From the experimental observation that CF_3 and F appear to exert the same net substituent effect on carbonyl basicities, it must therefore be the case that the hydrogen bonding and polarization interactions which favour CF_3 basicities are almost exactly counterbalanced by the inductive and resonance interactions favouring F substitution.

Conclusions

Gas phase proton affinities have been determined for a number of fluorine- and trifluoromethyl-substituted carbonyl compounds. From the data obtained, it is evident that these two substituents exert the same net effect on carbonyl basicity. This is shown to be so, however, because of a complex combination of constituent substituent effects including inductive, resonance, polarization, and hydrogen bonding interactions. The inductive and resonance effects are predicted to favour basicities involving fluorine as a substituent rather than trifluoromethyl, while the polarization and hydrogen bonding interactions give rise to a more favourable situation for CF_3 substituents. Coincidentally, these biases appear to cancel each other giving rise to no net advantage for either F or CF_3 in affecting carbonyl basicities.

In addition to quantifying F and CF_3 substituent effects, the present work has provided a number of valuable reference compounds for the intermediate basicity range of the gas phase proton affinity scale. Our continuing proton affinity determinations will be directed toward further elaborating this basicity region.

Received April 10, 1981

ANDRZEJ LENIEWSKI, DAVID B. MACLEAN, and JOHN K. SAUNDERS. Can. J. Chem. **59**, 2695 (1981).

The carbon-13 chemical shifts of isomeric phlegmarines and analogues are presented. The chemical shifts at C-7 and C-9 confirm the assignment of the stereochemistry at C-5. The stereochemistry at C-2′ of the isomeric phlegmarines was assigned by comparing the observed shifts with those predicted from conformer populations and conformer shifts for the various conformers obtained by rotation about the (C-5, C-11) and (C-11, C-2′) bonds. In particular it is possible to assign the relative configuration **1***b* to the naturally occurring N_α-methyl-N_β-acetylphlegmarine.

ANDRZEJ LENIEWSKI, DAVID B. MACLEAN et JOHN K. SAUNDERS. Can. J. Chem. **59**, 2695 (1981).

On présente les déplacements chimiques du ^{13}C des phlegmarines isomères et de leurs analogues. Les déplacements chimiques des carbones en positions 7 et 9 confirment la stéréochimie attribuée au carbone en position 5. On a déduit la stéréochimie du carbone en position 2′ des phlegmarines isomères en comparant les déplacements observés à ceux attendus à partir des populations des conformères et aux déplacements de divers conformères obtenus par la rotation autour des liaisons (C-5, C-11) et (C-11, C-2′). En particulier il est possible d'attribuer la configuration relative **1***b* à la N_α-méthyl N_β-acétylphlegmarine naturelle.

[Traduit par le journal]

We have recently reported a synthesis of (±)-N_α-methyl-N_β-acetylphlegmarine (1) that has established that the compound has the relative stereochemistry shown in structure **1***a* or **1***b*. Here we report an analysis of the ^{13}C spectra of racemic **1***a* and **1***b* that has enabled us to derive the relative stereochemistry at C-2′ in the two compounds and thereby to establish the relative stereochemistry of all five centres of the naturally-occurring alkaloid (2). The configurational assignment is based upon an approach recently developed by Beierbeck and Saunders (3). In the course of this work we also examined the ^{13}C spectra of two other diastereomers of the alkaloid, **2***a* and **2***b*, and several intermediates prepared in the synthetic work. The model compounds, *trans*-7-methyldecahydroquinolines **3**, *trans*-*N*-acetyl-7-methyldecahydroquinoline **4**, and the 2,2,5-trideutero derivatives of each were also prepared and examined to aid in the interpretation of the spectra. The data for all compounds are collected in Table 1.

7-Methyldecahydroquinoline was prepared by lithium aluminum hydride reduction of the tosyl hydrazone of ketolactam **5** according to an established procedure (4). Besides **3** the reduction mixture contained ca. 1% of monounsaturated product, probably the $\Delta^{5,10}$ or $\Delta^{5,6}$ derivative of **3** or a mixture of the two. The trideutero derivative was prepared by reduction with lithium aluminium deuteride. The acetyl compounds, **4**, and **4**-d_3, were prepared in the conventional manner.

In the spectrum of **3** the signals of the *C*-methyl and of the three methine carbon atoms were differentiated from the rest in the off-resonance spectrum. The methine carbon signals at 61.7, 42.8, and 32.1 were assigned to C-9, C-10, and C-7, respectively, based on substituent effects. Of the six signals associated with methylene carbon atoms the signal at lowest field, 47.2, is assigned to C-2. (This signal is absent in the spectrum of the deuterated analogue.) The signal at 32.4 has been assigned to C-5. Not only does it undergo the expected isotopic shift (5) but it also appears as a triplet in the noise decoupled spectrum and is reduced in intensity because of deuteration. Assignments at C-3, C-4, C-6, and C-8 were made by comparison with the published spectra of *trans*-decahydroquinolines (6) and by calculation according to the approach of Beierbeck *et al.* (7). The observed and calculated spectra were in good agreement with the exception of the signal attributed to the C-Me group.

In the *N*-acetyl compound **4** the signals at C-2, C-3, C-4, C-8, and C-10 are shielded with respect to

the corresponding signals of **3** with the largest effect apparent at C-2. These assignments were made by comparison of the spectrum of **4** with that of **4**-d_3. The signals attributed to C-2 and C-5 are directly affected by deuteration while the signals at C-3, C-6, and C-10 show isotopic shifts. The signals at C-7 and C-9 were easily differentiated from the signals of the methylene carbon atoms in the off-resonance spectrum and were assigned by comparison with the spectrum of **3**. The assignment of signals to C-4 and C-8 was also made by comparison with the spectrum of **3**.

The spectrum of the *trans*-ketolactam **5** was also analysed and assignments were made by comparison with the published spectra of *cis*-ketolactam **6** (8)[2] and 2-piperidine (9).[3] The assignments of signals to C-3 and C-4 were made by comparison with the spectrum of 2-piperidone and those to C-2 and C-5 as a consequence of their carbonyl character. The signals assigned to C-7, C-9, and C-10 are differentiated from the rest in the off-resonance spectrum and assignments made to each on the basis of substituent parameters. Of the two remaining signals, that at lower field is assigned to C-6 because of the proximity to the carbonyl group.

The assignment of signals in the spectra of **7**, **8**, **9**, **10**, and **11** was made by off-resonance studies and by comparison with the spectra of **5**, **3**, α-picoline, and vinyl pyridine (10). The differences observed for the signals in the carbocyclic ring between **8** and **9** on the one hand and **10** and **11** on the other reflect the equatorial and axial character of the substituents at C-5 in the two pairs of isomers and are in accord with predictions (see ref. 5, p. 29).

The assignments made in the spectra of the isomeric pairs **1***a*, **1***b* and **2***a*, **2***b* are based on comparison with the spectra of **4** and 1,2-dimethylpiperidine (12).[4] Again it is possible to differentiate the axial from the equatorial isomers at C-5, i.e. **1***a* and **1***b* from **2***a* and **2***b*, on the basis of the chemical shifts of the carbon atoms at C-7 and C-9 of the carbocyclic ring. The distinction between **1***a* and **1***b* and between **2***a* and **2***b* is not as straightforward. However, inspection of the data in Table 1 reveals that in each series, C-5, C-6, C-11, C-2′, and C-3′ are more shielded in one molecule than in the other. There follows a detailed study of the assignments

[a] All samples were run in solution in $CDCl_3$; values are accurate to ±0.1 ppm from internal TMS.
[b] Triplet (J = 18.4 Hz).
[c] Chemical shift of carbonyl carbon atom = 169.8 (in **4**-d_3 = 169.9 ppm).
[d] A gated decoupling experiment showed that the doublet centered at 124.9 ppm did not have an additional coupling of ca. 7 Hz characteristic of "*meta*" spin interactions (11). In this way this signal was differentiated from those at 124.3 and 121.5 ppm where an additional 7 Hz coupling was observed.
[e] C-6 and C-8 may be reversed.
[f] C-6, C-8, and C-11 may be interchanged.
[g] C-3 and C-4′ as well as C-4 and C-5′ may be reversed.
[h] COMe and N–Me may be reversed.

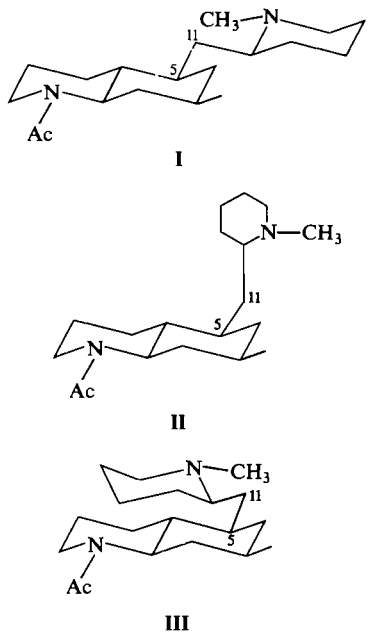

FIG. 1. Various conformations about the (C-5, C-11) bond in **2**.

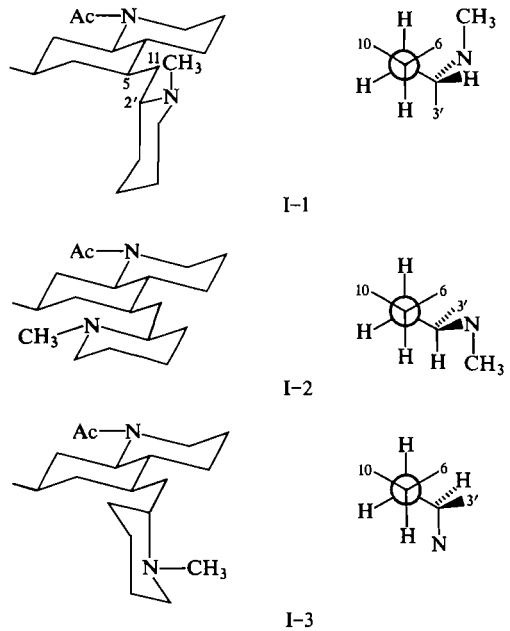

FIG. 2. Conformation about the (C-11, C-2′) bond in **2***a*.

of **2***a* and **2***b* in which the substituent at C-5 occupies the equatorial orientation.

The difference between **2***a* and **2***b* rests in the stereochemistry at C-2′. If one chooses as a reference that enantiomer in which C-5, C-7, C-9, and C-10 have the *R* configuration it is then necessary to determine which isomer, **2***a* or **2***b*, has the *R* and which the *S* configuration at C-2′. This can be accomplished by using the method reported for acyclic hydrocarbons (3). Basically the method consists of determining conformer shifts for each orientation and using the sum of conformer population multiplied by conformer shifts to obtain the predicted shift for each carbon atom in the molecule. For the molecules of interest, rotation is possible about the (C-5, C-11) and the (C-11, C-2′) bonds. Rotamer energies were estimated by considering the number of *gauche* butane interactions (referred to as γ interactions) and the number of δ *syn* interactions. The γ interaction is evaluated at 3.8 kJmol and the δ interaction at 15.4 kJ/mol (13, 14).

There are three possible orientations about the (C-5, C-11) bond and these are shown in Fig. 1. Fortunately two, II and III, can be neglected since these involve more severe steric interactions than those in I. For II the (C-11, C-2′) bond is *gauche* with respect both to the (C-5, C-6) and the (C-5, C-10) bonds. For III, the piperidine ring is *syn* with respect to the nitrogen containing ring and it is impossible for either stereoisomer to possess rotamers without severe steric interactions. Thus only conformers which have the rotamer denoted I about the (C-5, C-11) bond need be considered. The three rotamers about the (C-11, C-2′) bond for both the *R* and *S* stereoisomers are shown in Figs. 2 and 3, respectively.

For the *R* stereoisomer, conformer I-1 has three γ interactions, one between the N-CH_3 and C-11, one between C-3′ and C-5, and one between C-6 and C-2′. The energy is thus evaluated at 11.4 kJ/mol. In conformer I-2, there is an ε interaction between the N-CH_3 and C-6 which is an extremely severe interaction and this rotamer can be neglected. For I-3, there is a δ *syn* interaction between C-6 and C-3′, and γ interactions between the nitrogen and C-5 and between the N-CH_3 and C-11. The relative energy of this conformer is thus evaluated at 23.4 kJ/mol which is significantly higher than that for conformer I-1 and can be neglected. We can therefore conclude that the *R* stereoisomer exists predominantly as conformer I-1.

For the *S* stereoisomer conformer I-1 has a δ interaction between C-3′ and C-6 and a γ interaction between the N-CH_3 and C-11 which gives an estimated energy for this conformer of 19.2 kJ/mol. For conformer I-2, the relative energy is estimated to be 19.2 kJ/mol as this conformer has a δ interaction[5] between the N-CH_3 and C-5 and a γ interaction between C-6 and C-2′. The N-CH_3 could also exist in the axial orientation, conformer I-2′,

[5]The same energy value is estimated for a CH_3 placed on nitrogen as for a CH_3 on a carbon.

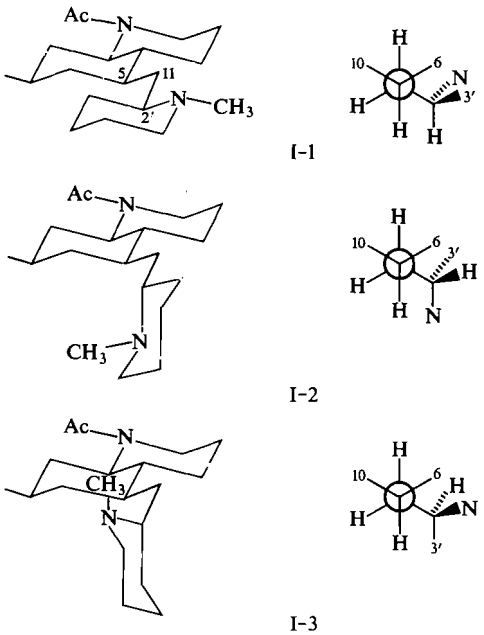

FIG. 3. Conformations about the (C-11, C-2′) bond in **2***b*.

which would alleviate the severe δ interaction. The energy would then be estimated at 19.0 kJ/mol since there are 5 γ interactions involved; N-CH_3 with C-3′, C-5′, and C-11; C-6 with C-2′; and the nitrogen with C-5. The final conformer I-3 has an estimated energy value of 26.8 kJ/mol (1 δ and 3 γ interactions) which is significantly higher than that for I-1 or I-2 and can therefore be neglected. We would thus predict that the *S* stereoisomer exists as a 1:1:1 mixture of I-1, I-2, and I-2′.

From the predicted conformer populations for the two stereoisomers, the predicted chemical shifts for each conformer were calculated. This was accomplished by using the method (7) which takes a reference shift for each carbon atom and takes account of the number of 1,3 diaxial H,H interactions, the number of *gauche* C,C (or C,N) interactions, and the number of δ *syn* interactions present in the molecule which are absent in the reference. The reference shifts for C-5 and C-6 are the corresponding shifts in **4**, for C-11 the shift of the CH_2 of propane, and for the C-atoms of the piperidine ring the corresponding shifts in 1,2-dimethylpiperidine. For C-5, an α shift is also necessary. Each time a 1,3-diaxial H,H interaction (henceforth referred to as an HC interaction) is present in the molecule of interest which was absent in the reference, an increment of +4.5 ppm is added. For each *gauche* interaction present in the molecule which was absent in the reference, a shift of 1.80 ppm is added to the italicized carbon

atom, and finally for each δ interaction introduced a shift of 2.6 ppm is added. The predicted shifts for each carbon atom in I-1 in which C-2′ has been assigned the *R* configuration are as follows

C-5	32.5	(reference)
	6.0	(introduction of C-11)
	−2.7	(replacement of H-4, H-5 interaction in reference by (C-4, C-10), (C-5, C-11) *gauche* interaction)
	1.8	*gauche*, ((C-2′, C-11), (C-5, C-6) interaction)

	4.0	(H-11 with N)	4.0	(H-11 with N)
	1.8	*gauche*, (C-3′, C-2′), (C-11, C-5)	1.2	*gauche*, (N-1′, C-2′), (C-11, C-5)
	1.8	*gauche* (C-6, C-5), (C-11, C-2′)	1.8	*gauche*, (C-6, C-5), (C-11, C-2′)
	38.7		42.6	
C-2′	59.4		59.4	
	4.5	(H-2′ with H-5)	1.2	*gauche*, (C-5, C-11), (C-2′, N-1′)
	1.8	*gauche*, (C-5, C-11), (C-2′, C-3′)		
	65.7		60.6	
C-3′	34.9		34.9	
	−4.5	(removal of H-3′ with H-11)		
	2.6	(δ *syn*)		
	33.0		34.9	

The differences between I-2 and I-2′ are the following: for C-5 the δ interaction is absent, C-6 is unchanged, for C-11 the H-11 with N interaction is absent, for C-2′ the HC interaction is replaced by a CC interaction, and for C-3′ the H-3′ with N interaction is removed. The predicted shifts for I-2′ are therefore: C-5, 37.6; C-6, 39.6; C-11, 38.6; C-2′, 57.9; C-3′, 30.9.

If we assume that the *S* isomer exists as a 1:1:1 mixture of I-1, I-2, and I-2′ then the predicted shift for C-5 is 40.0 ppm, for C-6 is 40.5, for C-11 is 40.0 ppm, for C-2′ is 61.4, and for C-3′ is 32.9 ppm. The predicted shifts for all the carbons in the *S* isomer are more deshielded than in the *R* stereoisomer and we can therefore assign configuration. The results are summarized in Table 2.

The neglect of less highly populated conformations will affect the absolute values of the predicted chemical shifts but will not change the sign of the difference between the two configurations.

The difference for the N-CH_3 group between the two stereoisomers is relatively small and for this reason it was not included in the analysis. In the *R* stereoisomer, it should appear at the same position as in 1,2-dimethylpiperidine, which it does. For the *S* stereoisomer, one would predict,

TABLE 2. Observed and predicted chemical shifts for **2***a* and **2***b*

	R (**2***a*)		*S* (**2***b*)	
	Observed	Predicted	Observed	Predicted
C-5	38.2	37.6	40.3	40.0
C-6	41.4	39.6	43.0	40.5
C-11	36.3	38.7	38.1	40.0
C-2′	61.4	61.2	62.5	61.4
C-3′	30.6	30.4	32.6	32.9

TABLE 3. Observed and predicted chemical shifts for **1***a* and **1***b*

	R (**1***a*)		*S* (**1***b*)	
	Observed	Predicted	Observed	Predicted
C-5	36.9	34.7	35.2	32.2
C-6	40.2	37.8	38.4	36.9
C-11	30.3	30.8	28.3	29.5
C-2′	63.5	61.4	62.0	61.2
C-3′	32.0	33.4	30.4	30.6

relative to 1,2-dimethylpiperidine, an increment of zero for conformer I-1, an increment of 2.6 ppm (δ interaction) for I-2, and an increment of −9.0 ppm for conformer I-2′. Thus this carbon is predicted to be shielded by 2.1 ppm in the *S* relative to the *R* stereoisomer. Again the predicted sign of the difference between the two stereoisomers for these carbons corresponds to that observed.

The assignment of stereochemistry for the axially substituted compounds **1***a* and **1***b* follows in a logical fashion since the same conformers are present. The *R* stereoisomer of **1** is the mirror image of the *S* for **2** with respect to the chiral centres at C-5 and C-2′ and it is this compound which has the more deshielded carbons at 5, 6, 11, 2′, and 3′. The analysis of the stereoisomers of **1** is summarized in Table 3.

The same situation is present with respect to the N-CH_3 group in the axial isomers, **1***a* and **1***b*, as that already discussed for the equatorial isomers, **2***a* and **2***b*.

The analysis of the carbon-13 chemical shifts has permitted the assignment of the relative stereochemistry at the fifth asymmetric centre of the four molecules examined and has confirmed the assignment at other centres. It should be emphasized that both stereoisomers at C-2′ were necessary to assign the stereochemistry at this carbon since it is the differences which are important rather than the absolute values.

In the previous paper on the phlegmarines (1) it was shown that **1***b* and N_α-methyl-N_β-acetylphlegmarine derived from nature had common physical properties in solution including the same R_f value in several solvent systems. This study has therefore resolved the relative stereochemistry of the alkaloid.

Experimental

Apparatus, Methods, and Materials

The reader is referred to ref. 1 for complete details.

trans-(7H, 10H), trans-(9H, 10H-7-Methyldecahydroquinoline 3 and its 2,2,5-Trideutero Derivative, 3-d_3

Tosylhydrazone of **5**

To a solution of *trans*-ketolactam **5** (905 mg, 5.0 mmol) in warm methanol (16 mL), *p*-toluenesulphonylhydrazide (98%, 950 mg, 5.1 mmol) was added and the mixture kept at 50°C for 2 h. The precipitated product was filtered off when the solution had cooled. The tosylhydrazone (1.50 g, yield 86%) melted at 199–200°C; ir ν_{max} (cm^{-1}): 3405, 3245 and 3180 (NH), 3080, 1605 (aromatic), 1675 (C=N), 1658, 1648 (C=O), 1352, 1169 (SO_2N); ^{1}H nmr $\delta_{80\,MHz}$ (ppm): 1.04 (3H, d, J = 5.6 Hz, CH—CH_3), 2.44 (3H, s, phenyl—CH_3), 5.9 (2H, br. s, NH), 7.3 and 7.8 (4H, AA′BB′ system, aromatic protons).

Hydride (Deuteride) Reduction of Tosylhydrazone of **5**

To a suspension of LAH (300 mg, ~8 mmol) in THF (40 mL), solid hydrazone (1.05 g, 3.0 mmol) was added at room temperature and the solution heated under reflux for 20 h. After cooling the mixture, water (8 mL) and ether (60 mL) were added. A white precipitate was filtered off and from the filtrate 135 mg of a colorless volatile slightly impure (tlc) solid were obtained. The white precipitate was treated with aqueous sodium hydroxide solution and the mixture steam distilled. The distillate (50 mL) was collected and extracted with ether to give 134 mg of the same product isolated above.

By the same procedure but using LAD instead of LAH 312 mg of deuterated compounds were obtained.

Pure **3** and **3**-d_3 were obtained by transformation of the crude products to their *N*-acetyl derivatives, that were purified by chromatographic separation on alumina, and then hydrolysed in 20% H_2SO_4.

N-*Acetylation of* **3** *and* **3**-d_3

The same procedure was used in both cases. Crude **3** (135 mg) was dissolved in absolute pyridine (4 mL) and treated with acetyl chloride (0.3 mL) at 0°C. When the mixture reached room temperature, water was added (50 mL) and most of the pyridine was evaporated at reduced pressure. To the residue 10% aqueous HCl (5 mL) was added and the solution extracted with chloroform. The collected extracts were washed with water and dried over anhydrous $MgSO_4$; 164 mg of undeuterated and 160 mg of deuterated amides were obtained as oils. Column chromatography on neutral alumina (activity 3, 10 g) gave 138 mg of the *N*-acetyl derivative of **3**, and 130 mg of the *N*-acetyl derivative of **3**-d_3, respectively, and 2 mg of *N*-acetyl-5,10- or 5,6)-dehydro derivatives of each or a mixture of both were also obtained.

Compound **4**: colorless oil, solidifying at temperatures below 0°C; ^{1}H nmr $\delta_{90\,MHz}$ (ppm): 0.91 (3H, d, J = 6 Hz, $CHCH_3$), 2.06 (3H, s, $COCH_3$), 3.1 (1H, m, H-2a), 3.30 (1H, m, H-9), 3.70 (1H, m, H-2e); ms: 195 (M^+, 30), 180 (12), 152 (9), 138 (65), 136 (9), 96 (100), 83 (11), 82 (10), 67 (8), 55 (15%).

Compound **4**-d_3: colorless oil, solidifying at temperatures below 0°C; ms: 198 (M^+, 47), 183 (8), 154 (6), 141 (74), 140 (6), 139 (9), 127 (2), 125 (2), 99 (100), 86 (4), 84 (4%).

N-acetyl-5,10(6)-dehydro-2-d_2 derivative, colorless oil; ms: 196 (26), 195 (82), 180 (63), 166 (6), 153 (23), 152 (38), 138 (100), 136 (36), 124 (39%).

Hydrolysis of N-*Acetyl* **3** *and* N-*Acetyl* **3**-d_3

Portions (100 mg) of the pure undeuterated and deuterated acetamides were refluxed separately with 20% aqueous H_2SO_4 (5 mL) for 6 h, 30% aqueous NaOH was carefully added to the cooled solution and the mixture extracted with chloroform yielding **3** and **3**-d_3 as colorless, volatile solids. Compound **3** (68 mg, yield 87%), mp 47–48°C; ^{1}H nmr $\delta_{90\,MHz}$ (ppm): 0.90 (d, J = 6 Hz, CHCH_3), 2.12 (1H, m, H-9), 2.32 (1H, br s, NH), 2.64 (1H, td, J = 11 and 4.5 Hz, H-2a), 3.10 (1H, d of q, J = 11.5 and 2 Hz, H-2e); $\delta_{90\,MHz}$ (C_6D_6) (ppm): 0.88 (d, J = 6 Hz, CHCH_3), 1.93 (1H, m, H-9), 2.48 (1H, m, H-2a), 2.92 (1H, d of q, J = 12 and 3 Hz, H-2e); ms: 153 (M^+, 14), 152 (12), 138 (3), 136 (3), 125 (3), 124 (3), 112 (7), 110 (4), 96 (100), 83 (9), 82 (8), 69 (6), 55 (12%). *Exact Mass* calcd. for $C_{10}H_{19}N$: 153.152; found (hrms): 153.153. Compound **3**-d_3 (66 mg, yield 84%), mp 47.5–48°C; ^{1}H nmr $\delta_{90\,MHz}$ (C_6D_6) (ppm): 0.90 (d, J = 6 Hz, CHCH_3), 1.90 (1H, br s, NH), 2.12 (1H, m, H-9); $\delta_{90\,MHz}$ (C_6D_6) (ppm): 0.89 (d, J = 6 Hz, CHCH_3), 1.94 (1H, t of d, J = 9 and 4 Hz, H-9); ms: 156 (M^+, 16), 155 (7), 99 (100), 98 (5), 85 (7), 84 (7), 58 (5), 56 (3), 55 (4%). *Exact Mass* calcd. for $C_{10}H_{16}D_3N$: 156.170; found (hrms): 156.170.

Carbon-13 isotopic selectivity in the infrared multiphoton photolysis of CF_2Cl_2–O_2 mixtures[1]

W. S. NIP,[2] P. A. HACKETT, and C. WILLIS

Laser Chemistry Group, Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received April 24, 1981

W. S. NIP, P. A. HACKETT, and C. WILLIS. Can. J. Chem. **59**, 2703 (1981).

The infrared multiphoton chemistry of CF_2Cl_2–O_2 mixtures has been studied at laser frequencies where the product CF_2O is highly enriched in carbon-13. Yield enhancements with no loss of isotopic selectivity are attributed to suppression of radical–atom recombination reactions. It is demonstrated that addition of up to 60 Torr of either excess O_2 or N_2 suppresses a thermal, non-selective channel important at higher fluences. A selectivity factor greater than 30 is observed for 4 Torr CF_2Cl_2 in the presence of 80 Torr of oxygen.

W. S. NIP, P. A. HACKETT et C. WILLIS. Can. J. Chem. **59**, 2703 (1981).

On a étudié la chimie multiphotonique dans l'infrarouge des mélanges de CF_2Cl_2–O_2 à des fréquences laser où le produit CF_2O est fortement enrichi en ^{13}C. On a attribué l'augmentation des rendements sans la perte de sélectivité isotopique, à la suppression des réactions de recombinaison radical–atome. On démontre que l'addition jusqu'à 60 Torr soit d'un excès de O_2 ou de N_2 supprime un canal thermique, non sélectif, mais important à de plus hautes pressions. On a observé un facteur de sélectivité supérieur à 30 à une pression de CF_2Cl_2 de 4 Torr et en présence d'oxygène à une pression de 80 Torr.

[Traduit par le journal]

Introduction

Interest in the infrared multiphoton chemistry of CF_2Cl_2 (1–13) was stimulated by early demonstration of isotope separation (3, 4, 6) and has been sustained by attempts to understand the primary decomposition channels (5, 10, 11) and their relative importance. It now seems clear that the free radical channel ($\rightarrow CF_2Cl + Cl$) dominates (14) because of an exit barrier in the lower enthalpy channel ($\rightarrow CF_2 + Cl_2$). The final decomposition products in the CF_2Cl_2 system are not well understood because of the formation of a complex array of compounds. Early workers (4) and more recently Fettweiss and de Mévergnies (13) noted a simplification in product array caused by addition of small amounts of oxygen; CF_2O and Cl_2 were the only observed products. These latter authors (13) made an additional brief mention that the isotopic enrichment in the products showed a three-fold increase with the addition of oxygen. This, together with the fact that both sets of workers concentrated on measuring selectivities rather than yields, stimulated the present, more detailed, examination of the CF_2Cl_2–O_2 system.

Experimental

The main details of our experiments are similar to those reported elsewhere (15). Briefly, output from a Lumonics (model 103) TEA CO_2 laser was passed through a 1.4 cm aperture to select the central portion of the beam which was then collimated by a 1 m focal length germanium lens. The beam passed through the salt windows of a 18 cm long, 5 cm diameter Pyrex cell. Typically, fluences of 2–5 J cm^{-2} were used.

CF_2Cl_2 (Freon-12, Matheson) was extensively outgassed by several freeze–pump–thaw cycles. The photolyzed mixture was analysed directly by a Hitachi RMU-6D magnetic sector mass spectrometer; relative mass spectrometric responses were determined by calibration with authentic sample mixtures and absolute yields were obtained by relating the sample pressure in the inlet manifold to the relative yields of products in that sample.

Preliminary experiments on neat substrate at the relatively low fluences of our experiments gave very small yields and confirmed that the product array was complex. In addition to the major products, which were C_2F_4, $C_2F_4Cl_2$, and Cl_2, we noticed several three and four carbon-atom-containing species. Addition of small amounts of oxygen suppressed production of molecules containing more than one carbon atom and the dominant products were CF_2O and Cl_2. In the experimental set-up, some of the CF_2O underwent hydrolysis with trace amounts of H_2O (15) (adsorbed or absorbed on glass tubing and metal surfaces of mass spectrometer inlet system) to form CO_2. Therefore, we report CF_2O plus CO_2 as CF_2O and equate the yield of CF_2O directly to the amount of CF_2Cl_2 decomposed. We find justification for this in that no other carbon-containing products were observed and that the product yield increased three- to four-fold with the addition of even trace quantities of O_2.

In a typical experiment, the photolyzed mixture was trapped at liquid nitrogen temperature and excess O_2 was pumped away through a spiral trap also held at liquid nitrogen temperature. The condensed products were then directly transferred to the inlet system of the mass-spectrometer via an isopentane slush bath (−160°C) which prevented Cl_2 and excessive amounts of CF_2Cl_2 from entering the mass spectrometer. The non-condensible fraction contained CF_2O and CO_2 with only traces of CF_2Cl_2. The condensate at −160°C was analysed confirming that Cl_2 was the only other product.

$^{12}CF_2O$ was characterized by its peaks at m/e = 47 and 66. Isotope ratios were determined from the relative peak heights of m/e = 47, 48 and 66, 67. A possible complication in this analysis

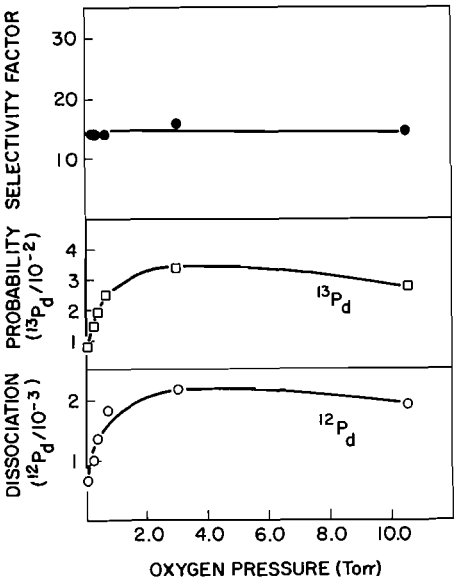

FIG. 1. Effect of oxygen addition on the dissociation probability, P_d. CF_2Cl_2 pressure: 0.5 Torr; laser frequency: 1039 cm^{-1} (9P28); fluence: 5 J cm^{-2}.

was the potential presence of SiF_4 formed after hydrolysis of CF_2O on silicate glass; peaks of $^{28}SiF^+$ at $m/e = 47$ and $^{28}SiF_2^+$ at $m/e = 66$ would negate our interpretation (16). However, we could detect no trace of a peak at $m/e = 86$ ($^{28}SiF_3^+$) and since $[SiF_3^+]/[SiF_2^+]$ is reported to be 10:1 for SiF_4, we conclude that this interference with our analytical method is negligible.

Results

Unlike most previous workers who have attempted to derive product yields and selectivities by analysis of changes in the starting material, we have measured product yields directly and obtain selectivities from ratios of the isotopic variants of the products. The effect of O_2 on the dissociation probability, P_d,

$$\left(P_d = \frac{\text{no. of molecules decomposed per laser pulse}}{\text{no. of molecules irradiated per laser pulse}}\right)$$

is illustrated in Fig. 1. Small additions of O_2 increase the probability of decomposition of both carbon-12- and carbon-13-substituted molecules. The increase is proportionate in each case giving a selectivity factor, α, ($\alpha = {}^{13}P_d/{}^{12}P_d$) which is invariant with added O_2. This constant selectivity indicates that the effect of O_2 is simply reaction with some intermediate rather than initiation or participation of a chain reaction which would be expected to introduce a reduction in selectivity depending on the O_2 mole fraction.

The spectral dependence of the dissociation probability and the consequent variation of isotopic selectivity is shown in Fig. 2. Laser irradiation

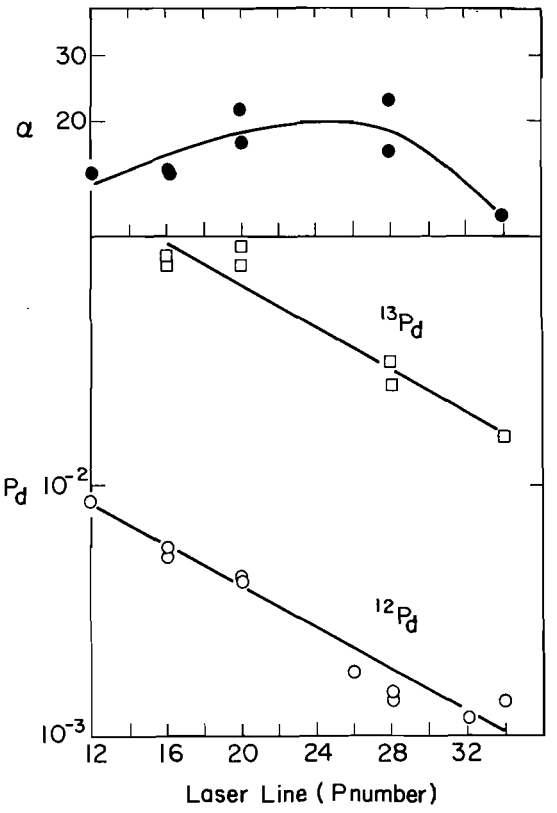

FIG. 2. Effect of laser frequency on dissociation probabilities. Frequency range: 9P12–9P34, 1054–1033 cm^{-1}; CF_2Cl_2 pressure: 0.5 Torr; O_2 pressure: 0.5 Torr; fluence: 5 J cm^{-2}.

progressively further to red of the absorption band (11) results in a steadily declining dissociation probability with small change in isotopic selectivity over the entire range of wavelength; only a small increase in going from 9P12 to 9P28 laser lines is observed. This effect is unusual but not totally unexpected. The carbon-13 isotope shift of the ν_1 band has been estimated (6) to be of the order of 33 cm^{-1} and it is not unreasonable that the frequency range of the present experiments, which is 50–70 cm^{-1} from ν_1 band centre, lies entirely to the red of the peak for multiphoton decomposition of $^{13}CF_2Cl_2$. In the case of CF_3COCF_3 we have observed that C-13 selectivity is frequency independent under these irradiation conditions (17) and such a phenomenon should be general.

Figure 3 compares the effect of pressure for two frequencies, 1050 cm^{-1} 9P16 and 1041 cm^{-1} 9P26 for a constant 1:5::CF_2Cl_2:O_2 mixture. The data are given as a function of the partial pressure of CF_2Cl_2. The outstanding feature in these experiments is the different behaviour of selectivity with pressure. For photolysis at 1050 cm^{-1}, α decreases

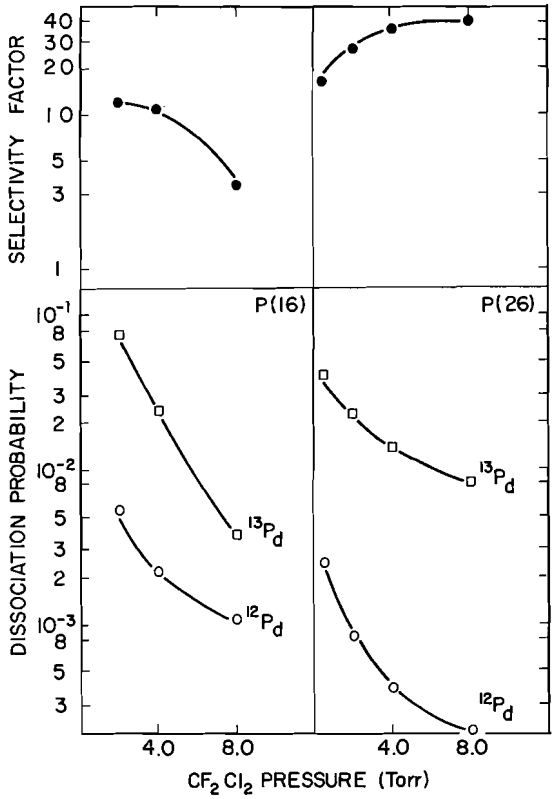

FIG. 3. Effect of sample pressure on dissociation probabilities for 9P16 and 9P26 laser excitation; CF_2Cl_2:O_2 ratio, 1:5; fluence, 5 J cm^{-2}.

as the total pressure of the mixture is raised from 6 Torr to 48 Torr (1 Torr CF_2Cl_2 to 8 Torr CF_2Cl_2) while at 1041 cm^{-1} α increases over the same pressure range. We have observed a similar behaviour in a number of other systems (15, 18, 19).

Figure 4 again compares two frequencies, 1050 cm^{-1} (P16) and 1039 cm^{-1} (P28), but at a constant total pressure (12 Torr) with the proportions of CF_2Cl_2 and O_2 being varied. Increasing partial pressure of CF_2Cl_2 decreases the dissociation probability at both frequencies but once again differential effects lead to a decrease in selectivity at the higher frequency and an increase in selectivity for the lower. We have explained increasing selectivity with pressure in terms of collisional deactivation of molecules with relatively low vibrational energies (19) (in Region I in the three region model of multiphoton decomposition (20)). CF_2Cl_2 is undoubtedly a more efficient quencher of vibrationally excited CF_2Cl_2 than is O_2 and the fact that substitution of CF_2Cl_2 for O_2 leads to an increased selectivity far to the red is entirely consistent with the model we have proposed.

Figure 5 compares an effect of fluence with an inert gas effect. A mixture originally containing 4 Torr CF_2Cl_2 and 8 Torr O_2 is irradiated at progressively increasing fluences (2 to 5 J cm^{-2}). Large increases in yield with consequent drop in selectivity, from $\alpha = 30$ to $\alpha = 2$, are obtained. Taking the system at a constant fluence of 5 J cm^{-2} and adding either extra O_2 or N_2, can essentially reverse the effect. The selectivity is driven up from $\alpha = 2$ to $\alpha \simeq 30$, at 60 Torr of added "inert" gas; O_2 and N_2 behave the same within the precision of the present data. As shown in the figure, this increase is almost entirely due to the suppression of dissociation of carbon-12-bearing species rather than to any increase in the decomposition yield of carbon-13-bearing molecules.

Discussion

The major dissociation channel for CF_2Cl_2, in multiphoton infrared, yields CF_2Cl and Cl. Although the molecular elimination of CF_2 and Cl_2 has a lower reaction enthalpy, there is a significant reverse activation barrier (14). We shall make our points of discussion, then, assuming reaction [1] is

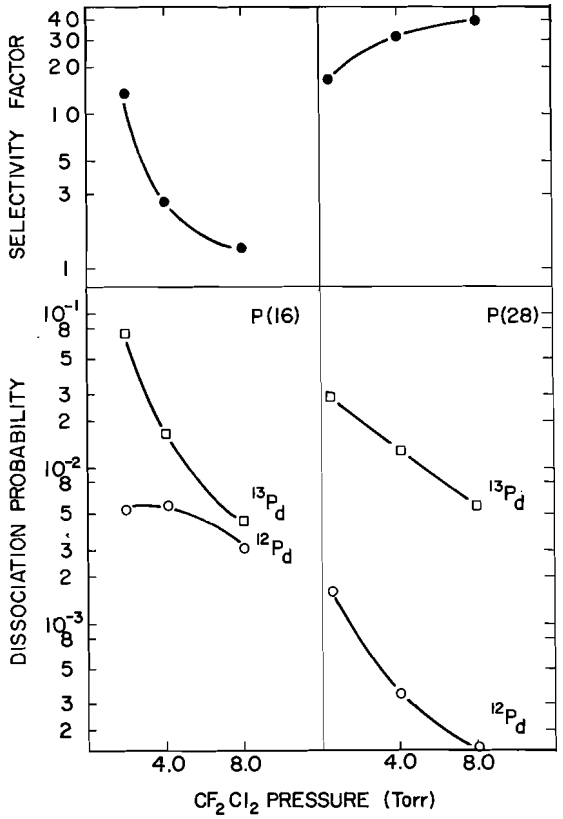

FIG. 4. Effect of CF_2Cl_2:O_2 ratio on dissociation probabilities for 9P16 and 9P28 laser excitation. Total pressure: 12 Torr; fluence: 5 J cm^{-2}.

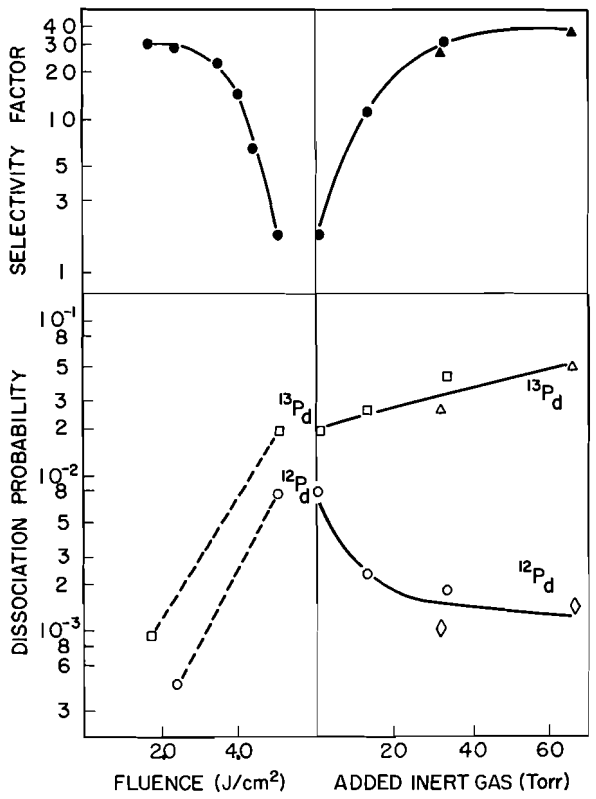

FIG. 5. Effect of fluence and added inert gas on dissociation probabilities; laser frequency: 1050 cm^{-1} (9P16); basic mixture: 4 Torr CF_2Cl_2, 8 Torr O_2; fluence for inert gas experiments: 5 J cm^{-2}; ○, □, ●, added oxygen; △, ◇, ▲, added nitrogen.

the unique primary process, recognizing at the same time that reaction [2] may make contributions to the effects we discuss.

[1] $CF_2Cl_2 \xrightarrow{nh\nu} CF_2Cl + Cl$ $\Delta H_1 = 78$ kcal mol^{-1}

[2] $CF_2Cl_2 \xrightarrow{nh\nu} CF_2 + Cl_2$ $\Delta H_2 = 73$ kcal mol^{-1}

For low conversions, the most important reactions subsequent to decomposition will be those involving radical combination,

[3] $CF_2Cl + CF_2Cl \rightarrow C_2F_4Cl_2$

[4] $CF_2Cl + Cl \rightarrow CF_2Cl_2$

[5] $Cl + Cl \xrightarrow{[M]} Cl_2$

[6] $CF_2Cl + O_2 \rightarrow CF_2O + ClO$

[7] $ClO + ClO \rightarrow Cl_2 + O_2$

These seven reactions are sufficient to explain the present observations. The increase in observed decomposition probabilities simply requires that reaction [4], the back reaction to CF_2Cl_2, occurs with a significant rate, which is not at all unlikely. To test our quantitative data requires a detailed knowledge of the three combination rate constants and these are not available.

Other potential chemical sources of increased yield are (*i*) a chain reaction or (*ii*) reaction of oxygen with highly vibrationally excited species. Both are improbable. The absence of an oxygen effect on the isotopic selectivity of the decomposition, while entirely compatible with the explanation involving suppression of a back reaction, places unreasonable demands on these two alternatives. If a chain reaction is involved, the reaction step where substrate CF_2Cl_2 is consumed must involve reaction only with vibrationally-excited molecules *and* the C-13 to C-12 ratio for consumed species must match closely that for molecules undergoing unimolecular decomposition. This second requirement also applies to a direct reaction (non-chain) of O_2 with vibrationally-excited CF_2Cl_2 molecules. The main problem with envisaging such bimolecular reactions, however, lies in their concerted nature. Reactions of this type are not common because of the large entropy changes in forming the activated complex. There is no reason to expect this constraint to be significantly less severe for vibrationally excited species. The question in point then becomes whether the larger amount of energy possessed by vibrationally excited CF_2Cl_2 can overcome such activation (entropy or energy) barriers. In the absence of further evidence we cannot completely eliminate these two alternatives. However, as long as suppression of the back reaction is sufficient to explain the observations there is no compelling reason to invoke them.

The main points related to variation of selectivity with pressure for conditions covered by the data in Figs. 3 and 4 have been discussed in the Results section or elsewhere (17) and require only brief amplification here. In multiphoton chemistry collisional processes lead to many different effects including rotational redistribution, vibrational quenching, inter- and intra-molecular energy redistribution and so on. In systems, such as those under present study, where only a small fraction of the molecules are excited, collisional deactivition among the first few vibrational levels is very important in controlling the extent of decomposition. Further, in working with the relatively long excitation pulses typical of most TEA CO_2 lasers, multiple deactivation–excitation–deactivation sequences are possible. Because the up-pumping rate depends upon the excitation probability and hence the closeness to resonance for the particular transi-

tion involved, we expect to see apparently different quenching behaviour for differing isotopic species when the off-resonance of the laser radiation is comparable with the isotope shift in the spectrum. This is precisely the case under present discussion and, as reviewed in the Results section, the observed behaviour is qualitatively in agreement with proposed models. We do not attempt a quantitative description because of various uncertainties but with shorter pulse devices becoming available, such a description should be forthcoming.

More interesting perhaps is the contrast displayed in Fig. 5. It is clear that increasing the fluence from 2 to 5 J cm^{-2} leads to a disproportionate increase in yield of C-12-bearing products. In work on other systems, (19, 21) we have attributed this behaviour to the onset of a process loosely described as "pyrolysis", a non-selective, thermally equilibrated decomposition channel whose yield is dependent on the *absorbed* energy per molecule. Addition of increasing amounts of oxygen or nitrogen provides a cold bath gas increasing the heat capacity of the mixture and lowering its effective "temperature". Thus the observed yield of decomposition of C-12 bearing molecules is reduced.

The increase in dissociation probability for C-13 bearing molecules which accompanies increasing inert gas pressure most probably is associated with repopulation of rotational states depleted by the intense laser field. In preliminary experiments where absorption coefficients are measured (22), we observe between a two- and three-fold increase in cross-section for similar conditions when the pressure of nitrogen is increased to 60 Torr. Any parallel effect on C-12 molecules would be buried in the much larger decrease in yield associated with the suppression of the non-selective thermal process.

An electron spin resonance and time-resolved CIDEP study of the oxidation of ascorbic acid by pyruvic acid, duroquinone, and vitamin K_1

M. Catherine Depew, Babatunde B. Adeleke,[1] and Jeffrey K. S. Wan
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received February 24, 1981

M. Catherine Depew, Babatunde B. Adeleke, and Jeffrey K. S. Wan. Can. J. Chem. **59**, 2708 (1981).

The photooxidation of vitamin C by pyruvic acid and its derivatives, duroquinone, and vitamin K_1 is systematically studied by the combined esr and time-resolved CIDEP technique. Because of the unique property of the triplet pyruvic acid which is different from that of the duroquinone triplet, the choice of these model systems allowed the CIDEP observations of the initial polarization of the ascorbate radical anion and its counter primary radical in either the enhanced absorptive or the emissive mode. The results demonstrate the efficient photooxidation of vitamin C by the triplet vitamin K_1 and that the latter triplet possesses similar properties as the triplet quinones. In the photooxidation system involving vitamin C and pyruvic acid, the adjustment of the pH of the aqueous solution afforded an opportunity to observe the photochemical reaction between two anions, the pyruvate anion and the ascorbate anion. Arguments were made in favor of an electron transfer mechanism for the oxidation of vitamin C by triplet vitamin K_1 but against the electron transfer mechanism for the oxidation of vitamin C by triplet pyruvate anion. T_1 values of the primary radicals estimated from their CIDEP transient responses at low microwave power are reported and it was suggested that the hydrogen-bonding capacity of the ascorbate radical anion in water does not contribute significantly to the relative difference of T_1's between itself and the counter pyruvic ketyl radical.

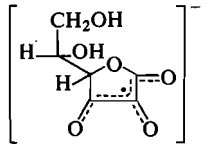
M. Catherine Depew, Babatunde B. Adeleke et Jeffrey K. S. Wan. Can. J. Chem. **59**, 2708 (1981).

En faisant appel à la rpe combinée à la technique de PEDIC résolue en fonction du temps, on étudie systématiquement la photooxydation de la vitamine C par l'acide pyruvique et ses dérivés, par la duroquinone et par la vitamine K_1. Compte tenu de la propriété unique du triplet de l'acide pyruvique qui est différente de celle du triplet de la duroquinone, le choix de ces modèles permet des observations de PEDIC de la polarisation initiale de l'anion radical ascorbate et de son radical primaire opposé lors de l'absorption ou de l'émission. Les résultats démontrent l'efficacité de la photooxydation de la vitamine C par le triplet de la vitamine K_1 et que le dernier triplet possède des propriétés identiques à celles du triplet des quinones. Dans la photooxydation qui implique la vitamine C et l'acide pyruvique, l'ajustement du pH de la solution aqueuse fournit l'opportunité d'observer la réaction photochimique entre deux anions, l'anion pyruvate et l'anion ascrobate. On suggère un mécanisme par transfert d'électrons pour l'oxydation de la vitamine C par le triplet de la vitamine K_1, mais on n'admet pas ce mécanisme dans le cas de l'oxydation de la vitamine C par le triplet de l'anion pyruvate. On rapporte les valeurs de T_1 des radicaux primaires évalués à partir de leurs réponses intermédiaires en PEDIC en microondes de faible puissance, et on suggère que la capacité en liaison hydrogènes de l'anion radical ascorbate dans l'eau ne contribue pas de façon significative à la différence relative des T_1 entre cet anion et le radical cétylpyruvique opposé.

[Traduit par le journal]

Introduction

Interest in the biological significance of vitamin C and vitamin E continues to be stimulated by reports of their involvement in many biochemical processes including cancer (1) and iron nutrition (2). It has been established that L-ascorbic acid (vitamin C) is readily oxidized in aqueous solution to a relatively stable radical whose controversial structure has been determined by esr spectroscopy (3). The ascorbic acid radicals generated in non-aqueous and aprotic solvents have also been reported (4). A recent theoretical calculation (5) has confirmed the esr assignments of the ascorbate anion free radical (**1**) in aqueous solution with the following structure



1

In the non-enzymatic systems, formation of the ascorbate free radical may involve either an electron-transfer process and/or a molecular elimination process. For example, a time-resolved esr study of the oxidation of ascorbic acid by hydroxyl radical produced in pulse radiolysis of water (6) has suggested that addition of ȮH at C-2 followed by rapid elimination of a water molecule resulted in the formation of the ascorbate radical anion. However, a direct electron-transfer process between the ascorbate and the ȮH radical

was considered to be also possible.

In the past five years we have extensively used the photoreduction of quinone by phenol as model systems for chemically induced magnetic polarization studies (7). In addition to providing some insights into the mechanistic aspects of free radical reactions, CIDEP could be used to probe the dynamic/structural properties of the transient radicals such as their spin–lattice relaxation times in solution. The interesting ascorbate free radical has a semiquinone-like structure and various probable sites for hydrogen-bonding interaction with the water solvent. It is our hope that a systematic CIDEP study of the photooxidations of vitamin C and vitamin E may yield further valuable information on the mechanism and the dynamic properties of the transient free radicals involved in these processes. In this report we have carefully chosen three model systems: the oxidation of vitamin C by excited pyruvic acid, the oxidation of vitamin C by excited duroquinone, and the oxidation of vitamin C by excited vitamin K_1. The choice of the first two systems is most significant in that the excited triplet states of pyruvic acid and of duroquinone have distinctly different spin dynamic properties (8) which lead to an initial polarization of the ascorbate radical anion being totally enhanced absorptive in the first case and totally emissive in the latter reaction. Spin–lattice relaxation times estimated from both the emissive and the absorptive ascorbate radical anions should be the same and this provides a critical test for the photo-triplet mechanism as well as the reliability of the CIDEP method in estimating T_1 of transient free radicals. Furthermore, by using sodium pyruvate as a control the oxidation of vitamin C by pyruvate affords an interesting opportunity to study a primary photochemical reaction between *two anions*.

Experimental

Pyruvic acid, ethylpyruvate, D-arabascorbic acid, and duroquinone were supplied by Aldrich. L-Ascorbic acid (vitamin C) was purchased from Anachemia and vitamin K_1 was obtained from Sigma. 2,3-Dimethylascorbic acid was custom synthesized and was a gift from Professor W. A. Szarek and Dr. K. S. Kim. The quinones were sublimed before use and laboratory grade benzene and toluene were distilled and dried over $MgSO_4$. A typical organic solution sample was prepared by placing a 0.1 *M* solution of the respective reagents in a Pyrex tubing of 2 mm i.d. and the solution was degassed under high vacuum before being sealed off. For aqueous solution samples, the solution was placed in a quartz flat cell of 0.1 mm thickness and deoxygenated by purging with gaseous nitrogen.

The esr spectra were recorded on a Varian E3 spectrometer equipped with a variable temperature control accessory. The samples were irradiated within the cavity by using a 200 W super pressure mercury lamp. Time-resolved CIDEP experiments were performed on the Varian E3 spectrometer using dc detection. The amplified dc signal was digitized by a Nicolet Explorer III digital scope at 50 ns per point and the digitized data were collected and processed on-line by a Nicolet 1180 computer in a synchronous mode. The design of the dc detection system is similar to that reported by Kim and Weissman (9). The light source used is a Molectron UV24 1-MW nitrogen pulsed laser. A detailed description and evaluation of the present system and the analysis of the data to obtain the spin–lattice relaxation times have been given elsewhere (10).

Results and Discussion

Photooxidation of Vitamin C by Pyruvic Acid in Aqueous Solutions

Photolysis of a saturated aqueous solution of ascorbic acid containing 10% v/v of pyruvic acid at room temperature led to the observation of an esr spectrum which is the superposition of the two primary radicals, the ascorbate radical anion **1** and the pyruvic ketyl radical $CH_3\dot{C}(OH)COOH$. Radical **1** exhibits a hyperfine structure of a doublet (A_H = 1.85 G) which is further split into a triplet (A_{CH_2} = 0.18 G). The pyruvic ketyl radical shows a quartet (A_{CH_3} = 16.9 G) of doublets (A_{OH} = 1.8 G). These assignments are consistent with those reported in the literature (3, 8). Direct inspection of the cw esr spectrum revealed that the low field hyperfine lines of the pyruvic ketyl radical were less intense than the corresponding high field lines. This is typically due to the E/A polarization originating from the radical-pair mechanism of the CIDEP effect (7, 8). Time-resolved CIDEP experiments, however, showed that both primary radicals, **1** and $CH_3\dot{C}(OH)COOH$, exhibit strong *initial* polarization with all hyperfine lines in the enhanced absorption mode. In the time-resolved experiments the effective radical concentrations generated by the 5 ns nitrogen laser pulse were much lower than those achieved by continuous irradiation and thus leading to a predominant *initial* polarization (originated from the photo-triplet mechanism) as observed. The results can be accounted for by the following reactions:

[2] $CH_3COCOOH + h\nu \xrightarrow{ISC} {}^3(CH_3COCOOH)^*$

[3] $^3(CH_3COCOOH)^*$ + Ascorbic acid → $CH_3\dot{C}(OH)COOH^*$ + **1***

The * denotes initial electron polarization.

In a neutral solution ascorbic acid exists mainly in the form of an ascorbate anion and its presence suppresses the ionization of pyruvic acid, as confirmed by nmr (the chemical shifts for the methyl protons are different for pyruvic acid and for pyruvic anion). In the pyruvic/ascorbic acid system most of the excitation light at the laser wavelength of 337 nm would be absorbed by the pyruvic acid only. In a previous study of the photochemical reactions between triplet pyruvic acid and lactic acid, the initial polarization originating from the photo-triplet mechanism led to the polarization of the primary radicals in the enhanced absorption mode (8). To the best of our knowledge, this is the only confirmed photochemical system giving a totally absorptive initial polarization for the primary radical pair. Since the mode of the primary radical initial polarization depends upon the triplet property alone (11), it is expected that in the present pyruvic/ascorbic acid system the reaction of the polarized pyruvic acid triplet should lead to an initial polarization in the totally absorptive mode for both the ascorbate radical anion and the pyruvic ketyl radical. According to the photoexcited triplet model (11) in which the population of each of the spin sublevels can be approximated by

$$P_{\pm 1} \propto (P_x + P_y - 2P_z)(D/B_0)$$

the excited triplet pyruvic acid must either have $D > 0$ and $P_z > P_x, P_y$, or $D < 0$ and $P_z < P_x, P_y$, where D is electron dipolar parameter related to the zero-field splittings of the sublevels. Unfortunately, CIDEP studies in liquid solutions alone can not yield the information of the sign of D. But the observed enhanced absorption for both pyruvic ketyl radical and ascorbate radical anion establishes the oxidation of vitamin C by pyruvic acid via an excited triplet mechanism.

The detailed mechanism of the reaction [3] is of great significance. Although triplet pyruvic acid has been found to abstract hydrogen with a rate similar to benzophenone triplet in various alcohols (12) and thus hydrogen abstraction from ascorbate anion could account for the reaction leading to CIDEP of the primary radicals, it must be recognized that the reaction could also proceed rapidly via an electron-transfer mechanism:

[4] $^3(CH_3COCOOH)^*$ + $ascorbate^-$ → $(CH_3COCOOH)^{\dot{-}*}$ + ascorbic acid radical*

[5] Ascorbic acid radical* → Ascorbate radical anion **1*** + H^+

[6] $H^+ + (CH_3COCOOH)^{\dot{-}*} \rightarrow (CH_3\dot{C}(OH)COOH)^*$

In the initial series of experiments the pH of the solutions was at 3.5, so that appreciable concentrations of both the unionized pyruvic acid and the pyruvate anion could be involved in the photooxidation of vitamin C. The triplet property of the unionized pyruvic acid is not expected to be different from that of the triplet pyruvate anion. By adjusting the pH of the solution to 10.2 using KOH, the concentrations of the pyruvate anion and the ascorbate anion would be greatly enhanced so that the actual photooxidation is now represented by the reaction

[7] $^3(CH_3COCOO)^{-*}$ + $ascorbate^-$ → $(CH_3\dot{C}(OH)COO)^{-*}$ + **1***

This presents an interesting opportunity to study the photochemical reaction between two anions and at this time there is no compelling argument that reaction [7] should proceed via an electron-transfer from the ascorbate anion to the excited pyruvate anion as an efficient means to preserve the initial polarization later developed in the observed radicals. The experimental results clearly show that in the basic solution, the CIDEP intensity as well as the mode of polarization were unchanged from those observed in acidic solutions. Similar CIDEP results were obtained in the sodium pyruvate/ascorbic acid system. We thus suggest that the photoredox reaction between triplet pyruvic acid/pyruvate and ascorbate involves mainly a hydrogen abstraction mechanism. The approach of the triplet anion towards another anionic reactant apparently does not slow down the reaction as the triplet anion possesses sufficient excitation energy to overcome any small energy barrier for two approaching anions. We must reiterate that the present results are insufficient to establish the detailed mechanism of the primary process, i.e. whether it involves electron-transfer to be followed by a proton transfer, or it is a direct H atom abstraction. Experimental differentiation of these two mechanisms is extremely difficult at the present time and it is hoped that further technical improvements of the time-resolution to the 10^{-12} s range may help solve the problem.

From the CIDEP observations the T_1's of both the primary radicals/radical ions were estimated and these will be reported and discussed in another section below.

Photooxidation of Ascorbic Acid by Ethyl Pyruvate, 2-Ketobutyric Acid, and Ethylacetoacetate

To further probe the "unique" triplet property of pyruvic acid which leads to enhanced absorptive initial polarization, a systematic study using various available pyruvic derivatives was carried out. In the cw photolysis of ethyl pyruvate and vitamin C in a mixed ethanol/water solvent between 0 and 10°C, both the ascorbate radical anion **1** and the $CH_3\dot{C}(OH)COOC_2H_5$ radical were observed. The latter was identified by its hyperfine pattern with A_{CH_3} = 16.8G and A_{OH} = 1.9G as reported in literature (13). Time-resolved CIDEP experiments again showed that for both primary radicals all their hyperfine lines were in totally enhanced absorption, as expected from the phototriplet mechanism having the ethyl pyruvate triplet similar to the triplet pyruvic acid in the spin sublevel populations. In the cw photolysis of 2-ketobutyric acid and vitamin C in ethanol/water solvent, again both the radical anion **1** and the $CH_3CH_2\dot{C}(OH)COOH$ radical were observed. The latter radical has hyperfine coupling constants A_{CH_2} = 11.6G, A_{OH} = 2.0G, and A_{CH_3} = 0.8G. In the cw spectrum the 2-ketobutyric ketyl radical also exhibits the E/A type polarization originated from the radical-pair mechanism. Time-resolved CIDEP observations in this system also showed a predominant initial polarization with both primary radicals clearly in the enhanced absorptive mode for all their hyperfine components. However, a similar experiment using ethyl acetoacetate as the triplet precursor failed to yield any CIDEP effects. Thus, we are inclined to believe that the similar and "unique" triplet property of pyruvic acid and its derivatives is characteristic of alkyl carbonyl compounds having a functional group —CO—COO—. It is interesting to speculate here that a substitution of the alkyl group next to the carbonyl by an aromatic group might alter the triplet property and thus leading to a different CIDEP pattern.

The photoredox systems were repeated using D-arabascorbic acid instead of vitamin C. In all cases, no significant differences in CIDEP and the T_1's of the ascorbate radical anions were observed.

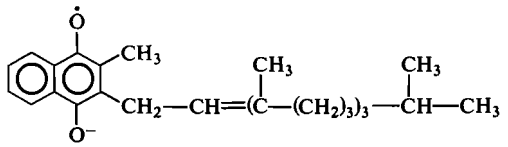
Photooxidation of Vitamin C by Duroquinone

The photoredox reactions between quinones and phenols have been extensively used in this laboratory as model systems for CIDEP study. It is generally recognized that photoexcited triplet duroquinone is spin polarized which in subsequent reactions transfers the initial polarization to the primary radicals in a totally emissive mode. Thus, the triplet property of the duroquinone with respect to spin population of the sublevels is directly opposite to that of pyruvic acid. As a comparison the photooxidation of vitamin C by duroquinone was studied in ethanol solution. Continuous photolysis led to the observation of an esr spectrum which is the superposition of the ascorbate radical anion **1** and the durosemiquinone radical. Time-resolved CIDEP experiments showed again the strong initial polarization of both primary radicals. Because of the triplet duroquinone property, the initial polarizations of both radicals were in the totally emissive mode, as expected by the phototriplet mechanism.

The detailed mechanism of the reaction of duroquinone triplet with the ascorbate anion again deserves some attention. It remains probable that the reaction involves an electron transfer from the ascorbate anion to the triplet duroquinone which is a good electron acceptor. In this regard, we have studied the photooxidation of 2,3-dimethyl ascorbate by duroquinone. Here, no radicals nor CIDEP were observed. Although esr negative results can not be used to exclude the possibility of chemical reactions, it is fairly safe to say that under identical experimental conditions the free radical processes involved in the photooxidation of 2,3-dimethyl ascorbate by quinone are insignificant. This can be attributed to the fact that the "efficient" hydrogen abstraction reaction by the triplet quinone from the —OH group on the vitamin C is no longer operative in the case of the 2,3-dimethyl ascorbate. On the other hand, the 2,3-dimethyl ascorbate is probably unionized in solution but an electron transfer mechanism from the substituted ascorbate to the triplet quinone is still possible. A definitive conclusion of the detailed mechanism of the photooxidation of vitamin C by quinone, however, must await further elucidation.

Photooxidation of Vitamin C by Vitamin K_1

Vitamin K_1 is known to form semiquinone radical with the following structure (14):



The biochemical importance of vitamin K_1 semiquinone suggested that the possible photooxidation of vitamin C by vitamin K_1 would be of some interest.

When vitamin K_1 was photolyzed alone in ethanol, an esr spectrum of the vitamin K_1 semiquinone radical having the same spectral parameters as reported in the literature (14) was observed. Time-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

resolved CIDEP study of this system revealed no polarization. However, addition of vitamin C to the solution showed the formation of both the vitamin K_1 semiquinone radical and the ascorbate radical anion **1**, and the CIDEP experiments produced totally emissive polarization for both primary radicals. On the whole, these experiments suggest that the photooxidation of vitamin C involves the spin-polarized vitamin K_1 triplet molecule which possesses property similar to that of other 1,4-quinone triplets. The more salient conclusion to be drawn is the experimental fact that the vitamin K_1 triplet is photoreduced much more efficiently by vitamin C than by ethanol, a suggested by the CIDEP triplet mechanism argument (7). Here the electron transfer mechanism from vitamin C to the triplet vitamin K_1 is particularly attractive as it can account for both the direct formation of the semiquinone radical anion and the efficient reaction rate required by the phototriplet mechanism.

The spin–lattice relaxation times of the vitamin K_1 semiquinone radical and the ascorbate radical anion were measured by CIDEP and reported in the next section.

Spin–Lattice Relaxation Times of Ascorbate Radical Anion, Pyruvic Ketyl Radical, Durosemiquinone Radical, and Vitamin K_1 semiquinone Radical Anion

The choice of the two different triplet precursors, the duroquinone and the pyruvic acid, in the photooxidation of vitamin C affords a unique opportunity to produce the *same* ascorbate radical anion with initial polarization in the emissive mode in the case of pyruvic acid. Figure 1 shows the typical transient enhanced absorptive response from the ascorbate radical anion in the photooxidation by pyruvic acid and Fig. 2 gives the typical transient emissive response from the same radical anion in the photooxidation by duroquinone. In all

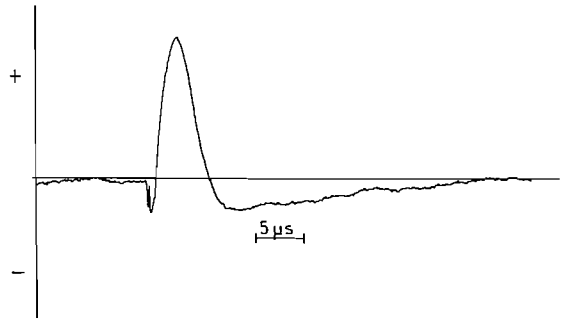


FIG. 1. Transient enhanced absorptive response from the ascorbate radical anion generated in the photooxidation by triplet pyruvic acid in an aqueous solution at 6°C. B_1 is about 40 mG. The curve represents the *difference* between the on-resonance and off-resonance responses.

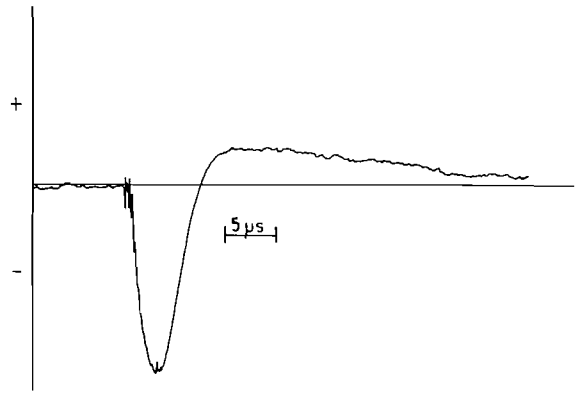

FIG. 2. Transient emissive response from the ascorbate radical anion generated in the photooxidation by triplet duroquinone in an ethanol solvent at −20°C. B_1 is about 40 mG. The curve represents the *difference* between the on-resonance and off-resonance responses.

the CIDEP observations on all systems, the presence of both primary radicals allowed the simultaneous estimates of the T_1's of both radicals under the identical experimental conditions. In all cases, the T_1 measurements used only data obtained from experiments at low microwave power (at or below 1 mW which is equal to B_1 less than 40 mG (10)). Since the Varian E3 is not equipped with a low-power operation configuration, the lowest B_1 usuable is about 15 mG and the extrapolation to $B_1 = 0$ will only provide an estimate of T_1. The estimated values of T_1's for various primary radicals observed in the photooxidation of vitamin C are given in Table 1.

The data show that in general the T_1 of the L-ascorbate radical anion is the same as that of D-arabascorbate radical anion. The apparently shorter spin–lattice relaxation time of the ascorbate radical anion as compared to its counter radicals such as pyruvic ketyl radical under the same experimental conditions is rather surprising. It was expected that in aqueous solutions the ascorbate radical anion may interact with water via substantial hydrogen-bonding and this effect would have increased the value of T_1. In a recent theoretical consideration of T_1's for semiquinone radical in solution (15) it was shown that the T_1 depends upon three major factors which are the orientational correlation time τ_2 for a second rank tensor, the average excitation energy $\Delta\varepsilon$ and some quantities related to **G** tensor deviation. The hydrogen-bonding interaction could conceivably affect the value of τ_2 but Rengan *et al.* (16) have investigated the hydrogen-bonding interaction among semiquinone radicals and obtained a low activation energy, about 4 kJ mol^{-1}. Taking into account that similar hydrogen-bonding interaction is also probable for the counter pyruvic ketyl radical, it is

TABLE 1. Estimated T_1 values from CIDEP measurements of transient radicals in solutions

Radicals in the primary pair	Mode of initial polarization	Temperature (°C)	Solvent	T_1 (μs)
L-Ascorbate radical anion	Absorptive	6	Water	2.1±0.4
Pyruvic Ketyl radical	Absorptive	6	Water	3.4
L-Ascorbate radical anion	Absorptive	29	Water	1.0
Pyruvic Ketyl radical	Absorptive	29	Water	2.3
L-Ascorbic radical anion	Absorptive	27	Water	1.4
Pyruvic Ketyl radical anion	Absorptive	27	(pH = 10.2)	2.5
L-Ascorbate radical anion	Emissive	19	Ethanol	2.0
Vitamin K_1 semiquinone	Emissive	19	Ethanol	4.0
L-Ascorbate radical anion	Emissive	−20	Ethanol	2.4
Durosemiquinone	Emissive	−20	Ethanol	3.0
D-Arabascorbate radical anion	Absorptive	11	Water	2.0
$CH_3CH_2\dot{C}(OH)COO^-$ [a]	Absorptive	11	Water	3.6

[a] T_1 in $CH_3CH_2\dot{C}(OH)COO^-$ radical is slightly dependent on the hyperfine components with T_1 for the center component (0) slightly larger than those associated with the (+1) and (−1) components.

reasonable to argue that the difference in T_1's between the ascorbate radical anion and the pyruvic ketyl radical is not mainly due to hydrogen-bonding. Another factor which comes into the comparison here is the contribution of the hyperfine interaction to the relaxation of these two radicals. Usually the anisotropic contribution is more important because this interaction is readily modulated by the rotational tumbling of the molecule. In the case of the pyruvic ketyl radical with a rotating methyl group, the anisotropic splitting is small and the only contribution to the relaxation will come from the modulation of the isotropic splitting, which is not expected to affect the T_1 significantly. On the other hand, the isotropic hyperfine splitting of the proton at the C-5 position in the ascorbate radical anion may be small but the angular dependence of the anisotropic hyperfine interaction and thus its modulation by the tumbling molecule may contribute to the relaxation in a manner as to reduce the observed T_1. Experimental evidence of such an anisotropic hyperfine interaction contribution to relaxation for the $CH_3CH_2\dot{C}(OH)COO^-$ radical is found in the observed small dependence of T_1's on the hyperfine components with T_1 slightly larger for the central component ($m_I = 0$) than for the outer components having $m_I = \pm 1$. This observation is consistent with those reported for the nitroxide radicals (17). It is hoped that further T_1 studies of vitamin C radical and its derivatives will provide some insight into the dynamics of this class of important radicals.

Another interesting observation is that T_1 of the large vitamin K_1 semiquinone radical appears to be in the same magnitude as the corresponding unsubstituted naphthosemiquinone radical in solution (15). This, however, is not too surprising as the recent theoretical treatments (15) on T_1's of semiquinone radicals in solution showed that a combined argument based upon a modest size effect and upon the extent of the π system provides a better understanding of the T_1 observations than either consideration by itself.

The direct electrochemical synthesis of triphenylphosphine adducts of Group IB monohalides

MASOOD KHAN, COLIN OLDHAM,[1] AND DENNIS G. TUCK

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

MASOOD KHAN, COLIN OLDHAM, and DENNIS G. TUCK. Can. J. Chem. **59**, 2714 (1981).

The electrochemical oxidation of copper, silver, or gold into acetonitrile solutions of benzyl chloride or hydrogen halide plus triphenylphosphine leads to the formation of the adducts MXL_n (M = Cu, Ag, Au; X = Cl, Br, I; L = Ph_3P; n = 1, 1.5, 2; not all combinations). The value of n depends markedly on the mole ratio Ph_3P:dissolved metal. The reaction pathway is discussed in the light of measurements of current efficiency. The results of X-ray structural studies of AuCl · L and $AuClL_2$ are briefly reported.

MASOOD KHAN, COLIN OLDHAM et DENNIS G. TUCK. Can. J. Chem. **59**, 2714 (1981).

L'oxydation électrochimique du cuivre, de l'argent ou de l'or dans du chlorure de benzyle ou dans un halogénure d'hydrogène et du triphénylphosphine en solution dans l'acétonitrile conduit à la formation d'adduits du type MXL_n (M = Cu, Ag, Au; X = Cl, Br, I; L = Ph_3P; n = 1, 1,5, 2; on n'obtient pas toutes les combinaisons). La valeur de n dépend fortement du rapport molaire Ph_3P:métal dissout. On discute du cheminement de la réaction à partir des mesures de l'efficacité du courant. On rapporte brièvement les résultats des études par cristallographie de rayons-X du AuCl·L et du $AuClL_2$.

Introduction

A number of recent publications from this laboratory have described the preparation of organometallic halides by the electrochemical oxidation of a metal in the presence of the appropriate alkyl or aryl halide. For main group metallic elements, the products are readily stabilised as adducts with various monodentate and bidentate donors (1–4). Amongst the transition metals, we have shown that the Group IVB elements (5), and nickel and palladium (6), can be similarly oxidised to R_2MX_2 or RMX compounds, again conveniently stabilised and characterised as adducts with donor ligands.

The present work was initiated in order to investigate the applicability of the technique of direct electrochemical synthesis to organometallic compounds of the coinage metals. In essence, we find that although each of these metals can be oxidised in the presence of organohalides, the products isolated are in fact inorganic derivatives of the monohalides. A similar conclusion was reached in parallel experiments in which the ultimate products were anionic halogen-complexes of copper (I) (7). We have also found that these MX adducts can be more simply prepared in cells in which the medium is acetonitrile containing approximately 5% concentrated aqueous hydrohalic acid. Such media, which require a lower applied voltage than that required for purely organic solvent systems, have also been successfully used in other electrochemical syntheses (8). Further useful applications of the electrochemical oxidation of noble metals in such quasi-non-aqueous media will no doubt be forthcoming.

Experimental

General

With gold (M4N) or copper (electrolytically purified), strips of metal approximately 2 × 1 × 0.1 cm suspended on a platinum wire, formed the anode of the cell. Silver metal (Puratonic) was used as a 7 mm rod.

Acetonitrile was dried over calcium hydride, and diethyl ether over sodium. All experiments were carried out in a nitrogen atmosphere. Concentrated aqueous acids (A.R. grade) were used as supplied.

Analysis for silver and gold was by atomic absorption spectrophotometry. Decomposition of the silver chloride derivative by concentrated nitric acid left a deposit of AgCl, which was collected and weighed. Microanalysis was carried out by Guelph Chemical Laboratories Ltd. Analytical results and melting points for triphenylphosphine adducts are given in Table 1.

Electrochemical Synthesis

The electrochemical procedures were similar to those described in earlier papers (1–8). The metal to be oxidised formed the anode of a single cell containing an acetonitrile solution of either the organohalide or a quantity of concentrated aqueous hydrohalic acid, plus the neutral donor triphenylphosphine; details of the solution compositions used in the preparation of triphenylphosphine adducts are shown in Table 2. Tetraethylammonium chloride (ca. 20 mg) was generally added to enhance the conductivity in the benzyl chloride experiments. A major advantage in using solutions of hydrohalic acid in acetonitrile is that a sufficient current flows in the absence of other added electrolyte.

In some cases, products precipitated during the electrolysis, and in the remainder, addition of diethylether led to precipitation. For the Au/benzyl chloride system, addition of an equal volume of diethylether, followed by cooling, resulted in the formation of needle-like crystals of $AuCl(Ph_3P)_2$ together with a small quantity of adherent AuCl · Ph_3P. A crystal of $AuCl(Ph_3P)_2$ was selected from this material for X-ray structural analysis (see

below). Addition of a three-fold excess of diethylether to the filtrate, followed by cooling, produced crystals of $AuCl \cdot Ph_3P$. For the $Au/CH_3CN/HCl$ system, crystals of $AuCl \cdot Ph_3P$ began to grow in the cell approximately 30 min after the beginning of the electrolysis.

The compound $Ag_2Cl_2(Ph_3P)_3$, which precipitated during electrolysis, was purified by reprecipitation from chloroform solution by diethylether.

For the Cu/benzyl chloride system, addition of an equal volume of diethylether to the electrolysis mixture, followed by cooling, produced crystalline $CuCl \cdot Ph_3P$, and this substance was also precipitated when diethylether was added to the $Cu/CH_3CN/HCl$ electrolyte solution. When the volume of this filtrate was reduced, $Cu_2Cl_2(Ph_3P)_3$ precipitated, and similar procedures yielded the corresponding bromide. In the $Cu/CH_3CN/HI$ system a mixture of $Cu_2I_2(Ph_3P)_3$ and $[PPh_3H]^+I^-$ precipitated from the anode, and was separated by extracting the copper(I) complex into acetonitrile and reprecipitating. All products were washed well with ethanol and diethylether, and dried *in vacuo*. Total yields were in the range 40–70%, based upon the quantity of anode metal dissolved.

Ethyl bromide and methyl iodide, in combination with 2,2′-bipyridine, were also used in electrolyses of gold, but in no case was any organogold product isolated.

X-ray Crystallography

X-ray structural procedures were identical to those described in a previous paper (13).

Results and Discussion

As noted in the Introduction, none of the systems investigated gave rise to stable compounds containing M—C bonds, although some evidence was obtained from vibrational spectroscopy for the formation of unstable organogold intermediates. Gold systems were the subject of the most extensive range of experiments, and we discuss the preparative results in order of decreasing atomic number of the metal concerned. The adducts formed all involve triphenylphosphine as donor, but there is no reason to doubt that the electrochemical method can be used with other suitable neutral donors.

Gold

Despite the fact that gold is classically resistant to attack by aqueous mineral acids, the metal is readily oxidised under electrochemical conditions in various media. In addition to the series of experiments involving acetonitrile solutions of benzyl chloride or hydrochloric acid, a number of other organohalides were examined and shown to support the dissolution of gold from the anode. In view of the extensive organometallic chemistry of the element, it is disappointing that no stable organogold species could be isolated. When gold serves as the anode of an electrochemical cell containing an acetonitrile solution of benzyl chloride and triphenylphosphine, the metal readily dissolves under an applied voltage of 20 V at room temperature. No solid material precipitated during the electrolysis, but addition of diethylether to the solution formed by electrolysis threw down a mixture of the 1:1 and 1:2 gold(I) halide triphenylphosphine complexes. When triphenylphosphine was replaced by 2,2′-bipyridine, dissolution of gold again occurred, and precipitation with ether gave an oily material whose principal component was identified as $[AuCl_4]^-$ by vibrational spectroscopy. Thus in neither case was an organogold complex isolated, and qualitatively similar results were obtained with solutions of C_2H_5Br or CH_3I in acetonitrile and other solvents. On the basis of experience with these and related organometallic systems, we tentatively suggest that any organogold halides formed by electrolysis decompose by subsequent reaction with excess organic halide present in the solution phase.

Gold is also easily oxidised electrochemically using a solution phase of acetonitrile + aqueous hydrochloric acid + triphenylphosphine. In the

[c]L = Ph_3P.

experiment reported in Table 2, the quantity of triphenylphosphine used was close to the quantity of gold dissolved, and the only product isolated was the 1:1 complex $AuCl \cdot Ph_3P$.

The current efficiency (E_F), expressed as moles of metal dissolved per Faraday of electricity, was measured for both CH_3CN/benzyl chloride and CH_3CN/HCl. In each case the value was 0.34 ± 0.01 mol F^{-1}, implying that the gold species generated at the anode surface is in the +III state. Following previous discussions (14), the cathode reactions for both systems are written as

[1] $RCl + e \rightarrow R\cdot + Cl^-$

[2] $2R\cdot \rightarrow R_2$

(R = H, $C_6H_5CH_2$), and hydrogen evolution was certainly detected for R = H. At the anode, the process which gives $E_F = 0.33$ most readily is

[3] $3Cl^- + Au \rightarrow AuCl_3 + 3e$

but this should be treated with some reserve, since the essentially simultaneous attack of three anions at one metal site is unlikely at the current densities (ca. 10 mA cm^{-2}) used. An attractive alternative is the sequence of reactions

[4] $Cl^- + Au \rightarrow AuCl + e^-$

[5] $3AuCl \rightarrow AuCl_3 + 2Au$

since gold(I) chloride is known to be unstable with respect to disproportionation (ref. 15, p. 33). Such processes will also give $E_F = 0.33$, provided that reaction [5] occurs sufficiently quickly at the electrode surface for the gold metal formed to be redeposited. The postulated primary anode reaction, [4], is that proposed for the discharge of halide ion at other sacrificial electrodes (14), and confirmed in the particular case of indium (4) by the observation that InI can be detected visually on the anode. In many of these systems, the freshly formed MX is assumed to react with excess RX

[6] $MX + RX \rightarrow RMX_2$

or

[7] $MX + RX \rightarrow RMX + X$

Reaction [6] gives $E_F = 1$; reaction [7] gives $E_F > 1$, since reaction [7] may be followed by the formation of more MX, setting up a repeating sequence. The measured E_F values demonstrate that reaction [7] does not occur in the present case, and in fact there do not appear to be any reports (12) of oxidative insertion reactions of AuX of the type which would be required by reaction [6].

Despite the current efficiency evidence, which as noted above implies the generation of Au(III)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

species at the electrode, the final products are adducts of gold(I) chloride. This is ascribed to the reducing action of triphenylphosphine, used by earlier workers (10) in the preparation of $AuX \cdot PR_3$ adducts:

[8] $AuCl_3 + 2PPh_3 \rightarrow AuCl \cdot PPh_3 + PPh_3Cl_2$

and

[9] $AuCl_3 + 3PPh_3 \rightarrow AuCl(PPh_3)_2 + PPh_3Cl_2$

Such reactions explain the formation of both mono- and bis-triphenylphosphine derivatives at high mole ratio of PPh_3: dissolved metal (c.f. Table 2). The effect of changes in this mole ratio are discussed more fully below for the case of copper. The reaction scheme in reactions [8] and [9] is further supported by the identification of PPh_3Cl_2 among the reaction products (chloride content 19.8, calcd. 21.2; nmr spectroscopy).

Silver

When silver forms the anode of a cell containing acetonitrile + benzyl chloride + triphenylphosphine, dissolution of the metal occurs, with $E_F = 0.9 \pm 0.01$ mol F^{-1}. When the mole ratio PPh_3:dissolved Ag is < 1, colourless needles of $AgCl \cdot PPh_3$ gradually form in the reaction mixture. When this mole ratio is > 1, the addition of diethylether to the reaction mixture precipitates $Ag_2Cl_2(PPh_3)_3 \cdot Et_2O$ from the clear solution. Thus again benzyl chloride appears to be acting as a source of halide ion, with current efficiencies and product stoichiometries implying the reactions

[10] $Ag + Cl^- \rightarrow AgCl + e$

[11] $AgCl + PPh_3 \rightarrow AgCl \cdot PPh_3$

$2AgCl \cdot PPh_3 + PPh_3 \rightleftharpoons Ag_2Cl_2(PPh_3)_3$

Electrolysis with acetonitrile/aqueous hydrochloric acid was unsuccessful, since a dark coating (AgCl?) quickly formed on the anode surface, after which no current flowed at the voltages accessible to us.

Copper

Anodic copper dissolves readily in an electrochemical cell containing acetonitrile + benzyl chloride + triphenylphosphine, with $E_F = 1.0$ mol F^{-1}. Addition of diethylether to the clear solution precipitated $CuCl \cdot PPh_3$. Again no organometallic derivatives are formed, as with previous studies of sacrificial copper electrodes (7), and the reactions involved are presumably the analogues of reactions [10] and [11].

The results obtained when benzyl chloride is replaced by aqueous hydrohalic acid require some discussion. With hydrochloric acid, the addition of diethylether to the clear solution in the cell results in the isolation of $CuCl \cdot PPh_3$ and $Cu_2Cl_2(PPh_3)_3$. When hydrobromic acid is used, crystals of $Cu_2Br_2(PPh_3)_3$ grow from the copper anode; with hydroiodic acid, $Cu_2I_2(PPh_3)_3$ again forms at the anode, sometimes accompanied by $[PPh_3H]^+I^-$.

The current efficiencies for all three hydrohalic acids systems have been determined: X = Cl, $E_F = 0.81$ mol F^{-1}; X = Br, $E_F = 0.75$ mol F^{-1}; X = I, $E_F = 0.73$ mol F^{-1}. A complicating factor here is the slow but visible attack of the cell solution upon the copper metal in the absence of applied voltage, to give copper(II) species. Such chemical attack can only give an artificially high values of E_F and we therefore tentatively conclude that the limiting E_F is 0.5 mol F^{-1}, and that the mechanism for the formation of Cu(II) species at the anode in these systems is probably similar to that proposed above for gold (c.f. reactions [4] and [5]). Reduction by triphenylphosphine then yields CuX, which complexes with excess ligand to give the adducts isolated.

The stoichiometry of the adduct which is isolated must depend, *inter alia*, on the Cu:L ratio in the solution phase, since the adducts of copper(I) halides with neutral donor ligands have a range of stoichiometries (c.f. ref. 17). Tables 1 and 2 show that with copper, as with gold, a mixture of products can be obtained, and that the stoichiometry depends in part on the Cu:Ph_3P ratio in the reaction mixture. The ratios shown in Table 2 are simply $[Ph_3P]_{t=0}$: metal dissolved, and cannot be taken as specifying reaction conditions; in particular no allowance is made for oxidation of triphenylphosphine via reaction [8] or [9], for possible cathodic reduction of Ph_3PCl_2, or for loss of metal by cathodic deposition. Despite these simplifications, the results are in agreement with the reaction scheme proposed. In general, the experiments offer a simple and direct synthesis of adducts of the monohalides of copper, silver, and gold.

X-ray Crystallography of AuCl Complexes

Microscopic examination of the crystalline product obtained from $Au/C_6H_5CH_2Cl/CH_3CN$ systems revealed the presence of two different substances, and subsequent X-ray structural analysis showed these to be chloro(triphenylphosphine) gold(I) and chlorobis(triphenylphosphine) gold(I).

The compound $AuCl \cdot Ph_3P$ was obtained as equi-dimensional cubic crystals. The X-ray analysis yielded a structure which on refinement ($R = 0.041$) proved to be identical with that previously

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

reported by Bennett, Soboroff, and Baenziger (18). The second compound had elongated acicular crystals, one of which (dimensions 0.42 × 0.12 × 0.08 mm) was selected for crystal structure analysis. Preliminary results showed that the crystal of $AuCl(Ph_3P)_2$ was twinned, but it was decided to proceed with the analysis in order to establish the structural differences, if any, between this substance and the previously reported chlorobis(triphenylphosphine)gold(I) hemibenzene (19). The orientation matrix for the single crystal component of the twinned crystal was successfully obtained, and the intensity data were collected. We had hoped that overlapping of reflections due to twinning would be negligible in terms of the final analysis, but in the event this proved not to be the case. Various procedures were explored in attempts to overcome this significant overlapping, include assigning an artificially large σ value to the suspect reflections and suppressing the zonal reflections completely, but it was not possible to improve the refinement beyond an R-value of 0.108. This analysis thus served to identify the compound $AuCl(Ph_3P)_2$ beyond any doubt, but did not permit a complete structural determination. In particular, the final difference map showed seven large peaks (3.0–7.0 e Å^{-3}) in the xz plane, which contains the gold atom (0.0327X, 0.0611Y, 0.2739Z), and all approximately 0.06Y from the gold. Table 3 shows the main structural features of $AuCl(Ph_3P)_2$, and the corresponding values for $AuCl(Ph_3P)_2 \cdot 0.5C_6H_6$. Comparison of the two sets of results shows no significant differences in the Au—Cl or Au—P distances, but there are important differences in the bond angles in the coordination kernel, due in part presumably to the presence or absence of benzene in the lattice.

TABLE 3. Important structural features of $AuCl(Ph_3P)_2$ and $AuCl(Ph_3)_2 \cdot 0.5C_6H_6$ (19). Distances in Å, angles in degree

SONJA SOLAR, NIKOLA GETOFF, WOLFGANG SOLAR, and FRANZ MARK. Can. J. Chem. **59**, 2719 (1981).

The reaction mechanism of the H-attack on thionine (TH^+) in aqueous solutions (5×10^{-6} to 2×10^{-5} mol dm^{-3} TH^+; 2×10^{-2} mol dm^{-3} *t*-butanol, pH 1 and 4) was investigated by pulse radiolysis in combination with simulation by computation. Applying a least-squares fitting procedure it was possible to state that at pH 1, 89.5% of the H-atoms react with TH^+, $k = (8.5 \pm 0.3) \times 10^9$ dm^3 mol^{-1} s^{-1}, to form semiquinone ($^{\cdot}TH_3^{2+}$, $\lambda_{max} = 390$ nm, $\varepsilon_{390} = 685 \pm 20$ m^2 mol^{-1}; $\varepsilon_{770} = 720$ m^2 mol^{-1} and $\lambda_{max} = 790$ nm, $\varepsilon_{790} = 775 \pm 20$ m^2 mol^{-1}), which dismutates to TH^+ and leucodye with $2k = (2.4 \pm 0.1) \times 10^9$ dm^3 mol^{-1} s^{-1}. In addition to this a second H-attack (10.5% H) occurs on the ring carbon of the dye with $k = (1.0 \pm 0.1) \times 10^9$ dm^3 mol^{-1} s^{-1}, resulting in the production of H-adducts. These results are of interest for photogalvanic cells using thionine as a sensitizer.

SONJA SOLAR, NIKOLA GETOFF, WOLFGANG SOLAR et FRANZ MARK. Can. J. Chem. **59**, 2719 (1981).

Utilisant la radiolyse par pulsation combinée avec une simulation obtenue par le calcul, on a étudié le mécanisme de la réaction d'attaque du H sur la thionine (TH^+) dans des solutions aqueuses (5×10^{-6} à 2×10^{-5} mol dm^{-3} TH^+; 2×10^{-2} mol dm^{-3} *tert*-butanol, pH 1 et 4). En utilisant la méthode des moindres carrés il est possible de dire qu'à un pH de 1, 89,5% des atomes d'hydrogène réagissent avec la TH^+, $k = (8{,}5 \pm 0{,}3) \times 10^9$ dm^3 mol^{-1} s^{-1}, pour conduire à la semithionine ($^{\cdot}TH_3^{2+}$, $\lambda_{max} = 390$ nm, $\varepsilon_{390} = 685 \pm 20$ m^2 mol^{-1}, $\varepsilon_{770} = 720$ m^2 mol^{-1} et $\lambda_{max} = 790$ nm, $\varepsilon_{790} = 775 \pm 20$ m^2 mol^{-1}) qui se dismute en TH^+ et en leucocolorant avec $2k = (2{,}4 \pm 0{,}1) \times 10^9$ dm^3 mol^{-1} s^{-1}. De plus, il se produit une deuxième attaque de l'hydrogène (10,5% H) sur le cycle carboné du colorant avec $k = (1{,}0 \pm 0{,}1) \times 10^9$ dm^3 mol^{-1} s^{-1} qui conduit à la formation d'adduits d'hydrogène. Ces résultats intéressants se rapportent aux cellules photogalvaniques qui utilisent la thionine comme sensibilisateur.

[Traduit par le journal]

Introduction

Thionine (TH^+) in aqueous solutions has been the subject of numerous photochemical, photophysical, and photoelectrochemical investigations in respect of both, basic chemistry (1–16) and solar energy utilization (3, 17–22). The main primary photochemical induced intermediate is thionine triplet, $^3TH^+$ ($Q_T = 0.4$ (23), absorption maxima: 375 nm and 665 nm at pH 1 (8)), whereas the fluorescence quantum yield is relatively low ($Q_F = 0.047$ (11)).[1] Special attention was drawn to the formation of semiquinone ($^{\cdot}TH_2^+$) by means of appropriate triplet quenchers. Using, e.g., ferrous ions in acid solution, the process can be summarized as follows:

[1] $TH^+ \longrightarrow {}^1TH^+ \xrightarrow{ISC} {}^3TH^+$

[2] $^3TH^+ + H^+ \rightleftharpoons {}^3TH_2^{2+}$ ($pK_T = 6.3$ (24))

[3] $^3TH_2^{2+} + Fe^{2+} \xrightarrow{k_3} {}^{\cdot}TH_2^+ + Fe^{3+}$
$k_3 = 6 \times 10^7$ dm^3 mol^{-1} s^{-1} (25)

[4] $^{\cdot}TH_2^+ \rightleftharpoons {}^{\cdot}TH + H$ ($pK = 8.1$ (8, 26))

[5] $^{\cdot}TH_2^+ + {}^{\cdot}TH_2^+ \xrightarrow{H_{aq}^+} TH^+ + TH_4^{2+}$

It was further established that semiquinone is formed not only from $^3TH_2^{2+}$, but also from $^1TH^+$ by an electron transfer process (7, 11, 16). The absorption spectrum of $^{\cdot}TH_2^+$ has been measured by some authors, applying the flash photolysis method. Using ferrous ions as the electron donor in aqueous solutions its absorption maxima were found to be at 390–400 nm ($\varepsilon = 650$ to 680 m^2 mol^{-1}) and at >750–770 nm ($\varepsilon = 820$–1200 m^2 mol^{-1}) (7, 13, 27). Applying allythiourea (8, 28) or paraphenylendiamine (9) as triplet quenchers in neutral solutions absorption bands at 400 nm ($\varepsilon = 700$–870 m^2 mol^{-1}) and at 750–775 nm ($\varepsilon = 1360$–1750 m^2 mol^{-1}) were observed. The scattering of the results could be explained by different protonation forms of semiquinone in addition to other factors. Some of these are briefly mentioned, e.g. the kind and concentration of the electron donor can influence the yield of semiquinone (12, 15, 29, 30). Besides, the absorption of the dye triplet interferes significantly with that of semiquinone in the range of 350–450 nm; further, in some cases the absorption

of the donor or its oxidized form is overlapping with that of semiquinone.

A direct formation of semiquinone, avoiding all above mentioned factors can be achieved by reaction of thionine with H-atoms. The pulse radiolysis technique offers this possibility.

In the present paper experimental and simulation computation data concerning the formation and decay kinetics, as well as spectroscopic data of semireduced thionine in strong acid aqueous solutions are presented. Such investigations have been recently performed with aqueous methylene blue (MB^+) at pH = 1 which is the *N,N,N',N'*-tetramethyl derivative of thionine (31).

Experimental section

Chemicals and Preparation of Solutions

The substances (*t*-butanol, $HClO_4$, and H_2SO_4) were of reagent grade (E. Merck) and were used without further purification. Thioninehydrochloride (3,7-diamino-5-phenothiaziniumchloride; MW 263.75; EGA-Chemie, FRG) was recrystallized from 50% water–ethanol solutions (32). The determined molar extinction coefficient, $\varepsilon_{598} = 5480\ m^2\ mol^{-1}$ was in good agreement with that of other authors measured under the same conditions (9, 32). The dye solutions (5×10^{-6} to 2×10^{-5} mol dm^{-3} TH^+, 2×10^{-2} mol dm^{-3} *t*-butanol as OH scavenger with $k(OH + t\text{-butanol}) = 5.5 \times 10^8\ dm^3\ mol^{-1}\ s^{-1}$ (33)) were prepared using water distilled at least four times, and immediately before the experiment, were saturated with high purity argon for about 1 h. For adjusting pH = 1.0 ± 0.1 of the dye solutions, sulfuric acid, or in some cases perchloric acid, was used. Some experiments with the same dye concentrations were also carried out at pH = 4 ± 0.1. No difference between the spectroscopic and kinetic data of the transients was observed by applying either of the two acids in the range of the dye concentrations given above. The solvated electrons were converted rapidly into H-atoms ($k(e_{aq}^- + H_{aq}^+) = 2.3 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$ at pH 1 (34)), hence G_H (total) was taken to be 3.55 (35).

Pulse radiolysis[2]

The pulse radiolysis set-up was previously described in detail (36, 37). A 3 MeV Van de Graaff accelerator (High Voltage Eng. Co, Burlington, type K) provided electron pulses of 0.4 μs duration. The dose per pulse was varied from 1 to 5 J/kg (100–500 rad) producing 0.37×10^{-6} to 1.85×10^{-6} mol dm^{-3} H-atoms. A double monochromator (Zeiss MQ 12) in combination with a wide range photomultiplier (Hamamatsu, type R 955) and an oscilloscope (Tektronix, type 555) were used for registration of the intermediate absorption in the range of 280 to 900 nm. All solutions were irradiated at 20 ± 2°C in a suprasil quartz cell with light path of 3 × 2 cm and were exchanged after each single pulse by means of a remote-controlled valve. The optical density of all measurements has been normalized for 1 cm light path and to a dose of 10 J/kg (1 krad) per pulse.

Simulation Computation

Based on the kinetic and spectroscopic results obtained by pulse radiolysis, calculations were performed on the CDC computer of the Vienna University in order to elucidate the reaction mechanism.

Results and Discussion

Pulse Radiolysis

The absorption spectrum of the intermediates, formed by attack of H-atoms on thionine, was measured in air-free solutions at pH = 1 ± 0.1 using three different dye concentrations (5×10^{-6}, 1×10^{-5}, and 2×10^{-5} mol dm^{-3} TH^+ in the presence of 2×10^{-2} mol dm^{-3} *t*-butanol) in the range from 280 to 900 nm. Two strong absorption maxima at 390 and 790 nm were observed, which correspond to semithionine, in accordance to the above mentioned flash photolysis studies (7–9, 22). In addition to this an absorption at about 300 nm was obtained, after correction for depletion of the dye. This absorption was attributed to the H-adduct, produced by an addition of H-atoms to ring carbon, as previously shown for methylene blue (31) and aromatic amines (38–40).

Preliminary information about the reaction mechanism for the formation and dismutation of semithionine was obtained by kinetic analysis at the absorption maxima at 390 and 790 nm for short (up to about 15 μs) and long times (from 100–1500 μs). The intermediate time range, where the build-up and decay processes overlap, was first neglected. For illustration in this respect typical oscilloscope traces of the transients absorbing at 390 and 770 nm are shown in Fig. 1. It is obvious that the course of

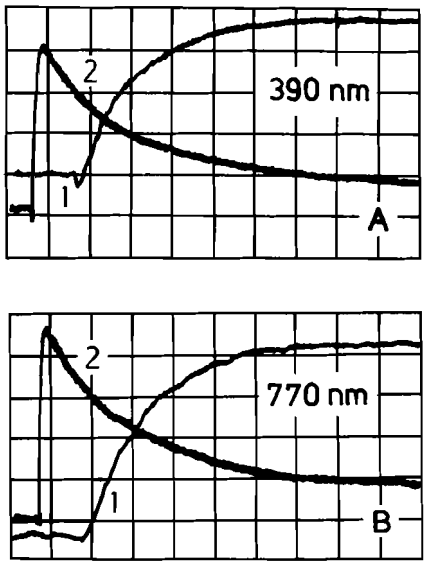

FIG. 1. Oscilloscope traces of transients formed by H-attack on TH^+ (1×10^{-5} mol dm^{-3} dye, 2×10^{-2} mol dm^{-3} *t*-butanol, pH = 1) in airfree aqueous solution. Vertical displacements correspond to the relative absorbance; horizontal displacements represent the time scale: for *A* 1 and *B* 1: 5 μs/div., for *A* 2 and *B* 2: 200 μs/div. (*A*, λ = 390 nm, dose: 4.8 J/kg; *B*, λ = 770 nm, dose: 5.2 J/kg).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

the corresponding traces is similar and the H-attack on TH^+ with formation of semiquinone is completed within 30 μs (Fig. 1, curves 1*A* and 1*B*).

The evaluation of the traces from at least ten individual measurements for each of the above mentioned three thionine concentrations shows purely first-order kinetics, giving a mean value of $k_6 = 1.0 \times 10^{10}$ dm^3 mol^{-1} s^{-1} at both wavelengths. This fact gives evidence that only one short-living species ($\cdot TH_3^{2+}$) absorbs at these wavelength ranges. Thus, there is a difference in the reactivity of H-atoms with TH^+ and MB^+, since in the case of MB^+ the absorption at 400 nm was superimposed by a second transient, resulting from the H-attack by splitting the chromophore group of the dye molecule (31).

Purely second order plots of 1/OD values vs. time (up to about 1.5 ms) were obtained for the dismutation reaction of semithionine at 390, 770, and 790 nm for a number of measurements using all three different dye concentrations. Taking the slopes of these plots of both absorption bands and mean ε-values based on the previously reported flash photolysis data for $\varepsilon_{390} = 650$ m^2 mol^{-1} and $\varepsilon_{770} = 1200$ m^2 mol^{-1} (e.g. ref. 13), no significant difference between the kinetic data at both wavelengths was observed. The resulting mean value for semiquinone decay was $2k_9 = 2.4 \times 10^9$ dm^3 mol^{-1} s^{-1}. This fact supports again the assumption that only one transient with absorption maxima at 390 to 790 nm is produced.

The kinetic evaluation at 300 nm was not carried out graphically, because at this wavelength there is a significant superimposition with the primary absorption of the dye.

Simulation Computation

Both processes, the formation of semiquinone and that of H-adducts (reactions [6] and [7]), are in competition with the combination of H-atoms (reaction [8]), because of the very low dye concentration used. Hence, the reaction scheme at pH = 1 may be summarized as follows (the structure of semithionine is based on esr measurements (41, 42), whereas that of the H-adduct is reasonable in accordance with results for other aromatic compounds (33, 38)):

[6] 
[7] 
[8] $H + H \longrightarrow H_2$ ($2k_8 = 2.3 \times 10^{10}$ dm^3 mol^{-1} s^{-1} (31))

[9] $\cdot TH_2^{2+} + \cdot TH_3^{2+} \xrightarrow{2k_9} TH_4^{2+} + TH^+ + H^+$

Based on the assumption of a homogeneous distribution of the H-atoms in the acid dye solution one can apply normal chemical kinetics for reactions [6] to [9]. Thus, the following kinetic equations can express the reaction mechanism:

[10] $$d[TH^+]/dt = -(k_6 + k_7)[TH^+][H] + k_9[\cdot TH_3^{2+}]^2$$

[11] $$d[H]/dt = -(k_6 + k_7)[TH^+][H] - 2k_8[H]^2$$

[12] $$d[\cdot TH_3^{2+}]/dt = k_6[TH^+][H] - 2k_9[\cdot TH_3^{2+}]^2$$

[13] $$d[TH_4^{2+}]/dt = k_9[\cdot TH_3^{2+}]^2$$

The unknown model-parameters (rate constants for reactions [6], [7], and [9]), for $\cdot TH_3^{2+}$: ε_{390} and ε_{790}, have been determined by approximating the experimental OD-values to the OD-values calculated for the reaction scheme (reactions [6] to [9]), using a non-linear least-squares fitting procedure (31). The system of non-linear differential equations ([10] to [13]) has been solved numerically by the Runge–Kutta method (43) for various parameter sets, until the sum of the squared deviations between calculated and experimental OD-values was minimised (44). All experimental data obtained by using different dye concentrations were applied for this computation. The parameter data at the beginning of the iterative procedure were: $k_6 = 1.0 \times 10^{10}$ dm^3 mol^{-1} s^{-1} and $2k_9 = 2.6 \times 10^9$ dm^3 mol^{-1} s^{-1}, which were experimentally determined as

TABLE 1. Computed molar extinction coefficients (ε) and rate constants (k) for formation and decay of short-lived species formed by reaction of H-atoms with thionine.

Species	Molar extinction coefficients (ε in m^2 mol^{-1}) ε_{390}	ε_{770}	ε_{790}	Rate constants (dm^3 mol^{-1} s^{-1}) Formation (k)	Decay ($2k$)

H-adducts	—	—	—	$(1.0\pm0.1)\times10^9$	—

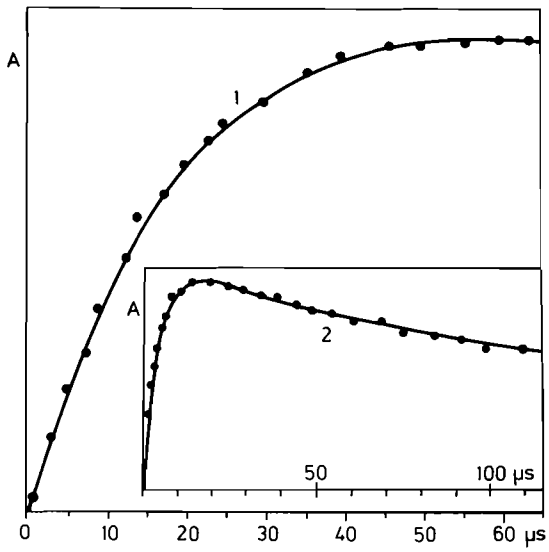

FIG. 2. Absorbance (A; arbitrary scale) as a function of time for experimentally determined (○) and computed data (solid line) for formation and decay of semiquinone ($^{\bullet}TH_3^{2+}$) at 770 nm (*1*) and 390 nm (insert, curve *2*). Solution: (*1*) 5×10^{-6} mol dm^{-3} TH^+, 1×10^{-2} mol dm^{-3} *t*-butanol, pH = 1; dose/pulse: 2.1 J/kg (*2*) 2×10^{-5} mol dm^{-3} TH^+, 2×10^{-2} mol dm^{-3} *t*-butanol, pH = 1; dose/pulse: 4.9 J/kg.

mentioned before. The rate constant for reaction [7] was taken to be the same as in the case of methylene blue, namely $k_7 = 0.6 \times 10^9$ dm^3 mol^{-1} s^{-1} (31).

It might be further mentioned that each pulse radiolysis measurement was performed at least five times, using various doses/pulse for each of the three dye concentrations. Afterwards the obtained measurements were analyzed together in one single computation step. Hence, only one set of rate constants and ε-values, satisfying all individual chosen experimental conditions, was obtained. Typical computer plots of absorbance vs. time (μs) of calculated and experimental data are shown in Fig. 2 for illustration.

The final computed rate constants for formation and decay of the transients together with ε_{390}, ε_{770}, and ε_{790} for $^{\bullet}TH_3^{2+}$ are presented in Table 1, having confidence limits of 99%. Our ε_{390}-value agrees well with those determined by flash photolysis in acid solutions (7, 13), however, their ε_{770}-values are essentially higher than ours. The rate constant for dismutation of $^{\bullet}TH_3^{2+}$ ($2k_9$) is rather similar to some of those determined previously, e.g. $2k_9 = 2.4 \times 10^9$ dm^3 mol^{-1} s^{-1} (7, 8). Based on the results given in Table 1 it was calculated that 89.5% of the H-atoms are reacting with thionine with the production of semithionine (reaction [6]) and that the remaining 10.5% yield H-adducts (reaction [7]). However, the root-mean-square error in the calculated OD-values is about two times larger, if the calculations are performed under the assumption that reaction (7) is negligible.

Simulation computations were also performed with some preliminary pulse radiolysis data obtained with TH^+ at pH = 4. The ε_{390}-values and the kinetic data for formation of semiquinone and H-adducts at both pH's (1 and 4) are found to be rather similar, but at pH 4 $\varepsilon_{770} = 1870$ m^2 mol^{-1}, whereas at pH 1 $\varepsilon_{790} = 775$ m^2 mol^{-1}. The reason for this difference is the two protonation forms of semiquinone, namely $^{\bullet}TH_3^{2+}$ (pH 1) and $^{\bullet}TH_2^{+}$ (pH 4). The semiquinone decay constant ($2k_9$) at pH 4 is about 20% larger than that at pH 1.

Finally it might be mentioned that the presented data are also of interest for photogalvanic and other redox systems, using thionine as a sensitizer for solar energy utilization (3, 21). These devices are still not stable enough for practical use. The electrons ejected from the cathode are converted into H-atoms in acid solution, and lead to formation of semiquinone, leuco-dye, and H-adducts. The first two products can be reversed to the original dye form by a dark reaction with the oxidized electron donor of the system (e.g. Fe^{3+}). The formation of H-adducts on ring carbon, however, is an irreversible process, which could explain at least partly the instability of such devices.

The reaction between carbon disulfide and some α-methylaminonitriles. The supposed isomerism of 4,4-dialkyl-5-imino-3-methylthiazolidine-2-thiones

FRANCIS L. CHUBB AND JOHN T. EDWARD

Received February 20, 1981

FRANCIS L. CHUBB and JOHN T. EDWARD. Can. J. Chem. **59**, 2724 (1981).

The reaction of carbon disulfide with α-methylaminonitriles **1** yields 5-iminothiazolidine-2-thiones **3**, which on prolonged reaction are converted to 5-methyliminothiazolidine-2-thiones **5** and 2,4-dithiohydantoins **9**. A mechanism for this apparent methyl transfer is advanced. The yellow compounds obtained by prolonged reaction of the aminonitriles **1** ($R^1 = R^2 =$ Me and $R^1 =$ Et, $R^2 =$ Me) are not isomers of the imines **3** ($R^1 = R^2 =$ Me and $R^1 =$ Et, $R^2 =$ Me), but 2:1 complexes of these imines with the corresponding 2,4-dithiohydantoins **9** ($R^1 = R^2 =$ Me and $R^1 =$ Et, $R^2 =$ Me).

FRANCIS L. CHUBB et JOHN T. EDWARD. Can. J. Chem. **59**, 2724 (1981).

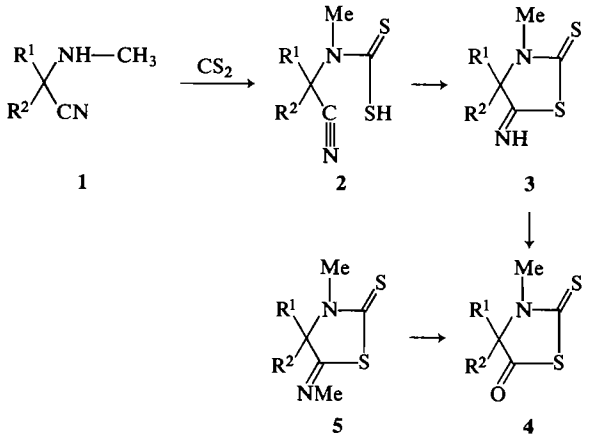
Le bisulfure de carbone réagit avec les α-méthylaminonitriles **1** en donnant les imino-5 thiazolidinethiones-2 **3**. En prolongeant le temps de réaction on transforme les composés **3** en méthyl-5 iminothiazolidinethiones-2 **5** et en dithio-2,4 hydantoïnes **9**. On propose un mécanisme pour expliquer ce transfert apparent d'un méthyle. Les composés jaunes obtenus par la réaction prolongée des aminonitriles **1** ($R^1 = R^2 =$ Me et $R^1 =$ Et, $R^2 =$ Me) ne sont pas des isomères des imines **3** ($R^1 = R^2 =$ Me et $R^1 =$ Et, $R^2 =$ Me), mais sont des complexes 2:1 de ces imines avec les dithio-2,4 hydantoïnes correspondants **9** ($R^1 = R^2 =$ Me et $R^1 =$ Et, $R^2 =$ Me).

[Traduit par le journal]

Carrington (1) reported that both α-methylaminoisobutyronitrile (**1**; $R^1 = R^2 =$ Me) and α-methylamino-α-methylbutyronitrile (**1**; $R^1 =$ Et, $R^2 =$ Me) reacted with carbon disulfide to give, after 24 hours, yellow crystalline compounds, formulated as **3** ($R^1 = R^2 =$ Me or $R^1 =$ Et, $R^2 =$ Me). Each yellow compound, he claimed, was converted by warm alcoholic sodium hydroxide into a colourless isomer. The relationship between the yellow and colourless isomers could not be elucidated; both isomers, it was claimed, were hydrolysed by acid to the common product **4** ($R^1 = R^2 =$ Me and $R^1 =$ Et, $R^2 =$ Me). On the other hand, reaction of carbon disulfide with the aminonitriles **1** ($R^1R^2 = (CH_2)_5$ and $CH_3CH\langle[CH_2]_4\rangle$) gave only colourless products **3** ($R^1R^2 = (CH_2)_5$ and $R^1R^2 = CH_3CH\langle[CH_2]_4\rangle$) and no yellow isomer.

In a reinvestigation of Carrington's reactions, we found that α-methylaminoisobutyronitrile (**1**; $R^1 = R^2 =$ Me) after 12 hours reaction with carbon disulfide gave only the colourless product reported by him. Its analysis and spectral characteristics supported his formulation **3** ($R^1 = R^2 =$ Me). However, when the reaction time was prolonged to 30 hours his yellow product was obtained in 38% yield, together with a new colourless product $C_7H_{12}N_2S_2$.

The analysis and spectra of this second colourless compound showed it to be the *N*-methylimine **5** ($R^1 = R^2 =$ Me), a structure following also from the fact that both compounds **3** and **5** ($R^1 = R^2 =$ Me) were hydrolysed by dilute acid to the same carbonyl compound **4** ($R^1 = R^2 =$ Me).



SCHEME 1

The yellow compound proved to be a complex (C-1) made up of one mole of 5,5-dimethyl-2,4-dithiohydantoin (**9**; $R^1 = R^2 =$ Me) (2) and two of the imine **3** ($R^1 = R^2 =$ Me). As reported by Carrington, the yellow solid was converted by dilute aqueous sodium hydroxide to the colourless imine **3** ($R^1 = R^2 =$ Me); however, the alkaline filtrate contained 5,5-dimethyl-2,4-dithiohydantoin (2), which was precipitated by acidification. Furthermore, a yellow product of identical properties (mp, ir) crystallized out when methanolic solutions of the imine **3** ($R^1 = R^2 =$ Me) and the 2,4-dithiohydantoin **5** ($R^1 = R^2 =$ Me) were mixed in varying proportions; its uv spectrum showed that the mole ratio of **3**:**5** in the product was invariably 2:1. It is presumably a hydrogen-bonded complex, dissociated

completely into its components when dissolved in ethanol (as shown by the uv spectrum of the solution).

A reaction mixture similar to that which had given first **3** ($R^1 = R^2 =$ Me) and later **5** and **9** ($R^1 = R^2 =$ Me) was heated to 50°C, and samples were withdrawn at various intervals of time and examined by nmr and ir spectroscopy. The disappearance of **1** ($R^1 = R^2 =$ Me), and the appearance first of **3** ($R^1 = R^2 =$ Me), and then of **5** ($R^1 = R^2 =$ Me), could be followed by changes in the areas of their *N*-methyl peaks in the nmr spectrum.[1] The results are shown in Fig. 1.[2]

The same changes were apparent when the ir spectrum of the reaction mixture was scrutinized at various times. This spectrum showed that the disappearance of the C≡N band (2220 cm^{-1}) due to **1** ($R^1 = R^2 =$ Me) was accompanied by the appearance of a C=NH band (1630 cm^{-1}) due to **3** ($R^1 = R^2 =$ Me). The latter band increased in intensity up to a maximum after about 24 hours, and then declined, while three new bands became apparent after 18–24 hours; one at 1660 cm^{-1} (C=NMe) due to **5** ($R^1 = R^2 =$ Me); another (somewhat more slowly) at 1530 cm^{-1} (>N—CS—) due to **9** ($R^1 = R^2 =$ Me); and a third at 2050 cm^{-1} (—N=C=S (3)) due to **8**. This last peak is interesting in supplying the first direct experimental evidence for the involvement of an isothiocyanate intermediate (4) **8** in the formation of a 2,4-dithiohydantoin **9** by the route shown in Scheme 2 and pioneered by Carrington (2). Unfortunately, attempts to isolate the compound **8** ($R^1 = R^2 =$ Me) from the complex reaction mixture by chromatography on Florosil failed, possibly because the compound rearranged to **9** ($R^1 = R^2 =$ Me) on the adsorbent. When the reaction mixture was extracted with dilute aqueous acid, basic products such as **3** and **5** ($R^1 = R^2 =$ Me) were removed, as shown by the disappearance of the peaks at 1630 and 1660 cm^{-1}, but the peak at 2050 cm^{-1} remained. However, when the reaction mixture was extracted with dilute aqueous sodium hydroxide, the peaks due to the basic products remained but the peak at 2050 cm^{-1} disappeared. This was to be expected from the weak acidity ($pK_a \sim 10$) (5) which one could anticipate for **8** ($R^1 = R^2 =$ Me).

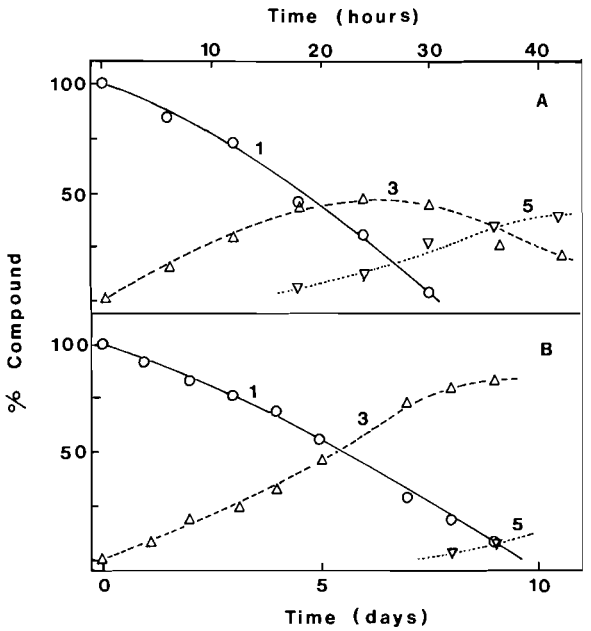

FIG. 1. Rate of disappearance of compound **1** (Scheme 1) and of appearance of compounds **3** and **5**. A: $R^1 = R^2 =$ Me; B: R^1 = Et, R^2 = Me.

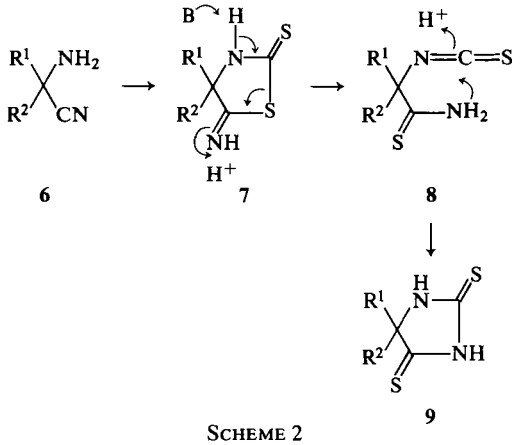

SCHEME 2

However, when the aqueous alkaline extract was acidified only the 2,4-dithiohydantoin **9** ($R^1 = R^2 =$ Me) was obtained, the reaction **8** → **9** evidently being rapid under these conditions.

In considering mechanisms for the general reaction [1] we must postulate

[1] 2 **3** → **5** + **9**

the formation of the aminonitrile **6**, the only plausible precursor to the 2,4-dithiohydantoin **9**. A pos-

[1]No *N*-methyl peak due to **2** ($R^1 = R^2 =$ Me) could be detected, and it seems probable that **2** does not accumulate because **2** → **3** is fast.

[2]The percentages shown in Fig. 1 were obtained first from the relative areas *A* of the *N*-methyl peaks of **1** and **3**; later, when **5** appeared, from the relative areas of the peaks for **1**, **3**, and **5**, with 100% given by the summation

$$A(1) + A(3) + 2A(5) = 100\%$$

as required by the stoichiometry (see below) of

2 **1** → 2 **3** → **5** + (**8** and/or **9**)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

sible route involving **6** is:

[2] $\mathbf{3} \rightleftarrows \mathbf{1} + CS_2$

[3] $\mathbf{1} + NH_3 \rightleftarrows \mathbf{6} + CH_3NH_2$

[4] $\mathbf{6} + CS_2 \rightarrow \mathbf{9}$

[5] $CH_3NH_2 + \mathbf{3} \rightleftarrows \mathbf{5} + NH_3$

four equations which sum up to [1]. We have found that methylamine in aqueous ethanol displaces ammonia from the imine **3** (R^1 = Et, R^2 = Me) to give the *N*-methylimine **5** (R^1 = Et, R^2 = Me), as required by [5]. Under the same conditions, the reaction of methylamine with the imine **3** ($R^1 = R^2$ = Me) gives another compound along with *N*-methylimine **5** ($R^1 = R^2$ = Me); this reaction is being investigated further. The reversibility of [3] seems plausible from the work of Tallaides and Commeyras (6). This mechanism depends on the adventitious presence of traces of ammonia or methylamine (or, equivalently, water) which are regenerated during the overall reaction sequence [2]–[5]. Some evidence was obtained that "spiking" the reaction mixture with small amounts of ammonia or methylamine accelerated overall reaction [1], but systematic studies were not made.

