ is equal to the

$$[19] \quad A^{\pm} + B \underset{v_r}{\overset{v_f}{\rightleftharpoons}} C^{\pm}$$

$$[20] \quad \Delta X = [A^{\pm}]_t - [A^{\pm}]_{eq} = [C^{\pm}]_{eq} - [C^{\pm}]_t$$

$$[21] \quad \Delta X = \Delta X_0 e^{-t/\tau}$$

$$\tau = \frac{1}{v_f + v_r}$$

inverse of the sum of the pseudo first order rate constants (reaction frequencies) v_f and v_r. According to [21], a plot of ln (ΔX) versus t should give a straight line with slope $-1/\tau$. Two such plots of the data in Fig. 6 are shown in Fig. 7. The first plot is for the system going to equilibrium at the normal ion source temperature before the RF pulse was applied i.e. during the time interval 0.5 to 0.8 ms after the ionizing electron pulse (see Figs. 6 and 7). The other plot is for the system relaxing to equilibrium after the RF pulse was turned off. The plot starts some 0.1 ms after the RF was turned off, at a time when, presumably, the ions have already become thermalized to the ion source temperature so that the plotted ion concentration changes are due to the kinetic approach to the equilibrium at the ion source temperature. The two slopes lead to relaxation times τ = 0.159 msec and τ = 0.158 ms which are virtually identical. Since τ gives the sum of the

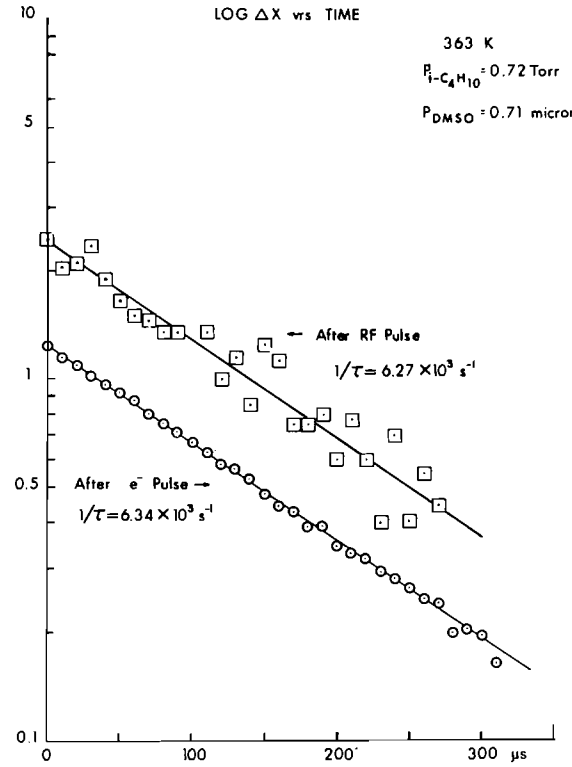

FIG. 7. Plot of ln ΔX versus time t. Slope leads to $-1/\tau = \nu_f + \nu_r$; □ relaxation to equilibrium after RF pulse; ○ approach to equilibrium after electron pulse (see Fig. 6).

forward and reverse reaction frequency, additional experiments must be done in order to obtain separate values for ν_f and ν_r. For reaction [19], ν_f is proportional to the concentration of B. Therefore the reciprocal of τ can be expressed by eq. [22],

$$[22] \quad 1/\tau = \nu_f + \nu_r = k_f[B] + k_r$$

where f_f is a second order and $k_r = \nu_r$ a first order rate constant. In a series of experiments with different pressures of the clustering gas (DMSO in the present case), τ can be obtained in function of the concentration of the clustering gas. A plot of $1/\tau$ versus the concentration of B leads, see [22], to a straight line whose slope equals k_f and intercept equals k_r. The equilibrium constant for the clustering reaction can then be obtained from $K = k_f/k_r$. We are presently engaged in determining k_f, k_r, and K for several systems whose equilibria were determined previously [1] by the conventional way, i.e. by measuring the equilibrium constant eq. [23].

$$[23] \quad K_{eq} = \frac{[C^+]_{eq}}{[A^+]_{eq}[B]}$$

The purpose of these experiments is to discover whether any systematic deviations of the equilibrium constants obtained via the kinetic eq. [22] and eq. [23] exists. It will be noted that the equilibrium constant obtained via the kinetic plots in Fig. 7 and eq. [22] is independent of the values of the ion concentration $[A^\pm]$, $[C^\pm]$, or the ratio $[A^\pm]/[C^\pm]$. Thus these kinetic results are free of problems which can arise from selective losses of ions to the walls of the ion source and selective transmission losses occurring in the passage of the ions out of the ion source and in the mass analysis and detection system. Therefore the measurement of the equilibrium constants with the kinetic and relaxation technique of Fig. 6 and eq. [22] represents an important check of the reliability and accuracy of the previous equilibrium determinations.

As pointed out earlier, the plots of ΔX versus time (see Fig. 4) can be obtained from the ordinary kinetic approach to the equilibrium *and* the relaxation after the RF pulse. In fact the scatter in the points after the RF pulse is considerably larger than that after the e^- pulse. What is then the advantage of using an RF pulse? The point is best explained

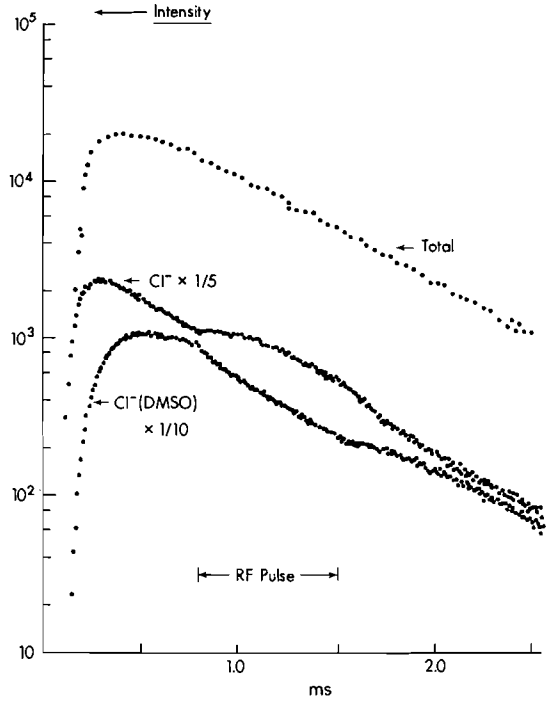

FIG. 8. Total ionization in experiment undertaken at conditions similar to that in Fig. 6. Onset of negative ions is delayed by ~200 μs due to trapping of the positive space charge produced by ambipolar electron – positive ion diffusion. First ~300 μs correspond to rapid positive negative ion changes which may affect measurement of ion molecule reaction kinetics. RF relaxation kinetics can be executed when above phenomena are over.

with reference to Fig. 8 which shows the total ion currents observed in a run for conditions very similar to those used in Fig. 6. The stage of conventional kinetics generally occurs in the range 0 to 0.6 ms. At short reaction times the negative ions are trapped inside the ion source due to the net positive potential in the positive ion–electron ambipolar diffusion stage. The change over from ambipolar electron to ambipolar ion–ion and free ion diffusion is signalled by a rapid drop off of positive ions and a large rapid increase of negative ions. The stage occurs after some 100 μs in Fig. 8. Even after this period up to about 300–400 μs there is a fairly rapid change of total ion concentration. Therefore the kinetic results obtained from plotting the normalized ion intensities are somewhat suspect over the first 200 μs and probably also slightly affected even for somewhat longer reaction times. The application of the RF pulse and the measurement of the relaxation time to the equilibrium can be done some 500 μs after the electron pulse, i.e. at a time where the ion concentration is low and space charge effects and higher than first order ion diffusion modes are minimal. Agreement of the RF relaxation kinetics with the kinetics at short reaction times provides support for the kinetic treatments used in earlier work.

We have recently put in operation a much faster multiscaler (1 μs/channel rather than the 10 μs per channel utilized in Fig. 6). With this more rapid device relaxation times of 100 or even 10 μs are accessible. This allows measurement of faster kinetics and shorter relaxation times, i.e. fast kinetics. Such fast kinetic measurements are not possible without the T-jump technique, because of the rapid changes of positive–negative ion intensities immediately after the electron pulse.

Received November 26, 1980

This paper was presented, in part, at a Special Symposium "The Structure and Thermochemistry of Gaseous Ions", held in honour of Dr. F. P. Lossing of the National Research Council of Canada, during the Second Canadian Conference on the Gas Phase Chemistry of Ions, Trent University, June 5–8, 1980, and is dedicated to him on the occasion of his 65th birthday

JOHN B. WESTMORE, MARK L. J. REIMER, and CHARLES REICHERT. Can. J. Chem. **59**, 1797 (1981).

For several β-diketonate complexes of metals of the first transition series the electron impact ionization efficiency curves obtained using unfiltered electron beams were fitted to empirical post-threshold ionization laws. In the energy region extending to 2–3 V above threshold, fits of high quality were obtained for a second power ionization law (i.e. ion current was proportional to the square of the electron energy in excess of the threshold energy) for complexes of Al(III), Sc(III), Mn(III), Fe(III), and Co(III) (d^0, d^0, d^4, d^5, and d^6, respectively). In the cases of Ti(III), V(III), and Cr(III) complexes (d^1, d^2, and d^3, respectively) the experimental points lay above the "best fit" curves in the immediate post-threshold region. Electron energies were initially calibrated by fitting experimental data points for xenon to its published ionization functions. In later experiments, $Al(tfa)_3$ or $Al(hfa)_3$ was used for calibration purposes. When the electron impact results were compared with published photoelectron spectra of the complexes (where available) it became apparent that, in the threshold region, the strongest ionization processes involved electron removal from ligand dominated π orbitals. In the cases of Ti(III), V(III), and Cr(III) complexes, weaker ionization processes involving electron removal from orbitals of predominantly metal 3*d* character (correlating with t_{2g} in octahedral symmetry) could also be detected at lower electron energies.

JOHN B. WESTMORE, MARK L. J. REIMER et CHARLES REICHERT. Can. J. Chem. **59**, 1797 (1981).

Dans le cas de plusieurs complexes de β-dicétonates des métaux de la première série de métaux de transition, les courbes d'efficacité de l'ionisation par impact électronique obtenues en utilisant un faisceau d'électrons non filtré sont ajustées à des lois empiriques relatives aux ionisations post seuils. Dans la région d'énergie s'étendant jusqu'à 2 à 3 V au-dessus du seuil, on a réalisé des ajustements de haute qualité pour une loi d'ionisation du deuxième ordre (i.e. le courant lionique est proportionnel au carré de l'énergie de l'électron en excès par rapport à l'énergie de seuil pour les complexes de Al(III), Sc(III), Mn(III), Fe(III) et Co(III) (d^0, d^0, d^4, d^5 et d^6 respectivement). Dans le cas des complexes du Ti(III), du V(III) et du Cr(III) (d^1, d^2 et etd^3 respectivement), les points expérimentaux de la loi restent au-dessus des courbes qui assurent une meilleure corrélation dans la région immédiate du post seuil. On a initialement calibré les énergies de l'électron en insérant les données expérimentales du xénon dans ses fonctions d'ionisation déjà connues. Dans des expériences subséquentes, on a tenté d'utiliser les complexes $Al(tfa)_3$ ou $Al(hfa)_3$ pour l'étalonnage. Quand on compare les résultats de l'impact électronique avec les spectres photoélectriques connus des complexes (quand ils sont disponibles), il devient apparent que dans la région du seuil, le processus d'ionisation le plus important fait intervenir l'enlèvement de l'électron des orbitales π dominées par le ligand. Dans les cas des complexes de Ti(III) de V(III) et de Cr(III), des processus d'ionisation plus faibles impliquant l'enlèvement d'un électron des orbitales à caractère 3d métallique prédominant (en accord avec t_{2g} dans une symétrie octaédrique) peuvent aussi être décelés à des plus faibles énergies des électrons.

[Traduit par le journal]

Introduction

Studies of the ionization of many metal β-ketoenolate complexes by electron and photon impact have been summarized in an earlier review (1) which contains the leading references. In the case of electron impact ionization the threshold energies reported by several authors, including ourselves, were determined from ionization efficiency curves by such techniques as semi-logarithmic plot (2), vanishing current (3), critical slope (4), extrapolated voltage difference (5), and energy compensation (6). All involve certain assumptions about threshold ionization behavior in an absolute and/or relative way as compared to reference species (such as xenon) used to calibrate the electron energy and have been criticized on theoretical and practical grounds (7). Successful application of deconvolution methods, i.e. derivative (8–12), "energy distribution difference" (EDD) (13), and double EDD methods (14), to obtain the maximum information from the ionization efficiency curves requires data with a very high signal-to-noise ratio (S/N). Methods of noise removal to improve the S/N have been described (13, 15) which result in some inevitable loss of energy resolution. There is no doubt that the highest quality information would be obtained using energy selected electron beams, or, less ideally, by rapid, repetitive scans of the ion

yield vs. electron energy through interfacing the mass spectrometer to a data acquisition system. Nevertheless, we demonstrate here, using data of insufficiently high S/N for successful application of the deconvolution methods, that reliable threshold energies can be determined by a least squares curve fitting procedure using only a programmable pocket calculator as the most sophisticated computing instrument. The method was successful even when the threshold ionization laws for the molecule of interest and the calibrating species (in this case xenon) were very different. The general approach could therefore be considered by the many workers lacking the specialized instrumentation referred to above.

The method was applied to the electron impact ionization data for the title compounds, for which the origin of the electron removed at the ionization threshold has been the subject of debate (1). For some of these compounds the results can be compared with published photoelectron spectra.

Results and Discussion

Theory

When an unfiltered electron beam is used the observed ion current will be given by a convolution of the electron energy distribution with the post-threshold ionization law. In the general case, we may assume the ionization probability to depend upon the nth power of the energy (E) of the electron in excess of the threshold value (IE); that is

$$p(E) \propto (E - \mathrm{IE})^n$$

For electron impact ionization of a neutral molecule in its ground state to a single electronic state of the molecular ion the value of n is theoretically expected to equal unity, and experimental evidence to support this has been cited (16). However, in the development of the critical slope method Honig (4) assumed $n = 2$. This may well be a better assumption for polyatomic molecules containing several atoms and many rotational–vibrational energy levels. As will be shown, the ionization of the title compounds gives excellent agreement with the assumption that $n = 2$.

The thermal energy distribution of the electron beam was assumed to be Maxwellian, that is:

$$\mathrm{d}N_U = \frac{4\pi mA}{h^3} U \exp\left(-\frac{(\phi + U)}{kT}\right) \mathrm{d}U$$

where $\mathrm{d}N_U$ is the number of electrons with energies between U and $U + \mathrm{d}U$ leaving the filament per second; m is the electron mass; h and k are the Planck and Boltzmann constants, respectively; and A, ϕ, and T are the area, work function, and absolute temperature, respectively, of the filament. At an electron accelerating voltage V the total electron energy is $E = U + V$. When convoluted with empirical post threshold ionization laws standard mathematical methods lead to the following expressions for the ion current as a function of V:

First power post threshold ionization law, i.e. $p(E) \propto (E - \mathrm{IE})$

$$[1a] \quad I_V = B(2kT - V + \mathrm{IE}) \times \exp\left(\frac{V - \mathrm{IE}}{kT}\right) \qquad \text{for } V \leq \mathrm{IE}$$

$$[1b] \quad I_V = B(2kT + V - \mathrm{IE}) \qquad \text{for } V \geq \mathrm{IE}$$

Second power post threshold ionization law, i.e. $p(E) \propto (E - \mathrm{IE})^2$

$$[2a] \quad I_V = 2kTC(3kT - V + \mathrm{IE}) \times \exp\left(\frac{V - \mathrm{IE}}{kT}\right) \qquad \text{for } V \leq \mathrm{IE}$$

$$[2b] \quad I_V = C[6(kT)^2 + 4kT(V - \mathrm{IE}) + (V - \mathrm{IE})^2] \qquad \text{for } V \geq \mathrm{IE}$$

B and C are scaling constants. Although presented in a different way, convenient for the present studies, these equations are really the same as those given by other authors (17, 18). Non-integral values of n were not investigated because in the present work satisfactory results were obtained using $n = 1$ or 2. We will return to this point later.

Rationale

We had observed when studying ionization efficiency curves of β-diketonate complexes of several metals that an extended linear portion occurred when the square root of the ion current was plotted versus the electron energy, thus implying that $p(E) \propto (E - \mathrm{IE})^2$. Consequently, if a simple relationship such as this extended downward to the ionization threshold then the curved "foot" of the ionization efficiency curve would be defined by convolution of this function with the high energy portion of the electron energy distribution. The contribution of any weak ionization processes at lower energies, should they be present, can then be detected by positive deviations of the experimental points from the "defined" foot of the curve.

A second reason for trying to establish the nature of the ionization probability functions was to compare the results for closely related complexes of non-transition and transition metals to attempt to evaluate the contribution of d electrons in the ionization threshold region.

Curve Fitting and Electron Energy Calibration

The expressions $[1a, 1b]$ and $[2a, 2b]$ for the ion currents contain three variable parameters, namely, IE, kT, and B or C. Attempts were made to fit the expressions to experimental data points obtained for the metal complexes. The least squares method (see Experimental section) was used to fit the expressions in two alternative ways, viz.

(*a*) $\sqrt{[1a, 1b]}$ or $\sqrt{[2a, 2b]}$ to $\sqrt{I_V/I_{50}}$

(*b*) $[1a, 1b]$ or $[2a, 2b]$ to I_V/I_{50}

where I_V and I_{50} are the ion currents at V and 50 volts respectively. These methods weight the upper data points more heavily than the lower ones, method (*b*) more so than method (*a*). In fact, this is desirable because the upper points are used to define the contribution to the lower part of the ionization efficiency curve which results from ionization caused by the high energy tail of the electron energy distribution. Consequently, weak ionization processes occurring at lower thresholds should be more readily observable. Although there was no theoretical basis for different methods of weighting the data points it was found that when good fits between test expressions and data points were obtained that methods (*a*) and (*b*) led to virtually identical values of IE, kT, and B or C.

For none of the metal complexes could expressions $[1a, 1b]$ be fitted satisfactorily to the experimental data points. However, for several complexes expressions $[2a, 2b]$ gave excellent fits, as illustrated in Fig. 1 for Al(III) complexes (where attempted fits to $[1a, 1b]$ are also shown for comparison). We have judged this visual presentation of the results to be a more effective way of presenting the quality of the fit than a statistical method. The electron energy scale has been calibrated with reference to xenon also present in the ion source as will now be described.

Attempts to fit expressions $[1a, 1b]$ or $[2a, 2b]$ to experimental data points for xenon were unsuccessful. This was not surprising in view of the known complexity of the ionization efficiency curve for xenon in the threshold region. Several authors have identified additional ionization processes (including, in some cases, autoionization) lying slightly above the lowest ionization threshold. These results are summarized in Table 1. For each ionization process a function of the type $p(E) \propto (E - \mathrm{IE}_n)$ was valid, where IE_n was the threshold value for the particular process. The ionization efficiency curve for xenon in the threshold region was thus a summation of the individual processes. Consequently, in the present work, the parameters from

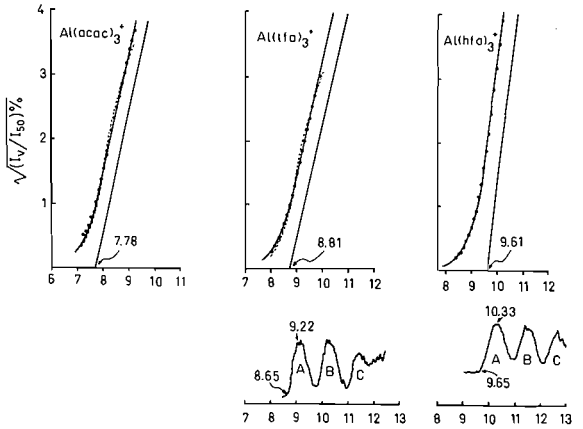

FIG. 1. Threshold ionization efficiency curves and photoelectron spectra of Al(III) complexes. Solid lines, $n = 2$ fit; broken lines, $n = 1$ fit. The straight line representing the ionization probability function is drawn from the ionization energy intercept with a slope arbitrarily made parallel to the nearly straight portion of the "best fit" $n = 2$ curve.

Table 1 were used to generate test functions for fitting to our experimental data points. Composite expressions $[1a', 1b']$ given by $I_V = I_{V,0} + I_{V,1} + \ldots + I_{V,n}$ (where each term has its own threshold IE ($= \mathrm{IE}_0 + \Delta\mathrm{IE}_n$) with relative weighting according to Table 1) were fitted to experimental data points for xenon. The fits to one set of experimental data are shown in Fig. 2. With the exception of the parameters of Melton and Hamill fits of high quality were obtained (in spite of the apparent diversity of the parameters used) and the values of the lowest ionization threshold, IE_0, were nearly the same (11.04 ± 0.02 eV). Because of this, and because they gave the best fit (though the other fits were nearly as good), the parameters of Foner and Nall were used to generate the composite function $[1a', 1b']$ for fitting to experimental data points for xenon. When this had been done, the difference between the fitted ionization energy and the spec-

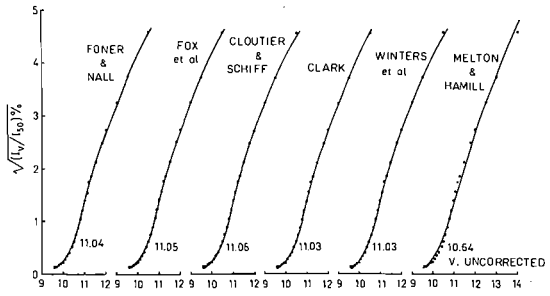

FIG. 2. "Best fit" threshold ionization efficiency curves to the same set of experimental data points for xenon, using parameters from the work of several authors. The values shown are for the resulting lowest ionization threshold.

troscopic value (12.13 eV) was used to correct the energy values for the particular complex studied concurrently.

Although xenon was used as a standard to calibrate the electron energy its use was not without problems. In particular, there was always the possibility that a fragment ion from the metal complex would have the same m/z value as Xe^+. Fortunately, xenon has a variety of isotopes which can be selected to minimize this problem. In some of the later experiments Al(III) complexes were used to calibrate the electron energy.

The least squares method was applied to both the sample ion and reference ion using three variable parameters, i.e. IE, kT, and B or C. At a filament temperature of 2500 K the value of kT is 0.215 eV. Although the values of kT for which the sum of the squares of the deviations were minimized were generally within ±0.02 eV of this result the values were usually not exactly the same for sample and reference ion. This was not a serious difficulty because the resulting values for the IE were relatively insensitive to kT, and varied with kT by almost exactly equal amounts for sample and reference ion. Consequently, the value of IE for the sample was calculated using the same value of kT for both sample and reference ion.

Ionization Efficiency Curves for the Metal Complexes

The results of fitting expression [2*a*, 2*b*] to experimental data points obtained for electron impact ionization of complexes of Sc(III), Ti(III), V(III), Cr(III), Mn(III), Fe(III), and Co(III) are shown in Figs. 3–9. Like Al(III), fits of high quality were given by the complexes of Sc, Mn, Fe, and Co, while for the complexes of Ti, V, and Cr the experimental points lie above the "best fit" curve in the low energy regions. Also shown in Figs. 1 and 3–9 are available photoelectron spectra for the complexes. These spectra were redrawn and positioned to the same energy scale as the ionization efficiency curves from photographic enlargements of the published PE spectra (24).

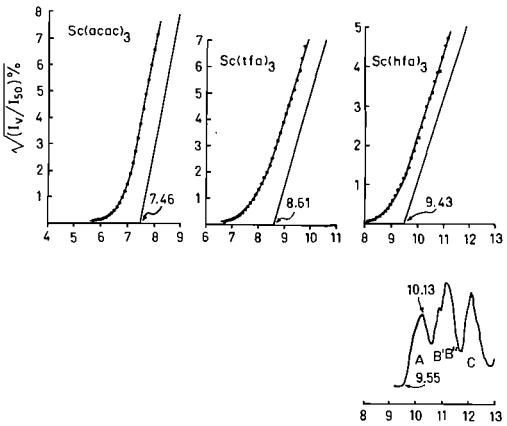

FIG. 3. Threshold ionization efficiency curves and photoelectron spectra of Sc(III) complexes. For explanation see Fig. 1.

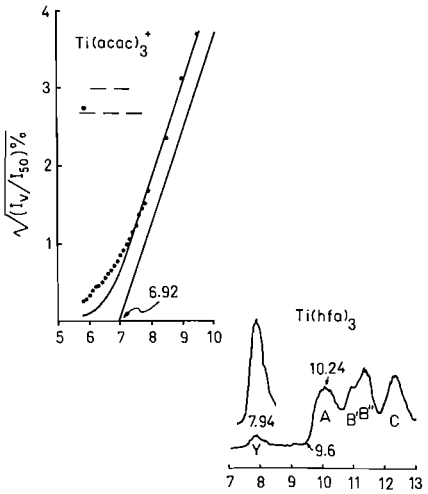

FIG. 4. Threshold ionization efficiency curves and photoelectron spectra of Ti(III) complexes. For explanation see Fig. 1.

In their interpretation of the PE spectra the authors assigned bands A, B, and C to ionization by electron removal from ligand dominated π orbitals, and band Y to ionization by electron removal from metal 3*d* dominated orbitals ($a_1 + e_a$ in the D_3 point group, correlating with t_{2g} in octahedral symmetry).

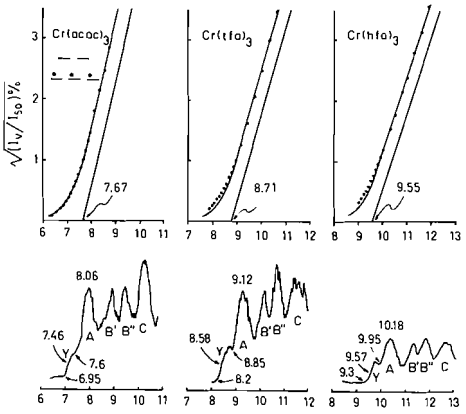

FIG. 6. Threshold ionization efficiency curves and photoelectron spectra of Cr(III) complexes. For explanation see Fig. 1.

Assignments of bands K, L, and M, observed in some spectra, were more tentative. They arise when the ligand π and metal $3d$ orbitals are close in energy and substantial interaction between the orbitals occurs. The preferred assignment of the leading band K was to ionization by electron removal from an orbital of mainly ligand π type. The authors tabulated values of band maxima (vertical ionization energies). These values are shown for the leading band(s) in Table 2, together with values of band onsets ($\geq$ adiabatic ionization energies) that we have estimated from their published spectra.

It was noted earlier in this paper that electron impact ionization of a neutral molecule in its ground state to a single electronic state of the molecular ion should yield an ionization probability of the form $p(E) \propto (E - \mathrm{IE})$. The fitted portions of

the $\sqrt{I}$ versus electron energy plots for the chelates of Al(III), Sc(III), Mn(III), Fe(III), and Co(III) extend upward from the ionization threshold by at least 3 eV in some cases, indicating that $p(E) \propto (E - \text{IE})^2$. This result implies a linear progression of excited states for the ion. Such a condition may be approximately true while ascending the steeply rising portion of the leading edge of the rotation–vibration envelope of an electronically excited state. In the PE spectra this region extends typically over not more than 0.5 eV. However, electron impact ionization is not subject to the selection rule restrictions of photon impact with the result that many more rotation–vibration levels of the excited ion should be accessible over a more extended energy range.

It is apparent from the foregoing that the optimum value of n to be used in the ionization probability function $p(E) \propto (E - \text{IE})^n$ will depend upon the structure of the rotation–vibration envelopes of the electronically excited states involved. Fine structural details cannot, of course, be detected by the methods we have used and the optimum value of n will be a "smoothed" value. One approach to finding this optimum value would be to treat n as a variable parameter in the curve fitting procedures (with a concomitant great increase in complexity). This approach was not attempted in this work because the results for the metal complexes using $n = 2$ were very satisfactory and would not have been significantly better for other values of n.

The values of the ionization energies obtained in this work are consistently lower than the previously reported values, usually by 0.2–0.6 eV (Table 2). (They are also lower than the IE values extracted from the poor $n = 1$ fits by similar amounts.) The "semi-log" plot method was recommended only for situations in which the sample and reference ions had log I plots closely parallel in the 1% region of the I_{50} value (2), a condition not achieved for the metal chelates when xenon was the calibrating species. A further complication in the case of the metal chelates arises from the much more extensive fragmentation of the molecular ions of some complexes than of others (i.e. there are

wide variations in relative I_{50} values). The "extrapolated voltage difference" method attempts to overcome these complications but even here there may be difficulties in making a reliable extrapolation.

We believe that the curve fitting procedure (which is not subject to the restrictions above) yields more reliable ionization energies than reported previously for the metal chelates, a viewpoint supported by comparisons with available PE spectra. These comparisons show that the electron impact ionization energy of a complex normally lies between the band maximum and band onset of the leading band, i.e. between the vertical and adiabatic ionization energies.

The chelates of Sc(III) (electron impact data reported for the first time) and Al(III) illustrate the variation in ionization energy with CF_3 for CH_3 substitution for complexes having no *d* electrons. The variations, which have been summarized in more detail elsewhere (1), are similar whether or not low lying *d* orbitals are available.

The PE spectra of $Ti(hfa)_3$, d^1, and $V(hfa)_3$, d^2, contain a weak band (band Y) appearing at lower energies than the stronger band A. Band Y was assigned to ionization by electron removal from orbitals of mainly 3*d* character. On the assumption that for the $Ti(acac)_3$ and $V(acac)_3$ complexes the deviations of the low energy data points from the "best fit" curves are caused by similarly assigned weak ionizations it is possible to estimate the threshold values for these processes. This was done by subtracting the extrapolated contribution of the "best fit" results from the experimental points, and fitting the resulting values to an expression of the type [2*a*, 2*b*]. The threshold values, and the ionization probability relative to the main threshold processes, are given in Table 2. The uncertainty in the thresholds for these weak processes is greater than for the main thresholds because of the smaller number of data points and the higher signal-to-noise ratio for the low ion currents involved. Even though comparison PE spectra are not available for these complexes the extracted values are reasonable when compared with observed changes in energies of metal and ligand orbitals as CH_3 is replaced by CF_3. The energies of metal dominated orbitals are shifted by slightly less than those of ligand dominated π orbitals (as illustrated very well by the PE spectra of the Cr(III) complexes) and also band Y moves closer to band A as the number of *d* electrons increases (24). The weak processes should influence the values of the ionization energies extracted from the "best fit" curves for $Ti(acac)_3$ and $V(acac)_3$. More satisfactorily, a composite function involving two threshold values should be used in an approach similar to that adopted for xenon. This was not attempted since we do not know what form the ionization probability function for these weak processes would take at values 1–3 V above their thresholds. We anticipate that the corrections to the IE values reported in Table 2 would be small.

The PE spectra of the Cr(III) complexes (d^3) show that as CF_3 replaces CH_3, the separation between the bands A and Y increases slightly. Correspondingly, the low energy electron impact ionization data points lie above the "best fit" curves in the cases of the $Cr(tfa)_3$ and $Cr(hfa)_3$ complexes. It was not possible to obtain reliable threshold values for assumed weak ionizations in these regions because they are too close to the main threshold. The signal-to-noise ratio became too difficult to handle when the weak ionization contributed only a small proportion of the total ion current. The "best fit" curve for the $Cr(acac)_3$ complex shows no detectable deviation from the experimental points, even in the low energy region, perhaps because, as shown by the PE spectra, in this case band Y is largely unresolved from band A.

The "best fit" curves for the Mn(III), Fe(III), and Co(III) chelates (d^4, d^5, and d^6 respectively) all fit the experimental data points very well. In agreement with this, the PE spectra show no weak, low energy bands that are well resolved from the main bands. The results for the Mn(III) and Fe(III) chelates show no obvious evidence, in either electron or photon impact, for ionization by electron removal from an e_b orbital (correlating with e_g^* in octahedral symmetry) of mainly metal 3*d* character. Although the barely discernible shoulder Z in the PE spectrum of $Mn(hfa)_3$ was suggested to arise in this way (24) we believe other assignments are possible and regard the energies of the e_g^* orbitals as a currently unsolved problem.

Experimental

The acetylacetonates (25), tri- and hexafluoroacetylacetonates (29) of Al(III), Ti(III), V(III), Cr(III), Mn(III), Fe(III), and Co(III) were prepared as described previously. The Sc(III) complexes were prepared by reacting slightly more than the stoichiometric quantity of the β-diketone with scandium nitrate in methanol buffered with ammonium acetate. After removal of solvent with a stream of air under partial vacuum, the wet residue was extracted with chloroform. The residue of ammonium salts was removed by filtration. Evaporation of the chloroform left a sticky residue which on treatment with hexane yielded the desired product as a dry white powder. $Co(tfa)_3$ was prepared by electrochemical oxidation at a platinum electrode of a methanolic solution containing cobalt(II) nitrate and trifluoroacetylacetone buffered with potassium acetate. It was recovered from the solution as dark green crystals.

Ionization efficiency curves were measured using a Hitachi RMU-6D single focussing mass spectrometer. Metal chelates were introduced to the ion source through the direct insertion probe and heated carefully until the vaporization rate (as determined by the mass spectral peaks) was steady. The temperature of the ion source was about 150°C. In the early work a Hewlett-Packard Model 3459A digital voltmeter was used to monitor both the amplified ion current and the chamber voltage (electron accelerating voltage) when ionization efficiency curves were being measured. The chamber voltage was stable to within ±0.001 V. Ion current readings for a particular ion were taken at 0.100 V intervals upward from the ionization threshold and also at a chamber voltage of 50 V before and after these readings. To calibrate the electron energy, ionization efficiency curves for xenon admitted to the ion source simultaneously were similarly measured. In the recent studies the DC amplifier was replaced by an ion counting system comprised of a Galileo CEM4039 Channeltron electron multiplier, SSRI model 1120 amplifier discriminator, SSRI model 1127 NIM adaptor, Ortec model 776 counter and timer, and Ortec model 777A line printer (the last three items installed in an Ortec model 401A bin). This system greatly improved both sensitivity and signal-to-noise ratios. Calibration of the electron energy was accomplished by similar measurements on a metal chelate ($Al(tfa)_3$ or $Al(hfa)_3$ in these studies) of previously determined ionization energy, admitted to the ion source simultaneously via the gas inlet system.

Initially, curve fitting was achieved using a Hewlett-Packard HP-67 programmable pocket calculator. The sum of the squares of the deviations (χ^2) was minimized for the three parameters IE, B or C, and kT by an iterative method. After it was established that the value of IE extracted by this procedure varied for the sample and reference by almost exactly the same amount (the change in the difference was within 0.02 eV in most cases) as kT was varied, then for subsequent fittings kT was put equal to 0.215 eV (T = 2500 K). This resulted in significant reductions in time taken to find the "best fit" values of IE and B or C. With experience these values could be found quite quickly (usually within 30 min) by manual control of the iterations, which required only minimal attention of the operator (i.e. entering test values of IE and B or C).

In the later stages of the work the Hewlett-Packard HP-41C programmable pocket calculator became commercially available. With its much more extensive memory and programming capabilities the iterations were controlled by the calculator. The value of χ^2 was minimized using a parabolic extrapolation method (31).

Received November 24, 1980

This paper is dedicated to Dr. F. P. Lossing of the National Research Council of Canada on the occasion of his 65th birthday

J. L. HOLMES, P. C. BURGERS, and J. K. TERLOUW. Can. J. Chem. **59**, 1805 (1981).

The keto and enol forms of ionised ethylacetate both lose H_2O to generate the keto and enol ions of methylvinylketone, probably via common reacting configurations. All hydrogen atoms and both oxygen atoms participate in this mechanistically complex reaction; the degree of their involvement depends upon the internal energy content of the fragmenting ions.

J. L. HOLMES, P. C. BURGERS et J. K. TERLOUW. Can. J. Chem. **59**, 1805 (1981).

Les formes cétoniques et énoliques de l'acétate d'éthyle ionisé perdent H_2O et conduisent aux ions de formes cétonique et énolique de la méthylvinylcétone, probablement par l'intermédiaire de configurations réactionnelles communes. Tous les atomes d'hydrogène et les deux atomes d'oxygène prennent part à cette réaction dont le mécanisme est complexe; le taux de leur participation dépend de l'énergie interne des ions qui subissent la fragmentation.

[Traduit par le journal]

Introduction

The unimolecular reaction of lowest energy requirement for ionised ethylacetate is the elimination of H_2O. This reaction is the predominant process observed in the μs time-frame; loss of $CH_3^{\bullet}$ and $C_2H_3^{\bullet}$ compete unfavorably with H_2O elimination and only produce weak metastable peaks. The elimination of H_2O was last studied by Yeo (1) in 1970. He concluded that the metastable molecular ions (species having little internal energy in excess of the fragmentation threshold) underwent appreciable positional mixing of all H-atoms (but not to the statistical limit), whereas for ion-source reactions only H atoms within the C_2H_5 group extensively lost their positional identity. The chosen daughter ion structure was the four-membered ring-closed form of ionised methylvinylketone, $[CH_3C(O)CH—CH_2]^{+\bullet}$.

It has been shown previously that ionised α–β unsaturated methyl and ethyl esters (2) such as $CH_2=CH—C(O)O—CH_3$, also fragment by the loss of H_2O, a reaction of minor importance in the ion source but prominent in the field-free regions. From analyses of metastable peak shapes it was concluded that although this reaction could result from an interchange of the alkyl group with a β-vinylic hydrogen atom (ester → acid rearrangement), it actually involved a facile 1,4-hydrogen migration followed by cyclization to yield the enol form of ionized γ-butyrolactone. For α–β unsaturated benzylesters (3) the reaction appeared to have structure diagnostic value in the normal mass spectra.

In contrast to the above, the saturated isomers ethylacetate and the $[C_4H_8O_2]^{+\bullet}$ acids do not have loss of H_2O as a common fragmentation pathway and so their interchange does not take place.

The present paper reports our investigation of the H_2O loss from ethylacetate, using metastable ion (MI) characteristics (MI spectra and peak shapes), collisional activation (CA) spectra, appearance energy (AE) measurements, thermochemical data and measurements performed with labelled compounds. This paper also forms part of our continuing study of the thermochemistry and reactions of isomeric keto and enol ions (4–6). Thus it will be shown here that the enol ion of ethylacetate, which is thermodynamically much more stable than its keto counterpart, also loses H_2O abundantly in the μs time frame, probably via the same reacting configuration as for the keto tautomer.

Results and Discussion

In order to establish the structure of the $[C_4H_6O]^{+\bullet}$ daughter ions produced from each tautomer, the following experiments were performed.

(1) The appearance energies (AE) of the daughter ions were measured using energy selected electrons and the results were compared with established thermochemical data. The AE for *m/z* 70 from $CH_3COOCH_2CH_3$ was found to be 10.32 ±

0.05 eV, leading to $\Delta H_f[C_4H_6O]^{+\cdot}$ = 190 kcal mol^{-1} ($\Delta H_f[CH_3COOCH_2CH_3]$ = −106.3 kcal mol^{-1} (4); $\Delta H_f[H_2O]$ = −57.8 kcal mol^{-1} (7)). AE *m/z* 70 from $CH_3CH_2CH_2CH_2COOCH_2CH_3$ (4) = 11.00 ± 0.05 eV, leading to $\Delta H_f[C_4H_6O]^{+\cdot}$ = 185 kcal mol^{-1} ($\Delta H_f[CH_3(CH_2)_3COOCH_2CH_3]$ = −121.3 kcal mol^{-1} (4); $\Delta H_f[CH_2{=}CHCH_3]$ = +4.9 kcal mol^{-1} (7)). Now $\Delta H_f[CH_3COCH{=}CH_2]^{+\cdot}$ = 195 kcal mol^{-1} (8). Of the $[C_4H_6O]^{+\cdot}$ ions studied in this work, five have energies which (with $\Delta H_f[H_2O]$) lie close to or below the threshold for the ethylacetate fragmentation. These are $[CH_2{=}C(OH)CH{=}CH_2]^{+\cdot}$, ΔH_f = 182 kcal mol^{-1} (8); $[CH_2{=}CHCH{=}CH(OH)]^{+\cdot}$, ΔH_f = 176 kcal mol^{-1} (8); $[(CH_3)_2CCO]^{+\cdot}$, ΔH_f = 163 kcal mol^{-1} (from IE = 8.38 eV (9), $\Delta H_f[(CH_3)_2CCO]$ = −30.7 kcal mol^{-1} (10)); $[\overbrace{CH_2CH{=}CHCH_2O}]^{+\cdot}$, ΔH_f = 194 kcal mol^{-1} (IE = 9.14 eV, energy selected electrons, $\Delta H_f[\overbrace{CH_2CH{=}CHCH_2O}]$ = 17 kcal mol^{-1} (10)). Of the above, ionised dimethylketene is unlikely to be generated on mechanistic grounds and as will be described below, the dihydrofuran molecular ions have characteristic collisional activation mass spectra which permits their being ruled out. It can be concluded therefore that *at threshold* the $[C_4H_6O]^{+\cdot}$ daughter ions from both tautomers are not ionised methylvinylketone. These results are also presented in the energy diagram, Fig. 1; it should be noted that ionised ethyl acetate is "hot" with respect to the above enol product ions at its ionisation threshold whereas an appreciable activation energy exists for their generation from the ionised enol ester.

Note (Fig. 1) that the second least energy demanding fragmentation of ethyl acetate, loss of $C_2H_3^{\cdot}$, producing $[\overset{+}{C}H_3C(OH)_2]$, also takes place in the μs time frame (AE *m/z* 61 = 10.62 ± 0.05 eV, $\Delta H_f[C_2H_3^{\cdot}]$ = 64 kcal mol^{-1} (average value from ref. 11) $\Delta H_f[\overset{+}{C}H_3C(OH)_2]$ = 74 kcal mol^{-1}). The metastable peak, however, is only ca. 0.02 as intense as that for the H_2O loss process.

(*2*) The MI and CA characteristics of the daughter ions were compared with those of selected $[C_4H_6O]^{+\cdot}$ ions of known structure.

The $[C_4H_6O]^{+\cdot}$ daughter ions from ethyl acetate and its tautomer produced only very weak MI spectra, too weak to be of value in ion structure identification. The CA results are presented in Table 1 where it can be seen that the major portion of the $[C_4H_6O]^{+\cdot}$ ions derived from either *metastable* ester ions or those fragmenting in the ion source consist of $[CH_3COCH{=}CH_2]^{+\cdot}$, but the enhanced intensity of *m/z* 69 in the CA spectra (and that obtained from the $[M - H_2O]^{+\cdot}$ ion from the enol

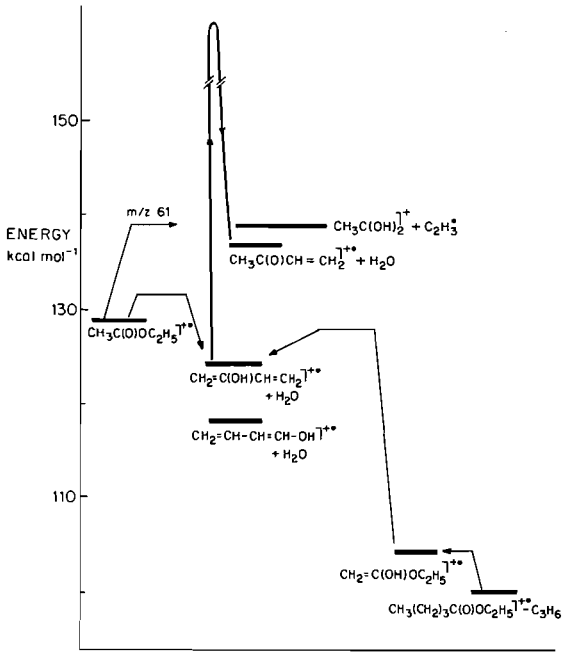

FIG. 1. Energy diagram for the primary fragmentations of the keto and enol forms of ionised ethyl acetate. The broken line indicates that there is a large barrier (at least 53 kcal mol^{-1} (8)) for the isomerisation of methylvinylketone to its enol.

ion of ethylacetate), compared with that from $[CH_3COCH{=}CH_2]^{+\cdot}$, may arise from contributions from other ion structures. Note that a very small amount of $[CH_2{=}CHCH{=}CHOH]^{+\cdot}$ ions in admixture with $[CH_3COCH{=}CH_2]^{+\cdot}$ would only be observable by an enhanced abundance at *m/z* 69 in CA spectra. The possible formation of ionised dihydrofuran, although energetically and mechanistically feasible, can be ruled out by virtue of its CA spectrum (Table 1). The possible presence of the ether ion $[CH_2{=}CH{-}O{-}CH{=}CH_2]^{+\cdot}$ must also be considered on energetic and mechanistic grounds; $\Delta H_f[CH_2{=}CH{-}O{-}CH{=}CH_2]^{+\cdot}$ = 197 kcal mol^{-1} (IE = 8.68 ± 0.05 eV, $\Delta H_f[CH_2{=}CH{-}O{-}CH{=}CH_2]$ = −3.1 kcal mol^{-1} (10)), but it too need not be considered further in view of its significantly different CA spectrum, see Table 1.

Labelling Experiments

The metastable peaks for loss of H_2O from the tautomeric molecular ions $[CH_3COOCH_2CH_3]^{+\cdot}$, *a*, and $[CH_2{=}C(OH)OCH_2CH_3]^{+\cdot}$, *b*, (produced by C_3H_6 loss from ionised ethyl pentanoate (4)) are of simple Gaussian shape (n = 1.8 and 1.9 (12)) respectively and have very closely similar profiles indicating that the same reacting configuration may well be involved. However, the kinetic energy releases evaluated from the peak widths at half-height, $T_{0.5}$, depended upon the timescale of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

observations; in increasing times, MS902 (first field-free region) $T_{0.5}(a)$ = 13.5 meV, (second ffr) $T_{0.5}(a)$ = 10.6 meV and ZAB-2f (second ffr) $T_{0.5}(a)$ = 9.2 meV. This systematic change of kinetic energy release can arise from either the relationship between energy partitioning and the internal energy content for a single reacting configuration or from the presence of more than one reacting configuration (12). The MI spectra of ^{18}O labelled ionised ethyl acetate and its enol were also investigated and the results are shown in Table 2. For ion source decompositions and all metastable ion observation times the keto and enol O atoms are similarly preferentially lost and it appears that this process has a lower energy requirement than the H_2O loss which involves the ester O atom because (*i*) the $T_{0.5}$ value (keto, enol) is lower than that for the ester O atom and (*ii*) the former process becomes increasingly more important at longer ion lifetimes. Thus both oxygen atoms participate in H_2O loss and the similarity of the results for both tautomers again indicates that common reacting configurations are involved. (It must be noted that keto and ester O atoms do not readily exchange in the *neutral* ester (13).)

The results of observations on deuterium labelled compounds are presented in Table 3.

For the keto ions, ion source fragmentations largely involve the H atoms in the ethyl group but at the longest times the observations indicate that all H atoms participate in water loss, tending towards their complete loss of positional identity. These observations agree with those previously reported by Yeo (1). The metastable peaks for the various labelled water losses had a common shape.

In the case of the labelled enol ions, the methylene hydrogen atoms barely participate in ion-source reactions and a trend towards positional randomisation at long ion lifetimes similar to but not identical with that for the keto ions was observed.

We have also compared the CA mass spectra of the $[M - D_2O]^{+\cdot}$ and $[M - HDO]^{+\cdot}$ daughter ions produced from $[CH_2{=}C(OH)OC_2D_5]^{+\cdot}$. The feature that should be emphasized is that *both* CA spectra showed mostly loss of $CH_2D^{\cdot}$ from the daughter ions. These results are shown in Table 4 where it can also be seen that the $[M - D_2O]^{+\cdot}$ ion clearly contains some enol-characteristic fragments in its CA spectrum by virtue of the enhanced peak for $H^{\cdot}$ loss.

It may therefore be concluded that prior to loss of both HDO and D_2O from the enol ion in the ion source, deuterium is transferred irreversibly to the CH_2 group. Although observations from the deu-

terium labelling experiments can most simply be interpreted as resulting from enol → keto tautomerisation preceding the loss of water from the enol ion, we cannot unequivocally distinguish this from among other potential reaction paths. Note that the CA mass spectra of the keto and enol ester ions are not the same, Table 5. The observations however do not imply that keto ions cannot partially tautomerize, i.e., there is no evidence that the CA spectrum of the keto ions is that of a *single* ionic species; the very small energy difference between ionisation and fragmentation precludes any experiment designed to show energy dependence in the CA mass spectrum. For the enol ion, the CA mass spectrum was found to be unaffected by reduction of the ionising electron energy to a level compatible with maintaining the signal strength. For the longer-lived ions which fragment in the field-free regions, the results tend towards complete loss of positional identity of H/D atoms at the longest observation times. For such ions the tautomerisation possibly is reversible; this too is in keeping with the observation (Table 3) that label randomisation is more complete for keto ions in any given field-free region than for the enol species (compare the first and third columns in Table 3). This latter effect cannot readily be attributed to internal energy differences because the metastable peak shapes for water loss from ions initially having keto or enol configurations are so very closely similar.

It is tempting to try to write mechanistic pathways for this water elimination reaction; however, the experiments give no clear indication as to what the reacting configuration(s) might be. Note for example that although the loss of keto oxygen becomes nearly specific among ions of lowest internal energy, these are the very ions in which loss of positional identity of H atoms becomes maximal — and vice-versa for the ions fragmenting in the ion source.

Two other experimental observations deserve brief mention. Whereas the isomeric ionised mole-

cule, $CH_3COCH(OH)CH_3$, does not lose H_2O, or generate *m/z* 61 (the second most intense peak in the mass spectrum of ethyl acetate); the related keto-alcohol $[CH_3COCH_2CH_2OH]^{+\cdot}$ eliminates H_2O producing an intense metastable peak, ($T_{0.5}$ = 6.9 meV) and also generates *m/z* 61 in its mass spectrum. It is possible therefore that 4-hydroxybutan-2-one is a participating structure in the complex behaviour of the keto and enol ions of ethyl acetate.

Conclusions

The investigation described in this paper employed most of the presently available techniques for the detailed study of unimolecular ionic fragmentations. Disappointingly few firm conclusions can be drawn from this study (see abstract). The acquisition of more detailed information, which might for example permit the reaction mechanism to be elucidated, probably could be achieved if ions having known, sharply defined, internal energy contents were studied. Note for example (Fig. 1) the small energy range between the fragmentation threshold for ethylacetate and the thermochemical threshold for [methylvinylketone]$^{+\cdot}$ + H_2O. Although metastable ion phenomena relate to a small range of rate constants, ca. 10^5–10^6 s^{-1}, normal electron impact ion sources produce ions having broad, ill-defined energy contents.

Experimental

CA mass spectra and metastable peak observations were recorded on a VG-Micromass ZAB 2f mass spectrometer as described in ref. 14. For metastable peak observations the main beam width at half height was reduced to 0.1 V at an electric sector potential of 422.1 V. Metastable peak shapes were also recorded on a AEI-MS902S mass spectrometer with a main beam width of 1.8 V at 6300 V accelerating voltage. Kinetic energy release values were calculated in the usual way with correction for the main beam width (12).

Ethylacetate, methylvinylketone, and methylacetyl carbinol were purchased from Aldrich Europe and used without further purification. Divinyl ether was prepared as described in ref. 15. 4-Hydroxy-2-butanone was synthesized by the method Hays *et al.* (16).

The OC_2D_5-labelled esters were prepared by esterification of acetic acid or pentanoic acid with C_2D_5OD (Merck, Sharpe and Dohme, 99.5 atom %D). The methylene-labelled esters were prepared as follows:

To a solution of butyldiisopropylamine (0.1 mol) in dry ether (80 cm^3) was slowly added (N_2 atmosphere), 0.1 mol of acetonitrile-d_3 (Aldrich, Europe) at −40°C. After raising the temperature to −20°C, C_3H_7I (10.5 cm^3) in ether (50 cm^3) was slowly added. The mixture was agitated for 2 h and subsequently poured into ice-water (100 cm^3). The mixture was extracted five times with ether (50 cm^3), and the combined organic layers were dried over calcium chloride. Distillation yielded 3.0 g (30%) $CH_3CH_2CH_2CD_2C{\equiv}N$ (95%D). The corresponding acid was made as described in ref. 17 and the esters were prepared therefrom using C_2H_5OH or C_2D_5OD.

The ^{18}O-labelled esters were synthesized on a microscale by converting the purified acid chlorides to the ^{18}O-labelled acids with $H_2{}^{18}O$ (Prochem 90 atom%) in a small Pyrex tube at room temperature and subsequently adding C_2H_5OH.

Flame-ion probe of the reaction zone in a CH_4–O_2–Ar flame with added HCN, NH_3 and NO

JOHN M. GOODINGS, GARY B. DE BROU,[1] AND DIETHARD K. BOHME

Department of Chemistry, York University, 4700 Keele Street, Downsview, Ont., Canada M3J 1P3

Received October 22, 1980

This paper was presented at a Special Symposium "The Structure and Thermochemistry of Gaseous Ions," held in honour of Dr. F. P. Lossing of the National Research Council of Canada, during the Second Canadian Conference on the Gas Phase Chemistry of Ions, Trent University, June 5–8, 1980, and is dedicated to him on the occasion of his 65th birthday

JOHN M. GOODINGS, GARY B. DE BROU, and DIETHARD K. BOHME. Can. J. Chem. **59**, 1810 (1981).

The addition of 0.3% of the fuel-nitrogen (fuel-N) compounds HCN, NH_3, or NO to a premixed, fuel-rich, CH_4–O_2–Ar flame burning at atmospheric pressure demonstrated the rapid interconversion of nitrogenous intermediates in the reaction zone. The nitrogenous species (HCN/CN, HNCO/NCO, NH_3, NH_2, NH, NO, NO_2) were observed as ions (CN^-, H_2CN^+, NCO^-, H_2NCO^+, NH_4^+, NH_3^+, NH_2^+, NO^+, NO_2^-, and hydrate ions) formed in chemical ionization processes discussed previously (1). The ions were sampled directly into a flame-ion mass spectrometer which had sufficient spatial resolution for the measurement of ion concentration profiles through the reaction zone. The study bears on Fenimore's suggestion for the formation of "prompt NO" in fuel-rich hydrocarbon flames. These additive results were compared with previous results involving nitrogenous species present in a similar CH_4–O_2 flame doped with 10% N_2. The increased sensitivity of the additive approach confirmed many of the mass assignments and mechanisms involved in the N_2 study. Reasonably good evidence was obtained for the elusive intermediate HNCO (and possibly isomeric HCNO as well) in protonated form, and also formamide, NH_2CHO, which had not been detected previously. Similarities in profile peak positions and magnitudes observed for many ions, irrespective of the nature of the fuel-N additive, indicated that the nitrogenous species were linked by a network of fast bimolecular reactions, many of which appeared to be balanced in the reaction zone.

JOHN M. GOODINGS, GARY B. DE BROU et DIETHARD K. BOHME. Can. J. Chem. **59**, 1810 (1981).

L'addition de 0,3% de combustibles azotés (combustible-N) HCN, NH_3 ou NO à la flamme de CH_4–O_2–Ar riche en combustible, prémélangée et brûlant à pression atmosphérique démontre qu'il se produit une interconversion rapide des intermédiaires azotés dans la zone de réaction. On a observé que les espèces azotées (HCN/CN, HNCO/NCO, NH_3, NH_2, NH, NO, NO_2) sont présentes sous forme d'ions (CN^-, H_2CN^+, NCO^-, H_2NCO^+, NH_4^+, NH_3^+, HN_2^+, NO^+, NO_2^- et sous forme d'ions hydratés) formés selon un processus d'ionisation chimiques discuté antérieurement (1). Les échantillons d'ions sont injectés directement dans un spectromètre de masse à ionisation par flamme qui a une résolution spatiale suffisante pour mesurer les profils de concentrations en ions dans la zone de réaction. L'étude est reliée à la suggestion de Fenimore relative à la formation "rapide de NO" dans des flammes d'hydrocarbures riches en combustibles. On a comparé ces résultats additifs aux résultats antérieurs impliquant des espèces azotées présentes dans un flamme semblable de CH_4–O_2 dopée avec 10% de N_2. L'augmentation de la sensibilité dans l'approche additive confirme plusieurs des attributions de masse et des mécanismes impliqués dans l'étude du N_2. Les données obtenues sont suffisantes pour justifier la présence de l'intermédiaire insaisissable HNCO (et peut être aussi de son isomère HCNO) sous forme protonée ainsi que du formamide NH_2CHO, qui n'avait pas été décelé antérieurement. Des ressemblances dans les profils des positions des pics, dans les amplitudes observées pour plusieurs ions, indépendamment de la nature de l'additif combustible-N indiquent que les espèces azotées sont liées par un réseau de réactions bimoléculaires rapides dont plusieurs semblent être balancées dans la zone de réaction.

[Traduit par je journal]

Introduction

In a previous paper (1), we discussed how flame ionization can be employed as a probe for nitrogenous intermediates leading to NO_x formation in the reaction zone and burnt gas of CH_4–O_2–N_2 flames. Ion concentration profiles along the axis of a fuel-rich flame indicated the presence of nitrogenous ions (CN^-, H_2CN^+, NCO^-, NH_2^+, NH_3^+, NH_4^+, NO^+, NO_2^-) formed in chemical ionization (CI) processes of nitrogenous neutral species (CN/HCN, NCO/HNCO, NH, NH_2, NH_3, NO, NO_2). The relevant ion chemistry was discussed in detail. The nitrogenous neutral chemistry based on Fenimore's initial concept of "prompt NO" (2) in fuel-rich hydrocarbon combustion was briefly summarized, involving a sequence of nitrogenous intermediates N_2–HCN–HNCO–NH_i (i = 0–3)–NO_x; a recent and detailed review is available (3).

The experiments to be described here involve stepping into this sequence at various stages by the addition of 0.3% of fuel-nitrogen (fuel-N) in the form of HCN, NH_3, and NO to essentially the same methane–oxygen flame discussed previously (1). In similar experiments involving a variety of fuel-N additives, Morley (4) used a flame-ion mass spectrometer to sample the nitrogenous ions present in hydrocarbon flames. His published data pertain to the region downstream of the reaction zone in the

burnt gas. In our case, we emphasize nitrogenous ions present in the reaction zone of conical flames where the chemistry is initiated, taking advantage of good spatial resolution. Flame-ion sampling is one of a very few techniques available for probing the reaction zone of a flame and, while possibly causing some distortion of the ion concentrations, is unlikely to falsify the result in any qualitative sense.

The high concentrations of available nitrogen from the addition of HCN, NH_3, and NO clarify the identities of the nitrogenous species present in the reaction zone which were reported in our previous study of N_2-doped flames (1). The data also offer confirmation of the kinds of CI processes which are dominant. Perhaps most important, however, is the demonstration of the rapid interconversion of the nitrogenous neutral intermediates within the confines of the reaction zone, a distance ca. 0.3 mm corresponding to a residence time <300 μs.

Experimental

The results will be presented for five variations of essentially the same fuel-rich, premixed, CH_4–O_2-diluent flame burning at atmospheric pressure. The CH_4 and O_2 flow rates were always maintained at 8.00 and 7.90 mL s^{-1}, respectively, amounting to an equivalence ratio $\phi = 2.03$. Flame 1 had a diluent flow rate of Ar of 2.15 mL s^{-1}. Flame 2 had a diluent flow rate of N_2 of 1.69 mL s^{-1}, amounting to a molar dilution of the unburnt gas of roughly 10%. The Ar flow rate for flame 1 was chosen so that flames 1 and 2 had the same adiabatic flame temperature of 2510 ± 20 K. These are the two flames which have been described and studied previously (1). Flames 3, 4, and 5 are the same as flame 1 with the addition of 0.3 mol% of HCN, NH_3, and NO, respectively. Such a small amount of an additive is not expected to have any appreciable effect on the physical flame characteristics (5). The constancy of the measured sampling temperature was checked for flame 4 (NH_3 additive) and flame 1 using a pneumatic probe consisting of two critical-flow (i.e., choked-flow) orifices in series described previously (1, 6). The compressed gases used were all of CP grade ($CH_4 > 99.6\%$, $O_2 > 99.6\%$, $N_2 > 99.9\%$, Ar > 99.9%). The HCN was added as a 2.7 ± 0.1% mixture of HCN in Ar. The NH_3 (anhydrous, >99.99%) and NO (CP grade, >99.0%) were added directly from lecture bottles into the premixed gas stream.

All flames were laminar with conical luminous reaction zones (height ~5 mm, base diameter ~3 mm, thickness ~0.3 mm) to facilitate ionic sampling along the flame axis into a mass spectrometer. The burnt gas velocity was approximately 1 m s^{-1}. The flames were stabilized on a simple, tubular, quartz burner (2.3 mm id) surrounded by a flowing argon shield to minimize the entrainment of atmospheric air. The burner was mounted on a motor-driven carriage with accurate axial alignment and calibrated drive providing spatial resolution of ±0.02 mm along the flame axis (designated z) for both positive and negative ion profiles.

The flame-ion mass spectrometer has been described previously in detail (7) and in summary form (1). For these additive studies, the flame burned against a 60°, conical, chromium, sampling nozzle of orifice diameter ca. 0.1 mm mounted in a water-cooled flange. The sampled ions pass through two stages of differential pumping into a quadrupole mass filter. The mass-analyzed ions are detected with a parallel-plate Faraday cage connected to a vibrating reed electrometer having a grid-leak resistance of 10^{11} ohms. The ion signal magnitudes in Figs. 2, 3, and 5 are quoted in mV based on the detected ion current passing through 10^{11} ohms. Profiles can be drawn for ion species having a peak concentration as low as 5×10^5 ions mL^{-1}, corresponding to a signal magnitude of about 0.5 mV. A method has been described (1, 7) for locating a reproducible origin ($z \equiv 0$) in the *flame* (not referred to the burner) corresponding to the downstream edge of the luminous reaction zone on the flame axis. In this way, a family of ion profiles at different mass numbers (m/e), can be accurately overlaid on the distance scale z.

Results and Discussion

Total Ion Profiles

In order to appreciate the behaviour of individual ion signals, it is first necessary to recognize the effects of the additives on the total ionization characteristics of the flames. Total ion profiles, both positive and negative, are shown in Fig. 1 for each of the five flames. The total positive profiles are shown normalized to unity at the profile maxima. This constancy of peak signal corresponding to approximately 10^{10} ion mL^{-1} was observed to be true within an experimental error of ±10%. It reflects the basic chemi-ionization process responsible for the formation of flame ions in the reaction zone (8, 9)

[1] $CH + O \rightarrow HCO^+ + e^-$

whose rate will be approximately constant for all five flames at the same temperature. An appreciable upstream shoulder is apparent for flame 4 (NH_3 additive), and a smaller one for flame 5 (NO), but is absent in flames 3 (HCN) and 2 (N_2). These shoulders are indicative of an additional chemi-ionization source term. One such process deduced by other workers (10) to be responsible for the ions observed in an NH_3–O_2–N_2 flame

[2*a*] $N(2^2D) + O(^3P) \rightarrow NO^+ + e^-$

might be applicable here, particularly if the order of availability for excited N atoms in the chemical decomposition of the nitrogen additives is $NH_3 > NO > HCN, N_2$. A second reaction which has been considered as a source of ions in CO–O_2–N_2 (11) or H_2 – air diffusion (12) flames, both with added cyanogen, C_2N_2

[2*b*] $CN + O + O \rightarrow NO^+ + e^- + CO$

is less likely to be significant in the fuel-rich flames employed in this study; in any case, it is of little help in explaining the absence of a shoulder with the HCN additive (flame 3).

In contrast, a considerable enhancement of the

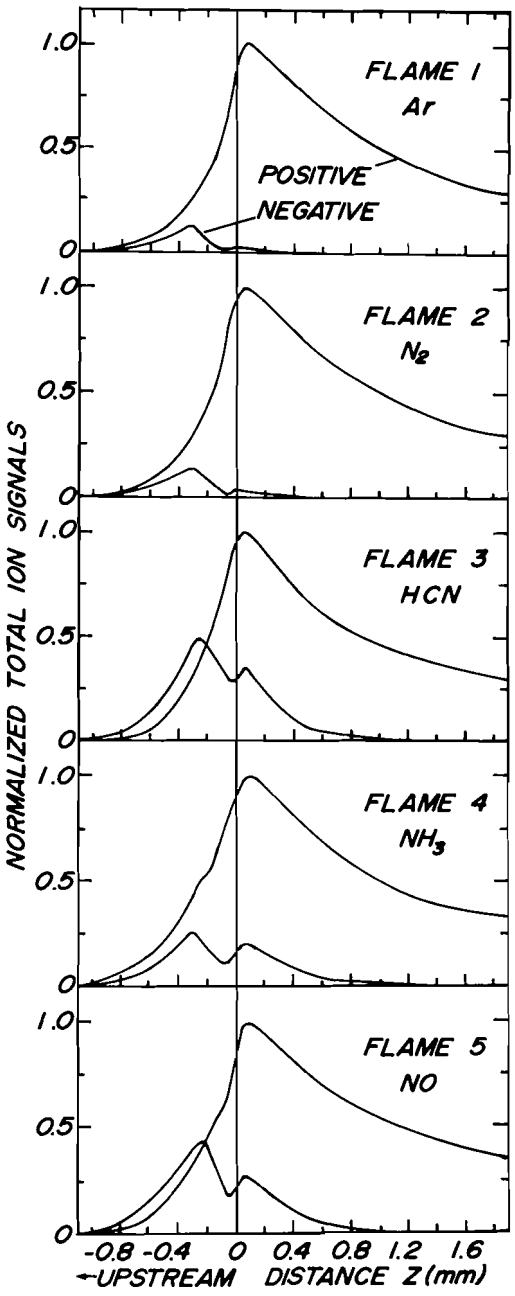

FIG. 1. Positive and negative total ionization profiles for flames 1–5 with added Ar, N_2, HCN, NH_3, and NO, respectively. The curves are normalized to unity at the peaks of the positive ion profiles.

peak negative ion signal in the reaction zone is apparent for each of the fuel-N additives (HCN > NO > NH_3) compared with the signals observed for flames 1 (Ar) and 2 (N_2). In flames 1 and 2, the primary negative ion formation process is three-body electron attachment to oxygen (13)

[3] $e^- + O_2 + M \rightleftharpoons O_2^- + M \qquad \Delta G^0_{1800} = 16.8$

(Standard free energies and enthalpies of reaction are quoted in kJ mol^{-1} based on data from JANAF Tables (14). The subscript temperature of 1800 K is typical in these flames for a region near the middle of the reaction zone.) Secondary negative ions are formed rapidly in the reaction zone; e.g., by charge transfer from O_2^-. The negative ion spectrum for each of flames 3 and 4 is dominated by CN^- (given later in Fig. 3), arising from proton abstraction from HCN by a basic source ion

[4] $X^- + HCN \rightarrow CN^- + HX$

or possibly three-body attachment to CN radicals

[5] $e^- + CN + M \rightarrow CN^- + M \qquad \Delta H^0_{1800} = -406$

or, probably to a much smaller extent, dissociative electron attachment to HCN

[6] $e^- + HCN \rightarrow CN^- + H \qquad \Delta H^0_{1800} = 118$

which is quite endothermic. The high electron affinity of CN (EA = 3.8 eV) and moderate base strength of CN^- (proton affinity PA = 1468 kJ mol^{-1} at 1800 K) cause CN^- to be a comparatively stable species in the chemical environment of the reaction zone, resulting in the negative ion enhancement observed for flames 3 and 4. That the peak signal for flame 4 is lower is not surprising: the added NH_3 must first react to form HCN (or perhaps CN) before CN^- can be formed. The data indicate that roughly half of the NH_3 is converted to HCN at a point midway through the reaction zone.

On the other hand, the negative ion spectrum for flame 5 is dominated by approximately equal contributions from CN^- and NO_2^- (given later in Fig. 3). The large CN^- signal indicates a rapid chemical conversion of nearly half the NO additive to HCN halfway through the reaction zone. Presumably NO_2^- is formed by three-body electron attachment to NO_2, or by charge transfer to NO_2 from O_2^-. Evidently an appreciable amount of NO is oxidized to NO_2 in the reaction zone of this fuel-rich flame before the molecular oxygen is exhausted downstream. The important point demonstrated is the rapid conversion of NH_3 (flame 4) and NO (flame 5) to HCN; this is consistent with Morley's statement (4) that the chemical "route passes through HCN and this compound is formed quantitatively from fuel nitrogen irrespective of its chemical nature".

Finally, the observation that the total negative ion signal appears to exceed the positive ion signal upstream in flames 3 and 5 is, at first, surprising for a quasi-neutral flame plasma. The phenomenon was encountered previously for fuel-lean, CH_4–O_2 (13) and CH_3OH–O_2 (15) flames. An explanation was offered in terms of the back-diffusion of elec-

trons a distance of the order of a Debye length followed by three-body attachment to electronegative O_2 molecules in the cooler unburnt gas upstream where the O_2 concentration is highest. The [negative ion]/[free electron] concentration ratio is shifted in favour of negative ions if an additive results in the formation of negative ions more stable than O_2^- in the flame environment. As described above, these are CN^- in flame 3, NO_2^- and CN^- in flame 5 and, to a lesser extent, CN^- in flame 4.

Individual Ion Profiles

Nearly all profiles observed for nitrogenous ion species, both positive and negative (and many non-nitrogenous ones also), exhibit the same basic double-peaked structure illustrated in Fig. 2 at +16 amu ($\sim NH_2^+$) for flame 4 with added NH_3; the ratio of the upstream/downstream peak magnitudes can vary considerably, however. The reasons for this profile structure encountered in fuel-rich flames have been discussed previously (1, 7, 13). Although the reaction zone is only about 0.3 mm thick extending back from $z = 0$, it appears thicker in profiles such as Fig. 2 because the distance scale is spread out upstream when a conical flame is sampled along its axis; even when the mass-spectrometer sampling probe is inserted well upstream of $z = 0$, ions can still diffuse through the orifice from the inside surface of the truncated luminous cone.

We shall confine our attention here to the profile peaks occurring upstream in the reaction zone. The presentation of profiles at all relevant mass numbers (m/e) would constitute an overwhelming body of data. Instead, we shall characterize the upstream peaks in terms of two simple parameters: the peak height, and the peak position on the distance scale z. The peak heights are presented in Fig. 3 for each mass number as a "histogram" giving the peak magnitudes of the ion signals for flames 1–5 (with added Ar, N_2, HCN, NH_3, and NO, in order). Similarly, a peak position plot is given in Fig. 4 where the horizontal lines indicate an uncertainty in peak position of ± 0.02 mm; the uncertainty can be larger for small, broad peaks, however. In both Figs. 3 and 4, selected ionic species are placed into one of six groups depending upon the role played by the species.

In general, the nitrogenous ions in the reaction zone are formed by chemical ionization (CI) processes involving a source ion reacting with a nitrogenous neutral. The first group in Fig. 3, labelled positive source ions, consists of the major protonated species in the reaction zone which can

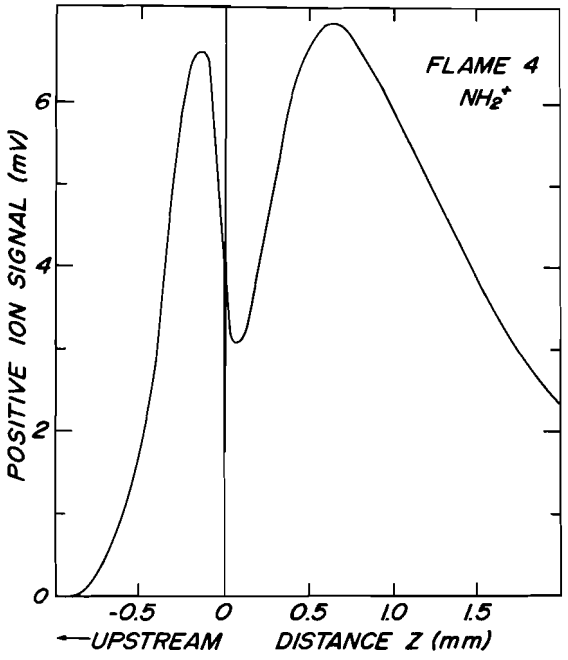

FIG. 2. Typical double-peaked profile structure observed for most individual ionic species, both positive and negative. The curve shown was recorded at +14 amu in flame 4 with the NH_3 additive. The reaction zone is located upstream of $z = 0$.

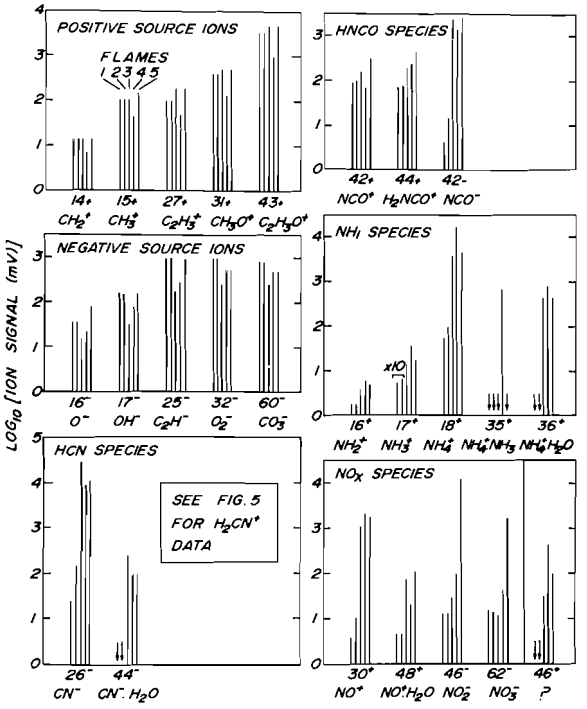

FIG. 3. Histograms for individual mass numbers m/e giving the profile magnitudes of the upstream peaks occurring in the reaction zone. Each histogram consisting of five vertical lines, from left to right, represents the peak heights measured in flames 1–5 with added Ar, N_2, HCN, NH_3, and NO, respectively.

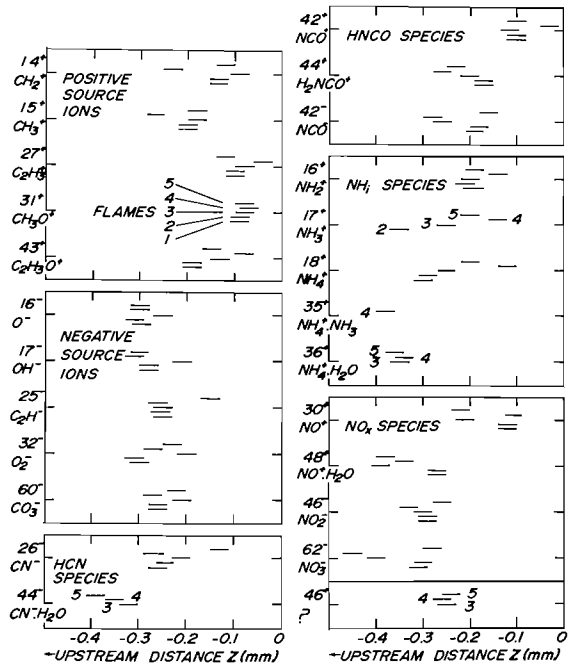

FIG. 4. Profile peak position plot for individual mass numbers *m/e* giving the peak positions on the flame axis of the upstream peaks occurring in the reaction zone. Each group of five horizontal lines, from bottom to top, represents the peak positions measured with an uncertainty of ±0.02 mm in flames 1–5 with added Ar, N_2, HCN, NH_3, and NO, respectively.

chemically ionize neutrals by proton transfer. The striking similarity of the histograms is evident. The very high proton affinity of ammonia causes all five source ions to be depleted in flame 4. The histograms of the second group, labelled negative source ions, again show a basic similarity to each other. All five source ions are depleted by proton transfer reactions with HCN to form CN^- in flames 3 and 4; flame 4 requires the prior conversion of NH_3 to HCN as mentioned above in the discussion of total ion profiles. The least regular behaviour is evident for the NO addition in flame 5. The net reaction of OH^- and C_2H^- is very small. The reaction

[7] $O_2^- + NO \rightarrow O^- + NO_2$

could account for the decrease of O_2^- and increase of O^-. The CO_3^- peak will be depleted by the known reaction (16)

[8] $CO_3^- + NO \rightarrow NO_2^- + CO_2$

With regard to the peak position plot given in Fig. 4, the actual peak position of a given ion signal is a less meaningful parameter than the peak magnitude. Downstream in the burnt gas, the peak positions provide some evidence for a chemical sequence of the nitrogenous species N_2–HCN/CN–HNCO/NCO–NH_i (i = 0–3)–NO_x (1, 4). No such sequence is evident in the spatially-limited reaction zone. In fact, the peak position of a nitrogenous ion is more revealing of its source ion than the nitrogenous neutral from which it is made. This situation can sometimes be used to advantage to clarify the dominant CI process. Figure 4 is also useful for the identification of cluster ions which tend to peak far upstream at lower temperature.

In addition to the positive and negative source ions given in Figs. 3 and 4, the remaining four groups of ions provide evidence for particular nitrogenous neutrals in the reaction zone of the flame doped with various additives. These four groups designated as HCN species, HNCO species, NH_i species, and NO_x species will be discussed in turn.

HCN Species

Evidence for HCN and /or CN radicals is obtained from ion signals corresponding to CN^- and its hydrate $CN^-.H_2O$, and also from the H_2CN^+ profiles given in Fig. 5. The CN^- ions can be formed by proton transfer from HCN; e.g.

[9] $C_2H^- + HCN \rightleftharpoons CN^- + C_2H_2$

or by charge transfer to CN radicals from negative ions such as O^-, OH^-, C_2H^-, and O_2^-. This am-

biguity concerning the identity of the dominant source, neutral stable molecule or free radical, has occurred frequently in these studies (1). In an attempt to resolve the dilemma, consider the behaviour of flame 3 with 0.3% HCN additive. The HCN molecules will be attacked to form CN radicals by reactions such as (17, 18)

[10] $HCN + H \rightleftharpoons CN + H_2 \quad \Delta G^0_{1800} = 58.6$

or its OH/H_2O counterpart. In these fuel-rich flames, however, reaction [10] will tend to dominate. Assuming a forward rate constant k_{10} of 10^{-10} cm^3 molecule^{-1} s^{-1}, reaction [10] has a relaxation time $\tau \simeq 1/k_{10}[HCN] = 0.1$ μs in the forward direction and considerably smaller in the reverse direction. The forward relaxation time corresponds to 5×10^{-5} mm on the flame axis, assuming a velocity midway in the reaction zone of 500 mm s^{-1} (downstream velocity $\simeq 1$ m s^{-1}), so that reaction [10] will be locally balanced. Using mole fractions for H of 0.009 and H_2 of 0.25 obtained by Hastie (19) in the middle of the reaction zone of a very similar CH_4–O_2 flame and an equilibrium constant $K = 0.02$ at 1800 K, the equilibrium ratio $[CN]/[HCN] = K_{1800}[H]/[H_2] = 7 \times 10^{-4}$. Even if [CN] were to overshoot its local equilibrium value considerably, CN will still be a minor species compared with HCN. Thus, the formation of CN^- by proton transfer from HCN should dominate its formation by charge transfer to CN radicals. Even for the flames 2, 4, and 5 involving nitrogenous additives other than HCN, the same considerations should apply. Therefore, the high CN^- peak magnitudes in Fig. 3 for flames 4 and 5, only slightly less than that for flame 3, illustrate the rapid conversion of NH_3 and NO to HCN.

If a reaction such as [10] is locally balanced in the reaction zone, the same should be true for the proton transfer reactions like [9] or

[11] $OH^- + HCN \rightleftharpoons CN^- + H_2O$

since their relaxation times involve ion–molecule rate constants which are even larger than k_{10}. Not surprisingly, the CN^- peak shapes follow those of the major negative source ions as indicated in Fig. 4; the corresponding peak positions of CN^- and C_2H^- are remarkably similar.

The relative magnitudes of the $CN^-.H_2O$ peaks in Fig. 3 are very nearly 1% of the corresponding CN^- peaks in flames 3, 4, and 5. The signals at −44 amu are assigned to the CN^- hydrate on the basis of the peak position plot in Fig. 4; the hydrate signals peak considerably upstream of CN^- where the lower flame temperature favours hydrate formation.

The H_2CN^+ profiles are shown separately in Fig. 5 for flames 3, 4, and 5 since they represent one of the few cases where single-peaked profiles were observed. Nevertheless, the upstream tails through the reaction zone are considerable. The large positive source ions in the reaction zone involve species with proton affinities (PA's) > PA(HCN). The formation of appreciable H_2CN^+ must await the rise of H_3O^+ since PA(HCN) > PA(H_2O) (20). Once again, a rough calculation of the relaxation times for the forward and reverse directions of

[12] $H_3O^+ + HCN \rightleftharpoons H_2CN^+ + H_2O$

indicates that reaction [12] is locally balanced. Thus, the shapes of the H_2CN^+ profiles are dominated by the corresponding H_3O^+ profiles in the reaction zone and for some distance downstream. The slight upstream shoulder apparent for the HCN additive profile in Fig. 5 is explicable in terms of the production of H_2CN^+ via an exothermic proton transfer reaction such as

[13] $C_2H_3^+ + HCN \rightleftharpoons H_2CN^+ + C_2H_2$

where PA(HCN) > PA(C_2H_2) at room temperature (20, 21).

It should also be mentioned that the profiles at +45 amu for flames 1–5 (not presented in the figures) showed the usual double-peaked structure except that flame 4 with the NH_3 additive had a third peak relatively far upstream at $z = -0.30$ mm indicative of NH_4^+.HCN cluster ions. As a final observation concerning the HCN species, no clear evidence was obtained for either CN^+ or HCN^+. This is not surprising in view of the fact that the CN radical has a high ionization energy and a low proton affinity.

In summary, these ion data show the rapid conversion of NH_3 and NO to HCN. At a given point z in the reaction zone, the signal magnitudes for each of CN^-, $CN^-.H_2O$, and H_2CN^+ invariably exhibit the order flame 3 (HCN) > flame 5 (NO) > flame 4 (NH_3) for 0.3% of these three fuel-N additives. The results suggest the existence of a direct chemical path linking HCN and NO involving CH_i radicals

[14a] $CH_i(i = 1\text{–}3) + NO \rightleftharpoons HCN + H_{i-1}O(i = 1\text{–}3)$

[14b] $\rightleftharpoons CN + H_iO(i = 1, 2)$

All five reactions [14] are exothermic in the forward direction.

HNCO Species

The large NCO^- signals observed at −42 amu in flames 3, 4, and 5 may be formed by proton transfer from HNCO or charge transfer to NCO radicals. Several authors have postulated the oxidation of HCN/CN to form HNCO/NCO (4, 22–24) although direct evidence of the latter species is lacking. Pre-

TABLE 1. Structural features of profiles at −42 amu in the reaction zone

		Upstream		Downstream	
Flame	Additive	z(mm)	Feature	z(mm)	Feature
2	N_2	−0.32	Slight shoulder	−0.18	Main peak
3	HCN	−0.26	Main peak	−0.10	Second peak, barely resolved
4	NH_3	−0.28	Single peak		
5	NO	−0.25	Slight shoulder	−0.16	Main peak

sumably the species are linked by fast balanced reactions

[15a] $HNCO + H \rightleftharpoons NCO + H_2$ $\Delta G^0_{1800} = 25.2$

[15b] $HNCO + OH \rightleftharpoons NCO + H_2O$ $\Delta G^0_{1800} = -15.8$

Using Hastie's concentration values (19) and data from JANAF Tables (14), the equilibrium ratio [NCO]/[HNCO] = 7×10^{-3} at 1800 K. Although this ratio is an order of magnitude larger than [CN]/[HCN], a similar conclusion seems justified. That is, NCO is a relatively minor species compared with HNCO, so that the formation of NCO^- by proton transfer from HNCO will dominate its formation by charge transfer to NCO radicals in the reaction zone.

Although the profiles at −42 amu have the usual double-peaked shape, the peak in the reaction zone of flames 2, 3, and 5 shows further structure in addition to the main peak position given in Fig. 4; these details are listed in Table 1. One possible interpretation involves the two isomeric forms HNCO/NCO (designated form A, having a CO bond) and HCNO/CNO (form B, with an NO bond). However, it is difficult to associate one particular isomeric form with the upstream or downstream position of the features. Perhaps the rising concentration of CO favours form A in the downstream position. In any case, the similar magnitude of the major peaks in flames 3, 4, and 5 again illustrates the rapid interconversion of the fuel-N additives in the reaction zone.

The histogram at +42 amu in Fig. 3 is similar to those designated as positive source ions with one difference; the enhanced peak height for flame 5 provides possible evidence for ionized NCO radicals. Also, the enhanced signals in flames 3–5 at +44 amu provide reasonably good evidence for protonated HNCO. The peak heights are not consistent with an assignment as $^{13}C^{12}CH_3O^+$ stemming from the large source ion signals at +43 amu representing protonated ketene. Nor is N_2O^+ a likely contender in view of the high ionization energy of $N_2O \sim 13$ eV; the preferred source reaction involving charge transfer from O^+ (1, 25) is highly unlikely in a fuel-rich flame where O^+ was not detected.

NH_i Species

The histograms in Fig. 3 at +16, 17, and 18 amu are distinctly different from those at +14 and 15 amu. Major contributions to the former arise from protonated NH_i (i = 1–3) species whereas the latter represent CH_2^+ and CH_3^+, respectively. No evidence was obtained for NH^+ at +15 amu. From Fig. 4, the peak positions of the NH_i^+ ions in flames 3–5 are similar. If the NH_i species are protonated by the same source ions, the evidence is indicative of a rapid interconversion of the NH_i species

[16] $NH_i + H(OH) \rightleftharpoons NH_{i-1} + H_2(H_2O)$

for i = 2, 3. Presumably the very high proton affinity of NH_3 leading to the very large NH_4^+ signal detected in flame 4 accounts for the depression of all of the positive source ions in flame 4 as shown in Fig. 3. In conclusion, it is again worth emphasizing the evidence presented by this data for the rapid interconversion of the fuel-N additives; in this case, the conversion of HCN and NO to NH_3, NH_2, and NH.

Of minor interest are a number of cluster ions assigned on the basis of their peak positions shown relatively far upstream in Fig. 4. These include $NH_4^+.NH_3$ at +35 amu which was observed only in flame 4 with the NH_3 additive, and $NH_4^+.H_2O$ at +36 amu for flames 3–5.

NO_x Species

From Fig. 3, the NO^+ signals at +30 amu in flames 3–5 are of comparable magnitude. At first glance it is somewhat surprising to find the largest signal in flame 4 with the NH_3 additive. The probable explanation offers some confirmation of a mechanism discussed previously (1), involving a contribution from $CH_2NH_2^+$, also at +30 amu, by condensation reactions of $NH_i^+ + CH_j$ or $CH_j^+ + NH_i$ (26). This explanation is reinforced by the peak position in Fig. 4, since the signals at +30 amu in flames 3 and 5 peak upstream of the flame 4 peak; the latter occurs in close proximity to those of the NH_i^+ ions. Presumably the major portion of the signals in flames 3 and 5 is due to NO^+ produced by exothermic charge transfer to NO by source ions such as CH_3^+ and CH_2^+. Similar *relative* peak posi-

tions at +48 amu occurring considerably further upstream are indicative of hydrate ions. However, the depressed peak height for flame 4 shown in Fig. 3 is consistent with $CH_2NH_2^+.H_2O$ being less stable than $NO^+.H_2O$.

The NO_2^- ions at −46 amu can be produced by exothermic charge transfer to NO_2 by O^-, OH^-, and O_2^-. However, NO_2 is not expected to be abundant in these fuel-rich flames. A probable major formation mechanism involving NO directly, particularly in flame 5, is

[8] $CO_3^- + NO \rightarrow NO_2^- + CO_2$

as discussed previously (1). Certainly the signals at −46 amu peak together in a group in proximity to the CO_3^- peaks, as shown in Fig. 3. The peaks at −46 amu in flames 1 and 2 are due to isotopic $^{13}CHO_2^-$ from the very large $^{12}CHO_2^-$ signals detected at −45 amu. Data at −45 amu have not been included as source ions because the profiles are remarkably constant over the range of flames 1–5. Nevertheless, they provide a useful internal "calibration standard" for comparing other negative ion profile magnitudes in the various flames.

The signals observed at −62 amu cover a wide range on the peak position plot, Fig. 4. In these fuel-rich flames, it is probable that the signal represents NO_3^- only in flame 5, formed by the known reaction (16)

[17] $CO_3^- + NO_2 \rightarrow NO_3^- + CO_2$

The peak positions for flames 3 and 4 located very far upstream are indicative of hydrates, most probably $CN^-.2H_2O$; another possibility for flame 4 is $CHO_2^-.NH_3$ since an additional shoulder is observed on the profile at $z = -0.30$ mm.

Finally, the nitrogenous ions at +46 amu in flames 3–5 shown at the lower right of Figs. 3 and 4 present a problem of assignment; all of NO_2^+, $H_2CN^+.H_2O$, $NH_4^+.CO$, and CH_4NO^+ have the right mass number (m/e). However, the signal is largest for the NH_3 additive, and the peak positions given in Fig. 4 are not indicative of cluster ions. We believe the most logical candidate to be CH_4NO^+, interpreted as protonated formamide $NH_2CHO.H^+$. The parent molecule can be formed from the reaction of NH_3 with formaldehyde.

[18] $NH_3 + HCHO \rightarrow NH_2CHO + H_2$

and considerable formaldehyde is present in the reaction zone of these flames (detected as the source ion CH_3O^+).

Conclusions

These studies in the reaction zone of a fuel-rich hydrocarbon flame with fuel-N additives provide confirmation of many of the mass assignments and mechanisms discussed previously for N_2 addition (1). The nitrogenous chemistry, both neutral and ionic, is much easier to sort out using the fuel-N additives, however. The present results also indicate the presence of formamide, a new species not previously detected. When ions are used to probe the neutral chemistry, a question frequently arises: is a given nitrogenous ion representative of a related nitrogenous neutral (e.g., NO^+ from NO), formed in a simple chemical ionization process such as proton transfer or charge transfer? Or, is the identity obscured by a more complicated ion–molecule source reaction involving rearrangement or condensation (e.g., NO_2^- from NO, not NO_2; $CH_2NH_2^+$ as well as NO^+ at +30 amu)? The present experiments answer this question in a number of important cases.

The picture emerging from these studies is that of a spatially limited reaction zone containing a wide variety of nitrogenous neutral intermediates intermingled together, temporally independent of the nitrogen source. The main value of the additive approach is realized when one adds a neutral species (HCN, NH_3, NO) and observes a nitrogenous ion signal which cannot reasonably result from a direct ion–molecule reaction of the neutral flame ions. In this circumstance, rapid interconversion of the nitrogenous neutrals can be demonstrated, the ions merely functioning as a probe of the neutral chemistry.

Received October 28, 1980

This paper is dedicated to Dr. F. P. Lossing of the National Research Council of Canada on the occasion of his 65th birthday

T. McALLISTER, A. J. C. NICHOLSON, and J. D. SCOTT. Can. J. Chem. **59**, 1819 (1981).

The mass spectra observed on sampling the unburnt gases of a flame ionization detector to which nitromethane has been added are due mostly to proton transfer reactions of NH_4^+ and H_3O^+. These are formed in the reaction zone from the primary ion HCO^+, and pass through the unburnt gases to the sampling orifice. The ions which are detected may be attributed to pyrolysis (CH_4NO^+ and NO^+) or hydrogenation products ($CH_2NH_2^+$ and $CH_3NH_2^+$) of nitromethane. The small amount of NO^+ observed in the unburnt gases is attributed either to a primary ionization mechanism which produces NO^+ from excited nitrogen atoms or molecules in the reaction zone, or to a reaction of H_3O^+ with HNO_2, a pyrolysis product of nitromethane. Observations of $CH_2NH_2^+$ in the flame and in double resonance experiments performed in an ion cyclotron resonance mass spectrometer give limits on the proton affinity of methanimine (CH_2NH) of 847.6–862.3 kJ mol^{-1}.

T. McALLISTER, A. J. C. NICHOLSON et J. D. SCOTT. Can. J. Chem. **59**, 1819 (1981).

Les spectres de masse d'échantillons de gaz qui n'ont pas brulé dans un détecteur par ionisation à flamme auxquels on a ajouté du nitrométhane sont dus principalement aux réactions de transfert de proton du NH_4^+ et du H_3O^+. Ceux-ci se forment dans la zone de réaction à partir de l'ion primaire HCO^+ et sont véhiculés, par les gaz qui n'ont pas brulé, dans l'orifice d'échantillonnage. Les ions qui sont détectés peuvent être attribués à la pyrolyse (CH_4NO^+ et NO^+) ou aux produits d'hydrogénation ($CH_2NH_2^+$ et $CH_3NH_2^+$) du nitrométhane. On attribue les faibles quantités de NO^+ observées dans les gaz qui n'ont pas brulé soit à un mécanisme d'ionisation primaire qui produit du NO^+ à partir des atomes d'azote excités ou des molécules présentes dans la zone de réaction, soit à une réaction de H_3O^+ avec HNO_2, un produit de pyrolyse du nitrométhane. Les ions $CH_2NH_2^+$ observés dans la flamme ou dans des expériences de double résonance réalisées dans un spectromètre de masse à résonance d'ion dans un cyclotron donnent des limites de l'affinité de la méthanimine (CH_2NH) pour le proton de 847,6–862,3 kJ mol^{-1}.

[Traduit par le journal]

Introduction

Studies of ions in flames have tended to concentrate on premixed flames of hydrocarbons (1–6), although some work has been done on ammonia and cyanogen flames (7, 8). The flame ionization detector (FID) operates with a wide range of organic compounds and uses a small, conical, diffusion flame, in contrast to the large, flat, premixed flames employed in most of the recent studies. Investigations of the FID type of flame (9, 10) have shown the ionization mechanism is similar to that suggested for premixed flames (3), namely the reactions:

[A] $CH + O \rightarrow HCO^+ + e$,

[B] $HCO^+ + H_2O = H_3O^+ + CO$.

In flames containing inorganic nitrogen compounds, it is possible that the ionization reaction is either (7, 8)

[C] $N(^2P) + O \rightarrow NO^+ + e$

or (11)

[D] $N_2(A\,^3\Sigma_u^+) + NO(a\,^4\Pi) \rightarrow NO^+ + N_2 + e$

but, with organic nitrogen compounds in an FID type flame, both HCO^+ and NO^+ mechanisms should be possible.

A feature of conical flames, first noted by Bascombe *et al.* (12), is that ions can be sampled in such a way as to detect the products of their reactions with the constituents of the unburnt gases (see Fig. 1): oxonium ions (H_3O^+), for example, may undergo proton transfer with the organic additive, or with its pyrolysis and (in the case of the FID) its hydrogenation products. Such effects have already been noted in the FID flames of benzene, toluene, and cyclohexane (10). This paper presents observations on the unburnt gases of an FID-type flame containing nitromethane, which are relevant to the pyrolysis (13–15) and hydrogenation of that compound, as well as to the mechanism of secondary ionization in cyanogen/hydrogen flames (8).

Experimental

Our FID-type flame burns a mixture of 1.5 mL s^{-1} of hydrogen with 0.6 mL s^{-1} of argon containing approximately 1% of the

additive. For these experiments, a moveable burner of 0.75 mm id was positioned horizontally on an axis coincident with the axis of the entrance hole (0.1 mm diameter in a titanium plate) of the mass spectrometer sampling system. This gave a flame with a conical-shaped luminous reaction zone of about 1 mm base diameter and 3–4 mm apex height. The mass spectrometer, the three-stage sampling system, and the electric potentials required for the detection of ions have been described previously (9, 10). Deuterium flames were also investigated, in order to elucidate the formulas of ions which were not clearly identified by the *m/z* values in hydrogen flames.

Proton affinities were determined by means of an ion cyclotron resonance (icr) mass spectrometer (16).

The FID sensitivity of nitromethane was determined by gas chromatography of solutions of nitromethane and hexane in di-*tert*-butyl ketone.

Results

The identification of ions found in the unburnt gases is illustrated by Fig. 2, in which typical mass spectra from the hydrogen and deuterium flames are compared. H_3O^+, NH_4^+, and their hydrates, $H_3O^+ \cdot H_2O$ and $NH_4^+ \cdot H_2O$, and protonated nitromethane ($CH_3NO_2H^+$) were clearly identified. It appears that the ion of *m/z* 30 is mostly $CH_2NH_2^+$ with a minor proportion being NO^+, but there remains an ambiguity concerning a proportion of the ions at *m/z* 30 and 32 in the hydrogen flame; a deuterium shift to *m/z* 34 may be explained by the presence of both protonated methanimine ($CH_2NH_2^+$) and nitroxide ion (NH_2O^+). The protonated imine (or its isomer, vinylamine) is also a possible structure for the ions of *m/z* 44 and 58, with formulas $C_2H_4NH_2^+$ and $C_3H_6NH_2^+$. Shifts of *m/z* 32 to 38 and 46 to 54 may be explained by the presence of protonated methylamine ($CH_3NH_3^+$) and ethylamine ($C_2H_5NH_3^+$); for *m/z* 46, also, a shift to *m/z* 50 indicates the presence of protonated nitrosomethane (CH_3NOH^+) or perhaps formamide (NH_2CHOH^+).

It has been shown (3, 5) that the hydrates observed when a flame is sampled by a mass spectrometer are usually formed in the cool boundary layer next to the orifice or the expansion region inside the orifice. The temperature dependence of the equilibrium constants obtained by Kebarle *et al.* (17) for the oxonium hydrates also suggests that only negligible amounts of hydrate will be present in flames at temperatures > 1000 K. Therefore profiles of ion intensity (expressed as a percentage of total ion current) with varying burner to orifice distance were plotted, in which the intensities of all members of a hydrate series, e.g. NH_4^+, $NH_4^+ \cdot H_2O$, etc., were summed. The profiles of NH_4^+ thus obtained peaked a few tenths of a mm downstream of the luminous reaction zone; this was made the zero of the distance scales of the profiles, to facilitate comparison between the hydrogen and deuterium flames (see Figs. 3 and 4).

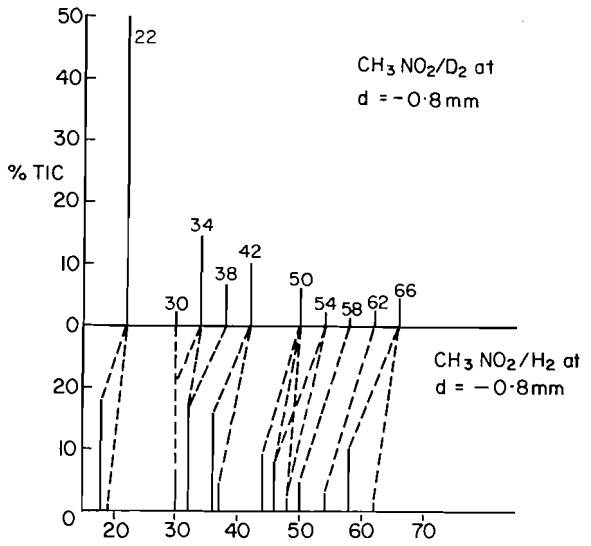

FIG. 2. Deuterium shifts in a nitromethane/FID flame.

Double resonance experiments in the icr mass spectrometer on mixtures of ethylene diamine with diethyl ether and acetone, in which the $CH_2NH_2^+$ ion was observed to undergo proton transfer to diethyl ether, but not to acetone, established that the proton affinity of methanimine (CH_2NH) lies between 847.6 and 862.3 kJ mol^{-1} on the scale given by Kebarle *et al.* (18), and modified by the recent redetermination of the proton affinity of isobutene (19) which sets proton affinity of ammonia at 873.2 kJ mol^{-1}. This is compatible with an unpublished observation of Huntress and Beauchamp (see ref. 23).

The FID sensitivity of nitromethane was found to be 0.7 of that expected from the equal-per-carbon response scale, on which the sensitivity of hexane is 6.0. The sensitivities of NH_3 and NO on this scale are about 10^{-3} (20).

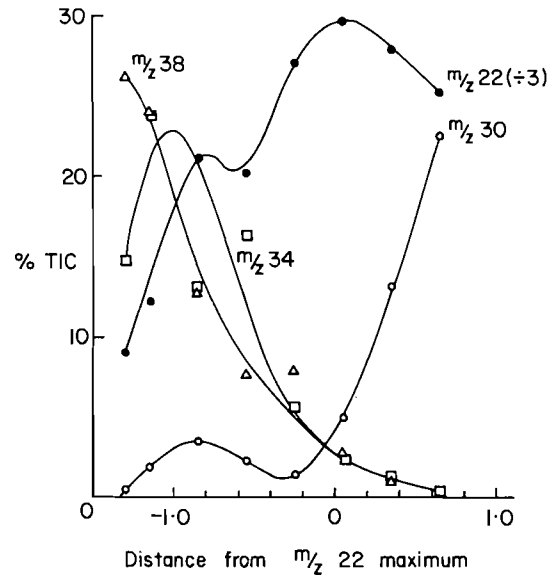

FIG. 4. Ion profiles in $D_2/Ar/CH_3NO_2$flame.

Discussion

Only tentative conclusions may be drawn on the mechanisms which produce the observed flame ions. Although proton transfer reactions appear to be important in many flames, it is possible to write more complicated alternative mechanisms. Where there are no absolute criteria for deciding between these alternatives, we prefer the simpler mechanism.

Most of the ions found in the unburnt gases may be grouped into three sets for discussion: those which originate in the reaction zone, those apparently derived from pyrolysis products of nitromethane, and those apparently derived from reduction products of nitromethane. NO^+ is an exception to this classification, as it may be considered both as a reaction zone ion and as a pyrolysis-derived ion.

(a) *Ions Originating in the Reaction Zone: NH_4^+, H_3O^+, and NO^+*

The FID sensitivity of nitromethane, combined with the preponderance of NH_4^+ and H_3O^+ over NO^+ in the unburnt gases and reaction zone, in comparison with that observed by Bertrand and Van Tiggelen in ammonia flames (7) where NO^+ is the major ion, suggests that most of the flame ionization is from reaction [A]. An ionization scheme with NO^+ as the primary ion, from reactions [C] and [D], would be expected to give a much lower sensitivity as well as a greater intensity of NO^+ in relation to NH_4^+ and H_3O^+. Apart from this, there is the difficulty of the reaction mechanism whereby NO^+ gives H_3O^+. One suggestion is that an intermediate HNO^+ is formed, which undergoes rapid proton transfer reactions so that its concentration is too low to detect (7). Another (7) is that the reactions suggested by Fehsenfeld *et al.* for the formation of oxonium hydrates from nitrosyl hydrates in the ionosphere (21) are also applicable to flames:

$$NO^+(H_2O)_n + H_2O = H_3O^+(H_2O)_{n-1} + HNO_2$$

In this case, it should be noted that the relevant reaction in flames would be of unhydrated ions, because of the flame temperature:

[E] $NO^+ + 2H_2O = H_3O^+ + HNO_2$

$\Delta H = +8.2\,kJ\,mol^{-1}$ at 2000 K (22).

NH_4^+ and H_3O^+ are formed by proton transfer from the primary ion HCO^+:

$$HCO^+ + NH_3 = NH_4^+ + CO$$

$$HCO^+ + H_2O = H_3O^+ + CO$$

The strongly reducing conditions in the unburnt gases of the FID flame are expected to produce ammonia from nitromethane. The equilibrium constants, K, for these proton transfer reactions are largely determined by the relative proton affinities of the neutral species, as the entropy of proton transfer is relatively small (23). Approximate calculations of K_p using the proton affinity table (18) indicate that the ratios of NH_4^+ and H_3O^+ to HCO^+ will be of the order of 10^3 or 10^4, where the concentrations NH_3, H_2, and CO are similar. NH_4^+ and H_3O^+ may participate in further proton transfer

reactions in the unburnt gases and, because of the higher proton affinity of NH_3 (134 kJ mol^{-1} greater than that of H_2O), it will be the reactions with NH_4^+ which will determine the relative intensities of the ions derived from the unburnt gas constituents.

(b) *Ions Derived from Nitromethane and its Pyrolysis Products: $CH_3NO_2H^+$, CH_3NOH^+, NO^+, and the Problem of NH_2O^+*

A weak signal was observed for the protonation of undecomposed nitromethane to give *m/z* 62. This is to be expected because the proton affinity of nitromethane is 84 kJ mol^{-1} less than that of ammonia (23, 24). The stronger signal observed for CH_3NOH^+ and/or NH_2CHOH^+ is an indication that the proton affinity of these products is greater than that of nitromethane (assuming that their concentrations are no greater than that of nitromethane).

NO is a pyrolysis product of nitromethane, and the possibility exists that some of the NO^+ observed in the unburnt gas is of secondary rather than primary origin. The formation of NO^+ in the *burnt* gases of flames has been noted since the earliest work on flame ionization (2), and recently it has been closely associated with H_3O^+ (25). It may be that the reverse of the reaction [E] is significant in the unburnt gases, with the HNO_2 being supplied from the nitromethane pyrolysis (13–15).

The presence of NH_2O^+ is one explanation of the deuterium shifts observed for *m/z* 30 and 32 to 34 (see Fig. 2). It could be produced by proton transfer to the pyrolysis product HNO (13–15), the proton affinity of which is calculated to be 757.3 kJ mol^{-1} (26, 27). This is, however, very similar to the proton affinity for nitromethane, for which, as we have seen, there is only a weak signal because of the unfavourable equilibrium constant for proton transfer with NH_4^+. The amount of HNO present is unlikely to be sufficiently large to overcome this disadvantage, and we conclude that NH_2O^+ will be present in only negligible intensity. This conclusion is reinforced by the absence of other ions which could be derived from pyrolysis products of comparatively low proton affinity: CH_3OH^+ from CH_3O, CH_3O^+ from CH_2O, and H_2CN^+ from HCN (28, 29).

(c) *Ions Derived from Reduction Products of Nitromethane: $CH_2NH_2^+$ and $CH_3NH_3^+$*

These ions may be produced by proton transfer to methanimine and methylamine. The reduction of nitromethane to methylamine by catalytic methods at lower temperatures is known, but there have been no high-temperature, homogeneous studies. It is possible that methylamine is the precursor of methanimine, which may be formed from it by pyrolysis (30). On the other hand, the possibility that HCN is present, although H_2CN^+ is not detected (see previous section), suggests also that a stepwise reduction of HCN by H_2 may be taking place:

$$HCN \rightarrow CH_2NH \text{ (methanimine)} \rightarrow CH_3NH_2.$$

The proton affinity of methylamine is 929 kJ mol^{-1}, 55.8 kJ mol^{-1} greater than that of ammonia, so that the proton transfer equilibrium will favour its detection. The proton affinity of methanimine is less (by 9–16 kJ mol^{-1}) than that of ammonia, but still sufficiently close to allow detectable quantities of CH_2NH_2 in the presence of NH_4^+, given similar amounts of CH_2NH and NH_3. The lower intensity of $CH_2NH_2^+$ in comparison with $CH_3NH_3^+$ is in keeping with the known order of proton affinities of the neutrals.

A stepwise reduction mechanism for the formation of ions of *m/z* 28, 30, and 32 in C_2N_2/H_2 flames has been suggested by Bredo *et al.* (8). In their case they suggest a form of association reaction of the ions, e.g.

$$H_2CN^+ + H_2 \rightarrow H_4CN^+$$

This is very unlikely. Association reactions of this kind have been postulated for interstellar clouds by Herbst (31) but would not apply to flames at 2000 K. It is much more likely that the ions which they observe are, as in our experiments, formed by protonation of neutral substances. Such a mechanism would give a dependence of ion intensity on cyanogen concentration similar to the one which they have adopted.

A further alternative to the proton transfer mechanism is provided by the reactions of CH_3^+ and CH_2^+ with NH_3, investigated by Smith and Adams (32):

$$CH_2^+ + NH_3 \rightarrow CH_2NH_2^+ + H,$$

$$CH_3^+ + NH_3 \rightarrow CH_3NH_3^+.$$

In this case the rate coefficients are suitable for our system ($\sim 10^{-9}$ cm^3 s^{-1}) but we did not detect the precursor ions. Therefore it must be assumed that the reactions go to completion, as significant amounts of CH_2^+ and CH_3^+ are required to produce the observed signals for $CH_2NH_2^+$ and $CH_3NH_3^+$. Such amounts have not been detected by us in other nonnitrogenated FID-type flames (9, 10). We therefore conclude that these reactions are less important than the protonation of methanimine and methylamine.

The very likely presence of methanimine and its

relatively high proton affinity lead us to conclude that ND_2O^+ contributes at most only a minor proportion of the peak at m/z 34 observed in the deuterium flame (see Fig. 4), and reinforces the argument of section (b) against the presence of NH_2O^+ in the hydrogen flame (see Fig. 3).

A note on mass spectrometric studies concerning a role of free radicals in catalytic reactions

ZDENEK DOLEJŠEK AND JANA NOVÁKOVÁ

J. Heyrovský Institute of Physical Chemistry and Electrochemistry, Czechoslovak Academy of Sciences, 121 38 Prague, Czechoslovakia

Received November 13, 1980

This paper is dedicated to Dr. F. P. Lossing of the National Research Council of Canada on the occasion of his 65th birthday

ZDENEK DOLEJŠEK and JANA NOVÁKOVÁ. Can. J. Chem. **59**, 1824 (1981).

Free radicals were detected by means of mass spectrometry in the low pressure interaction of reactants with solid catalysts. The same radicals were also prepared by very low pressure pyrolysis and their reactivity studied both with a catalyst (as a model study of the radicals' role on the catalyst surface) and with other gas phase components present in the system, with the aim to observe a possible shift of the reaction to the gas phase.

ZDENEK DOLEJŠEK et JANA NOVÁKOVÁ. Can. J. Chem. **59**, 1824 (1981).

Au cours de l'interaction des corps réagissants à pression basse avec des catalyseurs on a observé la présence des radicaux libres par la spectrométrie de masse. Les mêmes radicaux furent aussi préparés par la pyrolyse à pression très basse et on a étudié leur réactivité avec un catalyseur (pour modeler leur rôle sur la surface du catalyseur) ainsi qu'avec d'autres composants de la phase gazeuse pour pouvoir étudier le transport possible de la réaction en phase gazeuse.

Considerable evidence, especially of an indirect nature, suggests that a reaction may shift from a catalytic surface to the gas phase (e.g. refs. 1, 2). It is assumed that such hetero–homogeneous reactions proceed by a radical mechanism initiated on the catalyst surface. In only a few cases (3, 4) was the presence of radicals in the gas phase confirmed directly following the catalytic interaction. The question whether the observed radicals are merely reaction by-products or whether they play a more important role in further steps of the reaction remains unanswered thus far. For this reason it is important not only to detect the free radicals if present but also to check simultaneously for their reactivity with all potential reactants in the system. We have tried to use mass spectrometry for this purpose.

Experimental

A cylindrical quartz tube reactor similar to the one used by Lossing and co-workers (5) for measurements of the ionization potential of free radicals was placed close to the ionization chamber of a modified MI 1305 sector field mass spectrometer. The reactor was loosely packed with several grains of a catalyst. In this way we were able to study catalytic reactions under molecular flow conditions at pressures $1–10^{-3}$ Pa. Both the reaction products and unstable intermediates of radical character could be followed simultaneously using ionization with low energy electrons in the latter case. In the second part of the experiments, where radicals in the gas phase were prepared by pyrolysis (~1 Pa), a reactor with two separately heated sections was used. The radicals prepared in the first section passed through the second section over a catalyst and thence directly to the detection region.

With these two experimental arrangements (the single or double section reactor) the following reactions were studied: (*i*) selective oxidation of propylene to acrolein on bismuth molybdate (6, 7); (*ii*) oxidation of methanol to formaldehyde on a silver catalyst (8). In the first case a shift of the reaction to the gas phase, with participation of allyl and allylperoxyl radicals has been assumed (1, 2). In the second case the presence of RO, RO_2, and HO_2 radicals in the gas phase was proven by epr at atmospheric pressure (4).

Results and Discussion

In order to check our instrument's ability to detect free allyl radicals in a catalytic reaction we have repeated Hart and Friedli's experiments (3) involving the interaction of propylene with manganous oxide. In an extension of this work we have detected allyl radicals in the gas phase also in the ZnO/propylene interaction (9). On the other hand no allyl radicals were found with bismuth molybdate/propylene, where the appearance of free allyl radicals as a first step in the transfer of the reaction in the gas phase had been expected (9). Due to the presence of a large amount of unreacted propylene the increase of the ratio of the peaks at the mass-to-charge ratios 41/42 had to be used as an evidence for the free allyl radical formation on the heated oxide catalysts (Table 1).

In order to check for the possibility that even with bismuth molybdate/propylene allyl radicals are formed on the catalyst surface but that they quickly react with lattice oxygen, in which case they would probably appear in the gas phase as oxygen-containing species, additional experiments aimed to study the reactivity of allyl radicals were carried out. Allyl radicals were prepared by pyrolysis of 1,5-hexadiene in the first part of the two section reactor and allowed to react with a catalyst in the second section. With a catalyst kept at moderate temperature (370 K), acrolein was

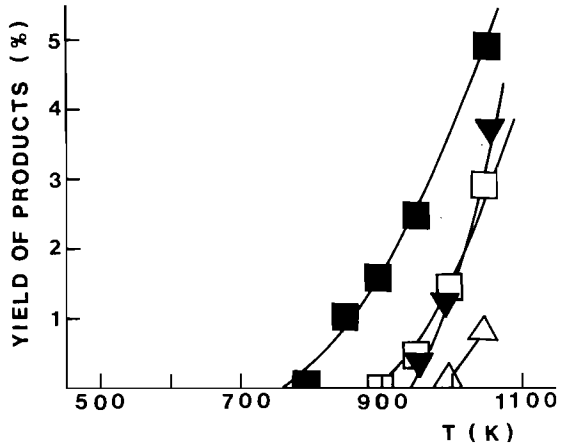

FIG. 2. Products of allyl radical interaction with MoO_3 catalyst plotted against temperature of pyrolyzer, reactor temperature ≤ 470 K: acrolein (■), propylene (□), CO (▼), CO_2 (△). (At 1000 K only one third of the allyl radicals formed passed through catalyst region without reaction.)

found as a product not only with catalysts generally used for acrolein production, but also with other oxides, e.g. MoO_3, ZnO, Co_3O_4 (6, 7). It is evident that the allyl radical, once formed, could be easily oxidized to acrolein by lattice oxygen. In an experiment with a very active oxidation catalyst, Co_3O_4, allyl radicals were easily overoxidized to CO and CO_2 by a relatively moderate warming of the catalyst to 500 K. These experiments with the two section reactor are illustrated for the case of MoO_3 in Figs. 1 and 2. Figure 1 shows the formation of allyl radicals by pyrolysis of 1,5-hexadiene in the first section of the quartz tube (pyrolyzer); Fig. 2 gives the products of the allyl radical-catalyst interaction in the second section (reactor).

Further experiments concerned the possible interaction of allyl radicals in the gas phase. At our low pressure conditions (~1 Pa) allyl radicals were not oxidized by molecular oxygen in the absence of a catalyst (see also ref. 10). When the residence time in the reactor was increased by a quartz wool plug inserted into the reactor exit, only increased recombination of allyl radicals was observed. Under comparable conditions (in the absence of a catalyst and the quartz wool plug) oxidation of benzyl radicals after admission of molecular oxygen was clearly observed. Thus, in our conditions we were unable to verify the role of allyl radicals as an active intermediate in the shift of the reaction into the gas phase. On the other hand, allyl radicals were found to react easily with lattice oxygen to yield acrolein as a product.

In the more recent experiments on the reaction of methanol vapour with a heated silver wire we observed, using low energy electrons (14 eV), a very small amount of a product contributing to the peak at mass-to-charge ratio $m/e = 15$ (8). Because of large concentration differences we were unable to obtain a reliable ionization potential of this product and to assign it unambiquously to the methyl radical. As the concentration of this species decreased with addition of oxygen while the concentration of the main product, formaldehyde, rose at the same time, it seems likely that the observed additional product at $m/e = 15$ acts as an intermediate in the mechanism of the main product formation (Table 2).

From the experiments described it follows that low pressure mass spectrometry can provide information on primary reaction products as well as, in special cases, on radical intermediates in interactions of reactants with catalysts. Comparative studies concerning the reactivity of these radicals with other components in the gas phase probably will require measurements at rather higher pressures, which we were unable to carry out with the present simple apparatus.

Gas phase photochemical decomposition of 1-bromopropane

STUART G. BAYLISS, ROBERT L. FAILES, AND JACOB S. SHAPIRO[1]

School of Chemistry, Macquarie University, North Ryde, N.S.W., Australia

Received December 30, 1980

This paper is dedicated to Dr. F. P. Lossing of the National Research Council of Canada on the occasion of his 65th birthday

STUART G. BAYLISS, ROBERT L. FAILES, and JACOB S. SHAPIRO. Can. J. Chem. **59**, 1827 (1981).

The gas phase photochemical decomposition of 1-bromopropane (1bp) was studied over the temperature range 374–483 K and the pressure range 10–95 kPa. Within these ranges the overall kinetics are expressed by:

$$\frac{-d[1bp]}{dt} = k[1bp]^{3/2}\frac{[HBr]^{1/2}}{[C_3H_6]^{1/2}}I_0^{1/2}$$

where I_0 is the incident light intensity. The principal propagation step involves the abstraction of the secondary hydrogen by a bromine atom leading to two major products: propene and hydrogen bromide. Termination involving allyl radical is postulated, a feature that sets this photolysis apart from those of ethyl and neopentyl bromides. The overall activation energy is 33.8 ± 0.8 kJ mol^{-1} and it leads to Arrhenius parameters for the propagation step [3] of $E_a = 29.7$ kJ mol^{-1} and $\log_{10}A = 9.1$ (A in dm^3 mol^{-1} s^{-1}).

[3] $Br^{\cdot} + CH_3CH_2CH_2Br \rightarrow CH_3\dot{C}HCH_2Br + HBr$

STUART G. BAYLISS, ROBERT L. FAILES et JACOB S. SHAPIRO. Can. J. Chem. **59**, 1827 (1981).

On a étudié la décomposition photochimique en phase gazeuse du bromo-1 propane (1bp) dans des intervalles de température et de pression allant de 374 à 483 K et de 10 à 95 kPa respectivement. A l'intérieur de ces limites, on peut exprimer la cinétique globale par le relation

$$\frac{-d[1bp]}{dt} = k[1bp]^{3/2}\frac{[HBr]^{1/2}}{[C_3H_6]^{1/2}}I_0^{1/2}$$

où I_0 est l'intensité de la lumière incidente. L'étape principale de la propagation fait intervenir l'enlèvement d'un hydrogène secondaire par l'atome de brome, conduisant ainsi à deux produits principaux: le propène et le bromure d'hydrogène. On envisage la présence de radicaux allyles pour expliquer l'arrêt de la réaction. C'est une caractéristique qui convient parfaitement à cette photolyse à l'exception de celle des bromures d'éthyle et de néopentyle. L'énergie d'activation globale est de 33,8 ±0,8 kJ mol^{-1} et elle conduit à des paramètres d'Arrhénius pour l'étape de propagation [3] de E_a = 29,7 kJ mol^{-1} et $\log_{10} A$ = 9,1 (A en dm^3 mol^{-1} s^{-1}).

[3] $Br^{\cdot} + CH_3CH_2CH_2Br \rightarrow CH_3\dot{C}HCH_2Br + HBr$

[Traduit par le journal]

Introduction

Photochemically initiated decompositions of alkyl bromides in the gas phase have received little attention, possibly because of their complexity. In bromides possessing more than one type of hydrogen atom several kinds of free radical intermediates may be formed. When both α- and β-bromoalkyl radicals may be formed (1*a*), the former are incapable of propagating kinetic chains. In other cases facile isomerisation of bromoalkyl radicals via bridged transition states (2, 3) obscures the identity and relative importance of the initially formed radical. Nevertheless in the case of some primary alkyl bromides, e.g. ethyl (4, 17) and neopentyl (5) bromides, it has been found possible to use the results of the photolyses to examine Arrhenius parameters of individual elementary steps including that for dissociation of the bromoalkyl radical into a molecule and a bromine atom for which information is still scant.

In view of the above considerations we have started a systematic examination of some alkyl bromide photolyses in an attempt to examine the effect of variation of molecular structures on their kinetics and mechanism. The choice of 1-bromopropane arose from its relationship to the corresponding pyrolysis of the compound for which it has been proposed (8) that the experimentally observed 3/2-order kinetics (6, 7) result from a combination of 1st-order unimolecular reaction and a 2nd-order radical chain reaction.

Experimental

1-Bromopropane, 1bp, was dried over P_2O_5 and distilled through a packed column. The fraction boiling at 70–72°C (71.0°C) (9), n_D^{22} 1.4336 (n_D^{20} 1.4343) (9) was used. Allyl bromide (May and Baker, Dagenham, England) was freshly distilled prior to use and the fraction boiling at 71.0°C (70°C[753]) (9) was used. The purity of the bromoalkanes, checked by gas chromato-

graphic analysis using a flame ionization detector showed no observable impurities. Propane and propene (Matheson research grade) were used directly for identification by glc. Neopentane (Matheson research grade) was used as an internal standard in the quantitative analysis of the hydrocarbon products.

Hydrogen bromide (Matheson research grade) was purified by trap-to-trap distillations at −77°C then stored in a darkened bulb attached to a vacuum line.

Photolyses were carried out in a cylindrical fused quartz cell, 5 cm long and 89.6 cm^3 in volume, with flat quartz windows, joined to a mercury-free high vacuum line. The pressure and temperature measurement systems, the glc analysis, and the photolysis equipment have been described in a previous publication (5). Two lamps were used in the study over a period of four years, their output at 254 nm was measured and was found to be similar (9.7 and 8.9 × 10^{13} photons s^{-1} for lamps I and II, respectively). The fraction of light absorbed did not exceed 6%, leading to errors of less than 2% in the measured values of I_0 with the HBr actinometer (31).

It was possible to follow the progress of the reaction by the pressure increase which was shown to be directly proportional to the amounts of hydrogen bromide and propene evolved, confirming the stoichiometric relationship to be

$$C_3H_7Br \rightarrow C_3H_6 + HBr$$

Such a relationship was shown to be valid at least up to 6% reaction for C_3H_6 and up to 20% reaction for HBr. However, kinetic data were collected from runs restricted to only 2% decomposition or less.

Results

The major chemical process occurring during the photolysis was shown to be the formation of hydrogen bromide and propene in equimolar yields. Propane was formed with a quantum yield of 0.9 ± 0.1 but represented only between 0.1 and 2% of the propene yield depending on experimental conditions, as displayed in Table 1.

Low temperatures, long photolysis times, and low reactant pressures are seen to increase the proportion of propane. Traces of 2-bromopropane were observed in runs carried out to high conversion (>40% reaction and photolysis times >5 × 10^4 s). Examination of reaction products by combined gas chromatography – mass spectrometry failed to detect high boiling products such as 1,5-hexadiene or allyl bromide. No evidence was found for noncondensible products such as methane or hydrogen.

The pressure–time plots in Fig. 1 exhibited an almost imperceptible induction period, which became somewhat longer at the lower temperatures. This was followed by an approximately linear region with the rate of pressure increase slowly falling off as the reaction proceeded. The pressure–time data for the first 2% of the reaction were fitted to a second order polynomial equation (10) from which the initial photolysis rate, $\Delta P/\Delta t$, was determined. The initial rate, given by the first coefficient of the fitted equation, was shown to be independent of the extent of reaction considered for 1 to 5% conversion. A correction (up to 15% maximum) was made in each run to individual rates to allow for the reactor dead space (11) (ca. 10% of reactor volume).

51.43	2376	482.7	979
42.19	5680	482.7	815

Kinetic data were found to be best interpreted in terms of a 1.5-order process:

$$(\Delta P/\Delta t)_{initial} = k_{1.5}P_{1bp}^{3/2}I_0^{1/2} = k_{1.5}^1 P_{1bp}^{3/2}$$

where

$$k_{1.5}^1 = k_{1.5}I_0^{1/2}$$

The 1.5-order rate constant, $k_{1.5}^1$, was independent of pressure in the range 10–95 kPa and over the temperature range 373–483 K as shown in Fig. 2. The rate was proportional to I_0^n where $n = 0.5 \pm 0.05$ over a tenfold range of I_0.

Least-squares treatment of the data obtained at different temperatures and a range of initial pressures, 30–70 kPa (40 runs with a constant light intensity), yielded

$$k_{1.5}^1 = 10^{0.307\pm0.84} \times \exp(-33\,800 \pm 800/RT)\ L^{1/2}\ mol^{-1/2}\ s^{-1}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

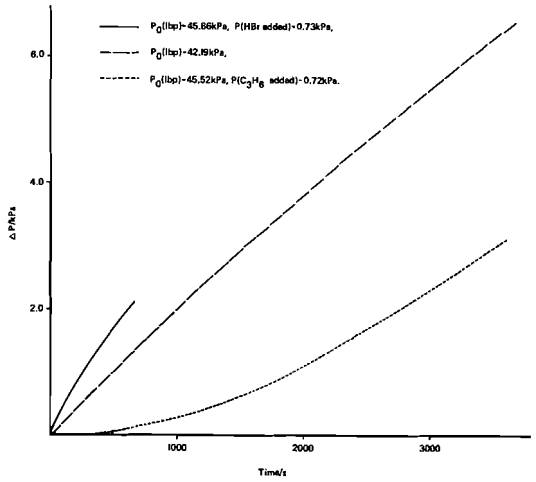

FIG. 1. Typical pressure–time plots, 482.7 K.

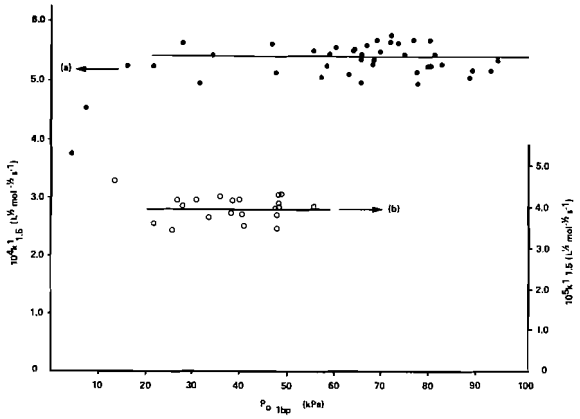

FIG. 2. Variation of $k^1_{1.5}$ with initial pressure of 1-bromopropane; (*a*) ● 482.7 K, (*b*) ○ 373.8 K.

and

$$k_{1.5} = 10^{-6.67\pm0.84} \times \exp(-33\,800 \pm 800/RT)\ \mathrm{L^{1/2}\ mol^{-1/2}\ s^{-1/2}}$$

with

$$R = 8.314\ \mathrm{J\ K^{-1}\ mol^{-1}}$$

The effects of added hydrogen bromide and propene, seen in Fig. 1, illustrate the profound effect of the reaction products on the rate even at low levels of addition. In the case of propene addition, while the effect is particularly marked, after a long photolysis time the pressure–time plot for the propene-added photolysis becomes almost parallel to that of the normal photolysis indicating that the propene acts as a retarder rather than an inhibitor (12). Runs without added hydrogen bromide or propene display only a slight fall off in rate up to 10% reaction even though both hydrogen bromide and propene are formed in the reaction.

The pressure–time data for runs in the presence of added propene or hydrogen bromide could no longer be satisfactorily fitted to a parabolic equation. With added HBr the initial slope is steep but falls off rapidly as the reaction proceeds and is therefore highly dependent on the first few data points. A plot (not shown) of log (initial rate) versus log (pressure added HBr), at constant P_{1bp}, gives scattered results but the order is close to 0.5 with respect to P_{HBr}. For experiments with added C_3H_6 the rate is extremely slow initially but increases as the reaction proceeds (and hydrogen bromide is produced). Meaningful interpretation in terms of initial rates, however, is not possible.

Analysis of runs with added HBr and propene becomes possible in terms of a rate equation of the form

$$[\mathrm{I}]\quad \frac{\mathrm{d}(\Delta P)}{\mathrm{d}t} = k^1_{1.5} P_{1bp}{}^{3/2} \left[\frac{P_{HBr}}{P_{C_3H_6}}\right]^{1/2}$$

In the presence of added HBr, eq. [I] becomes

$$\frac{\mathrm{d}(\Delta P)}{\mathrm{d}t} = k^1_{1.5} P_{1bp}{}^{3/2} \left(\frac{C + \Delta P}{\Delta P}\right)^{1/2}$$

where $C = P_{HBr}$ added and ΔP = observed pressure increase. Over the first few percent of photolysis P_{1bp} is approximately constant and is equal to $(P_{1bp})_0$. On integrating the above expression the following result is obtained:

$$\sqrt{\Delta P(C+\Delta P)} + \frac{C}{2} \ln\left[\frac{\sqrt{\Delta P(C+\Delta P)} - \Delta P}{\sqrt{\Delta P(C+\Delta P)} + \Delta P}\right] = k^1_{1.5}(P_{1bp})_0{}^{3/2}(t - t_0)$$

For runs of 1-bromopropane with added HBr a plot of the left hand side of the equation (= F_{HBr}) against time is found to be almost linear with only a small amount of fall off, as seen in Fig. 3. Values of $k^1_{1.5}$ calculated from these plots are independent of $(P_{1bp})_0$ between 25 kPa and 63 kPa and of $P_{HBr\,added}$, up to 10 kPa at 482.7 K. The light intensity dependence (graph not shown) is close to half-order (exponent is 0.57). Rate constants calculated in this manner are approximately the same as those without added HBr, e.g. 4.89×10^{-4} and 4.65×10^{-4} $\mathrm{L^{1/2}\ mol^{-1/2}\ s^{-1}}$, respectively at 482.7 K.

For the photolysis with added propene the corrected rate expression, [I], becomes

$$\frac{\mathrm{d}(\Delta P)}{\mathrm{d}t} = k^1_{1.5}(P_{1bp})^{3/2} \left[\frac{\Delta P}{g + \Delta P}\right]^{1/2}$$

where $g = P_{C_3H_6}$ added. On integration (with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

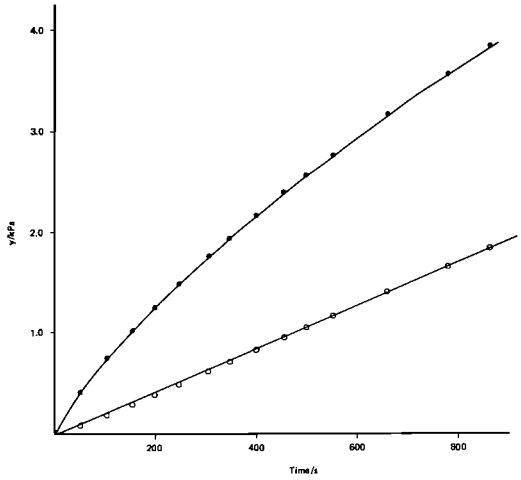

FIG. 3. Integrated plot for typical run with added hydrogen bromide at 482.7 K with P_{1bp} = 45.96 kPa and P_{HBr} added = 5.40 kPa. Plots of y = (*a*) ΔP (●), (*b*) F_{HBr} (○).

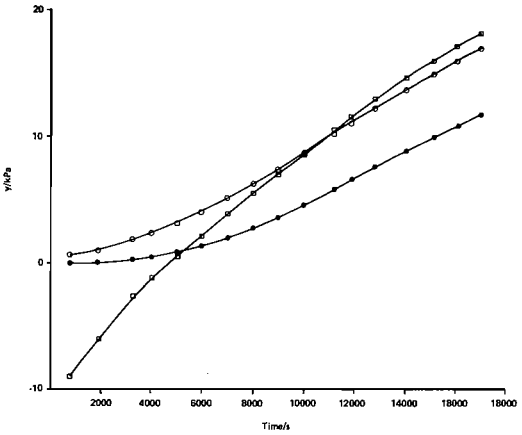

FIG. 4. Integrated plots for typical run with added propene at 482.7 K with P_{1bp} = 46.31 kPa and $P_{C_3H_6}$ added = 2.60 kPa. Plots of y = (*a*) ΔP (●), (*b*) $F_{C_3H_6}$ (○), (*c*) $\Delta P + 2.60 \ln(\Delta P)$ (□).

assumption that P_{1bp} is essentially constant) the following equation is obtained:

$$\sqrt{\Delta P(g + \Delta P)} - \frac{g}{2} \ln\left[\frac{\sqrt{\Delta P(g + \Delta P)} - \Delta P}{\sqrt{\Delta P(g + \Delta P)} + \Delta P}\right] = k_{1.5}^{\dagger}(P_{1bp})_0^{3/2}(t - t_0)$$

Plots of the left hand side of the equation, $F_{C_3H_6}$, versus time, shown in Fig. 4, display a significant "induction" period, the duration of which increases with pressure of added C_3H_6. This is followed by an approximately linear region. The values of $k_{1.5}^{\dagger}$ determined from the slope of this linear region, however, fall off with increasing pressure of added propene.

It is likely, however, that large added pressures of propene lead to a change in termination (Step 7 replacing Step 6 in the mechanism given later) leading to the rate expression

$$d(\Delta P)/dt = k_x P_{1bp}^{3/2} P_{HBr}/P_{C_3H_6}$$

Integration (with $P_{C_3H_6 added} = g$) yields

$$k_x P_{1bp}^{3/2}(t - t_0) = \Delta P + g \ln \Delta P$$

Plots of ($\Delta P + g \ln \Delta P$) against time are found to be reasonably linear (Fig. 4) and values of k_x derived from the slope do not now vary with pressure of added propene ($P_{HBr} < 20$ kPa). For example $k_{1.5}^{\dagger}$ in the absence of added C_3H_6 at 482.7 K is 5.00 × 10^{-4} $L^{1/2}$ $mol^{-1/2}$ s^{-1} while k_x (P_{1bp} = 46–54 kPa, $P_{C_3H_6}$ = 0.05–2.6 kPa, 6 runs) ranges from (4.02–4.20) × 10^{-4} $L^{1/2}$ $mol^{-1/2}$ s^{-1}.

Discussion

A mechanism, consistent with the above experimental results, is described below.[2]

Initiation

$$C_3H_7Br + h\nu \xrightarrow{[1]} C_3H_7^{\cdot} + Br$$

$$C_3H_7^{\cdot} + C_3H_7Br \xrightarrow{[2]} C_3H_6Br^{\cdot} + C_3H_8$$

$$C_3H_7^{\cdot} + HBr \xrightarrow{[2a]} Br^{\cdot} + C_3H_8$$

Propagation

$$Br^{\cdot} + C_3H_7Br \underset{[-3]}{\overset{[3]}{\rightleftharpoons}} CH_3\dot{C}HCH_2Br + HBr$$

$$Br^{\cdot} + C_3H_7Br \underset{[-3a]}{\overset{[3a]}{\rightleftharpoons}} CH_3CH_2\dot{C}HBr + HBr$$

$$CH_3\dot{C}HCH_2Br \overset{[4]}{\rightleftharpoons} CH_3CH{=}CH_2 + Br^{\cdot}$$

$$CH_3CH_2\dot{C}HBr + C_3H_7Br \underset{[-4a]}{\overset{[4a]}{\rightleftharpoons}} CH_3\dot{C}HCH_2Br + C_3H_7Br$$

$$CH_3CH{=}CH_2 + Br^{\cdot} \underset{[-5]}{\overset{[5]}{\rightleftharpoons}} CH_2{=}CH{-}\dot{C}H_2 + HBr$$

Termination

$$CH_2{=}CH{-}\dot{C}H_2 + Br^{\cdot} \xrightarrow{[6]} C_3H_5Br$$

$$2CH_2{=}CH{-}\dot{C}H_2 \xrightarrow{[7]} C_6H_{10}$$

Since propene and propane are products of propagation and initiation respectively, their ratio $Y_{C_3H_6}/Y_{C_3H_8}$ serves as a measure of the kinetic chain length. As seen from Table 1, the kinetic chain length varies from 60 to 980 depending on experi-

[2]Computer simulation of the reaction mechanism has been carried out along lines similar to those applied by Frank and Hanrahan (17) to ethyl bromide photolysis. Results in complete agreement with experimental data were obtainable for runs with and without added HBr and C_3H_6. These results will be published separately.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

mental conditions. This large chain length, coupled with the fact that this study was performed at large reactant pressures, tends to rule out the possibility of direct formation of HBr and C_3H_6 via a unimolecular mechanism which would be expected to occur with a quantum yield of unity. Another possible initiation process believed to occur thermally (8), i.e. RX + HX → RH + 2X, is not evident in this case, since there is no dark reaction at 373 K and only a very slight one at 483 K.

The three major carbon-containing radicals in the mechanism are the bromopropyl radicals, $CH_3CH_2\dot{C}HBr$ and $CH_3\dot{C}HCH_2Br$ and the allyl radical, $CH_2{=}CH{-}\dot{C}H_2$. Termination steps involving the μ radical $CH_3\dot{C}HCH_2Br$ lead to ${}^1\mu\mu_{1/2}$ or ${}^1\beta\mu_1$ mechanisms (30) and can be excluded since they do not lead to 3/2-order kinetics. Termination steps involving the α-bromopropyl radical,

$$CH_3CH_2\dot{C}HBr + Br^{\cdot} \rightarrow C_3H_6Br_2$$

or

$$2CH_3CH_2\dot{C}HBr \rightarrow C_6H_{12}Br_2$$

while giving 3/2-order kinetics (they lead to ${}^1\beta\beta_{3/2}$ mechanisms) can be excluded on the grounds of low concentration of that radical relative to the allyl radical. An upper limit to this ratio can be calculated simply by neglecting reactions [4*a*] and [−4*a*] (reaction [4*a*] can only reduce the concentration and reaction [−4*a*] would be so much slower than reaction [−3*a*] — even at low [HBr] — as to be negligible). The steady-state ratio is

$$\frac{[CH_3CH_2\dot{C}HBr]}{[CH_2{=}CH\dot{C}H_2]} = \left(\frac{k_{3a}}{k_{-3a}}\right)\left(\frac{k_{-5}}{k_5}\right)\left(\frac{[C_3H_7Br]}{[CH_3CH{=}CH_2]}\right)$$

Now the factor (k_{3a}/k_{-3a}) is the equilibrium constant for reactions [3*a*], [−3*a*], and estimated from $\Delta H^0 = 9.2\,\text{kcal mol}^{-1}$ and $\Delta S^0 = 8.0\,\text{cal mol}^{-1}\,\text{K}^{-1}$ (themselves calculated from estimated ΔH_f^0 and S^0 values by Benson's method (1)), it has a value of approximately $10^{-3.6}$ at 373 K and $10^{-2.4}$ at 482 K. Similarly, the factor (k_{-5}/k_5) is the equilibrium constant for reactions [−5], [5], and estimated from $\Delta H^0 = -1.3\,\text{kcal mol}^{-1}$ and $\Delta S^0 = -5.6\,\text{cal mol}^{-1}\,\text{K}^{-1}$ it has a value of approximately $10^{-0.4}$ at 373 K and $10^{-0.6}$ at 482 K. Hence, the expression $(k_{3a}/k_{-3a})\,(k_{-5}/k_5)$ is approximately $10^{-4.0}$ at 373 K and $10^{-3.0}$ at 482 K and after a very small amount of reaction the relative concentration of the α-bromopropyl radical would be too small for it to be involved in termination. Thus, of the possible propagation steps only [3], [4], [5], and [−5] are important in this photolysis.

It is difficult to confirm experimentally the actual intermediacy of the allyl radical in the photolysis since allyl bromide and 1,5-hexadiene were not found among the minor products even on examination by gc–ms analysis. A control experiment at 482.7 K in which 0.53 kPa of allyl bromide and 40.22 kPa of 1-bromopropane were photolysed for 8.1×10^4 s showed that the former disappears many times faster than the latter. Hence it is not unreasonable not to find evidence of the end products of the allyl radicals during the photolysis of 1-bromopropane.

Termination steps involving allyl radicals were included in a kinetic scheme proposed by Cross and Stimson (8) for the thermal decomposition of 1-bromopropane and by Field and Abell (14) for the photoaddition of hydrogen bromide to propene.

Benson (1*b*) has also postulated that any free radical mechanism of the pyrolysis of *t*-butyl bromide would involve termination through the combination of a methylallyl radical and a bromine atom.

The prospect of the reverse overall reaction merits a brief consideration, i.e. the photoaddition of hydrogen bromide to propene (14), despite the fact that the kinetics of the photolysis in this study are determined from very low conversion runs. Unfortunately the work of Field and Abell (14) is not completely comparable with the experimental conditions of the present study. Their study was conducted at temperatures from 324 to 423 K, much lower pressures, and for $[HBr]:[C_3H_6] > 1$. High reactant pressures used in the current study permit omission of consideration of excited bromoalkyl radicals as intermediates (14). The only yard stick for estimating the extent of the reverse reaction—the formation of 2-bromopropane (which itself photolyses at a slower rate than the 1-bromopropane)—suggests that the reverse reaction in the normal photolysis is not worthy of serious consideration in the early stages of the decomposition.

Assuming long chains ($\phi C_3H_6 \simeq 10^2$–10^3) and applying the steady state approximation the following rate expression is obtained:

$$\frac{-d[C_3H_7Br]}{dt} = k_3\left[\frac{k_1}{k_6K_5 + k_7K_5^2([C_3H_6]/[HBr])}\right]^{1/2} \times I_0^{1/2}\left[\frac{[HBr]}{[C_3H_6]}\right]^{1/2}[C_3H_7Br]^{3/2}$$

For runs in the absence of added HBr and C_3H_6, since HBr and C_3H_6 are formed in equal amounts, their ratio is unity, hence the rate should appear to be independent of both products, which is the case at low conversions. The derived rate equation is

TABLE 2. Arrhenius parameters for elementary reactions

Reaction	E/kJ mol^{-1}	log A*	Comments
[1]	~8.4	†	A and E_a were estimated from the temperature dependence of the extinction coefficients of alkyl bromides (28, 29)
[6]	~0	10.9	$k_6 \simeq 10k_7$
[7]	~0	9.9	References 25, 26
Equilibrium [5]: at 373.6 K $\log_{10} K_5 = 1.06 \pm 1.76$‡ at 482.7 K $\log_{10} K_{-5} = 1.04 \pm 1.36$§			

*Units for A and k are either dm^3 mol^{-1} s^{-1}, s^{-1}, or dm^6 mol^{-2} s^{-1}.
†Reaction [1] n-$C_3H_7Br + h\nu \rightarrow n$-$C_3H_7^{\cdot} + Br^{\cdot}$.
For k_1 defined by rate = $k_1 I_0(C_3H_7Br)$ k_1 and the extinction coefficient, ε, for absorption of light by C_3H_7Br are related (31) by

[I] $k_1 = 2.3\varepsilon b\phi/N_a V_{Rv}$

where b is the path length, ϕ is the quantum yield, and V_{Rv} is the volume of the reaction vessel. Substitution of $\varepsilon_{253.7\,nm} = 1.2\,cm^3\,mol^{-1}\,cm^{-1}$ at 298 K (our measurements) and activation energy of 8.4 kJ mol^{-1} for temperature dependence of extinction coefficients of alkyl bromides (28, 29) give

$$k_1 = 10^{-20.06} \exp(-8.4 \times 10^3/RT)$$

(The expression for k_1 given by eq. [I] will be in error when the fraction of light absorbed becomes large (31). At the highest temperatures and pressures used this fraction may be as large as 40%. Uncorrected values are reported however since the errors involved amount to only 0.2 in log A and 1 kJ in E_a.)
‡From values of $(\Delta H_f^0)_g$, S^0, and C_p^0 at 300–500 K for Br (20), C_3H_6 (21), HBr (20), and CH_2CHCH_2 (22–26), $\log_{10} K_5 = 1.06$ and 1.04 at 373.8 K and 482.7 K, respectively.
§References 20–26.

also consistent with the effect of added HBr where the very rapid initial rate falls off quickly as propene is formed and with the effect of added propene where the initial rate is extremely small but increases as reaction proceeds.

From the overall rate constant, it is possible to evaluate k_3, i.e. the rate constant for secondary hydrogen abstraction from 1-bromopropane. Thus from the overall kinetics it follows that,

$$k_{1.5} = k_3 \left[\frac{k_1}{k_6 K_5 + k_7 K_5^2}\right]^{1/2}$$

Upon substituting the appropriate Arrhenius equations for rate constants, k_1, k_6, k_7, and a numerical value for K_5 (these are discussed in Table 2), the rate constant k_3 is then found to be expressible by the equation:

$$k_3 = 10^{9.1} \exp(-29\,700/RT)\ \text{L mol}^{-1}\ \text{s}^{-1} \qquad (R \text{ in J K}^{-1}\ \text{mol}^{-1})$$

Arrhenius factors reported for the abstraction of secondary hydrogen atoms from propane (15) by bromine atoms are log A/M^{-1} s^{-1} = 10.96 and E_a = 43.6 kJ mol^{-1} and those for abstraction from n-butane are similar (15, 16). Thus log A and E_a are less for abstraction from bromosubstituted alkanes than from unsubstituted alkanes by 1.4 and 13.9 kJ mol^{-1}, respectively (13, 27). These decreases are almost identical to those observed in the case of the corresponding liquid phase reactions (decreases of 1.5 in log A and 13.0 kJ mol in E_a, observed in this study and in ref. 15) supporting the statement by Pryor (18) and Poutsma (19) regarding the applicability of liquid phase results to gas-phase bromination studies. The faster abstraction of hydrogen atoms in bromoalkanes can be attributed to the anchimeric assistance of the bromine substituent (27).

A number of publications have considered the relative ease of β- versus α-hydrogen abstraction from bromoalkanes (13, 27). The most recent and definitive report is one by Tanner *et al.* (27) for the vapour phase bromination of 1-bromobutane at 296 K under which conditions the rate for β- relative to α-hydrogen abstraction is found to be 34.6:1. This value may possibly vary at the higher temperatures (i.e. up to 483 K) employed in the present study, nevertheless it is not expected to change so significantly as to alter the conclusions that follow.

Finally, it is noteworthy that whereas the 1-bromopropane photolysis is a 3/2-order process the only other bromide photolyses so far studied (those of ethyl (4) and neopentyl (5) bromides) are found to be predominantly 1st-order processes. For these the prospect of termination involving allylic type radicals does not arise and chain termination appears to involve combination of bromine atoms with μ-type radicals (the γ-bromoalkyl radical in the case of neopentyl bromide and the β-bromoalkyl radical in the case of ethyl bromide).

Interfacial excess entropies and solvent structures

GRAHAM HILLS AND FERNANDO SILVA
Department of Chemistry, The University, Southampton S09 5NH, England
Received October 15, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

GRAHAM HILLS and FERNANDO SILVA. Can. J. Chem. **59**, 1835 (1981).

Detailed consideration is given to thermodynamic relationships describing the temperature dependence of the properties of electrified interfaces. Excess entropies are derived for multicomponent systems and in particular it is shown that the effect on the residual excess entropy, S^*, of the specifically adsorbed organic species can be directly determined by experiment. Values of S^* in the presence of thiourea (TU) can be understood in terms of the surface excesses of TU and the degree of solvent orientation. The preferred orientation of water is shown to be charge-dependent, under all conditions to be zero at $-3\,\mu C\ cm^{-2}$, and largely determined by its molecular polarisability. Temperature-invariant capacities are shown to occur widely and are not easily explained in terms of cluster models or time-dependent solvent orientation.

GRAHAM HILLS et FERNANDO SILVA. Can. J. Chem. **59**, 1835 (1981).

On considère en détail les relations thermodynamiques qui décrivent l'influence de la température sur les propriétés des interfaces électrifiées. On décrit les entropies d'excès pour des systèmes à plusieurs constituants et on démontre en particulier que l'effet sur l'entropie d'excès résiduelle, S^*, d'une espèce organique adsorbée peut être mesuré directement par expérimentation. On peut interpréter les valeurs de S^* que l'on obtient en présence de la thiourée (TU) en termes de l'excès de TU en surface et du dégré d'orientation du solvant. L'orientation préférée de l'eau dépend de la charge, est zéro à $-3\,\mu C\ cm^{-2}$ pour toutes conditions, et est déterminée en grande mesure par la polarisabilité moléculaire de l'eau. Il existe souvent des capacités indépendantes de la température mais on ne peut pas les expliquer en termes de modèles "cluster" ou de variations dans l'orientation du solvant.
[Traduit par le journal]

Introduction

This paper is dedicated to Sam Levine who stimulated the authors to examine more closely the evidence for orientational states of the solvent at the mercury/aqueous electrolyte interface.

The story is told of a research seminar by Sir Eric Rideal on the subject of double layers after which an earnest young man persisted in questioning the lecturer about certain aspects of the theory. In desperation, Rideal is said to have replied "That is too difficult a question for me, you will have to ask a Dr. Levine about that", to which the questioner replied "But I am Levine". That story, hopefully not too apocryphal, describes at least two things about Sam Levine, (1) his persistent thrusts into the fundamentals of double layer theory and (2) his cheerful North American assertiveness which enlivened any discussion.

His contributions to the theory of the double layer have been noteworthy throughout two or more decades when effectively there was no theory. The marvellous thermodynamic analyses of Grahame, Frumkin, and Parsons had invited all sorts of imaginative improper microscopic interpretations requiring for their quantitative evaluation the best of statistical mechanical treatments of condensed phases, all beyond the ability, not to say the comprehension, of but a handful of chemical physicists. Sam Levine had that ability since he was by nature and by training a mathematician. His analytical treatments of the electrical state of the interface and later of its structural state were milestones in the conceptual description of the interface and the latter led to the firm suggestion that the capacity maximum, so charmingly described as the "hump", was due to reorientation of the solvent. The fact that one or two systems displayed more than one maximum was neither here nor there but Sam Levine's (1) treatment of the Watts–Tobin's proposals (2) stimulated a more detailed thermodynamic study of the interface and the paper which follows is a further step in that direction.

Excess Entropies of the Charged Interface

A number of formal descriptions have been given of the temperature coefficients of the electrical and compositional state of the metal solution interface. The Gibbs equation for the equilibrium interfacial free energy per unit area can be written as

$$[1] \qquad d\sigma = -\Gamma_s\,dT + \Gamma_v\,dP - \sum \Gamma_i\,d\mu_i - q\,d\varepsilon_\pm$$

where $\varepsilon_\pm$ is the electrochemical potential and the other terms have their usual significance. The important term here is Γ_s, the excess entropy, and it is evidently defined as

$$[2] \qquad \Gamma_s = -\left(\frac{\partial\sigma}{\partial T}\right)_{P,\mu,\varepsilon_\pm}$$

where σ is simply the interfacial tension but where, because both μ and $\varepsilon_\pm$ are not necessarily independent of temperature even though the composition remains unchanged, care must be given to the exact evaluation of the partial derivative. By implication, the system described by eq. [1] contains a reference electrode reversible to one of the constituent ions and it is a straightforward matter to show (3) that Γ_s is given by

$$[3] \qquad \Gamma_s = \int\int \left(\frac{\partial \frac{1}{C}}{\partial T}\right)_{m,q}$$

where m is the molality of the solution components and where the two constants of integration are, in order,

$$\left(\frac{\partial E_\pm}{\partial q}\right)_\mu \quad \text{and} \quad \left(\frac{\partial \sigma}{\partial T}\right)_{q,\mu}$$

at $q = 0$. In all the equations subsequent to [2] the subscript P denoting constant pressure has been omitted for the sake of clarity.

The excess entropy contains contributions from all the components present in the interface although it is believed that its charge dependence is largely determined by the reorganisation of the solution side. This is likely to be so if the metallic phase is a one component system and, in any case, interest principally attaches to variations in Γ_s with solution composition. The contribution to the excess entropy from species adsorbed into the interface can be resolved if their relative excesses and partial molar entropies are known. Thus, it is possible (4) to define a residual excess entropy, S^*, as

$$[4] \qquad S^* = \Gamma_s - \sum_i \Gamma_i \bar{S}_i$$

If the adsorbed components are ions, then a non-thermodynamic assumption intervenes in that single ion entropies are not known. However, seemingly reasonable estimates have been made of partial molar ionic entropies in aqueous solution and their use in this context leads to consistent values of S^*.

The complete route to S^* is a slightly complex one and needs to be firmly established, especially in the presence of several adsorbed components. Alternative but equivalent routes to S^* are given here and are extensions of previous formulations (5) in that they allow its straightforward determination in the presence of adsorbed organic compounds.

Thus, for a system of a single uni-univalent electrolyte, eq. [4] becomes

$$[5] \qquad S^* = \Gamma_s - \Gamma_- \bar{S}_- - \Gamma_+ \bar{S}_+$$

or, because of the electroneutrality condition,

$$[6] \qquad \begin{aligned} S^* &= \Gamma_s - \left(\Gamma_+ + \frac{q}{F}\right)\bar{S}_- + \Gamma_+ \bar{S}_+ \\ &= \Gamma_s - \Gamma_\mp \bar{S}_{\text{salt}} \pm \frac{q}{F}\bar{S}_\pm \end{aligned}$$

The $\bar{S}_\pm$ terms are the separate partial molar ionic entropies and $\bar{S}_{\text{salt}}$ is the readily determinable partial molar entropy of the salt. The total relative excess entropy is thus redefined by re-arrangement of eq. [6] as

$$[7] \qquad \Gamma_s = S^* + \Gamma_\mp \bar{S}_{\text{salt}} \pm \frac{q}{F}\bar{S}_\pm$$

and this can be substituted into the alternative form of [1], namely

$$[8] \qquad -d\xi_\pm = +\Gamma_s\, dT + \sum \Gamma_i\, d\mu_i - \varepsilon_\pm\, dq$$

where ξ is the Parsons auxiliary variable. Thus, at constant composition,

$$[9] \qquad -d\xi_\pm = \left(S^* + \Gamma_\mp \bar{S}_{\text{salt}} \mp \frac{q}{F}\bar{S}_\pm\right) dT - \varepsilon_\pm\, dq + \Gamma_\mp\, d\mu_{\text{salt}}$$

and because at constant composition

$$[10] \qquad d\mu_{\text{salt}} = -\bar{S}_{\text{salt}}\, dT$$

eq. [9] simplifies to

$$[11] \qquad -d\xi_\pm = \left(S^* \mp \frac{q}{F}\bar{S}_\pm\right) dT - \varepsilon_\pm\, dq$$

Because $\xi_\pm$ is a total differential, cross-differentiation leads to

$$[12] \qquad \frac{d}{dq}\left(S^* \mp \frac{q}{F}\bar{S}_\pm\right)_{m,T} = -\left(\frac{\partial \varepsilon_\pm}{\partial T}\right)_{m,q}$$

and therefore

$$[13] \qquad \left(\frac{\partial S^*}{\partial q}\right)_{m,T} = -\left(\frac{\partial \varepsilon_\pm}{\partial T}\right)_{m,q} \pm \frac{\bar{S}_\pm}{F}$$

The temperature coefficient of the electrochemical potential is related to the temperature coefficient of the potential, $E_\pm$ of the metallic interface with respect to a reversible reference electrode. Changes in temperature of the cell (even at constant $E_\pm$) must take account of the entropies of the reference components not directly related to the compositional dependence of the potential, e.g. of the solid Hg_2Cl_2 and liquid mercury in a directly reversible calomel reference electrode.

In general terms,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

$$[14] \quad \left(\frac{\partial \varepsilon_{\pm}}{\partial T}\right)_{m,q} = \left(\frac{\partial E_{\pm}}{\partial T}\right)_{m,q} + \frac{1}{F}\frac{dk}{dT}$$

where k is a sum of known free energy terms independent of composition and electric potential.

Since

$$[15] \quad \left(\frac{\partial E_{\pm}}{\partial T}\right)_{m,q} = \left(\frac{\partial E_{\pm}}{\partial T}\right)_{m,q=0} + \int_0^q \left[\frac{\partial\left(\frac{1}{C}\right)}{\partial T}\right]_{m,q} dq$$

eq. [13] can be rewritten to include [14] and [15] and then integrated to give

$$[16] \quad S_q^* - S_{q_r}^* = -\int_{q_r}^q \left[\int_0^q \left(\frac{\partial\left(\frac{1}{C}\right)}{\partial T}\right)_{m,q} dq + \left(\frac{\partial E_{\pm}}{\partial T}\right)_{m,q=0}\right] dq - \left[\frac{1}{F}\frac{\partial k}{\partial T} \mp \frac{\bar{S}_{\pm}}{F}\right](q - q_r)$$

where q_r refers to any reference state of the system and which might well be but not necessarily that of $q = 0$. The principal variables on the right hand side of [16] are directly obtainable from the routine measurement of differential capacity as a function of charge and temperature at a series of different compositions. The last bracketted term contains only constants.

Equation [16] can also be obtained from the cross-differentiation of eq. [8] at constant composition, i.e.

$$[17] \quad \left(\frac{\partial \Gamma_s}{\partial q}\right)_{\mu,T} = -\left(\frac{\partial \varepsilon_{\pm}}{\partial T}\right)_{\mu,q}$$

where, as before,

$$[18] \quad \left(\frac{\partial \varepsilon_{\pm}}{\partial T}\right)_{\mu,q} = \left(\frac{\partial E_{\pm}}{\partial T}\right)_{\mu,q} + \frac{1}{F}\frac{dk}{dT}$$

But

$$[19] \quad \left(\frac{\partial E_{\pm}}{\partial T}\right)_{\mu,q} = \left(\frac{\partial E_{\pm}}{\partial T}\right)_{m,q} - \left(\frac{\partial E_{\pm}}{\partial \mu}\right)_q \left(\frac{\partial \mu}{\partial T}\right)_m$$

where also from eq. [1]

$$\left(\frac{\partial E_{\pm}}{\partial \mu}\right)_q = -\left(\frac{\partial \Gamma_{\pm}}{\partial q}\right)_{\mu}$$

and where

$$\left(\frac{\partial \mu}{\partial T}\right)_m = -\bar{S}_{salt}$$

Thus

$$[20] \quad \left(\frac{\partial E_{\pm}}{\partial T}\right)_{\mu,q} = \left(\frac{\partial E_{\pm}}{\partial T}\right)_{m,q} - \left(\frac{\partial \Gamma_{\pm}}{\partial q}\right)_{\mu} \bar{S}_{salt}$$

and substitution of eqs. [18], [19], and [20] into [17] followed by integration then gives eq. [16], as indeed it must.

The first route to eq. [16] is, however, preferred because of the ease with which it can be extended to systems of several components. In this work, the full details of which will be given elsewhere (6), we were concerned with the adsorption of thiourea at a mercury interface and with the competition between the organic adsorbate and anions and between both and the solvent water. The effect on the solvent is well reflected in S^* which is strongly affected by the presence of adsorbed thiourea.

Thus, it is a straightforward matter to include appropriate terms for this molecule (here denoted by TU) into eq. [9], such that

$$[21] \quad -d\xi_{\pm} = \left(S^* \mp \frac{q}{F}\bar{S}_{\pm} + \Gamma_{\mp}\bar{S}_{salt} + \Gamma_{TU}\bar{S}_{TU}\right) dT + \Gamma_{\mp}\, d\mu_{salt} + \Gamma_{TU}\, d\mu_{TU} - \varepsilon_{\pm}\, dq$$

But at constant composition,

$$[22a] \quad d\mu_{salt} = -\bar{S}_{salt}\, dT$$

and

$$[22b] \quad d\mu_{TU} = -\bar{S}_{TU}\, dT$$

and substitution for $d\mu_{salt}$ and $d\mu_{TU}$ in eq. [21] gives simply

$$[23] \quad -(d\xi_{\pm})_{m_{salt},m_{TU}} = \left(S^* \mp \frac{q}{F}\bar{S}_{\pm}\right) dT - \varepsilon_{\pm}\, dq$$

which is identical to eq. [11], except for the condition that the concentration of TU is also constant. The same sequence of equations then follows to give again eq. [16] which contains only observable quantities and $\bar{S}_{\pm}$ but *no* term directly related to thiourea. The influence of the strongly adsorbed thiourea is of course manifested in the experimental values of $d(1/C)/dT$ and $(dE_{\pm}/dT)_{q=0}$ determined at constant composition but dependent on the concentration and surface excess of TU. Thus if we label S^* in the presence and absence of TU as S_{TU}^* and S_b^*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

respectively (b denotes base electrolyte) and so on for the other terms, then

$$[24]\quad \frac{\partial}{\partial q}(S_{TU}^* - S_b^*) = -\left(\frac{\partial E_{\pm,TU}}{\partial T}\right)_{q=0} - \int_0^q \left(\frac{\partial \frac{1}{C_{TU}}}{\partial T}\right)_{q,m_{TU}} + \frac{\bar{S}_{\pm,TU}}{F} + \left(\frac{\partial E_{\pm,b}}{\partial T}\right)_{q=0} + \int_0^q \left(\frac{\partial \frac{1}{C_b}}{\partial T}\right)_{q,m_b} - \frac{\bar{S}_{\pm,b}}{F}$$

If the reasonable assumptions are then made (*i*) that the degree of ionic adsorption is independent of the concentration of thiourea and (*ii*) that $\bar{S}_\pm$ is also independent of the presence of the thiourea (see ref. 7), the difference $\bar{S}_{\pm,TU} - \bar{S}_{\pm,b}$ can be equated to zero and the integration of eq. [24] then gives $S_{TU}^* - S_b^*$ irrespective of the nature of the base electrolyte or the reference electrode, i.e. determined solely by the experimental quantities, C and $E_\pm$. The resultant integral,

$$[25]\quad S_{TU}^* - S_b^* = \int_{q_r}^q \left[\int_0^q \left(\frac{\partial \frac{1}{C_b}}{\partial T}\right)_{m_b,q} - \int_0^q \left(\frac{\partial \frac{1}{C_m}}{\partial T}\right)_{m_{TU},q} + \left(\frac{\partial E_{\pm,b}}{\partial T}\right)_{m_b,q=0} - \left(\frac{\partial E_{\pm,m}}{\partial T}\right)_{m_{TU},q=0}\right]$$

is therefore the basis of the direct determination of the effect of adsorbed molecules, especially organic molecules, on the residual interfacial entropy and hence on the configuration of the solvent in the interface. The same procedure could be followed in studying the adsorption of an additional ionic component but it would be necessary to involve an indifferent base electrolyte, e.g. NaF, and to carry out the measurements at constant total ionic strength.

The Charge Dependence of Γ_s and S*

Values of Γ_s and S^* were obtained from a range of aqueous solutions of KCl and for the same solutions containing a wide concentration range of thiourea (6). The number of results from such a multivariate system was very large and only a sample can be presented here. The new capacitance–potential data were recorded on paper tape and processed off-line. Potentials of zero charge were determined using either a streaming electrode or the method of back integration. The details of these and other related studies will be given elsewhere (6). The data were processed to give the interfacial tension, σ, and also q, Γ_{Cl^-}, Γ_{TU}, Γ_s, and S^*.

Figure 1 shows a typical set of capacity – surface charge density curves as a function of temperature for one composition, namely 0.04 *M* thiourea in 0.1 *M* KCl. The first aspect to note is the temperature invariant point characteristic of many if not all capacitance charge curves in aqueous solutions; this will be referred to later. Values of ΔS^* (i.e. $S_{TU}^* - S_b^*$) for a range of thiourea concentrations in 0.1 *M* KCl and at 25°C are shown in Fig. 2 as a function of surface charge density. The falling curves reflect the change in interfacial composition. The effect of the specific adsorption of the chloride ions is already taken into account in the evaluation of ΔS^*, subject only to the assumption that $\bar{S}_{Cl^-}$ is independent of its own surface coverage and that of other species. The fall in ΔS^* is therefore predominantly due to the change in the relative surface excess of thiourea. That this is so is evident from Fig. 3 which shows the dependence of ΔS^* on Γ_{TU} for different concentrations of thiourea. The lines have similar slopes and the systematic difference in the absolute values of ΔS^* even at constant Γ_{TU} result solely from the

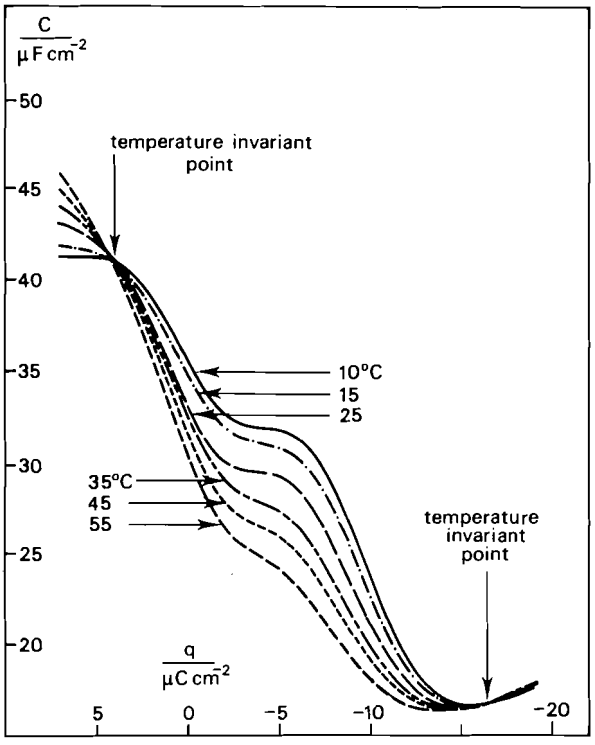

FIG. 1. Differential capacity of Hg/0.1 *M* KCl, 0.04 *M* thiourea as a function of charge and temperature.

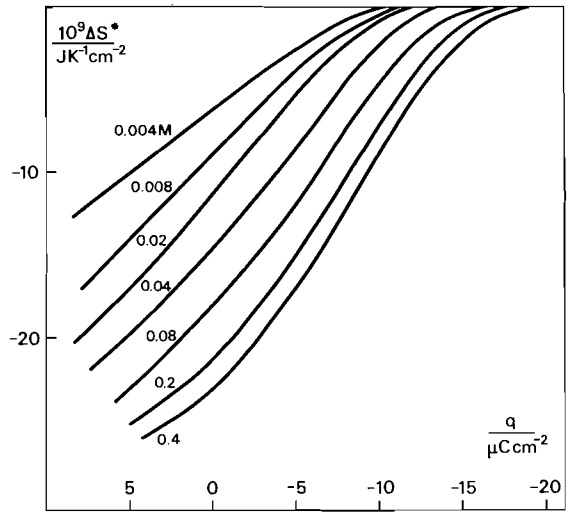

FIG. 2. ΔS^* as a function of surface charge density for seven concentrations of thiourea.

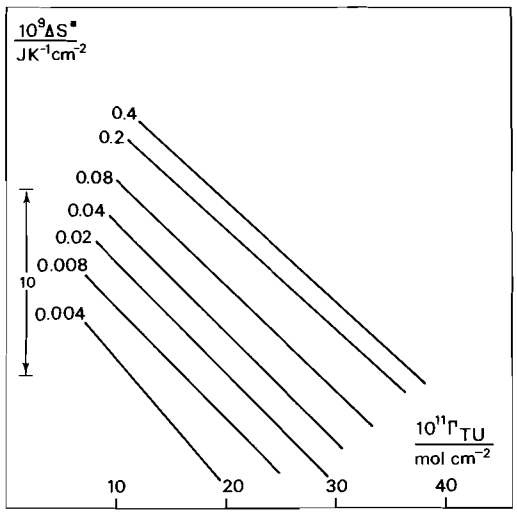

FIG. 3. ΔS^* as a function of the surface excess of thiourea at different bulk concentrations of thiourea in 0.1 M aqueous KCl at 25°C.

choice of integration constant which was conveniently but arbitrarily made zero for all concentrations at $q = 0$. A knowledge of the variation of the absolute values is not essential to this paper but to clarify the complex interdependence of ΔS^*, Γ_{TU}, and q, values of S^* were calculated as a function of charge density but at constant molality of thiourea. The derived relationships shown in Fig. 4 as the full lines are all parabolic in nature and have been adjusted here to a common value at extreme cathodic potentials where the differential capacity is no longer temperature dependent and where, therefore, ΔS^* is effectively zero. The important feature of all these curves is that

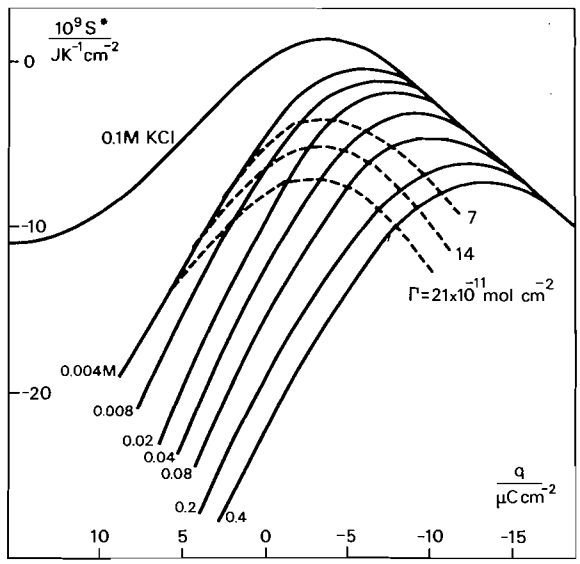

FIG. 4. S^* (full lines) and $S^* - \Gamma_{TU}(d\Delta S^*/d\Gamma_{TU})$ (dashed lines) as a function of q and of the bulk concentration of thiourea at 25°C.

each shows a maximum but the height and, more importantly, the position on the charge axis are systematically dependent on the composition of the solution and therefore of the interface, i.e. on the value of m_{TU}. The decrease of S^* with Γ_{TU} at constant solution composition is evidence of the significant contribution to ΔS^*made by the solvent water which has been the principal conclusion of all previous studies (3–5, 8, 9). The lateral displacement of the maxima to more cathodic potentials is evidence that reorganisaton of the complex interface still occurs as the charge density is varied.

The forced fit of the parabolas in Fig. 4 can also be applied to the lines in Fig. 3. Figure 5 shows them stemming from a common origin at $\Gamma_{TU} = 0$. The slopes are essentially the same and certainly no significant dependence on m_{TU} was observed. It is easy to show (4) that ΔS^*, as operationally defined by eq. [25], is also given by

$$[26] \quad \Delta S^* = \left[\sum_i m_i^\sigma(\bar{S}_i^\sigma - \bar{S}_i)\right] - \left[\sum_j m_j^\sigma(\bar{S}_j^\sigma - \bar{S}_j)\right]_r$$

where r denotes a convenient reference state, in this case where $m_{TU} = 0$, and where m_i^σ and m_j^σ are the number of moles of each component in the same arbitrary volume of interface for the given and reference states respectively. Since the surface excess is closely related to the surface composition, it follows from eq. [26] that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

$$[27]\quad \frac{d\Delta S^*}{d\Gamma_{TU}} = \frac{dS^*}{d\Gamma_{TU}} \approx \frac{dS^*}{dm_{TU}^{\sigma}} = -(\bar{S}_{TU}^{\sigma} - \bar{S}_{TU}) + n(\bar{S}_{H_2O}^{\sigma} - \bar{S}_{H_2O})$$

where n is the number of water molecules displaced or replaced by adsorption or desorption of a thiourea molecule. The linearity of the slopes in Fig. 3 and 5 suggests (*i*) that the partial molar entropy of adsorption of thiourea into the interface is not significantly dependent on its surface coverage and (*ii*) that the predominant term in eq. [27] is $(\bar{S}_{TU}^{\sigma} - \bar{S}_{TU})$ which in fact is large and negative.

Given the observed dependence of ΔS^* on Γ_{TU}, it is now possible to refine ΔS^* still further by deconvoluting from the lines in Fig. 4, the contribution due to Γ_{TU} thus leaving the residual contribution due solely to the remaining component, namely water. Thus, at each value of q, the quantity $\Delta S^* - \Gamma_{TU}(d\Delta S^*/d\Gamma_{TU})$ was evaluated and the new relationships are shown as the dashed lines on the same figure. These parabolic curves corresponding to the variation with surface charge density of the residual excess entropy at constant surface excess of thiourea are remarkable in that their maxima occur at the same value of q as for solutions containing no thiourea, i.e. where $\Gamma_{TU} = 0$. The charge density at zero preferred solvent orientation is therefore, as before, -3 ± 1 μC/cm^2. The electric potential at that point is a reference potential probably no less important than the potential of zero charge, but the more important conclusion here is that it depends on the preferred orientation of *individual* solvent molecules (see refs. 8–15).

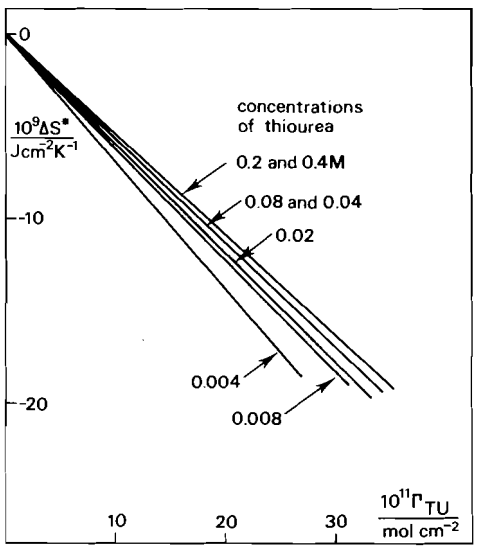

FIG. 5. ΔS^* as a function of Γ_{TU} for different concentrations of thiourea in 0.1 *M* KCl.

It is also clearly evident that the entropic nature of water in the interface, at least as it depends on charge density, is independent of its molecular number density even up to higher coverages of thiourea, in this case ~50%. This casts doubt, to say the least, on suggestions that the clustering of water molecules is an important feature of their interfacial state, particularly as it affects their electrical properties.

The dashed lines in Fig. 4 appear to be parallel and this is also to be expected from thermodynamic argument. Thus, their slopes are given by $(d\Delta S/\partial q)_\Gamma$ and it follows that this can be rewritten as

$$[28]\quad \left(\frac{d\Delta S^*}{dq}\right)_\Gamma = \left(\frac{d\Delta S^*}{dq}\right)_m - \left(\frac{d\Delta S^*}{d\Gamma}\right)_q \left(\frac{d\Gamma}{dq}\right)_m$$

From considerations of congruence (6) it can be shown that

$$[29]\quad \left(\frac{\partial S^*}{\partial \Gamma}\right)_m = \left(\frac{\partial S^*}{\partial \Gamma}\right)_q$$

and experimentally it was observed (Figs. 3 and 5) that

$$[30]\quad \left(\frac{d\Delta S^*}{\partial \Gamma_{TU}}\right)_m = \text{constant} = k'$$

Substitution of [29] and [30] into [28] and integration with respect to q, gives

$$[31]\quad \Delta S^*_{\Gamma_{TU}} = \Delta S^*_{m_{TU}} - k'\Gamma_{TU}$$

so that the dashed lines in Fig. 4 should be parallel.

It is unlikely that the thiourea undergoes any orientation over the range of charge densities used here because (*1*) the Hg–S linkage is evidently very strong and (*2*) the near constancy of the slopes of $(d\Delta S^*/\partial\Gamma_{TU})$ for all conditions of composition and charge density indicate that $(\bar{S}_{TU}^{\sigma} - \bar{S}_{TU})$ and therefore the polarisability of the molecule remains constant so far as $\bar{S}_{TU}^{\sigma}$ is concerned.

The fact remains that the entropic nature of interfacial water as a function of charge density is not dependent on *its* molecular number density. It follows that its smooth, monotonic entropy–charge density dependence is adequately explained in terms of a simple two state model of the kind put forward by Conway and Gordon (10) and by Bockris and Habib (11). The intensive property of the interfacial water is its preferred state of orientation and the corresponding extensive property is the surface number density of individual water molecules.

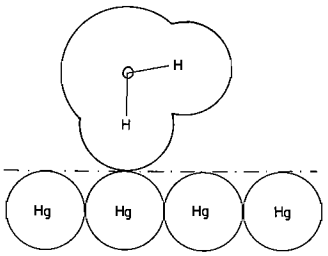
Solvent Orientation and Temperature Invariant Capacities

The state of the solvent in the interface is not only a necessary aspect of the explanation of the observed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

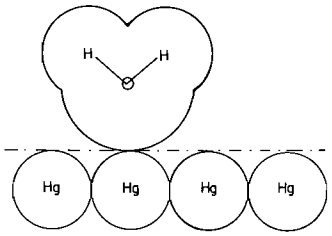
excess entropies, it is also a vital ingredient of the understanding of the much more widely observed electrical capacity – potential relationships and, in particular, of the striking points of temperature invariant capacity these curves display as a function of temperature.

The word individual used in the last paragraph of the previous section was intended to stress that the present work offers no evidence of co-operative phenomena involving many-state models. It follows that the electrical response of individual molecules is likely to be that of their individual polarisabilities and that would at once explain the first order difference between inner layer differential capacities on either side of the charge or potential of zero preferred orientation. On the far cathodic side, the lower polarisability of the misfit configuration and the



The misfit configuration.

saturation coverage of water molecules leads to the low, charge and temperature independent capacities that are invariably recorded. On the anodic side of the charge of zero preferred orientation, the higher capacity reflects the higher polarisability of the better



The better fit configuration.

fit configuration and the competition between water molecules and electrostatically attracted anions.

The nature and values of the two extreme polarisabilities, $\alpha_\uparrow$ and $\alpha_\downarrow$, are not known. They are unlikely to be satisfactorily explained in terms of "homogeneous" interactions between multipoles in the solvent molecule and their images in the metal. Were this not so, it would be difficult to explain the first order sensitivity of the differential capacity to metal type as well as to solvent type. In other words, statistical mechanical *molecular* calculations are likely to be less important than equivalent calculations involving site–site interactions, i.e. of constituent atoms, each determined by the particular quantum mechanical interactions of the atom pair in question. These speculations are necessary to direct attention away from macroscopic considerations of dielectric constant and of time-dependent orientational contributions to the capacity which are not easily reconciled with the precise invariance of the isosbestic point on the anodic side of the potential or charge of zero preferred orientation.

Figure 1 is a direct descendent of an earlier famous figure by Grahame reproduced here for convenience as Fig. 6(*a*). Such isosbestic points are commonly found with many other systems but are not so well defined on a normal inner layer capacity–potential plot. The lack of definition arises because the potential scale itself is temperature dependent for the reasons touched on in the earlier part of this paper. If, however, at each temperature the electric potential is re-expressed on a rational scale, cf. Fig. 6(*b*), then the convergence of the intersections also occurs, confirming that we are dealing with a single electrical state of the system at each temperature, the result of which is independent of whether it is expressed as charge or potential. The result of that electric state is to determine and to be determined by the relative populations of solution species in the interface, i.e. the degrees of adsorption. The temperature invariant capacity simply corresponds to an electric state of the system no longer temperature dependent.

Now, it is in the nature of thermodynamics that the simple statement

$$[32] \quad \left(\frac{dC}{dT}\right)_{q,m} = 0 = \left(\frac{d\frac{1}{C}}{dT}\right)_{q,m} \text{ etc.}$$

can be re-expressed in many ways, e.g. as to involve Γ_s or S^* at the point in question. The arguments are, of course, circular in nature and most re-statements of eq. [32] offer little further insight than [32] itself. It is, however, worth noting that

$$[33] \quad \frac{1}{C} = \left(\frac{dE_\pm}{dq}\right)_m$$

and that

$$[34] \quad \left(\frac{d\frac{1}{C}}{dT}\right)_{m,q} = \frac{d}{dT}\left(\frac{dE_\pm}{dq}\right) = \frac{d}{dq}\left(\frac{dE_\pm}{dT}\right)$$

A typical plot for this system of (dE_-/dT) vs. q is shown in Fig. 7. Not surprisingly, the temperature invariant point is now defined by the maximum in dE_-/dT and this has been noted previously (4). A feature not noted previously is that the potential of

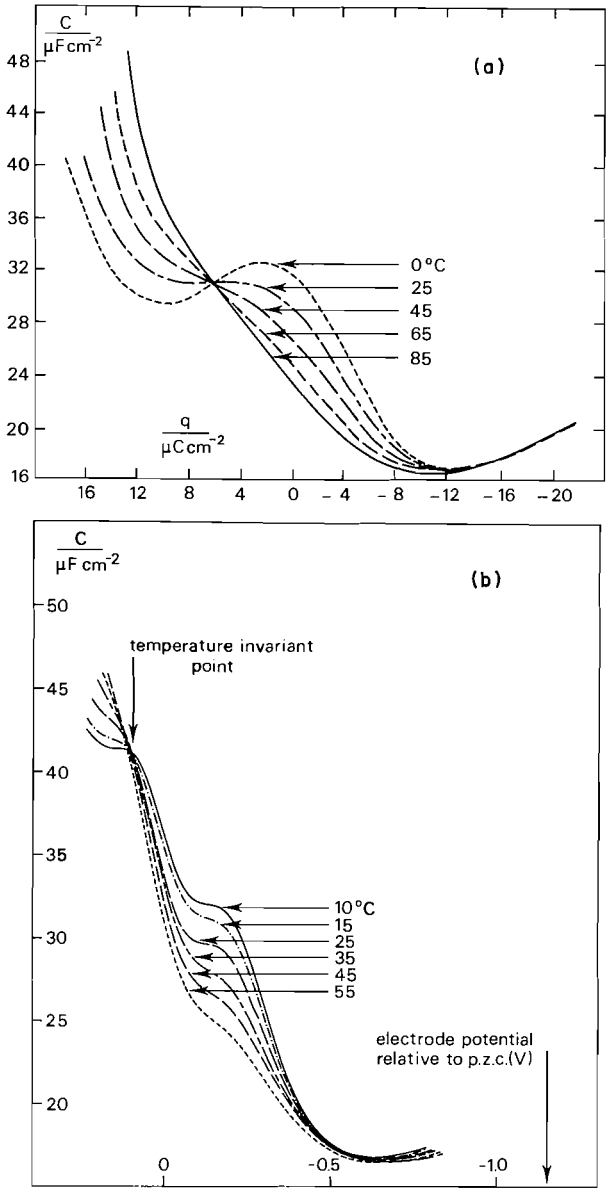

FIG. 6(a). Calculated capacity C_{M-2} of the compact double layer for mercury in 0.8 M sodium fluoride at several temperatures; (b) Differential capacity of 0.04 M thiourea in 0.1 M KCl as a function of temperature and rational potential.

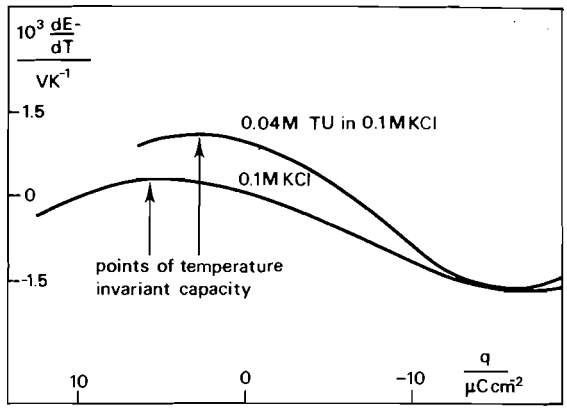

FIG. 7. Charge dependence of $(dE_-/dT)_c$ for aqueous 0.1 M KCl and 0.04 M thiourea in 0.1 M KCl.

zero preferred solvent orientation (when ΔS^* is a maximum) coincides with the value of $d\varepsilon_-/dT = 0$. At far cathodic values of E_- or q, dE_-/dT passes through a minimum indicating another isosbestic point.

The general symmetry of the dE_-/dT vs. q relationship about the potential or charge of zero preferred solvent orientation is satisfying and will no doubt be explained in terms of changing interfacial composition and changing degree of solvent orientation. Both the maxima in dE_-/dT and the isosbestic points beg for an elegant explanation which, unfortunately, is unlikely to come from further thermodynamic argument or statistical mechanical modelling. Given the simple fact that at a particular state of the system $C \neq f(T)$, it is difficult to escape the conclusion that the composition of the interface and its electrical state are also temperature invariant, i.e. that it is improbable that, as argued previously (16), there should be some fortuitous intersection of two equivalently temperature dependent processes, i.e. the temperature analogue of the normal explanation of an isosbestic point. The capacity can be written in general terms as

$$[35] \quad C = \sum_i m_i^\sigma \alpha_i$$

where the m_i^σ terms represent the surface composition and the α_i terms the corresponding polarisabilities. Because of the extreme sensitivity of the capacity to the nature of metallic phase, the polarisabilities are assumed to be wholly electronic and intramolecular in character, i.e. any contribution from time-dependent dipolar or even quadrupolar re-orientation is assumed to be negligible. As such, they *will* be temperature independent and the fact that *both* the m_i amd α_i values must be temperature invariant for C to be constant, is taken as *prima facie* evidence this is so.

The compositional invariance is slightly harder to live with especially for multicomponent systems, but there will be values of m and q at which the individual partial molar free energies of adsorption or, more correctly, of their interchange, will each and all be zero. It could further be argued that the composition and state relating to this invariant condition might be unique for a particular system. Thus to maintain the temperature invariant state an increase in the bulk concentration of thiourea would need to be com-

TABLE 1. The dependence of the temperature invariant point on concentration (*i*) of thiourea in 0.1 *M* KCl and (*ii*) of KCl in aqueous solution

Concentration of thiourea (mol/dm³)	$q_{dC/dT=0}$ (μC cm⁻²)	Concentration of KCl (mol/dm³)	$q_{dC/dT=0}$ (μC cm⁻²)
0.04	+3.0	0.1	5.8
0.08	+2.0	0.5	5.5
0.20	+1.2	1.0	5.5
0.40	+1.0		
0.60	+0.8		

pensated by a decrease in the positive charge density on the mercury surface. The results obtained here (Table 1) indicate that this is so both for the thiourea system and for the simple two component water – potassium chloride system. However, derived values of Γ_{TU} for the range of temperature invariant points corresponding to different bulk concentrations of thiourea and different values of q are not constant, so that the notion of a unique composition is too simple.

Equation [35] may nonetheless describe the best model along which the physics of the temperature invariant points can be further explored. Certainly, the points themselves deserve to be looked for in many other systems and their characteristic values q, Γ, Γ_s, S^*, etc, examined in detail. Some results of such further studies will be reported on at a later date.

The location of the reaction site and discreteness-of-charge effects in electrode kinetics

W. R. FAWCETT

The Guelph-Waterloo Centre for Graduate Work in Chemistry (Guelph Campus), Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received August 26, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

W. R. FAWCETT. Can. J. Chem. **59**, 1844 (1981).

Discreteness-of-charge effects for simple heterogeneous electron transfer reactions, namely, the self-image effect, the exclusion disc effect, and the effect of local attractive ion–ion interactions, are considered for a variety of reaction sites in the double layer, both in the presence and in the absence of ionic specific adsorption. An expression is derived for the local activity coefficient of the activated complex; this quantity is shown to be a function of both the potential drop across the inner layer and the adsorbed charge density due to specifically adsorbed ions when the standard state is chosen on the basis of the reaction conditions considered in the classical Frumkin theory (reaction site at the outer Helmholtz plane). The consequences of discreteness-of-charge effects for reactions occuring in three different double layer environments of increasing complexity are described. These effects are discussed on the basis of data obtained earlier for the electroreduction of periodate anion in the presence of specifically adsorbed anions.

W. R. FAWCETT. Can. J. Chem. **59**, 1844 (1981).

On a examiné les effets du caractère discret des charges lors de réactions simples de transfert hétérogène d'électron, en particulier l'effet d'auto-image, l'effet d'exclusion du disque et l'effet des interactions locales ion–ion attractives sur divers sites réactionnels de la couche double en présence ainsi qu'en l'absence d'adsorption ionique spécifique. On a déduit une expression pour le coefficient d'activité locale du complexe activé; on montre que cette quantité est une fonction de la chute de potentiel à travers la couche interne et de la densité de charge adsorbée provenant d'ions spécifiquement adsorbés quand l'état normal est choisi en fonction des conditions de la réaction considérée dans la théorie classique de Frumkin (site réactionnel au plan extérieur de Helmholtz). On décrit les conséquences des effets du caractère discret de la charge de la couche double pour des réactions qui ont lieu dans trois environnements différents de complexité croissante. On discute de ces effets en fonction de données relatives à l'électro-réduction de l'anion périodate en présence d'anions spécifiquement adsorbés que nous avons obtenus antérieurement.

[Traduit par le journal]

Introduction

In a recent discussion of discreteness-of-charge effects in electrode kinetics (1), it was pointed out that most theoretical treatments (2–7) assume that the reaction site for the electron transfer process is located on the inner Helmholtz plane (i.H.p.), that is, on the plane through the charge centres of specifically adsorbed non-reacting ions. The treatment of discreteness-of-charge effects in these papers is based on the work of Levine and co-workers first presented in this Journal nineteen years ago (8) and subsequently developed in a series of papers (9–17). On the basis of Levine's theory one may estimate the discreteness-of-charge effect for any reaction site in the inner layer (10, 17). This is especially important in understanding discreteness-of-charge effects in electrode kinetics since, in general, ionic reactants have different sizes and different locations in the double layer depending on the nature of the reaction.

It has also been suggested (1) that to improve the understanding of double layer effects in electrode kinetics one should distinguish three types of reactions. The double layer effect is called Type I in the case of a simple redox reaction occuring in an environment composed chiefly of ions of the same sign. A simple example is the electroreduction of $Cr(H_2O)_6^{3+}$ to $Cr(H_2O)_6^{2+}$ at a negatively charged inert electrode at which the region of the double layer near the electrode is predominantly populated by cations. A Type II effect holds when the reaction occurs in an environment composed chiefly of ions of the opposite sign. This situation arises when anions are reduced at negatively charged electrodes in the absence of specific adsorption. The Type III effect is the most complex and is present for reactions occurring in ionic atmospheres with both cations and anions in close proximity. Both of the above systems involve Type III double layer effects when specifically adsorbed non-reacting anions are present on the i.H.p.

The purpose of this paper is to present a general model for discreteness-of-charge effects applicable to situations in which the reaction plane (r.p.) is not coincident with either the i.H.p. or outer Helmholtz plane (o.H.p.). Examples of data from the literature are discussed within the context of the theory and methods of data analysis to determine the extent of the discreteness-of-charge effects are presented.

Estimation of the Discreteness-of-Charge Effect

According to the generally accepted convention (1), the electrochemical potential of ion i at a

reaction site near a polarizable inert electrode may be written

$$[1] \quad \tilde{\mu}_i = \mu_i^0 + RT \ln \gamma_i^r c_i^r + z_i F \phi^r$$

μ_i^0 is the standard chemical potential, c_i^r, the local concentration of ion i, γ_i^r, its local activity coefficient, z_i the charge on the ion, and ϕ^r, the average potential on the plane which is parallel to the interface and a distance x_r from it. In the following it is assumed that the reacting system interacts weakly with the electrode. In this case, and for reactants which can be represented as point charges, the local activity coefficient is associated with discreteness-of-charge effects:

$$[2] \quad RT \ln \gamma_i^r = N_0 \int_0^{z_i e_0} \zeta_i^r de = \xi_i^r$$

ζ_i^r is the discreteness-of-charge potential and ξ_i^r, the corresponding energy (3, 5). When the reactant interacts strongly with the electrode or when interfacial solvent molecules are involved in the reaction mechanism, an entropic term must be considered in estimating the local activity (1, 3). On the basis of Flory–Huggins statistics (18, 19), this term is given by

$$p_i \ln \left(1 - \sum_j p_j \theta_j\right)$$

were p_i is the number of solvent molecules displaced by species i, and $p_j\theta_j$, the fraction of the surface covered by species j. One should also consider the non-electrostatic work w_i associated with removal of solvent molecules from the inner layer. The expression for γ_i^r is then

$$[3] \quad RT \ln \gamma_i^r = \xi_i^r + w_i + p_i RT \ln \left(1 - \sum_j p_j \theta_j\right)$$

Three contributions to the discreteness-of-charge energy may be distinguished, namely, the self-image energy, $\xi_{i,s}^r$, the exclusion disc energy, $\xi_{i,d}^r$, and the contribution due to local ion pairing, $\xi_{i,p}^r$. In order to estimate these energies, a fairly detailed model of the dielectric properties of the double layer must be specified. These models have been described in detail in previous papers (6, 10–14, 17) and are only briefly discussed here. It is generally recognized that the average dielectric permittivity ε_i of the inner layer is less than that of the bulk of the solution. The simplest model for the spatial variation in ε with distance from the interface x is to assume that it is constant in the inner layer and changes sharply from its value ε_i in this region to its value in the bulk ε_s at the o.H.p. A value for ε_i may be estimated from data for the integral capacity of the inner layer K_i on the basis of an assumed inner layer thickness x_d. In a more detailed model, it is assumed that the dielectric permittivity increases in two steps, from its lowest average value ε_1 in the inner part of the inner layer, to a value ε_2 in the outer zone, and then to the bulk value ε_s (Fig. 1*a*). The plane dividing the inner layer into inner and outer zones is the i.H.p. If one assumes values for the thickness of these regions, one may estimate ε_1 and ε_2 from the corresponding integral inner layer capacities K_1 and K_2; the latter quantities can be determined from experiment in the presence of significant ionic specific adsorption (20). The most detailed model used until now requires that ε change in a continuous and smooth manner with distance from the interface (Fig. 1*b*). Although the last approach is necessary if one wishes to avoid physically meaningless infinities in the estimation of the discreteness-of-charge potential due to the self-image effect (17), it cannot be tested experimentally at present. In fact, introduction of a molecular approach to this problem would be much more preferable to the presently used continuum concepts in a region of space whose thickness corresponds to that for several molecules.

The present paper is concerned mainly with the role of the exclusion disc term in the discreteness-of-charge energy. On the basis of previous theoretical work in which a continuous variation in ε with distance in the inner layer was assumed (Fig. 1*b*), it has been shown that the self-image contribution is small provided the reactant and/or product are not closer to the electrode than the i.H.p. in the transition state (14, 17). When an ion enters the region of lower dielectric permittivity near the electrode it experiences the stabilizing effect of the images formed in the electrode and in the diffuse layer. On the other hand, work must be done to take the ion from a region of higher dielectric permittivity to a region where it is lower. On the basis of reasonable models, these two effects cancel one another, and $\xi_{i,s}^r$ may be neglected for a reacting system which interacts weakly with the electrode. Estimation of the contribution to discreteness-of-charge energy due to ion pairing also requires a detailed knowledge of the dielectric properties of the region of the double layer near the electrode and of the sizes of the interacting ions (6, 7). This contribution is definitely not negligible but will be treated here in a qualitative manner only. In conclusion, the total discreteness-of-charge energy is approximately given by the relation

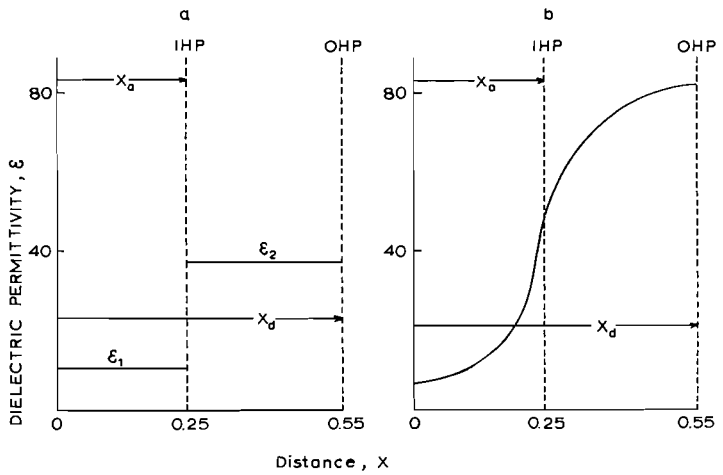

FIG. 1. Dielectric permittivity of the inner layer according to the discontinuous model (*a*) with dielectric constants ε_1 and ε_2 in the inner and outer zones, respectively, and according to the continuous model (*b*). The positions of the i.H.p. and o.H.p. are arbitrarily set at 0.25 and 0.55 nm respectively.

[4] $\xi_i^r = \xi_{i,d}^r + \xi_{i,p}^r$

The important result of the exclusion disc effect is that the neglect of the discrete nature of ions near the electrode leads to a serious overestimation of ion–ion interactions when these are estimated on the basis of the electrostatic potential calculated from a one-dimensional solution of the Poisson–Boltzmann equation. This effect has most often been treated for the case that all ions near the electrode are located on the i.H.p. (3, 4). However, the necessary electrostatic relations have been given for the case that all ions are not located on one plane (10), and the consequences considered for the case of simple electrode kinetics (1). These consequences are examined in more detail below.

When the r.p. is coincident with the i.H.p., the average potential on this plane is given by

[5] $$\phi^r = \phi^d + \frac{\sigma_m + \sigma_a}{K_2}$$

where ϕ^d is the average potential on the o.H.p., σ_m, the charge density on the metal electrode, and σ_a, that due to ions adsorbed on the i.H.p. It is more convenient to express ϕ^r in terms of the potential drop across the inner layer, $\phi^m - \phi^d$ rather than the electrode charge density σ_m. Using the relationship (see Fig. 1)

[6] $$\phi^m - \phi^d = \frac{\sigma_m}{K_i} + \frac{\sigma_a}{K_2}$$

it is easily shown that

[7] $$\phi^r = \phi^d + \lambda(\phi^m - \phi^d) + \frac{(1 - \lambda)\sigma_a}{K_2}$$

where $\lambda = K_i/K_2$. From the work of Levine *et al.* (8, 10, 12), the exclusion disc potential ζ_d^r on the basis of the discontinuous model (Fig. 1*a*) is given by

[8] $$\zeta_d^r = \frac{-K_i}{K_1 K_2} g\sigma_a$$

where g is a dimensionless factor close to unity and given by

[9] $$g = \frac{C_d + K_2}{C_d + K_i}$$

C_d being the differential capacity of the diffuse layer. Robinson and Levine (13) have shown that the estimate of ζ_d^r is not sensitive to the model chosen for ε in the inner layer. Thus, the discontinuous description of ε is assumed to suffice for the estimation of ζ_d^r. The discreteness-of-charge potential on the i.H.p. neglecting ion pairing is given by

[10] $$\psi^r = \phi^r + \zeta^r = \phi^d + \lambda(\phi^m - \phi^a) + \frac{(1 - \lambda)(1 - g)\sigma_a}{K_2}$$

Since g is close to unity the last term on the right-hand side of eq. [10] is approximately zero. It follows that the influence of the exclusion disc potential is to reduce greatly the effect of the adsorbed charge density σ_a on the local potential ψ^r.

When the r.p. is located in the inner region of the inner layer ($0 < x_r \leq x_a$), the average potential on the r.p. is given by

[11] $$\phi^r = \frac{\sigma_m}{K_{ra}} + \frac{\sigma_m + \sigma_a}{K_2} + \phi^d = \phi^d + \frac{\sigma_m}{K_{rd}} + \frac{\sigma_a}{K_2}$$

K_{ra} is the integral capacity of the region between the r.p. and i.H.p., and K_{rd}, that between the r.p. and o.H.p. ($1/K_{rd} = 1/K_{ra} + 1/K_2$). Making use of eq. [6], eq. [11] may be rewritten

[12] $$\phi^r = \phi^d + \lambda'(\phi^m - \phi^d) + \frac{(1 - \lambda')\sigma_a}{K_2}$$

where $\lambda' = K_i/K_{rd}$. Equation [12] is identical with eq. [7] once it is realized that λ' is identical to λ when K_{rd} equals K_2. This is indeed the case when the r.p. is coincident with i.H.p. In the inner region the exclusion disc potential is given by (1, 10)

[13] $$\zeta_d^r = \frac{-K_i g}{K_{mr} K_2}\sigma_a = \frac{-(1 - \lambda')g}{K_2}\sigma_a$$

and the discreteness-of-charge potential by

[14] $$\psi^r = \phi^d + \lambda'(\phi^m - \phi^d) + \frac{(1 - \lambda')(1 - g)}{K_2}\sigma_a$$

When the r.p. is located in the outer region of the inner layer ($x_a < x_r \leq x_a$), ϕ^r is given by

[15] $$\phi^r = \phi^d + \frac{\sigma_m + \sigma_a}{K_{rd}}$$

On the basis of the same transformation used above, this may be rewritten

[16] $$\phi^r = \phi^d + \lambda'(\phi^m - \phi^d) - \frac{\lambda'\sigma_a}{K_2} + \frac{\sigma_a}{K_{rd}}$$

In this region, the exclusion disc potential is given by (1, 10)

[17] $$\zeta_d^r = \frac{-(1 - \lambda')g}{K_2}\sigma_a + \frac{\sigma_a}{K_{ar}}$$

When eqs. [16] and [17] are added, the expression obtained for ψ^r is

[18] $$\psi^r = \phi^d + \lambda'(\phi^m - \phi^d) + \frac{(1 - \lambda')(1 - g)\sigma_a}{K_2}$$

On comparing eqs. [11], [14], and [18] it is apparent that the same expression for ψ^r holds for all reaction sites within the inner layer provided $\lambda' = \lambda$. Since the case that the r.p. is coincident with the i.H.p. is a special case in the general problem being treated, the distinction between them is dropped in the following, λ being now defined as K_i/K_{rd}.

The final contribution due to attractive ion–ion interaction in the vicinity of the reaction site results in an increase in the activity of the reactant at the reaction site. Although detailed models have been developed for this effect (6, 7), it will simply be assumed in the present paper that the corresponding contribution to the discreteness-of-charge energy $\xi_{i,p}^r$ is proportional to the charge density of the oppositely charged ion on a plane or planes sufficiently close to the r.p. that ion pair formation is possible. Thus, one may write

[19] $$\xi_{i,p}^r = a_{ij}\sigma_j$$

where σ_j is the charge density of the oppositely charged ion in the vicinity of the r.p., and a_{ij}, the interaction parameter which depends on the dielectric properties of the inner layer, and thus, on electrode potential. In the case that the ion involved in attractive ion–ion interactions is adsorbed, then $\sigma_j = \sigma_a$. On the other hand, the ion involved may be the predominant ion in the region of the o.H.p. in which case $\sigma_j = \sigma_d$; σ_d represents the number density of these ions in a region close to the o.H.p. in which attractive ion–ion interactions are important for the ions of the reaction couple (Fig. 2). Estimation of σ_d is difficult but a reasonable approximate value may be calculated from Gouy-Chapman theory. Accordingly, the potential in the diffuse layer as a function of distance from the interface, x, for a 1-1 electrolyte is given by

[20] $$\phi = \frac{2}{f}\ln\left[\frac{1 + t\exp\left[-\kappa(x - x_d)\right]}{1 - t\exp\left[-\kappa(x - x_d)\right]}\right]$$

where $t = \tanh(f\phi^d/4)$, x_d is the distance of the o.H.p. from the interface, κ is the reciprocal Debye–Hückel length, and $f = F/RT$. The charge density σ_d may be estimated using the equation

[21] $$\sigma_d = z_i F c_s \int_{x_d}^{x} \exp\left(-z_i f\phi\right) dx$$

where c_s is the concentration of the 1-1 electrolyte. When ϕ^d is negative and cations predominate at the o.H.p. ($z_i = 1$), solution of eq. [21] using the Gouy–Chapman expression for ϕ (eq. [20]) gives the following result:

[22] $$\sigma_d = A\left[\frac{\kappa r}{2} + \coth\left(-\frac{\ln t}{2}\right) - \coth\left(\frac{\kappa r}{2} - \frac{\ln t}{2}\right)\right]$$

where $A = (2RT\varepsilon\varepsilon_0 c_s)^{1/2}$ and $r = x - x_d$, ε being the dielectric constant of the solvent and ε_0, the permittivity of free space. Plots of σ_d against the potential drop across the inner layer, $\phi^m - \phi^d$ for various values of r and c_s are illustrated in Fig. 3. It is clear that σ_d is not a linear function of $\phi^m - \phi^d$ but no potential regions are found where σ_d changes sharply with $\phi^m - \phi^d$. On the other hand, the value

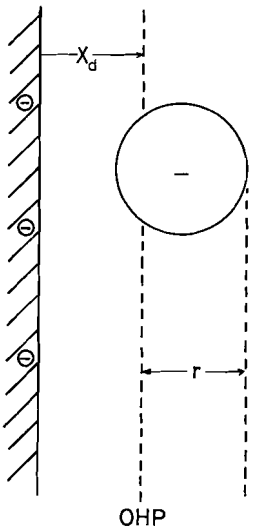

FIG. 2. Schematic diagram showing an anion at its reaction site in the double layer and indicating the thickness of the inner layer (position of o.H.p.) and effective distance for ion pairing in the diffuse layer, r.

of σ_d changes greatly with ϕ^d at constant salt concentration (Fig. 4). As will be seen below, this result has important consequences in the interpretation of the effects of ion–ion interactions on kinetic parameters.

As pointed out previously (1), it is much more convenient to define an effective local activity coefficient γ_i^e which accounts for the departure of the local potential at the reaction site from the average potential on the o.H.p. This choice is made in view of the traditional treatment of double layer effects which dates from the work of Frumkin (21) and which assumes that the r.p. is coincident with the o.H.p. In addition, reasonable estimates of the average potential drop across the diffuse layer may be made using the Gouy–Chapman theory. Accordingly, one writes the electrochemical potential of species i as

$$[23] \quad \tilde{\mu}_i = \mu_i^0 + RT \ln \gamma_i^e c_i^r + z_i F \phi^d$$

where

$$[24] \quad \ln \gamma_i^e = \ln \gamma_i^r + z_i f(\phi^r - \phi^d)$$

$$= z_i f \lambda (\phi^m - \phi^d) + \frac{z_i f (1-\lambda)(1-g)}{K_2} \sigma_a + \frac{a_{ij}\sigma_j}{RT} + \frac{w_i}{RT} - p_i \ln \left(1 - \sum_j p_j \theta_j\right)$$

In conclusion, on the basis of the above derivation, it is clear that one expression applies to the discreteness-of-charge effect in the inner layer, independent of the position of the r.p. with respect to the i.H.p. and o.H.p. Changes in the dielectric properties of the inner region, and of the relative positions of the r.p., i.H.p., and o.H.p. due to change in the nature of the non-reacting ions in the double layer will result in changes in λ, a_{ij}, and to a lesser extent, g. Thus, the activity coefficient γ_i^e is a complex function of electrode potential. However, in certain limiting cases where simplifying assumptions can be made, it is possible to neglect variation in one or more of the contributions to γ_i^e and thus, analyze one aspect of the discreteness-of-charge effect in more detail.

Analysis of Kinetic Data for Simple Electrode Reactions

In the case of the simple electrode reaction

$$[25] \quad A + e \longrightarrow B$$

the expression for the rate of the forward reaction with consideration of local activity coefficients is (1)

$$[26] \quad \ln \vec{v} = \ln k_c + \ln (\gamma_A^s c_A^s) - \ln \gamma_{\pm}^e + (\alpha - z_A) f \phi^d - \alpha f \phi^m$$

where k_c is the potential independent part of the rate contant, γ_A^s, the activity coefficient for reactant A in the bulk of the solution, c_A^s, its bulk concentration, $\gamma_{\pm}^e$, the local effective activity coefficient of the activated complex, and α, the intrinsic transfer coefficient. On the basis of the Bronsted relation, the activity coefficient $\gamma_{\pm}^e$ is given by

$$[27] \quad \ln \gamma_{\pm}^e = (1 - \alpha) \ln \gamma_A^e + \alpha \ln \gamma_B^e$$

Defining the forward rate constant $\vec{k}$ with respect to the bulk reactant concentration ($\vec{k} = \vec{v}/c_A^s$), the logarithm of the rate constant corrected for the effect of the diffuse layer on reactant concentration may be written

$$[28] \quad \ln \vec{k} + z_A f \phi^d = \ln k_c + \ln (\gamma_A^s/\gamma_{\pm}^e) + \alpha f (\phi^d - \phi^m)$$

From eq. [28], the slope of a corrected Tafel plot, that is, a plot of $\ln \vec{k} + z_A f \phi^d$ against $\phi^d - \phi^m$ gives the apparent transfer coefficient defined as

$$[29] \quad \alpha_a = \frac{\partial(\ln \vec{k} + z_A f \phi^d)}{f \partial(\phi^d - \phi^m)} = \alpha - \frac{\partial \ln \gamma_{\pm}^e}{f \partial(\phi^d - \phi^m)}$$

It is of interest to examine the difference in the apparent and intrinsic transfer coefficients in more detail insofar as discreteness-of-charge effects are concerned.

For Type I reactions occuring in the absence of ionic specific adsorption, local ion pairing is negli-

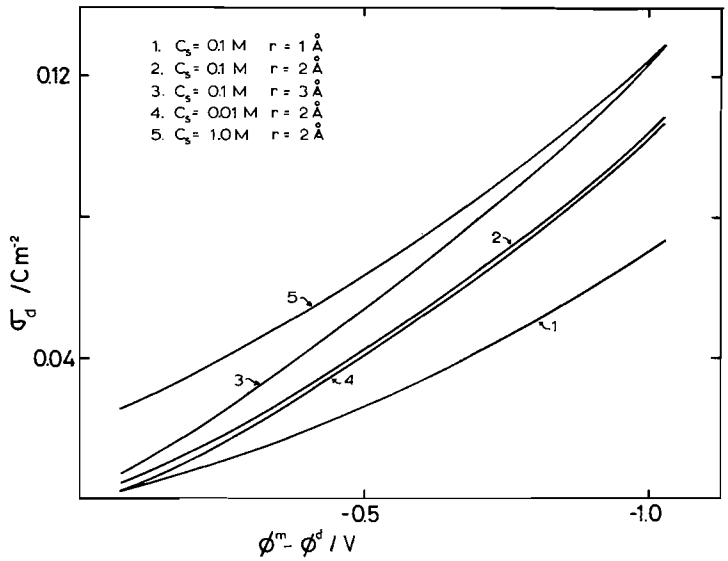

FIG. 3. Plot of the charge density σ_d in the diffuse layer adjacent to an ion at its reaction site which is positioned such that it can interact with ions in the diffuse layer a distance r from the outer Helmholtz plane. The values of r are 1 Å (*1*), 2 Å (*2*, *4*, *5*), and 3 Å (*3*). The concentration of the base electrolyte is 0.01 *M* for (*4*), 0.1 *M* for (*1*, *2*, *3*) and 1.0 *M* for (*5*).

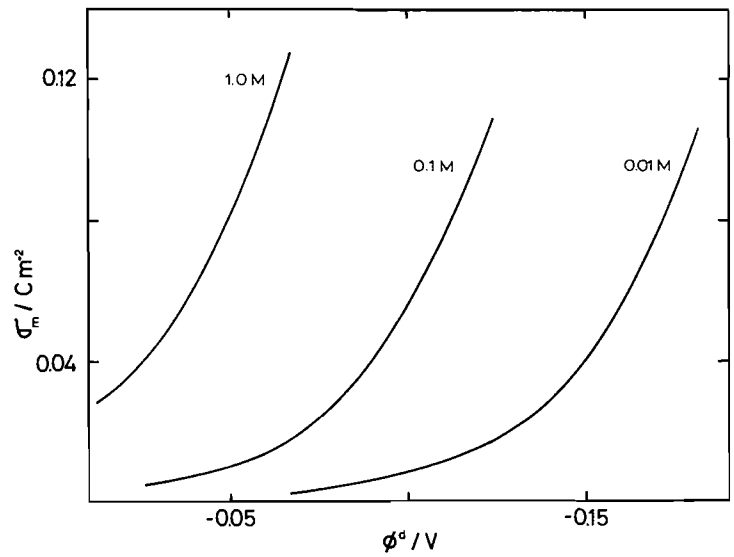

FIG. 4. Plot of the charge density σ_d in the diffuse layer adjacent to an ion at its reaction site which is positioned such that it can interact with ions in the diffuse layer a distance r (r = 2 Å) from the outer Helmholtz plane, as a function of the potential drop across the diffuse layer ϕ^d. The concentration of the electrolyte is indicated on the figure.

gible and the local activity complex in the case of weak interaction is given by

$$[30] \quad \ln \gamma_{\pm}^{e} = z_{\pm} f\lambda(\phi^m - \phi^d)$$

Within the context of the transition state model of electron transfer kinetics, $z_{\pm} = z_A - \alpha$ for a one electron reduction process. Then, from eq. [29], the apparent transfer coefficient may be written

$$[31] \quad \alpha_a = \alpha + \lambda(z_A - \alpha)$$

This expression was first derived by Frumkin in connection with the analysis of data for the electroreduction of H^+ at Hg (22) and can be used to explain the dependence of α_a on the nature of the inert cation in this reaction system (23). The effects of the nature of the alkali metal cation on the kinetic parameters for the electroreduction of H^+ have been discussed in more detail elsewhere (1, 23).

For a Type II reaction, for instance, the electroreduction of anions at negatively charged electrodes, the local activity coefficient is given by

$$[32] \quad \ln \gamma_{\pm}^{e} = z_{\pm} f \lambda (\phi^{m} - \phi^{d}) + \frac{a_{\pm}\sigma_{d}}{RT}$$

where $a_{\pm}$ is the interaction parameter for the activated complex. Because attractive ion–ion interactions occur between the reacting anion and surrounding cations in the diffuse layer, $a_{\pm}$ is negative. The apparent transfer coefficient in this case is

$$[33] \quad \alpha_{a} = \alpha + \lambda(z_{A} - \alpha) + \frac{\partial(a_{\pm}\sigma_{d})}{F\partial(\phi^{d} - \phi^{m})}$$

Both the size term and interaction term in this expression are negative and result in values of α_a which are less than α. Since $\partial\sigma_d/\partial(\phi^d - \phi^m)$ is not constant, it is highly probable that the interaction term results in some potential dependence of the apparent transfer coefficient α_a. Potential dependence of α_a is clearly seen with data for the electroreduction of peroxydisulphate anion (24). It was previously suggested that curvature of the corrected Tafel plots could be attributed to an electrostrictive effect (change in λ with electrode potential) (25). However, this effect cannot explain the observed dependence of the heat of activation on the nature of the non-reacting cation (26) and probably is not quantitatively important. In conclusion, the large cation effects observed for kinetic data involving the electroreduction of anions can be attributed largely to the interaction term as suggested earlier by Frumkin (24, 26).

When non-reacting anions are adsorbed at the electrode under conditions for which the potential drop across the inner layer remains negative, the double layer conditions correspond to those for Type III reactions. In the case of a cation reacting in such an atmosphere (Type IIIA), the local activity coefficient is

$$[34] \quad \ln \gamma_{\pm}^{e} = z_{\pm} f \lambda (\phi^{m} - \phi^{d}) + \frac{z_{\pm} f (1 - \lambda)(1 - g)}{K_{2}} \sigma_{a} + \frac{a_{\pm}\sigma_{a}}{RT} + \frac{w_{\pm}}{RT} - p_{\pm} \ln (1 - \sigma_{a}/\sigma_{am})$$

where σ_{am} is the maximum charge density due to the adsorbed non-reacting ions. Although the expression for $\gamma_{\pm}^{e}$ is rather complex, it is clear that this quantity is a function of two variables, namely, $\phi^m - \phi^d$ and σ_a. When the reacting system interacts weakly with the electrode, or when interfacial solvent molecules are not involved in the reaction mechanism, the last two terms in eq. [34] are negligible. The interaction coefficient $a_{\pm}$ for the cationic system in the presence of adsorbed anions (σ_a is negative) is a positive number indicating that $\gamma_{\pm}^{e}$ decreases with increase in adsorbed anion charge density, and the reaction rate increases.

The analysis of the effects of specifically adsorbed ions is facilitated if a comparison is made between the rates of a given reaction in the absence and presence of the adsorbed species, the ionic strength of the solution, or more precisely, the bulk activities of the ions in the reaction couple, being maintained constant. From the above, the difference between the logarithms of the rate constants corrected for the diffuse layer effect at constant $\phi^m - \phi^d$ is given by

$$[35] \quad \Delta = [(\ln \vec{k} + z_{A} f \phi^{d}) - (\ln \vec{k} + z_{A} f \phi^{d})_{0}]_{\phi^{m} - \phi^{d}} = [(\ln \gamma_{\pm}^{e})_{0} - (\ln \gamma_{\pm}^{e})]_{\phi^{m} - \phi^{d}}$$

where the subscript 0 refers to the system with no adsorbing ions. On the basis of eqs. [30] and [34], Δ is given by

$$[36] \quad \Delta = -\frac{z_{\pm} f (1 - \lambda)(1 - g)}{K_{2}} \sigma_{a} - \frac{a_{\pm}\sigma_{a}}{RT} + p_{\pm} \ln (1 - \sigma_{a}/\sigma_{am})$$

and is a function of σ_a only. The comparison described here was first suggested by Parsons (27) in a somewhat different manner, that is, without consideration of diffuse layer effects. Parsons showed that the acceleration of the electroreduction of hydrogen at Hg by adsorbed halide ions is a function of adsorbed anion charge density when kinetic data are compared at constant electrode potential. The accelerating effect increases in the order $I^- < Br^- < Cl^-$ which suggests that the interaction term involving $a_{\pm}$ is the most important; as the radius of the adsorbed anion decreases, its ability to influence the local potential at the reaction site becomes stronger.

Detailed studies of the effects of ionic specific adsorption on the electroreduction of hexaquochromium(III) (28, 29) and a variety of other cationic complexes of Cr(III) (30–32) have been described in the literature. In the case of hexaquochromium(III), the accelerating effect of adsorbed anions is accounted for by the classical double layer correction which suggests that the reaction site is at the o.H.p. or further away in the diffuse layer (28, 32). In the case of hexamminochromium(III), the accelerating effect of adsorbed anions is significantly larger than that for $Cr(H_2O)_6^{3+}$ which suggests that the reaction site is closer to the electrode and that discreteness-of-charge effects may be important (32). In the case that the complex

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

cation contains an anionic ligand which is adsorbable at the electrode, the effects of specifically adsorbed non-reacting ions result in deceleration of the reaction rather than acceleration (30–32). These results clearly show that models in which the components of the reaction system are treated as point charges are unable to describe the observed double layer effects. One method of treating this result is to consider the reactant as two contiguous charged spheres, the adsorbed anionic ligand being one and the central transition metal cation the other. Since the anion is closer to the electrode, it experiences a larger repulsion effect from coadsorbed non-reacting anions; the more distant cation correspondingly experiences less attraction from the same species (30). Alternatively, the reacting system may be treated as a point charge and dipole, the electrostatic effects on these components acting in opposite directions (33).

The reduction of anions in the presence of adsorbed non-reacting anions is the most complex double layer effect to be considered here (Type IIIB). In this case the local activity coefficient is given by

$$[37]\quad \ln \gamma_{\pm}^{e} = z_{\pm} f\lambda(\phi^{m} - \phi^{d}) + \frac{z_{\pm} f(1-\lambda)(1-g)\sigma_{a}}{K_{2}} + \frac{a_{\pm}\sigma_{d}}{RT} + \frac{w_{\pm}}{RT} - p_{\pm}\ln(1-\sigma_{a}/\sigma_{am})$$

$\gamma_{\pm}^{e}$ is now a function of three variables, namely, $\phi^{m} - \phi^{d}$, σ_{a} and σ_{d}. The advantages of comparing reaction rates in the presence and absence of adsorbed non-reacting ions discussed above for Type IIIA reactions no longer hold; since ϕ^{d}, and thus, σ_{d} change significantly with changes in σ_{a} at constant $\phi^{m} - \phi^{d}$, quantitative separation of the factors contributing to the change in the local activity coefficient is difficult to make. On the basis of eqs. [32] and [37],

$$[38]\quad \Delta = -z_{\pm} f(1-\lambda)(1-f)\sigma_{a} + \frac{(a_{\pm}\sigma_{d})}{RT} - \frac{a_{\pm}\sigma_{d}}{RT} + p_{\pm}\ln(1-\sigma_{a}/\sigma_{am})$$

The role of discreteness-of-charge effects in the kinetics of electroreduction of periodate ion at high pH

$$[39]\quad H_{3}IO_{6}^{2-} + 2e \longrightarrow IO_{3}^{-} + 3OH^{-}$$

has been discussed previously (34) and is reassessed here on the basis of the above analysis. As one would expect, the adsorption of anions, in this particular case, toluene-*p*-sulphonate (TPS), lowers the rate of reaction at constant electrode potential when the bulk concentration of the adsorbing anion is increased at constant ionic strength (34). The variation in the logarithm of the rate constant corrected for the diffuse layer effect, $\ln \vec{k} + z_{A} f\phi^{d}$, is shown as a function of the adsorbed charge density σ_{a} in Fig. 5. It is clear that the corrected rate constant *increases* with increase in σ_{a} at lower coverages; as coverage increases, the entropic term which accounts for the loss in interfacial water molecules becomes dominant and the corrected rate constant decreases at high coverage. When the logarithm of the rate constant is corrected for both the diffuse layer and the entropic terms (Fig. 6), a continuous increase in the function $\ln \vec{k} + z_{A} f\phi^{d} - p_{A}\ln(1-\sigma_{a}/\sigma_{am})$ is observed. On the basis of the analysis of the equilibrium double layer data for the TPS system, σ_{am} is assumed to be -0.17 C m^{-2} and $p_{A} = 1$.[1] The increase in the corrected rate constant can be attributed to two factors. Firstly, since the parameter g is slightly greater than unity (34), the local potential at the reaction site is slightly more positive than the value estimated on the assumption that the potential in the inner layer changes linearly with the *average* potential drop in that region, $\phi^{m} - \phi^{d}$. In assessing this conclusion, one should keep in mind that if discreteness-of-charge effects were ignored, one would conclude that the potential at the reaction site should be considerably more negative in the presence of specifically adsorbed anions than it is in their absence. It follows that the decelerating effect of adsorbed anions on an anionic reacting system would be much greater than that observed if the charged species near the interface were not discrete. The second effect resulting in reaction acceleration with increase in σ_{a} at constant $\phi^{m} - \phi^{d}$ follows from the fact that ϕ^{d}, and thus, σ_{d} also increase; for example, at $\phi^{m} - \phi^{d} = -0.7$ V, ϕ^{d} changes from -0.035 V in the absence of specific adsorption to -0.074 V when $\sigma_{a} = -0.125$ C m^{-2}. If the interaction parameter $a_{\pm}$ is sufficiently large, a concomitant increase occurs in the rate of the electrode reaction. The best evidence for the presence of an attractive interaction effect is the large change in the corrected rate constant between the system with no TPS and that with the lowest bulk concentration where the change in ϕ^{d} is greatest. For this reason the data for the system

[1] In the previous analysis σ_{am} was assumed to be -0.25 C m^{-2}. Because of the complexities of the TPS system due to reorientation of the anion (35), the method of analysis used earlier can be questioned. The value used in the present analysis is simply the apparent limiting adsorbed charge density at low bulk concentration of TPS under conditions where the adsorbed anion may be assumed to lie flat on the electrode (34, 35)

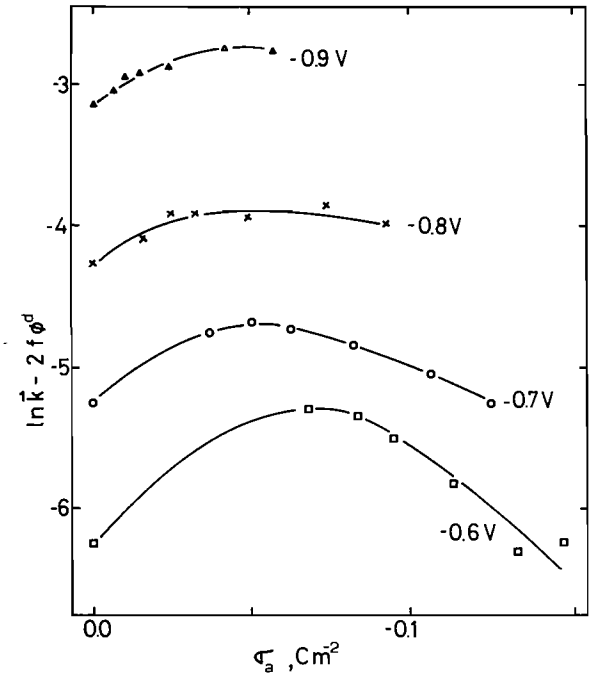

FIG. 5. Plot of the logarithm of the rate constant for the electroreduction of periodate ion corrected for the potential drop across the diffuse layer against charge density due to adsorbed toluene-*p*-sulphonate anion for constant potential drop across the inner layer ($\phi^m - \phi^d$) as indicated.

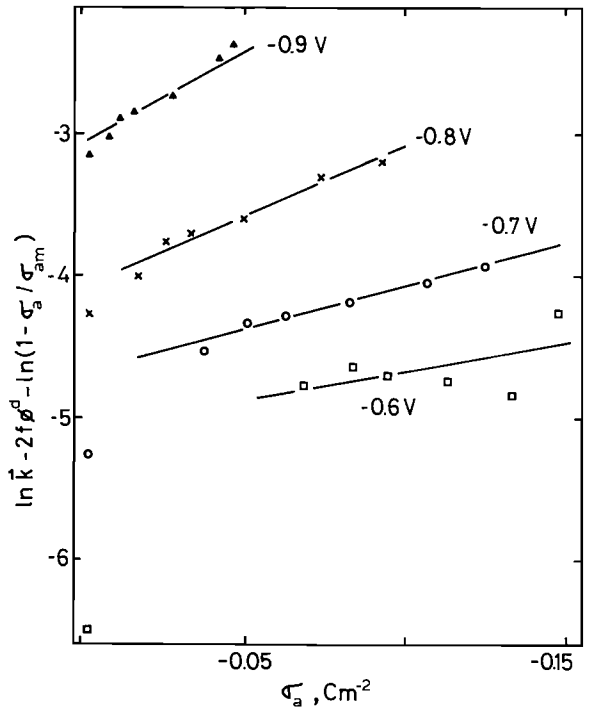

FIG. 6. The data presented in Fig. 5 also corrected for coverage of the electrode by adsorbed toluene-*p*-sulphonate anion.

without TPS were not considered when the straight lines shown in Fig. 6 were constructed. The slope of these lines vary from 4 $m^2\ C^{-1}$ at $\phi^m - \phi^d = -0.6$ V to13 $m^2\ C^{-1}$ at $\phi^m - \phi^d = -0.9$ V. On the basis of the double layer data (34), $f(1 - g)/K_2 \simeq -4\ m^2\ C^{-1}$. Thus, the observed acceleration is of the correct order of magnitude on the basis of the Levine model for discreteness-of-charge effects (8–13). Because of the complexity of this system, no attempt is made here to separate the exclusion disc term from the ion–ion interaction term.

Other studies of the effects of specifically adsorbed anions on the rate of reduction of anions have been carried out by Guidelli and co-workers (36–38). Unfortunately, these experiments were carried out at varying ionic strength so that the role of ion–ion interactions at the reaction site is more complex than that discussed above. In addition, the effect of change in ionic strength on reactant activity was not accounted for. However, the chief criticism which can be made of the previous work (34, 36–38) is that the discreteness-of-charge effects were interpreted assuming that the reaction site is coincident with the i.H.p. This leads to parameters for the inner layer estimated from analysis of the kinetic data which are unrealistic in comparison with similar parameters obtained from analysis of equilibrium data for the interface in the presence of adsorbed anions only.

Discussion

The important conclusion of the above analysis is that the expression derived earlier for the micropotential on the i.H.p. (3) is valid for any location in the inner layer provided that the position parameter λ is recognized to equal the ratio of the total integral capacity of the inner layer to that between the r.p. and o.H.p. The treatment of discreteness-of charge effects discussed earlier (3, 4) in which the r.p. and i.H.p. were assumed to be coincident is therefore a special case of the general problem outlined in this paper. It is also very important to consider the effects of ion–ion interactions separately from the estimation of the exclusion disc contribution to the micropotential (6) and not as part of the exclusion disc contribution (3). Although a quantitative estimate of the ion–ion interaction term cannot be made on the basis of the theory presented in this paper, it is quite clear that this contribution to the total double layer effect is quite important.