The reaction of the aminonitrile **1** (R^1 = Et, R^2 = Me) with carbon disulfide paralleled precisely that of the aminonitrile **1** ($R^1 = R^2$ = Me), but was much slower, as shown in Fig. 1. Again, the yellow product was found to be a 2:1 complex (C-2) of the imine **3** (R^1 = Et, R^2 = Me) and the dithiohydantoin **9** (R^1 = Et, R^2 = Me), and could be obtained also by mixing warm solutions of appropriate amounts of the imine and of the 2,4-dithiohydantoin in 50% aqueous methanol, and allowing the solution to cool. However, a 1:1 yellow complex (C-3) could also be obtained if different amounts of imine and of 2,4-dithiohydantoin were mixed in solution. Both complexes had similar melting points (121–122° and 122–123°C), but were distinguishable by differing ultraviolet absorption spectra in solution in ethanol.

In agreement with Carrington (1), the aminonitrile **1** ($R^1R^2 = (CH_2)_5$) derived from cyclohexane gave the colourless imine **3** ($R^1R^2 = (CH_2)_5$), but no yellow compound on prolonged reaction. This was not due to the failure of **3** ($R^1R^2 = (CH_2)_5$) to react further: both the *N*-methylimino compound **5** ($R^1R^2 = (CH_2)_5$) and the spiro-2,4-dithiohydantoin **9** ($R^1R^2 = (CH_2)_5$) were obtained on prolonged reaction. However, a methanolic solution of **3** and **9** ($R^1R^2 = (CH_2)_5$) failed to deposit crystals of a yellow complex. This may be due to steric hindrance: yellow complexes of mixed composition could be obtained from methanolic solutions of the imine **3** (R^1 = Et, R^2 = Me) and the dithiohydantoin **9** ($R^1 = R^2$ = Me) (C-4, mole ratio 1:1), and of the imine **3** ($R^1 = R^2$ = Me) and the dithiohydantoin **9** (R^1 = Et, R^2 = Me) (C-5, mole ratio 2:1). On the other hand, no yellow complex could be obtained from methanolic solutions of the imines **3** ($R^1 = R^2$ = Me or R^1 = Et, R^2 = Me) with the dithiohydantoin **9** ($R^1R^2 = (CH_2)_5$), nor from methanolic solutions of the imine **3** ($R^1R^2 = (CH_2)_5$) with the dithiohydantoins **9** (R^1 = Et, R^2 = Me or $R^1 = R^2$ = Me). Furthermore, no yellow complexes could be obtained when 5,5-dimethyl-2- or 4-thiohydantoin was substituted for 5,5-dimethyl-2,4-dithiohydantoin, nor when the *N*-methylimine **5** ($R^1 = R^2$ = Me) was substituted for the imine **3** ($R^1 = R^2$ = Me). It seems likely that formation of the yellow complexes depends upon a very precise alignment of hydrogen bonding donor and acceptor groups, and hence on a very precise packing of imines and of 2,4-dithiohydantoins in the crystal.

Experimental

Reaction of α-Methylaminoisobutyronitrile (1; $R^1 = R^2$ = Me) with Carbon Disulfide

α-Methylaminoisobutyronitrile (18 g) and carbon disulfide (24 g) were heated to 50°C by a water-bath and stirred under reflux for 30 h. After evaporation of carbon disulfide, benzene (15 mL) was added. On standing, 11.5 g (38%) of yellow crystals (C-1) separated, mp 114–118°C, raised to 117–118°C (lit. (1) mp 115–116°C) by recrystallization from aqueous methanol; ir (Nujol): 3210 (N—H), 1620 (C=N), 1530 (2,4-dithiohydantoin) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.55 (s, 6H), 1.60 (s, 12H), 3.33 (s, 6H), 8.61 (s, 1H). *Anal.* calcd. for $C_{17}H_{28}N_6S_6$: C 40.13, H 5.55, N 16.52; found: C 40.13, H 5.61, N 16.45.

The benzene filtrate was evaporated and the oily residue extracted with hot petroleum ether (bp 30–60°C). On cooling, the extract yielded 3.75 g (13%) of crude 3,4,4-trimethyl-5-methyliminothiazolidine-2-thione (**5**; $R^1 = R^2$ = Me); mp (after recrystallization from aqueous methanol) 80–81°C; ir (Nujol): 1660 (C=N) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.58 (s, 6H), 3.20 (s, 3H), 3.36 (s, 3H). *Anal.* calcd. for $C_7H_{12}N_2S_2$: C 44.64, H 6.43, N 14.88; found: C 44.70, H 6.52, N 14.98.

Alkaline Decomposition of Yellow Complex C-1

Treatment of the yellow complex C-1 (5 g) with 2% sodium hydroxide (50 mL) discharged the yellow colour after a few minutes. After 2 h, white crystals (3.15 g, 92%), of 3,4,4-trimethyl-5-iminothiazolidine-2-thione (**3**; $R^1 = R^2$ = Me), mp 73–75°C (lit. (1) mp 70°C), were removed by filtration; ir (Nujol): 3140 (NH), 1630 (C=N) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.66 (s, 6H), 3.33 (s, 3H), 9.59 (s, 1H).

Acidification of the alkaline filtrate yielded 1.35 g (80%) of crude 5,5-dimethyl-2,4-dithiohydantoin, mp 122–135°C, raised by one recrystallization from benzene to 145–147°C (lit. (2) mp 144°C); ir (Nujol): 3140 (NH), 1545 (2,4-dithiohydantoin) cm^{-1}; ^1H nmr (DMSO-d_6) δ: 1.33 (s, 6H), 10.66 (s, 1H), 13.00 (s, 1H).

Hydrolysis of 3,4,4-Trimethyl-5-methyliminothiazolidine-2-thione (5; $R^1 = R^2$ = Me)

3,4,4-Trimethyl-5-methyliminothiazolidine-2-thione (0.5 g) was dissolved in 10 mL of water and 5 mL concentrated hydrochloric acid and heated on the steam bath for 10 min. After

the mixture had cooled, crystalline precipitate (10.43 g, 92%) was removed by filtration; mp 87–89°C (lit. (1) mp 85°C), identical (ir, nmr) with an authentic sample of 3,4,4-trimethylthiazolidine-5-one-2-thione (**4**; $R^1 = R^2 =$ Me); ir (Nujol): 1725 (C=O) cm^{-1}, prepared by hydrolysis of the imine **3** ($R^1 = R^2 =$ Me) according to Carrington (1).

Reaction of α-Methylamino-α-methylbutyronitrile (1; R^1 = Et, R^2 = Me) with Carbon Disulfide

A solution of α-methylamino-α-methylbutyronitrile (23.5 g) in carbon disulfide (27 g) was heated and stirred under reflux at 50°C for 72 h. After evaporation of carbon disulfide the oily residue partially crystallized. The crystals were sucked as dry as possible on the filter and recrystallized from aqueous methanol to yield 8.0 g (20%) of crude 3,4-dimethyl-4-ethyl-5-iminothiazolidine-2-thione (**3**; R^1 = Et, R^2 = Me), mp 72–75°C, raised by recrystallization to 87–89°C (lit. (1) mp 85°C); ir (Nujol): 3080 (N—H) 1620, 1640 (C=N) cm^{-1}; ^1H nmr ($CDCl_3$) δ: (t, J = 7.5 Hz, 3H, CH_2—CH_3), 1.56 (s, 3H, C—CH_3), 1.91 (q, J = 7.5, 2H, CH_2), 3.26 (s, 3H, NCH_3), 9.37 (s, 1H, NH).

The original filtrate on standing deposited yellow crystals (complex C-2), mp 115–116°C, raised by crystallization from aqueous methanol to 121–122°C (lit. (1) mp 117°C); ir (Nujol): 3215, 3200 (NH), 1610 (C=N), 1525 (2,4-dithiohydantoin) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.85 (t, 9H), 1.50 (s, 3H), 1.60 (s, 6H), 1.93 (m, 6H), 3.30 (s, 6H), 8.4 (s, 1H), 8.9 (s, 2H). *Anal.* calcd. for $C_{20}H_{34}N_6S_6$: C 43.60, H 6.22, N 15.26; found: C 43.56, H 6.27, N 15.19.

The filtrate from C-2 was concentrated. Extraction of the oily residue with boiling petroleum ether and cooling of the extract yielded 2.0 g (4.8%) of white crystals, mp 74–75°C, of 3,4-dimethyl-4-ethyl-5-methyliminothiazolidine-2-thione (**5**; R^1 = Me, R^2 = Et); ir (Nujol): 1665 (C=N) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.80 (t, J = 7.5 Hz, 3H, CH_2—CH_3), 1.53 (s, 3H, C—CH_3), 1.90 (q, J = 7.5 Hz, 2H, CH_2), 3.26 (s, 3H, NCH_3), 3.33 (s, 3H, =NCH_3). *Anal.* calcd. for $C_8H_{14}N_2S_2$: C 47.48, H 6.97, N 13.84; found: C 47.56, H 7.08, N 13.86.

Alkaline Decomposition of Complex C-2

Treatment of C-2 (0.5 g) by the procedure described for C-1 yielded 3,4-dimethyl-4-ethyl-5-iminothiazolidine-2-thione (0.32 g, 94%), mp 85–87°C, and 5-ethyl-5-methyl-2,4-dithiohydantoin (0.08 g, 50%), mp 148–150°C (lit. (2) mp 147–148°C), identical (ir, nmr) to an authentic specimen (2).

Reaction of 3,4-dimethyl-4-ethyl-5-iminothiazolidine-2-thione with Methylamine

The thione **3** (R^1 = Et, R^2 = Me) (1 g) in 40% aqueous methylamine (10 mL) and methanol (5 mL) was heated to reflux overnight. The solution was concentrated to remove methanol, more aqueous methylamine was added, and a solid was removed by filtration. This was crystallized from aqueous methanol to give 0.55 g of *N*-methylimine **5** (R^1 = Et, R^2 = Me), mp 71–73°C, having an ir spectrum identical with that of the authentic compound.

Hydrolysis of 3,4-Dimethyl-4-ethyl-5-methyliminothiazolidine-2-thione (5; R^1 = Et, R^2 = Me)

3,4-Dimethyl-4-ethyl-5-methyliminothiazolidine-2-thione (0.5 g) was dissolved in 5 mL of concentrated hydrochloric acid and 15 mL of water and heated on the steam bath for 15 min. After cooling, crystals (0.43 g, 92%) of 3,4-dimethyl-4-ethylthiazolidine-5-one-2-thione (**4**; R^1 = Et, R^2 = Me), mp 76–77°C (lit. (1) mp 76°C), were removed by filtration. The product was identical (ir (Nujol): 1730 cm^{-1}; nmr) with authentic material prepared according to Carrington (1).

Reaction of 1-Methylamino-1-cyanocyclohexane (1; R^1R^2 = $(CH_2)_5$) with Carbon Disulfide

A solution of 1-methylamino-1-cyanocyclohexane (30 g) and carbon disulfide (28 g) was heated and stirred under reflux at 50°C for 24 h. On removal of carbon disulfide, a crystalline product separated. It was removed by filtration and washed with petroleum ether (30–60°C) to yield 9.5 g of crude 5-imino-5,5-cyclopentamethylene-3-methylthiazolidine-2-thione (**3**; R^1R^2 = $(CH_2)_5$), mp 122–125°C.

After further evaporation of solvent, the residue was stirred under reflux with 28 g of carbon disulfide for another 24 h giving a further 5 g of the imine **3** ($R^1R^2 = (CH_2)_5$). Since the ir of the residue of the reaction still showed a nitrile band, it was stirred under reflux at 50°C for a third 24 h period. An additional 2.9 g of crude imine **3** ($R^1R^2 = (CH_2)_5$) was obtained, making a total yield of 17.4 g (38%); after recrystallization from methanol, mp 126–128°C (lit. (1) mp 125°C); ir (Nujol): 3195 (NH), 1640, 1610 (C=N) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.5–1.9 (m, 10H), 3.33 (s, 3H), 9.50 (s, 1H).

Extraction of the residue with boiling petroleum ether (30–60°C) removed 0.1 g of crude *N*-methylimine **5** (R^1R^2 = $(CH_2)_5$). The residue on standing deposited yellow crystals (1.7 g) which, when recrystallized from alcohol, yielded 0.95 g (2.2%) of 5,5-pentamethylene-2,4-dithiohydantoin, mp 274–275°C (lit. (2) mp 276–278°C); ir (Nujol): 3220, 3160 (NH), 1530 (2,4-dithiohydantoin) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.57 (s, 10H), 10.9 (s, 1H), 13.0 (s, 1H), identical with authentic material (2).

After removal of the dithiohydantoin, dilution of the residue with 50 mL of methanol resulted in the separation of a crystalline product (2.8 g), which recrystallized from methanol to yield 3-methyl-4,4-pentamethylene-5-methyliminothiazolidine-2-thione (**5**; R^1R^2 = $(CH_2)_5$) (2.1 g, 4.3%), mp 110–112°C; ir (Nujol): 1650, 1660 (C=N) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.6–1.8 (m, 10H), 3.17 (s, 3H), 3.33 (s, 3H). *Anal.* calcd. for $C_{10}H_{16}N_2S_2$: C 52.59, H 7.06, N 12.27; found: C 52.67, H 7.23, N 12.23.

Direct Preparation of Yellow Complexes from Imines 3 and 2,4-Dithiohydantoins 9

Warm aqueous methanol solutions containing imine **3** and 2,4-dithiohydantoin **9** deposited the complexes C-1, C-2, C-3, C-4, and C-5 in 80–90% yield on cooling. C-1 and C-2 proved identical (ir, nmr) to the compounds described above; C-3, C-4, and C-5 are described in Table 1.

Oxidation products of arachidonic acid. V. The synthesis of 8*R*,11*R*,15(*R* and *S*)-trihydroxy-9*S*,12*S*-oxyeicosa-5*Z*,13*E*-dienoic acids

GEORGE JUST AND HUNSEUNG OH

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received April 13, 1981

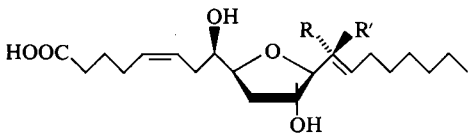
GEORGE JUST and HUNSEUNG OH. Can. J. Chem. **59**, 2729 (1981).

The synthesis of the title compounds is described. It is shown that β-nitro ketals are versatile intermediates for the synthesis of prostaglandin-type C-13 – C-20 side-chains.

GEORGE JUST et HUNSEUNG OH. Can. J. Chem. **59**, 2729 (1981).

La synthèse des composés sus-mentionnés est décrite et l'utilité des β-nitrocétales en tant qu'intermédiaires dans l'introduction de chaînes aliphatiques correspondantes au segment C-13 – C-20 des prostaglandines a été démontrée.

We wish to report the synthesis of title compounds **1** and **2** (1), which confirm the structure proposed for an oxidation product of arachidonic acid by Pace-Asciak and Wolfe (2), without, however, specifying its stereochemistry, since the R_f-values of **1** and **2** are different from that of the natural product.[1]



1 R = H, R′ = OH
2 R = OH, R′ = H

The strategy involved in the synthesis was to condense a readily available and suitably protected aldehyde such as ***6a*** with fragment **17**. The nitro function of **17** not only serves to generate the anion which adds to the aldehyde to give a nitro alcohol, but, after dehydration, it also serves as part of a nitro olefin which functions as Michael-acceptor for the tetrahydrofuran formation. Finally, being β to a potential ketone, its β-elimination then gives an α,β-unsaturated ketone, the reduction of which, followed by deblocking of protecting groups, provides title compounds **1** and **2**.

As a model compound, we used the readily available furanose **3** (3), which was transformed by the action of ethanethiol – zinc chloride to dithioacetal **4**, and hence to the corresponding isopropylidene compound **5**. Mercuric ion mediated hydrolysis then gave aldehyde ***6a*** in 75% yield, based on **3**.

Condensation of β-nitro ketal **7** and aldehyde ***6a*** in DMF (4), using diisopropylamine as base, gave a mixture of nitro alcohols **8** and **10** which were separable as their acetates **9** and **11**. Both acetates **9** and **11** were treated with anhydrous potassium carbonate and dicyclohexyl-18-crown-6 in benzene to give nitro olefin **12**. Selective hydrolysis of the isopropylidene group of **12** under various acidic reaction conditions failed because of the instability of dimethyl ketal to acid.

Treatment of nitro acetate **9** with methanolic *p*-toluenesulfonic acid gave bicyclic ketal **15**, probably via monocyclic ketal **13**. In contrast, the same acid treatment of the isomeric nitro acetate **11** gave a more polar product (tlc), which probably had the monocyclic ketal structure **14**, and which gave **16** upon reaction with triethylamine or during work-up ($NaHCO_3$). The structures of **15** and **16** were proven by their ^{1}Hmr, ir, and mass spectra.

These results can best be rationalized in the following manner. It is quite likely that the two nitro alcohols **8** and **10** have the two *threo*-configurations, since the addition ***6a*** + **7** → **8** + **10** is probably reversible, so that the most stable configurations permitting hydrogen bonding of the OH and NO_2 groups should be as depicted.

If these representations are correct, then the acid treatment of acetate **9** derived from **8** should give a mixture of conformers in which conformer **13** is populated to a considerable extent. Extrusion of the methoxy group at C-15, followed by cyclization, would then give **15**. In the case of acetate **11** derived from nitro alcohol **10**, a similar acid catalyzed cyclization would lead to a tetrahydropyran in which all secondary ring-substituents are equatorial. The other conformation being of little importance, no further acid-catalyzed cyclization takes place. Base treatment then results in elimination of the elements of acetic acid and formation of a nitro olefin which then cyclizes to bicyclic ketal **16**. Attempts to transform **16**, which has the carbon frame-work of the desired final product, to ***23a***, failed. Whereas the stereochemical assignments of **10**, **11**, **14**, and **16** are probably correct, is it quite

[1]We wish to thank Dr. C. Pace-Asciak for the chromatographic comparisons.

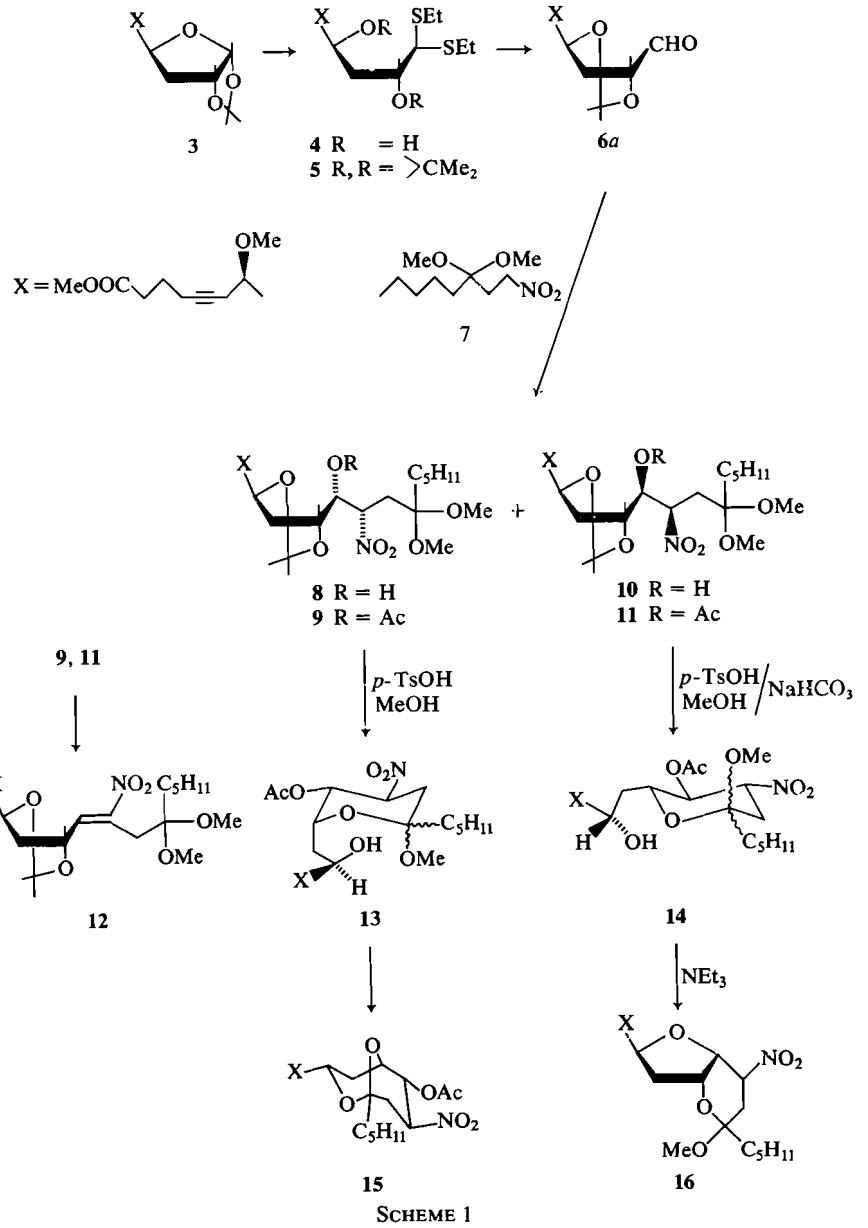
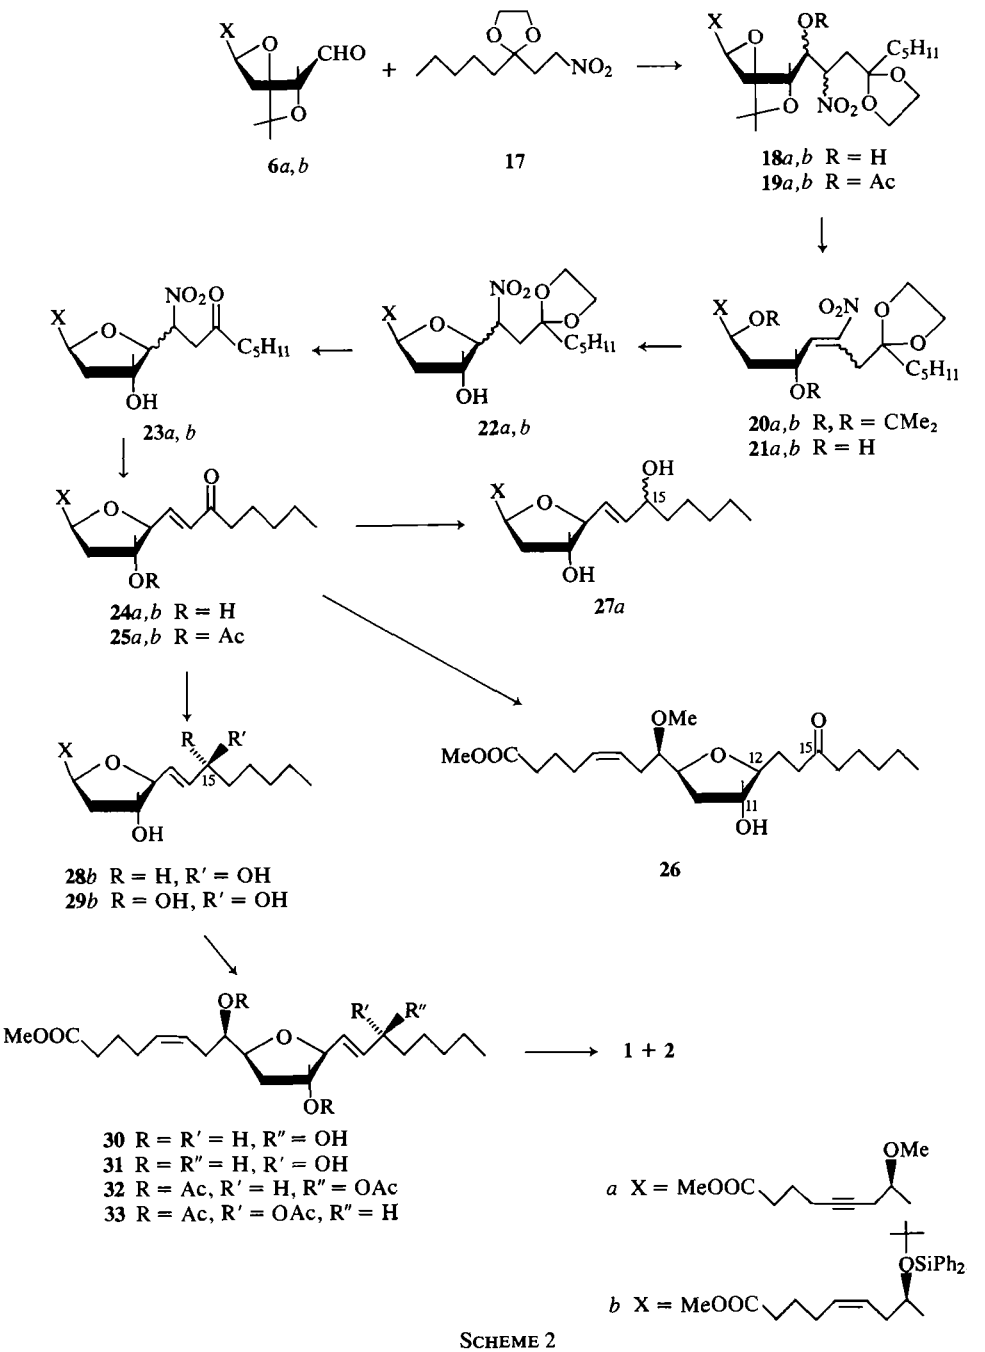


SCHEME 1

possible that the nitro and hydroxyl or acetate groups of **8**, **9**, **13**, and **15** have one of the *erythro*-configurations. A search of the literature revealed that little is known on the configuration of nitro alcohols derived from condensation of nitroalkanes with aldehydes (5).

Since we could not cleave the isopropylidene group in the presence of a dimethyl ketal in compounds of type **12**, the condensation of **6***a* was repeated with β-nitro ketal **17**. The resulting nitro alcohol **18***a* was acetylated, and nitro acetate **19***a* treated with anhydrous potassium carbonate and dicyclohexyl-18-crown-6 to give nitro olefin **20***a*. Mild acid hydrolysis of **20***a* gave the corresponding diol **21***a*, which, upon treatment with triethylamine, gave tetrahydrofuran **22***a* as a mixture of isomers. Acid hydrolysis of the ethylene ketal function gave nitro ketones **23***a*. Upon treatment with triethylamine, both isomers of **23***a* were transformed to one α,β-unsaturated ketone having structure **24***a*, which was characterized as its acetate **25***a*. This leads one to suspect that **23***a* was a mixture of isomers at C-13. Had the isomers of **23***a* differed because of difference of stereo-



SCHEME 2

chemistry at C-12, or C-12 and C-13, then acid treatment of **22***a* should have led to compounds of type **16**. In order to establish unambiguously the stereochemistry at C-12, **24***a* was hydrogenated with H_2/5% Pd–C to give **26**, which was treated under the same reaction conditions (*p*-TsOH/MeOH, 20°C) as for the transformation of **10** to **16**. No cyclic ketalization between the hydroxyl and the free carbonyl groups was observed, thus proving unambiguously that the structure assigned to **24***a* is correct.

Sodium borohydride reduction of **24***a* gave **27***a*, contaminated with products of 1,4-reduction, as a mixture of isomers at C-15, which were not separable.

Having accomplished the conversion of **6***a* to

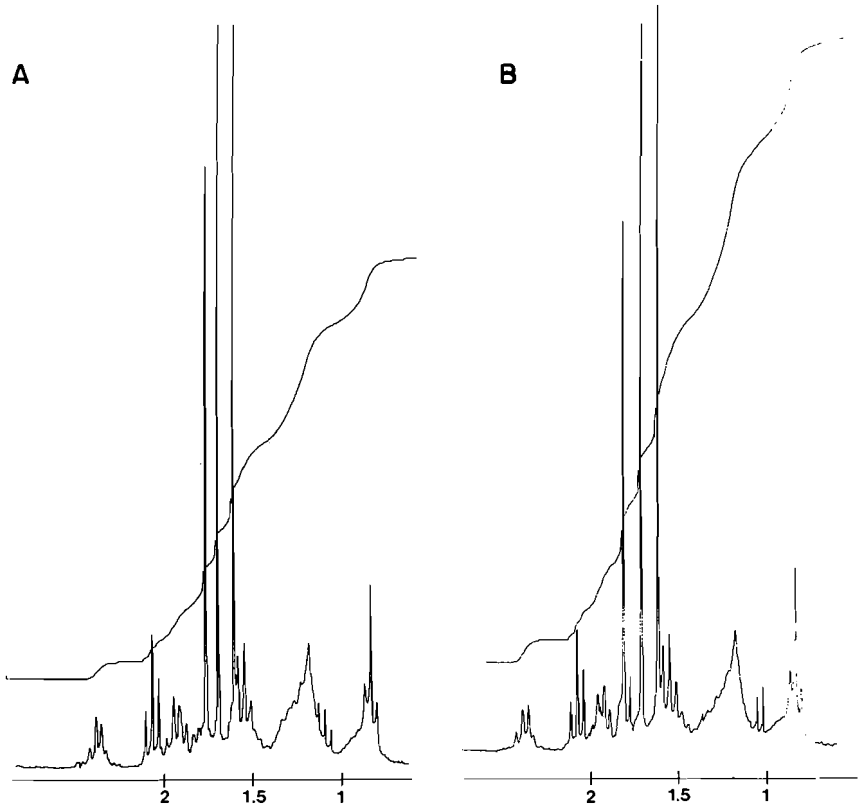


FIG. 1. 200 MHz ^{1}Hmr spectra of 8*R*,11*R*,15*S*-triacetate **32** (A) and 8*R*,11*R*,15*R*-triacetate **33** (B), betwen 0.6 and 2.6 ppm, in benzene-d_6.

27*a*, the sequence was repeated with aldehyde **6***b* (3). Except for minor details and the fact that **22***b* appeared to be one isomer only, the sequence of **24***b* paralleled the one discussed, and is the only one described in the Experimental.

Reduction of **24***b* by diisobornyloxyaluminum isopropoxide (6) gave **28***b* and **29***b* as a mixture of isomers, without contamination by 1,4-reduction products. They were cleanly separable by flash chromatography (7). Removal of the silyl protecting group of both isomers **28***b* and **29***b* by tetra-*n*-butylammonium fluoride gave the corresponding trihydroxy methyl esters **30** and **31**, respectively. They were virtually indistinguishable by mass spectrometry, ir, or ^{1}Hmr. However, the ^{1}Hmr spectra of their acetates **32** and **33** were clearly different and are reproduced in Fig. 1.

Using the method developed in our laboratory (8), the more polar fraction **30** was shown to have the *S*, and the less polar **31** the *R* configuration at C-15. Gas chromatography – mass spectra of tris-trimethylsilyl ether methyl esters of **30** and **31** showed mass spectra identical to that reported by Pace-Asciak and Wolfe (2), except for some minor differences in intensity of some peaks. The ^{1}Hmr (200 MHz) and ir spectra were all consistent with the structure proposed.

Base hydrolysis of trihydroxy methyl ester **30** gave the corresponding trihydroxy carboxylic acid **1**. Here again, the gc – mass spectrum of its tris-trimethylsilyl ether trimethylsilyl ester was identical to that of the natural product isolated by Pace-Asciak and Wolfe (2). This synthesis therefore proves the structure of **1** proposed by Pace-Asciak and Wolfe.

Experimental

Thin-layer chromatography (tlc) was performed on Merck Silica Gel 60 F_{254} aluminum-backed plates. Flash chromatography was done on Woelm Silica (32–63 μ). Melting points (mp) were measured on a Gallenkamp block and are uncorrected, unless specified otherwise. The ^{1}Hmr spectra were recorded on Varian T-60, T-60A, and where noted, XL-200 spectrometers. Infrared (ir) spectra were recorded on Perkin Elmer 257 and 297 spectrophotometers. Mass spectra (ms) were obtained on HP 5984A or LKB 9000 spectrometers, in the direct inlet mode unless indicated otherwise. Elemental analyses were performed by Midwest Microlab Ltd., Indianapolis.

Dihydroxy Dithioacetal **4**

A solution of acetonide **3** (0.978 g, 3 mmol) in ethanethiol

(3.5 mL) was cooled to −15°C in an ice–salt bath. To this was added anhydrous $ZnCl_2$ (1.4 g, 10 mmol). The flask was stoppered and allowed to stand for 30 min at −15°C. The ethanethiol was removed under diminished pressure, keeping temperature below 0°C, and the foamy residue was dissolved in ethyl acetate (30 mL). To this was added 5% aqueous $NaHCO_3$ solution (20 mL), and the white precipitate was filtered off. After separation of the organic layer, the aqueous layer was saturated with NaCl and further extracted with ethyl acetate (2 × 15 mL). The combined extracts were dried ($MgSO_4$) and concentrated to give dihydroxy dithioacetal **4** as a yellowish oil in quantitative yield; $[\alpha]_D^{23}$ −2.6° (*c* 2.65, $CHCl_3$); ir (film) ν_{max}: 3440 (OH), 2920, 1730 ($COOCH_3$) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.27 (t, 6H, *J* = 7 Hz, 2 SCH_2CH_3), 1.50–2.60 (m, 10H, 5 CH_2), 2.70 (q, 4H, *J* = 7 Hz, 2 SCH_2), 3.07–4.20 (m, 4H, 3 CH—O, SCHS), 3.44 (s, 3H, OCH_3), 3.67 (s, 3H, $COOCH_3$) ppm; ms (70 eV, 40°C), *m/e* (rel. int. %): 374 (0.3, $M^{+\cdot} - H_2O$), 345 (2.0, $M^{+\cdot} - CH_3OH - CH_3^{\cdot}$), 313 (3.8, 374 − $SC_2H_5^{\cdot}$), 257 (56.5, $M^{+\cdot}$ − 135), 239 (36.4, 257 − H_2O), 221 (7.4, 257 − $2H_2O$), 135 (86.2, $CH(SC_2H_5)_2^+$), 75 (100).

Isopropylidene Dithioacetal 5

A solution of dihydroxy dithioacetal **4** (588 mg, 1.5 mmol) and 2,2-dimethoxypropane (2 mL) in acetone (40 mL) containing a catalytic amount of *p*-toluenesulfonic acid was stirred for 30 min at room temperature. The acetone was evaporated under reduced pressure and the residual oil was dissolved in ether (20 mL). The ether solution was washed with 5% aqueous $NaHCO_3$ (2 × 20 mL), water (2 × 10 mL) and brine, dried ($MgSO_4$), and evaporated *in vacuo* to give isopropylidene dithioacetal **5** as a colorless oil in quantitative yield; ir (film) ν_{max}: 2930, 1740 ($COOCH_3$), 1437, 1380 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.25 (t, 6H, *J* = 7.5 Hz, 2 SCH_2CH_3), 1.38 and 1.43 (s and s, 6H, CMe_2), 1.62–2.63 (m, 10H, 5 CH_2), 2.74 (q, 4H, *J* = 7.5 Hz, 2 SCH_2), 3.02–4.29 (m, 4H, 3 CH—O, SCHS), 3.44 (s, 3H, OCH_3), 3.65 (s, 3H, $COOCH_3$) ppm; ms (70 eV, 52°C), *m/e* (rel. int. %): 432 (1.1, $M^{+\cdot}$), 371 (1.0, $M^{+\cdot} - SC_2H_5^{\cdot}$), 357 (7.8, $M^{+\cdot} - CH_3COOCH_3$), 297 (96.3, $M^{+\cdot}$ − 135), 293 (2.9, $M^{+\cdot} - CH_2C{\equiv}C(CH_2)_3COOCH_3^{\cdot}$), 265 (3.8, 297 − CH_3OH), 239 (34.6), 207 (44.8), 147 (60.8), 135 (32.7, $CH(SC_2H_5)_2^+$), 45 (100).

Aldehyde 6a

To a solution of dithioacetal **5** (216 mg, 0.50 mmol) in acetone (20 mL) and water (2 mL) were added HgO (976 mg, 4.5 mmol) and $HgCl_2$ (406 mg, 1.5 mmol). The heterogeneous mixture was stirred for 3 h at room temperature, and was filtered into 5% aqueous $NaHCO_3$ (20 mL); the HgO cake was washed with acetone (3 × 5 mL). Filtration and concentration to about 20 mL, followed by extraction with $CHCl_3$ (3 × 20 mL), and washing with 5% aqueous KI solution (3 × 10 mL) and water (20 mL), gave, after drying ($MgSO_4$) and evaporation *in vacuo*, crude ***6a***. Purification by flash chromatography, using petroleum ether – ethyl acetate (5:3) as eluant, afforded 123 mg (75%) of aldehyde ***6a*** as a colorless oil; $[\alpha]_D^{23}$ 11.5° (*c* 5.7, $CHCl_3$); ir (film) ν_{max}: 2990, 2935, 2820, 1736 ($COOCH_3$, CH═O), 1436, 1380 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.47 (s, 6H, CMe_2), 1.60–2.64 (m, 10H, 5 CH_2), 3.03–3.37 (m, 1H, CH—O), 3.45 (s, 3H, OCH_3), 3.68 (s, 3H, $COOCH_3$), 3.85–4.50 (m, 2H, 2 CH—O), 9.37 (s, 1H, CH═O) ppm; ms (70 eV, 41°C), *m/e* (rel. int. %): 311 (3.4, $M^{+\cdot} - CH_3^{\cdot}$), 297 (3.1, $M^{+\cdot} - CHO^{\cdot}$), 239 (2.0, $M^{+\cdot} - CH_2CH_2COOCH_3^{\cdot}$), 183 (7.8, $CH(OCH_3)CH_2C{\equiv}C(CH_2)_3COOCH_3^+$), 143 (25.7), 129 (47.3), 85 (45.1), 59 (46.7, $COOCH_3^+$), 45 (100).

Nitro Alcohols 8 and 10

A solution of aldehyde ***6a*** (326 mg, 1 mmol), β-nitro dimethyl ketal **7** (285 mg, 1.3 mmol), and diisopropylamine (152 mg, 1.5 mmol) in dry dimethylformamide (8 mL) was stirred overnight at room temperature. Water (100 mL) was added to the reaction mixture and the product was extracted with ether (3 × 20 mL). The combined extracts were washed with water (2 × 30 mL) and brine, dried ($MgSO_4$), and evaporated under reduced pressure to give crude adducts **8** and **10**. Purification by flash chromatography, using petroleum ether – ethyl acetate (7:3) as eluant, afforded 490 mg (90%) of nitro alcohols **8** and **10**, which were not separable, as a colorless oil; ir (film) ν_{max}: 3460 (OH), 2990, 2955, 2870, 1740 ($COOCH_3$), 1555 (NO_2), 1380 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.63–2.67 (m, 29H, 10 CH_2, 3 CH_3), 2.87–4.20 (m, 4H, 4 CH—O), 3.08 and 3.12 (s and s, 6H, $C(OCH_3)_2$), 3.40 (s, 3H, OCH_3), 3.63 (s, 3H, $COOCH_3$), 4.60–5.03 (m, 1H, CH—NO_2) ppm.

Nitro Acetates 9 and 11

To a solution of nitro alcohols **8** and **10** (327 mg, 0.6 mmol) in anhydrous ether (10 mL) were added acetic anhydride (73 mg, 0.72 mmol), triethylamine (85 mg, 0.84 mmol), and 4-dimethylaminopyridine (15 mg, 0.12 mmol). After 30 min at room temperature, the solution was washed with 0.1 *N* aqueous HCl (3 mL), 5% aqueous $NaHCO_3$ (2 × 5 mL), and water (2 × 10 mL), dried ($MgSO_4$), and concentrated under reduced pressure to give a 1:1 mixture of nitro acetates **9** and **11** with R_f = 0.31 and 0.40, respectively, in petroleum ether – ethyl acetate (3:1), in quantitative yield. Their spectroscopic data were virtually identical; ir (film) ν_{max}: 2995, 2960, 1758 and 1742 ($COOCH_3$, $OCOCH_3$), 1560 (NO_2), 1370, 1220 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.67–2.60 (m, 23H, 10 CH_2, CH_3), 1.37 and 1.41 (s and s, 6H, CMe_2), 2.07 (s, 3H, $OCOCH_3$), 3.03 and 3.07 (s and s, 6H, $C(OCH_3)_2$), 3.34 (s, 3H, OCH_3), 3.61 (s, 3H, $COOCH_3$), 2.90–4.13 (m, 3H, 3 CH—O), 4.80–5.20 (m, 2H, C*H*OAc, C*H*—NO_2) ppm; ms (70 eV, 61°C), *m/e* (rel. int. %): 572 (0.8, $M^{+\cdot} - CH_3^{\cdot}$), 556 (0.4, $M^{+\cdot} - OCH_3^{\cdot}$), 540 (1.3, $M^{+\cdot} - HNO_2$), 516 (3, $M^{+\cdot}$ − 71), 469 (6.3, 540 − 71), 458 (2.1, 516 − $CH_3^{\cdot}$ − $COCH_3^{\cdot}$), 448 (1.3, $M^{+\cdot}$ − 139), 404 (2.8, $M^{+\cdot}$ − 183), 346 (5.6, 404 − $CH_3^{\cdot}$ − $COCH_3^{\cdot}$), 314 (14.8, 404 − HNO_2 − $C_3H_7^{\cdot}$), 297 (12.7, $M^{+\cdot}$ − CH(OAc) − $CH(NO_2)CH_2C(OCH_3)_2C_5H_{11}^{\cdot}$), 286 (2.2, 404 − HNO_2 − 71), 254 (25.5, 314 − CH_3COOH), 183 (7.0, $CH(OCH_3)CH_2C{\equiv}C(CH_2)_3COOCH_3^+$), 145 (100, $C(OCH_3)_2C_5H_{11}^+$), 139 (8.0, $CH_2C{\equiv}C(CH_2)_3COOCH_3^+$), 71 (32, $C_5H_{11}^+$), 43 (88.7, $C_3H_7^+$, $COCH_3^+$).

Nitro Olefin 12

A mixture of nitro acetates **9** and **11** (117 mg, 0.2 mmol), powdered anhydrous K_2CO_3 (138 mg, 1 mmol), and a catalytic amount of dicyclohexyl-18-crown-6 in dry benzene (3 mL) was stirred for 5 h at 75°C under N_2 atmosphere. The solid K_2CO_3 was filtered off and, after evaporation of the solvent, the residual oil was purified by flash chromatography, using petroleum ether – ethyl acetate (8:2) as eluant, to afford 95 mg (90%) of nitro olefin **12** as a mixture of *E*- and *Z*-olefins; ir (film) ν_{max}: 2990, 2950, 1740 ($COOCH_3$), 1534 (NO_2), 1200 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.67–2.63 (m, 27H, 9 CH_2, 3 CH_3), 3.10 (bs, 2H, C(NO_2)—CH_2), 3.14 and 3.17 (s and s, 6H, $C(OCH_3)_2$), 3.42 (s, 3H, OCH_3), 3.65 (s, 3H, $COOCH_3$), 3.73–4.37 (m, 2H, 2 CH—O), 4.76 (ddd, 1H, *J* = 3, 8, 11 Hz, C═CHC*H*—O), 5.72 and 6.68 (d and d, 1H, *J* = 8 Hz, CH═C) ppm; ms (70 eV, 69°C), *m/e* (rel. int. %): 480 (0.2, $M^{+\cdot} - HNO_2$), 456 (0.6, $M^{+\cdot}$ − 71), 438 (0.3, $M^{+\cdot} - NO_2^{\cdot}$ − $C_3H_7^{\cdot}$), 344 (0.5, $M^{+\cdot}$ − 183), 286 (5.7, 344 − $CH_3^{\cdot}$ − $C_3H_7^{\cdot}$), 183 (1.7, $CH(OCH_3)CH_2C{\equiv}C(CH_2)_3COOCH_3^+$), 145 (100, $C(OCH_3)_2C_5H_{11}^+$), 139 (1.6, $CH_2C{\equiv}C(CH_2)_3COOCH_3^+$), 71 (8.3, $C_5H_{11}^+$), 43 (9.3, $C_3H_7^+$, $COCH_3^+$). *Anal.* calcd. for $C_{27}H_{45}O_9N$: C 61.48, H 8.54, N 2.66; found: C 61.70, H 8.79, N 2.39.

Bicyclic Ketal 15

A solution of more polar nitro acetate **9** (45 mg, 0.077 mmol, R_f = 0.31 in 3:1 petroleum ether – ethyl acetate) in methanol (2 mL, dried over molecular sieves) was stirred overnight at room

temperature with a catalytic amount of *p*-toluenesulfonic acid. The acid was neutralized with 5% aqueous $NaHCO_3$ solution and the methanol removed under reduced pressure. The residue was taken up in ether (20 mL), which was then washed with water (2 × 10 mL). The ether layer was dried ($MgSO_4$) and concentrated under reduced pressure. Purification by flash chromatography, using petroleum ether – ethyl acetate (3:1) as eluant, gave 27 mg (73%) of bicyclic ketal **15** as a colorless oil; ir (film) ν_{max}: 2950, 2870, 1740 ($COOCH_3$ and $OCOCH_3$), 1555 (NO_2), 1440, 1375, 1230 cm^{-1}; ^{1}Hmr 200 MHz ($CDCl_3$) δ: 0.91 (t, 3H, J = 7 Hz, CH_3), 1.13–2.55 (m, 20H, 10 CH_2), 2.07 (s, 3H, $OCOCH_3$), 3.28 (dt, 1H, J = 6, 6 Hz, C*H*—OCH_3), 3.43 (s, 3H, OCH_3), 3.68 (s, 3H, $COOCH_3$), 4.02 (dt, 1H, J = 4, 12 Hz, CH—O), 4.45–4.58 (m, 1H, CH—O), 5.10–5.25 (m, 1H, CH—NO_2), 5.38–5.47 (m, 1H, C*H*OAc) ppm; ms (70 eV, 107°C), *m/e* (rel. int. %): 437 (8.8, $M^{+\cdot} - NO_2^{\cdot}$), 377 (2.4, $M^{+\cdot} - NO_2^{\cdot} - CH_3COOH$), 345 (4.4, 377 – CH_3OH), 300 (27.2, $M^{+\cdot}$ – 183), 253 (9.5, 300 – HNO_2), 252 (8.8, $M^{+\cdot} - CH_3COOH - CH_3OH$ – 139), 240 (8, 300 – CH_3COOH), 237 (21.7, $M^{+\cdot} - CH_3COOH - HNO_2$ – 139), 209 (16.6, 252 – $C_3H_7^{\cdot}$), 196 (16.4, 253 – $C_4H_9^{\cdot}$), 193 (66.4, 253 – CH_3COOH), 183 (21, $CH(OCH_3)CH_2$-$C{\equiv}C(CH_2)_3COOCH_3^+$), 139 (8.6, $CH_2C{\equiv}C(CH_2)_3COOCH_3^+$), 99 (100), 71 (76.8, $C_5H_{11}^+$), 43 (67.7, $C_3H_7^+$, $COCH_3^+$); CI (110°C): 484 (24.5, MH^+), 406 (100, $MH^+ - HNO_2 - OCH_3^{\cdot}$), 377 (65.5, $MH^+ - HNO_2 - CH_3COOH$).

Bicyclic Ketal 16

A solution of less polar nitro acetate **11** (45 mg, 0.077 mmol, R_f = 0.40 in 3:1 petroleum ether – ethyl acetate) in methanol (2 mL, dried over molecular sieves) was stirred overnight at room temperature with a catalytic amount of *p*-toluenesulfonic acid. After neutralization with 5% aqueous $NaHCO_3$ solution and evaporation of the methanol, the residue was partitioned between ether (10 mL) and water (10 mL). The ether layer was dried ($MgSO_4$) and to this was added triethylamine (0.5 mL). The resulting solution was stirred overnight at room temperature. After the usual work-up, the crude product was purified by flash chromatography, using petroleum ether – ethyl acetate (3:1) as eluant, to afford 17 mg (50%) of bicyclic ketal **16**; ir (film) ν_{max}: 2955, 2870, 1738 ($COOCH_3$), 1553 (NO_2), 1385, 1040 cm^{-1}; ^{1}Hmr 200 MHz ($CDCl_3$) δ: 0.92 (t, 3H, J = 7 Hz, CH_3), 1.18–2.36 (m, 18H, 9 CH_2), 2.44 (t, 3H, J = 7 Hz, $COCH_2$), 3.20 (s, 3H, OCH_3), 3.47 (s, 3H, OCH_3), 3.44–3.60 (m, 1H, CH—O), 3.68 (s, 3H, $COOCH_3$), 4.21–4.30 (m, 1H, CH—O), 4.36–4.50 (m, 1H, CH—O), 4.52–4.62 (m, 1H, CH—O), 4.86–5.02 (m, 1H, CH—NO_2) ppm; ms (70 eV, 85°C), *m/e* (rel. int. %): 377 (8.2, $M^{+\cdot} - HNO_2 - OCH_3^{\cdot}$), 345 (2.8, 377 – CH_3OH), 337 (5.9, $M^{+\cdot} - HNO_2$ – 71), 269 (9.9, $M^{+\cdot} - HNO_2$ – 139), 252 (3.1, $M^{+\cdot} - CH_2{=}CHNO_2 - C_5H_{11}COOCH_3$), 237 (21.7, 269 – CH_3OH), 225 (3.4, $M^{+\cdot} - HNO_2$ – 183), 223 (7.6, 269 – $OCH_3^{\cdot} - CH_3^{\cdot}$), 194 (9.3, 225 – $OCH_3^{\cdot}$), 193 (9.6, 225 – CH_3OH), 183 (64.2, $CH(OCH_3)CH_2C{\equiv}C(CH_2)_3COOCH_3^+$), 181 (100, 269 – $OCH_3^{\cdot} - C_4H_9^{\cdot}$), 151 (37.7, 183 – CH_3OH), 139 (16.3, $CH_2C{\equiv}C(CH_2)_3COOCH_3^+$), 71 (38, $C_5H_{11}^+$); CI (80°C): 456 (27.8, MH^+), 377 (100, $MH^+ - HNO_2 - CH_3OH$).

β-*Nitro Ethylene Ketal 17*

A solution of 1-nitro-3-octanone (3.46 g, 0.02 mol), ethylene glycol (1.49 g, 0.024 mol), and *p*-toluenesulfonic acid (20 mg) in benzene (20 mL) was refluxed overnight using a Dean-Stark apparatus. The resulting solution was washed with 5% aqueous $NaHCO_3$ (15 mL) and brine, dried, and evaporated under reduced pressure. Distillation gave 3.34 g (77%) of β-nitro ethylene ketal **17** as a colorless oil (bp 88–90°C/0.02 Torr); ir (film) ν_{max}: 2950, 2870, 1552 (NO_2), 1380 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.67–1.80 (m, 11H, 4 CH_2, CH_3), 2.40 (t, 2H, J = 7 Hz, C$H_2$$CH_2NO_2$), 3.92 (s, 4H, OCH_2CH_2O), 4.40 (t, 2H, J = 7 Hz, CH_2NO_2) ppm.

Nitro Alcohol **18**b

A solution of aldehyde **6***b* (1.66 g, 3 mmol), β-nitro ethylene ketal **17** (0.847 g, 3.90 mmol), and diisopropylamine (0.455 g, 4.50 mmol) in dry dimethylformamide (25 mL) was stirred overnight at room temperature. Water (250 mL) was added to the reaction mixture and the product was extracted with ether (3 × 60 mL). The combined extracts were washed with water (2 × 100 mL) and brine, dried ($MgSO_4$), and concentrated under reduced pressure to yield crude adduct. Purification by flash chromatography, using petroleum ether – ethyl acetate (2:1) as eluant, afforded 2.08 g (90%) of nitro alcohol **18***b* as a colorless oil; ir (film) ν_{max}: 3450 (OH), 3060, 3040, 2930, 2850, 1730 ($COOCH_3$), 1545 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.67–3.10 (m, 23H, 10 CH_2, CH_3), 1.08 (s, 9H, *t*-Bu), 1.30 (s, 6H, CMe_2), 3.60 (s, 3H, $COOCH_3$), 3.87 (bs, 4H, OCH_2CH_2O), 3.40–4.04 (m, 4H, 4 CH—O), 4.63–5.10 (m, 1H, CH—NO_2), 5.12–5.40 (m, 2H, CH=CH), 7.13–7.80 (m, 10H, 2 C_6H_5) ppm; ms (20 eV, 95°C), *m/e* (rel. int. %): 608 (0.7, $M^{+\cdot} - 143 - H_2O$), 495 (26.5, $CH(CO)(OSi(t\text{-}Bu)Ph_2)CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 409 (12.7, $CH(OSi(t\text{-}Bu)Ph_2)CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 381 (64.2, $CH(CHO)(OSiPh_2)CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 353 (7.3, 381 – CO), 199 (17.3, 381 – $SiPh_2^{\cdot}$), 143 (100, $C(OCH_2$-$CH_2O)C_5H_{11}^+$), 141 (8.9, $CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 71 (10, $C_5H_{11}^+$).

*Nitro Acetate 19*b

To a solution of nitro alcohol **18***b* (1.02 g, 1.33 mmol) in anhydrous ether (20 mL) were added acetic anhydride (0.163 g, 1.60 mmol), triethylamine (0.188 g, 1.86 mmol), and 4-dimethylaminopyridine (0.033 g, 0.27 mmol). After 30 min at room temperature, the solution was washed with 0.1 *N* aqueous HCl (20 mL), 5% aqueous $NaHCO_3$ (2 × 10 mL), and water (1 × 10 mL), dried ($MgSO_4$), and evaporated *in vacuo* to give nitro acetate **19***b* as a colorless oil in quantiative yield; ir (film) ν_{max}: 3060, 2950, 2850, 1753 and 1735 ($COOCH_3$, $OCOCH_3$), 1550 (NO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.67–2.90 (m, 23H, 10 CH_2, CH_3), 1.07 (s, 9H, *t*-Bu), 1.35 (s, 6H, CMe_2), 2.01 (s, 3H, $OCOCH_3$), 3.67 (s, 3H, $COOCH_3$), 3.92 (bs, 4H, OCH_2CH_2O), 3.50–4.10 (m, 3H, 3 CH—O), 4.80–5.60 (m, 4H, CH=CH, C*H*OAc, CH—NO_2), 7.27–7.94 (m, 10 H, 2 C_6H_5) ppm; ms (70 eV, 76°C), *m/e* (rel. int. %): 811 ($M^{+\cdot}$), 796 (2.6, $M^{+\cdot} - CH_3^{\cdot}$), 740 (0.4, $M^{+\cdot} - C_5H_{11}^{\cdot}$), 696 (24.4), 693 (1.7, 740 – HNO_2), 682 (9.3), 637 (9.2, $M^{+\cdot}$ – 143 – $OCH_3^{\cdot}$), 636 (9.5, $M^{+\cdot}$ – 143 – CH_3OH), 437 (20.5, $CH(CO)(OSi(t\text{-}Bu)Ph_2)CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 409 (10.1, 437 – CO), 381 (22.8, $CH(CHO)(OSiPh_2)CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 199 (5.1, 381 – $SiPh_2^{\cdot}$), 143 (100, $C(OCH_2CH_2O)C_5H_{11}^+$). *Anal.* calcd. for $C_{44}H_{65}O_{11}NSi$: C 65.10, H 8.01, N 1.73; found: C 64.91, H 8.30, N 1.90.

*Nitro Olefin 20*b

A mixture of nitro acetate **19***b* (1.90 g, 2.34 mmol), powdered anhydrous K_2CO_3 (1.61 g, 11.7 mmol), and a catalytic amount of dicyclohexyl-18-crown-6 was stirred in dry benzene (25 mL) for 6 h at 75°C under a N_2 atmosphere. The solid K_2CO_3 was filtered off and after evaporation of the benzene, the residual oil was purified by flash chromatography, using petroleum ether – ethyl acetate (8:1) as eluant to give 1.67 g (95%) of nitro olefin **20***b* as an oil; ir (film) ν_{max}: 3060, 2950, 2925, 2850, 1735 ($COOCH_3$), 1525 (NO_2), 1423, 1106 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.67–2.40 (m, 21H, 9 CH_2, CH_3), 1.07 (s, 9H, *t*-Bu), 1.37 and 1.40 (s and s, 6H, CMe_2), 3.10 (bs, 2H, $C(NO_2)$—CH_2), 3.62 (s, 3H, $COOCH_3$), 3.80 (bs, 4H, OCH_2CH_2O), 3.60–4.00 (m, 2H, 2 CH—O), 4.36–4.90 (m, 1H, C=CHC*H*—O), 5.20–5.50 (m, 2H, CH=CH), 6.74 (d, 1H, J = 8 Hz; $C(NO_2){=}CH$), 7.17–7.80 (m, 10H, 2 C_6H_5) ppm; ms (70 eV, 119°C), *m/e* (rel. int. %): 409 (1.1, $CH(OSi(t\text{-}Bu)Ph_2)CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 381 (3.6, $CH(CHO)(OSiPh_2)CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 199 (7.6, 381 – $SiPh_2^{\cdot}$), 143 (100, $C(OCH_2CH_2O)C_5H_{11}^+$).

*Dihydroxy Nitro Olefin 21*b *and Hydroxy Tetrahydrofuran 22*b

A solution of isopropylidene nitro olefin **20***b* (975 mg, 1.30 mmol) in 2 *N* aqueous HCl (8 mL) and methanol (80 mL) was stirred for 2 h at room temperature. To this 5% aqueous $NaHCO_3$ solution was added until the solution became neutral and the methanol was removed under reduced pressure. The residue was partitioned between ethyl acetate (40 mL) and saturated salt solution (20 mL), and the aqueous layer was further extracted with ethyl acetate (2 × 20 mL). The combined extracts were dried ($MgSO_4$) and concentrated *in vacuo* to give a mixture of dihydroxy nitro olefin **21***b* and hydroxy tetrahydrofuran **22***b*. Purification by flash chromatography, using petroleum ether – ethyl acetate (3:1) as eluant, afforded 138 mg (15%) of dihydroxy nitro olefin **21***b* and 555 mg (60%) of hydroxy tetrahydrofuran **22***b*.

A solution of dihydroxy nitro olefin **21***b* (138 mg, 0.194 mmol) and triethylamine (24 mg, 0.234 mmol) in dry THF (3 mL) was stirred overnight at room temperature. The THF was removed under reduced pressure and the residue was taken up in ether (10 mL). The ether solution was washed with 0.1 *N* aqueous HCl (5 mL), 5% aqueous $NaHCO_3$ (5 mL), dried ($MgSO_4$), and concentrated *in vacuo* to give hydroxy tetrahydrofuran **22***b* in quantitative yield.

The separation of **21***b* and **22***b* proved to be unnecessary, and, in general, the mixture of **21***b* and **22***b* was submitted directly to the action of triethylamine.

Dihydroxy nitro olefin **21***b*; ^{1}Hmr ($CDCl_3$) δ: 0.67–3.30 (m, 23H, 10 CH_2, CH_3), 1.07 (s, 9H, *t*-Bu), 3.60 (s, 3H, $COOCH_3$), 3.81 (bs, 4H, OCH_2CH_2O), 3.50–3.97 (m, 2H, 2 CH—O), 4.30–4.76 (m, 1H, C=CHC*H*—O), 5.13–5.40 (m, 2H, CH=CH), 6.78 (d, 1H, J = 8 Hz, $C(NO_2)$=CH), 7.17–7.77 (m, 10H, 2 C_6H_5) ppm.

Hydroxy tetrahydrofuran **22***b*; ir (film) ν_{max}: 3460 (OH), 3065, 3040, 2950, 2925, 2850, 1737 ($COOCH_3$), 1550 (NO_2), 1423, 1105 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.63–2.93 (m, 23H, 10 CH_2, CH_3), 1.06 (s, 9H, *t*-Bu), 3.61 (s, 3H, $COOCH_3$), 3.84 (bs, 4H, OCH_2CH_2O), 3.53–4.80 (m, 5H, 4 CH—O, CH—NO_2), 5.06–5.43 (m, 2H, CH=CH), 7.17–7.83 (m, 10H, 2 C_6H_5) ppm; ms (70 eV, 96°C), *m/e* (rel. int. %): 711 ($M^{+\cdot}$), 654 (1.2, $M^{+\cdot}$ – *t*-Bu$^\cdot$), 640 (3.9, $M^{+\cdot}$ – $C_5H_{11}{}^\cdot$), 607 (3.9, 654 – HNO_2), 593 (2.3, 640 –HNO_2), 437 (3.3, $M^{+\cdot}$ – *t*-Bu$^\cdot$ – $O_2NCH_2CH_2C(OCH_2CH_2O)C_5H_{11}$), 409 (2,6, $CH(OSi(t\text{-}Bu)Ph_2)CH_2CH$=$CH(CH_2)_3COOCH_3{}^+$), 199 (25.6), 143 (100, $C(OCH_2CH_2O)C_5H_{11}{}^+$).

*Methyl 8*R-tert-*Butyldiphenylsilyloxy-11*R-*hydroxy-13-nitro-15-oxo-9*S,*12*S-*oxyeicosa-5Z-enoate 23*b

A solution of β-nitro ketal **22***b* (426 mg, 0.6 mmol) in acetone (8 mL) containing a catalytic amount of *p*-toluenesulfonic acid was stirred overnight at room temperature. The acetone was removed under reduced pressure and the residue was dissolved in ether (30 mL). The ether solution was washed with 5% aqueous $NaHCO_3$ (2 × 15 mL), water (15 mL) and brine, dried ($MgSO_4$), and concentrated to give crude product. Purification by flash chromatography, using petroleum ether – ethyl acetate (3:1) as eluant, afforded 320 mg (80%) of β-nitro ketone **23***b* as a colorless oil; ir (film) ν_{max}: 3460 (OH), 3065, 3045, 2950, 2930, 2855, 1735 ($COOCH_3$), 1720 (C=O), 1550 (NO_2), 1423, 1107 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.70–3.33 (m, 23H, 10 CH_2, CH_3), 1.07 (s, 9H, *t*-Bu), 3.60 (s, 3H, $COOCH_3$), 3.77–4.40 (m, 4H, 4 CH—O), 4.66–5.03 (m, 1H, CH—NO_2), 5.10–5.40 (m, 2H, CH=CH), 7.17–7.83 (m, 10H, 2 C_6H_5) ppm; ms (70 eV, 85°C), *m/e* (rel. int. %): 620 (1.1, $M^{+\cdot}$ – HNO_2), 610 (3.4, $M^{+\cdot}$ – *t*-Bu$^\cdot$), 593 (3.6, $M^{+\cdot}$ – CH_3COOCH_3), 563 (9.3, 610 – HNO_2), 545 (10.2, 563 – H_2O), 461 (1.0, 620 – H_2O – CH_2CH=$CH(CH_2)_3COOCH_3{}^\cdot$), 437 (5.6, 610 – $O_2NCH_2CH_2C(O)C_5H_{11}$), 409 (10.2, $CH(OSi(t\text{-}Bu)Ph_2)CH_2CH$=$CH(CH_2)_3COOCH_3{}^+$), 381 (15.3, $CH(CHO)(OSiPh_2)CH_2CH$=$CH(CH_2)_3COOCH_3{}^+$), 199 (83.1, 381 – $SiPh_2{}^\cdot$), 99 (32.8, $C(O)C_5H_{11}{}^+$).

*Methyl 8*R-tert-*Butyldiphenylsilyloxy-11*R-*hydroxy-15-oxo-9*S, *12*S-*oxyeicosa-5Z,13*E-*dienoate 24*b

A solution of β-nitro ketone **23***b* (180 mg, 0.264 mmol) and triethylamine (40 mg, 0.396 mmol) in chloroform (5 mL) was stirred overnight at room temperature. The resulting solution was washed with water (2 × 5 mL) and brine, dried ($MgSO_4$), and concentrated under reduced pressure. The residual oil was purified by flash chromatography, using petroleum ether – ethyl acetate (2:1) as eluant, to give 138 mg (85%) of α,β-unsaturated ketone **24***b* as a colorless oil; $[\alpha]_D{}^{23}$ −16.2° (*c* 1.75, $CHCl_3$); ir (film) ν_{max}: 3440 (OH), 3060, 3035, 2940, 2918, 2842, 1730 ($COOCH_3$), 1670 and 1626 (C=C—C=O), 1420, 1105 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.67–2.60 (m, 21H, 9 CH_2, CH_3), 1.07 (s, 9H, *t*-Bu), 3.62 (s, 3H, $COOCH_3$), 3.77–4.37 (m, 4H, 4 CH—O), 5.13–5.40 (m, 2H, CH=CH), 6.20 (dd, 1H, J = 1.5, 16 Hz, CH=C*H*—C=O), 6.72 (dd, 1H, J = 4.5, 16 Hz, C*H*=CH—C=O), 7.20–7.87 (m, 10H, 2 C_6H_5) ppm; ms (70 eV, 76°C), *m/e* (rel. int. %): 620 (2.1, $M^{+\cdot}$), 602 (1.1, $M^{+\cdot}$ – H_2O), 563 (19.9, $M^{+\cdot}$ – *t*-Bu$^\cdot$), 545 (19, 563 – H_2O), 531 (1.2, 602 – $C_5H_{11}{}^\cdot$), 409 (14.1, $CH(OSi(t\text{-}Bu)Ph_2)CH_2CH$=$CH(CH_2)_3COOCH_3{}^+$), 381 (20, $CH(CHO)(OSiPh_2)CH_2CH$=$CH(CH_2)_3COOCH_3{}^+$), 199 (100, 381 – $SiPh_2{}^\cdot$), 135 (80.5), 99 (38.1, $C(O)C_5H_{11}{}^+$). *Anal.* calcd. for $C_{37}H_{52}O_6Si$: C 71.62, H 8.39; found: C 71.34, H 8.37.

*Methyl 11*R-*Acetoxy-8*R-tert-*butyldiphenylsilyloxy-15-oxo-9*S, *12*S-*oxyeicosa-5Z,13*E-*dienoate 25*b

A solution of alcohol **24***b* (42 mg, 0.068 mmol), acetic anhydride (8.4 mg, 0.082 mmol), triethylamine (9.0 mg, 0.088 mmol), and a catalytic amount of 4-dimethylaminopyridine in anhydrous ether (3 mL) was stirred for 30 min at room temperature. The resulting solution was partitioned between ether (10 mL) and 0.1 *N* aqueous HCl (3 mL). The ether layer was washed with 5% aqueous $NaHCO_3$ (5 mL), water (5 mL) and brine, dried ($MgSO_4$), and evaporated under reduced pressure to afford 40 mg (90%) of acetate **25***b* as a colorless oil; $[\alpha]_D{}^{23}$ −25.1° (*c* 1.85, $CHCl_3$); ir (film) ν_{max}: 3060, 2945, 2920, 2845, 1735 ($COOCH_3$, $OCOCH_3$), 1670 and 1630 (C=C—C=O), 1420, 1230, 1104 cm^{-1}; ^{1}Hmr 200 MHz ($CDCl_3$) δ: 0.90 (t, 3H, J = 7 Hz, CH_3), 1.06 (s, 9H, *t*-Bu), 1.16–2.37 (m, 14H, 7 CH_2), 2.09 (s, 3H, $OCOCH_3$), 2.21 (t, 2H, J = 7 Hz, CH=CHCOCH_2), 2.47 (t, 2H, J = 7 Hz, CH_2—COO), 3.65 (s, 3H, $COOCH_3$), 3.98 (td, 1H, J = 4,8 Hz, CH—O), 4.06–4.20 (m, 1H, CH—O), 4.39 (ddd, 1H, J = 1.8, 3.5, 4.7 Hz, C*H*—CH=CH—C=O), 4.92–5.04 (m, 1H, C*H*OAc), 5.26–5.48 (m, 2H, CH=CH), 6.26 (dd, 1H, J = 1.8, 16 Hz, CH=C*H*—C=O), 6.72 (dd, 1H, J = 4.7, 16 Hz, C*H*—CH—C=O), 7.32–7.82 (m, 10H, 2 C_6H_5) ppm; ms (70 eV, 79°C), *m/e* (rel. int. %): 662 (0.4, $M^{+\cdot}$), 631 (2.0, $M^{+\cdot}$ – $OCH_3{}^\cdot$), 605 (45.7, $M^{+\cdot}$ – *t*-Bu$^\cdot$), 563 (5, $M^{+\cdot}$ – 99), 545 (33, 605 – CH_3COOH), 521 (1.4, $M^{+\cdot}$ – 141), 461 (11, 521 – CH_3COOH), 409 (17.2, $CH(OSi(t\text{-}Bu)Ph_2)CH_2CH$=$CH(CH_2)_3COOCH_3{}^+$), 381 (52.7, $CH(CHO)(OSiPh_2)CH_2CH$=$CH(CH_2)_3COOCH_3{}^+$), 199 (94.4, 381 – $SiPh_2{}^\cdot$), 141 (8, CH_2CH=$CH(CH_2)_3COOCH_3{}^+$), 135 (78.9), 99 (35.6, $C(O)C_5H_{11}{}^+$), 71 (20.5, $C_5H_{11}{}^+$), 43 (100, $C_3H_7{}^+$, $COCH_3{}^+$).

*Methyl 11*R-*Hydroxy-8*R-*methoxy-15-oxo-9*S,*12*S-*oxyeicosa-5Z-enoate 26*

A solution of α,β-unsaturated ketone **24***a* (64 mg, 0.163 mmol) in absolute ethanol (2 mL) containing 5% Pd–C (13 mg) was hydrogenated for 30 min at atmospheric pressure until hydrogen uptake stopped. After filtration, the ethanol was removed under reduced pressure to give ketone **26** in quantitative yield; ir (film) ν_{max}: 3440 (OH), 2950, 2920, 1730 ($COOCH_3$), 1705 (C=O), 1430 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.67–2.77 (m, 25H, 11 CH_2, CH_3), 3.33 (s, 3H, OCH_3), 3.58 (s, 3H, $COOCH_3$), 3.0–4.33 (m, 4H, 4 CH—O), 5.20–5.46 (m, 2H, CH=CH) ppm.

*Methyl 8*R-tert-*Butyldiphenylsilyloxy-11*R,*15(*S *and* R)-*dihydroxy-9*S,*12*S-*oxyeicosa-5*Z,*13*E-*dienoates 28*b *and 29*b

To a solution of α,β-unsaturated ketone **24***b* (102 mg, 0.165 mmol) in dry toluene (4 mL) was added a solution of 0.3 *M* diisobornyloxyaluminum isopropoxide (5) in toluene (1.12 mL, 0.336 mmol). The reaction mixture was stirred under a nitrogen atmosphere for 2 h at room temperature and partitioned between ethyl acetate (15 mL) and 5% aqueous KH_2PO_4 (pH = 4.1–4.5, 10 mL). The organic layer was separated and the aqueous layer further extracted with ethyl acetate (10 mL). The combined extracts were washed with water (10 mL) and brine, dried ($MgSO_4$), and concentrated under reduced pressure. Purification by flash chromatography, using petroleum ether – ethyl acetate (1:1) as eluant, afforded 82 mg (80%) of allylic alcohols as an approximately 5.5 : 4.5 isomeric mixture at C-15 (**28***b* R_f = 0.23 and **29***b* R_f = 0.33). The two isomers were cleanly separated by hplc, using petroleum ether – ethyl acetate (2:1) as eluant. Allylic alcohol **28***b* with R_f = 0.23; $[\alpha]_D^{23}$ −16.2° (*c* 2.1, $CHCl_3$); ir (film) ν_{max}: 3395 (OH), 3070, 3050, 2950, 2930, 2855, 1736 ($COOCH_3$), 1585, 1423, 1106 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.67–2.53 (m, 21H, 9 CH_2, CH_3), 1.06 (s, 9H, *t*-Bu), 3.62 (s, 3H, $COOCH_3$), 3.73–4.38 (m, 5H, 5 CH—O), 5.11–5.45 (m, 2H, *Z* CH=CH), 5.48–5.78 (m, 2H, *E* CH=CH), 7.20–7.84 (m, 10H, 2 C_6H_5) ppm; gc–ms (1.5% OV-101, 280°C, 70 eV, di-trimethylsilylated **28***b*), *m/e* (rel. int. %): 766 (0.6, $M^{+\cdot}$), 751 (0.9, $M^{+\cdot}$ – $CH_3^{\cdot}$), 709 (0.8, $M^{+\cdot}$ – *t*-Bu$^{\cdot}$), 676 (2.1, $M^{+\cdot}$ – Me_3SiOH), 625 (1.3, $M^{+\cdot}$ – 141), 619 (30.6, 676 – *t*-Bu$^{\cdot}$), 586 (1.1, $M^{+\cdot}$ – 2Me_3SiOH), 535 (6.7, 676 – 141), 503 (1.9, 676 – 173), 477 (1.3, 676 – 199), 409 (9, $CH(OSi(t\text{-}Bu)Ph_2)CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 381 (60.5, $CH(CHO)(OSiPh_2)CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 199 (38.1, $CH{=}CHCH(OSiMe_3)C_5H_{11}^+$), 173 (12, $CH(OSiMe_3)C_5H_{11}^+$), 141 (4.4, $CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 135 (63.9), 73 (100, $SiMe_3^+$).

Allylic alcohol **29***b* with R_f = 0.33; $[\alpha]_D^{23}$ −23.4° (*c* 2.5, $CHCl_3$); its ^{1}Hmr, ir, and ms data were virtually the same as compound **28***b* described above.

*Methyl 8*R,*11*R,*15*S-*Trihydroxy-9*S,*12*S-*oxyeicosa-5*Z,*13*E-*dienoate 30*

To a solution of silyl ether **28***b* (50 mg, 0.081 mmol) in dry THF (2 mL) was added a solution of 1 *M* *n*-Bu_4NF in dry THF (0.12 mL, 0.12 mmol) via a syringe, and the resulting solution was stirred for 7 h at 65°C under a N_2 atmosphere. The THF was removed under reduced pressure and the residue was taken up in ethyl acetate (10 mL). The solution was then washed with brine and the aqueous layer was further extracted with ethyl acetate (5 mL). The combined extracts were dried ($MgSO_4$) and concentrated under reduced pressure. The crude product was purified by flash chromatography, using ethyl acetate as eluant, to give 26 mg (85%) of trihydroxy methyl ester **30** as a white solid (mp 44–45.5°C); $[\alpha]_D^{23}$ −16.4° (*c* 0.95, $CHCl_3$); ir (film) ν_{max}: 3400 (OH), 2955, 2930, 2860, 1735 ($COOCH_3$), 1436 cm^{-1}; ^{1}Hmr 200 MHz ($CDCl_3$) δ: 0.89 (t, 3H, *J* = 7 Hz, CH_3), 1.18–2.46 (m, 18H, 9 CH_2), 3.68 (s, 3H, $COOCH_3$), 3.74–4.28 (m, 5H, 5 CH—O), 5.40–5.60 (m, 2H, *Z* CH=CH), 5.66 (dd, 1H, *J* = 8, 16 Hz, *E* C*H*=CH), 5.83 (dd, 1H, *J* = 7, 16 Hz, *E* CH=C*H*) ppm; gc–ms (1.5% OV-101, 220°C, 70 eV, tris-trimethylsilylated **30**), *m/e* (rel. int. %): 600 (2.0, $M^{+\cdot}$), 510 (13.8, $M^{+\cdot}$ – Me_3SiOH), 495 (3.4, 510 – $CH_3^{\cdot}$), 479 (2.8, 510 – $OCH_3^{\cdot}$), 459 (7.6, $M^{+\cdot}$ – $CH_2CH{=}CH(CH_2)_3COOCH_3^{\cdot}$), 439 (5.9, 510 – $C_5H_{11}^{\cdot}$), 420 (2.6, $M^{+\cdot}$ – 2 Me_3SiOH), 369 (53.4, 459 – Me_3SiOH), 357 (6.8, $M^{+\cdot}$ – 243), 337 (14, 510 – 173), 279 (17.6, 459 – 2 Me_3SiOH), 267 (11.7, 510 – 243), 243 (77.3, $CH(OSiMe_3)CH_2CH{=}CH(CH_2)_3COOCH_3^+$), 211 (11.8, 243 – CH_3OH), 199 (10.2, $CH{=}CHCH(OSiMe_3)C_5H_{11}^+$), 173 (23, $CH(OSiMe_3)C_5H_{11}^+$), 147 (20.1), 129 (46.8), 73 (100, $SiMe_3^+$).

Compound **31** was prepared from the corresponding silyl ether **29***b* as described above for the preparation of compound **30** in 90% yield (mp 52–53.5°C); $[\alpha]_D^{23}$ −28.6° (*c* 1.4, $CHCl_3$). Its ^{1}Hmr, ir, and ms data were virtually the same as compound **30**.

*8*R,*11*R, *15*S-*Trihydroxy-9*S,*12*S-*oxyeicosa-5*Z,*13*E-*dienoic acid 1*

To a solution of trihydroxy methyl ester **30** (18 mg, 0.047 mmol) in methanol (0.5 mL) was added 0.5 *N* aqueous methanolic NaOH (CH_3OH–H_2O = 7:3, 0.4 mL) and the resulting solution was stirred overnight at room temperature. NaOH was neutralized with glacial acetic acid. After evaporation of the solvent, the residue was dissolved in ethyl acetate (5 mL). The solution was washed with brine (3 mL) and the aqueous layer was further extracted with ethyl acetate (2 × 3 mL). The combined extracts were dried ($MgSO_4$) and concentrated under reduced pressure to give 15 mg (85%) of trihydroxy carboxylic acid **1**; ir (film) ν_{max}: 3370 (OH), 2960, 2930, 2860, 1710 (C=O) cm^{-1}; ^{1}Hmr 200 MHz ($CDCl_3$) δ: 0.88 (t, 3H, *J* = 7 Hz, CH_3), 1.18–2.50 (m, 18H, 9 CH_2), 3.58–4.44 (m, 5H, 5 CH—O), 5.34–5.94 (m, 4H, 2 CH=CH) ppm; gc–ms (1.5% OV-101, 240°C, 70 eV, fully trimethylsilylated **1**), *m/e* (rel. int. %): 658 (0.9, $M^{+\cdot}$), 643 (1.7, $M^{+\cdot}$ – $CH_3^{\cdot}$), 568 (10.5, $M^{+\cdot}$ – Me_3SiOH), 553 (4.4, 568 – $CH_3^{\cdot}$), 497 (2.7, 568 – $C_5H_{11}^{\cdot}$), 478 (3.1, $M^{+\cdot}$ – 2 Me_3SiOH), 459 (4.3, $M^{+\cdot}$ – $CH_2CH{=}CH(CH_2)_3COOSiMe_3^{\cdot}$), 395 (6.6, 568 – $CH(OSiMe_3)C_5H_{11}^{\cdot}$), 369 (34.6, 459 – Me_3SiOH), 357 (4,6 $M^{+\cdot}$ – 301), 301 (49.3, $CH(OSiMe_3)CH_2CH{=}CH(CH_2)_3COOSiMe_3^+$), 279 (12.1, 459 – 2 Me_3SiOH), 272 (30.6), 267 (12.0, 357 – Me_3SiOH), 211 (22.9, 301 – Me_3SiOH), 199 (9.7, $CH{=}CHCH(OSiMe_3)C_5H_{11}^+$, $CH_2CH{=}CH(CH_2)_3COOSiMe_3^+$), 191 (22.9), 173 (20.0, $CH(OSiMe_3)C_5H_{11}^+$), 147 (29.1), 129 (47.8), 75 (63.0), 73 (100, $SiMe_3^+$).

General Micromethod for the Determination of the Absolute Chemistry at C-15 of 30

Trihydroxy methyl ester **30** (1 mg, 2.6 μmol) was acetylated using a standard method. Ozone was bubbled into a solution of triacetate **32** in dry CH_2Cl_2 (35 mL) at a rate of 8 mmol/h at −78°C for 5 min. After excess ozone was removed by flushing with N_2 at −78°C, dimethylsulfide (2 mL) was added and stirred overnight at room temperature. The residue, after evaporation of the solvent, was taken up in ether (5 mL) and washed with water (2 × 10 mL) and brine. Concentration under reduced pressure gave crude 2-acetoxyheptanal. A solution of 2-acetoxyheptanal thus obtained and excess 1-ephedrine in CH_2Cl_2 (2 mL) was stirred for 1 h at room temperature. It was then diluted with ether (10 mL) and washed with water (3 × 5 mL) and brine. Evaporation and purification by column chromatography, using petroleum ether – ethyl acetate (9:1) as eluant, gave the oxazolidine derivative. Its R_f value (0.33, in petroleum ether – ethyl acetate 5:1) and 200 MHz ^{1}Hmr spectrum were identical with those of the authentic material with known stereochemistry (8).

Received November 21, 1980

HELEN ELAINE HOWARD-LOCK, COLIN JAMES LYNE LOCK, GRAHAM TURNER, and MARUTA ZVAGULIS. Can. J. Chem. **59**, 2737 (1981).

Crystals of *cis*-dichlorobis(cyclopropylamine)platinum(II), $PtCl_2(C_3H_5NH_2)_2$, are monoclinic, $a = 12.770(5)$, $b = 5.838(2)$, $c = 15.113(6)$ Å, $\beta = 104.46(3)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares to $R = 0.057$, $R_w = 0.055$ for 1577 reflections with $I > 3\sigma(I)$. Bond lengths and angles are normal. A vibrational analysis of the compound and its d_2-deuterated analogue was performed.

HELEN ELAINE HOWARD-LOCK, COLIN JAMES LYNE LOCK, GRAHAM TURNER et MARUTA ZVAGULIS. Can. J. Chem. **59**, 2737 (1981).

Les cristaux de dichloro bis(cyclopropylamine)platine(II) *cis*-$PtCl_2(C_3H_5HN_2)_2$ sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec $a = 12,770(5)$, $b = 5,838(2)$, $c = 15,113(6)$ Å, $\beta = 104,46(3)°$, $Z = 4$. On a résolu la structure par les synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'a des valeurs de $R = 0,057$ et de $R_w = 0,055$ pour 1577 réflexions avec $I > 3\sigma(I)$. Les angles et les liaisons ont des longueurs normales. On a réalisé une analyse vibrationnelle du composé et de son analogue deutéré d_2.

Introduction

cis-Dichlorodiammineplatinum(II) has been shown to be a useful anti-cancer agent both in animals and in man (1–8). Further studies have shown that other amine complexes also show anti-tumor activity in animals (1–8), and in particular, that certain cyclic amine complexes are very effective against some animal tumors (9, 10).[2] It has been suggested that the differences in the efficacies of the various complexes are related to structural features of the complexes (10), but until recently few, if any, accurate structures of these platinum amine complexes had been determined. We are currently determining the crystal structures of selected amine complexes of platinum and report here the results of our studies on *cis*-dichlorobis(cyclopropylamine)-platinum(II).

Experiments

Preparation of cis-*Dichlorobis(cyclopropylamine-*N)-*platinum(II), $PtCl_2(C_3H_5NH_2)_2$*

The method used is a modification of the method of Dhara (11).

An aqueous solution (10 mL) of K_2PtCl_4 (0.4272 g) was mixed with potassium iodide (0.6563 g) and left at room temperature for a few hours. Cyclopropylamine (0.12 g) was added dropwise and the yellow product filtered off after a half-hour. The product was stirred in 0.1 *M* aqueous silver nitrate solution (19 mL) for approximately 6 h. After removal of silver iodide by filtration, potassium chloride (0.15 g) was added to the filtrate. The yellow product separated over the course of a week and was removed by filtration, washed with a small amount of ice water, followed by ethanol and diethyl ether. Crystals suitable for X-ray diffraction studies were obtained by recrystallization from water at 20°C. *Anal.* calcd. for $C_6H_{14}Cl_2N_2Pt$: C 19.0, H 3.7, N 7.4; found: C 19.2, H 3.9, N 7.0.

Preparation of $PtCl_2(ND_2C_3H_5)_2$

Deuterated cyclopropylamine (0.1464 g) was added dropwise to a solution of K_2PtCl_4 (0.5221 g) in D_2O (10 mL) and left overnight at room temperature. The pale yellow powder which formed was collected by filtration, washed with a small amount of D_2O and cold acetone.

Preparation of $C_3H_5ND_2$

Cyclopropylamine (2.3240 g) was reacted with 1 *N* HCl (40 mL). The water was removed under vacuum on a rotary evaporator at ~40°C. The hydrochloride salt was dissolved in D_2O (50 mL) and allowed to stand in a stoppered flask at room temperature for 2 weeks. The D_2O was removed under vacuum on a rotary evaporator and the white powder redissolved in a minimum of D_2O (3 mL). Sodium bicarbonate (3.4319 g) was added and the solution left overnight. The deuterated amine was distilled from the solution at reduced pressure with gentle warming (~40°C).

Spectral Measurements

Infrared spectra of the platinum complexes were measured in Nujol and hexachlorobutadiene mulls suspended between potassium bromide or polyethylene windows. The amines were diluted with CCl_4 and run between potassium bromide windows with a CCl_4 reference. Spectra were recorded on a Perkin-Elmer PE 283 spectrometer between 4000–200 cm^{-1}. The cell compartment was flushed with dry nitrogen for several hours before spectra were recorded in the 400–200 cm^{-1} region.

Raman spectra were excited with ~100 mW of λ5145 Å radiation from a Spectra-Physics Model 164-02 Argon ion laser. Crystalline samples were contained in glass melting point tubes and liquid samples in nmr tubes. Radiation scattered at 90° to the incident beam was analysed with scanning double monochromators (Coderg PHO or Spex 14018). A rough intensity calibration was obtained by comparison with carbon tetrachloride standards. The spectrometer was calibrated regularly against an indene standard, and had been calibrated previously with a neon lamp; the wavelength readout scale was found not to change. The vibrational spectra are reported in Tables 4 and 5.

Collection of the X-ray Diffraction Data

A pale yellow crystal, chosen after examination under a polarizing microscope for homogeneity, was mounted on a glass fibre with the crystal 061 direction roughly parallel to the fibre axis. Precession photographs were obtained from a fit of χ, ϕ, and 2θ for 15 medium angle ($20° < 2\theta < 35°$) reflections recorded on a Syntex $P\bar{1}$ diffractometer using graphite-monochromated MoKα radiation ($\lambda = 0.71069$ Å at 22°C). Crystal data and other numbers related to data collection are summarized in Table 1. The density was determined by flotation in an aqueous zinc bromide solution. Intensity data were also recorded on the Syntex $P\bar{1}$ diffractometer using a coupled θ(crystal)–2θ(counter) scan. The methods of selection of scan rates and initial data treatment have been described (12, 13). Corrections were made for Lorentz-polarization effects and absorption.

Solution of the Structure

The coordinates of the platinum atom were found from a three-dimensional Patterson synthesis, and three-dimensional electron density difference maps revealed the remaining non-hydrogen atoms. After refinement the temperature factors of all the atoms, which were previously isotropic, were made sequentially anisotropic. Tests were made at each stage to show that the use of the increased parameters was significant (14). Further refinement using full least-squares refinement minimizing $\Sigma w(|F_o| - |F_c|)^2$, was terminated when the maximum shift/error was 0.006. Corrections for secondary extinction were made by the method of Larson (15).

Throughout the refinement, the scattering curves were taken from the International Tables (ref. 16, Table 2.2A, pp. 72ff), and anomalous dispersion corrections from International Tables (ref. 16, Table 2.3.1, pp. 149–150) were applied to the curves for platinum and chlorine. The atom parameters for the non-hydrogen atoms are listed in Table 2.[3]

Crystal data are given in Table 1.

Results and Discussion

Our earliest attempts to prepare *cis*-dichlorobis(cyclopropylamine)platinum(II) were based on the method of Connors *et al.* (9), which involves the reaction of cyclopropylamine hydrochloride with K_2PtCl_4 in water in the presence of sodium bicarbonate. We did obtain the mixture of black powder and yellow crystals described by the above authors, but the subsequent recrystallization from hot concentrated hydrochloric acid gave, in our laboratory, ammonium hexachloroplatinate. The product was identified uniquely both by powder and single crystal X-ray diffraction. We have repeated this preparation a number of times with the same result. On one occasion we did obtain a rather impure crystalline mass, where the crystals were needle-like in form, but a subsequent recrystallization, using the method of Connors *et al.* (9), again gave ammonium hexachloroplatinate.

It appears that under the conditions of recrystallization of our compound a reaction is taking place together with oxidation, by air, of Pt(II) to Pt(IV).[4] We did not pursue this further as it proved possible to get crystals, suitable for X-ray purposes, using the preparative method of Dhara (11).

The Structure

The molecule is illustrated in Fig. 1 and selected interatomic distances and angles are given in Table 2. The bonded ligand atoms are in a rough square around the platinum atom. The arrangement of the five atoms is essentially planar. The deviations from the best plane (Pt, 0.006(1); Cl(1), −0.003(4); Cl(2), 0.004(4); N(1), −0.04(1); N(2), 0.03(1) Å) are not significant.

The Pt—N distances (2.05(1), 2.04(1)) (Table 3)

[3] A table of the moduli for F_o and F_c is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

All calculations were carried out on CDC 6400 or CYBER 170/730 computers. Initial data treatment used programs from the XRAY 76 package (18). The structure was solved using internally written Fourier and full-matrix least-squares programs SYMFOU and CUDLS written by J. S. Rutherford and J. S. Stephens respectively. The least-squares planes were calculated using NRC-22 (19) and diagrams were prepared using ORTEP II (20).

[4] Discussions with Professor Tobe have revealed that the reason we did not obtain *cis*-dichlorobis(cyclopropylamine)-platinum(II) is that the procedure in the literature (10) is inaccurate. Instead of recrystallization from hot concentrated hydrochloric acid as reported, the correct procedure should call for the product to be leached with hot concentrated hydrochloric acid, when the material insoluble in hydrochloric acid is the desired product. We have confirmed by powder diffraction examination of the product that this is indeed the case.

†The temperature factor parameters U_{ij} were obtained from $\beta_{ij} - 2\pi^2 b_i b_j U_{ij}$ where β_{ij}'s appear as a temperature effect through $\exp[-(\beta_{11}h^2 + \ldots + \beta_{12}hk + \ldots)]$ in the structure factor expression and b_i are the reciprocal lattice vectors.

are normal as are the Pt—Cl distances (2.273(4), 2.286(5)) (21–24). All distances and angles within the amine group are normal (25). The dihedral angles between the best plane through the ligand atoms and the cyclopropyl groups are relatively small (3.9° for C(1)C(2)C(3) and 26.0° for C(4)C(5)-C(6)), and this is probably caused by crystal packing since there appear to be no intramolecular steric interactions requiring the planes to be parallel (see below). The amine group is in the *gauche* arrangement with respect to the cyclopropyl ring. (Torsion angles PtN(1)C(1)⟨C(2)C(3)⟩, 136(1)°, PtN(2)C(4)⟨C(5)C(6)⟩, 127(1)°), where ⟨C(A)C(B)⟩ is the midpoint of C(A)—C(B)).

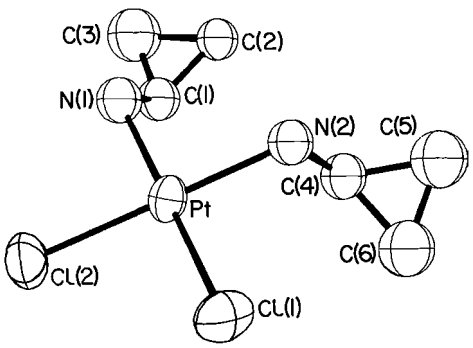

FIG. 1. *cis*-Dichlorobis(cyclopropylamine)platinum(II) showing the atom numbering.

The packing of the molecules within the cell is shown in Fig. 2. In the ***b*** direction molecules related by the *y* translation were packed head to tail, and inclined relative to the ***ab*** plane such that the square ligand planes were stacked roughly like tiles on a roof. The prime contacts were between N(1)···Cl(2), 3.35(1) Å, and N(2)···Cl(1), 3.25(1) Å, suggesting hydrogen bonding between the atom pairs. Hydrogen bonding also played a part in the packing in the ***a*** direction. The molecules related by x,y,z and $1-x, -y, -z$ had Cl(1)···N(2) contacts of 3.37(1) Å. The other contact in the ***a*** direction was between a chlorine atom on one molecule and the cyclopropyl group on the next. Thus the crystal was composed of layers of molecules centred at roughly $z = 0$ and $z = 1/2$ and within the layers rows of molecules arranged so that the dipoles were very roughly parallel to the ***b*** direction. In adjacent rows the dipoles point in opposite directions. Contact between rows (in different layers) was almost entirely between chlorine and platinum atoms of one mole-

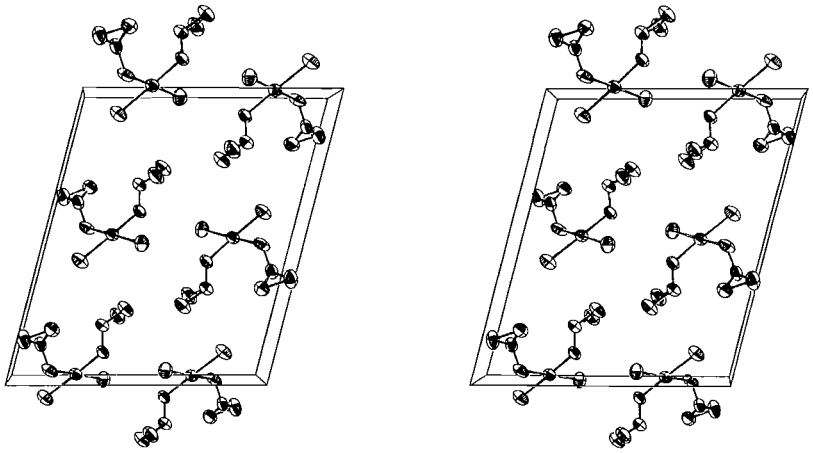

FIG. 2. The packing of the molecule within the unit cell. *a* and *c* are parallel to the bottom and side of the page respectively and the view is down *b*.

cule and the cyclopropyl groups of the adjacent molecule. There was no evidence of hydrogen bonding between layers. Other than the distances specifically enumerated above, all contact distances mentioned were greater than or equal to van der Waals contact distances.

The Vibrational Spectra

The infrared and Raman spectra of cyclopropylamine, the d_2-deuterated analogue and platinum complexes of the two ligands were recorded and examined. The cyclopropylamine spectrum was essentially the same as that reported by Kalasinsky *et al.* (26) with minor variations in wave number for some bands. We also report the spectrum of the analogue, deuterated at the amine, and the polarization ratios for both ligands, which have not been reported previously. The spectra are very similar, the only changes being those associated with the ND_2 group. These absorptions are shifted to lower wave number (ND_2 asym. str. 2533 ir, 2520 R, ND_2 sym. str. 2476 ir, 2474 R, ND_2 def. 1231 ir, ND_2 wag, 680 ir, ND_2 rock, 630 ir, ND_2 twist, not observed), the ratio ν_H/ν_D being 1.31–1.34. The complete spectra and assignments are listed in Table 5.

By studying the isotopic shifts in the ligand and the complex as well as bands exclusive to the complex, and by comparison with other platinum complexes, we have been able to assign most of the bands. These assignments together with the observed frequencies are shown in Table 4. The spectra for the complex in the ligand region are much less simple than those for the free ligand, firstly because there is a pair of symmetric and asymmetric modes for each vibration of the pure ligand; secondly because some modes shift on complexing and some do not; and finally because there may be interactions between the vibrations of the crystallographically inequivalent cyclopropylamine groups.

NH_2 and CH_2 Stretches and Deformations

The NH_2 stretching vibrations are shifted to lower energies ($\sim 100\,cm^{-1}$) in the complexes as compared with the ligand, as are the deformations ($\sim 50\,cm^{-1}$). The ratio $\nu_{ligand}/\nu_{complex} \cong 1.04$. The ND_2 shifts for these motions are in the ratio $\nu_H/\nu_D = 1.34–1.36$ for the complexes. Similar assignments have been made previously for several ethylenediamineplatinum(II) complexes (27).

The CH_2 stretching vibrational frequencies for the complexes are close to those observed for the ligand (for which the higher one is more intense in the infrared, and the lower one is more intense in the Raman and polarized). The positions are typical for the somewhat strained three-membered ring (28).

The CH stretch was assigned previously (26), on the basis of band contours, to the infrared band at $2975\,cm^{-1}$ for cyclopropylamine vapour. There are no distinct bands in the complexes that can be so assigned, but our $2965\,cm^{-1}$ ligand band disappears in the complexes and it is possible that this vibration occurs at a higher wave number in the complexes because of additional strain and is lost under the $—CH_2$ absorptions. Pairs of bands for the complex at 1462 and $1430\,cm^{-1}$ which do not shift on deuteration are assigned to the CH_2 symmetric and asymmetric deformations. These are very close to the pure ligand frequencies.

The pair of bands at $1370\,cm^{-1}$ is assigned to the CH bend (in-plane); it occurs at slightly higher energy in the complexes ($\nu_{complex}/\nu_{ligand} = 1.01$), and is slightly affected by deuteration, ($\nu_H/\nu_D = 1.01–1.02$). A similar assignment ($1374\,cm^{-1}$) was previously made for the ligand (26). The CH bend (out-of-plane) for the ligand (solid phase spectra) was previously assigned as $1026\,cm^{-1}$ (26). This frequency was not observed in our solution spectra of the ligand; for the complexes, it could be hidden under the $1030\,cm^{-1}$ bands which are broad in the infrared spectra, and the 1010 and $1012\,cm^{-1}$ bands for the d_2-complex have some additional intensity. Such an assignment would give the same $\nu_{complex}/\nu_{ligand}$ and ν_H/ν_D ratios that were noted for the CH in-plane bend.

The middle frequency range of the spectra ($1300\,cm^{-1} - 700\,cm^{-1}$) contains many bands with overlaps, intensity variations, and deuterium shifts in several ratios. There will obviously be some ambiguities and some of the assignments must be considered to be tentative. We have, however, succeeded in making reasonable assignments for all the observed bands, and will indicate where the anomalies lie.

Twisting, Wagging, and Rocking Vibrations

The $—NH_2$ twisting vibration is assigned to the $1267, 1260\,cm^{-1}$ bands (982, 975 d_2-complex, ν_H/ν_D ratio 1.29). This vibration is unique to the complexes. The corresponding motion in the ligand is a hindered rotation which was observed at fairly low energy ($254\,cm^{-1}$) in the infrared spectrum (26).

The NH_2 wags for the complexes are assigned by us to bands at $1122\,cm^{-1}$ ($887\,cm^{-1}$, $\nu_H/\nu_D = 1.26$) and $958\,cm^{-1}$ ($785\,cm^{-1}$, $\nu_H/\nu_D = 1.22$). The NH_2 rocks are assigned to bands at 757, $724\,cm^{-1}$ (618, $593\,cm^{-1}$, $\nu_H/\nu_D = 1.22$). The correlating ligand bands occur at $680\,cm^{-1}$ (ND_2 wag) and 826(630) cm^{-1} (rock), which is in disagreement with previous assignments (26), probably in part because of different nomenclature. The infrared spectrum of the d_2-ligand exhibits a shoulder at $680\,cm^{-1}$ on the broad, very intense $630\,cm^{-1}$ band. We assign $680\,cm^{-1}$ to the ND_2 wag. If the ν_H/ν_D ratios are 1.31 for both the rock and the wag, then the NH_2 wag would have a wave number of $890\,cm^{-1}$, and would be masked by the very broad ($250\,cm^{-1}$) group centred at $826\,cm^{-1}$.

Our ordering for these NH_2 group deformation modes is consistent with the usual ordering for similar CH_2 modes (28). The deuterium shift ratios are less than for the NH_2 stretching vibrations, more so for the complexes than for the ligands, a difference which would be expected as a result of moderately strong coupling with the skeletal motions.

The general order for CH_2 group vibrations is twist > wag > rock (28). Twisting vibrations usually result in lower intensity absorptions than wagging vibrations. We observe ligand bands at 1170, 1100; 1014, 1044; and 759, $826\,cm^{-1}$, which are assigned to pairs of twists, wags, and rocks respectively. These bands show no shifts on deuteration and the assignments are in agreement with previous work (26) except where noted. We observe bands for the complexes at 1170 and 1110, 1094; 1034, 1029 and 1068, 1050; and 744 and 829, 820 which are not affected by deuteration and which are similarly assigned. The 1170 band in the d_2-complex is not observed directly and appears to be lost under the $1180–1158\,cm^{-1}$ group where the upper band is quite broad and has weak components at 1179, 1172, and $1167\,cm^{-1}$. The $820\,cm^{-1}$ group is somewhat weaker in the d_2-complex, and it is possible that this frequency represents two or more overlapping bands, one of which is shifted.

Ring Deformation and CN Vibrations

The ring breathing mode for the ligand is observed at $1210–1214\,cm^{-1}$ in agreement with Kalasinsky *et al.* (26) who assigned the band at this wave number to the more stable *trans* configuration and a vapour phase Raman band at $1220\,cm^{-1}$ to the

gauche conformer. In the complex the ligand takes on the *gauche* configuration (see Fig. 1), and therefore an intense pair of bands at $\sim 1220\,cm^{-1}$ which shows no shift on deuteration is assigned to the ring breathing mode. This band is intensified in the d_2-complex by the overtone of $618\,cm^{-1}$.

The other two ligand ring deformations have been assigned to bands at $971\,cm^{-1}$ (*gauche*, vapour, ir, and Raman) and $884\,cm^{-1}$ (vapour, ir, and Raman) (26). We observe ligand bands at $968\,cm^{-1}$ and $880\,cm^{-1}$ and assign them as asymmetric (infrared inactive) and symmetric ring deformations respectively. For the complexes one expects considerable coupling between ring modes, CN stretching, and NH_2 group deformations and the assignments must be considered tentative, particularly as there are some changes in relative intensity in the $800\,cm^{-1}$ region: our preferred assignments for the complexes are 933, $921\,cm^{-1}$ (887, $880\,cm^{-1}$, $\nu_H/\nu_D = 1.05$); 845, 850 (850, $857\,cm^{-1}$, no shift). The 933, $921\,cm^{-1}$ bands are so close to the $958\,cm^{-1}$ NH_2 wag that coupling is likely and a slight deuterium shift is reasonable.

Alternatively it is to be noted that the $820\,cm^{-1}$ band which is assigned to the CH_2 rock is broader and has greater relative intensity in the h_2-complex than in the d_2-complex. This fact suggests that it represents more than one band, and that part of it shifts on deuteration. A shift from 820 to $785\,cm^{-1}$ (ratio 1.05), for example, might be reasonable for a ring deformation. The band at $785\,cm^{-1}$, which has been assigned as the ND_2 wag, also has enough intensity and breadth to encompass an extra band.

We assign the intense pair of bands at 1215, $1204\,cm^{-1}$ (1010, $1000\,cm^{-1}$, $\nu_H/\nu_D = 1.2$) to the C—N stretch. The $1215\,cm^{-1}$ region in the h_2-complex is complicated by Fermi resonance with the first overtone of the Pt—N stretch, as well as by strong coupling with both the NH_2 twisting vibration, and particularly the very intense symmetric ring breathing mode. In the ligand a band at $1145\,cm^{-1}$ was assigned to the C—N stretch ($\nu_H/\nu_D = 1.19$) and hence there is a shift to higher energy in the complex in the ratio 1.06.

A C—N—Pt deformation is assigned to the band at $406\,cm^{-1}$ ($353\,cm^{-1}$, $\nu_H/\nu_D = 1.15$).

The platinum–nitrogen stretching motions are exclusive to the complex and occur to the higher end of the frequency range for such vibrations in other platinum–nitrogen complexes (29). The bands at 601, $593\,cm^{-1}$ (555, 549) are assigned as the symmetric and asymmetric vibrations on the basis of Raman intensities. The ν_H/ν_D ratio is 1.08, indicating moderately weak coupling with an NH_2 vibration.

The platinum–chlorine stretching vibrations are observed at $333\,cm^{-1}$ (symmetric) and $302\,cm^{-1}$ (asymmetric) with no shift on deuteration. The predicted chlorine isotope effect is a splitting into three components of relative intensity 9:6:1. A splitting is observed for the totally symmetric vibration (333, 326, $317\,cm^{-1}$) but the middle com-

A crystallographic and spectroscopic study of mercury(II) dithiocarbamate

CHUNG CHIEH AND SING KWEN CHEUNG

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received February 24, 1981

CHUNG CHIEH and SING KWEN CHEUNG. Can. J. Chem. **59**, 2746 (1981).

Ammonium dithiocarbamate, $H_2NCS_2NH_4$, decomposes easily but the anion forms a stable mercury(II) complex, the crystals of which are orthorhombic with $a = 7.851(3)$, $b = 17.565(7)$, $c = 12.051(3)$ Å, and space group *Pbca*. The structure was solved by the Patterson method and refined by the full-matrix least-squares method to an R of 0.038 for 781 reflections. The structure consists of layers of two-dimensional polymeric networks. The dimeric subunits in the layer containing two each of mutually connected Hg atoms and dithiocarbamates are further linked by other bridging dithiocarbamates forming a sheet-like structure. Each Hg atom bonds to four S atoms from four separate dithiocarbamates with Hg—S distances of 2.499(4), 2.508(4), 2.533(4), and 2.629(4) Å. The ir bands observed were: $\nu(NH_2)$, 3320, 3220, 3125; $\delta(NH_2)$, 1600; ν(C—N), 1395; $\rho_r(NH_2)$, 1172; and ν(C—S), 840 cm^{-1}. The mass spectrum of this polymeric compound gave peaks corresponding to Hg, S_2, CNH_2, HNCS, S, CS_2, S_5, S_4, S_3, and S_8 in the order of their intensities.

CHUNG CHIEH et SING KWEN CHEUNG. Can. J. Chem. **59**, 2746 (1981).

Le dithiocarbamate d'ammonium, $H_2NCS_2NH_4$, se décompose facilement mais l'anion forme un complexe stable de mercure(II) dont les cristaux sont orthorhombiques avec $a = 7,851(3)$, $b = 17,565(2)$, $c = 12,051(3)$ Å, groupe d'espace *Pbca*. On a résolu la structure par la méthode de Patterson et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur de $R = 0,038$ pour 781 réflexions. La structure comprend des couches d'un réseau polymérisé bidimensionnel. Les sous unités dimères de la couche contiennent deux atomes de Hg et deux dithiocarbamates reliés l'un à l'autre et qui sont de plus reliés à d'autres dithiocarbamates formant ainsi une structure lamellaire. Chaque atome de mercure est lié à 4 atomes de soufre provenant de quatre dithiocarbamates avec les distances Hg—S = 2,499(4), 2,508(4), 2,533(4) et 2,629(4) Å. On a observé les bandes ir suivantes: $\nu(NH_2)$, 3320, 3220, 3125; $\delta(NH_2)$, 1660; ν(C—N), 1395; $\rho_r(NH_2)$, 1172; et ν(C—S), 840 cm^{-1}. Le spectre de masse de ce composé polymérisé donne des pics correspondants à Hg, S_2, CNH_2, HNCS, S, CS_2, S_5, S_4, S_3 et S_8 dans l'ordre de leurs intensités.

[Traduit par le journal]

Introduction

In our study of interaction between mercury(II) ion and tetraethylthiuram disulfide (1), we encountered and reported many crystal structures of dithiocarbamate complexes (2–5). Results from these structures indicate that mercury(II) and dithiocarbamates bond in various ways and the complexes formed depend not only on the solvent used, but also on the concentration of halide ions which are often incorporated into the complex.

Most dithiocarbamate or xanthate complexes of heavy metals have short metal-to-sulfur bonds (6). Their structural features led us to believe that these dithio acids might be potentially useful for removing metal ions from industrial waste waters. Therefore, we have explored further the properties of these dithio acids.

The ammonium salt of the first member of dithiocarbamates, $H_2NCS_2^-$, is not stable at 298 K. Although its formation from reaction between ammonia and carbon disulfide was noted as early as 1850 by Debus (7), and improved methods for its preparation were patented in 1940 and 1941 (8), structural studies on metal complexes of this compound are scarce (9). Two crystal structures of mercury(II) *N*,*N*-diethyldithiocarbamate were reported by Iwasaki (10), who indicated to us in May 1980 that he was refining the structure of mercury(II) *N*,*N*-dimethyldithiocarbamate. The structural features of these compounds and those published by us suggested that mercury(II) ion might form a compound with $H_2NCS_2^-$ through the coordination of sulfur atoms, thus stabilizing the anion. Indeed, mercury(II) dithiocarbamate was the first stable complex obtained in this laboratory and here we report its crystal structure as determined by X-ray diffraction.

Experimental

Chemicals and solvents used in these experiments were of reagent grade from BDH. Ammonium dithiocarbamate was prepared by the method described in ref. 11. The mass spectrum was measured on a VG 7070 (by VG Micromass) by electron bombardment. The ir spectrum was obtained on a Perkin Elmer 457 using KBr pellets.

Preparation of Mercury(II) Dithiocarbamate

This experiment was carried out in a cold room (273 K).

To 15 mL aqueous/ethanol (50/50 by volume) solution of ammonium dithiocarbamate (0.004 mol), 10 mL ethanol solution of $HgCl_2$ (0.002 mol) was added slowly. A white precipitate (A) which formed instantly was filtered off. The clear filtrate was allowed to evaporate slowly and colorless crystals (B) were obtained amongst a black material (HgS) resulting from decomposition. In an attempt to recrystallize the white precipitate A, it was suspended in an aqueous/ethanol solution and the white slurry turned black after a few hours. The filtrate from this yielded crystals similar to B when dried. The crystals were stable with no deterioration even when irradiated by X-rays. Although some well-formed crystals were covered with a thin

layer of black material, others could be visually identified as colorless.

Crystallographic Study

A prismatic crystal with dimensions of 0.20 × 0.18 × 0.10 mm was mounted on a Syntex $P2_1$ computer-controlled diffractometer and a rotation photograph was taken. Film coordinates of 15 reflections were measured; their angles were calculated and refined by repetitive measurements. These were used to determine cell constants and the orientation matrix. The space group was determined by noting the systematics of unobserved reflections.

Crystal Data

$C_2H_4HgN_2S_4$ fw = 384.9

Orthorhombic, a = 7.851(3), b = 17.565(7), c = 12.051(3) Å, V = 1662(1) Å^3. Space group *Pbca* (D_{2h}^{15} No. 61). D_o = 3.05(4) (by flotation in a mixture of *s*-tetrabromoethane and diiodomethane), Z = 8, D_c = 3.076 g cm^{-3}. mp = 438–439 K, λ(Mo Kα) = 0.71069 Å.

A total of 781 reflections with $2\theta \leq 45°$ was measured; those with F less than $\sigma(F)$ were given a value of $0.25*\sigma(F)$. They were all used in the structural analysis; no absorption correction was made. The structure was solved by the heavy-atom method and refined by full-matrix least-squares using the SHELX system (12). Anisotropic temperature factors were given to all non-hydrogen atoms and positions for the H atoms of the $—NH_2$ group were estimated from a difference Fourier map. These were included in the last cycle of the 93-variable least-squares with the isotropic temperature factor, U, of the H maintained constant at 0.05. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with $w = 1/\sigma^2(F)$. The final R and R_w factors were 0.039 and 0.044 respectively. The atomic parameters are given in Table 1.[1]

Results and Discussion

Many methods for the preparation of ammonium dithiocarbamate have been described in the literature, and we have tried various ways. The use of ether/ethanol as a solvent as described in ref. 11 for the reaction between NH_3 and CS_2 gave a reasonably pure crop of $H_2HCS_2NH_4$ and the product was even stable at 298 K for at least a day, provided it remained in the solvent. The yellow ammonium dithiocarbamate crystals changed to a liquid form when they were in contact with air at 298 K, possibly due to the absorption of moisture.

However, the crystal of its mercury complex was stable and the intensities of the checking reflections did not decline throughout the course of data collection. We further examined the stability of mercury(II) dithiocarbamate by carrying out the reactions in either absolute ethanol or water. Mercury(II) dithiocarbamate formed in an absolute ethanol solution was creamy white and no coloration was observed if kept under a dry N_2 atmosphere. This precipitate turned yellow when exposed to air. Mercury(II) chloride reacted with ammonium dithiocarbamate in an aqueous solution giving a similar precipitate, but it turned black in a few hours; these products are being studied. The crystal used in this study was prepared by reaction of $H_2NCS_2NH_4$ and $HgCl_2$ in an aqueous/ethanol solution at 273 K.

*$B = 8\pi^2 \sum_{i=1}^{3} U_{ii}/3$.

The simple formula of mercury dithiocarbamate $Hg(S_2CNH_2)_2$ does not represent the structure in the crystal, which consists of layers of networks as shown in Fig. 1. This network can be understood easily by employing a topological pattern, see Fig. 2. The subunits in the layer are dimers which contain two each of mutually connected mercury atoms, M, and dithiocarbamates, X. The center of this subunit is represented by B in Fig. 1. These dimers are further linked by bridging dithiocarbamate into a two-dimensional sheet extending to the

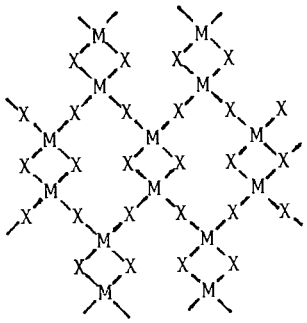

FIG. 2. Topological pattern of the layer structure.

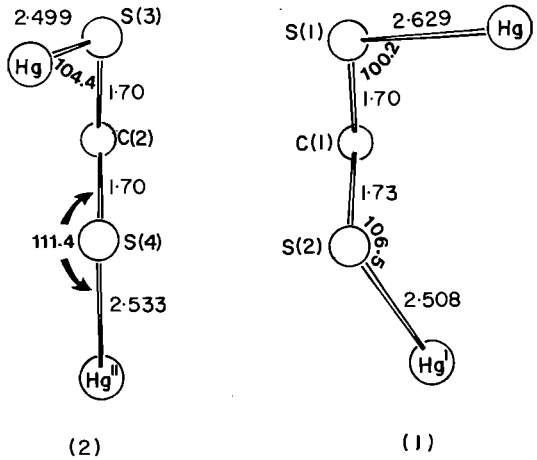

FIG. 3. The relative positions of the mercury atoms as seen from the C—NH_2 direction of the dithiocarbamates. (*1*) The anion bonded to two Hg atoms forming the dimeric subunit. (Hg′ at $-x, 1-y, 1-z$); (*2*) the anion linking the dimeric subunit into a two dimensional sheet. Standard deviations are σ(Hg—S) = 0.004 Å, σ(C—S) = 0.02 Å, σ(Hg—S—C) = 0.5° (Hg″ at $0.5+x, 0.5-y, 1-z$).

sides of the crystals. Two types of rings are found in the sheet structure, an 8-membered ring in the dimeric subunits and a 16-membered ring involving 4 dithiocarbamates and 4 subunits. The centers of these rings are crystallographic centers of symmetry. The 8-membered ring adopted an extended chair form. The *c* axis goes through the centers of the 8- and the 16-membered rings alternately, i.e. layers stack up switching their positions A and B in the [0 0 1] direction.

Each mercury atom is bonded to four sulfur atoms with Hg—S distances ranging from 2.499(4) to 2.629(4) Å (see Fig. 3). The six angles are S(1)HgS(2), 100.9; S(1)HgS(3), 108.7; S(1)HgS(4), 112.3; S(2)HgS(3), 113.3; S(2)HgS(4), 119.9; and S(3)HgS(4), 101.6°, all with standard deviation of 0.1°. Thus the coordination is distorted tetrahedral.

There is an interesting difference in the positions of the bonded mercury atoms with respect to the planes defined by the four atoms of the NCS_2 group. Both the Hg atoms (deviations: Hg, 2.35; Hg′, 1.17A) are on the same side of the NCS_2 plane of the dithiocarbamate in the dimeric subunits as shown in Fig. 3, which shows the views along the C—N bond for the anions. For the other dithiocarbamate, only one Hg atom deviates significantly from the NCS plane, (deviations: Hg, −1.07 and Hg″, 0.14 Å). These differences may account for the nonequivalence of the Hg—S bonds or the SHgS angles as given above. However, the C—S distances are virtually identical, as are the C—N bonds with a mean of 1.32 Å. These distances are in good agreement with those of nickel bis(dithiocarbamate), in which case, the two anions coordinate to one Ni atom as bidentate chelating ligands. The difference between bidentate and bridging coordination is in the SCS angles: for the Ni complex the mean value is 111.8(1.2)°, whereas for the Hg complex, they are 119.2(5) and 121.5(5)° respectively, for the ligands labeled as C(1) and C(2).

Despite the difference in bonding between the nickel and mercury complexes of dithiocarbamate, they exhibit similar ir spectra, which consist of five well separated bands in the sodium chloride optics region (13). A normal coordinate analysis for dithiocarbamate complexes of Pd, Pt, Ni, Co, Cr, and Cd led to the assignment of the bands at ~3200 cm^{-1} to NH_2 stretching, 1600 cm^{-1} to NH_2 bending, 1400 cm^{-1} to C—N stretching, 1225 cm^{-1} to NH_2 rocking, and 800 cm^{-1} to C—S stretching (14). For the mercury complex, these bands have their maxima at 3125 (a triplet with two other maxima at 3320 and 3220), 1600, 1395, 1172, and 840 cm^{-1}, respectively. From the published data on ir spectra, it appears that NH_2 bending and the C—N stretching modes of Ni, Pt, and Pd complexes are 30 cm^{-1} higher, whereas the ν(C—S) is 10 cm^{-1} lower than those of the mercury complex. The Hg—S band was not in this region.

After the crystal structure was determined, we were curious as to whether we could obtain a mass spectrum for such a 2-dimensional polymeric compound. Indeed, its mass spectrum showed some simple, but interesting fragmentations. Using the natural abundances of isotopes as guides, we clearly identified peaks due to Hg, S_2, CNH_2, HNCS, S, S_6, CS_2, S_5, S_4, S_3, and S_8 in the order of their intensities.

It is perhaps interesting to point out that the use of the computer assisted "Self-Training Interpretive and Retrieval System" (STIRS) (15, 16) suggested the possible substructures of azide, NNN, disulfide, SS, and phenothiazine. None of the suggested possible compounds resemble mercury

For personal use only.

dithiocarbamate. The compound does not contain disulfide linkage, but the presence of S_2 peaks led the system to suggest the disulfide as a possible substructure. Although this is a sulfur-rich compound, it might still be a surprise to find the S_6 peak more intense than those of S_4. The formation of the latter can be rationalized by the collapse of the four S atoms after the liberation of the Hg atom. However, there are many ways by which the S_6 can be formed and the stability of this 6-membered species may contribute to its high intensity. If we neglect the total count due to the various isotopes of mercury, S_2 peaks are the strongest. There are two possibilities: fragmentation from a single dithiocarbamate or from two anions.

Quantum yields in the photolytic oxidation of some sulphur compounds

D. F. SHERATON AND F. E. MURRAY

Department of Chemical Engineering, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received August 11, 1980[1]

D. F. SHERATON and F. E. MURRAY. Can. J. Chem. **59**, 2750 (1981).

The photolytic oxidation of methyl mercaptan, dimethyl sulphide, and dimethyl disulphide was studied in a batch photolysis apparatus. Short wavelength ultraviolet light was provided by a deuterium discharge lamp and monitored by a monochromator equipped with an extended response photomultiplyer tube. Sulphide concentrations were determined using a gas chromatograph equipped with a flame photometric detector having a sulphur response at 365 nm.

The rate of photo-oxidation of methyl mercaptan was found to be a linear function of the photon absorption rate and exhibited a quantum yield of 12. The methyl mercaptan photo-oxidation rate was found to be unaffected by increased oxygen concentration, decreased atmospheric pressure, or the presence of sulphur dioxide.

The quantum yield of dimethyl sulphide photo-oxidation was found to be dependent upon air pressure; the quantum yield of 4 at 1 atm pressure increased to 8 at $\frac{1}{4}$ atm.

The quantum yield of dimethyl disulphide photo-oxidation in air was found to be 1.9 at atmospheric pressure and a disulphide concentration of 7.04×10^{-5} *M*.

D. F. SHERATON et F. E. MURRAY. Can. J. Chem. **59**, 2750 (1981).

Utilisant un appareil à photolyse en discontinu, on a étudié l'oxydation photolytique du méthylmercaptan, du sulfure de diméthyle et du disulfure de diméthyle. On a utilisé une lumière ultraviolette de courte longueur d'onde fournie par une lampe à décharge au deutérium et enregistrée par un monochromateur équippé d'un tube photomultiplicateur à réponse prolongée. On a déterminé les concentrations en sulfure à l'aide d'un chromatographe muni d'un détecteur photométrique à flamme sensible au soufre à 365 nm.

On trouve que la vitesse d'oxydation photochimique du méthylmercaptan est linéaire en fonction de la vitesse d'absorption du photon et présente un rendement quantique de 12. On a trouvé que la vitesse d'oxydation photochimique du méthylmercaptan n'est pas affectée par une augmentation de la concentration en oxygène, par la diminution de la pression atmosphérique ou par la présence du bioxyde de soufre.

On a trouvé que le rendement quantique de l'oxydation photochimique du sulfure de diméthyle dépend de la pression d'air; le rendement quantique qui est de 4 à la pression atmosphérique passe à 8 à une pression de 0,25 atmosphère.

Dans le cas du disulfure de diméthyle le rendement quantique dans l'air est de 1,9 à la pression atmosphérique pour une concentration en disulfure de $7,04 \times 10^{-5}$ *M*.

[Traduit par le journal]

Introduction

A number of process industries generate bivalent sulphur compounds, some of which are emitted to the atmosphere. These compounds include methyl mercaptan (CH_3SH), dimethyl sulphide (CH_3SCH_3), and dimethyl disulphide (CH_3SSCH_3). They have odour thresholds in air of 2, 1, and 16 ppb, respectively (1).

The major mode of sulphide removal in the atmosphere is believed to be oxidation to SO_2 and SO_3, likely followed by washout through precipitation. The rate of thermal oxidation at atmospheric temperatures is rather low; however, the gases are capable of absorbing ultraviolet light which leads to oxidation of the sulphur to SO_2. Although the intensity of solar radiation at wavelengths below 300 nm is low at ground level, it is probably significant in the conversion of bivalent sulphur compounds to sulphur dioxide.

Rayner and Murray (2) determined that sulphides in air would oxidize when exposed to solar radiation and more rapidly under ultraviolet light. Short wavelength uv (254 nm) was found to be superior to longer wavelength (360 nm) and the order of reactivities was found to be

$$CH_3SH > (CH_3)_2S_2 \gg (CH_3)_2S$$

The oxidation of $(CH_3)_2S$ was found to be very slow.

In this study, the absorption spectra of CH_3SH,

SO_2, CH_3SCH_3 and CH_3SSCH_3 were measured using incident radiation from a deuterium source. Results of these measurements are shown in Figs. 1 and 2. For methyl mercaptan, the wavelength at which the maximum absorption of radiant energy occurred was 235 nm, corresponding to a photon energy of 121.6 kcal/einstein. This frequency was dependent not only on the absorbance but also on the radiation intensity from the chosen source at that wavelength. This energy is in excess of the bond energy for the bonds of interest by 32.8 kcal/mol for S—H scission, 46.4 kcal/mol for C—S scission, and 54.6 kcal/mol for S—S scission.

The primary modes of CH_3SH decomposition reported in the literature are:

$$CH_3SH + h\nu \rightarrow CH_3S + H \text{ (refs. 3, 4 to 21)}$$
$$\rightarrow CH_3 + SH$$

$$CH_3SCH_3 + h\nu \rightarrow CH_3S + CH_3 \text{ (refs. 7, 22)}$$

$$CH_3SSCH_3 + h\nu \rightarrow 2CH_3S \text{ (refs. 3, 7, 23 to 25)}$$

The mercaptan scission has been found to occur primarily at the S—H bond with C—S scission becoming more important at shorter wavelengths. This suggests that the photo-energized CH_3SH^* molecule attains a state where the S—H bonding force is repulsive and thus dissociation occurs with the production of the H atom. The dissociation also produces CH_3S, CH_3, and SH fragments, each of which is highly reactive.

Experimental

The reactions were performed in a parallel-ended, grease-free tubular reactor designed to transmit wavelengths down to 180 nm. Illumination was provided by a medium-pressure deuterium discharge lamp collimated by two quartz lenses. The polychromatic illumination passed through a fully illuminated 25-mm diameter, Teflon-sealed, 10 cm Pyrex reaction vessel fitted with 1.5 mm-thick Suprasil windows. Transmitted light was analysed using a Jarrel-Ash 0.25 meter monochromator. Exiting radiation of 0.25 nm bandwidth was measured by an EMT 9558QBM photomultiplyer.

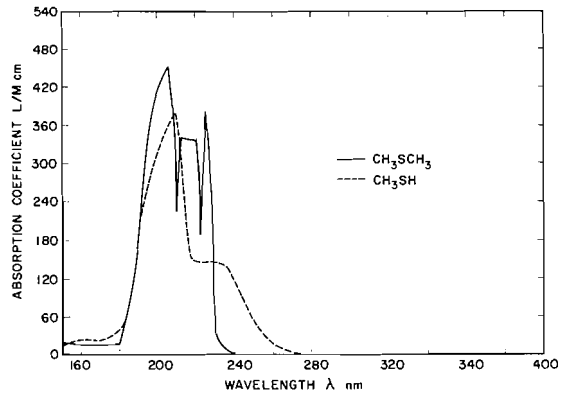

FIG. 2. The polychromatic absorption coefficients for CH_3SCH_3 and CH_3SH.

The sulphide gas concentrations were measured using a Varian gas chromatograph equipped with a Tracor flame photometric detector. The separation was carried out on a Carbopak BHT-100 column (1/8 in. × 5 ft) operated at 65°C. The chromatograph was calibrated for analysis of CH_3SH, CH_3SCH_3, SO_2, and CH_3SSCH_3.

The incident radiation intensity was measured using potassium ferrioxalate solution actinometry operated within the limits recommended by Nicodem *et al.* (26). The total incident intensity from the radiation source was first determined. A borosilicate glass filter was then inserted in the incident beam to eliminate radiant energy of wavelengths shorter than 320 nm. The incident energy in the wavelength range of interest, 180 to 320 nm, was obtained by difference. The ferrioxalate solution absorbed all of the incident radiation in the wavelength range of 180 to 320 nm.

The fraction of the incident radiation, in the wavelength range 180 to 320 nm, which was absorbed by the sulphur compound under study, was obtained by graphical integration. A spectrum of the radiation transmitted through an air-filled cell was used as the baseline. A spectrum of the radiation transmitted through the cell containing a mixture of air and the sulphur compound provided the additional data needed to determine the radiant energy absorbed by the sulphur compound. Rates of photo-oxidation were measured as soon as possible after initiation. No corrections were made for reflection from the cell windows. Calculations based on the refractive index of the windows indicated that the error involved from reflections would be less than 1% of the absorbed energy.

Calibration of the chromatograph was the first step in the experimental procedure. The reaction cells were swept with bottled air passed through drierite, molecular sieve 5A, and filtered through a Whatman Gamma 12 grade 10 filter to remove water vapour, oils, and small particles. The optical path was swept with 1 CFH of dry N_2 for a minimum of 12 h before the start of the run. The air-filled reaction cells were placed in the beam and a transmission spectrum was run on each cell. This measure of the air-filled cell light output for each run was used to correct for lamp changes and end-window fogging.

The CH_3SH was supplied by the Matheson Co. and contained no other components identifiable with the chromatograph. The CH_3SCH_3 and CH_3SSCH_3 were supplied by the Eastman Kodak Co. Gases were transferred by Hamilton Gas-Tite syringes and liquids were transferred using Hamilton micro-litre syringes.

The cells were allowed to sit for 30 min before measurement of the initial concentration. The cell was placed in the reaction position and a second transmission spectrum was measured when the illumination was begun. The area between the spectra when the cell was filled with air and with added sulphide provided the measure of light absorption by the sulphide and formed the basis for calculating quantum yield. The monochromator was then set for continuous measurements at 290 nm to observe the production of gases absorbing at that wavelength. On completion of radiation, the cells were allowed to equilibrate in the dark for ½/h. The contents were then analysed for H_2S, CH_3SH, SO_2, and CH_3SSCH_3. After analysis the cells were flushed with dry air.

Results

(a) Irradiation of Dimethyl Sulphide in Air

The results observed during irradiation of dim-

1.71	0.25	6.46	64.2	8.0	2.9	6

ethyl sulphide in air are shown in Table 1. The quantum yield of CH_3SCH_3 photo-oxidation was found to increase as the total pressure in the reaction vessel was decreased. Reaction rates were low, coinciding with the low level of energy absorption by CH_3SCH_3. At wavelengths below 300 nm, CH_3SCH_3 absorbed only 4% of the incident radiation.

(b) Irradiation of Dimethyl Disulphide in Air

The quantum yield of CH_3SSCH_3 photo-oxidation was found to be 2 at a concentration of 7.05×10^{-5} M in air at a total pressure of 1 atm. Results obtained with dimethyl disulphide are given in Table 2.

(c) Irradiation of Methyl Mercaptan in Air

Extensive studies on the photolysis of methyl mercaptan in air showed that the reaction rate is a linear function of the photon absorption rate, Fig. 3. The absorption of short wavelength radiation was found also to be a function of CH_3SH concentration, Fig. 4. Thus, it was concluded that the reaction occurred as a result of photon absorption by methyl mercaptan and not by oxygen.

Reactions were conducted in an oxygen atmosphere to assess further the possible role of oxygen initiation. No significant change in the rate of methyl mercaptan photo-oxidation resulted from change in the oxygen partial pressure from 0.2 to 1 atm. These observations also tend to show that ozone is not a significant factor in the photo-oxidation of CH_3SH.

Other experiments of a preliminary nature indicated that unfiltered room air or moist air in the reactor yielded erratic results. This problem was averted by using filtered and dried bottled air. It is apparent that the reaction rate is sensitive to the presence of moisture or other components in the air used.

The results observed for methyl mercaptan photo-oxidation are given in Table 3. The quantum yield indicates the number of CH_3SH molecules decomposed per photon absorbed by the sulphide gas.

TABLE 2. The quantum yield of CH_3SSCH_3 photo-oxidation

$[(CH_3)_2S_2]$ $\times 10^5$ M	Percentage absorbance	Reaction rate $\times$ 10^6 g/h	Quantum yield	Std. dev.	No. of expts.
7.05	28.4	93.6	2.0	0.940	40
14.1	42.8	90.5	1.3	0.825	7

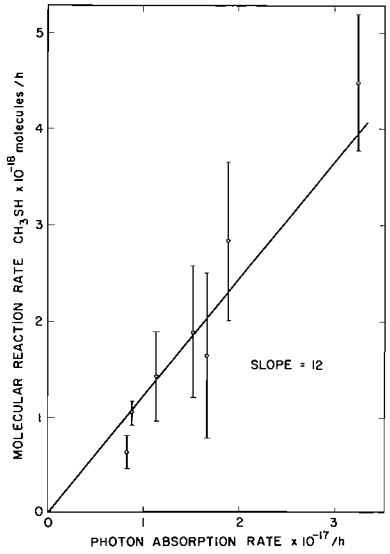

FIG. 3. Molecular reaction rate of CH_3SH as a function of photon absorption rate.

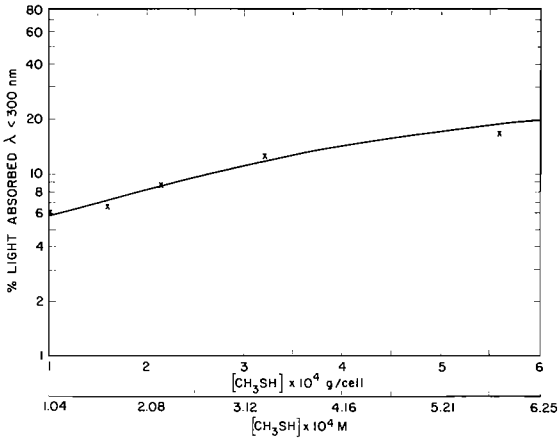

FIG. 4. Polychromatic light absorption as a function of CH_3SH concentration.

The average value of ϕ_{-SH} is 12 so that, in the concentration range studied (5.56×10^{-5} M to 2.78×10^{-4} M), the reaction may be described by the linear relationship:

$$R_{-SH} = 12\, I_a$$

Standard deviation = 4.16

No. of expts. = 85

Changes in air pressure in the reactor did not affect the quantum yield of CH_3SH removal.

The effect of SO_2 on CH_3SH photo-oxidation was studied by adding SO_2 to the air–mercaptan mixture in the photolysis cell. Addition of SO_2 did not cause any significant change in the rate of CH_3SH decomposition. There was, however, absorption of radiation by the SO_2 and the yield of CH_3SH per photon absorbed was reduced, although the quantum yield of mercaptan oxidation remained unchanged (Table 4).

The major reaction products found in all CH_3SH photo-oxidations were SO_2 and CH_3SSCH_3. There were two further unidentified peaks in the chromatographic trace, one after CH_3SH and the other a broad, low peak which emerged from the column after 1 h at 100°C.

A yellow oil appeared on the cell walls concentrated about the entrance end. The oil was likely a polymerized sulphur-containing product. A chromatographic analysis of the reaction products revealed a disulphide to sulphur dioxide formation ratio of $[CH_3SSCH_3]/[SO_2] = 0.633$. This indicates the methyl thiyl combination rate to be 1.26 times the oxidation rate to SO_2 at atmospheric oxygen concentrations.

A sulphur balance was examined using both chromatographic and spectroscopic techniques. The spectroscopic technique relied on the absorption coefficients of the reactant and product gases at 290 nm. The methyl mercaptan has a very low absorption coefficient at 290 nm whereas SO_2 and CH_3SSCH_3 have appreciable absorbancies.

When chromatographic data is used for a sulphur balance, 38.3% of the sulphur lost as CH_3SH appears as CH_3SSCH_3 or SO_2. If chromatographic data for CH_3SH and SO_2 are combined with absorption spectral information at 290 nm to estimate CH_3SSCH_3, the apparent concentration of disulphide obtained exceeds by a factor of 3.24 the disulphide analysis by gas chromatograph indicating the presence of other products which have significant absorption at 290 nm.

TABLE 3. Quantum yields in CH_3SH photolysis*

$[CH_3SH]$ × 10^5 M	I_a eins × 10^{10}	ϕ_{-SH}	Std. dev.	No. of expts.	ϕ_{SO_2}	ϕ_{SS}

*ϕ_{-SH} = quantum yield of CH_3SH removal; ϕ_{SO_2} = quantum yield of SO_2 production; ϕ_{SS} = quantum yield of CH_3SSCH_3 production.

TABLE 4. The effect of added SO_2 on CH_3SH photo-oxidation

$[CH_3SH]$ × 10^5 M	$[SO_2]$ × 10^5 M	CH_3SH Reaction rate × 10^6 g/h	% Absorbed light
5.85	0.	53.05	6.13
5.85	5.85	57.2	15.05
5.85	11.16	53.5	32.3

These other products probably give rise to the chromatographic peak after that of CH_3SH (at 7 min) and to the low broad peak at 1 h at 100°C. The identity of the small peaks has not been established.

The sulphur balance indicates the presence of an appreciable amount of sulphur in forms other than SO_2 or $(CH_3)_2S_2$. These are likely higher polysulphides and are probably involved in forming the oily deposit which clouded the entrance area of the reactant vessel. A similar deposit has been reported by other workers (4, 7, 14, 22, 27–29). The deposit has been reported insoluble in H_2O, CCl_4, $CHCl_3$, CH_3OH, or acetone (30) but is soluble in CS_2 (27). The cell could be cleaned by baking in air at 500°C overnight. Rao and Knight (22) found mass spectral analysis to suggest a molecular weight of about 258 and that the compound contained CH_2S and CH_3S groups.

The deposit caused a gradual decrease in transmission through the reaction cells during the course of a number of photo-oxidation reactions. Microphotographs revealed a series of droplets surrounded by smaller droplets. The X-ray emission spectrum revealed the presence of sulphur in the deposit, which is probably an organic polysulphide.

Chemical reactivity of lumazine derivatives. Acid–base and redox reactions of a number of lumazines, deazalumazines, and isoalloxazines. An unusual effect of methyl substitution[1]

ROSS STEWART, R. SRINIVASAN, AND STEWART J. GUMBLEY

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received March 19, 1981

ROSS STEWART, R. SRINIVASAN, and STEWART J. GUMBLEY. Can. J. Chem. **59**, 2755 (1981).

Three lumazines, seven deazalumazines, and two isoalloxazines have been studied and the following chemical properties measured; equilibrium acidity (pK_a), equilibrium basicity (pK_{SH^+}), polarographic reduction potential ($E_{\frac{1}{2}}$), and, where applicable, the rates of the general acid and general base catalyzed dissociation of the protons in the C-5 and C-7 methyl groups ($k_{SH^+ + A^-}$ and $k_{S + A^-}$, respectively). The latter quantities were determined by means of isotope exchange or iodination. Structural variations in the substrate produce compatible results in pK_a and pK_{SH^+} and, to lesser extents, in $E_{\frac{1}{2}}$ and in the catalytic rate data. Anomalies in the rate constants appear when a methyl group is present at C-6; it facilitates ionization of the C-5 and C-7 methyl groups, reversing the quite large effect of more distant methyl. Buttressing effects appear to be absent. The effects of methyl substitution are attributed, in part, to (*a*) resonance stabilization by 5- and 7-methyl groups in the reactant molecules (neutral substrate and conjugate acid), and (*b*) relief of steric strain in going from essentially aromatic reactants to nonplanar intermediates. The significance of the 6-methyl group in the lumazine–flavin conversion is noted.

ROSS STEWART, R. SRINIVASAN et STEWART J. GUMBLEY. Can. J. Chem. **59**, 2755 (1981).

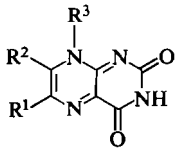
On a étudié trois lumazines, sept déazalumazines et deux isoalloxazines et on a mesuré les propriétés chimiques suivantes: l'acidité à l'équilibre (pK_a), la basicité à l'équilibre (pK_{SH^+}) le potentiel de réduction polarographique ($E_{\frac{1}{2}}$) et là où c'est applicable, les vitesses de dissociation, catalysée en général par un acide ou par une base, des protons des groupes méthyles en C-5 et C-7 ($k_{SH^+ + A^-}$ et $k_{S + A^-}$ respectivement). On a déterminé les dernières propriétés par échange isotopique ou par iodation. Les variations structurelles du substrat donnent des résultats compatibles pour le pK_a et le pK_{SH^+} et à un moindre degré pour $E_{\frac{1}{2}}$ et pour les données de vitesse catalytique. Des anomalies dans les constantes de vitesse apparaissent quand le groupe méthyle est présent en C-6; il facilite l'ionisation au niveau des méthyles en C-5 et en C-7 en inversant le large effect du méthyle le plus éloigné. Les effets de compression semblent être absents. On attribue les effets de substitution du méthyle en partie (*a*) à la stabilisation par résonance due aux groupes méthyles en position 5 et 7 dans les molécules en réaction (substrat neutre et acide conjugué) et (*b*) à une diminution de la contrainte stérique due au passage de réactifs essentiellement aromatiques à des intermédiaires non plans. On a noté l'importance du groupe méthyle en position 6 dans la transformation de lumazine–flavine.

[Traduit par le journal]

Introduction

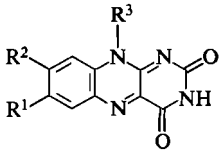
Lumazines (e.g. **1**)[2] constitute an important class of compounds on several grounds. First, the 6,7-dimethyl-8-ribityl compound (**1***a*) is known to be the precursor in nature of the important oxidative coenzymes, the flavins **2***a* (2). Secondly, they possess many of the structural features of the isoalloxazine ring system of the flavins and can serve as models for these compounds. Moreover, they possess a number of functional groups whose interaction is of general chemical interest.

It is known that the pathway for general conversion of lumazines to flavins, **1** to **2**, involves ionization of the 7-methyl group in the lumazine (2) and that this reaction is catalyzed by general acids and bases (3). Lumazines and to a lesser extent flavins have structural features that activate the methyl protons in question (the R^2 location in both **1** and **2**) and the present work, dealing chiefly with



1

1*a* $R^1 = R^2 = CH_3$, R^3 = ribityl
1*b* $R^1 = R^2 = R^3 = CH_3$
1*c* $R^1 = H$, $R^2 = R^3 = CH_3$



2

2*a* $R^1 = R^2 = CH_3$, R^3 = ribityl or ribityl phosphate
2*b* $R^1 = R^2 = H$, $R^3 = CH_3$

[1]A preliminary account of a portion of this work appeared in ref. 1.

[2]The numbering system for the lumazine and isolloxazine (flavin) ring systems is as follows:

4

5-deazalumazines, **3**, was initiated to obtain more information with regard to such activation.

A further reason for examining the 5-deazalumazine system is the importance of the analogous 5-deazaflavin system **4**. The latter has been used for some years in attempts to fix the location of hydrogen addition in the reduction of flavins, since the exchange characteristics of protons attached to nitrogen preclude the use of isotopic tracers in such reactions (4). Furthermore, it has recently been shown that 5-deazaflavins are the active coenzymes in the biological conversion of carbon dioxide to methane (*4d*, 5).

We report herein the preparation of a series of lumazines and isoalloxazines and a determination of the rate constants for the acetic acid/acetate catalyzed exchange at the compounds' reactive sites.[3] In addition the equilibrium acidity and basicity of the compounds have been determined and their polarographic reduction potentials measured.

Experimental

Materials

6,7,8-Trimethyllumazine (**1***b*) and 6,7-diphenyl-8-methyllumazine (**13**) were prepared as previously described (3, 7). All deazalumazines were prepared by condensing 6-methylaminouracil with either a 1,3-diketone, a 1,3-keto aldehyde, or the corresponding acetals (6). 6-Methylaminouracil (**5**) was prepared from 2,4,6-trichloropyrimidine according to the method of King and King (8), as modified by McAndless (9).

6,7,8-Trimethyl-5-deazalumazine (*6*)

6-Methylaminouracil (**5**) (1.41 g) and 2-methyl-3-oxobutanal (1.0 g) (10) were heated together at 100°C in 16 cm^3 of 1 *M* hydrochloric acid for 2 h. The dark solution was cooled and neutralized with aqueous ammonia. The light yellow solid that formed was filtered off and recrystallized from water giving 1.80 g (88%) of **6**. Ultraviolet maxima: 220, 275, 362 nm (neutral form); 256, 368 nm (anion); 217, 250, 323 nm (cation). Nuclear magnetic resonance in trifluoroacetic acid (TFA), δ: 2.68 (3H, 6-Me), 2.98 (3H, 7-Me), 4.37 (3H, 8-Me), 8.96 (1H, 5-H). *Anal.* calcd. for $C_{10}H_{11}N_3O_2$: C 58.53, H 5.40, N 20.48; found: C 58.41, H 5.39, N 20.36.

Since the condensation might have proceeded to give the isomeric compound **9** a structural assignment was required. This together with the nmr assignments given above was made on the basis of the nuclear Overhauser effect and the observation of hydrogen exchange. The methyl group absorbing at 2.98 δ underwent exchange and hence occupies either the 5 or 7 position. Irradiation of the 8-methyl signal produced a 7% enhancement in the 2.98 signal and hence this corresponds to the methyl group at C-7.

7,8-Dimethyl-5-deazalumazine (*7*)

Acetoacetaldehyde dimethyl acetal (1.32 g) (10) and **5** (1.41 g) were heated together in 20 cm^3 of 0.1 *M* hydrochloric acid for 3 h. After neutralization with aqueous ammonia the volume of the solution was reduced and the product allowed to crystallize. The yellow solid was recrystallized from water to give 0.57 g (30%) of pure product. Ultraviolet maxima: 272, 353 nm (neutral form); 255, 362 nm (anion); 206, 247, 315 nm (cation); nmr in TFA, δ: 3.04 (3H, 7-Me), 4.37 (3H, 8-Me), 7.80 (1H, doublet, J = 8 Hz, 6-H), 9.06 (1H, doublet, J = 8 Hz, 5-H). *Anal.* calcd. for $C_9H_9N_3O_2$: C 56.54, H 4.75, N 21.98; found: C 56.46, H 4.86, N 21.81.

Irradiation of the *N*-methyl signal in $CDCl_3$ caused a 20% enhancement of the *C*-methyl signal relative to the absorption of the lone hydrogen atom at C-5. This compound is thus almost certainly the 7,8-dimethyl compound, not the 5,8-dimethyl isomer. It should be noted that Paterson and Wood (6) assigned a 5-methyl structure to an analogous compound prepared from acetoacetaldehyde.

5,7,8-Trimethyl-5-deazalumazine (*8*)

Acetylacetone (1.5 g) and **5** (2.11 g) were heated at 100°C in 15 cm^3 of 85% aqueous phosphoric acid for 3 h. After dilution with 100 cm^3 of water and neutralization with aqueous ammonia, 1.9 g (64%) of a pale yellow precipitate formed and was recrystallized from hot water. Ultraviolet maxima: 223, 273, 345 nm (neutral form); 222, 258, 352 nm (anion); 222, 255 (sh), 310 nm (cation); nmr in TFA, δ: 2.95 (3H, 7-Me), 3.07 (3H, 5-Me), 4.28 (3H, 8-Me), 7.57 (1H, 6-H). *Anal.* calcd. for $C_{10}H_{11}N_3O_2$: C 58.53, H 5.40, N 20.48; found: C 58.54, H 5.28, N 20.15.

Irradiation of the *N*-methyl resonance at position 8 produced a 6% enhancement of the 2.95 δ signal, relative to the 3.07 signal, enabling the above assignments to be made.

5,6,8-Trimethyl-5-deazalumazine (*9*)

2-Methylbut-2-enal (tiglic aldehyde) (0.85 g) was stirred with 1.41 g of **5** at room temperature for 36 h in 20 cm^3 20% aqueous hydrochloric acid. After neutralization with aqueous ammonia several recrystallizations of the resulting yellow solid were necessary to remove the isomeric impurity (**6**). Ultraviolet maxima: 232, 272, 352 nm (neutral form); 235, 256, 360 nm (anion); 212, 248, 312 nm (cation); nmr in TFA, δ: 2.57 (3H, 6-Me), 3.13 (3H, 5-Me), 4.40 (3H, 8-Me), 8.52 (1H, 7-H). *Anal.* calcd. for $C_{10}H_{11}N_3O_2$: C58.53, H 5.40, N 20.48; found: C 58.33, H 5.30, N 20.22.

Structure assignment and nmr assignments were consistent with the observation that the methyl group at 3.13 δ underwent exchange and that the lone proton at 8.52 δ showed a 38% enhancement (relative to the 5-methyl peak) when the *N*-methyl resonance at position 8 was irradiated.

5,8-Dimethyl-5-deazalumazine (*10*)

Crotonaldehyde diethyl acetal (1.44 g) and **5** (1.41 g) were condensed as for compound **7**. The yield of yellow needles was 41%. Ultraviolet maxima: 228, 271, and 344 nm (neutral form); 228, 254, 353 nm (anion); 222, 249, 303 nm (cation); nmr in TFA, δ: 3.15 (3H, 5-Me), 4.43 (3H, 8-Me), 7.63 (1H, doublet, J = 7.0 Hz, 6-H), 8.58 (1H, doublet, J = 7.0 Hz, 7-H). *Anal.* calcd. for $C_9H_9N_3O_2$: C 56.54, H 4.75, N 21.98; found: C 56.48, H 4.72, N 21.75.

Nuclear Overhauser experiments were inconclusive with this compound partly because of low solubility in $CDCl_3$. However, comparison with the spectra of the 7,8-dimethyl isomer (**7**) shows it to be a different compound.

[3]Wood and co-workers (6), in a search for specific enzyme inhibitors, have prepared a number of 5-deazalumazines that are similar in structure to some of the compounds studied here.

5,6,7,8-Tetramethyl-5-deazalumazine (11)

3-Methyl-2,4-pentanedione (11) (1.71 g) and **5** (2.11 g) were heated together in 15 cm^3 of 85% phosphoric acid for 6 h at 100°C. After similar treatment to that accorded **8** a 16% yield of pure product was obtained. Ultraviolet maxima: 227, 274, 353 nm (neutral form); 233, 254, 362 nm (anion); 217, 250, 323 nm (cation); nmr in TFA, δ: 2.59 (3H, 6-Me), 2.97 (3H, 7-Me), 3.13 (3H, 5-Me), 4.32 (3H, 8-Me). *Anal.* calcd. for $C_{11}H_{13}N_3O_2$: C 60.26, H 5.98, N 19.17; found: C 60.06, H 5.93, N 19.01.

The nmr assignments came from the observation that the methyl groups at 2.97 δ and 3.13 δ underwent exchange and hence occupy the 5 and 7 positions and that the 2.97 δ signal showed a 9% enhancement and the 2.59 δ signal a 3% enhancement (relative to the 3.13 δ peak) when the *N*-methyl signal at 4.32 δ was irradiated.

7,8-Dimethyllumazine (1c)

Two cm^3 of a 40% aqueous solution of pyruvaldehyde and 5-amino-6-methylaminouracil (9, 12) (2.5 g) were mixed together in 50 cm^3 of methanol and refluxed for 3 h. A number of attempts to isolate pure product from this mixture were unsuccessful (as were other preparative variations), the best results being obtained as follows. The solvent was removed and the resulting solid dissolved in water and placed immediately on a column of alumina and eluted with water. The green fluorescent band was collected to give a small quantity of yellow crystals. This compound is light sensitive in solution and produces a dark coloured compound on decomposing. Consequently, the above process should be carried out in dim light with fluorescent lighting, in particular, being avoided. Ultraviolet maxima: 254, 272, 394 nm (neutral form); 260, 310, 294 (anion); 245, 350 (cation); nmr in TFA, δ: 3.14 (3H, 7-Me), 4.44 (3H, 8-Me); the upfield peak began decreasing in intensity when D_2O was added. The 6-H resonance is missing in TFA, possibly because of exchange broadening. In DMSO it appears at 8.12 δ, with the two methyl resonances appearing at 2.63 and 3.82. *Anal.* calcd. for $C_8H_8N_4O_2$: C 50.00, H 4.20, N 29.15; found: C 50.22, H 4.24, N 28.91.

This compound was also prepared using pyruvaldehyde dimethyl acetal followed by filtration, concentration, and elution on a silica gel column with 80% aqueous ethanol. A yellow-green fluorescent compound was collected and recrystallized from ethanol. Although sample purity appeared to be lower using this method, as indicated by less satisfactory microanalytical data, samples prepared by the two methods behaved similarly in their chemical reactions.

5,8-Dimethyl-7-ethyl-5-deazalumazine (12)

2,4-Hexanedione (0.52 g) and **5** (0.65 g) were heated together in 5 cm^3 of 85% phosphoric acid at 100°C for 4 h. The red solution was then neutralized with aqueous ammonia and cooled in ice. The cream-coloured product was filtered off and recrystallized from hot water. Ultraviolet maxima: 228, 272, 345 nm (neutral form); 228, 253, 353 nm (anion); 222, 247, 310 nm (cation); nmr in TFA, δ: 1.55 (3H, triplet, J = 7 Hz, 7-Et), 3.10 (3H, 5-Me), 3.24 (2H, quartet, J = 7 Hz, 7-Et), 4.30 (3H, 8-Me), 7.59 (1H, 6-H). *Anal.* calcd. for $C_{11}H_{13}N_3O_2$: C60.26, H 5.98, N 19.17; found: C 59.89, H 6.18, N 18.91.

This compound has been assigned the 7-ethyl-5-methyl structure on the basis of the positions of the nmr resonances. (Signal overlap makes nuclear Overhauser experiments extremely difficult to interpret for this compound.) Table 1 shows the chemical shifts for the various protons in methyldeazalumazines studied herein and it can be seen that the resonances for the 5-methyl groups vary from 3.07 to 3.15 δ, whereas the 7-methyl resonances vary from 2.95 to 3.04 δ. Since this compound has its exchanging methyl group at 3.10 δ we assign it the structure given above.

9-Aza-10-methylisoalloxazine (14)

Alloxan (0.4 g) was dissolved in glacial acetic acid and 3-amino-2-methylaminopyridine (13) (0.1 g) dissolved in a small quantity of glacial acetic acid was gradually added with stirring. The resulting solution was heated on a steam bath for 30 min. On cooling yellow crystals appeared, which, upon recrystallization from aqueous formic acid, gave a compound that melted with decomposition at 350°C. *Anal.* calcd. for $C_{10}H_7N_5O_2$: C 52.40, H 3.08, N 30.56; found: C 52.13, H 2.95, N 30.21. We thank Dr. K. Oyama for the preparation of this compound.

10-Methylisoalloxazine (2b)

This compound was prepared from alloxan and *N*-methyl-1,2-phenylenediamine essentially by the method of Matsukawa and Shirakawa (14). Recrystallization from 50% aqueous acetic acid gave a high yield of yellow-orange crystals melting above 300°C (15). We thank Dr. J. M. McAndless for the preparation of this compound.

6,7,8-Trimethyl-5-deazalumazine-7-methyl-d_3-3-N-d (15)

Compound **6** was boiled in D_2O (99.7 at.% D) for 24 h. The solution was allowed to cool and the separated crystals removed by filtration. After four such operations the nmr spectrum showed no detectable absorption for the 7-methyl group.

pK Measurements

The acidity constants for loss of the N-3 proton, designated herein as K_a, and gain of a proton at N-1, designated herein as K_{SH^+}, were determined spectrophotometrically at room temperature for all compounds except **2b** and **14**. Good isosbestic points for the pH absorbance curves were obtained in all cases (see Fig. 1).

In the case of the two isoalloxazines, **2b** and **14**, the spectral changes upon protonation and deprotonation are too small to allow pK_a values to be determined in the above way. The values for these compounds were determined by fluorescence measurements, since only the neutral molecules fluoresce. The concentration of the isoalloxazines in aqueous buffer was approximately 10^{-6} M and was such that the fluorescence intensity was linear with concentration. Measurements were made on a Turner 110 fluorometer.

Polarography

The polarographic half-wave potentials, $E_{\frac{1}{2}}$, were measured by the AC modulation method on a Metrohm polarograph E-354 equipped with Polarecord E 261 and AC Modulator E 393. The compounds were dissolved in an aqueous solution that was 0.05 M in phosphate buffer, pH 6.87, and 0.05 M in potassium chloride to give an approximate substrate concentration of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

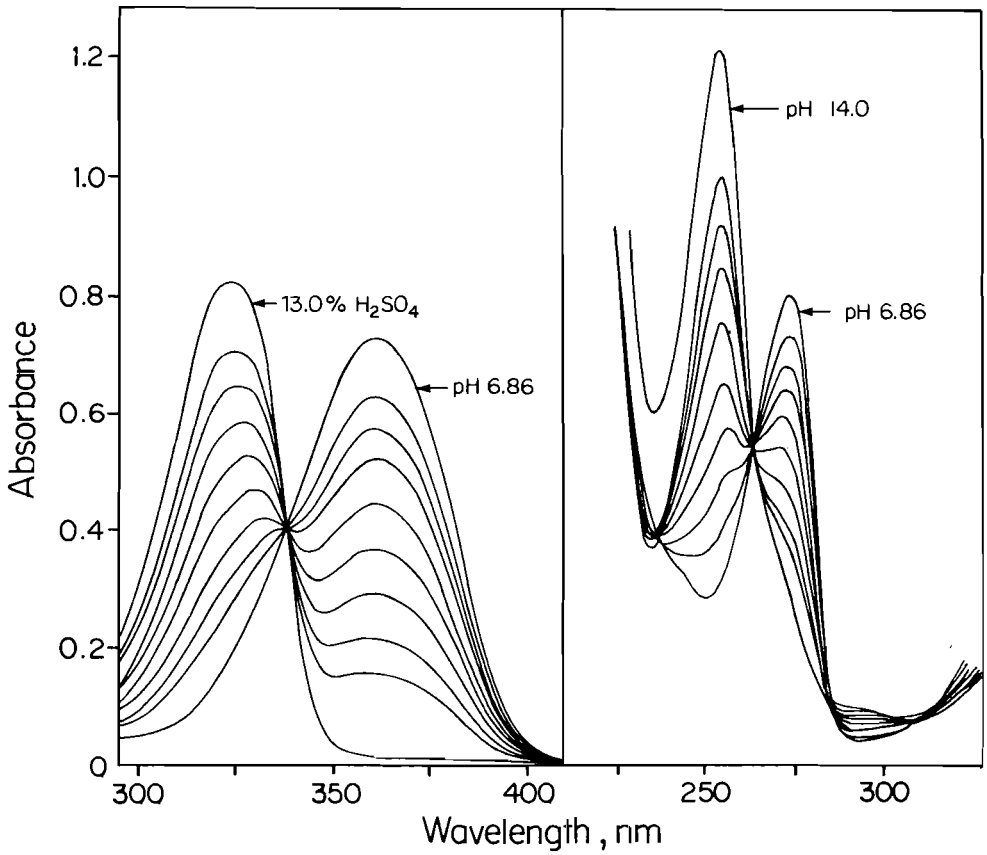

FIG. 1. Isosbestic plots for protonation (left) and deprotonation (right) of **6** in aqueous acid and in aqueous base. Intermediate pH values are, in order, for left-hand plot 1.59, 1.80, 2.01, 2.20, 2.41, 2.61, 2.80, and 3.01; and for right-hand plot 10.73, 11.01, 11.23, 11.40, 11.61, 11.80, 12.00, and 12.20; $pK_{SH^+} = 2.21$, $pK_a = 11.4$.

10^{-4} *M*. The solutions were then deaerated prior to the measurement of $E_{\frac{1}{2}}$ by flushing with N_2 for 15 min.

The instrument was calibrated using a set of metal ion solutions of known $E_{\frac{1}{2}}$ (16). The half-wave potentials obtained for the compounds were corrected using the least-squares line of the calibration graph.

Rate Measurements

The nmr rate measurements were made in D_2O as previously described (17). The iodination measurements (18) were made at 440 nm ($\varepsilon I^- = 1818$) in all cases except 5,8-dimethyl-5-deazalumazine, where the wavelength chosen was 450 nm ($\varepsilon I_3^- = 1340$). The acidity was adjusted using HCl or KOH and measured at approximately 25°C, with a Radiometer pH instrument. The carboxylic acids used as buffer sources were purified by recrystallization before use.

In a typical iodination experiment the substrate was suspended in 50 cm^3 of aqueous buffer of ionic strength 1.2 and the suspension agitated for several minutes in an ultrasonic bath at 35–40°C. (The 5-deaza compounds are much less water soluble than their 5-aza analogs.) After complete dissolution a 10 cm cell was filled with this solution, a fresh solution of sodium iodide added, and the cell allowed to equilibrate in the thermostatted cell compartment (35.7° ± 0.2°C) of a Cary 16 spectrophotometer. The reaction was initiated by adding by syringe 100 μL of a solution of iodine in spectral grade methanol. The concentration of iodine was 3×10^{-5} *M* and of sodium iodide 0.005 *M*. The substrate concentration was varied from 6×10^{-4} to 8×10^{-3} *M*. The ionic strength was kept at 1.2 by adding potassium chloride.

Partitioning of the iodination rates between the two methyl groups in **8** was done by allowing an exchange reaction of **8** in a saturated solution in D_2O to proceed for an extended period and then measuring the degrees of exchange using a 270 MHz spectrometer equipped with Fourier transform. The 7-methyl group (upfield) had undergone 2.4 times more exchange than the 5-methyl group. The same ratio was assumed to hold for the reactive groups in **11**.

Results and Discussion

The rate data for proton loss from the activated methyl groups in the compounds studied are given in Table 2. Two methods were required to obtain this data, isotopic exchange and iodination; the deazalumazines are not sufficiently soluble in water to follow the reaction by nmr, and absorption in the visible spectrum of the lumazines does not allow the iodination process to be monitored. The validity of comparing results obtained by the two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

different methods is considered in the next section. As found in previous work both methods gave satisfactory kinetic plots, the isotopic exchange reactions all being first-order in substrate and the iodination reaction being zero order in iodide to at least 50% of reaction.

Comparison of Isotopic Exchange and Iodination Methods

We have found previously that methylcreatininium ion, whose rate of reaction with bases can be followed both by deuterium exchange and by iodination, gives results by the two methods that are in satisfactory agreement (18). There is an enormous reactivity difference in the present case, however, between the lumazines (isotopic exchange) and the deazalumazines (iodination) and it is only prudent to make any further comparison between the two methods that is possible. Accordingly, we have studied the exchange of the activated methyl group of the deazalumazines in D_2O–D_2SO_4, a medium which will dissolve enough substrate to allow the rate of exchange to be followed by nmr. The first order rate constants are given in Table 2. In this medium (0.96 *M* D_2SO_4) the substrates are almost entirely protonated and the predominant general bases in the medium will be sulfate ion and water, whereas in the iodination studies at higher pH the substrate is only partly protonated, with the predominant general base being acetate ion. Figure 2 shows a comparison of the first-order rate constants for isotopic exchange in D_2O–D_2SO_4 and the second-order rate constants for iodination in water, catalyzed by acetate ion. A reasonably linear relation is obtained in the log–log plot, with the slope being close to unity. The near-unit slope indicates that the acetate rates have about the same sensitivity to structural changes in the substrate as do the combined sulfate and water rates, despite the much lower basicity of the latter bases compared to acetate ion. (On the basis of the work of Edward and Wong (20) and Lietzke and Stoughton (21) the sulfate concentration can be estimated to be of the order of 10^{-1} and at this concentration its considerably greater basicity, compared to D_2O, means that it will make a significant contribution to the exchange rate, though whether it is the more important proton abstractor is problematical.) There is precedent for bases of differing strength and reactivity having parallel but widely separated Brönsted lines (19) and the present results conform to this pattern.

It is well known that many pteridines, of which the lumazines are derivatives, undergo reversible

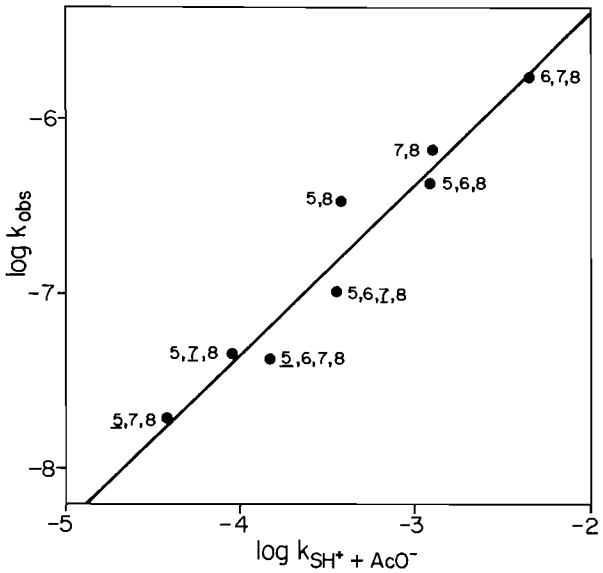

FIG. 2. A comparison of the first-order rate of isotopic exchange in D_2O–D_2SO_4 for 5-deazalumazines (ordinate) with the second-order rate of iodination of the same compounds (abscissa). The positions of the methyl groups are shown by numbers on the plot. In compounds with two exchange sites the position of the exchanging methyl group is underlined. Slope = 0.970, correlation coefficient 0.970.

covalent hydration (22). Both ultraviolet and nmr spectra would reveal this phenomenon if it took place to a significant extent and we saw no evidence for it in any of our experiments, except possibly in strongly basic solutions (pH ~ 14) where some nmr or uv spectra were anomalous. Since no rate measurements were done in this region we have discounted this phenomenon as an explanation for the effects considered below.

Buffer Catalysis and Methyl Reactivity

The way in which a change in pH affects the rate of proton loss from the 7-methyl group in 6,7,8-trimethyllumazine (**1***b*) is shown in Fig. 3 for both unbuffered and phosphate buffered media. The minima in the two curves come at almost the same pH, as expected, since the minimum depends only on the basicity of the substrate and on the proton activating factor (*paf*), which has generally been found to be independent of the base that is involved in the proton-removal step.[4] It can be seen that there is no plateau at the minimum of the curve for the unbuffered system and this indicates that there

[4]The quantity *paf* for any compound Z is the ratio of rate constants for the two reactions Z + B and ZH^+ + B, where B is any base or nucleophile. It can be obtained from buffer catalytic data using the relation $paf = k_{HA} K_{ZH^+}/k_{A^-} K_{HA}$, where HA is the buffer acid and A^- the base.

is not a great difference in the contributions made by the two kinetically equivalent paths shown in reactions [1] and [2] (24).

[1] $S + H_2O \rightarrow$ reactive intermediate

[2] $SH^+ + HO^- \rightarrow$ reactive intermediate

It should be noted that the true minimum for the unbuffered system is probably not as sharp as shown in Fig. 3. The rapid fall-off in rate that begins as the "pH" changes from positive to negative indicates that self-catalysis is important for this system, as observed previously in related systems

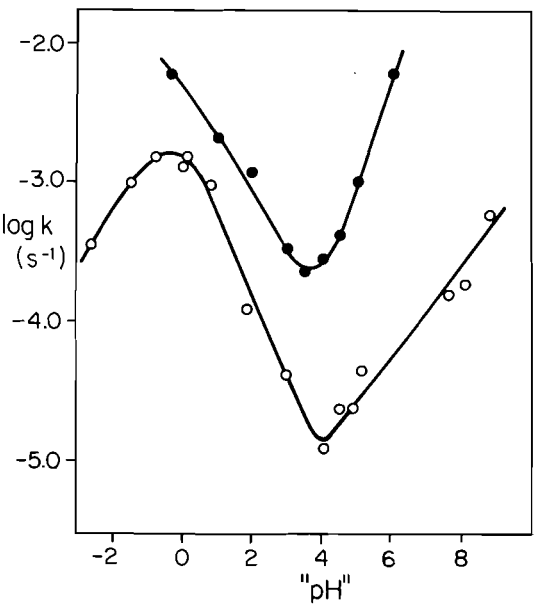

FIG. 3. The effect of acidity on the first-order rate constant for the isotopic exchange of the 7-methyl group of **1***b* in 0.1 M phosphate buffer in D_2O (upper curve) (3) and in unbuffered D_2O (lower curve). The "pH" values are uncorrected glass electrode readings except in highly acidic media where uncorrected H_0 values are used. The acidity of the unbuffered solutions was adjusted using D_2SO_4, DCl, and NaOD.

(25). Self-catalysis, the reaction of substrate S with its conjugate acid SH^+, will be at a maximum when pH = pK = 0.9, thus causing the rates in the pH range 1–3 to be elevated and making the minimum sharper than it would otherwise be.

The effect of replacing the 5-N unit in lumazines to give deazalumazines has a very large deactivating effect on the lone reactive site in lumazines, that at C-7, as can be seen from the results in Table 2. Compare **1***b* with **6** and **1***c* with **7**, where the rate differences are between 10^2 and 10^3. The source of this effect is presumably the electronegativity difference between carbon and nitrogen. It is noteworthy that the same change in reactivity can be seen whether one considers the rate constants $k_{S + AcO^-}$ or $k_{SH^+ + AcO^-}$, that is, whether proton loss involves the neutral molecule or the cation.

The effect of methyl groups elsewhere in the molecule on the activated sites in deazalumazines (positions 5 and 7) is interesting. It can be seen from the results in Table 2 that a methyl group at position 5 has a large deactivating effect on the methyl group at position 7, and vice versa. (We refer to this as next-but-one substitution.) A 5-methyl group lowers the kinetic acidity of a 7-methyl group by factors of 8.2 to 14; a 7-methyl group has a similar effect on the 5-methyl ionization (factors of 8.0–10.2).

The effect of methyl at an *adjacent* site has an *activating* effect on the rate of ionization of both 5-methyl and 7-methyl groups. For the deazalumazines the rate constants for dissociation of the protons of the 7-methyl group are increased by factors of 2.4 to 4.0 for the reaction $S + AcO^-$, 3.5–3.9 for the reaction $SH^+ + AcO^-$, and 2.2–2.6 for the reaction $SH^+ + SO_4^{2-}$ (or H_2O). The dissociation of the 5-methyl protons shows a similar effect, the factor being 3.4–3.8 for $S + AcO^-$, 3.2–3.9 for $SH^+ + AcO^-$, and 1.2–1.9 for $SH^+ + SO_4^{2-}$ (or H_2O).

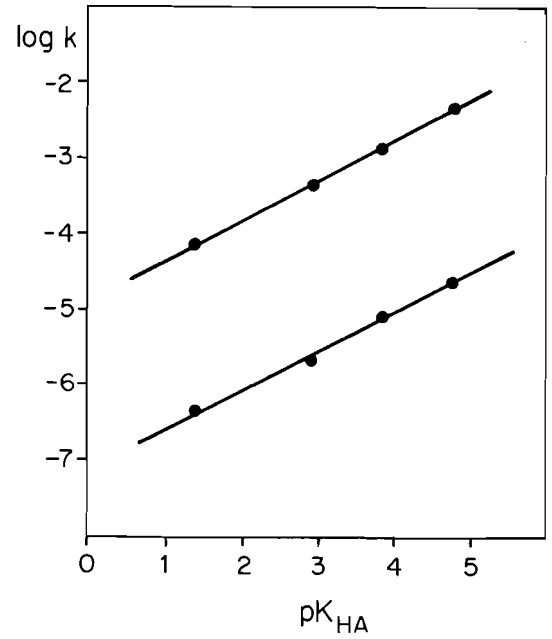

FIG. 4. Brönsted plots for **6**; upper curve log $k_{SH^+ + AcO^-}$; lower curve, log $k_{S + AcO^-}$. The buffer acids HA are, from left to right, dichloroacetic acid, chloroacetic acid, glycollic acid, and acetic acid.

The activating effect of adjacent methyl, a factor of roughly three, is not large but it is remarkable in that it reverses the quite substantial deactivating effect of methyl at a next-but-one location. Perhaps the most striking result of the reversed effect of methyl can be seen by comparing the reactivities of the 6,7,8- and 5,7,8-trimethyl isomers in the deazalumazine series, compounds **6** and **8** in Table 2. The former is 23 to 35 times the more reactive despite having only one reactive methyl group and the latter having two.

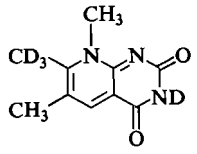
In the lumazine series there is only one comparison that can be made, that between compounds **1***b* and **1***c*. Here again an adjacent methyl group has an activating effect, though the difficulty we have had in preparing substantial quantities of pure **1***c* has precluded our gathering completely reliable rate data for this compound.

Brönsted Coefficients and paf *Values*

Brönsted plots for 6,7,8-trimethyl-5-deazalumazine are shown in Fig. 4. The slopes are virtually identical, 0.51 for the plot of log $k_{S + A^-}$ against pK_{HA} and 0.52 for the plot of log $k_{SH^+ + A^-}$ against pK_{HA}. The former is the conventional Brönsted β coefficient for catalysis by bases A^-; the latter can be converted to the Brönsted α coefficient for catalysis by acids HA by substracting from unity, though that makes little difference in the magnitude of the coefficient in the present case. The parallelism of the lines in Fig. 4 means that *paf* is independent of the base used to remove the proton from the 7-methyl group (17*a*), at least within the range of buffer acids used.[4] The *paf*, which can be obtained from the vertical separation of the two lines in Fig. 4, is 180, very near the value of 168 found for the much more reactive aza analog **1***b* (a value of 210 is given in ref. 23). The magnitude of *paf* has been previously linked to the degree of conjugation with the site of proton loss and since this is essentially unchanged in the aza and deaza compounds it is perhaps not surprising that protonation has the same activating effect in the two cases, despite there being a large reactivity difference between the two compounds.

Deuterium Isotope Effect

The protons of the 7-methyl group in **6** were exchanged for deuterium to produce **15** and the rate of ionization determined at 35.7°C in H_2O at pH 6.10 by means of iodometry. At this acidity k_{AcOH} is negligible and the observed rate constant $5.44 \times 10^{-6}\ M^{-1}s^{-1}$ corresponds to $k_{S + AcO^-}$, the isotope effect being 4.3.



15

Relationships between Acidity, Basicity, and Polarographic Half-wave Potential

The acidity constant K_{SH^+} was required for all compounds in order to convert the catalytic constants k_{HA} into the rate constants $k_{SH^+ + A^-}$ and they were determined in this work. At the same time the acidity constant K_a for dissociation of the 3-N proton in the neutral compound was determined in each case.

Substitution at the 5, 6, and 7 positions of lumazines and deazalumazines produces roughly the same change in pK_{SH^+} as in pK_a, as can be seen from the results in Table 2. It is significant that both pK_{SH^+} and pK_a measurements can be made in the present case in what is essentially an aqueous medium. Attempts to link acidity and basicity in other heterocyclic systems, aminopyrimidines and purines, for example (26), perforce used data acquired largely outside the aqueous standard state by means of acidity function and related extrapolative techniques, the reliability of which are open to question. (See ref. 27 and references therein.)

The polarographic reduction potential becomes

[a] Obtained from the results shown in Table 2, the order in which the Δ values are listed coming from the order in Table 2; e.g. the first set of values for the effect of 5-aza substitution comes from a comparison of **1***b* and **6**, the second from **1***c* and **7**, and similarly with the other substituents.
[b] Uncorrected for solvent isotope effect.
[c] The boxed values are anomalous (see text).

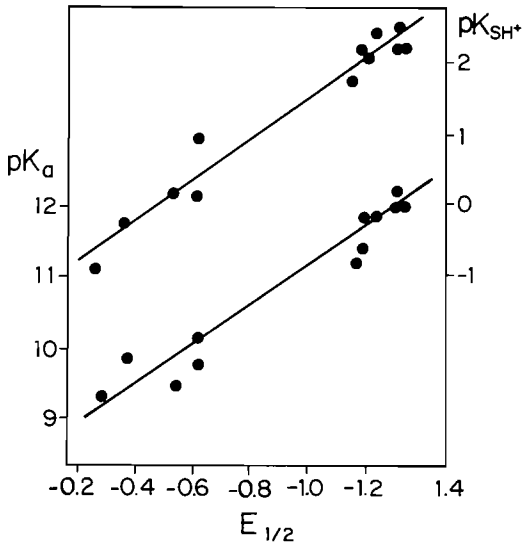

FIG. 5. Variation of polarographic half-wave potential with pK_a and pK_{SH^+} for compounds studied herein. Upper curve and right-hand axis, pK_{SH^+}, slope = −2.92, correlation coefficient = 0.980; lower curve and left-hand axis, pK_a, slope = −2.63, correlation coefficient = 0.966.

more negative the more electron-donating groups there are present in the molecule, as expected. Indeed, roughly linear correlations exist between $E_{\frac{1}{2}}$ and pK_{BH^+} and pK_a. The slopes of such plots (Fig. 5) are $-2.92\ V^{-1}$ and $-3.06\ V^{-1}$ for pK_{BH^+} and pK_a, respectively. The significance of these numbers can be seen by converting them to dimensionless quantities by dividing by $\alpha nF/2.303RT$, where α is the transfer coefficient for the reaction and n is the number of electrons transferred (28). The corrective factor is obtained from the variation of current with potential (29); in our case the average value of αn was 1.16 and $\alpha nF/2.303RT$ was 19.8 V^{-1}. Using this correction the absolute values of the dimensionless slopes in Fig. 5 are 0.15 and 0.16, indicating that proton gain and proton loss in these compounds are processes that are much less sensitive to structural changes than is the one-electron addition process that occurs during polarographic reduction.

The Problem of the 6-Methyl Group

Why does a methyl group at C-6 activate the adjacent sites in lumazines and deazalumazines instead of deactivating them as would be expected from the behaviour of methyl when it is at a next-but-one position? Both the general acid and general base catalyzed reactions are bimolecular with transition states whose geometries at the reaction sites are expected to be virtually identical and the steric effect of an adjacent group should hinder reaction, not facilitate it. If electronic effects are dominant, why is the effect reversed when the position of the group is changed?

The distinctive effect of the 6-methyl group can best be appreciated by considering the results given in Table 3 and those shown in Fig. 6.

Table 3 summarizes the effect of substituting the groups 5-aza, 5-methyl, 6-methyl, and 7-methyl on pK_{SH^+}, pK_a, $E_{\frac{1}{2}}$, $k_{S + AcO^-}$, and $k_{SH^+ + AcO^-}$. Except for perhaps the very modest effect of 7-methyl the pK results are unexceptionable. Likewise, the effect of 5-aza, 5-methyl, and 7-methyl on the rate constants for the general acid and general base reactions is qualitatively reasonable, though a comparison of the appropriate Hammett sigma (σ) values (−0.07 for 3-methyl and +0.65 for 3-aza (30)) suggests that the relative deactivating effect in our system of next-but-one methyl is particularly large. This may well be a result of contributions of

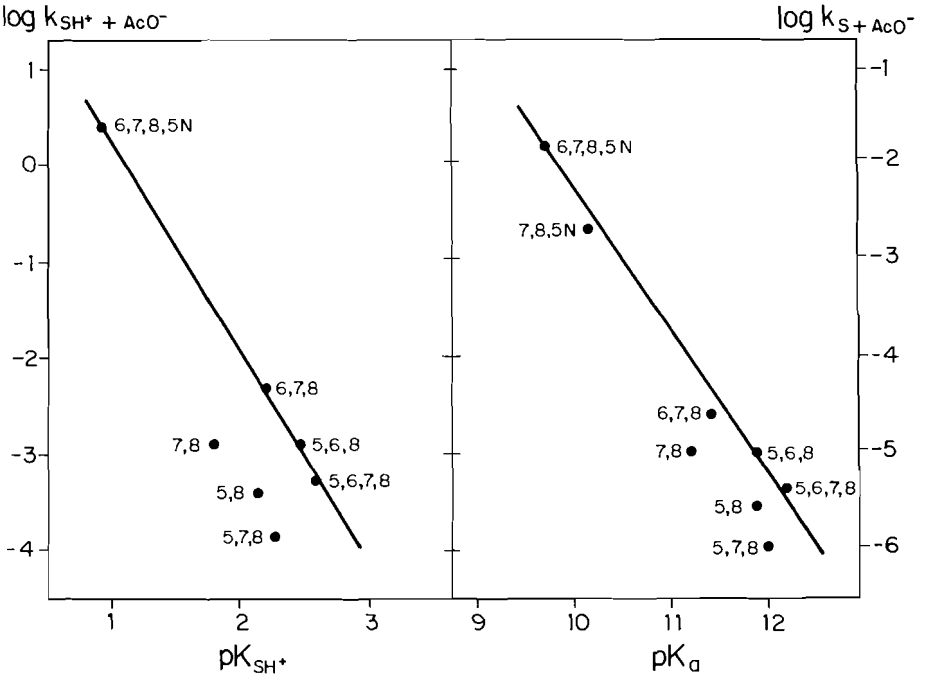

FIG. 6. Logarithm of the rate constant for the reaction of acetate ion with SH^+ as a function of the equilibrium acid strength of SH^+ (left; slope = −2.19, correlation coefficient, 0.999), and with S as a function of the equilibrium acid strength of S (right; slope = −1.46; correlation coefficient 0.994) for the lumazine and deazalumazine series; methyl (and nitrogen) positions indicated by numbers. The straight lines are drawn with respect to the compounds containing a 6-methyl group.

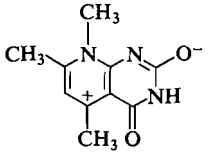
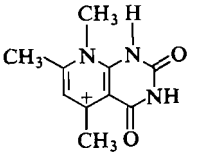
structures such as **16** and **17** (including hyperconjugation) in the neutral molecule and in the conjugate acid, and similarly at C-7.



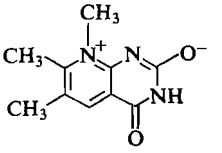
16



17

If the neutral molecule (and its conjugate acid) has considerable aromatic character as a result of contributions from structures such as **18** it will be closer to planarity than will the reactive intermediate and relief of steric strain may well contribute to the rate increases produced by adjacent methyl (*7b*, 31). If this interaction were dominant, however, we would not expect to find the additivity of effects that is observed with the tetramethyl compound **11**. There the rates can be calculated reasonably accurately on the basis of the rates of the dimethyl and trimethyl compounds. That is, there is no buttressing effect (32, 33).

Turning to Fig. 6, shown there is a plot of the logarithm of the rate of deprotonation by acetate ion against the logarithm of the equilibrium constant for deprotonation for both the neutral substrates and their conjugate acids. (These would be conventional Brönsted plots if the sites of deprotonation were the same in the rate and equilibrium processes.) It can be seen that the compounds that contain a 6-methyl group appear to form a separate series from those that do not; this is particularly noticeable in the case of the protonated substrate.



18

In summary we attribute much of the large deactivating effect of next-but-one methyl to hyperconjugative stabilization of the reactant molecule; the reversing of this effect when methyl is moved to an adjacent position we tentatively attribute, at least in part, to relief of steric strain accompanying conversion of reactant molecule to a puckered intermediate, though the lack of buttressing is paradoxical.

Although the polarographic reduction potentials correlate reasonably well with pK, as previously pointed out, a close look at the $E_{\frac{1}{2}}$ values for the 6-methyl compounds shows them to be less negative

than would be expected. This can be seen in Table 3 where the effect of a 6-methyl group on $E_{\frac{1}{2}}$ is highlighted and can be seen to be virtually nil. Whether this phenomenon is related to the anomalies in the catalytic rate data, discussed above, is uncertain but it points again to the cryptic role of a 6-methyl group in lumazine and deazalumazine chemistry.

We conclude by referring to the difficulties we had in synthesizing pure 7,8-dimethyllumazine, **1***c*, and the seemingly greater thermal and photochemical stability of the 6,7,8-trimethyl compound, **1***a*. Does the 6-methyl group, which must be present for biological conversion to flavins to take place, play a greater role than simply supplying a carbon atom in the flavin skeleton? Is the 6,7,8-trimethyl-5-deazalumazine, **6**, capable of self-condensation as is the aza analog? What are the effects on the reactive C-5 and C-7 positions of larger alkyl groups at C-6, and indeed at N-8? These questions are currently being addressed.

Received April 7, 1981

ERRATA

VINCENZO MALATESTA and ANGELO MUGNOLI. Can. J. Chem. **59**, 2766 (1981).

The crystal structure of *N,N'*-ethylenebis(benzoylacetoniminato)nickel(II), Ni^{II}(benacacen), has been determined by X-ray diffraction. Crystals are monoclinic and belong to the space group $P2_1/n$; the cell dimensions are a = 10.793(2), b = 7.910(1), c = 22.020(4) Å, β = 96.68(2)°. Intensity data were measured on a four-circle automatic diffractometer and the structure was solved by combined use of direct and Patterson methods. Full-matrix least-squares refinement converged at R = 0.032 for 3456 observed reflections. The geometry around the Ni atom is square planar; remarkable planarity extends to the whole ligand, aside from the rotation of the phenyl rings and the torsion along the dimethylene bond. Bond distances and bond angles are in agreement with corresponding values found for other Schiff-base type complexes. The packing of the molecules leaves empty channels running through the crystal, a relevant point in the study of chemical models for oxygen carriers of biological interest.

ERRATA

VINCENZO MALATESTA et ANGELO MUGNOLI. Can. J. Chem. **59**, 2766 (1981).

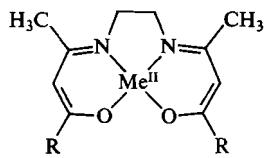
On a déterminé par diffraction de rayons-X, la structure du cristal de *N,N'*éthylènebis(benzoylacétoniminato)nickel(II), Ni^{II}(benacacen). Les cristaux sont monocliniques et appartiennent au groupe d'espace $P2_1/n$; les dimensions de la maille sont; a = 10,793(2), b = 7,910(1), c = 22,020(4) Å, β = 96,68(2)°. On a mesuré les données d'intensité dans un diffractomètre à 4 cercles et on a résolu la structure en combinant la méthode directe à celle de Patterson et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,032 pour 3456 réflexions. La géométrie autour de l'atome de Ni est plan carré et la planéarité s'étend remarquablement à tout le ligand à l'exception de la rotation du cycle phényle et de la torsion le long de la liaison diméthylène. Les distances et les angles de liaison sont en accord avec les valeurs correspondantes obtenues pour d'autres complexes de type base de Schiff. L'entassement des molécules laisse des canaux vides qui parcourent tout le cristal, un point important dans l'étude des modèles chimiques des transporteurs d'oxygène ayant une importance biologique.
[Traduit par le journal]

Low molecular weight model substances containing a transition metal center (mono or polynuclear) and being able to combine with oxygen have attracted a great deal of interest. The properties of many of these metal complexes have been extensively investigated with the aim of identifying the structural features which render them suitable model substances for the natural "oxygen carrier" systems (1). Most likely the conclusions drawn from the relationship of the structure to the oxygen binding ability of these model molecules should prove useful when trying to understand the analogous properties of more complex biological systems.

Although many esr studies of tetra- and pentacoordinate Schiff-base complexes have been reported (2–7), the identification of their ground states has been difficult and in some cases (2, 4) controversial. The difficulties stem from the fact that most of the work was done on frozen solutions or powders in which it is not possible to identify and assign, with any degree of confidence, the three g and A values in the spin Hamiltonian to specific molecular axes and/or define the relative orientation of the molecular axes with respect to the crystal axes.

It is, on the other hand, clear that the electronic requirements for the fixation of oxygen of many of the complexes are rather critical and that the elucidation of the electronic configuration (nature of the ground state) and of the intimate details of their crystal structure are of definite importance.

It has been stated that "... the stabilities of dioxygen adducts of Schiff-base complexes of cobalt(II) are very dependent upon the nature of the Schiff base and upon crystal-packing effects"



1*a*: R = CH_3, Me^{II}(acacen)
1*b*: R = C_6H_5, Me^{II}(benacacen) or Me^{II}(bzacen)

(8). As reported in a previous esr study (9), crystals of Ni^{II}(benacacen) can be doped with Co^{II}(benacacen) (**1***b*), which absorbs oxygen in the solid state. From that study some crystallographic and structural indication was obtained for the host crystal, Ni^{II}(benacacen). In order to confirm the esr predictions and as a first step in investigating structural features possibly related to the ability of the Co^{II} compound to absorb oxygen, the crystal structure of Ni^{II}(benacacen) has been determined by X-ray diffraction. Preliminary results were reported (10).

Experimental

The compound crystallizes in dark red prisms elongated parallel to the *y* axis. Preliminary film data showed that the crystals are monoclinic, space group $P2_1/n$ ($h0l$, only for $h + l = 2n$; $0k0$, only for $k = 2n$). Lattice constants were obtained from a least-squares fit of 15 reflections (plus their equivalents) measured on a Syntex $P\bar{1}$ automatic diffractometer. The crystal data can be summarized as follows:

$NiC_{22}H_{22}N_2O_2$ fw = 405.1

Monoclinic, space group $P2_1/n$, $a = 10.793(2)$, $b = 7.910(1)$, $c = 22.020(4)$ Å, $\beta = 96.68(2)°$, $V = 1867.1$ Å^3, $D_x = 1.441$, $D_m = 1.445$ g cm^{-3} (by flotation in CCl_4–C_6H_6), $Z = 4$ (20°C; MoKα, $\lambda = 0.71069$ Å), $F(000) = 848$, μ(MoKα) = 10.0 cm^{-1}.

Intensities were collected from a crystal ground in a sphere ($r = 0.25$ mm) with graphite monochromatized MoKα radiation, using the ω-scan technique, total ω scan 1°, variable scan speed between 2 and 12° min^{-1}. The background was counted for half the total scanning time 1° on each side of the Kα position. After every group of 50 reflections three standard reflections were monitored; no significant change in their intensities was observed. In the range explored (2θ between 4 and 55°) 4291 independent reflections were measured, of which 3462 having $I \geq 3\sigma(I)$ were considered observed. Lorentz and polarization factors were applied; absorption corrections were unnecessary (for a spherical specimen with $\mu R = 0.25$, the correction factor remains essentially constant within the explored range of θ).

Some preliminary attempts to solve the structure by direct methods were unsuccessful, until the five central atoms, i.e. Ni, N(1), N(2), O(1), O(2), were introduced in MULTAN 78 (11) in known positions (as determined by a sharpened Patterson synthesis). Using 350 reflections with $|E| \geq 1.56$ the structure solution arose from the set of phases having the best combined figure of merit, in spite of a very high residual (0.77). The corresponding *E*-map allowed recognition of all 27 non-hydrogen atoms.

Refinement on the 3462 observed reflections was performed by full-matrix least-squares process by means of the SHELX 76 system of programs (12), with isotropic and then anisotropic thermal factors, for a total of 244 variable parameters. The function minimized was $\Sigma w(\Delta F)^2$ with weights $w = 1/\sigma^2(F)$. The scattering factors for C, N, O atoms were taken from ref. 13 and for H from ref. 14; the nickel curve was corrected for anomalous dispersion (15).

All hydrogen atoms with the exception of two (whose positions were derived from geometrical considerations) were located on a difference Fourier map. They were not refined, but all were introduced in structure factor calculations with an isotropic thermal parameter $U_H = 0.05$ Å^2. In the last cycles, six very strong low-angle reflections were given zero weight because they were presumably affected by extinction or exper-

TABLE 1. Final atomic coordinates and their standard deviations. The equivalent positions for space group $P2_1/n$ are x, y, z; $-x, -y, -z$; $1/2 - x, 1/2 + y, 1/2 - z$; $1/2 + x, 1/2 - y, 1/2 + z$

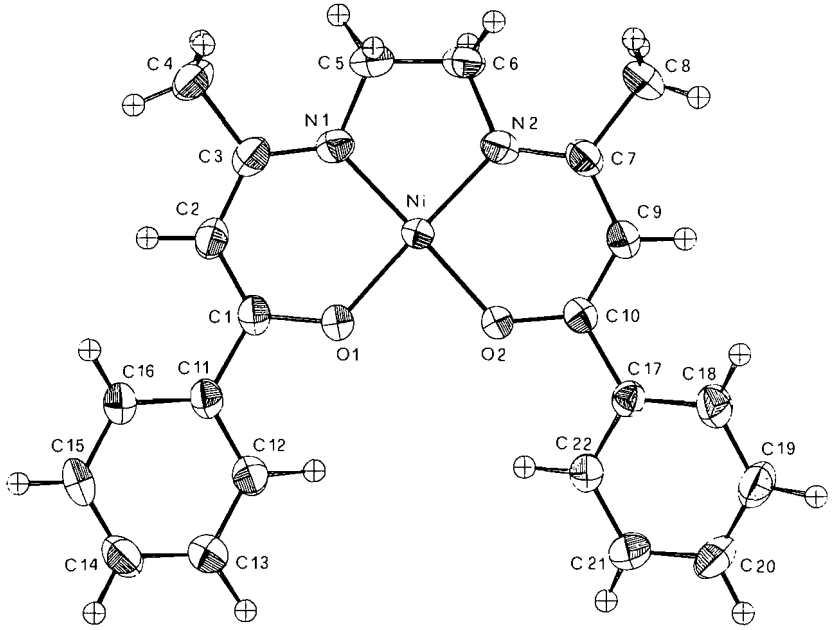

FIG. 1. A molecule of Ni(benacacen) viewed along the direction corresponding to the maximum moment of inertia of the ligand. Temperature ellipsoids of heavy atoms include 50% probability; hydrogen atoms, treated as isotropic, are on an arbitrary scale.

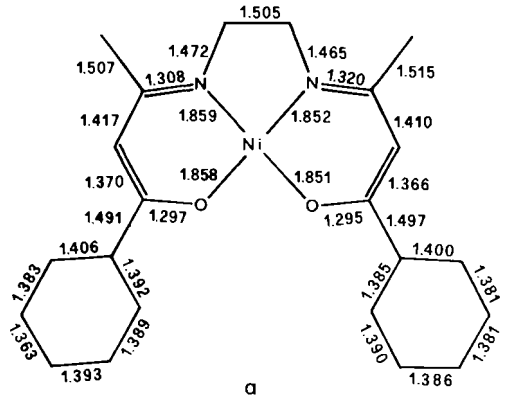

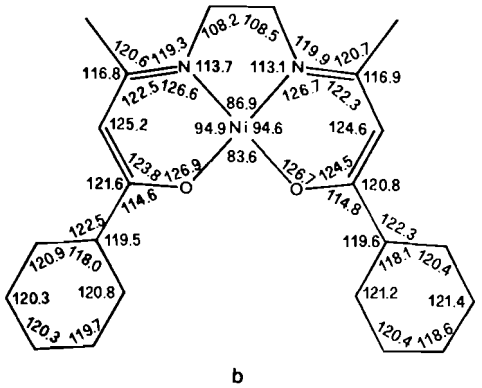

FIG. 2. Molecular geometry: (*a*) bond lengths; esd's are 0.002–0.004 Å; (*b*) bond angles; esd's are about 0.2°.

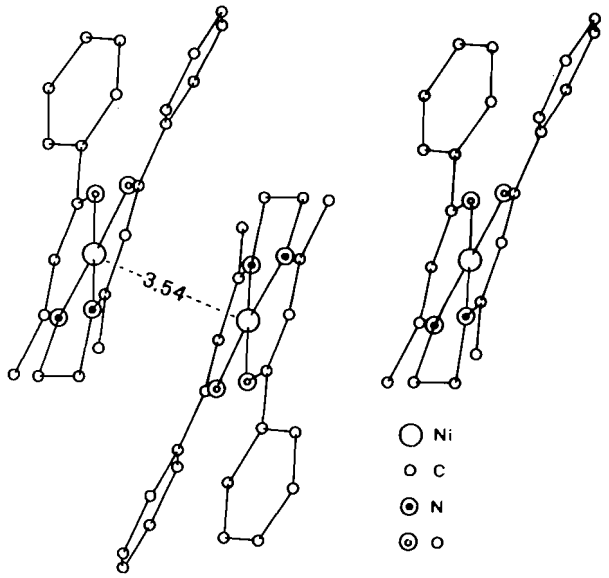

FIG. 3. Coupling of molecules of Ni(benacacen).

imental error. When all the shifts were less than 0.7σ the refinement was considered complete; the residual converged to a final value $R = 0.032$ for 3456 observed reflections. A final difference map showed no significant features. The coordinates are listed in Table 1; lists of anisotropic temperature parameters and of observed and calculated structure factors are available.[2] The overall conformation of the molecule and the numbering of atoms are shown on the thermal ellipsoids plot (16) of Fig. 1.

[2]These tables may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

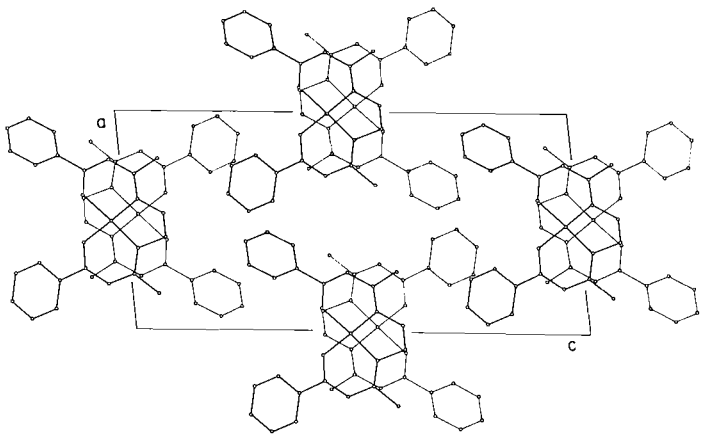

FIG. 4. Packing of molecules in the crystal, as seen along the y axis.

Results and Discussion

Bond distances and bond angles are reported in Fig. 2. The two N=C(—C)—C=C—O chelating chains and the Ni atom are nearly coplanar, the highest deviation from the least-squares plane (17) being 0.13 Å. The geometry around the Ni atom is approximately square planar, the deviations from the mean plane defined by the atoms Ni, N(1), N(2), O(1), and O(2) being within 0.02 Å; the Ni—N, Ni—O distances are in the range 1.85–1.86 Å. Predictions emerging from the previous single crystal esr study (9) have been confirmed: in particular referring to the crystal system, the approximate orientation of the ligand plane with respect to the elongation axis of the crystals, and the lack of coplanarity of the phenyl rings with respect to the chelating chains, the involved torsion angles being −15° for C(12)—C(11)—C(1)—O(1), and +15° for C(22)—C(17)—C(10)—O(2). The torsion angle along the dimethylene bond is −33°. The signs are given following a known convention (18).

Bond lengths along the ligand are in very good agreement with corresponding values found for 8 Schiff-base type complexes of V, Cu, Co (19):

Bond	Length (Å)	
	Average values from ref. 19	This work (average of two values, except for the last figure)
C(1)—O(1)	1.294	1.296
C(1)—C(2)	1.366	1.368
C(2)—C(3)	1.423	1.414
C(3)—N(1)	1.308	1.314
C(3)—C(4)	1.517	1.511
N(1)—C(5)	1.462	1.469
C(5)—C(6)	1.503	1.505

As already pointed out (19), the ligand bond lengths are independent of the nature of the metal. For all these compounds, including the present one, the chelating chains are always found to be planar or nearly planar, with the metal in the plane of the four donor atoms. These facts, along with the feasibility of growing crystals of Ni^{II}(benacacen) doped with Co^{II}(benacacen), support the hypothesis of isostructurality of the two compounds.

In the crystal the molecules are stacked in centrosymmetric pairs by van der Waals forces (Fig. 3), leaving voids between different couples and giving rise to empty channels which run parallel to the y axis through the whole structure (Fig. 4). This feature can be considered an important prerequisite for oxygen absorption in the solid state (20), a relevant point in the study of chemical models of biological interest.

Erysotrine-*N*-oxide and erythrartine-*N*-oxide, two novel alkaloids from *Erythrina mulungu*

MARIA HELENA SARRAGIOTTO, HERMOGENES LEITÃO FILHO,[1] AND ANITA J. MARSAIOLI[2]

Instituto de Química, Universidade Estadual de Campinas, CP 1170, 13100 Campinas, São Paulo, Brasil

Received February 13, 1981

MARIA HELENA SARRAGIOTTO, HERMOGENES LEITÃO FILHO, and ANITA J. MARSAIOLI. Can. J. Chem. **59**, 2771 (1981).

Erysotrine, erythrartine, hypaphorine, and two novel alkaloids, erysotrine-*N*-oxide and erythrartine-*N*-oxide, were isolated from the flowers of *Erythrina mulungu*. The *N*-oxide structures were determined by spectroscopic analysis (mass, ^{1}H, and ^{13}C nmr) and by partial synthesis.

MARIA HELENA SARRAGIOTTO, HERMOGENES LEITÃO FILHO et ANITA J. MARSAIOLI. Can. J. Chem. **59**, 2771 (1981).

A partir des fleurs de l'*Erythrina mulungu* on a isolé l'érysotrine, l'érythrartine, l'hypaphorine et deux nouveaux alcaloides, les *N*-oxydes d'érysotrine et d'érythrartine. On a déterminé les structures des *N*-oxydes par des analyses spectroscopiques (rmn du ^{1}H et du ^{13}C et spectroscopie de masse) et par synthèse partielle.

[Traduit par le journal]

Erythrina mulungu[3] (Leguminosae) is a medicinal plant used in folk medicine as a nervine sedative, febrifuge, and antiasthmatic (1). These pharmacological activities are very similar to those shown by *E. variegata* (2) and seem to be due to the presence of spiroamine alkaloids. These compounds, usually referred to as Erythrina alkaloids, have been exhaustively investigated from phytochemical (3), synthetic (4), biosynthetic (5), and spectroscopic (mass (6), gc–mass (3), ^{1}H nmr (7)) points of view; ^{13}C nmr spectroscopy, though, has not yet been fully applied (4, 8).

We now wish to report the isolation of five major alkaloids (**1**, **2**, **3**, **4**, and **5**) from the methanol extract of *Erythrina mulungu* flowers, as well as their ^{13}C nmr data.

Compounds **1**, **2**, and **3** were identified as erysotrine **1** (9), erythrartine **2** (10), and hypaphorine **3** (10). Compounds **1–3** are common constituents of the Erythrina species. Their identifications were based on previously published spectroscopic data and confirmed by their ^{13}C nmr spectra analysis.

The shift assignments, listed in Table 1, were made by standard chemical shift theory and analysis of the SFORD and fully coupled spectra (11). 1-(*p*-Methoxybenzyl)-6,7-dimethoxytetrahydroisoquinoline **6** (12) and 1-α-bromo-15,16-dimethoxy-*cis*-erythrinan-2,8-dione-2-ethylenacetal **7** (8) were used as models.

Comparison of the carbon signals of **1** with the corresponding signals of erythrartine **2** shows agreement for all, except for those at 128.3, 64.3, and 51.2 ppm which were assigned to C-12, C-11, and C-10 respectively. Similar changes are observed, in C-α and C-β, when an axial hydroxyl group is introduced to 5-α-cholest-8(14)-en-3-β-ol **8**, i.e. **8** to **9** (13). This corroborates the pseudo axial hydroxyl

[a] Signals in any vertical column may be reversed.

group at C-11 in erythrartine **2**, previously suggested on the basis of ^{1}H nmr data and $[\alpha]_D$ correlation with related alkaloids (10).

Compound **4** was isolated as an oily brown substance of molecular formula $C_{19}H_{23}NO_4$ (M^+ 329.1595) as determined by high resolution mass spectrometry. The ir (ν_{max} 1610 cm^{-1}) and the uv spectra (λ_{max} 231 (14000) and 278 (2900) nm) were almost identical with those of erysotrine **1** (9) and erythrartine **2** (10). The mass spectrum showed significant ions at *m/e* 329 (M^+), 313 ($M^+ - 16$), 298 ($M^+ - 16 - 15$), 282 ($M^+ - 16 - 31$), 269, 239 (100), 165, 152.

Based on these data an erythrinan carbon skeleton of the 1–6 diene type was assumed. The ^{1}H nmr spectrum of **4**, in deuteriochloroform, revealed two aromatic proton singlets at δ 6.83, 6.76 and three methoxyl group singlets at δ 3.43 (3H), 3.84 (3H), and 3.95 (3H). The presence of three olefinic proton signals at δ 5.92 (broad singlet, H-7), δ 6.30 (broad doublet, J = 10 Hz, H-1), and δ 6.86 (d, J = 3 Hz, low field arm of a double doublet partially covered by one of the aromatic singlets, H-2) corroborated the assumption of a diene system in the molecule. On irradiation at δ 4.10 (H-3) the double doublet at δ 2.14 (H-4e, J_{3e-4e} = 5.5 Hz; J_{4a-4e} = 11 Hz) collapsed to a doublet, the large multiplet at δ 3.08–3.36 (3 superimposed proton signals) was simplified, and the low field arm of the H-2 signal collapsed to a singlet. Further irradiation at δ 3.20 (H-4a) and δ 2.14 (H-4e) allowed the assignment of this ABXY system to that depicted in ring A of **4**.

These results were comparable with those of erythristemine **12** (7) and erythrartine **2** (10) except for the H-4a chemical shift ($\Delta\delta_{4-12}$ 1.12, $\Delta\delta_{4-2}$ 1.35 ppm). Further analysis of the ^{1}H nmr spectrum was not possible due to superimposed signals.

The clue to the structure elucidation of **4** was given by the analysis of the ^{13}C nmr spectrum. The main differences between compound **4** and **1** in the ^{13}C nmr spectra lie in the chemical shifts of the carbon atoms neighboring *N*. The shielding ($\Delta\delta_{1-4}$ 9.4, 3.5, and 3.6 ppm at C-4, C-7, and C-12 respectively) and deshielding ($\Delta\delta_{1-4}$ 14.7, 15.1, and 15.9 ppm at C-5, C-8, and C-10 respectively) effects are consistent with those observed for fumaritine **10** and fumaritine-*N*-oxide **11** (14).

The above arguments, and the presence of an ($M - 16$)$^+$ peak in the mass spectrum (characteristic of *N*-oxides (15)), led us to suggest the erysotrine-*N*-

oxide structure for compound **4**. Further confirmation of structure **4** was accomplished by treating **1** with *m*-chloroperbenzoic acid. The resulting *N*-oxide was identical in all aspects (ir, ^{1}H nmr) to the natural product **4**.

Compound **5** was isolated as an oil of molecular formula $C_{19}H_{23}NO_5$ (M^+ 345.1602) as determined by high resolution mass spectrometry. This compound exhibited the uv (λ_{max} 278 (2900), 231 (14000) nm) and ir (ν_{max} 1610, 3250 (OH) cm^{-1}) absorption bands attributable to the 1–6 diene moiety and an hydroxyl group respectively. The ^{1}H nmr spectrum (deuteriochloroform) showed the presence of the following functional groups: three methoxyl groups (δ 3.38, 3.78, and 3.92, each 3H, s), two aromatic protons (δ 6.68 and 7.08, each 1H, s), and three methines (δ 5.82 (broad singlet, 1H), 6.18 (d, J = 10 Hz), and 6.74 (dd, J = 10 and 2 Hz)), the latter characteristic of a 1–6 diene erythrinan skeleton.

On irradiation at δ 2.09 (dd, J_{3a-4e} = 5 Hz, J_{4e-4a} = 10.5 Hz), the triplet at δ 3.16 (J_{4a-4e} = 10.5 Hz, J_{3a-4a} = 10.5 Hz) collapsed to a doublet. Conversely, irradiation of the triplet at δ 3.16 changed the double doublet at δ 2.09 to a doublet. In compound **5**, as in erysotrine-*N*-oxide, H-4a (part of the ABX system of ring A) is shifted downfield (Δδ 1.31 ppm) when compared to that of erythrartine **2**. This supports an *N*-oxide structure. Finally, the existence of a carbinolic proton at C-11 was suggested, based on the signal at δ 5.28 (d, $J_{10a-11a}$ = 15 Hz, H-11a).

The ^{13}C nmr spectrum of **5** (Table 1) when compared to that of **2** revealed deshieldings ($\Delta\delta_{2-5}$ 15.2, 15.9, and 14.7 ppm at C-10, C-5, and C-8 respectively) and shieldings ($\Delta\delta_{2-5}$ 9.5, 4.5, and 2.2 ppm at C-4, C-7, and C-12 respectively) analogous to those observed in the transformation of erysotrine **1** into erysotrine-*N*-oxide **4**. Based on these arguments, we assumed compound **5** was erythrartine-*N*-oxide. Confirmation was obtained by treating erythrartine with *m*-chloroperbenzoic acid. The resultant synthetic *N*-oxide and the natural product **5** showed superimposable ir and ^{1}H nmr spectra.

The absolute configuration at C-3 and C-11 of **5** was established as follows. Methylation of the oily *N*-oxide **5** with sodium hydride – methyl iodide afforded the *O*-methyl derivative **13**, whose ^{1}H nmr spectrum analysis revealed the presence of an additional methoxyl group at δ 3.64. As observed in **4** and **5**, the ABX system of ring A appears at δ 2.00 (dd, J_{4e-4a} = 11 Hz, J_{4e-3a} = 5.5 Hz, H-4e), 3.34 (t, J_{4e-4a} = 11 Hz, J_{4a-3a} = 11 Hz, H-4a). The INDOR technique was used to identify H-3. Using the central peak of the triplet at δ 3.34 as the observed transition, responses were obtained at δ 2.00 and δ 4.30. Consequently H-3 must be at δ 4.30. Using the INDOR technique and observing the peak at δ 5.80 (broad s, H-7), H_{8a} and H_{8e} were detected at δ 4.20. Finally, observing each line of the doublet at δ 5.16 (d, J = 15 Hz, H-11), responses were obtained at δ 4.40. Thus, from δ 4.60 to δ 4.10 are located signals corresponding to H_{10a}, H_{10e}, H_3, H_{8a}, H_{8e}. Finally the large coupling (J = 15 Hz) of the carbinolic proton was indicative of an axial proton at H-11.[4] The analysis of the ^{13}C nmr spectrum of **13** was also carried out. The comparison of the δ values for **13** with the δ values for **5** revealed the concordance of all carbon shifts except for C-10, C-11, and C-13, where the methylation occurred. Furthermore, the C-11 and C-3 shifts (74.4 and 75.3 ppm respectively) suggested equatorial methoxyl groups at both carbons, thus corroborating the pseudo axial H-11.

Treatment of **13** with triethylphosphite in benzene produced the tertiary base erythristemine **12**, which showed $[\alpha]_D$ and ^{1}H nmr data analogous to that reported in the literature (7). The absolute configurations at C-11 and C-3 of **12** were determined by a crystallographic study. This indicates that indeed **5** and **12** have the same absolute configurations at C-3 and C-11.

This is the first time erythrinan *N*-oxides have been reported. The possibility that these *N*-oxides might be artefacts could not be ignored. Therefore fresh flowers were collected and extracted with cold methanol and the crude extract was immediately analyzed by thin layer chromatography. The presence of the *N*-oxides showed that in fact they are natural products. The water solubility of the *N*-oxides and the current methods for isolation of water soluble alkaloids are probably responsible for the lack of examples of erythrinan-*N*-oxides in the literature.

Interestingly, *N*-oxidation of each of the alkaloids erysotrine **1** and erythrartine **2** yielded only one of the two possible (considering inversion at the bridgehead nitrogen (16)) *N*-oxides. In fact the *N*-oxides **4** and **5** are those produced by introduction of oxygen from the more accessible convex face of the molecules **1** and **2**, and this can be shown in the ^{13}C nmr by the C-4 shielding ($\Delta\delta \simeq 9.5$ ppm) and in the ^{1}H nmr by the H-4a deshielding ($\Delta\delta \simeq$ 1.30 ppm) effects produced when *N*-oxidation of the tertiary bases occurs, similar to those observed when going from **10** to **11** (14).

[4]Erythristemine **12** and compound **13** possess the same absolute configuration at C-11 but their solution conformations are different (H-11 is equatorial in **12** and axial in **13**).

Experimental

The ^{1}H nmr spectra were determined on a Varian T-60 or a Varian XL 100 spectrometer using $CDCl_3$ solutions (unless otherwise indicated) and Me_4Si as an internal standard, chemical shifts are expressed in δ and coupling constants (J) are given in Hertz (s = singlet, d = doublet, t = triplet, m = multiplet). The ^{13}C nmr spectra were recorded in $CDCl_3$ solutions on a Varian XL-100 spectrometer operating at 25.2 MHz in the Fourier transform mode; the values are in parts per million downfield from Me_4Si ($\delta(Me_4Si) = \delta(CDCl_3) + 76.9$); low resolution mass spectra were obtained with a Finnigan Model 1015/SL spectrometer; optical rotations were measured in a Carl Zeiss photoelectric polarimeter. All melting points were determined on a Reichert hot-stage microscope and are uncorrected. Infrared spectra were run on a Perkin-Elmer 337 spectrophotometer using thin films or KBr pellets. Merck silica gel HF was utilized for thin layer plates (tlc) and spots were visualized by spraying Dragendorff solution (17) followed by $MeOH/H_2SO_4$ and heating at 110°C.

The *Erythrina mulungu* flowers were collected in 1979 at "Fazenda Santa Elisa" (Campinas, SP, Brazil) and dried at 40°C for 36 h. The finely ground flowers (690.00 g) were then extracted with methanol yielding 55.60 g of crude extract, which was adsorbed on celulose (120.00 g) and eluted with hexane (5.67 g), chloroform (7.06 g), chloroform–methanol 1:1 (23.33 g), and methanol (7.52 g). Column chromatography through silica gel afforded the alkaloids, further purified using preparative layer chromatography.

Erysotrine **1** (0.17 g) was isolated in 0.31% yield and was identified by ir (9), mass (6), and ^{1}H nmr (9) spectra; uv λ_{max} (EtOH) (ε): 2.30 (12 100), 280 (3300) nm; ir ν(KBr): 1610 cm^{-1}; ^{1}H nmr δ: 6.86 (s, H-14), 6.66 (s, H-17), 6.56 (d, J = 3 Hz, high field arm of a dd, H-2), 6.04 (broad d, J_{1-2} = 10 Hz, H-1), 5.76 (broad s, H-7), 3.86 (s, OMe), 3.76 (s, OMe), 3.34 (s, OMe), 1.89 (t, J_{4a-3a} = 10.5 Hz, H-4a); ms *m/e* (relative intensity): 313 (M^+, 65), 298 (41), 282 (100), 280 (12). The ^{13}C nmr data for **1** are given in Table 1.

Erythrartine **2** (0.17 g) was isolated in 0.31% yield and was identified by ir (10), mass (10), and ^{1}H nmr (10) spectra; $[\alpha]_D^{25}$ 256 (*c* 1.4, $CHCl_3$); uv λ_{max} (EtOH) (ε): 227 (15 135), 275 (3630) nm; ir ν (film) 1610 cm^{-1}; ^{1}H nmr δ: 7.08 (s, H-17), 6.92 (s, H-14), 6.68 (dd, J_{2-1} = 10 Hz, J_{2-3} = 2 Hz, H-2), 6.10 (broad d, J_{1-2} = 10 Hz, H-1), 5.82 (broad s, H-7), 4.80 (t, H-11e), 3.95 (s, OMe), 3.83 (s, OMe), 3.37 (s, OMe), 3.67 (dd, $J_{10a-10e}$ = 15 Hz, $J_{11e-10a}$ = 5 Hz, H-10a), 3.14 (dd, $J_{11e-10e}$ = 4 Hz, $J_{10e-10a}$ = 15 Hz, H-10e), irradiation at δ 4.8 (t) → 3.67 and 3.14 collapsed to a pair of doublets J = 15 Hz; 2.46 (dd, J_{4e-3a} = 5 Hz, J_{4e-4a} = 11 Hz, H-4e), 1.85 (t, $J_{4a-4e} \cong J_{4a-3a}$, H-4a), irradiation at δ 1.85 (t) → 2.46 collapsed to a doublet, conversely, irradiation at δ 2.46 collapsed δ 1.85 to a doublet; ms *m/e* (relative intensity): 329 (M^+, 75), 314 (26), 298 (100), 296 (28), 280 (12); ^{13}C nmr data of **2** are given in Table 1.

Hypaphorine **3** (0.13 g) was isolated in 0.24% yield, mp 247.8–248.8°C (lit. (10) mp 245–247°C); (HCl) 233.1–234.4°C (lit. (10) mp 231–233°C); ir ν_{max}(KBr): 3200, 1640 cm^{-1}; ^{1}H nmr (CF_3COOH) δ: 7.77–7.30 (6 aromatic protons), 4.53 (t, J = 8 Hz, 1H), 3.65 (d, J = 8 Hz, 2H), 3.47 (s, 9H, $3\overset{+}{N}Me$); ^{13}C nmr (D_2O) δ: 172.0 (C=O), 136.9 (C-7a), 127.2 (C-3a), 125.4 (C-2), 122.7 (C-6), 120.1 (C-5), 118.9 (C-4), 112.7 (C-7), 107.9 (C-3), 79.7 (C-β), 52.8 ($\overset{+}{N}Me$), 23.7 (C-α).

Erysotrine-N-*oxide* **4** (0.11 g) was isolated in 0.19% yield; $[\alpha]_D^{25}$ 78.3 (*c* 1, EtOH); uv λ_{max} (EtOH) (ε): 231 (14 000), 278 (2900) nm; ir ν_{max} (KBr): 1610 cm^{-1}; ^{1}H nmr δ: 6.83 (s, 1H), 6.76 (s, 1H), 6.86 (d, J = 3 Hz, low field arm of a double doublet, H-2), 4.60–4.12 (m, 4H), 3.95 (s, 3H, OMe), 3.84 (s, 3H, OMe), 3.43 (s, 3H, OMe), 3.36–3.08 (m, 3H), 2.14 (dd, J_{3e-4e} = 5.5 Hz, J_{4a-4e} = 11 Hz, H-4e); ms *m/e* (relative intensity): 329 (M^+, 5), 313 (10), 311 (10), 298 (12), 282 (20), 269 (90), 254 (36), 239 (100), 224 (55), 165 (62), 152 (52). *Exact Mass* calcd. for $C_{19}H_{23}N_1O_4$: 329.1627; found (ms): 329.1595. The ^{13}C nmr data for **4** are listed in Table 1.

Erythrartine-N-*oxide* **5** (0.089 g) was isolated in 0.16% yield as a yellowish oil; $[\alpha]_D^{25}$ 88.57 (*c* 1.4, EtOH); uv λ_{max} (EtOH) (ε): 231 (14 000), 278 (2900) nm; ir ν_{max} (KBr): 1610 cm^{-1}; ^{1}H nmr δ: 7.08 (s, H-14), 6.68 (s, H-17), 6.74 (dd, J_{1-2} = 10 Hz, J_{2-3e} = 2 Hz, H-2), 6.18 (d, J_{1-2} = 10 Hz, H-1), 5.82 (broad s, H-7), 5.28 (broad d, $J_{10a-11a}$ = 15 Hz, H-11a), 4.4–4.0 (m, 4H), 3.92 (s, 3H, OMe), 3.78 (s, 3H, OMe), 3.38 (s, 3H, OMe), 3.16 (t, J_{4a-4e} = 10.5 Hz, J_{3a-4a} = 10.5 Hz, H-4a), 2.09 (dd, J_{3a-4e} = 5 Hz, J_{4e-4a} = 10.5 Hz, H-4e), irradiation at 2.09 (dd) → 3.16 (t) collapsed to a doublet; conversely, irradiation at 3.16 (t) collapsed 2.09 (dd) to a doublet; ms *m/e* (relative intensity): 345 (M^+, 4), 329 (26), 326 (29), 298 (70), 239 (100), 224 (45), 165 (47), 152 (39). *Exact Mass* calcd. for $C_{19}H_{23}N_1O_5$: 345.1576; found (ms): 345.1602. The ^{13}C nmr data of **5** are given in Table 1.

Erysotrine-N-*oxide* **4**

m-Chloroperbenzoic acid (97.7 mg, 6 × 10^4 mol) was added to a cold stirred mixture (0–5°C) of erysotrine **1** (177.2 mg, 0.0006 mol) in chloroform (5 mL), and the mixture was left at room temperature for 3 h. The $CHCl_3$ solution was evaporated and the residue purified by preparative layer chromatography, developed with $CHCl_3$–MeOH 1:1, affording 110.7 mg (59.4% yield) of synthetic erysotrine-*N*-oxide **4**, which was identical (ir, ^{1}H nmr, uv) to the natural product **4**.

Erythrartine-N-*oxide* **5**

m-Chloroperbenzoic acid (25.28 mg, 1.47 × 10^{-4} mol) was added to a cold stirred mixture (0–5°C) of erythrartine **2** (48.4 mg, 1.47 × 10^{-4} mol) in chloroform (3 mL), and the mixture was left at room temperature for 3 h. The reaction mixture was then worked up as described above (58.7% yield).

O-*Methyl-erythrartine*-N-*oxide* **13**

Sodium hydride (16 mg) was gradually added to a cold stirred solution (5°C) of **5** (120 mg, 3.4 × 10^{-4} mol), followed by addition of ≈ 0.03 mL of methyl iodide and the mixture was left at room temperature for 24 h. Methanol was added to destroy the excess of sodium hydride and then evaporated. The residue was purified by preparative layer chromatography, developed with $CHCl_3$–MeOH 1:1, affording 40.0 mg (32% yield); ^{1}H nmr δ: 6.87 (s, H), 6.78 (s, H), 6.66 (d, J_{2-3} = 2 Hz, high field arm of a dd, H-2), 6.20 (d, J_{1-2} = 10 Hz, H-1), 5.80 (broad s, H-7), 5.16 (d, $J_{11a-10a}$ = 15 Hz, H-11), 4.60–4.10 (m, H-10a, H-10e, H-3, H-8a, H-8e), 3.95 (s, OMe), 3.81 (s, OMe), 3.64 (s, OMe), 3.40 (s, OMe), 3.34 (t, J = 11 Hz, H-4a), 2.00 (dd, J_{4e-4a} = 11 Hz, J_{4e-3a} = 5.5 Hz, H-4e). The ^{13}C nmr data for **13** are listed in Table 1.

Erythristemine **12**

O-Methyl-erythrartine-*N*-oxide **13** (0,040 g, 1.1 × 10^{-4} mol) and 0.025 mL of triethylphosphite in benzene (5 mL) were heated under reflux for one hour. The reaction mixture was then evaporated and the residue purified by preparative layer chromatography, yielding 0.030 g of erythristemine (78.9%); $[\alpha]_D^{25}$ 192 (*c* 0.8, $CHCl_3$) (lit. (7) $[\alpha]_D^{25}$ 189 ($CHCl_3$)); uv λ_{max} (EtOH) (ε): 225 (12 900), 278 (3300) nm; ^{1}H nmr (C_6D_6) δ: 7.12 (s, 1H), 7.00 (s, 1H), 6.35 (dd, J_{1-2} = 10.0 Hz, J_{2-3} = 2.0 Hz, H-2), 5.93 (d, J_{1-2} = 10.0 Hz, H-1), 5.38 (broad s, H-7), 3.42 (s, OMe, 6H), 3.20 (s, OMe, 3H), 3.02 (s, OMe, 3H), 2.52 (dd, J_{4a-4e} = 12.0 Hz, J_{3a-4e} = 5.0 Hz, H-4e, 2.13 (t, $J_{4a-4e} \cong J_{3a-4a}$ = 12.0 Hz, H-4a); ms *m/e*: 343 (M^+).

The oxidation of phenol and chlorophenols by alkaline permanganate

DONALD G. LEE[1] AND CARLOS F. SEBASTIÁN
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received October 9, 1980

DONALD G. LEE and CARLOS F. SEBASTIÁN. Can. J. Chem. **59**, 2776 (1981).

A kinetic study has been made of the oxidation of phenol and seven chlorophenols by alkaline permanganate. The initial reaction, which results in the formation of manganate(VI) ion, is first order with respect to permanganate ion, independent of the concentration of hydroxide ion, and of variable order with respect to phenol. At low phenol concentrations the order is unity, but at high concentrations it becomes zero. These observations can be accounted for quantitatively by the following mechanism:

$$Na^+ + PhO^- + MnO_4^- \rightleftharpoons [PhO—Na—OMnO_3]^-$$

$$[PhO—Na—OMnO_3]^- \rightarrow PhO^\cdot + MnO_4^{2-} + Na^+$$

$$PhO^- + [PhO—Na—OMnO_3]^- \rightarrow 2PhO^- + MnO_4^- + Na^+$$

DONALD G. LEE et CARLOS F. SEBASTIÁN. Can. J. Chem. **59**, 2776 (1981).

On a étudié la cinétique de l'oxydation du phénol et de 7 chlorophénols par le permanganate en milieu basique. La réaction initiale qui conduit à la formation de l'ion manganate(VI) est du premier ordre par rapport à l'ion permanganate, elle est indépendante de la concentration de l'ion hydroxyde et est d'un ordre variable par rapport au phénol. A de faibles concentrations de phénol la réaction est d'ordre un, mais elle est d'ordre zéro si les concentrations sont élevées. On peut justifier quantitativement les observations à l'aide des mécanismes suivants:

$$Na^+ + PhO^- + MnO_4^- \rightleftharpoons [PhO—Na—OMnO_3]^-$$

$$[PhO—Na—OMnO_3]^- \rightarrow PhO^\cdot + MnO_4^{2-} + Na^+$$

$$PhO^- + [PhO—Na—OMnO_3]^- \rightarrow 2PhO^- + MnO_4^- + Na^+$$

[Traduit par le journal]

Introduction

Knowledge of the oxidation of phenols by alkaline permanganate is of potential application in both organic synthesis (1) and water purification procedures (2). Previous studies of the mechanism of this reaction indicate that it is initiated by transfer of an electron from the phenolate ion to permanganate (3) as in eq. [1].

[1] $PhO^- + MnO_4^- \rightarrow Ph\dot{O} + MnO_4^{2-}$

The phenoxy free radicals so formed undergo further coupling and oxidation reactions which eventually produce the observed products (a mixture of *o* and *p*-diphenoquinones).

In this paper we wish to report new information that was obtained from a kinetic study of the oxidation of phenol and a number of chlorophenols.

Experimental

The initial reaction between phenolate (or a chlorophenolate) ion and permanganate ion is of such a rate that it can conveniently be monitored using stopped-flow equipment. The inorganic product of the reaction was identified from its uv–vis spectrum to be manganate(VI) ion, MnO_4^{2-}. Although this ion also oxidizes phenolate ions, the reaction rate is several orders of magnitude slower than the permanganate oxidation and thus would not influence the kinetics of the initial reaction (4).

Kinetic Procedure

A solution of sodium hydroxide (about 0.1 *M*) in doubly distilled, degassed water was prepared and standardized against potassium hydrogen phthalate. To part of this solution was added sufficient phenol or chlorophenol to give an appropriate concentration (about 1.5×10^{-3} *M*). Potassium permanganate was dissolved in another portion of the same sodium hydroxide solution to give a concentration of about 6×10^{-4} *M*. These solutions were then placed in the thermostated syringes of a Durrum D-150 stopped-flow apparatus with the wavelength set at 530 nm and plots of voltage against time were recorded. These were converted into plots of permanganate concentration against time by use of a previously prepared calibration curve and the initial reaction rates were obtained by taking a tangent to the curve at time zero (5).

Materials

Distilled water was redistilled from alkaline permanganate (6) and degassed by bubbling through nitrogen, boiling, and cooling under a nitrogen atmosphere. Phenol, obtained from Analar, was purified by distillation (bp 98–100°C/30 Torr) and recrystallization from hexane; mp 40.0–41.5°C, lit. (7) mp 40.9°C. *o*-Chlorophenol, obtained from Aldrich, was purified by fractional distillation. A middle fraction was collected and used; bp 169–170°C, lit. (8) bp 175–176°C. *p*-Chlorophenol, obtained from Aldrich, was first distilled (104–106°C/25 Torr) and then recrystallized from hexane; mp 42.5–44.0°C, lit. (8) mp 43°C. *m*-Chlorophenol, obtained from Aldrich, was recrystallized from hexane; mp 32–34°C, lit. (8) mp 33°C. 2,4-Dichlorophenol, obtained from Aldrich, was first distilled (103–105°C/30 Torr) and then allowed to solidify; mp 41.5–43.0°C, lit. (7) 42–43°C. 2,4,5-Trichlorophenol, obtained from Aldrich, was purified by sublimation; mp 66.0–67.5°C, lit. (7) mp 67°C. 2,4,6-Trichloro-

phenol, obtained from Aldrich, was recrystallized from acetic acid; mp 67.5–69.5°C, lit. (7) mp 67–68°C. 2,3,4,5-Tetrachlorophenol, obtained from Aldrich, was recrystallized from hexane; mp 117.5– 119.0°C, lit. (8) mp 116–117°C.

Results

Plots of the logarithm of the initial rate against the logarithm of the permanganate concentration (when the phenolate concentration was held constant) indicated that the reaction was first order with respect to oxidant (Fig. 1). However, the order with respect to phenolate concentration, although unity at low concentrations, approached zero order at high concentrations. Typical examples of this phenomenon are illustrated in Figs. 2 and 3. All other chlorophenols gave similar plots.

The reaction rate was unaffected by changes in the concentration of hydroxide ion between 0.04 and 0.8 *M* as the data in Table 1 illustrate.

Discussion

The observed change in order with respect to reductant suggests that the reaction may proceed

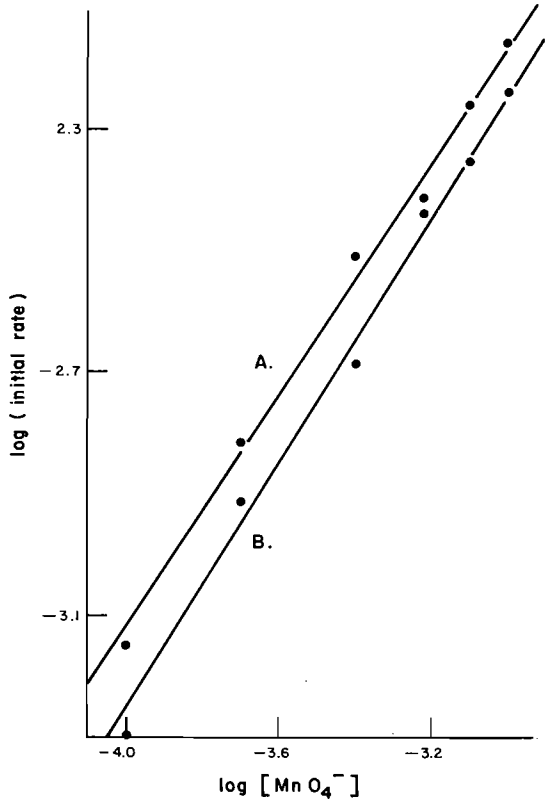

FIG. 1. Plots indicating that the order with respect to permanganate ion is unity. A. $[PhO^-] = 2.09 \times 10^{-2}$ *M*; B. $[PhO^-] = 1.19 \times 10^{-2}$ *M*.

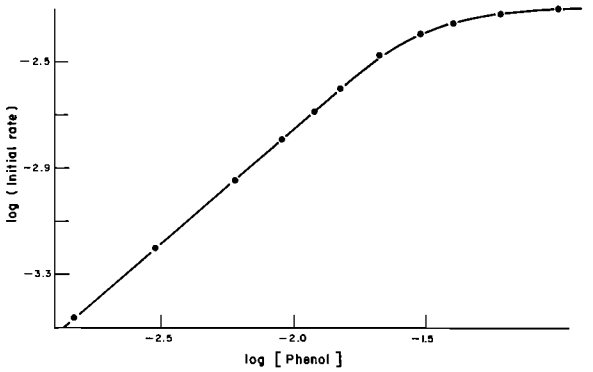

FIG. 2. Plot showing the changing order with respect to phenol concentration.

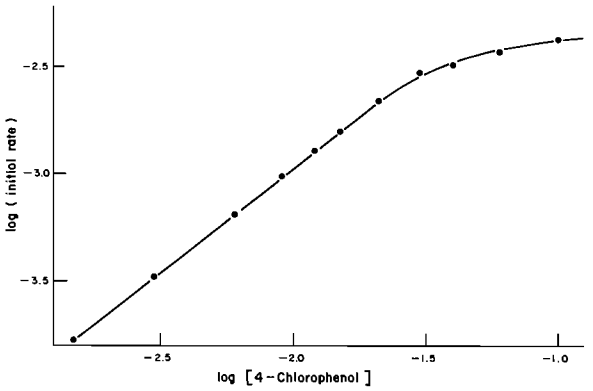

FIG. 3. Plot showing the changing order with respect to 4-chlorophenol.

TABLE 1. The reaction order with respect to hydroxide ion[a]

[NaOH] (*M*)	Initial rate (*M*/s) ($\times 10^4$)	Relative initial rate
0.048	2.32	1.00
0.095	2.28	0.98
0.191	2.30	0.99
0.381	2.35	1.01
0.571	2.19	0.94
0.762	2.30	0.99

[a]The conditions used to determine this order were: [Phenol] = 5.99×10^{-3} *M*, $[MnO_4^-] = 5.99 \times 10^{-4}$ *M*, temperature = 24.6 ± 0.1°C.

with formation of an intermediate that can either decompose to give products or react with phenolate ion to give back the reactants. Such a scheme is depicted in eqs. [2]–[4], where I is an intermediate.

$$[2] \quad MnO_4^- + PhO^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} I$$

$$[3] \quad I \xrightarrow{k_2} MnO_4^{2-} + Ph\dot{O}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

[4] $I + PhO^- \xrightarrow{k_3} 2PhO^- + MnO_4^-$

The rate of disappearance of permanganate ion for this mechanism would be given by eq. [5].

[5] $$-d[MnO_4^-]/dt = k_1[MnO_4^-][PhO^-] - k_{-1}[I] - k_3[PhO^-][I]$$

Assuming I to be a reactive intermediate and applying the steady state approximation gives an expression for the concentration of the intermediate (eq. [6]) that can be substituted into eq. [5] to give eq. [7].

[6] $$[I] = \frac{k_1[MnO_4^-][PhO^-]}{k_{-1} + k_2 + k_3[PhO^-]}$$

[7] $$-d[MnO_4^-]/dt = \frac{k_1k_2[MnO_4^-][PhO^-]}{k_{-1} + k_2 + k_3[PhO^-]}$$

The rate law in eq. 7 is of the required form to account for the observed kinetics. Under limiting conditions in which the concentration of phenolate is low the last term in the denominator could be neglected and the rate law would appear to be second order (eq. [8]), while under conditions of high phenolate concentrations this term could dominate and the reaction would appear to be first order (eq. [9]).

[8] $$-d[MnO_4^-]/dt = \frac{k_1k_2}{k_{-1} + k_2}[MnO_4^-][PhO^-]$$

[9] $$-d[MnO_4^-]/dt = \frac{k_1k_2}{k_3}[MnO_4^-]$$

By recasting eq. [7] in the form of eq. [10] and preparing the appropriate plots one can obtain values for $k_1k_2/(k_{-1} + k_2)$ and k_1k_2/k_3 from the inverses of the slopes and intercepts respectively. The good linearity of such plots (Fig. 4) substantiates the correctness of this approach.

[10] $$\frac{[MnO_4^-]}{-d[MnO_4^-]/dt} = \frac{k_{-1} + k_2}{k_1k_2[PhO^-]} + \frac{k_3}{k_1k_2}$$

From the results collected in Table 2 it can be seen that the values for the composite second order rate constants, $k_1k_2/(k_{-1} + k_2)$, decrease with increasing chlorine substitution. Except for *p*-chlorophenol the values for the composite first order rate constants, k_1k_2/k_3, also decrease regularly as the number of chlorine atoms is increased. These effects are likely of electronic origin, but difficult to understand exactly because of the complex nature of the rate constants. However, it is apparent that the more heavily chlorinated phenols are more resistant to oxidation and that it would be more difficult, for example, to remove them from contaminated water by treatment with permanganate. This observation is consistent with previous work where it was noted that nitrophenols were also difficult to oxidize (9).

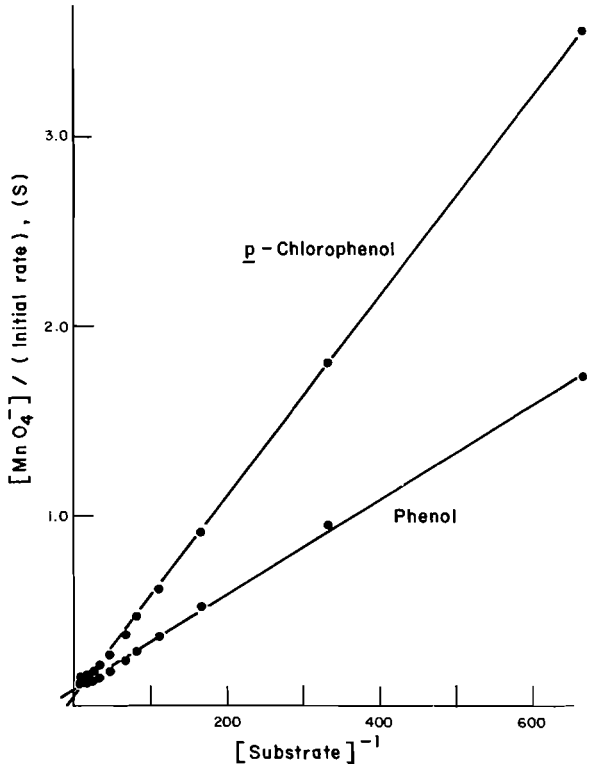

FIG. 4. Plots of eq. [10].

TABLE 2. Composite rate constants[a]

Substrate	$k_1k_2/(k_{-1} + k_2)$[b]	k_1k_2/k_3[c]	r[d]
Phenol	397	12.1	0.999
p-Chlorophenol	189	23.4	0.999
o-Chlorophenol	10.8	7.75	0.997
m-Chlorophenol	9.73	0.368	0.997
2,4-Dichlorophenol	2.44	0.191	0.993
2,4,5-Trichlorophenol;	2.07	0.171	0.995
2,4,6-Trichlorophenol	1.30	0.006	0.999
2,3,4,5-Tetrachlorophenol	0.76	0.005	0.989

[a]Conditions used were: $[MnO_4^-] = 6.0 \times 10^{-4}$ *M*, [NaOH] = 0.10 *M*, temperature = 25.0 ± 0.1°C; substrate concentrations from 0.001 to 0.100 *M*.
[b]M^{-1} s^{-1}.
[c]s^{-1}.
[d]Correlation coefficient for plot of $[MnO_4^-]/(-d[MnO_4^-]/dt)$ against $1/[PhO^-]$.

It should be noted that this analysis applies to the initial rates of reaction only. The entire reaction is not first order in oxidant; for example, linear plots are not obtained when ln (absorbance) is plotted against time for two or more half-lives. This means that the total sequence is complicated by reaction of products with the oxidant or other side reac-

For personal use only.

tions. A likely possibility that could account for this behavior is found if it is assumed that phenoxyl radicals are produced. These radicals would undergo coupling reactions that produce unsaturated compounds which would be attacked by permanganate.

One question that remains to be considered is the nature of the intermediate, I, which is formed from the reaction of permanganate ion with phenolate ion. Two limiting possibilities could be considered. The intermediate could be covalently bonded, having a structure such as **1** whose formation would be facilitated by polarization of the Mn—O bonds (eq. [11]) in the manner recently suggested by Sharpless *et al.* (10). They have presented evidence that all oxidations by transition metal oxy anions could be initiated by formation of similar intermediates. It is difficult, however, to understand how this intermediate could be decomposed by reaction with another phenolate ion as required by reaction [4].

[11] 
[12] 
1

On the other hand, permanganate and phenolate could combine to form a complex with sodium ion, **2**. Similar complexes have been proposed for other reactions such as the exchange of electrons between permanganate and manganate which involves the intermediate $[O_3MnO—Na—OMnO_3]^{2-}$ (11), and for a similar reaction between potassium ferricyanide and potassium ferrocyanide where an analogous transition state, $[KFe(CN)_6—K—Fe(CN_6K]^{4-}$, has been proposed (12). Other examples where experimental evidence for the involvement of cations in oxidation reactions has been observed include the exchange of electrons between various organic compounds and their negative ions (12).

[13] 
2

Although **2** has been depicted as a sodium bridged complex in analogy with the previous work cited above, it is possible that the role of the cation is simply to reduce the overall charge on the complex which forms prior to electron exchange. In other words, the formation of an intermediate from two anions is facilitated by the presence of a cation which reduces the net charge on the complex.

It would appear that a complex such as **2** is a more likely intermediate than **1** since it could be more easily decomposed by reaction with phenolate ion. Transfer of a sodium cation to a second phenolate ion before electron transfer had taken place would cause **2** to decompose with no net reaction having occurred. The kinetic consequence of this process would require the inclusion of a step such as eq. [4] in the reaction sequence.

Consequently, it is apparent that the reaction sequence depicted in eqs. [2]–[4] adequately accounts for the kinetic data obtained in this study.

The oxidation of phenol and chlorophenols by manganate(VI) ion

DONALD G. LEE[1] AND CARLOS F. SEBASTIÁN

Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received October 9, 1980

DONALD G. LEE and CARLOS F. SEBASTIÁN. Can. J. Chem. **59**, 2780 (1981).

The kinetics of the oxidation of phenol and three chlorophenols have been studied under alkaline conditions. Although the reaction is first order with respect to the oxidant it exhibits a fractional order with respect to the substrates, thus suggesting a free radical chain mechanism (eqs. [3]–[7]). The inverse dependence of the reaction rate on base concentration has been attributed to acid catalysis of the chain initiating step.

DONALD G. LEE et CARLOS F. SEBASTIÁN. Can. J. Chem. **59**, 2780 (1981).

On a étudié la cinétique de l'oxydation du phénol et de trois chlorophénols en milieu basique. Bien que la réaction soit d'ordre un par rapport à l'oxydant, elle montre un ordre fractionnaire par rapport au substrats, ce qui suggère un mécanisme radicalaire libre en chaîne (éqs. [3]–[7]). On a attribué l'influence inverse de la concentration de la base sur la vitesse de réaction à une catalyse acide de l'étape de formation de la chaîne.

[Traduit par le journal]

Introduction

The oxidation of phenols by alkaline permanganate proceeds in two distinct stages. In the first, permanganate ion is rapidly reduced as in eq. [1], while in the second, manganate(VI) ion is more slowly reduced to manganese dioxide (eq. [2]).

[1] $PhO^- + MnO_4^- \longrightarrow Ph\dot{O} + MnO_4^{2-}$

[2] $2PhO^- + MnO_4^{2-} + 2H_2O \longrightarrow 2Ph\dot{O} + MnO_2 + 4OH^-$

The kinetics of the first stage of this reaction have previously been described by ourselves and others (1, 2). In this paper we wish to focus on the kinetics of the second stage.

Experimental

The rates of reduction of manganate(VI) ion were monitored by following the decrease in absorbance at 606 nm using a Perkin-Elmer 356 uv–vis spectrophotometer. In a typical experiment two flasks, one containing a solution of phenol (2×10^{-2} *M*) in 0.1 *M* NaOH and the other containing potassium manganate(VI) (9×10^{-4} *M*), also in 0.1 *M* NaOH, were thermostated for 30 min. Then equal volumes of each solution were mixed and a timer started. This solution was returned to the thermostated bath and aliquots of about 7 mL each were withdrawn periodically. These were first centrifuged (to separate any MnO_2 present) and then transferred to a cuvette for absorbance measurements.

Identical reaction rates were obtained when the reaction was initiated by use of potassium permanganate which rapidly reduces to manganate(VI) ion on contact with the phenolate solution (1).

Materials

Many of the materials used in this study have previously been described (1). Potassium manganate(VI), K_2MnO_4, was obtained from the Carus Chemical Company.

[1]Author to whom correspondence may be addressed.

Results

Under conditions where the substrate and the hydroxide ion were in excess, linear plots of ln (absorbance) against time were obtained thus indicating that the reaction is first order with respect to manganate(VI) ion (Fig. 1).

The order with respect to substrate was then determined by plotting the logarithm of the pseudo first order rate constants (k_s) against the logarithm of the phenolate concentrations. Figures 2 and 3 give typical examples. Orders of 0.6 to 0.8 were obtained for all of the phenols studied (Table 1).

In a similar way the order with respect to hydroxide ion was found to be −0.79 (Fig. 4).

Discussions

Fractional orders such as those found in this study are indicative of radical chain processes and, therefore, it may be expected that the reduction of manganate(VI) ion to manganese(IV) oxide by phenols proceeds by such a mechanism. The reaction would most likely be initiated by the transfer of one electron from manganate(VI) ion to phenolate ion as in reaction [3].

[3] $PhO^- + MnO_4^{2-} \xrightarrow{k_3} Ph\dot{O} + MnO_4^{3-}$

Other studies have shown that the phenoxy radicals formed in this reaction would undergo a rapid dimerization to isomeric dihydroxybiphenyls (3). The manganate(V) ion, which is also formed in reaction [3], would be a very reactive oxidant under these conditions and might be expected to undergo one or more of three possible reactions: (*i*) it could react with water (reaction [4]), (*ii*) it could disproportionate into manganate(VI) ion and manganese

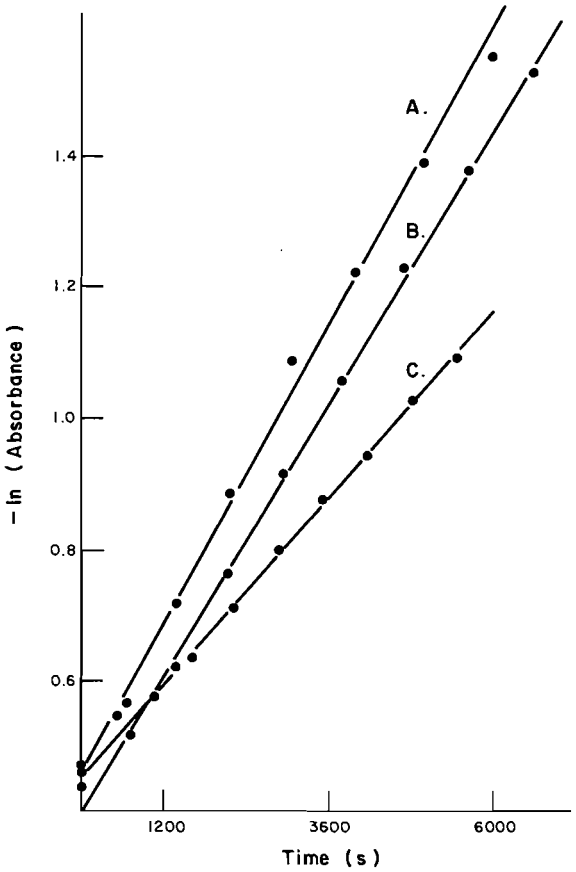

FIG. 1. Pseudo first order plots. $[MnO_4^{2-}] = 4.5 \times 10^{-4}$ *M*; [NaOH] = 0.10 *M*; A, [*o*-chlorophenol] = 6.75×10^{-3} *M*; B, [*o*-chlorophenol] = 6.75×10^{-3} *M*; C, [*m*-chlorophenol] = 4.49×10^{-3} *M*; temperature = 24.5 ± 0.1°C.