Further improvement in the theory of discreteness-of-charge effects must await the development of molecular models of the double layer such as those discussed recently by Blum and Henderson (39) and Carnie and Chan (40). It is obvious that one

of the limitations of the above treatment is that it relies on continuum concepts such as the dielectric permittivity in a region of the double layer a few molecules thick. The availability of these more sophisticated descriptions of the structure of the interfacial region will certainly improve the quantitative description of the effects discussed in this paper. Examination of the literature reveals far too few data which can be effectively tested by the existing theory. The acquisition of more kinetic data illustrating double layer effects would help considerably in improving the present state of understanding.

1. Introduction

The aqueous electric double layer is an extremely complex system so that its theoretical understanding is based on fairly simple models. Usually the double layer is divided into a compact part adjacent to the interface and a diffuse part extending into the electrolyte bulk. The regions are conventionally treated using modifications of the classical Gouy–Chapman–Stern theory (1–3). Gouy and Chapman initiated the theory of the diffuse double layer and they sought to calculate the mean electrostatic potential ψ for a system of point ions in a dielectric continuum. Numerous attempts have since been made to calculate ψ in the diffuse layer using this electrolyte model (4) and the primitive model electrolyte (charged hard spheres moving in a continuous dielectric medium) (5). The compact layer is perhaps more difficult to treat because of the adsorbed solvent and solute molecules which require a detailed treatment of polarisation and structural effects (6–11). Here we consider the effect of modelling the electrolyte by a system of charged hard spheres and dipolar hard spheres. The interface is chosen to be a semi-infinite charged plane wall so that important compact layer effects are neglected. Since the ions and dipoles have a finite size they are restricted in how close they can approach the wall so that there is a simple Stern layer. The chosen electrolyte model is the simplest model of an aqueous electrolyte solution which gives structure to both the solute and solvent molecules. This electrolyte model has been studied in the bulk situation by various authors (12–20).

We follow the bulk idea of ref. 15 and attempt to calculate the properties of the double layer via the mean electrostatic potential ψ. A possible alternative potential approach is suggested by the bulk work of Adelman and Chen (18). Our first step is the formulation of the integral equation and Poisson equation satisfied by ψ. To obtain a closed system of equations a mean field approximation is used which is analogous to that used by Gouy and Chapman. A systematic way of implementing a higher order closure in bulk is given in ref. 15 but we do not consider this extension. Within this mean field approximation the full set of non-linear equations for ψ cannot be completely solved analytically. However the linear equations can be solved and hence the relationship to the Gouy–Chapman theory studied. The dielectric constant ε of the electrolyte solution arises naturally out of the linear theory but unfortunately its value is only applicable to a very dilute dipolar system. The linear theory also predicts the expected Debye shielding in the singlet ion and singlet dipole potential of mean force.

2. Equations Satisfied by ψ

At an arbitrary point $\boldsymbol{r}_1$ in the electric double layer for a fixed surface distribution of molecules the mean electrostatic potential $\psi(1)$ can be expressed as

$$[1] \quad \psi(1) = \psi_m(1) + \sum_t \int [v_t(p, 1) + v_t^*(p, 1)] n^t(p)\, \mathrm{d}(p)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Here $v_t(p, 1)$ is the electrostatic potential at $\boldsymbol{r}_1$ due to the charge distribution of a molecule of species t at $\boldsymbol{r}_p$, $v_t^*(p, 1)$ is the corresponding image potential at $\boldsymbol{r}_1$ due to the molecule of species t at $\boldsymbol{r}_p$, $n^t(p)$ is the mean number density of molecules of type t at $\boldsymbol{r}_p$, the sum in t is over the molecular species while $\mathrm{d}(p) = \mathrm{d}\boldsymbol{r}_p\,\mathrm{d}\boldsymbol{\omega}_p$ where $\mathrm{d}\boldsymbol{r}_p$ denotes the positional elements and $\mathrm{d}\boldsymbol{\omega}_p$ the rotational elements. The electrostatic potential $\psi_m(1)$ comes from the fixed surface distribution and any arbitrary constant is determined by requiring that $\psi(1) \to 0$ at large distances from the interface. For a mobile surface distribution of molecules $\psi_m(1)$ needs to be replaced by an appropriate surface average.

Taking the Laplacian of [1] we obtain the generalised Poisson equation

$$[2] \quad \nabla^2\psi(1) = -4\pi \sum_t \int \left\{ e_t + \sum_{l=1}^{\infty} q_{lt} \left[\prod_{i=1}^{l} (-\hat{\boldsymbol{n}}_{it} \cdot \nabla) \right] \right\} n^t(1, \omega)\,\mathrm{d}\omega$$

since $\nabla^2\psi_m(1) = \nabla^2 v_t^*(p, 1) = 0$. Here e_t is the charge of a molecule of species t, q_{lt} the moment of the multipole of order l of species t and $\hat{\boldsymbol{n}}_{it}$ a unit vector associated with displacing a multipole of order i to obtain a multipole of order $i + 1$. The first term on the right hand side of [2] is simply $-4\pi \times$ (mean charge at $\boldsymbol{r}_1$) while the remaining averaged multipole terms give $-4\pi \times$ (mean apparent charge due to multipole distribution) which is a polarisation term.

For simplicity we now consider the aqueous electrolyte to be modelled by a system of charged hard spheres (the solute) and dipolar hard spheres (the solvent). We denote the charge on an ion of species s by e_s and the dipole moment of the dipole species α by $\boldsymbol{\mu}_\alpha$. The non-aqueous medium forming the interface is assumed to be uniform with the interface being a semi-infinite plane carrying a fixed surface charge density σ. In this situation eqs. [1] and [2] reduce to

$$[3] \quad \psi = \psi_m + \sum_s e_s \int \left(\frac{1}{r_{p_1}} + \frac{f}{r_{p_1}^*} \right) n^s(p)\,\mathrm{d}\boldsymbol{r}_p + \sum_\alpha \int \left(\frac{\boldsymbol{\mu}_\alpha \cdot \boldsymbol{r}_{p_1}}{r_{p_1}^3} + \frac{\boldsymbol{\mu}_\alpha^* \cdot \boldsymbol{r}_{p_1}^*}{r_{p_1}^{*3}} \right) n^\alpha(p)\,\mathrm{d}(p)$$

$$[4] \quad \nabla^2\psi = -4\pi \sum_s e_s n^s(1) + 4\pi \sum_\alpha \int \boldsymbol{\mu}_\alpha \cdot \nabla n^\alpha(1, \omega)\,\mathrm{d}\omega$$

where ψ and ψ_m are functions only of the perpendicular distance x_1 from the wall into the electrolyte, the sums in s and α are over the ion and dipole species respectively, fe_s is the image charge of e_s, $\boldsymbol{\mu}_\alpha^*$ the image dipole of $\boldsymbol{\mu}_\alpha$, $\boldsymbol{r}_{p_1}^*$ the distance of the image point in the wall from $\boldsymbol{r}_1$ and $n^s(p)$, $n^\alpha(p)$ the mean number density of ions and dipoles at $\boldsymbol{r}_p$ respectively. Also from symmetry considerations we have that $n^s(1) = n^s(x_1)$ and $n^\alpha(1, \omega) = n^\alpha(x_1, \omega)$.

The wall charge σ gives rise to an equal and opposite double layer charge so that we also have the overall neutrality condition

$$[5] \quad \sum_s e_s \int_0^\infty n^s(x)\,\mathrm{d}x = -\sigma$$

Note that this does not contradict the Poisson equation [4] as the integral over the apparent charge vanishes.

We now introduce cylindrical polar coordinates to simplify the integrals occurring in eq. [3]. Noting that $r_{p_1}^{*2} = 4x_1x_p + r_{p_1}^2$, $\mathrm{d}\boldsymbol{r}_p = r_p\,\mathrm{d}r_p\,\mathrm{d}\phi\,\mathrm{d}x_p$ and integrating with respect to ϕ and r_p leads to

$$[6] \quad \psi = \psi_m - \lim_{R\to\infty} 2\pi \sum_s e_s \int_0^\infty n^s(x)[|x_1 - x| + f(x + x_1) - \sqrt{(x_1 - x)^2 + R^2}$$
$$- f\sqrt{(x + x_1)^2 + R^2}]\,\mathrm{d}x - \lim_{R\to\infty} 2\pi \sum_\alpha \int\int_0^\infty n^\alpha(x, \omega) \left\{ \mu_{\alpha x} \left[\frac{x - x_1}{|x_1 - x|} - \frac{1}{\sqrt{(x_1 - x)^2 + R^2}} \right] \right.$$
$$\left. + \mu_{\alpha x}^* \left[1 - \frac{1}{\sqrt{(x + x_1)^2 + R^2}} \right] \right\} \mathrm{d}x\,\mathrm{d}\omega$$

where $x = x_p$, $\mu_{\alpha x}$ is the component of $\boldsymbol{\mu}_\alpha$ in the x-direction and $\mu_{\alpha x}^*$ is the component of $\boldsymbol{\mu}_\alpha^*$ in the x-direction.

Now for large R,

$$[7]\quad 2\pi\sum_s e_s\int_0^\infty n^s(x)[\sqrt{(x_1-x)^2+R^2}+f\sqrt{(x+x_1)^2+R^2}]\,dx \sim 2\pi R(1+f)\sum_s e_s\int_0^\infty n^s(x)\,dx = -2\pi R\sigma(1+f)$$

so we can discard this term in [6] as it is simply an additive (although infinite) constant. The other limit in the dipole term of [6] containing R vanishes and so

$$[8]\quad \psi = \psi_m - 2\pi\sum_s e_s\int_0^\infty n^s(x)[|x_1-x|+f(x+x_1)]\,dx - 2\pi\sum_\alpha\int\int_0^\infty n^\alpha(x,\boldsymbol{\omega})\left[\mu_{\alpha x}\frac{(x-x_1)}{|x_1-x|}+\mu_{\alpha x}^*\right]dx\,d\boldsymbol{\omega}$$

To determine ψ_m we use the condition that $\psi \to 0$ as $x_1 \to \infty$. This yields the expected linear form

$$[9]\quad \psi_m = 2\pi(f-1)\sum_s e_s\int_0^\infty xn^s(x)\,dx + 2\pi\sum_\alpha\int\int_0^\infty(-\mu_{\alpha x}+\mu_{\alpha x}^*)n^\alpha(x,\boldsymbol{\omega})\,dx\,d\boldsymbol{\omega} - 2\pi\sigma(1+f)x_1$$

Hence the integral equation for ψ can be written as

$$[10]\quad \psi = -2\pi\sum_s e_s\int_0^\infty n^s(x)[|x_1-x|-x_1+x]\,dx - 2\pi\sum_\alpha\int\int_0^\infty \mu_{\alpha x}n^\alpha(x,\boldsymbol{\omega})\left[\frac{(x-x_1)}{|x_1-x|}+1\right]dx\,d\boldsymbol{\omega}$$

which does not explicitly contain the image terms.

If the ions of species s have radii a_s and the dipoles of species α have radii a_α, then

$$[11]\quad \psi = -4\pi\sum_s e_s\int_{\max(a_s,x_1)}^\infty (x-x_1)n^s(x)\,dx - 4\pi\sum_\alpha\int\int_{\max(a_\alpha,x_1)}^\infty \mu_{\alpha x}n^\alpha(x,\boldsymbol{\omega})\,dx\,d\boldsymbol{\omega}$$

The formulae corresponding to the primitive model electrolyte are found by neglecting the dipole terms and dividing the right hand side of eqs. [4], [9]–[11] by the dielectric constant. In calculating ψ we may either use the integral equation [11] or the Poisson equation [4]. The Poisson equation [4] is the usual starting point in the Gouy–Chapman theory and to use it here we have to derive the boundary conditions on ψ. The mean potential is continuous everywhere but considering the derivative of [11]

$$[12]\quad \psi' = 4\pi\sum_s e_s\int_{\max(a_s,x_1)}^\infty n^s(x)\,dx + 4\pi\sum_\alpha H(x_1-a_\alpha)\int\mu_{\alpha x}n^\alpha(x_1,\boldsymbol{\omega})\,d\boldsymbol{\omega}$$

where $H(x)$ is the Heaviside (unit step) function so that ψ' is discontinuous at the distances of nearest approach of the dipoles to the wall. This is expected for at a macroscopic level we have regions of different solvent which could be characterised by different dielectric constants. At a point of discontinuity a_D,

$$[13]\quad \psi_+'(a_D) = \psi_-'(a_D) + 4\pi\sum_\alpha\int\mu_{\alpha x}n^\alpha(a_D,\boldsymbol{\omega})\,d\boldsymbol{\omega}$$

where the sum is over those species with radius a_D. We also see from [12] that $\psi_+'(0) = -4\pi\sigma$.

3. The Mean Field Approximation

To determine ψ through either the integral equation [11] or the Poisson equation [4] requires a knowledge of the functional dependence of $n^s(x)$ and $n^\alpha(x,\boldsymbol{\omega})$ upon ψ. This is a very difficult problem which requires recourse to statistical mechanical considerations. We shall simply consider here the mean field approximation

$$[14]\quad n^s(x) = \begin{cases}0 & x < a_s\\ n_s^0\exp(-\beta e_s\psi) & x > a_s\end{cases}$$

$$[15]\quad n^\alpha(x,\boldsymbol{\omega}) = \begin{cases}0 & x < a_\alpha\\ (n_\alpha^0/4\pi)\exp(-\beta\boldsymbol{\mu}_\alpha\cdot\nabla\psi) & x > a_\alpha\end{cases}$$

which is analogous to that used by Gouy and Chapman. Here n_s^0, n_α^0 are the bulk number densities of the ions and dipoles respectively and $\beta = 1/kT$. From bulk work (15) the approximations in this closure relate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

to the neglect of exclusion volume and fluctuation terms. We further suppose that all the ion species have the same radius a_I and all the dipole species the same radius a_D. With the mean field closure [14], [15], the integration over the dipole orientations can be performed so that the integral equation [11] for ψ is

$$[16]\quad \psi = 4\pi \sum_s e_s n_s^0 \int_{\max(a_I,x_1)}^{\infty} (x_1 - x) \exp(-\beta e_s \psi)\, dx - 4\pi \sum_\alpha n_\alpha^0 \mu_\alpha \times \int_{\max(a_D,x_1)} \left[\frac{\sinh\theta_\alpha - \theta_\alpha \cosh\theta_\alpha}{\theta_\alpha^2}\right] dx \qquad x_1 > 0$$

where $\theta_\alpha = \beta\mu_\alpha\psi'$. Unfortunately we cannot analytically solve this equation for ψ, but we can make some progress in determining ψ via the Poisson equation [4] which is

$$[17]\quad \psi'' = -4\pi H(x_1 - a_I) \sum_s e_s n_s^0 \exp(-\beta e_s\psi) - 4\pi H(x_1 - a_D) \sum_\alpha n_\alpha^0 \mu_\alpha \frac{d}{dx_1}\left[\frac{\theta_\alpha \cosh\theta_\alpha - \sinh\theta_\alpha}{\theta_\alpha^2}\right] \qquad x_1 > 0$$

A first integral of eq. [17] can be readily obtained, so using the conditions that $\psi, \psi' \to 0$ as $x_1 \to \infty$ we have

$$[18]\quad \tfrac{1}{2}\psi'^2 + (4\pi/\beta) \sum_\alpha n_\alpha^0 [(\theta_\alpha \cosh\theta_\alpha - 2\sinh\theta_\alpha + \theta_\alpha)/\theta_\alpha] = (4\pi/\beta) \sum_s n_s^0 [\exp(-\beta e_s\psi) - 1] \qquad x_1 \geq \max(a_I, a_D)$$

If $a_D < x_1 < a_I$ then from the general result [12] or integrating [17]

$$[19]\quad \psi'^3 + 4\pi\sigma\psi'^2 + (4\pi/\beta^2) \sum_\alpha (n_\alpha^0/\mu_\alpha)(\theta_\alpha \cosh\theta_\alpha - \sinh\theta_\alpha) = 0$$

The solution of this equation is $\psi = \eta x_1 + \gamma$ where η is the real root of the transcendental equation for ψ' corresponding to the linear solution and γ is a constant.

Alternatively if $a_I < x_1 < a_D$ then

$$[20]\quad \psi'^2 = (8\pi/\beta) \sum_s n_s^0 [\exp(-\beta e_s\psi) - \exp(-\beta e_s\psi(a_I))] + 16\pi^2\sigma^2$$

which can be formally solved for x_1 in terms of an integral over ψ. In the region next to the wall ψ has the linear form

$$[21]\quad \psi = -4\pi\sigma x_1 + \psi_+(0) \qquad x_1 < \min(a_I, a_D)$$

Thus the solution for ψ devolves upon the integration of eq. [18] and the subsequent fitting of the boundary conditions across a_D and a_I (remembering that $\psi'(a_D)$ is discontinuous, eq. [13]).

Consider now the effect of linearising terms incorporating θ_α. Poisson's equation [17] becomes

$$[22]\quad [1 + H(x_1 - a_D)(4\pi\beta/3) \sum_\alpha \mu_\alpha^2 n_\alpha^0]\psi'' = -4\pi H(x_1 - a_I) \sum_s e_s n_s^0 \exp(-\beta e_s\psi) \qquad x_1 > 0$$

or writing

$$[23]\quad \varepsilon(x_1) = 1 + H(x_1 - a_D)(4\pi\beta/3) \sum_\alpha \mu_\alpha^2 n_\alpha^0$$

we have

$$[24]\quad \psi'' = -[4\pi/\varepsilon(x_1)] \sum_s e_s n_s^0 \exp(-\beta e_s\psi) H(x_1 - a_I)$$

which is simply the Gouy–Chapman equation with dielectric constant $\varepsilon(x_1)$ given by [23]. The expression for $\varepsilon(x_1)$ depends solely upon the parameters of the hard dipolar solvent and in $0 < x_1 < a_D$ takes its vacuum value of unity. Writing $\varepsilon = \varepsilon(x_1)$ for $x_1 > a_D$, we note that this value of ε is the same as that found at the appropriate bulk closure (15) and is unfortunately only applicable to dilute gases. From [13] we have that the boundary condition for ψ' at $x_1 = a_D$ is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

[25] $\varepsilon\psi_+'(a_D) = \psi_-'(a_D)$

Hence in this linearisation approximation ψ can be determined analytically provided (*i*) the Gouy–Chapman equation can be solved and (*ii*) for $a_I < a_D$ eq.[20] is analytically solvable.

If we also linearise the charge terms then ψ can be found in all the cases. In particular if $a_D \leq a_I$ the Poisson equation becomes

[26] $\psi'' = 0$ $\qquad 0 < x_1 < a_I$

[27] $\psi'' = \kappa_1^2\psi$ $\qquad x_1 > a_I$

with the boundary conditions $\psi_+'(0) = -4\pi\sigma$, ψ and $\psi' \to 0$ as $x_1 \to \infty$, ψ continuous everywhere and ψ' continuous everywhere except at $x_1 = a_D$ where [25] holds. Here

[28] $\kappa_1^2 = \kappa_0^2/\varepsilon = (4\pi\beta/\varepsilon)\sum_s e_s^2 n_s^0$

so that κ_1 is the bulk Debye–Hückel constant with ε given by [23]. The solution of [26], [27] satisfying the boundary conditions is

[29] $\psi = -4\pi\sigma x_1 + (4\pi\sigma/\kappa_1\varepsilon)[1 - \kappa_1 a_D + \kappa_1 a_I + \varepsilon\kappa_1 a_D]$ $\qquad 0 < x_1 < a_D$

[30] $\psi = -(4\pi\sigma/\varepsilon)x_1 + (4\pi\sigma/\kappa_1\varepsilon)(1 + \kappa_1 a_I)$ $\qquad a_D < x_1 < a_I$

[31] $\psi = (4\pi\sigma/\varepsilon\kappa_1)\exp[-\kappa_1(x_1 - a_I)]$ $\qquad x_1 > a_I$

As expected the solution for ψ changes in the region close to the wall reflecting the distances of nearest approach of the solute and solvent molecules to the interface. The solution is linear in $0 < x_1 < a_D$ and $a_D < x_1 < a_I$ because of the absence of ionic charge in these regions, while for $x_1 > a_I$ the solution has the familiar damped form. Overall ψ has a monotonic decreasing behaviour for $\sigma > 0$. In the continuum limit ($a_D \to 0$), the solution for ψ is completely equivalent to the linear Gouy–Chapman theory with an effective Stern layer of thickness a_I and dielectric constant ε.

The solution for $a_I \leq a_D$ is of the form

[32] $\psi = -4\pi\sigma x_1 + \delta$ $\qquad 0 < x < a_I$

[33] $\psi = \beta\exp(\kappa_0 x_1) + \gamma\exp(-\kappa_0 x_1)$ $\qquad a_I < x_1 < a_D$

[34] $\psi = \alpha\exp(-\kappa_1 x_1)$ $\qquad x_1 > a_D$

where α, β, γ, δ are somewhat complex constants and nothing is gained by presenting them. The main difference with the solution for $a_D < a_I$ is in the intermediate region $a_I < x_1 < a_D$ where the solution is not linear but a linear combination of exponentials. In this region the interaction between the ions is not reduced by any solvent so that the exponential arguments are functions of κ_0. Again the solution has an overall monotonic behaviour. In the point ion limit ($a_I \to 0$), the linear solution in $0 < x < a_I$ vanishes.

The potentials of mean force W_s, W_α for an ion or dipole respectively in the diffuse layer are

[35] $W_s = e_s\psi = (4\pi\sigma e_s/\varepsilon\kappa_1)\exp(-\kappa_1 x_1)$

[36] $W_\alpha = \boldsymbol{\mu}_\alpha\cdot\nabla\psi = -(4\pi\sigma\mu_{\alpha x}/\varepsilon)\exp(-\kappa_1 x_1)$

on neglecting the hard sphere radii. The potentials of mean force display Debye shielding as in the equivalent bulk analysis (15). Also there is no contribution to the damping from the dipoles since $\kappa_1 = 0$ when all the ions are uncharged. In the bulk analysis a polynomial factor is found in the ion-dipole potential of mean force (15, 17) but no such polynomial (in x_1) occurs in W_α.

4. Conclusion

A preliminary attempt has been made to treat on an equal footing the solute and solvent molecules in the double layer. The theory is based on calculating the mean electrostatic potential ψ in the vicinity of a plane charged wall for a hard sphere ion-dipole system. The implications of a mean field approximation, analogous to that of Gouy and Chapman, have been considered. For the full non-linear system of equations only a first integral of Poisson's equation can be found while on linearising the dipole term the theory reduces to a non-linear theory similar to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

that of Gouy and Chapman. The full set of linear equations are solved and ψ is found to take different forms close to the wall because of the different distances of nearest approach of the ions and dipoles. The dielectric constant ε of the dipolar fluid arises naturally out of the linear theory. Discontinuities occur in ε in the vicinity of the wall due to the finite size of the dipoles, these discontinuities indicating the boundaries of different dielectrics. Regrettably ε is too small because of an inadequate treatment of dipole–dipole interactions.

The value of a numerical solution of the full set of non-linear equations is difficult to assess. We expect the non-linear theory to be inconsistent (in the thermodynamic properties) although a better value of ε may be obtained and perhaps a dependence of ε upon charge found. Any basic progress in the theory must come from a more accurate closure. A method of improving upon the mean field approximation has been given in the bulk (15) where a treatment of the fluctuation potential led to Onsager's ε and a damped oscillatory behaviour in the mean electrostatic potential. We hope to consider corrections along these lines in the future. Many other points need to be considered, for example higher order multipoles or more importantly a treatment of the compact layer. However, we hope that we have indicated a possible way in which the potential approach may be adapted to treat realistically both solute and solvent interactions.

The interaction of two charged spheres in the Poisson–Boltzmann equation

JOSEPH E. LEDBETTER, THOMAS L. CROXTON, AND DONALD A. MCQUARRIE[1]

Department of Chemistry, University of California, Davis, CA 95616, U.S.A.

Received May 22, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

JOSEPH E. LEDBETTER, THOMAS L. CROXTON, and DONALD A. MCQUARRIE. Can. J. Chem. **59**, 1860 (1981).

The Poisson–Boltzmann equation for two large charged spheres immersed in an ionic solution with either constant surface charge density or constant surface potential is solved numerically. The repulsion between the spheres is calculated from the electrostatic potential in the double layer surrounding the spheres. Good agreement between this numerically calculated force and the force computed using the Derjaguin formula for spheres with constant surface charge density is found at small separations of the spheres.

JOSEPH E. LEDBETTER, THOMAS L. CROXTON et DONALD A. MCQUARRIE. Can. J. Chem. **59**, 1860 (1981).

On a résolu numériquement l'équation de Poisson–Boltzmann relative à deux grosses sphères chargées immergées dans une solution ionique ayant soit une densité constante de charge superficielle soit un potentiel de surface constant. On a calculé la répulsion entre les sphères à partir du potentiel électrostatique de la double couche entourant les sphères. Lorsque les distances séparant les sphères sont courtes, on a trouvé un bon accord entre la force calculée numériquement et celle calculée en utilisant la formule de Derjaguin pour les sphères ayant une densité constante de charge superficielle.

[Traduit par le journal]

Introduction

The interaction between large charged particles in an aqueous ionic solution is a problem of central concern in colloid science (1). In particular, it is important to be able to calculate the forces acting between such colloid particles since these forces determine the stability of colloidal suspensions. A knowledge of the electrostatic potential in the double layer surrounding charged colloid particles allows one to calculate the electrostatic component of the force between such particles.

In this paper we consider a model system composed of two charged spheres immersed in a solution of point ions in a uniform dielectric medium. With the usual assumption of a Boltzmann distribution of ions (2), Poisson's equation becomes the well-known Poisson–Boltzmann equation for electrostatic potential in this model. Application of the Poisson–Boltzmann equation to the geometry considered here then becomes a boundary value problem of a second order non-linear partial differential equation. For the geometry of two charged spheres, however, an analytical solution to the Poisson–Boltzmann equation is not possible. We thus present in this paper a numerical solution of the Poisson–Boltzmann equation as applied to two identical large charged spheres in an ionic solution. Surface boundary conditions of constant charge density and constant potential are treated. The electrostatic repulsion between the spheres is calculated from the numerical solution of the potential in the double layer surrounding the particles.

A numerical solution to the Poisson–Boltzmann equation for this problem was first presented by Hoskin and Levine (3) for a constant surface potential boundary condition on the spheres. The accuracy of these calculations was later improved by McCartney and Levine (4). We present here a somewhat different approach to the numerical solution of the Poisson–Boltzmann than has been previously considered. Instead of solving for the total electrostatic potential we solve a differential equation for the correction to an approximate solution to the Poisson–Boltzmann equation. This approach not only results in a simpler numerical problem since the correction to the potential is often a slowly varying function, but it also shows directly the inadequacy of the approximate solution used in the method. Whereas previous numerical solutions have only considered the boundary condition of constant surface potential, our method allows us to also solve the Poisson–Boltzmann equation for spheres of constant surface charge density. These two different boundary conditions yield quite different results, and it is important to have definitive numerical calculations for both cases so that a comparison with approximate solutions to the Poisson–Boltzmann equation can be made. The choice of a particular boundary condition is dependent on the physical system which is to be modeled.

Due to its importance in colloid science, the

Poisson–Boltzmann equation has been well studied and many approximate solutions have been presented (5, 6). It is interesting to note that the linearized Poisson–Boltzmann equation applied to the problem of two interacting charged spheres can be solved exactly (7), but for large surface potentials, this linearized form is no longer valid. For small separations between the interacting spheres, a well-known approximation to the electrostatic force is the Derjaguin formula (8). At larger separations, a common approximation to the potential is the so-called linear superposition approximation (5). Bell *et al.* (5, 6) have combined these two approximations and have shown that the electrostatic repulsion calculated with these approximate methods agrees quite well with the numerical calculations of McCartney and Levine (4) for spheres with constant surface potential. We make a similar comparison at small particle separations of the Derjaguin formula appropriate to spheres of constant surface charge density with our numerical calculation of the force between the particles.

Theory

Consider two identical rigid spherical colloid particles of radius A, whose centers are separated by a distance R, immersed in a solution of point ions of uniform dielectric constant ε. This geometry is shown in Fig. 1*a*. The colloid particles are also assumed to be of uniform dielectric constant equal to that of the electrolyte so that image effects can be ignored. With this model, the mean electrostatic potential in the surrounding double layer is given approximately by the Poisson–Boltzmann equation

$$[1] \quad \nabla^2\psi(r_1, r_2) = (8\pi nze/\varepsilon) \sinh (ze\psi/kT)$$

with the appropriate boundary conditions. In this equation we have assumed a symmetric electrolyte where n is the number density of one type of ion, T is the absolute temperature, k is Boltzmann's constant, and ze is the magnitude of the charge of one ion. Defining the reduced potential and the Debye–Hückel screening constant

$$[2] \quad y = ze\psi/kT$$

$$[3] \quad \kappa = (8\pi nz^2e^2/\varepsilon kT)^{1/2}$$

we can rewrite eq. [1] in reduced form

$$[4] \quad \nabla^2 y = \sinh y$$

In this equation and in all following equations we have reduced all distances by κ. Thus A, R, and r_i are now all reduced by κ.

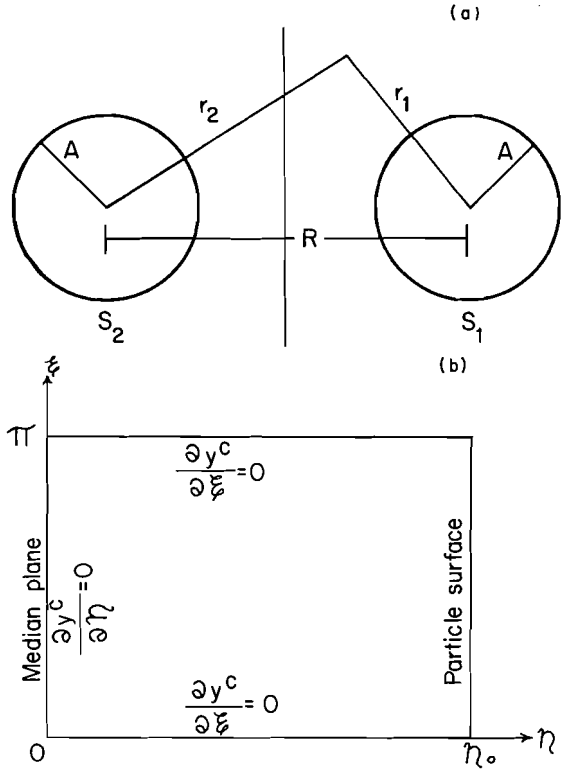

FIG. 1. (*a*) Geometry of two interacting spheres; (*b*) boundary conditions for the correction potential y^c on the half-plane in bispherical coordinates.

Equation [4] could be solved numerically for the total potential y, but we choose instead to formally divide this potential into the sum

$$[5] \quad y(r_1, r_2) = y_1(r_1) + y_2(r_2) + y^c(r_1, r_2) = y^s + y^c$$

The functions $y_i(r_i)$ are arbitrary, but a reasonable approximation to the Poisson–Boltzmann equation is a linear superposition of the potentials due to each sphere (5). We are thus led to choose $y_i(r_i)$ to be the potential due to a single sphere. The correction term $y^c(r_1, r_2)$ clearly goes to zero as the particle separation becomes very large, since the superposition solution $y^s(r_1,r_2)$ better approximates the total potential as the particle separation increases (5, 6). Substitution of eq. [5] into eq. [4] yields a differential equation for $y^c(r_1, r_2)$

$$[6] \quad \nabla^2 y^c = \sinh (y^s + y^c) - [\nabla_{r_1}^2 y_1(r_1) + \nabla_{r_2}^2 y_2(r_2)]$$

where

$$[7] \quad \nabla_{r_i}^2 y_i = r_i^{-2}\, \mathrm{d}(r_i^2\, \mathrm{d}y_i/\mathrm{d}r_i)/\mathrm{d}r_i$$

since $y_i(r_i)$ is spherically symmetric.

Since the electrostatic potential due to a single colloid particle is not known analytically, we choose the excellent approximation to this potential given by Brenner and Roberts (9)

$$[8] \quad y_i(r_i) = y_{DH}/(a_0 - a_3 y_{DH}^3)$$

In this approximation, the parameters a_0 and a_3 are determined by a variational principle associated with the free energy of the single sphere system. y_{DH} is the familiar Debye–Hückel potential

$$[9] \quad y_{DH}(r_i) = y_0 A\{\exp[-(r_i - A)]\}/r_i$$

where y_0 is the (constant) potential on the sphere. Although it is not obvious because we have not written out the forms of a_0 and a_3, if $y_{DH}(A)$ is substituted into eq. [8], we find that $y_i(A) = y_0$. Substitution of the $y_i(r_i)$ given by eq. [8] into eq. [6] gives the differential equation to be solved for $y^c(r_1, r_2)$ once the surface boundary conditions are given.

In the geometry of two charged spheres, it is convenient first to transform the problem into bispherical coordinates. In this system, surfaces of constant η are spheres, and surfaces of constant ξ are either spindles or dimples on the z-axis. For spheres of the same size, it is sufficient to consider the half-space including the median plane ($\eta = 0$) and excluding one sphere (S_1). This space is defined by the rectangle shown in Fig. 1*b*. The particle surface is defined by the spherical surface given by

$$[10] \quad \eta_0 = \cosh^{-1}(r/2A)$$

Also shown in Fig. 1*b* are the boundary conditions on $y^c(\xi,\eta)$ which are required by the symmetry of the problem.

In order to complete the description of this problem, the boundary condition on the sphere ($\eta = \eta_0$) must be given. A fixed surface potential requires

$$[11] \quad y^c(\xi,\eta = \eta_0) = -y_2(r_2)$$

A fixed surface charge density requires that the normal derivative of the potential on the surface of the sphere be proportional to the charge density

$$[12] \quad (\partial y/\partial r_1)_{\eta_0} = -4\pi z e\sigma/\kappa\varepsilon kT = -\sigma^*$$

Using eq. [5] this condition becomes

$$[13] \quad (\partial y^c/\partial r_1)_{\eta_0} = -\sigma^* - [\partial y_1/\partial r_1 + (\partial y_2/\partial r_2)(\partial r_2/\partial r_1)]_{\eta_0}$$

Evaluation of the partial derivatives in this equation yields

$$[14] \quad (\partial y^c/\partial r_1)_{\eta_0} = y_{DH}\left[\frac{r_2 + 1}{r_2}\right] \times \left[\frac{a_0 + 2a_3 y_{DH}^3}{(a_0 - a_3 y_{DH}^3)^2}\right]\left[\frac{r_2^2 + A^2 - R^2}{2r_2 A}\right]$$

where $y_{DH} = y_{DH}(r_2)$, and where we have identified the (uniform) reduced charge density

$$[15] \quad \sigma^* = y_0\left[\frac{A + 1}{A}\right]\left[\frac{a_0 + 2a_3 y_0^3}{(a_0 - a_3 y_0^3)^2}\right]$$

The boundary condition given by eq. [14] may be manipulated to yield a boundary condition for $(\partial y^c/\partial\eta)_{\eta_0}$ in bispherical coordinates.

After expressing the Laplacian in bispherical coordinates, eq. [6] may then be replaced by a standard set of finite difference equations (3, 10). Such a replacement assumes that third and higher order differences are negligible, which is justifiable since $y^c(\xi,\eta)$ is a rather smooth surface. The spherical surface boundary condition is incorporated into this scheme by using a finite difference equation which is appropriate along the $\eta = \eta_0$ line. Alternate line-by-line matrix inversion is performed over lines of constant η and over lines of constant ξ, and this procedure is iterated to a convergent solution.[2] In the calculations presented here, $y^c(\xi,\eta)$ is represented by a grid of 50 × 50 points. Previous numerical solutions (3, 4) have used fewer points.

Once the electrostatic potential is known, the force between the colloid particles may be obtained by an integration of the Maxwell stress over the median plane (3). This reduced force is given by

$$[16] \quad f^* = (8\pi/\varepsilon)(ze/kT)^2 f = 2\pi\int_0^\infty \left[(\partial y/\partial\xi)_{\eta=0} + \frac{2c^2(\cosh y - 1)}{(1 - \cos\xi)^2}\right]\sin\xi\, d\xi$$

where c is a parameter given by

$$[17] \quad c = A\sinh\eta_0$$

It is also convenient to define another reduced force

$$[18] \quad f^{**} = f^*/2\pi A y_0^2$$

A common and apparently successful approximation to the force between two spherical colloid particles which is good only at small separations is

[2]A copy of the computer program used is available from the authors upon request.

For personal use only.

the Derjaguin formula. In this method, the interacting spheres are essentially replaced by sections of charged parallel plates, and the force between the spheres is found to be proportional to the interaction free energy of this sum of parallel plates. For plates with constant surface charge density, the potential of these interacting plates at infinite separation can be related to the charge density by integrating the Poisson–Boltzmann equation for this one-dimensional geometry. The result is

$$[19] \quad \cosh y_\infty = 1 + (\sigma_p^*)/2$$

Derjaguin's method has been used by Bell and Peterson (6) to calculate interaction forces at small separations between spheres of different sizes and different surface boundary conditions. We compare our numerical calculations of the force between spheres with constant surface charge density with the force calculated from the expressions given by Bell and Peterson.

Results and Discussion

Graphs of the reduced force f^{**} versus the separation $\kappa(R - 2A)$ between the two spheres are given in Figs. 2 and 3. Results for both constant charge and constant potential spheres with reduced potentials of 2 and 4 and reduced radii of 5 and 15 are presented. The forces given here for constant potential spheres agree to within 1% with the force calculations of McCartney and Levine (4). For each radius the charge density is related to the constant surface potential through eq. [15]. Although not shown by the data presented here, the surface potential of the spheres with constant surface charge density does approach the corresponding constant potential y_0 in each case to within a few percent at a separation of approximately $\kappa(R - 2A) = 5$. As expected, the force between the spheres of constant charge is always greater than the force between particles of the corresponding constant potential, and the two force curves approach one another with increasing separation.

In the Derjaguin formula, the reduced force f^{**} is independent of the particle radius (6), and Bell *et al.* (5) have noted that the numerical calculations for spheres with constant surface potential (4) support this approximation. A similar comparison of the force curves in Figs. 2 and 3 for different radii reveals that this approximation is also reasonable for spheres of constant surface charge density.

In Fig. 4 the force curve calculated using Derjaguin's formula is compared with the numerical results for $\kappa A = 5$ and a surface charge density on the sphere of $\sigma^* = 2.78$. This charge density

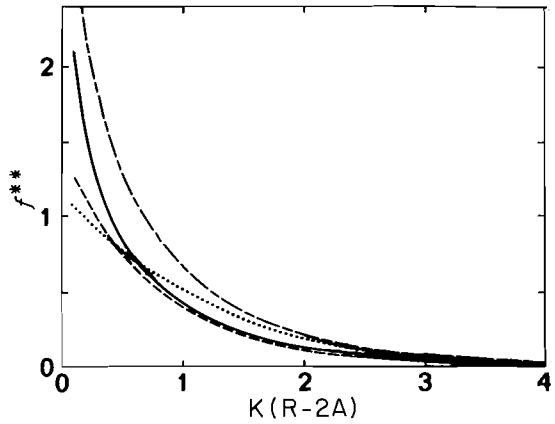

FIG. 2. Force–separation curves plotted as f^{**} versus $\kappa(R - 2A)$ from our numerical solution, for identical spheres with $\kappa A = 5$. The lines ---, —, ···, and ——— are for $y_0 = 4, \sigma^* = 7.91$, $y_0 = 2$, $\sigma^* = 2.78$, respectively. Data with y_0 = constant are for constant surface potential spheres, while data with σ^* = constant are for spheres with constant surface charge density.

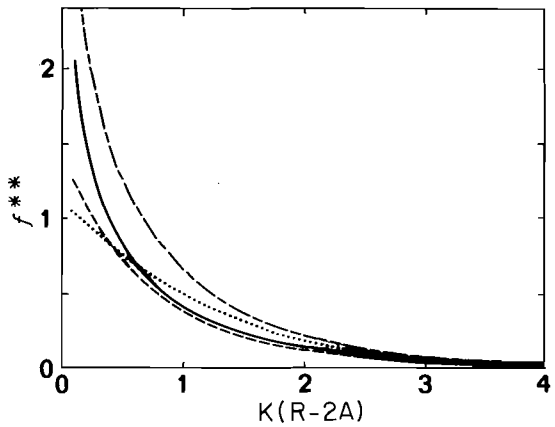

FIG. 3. Similar curves as in Fig. 2 for $\kappa A = 15$. The lines ---, —, ···, and ——— are for $y_0 = 4, \sigma^* = 7.42$, $y_0 = 2$, and $\sigma^* = 2.51$, respectively.

corresponds to a potential at infinite separation of $y_0 = 2$. In the Derjaguin approximation one must use the potential of the plates at infinite separation y_∞, which is related to the constant charge density on the plates by eq. [19]. For a *sphere* of a constant charge density, however, the potential at infinite separation is dependent on the size of the sphere. One must therefore decide whether to use $y_\infty = y_0$, or y_∞ obtained from eq. [19] by setting $\sigma_p^* = \sigma^*$ (constant charge density on the sphere). Figure 4 clearly shows that the correct choice for the potential at infinite separation of the plates is y_0 since good agreement with the numerical calculations of the force is achieved with this identification. Good agreement between Derjaguin's formula

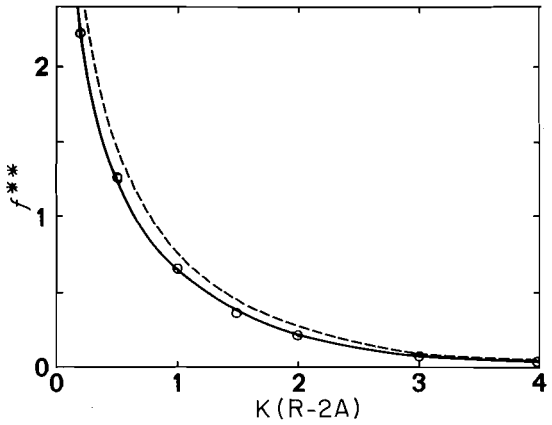

FIG. 4. Comparison of f^{**} calculated from Derjaguin's formula (ref. 6) with our numerical results for $\kappa A = 5$ and $\sigma^* = 2.78$. The lines — and --- are for spheres of constant surface charge density as calculated from Derjaguin's formula with $y_\infty = 2.00$ ($\sigma_p^* = 2.35$) and $y_\infty = 2.26$ ($\sigma_p^* = \sigma^*$), respectively. Circles are the numerical calculations from this work.

and the numerical results for higher reduced potentials and larger spheres is obtained as well with proper choice for y_∞.

In summary, we have presented calculations of the electrostatic repulsion between identical spheres with either constant surface charge density or constant surface potential by numerically solving the Poisson–Boltzmann equation. Forces calculated using the well-known Derjaguin formula appropriate to spheres with constant surface charge density are compared with numerically calculated forces. Good agreement is obtained provided the correct input is used in the Derjaguin method.

Thermodynamics of micellar systems: activity and entropy of sodium decanoate and *n*-alkylamine hydrobromides in water

ROSARIO DE LISI[1], GÉRALD PERRON, JEAN PAQUETTE[2], AND JACQUES E. DESNOYERS[3]

Department of Chemistry, Université de Sherbrooke, Sherbrooke (Que.), Canada J1K 2R1

Received June 16, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

ROSARIO DE LISI, GÉRALD PERRON, JEAN PAQUETTE, and JACQUES E. DESNOYERS. Can. J. Chem. **59**, 1865 (1981).

The freezing-point depressions of aqueous solutions of the homologous series RNH_3Br, where R varies from ethyl to *n*-octyl, and of sodium decanoate were determined and used to calculate osmotic and mean activity coefficients. In the case of the surfactants octylamine hydrobromide and sodium decanoate, the pre- and post-micellar regions were covered. Activity data at higher temperatures were calculated using previously published thermochemical data. Some difficulties arise in the critical micellar region of sodium decanoate at high temperatures as a result of the large concentration and temperature dependence of the heat capacity data. The activities from freezing point data are compared with those obtained from specific electrodes.

ROSARIO DE LISI, GÉRALD PERRON, JEAN PAQUETTE et JACQUES E. DESNOYERS. Can. J. Chem. **59**, 1865 (1981).

Les abaissements du point de congélation des solutions aqueuses des sels de la série homologue RNH_3Br, où R varie de méthyl à *n*-octyl, et du décanoate de sodium ont été mesurés et utilisés pour calculer les coefficients osmotiques et les coefficients d'activité moyenne. Dans le cas du bromhydrate d'octylamine et du décanoate de sodium, les régions pré- et post-micellaires ont été couvertes. Les fonctions d'activité aux températures plus élevées ont été calculées à partir de données thermochimiques. Certaines difficultés sont survenues avec le décanoate de sodium dans la région de micellisation à cause de la très grande variation de la capacité calorifique avec la température et avec la concentration. Les activités obtenues par cryoscopie ont été comparées avec celles venant de mesures de forces électromotrices.

Introduction

This paper is part of a series on the measurement of the complete excess thermodynamic properties of typical cationic, anionic, and nonionic surfactants. The thermodynamic properties of nonyl and decyltrimethylammonium bromides (1, 2), the thermochemical and volumetric properties of sodium decanoate (3), and of the homologous series alkylamine hydrobromides (3–5) have already been published. We will now present activity data for alkylamine hydrobromides and sodium decanoate. From these and the corresponding thermochemical data, the excess free energies and entropies can be calculated as a function of temperature. Our aim is to provide accurate data covering the micellar region for quantitative testing of various models or theories.

In recent years, most of the activity data on surfactants were obtained with the EMF method using various types of specific electrodes (see for example Sasaki *et al.* (6), Cutler *et al.* (7), Kale *et al.* (8), and Vikingstad (9)). The advantage of this approach is that individual ionic activity coefficients can be calculated and thus the degree of counterion binding can be evaluated. However, some questions remain on the absolute accuracy of these techniques in view of the non-Nernstian response of many of these electrodes. With the present surfactants, the critical micelle concentrations are all relatively high and the Krafft temperatures are all below the freezing temperature of water. We therefore felt that the freezing point technique would offer a simple method of evaluating the mean activity data in the pre- and post-micellar regions. This method has been used successfully with alkyltrimethylammonium bromides (2).

While these systems were being investigated it came to our knowledge that Vikingstad (9) had also investigated sodium decanoate with the EMF method. This therefore offered the possibility of comparing activities of surfactants obtained by very different methods.

Experimental

Two techniques were used for freezing point measurements. The homologous series RNH_3Br was investigated with a model 3R Advanced Instruments Osmometer. This technique, which supercools a liquid sample by several degrees, initiates ice nucleation, and measures the temperature at which the change of state takes place, is simple and rapid. It was used successfully to measure the salting out and salting in of alcohols by electrolytes (10, 11). However, it is a relative technique, and these studies (10, 11) have suggested that some error can be introduced in determining osmotic coefficients of solutions of organic ions or molecules. This systematic error cancels with ternary systems but not with binary ones. Measurements with the surfactants octylamine hydrobromide (OABr) and sodium de-

canoate (NaDec) were therefore made with the equilibrium method using a flow densimeter as analytical device, as previously described (12). A comparison of two sets of measurements with OABr can give some idea of the error introduced with the osmometer with these systems.

The origin of chemicals and the purification procedure are the same as in previous studies (3–5). For the osmometric measurements all solutions were prepared by weight. For the equilibrium technique the molality of samples of the solution in equilibrium with ice, prepared with distilled water, were obtained by comparing the density at 25°C with those previously published (3, 4). A few extra density data were obtained to get a good calibration curve and to check the purity of the present salt samples with those used in our previous studies. The data agree inside the expected experimental error.

Results and Discussion

The freezing point data can be used to calculate the osmotic coefficients ϕ, the mean activity coefficients $\gamma_\pm$, and the nonideal free energies $\bar{G}_2^{ni}$ through the following well-known relations (12–14)

$$[1]\quad \phi = \frac{55.51}{\nu m}(0.0042070\theta + 2.1 \times 10^{-6}\theta^2) \times 2.303$$

$$[2]\quad \ln \gamma_\pm = \phi - 1 + \int_0^m (\phi - 1)\, d \ln m$$

$$[3]\quad \bar{G}_2^{ni} = \nu RT \ln \gamma_\pm$$

where θ is the freezing-point depression and ν is the number of ions into which the electrolyte dissociates.

With these relations, the free energy data are obtained at the freezing temperature and can be calculated at any other constant temperature from the known enthalpies of dilution and excess heat capacities (3). The procedure to calculate $\ln \gamma_\pm$ in the micellar region has been reported previously (13). Some of the difficulties encountered should be stressed. Essentially, the integral in eq. [2] has been resolved by splitting it into two contributions and assuming that the Debye–Hückel limiting law (DHLL) was valid up to the lower experimental concentration at which the freezing temperature has been measured (generally about 0.01 m). Use of this approximation can lead to a small difference between the experimental ϕ and the theoretical one, and consequently a discontinuity in the behaviour of $\ln \gamma_\pm$ as a function of m can be obtained at this concentration. The trends observed for the $\ln \gamma_\pm$ of NaDec and other surfactants can be slightly in error due to this approximation.

The nonideal entropies can readily be calculated from the partial molal relative enthalpies $\bar{L}_2$ and $\bar{G}_2^{ni}$

$$[4]\quad \bar{S}_2^{ni} = (\bar{L}_2 - \bar{G}_2^{ni})/T$$

The relative enthalpies can be calculated at any temperature from the heat capacity data (3, 5).

The original freezing-point data are given elsewhere,[4] but a summary of the data for OABr and NaDec at rounded molalities for various temperatures is given in Table 1.

The osmotic coefficients of the homologous series RNH_3Br are shown at 25°C in Fig. 1. All data were obtained with the osmometer with the exception of those of OABr which were determined by both techniques. There is only a small difference between both sets of data for OABr above 0.1 mol kg^{-1} but the difference becomes appreciable at low concentrations.

There is not much difference between the concentration dependence of ϕ for the different homologs but when micellization occurs, as in the case of OABr, ϕ decreases sharply. Similar observations were made in the case of interactions between Bu_4NBr and *tert*-butanol (11). The relative independence of the trends in ϕ on the chain length of the homologs in the pre-micellar region suggests that the important parameter here is the distance of closest approach between Br^- and the ionic head $-NH_3^+$.

The total and nonideal partial molal free energies of OABr were also calculated and are shown at three temperatures in Fig. 2. Beyond the critical micelle concentration (CMC), the mean activity $a_\pm$ increases only slowly with m. This behavior is typical of most ionic surfactants (2, 6–9). The mean activity coefficient $\gamma_\pm$ becomes smaller and the transition less sharp at higher temperatures. This is again typical of hydrophobic solutes. The negative sign of the excess free energy may come from nonstructural interactions but hydrophobic interactions are largely responsible for the temperature dependence of $\ln \gamma_\pm$. In fact, as can be seen in Fig. 2, in the case of $MeNH_3Br$ where the hydrophobic interactions are negligible, the activity coefficient is very nearly temperature independent.

The nonideal contributions to the partial molal entropies of OABr and NaDec were calculated at several temperatures and from these the excess partial molal entropies $(\bar{S}_2 - \bar{S}_2^0)$ were evaluated by addition of the mixing contribution $(-\nu R \ln m)$. These data are shown in Fig. 3 for OABr at 5, 15, and 25°C. The particular shape of the concentration dependence of $\bar{S}_2 - \bar{S}_2^0$ makes it difficult to extract the change in entropy during micellization (2). Since the system is at equilibrium, $\Delta G_m = 0$ and

$$[5]\quad \Delta S_m = \Delta H_m/T$$

[4] A complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2.

[a] m in mol kg^{-1}.
[b] $\bar{S}^{ni}$ in J K^{-1} mol^{-1}.

The enthalpy of micellization ΔH_m is available experimentally as a function of temperature (3, 5). The function $\Delta H_m/T$ is shown at 5 and 15°C in Fig. 3 and seems reasonable with respect to the change in entropy in the micellar region. At 25°C $\Delta H_m/T$ for OABr (not shown) is somewhat smaller than the difference between the extrapolated $\bar{S}_2 - \bar{S}_2^0$ at the CMC, suggesting that the $\bar{S} - \bar{S}_2^0$ data in the post-

micellar region would have to be extrapolated to the CMC with a positive slope for self-consistency.

The osmotic coefficients of ϕ of NaDec are shown for various temperatures in Fig. 4. Near the freezing temperature the trends are similar to those of OABr and of alkyltrimethylammonium bromides (2). There is a single break near the CMC. At higher temperatures, however, there seem to be double breaks which sharpen as the temperature is increased. We thought (13) that we finally had thermodynamic evidence for the second CMC that had been reported by numerous authors. However, it turns out that it is rather difficult to calculate excess free energies of NaDec as a function of temperature since the excess partial molal heat capacities show such large concentration and temperature dependence in the CMC region (3) at low temperatures. Calculations of ϕ of NaDec as a function of temperature, but based on only two sets of data for $\bar{C}_{P,2}$, have already been reported (13). These results at 25°C are shown as a dotted line in Fig. 4.

Thus, the breaks in ϕ tend to merge as better values for the temperature dependence of the partial molal heat capacity $\bar{C}_{P,2}$ are taken.

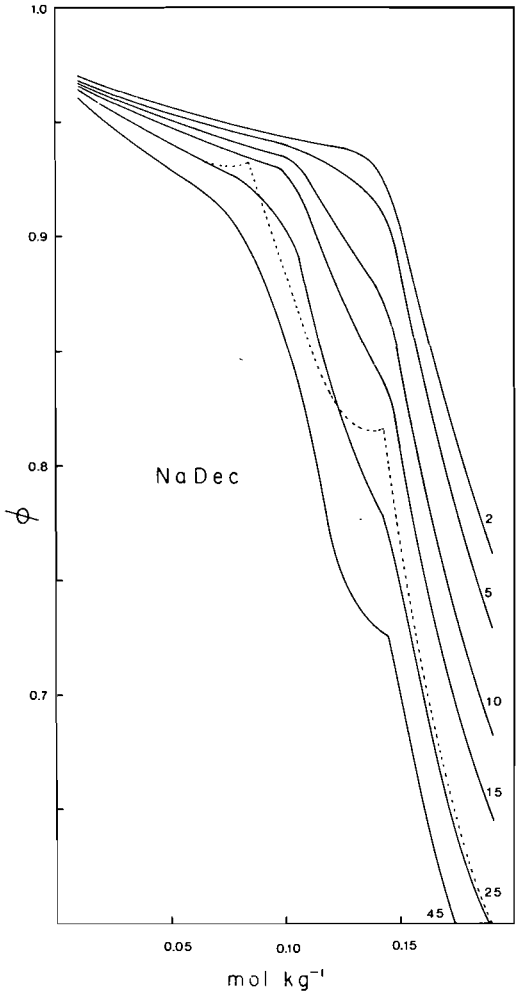

FIG. 4. Osmotic coefficients of sodium decanoate in water at various temperatures; ... data based on heat capacities measured at two temperatures only (13).

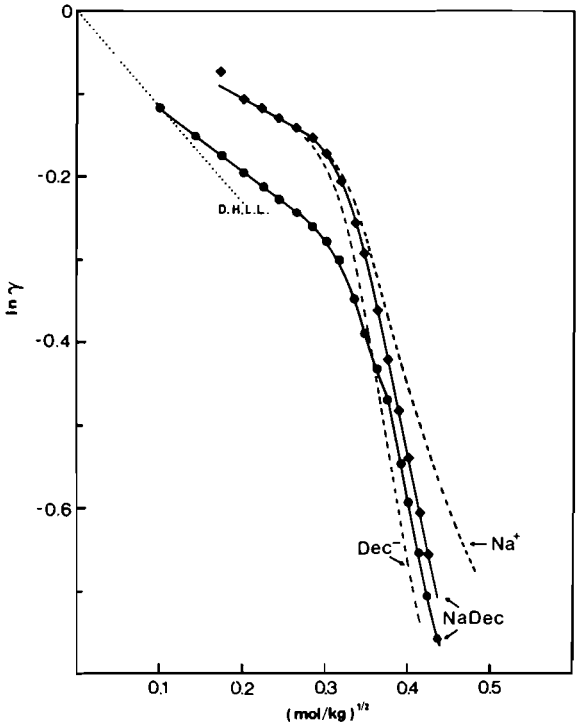

FIG. 5. Comparison of activity coefficients of sodium decanoate at 25°C obtained from freezing-point and EMF data (9).

Vikingstad (9) has recently measured the activity of NaDec at 25°C using a sodium and a Ag/AgDec electrode pair. His results are compared with ours in Fig. 5. Although there is a significant difference between the two sets of data, the EMF values do not show two breaks. Kale and Evans[5] have also investigated NaDec by an EMF method using a membrane decanoate electrode and find only one break. This therefore strongly suggests that the appearance of two breaks in the ϕ curve is most probably an artifact. On the other hand, the large difference between ln $\gamma_\pm$ of Vikingstad and ours is intriguing at first sight. As mentioned earlier, a small error can be introduced in our calculations of ln $\gamma_\pm$ from ϕ due to the method of application of the Gibbs–Duhem equation. Therefore, it is not certain if our ln $\gamma_\pm$ crosses the Debye–Hückel limiting law or if it simply tends to merge with it. On the other hand ln $\gamma_\pm$ from EMF tends to zero but not to the Debye–Hückel limiting law (DHLL).

The main difficulty with activity measurements using the EMF method is the non-Nernstian behavior of these specific electrodes. The method used in estimating the standard EMF, ε^0, in such cases can have a major effect on the trends of ln $\gamma_\pm$ as a function of m. This is best illustrated with decyltrimethylammonium bromide which has been investigated carefully with both the freezing point (2) and EMF (8) techniques. With specific membrane electrodes reversible to both cations and anions

$$[6]\quad \varepsilon = \varepsilon^0 - A \log a_\pm{}^2 = \varepsilon^0 - A \log m^2 - A \log \gamma_\pm{}^2$$

where A is not always equal to the theoretical Nernst slope of 0.059 volt. Different methods exist to derive ε^0 and A; ε can be plotted against log m^2 at low molalities, the slope giving A and the intercept ε^0. With this surfactant ε is not a linear function of log m^2, even at low concentrations. If average values for A and ε^0 are taken from the data at low concentrations then the top curve in Fig. 6 is obtained for ln $\gamma_\pm$. If ln $\gamma_\pm$ is assumed equal to the limiting Debye–Hückel law and again average

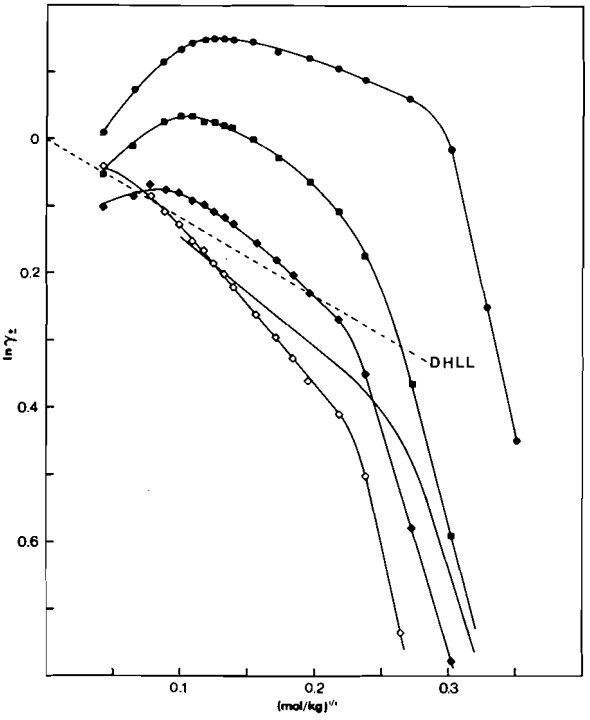

FIG. 6. Comparison of mean activity coefficients of decyltrimethylammonium bromide at 25°C obtained from freezing-points and from EMF data using various assumptions: ●, mean ε^0 and slope A assuming $\gamma = 1$ at low concentration; ■, mean ε^0 and A values assuming that in $\gamma = -Bm^{1/2}$ at low concentration; ◆, mean ε^0 and A values assuming that $\ln \gamma = -Bm^{1/2}/(1 + m^{1/2})$; ○, values of ε^0 and A extrapolated to $m = 0$ if $\ln \gamma = -Bm^{1/2}/(1 + m^{1/2})$ at low concentration.

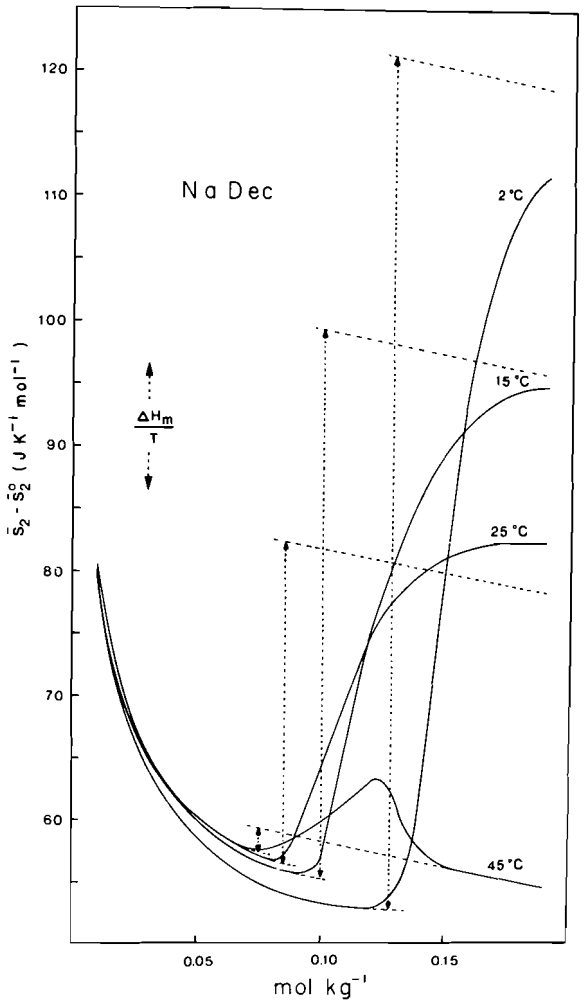

FIG. 7. Partial molal entropies of sodium decanoate in water at various temperatures; the entropies of micellization, $\Delta H_m/T$, were calculated from thermochemical data (2).

values for ε^0 and A are derived, then the new $\ln \gamma_\pm$ values are closer to the freezing point data. Still better agreement is obtained if $\ln \gamma_\pm$ in eq. [6] is taken as $-0.51\, m^{1/2}/(1 + m^{1/2})$. Finally if, instead of taking average values for ε^0 and A, values extrapolated to $m = 0$ are taken, still another curve is obtained for $\ln \gamma_\pm$. This shows that the absolute values of $\ln \gamma_\pm$ of ionic surfactants obtained by the EMF method can be seriously in error. On the other hand, the trends at higher concentrations should be correct.

We therefore have to conclude that the gradual appearance of a double break in the activity of NaDec as the temperature is increased is an artifact related to the difficulty in the analytical treatment of the heat capacity data in the CMC region at low temperature. The same difficulty would arise if we would try to calculate activity data at low temperatures from EMF measurements at 25°C using the thermochemical data.

The Krafft temperature for NaDec is probably just below the freezing temperature. As a result, it is not possible to measure activity data much above the CMC, since the solubility limit is rapidly reached. This limits seriously the data for the calculation of excess entropies. These are shown as a function of temperature in Fig. 7. It is not possible to extract entropies of micellization from these data but, as with OABr, $\Delta H_m/T$ calculated from thermochemical data (3) is shown and appears to be consistent with the entropy data.

Conclusion

It is generally true that it is better to calculate the temperature dependence of excess free energies from good thermochemical data than to try to derive excess heat capacities from the temperature dependence of activity data. Systems like NaDec which show very sharp changes in $\bar{C}_{P,2}$ near the CMC are to some extent exceptions to this rule.

Here both $\bar{C}_{P,2}$ and the activity data need to be measured as a function of temperature. The freezing point technique is probably the most accurate one for activity measurements but is unfortunately limited to the freezing temperature and is usable only with systems which have very low Krafft temperatures.

Effect of organic compounds on electrolyte chemical potential in aqueous solutions at various temperatures

DAVID M. MOHILNER, TAKASHI KAKIUCHI,[1] AND JOANNA TARASZEWSKA[2]

Department of Chemistry, Colorado State University, Fort Collins, CO 80523, U.S.A.

Received July 2, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

DAVID M. MOHILNER, TAKASHI KAKIUCHI, and JOANNA TARASZEWSKA. Can. J. Chem. **59**, 1872 (1981).

Data are reported on the concentration of Na_2SO_4 required to hold its chemical potential equal to its value in a 0.10045 *m* solution in pure water for aqueous solutions containing 2-butanol and 1-propanol at six different temperatures. The data were obtained from emf measurements on a galvanic cell without liquid junction containing a sodium reversible glass electrode and a 2-phase lead amalgam – lead sulfate electrode. The results of the measurements are interpreted in terms of the water structure making properties of the organic compound.

DAVID M. MOHILNER, TAKASHI KAKIUCHI et JOANNA TARASZEWSKA. Can. J. Chem. **59**, 1872 (1981).

On a déterminé la concentration du Na_2SO_4 requise dans des solutions aqueuses de butanol-2 et de propanol-1 à températures différentes pour maintenir son potentiel chimique au niveau qui est le sien dans une solution dans l'eau pure à une concentration de 0,10045 *m*. On a obtenu les données à partir de la mesure de fem d'une pile galvanique sans jonction liquide contenant une électrode de verre réversible au sodium et une électrode à 2 phases au sulfate de plomb amalgame de plomb. On a interprété les résultats des mesures en fonction de la structure de l'eau responsable des propriétés du composé organique.

[Traduit par le journal]

Introduction

Previously we showed (1, 2) experimentally that the additional of 2-butanol to an aqueous sodium sulfate solution could seriously alter the chemical potential of the electrolyte. Our method was to measure the emf of a galvanic cell without liquid junction in which one electrode was reversible to the cation and the other electrode was reversible to the anion. We showed how it was possible from such emf measurements to determine the recipe for preparing a series of solutions in which the chemical potential of the organic compound varies but in which the chemical potential of the electrolyte remains constant.

We are now engaged in a study of the effects of temperature on organic electrosorption (3) in order to determine the excess electrochemical entropy of mixing $\Delta\bar{S}^{E}$ of water and organic compound in the inner layer. For these studies it is necessary to measure the electrosorption isotherm of the organic compound at a series of temperatures. Therefore, at each temperature it is necessary to determine the recipe for preparing a series of solutions with varying organic chemical potential but with constant electrolyte chemical potential. We have now completed these measurements for two compounds, 2-butanol and 1-propanol, at 5°, 10°, 15°, 20°, 25° and 30°C. The purpose of this paper is to report the results of these measurements and to offer some explanation of the results in terms of the water structure making properties of the organic compound.

Experimental

The measurements carried out were emf measurements on a galvanic cell without liquid junction in which one electrode was a glass sodium ion electrode made with NAS11-18 glass (4) (Orion 94-11A) and the other was a two phase lead amalgam – lead sulfate electrode (5). These measurements were carried out in a cell of different design from that which we had employed previously (1, 6) in order to minimize the time required to reach equilibrium. In our previous work we had found that the emf of the cell always drifted slowly and usually reached a steady value only after waiting 12 h or more. Our old procedure was simply to flood the cell with a flow of argon and then pour in the amalgam and the solution. We decided that the reason for the slow drift of emf was that with this procedure some oxidation of the amalgam inevitably still occurred and therefore the electrode initially prepared was a mixed lead oxide – lead sulfate electrode. The waiting time was probably that required for the small amount of lead oxide to dissolve. Therefore a new cell was designed which would completely eliminate the possibility of the lead amalgam coming into contact with any atmospheric oxygen. A photograph of this new cell is shown in Fig. 1. The cell tops of the two amalgam compartments (left) in this new cell are No. 40 "O" ring joints and all stopcocks are No. 4 Kontes Kel F high vacuum stopcocks. Other connections into the cell are made with No. 5 "O" ring joints and all "O" ring joints are clamped tight with Thomas Clamps for "O" ring joints. The glass electrode compartment (right) is connected to the pair of amalgam electrode compartments by a V-shaped tube with fine frit at its apex by means of No. 9 "O" ring joints. Initially the glass electrode compartment is removed and the V-shaped tube is sealed with a No. 9 "O" ring stopper. The cell is then evacuated, filled with argon, and reevacuated three times. Then

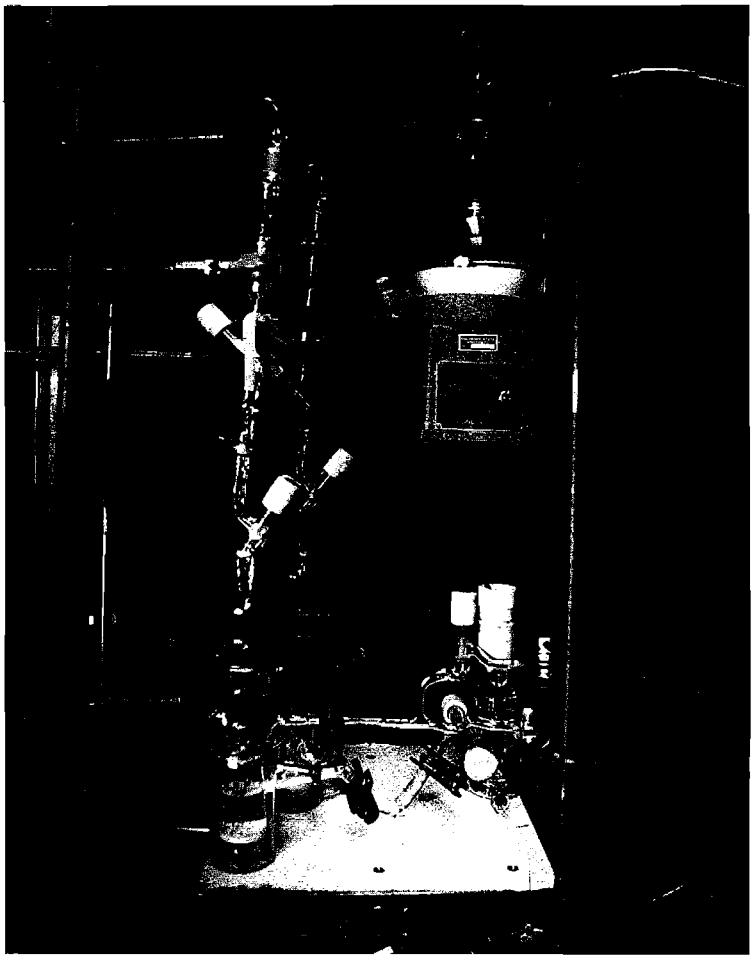

FIG. 1. Photograph of the cell used for the emf measurements.

the two-phase lead amalgam (reservoirs upper left) is admitted into each of the two evacuated amalgam electrode compartments through the high vacuum stopcocks until the platinum electrode contact is covered. (The cell interior is first dewetted with trimethylchlorosilane to prevent any creepage of solution to the platinum contact which would cause drift of the emf.) Then the cell is filled with argon and a slurry of lead sulfate, freshly prepared according to the method of Harned and Hecker (5), in the solution to be studied is admitted to the cell through the high vacuum stopcock. This slurry is kept in suspension by magnetic stirring in a flask (top of picture) which is provided with a bubbler to deaerate the solution. The solution flows down to the frit at the apex of the V-shaped tube and wets the frit. Then the glass electrode compartment is connected to the V-shaped tube at the No. 9 "O" ring joint, filled with deaerated solution, and the glass electrode inserted. This method of preparing the cell completely prevents the formation of any lead oxide on the lead amalgam electrode. The three electrode compartments are jacketed and thermostated water is pumped through the jackets during measurements. The emf is measured by a Keithley 610CR electrometer which has an input impedance in excess of 10^{14} ohms. The glass electrode and the lead amalgam – lead sulfate electrode are connected to the electrometer through a Keithley 6107 pH electrode adapter. The emf is read at the unity gain output of the electrometer on a Fluke 8300A digital voltmeter to the nearest 10 μV.

The electrolyte chosen was sodium sulfate because this compound exhibits no specific ionic adsorption at negative values of the excess charge density on the metal (7). It was decided to hold the chemical potential of the sodium sulfate in each solution containing organic compound at each temperature equal to its value at the same temperature in a solution of Na_2SO_4 at a concentration of 0.1 *M* (prepared at 25°C) which is 0.10045 *m* (6) in pure water. Therefore the emf of the cell containing 0.10045 *m* Na_2SO_4 solution was first measured at each temperature. Then for each concentration of the organic compound four solutions containing different concentrations of Na_2SO_4 were prepared, two of which gave emf values greater and two of which gave emf values less than the value obtained at the same temperature in the 0.10045 *m* Na_2SO_4 solution in pure water. The concentration–emf data at each fixed value of the organic concentration were then fitted to a least-squares quadratic equation in emf and interpolated to the value of emf obtained with the 0.10045 *m* sodium sulfate in pure water. The interpolated value of Na_2SO_4 concentration was thus the needed value to maintain the chemical potential of sodium sulfate in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

organic solution equal to its value in 0.10045 *m* sodium sulfate in pure water at the given temperature.

In the measurements the emf values of the cell consisting of the glass electrode and each of the two amalgam electrodes were measured. A value of emf was not accepted until the difference of these two emf's was less than 100 μV. The time required to obtain this condition varied with temperature. At 25°C it usually required only about 40 min. At 5°C, however, it usually required about 6 h. The sodium glass electrode was always stored in 0.1 *M* Na_2SO_4, and one hour before beginning the emf measurements it was put into the solution to be studied.

Results and Discussion

In our experimental study (6) of the electrosorption of 2-butanol at 25°C we included solutions with organic concentrations as high as 1.4 *M* (a_A = 0.5652). We found that in the high concentration region there was evidently a reorientation of the 2-butanol molecules on the electrode surface. Since our theory of noncongruent electrosorption (3) cannot accommodate molecular reorientation, it was unnecessary for the temperature dependence studies to include solutions with high concentrations. Therefore it was decided to have the concentration of 2-butanol in these solutions no higher than 0.4 *M* (measured at 25°C). Figure 2 shows the results of the emf measurements for 2-butanol at the six temperatures selected for study. The numerical data for this figure are given in Table 1. The ordinates on this graph are the needed molarity of Na_2SO_4 (measured at 25°C) required to hold the chemical potential of the Na_2SO_4 equal to its value in a 0.10045 *m* solution in pure water at the same temperature. The abcissae on this figure are the values of the molarity of the 2-butanol (measured at 25°C) in the solution. As expected from our previous studies (1) at 25°C covering concentrations up to 1.4 *M* (measured at 25°C) the data all fall on straight lines. The lines shown on the figure are least-squares straight lines constrained to pass through a Na_2SO_4 concentration of 0.1 *M* (measured at 25°C), i.e., 0.10045 *m*, when the 2-butanol concentration is zero. It can be noted from the figure that the slopes of the lines at all temperatures appear to be the same. The actual values of the slopes of these lines and the 95% confidence limits of these slopes are plotted in Fig. 3. It can be seen from the overlap of these 95% confidence limits that statistically these slopes really are the same. This fact has an important practical implication for the electrocapillary measurements, namely, regardless of the temperature, the needed concentration of Na_2SO_4 for a given concentration of 2-butanol is the same. Therefore the electrocapillary curves for all of the different temperatures can be measured on the same set of solutions.

As we stated in our first publication on this subject (1), we believe that the explanation of this effect of the organic compound on the electrolyte chemical potential is the structure making properties of the organic compound. The data are consistent with the following explanation. When an organic molecule is dissolved in the aqueous solution it induces the water molecules in its immediate neighborhood to become more highly structured,

probably in the form of a clathrate-like cage of water molecules surrounding the organic molecule. If we assume that the effective molality of the Na_2SO_4 in the remaining unstructured water is the same as in the original 0.10045 m solution in pure water, we can calculate how many water molecules are associated with each organic molecule. The calculation is made using the following formula

$$[1] \quad n = [x_W - (55.51/m_0)x_e)]/x_A$$

where n is the number of water molecules in the cage around each organic molecule, x_W, x_e, and x_A are the mole fractions of the water, the electrolyte, and the organic compound, respectively, in the solution, and m_0 is the molality of the electrolyte in the solution containing no organic compound which produces the desired electrolyte chemical potential. The mole fractions of the three components can be calculated from the composition data if the density of the solution is measured. The densities of all of the solutions were measured and the mole fractions of the three components were calculated. The data in Fig. 2 are consistent with a cage of 28 water molecules surrounding each 2-butanol molecule. This would be consistent with a clathrate in the form of a hexakaidecahedron with 12 pentagonal and four hexagonal sides which is one of the structures actually found by X-ray diffraction studies on crystalline hydrates (8). Our previous data on 2-butanol obtained at 25°C covering a range of concentration of up to 1.4 M had indicated a clathrate in the shape of a tetrakaidecahedron containing 24 water molecules. The 95% confidence limits of the slope of the line for that study are also indicated in Fig. 3. It will be noted that these confidence limits are considerably smaller than those we obtained in the present study. The explanation is simply that a better straight line is bound to be obtained when a larger concentration range is used. Actually we do not believe that the organic molecules are surrounded all of the time by a clathrate-like cage. Due to thermal fluctuations the clathrate will be continually broken up and reformed, i.e., any actual framework structure of the water molecules must be a "flickering structure" as originally described by Frank and Quist (9). Very likely at any instant in time an organic molecule is not completely enclosed in a complete clathrate cage but only partly surrounded by the beginnings of such a cage. Our thermodynamic data, of course, give an indication only of the long-time average situation. These data provide no direct information on the structural situation in the solution but they are consistent with the formation of clathrates. There is other thermodynamic evidence in the literature (10) for aqueous alcohol solutions which is consistent with the idea of an enhanced structure produced by the introduction of an alcohol molecule into water. This evidence is that although in dilute solutions the enthalpy of mixing is negative, the excess Gibbs free energy of mixing, ΔG^E, is positive, i.e., the solutions exhibit positive deviations from Raoult's law because the excess entropy of mixing, ΔS^E, is so large and negative that

$$[2] \quad T|\Delta S^E| > |\Delta H^E|$$

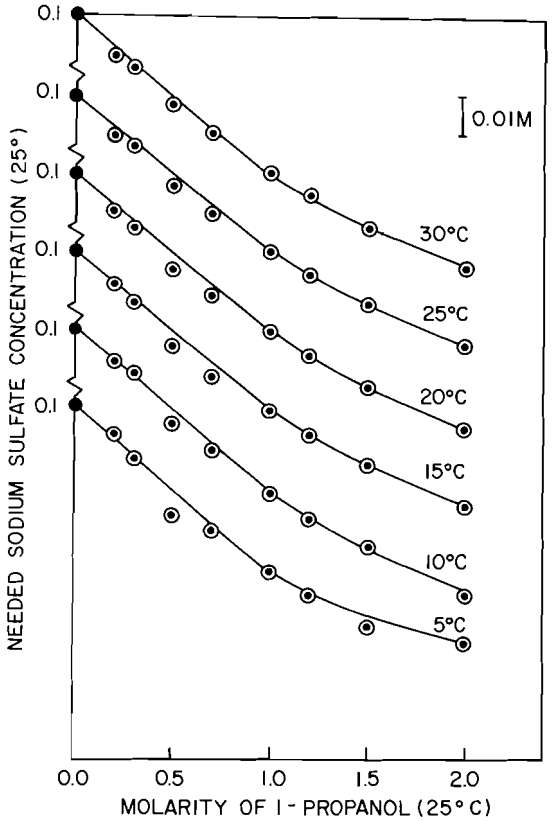

FIG. 4. Sodium sulfate concentration required to hold electrolyte chemical potential in 1-propanol solutions equal to its value in 0.10045 *m* solution in pure water.

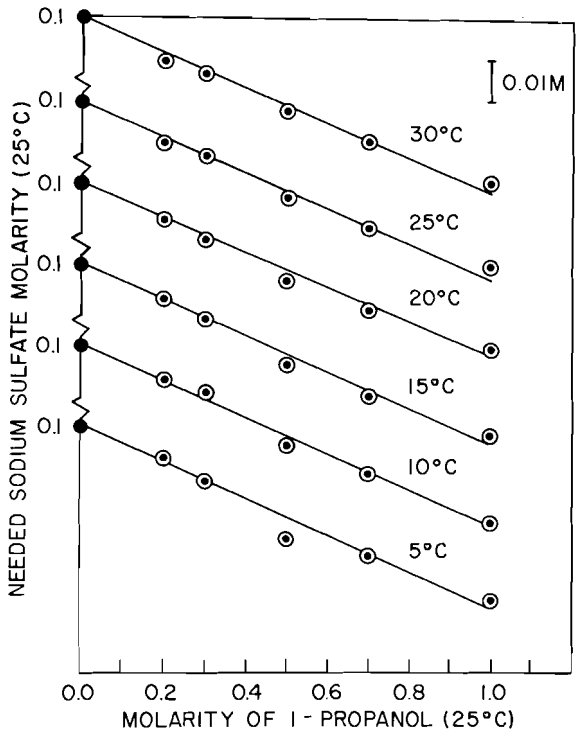

FIG. 5. Data from Fig. 4 fitted to constrained least-squares straight lines.

As Franks has said (11), the thermodynamic properties of aqueous solutions of organic compounds are under entropy control. We have predicted (3) that the thermodynamic properties of the inner layer in the case of organic electrosorption are also under entropy control and the present work was undertaken as a first step required to experimentally test this prediction.

Figure 4 shows the results of our measurements for 1-propanol. The numerical data for this figure are given in Table 1. In the case of this compound we have extended the measurements up to a concentration of 2.0 *M* (measured at 25°C) because we wish in our electrocapillary studies to test for evidence of molecular reorientation. These curves are linear up to a concentration of 1.0 *M* and the corresponding constrained least-squares straight lines are shown in Fig. 5. It will be noted that the slopes of these lines also appear to be all the same. The 95% confidence limits of the slopes of these lines are also shown in Fig. 3. It can be seen by the overlap of these confidence limits that statistically a single slope suffices to describe all the data at all temperatures. Therefore, as in the case of 2-butanol, it will be legitimate to use the same solutions in the electrocapillary measurements at all temperatures. The data for 1-propanol are actually consistent with a clathrate-like cage in the shape of a pentagonal dodecahedron with 20 water molecules, which is the same result we obtained earlier (2) for 2-methyl-2-propanol. As in the case of 2-butanol we do not believe that the molecules are actually all contained in such cages. Rather the true situation at any instant in time is probably a partial cage around any one organic molecule. The thermodynamic data merely indicate the long-time average.

Changes in the emf of the cell as a function of temperature and time for aqueous 0.10045 *m* Na_2SO_4 are shown in Fig. 6. Similar dependence on temperature was also observed in solutions containing 2-butanol and 1-propanol. The plot of emf against temperature is strongly curved. The reason for such behavior is complex because with change of temperature the potentials of both electrodes change due to the change of activity of sodium sulfate, the change of the standard potential of the lead amalgam – lead sulfate electrode, and the change of the asymmetry potential of the sodium glass electrode.

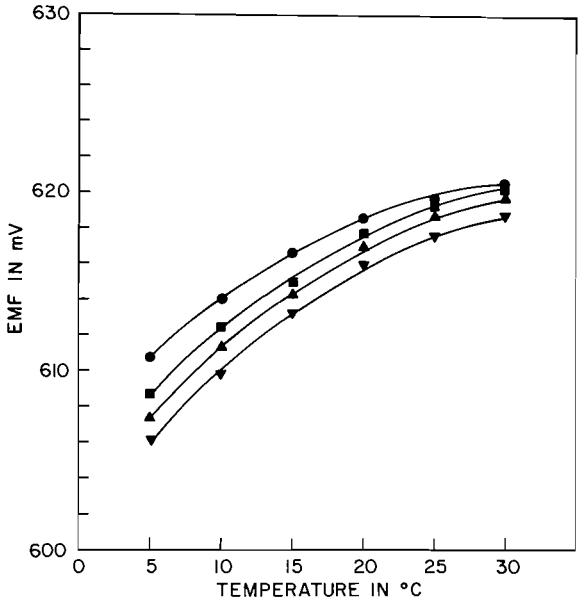

FIG. 6. Electromotive force of cell containing 0.10045 *m* in Na_2SO_4 in pure water as a function of temperature and time. Time of measurements: ●, 4 October 1979; ■, 31 October 1979; ▲, 30 November 1979, ▼, 11 January 1980.

To separate and to estimate these factors individually is not possible at the present time. However, a variation of the emf with time, especially significant at lower temperatures, is most likely due to the change of potential of the sodium glass electrode. As was pointed out by Eisenman and co-workers (12), the glass electrode is a perfect cation exchange membrane, whose standard potential represents a sum of contributions from both diffusion and phase boundary processes. If the properties of the ion exchange sites are modified as a result of the ion exchange, time variations of potential can arise. In the case of the sodium glass electrode the main reason for these variations seems to be the swelling of the glass membrane due to the exchange of some sodium ions for hydrogen ions which can bind water and alcohol molecules (13). This swelling process seems to be an irreversible one leading to a decrease of the measured emf values with time. It will be noted from Fig. 6 that our data are consistent with such behavior. Therefore in precise measurements of sodium activities, especially as a function of temperature where the measured results are small, frequent recalibration of the sodium glass electrode is necessary.

RICHARD WYNDHAM O'BRIEN and ROBERT JOHN HUNTER. Can. J. Chem. **59**, 1878 (1981).

Analytical approximation formulae linking ζ potential and electrophoretic mobility have been derived for a variety of limiting conditions. In this paper we present a simplified derivation of an equation first established by Dukhin and his collaborators for a large spherical particle with a thin double layer. Although potentially a very useful expression it has been little used to date, partly because of the complicated nature of Dukhin's derivation and partly because of the lack of a reliable method of testing its validity. The expression compares very favourably with the computer calculations of O'Brien and White, provided κa is sufficiently large.

RICHARD WYNDHAM O'BRIEN et ROBERT JOHN HUNTER. Can. J. Chem. **59**, 1878 (1981).

On a mis au point une formule d'approximation analytique reliant dans diverses conditions limites le potentiel zeta et la mobilité dans des conditions d'électrophorèse. Dans cet article, nous avons simplifié une équation établie pour la première fois par Dukhin et ses collaborateurs pour une grosse particule sphérique ayant une double couche mince. Cette équation pourrait être très utile, mais elle a été peu utilisée jusqu'à maintenant; cet état de fait est dû en partie à la nature compliquée de l'équation mise au point par Dukhin et en partie à l'absence d'une méthode sûre pour en vérifier la validité. A condition que ka soit suffisamment grand, l'expression se compare favorablement aux calculs faits par ordinateur par O'Brien et White.

[Traduit par le journal]

I. Introduction

Most students of colloid science are familiar with Smoluchowski's formula (1):

$$[1.1] \quad \mu = \varepsilon\zeta/4\pi\eta$$

for the electrophoretic mobility, μ, of a particle of arbitrary shape with uniform electrokinetic potential ζ, immersed in an electrolyte with viscosity η and permittivity ε. This formula, which is valid for particles whose dimensions are much greater than the double layer thickness, is based on the assumption that the double layer is not distorted by the application of the electric field; the ions are of course set into motion by the field, but for thin double layers they move parallel to the surface and since the double layer is approximately flat, the ionic densities do not alter.

This assumption is not valid for large ζ-potentials, for the density of counter-ions in the double layer is then so large that the ionic fluxes due to the small components of the applied electric field and fluid velocity normal to the surface become significant, and the double layer distorts. Thus Smoluchowski's formula breaks down at large ζ-potentials.

For spherical particles we can determine the range of validity of Smoluchowski's formula by comparing the formula with the computer calculated mobilities given in O'Brien and White's paper (2). In Fig. 1 the mobility of particles in KCl solution is plotted as a function of $e\zeta/kT$ for a number of κa values, where as usual e is the electronic charge, kT is the temperature in energy units, κ^{-1} is the double layer thickness, and a is the particle radius. From this figure it can be seen that the Smoluchowski formula ($\kappa a = \infty$) is invalid for $e\zeta/kT \gtrsim 4$ if κa is of the order of 150 or so. The range of validity of the Smoluchowski formula increases with κa, but only slowly.

In order to derive a formula for the mobility of a large particle which is valid for all ζ-potentials it is necessary to take the distortion of the double layer into account.

In 1965 Dukhin (3) solved this difficult problem for the case of a spherical particle in a symmetric electrolyte with two ionic species. Dukhin's mobility formula, which is valid for all ζ-potentials, is based on the observation that the ion densities and electrical potential in the double layer vary on a length scale of order κ^{-1} in the direction normal to the particle surface, while the variations in the tangential direction occur on a length scale of order a, the particle radius. Thus at large κa, the gradients in the electric field and ion densities in the double layer normal to the particle surface will be much larger

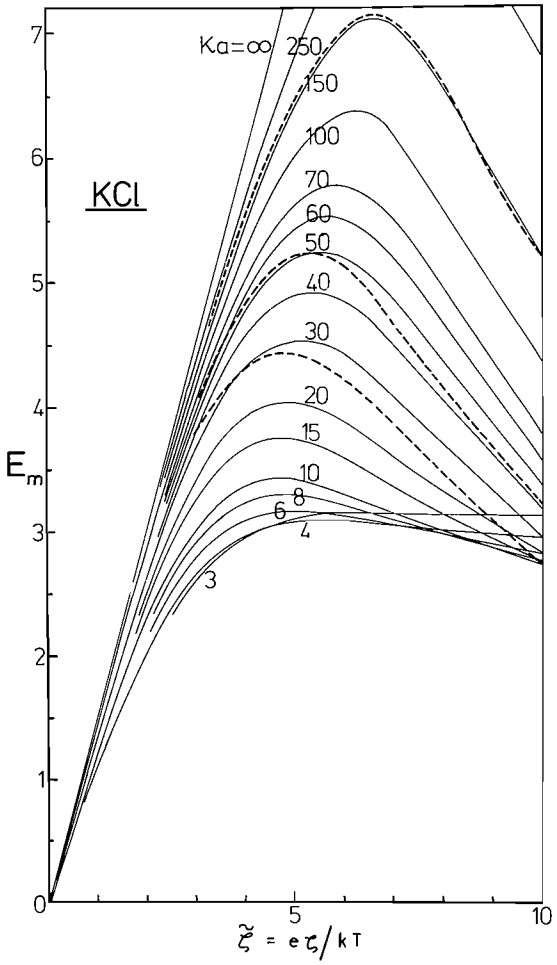

FIG. 1. Comparison of values of the reduced mobility, E_m, as a function of reduced zeta potential ($= ze\zeta/kT$). Full lines: computer solution of O'Brien and White (2). Broken lines: calculated from eq. [5.1] for κa = 150, 50, and 30 respectively (m = 0.184 in all cases).

than the gradients tangential to the surface; as a result there will be a local balance between diffusive flux and the flux of ions due to the component of the electric field normal to the surface. From this it follows that the ions in the double layer are distributed according to a Boltzmann-type expression (eq. [59] of ref. 4, p. 298) which may be written in the form

$$[1.2] \quad n_i(\boldsymbol{r}) = n_i(\infty)(1 - A_i) \exp\left(-\frac{z_i e\psi(\boldsymbol{r})}{kT}\right)$$

where $n_i(\boldsymbol{r})$ is the density of the ith ionic species, $n_i(\infty)$ is the density at large distances from the double layer, z_i is the valency, and ψ is the electrical potential. The quantity A_i is assumed to be approximately constant over distances of order κ^{-1}. This quantity, which is determined in the subsequent analysis, may be related to the local ion density and electrical potential just beyond the double layer. A full discussion of this point is given by Dukhin (5) and by Dukhin and Shilov (6).

In this paper we provide a simplified derivation of Dukhin's formula for the electrophoretic mobility. In sections 2 and 3 below we set out the equations which must be solved in order to calculate the mobility of a spherical particle, and in section 4 we solve these equations in the double layer, using Dukhin's formula [1.2] for the ion densities. By matching this inner solution to a solution which is valid beyond the double layer we obtain the required formula for the mobility. Coincidentally, Dr. Samuel Levine also studied the "polarised double layer" in collaboration with another member of the O'Brien clan (7) in connection with the motion of a liquid droplet in an electric field.

2. The Governing Equations

The problem of calculating the electrophoretic mobility is considerably simplified by the introduction of a set of quantities $\Phi_i(\boldsymbol{r})$, defined by the Boltzmann-type formula[1]

$$[2.1] \quad n_i(\boldsymbol{r}) = n_i(\infty) \exp\left(-\frac{z_i e}{kT}(\psi + \Phi_i)\right)$$

for the density of the ith ionic species. To determine the mobility of a particle we must solve a set of partial differential equations for the quantities $\Phi_i(\boldsymbol{r})$ and the velocity field $\boldsymbol{u}(\boldsymbol{r})$ in the electrolyte surrounding the particle.

In this section we briefly outline the derivation of these equations and the associated boundary conditions; a more complete derivation is given in ref. 2.

In a frame of reference moving with the particle the ionic densities do not vary with time, and consequently the net flux of ions through any closed surface is zero:

$$[2.2] \quad \nabla\cdot(z_i e n_i^0 \nabla\Phi_i) + \lambda_i \nabla n_i^0 \cdot \boldsymbol{u} = 0$$

there being one such equation for each type of ion. The quantity n_i^0 in this equation denotes the density of type i ions in the absence of an applied field, and λ_i is the ionic drag coefficient.

The remaining equations, which are obtained from

[1] In ref. 2 the quantities Φ_i are defined with the potential ψ in the exponent of [2.1] replaced by $\psi + \boldsymbol{E}\cdot\boldsymbol{r}$. For this reason our equations and boundary conditions for Φ_i are slightly different from those given in that paper.

the laws of conservation of momentum and mass are

$$[2.3] \quad \eta\nabla^2(\nabla \times \boldsymbol{u}) = \sum_{i=1}^{N} z_i e \nabla\Phi_i \times \nabla n_i^0$$

and

$$[2.4] \quad \nabla\cdot\boldsymbol{u} = 0$$

where N is the number of ionic species.

To determine the electrophoretic mobility we must solve eqs. [2.2], [2.3], and [2.4] subject to the following boundary conditions:
On the surface of the particle,

$$[2.5] \quad \boldsymbol{u} = 0$$

and

$$[2.6] \quad \nabla\Phi_i\cdot\hat{n} = 0$$

where $\hat{n}$ is the unit normal to the particle surface; and far from the particle,

$$[2.7] \quad \boldsymbol{u} \approx -\mu\boldsymbol{E}$$

and

$$[2.8] \quad \Phi_i \approx \boldsymbol{E}\cdot\boldsymbol{r}$$

where $\boldsymbol{E}$ is the electric field strength far from the particle and the position vector $\boldsymbol{r}$ is assumed to have its origin at a point in the particle. Since we are mainly concerned here with spherical particles we have assumed in formulating the boundary condition [2.7] that the particle moves in the direction of the applied field; for more complicated particle shapes this boundary condition must be modified.

In addition to these boundary conditions we must satisfy the constraint that the net force on the particle and double layer is zero. In section 8 of ref. 2 it is shown that the disturbance in the velocity field caused by a particle and double layer decays like F/r with increasing distance r from the particle, where F is the net force on the particle and double layer. In this case F is zero, and consequently the velocity disturbance decays to zero more rapidly than $1/r$ as $r \to \infty$; in fact it can be shown that the disturbance decays like $1/r^2$ in this case.

Hence by using the fact that the particle and double layer is force-free we may rewrite the outer boundary condition [2.7] as

$$[2.9] \quad \boldsymbol{u} = -\mu\boldsymbol{E} + O(1/r^2) \qquad \text{as } r \to \infty$$

where the symbol $O(1/r^2)$ denotes a term which decays in proportion to $1/r^2$. By replacing the boundary condition [2.7] by the requirement that $\boldsymbol{u}$ has the above asymptotic form we automatically ensure that the force-free condition is satisfied.

To determine the quantities $\boldsymbol{u}$, Φ_i, and μ we must solve eqs. [2.2] to [2.4] subject to the boundary conditions [2.5], [2.6], [2.8], and [2.9].

3. The Electrophoresis Problem for a Spherical Particle

For a spherical particle it can be shown by symmetry arguments (ref. 2, section 6) that the functions $\Phi_i(r)$ have the form

$$[3.1] \quad \Phi_i(r) = \phi_i(r)E\cos\theta$$

where E is the magnitude of the applied field, and the spherical polar coordinates r and θ are defined in Fig. 2. For a given particle and electrolyte the functions $\phi_i(r)$ depend only on distance from the centre of the sphere.

Similarly, the components of the fluid velocity may be written in the form[2]

$$[3.2] \quad u_r = -\frac{2}{r}g(r)E\cos\theta$$

and

$$[3.3] \quad u_\theta = \frac{1}{r}\frac{d}{dr}(rg(r))E\sin\theta$$

where u_r and u_θ are the components of $\boldsymbol{u}$ in the direction of increasing r and θ; the azimuthal component of the velocity is zero in this case.

The forms [3.2] and [3.3] for u_r and u_θ automatically satisfy the continuity equation [2.4]. By substituting these forms and the expression [3.1] for Φ_i in the remaining equations [2.2] and [2.3], we obtain

$$[3.4] \quad \frac{d^2\phi_i}{dr^2} + \left(\frac{2}{r} - \frac{z_i e}{kT}\frac{d\psi^0}{dr}\right)\frac{d\phi_i}{dr} - \frac{2\phi_i}{r^2} = -\frac{2\lambda_i}{kT}\frac{d\psi^0}{dr}\frac{g}{r}$$

and

$$[3.5] \quad \frac{d^4g}{dr^4} + \frac{4}{r}\frac{d^3g}{dr^3} - \frac{4}{r^2}\frac{d^2g}{dr^2} = \frac{1}{\eta r}\sum_{i=1}^{N} z_i e\frac{dn_i^0}{dr}\phi_i$$

where ψ^0 is the equilibrium potential in the absence of an applied field.

Similarly, the boundary conditions [2.5], [2.6], [2.8], and [2.9], when written in terms of the functions g and ϕ_i, become

$$[3.6] \quad g = 0, \quad dg/dr = 0$$

and

$$[3.7] \quad d\phi_i/dr = 0 \qquad \text{at } r = a$$

[2]These expressions are obtained by writing the formula [6.4] in ref. 2 in component form and replacing the symbol df/dr by $g(r)$.

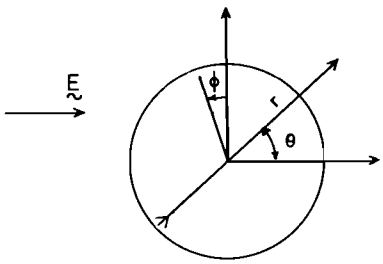

FIG. 2. The spherical polar coordinate system used in sections 3 and 4 in the calculation of the mobility of a sphere. The origin lies at the centre of the sphere and the polar axis ($\theta = 0$) is parallel to the applied electric field.

and

$$[3.8] \quad \phi_i \sim r$$

$$[3.9] \quad g = \frac{\mu r}{2} + O\left(\frac{1}{r}\right) \qquad \text{as } r \to \infty$$

To obtain g, ϕ_i, and μ we must solve the ordinary differential equations [3.4] and [3.5] subject to the above boundary conditions.

The form of the functions ϕ_i and g beyond the double layer may be obtained by using the fact that the coefficients $d\psi^0/dr$ and dn_i^0/dr in eqs. [3.4] and [3.5] are approximately zero in this region. Putting these coefficients to zero and solving the resulting equations subject to the outer boundary conditions [3.8] and [3.9] we find

$$[3.10] \quad \phi_i(r) = r + \frac{c_i}{r^2} \qquad i = 1, 2, ..., N$$

and

$$[3.11] \quad g(r) = \frac{\mu r}{2} + \frac{c_{N+1}}{r^2}$$

beyond the double layer. To determine the quantities μ and c_i in these expressions we must solve the problem for ϕ_i and g in the double layer and match the resulting formulae to the "outer forms" [3.10] and [3.11].

4. The Solution of the Equations for ϕ_i and g in the Double Layer

As we mentioned in the Introduction, the key to the solution of this problem lies in Dukhin's observation (5, 6) that the ions in the double layer are distributed according to the Boltzmann-type formula [1.2]. Comparing this formula with the expression [2.1] defining Φ_i, we see that

$$A_i = 1 - \exp\left(-\frac{z_i e \Phi_i}{kT}\right)$$

Replacing Φ_i in the exponent by the form [3.1] for a spherical particle and neglecting terms of order $(E)^2$ we find[3]

$$[4.1] \quad A_i = \frac{z_i e}{kT} \phi_i E \cos\theta$$

Since we are assuming that the quantity A_i is approximately constant over distances of order κ^{-1}, we may take ϕ_i to be approximately uniform over the double layer. Our analysis is based on this assumption.

By using simple order of magnitude estimates of the terms in the governing equations [3.4] and [3.5] for ϕ_i and g we may eliminate a number of terms from these equations. To begin with, consider the equation [3.5] for g in the double layer:

Let $\bar{g}$ denote the value of g at a distance of order κ^{-1} from the particle surface. Since g is zero at the surface (see [3.6]) g changes by an amount of order $\bar{g}$ over the double layer; hence the derivative dg/dr must rise to a value of order $\bar{g}\kappa$ in the double layer. Similarly d^2g/dr^2 is of order $\bar{g}\kappa^2$, and so on for higher derivatives. By comparing the magnitude of the various terms in eq. [3.5] and neglecting $O(1/\kappa a)$ terms we find that the equation reduces to

$$[4.2] \quad \frac{d^4g}{dx^4} = \frac{1}{\eta a} \sum_{i=1}^{N} z_i e \frac{dn_i^0}{dx} \phi_i$$

where $x = r - a$. This equation is only valid in the double layer, the relative error being of order $1/\kappa a$ in that region.

Integrating eq. [4.2] with respect to x, we obtain

$$[4.3] \quad \frac{d^3g}{dx^3} = \frac{1}{\eta a} \sum_{i=1}^{N} z_i e n_i^0(x) \phi_i + A$$

where A is a constant of integration.

To integrate eq. [4.3], we require expressions for the equilibrium ion densities $n_i^0(x)$. These quantities are related to the equilibrium potential $\psi^0(x)$ in the absence of the field by the Boltzmann formula:

[3]The assumed linear relation between particle velocity and applied field is only valid in the limit as $E \to 0$; hence we may neglect terms of $O(E^2)$ in the analysis.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$$[4.4] \quad n_i^0(x) = n_i(\infty) \exp\left(-\frac{z_i e\psi^0(x)}{kT}\right)$$

Neglecting terms of order $(\kappa a)^{-1}$ corresponds to treating the double layer as being locally flat, so that, for a symmetric electrolyte, the potential is given by (8):

$$[4.5] \quad \frac{ze\psi^0}{kT} = 2 \ln\left(\frac{1 + \alpha e^{-\kappa x}}{1 - \alpha e^{-\kappa x}}\right)$$

where

$$[4.6] \quad \alpha = \tanh\left(\frac{ze\zeta}{4kT}\right), \qquad \kappa^2 = \frac{8\pi e^2 z^2 n(\infty)}{\varepsilon kT}$$

and

$$z = z_1 = -z_2$$

Replacing $n_i^0(x)$ in [4.3] by the Boltzmann formula [4.4] and using the formula [4.5] for the potential we get

$$[4.7] \quad \frac{d^3g}{dx^3} = \frac{zen}{a\eta}\left\{\phi_1\left[\frac{1 - \alpha e^{-\kappa x}}{1 + \alpha e^{-\kappa x}}\right]^2 - \phi_2\left[\frac{1 + \alpha e^{-\kappa x}}{1 - \alpha e^{-\kappa x}}\right]^2\right\} + A$$

where

$$n = n_1(\infty) = n_2(\infty)$$

Integrating the expression [4.7] twice with respect to x and using the fact that dg/dx is zero on the particle surface $x = 0$ (see [3.6]) we obtain

$$[4.8] \quad \frac{dg}{dx} = \frac{\varepsilon kT}{2\pi a\eta ze}\left\{\phi_2 \ln\left(\frac{1 - \alpha e^{-\kappa x}}{1 - \alpha}\right) - \phi_1 \ln\left(\frac{1 + \alpha e^{-\kappa x}}{1 + \alpha}\right)\right\} + Ax^2 + Bx$$

where A and B are constants of integration.

From [4.8] we see that

$$[4.9] \quad \frac{dg}{dx} \approx \frac{\varepsilon kT}{2\pi a\eta ze}\{\phi_1 \ln(1 + \alpha) - \phi_2 \ln(1 - \alpha)\} + Ax^2 + Bx$$

at distances of more than a few double layer thicknesses from the surface. In this region the outer form [3.11] for g is also valid. On differentiating this formula and replacing r by $x + a$ we get

$$[4.10] \quad \frac{dg}{dx} = \frac{\mu}{2} - \frac{2c_3}{(a + x)^3} = \frac{\mu}{2} - \frac{2c_3}{a^3}\left(1 + O\left(\frac{1}{\kappa a}\right)\right)$$

Thus the "inner form" [4.9] for dg/dx approaches the constant value given by [4.10] as x increases, and hence A and B are approximately zero and

$$[4.11] \quad \frac{\mu}{2} - \frac{2c_3}{a^3} = \frac{\varepsilon kT}{2\pi a\eta ze}\{\phi_1 \ln(1 + \alpha) - \phi_2 \ln(1 - \alpha)\}$$

To determine μ and c_3 in terms of ϕ_1 and ϕ_2 we require another equation involving these quantities. It was noted earlier that the ratio $g(dg/dr)^{-1}$ is of order κ^{-1} in the double layer. This estimate is also valid just beyond the double layer where g is given by the outer form [3.11]. Hence, neglecting terms of order $(\kappa a)^{-1}$, we find that

$$c_3 = -a^3\mu/2$$

and thus the expression [4.11] reduces to:

$$\mu = \frac{\varepsilon kT}{3\pi a\eta ze}\{\phi_1 \ln(1 - \alpha) - \phi_2 \ln(1 + \alpha)\}$$

In terms of the non-dimensional mobility E_m, defined by

$$E_m = \frac{6\pi\eta e\mu}{\varepsilon kT}$$

this expression becomes

$$[4.12] \quad E_m = \frac{2}{za}\{\phi_1 \ln(1+\alpha) - \phi_2 \ln(1-\alpha)\}$$

To calculate E_m we must therefore determine the values of the functions ϕ_1 and ϕ_2 in the double layer. These quantities are obtained by solving eq. [3.4] in the double layer subject to the boundary condition [3.7] and matching the solution to the outer forms [3.10] for ϕ_i. To facilitate this matching we rewrite these outer forms as

$$\phi_i = \frac{3r}{2} - \frac{r}{2}\frac{d\phi_i}{dr}$$

obtained by differentiating [3.10] with respect to r and eliminating c_i. At a distance of a few double layer thicknesses from the particle surface the above expression takes the approximate form

$$[4.13] \quad \phi_i = \frac{3a}{2} - \frac{a}{2}\frac{d\phi_i}{dr}$$

By solving the equation [3.4] in the double layer we shall now obtain an expression for $d\phi_i/dr$ at a distance of a few double layer thicknesses from the surface. By substituting this expression for $d\phi_i/dr$ in [4.13] we will then obtain the values of ϕ_1 and ϕ_2, which appear in the formula [4.12] for E_m.

The term $a\,d\phi_i/dr$ in [4.13] is of order $\kappa a\delta\phi_i$, where $\delta\phi_i$ is the variation in ϕ_i over the double layer; although $\delta\phi_i$ is small the product $\kappa a\delta\phi_i$ may well be of order one since κa is large, and thus in order to determine the (approximately uniform) value of ϕ_i in the double layer using [4.13] we must now take into account the small variation in ϕ_i over the double layer. Since the term ϕ_i/r^2 in eq. [3.4] is approximately uniform over the double layer we may replace this equation by a simple first order differential equation for $d\phi_i/dx$, namely

$$[4.14] \quad \frac{d^2\phi_i}{dx^2} - \frac{z_i e}{kT}\frac{d\psi^0}{dx}\frac{d\phi_i}{dx} = \frac{2\phi_i}{a^2} - \frac{2\lambda_i}{akT}\frac{d\psi^0}{dx}g$$

where, as before, x denotes distance from the shear plane and we have dispensed with the small term $(2/r)(d\phi_i/dr)$.

Solving eq. [4.14] subject to the boundary condition [3.7], we obtain an expression for $d\phi_i/dx$ which at distances of more than a few double layer thicknesses from the particle surface reduces to:

$$[4.15] \quad \frac{d\phi_i}{dx} = \frac{2\phi_i}{a^2}\left[x + \int_0^\infty \left(\exp\left(-\frac{z_i e\psi^0}{kT}\right) - 1\right)dy\right] - \frac{2\lambda_i}{kT}\int_0^\infty g\exp\left(-\frac{z_i e\psi^0}{kT}\right)\frac{d\psi^0}{dy}dy$$

(The upper limits of integration have been extended to ∞ on the grounds that these integrals are dominated by the contributions from the double layer.)

Performing integration by parts on the second integral in [4.15] and using the expression [4.8] for dg/dx (with A and B set to zero), we find

$$[4.16] \quad \begin{cases} \dfrac{d\phi_1}{dx} = \dfrac{2\phi_1}{a}\left\{\dfrac{x}{a} - \dfrac{4\alpha}{\kappa a(1+\alpha)}\right\} - \dfrac{24m_1}{\kappa az^2}\left\{\dfrac{\phi_2}{2a}\ln(1-\alpha^2) - \dfrac{\phi_1}{a}\left[\ln(1+\alpha) - \dfrac{\alpha}{1+\alpha}\right]\right\} \\ \text{and} \\ \dfrac{d\phi_2}{dx} = \dfrac{2\phi_2}{a}\left\{\dfrac{x}{a} + \dfrac{4\alpha}{\kappa a(1-\alpha)}\right\} + \dfrac{24m_2}{\kappa az^2}\left\{\dfrac{\phi_2}{a}\left[\ln(1-\alpha) + \dfrac{\alpha}{1-\alpha}\right] - \dfrac{\phi_1}{2a}\ln(1-\alpha^2\right\} \end{cases}$$

where

$$m_i = \frac{\varepsilon kT\lambda_i}{6\pi\eta e^2}$$

is the usual non-dimensional ionic drag coefficient.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

The formulae [4.16] and [4.13] (obtained from the outer form for ϕ_i) are valid at distances from the surface which are large compared to the double layer thickness but small compared to the particle radius. Replacing $d\phi_i/dr$ in [4.13] by the expressions [4.16] for $i = 1$ and 2 and neglecting terms of order $(\kappa a)^{-1}$, we obtain a pair of simultaneous linear equations for ϕ_1 and ϕ_2, viz.

$$[4.17]\quad \begin{cases} \phi_1 - \dfrac{6m_1\phi_2}{\kappa a z^2}\ln(1-\alpha) = \dfrac{3a}{2} \\ \text{and} \\ -\dfrac{6m_2}{\kappa a}\ln(1-\alpha)\phi_1 + \phi_2\left\{1 + \dfrac{4\alpha}{\kappa a(1-\alpha)} + \dfrac{12m_2}{\kappa a z^2}\left[\ln(1-\alpha) + \dfrac{\alpha}{1-\alpha}\right]\right\} = \dfrac{3a}{2} \end{cases}$$

The terms in these equations which have κa in the denominator are negligible unless α is close to unity, which means $\exp ze\zeta/kT$ must be large, in which case [4.6] becomes:

$$[4.18]\quad \alpha \approx 1 - 2\exp\left(\frac{-ze\zeta}{2kT}\right)$$

We may then replace α in these equations by the approximate expression [4.18] for *all* values of ζ. The solution of the equations for ϕ_1 and ϕ_2 is then found by straightforward elimination to be

$$[4.19]\quad \phi_1 = \frac{3a}{2} \qquad \text{and} \qquad \phi_2 = \frac{3a}{2}\left[1 + \frac{2\exp\left(\dfrac{ze\zeta}{2kT}\right)}{\kappa a}\left(1 + 3\frac{m_2}{z^2}\right)\right]^{-1}$$

Thus the function ϕ_1 has the value $3a/2$ in the double layer for all ζ while ϕ_2 decreases monotonically to zero from $3a/2$ as ζ increases. The reason for the decrease in ϕ_2 is that at large values of $\exp ze\zeta/kT$ the density of counterions in the double layer is so great that the flux of ions around the surface due to tangential gradients in Φ_2 will be very large unless the gradient of Φ_2 is itself small; such large fluxes could not be balanced by the flow of ions from beyond the double layer and thus the tangential gradient of Φ_2 around the surface approaches zero as ζ increases. Thus Φ_2 becomes uniform over the surface, and from [3.1] it follows that ϕ_2 approaches zero at the surface as ζ increases.

The required formula for the mobility is obtained by substituting the formulae [4.19] for ϕ_1 and ϕ_2 in the expression [4.12] for E_m, which becomes, after some simple manipulations

$$[4.20]\quad E_m = \frac{3}{2}\frac{e\zeta}{kT} - \frac{\left[3\dfrac{e\zeta}{kT} - \dfrac{6\ln 2}{z}\left\{1 - \exp\left(-\dfrac{ze\zeta}{kT}\right)\right\}\right]}{\left\{2 + \left[\kappa a \exp\left(-\dfrac{ze\zeta}{2kT}\right)\right] \Big/ (1 + 3m_2/z^2)\right\}}$$

In deriving this expression we have used the formula

$$\ln\left[\frac{1+\alpha}{1-\alpha}\right] = \frac{ze\zeta}{2kT}$$

obtained by putting $x = 0$ in the expression [4.5] for ψ^0, and we have simplified the numerator of the second term of the right hand side of [4.20] by neglecting terms of order $(\kappa a)^{-1}$.

5. Comparison with Dukhin's Result

The relation derived by Dukhin (4) reads:[4]

$$[5.1]\quad E_m = \frac{3}{2}\frac{e\zeta}{kT} - 6\left\{\frac{\tilde{\zeta}M\sinh^2 Z + [2z^{-1}\sinh 2Z - 3m\tilde{\zeta}]\ln\cosh Z}{\kappa a + 8M\sinh^2 Z - (24m/z^2)\ln\cosh Z}\right\}$$

[4]Note that the term z^{-1} in the numerator of [5.1] is in-correctly rendered as z in ref. 4, p. 307.

where $\tilde{\zeta} = e\zeta/kT$, $Z = z\tilde{\zeta}/4$, and $M = 1 + 3m/z^2$. Values of E_m calculated from this relation as a function of $\tilde{\zeta}$ are shown in Fig. 1 for various (large) values of κa and for $m_1 = m_2 = m = 0.184$, an appropriate figure for KCl as electrolyte. The agreement with the computer calculation of O'Brien and White (2) is excellent, especially at the higher κa values.

Equation [5.1] may be reduced to eq. [4.20] by eliminating terms of order $(1/\kappa a)$. Rather surprisingly, a comparison of eq. [4.20] with [5.1] shows that in most cases formulation [4.20] is closer to the computer result. Table 1 shows this comparison for $z = 1$ and $m = 0.184$ whilst Table 2 shows it for $z = 2$ and $\lambda_{\pm}^{0} = 60$ ohm^{-1} cm^2 equiv.$^{-1}$ (i.e. $m_{\pm} = 0.4287$). Only at $z = 2$ and very low values of the ζ-potential is the more elaborate relation [5.1] superior and under these conditions it can be

replaced by the Smoluchowski equation with no loss of accuracy.

6. Discussion

It is clear that eq. [4.20] is a very considerable improvement on the Smoluchowski formula for large κa and that it is a useful approximation formula even at modest values of κa, below those at which its assumptions could be expected to remain strictly valid. This is not an uncommon occurrence in colloid science where the many assumptions and idealisations which are forced on the theoretical analysis are often mutually compensating to some extent.

The result obtained in this case is of some consequence on two counts. Firstly, it provides valuable confirmation of the validity of the notion of the "polarised double layer" as used by Dukhin and co-workers. Although Semenikhin and Dukhin (9) make a passing reference to a comparison of their analytical approach with results obtained by computer analysis, this is the first detailed comparison to be published. Apart from the electrophoresis problem this concept can be applied to a variety of other problems to generate approximate analytical solutions which should be useful for systems with thin double layers.

Secondly, it provides a very practical alternative to the use of the complete computer solution for calculating the mobility/ζ relation for particles with thin double layers. Although the O'Brien and White (2) computer solution is a significant improvement over its predecessor (10) it requires access to a fairly sophisticated computer and the expenditure of significant computation time. Not only does eq. [4.20] provide a reliable alternative in appropriate cases, but Tables 1 and 2 give an estimate of the likely correction which should be applied. It is also worth noting that the computer comparison referred to above (9) was not to eq. [5.1] but to a much more elaborate set of equations which are claimed to be valid for lower values of κa. The great merit of eq. [4.20] is, of course, its relative simplicity.

7. Summary

An analysis of the "polarised double layer" reveals that a very simple analytical approximation

formula can be derived to correct the Smoluchowski equation for the electrophoretic mobility of a large spherical particle with a thin double layer. The equation is a simplification of the earlier result of Dukhin and is in excellent agreement with detailed computer calculations for $\kappa a \geq 150$; even at $\kappa a \approx 30$, the error is tolerable and could easily be allowed for, most values of the ζ-potential.

A method previously developed by the authors is used to study the effects of adsorption of ions on the electric double layer interaction between dissimilar colloidal plates immersed in 1:1 electrolyte. For adsorption models which permit the total charge on a plate to change sign, the double layer force remains finite at all plate separations, including zero. For weak adsorption of the ions on the plates the force between two dissimilar plates tends to be repulsive at small separations, looking rather like a weakened constant surface charge density model. Conversely for strong ionic adsorption the force tends to be attractive at small separations, rather as in the constant surface potential model. In this paper we discuss three adsorption models: (*1*) fixed primary charge density on the plates with secondary adsorption of both counter-ions and co-ions; (*2*) fixed primary charge density on the plates with secondary adsorption of the counter-ions only, but including the effects of a Stern layer and self-atmosphere potentials; (*3*) zero primary charge on both plates with equilibrium adsorption of both anions and cations from solution, the net charge density on the plates arising from differential adsorption of the ion types.

G. M. BELL et G. C. PETERSON. Can. J. Chem. **59**, 1888 (1981).

On utilise une méthode que l'on a mise au point antérieurement pour étudier les effets d'adsorption d'ions sur l'interaction électrique de la double couche entre des plaques colloidales dissemblables immergées dans un électrolyte de type 1:1. Dans le cas des modèles d'adsorption qui permettent à la charge totale sur une plaque de changer de signe, la force de la double couche demeure finie pour toutes les séparations de plaque, y compris zéro. Pour l'adsorption faible d'ions sur les plaques, la force entre deux plaques dissemblables tend à être répulsive pour de petites séparations et se comporte comme un modèle de densité de charge superficielle constante faible. Dans le cas d'une adsorption ionique forte, la force devient au contraire attractive pour de petites séparations et elle se comporte plutôt comme un modèle de potentiel superficiel constant. Dans cet article nous discutons de trois modèles: (*1*) un modèle de densité de charge primaire fixe sur les plaques avec une adsorption secondaire à la fois des ions opposés et des co-ions; (*2*) un modèle de densité de charge primaire fixe sur les plaques avec seulement une adsorption secondaire des ions opposés mais incluant les effets d'une couche de Stern et des potentiels d'auto-atmosphère; (*3*) un modèle de charge primaire égale à zéro sur les deux plaques avec une adsorption équilibrée des anions et des cations à partir de la solution; la densité de charge nette sur les plaques provient d'une adsorption différentielle des deux types d'ions.

1. Introduction

We consider the electrical double-layer forces between dissimilar parallel plates, the left and right hand plates being labelled 1 and 2 respectively. The term "dissimilar" means here that when the width H of the diffuse region between the plates is infinite the reduced potential $\Phi_{1\infty}$ at the diffuse region boundary adjacent to plate 1 is unequal to the corresponding potential $\Phi_{2\infty}$ at plate 2. It has often been assumed that the plate potentials Φ_1 and Φ_2 remain equal to $\Phi_{1\infty}$ and $\Phi_{2\infty}$ for all values of H. However the "constant potential" assumption implies that the electrical force approaches an infinite attractive value as $H \to 0$, except when $\Phi_{1\infty} = \Phi_{2\infty}$. This occurs because the electric field and hence the Maxwell tension term in the force must become indefinitely large if Φ_1 and Φ_2 remain unequal as $H \to 0$. An alternative assumption that the plate charge densities, σ_1 and σ_2 respectively, remain constant implies that the electrical force approaches an infinite repulsive value as $H \to 0$, except when $\sigma_1 = -\sigma_2$. This happens because the total charge in the diffuse region per unit plate area is $-(\sigma_1 + \sigma_2)$ and hence if the latter remains non-zero as $H \to 0$ the ionic concentrations in the diffuse region and the osmotic term in the force become infinitely large. Double layer models are hardly realistic for very small H since, for instance, real ions have a finite size. Nevertheless an indefinite increase in force is unphysical and it seems likely that some mechanism operates to moderate the force by reduc-

[1]The authors much appreciate being able to participate in this issue in honour of Dr. Sam Levine's devoted work and many important contributions to theoretical chemistry. G.M.B. has had the privilege of collaboration with him over many years and would like to express his grateful thanks.

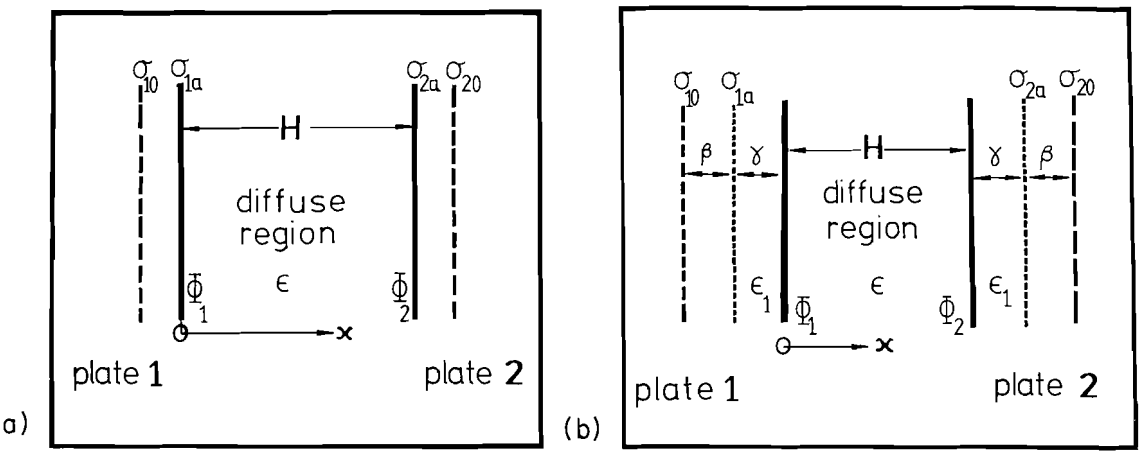

FIG. 1. Surface charges and diffuse layer.

ing the magnitude of the double-layer free energy. One possible mechanism is equilibrium specific adsorption of ions from the diffuse layer onto a plane at or near the diffuse layer boundary. In this paper we shall use several models to study the effect of such adsorption. For definiteness and comparability we fix the values of $\Phi_{1\infty}$ and $\Phi_{2\infty}$ in most of our illustrations of the theory at 2 and ± 0.8 respectively. The methods used here were developed in Bell and Peterson (1), which will henceforth be referred to as I, where they were applied mainly to plates with unequal constant charge densities.

Interactions between similar plates with a fixed primary charge and equilibrium adsorption of counter-ions were first considered by Bierman (2) and then by Levine and Bell (3, 4) and Melville and Smith (5). Models of this type are considered in § 3 and § 4 below. Stern layer and self-atmosphere effects are discussed in § 4. Melville and Smith (5) also considered the assumption that the potential stays constant at the plane of primary charge rather than the diffuse region boundary. Chan *et al.* discussed the interaction between similar (6) and dissimilar (7) "amphoteric" surfaces in which all surface ions are in equilibrium with the medium by way of association–dissociation reactions and gave a comprehensive survey of possible cases. The model we introduce in § 5 yields a similar adsorption isotherm to theirs and we discuss its relation to the results deriving from the other models.

2. Definitions and Method

We define a reduced (dimensionless) potential ϕ and distance ξ by

[1] $\phi = e_0\psi/kT \qquad \xi = \kappa x$

Here ψ is the potential in V, e_0 is the proton charge, k Boltzmann's constant, T the absolute temperature, κ the Debye–Hückel constant for the bulk electrolyte while the x-coordinate is perpendicular to the plates (see Fig. 1). We assume throughout that the electrolyte is of the 1–1 type and the Poisson–Boltzmann equation for the diffuse region can then be expressed as

[2] $d^2\phi/d\xi^2 = \sinh \phi$

A first integral of [2] can be immediately obtained and expressed in the physically perspicuous form

[3] $\mathscr{F}^+ = \cosh \phi - 1 - \frac{1}{2}(d\phi/d\xi)^2$

Here $\mathscr{F}^+$ is the reduced force per unit plate area defined for a 1–1 electrolyte by

[4] $\mathscr{F}^+ = \mathscr{F}/(2nkT)$

$\mathscr{F}$ being the electrical double-layer force per unit area and n the number of ions of each type per unit volume in the bulk electrolyte medium. In [3] the term $\cosh \phi - 1$ represents the repulsive osmotic pressure term in the force while $-\frac{1}{2}(d\phi/d\xi)^2$ represents the attractive Maxwell tension term. Equation [3] can also be expressed as

[5] $d\phi/d\xi = \pm g(\phi)$

where

[6] $g(\phi) = (2 \cosh \phi - 2 - 2\mathscr{F}^+)^{1/2} > 0$

To obtain the diffuse layer width H a second integration is necessary. This yields the relations

[7] $\kappa H = \left| \int_{\Phi_1}^{\Phi_2} \frac{d\phi}{g(\phi)} \right|$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$$[8] \quad \kappa H = \left| \int_{\phi_m}^{\Phi_1} \frac{d\phi}{g(\phi)} \right| + \left| \int_{\phi_m}^{\Phi_2} \frac{d\phi}{g(\phi)} \right|$$

The form [8] is to be used when the curve of ϕ against ξ has a turning point between the plates, the value of ϕ at the turning point being denoted by ϕ_m. This can only occur when $\mathscr{F}^+ > 0$. For $\mathscr{F}^+ < 0$ and when $\mathscr{F}^+ > 0$ but there is no turning point the alternative form [7] must be used. The reduced width κH can be obtained in terms of elliptic integrals, different formulas being necessary for different conditions. These are given in forms suitable for the dissimilar plate problem in the Appendix to I. However the results given in the present paper were all obtained by numerical integration.

We now consider conditions on the plates. It is assumed that the plate surface charge densities σ_1 and σ_2 are functions of the diffuse layer boundary potentials Φ_1 and Φ_2 respectively. Reduced densities f_1 and f_2 are defined by the relations

$$[9] \quad f_1(\Phi_1) = \frac{e_0}{\varepsilon \kappa k T} \sigma_1, \qquad f_2(\Phi_2) = \frac{e_0}{\varepsilon \kappa k T} \sigma_2$$

where ε denotes the dielectric permittivity of the diffuse layer aqueous medium and is assumed to be uniform. Bearing in mind that the left and right hand plates are labelled 1 and 2 respectively the electrostatic boundary conditions can now be written in dimensionless form as

$$[10] \quad (d\phi/d\xi)_1 = -f_1(\Phi_1) \qquad (d\phi/d\xi)_2 = f_2(\Phi_2)$$

For any given $\mathscr{F}^+$ the possible values of the boundary potentials can be obtained by combining [5] with [10] to yield

$$[11] \quad f_1(\Phi_1) = \pm g(\Phi_1) \qquad f_2(\Phi_2) = \pm g(\Phi_2)$$

At $\kappa H = \infty$ the signs are unambiguous since $(d\phi/d\xi)_2$ and Φ_2 have the same sign while $(d\phi/d\xi)_1$ and Φ_1 have opposite signs. Hence putting $\mathscr{F}^+ = 0$ in [11] we obtain

$$[12] \quad \begin{aligned} 2 \sinh (\Phi_{1\infty}/2) &= f_1(\Phi_{1\infty}) \\ 2 \sinh (\Phi_{2\infty}/2) &= f_2(\Phi_{2\infty}) \end{aligned}$$

It can be assumed without loss of generality that

$$\Phi_{1\infty} > 0 \qquad \Phi_{1\infty} \geq |\Phi_{2\infty}|$$

For definiteness we shall in most of our calculations adjust the parameters in f_1 and f_2 to make [12] yield $\Phi_{1\infty} = 2$, $\Phi_{2\infty} = \pm 0.8$.

In order to obtain force–separation curves we thus have to solve the non-linear differential equation [2] and, for adsorption models, the boundary conditions [10] are also nonlinear. For each case we have to pick the correct signs in [11] and, if $\mathscr{F}^+ > 0$, decide between [7] and [8]. This can be done during the whole process of taking the plates from infinite to zero separation with the aid of a graph of the type introduced in I, in which the ordinate is $-d\phi/d\xi$ and the abscissa is ϕ. It should be stressed that the aim of this graphical method is to give a general picture of the behaviour of the plate potentials and the electrical force $\mathscr{F}^+$ during this process and is not intended as a substitute for accurate calculation. Indeed either numerical techniques or tables are always essential to evaluate the integrals [7] or [8]. In this method it is necessary to plot the curves of $f_1(\phi)$ and $-f_2(\phi)$, which by [10] give the values of $-d\phi/d\xi$ at the diffuse region boundaries, against ϕ. These are termed "plate curves" and if they intersect this corresponds to a solution of the equation

$$[13] \quad f_1(\Phi_0) + f_2(\Phi_0) = 0$$

and gives the potential $\Phi_1 = \Phi_2 = \Phi_0$ in the mathematical limiting case of zero separation $\kappa H = 0$. Since it corresponds to finite values of the boundary potential and the electrical field at zero separation the existence of a solution to [13] is necessary if the force is to have a finite limit. If the charge densities on both plates are positive at $\kappa H = \infty$ then a solution of [13] implies that either (*i*) f_1 or f_2 changes sign during the approach of the plates or (*ii*) $f_1(\Phi_0) = f_2(\Phi_0) = 0$. Condition (*ii*) must occur for symmetrical plates since $f_1(\Phi_0)$ is then equal to $f_2(\Phi_0)$. However if $f_i(\phi)$ is a continuous monotonic function of ϕ then $f_i(\Phi_0) = 0$ implies that $f_i(\phi)$ changes sign at $\phi = \Phi_0$. The only other possibility for a continuous function is that $f_i(\phi)$ has both a zero and a turning point at $\phi = \Phi_0$ but this is unlikely for any physically reasonable isotherm. Hence for a solution of [13] to exist for all initial values $\Phi_{1\infty}$ and $\Phi_{2\infty}$ it must be possible to change the sign of the charge on at least one plate by an appropriate change of the potential at the diffuse layer boundary adjacent to the plate. This places some restriction on the type of adsorption model which will give a finite force at $\kappa H = 0$. If it is assumed that the primary ions are all of the same sign and that the number of adsorption sites is equal to the number of primary ions then the plate charge density cannot change sign under any circumstances. This implies that the limiting force is infinite even in the case of similar plates.

The other element of the graphical method is to draw isodynamic slope curves which are plots of $\pm g(\phi)$ against ϕ for fixed $\mathscr{F}^+$. By [5], these show the variation of reduced electric field $-d\phi/d\xi$ with reduced potential ϕ in the medium. By [11], the intersections of the plate and isodynamic slope curves give the possible values of the boundary potential for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

For personal use only.

given $\mathscr{F}^+$. The segment of an isodynamic slope curve between its intersections with two plate curves represents the behaviour of the reduced field $-d\phi/d\xi$ and the reduced potential ϕ between the two plates at the given $\mathscr{F}^+$ value. The most important isodynamic slope curves are those for $\mathscr{F}^+ = 0$ which, by [6], are in fact plots of $\pm 2 \sinh(\phi/2)$ against ϕ. These are the only isodynamic slope curves which pass through the origin and they divide the plane into regions of positive and negative $\mathscr{F}^+$ (see Figs. 2, 6, 8, and 10). The two regions containing the ϕ-axis correspond to positive $\mathscr{F}^+$ while the two containing the $-d\phi/d\xi$ axis correspond to negative $\mathscr{F}^+$. By [12] the intersection of an f_1 plate curve with the $2 \sinh \phi/2$ plot gives the potential $\Phi_{1\infty}$ at $\kappa H = \infty$ and that of a $-f_2$ plate curve with the $-2 \sinh \phi/2$ plot gives $\Phi_{2\infty}$. The general behaviour of $\mathscr{F}^+$ can be deduced from the regions through which the plate curves pass from the $\kappa H = \infty$ points to the intersection corresponding to $\kappa H = 0$. Generally this can be seen most easily from the curve for the plate with the lowest potential at infinity. Examples will be found in subsequent sections while I may be consulted for further details.

An alternative graphical approach of Chan *et al.* (7) depends on the square of the charge density function. We believe our method to be better than that of Chan *et al.* since by using σ rather than σ^2 as ordinate the plate curves assume a simpler form and the signs of the plate charges are clearly displayed. The simultaneous states of the two plate surfaces can be seen for any $\mathscr{F}^+$ value by using the appropriate isodynamic slope curve and it is easy to deduce the succession of $\mathscr{F}^+$ values and plate states between infinite and zero separation.

3. Constant Primary Charge with Adsorption

We assume that a plate surface carries a fixed charge density σ_0 of primary ions and a charge σ_a of ions adsorbed from the 1–1 electrolyte onto an adsorption plane coincident with the diffuse layer boundary or outer Helmholtz plane (see Fig. 1*a*). Each unit area of surface carries ν_+ and ν_- positive and negative adsorbed ions respectively randomly distributed over N_s adsorption sites (Langmuir isotherm). The adsorbed ions remain in equilibrium with the electrolyte medium for all plate separations and the equilibrium equations can be written

$$[14] \quad \ln \nu_+/(N_s - \nu_+ - \nu_-) + \Phi = \ln C_+$$

$$[15] \quad \ln \nu_-/(N_s - \nu_+ - \nu_-) - \Phi = \ln C_-$$

Here Φ denotes the diffuse-layer boundary potential while $\ln C_+$ and $\ln C_-$ are constants which include the chemical free energy of adsorption and the bulk electrolyte chemical potential, divided by kT. It can be shown from [14] and [15] that the adsorbed charge density is given by

$$[16] \quad \sigma_a = e_0(\nu_+ - \nu_-) = e_0 N_s \frac{C_+ e^{-\Phi} - C_- e^{\Phi}}{1 + C_+ e^{-\Phi} + C_- e^{\Phi}}$$

In this section we now specialise to the case $C_+ = C_- = C$ which means that co-ions are not hindered chemically from adsorption although they are less favoured than counter-ions by the electrical potential, at least at large plate separations where Φ has the same sign as the charge on the primary ions. Equation [16] now becomes

$$[17] \quad \sigma_a = 2e_0 N_s C \sinh \Phi/(1 + 2C \cosh \Phi)$$

It is convenient to introduce a primary charge parameter q defined by

$$[18] \quad \sigma_0 = e_0 N_s q$$

The sign of q is that of the primary charge while the magnitude $|q|$ is the number of primary ions per adsorption site. The value $|q| = 1$ means that there is one adsorption site per primary charge. Since $|\sigma_a| < N_s e_0$ for all finite positive or negative values of Φ it follows that the resultant charge density $\sigma_0 + \sigma_a$ cannot change sign. Hence, as remarked in § 2 above, it is necessary that the number of adsorption sites exceed the number of primary ions if the limiting force $\mathscr{F}^+$ at $H = 0$ is to remain finite, which implies $|q| < 1$.

We now reintroduce the labels 1 and 2 to distinguish the two plates. It will be assumed that the adsorption constant C and the density of adsorption sites N_s are the same for the two plates but that the primary charges are unequal. Combining [9] with [17] and [18] the following relations for the reduced plate charge densities f_1 and f_2 are obtained:

$$[19] \quad \begin{aligned} f_1(\Phi_1) &= \lambda\left(q_1 - \frac{2C \sinh \Phi_1}{1 + 2C \cosh \Phi_1}\right) \\ f_2(\Phi_2) &= \lambda\left(q_2 - \frac{2C \sinh \Phi_2}{1 + 2C \cosh \Phi_2}\right) \end{aligned}$$

where $\lambda = e_0^2 N_s/(\kappa \varepsilon kT)$ is a dimensionless constant. We now consider a specific example by supposing that the bulk medium contains 0.1 mol L^{-1} of electrolyte and that there are 10^{19} adsorption sites per square metre (i.e. the area per adsorption site is 10 Å^2) which gives $\lambda = 86.2$ at 25°C. (The same value of λ would correspond to a bulk electrolyte concentration of 0.01 mol L^{-1} if the area per adsorption site were changed to 31.6 Å^2.) Taking the adsorption constant C as 0.01 we use [12] to adjust the primary charge parameters q_1 and q_2 to give $\Phi_{1\infty} = 2$, $\Phi_{2\infty} = \pm 0.8$. This

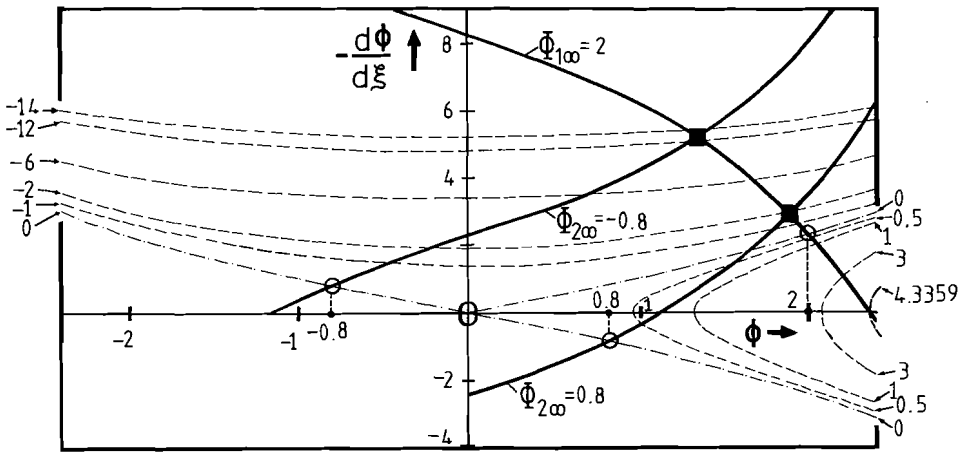

FIG. 2. Isodynamic slope diagram for primary charge with adsorbed counter-ions and co-ions. The plate curves are shown as full lines and the constant force curves as broken lines labelled with the force values. The points representing the plates at $\kappa H = \infty$ are circled while the points representing them at $\kappa H = 0$ are indicated by squares. Parameter values are $\lambda = 86.2$, $C = 0.01$ while for $\Phi_{1\infty} = 2$ the primary charge parameter $q_1 = 0.09473$ and for $\Phi_{2\infty} = \pm 0.8$, $q_2 = \pm 0.02683$.

corresponds to one primary ion per 105.6 Å^2 on plate 1 and one per 372.7 Å^2 on plate 2. Figure 2 is the isodynamic slope diagram for the plate interactions with these parameter values. For the (+ve,+ve) interaction the general force behaviour can be seen by following the segment of the $\Phi_{2\infty} = 0.8$ plate curve which starts at the $\kappa H = \infty$ point (i.e. its intersection with the $-2\sinh(\phi/2)$, $\mathscr{F}^+ = 0$, curve) and ends at the $\kappa H = 0$ point (i.e. its intersection with the $\Phi_{1\infty} = 2$ plate curve). Initially the plate point is in the positive $\mathscr{F}^+$ region. Then, after passing through a maximum $\mathscr{F}^+$ value between 0.5 and 1, it crosses into the negative region to reach the intersection with the $\Phi_{1\infty} = 2$ plate curve. Thus the force is positive (repulsive) at large κH but, after reaching a maximum, it becomes negative (attractive) at small κH. The force/distance curve itself, labelled "adsorbed charge", is shown in Fig. 3. For the (+ve,−ve) plate interaction the relevant segments of the $\Phi_{2\infty} = -0.8$ and the $\Phi_{1\infty} = 2$ plate curves can be seen in Fig. 2 to lie entirely in the negative $\mathscr{F}^+$ region. The force/distance curve is shown in Fig. 4.

In Figs. 3 and 4 the force/distance curves for the present model are compared with those calculated on the assumptions of constant potential and constant total plate charge respectively for the same values of $\Phi_{1\infty}$ and $\Phi_{2\infty}$. The "adsorbed charge" curves go to finite $\mathscr{F}^+$ values as κH decreases to zero while the "constant potential" and "constant charge" curves go to infinity. At non-zero κH values, the "constant potential" behaviour is qualitatively closer to that of the present model than is the "constant charge" behaviour. However, the behaviour of the force at small κH is highly sensitive to the parameter values

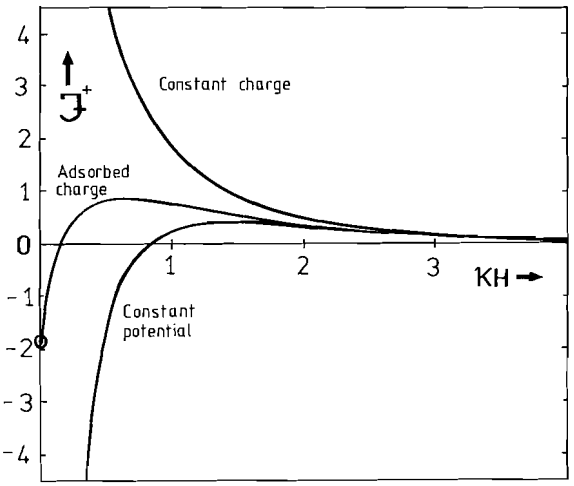

FIG. 3. Force/separation plots for $\Phi_{1\infty} = 2, \Phi_{2\infty} = 0.8$. The curve labelled "adsorbed charge" corresponds to the model of Fig. 2 and is compared with curves calculated on the constant potential and constant plate charge assumptions.

assumed in the model. This can be seen from Fig. 5 where the limiting value $\mathscr{F}_0{}^+$ of the force as $\kappa H \rightarrow 0$ is plotted against the logarithm of the adsorption constant C. The primary charge densities are kept constant on each curve at the values used in the previous calculations, which give $\Phi_{1\infty} = 2$, $\Phi_{2\infty} = \pm 0.8$ at $C = 0.01$. The labels (+ve,+ve) and (+ve,−ve) refer to the signs of the potentials and plate charges at large κH. For small values of C, the limiting force $\mathscr{F}_0{}^+$ is positive whatever the sign of the force at large κH. As $C \rightarrow 0$ ($\log_{10} C \rightarrow -\infty$) $\mathscr{F}_0{}^+$ rapidly approaches infinity. Physically this means that for very weak adsorption the behaviour is similar to that found with constant total plate

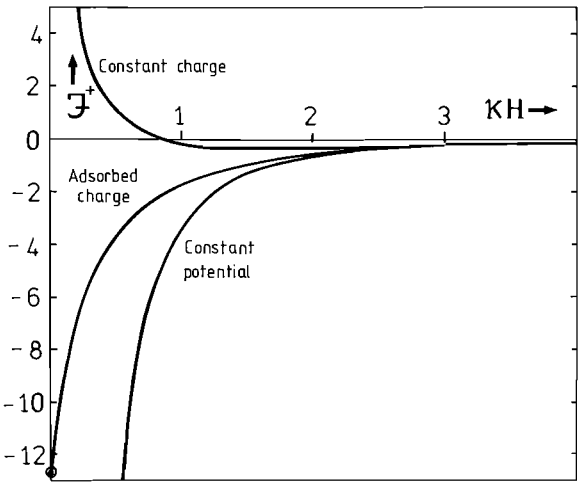

FIG. 4. As Fig. 3 for $\Phi_{1\infty} = 2, \Phi_{2\infty} = -0.8$.

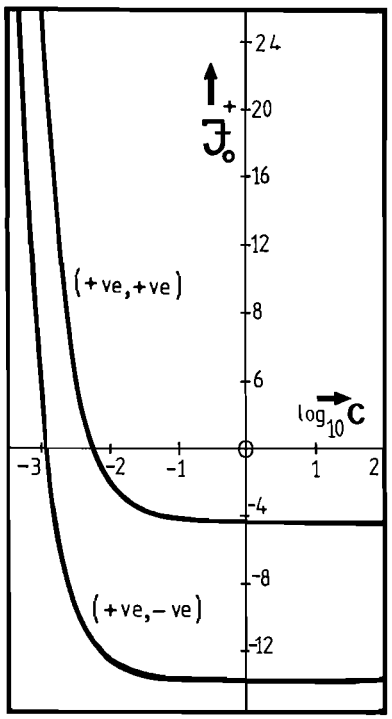

FIG. 5. Primary charge with adsorbed counter-ions and co-ions. Primary charge parameters $q_1 = 0.09473$, $q_2 = \pm 0.02683$. The limiting force $\mathscr{F}_0^+$ at $\kappa H = 0$ is plotted against the logarithm of the adsorption parameter.

charges. As C increases $\mathscr{F}_0^+$ becomes negative on both curves, which is the situation illustrated in Figs. 2, 3, and 4. For $C > 0.1$, $\mathscr{F}_0^+$ is nearly constant on both curves. It is noteworthy that even for very large C the "constant potential" situation of infinite attractive limiting force is not approached. There is a small intermediate range of C ($-2.992 < \log_{10} C < -2.204$) where the sign of $\mathscr{F}_0^+$ is the same as that of $\mathscr{F}^+$ at large separations for both the (+ve,+ve) and the (+ve,−ve) cases.

4. Counter-ion Adsorption: Stern Layer and Self-atmosphere Effects

Our main aim in this section is to investigate how Stern layer and self-atmosphere contributions to the potential at an adsorbed ion affect the inter-plate electrical force. However, we first consider a modification to the model of the last section which consists in assuming that only ions of opposite sign to the primary ions can be adsorbed. We must thus put $C_+ = 0$ in eq. [16] for the adsorbed charge density if the primary charge is positive and $C_- = 0$ if it is negative. Introducing indices 1 and 2 to distinguish the plates and taking q_1 as always positive, the reduced charge densities f_1 and f_2 are given by

$$f_1(\Phi_1) = \lambda\left[q_1 - \frac{C_{1-}\exp(\Phi_1)}{1 + C_{1-}\exp(\Phi_1)}\right]$$

$$[20]\quad f_2(\Phi_2) = \lambda\left[q_2 - \frac{C_{2-}\exp(\Phi_2)}{1 + C_{2-}\exp(\Phi_2)}\right] \quad q_2 > 0$$

$$f_2(\Phi_2) = \lambda\left[q_2 + \frac{C_{2+}\exp(-\Phi_2)}{1 + C_{2+}\exp(-\Phi_2)}\right]$$

$$q_2 < 0$$

It has been assumed that the adsorption site density is the same for both plates and that λ is defined as in § 3.

We now consider a specific example. We take $\lambda = 43.1$, corresponding to an area 20 Å^2 per adsorption site if the bulk electrolyte is 0.1 normal and for simplicity put $C_{1-} = C_{2-} = C_{2+} = C$, giving these adsorption constants the common value of 10^{-3}. As before, the primary charge parameters are adjusted to make $\Phi_{1\infty} = 2$, $\Phi_{2\infty} = \pm 0.8$. In the isodynamic slope diagram (Fig. 6) the plate curve intersection points both lie in the $\mathscr{F}^+ > 0$ region and the relevant segment of the $\Phi_{2\infty} = 0.8$ plate curve lies entirely in this region. On the other hand the corresponding segment of the $\Phi_{2\infty} = -0.8$ curve passes from the $\mathscr{F}^+ < 0$ region to the $\mathscr{F}^+ > 0$ region. Thus in the force/distance plots shown in Fig. 7, $\mathscr{F}^+$ is monotonic for the (+ve,+ve) case but passes through a minimum, changes sign and becomes positive at small κH for the (+ve,−ve) case.

We now suppose that the plane of adsorbed charge is separated by a distance γ from the diffuse layer boundary and that the region between these two planes has a dielectric permittivity ε_1 which is less than ε (see Fig. 1*b*). This region is known as the

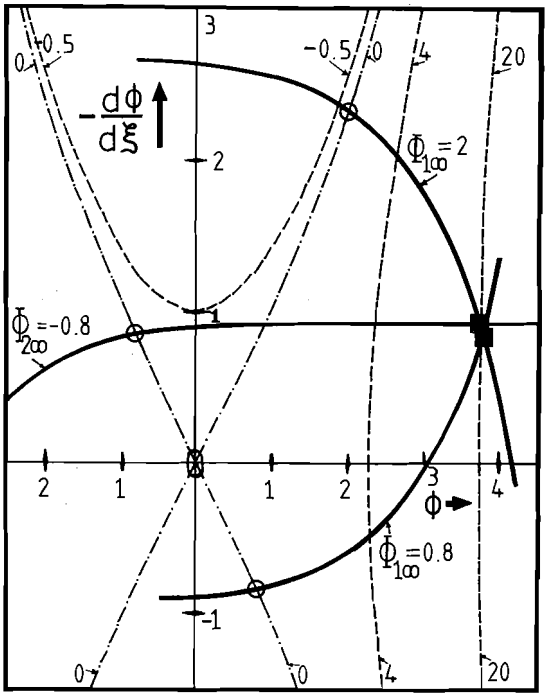

FIG. 6. Primary charge with adsorbed counter-ions. As Fig. 2. Parameter values are $\lambda = 43.1$, $C = 10^{-3}$ while for $\Phi_{1\infty} = 2, q_1 = 0.06189$ and for $\Phi_{2\infty} = \pm 0.8, q_2 = \pm 0.02188$.

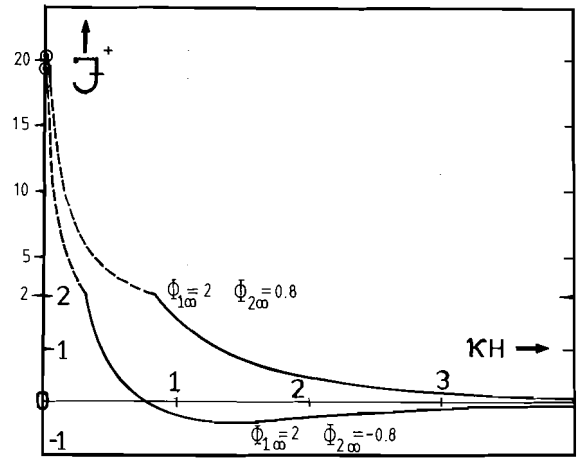

FIG. 7. Force/separation plots for model and parameter values of Fig. 6. Note change of scale at $\mathcal{F}^+ = 2$. Curves for $\mathcal{F}^+ > 2$ are shown as broken lines.

Stern layer and its introduction is intended to allow for finite ion size and decreased polarisability near the plate surface. The potential at the adsorption plane is denoted by Φ_γ and is related to the potential Φ at the diffuse layer boundary by

$$[21] \quad \Phi_\gamma = \Phi + \frac{e_0\gamma}{kT\varepsilon_1}(\sigma_0 + \sigma_a)$$

In a comprehensive theory allowance must be made for the "self-atmosphere" which each adsorbed ion creates by repelling other adsorbed ions and modifying the diffuse layer charge in its vicinity. Hence to obtain the potential at an adsorbed ion charge a self-atmosphere term $\Phi_{s.a.}$ must be added to the adsorption plane mean potential. We shall use a simple expression obtained by Levine *et al.* (8) and used in refs. 3 and 4, which is

$$[22] \quad \Phi_{s.a.} = -\frac{\beta\gamma g}{\varepsilon_1 d}\frac{e_0}{kT}\sigma_a$$

where β is the depth of the layer of permittivity ε_1 behind the adsorption plane (see Fig. 1*b*), $d = \beta + \gamma$ and g is a positive parameter depending on β, γ, the electrolyte concentration and the permittivities. Combining [21] with [22],

$$[23] \quad \Phi_\gamma + \Phi_{s.a.} = \Phi + \frac{e_0\gamma}{kT\varepsilon_1}\left\{\sigma_0 + \left(1 - \frac{\beta g}{d}\right)\sigma_a\right\}$$

It can be seen that the σ_a terms in the Stern layer effect and the self-atmosphere effect tend to cancel out. There is some simplification if $\varepsilon/\varepsilon_1$ and the electrolyte concentration are large enough for the diffuse layer boundary to act as a perfect conductor in relation to the inner layer and if the effective adsorption plane self-atmosphere radius is considerably larger than γ and β. Then $g = 1$ if the plate is metallic while if, on the other hand, it is of low dielectric permittivity and adsorbed ion image effects in the plate are neglected we can put $\beta g/d = 1$ (8). We shall make the latter assumption and then, using eq. [18] for the primary charge density parameter q, eq. [23] becomes

$$[24] \quad \Phi_\gamma + \Phi_{s.a.} = \Phi + \lambda\frac{\varepsilon}{\varepsilon_1}\kappa\gamma q$$

More refined theories of the self-atmosphere effect have been developed (9, 10) but their incorporation in the present formalism would be difficult.

We now introduce a specific example. Putting $\kappa\gamma = 0.2$ and $\varepsilon/\varepsilon_1 = 5$ we replace Φ_1 and Φ_2 in eq. [20] by $\Phi_1 + \lambda q_1$ and $\Phi_2 + \lambda q_2$ respectively. We take $\lambda = 43.1$ as before but modify C to 10^{-4} and adjust q_1 and q_2 to make $\Phi_{1\infty} = 2$ and $\Phi_{2\infty} = \pm 0.8$. Figure 8 is the isodynamic slope diagram for this case and it can be seen that the plate curve intersections are in the $\mathcal{F}^+ > 0$ region, just as they were before Stern and self-atmosphere effects were introduced into the adsorbed counter-ion model. One interesting feature is that for the (+ve,+ve) interaction it is the charge on the plate originally at the higher potential ($\Phi_{1\infty} = 2$) which changes sign. However, this makes little difference to the force/distance curves shown in Fig. 9 which are very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

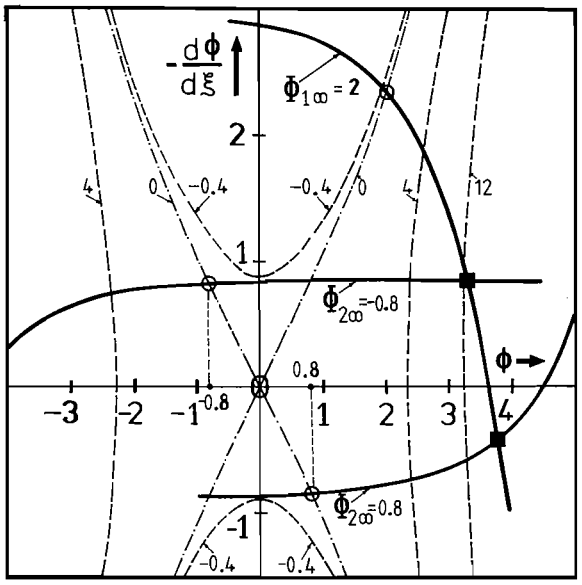

FIG. 8. Primary charge with adsorbed counter-ions: Stern layer and self-atmosphere effects incorporated. As Fig. 2. Parameter values are $\lambda = 43.1$, $C = 10^{-4}$ while for $\Phi_{1\infty} = 2$, $q_1 = 0.06847$ and for $\Phi_{2\infty} = \pm 0.8$, $q_2 = \pm 0.01958$.

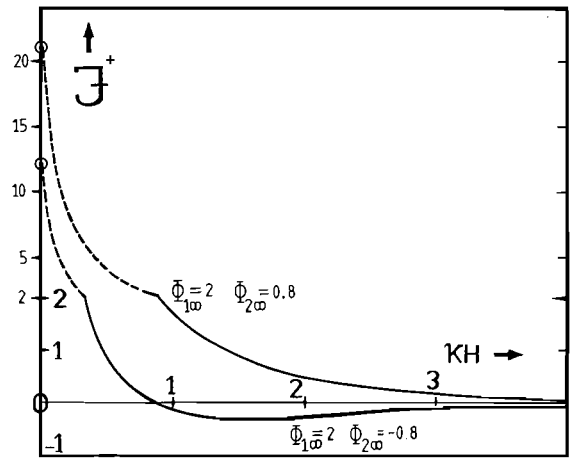

FIG. 9. Force/separation plots for model and parameter values of Fig. 8. Change of scale as on Fig. 7.

similar to those of Fig. 7. However, it should be noted that the adsorption constant C has been reduced by a factor of 10. This indicates that the main effect of introducing the Stern and self-atmosphere potentials is to produce similar behaviour with a smaller adsorption constant. In other words, they increase the effective adsorption strength for counter-ions.

5. Complete Adsorption Equilibrium

The theory of § 3 is now modified in another way. We assume that there is no fixed primary charge and that all the plate charge is adsorbed from the electrolyte medium and in equilibrium with it. Equation [16] now gives the total plate charge density and it follows that

$$f_1(\Phi_1) = \lambda \frac{C_{1+}\exp(-\Phi_1) - C_{1-}\exp(\Phi_1)}{1 + C_{1+}\exp(-\Phi_1) + C_{1-}\exp(\Phi_1)}$$

$$f_2(\Phi_2) = \lambda \frac{C_{2+}\exp(-\Phi_2) - C_{2-}\exp(\Phi_2)}{1 + C_{2+}\exp(-\Phi_2) + C_{2-}\exp(\Phi_2)} \quad [25]$$

For positive potentials at infinite separation

$$C_{1+} > C_{1-}\exp(2\Phi_{1\infty})$$

$$C_{2+} > C_{2-}\exp(2\Phi_{2\infty})$$

while if the potential $\Phi_{2\infty}$ is negative

$$C_{2-} > C_{2+}\exp 2|\Phi_{2\infty}|$$

In a specific example we put the larger adsorption constants equal to 0.3 and adjust the others till, again, $\Phi_{1\infty} = 2$, $\Phi_{2\infty} = \pm 0.8$. Figure 10 is the isodynamic slope diagram and it can be seen that as in the "strong adsorption" example given in § 3 above, the plate curve intersections are both in the $\mathcal{F}^+ < 0$ region. However, as would be expected, the range of variation of the plate charge densities is much larger, especially in the (+ve,−ve) interaction. The corresponding force/distance curves are given in Fig. 11 and resemble those given for the adsorbed charge model in Figs. 3 and 4 except that the limiting force magnitudes at $\kappa H = 0$ are much larger, due to the greater variation of plate charge.

A similar form of charge density function to [25] was derived by Chan *et al.* (6, 7) from association/dissociation surface equilibria. However, it may be noted that mathematically [25] is not as different as it first appears to be from the charge density function [19] based on constant primary charge plus equilibrium adsorbed charge. Both are monotonically decreasing functions of the diffuse layer boundary potential. Also, after some manipulation, $f_1(\Phi_1)$ as given by [25] can be transformed to

$$f_1(\Phi_1) = \frac{\lambda}{1 + C_{1+} + C_{1-}} \times \left\{ C_{1+} - C_{1-} - 2\sinh\frac{\Phi_1}{2} \frac{C_{1-}(1 + 2C_{1+})\exp(\tfrac{1}{2}\Phi_1) + C_{1+}(1 + 2C_{1-})\exp(-\tfrac{1}{2}\Phi_1)}{1 + C_{1+}\exp(-\Phi_1) + C_{1-}\exp(\Phi_1} \right\} \quad [26]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

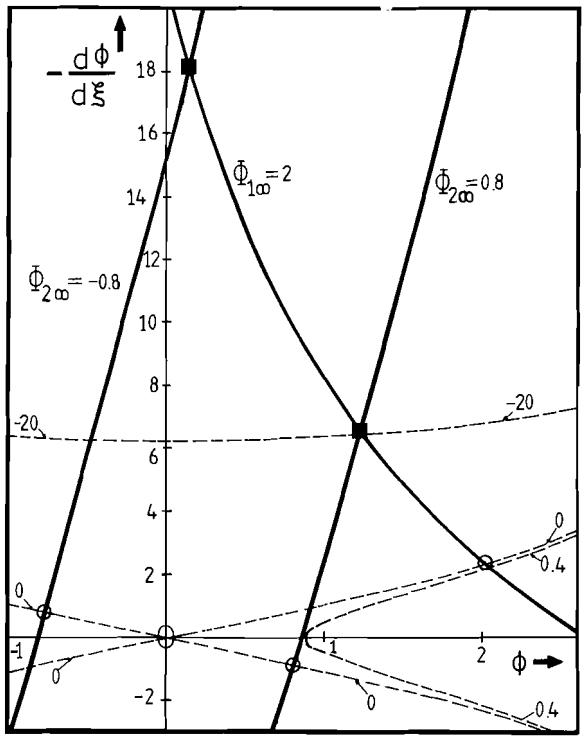

FIG. 10. Equilibrium adsorption of all plate charge. As Fig. 2. Parameter values are $\lambda = 86.2$ and for $\Phi_{1\infty} = 2$, $C_+ = 0.3$, $C_- = 0.001611$; for $\Phi_{2\infty} = 0.8$, $C_+ = 0.3$, $C_- = 0.05518$; for $\Phi_{2\infty} = -0.8$, $C_+ = 0.05518$, $C_- = 0.3$.

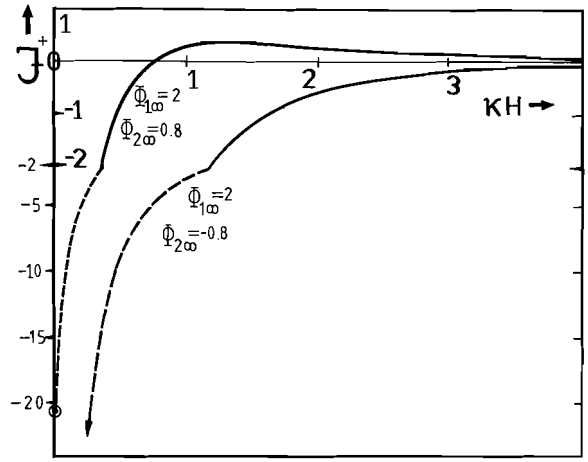

FIG. 11. Force/separation plots for model and parameter values of Fig. 10. Change of scale as in Fig. 7. The $\Phi_{1\infty} = 2$, $\Phi_{2\infty} = -0.8$ plot goes to a limiting value $\mathscr{F}^+ = -161.5$ as $\kappa H \to 0$.

and similarly, of course for $f_2(\Phi_2)$. Thus, as in the model of § 3 above, the charge density can be expressed as a constant term minus an increasing function of the diffuse region boundary potential Φ_1 which becomes zero at $\Phi_1 = 0$.

6. Discussion

The electrical forces between two parallel plates in a 1–1 electrolyte have been investigated for several adsorption models in cases where the plate potentials at large separation differ considerably in magnitude. Some attention has been given to the limiting value of the electrical force as the width of the diffuse layer between the plates approaches zero. Although the models treated can hardly be regarded as realistic at "zero separation" this attention is justified for two reasons. One is that the existence of a finite value for the force limit affords a test of the physical reasonableness of the model and the other is that the sign of the force limit provides valuable evidence for the behaviour of the force at non-zero separations. It has been found that at small κH all the adsorption mechanisms treated reduce the interaction free energy magnitude sufficiently to give a finite force limit. An essential condition is that it should be possible for the plate charge to change sign for a sufficiently large change of potential.

The behaviour of the electrical force at medium and small separations depends quite sensitively on the details of the model and the parameter values. There is some interaction between the two and it is found, for instance, that in the adsorbed counter-ion model the incorporation of Stern and self-atmosphere potentials has the same effect as decreasing the free energy of adsorption. Two main patterns of force behaviour have emerged for the dissimilar plates studied here. In what may be termed the "weak adsorption" situation there is no change in the sign of the force when it is repulsive at large separations and its magnitude increases steadily as the separation decreases. On the other hand, when the force is attractive at large separations it passes through a turning point and then changes sign to become repulsive at small separations. In the "strong adsorption" situation the opposite occurs. The force which is repulsive at large separations passes through a turning point and then becomes attractive at small separations while the originally attractive force remains attractive at all separations. There can be an intermediate adsorption parameter range where neither the originally repulsive nor the originally attractive force changes sign but in the case considered here this range is small. It might be larger if the ratio between the potentials at infinity were nearer to 1. We have not attempted here to incorporate the dispersive forces which are necessary for a consideration of colloidal stability. However in the "strong adsorption" case it seems unlikely that there is an effective energy barrier to the approach of two particles.

The contribution to the capacity of an electrode from a species adsorbed with partial charge transfer[1]

ROGER PARSONS

Laboratoire d'Electrochimie Interfaciale du C.N.R.S., 1, Place Aristide Briand, 92190 Meudon, France

Received July 7, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th brithday

ROGER PARSONS. Can. J. Chem. **59**, 1898 (1981).

The effect of partial charge transfer on the observed capacity of an electrode adsorbing a species from solution is discussed in a general way for the condition of constant fraction of charge transferred. It is confirmed that the width of the peaks is primarily determined by the interaction between adsorbed species. A simple model in which the degree of charge transfer changes rapidly with electrode potential is suggested. This may account for some of the sharp peaks observed experimentally.

ROGER PARSONS. Can. J. Chem. **59**, 1898 (1981).

On présente une discussion générale de l'effet du transfert partiel de charge sur la capacité observée pour une électrode adsorbant une espèce de la solution lorsque la fraction de charge transférée est constante. On confirme que la largeur des pics est déterminée premièrement par l'interaction entre les espèces adsorbées. On suggère un modèle simple dans lequel le taux de transfert de charge change rapidement avec le potentiel d'électrode. Ce modèle pourrait expliquer les quelques pics fins observés expérimentalement.

1. Introduction

Since Lorenz (1) introduced the concept of partial charge transfer into the consideration of adsorption and kinetics at electrodes, there has been a great deal of discussion of the effect of this possibility on the observed behaviour. Rather little has been said directly about the effect on capacity measurements and this paper is an attempt to treat this problem in a fairly general way. Since this work was first presented Conway and Angerstein-Kozlowska (2) have discussed interaction effects in adsorbed layers from this point of view and their work partially overlaps with the work presented here.

2. The Electrode Capacity

The observed charge dq which flows into unit area of an electrode interphase for a given change of potential dE may be regarded as the sum of dσ, the physical charge on the metal and the charge required in partial neutralisation of the adsorbed species λedΓ, where Γ is the surface excess of the species adsorbed (it is assumed that only one species undergoes charge transfer with the electrode), λ is the (fractional) number of electrons transferred to the electrode per ion adsorbed, and e is the unit charge. That is

$$[1] \quad dq = d\sigma + \lambda e d\Gamma$$

Hence the observed capacity is

$$[2] \quad C = \left(\frac{\partial q}{\partial E}\right)_\mu = \left(\frac{\partial \sigma}{\partial E}\right)_\mu + \lambda e \left(\frac{\partial \Gamma}{\partial E}\right)_\mu$$

which may be considered as a parallel combination of two capacities. Such a division is of course subject to the uncertainty in the determination of λ.

The first component $(\partial\sigma/\partial E)_\mu$ will be called the double layer capacity and can be analysed in a familiar way (3) by writing the potential across the inner layer (ϕ^{M-2}) as a function of the electrode charge and the charge on the specifically adsorbed ions (σ^1)

$$[3] \quad d\Phi^{M-2} = \left(\frac{\partial \Phi^{M-2}}{\partial \sigma}\right)_{\sigma^1} d\sigma + \left(\frac{\partial \Phi^{M-2}}{\partial \sigma^1}\right)_\sigma d\sigma^1$$

Note that σ and σ^1 are the charges supposed to be actually present in the double layer. These may be written

$$[4] \quad \sigma = q - \lambda e \Gamma$$

following [1] and

$$[5] \quad \sigma' = (z + \lambda) e \Gamma$$

where ze is the charge on the adsorbing ion when it is in the bulk solution.

Hence in the limit $\lambda \to -z$ (complete charge transfer) $\sigma^1 \to 0$ and the double layer capacity is simply

$$[6] \quad C^i = {}_\sigma C^i = \left(\frac{\partial \sigma}{\partial \phi^{M-2}}\right)_\mu = \left(\frac{\partial (q - ze\Gamma)}{\partial \phi^{M-2}}\right)_\mu$$

This is in parallel with the adsorption capacity.

In the opposite limit when $\lambda = 0$ only the double

[1]The main part of this article was presented at a Dechema Symposium in Tutzing, Germany, on February 13, 1979.

layer capacity exists and it has the well-known form (3).

For any value of λ, eqs. [2] and [3] may be combined, taking account of [4] and [5], to obtain

$$[7]\quad \left(C - \lambda e \frac{d\Gamma}{dE}\right)^{-1} = {}_{\sigma}C^{-1} + {}_{\sigma^1}C^{-1}(z + \lambda)e \frac{d\Gamma}{d(q - \lambda e\Gamma)}$$

$$= {}_{\sigma}C^{-1} + {}_{\sigma^1}C^{-1}(z + \lambda)e \left[\frac{dq}{d\Gamma} - \lambda e\right]^{-1}$$

$$[8]\quad = {}_{\sigma}C^{-1} + {}_{\sigma^1}C^{-1}\left[\frac{1}{(z + \lambda)e}\frac{dq}{d\Gamma} - \frac{\lambda}{z + \lambda}\right]^{-1}$$

Hence we can calculate the observed capacity C from a model which gives the geometric capacities ${}_{\sigma}C$ and ${}_{\sigma^1}C$, as well as λ, and Γ as a function of E (or q). This last relation is of course dependent on the adsorption isotherm.

3. The Adsorption Isotherm

The equilibrium condition for adsorption may be written (cf. ref. 4)

$$[9]\quad \tilde{\mu}^{soln} = \tilde{\mu}^{ads} + \lambda\tilde{\mu}_e{}^M$$

where $\tilde{\mu}^{soln}$ and $\tilde{\mu}^{ads}$ are the electrochemical potentials of the adsorbing species in the solution and adsorbed states respectively and $\tilde{\mu}_e{}^M$ is the electrochemical potential of electrons in the metal electrode. This equilibrium condition may be expanded in terms of local electrical potentials and local concentrations to obtain

$$\mu^{0,s} + ze\phi + kT\ln a_s = \mu^{0,a} + (z + \lambda)e\phi_1 + kT\ln f(\Gamma) + \lambda\mu_e{}^M - \lambda e\phi^M$$

or

$$[10]\quad kT\ln\{a_s/f(\Gamma)\} = \Delta G^{\theta} + ze(\phi_1 - \phi) - \lambda e(\phi^M - \phi_1)$$

where

$$\Delta G^{\theta} = \mu^{0,a} + \lambda\mu_e{}^M - \mu^{0,s}$$

is the standard Gibbs energy of adsorption and $f(\Gamma)$ is a function of the amount adsorbed deriving from the configuration of the monolayer and its short range interactions.

Vetter and Schultze (4) assumed that ϕ_1 was related to the total potential drop across the inner region of the double layer (ϕ^{M-2}) by a geometric factor g. They also included an energy due to the replacement of solvent dipoles by adsorbate dipoles. We neglect the latter for simplicity and use a method for the calculation of ϕ_1 which allows for the discreteness of charge effect [3].

$$[11]\quad \phi_1 - \phi = g\frac{\sigma}{{}_{\sigma}K} + \frac{h\sigma^1}{{}_{\sigma^1}K}$$

Here, we have neglected the difference between ϕ_2 and ϕ, the potential of the solution; g is the geometric factor $(x_2 - x_1)/x_2$ equal to that of Vetter and Schultze, with x_1 the distance of the charge centers of the adsorbed ion from the metal surface and x_2 the thickness of the inner region. The first term in [11] represents the constant field due to the smeared-out charge σ (a uniform permittivity being assumed), h is a factor, previously called $\gamma/(\beta + \gamma)$ which represents the distribution of the part of the potential due to the adsorbed charge. In the low density limit, $h \to g$ as originally shown by Ershler (5). In the high density limit or if the charge σ^1 is regarded as a uniformly smeared-out charge, $h \to 1$.

The integral capacity of the whole double layer K is defined as

$$[12]\quad K = \sigma/(\phi^M - \phi)$$

that is, it is the integral capacity related to the differential capacity which is the reciprocal of the right-hand side of [7]. Thus, from [11] and [12]

$$[13]\quad \phi_1 - \phi = g\frac{K}{\sigma K}(\phi^M - \phi) + \frac{h\sigma^1}{{}_{\sigma^1}K}$$

and obviously

$$[14]\quad \phi^M - \phi_1 = (1 - g)\frac{K}{\sigma K}(\phi^M - \phi) + (1 - h)\frac{\sigma^1}{{}_{\sigma^1}K}$$

Consequently eq. [10] may be written

$$[15]\quad kT\ln\frac{a_s}{f(\Gamma)} = \Delta G^{\theta} + e(\phi^M - \phi)[gz - \lambda(1 - g)]\frac{K}{{}_{\sigma}K} + \frac{e\sigma^1}{{}_{\sigma^1}K}[zh - \lambda(1 - h)]$$

In the limit of complete charge transfer $\sigma^1 \to 0$, [15] becomes

$$[16]\quad kT\ln\frac{a_s}{f(\Gamma)} = \Delta G^{\theta} + ze(\phi^M - \phi)$$

since it follows from [8] that $K/{}_{\sigma}K \to 1$. Equation [16]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

is the form used by Conway and Gileadi (6) and later by Bewick and Thomas (7) with

$$[17] \quad f(\Gamma) = \frac{\theta}{1-\theta}\exp A\theta$$

where $\theta = \Gamma/\Gamma_m$ and Γ_m is the maximum coverage.

On the other hand, in the limit of zero charge transfer ($\lambda \to 0$) eq. [15] becomes

$$[18] \quad RT \ln \frac{a_s}{f(\Gamma)} = \Delta G^\theta + egz\frac{K}{{}_\sigma K}(\phi^M - \phi) + \frac{zhF\sigma_1}{{}_{\sigma^1}K}$$

This is the same form as used by Parry and Parsons (3) with the second term on the right-hand side, expressed in terms of σ, giving the linear dependence of the standard Gibbs energy of adsorption on charge and the third term on the right-hand side giving the ionic interaction energy. Note that, in fact, this term adds to the interaction energy $A\theta$ of the uncharged species in [17]; the latter may be regarded as the short range contribution and may well be attractive.

4. The Origin of Large Capacity Peaks

If we consider the general equation [7] it is evident that large variations in the magnitude of the capacity can arise from the change in the amount adsorbed with potential or charge, that is from the magnitude of the term $\partial\Gamma/\partial E$, for example. It is evident from eq. [18] that variations in this term can arise as a result of the variations in the second or third terms on the right-hand side.

We consider the second term in its form with charge replacing potential i.e. $e[gz - \lambda(1-g)]\sigma$. It is evident from this that no large change in capacity can arise from this term when charge transfer occurs since the term in square brackets changes from gz to z as λ varies from 0 to $-z$. This is normally a change by a factor of 2 or so.

Consequently it must be concluded that the principal cause of the change in magnitude of the capacity must arise from the third term, that is the interaction term. If we add the interaction term from [17] to that in [18], we may write a general form of interaction term

$$[19] \quad A'\theta = A''\Gamma = \{(AkT/\Gamma_m) + (e/{}_{\sigma^1}K) \times [zh - \lambda(1-h)](z+\lambda)\}\lambda$$

Since the electrostatic (long range) interactions are included in the second part of the coefficient A'', the first part AkT/Γ_m is likely to be small and A may well be negative having a value around the critical value of -4. It is interesting to see whether the electrostatic contribution to [19] has a value large in comparison with this. When $\lambda = 0$ the quantity to be compared with A is $zhe\,\sigma^1{}_m/{}_{\sigma^1}KkT$. For a univalent ion with $h = \frac{1}{2}$, ${\sigma_m}^1 = 100\ \mu C\ cm^{-2}$ and ${}_{\sigma^1}K = 100\ \mu F\ cm^{-2}$ this term amounts to about 20. Consequently the repulsion is strong and the peaks are broad and low. For less highly charged ions (i.e. ones which have undergone partial charge transfer) the repulsion decreases and the peaks become higher and narrow. This is probably the strongest argument that submonolayer deposits of metals consist essentially of neutral atoms, as pointed out by Conway *et al.* (8). The consequences of this change in interaction parameter have been explored in detail (2).

Here we may simply note that with the definition [19] of the interaction coefficient and the allowance for adsorption of particles of a different size from the solvent they replace, we may write the adsorption isotherm in the forms:

$$[20] \quad \ln \theta(1-\theta)^{-r} + A'\theta = \ln a_s - \frac{\Delta G^0}{RT} - \frac{e}{{}_\sigma KkT}[gz - \lambda(1-g)]\sigma$$

$$[21] \quad = \ln a_s - \frac{\Delta G^0}{RT} - \frac{eK}{{}_\sigma KkT}[gz - \lambda(1-g)]\phi^{M-2}$$

$$[22] \quad = \ln \beta a_s$$

where one adsorbing particle replaces r solvent molecules.

Hence we may derive the coefficients:

$$[23] \quad \left(\frac{\partial \ln \beta}{\partial\theta}\right)_{a_s,\sigma} = \frac{1}{\theta} + \frac{r}{1-\theta} + A'$$

$$[24] \quad \left(\frac{\partial \ln \beta}{\partial\sigma}\right)_{a_s} = \frac{e}{{}_\sigma KkT}[gz - \lambda(1-g)]$$

$$[25] \quad \left(\frac{\partial \ln \beta}{\partial\phi^{M-2}}\right)_{a_s} = \frac{eK}{{}_\sigma KkT}[gz - \lambda(1-g)]$$

which are valid provided that ${}_\sigma K$, K, λ, and g are constant.

From [23] and [25] the coefficient $\partial\theta/\partial E$ required for the left-hand side of (8) is obtained if $d\phi^{M-2} = dE$ while from [23] and [24] the coefficient $\partial\theta/\partial\sigma$ is found. This must be combined with the relation

$$[26] \quad \partial q/\partial\sigma = 1 + \lambda e(\partial\Gamma/\partial\sigma)$$

obtained from [1] to find the coefficient $\partial q/\partial\Gamma$ required for the right-hand side of [8]. Hence the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

capacity C may be found knowing the adsorption isotherm.

As already shown (9) the capacity peak found for a species with attractive interaction will be higher and narrower than that for a species with repulsive interaction and this is qualitatively in agreement with experimental results for submonolayer metal deposition (8, 10). Nevertheless it is frequently observed in such systems as well as in the adsorption of hydrogen (11) and of halides on solid metals (12) that there are sharp peaks which correspond to the adsorption of substantially less than a monolayer of adsorbate and that these are surrounded by broader peaks. While there may be an explanation of these in terms of adsorption on defects, it is also interesting to consider whether they could be explained in terms of the transfer of charge from the adsorbate to the metal.

5. A Simple Model for a Variation in the Amount of Charge Transfer

In contrast to the previous sections where λ has been assumed to be constant, it is here assumed that this quantity depends on the electrode potential. Some suggestion that this might be so comes from the model proposed by Schmickler (13). However, very little evidence is available as to the extent to which such a variation may occur. This section is therefore only a speculation and further evidence may lead to extensive modification of the proposals made here.

It will be assumed that the adsorbed species transfers its charge over a rather narrow region of potential, that is λ/z changes quite rapidly from 0 to 1. In the absence of any knowledge of the functional dependence of this change it will simply be assumed that it follows a Fermi–Dirac-like function

$$[27] \quad \frac{\lambda}{z} = \frac{\exp(E - E_p)/\varepsilon}{1 + \exp(E - E_p)/\varepsilon}$$

where the parameter ε characterizes the range of potential over which λ/z changes. Clearly E_p is the potential at which $\lambda/z = \frac{1}{2}$.

It will be further assumed that if ε is sufficiently small, the change in Γ, the amount adsorbed, and σ, the physical charge on the metal electrode, is small and may be neglected. The latter assumption is perhaps the most questionable, because it is not known how the redistribution of charge takes place. It could also be assumed that as the charge on the adsorbed species changed by λe the charge on the electrode changed by $-\lambda e$ so that no external charge flowed. In the latter case only the effects due to changes in Γ and σ would be observable, so that it seems more interesting to investigate the limiting case of constant Γ and σ. However, it must be remembered that intermediate cases are also possible.

With the assumption of constant Γ and σ, it follows that the external charge flow is given by

$$[28] \quad dq = e\Gamma d\lambda$$

Or with the aid of [27]

$$[29] \quad dq = e\Gamma \frac{z}{\varepsilon} \frac{\exp(E - E_p)/\varepsilon}{\{1 + \exp(E - E_p)/\varepsilon\}^2}$$

Consequently the observed capacity is

$$[30] \quad C = \frac{ze\Gamma}{\varepsilon} \frac{\exp(E - E_p)/\varepsilon}{\{1 + \exp(E - E_p)/\varepsilon\}^2}$$

$$[31] \quad = \frac{ze\Gamma}{\varepsilon} \frac{\lambda}{z} \left(1 - \frac{\lambda}{z}\right)$$

The peak capacitance occurs at $E = E_p$ or $\lambda/z = \frac{1}{2}$ and has the value

$$[32] \quad C_p = ze\Gamma/4\varepsilon$$

It is thus proportional to the amount adsorbed and inversely proportional to the parameter ε. The width at half height of this capacity peak is readily shown to be 3.52ε. (The analogy with a Langmuirian adsorption peak should be obvious.)

If ε is given the value kT/e for a singly charged species and $ze\Gamma$ is taken as 100 μC cm^{-2} for an almost saturated monolayer of small ions, the peak height is 975 μF cm^{-2} and the peak width is 90 mV. This is rather more than twice the height observed for the sharp peaks in the adsorption of halide ions on silver single crystals and rather broader. If the model is correct this may result from a smaller value of Γ or from the lack of constancy of σ (or less probably of Γ).

If σ is constant, or nearly constant, then the external flow of charge q involves the flow of electrons in the metal and of ions in the solution to adjust the charge in the diffuse layer. This rapid change in the diffuse layer charge over a narrow potential range is likely to lead to a contribution to the measured impedance from the mass transport (see for example ref. 4) and this is in fact observed (12).

This suggestion for the origin of the sharp peaks in the adsorption of halide ions on silver and perhaps for some of the other sharp peaks observed in systems like those of the submonolayer deposition of metals is certainly oversimplified but it may suggest a route to a more detailed explanation.

DOUGLAS HENDERSON and LESSER BLUM. Can. J. Chem. **59**, 1903 (1981).

Simple arguments, based on perturbation theory, are used to derive expressions for the energy of a bulk ionic fluid and the potential difference in an electric double layer. These expressions are identical to those obtained from the much more elaborate mean spherical approximation.

DOUGLAS HENDERSON et LESSER BLUM. Can. J. Chem. **59**, 1903 (1981).

On a utilisé des arguments simples, fondés sur la théorie de perturbation, pour déduire les expressions de l'énergie de l'ensemble d'un fluide ionique et la différence de potentiel d'une double couche électrique. Ces expressions sont identiques à celles obtenues à partir de l'approximation sphérique moyenne beaucoup plus compliquée.

Introduction

For somewhat more than a decade, perturbation theory (1, 2) has been recognized as one of the most tractable, yet most useful, theories of simple liquids, such as argon. Until recently, it has been thought that perturbation theory does not have a similar utility in theory of ionic fluids because, due to the long range Coulomb forces in such systems, many of the terms in a perturbation expansion diverge. The purpose of this note is to demonstrate that, because of electroneutrality and screening, these divergent terms can be resumed and that perturbation theory is at least as useful for ionic fluids as for simple fluids. Perturbation theory yields results which are comparable in accuracy with those of other theories of ionic fluids. In particular, we show that perturbation theory can be used in a very simple, although nonrigorous, way to derive the mean spherical approximation (MSA) expressions for thermodynamic quantities both for bulk ionic fluids and for ionic fluids near an electrified interface (i.e., for the electrical double layer).

Perturbation Theory

Using the expressions of Barker and Henderson (3) the energy of a mixture of molecules, whose pair interactions are described by

$$[1] \quad u_{ij}(r) = \begin{cases} \infty & r < \sigma_{ij} \\ w_{ij}(r), & r > \sigma_{ij} \end{cases}$$

where $\sigma_{ij} = (\sigma_{ii} + \sigma_{jj})/2$ are the hard-sphere diameters of molecules, is

$$[2] \quad U = \frac{3}{2}NkT + \frac{1}{2}N\rho \sum_{ij} x_i x_j \int w_{ij}(r) g_{ij}{}^0(r)\, d\boldsymbol{r} - \frac{1}{2}N\rho\beta \sum_{ij} x_i x_j \int w_{ij}{}^2(r) g_{ij}{}^0(r)\, d\boldsymbol{r} + \ldots$$

where $\rho = N/V$, $\beta = 1/kT$, N is the number of hard spheres, V is the volume, T is the temperature, and $g_{ij}{}^0(r)$ are the radial distribution functions of a system of hard spheres (i.e., $w_{ij}(r) = 0$).

Bulk Ionic Fluids

Consider a fluid of charged hard spheres in a medium of dielectric constant ε. If the charge of the hard spheres is $z_i e$ then

$$[3] \quad w_{ij}(r) = z_i z_j e^2/r\varepsilon$$

For the moment assume that $\sigma_{ij} = \sigma$. If eq. [2] is applied to this system, the two integrals diverge. The first divergence is not troublesome. Because of electroneutrality

$$[4] \quad \sum_i z_i x_i = 0$$

and the net contribution of these terms vanishes.

The second set of integrals is slightly more difficult. Setting

$$g_{ij}{}^0(r) = h_0(r) + 1$$

and substituting eq. [3] into eq. [2] gives

[1]Supported in part by NSF Grant No. CHE80-01969.

0008-4042/81/131903-03$01.00/0
©1981 National Research Council of Canada/Conseil national de recherches du Canada

$$[5] \quad U_i/NkT = -\frac{\kappa^4}{8\pi\rho}\int_0^\infty dr - \frac{\kappa^4}{8\pi\rho}\int_0^\infty h_0(r)\,dr + \ldots$$

where

$$\kappa^2 = 4\pi\beta e^2\rho\sum_i x_i z_i^2/\varepsilon$$

The factor $3NkT/2$ has been subtracted from U to define U_i. The first integral is divergent. However, this integral is the first term in a "ring sum". Because of screening, this ring sum converges. Replacing the integral in [5] by its chain sum gives an integral over $e^{-\kappa r}$ rather than unity. This resummation of a ring sum and resultant screening is already familiar in the Debye–Hückel theory. Thus,

$$[6] \quad U_i/NkT = -\frac{\kappa^3}{8\pi\rho} - \frac{\kappa^4}{8\pi\rho}\int_0^\infty h_0(r)\,dr + \ldots = -\frac{\kappa^3}{8\pi\rho} + \frac{\kappa^4\sigma}{8\pi\rho} + \ldots$$

where the low concentration approximation, $h_0(r) = -1$, $r < \sigma$, and zero otherwise, has been used. The above series is due to Stell and Lebowitz (4). Brout and Carruthers (5) give a derivation in the context of an electron gas.

It is convenient to introduce the normalized screening parameter, Γ, defined by

$$[7] \quad \kappa = 2\Gamma(1 + \Gamma\sigma)$$

If [7] is substituted into [6] then, to order Γ^4,

$$[8] \quad U_i/NkT = -\frac{(2\Gamma)^3(1 + \Gamma\sigma)}{8\pi\rho}$$

Equation [8] is *exactly* the mean spherical approximation (MSA) for a system of charged hard spheres (6–9). Although the above derivation is nonrigorous, it is considerably simpler than the arguments involved in the MSA. Also as we shall see, this same procedure yields this MSA result for potential difference in an electric double layer.

Even if higher-order terms in κ are included in [6], eq. [8] still results provided that only MSA type terms (i.e., nodal diagrams of order κ^n/ρ) are included and evaluated using the low concentration limit of the correlation functions.

Electric Double Layer

Now let us apply perturbation theory to a system of N charged hard spheres of diameter σ and charged $z_i e$ and two charged hard spheres of diameter $R \gg \sigma$ and charge $\pm Q$. We choose two hard spheres of diameter R so that *both* sets of spheres satisfy charge neutrality. However, in every other way we regard the concentration of the spheres to be so small that each sphere of diameter R is independent of the other sphere of diameter R. That is, the concentration of each sphere of diameter R is $1/N$ and terms of order $1/N^2$ can be neglected.

Returning to eq. [2] we see that the excess energy due to the presence of each of the hard spheres of diameter R is

$$[9] \quad \Delta U = -\frac{\kappa^2 Q^2}{2\varepsilon}\int_{(R+\sigma)/2}^\infty g_0^w(r)\,dr + \ldots = -\frac{\kappa^2 Q^2}{2\varepsilon}\int_0^\infty dr - \frac{\kappa^2 Q^2}{2\varepsilon}\int_0^\infty h_0^w(r)\,dr + \ldots$$

where

$$g_0^w(r) = 1 + h_0^w(r)$$

is the radial distribution function for pairs of the large and small spheres. Equation [9] is obtained by applying eq. [2] to the above mixture of charged hard spheres of diameter σ and R, taking the difference between that result and eq. [5], and neglecting terms of order $1/N^2$. Replacing the divergent integral in [9] by the ring sum of which it is the first member and using the low concentration limit for $h_0^w(r)$ gives

$$[10] \quad \Delta U = -\frac{\kappa Q^2}{2\varepsilon} + \frac{\kappa^2 Q^2}{2\varepsilon}\left(\frac{R+\sigma}{2}\right) + \ldots$$

Introducing Γ gives

$$[11] \quad \Delta U = -\frac{Q^2}{\varepsilon}\Gamma(1 - \Gamma R) + \ldots = -\frac{Q^2}{\varepsilon}\frac{\Gamma}{1 + \Gamma R}$$

For large R, eq. [11] becomes

$$[12] \quad \Delta U = -\frac{Q^2}{\varepsilon R} + \frac{Q^2}{\varepsilon\Gamma R^2} + \ldots$$

The first term in [12] is the energy of a sphere and the second term is the energy of the double layer.

The potential difference across the double layer is

$$[13] \quad V = \partial(\Delta U')/\partial Q$$

where $\Delta U'$ is the second term in eq. [12]. Strictly speaking the potential difference is the derivative of the free energy. However, it is more convenient to use the energy because the summation of the ring diagrams is more straightforward. In any case, for the terms considered here, differentiating the energy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

yields the same potential as differentiating the free energy.

Thus,

$$[14] \quad V = 2Q/\varepsilon\Gamma R^2$$

If E is the electric field at the surface of the sphere, the surface charge density is $\varepsilon E/4\pi$ and $Q = \varepsilon E R^2/4$. Thus,

$$[15] \quad V = E/2\Gamma$$

which is the MSA result (10).

Again we see that we have obtained exactly the MSA result by a nonrigorous, but fairly simple, argument based upon perturbation theory.

Summary

Perturbation theory can provide a simple formalism for the development of the MSA expressions both for the bulk fluid thermodynamics and for the double layer potential difference.

These arguments can be extended to fluids in which the solvent consists of discrete molecules. However, in this case, they should not be expected to give results which are identical to those of the MSA since for such fluids the MSA does not yield explicit expressions. In any case, discreteness of the solvent leads to ring sums involving renormalized bonds and so the situation is much more complex. These questions will be treated in a later publication.

The application of the generalized mean spherical approximation to the theory of the diffuse double layer[1]

DOUGLAS HENDERSON
IBM Research Laboratory, San Jose, CA 95193, U.S.A.
AND
LESSER BLUM
Department of Physics, University of Puerto Rico, Rio Piedras, PR 00931, U.S.A.
Received October 7, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

DOUGLAS HENDERSON and LESSER BLUM. Can. J. Chem. **59**, 1906 (1981).

A system of charged hard spheres near a uniformly charged hard wall is considered. An approximation is established by postulating a closure for the Ornstein–Zernike (OZ) equations for this system. In this paper these OZ equations are solved for a closure in which the direct correlation functions are equal to the wall-ion potentials plus a sum of exponential functions. As a specific application of this solution we use one exponential and adjust two parameters to satisfy an approximate contact value theorem and give the same diffuse layer potential as is obtained using the hypernetted chain (HNC) approximation. Once this fit is made, the density, charge, and potential profiles can be easily calculated. The agreement with the corresponding HNC results is good. Comparison with the simpler Poisson–Boltzmann theory of Gouy and Chapman (GC) shows the GC theory to be better than one would expect. However, appreciable differences between the present results and the GC results for the diffuse layer potential are found.

DOUGLAS HENDERSON et LESSER BLUM. Can. J. Chem. **59**, 1906 (1981).

On a fait une étude d'un système de sphères dures chargées situées près d'un mur solide chargé d'une façon uniforme. On a établi une approximation en faisant l'hypothèse que les équations de Ornstein–Zernike (OZ) de ce système sont fermées. Dans le cadre de ce travail, nous avons résolu ces équations de corrélation OZ par le biais d'une fermeture dans laquelle les fonctions de corrélation directe sont égales aux potentiels mur-ions auxquels on ajoute une fonction exponentielle. Une application spécifique de cette solution a été faite; utilisant une exponentielle et ajustant deux paramètres afin de trouver des valeurs satisfaisantes pour le théorème de valeur de contact approximative, nous avons trouvé pour le potentiel de couche diffuse la même valeur que celle obtenue en faisant appel à l'équation d'hyperchaîne (EHC). Lorsque cette corrélation est établie, on peut facilement calculer les profils de densité, de charge et de potentiel. Il existe un bon accord avec les résultats correspondants obtenus par l'équation (EHC). Une comparaison avec la théorie plus simple de Poisson–Boltzmann développée par Gouy et Chapman (GC) révèle que cette théorie de GC est meilleure que prévue. Cependant on trouve que les différences appéciables entre les résultats actuels et les résultats de GC sont dues au potentiel de couche diffuse.

[Traduit par le journal]

Introduction

Henderson *et al.* (1) have formulated the Ornstein–Zernike equation in a form appropriate for the study of surfaces near a wall. Probably the most interesting applications of these equations is to the study of an ionic fluid near a charged wall both because the study of long range forces is of considerable theoretical interest and because this electrolyte–electrode system is of practical importance.

In this paper we consider the so-called restricted primitive fluid (a symmetric electrolyte of charged hard spheres all of equal diameter) near a uniform, hard, charged wall. This system is admittedly a gross simplification of a real electrolyte–electrode system. In particular by treating the solvent as a continuous dielectric medium, the explicit contributions of the solvent to the interfacial properties are lost. This is a serious loss since at high charge densities on the wall, and also at high electrolyte concentrations, these contributions dominate. Nonetheless, calculations based upon this primitive model are of interest for two reasons. Firstly, the development of theories which can adequately describe this relatively simple model is a necessary first step in the more general program of studying the full ion–solvent system. Secondly, the conventional method of determining the explicit contributions of the solvent to the interfacial properties is to subtract from experimental results the corresponding values calculated by the theory of Gouy (2) and Chapman (3) which is based upon this primitive model together with the additional assumption that the ions are point charges. Clearly, any errors in the Gouy–Chapman (GC) theory will lead to errors in the estimates of the solvent contributions.

This primitive model has been extensively studied

in recent years. Blum (4) and Henderson and Blum (5) have used the mean spherical approximation (MSA). Henderson *et al.* (6), Henderson and Blum (7), and Carnie *et al.* (8) have used the hypernetted chain (HNC) approximation. Levine and Outhwaite (9), Outhwaite *et al.* (10), and Bhuiyan *et al.* (11, 12) have used the modified Poisson–Boltzmann (MPB) approximation. In addition, Croxton and McQuarrie (13, 14) have used the Born–Green–Yvon (BGY) approximation. Each of these approximations reduces the GC theory if the diameter of the charged hard spheres is set equal to zero.

The most meaningful test of these calculations is comparison with the computer simulations of Torrie and Valleau (15, 16). In a direct test with experiment one is faced with the problem of disentangling the effects due to the model from those due to the approximation. Since the simulations are based upon the same model as the approximate theories, comparison with the computer simulations permits an unambiguous assessment of the validity of the theories. However, it is to be emphasized that comparison with computer simulations is not a goal in and of itself. The ultimate goal is the development of an accurate theory which can be generalized to a more realistic model and so can be fruitfully compared with experiment.

The MSA gives analytical results and so is easy to use. However, it is a linearized theory and is useful only in the limiting case of small charge on the wall. The other theories give rise to integral equations which must be solved analytically and so are difficult to use. One means of simplifying the calculation is to use the noniterative scheme of Henderson and Blum (7). Henderson and Blum used this scheme in the HNC approximation. However, the scheme is more widely applicable. This scheme is simple but has the drawback of yielding only the potential difference across the interface. Fortunately, this drawback can be overcome through the use of the generalized mean spherical approximation (GMSA) which we present here. In the GMSA, a solution of the OZ equations is obtained in terms of some adjustable parameters which can be chosen so as to yield the potential difference calculated by the noniterative procedure. The profiles calculated by this procedure agree well with those obtained from a full numerical solution of the integral equations but are much more easily obtained.

In the application considered here, we use the potential difference calculated by means of the noniterative scheme when applied to the HNC integral equations using the MSA to describe the bulk fluid (the so-called HNC/MSA, or more simply H/M, equations). Some of the other theories have advantages. However, HNC/MSA results agree with the computer simulations as well as, if not better than, those of the other theories. Also we believe that the HNC/MSA theory is the one most likely to be generalized to more realistic models.

Generalized Mean Spherical Approximation

Consider the general case of a system of charged hard spheres near a charged wall. The OZ equation for this system is (5)

$$[1]\quad h_{wi}(x) - c_{wi}(x) = 2\pi \sum_j \rho_i \int_{-\infty}^{\infty} h_{wj}(t)\,dt \int_{|x-t|}^{\infty} sc_{ij}(s)\,ds + 2\pi\beta z_i \sum_j \rho_j z_j \int_0^{\infty} h_{wj}(t)\,\{|x-t| + x + t\}\,dt$$

where $h_{wi}(x) = g_{wi}(x) + 1$, ρ_i, and z_i are the correlation function, bulk number density, and charge of a hard sphere of species i. Further, x is the distance of the center of the hard sphere from the wall and $\beta = 1/k_B T$ is the Boltzmann factor (k_B is Boltzmann's constant).

The bulk direct correlation functions, $c_{ij}(r)$, are assumed to be known. In this paper we assume them to be those obtained from the MSA when applied to the bulk. The interfacial direct correlation functions, $c_{wi}(x)$, are specified by some approximation. One purpose of this note is to give an explicit solution of [1] when the $c_{wi}(x)$ are given by

$$[2]\quad c_{wi}(x) = \sum_n A'_{ni} \exp[-\mu_{ni}x] + \sum_n B''_{ni} \exp[-\nu_{ni}x] - z_i B_0 x, \quad x > \sigma/2$$

for Re $\mu_{ni} > 0$, Re $\nu_{ni} > 0$, and the $g_{wi}(x) = 0$, $x < \sigma/2$.

If $A'_{ni} = B''_{ni} = 0$ and $B_0 = \beta E$, this is the MSA for charged hard spheres near a charged wall whose charge density is $\varepsilon E/4\pi$, where ε is the dielectric constant. If this is not the case, there are at least three ways of using

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

[2]. Firstly, the parameters A'_{ni}, B''_{ni}, μ_{ni}, and ν_{ni} can be regarded as potential parameters specifying some non-Coulomb interaction, perhaps a short range potential describing specific adsorption. As before, $B_0 = \beta E$ would describe the Coulomb interactions for the charged hard sphere/charged hard wall system. In this case, [2] is the MSA for this system.

Secondly, these parameters can be regarded as parameters which may be adjusted to fit some theoretical criteria for the charged hard sphere/charged hard wall system. When used in this manner, [2] is referred to as the GMSA. An example of this type of application has been given by Henderson and Blum (17) who chose 4 parameters to fit some contact value theorems (18) for the $g_{wi}(x)$ when the spheres are in contact with the wall and some approximate expressions for the derivatives of the $g_{wi}(x)$ at contact.

Thirdly, these parameters can be varied to satisfy some approximation for the $c_{wi}(x)$ to some level of accuracy. Used in this way, [2] becomes a numerical method for solving [1]. An example of this type of application has been given by Henderson *et al.* (19) who varied 16 parameters so that [2] satisfied, as well as possible, the extended mean spherical approximation (EMSA).

In this note we return to the second type of approximation, the GMSA. We adjust 2 parameters. One is adjusted to satisfy a contact value theorem and the other is adjusted to fit the potential difference calculated from the HNC/MSA by means of our noniterative scheme (7). We feel that this is preferable to our earlier GMSA calculation (18) because our approximate expressions for the derivatives of $g_{wi}(x)$ at contact are of uncertain accuracy. In addition, when used in this manner the GMSA gives a means of extending our non-iterative technique so that the $g_{wi}(x)$ are obtained. We assume that the charge density on the electrode is $\varepsilon E/4\pi$ and that this charge is positive. Thus $B_0 = \beta E$. Further we assume that the ions of species 1 are anions and the ions of species 2 are cations.

Solution of [1] and [2]

We now proceed to outline the solution of [1] and [2]. This section is of necessity somewhat abstract. Readers uninterested in the mathematical detail may go directly to the next section.

The general solution to this problem is given by [30] of Blum and Stell (20)

$$[3]\quad \Delta\tilde{g}_{wi}(s) = \sum_j \exp[-s\sigma_j/2]\left[\sum_l \frac{1}{s}\tilde{Q}_{lj}(0) - \tilde{F}_j(s)\right][\tilde{Q}(is)]^{-1}_{ji}$$

where $\Delta\tilde{g}_{wi}(s)$ is the Laplace transform of the distribution function $\Delta g_{wi}(x)$ which is the difference between $g_{wi}(x)$ and the corresponding distribution for the hard sphere/hard wall system. Thus,

$$[4]\quad \Delta\tilde{g}_{wi}(s) = \int_{\sigma_i/2}^{\infty} [\exp(-sx)]\,\Delta g_{wi}(x)\,dx$$

Further $\tilde{Q}_{lj}(k)$ is the Fourier transform of the Baxter function (21) $Q_{lj}(r)$,

$$[5]\quad \tilde{Q}_{lj}(k) = \delta_{lj} - \rho_j \int_{\lambda_{ji}}^{\infty} [\exp(ikx)]\,Q_{lj}(x)\,dx$$

$$[6]\quad \lambda_{ji} = \tfrac{1}{2}(\sigma_j - \sigma_i)$$

We have also used

$$[7]\quad \tilde{F}_j(s) = \frac{1}{2\pi}\sum_l \int_{-\infty}^{\infty} \frac{\exp(-ik\sigma_j/2)}{s + ik}\,\tilde{\phi}_l(k)[\tilde{Q}^{T}(-k)]^{-1}_{lj}\,dk$$

with

$$[8]\quad \tilde{\phi}_l(k) = \int_{\sigma_l/2}^{\infty} \exp(ikx)\left[\sum_n A'_{nl}\exp[-\mu_{nl}x] + \sum_n B''_{nl}\exp[-\nu_{nl}x] + z_l B_0 x\right]dx$$

$$= z_l B_0 \lim_{\nu_0 \to 0} \frac{\exp[(ik - \nu_0)\sigma_l/2]}{(\nu_0 - ik)^2}\left[1 - \frac{\sigma_l}{2}(ik - \nu_0)\right]$$

$$+ \sum_n \exp(ik\sigma_l/2)\left[\frac{A'_{nl}\exp(-\mu_{nl}\sigma_l/2)}{\mu_{nl} - ik} + \frac{B''_{nl}\exp(-\nu_{nl}\sigma_l/2)}{\nu_{nl} - ik}\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Substitution of this expression into [7] gives

$$[9] \quad \tilde{F}_j(s) = \tilde{F}_j^{(0)}(s) + \tilde{F}^{(1)}(s)$$

where

$$[10] \quad \tilde{F}_j^{(0)}(s) = \frac{B_0}{2\pi}\sum_l \int_{-\infty}^{\infty} \frac{\exp(-ik\sigma_j/2)}{s+ik}\left\{z_l \lim_{\nu_0\to 0} \frac{\exp[i(k-\nu_0)\sigma_l/2]}{(\nu_0 - ik)^2}\left[1 - \frac{\sigma_l}{2}(ik-\nu_0)\right]\right\}[\tilde{Q}^{\mathrm{T}}(-k)]_{lj}^{-1}\,dk$$

and

$$[11] \quad \tilde{F}_j^{(1)}(s) = \frac{1}{2\pi}\sum_l \int_{-\infty}^{\infty} \frac{\exp(-ik\sigma_j/2)}{s+ik}\sum_n \exp(ik\sigma_l/2)\left[\frac{A'_{nl}\exp(-\mu_{nl}\sigma_l/2)}{\mu_{nl}-ik} + \frac{B''_{nl}\exp(-\nu_{nl}\sigma_l/2)}{\nu_{nl}-ik}\right] \times [\tilde{Q}^{\mathrm{T}}(-k)]_{lj}^{-1}\,dk$$

The integrals in [10] and [11] can be evaluated by choosing a contour around the lower complex k plane, where $\tilde{Q}^{\mathrm{T}}(-k)$ is a nonsingular matrix (21). Furthermore, it can be shown (20, 21) that for $\mathrm{Im}\, k = k' \to \infty$,

$$[12] \quad [\tilde{Q}^{\mathrm{T}}(-k)]_{lj}^{-1} \to O[\exp(-k'\lambda_{lj})]$$

and for $|k| \to \infty$ the integrand is $O(1/|k|^2)$. Hence the only contributions to the integrals are those from the poles in the lower half-plane

$$[13] \quad k = i\mu_{nl};\quad -i\nu_{nl};\quad -i\nu_0$$

Using Cauchy's residue theorem we get for the ionic part

$$[14] \quad \tilde{F}_j^{(0)} = -\frac{B_0}{2\pi}\sum_l z_l \lim_{\mu_0\to 0} 2\pi i\ \mathrm{Res}\left\{\frac{\exp[i(k-\nu_0)\sigma_l/2]\exp(-ik\sigma_j/2)}{(\nu_0-ik)^2}\left[1-\frac{\sigma_l}{2}(ik-\nu_0)\right]\right\} \times [\tilde{Q}^{\mathrm{T}}(-k)]_{lj}^{-1}\Big|_{k\to -i\mu_0} = -\frac{B_0}{s}\sum_l z_l \lim_{\nu_0\to 0}\frac{\partial}{\partial\nu_0}[\tilde{Q}^{\mathrm{T}}(i\nu_0)]_{lj}^{-1}$$

Similarly, the other term, $\tilde{F}_j^{(1)}$, yields

$$[15] \quad \tilde{F}_j^{(1)}(s) = \sum_l\sum_n \left\{A'_{nl}\frac{\exp(\mu_{nl}\lambda_{lj})}{s+\mu_{nl}}[\tilde{Q}^{\mathrm{T}}(i\mu_{nl})]_{lj}^{-1} + B''_{nl}\frac{\exp(\nu_{nl}\lambda_{lj})}{s+\nu_{nl}}[\tilde{Q}^{\mathrm{T}}(i\nu_{nl})]_{lj}^{-1}\right\}$$

which together with [3] yields $\Delta\tilde{g}_i(s)$.

More explicit relations can be obtained if the sizes of the ions in the bulk are equal, and if also some reasonable assumptions are made about the coefficients A'_{nl} and B''_{nl}. From Blum (4) we have

$$[16] \quad [\tilde{Q}^{\mathrm{T}}(is)]_{kj}^{-1} = \delta_{kj} + \rho_k\tilde{P}^{(0)}(s)/\rho + z_k z_j \rho_k \tilde{P}^{\pm}(s)/\xi_0$$

where

$$[17] \quad \rho = \sum_{i=1}^{n}\rho_i$$

$$[18] \quad \xi_0 = \sum \rho_i z_i^2$$

$$[19] \quad \tilde{P}^0(s) = \rho\tilde{Q}_0(s)/[1-\rho\tilde{Q}_0(s)]$$

$$[20] \quad \tilde{P}^{\pm}(s) = \frac{-2\Gamma(s+\Gamma-\Gamma e^{-s\sigma})}{[s^2+2\Gamma s+2\Gamma^2(1-e^{-s\sigma})]}$$

with

$$[21] \quad \Gamma = \frac{1}{2\sigma}[-1+\sqrt{1+2\kappa\sigma}]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

and

$$[22]\quad \kappa^2 = 4\pi\beta \sum_i \rho_i z_i^2/\varepsilon$$

The parameter κ is the Debye screening constant. Further we recall that

$$[23]\quad \tilde{P}^0(s) = \frac{-m_0 - m_1 s - m_2 s^2 - N(s)\, e^{-s\sigma}}{M(s) + N(s)\, e^{-s\sigma}}$$

with

$$[24]\quad M(s) = s^3 + s^2 m_2 + s m_1 + m_0$$

$$[25]\quad N(s) = s n_1 + n_0$$

$$[26]\quad m_0 = -\frac{2\pi\rho}{\Delta^2}\left(1 + \frac{\pi\rho\sigma^3}{3}\right)$$

$$[27]\quad m_2 = \pi\rho\sigma^2/\Delta$$

$$[28]\quad m_1 = m_2^2/2$$

$$[29]\quad n_1 = \frac{2\pi\rho\sigma}{\Delta}\left(1 + \frac{\pi\rho\sigma^3}{4\Delta}\right)$$

$$[30]\quad n_0 = m_0\sigma$$

From [16] and [20] we have

$$[31]\quad \sum_l z_l \left[\frac{\partial}{\partial\nu}[\tilde{Q}^{\mathrm{T}}(i\nu)]^{-1}_{lj}\right]_{\nu=0} = z_j \lim_{s\to 0}\frac{\partial}{\partial s}\left[\frac{s^2}{s^2 + 2\Gamma s + 2\Gamma^2(1 - e^{-s\sigma})}\right] = z_j \frac{1}{2\Gamma(1 + \Gamma\sigma)} = \frac{z_j}{\kappa}$$

Substitution of [31] into [3] and [14] gives

$$[32]\quad \Delta\tilde{g}_{wi}(s) = -\frac{z_i B_0}{\kappa} e^{-s\sigma/2}\left[\frac{1 + \tilde{P}^{\pm}(s)}{s}\right] + \sum_{j,n}\frac{\exp[-(s + \mu_n)\sigma_j/2]}{s + \mu_n}\left\{\sum_l A'_{nl}[\tilde{Q}^{\mathrm{T}}(i\mu_n)]^{-1}_{lj}\right\}[\tilde{Q}(is)]^{-1}_{ji} + \sum_{j,n}\frac{\exp[-(s + \nu_n)\sigma_j/2]}{s + \nu_n}\left\{\sum_l B''_{nl}[\tilde{Q}^{\mathrm{T}}(i\nu_n)]^{-1}_{lj}\right\}[\tilde{Q}(is)]^{-1}_{ji}$$

Further, suppose that the coefficients are of the form

$$[33]\quad A'_{nl} = A'_n$$

$$[34]\quad B''_{nl} = z_n B'_n$$

Hence,

$$[35]\quad \Delta\tilde{g}_{wi}(s) = -\frac{z_i B_0}{\kappa} e^{-s\sigma/2}\left[\frac{1 + \tilde{P}^{\pm}(s)}{s}\right] + \sum_n A'_n \frac{\exp[-(s + \mu_n)\sigma/2]}{s + \mu_n}[1 + \tilde{P}^0(\mu_n)][1 + \tilde{P}^0(s)] - z_i \sum_n B'_n \frac{\exp[-(s + \nu_n)\sigma/2]}{s + \nu_n}[1 + \tilde{P}^{\pm}(\nu_n)][1 + \tilde{P}^{\pm}(s)]$$

If we recall that

$$[36]\quad 1 + \tilde{P}^{\pm}(s) = \frac{s^2}{s^2 + 2\Gamma s + 2\Gamma^2(1 - e^{-s\sigma})}$$

and

$$[37]\quad 1 + \tilde{P}^{(0)}(s) = \frac{s^3 e^{s\sigma}}{L(s) + S(s) e^s}(1 - \eta)^2$$

where $\eta = \pi\rho\sigma^3/6$ and $L(s)$ and $S(s)$ are polynomials defined by Wertheim (22, 23), we have an explicit expression for $\Delta\tilde{g}_{wi}(s)$.

Summary of Solution

It is convenient to define

$$[38]\quad A_n = A'_n \frac{\mu_n^3 \exp(\mu_n\sigma)}{L(\mu_n) + S(\mu_n)\exp(\mu_n\sigma)}$$

and

$$[39]\quad B_n = B'_n \frac{\nu_n^2}{\nu_n^2 + 2\Gamma\nu_n + 2\Gamma^2[1 - \exp(-\nu_n\sigma)]}$$

where $A'_n = A'_{nl}$, $B'_n = B''_{nl}/z_n$, $L(s)$, and $S(s)$ are polynomials defined by Wertheim (22, 23), and Γ is defined by [21] and [22]. Equation [35] simplifies somewhat if [38] and [39] are used. A further simplification is obtained if $x = 0$ is chosen to be the center of the spheres at their distance of closest approach to the wall. Thus,

$$[40]\quad \tilde{g}_{ws}(s) = \frac{a}{s}(1-\eta)^2 e^s f(s,\eta) + (1-\eta)^4 e^s f(s,\eta)\sum_n \frac{A_n}{s+\mu_n}$$

and

$$[41]\quad \tilde{g}_{wd}(s) = \frac{zB_0}{\kappa}\tilde{F}(s) + zs\tilde{F}(s)\sum_n \frac{B_n}{s+\nu_n}$$

where $g_{ws}(x) = [g_{w1}(x) + g_{w2}(x)]/2$ is the normalized density profile, $\rho(x)/\rho$ where ρ is the bulk density, and $g_{wd}(x) = [g_{w1}(x) - g_{w2}(x)]/2$ is the normalized charge profile, $-q(x)/z\rho$, $\eta = \pi\rho\sigma^3/6$, $a = (\beta\partial p/\partial\rho)^{1/2}$, the square root of the bulk fluid compressibility,

$$[42]\quad f(s,\eta) = \frac{s^3}{L(s) + S(s)e^s}$$

$z = |z_i|$, and

$$[43]\quad \tilde{F}(s) = \frac{s}{s^2 + 2\Gamma s + 2\Gamma^2(1 - e^{-s\sigma})}$$

The first term in [40] is the hard sphere/hard wall distribution function. Equation [40] has been given before by Waisman *et al.* (24) and Henderson *et al.* (25). The first term in [14] has been given before by Blum (4) in his solution of the MSA for charged hard spheres near a charged hard wall.

Inverting gives

$$[44]\quad g_{ws}(x) = \left[1 + \frac{(1-\eta)^2}{a}\sum_n A_n\right] g_0(x) - \frac{(1-\eta)^2}{a}\sum_n \mu_n A_n \int_0^x \exp[-\mu_n(x-t)]\, g_0(t)\, dt$$

and

$$[45]\quad g_{wd}(x) = \left[b + z\sum_n B_n\right] F(x) - z\sum_n \nu_n B_n \int_0^x \exp[-\nu_n(x-t)]\, F(t)\, dt$$

where $g_0(x)$ is the hard sphere/hard wall distribution function, $b = \beta zE/\kappa = zB_0/\kappa$, where κ is defined by [22], and $F(x)$ is the inverse of $\tilde{F}(s)$. Explicit expressions for $g_0(x)$ and $F(x)$ have been given by Henderson and Smith (26). Explicit expressions can be obtained for $g_{ws}(x)$ and $g_{wd}(x)$. However, they are complex. For most situations we found it more convenient to perform the integrations in [44] and [45] numerically.

From [44] and [45] we see immediately that

$$[46]\quad g_{ws}(0) = a + (1-\eta)^2\sum_n A_n$$

and

$$[47]\quad g_{wd}(0) = b + z\sum_n B_n$$

since $g_0(0) = a$ and $F(0) = 1$. Differentiating [44] and [45] gives

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

[48] $$g'_{ws}(0) = -(1-\eta)^2 \sum_n \mu_n A_n - \frac{6\eta}{1-\eta} g_{ws}(0)$$

and

[49] $$g'_{wd}(0) = -z \sum_n \nu_n B_n - 2\Gamma g_{wd}(0)$$

since

$$g'_0(0) = -\frac{6\eta}{1-\eta} a$$

and

$$F'(0) = -2\Gamma$$

Finally we can obtain, by expansion of [44] and [45] in powers of s, explicit expressions for the integrals

[50] $$\int_0^\infty [g_{ws}(x) - 1]\,dx = \frac{3\eta}{2(1+2\eta)} + \frac{(1-\eta)^4}{(1+2\eta)} \sum_n \frac{A_n}{\mu_n}$$

[51] $$\int_0^\infty g_{wd}(x)\,dx = \frac{b}{\kappa}$$

and

[52] $$\int_0^\infty x g_{wd}(x)\,dx = \frac{b}{\kappa^2}(1-\Gamma^2) - \frac{z}{\kappa} \sum_n \frac{B_n}{\nu_n}$$

The first and third integrals are, apart from numerical factors, the excess charge adsorbed by the electrode and the diffuse layer potential. The second integral is the charge neutrality condition

[53] $$\int_0^\infty q(x)\,dx = -\frac{\varepsilon E}{4\pi}$$

Setting $A_n = B_n = 0$ gives the MSA results for the charged hard sphere/charged hard wall system (4). Setting $B_0 = B_n = 0$ gives the results of Waisman *et al.* (24) for hard spheres near a hard wall.

Choice of the Parameters

Henderson *et al.* (27) have obtained the exact result

[54] $$g_{ws}(0) = \beta p/\rho + b^2/2$$

Thus, one possibility would be to retain only one term in the sums in [40], [44], [46], [48], and [50] and choose A so that [54] is satisfied. However, this leaves μ undetermined. In principle, μ could be determined by requiring that [50] be equal to its value calculated from the HNC theory. Unfortunately, this requires a full solution of the HNC equation. If the GMSA is to be useful it must be easy to use. Hence, the above procedure is not attractive.

Instead we use the result

[55] $$g_{wd}(0) = b\sqrt{1 + (b^2/4)}$$

Equation [55] is not exact. However, it is satisfied rather closely by the HNC $g_{wd}(x)$. Retaining only one term in the sums in [45], [47], [49], and [52] we have

[56] $$zB = b\sqrt{1 + (b^2/4)} - b$$

The parameter ν is chosen so that the diffuse layer potential,

[57] $$\phi = \frac{E(1-\Gamma^2)}{\kappa} - \frac{zE}{b}\frac{B}{\nu}$$

is equal to that calculated from the HNC approximation (in the HNC/MSA version). Since ϕ can be calculated rather easily by means of the noniterative scheme of Henderson and Blum (7), this procedure is attractive.

The function $g_{wd}(x)$ is now specified. All that remains is the determination of $g_{ws}(x)$. In the HNC approximation

[58*a*] $$g_{ws}(x) = \exp\{\xi(x)\} \cosh\{\eta(x) + \beta z e \phi(x)\}$$

and

[58*b*] $$g_{wd}(x) = \exp\{\xi(x)\} \sinh\{\eta(x) + \beta z e \phi(x)\}$$

where

[59] $$\xi(x) = 2\pi\rho \int_{-\infty}^{\infty} \{g_{ws}(t) - 1\}\,dt \times \int_{|x-t|}^{\infty} s c_s(s)\,ds$$

[60] $$\eta(x) = 2\pi\rho \int_0^\infty g_{wd}(t)\,dt \int_{|x-t|}^{\infty} s c_s^{sr}(s)\,ds$$

and

[61] $$\beta z \phi(x) = \kappa^2 \int_x^\infty (t-x) g_{wd}(t)\,dt$$

In [59] and [60], $c_s(r) = [c_1(r) + c_2(r)]/2$ and $c_d^{sr}(r) = [c_1(r) - c_2(r)] + \beta z^2/\varepsilon r$. Thus, $\xi(x)$ and $\eta(x)$ are contributions arising from the cores of the ions. For point ions, $\xi(x) = \eta(x) = 0$ and the HNC approximation reduces to the GC theory (28). For ions with a nonvanishing core, $\xi(x)$ is small and to a good approximation $g_{ws}(x)$ and $g_{wd}(x)$ are hyperbolic functions but with a different argument than that used in the GC theory. This suggests that $g_{ws}(x)$ be calculated from

[62] $$g_{ws}(x) = \cosh[\sinh^{-1} g_{wd}(x)] = \sqrt{1 + g_{wd}^2(x)}$$

Now both $g_{ws}(x)$ and $g_{wd}(x)$ are specified.

Results

Inasmuch as we use the HNC/MSA values of $\phi = \phi(0)$ to determine ν, it is important to establish the accuracy of these values of ϕ. In Fig. 1 it is seen that the HNC/MSA values of ϕ are in good agreement with the computer simulation values of Torrie and Valleau (16). The HNC/HNC values are poor and are not plotted. At low concentrations the HNC/HNC values of ϕ pass through a maximum at low charge densities. Blum *et al.* (29) have shown that the *total* potential must be monotonic. Although there seems to be no general theorem for ϕ (the *diffuse layer* potential) it seems probable that it too must be monotonic since there is no sign of nonmonotonic behaviour of ϕ in the computer simulations of Torrie and Valleau. At very high charge densities the HNC/MSA values of ϕ also exhibit a maximum. However, the charge densities at which this occurs are much higher than are experimentally accessible so that this behaviour of the HNC/MSA ϕ at high charge densities is of no practical interest. Some refined versions of the MPB and BGY theories predict a monotonic ϕ and are qualitatively superior to the HNC/MSA approximation. However, for values of the charge density which are of experimental interest, the HNC/MSA ϕ is quantitatively better than that of either of these refined approximations.

As seen in Fig. 1, the GC results for ϕ are considerably less satisfactory than the HNC/MSA results. In the GC theory, at high charge densities ϕ is a linear function of log c (where c is the concentration). There is indirect experimental evidence supporting this prediction. This is often taken to be an experimental confirmation of the GC theory. However, as is seen in Fig. 2, the HNC/MSA values of ϕ are also a linear function of log c at high charge densities.

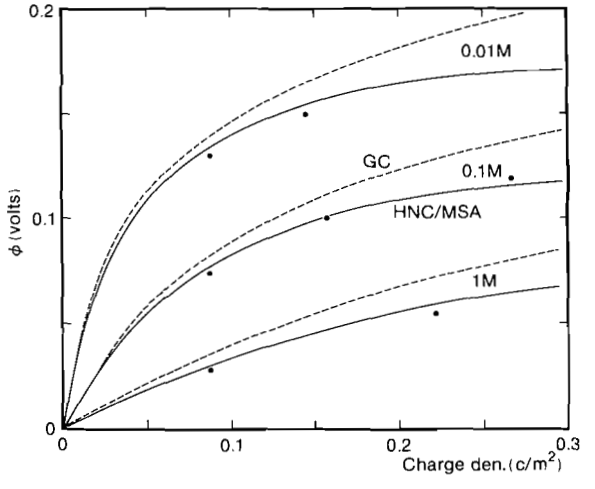

FIG. 1. Diffuse layer potential as a function of charge density on the electrode for a model monovalent ionic fluid (σ = 0.425 nm, T = 298 K, ε = 78.5). The points are the simulation values of Torrie and Valleau (16). The broken curve gives the Gouy–Chapman (GC) results and the solid curve gives the HNC/MSA results.

In Figs. 3 and 4 the distribution functions which result from the GMSA are compared with those resulting from a full HNC/MSA calculation. The agreement is good and indicates that the GMSA procedure is satisfactory.

Although the HNC/MSA ϕ is appreciably different from the GC result, it is insensitive to changes in ionic diameter. However, as is seen from Figs. 5 and 6 there is a diameter dependence in the distribution functions. In general in the GMSA, more counterions are found near the electrode (and consequently fewer further from the electrode, as required by charge neutrality) than is the case in the GC theory. However, as the diameter of the ions is increased, the number of counterions in the immediate vicinity of the electrode decreases. This, presumably, is due to the packing of the spheres right at the electrode. Somewhat further out there is a bulge in the counterion distribution function of the larger spheres so that ϕ is fairly insensitive to the size of the ions. At high charge densities this bulge becomes more pronounced but does not become as pronounced as in the computer simulations where a second layer of

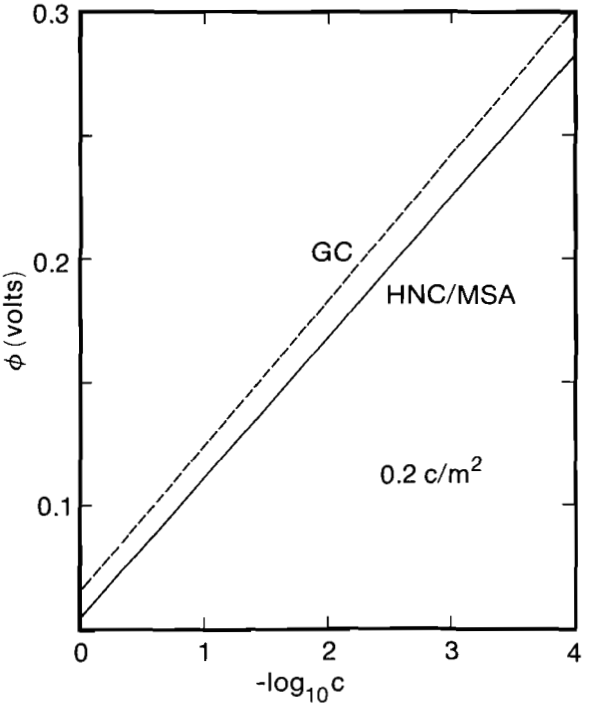

FIG. 2. Diffuse layer potential as a function of concentration for a model monovalent ionic fluid (σ = 0.425 nm, T = 298 K, ε = 78.5). The curves have the same meaning as in Fig. 1.

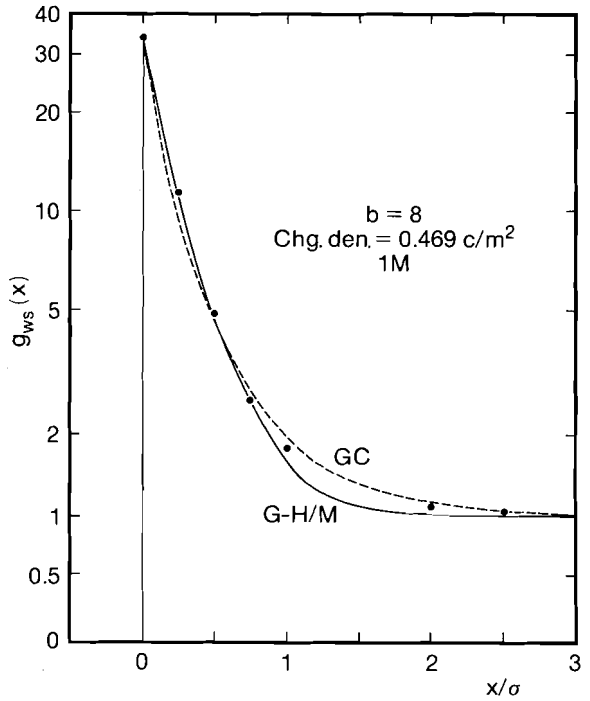

FIG. 3. The density profile of a model monovalent ionic fluid ($\sigma = 0.276$ nm, $T = 298$ K, $\varepsilon = 78.4$). The points are the results of full HNC/MSA calculation, whereas the solid curve gives the GMSA values when v is fitted to the HNC/MSA diffuse layer potential. This latter calculation is designated G-H/M.