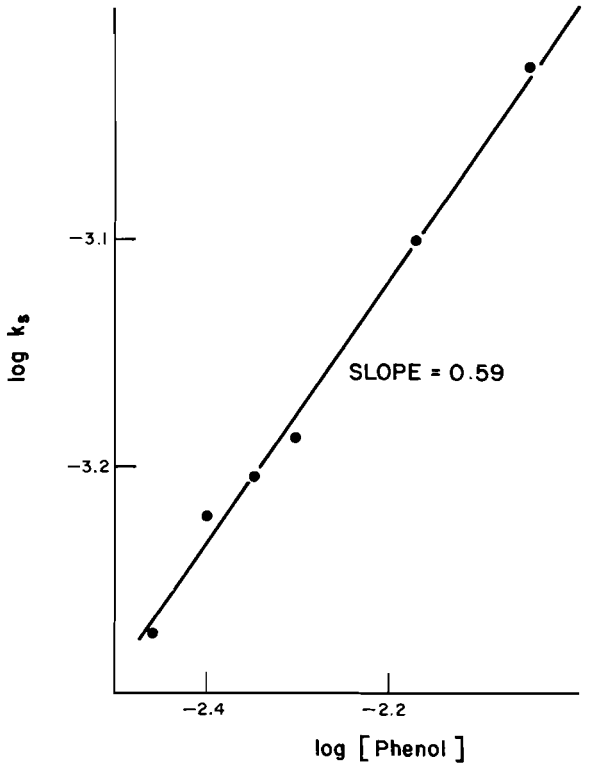

FIG. 2. The apparent order with respect to phenol concentration. $[MnO_4^{2-}] = 4.5 \times 10^{-4}$ *M*; [NaOH] = 0.10 *M*; temperature = 24.5 ± 0.1°C.

dioxide (reaction [4*a*]) (4), or (*iii*) it could react with phenolate ion (reaction [4*b*]).

$$[4]\quad MnO_4^{3-} + H_2O \xrightarrow{k_4} HMnO_4^{3-} + \dot{O}H$$

$$[4a]\quad 2MnO_4^{3-} \longrightarrow MnO_4^{2-} + MnO_4^{4-}$$

$$[4b]\quad MnO_4^{3-} + PhO^- \longrightarrow Ph\dot{O} + MnO_4^{4-}$$

Of these three bimolecular reactions the first is likely to predominate because water, since it is the solvent, is present in very high concentrations. Analogous reactions of transition metal oxides with water are known; for example, ruthenate(VI) ion (which is also a d^2 system) is stable only under very basic conditions and is reduced by water below pH 12 (5). Furthermore, if either [4*a*] or [4*b*] were the predominant reaction following [3], a chain reaction would not be produced.

It may be noted that each of the possible reactions of manganate(V) ion results in the formation of a manganate(IV) anion which would eventually precipitate as manganese dioxide (e.g. $HMnO_4^{3-} + H_2O \rightarrow MnO_2 + 3OH^-$).

TABLE 1. The order with respect to substrate[a]

Substrate	Order	r^b
Phenol	0.59	0.997
p-Chlorophenol	0.79	0.998

m-Chlorophenol	0.71	0.999
2,4-Dichlorophenol	0.67	0.996

[a] $[MnO_4^{2-}] = 4.5 \times 10^{-4}$ *M*; [NaOH] = 0.10 *M*; [Substrate] = 3.5×10^{-3} to 1.6×10^{-2} *M*; temperature = 24.5 ± 0.1°C.
[b] Correlation coefficient.

Previous work (6) has shown that the hydroxyl radical formed in reaction [4] would react readily with phenolate ion (reaction [5]) to give a radical anion (which we shall designate as "J" for the time being). Oxidation of J by manganate(VI) ion (reaction [6]) would then complete the chain propagation sequence.

$$[5]\quad \dot{O}H + PhO^- \xrightarrow{k_5} J$$

$$[6]\quad J + MnO_4^{2-} \xrightarrow{k_6} MnO_4^{3-} + \text{products}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

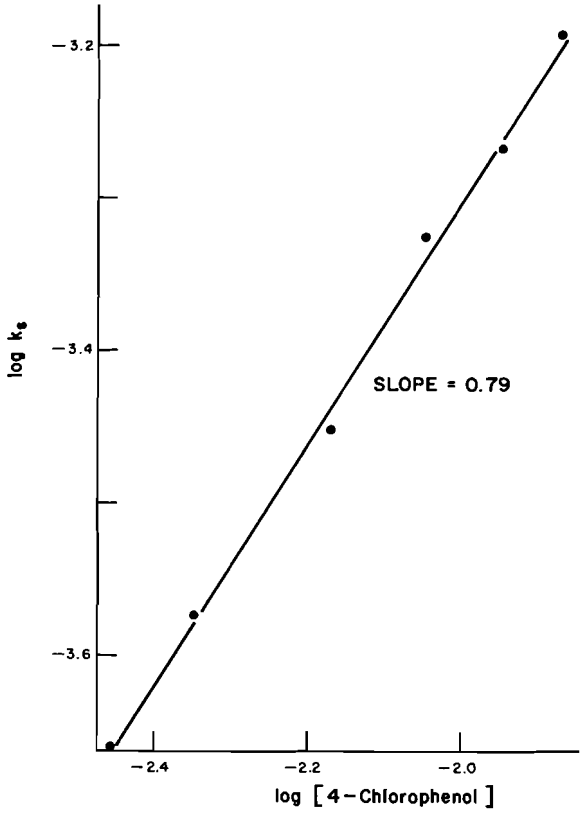

FIG. 3. The apparent order with respect to 4-chlorophenol concentration. $[MnO_4^{2-}] = 4.5 \times 10^{-4}$ *M*; [NaOH] = 0.10 *M*; temperature = 24.5 ± 0.1°C.

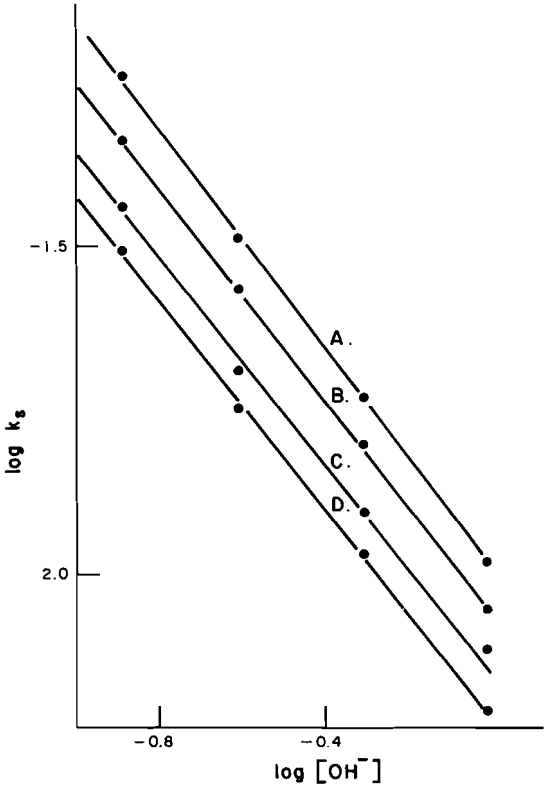

FIG. 4. The apparent order with respect to hydroxide ion concentration. $[MnO_4^{2-}] = 4.5 \times 10^{-4}$ *M*; temperature = 24.5 ± 0.1°C; $[PhO^-] = 3.5 \times 10^{-3}$ *M* (A); 4.5×10^{-3} *M* (B); 6.8×10^{-3} *M* (C); 9.0×10^{-3} *M* (D). Average slope = −0.79.

At least two chain terminating steps could be considered; the intermediate, J, could be oxidized by manganate(V) as in reaction [7], or J could dimerize. The latter possibility cannot be a major contributor to chain termination because its involvement leads to the prediction of a rate law that is not first order in manganate(VI) ion. It is possible that the rate of dimerization of J is suppressed relative to other free radicals because it bears a negative charge which would present an electrostatic barrier to coupling.

[7] $J + MnO_4^{3-} \xrightarrow{k_7} MnO_4^{4-} + \text{products}$

The sequence of reactions [3] to [7] thus describes a chain process, where reaction [3] is the initiation step, reactions [4], [5], and [6] are the chain propagation steps, reaction [7] is the termination step, and J is a reactive intermediate. Furthermore, as shown below, this sequence fits the available kinetic data quantitatively.

The rate of disappearance of the manganate(VI) ion for this scheme would be given by eq. [8].

$$[8] \quad -\frac{d[MnO_4^{2-}]}{dt} = k_3[PhO^-][MnO_4^{2-}] + k_6[J][MnO_4^{2-}]$$

Assuming that the steady-state approximation holds for the intermediates (ȮH, J, and MnO_4^{3-}), their concentrations would be given by eqs. [9]–[11].

$$[9] \quad [J] = \frac{k_5[\dot{O}H][PhO^-]}{k_6\,MnO_4^{2-}] + k_7[MnO_4^{3-}]}$$

$$[10] \quad [\dot{O}H] = k_4[MnO_4^{3-}]/k_5[PhO^-]$$

$$[11]\quad [MnO_4^{3-}] = [MnO_4^{2-}]\left(\frac{k_3[PhO^-] + k_6[J]}{k_4 + k_7[J]}\right)$$

Substitution of eqs. [10] and [11] into [9] gives a solution for [J] of the form depicted in eqs. [12] and [13].

$$[12]\quad [J]^2(2k_6k_7) + [J](k_3k_7[PhO^-]) - (k_3k_4[PhO^-]) = 0$$

$$[13]\quad [J] = \frac{-k_3k_7[PhO^-] \pm \sqrt{(k_3k_7)^2[PhO^-]^2 + 8k_3k_4k_6k_7[PhO^-]}}{4k_6k_7}$$

Substitution of eq. [13] into eq. [8] gives the exact rate law as expressed in eq. [14].

$$[14]\quad -\frac{d[MnO_4^{2-}]}{dt} = [MnO_4^{2-}]\left([PhO^-](k_3 - k_3/4) \pm \frac{k_3k_7}{4k_7}\sqrt{[PhO^-]^2 + \frac{8k_4k_6}{k_3k_7}\ PhO^-]}\right)$$

In order to further simplify eq. [14] one assumption may be made. Since $[PhO^-]$ is small, the square of the substrate concentration will be smaller. Therefore, it may be negligible compared to the other term under the square root sign. Further, the converse assumption (that the term $8k_4k_6[PhO^-]/k_3k_7$ is negligible compared to the $[PhO^-]^2$ term) cannot be accepted because it would predict a rate expression first order with respect to substrate. This cannot be correct, since experimentally it was found that the order was between 0.6 and 0.8, depending on the substrate.

Accepting this assumption, eq. [14] reduces to eq. [15].

$$[15]\quad -\frac{d[MnO_4^{2-}]}{dt} = [MnO_4^{2-}]\left(\frac{3}{4}k_3[PhO^-] \pm \left[\frac{k_3k_4k_6}{2k_7}\right]^{1/2}[PhO^-]^{1/2}\right)$$

It then follows that the pseudo first order rate constant could be equated with the term in parentheses as expressed in eq. [16].

$$[16]\quad k_s = \frac{3}{4}k_3[PhO^-] \pm \left(\frac{k_3k_4k_6}{2k_7}\right)^{1/2}[PhO^-]^{1/2}$$

The correctness of this expression can be tested quantitatively by recasting it in a linear form (eq. [17]) and preparing plots of $k_s/[PhO^-]^{1/2}$ against $[PhO^-]^{1/2}$.

$$[17]\quad \frac{k_s}{[PhO^-]^{1/2}} = \frac{3}{4}k_3[PhO^-]^{1/2} \pm \left(\frac{k_3k_4k_6}{2k_7}\right)^{1/2}$$

Since these plots are linear (Fig. 5) the reaction sequence and assumptions[2] are probably correct, and the values for the rate constants can be calculated from the slopes and intercepts (Table 2).

A perusal of the data in Table 2 shows that the intercepts are all positive, indicating that the positive root in eq. [17] should be considered in the solution.

It must be understood that the mechanism proposed is not necessarily the only possibility. However, it proves that such a free radical scheme can explain the fractional orders obtained experimentally. In this particular case it is found that the derived expression contains a term that is first order in substrate and another that is one-half order, thus accounting for the observation that the apparent order with respect to substrate is found to lie between unity and one-half for all the phenols studied (Table 1).

It was found experimentally that the order with respect to sodium hydroxide was fractional and negative. Such an inverse dependency on base suggests the possibility of acid catalysis in the reaction. (Many other oxidation reactions are also known to be subject to acid catalysis (7, 8).)

It is instructive therefore to consider the possibility that one or more of the steps in the reaction sequence may be subject to acid catalysis. For example, reactions [4] and [7] which both involve MnO_4^{3-} might be considered as likely points at which protonation of the oxidant would accelerate the reaction. Then by following an analysis similar to that described above it can be shown that the concentration of J would be given by eq. [18].

$$[18]\quad [J] = \frac{-k_3k_7[H^+][PhO^-] \pm \sqrt{(k_3k_7[H^+][PhO^-])^2 + 8k_3k_4k_6k_7[PhO^-][H^+]^2}}{4k_6k_7[H^+]}$$

[2]From the data in Table 2 it is possible to calculate values for the term $8k_4k_6/k_3k_7$, which appears in eq. [14]. The calculated values range from 0.02 to 0.80, thus indicating that the approximation will not introduce large errors.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

It can be seen that the proton concentration vanishes from eq. [18], and consequently from the rate expression as well. This result, therefore, allows for the possibility of acid catalysis in these steps, but does not account for the inverse dependence on base concentration.

Furthermore, if eq. [4] is considered to be accelerated by acid, the concentration of J is given by eq. [19].

$$[19]\quad [J] = \frac{-k_3k_7[PhO^-] \pm \sqrt{(k_3k_7)^2[PhO^-]^2 + 8k_3k_4k_6k_7[PhO^-][H^+]}}{4k_7k_8}$$

Following the procedure previously used the rate expression is then given by eq. [20] where $K_w = [H^+][OH^-]$.

$$[20]\quad -d[MnO_4^{2-}]/dt = [MnO_4^{2-}]\left(\frac{3}{4}k_3[PhO^-] \pm \left(\frac{K_wk_3k_4k_6}{2k_7}\right)^{1/2}\frac{[PhO^-]^{1/2}}{[OH^-]^{1/2}}\right)$$

If this approach were correct the observed pseudo first order rate constants should be linearly related to the inverse of the square root of the hydroxide ion concentration. The lack of linearity in the appropriate plots (Fig. 6) therefore indicates that acceleration of step 4 by acid does not adequately account for the observed results.

If, on the other hand, the first step of the sequence (eq. [3]) is considered to be subject to acid catalysis, the inverse dependence on base can be accounted for quantitatively, as shown in the following derivation (eqs. [21]–[26]).

$$[21]\quad [J] = \frac{-k_3k_7[H^+][PhO^-] \pm \sqrt{(k_3k_7[H^+][PhO^-])^2 + 8k_3k_4k_6k_7[H^+][PhO^-]}}{4k_6k_7}$$

$$[22]\quad -\frac{d[MnO_4^{2-}]}{dt} = [MnO_4^{2-}]\left(\frac{3k_3K_w[PhO^-]}{4[OH^-]} \pm \left(\frac{k_3k_4k_6K_w[PhO^-]}{2k_7[OH^-]}\right)^{1/2}\right)$$

Under conditions where the concentration of hydroxide ion is constant, eq. [22] would have the same general form as eq. [15]; i.e.:

$$[23]\quad -\frac{d[MnO_4^{2-}]}{dt} = [MnO_4^{2-}](k_m[PhO^-] \pm k_n[PhO^-]^{1/2})$$

where

$$k_m = 3k_3K_w/(4[OH^-]) \text{ and } k_n = (k_3k_4k_6K_w/(2k_7[OH^-])^{1/2}$$

Under conditions where the concentration of phenolate ion is constant and the hydroxide ion varied, eq. [22] may be rewritten in the form of eq. [24].

$$[24]\quad -\frac{d[MnO_4^{2-}]}{dt} = [MnO_4^{2-}](k_p[OH^-]^{-1} \pm k_q[OH^-]^{1/2})$$

where

$$k_p = \frac{3}{4}k_3K_w[PhO^-] \quad \text{and} \quad k_q = \left(\frac{k_3k_4k_6K_w[PhO^-]}{2k_7}\right)^{1/2}$$

The pseudo first order rate constant can be equated with the term in the parentheses of eq. [24] to give eq. [25].

$$[25]\quad k_s = k_p[OH^-]^{-1} \pm k_q[OH^-]^{-1/2}$$

Equation [25] can then be recast in a linear form (eq. [26]), where the slope and the intercept are given by k_q and k_p, respectively.

$$[26]\quad k_s[OH^-] = k_p \pm k_q[OH^-]^{1/2}$$

A plot of $k_s[OH^-]$ against $[OH^-]^{1/2}$ should be linear if the assumptions and the reaction sequence are correct. The fact that the plots appear to be linear with reasonably good correlation coefficients indicates that there is consistent agreement with the data (see Fig. 7).

Finally, it is necessary to consider a possible structure for the intermediate, J, which is formed by reaction of a hydroxyl radical with a phenolate ion (eq. [5]). This facile reaction, which has been

The acid-catalyzed oxido-reduction of spiroketals. Evidence for stereoelectronic control in hydride transfer to cyclic oxenium ions

PIERRE DESLONGCHAMPS, DARYL D. ROWAN, AND NORMAND POTHIER

Laboratoire de Synthèse Organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received April 3, 1981

PIERRE DESLONGCHAMPS, DARYL D. ROWAN, and NORMAND POTHIER. Can. J. Chem. **59**, 2787 (1981).

Tricyclic spiroketal **1** undergoes an acid-catalyzed oxidation–reduction reaction which yields equatorial bicyclic ether aldehyde **5** specifically. Similarly, spiroketals **2**, **3**, and **4** give equatorial bicyclic ether ketone **12**. These results are interpreted by invoking an internal hydride transfer from an alcohol function to a cyclic oxenium ion which takes place with stereoelectronic control. The reduction of tricyclic ketals **1** and **22** with sodium cyanoborohydride under acidic conditions is also reported.

PIERRE DESLONGCHAMPS, DARYL D. ROWAN et NORMAND POTHIER. Can. J. Chem. **59**, 2787 (1981).

Le spirocétal **1** subit une réaction d'oxydo-réduction acido-catalysée conduisant spécifiquement à l'aldéhyde-éther bicyclique équatorial **5**. De même, les spirocétals **2**, **3** et **4** donnent la cétone-éther bicyclique équatoriale **12**. Ces résultats sont interprétés en faisant appel à un transfert interne d'hydrure d'une fonction alcool à un ion oxénium cyclique qui se ferait avec contrôle stéréoélectronique. On rapporte aussi la réduction des cétals tricycliques **1** et **22** en milieu acide par le cyanoborohydrure de sodium.

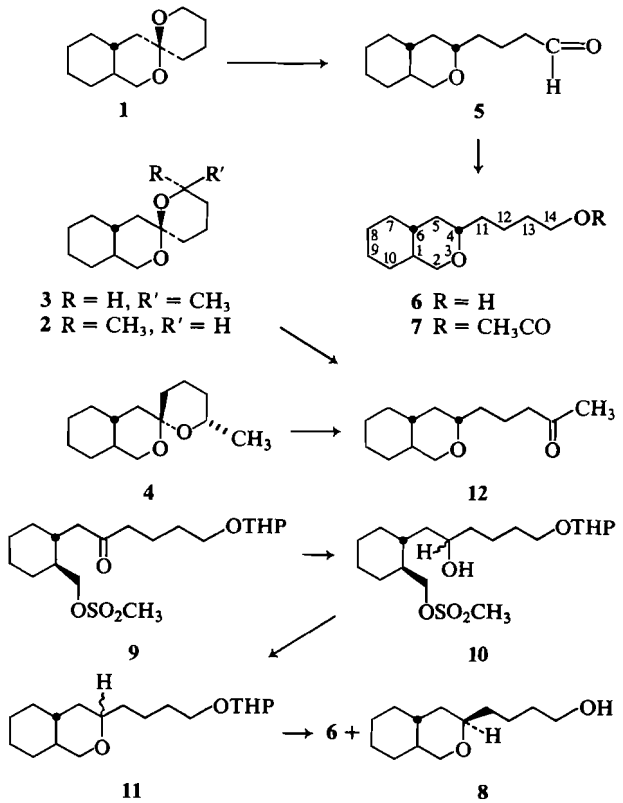
We have recently shown that 1,7-dioxaspiro[5.5]-undecane and its derivatives provide a very convenient system for the study of stereoelectronic effects (anomeric and *exo*-anomeric effects) in the acetal function (1, 2). In the course of that study, we observed that these spiroketals undergo an acid-catalyzed oxidation–reduction reaction. We wish to report that investigation.[1]

Results and Discussion

We have studied the tricyclic spiroketal **1** and the three isomeric methyltricyclic spiroketals **2**, **3**, and **4** (Scheme 1).

Treatment of tricyclic spiroketal **1** with hydrogen bromide in ether–pentane gave stereospecifically the bicyclic ether aldehyde **5** (≃ 40% yield). Reduction of compound **5** with lithium aluminium hydride in ether gave the bicyclic ether alcohol **6** which was further characterized by formation of the acetate derivative **7**.

The structure and the stereochemistry of bicyclic ether alcohol **6** was rigorously established by comparison with an authentic sample. Compound **6** and its isomer **8** were obtained from the monocyclic ketone mesylate **9** (4). Reduction of compound **9** with sodium borohydride in methanol gave a mixture of the isomeric alcohols **10** which was transformed (KH, THF) into the isomeric mixture of THP-bicyclic ethers **11**. Acid hydrolysis of the tetrahydropyranyl ethers **11** gave the bicyclic ether alcohols **6** and **8** which were separated by chromatography. The relative stereochemistry of isomers



SCHEME 1

6 and **8** was established by carbon nuclear magnetic resonance spectroscopy. In particular, the carbons 2, 4, and 6 which are γ, α, and γ respectively to C(11) of the side chain, show shieldings of 7.7, 4.8, and 5.8 ppm (5) on passing from **6** to its axial epimer **8**.

[1]These results have been reported in a preliminary form, see ref. 3.

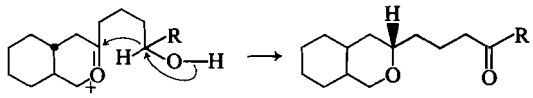
We have also observed that the tricyclic spiroketal **2** or a mixture of isomers **3** and **4** (interconvertible under mild acidic conditions) gave the bicyclic ether methyl ketone **12** (≃100% yield) with aqueous hydrochloric acid under reflux conditions. Similarly, treatment of isomer **4** or isomer **3** with *p*-toluenesulfonic acid in benzene (1), gave compound **12** upon reflux. Isomer **2** proved inert under these conditions. The structure and the stereochemistry of the bicyclic ether methyl ketone **12** was rigorously established by its conversion into bicyclic ether alcohol **6** (NaOBr, NaOH; $LiAlH_4$).

The acid-catalyzed oxido-reduction reactions described above can be readily explained by the opening of the spiroketals giving an hydroxy bicyclic oxenium ion intermediate such as **13** which undergoes an internal hydride transfer to yield the bicyclic ether **5** or **12**.



13 **5** R = H; **12** R = CH_3

This mechanism is very similar to the one proposed by Woodward *et al.* (6) to explain the acid-catalyzed interconversion of the normal and the *iso*-sapogenins **14** and **15** (Scheme 2). They have obtained strong support for this mechanism by observing that the isomeric aldehydes **16** and **17** are converted into a mixture of spiroketals **14** and **15** under acidic conditions. Also, Pettit and Boyer (7) have shown that the aldehyde intermediate (**16** or **17**) can be trapped with ethanedithiol.

The stereospecific formation of the equatorial bicyclic ethers **5** and **12** can be explained if stereoelectronic effects (8) are taken into consideration. If we accept that the hydride transfer will take place with minimum energy only when the intermediate oxenium ion can develop an electron pair which will become antiperiplanar to the newly formed C—H bond in the final product, the above results can be easily rationalized.

It can be readily seen that the β-attack on **13** (i.e. **18**) can occur with stereoelectronic control because the ether oxygen has an electron pair oriented antiperiplanar to the newly formed C—H bond in the resulting products **5** or **12** (Scheme 3). On the other hand, the α-attack on **13** with stereoelectronic control cannot yield the axial bicyclic ethers directly in the most stable conformation **21**. The α-attack on **13** (i.e. **19**) must first give conformer **20** of axial bicyclic ether having its ring B twisted in order to fulfill the orbital alignment requirement. Conformer **20** would then undergo a conformational change to the more stable conformation **21**. The transformation **19** → **20** → **21** requires more energy than the transformation **18** → **5** (or **12**). Consequently the formation of axial bicyclic ethers **21** cannot compete with the formation of equatorial bicyclic ethers **5** or **12**.[2]

The above rationalization further indicates that internal delivery of a hydride is not a requisite for the observed stereospecificity. Reduction of the oxenium ion with an external hydride reagent should also give equatorially oriented bicyclic ether only. We have found that this is indeed the case by observing that the reduction of tricyclic spiroketal **1** with sodium cyanoborohydride at pH ≃ 3–4 yields only the equatorial bicyclic ether alcohol **6**. When the reaction was repeated with deuterated sodium cyanoborohydride, compound **6** contained one deuterium which was found to be in α position to the ether oxygen (C(4)).

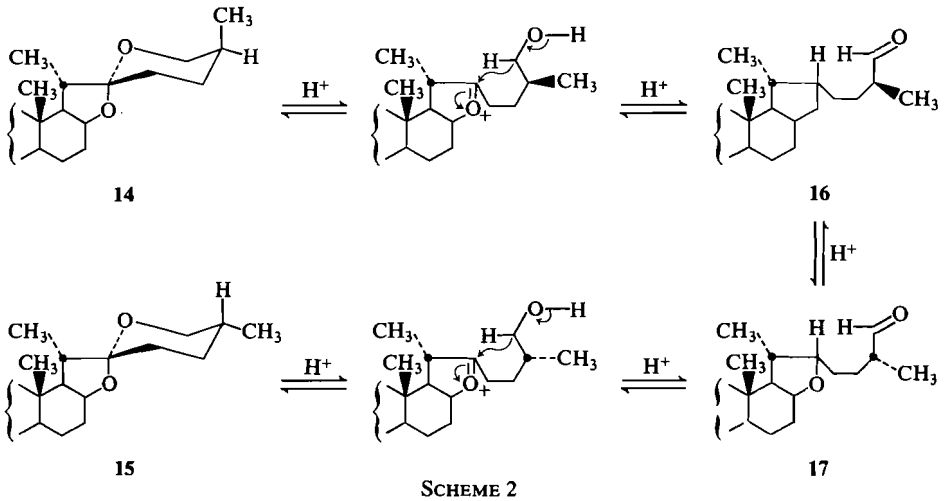
Finally, no stereospecificity should be expected in the hydride transfer step when the cyclic oxenium ion is conformationally labile. This was confirmed by the reduction ($NaBH_3CN$, pH ≃3–4) of bicyclic spiroketal **22** (1) which gave after acetylation a mixture of cyclic ether acetates **23** and **24** in a 3:1 ratio (Scheme 4). Compounds **23** and **24** were separated by chromatography and their relative stereochemistry was assigned on the basis of their ^{13}C nuclear magnetic resonance spectra. In particular, the minor ether acetate **24** (^{13}C nmr: C(3), 26.0 ppm and C(5), 21.1 ppm) showed a shielded methylene and methine carbon (6.4 and 5.7 ppm respectively) relative to the major isomer **23** (^{13}C nmr: C(3), 32.4 ppm and C(5), 26.8 ppm). This result indicates that the secondary methyl group in the ring of the minor isomer is axially oriented (5).

The above results complement our previous work on the stereoelectronically controlled addition of an hydroxyl group to cyclic oxenium ions, i.e. the kinetically controlled formation of acetal (10). The high stereoselectivity for axial attack in $AlCl_2H$ reduction of substituted 2-alkoxy-1,3-dioxanes has been observed by Eliel and Nader (11) and they have also explained their results on the basis of the principle of stereoelectronic control.

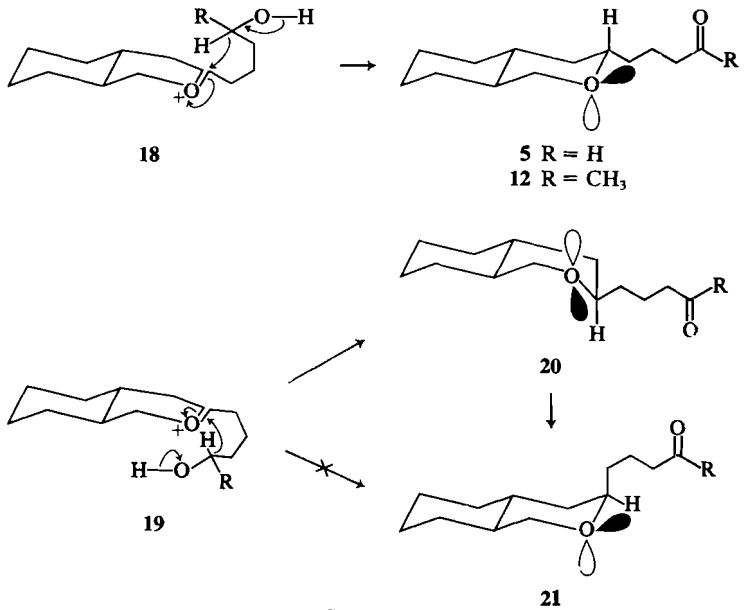
Experimental

Vapor phase chromatography (vpc) was performed on a Varian Aerograph Insrument, model 2800 equipped with a thermal conductivity detector. The following columns were used: column a: 10% APIEZON, 240°C; column b: 3% SE-30, 190°C; column c: 10% SE-30, 190°C; column d: 5% SE-30,

[2]The importance of the nonbonded electron pair on oxygen in $AlHCl_3$ reduction of 2-alkoxytetrahydropyran has been previously suggested (9).



SCHEME 2



SCHEME 3

190°C. All columns were of dimensions 5 ft × ¼ in. and packed with Chromosorb W 60–80 mesh. The infrared (ir) spectra were obtained in chloroform on a Perkin-Elmer 257 spectrophotometer. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded in chloroform on a Bruker WP-60 instrument with TMS as an internal standard. The ^{13}C nmr spectra were recorded in deuterochloroform on a Bruker HX-90 equipped with a Nicolet 1083 computer (8K memory for data) and operating in the Fourier transform mode. Mass spectra were obtained on Hitachi-Perkin-Elmer RMU-6-A and Micromass ZAB-2F machines.

The following abbreviations are used: % E/H: % of ether in hexane; % EA/H: % ethyl acetate in hexane; RT: room temperature; s: singlet; d: doublet; t: triplet, m: multiplet; b: broad; dt: deformed triplet.

Aldehyde 5

To a stirred solution of acetal (**1**) (1) (327 mg, 1.56 mmol) in pentane (15 mL) and ether (15 mL) was added a trace of water (2 drops) and then anhydrous hydrogen bromide gas to saturate the system. After 26 h, the reaction was quenched with saturated sodium bicarbonate and diluted with ether. After washing with brine (1×) and drying (Na_2SO_4) the organic phase was evaporated to give a clear oil (333 mg). Chromatography on silica gel gave, on elution with 5% E/H, unchanged acetal (**1**) (197 mg, 60.2%). Elution with 10% E/H gave aldehyde **5** (89.4 mg, 27.3%). The combined fore-fractions gave an analytical sample (21 mg, 97% by vpc column d, R_f 4.4 min); ir: 2700, 1730, 1176, 1107, and 1062 cm^{-1}; ^{1}H nmr δ: 1.52 (m), 2.46 (dt, $J \simeq 6$ Hz), 3.18 (bm, CH_2OR), 3.68 and 3.89 (2 multiplets, CHOR), 9.76 (t, $J = 1.6$ Hz, CHO); ms *m/e*: 210 (M^+), 165, 152, 139, 121.

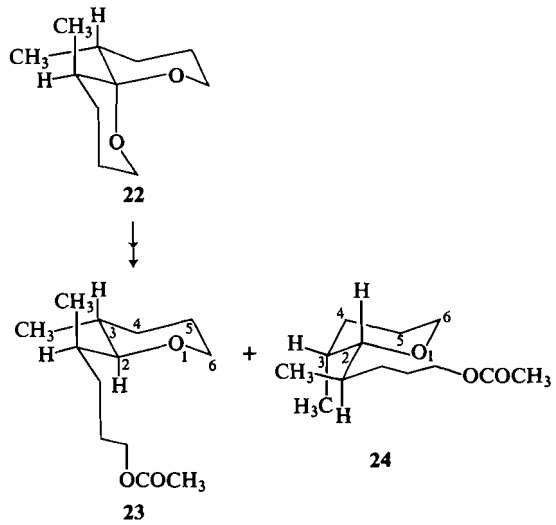

SCHEME 4

The 2,4-DNP of aldehyde **5**, prepared from a crude sample, resisted crystallization but showed ^{1}H nmr δ: 2.41 (2H, m) 3.20 (2H, m, CH_2OR), 3.69 and 3.89 (1H, 2 multiplets, CHOR), 7.53 (1H, t, J = 5 Hz, HCR=NR), isomeric aromatic AMX systems: 8.00 (7.83) (1H, s), 8.22 (8.02) (1H, d, J = 2 Hz), 9.12 (8.42) (1H, *d*, J = 2 Hz), 11.01 (1H, bs, NH).

Attempts to increase the yield of aldehyde **5** by either longer reaction times and/or addition of further hydrogen bromide were usually unsuccessful. It is possible that compounds **1** and **5** are in equilibrium (6).

Reduction of Aldehyde 5

Typically aldehyde **5** (68 mg, 0.34 mmol, the entire aldehyde fraction from the above reaction) in ether (10 mL) was stirred at RT with excess lithium aluminium hydride for 2 h. Excess reagent was destroyed with 10% hydrochloric acid, the reaction was diluted with ether, and the ethereal phase washed with brine (1 ×). Drying (Na_2SO_4) and evaporation gave alcohol **6** (55 mg, 80%). No isomer (**8**) was detected by tlc, vpc (column a), or Cmr; plc (40% EA/H) gave an analytical sample; ir: 3585, 3400, and 1070 cm^{-1}; ^{1}H nmr δ: 1.45 (18H, m), 1.77 (1H, s, OH, D_2O gave HDO δ 4.67), 3.19 (2H, m, CH_2OR), 3.64 (2H, t, J = 6 Hz, CH_2OH), ≃3.70 and 3.78 (1H, 2 multiplets, CHOR); ^{13}C nmr δ: 21.8 (C-12), 25.9 (C-8), 26.3 (C-9), 27.8 (C-10), 32.7 (C-13), 33.0 (C-7), 36.0 (C-11), 39.0 (C-5), 41.2 (C-6), 42.4 (C-1), 62.7 (C-14), 73.2 (C-2), 78.0 (C-4); ms *m/e*: 212.1774 (M^+, $C_{13}H_{24}O_2$ requires 212.1776), 194 ($M^+ - H_2O$).

Acetate 7

Alcohol **6** (25 mg, 0.12 mmol) was stirred with acetic anhydride (100 μL) and pyridine (100 μL) for 2 h at RT. The reaction was diluted with ether and washed successively with 5% sulfuric acid (1 ×), saturated sodium bicarbonate (2 ×), and brine (1 ×). Drying (Na_2SO_4) and evaporation gave acetate (**7**) (8.0 mg, 38%); plc (60% E/H) gave an analytical sample (4.8 mg) as a clear oil; ir: 1724, 1250, and 1082 cm^{-1}; ^{1}H nmr δ: 1.51 (18H, m), 2.05 (3H, s, OAc), 3.20 (2H, m, CH_2OR), 3.68 and 3.89 (1H, 2 multiplets, CHOR), 4.07 (2H, t, J = 6 Hz, CH_2OAc); ms *m/e*: 254 (M^+, weak), 194 (M^+ − HOAc), 165, 152, 139, and 121.

Mesylate-alcohols 10

To ketomesylate **9** (4) (619 mg, 1.58 mmol) in methanol (10 mL) at −18°C was added sodium borohydride (83 mg, 2.2 mmol) and the solution warmed to 0°C over 3½ h. After evaporation of the solvent at or below RT, ether was added and the solution was washed with 5% sulfuric acid (1 ×), saturated sodium bicarbonate (1 ×), and brine (1 ×). Drying (Na_2SO_4) and evaporation gave mesylate-alcohols **10** (580 mg, 84.9%) as a clear oil; ir: 3430, 1354, 1174, 1022, and 937 cm^{-1}; ^{1}H nmr δ: 1.48 (= 25H, m), 1.82 (1H, s; O*H*, D_2O gave HDO δ 4.69), 2.99 and 3.00 (3H, 2 singlets, OMs), 3.66 (5H, m, CHOR), 4.23 (2H, m, CH_2OMs), 4.56 (1H, OCHO).

THP-ethers 11

Mesylate-alcohols **10** (432 mg, 1.10 mmol) in THF (10 mL) were refluxed for 6 h with excess potassium hydride (washed hexane, 3 ×) and then left at RT for 2 days. The reaction was diluted with wet ether and water and saturated ammonium chloride slowly added. Extraction with dichloromethane (3 ×) gave, after drying (Na_2SO_4) and evaporation, the crude product (349 mg, 87.5%). Chromatography on Florisil, eluting with 20% EA/H, gave a midfraction of THP-ethers **11** (146 mg, 36.6%) as a clear oil, "two spot" by tlc; ir: 1319, 1064, and 1021 cm^{-1}; ^{1}H nmr δ: 1.46 (23H, m), 2.34 (1H, m), 2.8–4.1 (7H, m), 4.56 (1H, m, OCHO).

Alcohols 6 and 8

To THP-ethers **11** (138 mg, 0.47 mmol) in THF (5 mL) was added 5% sulfuric acid (0.5 mL). After 6 h at RT the reaction was concentrated and then diluted with ether and the aqueous phase saturated with sodium carbonate. The aqueous phase was adsorbed into sodium sulfate and the solvent filtered and evaporated to give 137 mg of clear oil; plc (2 × 25% EA/H) gave, from highest R_f, (*i*) THP-ethers **11** (45.1 mg, 32.7%) by tlc and ^{1}H nmr; (*ii*) alcohol **6** (35.0 mg, 35.4%) by tlc, vpc, ir, and ^{1}H and ^{13}C nmr identical with previously prepared material; and (*iii*) alcohol **8** (18.1 mg, 18.3%) as a clear oil. Pure by vpc (column 1, R_f 9.5 min) though tlc showed two minor contaminants; ^{13}C nmr δ: 22.5 (C-12), 26.0 (C-8), 26.4 (C-9), 28.1 (C-10), 30.0 (C-11), 32.7 (C-13), 33.3 (C-7), 35.5 (C-6), 36.1 (C-5), 42.7 (C-1), 63.1 (C-14), 65.6 (C-2), 73.2 (C-4); plc (50% EA/H) gave an analytical sample; ir: 3420, 1052, and 1013 cm^{-1}; ^{1}H nmr δ: 1.46 (19H, m), 1.58 (OH, D_2O gave HDO δ 4.68), 3.34 (2H, m, CH_2OR), 3.66 (2H, t, J = 6 Hz, CH_2OH), ≃ 3.83 (1H, m, CHOR); ms *m/e*: 212.1783 (M^+, $C_{13}H_{24}O_2$ requires 212.1776).

Bicyclic Ether Methyl Ketone 12

Spiroketal **2** (224 mg, 1 mmol) (1) in 2.4 *M* hydrochloric acid (10 mL) was refluxed for 24 h. Dilution with water (25 mL) and ether extraction (3 ×) gave, after drying ($MgSO_4$) and evaporation, bicyclic ether methyl ketone **12** quantitatively as a clear oil, melting below RT; ir: 1708, 1357, 1165, 1080, and 1065 cm^{-1}; ^{1}H nmr δ: 1.49 (16H, m), 2.09 (3H, s, CH_3CO), 2.40 (2H, dt, J ≃ 6 Hz, CH_2CO), 3.17 (2H, bm, CH_2OR), 3.64 and 3.83 (1H, 2 multiplets, CHOR); ^{13}C nmr δ: 20.1 (C-12), 25.9 (C-8), 26.2 (C-9), 27.8 (C-10), 29.8 (C-15), 33.0 (C-7), 35.7 (C-11), 39.0 (C-5), 41.2 (C-6), 42.2 (C-1), 43.7 (C-13), 73.2 (C-2), 77.7 (C-3), 208.9 (C-14); ms *m/e*: 224 (M^+).

Similarly reflux of a mixture of acetals **3** and **4** (1) (224 mg) for 6 h gave bicyclic ether methyl ketone **12** quantitatively (ir, ^{1}H and ^{13}C nmr superimposable).

Alternatively either acetal **3** or acetal **4** (224 mg, 1 mmol) was refluxed overnight in benzene (50 mL) with a trace of *p*-toluenesulfonic acid. Drying ($MgSO_4/K_2CO_3$) and evaporation gave **12** in each case (ir, ^{1}H and ^{13}C nmr). Acetal **2** was recovered unchanged under these conditions.

Bromoform Degradation of Ketone 12

Bromine (1.0 mL) was slowly added to a stirred solution of sodium hydroxide (2.18 g) in water (11 mL), maintained at 0°C. After 20 min, 1.5 mL of this solution was added at 0°C to ketone **12** (40 mg, 0.18 mmol) in dioxane (1 mL). The system was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

allowed to warm to RT over 4 h and then heated to 40°C for 90 min. The reaction was diluted with 5% sodium bicarbonate and washed with ether (1 ×). The ethereal phase was extracted with saturated sodium bicarbonate and the combined aqueous phases were acidified with 5% sulfuric acid. Extraction with dichloromethane (3 ×), drying (Na_2SO_4), and evaporation gave the corresponding acid (41 mg), 101%) as a clear oil; ir: 3540–2400 (b), 1708 and 1240 (b); ^{1}H nmr δ: 1.58 (≃ 16H, m), 2.38 (2H, t, J = 6 Hz, CH_2COOR), 3.20 (2H, bm, CH_2OR), 3.69 and 3.87 (1H, 2 multiplets, CHOR), 8.59 (1H, b, OH).

The derived acid (81 mg, 0.36 mmol) in tetrahydrofuran (10 mL) was refluxed under nitrogen with excess lithium aluminium hydride for 5 h and then left at RT for 2 days. With stirring, sufficient saturated ammonium chloride was added to destroy excess hydride and then ether. Filtration through Celite and evaporation gave alcohol **6** (55 mg, 72%) by tlc, vpc (column a), and ^{13}C nmr. Isomeric alcohol **8** was not observed; plc (50% EA/H) gave pure **6** (43 mg, 33%) by ir, and ^{13}C and ^{1}H nmr.

Cyanoborohydride Reduction of Acetal 1

A stirred solution of acetal **1** (104 mg, 0.50 mmol) in methanol (9 mL) and water (1 mL) was acidified to methyl orange by dropwise addition of a solution of hydrochloric acid (2 *N*) in 80% methanol. Portions of sodium cyanoborohydride, together with further acid and indicator as required, were added over a period of 4 days to give complete reduction of the acetal. the solution was concentrated under reduced pressure, then diluted with water and extracted with dichloromethane (2 ×). Drying (Na_2SO_4) and evaporation gave alcohol **6** (97.4 mg, 92.9%) as a clear oil, crystalline below RT (vpc, tlc, ir, ^{1}H, and ^{13}C nmr). Although tlc indicated that a trace of isomeric alcohol **8** was present, none was observed by vpc (column a) or ^{13}C nmr.

Cyanoborodeuteride Reduction of Acetal 1

A stirred solution of acetal **1** (104 mg, 0.50 mmol) in methanol-d_1 (9 mL) and deuterium oxide (1 mL) was acidified to methyl orange by dropwise addition of a solution of deuterium chloride (2 *N*) in 80% methanol-d_1 – 20% deuterium oxide. Portions of sodium cyanoborodeuteride, together with further acid and indicator as required, were added over a period of 24 h to give reduction of the acetal. The solution was concentrated under reduced pressure, then diluted with water and extracted with dichloromethane (2 ×). Drying (Na_2SO_4) and evaporation gave alcohol **6** (95 mg, 90%) as a clear oil. It was shown by ^{13}C nmr spectroscopy that carbon-4 of alcohol **6** has a deuterium atom axially oriented.

Cyanoborohydride Reduction of Acetal 22

A stirred solution of acetal **22** (152 mg, 0.83 mmol) (1) in methanol (12 mL) and water (2 mL) was acidified to methyl orange by dropwise addition of a solution of hydrochloric acid (2 *N*) in 80% methanol. Portions of sodium cyanoborohydride, together with further acid and indicator as needed, were added over 10 days. The solution was concentrated under reduced pressure, then diluted with water and continuously extracted with dichloromethane. Evaporation gave a clear oil (175 mg, 101%) which was acetylated in acetic anhydride (10 mL) and pyridine (10 mL) at RT overnight. The reaction was diluted with ether (100 mL) and washed sequentially with 5% sulfuric acid (1 ×), saturated sodium bicarbonate (2 ×), and brine (1 ×). Drying (Na_2SO_4) and evaporation gave acetates **23** and **24** with residual acetic anhydride (229 mg, 122%). A sample (84 mg) was separated by plc (3 × 15% E/H) to give (*i*) at higher R_f, acetate **23** (52 mg, 62%) as a clear oil; vpc (column d, R_t 4.5 min); ir: 1727, 1245, and 1082 cm^{-1}; ^{1}H nmr δ: 0.75 (3H, d, *J* = 5.5 Hz, CH_3), 0.85 (3H, d, *J* = 5.7 Hz, CH_3), 1.47 (10H, m), 2.03 (3H, s, OAc), 2.90 and 2.75 (1H, 2 multiplets), 3.26 (1H, bm), 4.04 (3H, deformed t, *J* = 6 Hz, CH_2OAc and CHOR); ^{13}C nmr δ: 12.8, 18.7, 21.0, 26.8, 26.9, 30.6, 32.4, 33.2, 33.5, 65.0, 68.7, 85.9, 171.2; ms *m/e*: 288.1706 ($C_{13}H_{24}O_3$ requires 228.1725). (*ii*) At lower R_f, acetate **24** (17 mg, 20%) as a clear oil; vpc (column d, R_t 7.1 min); ir: 1730, 1237, and 1040 cm^{-1}; ^{1}H nmr δ: 0.79 (3H, d, *J* = 6.8 Hz, CH_3), 0.93 (3H, d, *J* = 6.3 Hz, CH_3), 1.69 (10H, m), 2.04 (3H, s, OAc), 2.91 (1H, dd, *J* = 9 Hz, *J* ≃ 2 Hz), 3.36 (1H, deformed t, *J* ≃ 9 Hz), 4.05 (3H, deformed t, *J* = 6 Hz, CH_2OAc and CHOR); ^{13}C nmr δ: 11.3, 14.6, 21.1, 21.1, 26.0, 28.8, 29.8, 31.4, 34.8, 65.2, 69.5, 84.5, 171.2; ms *m/e*: 228.1702 (M^+, very weak), 227.1640 ($M^+ - 1$, $C_{13}H_{23}O_3$ requires 227.1646), 168 (M^+ – HOAc).

Received February 13, 1981

B. HALPERIN and J. A. KONINGSTEIN. Can. J. Chem. **59**, 2792 (1981).

A theoretical analysis is presented for conditions of optical pumping of an electronic excited state and the subsequent induction of Raman scattering thereof, using the radiation of a tunable laser with a specific λ for pumping and Raman probing.

The analysis shows that the number of excited states created by the optical pump can be estimated as a function of the photon flux from the (non-linear) behaviour of the transmission of the sample at the selected laser wavelength. It is shown that such transmission studies are a prerequisite before attempts are made to record any excited level Raman spectrum.

B. HALPERIN et J. A. KONINGSTEIN. Can. J. Chem. **59**, 2792 (1981).

On propose une analyse théorique des conditions de pompage optique d'un état électronique excité et de l'induction subséquente de la diffusion de Raman qui en découle, en utilisant un laser ajustable avec un λ spécifique pour le pompage et la recherche Raman.

L'analyse montre que l'on peut évaluer le nombre d'états excités, créés par la pompe optique, en fonction du courant de photons à partir du comportement (non linéaire) de la transmission produit par l'échantillon à la longueur d'onde du laser où l'on opère. On montre que de telles études de transmission sont un prérequis avant d'essayer d'enregistrer n'importe quel niveau de spectre Raman.

[Traduit par le journal]

I. Introduction

With the advent of tunable pulsed lasers, another area in Raman spectroscopy has become accessible in addition to spectra which involve transitions of the ground state. Recently, light-scattering (1–9) transitions from short-lived excited states of molecules and atoms or ions in solids have been observed. Due to the tunability of present-day lasers it is, in fact, possible to employ one particular frequency of the laser in order to both populate and scatter (2–7, 9) from the optically pumped excited state. It can be shown that by using cw lasers, only excited states with lifetimes of $\tau \geq 100$ μs may be populated, while with the radiation of an N_2-pumped dye laser, light-scattering of excited states having $\tau \geq 10$ ps has been detected (9, 10). From the experimental data presently available, one may even predict that by means of picosecond lasers, this limit could eventually be lowered towards states having $\tau > 1$ fs. However, in all cases one has to rely on the capability of the (Raman) detection system to process weak light pulses having a duration of a few nano or picoseconds.

Presently we are interested in the details of the optical pumping process, and in particular the types of calculations which have to be performed (2, 11–13) before such light-scattering experiments can be carried out. The calculations in this paper refer to the conditions for saturation population of the excited states, and a discussion is given of some experimental measurements which form the basis for an excited-state Raman study.

II. Absorption Models and Effective Absorption Cross Sections

We consider the experimental situation where a beam of coherent photons is travelling through a medium which shows some absorption at the frequency of the laser. We distinguish between two different cases which are schematically illustrated in Fig. 1. In both cases, the incident frequency is in resonance with a vibronic side-band of an electronic transition, and the energy of the laser reaches the excited state E. From there fluorescence (or radiationless) transitions $E \rightarrow A$ (ground-state) may provide a downward channel for the energy. If enough population of E is obtained, absorption of another laser photon may occur to raise the system indirectly into a higher-laying excited state Y (via pumping into a vibronic side band $E \rightarrow Y'$). The difference between the two cases I and II is in the relaxation process from Y. In case I, the system relaxes directly from Y into A. In case II we consider the situation where the relaxation from Y to A occurs via E.

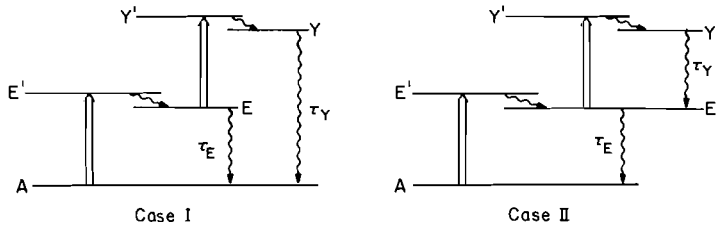

FIG. 1. Optical pumping and energy relaxation for the two cases considered in this paper. The levels E' and Y' are vibronic levels of the electronic states E and Y and it is assumed here that these vibronic levels relax instantaneously into E or Y. The energy difference of E' and A is equal to that of Y' and E and the corresponding absorption cross sections are σ_A and σ_E.

In both cases, we assume that the absorption is not directly into the states E or Y but rather into their vibronic side-bands (or other intermediate states E', Y') which immediately relax into E and Y. In what follows, the relaxations from E' into E and Y' into Y are considered to be instantaneous and accordingly, they do not explicitly appear in the equations which describe the kinetics of the system. This "short-circuiting" model resembles actual systems (e.g. ruby) and has the advantage that the pump field does not give rise to stimulated emission from E to A (or from Y to E).

Let us denote by N that total concentration (density) of absorbing centers, which we assume to be uniform throughout the medium. We have

$$[1] \quad N = n_A(x) + n_E(x) + n_Y(x)$$

where $n_A(x)$, $n_E(x)$, and $n_Y(x)$ are the densities of absorbing centers in the states A, E, and Y, respectively, measured at depth x inside the sample. The point $x = 0$ is the front edge where the laser beam enters the medium, and $0 \leq x \leq L$. The change in populations with time for case I is given by the following expressions:

$$[2] \quad \dot{n}_A(x) = \frac{1}{\phi}\left(\frac{dI(x)}{dx}\right)_A + \frac{n_E(x)}{\tau_E} + \frac{n_Y(x)}{\tau_Y}$$

$$[3] \quad \dot{n}_E(x) = -\frac{1}{\phi}\left(\frac{dI(x)}{dx}\right)_A - \left(\frac{dI(x)}{dx}\right)_E - \frac{n_E(x)}{\tau_E}$$

and

$$[4] \quad \dot{n}_Y(x) = -\frac{1}{\phi}\left(\frac{dI(x)}{dx}\right)_E - \frac{n_Y(x)}{\tau_Y}$$

In these expressions ϕ is the cross-sectional area of the laser beam, τ_E and τ_Y are, respectively, the lifetimes of the states E and Y, and $(dI(x)/dx)_A$ $(dI(x)/dx)_E$ describe the attenuation of the incident intensity due to absorptions from states A and E, respectively. For case II, the only difference in the above expressions is that the last term in the right hand side of eq. [2] should be deleted and transferred to eq. [3]. For both cases we have, in addition, the relations

$$[5] \quad \left(\frac{dI(x)}{dx}\right)_A = -\sigma_A[N - n_E(x) - n_Y(x)]I(x)$$

$$[6] \quad \left(\frac{dI(x)}{dx}\right)_E = -\sigma_E n_E(x) I(x)$$

where σ_A, σ_E are the absorption cross-sections of the centers in states A and E, respectively.

If the duration of the laser pulse is long compared to the lifetimes of the pertinent states, steady-state conditions exist, i.e.

$$[7] \quad \dot{n}_A(x) = \dot{n}_E(x) = \dot{n}_Y(x) = 0$$

By eliminating $n_E(x)$ and $n_Y(x)$ from the equations we obtain the following result for case I:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

$$[8]\quad \frac{dI(x)}{dx} = \left(\frac{dI(x)}{dx}\right)_A + \left(\frac{dI(x)}{dx}\right)_E = -\frac{\sigma_A N I(x)[1 + 2\sigma_E\tau_E I(x)/\phi]}{1 + \tau_E(\sigma_A + \sigma_E)\frac{I(x)}{\phi} + \sigma_A\sigma_E\tau_E\tau_Y\frac{I^2(x)}{\phi^2}}$$

The corresponding result for case II is:

$$[9]\quad \frac{dI(x)}{dx} = -\frac{\sigma_A N I(x)[1 + \sigma_E\tau_E I(x)/\phi]}{1 + \tau_E\sigma_A\frac{I(x)}{\phi} + \sigma_A\sigma_E\tau_E\tau_Y\frac{I^2(x)}{\phi^2}}$$

Integration of eqs. [8] and [9] over the path of the laser beam through the medium yields transcendental expressions for the transmission $T \equiv I(L)/I(0)$, as functions of the incident intensity $I(0)$. For case I we get

$$[10]\quad T = \left[\frac{1 + 2\sigma_E\tau_E T I(0)/\phi}{1 + 2\sigma_E\tau_E I(0)/\phi}\right]^{[(\sigma_E - \sigma_A)/2\sigma_E + \tau_Y\sigma_A/4\sigma_E\tau_E]} \exp\left(-N\sigma_A L + \frac{\tau_Y\sigma_A}{2}\frac{I(0)}{\phi}(1 - T)\right)$$

whereas for case II we find:

$$[11]\quad T = \left[\frac{1 + \sigma_E\tau_E T I(0)/\phi}{1 + \sigma_E\tau_E I(0)/\phi}\right]^{[(\sigma_E - \sigma_A)/\sigma_E + \tau_Y\sigma_A/\sigma_E\tau_E]} \exp\left(-N\sigma_A L + \tau_Y\sigma_A\frac{I(0)}{\phi}(1 - T)\right)$$

Equations [10] and [11] have been solved numerically for the transmissions T as functions of the incident flux $I(0)/\phi$, assuming characteristic values for the absorption cross sections and relaxation times. The results obtained in case I are presented in Fig. 2 and those for case II are presented in Fig. 3. In each figure, two curves are shown, one for the situation where the ground-state absorption cross section is greater than the excited-state absorption cross section ($\sigma_A > \sigma_E$) and the other for the inverse situation ($\sigma_E > \sigma_A$). As seen from the figures, the curves tend to flatten at extremely low as well as at extremely high intensities of the incident radiation. In the low-intensity limit $I(0)/\phi \to 0$, the simple Beer's law for ground-state absorption alone

$$[12]\quad T = T_A \equiv \exp(-N\sigma_A L)$$

is recovered from both eqs. [10] and [11].

In order to analyse the behaviour of the transmission curves in the high intensity regime, consider first case I, represented by eq. [10] and Fig. 2. The flattening of the curve occurs when the incident flux $I(0)/\phi$ obeys

$$[13]\quad \frac{I(0)}{\phi} \gg \frac{1}{\tau_E\sigma_E}$$

In the particular example which is represented in the figure, we have chosen $\tau_E = 1$ ns and $\sigma_E \gtrsim 10^{-18}$ cm^2, so that in order to obey condition [13], $I(0)/\phi$ should be greater than 10^{27} photons s^{-1} cm^{-2}. This is achieved by present-day N_2-pumped dye lasers which can deliver 10^{14}–10^{15} photons per pulse of 1 ns, provided the beam is focused down to a cross section $\phi \lesssim 10^{-4}$ cm^2. In the limit described by eq. [13], the attenuation of the incident radiation, eq. [8] becomes

$$[14]\quad \frac{dI(x)}{dx} = -N I(x)\frac{2\sigma_A\sigma_E}{\sigma_A + \sigma_E + \tau_Y\sigma_A\sigma_E I(x)/\phi}$$

One immediately realizes that if the additional condition

$$[15]\quad \tau_Y\sigma_A\sigma_E I(0)/\phi \ll \sigma_A + \sigma_E$$

holds as well, eq. [14] reduces to the form of an effective Beer's law where

$$[16]\quad T = T_{\text{eff}} \equiv \exp(-N\sigma_{\text{eff}}L)$$

with the effective absorption cross-section given by

$$[17]\quad \sigma_{\text{eff}} = (2\sigma_A\sigma_E)/(\sigma_A + \sigma_E)$$

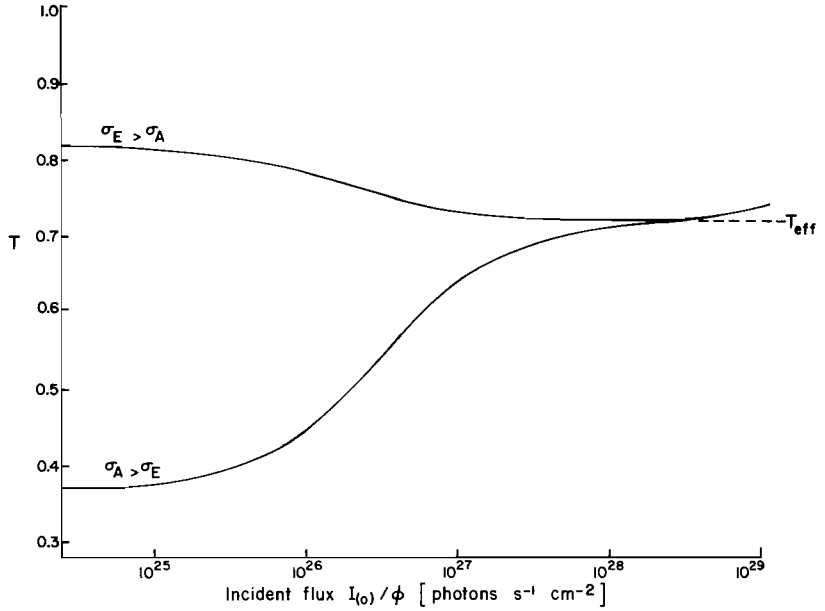

FIG. 2. The dependence of the transmission T of the sample on the incident photon flux for a molecular system in which energy transfer is that depicted in Fig. 1, case I where $\tau_E = 1$ ns, $\tau_Y = 1$ ps, and N (number of molecules) $\times$ L (length of cuvette) = 2×10^{17} cm^{-2}. The upper curve is for $\sigma_A = 10^{-18}$ cm^2. $\sigma_E = 5 \times 10^{-18}$ cm^2 and the lower curve is for a situation where the absorption cross sections for the transitions $E' \leftarrow A$ and $Y' \rightarrow E$ (see Fig. 1) are respectively $\sigma_A = 5 \times 10^{-18}$ cm^2 and $\sigma_E = 10^{-18}$ cm^2. T_{eff} is the value of the transmission where Beer's Law applies (see eq. [16]).

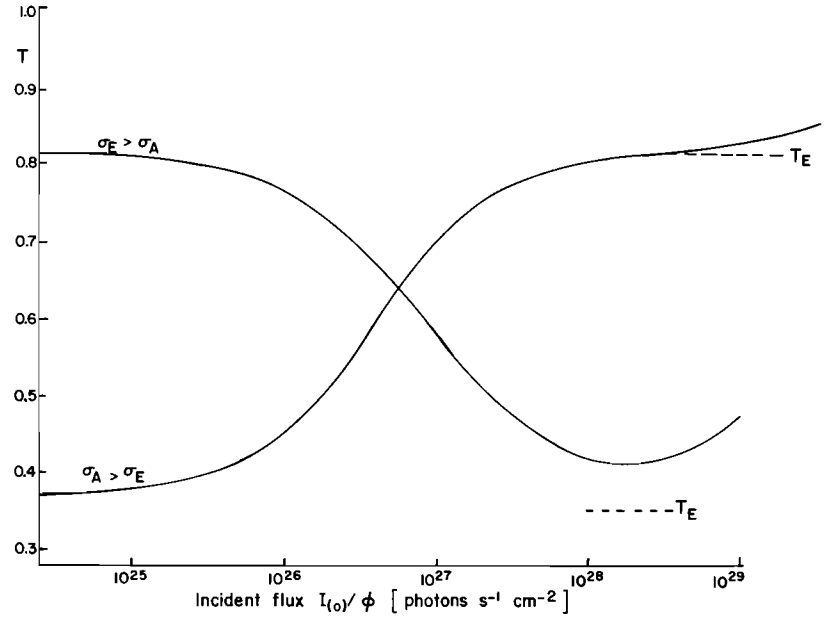

FIG. 3. The dependence of the transmission on I_{laser} for a system which follows case II of Fig. 1, assuming $\tau_E = 1$ ns, $\tau_Y = 1$ ps and $N \times L = 2 \times 10^{17}$ cm^2. Upper curve $\sigma_A = 10^{-18}$ cm^2, $\sigma_E = 5 \times 10^{-18}$ cm^2, lower curve $\sigma_A = 5 \times 10^{-18}$ cm^2, $\sigma_E = 10^{-18}$ cm^2.

In the particular example represented in Fig. 2, we have assumed $\tau_Y = 1$ ps and σ_A, $\sigma_E \gtrsim 10^{-18}$ cm^2. Hence, condition [15] holds as long as $I(0)/\phi$ does not exceed values of $\sim 10^{29}$ photons s^{-1} cm^{-2}. This is well realised by the deviation from an effective Beer's law behaviour, which is observed for higher flux values in Fig. 2.

In the extreme case where $\sigma_E \gg \sigma_A$; we have, from eq. [17], $\sigma_{eff} = 2\sigma_A$, whence

$$[18] \quad T_{eff} = (T_A)^2$$

On the other hand, for $\sigma_A \gg \sigma_E$ we have $\sigma_{eff} = 2\sigma_E$ and

$$[19] \quad T_{eff} = (T_E)^2 \equiv \exp(-2N\sigma_E L).$$

Equations [18] and [19] demonstrate that a determination of σ_E from the asymptotic behaviour of an excited-state absorption spectrum is much less straightforward than determining σ_A from a ground-state absorption experiment.

Returning to case II and assuming condition [13] to hold (for $1/\tau_E\sigma_A$ as well) we have from eq. [9]

$$[20] \quad \frac{dI(x)}{dx} = -NI(x)\frac{\sigma_E}{1 + \tau_Y\sigma_E I(x)/\phi}$$

and with the additional condition

$$[21] \quad \tau_Y\sigma_E I(0)/\phi \ll 1$$

We find an effective Beer's law of the form

$$[22] \quad T = T_E \equiv \exp(-N\sigma_E L)$$

This lends itself to a direct interpretation as a pure excited-state absorption spectrum due to a complete degree of excitation. The limiting degree of population in the excited state E and the conditions for saturation in both models are calculated in the next section. This kind of information is essential whenever an excited-state light-scattering experiment is proposed.

III. Excited-state Population and Effective Saturation

At steady-state conditions the density of absorbing centers in the excited state E is found to be

$$[23] \quad n_E(x) = -\frac{1}{\phi}\frac{dI(x)}{dx}\frac{\tau_E}{1 + \nu\sigma_E\tau_E I(x)/\phi}$$

where $\nu = 2$ in case I, $\nu = 1$ in case II.

From eqs. [8] and [9] we then have

$$[24] \quad n_E(x) = \frac{N\frac{I(x)}{\phi}\sigma_A\tau_E}{1 + \tau_E[\sigma_A + (\nu - 1)\sigma_E]\frac{I(x)}{\phi} + \tau_Y\tau_E\sigma_A\sigma_E\left[\frac{I(x)}{\phi}\right]^2}$$

In the limits described by eqs. [13], [15], and [21] this turns out to be

$$[25] \quad n_E(x) \simeq \begin{cases} N\dfrac{\sigma_A}{\sigma_A + \sigma_E} & \text{in case I} \\ N & \text{in case II} \end{cases}$$

The result, eq. [25] for case II, was anticipated in view of the Beer's law behaviour represented by eq. [22]. On the other hand, for case I, the Beer's law transmission represented by eq. [16] is not just exp $(-n_E\sigma_E L)$ but rather, exp $(-2n_E\sigma_E L)$. The factor 2 here manifests the fact that at saturation conditions in case I, the ground and excited states give rise to equal absorptions. In the ground state, the population is $N\sigma_E/(\sigma_A + \sigma_E)$ and the absorption cross-section is σ_A, whereas in the excited state the population is $N\sigma_A/(\sigma_A + \sigma_E)$ and the cross section is σ_E. We note in passing that in both cases $n_Y(x)$ is proportional to τ_Y and is therefore negligibly small.

IV. Population Numbers of Excited and Ground State in Relation to Photon Densities

We now wish to assess the number of photons N_{ph} (per unit time and unit volume of the sample) required in order to maintain the steady-state saturation population given by eq. [25]. This is defined by

$$[26] \quad N_{ph} \equiv \frac{I(0)}{L\phi}(1 - \bar{T})$$

where $\bar{T}$ is the asymptotic value of the transmission in the limit described by eqs. [13], [15], and [21]. By expanding eqs. [10] and [11] in terms of $[I(0)/\phi]^{-1}$, we find for case I

$$[27] \quad \bar{T} = T_{eff} + \frac{(1 - T_{eff})}{2\sigma_E\tau_E}\frac{(\sigma_E - \sigma_A)}{(\sigma_E + \sigma_A)}\frac{1}{I(0)/\phi} + O\left(\frac{1}{I(0)^2}\right)$$

where T_{eff} is defined in eqs. [16], [17]. For case II we find

$$[28] \quad \bar{T} = T_E + \frac{(1 - T_E)}{\sigma_E\tau_E}\frac{(\sigma_E - \sigma_A)}{\sigma_A}\frac{1}{I(0)/\phi} + O\left(\frac{1}{I(0)^2}\right)$$

where T_E is defined in eq. [22].

From an experimental point of view, one can always make sure that $\sigma_{eff}NL \ll 1$ and $\sigma_E NL \ll 1$, in which situation we find for case I

$$[29] \quad N_{ph} \simeq \frac{I(0)}{\phi} N \frac{2\sigma_A\sigma_E}{\sigma_A + \sigma_E} + \frac{\sigma_A(\sigma_A - \sigma_E)}{(\sigma_A + \sigma_E)^2}\frac{N}{\tau_E}$$

and for case II

$$[30] \quad N_{ph} \simeq \frac{I(0)}{\phi} N\sigma_E + \frac{(\sigma_A - \sigma_E)}{\sigma_A}\frac{N}{\tau_E}$$

If $I(0)/\phi \gg [(\sigma_A + \sigma_E)\tau_E]^{-1}$ in case I, or $I(0)/\phi \gg (\sigma_A\tau_E)^{-1}$ in case II (the necessary conditions to get the saturation limits of eq. [25]), we formally have

$$[31] \quad N_{ph} \gg \frac{\sigma_A}{(\sigma_A + \sigma_E)}\frac{N}{\tau_E} \quad \text{in case I}$$

and

$$[32] \quad N_{ph} \gg \frac{N}{\tau_E} \quad \text{in case II}$$

A closer inspection of the transmission curves in Figs. 2 and 3 reveals that the steepness of the curves is the highest when $I(0)/\phi$ is equal to $[(\sigma_A + \sigma_E)\tau_E]^{-1}$ in case I or to $(\sigma_A\tau_E)^{-1}$ in case II. In other words, at these values of the incident flux the transmission is most susceptible to any additional increment in $I(0)/\phi$, whereas at higher values the susceptibility is reduced. Hence, these incident flux values may effectively be considered as giving rise to the onset of saturation. The actual excited-state population (eq. [24]) is then half of the saturation population (eq. [25]). It is instructive to point out that eqs. [31], [32] only yield lower limits on N_{ph} but do not determine its magnitude. On the other hand, for a model system where the ground state alone absorbs ($\sigma_E = 0$), eq. [32] becomes a strict equality.

From a practical point of view, the incident flux values which give rise to the onset of saturation can be utilized in order to determine the values of the lifetimes τ_E. Apparently, an alternative way to determine τ_E is to plot the transmission as a function of $[I(0)/\phi]^{-1}$ for very high incident flux values, and use eqs. [27], [28] to obtain the relation between τ_E and the slope of such curves. However, at high flux values, population inversion occurs and stimulated emission may already play a noticeable role. As will be shown in the next section, this will give rise to an effective value τ_E' which is smaller than the intrinsic lifetime τ_E.

V. Optical Pumping and Stimulated Emission

Stimulated emission from a vibronic level of E, which is in resonance with that of the optical pump, was excluded in the discussion above because we assumed that the vibronic level of E' relaxes instantaneously

into E. Now, this level can emit radiation, and the lifetime of the radiative process $E \rightarrow A$ is denoted by τ_E. However, the results presented in section III, eq. [25], suggest that population inversion of the levels E and A can occur, and this in combination with the availability of a photon flux I_F/ϕ at the wavelength λ_{EA}, can result in stimulated emission from $E \rightarrow A$. In the following discussion, we shall assume that the population numbers n_A, n_E, and n_Y are all small compared to the number of photons in the pumping laser beam, and that population inversion of the level Y versus either E or A does not take place. The dynamical equation (14) describing the rate change of n_E becomes:

$$[33] \quad \dot{n}_E = -\frac{1}{\phi}\left(\frac{dI(x)}{dx}\right)_A - \left(\frac{dI(x)}{dx}\right)_E - \frac{n_E}{\tau_E} - \frac{1}{\phi} I_F(x)\sigma_E'(n_E - n_A)$$

where σ_E' is the gain cross section for stimulated emission. In the absence of the latter, the photon flux in the x direction may be obtained by a decay rate from a segment dx,

$$[34] \quad \frac{1}{\phi}\frac{dI_F(x)}{dx} = \Omega(x)\frac{n_E}{\tau_E}$$

where $\Omega(x)$ is a probability of a photon being emitted in the direction of propagation of the optical pump. It is normally assumed that the emitted photons experience exponential stimulated amplification so that eq. [34] is replaced by

$$[35] \quad \frac{1}{\phi}\frac{dI_F(x)}{dx} = \Omega(x)\frac{n_E}{\tau_E}\{\exp(n_E - n_A)\sigma_E' x\}$$

Integration of eq. [35] over length L and substitution of the result in eq. [33] gives:

$$[36] \quad n_E = -\frac{1}{\phi}\left(\frac{dI(x)}{dx}\right)_A - \left(\frac{dI(x)}{dx}\right)_E - \frac{n_E}{\tau_E'}$$

where

$$\frac{1}{\tau_E'} \approx \frac{1}{\tau_E}(1 + \Omega\{\exp[(n_E - n_A)\sigma_E' L] - 1\})$$

The difference between $\Omega(x)$ and Ω is that the latter represents a small solid angle in which light amplification occurs.

A comparison of eqs. [3] and [36] shows that formally the effect of stimulated emission is represented by replacing τ_E with τ_E' as given by eq. [36]. If the condition $n_E - n_A \rightarrow 0$ applies, the expressions of sections II and III remain useful.

The substitution of τ_E' for τ_E can still be valid if $n_E - n_A$ is finite, as long as $n_E - n_A < 1/\sigma_E' L$, because from eq. [36] it follows that $1/\tau_E \approx 1/\tau_E'$. Light amplification in the x direction can occur if $\sigma_E' L > 1/(n_E - n_A)$, and in that case, the term n_E/τ_E, which appears in the right hand side of eq. [33] is small compared to the stimulated emission term and a comparison of eqs. [3] and [36] cannot be made anymore. However, the assumption that the emitted photons experience stimulated exponential amplification may not hold anymore if the cross section σ_E'' for a transition $Y'' \leftarrow E$, which occurs at the same wavelength as that of the $E \rightarrow A$ fluorescence, becomes large.

In any case, from a practical point of view one does not want to generate laser action at the wavelength λ_{EA} because this would interfere with the Stokes part of the Raman spectrum excited with the tunable laser which serves simultaneously as an optical pump and Raman probe. From Fig. 1, it follows that the wavelength of the Raman probe is always smaller than that of the fluorescence $E \rightarrow A$.

Having in mind that one of the purposes of this paper is related to study the conditions which would make it possible to record an excited-level Raman (E.L.R.) spectrum, we emphasize that one should have $\sigma_A \neq 0$ in order that population of the E level can take place. This means that in all cases the intensity of Raman bands of the ground state A are resonance enhanced. In the case where eq. [25] is valid, conditions are favourable for the recording of the E.L.R. spectrum, in particular if $\sigma_E \rightarrow 0$. On the other hand, if $\sigma_E \neq 0$ one also deals with a resonance Raman effect which enhances intensities in the Raman spectrum of E, although the population number n_E of this level is reduced (case I only), and ground- and excited-level scattering can both contribute to the recorded spectrum. It is clear that the E.L.R. spectrum can be made to dominate over that of the spectrum associated with the electronic ground state after a judicious choice is made of the wavelength and power of the pulsed tunable laser.

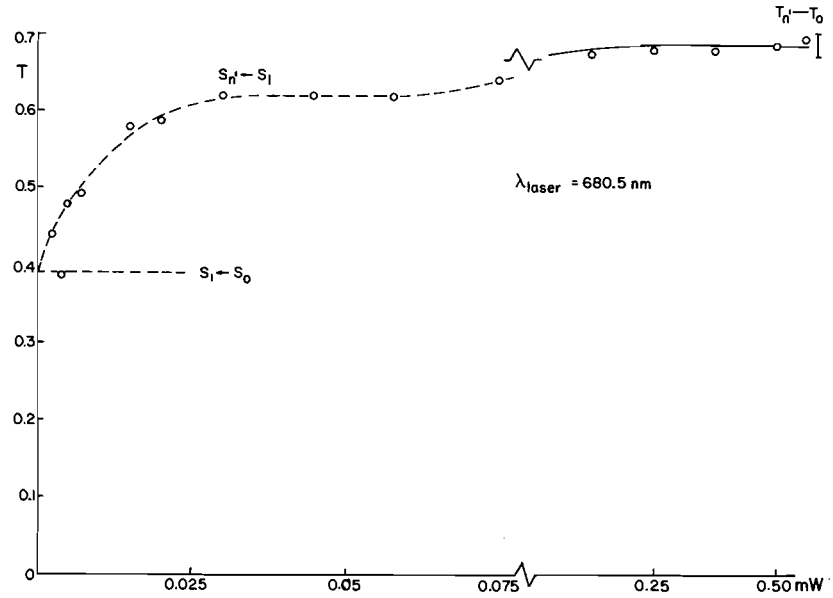

FIG. 4. The transmission T as function of the average power of a dye laser (repetition rate 25 Hz, pulse duration 3.2×10^{-9} s) at $\lambda = 680.5$ nm of a 1.45×10^{-4} M solution of chlorophyll a in pyridine. For the focused laser beam and $I_{laser} \approx 0.025$ mW (corresponding to $\sim 4 \times 10^{24}$ photons s^{-1} cm^{-2}) effective saturation occurs of the singlet S_1 state while for $I_{laser} \approx 0.50$ mW ($\sim 8 \times 10^{25}$ photons s^{-1} cm^{-2}) saturation of the T_0 triplet state occurs. Also indicated is the value of T for the ground state absorption process $S_1 \leftarrow S_0$ (laser beam not focused).

VI. Some Experimental Results

The absorption spectrum of chlorophyll a in pyridine in the visible spectral region is well known (15, 16). Its main features are two bands at ~ 680 nm and 440 nm, which are due to transitions from the singlet S_0 ground state to the excited singlets S_1 at $\sim 14\,780$ cm^{-1} and S_4 at $\sim 22\,280$ cm^{-1} above S_0.

When chlorophyll a is exposed to radiation with wavelengths < 680 nm, one finds that S_1 can be populated via vibrational relaxation. From there, part of the energy returns to the ground state S_0 giving rise to the well-known red fluorescence, while part of the absorbed *energy reaches* the lowest lying triplet state which is at $\sim 10\,150$ cm^{-1} above the ground state. From the decay time of the red fluorescence, a lifetime $\tau_{S_1} = 45$ ns was established (17) while $\tau_{T_0} \approx 70$ μs. Both lifetimes are longer than the duration of the pulses of a tunable dye laser used in the experiments described below (duration 3.2 ns at a repetition rate of 25 Hz).

Figure 4 shows the behaviour of transmission of the sample (1.45×10^{-4} M) when pumping at $\lambda = 680.5$ nm, that is, in the wing of the $S_1 \leftarrow S_0$ absorption band (towards longer wavelength). The transmission (~ 0.4) for low laser power is the value for T in the singlet spectrum when measurements of T are carried out with a non-focused laser beam. If, however, this beam is focused and its intensity is increased, one records an increase in T. Conditions for which Beer's law applies are met if 0.03 mW $< l <$ 0.06 mW and if $I \geq 0.25$ mW (average power). The value of the transmission $T = 0.69$ for the latter case is equal to that for T at 680.5 nm in the *triplet excited* (16) state absorption spectrum of chlorophyll a in pyridine (1.45×10^{-4} M). These experiments prove that with pumping at 680.5 nm, energy is transferred into the triplet system and that population of T_0 takes place. The value of the transmission $T = 0.62$ for 0.03 mW $< l <$ 0.06 mW agrees with the value of T in the *singlet–singlet* (and not triplet–triplet) absorption spectrum (16) and effective population of S_1 is achieved. It was found that while increasing the intensity of the focused laser beam a decrease was observed in the intensity of the $S_1 \rightarrow S_0$ red fluorescence. This suggests that the absorbed energy in the singlet excited-state spectrum does not return again to S_1 but reaches the ground state via another path. Hence the energy transfer within the singlet system maybe an example of case I, Fig. 1, except that the effect of intersystem crossing from $S_1 \rightarrow T_0$ (which occurs for chlorophyll) is not included. This effect may be incorporated in the equations of section II as playing the role of radiationless transitions from $E \rightarrow A$, ($E \equiv S_1$ and $A \equiv S_0$) representing another path for the return of energy to the ground state, in competition with the stimulated emission process. The introduction of radiationless transitions and energy transfer may be incorporated

in the reduction of the stimulated gain σ_E', see eqs. [33] and [35]. This means that the effective lifetime τ_E' ($\tau_E' < \tau_E$) takes on another meaning without affecting the derivations of section II.

Equation [31] cannot be directly applied to obtain an estimate of the lifetimes τ_{S_1} from the data shown in Fig. 4. This equation states that the number of photons per second delivered in the lifetime τ_E should exceed the number of molecules times $\sigma_A/(\sigma_A + \sigma_E)$ in the path of the laser beam. Pulsed lasers do not deliver photons per second but rather photons per duration of the laser pulse ($\hat{N}_{ph}$). Hence the lifetime τ_E can only be computed in terms of a fraction f, where

$$f = \frac{\sigma_A}{\sigma_A + \sigma_E} \frac{N}{\hat{N}_{ph}}$$

of the duration of the laser pulse t_p as can be seen from the following. In the situation where the duration of the pulse becomes equal to the lifetime τ_E, one finds from eq. [31] that the following expression applies:

$$[37] \quad \frac{\hat{N}_{ph}}{t_p} \gtrsim \frac{\sigma_A}{\sigma_A + \sigma_E} \frac{N}{\tau_E}$$

However, if $t_p \leq \tau_E$, we find that in order to reach conditions for the applicability of Beer's law, the number of photons $\hat{N}_{ph}$ has to be increased by the factor t_E/t_p, and the relevant expression now becomes

$$[38] \quad \hat{N}_{ph} \gtrsim \frac{\sigma_A}{\sigma_A + \sigma_E} N$$

Figure 5 shows the result of transmission studies with pulsed and cw lasers operating at 488.0 nm. For high laser powers, the transmission again approaches the value at 488.0 nm previously found in the triplet absorption spectrum. Because eq. [38] is valid for the pulsed case and eq. [37] for the cw measurements, we obtain $\tau_{T_0} \approx 70$ μs. One also notes that whereas for lower intensities of the pulsed laser, the S_1 state becomes populated. This is not the case with the cw laser. This is because the number of photons per second is not large enough to reach conditions for which eq. [31] applies. We also find that in the region $0.2 < I < 0.3$ mW the relation $(T_{S_1-S_0})^2 \sim T_{S^*-S_1}$ is valid. The singlet excited state spectrum of chlorophyll *a* in pyridine was recently recorded (16) and $\sigma_{S^*-S_1} \sim 10\,\sigma_{S_1-S_0}$ at 488.0 nm. The fact that conditions exist for which eq. [18] is valid is taken as another proof that case I of Fig. 1 applies to energy transfer within the singlet system. On the other hand, because we find, consistently, for large laser intensities that the value of the transmission is, within experimental error, equal to that found in the

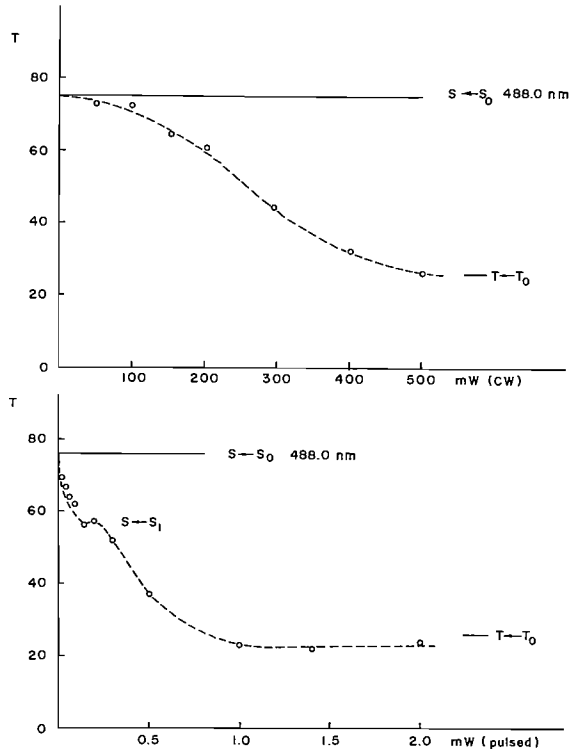

FIG. 5. Transmission studies at $\lambda = 488.0$ nm of a 1.45×10^{-4} *M* solution of chlorophyll *a* in pyridine. Top: studies with a cw laser, bottom: T as function of I_{laser} (pulsed). The horizontal solid line represents the value of T measured with a non-focused beam, the broken line is obtained if the laser is focused down to an effective radius of $r \approx 50$ μ. Population of the singlet excited state S_1 (via a rapid vibrational relaxation process) can be detected with the pulsed laser only because if given a lifetime of $\tau_{S_1} = 45$ ns of S_1, population of this state cannot be achieved with the cw laser (maximum incident flux at 500 mW is $\sim 6.25 \times 10^{21}$ photons s^{-1} cm^{-2}).

triplet excited spectrum, eq. [22] is seen to be valid. The energy flow inside the triplet system is an example of case II, Fig. 2. The data displayed in Fig. 6 represent transmission studies as function of the intensity of a non-focused, and of a focused, pulsed laser beam near the absorption maximum of the Soret band in the blue for a 1.45×10^{-5} *M* of chlorophyll *a* in pyridine in a 1 cm cell. We note that even for the unfocused beam an increase of T is recorded upon an increase of the intensity of the laser beam. From a comparison of photon densities in the focused and non-focused beams leading to the same value of the transmission, it follows that the former is ~250 times more effective than the latter. The effective radius of the unfocused beam amounts to ~1.0 mm, hence the effective radius of the focused beam in the absorbing medium is ~63 μ. A simple calculation shows that there are $N = 2.2 \times 10^{11}$ chlorophyll *a* molecules in the path of the laser beam

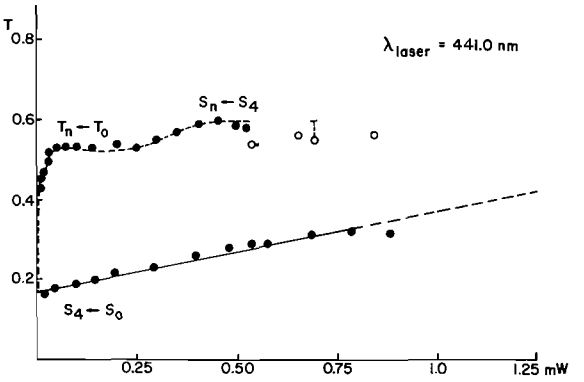

FIG. 6. Transmission studies of a 1.45×10^{-5} molar solution of chlorophyll *a* in pyridine at 441.0 nm. Even for non-focused radiation (solid line) of the pulsed laser one observes an increase in *T*. The rate of the data shows that the focused laser beam (broken curve) is $\sim 250 \times$ more effective than the non-focused beam with regard to the optical pumping process. For $I_{laser} > 0.50$ mW photo-decomposition of the solution occurs and the data become less reliable.

and employing eq. [37] yields $\tau_{S_4} \leq 160$ ps because population of S_4 occurs at $I \approx 0.4$ mW (which corresponds to 0.35×10^{14} photons per pulse of 3.2 ns at a repetition of 25 Hz). The observation of excited state Raman spectra of normal modes in either T_0, S_0, or S_4 for specific values of the intensity and wavelength of the pulsed laser is made difficult because of a strong background due to the $S_1 \rightarrow S_0$ and also an $S_4 \rightarrow S_0$ fluorescence.

Excited state spectra of several other molecular systems have been recorded in the past (1–10) but transmission studies before or during the time that Raman spectra were recorded were carried out only in a few isolated cases (2, 7, 9).

The recent study of (9) the excited state Raman spectrum of tris(2,2′-bipyridine) Cr(III) complex is a case in point. The energy level diagram of this complex is discussed in terms of that of Cr^{3+} in a distorted octahedral surrounding, and the states of interest here are the $^4A_2$ ground state, the ^2E excited at $\sim 13\,740$ cm^{-1} and $^4T_2$ at $\sim 17\,000$ cm^{-1}. This complex fluoresces at ~ 740 nm ($^2E \rightarrow {}^4A_2$) and the spectrum is quenched if the complex is exposed to radiation of $\lambda = 457.9$ nm of the tunable dye laser mentioned in the above. The quenching of the said fluorescence is interpreted on the basis that the energy transfer of the Cr complex is an example of case II, Fig. 1, because if exposed to the same power level at 457.9 nm of a cw laser, strong $^2E \rightarrow {}^4A_2$ fluorescence is recorded. Transmission measurements reveal that the $^4T_2$ state (with a ~ 10 ps lifetime) is populated during the experiments with the pulsed laser and absorption of radiation at 457.9 nm in the $^4T_2$ excited state spectrum takes place. The absorbed radiation reaches another high-lying excited state ^4Y and returns to the ground state via a path which does not involve the $^4T_2$ and (via intersystem crossing) ^2E excited states of $Cr(bpy)_3{}^{3+}$. The above interpretation of energy transfer is consistent with the fact that at 457.9 nm $(T_{4_{T_2}-4_{A_2}})^2 \approx T_{4Y-4_{T_2}}$. Consequently the intensity of vibrational Raman bands of $^4T_2$:$Cr(bpy)_3{}^{3+}$ are resonance enhanced to a larger degree than the corresponding modes of $^4A_2$:$Cr(bpy)_3{}^{3+}$ although, according to eq. [25], there are more ground state than optically pumped excited-state scattering centers in the laser beam. In the case of $^4T_2$:$Cr(bpy)_3{}^{3+}$, however, the assignment of the excited-state Raman scattering is made easier because of a larger band width for Raman shifts of modes in the excited state, compared to the width of the corresponding modes in the ground state.

The excited state electronic Raman effect of Cr^{3+}:αAl_2O_3 and Cr^{3+} in other solids was also recorded (18) after transmission studies were made, but the assignment here was straightforward in that there does not occur an electronic Raman process of the ground state which can interfere with that of the optically-pumped excited state. Earlier results (19) obtained by Szabo for the excited-state absorption cross section in ruby, by means of saturation-transmission measurements, indicate that ruby may well be an example of the situation depicted by case II in Fig. 1. The limiting transmission obtained at high incident flux values follows a Beer's Law of the form given by eq. [22], with a value of σ_E which equals excited-state absorption cross sections obtained by other methods.

VII. Summary

An attempt is made to lay down the ground rules for excited level Raman spectroscopy. It is shown that in order to record scattering from one specific excited state one must carry out transmission studies at some specific laser (which position is in resonance with an absorption band of the molecule) wavelength as function of laser power. The E.L.R. spectrum may then become detectable only after a judicious choice is made of (*i*) the wavelength and (*ii*) the intensity of the laser radiation. In addition to the above it appears that measurement of the transmission at a specific wavelength as function of I_l allows one to obtain the lifetime of an excited state. At the same time an insight is obtained of the energy transfer between excited states of the absorbing molecules, ions or atoms.

A study has been made of trapped electrons in *n*-propanol–hydrocarbon mixture glasses at 77 K by the optical absorption method. The yields of electrons trapped in alcohol clusters (e_{alc}^-) were measured for several γ-irradiated *n*-propanol–hydrocarbon glasses, where the yields of trapped electrons in these neat hydrocarbon glasses at 77 K are known to range from 0.015 to 1.1 G units. The results show that the yields of e_{alc}^- in the mixture glasses do not depend on the trapped electron yields in neat hydrocarbon glasses. Thus, it is concluded that electron migration from relaxed hydrocarbon matrix traps into alcohol clusters is not the major process for e_{alc}^- formation in the systems studied here. The major process for e_{alc}^- formation may be attributed to quasi-free electron scavenging by alcohol clusters and electron migration from unrelaxed hydrocarbon traps into alcohol clusters. Both ir-induced and isothermal changes in the e_{alc}^- yield have also been investigated. These investigations indicate that there is a correlation between the observed change in the e_{alc}^- yield and the matrix viscosity.

MASAYA ITO, TOYOAKI KIMURA et KENJI FUEKI. Can. J. Chem. **59**, 2803 (1981).

Utilisant la méthode d'absorption optique, on a étudié le piégeage d'électrons dans un mélange de *n*-propanol–hydrocarbure à l'état vitreux à 77 K. On a mesuré les rendements en électrons piégés dans les agrégats d'alcool pour plusieurs verres de *n*-propanol hydrocarbure irradiés au rayons γ et pour lesquels les rendements en électrons piégés dans ces verres d'hydrocarbures homogènes à 77 K sont de l'ordre de 0,015 à 1,1 unités G. Les résultats indiquent que les rendements dans le mélange de verre ne dépendent pas des électrons piégés dans les verres d'hydrocarbures homogènes. On en conclut alors que la migration de l'électron à partir des pièges de la masse hydrocarbonée en relaxation dans les agrégats d'alcool ne consittue pas le processus fondamental dans la formation des systèmes étudiés. On peut attribuer le processus principal de formation au piégeage des électrons à partir des pièges hydrocarbonés non relaxés aux agrégats d'alcool. On a également étudié le rendement des changements induits par ir et par des changements isothermiques. Ces études indiquent qu'il existe une corrélation entre le changement observé dans le rendement et la viscosité de la gangue.

[Traduit par le journal]

Introduction

Solvated and trapped electrons in γ-irradiated alcohol–hydrocarbon mixtures have been investigated in the liquid (1–6) and glassy states (7–14). Optical absorption bands were observed in the visible and ir region in a glassy alcohol–hydrocarbon mixture at 77 K, and they were, respectively, ascribed to electrons (e_{hc}^-) trapped in the hydrocarbon matrix and those (e_{alc}^-) trapped in alcohol clusters (8), the existence of which was confirmed by the infrared absorption method (15–17). The formation of e_{alc}^- has also been proposed in liquid alcohol–hydrocarbon mixtures from a study of free ion yields, suggesting that a fraction of electrons generated in a hydrocarbon region are probably scavenged by alcohol clusters (1).

Concerning the mechanism of e_{alc}^- formation in alcohol–hydrocarbon glasses the following findings seem to give us some suggestions on the mechanism: in a pulse radiolysis study of *n*-propanol (*n*-PrOH) – 3-methylpentane (3MP) mixture glasses Mayer *et al.* have shown the interesting result that an absorption peak in the visible region grows at 107 K after the pulse accompanied by decay of a peak in the ir region (11). This can be explained in terms of electron migration from 3MP matrix traps into *n*-PrOH clusters. However, the visible peak was not observed separately from the ir peak at 90 K during 500 μs after the pulse (11). On the other hand, both absorption peaks corresponding to e_{alc}^- and e_{hc}^- were observable in γ-irradiated *n*-PrOH–3MP glasses at 77 K (12). Shimizu *et al.* have reported that electron migration from 3MP matrix traps into *n*-PrOH clusters occurs within tens of minutes in γ-irradiated *n*-PrOH–3MP glasses at 77 K (18). These results seem to indicate a mechanism of e_{alc}^- formation in which electrons migrate from hydrocarbon matrix traps, in which electrons are originally trapped, into alcohol clusters. Thus, if this kind of electron migration is the major process of e_{alc}^- formation in alcohol–hydrocarbon mixture glasses, then yields of e_{alc}^- can be expected to depend on the trapped electron yield in the neat hydrocarbon glass: the higher the trapped electron yield in the hydrocarbon glass, the higher the e_{alc}^- yield in the alcohol–hydrocarbon glasses. In order to look at this point we have measured yields of e_{alc}^- and e_{hc}^- in *n*-PrOH–hydrocarbon glasses at 77 K. The matrices used are 2-methylpentane (2MP), 3-methylhexane (3MHx), methyl-

cyclohexane (MCH) – 31 mol% cyclopentane (CP), MCH and isopropylcyclohexane (*i*-PrCHx). The electron fraction (e.f.) of *n*-PrOH in these mixtures was varied from 0.01 to 0.2. We have chosen these hydrocarbons because the trapped electron yields in these neat hydrocarbon matrices at 77 K are known to range from 0.015 to 1.1 G units (19). In addition, we have investigated the isothermal growth of the optical absorption band of e_{alc}^- after γ-irradiation and the effect of ir illumination on the growth of e_{alc}^-.

Experimental

Hayashi Pure Chemical *n*-PrOH (extra pure) was refluxed over sodium borohydride under argon atmosphere for 70 h at 340 K, distilled, and then further purified *in vacuo* three times using molecular sieves 4A which were heated at 550 K *in vacuo* for 12 h before use. Tokyo Kasei 3MHx and *i*-PrCHx (extra pure), and Tokyo Kagaku Seiki MCH, CP, and 2MP (standard purity) were purified using molecular sieves 13X by the procedure described above. The hydrocarbons were taken by a volumetric flask *in vacuo* and vacuum-distilled into optical cells which contained the desired amount of *n*-PrOH taken by a microsyringe. Samples were sealed off a vacuum line. Optical cells were made of Suprasil quartz. γ-Irradiation was carried out by ^{60}Co γ-rays. The dose was 1.0–3.4 × 10^5 rad. Optical absorption spectra were measured on a Hitachi 323 spectrophotometer. γ-Irradiation and optical absorption measurements were made at 77 K. Photobleaching was carried out using a 300 W tungsten lamp with a Toshiba IR-DIA filter which cuts off light with wavelengths shorter than 900 nm.

Results and Discussion

γ-Irradiated *n*-PrOH–hydrocarbon glasses give two characteristic optical absorption bands due to e_{alc}^- with $\lambda_{max} \simeq 560$ nm and e_{hc}^- with $\lambda_{max} \simeq 1700$ nm. With increasing *n*-PrOH concentration the visible band increases whereas the ir band decreases. Figure 1 shows the optical densities of e_{alc}^- and e_{hc}^- at λ_{max} (560 and 1730 nm, respectively) vs. electron fraction of *n*-PrOH for *n*-PrOH–3MHx systems. The ir illumination reduces the ir absorption band to zero without any significant decrease in the visible band. In some cases the visible band increases with a slight blue shift of the peak as will be described later.

1. Trapped Electrons (e_{alc}^-) in Alcohol Clusters

The optical absorption spectrum of e_t^- in a neat hydrocarbon glass has a long tail towards the high energy side. Thus, the absorption spectrum of e_{alc}^- in a *n*-PrOH–hydrocarbon glass may overlap with the tail of the e_{hc}^- absorption spectrum. Since it is difficult to separate these two absorption bands, we use the observed optical density at λ_{max} in the visible region as a measure of the yield of e_{alc}^-. The error due to the neglect of such overlapping e_{hc}^- absorption is estimated to be at most 10% at a lower

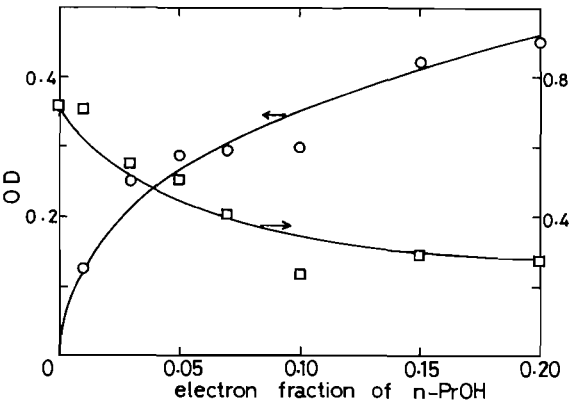

FIG. 1. Optical densities of e_{alc}^- (○) and e_{hc}^- (□) at λ_{max} (560 and 1730 nm, respectively) in *n*-PrOH–3MHx systems vs. electron fraction of *n*-PrOH. The dose is normalized to 1.1 × 10^5 rad and the optical path length to 3 mm.

n-PrOH concentration (0.03 e.f.) but less than 5% at a higher concentration (0.07 e.f.).

Optical densities of e_{alc}^- in *n*-PrOH–hydrocarbon glasses studied are shown in Fig. 2 as a function of the electron fraction of *n*-PrOH. The dashed line is the one extrapolation of which to pure *n*-PrOH (e.f. = 1.0) gives the observed optical density of e_t^- in pure *n*-PrOH. In view of the lack of data on the molar extinction coefficient, ε, for e_{alc}^-, we make an assumption that ε for e_{alc}^- in the systems studied here are all the same. It should be noted in Fig. 2 that the observed optical density of e_{alc}^- in each system lies far above the dashed line. Thus, we may say that a major part of e_{alc}^- formation can be ascribed to electron migration from hydrocarbon matrix into alcohol clusters via

the "trap to cluster" migration (18) and/or the quasi-free electron scavenging process (1).

It is seen from Fig. 2 that the yield of e_{alc}^- does not differ very much among the *n*-PrOH–hydrocarbon systems at specified alcohol concentration. On the other hand, the yields of e_t^- in these neat hydrocarbon glasses determined by the steady-state γ-radiolysis differ by two orders of magnitude as shown in the first and second column in Table 1 (19, 20). If e_{alc}^- is formed as a result of electron migration from relaxed hydrocarbon matrix traps into alcohol clusters, the yield of e_{alc}^- should depend on that of e_t^- in each neat hydrocarbon glass, namely, the yield of e_{alc}^- should be the highest in 2MP and lowest in *i*-PrCHx as shown in Table 1. However, this is not the case as seen from the experimental results in Fig. 2. Therefore it can be said that electron migration from relaxed hydrocarbon traps into alcohol clusters is not the major process for e_{alc}^- formation in our systems studied here.

The possibility of electron migration from unrelaxed hydrocarbon matrix traps, which can exist only transiently, into alcohol clusters has to be considered. Klassen *et al.* have shown that optical absorption bands in pulse irradiated hydrocarbon glasses decay to some extent within a short time after the pulse and that the absorption at a longer wavelength region decreases more than that at shorter wavelength region (21, 22). Thus, this part of electrons which decay within a short time after the pulse in a neat hydrocarbon system may migrate into alcohol clusters to form e_{alc}^- in alcohol–hydrocarbon systems. In the last column of Table 1 values of $G(e_t^-)\varepsilon \times 10^{-4}$ determined by the pulse radiolysis at 73 K (22) are listed. If one assumes that ε_{max} is roughly the same for all the hydrocarbon matrices, then the comparison of the values in the first and third columns in Table 1 leads to the conclusion that there is considerable decay of e_t^- in 2,4-dimethylpentane (2,4DMP). At present, we cannot exclude the possibility of electron migration from unrelaxed hydrocarbon traps into alcohol clusters, leading to e_{alc}^- formation. However, one cannot explain the results in Fig. 2 in terms of this mechanism alone: the value of $G(e_t^-)\varepsilon \times 10^{-4}$ in 2MP in Table 1 differs by a factor of about two from that in MCH, which means that the initial trapped electron yield in 2MP is roughly twice as high as that in MCH. Nevertheless, the yields of e_{alc}^- in *n*-PrOH–2MP systems are nearly the same as those in *n*-PrOH–MCH systems as seen from Fig. 2. Therefore, quasi-free electron scavenging by alcohol clusters may be another significant process for e_{alc}^- formation.

2. *Photobleaching of Trapped Electrons (e_{hc}^-) in Hydrocarbon Matrices*

Photobleaching of trapped electrons in γ-irradiated *n*-PrOH–hydrocarbon glasses by ir light ($\lambda > 900$ nm) reduces the absorption band in the ir region and increases the visible band for 2MP, 3MHx, and MCH–CP matrices. As an example, the effect of ir illumination on the e_{alc}^- yield in *n*-PrOH–2MP systems is shown in Fig. 3. On the other hand, in *n*-PrOH–MCH and *n*-PrOH–*i*-PrCHx glasses no increase in the e_{alc}^- absorption band could be observed as a result of ir photobleaching of e_{hc}^-. The effect of ir photobleaching on the optical density of the e_{alc}^- absorption for samples containing 0.07 e.f. *n*-PrOH (in the case of *i*-PrCHx matrix containing 0.1 e.f. *n*-PrOH) is given in Table 2. The increment of the e_{alc}^- yield due to ir photobleaching appears to depend on the rigidity (or viscosity) of the matrix except for 3MHx. The viscosities of the matrices at 77 K are given in Table

‡This work.

3 together with the time, $\tau_{2/3}$, required for the e_t^- yield to decay to 2/3 of its initial value. For comparison 3MP is also included in Table 3. Trapped electrons in 3MHx decay slowly and they decay in MCH and *i*-PrCHx too slowly to be observed within a few hours. The viscosity of the MCH–CP mixture is not available but may be estimated to be a value close to that of 3MP, because the value of $\tau_{2/3}$ for these two matrices are close to one another. Although the viscosity of *i*-PrCHx at 77 K is not known, *i*-PrCHx presumably has the highest viscosity among the matrices studied here, since it is most difficult to make a clear glass from this compound.

The data from Tables 2 and 3 indicate that ir photobleaching causes the e_{alc}^- yields to increase in the matrices which have lower viscosities and in which the decay of trapped electrons is observable. Although the viscosity of 3MHx is higher than that of MCH, the decay of e_t^- in 3MHx is faster than that in MCH and slight increase in the e_{alc}^- yield is observable in *n*-PrOH–3MHx glasses as a result of ir photobleaching but not in *n*-PrOH–MCH glasses. This exception might be explained in terms of the local viscosity, which is possibly different from the bulk viscosity. Since the value of the viscosity for MCH was obtained by the extrapolation from viscosities of MCH–3MP mixtures to that of MCH (25), the true viscosity of MCH might be higher than that of 3MHx. Then, this case may not be an exception.

The correlation between the change in the e_{alc}^- yield and the viscosity of the matrix may indicate that reorientation of alcohol molecules is necessary for electrons photoejected from electron traps that consist of hydrocarbon molecules to be retrapped in alcohol clusters. The lower is the viscosity of the matrix, the higher is the increase of the e_{alc}^- yield arising from ir photobleaching.

3. *Isothermal Growth of the e_{alc}^- Absorption Band*

The absorption bands of e_{alc}^- in *n*-PrOH–MCH and *n*-PrOH–*i*-PrCHx glasses did not change during at least 2 h after γ-irradiation. On the other hand, when 3MHx, 2MP, or MCH–CP was used as a matrix in *n*-PrOH–hydrocarbon systems, the e_{alc}^- absorption band grew during 30 min after γ-irradiation. As an example, the isothermal increase in the e_{alc}^- yield in *n*-PrOH–2MP glasses is shown in Fig. 4. The results on the isothermal increase in the e_{alc}^- absorption band are summarized in Table 4. The optical densities were not measured at the same specified time after γ-irradiation for each system. Also we did not measure systematically the growth of the e_{alc}^- absorption band as a function of time. Nevertheless, we can say that the e_{alc}^- absorption bands grow mainly within the first 30 min in these matrices. It can be seen from Table 4 that the isothermal increase in the e_{alc}^- absorption band is larger in *n*-PrOH–2MP and *n*-PrOH–MCH–CP glasses than that in *n*-PrOH–3MHx glasses. It should be noted that the isothermal increase in the e_{alc}^- yield occurs in low viscosity matrices such as 2MP and MCH–CP,

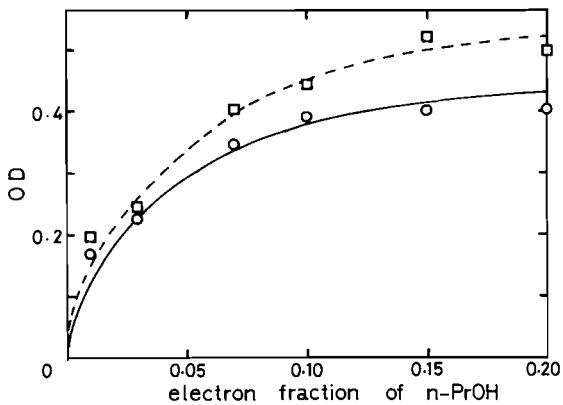

FIG. 4. Isothermal increase in the optical densities of e_{alc}^- at λ_{max} (560 nm) in *n*-PrOH–2MP systems. but not in high viscosity matrices such as MCH and *i*-PrCHx. Thus, it appears that reorientation of alcohol molecules plays an important part for the isothermal incease in the e_{alc}^- yield, as is the case for ir photobleaching already described.

In the preceding section we have shown that the e_{alc}^- yield is increased by ir illumination in the low viscosity matrices but not in high viscosity matrices and explained this in terms of reorientation of alcohol molecules in a cluster. However, since the visible band of e_{alc}^- in γ-irradiated *n*-PrOH–hydrocarbon glasses of high viscosity at 77 K is observed, reorientation of alcohol molecules occurs even in these rigid systems, although it takes rather a long time (500 μs (11, 14)) for alcohol molecules to reorient even at 90 K. Then the question arises as to why ir illumination does not lead to the increase in the e_{alc}^- yield in these rigid matrices. Further study is required to resolve this problem.

Enzymic aromatization of deuterium labelled testosterone and androst-4-ene-3,17-dione

HERBERT L. HOLLAND AND GREGG J. TAYLOR
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received March 24, 1981

HERBERT L. HOLLAND and GREGG J. TAYLOR. Can. J. Chem. **59**, 2809 (1981).

The preparation and aromatization by human placental microsomes of androst-4-ene-3-ones labelled with deuterium at C-4, C-6α, C-6β, C-16, and C-19 is described. Deuterium nmr spectra are reported for these compounds and for a sample of a 1,2-dideuterated androst-4-ene-3-one; the latter is formed nonstereospecifically by reduction of the C-1(2) double bond of a $\Delta^{1,4}$-diene-3-one. Aromatization by placental microsomes occurs with retention of deuterium at C-4 and C-6, but with some loss from C-16. The aromatization of 19-d_1 and 19,19,19-d_3 steroids in the presence of 16,16-d_2 steroids has been carried out to determine the deuterium isotope effect for the oxidative removal of C-19. The values obtained (k_H/k_D for 19-d_1 = 2.3, k_H/k_D for 19,19,19-d_3 = 3.2) are a combination of primary and secondary effects, but suggest that oxidation at C-19 is a rate-limiting reaction of the biosynthetic sequence.

The fungus *Pellicularia filamentosa* NRRL 2727, reported to hydroxylate androst-4-ene-3,17-dione at C-19, gave only the products of hydroxylation at C-11α, C-11β, and C-14.

HERBERT L. HOLLAND et GREGG J. TAYLOR. Can. J. Chem. **59**, 2809 (1981).

On décrit la préparation et l'aromatisation par les microsomes du placenta humain, d'androstène-4 ones-3 marquées au deutérium en C-4, C-6α, C-6β, C-16 et C-19. On rapporte les spectres de rmn du ^2H de ces composés ainsi que celui d'un échantillon d'androstène-4 one-3 dideutéré en positions 1 et 2. On a obtenu ce dernier de façon non stéréospécifique par la réduction de la double liaison en C-1(2) d'une Δ-diène-1,4 one-3. L'aromatisation par les microsomes du placenta se produit avec une rétention de configuration des deutérium en C-4 et en C-6 mais avec quelques pertes au niveau du C-16. On a réalisé l'aromatisation des stéroides deutérés 19-d_1 et 19,19,19-d_3 en présence de stéroides 16,16-d_2 dans le but de déterminer l'effet isotopique du deutérium lors de l'élimination oxydante de C-19. Les valeurs obtenues (k_H/k_D pour 19-d_1 = 2,3, k_H/k_D pour 19,19,19-d_3 = 3,2) sont une combinaison d'effets isotopiques primaires et secondaires mais elles suggèrent que l'oxydation au niveau de C-19 est l'étape déterminante de cette série de réactions biosynthétiques.

Le champignon *Pellicularia filamentosa* NRRL 2727 responsable de l'hydroxylation de l'androstène-4 dione-3,17 au niveau du C-19 donne seulement des produits d'hydroxylation en C-11α, C-11β et C-14.

[Traduit par le journal]

Introduction

In spite of the intense effort which has been expended over the last two decades on investigation of the later stages of the biosynthesis of estradiol (estra-1,3,5(10)-triene-3,17β-diol, **1***a*) and estrone (estra-1,3,5,(10)-triene-3-ol-17-one, **1***b*), several aspects of the conversion of testosterone (androst-4-ene-17β-ol-3-one, **2***a*) or androst-4-ene-3,17-dione (**2***b*), the C_{19} substrates of the aromatase enzyme system, to the estrogens, remain obscure. The established route for this conversion by human placental microsomes is presented in Fig. 1 (1–6).

The key features of this pathway are (*i*) the intermediacy of the 19-alcohol **21** and aldehyde **22**, and their formation by the action of a monooxygenase type enzyme utilizing molecular oxygen and NADPH (two equivalents); (*ii*) the apparent involvement of a third equivalent of oxidizing potential (O_2/NADPH); and (*iii*) the release of C-19 of the substrate as formic acid, the stereochemistry of oxidation at C-19 being that shown in Fig. 1.

Less well defined from a mechanistic standpoint are the following; firstly, the function of the third oxidizing equivalent and the pathway for conversion of **22** to **1***a* or **1***b*. Pathways have been postulated which involve 1β hydroxylation to give intermediate **23** (Fig. 2) (7–9), 2β hydroxylation to give **24** (10, 11), enzymic "Baeyer–Villiger" oxidation to give the ester **25** (12), or epoxidation to **26** (13, 14). The possible involvement of a Δ^5 steroid via a 5,6 epoxide has also been suggested (13). The proposed pathways for the aromatization of the aldehyde **22** are based on the experimental observations of the release of C-19 as formate (Fig. 1), and a stereospecific loss of hydrogen from C-1β and C-2β (15–18). Secondly, the relative rates of the steps shown in Fig. 1 have been the subject of some discussion, complicated by the possible distinction between "free" and enzyme-bound intermediates, which now seems to indicate that the transformations occur at a single enzyme site, with little dissociation of intermediates from the enzyme, and that hydroxylation at C-19 is rate limiting in the overall pathway (5, 6, 19).

Although the stereochemistry of loss of hydrogen from C-1 and C-2 of substrate during aromatization has been investigated (15–18), the possible fate of the hydrogens attached to C-4 and C-6 has

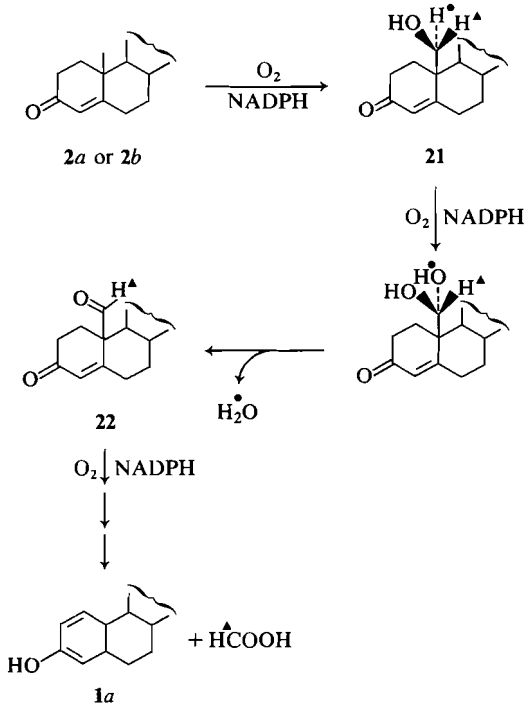

FIG. 1. Established mechanism of the aromatization of C_{19} steroids (1–6)

not hitherto been considered. Several of the mechanisms proposed for the aromatization of **22** have included intermediates in which the Δ^4 double bond is rearranged to the $\Delta^{5(10)}$ position (1, 13) or the $\Delta^{5(6)}$ position (13), and so a knowledge of the fate of the C-4 and C-6 hydrogens of **2***a* or **2***b* during conversion to the estrogens is desirable. In addition, the use of C-19-deuterium labelled steroids enables the kinetic isotope effect, k_H/k_D at C-19, for the aromatization to be determined. This information may provide additional evidence for the identity of the rate-limiting step of the overall process, and for the nature of the oxidation reaction occurring at C-19.

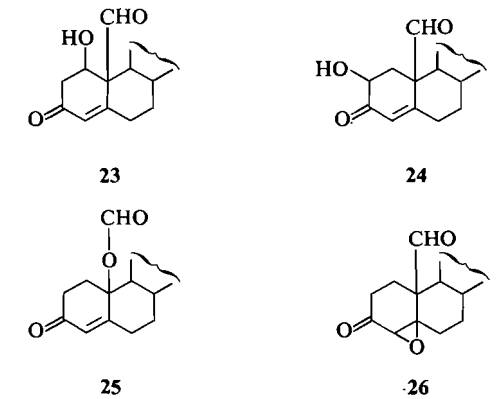

FIG. 2. Proposed intermediates in the conversion of **22** to **1***a*

Results and Discussion

The deuterium labelled steroids used in this study are listed in Table 1, and were prepared as outlined in the Experimental. The preparation of substrates labelled at C-2β, C-4, C-6α, and C-6β was straightforward, and ^2H nmr spectra of the products (Table 1) confirmed the essential integrity of the label. The presence of a small amount of additional deuterium in 4-d_1-**2***b*, presumably at C-6β, and in 6β-d_1-**2***b*, is apparent from both mass spectral and ^2H nmr data, but does not affect the conclusions discussed below. The ^2H nmr chemical shifts observed are consistent with those reported for analogous ^2H (20) and ^3H (21) labelled steroids. The 19-d_1 labelled steroids were prepared by two routes (see Experimental). The material obtained by route A (Scheme 1) was of slightly higher isotopic enrichment and was subsequently used for biotransformation. The 19,19,19-d_3 labelled testosterone was synthesized (Scheme 2) by a procedure similar to that of Baba *et al.* (22), and was obtained in high isotopic purity.

Synthesis of 1β,2β-d_2-testosterone was undertaken for comparative purposes. Reduction of androsta-1,4-diene-17β-ol-3-one (**27**) by deuterium gas gave a low yield of **2***a*. Although the sample was chemically pure and the predominant labelled species was dideuterated, ^2H nmr spectral analysis revealed the presence of deuterium in at least four different locations in **2***a*. The spectra were not sufficiently well resolved to allow quantification of the results, but a recent ^3H nmr study (21) of the product of reduction of **27** by tritium gas identified the presence of label at 1β (36.6%), 2β (2.3%), 1α,2α (12.3%), and 1β,2β (48.8%). Our results confirm that this reduction is indeed nonstereospecific. The substrates "specifically" labelled at C-1β which were originally used to demonstrate stereospecific removal of the C-1β hydrogen during estrogen biosynthesis were made by catalytic reduction of a $\Delta^{1(2)}$ bond (15), but more recent work with C-1α labelled material has confirmed the stereospecific loss of the C-1β hydrogen in this process (23).

By assignment of different chemical shifts to axial and equatorial deuterium (20) and tritium (21), the presence of two deuteron signals in the ^2H nmr spectra of steroids labelled at C-16 (Table 1) confirms the presence of stereochemically distinct deuterons. If ring D were predominantly in the planar or the envelope conformations then both C-16 deuterons would be virtually equivalent and only one signal would be expected. If ring D were conformationally mobile, a single average resonance might be expected. However, if ring D were

predominantly in the half-chair conformation, both pseudo-axial and pseudo-equatorial deuterons would be present. This compares favourably with X-ray crystallographic data (24) where, in the crystalline state, ring D adopts a conformation intermediate between the half-chair and envelope forms.

The results of the aromatization of deuterium labelled **2***a* and **2***b* are presented in Table 2. Both substrates are transformed by the same enzyme, at the same site (25, 26), and in both cases only a single product of aromatization (estradiol, **1***a*) is obtained. We have therefore used both 17β-alcohol and 17-keto substrates in the present study.

The values in Tables 1 and 2 indicate that

aromatization occurs with no loss of label from C-4 or C-6β. There is an apparent loss of some label from the C-6α position, the reason for which is not clear; its stereochemistry is inconsistent with a loss by enolization, in which major loss from C-6β should occur (27). The degree of retention is high, however, and this, together with the retention at C-4 and C-6β, eliminates from consideration any mechanism of aromatization in which the substrate may bind to the enzyme as a $\Delta^{3,5}$ enol (13) with loss of the C-6 hydrogen to the environment. The alternative binding as a $\Delta^{2,4}$ enol is consistent with the specific loss of the axial C-2β hydrogen (17), and thus appears to be the preferred mode of attachment of substrate to the enzyme (7, 15).

Transformations of substrates labelled at C-16 were carried out for control purposes to enable their use as internal rate standards in the determination of isotope effects at C-19 (*vide infra*). Surprisingly, there was a small but consistent loss of label from C-16 during aromatization. Recovered starting material in these experiments showed little or no loss of deuterium. In accord with this, substrate **2***b* labelled at all enolizable positions (2, 2, 4, 6, 6, 16, 16) also showed a greater deuterium loss on aromatization than could be accounted for by the known loss of the C-2β deuterium atom, and aromatizations of **2***b* in 50% and 95% D_2O produced estradiol with deuterium label appreciably greater than that of recovered substrate. The location of exchange of label was not determined in the latter experiments, but by inference is predominantly C-16, since previous work and the results discussed above rule out significant exchange at C-2, -4, or -6. Engel and co-workers (6) have reported appreciable loss of deuterium from C-17α of testosterone during conversion to estradiol by placental microsomes, and have demonstrated that reversible oxidation–reduction at C-17 may occur at any of the intermediate stages of the pathway shown in Fig. 1. We therefore attribute loss of label from C-16 to enolizable exchange, the loss from labelled **2***a* occurring at the carbonyl level at C-16.

In order to determine isotope effects at C-19, equimolar proportions of testosterone labelled at C-16 and at C-19 were incubated with placental microsomes, and the resulting estradiol assayed for deuterium. The deuterium content of product was then used to calculate the deuterium isotope effect for the oxidative removal of C-19 by the procedure of McMullen and Thode (28). The calculations were complicated by the loss of deuterium from C-16 discussed above, and so in order to establish the validity of the method, testosterone labelled at C-16 was co-incubated with unlabelled material, and deuterium content of product, corrected for the expected loss from C-16, was used to calculate the amounts of estradiol produced from labelled and unlabelled substrate (predicted ratio 1.0). The values obtained (1.02 ± 0.05 and 1.03 ± 0.05) demonstrate that correction of the observed deuterium content of product for the expected loss from C-16 could be confidently carried out in experiments with mixed C-16 and C-19 labelled substrates to give accurate values for the deuterium isotope effect at C-19. The values so obtained are listed in Table 2. These are intermolecular "mixed-labelling" effects which circumvent the problem of differential activities of individual microsome preparations. As the enzyme preparations used in studies on aromatization are not purified to homogeneity, individual batches can vary considerably in activity. This must be taken into account in studies which use only the absolute reaction velocities in order to study the kinetics of this system. In addition, during the preparation of labelled substrate, trace amounts of contaminants may be present which may act as inhibitors of the enzyme. In the mixed-labelling studies, such an inhibitor, if present, would be expected to act equally on the

conversion of both labelled and unlabelled substrate.

Previous studies on intermolecular isotope effects of cytochrome (cyt) P-450-dependent hydroxylations have generally shown deuterium isotope effects of 2 or less. The benzylic hydroxylation of phenylethane by liver microsomes was determined to proceed with a deuterium isotope effect of 1.8 (29). The 7β-hydroxylation of estr-4-ene-3,17-dione by *Botryodiplodia malorum* was found to have an isotope effect (k_H/k_D) of 1.4 (30), and the 21-hydroxylation of pregn-4-ene-3,20-dione was determined to proceed with an intramolecular isotope effect of 1.3 (31), whereas no isotope effect was observed in the 3-hydroxylation of estra-1,3,5(10)-triene-2,17β-diol when examined by mixed-labelling studies (32).

All of the above hydroxylations are presumed to involve cyt P-450. Some hydroxylations, however, are not mediated by carbon monoxide-sensitive cyt P-450; this appears to be the case for 19-hydroxylation during aromatization (33). Another such hydroxylation, the 7α-hydroxylation of taurodeoxycholic acid was determined to proceed with a tritium isotope effect of 3.8 (34), equivalent to a deuterium isotope effect of 2.5 (based on $(k_H/k_D)^{1.44} = k_H/k_T$).

The 16α-hydroxylation of pregn-5-ene-3β-ol-20-one and the 24-hydroxylation of 5β-cholestane-3α,7α,21α-triol were determined to proceed with a deuterium isotope effect of 3 to 4. These two processes appear to be insensitive to inhibition by carbon monoxide (35). Conney *et al.* (36) suggested a correlation between the degree of sensitivity toward carbon monoxide and the nature of the rate-limiting step in hydroxylation.

The rate-limiting step in these reactions has been identified in some cases as decomposition of the cyt P-450 – O_2-substrate complex to products (37). It has also been suggested (31, 37) that hydroxylations occurring at unactivated positions proceed by an oxene-type mechanism involving direct insertion of activated oxygen into a C—H bond. The analogous chemical insertion of carbene into a C—H or C—D bond proceeds with an observed isotope effect of 1.8 (38). This mechanism is consistent with the low observed isotope effects, and the retention of configuration observed in such processes (39, 40).