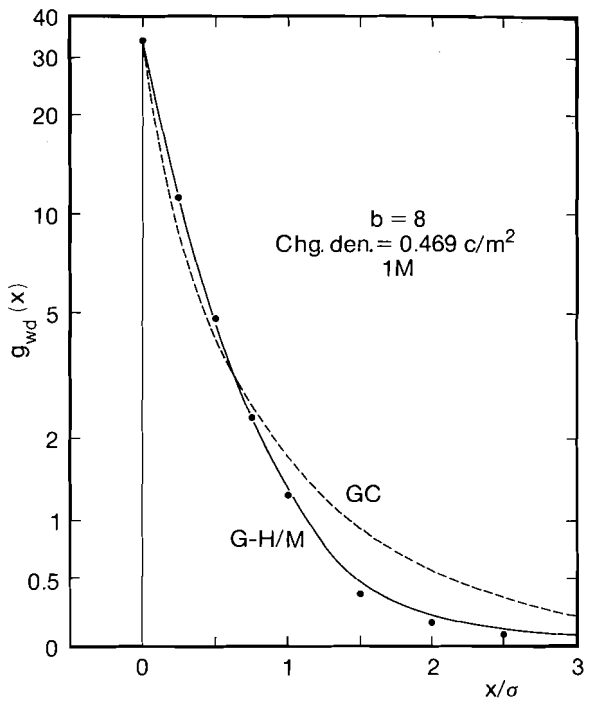

FIG. 4. The charge profile of a model monovalent ionic fluid ($\sigma = 0.276$ nm, $T = 298$ K, $\varepsilon = 78.4$). The points and curves have the same meaning as in Fig. 3.

counterions is formed. However, we note that this formation of a second layer occurs at higher charge densities than is of experimental interest. At the charge densities of practical interest, the GMSA distribution functions are reasonable.

The GMSA values of $g_{wd}(x)$ and $\phi(x)$ for a 1 M solution are plotted in Figs. 7 and 8. In Figs. 9–11 we have plotted $g_{wi}(x)$, $g_{wd}(x)$, and $\phi(x)$ for a 10^{-2} M solution. At both concentrations, errors in the GC profiles are seen. However, given the rapid rate of change of the counterion profile, the GC results for $g_{wi}(x)$ are reasonably good. In looking at Figs. 5–7 and 9–10 it should be kept in mind that the scale is nonlinear and magnifies differences where the distribution functions are small. The agreement of the GC and GMSA results would look better on a linear scale. Despite the fairly good agreement of the GC and GMSA charge profiles, the potential profiles of the two theories, plotted in Figs. 8 and 11, are appreciably different.

Finally, the excess charge adsorbed by the electrode is plotted in Fig. 12. The results of the GC theory and MSA are virtually identical. Of all the quantities considered here, this is the least sensitive.

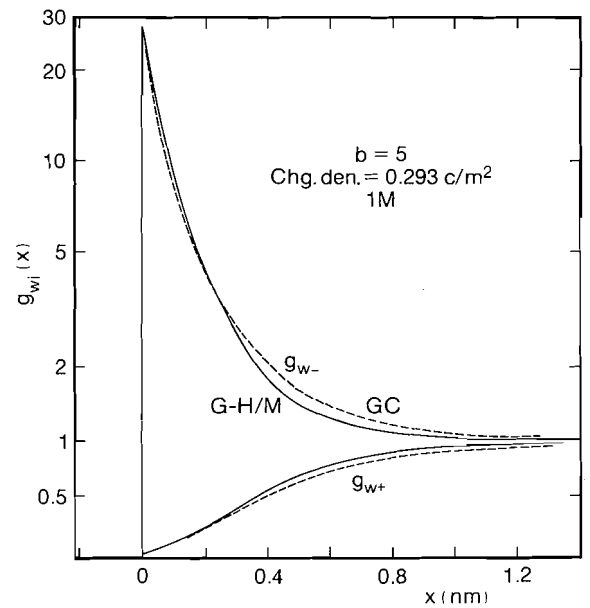

FIG. 5. Ionic distribution functions of a 1 M model monovalent ionic fluid ($\sigma = 0.276$ nm, $T = 298$ K, $\varepsilon = 78.4$). The broken curve gives the Gouy–Chapman (GC) results and the solid curve gives the GMSA results when v is chosen to fit the HNC/MSA results. This latter calculation is designated G-H/M.

Summary

We have made a GMSA calculation of the distribution functions of a system of charged hard spheres near a hard charged wall. We find that the distribution functions, and thus the density and charge profiles, are given fairly accurately by the GC theory. However, errors in the GC theory can be seen. Specifically, there are more counterions near the electrode than in the GC theory. Also at higher concentrations and high charge densities on the electrode there is charge oscillation. That is after the

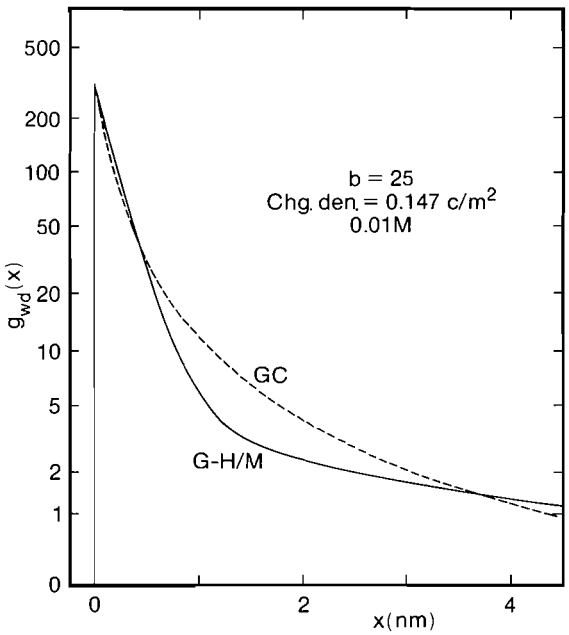

FIG. 10. Charge profile of a 10^{-2} M model monovalent ionic fluid (σ = 0.425 nm, T = 298 K, ε = 78.5). The curves have the same meaning as in Fig. 5.

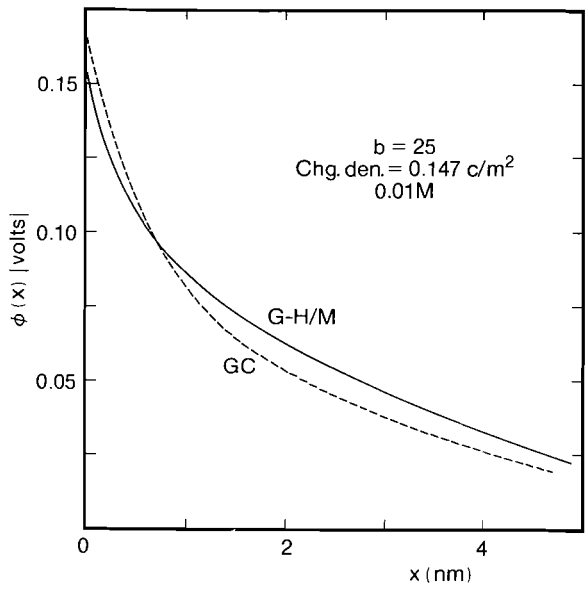

FIG. 11. Potential profile of a 10^{-2} M model monovalent ionic fluid (σ = 0.425 nm, T = 298 K, ε = 78.5). The curves have the same meaning as in Fig. 5.

layer of counterions near the electrode there is a small "layer" of ions of the same charge as the electrode. However, it occurs under extreme conditions and is probably not of practical importance. Given the rapid rate of change of the counterion profile, the GC profiles are fairly good.

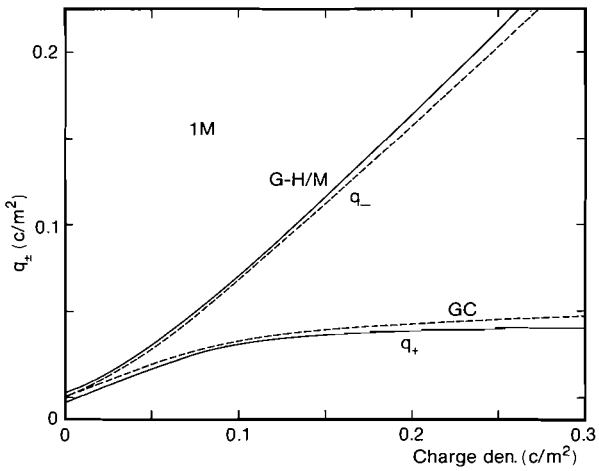

FIG. 12. Excess charge adsorbed by the electrode in a model monovalent ionic fluid (σ = 0.425 nm, T = 298 K, ε = 78.5). The curves have the same meaning as in Fig. 5.

The errors in the GC diffuse layer potentials and potential profiles are relatively more important. This is because the integrand in integral [52] is weighted towards larger values of $g_{wd}(x)$ where the GC values are too large. The integrands in [50] and [51] are unweighted and as a result more accurate values are obtained for these integrals.

The major defect in this calculation is the fact that the GMSA, in common with the HNC, BGY, and MGC approximations, does not adequately treat the excluded volume effects among the ions near the wall. As a result, at higher charge densities, too many counterions are allowed near the wall and the GMSA diffuse layer potential will be too small. However, this effect does not become serious until the charge density on the wall is greater than is experimentally relevant. For charge densities of experimental interest, the GMSA and the HNC approximations are satisfactory.

Since the number of counterions near the wall is small, it seems likely that the GMSA and the HNC approximations give better results for the co-ion distribution functions than for the counterion distribution functions.

Received July 18, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

MARCIN OPALLO, JADWIGA DOJLIDO, and ZBIGNIEW GALUS. Can. J. Chem. **59**, 1918 (1981).

The adsorption of *o*-phthalic acid (H_2Pht) on mercury electrodes was studied in the pH range 0.5–11.5 using surface tension, double layer capacity, and zero charge potential measurements. The calculated adsorption isotherms indicate a reorientation of H_2Pht molecules from flat to vertical orientation with increase of H_2Pht concentration in the solution. These results combined with the change of the zero charge potentials suggest that in the vertical position —COOH groups are directed to the surface of the metal. The change in the adsorption of phthalic acid at different pH's was explained by the different adsorbability of free acid H_2Pht and its ions $HPht^-$ and Pht^{2-}.

MARCIN OPALLO, JADWIGA DOJLIDO et ZBIGNIEW GALUS. Can. J. Chem. **59**, 1918 (1981).

On a étudié l'adsorption de l'acide *o*-phtalique (H_2Pht) sur des électrodes de mercure dans l'intervalle de pH 0,5–11,5 en utilisant des mesures de tension superficielle, de capacité de la double couche et de potentiel de charge zéro. Les isothermes d'adsorption calculées indiquent qu'il se produit une réorientation des molécules de H_2Pht d'une orientation plane vers une orientation verticale lorsque la concentration de H_2Pht augmente dans la solution. Ces résultats, combinés aux changements du potentiel de charge zéro, suggèrent que dans la position verticale les groupes COOH sont dirigés vers la surface du métal. La variation de l'adsorption de l'acide phtalique à différents pH s'explique par l'adsorbabilité différente de l'acide libre H_2Pht et de ses ions $HPht^-$ et Pht^{2-}.

Introduction

In a previous investigation we studied the adsorption of benzoic acid (1). From this and other studies (2–5) of the adsorption of monosubstituted benzene derivatives it follows that the substituent has an important role in the modification of the equilibrium constant and the mechanism of adsorption. These parameters are changed also by introducing a second substituent in the benzene ring (6, 7).

In the present investigation the adsorption of *o*-phthalic acid (H_2Pht) was studied in order to look for a correlation between the adsorption mechanism and the structure of the adsorbate. Inspection of the literature reveals that there is no paper on the adsorption of phthalic acid on mercury electrodes. Only the adsorption of phthalate ion was studied (8). However, this work was carried out under special conditions, with a high concentration of potassium phthalate without addition of an indifferent electrolyte.

We studied the adsorption of H_2Pht using three independent methods, namely, double layer capacity, surface tension, and potential of the zero charge measurements. Since these studies were carried out at different pH's, a knowledge of the distribution of H_2Pht and its anions in such solutions was important. The protolytic equilibrium of phthalic acid in aqueous solutions was previously described in the literature (9). The pK values of two dissociation steps are equal to 2.95 and 5.40. It should be emphasized that a protolytic equilibrium in the bulk of the solution of many organic compounds influences to a large extent the double layer capacity and zero charge potentials of mercury electrodes. This was illustrated in our earlier works (1, 10, 11).

Experimental

Reagent and Solutions

Phthalic acid, NaOH, Na_2SO_4, and KCl were reagent grade chemicals, H_2SO_4 was Merck for spectroscopy; Na_2SO_4 was additionally purified by recrystallization from thrice distilled water. Water of the same purity was used for preparation of all solutions. The second distillation of water was carried out from an alkaline solution of permanganate and a third one from an all-quartz still. Mercury was chemically purified by prolonged shaking with a solution of $Hg_2(NO_3)_2$ acidified with HNO_3 and then distilled under vacuum. Purity of all reagents was tested polarographically. Before measurements all solutions were deoxygenated with a stream of argon presaturated with the investigated solution.

Apparatus

The double layer capacity of the mercury electrode was measured using an impedance bridge type R 565 manufactured in the Soviet Union. The capacities were measured at different frequencies. Above pH 2 no frequency dispersion was found at potentials close to the capacity minimum and in its vicinity, in solutions of different phthalic acid concentration. At lower pH some frequency dispersion of the measured capacity was observed, also at the capacity minimum, both in presence of phthalic acid and for the background electrolyte alone, being, however, larger in the former case. Since it was difficult to linearize the capacities at the low frequency range, we selected on the basis of our experience the frequency 500 Hz hoping that this approach would result in smaller error. Such a procedure could influence the isotherm calculated on the basis of the

capacity measurements; however, since there is a similar deviation of the capacity from the equilibrium value in the different solutions considered in calculating θ, the calculated θ values should not be much different from the true values. The bridge was balanced after 3 s of drop growth. The precision of capacity measurement was ±0.1% and the reproducibility of results was about ±0.5%.

Surface tension was measured with the use of a capillary electrometer applying the maximum bubble pressure method (12). A simple drawn out nonsiliconized capillary dipping vertically into the solution was used. In preliminary experiments a U-shaped capillary was used; however, no improvement in the precision and accuracy of measurements was found. The level of the mercury meniscus in the tube was read by means of a KM 6 cathetometer (Soviet production) with a precision of 0.01 mm. This apparatus was calibrated with a 0.05 *M* solution of Na_2SO_4 taking the maximum value of surface tension to be 426.2 mN m^{-1} (13). The precision of these measurements was ±0.1 mN m^{-1} and the accuracy was about 0.5 mN m^{-1}. Zero charge potentials were measured using the streaming mercury electrode. The precision of these measurements was ±0.5 mV and the accuracy was about 2 mV.

All potentials in electrocapillary experiments were measured with respect to a calomel electrode with 1 *M* NaCl. Double layer capacity and zero charge potential (pzc) measurements were carried out with respect to a calomel electrode with 1 *M* KCl. According to Grahame (in ref. 14) the 1 *M* NaCl calomel electrode has a potential 5 mV more positive than the 1 *M* KCl calomel electrode. Numerical values of E^z in Fig. 6a were corrected for the liquid junction potential estimated using the Henderson formula. All measurements were carried out at 298 ± 0.5 K.

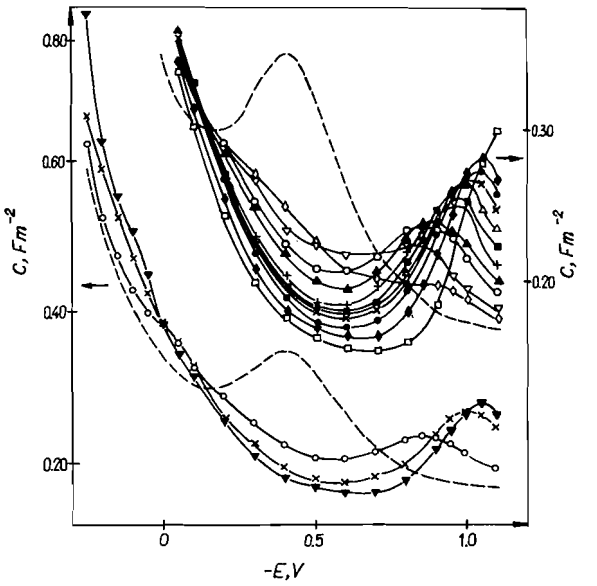

FIG. 1. The dependence of the differential capacity of the mercury electrode on the potential in 0.5 *M* H_2SO_4 containing the following molar concentrations of phthalic acid: (---) 0, (◇) 0.0005, (▽) 0.001, (○) 0.002, (▲) 0.003, (+) 0.005, (■) 0.006, (△) 0.008, (×) 0.010, (●) 0.012, (◆) 0.015, (▼) 0.017, (□) saturated solution.

Results

Protolytic equilibria of phthalic acid in the bulk of the solution suggest that different forms of this compound may be adsorbed on the mercury surface. The distribution of H_2Pht, $HPht^-$, and Pht^{2-} as a function of pH is shown in Fig. 6b. It should be emphasized that these equilibria at the electrode surface may be changed to some extent (see for instance ref. 1). Values of pH equal to 0.5 and 8.0 were chosen to study the adsorption of H_2Pht and Pht^{2-} respectively. Under such conditions the influence of adsorption of other forms was practically eliminated. The maximum mole fraction of $HPht^-$ in aqueous solution is equal to 0.89 (see Fig. 6b); as a consequence there is no pH at which the adsorption of this species could be studied neglecting the other forms.

Measurements in Acidic Solutions

The measured double layer capacities and surface tensions as a function of the mercury electrode potential for 5 × 10^{-4} *M* to saturated solution of H_2Pht in 0.5 *M* H_2SO_4 are given in Figs. 1 and 2. Zero charge potentials for the same H_2Pht concentration range are shown in Fig. 3.

The range of potentials was limited to +250 to −1100 mV and 0 to −1100 mV in double layer

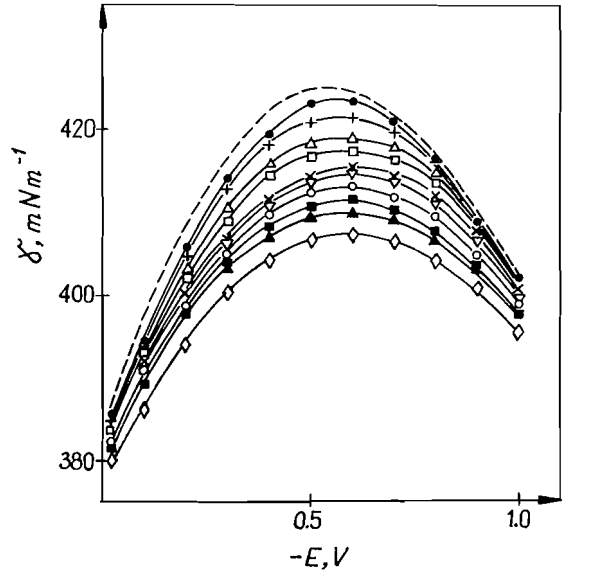

FIG. 2. The dependence of the interfacial tension on the potential in 0.5 *M* H_2SO_4 containing the following molar concentrations of phthalic acid: (---) 0, (●) 0.0005, (+) 0.001, (△) 0.002, (□) 0.003, (×) 0.005, (▽) 0.006, (○) 0.008 and 0.010, (■) 0.012, (▲) 0.015, (◇) saturated solution.

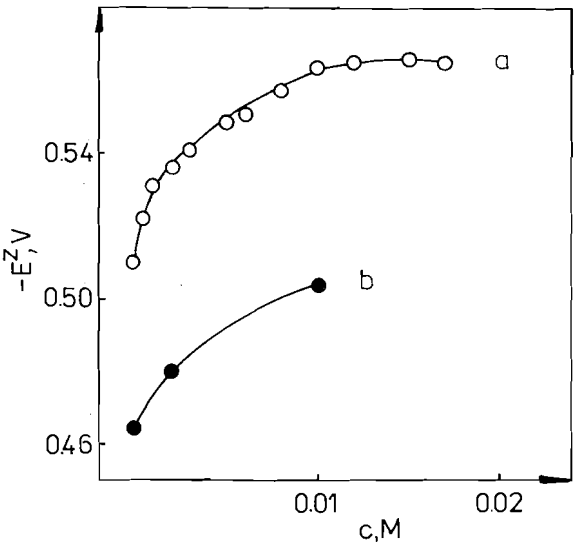

FIG. 3. The dependence of pzc (E^z) of the mercury electrode on the concentration of phthalic acid: (a) 0.5 *M* H_2SO_4 and (*b*) 0.5 *M* Na_2SO_4 with pH = 8.

capacity and electrocapillary measurements, respectively. A significant increase of capacity at potentials near to 0 V was caused by mercury oxidation. At potentials more negative than −1100 mV the measurements were difficult due to electroreduction of phthalic acid (15).

The surface tension decreases significantly with increase in the surfactant concentration. Even at low H_2Pht concentrations both surface tensions and differential capacities are considerably lower with respect to those for the pure background electrolyte. The electrocapillary curves do not coincide with that of the background electrolyte at a potential of −1100 mV. Probably phthalic acid desorbs completely from the electrode surface at more negative potentials not accessible to the experimental measurements.

The decrease in the minimum of the capacity is proportional to surfactant concentration. However, in the concentration range 0.005 to 0.010 *M*, the capacity changes only by 0.09 F m^{-2}, decreasing more significantly at concentrations exceeding 0.010 *M*. This effect may indicate reorientation of H_2Pht on the electrode surface and will be discussed later in this paper. The value of the capacity minimum in H_2Pht saturated solution is equal to 0.156 F m^{-2}.

At a lower H_2Pht concentration range, the pzc shifts to more negative values with increase in phthalic acid concentration. In the concentration range 0.010 to 0.017 *M* it attains a constant value. The maximum of this shift is equal to −55 mV.

Measurements in Alkaline Solutions

These measurements were carried out at pH = 8. As a background electrolyte 0.50 *M* Na_2SO_4 was used; pH was adjusted by addition of NaOH.

The dependence of the capacity on the potential for three concentrations of phthalic acid is shown in Fig. 4. Phthalate ion causes a decrease of the capacity of the mercury electrode at potentials near to 0 V but this effect is much smaller than in acidic solutions. At more negative potentials, the differential capacities were larger in comparison to that in the background electrolyte alone. A similar observation was made by Tilak and Devanathan (8) in their studies on phthalate ion adsorption in the absence of the background electrolyte.

It seems that in our case, at potentials positive with respect to the zero charge potential, the larger capacity is due to pseudo-capacity effects.

At potentials cathodic to E^z the reason for higher capacity in the presence of phthalates is not well understood, but the experimental data in Fig. 4 were confirmed in careful measurements.

It follows from Fig. 3 (curve b) that the pzc is shifted to more negative values with increasing phthalic acid concentration under the above conditions.

It was also found that phthalic acid in alkaline solution causes a small decrease of surface tension on the positive branch of the electrocapillary curve. For instance, this decrease amounts to about 5 mN m^{-1} at −450 mV in a solution saturated with H_2Pht. However, it must be emphasized that the reproducibility of the measurement was not satisfactory.

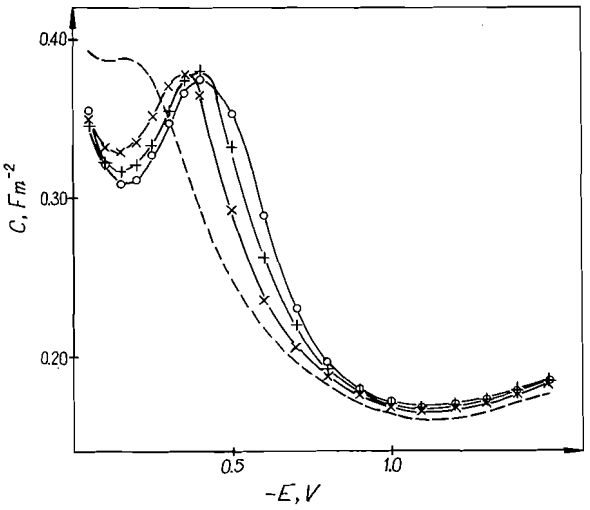

FIG. 4. The dependence of the differential capacity of the mercury electrode on potential in 0.5 *M* Na_2SO_4 at pH = 8, containing the following molar concentrations of phthalic acid (---) 0, (x) 0.002, (+) 0.010, (○) saturated solution.

Measurements at other pH's

The dependence of the differential capacity on the electrode potential at different pHs is presented in Fig. 5. The differential capacity and pzc were measured for 0.01 *M* H_2Pht solution with the pH changing from 0.45 to 11.60. A concentration of H_2Pht equal to 0.01 *M* was found to be the most appropriate in these experiments. The pH was adjusted by addition of the appropriate amount of H_2SO_4 or NaOH to the Na_2SO_4 solution. The total electrolyte concentration was kept constant and equal to 0.50 *M*.

Discussion

The results of the electrocapillary, differential capacity, and zero charge potential measurements in acidic solution indicate the adsorption of phthalic acid molecules at the mercury electrode.

Since our studies were carried out over a wide range of pH, fluorides could not be used as background electrolyte. Under such conditions the selection of sulphates was justified. However, these anions are adsorbed to some extent on mercury electrodes as was shown by Payne (16). Consequently our results are influenced to some extent by this adsorption especially at positive potentials with respect to E^z. Since the pK_2 value for H_2SO_4 is equal to 2.0, at lower pH, the HSO_4^- ion exists in solution, and is also adsorbed to some extent on the mercury electrode. This adsorption was studied by us, and it will be presented elsewhere, since its influence on results presented in the present paper is rather small.

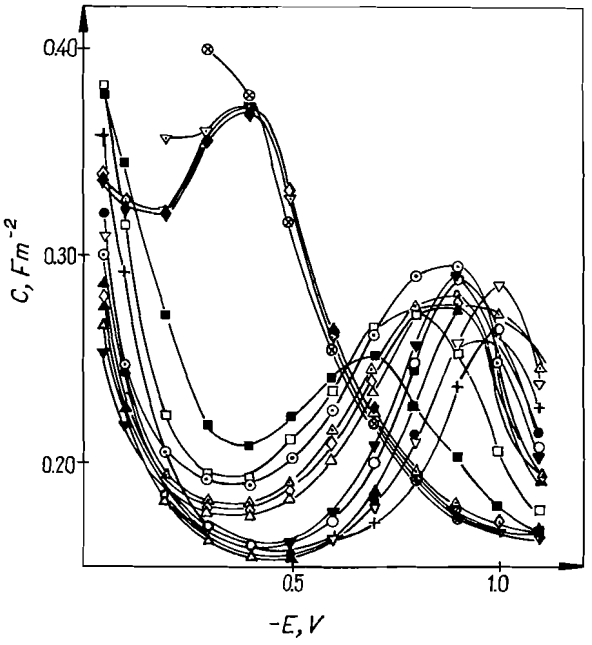

FIG. 5. The dependence of the differential capacity of the mercury electrode on the potential in solution of 0.01 *M* phthalic acid in 0.5 *M* Na_2SO_4 at following pH's: (+) 1.33, (○) 1.85, (▽) 2.02, (▲) 2.26, (○) 2.80, (▼) 3.02, (△) 3.45, (◇) 3.72, (▲) 4.01, (⊙) 4.32, (□) 4.60, (■) 5.02, (◇) 5.72, (◆) 8.05, (▽) 11.40, (⊗) 11.62.

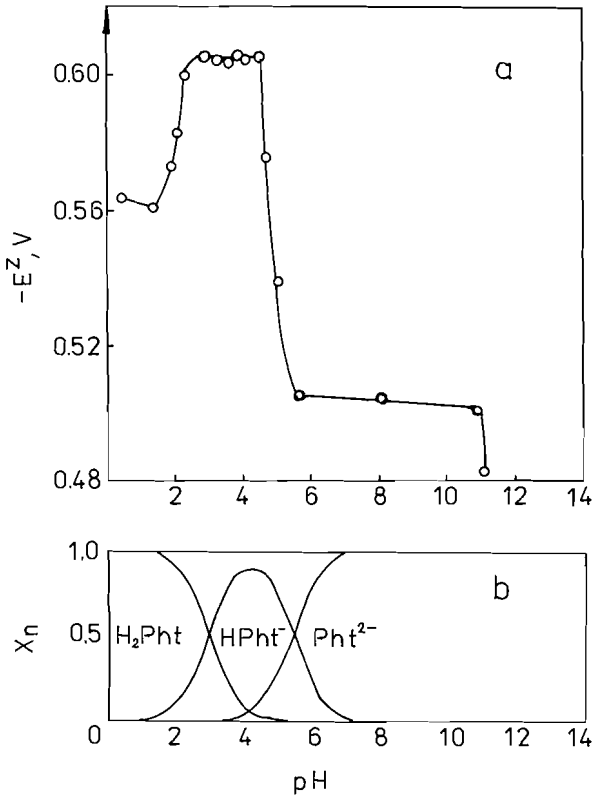

FIG. 6. (a) The dependence of pzc (E^z) of the mercury electrode on pH in a solution of 0.01 *M* phthalic acid in 0.5 *M* Na_2SO_4; (b) The distribution of H_2Pht, $HPht^-$, and Pht^{2-} as a function of pH in the bulk of the solution.

Adsorption isotherms (Fig. 7) determined on the basis of electrocapillary measurements can precisely describe the extent of adsorption. At potentials −500 to −700 mV the surface excess attains a constant value in the concentration range 0.003 to 0.01 *M* and is equal to about 1.6×10^{-6} Mm^{-2}. However, for concentrations of phthalic acid higher than 0.01 *M*, the value of the surface excess strongly increases. It may point to a change of adsorption mechanism. The surface of projection of the phthalic acid molecule with the benzene ring perpendicular to the electrode surface calculated from crystallographic data (17) is equal to 62 $Å^2$. The calculated value of the maximum surface excess on the basis of flat oriented molecules on the electrode is equal to 2.7×10^{-6} Mm^{-2}. This value is higher by 1.1×10^{-6} Mm^{-2} than the value corre-

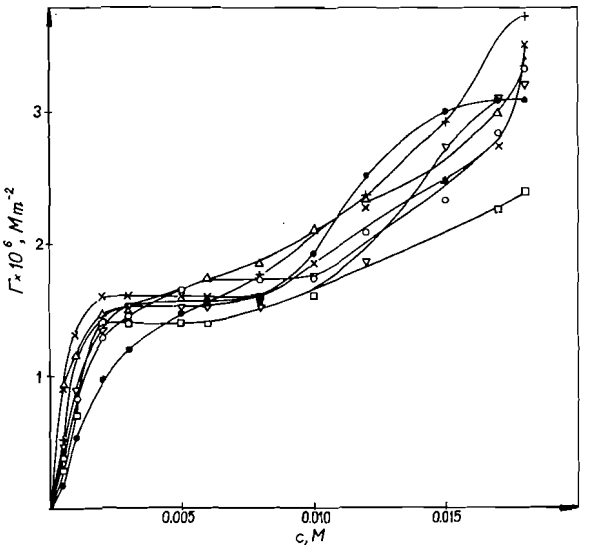

FIG. 7. The dependence of the surface excess concentration of phthalic acid on a mercury electrode on its bulk concentration in 0.5 M H_2SO_4 at the following potentials: (□) 200, (▽) 300, (+) 400, (×) 500, (△) 600, (○) 700, (●) 800 mV.

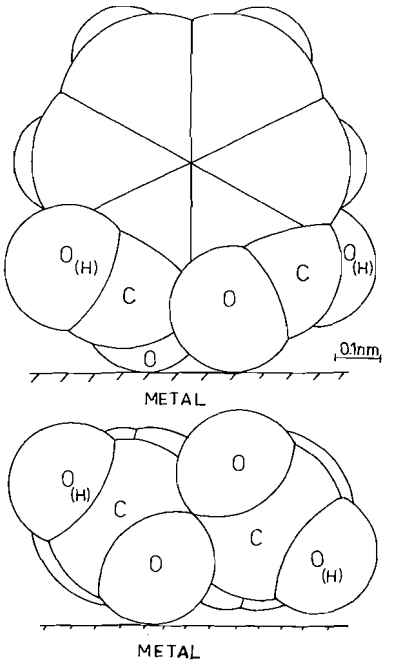

FIG. 8. Model for the adsorption of a phthalic acid molecule in vertical (a) and flat (b) orientation on mercury. Hydrogen atoms of carboxylic groups are not shown in the figure.

sponding to the plateau of the adsorption isotherms given in Fig. 7. In estimating the maximum surface excess in a vertical orientation, the model presented in Fig. 8 was used. Close-packed orientation and no hydration of H_2Pht was assumed in the calculation of Γ_m in both orientations.

The above conclusions are confirmed also by differential capacity data. The minimum value of capacity is much higher than those for various aromatic compounds of structure similar to that of phthalic acid (1–4) but in the minimum capacity range, vertical orientation of these molecules was proved. The small change of capacity in the concentration range 0.005 to 0.01 M (Fig. 1) also points to saturation of the electrode surface by phthalic acid molecules in the flat orientation (Fig. 8). The value of the minimum capacity for the 0.01 M phthalic acid solution ± 0.180 Fm^{-2}, is equal to the capacity corresponding to flat oriented adsorbed benzoic acid molecules (1). Our isotherms up to 0.01 M phthalic acid concentration show qualitative agreement with the isotherms of several flat oriented aromatic compounds in this concentration range, given by Bockris and co-workers (2).

At concentrations lower than 0.01 M of H_2Pht, where we postulate that the adsorption of this substance occurs in a flat orientation, the adsorption isotherm could also be calculated on the basis of the capacity measurements. As the most optimal potential, −600 mV was chosen, at which the adsorption–desorption effects should be the lowest and the measured capacity should be near to the equilibrium value. At this potential as well as at −500 mV a plot of $E_\theta^z - E_{\theta=0}^z$ against θ was nonlinear (with a shape similar, for instance, to that observed in the case of caproic acid (18)), pointing to the congruence of H_2Pht electrosorption with respect to potential.

The surface coverage calculation was based on the decrease of the differential capacity at a given potential using the well-known formula

$$\theta = \frac{C_0 - C}{C_0 - C_M}$$

where C_0 and C_M are capacities in the base electrolyte alone and at $\theta = 1$, respectively, and C stands for the capacity at a given θ. The determination of the capacity corresponding to maximum coverage of the electrode by phthalic acid could not be done simply by experiment due to the reorientation effect at higher bulk concentrations of acid. This problem was solved by determining C_M from a plot of the reciprocal of the measured capacity versus the reciprocal of phthalic acid concentration. This plot is shown in Fig. 9; the linear part at higher 1/C values corresponds to capacities for flat H_2Pht orientation. From extrapolation C_M equals 0.169 Fm^{-2}. This value is different from C_M found for other aromatic compounds of a similar structure, 0.070 for phenol, 0.070 for cresol, 0.050 for

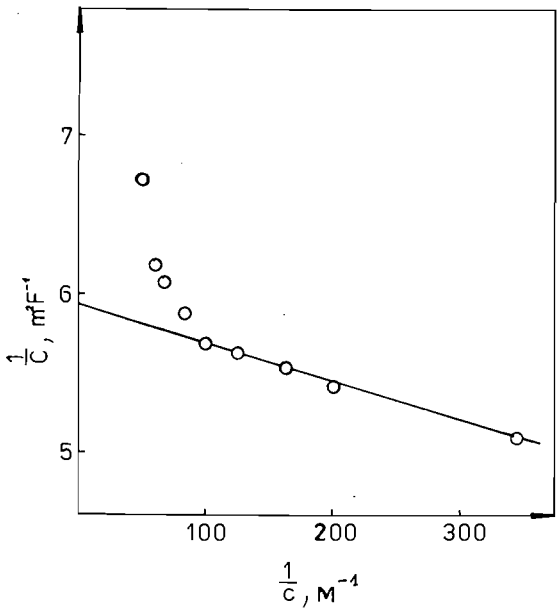

FIG. 9. The plot of reciprocal of the measured capacity versus reciprocal of phthalic acid concentration.

pyridine, and 0.063 Fm^{-2} for benzoic acid. These much lower values of the differential capacity correspond, however, to a vertical orientation of the adsorbed molecules. The strong deviation of 1/c from linearity at higher H_2Pht concentrations (Fig. 9) may point to reorientation of the phthalic acid molecules.

The calculated θ values as a function of concentration of H_2Pht are given in Fig. 10. Using the Frumkin isotherm the following values of the equilibrium adsorption constant and interaction coefficient, 295 M^{-1} and 0.7, respectively, were obtained. Attempts to get reliable values of the interaction coefficient at other potentials were not successful.

It follows from these considerations that for phthalic acid concentrations up to 0.01 *M*, the adsorption of this substance may be described by a model of two parallel condensers. The interior of the capacitors is filled by water and flat oriented phthalic acid molecules. For concentrations higher then 0.01 *M* the three-condenser model elaborated by Damaskin is valid (19). This conclusion is supported by the form of the isotherm shown in Fig. 7 as well as the change of capacity at higher H_2Pht concentrations presented in Fig. 9. However, the quantitative analysis of the adsorption according to the three-condenser model can not be carried out in the context of the Damaskin theory with satisfactory precision, in view of the number of parameters which should be known precisely in order to get meaningful results. In our case parameters such as $\theta_{vertical}$ or $E^z_{vertical}$ could only be estimated because full coverage of the surface in the vertical position is not attained due to the limited solubility of H_2Pht. Qualitative use of the Damaskin concept leads to the conclusion that there is an interaction of H_2Pht molecules in two different positions, because of the absence of the reorientation peak. Such interaction is possible in view of the model proposed in Fig. 8, where carboxylic groups in both orientations may not be too distant.

The estimated value of maximum surface excess corresponding to vertical orientation of H_2Pht on the electrode surface is equal to 5.4×10^{-6} Mm^{-2}. There is some difference in behaviour of phthalic acid in comparison to other aromatic compounds such as phenol (2, 3, 20) and benzoic acid (1). The influence of potential on reorientation of molecules is not evident in the present case of H_2Pht, though the disappearance of a plateau on the isotherm at −800 mV (Fig. 7) suggests that surface saturation by flat oriented molecules was not attained and that there is a progressive reorientation process with increase of H_2Pht concentration. It should be pointed out that our conclusion concerning the reorientation of H_2Pht on the electrode surface was based mainly on electrocapillary measurements. The differential capacity data were not so useful in view of the pseudocapacity peaks occurring over a large potential range. Moreover the charge vs. potential dependence obtained by the integration of the capacity curves was also studied. These dependences were grouped in two families of curves for lower and higher H_2Pht concentrations, eventually pointing also to reorientation.

When considering the independence of the zero charge potentials on H_2Pht concentration in the region of the change of orientation from flat to vertical, one may arrive at the conclusion that it is due to compensation of two effects acting in different directions. The interaction of the π-electrons of the benzene ring in the flat orientation is reflected in the change of the pzc to more negative potentials with increase of H_2Pht concentration. The influence of the reorientation process on E^z may be then expressed as (*i*) a shift of pzc to less negative values as a result of a decrease of the surface coverage of the electrode by H_2Pht in the flat orientation, and (*ii*) a shift of pzc to more cathodic values with an increase of the surface coverage of H_2Pht in the vertical orientation. Since the negative charge of the H_2Pht dipole should be localized on —COOH groups, the shift of pzc to negative values may indicate that these groups are directed to the electrode surface in the vertical orientation of H_2Pht.

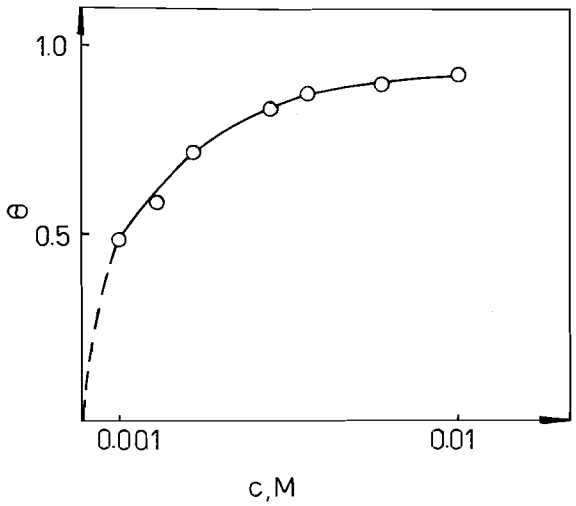

FIG. 10. The dependence of the surface coverage of the mercury electrode on the concentration of phthalic acid in 0.5 *M* H_2SO_4.

The proposed orientation is different from that observed for the aliphatic alcohols and acids (21) and probably also benzoic acid (1).

H_2Pht molecules interact with water by hydrogen bonding. As it follows from the model (Fig. 10b) there should exist also an internal hydrogen bond between two —COOH groups of H_2Pht molecule. Such interaction should decrease the hydrophilic nature of this part of the H_2Pht molecule and at least may explain the tendency of *o*-phthalic acid to have —COOH groups directed to the electrode surface when adsorbed in the vertical position.

Significant changes of the double layer capacity and of zero charge potential with pH (Figs. 5 and 6) at constant analytical concentration of phthalic acid make it possible to describe phthalic acid adsorption more precisely.

Adsorption of hydrogen phthalate ion was studied by Tilak and Devanathan (8). The flat orientation of this ion, with the COO^- group interacting through oxygen with the surface and the benzene ring parallel to the metal surface, was assumed, similar to that proposed by us for the neutral molecules at low bulk concentrations. While this assumption seems to be justified, the assumption that the second carboxylic acid group of the phthalate ion is ionized due to the intense electric field across the interface is questionable.

In Fig. 6a the dependence of the pzc on pH of the solution is shown. Three parts of this dependence at pH 0.5–1.5, 2.5–4.5, and 5.5–10.5 correspond, according to us, to the adsorption of the H_2Pht, $HPht^-$, and Pht^{2-} species, respectively. This view is based on the distribution curves of these species with pH given in part (b) of Fig. 6. By comparing both parts of this figure one may suggest a small influence of the electrical field on the increase of acidity of H_2Pht and $HPht^-$. One may mention that the dependence of the differential capacity at a constant potential (e.g. −0.40 V) on pH has a similar shape. Small changes in capacity and the flat part of the dependence of E^z on pH around pH 4 point to the predominance of $HPht^-$ on the electrode surface.

Determination of single ion activities by relying on the electrical double layer model: NaF aqueous solutions[1]

ANNA DAGHETTI AND SERGIO TRASATTI

Laboratory of Electrochemistry, University of Milan, Via Venezian 21, 20133 Milan, Italy

Received July 21, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

ANNA DAGHETTI and SERGIO TRASATTI. Can. J. Chem. **59**, 1925 (1981).

Single ion activity coefficients for aqueous solutions of NaF in the range $m = 0.1$ up to $m = 0.9$ mol kg^{-1} have been derived by measuring the potential difference of the cell Hg (σ = const)/NaF(m)/F$^-$-selective electrode. The approach rests on the assumption that the electric potential drop across the Hg/solution interface is independent of the electrolyte concentration once the diffuse layer effects are accounted for by the Gouy–Chapman theory, provided specific adsorption of ions is absent. The derived γ_- values have been compared with the "real" activity coefficients as determined by Rabinovich and Titov and with the predictions of the hydration theory of Bates and Robinson. It is shown that the latter do not agree with the present experimental observations. Possible reasons for this apparent discrepancy are discussed.

ANNA DAGHETTI et SERGIO TRASATTI. Can. J. Chem. **59**, 1925 (1981).

La mesure de la différence de potentiel d'une cellule Hg (σ = const/NaF(m)/F$^-$ une électrode sélective, a permis de déduire les coefficients d'activité d'un ion unique dans des solutions aqueuses de NaF pour des molalités variant de $m = 0{,}1$ à $m = 0{,}9$ mol kg^{-1}. Cette approche est fondée sur le fait que la chute de potentiel au niveau de l'interface Hg/solution est indépendante de la concentration de l'électrolyte quand les effets de diffusion de couche sont interprétés selon la théorie de Gouy–Chapman relative à l'absence de l'absorption spécifique de l'ion. On a comparé les valeurs de γ obtenues avec celles des coefficients "réels" d'activités tels que déterminés par Rabinovich et Titov et avec les prévisions de la théorie d'hydratation de Bates et Robinson. On montre que les résultats de ces derniers ne s'accordent pas avec les observations expérimentales. On discute des raisons probables de cette différence.

[Traduit par le journal]

Introduction

It is well known on the basis of strictly thermodynamic arguments (1–4) that single ion activities are not amenable to direct experimental determination, the resulting quantities being mean ionic activities. Even the concept of the former quantity is difficult to assess properly since "single-ion" activities are unavoidably related to the nature of the co-ions. Single ion activities are however much more significant than mean ionic activities for the investigation of the structure of solutions. Therefore, various methods have been proposed to derive single ion activities from measurable experimental quantities. All these approaches obviously imply some non-thermodynamic arguments and approximations. In other words, the necessary step to be taken to arrive at single ion activities is the introduction of some model assumptions.

The simplest experimental arrangement makes use of an electrochemical cell consisting of the electrode under study and a "constant" potential reference electrode (for instance, a saturated calomel electrode). Single ion activity coefficients (γ_i) can then be derived from the measured cell potential difference E by correcting for the unknown contribution due to the solution/reference electrode junction (5, 6). In such a case the model introduced is that for the liquid junction potential calculation.

Another experimental route, originally proposed by Szabo (7) and developed by Milazzo and Defay (8), involves the measurement of the emf for a non-isothermal system constituted by two equal electrodes. Assumptions and approximations are necessary in this case as well (9).

A further experimental method consists in measuring the potential difference for a cell of the type (10–13)

[1] $\quad Pt(H_2)/HCl(m)/air/HCl(m_{ref})/(H_2)Pt$

where m_{ref} is a reference solution. This method provides single ion activities directly, but these are related to *real* rather than to *chemical* potentials (14). This implies that the γ values are affected by some contribution from the surface potential of the solution.

[2] $\quad \ln \gamma_i^* = \ln \gamma_i + (F/RT)(\Delta\chi)$

where γ_i^* is the "real" activity coefficient and $\Delta\chi$ is the change in surface potential of the solution with

respect to the pure solvent. Beyond this point, a model must necessarily be introduced to derive the desired quantity γ_i (15, 16).

A proposed non-experimental route rests on the assumption (17) that for not very dissimilar ions the difference in γ_i is mainly related to the difference in solvation. The following equation has been proposed (18) for 1–1 electrolytes:

$$[3] \quad \ln \gamma_{+(-)} = \ln \gamma_{\pm} + 0.00782[h_{+(-)} - h_{-(+)}]m\phi$$

where h_+ and h_- are single ion hydration numbers, and ϕ is the osmotic coefficient. A number of factors which may make γ_+ differ from γ_- has been discussed by Frank (19).

The basic prerequisite for emf measurements to determine single ion activity coefficients is to reproduce possible conditions of constancy in potential for one of the two electrodes of the electrochemical cell. In this work, we propose to adopt the model of the electrical double layer at the electrode/solution interface in the absence of specific adsorption as the one best meeting the above requirement.

The Model

Presently accepted views on the structure of the electrical double layer at the electrode/solution interface (20) rest on the concepts introduced by Gouy, Chapman, and Stern and developed by Grahame. The interphase is assumed to consist of two adjacent regions, an inner layer and a diffuse layer. The electric potential drop across the whole interfacial region thus consists of two contributions: the potential drop across the diffuse layer is a function of the ionic concentration in solution, while the potential drop across the inner layer does not depend on the ionic concentration provided specific adsorption is absent. The potential drop across the diffuse layer can be calculated by means of the Gouy–Chapman theory; it vanishes as the charge on the metal vanishes (potential of zero charge). It ensues that an ideally polarizable electrode in the absence of specific adsorption, kept at the potential of zero charge, or at constant inner layer potential drop (which implies constant charge on the metal) is expected to work as a constant potential electrode insensitive to the activity of any of the species in solution.

The above feature is implicit in the original theory (21) and has been verified independently by Grahame (22) in terms of differential capacity. The possibility that such an electrode may work as a constant potential electrode also ensues (23, 24) from the analysis of the Esin and Markov effect. Thus far only one experimental approach (25) has however been attempted along the lines proposed in this work. Šťastný and Štráfelda (25) have stressed the possibility of determining single ion activity coefficients by measuring the zero charge potential of Hg. However, the difficult point in their work is that for the only electrolyte known (21) not to be specifically adsorbed (F^-) no reversible electrode was available at that time, while the reference electrode they used (Ag/AgCl) is reversible to Cl^- which is specifically adsorbed on Hg. Thus, their data are "vitiated" by the use of the Henderson equation to estimate some liquid junction potential. The present availability of electrodes reversible to the fluoride ion (26) makes it possible to set up electrochemical cells without any liquid junction.

Experimental

The following electrochemical system has been used

$$[4] \quad \mathrm{Hg}(\sigma = \text{const})/\mathrm{NaF}(m)/\mathrm{F^-}\text{-selective electrode}$$

Although KF is recommended (27) as the best reference standard for fluoride ion activity in that it is unassociated, NaF was used in this work because most of the experimental data with Hg electrodes were obtained with this electrolyte. Fluoride ions are probably adsorbed on Hg at positive charges, but adsorption can be ruled out at the potential of zero charge and at negative charges (28). In this region the potential difference for cell [4] is given by

$$[5] \quad E = \text{constant} - (RT/F) \ln \gamma_- m$$

where the constant term includes the electric potential drop across the Hg/solution inner layer.

A LaF_3-based Orion electrode was used as the F^--selective electrode. The potential of zero charge of Hg was determined directly by means of the jet electrode technique (29), while the potential at other charges was calculated by integrating differential capacity/potential curves from the potential of zero charge and correcting for the effect of the diffuse layer on the basis of the Gouy–Chapman theory.

The reliability of the response of the F^--selective electrode was checked by measuring the emf of the cell

$$[6] \quad \mathrm{F^-}\text{-selective electrode}/\mathrm{NaF}(m)/\mathrm{Na^+}\text{-selective electrode}$$

$\gamma_\pm$ values for NaF were then calculated and compared to published values (30). An Ingold glass electrode was used as the Na^+-selective electrode.

The potential of zero charge of Hg was in practice measured against a saturated calomel electrode, and the potential difference for cell [4] was obtained by adding the potential difference of the cell

$$[7] \quad \mathrm{F^-}\text{-selective electrode}/\mathrm{NaF}(m)/\text{saturated calomel electrode}$$

The design of the saturated calomel electrodes was such as to ensure the reproducibility of the liquid junction potential to better than 0.1 mV. The drift (31) in the potential of the ion-selective electrodes was accounted for by measuring the emf of cells [6] and [7] in a 0.1 *m* NaF solution before and after each run of measurements (practically, at the beginning and at the end of each day). In all experiments, the temperature of the solution was kept constant at 25 ± 0.1°C.

The experimental technique to measure capacity curves has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

been described elsewhere (32). The integration of the capacity data was carried out with the aid of a computer. All measurements of cell potential difference were repeated several times to check reproducibility and accuracy. The concentration range investigated was from 0.01 to 0.9 m NaF. All values of m in text and in figures are quoted in mol kg^{-1}.

Results

The data of potential difference for both cell [4] and cell [6] have been analyzed (33) by means of the extended Hückel equation (34) for the activity coefficients of 1–1 electrolytes

$$[8] \quad \log \gamma_i = bm - (A\sqrt{m})/(1 + aB\sqrt{m}) - \log (1 + 0.036m)$$

where γ_i may be either $\gamma_\pm$ or single ion activity coefficients, A and B are constants, b accounts for short-range interactions, and a is the cation–anion distance of closest approach. For NaF this parameter has been taken as 0.4 nm according to literature data (18).

In the particular case of cell [4], from eq. [8] and eq. [5], it results in

$$[9] \quad E + k \log m - (kA\sqrt{m})/(1 + aB\sqrt{m}) - k \log (1 + 0.036m) = \Psi = \text{constant} - kbm$$

where $k = 2.3(RT/F)$. All terms in the left-hand side of eq. [9] are known so that Ψ can be calculated for any value of m. A plot of Ψ against m is thus expected to yield a straight line whose slope determines the value of b. Once b is known, values of γ_i can be obtained by eq. [8] for any value of m. This procedure gives "smoothed" γ_i values. Alternatively, the intercept in the plot of Ψ vs. m (the "constant" term) may be introduced into eq. [5] to calculate "not smoothed" γ_i values. The linearization of eq. [9] was performed by the least square method.

Figure 1 shows a typical linearization of eq. [9] with the data of cell [4]. The mean square deviation is equal to 0.0004 V which points to the satisfactory accuracy of the experimental results.

Values of $\gamma_\pm$ were derived by applying the same procedure to the data of cell [6]. Figure 2 shows that the $\gamma_\pm$ values for NaF as obtained in this work are in good agreement with data reported in the literature (30) (solid line) obtained by the isopiestic method. The scatter of points is within the expected uncertainty as can also be seen in previous data reported by Bates (35) and obtained with a similar experimental set up.

Figure 3 shows the concentration dependence of the potential of zero charge of Hg in NaF aqueous solutions as obtained by the streaming electrode technique and measured against a saturated calomel electrode. The accuracy of this method is given as ± 0.5 mV. The different points refer to different measurements carried out by different operators with different electrodes not only in connection with the present work. The accuracy is in general within the limits claimed. A definite trend for the potential of zero charge to decrease as the NaF concentration increases can be recognized. At low m values E levels off at -432 to -433 mV. The change in potential with m is observed also in the original data of Grahame (22). The ΔE between low and high concentrations was of the order of 2 mV, in good agreement with the present data. The absolute values of the potential of zero charge are, however, about 1 to 2 mV more negative in Grahame's work over the entire concentration range. This may be due to the introduction of a calculated value for the liquid junction potential in Grahame's data, but an effect of the design of the jet electrode cannot be ruled out (28). However, in this work the relative values of the potential of zero charge as a function of m are more relevant than the absolute values. In this respect, our data and Grahame's run parallel.

Figure 4 displays the final picture of the results. The present approach is possible only with electrolytes which are not specifically adsorbed at $\sigma = 0$. Only F^- and perhaps SO_4^{2-} are known to meet this requirement (21, 28). In order to explore the possibility of using this method with electrolytes which are specifically adsorbed at $\sigma = 0$, γ_- values have also been calculated by using values of potential difference of cell [4] corresponding to Hg at negative charges, where specific adsorption of anions is expected to vanish. The procedure followed for the data with Hg at $\sigma = 0$ was thus extended to data of potential with Hg at $\sigma < 0$, in particular $\sigma = -10\ \mu C\ cm^{-2}$.

In Fig. 4 the γ_- values obtained with Hg at negative charges exhibit the same trend as those with Hg at $\sigma = 0$. The scatter of points is somewhat larger and this is very likely to be related to the fact that the accuracy in the measured differential capacity is of the order of 0.2 to 0.3% (36). Due to the integration procedure, the inaccuracy bears increasingly on the results as the charge becomes more negative. The inaccuracy which is probably small for double layer problems is significant for the present treatment of the data. The important point is to verify if the concentration dependence of E for cell [4] may be a function of the amount of charge on the Hg electrode.

Figure 5 shows that between 0.1 and 1 mol kg^{-1} the plot of E against $\log a_-$ (a_- is calculated from the data with Hg at $\sigma = 0$) gives straight lines with the same 0.059 mV slope. This indicates that in this concentration range the basic assumptions behind

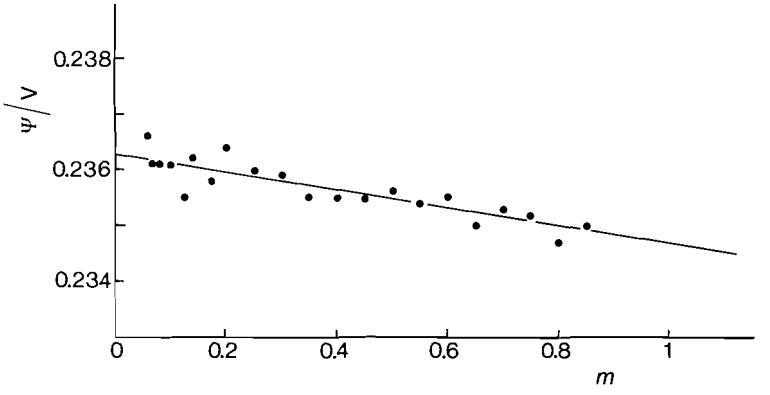

FIG. 1. Typical linearization of eq. [9] in the text. Data refer to cell Hg ($\sigma = 0$)/NaF(m)/F^--selective electrode. The straight line has been drawn by means of the least square method.

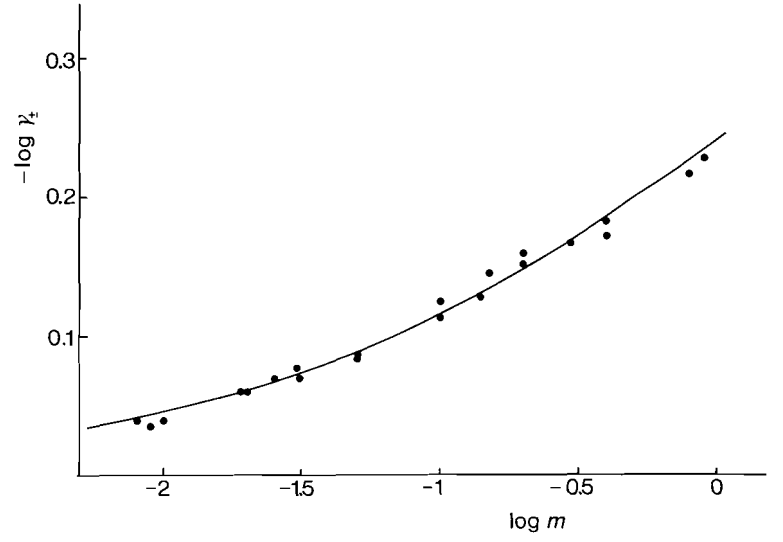

FIG. 2. Mean ionic activity coefficients for NaF in water as a function of electrolyte molality. (—) Literature data as obtained by the isopiestic method; (●) Data as obtained in this work by emf measurements for cell (*b*) in Fig. 1.

the method hold at any charge on Hg. This may also be taken as an indirect proof that the corrections for the diffuse layer as calculated by the Gouy–Chapman theory are probably accurate within the limit of validity of the present approach.

Scrutiny of Fig. 5 however reveals that some deviation from the linearity is increasingly apparent in the low concentration range as the charge becomes more negative. This can be better seen in Fig. 6 where the data on E are plotted against $\log a_-$ all over the range from 0.01 to 1 mol kg^{-1}. Whereas the points fit on the straight line of 0.059 mV slope when the charge on Hg is zero, a deviation from linearity is observed when the charge is $-10\ \mu C\ cm^{-2}$. This may be due to an incorrect compensation of the diffuse layer potential drop by the Gouy–Chapman theory. Actually, this effect is observed at concentrations below 0.1 m where the difference between γ_- and $\gamma_\pm$ are unimportant, and could be neglected for the purpose of this work. But it is important to try to understand whether the method itself is inapplicable because of failure of the basic assumptions or other causes are responsible for the observed behaviour.

In order to look at the same phenomena from a different point of view, the data published by Grahame (22) on the capacity of Hg in NaF aqueous solutions have been used. The available concentrations are in this case only 0.001, 0.01, 0.1, 0.66, and 0.916 mol dm^{-3}. Figure 6 shows that Grahame's data satisfy the linearity of the plot both at $\sigma = 0$ and $\sigma = -10\ \mu C\ cm^{-2}$. In the latter case the linearity is probably observed down to 0.001 mol dm^{-3}. Thus, it appears that the deviation from the linearity is probably related to the accuracy of the capacity data in the low concentration range. In

fact some difference with respect to Grahame's data was also observed by Parsons and Trasatti (37) at low concentrations of KCl (around 0.01 mol dm^{-3}). The design of the measuring apparatus (the same basic bridge and the same cell were used in this work and in the work of ref. 37) might be responsible for the observed deviation as a consequence of the high impedance of the interface. This effect can be neglected in double layer studies but may become significant in this particular way of treating the experimental data. If the above explanation is correct, the data indicate substantially that the present approach can be used also with electrolytes which are specifically adsorbed at the potential of zero charge but not at moderate negative charges. This is an interesting possibility to check the basic assumptions of this approach in that most of the determinations of single ion activity coefficients by other methods are in particular carried out with chlorides.

Grahame's data can be used independently to derive γ_- values. Figure 4 shows that the resulting (smoothed) values agree reasonably well with those derived with our data. Of course, the same values are obtained in this case with $\sigma = 0$ and $\sigma = -10\,\mu C\,cm^{-2}$. However, when Grahame's data are used independently, a slight deviation in the γ_- values can in fact be observed with respect to our

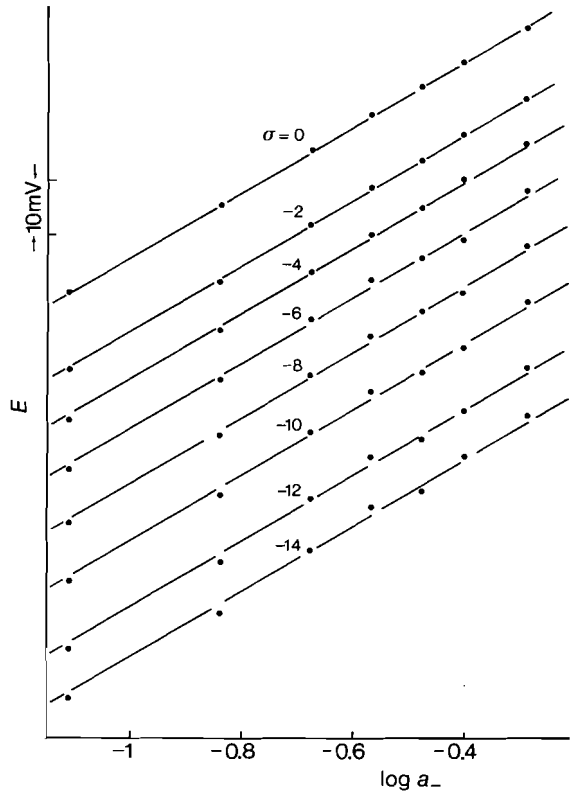

FIG. 5. Plot of the potential difference of cell (4) in the text against the fluoride ion activity (calculated at $\sigma = 0$) with the Hg electrode at various negative charges.

values. It is thought that this may be due to the fact that the original data on the potential of zero charge contain an estimated correction for the liquid junction potential which is not present in our data.

Discussion

The results in Fig. 4 indicate that γ_- is possibly higher than $\gamma_\pm$ for NaF in water. In order to appraise the significance of this observation, it is necessary to compare the present results with the predictions of theories or with the results by other methods.

Rabinovich and Titov (38, 39) have reported the values of the "real" activity coefficients of the single ions for NaF, KF and CsF.[2] Table 1 compares their results with ours. The agreement is reasonably good. In principle, our γ_- values are "real" activity coefficients in that the measurements include the surface potential contribution from the solution. However, whereas the double layer model for the metal/solution interface assumes explicitly that the surface potential of the solution does not vary with the electrolyte concentration (20, 23), the possibility that the surface potential at the free surface of the solution may change with the electrolyte concentration is concretely considered by Rabinovich *et al.* (11, 12). There are experimental results showing that this may well be the case (40, 41). If some correction is attempted by means of eq. [2], Rabinovich and Titov's results show that γ_- may become almost equal to γ_+ in KF (38). No data are available for NaF but the same effect may be expected also for this electrolyte, even though to a different extent. The agreement in Table 1 may thus be only apparent and not real. Some experimental results however show that the term $\Delta\chi$ may become significant only at higher concentrations than 0.5–1 mol dm^{-3}. Such a range of concentration cannot be explored with NaF because of the limited solubility.

TABLE 1. Comparison of activity coefficients for F^- in NaF aqueous solutions from this work with "real" activity coefficients as obtained by Rabinovich and Titov (38)

	γ_{F^-}	
m/mol kg^{-1}	Ref. 38	This work
0.1	0.760	0.765
0.2	0.719	0.720
0.5	0.641	0.655
0.7	0.618	0.633
1.0	0.591	0.615

Stokes and Robinson (17) have developed a hydration theory to calculate mean ionic activity coefficients which has then been extended by Bates *et al.* (18) to the calculation of single ion activity coefficients. According to the latter treatment, γ_- is expected to differ from γ_+ when the hydration number of the anion, h_-, differs from that of the cation, h_+. For 1–1 electrolytes, the resulting relationship between γ_i and $\gamma_\pm$ is given by eq. [3]. Once h_+ and h_- are known, γ_- can be derived from $\gamma_\pm$. Single ion hydration numbers are not amenable to direct experimental determination, but analysis of estimated data available in the literature (42) suggests that, for NaF, it is probably

$$[10] \quad h_+ - h_- = 1 \pm 2$$

More precise values for h_+, h_-, and h ($= h_+ + h_-$) have been suggested by Robinson *et al.* (27). According to Bates and Robinson (43) h can be derived by fitting the calculated curve containing the hydration number as the variable to the experimental points for the mean ionic activity coefficients. They suggest that $h = 5.37$ with $h_+ = 3.5$ and $h_- = 1.87$. Although the hydration theory has

[2]The authors are grateful to V. A. Rabinovich for making the original data available.

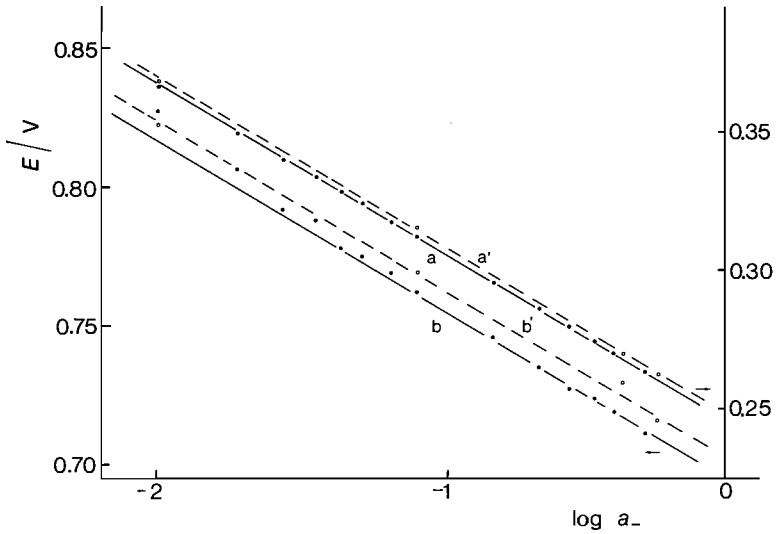

FIG. 6. Plot of the potential difference of cell (4) in the text against the fluoride ion activity. (a,b) Our data: (a',b') From Grahame's data. (a,a') Hg at $\sigma = 0$; (b,b') Hg at $\sigma = -10\,\mu C\,cm^{-2}$. (—) Straight line of 0.059 mV slope through our points; (---) straight line of 0.059 mV slope through Grahame's points.

been developed for unassociated electrolytes (NaF is probably somewhat associated in solution (27)), eq. [3] is expected to enable the calculation of γ_- if the experimental $\gamma_\pm$ (including the effect of ion pairing) is used.

The solid line in Fig. 4 has been obtained by calculating γ_- for NaF according to the hydration theory. This of course predicts that the ion with the higher hydration number should exhibit the higher activity coefficient. The predictions of the hydration theory are therefore at variance with our experimental results, but it is not yet clear if the two sets of data depend on the same factors which may be responsible for the difference between γ_+ and γ_-. Also taking into account Table 1, the observed discrepancy may be due to one or more of the following reasons: (*i*) The hydration theory does not include other factors which may be important; (*ii*) The estimated values of h_+ and h_- do not correspond to the true values, although it appears unlikely that h_- may be higher than h_+; (*iii*) The assumed concentration independence of the inner layer potential drop at constant charge on the electrode may be a good approximation in double layer studies but not in this case when as high an accuracy as 1 mV is required; (*iv*) Absence of specific adsorption is only an approximation. Work is in progress with other electrolytes to try to elucidate the role of the various factors.

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

R. N. O'BRIEN, B. B. KULKARNI, W. MICHALIK, and K. S. V. SANTHANAM. Can. J. Chem. **59**, 1933 (1981).

A laser interferometry study was done on the $Cu/CuSO_4/Cu$ system at natural pH to investigate the effects of natural convection with plane-parallel horizontal electrodes in the anode over cathode position. A constant concentration profile is established where migration is just equal to diffusion plus convection at cd's less than 0.2 mA cm^{-2} and electrode separations less than 1 mm. Above these values convective or roll cells reminiscent of Bénard cells always develop.

R. N. O'BRIEN, B. B. KULKARNI, W. MICHALIK et K. S. V. SANTHANAM. Can. J. Chem. **59**, 1933 (1981).

On a réalisé une étude par interférométrie au laser sur le système $Cu/CuSO_4/Cu$ à un pH naturel dans le but de trouver les effets de convection naturelle, avec des électrodes horizontales dans des plans parallèles alors que l'anode est dans la position au-dessus de la cathode. On a établi un profil de concentration constante où la migration est exactement égale à la diffusion plus la convection à des cd inférieurs a 0,2 mA cm^{-2} et pour des électrodes dont la distance de séparation est inférieure à 1 mm. Au-dessus de ces valeurs, il se développe toujours des convections ou des cellules en spirale qui rappellent les cellules de Bénard.

[Traduit par le journal]

Introduction

It has long been known that at vertical electrodes natural convection limits the extent of both thickness and concentration change in the diffusion layer. Optical methods have produced convincing visible evidence (1–3) of this. Electrochemical systems where the electrodes are not perfectly horizontal, plane-parallel, or do not intersect the total area of the electrolytic conduction path will usually within a short period of time show a constant concentration polarization. The assumption is also made that all other sources of polarization are small or absent as in, for example, the deposition of copper or zinc.

Recently another mode of stabilization of concentration polarization has been observed, the condition where migration is just equal to diffusion in horizontal plane-parallel electrodes (4). With no convection present this is the expected result. Considering the cathode, the attraction of cations to the cathode and their discharge (and the simultaneous replulsion of anions) will lower the concentration near the electrode giving rise to a concentration gradient and hence diffusion down that gradient. Interferometric evidence for the early part of such a process is difficult to obtain, but the process at a working electrode can be inferred from an electret immersion experiment. In this experiment on the formation of a double-layer at the electret surface, the straight-line dependence of concentration with distance expected for the effect of a field on an ion was observed, followed by the curved (error function) form characteristic of diffusion (5).

This work reports an interferometric study of another case of a stable or equilibrium concentration polarization. Plane-parallel horizontal electrodes where the anode is above the cathode (A/C) produce a type of convection cell analogous to Bénard cells but probably more consistent with the original Rayleigh theory than those investigated by Bénard (6). Tobias and Hickman (7) studied an A/C system under forced and natural convection and referred to the convection cells that formed as "roll cells". Their study was done with the acidified $Cu/CuSO_4/Cu$ system. Optical evidence for convective cell formation will be presented for the system $Cu/CuSO_4/Cu$ at natural pH.

Experimental

The electrolysis cell used was also a Fabry–Perot interferometer with 90% reflecting glass flats giving a finesse of about 7 with He–Ne laser light. The details of construction of this type of cell have been published elsewhere (8–10). The critical data are that the electrodes were of 99.999% polycrystalline Cu with exposed active surfaces of about 0.9 cm^2, and were three mm thick along the line of light propagation. The general cell construction was of Teflon and Teflon was used to space the electrodes at selected values between about 0.2 mm to 3 mm. The actual spacing was measured with a micrometer and then optically against a grid placed in the optical system for this purpose.

Wedge-type interference fringes were recorded on videotape and a running voice commentary was made in the audio mode on the tape. The video camera recorded the complete experiment through the view finder of a Nikon 35 mm camera with which interferograms were recorded at selected intervals and at other

times when other events of interest appeared on the monitor. The optical train was arranged to give magnifications on the monitor varying from about 30 to 100 as appropriate.

Electrolysis runs were generally limited to three minutes although a few were carried on to 10 min. The solution was 0.1 *N* $CuSO_4$ in all cases. Current densities were varied from 1 mA cm^{-2} to 56 μA cm^{-2}. In all cases the electrodes were plane-parallel and horizontal with the anode over the cathode.

The solution was used at the natural pH of 4.7. A stock solution was made up from AnalaR grade $CuSO_4 \cdot 5H_2O$. After each run, the solution was withdrawn by syringe and replaced. The interferometer was opened and the electrodes removed and polished after each set of runs, usually consisting of seven or eight at a given electrode separation.

The interferograms were hand measured in the usual way by projection onto a plotting table. Fringe displacements were converted to concentration by the modified Bragg equation, $2nt \cos\theta = N\lambda$, where θ must be near zero angle of incidence of light and hence $\cos\theta = 1$, n is the refractive index (~ 1.32950), t is the thickness of the electrodes (3 mm), N is the order of interference (~ 12 500), and λ is the He–Ne laser wavelength (632.8 nm). Distances from the electrode surfaces were calculated from the magnification.

Because, for even the highest current density runs, less than one atomic layer was anodically dissolved or deposited, electrode polishing did not seem necessary. However, in some cases at the higher cd runs, discoloration of the electrode surface was noticed. No increase or decrease of fringes within the field of view was evident, or the electrolyte solution retained its original concentration, although in the smallest separations less than 1.5×10^{-2} mL of solution were used with less than 1.5×10^{-6} equivalents of cupric ion present. All runs were at room temperature of 22.0°C ± 0.5.

Results and Discussion

Figure 1 is a series of interferograms showing a stable S-curve concentration profile between the two electrodes (the black edges, top and bottom) in the A/C configuration. Certain imperfections in the glass flat coatings should be ignored, as, for example, a scratch concave upwards just above the fringe bends at the cathode. Panels (a) and (b) were taken at 120 s and 180 s of electrolysis and show a concentration profile that is more characteristic of a far lower current density (~ 0.01 mA cm^{-2}) when no convection is occurring. Panels (c) and (d) at 5 s and 30 s after current off are included to show that when electrolysis ceases, convective relaxation occurs. The evidence of convection is distortion and uneven spacing of the fringes and (not shown) that relaxation was essentially complete at 50 s, whereas for nonconvective relaxation the usual time required is in excess of 5 min. Table 1 gives a comparison of the values for diffusion only, calculated using the expression for the solution by Laplace transform of Fick's Second Law and the value found in the A/C configuration with concentration profiles present similar to those in Fig. 1. The observed values of the change of concentration as close to the electrode as possible (<0.02 mm) are greater than the calculated values for times less

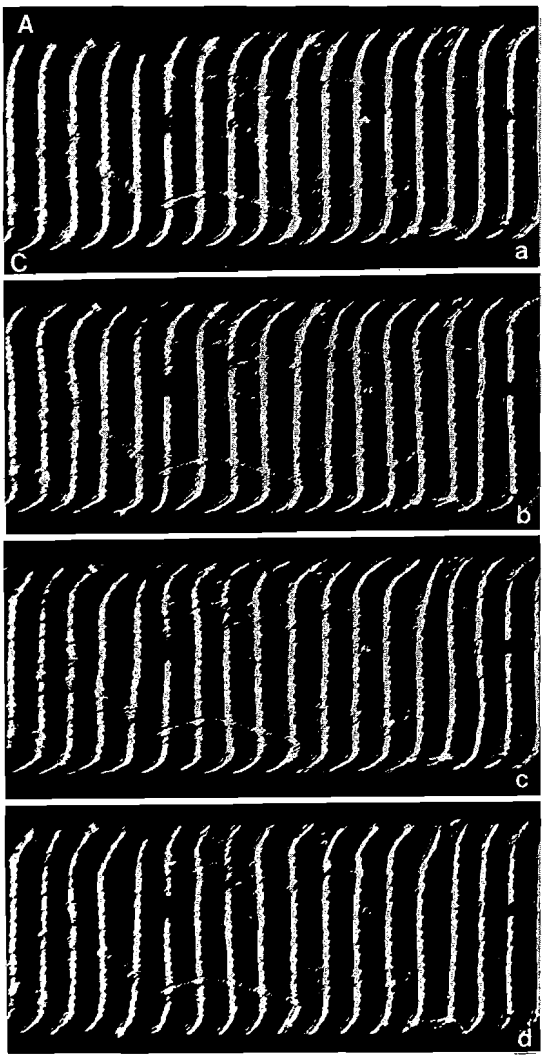

FIG. 1. Interferograms with the anode above the cathode (as shown) at 120 and 180 s of electrolysis in frames (a) and (b) at 0.1 mA cm^{-2}. Frames (c) and (d) are 5 and 30 s after current off, all with electrode separation of 2.3 mm.

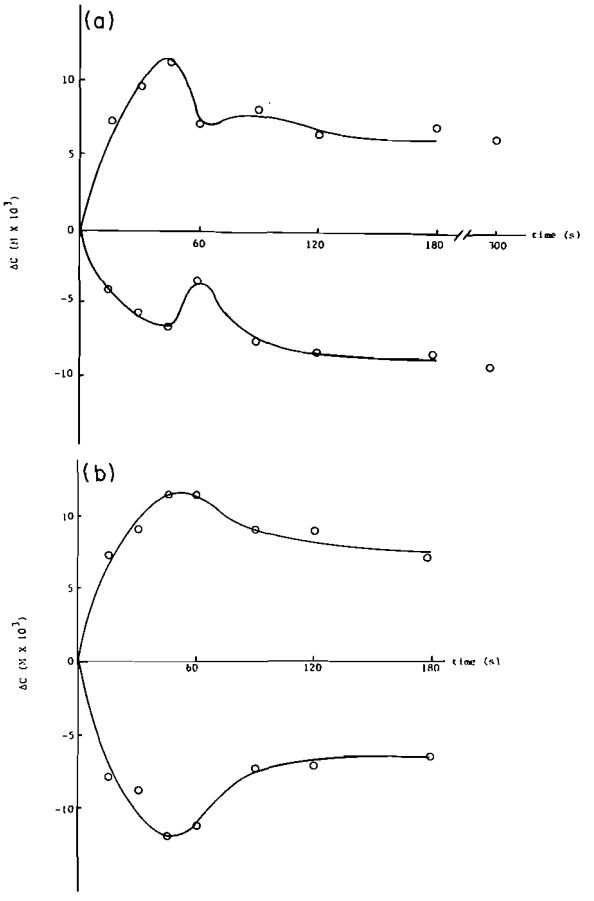

FIG. 2. Plots (a) and (b), change of concentration at the anode and cathode at the electrode surface vs. time in seconds (A/C) at 3.3 mm electrode separation at 0.1 mA cm^2 and 0.2 mA cm^2 respectively.

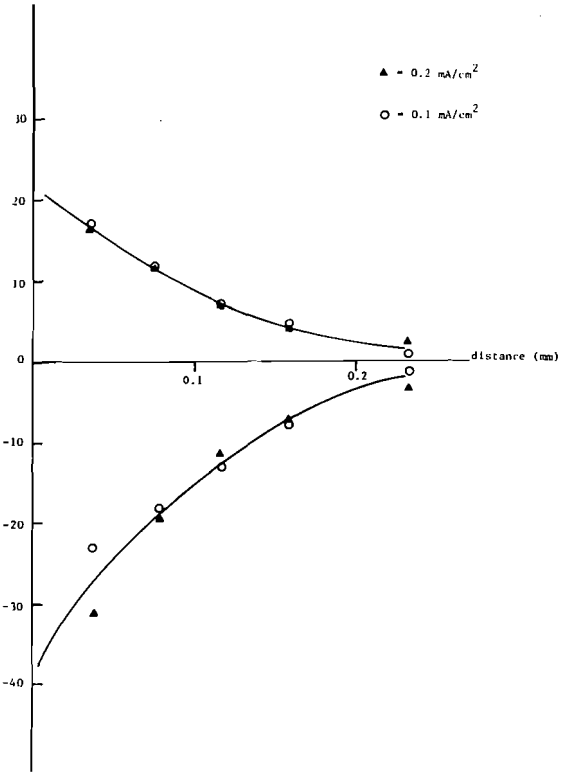

FIG. 3. The data from Fig. 2 with change in concentration plotted against time at 300 s of electrolysis.

than one minute but, at and after one minute, the calculated values (which are close to those observed for convectionless, cathode over anode systems (4, 8)) the measured values go through a maximum and decline to a reasonably constant value much lower than the calculated. Figures 2 (a) and (b) show this effect graphically for (a) a run at 0.1 mA cm^{-2} with electrode separation of 0.3302 mm and (b) 0.2 mA cm^{-2} at the same separation. Figure 3 shows these runs analysed at 300 s of electrolysis for concentration change vs. distance. The calculated value, ignoring convection, would be at least an order larger and the relatively flat curves would be the much more steeply formed asymptotes to the abscissa of the error-function type. Data point sizes approximate estimated measurement errors.

When conditions are more severe, that is at higher current densities and smaller electrode separations, the smooth convective–diffusive system breaks down into roll cells as shown in Fig. 4 (a)–(d). In panel (d) at 45 s there are large distortions of 1 or 2 fringes next to 2–3 fringes which are very little distorted (more obvious in Fig. 5). These distorted areas show the central part of a roll cell,

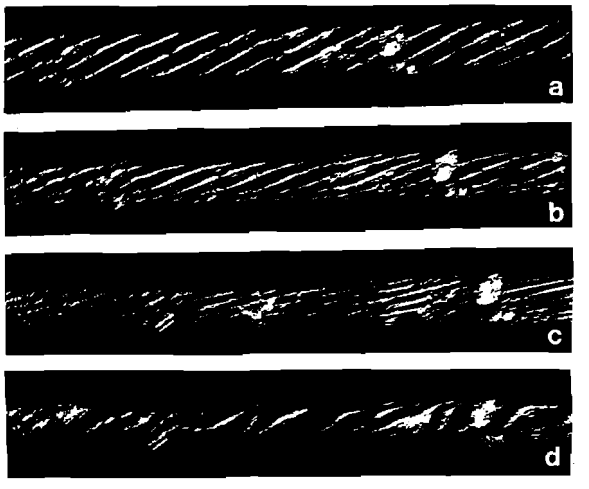

FIG. 4. Four interferograms taken at 10, 15, 25, and 45 s showing the onset of roll cells at 40–45 s A/C at 0.1 mA cm^{-2} with electrode separation of 0.46 mm.

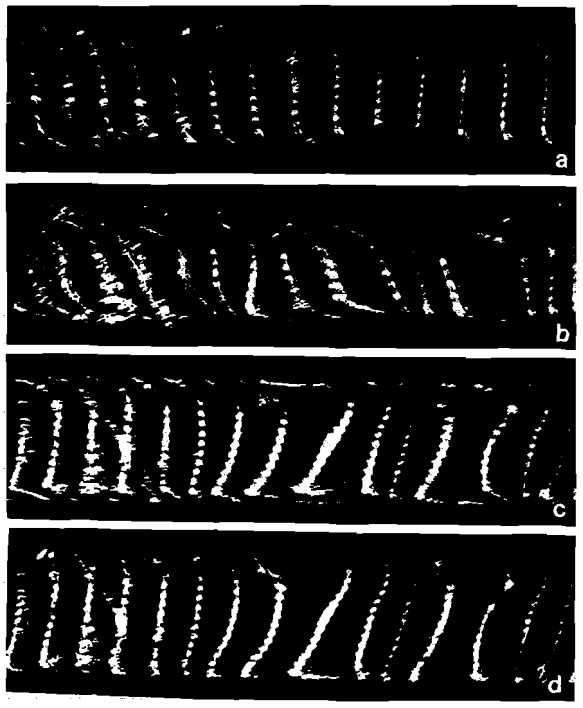

FIG. 5. Panels (a) and (b) are during electrolysis, 30 and 40 s respectively at 1.0 mA cm^{-2} at 1.15 mm electrode separation showing a transition from an S-curve to roll cells. Panels (c) and (d) are 5 and 15 s after switch-off showing persistence in the relaxation of concentration polarization. Relaxation was complete at 55 s.

the straight close-packed ones the areas of contact between rising and falling streams at the boundaries between cells. Figure 5 shows a well-developed set of roll cells. According to Normand and Pomeau (6) they should have their height equal to their width. We did not always find it so. Table 2 gives a list of conditions where roll cells developed at 40–45 s of electrolysis. From this list it can be seen that, for the $Cu/CuSO_4/Cu$ system, roll cell development occurs at approximately 0.2 mA cm^{-2} for electrode separations of greater than 1 mm, and at 0.46 mA cm^{-2} for lower cd's.

The regime of interest then, the smooth S-curve concentration polarization curve which becomes constant with time, is bounded by higher current densities and greater electrode separations. The regime itself resembles in character but not physical set-up the convective diffusion regime described by Levich at the rotating disc electrode (11) and is, to the best of our knowledge, the first report of this phenomenon.

TABLE 2. Occurrence of roll cells

Electrode separation (mm)	Current density (mA cm^{-2})
0.46	0.1
1.15	<0.2
1.55	0.2
1.94	0.2
2.28	0.2
3.30	>0.2

Conclusions

When plane-parallel horizontal electrodes in an electrolysis cell have the anode above the cathode, natural convection has always been found to be an important transport mechanism, limiting the diffusion layer thickness and therefore concentration polarization. The optical evidence obtained from laser interferometry suggests that there are two regimes, one in which an obvious equilibrium is set up to give a constant concentration profile of the S-curve variety, superficially resembling that in a nonconvecting system. This results in a system where migration is just equal to the combined diffusion and convection transport of ions. The second is one in which roll or Bénard type convective cells are set up. The appearance is of some turbulence and hence some possibility of local concentration polarization differences not due to electrode surface influences. Tobias and Hickman (7) found striations along the line of their roll cells.

The regime of smooth S curves and constant concentration polarization with convection is limited in extent by cd and electrode separation. It resembles Levich's convective diffusion except that the phenomenon he describes is a general, smooth flow of electrolyte over a spinning disc. In the present process convective transport must be in both directions, upward to the anode and downward to the cathode. The only explanation for the appearance of a smooth S-curve that presently seems reasonable is that convective cells of very small size (more than 10 across the electrode width of 3 mm or of less than 0.3 mm in diameter) are formed. We cannot at present give an explanation of why they should grow to approximately those predicted by Bénard theory very suddenly on slight increase in current density or electrode separation or why this occurs as soon as the current is switched off (open circuit conditions) after electrolysis. Relaxation by turbulent (large cell) convection is almost an order of magnitude faster than cathode over anode relaxation or at vertical electrodes.

Because the presence of roll cells seemed to result in surfaces that were not smooth, the implications for electromachining seem to be to use the A/C configuration where possible and attempt to stay in the smooth S-curve concentration polarization regime. Since electromachining uses hot con-

centrated electrolyte at very high cd's and forced convection, a further refining of the size of turbulent structures may help to produce the close tolerances the technique is noted for.

Received August 12, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday[1]

GRAHAM NEALE, VLADIMIR HORNOF, and CHRISTOPHER CHIWETELU. Can. J. Chem. **59**, 1938 (1981).

This paper reviews the potential importance of aqueous lignosulfonate solutions in the recovery of petroleum from existing partially depleted oil fields. The surfactant qualities of lignosulfonates are described and their ability to interact synergistically with petroleum sulfonate surfactants (which are currently popular in the industry) to produce ultra-low interfacial tensions with crude oil is discussed. The phase behaviour characteristics and oil recovery efficacies of these mixed surfactant systems are also examined.

GRAHAM NEALE, VLADIMIR HORNOF et CHRISTOPHER CHIWETELU. Can. J. Chem. **59**, 1938 (1981).

Dans ce travail, on présente une revue sur l'importance potentielle de solutions aqueuses de lignosulfonates pour la récupération du pétrole de champs existants mais partiellement épuisés. On décrit les propriétés des lignosulfonates comme agent de surface et on discute de leur possibilité d'avoir un effet synergétique sur les sulfonates dérivés du pétrole (qui sont des agents de surface populaire dans l'industrie) pour produire des tensions interfaciales très faibles avec l'huile brute. On a également étudié les caractéristiques du comportement de phase de ces systèmes d'agents de surface mixtes ainsi que leur efficacité dans la récupération du pétrole.

[Traduit par le journal]

Introduction

Petroleum occurs in nature within the pores of certain underground rock formations. Once an oil well has been drilled, a proportion of the oil originally in place (usually between 10% and 30%) flows naturally to the surface as a result of the very high pressure of the oil; this process is called "primary recovery". A further 10–30% of the original oil can usually be recovered by pumping water into the reservoir formation through a set of injection wells and retrieving the displaced oil at the surface via a central production well. This operation is known as "secondary recovery" and has been used successfully in the field for many years. Because of the very high current cost of oil it has now become economically feasible to attempt to recover the still remaining 40–80% of original oil using "tertiary recovery" schemes.

The basis for many tertiary recovery processes is the extremely low interfacial tension which can be obtained between petroleum and a displacing aqueous solution of certian surfactants, such as petroleum sulfonates (1, 2). Small quantities of a co-surfactant (usually alcohols) and an electrolyte (usually sodium chloride) are incorporated because these additives serve to improve the displacement efficiency. The co-surfactant assists in the adjustment of viscosity, permits the surfactant micelles to solubilize more oil and, in particular, helps to reduce the adsorption of the expensive petroleum sulfonate on the reservoir rock surface. The electrolyte also aids in viscosity adjustment.

The present paper reviews the use of a new class of surfactant known as lignosulfonates as possible alternatives to the more conventional petroleum sulfonates. Lignosulfonates are wood-based chemicals manufactured from the sulfite liquor effluents of pulp and paper plants. These effluents contain sulfonated lignin, polysaccharides and wood sugars dissolved in water. The sulfonated lignin, upon purification, yields lignosulfonate products, many of which possess important surfactant and emulsion stabilizing properties (3). Lignosulfonates can alternatively be obtained by the sulfonation of kraft lignin. The great appeal of lignosulfonates is that they are at least four times cheaper than petroleum sulfonates and are available in large quantities as by-products from the Canadian pulp and paper industry.

Characteristics of Lignosulfonates

Lignosulfonates are water soluble, anionic surface active derivatives of lignin and their properties can be adjusted with respect to sulfonate content, molecular weight, kind and amount of cation and surface activity. The Marasperse® products used in

[1]This paper is dedicated by G. N. to Sam Levine, who has been a friend, co-worker, and constant inspiration for the last ten years. It was written in recognition of his life-long committment to obtaining a better understanding of physical phenomena, which in recent years has included valuable studies concerned with the recovery of oil from the Alberta Tar Sand deposits.

this work are manufactured by the American Can Company and are amongst the purest available. The basic functional constituent of these products is lignosulfonate, an anionic polyelectrolyte of molecular weight between 1 000 and 20 000. The structure of the lignosulfonate molecule is not completely known, but the basic lignin monomer unit is a substituted phenyl propane. This complex structure renders lignosulfonates completely insoluble in oils. The type of metallic ions in the lignosulfonate molecule affects its properties to some degree, while the degree of sulfonation controls the magnitude of its electrical charge when in aqueous solution.

Emulsification Properties of Lignosulfonates

Emulsions stabilized by Marasperse lignosulfonates are quite resistant to pH variations and to the presence of electrolytes such as sodium chloride, sodium sulfate, and sodium phosphate (3, 4). However, sodium hydroxide enhances the activity of aqueous lignosulfonate solutions, tending to lower the interfacial tension in an oil–water emulsion thereby rendering it more stable. Lignosulfonate-stabilized emulsions are not adversely affected by mechanical agitation (in fact such action tends to stabilize them further) or by large temperature variations.

As lignosulfonate-stabilized emulsions are extremely stable, the conventional methods of breaking emulsions are not entirely effective. The most effective way of nullifying the action of lignosulfonate is by adding a cationic surface active agent; in this work small quantities of hexadecyl trimethyl ammonium bromide were found to be effective in breaking lignosulfonate-stabilized emulsions.

Stabilization Mechanisms in Lignosulfonate-based Emulsions

Aqueous solutions of lignosulfonates are subcolloidal, high molecular weight polyelectrolytes (3, 4). They do not show any marked tendency to form micelles and do not possess a hydrophobic–hydrophilic molecular structure. The mechanisms of emulsification and stabilization are therefore different from those of conventional surfactants. The stabilization is the result of adsorption of lignosulfonate at the oil–water interface, which establishes an electrokinetic charge and a semi-rigid film. The highly charged lignosulfonate molecules in the solution then cover the entire oil–water interface. This separation of charge leads to stabilization of the dispersed oil droplets in the aqueous phase. At higher lignosulfonate concentrations, its molecules are packed closer together and are forced into the interface, resulting in a decreased interfacial tension and more stable emulsion.

Previous Work involving Lignosulfonates

Very little work involving lignosulfonates in the tertiary recovery of petroleum has been reported, although the use of sulfite spent liquors in secondary waterflooding was first proposed in 1931 (5). However, Kalfoglou (6) recently patented a process involving the use of lignosulfonates as a "sacrificial" agent during tertiary oil recovery operations. His results indicated that the presence of lignosulfonates in admixture with petroleum sulfonate surfactants increased oil recovery through reduced loss by adsorption of the costly petroleum sulfonate. It was asserted that since lignosulfonates possess strongly ionized sulfonate groups they were capable of covering the potential adsorption sites of the rock by means of electrostatic attraction or hydrogen bonding, thereby imparting a negative charge to them. The surface would therefore have no affinity for anionic surfactants such as petroleum sulfonates. However, Kalfoglou did not consider that some part of the increased oil recovery could have been due to the favourable surfactant and emulsion stabilizing properties of the lignosulfonate itself.

Work has been continuing in our laboratories on ways of improving the oil recovery efficacy of lignosulfonate solutions. In an earlier paper (3), interfacial tensions as low as 10 mN/m were reported between commercial Fuel Oil No. 4 and Marasperse N-22 lignosulfonate solution. In displacement tests conducted using unconsolidated Ottawa sand packs additional recoveries of 1.3% and 8.5% (relative to those obtained with pure waterflooding) were obtained at 1% and 10% lignosulfonate concentrations respectively. The next phase of the study involved the screening of a number of organic and inorganic reagents as co-surfactants. These results have been reported elsewhere (2). The lowest interfacial tensions obtained were about 1 mN/m, upon the addition of small quantities of caustic soda and butanol-1 into lignosulfonate solutions. However, neither of the preceding studies (2, 3) produced interfacial tensions low enough (i.e. $\lesssim 0.001$ mN/m) for practical tertiary oil recovery operations.

More recent work has focused on the study of mixtures of lignosulfonates with petroleum sulfonates, since lignosulfonates alone are evidently not satisfactory. This work has produced some extremely encouraging results, in the form of interfacial tensions (IFT) as low as 10^{-4} mN/m with real

crude oils. Within this framework, the following parameters are of particular interest: (*a*) degree of mutual compatibility of lignosulfonates and petroleum sulfonates; (*b*) phase behaviour and interfacial activity of such mixtures; (*c*) optimization of a surfactant solution for the establishment of a minimum IFT with any given crude oil. In connection with item (*c*) above, Cayias *et al.* (7) have developed the important "Equivalent Alkane Carbon Number" (EACN) concept for characterizing crude oils and matching them to optimum petroleum sulfonate surfactant formulations for the attainment of minimum interfacial tensions. It is shown later in this article that the EACN concept appears also to be valid for lignosulfonate-based surfactant mixtures.

The EACN Concept

It is now accepted that the mechanisms involved in tertiary oil recovery are extremely complex and that the optimum composition of a displacing surfactant solution has to be determined in the laboratory for each prospective oil reservoir, with due consideration being given to the nature of the reservoir fluids, temperature, pressure, rock structure, etc.

Recently, work by Cayias *et al.* (7) and Wade *et al.* (8) has produced a model capable of relating the suitability of any particular surfactant system to any given crude oil. Their research has given rise to the "Equivalent Alkane Carbon Number" (EACN) concept for pure hydrocarbons and their mixtures. The EACN is determined in the following manner for pure compounds:

For *n*-alkanes

EACN = number of carbon units.

For *n*-alkylcyclohexanes

EACN = number of carbon units in alkyl side chain, plus 4.

For *n*-alkylbenzenes

EACN = number of carbon units in alkyl side chain.

For example, heptane, propylcyclohexane, and heptyl benzene each possess an EACN of 7. For mixtures of hydrocarbons the EACN is determined using the formula:

$$(\text{EACN})_{\text{mixture}} = \sum_i (\text{EACN})_i X_i$$

where X_i denotes the mole fraction of the ith component present. For example, an equimolar mixture of butylcyclohexane (EACN = 8) and propylbenzene (EACN = 3) would have an EACN of 5.5. This mixture, according to the EACN concept, would then be predicted to yield a minimum interfacial tension against any surfactant solution which provides ultra-low tensions against pure alkanes intermediate between pentane and heptane. The above equation has been verified for a wide range of binary mixtures using petroleum sulfonate and related surfactants (7). Moreover, the EACN concept has been successfully verified using a complicated synthetic crude oil made up from 29 different aliphatic, alicyclic, and aromatic hydrocarbons (7). Hence, its applicability to real crude oils (for which the EACN cannot usually be determined directly on account of their unknown composition) can be inferred. Preliminary data presented here confirms that the EACN concept is also valid for lignosulfonate-based surfactants. This is to be expected since, according to the theory, the EACN of a given mixture of oils is an inherent characteristic of the oil, being independent of the surfactant solution in question.

Results

The crude oil used was a light oil from the Gosfield South Field near Chatham, Ontario, having a specific gravity of 0.82 and viscosity of 5.3 mPa s at 25°C. The lignosulfonate used was calcium based Marasperse C-21, a brown powder of bulk density 600 kg/m^3 which is 100% soluble in water and completely insoluble in oils. The petroleum sulfonates used were Petrostep 420 and Petrostep 450 (manufactured by Stepan Chemical Co.), each containing approximately 61% sulfate, 15% free oil, 19% free water, and 5% inorganic salts. The numbers 420 and 450 refer to the equivalent weights of the two materials.

Two distinct aspects of the mixed lignosulfonate – petroleum sulfonate surfactant systems were investigated. Firstly, formulations of these two surfactants were prepared and their physicochemical properties (i.e. viscosity, density, pH, surface and interfacial tensions) were measured. Secondly, the most successful formulations were evaluated for their oil recovery efficacies by means of simulated oil displacement tests using packed sand beds. Fuller details of the experimental procedures and techniques are presented elsewhere (2, 3, 9).

A salinity level of 1.5% NaCl was maintained in all formulations, and various concentrations within the ranges 0–4% lignosulfonate and 0–5% petroleum sulfonate were employed. The oil displacement tests were conducted by displacing the oil from previously saturated sand packs of porosity 0.34. One pore-volume of pure 1.5% NaCl solution was first introduced (in order to simulate a conventional secondary recovery process) followed by two pore-volumes of surfactant solution (to simu-

late a tertiary recovery process). The recovered oil was usually in emulsified form; separation was effected by centrifugation followed by addition of the emulsion breaker hexadecyltrimethyl ammonium bromide. Representative surfactant solution properties and final oil recoveries are summarized in Table 1. The final oil recoveries represent the percentage of original oil recovered at the end of the displacement process. More detailed data showing the production history during each of the secondary and tertiary stages is available elsewhere (9).

Stable single phases were observed at all concentrations of Petrostep 420 and 450 when used alone (up to 4%) as well as for these systems when containing up to 1% C-21 lignosulfonate. However, increasing instability and phase separation was observed at higher lignosulfonate concentrations. At 2% petroleum sulfonate concentration the maximum tolerable lignosulfonate concentration was about 2%, while at 3% and 4% petroleum sulfonate precipitation occurred at about 3% lignosulfonate.

As displayed in Fig. 1, the surface tension of the Petrostep solutions drops to a minimum as lignosulfonate is added. Beyond a certain C-21 concentration the surface tension increases due to the appearance of multiple phases. The trend towards a minimum was similar but less pronounced with Petrostep 450 (not shown here). The pH of all solutions decreases with increasing lignosulfonate concentration.

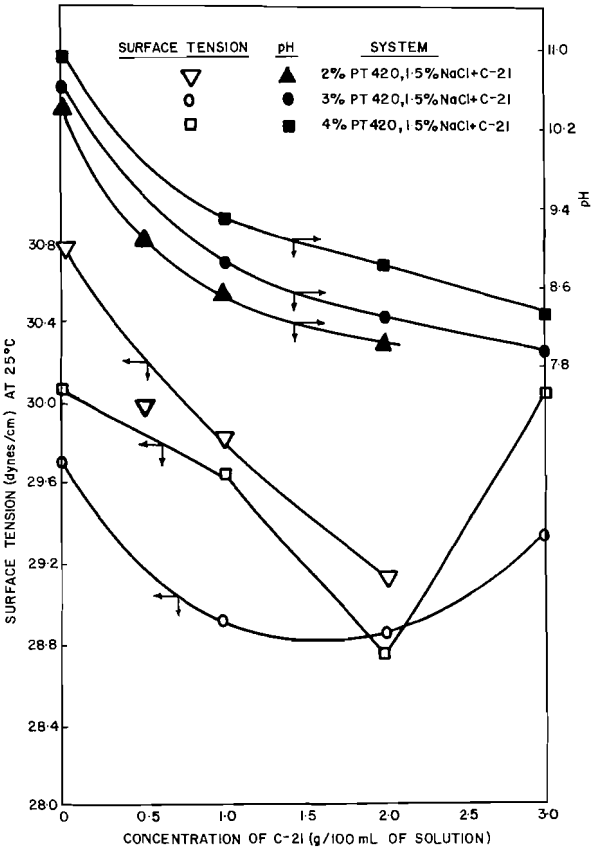

FIG. 1. Surface tension and pH plots for mixed surfactant systems containing Petrostep-420 and Marasperse C-21.

The significant changes in IFT and viscosity with increasing lignosulfonate concentration are clearly seen in Fig. 2. Beyond the mutual tolerance limits, further addition of lignosulfonate leads to an increase in IFT and decrease in viscosity, due to precipitation and consequent decreased synergistic action between the lignosulfonate and petroleum sulfonate. These effects are manifested in lower final oil recoveries in Table 1 (for example, compare Run 6 with Run 5 and Run 9 with Run 8). Under prolonged observation of the most highly viscous formulations, the viscosity was observed

TABLE 2. Effects of EACN on interfacial tension

Organic phase	EACN	IFT (mN/m) Without lignosulfonate	IFT (mN/m) With lignosulfonate
Hexane	6	1.393×10^{-1}	3.170×10^{-3}
Heptane	7	7.066×10^{-2}	6.564×10^{-4}
Octane	8	8.195×10^{-2}	3.021×10^{-3}
Dodecane	12	1.804×10^{-1}	3.613×10^{-2}
Hexadecane	16	2.260×10^{-1}	7.458×10^{-2}
Chatham crude	—	8.143×10^{-2}	2.435×10^{-3}

to vary with the age of the system, with the shearing rate, and with the duration of shearing at a fixed shear rate. Newly prepared systems were thixotropic, tending to become increasingly rheopectic with age.

Table 1 provides a summary of the 10 separate displacement runs conducted, and demonstrates very vividly the pronounced effect which ultra-low IFT's have on final oil recovery. Run 10, a 3 pore-volume pure brine (1.5% NaCl) displacement, served as the reference run for the other 9 runs conducted. The oil recoveries at the termination of the secondary displacements (of 1 pore-volume) all varied between 53 and 57%. It is clear from Table 1, therefore, that much additional oil was recovered during the ensuing 2 pore-volume tertiary displacements using surfactant solutions (compare with the recovery for Run 10 using only brine during the tertiary phase). The exceptions to this are Runs 6 and 9 in which the mutual tolerance limit was exceeded and precipitation occurred, thereby decreasing the surfactant solution effectiveness (resulting in reduced final oil recoveries).

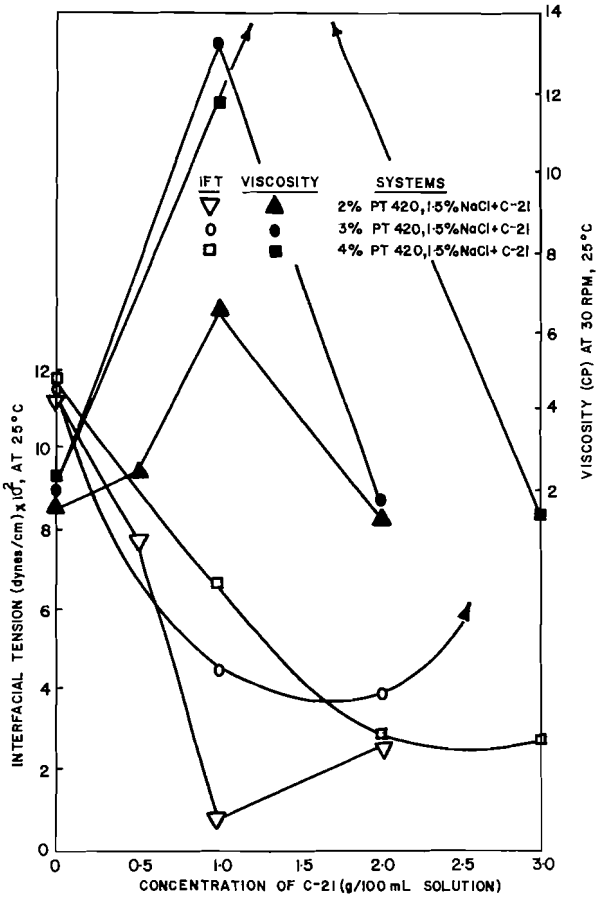

FIG. 2. Interfacial tension and viscosity plots for mixed surfactant systems containing Petrostep-420 and Marasperse C-21.

EACN Concept Results

In this very preliminary work the IFT's of the Chatham crude oil and pure hydrocarbons shown in Table 2 were measured against two surfactant solutions, the first containing 1% C-21 lignosulfonate, 5% Petrostep 420, and 1.5% NaCl, the second containing 5% Petrostep 420 and 1.5% NaCl with *no* lignosulfonate present. As usual, the organic liquids were pre-equilibrated for 48 h with the surfactant solutions (9) in order to attain mutually saturated phases and interfacial tensions were then measured using a spinning drop tensiometer. The results are summarized in Table 2.

From Table 2 it is apparent that, for both surfactant systems, a minimum IFT is observed at an EACN of about 7, in general agreement with the findings of Cayias *et al.* (7) of a minimum (for crude oils) within the 7–8 range. The EACN at which the minimum occurs is of course a function of the surfactant solution composition. The EACN of the natural crude oil cannot be accurately determined directly (since its composition is unknown) but it can be estimated by interpolation of the above data. For both surfactant mixtures, the extrapolated value would be approximately 8, again in good agreement with previous work on real crude oils (7, 8). The optimum surfactant for producing an ultra-low IFT against Chatham crude oil would therefore

be one which gives low tensions against alkanes intermediate between heptane and decane. The above data, although very preliminary, do seem to confirm that the EACN concept is valid for lignosulfonate-based surfactant solutions (in addition to the petroleum sulfonate and other surfactant solutions for which it was originally devised).

Discussion

Although the displacement experiments reported in this paper do not simulate exact conditions in real oil reservoirs, the conditions were unchanged from one run to another, thereby enabling a meaningful comparison of the individual runs to be made. By inspection of Table 1 it is clear that the high oil recovery obtained in Run 3 (compared with that of Run 1) can only be attributed to the much lower IFT and, to a lesser degree, to the improved system viscosity. This same conclusion applies also to Run 5 (when compared with Run 4) and, to a reduced extent, to Run 8 (when compared with Run 7). The recoveries in Runs 6 and 9 are low because of the incompatibility of the lignosulfonate and petroleum sulfonate at the prevailing concentrations. The phase behaviour of these mixed surfactant systems, corresponding to increasing lignosulfonate concentration, may be represented schematically as follows:

$$\text{Isotropic} \rightleftarrows \text{birefringent} \rightarrow \text{phase separation}$$

with the critical concentration ratio, C^*_{crit}, for mutual compatibility of the two surfactants being given approximately by:

$$C^*_{crit} = C_{Pet}/C_{lig} \gtrsim 1.5$$

This limiting concentration ratio is expected to depend upon the type and composition of both surfactants present. Work in this area is currently being pursued.

Shah *et al.* (10) have observed that at low surfactant concentrations, micro-emulsions consist of isotropic and spherical micelles, regardless of phase-externality. With increasing surfactant concentration anisotropic liquid crystalline structures appear. The appearance of such aggregates results in changes in the optical properties as well as in the electrical and rheological properties of the micellar systems. Although optical measurements have not been performed in this work, the rheology of the mixed surfactant systems does appear to indicate the presence of liquid crystalline structures. The variation in viscosity of these systems with age and with time of shear is consistent with the observations of Bansal and Shah (11), who identified such phenomena with liquid crystalline structures.

The problem of surfactant loss by adsorption onto the rock surface has not been investigated here. However, as Kalfoglou (6) has claimed, adsorption losses of petroleum sulfonates can be reduced in the presence of sacrificial agents, such as lignosulfonates. Another problem which has not been explicitly examined here concerns the mechanisms of oil displacement by aqueous solutions at the microscopic level, as discussed in some depth by Levine *et al.* (12). However, the present work does strongly affirm the great potential which lignosulfonates possess in the enhanced recovery of oil from existing, partially depleted oil fields.

The role of the supporting electrolyte cation in the kinetics of outer-sphere electrochemical redox processes involving metal complexes

MICHAEL J. WEAVER,[1] H. Y. LIU, AND YONGJOO KIM

Department of Chemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

Received August 12, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

MICHAEL J. WEAVER, H. Y. LIU, and YONGJOO KIM. Can. J. Chem. **59**, 1944 (1981).

The electroreduction rates of $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$ at the mercury–aqueous interface were monitored as a function of electrode potential in electrolytes containing univalent, divalent, or trivalent cations with systematically varying atomic number in order to scrutinize the role of the supporting electrolyte cation in the kinetics of these simple one-electron outer-sphere electrode reactions. The comparison between the corresponding rate responses for $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$ reduction brought about by changing the supporting electrolyte cation is expected to provide information on the influence of the cation upon the potential profile in the double layer; despite the close structural and mechanistic similarity of the reactants, the transition state for the latter reaction appears to lie significantly closer to the electrode than that for the former process. The virtues of comparing rate responses at a constant electrode charge density rather than at a constant electrode potential are pointed out. It was found that the variations in the effective average potential at constant charge $(\Delta\phi_r)_{q^m}$ for the two reactants are closely similar but noticeably smaller than the corresponding changes in the electrode potential $(\Delta E)_{q^m}$ derived from thermodynamic double-layer measurements. These results, along with the observed variations in the transfer coefficients for the two reactions, are semiquantitatively consistent with a model involving changes in the position of the oHp as the supporting electrolyte cation is altered, but are inconsistent with a model attributing the rate variations to cation specific adsorption.

MICHAEL J. WEAVER, H. Y. LIU et YONGJOO KIM. Can. J. Chem. **59**, 1944 (1981).

On a enregistré les vitesses d'électroréduction du $Cr(OH_2)_6^{3+}$ et du $Cr(NH_3)_6^{3+}$ au niveau de l'interface mercure–eau en fonction du potentiel d'électrode dans des électrolytes contenant des cations uni, di et trivalents en faisant varier systématiquement le numéro atomique dans le but d'étudier le rôle du cation de l'électrolyte de support dans la cinétique de ces réactions simples faisant intervenir un seul électron dans la couche extérieure de l'électrode. On s'attend à ce que les variations, dues au changement du cation de l'électrolyte de support, dans les taux de réponse lors des réductions du $Cr(OH_2)_6^{3+}$ et du $Cr(NH_3)_6^{3+}$ fournissent des informations relatives à l'influence du cation sur le profil du potentiel de la couche double; malgré les ressemblances des réactifs tant du point de vue structural que du point de vue mécanistique, l'état de transition de la dernière réaction semble se produire plus près de l'électrode que dans la première réaction. On signale l'utilité de comparer les taux de réponse à une densité constante de la charge de l'électrode plutôt qu'à un potentiel constant de l'électrode. On a trouvé que les variations du potentiel moyen efficace à charge constante $(\Delta\phi_r)_{q^m}$ des deux réactifs sont assez semblables mais nettement plus faibles que les variations correspondantes du potentiel d'électrode $(\Delta E)_{q^m}$ obtenu à partir de mesures thermodynamiques de la couche double. Ces résultats ainsi que les variations observées dans les coefficients de transfert des deux réactions sont semi-quantitativement en accord avec un modèle impliquant des variations dans la position pHo lorsqu'on modifie le cation de l'électrolyte de support mais ils ne correspondent pas avec un modèle dans lequel on attribue les variations de vitesse à l'adsorption spécifique du cation.

[Traduit par le journal]

Introduction

The various influences of the ionic double-layer composition upon the kinetics of electrode reactions at the mercury–aqueous interface have received extensive scrutiny over the years. Most early studies were concerned with testing the applicability of the Frumkin model in conjunction with the Gouy–Chapman–Stern theory of the double layer (GCSF approach) at potentials well negative of the potential of zero charge (pzc) where specific ionic adsorption is most likely to be weak or absent (1, 2). Broadly speaking, the GCSF model has been found to be surprisingly successful under these conditions, although unexpectedly large rate variations have been found when the nature of the supporting electrolyte cation is altered. These have been ascribed to cation specific adsorption, ion-pairing influences, and variations in the position of the outer Helmholtz plane (oHp) relative to the reaction plane (1, 2). More recently, there has been considerable interest in testing the GCSF model under conditions where there is extensive specific adsorption of the supporting electrolyte anions. Significant deviations from the GCSF predictions have been reported, which have been ascribed variously to deficiencies of the Gouy–Chapman theory, the noncoincidence of the reaction plane and the oHp, and discreteness-of-charge effects (e.g. refs. 3–5). However, the majority of these studies have employed reactions for which the chemical structure and spatial position of the transition state for electron transfer is unknown or ill-defined, particularly oxyanion reductions and hydrogen evolution. We have suggested (5–7) that

an attractive class of model reactants is provided by substitutionally inert transition-metal complexes containing aquo or ammine ligands that can be reduced (or oxidized) via a *single* electron transfer step. No metal–ligand bond cleavage or formation takes place prior to electron transfer so that the structure of the transition states is well defined, being approximately midway between those of the oxidized and the reduced forms. Moreover, we have found that the electroreduction kinetics of substitutionally inert Cr(III) and Co(III) complexes containing aquo or ammine ligands are uniformly in reasonable accordance with the predictions of the Frumkin model both in the absence and the presence of specific anionic adsorption, once the likely noncoincidence of the reaction planes and the oHp is taken into account (5–9) (*vide infra*).[2]

In view of these appealing features, it seems worthwhile to employ such reactions to examine further the effects of varying the supporting electrolyte cation upon electrode kinetics. In particular, $Cr(NH_3)_6^{3+}$ and $Cr(OH_2)_6^{3+}$ are both reduced irreversibly at negative potentials (ca. −800 to −1000 mV vs. sce) where the supporting electrolyte cation forms the predominant component of the diffuse layer. Moreover, both reactions probably proceed via outer-sphere pathways, i.e., where the "primary inner layer" of water adjacent to the electrode surface is not penetrated by the reacting species in the transition state for electron transfer (5, 7) so that the double-layer effects upon these reactions should be predominantly electrostatic in origin. Both reactants are spherical and of comparable size to the aquo cations that commonly form the supporting electrolyte. However, the reaction planes for the reduction of $Cr(NH_3)_6^{3+}$ and other Cr(III) and Co(III) ammines appear to lie significantly closer to the electrode surface than for the reduction of $Cr(OH_2)_6^{3+}$ and other aquo complexes, as deduced from the markedly larger double-layer effects observed for the former reactions (5–7). These differences appear to rise from the larger effective size of the aquo reactants; although the crystallographic radii of corresponding ammine and aquo complexes are closely similar, the hydrated radii of the latter reactants are significantly (~1 Å) larger as a result of hydrogen bonding between the aquo ligands and surrounding water molecules ("solvent structure-making") (5, 11, 12). Similarly, the increases in the inner-layer capacitance seen at electrode potentials negative of the pzc for supporting electrolytes with cations of increasing atomic number and charge arise from decreases in the inner-layer thickness due to decreases in the effective hydrated radii of the cations that form the oHp (13–15). However, some of these capacitance variations have also frequently been ascribed to specific adsorption of the heavier cations, particularly cesium (16). Distinction between these two possibilities has proved to be difficult purely on the basis of thermodynamic data since both models lead to predictions that are broadly in accordance with experiment (15, 16).

The comparison of the influence of varying the nature of the supporting electrolyte cation upon the reduction kinetics of $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$ is anticipated to shed light on this question since the relative rate responses obtained for these two similar reactants having the same charge yet different reaction planes to changes in the supporting electrolyte cation should be sensitive to the potential profile within the double layer. Such a study is reported in the present paper.

Experimental

Stock solutions of $Cr(OH_2)_6^{3+}$ and $Cr(OH_2)_5F^{2+}$ in excess perchloric acid were prepared essentially as described in refs. 17 and 18, respectively. Solid $Cr(NH_3)_6\cdot(ClO_4)_3$ was synthesized as outlined in ref. 19; $Ru(NH_3)_6\cdot(ClO_4)_3$ was obtained by recrystallizing samples of $Ru(NH_3)_6\cdot Cl_3$ (Alfa Inorganics) from solutions containing perchloric acid. Analytical grade reagents were often used without further purification, although they were recrystallized from water in a number of cases. Water for electrode kinetics experiments was either purified by a Milli-Q water purification system (Millipore Corp) or by distillation from alkaline permanganate followed by pyrodistillation (11), with identical results.

The apparatus employed was substantially the same as described in ref. 5. The apparent heterogeneous rate constants k_{app} were determined as a function of electrode potential E using either normal pulse or dc polarography, employing a PAR 174 Polarographic Analyzer (Princeton Applied Research Corp) coupled with a Hewlett-Packard 7045A X-Y recorder. A dropping mercury electrode having flow rates in the range 1.5–2 mg s^{-1} was used with a mechanically controlled drop time of 2 s. The analyses of the irreversible polarographic waves employed the methods due to Oldham and Parry (20). Normal pulse polarography was preferred to dc polarography for most measurements since larger rate constants (up to ca. 4×10^{-2} cm s^{-1}) could be obtained with the former technique and it is also less susceptible to polarographic maxima.

Since relatively small differences (often less than a factor of 2–3) in k^E_{app} for a given electrode reaction between the various electrolytes at a given electrode potential were required to be measured, a good deal of attention was paid to the optimization of experimental precision and accuracy. It was found that although noticeable discrepancies in the values of k^E_{app} (up to ca. 50%) for a given system could be obtained by different workers using different capillaries, etc., much better precision (values of k^E_{app} within 5%) could be obtained by a given worker using the

[2]Note that the apparent breakdown of the Frumkin model for Eu^{2+} oxidation in perchlorate electrolytes reported in ref. 10 now appears instead to be an artifact of the data analysis (9).

For personal use only.

same experimental setup, especially if a series of electrolytes was run consecutively so that the mercury flow rate, cell temperature, etc., remained essentially constant. As much kinetic data as possible were therefore obtained in this manner. The precision in k_{app} achieved was limited at the bottom and the top of the polarographic waves by the corrections for the background currents and the inevitable errors in the assignment of the diffusion-limited current i_{lim}, respectively. The polarographic analyses were therefore restricted to measured currents i such that $0.08 \lesssim i/i_{lim} \lesssim 0.92$. Reactant concentrations were usually between 0.5–1 mM to avoid polarographic maxima yet to allow currents at the foot of the wave to be separated from the background. Using these conditions, values of the apparent transfer coefficients α_{app} were usually reproducible to within 1–2%. All kinetic measurements were made at 25.0° ± 0.1°C, using a jacketed cell through which water was circulated from a Braun Melsungen thermostat.

Formal potentials for $Fe(OH_2)_6^{3+/2+}$ and $Ru(NH_3)_6^{3+/2+}$ in the various electrolytes were evaluated as described in ref. 11 by means of cyclic voltammetry using platinum "flag" and hanging mercury drop electrodes, respectively. Small concentrations of chloride ions (1–2 mM) were added to the solutions containing Fe^{3+} in order to enhance the electrochemical reversibility of the $Fe(OH_2)_6^{3+/2+}$ couple. All electrode potentials are reported with respect to the saturated (KCl) calomel electrode (sce), although measurements in concentrated perchlorate media employed an sce containing saturated NaCl in order to eliminate spurious liquid junction potentials caused by precipitation of $KClO_4$ in the fiber junction.

Results

Table 1 contains a summary of rate–potential data obtained for the electroreduction of $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$ in various supporting electrolytes containing univalent, divalent, and trivalent cations of systematically varying atomic number. The choice of electrolytes was determined partly by the conditions employed previously to study double-layer effects with these reactants (5, 17, 21–23), and partly by availability of accurate capacitance measurements. Grahame has reported capacitance–potential data for 0.1 M chloride salts with a wide range of cations (24). In view of the significant ion-pairing between the Cr(III) reactants and Cl^- at these high ionic strengths (21), the corresponding perchlorate or nitrate salts were used instead. At the negative electrode potentials of interest here ($-E > 800$ mV vs. sce) specific adsorption of nitrate, perchlorate, or chloride is negligible and the supporting electrolyte cation therefore provides the dominant contribution to the ionic charge in the double layer. For the divalent cation series Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, and the trivalent series Al^{3+}, Yb^{3+}, La^{3+}, 0.1 M perchlorate salts were employed since Grahame's capacitance data could then be used directly. For the univalent cation series Li^+, Na^+, K^+, Rb^+, Cs^+, and NH_4^+, 0.5 M solutions of the nitrate salts were used instead. This is because the Gouy–Chapman diffuse-layer potentials ϕ_d^{GCS} in 0.1 M MX salts (where M is a metal cation or NH_4^+), are sufficiently negative at the electrode charge densities q^m encountered here ($7 < -q^m \lesssim 10\,\mu C\ cm^{-2}$) so that the tripositive Cr(III) reactants are calculated to provide a significant influence on ϕ_d even for small bulk reactant concentrations (~0.5–1 mM). For 0.5 M MX salts (as well as for 0.1 M MX_2 and MX_3 salts), ϕ_d^{GCS} is estimated to be sufficiently small ($-\phi_d^{GCS} < 50$ mV) to render this effect negligible. Although nitrate is expected to have a greater tendency than perchlorate to form ion pairs with the Cr(III) reactants, $Cr(NH_3)_6^{3+}$ is insufficiently soluble in 0.5 M perchlorate solutions (<0.5 mM); also the use of nitrate rather than perchlorate salts allowed 0.5 M K^+, Rb^+, and Cs^+ solutions to be studied. Nevertheless, similar rate data were obtained for a given reactant in corresponding alkali nitrate and perchlorate media (Table 1).

The kinetic data in Table 1 are summarized as observed (apparent) rate constants k_{app} at −900 mV vs. sce together with the apparent transfer coefficient α_{app} ($= -(RT/F)(\partial \ln k_{app}/\partial E)_\mu$) obtained from the slope of the Tafel plot in a given electrolyte μ at the same potential. This potential was chosen since the most trustworthy rate data for both reactants were obtained in the potential region −850 to −950 mV. Essentially linear Tafel plots (i.e., potential-independent values of α_{app} were uniformly obtained for $Cr(NH_3)_6^{3+}$ reduction over the relatively narrow (ca. 150–200 mV) range of overpotentials that were conveniently accessible due to the large values of α_{app} (~0.8). The reduction of $Cr(OH_2)_6^{3+}$ yielded essentially linear Tafel plots in 0.5 M MNO_3 and $MClO_4$ electrolytes in the observable potential range −750 to −1100 mV vs. sce, as previously noted for concentrated $NaClO_4$ (17, 22). Small yet significant decreases in α_{app} with increasing overpotential (ca. 0.02–0.03 over the ~250 mV observable potential range) were seen in the dipositive and especially tripositive supporting electrolytes, as noted previously with $La(ClO_4)_3$ electrolytes (17, 22).

The reduction kinetics of $Cr(OH_2)_5F^{2+}$ were monitored for the divalent cation series 0.1 M $Mg(ClO_4)_2 \rightarrow$ 0.1 M $Ba(ClO_4)_2$. Decreases in k_{app} were again observed with increasing cation atomic number, although they were noticeably (40–50%) less than those for $Cr(OH_2)_6^{3+}$ reduction, as expected in view of the smaller charge of the fluoro complex (23).

Inspection of the rate data in Table 1 reveals that for a given series of electrolytes having the same concentration and cation charge there are progressive decreases in k_{app} and also α_{app} at a given electrode potential as the atomic number of the supporting electrolyte cation increases. The sim-

[a] Electrolytes contained 5 m*M* $HClO_4$ in order to suppress hydrolysis of $Cr(OH_2)_6^{3+}$ and some supporting electrolyte cations and to prevent precipitation of $Cr(OH)_2$ resulting from spurious pH changes in vicinity of electrode (5).

[b] k_{app} is measured (apparent) rate constant at electrode potential of −900 mV vs. sce. Experimental precision in log k_{app} is ca. ±0.02 (see text).

[c] α_{app} is apparent transfer coefficient (= $-(2.303\ RT/F)(\partial \log k_{app}/\partial E)_\mu$) at −900 mV vs. sce. Experimental precision ca. ±0.01 (see text).

[d] k_{corr}^{GCS} is double-layer corrected rate constant at −900 mV vs. sce; obtained from corresponding value of k_{app} using eq. [1] and assuming that $\phi_r = \phi_d^{GCS}$, where ϕ_d^{GCS} is the potential drop across the diffuse layer calculated from the Gouy–Chapman–Stern theory. The required value of the electrode charge q^m for each electrolyte was obtained from data in ref. 24 (see text).

[e] α_{corr}^{GCS} is double-layer corrected rate constant at −900 mV vs. sce; obtained from corresponding value of α_{app} using eq. [2] and assuming that $(\partial\phi_r/\partial E)_\mu = (\partial\phi_d^{GCS}/\partial E)_\mu$. Values of $(\partial\phi_d^{GCS}/\partial E)_\mu$ were obtained from Gouy–Chapman–Stern estimates of diffuse-layer capacitance coupled with values of electrode capacitance taken from ref. 24.

[f] Studies of $Cr(NH_3)_6^{3+}$ reduction precluded due to insufficient solubility of $Cr(NH_3)_6(ClO_4)_3$ in these media.

[g] Identical kinetic parameters within experimental error also were obtained for both reactions in 0.1 *M* $Mn(ClO_4)_2$ and 0.1 *M* $Co(ClO_4)_2$.

plest possibility is that these rate variations may be due to differences in the diffuse-layer potentials between the various electrolytes. We can write for a one-electron reduction at a given electrode potential E (e.g. ref. 8)

$$[1]\quad \log k_{app} = \log k_{corr} + \log(\gamma_r/\gamma_\pm) - \frac{F}{2.303RT}(Z_r - \alpha_{corr})\phi_r$$

where k_{corr} and α_{corr} are the ("double-layer corrected") rate constant and transfer coefficient, respectively, that would be observed in the absence of the ionic double layer, Z_r is the reactant charge, γ_r and $\gamma_\pm$ are the activity coefficients for the bulk reactant and the transition state, respectively, and ϕ_r is the average potential on the reaction plane. Similarly, we can relate the apparent and corrected transfer coefficients by

$$[2]\quad \alpha_{corr} = \frac{\alpha_{app} - Z_r(\partial\phi_r/\partial E)_\mu}{1 - (\partial\phi_r/\partial E)_\mu}$$

In the GCSF approach ϕ_r is assumed to equal the potential drop across the diffuse layer as calculated from the Gouy–Chapman–Stern (GCS) theory (ref. 1*b*, Chapt. 3), ϕ_d^{GCS}, and $\gamma_r/\gamma_\pm = 1$. Values of ϕ_d^{GCS} and $(\partial\phi_d^{GCS}/\partial E)_\mu$ were obtained for each electrolyte at the required electrode potential by reading off the corresponding values of the excess electrode charge density q^m and the electrode capacitance $(\partial q^m/\partial E)_\mu$ from the appropriate q^m–E plots, and then employing the GCS theory assuming that cation specific adsorption is absent (*vide infra*). These plots for the corresponding 0.1 *M* salts were extracted directly from Grahame's published data for the corresponding 0.1 *M* chloride electrolytes (24). The q^m–E plots for electrolytes at other ionic strengths were obtained by assuming that the displacement of E at each q^m is given by the difference in ϕ_d^{GCS} between 0.1 *M* and the desired salt concentration.

The resulting values of log k_{corr}^{GCS} and α_{corr}^{GCS} determined in this manner for $E = -900$ mV vs. sce are also given in Table 1. It is seen that there is a considerable variation in log k_{corr}^{GCS} as well as in log k_{app}^{GCS} with the nature of the supporting electrolyte cation; indeed the diffuse-layer correction acts to magnify the rate differences within each series of electrolytes containing cations of the same charge and concentration.

Since qualitative changes in the supporting elec-

trolytes are involved, it is possible that part of the observed rate variations arises from changes in the bulk activity coefficients of the reactants and/or liquid junction potentials. These possibilities can be checked by measuring the formal potentials E_f for the reactant redox couples in the various electrolytes. However, it is extremely difficult to determine E_f for the $Cr(OH_2)_6^{3+/2+}$ couple to the desired accuracy (±2 mV) in view of its extremely small standard rate constants in these media (ca. 1×10^{-5} cm s^{-1}); also values of E_f for $Cr(NH_3)_6^{3+/2+}$ cannot be measured due to the kinetic and thermodynamic instability of $Cr(NH_3)_6^{2+}$. Instead, values of E_f in each electrolyte were obtained for $Fe(OH_2)_6^{3+/2+}$ and $Ru(NH_3)_6^{3+/2+}$. Since these couples have the same charge and ligand composition and are of similar size to $Cr(OH_2)_6^{3+/2+}$ and $Cr(NH_3)_6^{3+/2+}$, respectively, it is likely that the observed variations in E_f for the former couples will mimic those for the latter systems. Table 2 contains a summary of the observed formal potentials. It is seen that only small variations in E_f (ca. $\lesssim$ 5 mV) were obtained for $Fe(OH_2)_6^{3+/2+}$ in the various perchlorate electrolytes, even between electrolytes with cations of different charges. Larger variations in E_f (up to 20 mV) were seen for $Ru(NH_3)_6^{3+/2+}$. In particular, the values of E_f in the heavier alkali nitrate media are significantly more negative than those in the perchlorate electrolytes.

[a]Electrolytes contained 10 m*M* $HClO_4$ to suppress hydrolysis of $Fe(OH_2)_6^{3+}$; 1–2 m*M* of Cl^- was also added to enhance electrochemical reversibility of $Fe(OH_2)_6^{3+/2+}$.

[b]Obtained using cyclic voltammetry from mean of forward (cathodic-going) and backward (anodic-going) peak potentials (11). Solutions contained 1 m*M* of either $Fe(OH_2)_6^{3+}$ or $Ru(NH_3)_6^{3+}$. Electrodes used were a platinum flag for $Fe(OH_2)_6^{3+/2+}$ and a hanging mercury drop for $Ru(NH_3)_6^{3+/2+}$. Experimental reproducibility of E_f is ca. ±1–2 mV in each case.

Discussion

The variations in k_{app} and k_{corr}^{GCS} for $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$ reduction summarized in Table 1 are qualitatively similar to those seen previously with a more limited range of supporting electrolyte cations for the reduction of protons (25, 26) and several other cations (2) in that rate decreases are seen with increasing cation atomic number. On the basis of eq. [1], these rate variations seem most likely to be due to alterations in ϕ_r caused by either (*i*) changes in the extent of cation specific adsorption, and/or (*ii*) changes in the position of the oHp as the supporting electrolyte cation is varied.

When analyzing electrode kinetic data for the effects of specific adsorption (model (*i*)) it has become conventional to monitor the change in the measured rate constant k_{app} at a given electrode potential, $(\Delta \log k_{app})_E$, and to compare the resulting variations in ϕ_r, $(\Delta\phi_r)_E$, obtained using eq. [1] with the corresponding estimates obtained from double-layer compositional data using the GCS model or other approaches (e.g. refs. 5, 8, 28). However, for the present purposes involving the comparison of both models (*i*) and (*ii*) with the kinetic data it is more convenient to monitor instead the change in k_{app} in response to an alteration in electrolyte composition at a *constant electrode charge density* q^m, $(\Delta \log k_{app})_{q^m}$. This quantity is related to the corresponding change in ϕ_r, $(\Delta\phi_r)_{q^m}$, by

$$[3] \quad (\Delta \log k_{app})_{q^m} = \Delta \log (\gamma_r/\gamma_\pm) - \frac{F}{2.303RT} \times [(Z_r - \alpha_{corr})(\Delta\phi_r)_{q^m} + \alpha_{corr}(\Delta E)_{q^m}]$$

where $(\Delta E)_{q^m}$ is the difference in the electrode potential between the two supporting electrolytes at the same value of q^m, and $\Delta\log(\gamma_r/\gamma_\pm)$ is the corresponding change in the activity coefficients. The values of $(\Delta E)_{q^m}$ were read from the appropriate q^m–E plots obtained from ref. 24. The virtue of computing estimates of $(\Delta\phi_r)_{q^m}$ rather than $(\Delta\phi_r)_E$ is that the diffuse-layer potential will very likely remain constant at constant q^m for a series of electrolytes containing different cations of equal charge and concentration, providing that cation specific adsorption is negligible. The comparison of $(\Delta\phi_r)_{q^m}$ for a series of such electrolytes with the corresponding changes in the potential drop across the entire metal–solution interface $(\Delta E)_{q^m}$ therefore provides an incisive way of comparing the kinetic data with the predictions of model (*ii*).

Table 3 contains a summary of the values of $(\Delta\phi_r)_{q^m}$ for $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$, labeled

[d] Change in average potential on reaction plane for $Cr(NH_3)_6^{3+}$ reduction at $q^m = -8$ or $-10\,\mu C\,cm^{-2}$, as noted, for listed eleetrolyte relative to "parent" electrolytes given in *b*. Obtained from kinetic data in Table 1 using eq. [3], as outlined in text.

$(\Delta\phi_r)_{q^m}{}^{OH_2}$ and $(\Delta\phi_r)_{q^m}{}^{NH_3}$, respectively, which result from the rate data given in Table 1 using eq. [3], assuming that $\alpha_{corr} = 0.5$ (5, 17, 22) and that $\Delta\log \gamma_r/\gamma_{\pm} = 0$ (8).[3] For the alkali metal series 0.5 *M* MNO_3 and 0.5 *M* $MClO_4$, the values of $(\Delta\phi_r)_{q^m}$ were calculated with respect to 0.5 *M* $LiNO_3$ and 0.5 *M* $LiClO_4$, respectively. Values of $(\Delta\phi_r)_{q^m}$ for the divalent and trivalent electrolytes were referred to 0.1 *M* $Mg(ClO_4)_2$ as the parent system. The corresponding values of $(\Delta E)_{q^m}$ are also listed in Table 3. Values of $(\Delta\phi_r)_{q^m}$ and $(\Delta E)_{q^m}$ are given for each system for the electrode charge densities $q^m = -8$ and $-10\,\mu C\,cm^{-2}$.

Inspection of Table 3 reveals that the corresponding values of $(\Delta\phi_r)_{q^m}{}^{OH_2}$ and $(\Delta\phi_r)_{q^m}{}^{NH_3}$ for most electrolytes are similar, although there is a tendency for $(\Delta\phi_r)_{q^m}{}^{NH_3}$ to be slightly (~10–20%) larger.[3] This similarity in the rate responses for the aquo and ammine reactants at constant electrode charge density is also seen at constant potential (Table 1) in that the differences in $\log k_{app}$ between the various electrolytes at -900 mV vs. sce, $\Delta\log k_{app}$, for the two reactants are often within 10–20% of each other. These results contrast those from our previous comparison of double-layer effects upon the reduction kinetics of Cr(III) ammine and aquo complexes (5). It was found that the corresponding values of $(\Delta\log k_{app})_E$ and hence $(\Delta\phi_r/\Delta q')_E$ resulting from the specific adsorption of a given charge density q' of anions at a constant ionic strength were both *three- to fourfold larger* for $Cr(NH_3)_6^{3+}$ compared with $Cr(OH_2)_6^{3+}$ reduction (5). Using the analysis at constant charge (eq. [3]), it is simple to show that the values of $(\Delta\phi_r)_{q^m}{}^{NH_3}$ are also about three- to fourfold larger than the corresponding values of $(\Delta\phi_r)_{q^m}{}^{OH_2}$ under these conditions. As noted above, these behavioral differences were traced to the ability of the more weakly hydrated $Cr(NH_3)_6^{3+}$ reactant to approach the surface more closely than $Cr(OH_2)_6^{3+}$, so that the former reactant will experience a greater fraction of the changes in the potential at the inner Helmholtz plane (iHp) induced by anion specific adsorption (5). Similarly, larger values of $(\Delta\phi_r/\Delta q^m)_\mu$ induced by changes in electrode potential in the absence of specific ionic adsorption were also seen for $Cr(NH_3)_6^{3+}$ compared to $Cr(OH_2)_6^{3+}$ reduction (5). For a given reaction in a given base electrolyte, the values of $(\Delta\phi_r/\Delta q^m)_\mu$ and $(\Delta\phi_r/q')_E$ were found to be consistently similar (5); this simple result was

[3] The likely negative shift in E_f for the ammine couple within the electrolyte series 0.5 *M* $LiNO_3 \rightarrow CsNO_3$ from the data in Table 2 suggests that $\Delta\log(\gamma_r/\gamma_{\pm})$ is negative; this would tend to make the actual values of $(\Delta\phi_r)_{q^m}$ for $Cr(NH_3)_6^{3+}$ reduction smaller for these electrolytes than the values listed in Table 3. Although the magnitude of this correction is difficult to estimate quantitatively, since $\Delta E_f = (2.303RT/F)\log(\gamma_r/\gamma_P)$, where γ_P is the coefficient of the bulk product, then if $\gamma_r/\gamma_{\pm} \sim 0.5$ (γ_r/γ_P) it follows that the actual values of $(\Delta\phi_r)_{q^m}$ for $Cr(NH_3)_6^{3+}$ reduction are smaller by up to 5 mV than the listed values; i.e., closer to or smaller than the corresponding values of $(\Delta\phi_r)_{q^m}$ for $Cr(OH_2)_6^{3+}$ reduction.

also seen for the outer-sphere electroreduction of various Co(III) ammines (6).

It would therefore be expected that if the observed cation effects upon the reduction kinetics of $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$ were due predominantly to cation specific adsorption (model (*i*)), markedly larger rate decreases should be obtained for the latter reaction, either at constant electrode potential or charge, as the extent of cation specific adsorption increases. This point is illustrated in Fig. 1*a*, which consists of a pair of schematic plots of the average potential ϕ against distance x from the electrode surface D. Curve I is such a profile as would be expected at negative electrode charges in the absence of specific cation adsorption. It contains three regions: the diffuse layer AB bounded by the oHp which is the plane of closest approach of the supporting electrolyte cations; the region BC between the oHp and the monolayer of water molecules adjacent to the electrode; these form the "primary inner layer" CD. (Although the shape of this profile is undoubtedly oversimplified, the use of more complicated double-layer models does not alter the qualitative treatment considered here.) Curve II is a corresponding potential profile at the same electrode charge resulting from significant cation specific adsorption at the site C′. Inspection of Fig. 1*a* shows that the vertical displacement $\Delta\phi$ between curves I and II increases with decreasing x for $x >$ C′D. Thus the values of $(\Delta\phi_r)_{q^m}$ for ammine reactants are expected to be noticeably larger than those for aquo reactants if the latter indeed react farther from the electrode surface. This prediction is in direct contrast to the experimental observations (Table 3).

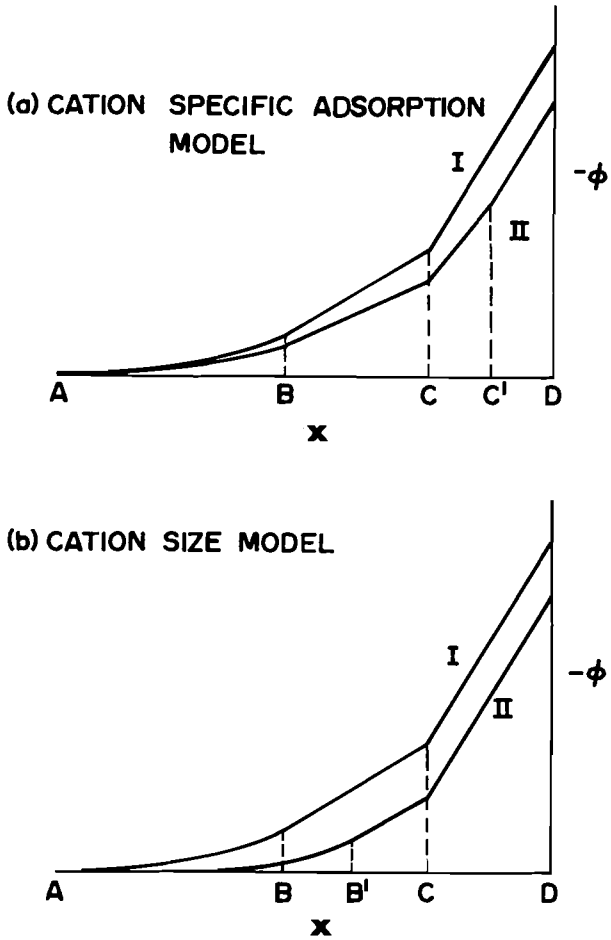

FIG. 1. Effect of varying supporting electrolyte cation at constant electrode charge density upon schematic potential profile within double layer.

Figure 1*b* consists of a corresponding pair of ϕ–x plots at a fixed electrode charge for two supporting electrolytes differing only in the effective cation size, specific adsorption being absent in both cases (i.e., model (*ii*)). The substitution of the smaller for the larger cation results in a shift of the oHp from B to B′. Providing that the inner-layer water structure is unaffected by this change, the smaller cation will yield a ϕ–x profile (curve II) which parallels that for the larger cation (curve I) but displaced vertically by an amount $(\Delta\phi)_{q^m}$ which is *independent* of x for $x <$ B′. Such a model is therefore able to account for the observation that $(\Delta\phi_r)_{q^m}$ for $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$ reduction are similar, provided that the reaction planes for these processes are inside, or within the vicinity, of the oHp for the various electrolytes scrutinized.

Estimates of the positions of these reaction planes with respect to the oHp can be obtained from a consideration of the relative hydrated radii of the transition state species and the supporting electrolyte cations. To a first approximation it might be expected that the distance between the oHp and the primary inner layer (BC in Fig. 1) would equal the effective hydrated radius of the supporting electrolyte cation (15, 27). Some direct evidence supporting this notion has been obtained from estimates of the thickness of the cation-free region derived from electrocapillary measurements (14, 29). Table 4 lists values of hydrated radii for the cations of interest here according to two commonly used scales: those from the compilation of Monk (r_h) derived from ionic molar volume data (30), and the "Stokes radii" (r_s) obtained from ion transport data. Table 4 also contains estimates of r_h and r_s for the two transition state species ($Cr(OH_2)_6^{2.5+}$ and $Cr(NH_3)_6^{2.5+}$) that will presumably determine the effective plane of closest approach and hence ϕ_r for the reduction of $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$, re-

[a]Hydrated radii estimated by Monk (30) from ionic molar volume data.
[b]Hydrated ("Stokes") radii quoted by Monk (30) unless otherwise indicated; estimated from equivalent conductance, diffusion coefficient, and solvent viscosity using Stokes–Einstein relations.
[c]Estimates of r_h and r_s for transition states for the outer-sphere one-electron reduction of $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$; obtained by taking an average of the estimated hydrated radii for the oxidized (Cr^{III}) and reduced (Cr^{II}) species (see text).
[d]From ref. 31.
[e]From ref. 32.
[f]Obtained from average of estimated crystallographic radii of $Cr(NH_3)_6^{3+}$ and $Cr(NH_3)_6^{2+}$.

spectively.[4] These were obtained from the average of the corresponding estimates of r_h and r_s for the reactant and product species. On the basis of the relative values of both r_h and r_s for the transition states versus those for the supporting electrolyte cations, the transition state for $Cr(NH_3)_6^{3+}$ reduction is expected to be situated within the oHp except when this is formed by univalent cations, whereas that for $Cr(OH_2)_6^{3+}$ reduction is anticipated to lie outside the oHp except when this consists of trivalent cations. On the basis of Fig. 1*b*, it is therefore somewhat surprising that the values of $(\Delta\phi_r)_{q^m}^{OH_2}$ tend to approach those for $(\Delta\phi_r)_{q^m}^{NH_3}$ even for pairs of univalent electrolytes (Table 3). The simplest explanation is that the fields in the diffuse layer close to the oHp are comparable to those within the "secondary inner layer" BC (Fig. 1*b*), so that $(\Delta\phi_r)_{q^m}$ will remain independent of x even for $x > B'D$.

The simple cation size model embodied in Fig. 1*b* also predicts that $(\Delta\phi_r)_{q^m}$ will equal $(\Delta E)_{q^m}$ for $x < B'D$, whereas it is seen in Table 3 that $(\Delta\phi_r)_{q^m}^{OH_2}$ and $(\Delta\phi_r)_{q^m}^{NH_3}$ are both typically a factor of two or so smaller than $(\Delta E)_{q^m}$. Two explanations can most readily account for this discrepancy. Firstly, ϕ_r appearing in eqs. [1]–[3] is really the micropotential at the reaction site which may differ from the average (macro-) potential on the reaction plane ϕ_{rp} due to discreteness-of-charge effects (3), whereas $(\Delta E)_{q^m}$ is a difference between average potentials. Secondly, the assumption that the potential profile inside the oHp (the region BD) is unaffected by the substitution of different cations at the oHp at constant q^m may be a serious oversimplification in that the water structure and hence the potential profile of the inner-layer, in particular the region BC, may well be influenced significantly by the nature of these cations.

In addition to analyzing the cation dependence of k_{app}, it is also instructive to examine the corresponding influences upon the transfer coefficients. As expected from the cation size model, both α_{app} and α_{corr}^{GCS} tend to decrease for cations of decreasing hydrated radius, these variations being similar for $Cr(OH_2)_6^{3+}$ and $Cr(NH_3)_6^{3+}$ reduction (Table 1). This is also seen in Fig. 2, which contains plots of α_{corr}^{GCS} for $Cr(OH_2)_6^{3+}$ (open symbols) and $Cr(NH_3)_6^{3+}$ reduction (closed symbols) at −900 mV vs. sce (Table 1) in each supporting electrolyte against the hydrated cation radii r_h (Table 4). The interesting feature of this figure is that although the slopes of the two plots are similar, the values of α_{corr}^{GCS} for $Cr(NH_3)_6^{3+}$ reduction at a given value of r_h are displaced by almost 0.2 above those for $Cr(OH_2)_6^{3+}$ reduction. If the only factor aside from the diffuse-layer influencing ϕ_r and hence $(\partial\phi_r/\partial E)_\mu$ is the position of the reaction plane relative to the oHp, then equal values of α_{corr}^{GCS} for the two reactions should be obtained for equal values of $r_h - r_\neq$, where $r_\neq$ is the hydrated radius of the transition state species. In particular, α_{corr}^{GCS} should equal the "true" value of α_{corr} (i.e., the "intrinsic" transfer coefficient α_I (33), normally taken as 0.5) when $r_h = r_\neq$. However, this expectation is not entirely borne out by the data in Fig. 2. Thus using the estimates of $r_\neq$ given in Table 4, the value of α_{corr}^{GCS} found from Fig. 3 for $r_h = r_\neq$ equals about 0.55 for $Cr(OH_2)_6^{3+}$ reduction but about 0.7 for $Cr(NH_3)_6^{3+}$ reduction. Similar results are obtained using Stokes radii r_s in place of r_h. Although it is possible that the GCS model may yield incorrect estimates of the diffuse-layer effect upon α_{app}, this is unlikely to account for

[4]According to the conventional theoretical treatment of outer-sphere (weak adiabatic) electron transfer processes, each transition state for these simple symmetrical one-electron reactions will have a structure, including that of the surrounding solvent and ionic atmosphere, appropriate to that for a hypothetical ground-state cation with the same ligand composition yet having a charge midway between that for the reactant and the product. (For example, see ref. 39.) The plane of closest approach and hence the values of ϕ_r will therefore be determined by the transition state rather than the ground state reactant structure.

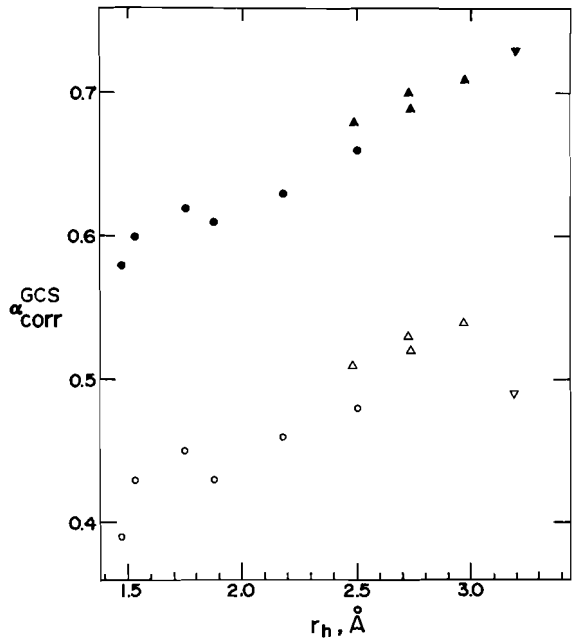

FIG. 2. Plot of the diffuse-layer corrected transfer coefficient α_{corr}^{GCS} at −900 mV vs. sce for $Cr(OH_2)_6^{3+}$ reduction (open symbols) and $Cr(NH_3)_6^{3+}$ reduction (closed symbols) (Table 1) in various electrolytes against the hydrated radius r_h of the supporting electrolyte cation (Table 4). Circles, univalent cations; upright triangles, divalent cations; inverted triangles, trivalent cations.

the unexpected large differences in α_{app} and α_{corr}^{GCS} between the two reactions. Also, the fact that the values of α_{corr}^{GCS} for a given reaction in electrolytes with uni-, di-, and trivalent cations all fall roughly on a common line (Fig. 2) indicates that the GCS model provides a consistent diffuse-layer correction. Some of the observed deficiencies of the GCSF model that were previously attributed to failures of GCS theory (17, 21) could well be due instead to a noncoincidence of the reaction plane and the oHp.

Three possibilities seem most likely to account for the unexpectedly large values of α_{corr}^{GCS} for $Cr(NH_3)_6^{3+}$ reduction. Firstly, α_1 for this reaction could be significantly larger than 0.5 as a result of the higher force constants expected for the reactant Cr^{III}—NH_3 bonds compared with the product Cr^{II}—NH_3 bonds. (This effect is likely to be smaller for the $Cr(OH_2)_6^{3+/2+}$ couple in view of the lower ligand field strength of OH_2 versus NH_3 ligands.) However, model calculations (34, 35) indicate that α_1 for such systems is likely to lie in the range ca. 0.45–0.55 at the small to moderate cathodic overpotentials considered here (22). Secondly, the reaction plane for $Cr(NH_3)_6^{3+}$ reduction may lie closer to the electrode than expected on the basis of the estimates of cation size given in Table 4; from Fig. 2 the reaction plane is estimated to lie about 1.5 Å closer than anticipated. Such a breakdown of the simple model may arise from a partial penetration of the primary inner layer of water molecules by the ammine ligands. Thirdly, for such reaction sites close to the electrode it is quite likely that discreteness-of-charge effects will be significant, in particular the "self-image" potential generated by the interaction of the reacting ion with its image in the electrode (36). Although the magnitude of this influence upon α_{corr} is uncertain, it is likely that the self-image effect would act to increase α_{corr} for cation reduction in the potential range of interest here (5, 36), and more so for an ion reacting closer to the electrode (37), in accordance with the present observations. A similar self-image effect was also invoked recently to explain the unexpectedly large rate constants seen for heterogeneous outer-sphere electron transfer reactions involving ammine versus aquo complexes in comparison with the rate constants for the corresponding homogeneous reactions (38).

Nevertheless, the simple average potential approach embodied in eqs. [1]–[3] is able to account at least semiquantitatively for the observed cation effects upon the electrode kinetics of these archetypically simple outer-sphere reactions, once the noncoincidence of the reaction plane with the oHp is taken into account using a simple cation size model. It seems that at least part of the disparate and frequently larger cation effects seen upon the electroreduction kinetics of various anions (1, 2, 16) arises from specific reactant–cation interactions at the reaction site (2) in addition to the average potential effects seen with the present cationic reactants. Although it is quite likely that cation specific adsorption is significant and even substantial at large negative electrode charges for weakly solvated cations such as cesium, the present results support the point of view (15) that such adsorption is minor at moderate electrode charges ($-q^m \lesssim 10\ \mu C\,cm^{-2}$). However, it is important to note that even the conceptual distinction between specific ion effects due to specific adsorption and variations in the planes of closest approach becomes clouded when the center of the adsorbed charge (iHp) lies outside the primary inner layer, as expected for large adsorbates or if the primary hydration sheath remains intact upon adsorption. Thus the discrimination between these two alternatives may ultimately prove to be illusory in some cases.

The effect of roughness on the wettability of an axisymmetric cylinder is investigated theoretically by making use of equilibrium meniscus shapes on solid surfaces analogously to previous studies for drops on horizontal surfaces. Employing circumferential sinusoidal and saw-toothed grooved structure, and using mechanistic arguments, one can explain wetting hysteresis, the formation of composite surfaces, and the presence of non-equilibrium jumps during contact line motion.

On unidirectionally random surfaces the maximum surface slopes mainly determine the value of the advancing, and the minimum slopes of the receding contact angle. These effects of surface slopes diminish with decreasing roughness size. Diminishing roughness size also gives rise to numerous small non-equilibrium jumps imposed upon larger jumps during wetting. The contact angle hysteresis is found to show a nearly linear relationship with the spread in the distribution of solid surface slopes.

ERDAL BAYRAMLI, THEODORE G. M. VAN DE VEN et STANLEY G. MASON. Can. J. Chem. **59**, 1954 (1981).

Comme on l'a fait d'une façon analogue lors d'études antérieures relatives à des chutes sur des surfaces horizontales, on a effectué une étude théorique de l'effet de la rugosité sur les propriétés de mouillage d'un cylindre de symétrie axiale qui est basé sur l'équilibre des formes du ménisque sur les surfaces solides. On peut expliquer l'hystérésis de mouillage, la formation de surfaces composites et la présence d'un saut non équilibré pendant le mouvement de la ligne de contact en faisant appel à des arguments mécanistiques et à des structures sinusoidales circonférentielles et à gorge en dents de scie.

Sur des surfaces unidirectionnelles, distribuées au hasard, ce sont principalement les pentes maximales des surfaces qui déterminent la valeur et l'angle de contact de l'avance et les pentes minimales de l'angle de contact de recul. Ces effets des pentes de surface diminuent avec la taille de la rugosité. La diminution de la taille de la rugosité donne également lieu à plusieurs petits sauts non équilibrés superposés à de plus grands sauts durant le mouillage. On a trouvé que l'angle de contact d'hystérésis présente une relation presque linéaire avec l'étalement dans la distribution des pentes de surface du solide.

Introduction

The effect of regular surface roughness on the wetting of solid surfaces was recently investigated experimentally by Oliver, Huh, and Mason (1) by a method in which liquid drops were formed in a well defined manner on horizontal solid surfaces. In general, their results were in agreement with a theory developed by Huh and Mason (2) according to which the wetting hysteresis due to roughness depends strongly on the geometrical nature of the roughness. Whereas results obtained on wetting of mathematically well-defined surfaces may not be directly applicable to real surfaces, nevertheless the simple models used in these studies revealed information which is not easy to obtain from theoretical or experimental investigations of complex surface morphologies.

In this study we extend the theoretical work on horizontal solid surfaces to vertical axisymmetric cylindrical solid surfaces penetrating a liquid interface which exhibit fewer mathematical difficulties than drops on a horizontal surface. Also, experimentally such surfaces can be investigated to a higher degree of accuracy and detail with a tensiometric technique called capillarography (3) where the formation of the meniscus on the solid surface is controlled with precision. Use is made of this tensiometric technique in experiments designed to test the present theory, which will be discussed in the following paper (4). Also, the wetting of such surfaces is basic to problems of wetting of fibrous structures.

In Section A we consider the general characteristics of wetting of cylindrical axisymmetric solid bodies which will be followed by studies of specific surface geometries.

The work of Oliver, Huh, and Mason (5) and Bayramli and Mason (6) has shown the importance of sharp edges in wetting. In Sections B and C the effects of circumferential saw-tooth shaped and of circumferential sinusoidal grooves are studied. The multiplicity of equilibrium states for the liquid meniscus, contact angle hysteresis, conditions for the formation of composite surfaces, and the mechanism of the non-equilibrium jumps between equilibrium states and its dependence on groove wavelength are investigated.

As an example of a surface which represents a more realistic surface more closely, we studied the wetting of an axisymmetric rod which has a random

distribution of roughness along its axis of symmetry. This is done in Section D where we investigate the wetting of a cylinder surface which has unidirectionally random roughness. We show the influence of roughness dimensions and solid surface slope distribution in observed contact angles and non-equilibrium jumps for a moving contact line.

Axisymmetric Roughness

A. General

Huh and Scriven (7) have studied liquid meniscus shapes around vertical cylindrical rods by numerically solving the Young–Laplace equation with specific boundary conditions, presenting the solutions in extensive numerical tables. In their analysis the angle of inclination of the liquid–fluid interface, ϕ, is employed as the main parameter.

When the cylinder radius, r_0, or the density difference between the phases 1 and 2, $\Delta\rho$, is small, or the interfacial tension σ_{12} very large, the approximate solution of James (8) can be used to calculate the meniscus shape without any significant error (a similar derivation was also made by Deryaguin (9)). The maximum height z_c (Fig. 1*a*) of the meniscus on the cylinder surface is, in this case, given by

$$[1] \quad \frac{z_c}{r_0} = \cos\theta \left[\ln\left\{ \frac{4}{ar_0}(1 + \sin\theta) \right\} - \gamma \right]$$

where θ is the apparent contact angle with $\phi = \theta$ at $r = r_0$; $\gamma = 0.57721$ is Euler's constant, $a = [g\Delta\rho/\sigma_{12}]^{1/2}$, and g the gravitational constant.

The experimentally measurable vertical capillary force is given by

$$[2] \quad F^* = 2\pi r_0 \sigma_{12} \cos\theta - F_B$$

where F_B is the buoyancy force. We define a dimensionless parameter F as

$$[3] \quad F = \frac{F^* + F_B}{2\pi r_0 \sigma_{12}} = \cos\theta$$

The buoyancy force is easily calculated for smooth cylindrical rods, but for a more general axisymmetric geometry a certain amount of care is required. Figure 1*b* shows a vertical axisymmetric solid body partially submerged at a liquid–fluid interface. Here F_B is equal to the pressure integral over the solid–liquid interface, S_1.

$$[4a] \quad F_B = -\int_{S_1} p\,dS$$

$$[4b] \quad F_B = -\int_{S_1+S_2} p\,dS + \int_{S_2} p\,dS$$

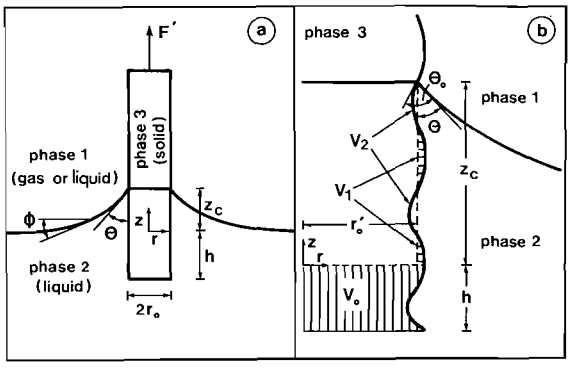

FIG. 1. (*a*) Diagram of a solid cylinder at a liquid-fluid interface. (*b*) Schematic geometry of a meniscus on a cylinder whose surface topography is given by a general function $f(r_0, z)$. V_1 is the portion of the rod volume where $r_0 > r_0'$ and V_2 shows the liquid volume where $r_0 < r_0'$ between $0 < z < z_c$, V_0 designates the solid volume below $z = 0$.

where S_2 is the cross sectional area of the rod at $z = z_c$. Using the divergence theorem, [4*b*] can be written as:

$$[4c] \quad F_B = -\int_V \nabla p\,dV + \int_{S_2} p\,dS$$

where V is the volume of the solid body submerged in phase 2. The pressure at z is

$$[5] \quad p = -\Delta\rho g z$$

Performing the integrations in [4*c*], using [5], yields

$$[6] \quad F_B = \Delta\rho g(V_0 + V_1 - V_2)$$

The volumes V_0, V_1, and V_2 are shown in Fig. 1*b* where r_0' is the distance of the contact line position from the fiber center. It is seen that for the calculation of the buoyancy factor, the portion of the solid volume V_1 where $r_0 > r_0'$ and $0 < z < z_c$ must be added and the liquid volume V_2 where $r_0 < r_0'$ and $0 < z < z_c$ must be subtracted from the solid volume V_0 below the hydrostatic zero level ($z = 0$). V_0, V_1, and V_2 are to be calculated from the explicit expression, $f(r_0, z)$, of a given solid surface geometry.

B. Concentric Saw-toothed Grooves

For a geometry of parallel circumferential grooves of triangular cross-section with angles θ_1, θ_2, θ_3 and minimum cylinder radius r_0^* (Fig. 2, inset), the cylinder radius r_0 located at the 1–2 interface depends on the inclination of the grooves and is given by

$$[7a] \quad r_0 = r_0^* + \frac{1}{g_0}[\varepsilon l(z_c - h - nl)] \quad \text{if } (z_c - h - nl) \leq g_0$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

$$[7b] \quad r_0 = r_0^* + \frac{1}{(l - g_0)}[\varepsilon l\{(n+1)l - (z_c - h)\}] \quad \text{if } (z_c - h - nl) > g_0$$

where

$$[7c] \quad g_0 = \varepsilon l/\tan\theta_2$$

Here $(z_c - h)$ is the length of the grooved surface submerged in phase 2, l and εl are the wavelength and the height of grooves respectively and n is an integer denoting the number of complete grooves below the contact line at $z = z_c$.

The macroscopically observed contact angle θ is given by

$$[8] \quad \theta = \theta_0 - \tan^{-1}(dr_0/dz)$$

where θ_0 is the intrinsic contact angle; from simple geometry we have $\theta = \theta_0 - \theta_2$ for the case [7*a*] and $\theta = \theta_0 + \theta_1$ for [7*b*].

A surface such as the one described above has a multiplicity of equilibrium states at a constant immersion depth, h, of the cylinder. We now investigate the wetting of a given geometry in more detail; as an example we choose $\theta_1 = \theta_2 = 30°$, $r_0^* = 0.025$ cm, $l = 0.1r_0$, and $ar_0^* = 0.1$. Figure 2 shows the permissible apparent contact angles on the cylinder surface for $\theta_0 = 40°$. For $h = 0$ many equilibrium sites exist on the grooved surface, indicated by the numerous intersections of $z_c(\theta)$ with the permissible contact line locations. In this calculation the meniscus height z_c was calculated using James' approximation [1] and [8]. As h is increased or decreased gradually, it is possible to construct a wetting hysteresis loop, due to the grooves as shown

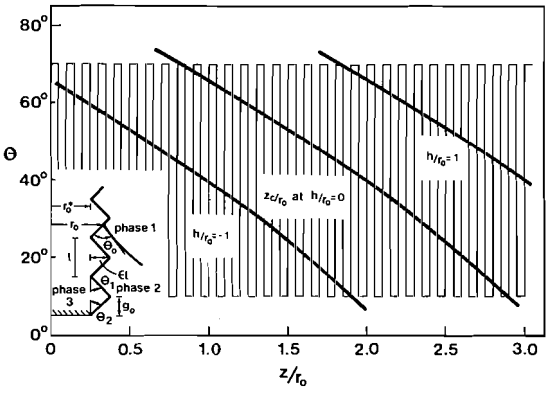

FIG. 2. The possible apparent contact angles on a saw-toothed cylinder surface with $r_0^* = 0.025$ cm, $l/r_0^* = 0.1$, $\theta_0 = 40°$, $\theta_1 = \theta_2 = 30°$, and $ar_0 = 0.1$. The continuous lines show the meniscus height on the cylinder as a function of θ at constant h. The numerous intersections are the available equilibrium positions for the contact line. Inset shows the surface geometry of the cylinder.

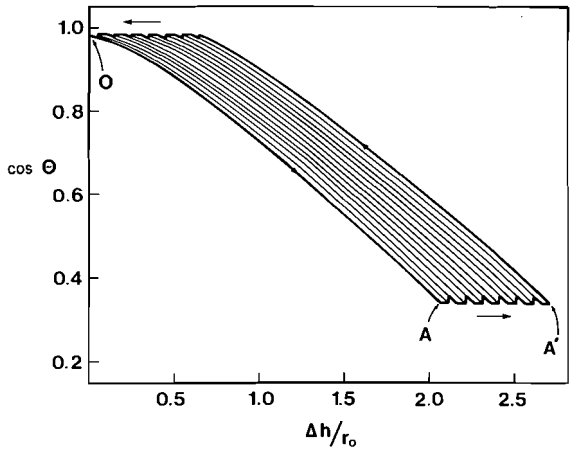

FIG. 3. cos θ as a function of displacement $(\Delta h/r_0)$ for system in Fig. 2. The bold line indicates the path followed by an advancing and receding contact line on the grooved surface.

in Fig. 3. The bold lines in Fig. 3 are for the path followed by an advancing and receding meniscus assuming the contact line jumps to the nearest equilibrium position. First, starting at O, the contact line hinges at a single groove as the contact angle changes from a receding to an advancing one until reaching A; it must then make non-equilibrium jumps from one stable position to another as Δh continuously increases. When the motion of the contact line is reversed at A', the advancing contact angle decreases until $\theta = 10°$ while hinging at a single groove, and then moves in a stick-jump fashion when Δh is decreased further. The difference in h values, Δh, is defined here as being positive in the $-z$ direction measured from an arbitrary reference height h_0. This result is analogous to the Haines' jumps across radial grooves considered by Huh and Mason (2).

The geometric constraints of a saw-toothed concentric groove exclude certain parts of the surface to an advancing or receding meniscus causing the formation of composite surfaces. For a receding contact line a composite surface in which liquid pockets are left behind is formed when $\theta_0 < (\theta_1 + \theta_2)$. For an advancing meniscus pockets of phase 1 are left behind the contact line when $\theta_0 > 2\pi - (\theta_1 + \theta_2)$. Therefore the condition of preventing the formation of a composite surface during a hysteresis loop is $(2\pi - (\theta_1 + \theta_2)) > \theta_0 > (\theta_1 + \theta_2)$. The schematic diagrams in Fig. 4 show the formation of composite surfaces during advancing and receding contact line motion.

A closer investigation of non-equilibrium jumps of the contact line shows that three possibilities exist: (*i*) the contact line jumps from O to O' (Fig.

For personal use only.

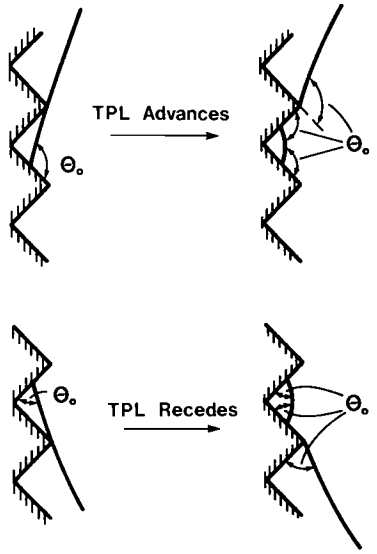

FIG. 4. Schematic diagram showing the formation of composite surfaces during advancing and receding of the three phase contact line (TPL). While advancing pockets of phase 1, and while receding of phase 2 are left behind a moving TPL.

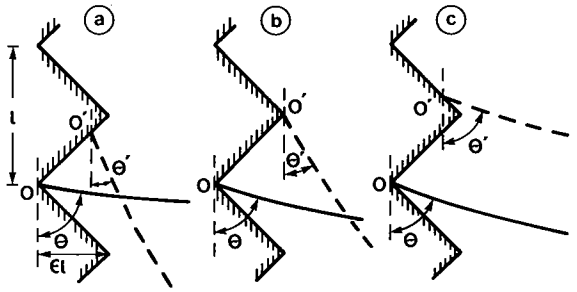

FIG. 5. Schematic diagram showing the three possible cases of non-equilibrium jumps of an advancing contact line on a cylinder surface with parallel circumferential saw-toothed shaped grooves.

5*a*) which may occur if $\varepsilon l \ll l$ or $l \simeq O(r_0)$; here $\theta > \theta'$; (*ii*) it may jump from one valley to the peak of the next groove when $\varepsilon l \simeq O(l)$ with $\theta > \theta'$ (Fig. 5*b*); (*iii*) a jump from a valley over a peak onto the next groove surface ($\theta = \theta'$), since it is possible that no equilibrium position at the sharp edge of the groove exists (Fig. 5*c*).

C. Sinusoidal Grooves

The surface shape of circumferential sinusoidal grooves on a cylinder surface is given by

$$[9] \quad r_0 = r_0^* + \varepsilon l \sin(2\pi z/l)$$

where l and εl are the wavelength and the amplitude of the grooves respectively and r_0^* is defined as the median position of the grooves (Fig. 6, inset). The slope angle of the surface is given by

$$[10] \quad \phi_0 = \tan^{-1}[2\pi\varepsilon \cos(2\pi z/l)]$$

from which the apparent contact angle θ ($\equiv \theta_0 - \phi_0$) can be calculated.

As in the case of parallel saw-toothed grooves we have a multiplicity of equilibrium states for a given immersion depth of the cylinder into the liquid phase. For a system where $\theta_0 = 70°$, $\varepsilon = 0.2$, $l/r_0^* = 0.1$, $r_0^* = 0.025$ cm, and $ar_0^* = 0.1$ we obtain a hysteresis loop as shown in Fig. 6, in which we used James' approximation [1] and [8] to calculate the equilibrium mensicus height on the cylinder surface starting from O. As the cylinder is immersed into the phase 2, with Δh increasing continuously, the contact line moves slowly on a single groove till it reaches A. From A to A′ the contact line moves with regular jumps. For the receding contact line, which is obtained by gradually withdrawing the rod vertically from phase 2, the contact line will remain (i.e. sticks) on the same groove until it reaches A″ where it starts to make non-equilibrium jumps while receding.

The formation of composite surfaces due to the constraints arising from surface geometry is shown in Fig. 7. The shaded area shows the region in which no composite surface formation occurs. Above and below the shaded area there is always a composite formation during wetting of the solid surface.

D. Randomly Rough Surfaces with Axial Symmetry

Randomly rough surfaces without axial symmetry are difficult to treat mathematically, not only because the capillarity equations become very complicated to solve, but also because the exact location of the contact line is not known *a priori* (2). Here we investigate the more tractable problem of wetting of a surface with one-dimensional random roughness.

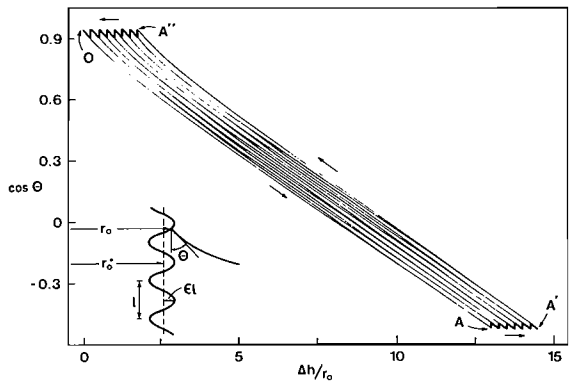

FIG. 6. cos θ vs. $\Delta h/r_0$ for sinusoidal circumferential grooves on a cylinder with $r_0^* = 0.025$ cm, $\varepsilon = 0.2$, $\theta_0 = 70°$, $l/r_0^* = 0.1$ and $ar_0 = 0.1$; starting from O a hysteresis loop is obtained by vertically immersing the cylinder into phase 2 from O to A′ and withdrawing from A′ to O.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

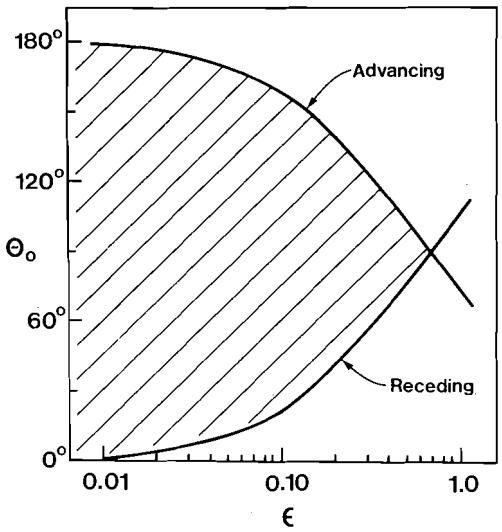

FIG. 7. The intrinsic contact angle θ_0 vs. ε; configurations below the advancing and above the receding line do not result in composite surface formation during advancing and receding contact line motions respectively and hence, in the shaded area no composite surface will be found during a hysteresis loop.

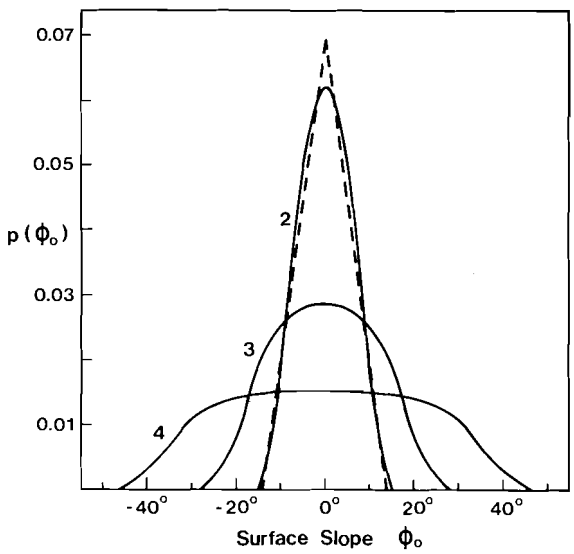

FIG. 8. Distribution of surface slopes for systems 2, 3, and 4 (Table 1). The dashed line shows the distribution for system 2 as calculated from ref. 11.

A unidirectional randomness on a cylinder surface is generated as follows: a uniformly distributed set of random points between r_0^* and $(r_0^* + \delta r_0^*)$ is generated by a computer subroutine at regular intervals Δz, along the z-axis with $0.01 \leq \delta \leq 0.1$ keeping δ constant for each surface generation. Here, δ can be defined as the roughness size. The set of points, $((r_{0i}, z_i), i = 1, 2, \ldots, n)$, is used to produce a surface numerically, making use of a cubic spline interpolation scheme. In each interval the surface is represented by a spline (a polynomial), the coefficients of which are chosen such that consecutive intervals are smoothly connected.

The slope of the generated surface is calculated analytically from the coefficients of the splines used in each interval. Details of the generated surfaces are summarized in Table 1 and Fig. 8, which shows the distribution of solid surface slopes ϕ_0 of systems 2, 3, and 4. Systems 1 and 5 have the same surface slope distribution as system 3 since $\delta/\Delta z$ is the same for systems 1, 3, and 5. Figure 8 is calculated by grouping ϕ_0 in 1° intervals and smoothing the final population distribution for a total of 1500 points for each curve.

Neglecting the smoothing, the probability distribution for the slopes can be readily determined from the set of points (r_{0i}, z_i) by connecting them with straight lines. In this case the probability, $p(\phi_0)d\phi_0$, of finding a slope between ϕ_0 and $\phi_0 + d\phi_0$ is given by

$$[11] \quad p(\phi_0) = \alpha(S - \tan|\phi_0|)$$

where $S = \delta/\Delta z$ and α is a normalization constant determined by

$$[12] \quad \int_{-\tan^{-1}S}^{\tan^{-1}S} \alpha(S - \tan|\phi_0|)d\phi_0 = 1$$

From eq. [12] we have

$$[13] \quad \alpha = [2S\tan^{-1}S - \ln(S^2 + 1)]^{-1}$$

Due to our method of generating surfaces by smoothly connecting the generated random points, a more gradual change of slopes occurs in the vicinity of $\phi_0 = 0$. Also, slopes with $\tan\phi_0 > S$ exist as indicated by the slight tail near $p(\phi_0) = 0$ (Fig. 8). In the limit $S \to 0$, the probability distribution of solid surface slopes will be given by [11]. Already, at $S = 1/4$, [11] is a close approximation of the numerically calculated $p(\phi_0)$ as shown by the dashed line in Fig. 8.

The autocorrelation function of the solid surface profiles indicated that the correlation length was approximately equal to Δz_i, and the Fourier transform of the autocorrelation function showed no dominant frequency, from which we can deduce that the surface profiles were unidirectionally random.

We now investigate the wetting behavior of our numerically generated surfaces. In the following calculations we chose $r_0^* = 0.025$ cm and $ar_0^* = 0.1$; [1] is used to find the equilibrium meniscus height z_e. A portion of the numerically generated surface profile for system 5 is shown in Fig. 9*a*. Figure 9 *b* and *c* show the apparent contact angles

on the solid surfaces, calculated from [8], for system 5 and system 1 respectively when $\theta = 70°$. The intersections of the lines $\theta(z_c/r_0)$ at a constant immersion depth h with $\theta(z/r_0)$ indicate the possible equilibrium positions for the contact line. As h/r_0 increased or decreased it is possible to obtain a hysteresis loop similar to the case of saw-toothed or sinusoidal grooves (Figs. 3 and 6).

We immediately notice that as the magnitude of roughness decreases (everything else being the same) only higher and lower surface slope sites for advancing and receding contact lines become accessible.

Using Fig. 9 one can construct theoretical wetting hysteresis loops by gradually increasing and decreasing the immersion depth from, say, $h = 0$. Figure 10 *a* and *b* are the hysteresis loops for the systems in Fig. 9 *b* and *c* respectively. Conceptually it is easier to form Fig. 10 using Fig. 9, but in numerical calculations it is much more practical to calculate the equilibrium meniscus heights at regular Δz_i intervals on the solid surface and search for the locations of non-equilibrium jumps to the nearest equilibrium positions as h continuously increases for advancing and decreases for receding contact lines. At smaller roughness dimension (Fig. 10*a*) we obtain more frequent smaller three phase contact line (TPL) jumps together with larger non-equilibrium jumps. Also the contact angle hysteresis ($\Delta\theta = \bar{\theta}_a - \bar{\theta}_r$) is larger at smaller roughness dimensions (Table 2).

The mean advancing contact angle $\bar{\theta}_a$ and the mean receding contact angle $\bar{\theta}_r$ are shown in Fig. 11 as a function of the roughness size of the solid surface when the standard deviation of the surface slope distribution $\sigma = 11.65$. The bars indicate the standard deviation from the mean apparent contact angle; they are slightly larger for larger roughness sizes (Table 1). For smaller roughness dimensions only the extreme surface slope values contribute to

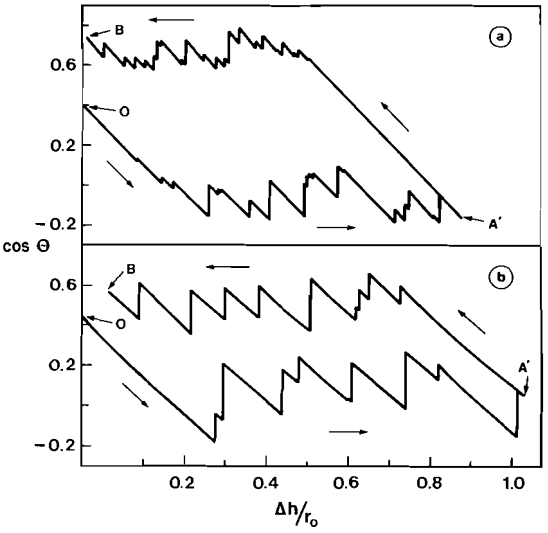

FIG. 10. cos θ vs. $\Delta h/r$ obtained by immersing the cylinder into phase 2 from O to A′ and withdrawing from A′ to B with $\theta_0 = 70°$. (*a*) For system 5 and (*b*) for system 1.

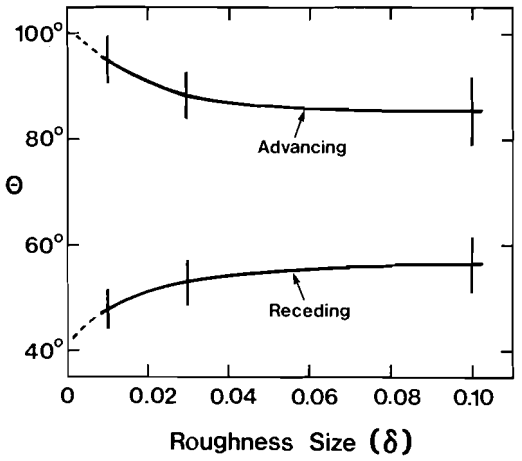

FIG. 11. Effect of roughness size δ on apparent contact angle for $\theta_0 = 70°$ and $S = 0.5$ (systems 1, 3, 5).

the hysteresis; at larger rough dimensions the hysteresis asymptotically approaches a constant value.

Figure 12 shows the dependence of contact angle hysteresis on the solid surface slope distribution for $\delta = 0.03$. The bars show the standard deviation from the mean advancing and receding contact angles. There is an almost linear relationship between σ and the amount of hysteresis in the range $5° < \sigma < 25°$.

Discussion

The effect of circumferential axisymmetric roughness on wetting hysteresis has been investigated by considering a cylindrical rod being immersed into or withdrawn from a flat liquid–fluid interface at very slow contact line velocities in order to approach equilibrium conditions. A general feature of contact line motion is jumps between equilibrium meniscus configurations, thus demonstrating that wetting of these surfaces is basically an irreversible phenomenon (2). We believe that treatments of wetting based on equilibrium thermodynamics should be extended to cover the irreversible aspects of contact line motion. Also the formation of composite surfaces during wetting due to constraints arising from solid surface geometry is a cause of irreversibility during wetting.

For axisymmetric unidirectionally random roughness, the reduction in absolute dimension of roughness produces a more distinct and larger hysteresis loop with smaller non-equilibrium jumps. The number of rugosities skipped over during non-equilibrium jumps increases with decreasing roughness dimensions. At the same time the contribution of large and small solid surface slopes ϕ_0 during advancing and receding of the contact line becomes more pronounced. It may be speculated that as the dimensions of roughness are progressively reduced, one will eventually observe a smooth motion of the contact line where, at a microscopic level, the contact line advances or recedes with very small jumps from one equilibrium site to the next. The question of the minimum roughness dimension which can be considered as a cause of wetting hysteresis seems to be a basic one. It has been claimed that surface roughnesses below 0.1–1 μm do not cause any significant hysteresis (10, 11), whereas the work of Oliver *et al.* (5) indicates that 0.05 μm high steps on a mica surface inhibit spreading. It seems that the nature of the roughness (surface texture (2)) rather than its absolute size is a determining factor as well (12).

At smaller roughness scales (~1 μm) we obtain many small jumps coupled with larger non-equilibrium jumps; this may prove to be significant in studies of contact line motion. Studies by Dussan (13), Hocking (14), Huh and Mason (15), and Levine *et al.* (16) indicate the importance of the mechanism(s) by which a meniscus moves on a solid surface. Most of the workers in this field assign a slip parameter at the contact line (10^{-6} to 10^{-9} cm) to overcome the infinite amount of force required to move a contact line (an unrealistic consequence of the no-slip boundary condition). It may be possible that at a submicroscopic level the contact line moves with non-equilibrium jumps rather than with continuous slippage of the leading edge of the meniscus. Again, the problem posed by the minimum roughness dimensions which can affect wetting needs to be answered.

In the following papers we investigate experimentally the influence of roughness shapes and dimensions, and of contact line velocities on wetting (4, 17).

Tensiometric studies on wetting. II. Some effects of surface roughness (experimental)

ERDAL BAYRAMLI AND STANLEY G. MASON

Pulp and Paper Research Institute of Canada and Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7

Received August 15, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

ERDAL BAYRAMLI and STANLEY G. MASON. Can. J. Chem. **59**, 1962 (1981).

The wetting of regularly rough solid bodies was investigated by means of capillarography. In this technique solid probes are immersed and withdrawn from liquid–fluid interfaces with steady velocities. Continuous observation of the three phase contact line (TPL) motion and recording of the capillary force are possible simultaneously. The effect of regular axisymmetric grooves on cylindrical rods on wetting hysteresis was found to follow theoretical predictions closely at large roughness dimensions (~86 μm) in which case the TPL makes jumps from one equilibrium position to another while advancing. At lower rugosities (~1 μm) the effect of regular roughness for a given concentric groove geometry is complicated by effects attributed to the dominant influence of chemical heterogeneity of the solid surface.

ERDAL BAYRAMLI et STANLEY G. MASON. Can. J. Chem. **59**, 1962 (1981).

On a étudié la capacité de mouillage de corps solides ayant une rugosité au moyen de la capillarographie. Dans cette technique, on immerge et on retire des sondes solides des interfaces liquide–fluide avec des vitesses constantes. On peut observer simultanément et d'une façon continue le mouvement des trois lignes de contact de phase (LCP) tout en enregistrant la force capillaire. On a trouvé que des gorges axio-symétriques régulières présentes sur des barres cylindriques provoquent sur l'hystérésis de mouillage des effets qui suivent de très près les prédictions théoriques pour les rugosités de grandes dimensions (~86 μm). Toutefois les LCP sautent d'une position d'équilibre à une autre lorsqu'elles avancent. A de plus faibles rugosités (~1 μm), l'effet d'une rugosité régulière pour une géométrie à gorge concentrique donnée est compliqué par des effets attribués à l'influence dominante de l'hétérogénéité chimique de la surface solide.

[Traduit par le journal]

Introduction

In the preceding study we theoretically investigated some effects of surface roughness on wetting of axisymmetric circular cylinders (1), which was the continuation of the theoretical and experimental work initiated by Huh and Mason (2) and Oliver *et al.* (3) for drops on horizontal solid surfaces. In this study a tensiometric technique called capillarography (4) is used to investigate the wetting of small solid bodies with regular roughness features. The technique is well-suited for the study of the envisaged mechanism of non-equilibrium jumps of the meniscus, the nature of wetting hysteresis and the effect of roughness shape and dimensions on wetting.

Among the surfaces investigated are a cylindrical rod with 1 μm parallel circumferential grooves of saw-tooth shape (the microgrooved cylinder, μgc) which has a roughness scale smaller than hitherto investigated regular roughnesses. Another cylinder with about 86 μm wavelength of saw-toothed grooves (the macrogrooved cylinder, Mgc) is used along with other surfaces with regular physical roughnesses to explore the effects of regular roughness of varying length scales on wetting of solids.

In actual experimental conditions, the effects of regular roughness on wetting coexist with those of the intrinsic chemical heterogeneity and the physical roughness of the surfaces. Therefore, with both the μgc and the Mgc two different hysteresis loops are obtained on the grooved and ungrooved parts of the same cylindrical rod (Fig. 1).

Experimental Part

1. Apparatus

Use was made of a micro- and macrocapillarograph (abbreviated as μc and MC) designed for small (e.g. 10 μm diameter fibers) and large solid bodies travelling respectively over small and large distances through an interface. Details of the experimental technique are given elsewhere (5). In each apparatus a platform holding the vessel containing the wetting liquid is moved vertically by means of a motor-powered hydraulic drive, whose speed can be varied sensitively and continuously. The vertical force F' is measured by an electrobalance (capacity up to 10^{-2} N, sensitivity down to 2×10^{-7} N), and the vertical displacement h of the platform by a magnetic transducer; F' versus h is plotted on an X–Y recorder. A plot obtained in this manner is called a capillarogram. In the μc, platform velocities (5×10^{-3} to 0.4 μm s^{-1} for a total vertical displacement of 0.3 cm) are obtained by a variable speed hydraulic drive which is mounted independently of the main electric driving motor to reduce vibration. The assembly is securely mounted on four pressurized air supports to reduce the ambient vibrations. The MC has higher stage velocities and a larger travel distance (2–14 μm s^{-1} over a distance of 5 cm) and is placed atop a large cement block on anti-vibration pads; again, the hydraulic drive for the platform is mounted separately. Both instruments provide platform velocities constant to ±0.5%.

The platform of the μc has a vertical displacement resolution of about 25 Å, i.e. of the same order as a low resolution electron microscope; this, of course, was vastly exceeded by vibration displacements (rms movement of 0.15 μm at a dominant frequency of 28.6 Hz no matter where located and independent of the speed of the hydraulic drive motors (15)); as a result this resolution cannot yet be realized. In addition there is an uncer-

tainty in the location of the contact line due to evaporation of the wetting liquid during the course of an experiment (~5×10^{-3} μm s^{-1} for water depending on the relative humidity, considerably less for the other, less volatile, liquids). For the MC, the displacement resolution is about 1 μm.

2. *Materials*

Solid Bodies

The microgrooved cylinder (μgc) was an aluminium-coated sapphire rod grating having parallel circumferential grooves 1 μm apart (made by Diffraction Products Inc., Woodstock, IL, USA). The polished sapphire rod was coated with aluminium by vacuum evaporation and a 1 cm long portion of the Al surface was grooved by a diamond tip one groove at a time, yielding the angles θ_1, θ_2, and θ_3 in phase 3 (Fig. 1) for the triangular cross-section of the grooves (Table 1). To prevent peeling of the Al coating, the surface was cleaned by washing in benzene, methanol, and then with copious quantities of distilled water, and followed by vacuum drying for 6 h at 50°C. The sensitive nature of the grooved surface precluded the use of oily or viscous liquids as wetting phases because of difficulties in subsequent cleaning.

The macrogrooved cylinder (Mgc) was similarly made on a 1 cm section of a 1.5 cm length of a polished bronze rod 0.3 cm diameter with groove dimensions listed in Table 1. The groove shape was analyzed in a Nikon Shadograph with a linear resolution ± 1 μm.

Other axisymmetric surfaces with regular macroscopic roughness were a jeweller's saw and a guitar string. The saw was a thin blade of steel with sharp teeth on one side; the guitar string was made of spirally wound steel wire on an iron wire core (see Table 1 and Fig. 2).

The plane grating, on which the drop shape observations were made, with parallel saw-tooth shaped grooves (Diffraction Products Inc., Woodstock, IL, USA), was a thin polymethylmethacrylate (PMMA) surface on a glass support, replicated from a master grating (Table 1).

Wetting Liquids

Purified water (conductivity 10^{-4} Ω^{-1} m^{-1}) was prepared by passing tap water through ion-exchange columns and then triply distilling it (single stage, from permanganate, and finally through a multistage unit), and then using it within 24 h. As non-aqueous liquids analytical grade tetrabromoethane (TBE), decane, and silicone oil (Dow Corning 200D series, 10cs.) were used as supplied.

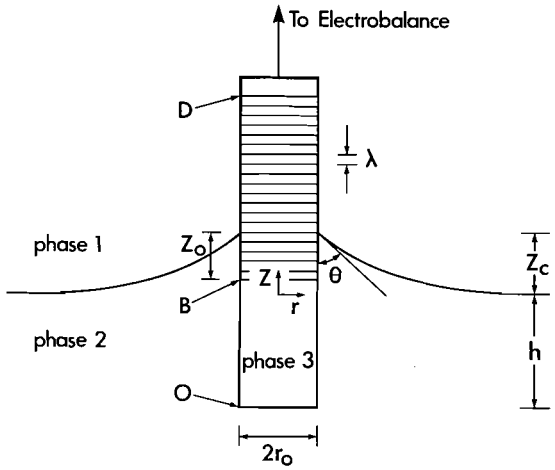

FIG. 1. Diagram of the grooved cylinder and the liquid meniscus; the region O to B designates the ungrooved part and B to D the grooved part of the cylinder; λ is the wavelength of the grooves. Other important parameters are shown.

The surface tension of the water was determined by the pendant drop shape method; and that of TBE, decane, and silicone oil by Pt ring tensiometry (Table 1). The MC with its recording microbalance and smooth displacement capability is ideally suited for the measurement of maximum force in ring tensiometry where a receding contact line was obtained in order to have the intrinsic contact angle $\theta_0 \simeq 0°$. Also the advancing and receding tensiograms were nearly identical, from which we can deduce that $\theta_0 \simeq 0$ in all cases (6). The cited values are well within the experimental accuracy required for the present work.

The liquid densities were determined pycnometrically; all measurements and experiments were performed in a room controlled at 23 ± 0.5°C.

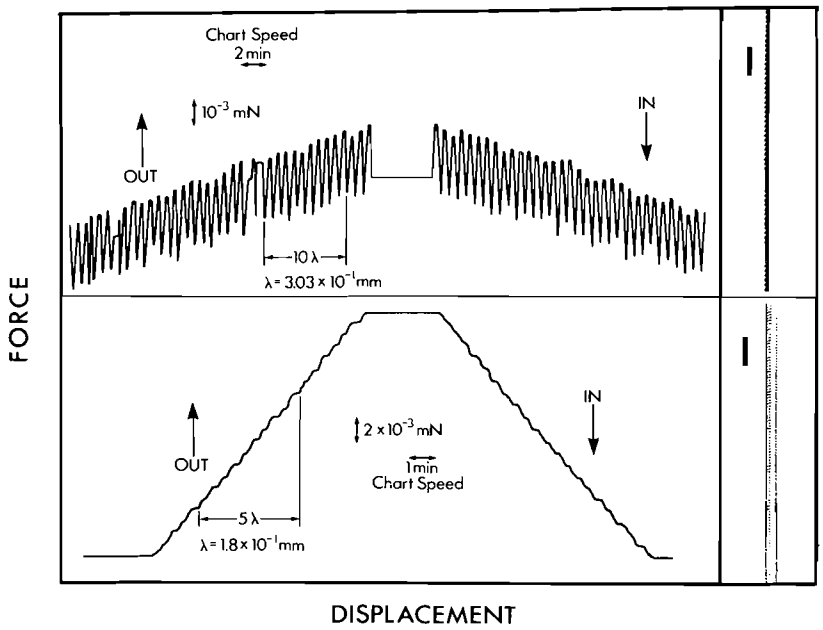

FIG. 2. Capillarograms of the jeweller's saw (upper) and the guitar string (lower) with silicone oil (10 cs) as the wetting liquid. The motion of the platform was reversed after stopping it about 4 min at the mid-point. The general increase in force while receding and decrease while advancing is due to buoyancy. The length scales on the photographs on the right, represented by the solid bars, indicate 2 mm.

3. Methods

In recording most capillarograms, a hysteresis loop was first obtained on the ungrooved portion of the rods and then on the grooved portion by moving the platform up and down at 0.30 μm s^{-1} in the μc and at 4 μm s^{-1} in the MC. Making use of the independent measurements of apparent receding contact angles measured photographically (normal to the cylinder axis), the force-displacement capillarograms were evaluated in terms of the apparent contact angle θ (7).

Results and Discussion

Large Solid Bodies

As a qualitative demonstration of the effect of macroscopic roughness on the apparent contact angle, we recorded capillarograms in the MC of the jewller's saw and the guitar string (Fig. 2) using silicone oil as the wetting phase for which $\theta \simeq 0°$. Figure 6 (upper) shows that at this scale of roughness (~0.3 mm) the apparent contact angle varied considerably as the three phase contact line (TPL) advanced or receded at 8 μm s^{-1} on the saw surface. Similarly, on the guitar string we observe from Fig. 2 (lower) that the TPL slope varied with respect to the vertical axis due to the spiral grooves, but in a less pronounced way; the sharp edges were more effective in inhibiting spreading (8). From the close symmetry of Fig. 2 we can deduce that the intrinsic contact angle was nearly constant (~0°) during advancing and receding of the TPL.

Macrogrooved Cylinder

The well defined geometry of the Mgc allows the theoretical predictions in ref. 1 to be tested. For an advancing TPL the apparent contact angle should be $\theta = \theta_0 + \theta_1$. The observed increase in θ when $\theta_1 = 13.6°$ is 13.1° ± 0.5° (Fig. 3) with TBE as the wetting phase and using the MC at 4 μm s^{-1} stage velocity, in good agreement with the theory. Here, r_0* is the minimum radius of the cylinder and Δh is the change in the downward vertical displacement h of the cylinder with respect to the horizontal level of the 12 interface (Fig. 1). For the ungrooved part of the surface, $\theta = 47.9°$ and 0° for the advancing and receding TPL's respectively. The periodicity of the advancing TPL 86 ± 4 μm matches well with the wavelength of the grooves measured using a Nikon Shadograph. The only discrepancy is that larger non-equilibrium jumps were observed than the expected jump value, calculated using Huh and Scriven's tables (7) of meniscus shapes around a cylinder, which corresponds to jumps from a valley to the nearest equilibrium position on the neighbouring peak of the grooves. Rather, the jump occurred from one valley to the next one which corresponded to a 6.0° (55.0°–61.0°) change in the observed contact angle. The dotted line (Fig. 3) indicates the capillarogram expected from a valley to peak jump with no change in intrinsic contact angle. This result is most probably due to experi-

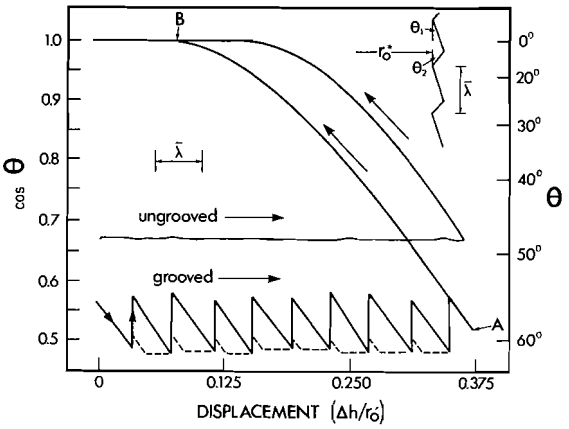

FIG. 3. cos θ vs. $\Delta h/r_0^*$ for the Mgc with tetrabromoethane, first on the ungrooved and then on the grooved part of the cylinder. The broken line shows an approximation of the expected capillarogram which can be calculated from Huh and Scriven's tables (7) assuming that the contact line makes a non-equilibrium jump from a groove valley to a neighbouring peak. The inset (upper right) shows the groove geometry.

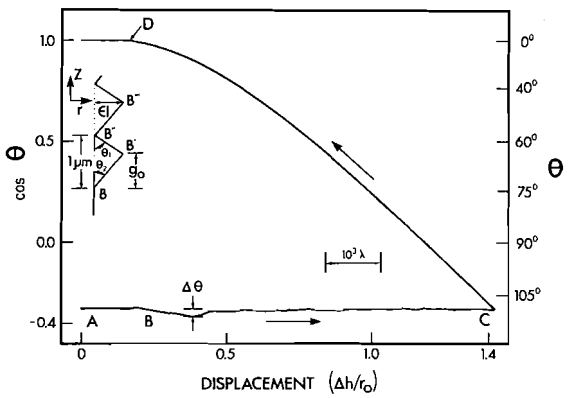

FIG. 4. cos θ vs. $\Delta h/r_0^*$ for the μgc with water as the wetting liquid. The slight increase Δθ at the start of grooved portion of the cylinder at B corresponds to an increase of 2.3°. Note the smooth section where (starting at C) the receding contact line sticks and hinges until it reaches θ_R which is very close to zero. The groove geometry is shown in the inset.

mental limitations because for sudden changes in capillary force, such as during the jumps, the arm of the microbalance overshoots its equilibrium position before coming to rest (5). Since hysteresis is present in the system even in the absence of grooves (due to surface chemical heterogeneity), the TPL can come to rest on the next valley after overshooting its equilibrium position (i.e. at the peak where $\theta_0 = 47.9°$).

For the receding TPL no effect of the grooves was observed due to liquid bridges filling the grooves left behind, creating a composite surface. This occurs because $\theta_0 \simeq 0°$ and $\theta_0 < (\theta_1 + \theta_2)$ is the condition for formation of a composite surface for a receding TPL (1).

Microgrooved Cylinder

For the μgc where the wavelength $\lambda \simeq 1$ μm and θ_1, θ_2 are equal to 50° and 30° respectively, an increase of about 50° can be expected on the grooved part of the cylinder compared to that of the ungrooved part for an advancing TPL. The jumps of the TPL from one groove to another are too small to be recorded since the force change for this effect will be of the order of $\lambda\varepsilon l 2\pi r_0 \Delta\rho g \simeq 10^{-9}$ N, εl being the height and λ the wavelength of the grooves, g denotes the gravitational constant and Δρ the density difference between phases 1 and 2 respectively. The change in advancing contact angle is a macroscopic effect and should be readily observable.

Figure 4 shows a typical experiment in the μc using the μgc with water as the wetting liquid at 0.3 μm s^{-1} stage velocity. When the TPL encountered the grooved portion of the μgc at B the decrease in tension corresponded to a 2.3° increase in θ. The final contact angle θ at C was the same as the one at A within experimental accuracy; the tension difference measured on ungrooved and grooved parts did not show any systematic difference; it was found to be 112.7° ± 4.0° for grooved and 112.2° ± 4.0° for ungrooved portions (Table 2). It seems that the first groove at B had some effect on the TPL motion, but subsequent motion was unaffected. On both surfaces (grooved and ungrooved), the contact line stuck between C and D while the contact angle changed from the advancing contact angle, θ_A, to the receding angle, θ_R, and the receding contact line was much smoother than the advancing TPL. The receding angle $\theta_R \simeq 0°$ was measured by photographs of the TPL.

A similar situation was observed when TBE was used instead of water as the liquid phase; there was no systematic difference in the magnitude of hysteresis loops over grooved and ungrooved portions of the μgc with $\theta_A = 47.6° \pm 6°$ and, as in the case of water, θ_R was very close to zero. The differences between the various runs were mainly due to the difficulty in reproducing the same Al surface given the limitations of the cleaning procedures. Still, it can be said that, on the μgc surface, no macroscopic contact angle variation was observed due to grooves, except a small change at the first groove while advancing.

Figure 5(*a*) and (*b*) shows SEM-graphs of the μgc surface. The experiments were made on a surface which was in a better condition than Fig. 5 suggests because an attempt for a more rigorous cleaning was made with dilute chromic acid solution which was terminated when the Al-coating started to peel

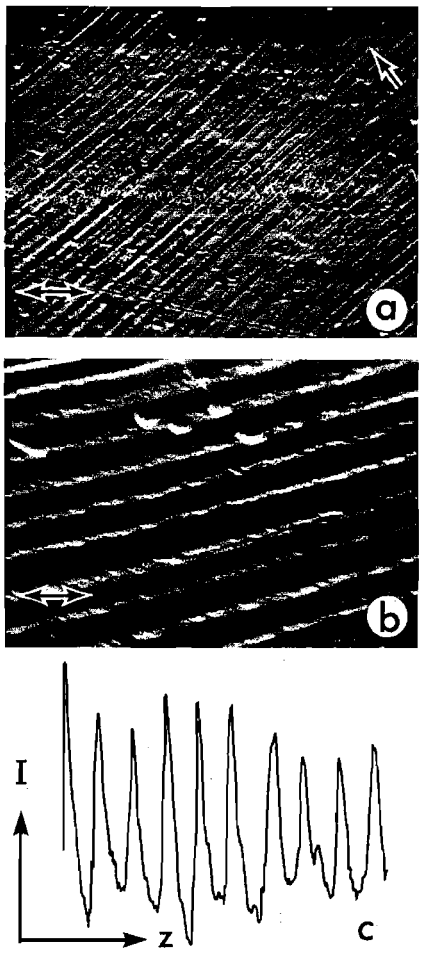

FIG. 5. SEM-graphs of the μgc. The arrows indicate the direction of the cylinder axis (ignore the faint signals in (*a*) which are artifacts). The length scales show 4 μm in (*a*) and 0.8 μm in (*b*). The light intensity I that passes through the negative of (*b*) which was obtained by a microdensitometer scanning in the Z-direction of the μgc is shown in (*c*); the intensity I is linearly proportional to the image density.

off from the smooth surface of the sapphire. The S.E.M. photograph in Fig. 5 shows the condition of the grooves after this attempt on which no experiments were performed. Nevertheless, the analysis of the negative of Fig. 5(*b*) by a recording densitometer indicates that groove spacings were quite regular, Fig. 5(*c*). A single scanning line in the Z-direction shows that the grooves are quite sharp and uniform as indicated by the intensity I of the scanning light source which passes through the negative of Fig. 5(*b*) and which is linearly proportional to the image density.

The most probable explanation of the lack of hysteresis due to the regular grooves is that the effect of chemical heterogeneity may overshadow the effects of regular roughness. If there are large differences in solid surface free energy the TPL may not be horizontal but traverse several grooves, as shown schematically by the broken line in Fig. 6, conforming to the variations in surface free energy of the solid. If the effect of groove edges (8) is neglected, one can make the following simplifications assuming the contact line traverses many grooves, so that statistically we have

$$[1] \quad t \simeq \frac{\varepsilon l}{\sin \theta_1} 2\pi r_0$$

$$[2] \quad d - t \simeq \frac{\varepsilon l}{\sin \theta_2} 2\pi r_0$$

where t is the area of one groove surface where $\tan^{-1}(dr/dz) = -\theta_1$ and $d - t$ is the area of groove surface where $\tan^{-1}(dr/dz) = \theta_2$. Then the average apparent contact angle, $\bar{\theta}$, is given by

$$[3] \quad \bar{\theta} = \theta + \frac{t}{d}\theta_1 - \frac{d-t}{d}\theta_2$$

Therefore for groove geometries where $t = (1/2)\,d$, effects of regular roughness cannot be observed due to traversing of the contact line over several grooves but, if $(1/2)\,d \neq t$, small changes in contact angle may be observable in accordance with [3]. For the μgc we have $t/d = 0.605$ and $(d - t)/d = 0.395$, therefore from [3], $\bar{\theta}_A = \theta_A + 1.6°$, i.e. little change in hysteresis due to regular roughness is expected. (The μc is capable of detecting contact angle changes to better than 0.1°, depending on the cylinder diameter and value of θ, but reproducibility of the runs in our experiments was about ±4° which is much larger than the expected change in contact angle.)

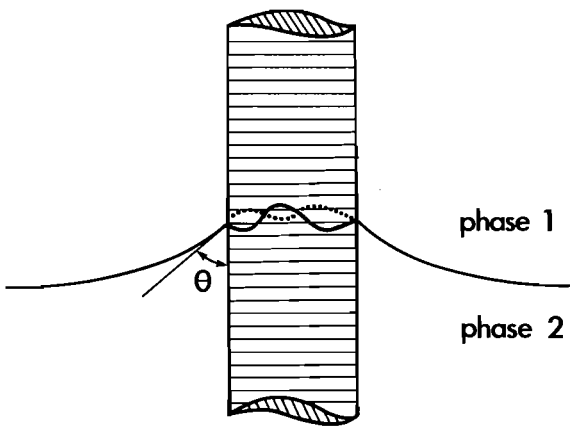

FIG. 6. Schematic of the meniscus on the grooved surface showing the contact line traversing several microgrooves.

[d]Photographic observation.

Another explanation is the presence of capillary waves caused by ambient vibrations which were measured using an accelerometer and were found to have a maximum vertical displacement of about 0.5 μm (5). If there is no resonance in the system it is reasonable to assume that capillary waves in the liquid surface are of the same order of magnitude and frequency as the instrument vibrations. A crude calculation, assuming waves are transmitted with major frequency of vibrations (28.6 Hz) with amplitude 0.3 μm (5), yields a wave velocity of 35.9 cm s^{-1} and 1.25 cm wavelength (9). It should be added that the surface vibrations alone do not suffice to explain the observations. The vibrations have to be considered in connection with the slip boundary condition of a moving TPL (10, 11). If the length scales involved in surface vibrations and slip boundary conditions are of the same order of magnitude as surface roughness, it would not be meaningful to make predictions about the magnitude of hysteresis due to either physical or chemical heterogeneity. Most probably the slippage phenomenon is operative at length scales smaller than 1 μm, and in our experiments both effects contribute to the lack of hysteresis due to regular grooves.

For a qualitative demonstration of the effects of regular roughness in the range of 1 μm < λ < 100 μm on liquid spreading, a drop formation experiment was carried out on a planar PMMA surface with parallel saw-tooth shaped grooves (Table 1). The TBE drops were formed using a slowly moving infusion pump with a fine syringe needle almost touching the surface. The final shape of the drop which is elongated in the direction of the grooves (Fig. 7) dramatically shows their effect.

In a wider context the results may be related to Wenzel's equation (12, 13)

$$[4] \quad \cos\theta = \bar{\sigma}\cos\theta_0$$

where $\bar{\sigma}$ is the ratio of the true to the geometric solid surface area which is derived thermodynamically from the minimization of total free energy of a system. The relationship between θ and θ_0 on regular grooves is easily visualized as shown by the experiments with the Mgc. In experiments with the μgc, the increase in surface area due to grooves did not have an observable effect on θ_0 which may indicate that the order of magnitude of roughness has to be much smaller than 1 μm in order to attach a thermodynamic meaning to Wenzel's equation.

FIG. 7. Photograph of a TBE drop on PMMA plane grating with λ = 10 μm. The groove direction is along the elongated axis of the drop.

Another relevant observation is that the contributions of chemical heterogeneity and physical roughness are not additive; this follows from the experiments with the μgc. The exact nature of this interaction requires further study.

In a subsequent paper (14), dealing with wetting of solid surfaces, we investigate thin fibers of high and low surface energies using the μc at very low and medium TPL velocities. Study of these fibers, made of commonly used materials such as glass, platinum, Teflon, reveals interesting observations relevant to the nature of contact angle hysteresis on more realistic solid surfaces.

ARIE DE KEIZER and JOHANNES LYKLEMA. Can. J. Chem. **59**, 1969 (1981).

The hydration of solid particles in aqueous solution is treated as a patchwise phenomenon, in which the orientation of water dipoles varies in a patchwise fashion along the surface. The idea is applied to the AgI system where besides the neutral surface Ag^+ patches and I^- patches are distinguished. A first-order elaboration is offered, including an analysis of the relation between overall macroscopic quantities and local properties. The model offers an interpretation of two characteristics of double layers on silver iodide: the asymmetry of its p.z.c. and the conspicuous capacitance rise on the positive side and may serve as a starting point for a better description of the typical differences between the double layers on AgI and Hg.

ARIE DE KEIZER et JOHANNES LYKLEMA. Can. J. Chem. **59**, 1969 (1981).

On considère l'hydratation des particules solides en solution aqueuse comme un phénomène impliquant des blocs dans lesquels l'orientation des dipôles de l'eau varie avec les blocs présents à la surface. On a appliqué ce concept à un système de AgI dans lequel en plus du bloc neutre, on peut distinguer des blocs de Ag^+ et d'autres de I^-. On présente une étude approfondie de premier ordre comportant une analyse de la relation entre les quantités macroscopiques globales et les propriétés locales. Le modèle propose une interprétation pour deux caractéristiques de la couche double sur l'iodure d'argent: l'asymétrie de son c.z.p. et l'augmentation manifeste de la capacité de la partie positive; ce modèle peut servir de point de départ pour une meilleure description des différences caractéristiques entre les couches doubles sur AgI et Hg.

[Traduit par le journal]

Introduction

The description of the orientation of water (and other) dipoles near a phase boundary remains one of the most difficult problems of interfacial electrochemistry. The majority of models refer to the metal–water interface. The state-of-art in this field has been covered in an excellent review by Trasatti (1). However, it is questionable whether the results obtained for metal–water interfaces are of immediate applicability to non-metal solid–water interfaces, as occurring in many disperse systems. More often than not the charge on the surface is localized, while in addition solid surfaces are often heterogeneous. It follows that the state of hydration, or, for that matter, the interfacial polarization, varies along the surface. For instance, with negatively charged AgI-sols one would expect a mode of orientation of the water dipoles near an adsorbed I^- ion differing from that near an uncharged part of the surface: the adsorbed I^- ion would create a small hydrophilic patch in an otherwise hydrophobic surface. Similar reasoning would apply to, say, negatively charged polystyrene latex particles.

Below we shall refer to models, based on interfacial water molecules treated as if their orientation is due to a homogeneous electrical field as "*homogeneous interfacial hydration models*", in contradistinction to "*patchwise interfacial hydration models*", in which the existence on the surface of loci or patches of differing hydration properties is explicitly accounted for. The first category encompasses the main body of what has hitherto been studied, but here we intend to emphasize the second. "Interfacial hydration" is interpreted here in the general sense as including *all* variations of the properties of water due to an adjacent phase, including those near water-rejecting surfaces, giving rise to hydrophobic hydration.

In this paper we will emphasize the orientational properties of the solvent molecules. The model to be developed will be applied to the silver iodide – aqueous solution interface (2) and incorporated in a theory of the AgI–electrolyte interface, which is based on the individual adsorptions of the potential determining (p.d.) ions. It will be shown that the proposed picture is entirely compatible with experimental charge–potential curves.

Patchwise Interfacial Hydration, Some Basic Aspects

The discrimination between systems, where a homogeneous hydration model applies and those in which a patchwise treatment is indicated, is not always obvious. Clearly, air in contact with water is homogeneous, so are other fluids, including mercury. If the mercury bears a charge, due to, say, an excess of electrons, these electrons move very rapidly along the surface, so that the surface charge density σ is really smeared-out and the electrical field near the

surface is homogeneous. A patchwise model is obvious for most heterogeneous surfaces. Heterogeneity can arise if the surface consists of a collection of different but homogeneous patches or if it carries a number of fixed charges (of one or more types) on an otherwise uncharged area. For instance, polystyrene latex spheres negatively charged by immobile covalently bound, completely dissociated sulphate groups clearly belong to the patchwise category because the charged groups cannot move at all. An intermediate situation exists for homogeneous surfaces on which the surface charges have a limited tangential mobility. The discriminating question is then whether or not the relaxation rate of the lateral motion of these ions exceeds that of the adjustment of water dipoles. Silver iodide is intermediate because the adsorbed p.d. ions (Ag^+ and I^-) have a certain tangential mobility, either inside the solid, or by desorption and readsorption at a different site.

Some indication of the applicability of the patchwise model can be obtained from different kinetic interfacial parameters. For the AgI – aqueous solution interface, the rotational relaxation time of water, as obtained from nmr-measurements, is of order 10^{-9} s or faster. The relaxation time for the adjustment of surface charges can be inferred from recent work by Peverelli and van Leeuwen (3), who found a relaxation time order of 10^{-3} s. Although the latter is related to the transfer of charges across the interface and is probably controlled by the dehydration process of p.d. ions, it is so much slower than the relaxation time for the adjustment of an interfacial water molecule that for the purpose of description of the properties of the interfacial water layer the distribution of adsorbed Ag^+ and I^- ions is virtually fixed. In other words, in this case a patchwise approach is indicated.

In a patchwise hydration model, the electrical interfacial properties due to free and induced charges will be locally dependent on the surface properties of the patch. We intend to evaluate the total Galvani-potential difference $\phi^S - \phi^L$ between the interior of the (homogeneous) solid and that of the liquid in terms of its components. To be rigorous, one should take into account both the discreteness of the surface charge (and counter charge), as well as the patchwise behaviour of interfacial hydration. However, for the present purpose, we will use the following first order approximation: (*i*) The Galvani potential is considered a statistical mean of the local properties. (*ii*) The charges will also be taken as smeared out except for their effect on interfacial hydration. (*iii*) Local solvent properties are calculated with a patchwise model, but in a later stage these properties will be averaged over the surface.

It is not always meaningful to average or to smear out the local hydration properties in the patchwise interfacial hydration model. This can be illustrated by considering the orientation of solvent dipoles and the dipolar potential. For reversible interfaces, like that between AgI and an electrolyte solution, the dipolar potential is part of the Galvani potential difference $\phi^S - \phi^L$. It is likely that adsorption of p.d. ions will be related to the dipolar (macro) potential. However, for systems consisting of a non-conducting solid and fixed surface groups chargeable by a dissociation equilibrium only the effect of hydration on the micropotential is meaningful. This local hydration can be incorporated in the equilibrium constant or the adsorption free energy.

Interfacial Dipole Potentials, In First Order Approximation

Assume a surface to be composed of a collection of patches of differing properties denoted by $i, j, k \ldots$. Patches i are characterized by a surface charge density σ_i, a relative dielectric constant in the fluid ε_i, and an effective number of normally oriented water molecules $n_i^\perp$. The sign of $n_i^\perp$ denotes the direction of the oriented dipoles. We will simplify our treatment by assuming σ_i, ε_i, and $n_i^\perp$ to be independent of the total surface charge density σ. This limits our treatment either to heterogeneous surfaces with a fixed surface charge, or to homogeneous surfaces with localized charges determining surface hydration. It is our aim to evaluate the dipolar potential difference of the entire interface $\Delta\phi(\text{dip})$ from local properties.

The electrical potential difference across a homogeneous layer of surface dipoles is given by the Helmholtz-equation [1].

$$[1] \quad \Delta\phi(\text{dip}) = \frac{n^\perp \mu}{\varepsilon_0 \varepsilon^H}$$

Rational units are used throughout, thus ε_0 is the dielectric permittivity of vacuum (8.854×10^{-12} C/V m). As discussed by Trassatti (1) difficult points in the application of [1] are assigning values to the effective dipole moment of water μ and to the relative dielectric constant ε^H. For μ we take the value for isolated water molecules, i.e. 1.84 D ($= 6.13 \times 10^{-30}$ C m). This choice automatically implies a choice on the value of ε^H, a point to which we return below. Before discussing ε^H it is useful to analyse the overall behaviour of the dielectric constant near the surface.

It is assumed that the region between the homogeneous surface and the Outer Helmholtz Plane (OHP), the inner or Stern layer, has a uniform dielectric constant ε^S. In the absence of specific adsorption the Stern layer can be considered as a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

molecular condenser for which the potential difference is written as

$$[2] \quad \Delta\phi(\text{Stern}) = \frac{\sigma d}{\varepsilon_0 \varepsilon^S}$$

where d is the thickness of the Stern layer. This potential difference is a function of the charge of the surface and the orientation of permanent dipoles at the surface and can thus formally be separated in two components, a dipolar contribution $\Delta\phi(\text{dip})$ and another one $\Delta\phi(\text{mol})$, to be discussed later:

$$[3] \quad \Delta\phi(\text{Stern}) = \Delta\phi(\text{mol}) + \Delta\phi(\text{dip})$$

Also formally, this separation can be extended to the right hand side of [2]. Assuming σ and d to be equal for the two components, we can write

$$[4] \quad \Delta\phi(\text{Stern}) = \frac{\sigma d}{\varepsilon_0 \varepsilon^M} - \frac{\sigma d}{\varepsilon_0 \varepsilon^O}$$

which is equivalent with a splitting-up of the reciprocal Stern permittivity ε^S according to

$$[5] \quad \frac{1}{\varepsilon^S} = \frac{1}{\varepsilon^M} - \frac{1}{\varepsilon^O}$$

Here, ε^M is the apparent dielectric constant due to molecular polarization only and ε^O is the same due to the orientational effect of the water dipoles only. The minus sign follows from the fact that the orientation of permanent dipoles is opposite to the field vector. The parameter ε^M is the dielectric constant at fixed orientation of the dipoles and will be close to the high-frequency value ε_∞. It is assumed that ε^M is isotropic and thus independent of $\Delta\phi(\text{dip})$. It follows also, that for different patches i, ε_i^M is independent of the patch properties ($\varepsilon_i^M = \varepsilon^M$). The quintessence of the separation of ε^S is that all variations of ε^S with surface charge are ascribed to ε^O and hence to $\Delta\phi(\text{dip})$. The dipolar potential dependence on surface charge follows from model considerations.

Let us now return to the choice of the value for dielectric permittivity of the Helmholtz layer, ε^H. First, it is noted that in [2], ε^S applies over the entire region between the centres of the surface charges and the OHP, whereas in [1] ε^H applies only to a monolayer of water molecules. Strictly speaking ε^H could well be unity, but we have to account for the approximation made above that for μ the value of isolated water dipoles has been substituted. This is an overestimation because of the lateral interaction of the dipoles (4, 5) and a correction factor is needed in the denominator of [1], which, in our formalism is included in ε^H. The precise resulting value of ε^H is difficult to assess, the actual choice has no influence on our line of reasoning although it affects the values of the parameters to be substituted.

Let the fraction of the surface covered with patches i be denoted by θ_i. The total surface charge density and the total effective number of normally oriented water molecules per unit area can be written as

$$[6] \quad \sigma = \sum_{i=1}^{N_p} \sigma_i \theta_i$$

$$[7] \quad n^\perp = \sum_{i=1}^{N_p} n_i^\perp \theta_i$$

where N_p is the number of patches. From the previous discussion it follows that ε^M, μ, and d are independent of the specific patch properties. In our first order approximation the density of the patchwise oriented dipoles and the surface charge density on the different patches can be taken as smeared out. The additivity of the components of the dipolar potentials and those of the molecular polarizability part of the Stern layer potential ([8], [9]) can be derived from [1], [4], [6], and [7].

$$[8] \quad \Delta\phi(\text{mol}) = \frac{\left(\sum_{i=1}^{N_p} \sigma_i \theta_i\right) d}{\varepsilon_0 \varepsilon^M} = \sum_{i=1}^{N_p} \Delta\phi_i(\text{mol})$$

$$[9] \quad \Delta\phi(\text{dip}) = \frac{\left(\sum_{i=1}^{N_p} n_i^\perp \theta_i\right) \mu}{\varepsilon_0 \varepsilon^H} = \sum_{i=1}^{N_p} \Delta\phi_i(\text{dip})$$

The potential differences $\Delta\phi_i(\text{mol})$ and $\Delta\phi_i(\text{dip})$ are considered as components of a total potential difference and analyzed, regarding the charge density and the density of oriented dipoles at the patches i respectively as smeared out over the whole surface.

If the origin of a patch on a surface is the adsorption of localized surface charges on a homogeneous neutral surface, the degree of occupation θ_i is mostly not well defined. However, we can eliminate θ_1, the surface fraction of neutral patches, from [9], because the condition [10] is valid.

$$[10] \quad \sum_{i=1}^{N_p} \theta_i = 1$$

Moreover, the surface fractions of the charged patches are proportional to the surface excesses of the corresponding ions, expressed in eq/unit area, according to [11].

$$[11] \quad \theta_i = k_i' F \Gamma_i$$

Here F is the Faraday constant and k_i' is a measure for the effective patch area per adsorbed ion. If we introduce [10] and [11] in [9] the surface fractions θ_i are eliminated.

$$[12]\quad \Delta\phi(\text{dip}) = \frac{n_1^{\perp}\mu}{\varepsilon_0\varepsilon^{H}} + \sum_{i=2}^{N_p}\frac{(n_i^{\perp} - n_1^{\perp})\mu}{\varepsilon_0\varepsilon^{H}}k_i'F\Gamma_i$$

$$= \Delta\phi_N(\text{dip}) + \sum_{i=2}^{N_p} k_iF\Gamma_i$$

$$= \Delta\phi_N(\text{dip}) + \sum_{i=2}^{N_p}\Delta\phi_i^{R}(\text{dip})$$

Application of the same procedure to [8] is not meaningful because σ_1 is zero. The value of $\Delta\phi_N(\text{dip})$ is a constant (independent of the surface charge) and applies to the neutral surface. On the other hand, the dipolar potential components $\Delta\phi_i^R$ are proportional to the surface excesses of the ions.

The Local Interfacial Hydration Model Applied to AgI

On silver iodide the surface charge σ is related to the surface excesses of silver and iodide ions according to [13].

$$[13]\quad \sigma = F(\Gamma_{Ag^+} - \Gamma_{I^-})$$

Physically, the charge may be a real surface excess of the p.d. ions (relative to AgI) or a surface vacancy or a space charge in the solid. In our model, all charges are attributed to local positive excesses on the surface.

As explained before, it is likely that the relaxation of water molecules near adsorbed p.d. ions is much faster than the lateral movement of these ions. Moreover, the absolute value of the charge density σ never exceeds 5 $\mu C/cm^2$ in experimental situations. This surface charge corresponds with mutual distances between the charges of minimally 1.8 nm. Hence, the charges are sufficiently well separated and localized on the timescale of the reorientation of water, and, therefore for the purpose of our analysis they may be treated as individual sites.

We distinguish three kinds of randomly distributed patches, Ag^+ patches, I^- patches, and the remaining uncharged AgI patch. The resulting expression for the dipolar potential according to [12] reads for this case

$$[14]\quad \Delta\phi(\text{dip}) = \Delta\phi_{Ag^+}^{R}(\text{dip}) + \Delta\phi_{I^-}^{R}(\text{dip}) + \Delta\phi_{AgI}(\text{dip})$$

$$= k_{Ag^+}F\Gamma_{Ag^+} + k_{I^-}F\Gamma_{I^-} + \Delta\phi_{AgI}(\text{dip})$$

The coefficients k_{Ag^+} and k_{I^-} are parameters related to the net degree of orientation of water molecules at an Ag^+ and an I^- patch respectively.

On the neutral part of an AgI surface the silver and iodide atoms are only partly charged, because the silver iodide lattice is essentially covalent. Here, the orientation is determined by a competitive effect of the solid *and* the solution phase. As silver iodide behaves as a hydrophobic solid, it is not unlikely that on the neutral part of the surface the orientation of H_2O dipoles (and hence the potential difference $\Delta\phi_{AgI}(\text{dip})$ is mainly determined by the solution side. Consequently, it is not very different from that at the air–solution interface. At the air–solution interface water molecules are oriented with the O-atom outwards. The surface or χ-potential amounts to ca. 0.13 V (1).

It may be a good first approximation that the hydration of the water molecules on the Ag^+ and I^- patches is similar (or at least related) to that of the corresponding ions in solution. The hydration free energies $G_{Ag^+}^{h,L}$ and $G_{I^-}^{h,L}$ of the silver and iodide ions in solution are very different and amount to -479.4 kJ/mol and -257.1 kJ/mol respectively (6). It appears that $G_{Ag^+}^{h,L}$ is very high compared to the same quantity for an alkali ion of the same radius. This fact points to a specific interaction between the Ag^+ ion and the surrounding water molecules. We assume that the high hydration free energy of Ag^+ corresponds to a relatively high degree of radial orientation of water molecules around the ion. If this behaviour is similar at the surface the effective orientation of water molecules on Ag^+ patches will be stronger than that on I^- patches. As a consequence k_{Ag^+} will exceed k_{I^-} and this fact is probably the main reason for the asymmetry of the charge–potential curve of AgI in 0.1 *M* KNO_3 as will be shown later.

The effective number of oriented water molecules of a given kind of patch can be estimated from the Helmholtz-equation [1] or [12]. To that end we will use some parameters obtained by anticipating the fitting of an experimental charge–potential curve to an electrical double layer model including patchwise interfacial hydration. The origin of the data will be given below. The data used are the values obtained in the p.z.c. For $\Delta\phi_{Ag^+}^{R}(\text{dip})$, $\Delta\phi_{I^-}^{R}(\text{dip})$, and $\Delta\phi_{AgI}(\text{dip})$ we have introduced -94 mV, $+34$ mV, and -140 mV respectively. $F\Gamma_{Ag^+}$ and $F\Gamma_{I^-}$ are both 1 $\mu C/cm^2$, whereas the relative dielectric constant ε^H was given a value of 6. Substituting these parameters into the Helmholtz-equation [1] the averaged number of oriented water dipoles nm^{-2} (inclusive sign indicating polarity) $\bar{n}_{Ag^+}^{\perp}$, $\bar{n}_{I^-}^{\perp}$, and $\bar{n}_{AgI}^{\perp}$ can be calculated as -0.81, $+0.29$, and -1.21 respectively. For Ag^+ and I^- patches this corresponds to a number of 11 and 5 effectively oriented water molecules per adsorbed p.d. ion respectively. These values seem rather high for half the hydration of a single ion. Although effectively the number of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

oriented water molecules are not only in contact with an adsorbed ion, but also with neighbouring (partly charged) atoms of the same kind, it is likely that a number of 11 water molecules on an Ag^+ patch is too high. Other values for $\Delta\phi^R_{Ag^+}$(dip) and $\Delta\phi^R_{I^-}$(dip) as resulting from a different parameter choice give a worse correspondence of calculated and experimental charge–potential curves. However, it must always be realized that assignment of reliable hydration numbers is thwarted by the uncertainty inherent in the choice of ε^H, as discussed above.