The results from the incubation of a 1:1 mixture of the 19-d_1 and 16,16-d_2 labelled steroids verified the presence of an isotope effect ($k_H/k_D = 2.3$) operating at the level of 19-hydroxylation. The complexity of this enzymic process makes unambiguous interpretation of the apparent isotope effect difficult. As expected, the effect observed for the 19-d_1 steroid was less than that for the 19-d_3 substrate. This may be the result of an isotope effect operating for a single hydroxylation at C-19 or the result of cumulative primary and secondary isotope effects incurred during both initial hydroxylation and subsequent hydroxylation (alcohol to aldehyde) at C-19. Equilibrium effects could result in the reduction of the intrinsic isotope effect of an early step in the reaction sequence, but in the absence of evidence for reversibility of any of the steps of the process, this would seem unlikely.

It is apparent from the observed isotope effects that a carbon–hydrogen bond cleavage during oxidation at C-19 is at least a partially rate-determining process in aromatization. This is consistent with previous proposals (6, 19) concerning the rate-determining step of aromatization.

It was our original intention to compare the isotope effect of aromatization with that observed for hydroxylation of **2***b* at C-19 by the fungus *Pellicularia filamentosa* (*Corticium microsclerotia*) NRRL 2727, a micro-organism reported to produce the desired alcohol **21** in high yield from **2***b* (41). However, in our hands this fungus yielded only products of C-11α, -11β, and -14 hydroxylation. Hasegawa and Takahashi (42) previously identified the 11α- and 11β-hydroxylated products from the incubation of pregn-4-ene-17α,21-diol-3,20-dione with another fungus of the same family, *Corticium sasakii*, and Takahashi (43) only found the 11β-hydroxylated product upon the incubation of the same substrate with *P. filamentosa*. It therefore appears that earlier claims of C-19 hydroxylation of C_{19} steroids by *P. filamentosa* are unsubstantiated, and that the microbial 19-hydroxylation of **2***a* or **2***b* is unknown (44, 45).

Experimental

Apparatus, Materials, and Methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with a Perkin-Elmer 237B spectrometer. Proton nmr spectra were obtained with a Varian A-60 or Bruker WP-60 at 60 MHz using $CDCl_3$ or DMSO-d_6 as solvent and TMS as internal standard, ^{13}C nmr spectra with a Bruker WP-60 at 15.18 MHz using $CDCl_3$ as solvent and TMS as internal standard, and ^2H nmr spectra at McMaster University, Hamilton, Ont., with a Bruker WH-90 at 13.8 MHz using CS_2 as solvent and $CDCl_3$ or acetone-d_6 as external standard. Mass spectra were obtained with an AEI MS30 spectrometer. Isotopic composition was determined by repetitive scanning of the relevant ions and application of the appropriate corrections for natural abundances; values are accurate to ±2%. Column chromatography was performed on silica gel (60–200 mesh), thin layer chromatography on Merck silica gel 60 F-254 (0.25 mm), and preparative layer chromatography on Merck silica gel F-254 (2.0 mm). Microanalyses were performed by the Guelph Chemical Laboratories, Guelph, Ontario. Human placental microsomes were obtained and

stored as previously described (46). *Pellicularia filamentosa* NRRL 2727 was maintained on slopes composed of malt agar (1.5%), tomato paste (2.0%), and oatmeal (2.0%).

Preparation of Substrates

Androst-4-ene-3,17-dione (**2***b*), androst-5-ene-3β-ol-17-one (**3***a*), androst-4-ene-17β-ol-3-one (testosterone) (**2***a*), estra-1,3,5(10)-triene-3-ol-17-one (estrone) (**1***b*), estra-1,3,5(10)-triene-3,17β-diol (estradiol) (**1***a*), androst-4-ene-3,17-dione-11β-ol (**2***d*), androst-4-ene-17β,19-diol-3-one, 17-benzoate (**4**), and androst-5-ene-3,19-diol-17-one (**3***b*) were commercial samples.

Authentic samples of androst-4-ene-3,17-dione-11α-ol, (**2***c*) and androst-4-ene-3,17-dione-14α-ol (**2***e*) were available in our laboratories from incubations of **2***b* with *Rhizopus arrhizus* ATCC 11145 (47) and *Mucor griseocyanus* ATCC 1207 (48), respectively.

The following substrates were prepared by published procedures (47) and gave satisfactory spectral and analytical data: androst-4-ene-3,17-dione, 4-*d*, (4-*d*-**2***b*), androst-4-ene-3,17-dione, 6α-d_1, (6α-d_1-**2***b*), androst-4-ene-3,17-dione, 2,2,4,6,6,16,16-d_7, and androst-4-ene-3,17-dione, 16,16-d_2.

Androst-4-ene-17β-ol-3-one, 19-d_1*, (19-*d_1*-2a) and Androst-4-ene-3, 17-Dione, 19-*d_1 *(19-*d_1*-2b) (Scheme 1)*

Route A: From Androst-4-ene-17β,19-diol, 17-Benzoate (4)

Androst-4-ene-17β,19-diol-3-one, 17-Benzoate, 19-Tosylate (5)

Toluene *p*-sulphonyl chloride (2.9 g) was added to a solution of androst-4-ene-17β,19-diol-3-one, 17-benzoate (**4**) (2 g) (Maybridge Chemical Co., U.K.) in pyridine (5 mL). The mixture was allowed to stand at room temperature overnight and then poured into ice water. The resultant precipitate was collected by filtration and treated briefly with refluxing ether (40 mL). Filtration of the mixture afforded the product (2.41 g, 88%), mp 142–147°C, which was used directly in the preparation of **6**.

5β,19-Cycloandrostan-17β-ol-3-one, 17-Benzoate (6)

The tosylate **5** (1.4 g) was dissolved in aqueous acetic acid (350 mL, 50%) and zinc dust (17 g, Shawinigan) added to the solution. The resulting suspension was stirred and refluxed for 90 min, then filtered. The zinc was washed with methanol and the total filtrate evaporated. The residue was crystallized from acetone–ether, and recrystallized from methanol to give the product (0.4 g, 41%), mp 184–186°C; ^{1}H nmr included signals at δ 0.50 (2H, s, C-19H), 0.97 (3H, s, C-18H), 2.55 (2H, br s, C-4H), 4.9 (1H, t, C-17H), and 7.3–8.3 (5H, m, aromatic H) ppm; ms *m/e* (%): 392 (6), 287 (3), 270 (13), 255 (6), 105 (100). *Anal.* calcd. for $C_{26}H_{32}O_3$: C 79.59, H 8.16%; found: C 79.26, H 8.42%.

Androst-4-ene-17β-ol-3-one, 17-Benzoate, 19-d_1 *(7)*

Conversion of **6** to **7** was performed by a modification of the procedure of Rakhit and Gut (49). To a solution of **6** (540 mg) in dried dioxan (10 mL) was added D_2O (80 mg) and DCl (1 mL, 38% in D_2O). The mixture was refluxed for 24 h, and the solvents then removed under vacuum. The crude residue was purified by column chromatography (benzene/ether gradient elution) affording **7** (460 mg, 85%), mp 187–190°C (lit. (50) mp 190°C); ^{1}H nmr included signals at δ 0.99 (3H, s, C-18H), 1.21 (2H, s, C-19H), 4.9 (1H, t, C-17H), 5.8 (1H, s, C-4H), and 7.3–8.3 (5H, m, aromatic H) ppm.

Androst-4-ene-17β-ol-3-one, 19-d_1 *(19-*d_1*-2a)*

A solution of **7** (0.17 g) in methanolic sodium hydroxide (5 mL, 5%) was refluxed for 1 h. The mixture was cooled, neutralized with acetic acid, and worked up in the usual way to give 19-d_1-**2***a* (0.12 g, 96%), mp 152–154°C (lit. (50) mp 154°C); ^{1}H nmr included signals at δ 0.81 (3H, s, C-18H), 1.22 (2H, s, C-19H), 3.75 (1H, t, C-17H), and 5.9 (1H, s, C-4H) ppm; ms *m/e* (%): 289 (28), 273 (5), 247 (28), 125 (100). Isotopic content: see Table 1.

Androst-4-ene-3,17-dione, 19-d_1 *(19-*d_1*-2b)*

Jones' oxidation of 19-d_1-**2***a* (0.16 g) afforded 19-d_1-**2***b* (0.12 g, 76%); ^{1}H nmr included signals at δ 0.92 (3H, s, C-18H), 1.22 (2H, s, C-19H), and 5.8 (1H, s, C-4H) ppm; ^{2}H nmr: see Table 1; ms *m/e* (%): 287 (100), 272 (14), 269 (13), 259 (20), 245 (96). Isotopic content: see Table 1.

Route B. From Androst-4-ene-3,17-dione, 19-ol (27) (Scheme 1)

An analogous series of reactions and conditions to those of the route described above for the conversion of **4** into **7** (Scheme 1) was used to convert the 19-ol **27** into androst-4-ene-3,17-dione, 19-d_1 (19-d_1-**2***b*). Alternatively, 19-d_1-**2***b* was available by the following procedure.

5β,19-Cycloandrostan-17β-ol-3-one

The benzoate **6** (0.5 g) was dissolved in methanolic sodium hydroxide (15 mL, 5%) and the solution refluxed for 1 h. Conventional work-up gave the product (81%), which was used in the next step without further purification.

5β,19-Cycloandrostan-3,17-dione

Jones' oxidation of the aforegoing alcohol (0.3 g) afforded the product (0.24 g, 81%), identical in all respects with an authentic sample (49).

Androst-4-ene-3,17-dione-19-d_1*, (19-*d_1*-2b)*

The cyclopropyl ketone was treated with DCl in D_2O by the procedure described above for the conversion of **6** into **7**. The product was then refluxed briefly in 5% methanolic sodium hydroxide to ensure removal of any enolizable deuterium. Conventional work-up afforded 19-d_1-**2***b* identical in physical and spectral properties with an authentic sample of unlabelled material. Isotope content is presented in Table 1.

Androst-4-ene-17β-ol-3-one, 19-d_1*(19-*d_1*-2a)*

The conversion of 19-d_1-**2***b* into 19-d_1-**2***a* was performed by a published procedure (51). The product was purified by preparative layer chromatography and obtained in 60% yield. Isotope content is presented in Table 1.

Androst-4-ene-17β-ol-3-one, 19,19,19-d_3 *(19,19,19-*d_3*-2a) (Scheme 2)*

The procedure followed was similar to that of Baba *et al.* (22).

Estra-2,5(10)-diene-3,17β-diol, 3-Methyl Ether (9) (52)

Isopropanol (30 mL) and a solution of estra-1,3,5(10)-triene-3,17β-diol, 3-methyl ether (5.0 g) in THF (30 mL) were added to redistilled ammonia (80 mL). To this mixture, sodium metal (total 4.5 g) was added in portions. After the addition was complete and all of the sodium consumed (ca. 1 h), methanol (20 mL) was added. The ammonia was then allowed to evaporate and the THF subsequently removed by distillation under reduced pressure. The precipitated product was collected, washed with water, and dried to give a product (5.0 g, 99%), mp 110–112°C (lit. (53) mp 118–119.5°C) of sufficient purity to be useable directly in the next step; ^{1}H nmr included signals at δ 0.77 (3H, s, C-18H), 2.69 (4H, m, C-1 and C-4H), 3.65 (1H, t, C-17H), 3.66 (3H, s, OCH_3), and 4.7 (1H, m, C-2H) ppm.

Estr-5(10)-ene-17β-ol-3-one (10)

The enol ether **9** (5.0 g) was dissolved in a mixture of THF (25 mL), water (12 mL), and sulphuric acid (96%, 1.5 mL), and the resulting solution stirred at room temperature for 45 min. Ammonium sulphate was then added until the solution became saturated, and the product was extracted into dichloromethane. The extract was washed (saturated $NaHCO_3$/$(NH_4)_2SO_4$), dried, and evaporated to afford the product **10** (4.10 g). Crystallization from ethyl acetate/hexane gave 3.84 g, mp 178–181°C (lit. (54) mp 181–182°C); ^{1}H nmr included signals at δ 0.79 (3H, s,

For personal use only.

C-18H), 2.47 (4H, m, C-1 and C-2 H's), 2.75 (2H, m, C-4H), and 3.65 (1H, t, C-17H) ppm.

5α-Estran-17β-ol-3-one-5α,10α-oxide, 17-Acetate, 3-Cyclic Ethylene Ketal (15)

Conversion of the ketone **10** to the title compound **15** as outlined in Scheme 2 was carried out precisely as described (22).

5α-Androstan-5,17β-diol-3-one, 3-Cyclic Ethylene Ketal (16)

The reagent CD_3MgBr (1 *M* in THF) was prepared by condensing CD_3Br (2.0 g, 99.5 at.% ^2H), by means of a cold-finger condenser, into an ice-cooled reaction flask containing dry THF (20 mL) and magnesium turnings (0.5 g). To this reagent was added dropwise a solution of the epoxide **15** (0.5 g) in dry THF (5 mL). The solution was refluxed for 2 h and then cooled, whereupon 10 mL 1.5 *M* NH_4Cl solution was added dropwise. The resultant mixture was diluted with water, extracted with methylene chloride, and washed successively with 3 *N* HCl, 5% $NaHCO_3$, and water. Drying over Na_2SO_4 followed by evaporation yielded 490 mg crude product. Purification by column chromatography (benzene/ether gradient elution) yielded 260 mg product (55%), identified by comparison with an authentic sample of unlabelled material prepared by reaction of (5,6α)-epoxytestosterone ethylene ketal with lithium aluminum hydride.

Androst-4-ene-17β-ol-3-one, 19,19,19-d_3 (19,19,19-d_3-2a)

The ketal **16** (0.26 g) was dissolved in a mixture of methanol (7 mL) and sulphuric acid (0.7 mL, 1 *M*), and the solution refluxed for 30 min. The solution was then cooled and diluted with ether and water and the organic layer removed. The aqueous layer was re-extracted with ether and the combined organic extract washed (5% $NaHCO_3$, water), dried, and evaporated to yield 180 mg of crude product. Column chromatography followed by preparative layer chromatography afforded 75 mg of pure product, identified by spectral and mp comparison with an authentic sample of unlabelled material. Isotope content is presented in Table 1.

Androst-4-ene-17β-ol-3-one, 16,16-d_2 (16,16-d_2-2a) (Scheme 3)

Androst-5-ene-17β-ol-3-one, 3-Cyclic Ethylene Ketal (17)

Androst-4-ene-17β-ol-3-one (**2***a*, 1.5 g) was dissolved in a mixture of dry benzene (80 mL), ethylene glycol (1.5 g), and *p*-toluene sulphonic acid (100 mg), and the solution refluxed for 24 h under a Dean–Stark trap. Conventional work-up gave 1.43 g (82%) product.

Androst-5-ene-3,17-dione, 3-Cyclic Ethylene Ketal (18)

The above ketal (1.4 g) was dissolved in pyridine (15 mL) to which Sarett reagent was added (15 mL, 0.1 g CrO_3 per mL). The mixture was stirred for 20 h and then diluted with dichloromethane. The resulting mixture was washed (5% HCl, water), dried, and evaporated to yield crude **18** (900 mg), which was purified by column chromatography and then crystallized from ethyl acetate/hexane to afford the title compound (0.6 g, 43%), mp 175–180°C (lit. (55) mp 197–198°C); ^1H nmr included signals at δ 0.90 (3H, s, C-18H), 1.08 (3H, s, C-19H), 3.98 (4H, s, $-OCH_2$), and 5.4 (1H, m, C-6H) ppm.

Androst-5-ene-3,17-dione, 3-Cyclic Ethylene Ketal, 16,16-d_2 (19)

A solution of **18** (0.5 g) in dry benzene (10 mL) was added to a solution of tetra *n*-butyl ammonium bromide (0.5 g) in basic D_2O (5% NaOD, 10 mL), and the resulting mixture stirred and refluxed for 20 h. Normal work-up afforded **19** (0.45 g), identified by comparison with an authentic sample of **18**.

Androst-5-ene-17β-ol-3-one, Cyclic Ethylene Ketal, 16,16-d_2 (20)

A solution of the ketal **19** (0.45 g) in benzene/ether (1:1, 25 mL) was added to a suspension of lithium aluminum hydride (0.45 g) in ether (30 mL) and the mixture refluxed for 3.5 h. Conventional work-up afforded **20** (0.4 g, 88%), identified by comparison with an authentic sample of **17**.

Androst-4-ene-17β-ol-3-one, 16,16-d_2 (16,16-d_2-2a)

The above ketal **20** (0.4 g) was dissolved in a mixture of methanol (6 mL) and dilute sulphuric acid (6%, 1 mL) and the solution refluxed for 30 min, diluted with water, and the product extracted into ether. The extract was dried and evaporated, and the residue crystallized from acetone/hexane to give 16,16-d_2-**2***a* (0.3 g, 86%), mp 149–151°C (lit. (50) mp 154°C). Isotope content is listed in Table 1.

Androst-4-ene-17β-ol-3-one, 2β-d, (2β-d_1-2a)

A solution of androst-4-ene-17β-ol-3-one (**2***a*, 0.25 g) in dry benzene (5 mL) was added to a solution of tetra *n*-butyl ammonium bromide (0.25 g) in basic D_2O (5% NaOD, 5 mL), and the mixture stirred at room temperature for 45 h. Conventional work-up afforded the title compound (0.18 g). Isotope content is listed in Table 1.

Androst-4-ene-17β-ol-3-one, 1β,2β-d_2 (1β,2β-d_2-2a)

A mixture of androsta-1,4-diene-17β-ol-3-one (**27**) (0.2 g) and 10% Pd/C (0.2 g) in ethyl acetate (10 mL) was stirred under deuterium gas at atmospheric pressure for 6 min. Conventional work-up afforded 0.2 g crude product, which was subjected to preparative layer chromatography (4% methanol in ether as solvent) to give the desired product (40 mg, 20%), identified by comparison with an authentic sample of unlabelled material. Isotope content is listed in Table 1. A reaction time of 25 min resulted in the production of 5β-androstan-17β-ol-3-one as major product.

Androst-4-ene-3,17-dione-19-ol (21)

Method A. From Androst-5-ene-3β,19-diol-17-one (3b) by Oppenauer Oxidation (56)

A solution of androst-5-ene-3β,19-diol-17-one (**3***b*, 0.5 g) (Bader Chemical Co.) and aluminum isopropoxide (0.5 g) in toluene (40 mL) and cyclohexanone (10 mL) was refluxed for 10 min. Work-up and chromatography afforded a 6–15% yield of **21** in several experiments; ^1H nmr included signals at δ 0.92 (3H, s, C-18H), 3.90 (2H, ABq, C-19H), and 5.7 (1H, s, C-4H) ppm.

Method B. From 3b via bis *Trityl Ether (3d) (57)*

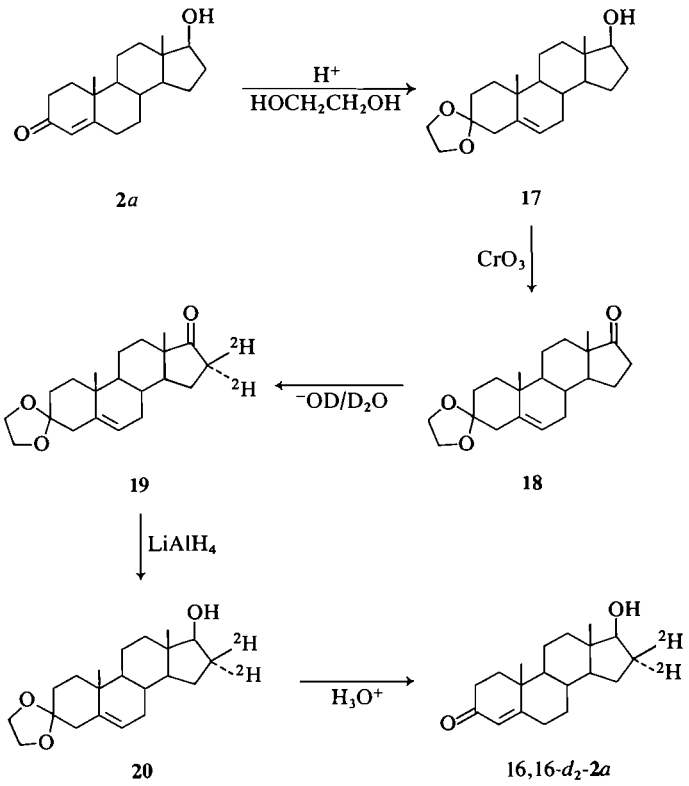
Conversion of **3***c* to the ether **3***d* was performed as described (58). The product was obtained in 92% yield. Triphenylmethylfluoroborate (1.3 g) (59) was added to a solution of **3***d* (2.93 g) in dichloromethane. The mixture was stirred for 12 h, then washed ($NaHCO_3$), dried, and evaporated to yield 1.6 g crude product. This was dissolved in a mixture of ethanol (100 mL), benzene (25 mL), and dilute sulphuric acid (2 *N*, 10 mL) and the mixture refluxed for 4 h. The product was isolated by extraction and purified by column chromatography to give **21** in 35% yield, mp 163–167°C (lit. (60) mp 164–166°C).

Method C. From Androst-5-ene-3β-ol-17-one, 3-Acetate (3c)

The conversion of **3***c* to **21** was performed as described (60) in an overall yield of 18%. The last step described in ref. 60 proceeded in acceptable yield in our hands only with the use of MCB zinc dust as a reagent.

Incubation with P. filamentosa *NRRL 2727*

The fungus was grown in 1-L Erlenmeyer flasks as described (41). After 3 to 4 days of fungal growth at room temperature, androst-4-ene-3,17-dione (**2***b*) in ethanol solution (80 mg in 0.5 mL ethanol per flask) was added, and growth allowed to continue for a further 8–12 h. The medium and mycelia were then separated by filtration, and each extracted with dichloromethane. The combined extract was dried and evaporated, and



SCHEME 3. Preparation of 16,16-d_2-**2***a*

the residue subjected to column chromatography (benzene/ether gradient elution) to give recovered starting material (typically 30–40%), androst-4-ene-3,17-dione-11α-ol (**2***c*, typically 35%), androst-4-ene-3,17-dione-11β-ol (**2***d*, typically 15%), and androst-4-ene-3,17-dione-14α-ol (**2***e*, typically 10%), all of which were identical in all respects with corresponding samples of authentic material.

Incubations with Placental Microsomes

Incubations of androst-4-ene-3,17-dione (**2***b*) and androst-4-ene-17β-ol-3-one (**2***a*) with a microsomal suspension from human placentae were performed as previously described (46). Isolated yields of estra-1,3,5(10)-triene-3,17β-diol were typically 5–10%. Isotope content of substrates and products are presented in Table 2.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada for a research studentship (to G.J.T.) and for financial support of this project. We are also grateful to Dr. P. H. Buist of McMaster University, Hamilton, Ontario, for preliminary work on the conversion of **3***c* into **21**, and to Dr. M. Gut of the Worcester Foundation for Experimental Biology for providing an authentic sample of 5β,19-cycloandrostan-3,17-dione. Thanks are also due to Drs. J. N. Wood and J. Lo of the St. Catharines General Hospital for their invaluable cooperation in obtaining placentae for use in this study, to Dr. P. Morand of the University of Ottawa for helpful discussions, and to T. Jones of Brock University and B. Sayer of McMaster University for their assistance in obtaining nmr spectra.

Approaches to the synthesis of lycoxanthol and similar natural products. Synthesis of coleon U

ROBERT H. BURNELL,[1] ANDRÉ ANDERSEN, MARTINE NÉRON-DESBIENS, AND SYLVAIN SAVARD
Département de chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received March 16, 1981

ROBERT H. BURNELL, ANDRÉ ANDERSON, MARTINE NÉRON-DESBIENS, and SYLVAIN SAVARD. Can. J. Chem. **59**, 2820 (1981).

Using suitable models the various problems anticipated in preparing lycoxanthol from podocarpic acid have been resolved. Five oxygen atoms are introduced by methods involving direct oxidation, ring fission, and after suitable functionalization, recyclization and nucleophilic substitution of intermediate *p*-quinones. The validity of this approach has been demonstrated in a synthesis of coleon U (as the tri- and tetra-*O*-methyl ethers).

ROBERT H. BURNELL, ANDRÉ ANDERSON, MARTINE NÉRON-DESBIENS et SYLVAIN SAVARD. Can. J. Chem. **59**, 2820 (1981).

En utilisant des modèles appropriés on a résolu les divers problèmes qui pourraient intervenir au cours de la préparation du lycoxanthol à partir de l'acide podocarpique. On a introduit 5 atomes d'oxygène par des méthodes qui impliquent une oxydation directe, une ouverture de cycle suivie d'une fonctionalisation convenable, d'une recyclisation et d'une substitution nucléophile sur les *p*-quinones intermédiaires. On démontre la validité de cette approche en synthétisant le coléon U (sous forme d'éthers tri- et tétra-*O*-méthyle).

During our preparation of dehydrocycloroyleanone **1** (1) we entertained the idea of continuing the synthesis to lycoxanthol (**2**) (2) or to coleon C (**3***a*) which has been previously converted to lycoxanthol (3). The last step of our synthesis of **1** involved the per-acid oxidation of the benzodihydrofuran **4***a* but this afforded only poor yields of the quinone **1** so a significant improvement was called for. Alternate approaches (4) did prove slightly more rewarding but when coupled with our inability to oxidize the benzylic methylene (C.7) in hydroquinone derivatives of dehydrocycloroyleanone **4***b* (a difficulty which others have observed in similar systems (5)) we were forced to explore other avenues leading to lycoxanthol.

After some experimentation and a literature search we concluded that no single reaction could be of direct utility so we imagined the use of "sequences of reactions" which could be performed without rigorous purification of the intermediates. In the "reaction suites" certain of the products were purified and characterized as confirmation that the sequence proceeded as predicted.

The aim of our first "reaction suite" was to convert the ketone **8***a* in which the aromatic ring bears one methoxyl residue to the ketone **10***a* in which there are two (neither in the original position, however). The ketone **8***a* is readily available from methyl-*O*-methyl podocarpate **7***a* by described methods (6*a* and *b*) and using this ketone as a model starting material, the synthesis of a lycoxanthol type molecule (lycoxanthol has a *gem* dimethyl grouping at C.4) involves the introduction of oxygen functions at C.6, C.11, C.14, and C.16. In the following series of experiments we have demonstrated methods which systematically affect these oxidations.

Baeyer–Villiger oxidation of the ketone **8***a* afforded a lactone which on acid catalysed methanolysis lead to the phenol ester **9***a*. *O*-Methylation of the latter gave the neutral hydroquinone diether **9***b* which by dilute basic hydrolysis was converted to the acid **9***c*. Trifluoroacetic anhydride at room temperature cyclized the acid with "rotation" of the aromatic ring to give the ketone **10***a*. This sequence, which in principle introduces one oxygen atom, was carried through without rigorous purification at each step and was inspired by similar results obtained by Pelletier and Ohtsuka (7) in another context. The overall yield was about 4.5% without any attempt to optimize the individual steps. When compared with the direct oxidation (above), and since the C.7 ketone is already incorporated, this result was considered encouraging so we sought to modify the "suite" to include the introduction of another oxygen function.

When the oxidation of the starting ketone **8***a* was performed with per-acetic acid prepared *in situ* from acetic anhydride, sulfuric acid, and hydrogen peroxide (rather than the *m*-chloroperbenzoic acid used previously) the only product isolated was the quinone **11***a*. 2,5-Dialkylquinones are often reluctant to react under Thiele acetylation conditions and such was the case with compound **11***a*. We had hoped that this method of introducing an *O*-acetyl residue (to give **12**) might be accompanied by

cyclization especially if trifluoroacetic anhydride were used in the Thiele reaction. To confirm the structure of the quinone **11***a* and to provide an alternate pathway in the aromatic ring rotation sequence, the quinone was catalytically reduced and methylated while still under an atmosphere of hydrogen. The product, ester **9***b*, had already featured in the sequence described above.

We achieved in another reaction suite what we hoped the Thiele reaction would do directly. The quinone acid **11***a* was treated with bromine in acetic acid affording the dibromo addition product **13***a*. We could not detect any quantity of the product arising from the addition to the other double bond. An ether solution of the dibromo derivative and diethylamine affected the elimination of hydrogen bromide allowing the isolation of the bromoquinone **11***b* in high yield. The latter was treated with dilute methanolic sodium hydroxide which replaced the bromo substituent by an hydroxyl group but, rather than isolate the product (**11***c*), dimethyl sulfate was added to the basic solution which probably partially methylated both the hydroxyl and carboxyl residues (**11***d*). The isolated product was reduced catalytically and methylated *in situ* to afford two products (5:1). The major neutral fraction showed five *O*-methyl peaks in the nmr spectrum and was identified as the ester **9***d* while the minor acid product proved to be the corresponding carboxylic acid **9***e*. The former was hydrolysed in mild aqueous base to the acid **9***e* which when stirred for several hours with trifluoroacetic anhydride gave the aromatic ketone **10***b*. The molecule now contains the C.7 carbonyl group and the fully substituted aromatic ring as in lycoxanthol. The overall yield from the ketone **8***a* to ketone **10***b* was 28% which implies an average yield of over 80% for each reaction and certainly shows the reaction suite to be manageable and effective.

Other than the sidechain hydroxyl, there remains one position where oxygen should be introduced to obtain the lycoxanthol (**2**) or coleon C (**3***a*) substitution pattern, that at C.6 which is an enolized ketone moiety. A different model was used for this transformation. The ketone **14** was obtained from the ester **4***c* prepared in another context, by reduction to the primary alcohol **4***d*, oxidation to the aldehyde **4***e*, and Huang–Minlon reduction which gave **4***a*. Chromium trioxide – acetic acid oxidation of the latter afforded **14**. The method of choice for introducing the enolized ketone function proved to be oxygenation in anhydrous strong base (*t*-BuOK in *t*-BuOH). The diosphenol (**15** in this case) was invariably accompanied by the neutral starting ketone which could be recycled to improve the yield. The use of other models such as ketone **8***a*, **10***a*, and **10***b* (which we tried first) was misleading since under these conditions, while there appears to be formation of a diosphenol, the C.4 carbomethoxy substituent is lost during the reaction.[2] The precise nature of the product is unknown at present.

The approach elaborated on these models was applied to the synthesis of coleon U (**3***b*) as the

15

tri- and tetra-*O*-methyl ethers (**3***c* and **3***d*). The naturally occurring diterpene (8) is one of the simplest coleons with no oxygen function in the isopropyl sidechain and has recently been synthesized by Matsumoto and Takeda (9) following a somewhat longer and different route. In our case the necessary starting material **8***b* (sugiol-*O*-methyl ether) was prepared from podocarpic acid (via **7***b*: see Experimental for references). Peracetic acid oxidation of **8***b* afforded the expected quinone **11***e* in excellent yield and the sequence of bromine addition (→**13***b*) and dehydrobromination gave regiospecifically the bromo-quinone **11***f*. The facile exchange of the bromo substituent by hydroxyl (→**11***g*) followed by catalytic reduction and immediate *O*-methylation *in situ*, following the procedures optimized for some of the models, gave a mixture which proved to be composed of partially *O*-methylated hydroquinone acids and methyl esters. Since the mixture had already been separated the individual fractions were further methylated to give the methyl ester **9***f*. The only base sensitive functionality in the latter is the ester itself which hydrolyzed readily to the corresponding acid **9***g* which smoothly cyclized in trifluoroacetic anhydride to the expected ketone **10***c*. The remaining oxygen function was introduced by oxygenation in strong base. The product, the enolic α-diketone **3***c* (coleon U tri-*O*-methyl ether) was *O*-methylated to give coleon U tetra-*O*-methyl ether **3***d*.

Neither of these ethers (**3***c* nor **3***d*) is described in the literature since in the methylation of naturally occurring coleon U the strongly chelated C.14 phenolic hydroxyl is unaffected by the conditions employed. However, the spectral characteristics of the products and the nonambiguity of the synthetic route (comparison with the model systems) leave no doubt as to the identity of the products. Particularly convincing is the Cmr spectrum summarized in Fig. 1 which with suitable adjustment for the presence of methoxyl rather than hydroxyl groups, is in excellent agreement with values in the literature (8).

The overall yield of the synthesis from sugiol methyl ether **8***b* is 18% in the case of the tri-*O*-methyl derivative **3***c* and 17.6% for the tetra-*O*-methyl derivative **3***d*. In another synthetic approach we prepared the quinone **11***e* from abietic acid. After reduction of the acid residue to methyl and benzylic oxidation to give the ketone analogous to **8***b* but with no methoxyl group at position 12, the quinone **11***e* was obtained by peracetic oxidation

but the time necessary for reaction to provide a reasonable yield was considerably longer than cases where the aromatic ring bears a methoxyl substituent.

Experimental

Unless otherwise stated the conditions and instruments used to characterize the products were: melting points, Electrothermal, uncorrected; ultraviolet spectra, ethanol solutions (ε in parenthesis), Beckman DK-1A; infrared spectra, carbon tetrachloride solutions, Beckman IR 12 and Perkin Elmer 457; proton magnetic resonance spectra, deuteriochloroform solutions, TMS internal standard, (multiplicity, integrated peak areas, coupling constants and assignments in parenthesis), Bruker HX 90; mass spectra, Varian M 66 (only molecular ions are given). Extraction in a procedure implies several extractions with the appropriate solvent, suitable washing, drying over anhydrous magnesium sulfate, and evaporation *in vacuo*. Elemental analyses were by Chemalytics, Arizona and Galbraith Laboratories, Knoxville. The high resolution mass spectrum was recorded on an A.E.I. model MS-50 at the University of Alberta, Edmonton.

*Reaction Suite from Ketone 8*a *to Ketone 10*a *(Methyl 7-Oxo-11,14-dimethoxy-13-isopropylpodocarpate)*

The ketone **8***a* was prepared from methyl-*O*-methyl podocarpate **7***a* following procedures described by Campbell and Todd (6*a*) and Cambie *et al.* (6*b*). The product showed mp 144–146°C (from ether, lit. (6*b*) mp 144–144.5°C).

To the ketone **8***a* (1.0 g) in $CHCl_3$ (5 mL) was added dropwise a solution of *m*-chloroperbenzoic acid (1.133 g) in $CHCl_3$ (18 mL). After stirring for 4 days at room temperature, the solution was washed (Na_2CO_3, NaCl) and filtered through a short column of silica gel. Evaporation gave a lactone as an orange foam (1.03 g) showing ir: 1770 and 1730 (lactone and ester) cm^{-1}.

The lactone (1.03 g) was refluxed in absolute MeOH (50 mL) containing concentrated H_2SO_4 (0.5 mL) for 30 min. After adding water, most of the MeOH was removed *in vacuo* and the solution then extracted with ether to afford a phenolic fraction (0.88 g) as a yellow foam. Normally this was used as such in the following steps but a portion of **9***a* recrystallized from hexane showed mp 134–136°C; ir: 3600–3200 (phenol OH), 1720 and 1705 (esters) cm^{-1}; H nmr δ: 7.10 (s, D_2O, phenol OH), 6.79 and 6.68 (2s, Ar—H), 3.81 (s, Ar—O—Me), 3.72 and 3.31 (2s, 2 COOMe), 1.30 and 1.18 (2s, 2 C—Me), 1.26 and 1.15 (2d, J = 7 Hz, isopropyl methyls).

To the preceding diester **9***a* (0.329 g) in dry acetone (33 mL) containing K_2CO_3 (3.29 g) was added dimethyl sulfate (3.0 mL). After 20 h at reflux, water (100 mL) was added and most of the acetone removed at the pump. Extraction with ether afforded a pale yellow oil (0.325 g), a portion of which was chromatographed over silica gel and gave pure **9***b* as a low melting waxy solid; ir: 1720 (br), 1610 and 1570 cm^{-1}; H nmr δ: 6.67 (s) and 6.79 (s, 2 Ar—H), 3.83 (s), 3.78 (s), 3.67 (s) and 3.23 (s, 4—OMe), 1.21 (s), 1.17 (d, J = 7 Hz) and 1.14 (s, 4 C—Me); *m/e*: 420 (M^+).

The crude fully methylated diester **9***b* (2.02 g) was taken up in MeOH (90 mL) to which aqueous KOH was added (90 mL of 10%). After 2 h at reflux, the MeOH was mostly removed *in vacuo* and the solution extracted to afford an acid fraction (1.08 g) which was purified by dry column chromatography over silica gel affording the acid **9***c* (0.780 g) as a pale yellow foam; ir: 3200–2900 (br acid trough), 1725 (ester), 1705 (COOH), 1510, 1240, 1210, and 865 cm^{-1}; H nmr δ: 6.76 (s) and 6.62 (s, 2 Ar—H), 3.78 (s) and 3.76 (s, 2 Ar—O—Me), 3.70 (s, COOMe), 1.20 (s) and 1.15 (s, 2C—Me), 1.15 (d, J = 7 Hz) and 1.11 (d, J = 7 Hz, isopropyl methyls).

The acid **9***c* (0.490 g) was dissolved in trifluoroacetic anhydride (4.9 mL) and stirred at room temp for 3.5 h. After pouring into ice-water, ether extraction gave the intermediate enol trifluoroacetate (0.390 g, ir 1805 cm^{-1}) which was hydrolysed by stirring in MeOH (39 mL) containing aqueous KOH (3.9 mL of 10%) for 1 h. After adding water, partial evaporation of the MeOH, and ether extraction, the aromatic *ketone* **10***a* (0.300 g) was obtained as a foam which crystallized on standing. Chromatography over silica gel gave the pure compound, mp 131–132°C (white needles, hexane); uv: 257 (6100) and 375 (4700) nm; ir: 1730 (ester), 1695 (aromatic ketone), 1600, 1235, 1160, 1145, and 870 cm^{-1}; H nmr δ: 6.98 (s, Ar—H), 3.82 (s) and 3.77 (s, 2Ar—O—Me), 3.69 (s, COOMe), 1.21 (d, 6H, J = 7 Hz, isopropyl methyls), 1.26 (s) and 1.18 (s, 2 C—Me); *m/e*: 388 (M^+). *Anal.* calcd. for $C_{23}H_{32}O_5$: C 71.10, H 8.30; found: C 71.40, H 8.27.

*Quinone 11*a *(2[6-Methoxycarbonyl-2(2-isopropyl-1,4-benzoquinone-5-yl)-2,6-dimethylcyclohexyl] Acetic Acid)*

Hydrogen peroxide (10 mL of 30%) was added dropwise to a solution of acetic anhydride (33 mL) and concentrated H_2SO_4 (0.2 mL) at 0°C. After stirring overnight, the ketone **8***a* (1.0 g) dissolved in acetic anhydride (20 mL) was added slowly with cooling and the mixture was allowed to come to room temperature and stirred for an additional 20 h. A yellow solid precipitated on pouring the solution onto ice (200 g) and this was collected by filtration after stirring for 2 h, dried *in vacuo*, and the quinone **11***a* crystallized from ethanol (0.850 g), mp 194–195°C; uv: 260 (15 600) nm; ir (br acid trough): 1730 (br), 1668, 1615 cm^{-1}; H nmr δ: 9.11 (br s, D_2O, COOH), 6.62 (s, 2H, 2=CH—), 3.72 (s, COOMe), 1.28 (s) and 1.01 (s, 2 C—Me), and 1.15 and 1.13 (2d, J = 7 Hz, isopropyl methyls); *m/e*: 376 (M^+) and 316 (base). *Anal.* calcd. for $C_{21}H_{28}O_6$: C 67.12, H 7.38; found: C 67.00, H 7.50.

*Diester 9*b *(by Reduction and Methylation of Quinone 11*a*)*

The quinone **11***a* (0.800 g) was hydrogenated at atmospheric pressure over prehydrogenated Adams catalyst (0.100 g). The uptake ceased after 47.5 mL. Aqueous NaOH (1 mL of 30%) was introduced while the mixture was still under hydrogen, followed 5 min later by dimethyl sulfate (1 mL). Similar portions of NaOH and dimethyl sulfate were added every hour (total 11 mL each) and the mixture then stirred for 30 h. Dilution with water and evaporation of much of the MeOH facilitated the benzene extraction of the basic solution which afforded a neutral fraction (0.230 g) while acidification and extraction of the aqueous layer gave the starting acid quinone **11***a* (0.580 g). Chromatography of the neutral product gave the *ester* **9***b* (0.204 g) identical with that obtained previously.

*Reaction Suite: Quinone 11*a *to Aromatic Ketone 10*b *(Methyl 7-Oxo-11,12,14-trimethoxy-13-isopropylpodocarpate)*

*(a) Bromoquinone 11*b *via Dibromo Compound 13*a

To the quinone (1.70 g) in acetic acid (20 mL) was added dropwise a solution of bromine (0.4 mL) in acetic acid (5 mL). After stirring for 5 h at room temperature the mixture was poured into water (200 mL) and the precipitated solid filtered, well washed, and dried *in vacuo*. The pale yellow powdery dibromo derivative **13***a* (2.03 g) showed ir (acid trough): 1720, 1696, 1610 cm^{-1}; H nmr δ: 6.52 (s, 1H, =CH—), 4.78 (s, —CHBr—), 3.71 (s, COOMe). No molecular ion was detectable in the mass spectrum which was identical with that of **11***b*.

The crude dibromo compound **13***a* (2.0 g) was taken up in ether (40 mL) and cooled to 10°C. With vigorous stirring, diethylamine (0.7 mL) in ether (5 mL) was slowly added. After 2 h at room temperature the reaction mixture was poured into water and the acid fraction obtained by suitable extraction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

afforded the bromoquinone **11***b* as a yellow glass (1.70 g); ir (acid trough): 1720 br, 1678, 1660, 1588 cm^{-1}; H nmr δ: 6.53 (s, 1H, =C—), 3.69 (s, COOMe), 1.25 (s, C—Me), 1.27 and 1.24 (2d, J = 7 Hz, isopropyl methyls), 1.02 (s, 3H, C—Me); *m/e*: 456 and 454 (M^+).

(b) The Diester **9***d via Hydroxyquinone* **11***c*

The bromoquinone **11***b* (1.70 g) was treated with a solution of NaOH (4.0 g) in water (30 mL) and methanol (30 mL) at room temperature for 1 h. Extraction of an acidified aliquot at this stage gave the hydroxyquinone **11***c* as an oil; ir: 3400, 1730, 1645, 1610 cm^{-1}; H nmr δ: 7.70 (br s, OH), 6.50 (s, =CH—), 3.71 (s, COOMe), 1.29 (s) and 1.02 (s, C—Me), 1.21 (d, J = 7 Hz, isopropyl methyls); *m/e*: 392 (M^+). The product showed a typical intense violet coloration in NaOH solution.

To the bulk of the basic solution of the hydroxyquinone **11***c* was added dimethyl sulfate (4.0 mL) and the mixture stirred at room temperature overnight. Dilution with water, acidification, and ether extraction of the solution gave a product (1.50 g) which appeared to be only partially methylated. Without further purification the crude material was taken up in MeOH (30 mL) and hydrogenated over Adams catalyst (0.050 g) at atmospheric pressure. After a rapid uptake of 90 mL of hydrogen, aqueous NaOH (1.5 mL of 30%) was introduced in a manner to keep the reaction mixture protected by an atmosphere of hydrogen and 10 min later dimethyl sulfate (1 mL) was added. These additions were repeated every hour up to a total of 10 mL of dimethyl sulfate and then stirring was continued at room temperature for 12 h. The catalyst was filtered, the solution diluted with water (50 mL), and most of the methanol removed at the pump before extracting with benzene. The neutral product obtained was chromatographed over silica gel affording the diester **9***d* (0.920 g) as a very pale yellow glass; ir: 1735 br, 1612, 1575 cm^{-1}; H nmr δ: 6.56 (s, Ar—H), 3.92 (s), 3.78 (s), 3.76 (s), 3.70 (s) and 3.37 (s, 5 O—Me), 1.33 (s, C—CH_3), 1.22 (d, J = 7 Hz, isopropyl methyls), 1.20 (s, 3H, C—Me); *m/e*: 450 (M^+).

Acidification of the basic solution from the extraction above and extraction with benzene provided an acidic compound (0.596 g) which contained the *acid* **9***e* (0.180 g) (see step (*c*)).

(c) Ketone **10**b *(Methyl 7-Oxo-11,12,14-trimethoxy-13-isopropylpodocarpate) via the Acid* **9**e

The diester **9***d* (0.040 g) was hydrolyzed with NaOH in MeOH—H_2O as described for **9***b*. The acid **9***e* obtained by extraction (0.035 g) showed the following, ir (acid trough): 1735, 1720, 1620 cm^{-1}; H nmr δ: 6.57 (s, Ar—H), 3.86 (s), 3.73 (s), 3.68 (s) and 3.67 (s, 4 OMe).

The acid **9***e* (0.120 g) was stirred with trifluoroacetic anhydride (5 mL) for 16 h at room temperature. The reaction mixture was decomposed with ice-water and extracted with ether and well washed. The intermediate product, the enol trifluoroacetate of the required ketone was hydrolyzed at room temperature in MeOH (40 mL) containing aqueous KOH (4 mL of 10%). After 1 h and dilution with water, most of the MeOH was removed at the pump and the solution then extracted with ether. The resulting pale yellow oil (0.091 g) was chromatographed over silica gel affording the pure ketone **10***b* (0.080 g); ir: 1731 (ester), 1695 (aromatic ketone) cm^{-1}; H nmr δ: no aromatic H, 3.79 (s, 3H), 3.76 (s, 6H), and 3.66 (s, 3H, 4 OMe), 3.61 (sept, J = 7 Hz, CH in isopropyl), 1.30 (d, J = 7 Hz, isopropyl methyls), 1.24 (s) and 1.22 (s, C—Me); *m/e*: 418.2354 (M^+). *Mol. Wt.* calcd. for $C_{24}H_{34}O_6$: 418.2355.

Preparation of Ketone **14** *(5-Oxo-3,7,7,10a-tetramethyl-2,3,5,6,6a,7,8,9,10,10a-decahydrophenanthro[2,3-b]furan) from* **4**c

The methyl ester group of the benzodihydrofuran **4***c* was reduced with $LiAlH_4$ following essentially the procedure of Zeiss *et al.* (10) in 85% yield. The primary *alcohol* **4***d* showed mp 86–88°C; ir: 3340, 1638, 1605 cm^{-1}; H nmr δ: 6.82 (s) and 6.72 (s, 2 Ar—H), 4.63 (t, J = 8.5 Hz) and 3.99 (t, J = 8.5 Hz, CH_2—O—R), 3.86 (d, J = 10 Hz) and 3.50 (d, J = 10 Hz, —CH_2—O(H), 3.44 (s, OH), the m for the *CH*—Me is hidden under the peaks in this area (integrated area 4.1 to 3.3 = 5H), 2.83 (m, 2H, C.7 benzylic protons), 1.29 (d, J = 7 Hz, CH—*Me*), 1.17 (s) and 1.06 (s, 2 C—Me). *Anal.* calcd. for $C_{20}H_{28}O_2$: C 79.95, H 9.39; found: C 79.95, H 8.95.

The alcohol **4***d* was oxidized with chromium trioxide – pyridine (the procedure of Matsumoto *et al.* (11)) and gave the *aldehyde* **4***e* in 93% yield, mp 123–124°C (from ethanol); ir: 2740, 1718, 1630, 1597 cm^{-1}; H nmr δ: 9.70 (d, J = 1.5 Hz, —CHO), 6.75 (s) and 6.61 (s, 2 Ar—H), 4.64 (t, J = 9 Hz) and 4.01 (dd, J = 9 and 8 Hz, —CH_2—O—R), 3.36 (sex, —*CH*—Me), 2.90 (m, 2H, C.7 benzylic protons), 1.30 (d, J = 6.5 Hz, CH—*Me*), 1.10 and 1.06 (s, C—Me). *Anal.* calcd. for $C_{20}H_{26}O_2$: C 80.49, H 8.78; found: C 80.19, H 9.08.

Huang–Minlon reduction (11) of aldehyde **4***e* afforded the cyclic ether **4***a*, identical in all respects with that described previously (1).

A solution of chromium trioxide (0.70 g) in 80% aqueous acetic acid (21.5 mL) was added slowly to the cyclic ether **4***a* (1.3 g) in acetic acid (35 mL). After 1 h, the reaction mixture was poured into ice-water and extracted with ether. Chromatography of the oily product gave the *ketone* **14** (1.10 g), mp 99–100°C; uv: 236 (8,550), 280 (6,400) and 305 (6,800) nm; ir: 1670, 1625, 1595 cm^{-1}; H nmr δ: 7.86 (s, C.14-H), 6.72 (s, C.11-H), 4.72 (t, J = 9 Hz) and 4.09 (dd, J = 9 and 7.5 Hz, CH_2—O—R), 3.49 (sex, J = 9, 7.5 and 7 Hz, *CH*—Me), 1.32 (d, J = 7 Hz, CH—*Me*), 1.20 (s), 0.98 (s) and 0.92 (s, 3 C—Me); *m/e*: 298 (M^+). *Anal.* calcd. for $C_{20}H_{26}O_2$: C 80.49, H 8.78; found: C 80.51, H 8.99.

Oxidation of **14** *to Diosphenol* **15** *(5-Oxo-6-hydroxy-3,7,7,10a-tetramethyl-2,3,5,7,8,9,10,10a-octahydrophenanthro-[2,3-b] furan)*

The ketone **14** (0.310 g) in *tert*-butanol (10 mL) was added to the cooled solution prepared by dissolving potassium (1.5 g) in *tert*-butanol (40 mL). The mixture was stirred in an atmosphere of oxygen for 2 h which resulted in the uptake of 30.6 mL. The solution was poured into dilute HCl and extracted with chloroform affording a yellow oil (0.350 g) which by chromatography over silica gel gave the *diosphenol* **15** (0.220 g), mp 90–91°C; uv: 232 (9,500), 262 (10 400), 295 (6,200) and 310 (6,000) nm; ir: 3380, 3040, 1635, 1610, 1600 cm^{-1}; H nmr δ: 7.98 (br s, C.14-H), 7.20 (s, D_2O, enol OH), 6.89 (s, C.11-H), 4.79 (t, J = 9 Hz) and 4.17 (dd, J = 9 and 7.5 Hz, —CH_2—O—R), 3.58 (sex, J = 9, 7.5 and 7 Hz, *CH*—Me), 1.51 (s), 1.44 (s) and 1.42 (s, 3 C—Me), 1.39 (d, J = 7 Hz, CH—*Me*); *m/e*: 312 (M^+).

Synthesis of Coleon U (Tri- and Tetra-O-methyl Ethers, **3**c *and* **3**d)

The starting material was prepared from methyl-*O*-methyl podocarpate **7***a* by published methods. The isopropyl residue was introduced (**6***a*) to give **7***b* and the methyl ester was converted to methyl (10, 11) (ferruginol methyl ether). The latter was oxidized with CrO_3/HOAc (see preparation of **14**) to afford **8***b* (sugiol methyl ether).

Quinone **11**e *(2[2(2-Isopropyl-1,4-benzoquinone-5-yl)-2,6,6-trimethylcyclohexyl] Acetic Acid)*

The ketone **8***b* was oxidized as described in the preparation of **11***a*. The crude product obtained by filtration was dried and purified by dry column chromatography (silica gel). After crystallization from ether the yield was 76%, mp 209–210°C (pale yellow needles); ir: 1710, 1640, 1590 cm^{-1}; H nmr δ: 6.54 (s, 1H, =CH—), 6.42 (d, J = 1 Hz, =CH—), 2.84 (sept, J = 7 Hz, 1H, CH in iso-Pr), 1.18 (s, 3H, C—CH_2), 1.11 (d, J = 7 Hz, 6H,

iso-Pr methyls), 0.93 (s, 6H, 2 C—CH_3); *m/e*: 332 (M^+). *Anal.* calcd. for $C_{20}H_{28}O_4$: C 72.26, H 8.49; found: C 72.40, H 8.60.

Bromoquinone 11f (2[2(2-Bromo-3-isopropyl-1,4-benzoquinone-6-yl)-2,6,6-trimethylcyclohexyl] Acetic Acid)

The quinone **11***e* was brominated with Br_2 (1 mol) in acetic acid (see bromoquinone **11***b*) and the dibromo derivative **13***b* obtained was dried and treated immediately with diethylamine (see **11***b*). The bromoquinone **11***f* was obtained by dry column chromatography in 92% yield from quinone **11***e*, orange needles, mp 182–183°C; ir: 1720, 1670, 1645, 1580 cm^{-1}; H nmr δ: 9.62 (s, 1H, COOH), 6.51 (s, 1H, =CH—), 3.35 (sept, J = 7 Hz, 1H, CH in iso-Pr), 1.29 and 1.26 (2d, J = 7 Hz, 6H, iso-Pr methyls), 1.21 (s, 3H, C—CH_3), 0.95 (s, 6H, 2 C—CH_3); *m/e*: 412 and 410 (M^+). *Anal.* calcd. for $C_{20}H_{27}O_4Br$: C 58.40, H 6.62, Br 19.43; found: C 58.38, H 6.70, Br 19.35.

Hydroxyquinone 11g (2[2(2-Hydroxy-3-isopropyl-1,4-benzoquinone-6-yl)-2,6,6-trimethylcyclohexyl] Acetic Acid)

The product, prepared in the same manner as **11***b*, was purified by dry column chromatography (90%), orange needles, mp 168–170°C (from ether/hexane); ir: 3320, 1715, 1660, 1640, 1600 cm^{-1}; H nmr δ: 7.39 (s, 1H, OH), 6.41 (s, 1H, =CH—), 3.12 (sept, J = 7 Hz, 1H, CH in iso-Pr), 1.19 (d, J = 7 Hz, 6H, iso-Pr methyls), 1.17 (s, 3H, C—CH_3), 0.92 (s, 6H, 2 C—CH_3). *Anal.* calcd. for $C_{20}H_{28}O_5$: C 68.94, H 8.10; found: C 69.19, H 8.21.

Ketone 10c (7-Oxo-11,12,14-trimethoxy-13-isopropyl-podocarpa-8,11,13-triene)

The hydroxyquinone **11***g* was catalytically reduced and methylated while still under hydrogen, as described for diester **9***d*. The product **9***f*, which has never crystallized, was purified by dry column chromatography (yield 79%); ir: 1730 cm^{-1}; H nmr δ: 6.54 (s, 1H, aromatic H), 3.93, 3.77, 3.74 and 3.29 (4s, 3H each, 4 OMe), 1.33 (s, 3H, C—CH_3), 1.27 (d, J = 7 Hz, 6H, iso-Pr methyls), 0.97 (s, 3H, C—CH_3), 0.91 (s, 3H, C—CH_3); *m/e*: 406 (M^+).

Without further purification the ester **9***f* was hydrolyzed to the acid **9***g* (see preparation of **9***e*). The crude product, obtained by suitable extraction (ir: 1705 cm^{-1}; H nmr: 11.1 (s, COOH), only three OMe resonances) was immediately cyclized in trifluoroacetic anhydride (see **10***b*). The product **10***c* was purified by dry column chromatography and crystallized from ether, 73% from **9***f*: needles, mp 93–95°C; ir: 1680 cm^{-1}; H nmr δ: no aromatic protons, 3.81, 3.73 and 3.72 (3s, 3H each, 3 OMe), 1.33 (s, 3H, C—CH_3), 1.31 (d, J = 7 Hz, 6H, iso-Pr methyls), 0.98 (s, 3H, C—CH_3), 0.94 (s, 3H, C—CH_3); *m/e*: 374 (M^+). *Anal.* calcd. for $C_{23}H_{34}O_4$: C 73.76, H 9.15; found: C 73.90, H 9.30.

Coleon U Tri-O-methyl Ether 3c

The oxidation of ketone **10***c* followed the same procedure used to prepare diosphenol **15**. Dry column chromatography afforded a neutral fraction (mostly the starting ketone **10***c*) and the oxidized product **3***c* (50%), needles, mp 148–150°C; ir: 3300, 1670, 1630 cm^{-1}; H nmr δ: 7.41 (s, OH), 3.82 (2s, 6H, 2 OMe), 3.72 (s, 3H, OMe), 3.54 (sept, J = 7 Hz, 1H, CH of iso-Pr), 1.62 (s, 3H, C—CH_3), 1.44 (s, 6H, 2 C—CH_3), 1.33 and 1.31 (2d, J = 7 Hz, 3H each, iso-Pr methyls); *m/e*: 383 (M^+). *Anal.* calcd. for $C_{23}H_3O_5$: C 71.10, H 8.30; found: C 71.38, H 8.46.

Coleon U Tetra-O-methyl Ether 3d

Methylation of **3***c* with methyl iodide and potassium carbonate in acetone afforded the tetra-*O*-methyl ether **3***d* which was purified by dry column chromatography (97%), needles, mp 145–146°C; ir: 1645; H nmr δ: 3.81 (2s, 6H, 2 OMe), 3.75 (s, 3H, OMe), 3.74 (s, 3H, OMe), 3.52 (sept, J = 7 Hz, 1H, CH of iso-Pr), 1.64 (s, 3H, C—CH_3), 1.43 (s, 6H, 2 C—CH_3), 1.36 and 1.34 (2d, J = 7 Hz, 3H each, iso-Pr methyls).

CHRISTIAN BELLEC, PIERRE MAITTE, JOSEPH ARMAND, and JEAN PINSON. Can. J. Chem. **59**, 2826 (1981).

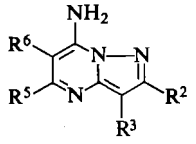
The pyrazolo[1,5-*a*]pyrimidine-7-amines are electrochemically reduced in hydroorganic medium at low pH into the corresponding 4,5-dihydro compounds. A mechanism is proposed featuring the intermediacy of the parent pyrazolo[1,5-*a*]pyrimidine itself. The 4,5-dihydroderivatives can be rearomatized, thus offering a facile synthetic route to the pyrazolo[1,5-*a*]pyrimidines.

CHRISTIAN BELLEC, PIERRE MAITTE, JOSEPH ARMAND et JEAN PINSON. Can. J. Chem. **59**, 2826 (1981).

Les amino-7 pyrazolo[1,5-*a*] pyrimidines peuvent être réduites électrochimiquement en milieu hydroorganique acide, elles conduisent par désamination et réduction aux dérivés 4,5-dihydro. Le mécanisme de cette réduction a été étudié; on propose la formation intermédiaire de la pyrazolo[1,5-*a*] pyrimidine correspondante. Les dihydro-4,5 pyrazolo[1,5-*a*] pyrimidines ont été réaromatisées. L'ensemble de ces deux étapes constitue une voie d'accès facile aux pyrazolo[1,5-*a*] pyrimidines.

Introduction

The reaction of hydrazine and of its derivatives with β-ketonitriles leads generally to 5-aminopyrazoles through the hydrazones or enehydrazines which can be isolated (1). However, under certain conditions it is possible to prepare fused heterocyclic compounds: the pyrazolo[1,5-*a*]pyrimidine-7-amines (2–5).



The synthesis of pyrazolo[1,5-*a*]pyrimidines (6–11) has been the subject of recent interest in pharmacological activities. Central nervous system depressor, tranquilizer, anticoagulant, and antiinflammatory properties have been found for some members of the series.

Therefore, the interest of an electrochemical investigation of pyrazolo[1,5-*a*]pyrimidine-7-amines was twofold: on the one hand, the opportunity of studying the reduction mechanism of a new fused heterocyclic system and, on the other hand, the possibility of preparing new compounds.

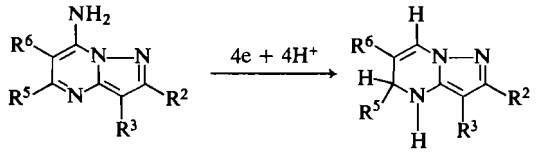
Compounds **1**(*a–f*) have been prepared and investigated (Table 1).

Electrochemical Behaviour of 1(a–f)

In an acidic buffered hydroorganic solution (50% acetonitrile, pH 1.15) all these compounds, or more likely a protonated form, present a single polarographic wave; the height is close to 4 F and the half wave potential lies between −1.20 V and −1.30 V (Table 1).

These waves are very close to the background. The precise measurement of their half-wave potential and of their height is rather difficult. This was achieved according to the following procedure: the half-wave potentials were measured by ac polarography ($E_p = E_{1/2}(12)$) and the height of the wave was obtained by multiplying by two the height at the level of the half-wave potential. Upon increasing the pH these waves disappeared.

A coulometry carried out at a potential corresponding to the foot of the wave (e.g. for **1***a*, pH = 1.38, $E = -1.25$ V) indicated the consumption of 4 F per mole. A preparative electrolysis under the same experimental conditions ($c = 9 \times 10^{-3}$ *M*) yielded 4,5-dihydropyrazolo[1,5-*a*]pyrimidines **2** (*a–f*) in good yields (Table 2).



1(*a–f*) **2**(*a–f*)

The cyclic voltammetry of **1***a* on a vitreous carbon electrode (Fig. 1) (starting from +0.9 V, v =

0.2 V s^{-1}) shows on the first cathodic scan the single peak I_c of **1***a* and two small anodic peaks II_a (E_p = +0.22 V) and III_a (E_p = +0.48 V) identical with those observed for the corresponding dihydroderivative **2***a*. On the second and successive cathodic scans, a small cathodic peak IV_c (E_p = −1.05 V) is observed, which is that of the pyrazolo[1,5-*a*]pyrimidine **3***a*. This same peak IV_c can be observed both on a vitreous carbon and on a hanging mercury drop electrode (Fig. 2; E_{p_c} = −0.975 V) when starting from −0.4 V and scanning at 200 V s^{-1}.

This could allow the determination of the rate of the chemical deamination step if one could measure the height of the peak of **1***a*, which should decrease from 4 to 2 F per mole (13). In our case, the peak of **1***a* is too close to the background to allow such a determination. However, the relative height of the peaks of **1***a* and **3***a* allows one to estimate the order of magnitude of this rate constant which is about 100 s^{-1}.

When the electrolysis is carried out on mercury in a thin layer cell inside a uv spectrophotometer, the spectrum of **1***a* (λ_{max} = 285 nm, ε = 18 400; 346 nm, ε = 5700; 50% CH_3CN) progressively disappears at the expense of that of **2***a* (λ_{max} = 275 nm, ε = 12 000; 325 nm, ε = 18 600) (Fig. 3). The spectrum presents two isobestic points at 306 and 350 nm.

The pyrazolo[1,5-*a*]pyrimidine **3***a* was also investigated by cyclic voltammetry on vitreous carbon; on the cathodic scan (starting from +0.8 V, v = 0.2 V s^{-1}) peak IV_c is observed, while peaks II_a and III_a appear on the anodic scan. Besides, a preparative electrolysis of **3***a* under the same conditions as for **1***a* (E = −1.15 V) furnished **2***a* in 87% yield.

Aromatization of 4,5-Dihydropyrazolo[1,5-a]-pyrimidines

As the pyrazolo[1,5-*a*]pyrimidines unfunctionalized on the 7-position have never been described in the literature, attempts were made to prepare them through the rearomatization of their dihydroderivatives. From the voltammogram of Fig. 1 this reoxidation seems possible by electrochemistry. However, it was more convenient to achieve the

[a]Solvent trifluoroacetic acid.

oxidation by MnO_2 in dimethylformamide according to an experimental procedure derived from that used for the aromatization of dihydropyrazines (14).

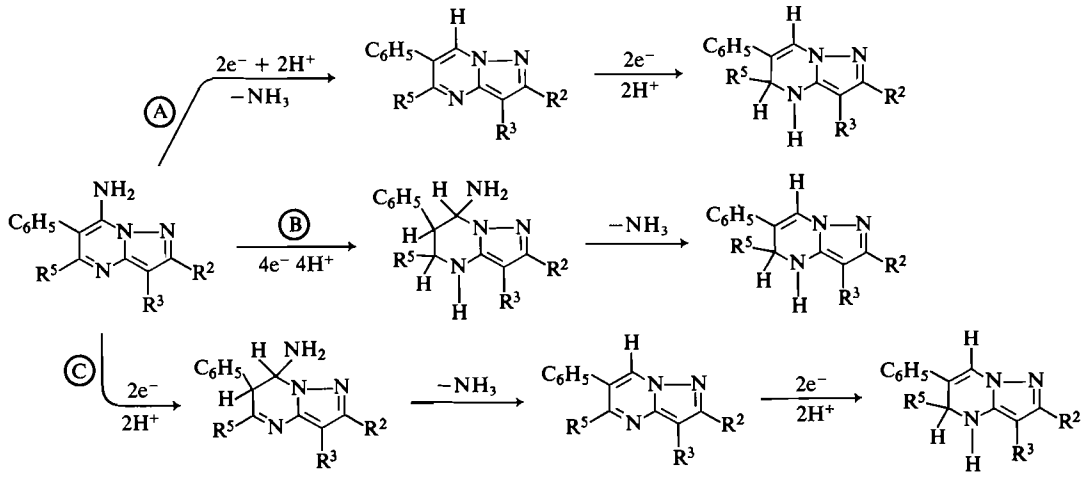
The yields and melting points of the compounds **3**(*a–f*) are given in Table 3.

Discussion

Reduction Mechanism

Three reduction pathways can be envisaged for the reduction of **1** into **2** as shown in Scheme 1.

The results of the fast scan cyclic voltammetry experiments indicate that **3** must be an intermediate



SCHEME 1

on the way from **1** to **2**. This allows one to exclude route B. Compound **3**, as it is easier to reduce than **1**, is converted into **2** during the electrolysis. The deamination of the 7-amino-6,7-dihydro intermediate must be fast as the spectra recorded during the electrolysis show an isobestic point. This was confirmed by cyclic voltammetry as no additional peak, which could have been assigned to this intermediate, could be observed up to a scan rate of 200 V s^{-1} at room temperature or up to 20 V s^{-1} at −17°C.

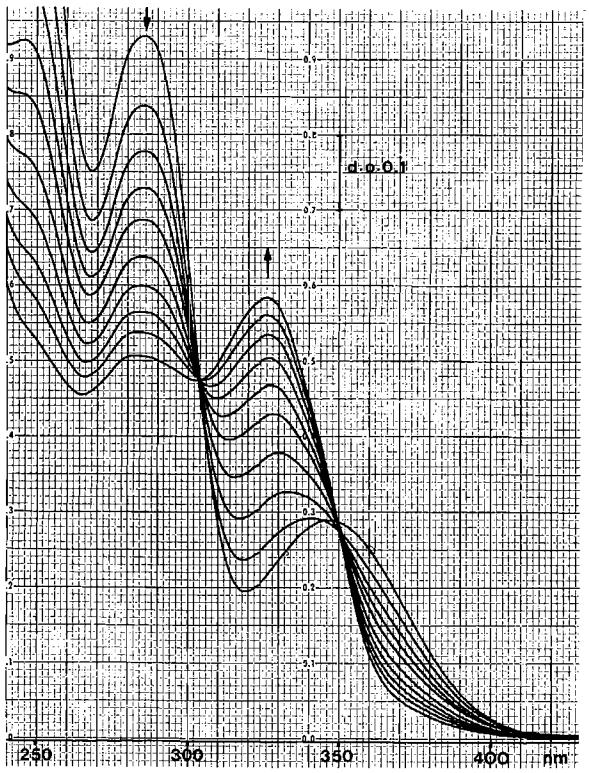


FIG. 3. Ultraviolet spectral changes during the electrolysis of **1***a* at pH 1. 15 (50% CH_3CN) at $E = -1.25$ V.

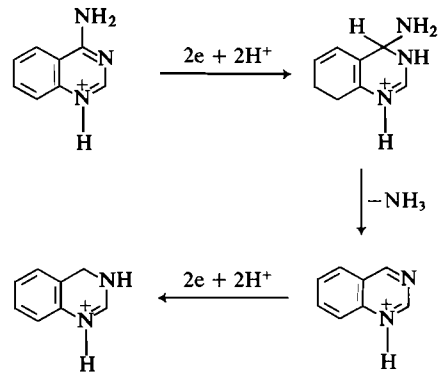
In the case of 4-amino-2,6-dimethylpyrimidine (15), 4-aminoquinazoline (16), and cytosine (17) a reduction path similar to route C was proposed. In the case of adenine, Smith and Elving (17) had suggested a mechanism analogous to route B, but it was shown later by Kwee and Lund (18) that a reduction scheme similar to C was more likely. For example, in the case of 4-aminoquinazoline (16) the mechanism was supported by the increase of the reduction wave from 2 to 4 F per mole upon increasing the pH.



There is, to the best of our knowledge, no published example of a mechanism similar to route A, featuring a C—N electrochemical cleavage. On the other hand, route C implies that a C=C bond be reduced before a C=N bond. Therefore, it is not possible at the present time to discriminate soundly between path A and path C.

Synthetic Interest

Although some derivatives dihydrogenated in the 4,7-position have been prepared recently by

reaction of sodium borohydride with pyrazolopyrimidines having an ester group on the 6-position (11), no 4,5-dihydropyrazolo[1,5-*a*]pyrimidines have ever been described. The same situation occurs for 6-aryl substituted pyrazolo[1,5-*a*]pyrimidines that we have obtained through the rearomatization of the dihydrogenated compounds.

As the pyrazolo[1,5-*a*]pyrimidine-7-amines are easily obtained from the β-ketonitriles, the electrochemical reduction provides a new and simple route to the 4,5-dihydropyrazolo[1,5-*a*]pyrimidines. These can be rearomatized into pyrazolo-[1,5-*a*]pyrimidines.

Experimental

The apparatus and techniques used for polarography and electrolysis have been described previously (19, 20). The reference electrode was a saturated calomel electrode. The pH values were measured with a Radiometer model 4 pHmeter equipped with a combined glass–calomel electrode GK 2302B standardized in aqueous buffer. The high scan rate voltammograms were recorded with the help of an apparatus composed of a Tacussel GSTP3 signal generator, a fast-rise wide bandpass potentiostat provided with an ohmic drop compensation device (21), and a memory oscilloscope Tektronix 7313. A vitreous carbon electrode (3 mm diameter) was used, and it was polished with 1 μ diamond paste before each experiment. The ac polarograms (10 mV, 320 Hz ac signal) were recorded on a Tacussel PRG3 polarograph. The uv spectra were recorded on a Cary 219 spectrophotometer by withdrawing samples from an electrolysis at regular intervals ($c = 5 \times 10^{-4}$ *M*; 50% CH_3CN, H_2SO_4 *N*/10; quartz cell 0.5 mm diameter). The microanalyses were performed by the "Service de Microanalyse du CNRS" (Gif sur Yvette). All the compounds described gave correct elemental analyses. The following abbreviations are used in reporting the nmr results: s = singlet, d = doublet; t = triplet, q = quadruplet, and m = multiplet.

Preparation of Pyrazolo[1,5-a]pyrimidine-7-amines

7-Amino-3,6-diphenylpyrazolo[1,5-a]pyrimidine (1a) was obtained by condensation in acidic medium of 5-amino-4-phenylpyrazole (22) with 2-formyl-2-phenylacetonitrile according to ref. 4; mp 224°C, $C_{18}H_{14}N_4$. A erroneous assignment has been proposed (4) for nmr data.

7-Amino-2-methyl-3,6-diphenylpyrazolo[1,5-a]pyrimidine (1b)

A mixture of 1.8 g of 3-methyl-4-phenyl-5-aminopyrazole and 1.5 g of 2-formyl-2-phenylacetonitrile was heated during 6 h in 60 mL of ethanol and 3 mL of concentrated hydrochloric acid. After cooling, the hydrochloride did not precipitate. The solution was poured into 300 mL of water and sodium carbonate was added until pH 7–8. The white precipitate was filtered, washed with water, and dried; 81% yield, mp 215–216°C (ethanol), $C_{19}H_{16}N_4$.

7-Amino-2-methyl-6-phenylpyrazolo[1,5,-a]pyrimidine: (1c) was obtained, as in the case of 1*b*, by condensation of 1.3 g of 5-amino-3-methylpyrazole (4) with 2 g of 2-formyl-2-phenylacetonitrile; 68% yield, mp 186–187°C (C_6H_6–ligroin 80:20), $C_{13}H_{12}N_4$.

7-Amino-2,6-diphenylpyrazolo[1,5-a]pyrimidine: (1d) was obtained under the same conditions as above with a mixture of 1.35 g of 5-amino-3-phenylpyrazole and 1.2 g of 2-formyl-2-phenylacetonitrile: 76% yield, mp 236–237°C (benzene), $C_{18}H_{14}N_4$.

7-Amino-5-methyl-3,6-diphenylpyrazolo[1,5-a]pyrimidine: (1e) was prepared by condensation of 2 g of 5-amino-4-phenylpyrazole and 1.8 g of 2-acetyl-2-phenylacetonitrile: 70% yield, mp 241–242°C (benzene), $C_{19}H_{16}N_4$.

7-Amino-2,3,6-triphenylpyrazolo[1,5-a]pyrimidine: (1f) was obtained by condensation of 1 g of 5-amino-3,4-diphenylpyrazole and 0.6 g of 2-formyl-2-phenylacetonitrile: 89% yield, mp 240–241°C (benzene–ligroin 80:20), $C_{24}H_{18}N_4$.

Electrochemical Reductions of Pyrazolo[1,5-a]pyrimidine-7-amines: Preparation of Dihydro Derivatives

Electrolysis of 7-Amino-3,6-diphenylpyrazolo[1,5-a]pyrimidine (1a): Preparation of (2a)

A solution (250 mL) was prepared from 125 mL of CH_3CN, 25 mL of a 1 *M* solution of sulfuric acid, and water; 200 mL of this solution and 500 mg ($c = 8.75 \times 10^{-3}$ *M*) of **1***a* were used to fill the cathodic compartment while the remainder was used in the anodic compartment, pH 1.38; $E = -1.25$ V. After consumption of 650 C (4 F = 675 C) the current decreased to 40 mA. A precipitate appeared in the cell at 700 C and the current increased to attain 100 mA at 900 C. The electrolysis was stopped, CH_3CN was evaporated, and the solution was filtered. The precipitate was washed with water and dried; 380 mg (80% yield) of 4,5-dihydro-3,6-diphenylpyrazolo[1,5-*a*]pyrimidine (**2***a*) were obtained, mp 234–235°C ($CHCl_3$), $C_{18}H_{15}N_3$.

Electrolysis of 7-Amino-2-methyl-3,6-diphenylpyrazolo[1,5-a]pyrimidine (1b): Preparation of 2b

A solution was prepared as in the case of **1***a*. Compound **1***b*, 600 mg ($c = 10^{-2}$ *M*) was reduced in 200 mL of this solution, pH 1.40; $E = -1.3$ V. After consumption of 800 C (772 C = 4 F) the current decreased to 15 mA and the electrolysis was stopped. Acetonitrile was evaporated to give a precipitate (440 mg, 78% yield) of 4,5-dihydro-2-methyl-3,6-diphenylpyrazolo[1,5-*a*]pyrimidine (**2***b*), mp 135–136°C, $C_{19}H_{17}N_3$.

Electrolysis of 7-Amino-2-methyl-6-phenylpyrazolo[1,5-a]pyrimidine (1c): Preparation of 2c

In the same condition as above, the electrolysis was carried out with 700 mg ($c = 1.6 \times 10^{-2}$ *M*) of **1***c*, pH 1.46; $E = -1.25$ V. After consumption of 1300 C (1206 C = 4 F) the current dropped to 30 mA. The electrolysis was stopped and acetonitrile was evaporated. Sodium carbonate was added to the solution until pH 7–8. A white solid precipitated: 545 mg (82.5% yield) of 4,5-dihydro-2-methyl-6-phenylpyrazolo[1,5-*a*]pyrimidine (**2***c*), mp 200–201°C, $C_{13}H_{13}N_3$.

Electrolysis of 7-Amino-2,6-diphenylpyrazolo[1,5-a]pyrimidine (1d): Preparation of 2d

Electrolysis was carried out with 590 mg ($c = 10^{-2}$ *M*) of **1***d*, pH 1.35; $E = -1.3$ V. After consumption of 760 C (772 C = 4 F) the electrolysis was stopped. A solid was obtained after evaporation of acetonitrile: 4,5-dihydro-2,6-diphenylpyrazolo-[1,5-*a*]pyrimidine (**2***d*), 390 mg (70% yield), mp 185–186°C (C_6H_6), $C_{18}H_{15}N_3$.

Electrolysis of 7-Amino-5-methyl-3,6-diphenylpyrazolo[1,5-a]pyrimidine (1e): Preparation of 2e

Electrolysis was carried out at $E = -1.30$ V with 700 mg of **1***e*, pH 1.20. After consumption of 2800 C (4 F = 906 C) the current was still 200 mA. This high intensity was due to the reduction of H^+. The electrolysis was stopped, CH_3CN evaporated, and Na_2CO_3 added until pH 7. A white solid precipitated: 4,5-dihydro-5-methyl-3,6-diphenylpyrazolo[1,5-*a*]pyrimidine (**2***e*): 520 mg (74% yield), mp 157°C, $C_{19}H_{17}N_3$.

Electrolysis of 7-Amino-2,3,6-triphenylpyrazolo[1,5-a]-pyrimidine (1f): Preparation of 2f

Electrolysis was carried out at $E = -1.30$ V with 700 mg of **1***f*. A solid precipitated during the electrolysis. After consumption of 1200 C the current was stopped. The precipitate was filtered

and dried: 4,5-dihydro-2,3,6-triphenylpyrazolo[1,5-*a*]pyrimidine (**2***f*), 410 mg (61% yield), mp 143°C, $C_{24}H_{19}N_3$.

Aromatization of 4,5-Dihydropyrazolo[1,5-a]pyrimidines
General Procedure

Three hundred milligrams of 4,5-dihydropyrazolo[1,5-*a*] pyrimidine (200 mg in the case of **3***b*) were dissolved in 10 mL of dimethylformamide; 300 mg of MnO_2 were added to the solution. The mixture was stirred and heated at 50°C during 12 h. The solution was filtered and 300 mL of water were added. The solid was washed with water and dried.

Preparation and reactions of 4b-acetoxy-4b,9b-dihydroindeno[2,1-*a*]indene-5,10-dione

STANLEY WAWZONEK

Department of Chemistry, University of Iowa, Iowa City, IA 52242, U.S.A.

Received March 25, 1981

STANLEY WAWZONEK. Can. J. Chem. **59**, 2833 (1981).

4b-Acetoxy-4b,9b-dihydroindeno[2,1-*a*]indene-5,10-dione prepared by treating 4b,9b-dihydroindeno[2,1-*a*]indene-5,10-dione with lead tetraacetate was hydrolyzed to the alcohol, 4b-hydroxy-4b,9b-dihydroindeno[2,1-*a*]indene-5,10-dione with hydrochloric acid and converted to 4b-methoxy-4b,9b-dihydroindeno[2,1-*a*]indene-5,10-dione with sodium hydroxide in methanol. The alcohol was stable to base and could not be converted to dibenzo[*a*,*c*]cyclooctadiene-5,6,11-trione. Attempts to form the epoxydiketone from the acetate with sodium hydroxide and hydrogen peroxide gave benzil dicarboxylic acid, 11-keto[1,2-*c*]isocoumarin and 4b-methoxy-4b,9b-dihydroindeno[2,1-*a*]indene-5,10-dione.

STANLEY WAWZONEK. Can. J. Chem. **59**, 2833 (1981).

L'acétoxy-4b dihydro-4b,9b indéno[2,1-*a*] indènedione-5,10, obtenu par la réaction des dihydro-4b,9b indéno[2,1-*a*] indènedione-5,10 avec le tétraacétate de plomb est hydrolysé en hydroxy-4b dihydro-4b,9b indéno[2,1-*a*] indènedione-5,10 sous l'influence de l'acide chlorhydrique et ce acétate soumis à l'action de l'hydroxyde de sodium en présence de méthanol conduit au méthoxy-4b dihydro-4b,9b indéno[2,1-*a*] indènedione-5,10. L'alcool est stable en milieu basique et ne peut être transformé en dibenzo [*a*,*c*] cyclooctadiène trione-5,6,11. On a essayé de former l'époxycétone à partir de l'acétate avec l'hydroxyde de sodium et l'eau oxygénée mais on obtient l'acide benzyle dicarboxylique, le céto-11[1,2-*c*] isocoumarin et la méthoxy-4b dihydro-4b,9b indéno[2,1-*a*] indènedione-5,10.

[Traduit par le journal]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Attempts to prepare dibenzo[*a*,*e*]cyclooctadien-5,6,11-trione (**3**) from dibenzo[*a*,*e*]cyclooctadien-5,11-dione were not successful; the product obtained was 11-keto[1,2-*c*]isocoumarin (**4**) (1). In the present work the product from the reaction of 4b,9b-dihydroindeno[2,1-*a*]indene-5,10-dione with lead tetraacetate, 4b-acetoxy-4b,9b-dihydroindeno[2,1-*a*]indene-5,10-dione, was investigated as a means of preparing this elusive compound. It was hoped that conversion of this acetate to the corresponding alcohol followed by a reverse aldol would yield the desired triketone.

Experimental

All melting points are uncorrected. Infrared (ir) spectra were recorded with a Perkin-Elmer Infracord spectrometer. The nmr spectra were obtained using tetramethylsilane as an internal standard with a Varian A60 NMR spectrometer.

4b-Acetoxy-4b,9b-dihydroindeno[2,1-a]indene-5,10-dione (1b)

The diketone (**1***a*) (11.7 g, 0.05 mol) was heated with lead tetraacetate (25 g, 0.056 mol) in acetic acid (200 mL) upon a steam bath for 48 h. The acetic acid was removed under reduced pressure and the resulting solid was treated with water and extracted with benzene. Removal of the benzene gave a solid (**1***b*) which was recrystallized from benzene; yield, 5.9 g; mp 120–124°C (gas evolution). The filtrate was chromatographed using benzene and silica and gave an additional 4.04 g of **1***b*. Two recrystallizations from a mixture of benzene and petroleum ether (bp 60–70°C) gave a sample melting at 125–127°C. Occasionally the sample obtained melted at 150–151°C. The lower melting sample upon remelting gave the higher melting point. Both samples gave the same ir and nmr spectra and elemental analysis.

The use of a two-fold amount of lead tetraacetate in this reaction did not change the nature of the product.

Infrared (Nujol): 5.68 (CH_3COO), 5.8–5.82 (CO), 8.26 (C—O) μ; nmr (chloroform-*d*), δ: 2.13 (s, 3H, CH_3), 4.45 (s, 1H, CH), 7.4–8.1 (m, 8H, aromatic). *Anal.* calcd. for $C_{18}H_{12}O_3$: C 73.97, H 4.11; found: 73.67, H 3.96.

4b-Hydroxy-4b,9b-dihydroindeno[2,1-a]indene-5,10-dione (1c)

The acetate (**1***b*) (0.74 g) was refluxed in a mixture of methanol (30 mL), water (10 mL), and 6 *N* hydrochloric acid (5 mL) for 25 h. Addition of water followed by removal of the solvent under reduced pressure gave a solid which was treated with water and filtered; yield, 0.62 g. Recrystallization from benzene gave the hydroxy ketone **1***c* melting at 140–142°C; ir (Nujol): 2.97 (OH), 5.82 (shoulder), 5.90 (C=O); nmr (chloroform-*d*), δ: 4.23 (s, 1H, CH), 4.50 (broad s, 1H, OH), 7.3–8.0 (m, 8H, aromatic). The broad singlet at 4.50 disappeared in the presence of D_2O. *Anal.* calcd. for $C_{16}H_{10}O_3$: C 76.80, H 4.00; found: C 76.99, H 4.21.

The alcohol (**1***c*) was stable to treatment with an aqueous methanol solution of sodium carbonate, *o*-phenylenediamine, and sodium hydroxide and benzaldehyde.

The alcohol (**1***c*) (0.09 g) upon treatment with acetic anhydride (2.5 mL) and potassium acetate (0.01 g) at 100°C for 2 h gave the acetate (**1***b*) (0.09 g) melting at 125–128°C after recrystallization from methanol.

Solvolysis of Acetate 1b

The acetate **1***b* (0.05 g) was heated at reflux in methanol (15 mL) and water (5 mL) for 41 h. The solution upon cooling gave a red solid (0.006 g) melting at 285–287°C (lit. (2) mp 284°C). The filtrate upon concentration gave the starting acetate (**1***b*) (0.03 g).

4b-Methoxy-4b,9b-dihydroindeno[2,1-a]indene-5,10-dione (1d)

A solution of the acetate (**1***b*) (0.12 g) in methanol (25 mL) was treated with 1.5 mL of 0.004 *N* sodium hydroxide and allowed to stand for 4 h at room temperature. The resulting solution was filtered from a small amount of high melting solid and the methanol was removed under reduced pressure. The resulting pink solid was triturated with water and filtered. Extraction of this solid (0.106 g) with hot petroleum ether (bp 60–68°C) gave 0.03 g of the methyl ether **1***d* which on heating softened at 85°C

0008-4042/81/192833-02$01.00/0

©1981 National Research Council of Canada/Conseil national de recherches du Canada

and melted at 91–94°C. Recrystallization from the same solvent gave a sample which softened at 85°C and melted at 96–97°C; ir (Nujol): 5.85 (CO); nmr (chloroform-*d*), δ: 3.35 (s, 3H, CH_3O), 4.35 (s, 1H, CH), 7.3–8.1 (m, 8H, aromatic). *Anal.* calcd. for $C_{17}H_{12}O_3$: C 77.27, H 4.55; found: C 77.13, H 5.03.

Higher melting products in this reaction were not investigated.

*Oxidation of Acetate 1*b

The acetate (**1***b*) (2.92 g) was dissolved in methanol (150 mL) by heating and the resulting solution after cooling was treated successively with 15% hydrogen peroxide (5 mL) and 4 *N* sodium hydroxide (7.5 mL). The solution turned dark red and was stirred at room temperature for 6 h and then allowed to stand for an additional 21 h; no change in color occurred in this period. Acidification with dilute acetic acid followed by concentration of the solution gave 1.40 g of *o*,*o*′-benzildicarboxylic acid melting at 250–254°C dec. Recrystallization from ethanol gave a sample melting at 261–265°C dec. (lit. (3) mp 265–270°C). Identification was made by the ir spectrum and formation of diphthalyl and phthalic anhydride upon melting (3).

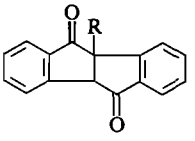
The methanol filtrate was evaporated to dryness and the residue was dissolved in benzene. Chromatography on silica gave 11-keto[1,2-*c*]isocoumarin (**4**) (0.03 g) and the methyl ether **1***d* (0.15 g). Identification of these two compounds was made by comparison with authentic samples.

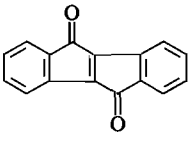
The use of 2.3 mL of 15% hydrogen peroxide and 5 mL of 4 *N* sodium hydroxide gave similar products to the above, but the amount of indenoisocoumarin **4** formed was larger.

Results and Discussion

Treatment of 4b,9b-dihydroindeno[2,1-*a*]indene-5,10-dione (**1***a*) with lead tetraacetate gave 4b-acetoxy-4b,9b-dihydroindeno[2,1-*a*]indene-5,10-dione (**1***b*); only monoacetylation occurred even when an excess of lead tetraacetate was used.

The acetate (**1***b*) was hydrolyzed by dilute hydrochloric acid to the alcohol **1***c* without dehydration of **1***c* to the unsaturated diketone **2** or its





2

1*a* R = H
1*b* R = $OCOCH_3$
1*c* R = OH
1*d* R = OCH_3

Diels–Alder dimer, which loses carbon monoxide readily (2). Such a dehydration is prevented in this reaction by the *cis* configuration of the alcohol **1***c* and the inability to form a planar carbonium ion in this system. The acetate (**1***b*) behaves differently under solvolytic conditions and slowly yields the dimer of **2**.

Alcohol **1***c* is the intramolecular aldol product expected from dibenzo[*a*,*c*]cyclooctan-5,6,11-trione (**3**) and could not be converted to the latter with sodium carbonate or sodium hydroxide. Attempts to trap the triketone (**3**) with *o*-phenylenediamine or benzaldehyde were likewise unsuccessful. These results suggest that the triketone (**3**) will be stable only under acid-free or base-free conditions.

4

The reaction of the acetate **1***b* with sodium hydroxide in methanol was abnormal and gave the methyl ether (**1***d*) instead of the alcohol **1***c*. This product (**1***d*) is formed by elimination of acetic acid from **1***b* with the formation of the diketone **2**. Addition of methanol or methoxide ion to the conjugated system occurs before the diketone **2** can dimerize. This elimination of acetic acid and formation of the intermediate diketone **2** is similar to the dehydrobromination of the 4b-bromo derivative (**1**, R = Br) observed by others (4); the intermediate diketone **2** in this example was trapped with furan.

The availability of a facile method for the formation of the transient diketone **2** using alkaline conditions suggested a study of its (**2**) conversion to an epoxide. Such an intermediate would be useful in the preparation of the tetraketone in the dibenzocyclooctane series.

Treatment of the acetate (**1***b*) in methanol sequentially with 15% hydrogen peroxide and sodium hydroxide gave a mixture of *o*,*o*′-benzil dicarboxylic acid (3), 11-keto[1,2-*c*]isocoumarin (**4**) (5), and the methyl ether **1***c*. These results suggest a preferential attack of the hydroperoxide ion on the carbonyl groups of **1***b* before elimination can occur to the unsaturated ketone **2**. This addition is followed by a Dakin Reaction (6) with subsequent elimination of acetic acid. 11-Keto[1,2-*c*]isocoumarin (**4**) is probably the precursor of *o*,*o*′-benzil dicarboxylic acid since more of it is formed if less base and hydrogen peroxide are used in the oxidation.

Fluorosulfates of palladium. Part 3. The tetrakis(fluorosulfato)palladate(II) ion

KEITH C. LEE AND FRIEDHELM AUBKE[1]

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received April 10, 1981

KEITH C. LEE and FRIEDHELM AUBKE. Can. J. Chem. **59**, 2835 (1981).

The reduction of ternary fluorosulfato complexes of palladium(IV) like cesium hexakis(fluorosulfato)palladate(IV) by bromine in liquid sulfur dioxide at room temperature or at slightly elevated temperatures results in the formation of cesium tetrakis(fluorosulfato)palladate(II), according to:

$$Cs_2[Pd(SO_3F)_6] + Br_2 \xrightarrow[25°C]{Br_2/SO_2} Cs_2[Pd(SO_3F)_4] + 2BrSO_3F$$

In contrast to all previously reported palladium(II) fluorosulfato derivatives, Pd^{2+} is found in a square planar environment resulting in diamagnetism.

KEITH C. LEE et FRIEDHELM AUBKE. Can. J. Chem. **59**, 2835 (1981).

La réduction des complexes ternaires de fluorosulfato de palladium(IV) tel l'hexakis(fluorosulfato) palladate(IV) de cesium. Par le brome dans le bioxyde de soufre liquide à la température ambiante ou à des températures légèrement supérieures conduit à la formation du tétrakis(fluorosulfato) palladate(II) de césium selon l'équation

$$Cs_2[Pd(SO_3F)_6] + Br_2 \xrightarrow[25°C]{Br_2/SO_2} Cs_2[Pd(SO_3F)_4] + 2BrSO_3F$$

Contrairement à tout ce qui a été publié antérieurement sur les dérivés fluorosulfato de palladium(II) on a trouvé que l'ion Pd^{2+} est dans un environnement carré plan résultant du diamagnétisme.

[Traduit par le journal]

Introduction

In the two preceding publications in this series we have reported on the synthesis, the spectroscopic and the magnetic properties of a number of paramagnetic palladium(II) fluorosulfates (1, 2). Most divalent palladium compounds are diamagnetic and, consistent with a d^8 electron configuration, have the metal in a square planar, or more rarely a five coordinate environment.

Octahedral coordination, resulting in a $^3A_{2g}$ groundstate for the central atom, is found in $Pd(SO_3F)_2$ (1), where the fluorosulfate group acts as a tridentate, weak field oxygen donor ligand, and in ternary fluorosulfates of the type $Pd^{II}M^{IV}(SO_3F)_6$ (2), where M = Pd, Pt, or Sn. In these compounds the fluorosulfate group acts as an anisobidentate ligand, seemingly strongly coordinated to the tetravalent metal and more weakly linked to palladium(II), again producing a regular octahedral environment and a $^3A_{2g}$ groundstate. Both $Pd(SO_3F)_2$ and the palladium(II) hexakis(fluorosulfato)metallates(IV), may be viewed as coordination polymers, with polydentate fluorosulfate groups as bridges between the metallic centers. Octahedral coordination to Pd(II) produces a weak ligand field, reflected in the measured D_q, B, and β parameters (1, 2) and the magnetic susceptibilities.

Comparable structures as well as magnetic and spectroscopic properties are reported for palladium(II) fluorides. PdF_2(3) has a rutile structure (4), with antiferromagnetic coupling (5) producing a lower magnetic moment than the one found for $Pd(SO_3F)_2$ (2). An octahedral environment and paramagnetism are also found for a number of ternary fluorides of the type Pd(II)M(IV)F_6, with M = Pd, Pt, Ge, or Sn (6). However, in addition, a number of anionic fluorocomplexes of Pd(II) have been synthesised and characterised, which show diverging magnetic properties. While both $CsPdF_3$ (7) and $ZnPdF_4$ (8) are paramagnetic for two unpaired electrons, $BaPdF_4$ is reported to be diamagnetic with a square planar environment for palladium.

Therefore we became interested in synthesising and characterising analogous anionic complex compounds of Pd(II) with possibly monodentate fluorosulfate groups. The similarity of F^- and SO_3F^- as weakly coordinating ligands in coordination chemistry (9) would suggest the possible existence of square planar, diamagnetic fluorosulfate complexes as well.

Results and Discussion

(i) *Synthesis*

A number of initial attempts at the synthesis of palladium(II) fluorosulfato complexes were unsuc-

cessful. Complexation according to

[1] $Pd(SO_3F)_2 + nCsSO_3F \xrightarrow{HSO_3F} Cs_n[Pd(SO_3F)_{2+n}]$, $n = 1$ or 2

did not proceed, because $Pd(SO_3F)_2$ was virtually insoluble in HSO_3F even up to 120°C. The starting materials were recovered after removal of HSO_3F *in vacuo*.

The attempted solvolysis of nitrosonium tetrachloropalladate(II) in either HSO_3F or $BrSO_3F$ was unsuccessful as well. In HSO_3F a precipitate of $PdCl_2$ occurred according to:

[2] $(NO)_2[PdCl_4] + 2HSO_3F \rightarrow 2(NO)SO_3F + PdCl_2 + 2HCl$

while in $BrSO_3F$ insoluble $Pd(SO_3F)_2$ was formed and some partial oxidation to Pd(IV) was noted.

A more feasible approach was suggested by the previously (1) reported thermal decomposition of $Pd(II)Pd(IV)(SO_3F)_6$ according to

[3] $Pd(II)Pd(IV)(SO_3F)_6 \xrightarrow{+160°C} 2Pd(II)(SO_3F)_2 + S_2O_6F_2$

a decomposition mode subsequently also found for complexes of the type $M_2[Pd(IV)(SO_3F)_6]$, where M = K or Cs. This decomposition and the rather uncommon (10) release of bis(fluorosulfuryl)peroxide pointed to the strong oxidizing ability of palladium(IV) fluorosulfate derivatives and while the resulting solid pyrolysis products were insufficiently pure, a reduction reaction with bromine provides a suitable synthetic route:

[4] $Pd(II)Pd(IV)(SO_3F)_6 + Br_2 \xrightarrow[30\ min]{100°C} 2Pd(II)(SO_3F)_2 + 2BrSO_3F$

Palladium(II) fluorosulfate so obtained is analytically pure. Coupled with the fast and efficient oxidation of palladium metal in a $HSO_3F/S_2O_6F_2$ mixture according to:

[5] $2Pd + 3S_2O_6F_2 \xrightarrow[3\ days]{100°C} Pd(II)Pd(IV)(SO_3F)_6$

the subsequent reduction to $Pd(II)(SO_3F)_2$ provides a more convenient route to this compound than the original oxidation of Pd by $BrSO_3F$, where reaction temperatures of 110°C and reaction times of two weeks are required (1). The ability of bromine to reduce Pd(IV) to Pd(II) under these conditions also provides an explanation as to why only $Pd(II)(SO_3F)_2$ was formed in the original reaction (1):

[6] $Pd + 2BrSO_3F \xrightarrow[14\ days]{100°C} Pd(II)(SO_3F)_2 + Br_2$

Surprisingly the complex $Cs_2[Pd(IV)(SO_3F)_6]$ does not react with bromine under similar conditions. A more reactive reducing agent is found in the mixture of Br_2 and SO_2. Like Br_2, sulfur dioxide does not reduce $Cs_2[Pd(IV)(SO_3F)_6]$, but mixtures of both provide a fast and efficient reaction medium, affording analytically pure $Cs_2[Pd(SO_3F)_4]$ according to:

[7] $Cs_2[Pd(IV)(SO_3F)_6] + Br_2 \xrightarrow[25°C,\ 1\ day]{Br_2/SO_2} Cs_2[Pd(II)(SO_3F)_4] + 2BrSO_3F$

followed by a subsequent reaction as evident from vibrational spectra:

[8] $2BrSO_3F + SO_2 \rightarrow Br_2 + S_3O_8F_2$

This procedure employing Br_2/SO_2 as the reducing agent can also be applied to the preparation of $Pd(SO_3F)_2$ and $Ba[Pd(SO_3F)_4]$ as well as of $(NO)_2[Pd(SO_3F)_4]$. All reactions proceed to completion at 25°C within a day.

Attempts to study the ionic dissociation of the palladium(II) fluorosulfato complexes in fluorosulfuric acid result in the instantaneous quantitative formation of insoluble polymeric $Pd(SO_3F)_2$ according to:

[9] $Cs_2[Pd(II)(SO_3F)_4] \xrightarrow{HSO_3F} 2Cs^+ + 2SO_3F^- + Pd(II)(SO_3F)_2$

which explains why all initial attempts to obtain tetrakis(fluorosulfato) complexes by reactions in HSO_3F had been unsuccessful.

Interestingly our efforts to extend the reduction method to corresponding platinum(IV) complexes or to $Pt(SO_3F)_4$ were unsuccessful even under more stringent conditions. This failure reflects the differences in oxidizing ability between Pd(IV) and Pt(IV).

(ii) Vibrational Spectra

The brown color of the samples containing the $[Pd(SO_3F)_4]^{2-}$ precluded the recording of Raman spectra. The observed infrared frequencies for $Ba[Pd(SO_3F)_4]$, $(NO)_2[Pd(SO_3F)_4]$, and $Cs_2[Pd(SO_3F)_4]$, as well as for $Cs[Au(SO_3F)_4]$ and the Raman bands for $Cs_2[Pd(SO_3F)_6]$ are listed in Table 1 together with a tentative assignment.

The observed band positions, in particular in the SO and SF stretching range are consistent with the presence of monodentate —OSO_2F groups in complex anions for all complexes. However, the relatively small splitting of the SO_2 stretching frequencies of $\sim 150\,cm^{-1}$, the occurrence of the highest frequency SO stretch at $\sim 1340\,cm^{-1}$, the position of the bridging SO stretch at a relatively high 1000 to $1035\,cm^{-1}$, and the low SF stretch at $800\,cm^{-1}$, all are indicative of the retention of ionic character and weak covalent interaction with the metal in the

tetrakis(fluorosulfato)palladate(II) complexes. Somewhat stronger covalent interaction is apparent for both $[Au(SO_3F)_4]^-$ and $[Pd(SO_3F)_6]^{2-}$, where the central metal has a +3 and a +4 formal oxidation state, but generally some strong similarity in the observed spectra is apparent. The observed band positions for the $[Pd(SO_3F)_4]^{2-}$ complexes are inconsistent with the presence of mere mixtures of $Pd(SO_3F)_2$ and the corresponding ionic fluorosulfates.

Finally, strong ir bands at ~ 650 and 450 cm^{-1} are assigned as M—O skeletal stretching vibrations, but obviously as argued by us previously (2, 11) for similar complexes, strong mixing with SO_3F deformation modes is probably present here as well.

(iii) Magnetic Susceptibilities

Consistent with a square planar environment and a d^8 electron configuration, the tetrakis(fluorosulfato)palladate(II) complexes are found to be diamagnetic. Detailed measurements for $Cs_2[Pd(SO_3F)_4]$ at room temperature give a molar magnetic susceptibility of $-214 \pm 18 \times 10^{-6}$ cgs units per mol. The χ_M value calculated from Pascal's constants of -247×10^{-6} cgs units per mol is in reasonable agreement with the experimental value. Appreciable contributions from temperature independent paramagnetism or from paramagnetic impurities to the molar magnetic susceptibility appear to be absent.

(iv) Electronic Spectra

The observed band positions for $Cs_2[Pd(SO_3F)_4]$ and $Ba[Pd(SO_3F)_4]$ are listed in Table 2 and compared to values for solid $K_2[PdCl_4]$, discussed previously by Gray and Ballhausen (12). All three bands found are assignable to *d–d* transitions, and charge transfer bands found in solution spectra of $[PdCl_4]^{2-}$ at 36 000 and 44 000 cm^{-1} were not observed for the fluorosulfates and are possibly outside the range of our instrument.

TABLE 2. Electronic spectra and ligand field parameters for $[Pd(SO_3F)_4]^{2-}$

	Value (cm^{-1})		
Parameter	$Cs_2[Pd(SO_3F)_4]$	$Ba[Pd(SO_3F)_4]$	$[PdCl_4]^{2-}$
ν_1, $^1A_{1g} \rightarrow {}^1A_{2g}$	−15 400 w	15 400 w	16 700
ν_2, $^1A_{1g} \rightarrow {}^1B_{1g}$	−20 000 s, sh	−20 000 s, sh	21 500
ν_3, $^1A_{1g} \rightarrow {}^1E_{1g}$	22 200 s	−22 700 s	23 300
Charge transfer			36 000
Charge transfer			44 900
Δ_1	17 850	17 850	19 150
Δ_2	6 000	6 000	6 200
Δ_3	1 850	2 350	1 450

Following a procedure previously applied to $PdCl_4^{2-}$ and using assumptions shown in Fig. 1, the ligand field parameters Δ_1, Δ_2, and Δ_3 were calculated and are listed also in Table 2. The Δ_1 value indicative of the energy separation of d_{xy} and $d_{x^2-y^2}$ is at the lower end of such values reported for

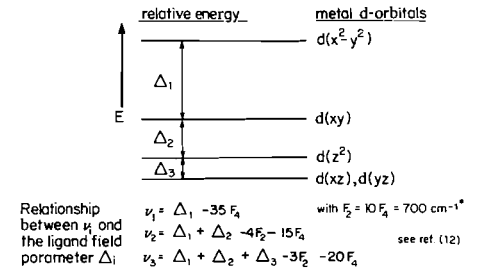

FIG. 1. Energy level diagram for a square planar complex.

For personal use only.

square planar palladium(II) complexes (13), in keeping with the weak field character of the SO_3F group, even in a monodentate environment. Obviously the ligand field parameters so derived for the $[Pd(SO_3F)_4]^{2-}$ ion are rather approximate since the observation of only three spin-allowed bands does not permit an accurate determination of the actual interelectronic repulsion parameter, valid for the complex.

While a direct comparison between ν_1 of $\sim 15\,400\,cm^{-1}$ or Δ_1 of $17\,850\,cm^{-1}$ for the $[Pd(SO_3F)_4]^{2-}$ complexes studied here and the ligand field parameter $10D_q$ for octahedral Pd(II) fluorosulfates (1, 2) found to range from 1105 to 1177 cm^{-1} is rather crude and open to criticism, it seems clear that a monodentate SO_3F group exerts a greater ligand strength than either bi- or tridentate fluorosulfate groups.

Experimental

(*a*) *Chemicals*

Palladium powder, 60 mesh and 99.95% purity, was obtained from Ventron Corporation. Technical grade fluorosulfuric acid from Allied Chemicals was doubly distilled at atmospheric pressure. Bis(fluorosulfuryl)peroxide (14) was synthesized from SO_3 (Allied Chemicals) and F_2 (Air Products) with AgF_2 as catalyst. Bromine was purified by treatment with P_4O_{10} and KBr and distilled before use. The synthesis of complexes containing the $[Pd(SO_3F)_6]^{2-}$ ion has been described previously (2).

(*b*) *Instrumentation*

The infrared spectrophotometer, equipment to record electronic and diffuse reflectance spectra and the Gouy apparatus to measure bulk magnetic susceptibilities have all been described in the two preceding articles in this series (1, 2).

All reactions were performed in Pyrex reaction vials of about 40 mL contents, fitted with Kontes Teflon stem values. Volatile materials were handled using vacuum line techniques. Moisture-sensitive solids were stored and manipulated in a Vacuum Atmosphere Corporation "Dri Lab" Model No. HE-43-2 filled with purified dry nitrogen, equipped with a "Dri Train" Model NO. HE-93-B circulating unit. Filtration of moisture-sensitive materials was carried out in an apparatus described by Shriver (15).

(*c*) *Synthetic Reactions*

(*i*) $Cs_2[Pd(SO_3F)_4]$

$Cs_2[Pd(SO_3F)_6]$ was prepared by the reaction of palladium metal (100 mg, 0.940 mmol) and CsCl (316 mg, 1.877 mmol) with $S_2O_6F_2/HSO_3F$ (2). After all volatile materials were removed *in vacuo*, SO_2 (~4 mL) and Br_2 (~1 mL) were added to the solid. The reaction mixture was stirred at room temperature for 1 day. The removal of all volatile materials gave a light brown material which analyzed as $Cs_2[Pd(SO_3F)_4]$ (721 mg, 938 mmol).

$Cs_2[Pd(SO_3F)_4]$ is a light brown hygroscopic powder which melts with decomposition at ~195°C. It is slightly soluble in HSO_3F, but deposits $Pd(SO_3F)_2$ immediately; the filtered solid shows only the ir spectrum of $Pd(SO_3F)_2$. *Anal.* calcd. for $Cs_2[Pd(SO_3F)_4]$: Cs 34.59, Pd 13.85, S 16.69, F 9.89; found: Cs 34.68, Pd 13.66, S 16.54, F 10.01.

(*ii*) $Ba[Pd(SO_3F)_4]$

In a manner analogous to the preparation of $Cs_2[Pd(SO_3F)_4]$ (196 mg, 0.941 mmol), $Ba[Pd(SO_3F)_6]$, prepared from the reaction of $BaCl_2$ and palladium metal (100 mg, 0.940 mmol) with $S_2O_6F_2/HSO_3F$, was reduced with a mixture of Br_2/SO_2 to give a compound suggesting the formulation of $Ba[Pd(SO_3F)_4]$ (602 mg, 0.941 mmol).

$Ba[Pd(SO_3F)_4]$ is a very light brown hygroscopic powder. It decomposes at ~200°C to a purple solid. It is insoluble in HSO_3F. *Anal.* calcd. for $Ba[Pd(SO_3F)_4]$: Ba 21.46, Pd 16.63, S 20.04, F 11.88; found: Ba 21.22, Pd 16.82, S 20.03, F 11.92. $(NO)_2[Pd(SO_3F)_4]$ can also be prepared in a similar manner.

Acknowledgement

Financial support by the Natural Sciences and Engineering Council of Canada in form of an operating grant and a postgraduate scholarship to one of us (K.C.L.) is gratefully acknowledged. Microanalyses on $Cs_2[Pd(SO_3F)_4]$ and on $Ba[Pd(SO_3F)_4]$ were performed by Analytische Laboratorien, vorm. A. Bernhardt, Gummersbach, West Germany.

Excess volumes of binary mixtures of tetrahydrofuran with various hydrocarbons at 313.15 K

S. K. SURI

Chemistry Department, Indian Institute of Technology, New Delhi 110016, India

Received January 6, 1981

S. K. SURI. Can. J. Chem. **59**, 2839 (1981).

Molar excess volumes of binary mixtures of tetrahydrofuran with *n*-propylbenzene, isopropylbenzene, 1,3,5-trimethylbenzene, 1,2,3,4-tetramethylbenzene, diphenylmethane, *n*-hexane, *n*-octane, 2,2,4-trimethylpentane, *n*-nonane, 3,3-diethylpentane, *n*-dodecane, 2,2,4,6,6-pentamethylheptane, cyclohexane, and methylcyclohexane at 313.5 K have been computed from the experimental density data. The systematic variation of V^E with the change in size, substitution, and molecular geometry of the hydrocarbon has been discussed.

S. K. SURI. Can. J. Chem. **59**, 2839 (1981).

A partir des données expérimentales de densité, on a calculé à 313,15 K les volumes molaires en excès des mélanges binaires de tétrahydrofuranne avec les composés suivants: *n*-propylbenzène, isopropylbenzène, triméthyl-1,3,5 benzène, tétraméthyl-1,2,3,4 benzène, diphénylméthane, *n*-hexane, *n*-octane, triméthyl-2,2,4 pentane, *n*-nonane, diéthyl-3,3 pentane, *n*-dodécane, pentaméthyl-2,2,4,6,6 heptane, cyclohexane et méthylcyclohexane. On discute de la variation systématique de V^E avec les variations de la grosseur, de la substitution et de la géométrie moléculaire de l'hydrocarbure.

[Traduit par le journal]

Introduction

In the earlier papers, we reported the excess volumes for the binary mixtures of tetrahydrofuran with alcohols (1), amides (2), various aliphatic compounds having different functional groups (3), and a few aromatic hydrocarbons, namely benzene, toluene, ethylbenzene, and the isomeric xylenes (4). As an extension of that work, we have determined the excess volumes for the mixtures of tetrahydrofuran with *n*-pyropylbenzene, isopropylbenzene, 1,3,5-trimethylbenzene, 1,2,3,4-tetramethylbenzene, diphenylmethane, *n*-hexane, *n*-octane, 2,2,4-trimethylpentane, *n*-nonane, 3,3-diethylpentane, *n*-dodecane, 2,2,4,6,6-pentamethylheptane, cyclohexane, and methylcyclohexane. The purpose of these investigations is to provide some information about the thermodynamic properties of tetrahydrofuran–hydrocarbon mixtures with a view to understand the factors determining the unlike interactions between molecules in such mixtures.

Experimental

Fisher (A.C.S. Certified) tetrahydrofuran was purified by the procedure described in the earlier paper (4). The samples of *n*-nonane (ir and gc analysed grade) supplied by Aldrich, and 3,3-diethylpentane supplied by Chemical Samples Company, OH, were dried over molecular sieves and fractionally distilled at a reflux ratio of 1:10 immediately before use. The densities and refractive indexes of tetrahydrofuran, *n*-nonane, and 3,3-diethylpentane have been compared with the accepted literature values (5–7) in Table 1. The purification procedure and criterion of purity of other hydrocarbons used in the present investigations have been described elsewhere (8).

The molar excess volumes of mixing, V^E, were calculated from the experimental density data. The solutions for the measurement of densities were prepared by weight, and the corrections for buoyancy were applied. The densities were measured with a vibrating flow densitometer (Sodev. Inc.). The details of the experimental technique for the preparation of solutions and measurement of densities have been described earlier (8). Each data point reported is an average of at least two different measurements. Duplicate densities agreed to within 1×10^{-5} g cm^{-3}. The maximum uncertainty in the molar excess volumes is expected to be less than ± 0.005 cm^3 mol^{-1}.

Results and Discussion

V^E values for the binary mixtures at 313.15 K are recorded in Table 2 and a graphical representation is given in Figs. 1–3. The data have been fitted to a smoothing equation:

$$[1]\quad V^E/(\text{cm}^3\ \text{mol}^{-1}) = X_1(1 - X_1)[A + B(2X_1 - 1) + C(2X_1 - 1)^2 + D(2X_1 - 1)^3]$$

where X_1 is the mole fraction of tetrahydrofuran. Values of the parameters A, B, C, and D and the standard deviations for the excess volumes, $\sigma(V^E)$, are given in Table 3.

It is observed from Figs. 1–3 that V^E varies almost symmetrically with the mole fraction of tetrahydrofuran (and shows a maximum somewhere between $X_{THF} = 0.4$ to 0.6) for all the binary mixtures studied except those containing *n*-hexane and 2,2,4-trimethylpentane. The V^E versus composition plots for these two binary mixtures are skewed towards the hydrocarbon and tetrahydrofuran axis respectively (Fig. 2). Geier and Bittrich (9) reported V^E for tetrahydrofuran solutions containing *n*-hexane and cyclohexane at 313.15 K. For *n*-hexane solutions, their results show a symmetrical V^E versus compo-

TABLE 1. Densities and refractive indexes of some liquids

Liquid	Density at 313.15 K (g cm^{-3}) Our value	Density at 313.15 K (g cm^{-3}) Literature value	Refractive index at 298.15 K Our value	Refractive index at 298.15 K Literature value
Tetrahydrofuran	0.86567	0.86554 (ref. 4)	1.4048	1.40474 (ref. 5)
n-Nonane	0.70235	0.7020 (ref. 6)	1.4032	1.40311*
3,3-Diethylpentane	0.73908	0.73923*	1.4185	1.41837*

*Extrapolated value from data given in ref. 7.

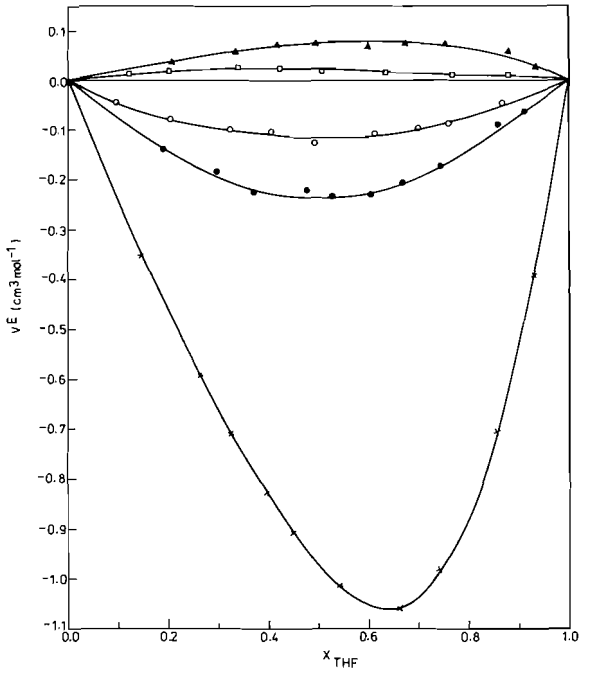

FIG. 1. Molar excess volumes of mixing at 313.15 K for the binary mixtures of tetrahydrofuran (THF) + *n*-propylbenzene (○), + isopropylbenzene (●), + 1,3,5-trimethylbenzene (▲), + 1,2,3,4-tetramethylbenzene (□), and + diphenylmethane (×).

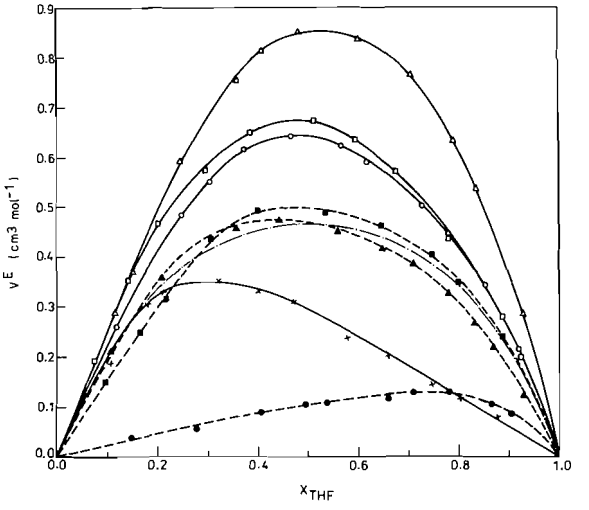

FIG. 2. Molar excess volumes of mixing at 313.15 K for the binary mixtures of tetrahydrofuran (THF) + *n*-hexane (×), + *n*-octane (○), + 2,2,4-trimethylpentane (●), + *n*-nonane (□), + 3,3-diethylpentane (■), + *n*-dodecane (△), and + 2,2,4,6,6-pentamethylheptane (▲). ------ Geier and Bittrich values for THF + *n*-hexane mixtures (ref. 9).

sition plot. Their V^E values for the two sets of binary mixtures are consistently higher over the entire composition range than the ones reported by us. A similar observation was made by us for tetrahydrofuran solutions containing benzene (4). Excess volumes for tetrahydrofuran + cyclohexane mixtures reported by Geier and Bittrich (9) at 298.15 K show poor agreement with the other available literature values (10–12) whereas their data at 303.15 K show a reasonably good agreement with the report of Deshpande and Oswal (13). To the best of our knowledge, no V^E data have been reported in the literature for the other binary mixtures considered in this paper.

It is established that the sign and magnitude of V^E give a good estimate of the strength of the unlike

interactions in a binary mixture (14). Large positive V^E's are taken as indicative of weak intermolecular interactions whereas large negative values of V^E are usually found when these interactions are strong and intermolecular "complexes" are believed to be present. We considered it worthwhile to compare the V^E values at equimolar concentration for the binary mixtures of tetrahydrofuran with some hydrocarbons. In Fig. 4, excess volumes at the equimolar concentration, $V^E_{0.5}$, has been plotted as a function of the number of carbon atoms in the hydrocarbon. A plot of $V^E_{0.5}$ versus molar volume of the hydrocarbon yields a similar plot. Our results lead to the following conclusions:

Cyclic Hydrocarbons

The n–π interactions: it is observed that a marked change in V^E occurs on changing from cyclohexane to benzene, which is indicative of specific interactions occurring between the lone pair of the electrons on the oxygen atom of tetrahydrofuran and the π-electron system of benzene. These interactions appear to be fairly strong.

Substituted Benzenes

The methyl substitution in cyclohexane or benzene produces structural changes in the hydrocarbon and in the case of benzene, a weakening of the like π–π interactions, resulting in increased n–π interactions. A comparison of curve *A* and the first part of curve *E* of Fig. 4 suggests that the volumetric effects caused by structural changes predominate over the change in n–π interactions caused by methyl substitution.

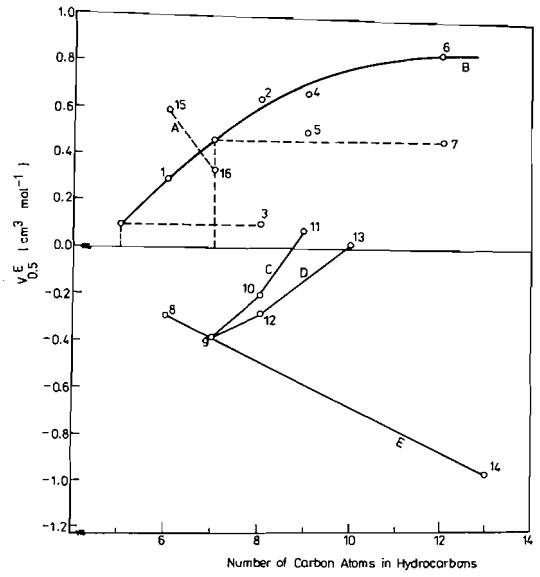

FIG. 4. Excess volumes at equimolar concentration, $V^E_{0.5}$ at 313.15 K plotted against the number of carbon atoms in the hydrocarbon: (*1*) *n*-hexane, (*2*) *n*-octane, (*3*) 2,2,4-trimethylpentane, (*4*) *n*-nonane, (*5*) 3,3-diethylpentane, (*6*) *n*-docecane, (*7*) 2,2,4,6,6-pentamethylheptane, (*8*) benzene (data from ref. 4), (*9*) toluene (data from ref. 4), (*10*) *m*-xylene (data from ref. 4), (*11*) *o*-xylene (data from ref. 4), (*12*) 1,3,5-trimethylbenzene, (*13*) 1,2,3,4,-tetramethylbenzene, (*14*), diphenylmethane, (*15*) cyclohexane, and (*16*) methylcyclohexane.

We find that when substitution in the benzene ring is restricted to one alkyl group, V^E increases for mixtures of tetrahydrofuran with the *n*-alkylbenzenes in the series from toluene to *n*-propylbenzene which is indicative of a significant decrease in n–π interactions. The effect on the π-electron density due to increase in the size of the alkyl substituents from methyl to *n*-propyl is relatively small, we may attribute the increase in V^E to: (*i*) the decrease in aromatic proportion of the total molecule, and (*ii*), the decrease in n–π interactions resulting from decrease in the number of contacts (due to increase in distance of closest approach) between the tetrahydrofuran and the aromatic part of the hydrocarbon because of the structural changes in the aromatic ring produced by alkyl substitution. Thus, although increasing the length of the side chain is likely to make the molecule more polarizable, and presumably therefore more strongly interacting through dispersion forces with the tetrahydrofuran molecule, V^E increases rather than decreases for the reasons given above.

The substitution of a second methyl group to benzene, likewise, because of structural changes in the ring, increases the distance of closest approach of the tetrahydrofuran and the hydrocarbon molecules, resulting in a decrease in n–π interactions, the magnitude of which is determined by the position of the substituent methyl group. It is observed that the value of V^E is higher for solutions containing *m*-xylene and *o*-xylene as compared to those containing *p*-xylene where we expect minimum steric repulsion. The substitution of a methyl group at the *meta* position deactivates the aromatic ring for n–π interactions as compared to substitution at *ortho* position (15). The plots of $V^E_{0.5}$ versus number of methyl groups on the ring (curves *C* and *D* of Fig. 4) are linear in each case. This further supports the conclusion that the volumetric effects caused by structural changes are significant in the binary solutions of tetrahydrofuran. The smaller V^E for isopropylbenzene solutions as compared to *n*-propylbenzene solutions may possibly be due to the steric factors facilitating the packing of the isopropylbenzene molecules in the tetrahydrofuran lattice. Diphenylmethane, because of the large

aromatic proportion in the molecule, offers appreciable volumetric effects as expected (curve *E*, Fig. 4).

n-*Alkanes*

The binary solutions of tetrahydrofuran with *n*-alkanes show expansion on mixing. The magnitude of V^E in these solutions increases sharply initially with the number of carbon atoms in the straight chain and has a tendency to reach a limiting positive value (curve *B* of Fig. 4). This feature for solutions containing *n*-alkanes is also observed from the data for solutions containing benzene (16), tetrabutyltin (17), triethylamine (8), alkyl nitriles (18), etc. The initial trend in the increase in V^E with number of C-atoms in the *n*-alkane chain can be explained on the basis of the packing property and the shape of the straight-chain molecules which allow them to fit into the lattice of the other component. Nevertheless, it is apparent that the volumetric behaviour of solutions containing higher *n*-alkanes is not solely due to the large size of the *n*-alkane molecule.