Adsorption of p.d. Ions and the Nernst Equation

Unlike the surface charge, given in [13], the individual surface excesses Γ_{Ag^+} and Γ_{I^-} are experimentally inaccessible. However, in order to obtain $\Delta\phi$(dip) these individual values are needed. They can be obtained by assuming some adsorption model and by making a proper choice of the isotherm parameters.

The adsorption of p.d. ions is an equilibrium process. This means that the electrochemical potentials ($\tilde{\mu}$) of these ions in the bulk of the solid (S), the interface (I), and the bulk of the solution (L) must be equal.

$$[15]\quad \tilde{\mu}^S_{Ag^+} = \tilde{\mu}^I_{Ag^+} = \tilde{\mu}^L_{Ag^+}$$

$$[16]\quad \tilde{\mu}^S_{I^-} = \tilde{\mu}^I_{I^-} = \tilde{\mu}^L_{I^-}$$

To split the electrochemical potentials of the interface into an electrical and a chemical contribution the position of the interface has to be fixed. The electrochemical potentials of p.d. ions in the two bulk phases are readily given by [17] to [20].

$$[17]\quad \tilde{\mu}^S_{Ag^+} = \tilde{\mu}^{S0}_{Ag^+}(T) + F\phi^S$$

$$[18]\quad \tilde{\mu}^S_{I^-} = \tilde{\mu}^{S0}_{I^-}(T) - F\phi^S$$

$$[19]\quad \tilde{\mu}^L_{Ag^+} = \tilde{\mu}^{L0}_{Ag^+}(T) + RT\ln c_{Ag^+} + F\phi^L$$

$$[20]\quad \tilde{\mu}^L_{I^-} = \tilde{\mu}^{L0}_{I^-}(T) - RT\ln c_{I^-} - F\phi^L$$

The potentials ϕ^S and ϕ^L are unmeasurable in principle, but variations of $\Delta\phi = \phi^S - \phi^L$ are accessible because they are related to changes of cell potentials. If the indifferent electrolyte concentration is much higher than c_{Ag^+} and c_{I^-}, the ionic strength is approximately constant during variations of c_{Ag^+} and c_{I^-}. The (constant) activity coefficients are then included in $\tilde{\mu}^{L0}_{Ag^+}$ and $\tilde{\mu}^{L0}_{I^-}$.

Equating [17] and [19] or [18] and [20] leads to the *Nernst equation.*

$$[21]\quad \Delta\phi = \tilde{\mu}^{L0}_{Ag^+}(T) - \tilde{\mu}^{S0}_{Ag^+}(T) + (RT/F)\ln c_{Ag^+}$$

$$[22]\quad \Delta\phi = \tilde{\mu}^{L0}_{I^-}(T) - \tilde{\mu}^{S0}_{I^-}(T) - (RT/F)\ln c_{I^-}$$

The Nernst equation is a relation between bulk properties of the system. Interfacial quantities, particularly interfacial potentials, are only obtainable by introducing model assumptions for the adsorption of p.d. ions. In our picture, it is assumed, that the adsorption of p.d. ions occurs on a lattice consisting of a finite number of adsorption sites. Let ϕ^A be the electrical potential in the adsorption plane. The potential ϕ^A will be equal for the adsorption of Ag^+ and I^- ions. This is so because for ϕ^A we substitute the average electrostatic macropotential, which is the same for each site by definition. Local deviations due to the discreteness of the charges are in first instance independent of Γ_{Ag^+} and Γ_{I^-} and are incorporated in $\tilde{\mu}^{I0}_{Ag^+}$ and $\tilde{\mu}^{I0}_{I^-}$. For a p.d. ion to become adsorbed from the solution, it must pass through the diffuse layer, the Stern layer, and the hydration layer successively. Hence, $\Delta\phi$(ads) can be written as [23].

$$[23]\quad \Delta\phi(\text{ads}) \equiv \phi^A - \phi^L = \Delta\phi(\text{diff}) + \Delta\phi(\text{mol}) + \Delta\phi(\text{dip})$$

Potential differences due to volume charges in or polarization of the solid phase are not included in [23], because we assumed positive excess adsorption values of p.d. ions being present *on* the solid surface.

We assume, that the adsorption of p.d. ions satisfies a *Langmuir equation.* The interfacial electrochemical potentials can then be written as

$$[24]\quad \tilde{\mu}^I_{Ag^+} = \tilde{\mu}^{I0}_{Ag^+} + RT\ln\frac{\Gamma_{Ag^+}}{\Gamma^{max}_{Ag^+} - \Gamma_{Ag^+}} + F\phi^A$$

$$[25]\quad \tilde{\mu}^I_{I^-} = \tilde{\mu}^{I0}_{I^-} + RT\ln\frac{\Gamma_{I^-}}{\Gamma^{max}_{I^-} - \Gamma_{I^-}} - F\phi^A$$

Our ultimate aim is to establish a relation between σ and $\Delta\phi$ (or between σ and c_{Ag^+} or c_{I^-}). To that end we have to express Γ_{Ag^+} and Γ_{I^-} as a function of σ. The values of Γ_{Ag^+} and Γ_{I^-} can be related with [15], [16], [17], [18], [24], and [25].

$$[26]\quad RT\ln\frac{\Gamma_{Ag^+}}{\Gamma^{max}_{Ag^+} - \Gamma_{Ag^+}}\frac{\Gamma_{I^-}}{\Gamma^{max}_{I^-} - \Gamma_{I^-}} = \tilde{\mu}^{S0}_{Ag^+} + \tilde{\mu}^{S0}_{I^-} - \tilde{\mu}^{I0}_{Ag^+} - \tilde{\mu}^{I0}_{I^-} = K$$

Hence, $\Gamma_{Ag^+}(\sigma)$ and $\Gamma_{I^-}(\sigma)$ can be solved from [13] and [26]. The value of K is related to the adsorption values of Ag^+ and I^- in the p.z.c. ($\sigma = 0$ and $\Gamma_{Ag^+} = \Gamma_{I^-}$) and hence to the molecular partial free energies of adsorbed ions. It is interesting to note, that [26] resembles an expression for the "solubility product in the interface", analogous to the solubility product in solution, which follows from [19] and [20].

Finally, the equations presented in this section enable the calculation of the potential difference between the bulk of the solid and the adsorption

plane. The value of $\Delta\phi$(solid) follows from equating [17] and [24] (or alternatively from [18] and [25]).

$$[27]\quad \Delta\phi(\text{solid}) \equiv \phi^S - \phi^A = \frac{\mu^{IO}_{Ag^+} + \mu^{SO}_{Ag^+}}{F} + \frac{RT}{F}\ln\frac{\Gamma_{Ag^+}}{\Gamma^{max}_{Ag^+} - \Gamma_{Ag^+}}$$

The necessity of a non-zero potential difference in the solid is thus a consequence of thermodynamic equilibrium within the theoretical framework presented. However, the molecular interpretation of $\Delta\phi$(solid) is not so clear. It may be due either or both to free space charges (Frenkel defects) and molecular polarization of the solid. We recall, that in our picture we neglect the presence of a space charge in the solid phase attributing the surface charge entirely to p.d. ions adsorbed at the interface proper.

It may be repeated, that for the purpose of our analysis only those components of the potential differences have to be accounted for, that are dependent on the surface charge or on the adsorption of ions or molecules. Other contributions, such as a constant dipolar potential inside the solid, may be included in the standard electrochemical potentials (e.g. $\tilde{\mu}^{IO}_{Ag^+}$).

The Point of Zero Charge

In the absence of specific adsorption the p.z.c. of AgI (pAg = 5.67) does not coincide with its stoichiometric equivalence point (pAg = 8.1). It is possible to interpret this fact within the theoretical framework of the previous section. In addition a more quantitative explanation can be offered by application of the principles of the patchwise hydrated interface model.

We assume, that the covalent part of the free energies of bonding for Ag^+ and I^- ions to the AgI surface is equal on the argument that bonding of each of these ions involves the forming of an AgI bond. Let this contribution be G^{cov}_{AgI}. Then the difference in affinity of the adsorption from solution is only a function of the difference of the hydration free energy in the surface ($G^{h,I}_{Ag^+}$, $G^{h,I}_{I^-}$) and in the solution ($G^{h,L}_{Ag^+}$, $G^{h,L}_{I^-}$). As silver ions are more difficult to dehydrate than iodide ions, they have a lower adsorption in the stoichiometric equivalence point. From this it follows immediately that the p.z.c. is to the positive side of the stoichiometric equivalence point, that is: at lower pAg.

The standard affinities of the p.d. ions for the AgI surface may be defined as

$$[28]\quad \Delta G^0_{Ag^+} = G^{cov}_{AgI} + G^{h,I}_{Ag^+} - G^{h,L}_{Ag^+} \quad (= \tilde{\mu}^{IO}_{Ag^+} - \tilde{\mu}^{LO}_{Ag^+})$$

$$[29]\quad \Delta G^0_{I^-} = G^{cov}_{AgI} + G^{h,I}_{I^-} - G^{h,L}_{I^-} \quad (= \tilde{\mu}^{IO}_{I^-} - \tilde{\mu}^{LO}_{I^-})$$

Considering that

$$\Gamma_{Ag^+}(\text{p.z.c.}) \ll \Gamma^{max}_{Ag}$$

and

$$\Gamma_{I^-}(\text{p.z.c.}) \ll \Gamma^{max}_{I^-},$$

the difference in standard affinities can be directly related to the position of the p.z.c. by application of [19], [20], [24], [25], [28], and [29].

$$[30]\quad \Delta G^0_{Ag^+} - \Delta G^0_{I^-} = 2.30RT[\text{pL} - 2(\text{pAg})_{pzc}] - 2F\Delta\phi\,(\text{dip})_{pzc} - RT\ln\frac{\Gamma^{max}_{Ag^+}}{\Gamma^{max}_{I^-}}$$

We have assumed the absence of any specifically adsorbing electrolyte in the p.z.c. Further, we used $\Delta\phi(\text{ads})_{pzc} = \Delta\phi(\text{dip})_{pzc}$ and the following expression for the solubility product of AgI in solution.

$$[31]\quad \text{pL} = -\log(c_{Ag^+}c_{I^-}) = \text{pAg} + \text{pI}$$

The last term in [30] is comparatively small and we shall neglect it in the following.

Equation [30] can be applied after making proper choices of the parameters. The value of $\Delta\phi(\text{dip})_{pzc}$ can be estimated from the maximum shift of the p.z.c. upon adsorption of non-polar or weakly polar organic molecules (7, 8). A value of -200 mV appears to be a good estimation. Using for the p.z.c. and pL the familiar values of 5.67 and 16.11 respectively, we find

$$[32]\quad \Delta G^0_{Ag^+} - \Delta G^0_{I^-} = 26.9RT = 65.6\ \text{kJ/mol}$$

If the AgI were structureless and the adsorbed Ag^+ and I^- ions were halfway immersed in the solid then upon adsorption the Ag^+ and I^- ions would be halfway dehydrated. In this case the difference in adsorption free energy would be half the difference of the bulk Gibbs energies of hydration, i.e. (479.4 − 257.1)/2 = 111 kJ/mol. The actual difference is lower, indicating that the effective dehydration is less than half. This is in accordance with the picture, that each adsorbed Ag^+ and I^- ion is surrounded by a number of ions of the same kind, giving a reinforcement of the hydration effect at the interface.

It must be realized that the shift of the p.z.c. upon adsorption of organic molecules is due to the variation of both the electrical and the chemical part of the difference in adsorption free energy of the two p.d. ions. If upon adsorption of the p.d. ions from a (dilute) aqueous solution of organic molecules the ions are more strongly dehydrated than they are from pure aqueous electrolyte, $\Delta G^0_{Ag^+} - \Delta G^0_{I^-}$ will be larger and consequently, a larger shift of the p.z.c. to more posi-

tive potentials is expected. Hence, the interpretation of the shift of the p.z.c. in terms of a dipolar potential on a neutral surface is thwarted by the lack of information of the separation of the electrical and chemical part. Consequently, one must be aware, that conclusions on the net orientation of water molecules at the silver iodide surface based on the shift of the p.z.c. must be taken with due care.

The Charge–Potential Relation

The model developed enables us to evaluate the relation between the surface charge σ and the Galvani potential difference $\Delta\phi = \phi^S - \phi^L$ or the pAg. To that end the components of ϕ are calculated as a function of σ.

$$[33] \quad \Delta\phi = \Delta\phi(\text{solid}) + \Delta\phi(\text{dip}) + \Delta\phi(\text{mol}) + \Delta\phi(\text{diff})$$

Expressions for the first three terms have already been given. The potential in the diffuse layer follows from the Poisson–Boltzmann equation for a flat surface.

$$[34] \quad \Delta\phi(\text{diff}) = \frac{2RT}{F} \sinh^{-1}\left(\frac{\sigma F}{2\varepsilon_0 \varepsilon^L RT\kappa}\right)$$

$$[35] \quad \kappa^2 = 2cF^2/\varepsilon_0\varepsilon^L RT$$

Here ε^L is the relative dielectric constant of the solution containing a (1–1) electrolyte of concentration c. The parameter κ is usually called the reciprocal thickness of the diffuse double layer. In our picture, for σ the surface charge is substituted, as specific adsorption is neglected.

We are now in a position to calculate the charge–potential curves theoretically by assigning proper values to the different parameters. The parameters are chosen so as to obtain an optimal fit to the experimental charge–potential curve.

The relative dielectric constant ε^M and the thickness of the Stern layer, d, are chosen as 6 and 0.5 nm respectively. These values are close to those obtained in earlier work (9). The apparent relative dielectric constant for the Stern layer at mercury is frequently (1) also taken as 6, whereas the thickness of the Stern layer at AgI is expected to exceed the corresponding value at mercury (ca. 0.3 – 0.4 nm) due to the radii of the silver and iodide ions of the crystal lattice.

We have estimated the value of $\Delta\phi(\text{dip})_{\text{pzc}}$ as -200 mV. This is almost identical to the value of -192 mV derived from the butanol work (2). This value is split up into -140 mV for $\Delta\phi_{\text{AgI}}(\text{dip})$ and -60 mV for $\Delta\phi^R_{\text{Ag}^+}(\text{dip}) + \Delta\phi^R_{\text{I}^-}(\text{dip})$. This choice followed from the optimization considering the fact that the number of water molecules to be oriented by Ag^+ and I^- ions is limited.

$F\Gamma^{\max}_{\text{Ag}^+}$ and $F\Gamma^{\max}_{\text{I}^-}$ were rather arbitrarily chosen as 15 μC/cm^2, which was considered as realistic. However, this choice is not critical at all, as long as the value exceeds 1.5 times the surface charge.

Finally, two adjustable parameters are left, i.e. the surface excesses of the two p.d. ions at the p.z.c. and the ratio $k_{\text{Ag}^+}/k_{\text{I}^-}$.

The values of Γ_{Ag^+} and Γ_{I^-} are solved from [13] and [26] as explained above. The potentials $\Delta\phi$(Stern), $\Delta\phi$(dip), $\Delta\phi$(solid), and $\Delta\phi$(diff) follow from [2], [14], [27], and [34], realizing that $\Delta\phi$(solid) at the p.z.c. is set equal to zero. Further, $\Delta\phi$ follows from [33] and the pAg is then calculated according to the Nernst equation. Following the procedure given, an optimal correspondence between the calculated and experimental charge potential was obtained, if the surface excesses of the two p.d. ions at the p.z.c. would correspond to $+1.0$ and -1.0 μC/cm^2 respectively and if the ratio $k_{\text{Ag}^+}/k_{\text{I}^-}$ amounts to 2.75. The agreement between the two curves is illustrated in Fig. 1. The correspondence between the calculated and experimental curve is excellent, except at the extreme negative side where the calculated curve somewhat exceeds the experimental one. A likely reason for this discrepancy is that at extreme negative surfaces specific adsorption of counter ions may not be neglected. Some numerical results obtained with these data are summarized in Table 1.

The effect of the various input parameters on the final outcome is quite different. It appears that ε^M, d, and $k_{\text{Ag}^+}/k_{\text{I}^-}$ do not affect the curvature of the charge–potential curve. Neither do the parameters $\Delta\phi_{\text{AgI}}(\text{dip})$, $\Gamma^{\max}_{\text{I}^-}$, and $\Gamma^{\max}_{\text{Ag}^+}$ affect the results significantly. However, the curvature is sensitive to the choices of $\Delta\phi^R_{\text{Ag}^+}(\text{dip})$, $\Delta\phi^R_{\text{I}^-}(\text{dip})$ and the surface excesses of the p.d. ions at the p.z.c. Other

[a]The following units are used: σ (μC cm^{-2}), $F\Gamma$ (μC cm^{-2}), Δφ (mV).
[b]Δφ(solid) is given relative to its value at the p.z.c.
[c]Experimental data from ref. 2. The reproducibility of the experimental curve is ca. 0.05 μC/cm^2 but deteriorates at the ends of the curve. The absolute accuracy depends mainly on the uncertainty of the specific surface area, which is much higher but of no consequence for the present analysis because it would affect the entire curve by a constant factor.

assignments of values to these parameters may mathematically appear equally successful but they are in the author's opinion physically less realistic.

The calculations are performed for a concentration of indifferent electrolyte of 0.1 *M*. As is shown by Lijklema (9) the differences between curves at different salt concentrations are completely accounted for by the different contribution of the diffuse part of the double layer. Hence, our model is also compatible with the behaviour of charge–potential curves at other salt concentrations.

Comparison with Previous Work

Mackor (10) has already interpreted charge–potential curves on AgI qualitatively by assuming a constant Stern layer capacitance and a variable dipolar potential. The behaviour of the dipolar potential on mercury and AgI were assumed to be equivalent. In later studies with the AgI system little attention has been paid to the dependence of the dipolar potential on the surface charge.

The steep rise in capacitance at the positive side of the p.z.c. is typical for the AgI system. In previous work, this has been explained by assuming that silver ions are adsorbed as $AgNO_3$ (9, 11). However, to this explanation some objections can be raised. The capacitance rise is also quite pronounced for the fluoride ion, although with this ion the p.z.c. is not shifted at all, indicating absence of specific adsorption, at least at the p.z.c.

Comparison with Other Models

Apart from the solute and solvent orientation, the given model is equivalent with the ionizable surface group model as described by Healy and White (12). Introduction of surface equilibria is equivalent to using the Langmuir model for the adsorption of p.d. ions. However, in the Healy and White model the charge–"potential" relation is almost linear over the same experimental range of charges as encountered in the AgI case, i.e. this picture implies a constant capacitance.

Trasatti (1) has reviewed the various models for the mercury–electrolyte interface in some detail. All these models predict an almost linear relationship of the potential with surface charge for charge-densities between +4 and −4 μC/cm^2, contrary to our model. It can be inferred from Table 1 that in our model the variation of dipolar potential with surface charge is in the order of 50–100 mV/μC cm^{-2}. For mercury Bockris and Habib (13) calculate 8 mV/μC cm^{-2}, whereas on the other extreme Levine *et al.* (14) find 360 mV/μC cm^{-2}. The other models discussed by Trasatti predict potential drops in the order of 30–50 mV/μC cm^{-2}. This is also the case for Parsons' model (15) in which a four-state water orientation was assumed with single water molecules and clusters. It is interesting, that in Parsons' model also an asymmetry of the charge–potential curves can arise around the p.z.c. dependent on a difference in free energy of the water clusters in the two orientations.

Conclusions

In this article we offered a patchwise hydration model for the interface between silver iodide particles and aqueous electrolyte solutions. Although several simplifying assumptions were made it was shown that with the present picture some typical properties of the AgI system, such as the asymmetry of the capacitance curve and that of the p.z.c. could be accounted for. Therefore, the model holds promises

for further quantitative analysis of other hydration-sensitive properties, such as the adsorption maximum of organic substances. In addition, it can be helpful in better understanding the quantitative differences between the double layers on mercury, silver iodide, and other systems.

Solvent accessibility and hydrophobicity in the adsorption of alkylammonium cations at air/water and Hg/water interfaces. Part 1. Behavior at the air/water interface in relation to hydration properties

R. BENNES[1] AND B. E. CONWAY

Chemistry Department, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received September 18, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

R. BENNES and B. E. CONWAY. Can. J. Chem. **59**, 1978 (1981).

By means of adsorption and surface-potential studies on a series of $R_{4-n}N^+H_n$ perchlorates at the air/water interface, the role of hydrophobic and hydrophilic interaction in the adsorption and ion distribution of these salts near the air/water interface is examined. While the adsorption of the alkylamine ions increases as n decreases from three to zero, inclusive, the surface-potential change accompanying the adsorption decreases. This effect is interpreted in terms of opposing hydrophilic, electrostatic and hydrophobic interactions between the organic ion and water near the liquid surface, leading to a progressive change of double-layer ion distribution. In Part II, comparative studies of the same series of compounds at the Hg/water interface are reported.

R. BENNES et B. E. CONWAY. Can. J. Chem. **59**, 1978 (1981).

Faisant appel à des études d'adsorption et de potentiel de surface d'une série de perchlorate de $R_{4-n}N^+H_n$ à l'interface air/eau, on étudie le rôle de l'interaction hydrophobe et hydrophile lors de l'adsorption et de la distribution de l'ion de ces sels près de l'interface air/eau. Alors que l'adsorption des ions alkylamines augmente lorsque n décroît de trois à zéro inclusivement, le changement de potentiel de surface qui accompagne l'adsorption diminue. On interprète cet effet en fonction d'interactions hydrophiles électrostatiques et hydrophobes opposées entre l'ion organique et l'eau au voisinage de la surface du liquide, conduisant ainsi à un changement progressif de la distribution de l'ion dans la couche double. On rapporte dans une deuxième partie, des études comparatives portant sur les mêmes séries composés à l'interface Hg/eau.

[Traduit par le journal]

Introduction[2]

The R_4N^+ and related $R_{4-n}NH_n^+$ ($1 < n \leq 3$) series of ions have attracted much attention in recent years (e.g. refs. 1, 2) from the ionic solvation and solution-structure point of view, and the individual cation properties have been well characterised (3). The properties of individual ions are of special interest in adsorption at interfaces, particularly at charged surfaces where predominantly one type of ion of an electrolyte is preferentially adsorbed so that its individual properties are manifested in the interfacial behavior.

The surface activity of primary to quaternary alkylammonium cations is thus of interest in detergency, mineral flotation, corrosion inhibition (4), and in some electrochemical syntheses (5) where a local hydrophobic double-layer is required. Previous studies at electrodes have been concerned with super-equivalent adsorption of symmetrical (6–8) and unsymmetrical (9) tetraalkylammonium (R_4N^+) salts with varying chain length of R while corresponding alkylpyridinium ions have also been examined (10, 11). The structure of the double-layer in the presence of R_4N^+ ions is of particular interest (cf. refs. 6, 12), since the ionic radii of the higher R_4N^+ ions are larger than those of most anions, thus changing the usual situation (13) where an inner Helmholtz plane is populated by anions and outer one by hydrated cations. Recently interest has centered on R_4N^+ ions as "phase-transfer" agents (14) and on the question of the double-layer at interfaces of immiscible liquids other than Hg and water (15, 16).

Restriction of hydration of an ion near an interface of water with air or its vapor is a major factor in determining the generally observed (17, 24) negative adsorption of simple ions at air/water interfaces. This effect has been treated theoretically in terms of the image effect by Wagner (17), Onsager and Samaras (18), Bell and Rangescroft (19), and by Conway (20) in terms of restriction of Born polarization energy. Useful reviews have been given by Llopis (21) and by Randles (22). With alkylammonium ions, opposing effects due to hydrophobicity arise and lead to a tendency for positive adsorption, depending on the length and number of R groups coordinating the N^+ charge center.

Some aspects of alkylammonium adsorption at the Hg electrode interface with water have previously been studied by Piro, Bennes and Bon Karam (6), and by Kimmerle *et al.* (9), while earlier work of Conway *et al.* (10, 11) was concerned

with the adsorption of quaternary pyridinium and related cyclic N^+ ions at the Hg/water interface. More recently, the interesting question of the relation between the adsorption of $R_{4-n}N^+H_n$ ions at the Hg/water interface and their entropies of hydration was examined by Ikeda *et al.* (30). The adsorption behavior of R_4N^+ ions at the air/water interface was also studied by Krylov (34) and Gurenkov (35).

Alkylammonium ions are of interest (25) because they present situations of systematically varying accessibility of the N^+ centre to solvating H_2O dipoles. Related measurements previously carried out in this laboratory have led to useful information on the hydration and ionization behavior of these species with respect to steric effects in hydration (25, 26). The partial molal volumes (27) and compressibilities (28) of a series of $R_{4-n}NH_n^+$ ($n = 0 \rightarrow 4$) salts were studied, as well as the H_2O–D_2O solvent isotope effects (26) on these thermodynamic properties, giving the transfer functions for $H_2O \rightarrow D_2O$. Thus, a considerable volume of information exists on the hydration behavior of these ions and on the role of hydrophobicity and hydrophobic interactions (1, 29) which can arise in their solutions at finite concentrations.

In the present papers (Parts I and II), we report investigations on the adsorption behavior and associated surface potential changes for aqueous solutions of $R_{4-n}N^+H_n$ perchlorates (where $n = 0 \rightarrow 4$) at both the air/water and the Hg/water interfaces.

Surface-potential and surface-tension measurements at the air–water interface enable the changes of surface potential, $\Delta\chi$, to be related to the surface excess, Γ, of the salt and to effects on the orientation of water molecules at the solution surface (31). The use of a series of salts with a common anion and with cations having varying accessibility to water solvent dipoles enables the relation between the opposing effects of hydrophobicity and hydration in adsorption to be explored.

Surface-tension measurements at the Hg/water interface enable a more detailed study to be made of the adsorption of the $R_{4-n}NH_n^+$ ions since the behavior as a function of surface charge density or electrode potential is thermodynamically accessible. At the Hg/water interface, similar hydrophobic adsorption effects will arise as at the air/water interface but, in addition, coulombic interaction between the charged Hg surface and the $R_{4-n}N^+N_n$ cations in the double-layer will be involved as well as image interactions of a different sign (17, 20) to those of the air/water interface.

The combined results enable some useful comparisons to be made on the *same type of ions* at the air/water and Hg/water interfaces.

Experimental

(1) Choice of Systems

$R_{4-n}N^+H_n$–perchlorates were used in order to compare the adsorption behavior at the air/water interface with that at Hg (Part II) where use of ClO_4^- as a counter anion minimizes specific adsorption of the anion (F^- could also have been used but was avoided for reasons connected with obvious difficulties in the preparation of impurity-free solutions of $R_{4-n}N^+H_n$-fluorides). Measurements were made in an excess of aq. $HClO_4$ (1 *M*) as supporting electrolyte (*a*) in order to make comparisons with the present and other results obtained at the Hg electrode in a similar supporting electrolyte; (*b*) in order to minimize concentration-dependent diffuse-layer effects (18, 19) at the air/water interface due to preferential adsorption of cations or anions, and (*c*) to ensure (cf. refs. 10, 32) that the alkylamine species in solution is predominantly in the cationic form.

(2) Surface Potential Measurements

$\Delta\chi$ values at the air/water interface were measured by the Kelvin–Volta method using a vibrating plate capacitor. The principles of this method have been fully described elsewhere (33, 36). The test solution was contained in a water-jacketed cell, thermostatted at 298 ± 0.1 K and provided with a solution bridge to a Ag/AgCl reference electrode. The whole cell was maintained in a small Faraday cage inside a thermostatted closet (±1°C) and mounted on a basement floor in order to minimize vibration. The solution meniscus was 7 cm in diameter to ensure a flat surface. The vibrating capacitor plate could be adjusted by means of a micrometer mounted on a rigid frame and reproducibility of its position with respect to the solution meniscus was achieved by lowering the plate and vibrator by means of the micrometer until an auxiliary point contact indicated electrical connection with the conducting solution. Measurements were made at low vibration amplitudes with the plate as close to the surface as possible. $\Delta\chi$ values are then independent of the position of the plate at close proximities to the surface.

The electronic instrumentation included a Tinsley highly tuned detector amplifier and a high impedance cathode follower (Keithley Instruments), as described by Pethica *et al.* (36). Null-point detection, in which the potential supplied from a potentiometer exactly opposed the solution surface potential, $\Delta\chi$, was achieved by observing the form of the elliptical Lissajous figure generated on an oscilloscope by combining the ac driving signal to the vibrator and the ac signal generated by the vibrating plate at the liquid surface on the X- and Y-plates of an oscilloscope, after the latter signal had been communicated to the oscilloscope by means of the cathode follower.

(3) Surface Tension Measurements

The surface tension of pure water (see below) and the test solutions was measured by the de Noüy ring method (37–41) using a Fisher-Cahn electrobalance. The liquid surface was maintained in a cell thermostatted at 298 ± 0.1 K and situated in a closed box in the electrobalance chamber. The whole system was set up in the thermostatted closet mentioned above. The surface tension values were derived from recorder plots of the maximum force required to withdraw the Pt ring from the surface using the calibration corrections tabulated by Harkins and Jordan (38). The surface tension values were reproducible

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

to ca. 0.2 dyn cm^{-1} and their absolute accuracy was estimated at 0.5 dyn cm^{-1}, referred to pure water as the calibrating material.

(4) Water and Electrolyte Solutions

Pyrodistilled water, specially prepared as described recently (42), was used for the surface tension and surface potential measurements on the salt solutions. This water had been previously shown (42) by sensitive electrochemical measurements at Pt to be free of organic surface-active impurities. Salt solutions were made up from the redistilled amines by titrating them into $HClO_4$ (Fisher ACS grade) solutions in the purified water. *n*-$Pr_4N^+ClO_4^-$ was prepared by titrating a solution of the tetra-*n*-propylammonium hydroxide (Aldrich Chemical Co.) into the aq. $HClO_4$. Measurements were also made on the aq. $HClO_4$ supporting electrolyte itself at various concentrations.

Results

The changes of surface tension, $\Delta\gamma$, of 1 *M* aq. $HClO_4$ solution due to various concentrations, *c*, of $R_{4-n}N^+H_n$ as perchlorates are shown in Fig. 1. The concentration range for the salts with $n > 2$ is limited by the restricted solubility of the ClO_4^- salts, especially the $(n\text{-Pr})_4N^+$ salt. The corresponding surface excess data, Γ, derived from the Gibbs equation[3] are shown in Fig. 2. The $\Delta\chi$ values, are plotted in Fig. 3 (*a*), (*b*), vs. *c* and Γ, respectively. While *n*-$Pr_4N^+ClO_4^-$ is the most strongly adsorbed salt (Figs. 1, 2), it is evident from Fig. 3 that it produces the *smallest* relative $\Delta\chi$. Thus, $\Delta\chi$ *increases* with decreasing hydrophobicity while the adsorbability, as measured by positive Γ values, decreases in this direction.

The relative effects are demonstrated by plotting $\Delta\chi$ vs. log *c* and evaluating the slopes which are analogous to Esin and Markov coefficients (43) in electrochemical studies of adsorption at the Hg electrode.Fig. 4 shows such plots while Fig. 5 shows the slopes, $d\Delta\chi/2.3d \log c$, vs. the number of *n*-Pr chains or total number of C atoms (as CH_2 or CH_3).

Figures 1, 2, and 4 show that $\Delta\chi$ is displaced to more positive values as the concentration of *n*-$Pr_{n-4}N^+H_n$ is increased but the displacement is less in the order $PrNH_3^+ > Pr_2NH_2^+ > Pr_3NH^+ > Pr_4N^+$. The relations between $\Delta\chi$ and log *c* are linear and have the following slopes, expressed in units of RT/F: *n*-$PrNH_3^+$, 3.97; $(n\text{-Pr})_2NH_2^+$, 2.66; $(n\text{-Pr})_3NH^+$, 1.0; and $(n\text{-Pr})_4N^+$, 0.3. For aq. $HClO_4$, the slope is 1.66. However, for the alkylammonium ions, it is to be

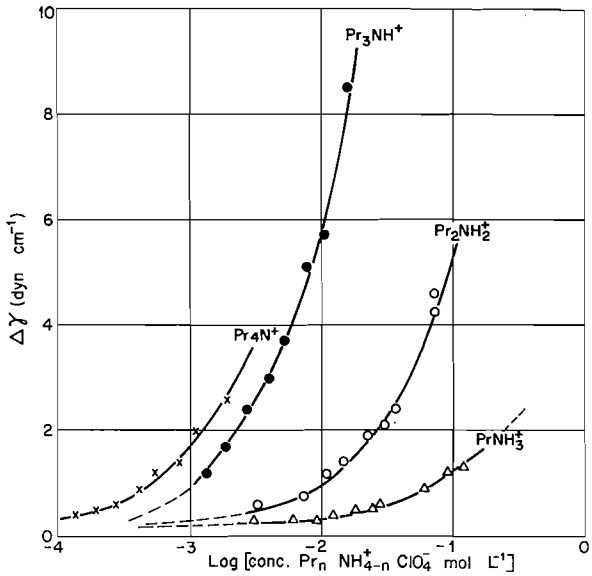

FIG. 1. Surface-tension change, $\Delta\gamma$, of the air/water interface as a function of log [concentration] of *n*-propylammonium perchlorates in 1 *M* aq. $HClO_4$ at 298 K.

remembered that all the results are obtained in an excess (1 *M*) of $HClO_4$ as supporting electrolyte so that the Debye parameter κ is constant with $1/\kappa \doteqdot 0.5$ nm, giving a constant shielding effect (18, 19) in the interphase region. Since ClO_4^- is a common anion between the supporting electrolyte and the added alkylammonium salt, the changes of γ and $\Delta\chi$ are due predominantly (apart from activity coefficient effects) to the adsorption of the organic cation, including any effects it has on the orientation of water dipoles at the air/water interface (cf. refs. 20, 31).

Discussion

(1) Relation between $\Delta\chi$ and Extent of Adsorption

In order to provide a basis for interpretation of the electrical aspects of adsorption behavior of the alkylammonium salts at the air/water interface, it is first necessary to state the main factors which give rise to changes of χ. These are (*a*) differential distribution of cations and anions near the interface due to different distances of closest approach connected with different radii of primary solvation shells of cations and anions. This gives rise to a double-layer p.d. near the interface; (*b*) differential distribution of cations and anions near the interface due to different charges on the ions (19) (inapplicable to the conditions of the present experiments); (*c*) effects of the ion on the intrinsic surface dipole p.d. at the water interface which arises from residual net orientation of H_2O dipoles (20, 21); and

[3]Unfortunately, the Γ values are not strictly thermodynamic due to the lack of activity coefficient data for salts of the type studied here. This has been a problem also in other work (6–12). Mohilner *et al*. (ref. 18 in Part II which follows) have discussed this problem in some detail and obtained some activity coefficient data for neutral molecules of interest in adsorption studies at Hg but reliable data are lacking for R_4N^+ types of adsorbates.

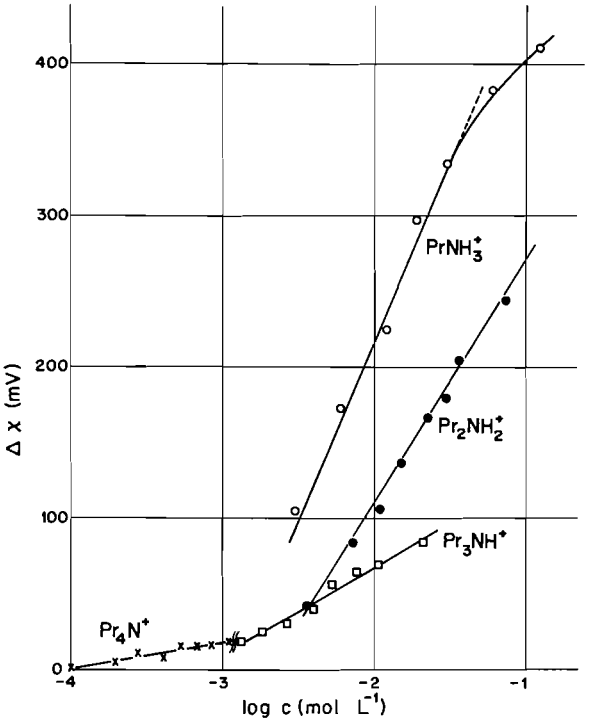

FIG. 4. Surface-potential changes, $\Delta\chi$, due to adsorption of n-propylammonium perchlorates as a function of the *log* of their concentrations.

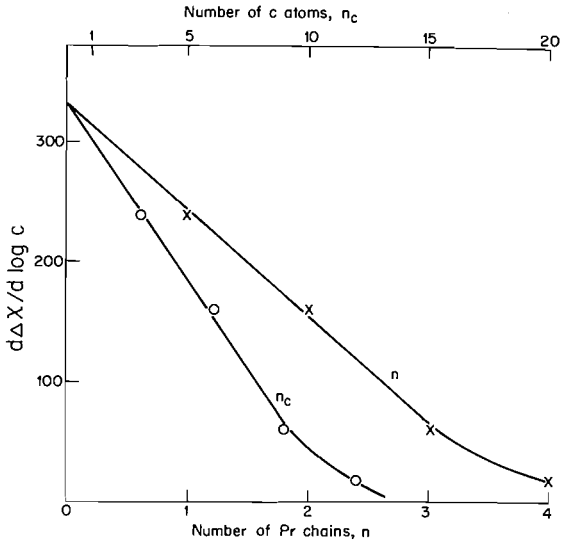

FIG. 5. Slopes, $d\Delta\chi/d \log c$, of the lines of Fig. 4 plotted against the numbers, n, of n-Pr chains or the number n_c of C atoms in the molecule, for the series of n-propylammonium perchlorates.

(d), connected with (c) above, any interaction (20) of the hydration co-sphere of the ion with the region of net orientation of water dipoles near the water interface. Factors (a) and (c) are probably the most important ones in the adsorption behavior of the alkylammonium ions.

The values of $\Delta\chi$ for n-$PrNH_3^+$ and $(n\text{-Pr})_2NH_2^+$ are relatively large[4] in comparison with those generated by simple salts. Large values, but at higher concentrations, were also found by Frumkin (46), Randles (22), and by Zagorska and Koczorowski (23) in the case of Me_4N^+ and Et_4N^+ salts. However, these $\Delta\chi$ values are opposite in sign from those for simple salts and for the present alkylamine salts.

Comparison of the behavior in Figs. 1 and 3 shows that the ions which are most strongly (positively) adsorbed give the least change of surface potential. This trend, shown in Table 1, is closely connected with the extent of hydration of the alkylammonium ion as measured e.g. by the electrostriction (27) or the partial molal adiabatic compressibility (28). Thus, Fig. 6 shows how $d\Delta\chi/2.3$ d log c for the n-Pr series of salts varies with the partial molal compressibility and electrostriction (relative to n-Pr_4N^+) of a corresponding series of methylammonium or n-propylammonium salts. It is clear from this type of relation that the stronger the cation–water interaction, the less is the cation adsorbed but the greater is the relative change of surface potential, a situation of some considerable interest.

The data on which Fig. 6 is based are the additivity relations w.r.t. CH_2-groups in R chains in R_4N^+ and $R_{4-n}N^+H_n$ salts for partial molal volume and adiabatic compressibility measurements derived by Conway and Verrall (27, 28) and by Conway, Desnoyers, and Verrall (44).

This trend of the data in Fig. 6 may be rationalized by noting (a) that the more strongly an ion is

TABLE 1. Molecular areas* and Γ_{max} values for the alkylammonium ions

	Area (Å²)		$\Gamma_{max} \times 10^{10}$ (mol cm^{-2})	
Ion	⊥	∥	⊥	∥
n-$PrNH_3^+$	~19	27.2	~8.7	6.1
$(n\text{-Pr})_2NH_2^+$	~19	40.4	~8.7	4.1
$(n\text{-Pr})_3NH^+$	39.6	56.3	4.2	3.0
$(n\text{-Pr})_4N^+$	43.7	51.4	3.8	3.2

*These values differ appreciably from those of Kimmerle and Menard (7) for the corresponding amines which seem too large. Although the apparent projected areas can depend somewhat on the conformations of the n-Pr chains assumed, this cannot account for the discrepancies.

[4]Separate experiments on $HClO_4$ solutions up to 5.0 M in water showed that $\Delta\chi$ due to $HClO_4$ is 7 ± 2 mV at 1.0 M concentrations. All the results obtained with the alkylammonium salts represent changes of χ due to the added organic salt since the supporting electrolyte (1 M $HClO_4$) was kept at constant concentration of 1.0 M.

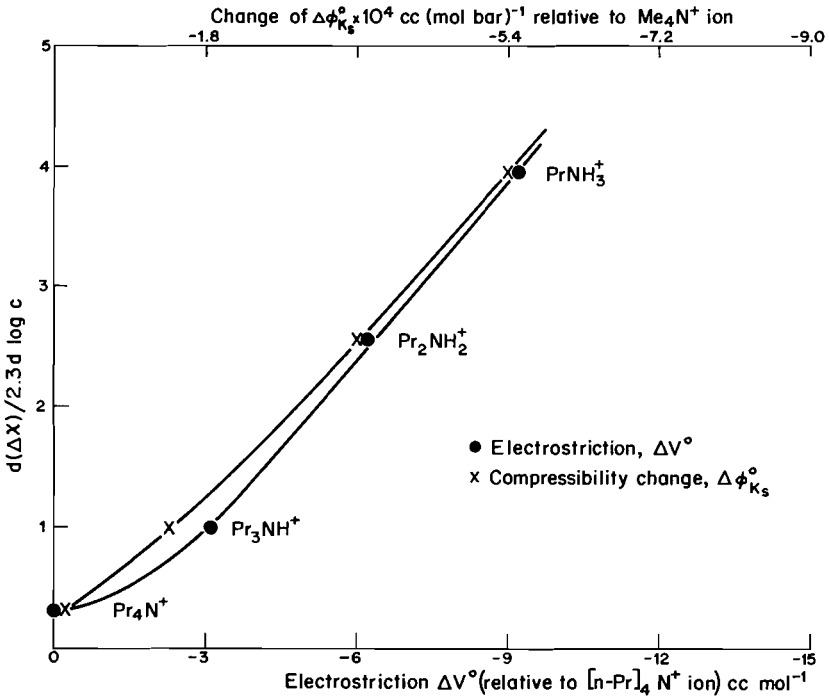

FIG. 6. Slopes, $d\Delta\chi/2.3\ d\log c$, in units of RT, for the effects of n-propylammonium perchlorates on $\Delta\chi$ at the air/water interface (1 M aq. $HClO_4$) plotted against two thermodynamic solution properties of these salts: $-\Delta V^0$, the electrostriction and $\Delta\phi_{K_s}{}^0$, the partial molar compressibility change at infinite dilution.

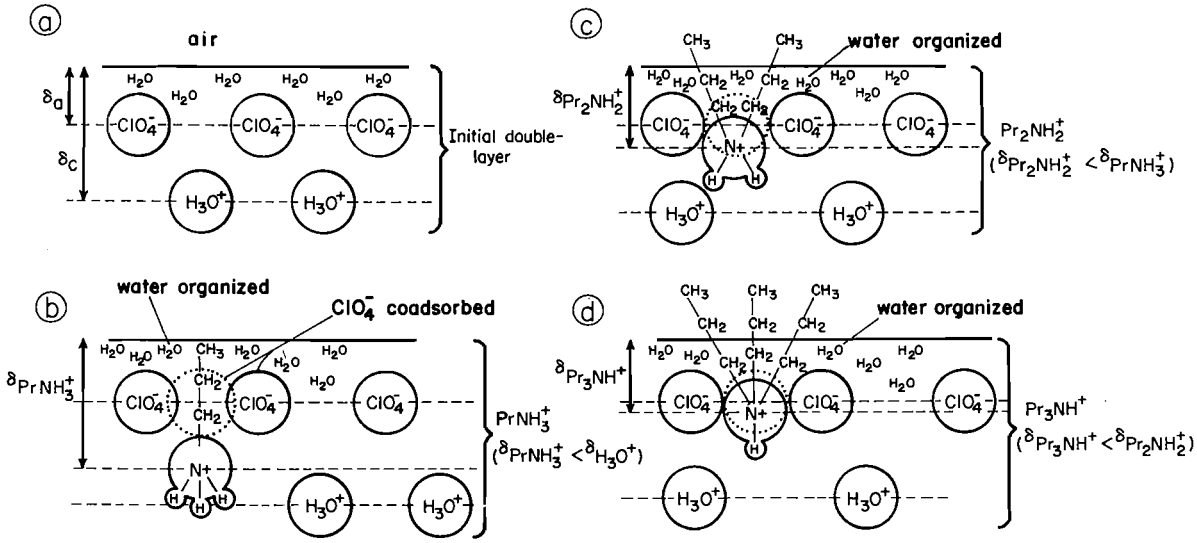

FIG. 7. Schematic model for cation/anion distribution with H_3O^+ and n-propylammonium cations in the air/water interphase.

hydrated, the greater is the tendency for it to be repelled[5] from the surface in order to minimize restriction of its interaction with the solvent dielectric; and (*b*) that the more hydrophobic is the ion (n decreasing in value from 4 → 0) the greater will be the tendency for it to be displaced out of the bulk water medium into the surface layer region where energetically unfavorable hydrocarbon–water interactions (47) are minimized. Thus, two opposing

[5]A distribution of ions repelled from the surface in fact arises, giving a diffuse-charge region (18, 19) over a distance dependent on the Debye κ parameter, as at electrode interfaces.

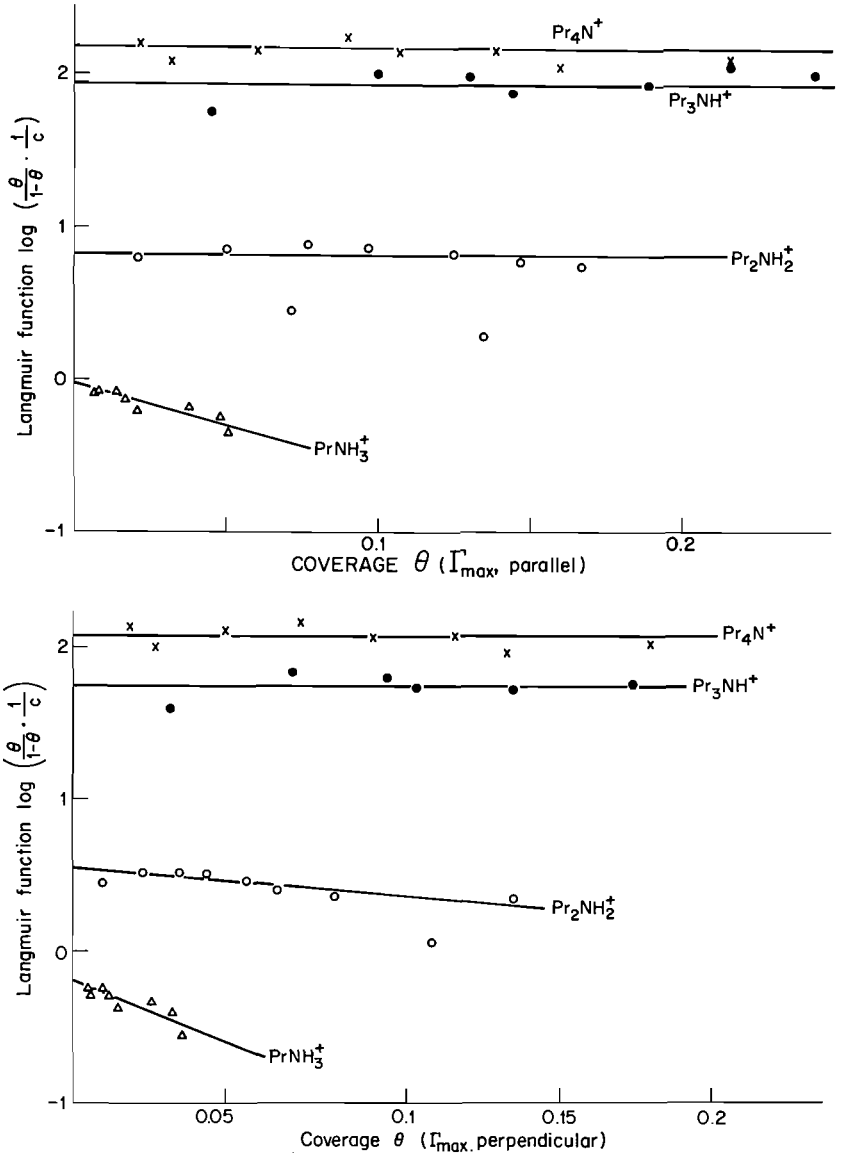

FIG. 8. Plot of the Langmuir adsorption function, $\log [\theta/(1-\theta)][1/c]$ vs. coverage θ for two estimates of Γ_{max}, giving the variation of $-\Delta G^0/RT$ for the adsorption process with coverage.

effects generate the trend of adsorption and surface potential behavior shown in Figs. 1–5.

The hydrophobic effect diminishes, as expected in the case of R_4N^+ salts, when the adsorption and $\Delta\chi$ measurements are made in progressively more methanolic solutions in CH_3OH–H_2O mixtures (23). This is consistent with the observed (45) lack of lyophobic interaction behavior of R_4N^+ salts in methanol.

In the behavior of this series of salts, the positive values of Γ do not uniquely signify that the alkyl chain resides above the surface in the air phase or the hydrophilic N^+ group just below the surface in the water phase that would otherwise be depleted of simple ions. The measured surface excess is one of cations and anions. Normally a large anion will be distributed up to a plane of closest approach to the interface which is nearer to the interface than that for simple cations which are relatively more hydrated (13, 20). As the number of chains is increased on the N^+ center, probably the cation would tend to be adsorbed progressively nearer to the surface of separation of the phases, so that the difference of position of the planes of approach of

For personal use only.

added alkylammonium cations and the solution anions tends to be reduced. The surface potential due to such an ionic double-layer would then tend to become diminished.

Since the alkyl chains may be supposed to be directed towards, or reside partly in, the air phase, an additional factor leading to a change of surface potential can arise, viz. an influence on the H_2O dipole contribution (cf. 31) to χ due to the effects of alkyl chains on the water structure at the surface on its local dielectric constant. This contribution to $\Delta\chi$ cannot, however, be separately evaluated.

The supposed progressive change of the distribution of cations and anions in the interphase near the air–water interface is shown schematically in Fig. 7 which illustrates how the double-layer ionic separation and consequent p.d. can diminish with increasing positive adsorption of the alkylammonium ion. The situation with the $(n\text{-Pr})_3N^+$ ion in Fig. 7*d*, or ultimately with the $(n\text{-Pr})_4N^+$ ion, is like that envisaged by Hayter and Hunter (12) for $R_3R'N^+$ ions at the Hg/water interface where adsorbed anions exist amongst the layer of adsorbed hydrophobic cations. This is consistent with the fact that it is found (6) that the Langmuir isotherm apparently applies (i.e. the apparent standard free energy of adsorption is independent of coverage θ up to $\theta = 0.8$) to the adsorption of Et_4N^+ at the Hg electrode. This means that repulsive coulombic interaction between Et_4N^+ ions must be attenuated by attractions between the Et_4N^+ ions and co-adsorbed anions and/or by hydration co-sphere sharing (see Part II).

(2) Coverage Dependence of the Free Energy of Adsorption, and Interaction Effects

Such effects are revealed by evaluation of the coverage-dependence of the apparent standard free energy of adsorption from a Langmuir type configurational free energy function $\ln [\theta/(1 - \theta)]$ for the adlayer. Thus, the standard free energy of adsorption ΔG^0 may be calculated in the usual way (6, 10, 11) from a Langmuir type isotherm function and its constancy examined with respect to coverage θ. Variation of ΔG^0 with θ indicates interaction and/or size effects not included in the isotherm expression.

In order to derive ΔG^0 values, some estimates of θ are required. Since $\theta = \Gamma/\Gamma_{max}$, where Γ_{max} is the surface excess at geometrical saturation of the surface, an evaluation of the molecular size of the adsorbate must be made to provide some estimates of Γ_{max}. These were obtained with the aid of Courtauld space-filling models which give the molecular areas and corresponding Γ_{max} values

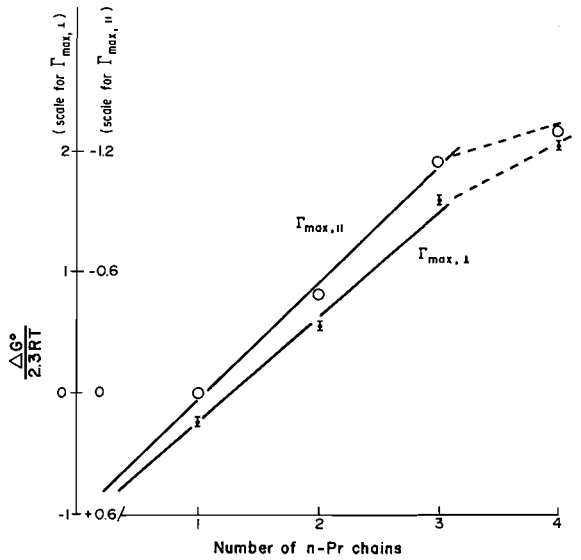

FIG. 9. Dependence of the apparent standard free energy of adsorption, ΔG^0, (as $\Delta G^0/2.3RT$) of the *n*-propylammonium perchlorates as a function of the number of *n*-Pr chains in the molecule.

shown in Table 1. Two mean orientations of the $R_{4-n}N^+H_n$ ions are possible giving two limiting Γ_{max} values for "perpendicular" ($\perp$) or "parallel" ($\parallel$) orientation at the surface, i.e. for the ions sitting "flat" or "standing up" at the surface — this difference is significant, of course, only for the ions for which $n > 0$. Of course, there will be molecular rotations or libration in the interphase, which averages out these differences.

Evaluations of ΔG^0 were made for both limiting values of Γ_{max} in Table 1. Figure 8 shows that ΔG^0 is surprisingly constant with increasing θ for $(n\text{-Pr})_4N^+$ and $(n\text{-Pr})_3NH^+$, while there is some evidence for $-\Delta G^0$ to become smaller with θ for $(n\text{-Pr})_2NH_2^+$ and $n\text{-PrNH}_3^+$ ions. This is consistent with the more separated layers of cations and anions in the interphase shown in Fig. 7. ΔG^0 also progressively becomes more negative with increasing number of *n*-Pr chains in an almost linear way (Fig. 9), paralleling the trend of decreasing $\Delta\chi$ with increasing ionic size (Fig. 6) and hydrophobicity. Similar effects are found for adsorption at the Hg electrode (Part II).

(3) Comparison with the Behavior at the Hg/Water Interface

It is of interest to compare the adsorption behavior of these salts at the air/water interface reported here with that at the Hg/water interface where the surface charge can be independently controlled. This forms the basis of Part II of this work, described in the following paper.

Received September 18, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

B. E. CONWAY and F. ROCHELEAU. Can. J. Chem. **59**, 1987 (1981).

The adsorption behavior of a series of *n*-propylammonium ions in which the N^+ center has varying accessibility to the solvent, and hence the ions exhibit varying hydrophobicity, is examined at the Hg/H_2O interface at various electrode potentials. With the most hydrophobic ion, $(n\text{-}Pr)_4N^+$, attractive interactions arise in the interphase. An attempt is made to explain this behavior in terms of Gurney hydration co-sphere sharing effects which are significant in 3-dimensional aqueous solutions of R_4N^+ salts.

The surface pressure behavior and Esin and Markov effects are also evaluated.

Comparisons are made with the adsorption and surface potential results reported in Part I for the air/water interface.

B. E. CONWAY et F. ROCHELEAU. Can. J. Chem. **59**, 1987 (1981).

Opérant à l'interface Hg/H_2O et à divers potentiels d'électrode, on étudie le comportement, lors de l'adsorption d'une série d'ions *n*-propylammonium dans lesquels le N^+ central est plus ou moins accessible au solvant et qui ont dans ce cas des caractères hydrophobes variés. Avec l'ion le plus hydrophobe $(n\text{-}Pr)_4N^+$ il se développe des interactions attractives à l'interface. On essaie d'expliquer ce comportement en fonction des effets de partage de la cosphère d'hydratation de Gurney tels qu'il en existe d'une façon importante en trois dimensions de sels R_4N^+.

On a également évalué le comportement de la pression de surface et les effets de Esin et Markov.

On a établi des comparaisons avec les résultats d'adsorption et de potentiel de surface relatifs à l'interface air/eau publiés dans la première partie de ce travail.

[Traduit par le journal]

Introduction

A general introduction was given in Part I (see preceding paper) where previous work both at the air/water and Hg electrode/water interfaces was referred to. In comparison with the situation at the air/water interface, studies at the Hg electrode enable the adsorption of the $R_{4-n}NH_n^+$ ions to be evaluated as a function of electrode potential or surface charge density, q. This has the effect of (*a*) changing the electrostatic attraction or repulsion between the $R_{4-n}N_n^+$ cations and the Hg surface and (*b*) changing the state of water structure (1, 2) and H_2O-dipole orientation (refs. 1, 3, 4*a*, see also ref. 4*b* for a 4-state model of H_2O adsorption) in the interphase and thus indirectly influencing the alkylammonium ion adsorption. Analysis of the results according to previously described procedures (5–7) enables standard free energies of adsorption to be derived as a function of coverage by the $R_{4-n}NH_n^+$ ions and of q, and the surface pressure behavior to be investigated. Special mention should be made of the work by Kimmerle and Menard (3) who made a thorough study of the adsorption of Me_4N^+ halides (F^- to I^-) at Hg with particular reference to the effects of the co-anions.

While changes of surface potential, $\Delta\chi$, cannot be directly measured as they can at the air/water interface (Part I), an equivalent quantity, the change of electrode potential, ΔE_q, evaluated for constant surface charge density (5), is of interest in relation to the ionic double-layer potential difference and the potential difference due to H_2O-dipole orientation as treated previously (2, 7, 8) for neutral molecule adsorption at the Hg electrode.

Finally, the results enable some interesting conclusions to be reached regarding lateral interactions between adsorbed alkylammonium ions, especially the most hydrophobic one of the present series $(n\text{-}Pr)_4N^+$, where Gurney hydration cosphere sharing effects (9) lead to attractive interactions between the cations in the interphase.

Experimental

(1) The Surface Tension Measurements

The surface tension of the Hg/water interface was determined at various potentiostatically controlled potentials by means of a drop-time tensiometer of the type recently described in the literature (10, 11). Drop-times were recorded electrically by interruption of a thin light beam incident on a photo cell. The signal from the photo-cell was shaped by a Schmidt trigger and communicated to a Hewlett-Packard electronic timer. All measurements were made at 298 ± 0.1 K in a thermostatted cell.

The precision of drop-timing depends largely on keeping the capillary free from mechanical vibrations; in order to minimize

vibrations, the cell, the mercury column, the lamp, and the photoelectric cell were fixed to a metal framework suspended from the ceiling by means of springs attached to a platform resting on a semi-inflated "inner tube" as recommended by Kimmerle and Menard (10). This system proved to be very satisfactory. Experimental runs gave a standard deviation of ±0.02% or better, i.e. ±0.1 dyn cm^{-1} in the surface tension, γ, over a range of ten drop-times for each potential. Most data were subsequently collected from three drop-time measurements at each potential. Other factors which are important in obtaining accurate and reproducible results have been discussed elsewhere (11) and in a thesis (12). γ-Data obtained by drop-time and capillary electrometer methods were shown to be in good agreement (13) for simple organic substances. γ-Values were derived from drop-times by procedures previously discussed in the literature (11, 14).

It should be mentioned that the drop-time method employed in the present work is a dynamic one so that problems of non-equilibrium in the adsorption at the Hg drops can arise. However, the direct comparison made in previous work (13) between the drop-time and electrocapillary method (in which equilibrium conditions more or less obtain), using compounds rather similar to those employed in the present work, gave good agreement between results obtained by the two methods. This implies that non-equilibrium in the present work is not a serious problem.

All measurements were made in a $NaClO_4$ or $HClO_4$ supporting electrolyte to minimize effects due to specific adsorption of anions. Since ClO_4^- does not form a reference electrode of the "second kind", a Ag/AgCl electrode in 0.1 *M* KCl, prepared by a method described by Ives and Janz (15), was employed. The liquid junction, which is unavoidable under the above conditions, was formed at a closed wetted stopcock between the reference electrode and the dropping Hg electrode compartments of the cell.

(2) Substances Employed in the Experiments

(*a*) *Sodium perchlorate*: Anachemia $NaClO_4$ was used.

(*b*) *Perchloric acid*: BDH "Aristar" grade $HClO_4$ was used without further purification in the experiments on alkylammonium ion adsorption. Its initial strength was determined by titration.

(*c*) *Hydrochloric acid*: BDH "Aristar" grade hydrochloric acid was used without further purification.

(*d*) *Sodium chloride*: ACS analytical grade reagent was used.

(*e*) *Potassium chloride*: BDH "analytical reagent" grade potassium chloride was dried under vacuum at 333 K for 12 h and used without further purification since the same results were shown to be obtained when a sample of KCl, doubly-recrystallized from water, was used. Potassium chloride was used for standardization of capillaries in terms of the published surface tension for the Hg/aq.KCl interface at various potentials (16).

(*f*) n-*Propylamines*: Mono-, di-, and tri-*n*-propylamines (Matheson, Coleman and Bell) were purified by distillation under dry N_2 at atmospheric or reduced pressure as required.

(*g*) *Tetra*-n-*propylammonium hydroxide*: The Eastman Kodak material (10% aq. solution) was used without further purification to prepare $(n\text{-Pr})_4N^+ClO_4^-$ solutions by titration with the $HClO_4$ mentioned above.

In the work at Hg, solutions of various concentrations of the amines in excess (1 *M*) aq. $HClO_4$ were used in order that the anion and total ionic concentrations remained constant. Each of the propylamine bases is sufficiently strong that virtually all the organic compound is in the form of the $R_{4-n}NH_n^+$ ($1 \leq n \leq 3$) ion under these conditions. Variation of the concentration of amine in excess $HClO_4$ is then almost quantitatively equivalent to variation of the alkylammonium ion concentration.

Results

(i) Derived Quantities

The electrocapillary curves obtained from the drop-time measurements at various potentials and concentrations were fitted to a polynomial function and treated in the manner described in previous publications (5, 7, 10), using appropriate computer programs, in order to obtain the surface excess values, Γ_q, at constant charge-density, q, and the q values themselves. Evaluation of strictly thermodynamic values of $\Gamma_q = -[(1/RT)(\partial\gamma/\partial \ln a)]_q$ presents some problems (as with other types of organic solutes in water) as the activity coefficients for the alkylammonium salts we have used are unavailable (some activity coefficient data for R_4N^+ salts were given in ref. 17*a*, but the derivation of these data has been criticized by Frank (17*b*)) except for some data recently published by Leyendekkers and Hunter (28) for the symmetrical R_4N^+ ions. Their data for $(n\text{-Pr})_4N^+$ (as Br^- salt) have been used here in the absence of any data for salts with other anions, in particular ClO_4^-.

The problem with activity coefficients for the other alkylammonium ions studied in the present work is diminished significantly since for all varying concentrations of $R_{4-n}N^+H_n$ ions, the total ionic strength was kept constant. Both Mohilner *et al.* (18) and one of the present authors in an earlier paper (19) on the adsorption of alkaloid cations at Hg have recognized this problem but adequate activity data are still lacking for most salts of organic ions. In the present work, these problems are diminished somewhat, in a relative sense, because the main purpose of the investigation is to make comparisons between the adsorption of the series of *n*-Pr ammonium ions at Hg and to compare the behavior at Hg with that at the air/water interface (Part I).

Free energies of adsorption, ΔG_q^0, at given values of q were obtained using the Flory–Huggins type of isotherm as in previously published papers (6, 20), viz.

$$[1] \quad \frac{\theta}{e^{x-1}(1-\theta)^x} = Kc$$

where x is the relative size of adsorbate and water molecules and $\theta = \Gamma/\Gamma_{max}$. Γ_{max}, the saturation coverage, cannot normally be determined reliably as the isotherms do not approach a well defined saturation limit over the accessible concentration ranges. Γ_{max} values were therefore estimated as shown in Table 1, from projection of Courtauld space-filling models (21) in various orientations, as in previous work (6, 22) and in Part I.

TABLE 1. Calculated maximum surface excess (Γ_{max}) values (10^{-10} mol cm^{-2}), figures in parentheses, and areas in Å^2 of *n*-propylammonium ions derived from measurements on Courtauld models*

Ion	"Perp." orientation	"Parallel" orientation	Expt.
$(n\text{-Pr})NH_3^+$	19.2 (8.7)	27.2 (6.1)	<57 (>2.9)
$(n\text{-Pr})_2NH_2^+$	18.5[a] (9.0) 33.8–40.4[b] (4.93 ~ 4.13)	40.4 (4.1)	<24 (>6.8)
$(n\text{-Pr})_3NH^+$	39.6 (4.2)	56.3[c] (2.96) 66.3[d] (2.50)	70 (2.4)
$(n\text{-Pr})_4N^+$	43.7 (3.8)	51.4 (3.2)	<36 (>4.6)

*Rather different values were estimated by Kimmerle and Menard (10) based on unspecified molecular models. It was not possible to reproduce their estimates using the Courtauld models. Shape basis of area measurement: (*a*) linear; (*b*) angular (30–180°); (*c*) triangular, (*d*) circular area swept out by rotational motion.

It is useful to derive apparent values of K and hence of ΔG^0 at various Γ values. They usually (6, 22, 23) depend on Γ due to coverage-dependent interactions in the interphase and to the coverage-dependent state of co-adsorbed water dipoles (1–4). The variation of apparent values of ΔG^0 then gives useful information about interaction effects in the interphase, with a rationally chosen value of x in eq. [1], as has been shown in various earlier publications (6, 7, 20, 22) on other systems, using this procedure. This method seems preferable to arbitrarily choosing an isotherm with an interaction term and then fitting the data to it, as we have argued previously (6).

The surface pressure, Φ, at constant q was also obtained in the usual way (cf. refs. 5, 7) as a function of Γ or relative free area, from the decrease of γ with increasing adsorbate concentration. Since the experiments were carried out at constant and large (1 M) ionic strength, there is virtually no diffuse-layer contribution to Φ_q, so that Φ_q derived from changes of γ due to alkylammonium ion adsorption represents, to a good approximation, the surface pressure exerted by the alkylammonium ions in the monolayer interphase at the Hg surface (cf. ref. 5).

(ii) Free Energies of Adsorption and Surface Charge

Figures 1 and 2 show the variation of the apparent ΔG_q^0, calculated for various Γ values, with surface charge density, q, for two of the alkylammonium ions $(n\text{-Pr})_2NH_2^+$ and $(n\text{-Pr})_4N^+$. There is a general trend for $-\Delta G_q^0$ to become larger with increasing negative q but there is some indication of a minimum in the curves around $q = -4 \sim -6\ \mu C\ cm^{-2}$, reminiscent of neutral molecule adsorption. The results shown in Figs. 1 and 2 have been calculated for several values of the size factor x in eq. [1] since it is (*a*) difficult to assign an *a priori* value to x and (*b*) desirable to show how the trend of ΔG^0 values depends on x. On the basis of geometrical considerations alone, x would be 3–4 but it may well be effectively less than this due to flexibility of the alkyl chains.

The general trend of ΔG_q^0 values with q is similar for various assumed values of x but the spread of ΔG_q^0 values with Γ is larger at a given q (see below), as x is taken larger.

(iii) Free Energies of Adsorption and Number, N_c, of Carbon Atoms in the $(n\text{-Pr})_{4-n}N^+H_n$ Series

ΔG_q^0 generally involves several contributions. That due to direct electrostatic interactions with the surface can be eliminated by considering ΔG_q^0 values for $q = 0$. Figure 3 shows the dependence of ΔG_q^0 on N_c for each cation, taken for $\theta \simeq 0.2$ in order to include the value of ΔG_q^0 for $n\text{-}PrNH_3^+$. It is seen that the relation ΔG_q^0 vs. N_c follows Traube's rule (1891) which relates strength or extent of adsorption of molecules in an homologous series of (aliphatic) organic substances to the length and the number of alkyl chains. From Fig. 3, it is seen that the decrease of ΔG_q^0 per C atom is approximately constant at about -380 cal mol^{-1}, a trend which reflects both the increasing hydrophobicity in the series of ions and the Van der Waals component of the adsorption energy. The figure of -380 cal mol^{-1} is about $0.66\,kT$, i.e., significantly less than the energy involved in complete removal of a CH_2 group from water. Figure 3 also shows the ΔG^0 values for adsorption at the air/water interface from Part I, for comparison.

(iv) Free Energies of Adsorption and Coverage

The dependence of ΔG_q^0 on Γ is of interest in relation to (*a*) direct coulombic interaction effects; (*b*) modification of the water structure in the electrode/solution interphase, and (*c*) Gurney co-sphere interaction (9) in the interphase (6). Plots of ΔG_q^0 for various q values vs. Γ for the four types of propylammonium ions are shown in Fig. 4. The predominant trend of ΔG_q^0 is to more *negative* values with increasing Γ when Γ is largest at appreciable negative q values (Fig. 4 *b*, *c*, *d*). For such conditions, co-anion adsorption will be minimal so that this decrease of ΔG_q^0 is unlikely to be associated with attractive lateral cation/anion in-

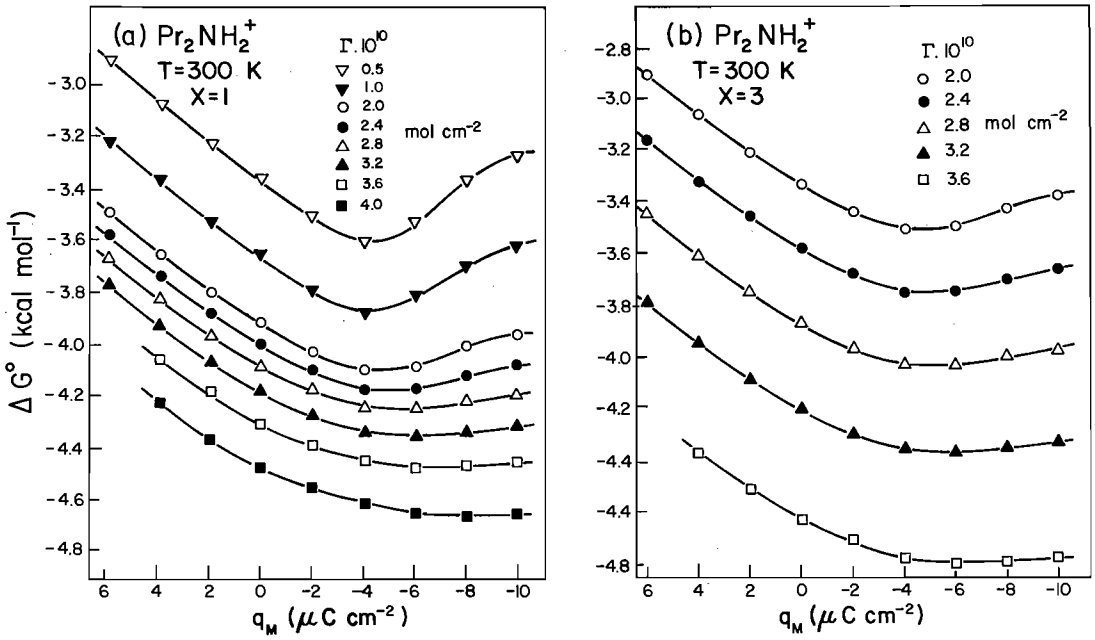

FIG. 1. Values of ΔG_q^0 calculated for various Γ values plotted against metal surface charge, q, for the adsorption of $(n\text{-Pr})_2NH_2^+$ at Hg (300 K). ΔG_q^0 is derived using eq. [1] for the indicated values of the size factor x.

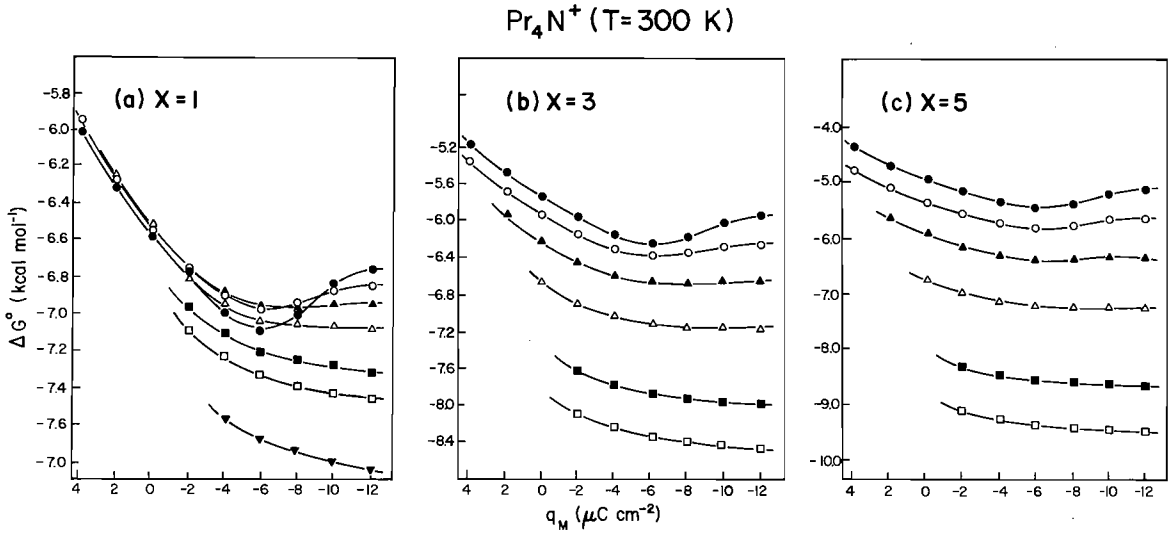

FIG. 2. As in Fig. 1, but for adsorption of $(n\text{-Pr})_4N^+$ at Hg for three values of the size factor, x.

teractions in the double layer. The effect is largest with the $(n\text{-Pr})_4N^+$ ion (Fig. 4*d*). Obviously it cannot arise from coulombic repulsions which would lead (cf. refs. 22, 23) to opposite dependence of ΔG_q^0 on Γ. The behavior found, especially with the $(n\text{-Pr})_nN^+$ ion, suggests that hydrophobic attractive interactions of the kind that have been postulated (9) for ions of this type in homogeneous aqueous solutions may be important. The effect arises through sharing of the Gurney co-spheres of the ions and leads to a minimization of free energy due to the diminished unfavorable interaction with water which can arise when two or more previously separate hydrophobic groups can passively (24) associate together. This point may be developed further in a more quantitative way, as follows.

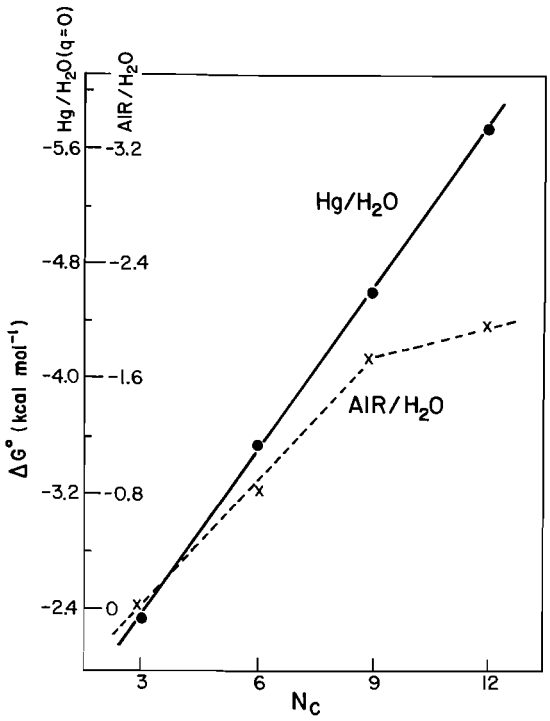

FIG. 3. Relation between ΔG_q^0 and the number of C atoms in each of the *n*-propylammonium ions studied at Hg in relation to the corresponding ΔG^0 values at the air/water interface (from Part I) for "||" orientation (size factor $x = 1$).

(v) Gurney Co-sphere Interaction Effects and ΔG^0 *as* $f(\Gamma)$

Co-sphere repulsive interactions due to overlap of dielectric polarization co-spheres, between hydrophilic ions in the double-layer were treated by Conway and Dhar (6) as a basis for explaining increases of ΔG_q^0 with Γ which can arise in addition to those due to simple coulombic repulsions between ions of like sign. The basis of evaluation of lateral co-sphere interactions is the model of Ramanathan and Friedman (25) for homogeneous solutions where such factors are important in the activity and osmotic coefficient behavior of salts at elevated concentrations (>1 *M*).

The Gurney co-sphere overlap free energy for two ions, *i* and *j*, is expressed by the relation (25)

$$[2]\quad \mathrm{GUR}_{ij} = A_{ij} V_{\mathrm{H_2O}}^{-1}\, V_c(r_i + r_{c,i}, r_j + r_{c,j}, r)$$

where A_{ij} is an empirical interaction free energy parameter, $V_{\mathrm{H_2O}}$ is the molar volume of water, and V_c is the volume of ion-influenced solvent which is returned to a normal bulk state with a resulting free energy change GUR_{ij} when two ions come together to a mean distance r. In eq. [2], $r_{c,i}$ or $r_{c,j}$ are the thicknesses of the co-spheres around ions *i* or *j*, and r_i and r_j are the ionic radii. The overlap volume, V_c, is given geometrically by the formula for the volume of spherical segments:

$$[3]\quad V_c = \pi\left[-\frac{(a^2-b^2)^2}{4r} + \frac{2}{3}(a^3+b^3) - \frac{1}{2}r(a^2+b^2) + \frac{r^3}{12}\right]$$

where a and b are the co-sphere radii $r_i + r_{c,i}$ and $r_j + r_{c,j}$ of the two ions. For lateral interaction in the double-layer between two identical R_4N^+ cations, the case of interest here, obviously $a = b$ so that

$$V_c = \pi((4/3)a^3 - ra^2 + r^3/12)$$

Some values of the A_{ij} parameters for various pairs of ions have been given by Ramanathan and Friedman (25) for aqueous electrolyte solutions. V_c is shown in Fig. 5 as a function of mean interionic separation, r, expressed in terms of Γ through the following relation:

$$[4]\quad r = (1/N_A\Gamma)^{1/2}$$

where N_A is Avogadro's number and a square lattice is assumed in eq. [4].

For R_4N^+ ions in aq. solution, there arise *attractive* cation–cation interactions which can be represented by the Gurney A_{ij} values given by Streng and Wen (26). These A_{ij} parameters (A_{++} for cations) can be used to estimate the (attractive) interaction effects that can arise in the double-layer (as in bulk water solution) due to sharing of structure-promoted regions of the solvent about such cations.

The volume of the water molecule to be taken in eq. [2] is ca. 30 $(Å)^3$ so that an attractive energy of the order of -85 to -300 cal mol^{-1} arises with increasing coverage of an electrode surface by R_4N^+ ions due to hydration shell sharing in the Gurney co-sphere. This energy adds (cf. ref. 25) to the coulombic repulsion (small with the larger R_4N^+ ions) and Van der Waals attraction contributions (23). Co-sphere "contact" for 1-H_2O thickness occurs at the following mean ionic charge densities in the double-layer for R_4N^+ ions: Me 13.1, Et 10.6, *n*-Pr 9.1, and *n*-Bu, 8.2 μC cm^{-2}. Significant contacts will, of course arise statistically below these limiting surface concentrations due to thermal fluctuations and be determined by the two-dimensional pair (++) distribution function for cation–cation encounters.

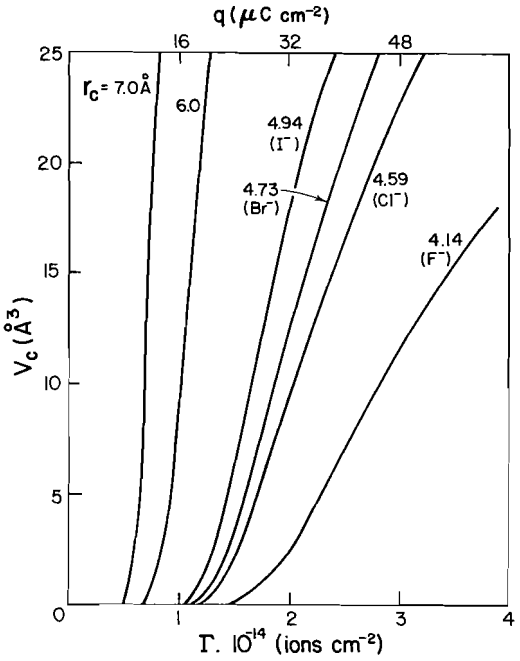

FIG. 5. Hydration co-sphere overlap volume, V_c, for ions with a single H_2O co-sphere hydration shell of radius, r_c, as a function of the surfaces excess Γ or corresponding charge q for univalent ions (as indicated) or larger ions with indicated r_c values.

$(n\text{-Pr})_4N^+$ and $(n\text{-Pr})_3NH^+$ ions in excess (1 *M*) $HClO_4$ from aqueous solution at Hg at 300 K as a function of Γ. As was shown in Fig. 4*d*, the $-\Delta G_q^0$ values *increase* with increasing coverage, i.e. apparent *attractive* interactions are predominant and the effect is greater with the tetra- than with the tri-*n*-propylammonium ion. Normally (22, 23) coulombic ionic repulsions lead, in the first order approximation, to $-\Delta G_q^0$ decreasing with coverage. The $-\Delta G_q^0$ values actually *increase* by ca. 2.5 kcal mol^{-1} which is of the correct order of magnitude for the quasi-attractive interaction effects which can evidently arise in this case due to the co-sphere overlap effects determined by A_{ij} values. In Table 2 are shown free energy changes, GUR_{ij}, for $(n\text{-Pr})_4N^+$, as calculated from eq. [2] for $A_{++} = -0.12$ kcal mol^{-1}, $V_{H_2O} = 30$ (Å)^3, and $r_c = 6.76$ Å (for 1 H_2O) for various Γ values. Also tabulated are the relative experimental free energy values, $\Delta G^0_{\Gamma\to 0} - \Delta G^0_{\Gamma}$, taken from Fig. 4*d*. The experimental relative energy values and the calculated GUR_{++} values for $(n\text{-Pr})_4N^+$ are plotted against Γ as shown in Fig. 6.

Quite good agreement with experiment is evidently obtained indicating that the co-sphere overlap effect is a major factor in the attractive interactions for this case. By contrast, for $(n\text{-Pr})_3NH^+$, the

TABLE 2. Comparison between relative values of experimental free energies of adsorption of $(n\text{-Pr})_4N^+$ and calculated Gurney co-sphere overlap energies at various surface concentrations

$\Gamma \times 10^{10}$ (mol cm^{-2})	r (Å)	V_c (Å^3)	GUR_{++} (kcal mol^{-1})	ΔG^0 (kcal mol^{-1})
1.0	12.9	0.97	~0	−0.06
1.5	10.5	83.6	−0.33	−0.16
2.0	9.10	181.6	−0.72	−0.40
2.5	8.19	260	−1.04	−0.86
3.0	7.46	329	−1.32	−1.54
3.5	6.93	383	−1.53	−3.32

effects are smaller owing to the greater hydrophilic character of this ion in comparison with $(n\text{-Pr})_4N^+$, and the anticipated co-sphere repulsion contribution (6) due to solvent polarization at the NH^+ centre (29). The coulombic repulsion effect will be almost the same at a given coverage (depending on the local dielectric properties of the interphase) and the Van der Waals interaction approximately 25% smaller.

(vi) Surface Pressure Behavior

Plots of Φ_q vs. Γ are shown in Fig. 7 *a–d*. For an ideal 2-dimensional surface gas, $\Phi = RT\Gamma$. The line of slope RT corresponding to this limiting relation is shown in Fig. 7 by the dotted lines. Normally (5, 27), deviations from this relation are observed due to (*a*) finite size of the adsorbate molecules and (*b*) their mutual interactions. In the case of ions in the double-layer, the interactions are complex, as has

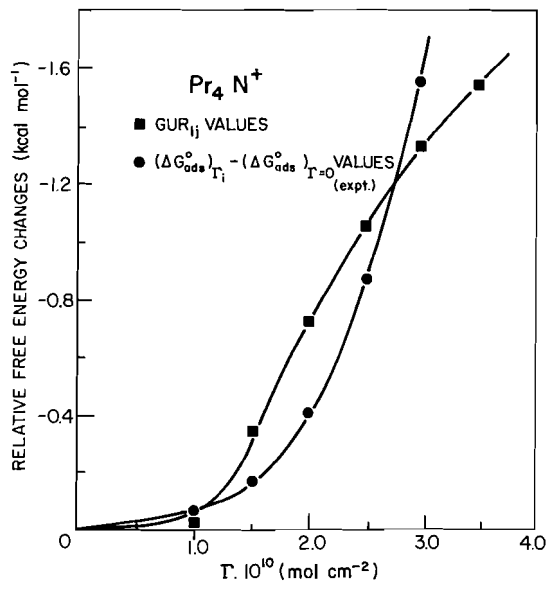

FIG. 6. Comparison of the experimental relative variation of $\Delta G_{q=0}^0$ with Γ for $n\text{-Pr}_4N^+$ adsorption at Hg with that calculated using Wen and Streng's solution Gurney A_{++} parameters.

8	24.6 (20%)	39.0	71.0	265	94.0

been discussed in relation to the coulombic and ion hydration effects. Both positive and negative deviations from the ideal relation arise, depending on ion size and charge q. The largest positive deviations arise for the $(n\text{-Pr})_4N^+$ ion (Fig. 7*d*). It is difficult to make a quantitative analysis of the observed behavior as obviously several effects to do with coulombic, solvent structure, and ion hydration effects will be involved. The co-area factor b (Volmer equation; $\phi(1/\Gamma - b) = RT$), will be important for the appreciable coverages that are reached, particularly because the areas of the ions in the $(n\text{-Pr})_{4-n}N^+H_n$ series are quite large. This factor would be allowed for by plotting Φ vs. $\Gamma/(1 - b\Gamma)$ instead of vs. Γ.

In concluding this section, it should be stated that we recognize that not all of the features of the surface pressure relations can be consistently reconciled with the variations of ΔG_q with coverage shown in section *iv*. This is probably due to the complexities of combined hydrophilic and hydrophobic interactions of these alkylammonium ions at the Hg/H_2O interface.

(vii) Effects on the Potential of Zero Charge and on the Potentials for Other Charges (Esin and Markov Coefficients)

The variation of E_q, the potential at which a given q is attained, with log [concentration] (or activity) of adsorbate is of interest in relation to (*a*) specific adsorption of ions (16) and (*b*) substitution of adsorbed oriented solvent dipoles at the Hg/water interface (4, 7) by the adsorbate. Both effects can contribute to changes, ΔE_q, in E_q when adsorption of organic species occurs.

Figure 8 shows how $\Delta E_{q=0}$, for the potential of zero charge, varies with log c of the four types of cations. The shifts arise at lower concentrations for the more adsorbable ions, as expected. Fig. 9, *a–d* show ΔE_q values as a function of Γ for various q. The simplest ion $n\text{-}PrNH_3^+$ exhibits behavior

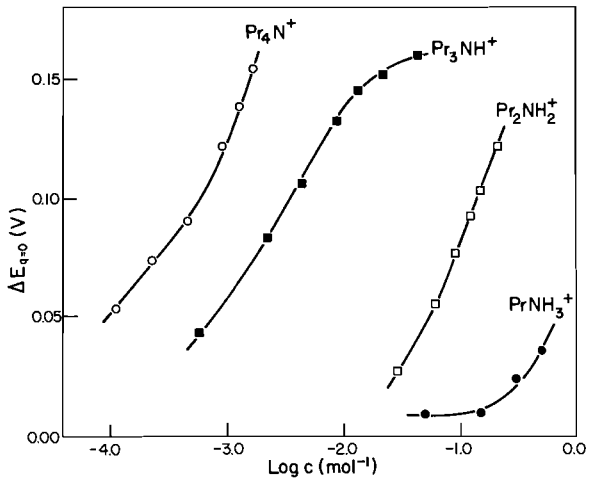

FIG. 8. Variation of shift, $\Delta E_{q=0}$, of potential of zero charge with log [concentration] of the 4 n-propylammonium perchlorates at the Hg electrode at 300 K.

similar to that of a simple neutral symmetrical molecule, e.g. pyrazine, where positive and negative changes of E_q occur depending on q. This type of effect is observed when the adsorbate replaces solvent dipoles whose orientation at the interface depends on q. For the other cations, ΔE_q is positive for all q values and increases with Γ in the expected way. This type of behavior is characteristic of the accumulation of strongly adsorbed positive ion charge and seems, unexpectedly, larger with $(n\text{-Pr})_3NH^+$ than with $(n\text{-Pr})_4N^+$ and may be connected with the greater electrical asymmetry of the former than the latter ion. The slopes $(\partial E/\partial\Gamma)_q$ of the lines in Fig. 9, *a–d* are recorded in Table 3.

The trends of the plots of ΔE_q as a function of Γ (Fig. 9) for various constant q values are rather unusual. At the pzc, ΔE_q shows expected positive values, increasing with Γ. However, for $Pr_2NH_2^+$, Pr_3NH^+, and Pr_4N^+, the slope $d\Delta E_q/d\Gamma$ becomes much diminished as q goes from 0 to −8 or

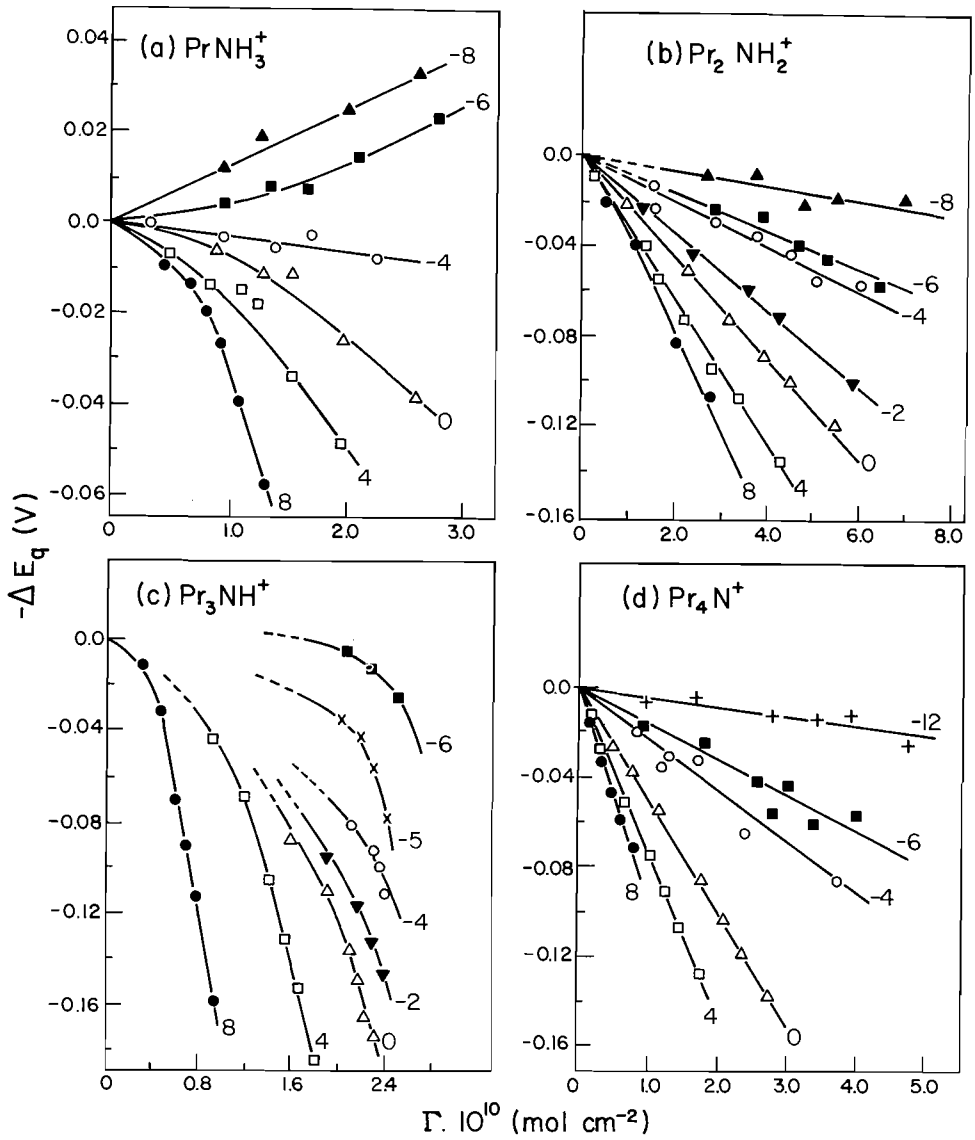

FIG. 9. Series of plots (*a*–*d*) for shift of potential at constant q due to adsorption of the series of *n*-propylammonium perchlorates at Hg, for various constant q values as a $f(\Gamma)$.

$-12\ \mu C\ cm^{-2}$ or, conversely, increases as q becomes positive. For $PrNH_3^+$, $d\Delta E_q/d\Gamma$ becomes negative as q becomes negative. Inspection of the raw data in terms of the electrocapillary curves shows that this effect is due to γ for $Pr_2NH_2^+$, Pr_3NH^+, and Pr_4N^+ solutions being less sharply curved with changing potential at large negative potentials and for the higher concentrations than are the curves for the base solution or for the solutions having low organic ion concentrations; that is, the capacity of the interface is diminished with increasing concentration, especially on the "negative branches" of the electrocapillary curves.

In contrast to the case with adsorbable simple ions, where $(\partial E/\partial\Gamma)_q$ tends to be larger at numerically increasing q values of opposite sign to that of the charge on the ion being adsorbed, e.g. as found in the case of $Me_4N^+F^-$ in the series of tetramethylammonium salts studied by Kimmerle and Menard (3), the present results with Pr-ammonium ions show a surprising opposite trend. The only reasonable, but speculative, rationalization we can offer for this interesting result is that adsorption of these large alkylammonium ions requires solvent displacement from the Hg surface to a much greater extent than does adsorption of simple specifically adsorbed ions, e.g. Cl^-. The adsorption of the

organic ions would be accompanied by a substantial $(\partial E/\partial \Gamma)_q$ component due to diminution of the dipole surface potential of oriented water dipoles, as is found in the case of neutral molecule adsorption, e.g. with pyrazine (7), pyridine (7), or thiourea (27). This effect, due to displacement of oriented solvent dipoles, tends to be greater at higher electrode/solution fields and gives rise to a larger $(\partial E/\partial \Gamma)_q$ contribution at larger negative q values but of *opposite sign* (cf. ref. 7) to the "normal" $(\partial E/\partial \Gamma)_q$ due to charge separation across the double-layer brought about by accumulation of specifically adsorbed (small) ion charge in the interphase. The solvent displacement effect is characteristic of adsorption of organic substances and reflects the hydrophobic behavior of the *n*-Pr chains.

Relation to $\Delta\chi$ Behavior at the Air/Water Interface

Finally, it is interesting to observe that the ΔE_q values at the Hg/water interface are substantially larger than the $\Delta\chi$ values at the air/water interface (Part I), for the same organic ions. This may be the result of the situation at the air/water interface where hydrophobic ions can have part or all of their organic residues "out" of the water phase while at the Hg/water interface, accommodation of alkyl groups of the ions can only be realized by displacement of previously adsorbed and oriented solvent molecules.

We studied the ion density in a dilute electrolyte solution which is next to an uncharged surface at which there is a discontinuity in the dielectric constant. In particular, we treated the restricted primitive model of a 1–1 aqueous solution next to a pure phase of unit dielectric constant. This served as a primitive model of the interface between an electrolytic solution and the air. Monte Carlo data are presented: the image forces are included and treated exactly. The model was also treated using the Born–Green–Yvon (BGY) integral equation approach; a modification of BGY theory which ensures electroneutrality is in very good agreement with the Monte Carlo data. The use of a "screened self-image" approximation to the potential energy has been tested using Monte Carlo computation and is found to be inadequate for the present model. Hypernetted-chain equation results using this approximation are also reported.

T. CROXTON, D. A. MCQUARRIE, G. N. PATEY, G. M. TORRIE et J. P. VALLEAU. Can. J. Chem. **59**, 1998 (1981).

Nous avons étudié la densité ionique d'une solution d'électrolyte diluée voisine d'une surface non chargée où se trouve une discontinuité dans la constante dielectrique. Nous traitons en particulier du modèle primitif restrient d'une solution aqueuse 1–1 au voisinage d'une phase pure de constante diélectrique égale à un. Ceci sert de modèle primitif de l'interface entre une solution d'électrolyte et l'air. On présente des données de Monte Carlo: on y inclut les images électrique et on les traite d'une façon exacte. On traite également le modèle en utilisant l'approche de l'équation intégrale de Born-Green-Yvon; une modification de la théorie BGY, qui assure une neutralité électrique, est en bon accord avec les données de Monte Carlo. Faisant appel à des calculs de type Monte Carlo, on a étudié l'approximation "auto-image tamisée" pour l'énergie potentielle et on a trouvé que cette approximation n'est pas utile pour le présent modèle. On rapporte également des résultats basés sur l'équation HNC qui font appel à cette approximation.

Introduction

This paper is concerned with the structure of an ionic solution next to an uncharged planar surface at which there is a discontinuity in the dielectric constant. The resulting electrostatic effects cause distortion of the ionic density near the surface; this is studied here using Monte Carlo and integral equation techniques.

Most studies of electrolytes next to surfaces have focussed on the classic "double-layer" problem of the ion distributions next to a *charged* surface. For real double layers there will be in addition a change of dielectric constant at the surface, the effects of which should be combined with those of the surface charge in a thorough theoretical treatment. Most commonly, however, the surface-charge effects have been examined in isolation, as in theoretical work based on the Gouy–Chapman theory. This paper reverses the procedure by examining in isolation the effects of a dielectric discontinuity. This allows us to examine the magnitude and character of the dielectric effects. A further purpose is to evaluate the ability of various approximate theories to handle accurately such effects. The classic Poisson–Boltzmann theory of Gouy and Chapman is not designed to take any account of them, and therefore does not predict any nonuniformity of ion density for the present model. This paper examines instead two versions of an approach based on the Born–Green–Yvon integral equation, and they are evaluated using Monte Carlo results.

We examine the particular case of a dielectric constant of unity outside the solution. The work may, therefore, be regarded as a study of the struc-

ture of the "free" surface of an ionic solution open to the air. The ion density distribution is then related to the surface tension of the solution. While the present results can be so interpreted we have not done this since such an interpretation could not likely be taken very seriously, due to the limitations of the model.

We consider the restrictive primitive model of an aqueous 1–1 ionic solution. That is, the solvent is represented only as a continuum of dielectric constant 78.5, and the ions are hard spheres, all of the same diameter d. The discontinuity in the dielectric constant occurs at $z = 0$, and it has values ε_0 for $z < 0$, outside the solution, and ε_1 for $z > 0$, within the solution. (For the results reported here $\varepsilon_0 = 1$ and $\varepsilon_1 = 78.5$.) The centres of the ions are allowed to approach to within one ionic radius of the surface, so they lie in $z \geq d/2$.

The electrostatic effects of the dielectric discontinuity are equivalent to those of a set of "images" of the ions located behind the surface of discontinuity, as shown in Fig. 1. For the reported results $\varepsilon_0 < \varepsilon_1$, so that each image charge is of the same sign as that of the ion which generates it. The average effect is therefore to repel the ions from the surface.

Following Buff and Stillinger (1) we write the potential energy as

$$[1] \quad u = \sum_i u_i^{(1)} + \frac{1}{2}\sum_{i,j} u_{ij}^{(2)}$$

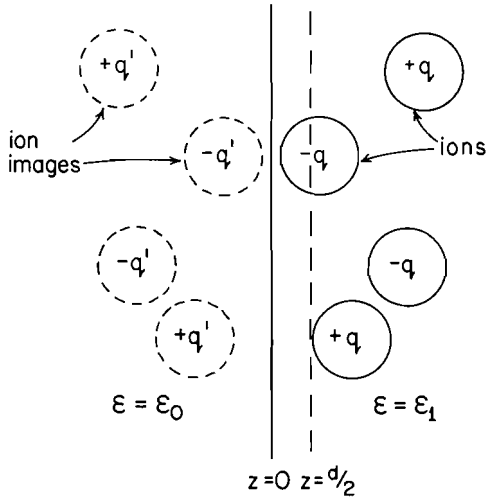

FIG. 1. Ions next to a discontinuity of the dielectric constant at $z = 0$. Each ion and its image are equidistant from $z = 0$, and $q'/q = (\varepsilon_1 - \varepsilon_0)/\varepsilon_1 + \varepsilon_0)$. Note that $z = d/2$ is the plane one radius from $z = 0$ and in the present model represents the closest allowed approach of the center of the ions to the surface.

expressing it in terms of a one-particle potential $u_i^{(1)}$ and a two-particle potential $u_{ij}^{(2)}$. Then

$$u_i^{(1)}(z_i) = u_i^{\text{elec}}(z_i) + u_i^{\text{hw}}(z_i)$$

$$[2] \quad u_i^{\text{elec}}(z_i) = \lambda q_i^2/4\varepsilon_i z_i$$

$$u_i^{\text{hw}}(z_i) = 0, \quad z_i \geq d/2$$

$$= \infty, \quad z_i < d/2$$

and

$$u_{ij}^{(2)}(r_i, r_j) = u_{ij}^{\text{elec}}(r, r_{\text{im}}) + u_{ij}^{\text{hs}}(r)$$

$$[3] \quad u_{ij}^{\text{elec}}(r, r_{\text{im}}) = \frac{q_i q_i}{\varepsilon_1 r} + \frac{\lambda q_i q_j}{\varepsilon_1 r_{\text{im}}}$$

$$u_{ij}^{\text{hs}}(r) = 0, \quad r \geq d$$

$$= \infty, \quad r < d$$

In these equations, q_i and $\boldsymbol{r}_i$ are the charge and position of ion i, and we define

$$\lambda \equiv \frac{\varepsilon_1 - \varepsilon_0}{\varepsilon_1 + \varepsilon_0}$$

$$[4] \quad r \equiv |\boldsymbol{r}_j - \boldsymbol{r}_i|$$

$$r_{\text{im}} = \sqrt{(r^2 + 4z_i z_j)}$$

These potential energy functions are used below in conjunction with Monte Carlo computations (MC) and with two versions of the Born–Green–Yvon theory (BGY).

In an early examination of the electrolyte surface problem Onsager and Samaras (2), following Wagner (3), began with the linearized form of the Poisson–Boltzmann equation, familiar in Debye–Hückel theory. To incorporate the image effects they solved that approximate equation for the electrostatic potential in the presence of an ion fixed in the solution and of the image of that ion. (The solution was simplified by the two further approximations that ε_0 (in our notation) can be neglected compared with ε_1, and that the Debye shielding constant $\kappa(\boldsymbol{r})$, which should depend on the local concentration at the field point $\boldsymbol{r}$, can be replaced by the constant value of κ appropriate to the bulk concentration of the electrolyte.) The resulting electrostatic potential was used to estimate the potential of mean force on an ion near the surface of the electrolyte, which is given by

$$[5] \quad \frac{q_i^2}{4\varepsilon_1 z_i} \exp(-2\kappa z_i)$$

This has the form of the repulsive potential of the ion's own image, screened by an exponential factor

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

typical of Debye–Hückel theory. In approximate double-layer theories based on versions of the Poisson–Boltzmann equation a generalized form of this result again emerges (4–8). It should be correct asymptotically at low concentrations. The predictions of [5] for the present model are compared below with MC computations at finite concentrations.

A different use of this result has been suggested (9). In the model, as summarized in [1]–[4], each ion interacts explicitly with its own electrostatic image and with the images of each of the other ions. This is electrostatically correct, but inclusion of this exact form of the potential energy in modern integral equation theories can lead to extremely difficult equations (10). The suggestion has therefore been made that the Poisson–Boltzmann result [5] be used to represent the effect of images in an approximate "effective potential energy" for insertion into modern theories. This would mean replacing the electrostatic terms of [2] and [3] by

$$[6]\qquad u_i^{\text{elec}}(z_i) = \frac{\lambda q_i^2}{4\varepsilon_1 z_i}\exp(-2\kappa z_i)$$

$$u_{ij}^{\text{elec}}(r) = q_i q_j/\varepsilon_1 r$$

The effects on an ion of images other than its own enter only through the screening of the self-image term. If it were adequate this "screened self-image approximation" (SSI) would be most useful, since it can be incorporated into various theories much more easily than the exact potential energy given by [1]–[3]. A secondary purpose of the present study is therefore to test this approximation for the potential energy. This has been done by direct comparison of Monte Carlo results generated for *both* the exact and the SSI potential energies.

The SSI approximation has been used to allow solution of the hypernetted-chain theory (HNC) for double-layer problems (11), and some results of this HNC–SSI approximation for the present model are also reported below.

In the following sections the Monte Carlo and theoretical techniques are briefly described, after which we present MC and BGY results for the exact treatment of the model, as well as a modification, BGY + EN, of BGY theory. The MC and HNC results are given for the SSI approximations as well, and the various results compared and discussed.

Monte Carlo Calculations

The Monte Carlo computations were carried out in the grand canonical ensemble, using ionic activity coefficients determined previously (12). The details of the Monte Carlo techniques are described elsewhere (11, 12). The ions included explicitly in the MC computation are enclosed in a rectangular box of dimensions $L \times W \times W$ between the surface under study, at $z = 0$, and a second hard wall, at $z = L$. The second wall is inert, in the sense that its dielectric constant is supposed equal to that of the liquid so there are no image forces there. The system is periodic in the x and y directions, i.e., parallel to the surface.

Around each ion may be pictured its own "central" box (such that the box is centered on the ion in the x and y directions) which contains just one of the periodic replications of each ion. In the "exact" computation the potential energies corresponding to all interactions with ions within this central box and with their images were calculated explicitly. Interactions with more distant parts of the system were calculated using a method described elsewhere (11, 13, 14) (but were anyway negligible for this problem involving no charge separation).

Convergence of the Monte Carlo Markov chains for the structure near the surface is rather slow for this field-free problem. Runs of roughly 10 000 configurations per particle were required to obtain the results reported below (in Figs. 2–4). The box dimensions L and W were chosen so that L was substantially greater than the thickness of the surface layer, and so that other boundary effects were negligible. Roughly 180 particles were involved.

To test the SSI approximation a second MC computation was carried out for the 1.0 M solution using [6] with the value of κ corresponding to the bulk concentration. The corresponding density profile is compared with that of the exact treatment in Fig. 4.

The BGY and BGY + EN Theories

The first member of the BGY hierarchy,

$$[7]\qquad -kT\frac{\partial \ln \rho_i^{(1)}(z_1)}{\partial z_1} = \frac{\partial u_i^{(1)}(z_1)}{\partial z_1} + \sum_{j=1}^{\omega}\int d\boldsymbol{r}_2 \frac{\partial u_{ij}^{(2)}(\boldsymbol{r}_1, \boldsymbol{r}_2)}{\partial z_1}\frac{\rho_{ij}^{(2)}(\boldsymbol{r}_1, \boldsymbol{r}_2)}{\rho_i^{(1)}(z_1)}$$

where ω is the number of components, is an exact equation relating the singlet and doublet density distribution functions $\rho_i^{(1)}$ and $\rho_{ij}^{(2)}$. Croxton and McQuarrie (15) have suggested as an approximate closure for this

$$[8]\qquad \rho_{ij}^{(2)}(\boldsymbol{r}_1, \boldsymbol{r}_2) \approx \rho_i^{(1)}(z_1)\rho_j^{(1)}(z_2)g_{ij}(r)\,[\exp(-\beta w_{ij}^{\text{im}}(r_{\text{im}}))]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

where $g_{ij}(r)$ is the radial distribution function in bulk solution and w_{ij}^{im} is the low density limiting expression for the image contribution to the potential of mean force given by

$$[9] \quad w_{ij}^{\text{im}}(r_{\text{im}}) = \lambda \frac{q_i q_j}{\varepsilon_1} \frac{\exp(-\kappa r_{\text{im}})}{r_{\text{im}}}$$

In this equation κ is the usual Debye–Hückel parameter. Solution of [7] under this approximation will be called the BGY theory.

When applied to the charged-wall system for which $w_{ij}^{\text{im}} \equiv 0$, this approximation was found to yield poor results (16). However, much improvement could be obtained by introducing a more flexible form for $\rho_{ij}^{(2)}$ including z_1 and z_2 dependence explicitly and requiring $\rho_{ij}^{(2)}$ to satisfy electroneutrality. In analogy to the expression used by Croxton and McQuarrie (16) in that work, we suggest the approximation

$$[10] \quad \rho_{ij}^{(2)}(r_1, r_2) \approx \rho_i^{(1)}(z_1)\rho_j^{(1)}(z_2)\{1 + f_i(z_1)f_j(z_2)[g_{ij}(r)\exp(-\beta w_{ij}^{\text{im}}(r_{\text{im}}))] - 1]\}$$

where the f_i's are arbitrary unknown functions. If this $\rho_{ij}^{(2)}$ is required to satisfy electroneutrality, we obtain an integral equation involving $\rho^{(1)}$ and f:

$$[11] \quad f(z_1) = -\left[\pi\rho\int_0^\infty dz_2 g^{(1)}(z_2)f(z_2)\int_{|z_1-z_2|}^\infty dr\, r \sum_{j=1}^{2}\frac{q_j}{q_1}\left(g_{1j}(r)\exp\left[-\lambda\frac{q_1 q_j}{\varepsilon KT}\frac{\exp(-\kappa r_{\text{im}})}{r_{\text{im}}}\right] - 1\right)\right]^{-1}$$

In writing [11], we have used the fact that $f_i = f$ and $\rho_i^{(1)} = \rho^{(1)}$ are the same for each species i for this system. Simultaneous solution of [7] and [11] for f and $\rho^{(1)}$ will be called the BGY + EN theory.

If we define $g_i^{(1)}(z)$ and $g_{ij}^{(2)}(r_1, r_2)$ by

$$[12] \quad \rho_{ij}^{(2)}(r_1, r_2) = \rho_i^{(1)}(z_1)\rho_j^{(1)}(z_2)g_{ij}^{(2)}(r_1, r_2)$$

$$[13] \quad \rho_i^{(1)}(z_1) = \rho_i g_i^{(1)}(z_1)$$

where $\rho = (\rho_1 + \rho_2)d^3$ and ρ_i is the bulk number density of species i, the BGY equation for this system may be written as

$$[14] \quad \ln g^{(1)}(z) = -\frac{u^{(1)}(z)}{kT} + \pi\rho\int_0^\infty dz_2 g^{(1)}(z_2)\int_z^\infty dz_1\int_{|z_1-z_2|}^\infty dr\, r\sum_{j=1}^{2}\frac{\partial}{\partial z_1}\left(\frac{u_{ij}^{(2)}}{kT}\right)g_{ij}^{(2)}(r_1, r_2)$$

As in [11] we have used the fact that $g_i^{(1)}(z) = g^{(1)}(z)$. After a considerable amount of manipulation, [14] may be brought into the more convenient computational form

$$[15] \quad \ln g^{(1)}(z) = F(z) + \pi\rho\int_0^\infty dz_2[g^{(1)}(z_2) - 1]K(z, z_2)$$

where

$$[16] \quad F(z) = -\frac{\lambda}{2}\frac{\beta^*}{z} + \frac{\pi\rho}{3}(m^2 - 3m + 2) - 2\pi\rho\int_0^\infty dz_1\left[\int_{M_1}^{z_1+d} dz_2(z_1 - z_2)h_s^{(2)}(r = d) - 2\beta^*\int_0^\infty dz_2\int_{|z_1-z_2|}^\infty dr\, r\left(\frac{z_1 - z_2}{r^3} + \lambda\frac{z_1 + z_2 + d}{r_{\text{im}}^3}\right)h_d^{(2)}\right]$$

$$[17] \quad K(z, z_2) = (m_2^2 - 1) + 2\int_z^\infty dz_1\left[-(z_1 - z_2)h_s^{(2)}(r = d)\Theta(d - |z_1 - z_2|) + 2\beta^*\int_{|z_1-z_2|}^\infty dr\, r\left(\frac{z_1 - z_2}{r^3} + \lambda\frac{z_1 + z_2 + d}{r_{\text{im}}^3}\right)h_d^{(2)}\right]$$

and where $\beta^* = q^2/\varepsilon_1 kTd$, $m = \min(z, \frac{1}{2}d)$, $M_1 = \max(0, z - \frac{3}{2}d)$, $h_s^{(2)} = (h_{12}^{(2)} + h_{11}^{(2)})/2$, $h_d^{(2)} = (h_{12}^{(2)} - h_{11}^{(2)})/2$, $m_2 = \min(d, |z - z_2|)$, and $\Theta(X)$ is the unit step function.

The numerical procedure used was first to calculate $g^{(1)}(z)$ from [15] with $f(z) = 1$ and then to use $g^{(1)}(z)$ to obtain $f(z)$ from [11]. This $f(z)$ was used to evaluate and store $F(z)$ and $K(z, z_2)$ and [15] is solved for $g^{(1)}(z)$ by direct iteration. This entire process was repeated until f and $g^{(1)}$ were stable. The bulk radial distribution functions used were those obtained from the second BGY equation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

under superposition (17). The BGY theory is solved similarly but with the constraint $f(z) \equiv 1$ and so requires only one master iteration. The results presented here were obtained using 61 points uniformly spaced over an interval of length L with L equal to about 5 D lengths. The infinite integrals required were evaluated as finite integrals with upper limits ranging from $2L$ to $4L$. An asymptotic tail was also added to the triple integral of $F(z)$ which exactly cancels the asymptotic contribution of the first, z^{-1}, term. The procedure described is quite stable numerically.

The HNC Theory in the SSI Approximation

The hypernetted-chain approximation (HNC) has recently been extended by Blum and Henderson (9, 18) and others to include electrolytes next to a charged surface. Inclusion of the exact forms of the one- and two-particle potential energies due to image forces (cf. eqs. [2]–[4]) leads to extremely difficult equations (10). It is relatively easy, however, to include the effects of image forces in the "screened self-image" approximation (SSI) since they appear only in the one-particle energy (cf. eqs. [5], [6]). This is described in detail elsewhere (11), and numerical solution of the equations has been carried out. Results for the present model are reported below for a bulk concentration of 1.0 M.

Results and Discussion

Figures 2–4 show the Monte Carlo results for the ion density profiles near the surface, along with theoretical results. We first consider results for the exact treatment of the model. At 0.1 M, BGY and BGY + EN are not very different, and both give

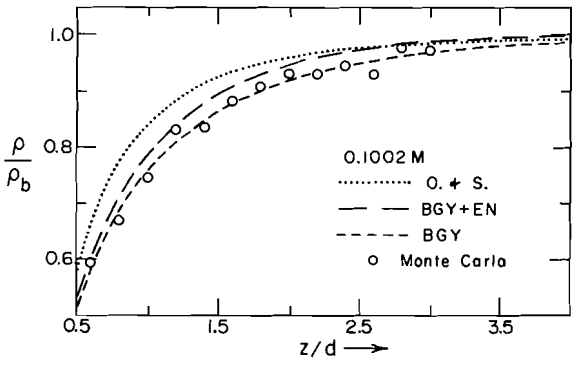

FIG. 2. Ionic density $\rho(z)$ near a planar dielectric interface, relative to the bulk density ρ_b, for a 0.1002 M 1–1 restricted primitive electrolyte. The parameters are $d = 4.25$ Å, $T = 298$ K, $\varepsilon_1 = 78.5$, and $\varepsilon_0 = 1$. The lines of short and long dashes are for the BGY and BGY + EN theories while the dotted line corresponds to that of Onsager and Samaras. The circles show Monte Carlo data, for which the uncertainty in ρ/ρ_b (one standard deviation) is about 0.015.

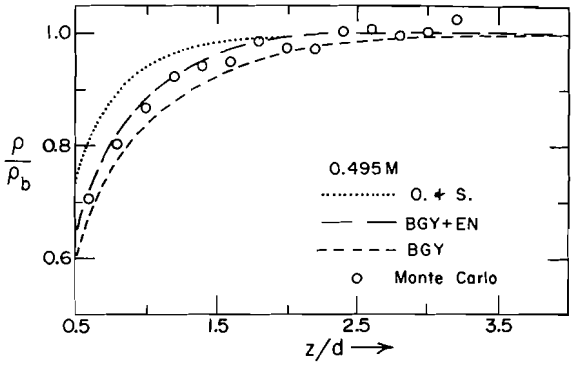

FIG. 3. Ionic density near the interface at 0.495 M. The other parameters and the symbols are described in the caption to Fig. 2. The Monte Carlo points have again an uncertainty of ± 0.015.

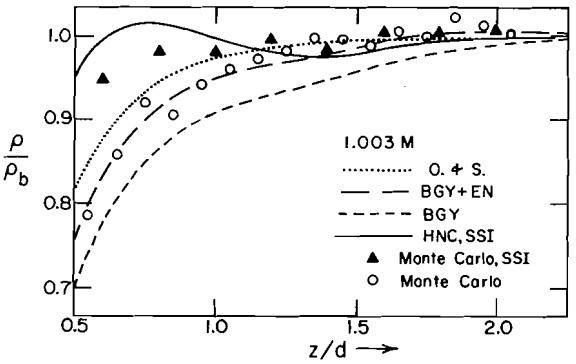

FIG. 4. Ionic density near the interface at 1.003 M. The other parameters and the symbols described for Fig. 2 apply here. This figure shows as well results using the SSI approximation to the potential energy: the triangles show Monte Carlo data and the solid line the result of using the approximation in the hypernetted-chain theory. The uncertainty in the Monte Carlo points is ± 0.02.

satisfactory descriptions of the MC results. As the concentration increases, however, BGY itself becomes rather unsatisfactory. It predicts a too-great repulsion of the ions from the surface, and a layer of surface distortion which is much too thick (cf. Fig. 4). BGY + EN, by contrast, continues to give a good description of the density profiles at the concentrations studied. In conjunction with the results of BGY + EN theory for the charged-wall system (16), the present results suggest that this may prove to be an accurate approximate theory for ion distributions near surfaces.

The figures show the ion density profiles predicted by the potential of mean force [5] in the theory of Onsager and Samaras (2). They are fairly successful, but evidently underestimate the ion depletion (and therefore underestimate the increase of surface tension caused by the ions). In particular the *thickness*

of the layer of ion depletion is substantially underestimated at finite concentrations. At 1.0 M the errors of [5] are being partially compensated by enhanced ion density due to volume exclusion effects ignored in the theory of Onsager and Samaras. It will be interesting to see the predictions of more sophisticated Poisson–Boltzmann theories such as that of Levine and Outhwaite (8).

Figure 4 contains results bearing on the use of the SSI approximation [6] in the potential energy. The MC results are shown for this SSI potential as well as for the exact potential energy [1]–[3] of the model. It is evident that they lead to very different behaviour. The error is in the direction of grossly underestimating the effect of the image forces. It appears therefore that for at least some regimes, such as this zero-field case, the SSI approximation is unreliable.

The SSI calculations have used in [6] the value of κ appropriate to the bulk concentration. In some applications of SSI a *local* value of κ has been used instead ((11), cf. refs. (3), (5)), corresponding to that of the local concentration at the position of the ion. In the present case the local concentrations differ so little from the bulk concentration that this modification would have little effect. This is confirmed by comparing HNC calculations, which have been carried out using *both* bulk and local values of κ. In typical double layer problems with charged surfaces the local concentrations will, however, exceed the bulk concentrations, and often substantially. Use of the SSI approximation with the local κ would then mean a still greater underestimate by SSI of the effects of images.

This failure of the SSI approximation seems doubly unfortunate in view of the relative success of the HNC theory in predicting the behaviour of the SSI system itself. The HNC density results are slightly higher than the MC results and show an oscillatory structure that at least is not obvious in the rather noisy MC data, but overall the agreement is very satisfactory. This means though that HNC, using SSI, fails completely to describe the model system itself, and this is due largely to the failure of the SSI approximation.

London – van der Waals forces and torques exerted on an ellipsoidal particle by a nearby semi-infinite slab

HOWARD BRENNER[1] AND LAWRENCE J. GAJDOS[2]

Department of Chemical Engineering, University of Rochester, Rochester, NY 14627, U.S.A.

Received October 7, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

HOWARD BRENNER and LAWRENCE J. GAJDOS. Can. J. Chem. **59**, 2004 (1981).

A Hamaker-type integration of the pairwise *en vacuo* intermolecular forces is performed for a homogeneous triaxial ellipsoidal particle in proximity to a homogeneous semi-infinite slab bounded by a plane wall. The orientation of the ellipsoid relative to the plane is taken to be arbitrary, as too is its distance from the plane. The integrated potential energy function of the ellipsoid with respect to the slab is found to possess nonadditive positional and orientational contributions. This macroscopic potential is employed to compute the force and torque on the ellipsoid as functions of both its position and orientation relative to the plane.

The novel integration scheme pertains to centrally-symmetric pairwise intermolecular potentials of arbitrary functional form. Specific results are derived for classical inverse-power intermolecular potentials possessing both attractive (r^{-n}) and repulsive ($-r^{-m}$) additive components (with $n > m$). In stable equilibrium the ellipsoid aligns itself with the shortest of its three principal axes perpendicular to the bounding wall, and at a separation distance comparable to the length scale of the intermolecular potential itself.

HOWARD BRENNER et LAWRENCE J. GAJDOS. Can. J. Chem. **59**, 2004 (1981).

On a effectué une intégration du type Hamaker des forces intermoléculaires *en vacuo* prises deux à deux pour une particule éllipsoidale triaxiale homogène au voisinage d'une plaque homogène semi-infinie reliée à un mur plan. On considère que l'orientation de l'ellipsoide par rapport au plan ainsi que sa distance par rapport à ce plan sont arbitraires. On a trouvé que la fonction d'énergie potentielle intégrée de l'ellipsoide par rapport à la plaque possède des contributions de position et d'orientation qui ne sont pas additives. On a employé cette propriété macroscopique pour calculer la force et la torsion appliquée à l'ellipsoide en fonction à la fois de sa position et de son orientation par rapport au plan.

Le nouveau schéma d'intégration s'applique à des potentiels intermoléculaires centro-symétriques considérées sous forme de paire dont la forme fonctionnelle est arbitraire. On a déduit des résultats spécifiques pour des potentials intermoléculaires de puissance inverse classique possédant à la fois des composantes additives (r^{-n}) et répulsives ($-r^{-m}$) (avec $n > m$). En équilibre stable, l'ellipsoide s'aligne lui-même avec le plus court de ses trois axes perpendiculaires principaux par rapport au mur plan liant et la distance qui le sépare d'un mur se compare à l'échelle de longueur du potentiel intermoléculaire lui-même.

[Traduit par le journal]

1. Introduction

Many areas within the field of colloid science are concerned with the interaction between a particle and a nearby boundary. The interaction may be *indirect*, through the agency of an intervening hydrodynamic field (1) — arising as a consequence of the motion of the particle through the viscous fluid in which it is suspended; or it may derive from *direct*, short-range interactions between the particle and surface — as in the case of dispersion forces (2, 3). The latter type of interaction constitutes the focus of the present contribution.

Our interest in this problem derives from questions relating to the boundary conditions to be imposed upon the solutions of the convective-diffusion equation involving the transport of orientable, i.e., nonspherical, Brownian solute particles (4–6) moving in proximity to surfaces (7–10). In attempting to solve the relevant particle continuity equation in bounded systems it is a nontrivial matter to explicitly account for the constraints imposed upon the translational and rotational particle motions by the presence of a nearby bounding wall (9).

This problem is largely avoided when attention is restricted to spherical particles, since particle orientation effects are physically irrelevant for such shapes. When, however, the arena of interest is enlarged to include nonspherical particles, the physico-mathematical description of such common boundary conditions as "adsorption" of the particle at the surface, or "impenetrability" of the surface to the particle, acquires a more complex character owing to the need to supplement the usual positional variables with orientational ones. Geometrically, hydrodynamically, and dynamically, "coupling" (7, 9, 11) between translational and rotational particle motions invariably occurs in proximity to a boundary, even for spherical particles.

These considerations may be recast and postponed by viewing the particle/boundary interaction on a finer length scale than is common in the usual macroscopic theory of transport processes. By

recognizing the boundary as the seat of short-range forces and torques external to the particle it is possible to incorporate these forces and torques directly into the continuity (i.e., conservation) equation itself (via the addition of Smoluchowski-type external force and torque contributions to the conventional constitutive equations for the translational and rotational particle fluxes) (5, 9, 10, 12). Such constitutive relations normally entail only diffusive and "piggy-back"-type fluid-convective contributions.

If the external force possesses a short-range repulsive component that tends to infinity sufficiently rapidly with diminishing distance of the particle from the boundary, intuition suggests that no boundary condition need be imposed. Rather, the repulsive force itself suffices to prevent penetration of the boundary by the particle. Furthermore, the variation of the resulting repulsive potential with particle orientation relative to the boundary provides an external torque on the particle, which then figures as a Smoluchowski-type contribution to the rotary particle flux (9) (in addition to the usual rotary diffusive and convective fluid contributions).

Thus, by modelling the bounding surface as the source of an external potential field acting upon the suspended particles, the continuity equation — supplemented by constitutive expressions for the flux densities appearing therein, including the Smoluchowski force and torque contributions — can be regarded as a self-contained descriptor of particle behavior in proximity to a boundary. Passage from this fine-scale view, which incorporates the short-range forces directly into its formulation, to a more conventional macroscopic view, can be accomplished by the methods of singular perturbation theory. This involves utilizing the ratio of short-range length scale to macroscopic boundary-length scale as a small perturbation parameter (10, 13). Matching of the inner and outer expansions then serves to furnish the proper macroscopic "boundary conditions" in a wholly rational manner (10, 13).

Though surface-derived particle forces have been extensively employed in the prior literature to describe the behavior of macroscopic particles moving near boundaries, the emphasis has been almost exclusively on the case of particle attraction towards the surface. Little consideration has been given to the effects of repulsion, except perhaps implicitly in the degenerate, infinitely-repulsive case of point contact between a rigid particle and rigid boundary. This unfortunately provides no repulsive length scale analogous to the length scale of the attractive forces. Moreover, the particles studied have almost invariably been taken to be spherical in shape, thus bypassing fundamental orientational issues involved in the present paper.

In the context of the above remarks Spielman *et al.* (14–16) have considered the capture of spheres on the surfaces of various collector geometries via London forces, including repulsive double-layer forces. Limiting themselves to non-Brownian particles they derived the deterministic particle trajectories followed by the suspended particles migrating towards the collecting surfaces. Spielman and Friedlander (17) and Ruckenstein and Prieve (18) extended this analysis to Brownian particles by replacing the particle-trajectory equation with a convective-diffusion equation. By specifying a boundary condition of zero particle concentration at the collector surface, corresponding to complete particle adsorption, each independently showed that (beyond a surface boundary layer) the macroscopic or bulk behavior could be modelled as an apparent first-order irreversible chemical reaction occurring at the collector surface.

In yet another application, Dahneke (19) studied the escape rates of adsorbed particles; that is, he considered the reversibility of the particle deposition process. This was accomplished by using a surface potential containing both attractive and repulsive components.

These applications indicate that short-range surface forces may indeed serve as the precursors of boundary conditions imposed upon the bulk properties of the fluid/particle system when the latter is viewed at the conventional macroscopic continuum level. Indeed, the classical reflection (zero normal flux) and adsorption (zero concentration) boundary conditions can immediately be deduced by assuming that the surface force is an infinitely repulsive or attractive step function. More realistic and rigorous physical modelling of such surface forces incorporates London – van der Waals forces (3), retardation effects (3, 20), and double-layer forces (3, 21). Dahneke (22) and others (23, 24) even go so far as to include Hertzian particle deformation upon contact.

The remainder of this paper is devoted to the exposition of a prototype "boundary potential" for an orientable particle — specifically, an ellipsoid in proximity to the plane surface of a semi-infinite slab. A summary outline of the subsequent analysis now follows.

In Section 2 we begin by writing the external boundary potential as the double integral of a continuous centrally-symmetric pairwise intermolecular potential. The latter expresses the interaction of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

material in the neighborhood of a point within the ellipsoid with the matter in the neighborhood of another point located in the slab. In order to utilize available results insofar as possible, the slab is modelled as a sphere whose radius is eventually allowed to become infinite. A geometric transformation of the resulting volume integral over the ellipsoid provides the *ansatz* by means of which the requisite integration can be effected. This transformation has the effect of replacing the ellipsoid by an equivalent sphere of appropriate radius. The resulting expression for the potential of the ellipsoid relative to the slab is then reduced from a two- to a one-dimensional quadrature of the intermolecular potential via a second transformation. Though the intermolecular potential appearing in the integrand of this remaining one-dimensional integral may be of arbitrary form, convergence requires that it tend to zero at infinity faster than r^{-3}.

In Section 3 the potential energy of the ellipsoid is explicitly calculated for inverse-power intermolecular potentials of the form r^{-q} ($q > 3$). Both attractive and repulsive potentials are included by an appropriate choice of the algebraic sign preceding r^{-q}. Additivity permits both attractive and repulsive contributions to be simultaneously considered within the same formulation.

The integrated, macroscopic attractive/repulsive potential is utilized in Section 4 to obtain the force and torque exerted by the slab on the ellipsoid. Each of these dynamical quantities is a function of the distance of the ellipsoid center from the plane and the orientation of the principal axes of the ellipsoid relative to the unit normal vector to the plane bounding the slab. These results are utilized to calculate the positions and orientations of the ellipsoid at which it experiences neither a net force nor torque (as a result of the cancellation of the separate attractive and repulsive components). These constitute necessary, but insufficient, conditions for equilibrium. Three pairs of positions and (symmetrical) orientations are found for which *both* the force and torque vanish simultaneously. Stability theory, involving minimization of the ellipsoid's potential energy, is then invoked to establish which of these three pairs corresponds to the *stable* equilibrium configuration. A close analogy is drawn between the present problem and that of a gravitating ellipsoidal particle in point contact with a horizontal plane. This analogy is used to conjecture that our calculations for ellipsoidal particles can, in fact, be extended to nonreentrant particles of any shape. Such more general considerations are, however, left for a future study.

It is shown in Section 5 that the ellipsoid positions itself at virtually molecular separation distances from the slab surface (with the shortest of the three principal axes of the ellipsoid lying normal to the plane). Available experimental data on the orientations of small spheroidal bacterial spores on a plane surface are shown to be not inconsistent with the present theory — though the inference can hardly be described as conclusive.

Finally, three appendices supporting and otherwise supplementing the calculations of the main text complete the presentation.

2. Ellipsoid/Slab System

The general theory underlying the calculations of the present section are summarized by Mahanty and Ninham (3), who also review all of the currently known two-body results for various geometrical configurations.

Let ξ denote the intermolecular potential energy shared between any pair of molecules located in bodies 1 and 2, respectively. Following Hamaker (25) it will be assumed that the net potential between the two ponderable bodies 1 and 2 may be obtained by summation over all such molecular pairs, and that the requisite summation may be effected by integrating over the volumes V_1 and V_2 of the bodies (assuming spatially continuous molecular number densities n_1 and n_2, respectively). In this work n_1 and n_2 will each be taken as constants, corresponding to homogeneous bodies. The net potential E is thus given by

$$[2.1] \quad E = \int_{V_1} \mathrm{d}V_1 \int_{V_2} \mathrm{d}V_2 \, \xi n_1 n_2$$

Alternatively, with E' the net potential of body 2 due to an arbitrary point P in V_1, such that

$$[2.2] \quad E' = \int_{V_2} \mathrm{d}V_2 \, \xi$$

there obtains

$$[2.3] \quad E = \int_{V_1} \mathrm{d}V_1 \, E' n_1 n_2$$

The volume V_2 will be assumed to be a sphere of radius a_s. After using an existing lemma to effect a partial integration of [2.2], the radius a_s will be allowed to become infinite, rendering the resulting calculation appropriate to that for a semi-infinite slab.

Following Chu (26), the sphere volume element $\mathrm{d}V_2$ can be twice integrated to give

$$[2.4] \quad \mathrm{d}V_2 = (\pi\bar{r}/R)[a_s^2 - (R - \bar{r})^2]\mathrm{d}\bar{r}$$

where R is the distance from the center of the sphere

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

V_2 to an arbitrary point P in V_1. Additionally, the remaining variable of integration $\bar{r}$ spans V_2, such that $\bar{r}$ = constant represents the open surface (a spherical cap) in V_2 formed by the intersection with V_2 of a sphere of radius $\bar{r}$ centered at P. Consequently, $\bar{r}$ takes on the range of values

$$[2.5] \quad R - a_s \leq \bar{r} \leq R + a_s$$

This is illustrated in Fig. 1.

Observe that the position vector $\boldsymbol{R}$ drawn from the center of V_2 to point P in V_1 possesses a magnitude R consistent with the above definition. This vector can be expressed as

$$[2.6] \quad \boldsymbol{R} = \boldsymbol{n}(a_s + d) + \boldsymbol{r}$$

where $\boldsymbol{n}$ is a unit vector from the center of V_2 directed towards an arbitrary, but fixed, reference point O in V_1. Further, d is the distance from the surface of V_2 to point O, and $\boldsymbol{r}$ is a position vector, locating point P relative to point O. Note that $\boldsymbol{n}$ is also the outward normal from V_2, a status that it will retain even in the limit as $a_s \to \infty$.

From eq. [2.6] the magnitude of $\boldsymbol{R}$ expressed in terms of these new variables is

$$[2.7] \quad R^2 = a_s^2 + 2a_s(d + \boldsymbol{n}\cdot\boldsymbol{r}) + (\boldsymbol{n}d + \boldsymbol{r})^2$$

so that

$$[2.8] \quad R = a_s + (d + \boldsymbol{n}\cdot\boldsymbol{r}) + O(a_s^{-1})$$

Hence, from [2.5], the range spanned by $\bar{r}$ becomes

$$[2.9] \quad (d + \boldsymbol{n}\cdot\boldsymbol{r}) + O(a_s^{-1}) \leq \bar{r} \leq 2a_s + O(1)$$

Furthermore, the volume element dV_2, given by [2.4], may be expressed as

$$[2.10] \quad dV_2 = 2\pi\bar{r}[\bar{r} - (d + \boldsymbol{n}\cdot\boldsymbol{r}) + O(\bar{r}^2/a_s)]d\bar{r}$$

Thus, from [2.2],

$$[2.11] \quad E' = 2\pi \int_{d+\boldsymbol{n}\cdot\boldsymbol{r}+O(a_s^{-1})}^{2a_s+O(1)} \bar{r}[\bar{r} - (d + \boldsymbol{n}\cdot\boldsymbol{r}) + O(\bar{r}^2/a_s)]\xi(\bar{r})d\bar{r}$$

Let E_∞' denote the limit of E' as $a_s \to \infty$. It is apparent that so long as

$$[2.12] \quad \xi(\bar{r}) = o(\bar{r}^{-3})$$

this limit is given by

$$[2.13] \quad E_\infty' = 2\pi \int_{d+\boldsymbol{n}\cdot\boldsymbol{r}}^{\infty} \bar{r}[\bar{r} - (d + \boldsymbol{n}\cdot\boldsymbol{r})]\xi(\bar{r})d\bar{r}$$

From this equation derives the important conclusion that E_∞' is a function of the single entity $d + \boldsymbol{n}\cdot\boldsymbol{r}$. (This quantity is the distance of the point P, as described by $\boldsymbol{r}$, from the surface of the plane; cf. Fig. 2 in Appendix A.) Consequently, with the functional dependence

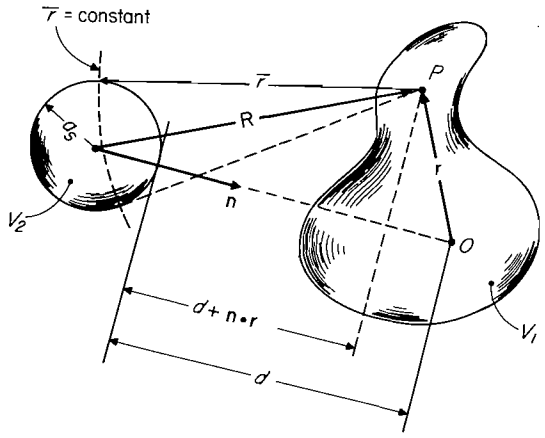

FIG. 1. Definition of variables for the interaction between a sphere of radius a_s (V_2) and another body (V_1).

$$[2.14] \quad E_\infty' = E_\infty'(d + \boldsymbol{n}\cdot\boldsymbol{r})$$

eq. [2.3] shows that

$$[2.15] \quad E_\infty = \lim_{a_s\to\infty} E = \int_{V_1} dV_1\, E_\infty'(d + \boldsymbol{n}\cdot\boldsymbol{r})n_1n_2$$

Henceforth we shall specialize the body V_1 to be ellipsoidal in shape. With the particle locator point O in V_1 chosen to lie at the center of the ellipsoid, the interior of the ellipsoid is described in invariant vector/dyadic form by the inequality

$$[2.16] \quad \mathbf{D}^{-2}:\boldsymbol{rr} \leq 1 \text{ (defines } V_1)$$

(The equality sign describes those points $\boldsymbol{r}$ lying on the surface of the ellipsoid.) In this relation $\mathbf{D}$ is the symmetric, positive-definite dyadic

$$[2.17] \quad \mathbf{D} = \boldsymbol{e}_1\boldsymbol{e}_1a_1 + \boldsymbol{e}_2\boldsymbol{e}_2a_2 + \boldsymbol{e}_3\boldsymbol{e}_3a_3$$

with (a_1,a_2,a_3) the semi-lengths of the principal axes of the ellipsoid, and $(\boldsymbol{e}_1,\boldsymbol{e}_2,\boldsymbol{e}_3)$ a trio of mutually perpendicular unit vectors colinear with each of the three principal axes. The notation in [2.16] is standard (27); namely, for $\boldsymbol{\Psi}$ any dyadic, $\boldsymbol{\Psi}^{-1}$ denotes the inverse dyadic; furthermore, $\boldsymbol{\Psi}^2 = \boldsymbol{\Psi}\cdot\boldsymbol{\Psi}$.

Observe that the position and orientation of the ellipsoid with respect to the plane, though arbitrary, are each to be held fixed during the integration of [2.15]. The position of the ellipsoid is completely specified by the distance d of its center O from the surface of the plane boundary, whereas its orientation is completely specified by the orientations of each of the unit vectors $(\boldsymbol{e}_1,\boldsymbol{e}_2,\boldsymbol{e}_3)$ with respect to the unit vector $\boldsymbol{n}$ drawn normal to the plane towards the ellipsoid.

It is convenient to define a new variable of integration,

$$[2.18] \quad \boldsymbol{r}_* = \mathbf{D}^{-1}\cdot\boldsymbol{r}\alpha$$

in place of $\boldsymbol{r}$ in [2.15]. For the time being the scalar α will be regarded as arbitrary. Inverse to [2.18] is the relation

$$[2.19] \quad \boldsymbol{r} = \mathbf{D}\cdot\boldsymbol{r}_*/\alpha$$

Equation [2.16] implies that the integration of $\boldsymbol{r}$ over V_1 in [2.15] is formally equivalent to integrating the integrand $dV_1{}^*E_\infty'(d + \mathbf{D}:\boldsymbol{n}\boldsymbol{r}_*/\alpha)$ over the volume $V_1{}^*$ of the sphere

$$[2.20] \quad \boldsymbol{r}_*\cdot\boldsymbol{r}_*/\alpha^2 \leq 1 \text{ (defines } V_1{}^*)$$

of radius α. Here,

$$dV_1 = dx_1dx_2dx_3 = a_1dx_1{}^*a_2dx_2{}^*a_3dx_3{}^*$$

whence

$$[2.21] \quad dV_1 = \alpha^{-3}\det\mathbf{D}\, dV_1{}^*$$

where $\boldsymbol{r} \equiv (x_1, x_2, x_3)$ and $\boldsymbol{r}_* \equiv (x_1{}^*, x_2{}^*, x_3{}^*)$. In addition,

$$[2.22] \quad \det\mathbf{D} = a_1a_2a_3$$

is a constant.

Define the positive scalar α as the magnitude of the vector $\boldsymbol{\alpha}$ defined as[3]

$$[2.23] \quad \boldsymbol{\alpha} = \hat{\boldsymbol{\alpha}}\alpha = \boldsymbol{n}\cdot\mathbf{D}$$

with $\hat{\boldsymbol{\alpha}}$ a unit vector along $\boldsymbol{\alpha}$. Thus,

$$[2.24] \quad \alpha = |\boldsymbol{n}\cdot\mathbf{D}|$$

or, equivalently,

$$[2.25] \quad \alpha^2 = \mathbf{D}^2{:}\boldsymbol{n}\boldsymbol{n}$$

In addition,

$$[2.26] \quad \hat{\boldsymbol{\alpha}} = \boldsymbol{n}\cdot\mathbf{D}/|\boldsymbol{n}\cdot\mathbf{D}|$$

Note that since $\mathbf{D}$ is a symmetric dyadic no difference exists between the vectors $\boldsymbol{n}\cdot\mathbf{D}$ and $\mathbf{D}\cdot\boldsymbol{n}$.

These transformations lead to a functional dependence of the potential E_∞' upon the following combination of variables:

$$[2.27] \quad d + \boldsymbol{n}\cdot\boldsymbol{r} = d + \mathbf{D}:\boldsymbol{n}\boldsymbol{r}_*/\alpha \equiv d + \boldsymbol{\alpha}\cdot\boldsymbol{r}_*$$

Equations [2.15], [2.20], and [2.21] combine with the latter to yield

$$[2.28] \quad E_\infty = \int_{\boldsymbol{r}_*\cdot\boldsymbol{r}_*\leq\alpha^2} dV_1{}^*\, E_\infty'(d + \hat{\boldsymbol{\alpha}}\cdot\boldsymbol{r}_*)n_1n_2 \times \alpha^{-3}\det\mathbf{D}$$

By comparing [2.15] with the above it is clear that the effect of the transformation of variables is such that the integrated potential for an ellipsoid (described by the dyadic $\mathbf{D}$, and whose center is at a distance d from a plane whose unit outer normal is $\boldsymbol{n}$) differs only by the scalar factor[4] $\alpha^{-3}\det\mathbf{D}$ from the integrated potential for a sphere (of radius α, whose center is at a distance d from a plane whose unit outer normal is $\hat{\boldsymbol{\alpha}}$). This theorem applies for all pairwise potentials ξ satisfying the restriction [2.12]. (Thus, for example, it would not be applicable to the potential between a uniformly charged plane and a uniformly charged ellipsoid, since such a case would result in $\xi = O(r^{-2})$, in violation of [2.12].)

Partial integration of [2.28] can be effected by defining a circular cylindrical coordinate system (ρ,ϕ,z) with unit vectors $(\hat{\boldsymbol{\rho}},\hat{\boldsymbol{\phi}},\hat{\boldsymbol{z}} = \hat{\boldsymbol{\alpha}})$ and with origin at O, the center of the ellipsoid V_1. In this coordinate system, $\boldsymbol{r}_* = \hat{\boldsymbol{\rho}}\rho + \hat{\boldsymbol{\alpha}}z$, whence $d + \hat{\boldsymbol{\alpha}}\cdot\boldsymbol{r}_* = d + z$. Consequently, the domain [2.20] corresponds to $\boldsymbol{r}_*\cdot\boldsymbol{r}_* = \rho^2 + z^2 \leq \alpha^2$. The volume element dV_1 is now $\rho d\rho d\phi dz$. Upon integration over the ranges $0 \leq \rho \leq (\alpha^2 - z^2)^{1/2}$ and $0 \leq \phi \leq 2\pi$, eq. [2.28] becomes

$$E_\infty = \pi n_1n_2\alpha^{-3}\det\mathbf{D}\int_{-\alpha}^{\alpha}(\alpha^2 - z^2) \times E_\infty'(d + z)dz$$

Explicitly,

$$[2.29] \quad E_\infty = 2\pi^2n_1n_2\alpha^{-3}\det\mathbf{D}\int_{z=-\alpha}^{\alpha}(\alpha^2 - z^2) \times \int_{\bar{r}=d+z}^{\infty}\bar{r}[\bar{r} - (d + z)]\xi(\bar{r})d\bar{r}dz$$

The latter follows from [2.13], [2.27], and the above definitions of the circular cylindrical coordinate system. It is convenient to scale distances with the body-dimension parameter α, in which case the integration variables appearing in [2.29] may be transformed via the definitions

$$[2.30] \quad u = \bar{r}/\alpha,\ \zeta = (z + d)/\alpha$$

and

[3]It is shown in Appendix A that the scalar $\alpha \equiv d - s$, where d is the distance of the ellipsoid center from the plane and s is the minimum separation distance between the ellipsoid and plane, i.e., the distance of the closest point on the ellipsoid surface from the plane. As such, α may be regarded as a body-size parameter whose value depends upon the ellipsoid's orientation.

[4]Note that this scalar factor is dimensionless and, hence, independent of the *size* of the ellipsoid. It depends only upon the *shape* $a_1 : a_2 : a_3$ of the ellipsoid and its orientation with respect to $\boldsymbol{n}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

[2.31] $\delta = d/\alpha$

Consequently,

$$[2.32] \quad E_\infty = 2\pi^2 n_1 n_2 \alpha^3 \det \mathbf{D} \int_{\zeta=\delta-1}^{\delta+1} [1 - (\zeta - \delta)^2] \times \int_{u=\zeta}^{\infty} u(u - \zeta)\xi(\alpha u)\mathrm{d}u\mathrm{d}\zeta$$

Upon reversing the order of the integrations appearing in [2.32], it is possible to reduce the two-dimensional integral to the sum of two one-dimensional integrals (over u):

$$[2.33] \quad E_\infty = 2\pi^2 n_1 n_2 \alpha^3 \det \mathbf{D} \times \left[\int_{\delta-1}^{\delta+1} u\xi(\alpha u)H(u; u)\mathrm{d}u + \int_{\delta+1}^{\infty} u\xi(\alpha u)H(u; \delta + 1)\mathrm{d}u \right]$$

in which

$$[2.34] \quad H(u; x) = \int_{\delta-1}^{x} (u - \zeta)[1 - (\zeta - \delta)^2]\mathrm{d}\zeta$$

The H integration is readily performed in closed form. However, we shall not bother to give the explicit result since, for the inverse-power potentials of interest to us here, the original two-dimensional integral [2.32] is actually algebraically easier to evaluate.[5]

3. Inverse-power Functions

In this section we perform the integration of [2.32] for inverse-power functions of the form

$$[3.1] \quad \xi(r) = K_q r^{-q} \quad (q > 3)$$

where K_q is a constant that may depend upon q. The restriction $q > 3$ is imposed by [2.12].

The intermediate result obtained after performing the u integration in [2.32] is

$$[3.2] \quad E_q = \frac{2\pi^2 n_1 n_2 K_q \alpha^{3-q} \det \mathbf{D}}{(q - 2)(q - 3)} \times \int_{\delta-1}^{\delta+1} [1 - (\zeta - \delta)^2]\mathrm{d}\zeta/\zeta^{q-3}$$

We have supressed the subscript ∞ (since it is no longer relevant), and introduced in its stead the subscript q, which denotes the inverse power of the intermolecular potential. After much algebra the remaining integral yields

$$[3.3] \quad E_q = 4\pi^2 n_1 n_2 K_q (\det \mathbf{D})\alpha^{3-q} f_q(\delta)$$

with

$$[3.4] \quad f_q(\delta) = \frac{1}{(q - 2)(q - 3)(q - 4)(q - 5)(q - 6)} \times \left\{ \frac{[\delta + (q - 5)](\delta - 1)^{q-5} - [\delta - (q - 5)](\delta + 1)^{q-5}}{(\delta^2 - 1)^{q-5}} \right\}$$

provided that $q \neq 4, 5, 6$ (and $q > 3$). An alternative, but perhaps simpler, form is

$$[3.5] \quad f_q(\delta) = \frac{1}{(q - 2)(q - 3)(q - 4)(q - 5)(q - 6)} \times \left[\frac{\delta + (q - 5)}{(\delta + 1)^{q-5}} - \frac{\delta - (q - 5)}{(\delta - 1)^{q-5}} \right]$$

The additional restrictions upon q are not intrinsic; that is, $q = 4$, 5, and 6 merely define special cases for which [3.4] or [3.5] are not valid due to the generation of a logarithmic term. Each of these three cases must be evaluated, one-by-one, directly from [3.2]. For example, in the physically important case $q = 6$, we obtain

$$[3.6] \quad f_6(\delta) = \frac{1}{4}\left[\frac{\delta}{3(\delta^2 - 1)} - \frac{1}{6}\ln\left(\frac{\delta + 1}{\delta - 1}\right) \right]$$

When the ellipsoid degenerates to a sphere of radius a, such that $\alpha = a_1 = a_2 = a_3 = a$, the above reduces to the classical result originally obtained by Hamaker (25).

The form of the intermolecular potential V_{12} between a pair of molecules within the ellipsoid and slab, respectively, when separated by a distance r_{12} will be assumed to be given by (28, 29)

$$[3.7] \quad V_{12} = 4\varepsilon[(\sigma/r_{12})^n - (\sigma/r_{12})^m] \qquad (n > m)$$

with σ the collision diameter (2 to 10 Å) and ε the interaction energy (ε/k = 10 to 1000 K, in which k is Boltzmann's constant). The first term corresponds to a short-range repulsion and the second to a long-range attraction. Such a potential was used by Bradley (30). Although Dahneke (22) is critical of the repulsive term — presenting sound arguments for particle flattening and the concomitant use of Hertz's theory of repulsion via the compressive stresses generated within the particle — we shall nevertheless utilize the repulsive term in [3.7]. All we really seek here is an illustrative example applicable to a prototype nonspherical particle. For this

[5] The utility of [2.33] would appear only for potentials where the inner integration in [2.32] could not be accomplished in closed form, thereby requiring numerical quadrature. It is obviously far easier to perform a one-dimensional numerical integration than a two-dimensional one.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

reason also, retardation effects, explained by the Lifshitz field theory, will also be ignored — although they are known to increase the exponent of the classical attractive potential from $m = 6$ to $m = 7$ at intermolecular distances $r_{12} > \sim 50$ nm (3, 23).

The potential energy E of the ellipsoid corresponding to the intermolecular potential [3.7] can be derived from the relation $E = E_n - E_m$ where E_n and E_m are given by [3.3] with the choice of the constants $K_n = 4\varepsilon\sigma^n$ and $K_m = 4\varepsilon\sigma^m$. In this manner there results

$$[3.8] \quad E = 4A\alpha^{-3} \det \mathbf{D} \left[-\left(\frac{\sigma}{\alpha}\right)^{m-6} f_m(\delta) + \left(\frac{\sigma}{\alpha}\right)^{n-6} f_n(\delta) \right]$$

where

$$[3.9] \quad A = 4\pi^2 n_1 n_2 \varepsilon \sigma^6$$

is Hamaker's "constant". Typical numerical values of A lie in the range 5×10^{-13} to 5×10^{-12} ergs (19).

Precedent exists for using a Leonard-Jones 6-12 potential ($m = 6$, $n = 12$). However, since the exponent of the repulsive term is not very well quantified, we will choose $n = 8$ in the interests of simpler algebra. Thus, [3.8] becomes

$$[3.10] \quad E = A\alpha^{-3} \det \mathbf{D} \left[\frac{1}{6} \ln\left(\frac{\delta + 1}{\delta - 1}\right) - \frac{\delta}{3(\delta^2 - 1)} + \frac{4}{45}\left(\frac{\sigma}{\alpha}\right)^2 \frac{\delta}{(\delta^2 - 1)^3} \right]$$

for the 6-8 intermolecular potential.

4. Force and Torque on the Ellipsoid

The results of the preceding section will now be used to illustrate how dispersion forces contribute to the *en vacuo* interaction between an ellipsoidal particle and a semi-infinite solid bounded by a plane. Of particular interest is the calculation of the equilibrium orientation and separation distance of the ellipsoid from the plane.

As regards possible applications to the class of boundary-layer problems outlined in the Introduction, the calculation to be performed should be regarded as purely expository with respect to the physics. Although double-layer forces are often important in liquid systems (3, 21), they do not give rise to an infinite repulsion. Since they do not provide qualitatively "correct" behavior they will not be further considered. Rather, the particle/boundary potential will be assumed to be the net effect only of the pairwise intermolecular interactions, which constitutes the sole theoretical thrust of the present paper.

The potential energy E of the ellipsoid may be regarded as a function of the location[6] $\boldsymbol{R}$ of its center and of its orientation $\boldsymbol{\phi}$. Thus,

$$[4.1] \quad E = E(\boldsymbol{R}, \boldsymbol{\phi})$$

The notation is that of Brenner and Condiff (5, 12). In terms of these variables the external force $\boldsymbol{F}$ and torque $\boldsymbol{T}$ (about the center O of the ellipsoid) exerted on the ellipsoid by the slab are, respectively,

$$[4.2a,b] \quad \boldsymbol{F} = -\partial E/\partial \boldsymbol{R})_{\boldsymbol{\phi}}, \quad \boldsymbol{T} = -\partial E/\partial \boldsymbol{\phi})_{\boldsymbol{R}}$$

It is convenient to choose the origin from which $\boldsymbol{R}$ is to be measured to lie on the bounding plane of the slab. With this choice,

$$[4.3] \quad d = \boldsymbol{R}\cdot\boldsymbol{n}$$

Relative to space-fixed axes locked into the slab, the body-fixed ellipsoidal unit vectors $\boldsymbol{e}_j$ ($j = 1, 2, 3$) appearing in the definition [2.17] of $\mathbf{D}$ are each functions of the orientation $\boldsymbol{\phi}$ of the ellipsoid. While the $\boldsymbol{e}_j$ can be expressed in terms of space-fixed unit vectors (of which $\boldsymbol{n}$ is one) via a system of Eulerian angles (5), such an explicit representation will not be required for our purposes. Rather, all the requisite calculations can be brought to fruition in invariant form. It will suffice in this respect merely to note that $\mathbf{D} = \mathbf{D}(\boldsymbol{\phi})$, whence [2.24] or [2.25] may be regarded as giving α as a function of $\boldsymbol{\phi}$ and $\boldsymbol{n}$. Thus, with these choices we have that

$$[4.4a,b] \quad d = d(\boldsymbol{R},\boldsymbol{n}), \qquad \alpha = \alpha(\boldsymbol{\phi},\boldsymbol{n})$$

where the former is given explicitly by [4.3]. In our space-fixed view, $\boldsymbol{n}$ is, of course, to be regarded as a given constant vector.

The results of Section 3 give E explicitly in the functional form

$$[4.5] \quad E = E(d,\alpha)$$

rather than in the form [4.1]. The transformations of partial derivatives between the (d,α) and $(\boldsymbol{R},\boldsymbol{\phi})$ systems, required to calculate $\boldsymbol{F}$ and $\boldsymbol{T}$ via [4.2], are readily effected by standard methods to obtain

$$[4.6] \quad \left(\frac{\partial E}{\partial \boldsymbol{R}}\right)_{\boldsymbol{\phi}} = \left(\frac{\partial d}{\partial \boldsymbol{R}}\right)_{\boldsymbol{n}} \left(\frac{\partial E}{\partial d}\right)_{\alpha} = \boldsymbol{n}\left(\frac{\partial E}{\partial d}\right)_{\alpha}$$

and

$$[4.7] \quad \left(\frac{\partial E}{\partial \boldsymbol{\phi}}\right)_{\boldsymbol{R}} = \left(\frac{\partial \alpha}{\partial \boldsymbol{\phi}}\right)_{\boldsymbol{n}} \left(\frac{\partial E}{\partial \alpha}\right)_{d}$$

[6]This position vector should not be confused with the vector $\boldsymbol{R}$ appearing in [2.6].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Equation [4.3] has to be utilized in the former of these relations. Upon differentiation, [2.25] yields

$$[4.8]\quad \left(\frac{\partial\alpha}{\partial\phi}\right)_n = \frac{1}{2\alpha}\left(\frac{\delta\mathbf{D}^2}{\delta\phi}\right):\boldsymbol{nn}$$

However, for any body-fixed dyadic, $\Psi = \Psi(\phi)$, Brenner and Condiff (5) show that

$$[4.9]\quad \frac{\delta\Psi}{\delta\phi} = -[\boldsymbol{\varepsilon}:\Psi + (\boldsymbol{\varepsilon}:\Psi^{\dagger})^{\dagger}]$$

in which $\boldsymbol{\varepsilon}$ is the unit alternating pseudoisotropic triadic ($\boldsymbol{\varepsilon} = -\mathbf{I}\times\mathbf{I}$, with $\mathbf{I}$ the unit dyadic). The dagger denotes a dyadic transposition operator. A straightforward calculation utilizing the symmetry properties of $\mathbf{D}^2$ (and $\boldsymbol{nn}$) eventually yields

$$[4.10]\quad \frac{\delta\mathbf{D}^2}{\delta\phi}:\boldsymbol{nn} = 2(\boldsymbol{\varepsilon}\cdot\boldsymbol{n})\cdot\mathbf{D}^2\cdot\boldsymbol{n} \equiv -2(\boldsymbol{n}\times\mathbf{D})\cdot(\mathbf{D}\cdot\boldsymbol{n})$$

Substitution of the latter into [4.8] followed by use of [2.24] and [2.26] thereby gives

$$[4.11]\quad \left(\frac{\partial\alpha}{\partial\phi}\right)_n = -\boldsymbol{n}\times\mathbf{D}\cdot\hat{\boldsymbol{\alpha}}$$

In this manner [4.7] becomes

$$[4.12]\quad \left(\frac{\partial E}{\partial\phi}\right)_R = -\boldsymbol{n}\times\mathbf{D}\cdot\hat{\boldsymbol{\alpha}}\left(\frac{\partial E}{\partial\alpha}\right)_d$$

Equation [4.2] for the force and torque may now be written as

$$[4.13]\quad \boldsymbol{F} = -\boldsymbol{n}\left(\frac{\partial E}{\partial d}\right)_\alpha$$

$$[4.14]\quad \boldsymbol{T} = \boldsymbol{n}\times\mathbf{D}\cdot\hat{\boldsymbol{\alpha}}\left(\frac{\partial E}{\partial\alpha}\right)_d$$

Alternatively, in terms of the vector defined as

$$[4.15]\quad \boldsymbol{r}_s = -\mathbf{D}\cdot\hat{\boldsymbol{\alpha}}$$

the torque may be expressed in the form

$$[4.16]\quad \boldsymbol{T} = -\boldsymbol{n}\times\boldsymbol{r}_s\left(\frac{\partial E}{\partial\alpha}\right)_d$$

It is demonstrated in Appendix A (see Fig. 2) that, for a fixed position and orientation of the ellipsoid, the vector $\boldsymbol{r}_s$ is the vector drawn from the center of the ellipsoid to that point on its surface which lies closest to the plane. The tendency of the torque is thus to rotate the body about an axis which is perpendicular to the plane formed from the vectors $\boldsymbol{n}$ and $\boldsymbol{r}_s$.[7]

Equation [4.13] shows that the direction of the force on the ellipsoid is always normal to the plane of the slab, while [4.16] shows that the torque possesses no component about an axis normal to the wall ($\boldsymbol{n}\cdot\boldsymbol{T} = 0$) that would otherwise tend to rotate the ellipsoid about such an axis. Both of these conclusions are obviously consistent with the transversely isotropic nature of the (homogeneous) slab with respect to the $\boldsymbol{n}$ axis. For there exists no mechanism by which the different perspectives offered by the body as it is rotated about the $\boldsymbol{n}$ axis can be physically distinct from one another. Rather, rotation of the body about such an axis cannot be physically distinguished from a rotation of the observer, and such a rotation clearly cannot result in any force or torque on the body.

We note also that in the special case where the ellipsoid degenerates to a sphere, $a_1 = a_2 = a_3 = a$, say, that $\mathbf{D} = \mathbf{I}a$. For this situation $\hat{\boldsymbol{\alpha}} = \boldsymbol{n}$, whence $\boldsymbol{T} = 0$. The vanishing of the torque under these circumstances is obviously consistent with the geometry symmetry of the sphere/slab system.

Of particular interest are the position(s) and orientation(s) for which the ellipsoid experiences no net force or torque. These states will be denoted by the superscript 0. Hence, d^0 (or $\boldsymbol{R}^0$) will denote the force-free position of the ellipsoid (which value will be shown generally to vary with the "orientation" α of the ellipsoid). Similarly, $\boldsymbol{e}_j{}^0 (j = 1, 2, 3)$ or ϕ^0 or $\mathbf{D}^0$ or α_0 will denote the torque-free state. (This state will be shown to be independent of the "position" d of the ellipsoid.) Double superscript notation, e.g. d^{00}, will represent the combined force- and torque-free states.

From [4.13], for a fixed orientation α, the condition $\boldsymbol{F} = 0$ corresponds to that value of $d = d^0$ for which $(\partial E/\partial d)_\alpha = 0$, i.e.

$$[4.17]\quad (\partial E/\partial d)_\alpha^0 \overset{\text{def.}}{=} (\partial E/\partial d)_\alpha|_{d=d^0} = 0$$

From [3.10] there follows

$$[4.18]\quad (\partial E/\partial d)_\alpha = A\alpha^{-4}\det\mathbf{D}\left[\frac{2}{3(\delta^2-1)^2} - \frac{4}{45}\left(\frac{\sigma}{\alpha}\right)^2\frac{5\delta^2+1}{(\delta^2-1)^4}\right]$$

[7] It is also demonstrated in Appendix A that $\boldsymbol{n}\cdot\boldsymbol{r}_s = -\alpha$. Thus, if $\boldsymbol{r}_s$ rather than α is used as the orientational variable, eq. [4.16] may be expressed in the interesting invariant form

$$\boldsymbol{T} = (\boldsymbol{n}\times\boldsymbol{r}_s)\boldsymbol{n}\cdot(\partial E/\partial\boldsymbol{r}_s)_{n,d}$$

directly in terms of the physically observable vectors $\boldsymbol{n}$ and $\boldsymbol{r}_s$.

The value

[4.19] $\delta^0 = d^0/\alpha$

corresponding to the vanishing of the term in square brackets in [4.18] is easily found to be

[4.20] $$\delta^0 = \left[1 + \frac{2}{\sqrt{5}}\left(\frac{\sigma}{\alpha}\right)\left\{1 + \frac{5}{36}\left(\frac{\sigma}{\alpha}\right)^2\right\}^{1/2} + \frac{1}{3}\left(\frac{\sigma}{\alpha}\right)^2\right]^{1/2}$$

Now σ is of molecular dimensions, whereas α — which is of the order of the size of the ellipsoid — is of macroscopic dimensions. Thus, $\sigma/\alpha \ll 1$. Hence, by the binomial theorem

[4.21] $$\delta^0 \simeq 1 + \frac{1}{\sqrt{5}}\left(\frac{\sigma}{\alpha}\right) + \frac{1}{15}\left(\frac{\sigma}{\alpha}\right)^2 + O\left(\frac{\sigma}{\alpha}\right)^3$$

In conjunction with [4.19] this equation yields the distance d^0 (for each orientation α) at which $\boldsymbol{F} = 0$. To establish whether, for a fixed orientation α, the condition [4.17] corresponds to a (local) minimum or maximum (if either), we calculate

$$\left(\frac{\partial^2 E}{\partial d^2}\right)_\alpha^0 \overset{\text{def.}}{=} \left(\frac{\partial^2 E}{\partial d^2}\right)_\alpha\Bigg|_{\delta=\delta^0} = \frac{8A(\det \mathbf{D})}{45\alpha^5}\left(\frac{\sigma}{\alpha}\right)^2 \frac{\delta^0[5(\delta^0)^2 + 7]}{[(\delta^0)^2 - 1]^5}$$

Inasmuch as $\delta^0 > 1$ this shows that

[4.22] $(\partial^2 E/\partial d^2)_\alpha^0 > 0$

whence the condition [4.21] corresponds to a minimum for each α. Equivalently, if we write $\boldsymbol{F} = \boldsymbol{n}F(d,\alpha)$ then $F < 0$ for $d > d^0$ and $F > 0$ for $d < d^0$. In words, (for each orientation) the force exerted on the ellipsoid by the slab is attractive if the ellipsoid center is further away from the plane than d^0, and repulsive if closer than d^0.

From [4.14] the condition that $\boldsymbol{T} = 0$ requires that the right-hand side be zero. By the chain rule,

$$(\partial E/\partial\alpha)_d = (\partial E/\partial\alpha)_\delta + (\partial\delta/\partial\alpha)_d(\partial E/\partial\delta)_\alpha$$

However, from the definition [2.31] of δ, we have $(\partial E/\partial\delta)_\alpha = (\partial E/\partial d)_\alpha$. The latter vanishes in the force-free state as a consequence of [4.17]. Hence, $(\partial E/\partial\alpha)_d^0 = (\partial E/\partial\alpha)_\delta^0$. Upon differentiating [3.10] with respect to α at constant δ and evaluating the result at the value of δ^0 given by [4.21] we eventually obtain

[4.23] $$\left(\frac{\partial E}{\partial\alpha}\right)_d^0 = \frac{A \det \mathbf{D}}{\alpha^4}\left(\frac{\sigma}{\alpha}\right)\left[\frac{2\sqrt{5}}{9} + O\left(\frac{\sigma}{\alpha}\ln\frac{\sigma}{\alpha}\right)\right]$$

It is a consequence of this that

[4.24] $(\partial E/\partial\alpha)_d^0 \overset{\text{def.}}{=} (\partial E/\partial\alpha)_{d=d^0} > 0$

for all orientations α.

Equation [4.14] thereby shows that the force- and torque-free condition requires that the vector $\mathbf{D}\cdot\hat{\boldsymbol{\alpha}}^0$ be colinear with $\boldsymbol{n}^0$,[8] whence it is required that

[4.25] $\mathbf{D}\cdot\hat{\boldsymbol{\alpha}}^0 = \lambda\boldsymbol{n}^0$

wherein (cf. [2.26])

[4.26] $\hat{\boldsymbol{\alpha}}^0 = \mathbf{D}\cdot\boldsymbol{n}^0/|\mathbf{D}\cdot\boldsymbol{n}^0|$

and λ is a scalar to be determined. Explicitly, the latter two equations necessitate that

[4.27] $\mathbf{D}^2\cdot\boldsymbol{n}^0/\alpha_0 = \lambda\boldsymbol{n}^0$

in which

[4.28] $\alpha_0 = (\boldsymbol{n}^0\cdot\mathbf{D}^2\cdot\boldsymbol{n}^0)^{1/2} \equiv |\mathbf{D}\cdot\boldsymbol{n}^0|$

Dot multiply [4.27] by $\boldsymbol{n}^0$ and use the definition of α_0 to obtain $\lambda = \alpha_0$. Consequently, [4.27] shows that the zero torque condition corresponds to those values of $\boldsymbol{n}^0$ for which

[4.29] $\mathbf{D}^2\cdot\boldsymbol{n}^0 = \alpha_0{}^2\boldsymbol{n}^0$

The preceding relation requires that the zero-torque orientation $\boldsymbol{n}^0$ be an eigenvector of $\mathbf{D}^2$ (and that $\alpha_0{}^2$ be an eigenvalue). However, [2.17] shows that, in general,

[4.30] $\mathbf{D}^2\cdot\boldsymbol{e}_j = a_j{}^2\boldsymbol{e} \qquad (j = 1, 2, 3)$

Comparison with [4.29] thereby yields[9]

[4.31] $\boldsymbol{n}^0 = \boldsymbol{e}_j \qquad (j = 1, 2, 3)$

with corresponding eigenvalues

[4.32] $\alpha_0{}^2 = a_j{}^2 \qquad (j = 1, 2, 3)$

Equation [4.31] is equivalent to the conclusion that the ellipsoid will experience no net torque when it is oriented in such a manner that one of its three

[8]Since we are concerned only with the *relative* orientations of the ellipsoid and plane, we have altered our notation here so as to regard the ellipsoid as being fixed and the plane as being rotated; that is, in place of the notation $(\mathbf{D}^0, \boldsymbol{n})$ we prefer to use $(\mathbf{D}, \boldsymbol{n}^0)$. The *relative* orientation is, of course, the same in both views. This is an algebraically simpler view than the prior one, in which in place of equation [4.25] there would arise the more complex-appearing equation $\mathbf{D}^0\cdot\hat{\boldsymbol{\alpha}}^0 = \lambda\boldsymbol{n}$, wherein $\hat{\boldsymbol{\alpha}}^0 = \mathbf{D}^0\cdot\boldsymbol{n}/|\mathbf{D}^0\cdot\boldsymbol{n}|$.

[9]If we revert back to our previous perspective, where the plane is regarded as fixed, and the ellipsoid free to rotate, the three zero-torque orientations of the ellipsoid $(\boldsymbol{e}_1{}^0, \boldsymbol{e}_2{}^0, \boldsymbol{e}_3{}^0)$ are those for which $\boldsymbol{e}_j{}^0 = \boldsymbol{n}$ $(j = 1, 2, 3)$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

principal axes is perpendicular to the wall. The other two principal axes will, of course, lie in a plane parallel to the wall.

In terms of the body-fixed vector $\boldsymbol{r}_s$ defined in [4.15], whose physical significance is described in Appendix A, these zero-torque orientations correspond to the three orientations

$$[4.33] \quad \boldsymbol{r}_s^0 = a_j \boldsymbol{e}_j \equiv a_j \boldsymbol{n} \qquad (j = 1, 2, 3)$$

In deriving [4.31] we have not actually used the explicit form of $E(d,\alpha)$ given in [3.10], except insofar as the inequality [4.24] is concerned. Thus, the orientational result is much more general than might otherwise be implied. Indeed, it is obviously a pure symmetry result, demanded by the geometric symmetry of the ellipsoid and the slab, and is quite independent of the explicit form of the potential.

Of the three possible orientations of the ellipsoid that result in no torque it remains yet to establish which of these is the stable, equilibrium orientation. The equilibrium position and orientation necessarily correspond to a minimum potential energy for the ellipsoid; that is, $(\partial E/\partial \boldsymbol{R})^*_\phi = 0$ and $(\partial E/\partial \phi)^*_R = 0$, where the asterisk denotes the equilibrium state. From [4.2] these correspond to a force- and torque-free state. While these conditions are necessary for a stable equilibrium, they are by themselves insufficient (31). Sufficient conditions require that the second variation

$$[4.34] \quad \Delta^2 E = \Delta \boldsymbol{R} \cdot \partial^2 E/\partial \boldsymbol{R} \partial \boldsymbol{R} \cdot \Delta \boldsymbol{R} + 2\Delta \boldsymbol{R} \cdot (\partial^2 E/\partial \phi \partial \boldsymbol{R})_{sym} \cdot \Delta \phi + \Delta \phi \cdot \partial^2 E/\partial \phi \partial \phi \cdot \Delta \phi$$

satisfy the inequality (31)

$$[4.35] \quad \Delta^2 E^* > 0$$

for arbitrary displacements $(\Delta \boldsymbol{R}, \Delta \phi)$ from the equilibrium state E^*. Here, "sym" denotes the symmetric portion of the dyadic. It is shown in Appendix B that [4.34] reduces in the state E^{00} of zero force and torque to

$$[4.36] \quad \Delta^2 E^{00} = (\boldsymbol{n} \cdot \Delta \boldsymbol{R})^2 \left(\frac{\partial^2 E}{\partial d^2}\right)^0_\alpha - \Delta \phi \cdot \left(\frac{\partial^2 \alpha}{\partial \phi \partial \phi}\right)^0 \cdot \Delta \phi \left(\frac{\partial E}{\partial \alpha}\right)^0_d$$

in which

$$[4.37] \quad \left(\frac{\partial^2 \alpha}{\partial \phi \partial \phi}\right)^0 = -\frac{1}{\alpha_0}[\alpha_0^2(\mathbf{I} - \boldsymbol{n}^0\boldsymbol{n}^0) + \boldsymbol{n}^0 \times \mathbf{D}^2 \times \boldsymbol{n}^0]$$

As regards the first term of [4.36], we have from [4.3] that

$$\Delta d = \boldsymbol{n} \cdot \Delta \boldsymbol{R}$$

Into [4.37] introduce the expressions [4.31] and [4.32]. In addition, write

$$\mathbf{I} = \boldsymbol{e}_j\boldsymbol{e}_j + \boldsymbol{e}_k\boldsymbol{e}_k + \boldsymbol{e}_l\boldsymbol{e}_l$$

and

$$\mathbf{D}^2 = \boldsymbol{e}_j\boldsymbol{e}_j a_j^2 + \boldsymbol{e}_k\boldsymbol{e}_k a_k^2 + \boldsymbol{e}_l\boldsymbol{e}_l a_l^2$$

in which (j,k,l) is a cyclic permutation of the indices 1, 2, and 3 (so that $j \neq k \neq l$). In this manner [4.37] becomes

$$\left(\frac{\partial^2 \alpha}{\partial \phi \partial \phi}\right)^0 = \frac{1}{a_j}[\boldsymbol{e}_k\boldsymbol{e}_k(a_l^2 - a_j^2) + \boldsymbol{e}_k\boldsymbol{e}_k(a_k^2 - a_j^2)]$$

with $\boldsymbol{e}_j$ the zero-torque orientation (cf. [4.31]) and $j \neq k \neq l$. An arbitrary infinitesimal rotation $\Delta\phi$ can be expressed as (5)

$$\Delta \phi = \boldsymbol{e}_j \Delta\phi_j + \boldsymbol{e}_k \Delta\phi_k + \boldsymbol{e}_l \Delta\phi_l$$

With these substitutions [4.36] becomes

$$[4.38] \quad \Delta^2 E^{00} = (\Delta d)^2 (\partial^2 E/\partial d^2)^0_\alpha + a_j^{-1}[(\Delta\phi_k)^2(a_l^2 - a_j^2) + (\Delta\phi_l)^2(a_k^2 - a_j^2)](\partial E/\partial\alpha)^0_d$$

The combined zero-force and zero-torque state (00) corresponds to a special case of the equilibrium state (*). Thus, in view of [4.22] and [4.24], the inequality [4.35] will be satisfied if, and only if, simultaneously,

$$a_l > a_j \text{ and } a_k > a_j$$

This is equivalent to the requirement that

$$[4.39] \quad a_j = \min(a_1, a_2, a_3)$$

since $j \neq k \neq l$. Inasmuch as $\boldsymbol{e}_j$ has been established to lie parallel to $\boldsymbol{n}$, it may be concluded that the stable equilibrium orientation of the ellipsoid is such that the shortest principal axis of the ellipsoid lies normal to the plane of the slab. Thus, for example, an oblate spheroid will be at equilibrium when its axis of revolution lies normal to the plane, whereas a prolate spheroid will be equilibrated with its axis of revolution parallel to the plane.

Though these conclusions may appear to be limited to situations for which the potential is specifically given by [3.10] ($m = 6$, $n = 8$), the result is clearly true for any attractive/repulsive potential for which the inequalities [4.22] and [4.24]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

are valid. And these inequalities can be shown[10] to obtain whenever $m > n$ in [3.8]. In this sense the stable equilibrium orientational conclusion may be regarded as arising essentially as a result of geometric symmetry rather than from the specific nature of the intermolecular potential energy function [3.7] (with $m = 6$ and $n = 8$).

A homogeneous ellipsoidal particle at rest under the influence of gravity on a horizontal plane wall would do so with its center (of mass) as close to the wall as possible (see Appendix C). This corresponds to the same stable orientation as was found for the attractive/repulsive potential. As such, it reinforces the view that the result may be attributed solely to the geometric symmetry of the ellipsoid/plane wall configuration. Note that in this analogy the short-range repulsive force exerted on the ellipsoid by the wall (i.e., the reaction force at the contact point) has an infinite step function character, rather than deriving from a "soft" potential.

The advantage of our method of calculating the stable equilibrium orientation of the ellipsoid over alternative methods lies in the fact that it shows that the conclusions are independent of the particular potential selected. However, it is also possible to arrive at this orientational conclusion by more elementary means for any specific potential, e.g. [3.10]. Let $d^0 \equiv d^0(\alpha)$ [or, equivalently, $\delta^0(\alpha) = d^0/\alpha$] represent the distance at which the ellipsoid experiences no force. This distance varies, of course, with each orientation α, and corresponds to those values of d for which $(\partial E/\partial d)^0_\alpha = 0$ (and $(\partial^2 E/\partial d^2)^0_\alpha > 0$). The function

$$[4.40] \quad E^0(\alpha) \overset{\text{def.}}{=} E(d = d^0, \alpha)$$

gives the potential energy as a function of α for this zero-force condition. Since the stable equilibrium configuration corresponds to the minimum value of the potential energy function, the stable equilibrium orientation α^* may then be found by establishing the value of α which minimizes $E^0(\alpha)$:

$$[4.41] \quad \alpha^* = \min_\alpha E^0(\alpha)$$

(for which orientation the minimum potential energy E^* is, in fact, $E^* = \min_{d,\alpha} E(d,\alpha) \equiv E^0(\alpha^*)$).

From its definition, [2.24], α spans the bounded range

$$[4.42] \quad a_{\min} \leq \alpha \leq a_{\max}$$

where $a_{\min}$ and $a_{\max}$ are, respectively, the minimum and maximum values of the three lengths (a_1,a_2,a_3). In conducting the search for the value of α which minimizes $E^0(\alpha)$ two possibilities (31) need be considered: (*i*) the point α^* is an interior point — that is, the end points $a_{\min}$ and $a_{\max}$ of the interval [4.42] are not included (in which case the minimum corresponds to the value of α for which $\partial E^0/\partial\alpha|_{\alpha=\alpha^*} = 0$ with $\partial^2 E^0/\partial\alpha^2|_{\alpha=\alpha^*} > 0$); or (*ii*) the point α^* satisfying [4.41] is one of the two boundary points, $a_{\min}$ or $a_{\max}$.

We carried out this search procedure (numerically) for the potential [3.10], for which case the function $E^0(\alpha)$ is given by [3.10] with δ replaced by the expression for δ^0 appearing in [4.20]. It was found that case (*ii*) applied, and that the $\alpha^* = a_{\min}$. This nonvectorial calculation confirms, albeit in a specific case, the more general geometrical conclusions arrived at earlier.

5. Discussion

Having established the stable equilibrium orientation such that $\alpha^* = a_{\min}$, with $a_{\min} = \min(a_1,a_2,a_3)$, eq. [4.21] (or, more accurately, [4.20]) yields the equilibrium distance

$$[5.1] \quad d^* \simeq a_{\min}\left(1 + \frac{1}{\sqrt{5}}\frac{\sigma}{a_{\min}}\right)$$

of the ellipsoid center from the plane. Alternatively, from [A.1], the minimum clearance distance s^* between the ellipsoid and the wall is

$$[5.2] \quad s^* \simeq \sigma/\sqrt{5}$$

Interestingly, this distance is independent of the actual dimensions of the ellipsoid, though such dependence would arise in the next order approximation, involving a term of $O(\sigma^2/a_{\min})$ in s^*. Since, typically, σ lies between 2 and 10 Å, the equilibrium gap width s^* is of the order of molecular dimensions. Considering the roughness of real surfaces, the effect of Hertzian flattening (22, 23), and the implicit approximations of the pairwise additive continuum model, such a result cannot be taken literally. However, the orientational result is likely to remain valid provided that $\boldsymbol{n}$ is interpreted as representing the normal to the *mean* or *projected* area of the rough

[10]Such proofs may be formulated by utilizing the definition $E = E_n - E_m$ $(n > m)$ in conjunction with the monotonicity condition $(\partial E_q/\partial d)_\alpha > 0$ applicable for all q. The zero-force condition then corresponds to $(\partial E_n/\partial d)^0_\alpha = (\partial E_m/\partial d)^0_\alpha$ at $d = d^0$, in addition to which the inequalities, $(\partial E_n/\partial d)_\alpha > (\partial E_m/\partial d)_\alpha$ for $d > d^0$ (and conversely), are readily established. Use of the Taylor series expansions about the zero-force point,

$$(\partial E_q/\partial d)_\alpha = (\partial E_q/\partial d)^0_\alpha + (\partial^2 E_q/\partial d^2)^0_\alpha(d - d^0) + \ldots$$

applied to $q = m$ and $q = n$ may then be employed to establish the general nature of the inequality [4.22]. Similar methods, utilizing the specific functional form [3.3] in conjunction with the fact that $\delta = d/\alpha$, may also be used to establish the general nature of the orientational inequality [4.24].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

and/or deformed surface,

$$[5.3] \quad \boldsymbol{n} = \int d\boldsymbol{s}/|\int d\boldsymbol{s}|$$

where $d\boldsymbol{s}$ represents the "true" directed element of surface area at a point on the "true" surface of the rough slab (32).

Gallily (33) photographed bacterial spores deposited on a plate. These spores were approximately 1 μm in size, and resembled prolate spheroids with an axis ratio of approximately 2:1. His experiments revealed that spores deposited from a liquid medium (which had subsequently been evaporated) do tend to lie flat on the surface, in agreement with the conclusions drawn here. However, for deposition from a gaseous medium he found a distribution of angles θ (between the normal to the plane and the symmetry axis of the spheroid), with a median angle of 30°, instead of the 90° angle predicted by the present theory. In both cases Gallily expected a completely random distribution of angles, for which the orientational probability density function would be sin θ. Thus, his results did not confirm his prediction in either case. He concluded that the liquid-deposited spores had been pulled flat by surface tension during the evaporation process, and that the gas-deposited spores showed deviations from the sin θ density distribution due to their being permanently charged, resulting in an electrostatic interaction with the metal plate upon which they were deposited. Were such the case the nature of the ellipsoid/plane interaction would be different from that considered here.

To the extent that the *en vacuo* ellipsoid/plane potential may be employed even in the presence of an intervening fluid (3), the potential energy function E gives rise to a Boltzmann probability density $P(\boldsymbol{R}, \phi)$ for the position $\boldsymbol{R}$ of the center of the ellipsoid and its orientation ϕ of the form

$$[5.4] \quad P(\boldsymbol{R},\phi) = P_{\max} \exp\left[\frac{E_{\min} - E(\boldsymbol{R},\phi)}{kT}\right]$$

The normalization constant $P_{\max}$ is determined by the requirement that (5)

$$[5.5] \quad \int_{\boldsymbol{R}} \int_{\phi} P \, d^3\phi \, d^3\boldsymbol{R} = 1$$

where the integration is over all positions and orientations. In the simple case of ellipsoids of revolution, [2.17] becomes

$$[5.6] \quad \mathbf{D} = \boldsymbol{ee}a_{\parallel} + (\mathbf{I} - \boldsymbol{ee})a_{\perp}$$

where $\boldsymbol{e}$ is a body fixed unit vector (5) along the symmetry axis and $a_{\parallel}$ and $a_{\perp}$ are, respectively, the semilengths parallel and perpendicular to the axis of revolution of the spheroid. With the cone angle θ between $\boldsymbol{n}$ and $\boldsymbol{e}$ defined as $\cos\theta = \boldsymbol{e}\cdot\boldsymbol{n}$, this yields

$$[5.7] \quad \alpha = [(a_{\parallel}^2 - a_{\perp}^2)\cos^2\theta + a_{\perp}^2]^{1/2}$$

In this manner [5.4] becomes

$$[5.8] \quad P(d,\theta) = P_{\max} \exp\left[\frac{E_{\min} - E(d,\theta)}{kT}\right]$$

with $P_{\max}$ chosen such that

$$[5.9] \quad 2\pi \int_0^{\infty} \int_0^{\pi} P(d,\theta) \sin\theta \, d\theta dd = 1$$

In this expression $E(d,\theta)$ is given by [3.10] with the value of $\alpha \equiv \alpha(\theta)$ cited in [5.7], and $\det \mathbf{D} = a_{\parallel}a_{\perp}^2$.

Integration of [5.8] over all positions defines the conditional probability density

$$[5.10] \quad p(\theta) = \int_0^{\infty} P(d,\theta) dd$$

that the spheroid will possess an orientation θ irrespective of its position. It is this type of quantity that was presumably measured in Gallily's (33) liquid-phase experiments, since the distances s^* are so small as to be unmeasurable.

In effect, these considerations show how the Brownian motion may be expected to influence the observed orientations of nonspherical particles in proximity to boundaries. Gravitational effects arising from different particle and fluid densities could be incorporated into the calculation by adding to the London – van der Waals potential E the appropriate gravitational potential (cf. Appendix C).

Appendix A. Separation Distance between an Ellipsoid and a Plane

In this appendix it will be demonstrated that the physical significance of the parameter α defined in [2.24] is such that (see Fig. 2)

[A.1] $\alpha = d - s$

where, for a fixed orientation of the ellipsoid relative to the plane, s is the minimum separation distance between a point on the surface of the ellipsoid and the plane.

To prove this relation let $\boldsymbol{r}$ be a position vector drawn from the center O of the ellipsoid to an arbitrary point P lying upon its surface; that is, $\boldsymbol{r}$ is a solution of the equation

[A.2] $\boldsymbol{r}\cdot\mathbf{D}^{-2}\cdot\boldsymbol{r} = 1$

Let l be the distance from the plane to the terminus of $\boldsymbol{r}$. Then

[A.3] $l = d + \boldsymbol{n}\cdot\boldsymbol{r}$

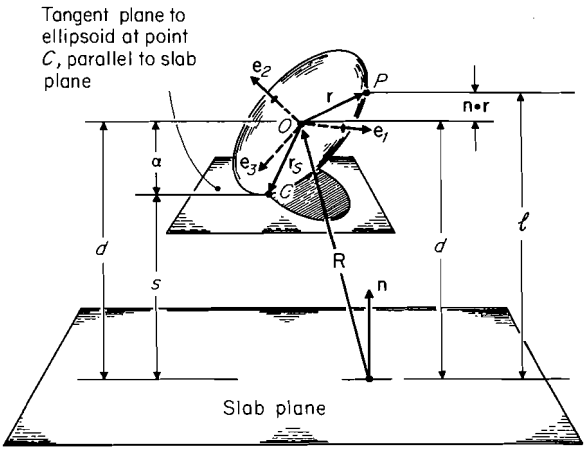

FIG. 2. Ellipsoid near a plane wall bounding a semi-infinite slab.

By definition

[A.4] $s = \min_{\boldsymbol{r}} l$

in which the minimization is to be accomplished subject to the constraints that

[A.5] d, $\boldsymbol{n}$, $\mathbf{D}$ are fixed

That $\mathbf{D}$ is fixed is, of course, a consequence of the fact that the ellipsoid orientation is fixed. From [A.3] and [A.4] there follows

[A.6] $s = d + \boldsymbol{n}\cdot\boldsymbol{r}_s$

where $\boldsymbol{r}_s$ is the particular vector $\boldsymbol{r}$ which minimizes (in an algebraic sense) the scalar $\boldsymbol{n}\cdot\boldsymbol{r}$, subject to the constraints [A.5]. That is,

[A.7] $\boldsymbol{n}\cdot\boldsymbol{r}_s = \min_{\boldsymbol{r}} (\boldsymbol{n}\cdot\boldsymbol{r})$

By identity,

[A.8] $\boldsymbol{n}\cdot\boldsymbol{r} = (\boldsymbol{n}\cdot\mathbf{D})\cdot(\mathbf{D}^{-1}\cdot\boldsymbol{r})$

From the definition of the dot product of the two vectors $\boldsymbol{n}\cdot\mathbf{D}$ and $\mathbf{D}^{-1}\cdot\boldsymbol{r}$, this yields

[A.9] $\boldsymbol{n}\cdot\boldsymbol{r} = |\mathbf{D}\cdot\boldsymbol{n}|\ |\mathbf{D}^{-1}\cdot\boldsymbol{r}| \cos(\mathbf{D}\cdot\boldsymbol{n}; \mathbf{D}^{-1}\cdot\boldsymbol{r})$

where $\cos(\boldsymbol{\beta};\boldsymbol{\gamma})$ denotes the cosine of the angle between the vectors $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$. Now, eq. [A.2] may be written alternatively as

$$(\mathbf{D}^{-1}\cdot\boldsymbol{r})\cdot(\mathbf{D}^{-1}\cdot\boldsymbol{r}) = 1$$

This shows that the vector $\mathbf{D}^{-1}\cdot\boldsymbol{r}$ is a unit vector:

[A.10] $|\mathbf{D}^{-1}\cdot\boldsymbol{r}| = 1$

Introduce the latter along with [2.24] into [A.9] and substitute the resulting expression into [A.7] to obtain

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

[A.11] $\boldsymbol{n}\cdot\boldsymbol{r}_s = \alpha \min_{r} \cos(\mathbf{D}\cdot\boldsymbol{n}; \mathbf{D}^{-1}\cdot\boldsymbol{r})$

The cosine function attains its minimum algebraic value of -1 when the vectors $\mathbf{D}\cdot\boldsymbol{n}$ and $\mathbf{D}^{-1}\cdot\boldsymbol{r}$ are antiparallel. Consequently,

[A.12] $\boldsymbol{n}\cdot\boldsymbol{r}_s = -\alpha$

and

[A.13] $\mathbf{D}^{-1}\cdot\boldsymbol{r}_s = -\lambda\mathbf{D}\cdot\boldsymbol{n}$

with λ a positive scalar. This scalar is easily determined by forming the magnitude of both sides of the latter equation and invoking eqs. [A.10] and [2.24]. In this manner we obtain $\lambda = 1/\alpha$. Thus, the solution $\boldsymbol{r}_s$, obtained from [A.13], is

[A.14] $\boldsymbol{r}_s = -\mathbf{D}\cdot\hat{\boldsymbol{\alpha}}$

with $\hat{\boldsymbol{\alpha}}$ the unit vector defined in [2.26]. Finally, substitution of [A.12] into [A.6] provides the requisite proof of [A.1].

The proof may be carried out in an alternative, and perhaps simpler, manner. As is well known (27), the unit normal vector $\boldsymbol{N}$ to any surface $f(\boldsymbol{r}) =$ constant and pointing in the direction of increasing f is $\nabla f/|\nabla f|$. This may be applied to the ellipsoidal surface [A.2], thereby obtaining

$$\boldsymbol{N} = \boldsymbol{r}\cdot\mathbf{D}^{-2}/|\boldsymbol{r}\cdot\mathbf{D}^{-2}|$$

for the direction of the *outer* normal unit vector at any point $\boldsymbol{r}$ on the surface of the ellipsoid. It is clear from Fig. 2 that when $\boldsymbol{r} = \boldsymbol{r}_s$, $\boldsymbol{N}$ must be identical to $-\boldsymbol{n}$. Thus we obtain

$$\boldsymbol{r}_s\cdot\mathbf{D}^{-2}/|\boldsymbol{r}_s\cdot\mathbf{D}^{-2}| = -\boldsymbol{n}$$

When solved for $\boldsymbol{r}_s$ subject to the constraint that $\boldsymbol{r}_s$ satisfy [A.2] this yields both [A.14] and [A.12].

Appendix B. Derivation of Equation [4.36]

A second application of the operator $(\partial/\partial\boldsymbol{R})_\phi$ to [4.6] gives the identity

[B.1] $\partial^2 E/\partial\boldsymbol{R}\partial\boldsymbol{R} = \boldsymbol{nn}(\partial^2 E/\partial d^2)_\alpha$

As in the derivation of [4.13] and [4.16],

$$\frac{\partial^2 E}{\partial\phi\partial\boldsymbol{R}} = \frac{\partial}{\partial\phi}\left[\boldsymbol{n}\left(\frac{\partial E}{\partial d}\right)_\alpha\right] = (\boldsymbol{n}\times\boldsymbol{r}_s)\boldsymbol{n}\frac{\partial^2 E}{\partial\alpha\partial d}$$

Symmetrization thereby yields

$$\left(\frac{\partial^2 E}{\partial\phi\partial\boldsymbol{R}}\right)_{\text{sym}} = \frac{1}{2}[(\boldsymbol{n}\times\boldsymbol{r}_s)\boldsymbol{n} + \boldsymbol{n}(\boldsymbol{n}\times\boldsymbol{r}_s)]\frac{\partial^2 E}{\partial\alpha\partial d}$$

Upon utilizing the zero-torque condition given in [4.33] it follows immediately that

[B.2] $(\partial^2 E/\partial\phi\partial\boldsymbol{R})^0_{\text{sym}} = 0$

Inasmuch as $\partial/\partial\phi = (\partial\alpha/\partial\phi)\partial/\partial\alpha$ (with $\boldsymbol{n}$ fixed), application of the chain rule gives

$$\frac{\partial^2 E}{\partial\phi\partial\phi} = \left(\frac{\partial^2\alpha}{\partial\phi\partial\phi}\right)\left(\frac{\partial E}{\partial\alpha}\right)_d + \left(\frac{\partial\alpha}{\partial\phi}\right)\left(\frac{\partial\alpha}{\partial\phi}\right)\left(\frac{\partial^2 E}{\partial\alpha^2}\right)_d$$

However, from [4.11] and [4.14] the zero-torque condition corresponds to $(\partial\alpha/\partial\phi)^0 = 0$. Consequently,

[B.3] $\left(\frac{\partial^2 E}{\partial\phi\partial\phi}\right)^0 = \left(\frac{\partial^2\alpha}{\partial\phi\partial\phi}\right)^0\left(\frac{\partial E}{\partial\alpha}\right)^0_d$

From [4.11] and [2.23] we have

$$\left(\frac{\partial\alpha}{\partial\phi}\right)_n = \frac{(\mathbf{D}^2\cdot\boldsymbol{n})\times\boldsymbol{n}}{\alpha}$$

A second differentiation gives

$$\frac{\partial^2\alpha}{\partial\phi\partial\phi} = \left[\frac{\partial}{\partial\phi_n}\left(\frac{1}{\alpha}\right)\right](\mathbf{D}^2\cdot\boldsymbol{n})\times\boldsymbol{n} + \frac{1}{\alpha}\left(\frac{\delta\mathbf{D}^2}{\delta\phi}\cdot\boldsymbol{n}\right)\times\boldsymbol{n}$$

However, from [4.29], $(\mathbf{D}^2\cdot\boldsymbol{n}^0)\times\boldsymbol{n}^0 = 0$, whence the first term vanishes in the zero-torque state. Hence, with use of [4.9], there follows

[B.4] $$\left(\frac{\partial^2\alpha}{\partial\phi\partial\phi}\right)^0 = -\frac{1}{\alpha_0}[(\boldsymbol{\varepsilon}\cdot\mathbf{D}^2\cdot\boldsymbol{n}^0)\times\boldsymbol{n}^0 + \{(\boldsymbol{\varepsilon}\cdot\mathbf{D}^2)^\dagger\cdot\boldsymbol{n}^0\}\times\boldsymbol{n}^0]$$

With the aid of [4.29] the first term in brackets in the above expression becomes

[B.5] $$(\boldsymbol{\varepsilon}\cdot\mathbf{D}^2\cdot\boldsymbol{n}^0)\times\boldsymbol{n}^0 = \alpha_0^2(\boldsymbol{\varepsilon}\cdot\boldsymbol{n}^0)\times\boldsymbol{n}^0 = \alpha_0^2(\mathbf{I} - \boldsymbol{n}^0\boldsymbol{n}^0)$$

Furthermore, by identity,

[B.6] $(\boldsymbol{\varepsilon}\cdot\mathbf{D}^2)^\dagger\cdot\boldsymbol{n} = -\boldsymbol{n}\cdot\boldsymbol{\varepsilon}\cdot\mathbf{D}^2 = \boldsymbol{n}\times\mathbf{D}^2$

since $\boldsymbol{\varepsilon} = -\mathbf{I}\times\mathbf{I}$. Substitution of [B.5] and [B.6] into [B.4] thereby yields the relation cited in [4.37]. In conjunction with [B.1] and [B.2] this thereby furnishes a proof of [4.36].

Appendix C. Ellipsoid in a Gravity Field in Contact with a Horizontal Plane Wall

That the equilibrium orientational gravity results are similar to those for a general attractive/repulsive potential is not coincidental. Rather, it is a manifestation of a much deeper, and potentially fruitful, analogy. Consider the case of an ellipsoid in contact with a horizontal plane, as in Fig. 3. As a result of gravity the ellipsoid experiences an external gravitational body force,

[C.1] $\boldsymbol{F} = -\boldsymbol{n}F$

with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

[C.2] $F = \rho g(4\pi/3) \det \mathbf{D}$

The former is parallel to the direction of the gravity force. Here, ρ is the density of the (homogeneous) ellipsoid and g is the strength of the gravity field. The action of this external force is to cause the center (of mass) of the ellipsoid to move in the direction of gravity, towards the plane.

Since the ellipsoid is homogeneous, no direct gravitational body-force couple exists with respect to an origin through its center. However, due to the action/reaction forces at the contact point (point C in Fig. 3) there does exist an external torque $\boldsymbol{T}$ about O which is the moment of the reaction force $-\boldsymbol{F}$. Thus, since $\boldsymbol{r}_s$ is the moment arm of this force,

[C.3] $\boldsymbol{T} = \boldsymbol{r}_s \times (-\boldsymbol{F}) = -\boldsymbol{n} \times \boldsymbol{r}_s F$

Since $F > 0$ the action of this torque is to cause the ellipsoid to rotate about an axis (through O) which lies perpendicular to the plane formed by the vectors $\boldsymbol{r}_s$ and $\boldsymbol{n}$, and in a sense such that a right-handed screw turned from $\boldsymbol{r}_s$ towards $\boldsymbol{n}$ would advance in the direction in which the axis of rotation points. Of course this axis of rotation lies in a plane parallel to the wall, and tends to cause the fixed point on the surface of the ellipsoid which lies closest to its center (i.e., the point at the intersection of the shortest principal axis and the ellipsoid surface; point M in Fig. 3) to move closer to the plane.

The important points to observe here are that the *directions* (i.e., the vector portions) of [C.1] and [C.3] are precisely those that appear in [4.13] and [4.16] respectively. This affords a simple explanation as to why the stable orientation of the ellipsoid is the same for the gravity case as it is for the London – van der Waals case.

The analogy can be pursued even further by expressing the preceding results in terms of the potential energy function

[C.4] $E = \rho g(4\pi/3)(\det \mathbf{D})\boldsymbol{n}\cdot\boldsymbol{R}$

where $\boldsymbol{R}$ is measured from a point on the surface of the plane.[11] Equivalently, from [4.3],

[C.5] $E = \rho g(4\pi/3)(\det \mathbf{D})d$

with $a_{min} \leq d < \infty$. While superficially this potential may appear to be independent of the orientation of the ellipsoid, this is not true since eq. [A.1] (with $s = 0$) shows that $d = \alpha$, owing to the constraint that the surface of the ellipsoid be in contact with the plane. Thus, [C.5] is also equivalent to

[C.6] $E = \rho g(4\pi/3)(\det \mathbf{D})\alpha$

[11] In addition, $E = \infty$ if any point of the ellipsoid lies below the plane, i.e. $\boldsymbol{n}\cdot\boldsymbol{R} < a_{min}$.

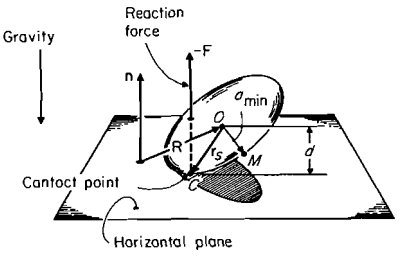

FIG. 3. Ellipsoidal particle in point contact with a horizontal plane.

In terms of this potential, eqs. [C.1] and [C.3] are equivalent to

[C.7a,b] $\boldsymbol{F} = -\boldsymbol{n}\dfrac{dE}{dd}, \quad \boldsymbol{T} = -\boldsymbol{n} \times \boldsymbol{r}_s \dfrac{dE}{d\alpha}$

These are identical to [4.13] and [4.16] except for the fact that the derivatives appearing in [C.7] are total, rather than partial, owing to the fact that d and α are no longer independent.

This analysis of a gravitating ellipsoid clearly applies to a (nonreentrant) body of any shape, provided that we simply replace the factor $(4\pi/3)$ det $\mathbf{D}$ by the volume of the body. On the basis of the analogy that we have pointed out, it would therefore appear that the attractive/repulsive potential results that we have obtained are essentially purely geometrical in nature, and that the attractive/repulsive potential energy E of *any* nonreentrant body near a slab can be expressed in the form

[C.8] $E = f(d, \alpha)$

where $\alpha = -\boldsymbol{n}\cdot\boldsymbol{r}_s$ is the orientational variable and $d = \boldsymbol{n}\cdot\boldsymbol{R}$ is the positional variable.[12] Concomitantly, these suggest that the force on any body will always be colinear with $\boldsymbol{n}$, and that the stable equilibrium orientation of any nonreentrant body will always be such that the body-fixed vector drawn from its centroid to the nearest point lying on its surface is antiparallel to $\boldsymbol{n}$. This is certainly true in the gravitational case, where the equilibrium orientation is such that the center (of mass) of the body is as close to the plane as is possible.

Exploration of these conjectures will form the subject matter of a future study.

[12] In this context we note from the arguments given at the end of Appendix A that if $f(\boldsymbol{r}) =$ constant defines the surface of the body from the viewpoint of a body-fixed observer (with $\boldsymbol{r}$ a position vector drawn from the centroid O to a point on the surface), then $\boldsymbol{r}_s$ as a function of the orientation of the body is given implicitly by the solution $\boldsymbol{r} = \boldsymbol{r}_s$ of the vector equation

$$(\nabla f)_{f=\text{const}}/|\nabla f|_{f=\text{const}} = -\boldsymbol{n}$$

This serves to define $\boldsymbol{r}_s$ in terms of $\boldsymbol{n}$ and of the geometry f of the body (27).

Effect of the crystallographic inhomogeneity of a polycrystalline electrode surface on the kinetics of the cathodic reduction of anions

Department of Electrochemistry, Faculty of Chemistry, Moscow State University, Lenin Hills, Moscow V 234, U.S.S.R.

Received July 2, 1980[1]

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

M. D. Levi, N. V. Fedorovich, and B. B. Damaskin. Can. J. Chem. **59**, 2019 (1981).

The effect of crystallographic surface inhomogeneity of a polycrystalline electrode on the kinetics of the electroreduction of anions was investigated. It was established theoretically that corrected Tafel plots for the reduction of anions of $S_2O_8^{2-}$ type should not coincide for different polycrystalline electrodes with a noticeable crystallographic inhomogeneity of the surface. The analysis of experimental data for a polycrystalline silver electrode fully confirms this conclusion.

M. D. Levi, N. V. Fedorovich et B. B. Damaskin. Can. J. Chem. **59**, 2019 (1981).

On étudie l'influence de l'hétérogénéité de la surface cristallographique d'une électrode polycristalline sur la cinétique de l'électroréduction des anions. On a établi théoriquement que les courbes corrigées de Tafel relatives à la réduction des anions du type $S_2O_8^{2-}$ ne doivent pas coincider dans les cas d'électrodes polycristallines différentes dont l'hétérogénéité de la surface cristallographique est apparente. L'analyse des données expérimentales relatives à une électrode polycristalline d'argent confirme tout à fait cette conclusion.

[Traduit par le journal]

Introduction

One of the most important problems in the kinetics of electrode processes is that of investigating the dependence of the rate of electrochemical reactions on the nature of the electrode. The reaction of the cathodic reduction of anions of $S_2O_8^{2-}$ type (anions of the first group (1)) can be regarded as a convenient model for establishing the causes of this dependence. The quantitative theory was proposed by Frumkin and co-workers (2–5) and is based on the assumption that the elementary act of the reaction proceeds at a certain finite rate. According to this theory, reaction rate i is related to the electrode potential E by the equation

$$[1] \quad i = KC_A \exp\left[\frac{\alpha F}{RT}\left(-E + \frac{n_1 + \alpha}{\alpha}\psi_1\right)\right]$$

where K is the constant of the reaction rate, C_A and n_1 are the concentration and charge of the reacting particles in the bulk solution, α is the transfer coefficient, ψ_1 is the mean value of the potential in the plane in which are located the centres of the charges of the reacting particles in the transition state of the reaction.

The theory is based on the following assumptions: during the flow of current, the steady-state concentration of all ions in the diffuse layer and, therefore, the electrode potential are maintained constant, the ionic concentrations being given by the Gouy–Chapman theory; the structure of the double layer at the electrode conforms to the Grahame model; the non-Coulombic interaction of reacting particles and reaction products, both with the electrode surface and with the ions of the double layer, does not depend on electrode potential; the anions are discharged from the outer Helmholtz plane, i.e. $\psi_1 = \psi_0$ (ψ_0 is the potential of the outer Helmholtz plane) and, therefore, the discreteness-of-charge effect in the diffuse part of the double layer is not taken into account; the dependence of the rate of the reaction in which the adsorbed particle takes part, expressed as ($\ln i + n_1F/RT$), on the potential difference ($E - \psi_0$) is described by the classical Tafel equation with a constant transfer coefficient α. As was shown for a large number of reduction reactions of anions of the first group (5–12), the dependence of the rate of the reaction on the electrode potential, and nature and concentration of the supporting electrolyte can be described quantitively by the theory of slow discharge. The dependence of the rate of the reaction on the nature of the metal was analysed in detail in a number of papers (13, 14), and it was established that the rate constant of electrochemical reactions for which the Brønsted relationship is applicable does not depend on the nature of the electrode if the potential is measured against a given standard reference electrode. This result is due to the fact that at constant electrode potential E, the difference between the chemical potentials of the electron in two different metals is balanced by the

For personal use only.

difference between the Galvani potentials at the interface of the two metals with the solution. The energy level of the electron with respect to the solution, and, consequently, the real activation energy of the reaction proves to be the same for different electrodes (15). In this case the difference in the rate of anion discharge on different metals, just as on different crystallographic faces of one and the same metal, is connected only with the corresponding changes in the structure of the double layer, i.e. with changes in the ψ_0-potential, the value and sign of which are determined by the position of the potential of zero charge (p.z.c.) of the electrode and the values of the capacity of the Helmholtz double layer.

If eq. [1] is re-written as:

$$[2] \quad \ln i + \frac{n_1 F}{RT}\psi_0 = \ln KC_A - \frac{\alpha F}{RT}(E - \psi_0)$$

it then follows that the dependence of the reaction rate on the potential in the coordinates ($\log i + n_1F/2{\cdot}3RT$) against ($E - \psi_0$), which are called corrected Tafel plots (c.T.p.) is linear; moreover c.T.p. for different concentrations of the supporting electrolyte and for different electrodes coincide.

This conclusion was confirmed quantitively when studying the cathodic reduction of the anions $S_2O_8^{2-}$, $S_4O_6^{2-}$, $Fe(CN)_6^{3-}$ both on electrodes with a homogeneous surface (liquid and single crystal faces) and on polycrystalline electrodes in aqueous and non-aqueous solutions (5–12). The sole exception proved to be the data for the reduction of the $S_2O_8^{2-}$ anion on polycrystalline silver (16). In this case, the c.T.p. did not coincide with the c.T.p. for silver single crystal faces (111), (100), and with those obtained for other solid polycrystalline electrodes.

It was suggested in ref. 16 that the different nature of the c.T.p in the case of polycrystalline silver could be due to a marked crystallographic inhomogeneity (17, 18) of the electrode surface caused by substantial differences in the values of the pzc of the individual silver single crystal faces. A detailed analysis of the effect of the crystallographic inhomogeneity of the surface and its influence on the structure of the electric double layer at polycrystalline electrodes in ref. 19 makes it possible to propose a quantitative criterion for its influence on the kinetics of the cathodic reduction of anions.

Within the framework of a model describing the structural properties of the surface of these electrodes, which are aggregates of individual single crystal faces, two possible ways in which the

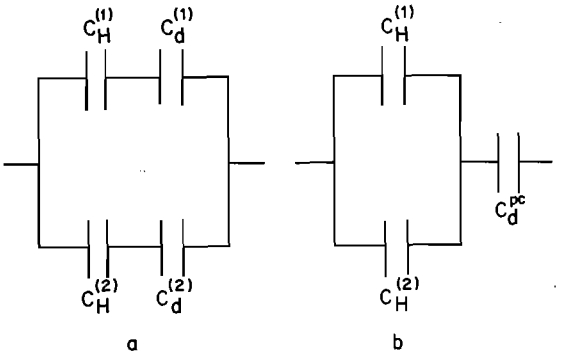

FIG. 1. Equivalent circuits for the double layer according to model I (*a*) and model II (*b*)

capacity of the diffuse part of the double layer are included have been examined (19): (*1*) each of the faces is assigned its own Helmholtz and diffuse double layer (model I) and (*2*) the faces retain the Helmholtz layers typical to them, while the diffuse double layer is common to both faces (model II) (Fig. 1). It can be easily seen that in model I, the charges in the diffuse double layer are distributed discretely and, consequently, the outer Helmholtz plane is non-equipotential.[2] Conversely, in model II the polycrystalline electrode, just like electrodes with a homogeneous surface, has an equipotential outer Helmholtz plane.

It follows from eq. [1] that a decrease in rate of anion discharge on the negatively charged surface of the electrode is, in the first approximation, connected with the dependence of the ψ_0-potential on the polarization and concentration of the inactive electrolyte in the solution (1, 5–12). Therefore, the ratio of the reaction rates on polycrystalline electrodes follow model II, and, on electrodes with a homogeneous surface, will be determined only by the difference in the mean values of the capacity of the Helmholtz layer at constant $E - \psi_0$, and the difference in the potentials of zero charge. The constant of the reaction rate K and the transfer coefficient α remain unchanged.

An entirely different effect can be expected for the discharge of anions on the surface of a polycrystalline electrode if the structure of its double layer follows the relationships of model I. Indeed, at a given value of the electrode potential E with respect to the reference electrode, the outer Helmholtz plane in the vicinity of which the electric

[2]The non-equipotential state of the outer Helmholtz plane arising from the discrete nature of the distribution of the ions in the diffuse layer was not taken into account. However, that does not affect the subsequent conclusions, since a certain analogy is observed in the dependence of the local value of the ψ_1-potential and mean value of the ψ_0-potential on the electrode potential E and concentration of the supporting electrolyte (8).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

centres of the discharging particles are to be found is non-equipotential and, therefore, the rate of the reaction on different sections of the surface is not the same. Under these circumstances when passing from the homogeneous to the polycrystalline structure of the electrode surface the values K and α could formally change greatly; this would lead to the c.T.p. for the anion reduction reaction not coinciding on different polycrystalline electrodes.

Method of Data Analysis

The computations were conducted on the assumption that two faces (1) and (2) in thermodynamic equilibrium are present on the surface of the polycrystalline electrode. Changes in the properties of the boundary regions were disregarded. Face (2) has more pronounced hydrophilic properties than face (1), i.e. $(C_H^{(2)})_{q=0} > (C_H^{(1)})_{q=0}$ where C_H is the capacity of the Helmholtz layer of the corresponding face. At large negative potential drops in the Helmholtz layer, $C_H^{(2)} = C_H^{(1)}$ and does not change when the cathodic polarization is further increased. The potential of zero charge of face (1), $E_{q=0}^{(1)}$ is less negative by 0.233 V than that of face (2), $E_{q=0}^{(2)}$ which is the result of their different hydrophilic properties.[3] The crystallographic inhomogeneity of the electrode is taken to be the maximum, i.e. $\theta^{(1)} = \theta^{(2)} = 0.5$, where $\theta^{(1)}$ and $\theta^{(2)}$ are the surface fractions of face (1) and face (2), respectively.

Initially, partial C_H, q curves for faces (1) and (2) were preset with parameters close to those observed experimentally in aqueous solutions. In keeping with the equivalent circuit of model I (Fig. 1*a*) at constant E, the capacity of the polycrystalline electrode C^{pc}

$$[3] \quad C^{pc} = 0.5(C^{(1)} + C^{(2)})$$

To find the dependence of the capacity of the Helmholtz double layer of the polycrystalline electrode C_H^{pc} on the potential drop in the Helmholtz layer $(E - \psi_0)$ it is necessary to know the values of $C_H^{(1)}$ and $C_H^{(2)}$ at the same potentials. For face (1) the potential $(E - \psi_0)$ corresponding to charge q is determined by the formula

$$[4] \quad (E - \psi_0) = \int_0^q (1/C_H^{(1)})\, dq$$

and for face (2)

$$[5] \quad (E - \psi_0) = (E - \psi_0)^* - \int_{q^*}^q (1/C_H^{(2)})\, dq$$

where $(E - \psi_0)^*$ is the potential drop in the Helmholtz layer corresponding to a charge q^* where the partial C_H, q-curves coincide.

To compute the dependence of the differential capacity of the polycrystalline electrode on electrode potential in solutions of different concentrations it is essential to know the dependence of $C^{(1)}$ and $C^{(2)}$ on E at constant q in the same solutions. To this end, in keeping with the main relationship of the Grahame theory

$$[6] \quad 1/C = 1/C_H + 1/C_d$$

where $C_d = 19.45\sqrt{137.8C + q^2}$. The values of $C^{(1)}$ and $C^{(2)}$ were found at constant q. Transformation from charge to potential for the faces was accomplished using equations similar to [4] and [5]. For face (1)

$$[7] \quad E = \int_0^q (1/C^{(1)})\, dq$$

And for face (2)

$$[8] \quad E = E^* - \int_{q^*}^q (1/C^{(2)})\, dq$$

where

$$[9] \quad E^* = \int_0^q (1/C^{(1)})\, dq$$

The dependence of the capacity of the polycrystalline electrode on potential in solutions of different concentrations was found using eq. [3]. To calculate the ψ_0-potential the value of the charge q corresponding to the electrode potential E was calculated from the following equation:

$$[10] \quad q^{pc} = q^* - \int_{E^*}^E C^{pc}\, dE$$

When analysing the experimental dependence of the capacity of the double layer on the polycrystalline electrode potential, it is usually assumed that, in dilute solutions the surface charge equals zero[4] at the minimum on the C against E-curve. Consequently in the computations used in this work, the electrode charge was also calculated from the charge corresponding to E_{min}.

The mean value of the ψ_0-potential at $q < 0$ was calculated in keeping with the theory of the diffuse double layer

$$[11] \quad \psi_0 = -0.0513 \sinh^{-1}(q/11.72\sqrt{c})$$

The numerical values in eq. [11] correspond to

[3]Neglect of the difference in the work functions of faces (1) and (2) does not affect the subsequent results, if the electrode charge is calculated from the charge corresponding to the potential of the minimum (E_{min}) on the C^{pc} against E curve.

[4]In reality, as was first noted in ref. 18, at E_{min} the mean charge of the polycrystalline electrode surface conforming to model I is not equal to zero and can have considerably negative values (19).

aqueous solutions with a non-adsorbing electrolyte at $T_0 = 25°C$.

The mean values of the reaction rate on the polycrystalline electrode at constant E were calculated from the equation

[12] $i^{pc} = 0.5(i^{(1)} + i^{(2)})$

where $i^{(1)}$ and $i^{(2)}$ are the partial discharge currents on the corresponding faces, the discharge currents on the individual faces being calculated according to [1] with $n_1 = -2$.

Results and Discussion

The initial c.T.p. was linear for the cathodic reduction of a hypothetical divalent anion (Fig. 2, line 1) for which the transfer coefficient α was assumed to be 0.23 (1, 5). Then, using eq. [11] for three concentrations, namely, 0.1 *M*, 0.01 *M*, and 0.001 *M*, the ψ_0 against E curves were calculated for individual crystal faces (Fig. 3, curves *1*, *2*, and *3* for face (2), and curve *4* for face (1).) To calculate the dependence of the partial discharge currents $i^{(1)}$ and $i^{(2)}$ on electrode potential E (Fig. 4, curve *1* and *2* for a solution concentration of 0.001 *M*) the calculated values of the ψ_0-potential were substituted into eq. [1]. Figure 4 also shows the dependence of the discharge rate on the potential E at the polycrystalline electrode calculated according to eq. [12].

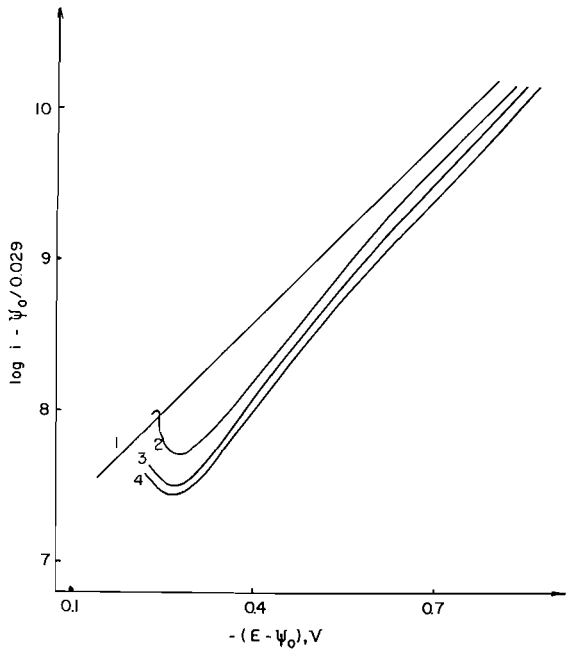

FIG. 2. Corrected Tafel plots for the reduction of a divalent anion: *1*, on faces (1) and (2) and *2–4* on a polycrystalline electrode in the presence of various concentrations of an inactive supporting electrolyte, *2*, 0.001 *M*, *3*, 0.01 *M*, *4*, 0.1 *M*.

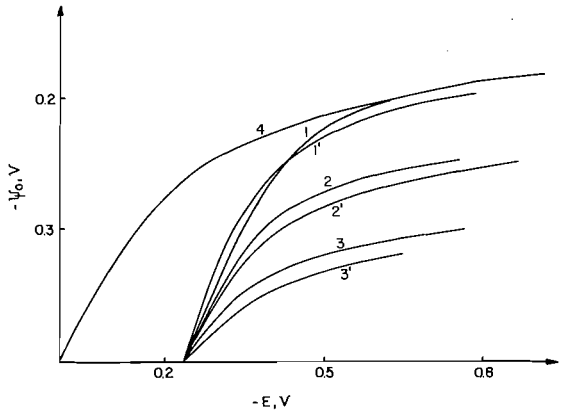

FIG. 3. Dependence of the ψ_0-potential on the electrode potential E: *1–3* and *1'–3'* on face (2) and on the polycrystalline electrode, respectively for different concentrations of the base electrolyte, *1*, *1'*, 0.001 *M*; *2*, *2'*, 0.01 *M*; *3*, *3'*, 0.1 *M*; and *4* on face (1) for a 0.001 *M* electrolyte concentration.

The rates of the electroreduction of anions found in this way were corrected by the effective values of the ψ_0^{pc}-potential calculated from eq. [11] for a polycrystalline electrode. The calculated ψ_0^{pc} against E curves are shown in Fig. 3. It can be seen from this figure that only when $E_{q=0}^{(2)} = -0.233$ V, in keeping with the accepted method of estimating the charge on the polycrystalline electrode, does $\psi_0^{pc} = \psi_0^{(2)} = 0$. At all other values of E $|\psi_0^{pc}| < |\psi_0^{(2)}|$ with the exception of highly dilute solutions (0.001 *M*) for which $|\psi_0^{pc}| > |\psi_0^{(2)}|$ at small negative departures from $E_{q=0}^{(2)}$. The reversal of the inequality is due to the fact that as the solution is made more dilute, the capacity of the polycrystalline electrode in the vicinity of $E_{q=0}^{(2)}$ moves not in the direction of zero, as on electrodes with a homogeneous surface, but to a certain finite value depending in general on the relative fractions of the two faces on the surface, and on the differential capacity at face (1) at p.z.c. of face (2) (18, 19). In more concentrated solutions at constant E, C^{pc} is always less than $C^{(2)}$; it also follows that $|q^{pc}| < |q^{(2)}|$ and, in keeping with eq. [11] that $|\psi_0^{pc}| < |\psi_0^{(2)}|$. The c.T.p. for the cathodic reduction of a hypothetical divalent anion calculated for three concentrations are shown in Fig. 2 (curves *2*, *3*, *4*). An analysis of the shapes of these curves and their dependence on the concentration of the supporting electrolyte leads to the conclusion that, on the c.T.p. for the polycrystalline electrode, unlike those for electrodes with a homogeneous surface, there are three regions with substantially different values of the apparent transfer coefficient α^{pc}.

In the vicinity of $E_{q=0}^{(2)}$, the transfer coefficient α^{pc} assumes negative values. This result is explained in Fig. 5 which shows the C against

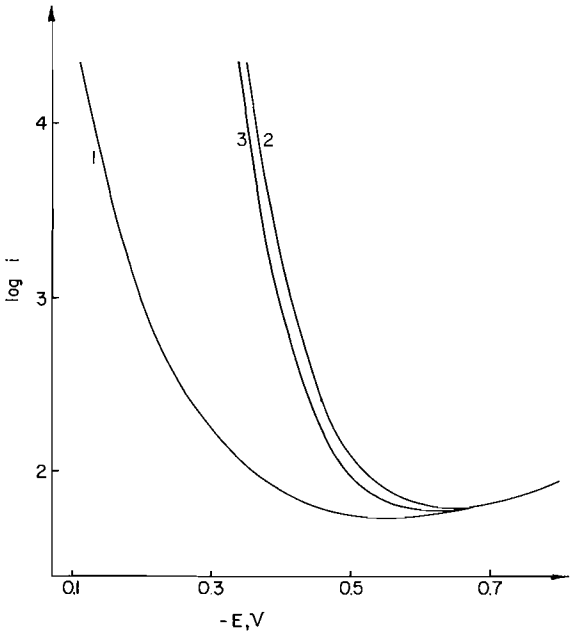

FIG. 4. Dependence of rate of reduction of a divalent anion on the electrode potential: *1*, at face (1); *2*, at face (2); and *3* at a polycrystalline electrode.

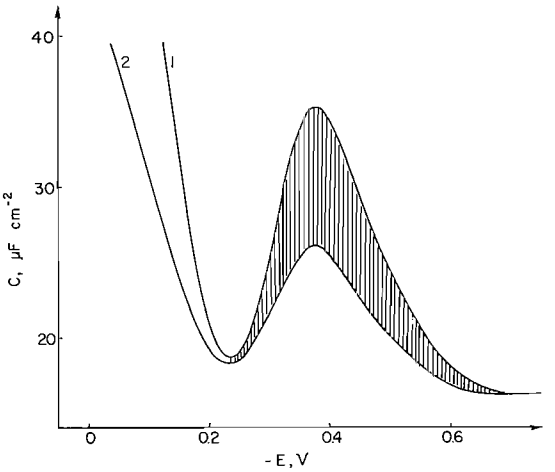

FIG. 5. Dependence of differential capacity on the electrode potential in a 0.01 *M* solution of a non-adsorbing electrolyte: *1*, at face (2) and *2*, at a polycrystalline electrode.

E-curves on face (2) and on a polycrystalline electrode in a 0.01 *M* solution of a surface inactive supporting electrolyte. The cross-hatched area corresponds to the difference in the surface charges of the two electrodes at E = constant. When the potential shifts from $E_{q=0}^{(2)}$ towards more negative values, the absolute value of $|q^{(2)}|$ increases more quickly than $|q^{pc}|$ (Fig. 6). In other words, the effective repulsion of anions from the negatively charged surface of the polycrystalline electrode is

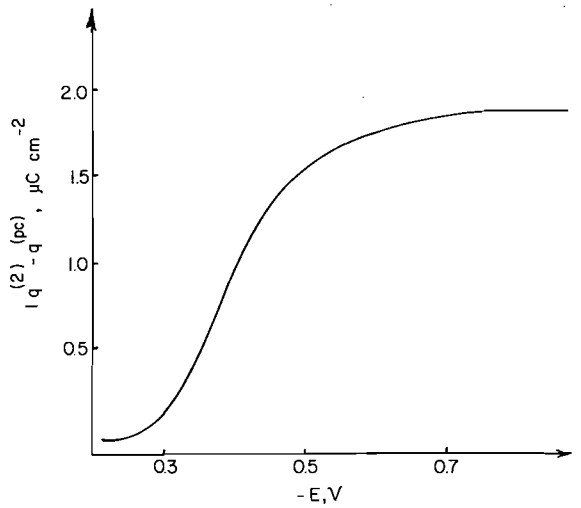

FIG. 6. Dependence of the absolute value of difference in surface charge on face (2) and on a polycrystalline electrode, $|q^{(2)} - q^{(pc)}|$ on electrode potential E.

less than on face (2), and the value of log i corresponding to the polycrystalline electrode remains "undercorrected" by the ψ_0-potential.

Starting from $E = -0.353$ V (where a minimum is observed on the c.T.p. of the polycrystalline electrode in a 0.01 *M* solution), the rate of growth of the absolute value of the difference in charges $|q^{(2)} - q^{pc}|$ decreases (Fig. 6) and the surface of the polycrystalline electrode begins formally to repulse the anions more strongly. In other words, in the examined region of potentials the value log i could be said to be "overcorrected" by the ψ_0-potential, which leads to the appearance in the middle part of the c.T.p. of a roughly linear section with a considerably larger value of α^{pc} than for the single crystal faces.

At potentials more negative than the potential at which the C against E-curves for faces (1) and (2) merge, the difference in the value of the charge on face (2) and on the polycrystalline electrode attains a constant value and, correspondingly, the c.T.p. for the polycrystalline electrode runs parallel to the c.T.p. for the single crystal faces. The formal decrease in the reaction rate constant on passing from a single crystal to a polycrystalline electrode is due to the method chosen for evaluating the charge on the crystallographic inhomogeneous surface.

Unlike the case of single crystal faces, the c.T.p. on a polycrystalline electrode depends on the concentration of the inactive electrolyte (see Fig. 2). This result stems from the fact that the concentration of ions in the diffuse double layer changes not only with distance from the surface of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

polycrystalline electrode, but also in a direction parallel to this surface. It follows that the one-dimensional model of the diffuse layer proposed by Gouy and Chapman is inapplicable for a polycrystalline electrode (19).

It was shown in ref. 19 that the crystallographic inhomogeneity of the surface is inherent in one degree or another to all polycrystalline electrodes, but in the case of gold and, particularly, silver, this effect reaches its maximum. From this point of view, let us analyse the kinetics of the cathodic reduction of persulphate anions on single crystal faces of silver with Miller indices (111), (100)[5] and on polycrystalline silver. These data were reported earlier (16). Figure 7 shows c.T.p. for the reduction of a persulphate anion on a number of polycrystalline electrodes, at silver single crystal faces and at polycrystalline silver. In ref. 16 the corresponding ψ_0^{pc} against E needed to obtain c.T.p. were calculated from the C^{pc} against E data (20) using a roughness factor $f = 1.3$.[6] However, in a later paper (21) it was shown that $f = 1.5$. That f cannot be equal to 1.3 is also evident from the analysis cited below. It can be seen from Fig. 2 that on the negatively charged surface of the polycrystalline electrode the rate of the cathodic reduction of anions corrected by the ψ_0-potential is always less than that on the single crystal face while the c.T.p. at a polycrystalline electrode calculated on the basis of $f = 1.3$ intersects the c.T.p. of the single crystal faces (Fig. 4 in ref. 16).