Branched Chain Alkanes

The solutions containing methyl substituted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

structural isomers exhibit smaller V^E values than those containing *n*-alkanes. The excess volumes for solutions of 2,2,4-trimethylpentane and 2,2,4,6,6-pentamethylheptane are of the same order of magnitude as one would expect for *n*-pentane and *n*-heptane respectively (from curve *B* of Fig. 4). A similar observation was made by plotting data for alkane solutions of tetrabutyltin (17) and of triethylamine (8). It is therefore evident that the magnitude of V^E in these solutions is determined by the chain length of the alkane molecule and the number of methyl substitutions in the molecule plays an almost insignificant role (8). This, however, does not hold when a relatively bulky alkyl group is substituted in the *n*-alkane chain as is apparent from V^E values for 3,3-diethylpentane solutions. Apparently the lattice of tetrahydrofuran is large enough to allow similar packing affinity to a methyl substituted alkane molecule as it does to an *n*-alkane molecule having the same chain length. This is not true for ethyl-substituted alkane molecules for steric reasons.

MICHAEL J. BLANDAMER, JOHN BURGESS, PHILIP P. DUCE, ROSS E. ROBERTSON, and JOHN W. M. SCOTT. Can. J. Chem. **59**, 2845 (1981).

The dependence on temperature of the acid dissociation constants in water for a range of carboxylic acids has been fitted to the Gurney equation using a modified Gauss–Newton method. The equation fits the data reasonably well and identifies the dependence on temperature of the electrical and non-electrical contributions to ln K.

MICHAEL J. BLANDAMER, JOHN BURGESS, PHILIP P. DUCE, ROSS E. ROBERTSON et JOHN W. M. SCOTT. Can. J. Chem. **59**, 2845 (1981).

On a introduit, dans l'équation de Gurney en utilisant une méthode de Newton-Gauss modifiée, l'effet de la température sur les constantes de dissociation dans l'eau d'une série d'acides carboxyliques. L'équation s'ajuste raisonnablement bien aux données et dentifie l'effet de la température sur les contributions électriques et non électrique à ln K.

[Traduit par le journal]

Over many years, extensive efforts have been aimed at formulating equations which describe the dependence of acid dissociation constants, K, on temperature (1). For the most part these equations have expressed the dependence of ln K on temperature T, in an equation which contains several terms each being a different function of T. Moreover, these equations have often been written in such a way that the data can be fitted to the final expression using a linear least-squares technique. A rather different approach to the problem is to start out with a model which attempts to describe those factors which determine the value of K at temperature T. Thus Gurney (2) suggested that ln K for a given acid is determined by two contributions arising from electrical interaction between solutes and solvent and from other non-electric forces. In this way, Gurney attempted to account for the observation that in many cases plots of ln K against T show a maximum value at some temperature, T_m, characteristic of the acid. The resulting equation, the Gurney equation, contains three parameters, C, a, and the Gurney temperature θ (eq. [1]).

$$[1] \quad \ln K = -C[a + \exp(T/\theta)]/T$$

This equation can be rewritten as follows:

$$[2] \quad \ln K = a_1T^{-1} + a_2T^{-1} \exp(T/\theta)$$

Although the Gurney equation is often mentioned in the literature, as far as we are aware no attempt has been made to fit the data to either eqs. [1] or [2] in any quantitative fashion apart from various comments on the general dependence of the two terms in eq. [2] on temperature. An explanation of this omission stems from the observation that the analysis cannot be based on a conventional least-squares technique to yield estimates of a_1, a_2, and θ. This paper reports the results of an attempt to fit the data for several acids to eq. [2].

Analysis

The basis of analysis described here is the Gauss–Newton method (3) which, starting with guessed values of a_1, a_2, and θ, obtains the estimates of these parameters which minimise the residual sum of squares, $[\ln K(\text{obs}) - \ln K(\text{calcd})]^2$. A computer program (FORTRAN-CDC Cyber 73 at the University of Leicester) contained subroutines which calculated the first and second derivatives of ln K with respect to a_1, a_2, and θ. The assumption is made that the local minimum obtained from a range of initial estimates is also the global minimum (3). From the best-fitted parameters the dependences on temperature of both a_1T^{-1} and $a_2T^{-1} \exp(T/\theta)$ were calculated.

Results

The results of the analysis are summarised in Table 1 for 15 carboxylic acids in water. We also

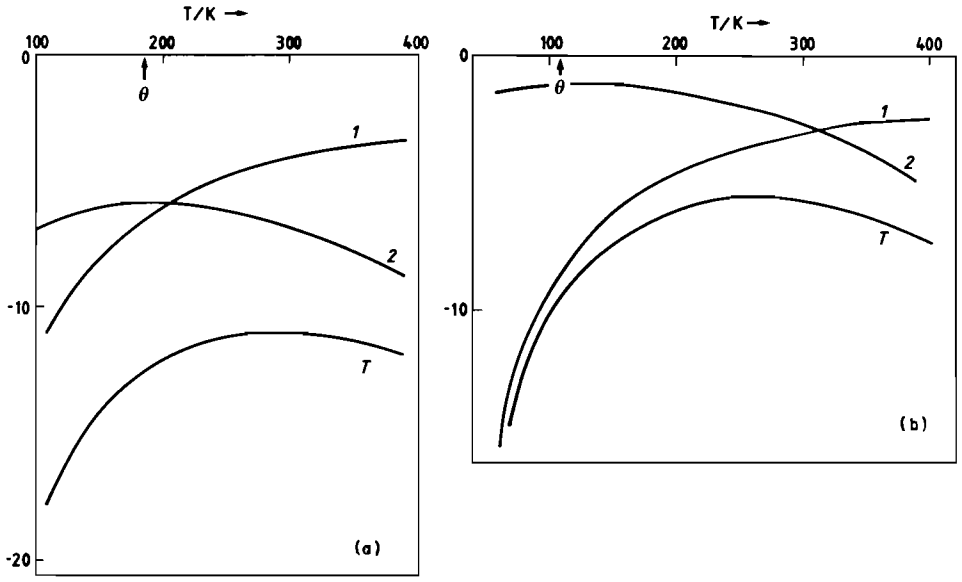

FIG. 1. Analysis of the dependence on temperature of ln K for (*a*) acetic and (*b*) cyanoacetic acids in water. Curve *1* shows the dependence on temperature of a_1T^{-1}, curve *2* shows that for $a_2T^{-1}\exp(T/\theta)$, and curve *T* indicates the dependence of their sum on temperature.

include for comparison the parameters calculated for the self-dissociation of water and deuterium oxide but we will not comment on these further because the chemical process is quite different, and it is not obvious that Gurney included these systems in his analysis. The fit, as measured by the residual sum of squares, is satisfactory.

The dependences on temperature of both a_1T^{-1} and $a_2T^{-1}\exp(T/\theta)$ for cyanoacetic and acetic acids in water are shown in Fig. 1 together with the

sum of the two curves over an extended temperature range to include θ where $a_2T^{-1}\exp(T/\theta)$ is a maximum. Thus for acetic acid, the non-electrostatic term shifts the maximum from 184 K to around 298 K, bringing it within the measured range. For cyanoacetic acid, θ is lower and hence the resulting curve (Fig. 1*b*) has its maximum near 270 K, just below the measured range.

Discussion

The most striking feature is the ability of the eqs. [1] and [2] to fit the data for a range of systems having quite marked differences in their dependence of ln K on T. Nonetheless, the residual sum of squares is, in all cases, larger than that obtained if the data are fitted using three parameters using, for example, the Valentiner (4) or the Clarke–Glew (5) equations. Thus for cyanoacetic acid, the residual sum of squares obtained from the latter two equations is 0.22×10^{-5}. In general we find that the residual sum of squares is only slightly larger than that obtained from the Valentiner equation, an equation which is less constrained than the Gurney equation. However, the optimism generated by these comments is dispelled to some extent following examination of the derived parameters in light of the points made by Gurney (2). Thus it is assumed that the non-electrical contribution to $\Delta G^\ominus$ ($= -RT \ln K$) is independent of temperature; the dependence of $\Delta G^\ominus$ on temperature is related to the temperature-dependent relative permittivity of the solvent, ε_r. For a range of solvents, ε_r^{-1} is directly proportional to $\exp(T/\theta)$ where θ is a characteristic property of the solvent (2). A plot of $-\exp(T/\theta)/T$ passes through a maximum at θ. When this electrical contribution is combined with the non-electrical contribution, the actual maximum in ln K is shifted away from θ (Fig. 1). For water, θ is 219 K but the maximum in ln K for acetic acid is shifted to 298 K. However, for cyanoacetic acid, the shift is less marked and so the maximum is below 273 K. However, the theory requires (2) that for all acids in water θ should be constant at 219 K (218 K for D_2O). This turns out not to be the case, and in most systems the calculated value is less than the theoretical value. Nonetheless, the disagreement is certainly not marked with the possible exception of fluoroacetic acid. Thus of the 15 carboxylic acids, 9 have values of θ within 50 K of the required temperature. Perhaps the most dramatic assumption in the Gurney treatment is the independence of temperature for the non-electrical contributions to $\Delta G^\ominus$. Unfortunately, even with the increase in understanding of solute–solvent interactions in aqueous systems, it is still not strikingly obvious how this equation should be modified. In this sense our criticism of the Gurney equation is not so harsh as that advanced by King (1), whose comments were based on a qualitative examination of the data. Moreover, the Gurney equation may provide a convenient basis for calculating ln K at other temperatures using the derived parameters.

The 1,3-dimethoxytrimethylene bridge as two latent carboxyl groups: synthesis of *cis*-isoaposantenic and *cis*-apocamphoric acids

PELAYO CAMPS[1] AND CARLOS JAIME

Departamento de Química Orgánica, Universidad Autónoma de Barcelona, Bellaterra, Barcelona, Spain

Received February 16, 1981

PELAYO CAMPS and CARLOS JAIME. Can. J. Chem. **59**, 2848 (1981).

The syntheses of *cis*-cyclopentane-1,3-dicarboxylic acid, *cis*-cyclohexane-1,3-dicarboxylic acid, *cis*-isoaposantenic acid, and *cis*-apocamphoric acid are described. The key step of each synthesis is the bromine oxidation of an appropriate bicyclic compound in which a 1,3-dimethoxytrimethylene bridge is converted into two *cis*-carboxyl groups.

PELAYO CAMPS et CARLOS JAIME. Can. J. Chem. **59**, 2848 (1981).

On décrit la synthèse des acides suivants: cyclopentane dicarboxylique-1,3 *cis*, cyclohexane dicarboxylique-1,3 *cis* isoaposanténique *cis* et apocamphorique *cis*. L'étape principale de chaque synthèse est l'oxydation par le brome d'un composé bicyclique approprié dans lequel un pont diméthoxy-1,3 triméthylène est transformé en deux groupes carboxyliques *cis*.

We have recently described a one-step synthesis of 2,4-dialkoxybicyclo[3.*n*.1]alkan-(*n*+6)-ones (*n* = 2, 3) (1, 2). We describe in this communication the easy, one-pot, medium yield bromine oxidation of the 1,3-dimethoxytrimethylene bridge to two *cis*-carboxyl groups.

This transformation could be carried out in three steps by cleavage of the ether functions at the methyl–oxygen bond, oxidation of the 1,3-diol to a 1,3-diketone, and haloform reaction. Although in recent years several sophisticated methods to selectively cleave dialkyl ethers have been described (Me_3SiI (3), BBr_3 (4)), the expected yield for such a three-step transformation would be low. Deno and Potter (5) reported the oxidation of dialkyl ethers to carbonyl compounds in moderate to good yields, depending on the particular substrates, by reaction with bromine in aqueous solution at pH 5 (acetic acid – sodium acetate buffer). Carrying out this reaction on a bicyclic compound having a 1,3-dimethoxytrimethylene bridge, followed by an haloform reaction, a *cis*-cycloalkane-1,3-dicarboxylic acid could conceivably be obtained and possibly in a one-pot reaction. The simplicity of the method makes it attractive in spite of the expected low yield.

We have studied the reaction of 2,4-dimethoxybicyclo[3.2.1]octane,[2] **1***a*, with bromine, first in aqueous buffer solutions at different pH and then in alkaline medium. After the work-up described in the Experimental, we have isolated either *cis*-cyclopentane-1,3-dicarboxylic acid, **5***a*, or its dimethyl ester, **5***b*. The yields of **5***a* or **5***b* obtained from **1***a* show a great dependence on the pH of the solution before the haloform reaction, the best results being obtained at pH 6–7 or, even better, using deficiency of buffer solution of pH 7–8, which makes the solution become acidic during the course of the reaction. The yields of the products isolated from the reaction of **1***a* with bromine at different pH conditions before the haloform reaction are shown in Table 1.

As by-products, we isolated in some of these reactions variable amounts (5–31.5%) of 3-(2,2-dibromoethenyl)cyclopentanecarboxylic acid, **9***a*, or its methyl ester, **9***b*, depending on the work-up. Both must be *cis* because of their origin, and on one occasion we isolated, in 8.5% yield, 3-bromobicyclo[3.2.1]oct-3-en-2-one, **10**. Compounds **9***a* and **10** might have been formed as depicted in Scheme 2, which implies that α-keto bromination takes place, at least in part, before the complete oxidation of the ether functions. No defined products were isolated when the reaction of **1***a* with bromine was carried out in a 1.2 *M* HBr aqueous solution. As can be seen from Table 1, we isolated 44.0% yield of **5***a* by reaction of 2,4-diethoxybicyclo[3.2.1]octane, **1***b*, with bromine using a deficiency of buffer solution of pH 7, which indicates that the 1,3-diethoxytrimethylene bridge can also be used as two latent carboxyl groups.

The reactions of 2,4-dimethoxybicyclo[3.3.1]nonane, **2**, *syn*-2,4-dimethoxy-8-methylbicyclo[3.2.1]octane, **3**, and 2,4-dimethoxy-8,8-dimethylbicyclo[3.2.1]octane, **4**, with bromine using deficiency or excess of buffer solution of pH 7

[1]Author to whom correspondence may be addressed.

[2]Compounds **1***a*, **3**, **4**, **14**, and **15** are mixtures of stereoisomers prepared as described in the Experimental from **12***a*, which in turn is a mixture of stereoisomers in which the nonsymmetric ones are the major components (1, 2). The same applies to **1***b* obtained from **12***b* and to **2** obtained from **13** (1, 2).

SCHEME 1

followed by haloform reaction and esterification gave medium yields of the corresponding dicarboxylic esters, dimethyl *cis*-cyclohexane-1,3-dicarboxylate, **6***b*, dimethyl (1*R*, 2*s*, 3*S*)-2-methylcyclopentane-1,3-dicarboxylate, **7***b*, and dimethyl *cis*-2,2-dimethylcyclopentane-1,3-dicarboxylate, **8***b*, respectively (see Table 1). Hydrolysis of compounds **6***b*, **7***b*, and **8***b* gave the known dicarboxylic acids **6***a*, **7***a*, and **8***a*, respectively.

Noteworthy is the isolation in 38% yield of 3-bromobicyclo[3.3.1]nonan-2,4-dione, **11**, which exists essentially in the enol form, from the reaction of **2** with bromine using excess buffer solution of pH 7 before the haloform reaction.

Compounds **1***a*, **1***b*, and **2** were prepared by Wolff–Kishner reduction of 2,4-dimethoxybicyclo[3.2.1]octan-8-one (1), **12***a*, 2,4-diethoxybicyclo[3.2.1]octan-8-one (1), **12***b*, and 2,4-dimethoxybicyclo[3.3.1]nonan-9-one (2), **13**, respectively (see Scheme 3). Compounds **3** and **4** were prepared from **12***a* by the sequence depicted in Scheme 3. Wittig reaction of **12***a* with methylenetriphenylphosphorane gave 2,4-dimethoxy-8-methylenebicyclo[3.2.1]octane, **14**, which on hydrogenation gave **3**. Compound **3** must be *syn* because of its correlation with **7***a*. Simmons–Smith reaction of **14** with methylene iodide and Zn gave 2,4-dimethoxy-8,8-ethylenebicyclo[3.2.1]octane, **15**, which on hydrogenation gave **4**.

Thus, the use of the 1,3-dimethoxytrimethylene bridge as two latent carboxyl groups has allowed us to bring about the first total synthesis of *cis*-isoaposantenic acid (6), **7***a*, and *cis*-apocamphoric acid (7), **8***a*, products previously obtained by degradation of natural products. Further work is in progress in order to apply this latent functionality.

[a]Where not indicated, yield refers to chromatographed product.
[b]Chromatographed and distilled product.
[c]Chromatographed and crystallized or crystallized product.

Experimental

Infrared spectra were recorded on a Perkin-Elmer spectrophotometer model 720, mass spectra on a Hewlett-Packard spectrometer model 5930A, and nmr spectra on a Perkin-Elmer spectrometer model R-12A. Chemical shifts are given in ppm relative to internal TMS (δ scale). Melting points were determined on a Kofler hot-stage and are corrected.

*2,4-Dimethoxybicyclo[3.2.1]octane, 1*a

In a 50 mL flask to which a distillation apparatus was connected, 2.042 g (11.1 mmol) of **12***a*, 2.0 g (32.7 mmol) of 80% $NH_2NH_2.H_2O$, and 2.67 g (46.7 mmol) of KOH in 18 mL diethyleneglycol were placed. The mixture was heated at 110°C for 1 h and at 180°C for 17 h. Water (25 mL) was added to the cold solution and it was extracted with CH_2Cl_2 (4 × 20 mL). Evaporation of the dried organic extracts and distillation gave 1.65 g (9.72 mmol) of **1***a*, bp 110–120°C (oven)/18 Torr, 87.6% yield; ir: spectrum not definitive; nmr (CCl_4), δ: 3.8–3.0 (broad), 3.17 (s) (total 8H), 2.5–2.1 (broad, 2H), 2.1–0.9 (broad, 8H); ms: 139 (M^+ − MeO, 3), 138 (M^+ − MeOH, 10), 107 (M^+ − MeOH − MeO, 6), 106 (M^+ − 2MeOH, 5), 103 (MeO—$\overset{+}{C}$H—CH_2—CH_2—OMe, 87), 101 (MeO—$\overset{+}{C}$H—CH=CH—OMe, 100), 71 (MeO—$\overset{+}{C}$H—CH=CH_2, 76). *Anal.* calcd. for $C_{10}H_{18}O_2$: C 70.55, H 10.66; found: C 70.69, H 10.68.

*2,4-Diethoxybicyclo[3.2.1]octane, 1*b

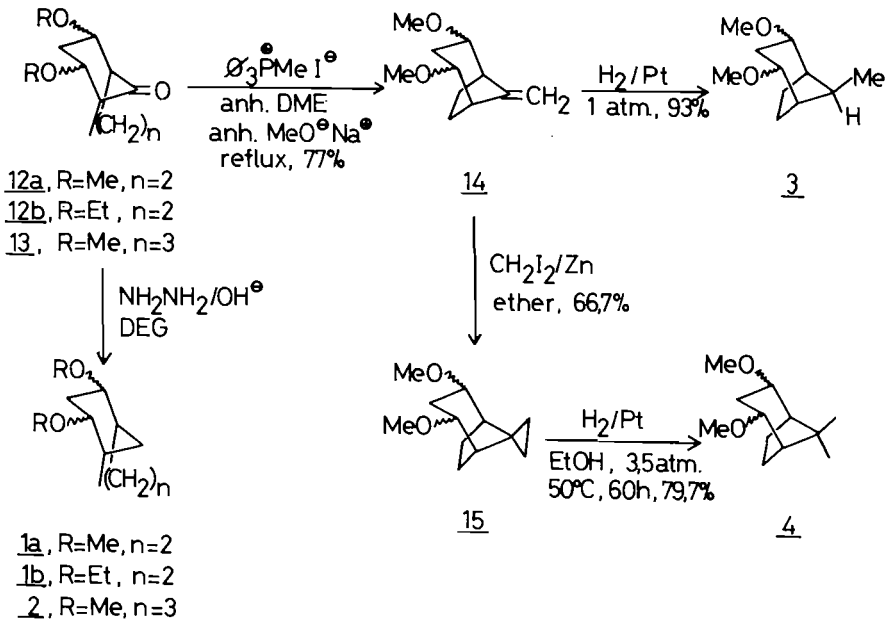
The title compound was prepared as described for **1***a*. From 1.15 g (5.45 mmol) of **12***b*, 0.65 g (3.3 mmol) of distilled **1***b* was obtained, bp 128–132°C (oven)/16 Torr, 61% yield; ir: spectrum not definitive; nmr (CCl_4), δ: 3.7–3.1 (complex m, 6H), 2.25 (broad, 2H), 2.1–1.0 (broad), 1.12 (t, J = 7 Hz) and 1.10 (t, J = 7 Hz) (total 14 H); ms: 198 (M^+, 2), 152 (M^+ − EtOH, 79), 131 (EtO—$\overset{+}{C}$H—CH_2—CH_2—OEt, 28), 129 (EtO—$\overset{+}{C}$H—CH=CH—OEt, 100), 85 (EtO—$\overset{+}{C}$H—CH=CH_2, 36). *Anal.* calcd. for $C_{12}H_{22}O_2$: C 72.68, H 11.18; found: C 71.74, H 11.14.

2,4-Dimethoxybicyclo[3.3.1]nonane, 2

The title compound was prepared as described for **1***a*. From 2.17 g (11 mmol) of **13**, 1.85 g (10.1 mmol) of distilled **2** was obtained, bp 95–100°C (oven)/12 Torr, 92% yield; ir: spectrum not definitive; nmr ($CDCl_3$), δ: 3.8–3.0 (broad), 3.31 (s), 3.29 (s) (total 8H), 2.5–1.0 (broad, 12H); ms: 184 (M^+, 3), 152 (M^+ − MeOH, 50), 103 (MeO—$\overset{+}{C}$H—CH_2—CH_2—OMe, 73), 101 (MeO—$\overset{+}{C}$H—CH=CH—OMe, 100), 71 (MeO—$\overset{+}{C}$H—CH=CH_2, 65). *Anal.* calcd. for $C_{11}H_{20}O_2$: C 71.70, H 10.94; found: C 71.53, H 10.79.

2,4-Dimethoxy-8-methylenebicyclo[3.2.1]octane, 14

In a one-liter three-necked flask fitted with mechanical stirrer, reflux condenser, and argon atmosphere, 400 mL of anhydrous DME and 6.23 g (115 mmol) of anhydous sodium methoxide were placed. Methyltriphenylphosphonium iodide (46.1 g, 114 mmol) was slowly added (30 min) and the mixture was heated at reflux for 2 h. Then 7.0 g (38 mmol) of **12***a* in 20 mL of anhydrous DME was added at once and reflux was continued for 21 h. Four hundred milliliters of water were added and the mixture was extracted with hexane (3 × 150 mL). Evaporation of the dried hexane extracts and distillation of the residue gave 5.35 g (29.4 mmol) of **14**, bp 80–85°C (oven)/12 Torr, 77% yield; ir (CCl_4), ν: 3025 (m), 1095 (vs) cm^{-1}; nmr (CCl_4), δ: 4.7–4.5 (broad, 2H), 3.7–3.2 (broad), 3.23 (s) (total 8H), 2.62 (broad, 2H), 2.1–1.1 (broad, 6H); ms: 182 (M^+, 1), 167 (M^+ − Me, 1.5), 150 (M^+ − MeOH, 100), 135 (6), 124 (61), 118 (M^+ − 2MeOH, 85), 109 (54), 101 (MeO—$\overset{+}{C}$H—CH=CH—OMe, 58), 94 (61), 91 (58), 79 (55). *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.14, H 9.66.



SCHEME 3

syn-2,4-Dimethoxy-8-methylbicyclo[3.2.1]octane, 3

A solution of 0.266 g (1.46 mmol) of **14** in 5 mL ethyl acetate was hydrogenated at atmospheric pressure using 25 mg PtO_2 as catalyst in 15 min. Filtration of the suspension through 1 g silica gel and evaporation of the solvent gave 0.249 g (1.35 mmol) of **3**, bp 90–95°C (oven)/20 Torr, 93% yield; ir: spectrum not definitive; nmr (CCl_4), δ: 3.8–3.2 (broad), 3.30 (s), 3.28 (s) (total 8H), 2.4–0.9 (broad), 1.24 (d, J = 8 Hz) (total 12H); ms: 184 (M^+, 2), 152 (M^+ − MeOH, 17), 101 (MeO—$\overset{+}{C}$H—CH=CH—OMe, 100), 71 (MeO—$\overset{+}{C}$H—CH=CH_2, 58). *Anal.* calcd. for $C_{11}H_{20}O_2$: C 71.70, H 10.94; found: C 71.62, H 10.89.

2,4-Dimethoxy-8,8-ethylenebicyclo[3.2.1]octane, 15

In a 250-mL three-necked flask fitted with mechanical stirrer, addition funnel, reflux condenser, and N_2 atmosphere, 7.25 g (110 mmol) Zn dust, 1.08 g (5.5 mmol) of Cu_2Cl_2, and 60 mL anhydrous ether were placed. The suspension was refluxed for 1 h and 2.0 g (11 mmol) of **14** were introduced, then 14.72 g (55 mmol) of CH_2I_2 were slowly added (1 h) and the mixture was refluxed for 16 h. To the cold mixture (ice was introduced), 60 mL of 3*N* HCl and 16 mL concentrated HCl were added. The organic phase was separated and the aqueous one was extracted with ether (3 × 60 mL). The combined extracts were successively washed with 1 *N* HCl (3 × 20 mL), saturated $NaHCO_3$ aqueous solution (2 × 10 mL), and water (2 × 10 mL). Evaporation of the dried extracts gave 1.92 g of crude product which was filtered through 20 g silica gel (ether as eluent) and distilled to give 1.44 g (7.34 mmol) of **15**, bp 128–132°C (oven)/15 Torr, 66.7% yield; ir: spectrum not definitive; nmr (CCl_4), δ (external TMS): 3.9–3.0 (broad), 3.18 (s) (total 8H), 2.1–1.0 (broad, 8H), 1.0–(−0.1) (complex m, 4H); ms: 196 (M^+, 1), 195 (M^+ − 1, 1), 165 (M^+ − MeO, 4), 164 (M^+ − MeOH, 16), 132 (M^+ − 2MeOH, 32), 106 (100), 101 (MeO—$\overset{+}{C}$H—CH=CH—OMe, 52), 91 (52), 71 (MeO—$\overset{+}{C}$H—CH=CH_2, 23). *Anal.* calcd. for $C_{12}H_{20}O_2$: C 73.43, H 10.27; found: C 73.10, H 10.58.

2,4-Dimethoxy-8,8-dimethylbicyclo[3.2.1]octane, 4

A solution of 0.342 g (1.73 mmol) of **15** in 10 mL ethanol was hydrogenated in a Parr apparatus at 4.5 atm and 50°C during 60 h, using 34 mg PtO_2 as catalyst. The suspension was filtered through 1 g silica gel; evaporation of the solvent and distillation gave 0.273 g (1.38 mmol) of **4**, bp 130–134°C (oven)/18 Torr, 79.7% yield; ir: spectrum not definitive; nmr (CCl_4), δ: 3.9–3.1 (broad), 3.25 (s) (total 8H), 2.3–1.3 (broad), 1.23 (s) (total 11H), 0.98 (s, 3H); ms: 198 (M^+, 1), 182 (1), 166 (M^+ − MeOH, 3), 101 (MeO—$\overset{+}{C}$H—CH=CH—OMe, 100), 71 (MeO—$\overset{+}{C}$H—CH=CH_2, 63). *Anal.* calcd. for $C_{12}H_{22}O_2$: C 72.68, H 11.18; found: C 72.51, H 10.82.

General Procedure for the Bromine Oxidation of the 1,3-Dialkoxytrimethylene Bridge to Two Carboxyl Groups

One mmol of the compound to be oxidized, 8 mmol of Br_2, and the required number of mL of buffer solution[3] were placed in a flask. The flask was stoppered and the mixture was magnetically stirred at room temperature for 62 h. The solution was basified by addition of NaOH; 2.5 mmol of Br_2 was added and it was stirred at room temperature for 24 h more. The solution was diluted with 20 mL water, acidified with concentrated HCl, the excess Br_2 destroyed by addition of solid Na_2SO_3, and extracted thoroughly with ether. Evaporation of the dried extracts yielded the crude product which was chromatographed through silica gel (mixture $CHCl_3$/ether as eluent) and crystallized. Alternatively, the crude product was esterified by reaction with ethereal diazomethane or by reaction with MeOH/HCl and then chromatographed.

*cis-Cyclopentane-1,3-dicarboxylic acid, 5*a (Reaction 4 from Table 1)

From 0.500 g (2.94 mmol) of **1***a*, 0.637 g of crude product was obtained, which on chromatography through 3 g silica gel, eluting with $CHCl_3$/ether, and crystallization from benzene gave 0.217 g (1.37 mmol) of **5***a*, mp 118–121°C (lit. (8) mp 121°C), 46.7% yield.

[3]The number of mL of buffer solution per mmol substrate for each reaction may be obtained from Table 1 by dividing the ratio mol base/mol substrate by the corresponding molar concentration of base (M_{base}).

Methyl cis-*3-(2,2-Dibromoethenyl)cyclopentanecarboxylate,* **9**b (Reaction 1 from Table 1)

From 0.251 g (1.36 mmol) of **1***a*, 0.277 g of crude acid was obtained which on methylation with ethereal solution of diazomethane and chromatography through 30 g silica gel, eluting with hexane/ether 9:1, yielded 0.089 g (0.28 mmol) of **9***b* (21% yield); ir ($CHCl_3$), ν: 1725 (s), 1620 (w) cm^{-1}; nmr ($CDCl_3$), δ: 6.41 (d, J = 10 Hz, 1H), 3.70 (s, 3H), 3.2–2.5 (broad, 2H), 2.5–1.2 (broad, 6H); ms: 310 (M^+, 3), 279 (M^+ − MeO, 4), 278 (M^+ − MeOH, 6), 251 ($M^+ - CO_2Me$, 6), 250 ($M^+ - HCO_2Me$, 7), 231 (M^+ − Br, 24), 210 ($C_4H_4Br_2^+$, 9), 197 ($C_3H_3Br_2^+$, 12), 171 ($M^+ - CO_2Me$ − HBr, 50), 151 (M^+ − HBr − Br, 25), 91 ($C_7H_7^+$, 100). *Anal.* calcd. for $C_9H_{12}Br_2O_2$: C 34.65, H 3.88, Br 51.22; found: C 34.92, H 3.75, Br 50.30.

Eluting with hexane–ether 8:2, 0.087 g (0.47 mmol) of **5***b* was obtained. Its spectroscopic data were identical with those reported by James and Stille (9).

3-Bromobicyclo[3.2.1]oct-3-en-2-one, ***10*** (Reaction 3 from Table 1)

From 0.405 g (2.38 mmol) of **3***a*, 0.432 g of crude product was obtained which was esterified by reaction with 20 mL of anhydrous MeOH and 3 drops of concentrated HCl. The solvent and HCl were evaporated and the crude liquid was chromatographed through 30 g silica gel. There were obtained successively 0.052 g (0.167 mmol, 7.0% yield) of **9***b* (hexane/ether 9:1), 0.040 g (0.20 mmol, 8.5% yield) of **10** (hexane/ether 17:3), and 0.137 g (0.73 mmol, 31.0% yield) of **5***b* (hexane/ether 8:2). Spectroscopic and analytical data of **10**: ir ($CHCl_3$), ν: 1690 (s), 1590 (w) cm^{-1}; nmr ($CDCl_3$), δ: 7.58 (d, J = 8 Hz, 1H), 3.4–2.7 (broad, 2H), 2.5–1.0 (broad, 6H); ms: 200 (M^+, 34), 172 (16), 159 (50), 131 (31), 93 (100), 91 (100), 77 (75). *Anal.* calcd. for C_8H_9BrO: C 47.81, H 4.51, Br 39.76; found: C 47.77, H 4.79, Br 39.71.

Dimethyl cis-*Cyclohexane-1,3-dicarboxylate,* **6**b (Reaction 7 from Table 1)

From 0.184 g (1.0 mmol) of **2**, 0.217 g of crude product was obtained which, after esterification with ethereal diazomethane and two chromatographies through 20 g silica gel, gave 0.084 g (0.42 mmol) of **6***b* (hexane/ether 8:2), in 42.0% yield. Its spectroscopic data were identical with those reported by James and Stille (9).

cis-*Cyclohexane-1,3-dicarboxylic Acid,* **6**a

Hydrolysis of **6***b* by refluxing with dilute aqueous HCl for 16 h gave **6***a* in quantitative yield, mp 165–167°C (lit. (8) mp 167–167.8°C).

3-Bromobicyclo[3.3.1]nonan-2,4-dione, ***11*** (Reaction 8 from Table 1)

From 0.233 g (1.26 mmol) of **2**, 0.240 g of crude product was obtained which was refluxed with 12 mL anhydrous MeOH and 2 drops of concentrated H_2SO_4 for 16 h. Water was added, the acid was neutralized with aqueous $NaHCO_3$, and the mixture was extracted with $CHCl_3$ (3 × 15 mL). Evaporation of the dried extracts gave 0.224 g of a semisolid crude which by crystallization from $CHCl_3$ gave 0.110 g (0.48 mmol, 38% yield) of **11** which exists essentially in the enol form; ir (KBr), ν: 3400–2500 (m), 1690 (s), 1650 (m) cm^{-1}; nmr ($CDCl_3$), δ: 9.9–7.7 (broad, 1H), 2.9–0.7 (broad, 10H); ms: 230 (M^+, 26), 151 (M^+ − Br, 59), 150 (M^+ − HBr, 11), 133 (14), 123 (21), 109 (29), 108 (26), 97 (14), 95 (26), 83 (26), 82 (33), 81 (100). *Anal.* calcd. for $C_9H_{11}BrO_2$: C 46.78, H 4.80, Br 34.58; found: C 46.69, H 4.75, Br 34.30.

Evaporation of the mother liquors of the crystallization gave 0.097 g (0.48 mmol, 38% yield) of **6***b* pure by nmr.

Dimethyl (*1*R,*2s*,*3*S)-*2-methylcyclopentane-1,3-dicarboxylate,* **7**b (Reaction 9 from Table 1)

From 0.249 g (1.35 mmol) of **3**, 0.205 g of crude ester was obtained after esterification with MeOH/HCl. This crude was chromatographed through 30 g silica gel to give 0.139 g (0.69 mmol, 51% yield) of **7***b* eluting with hexane/ethyl acetate 17:3, bp 80–85°C (oven)/15 Torr; ir ($CHCl_3$), ν: 1725 (s) cm^{-1}; nmr ($CDCl_3$), δ: 3.58 (s, 6H), 3.1–2.5 (broad, 3H), 2.5–1.5 (broad, 4H), 0.73 (d, J = 7 Hz, 3H); ms: 169 (M^+ − MeO, 18), 168 (M^+ − MeOH, 11), 140 ($M^+ - HCO_2Me$, 55), 108 (M^+ − MeOH − HCO_2Me, 45), 81 ($M^+ - HCO_2Me - CO_2Me$, 100). *Anal.* calcd. for $C_{10}H_{16}O_4$: C 59.99, H 8.05; found: C 59.72, H 8.05.

cis-*Isoaposantenic Acid,* **7**a

Hydrolysis of 0.266 g of **7***b* by refluxing in 12 mL of dilute aqueous HCl for 16 h gave, after crystallization from ethyl acetate/hexane, 0.192 g (1.12 mmol) of **7***a*, mp 160–163°C (lit. (6) mp 155°C), 84.0% yield. The cyclic anhydride, obtained by reaction of **7***a* with acetyl chloride, melts at 175–176°C (lit. (6) mp 174°C), and the monoanilide, obtained by reaction of this anhydride with aniline, melts at 197–198°C (lit. (6) mp 197–198°C).

Dimethyl cis-*2,2-Dimethylcyclopentane-1,3-dicarboxylate,* **8**b (Reaction 11 from Table 1)

From 0.256 g (1.30 mmol) of **4**, 0.367 g of crude product was obtained after esterification with ethereal diazomethane. This crude product was chromatographed through 30 g silica gel to give 0.147 g of **8***b* eluting with hexane/ether 9:1. It distilled at 116–120°C (oven)/13 Torr, giving 0.120 g (0.56 mmol) of **8***b*, pure by nmr (43.0% yield); ir (film), ν: 1730 (s) cm^{-1}; nmr ($CDCl_3$) δ: 3.8 (s, 6H), 2.9–1.6 (broad, 6H), 1.38 (s, 3H), 0.82 (s, 3H); ms: 214 (M^+, 1), 183 (M^+ − MeO, 12), 182 (M^+ − MeOH, 9), 154 ($M^+ - HCO_2Me$, 54), 122 (M^+ − MeOH − HCO_2Me, 57), 96 ($M^+ - 2\,CO_2Me$, 32), 95 ($M^+ - HCO_2Me - CO_2Me$, 100), 94 ($M^+ - 2\,HCO_2Me$, 49), 55 (62). *Anal.* calcd. for $C_{11}H_{18}O_4$: C 61.66, H 8.47; found: C 61.49, H 8.64.

cis-*Apocamphoric Acid,* **8**a

Hydrolysis of 0.118 g of **8***b* by refluxing with dilute aqueous HCl (5 mL) for 23 h, gave 0.071 g of **8***a* (70% yield), mp 206–208°C (water/ethanol) (lit. (7) mp 203 and 209°C).

The hydrolyses of benzamides, methylbenzimidatium ions, and lactams in aqueous sulfuric acid. The excess acidity method in the determination of reaction mechanisms[1]

ROBIN A. COX AND KEITH YATES

Department of Chemistry, University of Toronto, 80 St. George St., Toronto, Ont., Canada M5S 1A1

Received March 6, 1981

ROBIN A. COX and KEITH YATES. Can. J. Chem. **59**, 2853 (1981).

The excess acidity method has been applied to hydrolysis rate data for a number of benzamides, methylbenzimidatium ions, and lactams, obtained as a function of sulfuric acid concentration and temperature. All of the substrates studied except β-propiolactam (**8**) and methyl-2,6-dimethylbenzimidatium ion (**7**) were found to follow the A_0T2 mechanism at all acidities. The excess acidity method provided considerable mechanistic detail; in dilute acid the transition state contains *O*-protonated (or methylated) substrate and three water molecules (large negative ΔS^*), but in more concentrated solutions a one-water-molecule mechanism takes over (smaller negative ΔS^*). In strong acid bisulfate ion acts as the nucleophile (positive ΔS^*). *N*-protonated intermediates are not involved for "normal" substrates, being observed in this work only for **8**, which follows the A_ND1 pathway. Observed differences between benzamide and methylbenzimidatium ion (**4**) hydrolyses are due to their differing activity coefficient behaviour, the mechanism being the same for both. The hydrolysis of **7** involves a one-water-molecule S_N2 displacement at the *O*-methyl group. Comparison with **7** shows that this displacement is not likely to occur under the reaction conditions for **4**; however, for the *N*-methyl and *N*,*N*-dimethyl derivatives studied it is probably an important reaction pathway. A comprehensive mechanistic framework for amide hydrolyses in strong acid media is given.

ROBIN A. COX et KEITH YATES. Can. J. Chem. **59**, 2853 (1981).

On a appliqué la méthode d'acidité en excès aux données relatives aux vitesses d'hydrolyse d'une série de benzamides, d'ions méthylbenzimidatium et de lactames obtenues en fonction de la concentration en acide sulfurique et de la température. On a trouvé que tous les substrats étudiés, à l'exception du β propiolactame (**8**) et de l'ion méthyle diméthyl-2,6 benzimidatium (**7**) suivent le mécanisme A_0T2 pour toutes les acidités. La méthode d'acidité en excès fournit beaucoup de détails sur le mécanisme de réaction; en solution diluée d'acide, l'état de transition implique un substrat *O*-protoné (ou méthylé) et trois molécules d'eau (forte valeur négative du ΔS^*), mais dans des solutions plus concentrées un mécanisme à une molécule d'eau prédomine (valeur négative plus faible du ΔS^*). En milieu acide fort, l'ion bisulfate agit comme nucléophile (ΔS^* positif). Les intermédiaires *N*-protonés ne sont pas impliqués dans le cas des substrats "normaux"; dans ce travail, on les a remarqués seulement dans le cas du composé **8** qui suit un mécanisme A_ND1. Les différences observées entre l'hydrolyse du benzamide et de l'ion méthylbenzimidatium **4** sont dues au comportement différent de leur coefficient d'activité, le mécanisme étant le même dans les deux cas. L'hydrolyse du composé **7** fait intervenir une substitution S_N2 du groupe *O*-méthyle par une molécule d'eau. La comparaison avec le composé **7** révèle que ce déplacement ne se produit ordinairement pas dans les conditions de la réaction de **4**; cependant dans le cas des dérivés *N*-méthyle et *N*,*N*-diméthyle étudiés, il est probablement un mécanisme réactionnel important. On propose un mécanisme de base pour l'hydrolyse des amides en milieu acide fort.

[Traduit par le journal]

Introduction

Excess acidities (*X*-functions (1, 2) or M_C functions (3)) are used in a method for the evaluation of protonation acidity constants of weak bases, from ionization ratio measurements in strong acid solutions, by extrapolation to the aqueous standard state. Excess acidity analyses give accurate, reliable pK_{BH^+} values either in the absence (1, 2) or the presence (4, 5) of medium effects on the spectra used to obtain the ionization ratios. The method is also of considerable value in the analysis of rate data obtained in these media; the appropriate kinetic equations are derived and illustrated elsewhere (6). So far it has provided valuable mechanistic information concerning acid-catalyzed ketone enolizations (7), sterically crowded ester hydrolyses (8) and aromatic nitrations (9), and in this paper it is applied to amide hydrolyses in sulfuric acid.

Amide hydrolysis in acid media has been widely studied; the early work has been summarized (10). The consensus today (10, 11) would probably be that normal amides hydrolyze via the A_0T2 (acid-catalyzed, oxygen-protonated, tetrahedral intermediate, bimolecular (12)) mechanism shown in eq. [1] (11, 13–15). This mechanism received strong support when a small but detectable amount of ^{18}O exchange was observed into benzamide under the reaction conditions (16), as would be expected if a tetrahedral intermediate is formed. Also the oxygen-protonated amide involved in mechanism [1] is the only detectable protonated species present at any acidity, as we have discussed elsewhere (4, 5). The number of water molecules taking part in the hydrolysis, *n* in eq. [1], has been found in several cases to be three (17). Apart from eq. [1], well-established amide hydrolysis

[1]

mechanisms include that of *N-tert*-butyl amides via alkyl carbon–nitrogen bond fission (13, 18), that of some acetanilides via A-1 acylium ion formation (19), and that of *N*-nitroso amides via an *N*-protonated species (20).

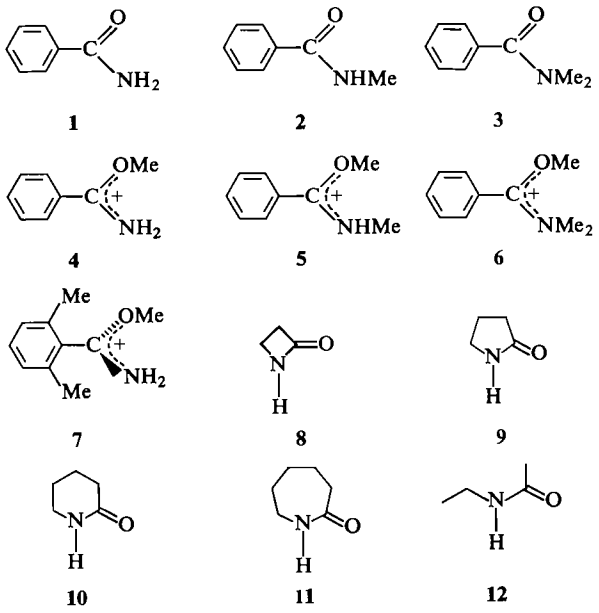
However, despite this general agreement it has often been suggested that reaction occurs via the *N*-protonated amide, either partially (21–24) or exclusively (12, 25–27). This species, although present in much lower concentration than the *O*-protonated amide (14), is attractive as an intermediate, being susceptible to nucleophilic attack or acylium ion formation (13). It is involved in some reactions; Perrin invokes it to explain the mechanism of rotation about the carbonyl–nitrogen bond in *N*-substituted amides (28). It is true that eq. [1] does not explain all the details of the kinetic behaviour; Yates *r*-plots (29), for instance, are often curved (25, 30). Bunton *et al.* (22) developed a kinetic equation based on parallel reactions via *N*- and *O*-protonated amides, as did Vinnik (21). Giffney and O'Connor (26) give an equation based on exclusive *N*-protonation which correlates the data well at low acidity, but is not easy to interpret mechanistically (26). Because of this situation we decided to apply the excess acidity method, which is capable of providing considerable mechanistic information (6–8), to this process.

Amides are protonated in dilute acid (4, 5), and so come under Case 2 in ref. 6; the appropriate kinetic equation for an A-2 reaction is reproduced here as eq. [2] (6). For an A-1 reaction the equation

$$[2]\quad \log k_\psi - \log (C_{SH^+}/(C_S + C_{SH^+})) = (m^\ddagger - 1)\, m^* X + \log a_{Nu} + \log k_0$$

is the same except that the term $\log a_{Nu}$ is not present (6). The observed pseudo-first-order rate constant is k_ψ, and C_{SH^+} and C_S are concentrations of protonated and unprotonated substrates, respectively; the protonation correction term containing these is negligible for full protonation. X is the excess acidity, and a_{Nu} is the activity of the nucleophile or base involved in the A-2 reaction, water or bisulfate ion in sulfuric acid (6–8, 31). m^* and $m^\ddagger$ are slope parameters, expressing the sensitivity of the substrate and transition state, respectively, to the changing acidity (6), and k_0 is the medium-independent second-order rate constant. Although the equivalent equations for predominantly unprotonated substrates have been used extensively (6–8), eq. [2] has not, and one of the aims of this work was to test this equation thoroughly.

The compounds involved in this study were benzamide, **1**, *N*-methylbenzamide, **2**, and *N*,*N*-dimethylbenzamide, **3** (23, 25, 34), with the corresponding methylbenzimidatium ions used as *O*-protonated models, **4**, **5**, and **6** (12); methyl-2,6-dimethylbenzimidatium ion **7** (32), used as a check for S_N2 displacement at the *O*-methyl group in these ions; and the 4-, 5-, 6-, and 7-membered ring lactams **8**, **9**, **10**, and **11**, with the open-chain compound *N*-ethylacetamide, **12** (33). With rate



data available at different temperatures (T), activation parameters can be obtained by substituting eq. [3] into eq. [2]; R is the gas constant and θ is

$$[3]\quad \log k_0 = 10.3188 + \log T - \Delta G^\ddagger_{25°}/R\theta \ln 10 + (\Delta H^\ddagger_{25°}/R\theta \ln 10) \times (T - \theta)/T$$

298.15 K (35). Equation [3] provides slightly more accurate $\Delta G^{\neq}$ and $\Delta H^{\neq}$ values (35) than does the equation used previously (8). $\Delta S^{\neq}$ is easily obtained via $\Delta G^{\neq} = \Delta H^{\neq} - \theta\Delta S^{\neq}$. All the activation parameters obtained in this study, using eqs. [2] and [3], are valid at 25°C in the aqueous standard state (6–8).

Experimental

The rate constants k_ψ for **1**, **2**, and **3** were taken from Smith and Yates (25), who give extensive data covering the 6–60% H_2SO_4 and 25–85°C ranges, with some additional measurements in stronger acid at 85°C by Smith (34); and from Bunton *et al.* (23), whose measurements were at 100.4°C and extended to 96% H_2SO_4 in the case of **1**. For **4**, **5**, and **6** the rate data in the 12–63% H_2SO_4 and 25–85°C ranges given by Smith and Yates (12) were used. McClelland (32) gives hydrolysis rates for **7** in the regions 0–60% H_2SO_4 and 86–108°C. Data for **9**, **10**, and **11** in the 5–60% and 65–97°C ranges were taken from Wan *et al.* (33), as were data for **8** between 5% and 46% H_2SO_4 at 33°C and for **12** between 5% and 60% at 25°C. The hydrolysis reaction products are detailed in the references cited.

Values of $\log (C_{SH^+}/(C_S + C_{SH^+}))$, i.e. $\log (I/(1 + I))$, are also required for eq. [2]. These were obtained using eq. [4] (1), listed values of X and $\log C_{H^+}$ (1) and the recently obtained accurate

$$[4] \quad \log I - \log C_{H^+} = m^*X + pK_{SH^+}$$

m^* and pK_{SH^+} values for **1–3** and **8–12** (5). X and $\log C_{H^+}$ were corrected to the reaction temperature as previously described (8). Little information is available concerning the temperature dependence of amide and lactam pK_{SH^+} values, and so these were corrected to the reaction temperature by assuming that $\Delta S^0 = 0$ and $\Delta H^0 = \Delta G^0$ for the protonation process, as assumed previously for esters (8), which was felt to be better than using the same pK_{SH^+} at different temperatures. Protonation corrections were not needed for **4–7**, which are positive ions under the reaction conditions (32, 36). Temperature-corrected log water activities in molarity units were obtained as before (8), and temperature-corrected log bisulfate ion concentrations were estimated from Raman spectroscopy measurements by Chen and Irish at 25°C (37) and by Young *et al.* at 0°, 25°, and 50°C (38). The computer program used for fitting eqs. [2] and [3], either for a single reaction or simultaneously for two or three parallel reactions, was the same as that used before (8).

Results

Inspection of eq. [2] reveals that if $m^{\neq} = 1$, i.e. the activity coefficients f_{SH^+} and $f_{\neq}$ for the protonated amide and for the hydrolysis transition state exactly cancel (6), and if the nucleophile is water, a plot of the left hand side (LHS) against log water activity will be linear with slope r, where r is the number of water molecules involved in the hydrolysis (29). In this case r-plots are curved (25, 33, 34); for the amides and lactams (excluding **8**) they vary from about slope 3 in dilute acid to about slope 1 in more concentrated solutions, and deviate still more in strong acid. Either the molarity-based water activities used in this work (7, 8) or the mole-fraction-based ones used before (25) give essentially the same result. This curvature has been suggested (25) to be due to an activity coefficient effect; in the terminology used here this means $m^{\neq} \neq 1$. Accordingly the LHS of eq. [2], minus r log a_{H_2O}, should be linear when plotted against X. However, when this was tried no value of r produced a linear plot. For instance for benzamide, with $r = 3$ (the most likely value (17)) the plots are horizontal until about half-way and then deviate upward; with $r = 1$ they curve down before levelling out. In view of the consistent linearity found before with plots of this type (6–8) this can only mean that a gradual mechanism change is occurring at intermediate acidities.

A computer program was available which enables dissection of k_ψ for two parallel reactions into its components (8), and this was used to investigate the change in mechanism, by trying various combinations of possible mechanisms (A-2 with 3 H_2O + A-1, A-2 with 3 H_2O + A-2 with 1 H_2O, A-2 with 2 H_2O + A-2 with 1 HSO_4^-, etc.) until the combination which fitted the data best was found. Equations [2] and [3] combine to form a multiple linear regression (8). In this work r was given a fixed value (see above), leaving an intercept term and two slopes, from which $\Delta H^{\neq}_{25°}$, $\Delta G^{\neq}_{25°}$, and $(m^{\neq} - 1)m^*$ can be calculated. Thus if one mechanism is sufficient to fit the data three coefficients are obtained; if two are necessary six coefficients result, and so on.

By far the best combination of mechanisms, for compounds **2–6** and **9–12**, was found to be an A-2 reaction with 3 H_2O in the dilute acid region and another A-2 process, this time using only one H_2O, in the more concentrated region, as suggested by the r-plots and in full agreement with the previous proposal for lactam hydrolysis (33). These mechanisms also fitted the experimental data well for benzamide, **1**, except in the highly concentrated acid region; it was found that inclusion of a third mechanism, involving one bisulfate ion, produced an excellent fit in this case. Benzamide is the only compound in the study that has been adequately investigated at high acidity. Indications of a bisulfate mechanism could be seen for **2** and **3** also, but not enough data points at high acidity were present to enable parameters to be calculated. No evidence for a 2 H_2O pathway was found in this work; neither substituting it for one of the 3 H_2O or 1 H_2O reactions, nor adding a 2 H_2O process as a third mechanism, resulted in reasonable fits of the experimental data. For **7** only one A-2 mechanism, involving one water molecule, was found. Compound **8** follows an A-1 pathway; a plot of the LHS of eq. [2] against X is linear, meaning that nucleo-

philes are not involved in the rate-determining step in this case (6).

The excellent agreement found in this work between the calculated curves due to the different mechanisms and the experimental data is illustrated for compounds **1**, **4**, **7**, and **9** in Figs. 1–6. Figures 1–3 concern benzamide; Fig. 1 covers hydrolysis in the 0–60% H_2SO_4 region at four different temperatures (25). For the 25°C data individual curves for the 3 H_2O and 1 H_2O mechanisms are given, along with the curve through the data points for the two in combination. All the lines curve downward, normal for an A-2 reaction involving water (6); it can be seen that the 3 H_2O mechanism is dominant in media more dilute than about 45% H_2SO_4, and that the 1 H_2O mechanism takes over in more concentrated solutions. Figure 2 illustrates benzamide hydrolysis data at 85°C in 0–80% H_2SO_4 (25, 34); the 1 H_2O mechanism is the dominant one in the 45–75% region, at which point the HSO_4^- mechanism begins to appear. This can be more clearly seen in Fig. 3, with data at 100.4°C extending to 96% H_2SO_4 (23), at which point only the HSO_4^- hydrolysis is occurring. This is to be expected, since the water activity is very low and the HSO_4^- concentration high in this acidity region (31).

Figure 4 shows that exactly the same hydrolysis mechanisms apply to the methylbenzimidatium ion **4** (12), but that the downward slope of the curves is much sharper; the m^+ values (i.e. activity coefficient behaviour) for **1** and **4** are quite different. In Fig. 5 it can be seen that only one mechanism, a 1 H_2O A-2 reaction, is sufficient to explain the hydrolysis of **7** (32) in 0–60% H_2SO_4. Figure 6 shows that the hydrolysis data for the lactam **9** (33)

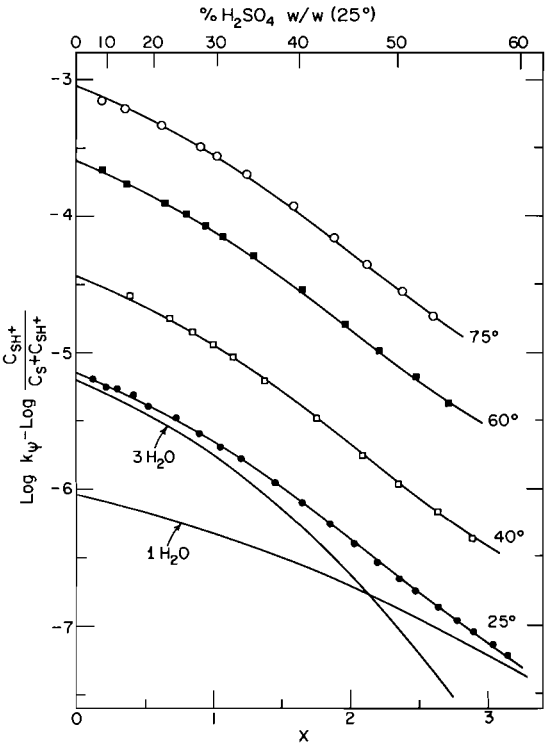

FIG. 1. Graphs according to eq. [2] for the hydrolysis of benzamide in sulfuric acid at several temperatures (25). Points are experimental, curves theoretical, assuming two parallel A-2 reactions, one involving three water molecules and the other one. Theoretical curves for the two individual reactions at 25°C are also shown.

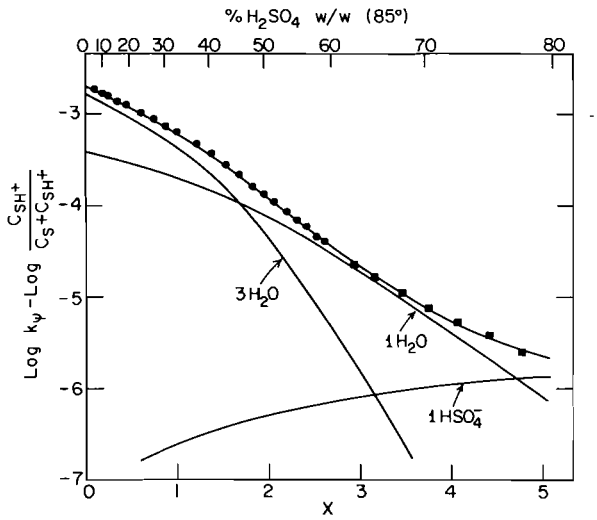

FIG. 2. The hydrolysis of benzamide in sulfuric acid at 85°C. Data from (●) Smith and Yates and (■) Smith (25, 34), plotted according to eq. [2]. Theoretical curves are shown for the three parallel A-2 reactions occurring in this medium; when these are combined the curve through the points results.

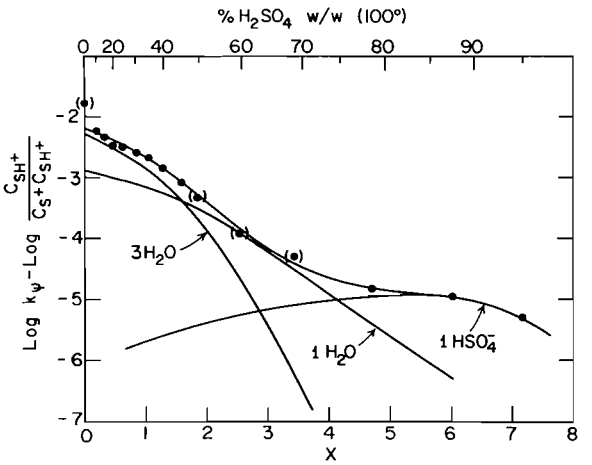

FIG. 3. The hydrolysis of benzamide in sulfuric acid at 100.4°C. Data from Bunton *et al.* (23); see Fig. 2.

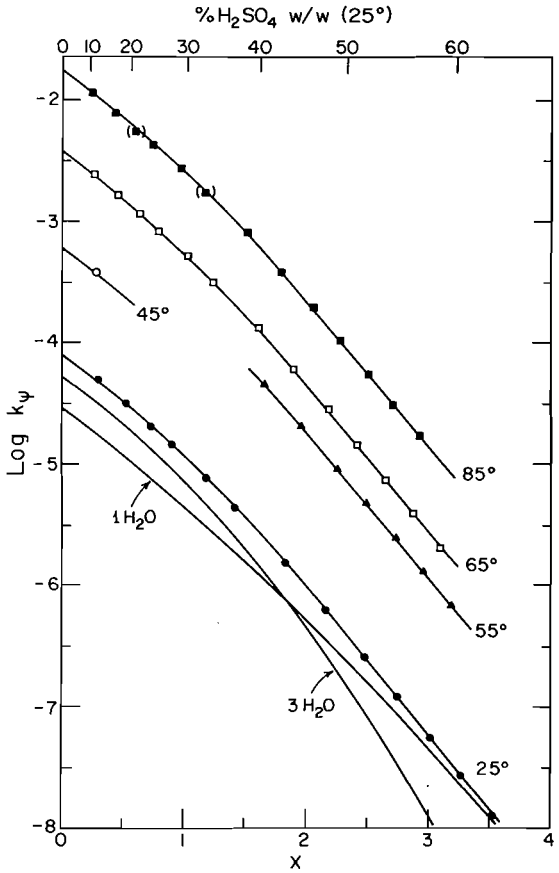

FIG. 4. The hydrolysis of methylbenzimidatium ion **4** in sulfuric acid at various temperatures (12), plotted according to eq. [2]. The theoretical curves assume two parallel reactions, as indicated for the 25°C data.

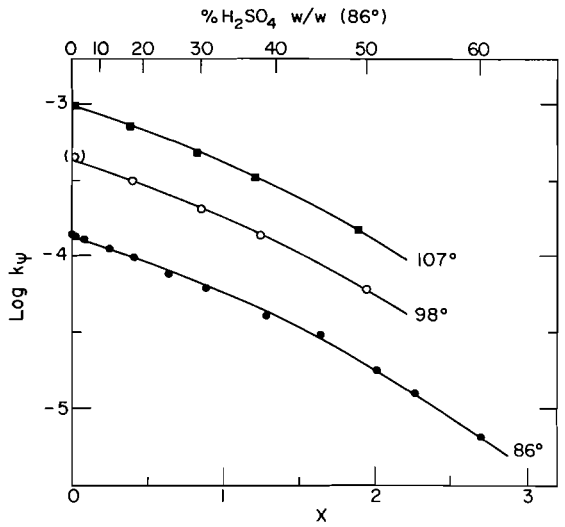

FIG. 5. The hydrolysis of methyl-2,6-dimethylbenzimidatium ion **7** in sulfuric acid at 86°, 98°, and 107°C (32), plotted according to eq. [2]. The theoretical curves shown assume a single A-2 reaction involving one water molecule.

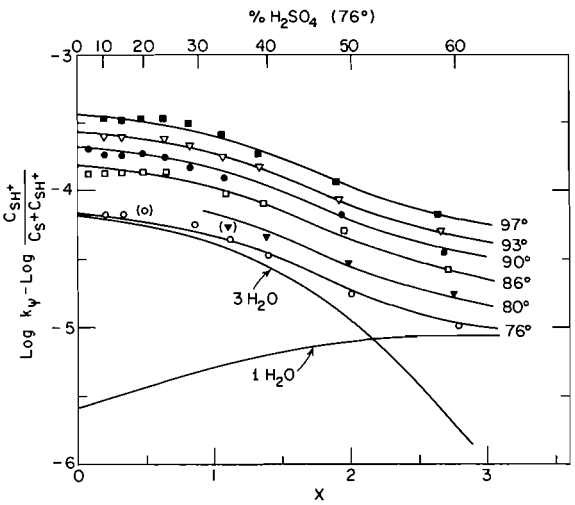

FIG. 6. The hydrolysis of 2-pyrrolidone **9** in sulfuric acid at various temperatures (33), plotted according to eq. [2]. The theoretical curves assume two parallel reactions, as indicated for the 76°C data.

is also fitted well by a combination of 3 H_2O and 1 H_2O hydrolysis mechanisms, the latter dominant above about 50% H_2SO_4.

The parameters found using the computer curve-fitting process are presented for all the compounds in Table 1. Rather than $\Delta G^{\ddagger}_{25°}$, the more familiar log k_0 at 25°C in water is quoted, along with aqueous standard state $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values, for each mechanism. Combined log k_0 values, including all mechanisms, are also given. $m^{\ddagger}$'s for **1–3** and **8–12** can be obtained from the $(m^{\ddagger} - 1)m^*$ slopes listed in Table 1 using the known m^*'s (5), and these are given in Table 2. Although the m^* concept has little meaning for the preformed positive ions **4–7** (especially **6**), an m^* value of 1.0 can be used for the $m^{\ddagger}$ calculation, since benzimidates protonate in the pH region (32, 36). Table 1 also contains the number of data points included and the root-mean-square error of the fit, used as a criterion of goodness of fit for the various combinations of mechanisms tried; for the ones in Table 1 these are well within the estimated experimental error on each point. Two compounds, **8** and **12**, were only studied at one temperature, so activation parameters could not be obtained. For **12** the data were only sufficient to permit calculation of a combined $(m^{\ddagger} - 1)m^*$, assumed to apply to both mechanisms.

Discussion

The combination of the excess acidity method with the curve-fitting procedure described above

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

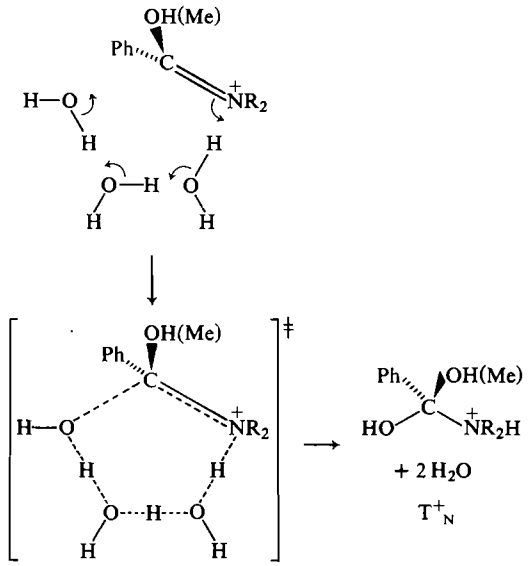
provides detailed insights into the various amide hydrolysis mechanisms, and good quantitative information about the rate-determining step for each of them; the $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, etc. given by eqs. [2] and [3] are aqueous standard state values, directly comparable with those obtained in aqueous buffer media (6). As can be seen the method works very well; none of the alternative rate equations proposed (21, 22, 26) fit experimental data over the wide ranges of acidity and temperature covered in this work. The various mechanistic possibilities will now be considered.

The $3\,H_2O$ process is probably best visualized as proceeding through a cyclic transition state as shown in eq. [5].

[5]



This involves an oxygen-protonated (or methylated) intermediate, shown in the canonical form with the positive charge on nitrogen, and three water molecules, in a five-membered ring (C, N, and 3 O's; hydrogen bonds are collinear). This differs somewhat from previous proposals for the role of two of the water molecules in these reactions (17, 25). Certainly the very large negative entropies of activation, −40 to −55 eu, only seem consistent with a highly structured transition state such as the one shown. The observed very small extent of ^{18}O exchange into benzamide under the reaction conditions (16) would be expected if an intermediate with the good leaving group $^{+}NR_2H$, T^{+}_{N} in eq. [5], were formed directly in the rate-determining step, rather than subsequently as in eq. [1]. Collapse of T^{+}_{N} to product would then be very much faster than the reverse of reaction [5]. Cyclic mechanisms of this type are not unknown; one involving four water molecules has recently been proposed for the water-catalyzed hydrolysis of 1-acetyl-1,2,4-triazole, following a proton inventory study (39). The fact that the *O*-methylated ions **4**, **5**, and **6** react via the same $3\,H_2O$ pathway in dilute acid, giving the corresponding ester and its acid hydrolysis product (25), is strong evidence against the involvement of an *N*-protonated amide in the benzamide and lactam $3\,H_2O$ hydrolyses.

The $1\,H_2O$ reaction can be understood with reference to the reaction scheme given in eq. [6], which applies to the amides, all the lactams except **8**, and, at least partially, to all of the methylbenzimidatium ions except **7**. (Another hydrolysis mechanism, discussed below, is possible for these.) The rate-determining step is attack of a water molecule on the *O*-protonated or methylated amide to give tetrahedral intermediate T^{+}_{O}, deprotonation of which gives the neutral species T^{0}; further proton transfers result in the intermediates T^{+}_{N} and $T^{\pm}$.

Intermediate T^{0} can protonate in three places. By far the most probable is protonation at N to give T^{+}_{N}; however, if protonation at O occurs loss of water or alcohol may result as shown to give the protonated amide (the stable form in the acid solutions in which the $1\,H_2O$ reaction is important (5)). If the substrate is an amide this leads to ^{18}O exchange; the likely basicity difference between N and O in T^{0} would account quite well for the small amount actually observed, $k_{hydrolysis}/k_{exchange}$ being 320 for benzamide in 6% H_2SO_4 at 85°C (16). If the substrate is a benzimidatium ion, amide formation is the result; McClelland and Potter have shown that the hydrolysis of *O*-ethyl-*N*,*N*-dimethyl-4-nitrobenzimidatium ion in 48% H_2SO_4 at 25°C gives 10% amide product, and that all of it is formed via the T^{0} pathway in eq. [6], as shown by ^{18}O exchange (40).

Protonation of T^{0} at nitrogen gives T^{+}_{N} (eq. [6]), and this is the major fate of T^{0}. In acid media strong enough to support the formation of protonated ester, T^{+}_{N} can lose NR_2H directly, as shown. More probable at moderate and low acid concentrations (40) is loss of an OH proton to give the zwitterion $T^{\pm}$, which then readily loses NR_2H to give the acid or ester product. As indicated in scheme [6], the $3\,H_2O$ pathway of eq. [5] is a "short cut" leading directly to T^{+}_{N}. This means that ^{18}O exchange in amides, or amide formation from benzimidatium ions, is an unlikely result of the $3\,H_2O$ pathway. Thus, since the relative importance of the $3\,H_2O$ and $1\,H_2O$ mechanisms changes as the acidity changes (Figs. 1–6), the extent of ^{18}O exchange into amides and the amount of amide formation

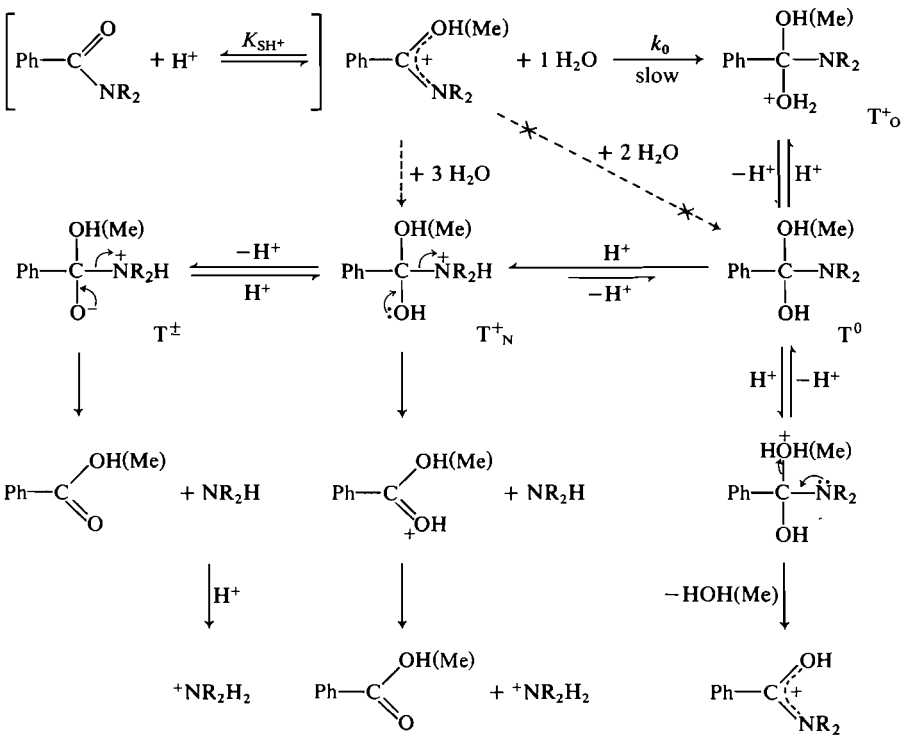
[6]

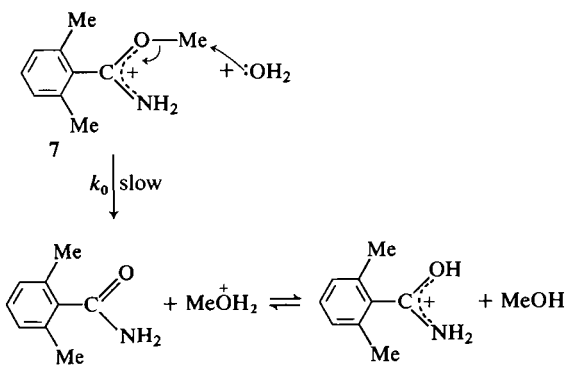


from benzimidatium ions should both increase with acidity. Evidence for the former is lacking, but experimental results support the latter prediction (12, 40).

No evidence for a $2\,H_2O$ reaction was found. By analogy with the ester hydrolysis mechanism (8) a $2\,H_2O$ process would lead to formation of T^0 from protonated amide directly, see scheme [6]. Here, however, it would seem that $T^+{}_O$ has to be formed first, with proton removal to T^0 occurring subsequently, rather than the two steps being concerted.

For the benzimidatium ions the situation is more complex, however, because an alternative hydrolysis pathway exists for them, S_N2 attack at the *O*-methyl group as in eq. [7], leading to amide formation. Product analysis shows that amide is the

[7]



exclusive hydrolysis product for **7** (32); presumably the eq. [5] and eq. [6] mechanisms leading to ester/carboxylic acid products are greatly retarded because of steric hindrance to the approach of water at the carbonyl carbon by the ring methyl groups (32). As can be seen from Fig. 5, only one mechanism, involving one H_2O, is observed for **7**, presumably eq. [7] above.

Reactions [6] and [7] are not kinetically distinguishable. However, a comparison of relative rates and activation parameters (Table 1) for **7** and the unsubstituted analog **4** shows that eq. [7] is an unlikely mechanism for **4**; in water the one-water-molecule process for **7** is slower than that for **4** by nearly $2\frac{1}{2}$ orders of magnitude. In contrast, the $1\,H_2O$ rates for **5** and **6** are much slower, in the latter case approaching that of the identified eq. [7] process for **7**, so presumably the S_N2 hydrolysis is much more important for these compounds. Product studies which have been made in 65% H_2SO_4 at 85°C (12, 34, 41), conditions under which the $3\,H_2O$ hydrolysis is negligible (Fig. 4), enable a more quantitative evaluation. Direct product analysis shows that amide is present (25), but since this is also hydrolyzed to carboxylic acid under the reaction conditions the amount of amide formed initially is best estimated from the kinetics. In this way it was found that amide is the *only* significant initial hydrolysis product for **6** under these condi-

tions, and that amide predominated by a factor of 2:1 for **5**, but that for **4** nearly 90% of the initial product was methyl benzoate (immediately hydrolyzed to benzoic acid (8)) (12, 34). For **5** and **6** ^{18}O exchange studies show that essentially all of this amide results from the S_N2 process of eq. [7] (41). Mechanism [6] can produce as much as 10% amide in favourable cases (40) (see above), but mechanism [7] produces only amide. So we may conclude, at least in 65% H_2SO_4 at 85°C, that almost all of the 1 H_2O pathway for **6** and two-thirds of it for **5** is the S_N2 mechanism [7], but that the reaction between one water molecule and **4** has an 80–90% probability of being mechanism [6]. In more dilute acid where the 3 H_2O process predominates, the amide-forming reactions are not available; the exclusive product found for **4**, **5**, and **6** in 5% H_2SO_4 at 25°C is methyl benzoate (25).

The β-lactam **8** hydrolyzes via a unimolecular route. The only reasonable mechanism for this would seem to be the A_NP1 (13) pathway of eq. [8] (33); reaction is very fast (Table 1), presumably due to the large relief of strain involved. This is the only compound in the study which reacts by way of a

[a] From $(m^* - 1)m^*$ values in Table 1 and known m^*'s, see text.

nitrogen-protonated intermediate. It will probably be argued that the 3 H_2O and 1 H_2O hydrolyses discussed above proceed via *O*- and *N*-protonated intermediates, respectively, rather than via exclusive *O*-protonation as proposed here. The major arguments against this can be summarized (see also refs. 10, 14, 15): a transition-state activity coefficient study of several amides showed that amide

[8] 
hydrolysis transition states behave similarly to ester hydrolysis ones over the whole acidity range, as scheme [6] would predict (13); the 1 H_2O process is important in the strong acid region where even the opponents of *O*-protonation (27) would agree that the concentration of *N*-protonated amide is very small, and decreasing; 90% of the 1 H_2O hydrolysis for methylbenzimidatium ion **4** occurs via scheme [6], at rates even faster than those for the benzamides and lactams (Table 1), and reaction via *N*-protonation for this species is unlikely in the extreme; the one *N*-protonation hydrolysis found in this work (eq. [8]) is not even bimolecular.

The bisulfate ion mechanism found in concentrated H_2SO_4 can best be represented by eq. [9]. The activation enthalpy is very high (HSO_4^- is a poor nucleophile compared to water (7)) so the reaction is only apparent at high temperatures, 85° and 100°C here (Figs. 2 and 3). On the other hand the nucleophilic attack in eq. [9] involves charge

[9] 
destruction, freeing solvating species, in agreement with the observed positive activation entropy, +8 eu. Fast breakup of the tetrahedral intermediate involving SO_3 loss as shown has precedent in these media (31, 42).

The trends in ΔH^* and ΔS^* in Table 1 are in accord with expectation, with some exceptions. The 3 H_2O process has the lower ΔH^*, i.e. eq. [5] is a lower energy route than eq. [6] or eq. [7], with the possible exception of the δ-lactam **10**. Increasing methyl substitution on nitrogen causes increasingly negative ΔS^* values for both mechanisms in the series **1–3** and **4–6**, in accord with decreasing probability for the favourable orientation of approaching water molecules, and with other reasonable expectations (25). Methyl substitution would be expected to increase ΔH^*, inductive effects and increasing steric repulsion both reducing the electrophilicity of the carbon centre (25); in fact the 3 H_2O hydrolyses of **4**, **5**, and **6** show a decrease and the 1 H_2O ones an increase (remembering the contribution of mechanism [7]). The ΔH^* of **3** is low compared to **1** and **2**, probably because the nonplanarity of **3** (5) enhances the carbon electrophilicity by reducing positive charge delocalization into the phenyl ring. Ring size effects in the lactams have been discussed elsewhere (33).

The values of m^* given in Table 2 reflect the sensitivity of the transition state to the changing medium acidity, as compared with the protonated substrate (6). Typical values for A-2 reactions are around 1.0 (6, 7), and the closer to it they are, the better for the success of the *r*-parameter treatment (see above). Increasing divergence from 1.0 means that the activity coefficient behaviour of the protonated substrate is an increasingly poor model for that of the transition state. All of the A-2 mechanism values in Table 2 lie between 0 and 2, but this

encompasses a very wide range of medium sensitivity. The activity coefficient variations which these values reflect account quite well for the previously puzzling differences between the medium sensitivities of **1–3** and **4–6**; the mechanisms are, in fact, the same, as shown here, but the rate–acidity profiles and *r*-plot behaviour are quite different (12, 25). A-1 reactions have quite large m^* values (6), and the 4.5 observed for **8** is added confirmation of the eq. [8] mechanism for this compound.

Trends are apparent in Table 2; increasing methyl substitution in **1–3** and **4–6** increases m^* for the 1 H_2O mechanism and decreases it for the 3 H_2O one. The eq. [7] mechanism seems to have m^* closer to one than does the eq. [6] mechanism. Increasing lactam ring size decreases m^* for both mechanisms. All of this probably reflects differing degrees of positive charge dispersal at the transition state. For instance in mechanism [5] it has to change from its initial state of delocalization over the oxygen, nitrogen, and phenyl in the protonated amide reactant, to a positive charge localized entirely on nitrogen in the T^+_N product, and in mechanism [6] to a position localized on the incoming oxygen in T^+_O. In view of this the supposition that the transition state does not closely resemble the protonated amide reactant if half-way or more along the reaction coordinate does not seem unreasonable; the activation entropies are indicative of a high degree of solvent orientation, and thus a late rather than an early transition state. At this time care in not overinterpreting the actual m^* magnitudes seems advisable, but it is apparent that once a large enough body of data for different reactions is available, m^* could well have the utility of other linear free energy relationship slope values.

In dilute acid where the water concentration is high, nucleophilic addition of water to the carbonyl group requires three water molecules for amide hydrolysis, compared to two for esters (6, 8, 29) and thiol- and thionesters (6, 43). This is understandable as the esters do not have an adjacent nitrogen to accept positive charge as in eq. [5], so this is dispersed onto the second H_2O, which becomes H_3O^+ (8). Even when water acts as a base some charge dispersal appears to be necessary, with observed *r*-values approaching two for acid-catalyzed acetophenone enolizations (7). However, when water takes part in a nucleophilic *substitution* as in eq. [7] above, only one water molecule appears in the transition state, even in dilute acid (Fig. 5). Evidently charge dispersal into the solvent is minimal, which may mean an early transition state, with little charge buildup on the incoming water, for this reaction. This receives some support from the observed m^* values, at least as far as the comparison between eqs. [6] and [7] is concerned, and it is consistent with Hammond's postulate (44), which predicts late transition states for eqs. [5] and [6], with their relatively high energy intermediates T^+_N and T^+_O, and an earlier one for eq. [7], which goes directly to product.

In summary, delineation of a comprehensive mechanistic framework for amide hydrolyses in strong acid media is now possible, based on the $A_O{}^T2$ mechanism and scheme [6]. In dilute acid the 3 H_2O pathway of eq. [5] is followed, and in concentrated sulfuric acid the bisulfate ion hydrolysis of eq. [9] can take place. For sterically crowded methylbenzimidatium ions the S_N2 displacement at the *O*-methyl group of eq. [7] becomes favourable. Hydrolysis via an *N*-protonated species is not a common reaction, being observed in this work only for the highly strained β-lactam **8**, which reacts via the $A_N{}^D1$ mechanism of eq. [8].

Reçu le 2 février 1981

GENEVIÈVE FABRE, NOËL COLLIGNON et PHILIPPE SAVIGNAC. Can. J. Chem. **59**, 2864 (1981).

La réaction des aldéhydes phosphoniques avec la benzylamine, en présence de $NaBH_3CN$, conduit aux *N*-benzylaminoalkylphosphonates qui sont débenzylés par hydrogénation catalytique. Lorsque l'amination est effectuée en présence d'hydrogène et de palladium, la réduction et la débenzylation sont simultanées. En l'absence de réducteur, l'énaminobenzylphosphonate peut être isolé puis alkylé à l'azote. L'hydrolyse des aminoesters phosphoniques par HCl dilué libère les amino-acides phosphoniques. L'ordre de déroulement de chacune des opérations, ainsi que le choix du catalyseur, sont étudiés.

GENEVIÈVE FABRE, NOËL COLLIGNON and PHILIPPE SAVIGNAC. Can. J. Chem. **59**, 2864 (1981).

The reaction of phosphonic aldehydes with benzylamine in presence of $NaBH_3CN$ yields benzylaminoalkylphosphonates which, submitted to catalytic hydrogenation, lead to phosphonic amino esters. When reductive amination is carried out with H_2/Pd reduction and debenzylation are observed simultaneously. In the absence of reducing agent the enaminobenzylphosphonate can be isolated and *N*-alkylated. Hydrolysis of phosphonic amino-esters with dilute HCl gives phosphonic amino acids. The order of occurrence of each operation, as well as the choice of the catalyst is discussed.

Introduction

L'étude de la biosynthèse de l'acide amino-2 éthylphosphonique (AEPA ou ciliathine), simultanément réalisée par plusieurs équipes (1), a montré que l'oxo-2 éthylphosphonate de diéthyle est un précurseur de cet acide. Cependant malgré sa disponibilité et sa réactivité, les possibilités synthétiques offertes par cet aldéhyde n'ont pas été exploitées; seule une préparation, due à Isbell *et al.* (2), le met en jeu. Son emploi ainsi que celui de ses homologues nécessitent la mise au point de réactions spécifiques permettant d'introduire sélectivement une fonction amine, primaire, secondaire ou tertiaire.

Dans le but d'accéder aux acides à fonction primaire, nous avons étudié l'aminobenzylation du phosphonoacétaldéhyde et des homologues. Cette réaction, quel que soit l'aldéhyde, conduit aux acides aminophosphoniques recherchés; avec le phosphonacétaldéhyde l'intermédiaire de l'aminobenzylation possèdant un hydrogène échangeable par un métal, elle conduit également aux acides aminoéthylphosphoniques secondaires. Le schéma réactionnel suivi, ainsi que les acides préparés, sont décrits dans la figure 1.

Résultats

L'ensemble des résultats est rassemblé dans le Tableau 1.

(a) Acides aminoalkylphosphoniques primaires

La synthèse est divisible en trois étapes: l'aminobenzylation, la débenzylation et l'hydrolyse. L'étude et la mise au point de ces réactions nous ont conduits à l'établissement de deux méthodes séquencées et d'une méthode directe. Les méthodes séquencées se différencient au niveau de l'ordre de réalisation des étapes (**1** → **2** → **3** → **4** → **5**) ou (**1** → **2** → **4** → **5**) qui sont chacune consécutives alors que dans la méthode directe les deux premières étapes sont simultanées (**1** → **2** → **3**) et la troisième (**3** → **5**) distincte. En prenant le phosphonoacétaldéhyde comme modèle, nous avons comparé chacune des méthodes. Dans les méthodes séquencées nous réalisons l'aminobenzylation (**1** → **2**) dans le méthanol à pH 7 en présence de $NaBH_3CN$ commercial. Le rendement est régulier mais n'excède pas 85%.

La débenzylation (**2** → **3**) s'effectue sur le composé brut dans l'éthanol à 20°C en présence du couple $H_2/Pd(OH)_2/C$; elle est totale au bout d'environ 16 h sans aucune autre dégradation apparente de l'aminophosphonate. Cependant, il est utile de préciser que l'emploi d'hydroxyde de palladium sur charbon, même fraîchement préparé, ne donne pas des réactions reproductibles et la débenzylation est fréquemment incomplète. Nous attribuons le déroulement irrégulier de cette réaction à un empoisonnement du catalyseur par l'aminophos-

phonate dont la qualité n'est pas toujours constante. Le remplacement de l'hydroxyde de palladium par le catalyseur commercial Pd/C s'est révélé inefficace quelles que soient les conditions opératoires (temps ou T^0). Dans les cas favorables, le rendement de débenzylation en présence d'hydroxyde de palladium est de 95%.

L'étape (**3** → **5**) utilise les procédés d'hydrolyse et de purification sur résines échangeuses d'ions précédemment décrits (3) (essai 5a).

Les difficultés rencontrées lors de l'emploi de l'hydroxyde de palladium sur charbon nous ont amenés à inverser l'ordre des réactions afin d'éviter son emploi. Ainsi après isolement de **2**, on procède à l'hydrolyse acide (**2** →**4**) (70%) puis à la débenzylation de l'acide aminobenzylphosphonique (**4** → **5**). Dans cette dernière étape, seul le catalyseur commercial Pd/C dans l'eau à 100°C permet une débenzylation complète (79%) (essai 5a′). L'emploi de $Pd(OH)_2/C$ que se soit dans l'eau ou l'acide acétique, conduit toujours à des mélanges d'aminophosphonates partiellement débenzylés.

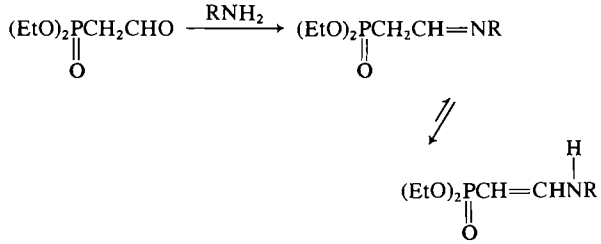
Cette seconde séquence, qui utilise un catalyseur commercial stable dont chaque étape est reproductible et dont les rendements sont réguliers, est préférable à la première.

Dans la méthode directe, nous réalisons simultanément l'aminobenzylation et la débenzylation (**1** → **3**). Nous opérons dans l'éthanol à 60°C en présence du couple $H_2/Pd/C$ avec un léger excès de benzylamine afin d'éviter la formation d'aminodiphosphonates (4). Cette opération conduit à l'isolement de **3** totalement débenzylé avec un très bon rendement (88%); on procède à l'hydrolyse sans purification préalable et obtient ainsi des acides **5** avec une pureté et un rendement supérieurs à ceux des deux précédentes méthodes (essai 5a″). Cette voie directe, qui est simple, rapide et également économique, est plus avantageuse que les deux précédentes.

L'extension de la réaction d'aminobenzylation aux homologues du phosphonoacétaldéhyde a été réalisée par la séquence directe (essais 5b, 5c). Ces structures moins énolisables et moins fragiles donnent à chaque opération des résultats très supérieurs à ceux observés avec le phosphonoacétaldéhyde. A la suite d'un travail récemment publié (5) nous avons substitué la dibenzylamine à la benzylamine. Son emploi n'apporte aucune amélioration sensible justifiant cette substitution (essai 5a‴).

(b) Acides aminoéthylphosphoniques secondaires

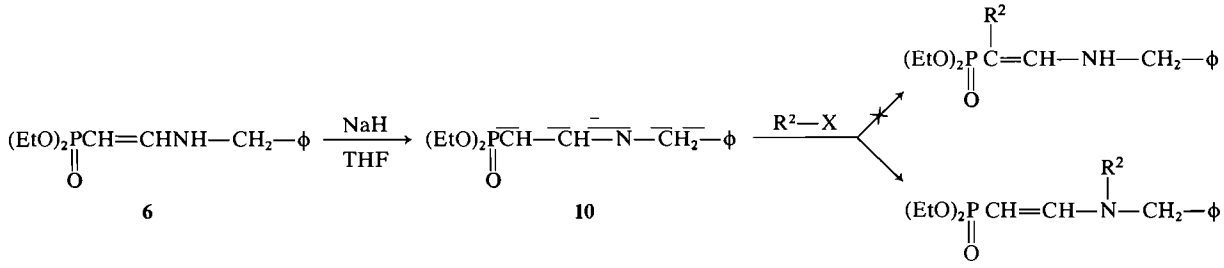
L'action d'une amine primaire sur l'oxo-2 éthylphosphonate de diéthyle conduit à un iminophosphonate dont Nagata et Hayase (6) ont montré qu'en solution il s'isomérisait en énaminophosphonate. L'existence de cet équilibre tautomère, dû à la présence du groupe phosphoryle, permet d'obtenir une métallation en α du phosphore conduisant ensuite, suivant l'électrophile engagé, soit à une alkylation, soit à une élimination.



Nous avons étudié cette réaction dans le cas du couple phosphonoacétaldéhyde–benzylamine, qui en solution, conduit à la formation prépondérante d'énaminophosphonate **6**. La géométrie de cette énamine phosphonique (7), lorsqu'elle est réalisée dans le benzène anhydre à la température ambiante, est majoritairement *cis*.

L'action de d'hydrure de sodium dans le THF sur **6** conduit à l'anion mésomère **10** dont l'alkylation fournit un énaminophosphonate **7** totalement substitué à l'azote. Trois alkylations ont été faites (R^2 = Me (67%), Et (80%), allyle (84%)).

A l'opposé du sodium et ainsi qu'il avait été observé par Nagata et Hayase (6) le magnésium ne donne jamais une réaction complète. L'énaminophosphonate **7** est réduit et débenzylé en **8** soit par le procédé séquencé, soit par le procédé direct puis hydrolysé en acides **9** (essais 9d, 9e, 9f).



6 10 7

Conclusion

Cette voie d'accès aux acides phosphoniques aminés en position β ou γ n'avait, à notre connaissance, jamais été décrite. Son emploi soustrait l'aldéhyde aux réactions de polycondensation qui constituent l'écueil principal des préparations d'amines primaires à partir d'une fonction bivalente. Elle représente la seule préparation spécifique d'amino-acides primaires à partir des précurseurs naturels.

Partie expérimentale

Les spectres rmn ^1H sont enregistrés à 60 MHz sur Varian T60 ou A60; les solvants sont $CDCl_3$, CCl_4 ou D_2O; le Me_4Si sert de référence interne; les abréviations suivantes sont utilisées: s = singulet, d = doublet, t = triplet, q = quadruplet, qi = quintuplet, m = massif, mu = multiplet. Les spectres ir sont tracés sur Beckman Acculab TM2 (liquide pur ou pastilles de KBr). Les chromatographies en phase gazeuse (cpg) ont été réalisées sur Girdel 300 FN1 (colonnes SE30 ou OV1). Les points de fusion sont déterminés sur banc Kofler et ne sont pas corrigés. La purification des acides aminoalkylphosphoniques est réalisée sur résine Amberlite IRA 410. Les analyses élémentaires (C, H, N) sont déterminées sur un appareil Technicon. Les hydrogénations sont effectuées avec un hydrogénateur simple de laboratoire sous la pression atmosphérique.

Préparation des matières premières et réactifs

Les aldéhydes phosphoniques

L'oxo-2 éthylphosphonate de diéthyle, l'oxo-3 propylphosphonate de diéthyle et le méthyl-1 oxo-3 propylphosphonate de diéthyle sont préparés suivant des procédés récemment décrits (8).

Les catalyseurs

Le palladium (Pd/C 10%) est le catalyseur commercial Merck. L'hydroxyde de palladium ($Pd(OH)_2/C$) est préparé suivant la méthode adaptée de Pearlman (9).

Séquence 1 → 2 → 3 → 5

Synthèse du N*-benzylamino-2 éthylphosphonate de diéthyle* (**2**, $n = 0$, $R^1 = H$)

A un mélange d'oxo-2 éthylphosphonate de diéthyle (2 g, 1.1×10^{-2} mol) et de benzylamine (1.2 g, 1.1×10^{-2} mol) en solution dans 20 mL de méthanol, on ajoute une solution de cyanoborohydrure de sodium (0.7 g, 1.1×10^{-2} mol) dans 20 mL de méthanol. Le pH de la solution est amené à 7–7,5 par addition d'une solution (≃ 10 *M*) de HCl gazeux dans le méthanol. Le mélange est agité magnétiquement à température ambiante dans un erlenmeyer bouché par un septum et la réaction suivie en cpg. La réduction est presque complète après l'addition d'HCl. L'agitation est poursuivie pendant 1 h environ. Le mélange est acidifié à pH ≃ 1 par HCl concentré. Le méthanol est évaporé et le résidu repris par 25 mL d'eau. Cette phase aqueuse est lavée à l'éther (3 × 30 mL), alcalinisée à pH ≃ 10 par KOH en pastilles, saturée avec NaCl et extraite par CH_2Cl_2 (4 × 25 mL). L'extrait séché et évaporé donne 2,6 g (86%) d'une huile brute à laquelle nous avons attribué la structure du *N*-benzylamino-2 éthylphosphonate de diéthyle, après examen des spectres ir et de rmn ^1H, résumés ci-dessous. Infrarouge ir (liq. pur) ν : 3280 (NH), 1230, 1050–1020 et 950 (O—P(O)), 730 et 680 (Ph) cm^{-1}; rmn ^1H (CCl_4) δ(ppm): 1.25 (t, 6H, CH_3—CH_2O, $J = 7$ Hz), 1,8 (2 t, 2H, P(O)CH_2, $J = 7$ Hz, $J_{PH} = 18$ Hz), 2.0(s, 1H, *NH*), 2.8(2 t, 2H, CH_2NH, $J = 7$ Hz, $J_{PH} = 17$ Hz), 3.7 (s, 2H, CH_2Ph), 4.0(qi, 4H, OCH_2CH_3, $J = 7$ Hz, $J_{PH} = 7$ Hz), 7.2 (s large, 5H, H_{ar}).

Synthèse de l'amino-2 éthylphosphonate de diéthyle (**3**, $n = 0$, $R^1 = H$)

Au *N*-benzylamino-2 éthylphosphonate de diéthyle (2.5 g, 9.2×10^{-3} mol) en solution dans 50 mL d'éthanol, on ajoute le catalyseur $Pd(OH)_2/C$ (1.21 g) fraichement préparé et hydrogène à température ambiante pendant 16 h. Le catalyseur est séparé par filtration sur Célite, l'éthanol est évaporé. L'huile brute obtenue pèse 1.56 g (94%); nous lui avons attribué la structure de l'amino-2 éthylphosphonate de diéthyle après examen de ses spectres ir et de rmn ^1H que nous résumons: ir (liq. pur) ν: 3360, 3280 et 1610 (NH_2), 1230, 1050–1020 et 950 (O—P(O)) cm^{-1}; rmn ^1H (CCl_4) δ (ppm): 1.3 (t, 6H, CH_3—CH_2O, $J = 7$ Hz), 1.9 (2t, 2H, P(O)CH_2, $J = 7$ Hz, $J_{PH} = 18$ Hz), 1.9 (s, 2H, NH_2), 2.9 (2t, 2H, CH_2—NH_2, $J = 7$ Hz, $J_{PH} = 15$ Hz), 4.1 (qi, 4H, OCH_2CH_3, $J = 7$ Hz, $J_{PH} = 7$ Hz).

Synthèse de l'acide amino-2 éthylphosphonique (ou AEPA) (**5**, $n = 0$, $R^1 = H$)

L'amino-2 éthylphosphonate de diéthyle (1.4 g, 7.7×10^{-3} mol) est porté au reflux dans 25 mL d'HCl 8 M pendant 18 h. La solution refroidie est lavée par CH_2Cl_2 (2 × 30 mL), puis évaporée. Le résidu est remis en solution dans 30 mL d'eau, puis la solution est évaporée à nouveau; cette opération est répétée 4 fois. Le résidu est remis en solution dans 100 mL d'eau et éventuellement décoloré à chaud au noir animal. La solution obtenue est passée sur colonne de résine Amberlite IRA 410 (sous forme OH^-) qui fixe les ions Cl^- et l'acide aminophosphonique. Après un lavage à l'eau de la résine, l'acide aminophosphonique est sélectivement décroché par une solution d'acide acétique à 5% en poids. L'évaporation de la fraction de pH 7–3 fournit 0.42 g (43%) de cristaux blancs, pF > 260°C, dont le spectre de rmn ^1H correspond à la structure de l'AEPA: rmn ^1H (D_2O) δ (ppm): 2.0 (2t, 2H, P(O)CH_2, $J = 8$ Hz, $J_{PH} = 17$ Hz), 3.2 (2t, 2H, CH_2NH_2, $J = 8$ Hz, $J_{PH} = 10$ Hz), mais dont l'analyse (à 1.2% près sur C et 0.7% près sur N) est médiocre.

Le rendement global de la séquence **1 → 2 → 3 → 5** s'établit à 34% (essai 5a).

Séquence 1 → 2 → 4 → 5

L'étape **1 → 2** est identique à celle de la séquence précédente.

Synthèse de l'acide N*-benzylamino-2 éthylphosphonique* (**4**, $n = 0$, $R^1 = H$)

Le *N*-benzylamino-2 éthylphosphonate de diéthyle (2.2 g, 8.1×10^{-3} mol) est porté au reflux dans 25 mL d'HCl 8 *M* pendant

18 h. La suite du traitement est identique à celui de la synthèse de l'AEPA. On isole 1.21 g (69,5%) de cristaux blancs, pF > 260°C, auxquels nous avons attribué la structure de l'acide *N*-benzylamino-2 éthylphosphonique; rmn ^1H (D_2O) δ (ppm): 2.2 (2t, 2H P(O)CH_2, J = 8 Hz, J_{PH} = 18 Hz), 3.5 (2t, 2H, CH_2—NH, J = 8 Hz, J_{PH} = 18 Hz), 4.3 (s, 2H, CH_2Ph), 7.5 (s, 5H, H_{ar}). *Anal.* calc. pour $C_9H_{14}NO_3P$: C 50.23, H 6.51, N 6.51; trouvé: C 50.09, H 6.56, N 6.59.

Synthèse de l'AEPA (**5**, n = 0, R^1 = H)

L'acide *N*-benzylamino-2 éthylphosphonique (1.2 g, 5.6 × 10^{-3} mol), le catalyseur commercial Pd/C 10% (0.6 g) et 20 mL d'eau sont placés dans un ballon équipé d'un réfrigérant à reflux, d'un agitateur magnétique et d'un capillaire de barbotage. Le mélange est dégazé par barbotage d'argon pendant 1 h 30 à température ambiante. L'argon est remplacé par l'hydrogène (≃ 50 mL/min) et on porte à 100°C en maintenant une agitation vigoureuse pendant 10 h. Le catalyseur est séparé par filtration sur Célite, le filtrat, évaporé à sec donne 0.55 g (79%) de cristaux blancs, pF > 260°C dont le spectre de rmn ^1H (dans D_2O) est analogue à celui de l'AEPA décrit ci-dessus. L'analyse est à 0.7% près sur N.

Le rendement global de la séquence **1** → **2** → **4** → **5** s'établit à 47% (essai 5a').

Méthode directe **1** → **3** → **5**

Synthèse de l'AEPA (**5**, n = 0, R^1 = H)

L'oxo-2 éthylphosphonate de diéthyle (3 g, 1.7 × 10^{-2} mol), la benzylamine (2.35 g, 2.2 × 10^{-2} mol), le catalyseur commercial Pd/C 10% (0.6 g) et 100 mL d'éthanol sont placés dans la fiole à hydrogéner et agités magnétiquement pendant 19 h à 65°C. Après séparation du catalyseur et évaporation de l'alcool et de la benzylamine en excès, on isole 2.7 g (88%) d'une huile brute à laquelle nous avons attribué la structure de l'amino-2 éthylphosphonate de diéthyle (**3**, n = 0, R^1 = H) grâce aux spectres ir et rmn ^1H analogues à ceux décrits ci-dessus. Cette huile brute est hydrolysée comme précédemment par HCl 8 M au reflux et l'acide obtenu, purifié sur résine Amberlite IRA 410 (Rdt d'hydrolyse: 64%); le spectre de rmn ^1H (dans D_2O) des cristaux blancs isolés est analogue à celui de l'AEPA décrit ci-dessus. L'analyse donne les résultats suivants. *Anal.* calc. pour $C_2H_8NO_3P$: C 19.20, H 6.40, N 11.20; trouvé: C 19.13, H 6.69, N 10.98.

Le rendement global s'établit à 56% (essai 5a'').

Synthèse de l'acide amino-3 propylphosphonique (**5**, n = 1, R^1 = H)

Le mélange d'oxo-3 propylphosphonate de diéthyle (2 g, 10^{-2} mol), de benzylamine (1.43 g, 1.3 × 10^{-2} mol), de catalyseur Pd/C 10% (0.4 g) et d'éthanol (50 mL) est hydrogéné pendant 17 h à 55°C. Après traitement, l'huile brute pèse 2 g (≃ 100%); nous lui avons attribué la structure de l'amino-3 propylphosphonate de diéthyle (**3**, n = 1, R^1 = H) d'après ses spectres ir et de rmn ^1H: ir (liq. pur) ν: 3380, 3300 et 1600 (NH_2), 1220, 1020 et 940 (O—P(O))cm^{-1}; rmn ^1H (CCl_4) δ (ppm): 1.25 (t, 6H, CH_3—CH_2O, J = 7 Hz), 1.3 à 1.4 (s large, 2H, NH_2), 0.9 à 2.0 (mu mal résolu, 4H, P(O) CH_2—CH_2), 2.6 (t, 2H, CH_2NH_2, J = 6 Hz), 4.0 (qi, 4H, OCH_2CH_3, J = 7 Hz, J_{PH} = 7 Hz). L'huile brute précédente (1.9 g, 9.7 × 10^{-3} mol) est hydrolysée dans 30 mL d'HCl 8 *M* au reflux 18 h. Après traitement, on isole 1.2 g (89%) de cristaux blancs, pF > 260°C auxquels nous avons attribué la structure de l'acide amino-3 propylphosphonique; rmn ^1H (D_2O) δ (ppm): 1.3 à 2.3 (mu mal résolu, 4H, P(O) CH_2—CH_2), 3.2 (t, 2H, CH_2—NH_2, J = 7 Hz). *Anal.* calc. pour $C_3H_{10}NO_3P$: C 25.89, H 7.19, N 10.07; trouvé: C 25.55, H 7.40, N 9.90.

Le rendement global s'établit à 89% (essai 5b).

Synthèse de l'acide amino-3 méthyl-1 propylphosphonique (**5**, n = 1, R^1 = Me)

Le mélange de méthyl-1 oxo-3 propylphosphonate de diéthyle (2 g, 9.6 × 10^{-3} mol), de benzylamine (1.33 g, 1.24 × 10^{-2} mol), de catalyseur Pd/C 10% (0.35 g) et d'éthanol (75 mL) est hydrogéné pendant 15 h à 60°C. Après traitement, l'huile brute pèse 2 g (≃ 100%): nous lui avons attribué la structure de l'amino-3 méthyl-1 propylphosphonate de diéthyle (**3**, n = 1, R^1 = Me) après examen de ses spectres ir et de rmn ^1H; ir (liq. pur) ν: 3340, 3280 et 1600 (NH_2), 1220, 1050–1020 et 950 (O—P(O)) cm^{-1}; rmn ^1H (CCl_4) δ (ppm): 1.1 (2d, 3H, —CH(CH_3), J = 7 Hz, J_{PH} = 18 Hz), 1.3 (t, 6H, CH_3—CH_2O, J = 7 Hz), 1.3 à 2.3 (m, 5H, P(O)—CH(CH_3)—CH_2 et NH_2, s large à 1.7), 2.7 (t mal résolu, 2H, CH_2NH_2, J ≃ 6 Hz); 4.0 (qi, 4H, OCH_2CH_3, J = 7 Hz, J_{PH} = 7 Hz).

L'huile brute précédente (1.9 g, 9.1 × 10^{-3} mol) est hydrolysée dans 25 mL d'HCl 8 *M* au reflux 15 h. Après traitement, on isole 1.2 g (86%) de cristaux blancs, pF > 260°C auxquels nous avons attribué la structure de l'acide amino-3 méthyl-1 propylphosphonique; rmn ^1H (D_2O) δ (ppm): 1.3 (2d, 3H, CH(CH_3), J = 6 Hz), J_{PH} = 17 Hz), 1.7 (mu mal résolu, 3H, P(O)CH(CH_3)-CH_2), 3.3 (t, 2H, CH_2NH_2, J = 7 Hz) *Anal.* calc. pour $C_4H_{12}NO_3P$: C 31.37, H 7.84, N 9.15; trouvé: C 31.12, H 7.68, N 9.00.

Le rendement global s'établit à 86% (essai 5c).

Synthèse d'acides aminoéthylphosphoniques secondaires

Nous décrivons la synthèse de l'acide *N*-propylamino-2 éthylphosphonique (essai 9f).

Synthèse de l'énaminophosphonate

L'oxo-2 éthylphosphonate de diéthyle (2 g, 1.1 × 10^{-2} mol) et la benzylamine (1.18 g, 1.1 × 10^{-2} mol) sont mélangés dans 30 mL de benzène anhydre et portés au reflux pendant 2 h avec distillation azéotropique. L'évaporation du benzène donne 2.95 g (≃ 100%) d'une huile brute à laquelle nous avons attribué la structure du *N*-benzylamino-2 vinylphosphonate de diéthyle après examen de ses spectres ir et de rmn ^1H: ir (liq. pur) ν: 3260 (NH), 3050 (=CH), 1615 (C=C *cis* majoritaire), 1585 (C=C *trans* minoritaire), 1190, 1055–1030 et 955 (O—P(O)), 750 et 700 (Ph) cm^{-1}; rmn ^1H (CCl_4) δ (ppm): 1.1 et 1.2 (2t imbriqués dont les intensités relatives sont dans le rapport ≃ 85/15, 6H, CH_3—CH_2O, J = 7 Hz), 3.8 (qi, 4H, OCH_2CH_3, J = 7 Hz), 3.7 à 4.5 (mu, > 3H, P(O)—CH=, CH_2Ph et NH de la forme *trans*), 6.7 à 7.6 (s large et mu, > 6H, =CH—NH, H_{ar} et NH de la forme *cis*).

Alkylation de l'énaminophosphonate

Dans un tricol équipé d'un agitateur magnétique, d'un thermomètre, d'un réfrigérant à reflux, d'une ampoule isobare et relié à un gazomètre, on place l'hydrure de sodium (0.58 g de la suspension commerciale à 50% dans l'huile, 1.2 × 10^{-2} mol) préalablement dégraissé, le THF anhydre (30 mL) et le bromure d'allyle (1.6 g, 1.3 × 10^{-2} mol). L'énaminophosphonate (2.9 g, 1.1 × 10^{-2} mol) en solution dans le THF (20 mL) est ajouté goutte à goutte sous agitation, la température atteint 27°C. Après addition, on chauffe à 30°C pendant 4 h jusqu'à obtention du volume théorique d'hydrogène. Après hydrolyse et traitement habituel, on isole 2.8 g (84%) d'une huile brute à laquelle nous avons attribué la structure du *N*-allyl, *N*-benzylamino-2 vinylphosphonate de diéthyle après examen des spectres ir et de rmn ^1H; ir (liq. pur) ν: 1620 (C=C), 1240, 1065–1040 et 960 (O—P(O)), 745 et 700 (Ph)cm^{-1}; rmn ^1H (CCl_4) δ (ppm): 1.2 (t, 6H, CH_3—CH_2O, J = 7 Hz), 3.9 (qi, 4H, OCH_2CH_3, J = 7 Hz, J_{PH} = 7 Hz), 4.3 (s, 2H, CH_2Ph), 3.5 à 4.5 (mu, 3H, P(O)—CH=, N—CH_2—CH=), 4.6 à 6.2 (mu, 3H, —CH=CH_2), 6.7 à 7.8 (s large et mu, 6H, H_{ar} et =CH—N).

Réduction–débenzylation du N-*alkylénaminophosphonate*

Le *N*-allyle *N*-benzylamino-2 vinylphosphonate de diéthyle (2.7 g, 8.7 × 10^{-3} mol) est hydrogéné en présence de catalyseur commercial Pd/C 10% (0.33 g) dans 50 mL d'éthanol, à 60°C pendant 15 h. Après filtration du catalyseur et évaporation, on isole 1.75 g (90%) d'une huile brute à laquelle nous avons attribué la structure du *N*-propylamino-2 éthylphosphonate de

diéthyle à l'examen de ses spectres ir et de rmn ^1H; ir (liq. pur) ν: 3300 (NH), 1240, 1060–1035 et 960 (O—P(O)) cm^{-1}; rmn ^1H (CCl_4) δ (ppm): 0.9 (t, 3H, CH_2—CH_2—CH_3, J = 7 Hz), 1.3 (t, 6H, CH_3—CH_2O, J = 7 Hz), 1.1 à 2.3 (mu, 4H, P(O)—CH_2 et CH_2—CH_2—CH_3), 2.1 (s, 1H, *NH*), 2.5 (t, 2H, N—CH_2—CH_2—CH_3, J = 7 Hz), 2.7 (2t, 2H, P(O) CH_2—CH_2—NH, J = 7 Hz, J_{PH} = 17 Hz), 4.0 (qi, 4H, OCH_2CH_3, J = 7 Hz, J_{PH} = 7 Hz).

Hydrolyse du N-*alkylamino-2 éthylphosphonate*

Le *N*-propylamino-2 éthylphosphonate de diéthyle (1.7 g, 7.6 × 10^{-3} mol) est hydrolysé dans 23 mL d'HCl 8 *M* au reflux 19 h. Après traitement et purification habituels, on isole 0.9 g (71%) de cristaux blancs, pF > 260°C auxquels nous avons attribué la structure de l'acide *N*-propylamino-2 éthylphosphonique; rmn ^1H (D_2O) δ (ppm): 1.1 (t, 3H, CH_2—CH_2—CH_3, J = 7 Hz), 1.3 à 2.4 (mu, 4H P(O)—CH_2 et CH_2—CH_2—CH_3), 3.2 (t, 2H, N—CH_2—CH_2—CH_3, J = 7 Hz), 3.3 (2t, 2H, (P(O)CH_2—CH_2—NH), J = 7 Hz, J_{PH} = 10 Hz). *Anal.* calc. pour $C_5H_{14}NO_3P$: C 35.93, H 8.38, N 8.38; trouvé: C 36.24, H 8.09, N 8.00.

Le rendement global de l'opération s'établit à 53%.

Carbon-13 magnetic resonance: hydrogen involvement in γ-*anti* substituent effects

T. P. FORREST AND J. THIEL[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received October 27, 1980[2]

T. P. FORREST and J. THIEL. Can. J. Chem. **59**, 2870 (1981).

Chemical shifts have been determined for the carbons in a series of 3,3-dimethylcyclohexyl derivatives, (substituent = H, CH_3, NH_2, OH, Cl, Br, I). Comparison of the γ-*anti* substituent effects at carbons 3 and 5 indicates that presence of axial protons on these carbons causes increased shielding by all of the above substituents. The shielding by γ-*anti* substituents is decreased by the replacement of either the α or γ protons by methyl groups; the extent of the decrease is dependent upon the substituent and upon the position of the hydrogen which is replaced.

T. P. FORREST et J. THIEL. Can. J. Chem. **59**, 2870 (1981).

On a déterminé les déplacements chimiques du carbone de dérivés du diméthyl-3,3 cyclohexyle (les substituants sont: H, CH_3, NH_2, OH, Cl, Br, I). La comparaison des effets de substituants γ-*anti* au niveau des carbones 3 et 5 indique que la présence de proton axiaux sur ces carbones provoque une augmentation du blindage par tous les substituants mentionnés. Le blindage par les substituants γ-*anti* diminue lorsqu'on remplace le proton α ou γ par des groupes méthyles; le taux de diminution dépend du substituant et de la position de l'hydrogène qui est remplacé.

[Traduit par le journal]

Carbon-13 chemical shifts have proven to be sensitive probes for the determination of the structure and stereochemistry of organic compounds. The effects of structural changes on chemical shift may be very complex, but satisfactory empirical correlations (1) have been established in many cases that allow the prediction of the chemical shifts. These empirical correlations continue to be developed and refined. The substituent parameter for a group in a γ-*anti* orientation has recently been purported to be dependent upon the presence or absence of hydrogens in a *syn* orientation on the α and γ carbons (2). We had observed (2*c*) in a series of compounds that shielding increased with increasing electronegativity of a γ-*anti* substituent, regardless of whether the *syn* α and γ protons were present, when the substituent was a higher row halogen (Cl, Br, I), whereas for the first row elements (CH_3, NH_2, OH, F) shielding increased with increasing electronegativity when the *syn* α and γ hydrogens were present, but decreased when they were absent. This observation of the change in electronegativity dependence of the substituent parameter for the first row elements rested solely on compounds with bridgehead substituents for those cases without the H–H interaction. We have now measured the γ-*anti* effect in a series of compounds without bridgehead substituents to determine the effect of the H–H interaction in these cases, and to attempt to quantify the effect.

For this purpose we prepared a series of 3,3-dimethylcyclohexyl derivatives to test the electronegativity dependence of the γ-substituent effect at carbons 3 and 5. This series was chosen because it gives a conformationally homogeneous system with the substituent *anti* to two γ-carbons, the one (C-5) which has an axial proton and the second (C-3) which does not. The synthetic scheme employed in the preparation of these compounds is shown in Scheme 1; preparation of derivatives by direct nucleophilic substitution reactions was not successful, nor were attempts to prepare the fluoro derivative.

Results

Chemical shifts for the carbons of each derivative are given in Table 1. Assignments were made on the basis of off-resonance decoupling and correlations with established empirical parameters (1) for cyclohexane chemical shifts. The chemical shifts of the methylene carbons (C-2, C-4, C-5, C-6) were different enough so that each assignment could be made unequivocally except in the case of C-4 and C-6 of the chloride and bromide. In each compound the methyl group with the higher field chemical shift (lower δ) was assigned the axial orientation (γ-*gauche* effect).

Discussion

Parameters for the substituent effects of the different groups are given in Table 2. The values for the α, β, and δ effects for the ring carbons are similar to values reported for these substituent parameters (ref. 1*c*, p. 45).

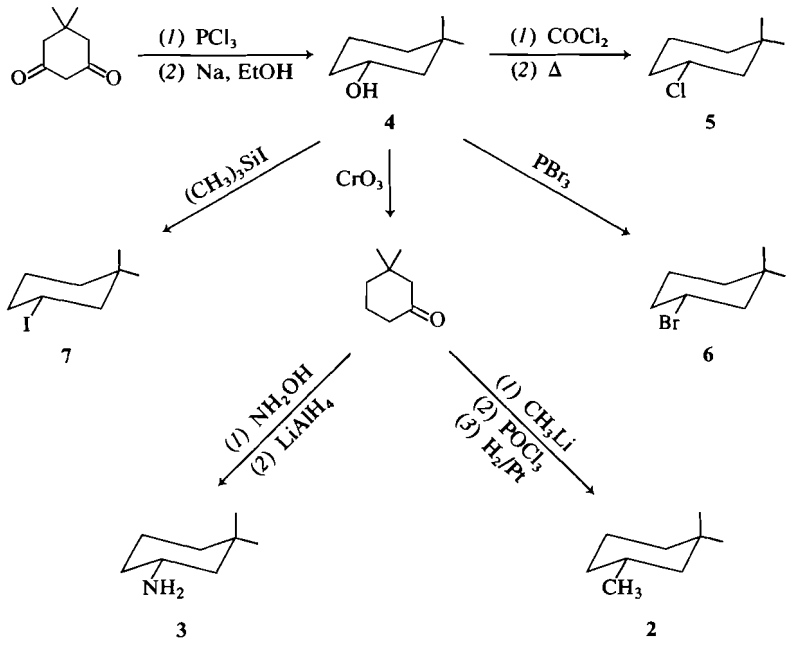

SCHEME 1

The γ-*anti* parameters observed for the two ring carbons (C-3 and C-5) are plotted against electronegativity (electronegativity values from ref. 3) in Figs. 1 and 2. In each case an approximately linear correlation is obtained for the halogens, and another with a different slope is obtained for the first row elements. The plots of the chemical shifts of C-5 are similar to those obtained from the simple cyclohexyl derivatives (4), whereas the plot of the C-3 shifts is characteristic of the γ carbon of the bridgehead substituted compounds (5). In the latter case the first-row elements have a reversed slope,

TABLE 1. Chemical shifts[a] of carbons in 3,3-dimethylcyclohexyl derivatives

Compound	X	C-1[b]	C-2	C-3	C-4	C-5	C-6	C_{eq}	C_{ax}

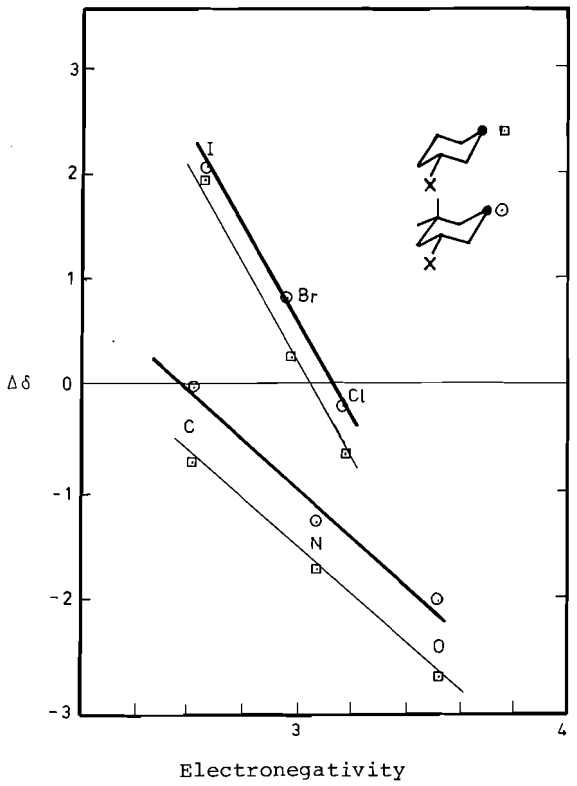

FIG. 1. γ-*anti* substituent effect on a methylene group vs. substituent electronegativity.

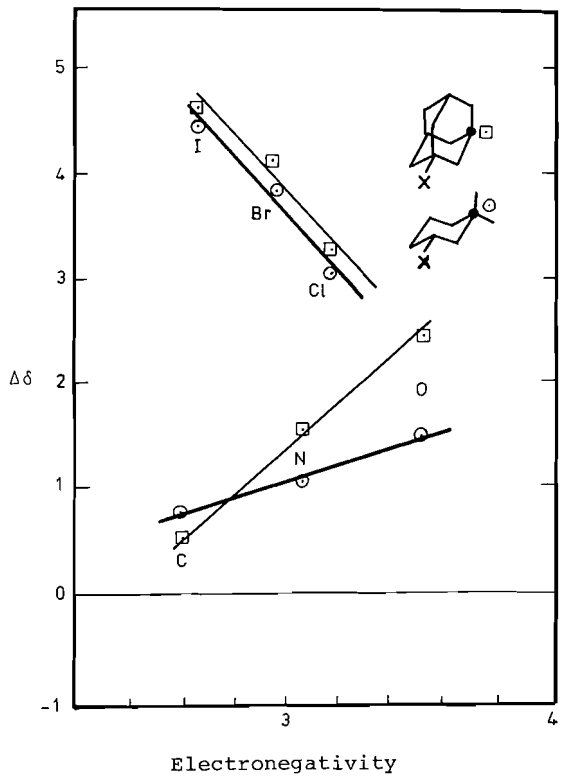

FIG. 2. γ-*anti* substituent effect on a quaternary carbon vs. substituent electronegativity.

the substituent effect becoming less shielding with increasing electronegativity. This observation supports the conclusion (2*b*) that the difference in effect is due to the substitution pattern rather than a pecularity of bridgehead substitution.

A quantification of the effect of the presence of the 1,3-diaxial hydrogen–hydrogen interaction may be sought in the difference $(\gamma_5 - \gamma_3)$ ($\Delta\gamma$ in Table 2), in the substituent effect on carbons 5 and 3. If this difference is attributed to the transmission of the substituent effect through the protons, it may be seen that this pathway contributes a shielding effect for all substituents. A plot of $\Delta\gamma$ against electronegativity shows once again that the first-row and higher-row elements have linear plots with different slopes, but in both cases the shielding increases with increasing substituent electronegativity.

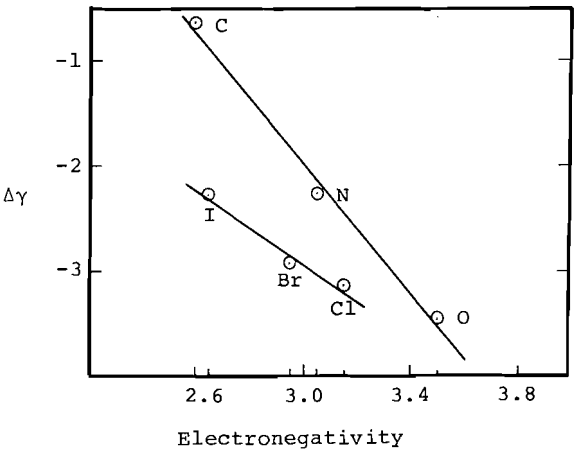

FIG. 3. Difference in γ-*anti* substituent effect with and without γ hydrogens vs. substituent electronegativity.

It might be argued that the equatorial methyl on C-3 could also be responsible, at least in part, for the change in the γ-anti substituent effect. The effect of an equatorial methyl may be detected in the chemical shift difference between C-5 and C-3 in the *cis*-3-methylcyclohexyl derivatives. As may be seen from Table 3, replacement of the equatorial hydrogen by a methyl group causes a decrease in the shielding effect of the substituents, but the decrease is significantly less than that caused by the replacement of both hydrogens of the γ carbons. The effect of the replacement of the α hydrogen by a methyl group can be seen in the comparison of the chemical shift of C-3 of 4-*tert*-butyl and *1*-methyl-

TABLE 3. Effect of α and γ protons on substituent parameters

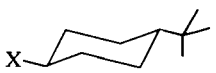
Substituent	Change in γ effect by presence of		
	both γ H's[a]	equatorial γ H[b]	α − H[c]
CH_3	−0.66	−0.40	—
NH_2	−2.47	−0.99	—
OH	−3.46	−1.44	−5.87
Cl	−3.15	−1.41	−4.29
Br	−2.93	−0.66	−3.45
I	−2.29	−0.66	−1.69

[a] $\gamma_5 - \gamma_3$ in 3,3-dimethylcyclohexyl derivatives.
[b] $\gamma_5 - \gamma_3$ in *cis*-3-methylcyclohexyl derivatives (ref. 2*b*).
[c] γ_3 in *trans*-4-*tert*-butylcyclohexyl derivatives (**8**) minus the γ_3 in the analogous 1-methyl-4-*tert*-butylcyclohexyl derivatives (**9**) (ref. 2*b*)

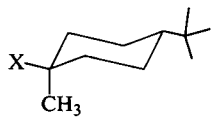
4-*tert*-butyl cyclohexyl derivatives **8** and **9** (Table 3). Loss of the α hydrogen causes the substituent to be less effective in shielding the γ carbons; the substituent effects reported for **9** (OH, Cl, Br, I, F) are in fact all deshielding (2*b*).