Figure 7 gives the c.T.p. for polycrystalline silver calculated on the basis of $f = 1.5$. This figure shows that for silver single crystal faces and polycrystalline electrodes of bismuth, tin, and lead, their c.T.p. coincide. The absence of any noticeable influence of surface crystallographic inhomogeneity for these electrodes on the reaction kinetics is, apparently, due to the small anisotropy of the p.z.c. of the single crystal faces of these metals. At the same time, the experimental data for polycrystalline silver can be rationalized on the basis of the analysis given in this paper.

A comparison of Figs. 2 and 7 shows that the c.T.p. of polycrystalline silver can be identified with the middle section of the calculated curve where the value of α^{pc} typically increases and a gradual transition occurs to that region of potentials in which the c.T.p. for the polycrystalline

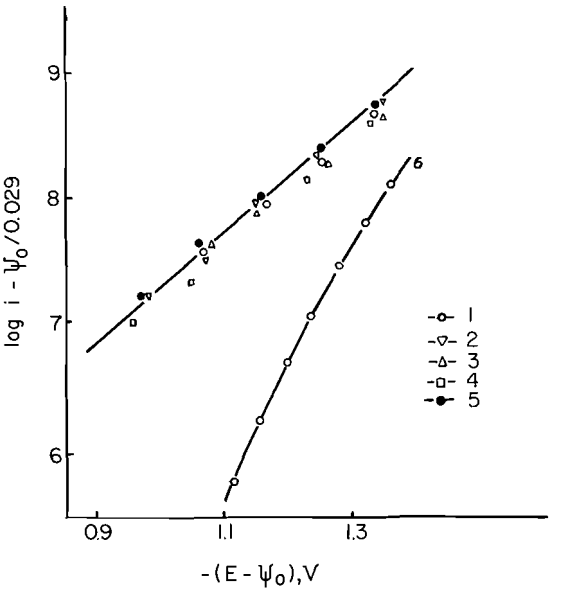

FIG. 7. Corrected Tafel plot of reduction of 10^{-3} N $K_2S_2O_8$ + 0.9×10^{-2} N KF on electrodes: *1*, Bi; *2*, Sn; *3*, Pb; *4*, Ag(111), *5*, Ag(100), *6*, Ag polycrystalline.

electrode and single crystal faces are parallel to each other.[7]

The absence of a section with a minimum ($\alpha^{pc} < 0$) on the experimental curve can be explained by the fact that the real rate of the reaction on a polycrystalline electrode in the vicinity of the potential minimum on the C^{pc} against E-curve is lower, apparently as a result of oxidation, than it should be according to the above model. The coincidence, within the limits of error of the experiment, of the c.T.p. for the reduction of persulphate anions on polycrystalline silver for different concentrations of a non-adsorbed electrolyte also becomes understandable, if it is remembered that the interval in changes in concentration amounts to only one-half of one order of magnitude.

Thus, in the case of electrodes with sharply differing values of potentials of zero charges for individual crystal faces, the c.T.p. for the discharge of anions should not coincide, since the structure of the electric double layer does not conform to the Grahame model. In order to establish the dependence of the reaction rate on the nature of the metal, it is necessary to conduct investigations on individual crystal faces.

[5]No study was made of the kinetics of the electroreduction of the persulphate anion on the silver single crystal face (110).

[6]In reality for a polycrystalline electrode the reciprocal of the slope of the Parsons–Zobel plot is $f = f_r \cdot f_{ci}$ where f_r is the roughness factor, and f_{ci} the coefficient of the crystallographic surface inhomogeneity (17, 19).

[7]The changes in the value of α with the electrode potential, as follows from the analysis, are connected with the crystallographic inhomogeneity of the surface of polycrystalline electrodes and cannot serve as proof of the dependence of α on E (22), as predicted by the quantum theory of the elementary act of discharge.

Kinetics of electrode processes in the presence of a discrete layer of a specifically adsorbed organic substance

V. S. KRYLOV AND I. F. FISHTIK

Institute of Electrochemistry, Academy of Sciences of the USSR, Moscow, USSR

Received July 2, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

V. S. KRYLOV and I. F. FISHTIK. Can. J. Chem. **59**, 2026 (1981).

The problem of an adequate statistical mechanical approach to the transition from the description of the elementary act of an electrochemical process occurring in the presence of electrochemically inactive specifically adsorbed species to the description of the resulting heterogeneous process for which the rate is measured in experiments is discussed. The analysis of the electrode kinetics is given for the particular case where the irreversible electron transfer reaction at the metal/solution takes place in the presence of a fixed discrete layer of specifically adsorbed dipole molecules. The theoretical results are compared with the available experimental data on the influence of adsorbed organic substances on the electrochemical reaction rate.

V. S. KRYLOV et I. F. FISHTIK. Can. J. Chem. **59**, 2026 (1981).

On discute d'une approche appropriée, par le biais de la mécanique statistique, au problème de la transition entre la description d'un acte élémentaire d'un processus électrochimique se produisant en présence d'espèces inactives électrochimiquement et spécifiquement adsorbées et la description de la réaction hétérogène résultante dont on a mesuré expérimentalement la vitesse. Dans le cas particulier où une réaction irréversible de transfert d'électron a lieu au niveau métal/solution en présence d'une couche discrète mixte de molécules polaires spécifiquement adsorbées, on présente l'analyse de la cinétique à l'électrode. On a comparé les résultats théoriques aux données expérimentales disponibles relatives à l'influence de substances organiques adsorbées sur la vitesse de la réaction électrochimique.

[Traduit par le journal]

The problem of decoding the mechanism of interaction between the elementary act of an electrochemical process and adsorption phenomena at a metal/solution interface is of principal interest because this problem is directly connected with the interpretation of electrochemical kinetic data as well as with the correct mathematical description of the effect of the electrical double layer on the electrode process rate. Because of this a fundamental problem arises, namely, the problem of an adequate statistical mechanical approach to the transition from the description of the elementary act of an electrochemical process occurring in the presence of electrochemically inactive specifically adsorbed species (ions and dipole molecules) to the description of the resulting electrode process for which the rate is experimentally measurable. The no less important aspect of the theory of heterogeneous processes at polarizable interfaces is related to consideration of the discrete nature of reactants and specifically adsorbed indifferent particles. One of the most significant achievements in recent years in the field of interpretation of electrochemical kinetic data was in substantiation of the role of the discreteness effects. A remarkable contribution to this work was made by Levine and co-workers (1–4). The local electric field acting near the interface on discrete particles possessing electric charge or dipole moment, due to polarization of the interface by these particles, differs from the average field described by the macroscopic equations of electrodynamics with a continuous charge and dipole moment distribution. The characteristic relaxation times of "the electrostatic image" forces, i.e., the redistribution times of free and bound charges at the interface due to its polarization by discrete particles present in solution, are of the order of 10^{-15}–10^{-14} s. The characteristic times of many types of electrochemical reactions, however, are comparable with the fluctuation reorientation time of dipole molecules of the solvent in the solvation shells of reactants (10^{-11} s), i.e., they are by 3–4 orders higher than the relaxation times of "the electrostatic self-image" forces. For this reason, the discrete nature of charges and dipole moments should affect the probability of the elementary act of electrochemical processes. Moreover, the local electric field associated with the discreteness effect can influence the rate of electrochemical processes by changing the concentration of reactants and reaction products in the layer adjacent to the electrode. Another aspect of the problem of taking into consideration the fine structure of the double layer in electrochemical kinetics is a correct, from the point of view of quantum mechanics and statistical physics, derivation of an equation for the electrochemical reaction rate taking into account the local electric field (5, 6).

In the present paper the problem of the statistical mechanical averaging of the probability of the elementary act of an irreversible electron transfer reaction occurring at a metal/solution interface in the presence of specifically adsorbed electrochem-

ically inert dipole molecules is considered for the particular case when the positions of all the molecules inside the adsorption layer are fixed and when the electrochemical process does not disturb the statistical equilibrium with respect either to ionic reactants or to supporting electrolyte ions.

Let us consider an irreversible electrochemical reaction

$$A^z + e \rightarrow B^{z-1}$$

occurring at an electrode partly covered by specifically adsorbed electroinactive dipole molecules. We shall assume for simplicity that the molecules are point-like dipoles the centers of which are located in the plane $x = 0$ inside the Helmholtz layer, $-\beta \leq x \leq \gamma$, at a distance β from the electrode surface, $x = -\beta$. Let us suppose that the positions of the adsorbed molecules in the plane $x = 0$ are strictly fixed and let us denote them by $\boldsymbol{r}_1, \boldsymbol{r}_2, ..., \boldsymbol{r}_M$, where M is the total number of molecules. The positions of ions which are present in the system (including the reactant ones) will be denoted by $\boldsymbol{R}_1, \boldsymbol{R}_2, ..., \boldsymbol{R}_N$. The probability, w, of electron transfer from the electrode to the reactant ion A^z is an exponential function of the activation energy, E_a:

$$[1] \quad w(\boldsymbol{R}_1, ..., \boldsymbol{R}_N, \boldsymbol{r}_1, ..., \boldsymbol{r}_M) = A(\boldsymbol{R}_1) \exp \{-E_a(\boldsymbol{R}_1, ..., \boldsymbol{R}_N, \boldsymbol{r}_1, ..., \boldsymbol{r}_M)/kT\}$$

where the factor $A(\boldsymbol{R}_1)$ is temperature independent. The density, i, of the current generated in the electrochemical reaction is connected with the probability w by the expression

$$[2] \quad i = eN_R f\langle w \rangle$$

where N_R is the total number of the reactant ions in the system, f is a factor accounting for the part of the electrode surface available for the electrochemical reaction to occur, and the symbol $\langle\ \rangle$ stands for the statistical averaging operation over the whole system of particles present in solution including the specifically adsorbed molecules.

In further consideration we shall treat the subsystem of the specifically adsorbed molecules as a factor providing a fixed external force field for the remaining, nonadsorbed particles and, accordingly, shall carry out the statistical averaging over only nonadsorbed particles. Furthermore, we shall assume that the electrochemical process under consideration does not disturb the statistical equilibrium for either reactant or supporting electrolyte ions. It means that the statistical averaging should be carried out using the Gibbs equilibrium distribution function $D_N(\boldsymbol{R}_1, ..., \boldsymbol{R}_N, \boldsymbol{r}_1, ..., \boldsymbol{r}_M)$ dependent on the coordinates of the specifically adsorbed molecules as on parameters. Thus we have

$$[3] \quad \langle w \rangle = \int A(\boldsymbol{R}_1) \exp [-E_a(\boldsymbol{R}_1, ... \boldsymbol{R}_N, \boldsymbol{r}_1, ... \boldsymbol{r}_M)/kT] \times D_N d\boldsymbol{R}_1, ..., d\boldsymbol{R}_N$$

where the function D_N is defined by the expression

$$[4] \quad D_N(\boldsymbol{R}_1, ..., \boldsymbol{R}_N, \boldsymbol{r}_1, ..., \boldsymbol{r}_M) = Q_N^{-1} \exp \left\{ -\frac{1}{kT} [V_Z(\boldsymbol{R}_1, ..., \boldsymbol{R}_N) + W_Z(\boldsymbol{R}_1, \boldsymbol{r}_1, ..., \boldsymbol{r}_M) + U_Z(\boldsymbol{R}_1) + U_{N-1}(\boldsymbol{R}_2, ..., \boldsymbol{R}_N) + U_{N-1,M}(\boldsymbol{R}_2, ..., \boldsymbol{R}_N, \boldsymbol{r}_1, ..., \boldsymbol{r}_M)] \right\}$$

Here V_Z is the energy of interaction between the ion A^Z and the remaining ions; W_Z is the corresponding energy of interaction with the adsorbed dipoles; the energy $V_Z(\boldsymbol{R}_1)$ accounts for the interaction of the ion A^Z with the electrostatic self-image forces; U_{N-1} is the energy of interaction of the ions located at the positions $\boldsymbol{R}_2, ..., \boldsymbol{R}_N$ with one another (including the interactions with the corresponding image forces); $U_{N-1,M}$ is the interaction energy of the same ions with the adsorbed dipoles and their "images" in metal; Q_N is the configuration integral. The methods of calculation of the energies V_Z, U_Z, and U_{N-1} were developed in refs. 7–9. For the function $U_{N-1,M}$, according to its definition, the expression

$$U_{N-1,M} = \sum_{k=2}^{N} W_Z(\boldsymbol{R}_k, \boldsymbol{r}_1, ..., \boldsymbol{r}_M)$$

is valid. Therefore the problem consists in calculating the functions E_a and W_Z and in carrying out the statistical averaging in [3].

According to the Brönsted equation the activation energy is a linear function of the thermal effect of reaction, ΔJ:

$$[5] \quad E_a = E_a^{(0)} + \alpha \Delta J$$

where $E_a^{(0)}$ is the term independent of coordinates and α is the electron transfer coefficient. The thermal effect ΔJ may be split into the following contributions:

$$[6] \quad \Delta J = E_0 - E_m + E_B^{(s)} - E_A^{(s)} + e\varphi_0 + U_{Z-1}(\boldsymbol{R}_1) - U_Z(\boldsymbol{R}_1) + V_{Z-1}(\boldsymbol{R}_1, ..., \boldsymbol{R}_N) - V_Z(\boldsymbol{R}_1, ..., \boldsymbol{R}_N) + W_{Z-1}(\boldsymbol{R}_1, \boldsymbol{r}_1, ..., \boldsymbol{r}_M) - W_Z(\boldsymbol{R}_1, \boldsymbol{r}_1, ..., \boldsymbol{r}_M)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Here $E_B^{(s)}$ and $E_A^{(s)}$ are the solvation energies of ions B^{Z-1} and A^Z; φ_0 is the electrode potential relative to the bulk of solution; E_0 and E_m are the energy levels of the electron transferred, respectively, in ion A^Z and in metal; the subscripts Z and $Z-1$ refer to ions A^Z and B^{Z-1}.

Now we can proceed to performing the integration in [3]. Using the definition of the one-particle distribution function, $g_Z(x_1)$, for ions with valence Z, namely,

$$g_Z(x_1) = \frac{1}{V}\int D_N(\boldsymbol{R}_1, ..., \boldsymbol{R}_N, \boldsymbol{r}_1, ..., \boldsymbol{r}_M)\, d\boldsymbol{R}_2, ..., d\boldsymbol{R}_N$$

where V is the total volume of solution, after simple transformations we arrive at the following equation:

$$[7]\quad i = eN_R\delta^* A^* f \exp\left\{-\frac{\alpha}{kT}[e\varphi_0 + U_{Z-1}(x_1^*) - U_Z(x_1^*)] - \frac{E_a^{(0)}}{kT} - \frac{1}{kT}[U_Z(x_1^*) - U_{Z-\alpha}(x_1^*) + W_{Z-\alpha}(x_1^*)]\right\} g_{Z-\alpha}(x_1^*)$$

Here the quantities marked with the asterisk are to be calculated at the point $\boldsymbol{R}_1^* = (x_1^*, 0, 0)$ in the plane $x_1 = x_1^*$ corresponding to the distance of the most probable place of ion discharge from the electrode; δ^* denotes the width of the region near the plane $x_1 = x_1^*$ which makes the main contribution to the integral over $\boldsymbol{R}_1$. The preferential distance x_1^* arises in the course of integration due to the fact that the integrand contains two factors, one of which, $A(\boldsymbol{R}_1)$, decreases sharply with the distance from the electrode while the other increases.

It is worthwhile to point out that the distribution function, $g_{Z-\alpha}(x_1^*)$, and the energy of interaction of a discharging ion with adsorbed dipoles, $W_{Z-\alpha}(x_1^*)$, correspond to a transition state of a discharging ion in which all the neighbouring ions and dipoles around the given ion would be in statistical equilibrium with the ion if the charge of the latter had been equal to $e(Z-\alpha)$. The ion with the charge $e(Z-\alpha)$ is, in some sense, an analog of the activation complex involved in the absolute reaction rate theory. However, in contrast with predictions given by that theory, the resulting rate of an electrode process is determined by the local electrical field rather than by the average field corresponding to continuously spread ionic charges and molecular dipole moments. In application to the case of specific adsorption of ions the equation analogous to [7] was obtained in ref. 10.

As was shown elsewhere (11) for the function $g_{Z-\alpha}(x_1)$, the expression

$$[8]\quad g_{Z-\alpha}(x_1) = \exp\{-[e(Z-\alpha)\varphi(x_1) + U_{Z-\alpha}(x_1) + V_{atm}(Z-\alpha, x_1)]/kT\}$$

is valid where $\varphi(x_1)$ is the average potential in the plane $x = x_1$ and the term $V_{atm}(Z-\alpha, x_1)$ accounts for interaction of an ion having the charge $e(Z-\alpha)$ with its own ionic atmosphere distorted by the image forces. Using [8] we can rewrite [7] in the following manner:

$$i = Kf(\theta)c_s \exp\left\{\frac{\alpha}{kT}[U_Z(x_1) - U_{Z-1}(x_1) - e\varphi_0 + e\varphi(x_1)] + \frac{1}{kT}[V_{atm}(Z, x_1) - V_{atm}(Z-\alpha, x_1) + U_{Z-\alpha}(x_1) - U_z(x_1) - W_{Z-\alpha}(x_1)]\right\}$$

where K is a constant independent of θ, the degree of coverage of the electrode surface by adsorbed molecules, c_s being the local concentration of the reactant ions at the plane $x = x_1$. Generally, all the energies entering the exponent in the last equation depend on θ, even the self-image terms, U_Z and $U_{Z-\alpha}$, because all of them contain the compact layer parameters, β, γ, and ε_1 which can change in the presence of adsorbed molecules. In the case of the compact layer parameters being independent of θ it is possible to present the kinetic equation in the form

$$[9]\quad i = K^* f(\theta)c_s \times \exp\left\{-\frac{\alpha e[\varphi_0 - \varphi(x_1)] + W_{Z-\alpha}(x_1, \theta)}{kT}\right\}$$

In order to calculate the energy $W_{Z-\alpha}(x_1, \theta)$ one must first specify the part of the double layer (either the compact or the diffuse one) into which the electron is transferred in the course of the reaction. In the case when the centers of discharging ions in the reaction state are located in the diffuse part of the double layer the following electrostatic problem must be solved:

$$[10]\quad \begin{aligned} \Delta\varphi_1 &= 0, && -\beta \le x < 0 \\ \Delta\varphi_2 &= 0, && 0 \le x \le \gamma \\ \Delta\varphi_3 &= -\frac{4\pi eZ}{\varepsilon_0}\delta(\boldsymbol{r} - \boldsymbol{R}_1) && \gamma \le x < \infty. \end{aligned}$$

where $\delta(x)$ is the Dirac delta-function, with the boundary conditions

$$\varphi_1 = 0 \quad \text{at} \quad x = -\beta$$

$$\varphi_1 - \varphi_2 = \frac{4\pi\mu}{\varepsilon_1}\sum_{m,n}\delta(y - y_{mn})\delta(z - z_{mn});$$

[11] $$\frac{\partial\varphi_1}{\partial x} = \frac{\partial\varphi_2}{\partial x} \quad \text{at} \quad x = 0$$

$$\varphi_2 = \varphi_3, \quad \varepsilon_1\frac{\partial\varphi_2}{\partial x} = \varepsilon_0\frac{\partial\varphi_3}{\partial x} \quad \text{at} \quad x = \gamma$$

$$\varphi_3 = 0 \quad \text{at} \quad x \to \infty$$

Here the quantity μ is the projection of the dipole moments of the adsorbed molecules on the x axis; ε_0 and ε_1 are the dielectric permittivities, respectively, of the diffuse and the compact parts of the double layer; y_{mn} and z_{mn} are the coordinates of the centers of the adsorbed molecules.

In the case of location of the discharging ions inside the compact layer ($-\beta \le x_1 \le \gamma$), one should solve one of the following electrostatic problems:

[12] $$\Delta\varphi_1 = -\frac{4\pi eZ}{\varepsilon_1}\delta(\boldsymbol{r} - \boldsymbol{R}_1); \Delta\varphi_2 = 0; \Delta\varphi_3 = 0$$

[13] $$\Delta\varphi_1 = 0; \Delta\varphi_2 = -\frac{4\pi eZ}{\varepsilon_1}\delta(\boldsymbol{r} - \boldsymbol{R}_1); \Delta\varphi_3 = 0$$

$$-\beta \le x < 0; \quad 0 < x \le \gamma; \quad \gamma \le x < \infty$$

depending on the location of the plane $x = x_1$. The boundary conditions [11] are the same for all the cases.

The solution of the system [10] with the boundary conditions [11] allows calculation of the so-called micropotential, φ_m, which is determined by the equation

$$\varphi_m = \lim_{\boldsymbol{r}\to\boldsymbol{R}_1}\left\{\varphi_3(\boldsymbol{r}, \boldsymbol{R}_1) - \frac{eZ}{\varepsilon_0|\boldsymbol{r} - \boldsymbol{R}_1|}\right\}$$

and then to find the energy W_Z using the simple relation $W_Z = eZ\varphi_m$. After calculations we obtain

[14] $$W_z(x_1) = \frac{eZ\mu}{\varepsilon_1}\sum_{m,n}\int_0^\infty (\exp -\lambda x_1)\,\chi(\lambda)J_0(\lambda R_{mn})\,d\lambda$$

where $J_0(\lambda R_{mn})$ is the Bessel function of the first kind; R_{mn} and $\chi(\lambda)$ are determined by the expressions

$$R_{mn} = \sqrt{y_{mn}^2 + z_{mn}^2}; \quad \chi(\lambda) = \frac{2\varepsilon_1\lambda}{\varepsilon_1 + \varepsilon_0}\frac{\omega - \xi}{1 - \xi}$$

$$\omega = \frac{\varepsilon_1 + \varepsilon_0}{\varepsilon_1 - \varepsilon_0}e^{2\lambda\gamma}; \quad \xi = \omega\frac{\tanh\lambda\beta + 1}{\tanh\lambda\beta - 1}$$

In the case of location of the plane $x = x_1$ inside the interval $-\beta \le x_1 < 0$ the solution of the system [12] leads to the Fourier–Bessel integral of the same form as [14], only one must substitute the expression

$$\left(\frac{\varepsilon_1 + \varepsilon_0}{\omega\varepsilon_1}\chi - 2\lambda\right)\frac{\sinh[\lambda(\beta + x_1)]}{\sinh\lambda\beta + \cosh\lambda\beta}$$

for $\exp(-\lambda x_1)\chi(\lambda)$. In the case of $0 < x_1 \le \gamma$ again one obtains [14] in which the product $\exp(-\lambda x_1)\chi(\lambda)$ must be substituted by

$$\frac{\varepsilon_1 + \varepsilon_0}{2\varepsilon_1}\left\{\exp(-\lambda x_1) + \frac{1}{\omega}\exp(\lambda x_1)\right\}$$

The effect of specifically adsorbed dipole molecules on the electrode kinetics can be characterized by the ratio of the current density, i, determined by [9] to the current density, i_0, in the absence of adsorbed molecules. The value i_0 is described by the equation

[15] $$i_0 = K_0 c_s^{(0)} \exp\left\{-\frac{\alpha e}{kT}[\varphi_0 - \varphi^{(0)}(x_1)]\right\}$$

Here the local concentration $c_s^{(0)}$ and the average potential $\varphi^{(0)}(x_1)$ are related to the electrode potential, φ_0, and the bulk concentration of the reactant ions, c_0, by the expressions

$$c_s^{(0)} = c_0 \exp\{-[eZ\varphi^{(0)}(x_1) + U_Z(x_1) + V_{atm}(Z, x_1)]/kT\}$$

$$\varphi^{(0)}(x_1) = \varphi_0\left(1 - \frac{x_1}{\beta + \gamma}\right)$$

From [9] and [15] we obtain

[16] $$i/i_0 = K^* f(\theta) \exp\{-[e(Z - \alpha)[\varphi(x_1, \theta) - \varphi^{(0)}(x_1)] + W_{Z-\alpha}(x_1, \theta)]/kT\}$$

where the average potential, $\varphi(x_1, \theta)$, in the presence of adsorbed molecules is determined by the relations

[17] $$\varphi(x_1,\theta) = \begin{cases} \varphi_0\left(1 - \dfrac{x_1}{\beta + \gamma}\right) - \dfrac{4\pi\mu x_1\Gamma_\infty\theta}{\varepsilon_1(\beta + \gamma)} & -\beta \le x_1 < 0 \\ \varphi_0\left(1 - \dfrac{x_1}{\beta + \gamma}\right) + \dfrac{4\pi\mu(\beta + \gamma - x_1)\Gamma_\infty\theta}{\varepsilon_1(\beta + \gamma)} & 0 < x_1 \le \gamma \end{cases}$$

the value Γ_∞ being the limiting number of adsorbed molecules per unit area.

Equation [16] describes the so-called inhibition effect of surface-active substances on electrochemical

kinetics. In ref. 12 this effect was estimated taking into account the phenomena of fractional charge transfer and formation of donor–acceptor complexes between metal and adsorbed molecules. However, calculations were carried out using [16] in which the term $W_{Z-\alpha}$ responsible for interaction between discrete charges and dipole moments in the adsorption layer was discarded. Our calculations, the details of which will be given below, show that in many real systems the contribution of the term $W_{Z-\alpha}$ into the inhibition effect is dominating.

The inhibition effect of surface-active substances was calculated for the cases of discharge of zinc and cadmium cations on mercury in the presence of specifically adsorbed *n*-butanol. Equations [16] and [17] were used in which the values of the parameters were chosen as follows: $\alpha = 0.5$; $\beta = 4$ Å; $\gamma = 1$ Å; $\varepsilon_1 = 8$; $\mu = -1.6$ D; $K^* = 1$. The negative value of μ means that the adsorbed alcohol molecules are oriented by their positive poles towards metal. The function $f(\theta)$ was approximated by the expression $f(\theta) = 1 - \theta$ that means that we take into account the simple effect of partial blockage of the electrode surface by the adsorbed molecules. For the case of zinc the values of x_1 and Γ_∞ were put equal to -3.17 Å and 1.2×10^{14} cm^{-2} (the value $x_1 = -3.17$ Å corresponds to the distance 0.83 Å from the electrode surface, and this distance is equal to the crystallochemical radius of zinc). In the case of cadmium the corresponding values were -3.08 Å and 1.5×10^{14} cm^{-2}. The results of calculation are presented in Figs. 1 and 2. In the same figures the experimental data on electroreduction of Zn^{2+} and Cd^{2+} in the presence of *n*-butanol are shown. The

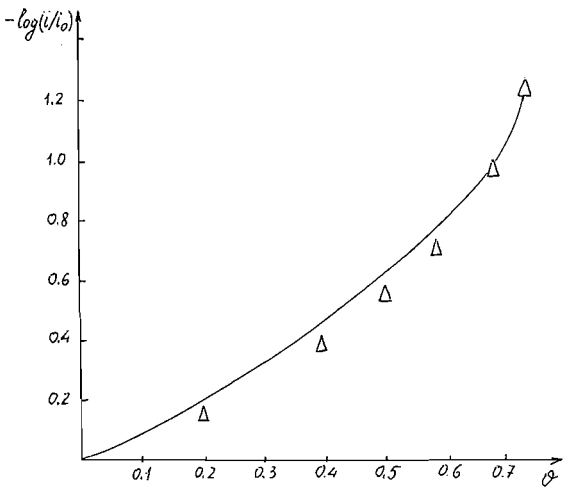

FIG. 1. Theoretical (solid line) and experimental (triangles) dependences characterizing the inhibition effect of *n*-butanol adsorbed on mercury for the reaction of discharge of zinc cations.

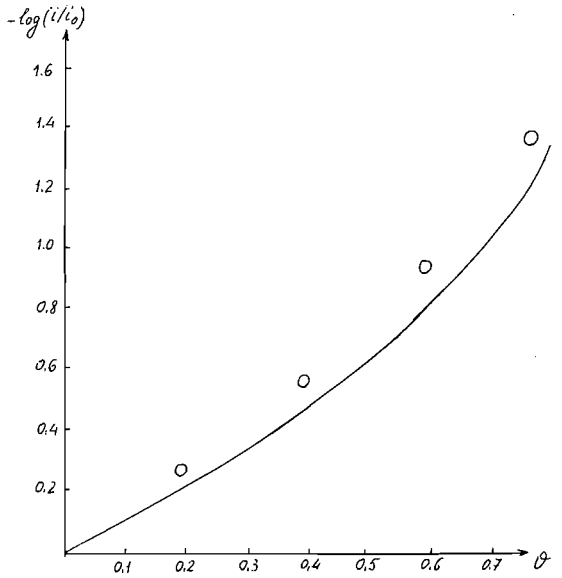

FIG. 2. The inhibition effect for the process of discharge of cadmium cations on mercury in the presence of specifically adsorbed molecules of *n*-butanol (solid line—the result of theoretical calculation; circles—the experimental data).

triangles in Fig. 2 correspond to the data obtained in ref. 13 for the system $Zn^{2+} + n\text{-}C_4H_{10}OH + 0.2\ N\ H_2SO_4 + 1.0\ N\ Na_2SO_4$. The data (14) on inhibition of discharge of Cd^{2+} ions by adsorbed molecules of *n*-butanol in the system $Cd^{2+} - n\text{-}C_4H_{10}OH + 0.1\ M\ HClO_4 + 0.9\ M\ NaClO_4$ are indicated by circles in Fig. 2. As can be seen from the figures there is quite good agreement between theoretical results and experimental data at reasonable values of the parameters.

A theory of the double layer in the electrolyte solution near the electrode surface is formulated in terms of the most general description of the electrode/solvent interface, the ionic plasma being treated in the Poisson–Boltzmann approximation. As a result, the differential capacitance of the electrochemical contact is calculated. In the case of low ionic concentrations ($\lesssim 0.1\ M$) it takes the form: $C^{-1} = C_{GC}^{-1} + C_*^{-1}$, where the C_{GC} is the Gouy–Chapman nonlinear differential capacitance and C_* is a "constant" capacitance, not depending on the concentration, but possessing a possible dependence on the charge of the electrode. The "compact layer" capacitance C_* is expressed through a unified nonlocal dielectric function of the electrode–solvent system. This may be considered as a formal approval of Grahame's parametrization of experimental data. But the physical meaning of the compact layer capacity is reconsidered subject to the relation obtained with the nonlocal dielectric function. The latter reflects the electronic structure of the metal and the structure of the solvent in contact. Thereby, the possible reasons for the dependence of the "compact layer" capacity on the nature of the electrode, solvent, and the interaction between them are revealed. A generalization of the results on the case of a more general description of ionic plasma is discussed.

A. A. KORNYSHEV et M. A. VOROTYNTSEV. Can. J. Chem. **59**, 2031 (1981).

On formule une théorie de la double couche dans une solution électrolytique au voisinage de la surface d'une électrode en fonction de la description la plus générale de l'interface électrode/solvant alors qu'on traite le plasma ionique par l'approximation de Poisson-Boltzmann. Il en résulte que l'on peut calculer la capacité différentielle du contact électrochimique. Dans le cas des faibles concentrations ioniques ($\lesssim 0{,}1\ M$), elle prend la forme $C^{-1} = C_{GC}^{-1} + C_*^{-1}$ où C_{GC} est la capacité différentielle non linéaire de Gouy–Chapman et C_* est une capacité constante indépendante de la concentration qui peut éventuellement dépendre de la charge sur l'électrode. On exprime la capacité de la "couche compacte" C_* au moyen d'une fonction diélectrique non locale unifiée du système électrode–solvant. On peut considérer ceci comme une confirmation formelle de la transposition des données expérimentales en paramètre qui a été faite par Grahame. Toutefois, on a reconsidéré la signification physique de la capacité de la couche compacte, en fonction de la relation obtenue avec la fonction diélectrique non locale. Cette dernière reflète la structure électronique du métal et la structure du solvant qui est en contact. On trouve aussi les diverses raisons qui pourraient expliquer pourquoi la capacité de la "couche compacte" dépend de la nature de l'électrode, du solvant et de l'interaction entre-eux. On discute de la généralisation des résultats dans le cas d'une description plus générale d'un plasma ionique.

Introduction

Much attention has been recently paid to the research and development of new methods for the investigation of the electrochemical interface *in situ*, based on the modern advances in surface science (see, e.g., papers in ref. 1). However, classical capacity measurements remain one of the major tools for studying the interfacial properties. Indeed, the capacitance and related characteristics are sensitive to the specific properties of the contact region when the electric potential changes in a distance comparable with its "thickness". It is difficult to realize such a rapid variation of the potential in electrode–vacuum systems (in order to do this, one should, e.g., place the second electrode at a microscopic distance from the first one). The rapid drop of the potential near the electrochemical interface is provided by the screening of the field in the electrolyte. For typical ionic concentrations the depth of the field penetration into the electrolyte solution is comparable with the dimensions of the interfacial region. Thus, the electrical properties of the electrochemical interface (the capacitance, in the equilibrium case) are sensitive to its structure. An adequate interpretation of capacitance data is one of the central points in electrochemistry.

Grahame's Hypothesis

In this paper we shall discuss systems without specific adsorption of electrolyte ions onto the electrode surface. A parametrization of capacitance data for such systems was proposed by Grahame (2, 3) which has been widely used during the last 30 years. According to Grahame's hypothesis, the total capacitance of the metal–electrolyte contact has the form of two capacitors in series

$$[1] \quad 1/C = 1/C_i + 1/C_d$$

Here C_d is the capacitance of the diffuse layer in the solution, depending on the electrode charge and electrolyte concentration; C_i is the, so called, inner layer (or compact layer) capacitance depending on the charge of the electrode but *not depending* on the concentration. Furthermore, Grahame assumed that

the dependence of C_d on the electrode charge σ (calculated per unit contact area) and on the total concentration of ionic species in the solution, c, can be described by the Gouy–Chapman theory. In the case of a binary symmetric electrolyte, the latter gives:

$$[2] \quad C_d = C_{GC} = \frac{\varepsilon}{4\pi}\sqrt{\kappa^2 + 4\pi\frac{L_B^2\sigma^2}{e^2}}$$

where κ^{-1} is the Gouy (Debye) length,

$$[3] \quad \kappa = \sqrt{\frac{4\pi e^2 c \sum_i Z_i^2 \nu_i}{\varepsilon\theta}}$$

and L_B is the Bjerrum length

$$[4] \quad L_B = e^2/\varepsilon\theta$$

(ε is the macroscopic dielectric constant of the solvent; Z_i and ν_i are the valencies and the stoichiometric coefficients for electrolyte ions and θ, the temperature in energetic units).

Testing Grahame's Assumption

By plotting the measured values of C^{-1} versus C_d^{-1} calculated via [2] for different values of the concentration c, one may check Grahame's hypothesis. This was first done by Parsons and Zobel (4) and later used for the interpretation of the capacitance of various electrochemical systems. The data obtained for systems without specific adsorption give a straight line with unit slope, thus supporting Grahame's assumption. In the light of the success of the Grahame's parametrization, the data are frequently presented in the "resolved form" of the dependence of C_i upon the charge of the electrode, the nature of the electrode, the solvent, temperature, etc. (for reviews see refs. 5–7).

The applicability of Grahame's assumption is frequently discussed in terms of whether C_i depends on the value of the concentration for which it was evaluated. It was proposed, in particular, to use the data obtained at low concentrations $c \lesssim 0.01\ N$ where the Gouy–Chapman theory is supposed to give the most reliable results (40). The values thereby obtained might differ slightly from $C_i(\sigma)$ evaluated by Grahame. At the same time, it is evident that the lowering of the experimental accuracy in the range of small concentrations and the increase in the contribution of the diffuse layer capacitance would enhance the inaccuracy in the determination of $C_i(\sigma)$. So, the question is then whether the results for $C_i(\sigma)$ obtained for different concentrations are in agreement *within the accuracy of its determination.*

A natural way to check it is as follows. The measured value of the inverse capacitance minus the inverse Gouy–Chapman capacitance is plotted versus concentration for fixed values of the charge σ. For each concentration the inaccuracy in the determination of the ordinate is indicated. If a horizontal line can be drawn through all the points within the range of accuracy, then Grahame's assumption is supported. The values thus obtained for $C_i(\sigma)$ are fitted to all concentrations, which may be regarded as an additional advantage of this method. Another, more decisive test is in plotting $[C^{-1}(\text{measured}) - C_d^{-1}(\text{calculated})]$ versus σ for different fixed values of concentration. If these $C_i(\sigma)$ curves, obtained for different c, coincide within the range of established accuracy, then Grahame's assumption does not contradict the experimental data. Examples of the application of both methods are given in the Appendix.

Physics of Grahame's Parametrization

The following two questions are usually the matter of discussion in the interpretation by Grahame. (*1*) What is the exact physical meaning of the concentration independent contribution to the inverse capacitance, C_i^{-1}, and what is the mechanism of the dependence on the charge of the electrode, the type of contact, and the thermodynamic parameters? (*2*) The expression [2] is a consequence of the nonlinear Gouy–Chapman theory. One is accustomed in literature to seeing criticism of it on statistico-mechanical grounds (8). Why then does [2] work so satisfactorily in the calculation of the diffuse layer capacity in Grahame's interpretation?

Let us discuss initially the second question which is less central for the aims of this paper than the first one. Computer simulation tests (9) and some other studies (10, 11) suggest an idea that a result similar to that of Gouy–Chapman may hold in a statistically justified theory (due to a compensation of corrections of different origins) even in a wide range of c and charges σ. However, even if the concrete form of [2] may only pretend to semiquantitatative results,[1] the interpretation of the data with its help possesses an "interpolation" accuracy. In fact, the contribution of C_d to the total capacitance [1] dominates in the vicinity of the zero charge point for small concentrations. Here,

$$[5] \quad C_d = \frac{\varepsilon\kappa}{4\pi}\cosh\left\{\frac{eV}{2\theta}\right\}$$

When the rationalized potential drop V tends to

[1]For not too large charges and concentrations, [2] predicts reasonable qualitative behaviour: before the beginning of the lattice effects (12) the characteristic thickness of the diffuse layer should decrease with the rise of the potential drop.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

zero, this result has a rigorous statistical foundation (13). With the increase of the charge and concentration the limiting form [5] no longer holds, but at the same time, C_d increases, and its contribution to the total capacitance diminishes. So, the latter is determined in this range mainly by the value of C_i, and the difference in the form of C_d predicted by different theories will be revealed but weakly in the experiment.

A variety of papers has been devoted to a physical interpretation of C_i (14). The Helmholtz idea that a plane condenser is arranged at the metal–electrolyte interface, the inner plane of which is the "metal surface" and the outer plane is determined by the distance of the closest approach of ions to the electrode, was utilized by Stern (15). He matched this inner layer condenser with the space charge in the electrolyte. The proper development of Stern's picture, given in an early paper by Grahame (2), attributed C_i just to this inner layer capacitor. A formula of macroscopic electrostatics was used to estimate C_i:

$$[6] \quad C_i = \varepsilon_i/4\pi L_i$$

where ε_i and L_i are the dielectric constant and the thickness of the inner layer. A reduced value of ε_i with respect to ε and its dependence on the voltage was discussed by Grahame (16) on the basis of Malsch's (17) observation of the bulk dielectric saturation effect. This approach was developed by Macdonald (18) and in some other publications (for review see refs. 8 and 9).

Later, microscopic molecular models were proposed for the inner layer structure. On the basis of these models, the capacitance was calculated and its dependence on charge analyzed (see reviews in refs. 14, 19–21). One common feature of these works, recognized in literature (10), is that the properties of the inner layer are considered spearately from the diffuse layer. The critical attitude to the description of an interfacial monolayer or bilayer of solvent molecules as a separate phase is evident: due to the structure of the solvent, the molecules of the "inner layer" are coupled with the outer solvent molecules (22, 23).

Electric Field Penetration into the Metal

Another group of papers discusses a contribution of the space charge in the metal. It originates in the paper by Rice (24). He utilized the Sommerfeld quantum theory of metals and applied it to the problem of the capacitance of an electrochemical interface prior to its development and application in the physics of metal surfaces. Different views on the role of the space charge in the metal were presented in the subsequent electrochemical literature. To put in order this controversial picture, it is worth discussing the question in more detail.

Rice's approach was analogous to a simple linearized Thomas–Fermi model with a sharp boundary for electrons at the surface. In modern terms this model prescribes for the capacitance of space charge in the metal:

$$[7] \quad C_M = \varepsilon_M \kappa_{TF}/4\pi$$

Here $\kappa_{TF} = (6\pi n_0 e^2/\varepsilon_M E_F)^{1/2}$ is the inverse Thomas–Fermi length (n_0, the average concentration of electrons; E_F, the Fermi energy); ε_M is the background dielectric constant due to the polarizability of the degrees of freedom having higher frequencies than the motion of free charge carriers (25). For instance, this might be the polarizability due to interband transitions, so that ε_M can be much greater than unity in semi-metals (e.g. Bi) and semiconductors, and close to one in simple metals like Hg. At Rice's time the band theory did not exist and he proposed a naive picture of the "solvent" composed of skeleton ions in which the electrons are dissolved. In the case of mercury, he attributed $\varepsilon_M \simeq 8$ to this "solvent". It seems hardly realistic now because the band gap in mercury is large enough and interband transitions cannot give a large contribution to the background polarizability, i.e., $\varepsilon_M \simeq 1$. After Grahame's measurements of the capacitance of the Hg/NaF–H_2O contact the value of C_i became known: $C_i = 29$ μF/cm^2, i.e., $1/4\pi C_i = 0.3$ Å. The metal capacitance is supposed to give a contribution in series with the contribution from the electrolyte side. The modern estimate with $\varepsilon_M \simeq 1$ and $\kappa_{TF}^{-1} = 0.5$ Å gives $1/4\pi C_M = 0.5$ Å which exceeds the experimental value of 0.3 Å (and, thus, does not allow any other contribution to the constant capacitance), while Rice's estimate is half that.

Attributing C_i to the metal capacitance only was criticized by Watts-Tobin and Mott (26, 27). They indicated a remarkable dependence of the experimental values of C_i on the temperature and the increase of C_i with anodic polarization. These cannot be provided by the metal, so that the solvent *must* take an important part. It should be emphasized that nowhere did they conclude that the inverse metal/vacuum capacitance is small compared to the experimental C_i^{-1}. They only argued against simply adding the vacuum value of the metal capacitance in series with a contribution from the solution part — otherwise the "pure metal" effect will be *too large*, in contradiction with experimental data! One cannot simply throw away the metallic space charge effect, but it must be somehow diminished. Thus, Mott and Watts-Tobin (27) argued against the model of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

sharp interface. They presumed that the "field does not jump sharply at the interface", implying that the metal electron cloud near the boundary is mixed with the solvent. That means, in other words, that the interfacial layer should be characterized by a unified background dielectric polarizability. A very rough estimate is appropriate for an illustration of this statement:

$$\frac{1}{4\pi C_i} \sim \frac{1}{4\pi C_M^{interf}} + \frac{1}{4\pi C_H}$$

where C_M^{interf} and C_H are the interfacial electronic gas and the Helmholtz layer contributions. Introducing some effective dielectric constant of the interfacial region $\tilde{\varepsilon}$ one may evaluate $C_M^{interf} \sim \tilde{\varepsilon}\kappa_{TF}/4$, $C_H \sim \tilde{\varepsilon}/4\pi L$ where L is the Helmholtz layer effective thickness. Then $1/4\pi C_i \sim (\kappa_{TF}^{-1} + L)/\tilde{\varepsilon}$, and one may speak about the metallic effect as a small distance added to L.[2] However more accurate estimates take into account $\tilde{\varepsilon}$ in the Thomas–Fermi length $\kappa_{TF}^{-1} \sim \sqrt{\tilde{\varepsilon}}\kappa_{TF_0}^{-1}$ ($\kappa_{TF_0}^{-1}$, the isolated metal value):

$$1/4\pi C_i \sim (\kappa_{TF_0}^{-1}\sqrt{\tilde{\varepsilon}} + L)/\tilde{\varepsilon}$$

Thus, the electric field penetration adds to L not 0.5 Å but rather more than 1 Å, which gives about 20% to the total result. So, Mott and Watts-Tobin's qualitative arguments (in contrast to their misleading quotes in some subsequent publications) mean only that a rigorous theory must be developed to justify why the metal effect is not large enough to cover the whole value of C_i^{-1}.

Quantum-mechanical Approach to the Structure of the Interface

Recent advances in the quantum self-consistent theory of metal surfaces (29, 30) demonstrate that the electronic "tails" are spread outside the metal skeleton edge into the vacuum. However, a simple matching of the vacuum–metal capacitance, calculated without an assumption of an infinite barrier for electrons at the surface, to the electrolyte capacitance in series would not lead to a resolution of the problem. Indeed it is natural to expect that the effective screening length in the surface region should be greater than the bulk value. A treatment of this kind was proposed by Kuklin (31) and, in fact, it does not agree with experimental data.[3]

Quantum self-consistent theory of the metal–insulator contact is not yet developed. Only the first steps have been made in purely electrostatic estimates of the effect of the bounding dielectric polarizability on the character of electronic distribution near the interface (32). The effect is, in addition, spread out inside the insulator. A proper treatment of the metal – polar solvent interface should also take into account the quantum interaction of the metallic electrons with the electronic orbitals of solvent molecules. In the case of chemisorption of the solvent, a corresponding exchange term would be involved in the Hamiltonian. These effects taken together will determine the resulting character of the electronic distribution in the interfacial region and the contact dielectric response. In the light of this general view, various data for the dependence of C_i on the nature of the metal, solvent, and their interaction may be understood. However, the quantitative explanation of the data can be given only by a model quantum treatment of the problem.

Phenomenological Approach

Prior to the creation of a theory of this kind, a "modelless" phenomenological analysis of the potential distribution in the system is relevant in order to reveal which properties of the capacitance depend on the model of the contact and which are general for any system. In particular, such an approach would permit one to investigate to what extent Grahame's parametrization is justified and, in the case of its validity, to express the "compact layer capacitance" C_i through the dielectric response of the system. For the potentials close to the zero charge point, such a problem has been solved by Schmickler and the authors of this paper (33) (for a discussion of these results, see also the review article by A. A. Kornyshev and M. A. Vorotyntsev in ref. 1).

[2]This would not be true, if the *vacuum* metal capacitance is added in series: $1/4\pi C_i = \kappa_{TF_0}^{-1} + L/\tilde{\varepsilon}$. Here the first term is of the same order as the second one, in contrast to the statement made in ref. 28.

[3]An apparent agreement with experimental data drawn in Fig. 3 of ref. 31 is caused by two circumstances. (*1*) For $c = 10^{-3}$ *M*, 10^{-2} *M* the compact layer contribution is negligible with respect to that of the diffuse layer. So, for low concentrations any mistake in the expression for the compact layer capacity is not observable in the plots of the charge dependence of the total capacitance. (*2*) At $c = 10^{-1}$ *M*, the results start to be sensitive to the description of the compact layer contribution. Therefore, a discrepancy between the experimental data and predictions of Kuklin's model should be expected. However, the theoretical point given in Fig. 3 for $c = 10^{-1}$ *M* lies rather close to the experimental curve, too close, probably, due to an arithmetical mistake. Indeed, from the formulae [32′], [34], [34′], [34″] of ref. 31 it follows that $C < C_M$. At the same time, C_M should be equal to 16 μF/cm² for the Thomas–Fermi model if one uses the estimate of ref. 31 for Thomas–Fermi parameter $K_s = 1.8 \times 10^{-8}$ cm^{-1} (p. 388), and be smaller for other models. This is in obvious contradiction to $C = 18$ μF/cm² obtained by the author for the total capacity. The discrepancy between the Kuklin's model of matching the metal and electrolyte contributions and the experimental data will be even more drastic for higher concentrations.

This phenomenological analysis enabled one to come to a qualitative conclusion concerning the microscopic structure of the interface: it has been unambiguously shown that no quantum model of the metal with an infinite potential barrier for electrons at the interface can be consistent with the capacitance data for mercury (and a set of simple metals) – sodium fluoride aqueous solution contact. That means that the electronic "tails", presumably, penetrate into the interfacial solvent region.

In the present paper we shall extend this theory to the case of a moderate deviation of the electrode potential from the zero charge point. It will be seen from its results that (*1*) Grahame's parametrization is valid for any model of the contact and has a rigorous foundation at moderate electrolyte concentrations and charges at the electrode. (*2*) The value of C_i is expressed through a unified dielectric function of the electrode–solvent system. (*3*) This expression provides the possibility for studying the dependence of C_i on the nature of the metal, solvent, electrode charge, temperature, etc., on the basis of models for this function.

Poisson–Boltzmann Equation with an Account of Spatial Dispersion of the Dielectric Permittivity of the Electrode–Solvent System

Let us consider firstly the potential distribution at the zero charge point (zcp), $\phi^0(z)$. It obeys the Poisson equation

$$\frac{d^2}{dz^2}\phi^0(z) = -4\pi(\rho_{ion}{}^0 + \rho_{ms}{}^0)$$

Here, $\rho_{ion}{}^0$ is the charge density for ions in the diffuse layer; $\rho_{ms}{}^0$ is the combined induced charge density due to the electrons of the metal and the bound charge of the solvent polarization; z is the coordinate normal to the interface which we consider being plane in this paper.[4] Within the classical theory of the compact layer, $\phi^0(z)$ is equal to zero in the diffuse layer region because $\rho_{ion}{}^0 = 0$. However, this is not true if the electron tails of the metallic electron density penetrate inside the solvent with nonlocal dielectric properties. In this case, the information about the nonzero field in the range of electron tails is spread into the solvent, inducing a nonzero field in a layer of a characteristic thickness associated with the correlation length for the fluctuations of the solvent polarization. The correlation is determined by the short-range dynamic structure of the solvent (for a detailed discussion see review, ref. 41). In associated liquids it may come to several molecular diameters. Thus, up to such distances the field is nonzero and, thereby, $\rho_{ion}{}^0 \neq 0$, strictly speaking.

When the interface is charged, the Poisson equation takes the form

$$\frac{d^2\phi^\sigma(z)}{dz^2} = -4\pi(\rho_{ion}{}^\sigma + \rho_{ms}{}^\sigma)$$

where the superscript σ indicates the value of the charge, calculated per unit area of the interface. Then, the deviation of the electric potential from that of zcp

$$\phi(z) \equiv \phi^\sigma(z) - \phi^0(z)$$

obeys the equation

$$\frac{d^2}{dz^2}\phi(z) = -4\pi(\rho_{ms} + \rho_{ion}{}^\sigma - \rho_{ion}{}^0)$$

where $\rho_{ms} = \rho_{ms}{}^\sigma - \rho_{ms}{}^0$.

Let us introduce a nonlocal dielectric permeability of the metal–solvent system, $\chi(z, z')$. It relates the change in the density of the metal electrons and the solvent bound charge, ρ_{ms}, with the change of the electric field due to the charging

$$[8] \qquad \rho_{ms}(z) = \frac{d}{dz}\int_{-\infty}^{\infty} dz'[\chi(z, z')]\frac{d\phi(z')}{dz'}$$

Then the equation for $\phi(z)$ takes the form:

$$\frac{d}{dz}\int_{-\infty}^{\infty} dz'[\varepsilon(z, z')]\frac{d\phi(z')}{dz'} = -4\pi[\rho_{ion}{}^\sigma(z) - \rho_{ion}{}^0(z)]$$

where

$$\varepsilon(z, z') = \delta(z - z') + 4\pi\chi(z, z')$$

is the *nonlocal dielectric function of the metal–solvent system.*[5]

In order to make the equation closed, we use the Boltzmann form, relating the electrolyte ionic density and the potential[6]

[4]The one-dimensional picture breaks down in the absence of translational invariance along the interfacial plane. These are the cases of (*a*) discrete translational invariance (single-crystalline electrodes), (*b*) inhomogeneous interface (polycrystalline electrodes), (*c*) microroughness of the electrode surface (solid metals, oxide covered metals with island formation, etc.). Here, the induction and potential would depend upon the coordinates along the interface. This case requires a special consideration and is not considered in this paper.

[5]The physical meaning and basic properties of this function are reviewed in ref. 34, (see also ref. 33). To ensure the smooth reading of this paper, we summarize them in Appendix 2.

[6]The case of a relation of an arbitrary form, $\rho_{ion}{}^\sigma(z) = \rho(\phi)$ is considered in one of the subsequent sections.

$$\rho_{ion}{}^{\sigma}(z) = ec \sum_i z_i \nu_i \theta(z - L_i) \times \exp\left\{-ez_i \frac{\phi^{\sigma}(z)}{\theta}\right\}$$

Here, the Heaviside step function $\theta(z - L_i)$ takes into account (for generality) the finite distance of the closest approach of ions of i-kind to the electrode. Assuming for simplicity L_i being the same for all species ($L_i = L$), we then arrive at the following nonlinear integro-differential equation

$$[9] \quad \frac{d}{dz}\int_{-\infty}^{\infty} dz'[\varepsilon(z, z')]\frac{d\phi(z')}{dz'} = -4\pi\theta(z - L)ec \times \sum_i z_i \nu_i \left\{\exp\left[-ez_i \frac{\phi^0(z) - \phi(z)}{\theta}\right] - \exp\left[-ez_i \frac{\phi^0(z)}{\theta}\right]\right\}$$

It is convenient to rewrite [9] in the equivalent form by introducing the induction $D(z)$:

$$[10] \quad D(z) = \int_{-\infty}^{\infty} dz'[\varepsilon(z, z')]\left[-\frac{d\phi(z')}{dz'}\right]$$

then

$$[9'] \quad \frac{dD}{dz} = 4\pi\theta(z - L)ec \sum_i z_i \nu_i \times \left\{\exp\left[-ez_i \frac{\phi^0(z) + \phi(z)}{\theta}\right] - \exp\left[-ez_i \frac{\phi^0(z)}{\theta}\right]\right\}$$

Since the electrode–solvent system is described by a unified dielectric function, the approach based on (9) includes any variants of the interaction between the electrode and the solvent. At the same time, the charge of the electrolyte plasma is extracted in the right-hand side of [9]. Thus, [9] (and [9']) are inapplicable in the case when chemisorption of ions onto the electrode surface is possible.

The Solution of [9] in the Range of Moderate Electrolyte Concentrations and Electrode Charges

In general, to solve the integro-differential equation [9], it is necessary to specify an analytical form of the kernel $\varepsilon(z, z')$, corresponding to each concrete model of the contact. However, in the case of a solution of a low concentration (when the effective screening length in the electrolyte is much greater than the characteristic scales of $\varepsilon(z, z')$ variation), it is possible to express the solution for the potential $\phi(z)$ through $\varepsilon(z, z')$ of an arbitrary form.

In order to do this we use the singular perturbation technique (the method of matching asymptotic expansions) (35). Since it has been considered rigorously and in detail for the case of the linearized Poisson–Boltzmann integro-differential equation (33), we shall give here only a schematic derivation, retaining the major terms in the asymptotic expansions.

Let us denote the characteristic distance of $\varepsilon(z, z')$ variation by z^*, and consider the case $z^* \ll \kappa^{-1}$. The solution for ϕ is represented in two different forms for the "internal" and "external" regions:

$$[11] \quad \phi(z) = \begin{cases} \phi_{int}(z), & z \ll \kappa^{-1} \\ \phi_{ext}(z), & z \gg z^* \end{cases}$$

with $\phi_{int}(z) = \phi_{ext}(z)$ for $z^* \ll z \ll \kappa^{-1}$. The boundary conditions then take the form

$$[12] \quad \phi_{int}(z \to -\infty) = V\,(=\phi^{\sigma}(-\infty) - \phi^0(-\infty)) \quad \phi_{ext}(z \to +\infty) = 0$$

$$[13] \quad \phi_{int}(z \to \infty) = \phi_{ext}(z \to L)$$

In [12], V is the change of the total potential drop between the bulk of the metal and solution with the charging of the electrode (i.e., the rationalized potential). Equation [13] is the matching condition for asymptotic expansions.

In the range of $z \ll \kappa^{-1}$ and for not too large deviations from the zero charge point, the leading term of the asymptotic expansion corresponds to the limit of $c \to 0$, i.e., to obtain it one may simply omit the right-hand side of [9]:

$$[14] \quad \frac{d}{dz}\int_{-\infty}^{\infty} dz'[\varepsilon(z, z')]\frac{d\phi_{int}(z')}{dz'} = 0$$

Other aspects of [9] are simplified in the range of $z \gg z^*$. In this region, $\phi^0(z) \simeq 0$, and, thereby, $\rho_{ion}{}^0 \simeq 0$. Furthermore, $\varepsilon(z, z')$ is a rapidly varying function. Therefore, $d\phi(z')/dz'$ in the integrand may be expanded in a power series near $z' = z$. If only the major term in the expansion is considered, the left-hand side is reduced to

$$\frac{d}{dz}\left\{\frac{d\phi_{ext}}{dz}\int_{-\infty}^{\infty} dz'[\varepsilon(z, z')]\right\}$$

Taking into account that $\varepsilon(z, z')$ coincides in this range with the bulk dielectric function of the solvent, $\varepsilon_s(z - z')$, and using the identity $\int dz'[\varepsilon_s(z - z')] = \varepsilon_S$ (ε_S is the macroscopic dielectric constant of the solvent) we obtain

$$[15] \quad \varepsilon_S \frac{d^2\phi_{ext}}{dz^2} = -4\pi ec\theta(z - L)\sum_i z_i \nu_i \times \exp\{-ez_i\phi_{ext}(z)/\theta\}$$

The integration of [14] gives

$$[16]\quad \int_{-\infty}^{\infty} dz'\,[\varepsilon(z, z')]\frac{d\phi_{int}(z')}{dz'} = -D$$

D is a constant of integration equal to the induction [10] in the range where ions are absent. Let us introduce the inverse function of $\varepsilon(z, z')$:

$$[17]\quad \int_{-\infty}^{\infty} dz''[\varepsilon(z, z'')][\varepsilon^{-1}(z'', z')] = \delta(z - z')$$

Using it, we may rewrite [17] as

$$[18]\quad \frac{d}{dz}\phi_{int}(z) = -D\int_{-\infty}^{\infty} dz'[\varepsilon^{-1}(z, z')]$$

Integrating [18] and taking [12] into account, gives

$$[19]\quad \phi_{int}(z) = V - D\int_{-\infty}^{z} dz''\int_{-\infty}^{\infty} dz'[\varepsilon^{-1}(z'', z')]$$

The integral in [19] diverges with $z \to \infty$. Therefore, it is convenient to rewrite [19] by adding and subtracting the asymptotic behaviour of this integral at $z \to \infty$:

$$[20]\quad \phi_{int}(z) = V - \frac{D}{\varepsilon}\theta(z - L)(z - L) - D \times \int_{-\infty}^{z} dz''\left[\int_{-\infty}^{\infty} dz'\,[\varepsilon^{-1}(z'', z')] - \frac{\theta(z'' - L)}{\varepsilon}\right]$$

The integral in [20] approaches the finite value[7]

$$[21]\quad l = \int_{-\infty}^{\infty} dz\left\{\int_{-\infty}^{\infty} dz'[\varepsilon^{-1}(z, z')] - \frac{1}{\varepsilon}\theta(z - L)\right\}$$

as $z \to \infty$.

The solution of the external region equation [15] coincides with that of the classical local Poisson–Boltzmann equation. Integrating it in a standard way we have

$$[22]\quad -[\operatorname{sgn}\phi_0]\sqrt{\frac{\varepsilon}{8\pi\theta c}} \times \int_{\phi_0}^{\phi_{ext}} \frac{d\psi}{\sqrt{\sum_i \nu_i\left[\exp\left(\frac{-ez_i\psi}{\theta}\right) - 1\right]}} = z - L$$

where the constant of integration $\phi_0 = \phi_{ext}(z)$ should be obtained from condition [13]. To do this we rewrite [22] in the range of $z \to L(z \ll \kappa^{-1})$, i.e., for $\phi_{ext} \to \phi_0$:

$$[23]\quad \underset{z\to L}{\phi_{ext}} = \phi_0 - (z - L) \times \sqrt{\frac{8\pi\theta c}{\varepsilon}\sum_i \nu_i\left[\exp\left(-\frac{ez_i\phi_0}{\theta}\right) - 1\right]} \times \operatorname{sgn}\phi_0$$

On the other hand, it follows from (20) that

$$[24]\quad \underset{z\to\infty}{\phi_{int}} = V - Dl - (z - L)D/e$$

The substitution of [23] and [24] into [13] leads to a pair of equations

$$[25]\quad \phi_0 = V - Dl$$

$$[26]\quad D = \sqrt{8\pi\varepsilon\theta c\sum_i \nu_i\left[\exp\left(-\frac{ez_i\phi_0}{\theta}\right) - 1\right]} \times \operatorname{sgn}\phi_0$$

Let us insert [25] into [26] and use the expression for D through the charge separated in the system per unit contact area,

$$[27]\quad D = 4\pi\sigma$$

We then have

$$[28]\quad \sigma = \sqrt{\frac{\varepsilon\theta c}{2\pi}\sum_i \nu_i\left\{\exp\left[-\frac{ez_i}{\theta}(V - 4\pi l\sigma)\right] - 1\right\}} \times \operatorname{sgn}\phi_0$$

We limit the subsequent discussion to a binary symmetric electrolyte. In this case, [28] can be rewritten as an explicit equation

$$[29]\quad V = 4\pi l\sigma - \frac{2\theta}{e}\operatorname{arcsh}\left\{\sqrt{\frac{\pi}{\varepsilon\theta c}}\sigma\right\}$$

Equation [8] has a form of a linear relationship between the induced charge density ρ_{ms} and the change in the electric field $(-d\phi/dz)$ with the charging of the contact from the zcp up to σ. At large values of σ, the linearity of this relationship starts to break down. However, this can be formally taken into account by the introduction of a parametric dependence of $\varepsilon(z, z')$ on σ. Such a possibility is

[7]We note that normally the existence and uniqueness of the inverse function $\varepsilon^{-1}(z, z')$, determined by [17] for a given $\varepsilon(z, z')$, take place. Indeed, $\varepsilon(z, z')$ contains a local part: $\varepsilon(z, z') = \delta(z - z') + \chi(z, z')$. Rewriting the solution of [17] in the form $\varepsilon^{-1}(z, z') = \delta(z - z') + \chi^{-1}(z, z')$, we reduce [17] to $\chi^{-1}(z, z') + \int dz''[\tilde{\chi}(z, z'') \cdot \tilde{\chi}^{-1}(z'', z')] = -\tilde{\chi}(z, z')$. This is the Fredholm inhomogeneous equation of the second kind. It possesses a unique solution except for the case when (-1) is an eigenvalue of the kernel $\tilde{\chi}(z, z')$. We are not aware of physical models for which the latter takes place.

caused by the following circumstance. The nonlinear dielectric properties are dominant in the range of z where the effect of electrolyte ions on the distribution of electric field is small. So, the form of the function $\varepsilon(z, z')$ is unambiguously determined by the value of σ and the properties of the uncharged metal–solvent contact, but is independent of the structure of the solution. Hence, l is a function of σ, independent of the concentration of electrolyte.

Differentiating [29] with respect to σ we obtain for the differential capacitance

$$[30] \quad C \equiv d\sigma/dV$$

the expression

$$[31] \quad \frac{1}{4\pi C} = l + \sigma\frac{dl}{d\sigma} + \frac{1}{4\pi C_{GC}}$$

where C_{GC} is given by [2]. This result supports the Grahame hypothesis [1], giving the expression for C_i

$$[32] \quad \frac{1}{4\pi C_i} = l + \frac{dl}{d\sigma}$$

One can obtain the integral capacitance

$$[33] \quad K \equiv \frac{\sigma}{V} \equiv \left\{\frac{1}{\sigma}\int_0^\sigma \frac{d\sigma}{C}\right\}^{-1}$$

by dividing [29] by σ:

$$[34] \quad 1/4\pi K = l + 1/4\pi K_{GC}$$

where K_{GC} is the Gouy–Chapman integral capacitance. Thus, the integral capacitance of the inner layer, K_i, is simply related to l:

$$[35] \quad l = \frac{1}{4\pi K_i} = \frac{1}{\sigma}\int_0^\sigma \frac{d\sigma}{4\pi C_i}$$

Expression [35] shows how to evaluate the characteristic length l via the data for the integral or differential inner layer capacity.[8]

On the Criterion of the Validity of [31]

The result [34] is rigorous if the matching of asymptotic expansions and their form are valid. Accurate criteria for the approximations used can be obtained if the next order terms of the asymptotic expansions are found. However, in order to get a semiquantitative estimate, we shall make a simple verification.

The result was achieved primarily by means of omitting the right-hand side of [9] in the internal solution. Evidently, this approximation is reasonable when the portion of the charge in the electrolyte layer of thickness z^* (the characteristic scale of $\varepsilon(z, z')$ variation) neighbouring the electrode is much smaller than the total charge in the double layer as a whole:

$$[36] \quad ec\sum_i z_i\nu_i \int_L^{z^*+L} dz \exp\left\{-\frac{ez_i\phi_{int}(z)}{\theta}\right\} \ll \sigma$$

From [20], let us estimate $\phi_{int}(z)$ in this interval by $(V - Dl)$. Inserting this into [36] we obtain the condition

$$[37] \quad z^*ec\sum_i \nu_i z_i \exp\left\{-\frac{ez_i}{\theta}(V - 4\pi\sigma l)\right\} \ll \sigma$$

For $\sigma \to 0$ the left-hand side of this inequality tends to $(z^*\kappa_0^2/4\pi C_{GC})\sigma$ so that we arrive at

$$[38] \quad z^*\kappa^2 \ll \sqrt{\kappa^2 + 4\pi L_B^2\sigma^2/e^2}$$

i.e.,

$$[39] \quad z^* \ll \kappa^{-1}$$

For larger σ, the sum in [37] can be estimated in the light of [28] by

$$1 + \frac{2\pi}{\varepsilon\theta c}\sigma^2 \sim \frac{2\pi}{\varepsilon\theta c}\sigma^2$$

Thus [37] is reduced to

$$[40] \quad |\sigma| \ll \frac{1}{2\pi}\frac{e}{L_B z^*}$$

At the same time the simplification of the external solution also implied the inequality [39].

Thus the obtained solution of [9] (which justifies Grahame's parametrizations) is appropriate for moderate concentration [39] and in the range around zcp determined by [40]. Taking for estimates an aqueous solution ($z_* \sim 5$ Å, $L_B \simeq 7$ Å) of 1–1 electrolyte, we come to the restrictions $|\sigma| \ll 10\ \mu C/cm^2$, $c \ll 1\ M$. These values belong to the typical range of charges and concentrations in electrochemical experiments.

Some Generalizations

We considered above the electrode–electrolyte solution system within a most general description of an electrode–solvent interface, while using Poisson–Boltzmann approximation (PBA) for ionic plasma. However, it is possible to go out of the framework of PBA.

Let us consider an equation

$$[41] \quad \frac{d}{dz}\int_{-\infty}^{\infty} dz'[\varepsilon(z, z')]\frac{d\phi(z')}{dz'} = -4\pi\rho[\phi]$$

[8]The quantities χ and ε in [8]–[10] characterize the response of the system to the charging from zcp to σ. Therefore, $l(\sigma)$ is naturally related with such an integral response characteristic of the integral capacitance. We could have introduced by analogy the "differential response" functions, prescribing how the metal–solvent system reacts to the charging from σ to $\sigma + d\sigma$, which can be strictly related to the differential capacitance.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

where $\rho[\phi]$ is a function of the potential ϕ. The concrete form of this functional can be specified for a model of electrolyte plasma, i.e., for a given statistical description of the diffuse layer (c.f. ref. 10). For instance, in a particular case of PBA, $-4\pi\rho[\phi]$ coincides with the right-hand side of [9]. We further assume that the form of $\rho[\phi]$ provides the existence and uniqueness of the solution of [41].

Let

$$[42] \quad \int_0^{z^*} dz\, \rho[\phi(z)] \ll \sigma$$

Then again we may use the concept of internal and external solutions [11]. Here the internal solution is valid in the range of z much smaller than the characteristic thickness of the diffuse layer. Boundary conditions [12] and the matching condition [13] (with $L = 0$)[9] can be used. The internal solution is given by [20] ($L = 0$). If the scales of variation of the potential in the outer region are much greater than z^*, one obtains by analogy to [15] the equation for the external solution:

$$[43] \quad \varepsilon \frac{d^2\phi_{ext}}{dz^2} = -4\pi\rho[\phi_{ext}]$$

Let us assume that the general solution of [43] is known. Then the matching of

$$[44] \quad \phi_{\substack{ext \\ z\to 0}} = \phi_{ext}(0) - z\left.\frac{d\phi_{ext}}{dz}\right|_{z=0}$$

and

$$[45] \quad \phi_{\substack{int \\ z\to\infty}} = V - Dl - zD/\varepsilon$$

gives

$$[46] \quad \phi_{ext}(0) = V - Dl$$

$$[47] \quad D = -\varepsilon\left.\frac{d\phi_{ext}}{dz}\right|_{z=0}$$

Equation [47] means that the charge at the "metal boundary of the classical diffuse layer" of the external solution is equal to charge at the electrode $\sigma = (D/4\pi)$. Thus, differentiating [46] with respect to σ we have

$$d\phi_{ext}(0)/d\sigma = 1/C - 4\pi(l + \sigma dl/d\sigma)$$

Since the meaning of $d\phi_{ext}(0)/d\sigma$ is the inverse capacitance $1/C_d$ of the diffuse layer, which is described by [43], we come finally to [1], where C_i is determined by [32], and C_d is determined by the "diffuse" layer theory [43].

[9]Below, we shall not introduce L, implying that all the information concerning the short-range effects is included in $\rho[\phi]$.

This is a remarkable result. Indeed the theoretical analysis of the distribution of the potential and charge density in an "academic" system of charges immersed in a continuum of a dielectric constant ε near a plane charged boundary was a subject of many papers (10). We see now that the expressions for the capacity obtained in these theories can be matched with the compact layer contribution in series, the compact layer capacity being expressed independently via [32] through the properties of the electrode and solvent in contact. However, such a simple procedure is justified only when the inequality [42] holds. Corresponding numerical criteria can be established for a given form of $\rho[\phi]$. Strictly speaking, this approach becomes inappropriate when the characteristic length of spatial dispersion of $\varepsilon(z, z')$ in the solvent is comparable with the characteristic thickness of the diffuse layer. In this case [41] should be solved exactly for specified $\varepsilon(z, z')$ and $\rho[\phi]$.

Concluding Remarks

Experimental data for the capacitance C_i (including dependencies on the charge, electrode material, solvent, temperature, etc., can be used in [35] to plot the values of the characteristic integral l [21]. This is done, e.g., in Figs. 1 and 2. Plots of this kind are valuable from two points of view. (*1*) The characteristic integral l arises in some other inter-

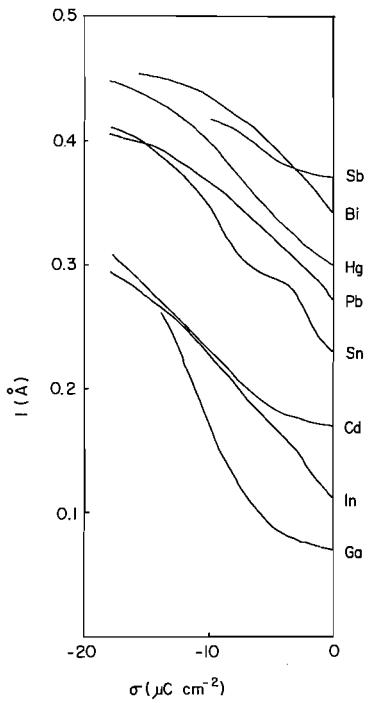

FIG. 1. Dependencies of l on σ, integrated via [36]. $l(\sigma)$ for aqueous solution of NaF on different metals at $T = 25°C$ (after the data for C_i taken from the review article ref. 5).

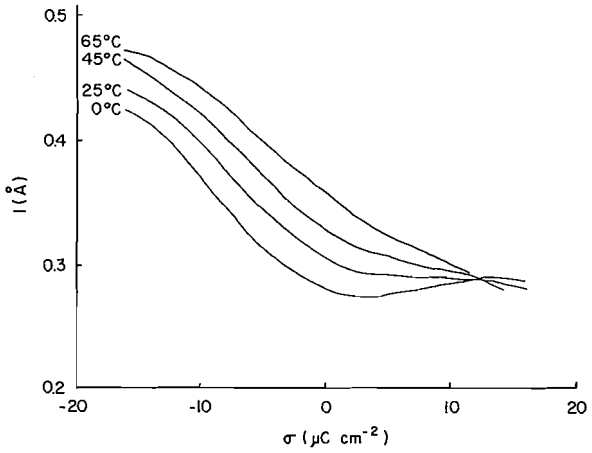

FIG. 2. $l(\sigma)$ for the aqueous solution of NaF on mercury at different temperatures via the Grahame's data for C_1 (2).

facial problems. In particular, it seems to be a basic parameter in the interaction of ions adsorbed at the interface (this will be shown in a subsequent publication). So, the experimental data for l enables one to analyze these problems with no relation to model calculation of l. (2) Approximations for $\varepsilon(z, z')$ and, thereby, $\varepsilon^{-1}(z, z')$ should be in accordance with the experimental data for l. The result of integration [21] would depend on the parameters involved in these approximations. Comparing these dependencies with the observed tendencies one may judge the adequacy of the approximation. The trends in these parameters with the variation of the charge, temperature, solvent, and electrode can be established. The same can be said about first-principle or micro-model calculations. For instance, Partenskii and Smorodinskii (36) extended Smith's version (37) of the self-consistent density-functional treatment of a neutral metal–vacuum interface to the study of the system properties in an external electric field. They arrived at some reconstruction of the electron density near the edge of the ionic skeleton (assumed to be a uniform rigid background) with the variation of applied field. Their numerical data revealed 10% variation of the "electronic tail" decay length for the fields of the order of 10^6–10^7 V/cm with respect to the zero field value. In higher fields (actual for the electrochemical interface) the reconstruction via this mechanism will be more considerable. The field (or charge) dependence of K_i or l may be in some way associated with such a reconstruction. Unfortunately, the results of ref. 36 cannot be applied immediately for the metal–solvent interface. *The simultaneous rearrangement of the structure of the solvent layer, adjacent to the metal, together with the solvent effect on the electron density must be taken into account.* The discrete ionic structure of the metal, shown to be important for the metal–vacuum systems (38), should be involved as well. The theory considering these effects will form the subject of future investigations. However, some qualitative conclusions on the possible physical effects can be already drawn from the curves of Figs. 1 and 2. They will be discussed in a paper to follow.

New Tests of Grahame's Parametrization

As discussed in the Introduction, it is relevant to plot the dependence of the experimental value of the inverse capacitance of the contact minus the inverse of the Gouy–Chapman capacitance versus concentration c for fixed values of the charge at the electrode, σ. For brevity, we call this difference the inverse compact later capacitance. We shall do it here for the integral capacitances, c.f. [35]. Then, for aqueous solution of 1–1 electrolyte at $T = 25°C$ one has

$$[A.1] \quad l = \frac{1}{4\pi K_i} = \frac{8.84}{\sigma}\left\{V - 0.051 \ln\left[0.085\frac{\sigma}{\sqrt{c}} + \sqrt{1 + \left(\frac{0.085\sigma}{\sqrt{c}}\right)^2}\right]\right\}$$

Here, σ is given in $\mu C/cm^2$, the rationalized potential V in V, c in N.

The plots of $l(c)$ at two values of σ are given in Fig. 3 for the Hg/H_2O–NaF system. The experimental data due to Grahame (39) (Table 1 for the dependence of σ on V and c) were used. We see that within the indicated accuracy one may draw the horizontal through the points corresponding to all the concentrations used. The values of l thereby evaluated are:

$$\sigma = -15, \; l = 0.440 \pm 0.001$$
$$\sigma = +10, \; l = 0.288 \pm 0.002$$

They are in very good agreement with the results obtained by the numerical integration of the curves of the compact layer differential capacitance versus σ (see Fig. 2: $l = 0.436$ ($\sigma = -15$) and $l = 0.288$ ($\sigma = +10$)).

Generally the inaccuracy in the determination of ordinates in Fig. 3 is associated not only by the dispersion in the experimental data for the capacitance C, but also due to the inaccuracy arising in plotting

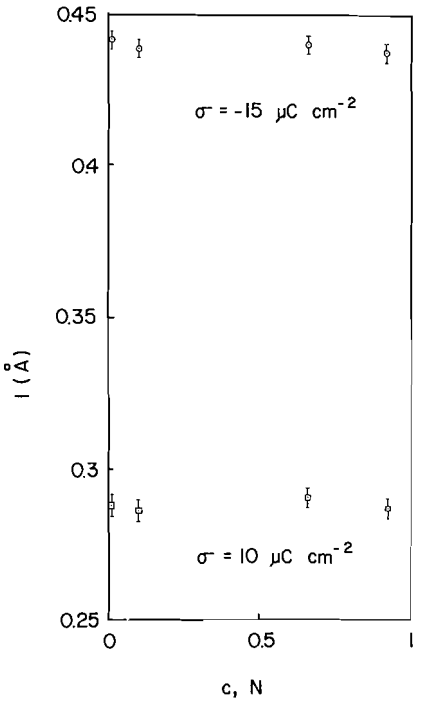

FIG. 3. Values for l estimated via [A.1] using Grahame's data (39). Values of charge are fixed, concentration is varied.

V versus σ at fixed c. The dispersion marked in Fig. 3 is determined by this latter source since we were limited by the data (39) tabulated with 100 mV interval. For this reason we presented the curves for large σ, for which the inaccuracy due to a numerical recalculation is not too high.

The accuracy of the proposed method can be essentially increased when using more detailed data.

The difficulty above is avoided in another test. This is simple plotting l via [A.1] versus the data for σ. In the classical Grahame's paper (39) just the data for σ and V are tabulated for different fixed c. Using these we plot $l(\sigma)$ in Fig. 4 for four concentrations employed by Grahame. The indicated dispersion was calculated via the formula

$$\sigma_{\substack{max \\ min}} = o(c) \pm \Delta(c) \, V$$

and the points $l(\sigma_{max})$ and $l(\sigma_{min})$ are calculated via [A.1]. The inaccuracy coefficient is estimated as (41): $\Delta(c) = 0.1$ at $c \gtrsim 10^{-1} M$, $\Delta(c) = 0.2$ at $c \sim 10^{-2} M$. From Fig. 4 we see that the $l(\sigma)$ curves obtained for different concentrations lie very close to each other within the range of scatter of experimental points $l(\sigma_{min})$, $l(\sigma_{max})$. Noticeably, the results of the preceding test (Fig. 3) are in excellent agreement with the data of Fig. 4.

Appendix 2

The nonlocal character of the relation [8], i.e. the dependence of the dielectric permeability χ and permittivity ε on two variables z, z' reflects the structure of the system. The latter manifests itself in the correlation of the bound charge density in space. Due to this correlation, σ_{ms} in a point z is determined not only by the gradient of potential in the point z but also by its values in points z', belonging to a certain region which we may call the correlation range. In the case of a simple metal in contact with vacuum, such a correlation would be caused by the electron gas structure (see reviews in refs. 29, 30). In a semi-infinite solvent the nonlocal response is a consequence of the correlation in the dipoles bound charge near the surface and in the bulk, determined by the polar liquid structure (ref. 1, p. 23, 23, 34).

In the bulk of the metal or of the solvent, the system may be regarded as translationally invariant if the discrete translational invariance of the solid crystal metal is neglected. Both χ and ε are then the functions of $z - z'$. The limiting behaviour of $\varepsilon(z, z')$ at z, z' tending to $+\infty$ (into the bulk of the solvent) is: $\lim \varepsilon(z, z') = \varepsilon_{solv}(z - z')$. The special properties of the interfacial region lead to a breakdown of the translational invariance in the direction normal to the interface, so that ε becomes a function both of z and z' separately.

The unidimensional dielectric function of the bulk solvent is simply related with the so called (41) wave number dependent dielectric function of a uniform unbounded solvent $\varepsilon_s(k)$:

$$\varepsilon_s(z - z') \equiv \varepsilon_s(z - z', \kappa = 0)$$

$$\varepsilon_s(z - z', \kappa) = \frac{1}{2\pi} \int_{-\infty}^{\infty} dA[\exp(iA)(z - z')] \times [\varepsilon_s(k = \sqrt{A^2 + \kappa^2})]$$

Hence

$$\int_{-\infty}^{\infty} d(z - z')[\varepsilon_s(z - z')]\{\exp[-iA(z - z')]\} = \varepsilon_s(k = A)$$

$$\int d(z - z')[\varepsilon_s(z - z')] = \varepsilon_s(k = 0)$$

The value $\varepsilon_s(k = 0)$ characterizes the response of the medium to a long wavelength electric field. In the systems without free charge carriers, $\varepsilon_s(k = 0)$ equals, by definition, the macroscopic dielectric constant ε_s. Since $\varepsilon_s(z - z')$ is symmetric with respect to z and z', $\varepsilon_s(z - z') = \varepsilon_s(z' - z)$, we may also write

$$\int dz'[\varepsilon_s(z - z')] = \int dz[\varepsilon_s(z - z')] = \varepsilon_s.$$

Medium effect. Adsorption of *N*-methylformamide (NMF) at the Hg electrode from H_2O + NMF + NaCl solutions

D. KOŹMIŃSKA, Z. BORKOWSKA, AND B. BEHR

Institute of Physical Chemistry, Polish Academy of Sciences, Kasprzeka 44/52, 01-224-Warszawa, Poland

Received July 24, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

D. KOŹMIŃSKA, Z. BORKOWSKA, and B. BEHR. Can. J. Chem. **59**, 2043 (1981).

The adsorption of NMF from H_2O + NMF + NaCl solutions has been studied in two series of experiments, one in which μ_{NaCl} was kept constant over the whole H_2O + NMF composition range and another in which constant concentration of NaCl was maintained. The results are compared and the medium effect discussed.

D. KOŹMIŃSKA, Z. BORKOWSKA et B. BEHR. Can. J. Chem. **59**, 2043 (1981).

On a étudié l'adsorption du NMF à partir de solutions de H_2O + NMF + NaCl dans deux séries d'expériences; dans l'une μ_{NaCl} est maintenu constant sur toute l'étendue de composition en H_2O + NMF alors que dans l'autre on a maintenu la concentration en NaCl constante. On compare les résultats et on discute de l'effet du milieu.

[Traduit par le journal]

Introduction

N-Methylformamide (NMF) is one of the hydrogen bonded solvents with high dielectric constant equal to 182. As a highly structured liquid and good solvent for electrolytes it is of wide interest. This solvent has unusual surface properties, e.g., a broad "hump" on the double layer capacity curve at the negatively charged mercury electrode (1). This hump has been attributed to the reorientation of the solvent dipoles by the electrical field in the inner layer. According to simple models of the solvent dipoles at electrified interfaces this implies a pronounced preferential orientation with the negative end of the dipole towards the electrode at the potential of zero charge (pzc) (2–4). Considerable data concerning the double layer in NMF solutions exist, especially concerning the adsorption of anions (5–7).

The adsorption of NMF from aqueous solutions up to 6.59 *M* was studied by Payne (8) who concluded that at the pzc specific orientation with the negative end of the dipole towards the electrode is negligible. This does not allow one to draw conclusions concerning the double layer structure in pure NMF. More information could be obtained by studying the adsorption of NMF from its mixtures with water over the whole concentration range of both solvents.

According to the electrocapillary equation [1], a strictly thermodynamic study of the adsorption from mixed solvents demands constant chemical potential of an electrolyte in solutions of varying chemical potential of the solvent (9–15). At constant T and p

$$[1] \quad -d\gamma = \sigma_M dE_{\pm} + \Gamma_{2(1)} d\mu_2 + \Gamma_{\mp} d\mu_{salt}$$

and

$$[2] \quad \Gamma_{2(1)} = -(\partial\gamma/\partial\mu_2)_{E_{\pm},\mu_{salt}} = -(\partial\xi/\partial\mu_2)_{\sigma_M,\mu_{salt}}$$

where γ is the surface tension, σ_M is the charge density on the metal, $E_{\pm}$ is the potential of the electrode with respect to the reference electrode reversible towards cations or anions of the salt, $\Gamma_{2(1)}$ is the relative surface excess of solvent 2 with respect to solvent 1, $\Gamma_{\mp}$ is the relative surface excess of anion or cation with respect to solvent 1, μ is the chemical potential, and $\xi = \gamma + \sigma_M E$.

Unfortunately, thermodynamic data for electrolyte solutions in mixed solvents are scarce. Therefore many authors use a constant concentration of the electrolyte and a constant potential reference electrode with liquid junction. This procedure, called by Battisti and Trasatti (12) "customary", introduces two sources of errors:

(*i*) $\mp(\partial\mu_{salt}/\partial\mu_2)_{c_{salt}}$ (see refs. 12 and 13)

(*ii*) $(\sigma_M/F)(\partial\mu_{\pm}/\partial\mu_2)_{c_{salt}}$

where (*i*), which is due to the change of the chemical potential of the electrolyte with the mixed solvent composition, the so-called medium effect, can be determined by independent thermodynamic measurements, but where (*ii*), which is due to the change of the potential of the reference electrode reversible to cation or anion with the mixed solvent composition, cannot be determined.

Although it is obvious that one should use the strictly thermodynamic procedure it seemed to us interesting to compare the former results with those obtained with the "customary" one. Such a comparison was made by Trasatti (12) and Mohilner and Nakadorami (11) for the adsorption of

organic substances within a limited range of concentrations. The aim of the present work was to study the adsorption of NMF from H_2O + NMF + NaCl solutions over the whole composition range of H_2O + NMF at constant chemical potential or at constant concentration of NaCl. This electrolyte has been chosen, because its solubility in both water and NMF is good and also because it is comparatively easy to determine the chemical potential of NaCl in the solvent mixtures under study from emf measurements (14).

Experimental

Reagents

NMF (Flukà or Merck-Schuchardt) was dried over 4 Å molecular sieves and purified by twofold distillation under nitrogen at low pressure. In the final product gas chromatography showed ca. 0.02% impurities other than water and ca. 0.01% water.

Analytical grade NaCl was purified by crystallization from triply distilled water and dried at 150°C. The purity of aqueous solutions of NaCl in triply distilled water was checked for electroactive impurities by dc polarography and for surface active impurities by ac polarography. The solutions were deaerated by the flow of hydrogen presaturated with the investigated solution.

Apparatus and Technique of Measurement

The chemical potentials and activity coefficients of NaCl were determined from the electromotive force (emf) of the following reversible cell:

[I] $\mathrm{Ag|AgCl|}x\mathrm{NMF} + (1-x)\mathrm{H_2O} + y\ M\ \mathrm{NaCl}\ \mathrm{Na^+|glass\ electrode}$

where x is the mole fraction of NMF and y is the molarity of NaCl ($10^{-3} \leq y \leq 10^{-1}$).

The emf was measured with a Radiometer PHM 4p pH meter. Sodium glass electrodes were produced by the M.Curie-Skłodowska University in Lublin (16). Silver chloride electrodes were prepared as described in the literature (17) and were stable in solutions up to ca. 0.41 mole fraction NMF (70 vol.%). In NMF solutions slow decomposition of the electrodes was observed due to the dissolution of the AgCl deposit (18). However, reproducible results were obtained using freshly prepared electrodes kept in contact with NMF not longer than 30 min. The performance of the electrodes was checked by measuring the emf of the cell given above with the saturated NaCl solutions in all solvent mixtures. The results were satisfactory, the emf values being constant within 1 mV. The equilibrium emf values were reached after ca. 3 or 15 min, in dilute or concentrated NMF solutions respectively.

The double layer capacity was measured with an ac Schering-type impedance bridge at 220 Hz using a thin walled glass capillary according to Randles (19) for the dropping mercury electrode and a Pt cylinder as auxilary elecrode. Two series of solutions were studied, the first at constant chemical potential of NaCl, fulfilling the thermodynamic requirements. The potentials should be referred to an electrode reversible towards Na^+ or Cl^- without liquid junction. As the Ag|AgCl electrodes were not very stable during the time-consuming impedance measurements, the potentials were fixed with respect to a mercury pool which should act as a calomel electrode under these circumstances.

However, the mercury pool electrode did not fulfil the thermodynamic conditions (the test of constant emf, independent of solvent composition, in saturated NaCl solutions). Therefore the potentials were recalculated using the data from a separate experiment and the potential scale referred to a Ag|AgCl electrode was found. The second series of solutions was with 0.1 M NaCl in all H_2O + NMF mixtures. In this case the aqueous 0.1 M NaCl calomel electrode was used as reference.

The capacity was independent of frequency in the range 100–500 Hz. The reliability of the results was additionally checked by replacing the cell with an equivalent circuit of the same impedance as that found from measurements. At higher frequencies or with thick walled capillaries the values measured in the solutions with $x_{NMF} > 0.41$ and $c_{NaCl} < 5 \times 10^{-2}$ were erroneous.

Zero charge potentials (pzc) and the maximum surface tensions γ_{max} were measured using a streaming mercury electrode (8) and a capillary electrometer respectively. Electrocapillary measurements were carried out by the maximum bubble pressure method (20), using "pipe type" thin walled capillaries, with an accuracy of ± 0.2 mN m^{-1}. The electrometer was calibrated with aqueous 0.05 M Na_2SO_4 solution using the value 426.2 $\pm$ 0.2 mN m^{-1} as γ_{max} at 25°C (21). Charge density and surface tension versus potential curves were calculated by numerical integration of the double layer capacities using the pzc and γ_{max} as integration constants. The interfacial tension at the free surface of H_2O + NMF solutions was measured by the maximum bubble pressure method. All measurements were carried out at 25 $\pm$ 0.2°C.

Results and Discussion

Thermodynamic Properties of NaCl + NMF + H_2O Solutions

Activity coefficients and some other thermodynamic data for NaCl solutions in NMF are reported in the literature (22, 23); however, no data are available for H_2O + NMF mixtures.

The chemical potentials of NaCl in H_2O + NMF mixtures were determined by means of cell [I]. The results of the emf measurements are presented in Fig. 1. The concentrations of NaCl which correspond to the constant emf of cell [I] (dashed line in Fig. 1) are those at which the chemical potential of NaCl is constant and equal to μ_{NaCl} in 0.1 M aqueous solution.

The free enthalpies of transfer of NaCl from 0.1 M aqueous solution to a given mixed solvent ${}^{s}_{w}\Delta\mu_{NaCl}$ are shown in Fig. 2 (full curve). The maximum value of ${}^{NMF}_{w}\Delta\mu_{NaCl}$ equal to 2.95 kcal mol^{-1} is in good agreement with that given by Povarov *et al.* (23). According to Trasatti, it is possible to neglect $\pm d\mu_{salt}$ if $\Delta\mu_{salt}$ is smaller than 1 kcal mol^{-1} for charge densities $-5 < \sigma < 5$ μC cm^{-2}. In H_2O + NMF + NaCl solutions this condition is met for $x_{NMF} < 0.2$ (45 vol.%). Therefore the results obtained by Payne (8), who investigated the adsorption of NMF from aqueous 0.1 M NaF solutions up to 30 vol.% are correct within the limited range of charge density in spite of the "customary" procedure used.

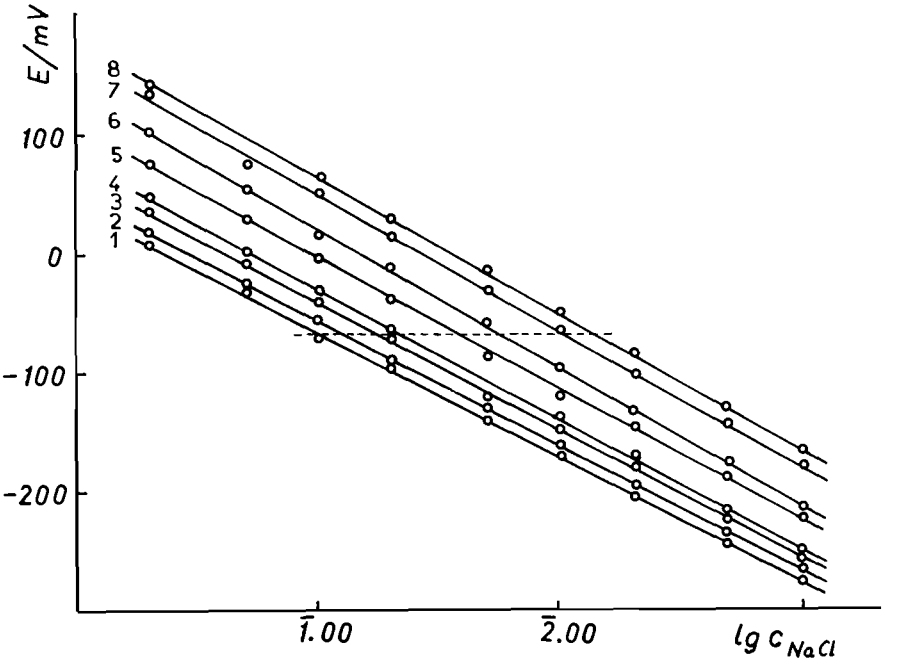

FIG. 1. The electromotive force E of the cell with NaCl solution in the mixed solvent: Ag|AgCl|xNMF + $(1 - x)H_2O$ + y M NaCl|Na^+ glass electrode, as a function of NaCl concentration: x, the mole fraction of NMF, is equal to: (1) 0; (2) 0.03(10); (3) 0.068(20); (4) 0.115(30); (5) 0.235(50); (6) 0.415(70); (7) 0.735(90); (8) 1.0 (the vol.% is given in parentheses). The dotted line indicates the concentrations of NaCl to be chosen at various x_{NMF} in order to prepare the solutions of chemical potential of NaCl equal to that of 0.1 M NaCl in aqueous solution.

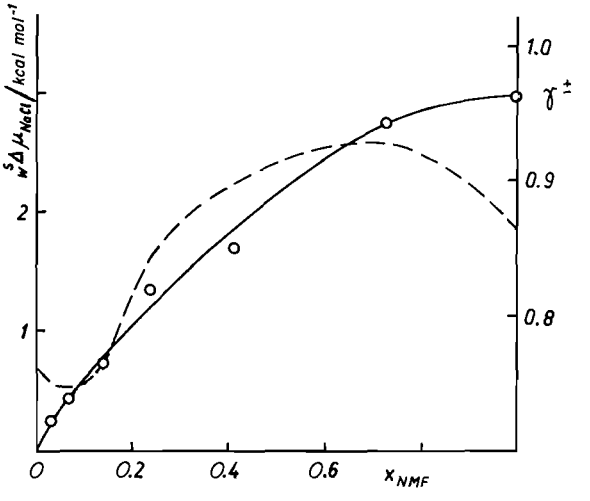

FIG. 2. The change of chemical potential of NaCl on transfer from 0.1 M solution in H_2O to 0.1 M solution in the mixed solvent xNMF + $(1 - x)H_2O$ (full curve) and of the activity coefficient of 0.1 M NaCl in these mixtures (dotted curve) as a function of mole fraction of NMF.

The activity coefficients for 0.1 M NaCl in investigated solutions are given in Fig. 2 (dotted curve). The $f_\pm$ values for aqueous and NMF solutions are in good agreement with the literature (22, 23). Up to $x_{NMF} = 0.165$ (40 vol.%) $f_\pm$ is practically equal to that in aqueous solution within the experimental error ± 0.02. It increases with increasing concentration of NMF, reaching the maximal value at ca. 0.7 mole fraction NMF (85 vol.%). This maximum on the $f_\pm$ versus x_{NMF} relationship may be related to the reinforcement or destruction of the solvent structure depending on the ratio of NMF to H_2O which was found by nmr measurements in H_2O + NMF solutions (24). Also, the viscosity and density of H_2O + NMF mixtures go through maxima at intermediate concentrations of NMF (Fig. 3). Activity coefficients for H_2O and NMF in solvent mixtures used here were estimated from the isobaric data given in the literature (25, 26). The activities of H_2O and NMF as a function of mole fraction of NMF are presented in Fig. 4.

Taking into account the approximations involved in the calculation procedure (30), the shape of the activity vs. mole fraction curves have no quantitative meaning. However, one may conclude that the deviation from ideal behaviour in this system, indicated by diagonal lines in Fig. 4, is small and positive.

Double Layer Measurements

The double layer capacity, charge density, and surface tension curves for the NMF + H_2O +

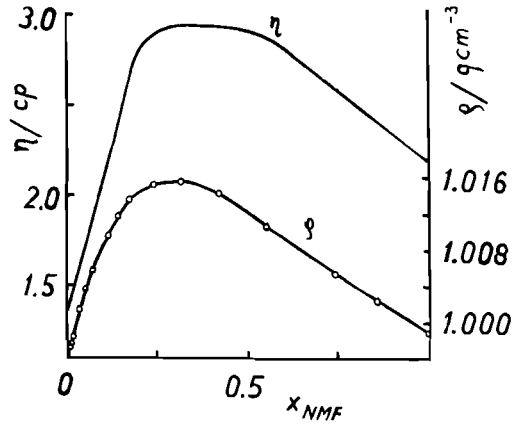

FIG. 3. The viscosity η (29) and density ρ of H_2O + NMF mixtures as a function of the mole fraction of NMF.

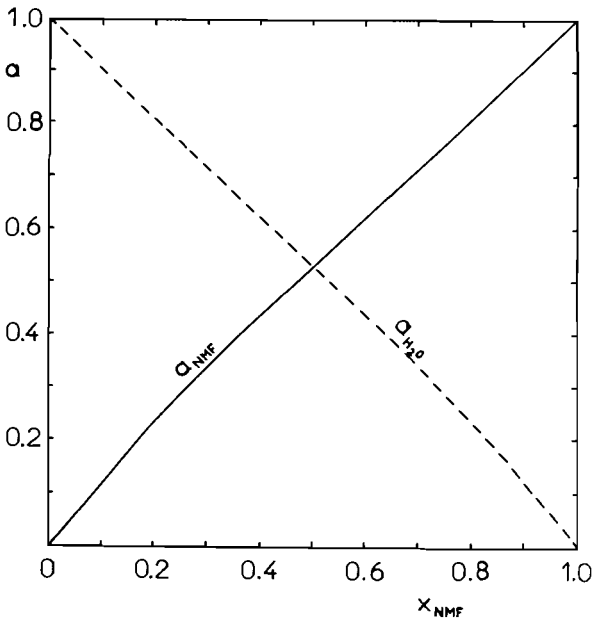

FIG.4. The activities of NMF and of H_2O in their mixtures as a function of the mole fraction of NMF.

NaCl|Hg interface are presented in Fig. 5. Series (*a*) corresponds to the solutions with constant chemical potential of NaCl equal to that of 0.1 *M* aqueous solution. The potential scale is referred to a Ag|AgCl electrode in the working solution. Series (*b*) corresponds to solutions of constant concentration of NaCl equal to 0.1 *M* and in this case the potential scale is referred to aqueous Ag|AgCl in 0.1 *M* NaCl.

The coordinates of the electrocapillary maximum and of the capacity hump are given in Tables 1 and 2.

The double layer capacity curve for 0.1 *M* NaCl solution in NMF is in good agreement with that given by Damaskin and Ivanova (5). The results obtained in both series (*a*) and (*b*) are similar up to ca. 0.165 mole fraction NMF (40 vol.%), which was to be expected according to the thermodynamic measurements. The hump is clearly visible on the double layer capacity curves measured in the solutions containing 20 or more vol.% NMF ($x \geq 0.068$) as was stated previously in the literature (1, 5). The hump becomes more pronounced with increasing NMF concentrations, but its potential is almost constant.

Charge–potential curves shown in the enlarged scale for NMF concentrations of 0–20 vol.% exhibit features typical for the adsorption of organic compounds. The potential of zero charge shifts towards more positive values as compared with aqueous solutions, and the parameters of the intersection point are 0.6 or 0.62 V and 0.025 or 0.027 C m^{-2} for the series μ_{NaCl} = const. and c_{NaCl} = const., respectively. This point corresponds to the maximum adsorption of NMF if Γ_{NMF} is plotted vs. charge or potential. At higher concentrations the charge–potential curves are no longer typical. At negative electrode charge they are almost parallel, or even overlap within a wide range and the potential of maximum adsorption can hardly be found, although it is rather certain that maximum adsorption for concentrated solutions occurs at more negative potentials (see Fig. 6). At these concentrations the electrocapillary curves obtained by integration are displaced, though still parallel, with increasing NMF concentration.

The charge density – potential curves for aqueous and 100% NMF solutions almost overlap from −0.9 to −1.3 V. This can be interpreted in terms of a simple model of the inner layer in both cases with a similar ratio of ε/d, i.e., of the dielectric permittivity to the distance of the Helmholtz plane from the electrode. It is possible that in NMF solutions the distance d is higher than in water, but that ε is also higher. In the case of less polar organic solvents the double layer capacity is as a rule much lower and has a minimum at the potentials at which in NMF solutions the hump is formed.

The comparison of both series μ_{NaCl} = const. and c_{NaCl} = const. shows that distinct differences are observed only at positively charged electrodes. The double layer capacity and charge density are much lower for solutions of high NMF content in the case of μ_{NaCl} = const. This fact can be explained when one considers the specific adsorption of chloride ions. In the μ_{NaCl} = const. series the solutions contain NaCl in lower concentrations (cf. Table 1) and therefore the adsorption of Cl^- is smaller.

It is not possible to compare the shift of zero

charge potential in both series because of the noncomparable potential scales, although it seems that the more negative value of the pzc in the c_{NaCl} = const. series is in accord with specific adsorption of chloride ions. Otherwise the similarity of both series is rather striking; the subtle differences can be found only with the double layer capacity measurements in the solutions containing more than 20% NMF.

One could conclude that in the particular case of the H_2O + NMF mixture, where both components are highly structured liquids of high dielectric permittivity, the "customary" procedure can be applied in the whole composition range, although the adsorption of Cl^- ions should be taken into account.

Relative Surface Excess of NMF

The surface tension data in the series μ_{NaCl} = const. were used to calculate the adsorption isotherms.

The relative surface excess of NMF, $\Gamma_{2(1)}$, is given by [2] which can be rearranged as follows:

$$[3] \quad \Gamma_{2(1)} = \frac{1}{2.3RT}\left(\frac{\partial \xi}{\partial \log a_2}\right)_{\mu_{NaCl},\sigma_M} = \frac{1}{2.3RT}\left(\frac{\partial \xi}{\partial \log x_2}\right)_{c_{NaCl},\sigma_M} \frac{\log x_2}{\log a_2}$$

where subscript 2 refers to NMF and subscript 1 refers to water.

The factor $\partial \log x_2/\partial \log a_2$ accounts for non-

ideality of NMF + H_2O mixtures. Depending on the detailed shape of the a vs x relationship (Fig. 4) this factor could become quite significant at ca. 0.3 mole fraction of NMF. However, as has been pointed out earlier, all one can tell from Fig. 4 is that the deviation from ideality is small. Therefore we felt justified in assuming that $f_{NMF} = f_{H_2O} = 1$ and $a_{NMF} = x_{NMF}$ over the whole concentration range of H_2O + NMF mixtures.

Relative surface excesses of NMF found by differentiation from the ξ vs. log x relationship are presented in Fig. 6 as a function of charge at constant x_{NMF}, and in Fig. 7 as a function of x_{NMF} at constant charge.

It can be seen in Fig. 7 that the adsorption isotherms reach a plateau at $x_{NMF} = 0.5$ or earlier, but the values of the maximum relative excesses are different at various charge densities. This plateau has no physical meaning since at high NMF concentrations relative surface excesses $\Gamma_{2(1)}$ may differ considerably from surface concentrations, Γ_2. Also, the approximation made concerning solvent activities could distort the adsorption isotherm at the concentrations corresponding to plateau.

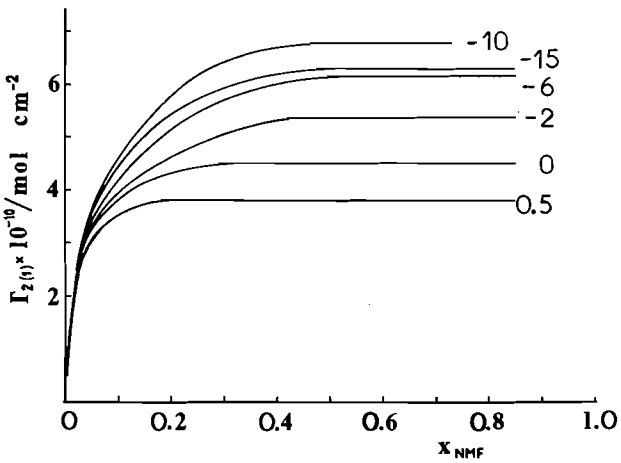

FIG. 7. The relative surface excess of NMF, Γ, at a Hg electrode in NaCl solutions of const. μ in xNMF + $(1-x)H_2O$ as a function of mole fraction of NMF at various charge densities indicated in the figure (σ in C m^{-2} × 100).

The highest value of $\Gamma_{2(1)}$ is reached at $\sigma = -0.1$ cm^{-2}. This can be seen also in Fig. 6, which also shows that the strongest adsorption at low NMF concentrations occurs at a different charge $\sigma = -0.025$ cm^{-2}. This change of the character of adsorption with increasing NMF concentration is accompanied by the development of the hump on the double layer capacity curves.

The $\Gamma_{2(1)}$ values in Fig. 6 can be compared with those given by Payne (8). These data were transformed from units of molecule cm^{-2} to mol cm^{-2}, and the concentrations of NMF from mol L^{-1} to mole fractions or vol.%. After doing so the surface excesses at low concentrations of NMF (< 10 vol.%) were in good agreement with our values.

At higher NMF concentrations there were discrepancies. There are differences in both the values and in the shape of the curves. The values of Payne for $\sigma = 0$ are higher than ours, which can be explained by the different concentration scale used. The derivative in [3] can be expressed using a different concentration scale as follows:

$$[4]\quad 2.3RT\Gamma_{2(1)} = \frac{\partial \xi}{\partial \log x} = \frac{\partial \xi}{\partial \log x}\frac{\partial \log c}{\partial \log x} = 2.3RT\Gamma_{\text{Payne}}\frac{\partial \log c}{\partial \log x}$$

As long as c is proportional to x the concentration scale used has no influence on the results. However, above 10 vol.% the relationship between c and x is no longer linear and $\partial \log c/\partial \log x < 1$. Thus, the value of Payne must be reduced to get the thermodynamic value $\Gamma_{2(1)}$, and the more so, the higher is the concentration.

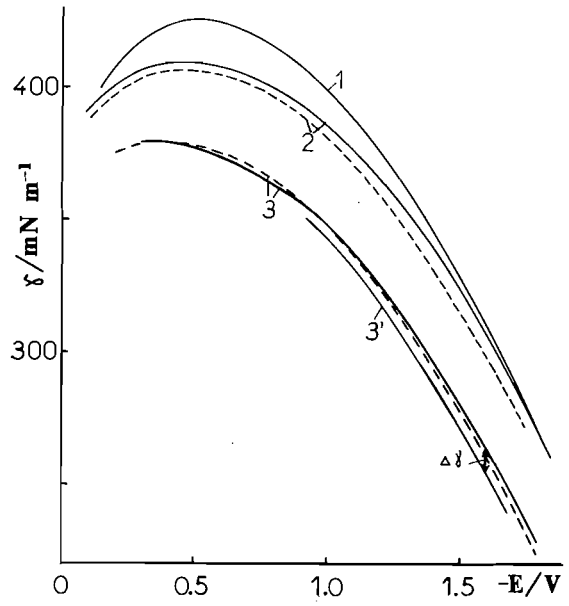

FIG. 8. The comparison of the surface tension of Hg vs. potential curves from series (*a*) (μ_{NaCl} = const., potential referred to Ag|AgCl electrode without liquid junction, full lines) with those from series (*b*) (c_{NaCl} = const., potential referred to aq. Ag|AgCl electrode in 0.1 *M* NaCl, dotted lines): x_{NMF} is equal to: (1) 0; (2) 0.068(20); (3) 1.0(100); (the vol.% is given in parentheses). The section of the curve 3′ shows how the change of potential scale $E^{\pm}$ corresponding to the change of NaCl concentration from 0.01 to 0.1 *M* would affect the γ value used for calculation of $RT\Gamma = (\partial\gamma/\partial \ln x)_{E^{\pm}}$.

The shapes of the curves different from ours can be explained by the different potential scale used. The problem of the potential scales is demonstrated in Fig. 8. Dotted curves from the c_{NaCl} = const. series are compared with those from the μ_{NaCl} = const. series. It can be seen that a small shift along the potential scale would result in an overlap of the cathodic branches, or, to the contrary, in increased differences of γ at constant potential. These changes would affect the calculated surface excess more as the γ–*E* curve becomes steeper because: $\Delta\gamma = (\partial\gamma/\partial E)\Delta E = q_M\Delta E$. The contribution of this uncertainty of potential scale, ΔE, can be quite significant at a highly charged electrode. If it is assumed that the shape of the cathodic branch of the electrocapillary curve in NMF does not depend on the NaCl concentration, one should expect that the change of NaCl concentration from 0.1 to 0.01 *M* should produce a shift of the cathodic branch of the electrocapillary curve by 60 mV if the Ag|AgCl electrode in the working solution were used as reference, which would give at 0.17 C cm^{-2} a difference of ca. 10 mN m^{-1}. The part of the curve, as measured in 0.1 NaCl, instead of the required 0.01 *M* NaCl vs. Ag|AgCl in the same solution, is shown in Fig. 8, curve 3′.

Thus, the "customary" procedure if the electrode without liquid junction were used would lead to too high surface excesses.

Generally one should keep in mind that the medium effect producing the change in chemical potential of the salt $\Delta\mu$ will result in a shift of the potential scale $\Delta E = \Delta\mu/nF$, and this can be quite large.

If, therefore, the proper concentrations of the salt cannot be used, e.g., because of the lack of information regarding μ, it is probably better to use a constant potential electrode, with liquid junction, as can be noted from the comparison of series (*a*) and (*b*) in Figs. 5 and 8.

The Composition of the Surface Phase

To calculate the composition of the heterogeneous region at the electrode surface the quasi-thermodynamic model of Randles and co-workers (27, 28) has been adopted. The surface layer is regarded as a surface phase of thickness τ and of determined thermodynamic properties related to those of the bulk of the solution at the same composition. Another assumption is that the molecules occupy constant areas, $A_1 = V_1/N\tau$ and $A_2 = V_2/N\tau$, where V_1 and V_2 are partial molar volumes assumed to be equal to the molar volumes of the pure components and *N* is Avogadro's number.

The adsorption isotherm has the following form:

$$[5]\quad \frac{a_2^s}{(a_1^s)^r} = \frac{a_2}{(a_1)^r}\exp\left[\frac{-V_2(\gamma_2 - \gamma_1)}{\tau RT}\right]$$

a_1^s and a_2^s are the activities in the surface phase averaged over the thickness τ, and γ_1 and γ_2 are the surface tension of the pure components water and NMF respectively.

The isotherm involves two adjustable parameters: one is the thickness τ; the other relates the activity coefficients in the surface phase to those in the bulk phase. In view of the approximation $a = x$ adopted in this work for H_2O + NMF solutions in the bulk phase, the same is assumed for the surface phase and only one parameter is needed.

In Fig. 9 the experimental γ values for Hg at the pzc and for the free surface are given, and the theoretical curves composed of two sections are indicated. It was impossible to fit the experimental data with the use of one value of τ in the whole composition range. The two segments correspond to τ = 4.6 Å at low NMF concentrations and τ = 5.36 Å at higher concentrations. If the change in τ has a physical meaning, it should support the view that

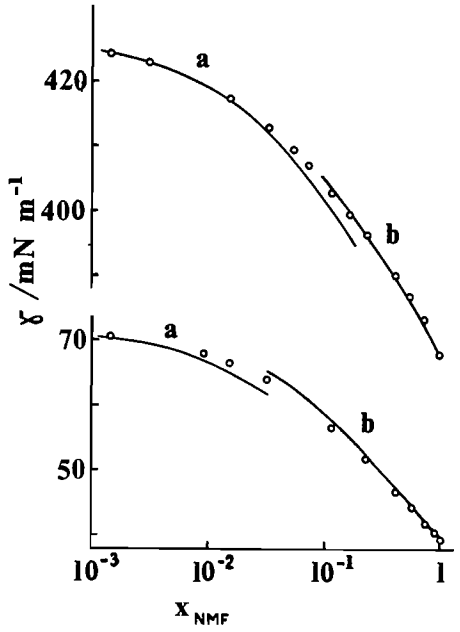

FIG. 9. The relationship between the surface tension of a Hg electrode at pzc in H_2O + NMF + NaCl (μ_{NaCl} = const.) (upper curve) or of the free surface of corresponding solutions (lower curve) and mole fraction of NMF. Points: experimental values; lines: the calculated values using the model of Randles and Behr (27) with $\tau = 4.6$ Å (section *a*) and $\tau = 5.36$ Å (section *b*); $a_{NMF} = x_{NMF}$; $a_{H_2O} = x_{H_2O}$.

the orientation of NMF at low bulk concentration when it behaves like a typical aliphatic solvent is different from that at higher concentrations. The thicker layer at higher concentrations should indicate an orientation at the surface close to perpendicular. The postulated change of τ is certainly not a result of the approximation $a_{NMF} = x_{NMF}$, because up to $x_{NMF} = 0.1$ the system obeys Henry's law (Fig. 4) and therefore the value of the activity coefficient does not affect the calculated γ values since $\partial\gamma/\partial \log a = \partial\gamma/\partial \log x$. The reorientation of NMF molecules at the Hg electrode as a function of the electrical variable σ or E was postulated in the literature (1) in order to explain the hump on the double layer capacity curve. The reorientation with increasing bulk concentration and with the electrical potential or charge are related to each other; thus our hypothesis is compatible with the general picture of NMF adsorption.

The surface concentrations of water and NMF, Γ_1 and Γ_2 respectively, were calculated from the experimentally found surface excess $\Gamma_{2(1)}$ (Fig. 7) using two equations: $\Gamma_{2(1)} = \Gamma_2 - \Gamma_1 x_2/x_1$, which is the definition of the relative surface excess, and $V_1\Gamma_1 + V_2\Gamma_2 = \tau$ which is related to the model. τ was equal to 5.36 Å for $x_{NMF}^s \geq 0.1$ and 4.6 Å for $x_{NMF}^s < 0.1$, as found from the γ vs. $\log x$ fit (Fig. 9). Surface concentrations of NMF, Γ_2 at constant electrode charge are presented in Fig. 10. Γ_2 increases continuously with the concentration of NMF in the bulk. In contrast to the $\Gamma_{2(1)}$ vs. x_{NMF} relationships (Fig. 7), a plateau is formed. However, as has been stated before, maximum adsorption from concentrated NMF solutions is observed at -0.1 C m^{-2}.

The composition of the solvent in the surface phase at uncharged Hg and at the free surface are compared in Fig. 11. The adsorption at both interfaces is similar but slightly stronger at the mercury–solution interface.

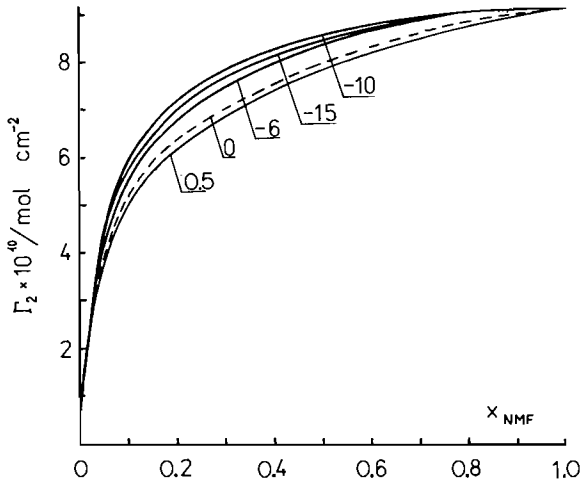

FIG. 10. The surface concentration of NMF, Γ_2, as function of mole fraction of NMF in the bulk solution, x_{NMF}, at various charge densities as indicated in the figure (σ in C m^{-1} × 100). Γ_2 calculated from the data in Fig. 7 using the surface phase model.

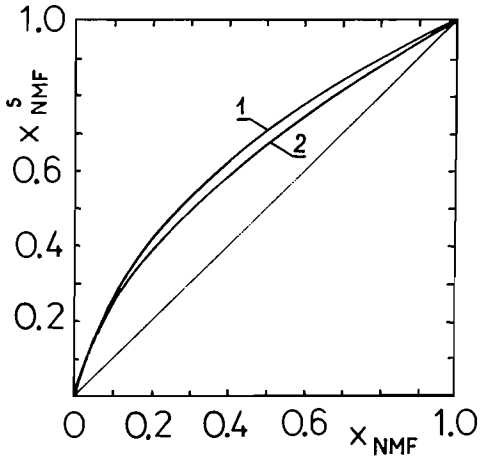

FIG. 11. Adsorption isotherms of NMF, $x_2^s = f(x_{NMF})$ at $Hg_{\sigma=0}$: (1) at the free surface and (2) according to the surface phase model.

According to [5], free enthalpies of adsorption are defined as follows:

$$[6] \quad -\Delta G_{ads} = (V_2/\tau)(\gamma_2 - \gamma_1)$$

The calculation with τ equal to 4.6 Å or 5.36 Å gives ΔG_{ads} equal to 1.4 or 1.22 kcal mol^{-1} for the Hg–solution interface and 1.03 or 0.88 kcal mol^{-1} for the air–solution interface. The higher ΔG_{ads} for uncharged mercury as compared with the free surface is in accordance with the lowering of the surface tension by NMF at both surfaces (45 mN m^{-1} and 32.5 mN m^{-1}) respectively. The adsorption energy at uncharged Hg is slightly higher than that for methanol and lower than that for acetone.

Conclusions

Adsorption of NMF from H_2O + NMF + NaCl solutions can be considered in two concentration regions. From dilute NMF solutions $c \leq 20$ vol.%, the adsorption of NMF is similar to that of other aliphatic solvents with the maximum at ca. 0.02 C m^{-2}. In this concentration range, no NMF hump is visible on the capacity curves. For more concentrated NMF solutions, maximum adsorption occurs at ca. -0.1 C m^{-2}, which is close to the NMF hump on the capacity curves.

The thickness of the adsorbed layer at uncharged Hg increases with increasing NMF concentration which may be caused by reorientation of the dipoles.

Comparison of the results obtained when strictly thermodynamic and "customary" procedures have been used shows that the "customary" procedure is satisfactory over the whole concentration range of NMF + H_2O mixtures. However, at higher NMF concentrations the adsorption of Cl^- ions must be taken into account.

Acknowledgements

We should like to thank Dr. T. Kubala from Jagiellonian University in Kraków for performing the measurements of surface tensions at the H_2O + NMF–air interface.

We are greatly indebted to Dr. St. Malanowski from the Institute of Physical Chemistry, Polish Academy of Sciences, for evaluating the activity coefficients of H_2O and NMF in their mixtures at 25°C from the isobaric literature data.

This work has been performed as a part of research project 03.10 and was also partly financed by research project MR I-11.

The surface phase at the ideal polarized mercury electrode. IV. Determination of molar entropies of adsorption of specifically adsorbed halide ions

M. H. CHARLES, M. MULENGA, A. JENARD, AND H. D. HURWITZ[1]

Faculty of Sciences, Université Libre de Bruxelles, C.P. 160, 50, av. F. D. Roosevelt, 1050 Brussels, Belgium

Received September 29, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

M. H. CHARLES, M. MULENGA, A. JENARD, and H. D. HURWITZ. Can. J. Chem. **59**, 2053 (1981).

Differential capacitances are measured as a function of temperature at the ideal polarized Hg electrode in systems of mixed sodium halides at ionic strength $J = 10^{-1}$ mol kg^{-1}. A quasi-thermodynamic treatment is presented according to which excess entropies of adsorption in the inner layer are determined. The formation entropy of the inner layer and the water and ion molar entropies of adsorption are presented for a range of moderate and small ionic surface coverages.

M. H. CHARLES, M. MULENGA, A. JENARD et H. D. HURWITZ. Can. J. Chem. **59**, 2053 (1981).

Utilisant des systèmes mixtes d'halogénures de sodium de force ionique $J = 10^{-1}$ mol kg^{-1}, on a mesuré, en fonction de la température, les capacités différentielles au niveau d'une électrode à Hg polarisée idéale. On présente un traitement quasi-thermodynamique selon lequel on détermine les entropies d'adsorption en excès de la couche interne. On rapporte l'entropie de formation de la couche interne et les entropies molaires d'adsorption de l'eau et de l'ion pour un certain nombre de surfaces ioniques moyennes et petites.

[Traduit par le journal]

I. Introduction

The problem of ionic specific adsorption at the electrode surface remains a crucial and largely unsettled subject of electrochemistry. Many theoretical attempts have been made in order to describe the adsorption process of inorganic anions. The Stern–Grahame–Devanathan theory of the electrochemical double layer was modified by introducing the so-called discreteness of charge effect. This concept was invoked initially by Esin and Markov (1). Later on it was developed within a model of ions distributed on the surface at the lattice points of an hexagonal array (2–5). One of the merits of Levine's work (6, 7) was to reconsider totally this approach and to propose a different expression of the discreteness-of-charge effect essentially in terms of cavity potential in the inner layer and self atmosphere potential in the inner and diffuse layer. In that way, his model led to a consistent statistical mechanical calculation of the free energy of adsorption, making allowance for the thermal motion of the adsorbed species and for the redistribution of the adsorbed particles upon adsorption of one ion. Further decisive improvements of the theory of ionic specific adsorption were, however, particularly impaired by our lack of knowledge of the role of the adsorbed solvent at the electrode. Accordingly, it was recognized for a few years that electrocapillary measurements as a function of temperature and pressure (8) might yield some fundamental thermodynamic criteria, with respect to the behaviour of the solvent, for defining new models of ionic specific adsorption. Nowadays, several electrocapillary studies of temperature effects at the ideal polarized Hg – aqueous electrolyte solution interface have already led to the evaluation of thermodynamic or quasi-thermodynamic quantities like the surface excess entropy (8), the interphase or inner layer entropy of formation (9–11), and the partial molar adsorption entropy of the solvent (12, 13).

In presence of fluoride anions, which are considered to be unspecifically adsorbed at 25°C, the thermodynamic data have provided some important characterization of the water adsorption at the electrode surface. Hills and Payne (8) gave particular consideration to the systematic use of temperature and pressure coefficients of the surface tension in the investigation of the water in the inner layer. Combining the thermodynamic deduction with previous assertion based on dielectric models of the interface, they envisioned a model of water adsorption based on the competitive influence of the changes of the inner layer ionic concentration and of the changes of the dielectric permittivity of the adsorbed water molecules. Later on, careful thermodynamic investigations as a function of temperature were carried out by Harrison *et al.* (9), Nguyen Huu *et al.* (12), and Hills and Hsieh (11). These measurements have contributed to bring out the following features pertaining to the water monolayer adsorbed at the Hg electrode: (*a*) there exists a maximum of entropy of adsorption of water at about -4×10^{-2} C m^{-2}; (*b*) the water molecules

are preferentially adsorbed at the p.z.c. with their negative poles pointing to the electrode; (*c*) even at the maximum of entropy of adsorption, the configuration of adsorbed water is slightly more ordered than that of bulk water; (*d*) the density of water dipoles in the inner monolayer changes only slightly within the experimental range of the electrode charge densities. Consequently, the orientational changes of the adsorbed water dipoles determine essentially the physical properties of the inner layer.

Temperature coefficients of surface tension were also determined in presence of specifically adsorbed anions. Attempts to relate these data to molecular models of the interface were largely frustrated by the inadequacies of the quasi-thermodynamic treatments used so far for the system of ionic surfactant and water co-adsorption. For example, the approaches used failed to present the relevant thermodynamic quantities like the inner layer entropy of formation in terms of the composition of the interphase. Furthermore, the formulation adopted for the derived surface excess entropies (8, 14) made it difficult to distinguish between the contributions of the various species involved in the adsorption process, namely the anion and water in the inner layer and the electrolyte in the diffuse layer. Accordingly, in presence of ionic specific adsorption, the numerous attempts to correlate the measurements involving the variable temperature with microscopic properties of the interface were rather contradictory. Hills and Payne (8) and Hills and Hsieh (11) concluded that the change of surface excess entropy is essentially dominated by the adsorption of water. The increase of this entropy in presence of Cl^-, NO_3^-, and SO_4^{2-} ions is therefore associated with the number of water molecules released from the inner layer by the adsorption of each ion. The observation of a decrease of the inner layer entropy of formation in presence of PF_6^-, NO_3^-, Cl^-, I^- led Harrison *et al.* (9) to the opposite suggestion. They assumed that the adsorption of the anion and its effect on the solvent is the overriding factor.

We endeavour in this paper to treat the system of halide specific adsorption by using a consistent quasi-thermodynamic frame-work. We expect to speculate, on this basis, about the microscopic properties of the inner monolayer. The first part of this work deals with the thermodynamic formulation.

II. Theoretical Derivation of Entropies of Adsorption

1. *General Thermodynamic Considerations*

The case corresponding to an isothermal electrochemical cell with an ideal polarized mercury electrode (in the absence of an amalgam) was treated previously (10) with respect to the condition of keeping at constant ionic strength a solution of a mixture of two symmetrical electrolytes with one common ion.

For clarity, in this article we are replacing A^{Z_a} by **A**, B^{Z_b} by **B**, and C^{Z_c} by **C**. For the electrolytes AB and AC with the common ion A^{Z_a} (**A**) at ionic strength $J = Z_a^2(m_{AB} + m_{AC}) = Z_a^2 m_{\mathbf{A}}$ where the m represents the molalities in the bulk phase β, the suggested treatment leads to write the Gibbs equation at constant pressure P and constant J in the following form:

$$[1] \quad (d\xi)_{J,P} = -[\Gamma_s^\sigma - q^\alpha E_T^{\beta,Hg}]\, dT - RT\Gamma_{i_C}\, d \ln m_{AC} + E\, d\, q^\alpha$$

The quantities ξ, Γ_s^σ, and Γ_{i_C} are taken as

$$[2] \quad \xi = \gamma + q^\alpha E$$

$$[3] \quad \Gamma_s^\sigma \equiv \frac{S^\sigma}{\Omega^\sigma} - \sum_{j^\alpha} \Gamma_{j^\alpha} \dot{s}_{j^\alpha}^{\alpha} - \sum_{j^\beta} \Gamma_{j^\beta} \dot{s}_{j^\beta}^{\beta} \qquad (j^\alpha = Hg^+, e^-;\ j^\beta = \mathbf{A}, \mathbf{B}, \mathbf{C}, w)$$

$$[4] \quad \Gamma_{i_C} \equiv \Gamma_C - \frac{m_{AC}}{m_{AB}} \Gamma_B$$

where γ, q^α, and E are respectively the surface tension, the charge density on Hg surface and the potential of mercury with respect to a constant reference electrode. The entropy of formation Γ_s^σ of the ideal polarized interphase of surface area Ω^σ is expressed as the difference between two entropies: the overall entropy of the surface phase S^σ and the entropy obtained as if the adsorbed components kept the same partial molar entropy at the surface as in their respective bulk phases (e.g. Hg^+ and electrons e^- in the metallic phase α and **A**, **B**, **C**, and the water w in the aqueous electrolyte solution β). These partial molar entropies in bulk phases α and β are respectively written as $\dot{s}_{j^\alpha}^{\alpha}$ and $\dot{s}_{j^\beta}^{\beta}$. The corresponding molar surface excesses of the species are indicated by Γ_{j^α} and Γ_{j^β}. By means of these quantities, the electroneutrality condition becomes:

$$[5] \quad q^\alpha = F \sum_{j^\alpha} \Gamma_{j^\alpha} Z_{j^\alpha} = -F \sum_{j^\beta} \Gamma_{j^\beta} Z_{j^\beta} \qquad (j^\alpha = Hg^+, e^-;\ \ j^\beta = \mathbf{A}, \mathbf{B}, \mathbf{C})$$

Let us stress that the validity of eq. [1] relies further on the assumptions that: (*1*) the values of the temperature coefficient of the KCl calomel electrode $E_T^{\beta,Hg}$ is correctly approached by means of experimental and quasi-thermodynamic determinations (15, 16). ($FE_T^{\beta,Hg} \equiv -\dot{s}_{Hg}^{\alpha} + \frac{1}{2}\dot{s}_{Hg_2Cl_2} - \dot{s}_{Cl^-}^{\beta} + \dot{s}_{e^-}^{Cu} = -0.581$ mV deg^{-1} at 25°C for 1 *M* KCl calomel electrode); (*2*) the temperature coefficients

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

of contact potentials ($\dot{s}_{e^-}{}^{\alpha} - \dot{s}_{e^-}{}^{Cu}$) in the circuit are negligible; (*3*) the changes of activity coefficients with salt concentration are very small in binary mixtures of strong electrolytes kept at constant ionic strength.

It is assumed that Γ_{i_C} represents the total amount of specifically adsorbed ions of species **C** per unit area. In connection with eq. [4], we have already pointed out that thereby the validity of the treatment is restricted to systems of electrolytes and to potential and temperature ranges chosen such as to let the ion **C** be the only ion of phase β involved in specific adsorption at the electrode (thus present in the inner Helmholtz layer). Consequently, the diffuse part of the double layer appears as the region of purely unspecific interactions with regard to the nature of ions B and C, which is consistent with the model of Gouy–Chapman. The ionic overall composition of the diffuse part of the double layer is therefore $N_{\mathbf{A}}{}^{\sigma}$, $N_{\mathbf{B}}{}^{\sigma}$, $N_{d_{\mathbf{C}}}{}^{\sigma} = (m_{AC}/m_{AB})N_{\mathbf{B}}{}^{\sigma}$.

Using simple mathematical analysis, we get from eq. [1]:

$$[6] \qquad \frac{1}{RT}\left(\frac{\partial \xi}{\partial \ln m_{AC}}\right)_{T,P,J,q^{\alpha}} = -\Gamma_{i_C}$$

$$[7] \qquad \left(\frac{\partial \xi}{\partial T}\right)_{P,J,q^{\alpha},m_{AC}} = -\left(\Gamma_s{}^{\sigma} - q^{\alpha}E_T{}^{\beta,Hg}\right)$$

$$[8] \qquad \left(\frac{\partial \xi}{\partial T}\right)_{P,J,q^{\alpha},\Gamma_{i_C}} = -\left[\Gamma_s{}^{\sigma} - \Gamma_{i_C}\left(\frac{\partial \Gamma_s{}^{\sigma}}{\partial \Gamma_{i_C}}\right)_{T,P,J,q^{\alpha}}\right] + q^{\alpha}E_T{}^{\beta,Hg}$$

2. Definition of the Surface Layer System

By carrying out some further thermodynamics on the system, we have to select two complementary conditions regarding the interphase. We have emphasized, in our previous work (10), that these conditions are completely conventional. Obviously, the values of the quantities so far defined, $\Gamma_s{}^{\sigma}$, q^{α}, Γ_{i_C} are independent of these conditions. But the relevancy of quantities such as $\Gamma_{j\alpha}$, $\Gamma_{j\beta}$, S^{σ} and of partial molar surface quantities such as:

$$\left(\frac{\partial S^{\sigma}}{\partial N_{j^{\beta}}{}^{\sigma}}\right)_{T,P,N_{j'^{\beta}\neq j^{\beta}}{}^{\sigma}} = \dot{S}_{j^{\beta}}{}^{\sigma}$$

$$\left(\frac{\partial \Omega^{\sigma}}{\partial N_{j^{\beta}}{}^{\sigma}}\right)_{T,P,N_{j'^{\beta}\neq j^{\beta}}{}^{\sigma}} = \dot{\Omega}_{j^{\beta}}{}^{\sigma}$$

$$\left(\frac{\partial V^{\sigma}}{\partial N_{j^{\beta}}{}^{\sigma}}\right)_{T,P,N_{j'^{\beta}\neq j^{\beta}}{}^{\sigma}} = \dot{V}_{j^{\beta}}{}^{\sigma}$$

is strictly assessed only by the choice of these two conditions. Regardless of which particular condition we select, we are then intrinsically led to define an arbitrary location and thickness of the interphase. Thus to this region will be assigned the set of independent extensive surface phase variables $N_{j\alpha}{}^{\sigma}$, $N_{j\beta}{}^{\sigma}$ (which are respectively the total number of particles of species j^{α} and j^{β} in the surface phase) and of extensive surface state functions Ω^{σ}, V^{σ}, and S^{σ} (which are respectively the overall surface area, volume, and entropy). We have also stressed the fact (10) that the convention adopted by Gibbs ($V^{\sigma} = 0$ and $\Gamma_w{}^{\sigma} = 0$) is by no means the most convenient, when the thermodynamic properties have to serve in conjunction with a theoretical interpretation in terms of the double layer model of Grahame. To this end we have advocated a more suitable convention. It amounts to select the functions:

$$[9a] \qquad \Gamma_{Hg^+} = \Gamma_{Hg^+}(T,P,J,q^{\alpha},m_{AC})$$

$$[9b] \qquad \Gamma_w = \Gamma_w(T,P,J,q^{\alpha},m_{AC})$$

in order to generate a surface phase equivalent to a monomolecular layer. Therefore, the value

$$[10a] \qquad \Gamma_{Hg^+} = 0$$

is given to eq. [9*a*] and eq. [9*b*] is taken as

$$[10b] \qquad \Sigma_{j\beta}\,\dot{\Omega}_{j\beta}\Gamma_{j\beta} = 1$$

in combination with the following set of partial molar surface phase areas.

$$[10c] \qquad \Omega_w{}^{\sigma} = a_w(T,P,J,q^{\alpha},m_{AC})$$

$$[10d] \qquad \Omega_{i_C}{}^{\sigma} = a_{i_C}(T,P,J,q^{\alpha},m_{AC})$$

$$[10e] \qquad \Omega_{\mathbf{B}}{}^{\sigma} = \Omega_{\mathbf{A}}{}^{\sigma} = 0$$

In view of this choice, the condition [10*b*] becomes

$$[10f] \qquad a_w\Gamma_w + a_{i_C}\Gamma_{i_C} = 1$$

The parameters a_w and a_{i_C} are assumed to represent approximately the areas occupied, under given conditions of T,P,J,q^{α},m_{AC} by one mole of each constituent w and **C** in a monolayer supposedly a two-dimensional rather close-packed liquid composed exclusively of Γ_w and Γ_{i_C} particles per unit area in direct contact with the electrode.

Having thus retained the conditions [10*a*] and [10*f*], it becomes evident that the surface phase to which we refer is bound on the metal side by the plane of zero adsorption of Hg^+ and extends towards the solution on an average distance $l^{\sigma} = \theta l_{i_C} + (1-\theta)l_w$ where θ represents $a_{i_C}\Gamma_{i_C}$ and where $\dot{V}_w{}^{\sigma}/a_w = l_w$ and $\dot{V}^{\sigma}/a_{i_C} = l_{i_C}$. Hence, the thickness of the surface phase is confined between the values of l_w and l_{i_C} and, since most frequently $\theta \ll 1$, l^{σ} is near l_w of the solvent.

According to the chosen definition, the set of independent surface composition variables can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

put as:

$$[11a] \quad \Gamma_{j^\beta}{}^\sigma = \frac{N_{j^\beta}{}^\sigma}{\Omega^\sigma} = \int_{l^\sigma}^{\infty} [n_{j^\beta}{}^\sigma(z) - n_{j^\beta}{}^\beta(\infty)]\, dz \qquad (j^\beta = \mathbf{A}, \mathbf{B})$$

where $n_{j^\beta}{}^\sigma(z)$ and $n_{j^\beta}{}^\beta(\infty)$ denote the local concentration of constituent j^β at distance z from the electrode and in the bulk.

$$[11b] \quad \Gamma_w{}^\sigma = \frac{N_w{}^\sigma}{\Omega^\sigma} = \frac{1-\theta}{a_w}$$

and

$$[11c] \quad \Gamma_{i_C} = \Gamma_{i_C}(T,P,J,q^\alpha,m_{AC})$$

as derived from eq. [6].

3. Entropies of Adsorption in the Surface Layer

The system of surface state variables [11*a*,*b*,*c*] enables the determination of S^σ as follows (see Appendix)

$$[12] \quad S^\sigma = \dot{S}_w{}^\sigma N_w{}^\sigma + \dot{S}_{i_C}{}^\sigma N_{i_C}{}^\sigma + S_d{}^\sigma$$

where $S_d{}^\sigma$ denotes the contribution of non-specific adsorption, thus:

$$[13] \quad S_d{}^\sigma = \dot{S}_A{}^\sigma N_A{}^\sigma + \dot{S}_B{}^\sigma N_B{}^\sigma$$

With the help of eqs. [3], [5], and [12], we are now in position to reformulate eqs. [7] and [8] as follows:

$$[14a] \quad -\left[\left(\frac{\partial \xi}{\partial T}\right)_{P,J,q^\alpha,m_{AC}} - q^\alpha E_T{}^{\beta,Hg}\right] = \Gamma_s{}^\sigma$$

$$[14b] \quad \Gamma_s{}^\sigma = \Gamma_w[\dot{S}_w{}^\sigma - \dot{s}_w{}^\beta] + \Gamma_{i_C}[\dot{S}_{i_C}{}^\sigma - (\dot{s}_{i_C}{}^\beta + Z_C \dot{s}_{e^-}{}^\alpha)] + \Gamma_{s,d}{}^\sigma$$

$$[15] \quad -\left[\left(\frac{\partial \xi}{\partial T}\right)_{P,J,q^\alpha,\Gamma_{i_C}} - q^\alpha E_T{}^{\beta,Hg}\right] = \frac{\dot{S}_w{}^\sigma - \dot{s}_w{}^\beta}{a_w} + F_{s,d}$$

Equations [14*b*] and [15] have been written so that the non-specific ionic effects are isolated in separate terms on the right hand side.

Taking into account our previous results obtained from a complementary analysis of electric forces and stresses at the interphase (10), we can readily deduce the following relations for $\Gamma_{s,d}{}^\sigma$ and $F_{s,d}$.

$$[16] \quad \Gamma_{s,d}{}^\sigma = -\left[\frac{\partial}{\partial T}\left(\int_0^{q^\alpha + Z_c F \Gamma_{i_C}} \psi(\delta^\beta)\, d\sigma\right)\right]_{P,J,q^\alpha,m_{AC}}$$

$$[17] \quad F_{s,d} = -\left[\frac{\partial}{\partial T}\left(\int_0^{q^\alpha + Z_c F \Gamma_{i_C}} \psi(\delta^\beta)\, d\sigma\right)\right]_{P,J,q^\alpha,\Gamma_{i_C}} = -\int_0^{q^\alpha + Z_c F \Gamma_{i_C}} \left(\frac{\partial \psi(\delta^\beta)}{\partial T}\right)_{P,J,\sigma} d\sigma$$

in which the electric potential $\psi(\delta^\beta)$ is taken at the outer Helmholtz plane. It is also appropriate at this stage to express the relationship between $\Gamma_{s,d}{}^\sigma$ and $F_{S,d}$. By simple application of analysis, we have:

$$[18] \quad \Gamma_{s,d}{}^\sigma = F_{s,d}{}^\sigma - \psi(\delta^\beta)\left(\frac{\partial Z_c F \Gamma_{i_C}}{\partial T}\right)_{P,J,q^\alpha,m_{AC}}$$

4. Calculation of Diffuse Layer Contribution

We now describe the distribution $n_{j^\beta}{}^\sigma(Z)$ of non-specific adsorbed ions at the interface by means of the model of diffuse layer of Gouy–Chapman. In this case the value of $\psi(\delta^\beta)$ is known to be (17, 18):

$$[19] \quad \psi(\delta^\beta) = \frac{2RT}{|Z_a|F} \sinh^{-1} \gamma$$

$$\gamma \equiv [(q^\alpha + Z_c F \Gamma_{i_C})/\sqrt{8RT\varepsilon\varepsilon_0 J \rho_d}]$$

where ρ_d is the specific weight of the electrolyte solution and ε the dielectric permittivity in the bulk.

Upon introduction of eq. [19] into eq. [17], the expression for $F_{s,d}$ becomes:

$$[20] \quad F_{s,d} = -R\left(\frac{2RT\varepsilon J \rho_d}{\pi Z_a{}^2 F^2}\right)^{1/2}\left\{2\gamma \cosh^{-1}(1+\gamma^2)^{1/2} - \left[3 + \left(\frac{\partial \ln \varepsilon \rho_d}{\partial \ln T}\right)_{P,J}\right](\{1+\gamma^2\}^{1/2} - 1)\right\}$$

Values computed by means of eq. [20] can be found in ref. 10.

III. Experimental

1. Method and Systems

Systematic differential capacitance measurements were carried out, using a symmetrical Wien Bridge similar to those described by Hills and Payne (8) and Privat and Grand (19). The experimental conditions (temperature, potential, and concentration range) were chosen such as to make the influence of specific adsorption of fluoride ions negligible. The three mixed electrolyte systems NaF–NaCl; NaF–NaBr; NaF–NaI were studied at 15, 25, and 35°C in a potential range included between 0 and +1.5 V versus N.C.E. In all cases, the total ionic strength was kept at 10^{-1} mol kg^{-1}. The following compositions were selected:

$m_{NaF} + m_{NaX} = 10^{-1}$ mol kg^{-1}

m_{NaX}: 0; 10^{-4}; 3×10^{-4}; 10^{-3}; 3×10^{-3}; 10^{-2}; 3×10^{-2}; 10^{-1} mol kg^{-1} (X = Cl^-, Br^-, I^-)

In order to avoid any non-equilibrium effects at low values of m_{NaX}, the balance point of the bridge was taken in all experiments at the 30th s on a drop, the total life of which was 90 s. Furthermore, no significant frequency dependence of the capacitance measurements was observed between 200 and 1200 Hz at all compositions and polarization within the experimental range. In all cases, the frequency effects were of the same order of magnitude as or even lower than the error made on the capacitance measurements, i.e. ~0.15%. The dimension of the tip of the dropping mercury electrode was always small enough to avoid any screening effect. In the absence of any significant frequency influence, all the capacitance measurements were made at 1000 Hz.

Some results obtained at 25°C are shown in Fig. 1. At the most negative potential range, between −1.2 and −1.5 V, capacitance values coincide for each solution with a scattering of less than 0.15%. This error represents the sum of the errors made on the capacity measurement itself as well as on the time, potential, and mercury flow determination.

2. Calculations

(a) Density of Charge, Surface Tension, and ξ Function

The capacitance curves were integrated with respect to the potential in order to obtain the density of charge at the electrode. The required integration constants at each temperature were taken at −1.5 V vs. N.C.E. (Table 1). Those charges were obtained from p.z.c. measurements of 0.1 *m* NaF system, using the streaming electrode. The integration procedure was carried out, using both a graphical method (potential range divided in trapezoids of 10 mV width) and a computation program that fits third degree polynomials to the curves. Both methods provide equally good results.

The constants for the integration of charge versus potential was obtained from direct measurements of surface tension for 0.1 *m* NaF system by means of the maximum bubble pressure method (Table 1). The surface tensions are calculated from integration with a precision of about 0.1 m*N* m^{-1}.

Values of E, γ, for each entire q^α value included in the polarization range, were computed by means of an interpolation programme. Thus values of $\xi = \gamma + q^\alpha E$ versus E were determined at each ionic strength.

(b) Adsorption Isotherms

The equation

$$[21] \quad \Gamma_{i_c}(T, P, q^\alpha, m_{AC}) = -\int_{-20\ \mu C}^{q^\alpha} \left(\frac{\partial \Delta E}{\partial \mu_{AC}{}^\beta}\right)_{q'^\alpha, T, P} dq'^\alpha$$

yields the most suitable method of deriving surface excesses Γ_{i_c} with a good precision (20). We have defined $\Delta E = E - E_0$. The electromotive forces E and E_0 are measured respectively in the system NaF + NaX and NaF at the same q^α and J. Plots of $(\Delta E)_{q\alpha}$ versus ln m_{AC} were drawn for entire q^α values included between -20×10^{-2} C m^{-2} and $+12 \times 10^{-2}$ C m^{-2}. The dispersion of the experimental results never exceeds 2 mV which is comparable with the expected errors arising from capacity measurements and integration. The slopes of these curves were evaluated, using the Lagrange interpolation formula. If one admits an error of about 1 mV on ΔE of the ordinate, one gets a standard deviation of the slopes of 0.7 for about 100 trials using a random generation of simulated experimental results. This represents a relative deviation of about 2% in most cases and reaches 20% only in the case of Cl^- ions at negative densities of charges or very low concentrations of the heteroion.

The values of $(\partial \Delta E/\partial \mu_{AC}{}^\beta)_{q\alpha}$, taken at each value of the selected concentration of NaX were integrated with respect to q^α. Thereby, the curves representing the integrand as a function of q^α were smoothed which reduces again the dispersion, so that the error on Γ_{i_c} lies at maximum within ±2%. As a matter of fact, the internal consistency of the resulting values of $F\Gamma_{i_c}$, as yielded by the dispersion of the computed points, is usually better than 0.3×10^{-2} C m^{-2}. Some adsorption isotherms are given in Fig. 2.

3. Entropy Excesses

Partial molar entropy of water adsorption can be obtained from eq. [15]. The temperature coefficient of 1 *N* calomel electrode reported by de Bethune (15) at 25°C is $E_T{}^{\beta,Hg} = -0.581$ mV K^{-1}. The contribution of the diffuse layer $F_{s,d}$, evaluated on ground of the Gouy–Chapman model, is calculated by means of eq. [20].

The results obtained from capacitance measurements of 0.1 *M* NaF solutions at 25°C are similar to those already published in our previous work using coulostatic techniques (12). In presence of halide adsorption, the partial differentials $-(\partial \xi/\partial T)_{J,P,q^\alpha,\Gamma_{i_c}}$ at 25°C were derived either at some selected values of the molalities $m_{AC}{}^\beta$ or at some selected values of Γ_{i_c}. The temperature coefficients were evaluated using a quadratic relation for ξ.

(i) Adsorption Entropies of the Solvent as a Function of Molalities

The values Γ_{i_c} corresponding to some chosen value of $m_{AC}{}^\beta$ and q^α is deduced from the isotherms at 25°C. The adsorption isotherms at 15°C and 35°C allow to relate this value of Γ_{i_c} to the corresponding molalities at 15 and 35°C. Plots of ξ versus m_{AC} at various q^α and T yield the three values of ξ corresponding to 15, 25, and 35°C which then allow to determine the differential of eq. [15] at 25°C for Γ_{i_c} and q^α constant. By repeating the same procedure at different densities of charges and correcting adequately for the reference electrode temperature coefficient one gets the results depicted in Fig. 3.

(ii) Adsorption Entropies of the Solvent as a Function of Surface Excess

The calculation of $(\partial \xi/\partial T)_{P,J,q^\alpha,\Gamma_{i_c}}$ at given values of Γ_{i_c} occurs quite in a similar way as in (*i*). This time, however, values of Γ_{i_c} and q^α are chosen and the corresponding molalities at each temperature are found. Deduction of the quantities ξ at 15, 25, and 35°C is made from ξ versus 1 g m_{AC} plots. Figure 4 represents the value of the right hand side term of eq. [15] at 25°C for different densities of charges and Γ_{i_c}. The correction for the reference electrode term has been made as previously stated and the contribution of the diffuse layer at the selected values of Γ_{i_c} and q^α is evaluated from eq. [20].

The errors associated with the data here reported in Figs. 3 and 4 have been estimated as follows. Within an error of $\simeq 10^{-3}$ C m^{-2} on Γ_{i_c} and on q^α, the subsequent error on ξ is of about 0.1 m*N* m^{-1}. Then the quantity $((\dot{S}_w{}^\sigma - \dot{s}_w{}^\beta)/a_w)_{T,P,J,q^\alpha,\Gamma_{i_c}}$ is determined within a precision of ±0.01 m*N* K^{-1} m^{-1}. Apparently, the dispersion of calculated results at low Γ_{i_c} does not exceed this value and is even much smaller at larger amounts of anions adsorbed.

(iii) Entropy of Formation of the Interface as a Function of Molalities

The entropy of formation $\Gamma_s{}^\sigma$ has been calculated by means of

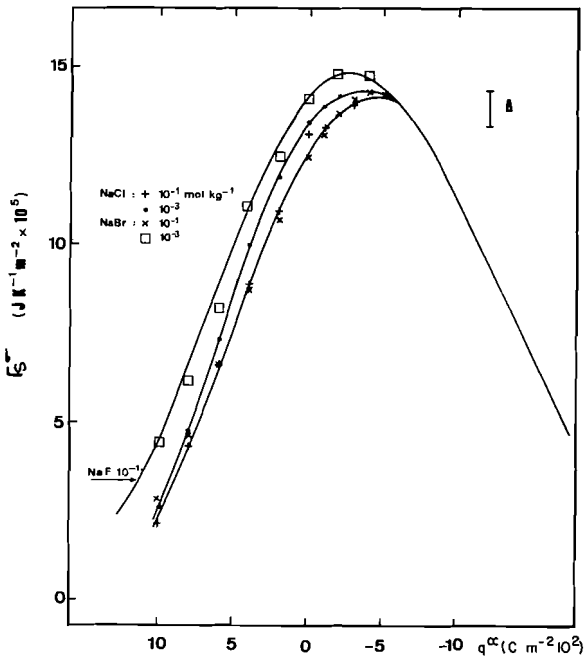

FIG. 5. The overall entropies of formation at 25°C of the double layer (without diffuse layer correction) at the mercury electrode in contact with mixed electrolyte solutions at constant ionic molality of 10^{-1} M kg^{-1}. The systems represented are NaF–NaCl and NaF–NaBr. The maximum indetermination arising from an error of 0.1 mN m^{-1} on ξ is shown in the figure.

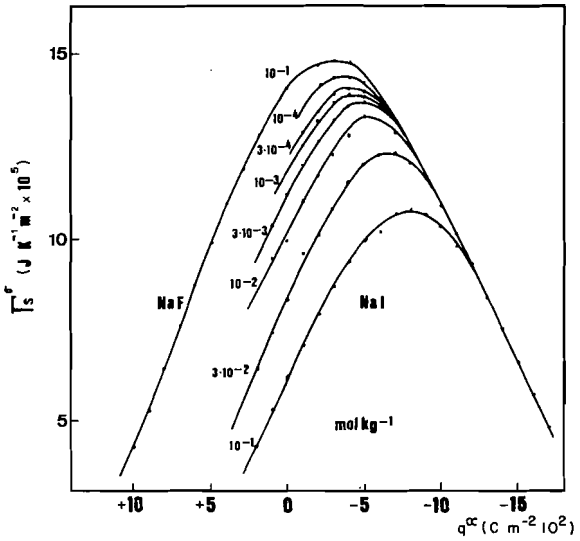

FIG. 6. The overall entropies of formation at 25°C of the double layer (without diffuse layer correction) at the mercury electrode in contact with NaF–NaI solutions kept at constant ionic molality of 10^{-1} M kg^{-1}.

eq. [7] at 25°C and for various values of the molality m_{AC}. These are thermodynamic quantities and thus include the contribution of the diffuse part of the double layer. In Fig. 5 are shown the values of Γ_s^{σ} as a function of q^{α} at $m_{NaX} = 10^{-1}$ and 10^{-3} mol kg^{-1} (X = Cl$^-$, Br$^-$) and in Fig. 6 is depicted the behaviour of Γ_s at various values of m_{NaI}. The indetermination on Γ_s arising from a prior error of 0.1 mN m^{-1} on ξ is represented in each figure. The dispersion of calculated results appears to be much less in most cases.

IV. Discussion

1. *Comparison of Adsorption Isotherms at 25°C with Previous Results*

We can compare directly the differential capacity curves recorded in Fig. 1 at 0.1 M and 25°C with the experimental data already published for single electrolyte systems. Deviations from these values never exceed 0.5% in the case of Cl$^-$ adsorption (21, 22) and are below 1% in the case of Br$^-$ (23) and I$^-$ (24) adsorptions. The capacity data for 0.1 M NaF, although slightly higher than Grahame's values (by about 1%) (25), were shown to be very reproducible over all the experimental range. These measurements have already been thoroughly discussed (12).

There is a large dissimilarity of patterns of adsorption isotherms of halides from single and from mixed alkaline halides solutions at constant J. In the mixed electrolytes system, each of the constant charge isotherms for Cl$^-$ and Br$^-$ ions displays a sharp bending followed by an inflexion point and tends asymptotically to zero amount adsorbed with decreasing m_{AC}. In the corresponding single alkaline halide solutions, the constant charge isotherms present a flattening and, at $q^{\alpha} > 0$, are asymptotic to a finite amount adsorbed which is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

numerically close to q^{α}. Consequently, both types of isotherms cannot be fitted easily to a common curve. This problem has been considered already by several authors (26–30). It has led to the analyses of the systems by means of the fitting of the experimental results to theoretical simple virial adsorption isotherms and by the electrical characterization of the inner layer properties (e.g. inner layer capacitances and potential drop).

The possibility of using the same virial isotherm for the description of the adsorption from single electrolytes and mixed electrolytes systems was attempted without much success in the case of Cl^- and Br^- adsorption (27–29) but provided better results in the case of I^- adsorption at small coverage (20, 29, 30). The following arguments are used to explain these discrepancies between both experimental methods. First, one considers that the most important effect is presumably due to the composition difference of the diffuse layer in the two types of systems. The electrical contribution to the standard free energy of adsorption ΔG^0 should depend: (*i*) on the potential at the outer Helmholtz plane (31, 32); (*ii*) on the effective thickness of the inner layer which is set under control of the countercations adsorbed at the outer Helmholtz plane (31, 34); (*iii*) on the increased efficiency of the image formation in the diffuse layer of the specifically adsorbed anions (33, 34).

Hills and Reeves further stressed the role of F^- specific adsorption (29, 35). It was also shown that the comparison of adsorption isotherms between single electrolytes and mixed electrolytes systems as recorded in Fig. 2, required a careful choice of the log of the bulk ionic activities to be used (20, 36). This problem is raised if no account is made of the buffering effect of the diffuse layer by introducing the potential at the outer Helmholtz plane in ΔG^0. This correction amounts to taking the concentration of the specifically adsorbing ion at the outer Helmholtz plane as a concentration variable.

Thus far all the corrections suggested above have been relatively inadequate in providing a good fit of the adsorption isotherms derived from single electrolytes and from mixed electrolytes systems. It is also noteworthy that the values of $\Gamma_{i_{Cl^-}}$ and $\Gamma_{i_{Br^-}}$ here derived for $10^{-1}\,M$ solution at 25°C are substantially lower than those obtained in refs. (21, 23). Similar discrepancies with the single halides systems were found at the largest **C** bulk concentration by Payne (27) in the mixed KF + KCl system (at $J = 1\,M$), by Sears and Lyons (28) in the mixed KF + KBr system (at $J = 1\,M$) and by Hills and Reeves (29) in the mixed NH_4F + NH_4Br system at ($J = 0.5\,M$). These differences are undoubtedly related to the method of derivation of Γ_{i_C}. In mixed electrolyte systems these values are obtained by differentiation at the end of the experimental range and are probably much in error. However, it is also worth mentioning that the calculations in both types of systems make use of different definitions of the ionic bulk activities. In most electrocapillary measurements with mixed electrolytes at constant J so far published the bulk activity coefficients are assumed to be constant. The influence of these coefficients was already analyzed in refs. (37, 38). In the case of binary mixtures, $\ln \gamma_{AB}$ and $\ln \gamma_{AC}$ can be estimated by means of Harned's rule (39–41). It follows that for most halides systems at constant J, the Harned's coefficients are small and do not affect significantly the data derived from eq. [1]. An attempt has been made more recently by Fawcett *et al.* (33, 34) to estimate the individual ionic activities. These authors consider that the activity coefficients of the anions γ_B and γ_C remain unaffected by the concentration m_C on account of the fact that the atmosphere around a given anion is largely unmodified when the solution composition is changed at J constant. As concerns the activity coefficient of the single cation γ_A, the Hückel–Brönsted–Guggenheim equation was used (39). This expresses $\ln \gamma_A$ as a function of m_c. In our systems, the tabulated activity coefficients in $0.1\,M$ NaF, NaCl, NaBr, and NaI are at 25°C respectively 0.765, 0.778, 0.782, 0.787 (42). These data yield a maximum difference of less than 3% between γ_{NaF} and γ_{NaI}. Under such conditions and upon application of the treatment developed by Fawcett *et al.*, provided that $J = 0.1\,M$, the maximum shift of the potential scale E_A with respect to that measured against a constant reference electrode E is 0.8 mV when the electrolyte is changed from $0.1\,M$ NaF to $0.1\,M$ NaI. The determination of surface excesses from eq. [1] will be affected by a maximum error of 3% in $m_{NaI} = 0.1$ mol kg^{-1}.

The measurements published so far on the degree of specific adsorption of Cl^- (27) and Br^- ions (28, 29), adsorbed from mixed electrolytes solution were performed at $1\,M$ (27, 28) and $0.5\,M$ (29) constant ionic strength. Furthermore, the lowest concentrations reported were 10^{-3}, 5×10^{-3}, and $2.5 \times 10^{-4}\,M$, respectively for KCl, KBr, and NH_4Br. These conditions contrast with ours as much for the concentration range as for the choice of the common cation. A direct comparison is therefore rather difficult. It is observed that our molar surface excesses are systematically lower than those so far reported and that the shapes of the isotherms are different. This is evidently related to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

the influences exerted by the diffuse layer. Damaskin *et al.* (36) have indicated that the buffering effect of the diffuse layer is the larger at $(q^\alpha + Z_c F\Gamma_{ic}) > 0$, the smaller the ionic strength. In our experiments the conditions $(q^\alpha + Z_c F\Gamma_{ic}) > 0$ is fulfilled at concentrations of Cl^- below $3 \times 10^{-2}\,M$ and of concentrations of Br^- below $10^{-3}\,M$. The buffering effect of the diffuse layer is thus expected to be quite different according to systems investigated at $J = 1\,M$ or $0.5\,M$ and at $J = 0.1\,M$ especially in the range of large q^α and low m_{AC}. It is further noticed that the nature of the common countercation might affect the specific adsorption of anions. Fawcett *et al.* (33, 34) suggested that the distance between the inner and outer Helmholtz plane decreases by approximately a factor of two when the countercation is changed from Na^+ to K^+. Consequently, the average potential at the adsorption plane becomes less negative and the screening of the adsorbed anion by the diffuse layer is more effective in presence of K^+ than of Na^+. Hence discreteness of charges contributes to Γ_{ic} being larger in the K^+ system than in the Na^+ system. It is also expected that the adsorption data at $J > 0.1\,M$ are more strongly subjected to the influence of F^- specific adsorption (29, 35, 43). In the worst experimental situation encountered in this respect with our measurements ($m_{AC} = 0$, $J = 10^{-1}\,M$, $q^\alpha = 10^{-1}$ C m^{-2}) a value of $|Z_c F\Gamma_{ic}| < 10^{-2}$ C m^{-2} can be deduced from the results of Hills and Reeves at 25°C (35). Therefore, in the present investigation, the amount of F^- specifically adsorbed will never exceed the absolute precision of the molar excess determination.

Finally, it is noteworthy that Payne (27) derived congruent isotherms with respect to q^α in the system KF + KCl at $J = 1\,M$, that Sears and Lyons (28) did not detect such congruency in the system KF + KBr at $J = 1\,M$ and that Hills and Reeves (29) could find such congruency with the system NH_4Br + NH_4F at $J = 0.1\,M$. We have not observed this property for the Cl^- and Br^- adsorption at any temperature. In the case of Br^- adsorption a change of curvature of the isotherms occurs if q^α is increased above 6×10^{-2} C m^{-2}. A similar change was observed in ref. 28. It might indicate either that some adsorption saturation is being approached or, if expressed in terms of virial isotherms, that the virial B coefficient decreases considerably with increasing q^α. At first approximation, the virial state equation corresponding to the virial adsorption isotherm takes the form:

$$[22] \qquad (\xi_0 - \xi)/RT = \Phi/RT = \Gamma_{ic}[1 + B(q^\alpha)\Gamma_{ic}]$$

where ξ and ξ_0 are measured respectively in the NaF + NaX solution and in NaF solution at the same values of q^α, J, and T.

Plots of the surface pressure Φ have been drawn in Fig. 7. If a state equation with B constant as a function of q^α is obeyed, and if the isotherms are congruent with respect to q^α, the curves should be parallel and linear, hence

$$[23] \qquad \left(\frac{\xi_0 - \xi}{\partial q^\alpha}\right)_{T,P,J,\Gamma_{ic}} = 0$$

According to eq. [22], it is evident from Fig. 7*a* and *b* that B decreases considerably with increasing q^α, especially with Br^- ions, the lowest value being somewhat smaller than that obtained in Fig. 7*c* with I^- ions.

The behaviour of I^- differs considerably from that observed with Cl^- and Br^- ions. The adsorption isotherms, as shown in Figs. 2*c* and 7*c* remain congruent with respect to q^α over the whole experimental range and the values of $\Gamma_{i_{I^-}}$ calculated at $10^{-1}\,M$ and 25°C agree within less than 1.5% with the data derived from a single electrolyte system (24). A plot of $\Gamma_{i_{I^-}}$ versus ΔE is shown in Fig. 8. According to the equation

$$[24] \qquad \Delta E = E - E_0 = RT\left(\frac{\partial \ln m_{AC}}{\partial q^\alpha}\right)_{T,P,J,\Gamma_{ic}} \Gamma_{i_c} = -RT\left(\frac{\partial \ln \beta}{\partial q^\alpha}\right)_{T,P,J} \Gamma_{i_c}$$

which is valid in the case of congruency with respect to q^α (37), the slopes of the plot recorded in Fig. 8 yield the coefficients $(\partial \ln \beta/\partial q^\alpha)_{T,P,J}$ where

$$[25] \qquad \ln \beta = -\Delta G^0/RT$$

It appears that these coefficients depend weakly on q^α. This behaviour reflects the fact that ΔG^0 cannot be represented strictly by a simple linear function of q^α. The values of the coefficients vary between 0.835 and 0.813×10^2 m^2 C^{-1} at respectively $q^\alpha = -8$ and -2×10^{-2} C m^{-2}, the lowest value being about 2.5% higher than the value found by Dutkiewicz and Parsons (20). A constant value of 3.4 (nm^2)/ion is deduced from the plot of Fig. 8 for the second virial coefficient B. This is in perfect agreement with the values derived in the literature which vary between 3.1 and 3.9 (nm)^2/ion over a wide range of charge densities (30, 44). Let us note however in this respect that adsorption isotherms derived by Fawcett and McCarrick (33) in the NaF–NaI and the KF–KI systems at $J = 0.25\,M$ did fit into a simple virial equation.

All the experimental evidence now available suggests that I^- ions manifest a much simpler behaviour in their process of specific adsorption

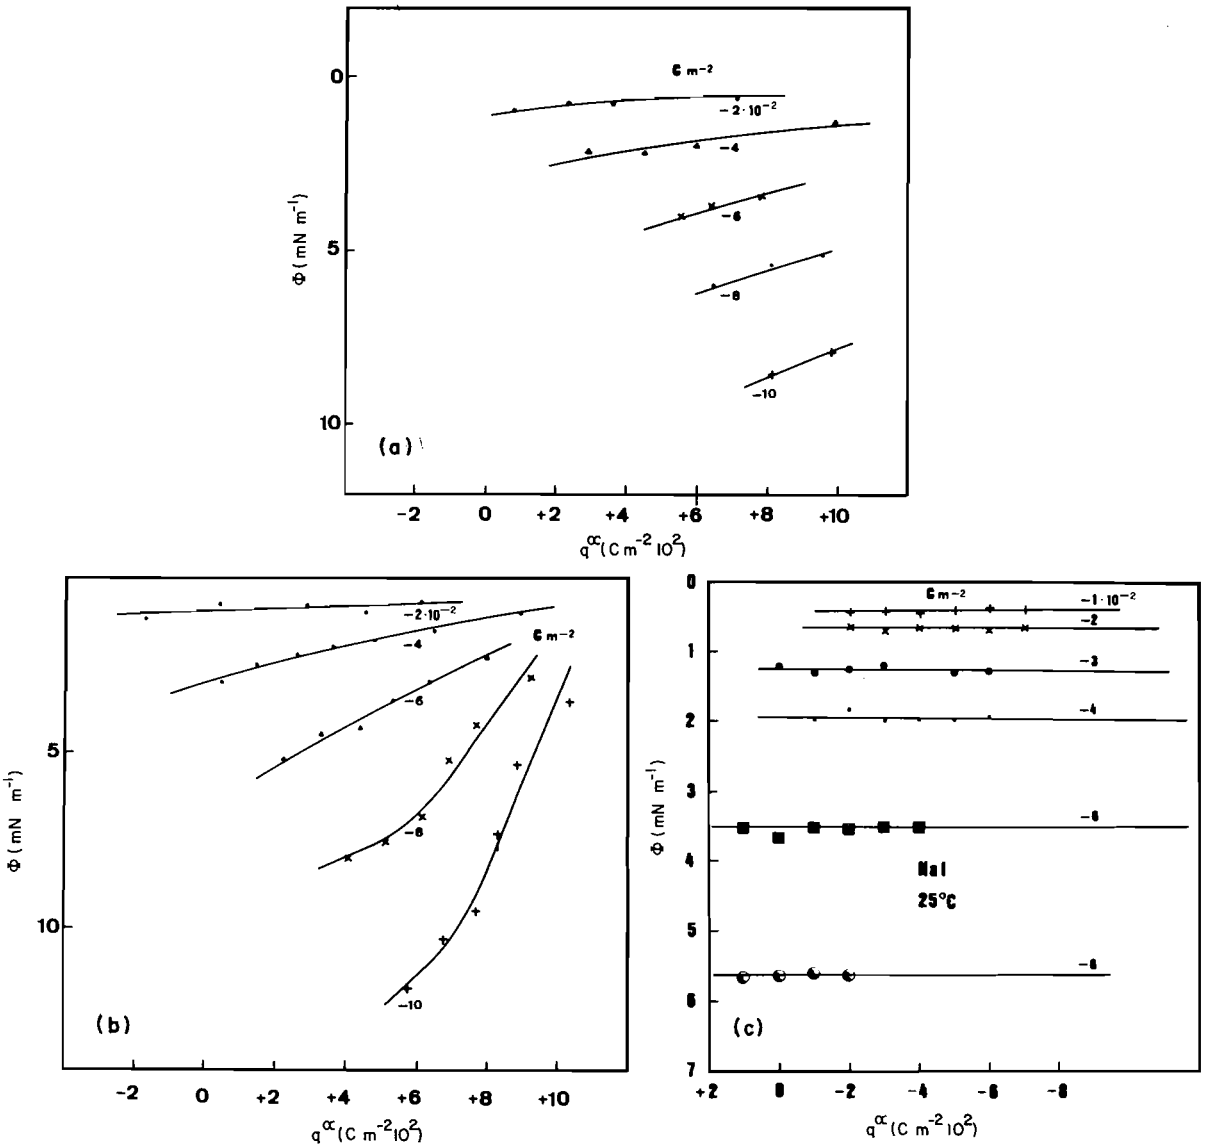

FIG. 7. Surface pressure Φ as a function of the surface charge density at 25°C. (*a*), The NaF–NaCl system at different molar excesses of Cl^- in the inner layer; (*b*), the NaF–NaBr system at different molar excesses of Br^- in the inner layer; (*c*), the NaF–NaI system at different molar excesses of I^- in the inner layer.

than Cl^- and Br^- ions. It happens generally that the *B* coefficient is constant in systems of strong ionic adsorption (30) and that furthermore this coefficient depends on the nature of the solvent (30). Consequently, we are led to assume that the average conformation of the coadsorbed solvent in the inner layer is less affected by the presence of the strongest adsorbed I^- ions than by Br^- and Cl^- ions. This hypothesis is confirmed in the following section on account of the dependence of the entropy of solvent adsorption with q^α and $\Gamma_{i_{I^-}}$. As opposed to the *B* constancy in the I^- system, the variation of *B* with Cl^- and Br^- adsorption might reveal a disturbance of the adsorbed solvent configuration. This might be considered as equivalent to an increase of the free energy of hydration of the Cl^- and Br^- ions at the surface as a function of decreasing q^α. In the case of solvent restructuring effects extending over a sufficiently large distance on the surface, this behaviour will also be formally equivalent to a reinforcement of the lateral repulsion between the adions.

The present investigation is essentially devoted to the thermodynamic analysis of temperature

effects on electrocapillary data. Accordingly, we do not intend to carry out further detailed and more quantitative computation of the adsorption parameters at the level of a microscopic model of the inner region like, for example, the potential drop and various types of capacities. We leave this important but distinct question to a forthcoming publication.

2. The Entropy of Adsorption of the Solvent in the Inner Layer

The results recorded in Fig. 3 indicate clearly that at 25°C the partial molar entropy of adsorption $\dot{S}_w^\sigma$ of the solvent is a complex function of q^α if plotted at constant m_{AC}. However, if we draw plots of $\dot{S}_w^\sigma$ at constant Γ_{i_C}, the dependence with q^α becomes nearly linear. The values of entropies presented in Fig. 4 decrease with increasing q^α at constant Γ_{i_C} and increase as a function of Γ_{i_C} at constant q^α. In the case of Cl^- and Br^- adsorption, the increment of $\dot{S}_w^\sigma$ with Γ_{i_C} depends on the value of q^α and is not linearly related to the ionic amount specifically adsorbed at constant q^α. In the case of I^-, however, an identical variation of $\dot{S}_w^\sigma$ with $\Gamma_{i_{I^-}}$ occurs at all values of q^α. The property of constant virial B coefficient has the following consequence upon the dependence of $\dot{S}_w^\sigma$ on q^α and on $\Gamma_{i_{I^-}}$. According to eq. [23], one gets within the range of isotherm congruency that

$$[26]\quad \left(\frac{\partial^2}{\partial T \partial q^\alpha}(\Phi)\right)_{P,J,\Gamma_{i_C}} = \left[\frac{\partial}{\partial q^\alpha}\left(\frac{\dot{S}_w^\beta}{a_w} - \frac{S_0^\beta}{a_{w0}}\right)\right]_{T,P,J,\Gamma_{i_C}} + \left[\frac{\partial}{\partial q^\alpha}(F_{s,d} - F_{s,d0})\right]_{T,P,J,\Gamma_{i_C}} = 0$$

where the subscript 0 refers to the system without specific adsorption. A similar equation has already been derived in ref. 10.

In Fig. 9, we have plotted the values of $(\dot{S}_w^\beta/a_w - F_{s,d})$ in presence of I^- as a function of Γ_{i_C}. It appears that good straight lines might be drawn with minor deviations at relatively low coverage. Since the experimental points lie markedly on the lines, these plots support the view that, at constant q^α, the internal accuracy of our results is better than $0.003\ mN\ m^{-1}\ K^{-1}$ although the absolute accuracy has been estimated to lie within $0.01\ mN\ m^{-1}\ K^{-1}$. The dependence on q^α of the extrapolated quantities $[(S_w/a_w)_{0,q^\alpha} - (S_{w0}/a_{w0})_{q^\alpha}]$ in Fig. 9 is illustrated in Fig. 10. The deviations of $(S_w/a_w)_{0,q^\alpha}$ from $(S_{w0}/a_{w0})_{q^\alpha}$ are below the acceptable experimental error and the validity of eq. [26] is thus assessed in the domain of low ionic coverage here considered. Consequently, it might be suggested that the shifts of the lines in Fig. 9 are due to systematic errors on the determination of q^α or Γ_{i_C}. Thus upon application of eq. [26], one gets an expression of the partial molar surface entropy of water as follows:

$$[27]\quad \left(\frac{\dot{S}_w^\sigma}{a_w}\right)_{\Gamma_{i_{I^-}},q^\alpha} = \left(\frac{\dot{S}_{w0}^\sigma}{a_{w0}}\right)_{q^\alpha} - \frac{R}{a_w}\ln a_w\Gamma_w + \int_{q^\alpha}^{q^\alpha + Z_c F \Gamma_{i_{I^-}}} \left(\frac{\partial \phi(\delta^\beta)}{\partial T}\right)_\sigma d\sigma$$

where the second term on the r.h.s. is independent of q^α.

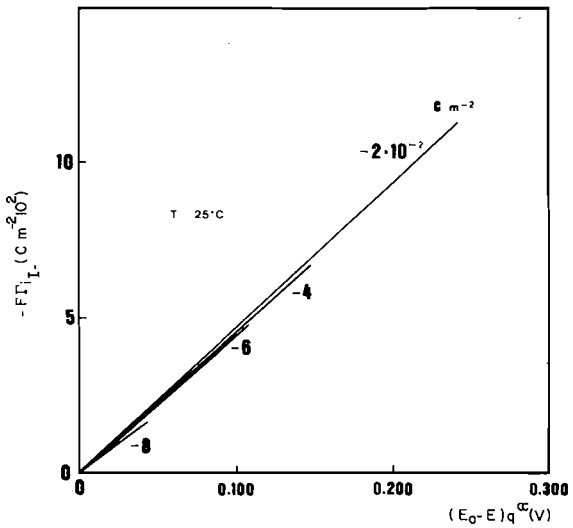

FIG. 8. Molar ionic excess of I^- in the inner layer as a function of the difference of potential $(E - E_0)$ at different densities of charges.

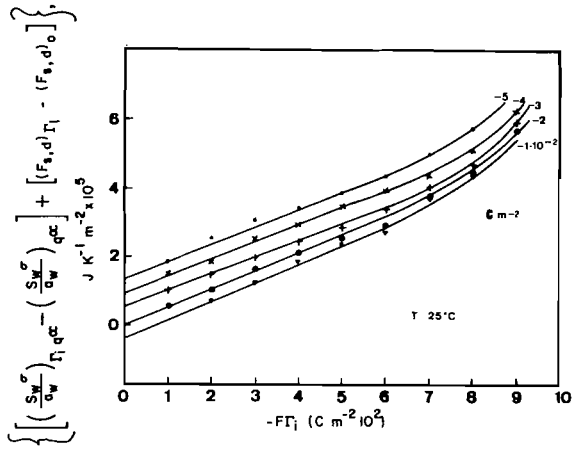

FIG. 9. Ionic molar inner layer excess dependence of the water adsorption entropies uncorrected for the diffuse layer contribution at different densities of charge in the NaF–NaI system at 25°C.

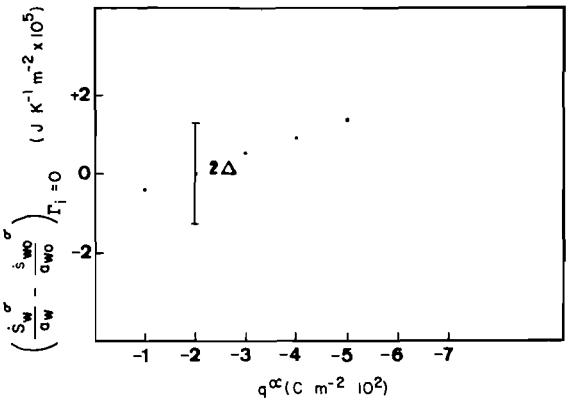

FIG. 10. Values of extrapolated partial molar standard entropies of the adsorbed water in presence of I^- adsorption plotted as a function of density of charge.

Equation [27] expresses the limiting condition of an ideal entropy of mixing as encountered in systems conforming to surface fraction statistics (45). Therefore terms such as the surface equivalent of osmotic or activity coefficients of water do not play any role. Indeed if this had not been the case, one would have to assume that the molecular interactions are independent of the average molecular configurations of water at the surface, which themselves are functions of q^α. This is of course very unlikely. Therefore the term $(\dot{S}_{w0}^\sigma/a_{w0})_{q^\alpha}$ carries alone all the effects resulting from the molecular conformation of adsorbed water as a function of q^α. For its part, the last term on the r.h.s. of eq. [27] bears exclusively the contributions of the diffuse layer. The choice of such simple equations for the partial molar surface entropies of water does not necessarily involve that the free energy expression is of the Langmuirian type. It suggests however that for example the virial B coefficient or some Frumkin coefficient in the isotherm is nearly independent of temperature.

In the experimental range of small surface excesses corresponding at the limit to the Henry's law domain, one has:

$$a_{I^-}\Gamma_{i_{I^-}} \ll a_w\Gamma_w$$

Hence one may approximate the second term of eq. [27] as follows:

$$[28] \qquad -\frac{R}{a_w}\ln \Gamma_w a_w \simeq R\left(\frac{a_{I^-}}{a_w}\right)\Gamma_{i_{I^-}}$$

Under this condition the slopes of the lines in Fig. 9 yield approximately the value $(a_{I^-}/a_w) \simeq 6.3$

Taking the average value of the diameter of one water molecule adsorbed at the surface as between 0.28 nm and 0.37 nm (12), one gets 0.7 to 0.95 nm for the diameter of the adsorbed anionic entity. A way of explaining this large figure is to regard the desolvated iodide adsorption process as involving a strong polarization of the nearest neighbour water molecules around the iodide ion in the inner layer. This amounts to an adsorbed entity made out, at vanishing ionic coverage, of one central ion surrounded by a circular sheet of thickness of the diameter of one water molecule. A similar hypothesis has been proposed by Hills and Payne (8) who suggested also that the ion could be adsorbed with a largely intact solvation shell. However, according to the results presented in Fig. 4, the conformation of the solvent beyond this peripheral solvation sheet should be unaffected.

3. *Formation Entropy of the Inner Layer and Adsorption Entropy of the Ions*

The influence of the adsorbed ion molalities m_{AC} on the surface formation entropies Γ_s^σ is depicted in Fig. 5 in the presence of Cl^- and Br^- ions. Only small deviations are observed from the curve recorded in absence of specific adsorption. The decrease of the surface entropy of formation is much more pronounced with I^-, as illustrated on Fig. 6. A comparison with Fig. 3, which reports the positive deviations of the adsorption entropy of water from the entropy in absence of specific adsorption as a function of m_{AC} bears out any simple explanation of the behaviour of Γ_s^σ and leads roughly to admit that this thermodynamic function is made out of several contributions working in opposite directions: (*a*) a positive deviation increasing with m_{AC} related to the solvent adsorption; (*b*) a negative deviation increasing with m_{AC} related to the specifically adsorbed ions; (*c*) a complex term given by eq. [18] expressing the formation entropy of the diffuse layer.

We shall attempt next a careful interpretation of these data and therefore compute the inner layer formation entropy which is defined as:

$$[29] \qquad \Gamma_{is}^\sigma = \Gamma_w^\sigma(\dot{S}_w^\sigma - \dot{s}_w^\beta) + \Gamma_{ic}^\sigma(\dot{S}_{ic}^\sigma - \dot{s}_{ic}^\beta)$$

Using eqs. [14], [16], [18], we calculate Γ_{is}^σ from the following relation:

$$[30] \qquad \Gamma_{is}^\sigma = \Gamma_s^\sigma - F_{s,d} + \psi(\delta^\beta) \times \left(\frac{\partial Z_c F\Gamma_{ic}}{\partial T}\right)_{P,J,q^\alpha,m_{AC}}$$

The values of the inner layer formation entropies are given in Fig. 11. In their general features, they agree with the results published by Harrison *et al.* (9). Thus, Γ_{is}^σ shows a tendency to decrease at constant q^α and m_{AC} with the increasing adsorbability of the ionic species. Furthermore, the influence of the ionic concentration is amplified by

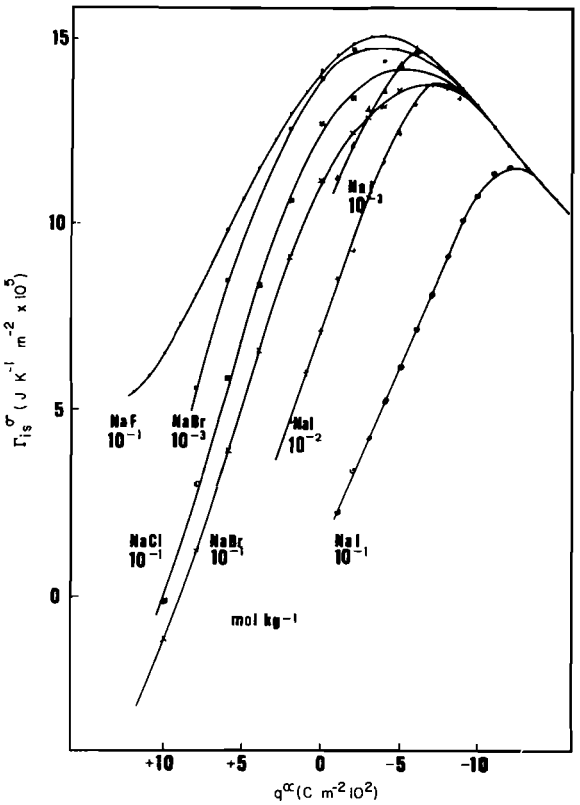

FIG. 11. The inner layer formation entropies at 25°C at the mercury electrode in contact with mixed electrolyte solutions at constant ionic molality of 10^{-1} M kg^{-1} for NaF–NaX systems (X = Cl$^-$, Br$^-$, I$^-$) at different molalities of NaX.

the ionic adsorbability. The reason for the negative deviation from the behavior in absence of specific adsorption can now be attributed to the overriding contribution of the partial molar entropy of specifical adsorption of ions. Denoting this quantity by $\Delta\dot{S}_{i_C}{}^{\sigma}$, we can express it as follows:

$$[31]\quad \Delta\dot{S}_{i_C}{}^{\sigma} = \dot{S}_{i_C}{}^{\sigma} - \dot{s}_C{}^{\beta_o} = \frac{1}{\Gamma_{i_C}}\left\{\Gamma_{is}{}^{\sigma} - \left(\frac{\dot{S}_w{}^{\sigma} - \dot{s}_w{}^{\beta}}{a_w}\right)(1 - \Gamma_{i_C}a_{i_C})\right\} - R\ln m_{AC}$$

where $\dot{s}_C{}^{\beta}$ has been decomposed in such a way as to leave only the standard partial molar bulk entropy $s_C{}^{\beta_o}$ in the definition of $\Delta\dot{S}_{i_C}{}^{\sigma}$. At relatively large ionic coverage, the ionic adsorption entropy depends on the arbitrary choice of a_{i_C}. These values have been selected by taking the ionic radii of Pauling (46). It results that $a_{Cl^-} = 8.4 \times 10^{-2}$ (nm)^2/ion; $a_{Br^-} = 10.2 \times 10^{-2}$ (nm)^2/ion; $a_{I^-} = 13.1 \times 10^{-2}$ (nm)^2/ion. The dependence of $\Delta\dot{S}_{i_C}{}^{\sigma}$ on q^{α} at constant Γ_{i_C} is depicted in Fig. 12. These plots show that satisfactory straight lines are obtained and it seems that within the experimental accuracy, the data can be fitted to a linear function even for chloride. The deviation arising from the limited accuracy of the experimental and computational methods might be estimated to lie roughly within a maximum of ± 8 J K^{-1} mol^{-1} of the value of $\Delta\dot{S}_{i_C}{}^{\sigma}$ and is certainly smaller in presence of iodide. It should be emphasized that the plots of Fig. 12 can be predicted from the strict application of the Gibbs–Duhem equation to the monolayer interphase. According to this condition, it is possible to evaluate the slopes of $\dot{S}_{i_C}$ vs. q^{α} from the slopes of the lines presented in Fig. 4. At equilibrium, the relationship is:

$$[32]\quad \Gamma_{i_C}\left(\frac{\partial\dot{S}_{i_C}{}^{\sigma}}{\partial q^{\alpha}}\right)_{\Gamma_{i_C}} = -\Gamma_w\left(\frac{\partial\dot{S}_w{}^{\sigma}}{\partial q^{\alpha}}\right)_{\Gamma_{i_C}} \simeq -(a_w\Gamma_w)\left(\frac{\partial(\dot{S}_w{}^{\sigma}/a_w)}{\partial q^{\alpha}}\right)_{\Gamma_{i_C}}$$

There is indeed a qualitative agreement between eq. [32] and our measurements. This is reflected by the opposite sign of the slopes computed from Fig. 4 and Fig. 12. In presence of Br$^-$ and I$^-$ adsorption, the graphical determination of the straight lines in Fig. 12 is sufficiently discriminating as to indicate that the slopes are decreasing when Γ_{i_C} is increased. Consequently, the value of the ratio

$$\left(\frac{\partial\dot{S}_{i_C}{}^{\sigma}}{\partial q^{\alpha}}\right)_{\Gamma_{i_C}} \Big/ \left(\frac{\partial(\dot{S}_w{}^{\sigma}/a_w)}{\partial q^{\alpha}}\right)_{\Gamma_{i_C}}$$

as deduced from Figs. 4 and 12 is decreased in function of increasing Γ_{i_C}, which conforms to the theoretical prediction of eq. [32] and further illustrates the internal consistency of our results.

For Cl$^-$ and Br$^-$, the range of variation of $\Delta\dot{S}_{i_C}{}^{\sigma}$ in Fig. 12 overlaps the value zero, the points on the positive side corresponding to the lowest experimental molality ($m_{AC} = 10^{-3}$ mol/kg). Except for these dilute systems, all the points are found at negative adsorption entropies, the values being the more negative, the more the ionic species are adsorbable. At constant charge, an increase of the ionic excess Γ_{i_C} leads to a decrease of $\Delta\dot{S}_{i_C}{}^{\sigma}$. It is likely that the source of the observed decrease in entropy is due, for a small part, to the entropy of mixing and that the main intervention is that of lateral electric repulsion between the ions located in the inner layer.

Since the range of entropy variation realized by a similar change of Br$^-$ and I$^-$ surface concentration is larger for Br$^-$ ions, it can be inferred that the lateral repulsion for Br$^-$ is larger than for I$^-$. There

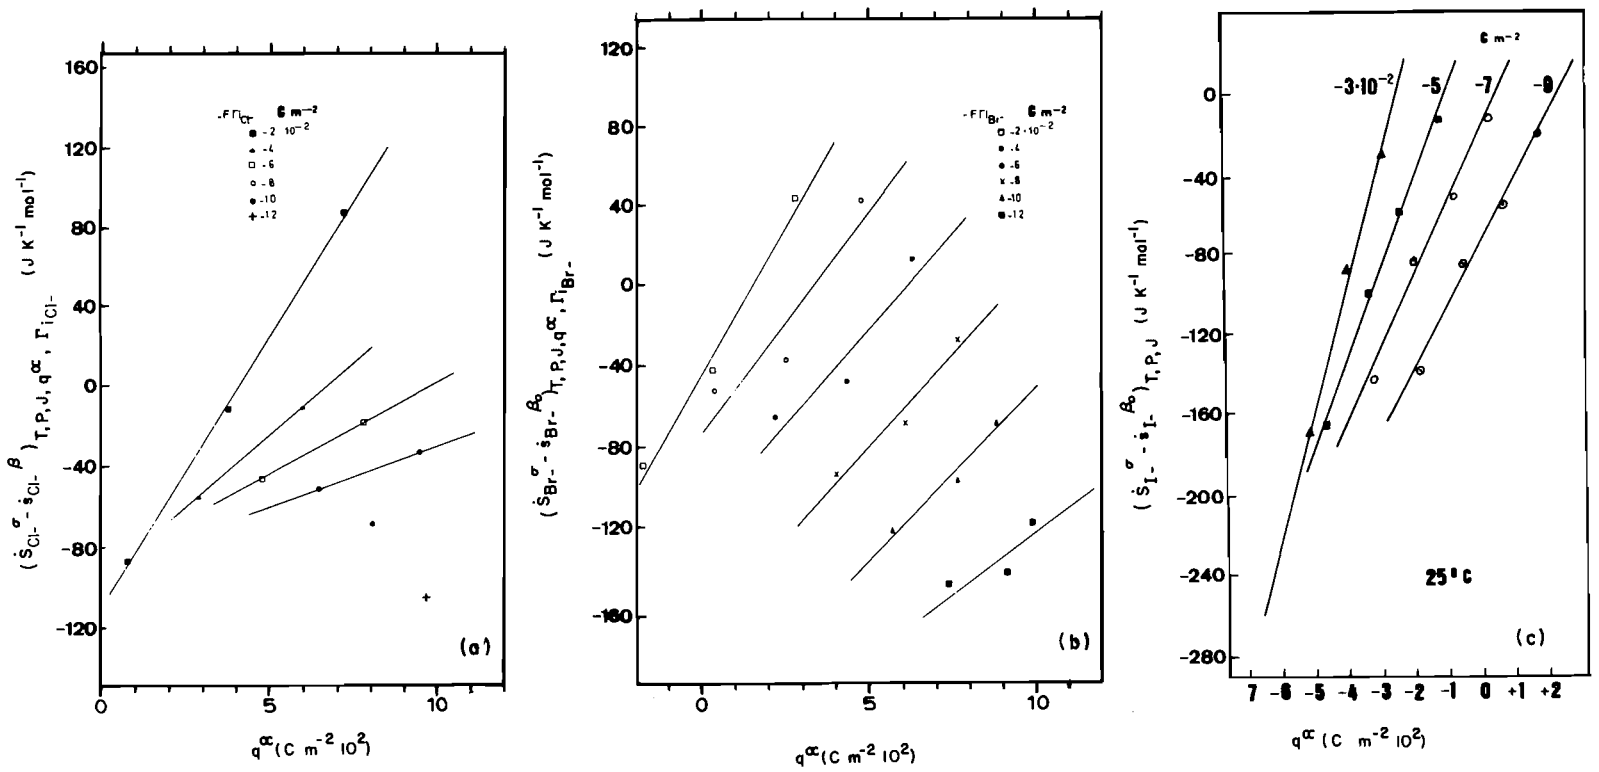

FIG. 12. The adsorption entropies of halide ions in the inner layer at 25°C as a function of the density of charge. (*a*) The case of Cl^- specific adsorption at different molar surface excesses in the inner layer. $a_{Cl^-} = 8.4 \times 10^{-2}$ (nm)²/ion; (*b*) the case of Br^- specific adsorption at different molar surface excesses in the inner layer. $a_{Br^-} = 10.2 \times 10^{-2}$ (nm)²/ion; (*c*) the case of I^- specific adsorption at different molar surface excesses in the inner layer. $a_{I^-} = 13.1 \times 10^{-2}$ (nm)²/ion.

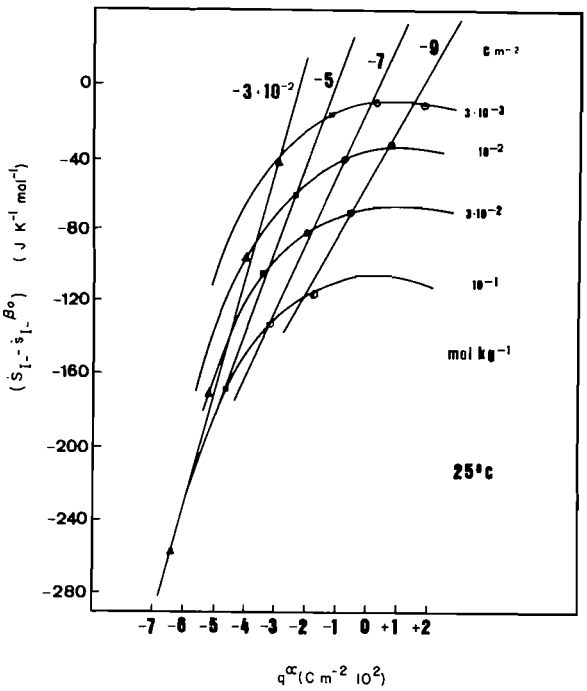

FIG. 13. The adsorption entropy of I^- ion in the inner layer at 25°C as a function of the density of charge. The curves at different molalities m_{NaI} in the mixed electrolytic solution and at different molar surface excesses of I^- in the inner layer are presented. $a_{I^-} = 47 \times 10^4$ m^2 M^{-1}.

is no simple explanation for the charge dependence of $\Delta\dot{S}_{i_C}{}^{\sigma}$ at constant Γ_{i_C}. Several factors might be suggested which could determine the increase of entropy with increasing positive charge. One might assume that an increase of standard entropy of the adions occurs by means of some partial charge transfer with the metal phase (47, 48). The adions Cl^- and Br^- might also act as structure promoting centers for the water dipoles adsorbed at the surface. This process should be all the less efficient as more dipoles are pointing their positive poles to the solution. Alternatively, one might suggest that the electric repulsion between the adions gets weaker under the effect of increased positive charge on the metal. This effect may be caused by the predominant orientation of the water dipoles with their positive poles pointing towards the solution and thereby neutralizing more efficiently the negative ionic charges penetrating in the inner layer. Such explanation has been invoked in the case of ionic adsorption at the Ga electrode where water dipoles are strongly adsorbed (49).

As regards the dependence of $\Delta\dot{S}_{i_C}{}^{\sigma}$ on the choice of the specific area a_C, it is shown in Fig. 13 that a value of $a = 78 \times 10^{-2}$ (nm)^2/ion corresponding to a radius of 0.5 nm does not modify the general features of the plot of Fig. 12. This value has been selected in relation to the determination of a from the initial slope of the function recorded in Fig. 9.

We show furthermore in Fig. 13 the general pattern of changes of $\Delta\dot{S}_{i_C}{}^{\sigma}$ at given ionic molalities. It is observed from this figure that the function increases strongly at constant m_{AC} with increasingly positive q^{α}, reaches a maximum and thereafter is levelled or even somewhat lowered. The lowering is practically controlled by the mechanism of ionic lateral repulsion. The initial rise of the function seems to be determined to a great extent by the overwhelming influence of the mechanism through which $\Delta\dot{S}_{i_C}{}^{\sigma}$ is increased with increasing q^{α} at constant ionic surface excess.

Appendix

In our previous theoretical publication (10), we have expressed the surface entropy S^σ as follows:

$$[A1] \quad S^\sigma = \sum_{j'\beta} \dot{S}_{j'\beta}{}^\sigma N_{j'\beta}{}^\sigma$$

where $j'\beta$ is a short notation for the set of constituents w (water), **A**, **B**, ^{i}**C** in which ^{i}**C** is heteroion **C** present in the inner layer. From Euler's theorem, we obtain

$$[A2] \quad S^\sigma = \sum_{j'\beta} \dot{S}_{j\beta}{}^\sigma N_{j'\beta}{}^\sigma + \dot{S}_{d_C}{}^\sigma \times \sum_{j'\beta} \left(\frac{\partial N_{d_C}{}^\sigma}{\partial N_{j'\beta}}\right)_{T,P,(N_{j'\beta^\sigma} - N_{j'\beta})} N_{j'\beta}{}^\sigma$$

The partial molar surface entropy $\dot{S}_{j\beta}{}^\sigma$ corresponds to the expression:

$$[A3] \quad \dot{S}_{j\beta}{}^\sigma = \left(\frac{\partial S^\sigma}{\partial N_{j\beta}{}^\sigma}\right)_{T,P,(N_{j\beta^\sigma} - N_{j\beta})}$$

and $j\beta$ refers to the set of constituants w, **A**, **B**, ^{i}**C**, ^{d}**C**, in which ^{d}**C** is the heteroion **C** adsorbed in the diffuse part of the double layer. Taking into account that $N_{d_C}{}^\sigma$ is a function of T, P, $N_{j'\beta}{}^\sigma$, eq. [A2] can be rewritten in the form:

$$[A4] \quad \dot{S}^\sigma = \sum_{j'\beta} \dot{S}_{j\beta}{}^\sigma N_{j'\beta}{}^\sigma + \dot{S}_{d_C}{}^\sigma N_{d_C}{}^\sigma = \sum_{j\beta} \dot{S}_{j\beta}{}^\sigma N_{j\beta}{}^\sigma$$

Therefore

$$[A5] \quad (\mathrm{d}S^\sigma)_{T,P} = \sum_{j\beta} \dot{S}_{j\beta}\, \mathrm{d}N_{j\beta}{}^\sigma$$

and

$$[A6] \quad \Gamma_s{}^\sigma = \sum_{j\beta} \dot{S}_j{}^\sigma \frac{N_{j\beta}{}^\sigma}{\Omega^\sigma} - \sum_{j\beta} \Gamma_{j\alpha} \dot{s}_{j\alpha}{}^\alpha - \sum_{j\beta} \Gamma_{j\beta} \dot{s}_{j\beta} = \sum_{j\beta} \Gamma_{j\beta} [\dot{S}_{j\beta}{}^\sigma - (\dot{s}_{j\beta}{}^\beta + Z_{j\beta} \dot{s}_{e^-}{}^\alpha)]$$

owing to the conditions [5] and [10*a*]. Accordingly, eq. [8] yields:

$$[A7] \quad \left(\frac{\partial \xi}{\partial T}\right)_{P,J,q^\alpha,\Gamma_{i_C}} - q^\alpha E_T{}^{\beta,\mathrm{Hg}} = -(\dot{S}_w{}^\sigma - \dot{s}_w{}^\beta)\left[\Gamma_w - \Gamma_{i_C} \times \left(\frac{\partial \Gamma_w}{\partial \Gamma_{i_C}}\right)_{T,P,J,q^\alpha}\right] - F_{s,d}$$

$$[A8] \quad F_{s,d} = \sum_{d_j} [\Gamma_{d_j} - \tau_{d_j} \Gamma_{i_C}] \times [\dot{S}_{d_j}{}^\sigma - (\dot{s}_{d_j}{}^\beta + Z_d \dot{s}_{e^-})]$$

where the notation $^d j$ stands for the set **A**, **B**, ^{d}**C** of ions present in the diffuse layer, and

$$\tau_{d_j} = \left(\frac{\partial \Gamma_{d_j}}{\partial \Gamma_{i_C}}\right)_{T,P,J,q^\alpha}$$

is the double layer transport number of an ionic species of the set $^d j$ (36, 50). Equation [7] yields:

$$[A9] \quad \left(\frac{\partial \xi}{\partial T}\right)_{P,J,q^\sigma,m_{AC}} - q^\alpha E_T{}^{\beta,\mathrm{Hg}} = -\Gamma_w[\dot{s}_w{}^\sigma - \dot{s}_w{}^\beta] - \Gamma_{i_C}[\dot{S}_{i_C}{}^\sigma - (\dot{s}_i{}^\beta + Z_{e^-} - \dot{s}_{e^-}{}^\alpha)] - \Gamma_{s,d}{}^\sigma$$

$$[A10] \quad \Gamma_{s,d}{}^\sigma \equiv \sum_{d_j} \Gamma_{d_j} [\dot{S}_{d_j}{}^\sigma - \dot{s}_{d_j}{}^\beta + Z_{d_j} \dot{s}_{e^-}]$$

Microscopic modelling of adsorption and the generalised surface layer hypothesis

M. V. SANGARANARAYANAN AND S. K. RANGARAJAN

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India

Received October 7, 1980

This paper is dedicated to Dr. Sam Levine on the occasion of his 70th birthday

M. V. SANGARANARAYANAN and S. K. RANGARAJAN. Can. J. Chem. **59**, 2072 (1981).

Two- and three-state models for the adsorption of organic compounds at the electrode/electrolyte interface are proposed. Different size requirements, if any, for the neutral molecule and the adsorbing solvent are also considered. It is shown how the empirical, generalised surface layer (GSL) relationship (between the potential difference and the electrode charge) formulated by Damaskin *et al.* can be understood at the molecular level.

M. V. SANGARANARAYANAN et S. K. RANGARAJAN. Can. J. Chem. **59**, 2072 (1981).

On propose des modèles à deux et trois états pour l'adsorption des composés organiques à l'interface électrode/électrolyte. On considère également, s'il y a lieu, les conditions imposées par des différences de grosseurs entre la molécule neutre et le solvant adsorbant. On montre comment on peut comprendre, au niveau moléculaire, la relation empirique de la couche de surface généralisé (entre la différence de potentiel et la charge de l'électrode) qui a été formulée par Damaskin *et al.*

[Traduit par le journal]

1. Introduction

Levine *et al.* have made significant contributions to the molecular modelling of the adsorption at charged interfaces and this report on some aspects of the statistical mechanics of the double layer is a token tribute to Professor Levine.

A primary question in electrical double layer is the relationship between the electrode charge (σ) and the potential difference (φ_{m_2}) existing at the interface. This is closely related to (*i*) the dependence of capacitance on coverage (θ) of the adsorbate (or solvent states); (*ii*) the issue of congruence (σ or φ_{m_2}?), and (*iii*) the nature of isotherms (4).

Earlier phenomenological approaches, notably of Frumkin (7), Hansen (8), and Parsons (9) led to some simple forms of σ vs. φ_{m_2}:

(*a*) Frumkin

$$[1] \qquad \sigma = \sigma_0(1 - \theta) + \sigma_1\theta = [C_0(1 + \theta) + C_1\theta]E - C_1E_N\theta$$

(*b*) Hansen

$$[2] \qquad \sigma = [C_0(1 - \theta) + C_1\theta](E - E_N\theta)$$

(*c*) Parsons

$$[3] \qquad \sigma = (E - E_N\theta)C_0/[(1 - \theta) + \theta C_0/C_1]$$

In the above equations, θ is the coverage by the adsorbate; C_0, C_1 are the capacitances at $\theta = 0$ and $\theta = 1$ respectively; and E_N is the total shift of the potential of zero charge (PZC) while going from $\theta = 0$ to $\theta = 1$. E is the potential difference measured with respect to the PZC at $\theta = 0$.

2. The Generalised Surface Layer Equation

Damaskin *et al.* (1–3) proposed on phenomenological grounds, an empirical equation governing the σ–E behaviour (for the adsorption of a class of organic compounds at the electrode/electrolyte interface) given as:

$$[4] \qquad \sigma = \frac{[C_0(1 - \theta) + nC_1\theta]E - nC_1E_N\theta[k(1 - \theta) + \theta]}{1 + n\theta - \theta}$$

There are two "adjustable parameters", n and k, in the above equation and the other parameters have been defined in Section 1. The motivation for such a hypothesis (4) — termed Generalised Surface Layer (GSL) model — is the failure of the earlier models of Frumkin (7), Hansen *et al.* (8), and Parsons (9) to account for several experimental observations. GSL model also served as a construct, *albeit* heuristic, synthesising the earlier results.

The success of GSL equation (4) in experimental "fits" has prompted us to ask the following questions:

(*a*) Is there any physical (molecular) picture of adsorption that would result in a functional form as [4]? Is the GSL equation an approximate or exact version? What are its limitations?

(*b*) Can the adjustable parameters be understood in terms of "molecular constants" like the dipole

moment, polarisability etc.? What is the molecular basis for n, k?

(*c*) Do different (n, k) pairs reflect the relative strength of adsorbate–solvent, adsorbate–adsorbate interactions etc.?

(*d*) Is the GSL hypothesis associated with a unique molecular picture?

We demonstrate, in what follows that answers to the above questions are possible. In our analysis of the models, permanent and induced dipole moment effects, discreteness of charge calculations and the substrate interactions are included.

One may take into account the polarisability effects which seem to play an important role in the electrochemical adsorption, following Levine's approach (5, 6). We have derived isotherms and charge potential relationship for the two-state and three-state descriptions. The GSL phenomenology can then be interpreted in this framework and the molecular basis for n and k can be unravelled. Table 1 shows a few typical n, k values. For a more exhaustive list, see refs. 3, 10, 19.

TABLE 1. Values of parameters n and k for the adsorption of various organic substances on mercury electrode (4, 19)

Organic substance	n	k
tert-$C_5H_{11}OH$	1	1.19
n-$C_5H_{11}OH$	1	1.57
iso-$C_5H_{11}OH$	1	1.47
n-C_3H_7OH	1	1.16
n-C_4H_9OH	1.13	1.31
C_2H_5COOH	0.91	0.21
n-C_4H_9COOH	1.12	1.09
n-$C_5H_{11}COOH$	1.25	1.15
n-$C_6H_{13}COOH$	1.45	1.20
	1.10	1.07
	0.6	1.0

3. Principles of Modelling

Adsorption at an electrochemical interface has several facets viz., multicomponent, multiconfigurational, and multisite aspects (11). Hence, *a priori*, one should not expect (except under limiting situations) naive cases of σ or φ_{m_2} congruence. Recent investigations (12–14, 17) have focussed attention on the multiconfigurational aspects of solvent adsorption. As long as site parity[1] is maintained among the various adsorbates including the solvent there is no need to distinguish between the multicomponent and multiconfiguration notions in modelling.

The basic principles in the microscopic modelling of adsorption at charged interfaces have been discussed in detail elsewhere (11, 14). Two important stages in such a modelling are those of the substrate description (cf. homogeneous/heterogeneous, order/disorder, etc.) and the representation of the adsorbate(s) configurations (orientational freedom, multicomponents etc). The simplest models in the hierarchy (*a*) stress on "the lattice" nature of the substrate and (*b*) postulate "a discrete" set of states for the adsorbate(s) — two (15), three (13, 16) or four (17) (ref. 14 for more details).[2] Where more than one adsorbing component is present in the interface, one may identify, on physicochemical grounds, some of the "states" with those of the solvent and the others with the "permitted configurations" of the adsorbates. The two- and three-state pictures outlined below (Sections 4 and 5) proceed on the above principles. For example in the two-state case, the solvent and the adsorbate are assumed to fill all the substrate sites (cf. if a void is to be permitted, the model becomes a "three-state" picture!).

It must be noted here that the classical Frumkin isotherm (4) for organic adsorption *in the presence of a solvent* can also be viewed as a two state version (an approximation of the lattice-gas (11)) *if one relegates the solvent to a continuum background* (ref. 11, Table 1, model A).[3] This obviously is not entirely molecular. A better representation of the solvent is desirable while analysing adsorption phenomena in the condensed phases and the *next* step is to permit *two* configurations for the polar solvent, thus resulting in a three-state model. The corresponding isotherm and other relationships are more complex than the two-state models but the reward is in achieving a more faithful representation of the phenomena!

In the context of adsorption of neutral molecules competing with solvents, multistate versions are not new in the scene — particular mention must be made of the so-called BDM (15) and BGM (16) models.

[1]We use the term "site-parity" to indicate that the several configurations of the same adsorbate or the many adsorbates need one site each of the underlying lattice. This is similar to (but not identical with) a mixture of hard cores of equal radii.

[2]See, in what follows, our comments on refs. 15 and 16.

[3]The fact that originally, the Frumkin isotherm was not based on any molecular model does not deter us from associating one at this stage!

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

The former (15) considers solvent adsorption as of two-state and consequently, *by implication*, the adsorption of organic compounds involves three-state (two-states are associated with the solvent and one-state with the organic compound). The latter (16) viz. BGM model is *apparently* a four-state version for adsorption (two each for the organic adsorbate and the solvent), but in reality, is concerned with *three states* (one state only for adsorbate) (ref. 16, Table 2 cases (I)–(V) and the condition $\Delta G_c^A \gg 0$ reducing effectively the permitted orientation of the adsorbate to one!). The analysis and the theory employed therein are not free from criticism and we shall revert to an examination of the BDM and BGM models elsewhere.

4. Results for Two State

We assume one state each for the solvent and the adsorbate. Under meanfield approximation, it can be shown that the isotherm is (Appendix A)

$$[5] \qquad \frac{\theta}{(1-\theta)} = \beta_0' c_{org} \times \exp\left[\Delta\alpha/2kT\left(\frac{c+b\sigma}{a_1+a_2\sigma}\right)^2\right]$$

where β_0' depends on the residual energy of the adsorbate ($U_r^{\uparrow}$) that of the solvent ($U_{r(0)}$) the standard chemical potential of the adsorbate (μ^0_{org}) that of the solvent (μ^0_{wat}) the dipole moment difference (ΔP) between the adsorbate and the solvent, and the polarisability difference ($\Delta\alpha$). c_{org} represents the concentration of the organic adsorbate relative to that of water. The various parameters in the eq. [2] are

$$[6] \qquad \beta_0' = \beta_0 \exp\left[-\Delta P^2/2\Delta\alpha kT\right]$$

$$[7] \qquad \beta_0 = \exp\left[(U_{r(0)} - U_r^{\uparrow} + \mu_{org}{}^0 - \mu_{wat}{}^0)/kT\right]$$

$$[8] \qquad \Delta P = P_{org} - P_0$$

$$[9] \qquad \Delta\alpha = \alpha_{org} - \alpha_0$$

$$[10] \qquad b = 4\pi$$

$$[11] \qquad c = \frac{c_e}{d^3} P_0 - a_1 \frac{\Delta P}{\Delta\alpha}$$

$$[12] \qquad a_1 = 1 + \frac{c_e}{d^3}\alpha_0$$

$$[13] \qquad a_2 = \frac{c_e}{d^3}\Delta\alpha$$

c_e is the coordination number, d is the nearest neighbour distance, P_0 and α_0 are the permanent dipole moment and the polarisability of the solvent respectively.

The relationship between φ_{m_2}, the potential drop across the inner layer and σ, the surface charge also follows as:

$$[14] \qquad \varphi_{m_2} = \frac{4\pi\sigma d}{\varepsilon} + \frac{4\pi N_T}{(a_1+a_2\theta)} \times \left[\Delta P\theta + P_0 - \Delta\alpha\theta\, 4\pi\sigma - \alpha_0 4\pi\sigma\right]$$

where N_T represents the number density of molecules and ε is the dielectric constant (non-orientational contributions)

Comparison with GSL

We note first that GSL hypothesis has phenomenological components like C_0, C_1, E_N and adjustable parameters like n, k. Before we compare our two-state model with GSL it is necessary to obtain molecular representations for such phenomenological components. This is done as follows: The surface charge σ can be written as (Appendix A)

$$[15] \qquad \sigma = \frac{(a_1+a_2\theta)\varphi_{m_2} - 4\pi N_T(\Delta P\theta + P_0)}{(4\pi/\varepsilon)[d(a_1+a_2\theta) - 4\pi N_T(\Delta\alpha\theta + \alpha_0)]}$$

The capacitances C_0 and C_1, defined as

$$[16] \qquad C_0 = \frac{\sigma}{\varphi_{m_2}(\theta=0) - \varphi_{m_2}(\theta=0, \sigma=0)}$$

and

$$[17] \qquad C_1 = \frac{\sigma}{\varphi_{m_2}(\theta=1) - \varphi_{m_2}(\theta=1, \sigma=0)}$$

can be shown to have the following expressions:

$$[18] \qquad C_0 = \frac{1}{4\pi[(d/\varepsilon) - 4\pi N_T\alpha_0/a_1\varepsilon]}$$

$$[19] \quad C_1 = \frac{1}{4\pi[(d/\varepsilon) - 4\pi N_T \alpha_{org}/(a_1 + a_2)\varepsilon]}$$

E_N, the shift of PZC from $\theta = 0$ to $\theta = 1$, can also be shown to be

$$[20] \quad E_N = \frac{4\pi N_T}{a_1} P_0 - \frac{4\pi N_T}{(a_1 + a_2)} P_{org}$$

A comparison of eqs. [4] and [15] indicates that the parameters n and k are written (from the two-state model) as

$$[21] \quad n = \frac{(a_1 + a_2)d - 4\pi N_T \alpha_{org}}{a_1 d - 4\pi N_T \alpha_0}$$

$$[22] \quad k = 1$$

The identification of GSL model with the two-state model is now complete.

The charge-potential equation [15] and the isotherm (eq. [5]) demonstrate how non-trivial consequences follow from even a simple physical representation like the one analysed in Section 4. Apart from obtaining a molecular justification for a particularised version viz $k = 1$ of the GSL equation [4], the two state model as presented here tells us (*a*) why congruence can fail (note the coupling between σ and θ in the r.h.s. of eq. [5]; also see ref. (18)), (*b*) how an inner layer dielectric constant that depends on σ and θ arises. We are also able to see how, as a special case, a pseudo-Frumkin isotherm can be realised with pseudo-interaction constant.

5. A Three-state Model and Comparison with the GSL

We assume here that the solvent has two orientations at the interface ("up" and "down") while the adsorbate has one orientation only. It can be shown in this case that (Appendix B)

$$[23] \quad \frac{R}{(1 - \theta)} = -\tanh\{K_1 + K_2\sigma + K_3 R + K_4\theta\}$$

where $R = (N^{\uparrow} - N^{\downarrow})/N_T$, $N^{\uparrow}$ and $N^{\downarrow}$ denote the number of solvent dipoles in the two orientations; K_1 depends on the difference in residual energies $(U_r^{\uparrow} - U_r^{\downarrow})$ of the two orientations. K_2, K_3, and K_4 are functions of dipole moment, polarisability, coordination number, nearest neighbour distance etc. (see Appendix B).

Writing $R/(1 - \theta) = \mathscr{R}$ an approximate equation for $\mathscr{R}$ is

$$[24] \quad \mathscr{R} \simeq -\tanh K_1 - [K_2\sigma + K_3(1 - \theta)\mathscr{R} + K_4\theta]\,\mathrm{sech}^2 K_1$$

Let us approximate $\mathscr{R}$ as

$$[24a] \quad \mathscr{R} \simeq Z_1 + Z_2\theta$$

where

$$[25] \quad Z_1 = Z_1^{\,0} + (4\pi\sigma/\varepsilon)K_R$$

$Z_1^{\,0}$ represents the value of Z_1 at $\sigma = 0$. The relationship between φ_{m_2} and σ in this case is

$$[25a] \quad \varphi_{m_2} = \frac{4\pi\sigma d}{\varepsilon} + \frac{4\pi N_T}{(a_1 + a_2\theta)}[P_w R + P_{org}\theta - \Delta\alpha\theta 4\pi\sigma - \alpha_0 4\pi\sigma]$$

$$[26] \quad = \frac{4\pi\sigma d}{\varepsilon} + \frac{4\pi N_T}{(a_1 + a_2\theta)}[P_w(Z_1 + Z_2\theta)(1 - \theta) + P_{org}\theta - \Delta\alpha\theta 4\pi\sigma/\varepsilon - \alpha_0 4\pi\sigma/\varepsilon]$$

As in the earlier description of the two-state model, the various phenomenological parameters can be defined consistently and identified with the molecular parameters in following way:

$$[27] \quad C_0 = \frac{a_1}{4\pi/\varepsilon[a_1 d + 4\pi N_T(P_w K_R - \alpha_0)]}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

[28] $$C_1 = \frac{a_1 + a_2}{4\pi/\varepsilon[(a_1 + a_2)d - 4\pi N_T\alpha_{org}]}$$

[29] $$E_N = \frac{4\pi N_T}{a_1}P_w Z_1^0 - \frac{4\pi N_T}{(a_1 + a_2)}P_{org}$$

where P_w is the permanent dipole moment of water and K_R is defined in eq. [25].

[30] $$\varphi_{m_2} - \varphi_{m_2}(\theta = 0, \sigma = 0) = \frac{4\pi\sigma d}{\varepsilon} + \frac{4\pi N_T}{a_1}\left[P_w\frac{4\pi\sigma}{\varepsilon}K_R - \frac{4\pi\sigma}{\varepsilon}\alpha_0\right]$$

Now the surface charge σ can be written as

[31] $$\sigma = \frac{(a_1 + a_2\theta)\{\varphi_{m_2} - \varphi_{m_2}(\theta = 0, \sigma = 0)\} + (a_1 + a_2)\theta E_N\left[1 - \frac{P_w Z_2(1 - \theta)}{(a_1 + a_2)P_w Z_1^0/a_1 - P_{org}}\right]}{4\pi/\varepsilon[(a_1 + a_2\theta)d + 4\pi N_T\{(P_w K_R - \alpha_0)(1 - \theta) - \alpha_{org}\theta\}]}$$

Comparison of eqs. [4] and [31] shows that

[32] $$n = \frac{(a_1 + a_2)d - 4\pi N_T\alpha_{org}}{a_1 d + 4\pi N_T(P_w K_R - \alpha_0)}$$

or $$n = (a_1 + a_2)C_0/a_1 C_1$$

[33] $$k = 1 - \frac{Z_2}{(a_1 + a_2)Z_1^0/a_1 - P_{org}/P_w}$$

k can also be written in terms of E_N as

[34] $$k = 1 - \frac{Z_2 4\pi N_T P_w}{(a_1 + a_2)E_N}$$

Substitution of the expressions for C_0, C', E_N, n, and k in eq. [4] leads to eq. [26], thereby showing the complete analogy between this model and the GSL model. While the expression for C_1 remains the same in both two- and three-state models, that for C_0 is different in the two. This is a consequence of the assumption of one more "state" for solvent in the three-state model.

Let us recall that to obtain identity with the GSL model, we have used only an approximate version of eq. [23]. This means that the charge–potential relation appropriate to this three-state model is more general than the GSL. The first approximation of such a σ–E relation (not given here) leads to the GSL equation as a limit. We also note that k is no longer constrained to be equal to unity (can be, in principle even positive or negative) and that the deviation of k from unity is a measure of adsorbate–solvent interactions. This also serves to decide whether a two- or three-state model is desirable. The parameter Z_2 in eq. [26] is the coefficient of $\theta(1 - \theta)$ in the expression for R and is, thus, an index of strength of adsorbate–solvent interactions vis-à-vis ordering of solvent states.

6. Multisite Models

This differs from the two-state picture of Section 4 only in that the solvent and the adsorbate configurations are of different sizes. To be more specific, let us consider the solvent as a cluster occupying n lattice sites. The adsorbate occupies only one site as before. The total number of nearest neighbour interactions experienced by a cluster (17) is

[35] $$qc_e = nc_e - 2n + 2$$

The p.d. across the interface is

[36] $$\varphi_{m_2} = \frac{4\pi\sigma d}{\varepsilon} + 4\pi(M_m + M_c)$$

where M_m and M_c are the mean net dipole moments due to the adsorbate and the cluster respectively. Writing M_m and M_c in terms of reaction fields X_m (see ref. 17) and X_c

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

$$[37] \quad \varphi_{m_2} = \frac{4\pi\sigma d}{\varepsilon} + \frac{4\pi N_T}{(A + B\theta)}\{(d^3/c)P_{c1} + k'\theta + k''\theta^2 - E(k_1' + k_2'\theta + k_3'\theta^2)\}$$

where $P_{c1} = P_c q/n^2$; $\alpha_{c1} = \alpha_c q/n^2$; $\Delta P = P_m - P_{c1}$; $\Delta\alpha = \alpha_m - \alpha_{c1}$; P_c and α_c represent the permanent dipole moment and the polarisability of the solvent respectively. The other parameters are as follows:

$$[38] \quad A = (d^3/c_e)(q/n) + \alpha_{c1}q/n$$

$$[39] \quad B = (d^3/c_e) + \alpha_m - A$$

$$[40] \quad k_1' = A\alpha_{c1}n/q - \alpha_{c1}^2$$

$$[41] \quad k_2' = A\alpha_m - A\alpha_{c1}n/q - 2\Delta\alpha\alpha_{c1} + B\alpha_{c1}n/q$$

$$[42] \quad k_3' = B\alpha_m - B\alpha_{c1}n/q - \Delta\alpha^2$$

$$[43] \quad k' = BP_{c1}n/q - \Delta P\alpha_{c1} + AP_m - AP_{c1}n/q - P_{c1}\Delta\alpha$$

$$[44] \quad k'' = BP_m - \Delta P\alpha_m - BP_{c1}n/q + \Delta P\alpha_{c1}$$

From eq. [37]

$$[45] \quad \sigma = \frac{(A + B\theta)\varphi_{m_2} - 4\pi N_T[(d^3/c_e)P_{c1} + k'\theta + k''\theta^2]}{4\pi/\varepsilon[d(A + B\theta) - 4\pi N_T(k_1' + k_2'\theta + k_3'\theta^2)]}$$

We attempt a comparison with the GSL; in the usual manner n in GSL result can then be identified as

$$[46] \quad n(\text{GSL}) = \frac{d/(A + B) - 4\pi N_T(k_1' + k_2' + k_3')}{Ad - 4\pi N_T k_1'}$$

Also,

$$n = C_0(A + B)/C_1A$$

As in the earlier models, C_0, C_1, and E_N can be shown to have the following expressions:

$$[47] \quad C_0 = A/4\pi/\varepsilon[Ad - 4\pi N_T k_1']$$

$$[48] \quad C_1 = (A + B)/(4\pi/\varepsilon)[d(A + B) - 4\pi N_T(k_1' + k_2' + k_3')]$$

$$[49] \quad E_N = \frac{4\pi N_T d^3}{A \quad c_e} P_{c1} - \frac{4\pi N_T}{(A + B)} \times [(d^3/c)P_{c1} + k' + k'']$$

k in GSL can now be found:

$$[50] \quad k = \frac{B(d^3/C_e)P_{c1} - Ak'}{B(d^3/C_e)P_{c1} - A(k' + k'')}$$

The two-state site parity case discussed in Section 4 is a special case of the above treatment. Setting n in eq. [35] to 1, it follows from [35] that $q = 1$. Consequently $k'' = 0$ and k becomes unity, as has indeed been shown earlier (eq. [22]).

The σ–φ_{m_2} relationship [45] is more general than the empirical GSL (4), reducing the latter, at best, to a valid approximation.

Finally, it is not our aim in the above multi-site analysis to assert that the solvent state is always a cluster and is "larger" in size than the adsorbate. The above is only an illustration of possibilities. Other cases, including the four-state models of adsorption have been rigorously analysed and will be reported later.

7. Conclusions

We now turn back to the questions posed in the beginning of this paper (Section 1) and answer them.

(*a*) It is possible to relate a molecular basis for the GSL phenomenological equation. A simple two-state version with site parity leads to the GSL equation except that k is always unity, irrespective of the values chosen for energetics, dipole moments, polarisabilities, etc.! If site parity is relaxed the σ–φ_{m_2} expressions, more general than that of GSL, would follow. Similarly the three-state model leads to the GSL under some approximations. But in the case of the three-state, site-parity need not be relaxed.

(*b*) In all cases where the GSL result is derived from molecular considerations (as exact or approximate), the parameters n and k can be written explicitly in terms of molecular "constants" like the permanent dipole moment, polarisability, the size-ratio etc.

(*c*) As mentioned in the discussion above, the composition of (n, k) and their dependence on the energetic parameters reveal their close connection

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

with the adsorbate–solvent and adsorbate–adsorbate interactions etc. existing at the interface. It should be possible to use these to "classify" adsorbates.

(*d*) Higher-state versions unfold progressively the complex nature of the coupling that exists at the interface and in this process, even the GSL result is reduced to a mere approximation. Thus it is possible for us to look for proper relationships governing σ and φ_{m_2} *with justification*. We have already seen that both the two-state (without site-parity) and the three-state (site-parity) cases lead to the GSL result as approximations! Which model is nearer the "truth"? In our opinion, the issue is to be decided mostly by the appropriateness of parameters needed to obtain agreement with experiments.

We want to reiterate that it is necessary to couple such analysis with explicit molecular details (15, 16) like choosing values for P_{org}, P_{water}, α_{org}, α_{water} etc. More details on the models considered here and their generalisations along with their predictions and experimental fits will be reported in subsequent publications.

Appendix A

Two-state Model Isotherm

The analysis given here closely follows the one given in ref. 13 in a different context.

Let us assume that the electrode is covered by a hexagonally closepacked monolayer of solvent and adsorbate molecules. The total number density of molecules is N_T, the nearest neighbour distance is d and the effective co-ordination number is c_e

$$[A1] \quad N_T = N^{\uparrow} + N_0$$

where $N^{\uparrow}$ and N_0 denote the number densities of the adsorbate and the solvent respectively.

The field acting at any site due to its neighbours must be proportional to $(m_p + m_i)$ where m_p is the net polarisation per site due to permanent dipole moments and m_i that due to induced dipole moments. E is the field due to σ, the charge on the electrode.

$$[A2] \quad x = c_e/Ad^3[P_{org}\theta + P_0(1 - \theta) - qE]$$

$$[A3] \quad q = \alpha_{org}\theta + \alpha_0(1 - \theta)$$

$$[A4] \quad A = 1 + c_e q/d^3$$

The excess internal energy per unit area for dipoles at a charged surface may be written (13)

$$[A5] \quad U = \frac{N_T c_e}{2d^3}(m_p + m_i)^2 + \tfrac{1}{2}N^{\uparrow}\alpha_{org}(E + X)^2 + \tfrac{1}{2}N_0\alpha_0(E + X)^2 + N_T E(m_p + m_c) + N^{\uparrow}U_r^{\uparrow} + N_0 U_{r(0)} - \mu_{org}N^{\uparrow} - \mu_0 N_0$$

where μ_{org} and μ_0 represent the chemical potentials of the adsorbate and the solvent respectively.

Assuming random mixing of dipoles, the configurational entropy is given by

$$[A6] \quad S = -kN^{\uparrow}\ln(N^{\uparrow}/N_T) - kN_0\ln(N_0/N_T)$$

Since $F = U - TS$, the equilibrium condition can be derived from $(\partial F/\partial N^{\uparrow})_{N^{\uparrow}+N_0} = 0$.

$$[A7] \quad N^{\uparrow}/N_0 = \beta_0 c_{org}\exp\{[-2\Delta P(E + X) + \Delta\alpha(E + X)^2]/2kT\}$$

where c_{org} is the concentration of the adsorbate relative to that of water and β_0 has been defined in [9]. If $N^{\uparrow}/N_T$ is defined as θ and N_0/N_T as $(1 - \theta)$,

$$[A8] \quad \frac{\theta}{(1 - \theta)} = \beta_0' c_{org}\exp\left[\left(\frac{\Delta\alpha}{2kT}\right) \times \left(E + X - \frac{\Delta P}{\Delta\alpha}\right)^2\right]$$

It can be shown that

$$\left(E + X - \frac{\Delta P}{\Delta\alpha}\right) = \left(\frac{C + b\sigma}{a_1 + a_2\theta}\right)$$

Therefore the isotherm becomes

$$[A9] \quad \frac{\theta}{(1 - \theta)} = \beta_0' c_{org}\exp\left\{\frac{\Delta\alpha}{2kT}\left(\frac{c + b\sigma}{a_1 + a_2\theta}\right)^2\right\}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

where all the parameters have been defined in eqs. [6]–[13]. The potential drop across the monolayer region is

$$[A10] \quad \varphi_{m_2} = \frac{4\pi\sigma d}{\varepsilon} + \frac{4\pi N_T d^3 X}{c_e}$$

Substituting [A2] in [A10],

$$[A11] \quad \varphi_{m_2} = \frac{4\pi\sigma}{\varepsilon(a_1 + a_2\theta)} [d(a_1 + a_2\theta) - 4\pi N_T(\Delta\alpha\theta + \alpha_0)] + \frac{4\pi N_T}{(a_1 + a_2\theta)} (\Delta P\theta + P_0)$$

Hence eq. [15] of the text follows.

Appendix B

A Three-state Model

Next in the hierarchy in modelling, the solvent is assumed to have two different configurations at the interface ("up" and "down"). The adsorbate has still only one configuration. The solvent and the adsorbate are considered as occupying only one site each.

Proceeding as in Appendix A,

$$[B1] \quad N^{\uparrow}/N^{\downarrow} = \exp\{[U_r^{\downarrow} - U_r^{\uparrow} - 2P_w(E + X)]/kT\}$$

P_w is the permanent dipole moment of the solvent; $N^{\uparrow}$ and $N^{\downarrow}$ denote respectively, the number of solvent molecules in the "up" and "down" orientation.

If R is defined as $R = (N^{\uparrow} - N^{\downarrow})/N_T$, it is easy to show that

$$[B2] \quad R = -(1 - \theta)\tanh\left\{\frac{1}{2kT}\left[U_r^{\uparrow} - U_r^{\downarrow} + \frac{2P_w}{A}\left(E + \frac{c_e}{d_3}\overline{P_w R + P_{org}\theta}\right)\right]\right\}$$

This can be written as

$$[B3] \quad R = -(1 - \theta)\tanh\{K_1 + K_2\sigma + K_3 R + K_4\theta\}$$

where

$$K_1 = \frac{U_r^{\uparrow} - U_r^{\downarrow}}{2kT}$$

$$K_2 = \frac{P_w 4\pi}{AkT\varepsilon}$$

$$K_3 = \frac{P_w P_w c_e}{Ad^3 kT}$$

$$K_4 = \frac{c_e P_{org} P_w}{Ad^3 kT}$$

The potential difference across the monolayer region is given as before, by

$$[B4] \quad \varphi_{m_2} = \frac{4\pi\sigma d}{\varepsilon} + \frac{4\pi N_T d^3 X}{c_e}$$

$$[B5] \quad = \frac{4\pi\sigma d}{\varepsilon} + \frac{4\pi N_T}{(a_1 + a_2\theta)}[P_w R + P_{org}\theta - \Delta\alpha\theta E - \alpha_0 E]$$

Writing $R/(1 - \theta)$ as $\mathscr{R}$ and approximating $\mathscr{R}$ as $\mathscr{R} \simeq Z_1 + Z_2\theta$ (see text for the definition of Z_1 and Z_2),

$$[B6] \quad \varphi_{m_2} = \frac{4\pi\sigma d}{\varepsilon} + \frac{4\pi N_T}{(a_1 + a_2\theta)}[P_w(Z_1 + Z_2\theta) \times (1 - \theta) + P_{org}\theta - \Delta\alpha\theta E - \alpha_0 E]$$

From eq. [B3]

$$[B7] \quad \mathscr{R} \simeq -\tanh K_1 - [K_2\sigma + K_3(1 - \theta)\mathscr{R} + K_4\theta]\,\mathrm{sech}^2 K_1$$

$$[B8] \quad \mathscr{R} \simeq \frac{-\tanh K_1}{1 + K_3\,\mathrm{sech}^2 K_1} - \frac{(K_2\sigma + K_4\theta)\,\mathrm{sech}^2 K_1}{1 + K_3\,\mathrm{sech}^2 K_1} = Z_1 + Z_2\theta$$

where

$$[B9] \quad Z_1 = -\frac{(\tanh K_1 + K_2\sigma\,\mathrm{sech}^2 K_1)}{1 + K_3\,\mathrm{sech}^2 K_1}$$

$$[B10] \quad Z_2 = -\frac{K_4\,\mathrm{sech}^2 K_1}{1 + K_3\,\mathrm{sech}^2 K_1}$$

Z_1 can be written as $Z_1^0 + (4\pi\sigma/\varepsilon)K_R$, where Z_1^0 is the value of Z_1 at $\sigma = 0$. Therefore

$$Z_1^0 = -\frac{\tanh K_1}{1 + K_3\,\mathrm{sech}^2 K_1}$$

$$K_R = \frac{K_2\,\mathrm{sech}^2 K_1}{1 + K_3\,\mathrm{sech}^2 K_1}\frac{\varepsilon}{4\pi}$$

Structural studies of the capsular polysaccharide from *Streptococcus pneumoniae* Type 12F

KARIN LEONTEIN, BENGT LINDBERG, AND JÖRGEN LÖNNGREN

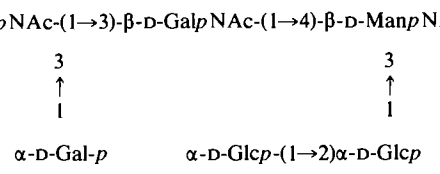
Department of Organic Chemistry, Arrhenius Laboratory, University of Stockholm, S-106 91 Stockholm, Sweden

Received February 13, 1981

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

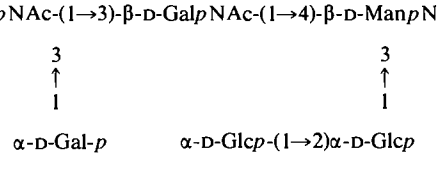
KARIN LEONTEIN, BENGT LINDBERG, and JÖRGEN LÖNNGREN. Can. J. Chem. **59**, 2081 (1981).

The capsular polysaccharide from *Streptococcus pneumoniae* type 12F is composed of D-glucosyl, D-galactosyl, 2-acetamido-2-deoxy-D-galactosyl, 2-acetamido-2,6-dideoxy-L-galactosyl, and 2-acetamido-2-deoxy-D-mannuronic acid residues in the proportions 2:1:1:1:1. The main structural evidence was adduced from nmr spectroscopy, methylation analysis, and specific degradations whereby it could be concluded that the polysaccharide is composed of hexasaccharide repeating-units having the structure:



KARIN LEONTEIN, BENGT LINDBERG et JÖRGEN LÖNNGREN. Can. J. Chem. **59**, 2081 (1981).

Le polysaccharide capsulaire provenant du *Streptococcus pneumoniae* de type 12F se compose d'unités D-glucosyle, D-galactosyle, acétamido-2 déoxy-2-D-galactosyle, acétamido-2 didéoxy-2,6 L-galactosyle et acide acétamido-2 déoxy-2 D-mannuronique dans les proportions de 2:1:1:1:1. Les principales preuves de structure sont fournies par la spectroscopie de rmn, par l'analyse de la méthylation et par des dégradations spécifiques qui ont permis de conclure que le monomère du polysaccharide est un hexasaccharide ayant la structure suivante:



[Traduit par le journal]

Introduction

The capsular polysaccharide from *Streptococcus pneumoniae* type 12F (1) (previously called type 12) has been investigated by different groups (2–4). Sugar analyses revealed that it contains D-glucose, D-galactose, 2-amino-2,6-dideoxy-L-galactose, and 2-amino-2-deoxy-D-galactose in the proportions 2:1:1:1. Immunological and chemical studies showed the presence of terminal kojibiosyl (2-*O*-α-D-glucopyranosyl-D-glucopyranosyl) and α-D-galactopyranosyl groups. In agreement with these results, the polysaccharide was precipitated by concanavalin A. From the combined results it was suggested (4) that the polysaccharide is composed of pentasaccharide repeating-units in which kojibiose and D-galactose are linked to a backbone of amino sugar residues. We now report further structural studies on this polysaccharide, in the following called S 12F.

Results and Discussion

In our preliminary studies crude S 12F was purified by chromatography on a concanavalin A – Sepharose column (3). The purified samples contained the sugars listed above but also some 2-amino-2-deoxy-D-glucose, indicating that the material was not quite pure. As the structural studies gave results which were difficult to interpret, we eventually concluded that S 12F contains a further component. This was subsequently identified as 2-acetamido-2-deoxy-D-mannuronic acid (see below). Having established this, the material was purified by chromatography on a DEAE–Sepharose column. Only traces of 2-amino-2-deoxy-D-glucose were obtained on acid hydrolysis of this material, which showed $[\alpha]_{578}$ − 2°.

In the sugar analyses of S 12F and modified polysaccharides prepared from S 12F, the best yield of monomers was obtained when the hydrolysis was performed with 4 *M* hydrochloric acid at 100°C for 2 h. When the hydrolysate from S 12F was reduced with sodium borohydride, acetylated, and analysed by glc, the alditol acetates of D-glucose, D-galactose, 2-amino-2,6-dideoxy-L-ga-

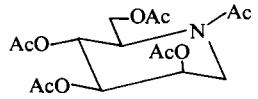
lactose, 2-amino-2-deoxy-D-galactose, and a further component were obtained in the proportions 1.9:1.0:0.9:1.2:0.6 (f.i. detector response). The latter component was identified as fully acetylated 1,5-dideoxy-1,5-imino-D-mannitol (**1**). The identification of **1** and its mode of formation will be discussed in a separate communication. When the hydrolysate was *N*-acetylated before the borohydride reduction, no **1** was formed but the alditol acetate of 2-amino-2-deoxy-D-mannose was obtained. The ratio between this component and 2-acetamido-2-deoxy-D-galactitol was 0.7. The results indicate that the hydrolysate contains a lactone of 2-amino-2-deoxy-mannuronic acid. The alditol acetates of 2-amino-2-deoxy-D-glucose, -D-galactose, and -D-mannose were well separated by glc on SP-1000 or SE-30 glass capillary columns. The absolute configurations of the amino sugars were established using the method of Gerwig *et al.* (5) and that of the neutral sugars using the method of Leontein *et al.* (6).



1

The presence of 2-amino-2-deoxy-D-mannuronic acid in the hydrolysate of S 12F was also indicated by paper electrophoresis in molybdate buffer at pH 5 (7). This acid is well separated from the *gluco*- and *galacto*-isomers in this system.

S 12F proved to be resistant to carboxyl reduction according to Taylor *et al.* (8). A product which had been subjected to several reductions yielded on acid hydrolysis only traces of 2-amino-2-deoxy-D-mannose. Modified S 12F, in which the side-chains had been selectively split off, (see below) was easier to reduce, and 2-amino-2-deoxy-D-mannose was identified in the hydrolysate of this material.

The ^{1}Hmr spectrum of S 12F showed, *inter alia*, signals for the methyl protons of the 2-acetamido-2,6-dideoxy-L-galactosyl residue at δ 1.24, $J_{5,6} \sim 5$ Hz (3H), for the methyl protons of three acetamido groups at δ 2.02 (s, 6H) and δ 2.14 (s, 3H), and for the anomeric protons at δ 5.26, $J_{1,2} \sim 2$ Hz (2H) and δ 5.42, $J_{1,2} \sim 2$ Hz (1H). The signals for the other anomeric protons, which were not well resolved, appeared at higher fields (δ < 5).

The ^{13}Cmr spectrum of S 12F showed, *inter alia*, signals for C-6 of the 2-acetamido-2,6-dideoxy-L-galactosyl residue at δ 17.9, for the methyl carbons of *N*-acetyl groups at δ 24.3 (3C), for C-2 of the three amino sugar residues at δ 50.5, 53.7, and 54.1, for unsubstituted C-6 of hexosyl residues at δ ≃ 63 (4C), for one anomeric carbon at δ 97.4, and for five anomeric carbons at δ ≃ 101.5 (not well resolved).

The above results, in conjunction with those from previous studies, indicate that S 12F is composed of hexasaccharide repeating-units, containing two residues of D-glucose and one residue each of D-galactose, 2-acetamido-2,6-dideoxy-L-galactose, 2-acetamido-2-deoxy-D-galactose, and 2-acetamido-2-deoxy-D-mannuronic acid. Further the ^{13}Cmr data also imply that all sugar residues are pyranosidic.

Methylation analysis of S 12F and analysis of the sugars as the alditol acetates (9, 10) (Table 1, column A) confirmed the presence of terminal D-glucopyranosyl and D-galactopyranosyl groups and of 2-linked D-glucopyranosyl residues. The analysis further demonstrated that the 2-acetamido-2,6-dideoxy-L-galactopyranosyl residue is linked through *O*-3 and *O*-4 and that the 2-acetamido-2-deoxy-D-galactopyranosyl residue is linked through *O*-3. No derivative of the 2-acetamido-2-deoxy-D-mannopyranosyluronic acid residue was obtained in this analysis. As the above ethers correspond to two terminals but only to one branching point, the latter sugar should also represent a branching point and be linked through *O*-3 and *O*-4, the only positions available.

The methylation analysis indicates that the D-glucose and D-galactose residues in S 12F, but not the amino sugar residues, should be oxidized by periodate. S 12F was therefore subjected to a Smith degradation (11), i.e. periodate oxidation, borohydride reduction, and mild acid hydrolysis. Methylation analysis of the product (Table 1, column B) showed that the 2-acetamido-2,6-dideoxy-L-galactopyranosyl residues are linked through *O*-4 and confirms that the 2-acetamido-2-deoxy-D-galactopyranosyl residues are linked through *O*-3. Carboxyl reduction of this material yielded a product $[\alpha]_{578}$ −36°, which on hydrolysis yielded 2-amino-2,6-dideoxy-L-galactose, 2-amino-2-deoxy-D-galactose and 2-amino-2-deoxy-D-mannose in the proportions 0.95:1.0:0.64. Nitrous acid deamination (12) of the hydrolysate and conversion of the products to alditol acetates yielded 2,5-anhydro-D-talitol, 2,5-anhydro-6-deoxy-L-talitol, and D-glucose. These compounds derive from D-galactosamine, L-fucosamine, and D-mannosamine, respectively (13). Methylation analysis (Table 1, column C) demonstrated that the 2-acetamido-2-deoxy-D-mannopyranosyluronic acid residue in the degraded product is linked through *O*-4. The amino sugars in S 12F consequently form a linear backbone and the side chains, D-galactopyranosyl and kojibiosyl groups, are linked to the 3-positions of the 2-acetamido-

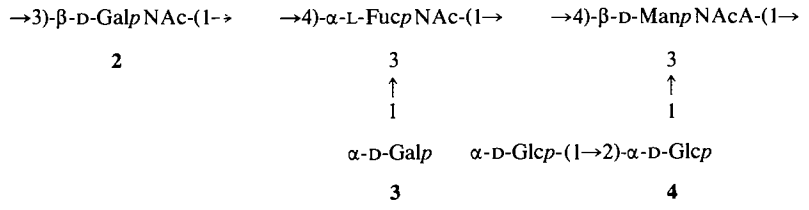
2,6-dideoxy-L-galactopyranosyl and the 2-acetamido-2-deoxy-D-mannopyranosyluronic acid residues, respectively. In the ^{1}Hmr spectrum of the degraded product signals at δ 1.22 (3H), δ 2.02 (6H), and δ 2.10 (3H) confirmed the presence of one 6-deoxysugar and three *N*-acetyl groups. The three low-field signals for anomeric protons in the spectrum of unmodified S 12F had disappeared but the poorly resolved signals at higher fields (δ < 5) remained. This result therefore indicates that the D-glucopyranosyl and D-galactopyranosyl residues are α-linked. In the ^{13}Cmr the C-2 signals of the three acetamidosugars appeared at δ 52.1, 53.5, and 54.2. The anomeric carbons appeared at δ ≃ 101. The signal at δ 97.4 in the spectrum of unmodified S 12F most probably derives from the 2-substituted α-D-glucopyranosyl residue of the kojibiose side chain.

The product from the Smith degradation was carboxyl reduced, acetylated and treated with chromium trioxide in acetic acid (10, 14). The β-linked sugar residues should be oxidized but not the α-linked residues. Sugar analysis of the product showed that the 2-acetamido-2,6-dideoxy-L-galactopyranosyl residues had survived this treatment. These residues are consequently α-linked and the other sugar residues β-linked.

The terminal α-D-galactopyranosyl group with a pair of *cis*-oriented vicinal hydroxyl groups is oxidized more readily by periodate than the kojibiose residue. It was therefore possible to remove the α-D-galactopyranosyl group selectively by a Smith degradation, in which the periodate oxidation was performed under mild conditions. Methylation analysis of this material (Table 1, column D), showed that the α-D-galactopyranosyl group in the original S 12F is linked to *O*-3 of the 2-acetamido-2,6-dideoxy-L-galactopyranosyl residue. The results therefore demonstrate the presence of the structural elements **2**, **3**, and **4** in S 12F.



In order to establish the sequence of the three elements, S 12F was treated with liquid hydrogen fluoride. This reagent cleaves glycosidic linkages but leaves amide linkages intact (15). The hydrolysed product of S 12F contained D-glucose, D-galactose, and 2-acetamido-2,6-dideoxy-L-galactose as the only monomeric sugars. In addition an acidic disaccharide was isolated by gel filtration and ion exchange chromatography. Sugar analysis of this disaccharide revealed that it was not pure, but 2-acetamido-2-deoxy-D-galactose and 2-acetamido-2-deoxy-D-mannuronic acid (as **1**) were the main components.

The product was reduced with sodium borodeuteride, methylated, and investigated by glc–ms (16). The spectrum of the main component demonstrated that it derived from a pseudoaldobiouronic acid in which both the aldehyde group and the carboxyl group had been reduced. The material was hydrolysed and transformed into alditol acetates. 2-Deoxy-3,4,6-tri-*O*-methyl-2-*N*-methylacetamido-D-galactose and a 2-deoxy-3,5,6-tri-*O*-methyl-2-*N*-methylacetamido-D-mannitol, deuterium labelled at C-1 and C-6, were obtained. The latter compound was formed by demethylation of the corresponding 1-*O*-methyl ether during the hydrolysis (17). These results, in conjunction with other evidence discussed above, show that the pseudoaldobiouronic acid has structure **5** and the reduced

5

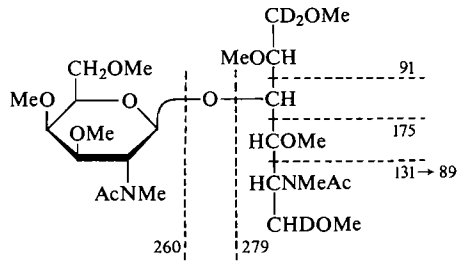
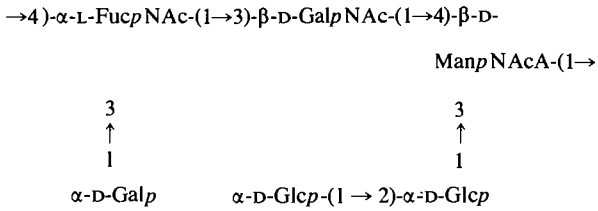
and methylated product structure **6**. (The origin of some pertinent fragments is indicated in the formula.) The identification of **5** defines the sequence of



6

the sugar residues in S 12F, the hexasaccharide repeating unit of which has the structure **7**.

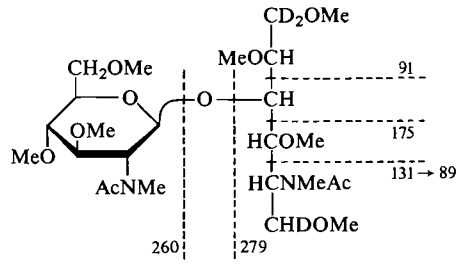


7

The capsular polysaccharide from *Haemophilus influenzae* type e, strain NCTC 8455, is composed of disaccharide repeating units (**8**) (18). The main

8

product formed on treatment of this polysaccharide with hydrogen fluoride, followed by aqueous acetic acid, reduction with sodium borodeuteride, and methylation, gave a mass spectrum which was superimposable with that of **6**. It thus has structure **9** and the only difference between this substance



9

and **6** is that the glycosyl group has the D-*gluco* configuration in the former and the D-*galacto* configuration in the latter. The results are consequently analogous for the two polysaccharides. A pseudoaldobiouronic acid derivative is selectively formed on treatment with hydrogen fluoride. On treatment of this product with sodium borohydride, not only the aldehyde group but also the carboxyl group is reduced. These unexpected results merit further studies.

Experimental

For glc, Perkin-Elmer 990 or Hewlett-Packard 5830 A instruments equipped with flame-ionization detectors were used. Separations were performed on glass columns (180 × 0.15 cm, with 100/120 mesh Gas Chrom Q as support material) containing 3% OV-225 or 3% OV-17 (for alditol acetates, partially methylated alditol acetates, and oligosaccharide derivatives). Some separations of alditol acetates, silylated butyl glycosides (5), and acetylated octyl glycosides (6) were performed on SP-1000 or SE-30 glass capillary columns (0.25 mm × 25 m). The alditol acetates of 2-amino-2-deoxy-D-glucose, -D-mannose, and -D-galactose showed T = 3.3, 4.0, 3.9 (retention time relative to glucitol hexaacetate) and T = 1.8, 1.9, 2.0 on SP-1000 (230°C) and SE-30 (170°C) columns, respectively. The glc–ms measurements were performed with a Varian MAT 311-SS 100 ms-computer system fitted with the appropriate glc columns. For nmr a JEOL FX-100 instrument operated in the PFT-mode was used. The spectra were recorded in D_2O at 85°C. Chemical shifts are given in ppm relative to external tetramethylsilane (^{13}C) or internal sodium 1,1,2,2,3,3-hexadeuterio-4,4-dimethyl-4-silapentane-1-sulfonate (^1H), respectively. For treatment with hydrogen fluoride an apparatus (Type II) from Peninsula Laboratories, Inc., P.O. Box 1111, San Carlos, CA 94070, U.S.A. was used.

Purification of the Polysaccharide

Crude polysaccharide samples were obtained from Professor Michael Heidelberger (New York) and Dr D. J. Carlo (New Jersey). Crude material (80 mg) was dialysed, freeze-dried, and dissolved in water (72 mg, 3 mL), applied to a column (1.0 × 40 cm) of DEAE – Sepharose CL 6B and washed with water (200 mL), followed by a linear gradient of ammonium hydrogen carbonate (0–1 M). The separation was monitored with phenol – sulfuric acid assay. S 12F was eluted at a salt concentration of approximately 0.2 M and recovered by freeze-drying. The polysaccharide (66 mg) had $[\alpha]_{578}$ −2° (c 0.6, water) and contained only traces of sulphur and phosphorus.

Sugar and Methylation Analyses

Sugar analyses were performed by hydrolysis of polysaccharide samples (1 mg) for 2 h at 100°C with 4 M aqueous hydrochloric acid. The hydrolysate was concentrated to dryness and codistilled with methanol (3 × 3 mL). The sugars were then transformed into alditol acetates and analysed by glc (19) and glc–ms (20). The acetate of compound **1** showed T_{Glc} = 1.35 (retention time relative to glucitol hexaacetate on an OV-17 column at 180°C). The mass spectrum of this compound was superimposable on that of acetylated deoxynojirimycin (the *gluco*-analog of **1**, see ref 21), and showed, *inter alia*, peaks at *m/e* (relative intensities in brackets): 96(100), 110(12), 138(82), 152(19), 180(19), 198(12), 212(6), 240(16), 254(16), and 313(6). Sugar analysis including deamination was performed essentially as described elsewhere (12). Methylation analyses were performed as described elsewhere (9), except that the hydrolysis steps were performed as described above. Electrophoresis in molybdate buffer (pH 5.0) was performed as described by Mayer and Westphal (7). 2-Amino-2-deoxy-D-mannuronic acid showed M_{Man} = 0.79 (migration relative to mannitol), (lit. (7) M_{Man} = 0.78).

Carboxyl Reduction

Attempted carboxyl reduction of original S 12F and of Smith degraded S 12F (see below) was performed as described elsewhere (8) except that the reaction mixture was not heated during the treatment with sodium borohydride.

Smith Degradation of S 12F

S 12F (30 mg) was dissolved in 0.1 *M* sodium acetate buffer (pH 3.9, 24 mL), and sodium metaperiodate (350 mg) in the same buffer (8 mL) was added. The solution was kept in the dark at 6°C for 192 h. Excess of sodium metaperiodate was reduced by addition of ethylene glycol (2 mL), the mixture was dialysed and concentrated to 20 mL, and sodium borohydride (160 mg) was added. After stirring for 6 h at room temperature, excess of borohydride was decomposed by adding 50% acetic acid, and the solution was dialysed and freeze-dried (27 mg). Sugar analysis of part of the material (1 mg) showed that only trace amounts of D-galactose and D-glucose remained. The remaining material was hydrolysed under mild conditions (0.5 *M* trifluoroacetic acid, 8 h, room temperature), neutralized with 0.1 *M* sodium hydroxide, dialysed, and freeze-dried. The product (18 mg) showed $[\alpha]_{578}^{25}$ −33° (*c* 0.2, water). Part (2 mg) of the product was subjected to methylation analysis (Table 1, column B). Another part (10 mg) was subjected to carboxyl reduction (3 treatments). The carboxyl-reduced product (7 mg) showed $[\alpha]_{578}^{25}$ −36° (*c* 0.3, water). Part (2 mg) of this material was subjected to methylation analysis (Table 1, column C), part (1 mg) to sugar analysis (see text), and part (1 mg) to sugar analysis including deamination (see text). Another part (3 mg) was dissolved in formamide (4 mL) and acetylated using acetic anhydride (2 mL) and pyridine (2 mL). After work-up by dialysis and freeze-drying, the procedure was repeated once and the acetylated polysaccharide (3 mg) was subjected to chromium trioxide oxidation as described earlier (14). The oxidized material was subjected to sugar analysis; essentially all 2-amino-2,6-di-deoxy-L-galactose was recovered but only traces of 2-amino-2-deoxy-D-mannose and 2-amino-2-deoxy-D-galactose were detected.

Modified Smith Degradation

S 12F (32 mg) was dissolved in water (48 mL) and sodium metaperiodate (274 mg) in water (16 mL) was added. The solution was kept in the dark at 6°C for 1 h and processed as described above. Sugar analysis of the polyalcohol showed less than 15% of the original D-galactose remained. The modified polysaccharide (31 mg) recovered after mild acidic hydrolysis showed $[\alpha]_{578}$ −26° (*c* 0.4, water). A sample (2 mg) was subjected to methylation analysis (Table 1, column D).

Treatment of S 12F with Hydrogen Fluoride

S 12F (30 mg) was treated with liquid hydrogen fluoride (6 mL). After 1 h at room temperature the hydrogen fluoride was evaporated at reduced pressure and the residue was treated with 5% aqueous acetic acid for 16 h at room temperature. The solution was concentrated to dryness and the monomeric sugars were analysed by sodium borohydride reduction, acetylation, and glc. The product was fractionated on a column of Sephadex G-15 (1.5 × 60 cm) and eluted with water. The material eluted in the disaccharide region was further enriched on a DEAE – Sepharose CL 6B column (1.0 × 20 cm) which was irrigated first with water and then with 0.5 *M* ammonium hydrogen carbonate. Part (~2 mg) of this material was used for sugar analysis.

Another sample (20 mg) of S 12F was treated in the same manner with liquid hydrogen fluoride and aqueous acetic acid. The product was reduced with sodium borodeuteride and methylated. Compound **6** showed $T_{\text{Chitobiitol}}$ = 1.01 (retention time relative to methylated chitobiitol on an OV-17 column at 230°C). The mass spectrum of this compound showed, *inter alia*, peaks at *m/e* (relative intensities in brackets and some assignments (16) in square brackets): 89(100), 91(22), 101(80), 129(57) [H], 131(51), 175(19), 228(35) [aA_2], 260(42) [aA_1], 279(40) [bA_1]. The degradation and analysis of *Haemophilus influenzae* type e polysaccharide was performed as described above for S 12F. Compound **9** showed $T_{\text{Chitobiitol}}$ = 0.91.

Acknowledgments

We thank Professor Michael Heidelberger for his interest, and, together with Dr. D. J. Carlo, for generous gifts of polysaccharide material. Professor Hans Paulsen kindly supplied a sample of deoxynojirimycin. The expert assistance of Miss Viveka Eriksson and Mrs. Helena Liedgren is gratefully acknowledged. This work was supported by grants from the Swedish Natural Science Research Council, The Swedish Medical Research Council (B79-03X-02522-11C), and Stiftelsen Sigurd och Elsa Goljes Minne.

The synthesis and characterization of α- and β-L-fucopyranosyl phosphates and GDP fucose[1]

HERNAN A. NUNEZ, JOHN V. O'CONNOR,[2] PAUL R. ROSEVEAR, AND ROBERT BARKER[3]

Department of Biochemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

Received November 25, 1980

HERNAN A. NUNEZ, JOHN V. O'CONNOR, PAUL R. ROSEVEAR, and ROBERT BARKER. Can. J. Chem. **59**, 2086 (1981).

Guanosine diphosphate fucose (GDPFuc) has been synthesized chemically in an overall yield of 40% from fucose. This synthesis was made possible by increasing the yield of the key intermediate, β-L-fucopyranosyl phosphate, five-fold over that previously reported (Prihar and Behrman. Biochemistry, **12**, 997 (1973)), by utilizing guanosine 5′-phosphoric di-*n*-butylphosphinothioic anhydride (Furusawa *et al.* J. Chem. Soc. Perkin Trans I, 171 (1976)) or GMP morpholdate for the synthesis of GDPFuc, and by improving the method of isolating intermediates and the final product. At pH 3, GDPFuc is degraded to GDP with a half-life of 7 h at 37°C and 52 h at 4°C. At pH values between 5 and 8, less than 10% is degraded after 7 days. Neither 20 m*M* Mn^{2+} nor Mg^{2+} in 0.2 *M* PIPES buffer at pH 7.5 stimulate the hydrolysis of GDPFuc. Heteronuclear, C–P and H–P coupling constants indicate that the preferential position of the phosphate moiety in both β-L-fucopyranosyl phosphate and GDPFuc is *trans* to C-2. In the ribose moiety of GDPFuc, the 5′-phosphate is *trans* to C-4. The ^1H and ^{13}C nmr parameters of intermediates and products are reported.

HERNAN A. NUNEZ, JOHN V. O'CONNOR, PAUL R. ROSEVEAR et ROBERT BARKER. Can. J. Chem. **59**, 2086 (1981).

On a synthétisé chimiquement le fucose diphosphate de guanosine (FucDPG) avec un rendement global de 40% à partir du fucose. Cette synthèse a pu être réalisée en préparant l'intermédiaire principal, le phosphate de β-L-fucopyrannosyle, avec un rendement 5 fois supérieur à celui obtenu antérieurement (Prichar et Behrmann. Biochemistry, **12**, 997 (1973)); pour parvenir à cette fin, on utilise soit l'anhydride mixte de l'acide guanosine phosphorique-5′ et de la di-*n*-butylphosphinothioique (Furusawa *et al.* J. Chem. Soc. Perkin Trans. I, 171, (1976)) ou le morpholybdate de GMP pour la synthèse du FucDPG, et on améliore le mode de séparation des intermédiaires et du produit final. A un pH de 3, le FucDPG se dégrade en DPG dont la demi-vie est de 7 h à 37°C et de 52 h à 4°C. A des pH entre 5 et 8 moins de 10% du produit se dégrade après 7 jours. Ni le MN^{2+} à 20 m*M*, ni le Mg^{2+} dans un tampon de PIPES à 0,2 *M* à pH 7,5 ne stimule l'hydrolyse du FucDPG. Les constantes de couplage hétéronucléaire C–P et H–P indiquent que la position préférentielle de la portion phosphate dans le β-L-fucopyrannosyle et le FucDPG est celle où elle est *trans* par rapport à C-2. Dans la portion ribose du FucDPG, le phosphate-5′ est *trans* par rapport à C-4. On rapporte les donnés de la rmn du ^1H et du ^{13}C des intermédiaires et des produits.

[Traduit par le journal]

Introduction

Guanosine diphosphate fucose (GDPFuc)[4] is the substrate for the fucosyl transferases involved in the biosynthesis of blood group substances and other tissue antigens. The study of these important enzymes is limited by the lack of GDPFuc which is available commercially only in a radioactive form of relatively high specific activity. Previously GDPFuc has been synthesized enzymatically by two different methods. Starting with L-fucose, Heath and co-workers (1–3) described a synthesis using fucokinase and ATP to phosphorylate fucose yielding β-L-fucopyranosyl phosphate which, with guanosine triphosphate pyrophosphorylase and GTP, produces GDPFuc and inorganic pyrophosphate. Ginsburg (4) used an enzyme that reduces the C6 hydroxymethyl of GDPMan to a methyl group, and epimerizes the C3 and C5 positions to convert the α-D-mannopyranosyl moiety to a β-L-fucopyranosyl moiety. Although the enzymatic methods are efficient, purification of the enzymes is difficult. Only small amounts of GDPFuc have been prepared and the products have not been fully characterized.

The chemical synthesis of many nucleotide diphosphate sugars has been achieved by condensation of an activated nucleoside monophosphate and the appropriate glycosyl phosphate (5). However, chemical synthesis of GDPFuc has not been described, probably because β-L-fucopyranosyl phosphate is difficult to prepare and is much more acid labile than most glycosyl phosphates (6).

Behrman and co-workers have reported the synthesis of β-L-fucopyranosyl phosphate in 10% yield from L-fucose by condensation of 2,3,4-tri-*o*-acetyl-β-fucopyranose with *o*-phenylene-

phosphochloridate (7) and in 20% yield from L-fucose orthoacetates (8). Khwaja and Reese (9, 10) and Khwaja *et al.* (11), who developed the phosphorylating reagent used by Prihar and Behrman (7), reported much higher yields of other phosphates that are at least as labile as fucopyranosyl phosphate. Prihar and Behrman (7) used Br_2–H_2O to oxidize the phosphodiester although Khwaja *et al.* (11) had suggested four additional ways of removing the protecting group: hydrogenolysis, periodic acid oxidation, hydrolysis with snake venom phosphodiesterase, and lead tetraacetate oxidation. With the possible exception of periodic acid, these reagents are milder than Br_2–H_2O.

Shibaev *et al.* (12, 13) reported the synthesis of β-L-rhamnopyranosyl phosphate (6-deoxy-β-L-mannopyranosyl phosphate) and 4,6-dideoxy-α- and β-L-lyxopyranosyl phosphate in 50–70% yields using lead tetraacetate to oxidize the *o*-phenylene group. These compounds, especially the *rhamno*-derivative, should be as labile as the *fuco*-derivative because of the methyl group at C6 and the axial hydroxyl group at C2.

In this paper, we describe improved methods for the preparation of β-L-fucopyranosyl phosphate, and from it, of GDPFuc in 40 percent overall yield based on L-fucose. The method is as efficient as the enzymatic methods and is suitable for the preparation of millimolar amounts and for the preparation of isotopically enriched products.

Experimental

GMP and L-fucose were purchased from Sigma, (1-^{14}C)-L-fucose was purchased from New England Nuclear, and *o*-phenylene phosphochloridate was purchased from Aldrich. Silver carbonate was prepared by the method of McCloskey and Coleman (14). Freshly prepared silver carbonate can be kept, in the dark, as a dispersion in the reaction mixture for several hours. Immediately before use, a portion is removed with a wide-bore pipet and filtered on a sintered glass filter in a darkened area. The precipitate is washed on the filter with acetone until, on air drying, it gives a bright yellow powder. This powder forms a fine dipersion when added to reaction mixtures. Di-*n*-butylphosphinothioyl bromide was prepared by the method of Furusawa *et al.* (15), and used immediately. Guanosine 5′-phosphoromorpholidate was prepared according to Moffat (5). All other reagents were ACS Reagent grade or better. Pyridine was boiled under reflux over calcium hydride, distilled, and stored over calcium hydride. Molecular sieves (4 Å, Fisher Scientific) were added to tetrahydrofuran at least 12 h prior to its use in the phosphorylation step.

Thin layer chromatography was performed on Silica gel G plates (250 μM Fisher Scientific). The plates were developed with hexane–ethylacetate (1:1, v/v) and spots were detected by spraying with 2 *N* sulfuric acid and charring. Gas chromatography separations were performed on a 2 m × 3 mm id glass column of HiEFF-3CP (10% on Gas-Chrom Q, 80–100 mesh, Applied Science Laboratories, Inc.). Tetramethylsilyl derivatives of samples were prepared with the standard mixture used by Sweeley *et al.* (16) (hexamethyldisilazene–trimethylchlorosilane–pyridine, 4:1:10, v/v/v). High pressure liquid chromatography was performed on a Partisil-10 SAX column (4.6 mm × 2.5 cm, Anspec, Inc.) in 0.2 *M* potassium phosphate, pH 3.4, at 500 psi.

Paper electrophoresis was performed on Whatman 40 paper in 0.05 *M* TEAB, pH 7.5, for 50 min at 43 V/cm. Picric acid and caffeine were used as standards.

The ^{13}C nmr spectra were obtained on a Bruker WP-60, equipped for Fourier transform operation with quatrature detection, operating at 15.08 MHz, a sweep width of 3000 Hz with 4096 data points and broad band proton decoupling. Probe temperature was 38° ± 1°C. Resonances are reported in ppm from tetramethylsilane. The ^{1}H nmr spectra were obtained either on a Varian HA-100 or on a Bruker WH-180 equipped for Fourier transform operation using sweep width of 1800 Hz and 16K data points. Chemical shifts in D_2O are reported in ppm downfield from internal sodium 3-(trimethylsilyl)-1-propanesulfonate; in deuterochloroform from TMS.

L-Fucopyranosyl Tetraacetates (I)

L-Fucose (5 g, 30.5 mmol) was dissolved in 50 mL of dry pyridine, 35 mL acetic anhydride was added, and the reaction mixture was stored at 4°C for 12 h, at which time 9 mL of water was added. After the reaction mixture was cool (1 h), the volume was reduced to 40 mL *in vacuo* at 40°C and 200 mL of water was added. The solution was extracted with four 100-mL portions of chloroform. The combined chloroform washings were extracted three times with 100 mL of cold 2 *N* H_2SO_4 until the water layer was strongly acidic, and then twice with 100 mL of cold saturated $NaHCO_3$, and once with 100 mL of water. The chloroform layer was dried over calcium chloride for 2 h and evaporated to a thick syrup (11 g, 100%). The tetraacetate gives one spot, R_f = 0.8 on tlc; glc using a temperature program of 180–240°C at 4°/min shows two components corresponding to α:β pyranosyl acetates in the ratio 3:1.

2,3,4-Tri-O-acetyl-α-L-fucopyranosyl Bromide (II)

To a stirred solution of a mixture of α- and β-fucopyranosylacetates (5 g, 15.05 mmol) dissolved in 10 mL of glacial acetic acid, 15 mL of 31–32% HBr in glacial acetic acid was added at 22°C. Stirring was continued for 20 min and then the straw-colored solution was dissolved in 100 mL dichloromethane and extracted twice with 100 mL ice water, with 100 mL of cold 1 *M* $NaHCO_3$, and again with 100 mL of water. The organic layer was dried over powdered anhydrous sodium sulfate for 2 h, filtered, and evaporated *in vacuo* to a light yellow syrup which was stored in a vacuum desiccator over P_2O_5. The yield is essentially quantitative (5.2 g, 14.7 mmol). On tlc, the product gives a single spot R_f = 0.88. The ^{13}C nmr spectrum of the syrup in deuterochloroform has a resonance at 89.8 ppm in the anomeric region corresponding to C1 of α-L-fucopyranosyl bromide.

2,3,4-Tri-O-acetyl-α- and β-L-fucopyranoses (III)

The syrupy acetobromofucose (5.0 g, 14.1 mmol) was dissolved in 27 mL of acetone containing 0.7 mL of water and the solution was cooled to 0°C. Freshly prepared silver carbonate (4 g, 14.5 mmol) was added. The reaction was stirred vigorously for 15 min in the dark, filtered through a sintered glass funnel, washed with acetone, and the combined filtrate and washings evaporated to a syrup (4.4 g, 100%). At this stage more than 95% of the mixture is the β-anomer as determined by glc of the TMS derivatives and by ^{13}C nmr spectroscopy. Separation of the anomers is not necessary for the phosphorylation step since the α and β phosphates can be separated as indicated below. Drying

is, however, necessary prior to phosphorylation. To obtain high yields of the β phosphate the syrup should be dried *in vacuo* over P_2O_5 for no longer than 3 h at 22°C. Drying for 24 h gives a mixture containing up to 50% of the α-anomer.

For characterization, the anomeric triacetates were separated by fractional crystallization. The β-anomer was obtained by dissolving the syrup (10 g) in dry diethyl ether (12 mL) and storing the solution at 4°C for 4 h. The crystals were separated by filtration, washed with dry ether, and dried in a desiccator over P_2O_5; mp 121°C; $[\alpha]_{578}^{22}$ −16.8° ± 0.5 (*c* 1, dry ethanol); Prihar and Behrman (7) reported $[\alpha]_D^{22}$ −5.8° for the anomer obtained by this method.

The filtrate from the β-anomer, containing approximately equal amounts of the α- and β-anomers, was treated with a trace of water and stored in a hood for a week. Trituration of the residual syrup with ether and cooling at 6°C for 12 h gave the crystalline 2,3,4-tri-*O*-acetyl-α-L-fucopyranose; mp 103°C; $[\alpha]_{578}^{22}$ −125° ± 1; (*c* 1, dry ethanol); Prihar and Behrman (7) reported $[\alpha]_D^{22}$ −118°; nmr parameters of both anomers are listed in Tables 1 and 2.

α- and β-L-Fucopyranosyl Phosphates (IV)

The 2,3,4-tri-*O*-acetyl-α- and β-fucopyranoses (3 g, 10.3 mmol) dried for no more than 3 h *in vacuo* over P_2O_5 were dissolved in 80 mL of dry tetrahydrofuran. The solution was added gradually (5 min) under anhydrous conditions to a stirred and efficiently cooled (0°C) solution of *o*-phenylene phosphochloridate (freshly distilled at 110°C and 5 Torr; 6.0 g, 32 mmol) and 5 mL of dry *s*-collidine in 100 mL of dry tetrahydrofuran (6, 10). After the addition was complete, stirring was continued for 30 min at 0°C and then the collidinium chloride was removed rapidly by filtration on a sintered glass funnel. Water (1.24 mL) and collidine (5 mL) were added to the cold filtrate. After stirring for 30 min at 22°C, the reaction mixture was cooled to 0°C and filtered. The tetrahydrofuran was removed *in vacuo*. If additional precipitate formed during this manipulation, the mixture was taken up in dry tetrahydrofuran and filtered. After removal of tetrahydrofuran, the residual syrup was dried over magnesium perchlorate under high vacuum for 12 h. The syrup was dissolved in 80 mL of dry dioxane and cooled to 12°C. Lead tetraacetate (13.0 g, 30 mmol) was added with vigorous stirring. The dark brown solution was stirred at 22°C for 30 min and then tested for the presence of lead tetraacetate using a qualitative starch–iodide test. If the test was negative, an additional 1 g of lead tetraacetate was added. After a positive lead tetraacetate reaction had been obtained for 30 min, the solution was added dropwise with stirring to 300 mL of cold 1 *N* NaOH (300 mequiv.) and the reaction mixture stored at 22°C for 2 h. light-brown reaction mixture was cooled in an ice bath, and adjusted to pH 4 with Dowex 50 H^+ (20–50 mesh). The mixture was filtered on a coarse sintered glass funnel and the filtrate adjusted immediately to pH 7.5 with 1 *N* NaOH. The resin was transferred to a beaker, 100 mL of water added, and the mixture sitrred and adjusted to pH 4 with Dowex 50 (H^+) if necessary. The mixture was filtered and the filtrate adjusted to pH 7.5 with 1 *N* NaOH. The combined filtrates were centrifuged for 20 min at 20 000 g. The supernatant, obtained by decantation, was diluted to 4 L with water and applied to a Dowex 1-(HCO_3^-) column (200–400 mesh, 4.5 × 100 cm). The column was developed with a linear gradient of 4 L of 0.05 *M* TEAB buffer and 4 L of 0.3 *M* TEAB buffer, pH 7.5. The eluent was monitored for radioactivity or for acid-labile organic phosphate. α-L-Fucopyranosyl phosphate is eluted at 0.22 *M* TEAB, the β-anomer is eluted at 0.24 *M* TEAB, and a third component, fucose 2-phosphate is eluted with 0.26 *M* TEAB. The fractions containing the β-anomer were pooled and evaporated to a thick syrup. The syrup was dissolved in water and evaporated three times to remove triethylammonium bicarbonate, leaving the triethylammonium salt of the product which can be used for analysis and GDPFuc synthesis. To obtain the cyclohexylammonium salt the product was dissolved in water and 1 mL of cyclohexylamine was added. The solution was evaporated three more times from water to remove triethylamine. The residual white solid was dissolved in warm ethanol and an equal volume of acetone was added in portions over a period of 2 days. The crystalline material was removed by filtration, washed with cold acetone, and dried over P_2O_5 (2.8 g, 50%). The material has $[\alpha]_{578}^{22} -19.4° \pm 1.0$ (*c* 1, water). Prihar and Behrman (7) report $[\alpha]_D^{25} -20.5°$.

*Guanosine 5-Phosphoric Di-*n*-butylphosphinothioic Anhydride*

GMP disodium salt (0.93 g, 2 mmol) was dissolved in 100 mL of water and the solution was adjusted to approximately pH 2.0 with Dowex 50 (H^+). The resin was removed by filtration and washed with water. The acidic filtrate and washings were applied to a 2.8 × 45 cm column of Dower 50 (H^+) which was eluted with 1.8 L of water. Pyridine (10 mL) was added to the acidic eluate and the resulting solution concentrated *in vacuo* to give the pyridinium salt of GMP which was dried by repeated evaporation from 30 mL portions of pyridine. After each evaporation, air was admitted to the apparatus slowly through a drying tube containing magnesium perchlorate to ensure the absence of moisture. Approximately 50 mL of dry *tert*-butanol was added followed by di-*n*-butylphosphinothioyl bromide (15) (1.8 g, 7.0 mmol) and tri-*n*-butylamine (1.5 g, 8 mmol). A clear solution forms after a few min at 35–40°C and the reaction is complete in 2 to 3 h at this temperature. *tert*-Butanol was removed *in vacuo*, 100 mL of water was added, and the excess di-*n*-butylphosphinothioyl bromide was extracted with ether. The water layer was concentrated *in vacuo* to 20 mL and stored at 4°C to produce crystals (white needles) which were removed by filtration, washed with cold water, and dried *in vacuo* over magnesium perchlorate; mp 154–155°C. The crystalline product is homogeneous by electrophoresis in 0.05 *M* triethylammonium bicarbonate, pH 7.5; $R_{GMP} = 0.25$ $\lambda_{max} = 256$ nm.

High pressure liquid chromatography was used to follow the course of this reaction. Samples (10 μL) were evaporated to dryness in a small test tube. The *tert*-butanol-free residue was dissolved in 0.2 *M* potassium phosphate buffer (pH 3.4) and applied to the hplc system. The retention times for GMP and GMP-di-*n*-butylphosphinothioic anhydride are 8.4 and 12.0 min, respectively, at a flow rate of 40 mL/h.

Guanosine Diphosphate Fucose

*A. Using Guanosine 5'-phosphoric Di-*n*-butylphosphiothioic Anhydride*

Dry monotriethylammonium-α-L-fucopyranosyl phosphate (0.5 mmol) and dry guanosine-5 phosphoric-di-*n*-butylphosphinothioic anhydride (0.5 mmol) were dissolved in 10 mL dry pyridine and evaporated to dryness *in vacuo* with care being taken to exclude moisture. Pyridine evaporation was repeated 3 times. The residue was dissolved in 10 mL of dry pyridine and 3.3 g (2 mmol) of dry silver acetate was added with stirring at 22°C. When the reaction was completed (3 to 5 h), 0.5 mL of water was added and the reaction was stirred to complete the hydrolysis of any unreacted di-*n*-butylphosphinothioic anhydride. The mixture was saturated with H_2S to precipitate silver sulfide. The precipitate was removed by filtration and washed with 50% water–pyridine. The filtrate and washings were diluted to 200 mL with water and applied to a 1.8 × 30 cm column of Dowex 1 (Cl^-) 200–400 mesh. The column was washed with 200 mL of water, then developed with a gradient of 0 to 0.4 *M* LiCl or NaCl using 4 L total of eluent. The eluent was monitored at 260 nm and fractions containing GDPFuc, which elutes at 0.2 *M* LiCl, were concentrated to approximately 5 mL and desalted on a 5 × 100 cm column of Bio-Gel P-2 (200–400 mesh), using water as the eluent. Yields based on apparent purity as judged from hplc and $E_{256}^M = 12.2 \times 10^3$ for GMP range from 50 to 80%, averaging 70%.

The course of the reaction was monitored by hplc using the system described above in which the GDPFuc has a retention time of 11.7 min. Samples (20 μL) were evaporated to dryness to remove pyridine, and the dark residue redissolved in buffer. The silver salt of GDPFuc seems to be less soluble in the reaction mixture than that of the di-*n*-butylphosphinothioic anhydride. Therefore, the apparent ratio of starting material to product depends on the amount of supernatant and precipitate in the sample taken for analysis.

B. Using Guanosine 5'-Phosphoromorpholidate

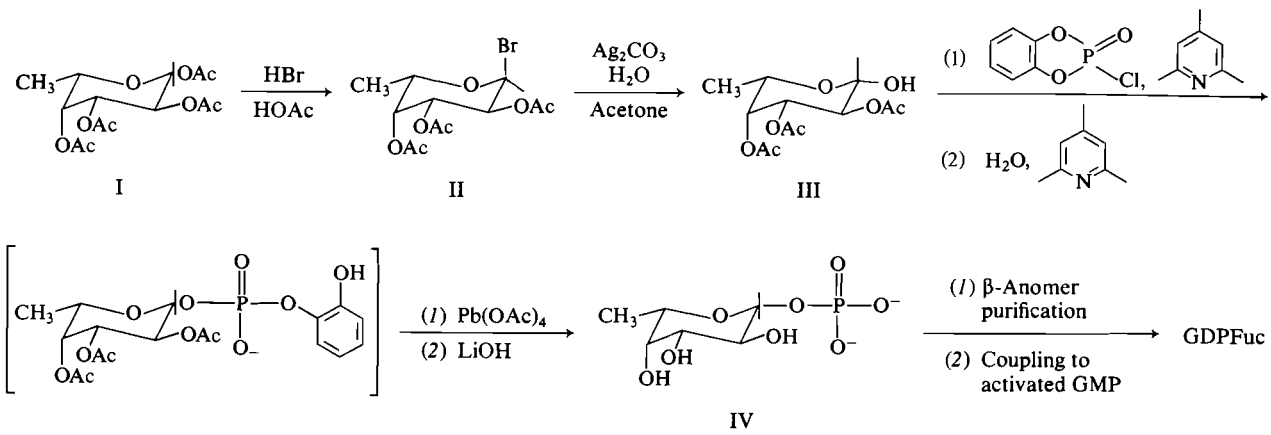
β-L-Fucopyranosyl phosphate bistriethylammonium salt (IV) (195 mg, 0.5 mmol) was dissolved in 10 mL of pyridine and the pyridine evaporated under reduced pressure at 30°C. This process was repeated three times with care to allow only dry air ($CaCl_2$ drying tube) to enter the flask. GMP morpholidate (5) (400 mg, 0.5 mmol) was added. The mixture was evaporated to dryness from 10 mL dry pyridine and the process repeated three times to remove traces of moisture. Finally, the reaction mixture was redissolved in 10 mL dry pyridine, and stored at 22°C under anhydrous conditions. The reaction was monitored by paper electrophoresis ($R_{picrate}$; GMP morpholidate = 0.5, GDPFuc = 1.0, fucopyranosyl phosphate = 1.6) or hplc after removal of pyridine. After three days, the pyridine was removed *in vacuo* at 30°C and the residue was dissolved in 400 mL water and applied to a column of Dowex 1 (Cl^-) and eluted as described previously. Yield based on β-L-fucopyranosyl phosphate was variable and never exceeded 50%.

Results and Discussion

The reaction sequence for the synthesis of GDPFuc is shown in Scheme 1.

*The Synthesis and Characterization of 2,3,4-Tri-*O*-acetyl-α- and β-L-Fucopyranoses*

A mixture of the anomers of 2,3,4-tri-*O*-acetyl-L-fucopyranose is prepared readily in quantitative yield by hydrolysis of the acetobromofucose using silver carbonate as the catalyst. The product mixture contains mostly the β-anomer. The α-anomer can be increased up to 80% by allowing a syrup or a wet pyridine solution to stand at room temperature. Because of the mutarotation process, drying the syrup for the phosphorylation



SCHEME 1

step should be limited to two or three hours at 22°C when the β-anomer of the phosphate is desired. The melting points reported for the α- and β-triacetates in the Methods section differ from the values reported by Prihar and Behrman (7). We have assigned anomeric configurations on the basis of the ^{1}H and ^{13}C nmr spectra of the purified compounds. The ^{1}H nmr spectrum of 2,3,4-tri-*O*-acetyl-α-L-fucopyranose is shown in Fig. 1A. The coupling constants and chemical shifts assigned on the basis of a first order analysis are shown in the figure. In Fig. 1B, the spectrum of the same sample after addition of ^2H_2O is shown; in it the hydroxyl resonance at 3.67 ppm is absent, indicating complete exchange of deuterium for hydrogen. The resonance (due to H1) at 5.33 ppm is converted from a triplet to a doublet, since exchange with deuterium removes the coupling between H1 and OH. The doublet has $^3J_{H1-H2} = 3.5$ Hz, indicating a *gauche* arrangement between H1 and H2 (17). This is the arrangement present in α-L-fucopyranose in the $^1C_4$-conformation.

The ^{1}H nmr of 2,3,4-tri-*O*-acetyl-β-L-fucopyranose is shown in Fig. 2. Only the resonances due to H5, H6, and the OH of C1 are first order. On treatment with ^2H_2O the resonance of OH at 3.93 ppm disappears and the multiplet at 4.59 ppm is simplified, indicating that it is due to H1. The coupling constant $^3J_{H1-H2} = 8$ Hz, indicating a *trans* arrangement between H1 and H2, is consistent with this anomer being in the $^1C_4$ conformation as expected. Complete analysis of this spectrum was achieved by computer fitting using the ITRCEL program (18).

The ^{13}C nmr spectra of these compounds also support the anomeric assignment based on ^{1}H nmr. The C1 of the β-anomer resonates further downfield (95.6 ppm) than the α-anomer (90.4 ppm), similar to the anomeric resonances of the galactose analogs.[5] Specific rotations of the two compounds also support the assignments made here. The α-anomer has $[\alpha]_{578}^{22} -125 \pm 1°$ and the β-anomer has $[\alpha]_{578}^{22} -16.8 \pm 0.5$. The β-anomer mutarotates slowly (7 days) in absolute ethanol to give $[\alpha]_{578}^{22} -106.5 \pm 1°$, reflecting the expected greater stability of the α-anomer.

From these data, we conclude that the triacetate with mp 102–103°C is the α-anomer while that with mp 120–121°C is the β-anomer. The values reported by Prihar and Behrman (7) were, for α, mp 117°C, and for β, mp 102–103°C.

Formation of the o-*Hydroxyphenyl Phosphate Diester*

Traces of water interfere with the formation of the phosphodiester by hydrolyzing the phosphorylating reagent. For this reason the reagents were dried and a three-fold excess of *o*-phenylenephosphochloridate was used. (In the ^{13}C nmr spectrum of the reaction mixture the C1 resonance appears as a doublet at 97.5 ppm with $^2J_{P-C} = 5.2$ Hz, consistent with the formation of a β-L-phosphate.)

Tetrahydrofuran was the solvent of choice for this reaction because of its low boiling point and the low solubility of the collidinium chloride formed during the reaction. Dioxane and methylene chloride were not as satisfactory.

s-Collidine is the most satisfactory base for use in this reaction. Khwaja *et al.* (11) used triethylamine and 2,6-lutidine (2,6-dimethylpyridine) in addition to collidine in their preliminary studies with *o*-phenylenephosphochloridate. Prihar and Behrman (7) used triethylamine in attempts to phosphorylate 2,3,4,6-tetra-*O*-acetyl-β-D-mannopyranose with this reagent but found that no reaction occurred.

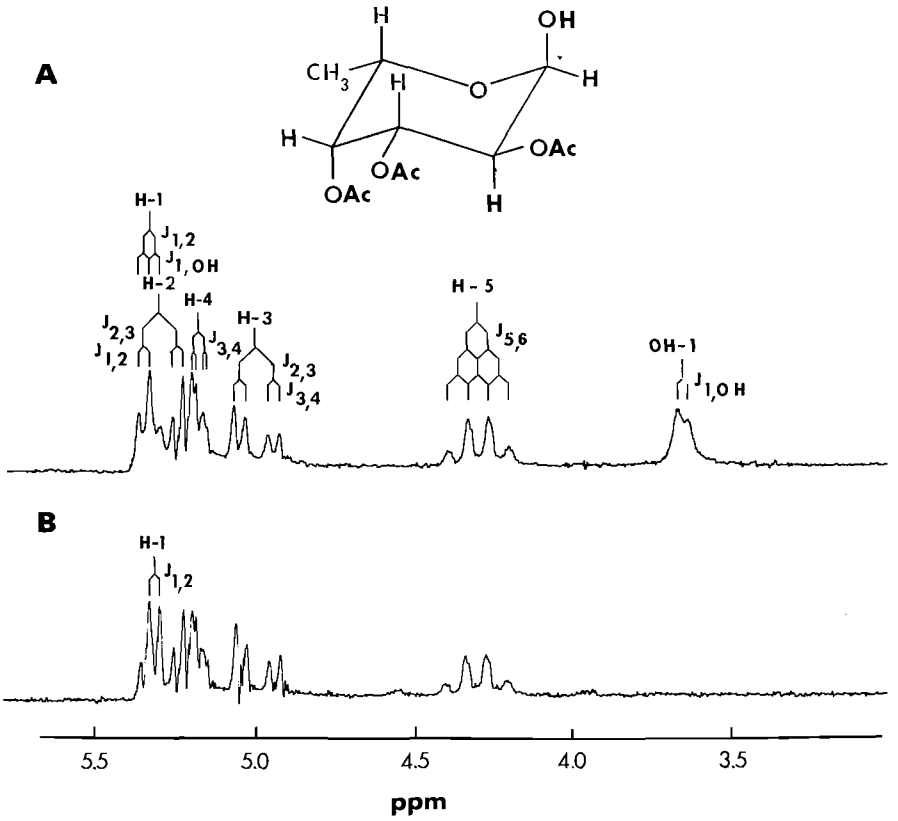

FIG. 1. The 100 MHz ^{1}H nmr spectrum of a 0.2 *M* solution of (A) 2,3,4-tri-*O*-acetyl-α-L-fucopyranose in $CDCl_3$, and (B) the same solution after treatment with D_2O to exchange the H of the OH group on C1. Chemical shifts are in ppm downfield from tetramethylsilane.

Lutidine is not satisfactory because the chloride is somewhat soluble in tetrahydrofuran.

Reaction time is also important. The formation of the phosphodiester bond is very fast at 4°C. Reaction times longer than 30 min at this or higher temperature result in the formation of a side product which seems to be a 1,2-orthoester formed at the expense of the β-phosphate triester intermediate.

Oxidation of the o-*Hydroxyphenyl Group*

At least three methods different from the lead tetraacetate used here for the oxidative removal of the *o*-hydroxyphenyl protecting group have been reported in the literature: catalytic hydrogenation (19), bromine–water oxidation, and periodic acid oxidation (11).

Removal of the *o*-hydroxyphenyl group by lead tetraacetate was first reported for the phosphodiesters of *tert*-butanol, neopentyl alcohol, 2,2,2-trichloroethyl alcohol, and 1,1-dimethylallyl alcohol (9–11). All of these compounds are acid labile and are good models for the labile glycosyl phosphates. In addition, at the same time the present investigation was in progress, Kochetkov and co-workers (12, 13) reported the synthesis of β-L-rhamnopyranosyl-1-phosphate with *o*-phenylenephosphochloridate using lead tetraacetate oxidation. In our hands, lead tetraacetate oxidation of the *o*-hydroxylphenylphosphate group routinely gives yields of glycosyl phosphates greater than 60%, based on starting aldose.

Separation of the Anomeric Fucopyranosylphosphates

Excellent separation of L-fucose 1-phosphate anomers was achieved by the method of MacDonald (20). A small amount of fucose 2-phosphate formed in the process is also well separated. This characteristic makes the separation of the anomeric triacetates unnecessary and at the same time the yield of the β-L-phosphate based on starting aldose is increased. Thus, this method makes practical the synthesis of GDPFuc containing isotopes such as ^{13}C, ^{14}C, ^3H.

Synthesis of GDPFucose.

Two forms of activated GMP were used, guanosine 5′-phosphoric di-*n*-butylphosphinothioic anhydride (15) and GMP morpholidate (5), to

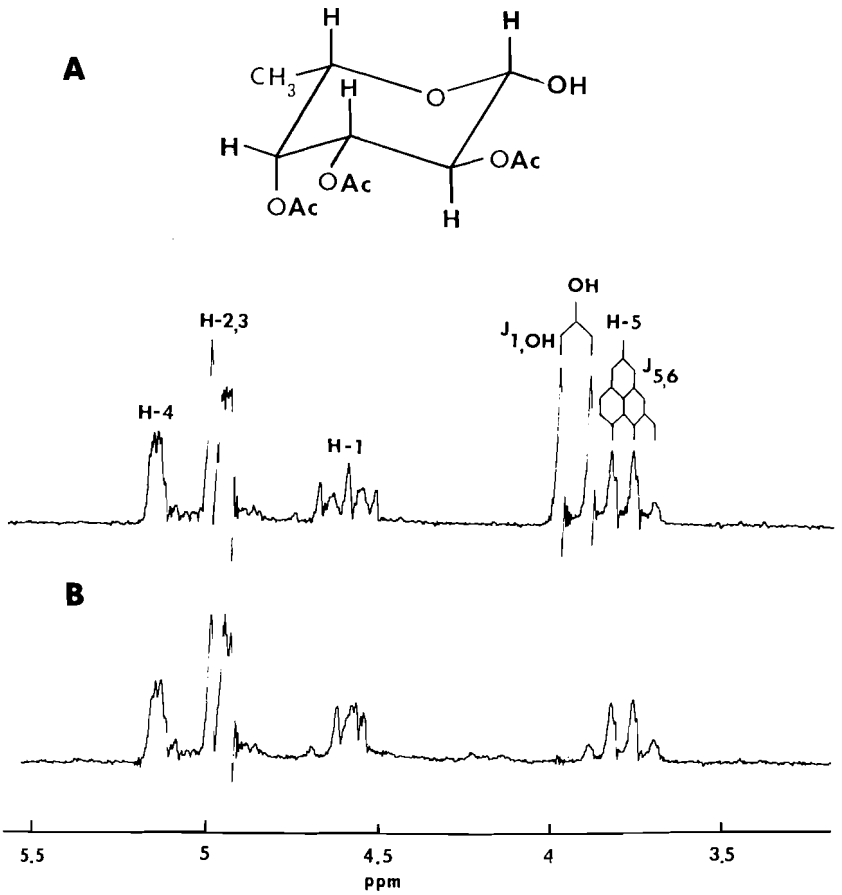

FIG. 2. The 100 MHz ^1H nmr spectrum of a 0.2 *M* solution of (A) 2,3,4-tri-*O*-acetyl-β-L-fucopyranose in $CDCl_3$, and (B) the same solution after treatment with D_2O to exchange the H of the OH group on Cl. Chemical shifts are in ppm downfield from tetramethylsilane.

synthesize GDPFuc. Both require careful elimination of water from the reaction mixture.

The purified GDPFuc can be stored in a frozen neutral solution or after lyophilization as an amorphous white powder for several months at −20°C without noticeable decomposition. The product has the same electrophoretic and hplc properties as the commercially available radioactive GDPFuc. In addition, its ^{13}C nmr (Fig. 3) and ultraviolet spectra were those expected on the basis of the presence of β-L-fucopyranosyl phosphate and guanosine 5′-phosphate in the molecule. The fucose moiety could be transferred to D-galactopyranosyl β(1-4)-2-acetamido-2-deoxy-D-glucopyranosyl-β-hexanolamine by the action of a fucosyl transferase isolated from porcine submaxilary glands. The trisaccharide product was fully characterized as containing an L-fucosyl moiety linked α(1-2) to the galactosyl residue (21).

The Stability of GDPFucose

The stability of GDPFuc over the pH range of 3 to 8 was investigated using hplc. At pH 3 the GDPFuc was degraded to GDP with a half life of 7 h at 37°C and 52 h at 4°C. At pH 5, 6, 7, and 8, there was less than 10% hydrolysis after a week at 37°C.

The effect of Mn^{2+} and Mg^{2+} on the hydrolysis of GDPFuc was studied using concentrations similar to those used in enzyme assays. In agreement with previous findings (2), neither 20 m*M* Mn^{2+} nor Mg^{2+} in 0.2 *M* PIPES buffer at pH 7.5 stimulated the hydrolysis of GDPFuc. During 48 h at 37°C, less than 5% of the GDPFuc is hydrolyzed, a highly desirable property for in vitro enzymatic studies and for manipulations during chemical synthesis.

Because of these findings all the manipulations of the GDPFuc were carried out at near neutral pH. Thus, the chromatography on Dowex 1 (Cl^-) was carried out using a neutral salt gradient rather than the acidic eluent used with other nucleoside diphosphate sugars (5). The high salt concentrations reached during concentration prior to desalting on a BioRad P-2 column does not degrade GDPFuc since only traces of other uv absorbing

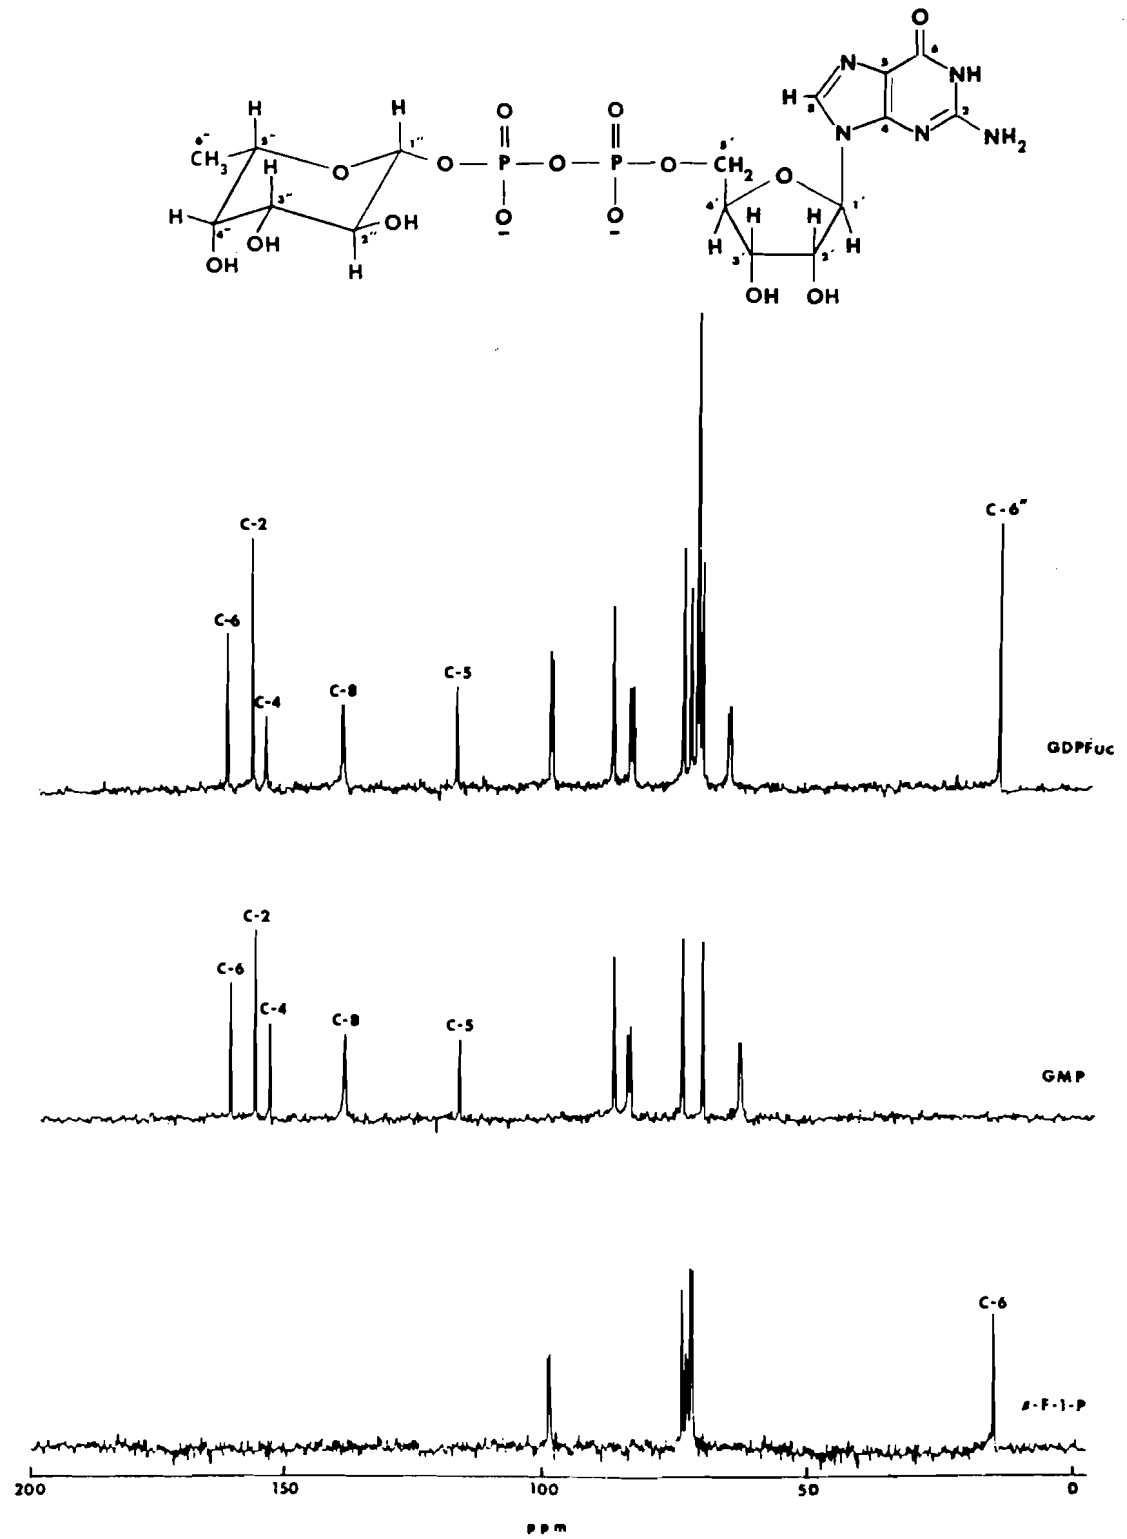

FIG. 3. The 15.08 MHz, proton-decoupled, ^{13}C nmr spectrum of a 0.1 *M* pH 7 solution of the sodium salt of GDPFucose compared to the spectra of GMP and β-L-fucopyranosyl phosphate.

material can be detected in the eluent from the P-2 column and by hplc.

The Conformation of GDPFucose

The solution conformation of GDPFuc was evaluated by ^{13}C and ^{1}H nmr spectroscopy. The fucopyranosyl ring exists in the $^{1}C_4$ conformation as evaluated by ^{1}H–^{1}H coupling constants. The ribofuranosyl ring appears to exist principally in the ^{2}E conformation (70%). Coupling constants between P and C2 of the fucose and P and C4 of the ribose moiety are 9.1 and 8.8 Hz, respectively. From these values it appears that more than 60% of the population of GDPFucose has the pyrophosphate group *trans* to both C4′ of ribose and C2 of fucose (23).

Protonated cyclopropanes in α-aminoketone deamination[1,2]

OLIVER E. EDWARDS, JOHN DIXON,[3] JOHN W. ELDER,[4] RALPH J. KOLT, AND MAURICE LESAGE
Chemistry Division, National Research Council of Canada, Ottawa, Canada K1A 0R6

Received October 22, 1980

OLIVER E. EDWARDS, JOHN DIXON, JOHN W. ELDER, RALPH J. KOLT, and MAURICE LESAGE. Can. J. Chem. **59**, 2096 (1981).

Deamination of 2-amino-4,4-dideuterio-6,6-dimethylcyclohexanone, 2-*exo*-amino- and 2-*endo*-amino-norbornane-3-one, 2-diazonorbornan-3-one, 2-*exo*-amino-5,6-*exo*-dideuterionorbornan-3-one and the corresponding 5,6-*endo*-dideuterio isomer has been studied. The nature of the products, the deuterium location in them, and the high retention of steric identity in the carbocations are interpreted in terms of σ-bond participation leading to corner- and edge-protonated cyclopropanes as reaction intermediates. Results with other destabilized carbocations are correlated.

OLIVER E. EDWARDS, JOHN DIXON, JOHN W. ELDER, RALPH J. KOLT et MAURICE LESAGE. Can. J. Chem. **59**, 2096 (1981).

On a étudié la désamination de l'amino-2 dideutéro-4,4 diméthyl-6,6 cyclohexanone, des amino-2 *exo* et amino-2 *endo* norbornanones-3, de la diaza-2 norbornanone-3, de l'amino-2-*exo* dideutéro-5,6-*exo* norbornanone-3, ainsi que de son isomère dideutéro-5,6-*endo*. On interprète la nature des produits, la position des deutérium qu'ils contiennent ainsi que le taux élevé de rétention d'identité stérique des carbocations en fonction d'une participation de la liaison σ qui conduit à des intermédiaires du type cyclopropanes protonés au sommet et sur le bord. On établit une corrélation entre ces résultats et ceux obtenus pour d'autres carbocations déstabilisés.

[Traduit par le journal]

We have long been interested in the nature and behaviour of cations generated on carbons attached to carbonyl groups, considered as *destabilized* carbocations (1–3). Related studies have been conducted by Yates (4, 5), Hanack (6), Baumgarten (7), Granger (8), Gassman (9), Levisalles (10*a*), Creary (10*b*), and Charpentier-Morize (11) and their co-workers. In cyclic systems where the carbonyl and the bonds to the electron-deficient carbon are held in a roughly coplanar relationship it has been estimated (11, 12) that such carbonium ions are destabilized relative to the isolated cation by 5 kcal/mol because of proximity to the positive end of the carbonyl dipole. We (see also ref. 10*b*) rationalized our early observations, as did Yates and Crawford (4), in terms of increased σ-bond participation in the ionization to offset this expected destabilization.

Among the most interesting products from these putative α-ketocarbonium ions were cyclopropyl ketones,[5] which we considered (1) to arise via intermediate bridged ions (protonated cyclopropanes) and products of apparent 1,3 hydrogen shift which could also have arisen via protonated cyclopropanes (1). Of great interest also was the cause of the remarkably high retention of steric identity during product formation from these cations (1–5). The present work reports an investigation of the nature of these processes using specific deuterium labelling and comparison of products from deamination of stereoisomeric amines and a diazoketone.

The carbonium ions chosen for study were those produced by nitrous acid deamination of 2-amino-4,4-dideuterio-6,6-dimethylcyclohexanone (**1**), 2-*exo*-amino-5,6-*exo*-dideuterionorbornan-3-one (**2**), 2-*exo*-amino-5,6-*endo*-dideuterionorbornan-3-one (**3**), and 2-*endo*-aminonorbornan-3-one (**4**), and by protonation of 2-diazonorbornan-3-one (**5**). The movement and/or loss of deuterium in product formation occurred in very specific ways, throwing light on the nature of the intermediate ions and suggesting a unified interpretation of the behaviour of these and related carbonium ions.

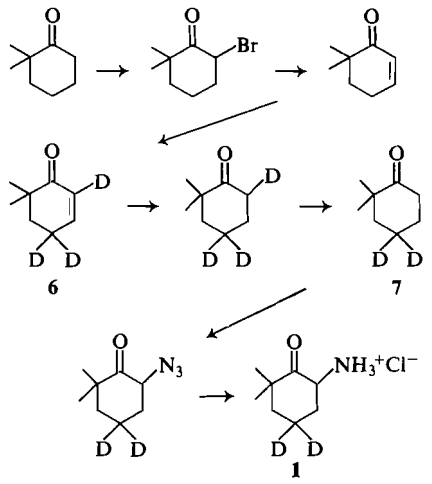
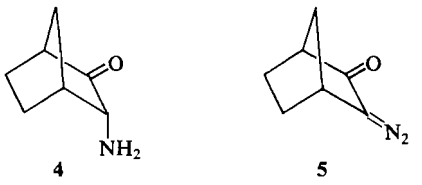


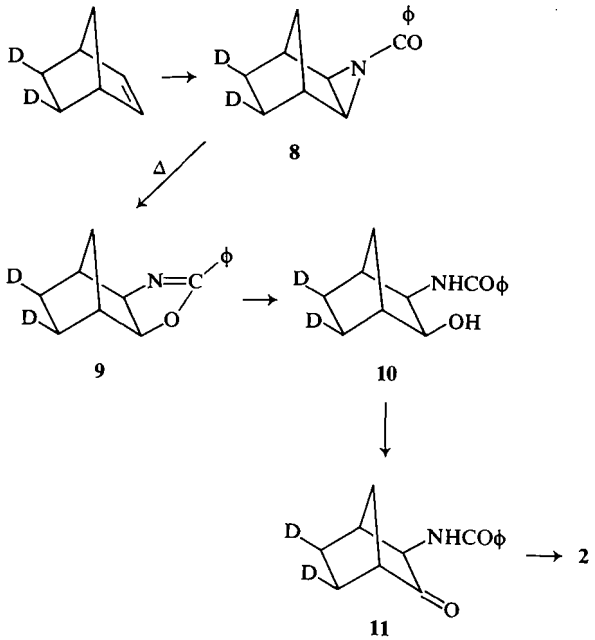
SCHEME 1

age yields starting with 2-methylcyclohexanone.[6] Four methods were attempted for the reduction of the C—C double bond of **6** (see Experimental). Catalytic reduction gave a 70% yield of **7**, but some loss and possible scrambling of deuterium occurred. Lithium in ammonia reduction followed by Jones' oxidation gave the best yields, although some runs gave much polymeric material. Deuterium analysis indicated the presence of 1.95 D per molecule of **7** after exchange of any deuterium α to the carbonyl. The mass spectrum indicated **7** to be a mixture with 8% d_3, 76% d_2, and 16% d_1 species.[7]



2-exo-*Amino-5,6*-exo-*dideuterionorbornan-3-one (2)*

Norbornadiene was partially reduced using deuterium over 30% Pd/C. The mixture of deuterated norbornene and norbornane was converted following Huisgen *et al* . (14) into the benzoyl aziridine **8** (Scheme 2). This was heated to rearrange it to the phenyloxazoline **9** which was then hydrolysed in aqueous acid to the *N*-benzoyl alcohol **10**. Of the methods tried, only the method of Ratcliffe and Rodehorst (15) gave high yields in the oxidation of **10** to the *N*-benzoyl ketone **11**. A final acid hydrolysis converted this into the desired α-aminoketone isolated as its hydrochloride.

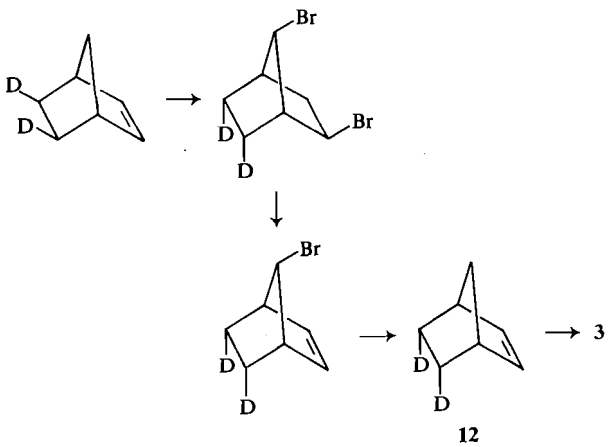


SCHEME 2

2-exo-*Amino-5,6*-endo-*dideuterionorbornan-3-one (3)*

A mixture of 5,6-*exo*-dideuterionorbornene and tetradeuterated norbornane was converted by the method of Werstiuk (16) into 5,6-*endo*-dideuterionorbornene (**12**) (Scheme 3). This was transformed into the desired α-aminoketone by the route described above for the *exo*-dideuterio isomer.

The 2-diazonorbornan-3-one (**5**) was prepared from the mono-*p*-toluenesulfonylhydrazone of 2,3-norbornadione essentially following Wiberg *et al*.



SCHEME 3

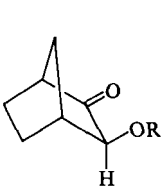
(17). However, the reaction in our hands was complete in around 1.5 h. The product was distilled over a short path at 65°C under 0.05 Torr and used promptly.

A sample of 2-*endo*-aminonorbornan-3-one **4** was prepared by stannous chloride reduction of 2-oximinonorbornan-3-one, an improvement over the published procedure (18).

Reference samples of the ketol acetates **13** and **14** were prepared from the known 2-*exo*-3-*exo* and 2-*endo*-3-*endo* diols, while those of **15**, **16**, and **17** were made following literature procedures. A sample of **18** (R = H) was separated from the products from deamination of **4**, then acetylated.



13

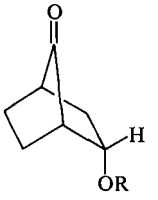
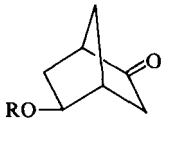
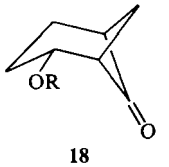
15



16



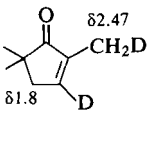
17



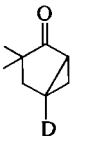
18

Results

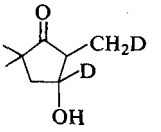
The deamination of the deuterated aminocyclohexanone **1** was carried out in dilute aqueous sulfuric acid by addition of sodium nitrite as described earlier (1). Considerable diazoketone (ν_{max} 2080 cm^{-1}) was produced. In order to avoid complication with carbenoid-type reactions, this was destroyed by stirring the ether-extracted products with dilute *p*-toluenesulfonic acid in water. The total extracted products were separated into neutral components and acids, then the neutral ones separated by chromatography on tlc silica gel. The structure **19** was assigned to the trimethylcyclopentenone on the following evidence. Mass spectrometry showed[7] the presence of approximately 73% d_2 and 27% d_1 species. Its ^1H nmr spectrum showed no vinyl hydrogen and approximately equal amounts of CH_2 hydrogens at δ 1.8 and δ 2.47. Its ^2H nmr spectrum had two signals with equal areas at +0.57 (br s) and +5.8 ppm (br t, J = 2.2 Hz) (relative to $CDCl_3$ in hexane).



19



20

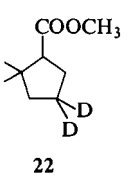


21

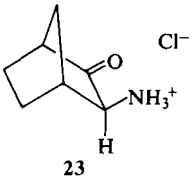
The bicyclohexanone was assigned structure **20**. Its mass spectrum[7] showed the presence of 5% d_2, 74% d_1, and 21% d_0 species. Its ^1H nmr spectrum had signals identical to those of the undeuterated molecule except for the absence of a ^1H multiplet near δ 2.0 and a sharpening of the signals between δ 1.7 and 2.1. Its ^2H nmr spectrum had a signal at 5.6 ppm (br s) upfield from deuteriochloroform in cyclohexane.

The more polar products had the same glc retention times as the products identified (1) as two isomers of 3-hydroxy-2,5,5-trimethylcyclopentanone. When a sample of the mixture was absorbed on neutral alumina for 17 h it was largely dehydrated to **19** containing 74% d_2 and 26% d_1 species. We hence conclude that the hydroxy ketone had structure **21**.

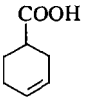
The acid fractions were distilled, converted to methyl esters, then these distilled giving essentially pure **21**. Its mass spectrum indicated the presence of 5% d_3, 60% d_2, 29% d_1, and 6% d_0 species.[7]



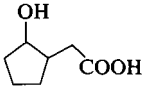
22



23



24



25

The deamination of 2-*exo*-aminonorbornan-3-one (**23**) in aqueous acid gave 3% of nortricyclanone and 15% of 2-*exo*-hydroxynorbornan-7-one. No significant amounts of 2-*exo*-hydroxynorbornan-2-one (**13**, R = H), 2-*exo*-hydroxynorbornan-5-one (**17**, R = H), or 2-*endo*-hydroxynorbornan-3-one (**14**, R = H) could be detected. In addition, 3-cyclohexene-1-carboxylic acid **24** (6%), a hydroxy acid tentatively assigned structure **25** on the basis of analysis and spectra, and a mixture of other unidentified acids were produced.

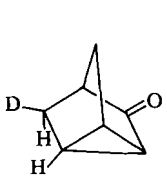
When the deamination of **23** was conducted in acetic acid containing 1 *M* sodium acetate the yield of nortricyclanone rose to 9%. Eleven other neutral products were evident from glc on column A. The main one, and the only one characterized, was the 2-acetoxy-7-ketone **15** (R = Ac) (12%). Less than 3%, if any, of 2-*exo*-acetoxynorbornan-3-one was present.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

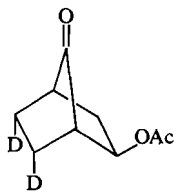
Deamination of 2-diazonorbornan-3-one (**5**) in contact with water (autocatalytic) gave around 1% of nortricyclanone, 50% of 2-*endo*-hydroxynorbornan-3-one (**14**, R = H), 35% of 2-hydroxybicyclo[3.1.1]heptan-6-one (18, R = H), and 17% of readily extracted acid which was mainly 3-cyclohexene-1-carboxylic acid. These results are very comparable to those of Yates and Crawford (4).

The deamination of **5** in 50% acetic acid was rapid and, aside from the production of ketol acetates as well as ketols, the products were similar to those obtained in water. However, the presence of 1 *M* sodium acetate produced striking changes. The rate of reaction dropped considerably, the yield of nortricyclanone rose from 1.5% to 12% and the 2-*exo*-acetoxy-7-one **15** (R = Ac) became a major product (glc peak area three times that of the bicyclo[3.1.1] ketol acetate **18**). When the sodium acetate concentration was increased to 4 *M* in 50% acetic acid the deamination became very slow (45 min for completion), the yield of nortricyclanone rose to 17.5%, and the ratio of **15** to **18** (glc areas) was 4:1. In acetic acid the deamination was very slow (5 min, 0°C) the yield of nortricyclanone was 8.5%, and the ratio of areas (glc) of **15** to **18** was 2.5:1. In this medium 1 *M* sodium acetate had practically no effect on product formation. Deamination of diazo ketone **5** in a slightly acidified aqueous 1.4 *M* sodium nitrite solution gave the same major products as decomposition in water. However, the nortricyclanone yield increased to 3.6%. The yield of recovered neutral product (as ketols) was 71%.

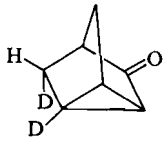
The *endo* aminoketone **4** gave comparable results to the diazoketone (**5**) except that the yield of neutral products was only one-third that from **5**. The yield of nortricyclanone in water was less than 0.2%, in 50% acetic acid 1.5%, and in 1 *M* sodium acetate in 50% acetic acid it was 2.9%. In acetic acid the yield was 2.3% and in 1 *M* sodium acetate in acetic acid it was 3.6%. Without sodium acetate the predominant products were the ketols (acetates) **14** and **18**. Again in the media containing the salt the 7-ketone **15** became a dominant product. The ratio of **15** to **18** in 1 *M* sodium acetate in acetic acid was 3:1.



26



27



28

Although the ketols **13**, **14**, and **18** (R = H) were rather labile, the samples could be recovered in good yield after exposure to nitrous acid deamination conditions. We conclude that the absence of one or more of these in specific deaminations is not the result of destruction by nitrous acid or oxides of nitrogen, or during work-up.

Deuterium Labelled Aminonorbornanones

The deamination of 2-*exo*-amino-5,6-*exo*-dideuterionorbornan-3-one (**2**) in aqueous acid gave an average of 2.1% of deuterated nortricyclanone. This was shown to be mainly **26** by the following evidence. Its mass spectrum (4% d_2, 93% d_1, and 3% d_0) indicated nearly complete loss of one deuterium. Its ^2H nmr spectrum (Fig. 1) was a doublet 1.1 ppm upfield from external CD_3I with J = 0.9 Hz and its proton decoupled ^{13}C nmr spectrum (Fig. 2) had a peak for C-7 with half the relative intensity of that for the undeuterated molecule (C-6 + C-7) while C-6 gave a triplet centered very close to it.

The most abundant neutral product was a labelled 2-*exo*-hydroxynorbornan-7-one (16%). This

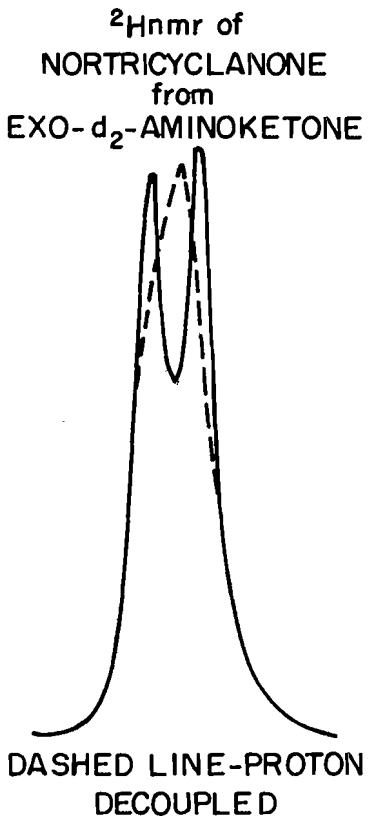


FIG. 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

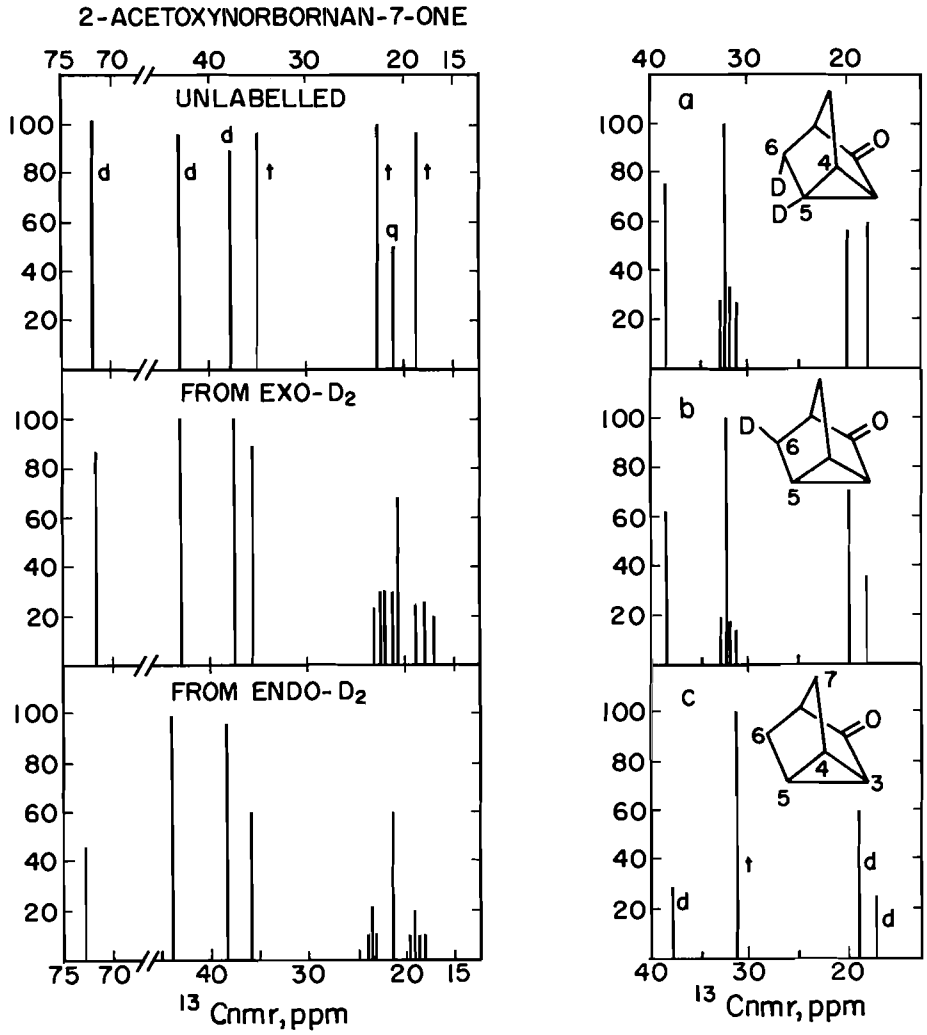

FIG. 2.

was shown to be dideuterated by mass spectrometry of its acetate[7] (6% d_3, 83% d_2, 12% d_1). Its ^{2}H nmr spectrum gave only a broad singlet 1.3 ppm upfield from external CD_3I, which was not resolved on proton decoupling. Its ^{13}C nmr spectrum (Fig. 2) showed the presence of two CHD groups (triplets at 18.1 and 22.3 ppm) and the C-2 signal (72 ppm) was as intense as expected if no deuterium was on this carbon. On this basis we consider its structure to be mainly **27**.

The mixture of readily extracted acids from the deamination of **2** was rich in deuterated 3-cyclohexene-1-carboxylic acid. The mass spectrum of its methyl ester showed a content of 1.5% d_3, 87% d_2, and 12% d_1 species.

The hydroxy ester from **2** analysed for $C_8D_2H_{12}O_3$. The presence of the hydroxyl group was evident from infrared bands at 3450 and 3600 cm^{-1}. This appears identical, except for the labelling, with the main hydroxy acids from **3** and **4** (see Experimental for deamination of **3**). A possible gross structure is **25**.

The deamination products from the *endo*-d_2 isomer **3** were comparable to those from **2**. The yield of deuterated nortricyclanone was higher (average 4.2%). In this case essentially no deuterium was lost[7] (8% d_3, 86% d_2, 6% d_1). Its ^{2}H nmr spectrum (Fig. 3) showed the presence of two types of deuterium giving a broad singlet at 0.65 ppm and a doublet at 0.80 and 0.90 ppm upfield from external CD_3I with relative areas 1:1. The doublet collapsed to a singlet when proton-decoupled. The assignment of deuterium labelling as in **28** was confirmed by its ^{13}C nmr spectrum (Fig. 2). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

signal for C-4 and C-5 at 18.9 ppm was halved in intensity as expected due to coupling with the deuteron, absence of nuclear Overhauser enhancement, and possible quadrupole broadening of the signal for the deuterated carbon (19).

The deuterium labelling of the 2-acetoxy-7-ketone was revealing. The ^2H nmr spectrum showed the presence of two deuterons at σ 4.6 and 1.6 in the ratio of 1:9. The low-field deuterium was clearly on C-2 as in **29** (20% of the mixture), while the remainder was most probably located as in **30**. The ^{13}C nmr spectrum confirmed this since the peak for C-2 at 73 ppm had only 53% of the relative intensity of the signal at 21 ppm, in comparison with the corresponding signals in the spectrum of **15** (R = Ac) (Fig. 2).

The mass spectrum of the 3-cyclohexen-1-carboxylic acid from the *endo*-d_2 isomer showed retention of most of the deuterium[7] (2% d_3, 89% d_2, 12% d_1). However, the ^2H nmr spectrum of the *p*-bromophenacyl ester of the acid had deuterium signals at δ 5.4 and 1.5 with areas in the ratio 1:25.

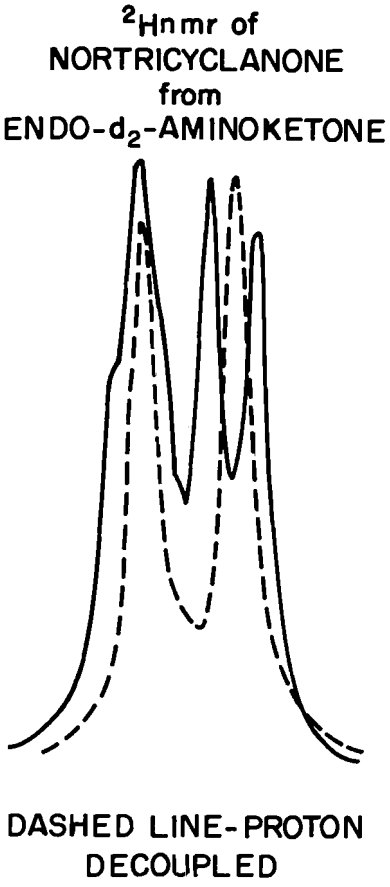

FIG. 3.

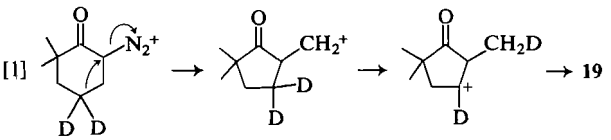
This is consistent with the presence of 8% of **31** and 92% of **32**.

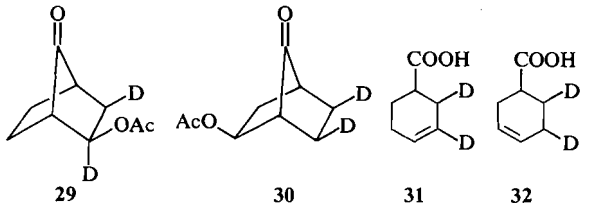
The hydroxy ester from the *endo*-d_2 isomer **3** analysed for $C_8D_2H_{12}O_3$ and appeared identical except for labelling with the main hydroxy ester from **2** and **4**. A possible gross structure is **25**.

Discussion

Two explanations for the deuterium labelling pattern in the 5,5-dimethylcyclopenten-2-one **19** seem possible. The first would require the formation of a primary cation as an intermediate as in eq. [1]. This would be around 13 kcal/mol less stable than



the initial ion.[8] A direct 1,3 deuterium shift has been discredited (20), hence a 1,2-shift on a protonated cyclopropane intermediate would have to be invoked to account for the final product.



The second alternative (1) would avoid the high energy primary cation by going directly from the initial ion to a corner-protonated cyclopropane. A very specific deuterium shift[9] to give an edge deuteronated cyclopropane (Scheme 4) would then be followed either by loss of a deuteron to give the cyclopropyl ketone or rearrangement to the secondary cation with the charge now remote from the positive end of the carbonyl dipole. Thus all three major neutral products could be accounted for.

The formation of nortricyclanones from norbornyl cations can involve essentially loss of either *exo* hydrogen or deuterium, as in the present results and one of Collins' examples (23), or predominant loss of *endo* deuterium as in one case studied by Collins and Benjamin (24) and one studied by Werstiuk (25). Clearly the simple explanation that *either* the back lobe of the 6-*exo* CH bond (as in **33**) *or* the *endo* CH bond on C-6 (as in **34**) participate in

[8]18 kcal/mol (secondary vs. primary cations) (21) less the 5 kcal/mol destabilization of a cyclic α-ketocarbonium ion (11).

[9]Baird and Aboderin were the first to demonstrate such a migration (22). The reason for the specificity is discussed later in the paper.

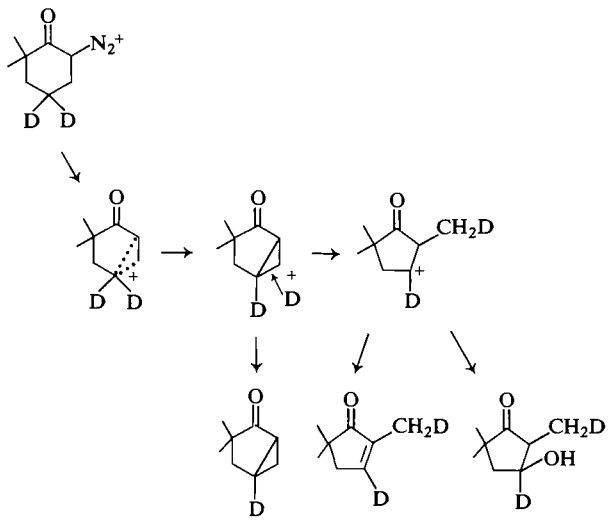
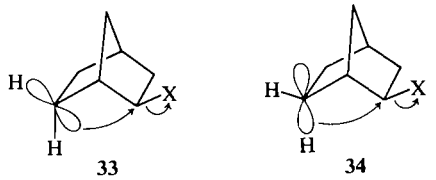


SCHEME 4

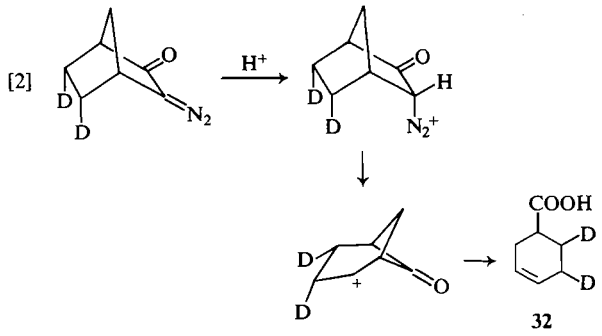
the ionization does not account for the facts. However, a mechanism parallel to that outlined in Scheme 4 can account for our observations and, as will be discussed later, those of Collins and Benjamin and Werstiuk also. This is outlined in



33 34

Scheme 5 for the *endo*-d_2 isomer **3**. By analogy to the aminocyclohexanone case we postulate that a corner-protonated cyclopropane **35** is first formed and that this is converted[9] in part to the edge-protonated cyclopropane **36** and in part directly to the Wagner–Meerwein ion **37**. Since **36** is almost symmetrical, nearly equal proportions of **37** and **38** would form from it. If the activation energy for the transitions **35** → **36** and **35** → **37** is of similar magnitude, it follows, since the amount of nortricyclanone formed is small, that **37** and **38** (and hence **30** and **29**) would be formed in a ratio of roughly 3:1. In actuality the ratio of **30** to **29** was 2.9:1.

We expected to find the same ratio of the two labelled acids **31** and **32** as was found for **29** and **30**. However, the ratio of **32**:**31** estimated from ^{2}H nmr spectrum was 11:1. If the scheme is correct, this must mean that there was an alternate source of **32**. We can only account for this by assuming that considerable diazoketone was formed in the deamination, giving rise to **32** as in eq. [2]. The argument could be advanced against this interpretation that neither of the neutral products expected from the



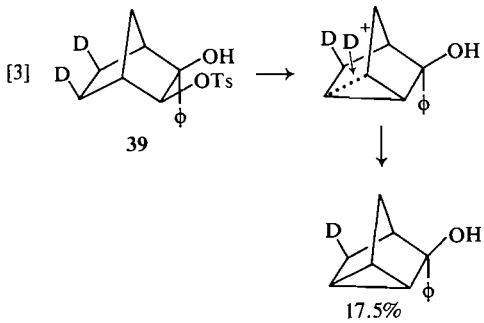
32

diazoketone were observed in deamination of the *exo* amino ketone in water. However, neither is the expected 2-*exo*-hydroxy-3-one (**13**, R = H). Nitrous acid deamination in water gives acids at the expense of neutral products, possibly accounting for this absence.

The deamination of the *exo*-d_2 isomer **2** leading to nearly exclusive loss of one deuterium in the formation of nortricyclanone is consistent with a mechanism parallel to that in Scheme 5.

Schemes 4 and 5 demand two important postulates: (*a*) that mainly one of the two possible edge-protonated cyclopropanes form from the initial corner-protonated cyclopropanes, and (*b*) that proton (deuteron) loss from the intermediate ions is only from the edge-protonated species.

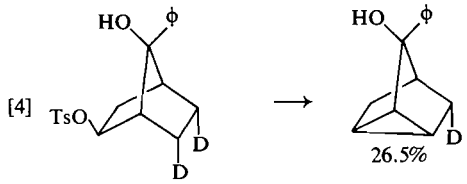
Strong support for these postulates comes from the work of Collins and co-workers (23, 24) and of Werstiuk (25). The former observed mainly loss of *exo* deuterium in the formation of nortricyclene in the solvolysis of **39** (eq. [3]). But in the formation of



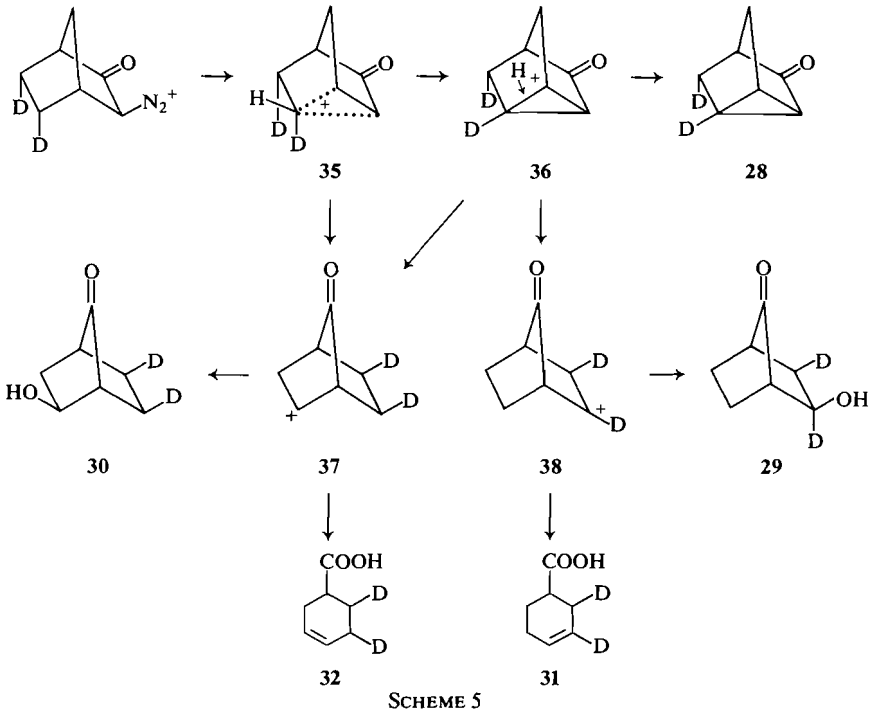
39 17.5%

the substituted nortricyclene from **40**, mainly *endo* deuterium was lost (eq. [4]).

Werstiuk (25) observed predominant loss of



40 26.5%



SCHEME 5

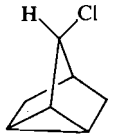
endo deuterium in the solvolysis of **41** (eq. [5]). Each of these cases, and our own results, can be rationalized in terms of the two above postulates if the edge-protonated cyclopropane formed has the proton (deuteron) on the *most basic* (electron rich) bond of the *respective cyclopropane*, i.e. the one most remote from the carbonyl or electronegative group (e.g. OH, phenyl).

[5] 
41

Recent work by Nickon *et al.* (26) on cyclopropane ring formation can be rationalized in the same way, with the *p*-anisyl group as the electronegative substituent on the initial corner-protonated cyclopropane.

Collins and Benjamin (24) had postulated involvement of the protonated cyclopropane (as in eq. [3]) as an intermediate or transition state but did not extend the conception to their other example (eq. [4]) or provide an explanation for the specific ion formed. Werstiuk suggested for his cases that the transition state for cyclopropane formation resembled an edge-protonated cyclopropane, but gave no explanation for the specificity (25).

The concept of the proton shift from a corner-protonated cyclopropane to give one with the proton on the most electron rich bond has already been invoked by Hart and Schlosberg (27) to account for isomerization during acylation of cyclopropanes. The validity of this is supported by the evidence of Werstiuk and co-workers (28) that edge-protonation of **42** took place selectively on the bond remote from the chlorine. Since cyclopropyl ketones protonate preferentially on oxygen, the principle of microscopic reversibility cannot be tested in this way for our examples.



42

Another point of great interest is the high retention of steric identity encountered in the deamination of 2-*endo*- and 2-*exo*-aminonorbornan-3-ones and in protonation of various diazoketones (4, 5). The only common products isolated from the deamination of the two amines in water were nortricyclanone and cyclohex-3-enoic acid. The small amount of nortricyclanone from the *endo* amine most probably arose by *endo* protonation of some diazoketone produced as a transient intermediate. The major neutral product from the *exo* amine, 2-*exo*-hydroxynorbornan-7-one, was not

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

For personal use only.

detectable in the products from the *endo* amine or diazoketone in aqueous acid. The acid can arise by different pathways from each developing cation (Scheme 5 and eq. [2]).

Three possible explanations[10] for this retention of steric identity in deamination have been considered:

(A) Configuration holding by tight ion pair formation.

(B) Highly asymmetric solvation of the carbocation, with the solvent closest to the side of the ion from which the nitrogen departs.

(C) Sigma (σ) bond participation as the nitrogen departs, or so rapidly after carbocation formation that no other process intervenes.

An evaluation of these explanations follows:

(A) Collins and co-workers not only considered the location of the initial counter ion to be product determining but considered its position to be held through several molecular rearrangements (30). (An alternate explanation of their results is given in the Appendix.) Much evidence against this postulate for reactions in polar solvents is available. For example, in the 2-diazonorbornan-3-one (5) decompositions reported herein and in the work of Yates and co-workers (4, 5), regardless of the presence of only traces of bicarbonate ions and carboxylate anions, bisulfate anions, or up to 4 *M* sodium acetate, the *unrearranged* product had clean *endo* configuration.

Even with 4 *M* acetate ion present in 50% acetic acid as much of the ketols as ketol acetates were formed, i.e. at least a solvent-separated ion pair was involved.

In the work of Yates and Blattel (5) the presence of chloride or trifluoroacetate ions in 50% acetic acid resulted in no products containing these ions.

Whiting and co-workers (31*a*) showed that in deamination of 1-octylamine only 3% of product derived from the initial counter ion was formed, while 4-octylamine gave 25% of product from the initial counter ion. In our study of medium ring nitrosamides (32) attack of external nucleophiles was favored over that of the internal counter-ion (eq. [6]).

In Collins and Benjamin's own work (33) nearly as much *exo* product **44** (29%) as *endo* product **45** (34.5%) was produced in deamination of **43** in acetic acid. If one adds the other products probably arising from an *exo* cation, the sum of its contribution rises to 62.5%, a clear indication that *initial counter ion control of products is not important in polar solvents*.

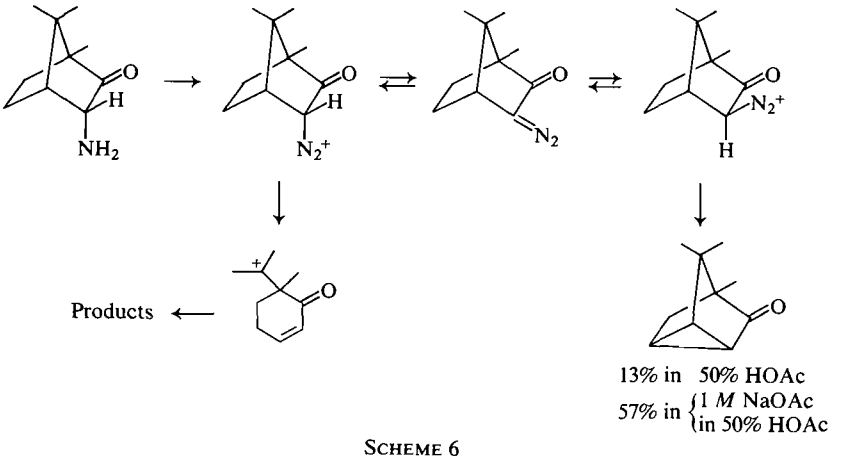
[6] 
[7] 
(B) In the deamination of the diazoketone **5** in acetic acid, the departing nitrogen and presumably a solvated acetate ion plus the 5,6 *endo* hydrogens all impede approach to the *endo* face of the presumed classical cation. However, one could argue that the acetic acid solvating the anion would be much more nucleophilic than bulk solvent, so that *endo* capture of acetic acid dominates. However, in the presence of 1 *M* sodium acetate in this solvent, the nucleophilicity of the bulk solvent should be comparable and one would expect major *exo* capture. Actually no 2-*exo* acetate was observed. Hence this explanation is discredited.

(C) The following facts are readily accounted for if bridged ions are formed synchronous with, or very rapidly after, nitrogen loss.

1. The yield of products arising via bridged ion intermediates (Wagner–Meerwein products, cyclopropanes) can be as high as 70%. The yield of cyclopropanes seems directly related to the steric impedance to nucleophilic attack on the cationic centers (5, 13).

2. Sodium acetate acts as a base increasing the cyclopropane yield (present work and that of Yates and Blattel, ref. 5). This can be the result of two effects, (*a*) the catalysis of the equilibrium between the two possible diazonium ions, as illustrated for

[10]Micellar effects are not considered probable for the small rigid polar molecules studied in this work, with concentrations below 1 *M*. The near 100% retention in the absence of acetate ions is strikingly greater than encountered in deaminations in which micelles are important (29).



SCHEME 6

3-*endo*-aminocamphor (1, 5) in Scheme 6, and (*b*) action as a base in removing the proton from edge-protonated cyclopropanes. The acetate attack on the carbons of corner- or edge-protonated cyclopropanes derived from 3-*endo*-aminocamphor should be inefficient because of impedance by the methyl groups. Thus the amount of 3-acetoxy-7-one only increases from a trace to 5% when 1 *M* sodium acetate is added (5).

3. Our deuterium labelling studies show that at least 40% of the neutral products from the *exo*-diazonium ion from **3** came from an edge-protonated cyclopropane (Scheme 5) and at least 55% of the products from deamination of **1** arose from protonated cyclopropanes. If our interpretation is correct, Collins' results require at least 26% involvement of protonated cyclopropanes (24) (eq. [4]), and Werstiuk's example requires over 44% of such species (25) (eq. [5]).

Recent support for involvement of protonated cyclopropanes in carbonium ion reactions is found in the work of Lee *et al.* (34), Hudson and co-workers (35), Kirmse and Siegfried (36), and Liu (37). Nuclear magnetic resonance evidence for their existence in superacids is reviewed by Saunders *et al.* (38). Köhler and Lischka (39) have calculated that edge and corner-protonated cyclopropanes in the norbornane series have nearly equal energy in the gas phase, both being more stable than a classical norbornyl cation.

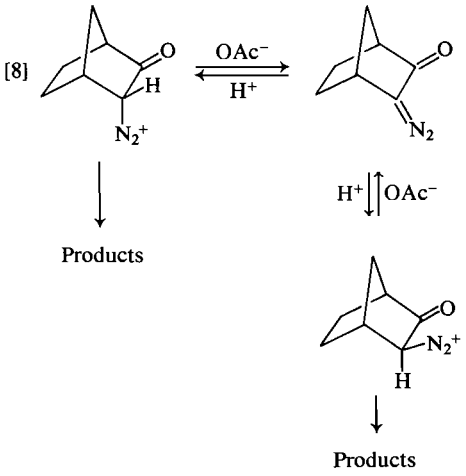
The above work does not enable one to conclude whether σ-bond participation is synchronous with nitrogen departure or whether the participation follows, extremely rapidly, the formation of a classical cation. Indeed the solvolysis studies of Lambert (40) and Brown (41) and their co-workers suggest that the latter is the correct picture. However, the role of acetate ions discussed below leads us to conclude that, at least for α-aminoketone deamination, the participation is synchronous with C—N bond rupture.

Medium Effects

The transition from water to acetic acid as medium for deamination of the diazoketone **5** would be expected to increase the yield of elimination products since acetic acid is a poorer nucleophile. This was indeed observed (increase of nortricyclanone from ca. 1% to 8%). The expectation on adding sodium acetate is less clear since it can act both as a base aiding proton removal, and as a nucleophile capturing intermediate ionic species. In fact, in 50% acetic acid the salt markedly increased the yield of nortricyclanone (0.5% → 17%), hence its role as a base is dominant, which seems totally inconsistent with any tight ion pair concept for the initial cation (see above). In view of our other evidence, the role of acetate can be conceived to be diversion of edge-protonated cyclopropane to cyclopropane at the main expense of Wagner–Meerwein product (see also ref. 11*b*).

The most striking effects of acetate ion are a reduction in reaction rate, and a shift of products from those derived purely from *endo* diazonium ion to those derived from a mixture of *endo* and *exo* ions. We account for this in terms of the equilibria in eq. [8] (42, 11b); without acetate ion the protonation is predominantly *exo* and essentially irreversible. Acetate ion as base makes the process reversible, and permits the few percent of *endo* protonated species to play a role. The key point in our interpretation is that, because of the more favorable overlap of the 1,6 bond, the decomposition of the *exo* diazonium ion is much faster than that of the *endo* ion (1,7 bond overlap) (see ref. 10*b* for a similar conclusion for solvolysis). Thus, despite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.



the low ratio of *endo* protonation of the diazoketone, products from the resultant *exo* diazonium ion begin to predominate (more than 50% in 4 *M* sodium acetate in 50% acetic acid) when the equilibration (eq. [8]) is accelerated by the acetate ions.

In the deamination of the *endo* and *exo* aminoketones **2**, **3**, and **4**, nitrite and/or acetate ions were present, hence additional sodium acetate did not have the marked effect on tricyclanone yield that was observed for the diazoketone. The *endo* amine **4** showed an increase in proportion of Wagner–Meerwein product **15** arising from *exo* diazonium ion, when acetate was added, in harmony with the diazoketone observation.

Summary

The following conclusions have been reached.

1. Proton loss from protonated cyclopropanes is from the edge-protonated, not corner-protonated, species; i.e. the principle of microscopic reversibility holds.

2. The bond in a cyclopropane ring most remote from an electronegative substituent on a side chain is the most basic of the three, i.e. is the best proton acceptor. This is the predominant protonated cyclopropane formed (see also ref., 28).

3. Initial counter-ions in deamination are solvent separated, and in the presence of an abundance of ions in polar solvents do not play a major role in product determination.

4. For destabilized carbonium ions, neighboring groups and/or σ-bonds participate either during or very rapidly after C—N bond rupture, resulting in high retention of steric identity at the cationic center.

Experimental

Infrared spectra were for chloroform solutions (s = strong, m = medium and w = weak) and ^{1}H nmr spectra in deuterochloroform unless otherwise indicated. Mass spectra were determined on a Perkin-Elmer-Hitachi R.M.U. 60 instrument at 70 eV. The calculated content of deuterated isomers was estimated as follows: The ratio of $M + 1^+$ and $M - 1^+$ peaks to the M^+ peak was determined for the unlabelled compound, and the corresponding values for the deuterated molecules corrected for these, with M^+ being in this case the main deuterated species. The resultant values were summed, then the percentage of each species relative to the sum calculated. This ignores any possible deuterium isotope effects on the ratio within the cluster. Deuterium nmr spectra were determined on a modified Varian XL-100 instrument, and ^{13}C nmr on a Varian CFT-20 Fourier transform spectrometer. The glc analyses were done using a Victoreen 4000 gas chromatograph with either Column A, 6 ft × 1/4 in. 3% OV-1 (methyl silicone) on acid-washed, DMCS treated 60–80 mesh Chromosorb G, or Column B, 6 ft × 1/4 in. 20% OS-138 (polyphenyl ether) on acid-washed, DMCS treated 80–100 mesh Chromosorb G. Preparative glc was done using a 10 ft × 3/8 in. column with 20% SE-30 (methyl silicone) on 60–80 mesh Chromosorb W or on a 10 ft × 3/8 in. column with 10% OS-138 on gas chromatographic CLA.

High pressure liquid–liquid chromatography was performed on a Waters Assoc. HPLC model ALC-100 instrument using a 4 ft × 3/8 in. Porasil-A column, eluting with 2.5% acetone in hexane (4 mL/min).

2,2-Dimethylcyclohexanone

This was prepared following King and Topliss (43) in 44–50% yield from 2-methylcyclohexanone. It had ν_{max} 1075 cm^{-1} and gave ^{1}H nmr signals at δ 1.15 (6H, s), 1.89 (6H, m, $w_{1/2}$ = 5 Hz), and 2.52 (2H, m, $w_{1/2}$ = 12 Hz).

2-Bromo-6,6-dimethylcyclohexanone[6]

A solution of 50.4 g (0.314 mol) of bromine in 45 mL of acetic acid was added over two hours to a stirred solution of 39.6 g (0.314 mol) of 2,2-dimethylcyclohexanone in 45 mL of acetic acid containing a trace of hydrogen bromide. The reaction mixture was poured into 300 mL of crushed ice – water mixture. The crystalline solid which separated was collected by filtration. It was dissolved in ether, the ether dried, and concentrated. Addition of hexane gave 48 g (0.235 mol) of bromo compound (75%) mp 55–57°C. It had ν_{max} 1728(s) and 1705(m). Its ^{1}H nmr spectrum had signals at 1.24 (6H, s), 1.87 (4H, m), 2.47 (2H, m), 4.99 (1H, m). *Anal.* calcd. for $C_8H_{13}BrO$: Br 38.97%; found: Br 38.77%.

4,4-Dimethylcyclohex-1-en-3-one[6]

A mixture of 2-bromo-6,6-dimethylcyclohexanone (61.5 g, 0.30 mol), 78 g (0.885 mol) of dry lithium bromide, and 21 g (0.29 mol) of lithium carbonate in 400 mL of dry dimethylformamide was heated for 7 h at 130°C. The mixture was cooled, poured into 300 mL of water, then the product extracted into pentane. The residue from evaporation of the pentane was distilled at 77°C, 24 Torr, giving 27 g (72%) of oil with ν_{max} 1670 (s) and 1640 (w) cm^{-1} and λ_{max} 224 nm, ε 10250. Its ^{1}H nmr had signals at δ 1.07 (6H, s), 1.80 (2H, t, J = 6 Hz), 2.36 (2H, m), 5.80 (1H, d of t, J_1 = 2, J_2 = 10 Hz), and 6.82 (1H, d of t, J_1 = 4, J_2 = 10 Hz). *Anal.* calcd. for $C_8H_{12}O$: C 77.37, H 9.79; found: C 77.10, H 9.56%.

6,6-Dideuterio-4,4-dimethylcyclohex-1-en-3-one

A solution of 12.6 g of 4,4-dimethylcyclohex-1-en-3-one in 150 mL of methanol-*d* containing 0.2 *N* sodium methoxide was left for 7 h at room temperature. The solution was neutralized by bubbling in carbon dioxide, then 100 mL chloroform was added. After filtration to remove salts, the solvent was distilled. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

residue was distilled under 18 Torr to give 6.4 g, bp 65–78°C, which was mainly trideuterated cyclohexenone **6**. The 2.5 g of higher boiling product was partly the corresponding 3-methoxycyclohexanone (δ 3.23 (s) and 3.6 (m) ppm). The enone still contained a small amount of partially deuterated species (weak ^{1}H nmr signals at 2.2–2.6 and a trace of multiplet centered at δ 5.80). The ratio of the signals at δ 6.8 and 1.8 was 1:2 showing that no exchange of the 3-hydrogen had taken place.

The crude 3-methoxycyclohexanone was heated to 120°C in the presence of 20 mg of *p*-toluenesulfonic acid-*d*. The product was diluted with pentane, then washed with a solution of sodium carbonate in deuterium oxide. The dried pentane solution gave 2.3 g of deuterated enone. Total yield, 8.7 g (70%).

4,4-Dideuterio-6,6-dimethylcyclohexanone (7)

Reduction of the enones was repeatedly attempted, as follows.

(*a*) Sodium borohydride reduction followed by hydroboration and treatment with propionic acid (44). Much polymeric material resulted in most runs. Reoxidation of monomeric product gave good quality deuterated dimethylcyclohexanone but in average yield 14%. After base exchange of α-protons this had 76% d_2 and 18% d_1 by mass spectrometry.

(*b*) Sodium borohydride in pyridine (45) followed by Jones' oxidation also gave much polymer, but 40% of dideuterated ketone was obtained.

(*c*) Catalytic reduction gave a 70% yield of deuterated ketone, but mass spectrometry showed considerable deuterium scrambling. After exchange of the α-hydrogen using base the product had 14% d_3, 54% d_2, 22% d_1, and 17% d_0.

(*d*) The best method proved to be reduction with lithium in ammonia (46). To a solution of 2.0 g of lithium in 100 mL of liquid ammonia was added 36 g of *tert*-butyl alcohol. During 5 min stirring, the mixture turned bronze. A solution of 2.56 g of deuterated enone **6** in 25 mL of dry tetrahydrofuran was added dropwise in the course of one hour. Excess lithium was destroyed by addition of 50% water–tetrahydrofuran mixture, then water. After evaporation of the ammonia the residue was distributed between methylene chloride and water. The methylene chloride extract was oxidized with Jones' reagent (47). The resulting ketone was distilled over a short path at 60–70°C, 10 Torr pressure, giving 1.7 g (68%) of saturated ketone **7**.

The combined ketone from experiments following methods (*a*), (*b*), and (*d*) analysed for 1.97 D. It had ν_{max} 1700 cm^{-1}(s), 2210 (w), 2170 (w), and 2120 (w) cm^{-1}. Its ^{1}H nmr had signals at δ 1.14 (6H, s), 1.69 (2H, br s, $w_{1/2}$ = 3.5 Hz), 1.65–2.04 (2H, m, partly under the signal at δ 1.69), and 2.18–2.61 (2H, m). Its mass spectrum had peaks at *m/e* 129 (0.8), 128 (8.0), and 127 (2.8). The undeuterated ketone had peaks at 126 (8) and 125 (0.9), from which we estimate[7] that the deuterated sample contained 8% d_3, 76% d_2, and 16% d_1 species.

2-Bromo-4,4-dideutero-6,6-dimethylcyclohexanone

To 8.9 g (69.5 mmol) 4,4-dideutero-6,6-dimethylcyclohexanone dissolved in 10 mL glacial acetic acid was added with ice cooling one drop of a solution of hydrobromic acid in glacial acetic acid; then 11.1 g (69.5 mmol) of bromine dissolved in 20 mL glacial acetic acid was added over a period of 45 min. The solution was stirred for 10 min after addition and the reaction mixture was poured into 100 mL of a water – crushed ice mixture. The crude precipitate was filtered, washed with water, pressed dry, and recrystallized from ether–pentane giving 3 crops of crystals, mp 53–55°C, for a total yield of 9.6 g (46.5 mmol, 67%) of deuterated bromo ketone.

Its ^{1}H nmr spectrum had signals at δ 1.22 (6H, s) 1.74 (2H, br s, $w_{1/2}$ = 4 Hz), 1.84–2.7 (2H, m), 4.95 (1H, q, J_1 = 12 Hz, J_2 = 6 Hz).

2-Azido-4,4-dideutero-6,6-dimethylcyclohexanone

A 0.9 *N* methanolic solution of lithium azide was prepared (48) by refluxing for 5 h a mixture of 8.5 g lithium chloride and pulverized sodium azide in 200 mL methanol. After cooling and filtration, 160 mL of this solution was added dropwise with stirring to 9.6 g (46.5 mmol) of deuterated bromo ketone dissolved in 30 mL methanol. The solution was stirred at room temperature for 6 h after addition,and concentrated on a rotary evaporator near room temperature. A 100 mL mixture of crushed ice and water was added and the aqueous layer was extracted 5 times with 100 mL portions of pentane. Evaporation of the pentane near room temperature gave 7.6 g (45 mmol, 97%) of crude 2-azido-4,4-dideutero-6,6-dimethylcyclohexanone. This material was used in the next step without further purification. It had ν_{max} (chloroform) 1715 (s) and 2095 (s) cm^{-1}. The latter signal partially masked some C—D stretching bands.

2-Amino-4,4-dideutero-6,6-dimethylcyclohexanone Hydrochloride (1)

To an ice-cooled solution of 7.6 g (45 mmol) crude deuterated azido ketone in 25 mL 95% ethanol was added dropwise, through a dropping funnel, a solution of 15.8 g of $SnCl_2 \cdot 2H_2O$ in 70 mL of 95% ethanol containing 5 mL concentrated hydrochloric acid. After 3 h stirring, another 5 mL of concentrated hydrochloric acid was added and the reaction was allowed to proceed another 3 h, after which time nitrogen evolution had ceased. The ethanol was removed on a rotary evaporator and hydrogen sulfide was bubbled through an aqueous solution of the residue. A golden yellow precipitate which formed was filtered off through a bed of Celite and the filter cake was washed with water. The procedure was repeated twice until no more precipitate formed upon treatment of the aqueous layer with hydrogen sulfide. Water was removed on a rotary evaporator at 40°C, the residue dissolved in absolute ethanol, then 100 mg of insoluble material removed by filtration. After evaporation of the alcohol, the residue was treated with hot acetone and 3.5 g, mp 170–175°C, which did not dissolve, was collected on a filter. This was recrystallized from absolute ethanol – ethyl acetate yielding 2.3 g of crystals, mp 179–183°C. The mother liquor was combined with the acetone-soluble portion. The mixture was taken to dryness, then the residue triturated with acetone. The acetone-insoluble residue was recrystallized as before, yielding 1.0 g of crystals, mp 179–182°C (total yield 3.3 g, 18.5 mmol, 41%), of deuterated aminoketone hydrochloride **1**. After recrystallization from ethanol – ethyl acetate it had mp 181–184°C. It had ν_{max} 1722 cm^{-1} and its ^{1}H nmr spectrum had signals at δ 1.12 (3H, s), 1.31 (3H, s), 1.76 (2H, br s, $w_{1/2}$ = 5 Hz). *Anal.* calcd.[11] for $C_8D_2H_{14}ClNO$: C 53.48, H 8.97, N 7.80; found: C 53.53, H 9.20, N 7.61%.

Deamination of 2-Amino-4,4-dideuterio-6,6-dimethylcyclohexanone

This was carried out essentially as described earlier (ref. 1, method *b*). The neutral products were first analysed by glc – mass spectrometry[12] on a 10% SE-30 column at 100°C. Five peaks were examined. The first, with M^+ 140, has not been identified. The second was the trimethylcyclopentenone **19** with close to two deuterium atoms. The third was the bicyclic ketone **20** with approximately one deuterium atom. The more strongly retained peaks 4 and 5 appeared to be the isomeric hydroxy ketones rich in d_2 species. These were later shown to be the two isomers of **21** (see below) as expected from our early work (1).

The neutral products from 932 mg of the aminoketone hy-

[11]The gas chromatographic C, H, N determination does not distinguish hydrogen and deuterium, so the calculations are made correcting for this.

[12]We are grateful to Dr. Ross Pottie for help with this work.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

drochloride were separated on a 30-fold ratio of tlc silica gel (flat base column) into two fractions; A (350 mg, pentane–ether) containing the unknown product, **19** and **20**; B (175 mg, ether) containing the ketols (ν_{max} 3450, 1725 cm^{-1}).

Fraction A was chromatographed on a 60-fold ratio of tlc silica gel using 10% ether in pentane for elution. The unknown (6 mg) was followed by 39 mg of a mixture of it and **19**, then 35 mg of pure **19**, 15 mg of a mixture of **19** and **20**, and 145 mg of pure **20**. The two major components were distilled in a chain of bulbs at a bath temperature of 70°C under 30 Torr. These samples were used for mass spectra and ^1H nmr.

Fraction B (67 mg) in 10 mL of 1:1 ether–pentane was stirred with 1 g of neutral alumina, activity III, for 18 h. The suspension was filtered, then the solvents distilled. The residual oil was distilled in a chain of bulbs at a bath temperature of 80°C under 35 Torr giving 35 mg of **19** (identified by glc and infrared spectrum).

3,3-Dimethylbicyclo[3.1.1]hexan-2-one

This gave ^1H nmr signals at δ 1.7–2.15 (4H, m), 1.2 (center of a 1H, m), 1.09 (3H, s), 1.07 (3H, s), 0.89 (center of a 1H, m). It gave *m/e* 125 (4.5), 124 (46), and 123 (0.4).

*5-Deuterio-3,3-dimethylbicyclo[3.1.0]hexane-2-one (**20**)*

The product from deamination of **1** (yield 22%) gave a mass spectrum with *m/e* 126 (8), 125 (46), 124 (13), from which we calculate[7] its deuterium content to be 6% d_2, 74% d_1, and 21% d_0 species. Its ^1H nmr spectrum gave a single peak near δ 1.7 (internal $CDCl_3$ as reference). Its ^1H nmr spectrum had peaks at δ 1.75–2.2 (3H, m), 1.38 (center of a 1H, m), 1.10 (3H, s), 1.05 (3H, s), 0.89 (center of a 1H, m).

2,4,4-Trimethylcyclopenten-3-one

This gave ^1H nmr signals at δ 7.34 (1H, m), 2.46 (2H, m), 1.80 (3H, m), 1.09, 1.11 (3H, singlets). It gave *m/e* 125 (5), 124 (51), 123 (3).

*1-Deuterio-2-monodeuteriomethyl-4,4-dimethylcyclopenten-3-one (**19**)*

(a) Directly Isolated (Yield 10%)

This gave *m/e* 127 (6), 126 (51), and 125 (26). From this we estimate[7] a content of 69% d_2 and 31% d_1 species. Its ^2H nmr spectrum gave two signals at approx δ 7.0 (s) and 1.8(t, J = 2.2 Hz) (internal $CDCl_3$ reference) with relative areas 1:0.92. Its ^1H nmr spectrum (trace of hexane) gave signals at δ 2.47, 1.80, and 1.1 in the ratios 2:2.3:6.2.

*(b) From Dehydration of the Ketol **21** (Yield 23%)*

This had ν_{max} 1690 (5), 1635 (w), and 1620 (w) cm^{-1} and gave *m/e* 127 (5), 126 (51), 125 (19), from which the calculated content[7] was 73% d_2 and 27% d_1 species.

Methyl 2,2-Dimethylcyclopentanecarboxylate

This gave a mass spectrum with peak at *m/e* 157 (17), 156 (M^+, 5.6), 155 (0).

*Methyl 3,3-Dideuterio-5,5-dimethylcyclopentanecarboxylate (**22**)*

The mass spectrum of this ester had peaks at *m/e* 159 (1.2), 158 (M^+, 5.6), 157 (2.7). From this we calculated[6] a content of 63% d_2 and 30% d_1 species. It had ν_{max} (film) 2220, 2180, 2130, 1735 cm^{-1} and gave ^1H nmr signals at δ 0.90 (3H, s), 1.18 (3H, s), 2.51 (1H, q, J_1 = 8.5 Hz, J_2 = 7.5 Hz), 3.78 (3H, s). The methylene signals between δ 1.4 and 2.2 were simplified relative to the undeuterated ester.

2-exo-Benzamidonorbornan-3-one

This was prepared by oxidation of the known benzamido alcohol (14) using the Ratcliffe–Rodehorst reagent (15) (see the *endo-d_2* analogue). It had mp 209°C, and was sparingly soluble in chloroform, but a saturated solution in $CDCl_3$ gave ^1H nmr peaks at δ 7.9–7.25 (aromatic), 6.25 (NH), 3.88 (q, J_1 = 6, J_2 = 3 Hz, 1H), 2.84 (1H), 2.69 (1H), 2.3–1.5 (m, 6H).

*2-exo-Aminonorbornan-3-one Hydrochloride (**23**)*

This was prepared by acid hydrolysis of the benzamido ketone (see the *endo-d_2* analogue). It had mp 145°C and gave ^1H nmr peaks in D_2O–DSS centered at δ 3.43 (d, J = 3 Hz), 3.0, 2.80, and 2.35 representing 1, 0.5, 3, and 1.1 hydrogens respectively. The signal at δ 3.43 had only 58% of the expected intensity for one hydrogen. We attribute this to partial hydration of the carbonyl group in D_2O. Attempts to recrystallize the salt from ethanol – ethyl acetate did not raise the melting point and much was apparently converted to ketal or hemiketal which did not crystallize.

5,6-exo-d_2-Norbornene and 5,6-endo-d_2-Norbornene

Norbornadiene was reduced in methanol over 30% palladium charcoal until an excess of 30% over one mole of deuterium was absorbed. Gas–liquid chromatography on a 20 ft × 3/8 in. column with 30% SE-30 packing at 120°C gave retention times for norbornadiene of 15.5 min, norbornene 16.5 min, and norbornane 20 min. The product from the reduction contained 80% 5,6-*exo*-dideuterionorbornene and 20% of deuterated norbornane. This mixture was used for preparation of the deuterated *N*-benzoyl aziridine or converted by the method of Werstiuk (16) to 5,6-*endo*-dideuterionorbornene.

*N-Benzoyl 6,7-exo-Dideuterio-3-exo-azatricyclo[3.2.1.$0^{2,4}$]octane(**8**)*

A mixture of 10 g of 5,6-*exo*-dideuterionorbornene and 31 g of benzoyl azide was heated at 40°C for four days. Excess azide was destroyed by heating the mixture to 90°C. Isocyanate was removed by distillation in a bath at 50°C under 10 Torr. The residual oil was purified by distillation over a short path at 120°C, 5 × 10^{-3} Torr; ^1H nmr δ: 7.3–8.3 (5H, aromatic), 2.75 (2H), 2.6 (2H), and a set of signals between 1.8 and 0.8 (4H). Its ^2H nmr spectrum gave a single peak near δ 1.6.

*5,6-exo-d_2-Oxazoline (**9**)*

The *N*-benzoyl aziridine **8** was heated at 240°C for 25 min, then the resulting oxazoline distilled over a short path at 110°C, 0.3 Torr. The yield from the norbornene was 14.6 g (69%). It had ν_{max} 2225 (w), 2200 (w shoulder), 2180 (w), 1675 (w shoulder), 1645 (s), 1448 (s), 1355 (s) 1320 (s), 1025 (s), 985 (s) cm^{-1}. Its ^1H nmr spectrum had signals at δ 7.4 to 8.35 (aromatic, 5H), 4.56 (d, J = 7 Hz, 1H), 4.2 (d, J = 7 Hz, 1H) 2.46 (2H), 0.9–1.15 (m, 4H). Its ^2H nmr spectrum gave a single peak near δ 1.6.

*5,6-exo-d_2 Hydroxybenzamide (**10**)*

A suspension of 14.6 g of oxazoline **9** in 50 mL of 2 *N* sulfuric acid was heated under reflux (N_2 atmosphere) for 5 h. The mixture was cooled, neutralized with sodium carbonate, then extracted with methylene chloride. The extracted product crystallized from ethyl acetate giving 11 g, mp 115°C. The mother liquor contained 3.7 g, mainly unchanged oxazoline.

The hydroxybenzamide **10** had ν_{max} 3620 (w), 3420 (m), 2180 (w), 1640 (s), 1602 (w), 1580 (m), 1510 (s), 1485 (s), and 1040 (m) cm^{-1}. Its ^1H nmr spectrum had signals at δ 6.8–8.1 (6H reduced to 5H on exchange with *p*-toluenesulfonic acid in D_2O), 4.6 (1H, exchanged with D_2O), 3.77 (2H), 2.3 (2H, d, J = 9 Hz), and a set of signals between δ 0.66 and 2.0 (4H). Its ^2H nmr gave a single signal near δ 1.5 in trifluoroethanol relative to external TMS.

*5,6-exo-d_2 Ketobenzamide (**11**)*

Dry chromium trioxide (6 g; 60 mmol) was added to a cooled,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

stirred solution of 9.5 g of pyridine (120 mmol) in 150 mL of pure dichloromethane (15). The solution was left at room temperature for 15 min, then a concentrated solution of the hydroxybenzamide **10** (2 g, 10 mmol) was added rapidly. The mixture was stirred for 15 min, then the solution decanted from the dark gum. The gum was washed twice with dichloromethane. The combined CH_2Cl_2 layers were washed with three 100 mL portions of 5% sodium hydroxide solution, 100 mL of 5% hydrochloric acid, 100 mL of 5% aqueous sodium bicarbonate solution, then 100 mL of saturated brine. The product recovered from the CH_2Cl_2 crystallized from a methanol–chloroform mixture to give 1.97 g, mp 207–208°C.

Its ^2H nmr spectrum in chloroform gave a single signal near δ 2.2.

*2-*exo*-Amino-5,6-*exo*-dideuterionorbornan-3-one Hydrochloride (2)*

A suspension of the benzamido ketone **11** (6.95 g) in 400 mL of 1 *N* hydrochloric acid under argon was refluxed for 3 h. The cooled solution was extracted with ether, then the ether back-washed with 1 *N* hydrochloric acid. The aqueous layers were evaporated to dryness in a bath at 50°C under 15 Torr yielding a white crystalline solid. This was purified by suspension in ethyl acetate, then filtration. It had mp 148–152°C dec. (Pyrex capillary). Attempted recrystallizations from ethanol – ethyl acetate led to much amorphous material (hemiketal) and crystals with wider melting range. Its ^1H nmr spectrum in D_2O–DSS gave signals at δ 3.40 (d, J = 3 Hz), 2.97, 2.78, and 2.32 in the ratios 1:0.69:2.2:1.3 respectively. The signal at δ 3.40 had only 60% of the expected intensity. We consider this to be due to partial hydration of the carbonyl (see unlabelled analogue). *Anal.* calcd.[11] for $C_7H_{10}D_2ClNO$: C 52.03, H 7.43, N 8.67; found: C 51.99, H 7.44, N 8.78.

*N-Benzoyl-6,7-*endo*-dideuterio-3-*exo*-azatricyclo-[3.2.1.0^{2,4}]octane (8,* endo-d_2*)*

This was prepared from the 3,6-*endo* deuterated norbornene and benzoyl azide by heating at 40°C for nine days. The *N*-benzoyl aziridine distilled over a short path at 120°C under 4 × 10^{-3} Torr, yield 75%. It had ν_{max} (CCl_4) 2190 (w) and 1679 (s) cm^{-1}. The ^1H nmr spectrum δ: 7.2–8.2 (aromatic, 5H), 2.84 (2H), 2.63 (2H), 1.63, 1.52, 1.23, 0.97, and 0.78 (4H).

*5,6-*endo*-d_2-2,3-*exo*-Oxazoline (9,* endo-d_2*)*

This was prepared by heating the *N*-benzoylaziridine at 245°C for 30 min. It distilled over a short path at 130°C under 0.05 Torr. It gave ^1H nmr signals at δ 7.2–8.3 (aromatic, 5H), 4.58 (d, J = 7 Hz, 1H), 4.20 (d, J = 7 Hz, 1H), 2.45 (2H), 1.5 (m, 2H), 1.23, 1.03 (multiplets, 1H).

*5,6-*endo*-d_2-Hydroxybenzamide (10,* endo-d_2*)*

The oxazoline **9** (*endo-d_2*) was hydrolysed by 2 h refluxing with 2 *N* sulfuric acid. The hydroxybenzamide was surprisingly soluble in acid, so the aqueous solution was neutralized before extraction with chloroform. It crystallized from dichloromethane–hexane mixture, mp 114°C. It had ν_{max} 3620 (w), 3420 (s), 2190 (w), 1642 (s), 1580 (m), 1512 (s), 1470 (s) cm^{-1}. It gave ^1H nmr signals at δ 3.88 (2H), 3.80 (1H, exchanged with D_2O), 2.35 (1H), 2.22 (1H), 1.83, 1.67, 1.46, 1.2, 1.03 (4H). Its ^2H nmr spectrum in chloroform gave a single peak. A small shoulder on the lower-field side of the peak corresponded to approximately 2% of another deuterated species.

*5,6-*endo*-d_2-Ketobenzamide (11,* endo-d_2*)*

The hydroxybenzamide was oxidized in methylene chloride – pyridine (see *exo* isomer for details) giving the sparingly soluble ketone, mp 215°C. It had ν_{max} 3440 (w), 2200 (w), 1703 (s), 1663 (s), 1603 (w), 1593 (w), 1511 (s), and 1485 (s) cm^{-1}. Because of its low solubility its ^1H nmr spectrum was not recorded. Its ^2H nmr spectrum in chloroform gave a single signal near δ 2.2.

*2-*exo*-Amino-5,6-*endo*-dideuterionorbornan-3-one Hydrochloride (3)*

The benzamido ketone (**11**, *endo-d_2*) (3.4 g) was hydrolysed as for the *exo-d_2* isomer. The crystalline solid after evaporation of the water was suspended in dioxane, then collected by filtration. The first crop (1.7 g, 71%) had mp 153°C dec. after drying *in vacuo*. Subsequent crops (297 mg) melted at 150°C dec. Its ^1H nmr spectrum in D_2O–DSS had signals at δ 3.42 (d, J = 3 Hz), 3.02, 2.82, and 2.4 in the ratio of 1.0, 0.5, 1.7, and 1.35 hydrogens respectively. The signal at δ 3.42 (2-hydrogen) had only 59% of the expected intensity. As in the case of the unlabelled and 5,6-*exo* dideuterio analogues we believe this is due to partial hydration of the carbonyl.

*2-*endo*-Aminonorbornane-3-one Hydrochloride (4)*

The mono-oxime of norbornane-2,3-dione (18) (5 g) was added slowly to a stirred cold solution of 15 g of stannous chloride in 20 mL of concentrated hydrochloric acid. The mixture was left at room temperature for 2 h, then diluted with 300 mL of water and extracted with 3 × 100 mL of ether. The aqueous layer was saturated with hydrogen sulfide, then filtered. The filtrate was taken to dryness on a rotary evaporator below 50°C, giving 4.5 g of crude hydrochloride. Quick recrystallization of this from ethanol on addition of ethyl acetate gave 1.5 g of quite pure amine hydrochloride, mp 153–157°C. Its ^1H nmr spectrum had peaks centered near δ 1.78 (8H), a broad signal centered at δ 2.90 (3H), and a doublet centered at δ 3.80 (1H, J = 4 Hz). After 60 h in D_2O the signal at δ 2.9 had reduced to two hydrogens. Addition of *p*-toluenesulfonic acid resulted in a spectrum with signals at δ 1.78 (6H), 2.90 (2H), and 3.80 (1H, d, J = 4 Hz). *Anal.* calcd. for $C_7H_{12}ClNO$: C 52.03; H 7.43, N 8.67; found: C 51.99, H 7.44, N 8.78.

2-Diazonorbornan-3-one (5)

To a stirred suspension of 1.44 g of the monotosylhydrazone of norbornan-2,3-dione (17) in 4 mL of water under 10 mL of pentane, was added 464 mg of sodium hydroxide in 1 mL of water. The pentane layer was separated and replaced at roughly 15 min intervals until no color entered the organic phase (ca. 2 h). The pentane was dried, then distilled. The yellow residue was distilled over a short path at 65°C, 0.05 Torr, giving a yellow oil (389 mg, 62%).

This gave ^1H nmr signals at δ 3.55 (1H, s), 2.78 (1H, s), 2.2–1.3 (6H, m). The diazoketone could be stored for a few days at 0°C in the dark.

*Deamination of 2-*exo*-Amino-5,6-*endo*-dideuterionorbornan-3-one (3)*

A solution of 2.0 g of the hydrochloride of **3**, mp 153°C dec., in 15 mL of 0.5 *N* sulfuric acid was cooled to 15°C. A solution of 3 g of sodium nitrite in 4 mL of water was added slowly to the magnetically stirred solution over the course of 40 min. Another 10 mL of 0.5 *N* sulfuric acid was added in two portions, then the solution stirred for a further 40 min. A layer of pure ether was added, then solid sodium bicarbonate was added cautiously until the solution was neutral. The aqueous layer was extracted with three 25 mL portions of ether. The ether layers were washed with 5 mL of sodium bicarbonate solution, dried, and carefully distilled to a volume of around 8 mL. This was then made up to 10.0 mL for determination of nortricyclanone; glc comparison with a standard showed this to contain 59 mg of deuterated nortricyclanone (4.3%). The ether solution (A) was then concentrated for examination of the nortricyclanone and ketols (see below).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

The aqueous layers were extracted with three 15 mL portions of chloroform, giving 127 mg of oil which was immediately acetylated with acetic anhydride – pyridine (B).

The combined aqueous layers (pH ~ 8) were evaporated to dryness under reduced pressure. Enough 6 *N* sulfuric acid was added to make the suspension strongly acid, then this was extracted successively with methylene chloride and chloroform, finally drying the aqueous layer to a paste, using anhydrous sodium sulfate in the presence of chloroform. The combined extracts were dried and distilled giving 1.23 g of acids (yield calculated as $C_7H_{10}O_4$, 64%).

The ether extract (A) was absorbed on 5 g of neutral alumina, activity I. The nortricyclanone was eluted rapidly with ether. It was pure enough after short path distillation for determination of its ^{2}H nmr, ^{13}C nmr, and mass spectra. The ketols (142 mg) were eluted with 10% methanol in chloroform, then converted to their acetates (C). The total yield of ketol acetates (B + C) was 17% (calcd. as $C_9H_{12}O_3$).

The water soluble acids were converted to methyl esters using diazomethane. A mixture of three hydroxy esters was separated from this by chromatography on a 25-fold ratio of alumina (activity I) eluting with 1:1 ether–chloroform. The 211 mg of hydroxy esters was further purified by hplc. Only one was obtained reasonably pure. It had ν_{max} 3610, 3450, 2175, and 1725 cm^{-1}. Its ^{1}H nmr spectrum had a broad set of signals from δ 0.7–2.7 (7H), 2.9 (OH) (0.8H, s), 3.73 (3H, s) superimposed on a multiplet from 3.2 to 4.3 (0.6H). *Anal.* calcd.[11] for $C_8H_{12}D_2O_3$: C 59.98, H 8.80; found: C 59.32, H 8.75.

Deamination of 2-exo-*Amino-5,6-exo-dideuterionorbornan-3-one*

(a) In Dilute Acid

The *exo*-d_2 was deaminated in dilute sulfuric acid as described for the *endo*-d_2 amine. The yield of nortricyclanone was 2.1% and that of 2-*exo*-hydroxynorbornan-7-one was 15.5%. Preparative runs on a total of 4.0 g of hydrochloride gave a 6.4% yield of pure **27**, 1.8 g of readily extracted acids rich in 3-cyclohexene-1-carboxylic acid, and 1.0 g of very water soluble acids. The latter contained three hydroxy acids of which one was obtained fairly pure by chromatography of the methyl esters on alumina, followed by hplc. The ester had ν_{max} 3620, 3450, 2170, and 1725 cm^{-1}. *Anal.* calcd. for $C_8D_2H_{12}O_3$: C 59.98, H 8.80; found: C 59.70, H 8.55.

(b) In 1 M Sodium Acetate in 50% Aqueous Acetic Acid

Sodium nitrite (195 mg) was added to an ice-cold solution of 457 mg of the hydrochloride of **2** in 4 mL of 50% (v/v) aqueous acetic acid. After four min the cooling bath was removed. A further 150 mg of sodium nitrite was added in portions over the next 2 h. After a total time of 4 h the solution was cooled in ice, a layer of ether added, then neutralized with cooling, using sodium carbonate (pH ca. 8). Ether extraction gave 218 mg of neutral product (containing some cyclohexenoic acid). The nortricyclanone yield was 2.5%.

The neutral product was acetylated yielding 170 mg of acetates (36% calculated as ketol acetate). The yield of 2-*exo*-acetoxynorbornan-7-one was approximately 18%.

Deamination of 2-exo-*Aminonorbornan-3-one*

(a) In Dilute Sulfuric Acid

This was performed as described for the 5,6-*endo*-d_2 aminoketone. The yield of nortricyclanone was 3.1% and that of 2-acetoxynorbornane-7-one was 15.5%. The total yield of neutral product calculated as ketol was 25%. Varying the ratio of sulfuric acid to amine five-fold did not significantly alter the yield of either product. No 2-*endo* or 2-*exo*-acetoxynorbornan-3-one were detected among the products after acetylation. The yield of readily extracted acids was 10% by weight. Of this, the main acid (6% yield) was 3-cyclohexenoic acid. This was converted to its *p*-bromophenacyl ester and methyl ester for identification and spectra. Three hydroxy acids were isolated from the very water-soluble acids, but their structures were not established (see deamination of **3**).

(b) In 50% Aqueous Acetic Acid

(1) Sodium nitrite (284 mg) was added in portions during 22 min to a stirred solution of 262 mg of 2-*exo*-aminonorbornane hydrochloride in 3 mL of 50% acetic acid (v/v) in an ice bath. The mixture was left at room temperature for 1.5 h. After addition of 10 mL of ether, the solution was cooled in an ice-bath, then neutralized by addition of 0.9 g of sodium hydroxide in 3 mL of water, followed by sodium carbonate, then excess sodium hydrogen carbonate (pH ~ 8). Ether extraction (3 × 15 mL) gave an ether solution which was concentrated to ca. 3 mL, then made up to 5.0 mL for glc analysis. The yield of nortricyclanone was 4.1%. The isolated neutral product, which was a mixture of ketols and their acetates, weighed 94 mg.

(c) In 1 M Sodium Acetate in 50% Aqueous Acetic Acid

When 238 mg of amine hydrochloride was deaminated as in (b), but in 3 mL of 1 *M* sodium acetate in 50% (v/v) acetic acid, 92 mg of ether-extracted neutral product was obtained. The yield of nortricyclanone was 4.1%. The neutral compounds from runs (b) and (c) were combined, acetylated, and the main acetate isolated by preparative tlc (10% yield from hydrochloride). It was shown to be 2-*exo*-acetoxynorbornan-7-one by glc and ^{1}H nmr.

(d) In a 1 M Solution of Sodium Acetate in Acetic Acid

A suspension of 435 mg of 2-*exo*-aminonorbornan-3-one hydrochloride in 6 mL of 1 *M* sodium acetate in acetic acid was warmed until the bulk dissolved. Under an argon atmosphere, 600 mg of sodium nitrite was added over a period of 1.5 h to the stirred solution at room temperature. After 4 h a further 110 mg of sodium nitrite was added, then stirring continued for 1 h. Ether and 5 mL of water were added, then the solution was cooled to 0°C and taken to pH 8, first with sodium hydroxide solution, then solid sodium bicarbonate. It was then extracted three times with equal volumes of ether. The dried ether solution was concentrated carefully to ca. 3 mL volume, then made up to 5.0 mL for quantitative glc analysis. The nortricyclanone yield was 9%. The solution was then combined with 18 mg of product extracted by methylene chloride, then made up to 1.0 mL for glc analysis of the 2-acetoxy-7-one **15**. The yield of **15** was 12%.

The total neutral yield (some loss of nortricyclanone) was 273 mg (estimated as ketol acetate, 61%). Besides the 7-ketone and nortricyclanone, nine other products were present in low yield as indicated by glc on column B. If 2-*exo*-acetoxynorbornan-3-one was present it amounted to less than 3% of the total product.

Deamination of 2-endo-*Aminonorbornan-3-one* (*4*)

(a) In Water

A solution of 300 mg of *endo* amine hydrochloride in 2 mL of 0.5 *N* sulfuric acid was cooled to 15°C. A solution of 0.5 g of sodium nitrite in 1 mL of water was added dropwise during 20 min to the stirred acid solution. A further 1 mL of 0.5 *N* sulfuric acid was then added and stirring continued for 15 min. After addition of 5 mL of ether, the mixture was neutralized using sodium bicarbonate. The ether layer was separated, then the aqueous layer washed with 2 × 10 mL of ether. The ether extracts were back-washed with saturated sodium bicarbonate solution. The dried ether extracts were concentrated, then made up to 10.0 mL for quantitative glc analysis. Less than 0.2% of nortricylanone was formed.

The aqueous solutions were acidified and extracted with 3 ×

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

10 mL of ether, yielding 50 mg of acid. This was mainly 3-cyclohexene-1-carboxylic acid, identified by the nmr, ir, and mass spectra of its methyl ester.

The water soluble acidic products contained a hydroxy acid with nearly identical spectral properties to the main one described for deamination of 2-*exo*-aminonorbornan-3-one and its deuterated analogues (see deamination of **3**).

(b) In 50% Acetic Acid

A solution of 352 mg of the base hydrochloride in 3 mL of 50% (v/v) acetic acid was cooled in ice, then 150 mg of sodium nitrite added with stirring over 3 min. The solution was removed from the ice bath. After 15 min a further 100 mg of nitrite was added, followed after 20 min by 50 mg of nitrite. After a further 30 min at room temperature the mixture was cooled in ice, 10 mL of ether added, followed by slow addition of a solution of 0.9 g of sodium hydroxide in 3 mL of water. Neutralization was completed using solid sodium carbonate, the final pH being near 8. Three extractions using 15 mL of ether for each gave a solution which was dried, concentrated, then made up to 10.0 mL for quantitative glc analysis. The yield of nortricyclanone was 1.5%. The total neutral product was acetylated. Three ketol acetates were identified by glc. In order of decreasing yield these were 2-*endo*-acetoxynorbornan-3-one (**14**), 2-*exo*-acetoxynorbornan-7-one (**15**), and 2-acetoxybicyclo[3.1.1]heptan-6-one (**18**).

(c) In 1 M *Sodium Acetate in 50% Acetic Acid*

A solution of 351 mg of amine hydrochloride in 3 mL of 1 *M* sodium acetate in 50% (v/v) acetic acid was deaminated as described in (b). The yield of nortricyclanone was 1.5%. The ketol products were formed in similar ratio to those described in (b).

(d) In Acetic Acid

A solution of 350 mg of base hydrochloride in 3 mL of acetic acid was deaminated as in (b), except that the reaction mixture was left for 2 h after the final nitrite addition, and 3 mL of water was added prior to neutralization. The yield of nortricyclanone was 2.3%. Again the same ketols were produced, in similar ratios.

(e) In 1 M *Sodium Acetate in Acetic Acid*

The deamination was carried out as in (d) except that the final reaction period was extended to 3 h. The yield of nortricyclanone was 3.6%. The 2-*exo*-hydroxynorbornan-7-one now became the major ketol product followed by 2-*endo*-hydroxynorbornan-3-one and 2-hydroxybicyclo[3.1.1]heptan-6-one (as alcohols and acetate) in decreasing abundance.

Deamination of 2-Diazonorbornan-3-one (5)

(a) In Very Dilute Sulfuric Acid

Freshly distilled diazoketone (407 mg) was suspended in 5 mL of water containing 0.05 mL of 0.5 *N* sulfuric acid. There was rapid gas evolution. When this ceased the solution was made basic using sodium bicarbonate, then extracted with 3 × 5 mL of methylene chloride. This gave 329 mg (87% calculated as ketol) of neutral product containing some 3-cyclohexene-1-carboxylic acid. The ratio of areas of the two main products was 1.4 (2-*endo*-hydroxynorbornan-3-one **14**) to 1 (2-hydroxybicyclo-[3.1.1]heptan-6-one **18**). The yield of nortricyclanone was in the order of 1%.

(b) In Water

A mixture of 639 mg of diazoketone **5** and 5 mL of water was stirred in a bath at 15°C. Evolution of gas started in less than 1 min and accelerated with time. After 30 min the main reaction was complete. Two drops of 0.6 *N* sulfuric acid were added to ensure complete reaction. The mixture was extracted with ether, then the ether washed with saturated sodium bicarbonate solution. The original aqueous solution was saturated with sodium sulfate, then extracted three times with 10 mL portions of chloroform, which were in turn washed with the bicarbonate solution. The aqueous layers were acidified and extracted with chloroform to give the acidic products.

The ether extract was concentrated to ca. 5 mL, then made up to 10.0 mL for glc analysis. The yield of nortricyclanone was thus estimated by comparison with a standard solution to be 1.3%.

The yield of the various fractions was: (*a*) ether extract, 222 mg; (*b*) chloroform extracted neutrals, 127 mg; (*c*) acids (containing any very water-soluble neutral products), 153 mg. The acid was mainly cyclohexene-3-carboxylic acid, while the neutral extracts were mixtures of **14** (R = H) (approximately 39% yield) and **18** (R = H) (approximately 20% yield).

(c) In 50% Acetic Acid

Freshly distilled diazoketone (ca. 450 mg) was added to ice-cold 50% (v/v) acetic acid with or without added sodium acetate. After disappearance of the yellow color and cessation of nitrogen evolution, the solution was partially neutralized using 0.8 g of sodium hydroxide in 3 mL of water, with ice cooling. A layer of ether was added, and neutralization completed using sodium bicarbonate. The neutral products and some 3-cyclohexene-1-carboxylic acid were extracted into ether (3 × 10 mL). The dried ether solution was concentrated, then made up to 5.0 mL for analysis.

(1) 50% Acetic Acid. Reaction was complete in less than 1 min. The yield of nortricyclanone was 1.5%. The total neutral product was 93% by weight of diazoketone used.

(2) 1 M *Sodium Acetate in 50% Acetic Acid.* Reaction was complete in 5 min. Yield of nortricyclanone 12%. The total neutral product was 82% of the diazoketone used.

(3) 4 M *Sodium Acetate in 50% Acetic Acid.* Reaction was very slow even at room temperature. It was complete in 45 min at 20°C. The yield of nortricyclanone was 17.5%. The neutral products isolated were 65% by weight of diazoketone.

Aside from the increase in nortricyclanone yield, the most striking effects of the sodium acetate were the slowing of reaction and the increase in amount of 2-*exo*-acetoxynorbornan-7-one formed. This was produced in trace amounts in 50% acetic acid, in three times the amount of ketol acetates **14** or **18** when 1 *M* acetate was present, and four times the amount of each of these acetates in the presence of 4 *M* sodium acetate. Even with 4 *M* NaOAc present, the amount of ketols (**14**, **15**, and **18**, R = H) exceeded the amount of ketol acetates (ratio of areas 1.6). For 1 *M* sodium acetate the ratios of areas was 2.9.

(d) In 100% Acetic Acid

Cold glacial acetic acid (3 mL) or 1 *M* sodium acetate in glacial acetic acid was added rapidly to ca. 300 mg samples of freshly distilled diazoketone. When the diazo color had gone and gas evolution ceased, 2 mL of water was added, then during cooling in ice a solution of 1.5 g of sodium hydroxide in 3 mL of water was added. A 10 mL layer of ether was added, then neutralization completed using first sodium carbonate, then sodium hydrogen carbonate (pH taken to near 8). Thorough ether extraction (4 × 15 mL) gave the neutral products and some acid. The dried solutions were concentrated, then made up to 5.0 mL for glc analysis.

(1) Acetic Acid. The reaction time was approximately 5 min. The neutral products weighed 233 mg, of which 16 mg was nortricyclanone. The yield of nortricyclanone was 8.5% and ketols (calcd. as acetates) 66%.

(2) 1 M *Sodium Acetate in Acetic Acid.* The reaction time was approximately 5 min. The yield of nortricyclanone was 8.4% and of ketols and ketol acetates was 67% (calcd. as acetates).

The products from deamination in acetic acid or 1 *M* sodium acetate in acetic acid were nearly identical. The ratio of peak

areas (column B, 190°C) for 2-*exo*-acetoxynorbornane-7-one and the ketol acetates **14** and **18** was 2.5 : 1 : 1. Small amounts of ketols were also present.

To study the action of nitrous acid and nitrogen oxides on the ketols **14** and **18** (R = H), 122 mg of neutral mixture from deamination of diazoketone was dissolved in 1 mL of water plus 1 mL of 0.5 *N* sulfuric acid. To this was added dropwise over 30 min at 10°C a solution of 205 mg of sodium nitrite in 1 mL of water. The solution was then neutralized with sodium bicarbonate and extracted with methylene chloride. The recovered material (115 mg) had very similar composition (glc) to the starting material.

Diazoketone (208 mg) was suspended in 3 mL of water containing 300 mg of sodium nitrite. To the stirred solution was added 0.3 mL of 0.6 *N* sulfuric acid during 10 min. The solution was made basic (pH 8.5) using sodium carbonate, then the neutral products extracted into ether. The dried ether extract was concentrated, then made up to 5.0 mL for glc analysis. The yield of nortricyclanone was 3.6%. On evaporation the ether yielded 78 mg of crystalline ketols (41%). The basic solution yielded 36 mg of 3-cyclohexene-1-carboxylic acid and 50 mg of ketols (30%).

Nortricyclanone

Unlabelled

Authentic nortricyclanone (49) had ν_{max} 1770 (m, shoulder), 1750 (s) cm^{-1}; ^1H nmr signals at δ 2.56–2.06 (2H, m), 2.06–1.75 (3H, m), 1.65 (s, 1H), and 1.22 (t, J = 5 Hz, 2H). Its mass spectrum had *m/e* 109 (5), 108 (40), 107 (5), 81 (9), 80 (75), 79 (100), 8 (10), 77 (32).

From endo-d_2 *Aminoketone 3*

The ether eluates from chromatography of neutral products (extract A) were distilled in a chain of bulbs at 70°C under 13 Torr. Its mass spectrum had *m/e* 111 (7), 110 (34), 109 (7), 83 (8), 82 (69), 81 (100), 80 (34), 79 (21), 78 (20). From this we estimate it to contain 8% d_3, 86% d_2, and 6% d_1 species. Its ^2H nmr spectrum is shown in Fig. 3 and its ^{13}C nmr spectrum in Fig. 2.

From exo-d_2 *Aminoketone 2*

Its mass spectrum had peaks *m/e* 111 (1.0), 110 (12), 109 (87), 108 (13), 82 (23), 81 (100), 80 (99), 79 (48), 78 (51), 77 (24). From this it was estimated to contain 4% d_2, 93% d_1, and 3% d_0 species.

Its ^2H nmr spectrum is shown in Fig. 1 and its ^{13}C nmr spectrum in Fig. 2.

2-exo-*Acetoxynorbornan-3*-exo-*ol*

This was prepared by partial acetylation of the known 2,3-*exo*-diol (50) using 1.2 mol of acetyl chloride in pyridine at 0°C. After purification by chromatography on tlc silica gel using 2% ethanol in chloroform for elution it crystallized as plates from pentane, mp 46–47°C. It had ν_{max} 3595, 3460, and 1728 cm^{-1}, and gave ^1H nmr signals at δ 4.60 (1H, pair of barely resolved doublets, J_1 = 6 Hz), 3.88 (1H, d, J = 6 Hz), 2.13 (3H, s). *Anal.* calcd. for $C_9H_{14}O_3$: C 63.51, H 8.29; found: C 63.68, H 8.19.

2-exo-*Acetoxynorbornan-3-one (13, R = Ac)*

Oxidation of 2-*exo*-acetoxynorbornan-3-ol with Jones' reagent (47) in acetone or Ratcliffe–Rodehorst reagent (15) in methylene chloride gave good yields of the acetoxy ketone as an oil. It was purified by chromatography on 100-fold weight of tlc silica gel using 2% ethanol in chloroform for elution, then distilled over a short path at 115°C, 15 Torr. It had ν_{max} 1763 and 1742 cm^{-1} and ^1H nmr signals at δ 4.60 (1H, d, J = 3 Hz), 2.61 (2H, s), and 2.11 (3H, s). *Anal.* calcd. for $C_9H_{12}O_3$: C 64.27, H 7.19; found: C 64.08, H 7.17.

2-exo-*Hydroxynorbornan-3-one (13, R = H)*

The corresponding acetate could by hydrolysed using 10 mol% of sodium methoxide in methanol at 0°C for 1 h, or a saturated solution of sodium carbonate in 50% aqueous methanol at room temperature for 1 h. The product had mp 146°C and ν_{max} 3580, 3380, and 1700 cm^{-1}. It deteriorated quite rapidly at room temperature in air.

A solution of 48 mg of 2-*exo*-hydroxynorbornan-3-one in 2 mL of 50% acetic acid was prepared. Sodium nitrite (176 mg) was added over 15 min to the stirred solution, then the mixture was left at room temperature for 25 min. The acid was neutralized as in the work-up of comparable deamination and the neutral product recovered (50 mg). This appeared to be essentially pure starting material by glc.

2-endo-*Acetoxynorbornan-3*-endo-*ol*

The known diol (50, 51) was partially acetylated by slowly adding 1.2 mol of acetyl chloride to a solution of the diol in pyridine at 0°C, then leaving for 3 h at room temperature. Purification as for the 2,3-*exo* monoacetate gave the monoacetate as crystals, mp 47–49°C. It had ν_{max} 3590, 3495, and 1725 cm^{-1} and gave ^1H nmr signals at 4.72 (1H, q, J_1 = 9, J_2 = 5 Hz), 4.05 (1H, q, J_1 = 9, J_2 = 5 Hz), 2.79 (1H, s, OH), 2.41 (2H, br s), 2.13 (3H, s). *Anal.* calcd. for $C_9H_{14}O_3$: C 63.51, H 8.29; found: C 63.69, H 8.35.

2-endo-*Hydroxynorbornan-3-one (14, R = H)*

The ketol from deamination of 2-diazonorbornan-3-one **5** had ν_{max} 3450 and 1746 cm^{-1}. Its mass spectrum had peaks at *m/e* 127 (M + 1) (3.5), 126 (12), 124 (3), 99 (3), 98 (13), 97 (3), 86 (6), 84 (9), 80 (5), 79 (3), 70 (3), 69 (4), 68 (5), 67 (12), 66 (3.5), 65 (4), 58 (23), 57 (100), 55 (21).

Its acetate (**14**, R = Ac) was an oil with ν_{max} 1759 cm^{-1} and shoulders at 1745 and 1731 cm^{-1}. Its ^1H nmr spectrum had signals at δ 5.00 (1H, d, J = 5 Hz), 2.93, 2.76 (2H), and 2.17 (3H, s). Its mass spectrum had peaks at *m/e* 168 (33), 126 (15), 125 (100), 99 (24), 97 (34), 79 (3), 71 (4), 67 (21), 57 (15). This proved identical to an authentic sample prepared by oxidation of 2-*endo*-acetoxynorbornan-3-*endo*-ol using Ratcliffe–Rodehorst reagent (15).

2-Hydroxybicyclo[3.1.1]heptan-6-one (18, R = H)

This ketol from deamination of diazoketone **5** (4) had ν_{max} 3600, 3440, and 1768 cm^{-1} and gave ^1H nmr signals at δ 4.6 (1H, m), 3.88 (1H, OH), 3.10 (2H, m). Its mass spectrum had peaks at *m/e* 126 (3), 108 (5), 98 (26), 97 (15), 84 (11), 83 (26), 82 (5), 81 (10), 80 (12), 79 (9), 77 (4), 71 (10), 70 (35), 69 (15), 68 (5), 67 (23), 66 (7), 65 (3), 57 (28), 56 (35), 55 (100), 54 (40), 53 (15).

The corresponding acetate **18** (R = Ac) had ν_{max} 1774 and 1732 cm^{-1} and gave ^1H nmr signals at δ 5.58 (1H, m), 3.21 (2H, br), 2.07 (3H, s). Its mass spectrum had peaks at *m/e* 168 (1.5), 140 (6), 126 (12), 125 (10), 109 (6), 108 (58), 107 (4), 99 (8), 98 (9), 97 (12), 84 (9), 83 (13), 82 (6), 81 (50), 80 (100), 79 (58), 78 (6), 71 (20), 70 (15).

2-exo-*Acetoxynorbornan-5-one (17, R = Ac)*

A sample prepared following ref. 52 had ν_{max} 1740 cm^{-1} and ^1H nmr signals at δ 4.8 (1H, m, $w_{1/2}$ = 13 Hz), 2.63 (2H, $w_{1/2}$ = 18 Hz), and 2.01 (3H, s).

2-exo-*Acetoxynorbornan-7-one (15, R = Ac)*

Authentic **15** (R = Ac) (53) had ν_{max} 1903 (w), 1783 (s), 1770 (s), 1741 (s), 1729 (s), 1375 (m), 1240 (s), 1210 (w), 1139 (w), and 1065 (m) cm^{-1}. Its ^1H nmr spectrum was nearly identical to one kindly sent by Prof. Gassman, with signals at δ 4.83, 4.92, 4.98 (1H), and 2.03 (3H, s). Its mass spectrum had *m/e* 168 (1.6), 108 (78), 81 (58), 80 (100), 79 (30). A more intense spectrum gave *m/e* 175 (5), 169 (18), 168 (100), 167 (10.6). Its ^{13}C nmr spectrum had

signals at δ 213, 170.4, 71.7 (d, C-2), 43.2 (d, C-1) 37.8 (d, C-4), 35.1 (t, C-3), 22.9 (t, C-6), 21.1 (q, CH_3CO), 18.7 (t, C-5).

Labelled ***15*** *from* endo-d_2 *Aminoketone* ***3*** *(****29*** *+* ***30****)*

This was purified by hplc on a Porasil-A column using 2.5% acetone in hexane as solvent. It had ν_{max} 2200 (w), 1837 (w), 1775 (s), 1740 (s), 1725 (shoulder), 1375 (m), 1245 (s), 1105 (s) cm^{-1}. Its mass spectrum had signals at *m/e* 170 (1), 142 (4), 141 (1), 129 (1), 128 (12), 127 (8), 126 (2), 114 (1), 113 (2), 112 (4), 111 (7), 110 (43), 109 (57), 108 (6), 100 (15), 99 (15), 98 (13), 97 (5), 86 (11), 85 (13), 84 (28), 83 (89), 82 (100), 81 (99). A more intense spectrum gave *m/e* 171 (17), 170 (100), 169 (17.6) from which we estimate[7] a content of 94% d_2 and 6% d_1 species. Its ^1H nmr spectrum is illustrated in Fig. 3, and its ^{13}C nmr spectrum in Fig. 2.

Labelled ***15*** *from* exo-d_2 *Aminoketone* ***2*** *(****27****)*

This was purified by hplc on a Porasil-A column using 2.5% acetone in hexane as eluant. It had ν_{max} 2200 (w), 1835 (w), 1770 (s), 1740 (s), 1725 (s, shoulder), 1135 (s), 1105 (s) cm^{-1}.Its mass spectrum had peaks at *m/e* 170 (1), 142 (2), 141 (1), 129 (1), 128 (11), 127 (7), 126 (2), 114 (2), 113 (2), 141 (1), 129 (1), 128 (11), 127 (7), 126 (2), 114 (2), 113 (2), 112 (4), 111 (9), 110 (88), 109 (10), 100 (15), 99 (16), 98 (7), 97 (5), 96 (3), 86 (7), 85 (12), 84 (17), 83 (89), 82 (100), 81 (71), 80 (26). A more intense spectrum had *m/e* 171 (25), 170 (100), 169 (25) from which we estimate[7] a content of 5% d_3, 83% d_2, and 12% d_1 species.

Methyl 3-Cyclohexene-1-carboxylate

The unlabelled ester gave a mass spectrum with *m/e* 141 (2.5), 140 (22), 139 (0.8), 125 (15), 111 (5), 109 (18), 108 (38), 82 (8), 81 (100), 80 (93), and 79 (51). It had ν_{max} 1728 (s) and 1650 (w) cm^{-1}.

Methyl Dideuterio-3-cyclohexene-1-carboxylate from ***3***

The readily extracted acid (CH_2Cl_2) from deamination of 2.1 g of *endo-*d_2 aminoketone hydrochloride **3** was esterified using diazomethane. The 463 mg of ester was absorbed from hexane onto 11 g of neutral alumina, activity 1. Hexane eluted 99 mg of nearly pure methyl ester of deuterated acid (**31** + **32**). Ether in hexane eluted 6 mg more (yield 105 mg, 5.8%). The remaining esters were much more polar. The purest ester after distillation over a short path at 100°C, 0.01 Torr, gave a mass spectrum with *m/e* 143 (3), 142 (27), 141 (4.5), 136 (4), 111 (20), 110 (16), 109 (39), 83 (100), 82 (76), 81 (78), 80 (20), 79 (12). The estimated composition is thus:[7] d_3, 0%; d_2, 88%; d_1, 12%.

p-*Bromophenacyl Ester of 3-Cyclohexene-1-carboxylic Acid*

The unlabelled ester had ν_{max} 3020 (wk), 2950 (wk), 2840 (w), 1740 (s), 1588 (s), 1160 (s), 1070 (m), and 1010 (m) cm^{-1}. Its ^1H nmr spectrum gave signals at δ 2.18 (7H), 5.30 (2H, s), 5.75 (2H, s), and 7.76 (4H, m).

p-*Bromophenacyl Esters of* ***31*** *+* ***32***

Deamination of 1.09 g of *endo-*d_2 aminoketone hydrochloride **3** in 0.5 *N* sulfuric acid was conducted as described above. The readily extracted acids (CH_2Cl_2) were converted to their potassium salts, then to the *p*-bromophenacyl esters in refluxing ethanol. The crystalline product (162 mg, 7.5%) gave a ^1H nmr spectrum with signals at δ 7.76 (4H, m), 5.75 (s, 1.4H), 5.30 (2H, s), and a set of signals centered at δ 2.2 (5.5H). This was identical to that of the unlabelled ester except for the diminished intensity of the vinyl hydrogen and high-field signals. Its ^2H nmr spectrum gave a signal near δ 5.8 and a pair near 2.2 and 1.9 with the intensity ratio of 1:25.

Acknowledgements

We are grateful to Drs. I. C. P. Smith and R. Deslauriers and their associates for the ^{13}C and ^2H nmr spectra, Dr. R. W. Retallack for preliminary experiments, Mr. P. Marshall for preparative work, and Mr. H. Seguin for analyses. We thank Professors P. Yates, N. H. Werstiuk, and J. C. Orr for valuable discussions.

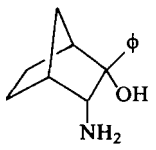
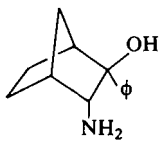
Appendix

Collins *et al.* argued (23, 30) that product control in deamination of **A** and **B** was largely determined by retention of the relative position of the *initial* counter ion through Wagner–Meerwein rearrangements and one or more hydride shifts. The carbocations were thus considered to be classical. In the sodium acetate containing medium we consider this to be highly improbable, and find their observations to be internally inconsistent with this hypothesis.

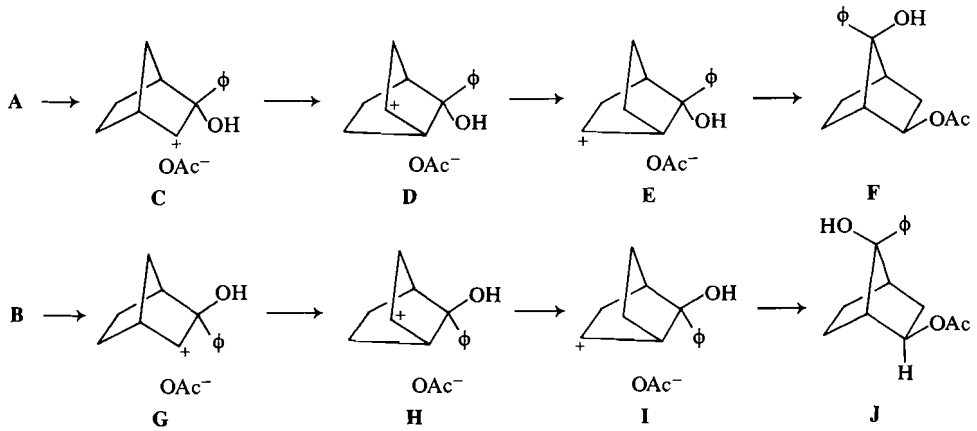


A



B

The situation pertaining if their hypotheses were correct is illustrated in the following equations:



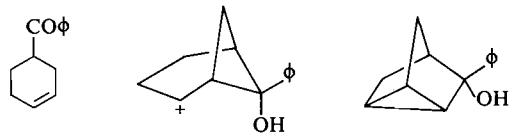
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

However, *no* product from collapse of the supposed initial tight ion pair **G** was observed[13] while only 10% of the *endo* acetate was produced from **C**. Although 29% of **J** was produced from **B**, consistent with their postulate, *37% of **F** was produced by exo* attack of acetate ion on ion **H**. Similarly, 22% of **J** was produced by *exo* attack on ion **D** in violation of their premise.

Their previous work (54) had shown that ions **D** and **I** with an *anti* orientation of the cation and hydroxyl should undergo cleavage to **K** while **E** and **H** should not. In actuality ion **D** did give rise to equal amounts of acetate **F** (22%) and the cleavage product **K**. Therefore since the capture of **D** by external acetate is efficient, as discussed above, the fission must also be an efficient process. However, ion **I** gave *no* fission product, from which we conclude that it did not exist as a classical ion.

No explanation was offered why ion **C** would rearrange to the bicyclo[3.1.1] ion **L** (20%) while ion **G** gave no such rearrangement. Similarly, the classical ion concept cannot account for the 22% of nortricyclene **M** from **B** in contrast to only 8% from **A**.

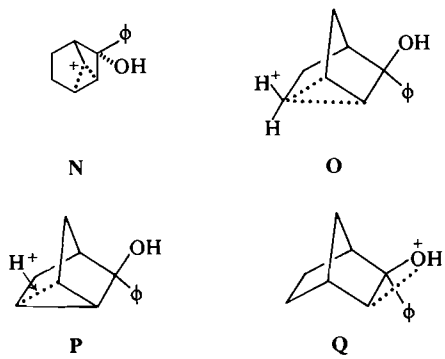


K **L** **M**

[13]It is probable however that the *endo*-phenyl group considerably hinders *endo* attack on C-2 of **G**.

We favor the following explanation of their results. The two electronegative groups on C-3 of **A** and **B** will destabilize the cations **C** and **G**, thus favouring delocalization. In the case of **C** this would be by participation of the 1–7 bond, giving cation **N** which would be the direct precursor of **L** and possibly **K**. Because of its higher energy, **N** could rearrange to the ion **O** which would give the nortricyclanone **M** via the edge-protonated ion **P**. Alternatively the original diazonium ion from **A** could in part rearrange to the *exo* diazonium ion via the diazo compound (see eq. [8], main text), thence to ions **O** and **P**.

In contrast, we suggest that the ion from **B** is delocalized by hydroxyl participation as in **Q**.



N **O**

P **Q**

Since *endo* attack on this is hindered[13] it would rearrange to ion **O**, then to **P**. These account for 88% of the observed products (**F**, **J**, and **M**).

The excess acidity of aqueous HCl and HBr media. An improved method for the calculation of X-functions and H_0 scales

ROBIN A. COX AND KEITH YATES

Department of Chemistry, University of Toronto, 80 St. George St., Toronto, Ont., Canada M5S 1A1

Received November 3, 1980

ROBIN A. COX and KEITH YATES. Can. J. Chem. **59**, 2116 (1981).

Excess acidity (X-function) scales for 0–40% w/w aqueous HCl and 0–60% w/w aqueous HBr solutions are derived, using ionization ratio data for 29 and 9 weak bases, respectively; in these media the resulting pK_{BH^+} values are quite similar to those obtained by standard acidity function treatments. A generalized derivation of the excess acidity enables the determination of pK_{R^+} values for protonation–dehydration processes, some of which are given, and the study of partially dissociated acids. An improved computer program was used, applicable to smaller data sets (up to 50 bases); this program permitted a determination of the inherent precision of the derived functions, and a more rigorous evaluation of previously derived X-functions and the whole excess acidity method.

ROBIN A. COX et KEITH YATES. Can. J. Chem. **59**, 2116 (1981).

En se basant sur des données de rapport d'ionisation respectivement pour 29 et 9 bases faibles, on a déduit des échelles d'acidité en excès (fonction-X) pour des solutions aqueuses de HCl à 0–40% w/w et de HBr à 0–60% w/w; dans ces milieux les valeurs de pK_{BH^+} obtenues sont tout à fait identiques à celles que donnent les fonctions d'acidité normale. Une dérivation générale de l'acidité en excès permet de déterminer les valeurs de pK_{R^+} pour des réactions de protonation–déshydration, dont quelques-unes sont connues, et d'étudier les acides partiellement dissociés. On a utilisé un programme d'ordinateur amélioré, applicable à des ensembles de données (jusqu'à 50 bases) plus petites; ce programme a permis de déterminer la précision inhérente des fonctions dérivées et d'évaluer d'une façon rigoureuse les fonctions-X dérivées antérieurement ainsi que la méthode totale d'acidité en excès.

[Traduit par le journal]

Introduction

For proton transfer to a weak base B, eq. [1], pK_{BH^+} is defined in terms of molar concentration C and molar activity coefficients f as in eq. [2]; the term C_{BH^+}/C_B, most often measured by uv–visible or nmr spectroscopy, is the ionization ratio I

$$[1] \quad B + H^+ \overset{K_{BH^+}}{\rightleftharpoons} BH^+$$

$$[2] \quad pK_{BH^+} = \log(C_{BH^+}/C_B) - \log C_{H^+} - \log(f_B f_{H^+}/f_{BH^+})$$

(1). The well-tested assumption (2–6) made regarding the activity coefficient term in eq. [2] is that it is linear in an equivalent term for some standard base B*. The latter term is defined as the excess acidity, X, in eq. [3], with slope parameter m^*, and

$$[3] \quad \log(f_B f_{H^+}/f_{BH^+}) = m^* \log(f_{B^*} f_{H^+}/f_{B^*H^+}) = m^* X$$

$$[4] \quad \log I - \log C_{H^+} = pK_{BH^+} + m^* X$$

eq. [2] becomes eq. [4] (6). The term excess acidity is used because X is the difference between the observed acidity and that which the system would have if it were ideal; the standard state at which $X = 0$ is the hypothetical ideal 1 M solution of the acid used, the same as for pH measurements. The above (6) is based on the original analysis due to Bunnett and Olsen (2), and later modifications by Marziano and co-workers (3–5).

X-functions have previously been given for aqueous sulfuric and perchloric acid mixtures (6), and eq. [4] has seen extensive use for extrapolative pK_{BH^+} determinations in these media (4–8). Related kinetic equations based on the excess acidity concept have also been derived (9) and tested (8). In this paper the aqueous HCl and HBr media are studied; due to the smaller amount of ionization ratio data available in these systems, a more statistically rigorous computer program could be used to derive X than the one used before (6). This improved program is used to test some points raised[1] in connection with the previous work, namely: does using different sets of bases in a given medium lead to the same X-function or to different ones; does the implicit definition of B* used before (6) make a difference to the resulting X; and are the initial trial values of m^* and pK_{BH^+} used in the calculation important or not.

Experimental

Computer Program

The program developed for this work is quite different from that used previously (6), although it performs essentially the same operation. The excess acidity X is expressed as a polynomial in the concentration unit involved, percent by weight w here; substitution into eq. [4] gives an eq. [5] for each

$$[5] \quad \log I = \log C_{H^+} + pK_{BH^+} + m^*(a_1 w + a_2 w^2 + a_3 w^3 + \ldots)$$

base in the set. Preliminary work showed that the use of z = antilog(w/100), as done before (6), was unnecessary here, and that three polynomial coefficients were sufficient, except for H_2SO_4, where four were used. Equation [5] has no a_0 because $X = 0$ at $w = 0$, i.e. the deviation from ideality in the standard state is zero. The equations are then solved by minimizing the difference d between experimental and calculated log I values. Previously this was done by using trial values of pK_{BH^+} and m^* to estimate X, using this to give new pK_{BH^+} and m^* values, which give a new X, and so on until no further improvement results; essentially d is minimized sequentially, and the method is good for large data sets, i.e. 50 or more compounds (6).

For smaller data sets it is possible to minimize d simultaneously for each coefficient (these being the polynomial coefficients a, and a pK_{BH^+} and m^* for each base). To do this the general-purpose curve-fitting subroutine CURFIT from Bevington (10) was utilized. This requires a subroutine FUNCTN containing the equation to be fitted (the set of eqs. [5] here, with some programming to enable discrimination among them), and another, FDERIV, which computes the derivatives of the fitted equation with respect to each coefficient in it (e.g. $d \log I/da_1 = m^*w$, $d \log I/dpK_{BH^+} = 1$), which are used in the fitting process (10). The difference d (actually a weighted $\sum_i d_i^2$) is calculated in a subroutine FCHISQ, and a matrix inversion subroutine MATINV is also required (10). The size of the matrix involved depends on the number of coefficients; 50 bases, each with its pK_{BH^+} and m^*, plus three polynomial coefficients, minus the defined $m^* = 1$ for B* (see below), needs a 102 × 102 matrix. Since inversion occurs many times during a computer run, 50 compounds represent a practical upper limit to the method, as both the computer time required and the memory storage needed increase rapidly with the size of the matrix. The procedure is iterative insofar as several passes through CURFIT are made until the change in d from the previous pass is negligible, the calculated coefficient values being essentially unchanged (convergence). Further details of the program may be obtained from the authors.

Data and Calculations

Ionization ratio data for 9 primary amines (11–21), 3 secondary amines (12, 18, 22), 8 tertiary amines (14, 23, 24), 7 amides (19, 26), and 2 anions (25) in hydrochloric acid, and 9 primary amines in hydrobromic acid (21, 27), were used. Measurements by different authors on the same compound were amalgamated and treated together. Percent by weight/molarity conversions were performed using available density data (28). An error function given by Kresge and Chen (29) was used to weight the log I values, to reflect their decreasing reliability with increasing distance from 50% ionization. They were also weighted by dividing the weight within each 0.5% acid region by the number of points in that region; this is in order to give equal weight to all acid regions in the calculation. For example, half of the 421 total data points for HCl lie within the range 0–7.5%, leaving the other half for the much larger 7.5–40% range.

The X_0 functions were derived using only primary aromatic amine data; for these the equations fitted are an eq. [5] for each base with m^* set equal to 1.0. For $HClO_4$ the primary amine data used before (30, 31), with some additional log I measurements for 2- and 4-nitroaniline by Kresge *et al.* (11), were analyzed. Straight-line plots according to eqs. [4] and [10] were calculated using a standard weighted line-fitting routine from Bevington (10), as before (6).

Results and Discussion

In comparison to the aqueous H_2SO_4 and $HClO_4$ systems, where ionization ratio data for 165 and 76 compounds, respectively, were available for the calculation of X, other acid media have received less attention. Thus for the systems under consideration here, 29 compounds have been studied in HCl, and only 9 in HBr. This has both advantages and disadvantages. An advantage is that the more statistically rigorous computer program applicable to sets of 50 or fewer bases, described above and discussed below, could be used. This program was used to calculate the X-function for HCl given in Table 1; the 29 primary, secondary, and tertiary amines, amides, and anions for which ionization ratio data were used (11–26), with the pK_{BH^+} and m^* values obtained using this X and eq. [4], are given in Table 2.

For the aqueous HBr system, a disadvantage becomes apparent in that the availablity of data for only primary aromatic amines (21, 27) does not permit the calculation of a full X-function. In cases like this it is best to set $m^* = 1$ for all compounds, and simply use the method to calculate H_0, as was done previously for D_0 in $DClO_4$ (32). Putting $m^* = 1$ for all compounds in eq. [3] leads to cancellation of f_{H^+}; upon rearrangement this becomes $f_B f_{B^*H^+}/f_{B^*} f_{BH^+} = 1$, the original Hammett cancellation assumption (33). Equation [4] then becomes eq. [6],

$$[6] \quad \log I - pK_{BH^+} = \log C_{H^+} + X_0 = -H_0$$

in which the zero subscript on X_0 indicates this *different and less valid* assumption (6). Despite the fact that, essentially, H_0 is being calculated, the advantages of the X-function calculation method are still present in that anchoring is not necessary, since $X_0 = X = 0$ in the aqueous standard state, and that overlap between adjacent indicators is not required (6). The resulting X_0 scale for HBr is given in Table 3; the bases used, with their pK_{BH^+} values, are in Table 4. Even though $m^* = 1$ has been assumed in the calculation, the m^*_0 values that result when data for the individual compounds are plotted against the derived X_0 sometimes differ considerably from unity, which means that the Hammett cancellation assumption (33) is not in fact very good even for these supposedly very similar compounds (6). In Fig. 1. the variation of excess acidity with percent by weight composition for the HCl and HBr systems is illustrated.

The computer program used in this work, described in the Experimental, is different from that used before (6). Although practically limited to data sets of 50 or fewer bases, it is more statistically rigorous, and gives standard deviations on the calculated coefficients. Tables 1 and 3 include 95% confidence limits on X obtained from these using error propagation (10) and statistical formulae (34). This program could not be used to derive X for sulfuric or perchloric acids using the full data set used before (165 and 76 bases) (6), but it can be used to calculate X-functions based on smaller subsets

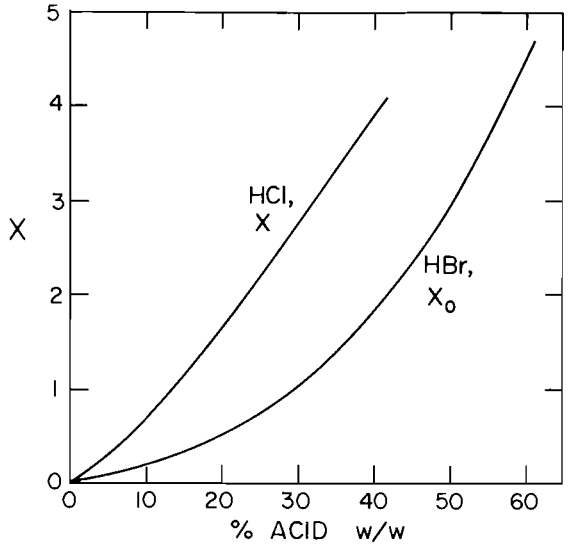

FIG. 1. Excess acidities of aqueous HCl and HBr as a function of percent acid.

of these, to see how well they compare among one another and with previously reported excess acidities. X-functions derived using different data sets, although broadly similar (6), differ in detail, and the point as to whether these differences are important or not has been raised.[1] In other words, a decision must be made as to whether using different data sets leads to the same function or to different ones. This can be done using the well-established (34) statistical test for significant differences, based on the confidence limits.

The ionization ratio data used before (see ref. 6, where the original references may be located), together with some additional primary (11, 13, 20, 35), secondary (14, 22), and tertiary (14, 24, 36) amine measurements, were used to calculate five X-functions for sulfuric acid based on: (A) primary and secondary amines only; (B) tertiary amines, amides, alkoxybenzenes, and α,β-unsaturated ketones; (C) alkenes, cations, anions, the H_S thiocompounds, benzophenones, and azobenzene (37); (D) indoles, carbonyl compounds, and other thiocompounds; and (E) the 50 compounds which have been measured in both H_2SO_4 and $HClO_4$ media. Scale E is compared to X (6) and $M_Cf(x)$ (5) in Fig. 2, which illustrates the differences in detail among X-functions under discussion.

The overall accuracy of the excess acidity method is good, as can be seen from the confidence limits and standard deviations in the tables. Illustrating the confidence limits on the sulfuric acid scales A–E is not easy, diagrams like Fig. 2 rapidly becoming too crowded to be useful, but an attempt to do this is presented in Fig. 3. This shows

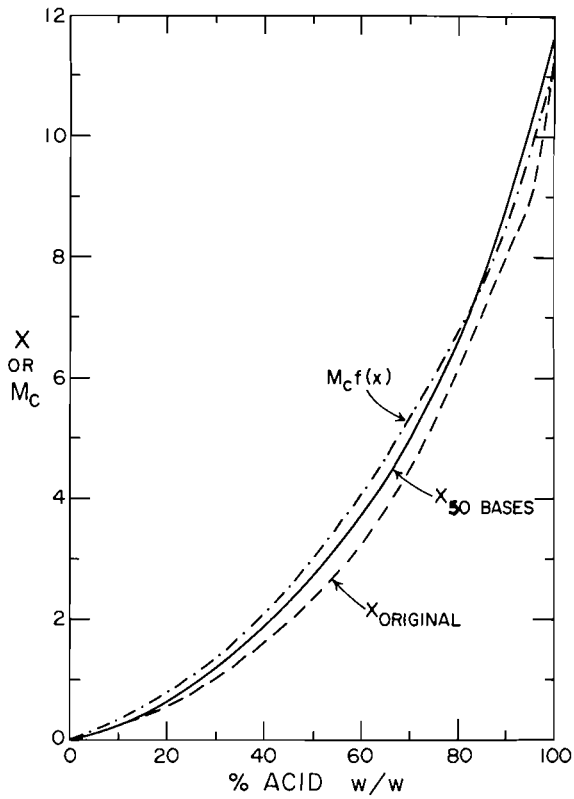

FIG. 2. The excess acidity of aqueous H_2SO_4 at 25°C. $M_Cf(x)$, ref. 5; $X_{original}$, ref. 6; $X_{50\ bases}$, this work.

the confidence limits in 98% sulfuric acid for the functions A–E above, together with X (6) (F), M_C (4) (G), and $M_Cf(x)$ (5) (H) at the same acidity, for comparison. 98% Acid is chosen as an example simply because the spread of the different functions is most noticeable at high acidity, and the accuracy is lowest, providing the most severe test for any significant differences between the scales. The conclusions are the same at any acidity.

Now if the confidence limits of any two scales in Fig. 3 overlap, the difference between them is not significant at the 95% confidence level (34), i.e. they are the same scale within the experimental uncertainties in the data used to calculate them. Amongst scales A–E, only scale C could be regarded as being significantly different from most of the rest. Comparisons with X, M_C, and $M_Cf(x)$ cannot be made with rigor; X was derived using six polynomial coefficients (6) as against four for A–E, the number used for $M_Cf(x)$ is not given (5), and M_C was derived using the older overlap method (4). Nevertheless it would seem probable that only M_C (G in Fig. 3) is really different from all of the others, and is in any case now superceded by $M_Cf(x)$ (5). With this exception, any of the scales

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

can be used with equal facility for extrapolative pK_{BH^+} measurements (6) and the analysis of kinetic data (9). This confirms and reinforces the conclusions reached by Marziano *et al.* (5) We will continue to use X, because of the large data set used in its derivation (6), and because the slope change at ~85% H_2SO_4 which X exhibits (see Fig. 2) is likely to be real, since 0–85% and 85–100% H_2SO_4 are quite different media (38). $M_C f(x)$ is a perfectly valid alternative, however; it is very similar to the scales A–E derived in this work.

The excess acidity is calculated using initial trial pK_{BH^+} and m^* values, which the computer iterates until convergence to the unchanging final ones occurs, as described in the Experimental. The question has been raised[1] as to whether or not this is important, insofar as the computer may in some way be "forced" by this choice of initial values. The improved program used here enables this question to be addressed because it gives standard deviations on the calculated coefficients. In general the CURFIT routine used converges rapidly and reliably from quite divergent initial values, because it consists of a combination of the gradient search and fitting function linearization procedures (10). For the X-function calculation for HCl the initial pK_{BH^+} values specified were the acidity function (AF) ones in Table 2, with initial m^* slopes of 1.0 for primary and secondary amines, and anions, 1.3 for tertiary amines, and 0.6 for amides; convergence occurred within 4 iterations. Convergence to the *same* values (i.e. well within the calculated standard deviations), also within 4 or 5 iterations, was found with initial coefficients consisting of the Table 2 AF values plus 1, all $m^* = 1.0$; the AF values plus 2, all $m^* = 1.3$; and the AF values minus 1, all $m^* = 0.5$.

In order to obtain an unambiguous set of m^* and a values, one m^* must be defined for the reference compound B*. Previously (6) this definition was implicit; the more rigorous program used here requires an explicit definition. Rather than arbitrarily choosing the first base in the set (or any single compound) as the reference, the definition used here was that the *average* of all the m^*'s for the set of bases used must be 1.0; this is closest to the previous implicit definition. This is a limitation on the generality of X, since this definition leads to an excess of compounds with large m^*'s producing a steep X-function, and an excess with low m^*'s producing a shallow one (see eq. [4]). Thus X will only be a unique function of the medium if a reasonably large and representative set of bases is available (i.e. some with low and some with high m^*'s), such as the 29 compounds used for HCl in this study (Table 2). Failing this, it is probably best to calculate an X_0 function and H_0 scale, as we have done for HBr. In deriving the H_2SO_4 scales A–E discussed above, a reasonable balance of compound types was attempted; however, the comparison in Fig. 3 is probably less good than it might be because of small differences caused by this factor.

To enable comparisons among the acidity function, X-function, and X_0 scale pK_{BH^+} values, X_0 for HCl was also calculated, using only the primary aromatic amine data. The AF values and those extrapolated using X (eq. [4]) are quite similar, the average deviation between them being $\pm 0.16 pK$ units (Table 2). This, however, is three times as large as the average of the standard deviations of the X-function values in the table. The values obtained using X_0 also differ from the AF ones by ± 0.16, but are otherwise slightly worse; X gives better linear plots than X_0 (lower σ_y, higher correlation coefficient) in 14 cases, worse in 11, and unchanged in 4. Interestingly, 7 of the 9 primary amines used in deriving X_0 give worse plots. However, the differences are very small, and the Bunnett–Olsen extrapolation (2), eq. [7], should

$$[7] \quad \log I + H_0 = \phi(-X_0) + pK_{BH^+}$$

give almost the same results as the X-function extrapolation of eq. [4], in this case. The situation for HBr is similar.

The polynomial coefficients used to calculate X and X_0 are given in Table 5. These can be used to calculate X and $-H_0$ at any percent by weight acid composition w by using X (or X_0) $= a_1w + a_2w^2 + a_3w^3$, and $-H_0 = X_0 + \log C_{H^+}$. The $-H_0$ scale for HCl obtained in this way is given in Table 1. Included in Table 5 is an X_0 scale for $HClO_4$; X for this system is already available (6). This recalculated $HClO_4$ scale is presented (*a*) because it is more accurate than the previous H_0 scale (30) (see below), and (*b*) in the expectation that better results may be obtained with it when using

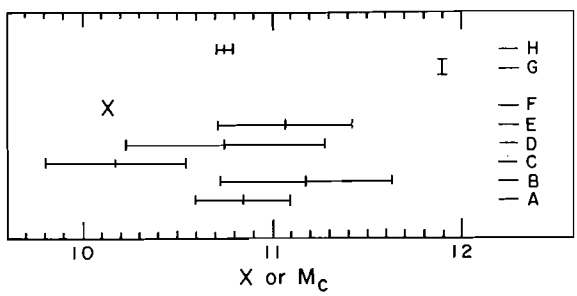

FIG. 3. 95% confidence limits on the excess acidity of 98% sulfuric acid, calculated for the different X-functions. For letter identifications see text.

TABLE 5. Polynomial coefficients for X and X_0

Acid	a_1	a_2	a_3
HCl, X	5.27767×10^{-2}	1.90497×10^{-3}	-1.97423×10^{-5}
HCl, X_0	3.76697×10^{-2}	1.50584×10^{-3}	-4.99680×10^{-6}
HBr, X_0	1.59513×10^{-2}	3.23181×10^{-4}	9.90298×10^{-6}
$HClO_4$, X_0	3.35096×10^{-2}	-7.45044×10^{-4}	2.22391×10^{-5}

the Bunnett–Olsen method (2). However, the X-function method is definitely to be preferred for $HClO_4$, as primary aromatic amines do not appear to be "well-behaved" in this system (6).

The H_0 scales given by Table 5, one of which is in Table 1, are undoubtedly the best available to date, being derived using *all* of the available log I data on primary aromatic amines, each value being properly weighted (29). They can be used for all applications requiring the use of H_0, always remembering the drawbacks associated with acidity functions, which we will not repeat here (6, 9). For HCl the H_0 scale averages 0.05 units more positive than the scale given by Rochester (1), and for HBr it is 0.07 units more positive than Rochester's (1) and 0.07 units more negative than Vinnik's (21) scales below about 45% w/w. This undoubtedly represents anchoring inaccuracies, avoided here because X_0 has to be zero in the standard state, water. Above about 45% the Table 5 HBr scale deviates from Vinnik's and Rochester's H_0 scales and approaches that of Marcus *et al.* (27); between 7.5% and 60% it averages 0.17 units more positive than the latter. (The polynomial coefficients given by Marcus are apparently not applicable below 7.5% w/w (27).) For $HClO_4$, up to 60% the scale averages 0.07 units more positive than that of Attiga and Rochester (31), and 0.08 more than that of Yates and Wai (30); above 60%, however, it averages 0.35 units more positive than the latter, a considerable difference. Aqueous HCl and HBr are quite strong acids; for instance the $-H_0$ values of 10 M $HClO_4$, HBr, HCl, and H_2SO_4 (16) are 5.82, 4.14, 3.53, and 4.89, respectively, and at a mole fraction of 0.25 are 6.16. 5.35, 4.75, and 4.97.

Values of log C_{H^+} for use in eq. [4] are obtained as follows. The stoichiometric acid concentration C_A is related to C_{H^+} via the degree of dissociation α:

$$\begin{array}{ccccc} HA & \rightleftharpoons & H^+ & + & A^- \\ C_A(1-\alpha) & & C_A\alpha & & C_A\alpha \end{array}$$

The acids HCl and HBr can be assumed to be fully dissociated[2] in the range accessible to study, like $HClO_4$ (see the discussion in ref. 6), i.e. $\alpha = 1$ and $C_{H^+} = C_A$. Values of C_A were calculated from listed densities (28) and are included in Tables 1 and 3. For acids which are not fully dissociated, $C_{H^+} = C_A\alpha$, $C_A\alpha_1(1 + \alpha_2)$, and $C_A\alpha_1(1 + \alpha_2 + \alpha_2\alpha_3)$ for mono-, di-, and tribasic acids, and the degrees of dissociation must be known. Values of C_{H^+} for H_2SO_4 derived in this way have already been reported (6); other partially dissociated acids, CF_3CO_2H, HNO_3, etc., will be studied in a future paper.

The α terminology is also useful in the analysis of protonation–dehydration processes, eq. [8]; the definition of pK_{R^+} leads to eq. [9]. In this case I is

$$[8] \quad ROH + H^+ \overset{K_{R^+}}{\rightleftharpoons} R^+ + H_2O$$

$$[9] \quad pK_{R^+} = \log (C_{R^+}/C_{ROH}) - \log (C_{H^+}/C_{H_2O}) - \log (f_{ROH}f_{H^+}/f_{R^+}f_{H_2O})$$

C_{R^+}/C_{ROH}, and the stoichiometric water concentration C_{H_2O} is related to C_A and the mole fraction of acid x_A via $C_{H_2O} = C_A(1 - x_A)/x_A$, so C_A cancels; $\alpha = 1$ here. It is customary not to include the water concentration in definitions of pK_{R^+}, and log(55.346) can be subtracted to account for this; eq. [10] results if the assumption is made that the

$$[10] \quad \log I - \log(x_A/(1 - x_A)) - 1.743 = pK_{R^+} + m^*X$$

activity coefficient term is linear in X, slope m^* as before. This assumption seems reasonable and is easily tested; in Fig. 4 the left-hand side of eq. [10] is plotted against X for some triarylcarbinols in aqueous HCl (14). The good linearity, particularly in the region log $I = \pm 1$, amply justifies the assumption made and the use of eq. [10]; the resulting pK_{R^+} and m^* values are given with statistical information in Table 6. The pK_{R^+} values are within two standard deviations of the AF ones, for all except the most basic compound. This is indicative of the good results to be obtained using the excess acidity method, even for compounds not used in deriving X.

Excluding the first compound, the average m^* in Table 6 is 1.80 ± 0.10, a steep acidity dependence, as expected (6). No particular consistency is evident among the m^* values in Table 2. Primary

[2]This seems reasonable, but hard evidence is difficult to find, e.g. see ref. 27.

Effect of reaction exothermicity on the proton transfer chemical ionization mass spectra of isomeric C_5 and C_6 alkanols

JAN A. HERMAN[1] AND ALEX. G. HARRISON

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 20, 1980

JAN A. HERMAN and ALEX G. HARRISON. Can. J. Chem. **59**, 2125 (1981).

The chemical ionization mass spectra of eight C_5 alkanols and fourteen C_6 alkanols have been obtained using H_3^+, N_2H^+, CO_2H^+, N_2OH^+, and HCO^+ as reactant ions. This choice of reactant ions allows the exothermicity of the protonation reaction to be varied from ~90 kcal mol^{-1} (H_3^+) to ~50 kcal mol^{-1} (HCO^+). The major fragmentation reaction in all cases was H_2O elimination from the protonated alcohol forming the appropriate $C_5H_{11}^+$ or $C_6H_{13}^+$ alkyl ion. The extent of further fragmentation of the alkyl ions decreased with decreasing exothermicity of the protonation reaction and was greatest for alkyl ions derived from primary alcohols, less for alkyl ions derived from secondary alcohols, and very small for alkyl ions derived from tertiary alcohols. The results indicate that there is negligible rearrangement to more stable alkyl ions prior to attaining the critical configuration which determines the energy partitioning between R^+ and H_2O in the fragmentation of ROH_2^+. Other less important reaction modes in the CI spectra involved formation of $(M - H)^+$ ions and formation of oxycarbonium ions by alkane elimination from protonated alcohols.

JAN A. HERMAN et ALEX. G. HARRISON. Can. J. Chem. **59**, 2125 (1981).

Les spectres de masse de chimiionisation de huit pentanols aliphatiques et quatorze hexanols aliphatiques ont été obtenus en utilisant les ions réactifs H_3^+, N_2H^+, CO_2H^+, N_2OH^+ et HCO^+. Ces divers ions réactifs permettent de faire varier l'exothermicité de la réaction de protonation de ~90 kcal mol^{-1} avec H_3^+ à ~50 kcal mol^{-1} avec HCO^+. Dans chaque cas, la principale réaction de fragmentation de l'alcool protoné est une élimination d'eau conduisant à l'ion alkyl $C_5H_{11}^+$ ou $C_6H_{13}^+$ approprié. Le degré de fragmentation ultérieure des ions alkyls décroît avec la diminuation de l'exothermicité de la réaction de protonation; il est maximal pour les ions alkyls dérivés d'alcools primaires, moindre pour ceux provenant d'alcools secondaires et le plus petit si l'alcool était tertiaire. D'après les résultats, l'atteinte de la configuration critique déterminant la répartition de l'énergie entre R^+ et H_2O lors de la fragmentation de ROH_2^+ n'implique aucun réarrangement important conduisant à des ions alkyls plus stables. D'autres modes de réaction moins importants dans les spectres CI impliquent la formation d'ions $(M - H)^+$ et celle d'ions oxycarbonium par élimination d'alcane des alcools protonés.

Introduction

The isobutane chemical ionization (CI) mass spectra of saturated monohydroxylic alcohols with five or more carbons are dominated (1) by the alkyl ion R^+, presumably derived by loss of H_2O from the protonated alcohol ROH_2^+. This observation suggested the possibility that by varying the exothermicity of the protonation reaction one could produce alkyl ions with varying amounts of internal energy and observe the fragmentation of the alkyl ions as a function of internal energy. This possibility is explored in the present work for isomeric C_5 and C_6 alkanols using H_3^+ ($PA(H_2)$ = 101 kcal mol^{-1}), N_2H^+ ($PA(N_2)$ = 117 kcal mol^{-1}), CO_2H^+ ($PA(CO_2)$ = 129 kcal mol^{-1}), N_2OH^+ ($PA(N_2O)$ = 137 kcal mol^{-1}), and HCO ($PA(CO)$ = 141 kcal mol^{-1}) as protonating reagents. The proton affinities given in brackets are derived from the work of Bohme *et al.* (2) and when compared with the estimate (3) of a proton affinity of ~190 kcal mol^{-1} for the higher alcohols, result in a protonation exothermicity ranging from ~90 kcal mol^{-1} to approximately 50 kcal mol^{-1}. As will be shown in the following, this variation in the protonation exothermicity does produce significant changes in the internal energy of the alkyl ions produced, which is reflected by the extent of further fragmentation of the ions resulting from the initial water loss from ROH_2^+. The results obtained will be compared, where possible, with the results obtained from fragmentations of alkyl ions produced by electron impact methods.

Experimental

The chemical ionization mass spectra were obtained using a DuPont 21-490 mass spectrometer equipped with a high pressure chemical ionization source. The source temperature was 60°C and the ionizing electron energy 70 eV with the repellers held at cage potential. The liquid samples were introduced through a heated inlet system held below 100°C. Reagent gas pressures were not measured directly but were estimated to be 0.2–0.3 Torr.

The H_3^+ reactant ion was produced in pure H_2. As discussed elsewhere (4), the N_2H^+, CO_2H^+, and HCO^+ reactant ions were produced by electron impact ionization of the appropriate gas N_2, CO_2, or CO (~10%) in H_2, giving in all cases the relevant ion as the dominant species. In the present work a similar mixture of 10% N_2O in H_2 was found to give largely N_2OH^+ as reactant ion, but, in this case, a significant (10–15%) fraction of the total ionization was observed as NO^+.

Reagent gases were of the highest possible purity (Matheson and Company) while the C_5 and C_6 alcohols were commercial samples of high purity.

Results and Discussion

Chemical Ionization Mass Spectra of Isomeric C_5 Alkanols

The chemical ionization mass spectra of the eight C_5 alcohols investigated are presented in Table 1 for the five reagent gases utilized. Several points deserve comment. First, in agreement with isobutane CI spectra (1), the major fragmentation route of the protonated alcohol is by loss of H_2O to give $C_5H_{11}^+$ alkyl ions. The $C_5H_{11}^+$ ions appear to fragment by three routes [1] to [3]

$$[1] \quad C_5H_{11}^+ \longrightarrow C_3H_7^+ + C_2H_4$$

$$[2] \quad \longrightarrow C_4H_7^+ + CH_4$$

$$[3] \quad \longrightarrow C_5H_9^+ + H_2$$

The first fragmentation reaction is known from metastable ion studies (5, 6) while the latter two have been proposed (5) for higher energy fragmenting ions. The extent of fragmentation of $C_5H_{11}^+$ decreases as the exothermicity of the protonation step decreases and also decreases in the order primary > secondary > tertiary alcohol. These observations will be discussed in more detail below.

Second, all alcohols, with the exception of the tertiary alcohol, 2-methylbutan-2-ol, show moderately abundant $(M - H)^+$ ions, presumably originating primarily from H^- abstraction from the alcohol. The abundance of this fragment ion decreases from the H_2 CI through the CO/H_2 CI (i.e. as the reaction exothermicity decreases). The exception to this trend is observed in the N_2O/H_2 CI spectra where, except for the tertiary alcohol, the $(M - H)^+$ ion intensity is enhanced as a result of H^- abstraction by NO^+, present as one of the reactant ions. Hydride ion abstraction from alcohols by NO^+ has been observed, as has the inability of NO^+ to abstract H^- from tertiary alcohols (7). It should be noted that a significant fraction of the $C_5H_9^+$ ion signal may originate by H_2O loss from the $(M - H)^+$ ion rather than by reaction [3]. In a related study (8) of the CI spectra of pentyl acetates, where hydride abstraction is of lesser importance, we have observed lower yields of $C_5H_9^+$ relative to $C_5H_{11}^+$.

Third, those alcohols containing the —CH(OH)-CH_3 moiety show ion signals at *m/z* 45 and *m/z* 73 corresponding, respectively, to the $CH_3CH{=}OH^+$ and $C_3H_7CH{=}OH^+$ ions. Similarly, pentan-3-ol and 2-methylbutan-2-ol both show ion signals at *m/z* 59 corresponding nominally to the CH_3CH_2-$CH{=}OH^+$ and $(CH_3)_2C{=}OH^+$ structures respectively. The abundances of these oxygen-containing fragments, which reflect the structures of the original alcohol, are particularly pronounced in the H_2 CI mass spectra; however, they do persist through the remaining spectra. They most likely represent alternative modes of fragmentation of the protonated alcohol, i.e.

$$[4] \quad R^1{-}\overset{\overset{+OH_2}{|}}{CH}{-}R^2 \longrightarrow \begin{cases} R^1CH{=}OH^+ + R^2H \\ R^2CH{=}OH^+ + R^1H \end{cases}$$

By far the most interesting observations are that the extent of fragmentation of the $C_5H_{11}^+$ ions depends not only on the exothermicity of the initial protonation reaction but also on the structure of the alcohol, being greatest for primary alcohols, less for secondary alcohols, and least for the tertiary alcohol. This is shown most clearly by the H_2 CI mass spectra presented in Fig. 1. The energetics of the CI systems are presented graphically in Fig. 2, with the energy scale being referenced to the protonated alcohol. The heats of formation of $C_3H_7^+$ (isopropyl) and the $C_5H_{11}^+$ ions were taken from Lossing and Maccoll (9) or calculated from their data by the method outlined by Bowen and Williams (6). The remaining thermochemical data were taken from standard sources (10, 11). The data used are summarized in the Appendix.

Thermochemically, fragmentation of $C_5H_{11}^+$ to $C_4H_7^+ + CH_4$ or $C_5H_9^+ + H_2$ is more favourable than fragmentation to $C_3H_7^+ + C_2H_4$. However, as pointed out by Bowen and Williams (6), the fragmentation route of lowest activation energy (and that observed in metastable ion fragmentations) is the latter, indicating that reactions [2] and [3] have activation energy barriers sufficient to make these routes noncompetitive for decomposing ions of low internal energies. Their occurrence for ions of high internal energy, such as are examined in the present work, must mean that the energy independent term (frequency factor) in the rate expression is more favourable for these reaction modes than for ethylene loss.

As Fig. 2 shows, protonation of $C_5H_{11}OH$ by any of the reagent ions used in the present study is sufficiently exothermic to lead to rapid H_2O elimination in all cases; consequently, it is not surprising that the $C_5H_{11}OH_2^+$ ion intensities are extremely small. Further, if all of the protonation exothermicity were retained by the product $C_5H_{11}^+$ ion, this ion should have sufficient energy to fragment further. In fact, the extent of fragmentation of $C_5H_{11}^+$ is small for the weaker protonating agents and, as noted above, for the stronger protonating agents is dependent on the original structure of the alcohol (primary > secondary > tertiary). FIG. 2. Energetics of protonation and fragmentation of pentanols.

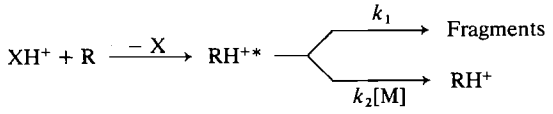
simplest rationalization of this latter observation is as follows. The enthalpy change for the overall reaction

[5] $H_3^+ + C_5H_{11}OH \longrightarrow C_5H_{11}^+ + H_2O + H_2$

is ~ -60 kcal mol^{-1} for primary alcohols, ~ -73 kcal mol^{-1} for secondary alcohols, and ~ -80 kcal mol^{-1} for the tertiary alcohol, assuming no rearrangement of the alkyl function. If, on average, the same fraction of this exothermicity is retained by the $C_5H_{11}^+$ ion, in all cases, the average energy content of the $C_5H_{11}^+$ ions, relative to their fragmentation products, will be greatest for primary ions and least for tertiary ions. (For example, the levels shown as dotted lines in Fig. 2 assume 50% of the exothermicity is retained by the alkyl ion.) Clearly, if this is the situation, a greater fraction of the $C_5H_{11}^+$ ions derived from primary alcohols will have internal energies sufficient to undergo fragmentation before they are collisionally deactivated to below the decomposition threshold. As has been discussed previously (4), fragmentation following chemical ionization is in competition with collisional deactivation, Scheme 1. At the pressures used in the present work $k_2[M] \simeq 10^7$ s^{-1} with the result that significant fragmentation will be observed only for ions which have an internal energy sufficient to give $k_1 \geq 10^7$ s^{-1}.



SCHEME 1

If this picture is correct, the extent of fragmentation should be greatest for $C_5H_{11}^+$ ions derived from primary alcohols and least for $C_5H_{11}^+$ ions derived from tertiary alcohols. An essential feature of this rationalization is that the alkyl function does not rearrange to a more stable structure during H_2O elimination from the protonated alcohol or, if it does so, that rearrangement occurs at a sufficiently late stage in the decomposition process that it does not influence the energy partitioning between the neutral H_2O and the $C_5H_{11}^+$ ion. If rearrangement were to occur at an early stage in the decomposition process the distinction between the alcohols should be lost and the extent of further fragmentation should be the same for the isomeric alcohols. This clearly is not the case. In a related study of the CI of pentyl acetates, reported in the following paper, we have observed that the competition between fragmentation reaction channels suggests rearrangement to more stable alkyl ions by (1,2)-H shifts, while the extent of further fragmentation of $C_5H_{11}^+$ reflects the original structure (primary or second-

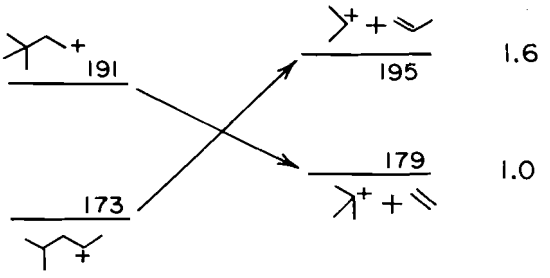
For personal use only.

ary) of the acetate. These results suggest that the critical activation energy for decomposition of MH^+ reflects the original structure of the alkyl group and determines the partitioning of the excess energy between neutral and ionic species but that the competition between fragmentation reaction channels is determined at a later stage in the decomposition process.

The conclusion that rearrangement in the alcohols does not occur to a significant extent is particularly interesting for 2-methylbutan-1-ol and 3-methylbutan-2-ol where, in each case, a relatively simple (1,2)-H shift would lead to the very stable tertiary carbonium ion. A close examination of the CI mass spectra shows that the extent of fragmentation of $C_5H_{11}^+$ derived from 2-methylbutan-1-ol is less than that observed for any other primary alcohol. Similarly the extent of fragmentation of $C_5H_{11}^+$ from 3-methylbutan-2-ol is less than $C_5H_{11}^+$ derived from other secondary alcohols. These results suggest that rearrangement may be occurring but that the effect on the partitioning of the excess energy between the neutral and ionic fragment is small.

Chemical Ionization Mass Spectra of C_6 Alkanols

The observation that the extent of fragmentation of the $C_5H_{11}^+$ ions produced from the isomeric C_5 alkanols reflected the structure (i.e., primary, secondary, or tertiary) of the carbonium ion initially formed by H_2O elimination encouraged us to extend the study to the isomeric C_6 alkanols. The fragmentation of $C_6H_{13}^+$ alkyl ions has been discussed in detail by Bowen and Williams (6). In the metastable ion region two competing fragmentation reactions are observed, leading to formation of $C_4H_9^+ + C_2H_4$ and to formation of $C_3H_7^+ + C_3H_6$. This has been rationalized in terms of the energy diagram shown in Fig. 3 which assumes that the reacting configuration leading to ethylene elimination is the 3,3-dimethyl-1-butyl carbonium ion which has an energy similar to that of the $C_3H_7^+ + C_3H_6$ products; thus, in the absence of any additional activation barriers the two reaction modes would be competitive. The ratio of metastable abundances for C_2H_4 and C_3H_6 losses are 1:1.6 (12). The reacting configuration leading to loss of C_3H_6 was assumed to be the 4-methyl-2-pentyl carbonium ion. It appeared of interest to attempt the preparation of specific $C_6H_{13}^+$ ion structures by dissociative protonation of the C_6 alcohols to examine the competition between the two major reaction channels as a function of structure. In particular, preparation of the two ions depicted in Fig. 3 might be expected to lead to preferential loss



Bowen and Williams, J.C.S. Perk II 1479 (1976)

FIG. 3. Fragmentation mechanisms, $C_6H_{13}^+$ ions.

of C_2H_4 for the primary ion and C_3H_6 for the secondary ion under the higher energy CI induced fragmentation conditions, since these reactions involve only simple bond cleavage reactions and should be favoured over the alternative reaction(s) requiring skeletal rearrangement.

The CI mass spectra of the 14 C_6 alkanols studied are presented in Table 2. The main features of the spectra are essentially the same as described for the C_5 alcohols. The major fragmentation reaction of the protonated alcohol involves H_2O elimination. The resulting $C_6H_{13}^+$ ions fragment further by the following paths.

[6] $C_6H_{13}^+ \longrightarrow C_3H_7^+ + C_3H_6$
[7] $\longrightarrow C_4H_9^+ + C_2H_4$
[8] $\longrightarrow C_5H_9^+ + CH_4$
[9] $\longrightarrow C_6H_{11}^+ + H_2$

Reactions [6] and [7] are the lowest energy fragmentation routes (Fig. 3) while reactions [8] and [9], analogous to reactions [2] and [3] for $C_5H_{11}^+$, have been reported earlier (5) as higher energy fragmentation routes. In agreement with the results for the $C_5H_{11}^+$ ions, the extent of fragmentation of the $C_6H_{13}^+$ ions decreases as one proceeds from primary to secondary to tertiary alcohols. This structural dependence provides additional evidence that structural rearrangement of the alkyl ion does not occur prior to achievement of the critical configuration which determines the energy partitioning between the alkyl ion and neutral H_2O.

As for the C_5 alkanols, $(M - H)^+$ ions are observed for primary and secondary alcohols and show enhanced abundances in the N_2O/H_2 CI spectra due to H^- abstraction by NO^+. In addition, formation of the oxycarbonium ions corresponding to $(M - CH_3)^+$, $(M - C_2H_5)^+$, and $(M - C_3H_7)^+$, as well as formation of $CH_3CH{=}OH^+$, is observed when the neutral structure permits formation of these products without skeletal rearrangement.

[a]Fragment ion masked by reagent ion peak.

The dependence of the reaction competition between propylene loss and ethylene loss on the nominal $C_6H_{13}^+$ ion structure is examined in Table 3 which records the intensity ratio $C_3H_7^+/C_4H_9^+$ observed in the N_2/H_2 CI mass spectra. The results clearly show that the carbonium ion derived from 3,3-dimethylbutan-1-ol preferentially eliminates ethylene. This is the reaction mode predicted (Fig. 3) for the 3,3-dimethyl-1-butyl cation. On the other hand the $C_6H_{13}^+$ ion derived from 4-methylpentan-2-ol, which, in the absence of rearrangement, should have the 4-methyl-2-pentyl structure, does not show an enhanced elimination of propylene as one would predict it should if it is in fact the reacting configuration for propylene elimination. It is not clear whether in this case there has been a rearrangement of the carbonium ion or whether, as is more likely, propylene elimination is a more complex reaction which cannot be attributed to this specific reacting structure. The results of Table 3 show that for all $C_6H_{13}^+$ ions, except that derived from 3,3-dimethylbutan-1-ol, elimination of propylene is favoured over elimination of ethylene. This is in agreement with the metastable ion studies. The ratio shows considerable variation for the $C_6H_{13}^+$ ions derived from different alcohols; the significance of this variation is not clear.

TABLE 3. $C_3H_7^+/C_4H_9^+$ ratio in N_2/H_2 CI of C_6 alkanols

Alkanol	Ratio	Alkanol	Ratio

[e]Estimated as outlined by Bowen and Williams (6).

Obviously for both the $C_5H_{11}^+$ and $C_6H_{13}^+$ ions additional studies involving isotopic labelling, metastable ion characteristics, and collisional activation spectra are desirable. The present results show only that the extent of rearrangement in forming the alkyl ions by chemical ionization is minimal but provide no information on the facility with which rearrangements occur after the carbonium ions are formed. The further studies

suggested should provide information on this aspect.

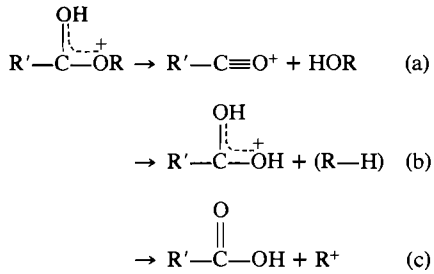
JAN A. HERMAN and ALEX. G. HARRISON. Can. J. Chem. **59**, 2133 (1981).

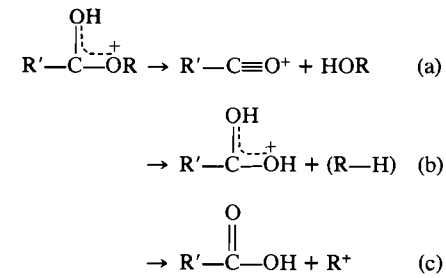
A series of formate (methyl through butyl) and acetate (methyl through pentyl) esters have been protonated in the gas phase by the Brønsted acids H_3^+, N_2H^+, CO_2H^+, N_2OH^+, and HCO^+. Carbonyl oxygen protonation is 87–97 kcal mol^{-1} exothermic for H_3^+ and 47–57 kcal mol^{-1} exothermic for the weakest acid HCO^+, permitting a study of the effect of protonation exothermicity on the decomposition modes of the protonated esters. With the exception of protonated methyl formate, three decomposition modes, (a) to (c) are observed.



Reaction (a) is unimportant for formates; for acetates it is the sole decomposition channel for the methyl ester, but is less important for higher acetates. The dependence of the relative importance of this reaction mode on the protonation exothermicity indicates an activation energy considerably in excess of ΔH^0, presumably because the reaction involves a symmetry-forbidden 1,3-H shift for the carbonyl protonated ester. For the higher acetates where the difference in the proton affinities of the carbonyl and ether oxygens is less, acyl ion formation results, in part, from protonation at the ether oxygen. For protonated methyl formate the major fragmentation reaction yields $CH_3OH_2^+ + CO$; this reaction also appears to have an activation energy considerably in excess of the ΔH_0. For the remaining esters either reaction (b) or (c) is the major decomposition mode. The competition between these two channels depends strongly on the protonation exothermicity and the relative activation energies. From the reaction competition we conclude that 1,2-H shifts occur in the case of primary alkyl esters yielding more stable secondary or tertiary alkyl ions. This rearrangement appears to occur after the excess energy has been partitioned between the alkyl ion and the neutral acid since the extent of further fragmentation of the alkyl ion reflects the original structure of the alkyl group.

JAN A. HERMAN et ALEX. G. HARRISON. Can. J. Chem. **59**, 2133 (1981).

Les acides de Brønsted H_3^+, N_2H^+, CO_2H^+, N_2OH^+ et HCO^+ ont servi à l'étude de la protonation en phase gazeuse des deux séries d'esters: formiates (de méthyle à butyle) et acétates (de méthyle à pentyle). L'exothermicité de la réaction de protonation du groupement carbonyle varie de 87–97 kcal mol^{-1} pour H_3^+ à 47–57 kcal mol^{-1} pour l'acide le plus faible, HCO^+, ce qui permet d'étudier l'effet de la chaleur de la réaction de protonation sur les modes de décomposition des esters protonés. Sauf dans le cas du formiate de méthyle protoné, on observe trois modes de décomposition, (a) à (c).