From the above examples it can be clearly seen that the presence of *syn* diaxial α and γ hydrogens can be directly correlated with increased shielding by γ-*anti* substituents. Removal of either of these hydrogens causes decreased shielding by the substituent, but the effect of replacing the separate protons by methyl groups is not the same numerically, thus vitiating the use of a single parameter assignable to the 1,3-*syn* hydrogen effect for γ-*anti* substituents.

Because substituent effects on carbon chemical shifts can represent a small difference between large opposing paramagnetic and diamagnetic effects, it is often difficult to rationalize the effect in



8



9

terms of factors familiar to the organic chemist. Casual observation of the plot in Fig. 3 indicated a striking similarity with the plot of the proton chemical shift of the methyl group bearing those substituents. Indeed, a plot of $\Delta\gamma$, $(\gamma_5 - \gamma_3)$, against the chemical shift of CH_3X yields a straight line (correlation coefficient = 0.995) (Fig. 4).

The observation of the direct correlation between the proton chemical shift of the simplest possible compounds in which the substituent effect on the α hydrogen can be observed is curious and perhaps entirely fortuitous; however, it does illustrate a case in which the "heavy atom effect" can be experienced by a γ carbon to the same extent as by an α proton.

A difference in the γ-*anti* effect of first-row

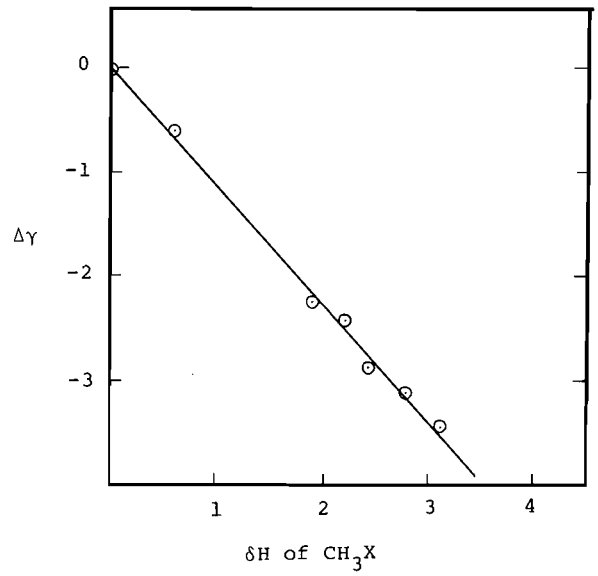


FIG. 4. Difference in γ-*anti* substituent effect vs. proton chemical shift of methyl X (ref. methane).

heteroatoms (N, O, F) and higher-row elements was well established by Eliel *et al.* (6). They concluded that first-row heteroatoms were shielding because of a hyperconjugative interaction involving the nonbonded electrons of the heteroatoms, and that this interaction would not be effective with higher-row elements. This conclusion seemed to be sound and was widely acknowleged (4), but later measurements on additional compounds indicated that the first-row heteroatoms were not always shielding as had been thought, and thus the proposed shielding mechanism is now considered unlikely (ref. 1*d*, p. 205). It is now clear that in the absence of α and γ hydrogens both first-row and higher-row elements are deshielding (Fig. 2), and that the additional shielding associated with the presence of the hydrogens is effective with the higher-row elements as well as with the first-row elements (Fig. 3 and Table 2). However, in both cases, that is in the presence or absence of α and γ hydrogens, the first-row elements are more shielding than the higher-row elements (Figs. 1 and 2 and Table 2), an observation which could be used to support the hyperconjugative donation mechanism as a contributor to the shielding mechanism.

Whatever the reasons, it would appear that the heavy atom effect may be detected at the γ-*anti* carbon through the participation in some way by the α and γ hydrogens. The nature of this participation is difficult to ascertain, but it is not essential to postulate a direct interaction between the two protons. The protons on the two carbons may

indeed act independently; polarization of either could increase the electron density at the γ carbon thus increasing the shielding effect. Although the rationalization of the effect must be speculative, the empirical observation is straightforward in that all γ-*anti* substituents cause increased shielding when α and γ protons are present compared to their effect when these protons are absent. The fact that the substituent shielding effect is decreased by replacement of any one of the three hydrogens attached to the α and γ carbons but by different amounts for the different hydrogens does not offer direct support to the proposal that the substituent effect is transmitted through a *syn* α–γ proton–proton interaction.

Experimental

Nuclear magnetic resonance spectra were determined on a Varian CFT-20 spectrometer using approximately 15% solutions in $CDCl_3$ with tetramethylsilane as internal reference. Mass spectra were determined on a CEC 21-104 mass spectrometer using a direct inlet system with a source temperature of 50°C and an ionization potential of 70 eV.

3,3-Dimethylcyclohexanol (**4**) was prepared from 5,5-dimethyl-1,3-cyclohexanedione (dimedone) by reaction with phosphorous oxychloride followed by reduction with sodium according to the procedure of Crossley *et al.* (7).

3,3-Dimethylcyclohexyl Chloride (**5**)

3,3-Dimethylcyclohexyl chloroformate was prepared (8) by the addition of excess phosgene to 3,3-dimethylcyclohexanol (5 g). The crude chloroformate was pyrolyzed at 150°C for 7 h and the product washed with concentrated sulfuric acid to remove alkenyl products. Distillation at 172–179°C at atmospheric pressure yielded 3.8 g (57%); ^{1}H nmr: 0.93 (s, 3H), 0.96 (s, 3H), 1.2–2.3 (m, 8H), 3.7–4.3 (m, 1H); mass spectrum: 148 (2.5), 146 (8.8), 133 (7.6), 131 (20.2), 111 (10.1), 110 (12.6), 95 (100), 69 (41.7), 67 (12.6), 56 (16.4), 55 (20.2), 43 (6.3), 41 (23).

3,3-Dimethylcyclohexyl Bromide (**6**)

Phosphorous tribromide (0.3 mL) was added dropwise to 3,3-dimethylcyclohexanol (1 mL) with stirring and the mixture was stirred at room temperature for 20 h. The reaction mixture was then shaken with pentane and ice water and the pentane layer washed with aqueous bicarbonate solution. The pentane solution was dried over calcium chloride and washed with concentrated sulfuric acid. Removal of the solvent *in vacuo* yielded 0.7 g of **6**; ^{1}H nmr: 0.97 (s, 3H), 0.94 (s, 3H), 1.2–2.5 (m, 8H), 3.9–4.5 (m, 1H); mass spectrum: 192–190 (1), 177–175 (0.4), 111 (4.5), 110 (100), 94 (26), 79 (50), 68 (72), 55 (34), 41 (30), 39 (14).

3,3-Dimethylcyclohexyl Iodide (**7**)

Trimethylsilyl iodide (9) (3 mL) was added by a syringe through a serum cap to 3,3-dimethylcyclohexanol (1.4 g) under nitrogen. The reaction mixture was poured into ice/pentane and the pentane layer washed with sodium bisulfite solution and water and then dried over magnesium sulfate. The product (2.7 g, 95%) was used without distillation as it decomposes rapidly on heating; ^{1}H nmr: 0.8 (s, 6H), 1–2.5 (m, 8H), 4.1–4.6 (m, 1H).

3,3-Dimethylcyclohexanone

3,3-Dimethylcyclohexanol (2 g) in acetone (40 mL) was cooled to 0°C and Jones reagent (10) (9 mL) was added with stirring over a 2 h period. After 2 h at room temperature the solvent was removed *in vacuo*, water (10 mL) was added, and the mixture extracted with ethyl acetate. The extract was dried over magnesium sulfate, the solvent removed, and the product distilled at atmospheric pressure at 175–180°C yielding 1.4 g (70%).

3,3-Dimethylcyclohexylamine (**3**)

3,3-Dimethylcyclohexanone (1 g) in methanol (4 mL) was added to a solution of hydroxylamine hydrochloride (2 g) and sodium acetate (4 g) in water (20 mL). The mixture was heated under reflux for one hour and then extracted with ether. The ether layer (15 mL) was dried with magnesium sulfate and then added to a stirred suspension of lithium aluminium hydride (2.2 g) in ether (60 mL) over 15 min. After heating under reflux for 24 h the excess hydride was decomposed by slow addition of 5% aqueous sodium hydroxide (25 mL). The resultant slurry was extracted four times with ether and the combined ether extract shaken with aqueous 1 *M* hydrochloric acid. The aqueous layer was made basic and extracted twice with ether. The ether layer was dried over anhydrous potassium carbonate and the solvent removed to yield an oil (0.4 g, 40%); ^{1}H nmr: 0.90 (s, 3H), 0.96 (s, 3H), 1.1–1.8 (m, 8H), 2.06 (bs, 2H), 2.5–3.1 (m, 1H); mass spectrum: 127 (26), 126 (5), 112 (19), 110 (2), 95 (14), 84 (100), 70 (13), 69 (10), 56 (89), 43 (32).

1,3,3-Trimethylcyclohexanol

3,3-Dimethylcyclohexanone (12 g) in dry ether (5 mL) was added under nitrogen over 10 min to a 0.6 *M* ethereal solution (30 mL) of methyl lithium while cooling with acetone – Dry Ice. After the addition was complete the cooling bath was removed and the solution heated under reflux for ½ h. The excess methyl lithium was decomposed by careful addition of water while stirring vigorously. The ether solution was washed with water, dried over magnesium sulfate, and the solvent removed to yield 1.26 g (93%) of a crystalline solid (mp 72°C); ^{1}H nmr: 0.90 (s, 3H), 1.10 (s, 3H), 1.20 (s, 3H), 1.27–2.06 (m, 8H), 2.2 (bs, 1H).

1,1,3-Trimethylcyclohexane (**2**)

Phosphorous oxychloride (1.5 mL) was added dropwise with stirring to a solution of 1,3,3-trimethylcyclohexanol (1.26 g) in pyridine (15 mL) which was maintained at 0°C. After the addition was complete the mixture was allowed to come to room temperature and after 4 h at room temperature was heated under reflux for 1.5 h. The reaction mixture was then cooled and poured onto cracked ice and then extracted three times with pentane. The combined pentane extracts were successively washed with dilute hydrochloric acid and water and after drying over potassium carbonate the solvent was removed to yield 1.08 g of mixed alkene. This dehydration product was then dissolved in acetic acid (30 mL) and hydrogenated by shaking with Adams catalyst (PtO_2) (0.25 g) under hydrogen (26 psi) at room temperature for 3 h. The catalyst was then removed by filtration and the filtrate poured into excess dilute sodium hydroxide solution containing crushed ice. The aqueous layer was extracted with pentane yielding, after evaporation of the solvent, 0.7 g of **2**; ^{1}H nmr: 0.90 (s, 6H), 0.85 (d, 3H overlaps with singlet), 1.15–1.90 (m, 9H); mass spectrum (11): 126 (7), 111 (82), 97 (4), 95 (3), 83 (44), 70 (22), 69 (100), 57 (15), 56 (30), 55 (56), 43 (15), 41 (37), 39 (11).

The synthesis and X-ray crystal structure of triiodotellurium(IV) hexafluoroarsenate(V), TeI_3AsF_6

JACK PASSMORE, GEORGE SUTHERLAND, AND PETER S. WHITE
Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received February 20, 1981

JACK PASSMORE, GEORGE SUTHERLAND, and PETER S. WHITE. Can. J. Chem. **59**, 2876 (1981).

TeI_3AsF_6 was prepared quantitatively from the reaction of iodine, tellurium, and arsenic pentafluoride in sulphur dioxide solution. Single crystals of TeI_3AsF_6 are monoclinic, $a = 8.243(2)$, $b = 10.755(2)$, $c = 12.660(2)$ Å; $\beta = 100.91(2)°$, $V = 1102$ Å^3. The structure was refined in the space group $P2_1/c$ to a conventional R factor of 0.075 for 1551 independent reflections with $I \geq 2\sigma(I)$. The structure consists of essentially discrete TeI_3^+ cations and AsF_6^- anions with some cation–anion interaction. The TeI_3^+ cation has approximate C_{3v} symmetry with an average Te—I distance of 2.667 Å and I—Te—I angle of 99.90°.

JACK PASSMORE, GEORGE SUTHERLAND et PETER S. WHITE. Can. J. Chem. **59**, 2876 (1981).

On a préparé quantitativement le composé TeI_3AsF_6 à partir de la réaction entre l'iode, le tellure et le pentafluorure d'arsenic dans une solution de bioxyde de soufre. Les cristaux simples de TeI_3AsF_6 sont monocliniques et appartiennent au groupe d'espace $P2_1/c$ avec $a = 8{,}243(2)$, $b = 10{,}755(2)$, $c = 12{,}660(2)$ Å, $\beta = 100{,}91(2)°$, $V = 1102$ Å^3. Le facteur d'accord R est de 0,075 pour 1551 réflexions indépendantes avec $I > 2\sigma(I)$. La structure comprend essentiellement des cations TeI_3^+ et des anions AsF_6^- discrets avec quelques interactions cation–anion. Le cation TeI_3^+ a approximativement une symétrie C_{3v} avec une distance moyenne Te—I de 2,667 Å et un angle I—Te—I de 99,90°.

Introduction

Salts of MF_3^+, MCl_3^+, and MBr_3^+ (M = S, Se and Te) have been prepared, and (with the exception of SBr_3^+) their structures determined by X-ray diffraction methods (1–9). The only related iodine cation known is SeI_3^+ in SeI_3AsF_6 (10) for which preliminary X-ray data were reported; however, no structural data, spectroscopic or crystallographic, were obtained. Attempts to prepare SI_3^+ salts were unsuccessful and lead initially (11) to the isolation of S_7IMF_6 (M = As, Sb). We report below the preparation and X-ray crystal structure of TeI_3AsF_6.

The structures of the binary tellurium iodides, α- and β-TeI (12), Te_2I (13), $(TeI_4)_4$ (14), the anionic tellurium iodide TeI_6^{2-} contained in K_2TeI_6 (15), and various neutral and anionic organo-tellurium iodides (16–25) are known. As far as we are aware, this is the first report on the structure of a tellurium–iodine cation.

Experimental

Apparatus, reagents, and techniques have been previously reported (10). Tellurium sticks (99.998%) supplied by Alfa-Ventron were ground to a powder before use.

In one reaction, AsF_5 (1.73 g, 10.2 mmol) was condensed onto a mixture of excesses of Te (3.90 g, 30.6 mmol) and I_2 (3.80 g, 14.9 mmol) in SO_2 (6.61 g), in a two-bulbed vessel incorporating a coarse sintered glass frit. The red–brown solution was stirred for 36 h and then filtered. The volatile material was then condensed back across the frit and the solution refiltered. TeI_3AsF_6 has a low solubility in the SO_2/AsF_3 mixture, and 38 filtrations were necessary for complete separation. On removal of the volatiles over an 8 h period 4.750 g of a highly crystalline red–black soluble product (essentially 100% yield based on AsF_5) and 3.95 g of insoluble product (excess Te and I_2) was obtained. In other preparations with shorter reaction times, yields were less than 100%.

X-Ray Data Collection

A suitable crystal was mounted in a capillary tube under dry nitrogen as previously described (10), except that the crystals were examined and manipulated with the aid of a Wild M3 microscope of long focal length mounted outside the dry box. A preliminary photographic investigation showed the space group to be $P2_1/c$ and the compound to be isostructural with $TeBr_3AsF_6$. The crystal was mounted on a Picker FACS-I diffractometer equipped with a molybdenum tube ($\lambda(K\alpha) = 0.71069$ Å) and a graphite monochromator. Final cell dimensions were obtained by a least-squares fit to the coordinates of 14 Friedel pairs of well centered reflections.

Intensity data were collected using an ω–2θ scan of 2 deg (2θ) corrected for dispersion of the Kα doublet with a scan rate of 2 deg (2θ) min^{-1}. Backgrounds were estimated from a stationary count of 1/10 of the scan time at each end of the scan. If the net intensity was greater than $2\sigma(I)$ then an analysis of the scan profile was performed and those portions which were not part of the peak were included in the background estimate. Data were collected for $2\theta \leq 50°$ which resulted in 1941 unique reflections of which 1551 were considered observed ($I \geq 2\sigma(I)$) and included in the subsequent refinement. Three standard reflections monitored every 100 reflections throughout data collection showed no significant change in their intensities. The crystal data are:

TeI_3AsF_6 fw = 697.2
Monoclinic, $P2_1/c$, $a = 8.243(2)$, $b = 10.755(2)$, $c = 12.660(2)$ Å, $\beta = 100.91(2)°$, $V = 1102$ Å^3, $Z = 4$, $\rho_c = 4.20$ Mg m^{-3}, $F(000) = 1192$, μ(Mo Kα) = 14.48 mm^{-1}, crystal size = 0.13 × 0.17 × 0.08 mm, $\lambda = 0.71069$ Å (20(±2)°C).

Structure Refinement

After correction of the data for absorption the atomic coordinates of $TeBr_3AsF_6$ were used as a starting point for

refinement. The structure was refined by a block diagonal least-squares routine using anisotropic thermal parameters for all atoms. The function minimised was $\Sigma w(\Delta F)^2$ where $w = 1/(\sigma^2(F) + pF^2)$; the measurements of the standards indicated a value of 0.005 for p. Atomic scattering factors were taken from the International tables for X-ray crystallography (26) and were corrected for anomalous dispersion. The final values of $R = \Sigma|\Delta F|/\Sigma|F_0|$ and $R_w = (\Sigma w|\Delta F|^2/\Sigma w|F_0|^2)^{1/2}$ were 0.075 and 0.100 (0.089 and 0.106 including unobserved reflections) respectively. Final positional and isotropic thermal parameters are given in Table 1.[1] All computations were performed on a PDP8/A computer using the programs of Gabe *et al.* (27).

Discussion

TeI_3AsF_6 was prepared quantitatively, in sulphur dioxide solution, according to reaction [1].

[1] $2Te + 3I_2 + 3AsF_5 = 2TeI_3AsF_6 + AsF_3$

As far as we are aware, this is the first report of a salt of TeI_3^+.

TeI_3AsF_6 is isostructural with MBr_3AsF_6 (M = Se, Te) (9), and isomorphous and probably isostructural with SBr_3AsF_6 (9) and SeI_3AsF_6 (10). Figure 1 shows the TeI_3^+ cation with anion contacts; corresponding bond distances and angles are presented in Tables 2 and 3. The closest Te···F and I···F contacts of 2.88(1) and 3.04(1) Å respectively indicate that the structure is essentially ionic, with some cation–anion interaction (c.f. sum of van der Waals radii of Te and F (3.55 Å), and I and F (3.50 Å) (28)).

The TeI_3^+ cation is of very approximately C_{3v} symmetry, with an average bond distance of 2.667(1)[2] Å and I—Te—I angle of 99.90(3)° in reasonable agreement with predictions (9) (2.65 Å, 99.2°) made by extrapolation of structural data for Group V trihalides and Group VI trihalide cations.[2] The bond distance is shorter than that found in the isoelectronic SbI_3 (g) (29) (2.719(1) Å), a consequence of the greater charge and smaller size of tellurium (formally Te^{IV}) than antimony (formally Sb^{III}). Although the TeI_3^+ bond angles vary (see Table 3), the average is larger (95.8(3)°) than that found for SbI_3(s) (30), consistent with the general observation, that chalcogen trihalide cation angles are larger than those of the corresponding Group V trihalide neutral isoelectronic partners (9).

Three fluorine contacts give a distorted octahed-

TABLE 2[a]

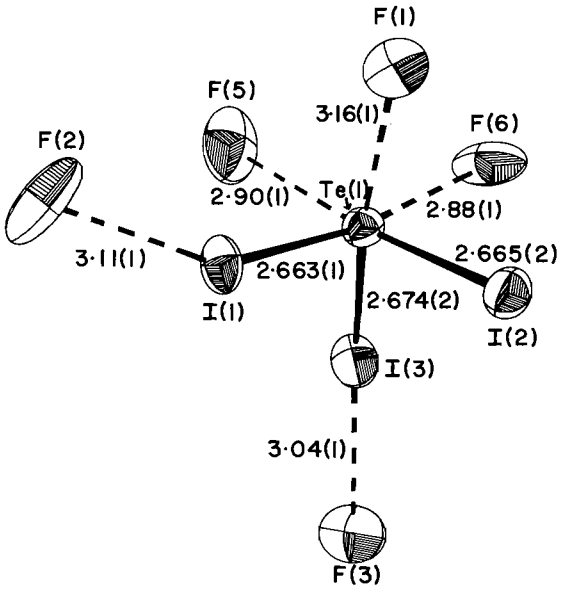

FIG. 1. TeI_3^+ with anion contacts.

ral arrangement about tellurium atom in TeI_3^+ (see Fig. 1). The strengths of contacts to TeX_3^+ cations (see Table 4) are proportional to the effective charge on tellurium. Two of the iodine atoms in TeI_3^+ have weak fluorine contacts that are somewhat stronger than the corresponding contacts to $TeBr_3^+$, consistent with the more positive character of iodine.

The AsF_6^- anions are approximately octahedral with an average As—F distance of 1.70 Å and F—As—F angle of 90.0°.

The crystal and molecular structure of 1,4-bis(1-oxa-4,10-dithia-7*H*-7-azonia cyclododecan-7-ylmethyl)benzene tetrachlorooxotetrahydrofuran molybdate(V) $[C_{24}H_{42}N_2O_2S_4]^{2+}[MoOCl_4(THF)]_2^-$

PETER H. BIRD[1] AND WASANTHA A. WICKRAMASINGHE

Department of Chemistry, Concordia University, Montreal, P.Q., Canada H3G 1M8

Received September 11, 1980

PETER H. BIRD and WASANTHA A. WICKRAMASINGHE. Can. J. Chem. **59**, 2879 (1981).

The title compound is prepared by the consecutive reaction of $MoOCl_4$ with THF and then the bismacrocyclic compound 1,4-bis(1-oxa-4,10-dithia-7-azacyclododecan-7-ylmethyl) benzene. The crystals are triclinic, space group $P\bar{1}$ (No. 2), $a = 11.993(7)$, $b = 13.196(8)$, $c = 7.928(5)$ Å, $\alpha = 104.54(4)$, $\beta = 94.89(3)$, $\gamma = 81.59(1)°$, $V = 1199.9$ Å^3, $Z = 1$. The final R factor was 0.059 for 2846 reflections where $I > 3\sigma(I)$. The compound is ionic with the macrocycles protonated on both the nitrogen atoms while the anions are octahedral $[MoOCl_4(THF)]^-$ units. These units have the oxo group (Mo═O, 1.655(7) Å) *trans* to THF (Mo—O, 2.331(5) Å). The cations adopt a centrosymmetric *trans* conformation with no strong interactions with the molybdenum.

PETER H. BIRD et WASANTHA A. WICKRAMASINGHE. Can. J. Chem. **59**, 2879 (1981).

On a préparé le composé mentionné dans le titre par la réaction du $MoOCl_4$ avec le THF, puis avec le composé bismacrocyclique bis(oxa-1 dithia-4,10 aza-7 cyclododécanyl-7 méthyl)-1,4 benzène. Les cristaux sont tricliniques et appartiennent au groupe d'espace $P\bar{1}$ (No. 2) avec $a = 11,993(7)$, $b = 13,196(8)$, $c = 7,928(5)$ Å, $\alpha = 104,54(4)$, $\beta = 94,89(3)$, $\gamma = 81,59(1)°$, $V = 1199,9$ Å^3, $Z = 1$. Le facteur d'accord R est de 0,059 pour 2846 réflexions avec $I > 3\sigma(I)$. Le composé est ionique avec les macrocyles protonés sur les deux atomes d'azote tandis que les anions sont des unités octaédriques de $[MoOCl_4(THF)]^-$. Ces unités ont le groupe oxo (Mo═O, 1,655(7) Å) en position *trans* par rapport au THF(Mo—O, 2,331(5) Å). Les cations adoptent une conformation centrosymétrique *trans* sans interactions fortes avec le molybdène.

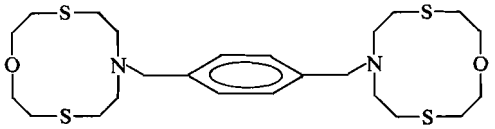
Introduction

The ligand 1,4-bis(1-oxa-4,10-dithia-7-azacyclododecan-7-ylmethyl) benzene which contains two macrocyclic $C_8H_{16}NOS_2$ rings has shown some promise for the synthesis of bimetallic complexes.



In such compounds metal–metal interaction is possible and vacant coordination sites are available, thus conferring on the molecule a potential for novel catalytic activity (1, 2). The molecule whose structure is reported here was prepared as part of a general screening process intended to establish the range of metal ions which the ligand may complex. Molybdenum in oxidation states V and VI was selected as a candidate for investigation since it is involved in a number of biochemical systems where binuclear complexes are implicated (3, 4).

Experimental Section

In a typical preparation, $MoOCl_4$ 0.17 g (0.67 mmol) (Alfa Products, used as purchased) were dissolved in 5 mL of dry, deoxygenated THF. The solution, initially brown, became green in about 5 min at room temperature. To this solution was added 0.05 g (0.097 mmol) of $C_{24}H_{40}N_2O_2S_4$ (2) dissolved in 5 mL of THF. A pale green precipitate was formed immediately and separated by centrifugation. Crystals suitable for a crystal structure analysis were grown by dissolving the precipitate in CH_3CN and reprecipitating with THF: a small quantity of the CH_3CN solution contained in a test tube was placed in a closed jar containing THF which diffused slowly into the solution, leading to slow crystallization. Elemental analysis (Service Central de Microanalyse, CNRS, France) gave C 32.60, H 4.99, N 2.56, Cl 23.96, S 9.91, Mo 16.32, calcd for $C_{32}H_{58}Cl_8Mo_2N_2O_6S_4$: C 32.83, H 4.99, N 2.39, Cl 24.23, S 10.95, Mo 16.39.

Crystal Data

$C_{32}H_{58}Cl_8Mo_2N_2O_6S_4$ f.w. = 1168.65

Triclinic, $a = 11.993(7)$, $b = 13.196(8)$, $c = 7.928(5)$ Å, $\alpha = 104.54(4)$, $\beta = 94.89(3)$, $\gamma = 81.59(1)°$, $V = 1199.9$ Å^3, $Z = 1$, $\rho_o = 1.61(2)$, $\rho_c = 1.58$ g cm^{-3} (MoK_α $\lambda = 0.71069$ Å, 20°C, $\mu = 11.7$ cm^{-1}.

Preliminary Weissenberg and precession photographs showed only $\bar{1}$ Laue symmetry and no systematic absences which limited the space group to $P1$ (No. 1) or $P\bar{1}$ (No. 2). The latter choice leads to a successful structure solution and refinement.

Accurate cell dimensions were obtained on a fully automated Picker FACS-1 4 circle diffractometer, equipped with a graphite monochromator and coupled to a PDP-8S minicomputer, by centering 12 reflections widely scattered in the reciprocal space ($20° < 2\theta < 30°$: the α_1/α_2 doublet was not resolved). Each reflection was centered at both positive and negative 2θ values. The 2θ, ω, χ, and ϕ values thus obtained were appropriately averaged. These were used in the least-squares refinement to obtain the final unit cell parameters with their estimated standard deviations. These cell parameters were used in subsequent calculations.

Data were collected using a 2θ scan routine in a unique hemisphere of $4.0° < 2\theta < 45°$ for $\pm h$, $\pm k$, $\pm l$ using MoK_α

radiation. The reflection intensity was computed as

$$I = [N - Bt_s/t_b]$$

and $\sigma(I)$ the standard deviation was computed as

$$\sigma(I) = [N + B(t_s/t_b)^2 + 0.02N^2]^{1/2}$$

where N is the total counts accumulated during the scan time t_s and B is the total background counts accumulated in time t_b.

Instrument and crystal stability were monitored by measuring the intensities of 3 standard reflections after every 50 cycles. These reflections showed a random deviation of not more than ±3%. Data for which $I < 3\sigma(I)$, (1123 reflections) were considered as unobserved and discarded. The remaining 2846 intensities were corrected for crystal absorption[2] and for Lorentz and polarization effects, thus:

$$(Lp)^{-1} = \sin 2\theta_s (\cos^2 2\theta_m + 1)/(\cos^2 2\theta_m + \cos^2 2\theta_s)$$

where $2\theta_m$ and $2\theta_s$ are the diffraction angles at the monochromator and the sample crystal respectively. Transmission factors ranged from 0.70 to 0.83 for the sample which was approximately brick shaped (0.2 × 0.5 × 0.8 mm, longest dimension parallel to diffractometer ϕ axis).

Structure Determination

A 3-dimensional Patterson[3] synthesis yielded the positions of molybdenum and the four chlorine atoms bound to it. The remaining non-hydrogen atoms were found from successive structure factor and Fourier calculations. Full-matrix isotropic refinement[4] (five cycles) converged at the rather high R value of 0.20. We were unable to find any obvious reason for this other than signs of considerable anisotropic motion particularly of the cation. Indeed, anisotropic refinement (5 cycles) reduced the residual F to 0.069. At this stage of refinement, a geometry calculation and a difference Fourier synthesis revealed disordering of the macrocyclic rings at C(7), C(8), C(9), and C(10). Thus, bond distances within this portion of the ring were all too short, and, whereas the hydrogen atoms were clearly visible in other parts of the difference map, the region around the disordered atoms showed a confused collection of minor peaks. In addition atoms C(7), C(8), C(9), and C(10) had abnormally elongated thermal ellipsoids. An attempt to resolve the disordered atoms into pairs of atoms with fractional occupancy did not improve the R values or produce a satisfactory geometry. Anisotropic refinement was continued for 3 more cycles with hydrogen atoms placed in calculated positions (C—H and N—H, 0.98 Å) on all carbon atoms except those exhibiting the disorder. The final unweighted and weighted residuals are: $R_1 = 0.059$, $R_2 = 0.065$ and the "goodness of fit" = 6.3. The entire structure was re-refined in space group $P1$, but the residuals were not significantly improved. There was no evidence for systematic variation of $\omega(|F_o| - |F_c|)^2$ with $\sin\theta/\lambda$ or $|F_o|$ or h, k, and l, therefore we attribute the high value of the goodness of fit to inadequacies in the structure model in the regions of disordering. Indeed, a final difference Fourier map showed numerous peaks of residual electron density (0.8 e/A^3 maximum) in regions around the disordered atoms C(7), C(8), C(9), and C(10), and around the chlorine atoms of the anion, which also display large thermal motion. Table 1 contains the final positions of all non-hydrogen atoms. Tables of observed and calculated structure amplitudes and of temperature factors are available.[5]

Results and Discussions

Figure 1 shows the unit cell packing diagram, Fig. 2 shows the anion $[MoOCl_4(THF)]^-$, and Fig. 3 depicts the cation $[C_{24}H_{42}NOS_2]^+$. Selected bond lengths and angles are collected in Table 2.

A study of the interaction of $MoOCl_4$ with a variety of common solvents (9) has shown that $MoOCl_4$ probably reacts with diethyl ether to give a chloroether and HCl. An analogous reaction with THF is adequate to rationalize the isolation of the title compound, indeed it seems probable that the species $[MoOCl_4(THF)]^-$ is already present in the solution prior to the addition of the base/ligand.

The anion $[MoOCl_4(THF)]^-$ has not been described previously. However, there are a number of similar $[MoOX_4L]^{n-}$ complexes whose structures have been reported: where X = Cl, L = H_2O or Cl (10), or $OP(OMe)_2$ (11); where X = CN and L is H_2O or OH (12), or O (13); and the ion $[MoOBr_4(OH_2)]^-$ (14). A structure of the parent square

[2]Using GNABS by Burnam (5).

[3]Fourier and Patterson calculations were performed using FORDAP by A. Zalkin.

[4]Structure factor and least squares calculations were performed using SFLS-5 by C. W. Prewitt. The quantity minimized in least squares calculations was: $w(|F_o| - |F_c|)^2$ where $w = [\sigma(F_o)]^{-2}$. Scattering factors used were those of Cromer and Waber (6) (non-hydrogen atoms) and Churchill, De Boer, and Donovan (7) for hydrogen. The anomalous dispersion corrections for Mo, Cl, and S were applied (8).

[5]The supplementary tables are available at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

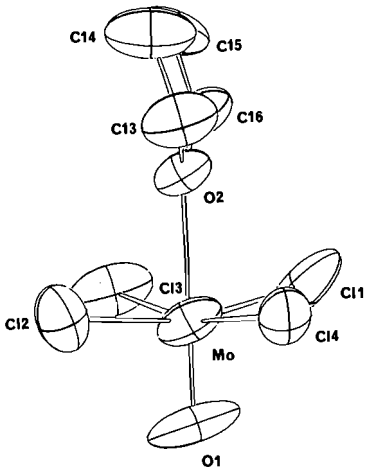

FIG. 2. The anion $[MoOCl_4(THF)]^-$.

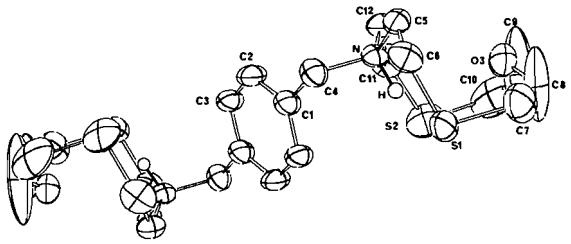

FIG. 3. The cation $[C_{24}H_{42}N_2O_2S_4]^{2+}$.

pyramidal $[MoOCl_4]^-$ ion is also available (15). The Mo—O multiple bond which is 1.61(1) Å long in the five coordinate $[MoOCl_4]^-$ ion is lengthened to 1.655(7) Å in the THF complex. The *trans* influence of the THF is thus most similar to that of coordinated water; in such complexes the Mo—O bond lengths range from 1.64(7) Å to 1.672(15) Å (10, 12). This bond is lengthened to 1.698(7) Å in $[MoO(CN)_4(OH)]^{3-}$ and 1.834(9) Å in $[MoO_2(CN)_4]^{4-}$. Comparison with the short distance 1.604(23) Å quoted for $[MoOCl_4OP(OMe)_2]^{n-}$ is difficult because of the disorder of the phosphite ligand and the ambiguity concerning the oxidation state of the Mo in this ion. The THF oxygen (O(2)) is 2.331(5) Å from the Mo, within the range of 2.27 to 2.39 Å observed in the aquo complexes. The THF moiety which is folded in an envelope conformation with O(2) as the out-of-plane atom, has quite high thermal motion (Fig. 2). It is commonly observed (16) that all bond lengths within this ligand appear unreasonably short. A libration correction (17) for the THF moiety produced much more plausible values (Table 2). The Mo—Cl distances in these six-coordinate complexes are quite insensitive to changes in L and range from 2.35 to 2.37 Å: the average uncorrected distance in $[MoOCl_4(THF)]^-$ is 2.363 Å, but there is a considerable spread in values; 2.347(2) to 2.394(2) Å. There are no unusual intermolecular contacts involving the chlorine atoms. Correction for librational motion of the $MoCl_4O_2$ moiety reduced but did not eliminate the spread, while consistently indicating longer Mo—Cl bonds.

The cation has crystallographically imposed transoid symmetry and presents no particularly striking features except the method of folding of the macrocycles. The adopted conformation, clearly visible in Fig. 3, places the hydrogen atom of the quaternary nitrogen so that it hydrogen bonds weakly to the two sulphur atoms, at about 2.4 Å from S1 and 2.6 Å from S2 (a normal Van der Waals contact lies between 2.9 and 3.1 Å (18, 19)).

Contribution à l'étude par spectroscopie ultra-violette de Δ-4 imidazolinethiones-2 et d'alkylthio-2 imidazoles. Calculs théoriques

D. BOUIN-ROUBAUD, J. KISTER, M. RAJZMANN et L. BOUSCASSE

Laboratoire de Chimie Organique A, Faculté des Sciences et Techniques de St-Jérôme, Université d'Aix-Marseille III, 13397 – Marseille, Cedex 13, France

Reçu le 20 janvier 1980

D. BOUIN-ROUBAUD, J. KISTER, M. RAJZMANN et L. BOUSCASSE. Can. J. Chem. **59**, 2883 (1981).

L'incidence des interactions stériques sur les transitions électroniques de Δ-4 imidazolinethiones-2 et d'alkyl-1 méthylthio-2 imidazoles et de méthyl-1 alkylthio-2 imidazoles est décrite. Les transitions électroniques étudiées sont toutes de type $\pi \rightarrow \pi^*$ et leur localisation dans les systèmes électroniques **1** et **2** est précisée au moyen de calculs CNDO/S.

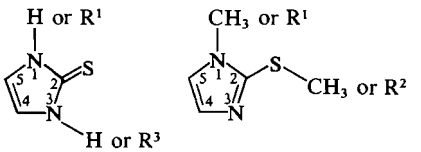
D. BOUIN-ROUBAUD, J. KISTER, M. RAJZMANN, and L. BOUSCASSE. Can. J. Chem. **59**, 2883 (1981).

Steric effects on electronic transitions for the systems **1** and **2** are reported. The $\pi \rightarrow \pi^*$ transitions studied are defined precisely by means of CNDO/S calculations.



1 **2**

Introduction

Nous nous proposons, dans le présent mémoire, de décrire l'influence de la compression stérique sur les transitions électroniques. Les Δ-4 imidazolinethiones-2, substituées soit en 1, soit en 1 et 3 par des groupements alkyles encombrants, ainsi que les alkyl-1 méthylthio-2 imidazoles et les méthyl-1 alkylthio-2 imidazoles sont les substrats de base pour cette étude.

Conditions expérimentales et méthode de calcul

La préparation des produits a été décrite ailleurs (1–3). Les produits de type **1** sont des solides bien cristallisés; les produits de type **2** dont la synthèse a été réalisée par catalyse par transfert de phase ont été distillés sur hydrure de calcium ou sur potasse et conservés en ampoules scellées à l'abri de la lumière.

L'enregistrement des spectres ultra-violets a été réalisé sur spectrophotomètre Cary 14. L'éthanol utilisé a été purifié, le chlorure de méthylène est un produit pour spectroscopie.

La géométrie du cycle imidazole a été estimée et compte tenu des résultats cristallographiques obtenus par Ansell *et al.* (4) la molécule a été supposée plane.

La paramétrisation de la méthode CNDO/S utilisée a été décrite ailleurs (5–7).

L'interaction de configuration est limitée aux 30 configurations de plus basse énergie. Pour l'atome de soufre, nous avons tenu compte des orbitales *d*. Pour le traitement de celles-ci nous avons employé le procédé de Schulte et Schweig (5) dans lequel le recouvrement est multiplié par 0,3 quand intervient une orbitale *d*.

Résultats expérimentaux

Seules les bandes susceptibles d'être pointées précisément seront discutées dans ce qui suit. L'ensemble du spectre des systèmes de base, ici étudiés, a déjà été discuté (8, 9). Les résultats sont consignés dans les tableaux 1 et 2.

De façon générale, l'effet de substitution par un substituant de plus en plus encombrant ne se manifeste qu'à partir du groupement tertiobutyle.

D'autre part, nous constatons un effet bathochrome lors du passage d'un solvant protique à un solvant aprotique.

Discussion des résultats théoriques

Δ-4 *Imidazolinethione-2*

Les résultats sont consignés dans le tableau 3. Nous constatons une bonne coïncidence entre les résultats expérimentaux et les résultats des calculs.

La paramétrisation adoptée (5, 6), compte tenu de la géométrie choisie, paraît mieux convenir que celle utilisée par Arbelot *et al.* (10) pour décrire ce même type de molécule.

Le schéma 1 donne les valeurs des carrés des coefficients des orbitales atomiques intervenant dans l'orbitale moléculaire correspondante (multipliés par 10^2). La première transition calculée est de type $n \rightarrow \pi^*$. Elle n'a pas été retrouvée expérimentalement. La transition suivante est de type $\pi \rightarrow \pi^*$. Elle a été calculée à 4,58 eV et apparaît dans le chlorure de méthylène à 4,57 eV. Cette transition correspond principalement au passage d'un électron de la plus haute orbitale moléculaire occupée vers la plus basse orbitale moléculaire vide. Elle met en jeu dans l'orbitale moléculaire occupée le soufre exocyclique, et dans l'orbitale moléculaire virtuelle le carbone du groupement thiocarbonyle.

Pour cette transition, caractéristique du groupement thiocarbonyle, la charge de l'atome de soufre exocyclique à l'état excité est inférieure à celle de l'état fondamental.

Cet atome de soufre étant le site de protonation de la molécule, l'utilisation de la discussion des effets de solvant conduite par Brealey et Kasha (11) nous permet de conclure que la différence de basicité de l'atome de soufre entre l'état excité et l'état fondamental rend bien compte de l'effet hypsochrome observé lors du passage d'un solvant aprotique à un solvant protique.

La transition suivante est calculée à 5,15 eV. Elle a un caractère de transfert de charge du soufre exocyclique vers les carbones doublement liés. Elle n'apparaît pas dans le chlorure de méthylène, mais se retrouve sous forme d'épaulement dans l'éthanol.

Nous notons ensuite une transition de type $n \rightarrow \sigma^*$ à 5,88 eV (210,6 nm) dont la force oscillatrice est de $0{,}122 \times 10^{-3}$ cgs. Cette transition met en jeu dans l'orbitale moléculaire occupée presque exclusivement les électrons de l'atome de soufre exocyclique. Dans l'orbitale moléculaire virtuelle, on remarque une forte participation des orbitales *d* ($d_{x^2-y^2}$ et d_{z^2}) de l'atome de soufre.

TABLEAU 3. Détermination expérimentale (solvant CH_2Cl_2) et calcul CNDO/S des spectres uv d'alkyl-1 Δ-4 imidazolinethione-2

Nature de la transition	R							
	H		Me		Et		*t*-Bu	
	Théor.	Exp.	Théor.	Exp.	Théor.	Exp.	Théor.	Exp.
$n \rightarrow \pi^*$	470,5 (0,000)		465,3 (0,000)		467,3 (0,000)			
$\pi \rightarrow \pi^*$	270,5 (0,443)	270 (4,458)	272,4 (0,434)	270 (4,215)	273,1 (0,4409)	270 (3,704)	276,1 (0,4288)	275 (4,165)
$\pi \rightarrow \pi^*$	240,4 (0,153)		242,3 (0,155)		243,5 (0,1536)	240(e)	245,0 (0,1630)	
$n \rightarrow \sigma^*$	210,6 (0,0001)		201,2 (0,0001)		201,7 (0,000)		197,2 (0,0002)	
$\pi \rightarrow \pi^*$	183,5 (0,205)	217 (3,756)	183,2 (0,221)	223 (3,756)	183,9 (0,1325)		186,1 (0,1552)	225 (3,81)

La dernière transition à 6,75 eV (183,5 nm) de type $\pi \rightarrow \pi^*$ se retrouve à 5,68 eV (217 nm) dans le chlorure de méthylène. Elle fait intervenir les deux carbones doublement liés dans l'état fondamental et le carbone du groupement thiocarbonyle dans l'état excité.

Méthyl-1 Δ-4 imidazolinethione-2

Géométrie

Nous avons conservé la valeur des angles de valence utilisée pour la Δ-4 imidazolinethione-2.

Résultats

Si nous comparons les résultats expérimentaux avec les résultats théoriques, nous voyons un bon accord, comparable à celui que nous trouvions pour la molécule non substituée. Le calcul indique, tout de même, un effet bathochrome de 1,9 nm qui n'est pas mis en évidence expérimentalement. La nature et les positions relatives des transitions restent inchangées par rapport au composé non substitué.

Ethyl-1 Δ-4 imidazolinethione-2

Géométrie

L'introduction dans la molécule d'un substituant non symétrique nous a amenés à effectuer une

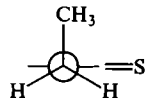
For personal use only.

minimisation de l'énergie à l'aide de la méthode EHT, en faiant tourner le groupement éthyle autour de l'axe C–N tout en conservant constants les autres éléments.

Le choix de la méthode EHT est justifié par le fait que la méthode CNDO/S n'est pas adaptée à l'étude de l'état fondamental. Nous signalons d'autre part que la méthode EHT s'avère moins coûteuse du point de vue temps de calcul que les méthodes CNDO.

Le calcul EHT montre que le minimum d'énergie correspond à un angle de 90°, c'est-à-dire à la représentation de Newman suivante.



Les résultats du calcul CNDO/S obtenus pour cette conformation sont consignés dans le tableau 3.

Tertiobutyl-1 Δ-4 imidazolinethione-2

Géométrie

La variation assez importante de la longueur d'onde d'absorption de la bande principale (de 270 à 275 nm dans le chlorure de méthylène) quand on passe de la Δ-4 imidazolinethione-2 à la tertiobutyl-1 Δ-4 imidazolinethione-2, pouvait laisser penser que cette substitution entraînait soit une déformation du cycle, soit une modification des angles valentiels. Ce phénomène avait déjà été observé par rmn ^{13}C, et la question était donc déjà posée (12).

Une étude en rmn ^{1}H basée sur les signaux observés pour les atomes 4 et 5 du cycle imidazolique diversement substitué en 1, nous montre que suivant la nature du solvant, on observe soit un singulet dans $CDCl_3$ (les deux protons 4 et 5 équivalents), soit deux doublets dans l'acétone-d_6, excepté pour le tertiobutyle où on constate la non équivalence magnétique quel que soit le solvant (13). Ceci se traduit numériquement par une variation de la différence de glissement chimique entre les deux protons 4 et 5 dans l'acétone-d_6.

TABLEAU 4. Détermination expérimentale (solvant CH_2Cl_2) et calcul CNDO/S du spectre uv de la phényl-1 Δ-4 imidazolinethione-2

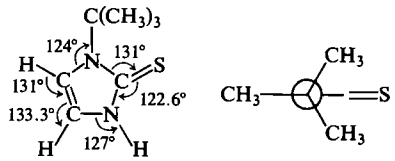
Nature de la transition	Théorique		Expérimental	
	λ (nm)	F.O.	λ (nm)	log ε
$n \rightarrow \pi^*$	465,1	0,0000		
$\pi \rightarrow \pi^*$	282,9	0,2720	292	3,737
$\pi \rightarrow \pi^*$	272,3	0,0067		
$\pi \rightarrow \pi^*$	258,6	0,2439	250(e)	
$\pi \rightarrow \pi^*$	244,4	0,1297		
$n \rightarrow \pi^*$	202,0	0,2274		

	Δδ (acétone-d_6) ppm	Δδ ($CDCl_3$) ppm
Me	0,10	0
Et	0,14	0
*i*Pr	0,17	0
t-Bu	0,25	0,20

Nous remarquons une variation régulière d'environ 0,04 ppm correspondant à l'introduction d'un méthyle supplémentaire quand on passe du méthyle à l'isopropyle. La variation de 0,08 ppm quand on passe de l'isopropyle au tertiobutyle est bien en accord avec l'introduction d'une dissymétrie supplémentaire que nous allons essayer de mettre en évidence.

Nous avons, dans un premier temps, étudié la déformation de la planéité du cycle par la méthode EHT. Pour cela nous avons plié la molécule autour de l'axe C-2 C-5, en maintenant l'hydrogène porté par le carbone en 5 dans le plan formé par les atomes N-1, C-5, C-4 et la liaison C=S dans le plan formé par N-1, C-2, C-3. Un autre type de déformation a été introduit, cette fois autour de l'axe N-1 N-3.

C'est toujours la molécule plane qui présente l'énergie minimum. La méthode EHT a été utilisée pour optimiser les angles valentiels formés par les substituants avec le cycle dont la géométrie est laissée invariante. Les valeurs obtenues sont les suivantes:



Parallèlement à cette étude théorique, une détermination complète de cette molécule a été réalisée par cristallographie (14). Les résultats de cette mesure confirment en tous points nos hypothèses à la fois sur la conservation de la planéité du cycle et sur la valeur des angles de valence.

D'autre part, nous avons déterminé la conformation du groupement tertiobutyle par rapport au plan de la molécule représentée par les atomes C-2, C-5 et S. Cette conformation a été confirmée par cristallographie.

La même méthode EHT utilisée pour la Δ-4 imidazolinethione-2 donne les valeurs suivantes pour les angles HN-1, C-5 = 127°; SC-2, N-1 = 126,8°; HC-5, C-4 = 133,3°.

Nous observons donc que l'angle de valence de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

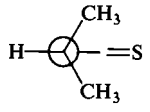
la liaison C=S augmente, tandis que l'angle C-5, N-1H diminue, traduisant ainsi un effet de répulsion entre le soufre et le groupement tertiobutyle. Cet effet s'observe aussi pour l'atome d'hydrogène porté par le carbone en 5, ce qui explique les résultats obtenus en rmn ^{1}H. L'utilisation de cette géométrie nous permet d'obtenir les résultats consignés dans le tableau 3. Ils traduisent bien l'effet bathochrome observé expérimentalement.

Nature de l'effet bathochrome

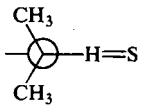
Pour déterminer la participation de l'effet stérique et de l'effet inductif, nous avons effectué les calculs CNDO/S suivants.

Tout d'abord le calcul de la molécule de tertiobutyl-1 Δ-4 imidazolinethione-2 a été effectué en utilisant la géométrie de base, c'est-à-dire sans optimisation des angles de valence. La transition principale est calculée à 278,8 nm (au lieu de 276,1 nm avec optimisation de géométrie). Ceci tend à montrer que la déformation des angles de valence produit un effet inverse de l'effet bathochrome observé.

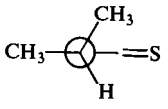
Nous avons ensuite effectué le calcul des transitions électroniques pour la molécule d'*i*Pr-1 Δ-4 imidazolinethione-2 en utilisant trois conformations, conservant ainsi constant l'effet inductif dû aux différents groupements méthyles.



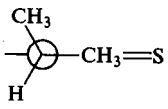
1



2



3



4

Les transitions n'ont pas été calculées pour la forme *4* qui est selon le calcul EHT extrémement défavorisée énergétiquement du fait de l'interaction entre l'un des méthyles et l'atome de soufre. La transition principale $\pi \rightarrow \pi^*$ qui apparaît expérimentalement dans le chlorure de méthylène à 270 nm se retrouve par le calcul à 274,2 nm pour la conformation *1*, à 273,1 nm pour la *2* et à 276,2 nm pour la *3*. Le calcul EHT montre d'ailleurs que la conformation *2* est la plus favorisée énergétiquement. La diminution de l'interaction stérique entre le soufre et les groupes méthyles quand on passe de la forme *1* à la forme *2* se traduit par un abaissement de 1 nm de la longueur d'onde d'absorption de la transition principale.

Dans la conformation *3*, un groupement méthyle éclipse et donc devient plus proche du motif C-5—H du cycle, et le calcul donne un effet bathochrome de 3 nm par rapport à la conformation *2*. Or la conformation la plus favorisée de la molécule substituée par un tertiobutyle correspond à la conformation *3* dans laquelle l'hydrogène est substitué par un méthyle. On peut donc dire que l'effet bathochrome observé pour cette molécule est principalement dû à une interaction stérique entre une groupe méthyle et le motif C-5—H. Il est également causé par une accumulation d'effet inductif et, dans une moindre mesure, par un effet de contact entre le soufre et les groupements méthyles.

Phényl-1 Δ-4 imidazolinethione-2

Nous avons effectué un calcul EHT de minimisation d'énergie pour déterminer la valeur de l'angle entre le plan de l'hétérocycle et le plan du groupement phényle. Des travaux précédents (15) ont montré que la méthode EHT sous-estime l'énergie de conjugaison et qu'il est nécessaire de diviser le sinus de l'angle par un facteur 1,2. L'application de ce facteur ramène l'angle de 68° à 58°. La valeur des angles de valence, calculée par cette même méthode est la suivante: angle SC-2, N-1 = 127,8°; angle HN-3, C-4 = 127°; angle C-Ph, N-1, C-5 = 124,5°. La valeur donnée par le calcul pour la transition de plus basse énergie coïncide avec la valeur obtenue dans l'éthanol et diffère de 9 nm de la valeur obtenue dans le chlorure de méthylène. Cet écart plus important que pour les autres composés peut s'expliquer en considérant que la valeur de l'angle est probablement surestimée malgré le facteur appliqué.

Méthylthio-2 imidazole et dérivés alkyles

Ces composés résultent d'une réaction de transposition catalysée par des sels quaternaires (obtenus par quaternisation des thioéthers par ICH_3) (2). Du fait de la faible différence de longueur d'onde d'absorption entre les bandes caractéristiques d'absorption uv des thiones et des thioéthers *N*-méthylés, c'est le dosage par rmn ^{1}H (16) qui a été retenu pour l'étude de la transposition SR ⇌ NR.

Les résultats de l'étude spectroscopique sont consignés dans le tableau 5. Nous notons tout d'abord que les dérivés thioéthers absorbent à longueur d'onde plus faible que leurs homologues thiones. Comme pour les thiones nous constatons une invariance de la transition lors d'une substitution de l'hydrogène en position 1 par un groupement méthyle ou éthyle. Le passage d'un solvant protique (éthanol) à un solvant aprotique (CH_2C1_2) produit un effet bathochrome.

TABLEAU 5. Détermination expérimentale (solvant EtOH) et calcul CNDO/S des spectres uv d'alkyl-1 alkylthio-2 imidazoles

Les nombres attenant aux schémas des molécules sont les carrés des coefficients des orbitales atomiques intervenant dans l'orbitale moléculaire correspondante multipliés par 10^2

SCHÉMA 2

Toutes les transitions calculées sont de type $\pi \rightarrow \pi^*$ (Schéma 2). La première transition qui apparaît à 4,90 eV met en jeu l'ensemble du cycle à la fois à l'état fondamental et à l'état excité. La transition suivante calculée à 4,64 eV (219,5 nm) met aussi en jeu l'ensemble du cycle à l'état fondamental et à l'état excité. La transition correspondante apparaît dans l'éthanol à 220 nm. Elle est en partie recouverte par la transition qui apparaît à plus grande longueur d'onde. La dernière transition calculée à 6,65 eV est un mélange de deux configurations de type $\pi \rightarrow \pi^*$.

Conclusion

La transition caractéristique du groupement thiocarbonyle des Δ-4 imidazolinethione-2 est de type $\pi \rightarrow \pi^*$. Pour cette transition la charge de l'atome de soufre exocyclique à l'état excité est inférieure à celle de l'état fondamental. Ceci est en accord avec le déplacement hypsochrome observé lorsque l'on passe du chlorure de méthylène à l'éthanol. En effet l'état fondamental est stabilisé dans les solvants protiques.

L'optimisation des angles valentiels et l'étude des conformations nous a permis de constater que l'effet stérique est moins important que l'effet électronique et par là même, de rendre compte de la quasi invariance des longueurs d'onde des transitions observées. L'importance relativement faible du déplacement bathochrome dans le cas du dérivé phénylé a été expliqué par le défaut de la conjugaison dû à l'angle de 58° que font les plans des deux cycles entre eux.

Les résultats obtenus dans le présent travail montrent que la méthode CNDO/S conduit, sur l'ensemble des composés que nous avons étudiés, à des résultats satisfaisants pour l'étude des transitions électroniques aussi bien sur le plan qualitatif que quantitatif.

CHAKIB BENNOUNA, FRANÇOISE PETRUS, JEAN VERDUCCI, CHRISTIAN HAUW et JACQUES GAULTIER. Can. J. Chem. **59**, 2891 (1981).

Ce travail décrit l'addition de type Michael des hydroxyurées sur les maléate et fumarate de méthyle. La cyclisation des uréidoxydiesters ainsi obtenus conduit aux carbométhoxyméthyl-5 oxa-6 dihydrouraciles dont la structure est prouvée par analyse au rayons X. Ces derniers, relativement instables, se transposent en carbométhoxyméthylène-5 hydantoïnes par traitement en milieu basique.

CHAKIB BENNOUNA, FRANÇOISE PETRUS, JEAN VERDUCCI, CHRISTIAN HAUW, and JACQUES GAULTIER. Can. J. Chem. **59**, 2891 (1981).

We describe in this paper the Michael-type addition of hydroxyureas with methyl maleate and fumarate. The cyclization of the ureidoxyester intermediates obtained leads to the isolation of 5-carbomethoxy 6-oxadihydrouracils; their structure is proved by X-ray analysis. These relatively unstable compounds undergo transposition under basic conditions and give 5-carbomethoxyhydantoins.

Les travaux précédents réalisés dans notre laboratoire ont permis de mettre en évidence le caractère "hydroxylamine *N*-protégée" des hydroxyurées: une attaque par l'atome d'oxygène est observée dans les réactions d'addition sur les nitriles α-éthyléniques (1), les esters α-éthyléniques (2), les cétones α-éthyléniques (3, 4) ainsi que dans les réactions de substitution sur les α-bromoesters (5).

Ces résultats permettent de prévoir *à priori* une addition-1,4 des hydroxyurées sur les maléate et fumarate de méthyle.

Résultats

L'action des hydroxyurées sur ces esters insaturés conduit aux mêmes résultats quel que soit l'isomère de départ. La réaction, réalisée dans des conditions douces (en absence de base ou en présence de triéthylamine), conduit à l'α-uréidoxysuccinate de méthyle **1** ou à un mélange de **1** et de carbométhoxyméthyl-5 oxa-6 dihydrouracile **2** (tableau 1, schéma 1). En présence d'une base plus forte telle que le méthylate de sodium et avec un temps de réaction de 30 min, l'uréidoxydiester **1** n'est plus isolé; la réaction conduit soit à **2**, soit à un mélange de **2** et de carbométhoxyméthylène-5 hydantoïne **3**. Si le temps de réaction est prolongé à

*Le nombre d'équivalents de base est en général égal à celui de l'hydroxyurée et du diester, sauf pour l'expérience 1 (absence de base) et l'expérience 5 où la quantité de base est le dixième du nombre d'équivalents des autres réactifs.

24 h, seule l'hydantoïne est isolée, sauf **3***d* à partir de la *N*(1)-méthylhydroxyurée. Il faut en outre noter la formation d'un certain pourcentage d'α-méthoxysuccinate de méthyle **4** lorsque la réaction est réalisée en présence de méthylate de sodium.

Discussion

L'emploi de différentes conditions expérimentales dans cette réaction permet d'isoler, dans certains cas, les composés **1** et **2** qui sont bien les intermédiaires de la réaction puisque, traités par une solution de méthylate de sodium, ils conduisent à **3** (excepté **2***d*).

La première étape correspond à l'addition-1,4 des hydroxyurées pour conduire aux α-uréidoxysuccinates de méthyle **1** dont la caractérisation sera donnée plus loin. La seconde étape de la réaction, correspondant à la cyclisation de **1**, conduit à un composé dont la détermination de structure présente des difficultés; en effet, trois types de cyclisation peuvent être envisagés pour **1** (schéma 2):

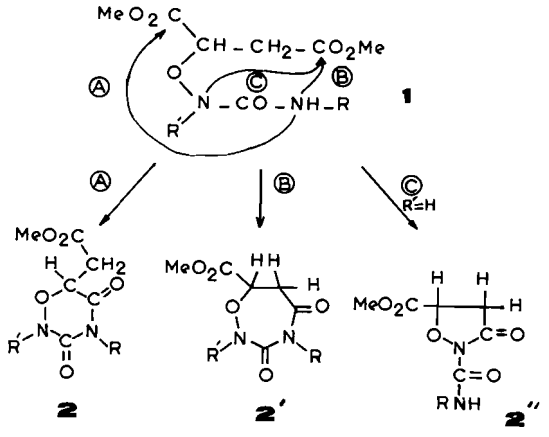

SCHÉMA 2

Le processus C, par attaque de l'azote N(1) sur l'ester en β de la fonction uréidoxy, doit être envisagé puisque c'est le seul type de cyclisation observé dans le cas des β-uréidoxymonoesters (2). Cependant un tel processus ne peut avoir lieu dans le cas où R' = CH_3; or, les composés cycliques obtenus (*a*, *b* et *d*) présentent tous des caractéristiques spectrales tout à fait comparables, permettant d'exclure le processus C et par suite la structure *N*-carboxamidoisoxazolidinone **2″**. Ce résultat est confirmé par l'absence de couplage entre le N(3)—CH_3 et le N(3)—H qui aurait dû être observé pour la structure **2″***b*.

Le processus B, déjà observé pour certaines β-uréidoxycétones (4), implique l'azote N(3) et le carbonyle en β de la fonction uréidoxy pour conduire à l'hétérocycle à 7 chaînons **2′**.

Le processus A, conduisant à **2** par attaque de l'azote N(3) sur l'ester en α de la fonction uréidoxy, doit aussi être envisagé; ce type de cyclisation à 6 chaînons, en général favorable, a été obtenu dans le cas α-uréidoxyesters (5).

Par régression de cycle, **2** et **2′** sont susceptibles de se transposer en hydantoïne **3**. Compte tenu de la fragilité de la molécule, les méthodes chimiques (hydrolyse, décarboxylation, réduction, etc.) ne nous ont pas permis de trancher entre les structures **2** et **2′**. Il en est de même pour les études ir et de rmn qui apportent peu de renseignements comme nous le verrons plus loin. Seule une analyse par rayons X prouve que nous avons à faire à la structure **2**.

La troisième étape de la réaction correspond à la transposition de **2** en carbométhoxyméthylène-5 hydantoïne **3**. Celle-ci se fait par perte d'une molécule d'eau impliquant l'atome d'oxygène intracyclique. Un tel mécanisme a déjà été proposé pour la formation des carbométhoxy-2 pyrroles à partir des carbométhoxydihydrooxazines (6). En milieu basique, la formation d'un carbanion en

SCHÉMA 3

position 5 induit la rupture de la liaison N—O pour conduire à l'intermédiaire ouvert **5** (schéma 3). Dans le cas du composé **2***d* (R′ = CH_3), le réarrangement n'est pas observé; en milieu méthylate de sodium à température ambiante, **2***d* reste inchangé; à reflux, il conduit à des produits de dégradation non identifiés. Une plus grande stabilité de la liaison N—O due à l'effet donneur du N(1)—CH_3 peut expliquer ce résultat. La cyclisation de **5** conduit après déshydratation à l'hydantoïne **3**, mais on ne pouvait *à priori* rejeter la cyclisation de la forme énol tautomère **5′**, conduisant à l'ester orotique **3′** (schéma 3). La distinction des composés **3** et **3′** est difficile vu la similitude de leurs points de fusion (7–9) et de leurs caractéristiques physicochimiques. D'autre part, l'hydrolyse basique de la carbométhoxyméthylène-5 hydantoïne conduit à l'ester orotique (10–12). Seule la comparaison de plusieurs composés diversement substitués avec les dérivés cités dans la littérature nous a permis de prouver la structure hydantoïne de ces produits de réarrangement.

Caracterisation des composés

Uréidoxyesters 1

Les uréidoxyesters **1** sont caractérisés sans ambiguité par ir et rmn. En ir, les bandes observées pour les fonctions ester et uréide sont tout à fait comparables à celles données pour les α-uréidoxyesters (5) (tableau 2).

Les spectres de rmn sont en accord avec la structure uréidoxyester (tableau 3).

Caractérisation des carboxyméthyl-5 oxa-6 dihydrouraciles 2

Les méthodes physicochimiques classiques se sont révélées peu efficaces pour trancher entre les structures carbométhoxyméthyl-5 oxa-6 dihydrouracile **2** et carbométhoxy-6 oxa-7 hexahydrodiazépinedione **2′**. Les spectres ir (large bande entre 1680 et 1740 cm^{-1} et ν_{NH} à 3395 cm^{-1}) et de rmn ^1H (tableau 4) sont compatibles avec les structures **2** et **2′**.

Seule l'étude des spectres de rmn ^{13}C (tableau 5) apporte quelque argument en faveur de la structure **2**. Pour l'attribution des deux pics dans la région des 170 ppm, on note une faible variation du déplacement chimique de l'un d'eux en fonction de la nature des substituants sur les azotes du cycle, l'autre signal étant pratiquement inchangé; ce dernier est attribué au carbonyle de la fonction ester, plus éloigné des modifications apportées par les substituants, le signal le plus perturbé correspondant au C(4). Cette attribution est confirmée par l'étude du spectre du dérivé *O*-méthylé **6** obtenu simultanément avec **2***e* lors de la méthylation de **2***b*; l'introduction d'un O—CH_3 et d'une double liaison dans le cycle modifie le déplacement chimique du C(4) (de l'ordre de 2 ppm) laissant pratiquement inchangé le signal du carbonyle de la fonction ester. D'autre part, l'intensité nettement supérieure des signaux de la fonction ester par rapport à celle du C(4) (sauf pour **2***a* où les bandes sont confondues) est un élément en faveur de la présence d'un CH_2 en α de la fonction ester, donc de la structure **2**.

6

Les résultats de l'analyse radiocristallographique confirment, sans ambiguïté, les propositions précédentes d'une structure cyclique à 6 chaînons. Une représentation de la molécule est donnée (schéma 4), les longueurs de liaisons sont reportées; les écarts-type sont de 0,003 Å pour les liaisons entre atomes "lourds" et 0,02 Å pour les liaisons mettant en jeu un atome d'hydrogène.

L'hétérocycle n'est pas plan; les deux liaisons N(1)—C(2) et C(4)—C(5) sont sensiblement parallèles et l'hétérocycle apparaît plié autour de la direction N(1) ... C(5). Ces observations sont consignées (tableau 7) qui donne les écarts des atomes au plan moyen de l'hétérocycle d'équation $-0{,}3877x + 0{,}250y + 0{,}8870z' = 1{,}650$ (référentiel a, b, ab).

[2]On peut obtenir la série complète des données à un prix nominal, en s'adressant au Dépôt des données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa, Canada K1A 0S2.

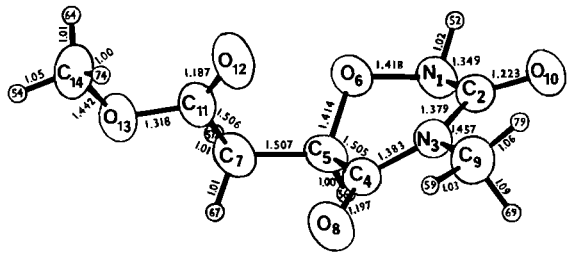

SCHÉMA 4

TABLEAU 7. Ecarts des atomes au plan moyen de l'hétérocycle

Atome	Å	Atome	Å
O(6)	0,33	C(5)	−0,29
N(1)	−0,25	C(7)	0,25
C(2)	−0,05	O(8)	−0,10
N(3)	0,17	C(9)	0,35
C(4)	−0,06	O(10)	−0,12

La structure cristalline est caractérisée par l'existence de colonnes de molécules de direction c; ces colonnes sont associées entre elles par liaisons hydrogène ainsi définies: distance N ... O = 2,82 Å; angle N—H ... O = 152,4°.

Une représentation de l'organisation structurale est donnée dans le schéma 5.

Caractérisation des carbométhoxyméthylène-5 hydantoïnes 3

La caractérisation des carbométhoxyméthylène-5 hydantoïnes **3** est réalisée par comparaison aux dérivés décrits dans la littérature. En ir, l'attribution des différentes bandes est faite en

accord avec les résultats de Ivin *et al.* (13) et Lemieux et Puskas (10) pour les carbéthoxy-5 hydantoïnes. Dans le but d'obtenir les mêmes composés, nous avons réalisé la transestérification de 3*b* et 3*c* conduisant à 7*b* et 7*c* dont les spectres ir sont identiques à ceux de la littérature (tableau 8); par contre, le spectre de 3*a* est différent de celui de l'orotate de méthyle (8).

De même en rmn (tableau 9), le déplacement chimique du proton éthylénique de 3*a* (5,48 ppm) est différent de celui observé pour l'orotate de méthyle (6,04 ppm) (8). Par contre, les spectres de rmn des composés 7*a* et 7*b* sont identiques à ceux des hydantoïnes (13, 14) à l'exception des déplacements chimiques de l'éthyle de la fonction ester de 7*a*; ceux-ci sont donnés à des valeurs différentes dans deux publications (13, 14) et de ce fait ne sont pas crédibles.

Conclusion

En conclusion, le caractère "hydroxylamine *N*-protégée" des hydroxyurées est confirmé par l'étude de leur action sur les maléate et fumarate de méthyle qui conduit aux uréidoxyesters correspondants. Ces derniers, bien que présentant trois types de cyclisation possibles (à 5, 6 et 7 chaînons) donnent uniquement les carbométhoxyméthyl-5 oxa-6 dihydrouraciles (cycle à 6 chaînons) dont la structure est prouvée par une analyse aux rayons X. Ces composés, relativement instables, conduisent en milieu basique aux carbométhoxyméthylène-5 hydantoïnes par une régression de cycle correspondant à la perte d'une molécule d'eau impliquant l'atome d'oxygène intracyclique.

Partie expérimentale

Les points de fusion non corrigés ont été pris en capillaire. Les analyses ont été déterminées par le laboratoire Central de Microanalyse du CNRS.

Les spectres rmn ^1H ont été réalisés au moyen d'un appareil Varian modèle T 60; les spectres rmn ^{13}C ont été réalisés par le laboratoire de Résonance Magnétique Nucléaire de l'U.S.T.L., au moyen d'un appareil JEOL PS 100 ou Bruker WP 80. Les déplacements chimiques sont exprimés en ppm par rapport au TMS pris comme référence interne.

Les spectres ir ont été enregistrés sur un appareil Perkin Elmer 457.

Analyse radiocristallographique

Les mesures de diffraction des rayons X (mesures en cinq points) ont été effectuées sur diffractiomètre automatique Siemens; 1003 réflextions indépendantes d'indices *hkl* et $\bar{h}kl$ ont été observées dans l'espace limité à $\theta < 26°$. La longueur d'onde Kα du molybdène a été utilisée ($\lambda = 0{,}71069$ Å). Les dimensions de cristal choisi pour ces mesures étant comprises entre 0.2 et 0.25 mm aucune correction d'absorption n'a été effectuée. La structure a été résolue par méthodes statistiques (programmes MULTAN). L'affinement a porté sur les paramètres de positions atomiques, d'agitation thermique anisotrope des atomes de carbone, d'azote et d'oxygène. Les atomes d'hydrogène ont été positionnés sur cartes de densité électronique. Le facteur de reliabilité final est $R = 0.058$ avec $R = (\Sigma |F_o| - |F_c|)/\Sigma |F_o|$

Une méthode de moindres carrés, utilisant l'approximation par blocs diagonaux, a été adoptée pour minimiser la fonction $w(F_o - F_c)^2$. Le facteur de pondération w a été choisi selon le schéma: $w = 1$ si $|F_o| < P$; $w = P/|F_o|$ si $F_o > P$ avec $P = |F_{max}|/3$.

Les facteurs de diffusion atomiques utilisés pour les calculs des facteurs de structure sont issus de International Tables for X-ray Crystallography Vol. IV, 1974.

Synthèse des hydroxyurées

Hydroxyurée: elle a été obtenue par action de l'hydroxylamine sur le carbamate d'éthyle suivant le mode opératoire décrit par Deghenghi (15).

β-*Méthylhydroxyurée*: préparée par action de l'hydroxylamine sur l'isocyanate de méthyle suivant le mode opératoire décrit par Kjellin (16) pour la β-phénylhydroxyurée. Ce composé avait $F = 130$–132°C. *Anal.* calc. pour $C_2H_6N_2O_2$: C 26,67, H 6,67, N 31,11; trouvé: C 26,68, H 6,58, N 31,23.

α-*Méthylhydroxyurée*: préparée par action du cyanate de potassium sur la *N*-méthylhydroxylamine suivant le mode opératoire décrit par Mathieson (17).

Action des hydroxyurées sur le maléate (ou fumarate) de méthyle

A une solution de 0,1 mol de base dans 150 cm³ de méthanol on ajoute 0,1 mol d'hydroxyurée; après solubilisation complète,

une solution de 0,1 mol de maléate (ou fumarate) de méthyle dans 40 cm^3 de méthanol est ensuite ajoutée goutte à goutte. Le mélange est agité à température ambiante, puis le solvant est évaporé sous pression réduite. Le résidu, repris par un minimum d'eau, est neutralisé par une solution d'acide chlorhydrique (40%). Le précipité de carbométhoxyméthylène-5 hydantoïne est filtré; la phase aqueuse est extraite à l'acétate d'éthyle; la phase organique est séchée (Na_2SO_4) et concentrée sous vide. Le résidu est chromatographié sur un appareil Waters Prep LC 500 muni de deux colonnes de silice en série, en utilisant comme éluant un mélange hexane–chloroforme 6:4 à 7:3 suivant la nature des composés.

Les différents résultats obtenus suivant la nature de la base, le temps de réaction et les substituants sont résumés dans le tableau 1 discuté dans la partie théorique.

Les caractéristiques physiques et les analyses centésimales des différents produits obtenus sont données dans le tableau 10.

Méthylation du méthyl-3 carbométhoxyméthyl-5 oxa-6 dihydrouracile, 2b

A une solution de 5 g (0,025 mol) de 2*b* dans 100 cm^3 d'éther on ajoute à 0°C 75 cm^3 d'une solution 0,66 *M* de diazométhane (0,05 mol). La solution est agitée pendant 4 h à cette température puis ramenée à la température ambiante. Le solvant est évaporé sous pression réduite et le résidu chromatographié sur l'appareil Waters Prep LC 500, muni de deux colonnes de silice, en utilisant comme éluant un mélange hexane – acétate d'éthyle 7:3. On obtient, par ordre d'élution: (*1*) le diméthyl-1,3 carbométhoxyméthyl-5 oxa-6 dihydrouracile **2***e* (1,6 g, 30%); $Eb_{0,2}$ = 95–98°C; *Anal.* calc. pour $C_8H_{12}N_2O_5$: C 44,44, H 5,55, N 12,96; trouvé: C 44,16, H 5,32, N 13,12; et (*2*) le méthoxy-2 méthyl-2 carbométhoxyméthyl-5 oxa-4 diazine-1,3 one-6 **6** (1 g; 20%); *F* = 69–70°C (éther); ir ($CHCl_3$): 1630 et 1730 cm^{-1}; rmn ($CDCl_3$): 3,75 (s, 3H, CO_2CH_3), 3,90 (s, 3H, OCH_3), 3,16 (s, 3H, N—CH_3), CH_2—CH: système ABX: H_A 2,74, H_B 3,00, H_X 4,50, J_{AX} = 4,3 Hz, J_{BX} = 7,4 Hz, J_{AB} = 16,3 Hz. *Anal.* trouvé pour $C_8H_{12}N_2O_5$: C 44,50, H 5,60, N 12,93.

Transestérification des carboxyméthylène-5 hydantoïnes 3a–c

A 20 cm^3 d'éthanol anhydre saturé d'acide chlorhydrique gazeux on ajoute 0,01 mol de **3**; le mélange est porté à reflux pendant 10–12 h. Le solvant est ensuite évaporé sous vide et le résidu repris par l'eau est neutralisé. La carbéthoxyméthylène-5 hydantoïne **7** qui précipite est recristallisée dans l'éthanol. La réaction est pratiquement quantitative.

Les composés ont été caractérisés par comparaison aux données de la littérature: 7*a*: 190°C; litt. (18): 186–187°C; 7*b*: 144°C; litt. (10): 141°C; 7*c*: 190°C; litt. (10): 191°C.

Phosphine–borane derivatives. 10[1]. Vibrational spectra of the dimethylphosphine adducts of boron trihalides

JOHN E. DRAKE, J. LAWRENCE HENCHER, AND LAYLA N. KHASROU
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received February 25, 1981

JOHN E. DRAKE, J. LAWRENCE HENCHER, and LAYLA N. KHASROU. Can. J. Chem. **59**, 2898 (1981).

The infrared (200–4000 cm^{-1}) and Raman (0–3100 cm^{-1}) spectra of $(CH_3)_2PHBX_3$, $(CH_3)_2PDBX_3$, and $(CD_3)_2PHBX_3$, where X = Cl, Br, I, have been recorded in solid state and in solutions at room temperature. The fundamentals have been assigned on the basis of C_s molecular symmetry. A modified Urey–Bradley force field model has been used in calculating the frequencies and potential energy distributions as well as the force constants. The (P—B) force constant was found to be consistent with the structural change upon adduct formation.

JOHN E. DRAKE, J. LAWRENCE HENCHER et LAYLA N. KHASROU. Can. J. Chem. **59**, 2898 (1981).

On a enregistré les spectres infrarouges (200–4000 cm^{-1}) et Raman (0–3100 cm^{-1}) des composés suivants: $(CH_3)_2PHBX_3$, $(CH_3)_2PDBX_3$ et $(CD_3)_2$ $PHBX_3$ ou X = Cl, Br, I à l'état solide et en solution à la température ambiante. On a identifié les vibrations fondamentales à partir de la symétrie moléculaire C_s. On a utilisé un modèle de champ de force de Urey–Bradley modifié pour calculer les fréquences, les distributions de l'énergie potentielle ainsi que les constantes de force. On a trouvé que la constante de la force (P—B) est en accord avec les changements de structure résultant de la formation d'un adduit.

[Traduit par le journal]

Introduction

In recent years, several vibrational spectroscopic investigations on phosphorus donor molecules $(CH_3)_nPH_{3-n}$ $n = 0$–3 with the boron acceptor BH_3 have appeared in the literature (1–4). These studies reflect the interest in understanding the nature of the coordinate link between phosphorus and boron in adducts. Vibrational analyses have been reported on the PH_3BX_3 (5) where X = Cl, Br, I, and on the $(CH_3)_3PBX_3$ (6) series, but none as yet involving partially methylated phosphines. We report on the vibrational analysis of the series $(CH_3)_2PHBX_3$ and the specifically deuterated analogues $(CH_3)_2PDBX_3$ and $(CD_3)_2PHBX_3$.

Experimental

The preparation of dimethylphosphine $(CH_3)_2PH$ was by modification (7) of the procedure described by Jolly (8). The purity was checked by its ir (9) and ^1H nmr spectra (10, 11). Dimethylphosphine-d_1, $(CH_3)_2PD$, was prepared in >98 mole% by exchange between $(CH_3)_2PH$ and KOD in D_2O and its purity also checked by its ir (12) and ^1H nmr spectra (11). The procedure was similar to that used for the preparation of $(CH_3)_2AsD$ (13). The boron trihalides were checked for purity as previously reported (5). The preparation of all adducts $(CH_3)_2PHBX_3$, $(CH_3)_2PDBX_3$, $(CD_3)_2PHBX_3$ (X = Cl, Br, I) was by the direct combination of reactants at room temperature. The reactions were carried out on a conventional Pyrex–glass vacuum system, using the same method and equipment used in the formation of H_3PBX_3 and $(CH_3)_3PBX_3$ adducts (5, 6). Raman spectra were recorded on solid samples in thin-walled glass tubes on a Spectra-Physics Model 700 spectrometer in conjunction with a Model 164 Argon-ion laser and Model 265 Exciter Unit. Typical power output was varied between 100 and 300 mW, using the 488.0 nm line. Polarization data were secured by use of MeI and CH_2Cl_2 solutions of the adducts. These solvents are far from ideal but were the only ones that gave significant, though low, solubility for solution spectra. The low solubility of the adducts required high instrument gain and laser output between 300 and 700 mW. Infrared spectra were recorded on a Beckman IR-12 spectrometer using CsI pellets. Far ir spectra were recorded, as Nujol mulls between polyethylene plates, on a Perkin–Elmer 180 spectrometer operating in conjunction with an Interdata model 6/16 computer.

Normal coordinate analysis was carried out using a computer program (Larmol) (14) in which the normal coordinates are expressed as mass-weighted Cartesian coordinates. The Cartesian coordinates were calculated with the aid of Euclidean construction devised by Hilderbrandt (15), from the following geometric parameters: bond lengths (in Å = 100 pm) C—H (1.093), P—H (1.410), P—B (1.901), P—C (1.819), B—Cl (1.840), B—Br (2.020), B—I (2.265), and bond angles (in degrees) XBP (109.5), HCP (109.5), CPC (105.4), HPC (103.6), and HPB (111.5). These parameters were obtained from structural studies on related molecules, $(CH_3)PH_2BH_3$, $(CH_3)_3PBH_3$ (16), $(CH_3)_3P$ (17), $(CH_3)_2PHBH_3$ (18), and PH_3BX_3 (9, 19).

Results and Discussion

Raman spectra of solid $(CH_3)_2PHBCl_3$ (Fig. 1), $(CH_3)_2PDBCl_3$ and $(CD_3)_2PHBCl_3$ (Fig. 2), and their infrared spectra between 1100 and 200 cm^{-1} (Fig. 3) are displayed as representative samples. The approximate description, with point group classification and symmetry species, of the fundamental vibrations are given in Table 1. The assignments of the fundamental vibrations are given for $(CH_3)_2PHBCl_3$, $(CH_3)_2PDBCl_3$, and $(CD_3)_2PHBCl_3$ (Table 2), $(CH_3)_2PHBBr_3$, $(CH_3)_2PDBBr_3$ and $(CD_3)_2PHBBr_3$ (Table 3), and $(CH_3)_2PHBI_3$, $(CH_3)_2PDBI_3$ and $(CD_3)_2PHBI_3$ (Table 4). The force constant numbering and evaluation is in Table 5 and the potential energy distributions in Tables 6, 7, and 8

for the chloride, bromide, and iodide series, respectively.

The adducts are assumed to have C_s symmetry so that the thirty-six vibrations are divided into twenty *a'* and sixteen *a"*, all being active in both effects. In general, there is good agreement between the solid and solution Raman and infrared data indicating that the influence of torsional and/or translational lattice modes in the solid state is minimal. One obvious feature in the spectra is the unaltered position of the BX_3 symmetric stretch on deuteration. This indicates that appreciable cou-

ν_{20}	ν_{35}, ν_{36}	Torsions

pling of donor and acceptor group vibrational modes is not dominant and, as with previous studies, the vibrations can be treated as essentially group frequencies.

The previous vibrational assignments of $(CH_3)_2PH$, $(CH_3)_2PD$, $(CD_3)_2PH$, (9, 12, 20), H_3PBX_3 (5), $(CH_3)_3PBX_3$ (6), $(CH_3)H_2PBH_3$ (1), and $(CH_3)_2PHBH_3$ (2), provided the background to the assignments of these dimethylphosphine adducts. Thus in the spectra of $(CH_3)_2PHBCl_3$ and $(CH_3)_2PDBCl_3$ the two features that correspond to the asymmetric CH_3-stretching modes (ν_1, ν_2, ν_{21}, ν_{22}) at ca. 3000 cm^{-1} and the symmetric CH_3-stretches (ν_3, ν_{23}) at ca. 2924 cm^{-1} and clearly polarised in the Raman effect, can be described as typical (Figs. 1, 2 and Table 2). The same can be said for $(CH_3)_2PHBr_3$, $(CH_3)_2PDBBr_3$, $(CH_3)_2PHBI_3$, and $(CH_3)_2PDBI_3$ (Tables 3, 4). The expected shifts to lower wave-numbers for the $(CD_3)_2PHBX_3$ species are also clearly seen (e.g. in Fig. 2). The asymmetric and symmetric methyl deformation modes appear for all of the d_0 and d_1 adducts at around 1400 and 1300 cm^{-1} respectively with the shift to 1060 and 1025 cm^{-1} for the d_6 adducts. In the past, some uncertainty existed in the assignments of the CH_3 rocks and PH deformations in free dimethylphosphine (9, 20). Recently, the vibrational assignments of $(CH_3)_2PH$ has been reassessed (12) and the CH_3 rocking modes placed between 1003 and 801 cm^{-1} (well above the PH deformations). We have recently received a pre-print of a paper in which it is proposed that the CH_3-rocks be placed between 947 and 991 cm^{-1} (21). The CH_3-rocks were also assigned in $(CH_3)_2AsH$ and $(CH_3)_2AsD$ (22) in the region 933–862 cm^{-1}, with the corresponding CD_3-modes between 672 and 496 cm^{-1}. Thus the assignment of the CH_3-rocks, ν_8, ν_9, ν_{27}, ν_{28}, in the $(CH_3)_2PHBX_3$ and $(CH_3)_2PDBX_3$ adducts to the features immediately below 1000 cm^{-1} is reasonable, as is the assignment of the CD_3-rocks in $(CD_3)_2PHBX_3$ to the region 770–550 cm^{-1}.

The PH stretching frequencies are unambiguously assigned to the sharp band, clearly polarised in the Raman effect, at ca. 2400 cm^{-1} in all $(CH_3)_2PHBX_3$ and $(CD_3)_2PHBX_3$ species and at ca. 1750 cm^{-1} in $(CH_3)_2PDBX_3$ compounds. This is at considerably higher wave-numbers than in the corresponding free dimethylphosphine (12, 21).

The two P—H asymmetric and symmetric deformation modes have been assigned in free $(CH_3)_2PH$ at 729 and 714 cm^{-1} respectively and in $(CH_3)_2PD$ at 590 and 561 cm^{-1}, which at least conforms with the polarisation data (12). Recently an alternate assignment has been proposed, placing these modes at 1012 and 729 cm^{-1} for $(CH_3)_2PH$ and 709 and

556 cm^{-1} for $(CH_3)_2PD$ (21). In these $(CH_3)_2PDBX_3$ adducts, two peaks at ca. 590 (depolarised) and 561 cm^{-1} (polarised) are assigned to the asymmetric, ν_{31}, and symmetric, ν_{14}, P—H deformation modes. These two features are clearly fundamentals and cannot be sensibly assigned to any other modes. The calculations that agree with these assignments suggest that the P—H deformations should be above the 730 cm^{-1} region but below the 1000 cm^{-1} region and they are assigned accordingly. It is notable that in any case, both ν_{31} and ν_{14} apparently appear at considerably different positions in the adducts $(CH_3)_2PHBX_3$ and $(CD_3)_2PHBX_3$ relative to the free phosphine, whereas they are virtually unchanged when $(CH_3)_2PDBX_3$ spectra are compared with $(CH_3)_2PD$. This could be associated with the fact that the P—D deformations are "purer" modes and so show less change on adduct formation than does the P—H deformation. This is indicated in the normal coordinate analysis where force constant values for $f(CPH^2)$, $f(HPB^2)$, $f(HCP)^2$ that correspond well to literature values for related systems (5, 6) produce good agreement between the observed and calculated P—D deformations. These same values predict that the corresponding P—H deformations will be in the region of 800–900 cm^{-1} in $(CH_3)_2PHBX_3$ and $(CD_3)_2PHBX_3$ rather than either the 720 or 1000 cm^{-1} regions.

The PC_2 asymmetric and symmetric stretching

*See footnote to Table 2

modes, ν_{29} and ν_{11}, were assigned at ca. 704 and 660 cm^{-1} respectively in $(CH_3)_2PH$ with the former hardly shifting at all in $(CH_3)_2PD$ but the latter moving very slightly to higher wave-numbers. There are features in all the spectra of the adducts that correspond to these modes slightly shifted to higher wave-numbers. Thus, for example, there is a strong, polarised band at 696, 683, and 682 cm^{-1} in the Raman spectra of $(CH_3)_2PHBCl_3$, $(CH_3)_2PDBCl_3$, and $(CD_3)_2PHBCl_3$, respectively, corresponding to the symmetric PC_2 stretch, ν_{11}, and a medium-strong band in the infrared spectrum at 740, 741, and 743 cm^{-1}, corresponding to the asymmetric PC_2 stretch.

The only mode remaining to be assigned in the region above 700 cm^{-1} is the P—B stretch, ν_{10}. This is usually observed as a pair of lines, with the lower frequency, more intense line assigned to the stretch attributed to the ^{11}B isotope and the weak shoulder at higher frequency attributed to the ^{10}B—P stretch. In the spectra of the adducts, these pairs of frequencies are observed at 780, 765; 785, 775; 750, 743 cm^{-1} in d_0, d_1, d_6 $(CH_3)_2PHBCl_3$; 775, 765; 775, 770; 762, 742 cm^{-1} in d_0, d_1, d_6 $(CH_3)_2PHBBr_3$ and 790 (?), 756; 775, 759; n.o., 723 cm^{-1} in d_0, d_1, d_6 $(CH_3)_2PHBI_3$. Thus in the PD-containing compound the principal ^{11}B—P stretch is shifted to slightly higher wave-numbers (3–10 cm^{-1}) whereas in the $(CD_3)_2PH$-containing series it is shifted by over 20 cm^{-1} to lower wave-numbers. Such features have been noted for related compounds (3, 5, 6).

The assignment of the BX_3 symmetric stretch is straightforward in the spectra of all adducts; showing up as an intense and strongly polarised band. The position is not affected by deuteration and it is consistently lower than the corresponding free boron trihalides (23, 24). Relative to other phosphine adducts with BX_3, such as PH_3BX_3 (5) and

*See footnote to Table 2

$(CH_3)_3PBX_3$ (6), the position of the symmetric BCl_3 stretch, ν_{13}, at ca. 399, 391, and 392 cm^{-1} in $(CH_3)_2PHBCl_3$ (d_0, d_1, d_6) virtually remains unchanged throughout the series $H_n(CH_3)_{3-n}PBX_3$. However, its location is somewhat lower by ca. 30–40 cm^{-1} in comparison with the H_3PBX_3 and $(CH_3)_3PBX_3$ adducts, where X = Br and I.

The BX_3 asymmetric vibrations, ν_{30}, ν_{12}, are assigned in the $(CH_3)_2PHBI_3$ adducts to the broad band in the infrared spectra, with a corresponding apparently depolarised band in the Raman, at ca. 540 cm^{-1} for all species. The breadth of this band is probably related to a slight loss of degeneracy. In the bromide this loss of degeneracy is sufficient for the peak to be split (centered around 616 cm^{-1}) and this appears to be a general feature of related BBr_3 adducts (25). Unfortunately, solvent peaks obscure this region of the spectrum so that polarisation data are not available. The BCl_3 asymmetric stretch, as with related BCl_3 adducts, appears in a crowded region of the spectrum, but it shows up as a strong band in the infrared spectrum at 720 cm^{-1} in $(CH_3)_2PHBCl_3$.

In the skeletal region, the PC_2 deformation, ν_{15}, is assigned to a medium-strong, polarised band at ca. 276 cm^{-1} in all $(CH_3)_2PHBCl_3$ analogues, while the corresponding PC_2 rocking modes, ν_{16} and ν_{32}, are assigned at 203, 180; 200, 195; 199, 178 cm^{-1} in the d_0, d_1, and d_6 $(CH_3)_2PHBCl_3$ compounds respectively. The PC_2 deformation mode is seen at slightly lower wave-numbers (ca. 25 cm^{-1}) for all of the bromide and iodide adducts. By contrast, the rocking modes are seen at progressively lower wave-numbers in the bromides and iodides as is expected since the rocking modes involve more motions of the B—X bonds. The order of the BX_3

[a] Units: stretching constants in mdyn Å^{-1} (10^2 N m^{-1}), bending constants mdyn Å rad^{-2} (10^2 N m rad^{-2}) and stretch/bend interaction constant mdyn rad^{-1} (uncertainties in parentheses).
[b] General valence force constants f_{ij}; Urey–Bradley force constants K (stretch), H (bend), and F (repulsion). Linear constant $F' = (1/10)F$ assumed.
[c] Interaction of HCP and CPH angles which are *trans* and *cis* to each other.
[d] Fixed value in least-squares analysis.

deformation and rocking modes is consistent with the earlier work on similar boron trihalides (26). Generally, good agreement is observed between our spectra and the spectra reported for H_3PBX_3 (5) and Me_3PBX_3 (6). The lowest mode is given to the BX_3 rocking at 147–140 cm^{-1} in the chloride; 110–95 cm^{-1} in the bromide and 97–85 cm^{-1} in the iodide. The BX_3 asymmetric and symmetric deformations are assigned to the Raman bands at 260, 242, and 178 cm^{-1}; 178, 160, and 144 cm^{-1}; and 130, 130, and 112 cm^{-1} in the dimethylphosphine adducts with boron trichloride, -bromide, -iodide, respectively. The corresponding deuterated analogues have slightly lower assignments.

Finally, *overtone and combination bands* are included in the comprehensive listings of the vibrational spectra, but they are not of particular use in this study as confirmations of the assignments of the fundamentals.

Normal Coordinate Analysis

The calculated frequencies and potential energy distributions are presented in Tables 6, 7, and 8 for the chloride, bromide, and iodide adducts, respectively. The force-field model can be claimed to be reasonable judging by the good correspondence between calculated and experimental frequencies for all $(CH_3)_2PHBX_3$ series and the good transfer to the $(CH_3)_2PDBX_3$ and $(CD_3)_2PHBX_3$ analogues. The potential-energy distribution reveals that there is no pure P—B bond stretching frequency because it is involved in the BX_3 and PC_2 symmetric modes. The degree of this involvement differs in the deuterated as well as in the iodide and bromide species. The ^{10}B-substituted frequencies are included in brackets. The potential energy distributions also indicate extensive vibrational coupling between the P—C and P—B stretching modes. The extent of this coupling is different in the deuterated

analogues as illustrated in the tables. Generally, the asymmetric modes are relatively pure. The "whiplash" *cis*- and *trans-f* HCP/CPH force constant is crucial in allowing for splitting of the methyl rocks and in lowering the PH deformation mode to an acceptable value.

The force-constants associated with the C—H stretching and H—C—H bending are similar to those calculated for the trimethylphosphine adducts (6). The values of the P—H constants are fairly similar for all three adducts but significantly higher than the value in free Me_2PH. This is entirely consistent with conclusions based on the value of J_{PH} in the nmr spectra where its value was considerably higher, 426 ± 6 Hz, for the adducts than in the free phosphine, 191.03 ± 0.03 Hz (11). This, in turn, is consistent with an increase of *s*-character in the P—H bond on adduct formation

*See footnote in Table 6.

as a result of reorganization towards tetrahedral angles. The increase in *s*-character would be expected to lead to higher J_{PH} values and a stronger bond as also reflected by the force constants. An analogous increase in the value of the C—P stretching force constant is then to be expected, and indeed is found, on comparing the free phosphine with the adducts. The value of K_{PB} associated with the stiffness of the P—B stretch, also suggests a successive strengthening of the P—B bond along with the series $BCl_3 < BBr_3 < BI_3$ which is in accord with the increased Lewis acidity of the BX_3 groups (27). The trend is identical to that observed in the H_3PBX_3 (5) and Me_3PBX_3 series (6). It is also notable that the values of K_{PB} in this Me_2PHBX_3 series do fall between those of the PH_3BX_3 and

Studies of silyl and germyl group VI species. Part VI. Synthesis and vibrational spectra of methylthiosilanes

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI,[1] AND LAYLA N. KHASROU
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received March 10, 1981

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI, and LAYLA N. KHASROU. Can. J. Chem. **59**, 2909 (1981).

Methylthiosilanes of the type $(CH_3)_nH_{3-n}SiSCH_3$, $n = 0$–3, and $(CH_3)HSi(SCH_3)_2$ have been prepared. Their ir and Raman spectra were recorded and assigned. The assignments were supported by normal coordinate analyses based on a modified valence force field.

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI et LAYLA N. KHASROU. Can. J. Chem. **59**, 2909 (1981).

On a préparé des méthylthiosilanes du type $(CH_3)_nH_{3-n}SiSCH_3$, $n = 0$–3 et $(CH_3)HSi(SCH_3)_2$. On a enregistré et identifié leurs spectres ir et Raman. Pour identifier les spectres on a fait appel à des analyses de coordonnées normales à partir du champ de force de valence modifié.

Introduction

The versatility of bisgermylcarbodiimides as convenient starting materials for germylchalcogenides has been demonstrated for various compounds including methylthiogermanes (1–3). However, the corresponding cleavage of the Si—N bond in bissilylcarbodiimides by protic species containing S—H, Se—H, or Te—H bonds is less effective as a synthetic route (1, 4) despite its ready cleavage by H_2O and ROH (2, 3, 5). The use of complex aluminates as synthetic reagents (6–8) suggested that $LiAl(SCH_3)_4$ might provide a convenient route to methylthiosilanes and indeed we find this method leads to high yields of the series $(CH_3)_nH_{3-n}SiSCH_3$, $n = 0 \rightarrow 3$, in a relatively short time. The characterisation of the fully methylated or protonated species did include some mention of their spectroscopic properties (9–11) although more extensive studies have been reported on the methoxymethylsilanes and $((CH_3)_nH_{3-n}Si)_2S$ series (12–14). We report herein the preparation and detailed vibrational analyses of the series $(CH_3)_nH_{3-n}SiSCH_3$ and also of $(CH_3)HSi(SCH_3)_2$ while ^1H and ^{13}C nmr, as well as mass spectra, are used to confirm the purity of the monomeric species.

Experimental

Reagents and Apparatus

All manipulations were carried out on a conventional vacuum line equipped with greaseless stopcocks. Iodosilanes were prepared from the corresponding hydrides with hydrogen iodide in presence of AlI_3 (15). Lithium tetramethylthioaluminate was obtained from recrystallized $Li(AlH_4)$ and methanethiol (Matheson) in dimethylether (16).

The ^1H nmr spectra were recorded on a JEOL C60-HL instrument. The ^{13}C nmr spectra were recorded under ^1H noise decoupling, using a Bruker CPX 100 (FT model) spectrometer operating at a resonance frequency of 22.639 MHz, at a probe temperature of 35°C. Neat samples were in sealed capillaries which were then placed in 5 mm nmr tubes containing $CDCl_3$ (as a lock) and TMS (as standard). The ir spectra were recorded on a Beckman IR-12 instrument, using gas cells of 9 mm path-length fitted with KBr windows. Raman spectra were recorded on a Spectra-Physics 700 spectrometer using the argon ion laser exciting line at 488.0 nm. The mass spectra were recorded at 70 eV on a Varian GMAT-CH5 spectrometer, fitted with a greaseless vacuum inlet system. The normal co-ordinate analysis was performed using an IBM S/360-50 series computer with a program written by Dr. J. L. Hencher of this department. The assignments are made for all molecules on the basis of C_s symmetry (17). All angles were assumed to be tetrahedral, the other dimensions: C—H, 110 pm; Si—C, 186.7 pm; S—C, 182 pm; Si—C, 215 pm; and Si—H, 148.4 pm were based on related molecules (7). The descriptions of the fundamental vibrations of $(CH_3)_nH_{3-n}SiSCH_3$ and $(CH_3)HSi(SCH_3)_2$ are presented in Tables 1 and 2, respectively.

Synthesis

All methylthiosilanes were prepared from $Li[Al(SCH_3)_4]$ and the corresponding iodosilane in a similar way to $(Me_nH_{3-n}Si)_2S,Se$ as previously reported (36). In a typical reaction, H_3SiI (1.020 mmol) was condensed at −196°C into the reaction vessel containing an excess of $Li[Al(SCH_3)_4]$ (1.285 mmol) and dimethyl ether (ca. 8.00 mL). The reactants were allowed to react at −45°C for ca. 2–3 h with occasional shaking of the reaction vessel. Fractionation of the volatile material through U-traps held at −78, −96, and −196°C gave pure H_3SiSCH_3 (1.00 mmol, 98%; *m/e* 75–80 $(H_nCSiS)^+$ 78 (100%)). Similar sets of experiments using $(CH_3)H_2SiI$ (2.201 mmol), $(CH_3)_2HSiI$ (2.456 mmol), $(CH_3)HSiI_2$ (1.791 mmol), and $(CH_3)_3SiI$ with an excess of $Li[Al(SCH_3)_4]$ at room temperature for ca. 3–4 h afforded the corresponding methylthiosilane: $(CH_3)H_2SiSCH_3$ (97%; *m/e* 90–94 $(H_nC_2SiS)^+$ 92 (50%); $(CH_3)_2HSiSCH_3$ (99%; *m/e* 105–108 $(H_nC_3SiS)^+$ 106 (20%)); $(CH_3)HSi(SCH_3)_2$ (98%; *m/e* 137–141 $(H_nC_3SiS_2)^+$ 138 (100%)); $(CH_3)_3SiSCH_3$ (94%; *m/e* 120–122 $(H_nC_4SiS)^+$ 120 (38%)).

Results and Discussion

In recent years some alkylthiosilanes have been

*C_s symmetry.

prepared by reaction of appropriate halogenosilanes with CH_3SMgI (10), RSNa (18), and CH_3SH in the presence of base (9, 10). The use of complex aluminates as synthetic reagents has been studied considerably (8, 19). In this study, these were extended to $Li[Al(SCH_3)_4]$ to include a convenient preparation of a series of methylthiosilanes by the general reaction:

$$[1]\quad Li[AlH_4] + 4CH_3SH \xrightarrow{Me_2O} Li[Al(SCH_3)_4] + 4H_2$$

$$[2]\quad Li[Al(SCH_3)_4] + 4(CH_3)_2HSiI \rightarrow 4(CH_3)_2HSiSCH_3 + AlI_3 + LiI$$

The formation of $Li[Al(SCH_3)_4]$ is rapid and it undergoes facile exchange with iodosilanes to give essentially quantitative yields of the corresponding methylthiosilane. All methylthiosilanes are clear, colorless liquids sufficiently volatile that they can be easily handled under vacuum line conditions. The silicon–sulfur linkage is known to be moisture-sensitive (20) to give the corresponding disiloxane. The Si—S bond is apparently less readily attacked in $(CH_3)HSi(SCH_3)_2$ and in $(CH_3)_2Si(SCH_3)_2$ than in the $(CH_3)_nH_{3-n}SiSCH_3$ species.

The methylthiosilanes all give first-order ^1H nmr spectra (Table 3) consistent with free rotation about the C—Si and Si—S bonds. The ^1H and ^{13}C chemical shifts and coupling constants correlate well with those of previously reported disilthianes (21), halogenosilanes (22, 23), methyltelluro-silanes and -germanes (24, 25) and provide the initial confirmation of the molecular species.

Vibrational Spectra

The Raman spectrum of H_3SiSCH_3 is shown in Fig. 1 and tabulated in Table 4, along with the previously published ir data (9). The polarisation data are very clear in establishing the asymmetric and symmetric CH_3 stretches and deformations as well as the SiH_3 stretches. Three rather weak overlapping bands are seen in the Raman spectrum in the region 900–970 cm^{-1}. However, the calculations and comparisons with related compounds such as CH_3SiH_3 and CH_3SiD_3 (26), SiH_4 (27), $(H_3Si)_2S$ (25), and organosulfur derivatives (28) allow us to assign the symmetric SiH_3 deformation, ν_9, to the sharper, more intense line at 914 cm^{-1}, the asymmetric SiH_3 deformations, ν_8 and ν_{18}, to the depolarised feature at 943 cm^{-1} and the CH_3 rocking vibrations, ν_7 and ν_{17}, to the shoulder at 968 cm^{-1}. The Si—C and Si—S stretches, ν_{10} and ν_{12}, are unambiguously assigned to the strong polarised maxima in the Raman at 695 and 507 cm^{-1}, respectively. The two SiH_3 rocking motions, ν_{19} and ν_{11}, are found as usual only slightly separated at 631 and 645 cm^{-1}. The remaining band, the SiSC bend, ν_{13}, appears as a broad feature at ca. 205 cm^{-1}. The weak feature at 406 cm^{-1} could be its overtone.

The Raman and infrared spectra of $(CH_3)H_2SiSCH_3$ are displayed in Figs. 1 and 2 while the assignment is in Table 5. The two types of methyl groups lead to overlapping bands in the ir spectrum so that band contours are not of much assistance. However, the presence of both methyl groups is clear for both the stretching and deformation modes in the Raman effect. In accord with the assignments on organic sulfur compounds (28), the bands at higher wave-number 2990dp and 2926p cm^{-1} are assigned to the CH_3—S asymmetric (ν_3 and ν_{20}) and symmetric (ν_4) stretches. The corresponding CH_3—Si stretches, ν_1, ν_{19}, and ν_2, are seen at 2967 and 2907 cm^{-1}, respectively. The small splitting of the asymmetric (ν_{25}) and symmetric (ν_{11}) SiH_2 stretches of about 20 cm^{-1} is typical of the $(CH_3)SiH_2$ group (29, 30). Similarly, the CH_3 deformations for the methyl group attached to sulfur ν_7, ν_{22}, and ν_8 are at higher wave-number than for that attached to silicon ν_5, ν_{21}, and ν_6, giving two sets of bands at ca. 1430 and 1319 for the former and 1417 and 1250 cm^{-1} for the latter. As with H_3SiSCH_3, the CH_3—S rocking modes, ν_{10} and ν_{24}, are placed at ca. 960 cm^{-1} while the CH_3—Si rocks are placed at 891 and 876 cm^{-1}. This leaves the band at 929 cm^{-1} to be assigned as the SiH_2 bend, ν_{12}, which compares favourably with the HSiH angle deformation in SiH_4 (27). The most prominent features in the Raman spectrum can be readily assigned to the Si—C, S—C and Si—S stretches, ν_{14}, ν_{16}, and ν_{15}, at 734, 701, and

500 cm^{-1}, respectively. All are, as expected, sharp, polarised bands. The placing of the Si—C stretch at higher wave-number than the S—C is consistent with data on related sulfides (10). In organic sulfides, the S—C stretch typically appears as a strong Raman band with a corresponding rather weak infrared feature (28), and the value of 701 cm^{-1} is close to that in H_3SiSCH_3 where there is no ambiguity. The SiH_2 wag, ν_{13}, and twist, ν_{26} are then appropriately assigned to the relatively weak features around 669 cm^{-1} by comparison with the methylsilyhalides (23). The SiH_2 rock, ν_{27}, is to be expected in the same region as the Si—S stretch, but with much less intensity in the Raman effect. The peak at 500 cm^{-1} is apparently split and this pair at 500 cm^{-1} and 483 cm^{-1} are both polarised. An assignment of the peak at 483 cm^{-1} to the SiH_2 rock ignores this polarisation and also ignores the fact that the splitting occurs in the same peak in $(CH_3)_2SiHSCH_3$ in which there is no SiH_2 rock. Alternately, the splitting could arise from Fermi resonance between the Si—S stretch and $2\nu_{18}$, or be an indication that two conformers exist. Finally, the SiSC, ν_{18}, and CSiC, ν_{17}, skeletal deformations are assigned to 241 and 177 cm^{-1}, respectively.

The Raman spectrum of $(CH_3)_2HSiSCH_3$ is displayed in Fig. 3, its ir spectrum in Fig. 2 and its assignment in Table 6. The SiH stretch, ν_6, is clearly seen in both effects at ca. 2130 cm^{-1}. The number and position of the bands associated with CH_3 stretches and deformations remain the same as noted for $(CH_3)H_2SiSCH_3$. There is an increase in the relative intensity of the band at 1265 cm^{-1} which is assigned to the CH_3—Si symmetrical deformation. There is also an increase in the relative intensity of the features assigned to CH_3—Si rocking modes at around 765 and 870 cm^{-1} relative to the CH_3—S rocks at 970 cm^{-1}. The band at 712 cm^{-1} in the ir spectrum which has no significant counterpart in the Raman effect is assigned as the

SiH deformation, ν_{35}. This leaves the strong polarised peak at 699 cm^{-1}, which is seen as a weak shoulder on the 712 cm^{-1} infrared feature, to be assigned as the S—C stretch, ν_{18}, in essentially the same position as observed in H_3SiSCH_3 and $(CH_3)H_2SiSCH_3$. Similarly, the symmetric Si—C stretch, ν_{15}, can be unambiguously placed at 661 cm^{-1} where there is a polarised, reasonably strong band. The position of the asymmetric Si—C stretch, ν_{34}, is less obvious. By comparison with some previous assignments of $(CH_3)_nSiX_{4-n}$ species (31, 32), it could be placed as coincident with the bands at ~765 cm^{-1} or even 840 cm^{-1}. However, more recent work on Me_3SiCl (33), $(CH_3)_2SiX_2$ (34), and $(CH_3)_2SiHX$ (23) suggests that the splitting between the Si—C asymmetric and symmetric stretching modes is small. This is confirmed by normal coordinate analysis. It is not possible, using a reasonable set of force constants, to produce a large calculated splitting of these two modes. Thus, the assignment of ν_{34} to the shoulder at 672 cm^{-1} in the infrared spectrum is made with some confidence. As was mentioned in discussing the spectrum of $(CH_3)H_2SiSCH_3$, the Raman band assignable to the Si—S stretching mode ν_{17}, is clearly split (481 and 472 cm^{-1}). In this molecule there is no obvious overtone to suggest as a candidate for Fermi resonance although the combination of ν_{19} at 229 cm^{-1} and ν_{21} at 261 cm^{-1} cannot be definitely excluded. Thus, again, this could be the result of two conformers being present. The asymmetric SiC_2 deformation, ν_{36}, and SiC_2 rocking mode, ν_{20}, are assigned to the bands of lowest wave-number at 208 cm^{-1} and 150 cm^{-1} in accord with the normal coordinate analysis.

The Raman and ir spectra of $(CH_3)_3SiSCH_3$ are displayed in Figs. 3 and 2 respectively. The assignment in Table 7, but for minor details, is essentially in agreement with the earlier partial assignment made along with those of other methylsilylsulfides (10). The relative intensity increase of the CH_3 stretching and deformation modes for the

$(CH_3)_3Si$ group relative to those of CH_3S underlines the placing of the latter modes to higher wave-number. The band at 960 cm^{-1} in the Raman (965 cm^{-1} in the ir) can be considered characteristic of the CH_3—S rocking motion while the $(CH_3)_3$—Si rocks can be placed, again characteristically, in the range 750–870 cm^{-1}. Consistent with the assignment of the previous three molecules, their normal coordinate analyses, and distinct features in the Raman spectrum, the S—C stretch, ν_{19}, can be placed at 702 cm^{-1} and the Si—C symmetric stretch, ν_{21}, at 632 cm^{-1}. The asymmetric Si—C stretches, ν_{20} and ν_{42}, might well be expected to be between these two vibrations. However, in the absence of any peaks in either effect, it must be assumed that they are coincident with one. Although assignments of SiC asymmetric modes have been made to the region ca. 700 cm^{-1} (35), the normal coordinate analyses and the expectation of a small separation from the Si—C symmetric stretch (23, 33, 34) suggests that near coincidence with the latter mode is more probable. Unlike the case in the mixed hydrido-methyl compounds, the Si—C symmetric stretch is seen, as in the case of H_3SiSCH_3, as a single sharp band (at 466 cm^{-1} in the Raman) with no sign of splitting. There are skeletal modes that could, in principal, provide overtones or combinations of the correct wave-number to lead to Fermi resonance, yet no splitting is observed. Thus, if the splitting in the cases of $(CH_3)H_2SiSCH_3$ and $(CH_3)_2HSiSCH_3$ can be interpreted as resulting from the presence of conformers, these are only observed for mixed hydrido-methyl silanes. In $(CH_3)H_2PBH_3$ the structural determination has shown (36) that the $(CH_3)H_2P$ group is not symmetrical but is askew of the "C_3" axis. Possibly in mixed hydrido-methyl species a slight distortion leads to conformers which could be exchanging much too rapidly to be observed on the nmr time-scale. Similar splitting of the Si—E (E = S, Se and Te) symmetric stretch was observed for the compounds $[(CH_3)H_2Si]_2E$ and $[(CH_3)_3Si]_2E$ (14).

The Raman and infrared spectra of $(CH_3)HSi(SCH_3)_2$ are assigned in Table 8. These assign-

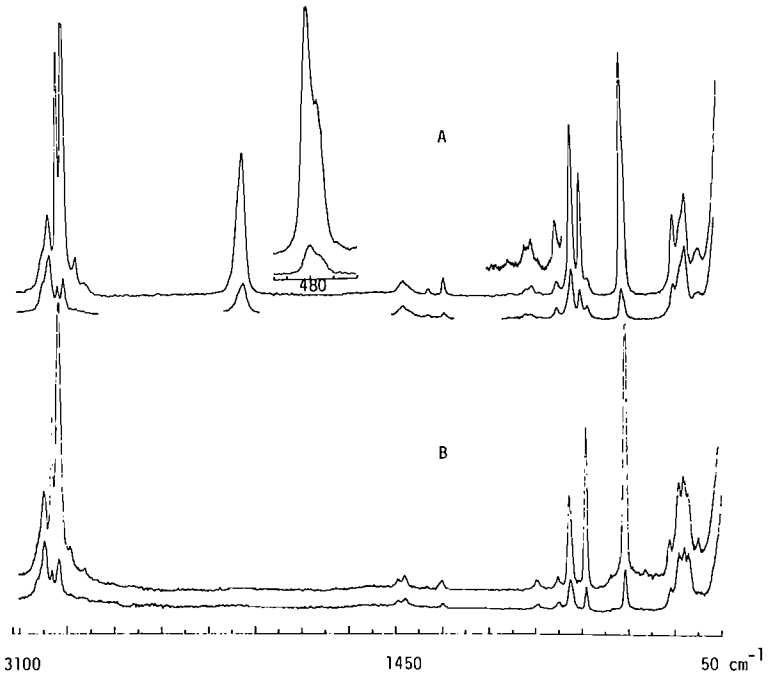

FIG. 3. The Raman spectra of $(CH_3)_2HSiSCH_3$ (*A*) and $(CH_3)_3SiSCH_3$ (*B*).

ments can be readily made by comparison with those of the $(CH_3)_nH_{3-n}SiSCH_3$ series and supported by the normal coordinate analysis. The molecule is assumed to have C_s symmetry with the two methyl groups on sulfur eclipsed relative to each other and a plane of symmetry passing through silicon and the H and C atoms attached to it. This model minimizes the non-bonding interactions. The forty-two fundamental vibrations break down into twenty-one a' and sixteen a'' modes that are both ir- and Raman-active. The five torsional modes were not observed. The methyl stretching, bending, and rocking modes all follow the pattern established for $(CH_3)_nH_{3-n}SiSCH_3$ with the relative intensities now reflecting the presence of two SCH_3 groups. The Si—H stretch is clearly seen at 2147 cm^{-1} in the Raman spectrum. The infrared spectrum in this region is slightly broadened because of the overlap of a combination of bands presumably enhanced by Fermi resonance. The methyl H_3C—S rocking frequencies are still characteristically weak in both effects and the Si—CH_3 rocking modes strong in the infrared spectrum appearing in regions of the spectrum anticipated from $(CH_3)_nH_{3-n}SiSCH_3$. The S—C stretching vibrations, ν_{16} and ν_{35}, are placed, as in the aforementioned series, at 698 (Raman) and 702 cm^{-1} (ir) while the Si—C stretch, ν_{15}, is clearly identifiable at ca. 730 cm^{-1}. Similarly, the S—Si stretching vibrations, ν_{18} and ν_{37}, are placed at 451 (Raman) and 479 cm^{-1} (ir) respectively. There is no sign of splitting in the sharp Raman band associated with ν_{18}. The only features remaining to be assigned in the region at 666 and 530 cm^{-1} are therefore given as Si—H deformation modes. These are considerably lower than those observed in the $(CH_3)_nH_{3-n}SiSCH_3$ compounds.

The skeletal deformations all appear below 300 cm^{-1} and are assigned on the basis of the polarisation data. The remaining mode, ν_{20}, is calculated to be at 182 cm^{-1}, but it is not clearly visible in the spectrum and could be essentially coincident with ν_{39}.

Normal Coordinate Analysis

The force field uses twenty-nine force constants in the $(CH_3)_nH_{3-n}SiSCH_3$ series and twenty-five in $(CH_3)HSi(SCH_3)_2$ (see Tables 9 and 10 respectively). The stretch–bend interactions involving a common bond (e.g. the force constant fX—C/HCX in X—CH_3 where X = S or Si) are important in calculating the CH_3 deformations. Two bend–bend interactions, fHCX/HCX and fHCH/HCH, keep the CH_3 deformations and rocks in the correct order. To avoid the number of force constants exceeding the number of frequencies, certain restrictions are placed on these interactions. Either two or three constants are set to zero, or one is

*Reported ir (10).

fixed and the other two allowed to change. The force constant, fHCS/HCS, is used with fSC/HCS because the former constant is found to have a significant effect on reducing the frequency of the a' mode of the CH_3S deformations as well as the CH_3S rocking modes, while fSC/HCS only effects the CH_3S deformations. Generally, in the absence of fHCX/XC, unreasonably large values are required for fXC/HCX to establish an agreement between the observed and calculated CH_3X deformations. The force constant, *fcis*-HCSi/HCSi, is introduced when there is more than one methyl group attached to silicon, in an attempt to produce some splitting in the rocking modes of the $(CH_3)_nSi$, n = 2–3 groups. In the molecule $(CH_3)HSi(SCH_3)_2$ with only one methyl group, this interaction is replaced by a corresponding interaction *fcis*-HCSi/CSiS, to give partial splitting of the CH_3Si rocking modes. In some recent reports (23, 37, 38), a reasonable match between the calculated and observed frequencies for the deformation and rocking CH_3 modes (e.g., in the normal coordinate analysis of $(CH_3)_2HSiX$ (23)) was achieved by separating the HCM (where M = Si or Ge) angles into those in the plane of the molecule ($HCM^{||}$), and those that are approximately perpendicular to the symmetry plane ($HCM^{\perp}$). This was based on the assumption that there is a considerable interaction between the deformations of the HCSi and CSiH angles *trans* to each other. However, with the introduction of substituents onto silicon, the HCSi angles are no longer equivalent. The results indicate that this alternative method is less satisfactory than that used in this work. Extensive mixing between CSiH and HCSi angle bending is observed and required the introduction of another very important interaction constant; namely, *ftrans*-HCSi/CSiH which describes the "whiplash" motion of the hydrogen atom in the *trans* position. As in the calculation reported on CH_3SiH_3, CD_3SiH_3,

CD_3SiD_3 (25), this interaction is prominent in the degenerate CH_3 modes and in SiH bending activity. When the force constant, *fcis*-HCSi/CSiH is used, a lesser but similar effect is also noticed, and this force constant plays an important role in splitting the two CH_3Si rocking modes ν_{14} and ν_{34} (Raman 814 and 862 cm^{-1} and ir 820 and 865 cm^{-1}) in the compound $(CH_3)HSi(SCH_3)_2$.

The values of the force constants for the $(CH_3)_n$-$H_{3-n}SiSCH_3$ series show a consistency that suggests the force field is probably a good approximation. The values of fCH are essentially constant throughout the series, except for a higher value still for fC—H(S) in H_3SiSCH_3, emphasizing the C—H bond is apparently stronger (stiffer) when attached to the more electronegative sulfur atom. The force constants fSi—H, fSi—C and fSi—S get smaller as methyl groups are substituted for hydrogen atoms. The same phenomenon can be seen when methyl groups are substituted for halide atoms in series such as $(CH_3)_{4-n}SiX_n$ (31, 32, 34) or $(CH_3)_{4-n}$-GeX_n (20, 39), indicating that the effect of the hydrogen atom is that of a "weakly electronegative halogen". Thus, when attached to silicon, hydrogen is more electron-withdrawing than a methyl group, as has been pointed out previously (40), and the effect of substituting the less electronegative methyl group is to loosen up all the bonds to silicon. By contrast, the force constant fS—C has a slightly higher value in the two mixed compounds than in the hydride or trimethyl derivative. The only stretching force constant that is significantly different in $(CH_3)HSi(SCH_3)_2$ relative to those in the $(CH_3)_nH_{3-n}SiSCH_3$ series, is fSi—S which has a lower value. On the basis that SCH_3 is expected to be more electron-withdrawing than CH_3, an increase might have been expected. The lowering could be indicative of a significant change from approximately all tetrahedral angles about silicon arising from a combined effect of the steric requirements of the two SCH_3 groups and the possible distortion arising from mixed hydrido-methyl groups mentioned earlier.

In general, the fit between calculated and ob-

served frequencies is good, but it is best for H_3SiSCH_3 and $(H_3C)_3SiSCH_3$ molecules (Tables 4–8). The extent of mixing between the Si—C stretch and the CSiH, HCS, and S—C modes is demonstrated in the potential energy distribution in the mixed species. Thus, in $(CH_3)H_2SiSCH$, the "Si—C stretch" is, in fact, made up of 50% *f*(Si—C), 20% *f*CSiH, 15% *f*HCS, and 8% *f*SiC. The Si—H bending modes, which appear in $(CH_3)_2HSiSCH_3$ in similar positions to those of other mixed hydrides, namely, ~710 and ~630 cm^{-1}, are much lower in $(CH_3)HSi(SCH_3)_2$ at 668 and 530 cm^{-1}. The values of the force constants *f*HSiC and *f*HSiS are only slightly lower; the decrease mainly

arises because, in the latter case, there is much less mixing with the SC or SiC stretch. In addition, relatively pure Si—C, S—C, and Si—S vibrations are observed in $(CH_3)HSi(SCH_3)_2$. Also, no extensive mixing is noted for the Si—S mode in all members of the series $H_nMe_{3-n}SiSMe$, and molecular skeletal motions are essentially decoupled from the motions involving hydrogen. Finally, in general, vibrations involving symmetrical motions show mixing of force constants while those involving more asymmetrical motions are essentially "pure".

Effects of organic solvents on immobilized enzyme catalyses.[1] Chymotrypsin immobilized on porous glass

J. Bryan Jones and Diana H. Pliura

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received January 30, 1981

J. Bryan Jones and Diana H. Pliura. Can. J. Chem. **59**, 2921 (1981).

The esterolytic activity of native chymotrypsin (CT) immobilized on ionically neutral porous glass beads has been studied in the presence of up to 20% (v/v) of the organic solvents methanol, ethanol, 2-propanol, *tert*-butyl alcohol, dioxane, and DMSO. In marked contrast to the variations observed with native CT, inhibition of CT immobilized on glass (CT–glass) was independent of the nature of the organic solvent. The overall activity, as indicated by $k_c(app)/K_m(app)$, decreased by 35–50% as the concentration of all solvents surveyed was increased up to 20%. In general, high organic solvent concentration accelerated the rate of protein release from the insoluble catalyst. For practical applications in aqueous organic solvents CT–glass conjugates are inferior to those of the enzyme attached to Sephadex.

J. Bryan Jones et Diana H. Pliura. Can. J. Chem. **59**, 2921 (1981).

On a étudié l'activité estérolytique de la chymotypsine naturelle (CT) immobilisée sur un lit de verre poreux ioniquement neutre en présence de solvants organiques tel le méthanol, l'éthanol, le propanol-2, le *tert*-butanol, le dioxanne et le DMSO à des concentrations allant jusqu'à 20% (v/v). L'inhibition de la CT immobilisée sur le verre (CT–verre) est indépendante de la nature du solvant organique ce qui contraste fortement avec les variations observées dans le cas de la CT naturelle. L'activité globale telle qu'indiquée par le $k_c(app)/k_m(app)$ décroît de 35 à 50% lorsque la concentration de tous les solvants utilisés augmente jusqu'à 20%. En général une forte concentration de solvant organique accélère la vitesse de libération de la protéine à partir du catalyseur insoluble. Du point de vue des applications pratiques dans des solvants organiques aqueux, les CT conjugées à des verres sont moins utiles que les enzymes immobilisés sur du Séphadex.