Alors qu'elle n'intervient guère dans le cas des formiates, la réaction (a) est l'unique voie de décomposition de l'acétate de méthyle et perd ensuite de l'importance pour les acétates supérieurs. La dépendance de l'importance relative de ce mode de réaction vis-à-vis l'exothermicité de la protonation indique une énergie d'activation excédant considérablement ΔH^0, probablement en raison du transfert d'H-1,3 symétriquement interdit impliqué dans la réaction de l'ester protoné. La différence des affinités protoniques des oxygènes du carbonyle et de l'éther étant moindres pour les acétates supérieurs, la formation de l'ion acylium provient en partie de la

protonation de l'oxygène de l'éther. Dans le cas du formiate de méthyle protoné, la principale réaction de fragmentation produit $CH_3OH_2^+ + CO$; cette réaction semble elle aussi avoir une énergie d'activation beaucoup plus grande que le ΔH^0. Le principal mode de décomposition des autres esters est l'une des deux dernières réactions (b) ou (c). La compétition entre ces deux voies est fortement influencée par l'exothermicité de la protonation et les énergies d'activation relatives. Cette compétition permet de voir que les transferts d'hydrogène-1,2 se produisent dans le cas des esters d'alkyle primaire pour conduire aux ions alkyles secondaires ou tertiaires plus stables. Ce réarrangement s'effectue apparemment après répartition de l'excès d'énergie entre l'ion alkyle et l'acide neutre puisque le degré de fragmentation ultérieure de l'ion alkyle reflète la structure originale du groupement alkyle.

Introduction

Since the original survey (1) of the chemical ionization (CI) mass spectra of esters, there have been numerous investigations (2–7) designed to elucidate details of the dissociation reactions occurring following proton transfer to esters in the gas phase. It has been established clearly that there are three main fragmentation modes, reactions [1] to [3].

[1] $R'CO_2R \cdot H^+ \rightarrow R'C{\equiv}O^+ + ROH$

[2] $\rightarrow R'CO_2H + R^+$

[3] $\rightarrow R'CO_2H_2^+ + (R{-}H)$

Reaction [1], involving formation of the acylium ion by acyl carbon–oxygen bond cleavage, and reaction [2], involving formation of the alkyl carbonium ion by alkyl carbon–oxygen bond cleavage, are analogous to the $A_{Ac}I$ and $A_{Al}I$ mechanisms for fragmentation of esters in concentrated acid solutions (8). Reaction [3] has no direct solution analogue.

The factors which determine the competition between these three channels in the gas phase have not been established clearly. In general, reaction [1] appears to be of lesser importance in the gas phase than in solution, possibly (6, 7) because it requires formation of the energetically less favourable ether oxygen-protonated ester. Alternatively, it has been suggested (7) that the ether oxygen-protonated species may fragment in the gas phase preferentially to form the protonated acid (reaction [3]) through formation of a six-membered cyclic transition state (reaction [4]).

[4] 
However, for propyl esters at least, it has been shown (6) that the hydrogen transferred from the alkyl group is not specifically the β-hydrogen as required by the proposed mechanism.

From a detailed study of the H_2 and CH_4 CI mass spectra of a series of formate esters, Harrison and Tsang (5) concluded that the relative importance of the fragmentation reactions of protonated formates was not determined by the relative enthalpies of decomposition of ground state $HCO_2R \cdot H^+$ but rather was determined by the relative fragmentation rate coefficients averaged over the appropriate internal energy distribution of the excited $HCO_2R \cdot H^+$ ions formed in the protonation reaction.

In electron impact studies a valuable approach in elucidating the factors controlling the competition between decomposition channels has been that of varying the average internal energy of the fragmenting species (9–11); it appeared that a similar approach should prove equally fruitful in chemical ionization systems. Recent work in this laboratory (12, 13) has shown that the protonation exothermicity and, thus, the average internal energy of the protonated species, can be varied over a significant and useful range by using the family of protonating agents XH^+, where X = H_2 (101), N_2 (117), CO_2 (129), N_2O (137), and CO (141); the numbers in brackets give the proton affinities of X in kcal mol^{-1} (14) and show that the protonation exothermicity can be varied by ~40 kcal mol^{-1}. The present work reports a detailed study of the effect of reaction exothermicity on the CI mass spectra of formate and acetate esters using this family of protonating agents. A similar study of a few selected esters using the flowing afterglow method has been reported recently (7).

Experimental

The chemical ionization mass spectra were obtained using a DuPont 21-490 mass spectrometer equipped with a high pressure chemical ionization source. The source temperature was ~60°C and the ionizing electron energy 70 eV, with the repellers at cage potential. The liquid samples were introduced through a heated inlet system held below 100°C. Reagent gas pressures were not measured directly but were estimated to be 0.2–0.3 Torr. The mass resolution of the instrument is sufficient to resolve the $C_2H_3O^+$–$C_3H_7^+$ doublet at m/z 43.

The H_3^+ reactant ion (X = H_2) was produced in pure H_2. As described elsewhere (12, 13) the N_2H^+, CO_2H^+, N_2OH^+, and HCO^+ reactant ions were prepared by electron impact ionization of the appropriate gas X (~10%) in H_2. Except for the N_2O/H_2 mixture the relevant XH^+ ion was the only significant ion in the reagent gas mass spectrum; in the N_2O/H_2 system ~10–15% of the total ionization was found as NO^+. As is evident from the results presented in the following section the NO^+ ion reacts with the esters primarily by addition to give the $M \cdot NO^+$ complex.

Reagent gases were of highest possible purity (Matheson and Co.) while the esters were either commercial samples of high purity or were prepared by standard procedures. Ethyl-d_5 formate was obtained from Merck, Sharp, and Dohme, Montreal.

Results and Discussion

Some general observations are in order to set the stage for the discussion of the chemical ionization results. The proton affinities reported (15) for formate and acetate esters range from 188 kcal mol^{-1} for methyl formate to 198 kcal mol^{-1} for *n*-propyl acetate; both refer to protonation at the carbonyl oxygen, the proton affinity of the ether oxygen being 11 to 22 kcal mol^{-1} lower depending on the ester (16). Thus carbonyl oxygen protonation of the esters by ground state H_3^+ is 87 to 97 kcal mol^{-1} exothermic, while protonation by ground state HCO^+ is 47 to 57 kcal mol^{-1} exothermic. In addition it is likely that the reagent ions in our system are not completely thermalized, making the protonation exothermicity even larger. The fraction of this reaction exothermicity which remains with the protonated molecule is not known, although arguments have been presented (12) from a detailed study of the protonation of C_3H_6O isomers, that, on average, a large fraction, approaching unity, of the exothermicity is retained by the product ions.

As discussed previously (12), the fragmentation of these excited ions (reaction [5]) is in competition with collisional stabilization (reaction [6]). At the

$$[5] \quad RH^{+*} \xrightarrow{k_5} \text{Fragments}$$

$$[6] \quad \xrightarrow[k_6[M]]{} RH^+$$

total pressures applicable in the present study, and assuming that a single collision with M is sufficient to stabilize RH^{+*} to below the decomposition threshold, $k_6[M] \simeq 1 \times 10^7 s^{-1}$. Thus the fragmentation reactions observed as reaction [5] correspond to those with rate coefficients, k_5, equal to or greater than $\sim 10^7 s^{-1}$. This is significantly higher than the threshold rate coefficients observed in electron impact mass spectrometry, particularly those observed as metastable ions ($k \simeq 10^4$–$10^6 s^{-1}$). This has important implications for the fragmentation reactions observed in chemical ionization mass spectrometry compared to those observed in electron impact mass spectrometry. The rate coefficient for the unimolecular decomposition of a gas-phase ion can be expressed in its simplest form (9–11) as

$$[7] \quad k(E) = \nu\left(\frac{E - \varepsilon_0}{E}\right)^S$$

where ν is an energy independent term or frequency factor, E is the internal energy, S is the effective number of oscillators, and ε_0 is the activation energy (referred to the ground state of the ion) for the reaction. It is well established (9–11) in electron impact studies that, at low internal energies, the relative rates of competing fragmentation reactions are determined largely by the relative activation energies, while at high internal energies the relative rates are strongly influenced by the energy independent term or frequency factor. In general, simple bond cleavage reactions have high frequency factors compared to those reactions which involve molecular rearrangement. Consequently, rearrangement fragmentation reactions cannot compete effectively with simple bond cleavage reactions at high internal energies and, normally, are observed following electron impact ionization because they have lower activation energies and, therefore, are dominant at lower internal energies. Similar considerations should apply in chemical ionization systems. Because, as discussed above, the average internal energy of fragmenting ions in CI systems is higher than in electron impact systems (especially for EI metastable ion studies), simple bond cleavage reactions should be favoured over rearrangement reactions. Further, as the average internal energy is increased by increasing the protonation exothermicity, the simple bond cleavage reactions should become increasingly favoured. These effects are observed in the results presented below.

The discussion which follows relies heavily on thermochemical arguments. The heats of formation of the carbonyl protonated esters and acids were derived from the reported proton affinities (15) or proton affinities estimated from these data, while the heats of formation of the ether oxygen-protonated species were derived from the estimates (16) of the proton affinities of these species. The heats of formation of alkyl ions were taken from the work of Lossing and Maccoll (17) or estimated from these data by the method outlined by Bowen and Williams (18). The remaining thermochemical data were taken from standard sources (19, 20). The data used are summarized in the Appendix.

Chemical Ionization Mass Spectra of Formate Esters

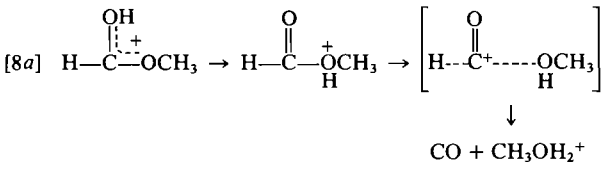
The chemical ionization mass spectra of the formate esters studied are summarized in Table 1. The H_2 CI mass spectra are in satisfactory agreement with those reported earlier (5).

The major fragmentation reaction of protonated methyl formate involves formation of protonated methanol (reaction [8]), a reaction which has a ΔH^0

$$[8] \quad \begin{matrix} & & OH \\ & & | \\ H- & C & -OCH_3 \end{matrix} \rightarrow CO + CH_3OH_2^+ \quad \Delta H^\circ = 15 \text{ kcal mol}^{-1}$$

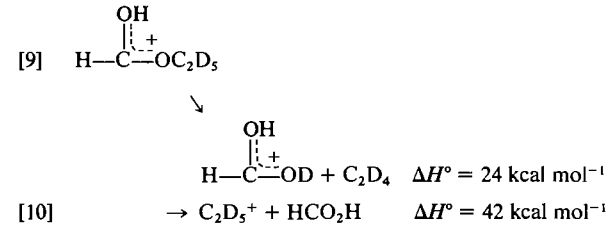
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

of 15 kcal mol^{-1} for the carbonyl protonated ester but would be ~5 kcal mol^{-1} exothermic for the ester protonated at the ether oxygen. Despite these low ΔH^0 values, the extent of fragmentation decreases rapidly with decreasing protonation exothermicity, with the $CH_3OH_2^+$ ion signal representing less than 20% of the total ionization in the N_2/H_2 CI system and less than 10% in the CO_2/H_2 CI system, where the protonation exothermicity is still >60 kcal mol^{-1}. This rapid decrease in the extent of fragmentation with decreasing exothermicity of protonation implies either that the fraction of the exothermicity retained by HCO_2-$CH_3 \cdot H^+$ is small or that the activation energy for fragmentation is considerably larger than the ΔH^0. The former explanation appears unlikely in view of the results obtained for the remaining esters and for other compounds (12, 13) and we conclude that the latter explanation holds. The overall reaction forming $CH_3OH_2^+$ probably is best represented by [8*a*] involving hydrogen migration from the carbonyl to the ether oxygen followed by bond cleavage accompanied by synchronous or near-synchronous proton transfer from the carbon to the developing methanol molecule (7, 21).

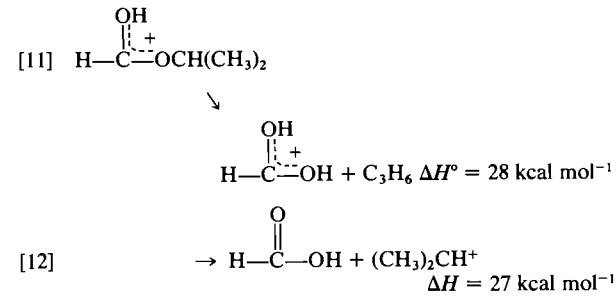


The initial step in this reaction has a ΔH^0 of 20 kcal mol^{-1} but probably has a considerably higher activation energy since the H transfer reaction is a [1,3]-symmetry-forbidden shift and such migrations have been shown to have an activation energy considerably in excess of the ΔH^0 (22). The ether oxygen-protonated form of the ester should have a much lower activation energy for fragmentation and it is possible that the small extent of fragmentation observed with weaker protonating agents represents fragmentation of this species.

In the CI of ethyl-d_5 formate, formation of $C_2D_5OH_2^+$ (*m*/*z* 52) is only a minor process even though this is the thermochemically favoured mode of fragmentation ($\Delta H^0 \simeq$ 12 kcal mol^{-1}); this supports the contention that the activation energy for this rearrangement is considerably higher than the ΔH^0. As observed previously (15), the major fragmentation reaction is [9] to form HCO_2HD^+; this fragmentation channel remains important (forming the base peak) even following protonation by HCO^+. The alternative fragmentation [10], forming $C_2D_5^+$ by simple bond fission, has a much higher ΔH_0 (and presumably, activation energy) and consequently competes ineffectively with the rearrangement reaction of lower activation energy. However, it should be noted that the simple bond fission reaction becomes more important at higher average internal energies (cf. H_2 CI), where the relative rates are more strongly influenced by frequency factors.



The CI mass spectra of both *n*-propyl and *i*-propyl formate are dominated, for all protonating agents, by the $C_3H_7^+$ alkyl ion, with $HCO_2H_2^+$ being only 10–20% of the alkyl ion intensity. For *i*-propyl formate the ΔH^0's, and, presumably, the activation energies, of the two reaction channels [11] and [12] are very similar consequently, it is not



surprising that the simple bond cleavage reaction [12] should dominate. The relative importance of the rearrangement reaction [11] increases slightly as the average internal energy is decreased by using weaker protonating agents. For protonated *n*-propyl formate, cleavage to form the *n*-propyl cation has a ΔH^0 of ~38 kcal mol^{-1}, considerably higher than that for formation of $HCO_2H_2^+$ ($\Delta H^0 \simeq$ 28 kcal mol^{-1}) yet $C_3H_7^+$ is the dominant fragment ion. It is probable that the bond fission is accompanied by a [1,2]-H shift to form the *i*-$C_3H_7^+$ ion. As Hopkinson *et al.* (7) have noted, *ab initio* MO calculations (23, 24) have shown that *n*-$C_3H_7^+$ collapses into *i*-$C_3H_7^+$ without an energy barrier. The alternative mechanism proposed by Hopkinson *et al.* (7) (reaction [13]), involving hydrogen transfer to the carbonyl oxygen followed by proton transfer from protonated formic acid to propene as the products separate, appears unlikely. First, it involves the thermochemically disfavoured ether

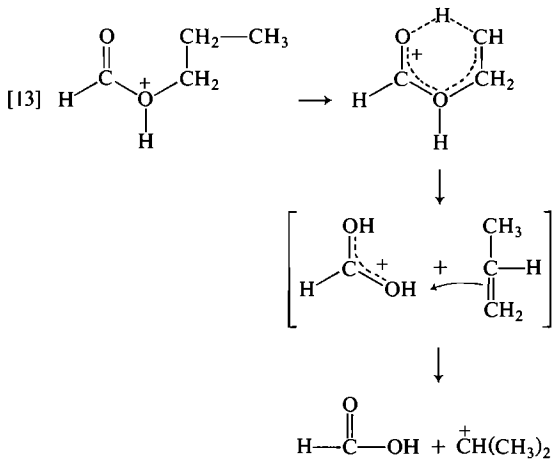
[a]Intensities as % of base peak arising from additive.
[b]R indicates fragment ion obscured by reagent ion peak.



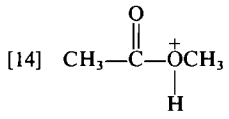
oxygen-protonated species. More importantly, it would suggest that with deuterated reagent gases, which form $HCO_2C_3H_7{\cdot}D^+$ originally, the isopropyl cation produced should contain significant deuterium; earlier studies (5) of the D_2 CI mass spectra of formates show that there is practically no deuterium incorporation in the $C_3H_7^+$ product from either *n*-propyl or *i*-propyl formate. Finally, reaction [13] is a rearrangement at least as complex as that resulting in formation of $HCO_2H_2^+$ and consequently one would not anticipate the observed increase in importance of $HCO_2H_2^+$ formation with decreasing internal energy in such a situation.

The butyl formates examined all show extensive fragmentation, with $C_4H_9^+$ the dominant fragment ion with all reagent gases. For protonated *sec*-butyl formate, formation of $s\text{-}C_4H_9^+$ (ΔH^0 = 24 kcal mol^{-1}) is favoured over formation of $HCO_2H_2^+$ (ΔH^0 = 26 kcal mol^{-1}); consequently, dominant fragmentation by simple bond cleavage is to be expected. However, for the *n*-butyl formate and *i*-butyl formate, formation of the primary butyl cations ($\Delta H^0 \simeq$ 40 kcal mol^{-1}) is thermochemically unfavourable compared to formation of $HCO_2H_2^+$ (ΔH^0 = 25 kcal mol^{-1}). It appears that in these two cases fragmentation must be accompanied by [1,2]-H shifts to form the more stable *sec*-butyl and *tert*-butyl structures respectively.

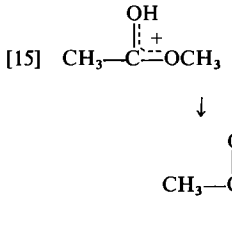
Chemical Ionization Mass Spectra of Acetates

The chemical ionization mass spectra of the methyl through butyl acetates are presented in Table 2, while the CI mass spectra of some isomeric pentyl acetates are presented in Table 3.

The only significant fragmentation channel for protonated methyl acetate involves methanol elimination to form the acetyl ion (*m*/*z* 43). The intensity of this fragment drops off markedly with decreasing protonation exothermicity, accounting for only ~20% of the total ionization in the CO_2/H_2 CI system. Pescheck and Butrill (3) have proposed that this fragment arises as a result of protonation at the ether oxygen followed by simple bond cleavage (reaction [14]), the analogue of the $A_{Ac}l$ solution



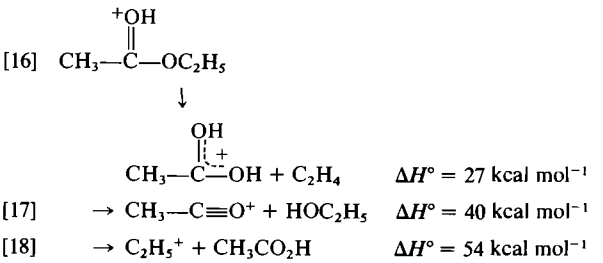
reaction. This simple bond cleavage reaction should not have an activation energy significantly greater than the endothermicity; consequently, assuming this mechanism, it is surprising that the acetyl ion is not more abundant in the CO_2/H_2 CI system where the protonation exothermicity to form the ether oxygen-protonated species is 53 kcal mol^{-1}. A likely explanation is that the major part of the acetyl ion arises by the route



This route, involving initial formation of the thermodynamically favoured carbonyl protonated species, requires a symmetry-forbidden [1,3]-H shift prior to fragmentation. The activation energy barrier for this step is undoubtedly much higher than the ΔH^0 of ~15 kcal mol^{-1} or the overall ΔH^0 of ~37 kcal mol^{-1}; such a high activation energy barrier would explain the strong dependence of the extent of fragmentation on the protonation exothermicity. The persistent $CH_3{-}C{\equiv}O^+$ ion signal with the weaker protonating agents may represent a contribution from reaction [14].

In the CI mass spectra of ethyl acetate the dominant fragmentation reaction involves formation of protonated acetic acid (reaction [16]), with minor formation of the acetyl ion (reaction [17]); formation of $C_2H_5^+$, the product of the $A_{Al}l$ fragmentation (reaction [18]), is observed with very low abundance in the H_2 CI spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.



[16] $CH_3—\overset{+}{C}(OH)—OC_2H_5$

$\downarrow$

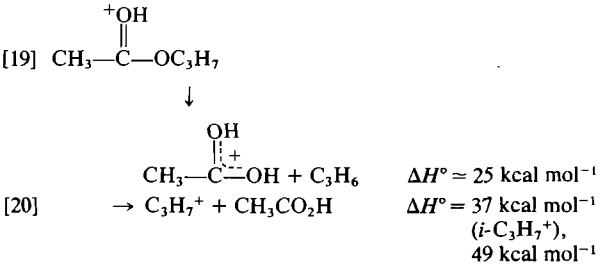
$CH_3—C(OH)=\overset{+}{O}H + C_2H_4$ $\Delta H° = 27$ kcal mol^{-1}

[17] $\rightarrow CH_3—C\equiv O^+ + HOC_2H_5$ $\Delta H° = 40$ kcal mol^{-1}

[18] $\rightarrow C_2H_5^+ + CH_3CO_2H$ $\Delta H° = 54$ kcal mol^{-1}

The relative fragment ion abundances are in agreement with the relative reaction endothermicities. The acetyl ion may arise, in part, by formation of the ether oxygen-protonated species and simple bond cleavage; this fragmentation reaction would have a ΔH^0 of $\sim$22 kcal mol^{-1} and, if it were a major route, should be more competitive with that leading to formation of protonated acetic acid. Thus it appears likely that the major route to acetyl ion formation is by fragmentation of the carbonyl protonated species, as discussed in detail for protonated methyl acetate.

Three fragmentation modes, reactions [19] to [21], are observed for protonated *i*-propyl acetate and protonated *n*-propyl acetate. Reaction [19],



[19] $CH_3—\overset{+}{C}(OH)—OC_3H_7$

$\downarrow$

$CH_3—C(OH)=\overset{+}{O}H + C_3H_6$ $\Delta H° \simeq 25$ kcal mol^{-1}

[20] $\rightarrow C_3H_7^+ + CH_3CO_2H$ $\Delta H° = 37$ kcal mol^{-1} (*i*-$C_3H_7^+$), 49 kcal mol^{-1} (*n*-$C_3H_7^+$)

[21] $\rightarrow CH_3—C\equiv O^+ + C_3H_7OH$ $\Delta H° \simeq 40$ kcal mol^{-1}

forming protonated acetic acid, has a considerably lower ΔH^0 and, presumably, activation energy, than the other fragmentation reactions and the protonated acetic acid ion froms the base peak in all CI mass spectra. The $C_3H_7^+$ and $CH_3—C\equiv O^+$ fragment ions are of approximately equal intensity in all CI spectra and decrease in abundance relative to the rearrangement product $CH_3CO_2H_2^+$ with decreasing protonation exothermicity. Reaction [21], as written, involves a symmetry-forbidden [1,3]-shift and, as discussed above, the activation energy should be considerably higher than the ΔH^0 and one would not anticipate that this reaction should be competitive with the other two reactions. However, the ether oxygen proton affinity of *n*-propyl acetate is only $\sim$12 kcal mol^{-1} less than the carbonyl oxygen proton affinity (16) and it may be that an appreciable fraction of the $CH_3—C\equiv O^+$ ion signals arises by the fragmentation

[22] $CH_3—\overset{O}{\overset{\|}{C}}—\overset{+}{O}(H)—C_3H_7$

$\downarrow$

$CH_3—C\equiv O^+ + C_3H_7OH$ $\Delta H° = 28$ kcal mol^{-1}

which would not be expected to have an activation energy significantly greater than the ΔH^0. The formation of $C_3H_7^+$ in the CI mass spectra of *n*-propyl acetate has a ΔH^0 of $\sim$49 kcal mol^{-1} (assuming *n*-$C_3H_7^+$ formation) and should not be competitive with the alternative fragmentations. It is probable that, here also, rearrangement to the *i*-propyl structure occurs. In addition, formation of alkyl ions by the $A_{Al}1$ mechanism from the ether oxygen-protonated species is possible and would have $\Delta H°$'s $\sim$12 kcal mol^{-1} lower than those quoted for reaction [20].

The CI mass spectra of the four butyl acetates show an interesting dependence of the relative importance of the three fragmentation reactions [23] to [25] on the identity of the butyl group.

[23] $CH_3—\overset{+}{C}(OH)—OC_4H_9 \rightarrow CH_3—C(OH)=\overset{+}{O}H + C_4H_8$

[24] $\rightarrow C_4H_9^+ + CH_3CO_2H$

[25] $\rightarrow CH_3—C\equiv O^+ + C_4H_9OH$

For *tert*-butyl acetate, formation of *t*-$C_4H_9^+$ is favoured thermochemically ($\Delta H^0 \simeq 21$ kcal mol^{-1}) over formation of protonated acetic acid ($\Delta H^0 \simeq 29$ kcal mol^{-1}) or formation of $CH_3—C\equiv O^+$ ($\Delta H^0 \simeq 40$ kcal mol^{-1}) and $C_4H_9^+$ is the dominant fragment ion in all CI mass spectra. For protonated *sec*-butyl acetate, fragmentation to form *s*-$C_4H_9^+$ has a ΔH^0 ($\sim$33 kcal mol^{-1}) higher than that for formation of protonated acetic acid ($\Delta H^0 \simeq 25$ kcal mol^{-1}); as a consequence, $CH_3CO_2H_2^+$ is the base peak in all CI mass spectra. The $C_4H_9^+$ ion is of appreciable intensity and increases in relative abundance with increasing protonation exothermicity, as expected for a simple bond cleavage reaction compared to a rearrangement fragmentation.

For both the *n*-butyl and *i*-butyl acetate systems fragmentation of the protonated ester to form the primary *n*-butyl or *i*-butyl cations would be much less favourable thermochemically ($\Delta H^0 \simeq 47$ kcal mol^{-1}) than formation of protonated acetic acid ($\Delta H^0 \simeq 25$ kcal mol^{-1}); nevertheless, $C_4H_9^+$ is the base peak in all CI mass spectra of *i*-butyl acetate

and is of appreciable abundance in the CI mass spectra of *n*-butyl acetate. It appears likely that there is significant rearrangement to the *tert*-butyl and *sec*-butyl structures, respectively, during fragmentation of these protonated esters. These rearrangements can occur by relatively simple [1,2]-H shifts in the developing cation. For all the butyl acetates there is significant formation of the $CH_3—C\equiv O^+$ ion; this may represent fragmentation of the ether oxygen protonated species. The proton affinity difference between the carbonyl oxygen and the ether oxygen of esters decreases as the size of the ester increases (16) and one might expect more protonation at the ether oxygen as a result.

The CI mass spectra of the six pentyl acetates examined are summarized in Table 3. The usual fragmentation reactions, [26] to [28], are observed.

[26] $CH_3—\overset{OH^+}{C}—OC_5H_{11} \rightarrow CH_3—\overset{OH^+}{C}—OH + C_5H_{10}$

[27] $\rightarrow C_5H_{11}^+ + CH_3CO_2H$

[28] $\rightarrow CH_3—C\equiv O^+ + C_5H_{11}OH$

In addition, in several cases extensive fragmentation of $C_5H_{11}^+$ is observed by the reaction channels, [29, [30], and [31], established previously (13).

[29] $C_5H_{11}^+ \rightarrow C_5H_9^+ + H_2$

[30] $\rightarrow C_4H_7^+ + CH_2$

[31] $\rightarrow C_3H_7^+ + C_2H_4$

The fragmentation of $C_5H_{11}^+$ ions produced by dissociative proton transfer to isomeric pentyl alcohols has been studied in detail (13). It was observed that the extent of fragmentation was greatest for $C_5H_{11}^+$ ions derived from primary alcohols, less for $C_5H_{11}^+$ derived from secondary alcohols, and very slight for the $C_5H_{11}^+$ ion derived from *tert*-pentanol. As expected, the extent of fragmentation decreased as the protonation exothermicity decreased. These results were interpreted as indicating that there was negligible rearrangement to more stable alkyl structures prior to achievement of the critical reacting configuration which determined the energy partitioning between R^+ and H_2O in the decomposition of ROH_2^+. In terms of the extent of further fragmentation of the $C_5H_{11}^+$ ions the present results for protonated pentyl acetates are in essential agreement with the results for the protonated pentyl alcohols. However, in terms of the competition between reactions [26] and [27] there is substantial evidence for alkyl ion rearrangement. This is illustrated most clearly in terms of the relative intensities for the $CH_3CO_2H_2^+$ and $C_5H_{11}^+$ ions observed in the CO_2/H_2 CI spectra summarized in Table 4, along with the ΔH^0 for formation of these ions from the ground state protonated ester. The ΔH^0 values for $C_5H_{11}^+$ formation have been calculated assuming an alkyl ion structure identical to the neutral alkyl moiety. For 2-pentyl acetate and 3-pentyl acetate the ΔH^0 for formation of $C_5H_{11}^+$ is slightly larger than that for formation of $CH_3CO_2H_2^+$ and we observe that the alkyl ion intensity is lower than that of the protonated acetic acid ion. For the secondary acetate, 3-methyl-2-pentyl acetate, the ΔH^0 values are very similar, yet the $C_5H_{11}^+$ ion is the dominant ion in the mass spectra. This strongly indicates a [1,2]-H shift to yield the more stable *tert*-pentyl ion. Collin and Herman (25) have reported an activation energy of $\sim$2 kcal mol^{-1} for this isomerization from studies of the protonation of 3-methyl-1-pentene in radiolysis experiments. Indeed, their results for the extent of fragmentation of $C_5H_{11}^+$ as a function of protonation exothermicity are in agreement with the present data. For the primary acetates the ΔH^0's for formation of the respective primary alkyl ions are much larger than the ΔH^0 for formation of $CH_3CO_2H_2^+$, yet the alkyl ion intensities are as great as, or greater than, the $CH_3CO_2H_2^+$ ion intensities. Clearly this unexpected result can only be accommodated by assum-

ing that rearrangement to a more stable secondary or tertiary alkyl ion occurs during fragmentation. The extent of formation of $CH_3—C\equiv O^+$ is higher than one would anticipate for fragmentation of the carbonyl protonated species and formation of this fragment may represent an increased importance of protonation at the ether oxygen.

Thus, we are left with the apparent paradox that the energy partitioning between neutral and ionic fragments, as reflected in the extent of further fragmentation of the alkyl ions, supports a reaction model in which no significant rearrangement in the alkyl moiety occurs, while the competition between fragmentation channels indicates that rearrangement has occurred in the alkyl moiety. A possible resolution of this paradox is given by the detailed reaction model proposed in Scheme 1 for a primary alkyl acetate. As the alkyl carbon–oxygen bond lengthens, a critical state (or transition state) *a* is reached corresponding to an unrearranged alkyl ion bonded to neutral acetic acid largely by ion–dipole interactions (21). The partitioning of the excess energy between the neutral acetic acid and alkyl ion appears to be determined at this stage. A simple [1,2]-H shift in the alkyl ion leads to the secondary ion interacting with acetic acid by ion–dipole forces; this structure *b*, which will be more stable than *a*, may then undergo simple fission of the weak bond to acetic acid yielding the alkyl ion or may transfer a proton to acetic acid yielding the protonated acid and an appropriate olefin. Isotopic labelling studies (6) in *n*-propyl acetate show that the H transferred from the propyl group does not originate from a specific position of the alkyl group but may come from any position. It is possible that this proton shift may go through the intermediacy of *c*, a proton solvated by both the olefin and acetic acid (21), which might be considered as an alterna-

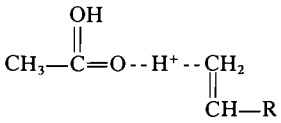
tive structure to *b*; in principle *c* could fragment to either the protonated acid or the appropriate stable alkyl ion. However, if such were the case, the rate constant expressions for formation of both the alkyl ion and protonated acetic acid should have similar frequency factors. As discussed above, the internal energy dependence of the relative fragment ion yields suggests that the reaction forming protonated acetic acid has a lower frequency



c

factor, indicating a more complex rearrangement. This is most readily interpreted on the basis that the alkyl ion originates by simple dissociation of the loosely-bound complex *b* of Scheme 1.

Appendix

The thermochemical data relevant to the heats of formation of protonated carboxylic acids and esters are summarized in Table 5. In view of the estimates made the uncertainty is probably at least ± 3 kcal mol^{-1} in the heats of formation.

Other relevant ion heats of formation (all in kcal mol^{-1}) are: $C_2H_5^+$, 219; n-$C_3H_7^+$, 208; i-$C_3H_7^+$, 192; n-$C_4H_9^+$, 201; i-$C_4H_9^+$, 199; s-$C_4H_9^+$, 183; t-$C_4H_9^+$, 167; all from ref. 17. A value of ΔH^0_f (CH_3—$C{\equiv}O^+$) = 158 kcal mol^{-1} was used (26). ΔH_{0f} ($CH_3OH_2^+$) = 136 kcal mol^{-1} was derived from the reported proton affinity of 182 kcal mol^{-1} (15).

Neutral heats of formation, from refs. 19 and 20, all in kcal mol^{-1}, are: CH_3OH, −48.1; C_2H_5OH, −56.1; n-C_3H_7OH, −61.2; i-C_3H_7OH, −65.1; n-C_4H_9OH, −65.8; i-C_4H_9OH, −67.8; s-C_4H_9OH, −70.0; t-C_4H_9OH, −74.7; C_2H_4, 12.5; C_3H_6, 5.0; 1-C_4H_8, −0.2; 2-C_4H_8, −1.9; i-C_4H_8, −4.3.

Oxidation of hydrocarbons. X. Concerning the formation of ketols and diones during the oxidation of alkenes by permanganate ion

DONALD G. LEE AND N. S. SRINIVASAN
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received September 26, 1980

DONALD G. LEE and N. S. SRINIVASAN. Can. J. Chem. **59**, 2146 (1981).

The oxidation of *E*-5-decene by potassium permanganate in slightly acidic aqueous acetone solutions has been studied. An analysis of the reaction mixture at various time intervals indicates that the ketol, 5-hydroxy-6-decanone, is the initially formed product under these conditions. The other major product, 5,6-decanedione, is formed sequentially from oxidation of the ketol rather than directly from the alkene.

DONALD G. LEE et N. S. SRINIVASAN. Can. J. Chem. **59**, 2146 (1981).

On a étudié l'oxydation du décène-5 (*E*) par le permanganate de potassium dans des solutions aqueuses d'acétone légèrement acides. Une analyse du mélange réactionnel après divers temps de réaction indique que, dans ces conditions, le premier produit à se former est le cétol hydroxy-5 décanone-6. L'autre produit principal, la décanedione-5,6 provient de l'oxydation subséquente du cétol plutôt que d'une oxydation directe de l'alcène.

[Traduit par le journal]

Introduction

Although the products obtained from the oxidation of alkenes by permanganate ion are largely determined by the reaction conditions, it is generally accepted that they are all formed from a single intermediate cyclic manganate(V) diester, **1** (1, 2, 3*a*). For example, Ogino and Mochizuki (4) have presented evidence which indicates that treatment of such an intermediate with aqueous base results in hydrolysis and yields a diol (eq. [2]). This observation provides concrete evidence in support of the widely accepted explanation for the formation of diols during the oxidation of alkenes by basic permanganate (3*a*).

[1] 
1

[2] 
On the other hand, treatment of **1** with aqueous acid leads to cleavage products (4). Protonation of the intermediate presumably increases the oxidation potential of manganate(V) (3*b*) and promotes a cyclic decomposition (eq. [3]).

[3] 
Under approximately neutral conditions two products have been obtained; in aqueous solutions ketols are the major products (5), while under nonaqueous conditions diones are often obtained (6). Previous studies (1, 7) have suggested that ketols are formed in neutral aqueous solutions because the intermediate manganate(V) ester, **1**, is oxidized to a manganate(VI) ester, **2**, before hydrolysis to the diol can occur; i.e. hydrolysis of **1** gives a diol, but oxidation of **1** to **2** followed by hydrolysis and oxidative decomposition gives a ketol.

[4] 
Wiberg and Saegebarth (7) have shown clearly that the ratio of ketol to diol formed is the result of a competition between oxidant and base for reaction with **1** as depicted in reaction [4].

In nonaqueous solvents it is conceivable that the products (diones) could be formed directly from **1** as in reaction [5] or from the sequential oxidation of the initial products (ketols) as in reaction [6].

It is not likely that diols could be precursors to the diones because the oxidation of diols by permanganate is known to lead to cleavage products (8).

The purpose of the experiments described in this paper was to determine if the diones are formed directly (reaction [5]) or sequentially (reaction [6]). The approach taken was to withdraw, quench, and analyze aliquots while *E*-5-decene was being oxidized by potassium permanganate in slightly acidic aqueous acetone solutions. The analysis was done by injection of a portion of the quenched solution into a gas chromatograph under conditions where the various possible products were separable.

Experimental

Reagents and Solvents

E-5-Decene (99+%), *n*-decane (99+%), and acetone (99+%) were obtained from the Aldrich Chemical Company and used without further purification. Reagent grade acetic acid was purified by refluxing with sodium dichromate and distilling under reduced pressure (9). Distilled water, obtained from an all-glass still, was redistilled from alkaline permanganate before use. Allyl alcohol, anhydrous sodium sulfate, and molecular sieves type 4A, all of certified grade, were obtained from the Fisher Scientific Company. Pentanoic and butanoic acid were purified by distillation using a microstill equipped with a thirty plate Teflon spinning band fractionation column. Authentic samples of 5-hydroxy-6-decanone (10) and 5,6-decanedione (11) were prepared and identified by use of nmr and ir spectroscopy. Potassium permanganate in a very finely powdered form (Cairox M) was obtained from the Carus Chemical Company.

The Rate of Oxidation of E*-5-Decene*

A 250 mL Erlenmeyer flask was charged with potassium permanganate (1.21 g, 0.00766 mol), acetone (25 mL), acetic acid 1.5 mL), and water (1.5 mL). It was placed in a thermostated bath (25.0 ± 0.1°C) and the solution was stirred magnetically. After 20 min *n*-decane (0.5 mL), which was used as an internal standard, and *E*-5-decene (1.00 mL, 0.00529 mol) were injected into the flask. A timer was started and approximately 0.75 mL aliquots were withdrawn at intervals and quenched by addition to an excess of cold allyl alcohol.

The quenched aliquot was dried over anhydrous sodium sulfate and the solids (sodium sulfate and manganese dioxide) were removed by centrifugation. The clear solution was pipetted into a test tube containing molecular sieves, stoppered, and refrigerated.

The aliquots were analyzed by injecting a portion (3 μL) into a dual column Hewlett-Packard Research Chromatograph 7620 A fitted with an 8 ft column containing 20% Carbowax 20 M and terephthalic acid on Chrom W DMCS 60/80 mesh. Peak areas were determined using a disc integrator and compared to those of the internal standard, *n*-decane. Calibration curves, correlating the ratios of the peak areas to the concentrations of *E*-5-decene and all detectable products, were prepared and used to calculate the amount of each product present. These were then plotted against the time at which each aliquot had been obtained (see Fig. 1).

The internal standard, *n*-decane, was stable to permanganate over the reaction time. The quenching agent, allyl alcohol, and the products of its oxidation did not interfere with the glc analysis. Similar procedures were used to determine the rates of oxidation of 5-hydroxy-6-decanone and 5,6-decanedione.

The Oxidation of 5-Hydroxy-6-decanone

A 250 mL Erlenmeyer flask, immersed in a water bath at room temperature, was charged with 5-hydroxy-6-decanone (2.50 g, 0.0147 mol), reagent grade acetone (50 mL), acetic acid (3 mL), and water (3 mL). To this was added potassium permanganate (3.0 g, 0.019 mol), and the solution was stirred magnetically for 40 min. It was then quenched by addition of a few drops of allyl alcohol and the precipitated manganese dioxide was removed by filtration. The precipitate was washed with ether (4 × 50 mL) and the combined organic solutions were dried (anhydrous magnesium sulfate) and concentrated using a rotary evaporator. The residue was analyzed by glc. The yield of 5,6-decanedione, based on the amount of ketol which had reacted, was 83%.

Rate Constants

Approximate second order rate constants were obtained from plots of ln ($[MnO_4^-]$/[substrate]) against time (12). The concentrations of the organic substrates were calculated using the glc

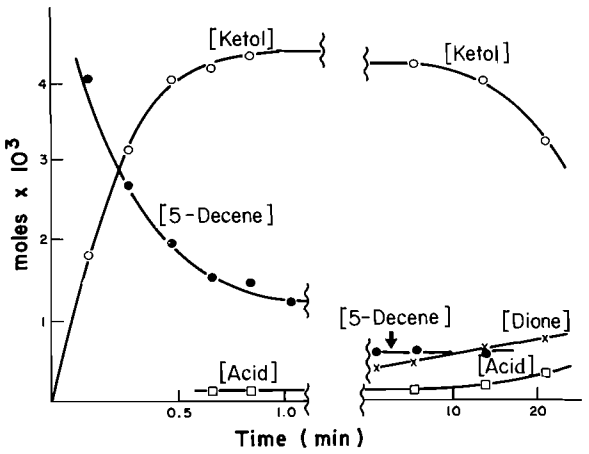

FIG. 1. Composition of the reaction mixture during the oxidation of *E*-5-decene by permanganate ion in acetone containing 5% water and 5% acetic acid.

analytical procedure described above and the permanganate concentrations were obtained from a knowledge of the initial concentration and the amount of organic product that had been produced.

Some typical rate plots have been reproduced in Figs. 2 and 3.

Results and Discussion

The results obtained from an analysis of the composition of the reaction mixture at various time intervals have been summarized in Fig. 1. This figure clearly indicates that the first detectable product formed is the ketol and that the dione is likely formed in a subsequent reaction. (This is also consistent with the fact that dione could be obtained in 83% yield from the oxidation of the ketol under these same conditions.) Furthermore, an examination of the reaction rates indicates that the second order rate constant of oxidation of the alkene ($0.414\,M^{-1}\ s^{-1}$) is almost twice that for oxidation of the ketol ($0.234\,M^{-1}\ s^{-1}$).

Oxidation of the dione would produce carboxylic acids (13). However, it is of interest to note that pentanoic acid began to accumulate before any dione could be detected in the product. This may simply reflect the fact that carboxylic acids are stable products and not susceptible to further degradation, whereas the diones can be oxidized.

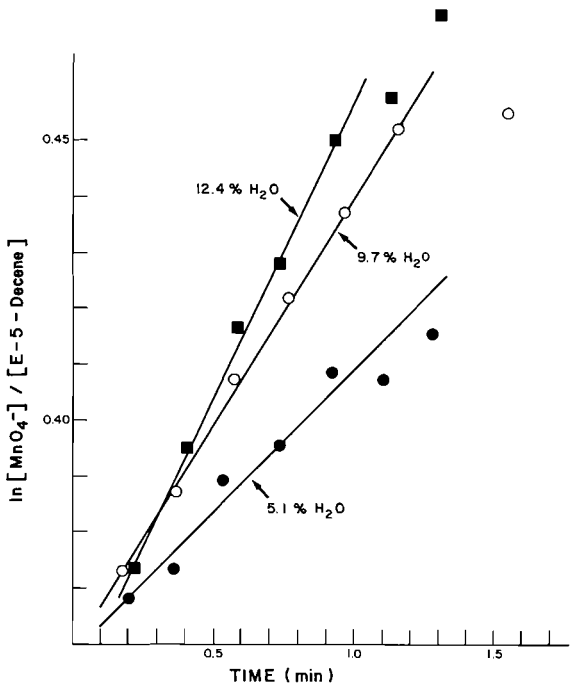

FIG. 2. Second order rate plots for the oxidation of *E*-5-decene by permanganate ion in aqueous acetone solutions containing 5% acetic acid.

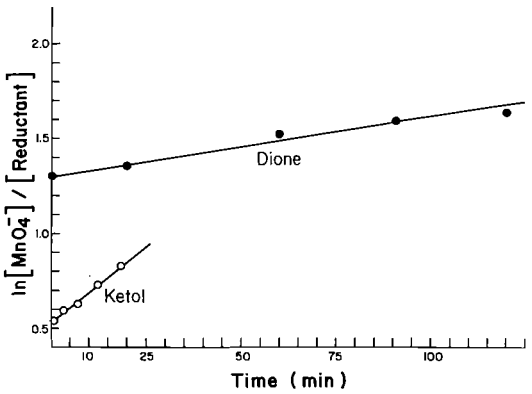

FIG. 3. Second order rate plots for the oxidation of 5-hydroxy-6-decanone and 5,6-decanedione by permanganate ion in acetone solutions containing 5% water and 5% acetic acid.

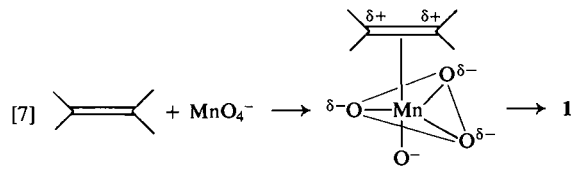
However, the rate constant for dione oxidation is very small ($0.00986\,M^{-1}\ s^{-1}$) compared to the reaction time scale and it seems more likely that some of the carboxylic acid is formed directly from the intermediate cyclic manganate(V) ester as in eq. [3]. The product of such a cleavage, pentanal, was not detected, probably because of the ease with which it would be oxidized to pentanoic acid.

It may also be noted that the rate of formation of ketol is accelerated by increasing the amount of water present in the solvent (Fig. 2). Since increasing the amount of water also increases the polarity of the solvent this result suggests that the transition state for reaction [1] must be more polar than the ground state. If it is assumed that the reaction involves a transfer of electrons from the HOMO of the alkene to the LUMO of the permanganate ion (14), a possible transition state may be visualized as follows:



A transition state of this type is also consistent with the evidence Sharpless *et al.* (15) have recently presented, which indicates that reactions between alkenes and transition metal oxides are initiated by an interaction between the π orbitals of the double bond and the *d* orbitals of the metal.

Finally, one may attempt, on the basis of these results, to understand why ketols are obtained as the products of permanganate oxidations in neutral aqueous media while diones are obtained in approximately neutral nonaqueous solvents. The

answer lies in a consideration of the relative rate constants. Although the rate constant for formation of ketol increased from 0.414 M^{-1} s^{-1} in a solvent mixture containing 5.1% H_2O to 0.819 M^{-1} s^{-1} for one containing 12.4% H_2O, the corresponding rate constants for oxidation of the ketol to the dione actually decreased slightly (from 0.234 M^{-1} s^{-1} to 0.205 M^{-1} s^{-1}). Hence in an aqueous solution it appears that the ketol would be formed much faster than the dione. Therefore in aqueous solutions the product would be a ketol unless excess oxidant was used. Furthermore, it is known that α-diones are rather easily cleaved by permanganate in aqueous solution (10) and a use of excess oxidant would tend to give carboxylic acids rather than diones. Under anhydrous conditions the rates of oxidation of the alkene and the ketol are more comparable and the dione less susceptible to cleavage. Hence the dione is more likely to accumulate when nonaqueous solvents are used.

The cybrodins, a new class of sesquiterpenes[1,2]

WILLIAM A. AYER AND ROBERT H. MCCASKILL
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 3, 1981

WILLIAM A. AYER and ROBERT H. MCCASKILL. Can. J. Chem. **59**, 2150 (1981).

The isolation and structure determination of the "cybrodins", a new group of sesquiterpenoids produced by a new strain of the bird's nest fungus *Cyathus bulleri*, is reported. Cybrodol (**3**), isocybrodol (**4**), cybrodal (**5**), trisnorcybrodolide (**6**), and cybrodic acid (**7**) may be classified as *seco*-illudalane sesquiterpenes. The evidence leading to the structural assignments is presented, along with chemical correlations among the cybrodins. The possible mode of biogenesis is discussed. Pterosin-C (**13**), a known norsesquiterpene, and 3-methyllumichrome (**17**) were also isolated. Small quantities of a new sesquiterpenoid, broderol, believed to possess structure **21**, were obtained on two occasions.

WILLIAM A. AYER and ROBERT H. MCCASKILL. Can. J. Chem. **59**, 2150 (1981).

On rapporte la séparation et la détermination de la structure des "cybrodines", un nouveau groupe de sesquiterpènes produits par une nouvelle déformation du champignon des nids d'oiseaux: le *Cyathus bulleri*. On peut classifier le cybrodole (**3**), l'isocybrodole (**4**), le cybrodale (**5**), le trisnorcybrodolide (**6**) et l'acide cybrodique (**7**) comme des sesquiterpènes du type *seco*-illudalane. On présente des données qui permettent d'attribuer des structures ainsi que les corrélations chimiques entre les cybrodines. On discute du mode possible de biogénèse. On a également isolé la ptérosine-C (**13**) un norsesquiterpènes connu ainsi que la méthyl-3 lumichrome (**17**). On a obtenu à deux reprises des petites quantités de brodérol, un nouveau sesquiterpène qui possèderait la structure **21**.

[Traduit par le journal]

Some time ago we reported the isolation and structure determination of the degraded eudesmane-type sesquiterpene cybullol (**1**) from *Cyathus bulleri* Brodie (Brodie strain 6620, ATCC 38347) (3). At that time we also reported the isolation and characterization of small amounts of a $C_{15}H_{28}O_3$ triol which had properties consistent with it being a biogenetic precursor of cybullol such as **2** (3, 4). In pursuit of further quantities of this triol we examined the metabolites of a different strain[3] of *C. bulleri* (Brodie strain 6680a, ATCC 38351) which we find does not produce cybullol (**1**) or the triol $C_{15}H_{28}O_3$ but which instead produces a series of new sesquiterpenes which we have called the cybrodins.[4] In this paper we discuss the isolation and structure determination of the cybrodins and other minor metabolites, and in the following paper we describe the total syntheses of the cybrodins.

Liquid cultures of *C. bulleri* were grown on an aerated yeast–malt extract medium in a fermentation apparatus. After a growth period of two weeks, the mycelial cells were removed by filtration, and the culture broth was extracted with ethyl acetate.

from the polypropylene glycol antifoaming agent necessary in the fermentation apparatus and also affords a useful preliminary separation of the metabolites) and then silica gel. The major metabolites isolated from the neutral fraction are two isomeric compounds $C_{15}H_{22}O_3$ (named cybrodol (**3**) and isocybrodol (**4**)), a compound $C_{15}H_{18}O_3$ (cybrodal (**5**)), and a compound $C_{12}H_{14}O_3$ (trisnorcybrodolide (**6**)). From the acid fraction, cybrodic acid ($C_{15}H_{20}O_3$ (**7**)) was the only compound isolated.

Inspection of the ^1H and ^{13}C nuclear magnetic resonance (nmr), infrared (ir), and ultraviolet (uv) spectra of cybrodol (**3**) and *O,O,O*-triacetylcybrodol (**3***a*) reveals that cybrodol is a pentasubstituted benzene derivative and that the substituents are two methyl groups, an hydroxymethyl group, a β-hydroxyethyl group, and a four-carbon unit containing a double bond, a methyl group, and an hydroxymethyl group. Thus the ^{13}C nmr spectrum has eight signals in the region δ 120–140 where sp^2 carbons not bonded to heteroatoms normally appear. Off-resonance decoupling reveals that six of these signals are due to fully substituted carbons, the remaining two bear single hydrogen atoms. The ^1H nmr spectrum of cybrodol has one proton signal at δ 7.10 and δ 6.45 corresponding to aromatic and olefinic hydrogens respectively. The ^{13}C nmr spectrum also has three methylene signals in the region δ 60–70 typical of oxygenated sp^3 carbons (5). That these represent the carbons of three primary alcohols is indicated by the presence of three two proton signals (δ 4.50, 4.23, and 3.76) in the ^1H nmr spectrum of cybrodol, all of which are shifted downfield by about 0.5 ppm in the spectrum of *O,O,O*-triacetylcybrodol. The signal at δ 4.50 is characteristic of a benzylic alcohol. Irradiation of the olefinic proton of cybrodol sharpens the signal at δ 4.23, indicating the presence of an allylic alcohol function. The signal at δ 3.76 is one half of an A_2X_2 system (J_{AX} = 7 Hz) the second half of which appears at δ 2.99. These shifts are consistent with the presence of the β-phenethyl alcohol grouping.[5] Mass spectral evidence supports this assignment, since the mass spectrum of cybrodol shows a strong peak (95%) at *m/e* 219 ($M^+ - CH_2OH$) for the resulting benzylic carbonium ion.

The ^1H nmr spectrum of cybrodol shows aromatic *C*-methyl signals at δ 2.36 and 2.18 and an olefinic methyl at δ 1.44. The latter signal is a doublet (J = 1 Hz) which collapses to a singlet when the olefinic proton at δ 6.45 is simultaneously irradiated. This latter finding establishes the structure of the four carbon side chain, except for stereochemistry, since the small splitting indicates that the olefinic hydrogen is not on the same carbon as the methyl group or the hydroxymethyl group. It now remains to determine the arrangement of the substituents on the aromatic ring.

Comparison of the aryl methyl group signals shows that the signal at δ 2.18 is noticeably sharper than the signal at δ 2.36, and a nuclear Overhauser experiment demonstrated that the latter methyl group is *ortho* to the aromatic proton. Ozonolysis of *O,O,O*-triacetylcybrodol (**3***a*) followed by oxidative work-up gave the acid **8**. This confirmed the structure of the olefinic sidechain and also provided evidence as to its environment. In going from a styrene type system to a benzoic acid it is expected that the groups *ortho* to the carboxyl group will experience substantial downfield shifts (7, 8). Only two of the groups in **8** are significantly shifted relative to their positions in **3***a*. The benzylic acetate methylene group is deshielded by 0.17 ppm, and the methyl group which is not *ortho* to the aromatic hydrogen is deshielded by 0.46 ppm. Thus the olefinic side chain in cybrodol is flanked by these two groups. In agreement with this the acid **8**, when treated with 10-camphorsulfonic acid in benzene–methanol, undergoes transesterification and lactonization to provide the phthalide **6**. This phthalide is identical with trisnorcybrodolide (**6**), one of the naturally occurring compounds mentioned above. Trisnorcybrodolide (**6**) has a uv spectrum very similar to that of phthalide itself (9), and the ir (1730 cm^{-1}) is consistent with the formulation. The methylene group in the five-membered ring resonates at δ 5.15 (phthalide itself δ 5.35), and the A_2X_2 system of the β-hydroxyethyl group appears at δ 3.06 and 3.79. This latter system displays the appropriate acetylation shift in the spectrum of *O*-acetyltrisnorcybrodolide (**6***a*). Thus the carboxyl group in the acid **8** is located *ortho* to the benzylic alcohol.

The fact that the β-hydroxyethyl group is located between the two aromatic methyl groups was demonstrated in the following way. Dehydration of trisnorcybrodolide (**6**) to the olefin **9** was effected, albeit in low yield, in two different ways. Firstly the alcohol was converted to the selenide **10** by treatment with 4-nitrophenylselenocyanate and tri-*n*-butylphosphine (10). Oxidative elimination then provided the olefin **9** in 15% overall yield. Secondly, mesylation of **6** followed by treatment of the mesylate with 1,5-diazabicycloundecene (DBU)

[5]β-Phenethyl alcohol itself shows shifts of δ 3.85 and δ 2.82 for these methylene groups (6).

gave **9** in about 20% yield. Ozonolysis of **9** followed by reductive work-up furnished the aldehyde **11** in 40% yield. Both methyl groups experience downfield shifts in **11** (C-5 CH_3 δ 2.69, C-7 CH_3 δ 2.98) relative to **6** (δ 2.48 and 2.73 respectively), now falling within the deshielding cone of the aldehyde carbonyl (7). The aromatic hydrogen of **11** is only slightly deshielded (δ 7.18, δ 7.11 in **6**). The synthesis of trisnorcybrodolide reported in the following paper provides confirmation of structure **6**.

The determination of the double bond geometry of cybrodol (**3**) was greatly facilitated by the isolation of three closely related metabolites: isocybrodol (**4**), cybrodal (**5**), and cybrodic acid (**7**). Comparison of the ^1H nmr spectra of cybrodol (**3**) and isocybrodol (**4**) reveals that the two compounds have the same aromatic substituents and differ only in the stereochemistry of the olefinic sidechain. This is confirmed by the fact that ozonolysis of *O,O,O*-triacetylisocybrodol (**4***a*) followed by methanolysis and lactonization provided trisnorcybrodolide (**6**). The olefinic hydrogen (δ 6.27) and allylic alcohol methylene group (δ 3.69) are both upfield relative to the analogous protons of cybrodol. The olefinic methyl group (δ 2.02) of isocybrodol resonates at lower field than that of cybrodol. Neither cybrodol nor isocybrodol shows a styrene-like chromophore in the uv, both display unconjugated benzenoid absorption. Inspection of space-filling models shows that the isobutenyl side chain is twisted out of the plane of the benzene ring. Some degree of restricted rotation also explains why in the case of isocybrodol (**4**) the protons of the benzyl alcohol methylene group show nonequivalence (AB quartet centered at δ 3.69, J = 12 Hz). This feature is precedented in biphenyl chemistry (ref. 8, p. 378). The high field position of the olefinic methyl group (δ 1.44) in cybrodol and its rather low field position (δ 2.02) in isocybrodol can be explained if in the former the methyl is in the shielding region of the aromatic ring (i.e., A in **12**) and in the latter it is in the deshielding region (i.e., B in **12**). The hydroxymethyl signals show the same trend (δ 4.20 in **3**, δ 3.69 in **4**). On this basis cybrodol was assigned the *E* configuration, isocybrodol the *Z* configuration.

Cybrodal (**5**) has two conjugated aldehyde groups (ir 1688 cm^{-1}, ^1H nmr δ 9.75 and 9.92). Reduction of *O*-acetylcybrodal (**5***a*) with lithium aluminum hydride (LAH) gave cybrodol (**3**). Oxidation of cybrodol (**3**) with manganese dioxide gave cybrodal (**5**). Relative to cybrodol the vinyl and the aromatic hydrogens of cybrodal are deshielded by 1.16 ppm and 0.51 ppm, respectively, in the ^1H nmr spectrum. The former perturbation reflects the β-position and *cis*-relationship of the olefinic hydrogen to a formyl group. The latter deshielding is consistent with an *ortho* relationship of a formyl group to the aromatic hydrogen in **5**.

Cybrodic acid (**7**) readily forms a methyl ester (**7***a*) on treatment with diazomethane. The chemical shifts (^1H nmr) of the aromatic substituents do not differ significantly from those of cybrodol. The allylic alcohol methylene group is not evident, however, and the vinylic proton is shifted significantly downfield (δ 7.65) relative to **3**. The vinyl methyl appears at δ 1.60 and is coupled to the vinylic hydrogen, thereby unambiguously identifying the two signals. Comparison of the vinyl hydrogen shift (δ 7.65) with that of *E*-α-methylcinnamic acid (δ 7.80) (11) and *Z*-α-methylcinnamic acid (δ 6.73) (11) provides compelling evidence for the *E*-geometry in cybrodic acid (**7**). Reduction of methyl cybrodate (**7***a*) with LAH gives cybrodol (**3**). The uv spectrum of methyl cybrodate (λ_{max} 215 (ε 18 000), 258 nm (ε 4300)) reveals that the benzene and acrylate chromophores, as expected, are twisted out of conjugation (*trans*-cinnamates normally absorb at ca. 275 nm (ε ~ 20 000) (ref. 8, p. 119)).

Final proof of the structures of cybrodol (**3**), isocybrodol (**4**), cybrodal (**5**), and cybrodic acid (**7**) is provided by the syntheses described in the following paper.

Several of the fractions (see Experimental) from the initial Sephadex chromatography deposited a crystalline compound when allowed to evaporate slowly. This compound, mp 160–162°C, has a molecular formula $C_{14}H_{18}O_3$ and was identified as (2*R*,3*R*)-pterosin C (**13**), a known norsesquiterpene isolated from *Pteridium* ferns, by comparison of spectroscopic (ir, ^{1}H nmr) and physical (mp, rotation) data with published values (12–14). Roughly two dozen 1-indanone sesquiterpenoids and norsesquiterpenoids with the skeleton of **13** and collectively known as the pterosins have been isolated from ferns (14, 15). The pterosins belong to the so-called illudalane class of sesquiterpenes, compounds which have the carbon skeleton **14** (16). The cybrodins possess the same carbon skeleton except that the five-membered ring is cleaved as indicated in **14**, and thus they may be classified as *seco*-illudalanes. The illudalanes are in turn *seco*-illudanes, the illudanes possessing the carbon skeleton **15** (16). It is tempting to speculate that the biosynthesis of the cybrodins proceeds from farnesyl pyrophosphate via humulene, a protoilludane, an illudane, and an illudalane (**14**) intermediate.[6] Pterosin L (**16**), or a derivative thereof, by retroaldolization involving the C-3 hydroxyl (indanone numbering) and the C-1 carbonyl (or a suitable leaving group) could give rise to the cybrodin skeleton. Retroaldol cleavage involving the hydroxymethyl group at C-2 leads to pterosin C (**13**), also formed by *C. bulleri*. The numbering scheme used for the cybrodins (as shown in **3** and **15**) is derived for the numbering of the presumed biosynthetic precursor, farnesyl pyrophosphate.

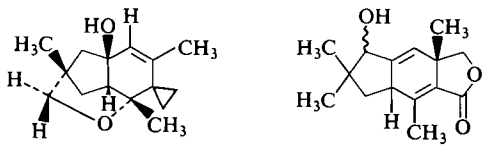
During the final chromatographic purification of the natural trisnorcybrodolide (**6**) a highly uv active (λ_{max} 250, 337, 383 nm) yellow substance $C_{13}H_{12}N_4O_2$ was isolated. This compound was identified as 3-methyllumichrome (**17**), a known (19, 20) riboflavin derivative which has not previously been reported as a natural product. Identity was indicated by comparison with literature data (20) and established by comparison with a synthetic sample. Lumichrome (**18**) was synthesized by the method of Berezovskii and Tul'chinskaya (21), and transformed to the *N*-oxide **19** by treatment with hydrogen peroxide in formic acid (22). Methylation of **19** provided the 3-*N*-methyl, 10-*N*-oxide **20**. The *N*-oxide oxygen was removed by treatment with triphenylphosphine in refluxing 1-propanol to give 3-methyllumichrome (**17**), identical with that isolated from *C. bulleri*.

Two of the early liquid cultures of *C. bulleri*, grown on Brodie's medium (23), provided a small amount of a crystalline compound which could not be isolated from later growths (either on Brodie's medium or on yeast–malt extract medium). This compound, for which we suggest the name broderol, has the molecular formula $C_{15}H_{24}O_2$ and shows hydroxyl absorption but no carbonyl absorption in the ir. The nmr (^{13}C and ^{1}H) spectra reveal the presence of a trisubstituted double bond, one of the substituents being a methyl group. The ^{13}C nmr spectrum reveals the presence of 3 sp^3 oxygenated carbon atoms, one a methylene group and the other two fully substituted carbons, which indicates that the oxygen atoms are present as an hydroxyl group and an ether function. A pair of double doublets at δ 3.25 (J = 10.8, 2.5 Hz) and δ 3.52 (J = 10.8, 1 Hz) in the ^{1}H nmr also indicates the presence of an oxygenated methylene group. Broderol is resistant to acetylation, but was derivatized in an nmr tube by treatment with trichloroacetyl isocyanate (24). A single carbamate NH signal is seen in the derivative, confirming the presence of a single hydroxyl group. Furthermore, since the protons *geminal* to oxygen have virtually the same chemical shift in broderol and in its carbamate derivative, the oxygenated methylene group is associated with the ether function. Broderol thus has a tertiary alcohol and a primary–tertiary ether.

The most striking feature of the ^{13}C nmr spectrum of broderol is the presence of two methylene group signals at unusually high field (δ 6.3, 8.7), indicative of cyclopropyl methylenes (25). The ^{1}H nmr spectrum of broderol has four complex one proton multiplets (δ 0.54, 0.68, 0.82, 0.95) in the region where cyclopropyl protons commonly resonate.

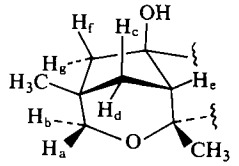
Given the demonstrated proclivity of *C. bulleri* to produce metabolites derived from the illudane–illudalane pathway, it is not unreasonable to assume that broderol possesses an illudane (**15**) skeleton. Of the several possible ways to arrange the known functionality of broderol in skeleton **15** we prefer that shown in **21** on the following grounds. A comparison of the chemical shifts of the vinyl hydrogen in broderol (**21**) (δ 5.70) and its trichloroacetylcarbamate (δ 6.11) reveals that the vinyl hydrogen is β to the hydroxyl group (26). In agreement with this the vinyl hydrogen also shows a pronounced (−0.32 ppm) pyridine shift in the ^{1}H nmr spectrum (27). The tertiary ether oxygen must

[6]For discussions of this biosynthetic pathway see refs. 17 and 18.



21

22



21*a*

then be located at C-2 or C-3 (see **15**) and since the remaining methyl signals are singlets, C-3 is indicated. Chemical shift data and coupling constants rule out the possibility that the ether is an epoxide, so the primary terminus of the ether must be at C-14 or C-15. Steric constraints then dictate a *cis*-fused hydrindane system with the cyclic ether on the concave side as shown in **21** (no absolute configuration implied). The protons of the oxabicyclo-[3.2.1]octane ring system present in broderol are all visible in the 400 MHz ^{1}H nmr spectrum determined in pyridine-d_5 and may be analyzed in terms of part structure **21***a*. H_e (δ 2.11), the ring junction proton has *ax–eq* (4.8 Hz) and *eq–eq* (2.0 Hz) couplings to H_c (δ 2.27) and H_d (δ 1.72) respectively. These latter two are *geminally* coupled (10.8 Hz) and H_c has an additional four bond *W* coupling (2.8 Hz) (ref. 8, pp. 334–344) to H_b (δ 3.28) which in turn is *geminally* coupled to H_a (δ 3.54). H_a has a four bond *W* coupling (1.2 Hz) to H_f (δ 2.10) which is *geminally* coupled (12.4 Hz) to H_g (δ 1.90). H_f and H_c are both *syn* to the hydroxyl group and are therefore deshielded (in pyridine) relative to their *geminal* partners (27).[7]

Small quantities of the alcohol nidulol (**22**) and the corresponding ketone, nidulone, also obtained from *Cyathus pygmaeus*,[8] were isolated from the neutral metabolites of *C. bulleri*.

The total synthesis of each of the cybrodins (cybrodol (**3**), isocybrodol (**4**), trisnorcybrodolide (**6**), and cybrodic acid (**7**)) is described in the following paper (28). To the best of our knowledge, these compounds represent the first *seco*-illudalanes to be reported.

Experimental

Fermentations were carried out in a New Brunswick Scientific MF-214 microferm laboratory fermentor. Water used at all stages of the fungal culturing process was distilled in an all glass apparatus.

All solvents were distilled prior to use. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C. A Hitachi CLC-3 centrifugal liquid chromatograph packed with Baker TLC Silica Gel 7 (< 40 μm) was used for centrifugal liquid chromatography. Macherey Nagel silica gel (< 80 μm) was used for column chromatography. Whatman LPS-2 Chromedia (37–53 μm) was used for flash chromatography (29). Analytical thin layer chromatography (tlc) was carried out on glass plates (75 × 25 or 75 × 50 mm) coated (~0.3 mm) with silica gel G (W. Merck, Darmstadt) containing 1% electronic phosphor (General Electric, Cleveland). Preparative thin layer chromatography (ptlc) was carried out on glass plates (20 × 20, 10 × 20, or 5 × 20 cm) coated (0.5 mm) with the same adsorbent. Materials were detected by visualization under an ultraviolet lamp (254 or 350 nm). The plate (only a thin vertical band in the case of ptlc) was then sprayed with a solution of vanillin (1%) in concentrated sulfuric acid and charred using a heat gun.

Mass spectra (ms) were recorded on an A.E.I. MS-50 mass spectrometer coupled to a DS 50 computer or an A.E.I. MS-9) mass spectrometer (chemical ionization). Data is reported as *m/e* (relative intensity). Unless diagnostically significant, peaks with intensities less than 20% of the base peak are omitted. Infrared spectra were recorded on a Nicolet 7199 FT interferometer, ultraviolet spectra on a Unicam SP 1700 ultraviolet spectrophotometer, and optical rotations on a Perkin Elmer Model 141 polarimeter. Optical rotatory dispersion and circular dichroism measurements were made with a Durrum Jasco ORD/UV-5 (SS-20 modification) recording spectropolarimeter. The ^{1}H nmr spectra were measured on a Bruker WP-60 spectrometer interfaced to a Nicolet 1080 computer, a Varian HA-100 spectrometer interfaced to a Digilab FTS/NMR-3 data system, a Bruker WH-200 spectrometer, or a Bruker WH-400 spectrometer. The ^{13}C nmr spectra were measured on the aforementioned Bruker WP-60 instrument or a Bruker HFX-90 spectrometer interfaced to a Nicolet 1085 computer. The numbering used in reporting nmr spectral data is that used in the systematic (IUPAC) name. All nuclear magnetic resonance measurements employed tetramethylsilane as an internal standard. Melting points were recorded on a Fisher-Johns melting point apparatus and are uncorrected. All compounds for which spectral data are reported showed single spots on tlc using at least two solvent systems.

Growth of C. bulleri *Cultures and Extraction of Metabolites*

Stock cultures of *C. bulleri* 6680a (ATCC 38351), obtained from Dr. J. H. Ginns, Biosystematics Research Institute, Agriculture Canada, Ottawa, were maintained in slant tubes on agar impregnated with Brodie's medium (23). To initiate large scale cultures petri dishes (9 cm × 1 cm) containing Brodie's agar were inoculated from stock cultures. These were allowed to mature for two weeks at which time the mycelial growth covered nearly the entire surface of the plate. The agar discs were blended (Waring blender) along with sterile yeast–malt extract medium (500 mL, containing the following nutrients per liter: dextrose, 4 g; yeast extract (Difco), 4 g; malt extract (Difco), 10 g). This inoculum was gently agitated in an Erlenmeyer flask (2 L) for a two week period, then transferred to a fermentation apparatus charged with 10 L of sterile culture medium and approximately 1 mL of the antifoaming agent polypropylene glycol. Fermentation proceeded for two weeks under the following standard conditions: 25°C, 200 rpm agitation rate, 3 L/min air flow.

The metabolites were isolated in the following manner. The mycelium was removed by vacuum filtration through coarse filter paper (Grade 230). The culture broth was then extracted with ethyl acetate (4 × 1/3 volumes). The ethyl acetate extracts

[7]Verification of structure **21**, which is contingent on the biogenetic argument presented, by X-ray crystallography will be attempted.

were heavily emulsified and filtration through Celite facilitated the separation of the organic and aqueous phases. The extracts were then concentrated *in vacuo* to 150 mL. Acidic components were removed by extraction with saturated aqueous sodium bicarbonate (3 × 50 mL). The bicarbonate extracts were then back-extracted with ethyl acetate (2 × 50 mL). The combined ethyl acetate solutions were washed with water (50 mL) and brine (50 mL). After drying over magnesium sulfate, filtration and concentration gave the neutral extract as a yellow oil. The bicarbonate extracts were acidified (~pH 1) with concentrated hydrochloric acid and then extracted with ethyl acetate (4 × 50 mL). These combined ethyl acetate extracts were washed with water (50 mL) and brine (40 mL) and then dried over magnesium sulfate. Filtration and concentration gave the acidic extract as a dark brown oil. From 20 L of fermentation broth a typical yield was: neutral extract, 1.6 g; acidic extract, 0.6 g; total metabolite yield, 2.2 g.

Preliminary Fractionation of the Crude Metabolites

The neutral extract (1.6 g) was dissolved in methanol (5 mL) and filtered through a cotton wool plug. The filtrate was applied to a column of LH-20 Sephadex (100 g, 65 cm × 2.8 cm). The column was eluted with methanol at a flow rate of 30 mL/h. Fractions (400 drops, ~7 mL) were collected with the aid of an automatic fraction collector equipped with a drop counter. The antifoaming agent, polypropylene glycol (mol. wt. >2000), eluted in tubes 18–25 (480 mg). The metabolites eluted in tubes 30–60 (1.14 g). The acidic extract (0.6 g) was handled in exactly the same fashion. No antifoaming agent was present in this extract. The acidic metabolites also eluted in tubes 30–60.

The next step in the fractionation of the neutral extract involved silica gel chromatography of selected Sephadex fractions. During the early phases of this work, a Centrifugal Liquid Chromatograph (CLC) was used for this purpose; however, ordinary column chromatography was found to be more reliable and convenient. Thus column chromatography (50 g of silica gel) of Sephadex fractions 38–41 (450 mg) gave some virtually pure metabolites as well as several semi-pure compounds. The preliminary column was eluted with the following solvent mixtures: Skellysolve B – chloroform (1:1, 500 mL), chloroform (500 mL), chloroform–methanol (100:1, 500 mL), chloroform–methanol (50:1, 500 mL), chloroform–methanol (20:1, 500 mL), and chloroform–methanol (10:1, 500 mL).

*Isolation of Cybrodol (**3**, 3-((3-(2-Hydroxyethyl)-6-hydroxymethyl-2,4-dimethyl)phenyl)-2-methyl-(E)-2-propenol)*

Cybrodol (**3**) eluted in Sephadex fractions 40–41 of the neutral extract. It was obtained in pure form as a colourless oil (62 mg) when the preliminary silica gel column of Sephadex fractions 38–41 was eluted with chloroform–methanol (20:1); uv (CH_3OH) λ_{max}: 210 (ε 6200), 270 nm (sh, ε ~320); ir ($CHCl_3$ cast): 3300, 1670 (w), 1440, 1380, 1030, 1010, 890, 760 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.46 (3H, d (1 Hz), vinyl CH_3), 1.8 (3H, bs, 3 × OH), 2.18 (3H, s, C-2 CH_3), 2.36 (3H, s, C-4 CH_3), 2.99 (2H, t (7 Hz), CH_2CH_2O), 3.76 (2H, t (7 Hz), CH_2CH_2O), 4.23 (2H, bs, $W_{1/2}$ = 2 Hz, CH_2O), 4.50 (2H, s, $ArCH_2O$), 6.45 (1H, bs, $W_{1/2}$ = 4 Hz, vinyl H), 7.10 (1H, s, ArH); ^{13}C nmr (CD_3OD) δ: 14.9, 16.5, 20.3, (CH_3); 34.3, 61.8, 63.3, 67.9, (CH_2); 123.9, 127.8, (CH); 134.9, 135.0, 135.8, 136.1, 137.9, 140.0, (C); ms *m/e* calcd. for $C_{15}H_{22}O_3$ (M^+): 250.1569; found: 250.1562 (5), 232 (35), 219 (95), 217 (90), 201 (100), 199 (35), 191 (68), 187 (42), 183 (20), 173 (29), 171 (38), 159 (20), 157 (32), 156 (20), 143 (24), 128 (20). Chemical ionization (NH_3) ms shows an M +18 (*m/e* 268) peak.

*Isolation of Trisnorcybrodolide (**6**, 6-(2-Hydroxyethyl)-5,7-dimethylphthalide)*

Trisnorcybrodolide (**6**) eluted in Sephadex fractions 43–48 (66 mg) of the neutral extract. Silica gel chromatography (chloroform–methanol, 50:1; 20 g of silica gel) of these combined fractions gave pure trisnorcybrodolide (**6**, 13 mg) as a tan powder. Crystallization (methanol) afforded white prisms, mp 188–190°C; uv (CH_3OH) λ_{max}: 242 (ε 6400), 282 (ε 1100), 289 nm (ε 1300); ir ($CHCl_3$ cast): 3450, 1730, 1610, 1590, 1460, 1380, 1350, 1260, 1040, 1030, 1010, 860, 800 cm^{-1}; ^1H nmr ($CDCl_3/CD_3OD$) δ: 2.48 (3H, s, C-5 CH_3), 2.73 (3H, s, C-7 CH_3), 3.06 (2H, t (7 Hz), CH_2CH_2O), 3.79 (2H, t (7 Hz), CH_2CH_2O), 5.15 (2H, s, CH_2O), 7.11 (1H, s, ArH); ^{13}C nmr (DMSO-d_6) δ: 12.7, 20.7, (CH_3); 32.1, 59.8, 67.9, (CH_2); 121.3, (CH); 120.5, 137.1, 137.4, 143.9, 145.6, (C); 171.1, (C=O); ms *m/3* calcd. for $C_{12}H_{14}O_3$ (M^+): 206.0944; found: 206.0944 (78), 191 (66), 175 (100), 163 (16), 147 (43), 119 (20). Chemical ionization (NH_3) ms shows a peak at *m/e* 224 (M +18).

*Isolation of Isocybrodol (**4**, 3-((3-(2-Hydroxyethyl)-6-hydroxymethyl-2,4-dimethyl)phenyl)-2-methyl-(Z)-2-propenol)*

Isocybrodol (**4**) eluted in Sephadex fractions 40–41 of the neutral extract. It was obtained in very crude form (75 mg) when the preliminary silica gel column of Sephadex fractions 38–41 was eluted with chloroform–methanol (20:1). The crude fractions of isocybrodol along with pyridine (0.1 mL) and acetic anhydride (1 mL) were refluxed overnight in methylene chloride (10 mL). Evaporation to dryness *in vacuo* gave a brown oil (123 mg) which was chromatographed (chloroform–ether, 97:3, 10 g of silica gel) affording crude triacetylisocybrodol (**4***a*, 65 mg). This material was stirred overnight in methanol (10 mL) along with potassium carbonate (1 g). The volatiles were removed *in vacuo* and the residue was partitioned between ethyl acetate (50 mL) and water (10 mL). The organic solution was dried over magnesium sulfate, filtered, and evaporated to dryness, leaving crude isocybrodol (**4**, 45 mg). Chromatography (chloroform–methanol, 50:1; 10 g of silica gel) gave pure isocybrodol (**4**, 39 mg). Crystallization (chloroform–methanol) gave white prisms, mp 102–103°C; uv (CH_3OH) λ_{max}: 210 (ε 6200), 270 nm (sh, ε ~350); ir ($CHCl_3$ cast): 3290, 1660 (w), 1440, 1380, 1035, 1030, 1005, 880, 750 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.02 (3H, d (1 Hz), vinyl CH_3), 2.16 (3H, s, C-2 CH_3), 2.36 (3H, s, C-4 CH_3), 2.97 (2H, t (7 Hz), CH_2CH_2O), 3.60 (1H, d)12 Hz), CH_2O), 3.70 (2H, t (7 Hz), CH_2CH_2O), 3.78 (1H, d (12 Hz), CH_2O), 4.35 (1H, d (11 Hz), $ArCH_2O$), 4.54 (1H, d (11 Hz), $ArCH_2O$), 6.27 (1H, bs, vinyl H), 7.05 (1H, s, ArH); ^{13}C nmr ($CDCl_3$) δ: 16.9, 20.3, 20.4, (CH_3); 34.3, 61.9, 62.4, 63.5, (CH_2); 126.3, 128.7, (CH); 134.3, 135.2, 136.0, 136.5, 138.0, 139.9, (C); ms *m/e* calcd. for $C_{15}H_{22}O_3$ (M^+): 250.1569; found: 250.1578 (3), 232 (52), 219 (92), 217 (85), 201 (100), 199 (37), 191 (62), 187 (46), 183 (21), 173 (34), 171 (34), 159 (22), 158 (22), 157 (38), 156 (21), 143 (27), 142 (22), 141 (21), 129 (21), 128 (23).

*Isolation of Cybrodal (**5**, 3-((2-Formyl-5-(2-hydroxyethyl)-4,6-dimethyl)phenyl)-2-methyl-(E)-2-propenal)*

Cybrodal (**5**) eluted in Sephadex fractions 40–41 of the neutral extract. It was obtained in crude form (26 mg) when the preliminary silica gel column of Sephadex fractions 38–41 was eluted with chloroform–methanol, 100:1. The crude material was chromatographed (Skellysolve B – ether, 3:1; 10 g of silica gel) affording pure cybrodal (**5**) as a yellow oil (12 mg); ir ($CHCl_3$ cast): 3450, 2740, 1688, 1630, 1040, 1010, 890, 860, 830 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.57 (3H, d (1 Hz), vinyl CH_3), 2.26 (3H, s, C-6 CH_3), 2.46 (3H, s, C-4 CH_3), 3.10 (2H, t (7 Hz), CH_2CH_2O), 3.80 (2H, t (7 Hz), CH_2CH_2O), 7.61 (2H, bs, ArH + vinyl H), 9.75 (1H, s, CHO), 9.92 (1H, s, CHO); ms *m/e* calcd. for $C_{15}H_{18}O_3$ (M^+): 246.1256; found; 246.1254 (1), 217 (100), 186 (24). Chemical ionization (NH_3) ms shows a peak at *m/e* 264 (M +18).

*Isolation of Cybrodic Acid (**7**, 3-((3-(2-Hydroxyethyl)-6-hydroxymethyl-2,4-dimethyl)phenyl)-2-methyl-(E)-2-propenoic Acid)*

Cybrodic acid eluted in Sephadex fractions 39–41 (96 mg) of the acidic extract. In early work, fractions similar to these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

(40 mg) were subjected to ptlc (toluene–acetone – acetic acid, 75:25:1) affording pure acid **7** as a yellow solid (5 mg). Crystallization (ethyl acetate – Skellysolve B) gave white plates, mp 176–178°C; ir (CH_3OH cast): 3320, 2600, 1693, 1640, 1440, 1400, 1380, 1340, 1260, 1130, 1040, 1030, 980, 870, 810, 750 cm^{-1}; ^1H nmr (CD_3OD) δ: 1.60 (3H, d (1 Hz), vinyl CH_3), 2.19 (3H, s, C-2 CH_3), 2.38 (3H, s, C-4 CH_3), 2.96 (2H, t (7 Hz), CH_2CH_2O), 3.61 (2H, t (7 Hz), CH_2CH_2O), 4.38 (2H, bs, CH_2O), 7.15 (1H, s, ArH), 7.65 (1H, bs, vinyl H); ^{13}C nmr (DMSO-d_6) δ: 16.2, 17.4, 19.9, (CH_3); 33.3, 60.0, 61.9, (CH_2); 126.4, 134.1, (CH); 130.8, 131.5, 133.0, 135.3, 136.6, 137.9, (C); 168.6, (C=O); ms *m/e* calcd. for $C_{15}H_{20}O_4$ (M^+): 264.1361; found: 264.1365 (4), 246 (47), 233 (64), 215 (100), 201 (24), 187 (48), 173 (32), 171 (54), 159 (23), 129 (21), 128 (23).

Isolation of Methyl Cybrodate (7a, Methyl 3-((3-(2-Hydroxyethyl)-6-hydroxymethyl-2,4-dimethyl) phenyl)-2-methyl-(E)-2-propenoate)

The acid was more conveniently isolated as its methyl ester, methyl cybrodate (**7a**). Thus Sephadex fractions 39–41 (96 mg) in methanol (5 mL) were treated with an excess of diazomethane in methylene chloride at 0°C. Evaporation to dryness gave crude methyl cybrodate (**7a**, 99 mg). Silica gel chromatography (chloroform–methanol, 50:1; 20 g of silica gel) gave pure methyl cybrodate (**7a**) as an oil (75 mg); uv (CH_3OH) λ_{max}:215 (ε 18 000), 258 nm (ε 4300); ir ($CHCl_3$ cast): 3400, 1715, 1640, 1430, 1380, 1340, 1260, 1210, 1190, 1120, 1080, 1040, 1000, 750 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.65 (3H, d (1 Hz), vinyl CH_3), 2.18 (3H, s, C-2 CH_3), 2.39 (3H, s, C-4 CH_3), 3.00 (2H, t (7 Hz), CH_2CH_2O), 3.75 (2H, t (7 Hz), CH_2CH_2O), 3.82 (3H, s, CO_2CH_3), 4.48 (2H, bs, CH_2O), 7.14 (1H, s, ArH), 7.66 (1H, bs, vinyl H): ^{13}C nmr (CD_3OD) δ: 13.9, 16.6, 20.2, 52.4, (CH_3); 34.0, 61.7, 63.0, (CH_2); 128.1, 140.2, (CH); 131.7, 133.1, 134.6, 135.4, 137.0, 137.3, (C); 169.5, (C=O); ms *m/e* calcd. for $C_{16}H_{22}O_4$ (M^+): 278.1518; found: 278.1522 (4), 260 (38), 247 (42), 233 (36), 229 (100), 218 (24), 203 (21), 201 (41), 188 (20), 187 (52), 173 (31), 171 (41), 170 (22), 128 (20).

O,O,O-*Triacetylcybrodol (3a, 3-((3-(2-Acetoxyethyl)-6-acetoxymethyl-2,4-dimethyl)phenyl)-2-methyl-(E)-2-propenyl Acetate)*

A mixture of cybrodol (**3**, 109 mg, 0.44 mmol), pyridine (0.1 mL), acetic anhydride (1 mL), and chloroform (10 mL) was refluxed for 6 h and then evaporated to dryness *in vacuo*. This gave, after chromatography, triacetylcybrodol (**3a**, 156 mg, 95%) as an oil; ir ($CHCl_3$ cast): 1745 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.44 (3H, d (1 Hz), vinyl CH_3), 2.05 (3H, s, OAc), 2.06 (3H, s, OAc), 2.12 (3H, s, OAc), 2.20 (3H, s, C-2 CH_3), 2.37 (3H, s, C-4 CH_3), 3.00 (2H, t (7 Hz), CH_2CH_2O), 4.14 (2H, t (7 Hz), CH_2CH_2O), 4.65 (2H, bs, CH_2O), 4.91 (2H, s, $ArCH_2O$), 6.39 (1H, bs, vinyl H), 7.05 (1H, s, ArH); ms *m/e* calcd. for $C_{21}H_{28}O_6$ (M^+): 376.1886; found: 376.1890 (1), 196 (100).

Ozonolysis of Triacetylcybrodol (3a).

A stirred solution of triacetylcybrodol (**3a**, 78 mg, 0.21 mmol) in methanol was cooled to −78°C. Ozone in oxygen was bubbled through the solution for 45 min (0.03 mL/min). After a further 45 min at −78°C, the solution was purged with nitrogen and then warmed to room temperature. Aqueous hydrogen peroxide (30%, 1 mL) was added and the mixture was refluxed for one hour. Most of the volatiles were removed *in vacuo*, the residue was taken up in ethyl acetate (100 mL) and then washed with water (10 mL) and brine (10 mL). After drying over magnesium sulfate, filtration and concentration gave crude 3-(2-acetoxyethyl)-6-(acetoxymethyl)-2,4-dimethylbenzoic acid (**8**, 73 mg); ^1H nmr ($CDCl_3$) δ: 1.98 (6H, s, 2 × OAc), 2.42 (3H, s, C-4 CH_3), 2.66 (3H, s, C-2 CH_3), 3.01 (2H, t (7 Hz), CH_2CH_2O), 4.10 (2H, t (7 Hz), CH_2CH_2O), 5.08 (2H, s, CH_2O), 7.04 (1H, s, ArH); ms *m/e* calcd. for $C_{16}H_{18}O_5$ (P − H_2O, parent ion not seen): 290.1154, found: 290.1154 (5), 248 (26), 188 (100), 187 (54), 175 (26), 160 (23), 159 (21), 147 (24), 115 (20), 91 (26).

The crude acid (**8**, 73 mg) and 10-camphorsulfonic acid (100 mg) in benzene–methanol (10:1, 30 mL) were refluxed for one day. Evaporation to dryness and column chromatography (methylene chloride – methanol, 50:1; 10 g of silica gel) of the residue afforded a white powder (29 mg, 69%) judged to be identical with natural trisnorcybrodolide (**6**) by comparison of tlc, ir, ^1H nmr, and ms data.

O-*Acetyltrisnorcybrodolide (6a, 6-(2-Acetoxyethyl)-5,7-dimethylphthalide)*

A mixture of trisnorcybrodolide (**6**, 20 mg, 0.097 mmol), pyridine (10 mL), and acetic anhydride (1 mL) was stirred overnight at room temperature. Evaporation to dryness *in vacuo* gave acetyltrisnorcybrodolide (**6a**, 23 mg, 96%) as a white powder. Crystallization (acetone) gave long clear needles, mp 117–118°C; ir ($CHCl_3$ cast): 1741 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.04 (3H, s, OAc), 2.48 (3H, s, C-5 CH_3), 2.73 (3H, s, C-7 CH_3), 3.08 (2H, t (7 Hz), CH_2CH_2O), 4.17 (2H, t (7 Hz), CH_2CH_2O), 5.14 (2H, s, CH_2O), 7.10 (1H, s, ArH); ms *m/e* calcd. for $C_{14}H_{16}O_4$ (M^+): 248.1048; found: 248.1050 (14), 188 (100), 176 (20), 159 (28), 147 (36), 129 (24).

6-(2-(4-Nitrophenylseleno)ethyl)-5,7-dimethylphthalide (10)

Freshly distilled tri-*n*-butylphosphine (45 μL, 36.5 mg, 0.18 mmol) and 4-nitrophenylselenocyanate (40 mg, 0.18 mmol) in dry tetrahydrofuran (500 μL) were added to a stirred solution of trisnorcybrodolide (**6**, 16.7 mg, 0.081 mmol) in dry tetrahydrofuran (500 μL) under a nitrogen atmosphere. The deep-red mixture was stirred for 30 min at room temperature and then evaporated to dryness *in vacuo*. The residue was chromatographed (10 g of silica gel). Nonpolar side products eluted with Skellysolve B and then chloroform eluted selenide **10** (15 mg, 43%) as a yellow foam. Continued elution with chloroform gave recovered starting material (6 mg); ^1H nmr ($CDCl_3$) δ: 2.23 (3H, s, C-5 CH_3), 2.70 (3H, s, C-7 CH_3), 3.10 (2H, t (7 Hz), $ArCH_2CH_2$), 4.28 (2H, t (7 Hz), $ArCH_2CH_2$), 7.11 (1H, s, ArH), 7.59 (2H, d (9 Hz), 2 × ArH), 8.10 (2H, d (9 Hz), 2 × ArH); ms *m/e* calcd. for $C_{18}H_{17}NO_4Se$ (M^+): 391.0323; found: 391.0318 (5), 189 (100).

6-Vinyl-5,7-dimethylphthalide (9)

Aqueous hydrogen peroxide (30%, 0.1 mL) was added to a solution of selenide **10** (15 mg, 0.038 mmol) in tetrahydrofuran (2 mL). The mixture was stirred at room temperature for one day and then evaporated to dryness *in vacuo*. The residue was dissolved in ether (50 mL) and washed with saturated aqueous sodium bicarbonate (10 mL), water (10 mL), and brine (10 mL). After drying over magnesium sulfate, filtration and concentration gave crude **9** (7.4 mg) as a yellow oil; ptlc purification (Skellysolve B – ether, 3:1 triple elution) gave pure **9** (2.3 mg, 32%) as a white powder. Crystallization (methylene chloride) gave clear needles, mp 93–95°C; ir ($CHCl_3$ cast): 1740, 1610, 1000, 910 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.38 (3H, s, C-5 CH_3), 2.65 (3H, s, C-7 CH_3), 5.16 (2H, s, CH_2O), 5.24 (1H, dd (2, 18 Hz), vinyl H), 5.65 (1H, dd (2, 11 Hz), vinyl H), 6.65 (1H, dd (11, 18 Hz), vinyl H), 7.10 (1H, s, ArH); ms *m/e* calcd. for $C_{12}H_{12}O_2$ (M^+): 188.0837; found: 188.0836 (100), 187 (22), 159 (26), 143 (38), 129 (43), 128 (25), 115 (20).

6-Formyl-5,7-dimethylphthalide (11)

Ozone in oxygen was bubbled through a stirred solution of olefin **9** (4 mg, 0.021 mmol) in methanol (5 mL) at −78°C for 30 min. The ozone was then purged with nitrogen and the solution was warmed to room temperature. Sodium iodide (150 mg, 1 mmol) and acetic acid (75 μL) were added and the

For personal use only.

solution was stirred for two days at room temperature. The volatiles were removed *in vacuo*, the residue was dissolved in ether (50 mL) and washed with water (10 mL), 10% aqueous sodium thiosulfate (10 mL), saturated aqueous sodium bicarbonate (10 mL), water (10 mL), and brine (10 mL). After drying over sodium sulfate, filtration and concentration gave crude aldehyde **11** (3 mg) which was purified by ptlc (benzene–ether, 1:1) affording pure **11** (1.6 mg, 40%) as a white powder. Crystallization (methylene chloride) gave white prisms, mp 159–160°C; ir ($CHCl_3$ cast): 1746, 1683 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.69 (3H, s, C-5 CH_3), 2.98 (3H, s, C-7 CH_3), 5.21 (2H, s, CH_2O), 7.18 (1H, s, ArH), 10.70 (1H, s, CHO); ms *m/e* calcd. for $C_{11}H_{10}O_3$ (M^{++}): 190.0629; found: 190.0629 (100), 162 (37), 161 (27), 149 (23), 133 (31), 103 (21).

O,O,O-*Triacetylisocybrodol (**4**a, 3-((3-(2-Acetoxyethyl)-6-acetoxymethyl-2,4-dimethyl)phenyl)-2-methyl-(Z)-2-propenyl Acetate)*

A mixture of isocybrodol (**4**, 40 mg, 0.16 mmol), pyridine (0.1 mL), acetic anhydride (0.5 mL), and methylene chloride (10 mL) was refluxed for 6 h and then evaporated to dryness *in vacuo*. After filtering through silica gel this gave triacetylisocybrodol (**4**, 59 mg, 98%) as an oil; ir ($CHCl_3$ cast): 1745 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.93 (3H, d (1 Hz), vinyl CH_3), 1.98 (3H, s, OAc), 2.06 (3H, s, OAc), 2.08 (3H, s, OAc), 2.21 (3H, s, C-2 CH_3), 2.36 (3H, s, C-4 CH_3), 3.00 (2H, t (7 Hz), CH_2CH_2O), 4.13 (2H, t (7 Hz), CH_2CH_2O), 4.26 (2H, bs, CH_2O), 4.84 (1H, d (12 Hz), $ArCH_2O$), 4.98 (1H, d (12 Hz), $ArCH_2O$), 6.30 (1H, bs, vinyl H), 7.02 (1H, s, ArH); ms *m/e* calcd. for $C_{21}H_{28}O_6$ (M^+): 376.1886; found: 376.1903 (3), 256 (24), 248 (28), 106 (100), 103 (20).

*Ozonolysis of Triacetylisocybrodol (**4**a)*

Ozone was bubbled through a stirred solution of triacetylisocybrodol (**4***a*, 14.6 mg) in methanol (5 mL) at −78°C for 45 min. The solution was stirred at −78°C for a further 45 min, purged with nitrogen, and then warmed to room temperature. Aqueous hydrogen peroxide (30%, 0.2 mL) was added and the mixture was refluxed for one hour. Benzene–methanol (10:1, 30 mL) and 10-camphorsulfonic acid (100 mg) were added and reflux was continued overnight. Evaporation to dryness and column chromatography (methylene chloride – methanol, 50:1; 10 g of silica gel) gave a white powder (7 mg, 70%) judged to be identical with natural trisnorcybrodolide (**6**) by comparison of tlc, ir, ^1H nmr, and ms data.

O-*Acetylcybrodal (**5**a, 3-((2-Formyl-5-(2-acetoxyethyl)-4,6-dimethyl)phenyl)-2-methyl-(E)-2-propenal)*

A mixture of cybrodal (**5**, 6 mg, 0.024 mmol), pyridine (0.5 mL), acetic anhydride (1 mL), and methylene chloride (8 mL) was refluxed overnight and then evaporated to dryness. Purification by ptlc (Skellysolve B – acetone, 7:3) gave pure acetylcybrodal (**5***a*, 5 mg) as a clear oil; ir ($CHCl_3$ cast): 2730, 1740, 1689, 1639 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.58 (3H, d (1 Hz), vinyl CH_3), 2.07 (3H, s, OAc), 2.27 (3H, s, C-2 CH_3), 2.47 (3H, s, C-4 CH_3), 3.12 (2H, t (7 Hz), CH_2CH_2O), 4.19 (2H, t (7 Hz), CH_2CH_2O), 7.63 (2H, bs, vinyl H + ArH), 9.77 (1H, s, CHO), 9.95 (1H, s, CHO); ms *m/e* calcd. for $C_{16}H_{19}O_3$ (M − CHO, parent peak not seen): 259.1334; found: 259.1337 (100), 199 (73). Chemical ionization (NH_3) ms shows a peak at *m/e* 306 (M + 18).

*Manganese Dioxide Oxidation of Cybrodol (**3**)*

Cybrodol (**3**, 9.7 mg, 0.039 mmol) and activated manganese dioxide (30) (150 mg, 1.7 mmol) in benzene (2 mL) were stirred for one day at room temperature. The mixture was filtered through Celite, the filter cake was washed with chloroform (5 × 10 mL), and the combined washings were concentrated to a syrup (8 mg). Purification by ptlc (methylene chloride – methanol, 10:1) gave a clear oil (6.7 mg) with physical properties (tlc, ^1H nmr, ms) identical with those of natural cybrodal (**5**).

Lithium Aluminum Hydride Reduction of Acetylcybrodal (5a)

Lithium aluminum hydride (20 mg, 0.53 mmol) was added to a stirred solution of acetylcybrodal (**5***a*, 5 mg, 0.017 mmol) in dry ether (2 mL). After two and one-half hours at room temperature, water (10 mL) was added and the mixture was extracted with ether (5 × 10 mL). The combined ether extracts were washed with brine (10 mL) and dried over magnesium sulfate. Filtration and concentration followed by ptlc purification (methylene chloride – methanol, 10:1) gave a clear oil (3 mg) judged to be identical with natural cybrodal (**3**) by comparison of tlc, ir, and ^1H nmr data.

*Lithium Aluminum Hydride Reduction of Methyl Cybrodate (**7**a)*

Lithium aluminum hydride (15 mg, 0.39 mmol) was carefully added to a stirred solution of methyl cybrodate (**7***a*, 5 mg, 0.018 mmol) in dry tetrahydrofuran (5 mL). The mixture was stirred for 6 h at room temperature. Water (15 mL) was added and the solution was extracted with chloroform (3 × 30 mL). The chloroform extracts were washed with water (10 mL) and brine (10 mL). After drying over magnesium sulfate, filtration and concentration gave a light yellow oil (4 mg) judged to be identical with natural cybrodol (**3**) by comparison of tlc, ^1H nmr, and ms data.

*Isolation of (2R,3R)-Pterosin C (**13**)*

(2*R*,3*R*)-Pterosin C (**13**) eluted in Sephadex fractions 43–46 (50 mg) of the neutral extract. Slow evaporation of these fractions usually caused this compound to crystallize as clear needles. Alternatively, it could be isolated by silica gel column chromatography (20 g of silica gel). Compound **13** (18 mg) eluted with chloroform–methanol, 50:1. Crystallization (ethyl acetate – Skellysolve B) afforded clear needles, mp 160–162°C (lit. (14) 162–164°C); $[\alpha]_D^{25}$ −61° (*c* 0.36, CH_3OH); ir ($CHCl_3$ cast): 3360, 1681, 1600, 1060, 1040, 1020, 1010 cm^{-1}; ^1H nmr (CD_3OD) δ: 1.30 (3H, d (7 Hz), C-2 CH_3), 2.48 (3H, s, C-5 CH_3), 2.5 (1H, dq (J_d = 4 Hz, J_q = 7 Hz), C-2 H), 2.65 (3H, s, C-7 CH_3), 2.99 (2H, t (7 Hz), CH_2CH_2O), 3.62 (2H, t (7 Hz), CH_2CH_2O), 4.67 (1H, d (4 Hz), C-3 H), 7.34 (1H, s, ArH); ^{13}C nmr (DMSO-d_6) δ: 12.7, 13.3, 20.8 (CH_3); 32.0, 59.8, (CH_2); 53.1, 73.7, 124.3, (CH); 130.7, 135.5, 136.9, 144.0, 153.6, (C); 205.1, (C=O); ms *m/e* calcd. for $C_{14}H_{18}O_3$ (M^+): 234.1256; found: 234.1254 (55), 203 (100), 185 (21).

*Isolation of 3-Methyllumichrome (**17**)*

3-Methyllumichrome (**17**) eluted in Sephadex fractions 43–46 (50 mg). Silica gel column chromatography (chloroform–methanol, 50:1; 20 g of silica gel) of fractions 43–48 (66 mg) gave 3-methyllumichrome (**17**, 8 mg) as a yellow powder. This compound eluted prior to trisnorcybrodolide (**6**). Crystallization (acetone – Skellysolve B) gave fine yellow needles, mp >300°C (lit. (20) >300°C); uv (CH_3OH) λ_{max}: 250 (ε 9000), 337 (ε 2400), 383 nm (ε 2400); ir ($CHCl_3$ cast): 3170, 3060, 1680, 757, 678 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.49 (3H, s, $ArCH_3$), 2.52 (3H, s, $ArCH_3$), 3.56 (3H, s, CH_3N), 7.76 (1H, bs, ArH), 8.06 (1H, bs, ArH), 8.7 (1H, bs, NH); ms *m/e* calcd. for $C_{13}H_{12}N_4O_2$ (M^+): 256.0959; found: 256.0959 (100), 199 (33), 171 (50), 156 (28).

*Preparation of 3-Methyllumichrome-N-oxide (**20**)*

Lumichrome (**18**, 2.5 g (21)) and 30% hydrogen peroxide (30 mL) in 99% formic acid (100 mL) were heated under reflux for 2 h. After cooling, the reactive mixture was made alkaline (saturated $NaHCO_3$) and the precipitate, lumichrome-10-*N*-oxide (**19**), was filtered off, washed with ethanol, water and acetone, and dried. The yield of crude product was 2.2 g (83%). Crude **19** (500 mg) and freshly distilled methyl iodide (20 mL) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

0.1 *N* aqueous sodium hydroxide (400 mL) were stirred for 4 days at room temperature. The organic layer was then removed and the aqueous layer acidified with glacial acetic acid. The yellow precipitate was filtered and recrystallized from dimethylformamide–water (3:7) to give 3-methyllumichrome-*N*-oxide (**20**, 300 mg), suitable for use in the next step.

Preparation of 3-Methyllumichrome (17)

3-Methyllumichrome-10-*N*-oxide (**20**, 100 mg, 0.37 mmol) and triphenylphosphine (200 mg, 0.76 mmol) in 1-propanol (100 mL) were heated at reflux for two days. The solvent was removed *in vacuo* and the residue was chromatographed over silica gel (chloroform, 130 g of silica gel) affording 3-methyllumichrome (**17**, 75 mg, 80%). Crystallization (acetone – Skellysolve B) gave fine yellow needles, mp >300°C, the physical properties of which were identical with those of the natural product (tlc, ir, ^{1}H nmr, ms).

Isolation of Broderol (21)

Broderol (**21**) eluted in Sephadex fractions 42 and 43 of the neutral extract. It was obtained in pure form as white flakes (17 mg) when these fractions were subjected to column chromatography (chloroform, 10 g of silica gel). Broderol (**21**) was only obtained in two early growths using Brodie's medium. The first isolation afforded 17 mg from 10 L of broth, the next harvest gave 2.5 mg from 20 L of broth. Broderol (**21**) was crystallized (carbon tetrachloride) affording white plates, mp 113–115°C; $[\alpha]_D^{25}$ −99 (*c* 0.09, CH_3OH); ir ($CHCl_3$ cast): 3400, 3360, 1660 (w), 1460, 1400, 1380, 1090, 1070, 1060, 1020, 800 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.54 (1H, m), 0.68 (1H, m), 0.82 (1H, m), 0.88 (3H, s), 0.95 (1H, m), 0.97 (3H, s), 1.49 (3H, d (1 Hz)), 1.5–2.0 (5H, m), 3.25 (1H, dd (10.8, 2.5 Hz)), 3.52 (1H, dd (10.8, 1 Hz)), 5.70 (1H, bs); ^{1}H nmr (C_5D_5N) δ: 0.40 (1H, ddd (4.8, 6.4, 9.2 Hz)), 0.58 (1H, ddd (4.8, 6.4, 9.2 Hz)), 0.84 (3H, s), 0.92 (3H, s), 0.9 (2H, m), 1.40 (3H, d (1 Hz)), 1.72 (1H, dd (2.0, 10.8 Hz)), 1.90 (1H, d (12.4 Hz)), 2.10 (1H, dd (1.2, 12.4 Hz)), 2.11 (1H, dd (2.0, 4.8 Hz)), 2.27 (1H, ddd (2.8, 4.8, 10.8 Hz)), 3.28 (1H, dd (2.8, 10.0 Hz)), 3.54 (1H, dd (1.2, 10.0 Hz)), 6.02 (1H, q (1 Hz)); ^{13}C nmr ($CDCl_3$) δ: 14.5, 18.8, 21.3 (CH_3); 6.3, 8.7, 36.8, 50.6, 74.0, (CH_2); 53.5, 127.5, (CH); 27.9, 41.2, 76.1, 79.4, 133.7, (C); ms *m/e* calcd. for $C_{15}H_{22}O_2$ (M^+): 234.1620; found: 234.1615 (48), 205 (22), 161 (23), 159 (27), 151 (70), 149 (36), 137 (100), 135 (48), 134 (20), 124 (29), 123 (50), 122 (37), 121 (20), 119 (34), 109 (46), 107 (28), 105 (38), 97 (49), 96 (20), 93 (31), 91 (41), 79 (26), 77 (31), 69 (24), 55 (35).

Derivatization of Broderol (21) with Trichloroacetyl Isocyanate

A few drops of trichloroacetyl isocyanate were added to a chloroform-*d* solution of broderol (**21**, 1 mg) in an nmr tube; ^{1}H nmr ($CDCl_3$) δ: 0.90 (3H, s), 0.98 (3H, s), 1.49 (3H, d (1 Hz)), 3.26 (1H, d (10.8 Hz)), 3.55 (1H, d (10.8 Hz)), 6.11 (1H, bs), 8.25 (1H, s).

The total synthesis of the cybrodins[1,2]

WILLIAM A. AYER AND ROBERT H. MCCASKILL
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 3, 1981

WILLIAM A. AYER and ROBERT H. MCCASKILL. Can. J. Chem. **59**, 2159 (1981).

The total syntheses of cybrodol (**1**), isocybrodol (**2**), cybrodal (**3**), cybrodic acid (**4**), and trisnorcybrodolide (**5**), starting from 2-bromomesitylene (**6**) are described. The route involves oxidation of the 5-methyl group of **6** by means of chromyl acetate, addition of the β-hydroxyethyl chain by aryllithiation and reaction with ethylene oxide, and addition of the fifth carbon substituent by aryllithiation and treatment with ethyl chloroformate to give the key intermediate, methyl 3-(2-hydroxyethyl)-6-methoxymethyl-2,4-dimethylbenzoate (**18***d*). The latter was transformed into trisnorcybrodolide (**5**), and further elaborated via the corresponding aldehyde **21** into the remaining cybrodins.

WILLIAM A. AYER et ROBERT H. MCCASKILL. Can. J. Chem. **59**, 2159 (1981).

On décrit les synthèse totales du cybrodol (**1**), de l'isocybrodol (**2**), du cybrodal (**3**), de l'acide cybrodique (**4**) et du trisnorcybrodolide (**5**) à partir du bromo-2 mésitylène (**6**). Le cheminement implique l'oxydation du groupe méthyle en position 5 du composé **6** par l'acétate de chromyle, l'addition de la chaîne β-hydroxyéthyle par lithiation arylique et réaction avec l'oxyde d'éthylène et finalement l'addition du cinquième carbone substituant par une lithiation arylique suivie de l'action du chloroformate d'éthyle qui conduit à l'intermédiaire principal le (hydroxy-2 éthyl)-3 méthoxyméthyl-6 diméthyl-2,4 benzoate de méthyle (**18***d*). Ce composé peut être transformé en trisnorcybrodolide (**5**) et on peut aussi l'utiliser pour obtenir les autres cybrodines par l'intermédiaire de l'aldéhyde correspondant **21**.

[Traduit par le journal]

In the preceding paper we described the isolation and structure determination of cybrodol (**1**), isocybrodol (**2**), cybrodal (**3**), cybrodic acid (**4**), and trisnorcybrodolide (**5**), metabolites of the bird's nest fungus *Cyathus bulleri* Brodie (2). In this paper we report the synthesis of each of the compounds (collectively called the cybrodins), providing confirmation of the assigned structures.

The approach to the synthesis of the cybrodins (Scheme 1) involves elaboration of a symmetrical diether A followed by addition of a one carbon unit at either of the equivalent unsubstituted centers to give B. This allows easy access to trisnorcybrodolide (**5**). Addition of a three carbon unit then provides the fifteen carbon cybrodin skeleton C.

The starting material for the preparation of the diether of type A (Scheme 1) was the readily available 2-bromomesitylene (**6**) (3). Chromyl acetate oxidation of toluenes is often a convenient route to benzylidene diacetates (4). Since 4-nitrotoluene is more readily oxidized than 2-nitrotoluene by chromyl acetate (5), we felt that **6** might

preferentially oxidize at the C-4 methyl group. Indeed, oxidation of **6** under controlled conditions (6) on a small (7 g) scale gave a 41% yield of crystalline diacetate **7**, the structure of which was apparent from the equivalence displayed in the ^1H and ^{13}C nmr spectra. When the reaction was carried out on a larger scale (100 g) a crystalline product was not obtained and ^1H nmr evidence indicated a mixture of **7** and the isomer **8** in a ratio of ca. 9:1. This mixture was normally used in the subsequent steps. Reduction of the mixture of **7** and **8** with lithium aluminum hydride (LAH) gave the corresponding alcohols **9** and **10** which were immediately transformed into the methyl ethers **11** and **12** by treatment with methyl iodide – sodium hydride. The methyl ethers **11** and **12** are separable by careful chromatography, but normally the mixture was carried forward into the next step. Nuclear magnetic resonance examination of the separated ethers **11** and **12** clearly demonstrates that the major product is the symmetrical bromoether **11**. One signal is seen for the aromatic methyl groups (^1H nmr δ 2.42, ^{13}C nmr δ 23.7) in **11**. The ^{13}C nmr has only four signals attributable to aromatic carbons. In contrast, the aromatic methyls of **12** are nonequivalent (^1H nmr δ 2.26, 2.35, ^{13}C nmr δ 20.8, 23.2) and six distinct aromatic carbon signals appear in the ^{13}C nmr spectrum.

A mixture of **11** and **12** (9:1) was lithiated (*n*-butyllithium) in tetrahydrofuran (THF)–hexane at room temperature and ethylene oxide was added. The major product, isolated by chromatography of the complex product mixture, was the alcohol **13**, resulting from Wittig rearrangement and protonolysis of the lithiated species. When this reaction was carried out at −78°C, however, the desired alcohol **14** was obtained in 66% yield after complexation with calcium chloride followed by distillation. The isomeric alcohol **15**, derived from bromoether **12**, did not contaminate this product. An authentic sample of **15** was prepared in low yield by lithiation of pure **12** and treatment with ethylene oxide overnight at −5°C. Presumably the aryllithium **16** reacts sluggishly due to intramolecular complexation with the ethereal oxygen, and at −78°C no reaction occurs with the ethylene oxide. In agreement with the assigned structure, alcohol **14** shows only one aromatic methyl signal (6H) and one sharp aromatic proton peak (2H).

We now turned our attention to the introduction of the fifth substituent on to the aromatic ring. Attempted Rieche formylation of the acetyl derivative (**14***a*) of alcohol **14** with α,α-dichloromethyl methyl ether and titanium tetrachloride (7) gave the benzylic chloride as the only product. When stannic chloride was used as the catalyst an intractable mixture of highly polar products was formed. Because of the known liability of benzyl methyl ethers to Wittig rearrangement (8) direct lithiation of **14***a* was not attempted, instead bromination followed by metal exchange was utilized. Treatment of **14** with bromine in nitromethane at 0°C gave bromoalcohol **18** in 94% yield. The alcohol function of **18** was then protected as the tetrahydropyranyl (THP) ether (**18***a*). Treatment of the bromide **18***a* with *n*-butyllithium gave the aryllithium **18***b* which was caused to react with methyl chloroformate (0°C) to give the ester **18***c* in 62% yield.

Olah *et al.* have reported that iodotrimethylsilane, generated *in situ* from chlorotrimethylsilane and sodium iodide in acetonitrile, will convert methyl esters to silyl esters, cleave methyl ethers to alcohols, and transform benzylic alcohols to iodides (9). We reasoned that exposure of **18***c* to this reagent might afford intermediate **19**, a species which should be well suited to lactonization and thus formation of trisnorcybrodolide (**5**) or a derivative thereof. The fate of the THP ether was unclear from Olah's results.

Treatment of **18***c* with the Olah reagent (9) gave a mixture of products from which trisnorcybrodolide (**5**) was isolated in 11% yield. The major product (60%) was the primary iodide **20**, likely formed from **5** by the action of excess reagent. In order to

avoid this side reaction, the THP protecting group was replaced by an acetyl group (methanolysis of **18***c* to **18***d* and acetylation to give **18***e*). Exposure of **18***e* to Olah's reagent in refluxing acetonitrile gave *O*-acetyltrisnorcybrodolide (**5***a*) which was hydrolyzed (K_2CO_3–CH_3OH) directly to trisnorcybrodol (**5**), identical with the natural product, in an overall yield of 75%.

In order to introduce the three carbons necessary for the elaboration of the side chain of the remaining cybrodins, the ester **18***c* was transformed (LAH reduction, pyridinium chlorochromate oxidation) to the aldehyde **21** in 76% overall yield. The first attempt at introducing the functionalized side chain involved treatment of **21** with isopropenyllithium prepared from 2-bromopropene (10). The product, isolated in low (15%) yield, was not the expected allylic alcohol **22** but the propargylic alcohol **23**. Removal of the THP group of **23** (pyridinium tosylate – methanol) was accompanied by solvolysis of the propargylic alcohol to give the hydroxy diether **23***a*. Neither **23** nor **23***a* show acetylenic triple bond stretching in the ir, but this is not too unusual for internal acetylenes (11). The presence of the triple bond in **23** was indicated by the ^{13}C nmr spectrum, which shows fully substituted carbons at δ 83.0 and δ 108.4, and most indicatively, a methyl signal at δ 3.8 (12). The alkyne methyl group is seen in the ^1H nmr spectrum of **23***a* as a doublet (δ 1.83, J = 3 Hz) coupled to the propargyl ether proton at δ 5.38 (J = 3 Hz). This is typical of acetylenic systems where protons on the α and α′ carbons usually couple by ~3 Hz (13). Presumably **23** arises by condensation with 1-lithiopropyne, formed from 1-propyne, which in turn results from dehydrohalogenation of 2-bromopropene by initially formed isopropenyllithium.

The desired allylic alcohol **22** was obtained in 80% yield by addition of isopropenylmagnesium bromide to aldehyde **21**. Mild acid hydrolysis (pyridinium tosylate – aqueous THF) gave the diol **22***a* with analytical and spectral properties in full

For personal use only.

accord with the assigned structure. The alcohol **22** was also prepared directly by the addition of the lithiated intermediate **18***b* to methacrolein, although the yield in this case was only twenty-five percent.

We now turned our attention to the allylic rearrangement of alcohol **22** which should lead directly to cybrodol and/or isocybrodol. Braude and Evans have reported that alcohol **24** is rearranged in ca. 50% yield to the alcohol **25**, which probably possesses the *E* stereochemistry shown (10). Accordingly, alcohol **22** was exposed to dilute sulfuric acid in refluxing 60% aqueous acetone. The THP ether was cleaved in short order as tlc examination revealed that diol **22***a* was formed within minutes. Over a period of several hours, the monitoring indicated the disappearance of diol **22***a* while two new products, **26** and **27**, were formed in an overall yield of 67%. Assignment of structure **26** followed readily from comparison of the ^{1}H nmr spectrum with that of cybrodol (1). Except for the presence of the *O*-methyl signal (δ 3.34) in the synthetic sample, the spectra are virtually superimposable. The second product was initially assigned structure **27***a*. However, when **27** was acetylated, it was the *benzylic alcohol rather than the allylic alcohol* which showed the typical acetylation shift. The assignment was verified by MnO_2 oxidation of **27** to the benzaldehyde, in which the aromatic proton, not the olefinic proton, undergoes a downfield shift (δ 7.11 → δ 7.60). The uv spectrum of **28** (λ_{max} 266, 310 nm) is very similar to that of mesitaldehyde (λ_{max} 264, 300 nm) (14). The formation of the rearranged ether **27** can be rationalized by the intermediacy of the cation **29** formed from an initially produced allylic carbonium ion.

32

It now remained to cleave the methyl ethers in **26** and **27** to generate cybrodol (**1**) and isocybrodol (**2**), respectively. Treatment of isocybrodol methyl ether (**27**) with pyridine hydrochloride – acetic anhydride (15) gave only the diacetyl derivative. Use of Fujita's method (BF_3–ethanedithiol) (16) led to the interesting, although undesired, formation of a compound $C_{15}H_{20}OS$, assigned the cyclic sulfide structure **30** on the basis of its spectral characteristics.[3] Success in the ether cleavage was achieved using the method reported by Ganem and Small (18). When an acetic anhydride solution of **27** and ferric chloride was stirred overnight at room temperature the product (78% yield after chromatography) was a 4:1 mixture (as judged by nmr) of triacetylcybrodol (**1***a*) and triacetylisocybrodol (**2***a*). When cybrodol methyl ether (**26**) was treated in like fashion, the same product mixture resulted. Compounds **1***a* and **2***a* were difficult to separate and the crude product mixture was hydrolyzed (CH_3OH–K_2CO_3) and the resulting cybrodol (**1**) and isocybrodol (**2**) were separated by chromatography. The synthetic compounds were identical (tlc, ir, ^{1}H nmr, ms) with natural materials.[4] Since cybrobol (**1**) has previously been transformed to cybrodal (**3**), the above synthesis also represents a total synthesis of cybrodal.

The results of the $FeCl_3$ – acetic anhydride cleavage, and those from the earlier cited acid catalyzed isomerization of **22** to **26** and **27** imply the intermediacy of interconverting carbonium ions (**31***a*, **31***b*) in these reactions. In the present case the bulky acetoxyl groups (or lack of H-bonding) appear to bias the product distribution in favor of the *E* olefin geometry. Based on these results, we felt that a more direct route to cybrodol (**1**) might result from direct treatment of **22***a* with $FeCl_3$ – acetic anhydride. In the event, diol **22***a* afforded, after deacetylation, a 51% overall yield of **1** and **2** (ratio 7:3), providing a somewhat shorter but not more efficient (in terms of yield) sequence.

[3]For a discussion of the possible mechanism of this reaction, see ref. 17.

[4]Natural cybrodol was obtained as a clear oil which had resisted all attempts at crystallization. The synthetic material crystallized readily from $CHCl_3$–CH_3OH, mp 101–102°C. The natural material, which is optically inactive, crystallized when seeded with synthetic **1**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

Since isocybrodol (**2**) is the minor product in the above deprotection sequence, we desired a synthesis of **2** which avoids the substantial isomerization to the *E* geometry that occurs when isocybrodol methyl ether (**27**) is exposed to Ganem's conditions. When the diacetyl derivative of **27** was treated with boron tribromide in methylene chloride at −20°C the product mixture (86% total yield) consisted of a mixture of **31** and **31***a*, the desired isomer **31** representing >95% of the mixture as judged by ^{1}H nmr. Treatment of the mixture of **31** and **31***a* with tetraethylammonium acetate in acetone afforded triacetylisocybrodol (**2***a*) in greater than 90% yield. Since **2***a* is readily hydrolyzed to isocybrodol (**2**), this route offers the most economical synthesis of the latter.

Cybrodic acid (**4**) was prepared from cybrodol methyl ether (**26**) in the following manner. Activated manganese dioxide oxidation of **26** gave aldehyde **32** in quantitative yield. Treatment of **32** with sodium cyanide, acetic acid, and manganese dioxide in methanol (19) gave a 95% yield of the ester **4***a*, which when treated with Ganem's ferric chloride reagent (18) gave methyl diacetylcybrodate (**4***b*) in 77% yield. Saponification of **4***b* (KOH, CH_3OH, reflux) gave cybrodic acid (**4**, 97% yield), identical with the natural product.

The syntheses of cybrodol (**1**), isocybrodol (**2**), cybrodal (**3**), cybrodic acid (**4**), and trisnorcybrodolide (**5**) described herein serve to confirm the structures proposed (2) for these metabolites of *C. bulleri*.

Experimental

The general experimental details are described in the preceding paper (2). Elemental analyses were carried out by the microanalytical laboratory of this department or by Schwarzkopf Microanalytical Laboratory, New York.

4-Bromo-3,5-dimethylbenzylidene Diacetate (7)

2-Bromomesitylene (99.5 g, 0.5 mol), acetic acid (770 mL), and acetic anhydride (770 mL) were cooled to 0°C in an ice–salt bath. Concentrated sulfuric acid (115 mL) was added dropwise over a ten minute period to the mechanically stirred solution. After the solution temperature reached 5°C, chromium trioxide (135 g, 1.35 mol) was added in small portions over a period of one hour. During the addition period the solution temperature was maintained between 5 and 10°C. The mixture was stirred at 5°C for a further 30 min and then poured onto crushed ice (3 L). Water was added to bring the total volume to six litres. When the reaction was conducted on a smaller scale (7.16 g) a crude, semi-crystalline product (5.20 g) could be filtered off at this point. This material was used to obtain spectral data. On a larger scale the product was quite oily and could not be effectively isolated by filtration. Instead, the product was isolated by ether extraction (3 × 2 L). The extract was taken to dryness leaving a green semi-solid which was dissolved in ether (500 mL). This solution was washed with water (100 mL) and brine (100 mL). After drying over magnesium sulfate, filtration and evaporation to dryness gave a yellow semi-solid (147 g) which was used without purification in the next step.

The crude product from 7.16 g of 2-bromomesitylene was recrystallized (95% ethanol) affording pure **7** (4.65 g, 41%) as white prisms, mp 91–93°C. Sublimation of this material (80°C, 1 Torr) gave an analytically pure sample, mp 94–95°C (clear prisms); ir ($CHCl_3$ cast): 1751, 1240, 1205 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.10 (6H, s, 2 × OAc), 2.43 (6H, s, 2 × $ArCH_3$), 7.20 (2H, s, 2 × ArH), 7.55 (1H, s, CH); ^{13}C nmr ($CDCl_3$) δ: 20.8 (2C), 23.9 (2C), (CH_3); 89.4, 126.3 (2C), (CH); 129.0, 134.0, 138.8 (2C)(C); 168.7 (2C), (C=O); ms *m/e* calcd. for $C_{13}H_{15}O_4{}^{81}Br$ (M + 2): 316.0133; found: 316.0140 (60); calcd. for $C_{13}H_{15}O_4{}^{79}Br$ (M^+): 314.0154; found: 314.0152 (64), 106 (100), 105 (48), 104 (77), 103 (56), 91 (28), 78 (33), 77 (65), 51 (21). *Anal.* calcd. for $C_{13}H_{15}O_4Br$: C 49.54, H 4.80, Br 25.35; found: C 49.52, H 4.78, Br 25.57.

4-Bromo-3,5-dimethylbenzyl Alcohol (9)

A solution of crude **7** (147 g) in anhydrous ether (750 mL) was added over a two hour period to a mechanically stirred slurry of lithium aluminum hydride (31 g, 0.82 mol) in anhydrous ether (1.2 L). The mixture was stirred for a further 90 min and then quenched by sequential dropwise addition of water (31 mL), 15% aqueous sodium hydroxide (31 mL), and water (93 mL). The solids, after removal by filtration, were washed with anhydrous ether (10 × 50 mL). The combined ether solutions were concentrated *in vacuo* leaving crude **9** (100 g) as a semi-solid which was used without purification in the next step.

Compound **9** has the following physical properties: ir ($CHCl_3$): 3600 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.42 (6H, s, 2 × $ArCH_3$), 4.55 (2H, s, CH_2O), 7.03 (2H, s, 2 × ArH); ms *m/e* calcd. for $C_9H_{11}O^{81}Br$ (M + 2): 215.9973; found: 215.9973 (73); calcd. for $C_9H_{11}O^{79}Br$ (M^+): 213.9993; found: 213.9988 (77), 135 (73), 107 (100), 106 (60), 105 (32).

4-Methoxymethyl-2,6-dimethylbromobenzene (11)

To a magnetically stirred solution of crude **9** (100 g) and methyl iodide (100 g, 0.70 mol) in dry dimethoxyethane (200 mL), sodium hydride (57% in oil, washed with Skellysolve B; 17 g, 0.71 mol) was added in small portions over a 30 min period. The mixture was stirred for a further two hours at room temperature. The solution volume was reduced to 50 mL by distillation at atmospheric pressure, ether (200 mL) was added, and the salts were removed by filtration. The filter cake was extracted with ether (5 × 50 mL) and the combined ethereal solutions were concentrated leaving a brown oil (62.5 g). Polar impurities were removed by rapid passage of a Skellysolve B solution of this material through a short column of acidic alumina (200 g). The washings were concentrated to a yellow oil (57.3 g) which on distillation (100–105°C, 0.8 Torr) gave an 89:11 mixture (as judged by ^{1}H nmr) of 4-methoxymethyl-2,6-dimethylbromobenzene (**11**) and 2-methoxymethyl-4,6-dimethylbromobenzene (**12**) (50.5 g, 44% from 2-bromomesitylene). These isomers could be separated by flash chromatography (Skellysolve B – ether, 9:1; 1 g of sample/5 cm column), however, for synthetic purposes the mixture was used as such in the next step. A small sample of pure **11** was evaporatively distilled (80°C, 0.03 Torr) for microanalysis.

Compound **11** has the following physical properties: ir ($CHCl_3$ cast): 1105, 1030, 860 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.42 (6H, s, 2 × $ArCH_3$), 3.38 (3H, s, CH_3O), 4.35 (2H, s, CH_2O), 7.04 (2H, s, 2 × ArH); ^{13}C nmr ($CDCl_3$) δ: 23.7 (2C), 58.0 (CH_3); 73.9 (CH_2); 127.4 (2C) (CH); 126.4, 136.9, 138.1 (2C) (C); ms *m/e* calcd. for $C_{10}H_{13}O^{81}Br$ (M + 2): 230.0129; found: 230.0113 (40); calcd. for $C_{10}H_{13}O^{79}Br$ (M^+): 228.0150; found: 228.0143 (40), 149 (100), 119 (24). *Anal.* calcd. for $C_{10}H_{13}OBr$: C 52.42, H 5.72, Br 34.88; found: C 52.40, H 5.67, Br 34.61.

Compound **12** has the following physical properties: ir (film): 1100 cm,$^{-1}$; ^{1}H nmr ($CDCl_3$) δ: 2.26 (3H, s, $ArCH_3$), 2.35 (3H, s, $ArCH_3$), 3.46 (3H, s, CH_3O), 4.48 (2H, s, CH_2O), 6.97 (1H, s, ArH), 7.08 (1H, s, ArH); ^{13}C nmr ($CDCl_3$) δ: 20.8, 23.2, 58.5

(CH_3); 74.5 (CH_2); 127.0, 130.6 (CH), 121.8, 136.6, 137.6, 137.9 (C); ms *m/e* calcd. for $C_{10}H_{13}O^{81}Br$ (M + 2): 230.0129; found: 230.0132 (30); calcd. for $C_{10}H_{13}O^{79}Br$ (M^+): 228.0150; found: 228.0156 (29), 149 (100), 119 (21), 104 (22).

*Attempted Preparation of **14** using* n*-Butyllithium at Room Temperature*

n-Butyllithium (8.8 *M* in hexane, 2.5 mL, 22 mmol) was added to a mixture of bromides **11** and **12** (4.35 g, 19 mmol) in dry tetrahydrofuran (20 mL) at room temperature under a nitrogen atmosphere. The mixture was stirred for one hour during which time a purple colour developed. Ethylene oxide (5 g, 0.11 mol) was distilled through a drying tube and condensed into the reaction vessel by means of a dry-ice condenser. The mixture was stirred at room temperature for one hour and then saturated aqueous ammonium chloride (10 mL) was added. The products were isolated by ether extraction (3 × 10 mL). The combined ether extracts were dried over magnesium sulfate, filtered, and concentrated to a brown oil (3.73 g). Thin-layer chromatographic examination of the reaction mixture revealed that compound **14** (*vide infra*) was not present. The major product, isolated as a clear oil by column chromatography (chloroform, 150 g of silica gel) was 1-(3,5-dimethylphenyl)ethanol (**13**, 1.06 g, 37%): ir (film): 3450 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.49 (3H, d (7 Hz), CH_3CH), 2.32 (6H, s, 2 × $ArCH_3$), 4.82 (1H, q (7 Hz), $CHCH_3$), 6.90 (1H, s, ArH), 6.97 (2H, s, 2 × ArH); ms *m/e* calcd. for $C_{10}H_{14}O$ (M^+): 150.1045; found: 150.1047 (55), 135 (53), 107 (100), 91 (28).

*2-(4-Methoxymethyl-2,6-dimethylphenyl)ethanol (**14**)*

A magnetically stirred solution of *n*-butyllithium (1.6 *M* in hexane, 75 mL, 0.12 mol) in dry tetrahydrofuran (80 mL) was cooled to −78°C under a nitrogen atmosphere. A mixture of bromides **11** and **12** (25.0 g, 0.109 mol) in dry tetrahydrofuran (30 mL) was added over a period of 15 min causing a creamy white precipitate to form. The solution was stirred at −78°C for a further hour. Ethylene oxide (25 g, 0.57 mol), purified by passage through a drying tube (2 × 30 cm) containing potassium hydroxide and anhydrous calcium sulfate, was condensed in the reaction flask by means of a dry-ice condenser. Introduction of the ethylene oxide required one hour. The reaction mixture was stirred for an additional four hours. Saturated aqueous ammonium chloride (50 mL) was added and the mixture was allowed to warm to room temperature. Water (200 mL) was added to dissolve the salts and the organic layer was removed. The aqueous phase was extracted with ether (5 × 100 mL), the combined organic extracts were dried over magnesium sulfate, filtered, and concentrated. On a smaller scale (5 g of starting material) purification was conveniently achieved by column chromatography (chloroform, 100 g of silica gel) which afforded pure **14** (2.16 g, 51%). On the present scale, however, the above crude product (24.6 g) was dissolved in Skellysolve B (250 mL). Finely powdered anhydrous (dried overnight at 120°C) calcium chloride (50 g) was added and the mixture was cooled to −70°C for two hours. The solids were filtered off and washed with cold (0°C) Skellysovle B (3 × 30 mL). The filtrate was set aside and water (200 mL) was added to the filter cake. After 30 min, the aqueous solution was extracted with ether (3 × 200 mL). The ether extracts were dried over magnesium sulfate, filtered, and evaporated to dryness leaving crude alcohol **14** (15.2 g) as a viscous yellow oil. Distillation (120–130°C, 0.12 Torr) gave pure **14** (14.0 g, 66%): ir ($CHCl_3$ cast): 3400 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.33 (6H, s, 2 × $ArCH_3$), 2.91 (2H, t (7 Hz), CH_2CH_2O), 3.37 (3H, s, CH_3O), 3.67 (2H, t (7 Hz), CH_2CH_2O), 4.35 (2H, s, CH_2OCH_3), 6.99 (2H, s, 2 × ArH); ^{13}C nmr ($CDCl_3$) δ: 20.0 (2C), 58.2 (CH_3); 32.8, 61.6, 74.7 (CH_2); 127.9 (2C), (CH); 134.3, 136.0, 137.1 (2C), (C); ms *m/e* calcd. for $C_{12}H_{18}O_2$ (M^+): 194.1307; found: 194.1310 (44), 163 (100), 132 (24). *Anal.* calcd. for $C_{12}H_{18}O_2$: C 74.19, H 9.34; found: C 74.03, H 9.36.

*2-(2-Methoxymethyl-4,6-dimethylphenyl)ethanol (**15**)*

n-Butyllithium (1.6 *M* in hexane, 0.63 mL, 1 mmol) was added to a solution of bromide **12** (200 mg, 0.87 mmol) in dry tetrahydrofuran (1 mL) at −78°C under a nitrogen atmosphere. The mixture was stirred at −78°C for one hour. Ethylene oxide (2 mL, 40 mmol) was added (cooled syringe) in one portion. The mixture was stirred at −78°C for 5 h and then left overnight at −5°C. The reaction mixture was diluted with water (20 mL) and extracted with ether (4 × 20 mL). The combined ether extracts were dried over sodium sulfate, filtered, and concentrated. Flash chromatography (methylene chloride – methanol, 100:1; 2 cm column) gave **15** as a clear oil (33 mg, 19%); ir (film): 3400 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.26 (3H, s, $ArCH_3$), 2.29 (3H, s, $ArCH_3$), 2.92 (2H, t (7 Hz), CH_2CH_2O), 3.38 (3H, s, CH_3O), 3.76 (2H, t (7 Hz), CH_2CH_2O), 4.40 (2H, s, CH_2O), 6.95 (2H, s, 2 × ArH); ^{13}C nmr ($CDCl_3$) δ: 19.8, 20.7, 58.0 (CH_3); 32.1, 61.7, 73.7 (CH_2); 128.8, 131.6 (CH); 133.2, 135.6, 136.1, 137.3 (C); ms *m/e* calcd. for $C_{12}H_{18}O_2$ (M^+): 194.1306; found: 194.1313 (17), 149 (34), 133 (68), 132 (100).

*2-(4-Methoxymethyl-2,6-dimethylphenyl)ethyl Acetate (**14**a)*

Alcohol **14** (750 mg, 3.87 mmol), acetic anhydride (1 mL), and pyridine (1 mL) in methylene chloride (10 mL) were stirred overnight at room temperature. Evaporation to dryness gave **42** as a clear oil (863 mg): ir (film): 1740 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.05 (3H, s, OAc), 2.36 (6H, s, 2 × $ArCH_3$), 2.98 (2H, t (7 Hz), CH_2CH_2O), 3.37 (3H, s, CH_3O), 4.15 (2H, t (7 Hz), CH_2CH_2O), 4.35 (2H, s, CH_2O), 6.98 (2H, s, 2 × ArH); ms *m/e* calcd. for $C_{14}H_{20}O_3$ (M^+): 236.1412; found: 236.1420 (35), 176 (100), 163 (43), 161 (59), 149 (20), 145 (36), 144 (21), 131 (20).

*2-(3-Bromo-4-methoxymethyl-2,6-dimethylphenyl)ethanol (**18**)*

A stirred solution of arene **14** (10.0 g, 51.5 mmol) in nitromethane (50 mL) was cooled to 0°C. Bromine (4.0 mL, 12.4 g, 78 mmol) in nitromethane (50 mL) was added dropwise over a 30 min period. The reaction mixture was stirred at 0°C for a further 30 min and then saturated aqueous sodium carbonate (50 mL) was added. Most of the nitromethane was removed *in vacuo* and the residue was extracted with ether (5 × 50 mL). The combined ether extracts were washed with water (50 mL) and brine (50 mL). After drying over magnesium sulfate, filtration and concentration gave bromide **18** (13.3 g, 94%) as a viscous orange oil. Attempted bulb to bulb distillation (150°C, 0.1 Torr) caused extensive decomposition. A small sample of crude **18** was crystallized from Skellysolve B – methylene chloride (1:1) affording buff coloured crystals, mp 101–106°C, which were sublimed (100°C, 0.023 Torr) giving analytically pure **18** (mp 104–106°C); ^1H nmr ($CDCl_3$) δ: 2.29 (3H, s, $ArCH_3$), 2.42 (3H, s, $ArCH_3$), 2.95 (2H, t (7 Hz), CH_2CH_2O), 3.42 (3H, s, CH_3O), 3.65 (2H, t (7 Hz), CH_2CH_2O), 4.44 (2H, s, CH_2OCH_3), 7.09 (1H, s, ArH); ms *m/e* calcd. for $C_{12}H_{17}O_2{}^{81}Br$ (M + 2): 274.0392; found: 274.0395 (1); calcd. for $C_{12}H_{17}O_2{}^{79}Br$ (M^+): 272.0411; found: 272.0403 (1), 243 (100), 241 (94), 213 (44), 211 (45), 132 (35), 131 (21), 115 (24), 91 (21). *Anal.* calcd. for $C_{12}H_{17}O_2Br$: C 52.76, H 6.27, Br 29.25; found: C 52.87, H 6.12, Br 29.13.

*1-Bromo-3-(2-(tetrahydro-2H-pyran-2-yl)oxyethyl)-6-methoxymethyl-2,4-dimethylbenzene (**18**a)*

A solution of alcohol **18** (18.05 g, 66.1 mmol), dihydropyran (17 mL, 15.7 g, 0.186 mol), and pyridinium tosylate (700 mg, 2.8 mmol) in methylene chloride (70 mL) was stirred at room temperature for one hour. The solution was washed with water (10 mL) and dried over magnesium sulfate. Filtration and evaporation to dryness gave crude ether **18***a* as a brown oil. Flash chromatography (Skellysolve B – ethyl acetate, 20:1) gave pure **18***a* (22.5 g, 95%) as a light yellow oil; ^1H nmr ($CDCl_3$) δ: 1.4–1.8 (6H, m, 3 × CH_2), 2.32 (3H, s, $ArCH_3$), 2.45 (3H, s, $ArCH_3$), 3.00 (2H, t (7 Hz), $ArCH_2CH_2$), 3.42 (3H, s, CH_3O), 3.5

For personal use only.

(2H, m, CH_2O), 3.70 (2H, t (7 Hz), $ArCH_2CH_2$), 4.44 (2H, s, CH_2OCH_3), 4.56 (1H, bs, CH), 7.09 (1H, s, ArH); ms *m/e* calcd. for $C_{17}H_{25}O_3{}^{81}Br$ (M + 2): 358.0965; found: 358.0968 (2); calcd. for $C_{17}H_{25}O_3{}^{79}Br$ (M^+): 356.0965; found: 356.0988 (2), 274 (1), 272 (1), 85 (100).

*Methyl 3-(2-(Tetrahydro-2*H*-pyran-2-yl)oxyethyl)-6-methoxymethyl-2,4-dimethylbenzoate (**18***c*)

A solution of *n*-butyllithium (1.6 *M* in hexane, 44 mL, 70 mmol) in dry tetrahydrofuran (100 mL) was cooled to −78°C under a nitrogen atmosphere. Bromide **18***a* (22.5 g, 63.0 mmol) in dry tetrahydrofuran (20 mL) was added over a 10 min period, the mixture was then stirred at −78°C for a further 50 min. Freshly distilled methyl chloroformate (36 mL, 44 g, 0.47 mol) was rapidly injected (syringe) into the reaction pot. The solution was warmed to 0°C and kept at this temperature for 16 h. The reaction was quenched by addition of saturated aqueous sodium carbonate (50 mL) followed by water (100 mL). The organic phase was removed and the aqueous residue extracted with ether (3 × 50 mL). The combined organic extracts were dried over magnesium sulfate, filtered, and concentrated *in vacuo*. Flash chromatography (Skellysolve B – ethyl acetate, 3 : 1; 5 cm column; 5 runs) provided pure ester **18***c* (13.2 g, 62%) as a clear oil; ir ($CHCl_3$ cast): 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.4–1.8 (6H, m, 3 × CH_2), 2.31 (3H, s, $ArCH_3$), 2.37 (3H, s, $ArCH_3$), 2.98 (2H, t (7 Hz), $ArCH_2CH_2$), 3.30 (3H, s, CH_3OCH_2), 3.5 (2H, m, CH_2O), 3.75 (2H, t (7 Hz), $ArCH_2CH_2$), 3.87 (3H, s, CO_2CH_3), 4.38 (2H, s, CH_2OCH_3), 4.56 (1H, bs, CH), 7.00 (1H, s, ArH); ms *m/e* calcd. for $C_{19}H_{28}O_5$ (M^+): 336.1936; found: 336.1939 (1), 305 (6), 190 (28) 85 (100).

*Trisnorcybrodolide (5, 6-(2-Hydroxyethyl)-5,7-dimethylphthalide, Direct Route from **18**c)*

Chlorotrimethylsilane (140 μL, 120 mg, 1.1 mmol) was added to a solution of ester **18***c* (52 mg, 0.15 mmol) and sodium iodide (165 mg, 1.1 mmol) in dry acetonitrile (5 mL). The mixture was refluxed for one day under nitrogen, extra chlorotrimethylsilane (140 μL) was added, and reflux was continued for a further 24 h. The reaction mixture was cooled and then diluted with ether (100 mL). The ether solution was washed with water (3 × 10 mL), 10% aqueous sodium thiosulfate (10 mL), and saturated aqueous sodium bicarbonate (3 × 10 mL). After drying over sodium sulfate, filtration and concentration gave a crude product mixture (53 mg) which was subjected to ptlc (Skellysolve B – ethyl acetate, 3 : 1) affording two major components: R_f 0.33 (28 mg, 60%) and R_f 0.09 (3.4 mg, 11%).

The R_f 0.33 component (mp 182–184°C, Skellysolve B) was identified as 6-(2-iodoethyl)-5,7-dimethylphthalide (**20**) on the basis of the following spectral properties; ir ($CHCl_3$ cast): 1750 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.43 (3H, s, $ArCH_3$), 2.67 (3H, s, $ArCH_3$), 3.2 (4H, m (A_2B_2), CH_2CH_2), 5.11 (2H, s, CH_2O), 7.08 (1H, s, ArH); ms *m/e* calcd. for $C_{12}H_{13}O_2I$ (M^+): 315.9960; found: 315.9949 (3), 189 (100).

The R_f 0.09 component was identical (tlc, ir, ^1H nmr, ms) with natural trisnorcybrodolide (**5**).

*Methyl 3-(2-Hydroxyethyl)-6-methoxymethyl-2,4-dimethylbenzoate (**18**d)*

A solution of tetrahydropyranyl ether **18***c* (303 mg, 0.902 mmol) and pyridinium tosylate (100 mg, 0.4 mmol) in methanol (5 mL) was stirred overnight at room temperature. The solvent was removed *in vacuo* and the residue was taken up in ether (100 mL) and then washed with water (10 mL) and brine (10 mL). After drying over sodium sulfate, filtration and concentration gave compound **18***d* (220 mg, 97%), a clear oil sufficiently pure for further work (*vide infra*). For the purpose of characterization, a small sample (500 mg) from a parallel run was chromatographed (Skellysolve B – ethyl acetate, 1 : 1; 20 g silica gel) affording pure **18***d* (450 mg). Evaporative distillation (110°C, 0.017 Torr) of a portion of this material provided an analytically pure sample; ir ($CHCl_3$ cast): 3440, 1727 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.26 (3H, s, $ArCH_3$), 2.32 (3H, s, $ArCH_3$), 2.50 (1H, s, OH), 2.90 (2H, t (7 Hz), CH_2CH_2O), 3.28 (3H, s, CH_3OCH_2), 3.60 (2H, t (7 Hz), CH_2CH_2O), 3.85 (3H, s, CO_2CH_3), 4.36 (2H, s, CH_2OCH_3), 7.00 (1H, s, ArH); ms *m/e* calcd. for $C_{14}H_{20}O_4$ (M^+): 252.1362; found: 252.1363 (29), 221 (25), 207 (21), 205 (100), 189 (32). *Anal.* calcd. for $C_{14}H_{20}O_4$: C 66.65, H 7.99; found: C 66.75, H 7.87.

*Methyl 3-(2-Acetoxyethyl)-6-methoxymethyl-2,4-dimethylbenzoate (**18**e)*

A solution of alcohol **18***d* (*vide supra*, 330 mg) in acetic anhydride (4 mL) and pyridine (10 mL) was stirred at room temperature for three hours. Evaporation to dryness under high vacuum gave crude **18***e* (241 mg) as a brown oil which was purified by chromatography; ir (film): 1750, 1745 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.01 (3H, s, OAc), 2.29 (3H, s, $ArCH_3$), 2.35 (3H, s, $ArCH_3$), 2.98 (2H, t (7 Hz), CH_2CH_2O), 3.30 (3H, s, CH_3OCH_2), 3.85 (3H, s, CO_2CH_3), 4.10 (2H, t (7 Hz), CH_2CH_2O), 4.36 (2H, s, CH_2OCH_3), 7.02 (1H, s, ArH); ms *m/e* calcd. for $C_{16}H_{22}O_5$ (M^+): 294.1468; found: 294.1472 (7), 263 (42), 262 (92), 247 (20), 234 (38), 219 (100), 207 (72), 203 (21), 189 (21), 187 (55).

*Trisnorcybrodolide (5) via Compounds **18**e and **5**a*

A mixture of crude **18***e* (241 mg), sodium iodide (1.2 g, 8 mmol), and chlorotrimethylsilane (1.0 mL, 856 mg, 7.9 mmol) in dry acetonitrile (20 mL) was refluxed under nitrogen for 24 h. Water (100 mL) was added and the product was extracted into ether (5 × 20 mL). The combined ether extracts were washed successively with water (20 mL), 10% aqueous sodium thiosulfate (20 mL), water (20 mL), and brine (20 mL). After drying over magnesium sulfate, filtration and concentration gave a brown powder. The major component of this crude product mixture was shown to be identical with the acetyl derivative (**5***a*) of natural trisnorcybrodolide (**5**) by tlc examination. Crude **5***a* and potassium carbonate (1.0 g) were taken up in methanol (10 mL) and stirred overnight at room temperature. The methanol was removed *in vacuo* and the residue was partitioned between ethyl acetate (100 mL) and water (10 mL). Nonpolar impurities were removed from the residue by trituration with methylene chloride (3 × 1 mL) leaving virtually pure trisnorcybrodolide (**5**, 139 mg, 74% overall from **18***c*). Recrystallization (methanol) gave colourless prisms, mp 189–191°C, which were sublimed (120°C, 0.015 Torr) providing an analytical sample. *Anal.* calcd. for $C_{12}H_{14}O_3$: C 69.89, H 6.84; found: C 69.87, H 7.05.

*3-(2-(Tetrahydro-2*H*-pyran-2-yl)oxyethyl)-6-methoxymethyl-2,4-dimethylbenzyl Alcohol*

Methyl ester **18***c* (7.07 g, 21.0 mmol) in dry ether (50 mL) was added over a 30 min period to a stirred slurry of lithium aluminum hydride (1.00 g, 26.3 mmol) in dry ether (100 mL). The mixture was stirred at room temperature for two hours and then quenched by dropwise addition of water (1 mL), 15% aqueous sodium hydroxide (1 mL), and water (3 mL). The granular precipitate was filtered off and washed with ether (5 × 50 mL). The combined ether solutions were concentrated leaving the crude title alcohol (6.5 g). Flash chromatography (Skellysolve B – ethyl acetate, 1 : 1; 5 cm column) afforded the pure alcohol (5.00 g, 77%) as a clear oil; ir ($CHCl_3$ cast): 3440 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.4–1.8 (6H, m, 3 × CH_2), 2.36 (3H, s, $ArCH_3$), 2.46 (3H, s, $ArCH_3$), 2.70 (1H, t (7 Hz), OH), 3.03 (2H, t (7 Hz), $ArCH_2CH_2$), 3.42 (3H, s, CH_3O), 3.5 (2H, m, CH_2O), 3.75 (2H, t (7 Hz), $ArCH_2CH_2$), 4.48 (2H, s, CH_2OCH_3), 4.58 (1H, bs, CH), 4.66 (2H, d (7 Hz), CH_2OH), 6.95 (1H, s, ArH); ms *m/e* calcd. for $C_{18}H_{28}O_4$ (M^+): 308.1988; found: 308.1984 (1), 174 (21), 162 (34), 146 (32), 85 (100).

*3-(2-Tetrahydro-2*H*-pyran-2-yl)oxyethyl)-6-methoxymethyl-2,4-dimethylbenzaldehyde (**21**)*

A solution of the above alcohol (5.00 g, 16.2 mmol) in methylene chloride (10 mL) was added in one portion to a solution of pyridinium chlorochromate (5.40 g, 25 mmol) and sodium acetate (400 mg, 4.88 mmol) in methylene chloride (20 mL). The mixture was stirred at room temperature for one hour, diluted with ether (100 mL), and then filtered through Celite. The filter cake was washed with additional ether (5 × 30 mL). The combined filtrates were rapidly passed through a Florisil column (50 g). An extra portion of ether (200 mL) completely eluted the product. Concentration provided aldehyde **21** (4.85 g, 98%) sufficiently pure for further work; ir ($CHCl_3$ cast): 1690 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.4–1.8 (6H, m, 3 × CH_2), 2.43 (3H, s, $ArCH_3$), 2.61 (3H, s, $ArCH_3$), 3.04 (2H, t (7 Hz), $ArCH_2CH_2$), 3.42 (3H, s, CH_3O), 3.5 (2H, m, CH_2O), 3.77 (2H, t (7 Hz), $ArCH_2CH_2$), 4.57 (1H, bs, CH), 4.69 (2H, s, CH_2OCH_3), 7.21 (1H, s, ArH), 10.54 (1H, s, CHO); ms *m/e* calcd. for $C_{18}H_{26}O_4$ (M^+): 306.1831; found: 306.1832 (15), 204 (37), 189 (24), 85 (100).

*1-((3-(2-(Tetrahydro-2*H*-pyran-2-yl)oxyethyl)-6-methoxymethyl-2,4-dimethyl)phenyl)-2-butyn-1-ol (**23**)*

2-Bromopropene (3.0 mL, 4.1 g, 34 mmol) was added to a suspension of finely divided lithium (1% sodium, 270 mg, 38.9 mmol) in dry ether (50 mL). The mixture was refluxed for three hours under nitrogen at which time little reaction (as indicated by dissolution of lithium) was evident. Extra lithium (200 mg, 28.8 mmol) was added and the mixture was stirred overnight. Aldehyde **21** (2.28 g, 7.45 mmol) in dry ether (10 mL) was added in one portion and the mixture was stirred for one hour. Saturated ammonium chloride (50 mL) was added and the products were extracted into ether (2 × 100 mL). After drying over magnesium sulfate, filtration, and concentration, the crude product was chromatographed (Skellysolve B – ether, 1 : 1; 150 g of silica gel) affording recovered starting material **21** (210 mg) and product **23** (391 mg, 15%) as a yellow oil; ir ($CHCl_3$ cast): 3400 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.4–1.8 (6H, m, 3 × CH_2), 1.84 (3H, d (3 Hz), $CH_3C{\equiv}C$), 2.34 (3H, s, $ArCH_3$), 2.48 (3H, s, $ArCH_3$), 3.02 (2H, t (7 Hz), $ArCH_2CH_2$), 3.40 (3H, s, CH_3O), 3.5 (2H, m, CH_2O), 3.77 (2H, t (7 Hz), $ArCH_2CH_2$), 4.32 (1H, d (11 Hz), CH_2OCH_3), 4.60 (1H, bs, CH), 5.26 (1H, d (11 Hz), CH_2OCH_3), 5.85 (1H, bs, CHOH), 6.98 (1H, s, ArH); ms *m/e* calcd. for $C_{21}H_{30}O_4$ (M^+): 346.2144; found: 346.2142 (1), 85 (100).

*1-((3-(2-Hydroxyethyl)-6-methoxymethyl-2,4-dimethyl)phenyl)-1-methoxy-2-butyne (**23**a)*

A solution of compound **23** (106 mg, 0.306 mmol) and pyridinium tosylate (50 mg, 0.199 mmol) in methanol (5 mL) was stirred overnight at room temperature. Methanol was removed *in vacuo*, the residue was dissolved in chloroform (100 mL) and washed with water (10 mL). After drying over magnesium sulfate, filtration and concentration gave **23***a* (82 mg, 97%) as an oil; ir (film): 3400 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.83 (3H, d (3 Hz), $CH_3C{\equiv}C$), 2.32 (3H, s, $ArCH_3$), 2.50 (3H, s, $ArCH_3$), 2.95 (2H, t (7 Hz), CH_2CH_2O), 3.33 (3H, s, CH_3O), 3.36 (3H, s, CH_3O), 3.67 (2H, t (7 Hz), CH_2CH_2O), 4.44 (1H, d (11 Hz), CH_2OCH_3), 4.60 (1H, d (11 Hz), CH_2OCH_3), 5.38 (1H, q (3 Hz), HCO), 7.00 (1H, s, ArH); ^{13}C nmr ($CDCl_3$) δ: 3.8, 16.2, 20.3, 56.2, 57.9 (CH_3); 33.2, 61.3, 73.1 (CH_2); 69.2, 129.5 (CH); 83.0, 108.4, 134.1, 134.2, 136.0, 136.7, 136.9 (C); ms *m/e* calcd. for $C_{17}H_{24}O_3$ (M^+): 276.1725; found: 276.1734 (2), 229 (100), 214 (32), 213 (22), 201 (33), 183 (21).

*1-((3-(2-(Tetrahydro-2*H*-pyran-2-yl)oxyethyl)-6-methoxymethyl-2,4-dimethyl)phenyl)-2-methyl-2-propen-1-ol (**22**)*

A solution of freshly distilled 2-bromopropene (7.1 mL, 9.67 g, 79.9 mmol) and 1,2-dibromoethane (0.9 mL, 1.96 g, 10.4 mmol) in dry tetrahydrofuran (30 mL) was added dropwise over a 30 min period to a magnetically stirred suspension of magnesium powder (2.20 g, 90.5 mmol) in dry tetrahydrofuran (10 mL) under a nitrogen atmosphere. The addition of the bromide solution caused vigorous boiling. Reflux was maintained for two hours after the addition was complete. The mixture was cooled to 0°C and then a solution of aldehyde **21** (5.00 g, 16.4 mmol) in dry tetrahydrofuran (30 mL) was added in one portion. The mixture was warmed to room temperature and then refluxed for two hours. The mixture was carefully poured over crushed ice (~500 g) and the products were isolated by ether extraction (5 × 100 mL). After drying over magnesium sulfate, filtration and concentration gave a brown oil (7.6 g). Flash chromatography (Skellysolve B – ethyl acetate, 5 : 1) afforded pure carbinol **22** (4.56 g, 80%) as a clear oil; ir ($CHCl_3$ cast): 3420, 1650, 900 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.4–1.8 (6H, m, 3 × CH_2), 1.56 (3H, bs, vinyl CH_3), 2.30 (3H, s, $ArCH_3$), 2.36 (3H, s, $ArCH_3$), 2.98 (2H, t (7 Hz), $ArCH_2CH_2$), 3.26 (3H, s, CH_3O), 3.5 (2H, m, CH_2O), 3.72 (2H, t (7 Hz), $ArCH_2CH_2$), 4.11 (1H, d (11 Hz), CH_2OCH_3), 4.56 (1H, bs, CH), 4.75 (1H, d (11 Hz), CH_2OCH_3), 4.93 (1H, bs, vinyl H), 5.08 (1H, bs, vinyl H), 5.47 (1H, bs, HCOH), 6.91 (1H, s, ArH); ms *m/e* calcd. for $C_{21}H_{34}O_4$ (M^+): 348.2301; found: 348.2295 (2), 214 (46), 199 (57), 85 (100).

*1-((3-(2-Hydroxyethyl)-6-methoxymethyl-2,4-dimethyl)phenyl)-2-methyl-2-propen-1-ol (**22**a)*

A solution of tetrahydropyranyl ether **22** (890 mg, 2.56 mmol) and pyridinium tosylate (500 mg, 2 mmol) in water–tetrahydrofuran (1 : 2, 30 mL) was refluxed overnight. Most of the tetrahydrofuran was removed *in vacuo*, water (15 mL) was added, and the product was isolated by chloroform extraction (5 × 20 mL). After drying over magnesium sulfate, filtration and concentration gave diol **22***a* (657 mg, 97%). Evaporative distillation (100–120°C, 0.017 Torr) of a small sample (80 mg) afforded analytically pure material; ir ($CHCl_3$ cast): 3380, 1650, 900 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.56 (3H, bs, vinyl CH_3), 2.26 (3H, s, $ArCH_3$), 2.32 (3H, s, $ArCH_3$), 2.90 (2H, t (7 Hz), CH_2CH_2O), 3.29 (3H, s, CH_3O), 3.63 (2H, t (7 Hz), CH_2CH_2O), 4.12 (1H, d (11 Hz), CH_2O), 4.73 (1H, d (11 Hz), CH_2O), 4.93 (1H, bs, vinyl H), 5.08 (1H, bs, vinyl H), 5.46 (1H, bs, HCOH), 6.91 (1H, s, ArH); ms *m/e* calcd. for $C_{16}H_{24}O_3$ (M^+): 264.1725; found: 264.1735 (4), 232 (100), 217 (85), 201 (67), 199 (25), 191 (66). *Anal.* calcd. for $C_{16}H_{24}O_3$: C 72.69, H 9.15; found: C 72.75, H 8.97.

*Direct Conversion of Bromide **18**a to Alcohol **22***

A solution of *n*-butyllithium (1.6 *M* in hexane, 10.6 mL, 17 mmol) in dry tetrahydrofuran (20 mL) was cooled to −78°C under nitrogen. A solution of bromide **18***a* (5.71 g, 16 mmol) in dry tetrahydrofuran (20 mL) was added and the mixture was stirred at −78°C for one hour. Freshly distilled methacrolein (6.6 mL, 5.6 g, 80 mmol) was added in one portion and the cooling bath was removed. The mixture was stirred at room temperature for five hours whereupon water (100 mL) was added. The organic layer was removed and the aqueous phase was extracted with ether (5 × 40 mL). The combined organic solutions were washed with brine (20 mL) and dried over sodium sulfate. Filtration and concentration gave a yellow oil (8.8 g) which was purified by flash chromatography (Skellysolve B – ethyl acetate, 5 : 1) affording alcohol **22** (1.38 g, 25%).

*Cybrodol Methyl Ether (**26**, 3-((3-(2-Hydroxyethyl)-6-methoxymethyl-2,4-dimethyl)phenyl)-2-methyl-(E)-2-propen-1-ol) and Isocybrodol Methyl Ether (**27**, 4-(2-Hydroxyethyl)-2-(3-methoxy-2-methyl-(Z)-1-propenyl)-3,5-dimethylbenzyl Alcohol)*

A mixture of alcohol **22** (610 mg, 1.75 mmol), 0.3 *M* aqueous sulfuric acid (16 mL), and acetone (24 mL) was heated at reflux for 7 h and then diluted with saturated aqueous sodium carbon-

For personal use only.

ate (50 mL). The products were extracted into methylene chloride (5 × 25 mL), the organic extracts were dried over sodium sulfate, filtered, and evaporated to dryness. Flash chromatography of the residue (methylene chloride – methanol, 50:1; 3 cm column) gave isocybrodol methyl ether (**27**, 152 mg) and cybrodol methyl ether (**26**, 158 mg) as yellow oils (67% combined yield). An analytically pure sample of **26** was obtained by evaporative distillation (130–140°C, 0.027 Torr). Compound **27** has the following physical properties: ir ($CHCl_3$ cast): 3350, 1680 (2), 880 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.00 (3H, d (1 Hz), vinyl CH_3), 2.19 (3H, s, $ArCH_3$), 2.38 (3H, s, $ArCH_3$), 2.99 (2H, t (7 Hz), CH_2CH_2O), 3.21 (3H, s, CH_3O), 3.48 (1H, d (11 Hz), CH_2OCH_3), 3.68 (1H, d (11 Hz), CH_2OCH_3), 3.76 (2H, t (7 Hz), CH_2CH_2O), 4.34 (1H, d (12 Hz), $ArCH_2OH$), 4.56 (1H, d (12 Hz), $ArCH_2OH$), 6.37 (1H, bs, vinyl H), 7.11 (1H, s, ArH); ms *m/e* calcd. for $C_{16}H_{24}O_3$ (M^+): 264.1725; found: 264.1723 (5), 232 (26), 219 (100), 217 (42), 202 (21), 201 (53), 197 (30), 191 (35), 187 (28), 183 (21), 171 (27), 157 (23).

Compound **26** has the following physical properties: ir ($CHCl_3$ cast): 3350, 1680 (2), 870 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.44 (3H, d (1 Hz), vinyl CH_3), 2.20 (3H, s, $ArCH_3$), 2.37 (3H, s, $ArCH_3$), 2.99 (2H, t (7 Hz), CH_2CH_2O), 3.34 (3H, s, CH_3O), 3.74 (2H, t (7 Hz), CH_2CH_2O), 4.3 (4H, bs, 2 × CH_2O), 6.38 (1H, bs, vinyl H), 7.08 (1H, s, ArH); ms *m/e* calcd. for $C_{16}H_{24}O_3$ (M^+): 264.1725; found: 264.1730 (5), 233 (33), 232 (74), 217 (60), 201 (100), 199 (29), 187 (36), 183 (22), 171 (35), 157 (27). *Anal.* calcd. for $C_{16}H_{24}O_3$: C 72.69, H 9.15; found: C 72.35, H 9.39.

4-(2-Acetoxyethyl)-2-(3-methoxy-2-methyl-(Z)-1-propenyl)-3,5-dimethylbenzyl Acetate (27a)

Alcohol **27** (222 mg, 0.84 mmol), acetic anhydride (10 mL), and pyridine (10 mL) were stirred overnight at room temperature. Concentration under high vacuum gave compound **27a** (287 mg, 98%) as a yellow oil; ir ($CHCl_3$ cast): 1740 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.95 (3H, d (1 Hz), vinyl CH_3), 2.06 (3H, s, OAc), 2.08 (3H, s, OAc), 2.21 (3H, s, $ArCH_3$), 2.37 (3H, s, $ArCH_3$), 3.01 (2H, t (7 Hz), CH_2CH_2O), 3.15 (3H, s, CH_3O), 3.59 (2H, s, CH_2O), 4.14 (2H, t (7 Hz), CH_2CH_2O), 4.85 (1H, d (12 Hz), $ArCH_2O$), 5.01 (1H, d (12 Hz), $ArCH_2O$), 6.25 (1H, bs, vinyl H), 7.02 (1H, s, ArH); ms *m/e* calcd. for $C_{20}H_{28}O_5$ (M^+): 348.1937; found: 348.1944 (1), 288 (49), 273 (23), 213 (41), 201 (22), 199 (22), 197 (100), 196 (87), 185 (21), 183 (43), 181 (21).

4-(2-Hydroxyethyl)-2-(3-methoxy-2-methyl-(Z)-1-propenyl)-3,5-dimethylbenzaldehyde (28)

Isocybrodol methyl ether (**27**, 27 mg, 0.10 mmol) and activated manganese dioxide (500 mg, 5.7 mmol) in methylene chloride (10 mL) were stirred for two hours at room temperature. The mixture was filtered through Celite and the filter cake was washed with ether (5 × 50 mL). The combined filtrates were concentrated and the residue was purified by flash chromatography (methylene chloride – methanol, 100:1; 1 cm column) affording **28** as a clear oil (25 mg, 93%); uv (CH_3OH) λ_{max}: 208, 266, 310 nm; ir ($CHCl_3$ cast): 3440, 1684 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.01 (3H, d (1 Hz), vinyl CH_3), 2.25 (3H, s, $ArCH_3$), 2.40 (3H, s, $ArCH_3$), 3.04 (2H, t (7 Hz), CH_2CH_2O), 3.10 (3H, s, CH_3O), 3.58 (2H, bs, CH_2OCH_3), 3.76 (2H, t (7 Hz), CH_2CH_2O), 6.47 (1H, bs, vinyl H), 7.60 (1H, s, ArH), 9.38 (1H, s, CHO); ms *m/e* calcd. for $C_{16}H_{22}O_3$ (M^+): 262.1569; found: 262.1568 (3), 217 (100).

Attempted Demethylation of 27 with Ethanedithiol

Isocybrodol methyl ether (**27**, 16.8 mg, 0.064 mmol) and boron trifluoride etherate (30 μL, 34 mg, 0.24 mmol) in ethanedithiol (0.5 mL) were stirred at room temperature for four days. The solution was diluted with brine (10 mL) and extracted with methylene chloride (3 × 10 mL). The combined organic solutions were washed with 20% aqueous sodium hydroxide (2 × 10 mL), brine (10 mL), and dried over sodium sulfate. Filtration and concentration gave a foul smelling oil which was subjected to ptlc (benzene–ether, 1:3) affording 5-(2-hydroxyethyl)-4,6,10-trimethyl-2*H*-benzothiapin (**30**) as a clear oil (10 mg, 63%); ir ($CHCl_3$ cast): 3360 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.06 (3H, d (1 Hz), vinyl CH_3), 2.20 (3H, s, $ArCH_3$), 2.34 (3H, s, $ArCH_3$), 2.81 (2H, s, CH_2S), 2.96 (2H, t (7 Hz), CH_2CH_2O), 3.43 (2H, s, $ArCH_2S$), 3.74 (2H, t (7 Hz), CH_2CH_2O), 6.34 (1H, s vinyl H), 6.93 (1H, s, ArH); ms *m/e* calcd. for $C_{15}H_{20}OS$ (M^+): 248.1235; found: 248.1232 (78), 233 (22), 217 (13), 207 (100). Chemical ionization (NH_3) ms shows a peak at *m/e* 266 (M + 18).

Cybrodol (1, 3-((3-(2-Hydroxyethyl)-6-hydroxymethyl-2,4-dimethyl)phenyl)-2-methyl-(E)-2-propen-1-ol) and Isocybrodol (2, 3-((3-(2-Hydroxyethyl)-6-hydroxymethyl-2,4-dimethyl)phenyl)-2-methyl-(Z)-2-propen-1-ol)

A solution of alcohol **27**[5] (201 mg, 0.76 mmol) and ferric chloride (100 mg, 0.62 mmol) in acetic anhydride (5 mL) was stirred for 18 h at room temperature. The mixture was diluted with water (50 mL) and then extracted with methylene chloride (5 × 20 mL). In a preliminary experiment (88 mg of **26**) the methylene chloride extracts were dried over sodium sulfate, filtered, and concentrated. Flash chromatography (Skellysolve B – acetone, 8:1; 1 cm column) gave an inseparable mixture of triacetylcybrodol (**1a**) and triacetylisocybrodol (**2a**, 98 mg total, 78%). The relative proportions were 78:22 in favor of the *E* isomer **1a** as determined by ^1H nmr. Normally, however, the wet methylene chloride extracts were taken to dryness under high vacuum and then dissolved in methanol (10 mL). Potassium carbonate (1 g) was added and the mixture was stirred at room temperature overnight. The volatiles were removed *in vacuo* and the residue was partitioned between ethyl acetate (50 mL) and water (10 mL). The organic phase was dried over sodium sulfate, filtered, and concentrated. Flash chromatography (methylene chloride – methanol, 20:1; 2 cm column) gave isocybrodol (**2**, 32 mg) and cybrodol (**1**, 111 mg, 75% combined overall yield) as oils. These materials were identical in all respects (tlc, ir, ^1H nmr, ms) with the natural products. Synthetic cybrodol (**1**) was crystallized (chloroform–methanol, 50:1) affording white prisms, mp 109–110°C. Synthetic isocybrodol (**2**) was crystallized (acetone – Skellysolve B) affording white prisms, mp 101–102°C. Analytically pure samples of both compounds were prepared by evaporative distillation (140–160°C, 0.025 Torr). Cybrodol (**1**), *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 72.27, H 9.08. Isocybrodol (**2**), *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 72.21, H 9.09.

Allylic Rearrangement of 22 with Ferric Chloride in Acetic Anhydride

A solution of alcohol **22** (103 mg, 0.39 mmol) and ferric chloride (50 mg, 0.31 mmol) in acetic anhydride (5 mL) was stirred for 18 h at room temperature. This reaction mixture was treated in exactly the same fashion as the previous one. In this instance, after deacetylation and flash chromatography, isocybrodol (**2**, 15.3 mg) and cybrodol (**1**, 34.3 mg, combined overall yield of 51%) were obtained as oils.

3-((3-(2-Acetoxyethyl)-6-bromomethyl-2,4-dimethyl)phenyl)-2-methyl-(Z)-2-propenyl Bromide (31) and 3-((3-(2-Acetoxyethyl)-6-bromomethyl-2,4-dimethyl)phenyl)-2-methyl-(E)-2-propenyl Bromide (31a)

A solution of boron tribromide (200 mg, 0.80 mmol) in dry methylene chloride (1 mL) was added to a solution of diacetyl methyl ether **27** (105 mg, 0.30 mmol) in dry methylene chloride (12 mL) at −20°C. The mixture was stirred under nitrogen at −20°C for one hour and then diluted with saturated aqueous

[5]Compound **26** or mixtures of compounds **26** and **27** may be used with the same results.

For personal use only.

sodium carbonate (20 mL). The organic layer was removed and the aqueous residue was extracted with methylene chloride (3 × 20 mL). The combined extracts were dried over sodium sulfate, filtered, and concentrated leaving dibromide **31** as an orange oil (114 mg, 86%). This material contained a small amount (< 5%) of isomer **31***a* as judged by ^{1}H nmr. In a preliminary experiment, the reaction was conducted at 0°C resulting in the production of **31** and **31***a* in a 3 : 1 ratio as determined by ^{1}H nmr. Compounds **31** and **31***a* have practically identical tlc characteristics, however, careful ptlc (Skellysolve B – acetone, 20 : 1; double elution) of this 3 : 1 mixture did allow isolation of sufficient quantities for spectral analysis of each compound (brownish oils). Compound **31** has the following physical properties: ir ($CHCl_3$ cast): 1740, 1240, 605 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.05 (3H, s, OAc), 2.10 (3H, d (1 Hz), vinyl CH_3), 2.23 (3H, s, $ArCH_3$), 2.35 (3H, s, $ArCH_3$), 3.00 (2H, t (7 Hz), CH_2CH_2O), 3.70 (2H, s, CH_2Br), 4.14 (2H, t (7 Hz), CH_2CH_2O), 4.29 (1H, d (11 Hz), $ArCH_2Br$), 4.46 (1H, d (11 Hz), $ArCH_2Br$), 6.35 (1H, bs, vinyl H), 7.07 (1H, s, ArH); ms *m/e* calcd. for $C_{17}H_{22}O_2{}^{81}Br$ (M − Br, parent ion not seen): 339.0783; found: 339.0802 (1); calcd. for $C_{17}H_{22}O_2{}^{79}Br$ (M − Br): 337.0803; found: 337.0799 (1), 217 (100). Compound **31***a* has the following physical properties: ir ($CHCl_3$ cast): 1740, 1240, 605 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.60 (3H, d (1 Hz), vinyl CH_3), 2.05 (3H, s, OAc), 2.20 (3H, s, $ArCH_3$), 2.36 (3H, s, $ArCH_3$), 3.00 (2H, t (7 Hz), CH_2CH_2O), 4.14 (2H, t (7 Hz), CH_2CH_2O), 4.17 (2H, s, CH_2Br), 4.35 (2H, s, $ArCH_2Br$), 6.60 (1H, bs, vinyl H), 7.07 (1H, s, ArH); ms *m/e* calcd. for $C_{17}H_{22}O_2{}^{81}Br$ (M − Br, parent ion not seen): 339.0783; found: 339.0786 (77); calcd. for $C_{17}H_{22}O_2{}^{79}Br$ (M − Br): 337.0803; found: 337.0806 (79), 279 (99), 277 (100), 257 (38), 215 (27), 198 (92), 197 (76), 185 (63), 184 (42), 183 (53), 171 (47), 170 (34), 169 (38), 156 (31), 155 (45), 153 (20), 141 (23), 128 (20), 87 (30).

*Conversion of Dibromide **31** to Triacetylisocybrodol (**1**a)*

A solution of dibromide **31** (109 mg, 0.25 mmol) and tetraethylammonium acetate (500 mg, 2.7 mmol) in acetone (10 mL) was refluxed for one hour and then taken to dryness. The residue was dissolved in ether (50 mL), washed with water (10 mL) and brine (10 mL), and then dried over magnesium sulfate. Filtration and concentration gave triacetylisocybrodol (**2***a*, 91 mg, 97%). This material was deacetylated in the usual fashion and the product was purified by flash chromatography. In this way, isocybrodol (**2**, 55 mg) plus a small amount of cybrodol (**1**, 3 mg) were obtained.

*3-((3-(2-Hydroxyethyl)-6-methoxymethyl-2,4-dimethyl)phenyl)-2-methyl-(E)-2-propenal (**32**)*

Cybrodol methyl ether (**26**, 104 mg, 0.39 mmol) and activated manganese dioxide (622 mg, 7.1 mmol) in methylene chloride (10 mL) were stirred overnight at room temperature. The mixture was filtered through Celite, the filter cake was washed with methylene chloride (5 × 10 mL), and the combined filtrates were concentrated, leaving aldehyde **32** (103 mg, 100%) as a clear oil; ir ($CHCl_3$ cast): 3460, 2850, 1687, 1640 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.57 (3H, d (1 Hz), vinyl CH_3), 2.18 (3H, s, $ArCH_3$), 2.38 (3H, s, $ArCH_3$), 3.00 (2H, t (7 Hz), CH_2CH_2O), 3.33 (3H, s, CH_3O), 3.74 (2H, t (7 Hz), CH_2CH_2O), 4.20 (2H, s, CH_2O), 7.12 (1H, s, ArH), 7.46 (1H, bs, vinyl H), 9.79 (1H, s, CHO); ms *m/e* calcd. for $C_{16}H_{22}O_3$ (M^+): 262.1571; found: 262.1597 (0.3), 217 (100).

*Methyl 3-((3-(2-Hydroxyethyl)-6-methoxymethyl-2,4-dimethyl)phenyl)-2-methyl-(E)-2-propenoate **4**a*

A mixture of aldehyde **32** (98 mg, 0.37 mmol), acetic acid (50 μL, 52 mg, 0.87 mmol), sodium cyanide (50 mg, 1 mmol), and activated manganese dioxide (1.4 g, 16 mmol) in methanol (10 mL) was stirred at room temperature for two days. The mixture was filtered through Celite and the filter cake was washed with ether (5 × 50 mL). The combined filtrates were washed with saturated aqueous sodium carbonate (20 mL), water (20 mL), and brine (20 mL). After drying over sodium sulfate, filtration and concentration gave methyl ester **4***a* (103 mg, 95%) as a clear oil; ir ($CHCl_3$ cast): 3400, 1720, 1640 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.65 (3H, d (1 Hz), vinyl CH_3), 2.18 (3H, s, $ArCH_3$), 2.38 (3H, s, $ArCH_3$), 2.98 (2H, t (7 Hz), CH_2CH_2O), 3.35 (3H, s, CH_3O), 3.74 (2H, t (7 Hz), CH_2CH_2O), 3.82 (3H, s, CO_2CH_3), 4.22 (2H, s, CH_2O), 7.11 (1H, s, ArH), 7.64 (1H, bs, vinyl H); ms *m/e* calcd. for $C_{17}H_{24}O_4$ (M^+): 292.1674; found: 292.1670 (1), 260 (56), 247 (32), 229 (100), 201 (29), 171 (25).

*Methyl 3-((3-(2-Acetoxyethyl)-6-acetoxymethyl-2,4-dimethyl)phenyl)-2-methyl-(E)-2-propenoate (**4**b)*

A solution of ester **4***a* (50 mg, 0.17 mmol) and ferric chloride (50 mg, 0.31 mmol) in acetic anhydride (5 mL) was stirred for two hours at room temperature. The reaction mixture was diluted with water (20 mL) and the product was extracted into methylene chloride (5 × 10 mL). After the solution was washed and dried over sodium sulfate, filtration and concentration gave crude **4***b* (65 mg) as a brown oil. Flash chromatography (Skellysolve B – ethyl acetate, 3 : 1; 1 cm column) gave pure **4***b* as a clear oil (48 mg, 77%); ir ($CHCl_3$ cast): 1740, 1720 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.65 (3H, d (1 Hz), vinyl CH_3), 2.05 (3H, s, OAc), 2.06 (3H, s, OAc), 2.20 (3H, s, $ArCH_3$), 2.39 (3H, s, $ArCH_3$), 3.03 (2H, t (7 Hz), CH_2CH_2O), 3.82 (3H, s, CO_2CH_3), 4.15 (2H, t (7 Hz), CH_2CH_2O), 4.90 (2H, bs, CH_2O), 7.07 (1H, s, ArH), 7.63 (1H, bs, vinyl H); ms *m/e* calcd. for $C_{20}H_{26}O_6$ (M^+): 362. 1729; found: 362.1719 (13), 302 (48), 289 (37), 288 (23), 259 (26), 243 (38), 242 (61), 229 (43), 228 (36), 227 (22), 215 (26), 201 (23), 200 (23), 199 (62), 183 (100), 171 (22), 151 (23).

*Cybrodic Acid (**4**, 3-((3-(2-Hydroxyethyl)-6-hydroxymethyl-2,4-dimethyl)phenyl)-2-methyl-(E)-2-propenoic Acid)*

A mixture of ester **4***b* (88 mg, 0.24 mmol), potassium hydroxide (1.2 g, 21 mmol), water (4 mL), and methanol (8 mL) was heated at reflux for 90 min. The solution was cooled to 0°C and acidified (~pH 1) with concentrated sulfuric acid. Brine (100 mL) was added and the product was isolated by ethyl acetate extraction (5 × 30 mL). The combined extracts were dried over sodium sulfate, filtered, and concentrated, leaving crude acid **4** (63 mg, 97%) as a brown oil which on prolonged refrigeration in acetone (2 mL) gave crystalline cybrodic acid (**4**, mp 179–180°C). This material was identical with the natural acid by the following criteria: mp, tlc, ir, ^{1}H nmr, and ms. Sublimation (160°C, 0.025 Torr) of the crystalline synthetic acid afforded an analytically pure sample. *Anal.* calcd. for $C_{15}H_{20}O_4$: C 68.16, H 7.63; found: C 68.18, H 7.62.

Activation parameters for transport and thermal expansion

ROBERT A. STAIRS

Department of Chemistry, Trent University, Peterborough, Ont., Canada K9J 7B8

Received November 11, 1980

ROBERT A. STAIRS. Can. J. Chem. **59**, 2170 (1981).

A correlation is proposed between the ratios: $Y = \pi\Delta V^{\ddagger}/E_{(p)}{}^{\ddagger}$ (where π is the internal pressure of a liquid, $\Delta V^{\ddagger}$ the volume of activation $RT(\partial \ln \eta/\partial p)_T$, and $E_{(p)}{}^{\ddagger}$ the activation energy at constant pressure for viscous flow, or the corresponding quantities for diffusion) and $X = E_{(p)}{}^{\ddagger}/E_\rho$ (where E_ρ is the "energy of thermal expansion", defined by: $-R[\partial \ln(\rho^{-1} - \rho_0{}^{-1})/\partial T^{-1}]_p$). The first, Y, involves quantities measured at high pressures, while X requires only measurements at ordinary pressure. The correlation will permit estimation of viscosities and diffusion coefficients at high pressures from low-pressure measurements.

ROBERT A. STAIRS. Can. J. Chem. **59**, 2170 (1981).

On propose une corrélation entre les raisons: $Y = \pi\Delta V^{\ddagger}/E_{(p)}{}^{\ddagger}$ (où π est la pression intèrnelle d'une liquide, $\Delta V^{\ddagger}$ est la volume d'activation, $RT(\partial \ln \eta/\partial p)_T$, et $E_{(p)}{}^{\ddagger}$ l'énergie d'activation à pression constante pour l'écoulement visqueux, ou les quantités correspondantes pour la diffusion) et $X = E_{(p)}{}^{\ddagger}/E_\rho$ (où E_ρ est "l'énergie d'expansion thermique", défini par: $-R[\partial \ln(\rho^{-1} - \rho_0{}^{-1})/\partial T^{-1}]_p$). La première, Y, comprend des propriétés qu'il faut mesurer à haute pression, mais X demande les mesures à la pression ordinaire seulement. La corrélation permettera l'estimation des viscosités et des coefficients de diffusion à haute pression à partir des mesures prises à basse pression.

Experiments conducted at high pressures are notoriously difficult and, therefore, expensive. It is highly desirable to be able to predict the results of high-pressure measurements using data obtained at low pressures only, using a reliable method of extrapolation. It would be better still if measurements at a single pressure, specifically at 1 atm, could be used for such predictions. For instance, knowledge of the dependence of viscosity of a liquid on pressure, especially at high pressures, is required in the study of convection in the Earth's mantle, of the movement of deep groundwater and of deep ocean currents. The measurement of viscosity as a function of temperature over moderate ranges at ordinary pressure is easy, but measurement of viscosity at extreme pressures is particularly difficult. High-pressure diffusion measurements are only a little easier.

Isobaric viscosity has in the past been considered from the points of view of the transition-state theory (1, 2) and of the free-volume theory (3, 4). Each has proponents claiming good fits of the data by their favoured equations, viz.

$$[1] \quad \ln \eta = \ln \eta^* + E_{(p)}{}^{\ddagger}/RT$$

and

$$[2a] \quad \eta^{-1} = B(V - V_0)/V_0$$

$$[2b] \quad = b(\rho^{-1} - \rho_0{}^{-1})$$

(In these equations η is viscosity, η^* a constant, $E_{(p)}{}^{\ddagger}$ is the energy of activation at constant pressure, R and T have their usual significance, B and b are empirical constants, V is the molar volume measured at the same temperature as η, V_0 is a constant, the intrinsic volume, and ρ and ρ_0 are the corresponding densities.)

For most non-associated liquids, not too close either to their critical temperatures or their freezing points, both equations are in fact very good, though Davies and Matheson (5) point out that with non-spherical molecules departures from both equations occur as rotation becomes restricted near the freezing point. Cleaver (6) and Macedo and Litovitz (7) have drawn attention to the role played by the volume of activation in viscosity and other transport properties of liquids of different types and suggest that, at low pressures,

$$E_{(p)}{}^{\ddagger} = E_{(v)}{}^{\ddagger} + (\alpha T/\beta)\Delta V^{\ddagger}$$
$$= E_{(v)}{}^{\ddagger} + \pi\Delta V^{\ddagger}$$

where $E_{(p)}{}^{\ddagger}$ and $E_{(v)}{}^{\ddagger}$ are the energies of activation at constant pressure and constant volume, α is the thermal coefficient of expansion, β the compressibility, π the internal pressure and $\Delta V^{\ddagger}$ the volume of activation, $RT[\partial \ln \eta/\partial p]_T$. That is to say, the empirical activation energy as usually measured at constant pressure consists of an energy apparently needed to create volume in order to permit flow, and another energy term, the origin of which Cleaver prudently leaves unspecified, "until an adequate theory of the liquid state is available". For most molecular liquids, the term $\pi\Delta V^{\ddagger}$ is a large fraction of $E_{(p)}{}^{\ddagger}$, i.e. $\pi\Delta V^{\ddagger} > E_{(v)}{}^{\ddagger}$. Flow in such liquids is described (6) as "volume restrained".

For some of these liquids, e.g. CCl_4, the term $E_{(v)}{}^{\ddagger}$ is very small. In these cases, one may make a connection between eqs. [1] and [2] by assuming a van't Hoff type dependence of free volume on temperature:

$$[3a] \quad \ln\left(\frac{V - V_0}{V_0}\right) = A - E_\rho/RT$$

*See footnote to Table 1.
†I have followed Cleaver (6) in using one set of data, for gallium, based on diffusion, since mercury is the only liquid in the "energy restrained" class for which data for viscosity as a function of pressure seem to be available.
‡Inferred from ref. 14.

or

$$[3b] \quad \ln(\rho^{-1} - \rho_0{}^{-1}) = a - E_\rho/RT$$

The "expansion energy" E_ρ represents work done against the internal pressure π, or if the external pressure is not small, against $\pi + P$, to create the volume needed for flow. (This terminology is loose (6, 8) but useful.) At low pressure it should be at least approximately equal to $\pi\Delta V^\ddagger$.

If one converts eq. [2a] into logarithmic form, and replaces $\ln[(V - V_0)/V_0]$ by the appropriate expression from eq. [3a], the result is of the form of eq. [1], with E_ρ in the place of $E_{(p)}{}^\ddagger$. Thus, it is suggested that for a "normal", molecular liquid, $E_{(p)}{}^\ddagger$, $\pi\Delta V^\ddagger$ and E_ρ should all be about equal.

For the other class of liquids, exemplified here by mercury and gallium, $\pi\Delta V^\ddagger$ is a small fraction of $E_{(p)}{}^\ddagger$. For these a mechanism must exist that does not require creation of free volume, but is more directly dependent on the availability of energy $E_{(v)}{}^\ddagger$. These liquids are termed "energy restrained" (6). For them the above analysis will fail.

The "expansion energy" E_ρ should be derived from fit of eqs. [3a], [3b] to molar volume or density data. Unfortunately it is not in a form convenient for least-squares fitting. Sets of three points, however, may be used to find values for ρ_0, by the requirement that the slope of the graph of $\ln(\rho^{-1} - \rho_0{}^{-1})$ vs. T^{-1} be constant. An average value may then be calculated. The other constants may then be found in a straightforward manner. Table 1 contains the results of applying this procedure to a number of liquids, chosen from Cleaver's "volume restrained" and "energy restrained" groups (see second footnote to Table 2). As the values of s_ρ, the standard error of estimate of density, indicate, the fit of eq. [3b] to the data is within or close to the claimed experimental error (judging by the number of significant figures in the sources) in all cases. For the "volume restrained" liquids, E_ρ is approximately equal to $\pi\Delta V^\ddagger$, and is only a little less than $E_{(p)}{}^\ddagger$ as may be seen in Table 2 and Fig. 1. (Omitting cyclohexane, the average ratios are $\pi\Delta V^\ddagger/E_\rho = 0.93 \pm 0.09$ and $E_\rho/E_{(p)}{}^\ddagger = 0.84 \pm 0.04$.). For these liquids, therefore, it is no surprise that they follow both the Arrhenius and the Batschinski–Hildebrand equations for viscosity. The other liquids, however, show another aspect. Each value of E_ρ, rather than being similar to $\pi\Delta V^\ddagger$ and smaller than $E_{(p)}{}^\ddagger$ is larger even than the latter quantity. The mechanistic implications of these facts seem to be that, on one hand, if creation of holes in the liquid of near-molecular size is relatively easy, then molecules can slip into these holes with little additional energy being required. On the other hand, if there exists a mode of flow that avoids the creation of

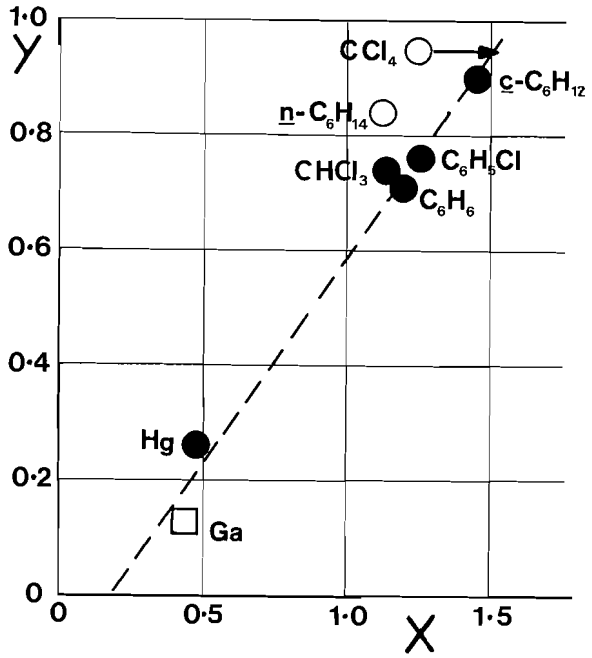

FIG. 1. Comparison of transport and expansion parameters. The ratios $Y = \pi\Delta V^{\ddagger}/E_{(p)}^{\ddagger}$ and $X = E_{(p)}^{\ddagger}/E_{\rho}$ as ordinate and abscissa. The square represents the self-diffusion of gallium, the circles viscosity data. The dashed line was drawn omitting the two open circles: the point for *n*-hexane because it was the only non-globular molecule, and the point for carbon tetrachloride because it was too uncertain (see footnote to Table 1).

large holes, flow will occur with a small volume of activation, but the energy of activation will arise from other sources. With the metals, it seems clear that the reason for this behaviour lies in the difference between the size of the ion, which is probably the entity for which free volume must be found, and the "atom", i.e. the ion plus its share of the common cloud of electrons. For the molecular liquids, $\Delta V^{\ddagger}$ is between one sixth and one third of the molar volume. For the metals it is less than one twentieth.

A consequence of the discrepancy between E_{ρ} and $E_{(p)}^{\ddagger}$ for the "energy restrained" liquids is that they cannot obey both viscosity equations. Mercury obeys eq. [1] and eq. [3*b*] better than it does eq. [2*b*]. Elimination of T between eqs. [1] and [3*b*] with $E_{\rho} \neq E_{(p)}^{\ddagger}$ leads to

$$\eta^{-r} = c(\rho^{-1} - \rho_0^{-1})$$

where c is a constant and $r = E_{\rho}/E_{(p)}^{\ddagger}$. For mercury, r is about 2. The graph of η^{-2} vs. ρ^{-1} is a somewhat better straight line than η^{-1} vs. ρ^{-1}, though η^{-3} vs. ρ^{-1} is better still: $s_{-1} = 0.030$, $s_{-2} = 0.026$, $s_{-3} = 0.008$ (s_{-r} is the standard error of estimate for η^{-r} vs. ρ^{-1} from 0 to 300°C).

A curious feature of the values of E_{ρ} obtained is that they are all rather similar, in spite of great differences in other properties between the various liquids. The mean and standard deviation of these nine values are 7.9 ± 1.6; compared to $\overline{E_{(p)}^{\ddagger}} = 8.0 \pm 3.5$ kJ mol^{-1} and $\overline{\pi\Delta V^{\ddagger}} = 6.0 \pm 4.2$ kJ mol^{-1}.

There appears to be potential utility in the correlation of $\pi\Delta V^{\ddagger}/E_{(p)}^{\ddagger}$ with $E_{(p)}^{\ddagger}/E_{\rho}$. The latter ratio contains only quantities measurable at ordinary pressure. The former ratio contains the constant-pressure quantity $E_{(p)}^{\ddagger}$ and two quantities that are pressure-related, the internal pressure π and $\Delta V^{\ddagger}$. The calculation of π requires the compressibility β, which is, however, known for a great many substances. The correlation described here permits, therefore, the estimation of the hard-to-obtain quantity $\Delta V^{\ddagger}$, and through it the prediction of the high-pressure viscosity and diffusion behaviour. That is to say, the high-pressure transport properties are now accessible by means of low-pressure measurements plus the state properties of the liquid.

Ring size and positional constraints for μ-hydrido-bridging in dimethylcycloalkyl cations (n = 6–9)

R. P. KIRCHEN, K. RANGANAYAKULU, B. P. SINGH, AND T. S. SORENSEN[1]

The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received November 26, 1980

R. P. KIRCHEN, K. RANGANAYAKULU, B. P. SINGH, and T. S. SORENSEN. Can. J. Chem. **59**, 2173 (1981).

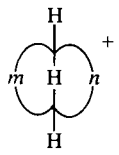
The *in situ* preparation and nmr characterization of a series of selected 1,*n*-dimethylcycloalkyl cations is reported. Both the 1,5-dimethylcyclononyl and the 1,5-dimethylcyclooctyl cations are assigned a μ-hydrido-bridged structure. However, the corresponding 1,4-dimethylcycloоctyl, 1,4-dimethylcycloheptyl, and 1,4-dimethylcyclohexyl cations are normal unbridged tertiary cations. The μ-hydrido-bridged cyclononyl cation rearranges in part to the 1-methyl-5-ethylcyclooctyl cation which is also μ-hydrido-bridged and this rearrangement can be followed by noting the disappearance of the δ −5.8 μ-H peak of the former and the appearance of a δ −6.4 μ-H peak for the latter. The 1,5-dimethylcyclooctyl cation is the most thermally stable μ-hydrido-bridged cation yet prepared and possesses a chair – twist boat (*TB*) conformation which is "frozen-out" in the nmr spectrum at −120°C. At higher temperatures one gets a chair–*TB* ⇌ *TB*–chair equilibration, $\Delta G^{\ddagger} = 30$ kJ mol^{-1} from nmr line-broadening observations.

R. P. KIRCHEN, K. RANGANAYAKULU, B. P. SINGH et T. S. SORENSEN. Can. J. Chem. **59**, 2173 (1981).

On rapporte la préparation *in situ* et l'identification à l'aide de la rmn d'une série choisie de cations diméthyl-1,*n* cycloalkyles. On attribue aux deux cations diméthyl-1,5 cyclononlye et diméthyl-1,5 cyclooctyle une structure contenant un pont μ-hydrido. Cependant les cations diméthyl-1,4 correspondants en séries cyclooctyle, cycloheptyle et cyclohexyle sont des cations tertiaires normaux n'impliquant pas de pont. Le cation cyclononyle μ-hydrido impliquant un pont se transpose en partie en cation méthyl-1 éthyl-5 cyclooctyle qui contient aussi un pont μ-hydrido; on peut suivre l'évolution de cette transposition en se basant sur la disparition à δ −5.8 du pic dû au μ-H du réactif et sur l'apparition à δ −6.4 du pic dû au μ-H du produit. Le cation diméthyl-1,5 cyclooctyle est le cation contenant un pont μ-hydrido le plus stable thermiquement à être préparé jusqu'à maintenant et il existe sous une conformation chaise bateau-croisé (*BC*) qui apparait comme figée dans le spectre rmn à − 120°C. A des températures plus élevées, on obtient un équilibre chaise–*BC* ⇌ *BC*–chaise pour lequel on a évalué le $\Delta G\ddagger$ à 30 kJ mol^{-1} à partir de l'observation de l'étalement des pics en rmn.

[Traduit par le journal]

A recent study in this laboratory involved the preparation of a series of secondary cycloalkyl cations (n = 7–11), which showed that the members from n = 8–11 could be directly observed by nmr spectroscopy and that they possess a μ-hydrido-bridged structure **1** (1, 2). However,

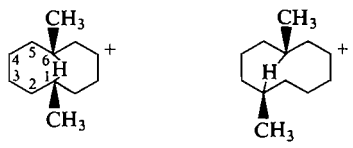


1

Cyclooctyl $n = m = 3$
Cyclononyl $n = 3$, $m = 4$
Cyclodecyl $n = 3$, $m = 5$
Cycloundecyl $n = 4$, $m = 5$ or $n = 3$, $m = 6$

these ions are not thermally very stable, the cyclononyl and cyclooctyl members, for example, collapsing very readily to the tertiary 1-methylcyclooctyl and 1-methylcycloheptyl cations, respectively (2). Attempts to prepare the secondary cycloheptyl cation were unsuccessful and only the ring-contracted 1-methylcyclohexyl cation was observed. Thus, one cannot ascertain whether or not the cycloheptyl cation is also bridged.

It is also possible to observe di-tertiary μ-hydrido-bridged cations and the 1,5- and 1,6-dimethylcyclodecyl cations **2** and **3** have been reported (3, 4). Note that even though the secondary cyclodecyl cation itself appears to favor a 1,5-bridge, it is possible by specific methyl substitution to create an "unnatural bridge", in this case between the 1- and 6-carbon positions in **3**. These di-tertiary cations are also, in general, much more stable than their secondary counterparts.



3 **2**

As part of a general characterization of these unique structures, it would be interesting to obtain crystalline salts for X-ray or neutron diffraction study and also to prepare cations which are relatively stable with respect to internal exchange of the μ-H with other hydrogens (for ir–Raman studies where one wishes to fix a μ-D atom in the cation). The previously prepared di-tertiary cyclodecyl systems **2** and **3** suffer in the above regard since these isomers readily interconvert at −100°C

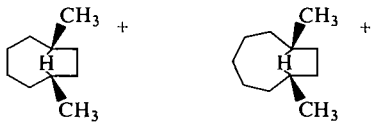
and a μ-D is even more rapidly scrambled with ring protons (these have a common origin).

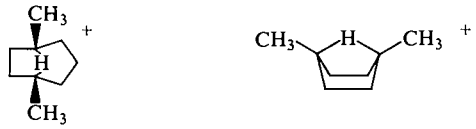
The corresponding 1,5-dimethylcyclononyl **4** and 1,5-dimethylcyclooctyl **5** cations, as yet unknown, appeared to be attractive alternatives for the above purposes since, besides the 1,5-μ-H bridge, the only bridged positional isomers which seemed remotely possible were the 1,4-dimethyl isomers **6** and **7**, and indeed these seemed unlikely.



7 **6**

In chemical reactions performed on various medium ring compounds, there are scattered reports of transannular 1,4-hydride shifts; nevertheless, ring conformational considerations certainly dictate against the possibility of an actual bridged intermediate (5).

In order to settle these questions, we set out to prepare and characterize the 1,5-dimethyl cations **4** and **5**, which we hoped would be bridged (and also relatively stable) and we have also investigated in this paper three 1,4-dimethylcycloalkyl cations, the 1,4-dimethylcyclooctyl cation **7**, the 1,4-dimethylcycloheptyl cation **8**, and the 1,4-dimethylcyclohexyl cation **9**, which are

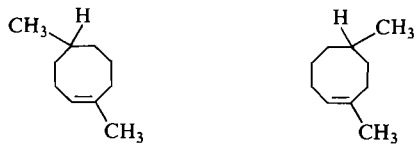


8 **9**

each shown in their possible, though seemingly improbable, μ-hydrido-bridged structures.

Results

The cations were prepared either from the tertiary alcohols, or in the case of **5** and **7**, by protonation of the alkenes **10** and **11**. Each case will be discussed separately.



10 **11**

1,5-Dimethylcyclononyl Cation

Although the nmr spectra appear at first sight to be consistent with either a normal tertiary carbocation undergoing a very rapid 1,5-hydride shift *or* a bridged structure, i.e. there are only six ^{13}C peaks, there are three crucial features which are consistent only with a μ-hydrido-bridged structure **4***a*. These criteria have been thoroughly discussed recently in connection with cyclodecyl cation systems (4) and are: (*1*) a very high field μ-hydrogen found in **4** at δ 5.8 ppm; (*2*) an abnormally small $^1H—^{13}C$ coupling constant for this μ-hydrogen, $J = 38$ Hz; and (*3*) a Saunders δ separation of only 1.5 ppm due to the isotopic perturbation caused by substitution of a single CD_3 group (structure **4***b*) (6). Pertinent nmr feature of **4***a* and **4***b* are noted with the structures. The ^1H spectrum shows the two equivalent methyls at δ 2.05, with the remaining ring protons in the range δ 1.69–2.74. The μ-hydrogen is coupled to a small extent with the methyl protons since mutual decoupling sharpens both peaks.

The assignment of peaks to the α and α′ carbons of the five- and six-membered sides in **4***a* is based on analogies with the 1,5-dimethylcyclooctyl cation (next section).

The ring conformation in **4***a* is unknown. It is not unexpected that both α′ carbons of the five-membered side are equivalent, but this is also found for the six-ring side, in contrast to the bridged 1,6-dimethylcyclodecyl cation, where a *cis*-decalin type geometry results in the nonequivalence of the two α carbons in each six-membered ring. There is a noticeable temperature dependence of the δ 33.1 ^{13}C peak assigned to the α carbons of the six-ring side in **4***a*, e.g. δ 33.1 at −110°C, but 34.4 at −92°C, with intermediate values in between, and this may indicate a shifting population consisting of several rapidly equilibrating conformers.

Cation **4** was not as stable as had been hoped for. At about −90°C, the ion begins to rearrange to produce a very complex nmr spectrum (^1H and ^{13}C), $k_{\text{loss of 4}} = 1.5 \times 10^{-3}\ s^{-1}$ at −90°C, $\Delta G^{\ddagger} = 54\ kJ\ mol^{-1}$. On the basis of work with the cyclooctyl system, one of the rearrangement products is easily identified as yet another μ-hydrido-bridged species, the 1-methyl-5-ethylcyclooctyl cation **12** and this is discussed in the following section.

1,5-Dimethylcyclooctyl Cation

This cation clearly has the μ-hydrido-bridged structure **5***a*, based on the same three criteria noted for the cyclononyl analog: (*1*) a μ-hydrogen found at δ −6.3; (*2*) an $^1H—^{13}C$ coupling constant for this μ-hydrogen of 40 Hz; and (**3**) a δ separation of 1.4–2.7 ppm on isotopic perturbation by substitution of a CD_3 group, structure **5***b* (6). Interestingly, this δ separation is temperature dependent but in the opposite sense compared to that observed for equilibrating systems. Thus, δ is 1.43 at −127°C, 1.57 at −115°C, 2.0 at −100°C, 2.35 at −85°C, and 2.7 at −75°C. Pertinent ^1H and ^{13}C nmr features of

4b

5*a* are noted with the structures. In this cation one sees the coupling between the μ-H proton and the methyl groups, J = 2.4 Hz, confirmed by decoupling experiments.

The conformation of **5***a* can be deduced because both the ^{1}H and ^{13}C nmr spectra show a very specific reversible line-broadening as the cation solution is warmed. In the ^{13}C spectrum, the only peaks affected are those assigned to the α- and β-CH_2 carbons. In the ^{1}H spectrum, these same CH_2 protons are involved but not the CH_3 signal. The ^{1}H and ^{13}C results undoubtedly have a common origin but the ^{13}C spectra are much simpler to evaluate and two extreme spectra are shown in Fig. 1. The two single intensity peaks at −120°C (frozen-out spectrum) must be from two different β-carbons. Previously, we have assigned a boat–chair conformation to the 1-methylcyclooctyl cation (7) and the present bridged ion fits this same pattern, i.e. as shown in structure **5***a*. The lower field of the two β-CH_2 carbons is assigned to the chair side on the basis of the previous work. The two sets of α-CH_2 carbons are nearly accidentally equivalent and are not resolvable into two separate peaks, although some broadening is evident.

The nmr line-broadening must be due to a conformational process which mutually interchanges these nonequivalent carbons, i.e. β = β′ and α = α′. This could involve either a *BC* (boat-chair) ⇌ [*CC*] or a BC ⇌ [*BB*] equilibrium, as shown below, with the former probably the more likely. From the coalescence temperature, $\Delta G^{\ddagger}$ for the process was determined as 30 kJ mol^{-1}.

Cation **5** is the most thermally stable μ-hydrido-bridged cation which has yet been prepared and is not rearranged/decomposed until about −60°C.

1-Methyl-5-ethylcyclooctyl Cation

As mentioned, rearrangement of **4** yields about 30% of a cation having nmr properties similar to those found for the 1,5-dimethylcyclooctyl cation **5** and this can be assigned a 1-methyl-5-ethyl-μ-hydrido-bridged cyclooctyl cation structure **12**. There is already precedent for the collapse of simple tertiary cyclononyl cations to cyclooctyl and smaller ring cations (8). The partial nmr parameters of **12** are shown with the structure (only those very diagnostic of the bridged ion can be unequivocally located). The kinetics for **4** → **12** can be conveniently followed by noting the decrease of the δ −5.8 signal of **4** and the appearance of the δ −6.4 signal of **12**.

1,4-Dimethylcyclooctyl Cation

This cation does not have a μ-hydrido-bridged structure, i.e. there is no very high-field μ-hydrogen. Moreover, there is no indication for even a conventional 1,4-hydride shift, at least on the nmr time scale. This is most clearly seen in the fact that the $>C^{+} - CH_3$ methyl signal remains sharp in both the ^{1}H and ^{13}C nmr spectra up to the temperature where rearrangements occur (~ −80°C). The ^{1}H and ^{13}C nmr assignments, taken from "averaged" spectra at −85°C, are given below (structure **13**), along with the probable chair–boat conformations of this cation (**13***a* and **13***b*). At low temperatures, four isomers are possible and there are indications from both the low

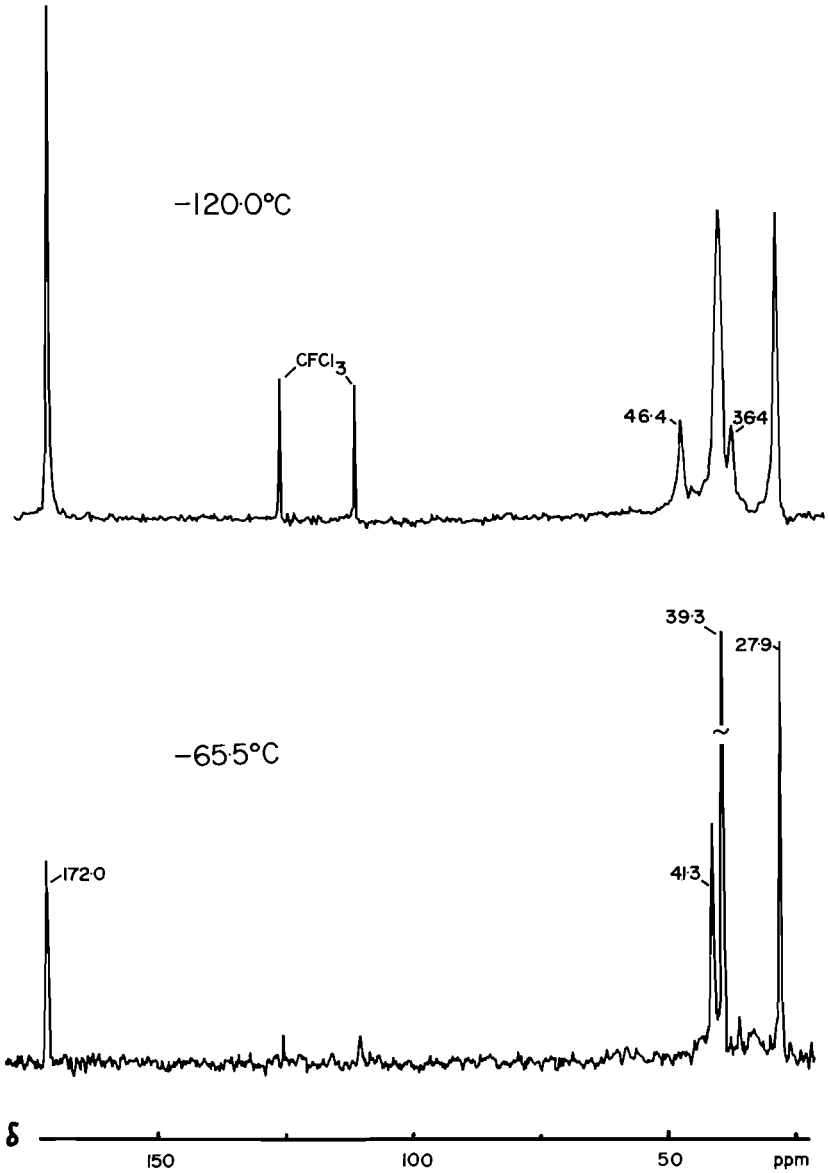

FIG. 1. ^{13}C nmr spectrum of the 1,5-dimethyl-1,5-μ-hydridocyclooctyl cation, broadband decoupled (assignments are given in the text). The upper spectrum at −120°C corresponds to "frozen-out" conditions for the conformational interchange process depicted in the text. The −65.5°C spectrum shows the same ion under conditions of rapid conformational interchange.

temperature ^1H and ^{13}C spectra that there is more than one populated species, probably the chair equatorial methyl ⇌ boat equatorial methyl pair **13***a* and **13***b* in about equal amounts.

The chair–boat conformations **13***a* and **13***b* are clearly not conducive to 1,4-μ-hydrido-bridging or even to 1,4-hydride transfer involving a transition state of less than about 35 kJ mol^{-1} (based on the lack of nmr line-broadening).

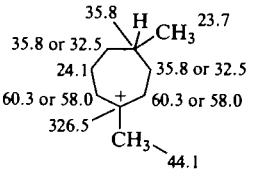
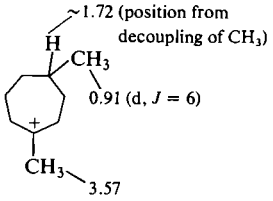
13*a* **13***b*

1,4-Dimethylcycloheptyl Cation

This cation **14** is also not a μ-hydrido structure for the same experimental reasons as for **13**, e.g. the potential μ-hydrido proton is found at the "normal" value of δ ~1.72. Likewise, there is no evidence for the occurrence of a conventional 1,4-hydride shift on the nmr time scale up to the decomposition temperature (~−90°C), therefore



14
^{13}C assignments (δ)



14
^{1}H assignments (δ), remainder are broad and overlapping

$\Delta G^{\ddagger}$ for this process must be >30 kJ mol^{-1}. Unlike the eight ring analog, there is no conformationally derived nmr line-broadening on cooling and like the parent 1-methylcycloheptyl cation (7), this implies low pseudo-rotation type barriers between conformers of similar energy. The pertinent nmr parameters for **14** are given with the structures.

Since **14** shows no sign of μ-hydrido-bridging or even hydride shifts, it is almost certain that the secondary cycloheptyl cation would also not have a μ-H-bridged structure. This same conclusion was tentatively reached on the basis of reactivity differences between cycloheptyl and cyclooctyl systems.

1,4-Dimethylcyclohexyl Cation

Based on the results from **13** and **14**, it comes as no surprise to find that the cyclohexyl member is also not μ-hydrido-bridged. Proton and ^{13}C nmr results are shown with the structure **15** and resemble those of other tertiary cyclohexyl cations. At higher temperatures, the 1,4-dimethyl isomer equilibrates with the 1,3-dimethyl isomer but even up to −40°C, there is no ^{13}C line-broadening evidence for a conventional 1,4-hydride shift.

In conclusion, we have found two new μ-hydrido-bridged systems **4** and **5**, one of which (**5**) is stable for short periods at temperatures as high as −60°C. We have also shown that 1,4-μ-hydrido bridges are not formed, even in a medium ring milieu.

Experimental

The tertiary alcohols, 1,5-dimethylcyclononan-1-ol (9), 1,4-dimethylcycloheptan-1-ol (10), and 1,4-dimethylcyclohexan-1-ol (11) were prepared as described in the literature, starting from the corresponding ketones. All are mixtures of *cis* and *trans* isomers by ^{13}C nmr spectroscopy but this is immaterial considering our intended use. The starting ketones were carefully purified and the purity checked by ^{13}C nmr spectroscopy. 5-Methylcyclononanone had ^{13}C peaks: δ 218.1, 43.9, 42.5, 34.3, 32.0, 30.4 (CH), 24.6 (2C, CH_3 + CH_2), 22.7 (2C). 5-Methylcyclooctanone (12) had ^{13}C peaks: δ 217.3, 42.5 (2C), 36.3 (2C), 31.4 (CH), 25.5 (2C), 25.2 (CH_3). 1,5-Dimethylcyclooct-1-ene and 1,4-dimethylcyclooct-2-ene, as a mixture, were a gift from Koninklijke/Shell Laboratorium, Amsterdam, Holland. They were separated by preparative glc on Carbowax 20 M. The 1,5-isomer had ^{13}C peaks: δ 137.0 (Cq), 124.8 (=CH_2), 39.6, 35.7, 33.4, 31.2, 27.5, 26.8, 26.2, 24.2. The 1,4-isomer had: δ 137.4 (q), 123.4 (=CH_2), 35.9, 35.1, 33.6, 30.0, 28.8, 24.7, 23.9, 22.4. The deuterated alcohols 1-methyl-d_3-5-methylcyclononan-1-ol and 1-methyl-d_3-5-methylcyclooctan-1-ol, as a *cis*–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

trans mixture, were prepared from the corresponding ketone and methyl-d_3-magnesium iodide. The cations were prepared *in situ* in a similar manner to that described previously (7). The acid system used for preparing the carbocations was 1:1 FSO_3H–SbF_5 diluted 1:4 with SO_2ClF solvent, or for very low temperatures, a mixture of SO_2ClF and SO_2F_2 (ca. 3:1) was used as solvent. The ^{13}C nmr spectra were referenced to internal $CFCl_3$, taken as δ 117.9 ppm relative to TMS, and the probe temperatures were calibrated as previously described (7). For the dynamic conformational interchange of **5**, a series of spectra were run at different temperatures (two of which are shown in Fig. 1). The coalescence temperature was found to be −103°C and a $\Delta G^{\ddagger}$ value determined from this by the standard procedure.

Acknowledgments

We wish to thank the Natural Sciences and Engineering Research Council of Canada for generous financial assistance and Shell Amsterdam for the gift of the dimethylcyclooctenes.

TERRY D. ROTSCH, W. R. CAHILL, JR., DONALD J. PIETRZYK, and FREDERICK F. CANTWELL. Can. J. Chem. **59**, 2179 (1981).

Chromatographic retention of substituted benzenesulfonate ions is studied on two nonpolar styrene–divinylbenzene adsorbents as a function of mobile phase ionic strength. On both Amberlite XAD-2 and Hamilton PRP-1, a plot of reciprocal of the capacity factor for each benzenesulfonate versus reciprocal of the square root of ionic strength is linear as predicted by Stern–Gouy–Chapman electrical double layer theory. Chromatographic resolution is improved by using an electrolyte-containing mobile phase.

TERRY D. ROTSCH, W. R. CAHILL, JR., DONALD J. PIETRZYK et FREDERICK F. CANTWELL. Can. J. Chem. **59**, 2179 (1981).

On étudie la retention chromatographique d'ions benzènesulfonates substitués sur deux adsorbants styrène–divinylbenzène non polaires en fonction de la force ionique de la phase mobile. Dans les cas de l'Amberlite XAD-2 ainsi que de l'Hamilton PRP-1, on obtient une corrélation linéaire entre l'inverse du facteur de capacité de chaque benzènesulfonate et l'inverse de la racine carrée de la force ionique; ce résultat est en accord avec la théorie électrique de la couche double de Stern–Gouy–Chapman. On améliore la résolution chromatographique en utilisant une phase mobile contenant un électrolyte.

[Traduit par le journal]

Amberlite XAD-2 is a macroporous nonionic copolymer of styrene and divinylbenzene that acts as a nonpolar (reversed phase) adsorbent and exhibits retention not only for organic nonelectrolytes but also for the charged forms of organic acids, bases, and ampholytes. It has several advantages as a stationary phase in liquid chromatography such as low cost, pH stability in the range of 0–14, compatibility with aqueous, organic, and mixed solvents, high linear sample capacity, and strong adsorbent properties. XAD-2 and related macroporous copolymers have been used as stationary phases for liquid chromatographic separations of many different organic analytes using eluting variables such as pH, type of organic solvent, solvent–water ratio, and type and concentration of inorganic or organic electrolytes (1–7). Also, it was recently shown that columns containing microparticulate XAD-2 exhibit efficiencies comparable to those obtained with columns containing microparticulate reversed bonded phases of the alkyl-modified silica type (8).

Recently a spherical, highly cross-linked, macroporous styrene–divinylbenzene copolymer of 10 μm particle diameter has appeared on the market as a liquid chromatography column packing (9). This packing, PRP-1, has been shown to closely resemble Amberlite XAD-2 and can be used interchangeably with it. Its commercial availability as both a loose packing and in the form of pre-packed columns makes PRP-1 an attractive alternative to silica-based reversed phase alkyl-bonded phases, which cannot be used at mobile phase pH above about 8.

Several workers have shown that the retention of organic ions, such as sulfonates, benzoates, phthalates, and protonated amines, increases on XAD-2 as the concentration of an inert electrolyte in the mobile phase increases (1, 2, 4, 10–12). The nature of the electrolyte was also shown to be a significant parameter (1, 2). In a study of this electrolyte effect on XAD-2, Cantwell and Puon (13) demonstrated that the retention of ions such as diphenylguanidinium and benzylammonium could be quantitatively described by the Stern–Gouy–Chapman (SGC) electrical double layer theory. In these systems the analyte cation is absorbed onto the XAD-2 surface and small inorganic counterions, such as chloride ion, occupy the diffuse part of the electrical double layer.

In this report the adsorption of substituted benzenesulfonate anions is studied on XAD-2 and PRP-1 as a function of concentration of inorganic electrolyte in the mobile phase. According to the SGC model the sulfonate analyte is adsorbed onto the adsorbent surface while the diffuse layer is made up of small inorganic cations, such as sodium ion. The fact that the retention data described here are consistent with the SGC theory is additional evidence in support of the postulate that this

sorption model is a general one and satisfactorily accounts for the retention of organic cations and anions on nonpolar adsorbents in the presence of small counterions.

Experimental

Reagents

Benzenesulfonic acids and their sodium salts were obtained from Eastman Organic Chemicals; Matheson, Coleman and Bell; and Pfister Chemical. The compounds used and their abbreviations are benzenesulfonic acid (BSA), *p*-aminobenzenesulfonic acid (*p*-NH_2BSA), *p*-methylbenzenesulfonic acid (*p*-CH_3BSA), sodium *m*-nitrobenzenesulfonate (*m*-NO_2BSNa), *p*-nitrobenzenesulfonic acid (*p*-NO_2BSA), sodium *p*-chlorobenzenesulfonate (*p*-ClBSNa), 2,5-dimethylbenzenesulfonic acid (2,5-diCH_3BSA), 2,4-dinitrobenzenesulfonic acid (2,4-diNO_2BSA), and 2,5-dichlorobenzenesulfonic acid (2,5-diClBSA). Inorganic salts were analytical reagent grade. Liquid chromatography quality acetonitrile (Matheson, Coleman, and Bell) and 95% ethanol were used in preparing aqueous – organic solvent mobile phase mixtures. Water was treated by passing distilled water through a Bantam Demineralizer Model BD-1 (mixed bed ion exchanger), a column of activated charcoal, and a series of 0.2 μm stainless steel filter discs.

Amberlite XAD-2 was purchased from Rohm and Haas or Mallinckrodt Chemical Works as 20–60 mesh average particles. The copolymer was washed with ethanol in a Soxhlet extractor for at least one week prior to crushing.

Procedures

The XAD-2 column was prepared as follows. A water–ethanol slurry of the XAD particles was ground in a Waring blender and those particles that passed through an 80 mesh screen were air dried. The portion of this dried material passing through a 200 mesh sieve was slurried with ethanol and placed in an ultrasonic bath for 20 min to break up aggregrates. Subsequently, this slurry was passed through a combination of 400 and 500 mesh screens (Cistron Corp., Elmsford, NY) and the particles retained on the 500 mesh screen (25–38 μm) were kept and washed with EtOH and water. This latter process was monitored with a microscope to ensure that fines were not present. Although the XAD-2 particles were nonspherical they were uniform in particle size. A stainless steel column with 5 μm end frits, that was 30 cm long and had an id of 0.236 cm, was slurry packed with the resin. A quantity of 0.5 to 1 g of the 25–38 μm resin was slurred in 20 mL of 20% ethanol – 80% water and pumped from a small stirred pressurized chamber into the column at an initial flow rate of 9.9 mL/min. As the pressure drop on the column increased the flow rate was decreased. Following this, the column was conditioned for several hours with 95% ethanol – 5% water as the mobile phase.

The PRP-1 column, 0.41 cm × 15 cm, was obtained prepacked from the manufacturer (Hamilton Co., Reno, NV).

Chromatograms were obtained with a Waters Model 202 chromatograph equipped with a Model 6000 pump, and a Model U6K injector (Waters Associates, Milford, MA). A Tracor Model 970 detector was used at 208 nm (Tracor Instruments, Austin, TX). Samples were prepared by dissolving 1 to 5 mg of sample per mL of water and stored in 6 mL Hypovials fitted with Hycar Septa and sealed with aluminum caps (Pierce Chemical Co., Rockford, IL). Pressure Lock Series B-110 μL syringes (Precision Sampling Corporation, Rockford, IL) were used to inject 5 μL of sample (1 to 16 μg of analyte). Flow rates were controlled at about 1 mL/min.

Water – organic solvent mixtures are expressed as percent by volume. The benzenesulfonic acid samples were used as the free acid, except where noted (Table 1); in these cases they were used as the sodium salt. The different ionic strength solutions of sodium chloride were prepared by dissolving a known weight in the solvent mixture. In calculating the weight required for a specific ionic strength it was assumed that the NaCl was 100% ionized.

Capacity factors were calculated by:

$$[1] \quad k' = (V_R - V_M)/V_M$$

where V_R is the retention volume for the sulfonate chromatographic peak and V_M is the retention volume for the unretained peak (sodium nitrate). Experiments were run in duplicate at a temperature of 24°C.

Results and Discussion

Benzenesulfonic acids are strong acids with pK_a values smaller than 1. Since they are highly ionized in aqueous solution, it is possible to study the retention of the sulfonate anion, free of the neutral sulfonic acid species, without having to add buffers to convert the sulfonic acid into its anionic form. This eliminates the effect of added buffer components on the retention.

The relationship between the capacity factor (k') of a sample ion such as a substituted benzenesulfonate and the ionic strength (μ) of the mobile phase is given by the SGC theory of double layer adsorption (13) as:

$$[2] \quad 1/k' = 1/C_1 + C_2/\mu^{1/2}$$

where C_1 and C_2 are constants. It is implicitly assumed in this expression that the concentration of sample ion in the mobile phase is small enough

that the surface potential of the resin (ψ_o) is independent of sample concentration (13). Since the quantity of sample injected was on the order of 10^{-7} equivalents this assumption is reasonable.

Equation [2] predicts a linear relationship between $(k')^{-1}$ and $\mu^{-1/2}$. This relationship was tested for six or seven substituted benzenesulfonate sample ions on both Amberlite XAD-2 and PRP-1 columns using sodium chloride to adjust the ionic strength of the mobile phase to values between 10^{-3} and 10^{-1}. The data for several of the compounds are plotted according to eq. [2] in Figs. 1 and 2 where the straight lines shown were calculated by the method of linear least-squares. Presented in Table 1 are the capacity factors obtained for all of the compounds along with the slopes, intercepts, and correlation coefficients obtained in the least-squares calculations for the linear regression of $(k')^{-1}$ on $\mu^{-1/2}$. Compounds with smaller k' values such as p-NH_2BSA and BSA are not included because of the relatively large uncertainties in measuring $(V_R - V_M)$ for use in eq. [1].

Considering all of the compounds and both nonpolar adsorbents, correlation coefficients vary from 0.9911 to 0.9995. The observed linearity of the relationship between $(k')^{-1}$ and $\mu^{-1/2}$ over a range of two orders of magnitude in ionic strength lends support to the view that the SGC theory describes the adsorption of organic *anions* from solutions of inorganic electrolyte into nonpolar adsorbents, just as it does for organic cations (13). From the chromatographic point of view, a knowledge of this reciprocal square root relationship makes the process of selecting a mobile phase composition less empirical.

A comment is in order about the choice of NO_3^- ion as the unretained component, since the values obtained for k' depend upon having an accurate value for V_M. The following values were obtained for V_M at the several ionic strengths (given in parentheses): 0.94 (0.001), 0.96 (0.0025), 1.00 (0.01), and 1.00 (0.1) on the XAD-2 column; and 1.36 (0.001), 1.39 (0.0025), 1.49 (0.01), and 1.49 (0.1) on the PRP-1 column. The slight increase in V_M with increasing μ is predictable from the SGC theory at the low surface potentials which are involved (13). Assuming a negative surface potential, the theory predicts a decrease in expulsion of the co-ion NO_3^- from the diffuse part of the electrical double layer as the NaCl concentration is increased. The effect is analogous to that of "Donnan exclusion" (14, 15) in gel type ion exchangers through, of course, the effect occurs to a much less extent in the double layer case. As expected, a maximum limiting value of V_M is obtained at higher μ (i.e. $\mu \gtrsim 0.01$) and this value of V_M is the same as that which would be found for the retention volume

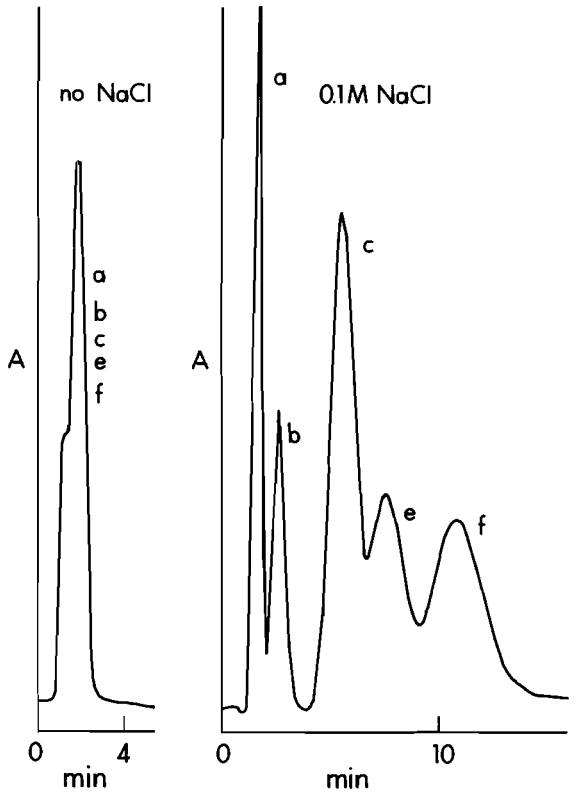

FIG 3. Chromatograms of (a) p-NH_2BSA, (b) BSA, (c) p-CH_3BSA, (e) p-NO_2BSA, (f) p-ClBSNa, on XAD-2 using 3% acetonitrile containing either no electrolyte or 0.1 M sodium chloride.

of an unretained neutral compound under the same conditions.

The use of a univalent anion as unretained component, rather than a neutral compound, is necessary to compensate for this slight electrolyte exclusion effect. To a first approximation, electrolyte exclusion, whether Donnan (15) or double layer (16), depends only on the sign and magnitude of the charge on the ion involved. For example, Waki and Tokunaga (14) working with an ion exchanger have shown that the retention volumes are the same for all univalent anions studied under conditions of Donnan exclusion.

As a consequence of this exclusion behavior, the slight decrease in retention of NO_3^- at lower μ is expected to be reflected in a corresponding decrease in the retention of the univalent sulfonate sample anions. In other words, the sulfonate ions are excluded from the same fraction of the intraparticle pore volume as is NO_3^- ion at the same μ. Consequently, V_M should be identified with the retention volume of NO_3^- obtained at the ionic strength in question.

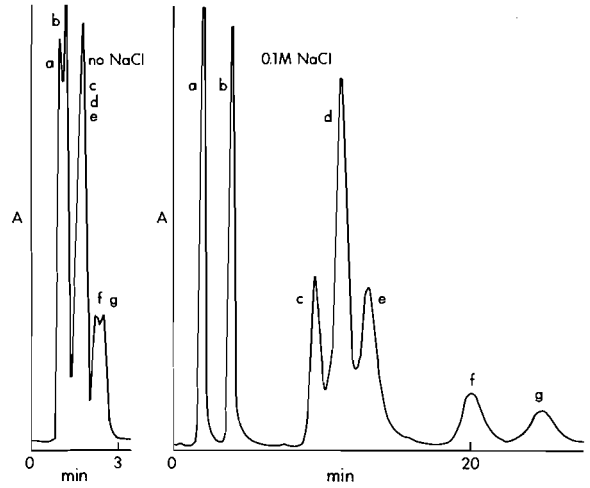

FIG. 4. Chromatograms of (a) p-NH_2BSA, (b) BSA, (c) p-CH_3BSA, (d) m-NO_2BSNa, (e) p-NO_2BSA, (f) p-ClBSNa, (g) unidentified impurity, on PRP-1 using 2.8% acetonitrile containing either no electrolyte or 0.1 M sodium chloride.

The linearity of the plots in Figs. 1 and 2 would not be expected to persist if the number of moles of sulfonate injected is made very much larger. At much higher concentrations the sulfonate ion would make a significant contribution to the surface potential which would then not be constant as μ is varied. To prevent this it would be possible to control the surface potential by the addition to the mobile phase of a relatively high and constant concentration of another potential-determining ion, as was done for the chromatography of cations on XAD-2 (13). The plots in Figs. 1 and 2 might also be expected to deviate from linearity if a very much lower number of moles of sulfonate sample is injected. In this case one would expect to see a perturbation of SGC behavior because of such phenomena as ion exchange involving the very small number of ionic impurity groups present even on nominally nonionic adsorbents (4).

Enhancement of chromatographic retention in the presence of electrolyte greatly improves the chromatographic resolution of ionic sample species. Figure 3 shows the chromatographic separation of a mixture of five substituted benzenesulfonates in a moderately efficient column of Amberlite XAD-2 using two mobile phases which differ only in their ionic strength. With 0.1 M NaCl, capacity factors are greatly increased over those in the electrolyte-free mobile phase and this leads to improved resolution. Compound d was omitted because of its severe overlap with compounds c and e. Figure 4 shows six of the compounds chromatographed on the high efficiency PRP-1 column in the presence and absence of 0.1 M NaCl.

Here too, increased ionic strength leads to enhanced retentions and resolutions. On the high efficiency column *compounds c, d, and e are resolved from one another*. Comparing the chromatograms in Fig. 4 with those in Fig. 3, it is evident that the use of a microparticle packing yields greatly enhanced column efficiency and resolution. Presumably the use of microparticle XAD-2 (8) would also yield high efficiency separations like those in Fig. 4, but the packing was not employed in the present study.

It is evident from the data in Table 1 that the retention *sequence* of benzenesulfonates on PRP-1 adsorbent is the same as that on XAD-2. Chromatography of a variety of other types of compounds on both XAD-2 and PRP-1 shows that this conclusion is a general one (17). This is a reflection of the very similar chemical nature of the two adsorbents. The nearly identical values of slope and intercept for a few of the compounds (e.g. p-CH_3BSA) on the two adsorbent columns is somewhat coincidental. It results probably from a cancelling of the effect of the larger specific surface area of PRP-1 (415 m^2/g vs. 330 m^2/g for XAD-2) by the use of a somewhat stronger solvent for PRP-1 (5% ethanol vs. 1% ethanol for XAD-2). The larger specific surface area leads to increased capacity factors, while the greater mobile phase strength has the opposite effect. Ethanol content of the mobile phases was chosen initially to give similar capacity factors for the same compound in both columns.

A kinetic electron spin resonance study of the reaction of some oxy radicals with vanadyl acetylacetonate[1]

J. A. HOWARD,[2] J. C. TAIT,[3] T. YAMADA,[4] AND J. H. B. CHENIER
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received October 14, 1980

J. A. HOWARD, J. C. TAIT, T. YAMADA, and J. H. B. CHENIER. Can. J. Chem. **59**, 2184 (1981).

Reactions of phenoxyl, iminoxyl, nitroxyl, peroxyl, and alkoxyl radicals with $VO(acac)_2$ in solution have been studied by kinetic esr spectroscopy. Rates of reaction are first-order with respect to each reactant and radical reactivity increases in the order galvinoxyl < 2,4,6-tri-*tert*-butylphenoxyl < di(1-adamantyl)methylene-iminoxyl < *tert*-butylperoxyl. Rates of reaction are retarded by pyridine and accelerated by methanol and there is an isotope effect on the rate when the hydroxyl proton of CH_3OH is replaced by deuterium. Vanadium-51 nmr spectroscopy has demonstrated that several vanadium(V) products are formed while conventional product studies have indicated that, in the case of phenoxyl and alkoxyl, the radical is reduced almost exclusively to the parent phenol and alcohol and that $VO(acac)_2$ is eventually regenerated in substantial yields. The net reaction is, therefore, catalytic reduction of the radical. Variable temperature esr studies have shown that phenoxyl and iminoxyl radicals and $VO(acac)_2$ exist in equilibrium with diamagnetic reaction products.

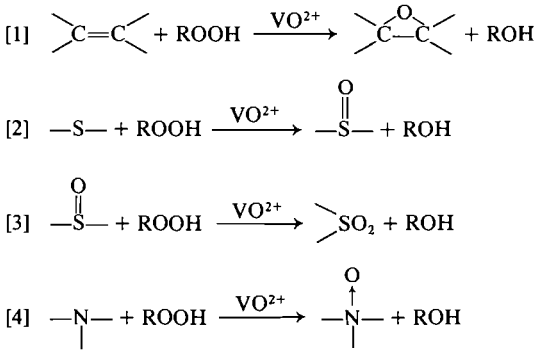
J. A. HOWARD, J. C. TAIT, T. YAMADA et J. H. B. CHENIER. Can. J. Chem. **59**, 2184 (1981).

Utilisant la spectroscopie de rpe cinétique, on a étudié les réactions des radicaux phénoxyle, iminoxyle, nitroxyle, péroxyle et alkoxyle avec le $VO(acac)_2$ en solution. Les vitesses de réaction sont du premier ordre par rapport à chaque réactif et la réactivité des radicaux augmente dans l'ordre suivant: galvinoxyle < tri-*tert*-butyl-2,4,6 phénoxyle < di(adamantyl-1) méthylène iminoxyle < *tert*-butylperoxyle. Les vitesses de réaction sont ralenties par la pyridine et accélérées par le méthanol et le remplacement du proton hydroxylique du CH_3OH par un deutérium provoque un effet isotopique cinétique. La spectroscopie de rmn du vanadium-51 a démontré qu'il se forme plusieurs produits du vanadium(V) tandis que des études conventionnelles des produits indiquent que, dans le cas du phénoxyle et de l'alkoxyle, le radical est presqu'exclusivement réduit en phénol apparenté et en alcool alors que le composé $VO(acac)_2$ est régénéré avec des rendements qui sont éventuellement substantiels. La réaction globale est cependant une réduction catalytique du radical. Des études de rpe à température variable révèlent que les radicaux phénoxyle et iminoxyle et le $VO(acac)_2$ existent en équilibre avec des produits de réaction diamagnétiques.

[Traduit par le journal]

Introduction

It is well known that oxidation of olefins, sulphides, sulphoxides, and amines by alkyl hydroperoxides (ROOH) is catalyzed by vanadyl acetylacetonate, $VO(acac)_2$ (1).



Furthermore there appears to be general agreement that the reaction mechanism involves association of the hydroperoxide with $VO(acac)_2$ to give a vanadium(V)–ROOH complex which is followed by nucleophilic attack at the "activated" —O—O— bond of the hydroperoxide by the nucleophile.

Although these oxidations are heterolytic there is some evidence that free-radicals are produced by reaction of $VO(acac)_2$ with ROOH. Thus Brandon and Elliott (2) detected *tert*-butylperoxy radicals by electron spin resonance spectroscopy during reaction of *tert*-BuOOH with $VO(acac)_2$ in ethanol at room temperature while Symons (3) suggested that this reaction also gives a vanadium(V) peroxy radical of the form $L_nVO_2^{\cdot}$ where L_n represents unspecified ligands.

The kinetics and mechanisms of VO^{2+} catalyzed nonradical oxidations have been thoroughly studied whereas free-radical reactions of these chelates have received little attention. In order to redress this imbalance we have investigated the reaction of $VO(acac)_2$ with several oxy radicals and the results of this work are reported here.

Experimental

Reagents

Commercial vanadyl acetylacetonate was purified either by recrystallization from methanol or sublimation and standard solutions were freshly prepared before use.

2,4,6-Tri-*tert*-butylphenol (Aldrich) was recrystallized from hexane to a purity of >99.9%.

Standard solutions of 2,4,6-tri-*tert*-butylphenoxyl, **1**, were prepared by passing solutions of 2,4,6-tri-*tert*-butylphenol down a column of PbO_2–Celite (4:1) (4). If oxygen was rigorously excluded during this procedure, conversion of the phenol to the radical was quantitative. Solutions of the radical could be kept for several hours with no loss in radical concentration. The concentration of **1** was determined either by uv spectroscopy at 630 nm (ε = 410) or by esr spectroscopy relative to a standard solution of DPPH.

tert-Butylperoxy radicals were produced either by photolysis of azoisobutane (Merck, Sharpe, and Dohme, Canada Ltd.) or 2,2,4,4-tetramethyl-3-pentanone (Chemical Samples Co.) in an air-saturated solvent. Cumylperoxy radicals were obtained by thermolysis of azocumene (5) in oxygen saturated chlorobenzene at 323 K. Cumyloxy radicals were generated by thermolysis of di-α-cumyl hyponitrite (6). Galvinoxyl was obtained from Aldrich and di(1-adamantyl) methylene-iminoxyl was a gift from Dr. K. U. Ingold. Hydrogalvinoxyl was prepared by the method described by Adam and Chiu (7).

Kinetic Procedures

Reactions of tri-*tert*-butylphenoxyl, galvinoxyl, and di(1-adamantyl)methylene-iminoxyl with $VO(acac)_2$ were studied in Pyrex tubes (5 mm od) directly in the cavity of a Varian E-4 EPR spectrometer. In a typical *dark* experiment 50 μL of a strong standard solution of $VO(acac)_2$ were added to 250 μL of a weaker standard solution of **1** as the solution was being agitated with a fine stream of argon to ensure rapid mixing. The decay of the minor component was then followed by monitoring the decrease in the intensity of its esr spectrum with respect to time. Faster reactions were studied by generating the radical photochemically in the presence of excess $VO(acac)_2$ directly in the cavity of the EPR spectrometer and following the change in the radical concentration with time after the initiating light was masked.

Stoichiometric factors n, i.e., the number of radicals destroyed by each molecule of $VO(acac)_2$, were determined by the esr titration method described previously (8).

Product Analysis

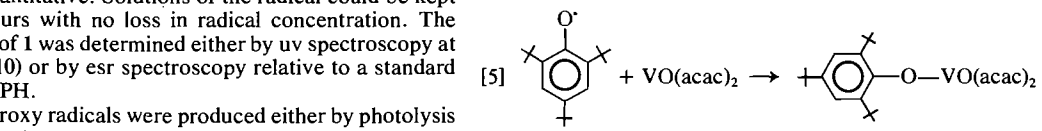
Volatile reaction products were identified and their yields determined by gas chromatography using a Varian model 2800 chromatograph equipped with an OV-101 column and flame ionization detector. Reaction products were also examined by infrared spectroscopy and high performance liquid chromatography before distillation. The volatile fraction was obtained by pumping the reaction mixture at room temperature into a trap maintained at 77 K. Vanadium-51 nuclear magnetic resonance spectra were obtained before pumping on a Bruker CXP 180 pulsed NMR spectrometer at 47.3 MHz.

Results and Discussion

*2,4,6-Tri-*tert*-butylphenoxyl, 1*

In nonpolar aromatic solvents, such as toluene, *tert*-butylbenzene, and *o*-dichlorobenzene, **1** disappeared completely upon addition of a large excess of $VO(acac)_2$ at 294 K. Decays of **1** were accurately exponential and pseudo-first-order rate constants were linearly dependent on the concentration of $VO(acac)_2$.

Similarly $VO(acac)_2$ disappeared completely upon addition of a large excess of **1**. Decays of $VO(acac)_2$ followed first-order kinetics and pseudo-first-order rate constants were linearly dependent on the concentration of **1**. These results suggest that the *initial* reaction is a straight-forward combination as shown in [5].



Bimolecular rate constants for reaction [5] were determined from decays of both **1** and $VO(acac)_2$ in several solvents and the results are summarized in Table 1. Somewhat surprisingly, rate constants obtained from decays of $VO(acac)_2$ were consistently smaller than rate constants obtained from decays of **1**. Furthermore, the nature of the solvent had an appreciable effect on the magnitude of k_5.

Attempts to measure the stoichiometric factor in nonpolar solvents suggested that $VO(acac)_2$ reacted with between 1 and 2 equivalents of **1** (Table 2). It did, however, become apparent that soon after the *minimum* concentration of $VO(acac)_2$ was reached the concentration of this reactant began to increase *slowly* with time until most of it had been regenerated. Clearly the diamagnetic product of reaction [5] is thermally unstable and decomposes irreversibly back to $VO(acac)_2$. The smaller values of k_5 obtained from decays of $VO(acac)_2$ are, therefore, almost certainly associated with regeneration of this reactant during reaction and values of k_5 determined from decays of **1** are probably the more reliable rate constants for reaction [5].

Values of k_5 determined from decays of **1** were measured from 223 to 303 K in toluene and approximately fit the Arrhenius equation

$$\log(k_5/M^{-1}\,s^{-1}) = (3.7 \pm 0.5) - (4 \pm 0.5)/\theta$$

where $\theta = 2.303RT$ kcal mol^{-1}. Clearly reaction [5] has a low activation energy and an extremely low pre-exponential factor.

Rapid changes in the temperature between 303 and 363 K when the minimum concentrations of

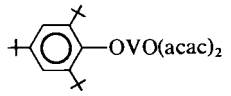
[a]A: toluene; B: toluene–methanol 9.5: 0.5, v/v.

$VO(acac)_2$ and **1** had been reached, after reaction of equimolar reactant concentrations, revealed the presence of reversible equilibria. Thus the concentration of both $VO(acac)_2$ and **1** could be increased and decreased by raising and lowering the temperature.

Analysis of the final products of reaction [5] by infrared spectroscopy and gas–liquid chromatography indicated that **1** was reduced almost quantitatively to 2,4,6-tri-*tert*-butylphenol. In most experiments a trace of 2,6-di-*tert*-butyl-*p*-benzoquinone was also formed. The most likely source of this product is oxidation of the phenol by a vanadium(V) species during work-up.

Examination of reaction mixtures by ^{51}V nmr spectroscopy revealed the presence of at least ten vanadium(V) products with δ_V between −466 and −614.5 ppm relative to external $VOCl_3$.

Attempts to prepare



from 2,4,6-tri-*tert*-butylphenol and $VO(acac)_2Cl$ have so far failed. In fact the reaction mixture did not give a ^{51}V nmr spectrum and appeared to contain mainly $VO(acac)_2$.

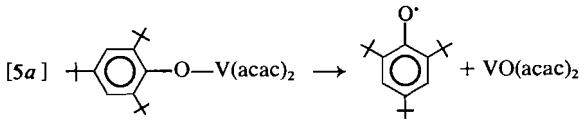
Rates of reaction [5] were much faster in toluene containing 5–20% methanol and were in fact so fast that radical decays could not be studied by the dark method. Instead **1** was produced by photolysis of a solution of 2,4,6-tri-*tert*-butylphenol in mixtures of toluene–methanol containing $VO(acac)_2$ and radical decays were monitored after the initiating light was masked. Using this method **1** was found to decay exponentially with k_5 (CH_3OH) = 120 M^{-1} s^{-1}. Interestingly a significant isotope effect was observed when the hydroxylic hydrogen of methanol was replaced by deuterium and k_5 (CH_3OD) = 30 M^{-1} s^{-1}, i.e., $k_5(H)/k_5(D) \sim 4$.

The stoichiometric factor, n, was exactly 1 in mixtures of toluene and methanol when *minimum* residual concentrations of reactants were determined after initial rapid reaction (Table 2).

Final reaction mixtures after reaction of equimolar concentrations of **1** and $VO(acac)_2$ were ruby red, indicative of the presence of vanadium(V) species. The ^{51}V nmr spectrum of the reaction products was much simpler in the presence of 5% methanol and two major vanadium(V) species were observed with chemical shifts of −488.6 and −586.6 ppm in the ratio of ~2:1. At higher concentrations of methanol the quantity of the species with δ_V = −586.6 ppm increased dramatically. In addition these two vanadium(V) products appeared to be in thermal equilibrium.

An esr spectroscopic study sometime after the reaction of almost equal concentrations of **1** (10 mM) and $VO(acac)_2$ (7.6 mM) in toluene–methanol indicated the presence of residual concentrations of $VO(acac)_2$ (2.6 mM) and **1** (0.022 mM). More interestingly, the concentration of both $VO(acac)_2$ and **1** could be increased and decreased reversibly by raising and lowering the temperature between 293 and 343 K. Both reactants were, therefore, in equilibrium with diamagnetic dimer(s). There was, however, a slow irreversible reaction because $[VO(acac)_2]$ increased slowly and [**1**] decreased slowly with time.

The difference in the residual concentrations of $VO(acac)_2$ and **1** appears to preclude a simple reversal of reaction [5]



If, however, we make the reasonable assumption that **1** was in reversible equilibrium with **1**-$VO(acac)_2$ we can calculate that ΔH_5^0 is ~ −10 kcal mol.

Unfortunately we were unable to measure [**1**-$VO(acac)_2$] and consequently values of K_5 and ΔS_5^0 could not be determined.

A product of reaction [5] prepared in the presence of MeOH was found to be photochemically unstable and photolysis gave $VO(acac)_2$. Furthermore, photolysis in the presence of phenyl *tert*-

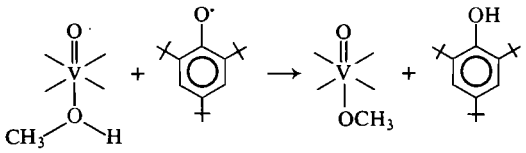
butylnitrone produced a nitroxide with the esr parameters $g = 2.0064$, $a_N = 13.33$ G, $a_H = 1.52$ G; values which are similar to the parameters for the nitroxyls obtained by adding alkoxy radicals to PBN (9). We also found that regeneration of $VO(acac)_2$ was significantly faster in the presence of oxygen than it was in degassed solution.

It is apparent from these results that one product of reaction [5], in methanol, behaves exactly like methoxo-oxobis(8-quinolyloxo)vanadium(V) (10) and we tentatively conclude that it is methoxo-oxobis(acetylacetonato)vanadium(V), $CH_3OVO(acac)_2$, and is probably the product with $\delta_V = -466$ ppm in the ^{51}V nmr spectrum. This assignment was made of the basis of the fact that a rather impure sample of methoxo-oxobis(8-quinolyloxo)-vanadium(V) gave strong ^{51}V nmr transitions with $\delta_V = -477$ and -467 ppm and the product from reaction of $VO(acac)_2Cl$ with methanol gave a strong peak at $\delta_V = -465$ ppm. The second transition in the ^{51}V nmr spectrum at $\delta_V = -586.6$ ppm had a chemical shift about 10 ppm upfield from $VO(OC_2H_5)_3$. It should be noted that $CH_3OVO(acac)_2$ is quite unstable and has a half-life of ~5.5 h in toluene at 295 K.

The observation of an isotope effect when CH_3OD was used instead of CH_3OH implies that the hydroxylic proton is abstracted in the rate controlling step, perhaps by reaction of **1** with coordinated methanol.



The reaction of **1** with $VO(acac)_2$ in aprotic solvents was retarded by low concentrations of pyridine, probably because pyridine coordinates at the reactive vacant coordination site of the complex and prevents inner sphere electron transfer.

Galvinoxyl 2

Galvinoxyl also reacted with $VO(acac)_2$ to destroy the paramagnetism of both reactants and rates of radical decay obeyed the rate law

$$-d[\mathbf{2}]/dt = k_6[\mathbf{2}][VO(acac)_2]$$

Values of k_6 were calculated from rates of radical decay because $-d[\mathbf{2}]/dt > -d[VO(acac)_2]/dt$ and the results are summarized in Table 3. It is apparent from this data that **2** is about 10 times less reactive than **1**, that CH_3OH accelerates the rate of reaction [6] by a factor of about 35 whereas CH_3OD only accelerates the rate by a factor of about 8, and that pyridine completely inhibits the reaction.

[6]  products

The vanadium-51 nmr spectrum obtained after reaction of **2** (38 m*M*) with $VO(acac)_2$ (38 m*M*) in toluene–methanol (5:1, v/v) showed three peaks at $\delta_V = -498$, -504, and -574 ppm in approximately equal yields. This solution contained a residual galvinoxyl concentration of 10 m*M* and a residual $VO(acac)_2$ concentration of 1 m*M*. This residual $[VO(acac)_2]$ was in thermal equilibrium with a vanadium(V) species. There was, however, only a small change in $[VO(acac)_2]$ over the temperature range studied, indicating a small enthalpy of activation, ΔH^0 (~2 kcal mol^{-1}). On the other hand, the concentration of galvinoxyl did not increase when the temperature was raised from 296 to 315 K, probably because the change in concentration was too small to measure.

Over a long period of time (several weeks) the original $VO(acac)_2$ concentration (38 m*M*) was regenerated and the galvinoxyl was completely destroyed. High pressure liquid chromatographic analysis of the final reaction mixture indicated the formation of hydrogalvinoxyl (**2**-H), a trace of 2,6-di-*tert*-butyl-*p*-benzoquinone and products indicative of methoxy radical attack on galvinoxyl and/or hydrogalvinoxyl.

Di(1-adamantyl)methylene-iminoxyl 3

In *tert*-butylbenzene at 294 K **3** (0.05 m*M*) decayed rapidly with first-order kinetics in the presence of a ten-fold excess of $VO(acac)_2$ and $VO(acac)_2$ (0.1 m*M*) decayed with first-order kinetics in the presence of a 100-fold excess of **3**. The half-life of **3** ($\tau_{1/2} = 4.2$ ms) was, however, about 3 times shorter than the half-life of $VO(acac)_2$ ($\tau_{1/2} = 12.5$ ms). Absolute values of the rate constants for reaction of **3** with $VO(acac)_2$ (k_7) determined from radical decays in different solvents are given in Table 4 and it is apparent that the overall rate of reaction [7] depends on the nature of the solvent and that the rate is enhanced by low concentrations of methanol and retarded by low concentrations of pyridine.

The stoichiometric factor estimated from *minimum* reactant concentrations was close to one for this radical. The concentrations of each reactant did not, however, reach zero when equal concentrations were mixed. The residual reactant concentrations, which were about 2% of the initial concentrations, were approximately equal in this case and there was a slow regeneration of $VO(acac)_2$ and a slow disappearance of **3**. A variable temperature study on this system demonstrated that the resi-

dual concentrations of both reactants could be increased and decreased reversibly by raising and lowering the temperature between 294 and 333 K. We can therefore conclude that **3** reacts reversibly with $VO(acac)_2$ to give di(1-adamantyl)methylene-imino-oxobis(acetylacetonato) vanadium(V) and that there is a slow irreversible decay of this compound to give reaction products.

[7] $(1\text{-Ad})_2C{=}NO^{\cdot} + VO(acac)_2 \rightleftharpoons (1\text{-Ad})_2C{=}NOVO(acac)_2 \rightarrow$ reaction products

The concentrations of **3** and $VO(acac)_2$ at the different temperatures allowed us to calculate an approximate value of -15.5 kcal mol^{-1} for the enthalpy change (ΔH_7^0) for reaction [7].

Vanadium-51 nmr spectra of reactions performed in toluene–methanol revealed the formation of three major vanadium products at -493, -503, and -578 ppm which can probably be assigned to **3**-$VO(acac)_2$, $CH_3OVO(acac)_2$, and a third vanadium species which could have been regenerated $VO(acac)_2$.

tert-*Butylperoxyl* ***4***

This radical reacts rapidly with $VO(acac)_2$ at 183 K and one radical is destroyed by each molecule of complex. Rates of decay of **4** were found to obey the rate expression

$$-d[\mathbf{4}]/dt = k_8[\mathbf{4}][VO(acac)_2]$$

where k_8 is the rate constant for reaction [8].

[8] $t\text{-}BuO_2^{\cdot} + VO(acac)_2 \rightarrow$ products.

Absolute values of k_8 from 173–233 K are given in Table 5. This data can be represented by the

TABLE 5. Rate constants for reaction of $(CH_3)_3COO^{\cdot}$ with $VO(acac)_2$ in toluene.

Temperature (K)	$10^5[VO(acac)_2]$ (M)	k_ψ (s^{-1})	$10^{-4}k_\psi/[VO(acac)_2]$ (M^{-1} s^{-1})
208	1.7	0.63	3.7
	2.5	0.82	3.3
198	1.7	0.58	3.4
	8.6	2.3	2.7
188	1.7	0.44	2.6
	8.6	2.1	2.5
178	1.7	0.34	2.0
	8.6	1.7	2.0

Arrhenius equation

$$\log(k_8/M^{-1}\text{ s}^{-1}) = (6.0 \pm 0.2) - (1.4 \pm 0.2)/\theta$$

indicating that reaction [8] has a normal A-factor and is fast because of a low activation energy.

A solution of azocumene (25 mM) and $VO(acac)_2$ (50 mM) in chlorobenzene absorbed oxygen at an initial rate of 2.7×10^{-6} M s^{-1} at 323 K, slightly faster than the rate in the absence of $VO(acac)_2$ (1.6×10^{-6} M s^{-1}). Oxygen (50 mM) was absorbed and acetophenone (13.3 mM), α-methylstyrene (10 mM), and α-cumyl alcohol (6 mM) were produced. If it is assumed that α-methylstyrene was formed by dehydration of α-cumyl alcohol, the alcohol to ketone ratio, A/K, was 1.2 which is about twice as large as the ratio in the absence of metal complex (A/K = 0.54) and is very similar to the ratio obtained from reaction of $PhCMe_2O_2^{\cdot}$ with $Co(acac)_2$ (11).

Cumyloxyl

No attempt was made to measure rate constants for reaction of cumyloxyl with $VO(acac)_2$ because of the expected high rate of this reaction. We did, however, investigate the products of this reaction and found that thermolysis of α-cumyl hyponitrite (22 mM) in chlorobenzene containing $VO(acac)_2$ (40 mM) at 303 K for 4 days gave α-cumyl alcohol (25 mM), acetophenone (2 mM), α-methylstyrene (3.2 mM), and chlorotoluene (2 mM); acetylacetone was not formed although there was a significant yield of 4-hydroxypentan-2-one. The ratio A/K was ~14 which is considerably higher than the ratio obtained from reaction of cumylperoxyl with $VO(acac)_2$ and is very similar to the ratio obtained from reaction of $PhCMe_2O^{\cdot}$ with $Co(acac)_2$ (11). The residue which remained after removing the solvent and volatile reaction products was dissolved in chlorobenzene and the esr spectrum showed that $VO(acac)_2$ (~20 mM) had been regenerated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

The vanadium-51 nmr spectrum of the reaction mixture before distillation showed the presence of two major vanadium(V) species ($\delta_V = -522.3$ and -564.8 ppm) in almost equal yields and one minor vanadium component ($\delta_V = -656.8$ ppm). The product with $\delta_V = -522.3$ ppm increased in concentration at the expense of the product with $\delta_V = -564.8$ ppm upon standing at room temperature.

Nitroxyls

Reactions of nitroxides with $VO(acac)_2$ were not studied in any detail. We did, however, find that di-*tert*-butyl nitroxide and 2,2,6,6-tetramethyl-4-oxo-piperidine-1-oxyl react slowly with $VO(acac)_2$ in toluene, e.g., the rate constant for $(Me_3C)_2NO^\cdot$ is $\sim 0.7\ M^{-1}\ s^{-1}$ at 296 K.

Conclusions

The results of the kinetic and product study of the reaction of oxy radicals ($RO^\cdot$) with $VO(acac)_2$ presented in this paper can best be rationalized on the basis of a mechanism which involves an initial reversible reaction between the complex and the radical to give a vanadium(V) species followed by the slow irreversible decomposition of this species to give the final reaction products.

$$RO^\cdot + VO(acac)_2 \underset{-a}{\overset{a}{\rightleftharpoons}} ROVO(acac)_2$$

$$ROVO(acac)_2 \xrightarrow{b} \text{reaction products}$$

This means that the rate of radical disappearance should be given by

$$\frac{-d[RO^\cdot]}{dt} = \frac{k_b K_a [RO^\cdot][VO(acac)_2]}{1 + K_a[VO(acac)_2}$$

and the rate of disappearance of $VO(acac)_2$ by

$$\frac{-d[VO(acac)_2]}{dt} = \frac{k_b K_a [RO^\cdot][VO(acac)_2]}{1 + K_a[RO^\cdot]}$$

Rates of disappearance of $RO^\cdot$ and $VO(acac)_2$ under pseudo-first-order conditions are linearly dependent on the concentration of the reactant in excess suggesting that $K_a[RO^\cdot]$ and $K_a[VO(acac)_2]$ are both < 1. The measured rate constants k_5, k_6, k_7, and k_8 are, therefore, composite rate constants made of k_b and K_a and differences in these rate constants almost certainly reflect differences in the stability of $ROVO(acac)_2$, i.e., stability increases in the order galvinoxyl < tri-*tert*-butylphenoxo < di(1-adamantyl)methylene-iminoxo < *tert*-butylperoxo.

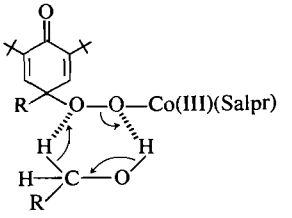
All the radicals except *tert*-butylperoxyl, for which the appropriate experiments were impossible to carry out, gave $-d[RO^\cdot]/dt > -d(VO(acac)_2]/dt$ suggesting that $VO(acac)_2$ was being regenerated during reaction.

Variable temperature studies on residual concentrations of phenoxy and iminoxy radicals, $VO(acac)_2$, and diamagnetic reaction products, very tentatively indicate that enthalpy changes, ΔH_a^0, increase in the order galvinoxy < 2,4,6-tri-*tert*-butylphenoxy < di-(1-adamantyl)methylene-iminoxy, in agreement with the order surmised from reactant decays.

Rates of reaction of oxy radicals with $VO(acac)_2$ are accelerated by methanol, an effect which may be accounted for by solvolysis of $ROVO(acac)_2$ to give the more stable $VO(OCH_3)_3$. The formation of a vanadium(V) species with a chemical shift similar to the shift for $VO(OC_2H_5)_3$ and quantitative reduction to ROH are, of course, consistent with this mechanism. We could, however, find no evidence for the formation of acetylacetone, a product of such a ligand exchange process.

The influence of the O—H bond strength in methanol on rates of reaction suggests that abstraction of the hydroxylic hydrogen from coordinated methanol as shown in [9] is rate controlling.

[9] 
Interestingly, Nishinaga *et al.* (12) have reported an isotope effect of 1.6 for the reductive cleavage of 3,5-di-*tert*-butyl-4-oxo-1-alkylcyclohexa-1, 4-dienyl-1-peroxo(bis-3-salicylidene aminopropyl) amino cobalt(III) by CH_3OH and CH_3OD. These workers suggested that reduction involves the concerted hydrogen transfer mechanism



An analogous mechanism is, of course, improbable for vanadium(V) species of the form $ROVO(acac)_2$.

Reactions of cumylperoxy and cumyloxy radicals with $VO(acac)_2$ gave the same ratios of cumyl alcohol to acetophenone as reactions of these radicals with $Co(acac)_2$ (11), suggesting a common reaction mechanism.

Final reaction products in some cases were quite

complex. It should, however, be realized that glc, hplc, and nmr studies were performed sometimes after minimum radical and $VO(acac)_2$ concentrations were reached. Secondary reactions could, therefore, have been quite significant.

Studies on the products resulting from the conversion of aspen poplar to an oil[1]

RICHARD L. EAGER, JOSEPH F. MATHEWS, JAMES M. PEPPER,[2] AND HUSSEIN ZOHDI

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received February 13, 1981

RICHARD L. EAGER, JOSEPH F. MATHEWS, JAMES M. PEPPER, and HUSSEIN ZOHDI. Can. J. Chem. **59**, 2191 (1981).

Some observations are made on the nature of the reactions involved in the conversion of aspen poplar into a variety of chemical products as a result of its interaction with carbon monoxide and water in the presence of sodium carbonate at elevated temperatures and pressures. The original carbon content of the wood is distributed between an oil phase, a complex mixture of highly oxygenated water-soluble products many of which have been identified as low molecular weight aliphatic alcohols, ketones, and acids, and a gaseous phase consisting of mainly hydrogen and carbon dioxide. Using model substances (cellulose, cellobiose, D-glucose, D-fructose, D-xylose, D-sorbitol, glycerol, and an isolated lignin) information was obtained on the origin of the oil and of the water-soluble products. Studies at temperatures from 160° to 360°C revealed a marked exothermic reaction occurring in the 200–240°C range for wood and cellulose and which was reflected in the nature of the resulting product. With increasing temperature there is an increase in the yields of the water-soluble derivatives and also a change in their relative abundance.

RICHARD L. EAGER, JOSEPH F. MATHEWS, JAMES M. PEPPER et HUSSEIN ZOHDI. Can. J. Chem. **59**, 2191 (1981).

On a fait quelques observations sur la nature des réactions impliquées dans la transformation du peuplier en un certain nombre de produits sous l'action du monoxyde de carbone et de l'eau en présence du carbonate de sodium à des températures et à des pressions élevées. Le carbone contenu dans le bois avant la réaction est distribué entre une phase huileuse formée d'un mélange complexe de produits fortement oxygénés solubles dans l'eau parmi lesquels on retrouve plusieurs alcools aliphatiques, les cétones et acides de faibles masses moléculaires et une phase gazeuse constituée principalement d'oxygène et de bioxyde de carbone. En utilisant des substances modèles (cellulose, cellobiose, D-glucose, D-fructose, D-xylose, D-sorbitol, glycérol et une lignine isolée), on a obtenu des informations sur l'origine de l'huile et des produits solubles dans l'eau. Des études à des températures allant de 160 à 360°C ont révélé que, dans le cas du bois et de la cellulose, il se produit une réaction fortement exothermique dans l'intervalle de 200–240°C et que cette réaction se réflète dans la nature des produits obtenus. Une augmentation de la température provoque une augmentation des rendements en dérivés solubles dans l'eau ainsi qu'une évolution dans leur abondance.

Introduction

The conversion of lignocellulosic materials into oils with potential use as fuels has been the subject of increasing interest. Several recent studies (1–6) have dealt with the variables affecting the yield and properties of the oil that is produced. In general the process involves the high temperature – high pressure reaction of carbon monoxide and/or hydrogen with the lignocellulosic material in the presence of water and a suitable catalyst. Similar studies are being conducted in these laboratories (6) using aspen wood (*Populus tremuloides*, Michx) to determine optimum conditions of reaction for oil production. The total conversion of the holocellulose (carbohydrate) and lignin (aromatic) components of the wood into markedly changed products must involve very complex chemical changes. It is best thought of as essentially a reductive process whereby oxygen is removed from the original lignocellulosic substrate to produce the oil with a greatly increased carbon content. The nature of this reducing action is not clear and may involve any or all of several pathways resulting from attack by the carbon monoxide, or by hydrogen (added or formed as a result of the water–gas shift reaction), or by other transient reducing species such as formate ion that may be generated under the conditions of the reaction.

By this process the lignocellulosic material is converted to products which are found to be distributed among the oil phase, the residual gaseous phase, and the aqueous phase which may be readily decanted from the oil phase. Since a significant amount (approximately one-third by weight) of the original mass of the wood was to be found in the aqueous phase, and since it was thought that such water-soluble compounds may be of relatively low molecular weight and thus more amenable to isolation and identification, this fraction was chosen for an initial more detailed study. It was believed that identification of these compounds could contribute to a clearer picture of the overall chemistry of the process. This paper reports mainly on the chemical nature of the compounds found in the aqueous layer, and, to a lesser extent, by means of a study of model substances, on the mechanism of formation of the oil, and of the water-soluble and gaseous products.

General Experimental Procedures

The reaction conditions chosen for this study were those

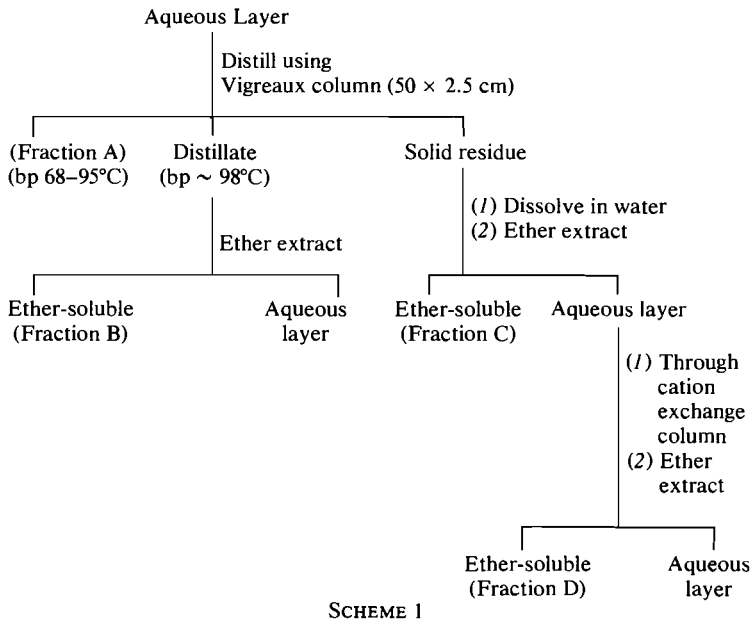

SCHEME 1

found earlier (6) to produce an oil in approximately 35% yield (based on wood meal) and whose fuel value was sufficiently attractive to warrant further study and to examine the mechanism of the reaction. The following standard conditions were adopted. The air-dried wood meal (5.4% moisture, 30 mesh) 100 g) from local aspen (*Populus tremuloides*, Michx) (18.8% lignin) was placed in the reaction vessel (1410 mL capacity) of a model 406-010A Aminco high pressure hydrogenator. To this was added a solution of water (500 mL) containing sodium carbonate (10 g), and carbon monoxide was admitted to an initial pressure of 3.4 MPa after twice flushing out the reactor. While being rocked the reactor was heated with continuous monitoring to 360°C (ca. 2.5 h required), held at this temperature (± 5°C) for one hour, and allowed to cool overnight. After sampling, the excess gases were released and the aqueous phase decanted from the oil phase. In a similar fashion cellulose (ashless powder for chromatographic use), cellobiose, D-glucose, D-fructose, D-xylose, an isolated lignin,[3] D-sorbitol, and glycerol were subjected separately to the same reaction conditions.

Gas Analysis

Chromatographic analysis of the gaseous phase was made using a copper column (1/8 in. × 15 ft) packed with silica gel (60–100 mesh), with argon as the carrier gas at a flow rate of 18 mL/min. Peak areas for individual gases were measured and their abundance determined from a previously prepared calibration curve.

Treatment of Aqueous Phase

From each run the aqueous phase (pH 6–7), which was initially colorless but rapidly darkened on exposure to air,[4] was treated as illustrated in Scheme 1.

Gas chromatographic analyses of fractions A, B, C, and D were made with a Model 5760 F & M Chromatograph with dual flame ionization detectors using stainless steel columns (1/8 in. od × 6 ft. Injections were made using 0.5 μL samples at an attenuation of $10^2 \times 16$ with nitrogen as carrier gas at a flow rate of 40 mL/min for fractions A, B, and C and 20 mL/min for fraction D. The amount of the cation exchange resin (REXYN 101; 220 mL) used was more than required to exchange the sodium ions.

Fraction A

The pale yellow liquid was chromatographed using a 1/8 in. od × 6 ft stainless steel column packed with Porapak Q (80/100 mesh), temperature programmed from 60 to 240°C at 6°/min and then held at 240°C. Typical chromatograms, with the main peaks identified, of this fraction from the runs using aspen wood, cellulose, and the isolated aspen lignin are shown in Figures 1, 2, and 3.

Fraction B

This small fraction was chromatographed using a 6 ft × 1/8 in. od column packed with 10% Carbowax 20 M on Chromosorb G (AW-DMCS treated) (60–80 mesh). The temperature was programmed from 40°C to 180°C at 6°/min and then held at 180°C. Several compounds were shown to be present differing from those found in fraction A but which have not been studied further.

Fraction C

The brown viscous liquid was chromatographed using the same column described for fraction B. The temperature was held at 30°C for six minutes, then programmed from 30°C to 180°C at 10°/min, and finally held at 180°C for two hours. Several peaks appeared representing higher boiling compounds than those found in fraction A. Their identification is under study but initial observations indicated the presence of low molecular weight phenolic compounds.

Fraction D

This fraction containing acidic compounds was chromatographed using a 6 ft × 1/8 in. od column packed with 10% SP-1200/1% H_3PO_4 on Chromosorb W (80–100 mesh, AW), programmed from 80°C to 180°C at 10°/min, and held at 180°C. Typical chromatograms with the main peaks identified from the runs using aspen wood and cellulose are shown in Figs. 4 and 5.

[3]Isolated according to the procedure of Pepper *et al.* (7, 8).

[4]For one run, emf measurements, relative to a standard calomel electrode, were made and showed an initial decrease from −0.0324 V to −0.496 V if done under nitrogen. Subsequent exposure to air resulted in a rapid increase of potential to around −0.12 V with simultaneous progressive darkening in color.

Discussion of Results

Any consideration of the overall mechanism of this reaction must involve an understanding of the changes undergone by the wood (or its component parts) in its conversion to the oil, gases, and water-soluble products. The magnitude and complexity of these changes is illustrated by the analytical data given in Table 1 and in Figs. 1 and 4.

A few general observations about the mechanism may now be made. It is significant that from the polymeric cellulose as well as from the smaller units of cellobiose, glucose, and xylose an oil is produced very similar to that obtained from the whole wood. This would suggest that all the wood components (cellulose, hemicelluloses, and lignin) are converted to a closely related product. If the oil were being produced from the cellulose only, then the yields using pure cellulose should have been correspondingly greater. However, using the isolated lignin there is a significant difference, the proportional yield of product is greater and is of a charry nature rather than an oil. It is suggested that

this may also occur if whole wood is used but that the char from the lesser lignin component is dissolved in the major oil fraction from the carbohydrates. Indeed this is borne out since the fluidity of wood oil is less than that from the carbohydrate model substances.

Of some mechanistic significance is that only from the potentially available aldoses was a fluid oil produced. Fructose (a ketose) gave rise to a char whereas sorbitol and glycerol gave minimal amounts of an oil product. A depolymerization of the cellulose (and likely the hemicelluloses) to smaller units more closely related to the dimer and the monomer is suggested, followed by conversion to the oil product. To check if the aqueous layer may contain such units, a recycling of this layer under the original conditions of temperature and pressure was made but no further oil was produced. Indeed this run also showed that the low molecular weight alcohols, ketones, and acids that were later found to be present in the aqueous layer did not contribute to the formation of the oil. The reduction (loss of oxygen content) of the starting materials to the oil product may result from a combination of dehydration and deoxygenation reactions with the oxygen reappearing in the highly complex mixture of highly oxygenated products (alcohols, ketones, and acids) found in the aqueous phase (Figs. 1 and 4) and in the components of the gaseous phase. The

specific mode of production of these low molecular weight products is not yet understood. A blank run with only water, sodium carbonate, and carbon monoxide did not give rise to any of these compounds with the exception of a small amount of methanol, which may be expected from the reduction of the carbon dioxide formed as a result of the shift reaction at 360°C.

It is significant that the gas chromatograms of fraction A obtained from aspen wood (Fig. 1), cellulose (Fig. 2), cellobiose, glucose, fructose, or xylose are, with one exception, essentially identical in terms of the types and relative abundance of the oxygenated compounds. This exception is the significant production of methanol from the wood only and presumably is derived from the lignin (see below). These same fractions from sorbitol and glycerol show the presence of the same oxygenated compounds but in different relative abundance. In the case of the isolated lignin (Fig. 3), the interesting feature is the large methanol peak, which may have arisen from the methoxyl groups of the lignin. The much lesser amounts of the alcohols and ketones from the lignin sample are thought to have originated from the small amount of carbohydrate still associated with the lignin as a result of the procedure used for the isolation.[5] Analysis of the various fractions A obtained from the aqueous layers of fourteen similar experiments carried out in these laboratories (6) using wood meal and combinations of temperatures of 320°, 340°, and 360°C, sodium carbonate concentrations of 7.5, 10, and 12.5% (relative to dry wood meal), and initial pressures of carbon monoxide of 1.7, 3.4, and 5.1 MPa revealed no significant differences. Whatever the reactions are that produce the multiplicity of compounds obtained, they were not affected significantly by the variations of these parameters that were studied.

No mechanistic significance can be attached to the composition of the residual gases of runs carried out at 360° (Table 1). Indeed it would appear that the final relative abundance is largely a result of the shift reaction involving carbon monoxide. The role of the necessary carbon monoxide is not clear: it may function in part as a direct oxygen abstractor or be involved in the production of formate as proposed by Appell *et al.* (2).

The observations from the use of wood and model compounds suggested that the water-soluble products may arise from the high temperature and high pressure decomposition of carbohydrates, unrelated to the process of the oil production and independent of the presence of sodium carbonate and/or carbon monoxide. Some further information was obtained from a set of experiments, the details of which are given in Table 2. There is ample evidence for the need of both sodium carbonate and carbon monoxide if an oily fraction is to be produced. Carbonization of carbohydrates is believed to occur after the decomposition of the polysaccharides into monosaccharides. The carbohydrate fragments are then converted to intermediates by elimination of oxygen as carbon dioxide and water. This elimination is in agreement with the data obtained from Run 2, which resulted in the production of ~12 g of carbon as carbon dioxide, only ~1.1 g of which would have arisen from the added sodium carbonate. It is also of interest to note that the water-insoluble product is produced in each case in similar yields (35 ± 7%). This suggests

[5] An attempt was made by Dr. Ian Reid, Prairie Regional Laboratory, NRC, Saskatoon, to remove any residual carbohydrate by microbial degradation. However, neither the use of ONEZUKA R-10 Cellulase enzyme or Driselase Enzyme effected any change in the percentage carbon.

TABLE 3. Observations on the effect of reaction temperature

Temperature °C	Solid products: Nature	Weight g	Analysis % C	H	Aqueous phase: pH	Fraction A g	Gas phase (Mole percentage) H_2	CO	CO_2

360	Oil	30.0	72.0	7.00	7	7.2	34	3	63

[a] From three replicate runs a total of ~45 g was recovered and recycled in an aqueous phase (no sodium carbonate added) and treated under standard conditions. A tarry material was produced weighing 12.5 g and analyzed: C 72.4%, H 7.4%.

[b] In a duplicate run when ~35 g were recycled in the aqueous phase (no sodium carbonate added) and treated under standard conditions, an oil was produced which weighed 28.6 g and analyzed: C 73.5%, H 7.4%.

that the overall conversion may be a two-stage process, an initial one to produce the significantly deoxygenated fraction, which is then subsequently converted (by reduction?) to the oily material.

Analysis of fraction A in each case showed essentially the same pattern of low-boiling monomeric compounds to be present (as per Fig. 1) but with a distinct variation in relative abundance. With the exception that from Run 5 there was negligible methanol produced, the products from Runs 3, 4, and 5 (without CO and Na_2CO_3) were similar, but the predominant compounds were the ketones with a much reduced relative abundance of the alcohols. If either carbon monoxide (Run 1) or sodium carbonate (Run 2) were present the relative abundance of the alcoholic components increased, suggesting a reducing role for each of these substances. The higher the initial applied pressure, be it from carbon monoxide or nitrogen (refer Runs 1, 2, 4), there is a marked increase in the yield of fraction A suggesting an enhanced penetration into the pores of the wood with a resulting increase in the overall reaction.

In monitoring the temperature of the reaction involving wood meal during the heating-up period, it had been noted that there always occurred a sudden rise in temperature indicative of a significant exothermic reaction. This happened in the 200–280°C range, depending on the initial reaction conditions. Such a temperature inflection appeared to a lesser degree with cellulose and not at all with the other model substances. To study this observation further a series of experiments, using wood meal, was carried out under the standard conditions used in this investigation but at several temperatures ranging from 160–360°C. The results are given in Table 3.

In this study of the liquefaction process of wood meal over the temperature range of 160–360°C, it is clear that a marked physical and chemical change of the wood substance occurs, which in turn appears to be associated in part with the observed exothermic reaction that occurs between 220°C and 240°C. It has been suggested (9) that such an exothermic reaction may be related to aromatization of carbohydrate substances. Before the inflection temperature (220°C) a powdery solid was left, representing 66% of the original wood mass, while after the inflection temperature (245°C) a light fluffy powder (11.7%) together with a charry material (~37%) was obtained. The carbon analysis of these products indicated that over the temperature range of the exothermic reaction, major chemical changes had also occurred and the overall conversion process had begun. The subsequent conversion, upon recycling, of the char and the fluffy powder (separately) into oil with an analysis similar to oil produced by a one-step treatment showed that these materials are the precursors of the oil in a standard run.

Another observation was made which may be of mechanistic significance. Recycling of the charry product (obtained at 245°C) resulted in the formation of 28.6 g of oil, while recycling of the fluffy powder (obtained from three runs at 245°C) produced 12.5 g of oil, or ~4 g of oil from one run. Combining the amount of oil obtained from recycling both the char and the fluffy powder (obtained from initially 100 g wood at 245°C) gives ~32.5 g of oil which is the average amount of oil obtained from a standard run. This observation suggests that each of the char and the fluffy powder is responsible for the production of a certain component of the oil. These products may differ in chemical composition and a further investigation of the nature of these oils will be required.

From the gas phase analyses it may be concluded that, as the temperature of the reaction increases,

TABLE 4. Gas chromatographic analysis of fractions A from runs at different temperatures[a]

[a] Data given are the abundances calculated relative to the yields from the run carried out at 360°C, and for which the sum of the peak areas identified and unidentified was assigned a value of 100.

carbon dioxide is being produced as a result of conversion of carbon monoxide by removal of oxygen from the wood components. Starting with the run at 220°C, the total number of moles of gases steadily increases. This may be seen from the data in Table 3 and as revealed by initial and final pressures measured at room temperature. It can be shown that for these runs the amount of carbon dioxide produced is greater than the corresponding loss of carbon monoxide, which suggests a removal of carbon from the wood and its conversion to carbon dioxide. At the higher temperatures further increases in the number of moles of gaseous products indicated that the shift reaction is becoming important. The relatively greater increase in carbon dioxide over hydrogen, however, may be the result of either more wood carbon being converted to carbon dioxide or the concurrent utilization of the hydrogen by some reduction process.

Although there is ample evidence (1) that water is necessary for oil production, its role is not clear. It should be noted that, as the temperature increases, the pH of the produced aqueous phase decreases from pH 12 (at 25°C; original sodium carbonate solution) to a minimum of pH 4 at 220–280°C and then increases again to pH 7 at 360°C. This suggests that as the temperature increases, acidic compounds are formed, and at higher temperatures (above 280°C), they are removed either by reduction or by decarboxylation.

It may be seen from Table 3, that as the temperature increases so does the yield of fraction A (low-boiling alcohols and ketones). From a gas chromatographic analysis of fraction A from each separate run, the relative abundances of the low-boiling compounds were calculated and are reported in Table 4. The relative abundance data are calculated relative to the yields of the run carried out at 360°C, and for which the sum of the peak areas (identified and unidentified) was assigned a value of 100. The peak area representing any compound (from any of the described runs) is reported as a percentage of the total area of the peaks in the chromatogram obtained from the run carried out at 360°C. It may be seen that at temperatures below the inflection point, the low-boiling distillate was composed, apart from methanol, mainly of ketonic compounds. As the temperature increases above the inflection temperature, the concentration of the alcoholic compounds increases while that of most of the ketonic compounds decreases. This suggests that the alcoholic compounds are formed by the reduction of ketonic compounds and/or formed directly from carbohydrate precursors.

Under the conditions used in this study the recovery of carbon and hydrogen in the oil represents approximately only half that originally present in the wood. Even though it has been shown (6) that the yield of the oil may be increased such that nearly two-thirds of the original carbon and hydrogen are recoverable in the oil, any successful commercialization of this type of process may depend on the utilization of all the products. In this study using aspen poplar wood, the recovery from 100 g of wood gave average yields of 33 g of an oil and a total of 19.5 g of water-soluble products (fraction A, 6.5 g; B, 0.7 g; C, 1.8 g; and D, 10.5 g).

These products represent a significant part of the wood in the form of recoverable chemicals of potential commercial value. Therefore an understanding of the chemical nature of water-soluble products is important and further research is needed to continue this study as well as to identify the chemical constituents of the oil. The approximately twenty percent oxygen content of the oil may mean that a secondary upgrading step would be required to produce a more useable higher quality fuel. In the long run it may be that this method of utilization of biomass be best adapted as a source of chemicals and, as such, as a viable alternative to the current use of fossil fuels for this purpose.

Reçu le 23 juin 1980[2]

DOMINIQUE AUDO, MAURICE VINCENS, CLAUDE DUMONT et MICHEL VIDAL. Can. J. Chem. **59**, 2199 (1981).

L'addition de RLi sur les alkyl-2 méthylène-3 cyclopropane carboxaldéhydes dans lesquels le groupement fonctionnel et le groupe alkyle présentent une relation *trans*, n'est pas diastéréosélective alors que la réduction des (alkyl-2 alkylidène-3 cyclopropyl) alkyl cétones présente pour certains termes une diastéréosélectivité élevée qui peut atteindre la stéréospécificité à basse température. Cette sélectivité dépend non seulement du degré de substitution du groupe fixé sur le carbonyle mais également du radical fixé en position 2 sur le cycle même s'il présente une relation *trans* par rapport au groupement fonctionnel. Les configurations relatives des alcools secondaires α-cyclopropylidéniques sont déterminées à partir de leurs données en ir et rmn; ces attributions de structures s'appuient, par ailleurs, sur une filiation chimique établie antérieurement.

DOMINIQUE AUDO, MAURICE VINCENS, CLAUDE DUMONT, and MICHEL VIDAL. Can. J. Chem. **59**, 2199 (1981).

The addition of RLi on *trans* 2-alkyl-3-methylene cyclopropane carboxaldehydes is not diastereoselective, while the reduction of *trans* (2-alkyl-3-alkylidene cyclopropyl) alkyl ketones shows for some compounds a high diastereoselectivity which may reach stereospecificity at low temperatures. This selectivity depends not only on the degree of substitution of the group fixed on the carbonyl but on the radical fixed in position 2 on the ring even though it shows a *trans* relation with the functional group.

The relative configurations of secondary α-cyclopropylidene alcohols are determined from their ir and nmr data.

Introduction

Un travail, actuellement en cours, sur la réactivité en milieu acide et à basse température des alcools secondaires α-cyclopropylidéniques nous a conduits à envisager l'étude de la réduction des (alkyl-2 alkylidène-3 cyclopropyl) alkyl cétones et de l'alkylation des alkyl-2 méthylène-3 cyclopropane carboxaldéhydes. Les alcools diastéréoisomères obtenus au cours de ces réactions, traités à basse température par un superacide (1), conduisent, en effet, au cation α-cyclopropylidénique. Ces dérivés peuvent donc apporter d'utiles informations pour la description de ce cation et pour l'étude de ses réactions de réarrangement.

L'induction asymétrique au cours de la réduction des cétones α-cyclopropaniques saturées ou vinyliques qui possèdent en α du carbonyle un carbone asymétrique, a motivé ces dernières années de nombreuses études (2 à 8). La diastéréosélection observée est généralement interprétée par le modèle stéréochimique de Karabatsos (9): le réactif nucléophile attaque la face du carbonyle la moins encombrée dans la conformation privilégiée du composé carbonylé. Ce type d'induction qui se situe dans le cadre plus général de l'induction asymétrique 1,2 (27, 28) et 1,3 (28, 29) a fait l'objet de nombreuses études.

La réduction des cétones α-cyclopropylidéniques qui possèdent, de même, un carbone asymétrique en α du groupement fonctionnel, n'a par contre pas été abordée. Cette étude pose le problème de l'identification des alcools diastéréoisomères qui résultent de cette réduction; à notre connaissance, seuls Bertrand et coll. ont proposé des attributions de configurations relatives dans le cas des (alkylidène-2 cyclopropyl) alkyl carbinols (10). On peut noter, par ailleurs, qu'en série cyclopropanique, il n'existe pas de méthode d'identification chimique simple permettant de distinguer les deux configurations relatives des alcools secondaires. Leur identification est généralement fondée sur des modèles stéréochimiques appliqués aux réactions de synthèse diastéréosélectives de ces alcools.

Dans ce mémoire, nous envisagerons successivement: (*1*) les résultats observés, quant à la diastéréosélection, au cours de la réduction des (alkyl-2 alkylidène-3 cyclopropyl) alkyl cétones dans lesquels le groupement fonctionnel et le groupe alkyle présentent une relation *trans* et de l'alkylation des aldéhydes homologues; (*2*) l'identification des configurations relatives des alcools secondaires α-cyclopropylidéniques. Cette identification est fondée sur les données ir et rmn de ces dérivés; les critères de configuration étant contrôlés sur un couple d'alcools diastéréoisomères, identifiés antérieurement par voie chimique (11); (*3*) le modèle stéréochimique permettant de prévoir la diastéréosélection observée. Nous envisagerons

essentiellement le cas de la réduction des cétones qui dans certaines conditions expérimentales peut être diastéréospécifique.

Partie expérimentale

(Alkyl-2 alkylidène-3 cyclopropyl) méthyl cétones 1, 7, 8, 9

A 0,2 mol d'acide cyclopropylidénique en solution dans 200 mL d'éther anhydre, on ajoute 0,4 mol de méthyllithium (1 *M* dans l'éther) en 30 min. Le mélange réactionnel est maintenu au reflux pendant une heure après la fin de l'addition. Après hydrolyse à 0°C en milieu acide (pH ≃ 3) et extraction à l'éther, la cétone est isolée par distillation sous pression réduite, puis purifiée par cpv (colonne Carbowax 20% de 6 m Chromosorb WAW 60/80, gaz vecteur H_2, θ = 140°C). Le rendement varie selon les termes de 70 à 80%.

Cétone 1: Composé **9** de la réf. 11.

Cétone 7: n_D^{20} 1,460$_5$; *E* 72°C/5 Torr; ir (film): ν(C=O) = 1700 cm^{-1}, ν(C=C) = 1740 cm^{-1}, ν(=C—H) = 3080 cm^{-1}, δ′(=CH_2) = 890 cm^{-1}; rmn (CCl_4/TMS): δH_1 = 2,18 ppm (1H, m), δH_2 = 2,00 ppm (1H, m), δ(=CH_2) = 5,38 ppm (2H, m), δ(CH_3—CO) = 1.98 ppm (3H, s), δ((CH_3)$_3$C) = 0,92 ppm (9H, s). Couplages: $^3J_{(H_1,H_2)}$ = 4,3 Hz, $^4J_{(H_2,H_{3b})}$ = 2,2 Hz, $^4J_{(H_1,H_{3b})}$ = 2,7 Hz, $^4J_{(H_1,H_{3a})}$ = 2.1 Hz, $^4J_{(H_2,H_{3a})}$ = 3,0 Hz.

Cétone 8: n_D^{20} 1,455$_0$; *E* 69°C/10 Torr; ir (film): ν(C=O) = 1696 cm^{-1}, ν(C=C) = 1750 cm^{-1}, ν(=C—H) = 3070 cm^{-1}, δ′(=CH_2) = 890 cm^{-1}; rmn (CCl_4/TMS): δH_1 = 2,10 ppm (1H, m), δ(=CH_2) = 5,32 et 5.37 ppm (2H, m), δ(*H_2*, CH_3CO) = de *1,80 à 2,00* (m), 1,96 ppm (s), (4H), δ(*CH_3*—CH_2) = 1,01 ppm (3H, t), δ(CH_3—*CH_2*) = 1,42 ppm (2H, m). Couplages: $^4J_{(H_2,H_{3b})} \simeq {}^4J_{(H_1,H_{3b})} \simeq {}^4J_{(H_1,H_{3a})} \simeq {}^4J_{(H_2,H_{3a})} \simeq$ 2,3 Hz. *Anal.* calc.: C 77,38, H 9,74, O 12,88; trouvé: C 77,48, H 9,52, O 12,85%.

Cétone 9: n_D^{20} 1,456$_0$: *E* 66°C/12 Torr; ir (film): ν(C=O) = 1695 cm^{-1}, ν(C=C) = 1750 cm^{-1}, ν(=C—H) = 3065 cm^{-1}, δ′(=CH_2) = 890 cm^{-1}; rmn (CCl_4/TMS): δH_1 = 2,06 ppm (1H, m), δ(=CH_2) = 5,36 et 5,41 ppm (2H, m), δ(*H_2*,CH_3CO) = de *1,80 à 2,00* ppm (m), 1,96 ppm (s), (4H), δCH_3 = 1,22 ppm (3H, d). Couplages: $^4J_{(H_2,H_{3b})} \simeq {}^4J_{(H_1,H_{3b})} \simeq$ 2,4 Hz, $^4J_{(H_1,H_{3a})}$ = 2,1 Hz, $^4J_{(H_2,H_{3a})}$ = 2,3 Hz. *Anal.* calc.: C 76,33, H 9,15, O 14,52; trouvé: C 76,47, H 9,11, O 14,46%.

(Alkyl-2 méthylène-3 cyclopropyl) alkyl cétones 2, 3, 4. Réaction d'alkylation

A une solution–suspension de 4 × 10^{-2} mol de $NaNH_2$ dans 50 mL de benzène, on ajoute 2 × 10^{-3} mol de cétone méthylée; le mélange réactionnel est maintenu à 40°C pendant 30 min. En maintenant la température constante, on ajoute alors 14 × 10^{-3} mol de MeI. L'agitation est poursuivie pendant deux heures. Après hydrolyse et extraction à l'éther la cétone est distillée puis purifiée dans les conditions précédentes. Le rendement est de l'ordre de 70 à 80%.

Cétone 2: *E* 75°C/8 Torr; ir (film): ν(C=O) = 1690 cm^{-1}, ν(C=C) = 1740 cm^{-1}, ν(=C—H) = 3075 cm^{-1}, δ′(=CH_2) = 885 cm^{-1}; rmn (CCl_4/TMS): δ(H_1,H_2) = 2 à 2,27 ppm (2H, m), δ(=CH_2) = 5,13 et 5,40 ppm (2H, m), δCH_3 = 1,02 (3H, d), δ((CH_3)$_3$C) = 1,14 ppm (9H, s).

Cétone 3: n_D^{20} 1,455$_6$; *E* 73°C/5 Torr; ir (film): ν(C=O) = 1690 cm^{-1}, ν(C=C) 1745 cm^{-1}, ν(=C—H) = 3067 cm^{-1}, δ′(=CH_2) = 882 cm^{-1}; rmn (CCl_4/TMS): δH_1 = 2,35 ppm (1H, m), δH_2 = 2,20 ppm (1H, m), δ(=CH_2) = 5,23 et 5,39 ppm (2H, m), δCH_3 = 1,01 (3H, t), δCH_2 = 1,42 (2H, m), δ(CH_3)$_3$C = 1,18 (9H, s). Couplages: $^3J_{(H_1,H_2)}$ = 4,4 Hz, $^4J_{(H_2,H_{3b})} = {}^4J_{(H_1,H_{3b})} \simeq$ 2,3 Hz, $^4J_{(H_1,H_{3a})}$ = 1,9 Hz, $^4J_{(H_2,H_{3a})}$ = 2,9 Hz.

Cétone 4: n_D^{20} 1,452$_5$; *E* 73°C/3 Torr; ir (film); ν(C=O) = 1695 cm^{-1}, ν(C=C) = 1745 cm^{-1}, ν(=C—H) = 3068 cm^{-1}, δ′(=CH_2) = 885 cm^{-1}; rmn (CCl_4/TMS): δH_1 = 2,46 ppm (1H, m), δH_2 = 2,13 ppm (1H, m), δ(=CH_2) = 5,20 et 5,30 ppm (2H, m), δ(CH_3)$_3$C = 0,93 ppm (9H, s), δ((CH_3)$_3$C—CO) = 1,18 ppm (9H, s).

(Tertiobutyl-2 méthylène-3 cyclopropyl) alkyl cétones 5, 6

Ces composés ont été préparés par alkylation partielle de la cétone méthylée **7** (26). A une solution–suspension de 7 × 10^{-2} mol de $NaNH_2$ dans 150 mL de benzène, on ajoute 4 × 10^{-2} mol de cétone méthylée; le mélange réactionnel est chauffé à 40°C pendant 30 min. En maintenant la température constante, on ajoute alors 4 × 10^{-2} mol de MeI; l'agitation est poursuivie pendant deux heures. Après hydrolyse, extraction à l'éther, la distillation du mélange brut (68 à 78°C/5 Torr) fournit 5 g de produits volatils dans lesquels on retrouve 50% de cétone **7** qui n'a pas réagi, 10% de cétone **6**, 25% de cétone **5** et 15% de cétone **4**. Ces quatre produits ont été séparés en chromatographie en phase gazeuse (dans les mêmes conditions que précédemment).

Cétone 6: ir (film): ν(C=O) = 1697 cm^{-1}, ν(C=C) = 1742 cm^{-1}, ν(=C—H) = 3070 cm^{-1}, δ′(=CH_2) = 885 cm^{-1}; rmn ^{1}H (CCl_4/TMS): δ$_1$(H_1,H_2) = 1,90 à 2,30 ppm (2H, m), δ(=CH_2) = 5,33 ppm (2H, m), δ(C*H_3*—CH_2) = 1,02 ppm (3H, t), $^3J_{(CH_2-CH_3)}$ = 7,2 Hz, δ(C*H_2*—CH_3) = 2,38 ppm (2H, q), δ(CH_3)$_3$C = 0,92 ppm (9H, s).

Cétone 5: n_D^{20} 1,450$_5$; ir (film): ν(C=O) = 1695 cm^{-1}, ν(C=C) = 1745 cm^{-1}, ν(=C—H) = 3068 cm^{-1}, δ′(=CH_2) = 885 cm^{-1}; rmn ^{1}H (CCl_4/TMS): δH_1 = 2,21 ppm (1H, m), δH_2 = 2,08 ppm (1H, m), δ(=CH_2) = 5,28 ppm (2H, m), δ$\left(CH(CH_3)_2\right)$ = 2,46 ppm (1H, h), δ$\left(CH(CH_3)_2\right)$ = 1,08 ppm (6H, d), $^3J\left(CH(CH_3)_2\right)$ = 8 Hz, δ(CH_3)$_3$C = 0,92 ppm (9H, s).

(Diméthyl-2,2 méthylène-3 cyclopropyl) méthyl cétone 10

En présence de cuivre en poudre (1 g) on ajoute lentement, en maintenant la température à 80°C, 0,35 mol de diazoacétate d'éthyle à 0,44 mol de bromo-2 méthyl-3 butène-2. Après décantation et distillation on obtient 0,046 mol de bromo-2 triméthyl-2,3,3 cyclopropanecarboxylate d'éthyle (rendement 13%). Les deux isomères n'ont pas été séparés; *E* 70 à 75°C/8 Torr; ir (film): ν(C=O) = 1725 cm^{-1}; rmn ^{1}H (CCl_4/TMS) du mélange des deux isomères: δ$\left(CH_3-C(Br)\right)$ = 1,99 et 1,50 ppm, δ(H—◁) = 1,92 et 1,87 ppm, δ$\left(C(CH_3)_2\right)$ = 1,29 ppm, δ(CH_2—CH_3) = 4,23 et 4,11 ppm, δ(CH_2—CH_3) = 1,29 et 1,25 ppm.

0,04 Mol de bromo-2 triméthyl-2,3,3 cyclopropanecarboxylate d'éthyle sont ajoutés à 100 mL d'une solution de potasse 3 *M* dans le butanol-1; le contact est maintenu pendant 12 h à 120°C. Après évaporation de l'alcool butylique sous pression réduite, le résidu est dissous dans l'eau et l'acide cyclopropylidénique précipité par addition d'acide chlorhydrique *N*.

Après extraction de la phase aqueuse à l'éther, la distillation fournit 4,3 g d'acide diméthyl-2,2 méthylène-3 cyclopropanecarboxylique (rendement: 80%); *E* 67°C/0,3 Torr; ir (film): ν(C=O) 1695 cm^{-1}, δ′(CH_2) = 895 cm^{-1}; rmn ^{1}H (CCl_4/TMS): δ$\left(H-\triangledown\right)$ = 1,85 ppm (1H, m), δ$\left(C(CH_3)_2\right)$ = 1,29 et 1,32 ppm (6H, 2 singulets), δ(=CH_2) = 5,37 ppm (2H, m), δ(OH) = 8,27 ppm (1H, s).

Le mode opératoire de la réduction de l'acide diméthyl-2,2 méthylène-3 cyclopropanecarboxylique par MeLi est identique à celui décrit pour la synthèse de **1**, **7**, **8**, **9**. La distillation (*E* 69°C/11 Torr) permet d'obtenir la cétone **10** avec un rendement de 46%.

Cétone 10: ir (film): ν(C=O) = 1700 cm^{-1}, ν(C=C) = 1745 cm^{-1}, ν(=C—H) = 3055 cm^{-1}, δ′(=CH_2) = 883 cm^{-1}; rmn ^1H (CCl_4/TMS): δ(H_1) = 2,11 ppm (1H, m), δ(H_{3a}) = 5,18 ppm (1H, d), δ(H_{3b}) = 5,26 (1H, d), $^4J_{H_1-H_{3a}} \simeq 2{,}0$ Hz, $^4J_{H_1-H_{3b}} \simeq 2{,}5$ Hz, δ(CH_3—C=O) = 2,05 ppm (3H, s), δ($(CH_3)_2$C) = 1,13 ppm et 1,24 ppm (6H, 2 singulets).

Réduction des cétones 1à 10

A une solution de 0,1 mol de cétone dans l'éther anhydre, on ajoute 0,1 mol de $AlLiH_4$ en solution–suspension dans l'éther. Après la fin de l'addition, le mélange réactionnel est maintenu au reflux pendant 30 min puis hydrolysé à 0°C, neutralisé par HCl (1 *N*) et extrait à l'éther. Le mélange d'alcools est distillé sous pression réduite; le rendement de réduction (diastéréoisomères I + II) varie de 80 à 95%. L'étude en cpv analytique du mélange réactionnel brut ne permet de détecter que les isomères I et II qui sont isolés en cpv préparative sur colonne Carbowax (20%) de 4 m (Chromosorb P, NAW 60/80, gaz vecteur H_2).

Les masses molaires déterminées par spectrométrie de masse correspondent aux composés décrits et les formules brutes sont en accord avec leur analyse élémentaire; quelques-unes de celles-ci seront détaillées. Les indices de réfraction n_D^{20} n'ont pas été déterminés pour les alcools **17**, **18**, **19**, **21** et **22** longs à obtenir à l'état pur. La rmn ^1H a été réalisée à 60 MHz.

Couple d'isomères 11 et 12: voir réf. 11.

Couple d'isomères 13 et 14: *E* (du mélange) ≃ 42 à 47°C/1,9 Torr. Alcool **13**: n_D^{20} $1{,}454_0$; ir (film): ν(=C—H) = 3055 cm^{-1}, ν(C=C) = 1750 cm^{-1}, δ′(=C—H) = 890 cm^{-1}, ν(OH) voir tableau 1; rmn ^1H (CCl_4/TMS): δR′ = 1,15 ppm (3H, pic large), δR = 0,92 ppm (9H, s), δH_4 = 2,70 ppm (1H, d), δH_{3a} et H_{3b} = 5,20 ppm (2H, pic large), δH_1 et H_2 massif entre 1,0 et 1,2 ppm (2H), $^3J_{H_1-H_4}$ = 7,4 Hz. Alcool **14**: n_D^{20} $1{,}454_7$; ir (film): ν(=C—H) = 3058 cm^{-1}, ν(C=C) = 1760 cm^{-1}, δ′(=C—H) = 885 cm^{-1}, ν(OH) voir tableau 1; rmn ^1H (CCl_4/TMS): δR′ = 1,20 ppm (3H, pic large), δR = 0,92 (9H, s), δH_4 = 2,64 ppm (1H, d), δH_{3a} et H_{3b} = 5,02 et 5.17 ppm (1H × 2), δH_1 et H_2 massif entre 1,2 et 1,4 ppm (2H), $^3J_{H_1-H_4}$ = 8,4 Hz. *Anal.* calc.: C 77,87, H 11,76, O 10,37; trouvée (**13**): C 77,60, H 11,82, O 10,75; (**14**): C 78,05, H 11,46, O 10,20%.

Couple d'isomères 15 et 16: *E* (du mélange) ≃ 44 à 49°C/1,5 Torr. Alcool **15** n_D^{20} $1{,}455_7$; ir (film): ν(=C—H) = 3060 cm^{-1}, ν(C=C) = 1755 cm^{-1}, δ′(=C—H) = 883 cm^{-1}, ν(OH) voir tableau 1; rmn ^1H (CCl_4/TMS): δR′, H_1 et H_2 massif entre 1,0 et 1,4 ppm (7H), δR = 0,97 ppm (9H, s), δH_4 = 2,77 ppm (1H, d), δH_{3a} et H_{3b} = 5,36 ppm (2H, pics larges), $^3J_{H_1-H_4}$ = 6.9 Hz. Alcool **16** n_D^{20} $1{,}454_8$; ir (film): ν(=C—H) = 3058 cm^{-1}, ν(C=C) = 1755 cm^{-1}, δ′(=C—H) = 888 cm^{-1}, ν(OH) voir tableau 1; rmn ^1H (CCl_4/TMS): δR′, H_1 et H_2 massif entre 1,0 et 1,4 ppm (7H), δR = 0,95 ppm (9H, s), δH_4 = 2,65 ppm (1H, d), δH_{3a} et H_{3b} = 5,20 et 5,32 ppm (1H × 2), $^3J_{H_1-H_4}$ = 8,5 Hz.

Couple d'isomères 17 et 18: *E* (du mélange) ≃ 50 à 55°C/0,8 Torr. Alcool **17**: ir (film): ν(=C—H) = 3055 cm^{-1}, ν(C=C) = 1750 cm^{-1}, δ′(=C—H) = 890 cm^{-1}, ν(OH) voir tableau 1; rmn ^1H (CCl_4/TMS): δR′ = 0.88 ppm (9H, s), δR = 0,92 ppm (9H, s), δH_4 = 2,81 ppm (1H, d), δH_{3a} et H_{3b} = 5,20 et 5,40 ppm (1H × 2), δH_1 et H_2 massif vers 1,1 ppm (2H), $^3J_{H_1-H_4}$ = 5,7 Hz. Alcool **18**: ir (film): ν(=C—H) = 3060 cm^{-1}, ν(C=C) = 1755 cm^{-1}, δ′(=C—H) = 890 cm^{-2}, ν(OH) voir tableau 1; rmn ^1H (CCl_4/TMS): δR′ = 0,87 ppm (9H, s), δR = 0,92 ppm (9H, s), δH_4 = 2,60 ppm (1H, d), δH_{3a} et H_{3b} = 5,25 ppm (2H, pic large), δH_1 et H_2 massif vers 1,4 ppm (2H), $^3J_{H_1-H_4}$ = 8,6 Hz. Remarque: les composés **17** et **18** dont les temps de rétentions sont voisins ont été purifiés par passages répétés en cpv sur colonne Carbowax. Le composé **18** a été isolé à partir du mélange de réduction de la cétone **4**, le composé **17** à partir du mélange de réduction de l'aldéhyde **38** par *t*BuLi.

Couple d'isomères 19 et 20; non distillé: la cétone **5** étant difficile à obtenir en quantité suffisante, **19** et **20** ont été isolés en cpv à partir du mélange brut de réduction. Alcool **19**: ir (film): ν(=C—H) = 3057 cm^{-1}, ν(C=C) = 1757 cm^{-1}, δ′(=C—H) = 887 cm^{-1}, ν(OH) voir tableau 1; rmn ^1H (CCl_4/TMS): δR′ = 0,90 ppm (9H, s), δR = 0,95 ppm (6H, d) et 1,55 ppm (1H, m), δH_4 = 2,90 ppm (1H, m), δH_{3a} et H_{3b} = 5,38 et 5,50 ppm (1H × 2), δH_1 et H_2 = 1,2 et 1,4 ppm (2H, m), $^3J_{(H_1-H_4)}$: mal lisible, $^3J((CH_3)_2$–C*H*) = 6,8 Hz, $^3J_{H_4-R} \simeq 7$ Hz. Alcool **20**: n_D^{20} $1{,}456_0$; ir (film): ν(=C—H) = 3062 cm^{-1}, ν(C=C) = 1752 cm^{-1}, δ′(=C—H) = 892 cm^{-1}; ν(OH) voir tableau 1; rmn ^1H (CCl_4/TMS): δR′ = 0,90 ppm (9H, s), δR = 0,95 ppm (6H, d), δH_4 = 2,80 ppm (1H, m), δH_{3a} et H_{3b} = 5,35 ppm (2H, pic large), δCH(R) et δH_1 et H_2: massif entre 1,2 et 1,5 ppm (3H), $^3J_{H_1-H_4}$ = 5,8 Hz, $^3J((CH_3)_2$–C*H*) = 6,8 Hz, $^3J_{H_4-R}$ = 7,0 Hz.

Couple d'isomères 21 et 22; non distillé: la cétone **6** étant difficile à obtenir en quantité suffisante, **21** et **22** ont été isolés en cpv à partir du mélange brut de réduction. Alcool **21**: ir (film): ν(=C—H) ≃ 3060 cm^{-1}, δ′(=C—H) ≃ 890 cm^{-1}, ν(OH) voir tableau 1; rmn ^1H: δR′ = 0,90 ppm (9H, s), δCH_3(R) = 0,95 ppm (3H, t), δH_4 = 3,00 ppm (1H, m), δH_{3a} et H_{3b}: massif entre 5,4 et 5,5 ppm (2H), δCH_2(R) et δH_1 et H_2: massif entre 1,2 et 1,5 ppm (3H), $^3J_{H_1-H_4}$ et $^3J_{H_4-CH_2}$ mal lisibles, $^3J(CH_2-CH_3) \simeq 6{,}8$ Hz. Alcool **22**: ir (film): ν(=C—H) ≃ 3060 cm^{-1}, δ′(=C—H) ≃ 890 cm^{-1}, ν(OH) voir tableau 1: rmn ^1H: δR′ = 0,89 ppm (9H, s), δCH_3(R) = 0,95 ppm (3H, t), δH_4 = 3,03 ppm (1H, m), δH_{3a} et H_{3b} = 5,35 ppm (2H, pic large), δCH_2(R) et δH_1 et H_2: massif entre 1,2 et 1,5 ppm (3H), $^3J_{H_1-H_4}$ = 6,2 Hz, $^3J_{H_4-CH_2}$ = 6,4 Hz, $^3J(CH_2-CH_3) \simeq 6{,}8 \pm 0{,}2$ Hz.

Couple d'isomères 23 et 24: *E* du mélange ≃ 47 à 55°C/2,6 Torr. Synthèse des alcools α-cyclopropylidéniques primaires 33 à 35

Les alcools α-cyclopropéniques **30** à **32** sont préparés selon réf. 14. On additionne les alcools ainsi obtenus (0,006 mol) à une solution–suspension de 0,03 mol de tertiobutylate de potassium dans 10 mL de diméthylsulfoxyde anhydre. Après une heure de réaction à 20°C, on hydrolyse à froid avec 80 mL d'eau. La phase organique, extraite à l'éther, lavée à l'eau, est séchée sur sulfate de sodium. La distillation conduit aux alcools cyclopropylidéniques **33** à **35** avec un rendement moyen de 70%.

Alcool 33: *E* 37°C/7 Torr; ir (film): ν(=CH) = 3065 cm^{-1}, ν(C=C) = 1758 cm^{-1}, δ′(=CH) = 880 cm^{-1}; rmn de H_1, 60 MHz (CCl_4/TMS): δ(CH_3) = 1,20 ppm (3H, d), δ(=CH_2) = 5,35 ppm (2H, m), δ(CH_2OH) = 3,40 ppm (2H, m). H_1 et H_2 résonnent entre 1,20 et 1,50 ppm et ne sont pas analysables; $J_{(H_2, CH_3)}$ = 6,4 Hz.

Alcool 34: *E* (**34**) 40°C/6 Torr; *E* (**35**) 42°C/3,4 Torr; ir (film): ν(=CH) = 3065 cm^{-1}, ν(C=C) = 1755 cm^{-1}, δ′(=CH) = 875 cm^{-1}; rmn de ^1H (CCl_4/TMS): δ(CH_2—CH_3) = 1,0 ppm (3H, t), δ(=CH_2) = 5,33 ppm (2H, m), δ(CH_2OH) = 3,43 ppm. H_1, H_2 et CH_2—CH_3 résonnent entre 1,20 et 1,70 ppm et ne sont pas analysables à 60 MHz; $J_{(H_2-CH_2CH_3)}$ = 6,4 Hz et $J(CH_2-CH_3)$ = 6,5 Hz, ont été déterminés à 250 MHz. L'alcool **35** présente en ir et rmn des caractéristiques analogues à celles de **33** et **34**.

Oxydation des alcools 33 à 35 en aldéhydes 36 à 38

Elle a été réalisée selon la méthode de Sarett et coll. (15); 4,5 g d'anhydride chromique sont introduits par petites portions dans 50 mL de pyridine anhydre maintenue à 15°C. On ajoute 0,01 mol d'alcool **33** à **35** et on poursuit l'agitation pendant 15 h. Le mélange réactionnel est versé dans de l'eau glacée et extrait à l'éther. La phase organique est acidifiée à pH ≃ 2 par une solution acide 3 *N*. Après sèchage, évaporation du solvant, la distillation fournit les aldéhydes **36** à **38**; rendement moyen: 45%.

Aldéhyde 36: *E* 45°C/2,5 Torr; ir (film): ν(=CH_2) = 3080 cm^{-1}, ν(CHO) = 2730 cm^{-1}, ν(C=O) = 1720 cm^{-1}, δ′(C=C) = 895 cm^{-1}; rmn de ^1H, 60 MHz (CCl_4/TMS): δ(CH_3) = 1,25 ppm (3H, d), δ(H_1 et H_2) ≃ 2,05 ppm, δ(CHO) = 8,70 ppm (1H, d), δ(=CH_2) = 5,55 ppm (2H, m); $^3J_{(H_1,CHO)}$ = 5,5 Hz, $^3J_{(H_2,CH_2)}$ = 6,0 Hz.

Aldéhyde 37: *E* 51°C/1,7 Torr; ir (film): ν(=CH_2) = 3080 cm^{-1}, ν(CHO) = 2730 cm^{-1}, ν(C=O) = 1715 cm^{-1}, δ′(C=C) = 890 cm^{-1}; rmn de ^1H, 60 MHz (CCl_4/TMS): δ(CH_2,CH_3) = 0,95 ppm (3H, t), δ(H_1,H_2,CH_2) vers 2 ppm, δ(CHO) = 8,70 ppm (1H, d), δ(=CH_2) = 5,40 ppm (2H, m), $^3J_{(H_1,CHO)}$ = 5,4 Hz.

Aldéhyde 38: *E* 55°C/1,9 Torr; ir (film): ν(=CH_2) = 3075 cm^{-1}, ν(CHO) = 2720 cm^{-1}, ν(C=O) = 1710 cm^{-1}, δ′(C=C) = 895 cm^{-1}; rmn de ^1H, 60 MHz (CCl_4/TMS): δ(*t*Bu) = 0,96 ppm (9H, s), δ(H_1,H_2) vers 2,10 ppm, δ(CHO) = 8,78 ppm (1H, d), δ(=CH_2) = 5,60 ppm, $^3J_{(H_1,CHO)}$ = 5,5 Hz.

Alkylation des aldéhydes 36 à 38 par RLi

Les alkyllithiums commerciaux utilisés sont en solution dans le pentane. La réaction est réalisée sous azote à −70°C, et l'alkyllithium est introduit à la seringue au travers d'une membrane dans les proportions suivantes: 0,016 mol de RLi dans une solution de 0,004 mol d'aldéhyde dans 50 mL d'éther. L'agitation est maintenue pendant 2 h, la température du mélange réactionnel demeurant inférieure à −60°C. Après hydrolyse sur un mélange eau–glace et extraction à l'éther, les alcools diastéréoisomères (**13** à **20**) sont séparés en cpv sur colonne Carbowax NAW, 4,30 m; rendement moyen: 50 à 60%.

Equilibration des alcools 23 et 24 en présence de Al(OiPr)$_3$

Une solution contenant 180 mg d'alcool **23** (ou **24**), 240 mg d'isopropylate d'aluminium, 50 μL d'acétone et 3 mL d'isopropanol est maintenue à ébullition pendant 5 jours. Après hydrolyse et neutralisation, le mélange est analysé en cpv sur colonne Carbowax (20%) de 4 m (Chromosorb P NAW 60/80, gaz vecteur: H_2; θ = 150°C).

Techniques analytiques

Les spectres rmn de ^1H ont été tracés sur appareils Perkin-Elmer R.10 (60 MHz) et Cameca (250 MHz). Les constantes de couplages allyliques et homoallyliques ont été déterminées à 250 MHz.

Les spectres ir ont été tracés sur un appareil Perkin-Elmer 521 à réseaux (vitesse 3 cm min^{-1}). Une dilution progressive dans CCl_4 séché, jusqu'à 10^{-3} mol L^{-1}, a permis d'éliminer les associations intermoléculaires. Les solutions ont été préparées sous atmosphère d'azote anhydre (KOH; P_2O_5) et les cuves maintenues dans une enceinte sèche pendant le tracé des spectres; ces conditions sont nécessaires pour éliminer les bandes d'absorption de l'eau.

Résultats et discussion

1. *Réduction des (alkyl-2 alkylidène-3 cyclopropyl) alkyl cétones (1 à 10)*

L'isomérisation en milieu basique des esters α-cyclopropéniques, dont la synthèse est maintenant bien connue (12), conduit aux acides α-cyclopropylidéniques dans lesquels le groupe alkyle et le groupement fonctionnel présentent une relation *trans* par rapport au cycle (13). La réduction du groupement carboxylique par le méthyllithium fournit les cétones α-cyclopropylidéniques méthylées **1**, **7**, **8**, **9**,**10**. L'alkylation de certains de ces termes, en solution dans le benzène et en présence d'amidure de sodium, par l'iodure de méthyle, permet d'accéder aux dérivés **2**, **3**, **4**, **5**, **6**.

La réduction à 39°C (par une solution–suspension dans l'éther d'aluminohydrure de lithium) des cétones α-cyclopropylidéniques **1** à **10**, dont les faces du carbonyle sont diastéréotopiques, conduit au couple d'alcools diastéréoisomères I et II (**11** à **29**). Les diastéréoisomères II sont ceux dans lesquels R et C_3 d'une part et H_4 et C_2 d'autre part peuvent être simultanément quasi-éclipsés.

Les alcools ont été isolés par cpv préparative à l'exception de **25***a* et **25***b* qui ont cependant été détectés et dosés en cpv analytique et en rmn de ^1H.

2. *Réduction des alkyl-2 méthylène-3 cyclopropane carboxaldéhydes (36 à 38)*

La réduction des esters cyclopropylidéniques par $AlLiH_4$ en solution dans l'éther conduit facilement aux alcools cyclopropéniques (14) qui, traités en milieu basique, subissent la migration exocyclique de la double liaison. L'oxydation ménagée (15) des alcools cyclopropylidéniques ainsi obtenus permet d'accéder aux aldéhydes **36** à **38**.

La transformation des aldéhydes **36** à **38** par les alkyllithium (EtLi, *i*PrLi, *t*BuLi), en solution dans l'éther à 0°C, présente une diastéréosélection négli-

geable. Cette méthode est cependant intéressante car elle permet d'avoir accès aux diastéréoisomères II qui sont obtenus avec des rendements souvent très faibles au cours de la réduction des cétones α-cyclopropylidéniques (ex: **17** et **19**).

3. *Attribution des configurations relatives aux alcools secondaires α-cyclopropylidéniques 11 à 29*

Les configurations relatives des alcools secondaires **11** et **12** ont été établies antérieurement par voie chimique (11).

Dans une première phase, l'identification des [éthyl-2 vinyl-3 cyclopropyl (1*R**,2*S**,3*S**)]-1 éthanol 4*S** (**39**) et 4*R** (**40**) est réalisée par l'étude en résonance magnétique nucléaire de ^1H et de ^{13}C des oxa-3 bicyclo[3.1.0] hexanes obtenus par oxymercuration cyclisante de ces alcools.

Dans une seconde phase, une filiation chimique est établie entre les alcools vinylcyclopropaniques **39** et **40** d'une part et les alcools cyclopropylidéniques **11** et **12** d'autre part.

Cette méthode d'identification chimique, si elle a permis d'affecter les configurations relatives 1*R**, 2*R**,4*S**(**11**) et 1*R**,2*R**,4*R** (**12**) aux (éthyl-2 éthylidène-3 cyclopropyl)-1 éthanols E, reste difficile à mettre en œuvre; par ailleurs, elle n'est pas applicable aux alcools méthylènecyclopropaniques. Nous avons donc recherché des corrélations en spectrophotométrie infrarouge et en résonance magnétique nucléaire qui permettent de généraliser facilement ce type d'attribution.

Spectrophotométrie infrarouge

L'ensemble des données infrarouge est en accord avec la structure cyclopropylidénique; on note en particulier les vibrations ν(=C—H), ν(C=C) et δ′(=C—H) localisées respectivement vers 3050, 1750 et 880 cm^{-1}.

L'étude des vibrations ν(OH libre) et ν(OH ché-

SCHÉMA 3

laté) réalisée par dilution des alcools dans CCl_4 est résumée dans le tableau 1. Ces données permettent de classer l'ensemble des alcools cyclopropylidéniques en deux catégories.

Composés I. Le spectre de ces alcools présente une bande d'absorption ν(OH libre), très intense, localisée vers 3617–3621 cm^{-1}. Cependant, dans tous les cas étudiés, on note la présence sur cette bande d'absorption d'un épaulement de faible intensité vers 3585–3595 cm^{-1} qui subsiste à dilution élevée. Cette bande ne peut donc être attribuée qu'à une vibration ν(OH chélaté).

Composés II. Le spectre de ces composés présente, pour une dilution élevée, deux bandes d'absorption, très nettement individualisées, localisées vers 3618–3620 cm^{-1} (ν(OH libre)) et vers 3570–3580 cm^{-1}. Cette dernière bande, d'intensité moyenne, a été attribuée comme précédemment à une vibration ν(OH chélaté).

Il est important de signaler, par ailleurs, l'homogénéité de ces deux catégories de composés. En effet, quelque soit le couple de diastéréoisomères considéré, l'intensité de la bande d'absorption attribuée à la vibration ν(OH chélaté) des composés I, est très inférieure à celle des composés II (tableau 1).

Les vibrations ν(OH chélaté) observées ne peuvent correspondre qu'à deux types d'interaction: l'interaction OH – double liaison cyclopropylidénique (16) qui se traduit généralement par une vibration ν(OH chélaté) localisée vers 3580 cm^{-1}; l'interaction OH – liaison σ du cycle propanique visualisée par une bande d'absorption localisée vers 3595 cm^{-1} (16, 17). Compte tenu de ces valeurs nous devons conclure que les composés I présentent une très faible chélation OH – liaison σ alors que pour les composés II la chélation est du type OH – double liaison.

Si l'on admet que les conformères privilégiés autour de la liaison C_1—COH sont décalés, seuls les conformères a et a′ peuvent permettre une liaison intramoléculaire OH... π. Dans cette conformation, en effet, l'hydrogène du groupement fonctionnel, lorsqu'il est au-dessus du plan du cycle, est situé à 2 Å environ de la double liaison cyclopropanique. Dans les conformères c et c′, l'hydrogène qui reste relativement éloigné du système $\pi(d \geq 3$ Å) tend à se rapprocher au contraire du plan du cycle ce qui défavorise l'interaction OH – double liaison.

Les conformères b, b′, c et c′, dans lesquels l'hydrogène du groupement OH peut se rapprocher du plan du cycle en C_3, favoriseront par contre la chélation OH – liaison σ du cycle.

Il est a priori difficile d'établir une relation entre les données infrarouges des alcools α-cyclopropylidéniques I et II et leur configuration relative. La libre rotation du groupement fonctionnel autour de la liaison C_1—COH combinée à celle de l'hydrogène autour de la liaison C—OH conduit, en effet, à neuf conformères dont les populations dépendent de cette configuration. Cependant, si nous faisons l'hypothèse que la nature de la liaison hydrogène observée dépend au premier ordre des populations conformationnelles autour de la liaison C_1—COH, on peut prévoir que les diastéréoisomères (II) présenteront une liaison hydrogène OH – double liaison alors que dans le cas des configurations (I) on doit éventuellement observer une chélation OH – liaison σ. En effet, en raison de l'interaction stérique $R–H_{(2)}$, le conformère a, qui permet seul la chélation, OH – double liaison, sera nettement favorisé dans II par rapport à I.

L'étude des [éthyl-2 éthylidène-3 cyclopropyl ($1R^*$, $2R^*$)]-1 éthanol $4S^*$ (**11**) et $4R^*$ (**12**), dont les configurations ont été déterminées par voie chimique, confirme cette hypothèse; seul l'isomère **11** présente en effet une liaison hydrogène OH – π

*Epaulement.

(νOH = 3574 cm^{-1}) alors que dans le cas de l'alcool **12** on note uniquement la présence d'un épaulement (ν ≃ 3588 cm^{-1}) sur la bande OH libre. Ces résultats permettent d'attribuer à l'ensemble des composés I la configuration dans laquelle R et C_3 ainsi que H_4 et C_2 peuvent être quasi-éclipsés et à l'ensemble des composés II la deuxième configuration relative. Ils constituent, par ailleurs, une confirmation des attributions de structures proposées par Bertrand et coll. pour quelques couples de méthylènecyclopropylcarbinols (10).

Résonance magnétique nucléaire de ^1H

L'ensemble des données rmn est en accord avec une structure cyclopropylidénique dans laquelle les deux groupes substitués sur le cycle présentent une relation *trans*. La valeur de la constante de couplage $^3J_{H_1-H_2}$, qui a pu être déterminée pour quelques termes en utilisant un appareil fonctionnant à 250 MHz, est en effet de l'ordre de 5 Hz (18).

Les valeurs des constantes de couplage $^3J_{H_1-H_4}$ (tableau 1) permettent de confirmer, pour certains couples de diastéréoisomères, les attributions de configuration relative. La valeur de cette constante est en effet reliée aux populations conformationnelles par l'équation des équilibres rapides (19):

$$^3J_{H_1-H_4} = \Sigma\, n_i J_i$$

pour les composés I:

$$^3J_{H_1-H_4} = {}^3J_{60}\,(n_a + n_c) + {}^3J_{180} n_b$$

pour les composés II:

$$^3J_{H_1-H_4} = {}^3J_{60}\,(n_{a'} + n_{b'}) + {}^3J_{180} n_{c'}$$

Comparaison des valeurs des constantes $^3J_{H_1-H_4}$ pour les termes I et II d'un même couple de diastéréoisomères

Lorsque la taille du substituant R est très supérieure à celle de l'hydroxyle (R = *t*Bu), les populations conformationnelles autour de C_1—COH sont essentiellement déterminées par les interactions stériques R, H_2 et R, C_2—C_3. Dans une première approximation on peut admettre que les populations c et b′, très défavorisées par ce type d'interaction, sont négligeables.

$$n_c \simeq n_{b'} \simeq 0$$

On peut de même prévoir:

$$n_a < n_{a'}$$

$$n_b > n_{c'}$$

Ce qui conduit à la relation:

$$^3J_{H_1-H_4}\,(I) > {}^3J_{H_1-H_4}\,(II)$$

C'est effectivement ce que l'on observe pour les couples de diastéréoisomères **13–14, 15–16, 17–18.** Ce résultat confirme les attributions de configura-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

tion relative réalisées sur la base des données infrarouges.

Lorsque la taille de R est du même ordre de grandeur que celle du groupement fonctionnel (R = CH_3), il est difficile de prévoir l'influence de la configuration sur la valeur de la constante $^3J_{H_1-H_4}$ car, dans ce cas, on ne peut plus négliger l'un des conformères. Les données expérimentales démontrent, en effet, que les valeurs de cette constante pour les deux diastéréoisomères **23–24** ou **26–27** sont très voisines.

Evolution de la valeur de la constante de couplage $^3J_{H_1-H_4}$ avec la nature du substituant R'

Bien que le groupement fonctionnel et le groupe R' présentent une relation *trans* par rapport au cycle propylidénique, la valeur de la constante $^3J_{H_1-H_4}$ dépend du degré de substitution du groupe R'. L'influence de ce groupe sur les populations conformationnelles a ... c', qui est particulièrement sensible lorsque la taille de R est très importante (R = *t*Bu), ne peut être due qu'à une modification des interactions stériques entre R et R' ou R et H_2. Compte tenu de la relation *trans* de R et R' par rapport au cycle il est possible que, lorsque l'on parcourt les séries **13**, **15**, **17** et **14**, **16**, **18**, seules les variations d'interaction stérique R—H_2 soient à l'origine des modifications de populations conformationnelles: le pouvoir électrodonneur de R', qui augmente avec son degré de substitution, provoquerait alors une diminution de la longueur de la liaison C_1—C_2 ce qui accroitrait l'interaction R—H_2.

Dans cette hypothèse, si comme précédemment on admet dans une première approximation que lorsque R = *t*Bu, les populations n_c et n_b sont négligeables, lorsque le degré de substitution de R' augmente, on peut prévoir:

pour les diastéréoisomères I $n_b \nearrow$; $n_a \searrow$; $^3J_{H_1-H_4} \nearrow$

pour les diastéréoisomères II $n_{a'} \nearrow$; $n_{c'} \searrow$; $^3J_{H_1-H_4} \searrow$

Bien que la variation de ^3J reste faible pour les configurations (I), c'est effectivement ce que l'on observe pour l'ensemble des termes **13** à **18**.

*Analyse conformationnelle des alcools **13**, **14**, **17**, **18** et **23**, **24***

L'étude de la variation de la valeur de la constante de couplage $^3J_{H_1-H_4}$ avec la température a été réalisée pour les couples d'alcools diastéréoisomères **17**, **18** et **23**, **24** (tableau 2). Les populations conformationnelles obtenues sont en accord avec les hypothèses précédentes et confirment donc les attributions de structure.

Pour **23** et **24**, la valeur de cette constante n'évolue plus à partir de 120°C; à cette température on a donc égalité des populations conformationnelles:

$$n_a = n_b = n_c = 0{,}33$$
$$n_{a'} = n_{b'} = n_{c'} = 0{,}33$$

soit:

$$J_{H_1-H_2} = 6{,}3 = \tfrac{1}{3}(^3J_{180} + 2\,^3J_{60})$$

A l'aide des courbes de Karplus, cette valeur de J permet d'évaluer les deux constantes de couplage; nous avons retenu les valeurs suivantes:

$$^3J_{60} \simeq 3 \text{ Hz et } ^3J_{180} \simeq 13 \text{ Hz}$$

Ces paramètres permettent de déterminer les populations conformationnelles pour les autres couples d'alcools (tableau 2). Si pour R = Me, (**23** et **24**) les populations n_b et $n_{c'}$ sont très voisines, lorsque R = *t*Bu (**17**, **18** et **13**, **14**), on observe bien l'inégalité $n_b > n_{c'}$. De même, lorsque R = *t*Bu, et que le degré de substitution de R' augmente, on observe une légère augmentation de n_b alors que pour les diastéréoisomères II $n_{c'}$ décroît de manière très sensible.

Corrélation par chromatographie en phase gazeuse

Devant les difficultés d'attribution des configurations relatives aux alcools secondaires α-cyclopropylidéniques, certains auteurs utilisent la différence de temps de rétention des diastéréoisomères II et I sur colonne polaire (10*a*). Les composés II, qui présentent une liaison OH–π plus forte qu'une liaison OH – liaison σ, doivent avoir un temps de rétention plus faible que les composés I. Le tableau 3 montre clairement que selon la nature de R' le rapport des temps de rétention t_R(II)/t_R(I) peut être inférieur ou supérieur à 1; ce rapport ne constitue donc pas un critère de configuration. Cependant sa variation continue, en fonction des substituants R et R' confirme l'homogénéité des séries I et II, quant aux attributions de configurations relatives.

En conclusion, les configurations relatives des alcools secondaires α-cyclopropylidéniques peuvent être attribuées sans ambiguïté sur la base des données infrarouges de ces composés. En rmn de ^{1}H, les valeurs de la constante de couplage $^3J_{H_1-H_4}$ permettent également dans un certain nombre de cas des attributions de structure qui sont dans tous les cas en accord avec les attributions précédentes.

4. *Stéréosélection dans la réduction des cétones α-cyclopropylidéniques par $AlLiH_4$*

que l'utilisation d'une solution–suspension d'hydrure dans l'éther provoque une induction asymétrique comparable à celle que l'on observe avec une solution de $AlLiH_4$ dans ce même solvant (1,5 *M*); les différences d'induction observées sont en effet de 2 à 5% alors que la précision des mesures est, au maximum, de 2 à 3%.

La réduction des (alkyl-2 alkylidène-3 cyclopropyl) alkyl cétone par $AlLiH_4$ est sous contrôle cinétique

Un test classique de l'évaluation des proportions correspondant à l'équilibre thermodynamique entre alcools diastéréoisomères consiste à équilibrer dans les conditions de la réaction et en présence d'isopropylate d'aluminium l'un des alcools diastéréoisomères et la cétone homologue. Cette équilibration a été réalisée avec les deux alcools isomères **23** et **24**; dans les deux cas, nous avons obtenu, à l'équilibre, des proportions identiques: 47% de **23** (1*R**,2*S**,4*S**) et 53% de **24** (1*R**,2*S**,4*R**) ce qui correspond à une différence d'enthalpie libre négligeable entre les deux épimères.

Ces proportions sont nettement différentes de celles obtenues lors de la réduction de la (tertiobutyl-2 méthylène-3 cyclopropyl) méthyl cétone (**7**) par $AlLiH_4$ dans l'éther au reflux: 35% d'isomère **23** et 65% d'isomère **24**. Ces résultats démontrent que la réduction des cétones α-cyclopropylidéniques se fait essentiellement sous contrôle cinétique.

Cette conclusion est confirmée par l'étude de la réduction de la cétone **4** par $AlLiH_4$, en solution dans l'éther, à différentes températures. La variation du rapport des alcools diastéréoisomères obtenus **18/17** est indiquée ci-dessous.

θ (°C):	39	−10	−70
18/17:	9	20	>100

La diminution du pourcentage d'isomère minoritaire à basse température, constitue un argument complémentaire en faveur d'un contrôle cinétique de la réaction. Notons, par ailleurs, que dans ce cas l'abaissement de la température permet d'atteindre la stéréospécificité: à −70°C, l'alcool **17** n'est pas détecté dans le mélange réactionnel brut par rmn ou par cpv.

Modèle stéréochimique

La réduction étudiée présente une induction

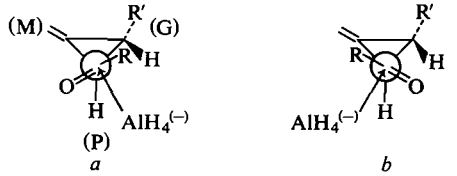
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

asymétrique 1,3 due à un effet de substitution à longue distance. L'interprétation de l'induction observée au cours de la réduction des composés carbonylés a progressé récemment grâce à la contribution de travaux théoriques (19, 20). Dans notre série, cependant, l'existence en α du carbonyle du carbone cyclopropylidénique C_1 permet difficilement de transposer les conclusions de Nguyen Trong Anh et coll. En particulier la spécificité du cycle propylidénique avec ses "orbitales moléculaires de Walsh" combinées aux orbitales π du système éthylénique, rend aléatoire l'examen d'un recouvrement optimal des orbitales de C_1 avec les orbitales π du carbonyle. En conséquence, il nous a semblé intéressant de discuter nos résultats expérimentaux en les confrontant aux modèles stéréochimiques de Cram (21), de Karabatsos (9) et de Felkin et coll. (25) comme cela a été fait dans d'autres séries (27 à 29).

Dans le modèle de Cram (21), l'oxygène du groupement fonctionnel qui complexe le réactif, est le groupe le plus volumineux de la molécule; il se placera de préférence entre les groupes M (▷═) et P (▷—H).

Le réactif attaquera, pour des raisons stériques, du côté du petit substituant P. L'attaque *a* conduit, selon Cram, à l'état de transition le plus stable donc au diastéréoisomère principal. C'est effectivement ce que l'on observe expérimentalement; cependant, ce modèle ne permet pas d'interpréter la variation d'induction observée lorsque la grosseur de R augmente. Dans ce cas, en effet, on devrait favoriser l'attaque *b* donc assister à une diminution de la stéréosélection et non l'inverse comme nous l'observons. Par ailleurs, la position quasi-éclipsée de $H_{(2)}$ et R dans l'état de transition nous semble très défavorisée en série cyclopropylidénique, en particulier lorsque R = *t*Bu.

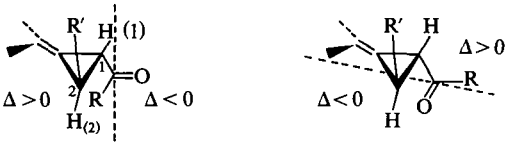
Le modèle de Karabatsos (9) postule que les populations conformationnelles des états de transition et du réactant sont approximativement dans le même rapport, l'attaque du réactif nucléophile se faisant toujours du côté du groupe P. Pour que ce modèle soit prévisionnel et puisse donner lieu à un traitement semi-quantitatif, il est nécessaire de connaître les différentes populations conformationnelles des composés carbonylés. Si les cétones α-cyclopropaniques saturées ont suscité de nombreuses études qui ont démontré la conformation préférentielle *s-cis* de ces composés (22, 23), la stéréochimie des composés carbonylés α-cyclopropylidénique n'a, par contre, pas été abordée.



Diastéréoisomère I majoritaire Diastéréoisomère II minoritaire

SCHÉMA 5

L'effet de solvant ASIS permet, en appliquant la règle empirique de Connolly et MacCrindle (24), de prévoir quelle est la conformation préférentielle des cétones. Pour les conformations *s-cis* et *s-trans*, on peut s'attendre aux effets Δ ($\Delta = \delta CCl_4 - \delta C_6D_6$) qui suivent:



Tous les Δ sont positifs

$\Delta R > 0$
$\Delta H_1 > 0$
$\Delta R' > 0$
$\Delta(= -H) > 0$
$\Delta H_2 < 0$

SCHÉMA 6

Les valeurs expérimentales (tableau 4), obtenues pour les composés **4**, **7** et **8**, démontrent clairement que l'ensemble de ces dérivés n'est pas homogène quant aux populations conformationnelles d'une part et que d'autre part les effets de solvant ne peuvent s'interpréter à partir d'un équilibre conformationnel *s-cis* ⇄ *s-trans*. Compte tenu de ces résultats, le modèle de Karabatsos nous semble difficilement applicable dans cette série.

Dans le modèle de Felkin (25), la stéréosélection est déterminée par les contraintes de Pitzer et les interactions stériques. Les trois états de transition favorisés seront:

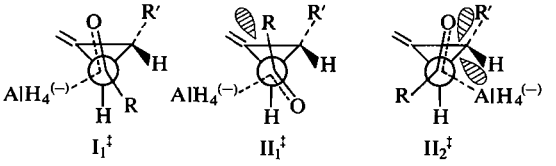


SCHÉMA 7

Ce modèle permet d'interpréter l'ensemble des résultats expérimentaux obtenus dans le cas de la réduction des cétones.

L'état de transition $I_1^{\ddagger}$, qui se forme préférentiellement et qui correspond par ailleurs à l'attaque du réactif sur la face diastéréotopique du carbonyle la moins encombrée dans la conformation *s-cis* du composé carbonylé, conduira à la configuration relative majoritaire (I), $II_1^{\ddagger}$ et $II_2^{\ddagger}$ conduiront au contraire au produit minoritaire (II).

TABLEAU 4. Cétones α-cyclopropylidéniques, effet de solvant $\Delta = \delta CCl_4 - \delta C_6H_6$ (Hz)

Composé	ΔH_1	ΔH_2	$\Delta = -H$	$\Delta R'$	ΔR
4	+3	−12	−2 +2	+6	+7
7	−2	−4	+9 +9	+12	+9
8	+4		+3 +4	+13 +12	+12

Lorsque la grosseur du groupe R′ augmente (série **2**, **3**, **4** ou **9**, **8**, **7**), $II_2^{\ddagger}$ est nettement défavorisé, la stéréosélectivité augmente. La présence d'un méthyle *cis* du carbonyle dans **10** accentue cet effet puisque la stéréosélectivité de la réduction de cette cétone atteint 97%; il est probable que dans ce cas l'intermédiaire $II_1^{\ddagger}$ est comme $II_2^{\ddagger}$ négligeable.

De même, lorsque l'encombrement de R augmente, $II_1^{\ddagger}$ est très nettement défavorisé en raison de l'interaction M ↔ R, le pourcentage du diastéréoisomère principal (I) sera plus élevé (série **7**, **6**, **5**, **4**).

Conclusion

Les attributions de configuration relative aux alcools secondaires α-cyclopropylidéniques ne font pas appel a un modèle stéréochimique de la réduction des précurseurs carbonylés. Ces attributions sont fondées sur les propriétés en ir et en rmn de ^1H des alcools diastéréoisomères et sont par ailleurs confirmées (pour un couple d'alcools) par identification chimique. Il est possible d'étendre ces déterminations de structure aux alcools α-cyclopropéniques, α-cyclopropaniques et α-spiropentaniques en réalisant des filiations chimiques entre ces alcools α-cycliques et les dérivés cyclopropylidéniques à l'aide de réactions dont la stéréochimie est bien connue (migration exocyclique de la double liaison cyclopropénique en milieu basique, réduction de la double liaison cyclopropylidénique, transfert de carbènes).

L'étude de la diastéréosélection au cours de la réduction par $AlLiH_4$ des (alkyl-2 alkylidène-3 cyclopropyl) alkyl cétones démontre que l'induction dépend de la taille du groupe R′ qui présente pourtant une relation *trans* par rapport au carbonyle. Par ailleurs, le modèle de Felkin dont une étude théorique récente a démontré qu'il représentait approximativement les états de transition de moindre énergie, permet d'interpréter et de prévoir la stéréosélectivité au cours de la réduction des cétones α-cyclopropylidéniques.

Excess volumes of an alcohol + 1,2-dichloroethane

NETTEM V. CHOUDARY AND PULIGUNDLA R. NAIDU

Department of Chemistry, College of Engineering, Sri Venkateswara University, Tirupati 517 502, India

Received December 9, 1980

NETTEM V. CHOUDARY and PULIGUNDLA R. NAIDU. Can. J. Chem. **59**, 2210 (1981).

Excess volumes for binary mixtures of 1,2-dichloroethane with *n*-propanol, *n*-butanol, *n*-pentanol, *n*-hexanol, *n*-heptanol, and *n*-octanol have been determined at 303.15 K. V^E is positive over the whole range of composition in all the mixtures. However, it is noticed that the positive values of V^E of mixtures of 1,2-dichloroethane with *n*-hexanol, *n*-heptanol, and *n*-octanol differ from those for the mixtures of 1,2-dichloroethane with corresponding alkanes. The difference has been explained in terms of the break up of hydrogen bonds, interstitial accommodation of 1,2-dichloroethane in alcohol aggregates, and possible hydrogen bond interaction of the type Cl...H—O between unlike molecules.

NETTEM V. CHOUDARY et PULIGUNDLA R. NAIDU. Can. J. Chem. **59**, 2210 (1981).

On a déterminé à 303,15 K les volumes en excès des mélanges binaires formés de dichloro-1,2 éthane avec les alcools suivants: *n*-propanol, *n*-butanol, *n*-pentanol, *n*-hexanol, *n*-heptanol et *n*-octanol. Sur toute l'étendue de composition de tous les mélanges, V^E est positif. Cependant on note que les valeurs positives de V^E dans les mélanges de dichloro-1,2 éthane avec le *n*-hexanol, le *n*-heptanol et le *n*-octanol diffèrent de celles des mélanges du dichloro-1,2 éthane avec les alcanes correspondants. On explique la différence en fonction d'une rupture des liaisons hydrogènes, de l'adaptation intersticielle du dichloro-1,2 éthane dans les agrégats d'alcools et d'une interaction possible de la liaison hydrogène du type Cl ... H—O entre les molécules dissemblables.

[Traduit par le journal]

Introduction

Excess volumes for binary mixtures of 1,2-dichloroethane with *n*-hexane, *n*-heptane, *n*-octane, and *n*-nonane, have been reported by Krishnaiah and Naidu (1). V^E is positive over the whole range of composition in the four mixtures. Since the unlike molecules are non-polar in character, the positive excess volumes may be ascribed to differences in sizes and shapes of molecules. If 1,2-dichloroethane is mixed with alcohols, derivatives of *n*-alkanes, new factors begin to influence excess volume. The factors include: (*a*) break up of hydrogen bonds, (*b*) interstitial accommodation of 1,2-dichloroethane molecules in self-associated alcohol, and (*c*) the possible hydrogen bond interaction between unlike molecules. With a view to study the effect of these factors on excess volume, V^E data for binary mixtures of 1,2-dichloroethane with *n*-propanol, *n*-butanol, *n*-pentanol, *n*-hexanol, *n*-heptanol, and *n*-octanol have been determined.

Experimental

The dilatometer used for measuring excess volumes was similar to that described by Rao and Naidu (2). The mixing cell contained two bulbs of different capacities that were connected through a U-tube having mercury to separate the two compartments. One end of the first bulb was fitted with a capillary outlet and the opposite end of the second bulb was closed with a ground glass stopper. Four dilatometers of this type were used to cover the whole range of composition. Composition of each mixture was determined directly by weighing. All weights were corrected for buoyancy. Measurements were made using a thermostatic bath controlled to within ±0.01 K. The excess volumes were reproducible to ±0.003 cm^3 mol^{-1}.

Purification of Materials

All materials were purified by the methods described by Reddick and Bunger (3). 1,2-Dichloroethane (BDH) was washed with dilute potassium hydroxide solution and water, dried over anhydrous calcium chloride, and fractionally distilled. 1-Propanol (J. T. Baker) and 1-butanol (BDH) were refluxed over freshly ignited calcium oxide for 6 h and distilled using a fractionating column. 1-Pentanol (J. T. Baker) was dried over Drierite and fractionally distilled. 1-Hexanol (B.D.H., England), 1-heptanol (Koch-Light Laboratories Ltd., England), and 1-octanol (B.D.H., England) were fractionally distilled. A fractionating column that contained 30 theoretical plates was used in all cases. The purity of the samples was checked by comparing the measured densities of the compounds with those reported in the literature (4). Densities were determined using a bicapillary type pycnometer which offered an accuracy of 2 parts in 10^5. The measured density data are reported in Table 1 along with those reported in the literature.

Results

The experimental excess volumes of the six binary mixtures are graphically presented in Fig. 1 along with those for mixtures of 1,2-dichloroethane with *n*-hexane, *n*-heptane, and *n*-octane. The dependence of V^E on composition may be expressed

TABLE 1. Densities, ρ, of liquids at 303.15 K

Component	Density ρ/(g cm^{-3})

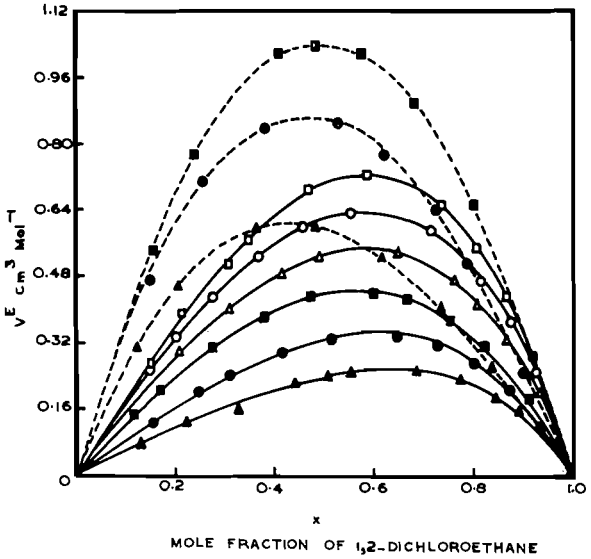

FIG. 1. Excess volumes V^E plotted against mole fraction of 1,2-dichloroethane at 303.15 K for the mixtures of 1,2-dichloroethane with alcohols (—) and alkanes (---); ▲, 1-propanol; ●, 1-butanol; ■, 1-pentanol; △, 1-hexanol; ○, 1-heptanol; □, 1-octanol; ⧋, 1-hexane, ⊙, 1-heptane; ⊡, 1-octane.

by an empirical equation of the form

$$[1]\quad V^E/(\text{cm}^3\ \text{mol}^{-1}) = x(1-x) \times \{a_0+a_1(2x-1)+a_2(2x-1)^2\}$$

where a_0, a_1, and a_2 are adjustable parameters and x is the mole fraction of 1,2-dichloroethane. The values of the parameters obtained by the least-square method, are included in Table 2 along with the standard deviation, $\sigma(V^E)$.

Discussion

The curves included in Fig. 1 show that V^E is positive over the whole range of composition in the six mixtures. The excess volumes for the six mixtures fall in the order: *n*-octanol > *n*-heptanol > *n*-hexanol > *n*-pentanol > *n*-butanol > *n*-propanol. This order is similar to that observed for mixtures of 1,2-dichloroethane with *n*-hexane, *n*-heptane, *n*-octane, and *n*-nonane. However, the values of V^E for the mixtures of 1,2-dichloroethane with *n*-hexanol and *n*-heptanol are smaller than those obtained for 1,2-dichloroethane with corresponding alkanes up to mole fractions 0.6 and 0.8 respectively of the halogenated hydrocarbon. V^E values of the two mixtures become more positive over the remaining mole fraction ranges. V^E values for mixtures of 1,2-dichloroethane with *n*-octanol are smaller than those for mixtures containing *n*-octane over the whole range of composition. These suggest that excess volumes of mixtures containing alcohols are influenced by break up of hydrogen bonds present in self-associated alcohols, interstitial accommodation of 1,2-dichloroethane in hydrogen bonded aggregates of alcohols, and possible hydrogen bond interactions of the type C1...H—O between unlike molecules. While the first factor contributes to the expansion of volume, the remaining two factors may lead to contraction in volume. The actual value of V^E would depend upon the balance between the two opposing contributions. The experimental values for mixtures of alcohols indicate that the factors responsible for opposing contributions counteract each other to different degrees in *n*-hexanol and *n*-heptanol mixtures. Further, the two factors that contribute to contraction in volume dominate over the whole range of composition in the system containing *n*-octanol.

Finally the maxima in V^E curves for the alcohol mixtures occur around 0.6 mole fraction of 1,2-dichloroethane while the maxima in mixtures containing corresponding alkanes occur below 0.5 mole fraction. This may be attributed to the effect of interstitial accommodation of 1,2-dichloroethane in alcohol aggregates which decreases with increase in concentration of the former.

Isentropic compressibilities of electrolytes in acetonitrile at 25°C

ISOBEL DAVIDSON,[1] GÉRALD PERRON, and JACQUES E. DESNOYERS[2]

Department of Chemistry, Université de Sherbrooke, Sherbrooke, P.Q., Canada J1K 2R1

Received October 15, 1980

ISOBEL DAVIDSON, GÉRALD PERRON, and JACQUES E. DESNOYERS. Can. J. Chem. **59**, 2212 (1981).

The sound velocities of some 1:1 electrolytes in acetonitrile were measured by the "sing around" method. Apparent molal isentropic compressibilities $\phi_{K,S}$ of the electrolytes were derived from these data and from previously determined densities. Infinite dilution partial molal compressibilities $\bar{K}_S^0$ were obtained by extrapolation from the plot $\phi_{K,S}$ against the square-root of the molality. Approximate ionic values are obtained on the assumption that $\bar{K}_S^0(\phi_4B^-) \simeq 0$. In general, $\bar{K}_S^0$ of inorganic ions are much more negative in acetonitrile than in water and, except for Li^+, show little dependence on ionic size. On the other hand, $\bar{K}_S^0$ of tetraalkylammonium bromides become increasingly positive as the size of the cations increases. This is again in contrast with $\bar{K}_S^0$ of these electrolytes in water which remain negative. These large positive values arise from the free space between the ions and the solvent molecules, which is large in acetonitrile solutions.

ISOBEL DAVIDSON, GÉRALD PERRON, et JACQUES E. DESNOYERS. Can. J. Chem. **59**, 2212 (1981).

Les vitesses ultrasonores de certains électrolytes 1:1 ont été mesurées dans l'acétonitrile à 25°C par la méthode "sing around". Les compressibilités molaires apparentes à entropie constante $\phi_{K,S}$ des électrolytes ont été dérivées de ces données et des masses volumiques déjà publiées. Les compressibilités isentropiques molaires partielles à dilution infinie $\bar{K}_S^0$ ont été obtenues par extrapolation de $\phi_{K,S}$ portés en fonction de la racine carrée de la molalité. Des valeurs ioniques approximatives ont été calculées à partir de l'hypothèse que $\bar{K}_S^0(\phi_4B^-) \simeq 0$. En général, les $\bar{K}_S^0$ des ions inorganiques dans l'acétonitrile sont beaucoup plus négatifs que les valeurs dans l'eau et, à part Li^+, montrent peu de dépendance sur la taille de l'ion. Par contre, $\bar{K}_S^0$ des sels quaternaires d'ammonium R_4NX deviennent très positifs pour les sels de gros cations, ce qui est contraire au système aqueux où ils demeurent négatifs. Ces grandes valeurs de $\bar{K}_S^0$ réflectent la grande quantité d'espace libre entre les ions et les molécules de solvant qui est présent dans les solutions d'acétonitrile.

Introduction

Recently, in an overview on the solvation of ions (1), a comparison was made of the main thermodynamic and transport properties of alkali and tetraalkylammonium halides in water, heavy water, urea–water mixtures and in typical protic and aprotic solvents. In the preparation of this manuscript, it was surprising to find very few precise compressibility data on electrolytes in nonaqueous solvents. Compressibilities are necessary for predicting the pressure dependence of various equilibrium properties, and, like other properties related to the second derivatives of the chemical potential (i.e. heat capacities and expansibilities), they should be highly sensitive to structural effects in ion–solvent interactions. Thus, a comparison of the compressibilities of ions in non-aqueous and in aqueous solvents should be very helpful in evaluating the relative importance of structural and coulombic interactions to this property, since no structural effects should be present in most non-aqueous systems.

The solubility of electrolytes is in general not very high in most non-aqueous solvents. However, with modern compressibility techniques based on sound velocities, e.g. "sing-around" method, it is possible to measure differences in compressibilities of fairly dilute solutions, thus allowing a study in many non-aqueous systems with solvents such as methanol, propylene carbonate, acetonitrile, dimethylsulfoxide.

The solvent chosen to initiate this study is acetonitrile (AN). It is a fairly typical aprotic solvent, and volumes and heat capacities of alkali and tetraalkylammonium halides in this solvent have already been measured in this laboratory (2).

II. Experimental

The electrolytes used in this study are the same as those of a previous study (2); their origin and purification procedures were given therein.

The sound velocities were obtained by the "sing around" method which has been described by various authors in the literature (3–5). The ultrasonic pulse repetition rate (frequency) was determined with a Nusonic Model 6105 solution monitor (Mapco Inc). The transducer area of stainless steel probe was coated with Teflon by the manufacturer.

The cell was thermoregulated to ±0.001 K with a Sodev circulating thermostat. The temperature of the bath was measured with a Hewlett-Packard quartz thermometer. It was kept at 25.00°C throughout this study. The cell and its thermostated jacket were covered with styro foam to minimize heat losses. The monitor was fitted inside the cylindrical cell with a rubber O-ring. The monitor could then be displaced like a piston, thus enabling further addition of one of the components while keeping the dead space to a minimum. It was found however that AN attacks the O-ring, and no Teflon O-rings of the proper size could be found. The situation was remedied by covering the O-ring with Teflon tape.

TABLE 1. Isentropic compressibilities of some electrolytes in water at 25°C: parameters $\bar{K}_S^0$ and A_K of eq. [3] for $\phi_{K,S}$ in $cm^3\ bar^{-1}\ mol^{-1}$[a]

	$-10^4\ \bar{K}_S^0$	$10^4\ A_K$	$m^{1/2}$
NaCl	51.0, 50.45 (10), 50.5(4), 50.4(5), 52.88 (11)	5.9	0.09–0.34
KCl	43.4, 43.6 (10), 43.5(4), 44.1(5), 46.34 (11)	4.9	0.09–0.34
KBr	35.0, 35.8 (10), 36.0(4), 35.0(5)	4.0	0.1 –0.34

[a]Reference numbers in parentheses.

Depending on the solubility of the salts, two different methods of making measurements were employed. For the more soluble salts, i.e. Bu_4NBr and Pr_4NBr, the cell was initially filled with solvent and the concentration was increased by the addition of aliquots of concentrated solutions. For the less-soluble salts, the salt wad added directly to the solvent in the cell and the concentration was decreased by the addition of solvent aliquots. All concentrations were prepared by weight. NaI and *n*-Pen_4NBr were done by both the dilution method and by the addition of stock solutions, and the results of the two methods were in good agreement.

The solvent was of M.C.B. spectroquality and was found to contain approximately 600 μg H_2O per cm^3 by the Karl-Fischer method. On very humid days it was found that the water content of the solution in the cell increased by as much as 380 μg H_2O per cm^3 over the time required to complete a series of measurements. With most systems this overall quantity of water did not appear to affect the results significantly. On the other hand, for LiBr, sodium tetraphenyl boride ($Na\phi_4B$) and tetraphenylphosphonium bromide (ϕ_4PBr), water had a significant effect on the results. In these cases, the AN was dried as much as possible by storing it over 3 Å molecular sieves prior to use.

III. Results

The isentropic compressibilities β_S in bar^{-1} were calculated from the ultrasonic pulse frequency with the relation (6)

$$[1]\quad \beta_S = \frac{10^2}{dc^2} = \left(\frac{7/f - B10^{-6}}{A(1+\alpha t)}\right)^2 \frac{10^2}{d}$$

where A is the sound path length, B is the electronic delay time, f is the ultrasonic pulse repetition rate in Hz, α is the coefficient of thermal expansion for the ultrasonic probe, c is the sound velocity in $m\ s^{-1}$, and d is the solution density in $g\ cm^{-3}$. The values of A and B obtained by calibration with water at various temperatures (7) are essentially those predetermined by the manufacturer. The densities were obtained by linear interpolation of the data of Zana *et al* (2).

The isentropic compressibility of AN, $\beta_{S0} = 78.95 \times 10^{-6}\ bar^{-1}$, compares reasonably well with those of Blandamer *et al*. (8), $76.0 \times 10^{-6}\ bar^{-1}$, considering the presence of traces of water. On the other hand, the agreement is less satisfactory with the value of $98 \times 10^{-6}\ bar^{-1}$ calculated from isothermal compressibility data of Dack *et al*. (9). The sound velocity in pure AN is $1277.03 \pm 0.13\ m\ s^{-1}$.

The apparent molal isentropic compressibilities were calculated from the difference between β_S and that of the pure solvent β_{S0},

$$[2]\quad \phi_{K,S} = \beta_S\phi_V + 1000\,(\beta_S - \beta_{S0})/md_0$$

where ϕ_V is the apparent molal volume given by Zana *et al*., d_0 is the density of AN containing 600 μg of H_2O per cm^3 (0.77668 $g\ cm^{-1}$), and m is the molality.

The accuracy of the technique was checked through measurements of the standard partial molal isentropic compressibilities of NaCl, KCl, and KBr in water at 25°C. The results obtained can be compared with reliable literature values in Table 1. This technique is therefore capable of measuring $\phi_{K,S}$ to $\pm 10^{-5}\ cm^3\ mol^{-1}\ bar^{-1}$.

The original data and derived apparent molal isentropic compressibilities are given in Table 2. Sound velocities can be calculated from β_S and d using eq. [1]. It would be possible to calculate isothermal compressibilities if precise heat capacities and expansibilities were known (12). Reliable heat capacities are available (2) but unfortunately not expansibilities.

Some typical results are plotted against the square-root of the molality in Fig. 1. In the case of NaI runs were repeated under different conditions (see Experimental section) and quite reasonable agreement was observed. The Debye–Hückel limiting slopes are not known for electrolytes in AN. Therefore, the standard values $\phi_{K,S}^0$ ($= \bar{K}_S^0$) have to be obtained by extrapolation of $\phi_{K,S}$ against $m^{1/2}$. Despite the increased uncertainty with this type of extrapolation, reasonably good values were obtained with most electrolytes. However, LiBr is a typical case where extrapolation is very difficult since this pair of ions forms a complex with the traces of water; as in the case of heat capacities (2), $\phi_{K,S}$ probably goes through a maximum or hump at low concentration. Therefore it is not possible to obtain a reliable $\bar{K}_S^0$ from LiBr data and the value for Li^+ was calculated from $LiClO_4$. Similar extrapolation difficulties were also encountered with RbI, ϕ_4PBr, and $Na\phi_4B$.

The best values of $\bar{K}_S^0$ that could be extracted

m: molality in mol kg^{-1}

β_S: isentropic compressibilities of the solution in bar^{-1}

β_{SO}: isentropic compressibility of acetonitrile

$\phi_{K,S}$: apparent molal isentropic compressibility in cm^3 bar^{-1} mol^{-1}

Δd: difference in density between the solution and the solvent in g cm^{-3}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

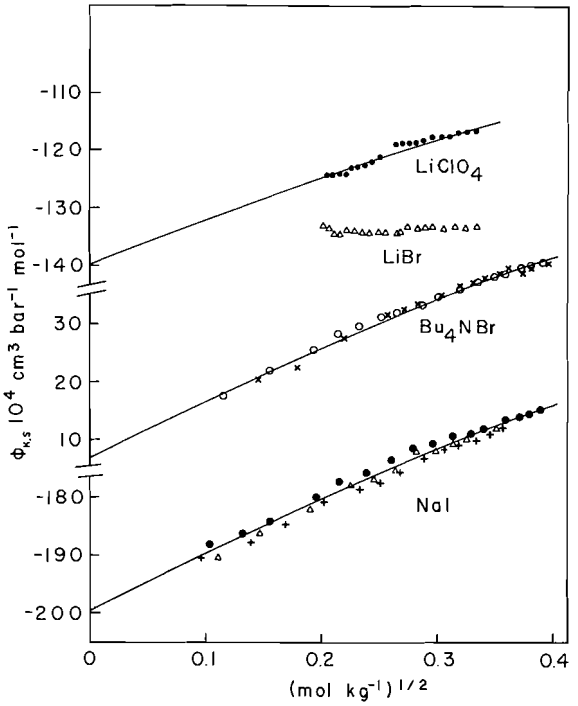

FIG. 1. Some typical plots of $\phi_{K,S}$ against the square root of the molality. With Bu_4NBr two sets of measurements were made. With NaI some runs were carried by the dilution method and others by the concentration one. With systems like $LiClO_4$, the extrapolation is difficult in view of the short working zone available. Cases like LiBr are extreme in that only estimates of infinite dilution values are possible assuming an average slope.

from our data and the slope A_K of the relation

[3] $\phi_{K,S} = \phi_{K,S}^0 + A_K m^{1/2}$

are given in Table 2. Ionic additivity can usually give some idea of the reliability of results. Unfortunately, very few pairs of electrolytes can be used for this purpose in the present case because of their limited solubility in AN. The differences between NaI and $NaClO_4$ and between Et_4NI and Et_4NClO_4 are respectively -21.9 and -12.5×10^{-4} cm^3 bar^{-1} mol^{-1}, which is not very satisfactory since the ultrasonic technique is capable of measuring $\phi_{K,S}$ to 10^{-5} cm^3 bar^{-1} mol^{-1}. Therefore, in view of the limited solubility range of most electrolytes, the method of extrapolation, the effect of association, and the influence of traces of H_2O in the solvent with some systems, the present $\bar{K}_S^0$ can probably be considered reliable to $\pm 5 \times 10^{-4}$ cm^3 bar^{-1} mol^{-1} only.

IV. Discussion

The best way of comparing and interpreting the values of $\bar{K}_S^0$ is to plot them against some function of the size of the ions. For this purpose, values of $\bar{K}_S^0$ were calculated for electrolytes with a common cation or anion by the additivity rule and plotted against the cationic radii for the series MBr and against the anionic radii for the series NaX (Fig. 2). For comparison, the same function is shown for the corresponding aqueous systems (1).

The most striking observation in Fig. 2 is the large negative values of $\bar{K}_S^0$ of alkali halides and the large positive values for the $\bar{K}_S^0$ of the larger R_4NBr in AN in comparison with the aqueous system. Most of the interpretations of $\bar{K}_S^0$ in terms of solvation effects (4, 5, 13–15) assume that $\bar{K}_S^0$ of unsolvated ions is negligible, although Conway and Verrall (15) recognized that large organic ions could have some intrinsic compressibility due to the intramolecular free space. This contribution to the compressibility should be much smaller than the observed 72×10^{-4} cm^3 bar^{-1} mol^{-1} for n-Pen_4NBr. Volumes and heat capacities of these ions in AN suggest very little solvation of the higher homologs (2). A plausible explanation for these high values comes from the compressibility studies of ionic surfactants (16, 17). For example, in the postmicellar region, $\bar{K}_S$ of nonyl and decyltrimethylammonium bromides (16) have constant values of about 85 and 95×10^{-4} cm^3 bar^{-1} mol^{-1}, corresponding to the values of the hypothetical liquid hydrocarbons. The values of $\bar{K}_S^0$ of alcohols in propylene carbonate are also all large and positive (18). Therefore, the high compressibility of the larger R_4NBr results from the compression of

[a] Actual fit of experimental data. This value was not used for the determination of $\bar{K}_S^0$ (Li^+) (see text).

the free space between the large unsolvated cation and AN. It is consequently incorrect to assume that the compressibility of "unsolvated" ions in solution is negligible. Even with small solutes some free space is present and a positive contribution to $\bar{K}_S^0$ would be observed. The only exceptions to this rule are the hydrophobic solutes in water. If, as it is usually believed (1), the hydrophobic co-sphere resembles to some extent that of a clathrate hydrate, very little free space is present between the solute and the solvent co-sphere, and this accounts to a large extent for the lower compressibilities of R_4NBr in water.

The values of $\bar{K}_S^0$ of alkali halides and other inorganic electrolytes are all much more negative than in water. To appreciate the significance of these values, it is convenient to consider the interpretations given in terms of solvation numbers. Although we recognize that solvation numbers have no absolute meaning (1), this concept is useful in comparing different solvents or different ions. Since the early work of Passynsky (19), many authors have tried to extract hydration numbers from compressibility data, e.g. Padova (13), Tamura and Sasaki (14), Allan and Lee (20), Bockris and Saluja (21). Their approaches vary to some extent, but they all essentially assume that the unsolvated ions and the water molecules in the hydration co-sphere are incompressible. Although these assumptions are obviously oversimplified, especially in non-aqueous solvents (e.g. the intrinsic $\bar{K}_2$ is not zero), they lead to a very simple relation between the isothermal $\bar{K}_2^0$ and the solvation number h;

$$[4]\quad \bar{K}_2^0 = -hv_0\beta_0$$

Neglecting the difference between isentropic and isothermal compressibilities, and taking the molar volume of AN, $v_0 = 53\ cm^3\ mol^{-1}$, and the compressibility of AN, $\beta_0 = 7.90 \times 10^{-5}\ bar^{-1}$ (isentropic value), the solvation numbers of LiBr, NaBr, and KBr are respectively 3.7, 5, and 5. These numbers are of the same magnitude as those obtained in water (22) and in methanol (20). Therefore, despite the crudeness of this approach, we can conclude that the number of solvent molecules affected by the ions are comparable in AN and in H_2O, and the large negative $\bar{K}_S^0$ observed in AN is a direct consequence of the larger volume and compressibility of AN.

The relative independence of $\bar{K}_S^0$ on the size of the alkali halides in AN in contrast with aqueous systems is harder to explain. The Born equation predicts that the coulombic solvation should vary inversely with the ionic radii. We would therefore expect that $\bar{K}_S^0$ in AN would increase with both the radii of the cations and anions with a more positive slope than in H_2O. The uncertainty of the data in AN is much larger than in water but it cannot be *much more than* $5 \times 10^{-4}\ cm^3\ K^{-1}\ mol^{-1}$. Even by allowing for maximum uncertainty, the slope in Fig. 2 would not be large. The trend therefore is real. Further systematic studies in other non-aqueous solvents would be required before we can venture an explanation. On the other hand, the less negative $\bar{K}_S^0$ of the salts made up of small cations or anions (Li^+, Cl^-) is a more general phenomenon and is usually explained through the smaller coordination number of these ions (2). The solvent molecules are held more tightly by these ions but few solvent molecules can fit in the first coordination shell of the ion.

There are no reliable methods of dividing $\bar{K}_S^0$ into its ionic components. However, some extrathermodynamic approach can be used to estimate these values. Millero (23) has suggested dividing $\bar{V}^0$ of $\phi_4As^+\phi_4B^-$ into ionic components assuming $\bar{V}^0$ (ϕ_4As^+)/$\bar{V}^0$ (ϕ_4B^-) is equal to the ratio of their van der Waals volumes. Such a method cannot be used since we do not know the ratio of the compressibilities of the pure (solid or gaseous) ions. However, if this pair of ions is split into two, the value of ϕ_4B^- is $-11 \times 10^{-4}\ cm^3\ bar^{-1}\ mol^{-1}$. A better assumption (2) seems to be the splitting into two of the pair $\phi_4P^+\phi_4B^-$. This gives a value for ϕ_4B^- near 0. The extrapolation method suggested by Conway *et al.* (24) for volumes cannot really be used for $\bar{K}_S^0$ in

TABLE 4. Ionic standard partial molal isentropic compressibilities in acetonitrile at 25°C based on the assumption $\bar{K}_S^0(\phi_4B^-) = 0$

Ion	$10^4\ \bar{K}_S^0$/(cm³ bar⁻¹ mol⁻¹)	Ion	$10^4\ \bar{K}_S^0$/(cm³ bar⁻¹ mol⁻¹)
Li^+	−56	Cl^-	−90

Pr_4N^+	+59	ϕ_4As^+	−21
Bu_4N^+	+112	ϕ_4P^+	−2
n-Pen_4N^+	+175		
i-Pen_4N^+	+182		

view of the large contribution of the intrinsic compressibility which does not seem to be a simple function of the size of the ions. Therefore, taking the value of $\phi_4B^- \simeq 0$ seems to be about the best we can do at the moment. Ionic $\bar{K}_S^0$ based on this assumption are given in Table 4. From this table $\bar{K}_S^0(Na^+) \simeq \bar{K}_S^0(Br^-)$. This is probably of the right magnitude since these two ions correspond to minimum values of $\bar{K}_S^0$ of cations and anions in Fig. 2.

A final remark can be made on the difference between n-Pen_4NBr and i-Pen_4NBr. In previous work with AN, it was observed that no significant difference in $\bar{V}^0$ and $\bar{C}_p^0$ could be observed with these isomers (2). The same seems to be true of $\bar{K}_S^0$ since they differ by only 7×10^{-4} cm³ bar⁻¹ mol⁻¹ and the uncertainty on each is of the order of 5×10^{-4} cm³ bar⁻¹ mol⁻¹. Therefore this confirms the unimportance of the compactness of the solute molecule on the thermodynamic properties in AN.

Field desorption mass spectrometry of sodium carboxylates. Intermolecular exchange of hydrogens and alkyl groups as shown by labelling

GORDON WALTER WOOD[1] AND WING FUNG SUN

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received December 23, 1980

GORDON WALTER WOOD and WING FUNG SUN. Can. J. Chem. **59**, 2218 (1981).

Field desorption mass spectra of sodium acetate and sodium propionate, labelled analogs, and mixtures were used to investigate hydrogen and alkyl group exchange accompanying the desorption process. At low anode temperatures, decomposition products are minimized and formation of homologous carboxylates by alkyl transfer is significant. The complexity of these intermolecular reactions precludes a simple mechanistic scheme. Reproducibility of minor ions is much improved by the addition of pentaerythritol to these samples.

GORDON WALTER WOOD et WING FUNG SUN. Can. J. Chem. **59**, 2218 (1981).

On a fait appel aux spectres de masse par désorption de champ de l'acétate et du propionate de sodium ainsi que de leurs analogues marqués et de leurs mélanges pour étudier les échanges entre l'hydrogène et le groupe alkyle qui accompagnent le phénomène de désorption. Lorsque les températures de l'anode sont faibles, les produits de décomposition sont nettement défavorisés et la formation des carboxylate analogues par transfert d'alkyles devient plus importante. La complexité de ces réactions intermoléculaires exclut un mécanisme simple. L'addition du pentaérythritol à ces échantillons permet d'améliorer grandement la reproducibilité des ions minoritaires.

[Traduit par le journal]

Introduction

Although sodium acetate has become the prototypical organic salt for field desorption mass spectrometry (FDMS) studies (1–5), a number of questions about its behavior remain unanswered. The first reported spectrum (1) showed m/z 23 (Na^+) as base peak at 25, 30, and 32 mA, with no other ions at the lowest anode temperature, some ions of structural significance at 30 mA (chiefly m/z 105), and decomposition products at 32 mA. In a later description of this work it was pointed out (4) that m/z 105 is only the first member of a series of cluster ions $[Na_xOAc_{x-1}]$ where $x = 2$ and that ions are found corresponding to higher values of x to the limit of the mass scale. In this later review, among other ions listed as characteristic were: $[Na\cdot HOAc]^+$, referred to as $(M + H)^+$, and fragments thereof, $[HOAc]^{+\cdot}$, and products of "thermally field-induced decomposition reactions", such as CH_2CONa^+, $HCO_2Na_2^+ + x$NaOAc, $CH_3CH_2CO_2Na_2^+ + x$NaOAc, where $x = 1, 2$. In subsequent presentation (3) and publication (2) the Bonn group showed a high resolution FD mass spectrum of sodium acetate obtained by photoplate. This full-mass range (to m/z 570) spectrum presented for the first time examples of the various types of ions derived from sodium acetate.

Ambiguities within these reports (1–4), and between them and concurrent work in our laboratory wherein we found some, but not all, of the reported ions led us to question (5) the purity of the sodium acetate as well as part of the interpretation offered in the earlier work. We now report that the purity of the samples has been verified, and that therefore the apparent formate and propionate entities found in sodium acetate spectra (2–5) must arise as part of the FD process. We have also extended the analysis of minor ions formed in addition to the fundamental m/z 105, 187, 269 ... series through use of labelled samples. Thoughout this work we have relied on matrix materials, such as earlier reported for fructose (5), to improve the desorption characteristics of the salt samples. As will be discussed in more detail later (6), pentaerythritol (PE) is a compound which greatly increases the detectable ion yield from sodium carboxylates without itself contributing to the spectrum. In several of the spectra presented here, addition of 0.5 mol of PE per mol of salt allows one to accumulate 5–7 scans (12 s each) to give a spectrum with a usable dynamic range of 10^3, about one order of magnitude greater than the pure salt. At the same time, the abundance of Na^+ is greatly reduced.

Results and Discussion

Field desorption of an equimolar mixture of NaOAc/NaOAc-d_3 gave spectra as summarized in Table 1. This sample was deposited on the field anode from a solution containing 0.5 mol of pentaerythritol per mol of salt. Species differing only in deuterium content are combined so that the most abundant cluster, Na_4OAc_3 containing 0–9 deuteriums, is reported as m/z 269–278. As expected, the major species correspond to clusters of this type,

294–300	0.6			693	0.03	Na_9OAc_8	14

[a] Peaks shown represent 99.7% of ionization above threshold of 0.25% of most abundant peak, m/z 274. The latter constitutes about one-quarter of the m/z 269–278 manifold (see Table 2). Most of the remaining 0.3% of ionization is accounted for by: m/z 44, 45(CO_2, HCO_2), m/z 84–85, 171–172 (NaHOAc-d_{1-2} and its dimer-d_{5-6}), m/z 129 (Na_3CO_3, see ref. 2).
[b] No ions related to pentaerythritol are found.
[c] Anode heating current 21.1–21.5 mA.
[d] Formate = OFor, acetate = OAc, propionate = OPr, butyrate = OBu.

with lesser amounts of clusters in which one of the acetates has been replaced by formate or proprionate.[2] With the Na_4 clusters these peaks are found at m/z 255–262 and 284–292 respectively. Further detail on several of these clusters, along with justification for the assignments made, is provided in Table 2 where single m/z values are normalized to m/z 274 = 100. The cluster which contains this peak shows a distribution of deuterium which corresponds to randomization of the equal numbers of H/D atoms over the 9 sites available in Na_4OAc_3. Similar results are found throughout, from the single site in formate (m/z 91, 92) to the 11 sites in Na_4OAc_2OPr and all the other species through m/z 606–610. In these latter examples the statistics are less precise because of reduced ion abundance.

Only two minor peaks in Table 1 have not been assigned. The m/z 324, 325 group doesn't fit with any expected composition, but the series m/z 294–300 is a good fit for Na_5OAc_3 where $d_0 = 292$ and the ions recorded would then correspond to d_2–d_8. This assignment is tentative, however, since that ion might be expected to be doubly-charged and the appropriate peaks, 147.5, 148.5, 149.5 are found in only one scan.

These results confirm the importance of some form of carbon exchange among the acetate moieties and demonstrate a concurrent complete exchange of hydrogen (deuterium). Altogether formate and propionate containing species account for more than 5% of the total ionization in this spectrum. Other species reported previously are either absent or negligible. Since we have achieved the same result within a lowered detection limit by omitting the pentaerythritol, the latter does not appear to explain the "clean" spectrum. Our anode temperature was maintained at a considerably lower value than in the previous work, 19–22 mA vs. 30–32 mA, which suggests that some of the previously observed low mass species may have been decomposition products.

The apparent presence of butyrate (m/z 302–304 in Table 1) and other higher carboxylates in trace amounts prompted the experiment with a mixture of sodium propionate (NaOPr) and labelled sodium acetate (NaOAc-d_3) summarized in Tables 3 and 4. When allowance is made for the "deficiency" of deuterium in this experiment (5H and only 3D for 8 sites), the results are the same as for sodium acetate. Thus, the most abundant cluster, Na_2OAc, is distributed among d_0, d_1, d_2, and d_3 in the expected fashion and m/z 91, 92 is now 57% d_0, close to the ratio 5/8 expected in the absence of isotope effects.

A much richer complement of intermolecular exchange products is found when proprionate is involved. There is evidence for mixed carboxylates containing caproate (C_6, m/z 162–168), valerate (C_5, m/z 147–155, 243–251), and butyrate (C_4, m/z 133–140, 230–237, 328–336) in addition to the previously observed formate. These various clusters represent most of the ionization from m/z 91

[2]Species which are apparent homologs of acetate will be referred to as carboxylate anions throughout. Although there is no proof of this structure, atomic composition is fixed by the earlier high resolution study (2) and we find this structural assumption more attractive than the alternative whereby $C_3H_5O_2$ and higher members would become esters: $CH_3COOCH_2^-$ or $^-CH_2COOCH_3$, for example.

through 419. Among the low mass ions previously reported only m/z 39, 65, and 129 were detected, two of these at very low levels.

A significant set of species shown in Table 3 are the *molecular ions* corresponding to hexameric sodium acetate (m/z 496–502) and the various formate containing analogs (m/z 424–426 through 480–489). Together these species amount to 5% of the most abundant cluster. The individual peaks are close to the detection limit which may explain the failure to detect the usually less intense propionate homologs. The apparent dominance of hexamers may reflect some facet of structure in the solid state, or of the vapor above it.

Sodium propionate and its 2-^{13}C- and 3-^{13}C-labelled analogs gave FD results typified by Table 5. Cluster ions containing carboxylates from C_1 through C_5 are detected throughout the complete mass range (to m/z 800). This spectrum shows remarkably low Na^+ abundance in spite of the presence of Na_2Cl^+ clusters amounting to 2% of total ionization. The m/z 39 peak, which we would ordinarily assign to K^+, has previously been identified as NaO^+ (2). Likewise, the series m/z 136, 233, 330 ... may perhaps contain NaO^+ instead of K^+. Trace levels of doubly-charged ions are included mainly to indicate that the complexity of this FD spectrum is no doubt a function of the level of minimum detectable signal (ca. 0.01% of total ionization).

Comparison of the spectra from sodium propionate and its labelled analogs yields some information on the origin of the carbons transferred in the formation of homologs. Since formate from labelled substrate contains no excess ^{13}C, it appears to arise completely from C-1 of propionate. Acetate gets excess ^{13}C from C-2, but not from C-3, and thus is composed of C-1 and C-2. Propionate contains the original level of ^{13}C and, therefore, these carbons are not scrambled. Butyrate from C-3 labelled substrate contains 2 × ^{13}C and therefore the "extra" carbon must come by transfer of C-3. Valerate contains 2 × ^{13}C from both labelled substrates, suggesting transfer of CH_3CH_2— to propionate in intact form. While these generalizations are fairly straightforward, we have been unable to construct any simple mechanism consistent with these results as well as those reported for acetate and mixed carboxylates.

In summary, we have shown that sodium acetate and sodium propionate may be field desorbed from conditioned 10 μ wires at heating currents of 19–22 mA. Desorption in the presence of pentaerythritol has little effect on the temperature or the composition of cluster ions detected. This additive does, however, reduce the abundance of free sodium ion and increase the total ionization per unit time so that minor ions may be recorded reliably. Perhaps most importantly, the desorption process is much smoother, short-time fluctuations of ion current are greatly reduced, and ion production from a given sample extends over a longer time.

[c] Sum of ionization between m/z 20 and 800.

Several of the ions previously reported from sodium acetate probably arise from thermal decomposition at an overheated anode. However, formation of apparent homologs by alkyl transfers between carboxylate substrates is shown to be a significant process even at the lowest desorption temperatures. This alkyl transfer is accompanied by scrambling of all hydrogen sites. Our mechanistic speculations have not proven fruitful, and considering the complications inherent in the condensed phase where these reactions occur, further effort in this direction may not be justified. Finally, the demonstrated complexity of intermolecular reactions accompanying FD of sodium carboxylates at moderate temperatures strikes a cautionary note on interpretation of other FD spectra.

Experimental

Mass spectra were recorded on a Varian MAT CH5 DF spectrometer operating under the control of an INCOS 2000 data system as previously described (7), except that the mass range 900-10 was scanned in 12 s.

Sodium acetate (Fisher), pentaerythritol (Aldrich), and the deuterium and carbon-13 labelled compounds (Merck Sharp and Dohme) were used as received. Sodium propionate was prepared from an equimolar mixture of propionic acid and sodium hydroxide. The product was then recrystallized twice from a chloroform/methanol mixture. Purity of this and the other carboxylates was checked by nmr. A standard qualitative method was used to demonstrate the absence of formate in the acetate used (8).

Samples were prepared for analysis by dissolving 10–20 mg in 1 mL of deionized H_2O, and loaded on the activated anodes by dipping.

Synthesis of some new tetracyclic heteroaromatic chromans via quinone methide intermediates

MOHINDER S. CHAUHAN AND DAVID M. MCKINNON
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2
Received January 19, 1981

MOHINDER S. CHAUHAN and DAVID M. MCKINNON. Can. J. Chem. **59**, 2223 (1981).

Synthesis of several new tetracyclic heteroaromatic chromans has been achieved through the reaction of various uracil and 1,3-thiazine derivatives with 1,2-naphthoquinone-1-methide. The spirodimer **4** is a better source of naphthoquinone methide than the naphthol derivatives which provide chromans in low yield due to side reactions. The structure and mechanisms of the various products formed are discussed.

MOHINDER S. CHAUHAN et DAVID M. MCKINNON. Can. J. Chem. **59**, 2223 (1981).

On a réalisé la synthèse de plusieurs chromanes tétracycliques hétéroaromatiques en faisant appel à la réaction de divers dérivés de l'uracile ou de la thiazine-1,3 avec le méthide-1 de la naphtoquinone-1,2. Le spiro-dimère **4** est une meilleure source de méthide-1 de la naphtoquinone-1,2 que les dérivés du naphtol qui ne fournissent les chromanes qu'avec de faibles rendements par suite des réactions secondaires. On discute de la structure et du mécanisme de formation des divers produits.

[Traduit par le journal]

Introduction

As a suitable model approach to the preparation of some potentially biologically active chroman derivatives, especially those fused to other heterocyclic nuclei, we have examined the reactions of 1,2-naphthoquinone-1-methide, (**1**), with uracil and 1,3-thiazine derivatives. In addition these reactions permit a suitable variation of the nature of groups attached to the 5–6 carbon to carbon bond in the uracil and 1,3-thiazine derivatives respectively, which is expected to be one substrate for the quinone methide in these reactions. However, in such studies it is known (1) that the *o*-quinone methide may react in either a dipolar form, **2**, or a diradical form, **3**. Thus although **1** may add stereo- and regiospecifically to *cis* or *trans* stilbene via a (4 + 2) cycloaddition (2*a*), the reaction of **1** with ethyl maleate or fumarate proceeds nonstereospecifically and thus gives the same products (2*a*, *b*). Also its addition to dihydropyran, vinyl ethers, and unsaturated esters occurs via a polar mechanism, while the formation of the *o*-quinone methide spiro dimer, **4**, and a benzofuran adduct indicates a diradical mechanism. The reactivity has been rationalized in terms of ready polarizability of *o*-quinone methide by the substrate (2*c*).

4

Results

In these studies, *o*-quinone methides were made by *in situ* thermal decomposition of the spirodimer (**4**) in refluxing mesitylene, which provides a better source than other methods, such as thermal elimination of water, methanol, or dimethylamine from 2-naphthol derivatives (2*b*). These methods are unsuitable because of side reactions, especially those induced by the above eliminated species (3–11). Some of the various uracil (**5***a–d*) and 1,3-thiazine-2-thione derivatives (**6**) were prepared by literature methods (12–15) or were commercially available. The preparation of one other (**5***e*) is described.

The reaction with 1,3-dimethyluracil (**5***a*) gave two products. One of these appears to be a chroman, assigned the structure **7***a*. This compound is likely formed by a (4 + 2) cycloaddition reaction. A *cis* geometry is indicated since the coupling constant of the protons on the bridgehead carbon atoms ($J_{2,3}$) is 2.5 Hz. This value is too small to indicate a *trans* fused ring system. It is known that dihydropyran, coumarin, 1,4-napthoquinone, and other unsaturated substrates also give adducts with *cis* geometry with *o*-quinone methides (2*a*), and with similar *J* values. The other product appears to be a phenol, assigned the structure **8***a*, indicated by an ir absorption at 3300 cm^{-1} and a peak in the nmr spectrum at δ 6.68, assigned to the olefinic proton

b X = S, Y = O
c X = Y = S

on the uracil nucleus. The peak appears to be slightly broadened, possibly by *cis* allylic coupling to the two methylene protons. This phenol probably arises from the fission of the chroman ring in **7***a* by a mechanism similar to that proposed for an *o*-quinone methide – indole adduct (2*b*), involving electron release from the nitrogen atom. The adduct **7***a* was not converted to **8***a* by chromatography on silica gel, a possible acidic catalyst, indicating that it is not an artifact of the work-up procedure. This mechanism also seems more likely in view of the results obtained with other uracils, which will be discussed later.

The possible formation of phenol **7***a* from the thermal rearrangement of chroman **8***a* was also investigated by heating pure chroman **8***a* in refluxing mesitylene. No phenol was observed and a careful chromatographic analysis of the reaction mixture gave a small amount of the starting spirodimer, 1,3-dimethyluracil, and 1,1-ethylenedi-2-naphthol, along with resinous material and some unidentified products. Similar retro additions have been reported (2*a*).

1,3-Dimethyl-4-thiouracil (**5***b*) and 1,3-dimethyl-2,4-dithiouracil (**5***c*) gave only the phenols **8***b* and **8***c* respectively. No chroman products were isolated. These structures were confirmed by ir and nmr data. It may be that ring opening of the chroman ring, with regeneration of the conjugated uracil structure, is more favored by the presence of thione sulfur in the uracil ring.

In contrast, the reaction of 1,3,6-trimethyluracil (**5***d*) gave two isomeric chromans. One of these exhibited a multiplet at δ 2.85 to 3.68, consistent with the protons at positions 3 and 4 of the chroman ring in **7***b*. The other compound exhibited two singlets at δ 3.20 and 4.13 assigned to the methylene and methine protons of the isomeric structure **9**, the chroman C-4 and C-2 positions, respectively. No ir absorptions characteristic of phenols were evident. Interestingly, when *o*-quinone methide was treated with 1,3,6-trimethyl-4-thiouracil (**5***e*), it produced, in high yield, an entirely different product. This was a very insoluble material whose analysis showed a loss of a sulfur and a nitrogen atom. Its insolubility has prevented much further investigation of its structure. The reactions of the two 1,3-thiazine-2-thiones (**6***a*, *b*) with the *o*-quinone methide gave in each case a 1:1 cyclic adduct, assigned the structures **10***a*, *b* respectively, and the 2-methyl derivative **11** afforded the adduct **12**. No phenolic products were detected in these reactions. If the fission of the chroman ring occurs by electron release from a heteroatom, N or S in the uracil and thiazine rings respectively, then these results are consistent with the electron releasing effects of these atoms. The formation of π bonds, as would be required by the mechanism of fission, would be less favored for sulfur than nitrogen.

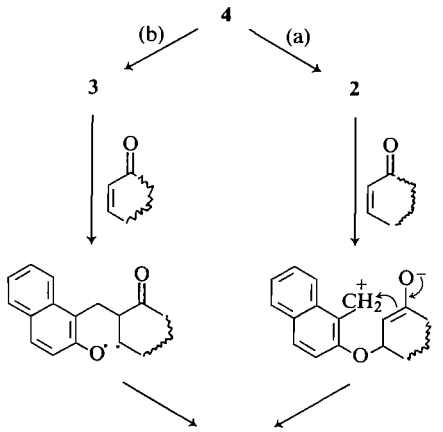
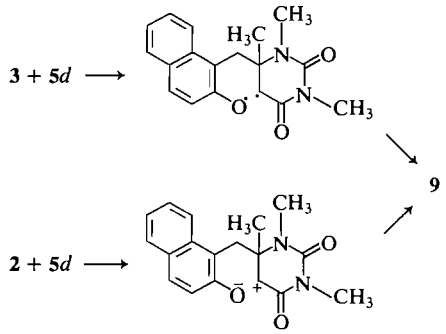
12

Discussion

In view of the similarity of the double bond substrate in the uracils and thiazines to those in unsaturated esters (2*b*), we favor the ionic mechanism (Scheme 1a) for the formation of all of the above products, except the product **9** (Schemes 1b, 2). Nevertheless a discrete dipolar initial addition product (Scheme 1a) could conceivably cyclize in a *cis* or *trans* fashion. Fortunately, examination of a molecular model and application of ring closure rules (6-*endo* trig, when appropriate resonance structures are considered), also indicates that the *cis* fusion is favored. The formation of product **9** appears to be consistent with a radical mechanism. An ionic mechanism in this case would involve an intermediate which would possess a carbonium ion



SCHEME 1



SCHEME 2

adjacent to a carbonyl group. This mechanism could be in agreement with that proposed for benzofuran reactions (2*a*).

The formation of this chroman **9** by a different mechanism only in the case of reaction of **5***d* suggests that the methyl substituent at position 6 has some special bearing on the course of the reaction. It possibly may provide extra stability at some reaction intermediate, and/or interfere sterically, allowing an alternate reaction mode. In all of these reactions the products isolated arise by reaction of the quinone methide with the 5–6 double bond of the substrate. No products were isolated by reaction of the quinone methide with either a thione function, or the imine function in compound **11**. This is surprising in view of the known reactivity (16) of the thione function to electrophilic and nucleophilic reagents, but it may be that steric effects are very important. In the one case studied, **5***e*, where the uracil has a *C*-methyl substituent and the 4-thione function, the reaction takes an entirely different course.

Experimental

Chromatography was performed on 1 mm thick "Camag" silica gel type D.S.F. 5 supplied by Terochem Laboratories. The ir spectra were obtained on a Perkin-Elmer model 337 spectrophotometer and nmr spectra on a Varian model 56/60 A spectrometer using tetramethylsilane as internal standard. Mass spectra were obtained on a Finnegan 1015 quadruple mass spectrometer and melting points obtained on a precalibrated "Thermopan" apparatus. Microanalyses were performed by Micro-Tech Laboratories, Inc. and are given in Table 1.

Preparation of the Spirodimer (4)

1-Dimethylaminomethyl-2-naphthol (5.0 g) was refluxed with xylene (150 mL) under nitrogen until there was no further evolution of dimethylamine. The solvent was removed under reduced pressure on a rotary evaporator and the residue chromatographed on a silica gel column. Elution with benzene followed by a mixture of benzene/chloroform (1 : 1, v/v) gave the spirodimer (4.0 g) in 51.5% yield. It was crystallized from a mixture of methanol/ether, mp 142–143°C identical with an authentic specimen (2*b*).

Preparation of 1,3,6-Trimethyl-4-thiouracil (5e)

1,3,6-Trimethyluracil (15) (2 g) was refluxed with phosphorus pentasulfide (2 g) in dry toluene for 7 h. Toluene was removed under reduced pressure and the residue was treated with 10% sodium carbonate solution. The basic solution was extracted with chloroform (25 mL × 4) and the combined organic extract was dried over anhydrous magnesium sulfate. The organic solvent was removed and the residue (2.1 g) crystallized from benzene, mp 172–173°C. The nmr spectrum in $CDCl_3$, δ: 6.57 (s, 1H, olefinic proton), 3.4 (s, 3H, N—CH_3), 3.75 (s, 3H, N—CH_3), 2.18 (s, 3H, C—CH_3). The infrared spectrum: 1685 cm^{-1}, C=O stretch. Mass spectrum, calcd.: 170; found: M^+ 170. *Anal.* calcd. for $C_7H_{10}N_2OS$: C 49.41, H 5.88, N 16.47, S 18.82; found: C 49.14, H 5.99, N 16.25, S 19.10.

General Method for Chroman Synthesis

The uracil or thiazine derivative under study (2 mmol) was treated with an excess of the spirodimer **4** (4 mmol) in refluxing pure, dry mesitylene (25 mL) for 7–8 h under nitrogen. Stirring was maintained throughout the course of reaction and, after the stated reaction time, the organic solvent was removed under reduced pressure. The residue was chromatographed over silica gel to separate the desired adduct from the starting material and other minor by-products. The adducts were then crystallized from chloroform or a mixture of chloroform and benzene for further purification. The results are summarized in Table 1.

Reaction of 1,3-Dimethyluracil (5a) with Spirodimer 4

The reaction was performed as above, and chromatography using chloroform as an eluant gave chroman **7***a* (332 mg) and the phenol **8***a* (156 mg). They were further purified by crystallization from a mixture of chloroform and benzene. The nmr spectrum of chroman **7***a* in $CDCl_3$, δ: 3.17 (s, 3H, *N*-methyl), 3.27 (s, 3H, *N*-methyl), 3.29 (d, 2H, methylene protons), 3.8–4.3 (m, 1H, methine proton), 5.15 (d, J = 2.5 Hz, 1H, methine proton), 6.88–7.98 (m, 6H, aromatic protons). The infrared spectrum: 1685 and 1720 (shoulder) cm^{-1}, C=O stretch. Mass spectrum, calcd.: 296; found: M^+ 296. The nmr spectrum of the phenol **8***a* in $CDCl_3$ and CD_3OD, δ: 3.06 (s, 3H, *N*-methyl), 3.25 (s, 3H, *N*-methyl), 3.92 (d, J = 1.8 Hz, 2H, methylene protons), 6.68 (d, J = 1.8 Hz, olefinic proton), 6.8–8.0 (m, 6H, aromatic protons). The infrared spectrum: 3300 cm^{-1}, OH; 1665 and 1712 cm^{-1}, C=O; 1625 cm^{-1}, C=C stretch. Mass spectrum, calcd.: 296; found: M^+ 296.

Thermolysis of Chroman (7a) with Mesitylene

Chroman (100 mg) was refluxed with pure, dry mesitylene

(10 mL) under nitrogen for 14 h. Mesitylene was removed under reduced pressure and the residue chromatographed over a silica gel plate. Elution of the plate with a mixture of chloroform/benzene (9:1) gave starting spirodimer (1.5 mg), 1,3-dimethyluracil (3 mg), and 1,1-ethylenedi-2-naphthol (1 mg), mp 252°C (lit. (17) mp 252°C), along with a large amount of resinous material and some minor unidentified products.

*Reaction of 1,3-Dimethyl-4-thiouracil (5*b*) with Spirodimer 4*

Chromatography of the reaction mixture using chloroform containing 0.5% methanol gave the phenol **8***b* (461 mg). The phenol was crystallized from chloroform for further purification. The nmr spectrum in acetone-d_6, δ:3.17 (s, 3H, *N*-methyl), 3.8 (s, 3H, *N*-methyl), 4.37 (d, J = 1.8 Hz, 2H, methylene protons), 6.62 (d, J = 1.8 Hz, 1H, olefinic proton), 7.0–8.0 (m, 6H, aromatic protons). The infrared spectrum: 3300 cm^{-1}, OH; 1710 cm^{-1}, C=O stretch. Mass spectrum, calcd.: 312; found: M^+ 312.

*Reaction of 1,3-Dimethyl-2,4-dithiouracil (5*c*) with Spirodimer 4*

Chromatography of the reaction mixture with chloroform gave the phenol **8***c* (524 mg). It was crystallized from a mixture of chloroform and benzene for further purification. The nmr spectrum in acetone-d_6, δ:3.6 (s, 3H, *N*-methyl), 4.38 (s, 3H, *N*-methyl), 4.44 (d, J = 1.8 Hz, 2H, methylene protons), 6.90 (d, J = 1.8 Hz, 1H, olefinic proton), 7.18–8.00 (m, 6H, aromatic protons). The infrared spectrum: 3300 cm^{-1}, OH; 1630 cm^{-1}, C=O stretch. Mass spectrum, calcd.: 328; found: M^+ 328.

*Reaction of 1,3,6-Trimethyluracil (5*d*) with Spirodimer 4*

Chromatography of the reaction mixture in chloroform gave the chromans **7***b* (348 mg) and **9** (87 mg). These were crystallized from a mixture of chloroform and benzene for further purification. The nmr spectrum of chroman **7***b* in $CDCl_3$, δ:1.73 (s, 3H, *C*-methyl), 3.1 (s, 3H, *N*-methyl), 3.2 (s, 3H, *N*-methyl), 2.8–3.68 (m, 3H, methylene and methine protons), 7.0–8.0 (m, 6H, aromatic protons). The infrared spectrum: 1722 and 1670 cm^{-1}, C=O stretch. Mass spectrum, calcd.: 310; found: M^+ 310. The nmr spectrum of the isomeric chroman **9** in $CDCl_3$, δ:2.3 (s, 3H, *C*-methyl), 3.23 (s, 2H, methylene protons), 3.33 (s, 3H, *N*-methyl), 3.40 (s, 3H, *N*-methyl), 4.13 (s, 1H, methine proton), 6.9–8.0 (m, 6H, aromatic protons). The infrared spectrum: 1705 cm^{-1}, C=O stretch. Mass spectrum, calcd.: 310; found: M^+ 310.

*Reaction of 1,3,6-Trimethyl-4-thiouracil (5*e*) with Spirodimer 4*

The reaction mixture formed an insoluble product in mesitylene. It was removed by filtration (550 mg). It is insoluble in most organic solvents. Its structure is under investigation.

Chromatography of the filtrate in chloroform gave only the starting materials in small amounts.

*Reaction of 1,3-Thiazine-2-thione (6*a*) with Spirodimer 4*

Chromatography of the reaction mixture in chloroform gave the chroman **10***a* (433 mg). It was crystallized from a mixture of benzene and chloroform for further purification. The nmr spectrum in DMSO-d_6 and $CDCl_3$, δ:5.75 (d, J = 2.5 Hz, 1H, methine proton), 6.9–8.1 (m, 6H, aromatic protons). Since the signals due to the methylene and other methine protons (δ 3.75–3.0) were overlapped by the DMSO and water, their assignments could not be made. The infrared spectrum: 1700 cm^{-1}, C=O stretch. Mass spectrum, calcd.: 301; found: M^+ 301.

Reaction of N*-Methyl-1,3-thiazine-2-thione (6*b*) with Spirodimer 4*

Chromatography of the reaction mixture in benzene gave the chroman **10***b* (473 mg). It was crystallized from benzene for further purification. The nmr spectrum in $CDCl_3$, δ:3.7 (s, 3H,

N-methyl), 3.0–4.24 (m, 3H, methylene and methine proton), 5.33 (d, J = 2.5 Hz, 1H, methine proton), 6.9–8.1 (m, 6H, aromatic protons). The infrared spectrum: 1710 cm^{-1}, C=O stretch. Mass spectrum, calcd.: 315; found: M^+ 315.

Reaction of 2-Methylthio-1,4-dihydro-1,3-thiazine-4-one (11) with Spirodimer 4

Chromatography of the reaction mixture in chloroform yielded the chroman **12** (378 mg). It was crystallized from benzene for further purification. The nmr spectrum in $CDCl_3$, δ: 2.60 (s, 3H, *S*-methyl), 3.15–3.76 (m, 3H, methine and methylene protons), 5.85 (d, J = 2.5 Hz, 1H, methine proton), 6.9–8.0 (m, 6H, aromatic protons). The infrared spectrum: 1705 cm^{-1}, C=O stretch. Mass spectrum, calcd.: 315; found: M^+ 315.

Received February 6, 1981

F. P. LOSSING, YAI-TAI LAM, and ALLAN MACCOLL. Can. J. Chem. **59**, 2228 (1981).

Using an energy-resolved electron beam, the gas-phase heats of formation of $[CH_2NH_2]^+$, $[CH_3CHNH_2]^+$, $[CH_3NHCH_2]^+$, $[(CH_3)_2CNH_2]^+$, $[(CH_3)_2NCH_2]^+$, $[CH_3CHNHCH_3]^+$, $[CH_3CH_2NHCH_2]^+$, and $[CH_3CH_2CHNH_2]^+$ ions have been measured from their appearance energies in ionic dissociations. All of these ions can have a quaternary immonium structure as one of the canonical forms and are consequently more stable than other isomers. Introduction of the $—NH_2$ group into a CH_3^+ ion brings about a decrease of over 4 eV in the heterolytic bond dissociation energy $D(R^+—H^-)$, with slightly larger decreases for —NHR and $—NR_2$ groups.

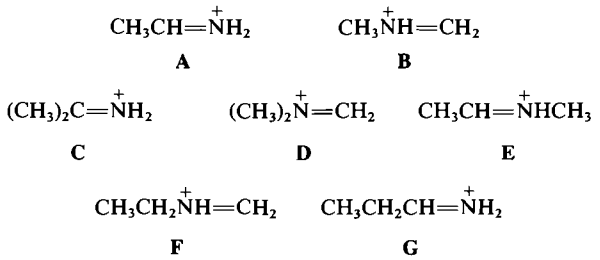
F. P. LOSSING, YAI-TAI LAM et ALLAN MACCOLL. Can. J. Chem. **59**, 2228 (1981).

En utilisant un faisceau d'électron à énergie résolue, on a mesuré les chaleurs de formation en phase gazeuse des ions $[CH_2NH_2]^+$, $[CH_3CHNH_2]^+$, $[CH_3NHCH_2]^+$, $[(CH_3)_2CNH_2]^+$, $[(CH_3)_2NCH_2]^+$, $[CH_3CHNHCH_3]^+$, $[CH_3CH_2NHCH_2]^+$ et $[CH_3CH_2CHNH_2]^+$ à partir de leurs potentiels d'apparition lors de dissociations ioniques. Tous ces ions peuvent avoir une structure immonium quaternaire comme forme canonique et ils sont par conséquent plus stables que les autres isomères. L'introduction du groupe $—NH_2$ dans l'ion CH_3^+ provoque une diminution (plus de 4 eV) de l'énergie de dissociation hétérolytique de la liaison $D(R^+—H^-)$; cette diminution est légèrement plus grande dans les cas des groupes —NHR et $—NR_2$.

[Traduit par le journal]

Introduction

Studies of the structure and reactivity of the gaseous ions $[C_2H_6N]^+$ and $[C_3H_8N]^+$, using metastable ion dissociation patterns (1) and collisional activation (CA) (2) techniques, have shown that two $[C_2H_6N]^+$ isomers and five $[C_3H_8N]^+$ isomers (2) are non-interconverting under mass spectrometric conditions. These ions are the following:



A B C D E F G

As pointed out by Levsen and McLafferty, these structures are formally immonium ions, and would consequently be expected to be considerably more stable than other isomeric structures such as $\overset{+}{C}H_2CH_2NH_2$, $CH_3\overset{+}{N}HCH_3$, and $CH_3CH_2\overset{+}{N}H$. These ions were found not to retain their identity, but to isomerize to one of the immonium ion structures (2). These results indicate that the appearance energies (AE) for production of these immonium ions in the ionic dissociations of suitable precursors can be used to derive their gas-phase heats of formation without interference from rearrangements. A similar study of $[C_2H_5O]^+$, $[C_3H_7O]^+$, and $[C_4H_9O]^+$ isomeric ions has been published recently (3).

Experimental

As in the earlier work (3), the ionic dissociations used in this study were carefully chosen to be the minimum-energy single-bond rupture processes in order to minimize interference from kinetic shift and reverse activation energy (4). The appearance energies were measured as described previously (3), using an electrostatic electron monochromator coupled to a quadrupole mass spectrometer (5). The initial portions of the ionization efficiency curves were scanned repeatedly over a range of 0.8 eV, and analyzed using a minicomputer data system (6). The electron beam from the monochromator was of the order of 2×10^{-8} Å, with an energy dispersion (FWHM) of about 0.07 eV.

For many of these dissociations, the onsets were unusually gradual; extreme care was therefore taken to avoid interference at the threshold from ions of neighboring mass. Because of these experimental difficulties, measurements were made in two similar, but not identical, instruments; one at University College London, and the other at the National Research Council of Canada in Ottawa. The agreement between the appearance energies measured in the two laboratories was in all cases better than 0.1 eV.

Results and Discussion

$[H_2NCH_2]^+$ *Ion*

The heat of formation of this ion has been established by photoionization studies (4) as 178 kcal mol^{-1}. Further measurements made in this work, shown in Table 1, are in excellent agreement with this value.

$[CH_3NHCH_2]^+$ *and* $[CH_3CHNH_2]^+$

The appearance energies and derived heats of formation for these two isomeric species are given in Table 2, together with the heats of formation for the parent molecules. For both ions, the internal agreement of the results is good, fortuitously better than the thermochemical data would warrant. The overall uncertainty in the ΔH_f(ion) values is estimated to be ±2 kcal mol^{-1}. It has been assumed that the neutral products C_2H_5 and CH_2OH are not dissociated; to assume C_2H_4 + H and CH_2O + H as the neutral products leads to impossibly low values for the ionic heats of formation.

Also given in Table 2 are four AE-values from an earlier study of $[C_2H_6N]^+$ ions (7), using the Retarding Potential Difference (RPD) method for obtaining a quasi-monoenergetic electron beam. Although the two H-loss values agree reasonably well with the present results, those for the CH_3 loss reactions are in poor agreement. The reason for the discrepancy is not known. It is clear from the present result that ions A and B retain their identity during the dissociation process, in agreement with earlier conclusions (1, 2).

$[C_3H_8N]^+$ *Ions*

The appearance energies and the derived heats of formation for the five isomeric $[C_3H_8N]^+$ ions are given in Table 3, together with heats of formation of the parent molecules. The internal agreement is reasonably good, with the exception of the loss of CH_2OH from $(CH_3)_2C(NH_2)CH_2OH$, which appears to be about 6 kcal mol^{-1} too high. For ion **E** there is only one value. The H-loss reaction from the precursor $CH_3CH_2NHCH_3$ could form either ion **E** or ion **F**:

$$CH_3CH_2NHCH_3 \rightarrow H + [CH_3CHNHCH_3]^+ \quad \mathbf{E}$$

$$CH_3CH_2NHCH_3 \rightarrow H + [CH_3CH_2NHCH_2]^+ \quad \mathbf{F}$$

TABLE 4. Heterolytic bond dissociation energies (HBDE, kcal mol^{-1}) and relative stabilization ΔHBDE

Bond	ΔH_f(parent molecule)	ΔH_f(ion)	HBDE[a]	ΔHBDE[b]
HCH_2^+—H^-	−17.89[c]	259[d]	312	0
$HOCH_2^+$—H^-	−48.07[c]	169[c]	252	60
$H_2NCH_2^+$—H^-	−5.5[c]	178	218	94
$[CH_3CHNH_2]^+$—H^-	−11.4[c]	157	203	109
$[CH_3NHCH_2]^+$—H^-	−4.4[c]	166	205	107
$[(CH_3)_2CNH_2]^+$—H^-	−20.0[c]	141	196	116
$[(CH_3)_2NCH_2]^+$—H^-	−5.7[c]	158	198	114
$[CH_3CH_2CHNH_2]^+$—H^-	−16.8[c]	152	204	108
$[CH_3CH_2NHCH_2]^+$—H^-	−11.4[f]	156	202	110
$[CH_3CHNHCH_3]^+$—H^-	−11.4[f]	147	193	119

[a] Using $\Delta H_f(H^-) = 34.7$ kcal mol^{-1}.
[b] $D(CH_3^+—H^-) - D(R^+—H^-)$.
[c] Reference 9.
[d] Reference 13.
[e] Reference 3.
[f] Calculated, ref. 10.

Because of this ambiguity, the AE for this reaction was not considered sufficiently reliable for inclusion.

It seems evident that dissociation processes leading to an isomeric ion other than an immonium ion cannot interfere at the observed thresholds. For example, the dissociation

$$(CH_3)_2NCH_2CH_3 \rightarrow CH_3 + CH_3\overset{+}{N}CH_2CH_3$$

will have a much higher AE than that given in Table 3.

Stabilization in Alkyl Immonium Ions

The stabilizing effects of substitution of —NH_2, —NHR, and —NR_2 groups in alkyl ions can best be evaluated in terms of the heterolytic bond dissociation energy (8) (hydride ion affinity):

$$\begin{aligned} \text{HBDE} &= D(R^+—H^-) \\ &= \Delta H_f(R^+) + \Delta H_f(H^-) - \Delta H_f(RH) \end{aligned}$$

Table 4 gives the values of HBDE for the eight immonium ions, together with those for CH_3^+ and $\overset{+}{C}H_2OH$ for comparison. It can be seen that substitution by the —NH_2 group has a much larger stabilizing effect than that caused by substitution by the —OH group into CH_3^+ ion. The stabilization (ΔHBDE) brought about by substitution by —NH_2, —$N(H)CH_3$, and —$N(CH_3)_2$ groups are respectively 94, 107, and 114 kcal mol^{-1}.

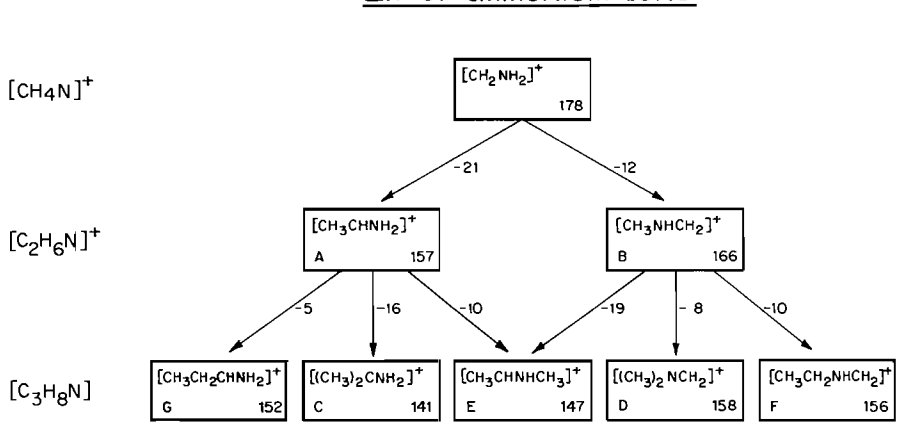

FIG. 1. Schematic illustration of the relationships in ionic heats of formation of alkyl immonium ions.

It is of interest to note that, using $D(R^+—H^-)$ as the criterion, the most stable $[C_3H_8N]^+$ isomer is $[CH_3CHNHCH_3]^+$, although it is not the isomer with the lowest heat of formation. This reversal arises from the heats of formation of the neutral parent molecules: $(CH_3)_2CHNH_2$ is 8.6 kcal mol^{-1} more stable than $CH_3CH_2NHCH_3$.

The effect of substitution on the heats of formation of $[C_2H_6N]^+$ and $[C_3H_8N]^+$ isomeric ions is shown schematically in Fig. 1. It can be seen that the stabilization brought about by CH_3 substitution is significantly greater when the substitution is on a C atom rather than on an N atom. The situation is similar to that found recently (3) for substitution on C and O atoms in $[CH_2OH]^+$, although the differences for the C and N positions are less marked. Of the canonical forms

$$^+CH_2NH_2 \leftrightarrow CH_2{=}\overset{+}{N}H_2$$

the quaternary immonium structure may well play a greater role in stabilization than does the oxonium structure $CH_2{=}\overset{+}{O}H$ in oxycarbonium ions.

Kinetics of the oxidation of ethane by nitric oxide over manganese(III) oxide

R. A. Ross[1] and C. Fairbridge

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received October 29, 1980

R. A. Ross and C. Fairbridge. Can. J. Chem. **59**, 2232 (1981).

The catalytic reaction between ethane and nitric oxide over manganese(III) oxide has been investigated in a continuous flow system from 673 to 573 K at atmospheric pressure. The products of catalysis were nitrogen, carbon dioxide, nitrous oxide, and water. The rate of nitrous oxide formation was constant over this temperature region, while the apparent activation energies for nitrogen and carbon dioxide formation increased from 32 ± 4 and 22 ± 4 kJ mol^{-1}, respectively, at 573 to 613 K, to 78 ± 4 and 63 ± 4 kJ mol^{-1} between 613 and 673 K. The kinetic results were best described by the rate equation:

$$r = \frac{kap_{C_2H_6}bp_{NO}}{(1 + ap_{C_2H_6} + bp_{NO})^2}(p_{C_2H_6}p_{NO})$$

The surface mechanism appears to be complex and has been interpreted by a scheme involving interaction of the reactants in an absorbed layer. Both nitric oxide and ethane are believed to be involved further in subsequent steps. Infrared evidence indicates the possibility of a surface nitrate intermediate consistent with the mechanistic proposal. Scanning electron microscopy and X-ray powder diffraction techniques were used to assess the catalyst structure.

R. A. Ross et C. Fairbridge. Can. J. Chem. **59**, 2232 (1981).

Opérant dans un système à écoulement continu à pression atmosphérique entre 673 et 573 K, on a étudié la réaction catalytique entre l'éthane et l'oxyde nitrique déposé sur l'oxyde de manganèse(III). Les produits de la catalyse sont l'azote, le bioxyde de carbone, l'oxyde nitreux et l'eau. La vitesse de formation de l'oxyde nitreux est constante dans cet intervalle de température, tandis que les énergies apparentes d'activation pour la formation de l'azote et du bioxyde de carbone augmentent respectivement de 32 ± 4 et 22 ± 4 kJ mol^{-1} entre 573 et 613 K à 78 ± 4 et 63 ± 4 kJ mol^{-1} entre 613 et 673. On peut convenablement décrire les résultats cinétiques par l'équation de vitesse

$$r = \frac{kap_{C_2H_6}bp_{NO}}{(1 + ap_{C_2H_6} + bp_{NO})^2}(p_{C_2H_6}p_{NO})$$

Le mécanisme de surface semble être complexe et on l'a interprété selon un schéma impliquant une interaction des réactifs dans la couche absorbée. On croit que l'oxyde nitrique ainsi que l'éthane sont aussi impliqués dans les étapes suivantes. Les données infrarouges suggèrent la possibilité d'un intermédiaire nitrate à la surface qui est en accord avec le mécanisme proposé. Pour déterminer la structure du catalyseur, on a utilisé les techniques de la microscopie par balayage électronique et la diffraction des poudres par rayons-X.

[Traduit par le journal]

Introduction

The activities and surface chemical properties of manganese oxides have been observed for a number of heterogeneous catalytic reactions including the decomposition of 2-propanol (1), the water–gas shift reaction (2), the decomposition of formic acid (3) and, more recently, the reaction of nitrous oxide with carbon monoxide (4). The present work was designed to expand the redox reaction studies to include the evaluation of the catalytic activity of manganese(III) oxide in hydrocarbon oxidation. In the first instance, ethane has been used as the hydrocarbon and nitric oxide as the oxidizing species.

It is important also to note that the technological development of catalysts suitable for the control of the emission of nitrogen oxides from both mobile and stationary sources has received and continues to receive considerable attention. Much of the published work has focused on reactions of nitric oxide and especially the NO/CO reaction (5). Previously, it has been postulated that nitrous oxide may be an important intermediate in the mechanism of such reactions (6, 7).

Experimental

Apparatus and Procedure

The all-glass flow system and quartz reactor were described previously (8). High-purity helium, passed through a molecular sieve drying column (Davison, Grade 564), was used as the carrier gas in both the flow system and the Hewlett-Packard Research Chromatograph, Model 5754B. Nitrogen, nitric oxide, carbon dioxide, nitrous oxide, ethane, and water were analysed by a thermal conductivity bridge using stainless steel columns 305 × 0.32 cm o.d. packed with Poropak Q and run at 293 K. A Beckman Model 951 NO/NO_x Analyser was used in series with the gas chromatograph for calibration purposes as well as to monitor the atmosphere in the laboratory.

To establish the experimental conditions for which the reaction rates were not influenced by external or internal diffusion, the influences of space velocity, catalyst mass, and particle size were studied in the usual manner (9). As a result,

kinetic measurements were conducted at a total gas flow rate of 350 mL min^{-1} (NTP) on 1 g catalyst samples of particle size $<37\,\mu m$ with surface area 15.5 $m^2\ g^{-1}$ as measured by low temperature krypton adsorption (BET; 77 K; $\sigma = 19.5\ A^2$).

All reaction rate measurements were recorded after steady catalyst activity had been obtained and at less than 15% total conversion. Exposure of black manganese(III) oxide to nitric oxide and ethane (approximately 2.66 kPa of each) produced a brownish surface colouration on the samples but no significant change of structure was found after catalysis from XRD, chemical analysis, and surface area measurements. Infrared spectra were obtained with a Beckman IR-12 Spectrophotometer using 0.5% w/w samples in KBr pellets.

Materials

Manganese(III) oxide was prepared and analysed as described previously (1). Analysis by XRD confirmed the α-Mn_2O_3 structure (10) and chemical analysis (11) indicated 69.73% w/w manganese (theory 69.59%).

Ethane (99.0%), carbon dioxide (99.5%), nitrogen (99.99%), and helium (99.995%) were obtained from Canadian Liquid Air Ltd. Nitric oxide (99.0%) was supplied by Matheson of Canada Ltd. and nitrous oxide (99.9%) by Liquid Carbonic Ltd. The nitric oxide contained approximately 2.5% nitrous oxide impurity as determined by gas chromatography. A simple cold trap of liquid nitrogen and technical pentane (150 K) was demonstrated to be sufficient to remove this impurity to within limits of detection < 0.002 kPa.

Results

Reaction Rate Order Measurements

Rate orders for the NO/C_2H_6 reaction were measured at 623 K for nitrogen (r_1), carbon dioxide (r_2), and nitrous oxide (r_3) formation.

Ethane

The dependence of reaction rates on variations in the ethane partial pressure from 0.73 to 6.59 kPa was examined with nitric oxide maintained constant at 3.0 kPa. Plots of ln (rate) versus ln (partial pressure of ethane) exhibited linear relationships over the range studied, Fig. 1, and the reaction rate orders with respect to the ethane partial pressure were given by $r_1 \propto p_{C_2H_6}{}^{0.5}$; $r_2 \propto p_{C_2H_6}{}^{0.7}$, and $r_3 \propto p_{C_2H_6}{}^{0.5}$.

Nitric Oxide

With the partial pressure of ethane held constant at 2.71 kPa, the effect of nitric oxide on reaction rates was observed by varying its partial pressure from 0.83 to 11.75 kPa. Again, linear relationships were observed, as shown in Fig. 1, and rate orders with respect to the nitric oxide partial pressure were described by $r_1 \propto p_{NO}{}^{0.5}$; $r_2 \propto p_{NO}{}^{0.3}$; and $r_3 \propto p_{NO}{}^{1.2}$.

Nitrogen

The effect of nitrogen on the reaction rates r_2 and r_3 was observed by maintaining the partial pressures of ethane and nitric oxide constant at 2.52 and 2.61 kPa, respectively, and altering the partial pressure of nitrogen from 0.09 to 9.21 kPa. The rate orders with respect to nitrogen were zero throughout the range investigated.

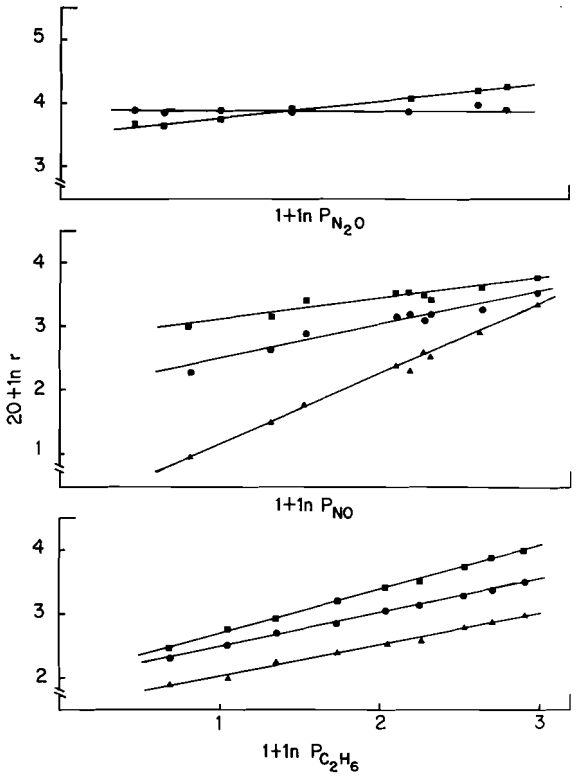

FIG. 1. The effects of component partial pressures on the rates of formation of nitrogen (●), carbon dioxide (■), and nitrous oxide (▲).

Carbon Dioxide

Carbon dioxide partial pressure was altered from 0.15 to 5.87 kPa with the partial pressures of ethane, 2.57 kPa, and nitric oxide, 2.93 kPa, held constant in order to observe the effects of carbon dioxide on reaction rates. The relationships were: r_1 and $r_3 \propto p_{CO_2}{}^0$).

Water Vapour

With the partial pressures of ethane and nitric oxide maintained at 2.47 and 2.88 kPa, respectively, from 0.04 to 1.4 kPa of water vapour was added to the system and shown to have no effect on the reaction rates.

Nitrous Oxide

The partial pressure of nitric oxide was maintained at 2.82 kPa and ethane at 2.41 kPa while the partial pressure of nitrous oxide was varied from 0.23 to 6.06 kPa. Over the range studied, nitrous oxide had no effect upon the rate of nitrogen

For personal use only.

formation ($r^1 \propto p_{N_2O}{}^0$) and a linear relationship was observed for the rate of carbon dioxide formation, $r_2 \propto p_{N_2O}{}^{0.3}$, as shown in Fig. 1.

On the basis of these studies, the rate of reaction of nitric oxide with ethane over the manganese(III) oxide catalyst at 623 K can be expressed as:

[1] $r_1 = k_1 p_{NO}{}^{0.5} p_{C_2H_6}{}^{0.5}$ mol m^{-2} s^{-1}

[2] $r_2 = k_2 p_{NO}{}^{0.3} p_{C_2H_6}{}^{0.7} p_{N_2O}{}^{0.3}$ mol m^{-2} s^{-1}

[3] $r_3 = k_3 p_{NO}{}^{1.2} p_{C_2H_6}{}^{0.5}$ mol m^{-2} s^{-1}

The Effect of Temperature

The catalytic reaction rates were determined from 673 to 573 K in decreasing 10 K intervals after catalyst pretreatment at 673 K for 2 h with nitric oxide and ethane at 2.74 and 2.71 kPa, respectively. Rate constants were calculated by integration of eqs. [1], [2], or [3] as a function of concentration and the values obtained were plotted in the Arrhenius fashion, Fig. 2. The rate of nitrous oxide formation was constant over this temperature range and hence the specific rate constant did not change with temperature. Two distinct temperature regions were observed in the linear plots obtained for both nitrogen and carbon dioxide formation, namely, from 673 to 613 K and from 613 to 573 K as shown in Table 1.

Infrared Spectra

The infrared spectrum of unreacted Mn_2O_3, Fig. 3 *A*, consisted of peaks at 670 (m), 600 (sh), 570 (s), 525 (s), 495 (sh), 450 (sh), and 400 (w) cm^{-1}. The spectrum of pure Mn_2O_3 (Alfa Inorganics, Ventron) was similar with the single exception that no peak was apparent at 400 cm^{-1}. This may be ascribed to a very small amount of MnO_2 (Alfa Inorganics, Ventron), 615, 400, and 335 cm^{-1}.

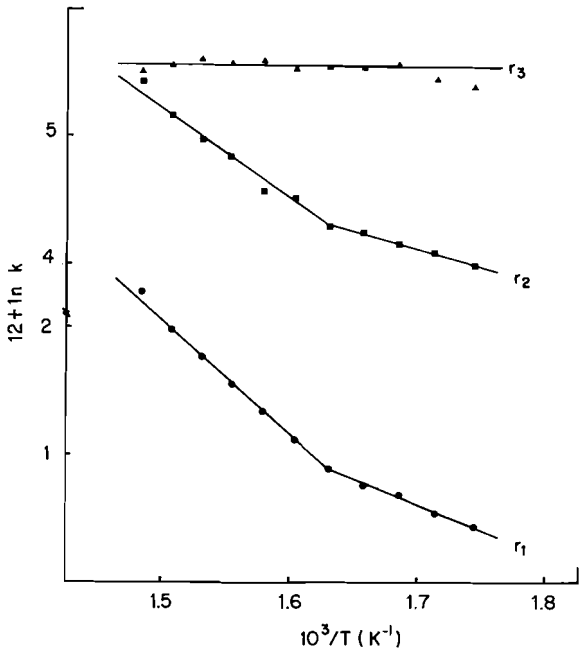

FIG. 2. Arrhenius plots for the reaction of nitric oxide (2.74 kPa) and ethane (2.71 kPa) on manganese(III) oxide. Symbols correspond to Fig. 1.

TABLE 1. Kinetic parameters for the ethane/nitric oxide reaction over manganese(III) oxide

T (K)	E_a (from [1]) (kJ mol^{-1})	A	E_a (from [1]) (kJ mol^{-1})	A
673–613	7.48±4	1.10×10^7	63 ± 4	1.59×10^7
613–573	32 ±4	1.28×10^3	22 ± 4	6.08×10^3

After catalysis of the NO/C_2H_6 reaction, the sample spectrum was altered to yield peaks at 1630 (m), 1390 (s), and 845 (w) cm^{-1}, which, along with the peak at 350 (m) cm^{-1}, Fig. 3 *C*, is consistent with the spectrum of manganese(II) nitrate, Fig. 3 *B*. Other peaks appeared at 615 (s), 490 (s), and 425 (m) cm^{-1} and these may indicate the presence of an Mn_3O_4 phase. The spectrum observed for pure MnO (Alfa Inorganics, Ventron) also indicated a single peak at 340 cm^{-1}. Thus, the catalyst may contain a trace of MnO after reaction but chemical analysis and XRD indicated no significant difference from the starting material.

Scanning Electron Micrographs

The scanning electron micrographs, Fig. 4, appear to show a separate crystalline phase on the oxide surface after catalysis at 673 K. The observation resembles that made previously in studies of the surface formation of manganese(II) formate from the dehydration and dehydrogenation of formic acid on manganese(II) oxide (3). The presence of smaller, more ordered particles may be observed in Fig. 4 *A* and *B*, while the condition of the remainder of the surface of the particles, Fig. 4 *C*, indicates rounded edges and a high degree of surface roughness. This surface appears identical to that noted for manganese(III) oxide prior to catalysis. Samples which were further heated under reaction conditions to 873 K exhibited surface sintering and crack formations, Fig. 4 *D*.

Discussion

The kinetic results were analysed by computer tests of standard gas/solid reaction rate expressions based mainly on the Langmuir–Hinshelwood model (12, 13). On the basis of statistical criteria (14–16), eq. [4] described the data best and was thus adopted as a general guide to the nature of the surface reaction:

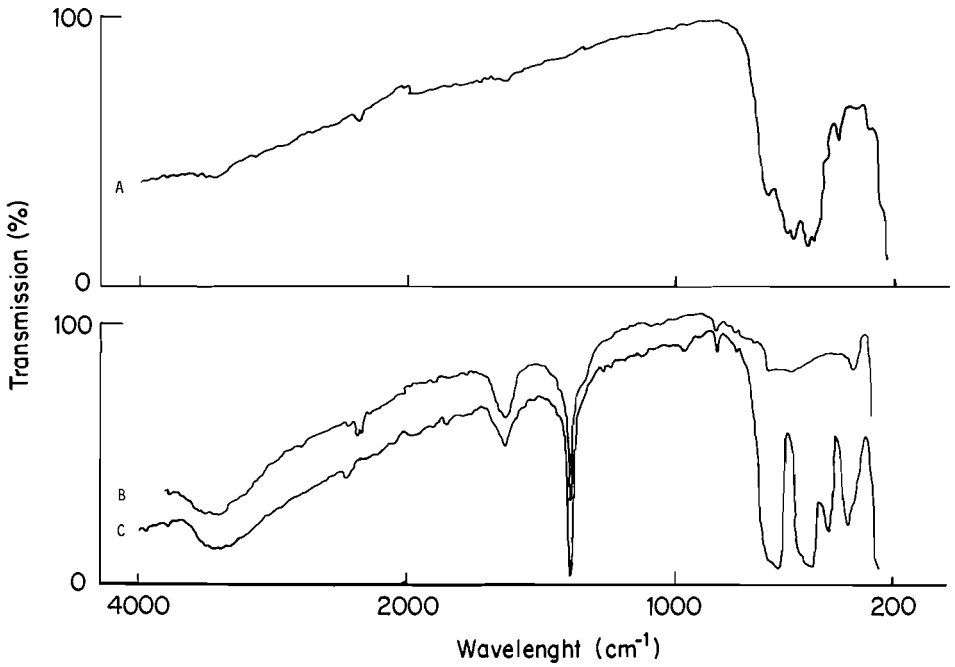

FIG. 3. The infrared spectra of unreacted manganese(III) oxide, *A*; manganese(II) nitrate, *B*; and catalyst after reaction, *C*.

$$[4] \quad r = \frac{kap_{C_2H_6}bp_{NO}}{(1 + ap_{C_2H_6} + bp_{NO})^2}\,(p_{C_2H_6}p_{NO})$$

where a and b represent adsorption coefficients. Plots of $p/r^{0.5}$ versus p were linear as shown in Fig. 5. The form of the equation is consistent with that for an irreversible bimolecular reaction between reactive species adsorbed on the same type of site (17). The reaction rate is proportional to the probability that the reactants are adsorbed on neighbouring sites and, in turn, proportional to the product of the fractions of surface covered by the reactants, $\theta_{C_2H_6}$ and θ_{NO}. Thus:

$$[5] \quad r = k\theta_{C_2H_6}\theta_{NO}$$

where

$$[6] \quad \theta_{C_2H_6} = \frac{K_{C_2H_6}p_{C_2H_6}}{(1 + K_{C_2H_6}p_{C_2H_6} + K_{NO}p_{NO})}$$

and

$$[7] \quad \theta_{NO} = \frac{K_{NO}p_{NO}}{(1 + K_{C_2H_6}p_{C_2H_6} + K_{NO}p_{NO})}$$

The additional $(p_{C_2H_6}p_{NO})$ multiplier term in [4] indicates that, at the steady-state, catalysis includes additional interactions involving nitric oxide with ethane molecules either from the gaseous state or as weakly chemisorbed species. Previously, a mechanism for the oxidation of hydrocarbons has been postulated to occur through the initial interaction of chemisorbed hydrocarbon species with either gaseous or chemisorbed oxygen followed by a complex sequence of steps which invokes surface radical reactions (18). The chemisorption of ethane on iron(III) and nickel(II) oxides has been shown to involve C—H bond rupture (19) while studies on ethane oxidation (20) on nickel(II) oxide indicated that the hydrocarbon was adsorbed prior to any surface reaction with preadsorbed oxygen.

A plausible scheme consistent with eq. [4] for the nitric oxide/ethane surface reaction is:

$$[8] \quad C_2H_{6(g)} \rightleftharpoons C_2H_{6(ads)}$$

$$[9] \quad NO_{(g)} \rightleftharpoons NO_{(ads)}$$

$$[10] \quad C_2H_{6(ads)} + NO_{(ads)} \rightarrow C_2H_{5(ads)} + HNO_{(ads)}$$

$$[11] \quad 2HNO_{(ads)} \rightarrow N_2O_{(ads)} + H_2O_{(ads)}$$

The formation of $C_2H_{5\,(ads)}$ in [10] is a step similar to that in the proposal (20) regarding the oxygen/ethane reaction on nickel(II) oxide. The formation of N_2O and H_2O from adsorbed HNO species in [11] has been described in observations of the reduction of nitric oxide by both hydrazine (21) and ammonia (22).

In a current review of nitric oxide surface reactions (23), evidence obtained from ir, epr, and oxygen-exchange experiments is cited in favour of the proposal that adsorption of nitric oxide on transition metal oxides occurs through partial coordination to a surface oxygen ion, O^{2-}. An intermediate surface nitrite or nitro complex was invoked

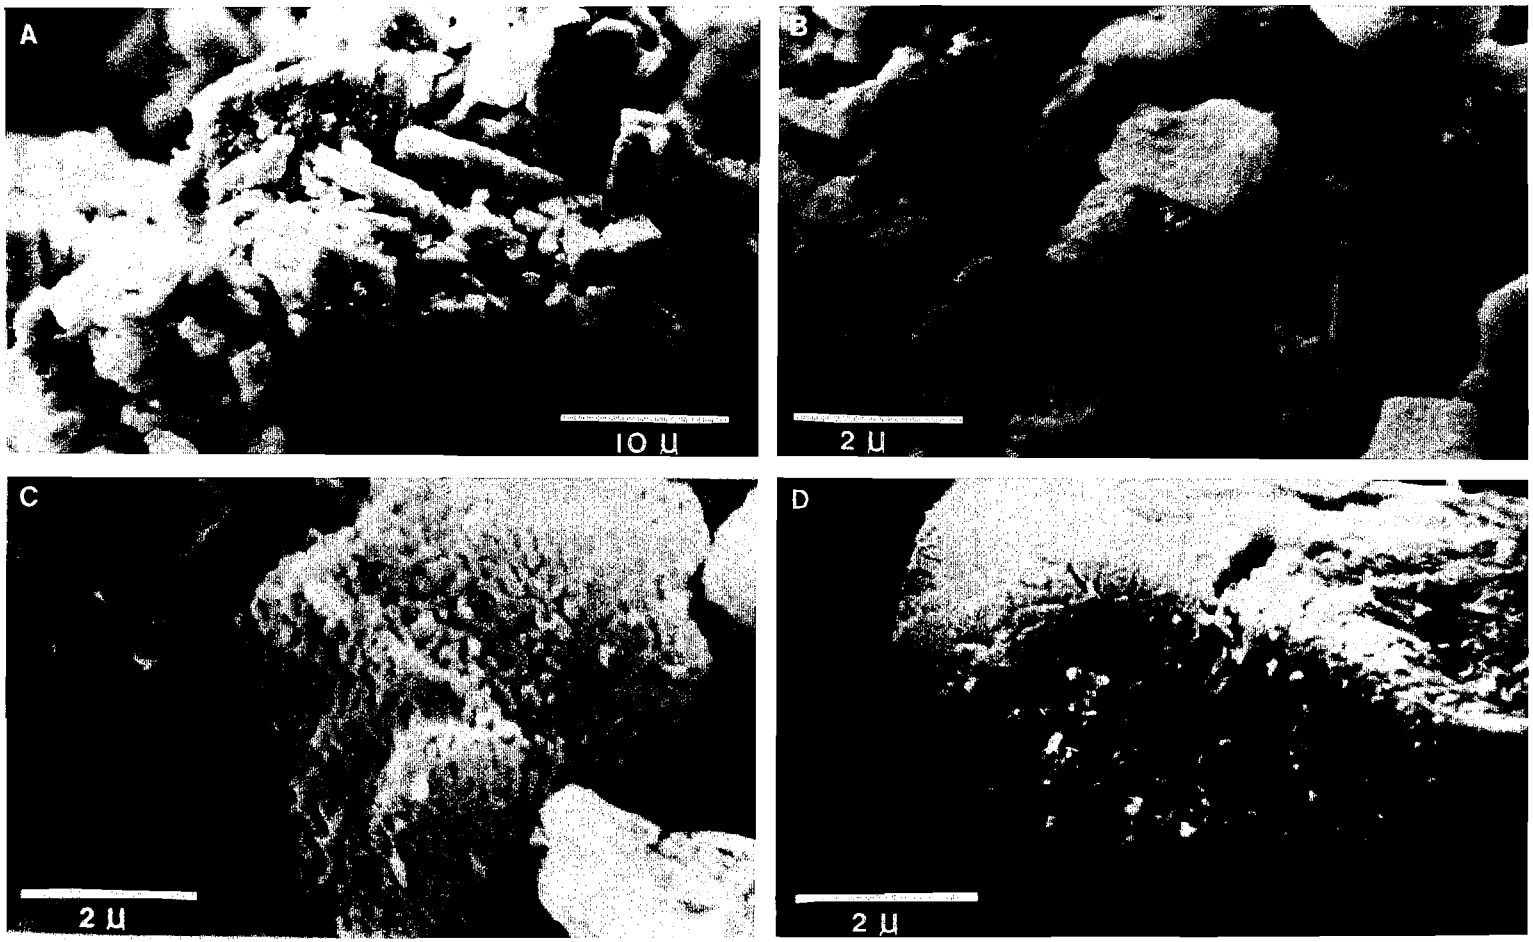

FIG. 4. Scanning electron micrographs of manganese(III) oxide after catalysis with nitric oxide and ethane at 673 K, *A*, *B*, and *C*; and after further heat treatment at 873 K, *D*.

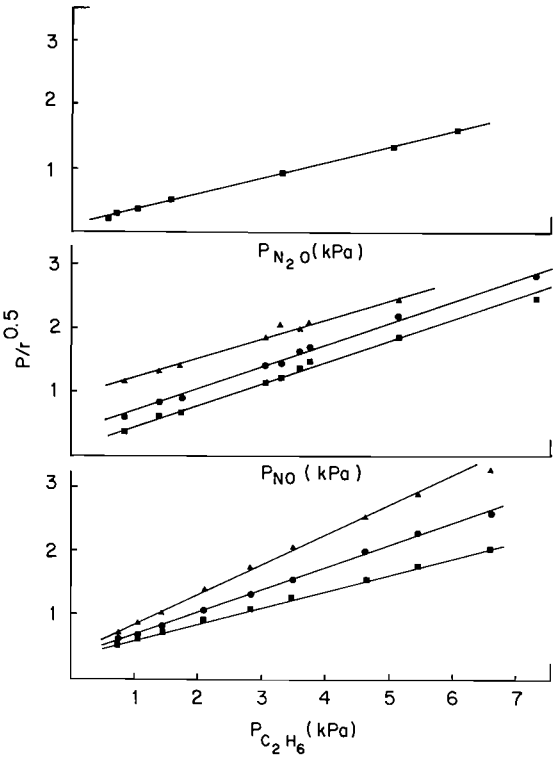

FIG. 5. Reduced plots for the rate order results according to expression [7]. Symbols correspond to Fig. 1.

and such a species has been identified from infrared evidence in this work.

Nitric oxide has been shown to oxidize MnO to Mn_2O_3 with subsequent chemisorption of nitrous oxide (24), thus:

[12] $2NO_{(ads)} + \square + Mn^{2+} \rightarrow N_2O_{(ads)} + [O^-] + Mn^{3+}$

where $\square$ represents a surface anion vacancy. The nitrous oxide produced from [11] or [12] could subsequently react with the $C_2H_{5(ads)}$ species to form carbon dioxide, water vapour, and nitrogen.

The values of the apparent activation energies for both carbon dioxide and nitrogen formation were similar to those obtained for the water–gas shift reaction on manganese(II) oxide (2) which was believed to involve an active [Mn^{3+}—O^-] surface species. A two-step Arrhenius plot was also observed from 623 to 673 K and from 573 to 613 K with activation energies 67 and 46 kJ mol^{-1}, respectively. This effect may be related to the presence of two forms of chemisorbed oxygen which have not been distinguished (25) or to a change in surface oxygen mobility at the Curie transition temperature which lies around 610 K.

The mechanism of the decomposition of nitrous oxide on manganese oxides (25) has been explained by a redox scheme which shows that oxidation should be enhanced by conditions that tend to preserve the 3+ oxidation state. And, although the proposed chemisorbed oxygen species were not identified (25), it was suggested that a weak form such as O_2^- or O_2^{2-} could be sustained during catalysis. Oxygen desorption studies from MnO_2 have also indicated the presence of two surface states which have apparent activation energies for desorption of 67 and 126 kJ mol^{-1} (26).

In the present study, the rate of formation of nitrous oxide appears to be constant from 573 to 673 K. Nitrous oxide has been observed as a gaseous intermediate (7) in the NO/CO reaction on various supported oxides and mixed oxide catalysts, but not when the reaction took place over supported MnO. In most cases, nitrous oxide was observed to reach a maximum concentration at various temperatures from a low of 453 K for $CuCr_2O_4$ to a high of 623 K for Co_3O_4.

Studies of the NO/CO reaction on platinum indicate that the dissociation of nitric oxide may be rate-limiting (27, 28):

[16] $NO(ads) \rightarrow N(ads) + O(ads)$

followed by nitrogen formation:

[17] $N(ads) + N(ads) \rightarrow N_2(ads)$

The adsorbed oxygen species could act as a hydrocarbon oxidation source. However, the reaction of nitric oxide with ethane is quite complex since it does not appear to occur by a simple two-step process involving first the formation of nitrous oxide followed by ethane reduction. This is evidenced by the rates of product formation. In the direct reaction of nitrous oxide with ethane over manganese(III) oxide (29), the rates of formation of carbon dioxide and nitrogen coincide with that expected for complete oxidation in excellent accord with an overall stoichiometry:

[18] $C_2H_6 + 7N_2O \rightarrow 2CO_2 + 3H_2O + 7N_2$

The rates of product formation in the nitric oxide/ethane reaction, however, do not lend themselves to such a facile interpretation; indeed, the low apparent activation energy value for the low temperature region may imply that the boundary between diffusion rate control and chemical reaction rate control is at hand.

COMMUNICATION

Electrophilic cyclization of an olefinic β-keto ester

MARGOT ALDERDICE AND LARRY WEILER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received January 20, 1981

MARGOT ALDERDICE and LARRY WEILER. Can. J. Chem. **59**, 2239 (1981).

Benzeneselenenyl chloride and aluminum chloride or benzenesulphenyl chloride and silica gel initiate an electrophilic cyclization of methyl 7-methyl-3-oxo-7-octenoate to cyclohexyl derivatives. These products of the cyclization reaction have been converted into intermediates of potential use in the synthesis of unusual carotenoids.

MARGOT ALDERDICE et LARRY WEILER. Can. J. Chem. **59**, 2239 (1981).

Le chlorure de benzènesélényle en présence de chlorure d'aluminium ou le chlorure de benzènesulfényle en présence de gel de silice induisent la cyclisation électrophile du méthyl-7 oxo-3 octène-2 oate de méthyle en dérivés cyclohexaniques. On a transformé les produits de cyclisation en des intermédiaires ayant une utilité potentielle dans la synthèse de caroténoides particuliers.

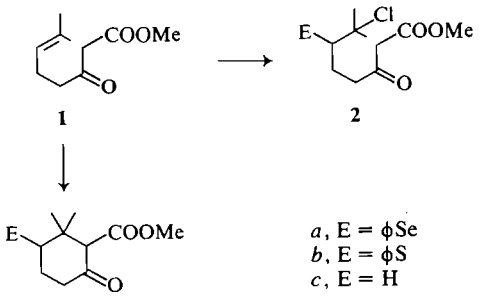
[Traduit par le journal

Following the initial suggestion that the biosynthesis of several steroids and other terpenoid compounds may involve an electrophilic cyclization of a polyolefin (1), there has been a continuing interest in this type of reaction from a mechanistic, biosynthetic, and synthetic viewpoint (2). A number of these polyolefin cyclizations are initiated by protons and frequently these cyclizations do not allow for the introduction of functional groups at the electrophilic terminus of the cyclization. In an effort to overcome this limitation a variety of electrophiles have been utilized to initiate cyclizations related to eq. [1] (3). However, in most of

[1] 
these cyclizations there are serious drawbacks due to low yields and/or generation of isomeric mixtures. Although the synthesis of heterocyclic systems by electrophilic cyclization of a substituted olefin is frequently used in synthetic chemistry, there are very few examples of C—C bond formation in nonproton initiated electrophilic cyclizations proceeding in useful yields. Usually the successful examples of C—C bond formation involve transannular cyclizations (3*d*, 4).

We would like to present some preliminary studies on the cyclization of an olefinic β-keto ester initiated by electrophiles other than protons.[2] In our studies, we have concentrated on selenium and sulfur electrophiles because of the potential to convert seleno- or thioethers into other functional groups (6). We chose β-keto ester **1** (5*b*) for this study because of the potential utility of this cyclization in the synthesis of C-2 substituted carotenoid end groups (7).

Treatment of the olefin **1** with benzeneselenenyl chloride in acetonitrile or dichloromethane gave a mixture of products containing predominantly the product **2***a* as a result of addition to the double bond.[3] Earlier we had found that benzeneselenenyl chloride added cleanly to the alkene of methyl 3-oxo-6-heptenoate without any cyclization (5*c*) and Kametani *et al.* have reported that treatment of



geranyl acetate with benzeneselenenyl chloride in acetic acid gave only an addition product (4*b*). However, when benzeneselenenyl chloride was added to a vigorously stirred suspension of aluminum chloride in dichloromethane containing **1**, a smooth (84%) and facile (30 min at room tempera-

[1]Author to whom correspondence should be addressed.

[2]There are several examples of proton initiated cyclizations of olefinic β-keto esters, see ref. 5, and a single example of cyclization of an olefinic β-keto ester enol phosphate, see ref. 4*e*. However, we are unaware of any cyclizations initiated by a nonprotonic electrophile and trapped at the nucleophilic terminus by a β-keto ester.

[3]Although the regiochemistry of the adduct **2***a* is not known unambiguously the ^{1}H nmr data on the crude material suggest the structure of the adduct is **2***a*.

ture) cyclization to **3***a* occurred. No addition product could be detected in the crude reaction mixture. Although the cyclic product **3***a* is a mixture of two diastereomers as determined from its ^{1}H nmr and chromatographic properties, its structure was consistent with the observed spectral data and with the reductive cleavage (4*a*) of **3***a* to **3***c* (5*b*).

A similar addition of benzenesulphenyl chloride to a suspension of aluminum chloride and **1** in dichloromethane did not lead to significant amounts of cyclic product **3***b*. However, the synthesis of **3***b* from **1** could be carried out in the following fashion. Benzenesulphenyl chloride added cleanly to the olefin of **1** in dichloromethane to give a single addition product **2***b* in quantitative yield of crude material. Refluxing a suspension of silica gel (8) and adduct **2***b* in dichloromethane gave the cyclic product **3***b*. Eventually the reaction was carried out on a preparative scale by adding the benzenesulphenyl chloride to a suspension of silica gel and **1** in dichloromethane. After the addition was complete (30 min) the reaction mixture was refluxed for three hours and worked up to give **3***b* in 90–95% crude yield. Again the spectral data was consistent with the assigned structure of **3***b*, but the ^{1}H nmr data and chromatographic properties of **3***b* indicated that it was a mixture of diastereomers. Thus we have been able to cyclize an olefinic β-keto ester using either a sulphenyl or selenenyl electrophile to initiate the cyclization and a β-keto ester as the nucleophilic terminus. Both of these functional groups have the potential to introduce additional groups at either side of the molecule. Some of our preliminary results from manipulating these groups are outlined below.

The crude diastereomers of **3** were easily converted into their corresponding enol phosphates **4** (9). Usually it was more efficient to purify at this stage because **4** no longer exists as a pair of diastereomers. The enol phosphates **4** react with lithium dimethylcuprate (9) to give the ester **5** in yields of 75–80% from **1**. The selenide **5***a* was oxidized (10) to the corresponding selenoxide which was not isolated, but on refluxing in dichloromethane solution gave the diene **6** in approximately quantitative yield. The sulphide **5***b* has been reduced with excess diisobutylaluminum hydride to the alcohol and protected (11) as the *tert*-butyldimethylsilyl ether **7** in 60% yield. The sulphoxide from **7** can be alkylated in 60–80% yield (3 equiv. *n*-butyllithium and iodomethane) to give **8**. Both **6** and **8** should serve as useful precursors in the synthesis of ring A substituted carotenoids. The crucial step in this sequence was the successful introduction of E in **3**.[4]

Correlation between thermodynamic parameters (GLC) and structure of esters

F. SAURA CALIXTO AND P. M. DEYÁ

Organic Chemistry Department, Faculty of Science, University of Palma de Mallorca, Balearic Islands, Spain

Received December 18, 1980

F. SAURA CALIXTO and P. M. DEYÁ. Can. J. Chem. **59**, 2243 (1981).

The ΔH_s and $\Delta G_s - \Delta G_{s_0}$ (ΔG_{s_0} = value of *n*-decane) values of some one hundred esters belonging to twenty different homologous series are determined experimentally in the polar stationary phase (Carbowax 1540) by gas–liquid chromatography.

Correlations between thermodynamic values and the molecular structure of esters are studied. The influence of the number of carbon atoms in the acid and alcohol chains and the position of the carboxylic group and branching chains on the ΔH_s and $\Delta G_s - \Delta G_{s_0}$ values is considered.

F. SAURA CALIXTO et P. M. DEYÁ. Can. J. Chem. **59**, 2243 (1981).

Faisant appel à la chromatographie en phase gazeuse impliquant du Carbowax 1540 comme phase stationnaire on a déterminé expérimentalement les valeurs de ΔH_s et de $\Delta G_s - \Delta G_{s_0}$ (ΔG_{s_0} = valeur du *n*-décane) d'une centaine d'esters appartenant à 20 séries homologues différentes.

On a étudié les corrélations entre les valeurs thermodynamiques et la structure moléculaire des esters. On a considéré l'influence du nombre d'atomes de carbone dans les chaînes d'acides et d'alcool, la position du groupe acide carboxylique et les chaînes latérales sur les valeurs de ΔH_s et de $\Delta G_s - \Delta G_{s_0}$.

[Traduit par le journal]

Introduction

As is well known since the inception of gas chromatography, its application to the determination of thermodynamic parameters has experienced a progressive development, becoming one of the most precise and rapid methods for this purpose.

Since the publication of the work of Greene and Pust (1) concerning the determination of heats of adsorption of some light hydrocarbons on alumina and silica gel, many papers have been published on the determination of ΔH_{ads} (heat of adsorption) by gas–solid chromatography. Other papers deal with the calculations of several parameters concerning solution phenomena by gas–liquid chromatography. Some of the more significant are referred to in the bibliography (2–7). Some authors also employ thermodynamic values for quantitative determinations of polarity of stationary phases in gas chromatography (8, 9).

Several different procedures are available for calculating ΔH_s (heat of solution) and ΔG_s (free enthalpy of solution) by gas–liquid chromatography. Oberholtzer and Rogers (7) calculate ΔH_s from the following eq. [1]:

$$[1] \quad \ln \frac{V_R^0 - V_M}{V_M} = -\frac{\Delta H_s}{RT} + C$$

where V_R^0 is the corrected retention volume, V_M is the dead volume, R is the gas constant, T is the absolute temperature, and C is a constant of integration.

Golovnya and Arsenyev (10, 11) compare the ΔH_s values found from ln V_g^0 (specific retention volume) versus $1/T$ plots with the values calculated by means of eq. [2]:

$$[2] \quad \Delta H_{s_x} = -\Delta H_{v_n} + \Delta H_{s_n} + \frac{4.6 \cdot 10^{-5} T_1 T_2}{T_2 - T_1} \times [b_{T_1} \Delta I + \Delta b (I_{T_1} - 100n)]$$

where T_1 and T_2 are temperatures, ΔH_{s_x} is the partial molar enthalpy of solution of the unknown substance, ΔH_{v_n} is the partial molar enthalpy of evaporation of the *n*-alkane with "*n*" number of carbons, ΔH_{s_n} is the partial molar enthalpy of solution of the *n*-alkane, b is the slope of the straight line of ln V_g^0 versus "*n*" plot, I_T is the retention index at T temperature and V_g^0 is the specific retention volume. Significant differences between the two methods have not been found.

These authors also determined ΔG_s values using the classical expression [3]:

$$[3] \quad \Delta G_s = 2.3RT \log K_H$$

where K_H is the Henry's law constant.

In our laboratories, the heats of adsorption of some alkyl-aromatic hydrocarbons on several porous solids have been estimated (12) by the above mentioned methods.

In this paper an attempt has been made to correlate the ΔH_s and ΔG_s values with the molecular structure of esters. In this way we have determined experimentally the retention chromatographic parameters of some one hundred esters in Carbowax 1540 stationary phase at different temperatures. We can group these esters in twenty

different homologous series. As the purpose of this work has been to study the relationship between thermodynamic parameters and molecular structure in order to deduce the general behaviour of esters, and since the quantitative differences between the values obtained by using different methods were not significant, we have chosen the more general method described by eq. [4]:

$$[4] \quad \ln V_g^0 = -\Delta H_s/RT + C$$

The values of ΔH_s can be calculated from the values of the slopes obtained by plotting V_g^0 versus $1/T$ or by plotting V_R^0/T versus $1/T$, where V_R^0 is the corrected retention volume. In this study we have used the latter, thereby avoiding any discussion of their theoretical precision.

In order to study the relationship between free energy and ester structure, we have compared values of this magnitude to a standard linear hydrocarbon, *n*-decane. In this way, the magnitude used ($\Delta G_s - \Delta G_{s_0}$) is easily calculated from the retention data by means of eq. [5]:

$$[5] \quad \Delta G_s - \Delta G_{s_0} = -RT \ln (V_R^0/V_{R_0}^0)$$

This expression can be deduced from eq. [3], taking into account the corresponding expressions of Henry's constant [6] and the specific retention volume [7]:

$$[6] \quad K_H = V_g \cdot T \cdot \rho/273.16$$

$$[7] \quad V_g^0 = \frac{V_R^0}{w_L} \cdot \frac{p_0 - p_w}{p_0} \cdot j \cdot \frac{273.16}{T}$$

where:

w_L = weight of the stationary phase

$\frac{p_0 - p_w}{p_0}$ = correction for partial pressure of water vapor at T temperature

j = compressibility factor, $\frac{3}{2} \cdot \frac{(p_i/p_0)^2 - 1}{(p_i/p_0)^3 - 1}$

p_i = inlet pressure

ρ = density of stationary phase at the column temperature.

Experimental

Determinations of V_R^0 were carried out with a Perkin Elmer chromatograph, Model 900, equipped with a SIP-1 digital integrator and a counter, model 56. The detection system was flame ionization. One capillary column of Carbowax 1540 + KOH (99:1) made of stainless steel with dimensions of 150 ft × 0.02 in. was used.

Most of the esters used came from the firm Merck and Fluka. In some cases they were synthesized and purified using standard laboratory methods.

The assays were carried out at three different temperatures, 70, 81, and 90°C, and the gas flow rate at these temperatures was 2.8, 2.7, and 2.6 mL min^{-1} respectively. The other experimental conditions were: inlet pressure, 930.9 Torr; outlet pressure, 760.0 Torr; detector temperature, 200°C; injector temperature, 200°C, and splitter 44:1. The vapor pressure of water at ambient temperature (20°C) was 17.5 Torr.

The sample size was 0.04 μL which proved ideal to obtain symmetrical chromatographic peaks, a necessary condition for the correct calculation of retention data. These conditions produce reproducible retention data with a standard deviation of 0.02% which was stated in an earlier work (13).

Dead volume (V_M) was determined by injection of methane by the Peterson and Hirsch method (14) using measurements on a homologous series of *n*-paraffins (nonane, decane, undecane, dodecane, and tridecane).

Some one hundred esters were used which can conveniently be grouped in the following homologous series: formates, acetates, propionates, butyrates, pentanoates, hexanoates, heptanoates, octanoates, nonanoates, isobutyrates and isopentanoates; methyl, ethyl, propyl, butyl, pentyl, hexyl, isopropyl, isobutyl, and isopentyl esters.

Results and Discussion

Figure 1 shows $\ln V_R^0/T$ versus $1/T$ plots for a few compounds. In all cases, however, the correlation coefficients of the straight lines are equal to or greater than 0.999.

The ΔH_s values obtained from the slopes of the above straight lines are shown in Table 1 which refers to homologous series with linear chains. The values for different series can be seen by reference to the horizontal rows and vertical columns. By

reading diagonally, it can be observed that the ΔH_s values of esters which have the same total number of carbon atoms ($n_t = n_{ac} + n_{al}$) always show minimum ΔH_s values when the charge center and the mass center are as close as possible.

We were able to find very few values for ΔH_s relating to esters in the literature. We can cite the work of Golovnya and Arsenyev (11) which determines ΔH_s of several substances, among which the following esters are found: pentyl acetate, hexyl acetate, and butyl propionate. These ΔH_s values were determined in polar stationary phases of PEG-20.000 and XF-1153. They are of the same order as those referred to in this paper. Thus, the ΔH_s values expressed in kcal mol^{-1} for butyl propionate are −9.55 (PEG-20.000) and −9.83 (XF-1153) while the calculated value in this work is −10.44 (Carbowax 1540). The polarities of these stationary phases according to the Tarján *et al.* (15) scale are 70.75 for PEG-20.000, 75.43 for XF-1153, and 86.24 for Carbowax 1540.

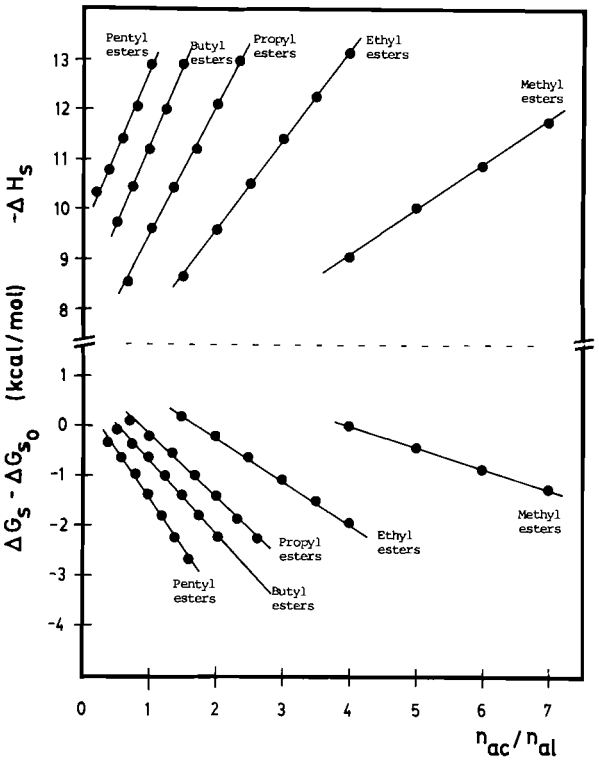

FIG. 2. Variation of ΔH_s and $\Delta G_s - \Delta G_{s_0}$ with n_{ac}/n_{al}. (For an ester R-COOR,' n_{ac} = number of carbon atoms in the R-COO group; and n_{al} = number of carbon atoms in the R' group.)

The graphs in Fig. 2, taken from the data in Table 1, show that like $\overline{\Delta(\Delta H_s)}$ values corresponding to step-by-step numerical increase in the number of —CH_2— groups in the acid chain are nearly constant for each series, although a slight decrease of the values can be seen as we progress from methyl, to ethyl, to propyl esters, and so on.

By comparing the ΔH_s of esters of complementary chain-lengths of acid and alcohol groups, it can be deduced that the values increase from the acetate, propionate, butyrate series and so on, which shows that the successive addition of —CH_2— groups in the alcohol chains is a greater contributing factor than a similar addition in the acid chains (Table 1).

The length of the alcohol chain has a greater influence on ΔH_s than the length of the acid group. This can be shown taking into account the values from Table 1 corresponding to esters of comple-