[Traduit par le journal]

The potential of enzymes as chiral catalysts for asymmetric synthesis is attracting increasing attention in both academic and industrial laboratories. A broad spectrum of applications has already been documented (1*b*), but future exploitation of enzymes in organic synthesis will undoubtedly require more extensive use of organic cosolvents in order to ensure the solubility of hydrophobic substrates in the predominantly aqueous reaction media. While the effects of organic cosolvents on enzymes are usually detrimental (2) their adverse influences can be mitigated by using immobilized enzyme preparations (3–7). Furthermore, the use of enzymes in insolubilized form offers considerable practical advantage since problems of product separation, and catalyst recovery and reuse, are greatly reduced, particularly for processes where continuous operation is required (8).

In a previous report (1*c*) we described the influences of representative water-miscible organic solvents on the catalytic properties of chymotrypsin (CT)[2] bound to Sephadex. Hydrophilic gels such as Sephadex shrink in aqueous organic solvent solutions (1*c*, 9, 10). The enzyme embedded within the gel thus becomes less accessible to substrate and the activity of the immobilized enzyme preparation decreases. Deleterious solvent effects of this kind are avoided when ionically neutral but rigid supports such as porous glass are employed. In this paper we report on the effects of up to 20% (v/v) methanol, ethanol, 2-propanol, *tert*-butyl alcohol, dioxane, and DMSO on CT–glass preparations.

Experimental

Materials

α-Chymotrypsin (EC 3.4.21.1) from bovine pancreas was obtained as a lyophilized powder from Worthington Biochemical Corporation and was used without further purification. The porous glass supports (CPG-1350 and CPG-550) and γ-aminopropyltriethoxysilane were purchased from Pierce Chemicals. Alkylamine glass derivatives were prepared by a general procedure outlined by the Corning Bioorganic Technology Group (11).[3] *N*-Acetyl-L-tyrosine ethyl ester (NATEE) was purchased from Sigma Chemical Co. All other chemicals were of the highest purity available.

Preparation of CT–Glass Derivatives

(a) CT–Glass–Glu

The CT–glass–glu derivatives were prepared by the standard method of coupling protein to glutaraldehyde-activated alkylamine glass beads (11, 12). The conjugates were washed exhaustively with 0.1 *M* aqueous potassium phosphate buffer

[1]Enzymes in Organic Syntheses 21. For Part 20 see ref. 1*a*. Abstracted from the Ph.D. thesis of D.H.P., University of Toronto, 1977.

[2]Abbreviations used: CT, chymotrypsin; CT–Sephadex, CT immobilized on Sephadex; CT–glass–glu, CT linked to glass via glutaraldehyde method; CT–glass–azo, CT coupled to glass via diazo method; NATEE, *N*-acetyl-L-tyrosine ethyl ester; (app), apparent; DMSO, dimethyl sulfoxide; CPG, controlled pore glass.

(pH 7) until no enzyme was detected in the effluent by monitoring the absorbance at 280 nm.

(b) CT–Glass–Azo

Diazotized glass beads were prepared from alkylamine glass by *p*-nitrobenzoylation, reduction, and diazotization according to the usual procedure (12). The diazotized glass beads were then coupled to CT by reaction at pH 8.5 at 20°C for 1 h. After the coupling reaction was complete, the CT–glass–azo (10 g) was transferred to a fritted glass filtering funnel and washed with 0.05 *M* aqueous $NaHCO_3$ (350 mL) under suction. The following sequence of wash media was then supplied by a peristaltic pump: 0.05 *M* aqueous $NaHCO_3$ (1 L); 1 m*M* aqueous HCl (100 mL); 0.5 *M* aqueous NaCl (200 mL); and finally distilled water until no enzyme was detected in the wash media.

Both of the CT–glass conjugates were stored at 4°C in a minimum of distilled water. Their protein contents were determined by amino acid analysis as before (1*c*).

Kinetic Measurements

The rates of CT–glass-catalyzed hydrolysis of NATEE were determined using a Radiometer Automatic Titrator at 25°C under a nitrogen stream in a 10 mL capacity reaction vessel as described previously (1*c*, 13).

Specific Activities

The specific activities of CT–glass derivatives (0.1–0.5 mL of wet packed beads) were assayed using 9 mL of a solution of NATEE (11 m*M*) in 0.1 *M* aqueous KCl containing 2% (v/v) methanol. The total assay volume was brought up to 10 mL by the addition of doubly distilled water.

pH–Activity Profiles

The esterolytic activity as a function of the pH of the reaction mixtures was assayed at 25°C against NATEE (10 m*M*) in 2% (v/v) methanol or 20% (v/v) organic solvent, 1.0 *M* in KCl at 25°C. Typically, the enzyme concentration was 2.6×10^{-6} *M* based on the total protein content of the CT–glass derivatives. Rates of hydrolysis were measured from the linear portions of the titration curves and, when necessary, were corrected for nonenzymic hydrolysis at very high pH.

Determination of Apparent Kinetic Parameters

The kinetic parameters K_m(app) and k_c(app) were determined at pH(app) 9.8 at 25°C for 1.0 *M* KCl solutions containing different concentrations of organic solvent. Typically, a substrate concentration range of 0.7–8 m*M* NATEE and an enzyme concentration of 3×10^{-6} *M* were employed. No nonenzymic ester hydrolysis was detected under the experimental conditions. Rates were measured from the initial slopes of the titration curves and rate constants in each hydroorganic reaction mixture were determined by linear regression analysis of a Lineweaver–Burk plot.

Stability of the CT–Glass–Azo Conjugate

To determine the stability of the conjugate, CT–glass–azo (1–1.5 mL of beads) was stored in water or in 20% (v/v) organic solvent, 0.1 *M* KCl, pH(app) 9.8 at 20°C in a stoppered flask. The activity of CT–glass–azo (0.2–0.3 mL of beads, 0.8–0.7 mL of incubation medium) was assayed periodically against NATEE (9 mL, 11 m*M* in substrate). After each activity determination the glass beads were filtered, washed with distilled water (60 mL), and returned to the incubation flask. After two months, the glass beads were washed with acetone, air-dried, and analyzed for protein content by amino acid analysis.

Results and Discussion

The two principal methods for the covalent coupling of proteins to porous glass are the diazo and glutaraldehyde methods (11, 12). The results of experiments evaluating the two methods for coupling CT to porous glass of 550 Å and 1350 Å pore diameters are shown in Table 1. For all four CT–glass conjugates, a considerable portion of the immobilized CT does not contribute to the catalytic activity. All subsequent work was carried out with the most active conjugate, CT–glass–azo on CPG 1350.

Contrary to the observations of Tanizawa and Bender (4), the pH optimum for the esterolytic activity of CT–glass–azo was displaced two pH units towards more alkaline pH values relative to the optimum pH of 7.8 for native CT (Fig. 1). These conflicting observations are accounted for by differences in assay conditions. Tanizawa and Bender (4) measured their pH–activity profiles in highly buffered solutions, whereas the present experiments were done in unbuffered media. It is known that displacements of pH–activity profiles toward alkaline pH values of the form seen in Fig. 1 are characteristic of enzymically generated pH gradients when the catalyst is operating under diffusional restrictions (6*b*, 14). These displacements can be negated by using buffered solutions (6*c*, 15) or by decreasing the reactivity of the enzyme toward substrate (16). Although concentrations of organic solvent up to 20% decrease the measurable catalytic activity of CT–glass–azo, no shift in pH–activity profiles back toward pH 7.8, the optimum pH for native CT, was observed. On the contrary, for the three solvents surveyed, namely 2-propanol, *tert*-butyl alcohol, and DMSO, addition of 20% organic solvent further displaced the pH optimum toward more alkaline pH values (Fig. 1).[4] Unlike the CT–Sephadex conjugates in the previous study (1*c*), increasing the pH of the 20% aqueous DMSO solution did not reverse the DMSO-induced inhibition of the catalytic activity of CT–glass–azo.

For CT–Sephadex conjugates, the intrinsic catalytic parameters of the enzyme are not altered by the immobilization procedure (16, 17). Unfortunately, similar assurances regarding the effect of azo-coupling of CT to glass on the intrinsic k_c and K_m constants are not available. Substrate and product diffusion limitations of enzymes bound to

[4]The measured pH of the carbonate–borate buffer solutions used is shifted toward more alkaline values with increasing concentration of organic solvent, presumably due to modification of the buffer pK_a as the dielectric constant of the aqueous medium is progressively altered (7). These perturbations of the apparent pH are greatest (up to 0.7 pH units) when the solvent is DMSO and it is significant that the most pronounced pH optimum shift observed is for CT–glass–azo in 20% DMSO.

TABLE 1. Characterization of glass-bound CT derivatives

Support	Coupling method	Protein content[a] (mg enzyme/g support)	Specific activity[b] (μmol/min/mg enzyme)	Residual activity of CT after coupling[c]

[c] Specific activity of native CT under assay conditions: 294 μmol/min/mg enzyme.
[d] Surface area 70 m^2/g.
[e] Surface area 34 m^2/g.

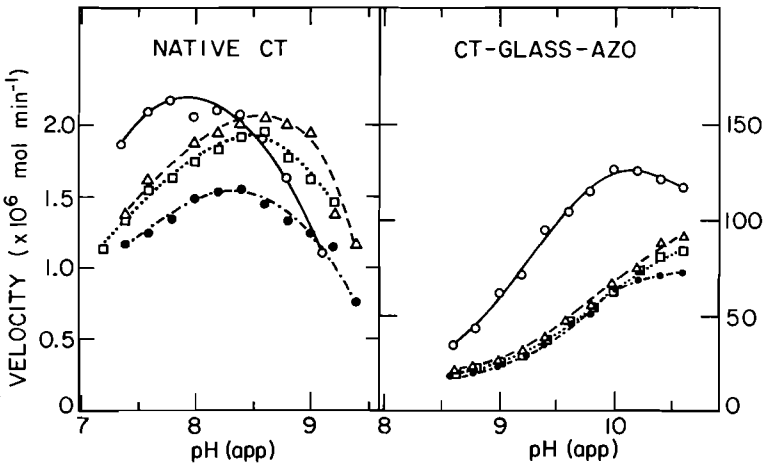

FIG. 1. Effects of 20% organic solvent on the pH–activity profiles for native CT and CT–glass–azo. The enzyme activities were assayed against NATEE (10 m*M*) in 2% methanol (○), 20% 2-propanol (●), 20% *tert*-butyl alcohol (□) and 20% DMSO (△) solutions 1.0 *M* in KCl at 25°C.

glass (18, 19) also complicate interpretation of the apparent k_c and K_m values obtained directly from Lineweaver–Burk plots[5] (21). However, the apparent specificity constants $k_c(app)/K_m(app)$ remain useful overall indicators of the relative catalytic activities under the various organic solvent conditions. These data are summarized in Table 2. The catalytic activity of CT–glass–azo is seen to be dramatically lower than that of native CT under all conditions assayed. Furthermore while the activities decrease monotonically as the concentration of each solvent is increased, CT–glass–azo is surprisingly insensitive to both the nature and concentration of the organic solvent used.[6] The apparent specificity constants for the immobilized enzyme vary by a factor of only ~4-fold under any of the conditions surveyed.

For long term practical applications, immobilized enzymes must retain their activity for extended periods (8). The half-lives for native CT and CT–glass–azo in different organic solvent media are compared in Table 3. With the exception of its behaviour in 20% aqueous dioxane and DMSO, the CT–glass–azo conjugate is somewhat more stable than the native enzyme. However, the half-lives observed are generally well below the levels necessary for an immobilized catalyst to be practicable.

The glass-immobilized enzyme suffers considerable loss of activity on storage for two months (Table 4) under normal operating conditions. Part of the instability of CT–glass–azo can be accounted for by the known susceptibility of porous glass to degradation under alkaline conditions (22) but the higher levels of protein loss in 20% solvent solutions than in water were unexpected. Although in each case the overall activity of CT–glass–azo drops as protein is lost during storage, the rate of activity loss is significantly slower than in water for all solvents except dioxane. Paradoxically, this results in conjugates of increased specific activity

[5] Recently, Brown *et al.* (20) have demonstrated that immobilization of CT to glass via a thioester linkage does not alter the intrinsic catalytic parameters. However, diffusion limitations of the catalytic activity still remained.

[6] Reduced availability of water in the higher organic solvent concentrations (4) is clearly not a significant factor here.

in terms of catalytic power per mg of the bound protein remaining in the aged preparations. A similar increase in specific activity on partial protein removal has been observed for CT bound to glass via thioester linkages (20). With protic solvents, the apparent stability of CT–Sephadex increases with increasing hydrophobic character of the organic solvent (1c). As Table 4 shows, the converse is true for CT–glass–azo. Both the stability of the covalent link (as reflected by the proportion of retained protein) and the stability of the catalyst (as measured by the residual activity) decrease with increasing hydrophobic character of the alcoholic solutions.

From the data obtained, it is evident that porous glass is not a suitable immobilized enzyme support for general use in aqueous organic solutions. Its rigid character does extend the viability of CT–glass–azo at high organic solvent concentrations, thereby avoiding the shrinkage problems encountered with Sephadex (1c). Nevertheless, overall CT–Sephadex is much preferable as a practical catalyst. Coupling of CT to Sephadex rather than porous glass provides a conjugate that has two-fold higher specific activity and that is considerably more stable, particularly in aqueous *tert*-butyl alcohol and DMSO for which the half-lives of CT–Sephadex are in excess of three months and 1 year respectively (1c). Clearly, however, many other carriers must be evaluated before optimum supports and coupling methods can be recommended with confidence for immobilized enzyme operations in aqueous organic solvents. Further work on this is to be carried out.

Clay chemistry: Investigation of thermodynamics of ion exchange reactions by titration calorimetry

GAVIN J. EWIN,[1] BRIAN P. ERNO,[2] AND LOREN G. HEPLER

Department of Chemistry and Oil Sands Research Laboratory, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4

Received November 19, 1980[3]

GAVIN J. EWIN, BRIAN P. ERNO, and LOREN G. HEPLER. Can. J. Chem. **59**, 2927 (1981).

We have built a titration calorimeter that is suitable for measurements on colloidal suspensions as well as more conventional chemical reactions in solution. This calorimeter has been used for investigation of a number of ion exchange reactions involving kaolinite and montmorillonite clays. Results of these measurements have led to cation exchange capacities, to enthalpies of ion exchange reactions, and also to equilibrium constants for some of these same reactions. These calorimetrically determined cation exchange capacities and equilibrium constants agree well with corresponding quantities obtained by way of conventional methods based on chemical analyses. It has been demonstrated that titration calorimetry is a useful and convenient method for investigation of ion exchange in clays.

GAVIN J. EWIN, BRIAN P. ERNO et LOREN G. HEPLER. Can. J. Chem. **59**, 2927 (1981).

Nous avons construit un calorimètre de titrage qui convient à la mesure des suspensions colloidales aussi bien qu'à celle des réactions chimiques conventionnelles en solution. On a utilisé ce calorimètre pour étudier un certain nombre de réactions d'échange d'ions impliquant des argiles à base de kaolinite et de montmorillonite. Les résultats de ces mesures ont conduit aux capacités d'échange de cations, aux enthalpies des réactions d'échange d'ions et également aux constantes d'équilibre de ces réactions. Ces constantes d'équilibre et ces capacités d'échange de cations déterminées par calorimétrie s'accordent bien avec les quantités correspondantes obtenues par des méthodes conventionnelles s'appuyant sur des analyses chimiques. On a démontré que le titrage par calorimétrie est une méthode utile et pratique d'étude de l'échange d'ions dans les argiles.

Introduction

Ion exchange equilibria involving clays (also other minerals and synthetic substances) are important in such diverse fields as soil chemistry, disposal of radioactive wastes, treatment of industrial and municipal waste waters, properties of tailings from mineral extraction and oil sands plants, etc. Thermodynamic investigations of these ion exchange equilibria are useful in several ways. Knowledge of enthalpies and volumes permits calculation of the effects of temperature and pressure on such equilibria; conversely, investigations of ion exchange equilibria at different temperatures and pressures permit evaluation of enthalpies and volumes. Knowledge of thermodynamic quantities associated with ion exchange reactions can be combined with theoretical models to improve our understanding of such systems and processes. Also, as shown later in this paper, experimental methods that are commonly thought of as "thermodynamic" can be used as analytical tools.

Many investigations of ion exchange reactions of clay minerals are reviewed in excellent books (1–4). Various methods based on chemical analyses have been applied usefully to evaluation of equilibrium constants for ion exchange in clay systems. Some of these equilibrium investigations have been carried out at two or more temperatures with subsequent calculation of enthalpies and entropies. Although sound in principle, this latter approach is not entirely satisfactory in practice. Partly from studies (5, 6) of such "simple" equilibria as ionization of aqueous acids, it is now well known that very accurate equilibrium constants are required to withstand the magnification of uncertainties and errors that goes with differentiation as in $d \ln K/dT$.

Various investigators have applied ampoule or batch mixing calorimetry to the measurement of enthalpies of ion exchange reactions. Early investigations of this kind were carried out by Coleman (7, 8). Others, a few of whom we cite later, have applied similar calorimetric methods. These investigators have used the method of common final states, which requires multiple calorimetric measurements, or have used a combination of calorimetric results with results of separate equilibrium measurements on the same systems. Although such investigations have yielded useful results, we point out that these well established calorimetric methods are limited in that they lead only to enthalpies; other useful quantities such as cation exchange capacities and equilibrium constants must be determined separately.

Modern methods of titration calorimetry offer several advantages for investigation of ion ex-

change reactions. First, titration calorimeters are relatively easy to build or inexpensive to buy as compared to the microcalorimeters that have been used in many previous calorimetric investigations of ion exchange reactions. Second, previous applications (9–12) of titration calorimetry have demonstrated that this method can lead to both thermodynamic and analytical information about complex systems.

Ragland (13) has applied titration calorimetry to investigation of enthalpies of reaction of hydrogen and aluminum bentonites with aqueous sodium hydroxide. Because of uncertainties in the characterization of the clays used by Ragland and complications associated with acid–base reactions of clays, we will not be concerned with the details of his reported results, but we do emphasize that Ragland's early investigation demonstrated that titration calorimetry could lead to enthalpies *and* to cation exchange capacities of clays.

It is now well established (9–12) that calorimetric titrations can have endpoints similar to the endpoints observed in traditional titrimetry. As shown by Ragland (13) and also later in this paper, it is possible to use the endpoints observed in certain calorimetric titrations for evaluation of cation exchange capacities of clays.

Results of some calorimetric titrations also permit simultaneous evaluation of the enthalpies and equilibrium constants of reactions. The quantity of heat evolved or absorbed (enthalpy decrease or increase) as a result of mixing reactants is given by the molar ΔH of the calorimetric reaction multiplied by the number of moles that react. The number of moles that react is determined by the amounts and concentrations of various chemicals and by the equilibrium constant for the reaction. The results of appropriate calorimetric titrations can therefore be used in solving simultaneous equations for both the enthalpy and equilibrium constant for the calorimetric reaction. We call particular attention to the work of Christensen, Izatt, and colleagues (14–16), who have applied the method extensively and developed useful calculational procedures. A principal aim of the present investigation has been to apply this kind of titration calorimetry to the simultaneous determination of equilibrium constants and enthalpies for ion exchange reactions involving clays.

Experimental

The calorimetric reaction vessel consists of an inexpensive and replaceable 250 cm^3 polypropylene beaker suspended inside a stainless steel canister, which is submerged in a constant temperature bath maintained at 25.00°C for this investigation. Bath temperature was held constant to ±0.001°C for times longer than the duration of one calorimetric run.

The titration burette consists of a motor driven syringe having 20 cm^3 capacity and delivery rates adjustable from 0.5 to 20 cm^3 min^{-1}. Test experiments with different delivery rates, including halts in the titration, showed that chemical and thermal changes in most of our systems could keep up with a delivery rate of about 1 cm^3 min^{-1}. Most measurements were made with a delivery rate of 1.1258 ± 0.0014 cm^3 min^{-1}, accurately determined by weighing samples of water collected during accurately timed delivery intervals. Delivery of titrant from syringe to calorimeter is by way of a coil of Teflon tubing submerged in the constant temperature bath to ensure that titrant is at the temperature of the bath as it enters the calorimeter.

Our calorimeter has been constructed throughout to have low heat capacity along with minimal thermal lags and consequent rapid response. Because the systems we have expected to investigate are known to have widely different viscosities and mixing characteristics, we have included variable speed stirring with a choice of several different stirrer blade sizes and shapes.

Temperature in the calorimeter is measured with a 2000 ohm Fenwall rapid response thermistor enclosed in Teflon heat shrink tubing. This thermistor forms one arm of an operational amplifier self-balancing Wheatstone bridge (17). Noise and shunting effects were reduced by means of a 1 Hz single pole low pass filter (18). Temperature sensitivity varied from (1–5) × 10^{-5} K, depending on the stirring characteristics of the clay suspension in the calorimeter.

The calorimeter was calibrated electrically for each experiment. All timing was done automatically by electrical coupling with a Standard Electric clock, accurate to ±0.02 s.

Output data (bridge voltage or temperature versus volume of titrant added) from our first series of experiments were collected with a strip chart recorder. Readings from the strip chart were then used as input for a computer program[4] that calculates "corrected" enthalpy changes by allowing for enthalpies of dilution, which were measured separately, and for stirring effects. Output data from later experiments were obtained directly in digital form by way of an automatic digital printer.

Experimental accuracy and procedures for calculation were tested using the neutralization of dilute excess NaOH with HCl. Our results led to $\Delta H^0 = -55.80 \pm 0.20$ kJ mol^{-1}, in which ± indicates standard deviation, as compared with the previously selected (20, 21) best value, $\Delta H^0 = -55.815$ kJ mol^{-1}.

All chemicals used were of analytical reagent grade. Solutions of cations used in calorimetric titrations were made from corresponding chlorides dissolved in distilled water and analyzed by thermometric titration with suitable titrants as described by Vaughan (10) and also by more traditional volumetric methods. Sodium and potassium determinations were carried out with a Corning 450 Flame Photometer.

Fisher K-3 "colloidal kaolin" from Florida was used as starting material for preparation of Na^+-kaolinite and NH_4^+-kaolinite, following procedures similar to those previously described by Ferris and Jepson (22).

Wyoming montmorillonite (VOLCLAY KWK, American Colloid Co.) was thoroughly dispersed in distilled water by stirring for several hours. The resulting suspension contained about 4% clay. Centrifuging this suspension for an hour at 2000 g gave a sediment consisting of a small amount of coarse black particles at the bottom of the centrifuge bottle and two other well

[4]Our computer program is a modified version of a procedure reported earlier by Christensen and Izatt (19).

For personal use only.

defined layers. The upper yellow–white layer was removed for further treatment. This yellow–white clay was mixed with acetic acid – sodium acetate buffer (pH = 3.8 at room temperature) and then maintained with stirring at 70°C for 3 h to remove soluble impurities. The suspension was then allowed to stand at room temperature for 3 days before the clay was recovered by centrifuging. The recovered clay was dispersed in 1 *M* NaCl solution, adjusted to pH = 7 with NaOH, and recovered by centrifuging again. This NaCl treatment was repeated and followed by several washings with distilled water. Finally, suspensions of the clay in distilled water were concentrated to 2% clay by use of an Amicon Model DC3 hollow fiber ultrafiltration unit.

All solutions in which clays were suspended were analyzed for Na^+, for which concentrations were found to range between 0.0008 and 0.011 *M*.

Most calorimetric measurements described in this paper were carried out with 20 g of Na^+-kaolinite suspended in 180 g of water or with 2 g of Na^+-montmorillonite suspended in 198 g of water. Most calorimetric titrant solutions were 0.1 *M* solutions of MCl_n salts.

Results

Calorimetric titrations of suspensions of Na^+-clays with solutions of divalent or trivalent chlorides lead to nearly linear endothermic thermograms that show moderately sharp "breaks" typical of endpoints in many kinds of titrations. We analyze these thermograms in terms of ion exchange reactions represented generally by

[1] $M^{n+}(aq) + nNa^+\text{-clay} = M^{n+}\text{-clay}_n + nNa^+(aq)$

The straight part of the thermogram is consistent with the equilibrium constant for the exchange reaction [1] being sufficiently large that nearly all added $M^{n+}(aq)$ is exchanged up to the break. Taking the exchange reaction to be complete at the break, which we now call an endpoint, permits calculation of the cation exchange capacity from our knowledge of the amount and concentration of added titrant and the amount of clay in the calorimeter. Results of these determinations of cation exchange capacities are summarized in Table 1. We have also determined cation exchange capacities of these same clays by means of conventional chemical analyses, with results in agreement (better than ±4%) with those shown in Table 1. We also note that our calorimetrically determined cation exchange capacities are within the ranges of values found by previous investigators of similar clays, as summarized by Marshall (1) and Grim (23).

TABLE 1. Cation exchange capacities of Na^+-clays

Clay	Replacing cation	Cation exchange capacity, μmol Na^+ g^{-1}
Kaolinite	Mg^{2+}	35.2±0.6
	Ca^{2+}	35.6±0.5
Montmorillonite	Mg^{2+}	780±40
	Ca^{2+}	800±50
	La^{3+}	730±30

As stated above, we have interpreted the breaks in our thermograms as endpoints associated with M^{n+}/Na^+ exchange reactions. Subsequent measurements and data analyses by Schramm and Kwak (24) have shown that effects of tactoid formation and not-quite-complete exchange should also be considered. Although it is probable that detailed consideration of these effects (24) would improve the agreement (now better than ±4%) between our calorimetrically evaluated cation exchange capacities and those obtained more accurately (and more laboriously) by chemical analyses, we will in this paper retain our initial simple interpretation and use the values for cation exchange capacities listed in Table 1.

Because nearly all of the added $M^{n+}(aq)$ is exchanged at any point along the linear portion of the titration thermogram (before the endpoint), it is also possible to obtain the desired enthalpy for the exchange reaction [1] quite simply from

[2] $\Delta H = Q/r$

in which Q represents the total heat evolved or absorbed at any point and r represents the number of moles of $M^{n+}(aq)$ that have exchanged (reacted), with r being almost exactly equal to the number of moles of $M^{n+}(aq)$ added. Results are summarized in Table 2.

Calorimetric titrations of suspensions of Na^+-clays with solutions of monovalent chlorides lead to curved thermograms, which do not exhibit endpoints. It is intended to obtain from such thermograms the enthalpies *and* equilibrium constants of the ion exchange reactions represented generally by

[3] $M^+(aq) + Na^+\text{-clay} = M^+\text{-clay} + Na^+(aq)$

The equilibrium constant for the exchange reaction [3] is

[4] $K = (a_{M^+\text{-clay}})(a_{Na^+})/(a_{Na^+\text{-clay}})(a_{M^+})$

in which the terms in parentheses represent the indicated thermodynamic activities. We will take ratios of activity coefficients for $Na^+(aq)/M^+(aq)$ and for M^+-clay/Na^+-clay to be unity so that [4] becomes

[5] $K = [M^+\text{-clay}][Na^+]/[Na^+\text{-clay}][M^+]$

and thence

[6] $K = (f_{M^+})[Na^+]/(f_{Na^+})[M^+]$

in which square brackets indicate molarities and f_{M^+} and f_{Na^+} represent fractions of the clay in the M^+ and Na^+ forms. The equilibrium constant for the exchange reaction [3] can also be expressed as

$$[7] \quad K = [r][r + (Na^+)_i V_i]/[W \cdot CEC - r][TV_a - r]$$

in which the symbols have the following meanings and are conveniently expressed in the indicated units: r: number of moles of M^+ that react (exchange), in mol; $(Na^+)_i$: initial concentration of Na^+(aq) in the suspending solution in mol/L; V_i: the initial volume of suspension in L; W: the mass of Na^+-clay initially present in g; CEC: cation exchange capacity; moles exchangeable Na^+/g of clay; T: concentration of titrant solution in mol/L; and V_a: volume of titrant solution added in L.

It is possible to use the values of Q and V_a from any two points on a thermogram in eqs. [2] and [7] to obtain the desired values of K and ΔH^0; we have carried out such calculations using a large number (usually 28) of such points as follows. First, we have chosen an arbitrary value of K and then used eq. [7] in calculating the values of r that correspond to each of the selected points along the titration thermogram. Next, these values of r were used with corresponding values of Q in eq. [2] to obtain a value of ΔH corresponding to each of the selected points along the titration thermogram. This sequence of calculations was then repeated with various other selected values of K. Finally, the "best" value of K was taken to be the value that leads to the most consistent (as judged by standard deviation) ΔH. Some practical procedures for carrying out these calculations have been cited by Eatough, Izatt, and Christensen (15). Our results are summarized in Table 3.

Several tests of the results summarized in Table 3 are possible; we have done the following. First, we have determined equilibrium constants for all of the exchange reactions by means of chemical analyses for Na^+(aq) and M^+(aq) in various solutions at equilibrium. Values of these conventionally determined equilibrium constants, which have uncertainties smaller than those indicated in Table 3, are all in agreement with the listed values that have been determined calorimetrically. It is also possible to use these conventionally determined equilibrium constants in eq. [7] for calculation of values of r at various points along the thermogram and then apply eq. [2] to obtain ΔH values. All ΔH values so obtained are in good agreement with the values listed in Table 3. The values of ΔH calculated in this latter way have somewhat smaller uncertainties than the values listed in Table 3, because the latter procedure requires evaluation of only one quantity (ΔH) instead of two (K and ΔH) from a single thermogram.

Next, we have combined results from Table 3 for exchange of Cs^+(aq) and NH_4^+(aq) with Na^+-kaolinite to obtain the following calculated equilibrium constant and ΔH for exchange of Cs^+(aq) with NH_4^+-kaolinite:

$$[8] \quad Cs^+(aq) + NH_4^+\text{-kaol} = Cs^+\text{-kaol} + NH_4^+(aq)$$

$$K = 3.2$$

$$\Delta H = -8.4 \pm 1.4 \text{ kJ mol}^{-1}$$

Direct calorimetric titration of NH_4^+-kaolinite with a solution of CsCl led to $K = 3.2$ and $\Delta H = -10.7 \pm 1.3$ kJ mol^{-1} for the reaction represented by eq. [8]. The two independent K values are in excellent agreement and the two ΔH values agree within their stated uncertainties.

Discussion

Test measurements with our calorimeter on "simple" chemical systems, such as the acid–base neutralization reaction mentioned earlier, have demonstrated that purely calorimetric uncertain-

ties for homogeneous systems without stirring problems range from about 0.2% to about 1% for ΔT values in the range we have investigated. Actual uncertainties in results we have reported in Tables 2 and 3 are larger than these purely calorimetric uncertainties, for reasons that are outlined below.

Our application of eq. [2] to the linear portions of thermograms from titration of Na^+-clay with M^{n+}(aq) implies that the enthalpy of exchange is independent of the extent of exchange that is represented by r. Partly because this implication is not exactly correct and partly because of a small scatter in our results that we attribute mostly to heats of stirring, the standard deviations indicated by ± in Table 2 are significantly larger than purely calorimetric uncertainties cited in the preceding paragraph. All of these ΔH values in Table 2 are to be regarded as average values for fraction exchanged equal to zero up to fraction exchanged nearly equal to unity.

We have assumed in our derivation of eq. [7] that the ratios of activity coefficients for Na^+(aq)/M^+(aq) and for M^+-clay/Na^+-clay are unity. This assumption for Na^+(aq)/M^+(aq) is quite accurate for the dilute solutions used in this investigation and can be neglected as a source of significant error. On the other hand, Argersinger, Davidson, and Bonner (25) and Gaines and Thomas (26) have shown that the ratio of activity coefficients for M^+-clay/Na^+-clay is not necessarily unity, which means that the equilibrium "constants" we have used are not necessarily independent of the extent of exchange of M^+ for Na^+. Similarly, the enthalpies of exchange are not necessarily constant, being expected to vary a little with extent of exchange.

At the beginning of a calorimetric titration of Na^+-clay with MCl(aq) all of the clay is in the sodium form and the fraction converted to the M^+ form (f_{M^+}) is zero. At the end of a calorimetric titration ($V_a \leq 0.020$ L), f_{M^+} (calculated conveniently as $r/\text{CEC}\cdot W$) might be as large as 0.6 but was typically less than 0.5. Our analyses of calorimetric titration thermograms in terms of eqs. [2] and [7] therefore yield average values of the equilibrium "constant" and enthalpy of exchange that refer to f_{M^+} values in the range from zero to less than 0.5. The standard deviations indicated by ± values in Table 3 are expected to be a good indication of uncertainties in these *average* values for equilibrium "constants" and corresponding enthalpies of exchange. Results of a considerable number of investigators who have applied the method of Gaines and Thomas (26) to determination of true thermodynamic equilibrium constants permit us to estimate that the further uncertainties resulting from our approximation concerning the activity ratio for M^+-clay/Na^+-clay are approximately the same size as the cited standard deviations, thus making the *total* uncertainties in our thermodynamic K and ΔH values equal to about twice the standard deviations.

We now turn to comparison of some of our results in Tables 2 and 3 with results of earlier investigations.

Our ΔH values for exchange of M^{2+} on Na^+-montmorillonite (Table 2) are distinctly smaller than corresponding values reported by Laudelot, Van Bladel, Bolt, and Page (27), but are in close agreement with more recently reported values from

Maes and Cremers (28) and Schramm and Kwak (24).

Our ΔH value for exchange of K^+ on Na-montmorillonite (Table 3) is in good agreement with the results of four investigations (24, 29–31) of five different montmorillonites. However, our ΔH is considerably more exothermic than the value found in one investigation (31) of one montmorillonite.

Our ΔH value for exchange of Cs^+ on Na-montmorillonite is in good agreement with results of two other investigations (29, 31) of three montmorillonites. However, our ΔH is also considerably more exothermic than the values reported for three other montmorillonites (24, 30, 31).

On the basis of the above comparisons and also the results of our test of internal consistency involving exchanges of Cs^+, NH_4^+, and Na^+ on kaolinite, we conclude that our ΔH values have about the same accuracy and reliability as similar values from other calorimetric investigations. In this connection we note that only a few previous investigators have carried out consistency checks similar to our investigations of exchange of Cs^+, NH_4^+, and Na^+ on kaolinite; of these, we call attention to four such investigations (24, 29, 30, 32) leading to internal consistencies about the same as ours.

The enthalpies of exchange of M^{2+}(aq) and La^{3+}(aq) with Na^+-clay are all endothermic. Because the equilibrium constants for these exchanges are all larger than unity, corresponding to negative values of ΔG^0, we see that all of these exchanges are "entropy driven" with values of $T\Delta S^0$ that are larger than the corresponding values of ΔH.

The results in Table 3 for M^+/Na^+ exchange show that there is partial compensation between ΔH and $T\Delta S^0$ so that ΔG^0 is nearer zero than either ΔH or $T\Delta S^0$. This kind of enthalpy–entropy compensation has been observed before for ion exchange reactions and also for many other reactions (33–44).

Summary

The principal point of this paper has been to demonstrate that titration calorimetry can lead to satisfactorily accurate determinations of cation exchange capacities and equilibrium constants for ion exchange reactions as well as the enthalpies of exchange that are commonly determined by other calorimetric methods. Further, it is our experience that such determinations using titration calorimetry can be carried out more quickly than the traditional determinations that depend heavily on various chemical analyses.

We have also provided some thermodynamic results for ion exchange in certain clay systems.

Finally, we suggest that application of methods similar to those described here to ion exchange reactions on various synthetic substances is likely to be useful.

Synthesis of fluorescent probe – carbohydrate conjugates[1]

MANSUR YALPANI[2] AND LAURANCE D. HALL
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received May 6, 1981

MANSUR YALPANI and LAURANCE D. HALL. Can. J. Chem. **59**, 2934 (1981).

A new type of luminescent label has been synthesized and a range of carbohydrates has been derivatized with various fluorescent probes. Amine-containing labels were readily transformed with chloroacetylchloride into the corresponding fluorescent chloroacetamide reagents **1–4**. Suitably blocked monosaccharides containing either a free thio **9**, hydroxyl **11**, or carboxyl **17** functionality have been conjugated with (*a*) 4-chloroacetamido labels **1** and **2**, (*b*) with 4-aminobenzophenone **5**, and (*c*) with 1-dimethyl-1-aminonaphthalene-5-sulfonylchloride **21**, to form the fluorescent carbohydrate conjugates **10**, **16**, **18**, and **20**. Direct derivatization of the unblocked disaccharides **22** and **23** was achieved by reductive amination with amines **5** and **7** and sodium cyanoborohydride affording the 1-deoxyglycit-1-yl derivatives **24–26**, which were characterized by ^{13}C nmr spectroscopy. The synthesis of fluorescent polysaccharides is exemplified by the condensation of 9-anthraldehyde with chitosan either via Schiff's base formation to afford **32**, or via reductive alkylation to form **33**.

MANSUR YALPANI et LAURANCE D. HALL. Can. J. Chem. **59**, 2934 (1981).

On a synthétisé un nouveau type de marqueur luminescent et l'on a attaché divers groupes fluorescents à des hydrates de carbone. Les marqueurs contenant des amines réagissent facilement avec le chlorure de chloroacétyle et donnent les réactifs chloroacétamides correspondants **1–4**. On a fait réagir des monosaccharides convenablement protégés comportant soit des groupes thio (**9**) soit des groupes hydroxyles (**11**) ou des groupes carbonyles (**17**) (*a*) avec les marqueurs chloroacétamido-4 **1** et **2**, (*b*) avec l'amino-4 benzophénone **5** et (*c*) avec le chlorure de diméthylamino-1 naphthalène sulfonyle-5 **21** pour former des hydrates de carbone conjugués fluorescents **10**, **16**, **18** et **20**. On a formé des dérivés des disaccharides non protégés **22** et **23** en procédant à une amination réductrice par les amines **5** et **7** en présence de cyanoborohydrure de sodium; il y a formation de dérivés déoxy-1 glycityle-1 **24–26** que l'on a caractérisé par la spectroscopie de rmn du ^{13}C. On a utilisé comme exemple de synthèse de polysaccharides fluorescents, la condensation de l'anthraldehyde-9 avec le chitosane soit par l'intermédiaire de la formation d'une base de Schiff qui conduit au composé **32** ou par l'alkylation réductrice pour aboutir au composé **33**.

[Traduit par le journal]

Introduction

The complexity of many biologically important carbohydrates has prompted the development in recent years of new analytical techniques for their characterization. Spectroscopic methods based on either fluorescence or magnetic resonance are particularly attractive in this regard in view of the wealth of information which they can provide at the molecular level. Fluorescent carbohydrate conjugates have received considerable attention in a variety of fields ranging from studies of cell surface topography (2), membrane transport (3), polysaccharide mobility (4), and gelling mechanism (5), to the analysis of glycoproteins (6). Concurrently, the need has arisen for a broader spectrum of labelling methods and reagents (7, 8).

As part of our interest in synthetic methods for the specific labelling of complex, carbohydrate-containing systems (9), we describe here the synthesis of a new type of luminescent reagent as well as typical protocols whereby mono-, oligo-, and poly-saccharides can be transformed into the corresponding luminescent derivatives. Emphasis was directed in this work towards methods which require relatively mild reaction conditions, including some which operate in aqueous media.

Results and Discussion

A series of luminescent probes **1–4** were readily prepared by the reaction of the luminescent amines (10) **5–8** with chloroacetylchloride in ethyl acetate or diethyl ether under reflux, followed by concentration at ambient temperature using a stream of dry nitrogen. The chloroacetamide derivatives **1–4** were obtained in good to high yields (59–100%), and constitute a versatile type of reagent which can be employed for the alkylation of thiol, amino, or hydroxyl functionalities under appropriate reaction conditions. Being less reactive than the equivalent iodoacetamides (11), these reagents offer the advantage of greater selectivity.

This selectivity was demonstrated using as an exemplar label **1**, which readily condensed with the thiosugar tetraacetate **9** in boiling chloroform in the presence of solid sodium bicarbonate to afford **10** in good yield. In contrast, neither *N*- or *O*-alkylation could be accomplished under similar conditions; thus, the luminescent probes **1** and **2** failed to react when either the partially blocked primary and

[1]Aspects of this work were presented at the 62nd Canadian Chemical Conference, Vancouver, Canada, June 3–9, 1979; for a preliminary communication on this work, see ref. 1.

secondary alcohols **11–14** or the amino sugar **15** were used. However, the ether **16** was produced, from condensation of the diisopropylidene galacto derivative **11** and **2** using sodium hydride in dimethyl formamide (12).

Amide-linked luminescent derivatives were obtained via carbodiimide-mediated coupling (13); for example, reaction of the D-galacturonic acid derivative **17** with amine **5** in dichloromethane solution gave the amide **18** in acceptable yield[3] (48%) upon treatment with dicyclohexylcarbodiimide.

The intense fluorescence of 5-dimethylamino-1-naphthalene sulfonyl (DANSYL) derivatives has previously been exploited for the investigation of several carbohydrate systems (7, 14) and in this study the sulfonate ester derivative **20** was prepared in high yield (73%) by condensation of the D-galactose derivative **11** with DANSYL-chloride **21** in acetone with triethylamine as base acceptor. However, because attempts to remove the isopropylidene blocking groups of the crystalline derivative **20** were unsuccessful, this particular approach was not pursued further. More recently, Zissis and Glaudemanns (7) have reported methods for the direct dansylation of the primary hydroxyl function of methyl-β-D-galactopyranoside to afford an amorphous product.

Complementary to the foregoing procedures are methods for selectively labelling unprotected sugars in polar media. Aldehydo- or keto-sugars, for example, are readily derivatized using the versatile reductive amination reaction (15). We found that condensation of amine-containing fluorescent probes with disaccharides proceeded in excellent yields in refluxing methanol with sodium cyanoborohydride as reducing agent. Facile conversion of lactose **22** and cellobiose **23** into the corresponding luminescent derivatives **24** and **25**, and **26**, respectively, was observed. These products were obtained even under conditions which were not strictly anhydrous, e.g. by employing commercial samples of β-lactose or nonanhydrous methanol. The luminescent disaccharide derivatives were isolated by column chromatography on silica gel and were further characterized as their nonaacetates.

The 1-deoxyglycit-1-yl derivatives were also characterized by ^{13}C nmr spectroscopy. The ^{13}C chemical shifts of the carbohydrate moieties together with their assignments are gathered in Table 1. The assignments are based on off-resonance

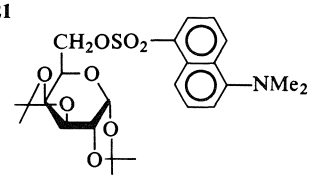
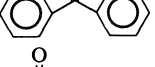
17 R = OH

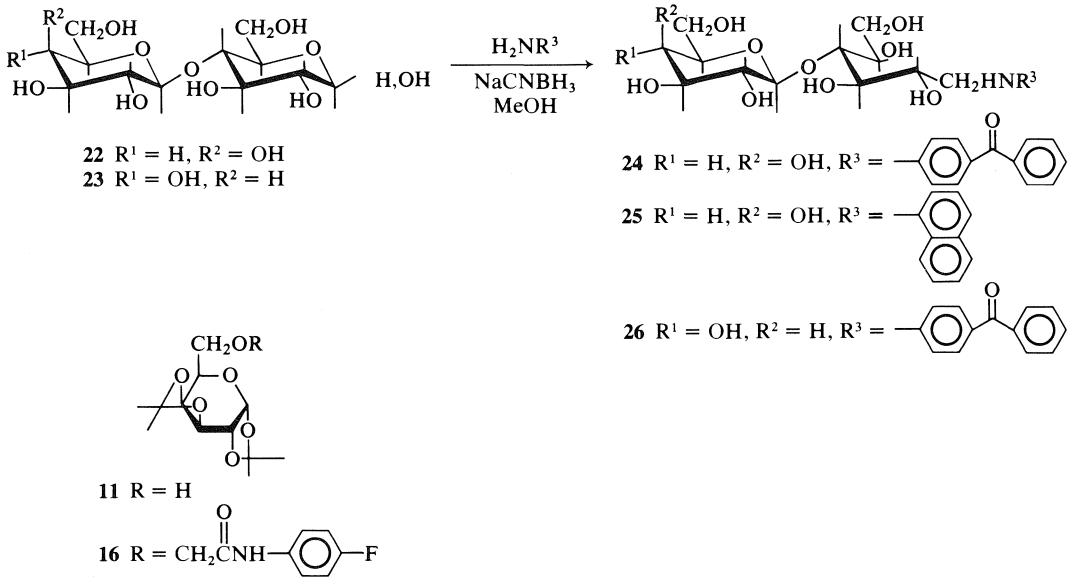


20



19 R = $N(C_6H_{11})CNHC_6H_{11}$

[3]We have generally obtained essentially quantitative yields for amidations of various water soluble carbohydrates, including polysaccharides, by employing the equivalent water soluble carbodiimides (e.g. 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide; the higher yields may be chiefly attributed to suppression of *N*-acylurea by-product formation (e.g. **19**) (13).



decoupling experiments and comparison with data recently reported by Pfeffer *et al.* (16) as well as from ^{13}C nmr results obtained from branched 1-deoxyglycit-1-yl chitosan derivatives (9, 17). The fact that the C-1′ resonances of the fluorescent derivatives exhibit a downfield shift relative to the corresponding alkyl derivatives of Hoagland *et al.* (18) can be attributed to the presence of the aromatic moieties.

The luminescent disaccharide derivatives exhibited a pH-dependence, similar to that observed by Hoagland *et al.* (18) at high pH, in which peak-splitting was observed on lowering the pH from 7.5 to 6.5. These pH-induced splittings occurred for the resonances of C-1, C-1′, C-4′, C-5, C-6, and C-6′ of all three derivatives. We are unable, however, to offer a plausible explanation for this effect, which Hoagland *et al.* (18) proposed to be due to "restricted intermolecular interactions".

The selective labelling of chitosan was accomplished using the reductive amination procedure. Thus, condensation of chitosan **28** with 9-anthraldehyde **29** in aqueous acetic acid – methanol (1:1) produced a stiff gel, which, after purification by extensive washing, afforded the fluorescent Schiff's

base derivative **30**. The degree of substitution (ds 0.73) of **30** was determined by elemental microanalysis. The imine moiety of **30** could be further stabilized against hydrolysis by reduction with sodium cyanoborohydride to yield **31**. Alternatively **31** was obtained directly by reductive alkylation of **28**.

Conclusions

Of the above methods for labelling partially blocked monosaccharide derivatives, alkylation with luminescent chloroacetamide reagents seems to offer a somewhat greater potential, in terms of overall facility and selectivity, than either dansylations or carbodiimide-mediated amidations. Based on the results described here and in the literature (14), we consider specific derivatization of the reducing end of mono- or oligo-saccharides, via either Schiff's base formation or reductive amination using sodium cyanoborohydride, to be the method of choice in view of the mild reaction conditions, the excellent yields, and the convenience of using unblocked sugars. The advantages of the latter approach are further emphasized when complex carbohydrate-containing systems, such as polysaccharides, are to be labelled. Insofar as the yields reported here for chitosan are typical of those we have obtained for other similar polysaccharide derivatizations (9, 17, 19), we believe that this method will find general application in covalent labelling of many sugar-containing systems.

Experimental

General Methods and Materials

All solutions were concentrated using a Buchi rotary evaporator unless otherwise stated. All melting points were measured using a Thomas Hoover Unimelt instrument (Model 6406-K) and are corrected. Optical rotations were determined on a Perkin-Elmer Polarimeter (Model 241-MC).

Thin-layer chromatography (tlc) was performed on silica gel plates (Baker-flex Silica gel 1B2-F) using the following solvent systems: (A), 1-butanol – acetic acid – water (6:3:1); (B), benzene – methanol – ethyl acetate (4:3:1); (C), toluene–ether (2:1); (D), toluene – ethyl acetate (2:1 or 1:1); (E), benzene–methanol (4:1); (F), methanol–chloroform (5:1). The fluorescent chloroacetamide derivatives (**1–4**) were checked for purity by tlc in solvents (E) and (C) and were detected as dark nonfluorescent spots under uv light. The corresponding blocked acetamido sugar derivatives (tlc solvents (C), (D), or (E)) were fluorescent under uv light and were also checked by charring with H_2SO_4–EtOH. The fluorescent disaccharide derivatives (**24–26**) were checked by tlc using solvent (A) and were also tested by spraying with 2% ninhydrin in acetone. Column chromatography was performed using 100–200 ASTM mesh silica (Fisher) packed in columns approximately 2.5 × 50 cm and solvents (B), (C), or (F) as eluants.

All microanalyses were carried out by Mr. P. Borda of this Department. The mass spectra were obtained from an Atlas CH-4B mass spectrometer and high resolution measurements were performed using an AE1 MS-9 or an MS-50 mass spectrometer. Proton nmr spectra were obtained from the following instruments: Varian T-60 (60 MHz); Bruker WP-80 (80 MHz), WH-400 (400 MHz); or at 270 MHz from the prototype of a homebuilt spectrometer based on a Bruker WP-60 console, a Nicolet 1180 computer (40K), a Nicolet 293 A′ pulse controller unit, a Diablo Disk, and an Oxford Instruments Superconducting Solenoid.

Carbon-13 nmr spectra were obtained using a Varian CFT-20 spectrometer equipped with a 16K computer. All deuterated solvents were purchased from Merck Sharp & Dohme (Montreal, Canada). Tetramethylsilane and *p*-dioxane (67.40 ppm) were used as standards for proton and carbon nmr, respectively.

4-Aminobenzophenone, *p*-fluoroaniline, 9-anthraldehyde, 1-dimethylaminonaphthalene-5-sulfonylchloride (DANSYL-Cl), 1-aminonaphthalene, and sodium cyanoborohydride were obtained from Aldrich Chemical Co.; chloroacetyl chloride, lactose, and *N*,*N*-dicyclohexylcarbodiimide were from Eastman Chemical Co. Sodium periodate and propionic acid were purchased from Fisher Scientific Co.; benzoic acid, acetic anhydride, and pyridine from Mallinckrodt; sodium hydride from Metal Hydride Inc. 7-Amino-4-methylcoumarin was obtained from Chemical Dynamics Corp. 1,2:3,4-di-*O*-isopropylidene galactopyranose and 1,2:5,6-di-*O*-isopropylidene glucofuranose were from Koch Light Laboratories Ltd. Chitosan was purchased from Sigma Chemical Co. Alginate (Keltone) was a gift from Kelco Co. 2,3,4,6-Tetra-*O*-acetyl-thio-α-D-glucopyranoside (**9**) was prepared by Ms. L. Evelyn of this laboratory; 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranuronic acid (**17**) was prepared by permanganate oxidation of the corresponding galactopyranose derivative according to known procedures.

Preparation of Fluorescent Chloroacetamide Labels

General Procedure

To a solution of chloroacetyl chloride (0.95 mL, 12 mmol) in either diethyl ether or ethyl acetate (10 mL) was added a solution of the fluorescent amine (6 mmol) in anhydrous diethyl ether or ethyl acetate (4–5 mL), causing immediate precipitation. The reaction mixture was then refluxed for 2–3 h under anhydrous conditions and subsequently filtered; the filtrate was concentrated using a slow stream of dry N_2 at ambient temperature. The crystalline material separating out of solution was filtered and dried, being analytically pure in most cases.

4-Chloroacetamido Benzophenone (1)

White crystals were obtained (90%) using ethyl acetate as solvent; mp 133.5°C (from toluene); tlc: solvent (C); nmr (270 MHz, $CDCl_3$) δ: 10.0 (s, 1H, NH), 7.99–7.61 (m, 9H, arom. H's), 4.35 (s, 2H, —CH_2—); ms *m/e* (relative intensity): 273 (64) M^+, 238 (13) $M^+ - Cl$, 198 (70), 197 (31), 196 (100) $M^+ - C_6H_5^+$, 167 (14), 140 (11), 120 (32) $(COC_6H_4NH)^+$, 119 (78) *m/e* 120 − H^+, 105 (49) $C_6H_5CO^+$, 77 (28). *Anal.* calcd. for $C_{15}H_{12}NO_2Cl$: C 65.82, H 4.42, N 5.12; found: C 66.00, H 4.38, N 5.18.

p-*Fluorochloroacetamidoaniline (2)*

The reaction was carried out in ethyl acetate yielding (100%) white crystals, mp 131–131.5°C (dec., from toluene); tlc: solvent (E); nmr (60 MHz, $CDCl_3$) δ: 7.95 (s, 1H, NH), 7.35–6.60 (m, 4H, arom. H's), 4.05 (s, 2H, —CH_2—); ms *m/e* (relative intensity): 189 (2) $M^+ + 2$, 188 (18) $M^+ + 1$, 187 (54) M^+, 138 (17), 112 (10), 111 (100), 100 (16). *Anal.* calcd. for C_8H_7FNOCl: C 51.22, H 3.76, N 7.47; found: C 51.02, H 3.73, N 7.54.

1-Chloroacetamidonaphthalene 3

Using ethyl acetate as solvent a white crystalline material was obtained (75%); mp 92°C; tlc: solvent (E); nmr (270 MHz, $CDCl_3$) δ: 8.88 (s, 1H, NH), 7.9–7.5 (m, 7H, arom. H's), 4.4 (s, 2H, —CH_2—); ms *m/e* (relative intensity): 219 (89) M^+, 170 (33), 144 (45), 143 (100), 142 (21), 127 (14), 115 (54), 50 (15). *Exact Mass* calcd. for $C_{12}H_{10}NOCl$: 219.0452 amu; found (hrms): 219.0452.

7-Chloroacetamido-4-methylcoumarin ***4***

The reaction proceeded in diethyl ether or ethyl acetate yielding a white product (59%) soluble in DMSO; mp 240–241°C; tlc: solvent (E); nmr (270 MHz, DMSO-d_6) δ: 8.9 (s, 1H, NH), 6.76 (d, 1H, H6), 6.65 (d, 1H, H8), 6.52 (dd, 1H, H5), 5.54 (q, 1H, H3), 4.36 (s, 2H, —CH_2—), 2.32 (d, 3H, Me); ms *m/e* (relative intensity): 251 (100), 175 (55), 174 (42), 147 (60), 119 (87). *Exact Mass* calcd. for $C_{12}H_{10}NO_3Cl$: 251.0349 amu; found (hrms): 251.0346.

*Preparation of 2,3,4,6-Tetra-*O*-acetyl-(4-acetamidobenzophenone)-1-thio-α-*D*-glucopyranoside (**10**)*

A solution of the chloroacetamide label **1** (0.82 g, 3 mmol) in a 1:2 mixture of ethyl acetate – $CHCl_3$ (15 mL) was added to a mixture of 2,3,4,6-tetra-*O*-acetyl-1-thio-α-D-glucopyranoside (**9**), (1.09 g, 3 mmol), and sodium bicarbonate (0.5 g) in ethyl acetate (15 mL). After refluxing for 18 h, the reaction mixture was cooled and concentrated yielding a yellow syrup from which white crystals separated on standing overnight at 22°C. The product was recrystallized once from 95% EtOH; yield 67%, mp 130°C, $[\alpha]_D^{22}$ −30° (*c* 1.6, $CHCl_3$); tlc: solvent (E); nmr (270 MHz, $CDCl_3$) δ: 8.80 (s, 1H, NH), 7.82–7.48 (m, 9H, arom. H's), 5.25 (t, 1H, H-4), 5.16–5.09 (m, 2H, H-2 and H-3), 4.64 (d, 1H, H-1), 4.11–4.03 (m, 2H, H-6's), 3.81–3.75 (m, 1H, H-5), 3.68–3.41 (2d, 2H, SCH_2—), 2.09–1.87 (3s, 12H, —OAc); ms *m/e* (relative intensity): 601 (16) M^+, 422 (30), 421 (37), 408 (33), 380 (34), 379 (38), 367 (29), 366 (38), 331 (37), 276 (33), 275 (50), 274 (43), 273 (66), 272 (35), 271 (46), 240 (35), 239 (54), 238 (31), 229 (32), 224 (42), 223 (40), 211 (40), 210 (38), 199 (44), 198 (75), 197 (68), 196 (82), 169 (77), 105 (77), 77 (80), 45 (65), 44 (64), 43 (100) $COCH_3^+$. *Anal.* calcd. for $C_{29}H_{31}NO_{11}S$: C 57.89, H 5.19, N 2.33; found: C 57.97, H 5.27, N 2.44.

*Preparation of 1,2:3,4-Di-*O*-isopropylidine-6-*O*-(4-fluoroacetamidoaniline)-α-*D*-galactopyranose (**16**)*

Sodium hydride (0.49 g, 20.5 mmol) was added to a stirred, cooled (0°C) solution of 1,2:3,4-di-*O*-isopropylidine-α-D-galactopyranose (**11**) in dry dimethyl formamide (DMF) (30 mL). After 1 h, a solution of *p*-fluorochloroacetamidoaniline (**2**, 1.5 g, 8 mmol) in DMF (25 mL) was added in portions to the mixture. After 0.5 h, the product began to form as indicated by a fluorescent spot (tlc: solvent (D)) which was also carbohydrate positive (H_2SO_4–EtOH). The reaction mixture was left stirring overnight. After addition of dry methanol (15 mL) the solution was concentrated to dryness at 0.01 Torr pressure and 80°C. The crude product thus obtained was extracted with 1:1 chloroform–water (100 mL). The organic layer was washed with water (3 × 40 mL), dried over magnesium sulfate, and concentrated. The crude product was purified by silica gel column chromatography (eluant: solvent (F)), to yield 390 mg (39%) of a brown syrup which decomposed on prolonged air exposure, mp 128°C (from isopropanol); $[\alpha]_D^{22}$ − 12° (*c* 1.1, benzene); nmr (80 MHz, $CDCl_3$) δ: 8.75 (s, 1H, NH), 7.65–6.91 (m, 5H, arom. H's), 5.59 (d, 1H, H-1), 4.65 (q, 1H, H-5), 1.55–1.36 (3s, 12H, CH_3); *Exact Mass* calcd. for $C_{20}H_{26}FNO_7$: 411.1685 amu; found (hrms): 411.1693 amu.

Attempted Synthesis

The above reaction failed to proceed under the following conditions: (*a*) using the same starting material with benzene as solvent together with crushed KOH pellets; (*b*) using 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose **12** and 4-chloroacetamidobenzophenone (**1**), under the same conditions as in (*a*); (*c*) using 1,3,4,6-tetra-*O*-acetyl-(2-deoxy-2-amino)-D-glucopyranose (**15**) and 4-fluorochloroacetamidoaniline in chloroform with pyridine; (*d*) using methyl (1-*O*-methyl-2-*O*-methyl-4,6-benzylidene)-α-D-altropyranoside (**13**) or methyl (1-*O*-methyl-3-*O*-methyl-4,6-benzylidene)-α-D-altropyranoside (**14**) and 4-chloroacetamidobenzophenone (**1**) in chloroform with solid sodium bicarbonate.

*Preparation of 4-(1,2:3,4-Di-*O*-isopropylidine-α-D-galactopyranuronamide)benzophenone (**18**)*

A mixture of 4-aminobenzophenone (243 mg, 1.1 mmol) and *N,N*-dicyclohexylcarbodiimide (277 mg, 12 mmol) in dry CH_2Cl_2 (15 mL) was cooled to 0°C. To this mixture was added in portions a solution of 1,2:3,4-di-*O*-isopropylidene-α-D-galactpyranuronic acid (17) (329 mg, 1.2 mmol) in CH_2Cl_2 (10 mL). After keeping the reaction mixture at 0°C for 1 h, it was left standing at room temperature for 35 h. The precipitated dicyclohexylurea side-product was filtered off, the filtrate containing some unreacted amine (tlc: solvent (C)). After silica gel column chromatography (solvent (C)), the product was obtained in 48% yield, mp 117°C (dec.); $[\alpha]_D^{22}$ −16.0 (*c* 0.4, $CHCl_3$); nmr (270 MHz, $CDCl_3$) δ: 8.37 (s, 1H, NH), 7.77–7.40 (m, 9H, arom. H's), 5.61 (d, 1H, H-1), 4.68 (q, 1H, H-4), 4.65 (q, 1H, H-3), 4.38 (d, 1H, H-5), 4.36–4.33 (q, 1H, H-2), 1.30–1.25 (4s, 12H, Me); ms *m/e* (relative intensity): 454 (8)M^+ + 1, 453 (26) M^+, 438 (8) $M^+ - CH_3$, 326 (10), 279 (10), 197 (9), 167 (19), 155 (100), 149 (50), 127 (46), 113 (10), 100 (12), 85 (11), 57 (13). *Exact Mass* calcd. for $C_{25}H_{27}NO_7$: 453.1788 amu; found (hrms): 453.1795.

*Preparation of 1,2:3,4-Di-*O*-isopropylidine-6-*O*-(5-dimethylamino-1-naphthalenesulfonyl)-α-*D*-galactopyranose (**20**)*

A solution of DANSYL-Cl (1.21 g, 4.5 mmol) in dry acetone (5 mL) was added to a mixture of 1,2:3,4-di-*O*-isopropylidine-α-D-galactopyranose (**11**), (1.18 g, 4.5 mmol) and triethylamine (3 mL) in dry acetone (15 mL). The reaction mixture was stirred for 2 h in the dark at 22°C, yielding a yellow crystalline product which was filtered and dried. Two recrystallizations from isopropanol yielded 1.62 g (73%) green needle-shaped crystals, mp 146–147°C; $[\alpha]_D^{22}$ −55 (*c* 0.9, acetone); tlc: solvent (C); ^{1}H nmr (270 MHz, $CDCl_3$) δ: 8.6–8.3 (m, 3H, arom. H's), 7.6–7.2 (m, 3H, arom. H's), 5.36 (d, 1H, H-1), 4.53 (q, 1H, H-3), 4.30 (q, 1H, H-2), 4.16–4.05 (m, 2H, H-4 and H-6), 4.00 (m, 1H, H-5), 2.90 (d, 6H, NMe_2), 1.34–1.14 (4s, 12H, Me); ms *m/e* (relative intensity): 494 (20) M^+ + 1, 493 (52) M^+, 478 (14) $M^+ - CH_3$, 252 (16), 251 (100), 250 (15), 171 (10), 170 (25), 168 (10). *Anal.* calcd. for $C_{24}H_{31}NO_8S$: C 58.40, H 6.33, N 2.84; found: C 58.26, H 6.35, N 2.86.

Preparation of Fluorescent Disaccharide Derivatives

General Procedure

Method A: to a solution of the disaccharide (3.18 g, 9.3 mmol) in dry methanol (20 mL) was added the fluorescent amine derivative (14 mmol), the solution was acidified with acetic acid to pH 4[4] and then brought to reflux under anhydrous conditions. A solution of sodium cyanoborohydride (2.86 g, 45.5 mmol) in methanol (15 mL) was added to the refluxing mixture over a 20 min period. The initially clear solution formed some precipitate after a few hours. The reflux was continued for ca. 18 h. The reaction mixture was cooled and then concentrated under diminished pressure yielding a syrupy material which was diluted with aqueous methanol (10 mL) and poured into a large volume of acetone (250 mL). The precipitated product was collected, dried, and purified by silica gel column chromatography (eluant (C)), yielding a crystalline material, which could be further characterized as its nona-acetate; tlc: solvent (A).

Method B: this was the procedure of Hoagland *et al.* (18).

*Preparation of 4-[(1-Deoxylactit-1-yl)-amino]benzophenone (**24**)*

Method A: the crude yellow product isolated after 18 h reflux was purified by column chromatography yielding 4.10 g (78%), mp 156–159°C; $[\alpha]_D^{22}$–16° (*c* 1.1, H_2O).

Method B: 3.90 g (74%) material was isolated after refluxing for 23 h; ms *m/e* (relative intensity): 523 (4) M^+, 343 (1) M^+ −

[4]Efforts to substitute IR-120 (H^+ form) resin for the organic acids were unsuccessful.

$HNC_6H_4COC_6H_5^+$, 305 (2) $M^+ - C_6H_5NH^+$, 281 (12), 210 (21), 197 (15), 122 (92), 120 (42) $C_6H_5NH^+$; 106 (10), 105 (100) $C_6H_5CO^+$; 77 (33).

Preparation of Nona-acetate Derivative

Compound **24** (1.08 g) was acetylated according to the procedure of Wolfrom and Thompson (20). The acetylated product was recrystallized three times from 95% ethanol to yield yellowish crystals (0.82 g), mp 61–63°C; $[\alpha]_D^{22}$ 26°, (*c* 1.1, $CHCl_3$); tlc: solvent (D). *Anal.* calcd. for $C_{43}H_{51}NO_{20}$: C 57.21, H 5.70, N 1.55; found: C 57.00, H 5.80, N 1.64.

Preparation of 1-[(1-Deoxylactit-1-yl)-amino]naphthalene (25)

Method A: the reaction proceeded in 83% yield after 18 h reflux. After chromatography, a pink product was obtained, mp 148–150°C (dec.); $[\alpha]_D^{22}$ −16° (*c* 1.7, MeOH); ms *m/e* (relative intensity): 469 (7) M^+, 452 (10), 451 (34) $M^+ - H_2$, 331 (19), 307 (14), 289 (28), 271 (45), 229 (12), 228 (39), 180 (25), 168 (39), 157 (79), 143 (100). *Exact Mass* calcd. for $C_{22}H_{31}NO_{10}$: 469.1948 amu; found (hrms): 469.1917 amu.

Preparation of 4-[(1-Deoxycellobiit-1-yl)-amino]benzophenone (26)

Method A: after 27 h reaction time and column chromatography, 4.0 g (76%) yellow product was obtained, mp 82–85°C; $[\alpha]_D^{22}$ 39° (*c* 1, H_2O); ms *m/e* (relative intensity): 550 (0.2) M^+, 211 (1), 199 (3), 198 (54), 197 (2), 184 (13), 183 (10), 168 (2), 166 (3), 121 (100). *Anal.* calcd. for $C_{25}H_{33}NO_{11}\cdot 1.5H_2O$: C54.52, H 6.59, N 2.54; found: C 54.40, H 6.62, N 2.46.

A 1 g portion of this material was acetylated to give 0.95 g of the nona-acetate derivative, mp 71–74°C (from 95% EtOH); $[\alpha]_D^{22}$ 20° (*c* 1, $CHCl_3$); ms *m/e* (relative intensity): 910 (0.1) M^+, 901 (0.1) $M^+ - 1/2H_2O$, 859 (2), 549 (1), 331 (3), 323 (3), 295 (5), 279 (4), 240 (3), 239 (4), 43 (100). *Exact Mass* calcd. for $C_{43}H_{51}NO_{20}$: 901.2988 amu; found (hrms): 901.2994.

Preparation of N-*methylene[-9-anthracenyl]-chitosan (32)*

To chitosan (500 mg, 3.0 mmol) dissolved in 2% aqueous acetic acid (25 mL) was added dropwise with vigorous stirring a solution of 9-anthraldehyde (1.15 g, 5.5 mmol) in methanol (25 mL). The reaction mixture was left standing for 12 h until a soft yellow gel had formed, which was treated repeatedly with methanol (100 mL) and diethyl ether (100 mL). The product had a ds of 0.73, after drying. *Anal.* calcd. for $[(C_{21}H_{19}NO_4)_{0.73}(C_6H_{11}NO_4)_{0.27}]\cdot 0.99\ H_2O$: C 64.31, H 6.00, N 4.43; found: C 64.12, H 5.90, N 4.46.

Preparation of N-*methyl-[9-anthracenyl]-chitosan (33)*

The same procedure as for **32** was followed using sodium cyanoborohydride (0.84 g, 13.4 mmol). A stiff porous gel formed in this case after 3 h reaction time. The product had ds 0.5. *Anal.* calcd. for $[(C_{21}H_{21}NO_4)_{0.5}(C_6H_{11}NO_4)_{0.5}]\cdot 0.43H_2O$: C 61.41, H 6.44, N 5.31; found: C 61.36, H 6.21, N 5.21.

Antimony-121 nuclear magnetic resonance study of hexahaloantimonate anions

R. GARTH KIDD AND H. GARTH SPINNEY

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received March 3, 1981

R. GARTH KIDD and H. GARTH SPINNEY. Can. J. Chem. **59**, 2940 (1981).

The seven hexahaloantimonate anions in the series $[SbCl_nBr_{6-n}]^-$ have been prepared and their antimony-121 nmr spectra show that for $[SbCl_4Br_2]^-$, $[SbCl_3Br_3]^-$, and $[SbCl_2Br_4]^-$, only the *cis* isomers are present in acetonitrile solution. The pairwise additivity model for central atom shielding has been used for configuration assignments. Models relevant to the higher incidence of *cis* over *trans* isomers are discussed. The nuclear shielding of ^{121}Sb is the most sensitive to halogen substitution of all the elements whose halide chemical shifts have been studied. Antimony shieldings exhibit normal halogen dependence, with bromine substitution causing *upfield* shifts relative to chlorine substitution.

R. GARTH KIDD et H. GARTH SPINNEY. Can. J. Chem. **59**, 2940 (1981).

On a préparé les sept anions hexahaloantimonates de la série $[SbCl_nBr_{6-n}]^-$; leurs spectres rmn du Sb-121 révèlent que seuls les isomères *cis* des anions $[SbCl_4Br_2]^-$, $[SbCl_3Br_3]^-$ et $[SbCl_2Br_4]^-$ sont présents en solution dans l'acétonitrile. On a utilisé le modèle d'additivité par paire du blindage de l'atome central pour attribuer les configurations. On discute de modèles appropriés pour expliquer la présence prépondérante des isomères *cis* sur les isomères *trans*. De tous les éléments dont on a étudié les déplacements chimiques des halogènes, le blindage nucléaire du Sb^{121} est le plus sensible à la présence des halogènes. L'effet de l'halogène sur le blindage de l'antimoine est normal par rapport au chlore alors que le brome provoque un déplacement vers les champs forts.

[Traduit par le journal]

It was established some time ago (1, 2) that when mixed halide complexes of metals having $MX_4Y_2^{n-}$ stoichiometry are prepared, it is the *cis* isomers which crystallize from solution.[1] What remains to be established is whether the higher incidence of *cis*-isomers in the solid state reflects an enthalpic bonding preference for *cis*-isomers or merely the lower solubility of *cis*-isomers present as the minor fraction in an equilibrium solution mixture of the two. Although electronic and vibrational spectroscopy will distinguish *cis*- and *trans*-isomers when only one or the other is present, there are few techniques capable of making the distinction in an equilibrium mixture that might contain both along with eight other redistribution products. The possibility of drawing invalid bond energy conclusions from distinctions that may only reflect solubility differences is thus a recurring problem for chemists.

This paper reports molecular structure determinations *in solution* for seven hexahaloantimonate anions. The experimental method used is ^{121}Sb nmr spectroscopy. The chemical shift data obtained has been analyzed in terms of the pairwise additivity model and the results indicate exclusively *cis*-isomers in solution. The implications of this *cis*-isomer preference are discussed in terms of bonding models which emphasize ligand-to-metal π-bonding and steric repulsion, respectively.

While some early skepticism concerning the existence of six-coordinate mixed chlorobromoantimonate(V) species of the type $[SbCl_nBr_{6-n}]^-$ was expressed (3, 4) the $[SbCl_5Br]^-$ ion has now been characterized in the solid state (5), and the octahedral geometry of six-coordinate antimony(V) halides has been verified by single-crystal X-ray analysis (6). In the present study all seven stoichiometries in the series $[SbCl_nBr_{6-n}]^-$ have been prepared for the first time and seven out of the ten possible configurations have been identified in the equilibrium mixture.

The noteworthy fact that bromine substitution leads to higher magnetic shielding of the ^{121}Sb nucleus than does chlorine substitution is demonstrated in this study and serves to place antimony in that class of elements whose nuclear shielding exhibits *normal halogen dependence*. The 2430 ppm chemical shift of $[SbBr_6]^-$ relative to $[SbCl_6]^-$, however, establishes ^{121}Sb as the nucleus whose sensitivity to halogen substitution is the largest of all those elements whose halides have undergone nmr measurement.

Experimental

All the antimony compounds subjected to nmr study were prepared under anhydrous conditions using high purity $SbCl_5$, $SbCl_3$, and $SbBr_3$ obtained from Alfa Inorganics. Acetonitrile solvent was purified and dried by fractional distillation from calcium hydride. Et_4NSbCl_6 was prepared by the method of Furlani and Zinato (7) from $SbCl_5$ and Et_4NCl in thionyl chloride. Et_4NSbBr_6 was prepared by the method of Lawton

[1]For the $[SbCl_3Br_3]^-$ complex, the structure of the *mer*-isomer is characterized by two *trans* relationships while the *fac*-isomer contains only *cis* relationships. In order that the generality of the behaviour observed in this study be recognized, statements about *cis*-isomers will only be made if they are also valid for the *fac*-isomer case.

and Jacobson (8) in which a mixture of $SbBr_3$ and Et_4NBr in acetonitrile is oxidized with Br_2. The shapes and positions of ^{121}Sb nmr lines for acetonitrile solutions of hexachlorobromoantimonate(V) anions were found to be independent of total antimony concentration and Cl:Br:Sb ratio. For all solutions studied, antimony concentration was about 0.5 *M* and Cl:Br:Sb ratios producing the best spectra were selected.

Acetonitrile solutions containing mixed hexahaloantimonates were prepared by mixing constituents in the following proportions:

$$n\,Et_4NSbCl_6 + (6\text{-}n)\,Et_4NSbBr_6 \quad (1 \leq n \leq 5)$$

$$Et_4NSbCl_6 + n\,KBr \text{ (or } Et_4NBr) \quad (1 \leq n \leq 10)$$

$$Et_4NSbBr_6 + n\,KCl \text{ (or } Et_4NCl) \quad (1 \leq n \leq 6)$$

The rates of halogen exchange were slow; redistribution half-life for Et_4NSbCl/Et_4NSbBr_6 at 28°C was ca. 40 h while that for bromide ion exchange with Et_4NSbCl_6 was ca. 20 h. In the latter case the exchange could be observed visually as the solution colour changed from the very pale yellow of $[SbCl_6]^-$/MeCN to light orange as the concentration of the deep orange–red $[SbBr_6]^-$/MeCN increased. Solubility decreased with increasing bromide content of the complex.

^{121}Sb nmr spectra were measured at 14.37 MHz using a modified Varian 4200B spectrometer which has been described elsewhere (9). Spectra were recorded as dispersion mode derivatives and calibration was effected by the generation of audio-frequency sidebands. Chemical shifts are reported relative to $[SbCl_6]^-$ in acetonitrile as internal reference, and negative shifts represent increased shielding. Experimental uncertainty in line positions was ±5 ppm.

Results and Discussion

The pattern of ^{121}Sb resonances obtained from acetonitrile solutions containing hexahaloantimonate(V) anions is shown in Fig. 1. For the solution prepared from a 1:1 mole ratio Et_4NSbCl_6:Et_4NSbBr_6, all seven resonances were observed with intensity ratios proportional to the binomial coefficients and indicating random distribution of halogens among antimony atoms. While spectra with different line intensities were obtained from solutions prepared with different Cl:Br ratios (see Experimental Section), no new resonances were observed, and the line positions for all resonances from all solutions studied coincided with those in Fig. 1 within experimental uncertainty.

Spectral Assignments to Stoichiometries

Spectral assignments of the seven lines in Fig. 1 to specific stoichiometries (*n*-values) were made on the basis of linewidth differences, the correlation between signal intensity and Cl:Br ratio of the solution, and the established monotonic variation in halogen dependence of metal shieldings generally. Previous nmr studies of ^{27}Al (10), ^{73}Ge (11), and ^{93}Nb (12) have established that successive replacement of Cl^- by Br^- in $[AlCl_4]^-$, $GeCl_4$, and $[NbCl_6]^-$ causes a monotonic change in metal atom chemical shift regardless of whether this shift is

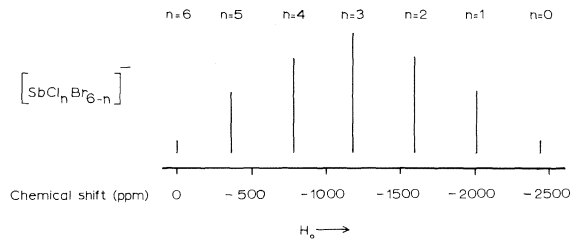

FIG 1. Line positions and relative intensities of ^{121}Sb resonances for $[SbCl_nBr_{6-n}]^-$ anions in acetonitrile solution.

upfield as in the ^{27}Al and ^{73}Ge cases or downfield as in the ^{93}Nb case. The chemical shift pattern in Fig. 1 is similar to that seen in these other systems and indicates a monotonic change in Sb shielding with successive Br^- substitution in $[SbCl_6]^-$. Those solutions having high Br:Cl ratios yielded spectra in which the high-field signals underwent intensity enhancement, while the low-field signal intensities were enhanced by low Br:Cl ratios. This enables the assignment of the −2430 resonance to $[SbBr_6]^-$. With an electric quadrupole moment of −0.8 barn, the ^{121}Sb nucleus is expected to yield broad nmr lines in environments of lower than cubic symmetry. While the resonances for $n = 0, 6$ were relatively narrow ($\nu_{1/2} \simeq 350$ Hz), the others were much broader, consistent with $\delta = 0$ for $[SbCl_6]^-$ and $\delta = -2430$ for $[SbBr_6]^-$ assignments.

Spectral Assignments to Configurations

Random redistribution of Cl^- and Br^- among the six coordination sites around Sb would give rise to the seven stoichiometries shown in Fig. 1 and the 10 configurations shown in Table 1. If all 10 configurations were formed in solution, 10 different ^{121}Sb resonances should be observed in the spectra. The fact that only seven resonances are seen indicates that only seven configurations are present in detectable concentrations. The detailed argument presented below leading to specific configurational assignments will show that rapid isomerization of *cis–trans* pairs leading to a single time-averaged resonance is *not* operating to reduce the number of observed lines.

Were the ^{121}Sb shieldings to show a first-order halogen dependence it would be possible to calculate ^{121}Sb chemical shifts by evaluating substituent constants for Cl^- and Br^- as has been attempted in Table 1 and Fig. 2. The lack of agreement between the substituent additive δ-values and the observed δ-values indicates that halide ions do not contribute independently to ^{121}Sb shielding and that a second-order model is required to explain the observed behaviour.

TABLE 1. ^{121}Sb chemical shifts for $[SbCl_nBr_{6-n}]^-$ anions in acetonitrile solution

Species	Coefficients, C_{ij} Cl,Cl	Cl,Br	Br,Br	δ calcd[a] ($\Sigma C_{ij}\eta_{ij}$)	δ obsd[b]	δ calcd[c] (substituent additive)
$[SbCl_6]^-$	12	0	0	+1	0	(0)
$[SbCl_5Br]^-$	8	4	0	−383	−380	−405
$[SbCl_4Br_2]^-$						−810
cis	5	6	1	−778	−780	
trans	4	8	0	−767		
$[SbCl_3Br_3]^-$						−1215
fac	3	6	3	−1183	−1180	
mer	2	8	2	−1172		
$[SbCl_2Br_4]^-$						−1620
cis	1	6	5	−1589	−1590	
trans	0	8	4	−1578		
$[SbClBr_5]^-$	0	4	8	−2005	−2005	−2025
$[SbBr_6]^-$	0	0	12	−2432	−2430	(−2430)

[a] Pairwise additivity parameter values (ppm): $\eta_{Cl,Cl} = +0.1$; $\eta_{Cl,Br} = -95.9$; $\eta_{Br,Br} = -202.7$ (uncertainty limits ±0.2 in each case).
[b] Negative shifts designate higher shielding. Experimental uncertainty ±5 ppm.
[c] Substituent constants (ppm): Cl = 0; Br = −405.

The pairwise additive model for metal-atom shieldings has been used to assign configurations to six-coordinate niobium(V) complexes (12), and its application to the present system of antimony complexes is shown in Fig. 2. The halides are regarded as contributing to the antimony shielding in pairs, with 12 independent contributions corresponding to the 12 edges of the octahedron. The chemical shift calculated according to this model is given by the sum of three $C_{ij}\eta_{ij}$ terms in which η_{Cl-Cl}, η_{Br-Cl}, and η_{Br-Br} are the three pairwise additivity parameters and C_{ij} are the numerical coefficients determined by the structure and summing to 12. Whereas the substituent additive model yields the same calculated shift for *cis*- and *trans*-isomers of the same complex, the pairwise additivity model gives calculated shifts that differ by more than the uncertainty in the observed shift, thus providing a method for identifying specific isomers in a solution mixture of several.

With seven observed resonance positions, one can set up seven linear equations containing the three η_{ij} as unknowns, and a multiple linear regression analysis yields the η_{ij} values listed at the bottom of Table 1. The configuration assignments shown in Table 1 are the only ones yielding a set of calculated shifts all of which lie within the uncertainty interval of the observed shifts. In particular the δ = −780, δ = −1180, and δ = −1590 resonances all lie within 3 ppm of the theoretical values calculated for *cis*-isomers. If rapid *cis*–*trans* isomerization were occurring, the calculated positions for the time-averaged resonances would be δ = −773, δ = −1177, and δ = −1583. For $[SbCl_4Br_2]^-$ and $[SbCl_2Br_4]^-$ these values lie 7 ppm from the observed positions thereby rendering the

For personal use only.

possibility of time-averaged signals unlikely on chemical shift grounds. The extremely slow rate observed for intermolecular redistribution of halide, while not ruling out the possibility of rapid intramolecular rearrangement, also makes it unlikely.

For the $n = 2, 3, 4$ members of the $[SbCl_nBr_{6-n}]^-$ system which could potentially adopt both *cis* and *trans* configurations, all of the experimental evidence supports the hypothesis that only the *cis*-isomers are present in solution. This observation provides us with a better understanding of the antimony–halogen bond.

Models for Configurational Preference

Antimony is not alone in showing this preference for *cis* halides. Among the transition metals, titanium(IV) (1) and niobium(V) (12) favour *cis*-configurations, while among the representative elements, tin(IV) (1) follows this same pattern. The traditional view has been that *cis* interactions between bulky ligands (in this case, Br^-) occasion destabilizing steric repulsions that are larger than those arising from *trans* interactions and, other things being equal, *trans* isomers will predominate. Where *cis* isomers predominate, other things are apparently not equal, and a number of workers (1, 16, 17) have taken a preference for *cis* isomers to indicate a higher order of ligand → metal π-bonding than could be achieved in the *trans*-isomer where the two (stronger) π-donor ligands are competing for the same vacant t_{2g}-orbital on the central atom. This model uses a preference for *cis*-isomers as evidence for the existence of π-bonding.

An alternative view presented by Zahrobsky (18) argues on geometrical grounds that steric factors alone favour the formation of *cis*-isomers by six-coordinate mixed halide complexes, thereby undercutting the argument for π-bonding contained in the traditional view of steric repulsion.

The *cis*-bonding preference observed in the present study, while consistent with the pattern observed previously for analogous systems, does not provide a basis for mediating between these two models.

Halogen Dependence of Antimony Shieldings

The nuclear shielding of all atoms is particularly sensitive to halogen substitution. For antimony compounds containing no bromine, all ^{121}Sb chemical shifts reported to date lie in the 1000 ppm region downfield of $[SbCl_6]^-$ (9). The six compounds containing bromine reported in this study extend the ^{121}Sb shielding range by another 2400 ppm and, together with $[SbCl_6]^-$, span 70% of the total shielding range for this nucleus. While the effect of iodine substitution on ^{121}Sb shielding has not yet been tested, one can safely extrapolate from the halogen dependence patterns for other shieldings that the $[SbI_6]^-$ resonance will lie another ca. 5300 ppm upfield of $[SbBr_6]^-$. The 2430 ppm MCl_6–MBr_6 chemical shift difference for ^{121}Sb is 1.3 times the difference for the ^{195}Pt halides (13),[2] and 3.3 times the difference for the ^{93}Nb halides (12), establishing ^{121}Sb as the nucleus most sensitive to halogen substitution among the 25 or so elements whose halides have undergone nmr investigation. Only ^{205}Tl exhibits a halogen dependence whose magnitude rivals that of ^{121}Sb (14), and the oxidative instability of thallium(III) has precluded to date the preparation of analogous $[TlCl_6]^{3-}$ and $[TlBr_6]^{3-}$ compounds. While ^{59}Co at 18 000 ppm has the largest chemical shift range of any nucleus, this span is achieved by virtue of the large variety of chemical environments adopted by cobalt. Its halogen dependence appears to be intermediate in magnitude, but the test of analogous compounds is again precluded, this time because $[CoCl_6]^{3-}$ and $[CoBr_6]^{3-}$ are high-spin d^6 configurations and hence paramagnetic.

Normal halogen dependence (NHD) is that in which a central atom M is more highly shielded by a bromide than by a chloride. The MX_4^{n-} tetrahalides of the representative elements from periodic groups III and IV all show NHD. The only MX_6^{n-} hexahalides reported heretofor involve transition metals; ^{93}Nb shows inverse halogen dependence (IHD) (12) and ^{195}Pt shows NHD (13). With ^{121}Sb here becoming a documented case of six-coordinate NHD among the representative elements, the possibility of a correlation between IHD and six-coordination is further discounted. A satisfactory explanation for the cause of inverse halogen dependence has yet to be fully worked out, but the topic has been explored elsewhere (15).

Studies related to antitumor antibiotics. Part XXIV. High field ^{1}H nmr analysis and conformations of saframycins A and C

J. William Lown, Alummoottil V. Joshua, and Hsiao-Hsiung Chen
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 20, 1981

J. William Lown, Alummoottil V. Joshua, and Hsiao-Hsiung Chen. Can. J. Chem. **59**, 2945 (1981).

A detailed analysis of the high field (400 MHz) ^{1}H nmr spectra of the basic antitumor antibiotics saframycin A and C in $CDCl_3$, C_6D_6, and in aqueous DMSO solutions has been carried out. Selective double irradiation experiments permitted the unambiguous assignment of all the proton chemical shifts and coupling constants. Consideration of the magnitudes of the latter together with specific nOe experiments permits assignment of molecular geometry and average conformations in solution. Selective shifts occurring in DMSO–D_2O solutions upon addition of CF_3COOD identified the 12-N atom as the site of protonation which result bears directly on the acid promoted binding of these antibiotics to DNA templates as part of their cytotoxic action.

J. William Lown, Alummoottil V. Joshua et Hsiao-Hsiung Chen. Can. J. Chem. **59**, 2945 (1981).

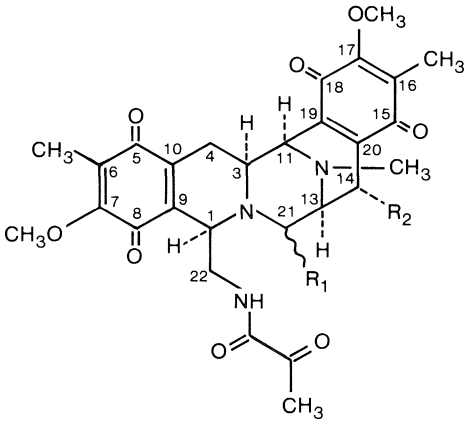
On a effectué une analyse complète des spectres de rmn à haut champ (400 MHz) des antibiotiques antitumescents fondamentaux, les saframycines A et C dans le $CDCl_3$, le C_6D_6 et dans des solutions aqueuses de DMSO. Des expériences d'irradiation double sélective ont permis d'identifier sans ambiguité les déplacements chimiques de tous les protons et toutes les constantes de couplage. En se basant sur l'amplitude des constantes de couplage et sur des expériences de eOn spécifiques on a pu établir la géométrie moléculaire et les conformations moyennes en solution. Les déplacements sélectifs que l'on observe dans les solutions de DMSO–D_2O lors de l'addition du CF_3COOD ont permis d'identifier l'azote en position 12 comme étant le site de la protonation; ce résultat établit donc directment le site de liaison en milieu acide de ces antibiotiques aux modèles de ADN dans le cadre de leur action cytotonique.

[Traduit par le journal]

Introduction

Saframycins (Fig. 1) are members of a new family of antibiotics isolated from the streptothricin-producing strain of *Streptomyces* lavendulae (1–3). The saframycins are yellow crystalline solids structurally related to the heterocyclic quinone antibiotics which include mitomycin C (4), streptonigrin (5), and naphthyridinomycin (6). Unlike the latter the saframycins contain two heterocyclic quinone moieties. Saframycin A differs from saframycin C by the fact that the former has a cyano group on C-21 (orientation not known), while the latter has a methoxy group on C-14. Saframycin S has a hydroxy group on C-21 and has been proposed as a precursor to saframycin A in the biosynthetic process (3). Saframycins A and S have also been interconverted chemically (3). Saframycin B has no substituents at these positions. The structures of saframycins D and E have not been established yet. The X-ray crystallographic structures of saframycins B and C have been determined, although such studies could not distinguish between the two possible optical antipodes (7). The structure of saframycin A has been established by ^{13}C nmr studies and by chemical means (8).

The saframycins exhibit wide-spectrum antimicrobial activity, but more particularly saframycin A is attracting interest because it exhibits extreme cytotoxicity towards cultured cells and shows antitumor activity against several experimental tumors including leukemias L1210 and P388 and Ehrlich carcinoma both in ascites and solid forms (2, 9). Saframycin A has been shown to block RNA synthesis in cultured L1210 cells (9). The mode of action, in common with that of other quinone-containing antibiotics, has been shown to involve direct interaction with a DNA template rather than interference with replicative enzymes



Saframycin A	R_1 = CN,	R_2 = H
B	R_1 = H,	R_2 = H
C	R_1 = H,	R_2 = OCH_3
S	R_1 = OH,	R_2 = H

(9). However, the precise nature of the interaction between the saframycins and DNA has not been elucidated and it has been suggested that in order to clarify the reaction a more sensitive assay employing covalently closed circular DNA should be carried out to detect any DNA strand scission (9).

Since any discussion of molecular recognition between the antibiotics and duplex DNA should also take into account the conformation of the antibiotics in solution, we have undertaken a detailed high field ^1H nmr analysis of saframycins A and C, which we report here. Also, since our preliminary studies on the binding of these antibiotics to DNA showed a pH dependence, it was necessary to establish the relative ease of protonation of the two basic nitrogens in the molecules. Therefore we report the ^1H nmr spectra of these antibiotics in aqueous acidic solutions. The 100 MHz ^1H nmr spectra of the saframycins have been reported (2, 3) although no assignments have been made.

Materials and Methods

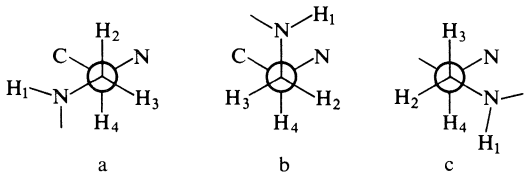
Saframycins A and C were kindly supplied by Dr. K. Ishiguro, Division of Chemotherapy, Chiba Cancer Centre Research Institute, Japan. Saframycins A and C were further purified by preparative thin layer chromatography on silica gel using ethyl acetate as eluent and by recrystallization from a mixture of ethyl acetate and petroleum ether (1:1).

The nmr measurements were carried out in the Fourier transform mode using the Bruker WH-400/DS NMR spectrometer and the Aspect 2000 Data System utilizing 16 or 32K of data memory. The spectra were measured in appropriate deuterated solvents at ambient temperature (298 K). The deuterium resonance of the solvent was used for the lock signal. The homonuclear decoupling experiments were also performed in the pulse mode. The chemical shifts and coupling constants were calculated to first order at 400 MHz and are reported with an accuracy of ± 0.01 ppm and ± 0.20 Hz, respectively.

Results and Discussion

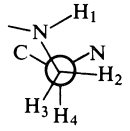
For the purposes of discussion of the nmr spectra of saframycins A and C, the twelve protons in each (excluding the methyl groups) have been assigned as shown in the figures. Irradiation of the dd absorption at δ 6.33 (H-1) in saframycin A in benzene-d_6 led to the collapse of the signal at δ 3.76 (H-2) from a ddd to a dd as well as the simplification of the signal at δ 2.50 (H-3) from a ddd to a dd. The same simplification was obtained by D_2O exchange. The signal at δ 3.76, which is overlapped by two methoxy signals, can be resolved by changing the solvent from benzene-d_6 to $CDCl_3$. Double irradiation of the ddd signal at δ 3.76 (H-2) led to the collapse of the signal at δ 2.50 (H-3) from a ddd to a dd. Further, double irradiation of the ddd at δ 2.50 (H-3) leads to a d signal at δ 6.33 (H-1) from its original dd and also decouples the H-2 signal at δ 3.76 from a ddd to a dd. These double irradiation experiments together with inspection of the spectra permitted the measurement of the following coupling constants: $J_{1,2} = 9.5$ Hz, $J_{1,3} = 4.0$ Hz, and $J_{2,3} = 14$ Hz. Values for J(H–C–N–H) have been observed to be in the range from 9 to 5 Hz (10*a*). Double irradiation of the signal at δ 3.76 (H-2) simplified the complex signal at δ 3.87 (H-4) to a dd. Similarly irradiation of the ddd signal at δ 2.50 (H-3) caused the collapse of the multiplet at δ 3.87 (H-4) to a dd, permitting the measurement of $J_{2,4} = 1.5$ Hz, $J_{3,4} = 4.0$ Hz. Irradiation of the signal at δ 3.87 (H-4) led to a simplification of the absorption at δ 1.32 (H-5) from a ddd to a dd while the δ 3.76 signal is simplified to a dd and the δ 2.50 signal (H-3) is simplified to a dd.

Stereochemical relationships among H-1, H-2, H-3, and H-4 may be analyzed by considering the relative populations of the three staggered rotamers a, b, and c. The magnitudes of *trans* vicinal



a b c

proton–proton coupling constants in ethane systems are about 9–10 Hz while *gauche* couplings are about 3–4.5 Hz (10*b*). While the magnitudes of these J values undoubtedly vary according to substituent pattern, for ethane derivatives the electronegativity dependence is rather low (10*c*), illustrated in this case by the observed "normal" geminal coupling $J_{2,3} = 14.0$ Hz. The observed values of $J_{2,4} = 1.5$ and $J_{3,4} = 4.0$ Hz would seem to preclude a high population of either rotamer a or c but suggest rather an average conformation of the side chain grouping as the slightly skewed rotamer b depicted in d, with the H_2–H_4 dihedral angle closer to 90° than is the H_3–H_4 dihedral angle.



d

Although $J_{1,2} = 9.5$ is $> J_{3,1} = 4.0$ there are insufficient model systems reported for one to draw stereochemical inferences of the disposition of H-1 relative to H_3 or H_2 and this is not implied in the depiction d. It is noteworthy that very similar values for all these coupling constants are observed in D_2O, $CDCl_3$, and C_6D_6.

Double irradiation of the ddd signal at δ 1.32

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

(H-5) led to the collapse of the signal at δ 2.89 (H-6) from a dd to a d which is overlapped with the H-12 doublet signal and in addition caused the collapse of the H-7 absorption at δ 3.02 from a ddd to a dd. In $CDCl_3$ H-7 resonates at δ 3.14 which is closely comparable with a similarly situated and axially oriented proton at δ 3.17 in the model compound 1-azabicyclo[3.3.0]decane (10*d*). Spin decoupling of the dd resonance at δ 2.89 (H-6) not only leads to the collapse of the ddd signal at δ 1.32 (H-5) to a dd, but also simplifies the ddd absorption at δ 3.02 (H-7) to a dd. Irradiation of the H-7 ddd signal at δ 3.02 caused simplification of the H-5, H-6, and H-8 signals at δ 1.32, 2.89, and 3.90, respectively. In the ^1H nmr spectrum of saframycin A the chemical shifts between H-4, H-5, H-6, and H-7 are quite large and double irradiation of each in turn produces clean d or dd signals. Therefore by normal criteria this system may be treated to a high degree of approximation as first order and this permits the estimation of the coupling constant values and assignment of $J_{4,5} = 3.0$, $J_{4,6} = 0.0$, $J_{5,6} = 17.0$, $J_{5,7} = 11.0$, and $J_{6,7} = 3.0$ Hz. The magnitude of the coupling between H-4 and H-5 over five bonds is consistent with such long range coupling over a W path (10*e*) and demands that H-4 and H-5 be *trans* to each other permitting unambiguous stereochemical assignment of H-4 and H-5.

Double irradiation of the signal at δ 3.90 ascribed to H-8 simplifies the ddd resonance at δ 3.02 (H-7) to a dd as well as the ddd signal at δ 2.57 (H-11) to a dd through a W – long range coupling effect. This permitted assignment of the coupling constants $J_{7,8} = 3.0$ and $J_{8,11} = 2.5$ Hz. Double irradiation of H-8 at δ 3.90 had no effect on the H-9 absorption at δ 2.83 nor on the H-10 absorption at δ 2.30 so there is

[a] The chemical shifts were obtained at 400 MHz and are given relative to that of DMSO taken as δ 2.50.
[b] The coupling constants were obtained by double irradiation experiments.

no evidence for long range coupling between H-8 and H-9 or H-10 through the quinone ring. Irradiation of the dd absorption at δ 2.31 (H-9) collapsed the H-10 signal at δ 1.68 (which is partially overlapped by the methyl signals) as well as the ddd signal at δ 2.57 (H-11) to a dd. Irradiation of the H-10 resonance at δ 1.68 caused the H-9 absorption at δ 2.31 to change from a dd to a d and the H-11 signal at δ 2.57 from a ddd to a dd. In turn irradiation of the ddd signal of H-11 at δ 2.57 caused the collapse of the dd signal of H-9 at δ 2.31 to a d and of the H-10 signal at δ 1.68 and of the H-8 signal at δ 3.90. From these decoupling experiments it was possible to deduce $J_{9,10} = 20.5$, $J_{9,11} = 7.5$, and $J_{10,11} < 0.5$ Hz. Finally, irradiation of the H-11 resonance at δ 2.57 led to the collapse of the d signal of H-12 at δ 2.90 to an s and double irradiation of H-12 d in turn leads to a simplification of the H-11 signal at δ 2.57 giving $J_{11,12} = 2.5$ Hz. (See Fig. 2 and Table 1).

A similar analysis of the high field nmr spectrum of saframycin C in $CDCl_3$ employing extensive double irradiation gave the spectral parameters shown in Table 2. The accurate chemical shifts and coupling constants for the protons of saframycin C in benzene-d_6 and $CDCl_3$ were obtained in a similar manner (see Fig. 3 and Table 2).

The nuclear Overhauser effect (nOe) difference experiments (11*a*) involve the measurement of the intensity change of a proton resonance upon saturating another proton (or group of protons) within the same molecule. Ordinarily an nOe change indicates that the two protons are in close proximity. However, the relaxation mechanisms available to the protons in question need to be considered. The experiments selected involved a dilute and degassed sample and irradiation of the methyl group of the α-dione amide side chain and inspection of the other methine and methylene protons in

[a] The chemical shifts were obtained at 400 MHz and are given relative to that of DMSO taken as δ 2.50.
[b] Coupling constants were obtained by double irradiation experiments.
[c] Coupling constants could not be measured either because of poor resolution or overlapping.

the molecule. The expression for the nOe phenomenon involves two terms (*i*) a direct dipolar term and (*ii*) an indirect term via polarization nOe transmission from adjacent protons (11*b*). In these situations the expression for nOe implies a dependence predominantly on the relaxation parameters of the protons being observed. The predominant relaxation mechanisms for the geminal protons H_{11} and H_{12} in saframycin C will be dipole–dipole (11*c*). A reported example of irradiation of the methyl groups in crotonaldehyde (*Z* and *E*) resulted in nOe enhancement of the adjacent protons implying molecular proximity (12). In the present application irradiation of the side-chain methyl group at 400 MHz produced no detectable nOe change in any of the methine or methylene protons in either saframycin A or C. Since nOe experiments can show a frequency dependence in the direction of increased enhancement at lower frequencies (13) the experiment was repeated at 200 MHz. Again no nOe changes were detected. It is tentatively concluded that the antibiotics in solution adopt conformations in which the side-chain methyl group is remote from other protons, which result is in accord with the conclusion drawn earlier from the rotamer analysis. Although we could not ascertain the orientation of the nitrile group in saframycin A on the basis of nmr coupling constants it is assigned the α-orientation as shown, which explains the easy elimination of the nitrile on mild acid treatment (3). This requires that the lone pair on N-2 be *trans* to the nitrile group. The problem of distinguishing between the two optical antipodes of the saframycins has to await a more refined X-ray crystallographic study.

The above conformation predicts that H-5 be placed in the strongly shielding zone of the quinone ring (adjacent to H-8) and also in close proximity to

the lone pair of the bridging central nitrogen atom (see Figs. 2, 3). These two shielding influences may account for the unusually high field position of H-5 in both antibiotics.

The resonance positions of the protons of the lower half of both antibiotics suffer a remarkable downfield shift in changing the solvent from benzene-d_6 to $CDCl_3$. In the case of saframycin A, the most affected protons are H-3 (0.76 ppm), H-9 (0.52 ppm), H-10 (0.62 ppm), H-11 (0.87 ppm), and H-12 (1.09 ppm) and for saframycin C, they are H-3 (0.56 ppm), H-10 (0.33 ppm), H-11 (0.47 ppm), and H-12 (0.65 ppm). The chemical shifts of the other protons and the coupling constants of all the protons are relatively unaffected. This downfield shift may be due to the change in the orientation of the α-dione amide side chain with respect to the methylene group in the two solvents.

To study any conformational change in aqueous solution and relative ease of protonation of the two basic nitrogen atoms in the saframycin molecules, the spectra of both antibiotics were recorded in DMSO-d_6 – D_2O (7:3) and DMSO-d_6 – D_2O–CF_3COOD (~ 5% CF_3COOD). The chemical shifts of the various protons were determined by extensive double irradiation studies as described before (see Tables 3 and 4). No conformational change could be ascertained from the spectra, except possibly for the α-dione amide side chain with respect to the methylene group, because the relative resonance positions of H-2 and H-3 were reversed in aqueous solution compared to those in benzene-d_6 and $CDCl_3$. This conclusion is based on the coupling constants $J_{2,4}$ and $J_{3,4}$.

In the presence of CF_3COOD, the resonance positions of H-8, H-11, and the N-Me in saframycin A and H-8, H-10, and N-Me in saframycin C were shifted relatively more downfield (0.91, 0.95, and 0.68 ppm, respectively for saframycin A and 0.82, 0.80, and 0.60 ppm respectively for saframycin C) compared to H-7 and H-12 in saframycin A and H-7, H-11, and H-12 in saframycin C, indicating preferential protonation of N-12 in both antibiotics. The chemical shift of H-4 was hardly affected. Examination of models indicates that the lone pair on N-12 is more accessible than on N-2.

The significance of the conformation of the saframycins as discussed above and the preferential protonation of N-12 over N-2 in both antibiotics in the molecular recognition process in their mode of action on duplex DNA will be discussed in a subsequent publication.

Acknowledgements

This investigation was supported by grants from the National Cancer Institute of Canada, the Natural Sciences and Engineering Research Council of Canada, and the Department of Chemistry of the University of Alberta. We wish to thank Mr. Glen Bigam for technical assistance in obtaining the decoupled high field nmr spectra.

The systems triethylamine–methylethylketone–dimethylsulfoxide and triethylamine–methylethylketone–formamide have been studied by the methods of isothermal equilibrium and thermal analysis. At least in the case of the system triethylamine–methylethylketone–dimethylsulfoxide, the equilibrium conditions have been completely established with respect to concentration and temperature. From these data a solid model can be constructed, as was previously done for the system nicotine–water–methylethylketone. It appears that the miscibility is greater in the system involving dimethylsulfoxide than in the system involving formamide.

ALAN N. CAMPBELL et ELINOR M. KARTZMARK. Can. J. Chem. **59**, 2953 (1981).

Faisant appel à l'équilibre isothermique et à l'analyse thermique, on a étudié les systèmes suivants: triéthylamine–méthyléthylcétone–diméthylsulfoxyde et triéthylamine–méthyléthylcétone–formamide. On a établi complètement, du moins, dans le cas du premier système, les conditions d'équilibre en fonction de la concentration et de la température. A partir de ces données, on a construit un modèle solide comme celui trouvé antérieurement pour le système nicotine–eau–méthyléthylcétone. Il semble que la miscibilité est plus grande dans le système impliquant le diméthylsulfoxyde que dans celui contenant le formamide.

[Traduit par le journal]

Introduction

The well known, completely closed, egg-shaped equilibrium diagram of the system nicotine–water (2) has a close analogue in the system methylethylketone–water, except that, in the case of the latter system, the lower critical solution temperature is unattainable, at least at atmospheric pressure: the curve of mutual solubility is intersected by the ice line (3). These two systems have been combined in a study of the ternary system nicotine–water–methylethylketone (1). In the ternary system, the heterogeneous (two liquid) region forms a tunnel, without ternary maximum.

In the present paper, the systems triethylamine–methylethylketone–dimethylsulfoxide and triethylamine–methylethylketone–formamide are investigated. The completely miscible pair in these two systems is triethylamine–methylethylketone, while triethylamine forms two layers with formamide and with dimethylsulfoxide.

Experimental

Triethylamine was determined conductometrically by titration with standard hydrochloric acid. The densities of numerous homogeneous mixtures were determined and plotted on a large triangular diagram. Points of equal density were joined. The lines of equal triethylamine content were of necessity parallel to the base of the triangle and were crossed by the curves of equal density at a sharp angle (for both systems).

The temperatures of homogeneity in the two-component systems were determined with the apparatus shown in Fig. 1. The apparatus was charged with various known compositions of mixture and heated on a Fisher Thermix apparatus, which permits simultaneous and vigorous (magnetic) stirring, while heating. Below the temperature of homogeneity, mixtures were turbid under vigorous stirring but promptly settled into two layers when the stirring was stopped. The transitions from turbid to clear (one homogeneous liquid) and conversely were quite sharp.

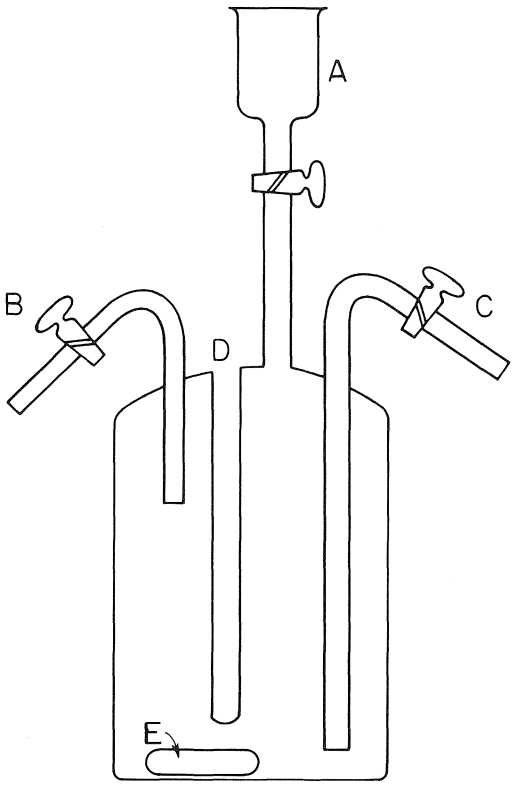

FIG. 1. Equilibrium apparatus.

For the system formamide–triethylamine, the critical solution

temperature is not realisable because, although the compositions of congruent layers are approaching with rising temperature and would therefore become identical at some high temperature, the L ⇋ V critical point intervenes before this temperature can be reached. This was confirmed by observations in thick-walled capillary tubes.

The technique whereby a heterogeneous mixture is observed in the field of a telescope while the mixture is being heated in an electric furnace has been frequently described (4). At room temperature, two menisci are clearly visible. On heating the system formamide–triethylamine there is a sudden disappearance of the $L_2 \leftrightharpoons V$ meniscus, leaving only $L_1 \leftrightharpoons V$ below the temperature at which $L_1 \leftrightharpoons L_2$ disappears. L_2 is the layer rich in triethylamine, L_1 is the layer rich in formamide.

For the high temperature study of the ternary system, the apparatus in Fig. 1 was used (approximately) isothermally. By careful manipulation of the rheostat controlling the heating element of the thermix an approximately constant temperature could be maintained for a short time and this is all that is necessary because (*a*) equilibrium is rapidly attained and (*b*) the effect of temperature on both the binary and ternary systems is not great. It is obvious from Fig. 1 how samples of both the equilibrium layers can be removed for analysis.

Thermal analysis of both systems was carried out, using a copper–constantan thermocouple and liquid nitrogen as cooling agent. In a binary system, after the appearance of a solid phase, the temperature (at constant pressure) remains constant, while the process $L_2 \rightarrow L_1 + S$ is taking place. In a three component system, the temperature should continue to fall while the above transformation is taking place and the compositions of the two liquid layers should change progressively (5). In practice, however, the compositions of the two layers differ so greatly that there is little or no change of temperature while the transformation goes to completion. Thermal analysis should yield two significant temperatures, that at which the above transformation takes place and, if continued to sufficiently low temperature, that of the ternary eutectic.

Results

The temperatures of homogeneity (temperature rising) in the binary system dimethylsulfoxide–triethylamine are listed in Table 1 and are expressed graphically in Fig. 2. The critical solution temperature is seen to be 122°C and corresponds to a composition of 75% triethylamine.

The temperatures of homogeneity in the binary system formamide–triethylamine are listed in Table 2 and are expressed graphically in Fig. 3.

In the experiments in sealed tubes on the system formamide–triethylamine, the $L_1 \leftrightharpoons L_2$ transition was never observed, but the critical point $L_1 \leftrightharpoons V$ or $L_2 \leftrightharpoons V$ occasionally was around a temperature of 270°C. The critical temperatures are given as 259°C for triethylamine (6) and 260°C for methylethylketone (7); it is probable that all mixtures of these liquids have critical temperatures around 260°C. At this temperature, the tubes frequently exploded. It seems clear that in the system formamide–triethyl-

Wt.% triethylamine	First halt (°C)	Eutectic (°C)
22.76	16.31	−181
85.64	15	−181

Fig. 10 is obtained. If any mixture of triethylamine and dimethylsulfoxide lying between 5 and 95% triethylamine is cooled, a first halt is observed at 16°C, 2° below the freezing point of pure dimethylsulfoxide. The temperature remains constant while the change

$$L_1 \rightarrow L_2 + \text{solid DMSO}$$

is taking place. Cooling then continues to the eutectic temperature, at which both components are present in the solid state.

Experiments similar to the above on the system triethylamine–formamide were not successful. The temperature of the transition

$$L_1 \rightarrow L_2 + \text{solid formamide}$$

appears to lie at −24°C, but the eutectic temperature did not appear, perhaps due to a slow rate of crystallisation.

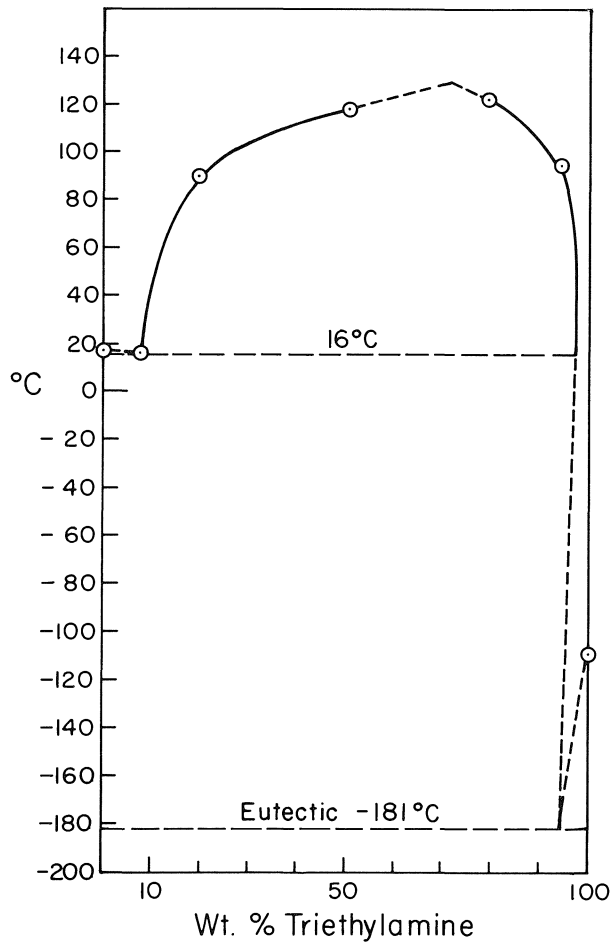

FIG. 10. The system triethylamine–dimethylsulfoxide at various temperatures.

Sufficient data are given in this paper for the construction of a solid model at least for the system dimethylsulfoxide–triethylamine–methylethylketone as was done for the system nicotine–water–methylethylketone (3).

ELZBIETA WAGNER, TERESA PAROL, and MAREK K. KALINOWSKI. Can. J. Chem. **59**, 2957 (1981).

The polarographic and voltammetric behaviour of dibiphenylene-ethene (DBPE) has been studied in benzonitrile, acetonitrile, propylene carbonate, acetone, *N*,*N*-dimethylformamide, *N*,*N*-dimethylacetamide, dimethylsulfoxide, *N*,*N*-diethylformamide, pyridine, and ethylenediamine. The two successive reversible electron transfers have been observed in all these solvents. The separation between the formal potentials of DBPE/DBPE$^{-\cdot}$ and DBPE$^{-\cdot}$/DBPE^{2-} systems was found to vary with the properties of solvents and with the kind of supporting elecrtrolyte cations (tetraethylammonium and sodium perchlorates were used as electrolytes). The variation of redox potentials both with the solvent and the cation is discussed in terms of the donor–acceptor concept for solvent–solute interaction. Numerical analysis using both the values of the donor numbers and the acceptor numbers leads to successful description of experimental results. It has further been observed that DBPE^{2-} dianion is protonized in ethylenediamine solutions.

ELZBIETA WAGNER, TERESA PAROL et MAREK K. KALINOWSKI. Can. J. Chem. **59**, 2957 (1981).

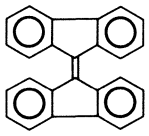
On a étudié le comportement polarographique et voltamétrique du dibiphénylène-éthène (DBPE) dans le benzonitrile, l'acétonitrile, le carbonate de propylène, l'acétone, la *N*,*N*-diméthylformamide, la *N*,*N*-diméthylacétamide, le diméthylsulfoxyde, la *N*,*N*-diéthylformamide, la pyridine et l'éthylène diamine. Dans tous ces solvants on a observé les deux transferts réversibles successifs d'électrons. On a trouvé que la séparation entre les potentiels formels de systèmes DBPE/DBPE$^{-\cdot}$ et DBPE$^{-\cdot}$/DBPE^{2-} varie avec la propriété des solvants et avec le type de cation de l'électrolyte de support (comme électrolytes on a utilisé les perchlorate de tétraéthylammonium et de sodium). On discute de la variation des potentiels rédox avec le cation et le solvant en fonction du concept de donneur–accepteur pour l'interaction solvent–soluté. L'analyse numérique utilisant à la fois les valeurs des différents donneurs et des différents accepteurs conduit à une description satisfaisante des résultats expérimentaux. On a de plus observé que le dianion DBPE^{2-} est protoné dans les solutions d'éthylènediamine.

[Traduit par le journal]

Introduction

The problem of successive electron transfers to organic molecules has been studied by many workers (1–8) and corresponding theoretical analysis has been presented (3, 4, 9, 10). According to Ammar and Savéant (3), the difference between the formal potentials for the first and second electron transfer steps is influenced both by structural and medium effects. These authors first pointed out that for the molecules containing two identical but completely isolated electroactive groups, $\Delta E_{1/2}$ values are only connected with entropic factors. On the other hand if these centers interact two possibilities should be differentiated: (*i*), the first electron transfer hinders the second one, for example, by a coulombic interaction, and (*ii*), the first electron transfer promotes the second transfer, because of solvation and ion pairing phenomena. Now, in the first case the second wave will move towards more extreme potentials causing an increase in $\Delta E_{1/2}$, whereas in the second case $\Delta E_{1/2}$ values will be diminished.

The purpose of this paper is to describe the medium effects on the separation of reversible



potentials for the first and second electron transfers. Thus, we report here electrochemical studies of dibiphenylene-ethene (DBPE) in a series of organic solvents. The perchlorates of $(C_2H_5)_4N^+$ and Na^+ were used as supporting electrolytes. The molecule of DBPE may be formally treated as two fluorene moieties joined together by a double bond, therefore it is an example of the molecule containing two identical and strongly interacting electroactive centers.

Experimental

Polarographic and stationary electron voltammetric measurements were carried out in a three-electrode system using a Radelkis OH-105 polarograph. For higher scan rates (up to 20 V s^{-1}) the digiscope polarograph OP-3 Unitra-Telpod (Poland) and Luggin capillary were applied. The working electrode was either a mercury drop electrode characterized by drop time 2.0 s (a drop timer was used throughout experiments) or a hanging mercury drop electrode of the design of Kemula and Kublik (11) with diameter 0.71 mm. The potentials were measured against an aqueous SCE using a two-part salt bridge. In one arm of this bridge, there was a solvent and electrolyte exactly as in the

polarographic vessel. Coulometric measurements were made by means of a Radelkis OH-404 apparatus.

DBPE of very high purity was kindly given by Dr. M. Jawdosiuk. Tetraethylammonium perchlorate was prepared (12) and recrystallized from triply distilled water and dried *in vacuo* at 60°C. $NaClO_4$ (AR grade) was dried at 120°C over P_2O_5 under reduced pressure. The solvents were dried and purified immediately before use according to the standard procedures (13). The water content in the solvents, analysed by Karl Fisher method, was about 10^{-3} *M*. All experiments were run at 23.0 ± 0.1°C. Before electrochemical measurements the solutions were deoxygenated with solvent-presaturated pure argon. The concentrations of the depolarizer and supporting electrolyte were usually 5.0×10^{-4} and 0.10 *M*, respectively.

Results

Two cathodic waves were observed in all solvents during the studies of DBPE on the dropping mercury electrode. Semi-logarithmic analysis gives $\Delta E/\Delta \log \{i/(i_d - i)\}$ slopes close to theoretical values for reversible one-electron transfer. Measurements of the wave height as a function of depolarizer concentration (in the range 0.08–0.75 m*M*) and as a function of the square root of a mercury height indicate that the limiting currents of both waves are controlled by diffusion. Coulometric determination yields one as the number of electrons for each electroreduction step. Such a behaviour was found in solutions containing $(C_2H_5)_4NClO_4$ and $NaClO_4$, respectively. The main difference in both these cases consists only in the different half-wave potentials of the second reduction step determined in some solvents. Essential characteristics of the polarographic waves of DBPE are summarized in Table 1. This table also contains some physicochemical parameters proper for the solvents.

Cyclic voltammograms of DBPE confirm reversible one-electron transfers for both electroreduction steps. Typical curve recorded at scan rate 0.1 V s^{-1} is presented in Fig. 1. On this curve one

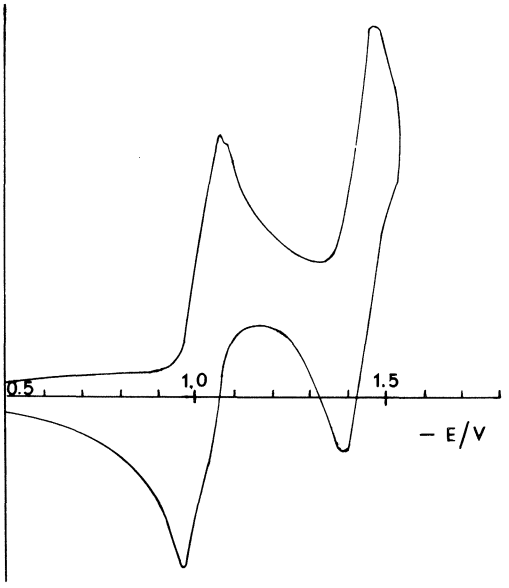

FIG. 1. Cyclic voltammetric curve of 5.0×10^{-4} *M* dibiphenylene-ethene in acetone containing 0.10 *M* $(C_2H_5)_4NClO_4$. Scan rate 0.05 V s^{-1}.

can observe corresponding pairs of cathodic and anodic peaks with i_{pa}/i_{pc} values close to unity and with theoretical separation (within ±5 mV). The ratios i_{pa}/i_{pc} and the peak potentials are independent of scan rate, v. We have observed that all these values remained practically constant when v changed from 0.05 to 10 V s^{-1}. It should also be pointed out that quite identical results were obtained in all remaining solvents applied in this work (both in the presence of $(C_2H_5)_4NClO_4$ and $NaClO_4$) with the exception of ethylenediamine.

Polarographic behaviour of DBPE in ethylenediamine differs markedly. Reversibility was only found for the first electroreduction step, whereas no anodic peak was recorded for the second wave

(using HMDE) even at $v = 20\,V\ s^{-1}$ (Fig. 2). Moreover, $E^{II}_{1/2}$ value was found to depend on the drop time ($\Delta E_{1/2}/\Delta \log t_1 = 28.5 \pm 3$ mV in solution containing tetraethylammonium perchlorate and in the t_1 range 1.0–10.0 s) but it is independent of the depolarizer concentration, at least in the range 0.1–1.2 m*M*. It should be noted that identical picture was observed when, instead of tetraethylammonium perchlorate, 0.10 *M* $NaClO_4$ was used.

Discussion

It follows from our experiments that relatively stable radical anions and dianions are produced during the electroreduction of DBPE in acetonitrile, acetone, propylene carbonate, *N*,*N*-dimethylformamide, dimethylsulfoxide, *N*,*N*-diethylformamide, pyridine, *N*,*N*-dimethylacetamide, and benzonitrile independently of electrolytes applied in this work. Thus, the general mechanism represented by scheme:

$$DBPE + e \rightleftharpoons DBPE^{-\cdot} \qquad E^{I}_{1/2}$$

$$DBPE^{-\cdot} + e \rightleftharpoons DBPE^{2-} \qquad E^{II}_{1/2}$$

is in agreement with the results reported previously in dimethylformamide solutions (14). The different behaviour of DBPE in ethylenediamine thus calls for an explanation.

Evidently, the irreversibility of the second wave under these conditions is connected with the protonization of $DBPE^{2-}$ dianions. We assume that the proton source are the molecules of the solvent, similarly it was demonstrated in the case of the electrochemistry of aromatic azo-compounds (15).[2] Accordingly, dibiphenylene-ethane was polarographically and spectrophotometrically identified as the product of the potentiostatic reduction (macroscale electrolysis) at the potential of the second wave of DBPE. It should be noted that taking into account these observations, we have not considered the values of $\Delta E_{1/2} = E^{I}_{1/2} - E^{II}_{1/2}$ for ethylenediamine solutions in the analysis presented below.

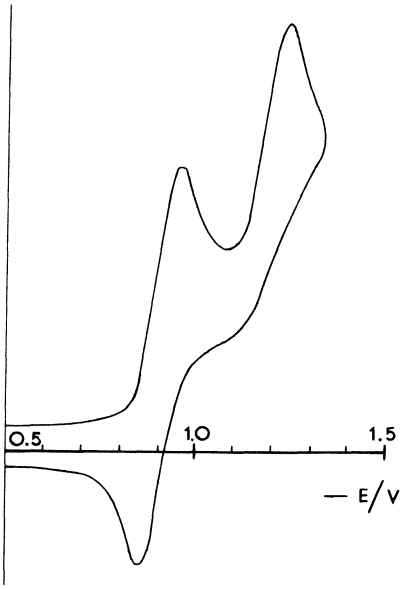

FIG. 2. Cyclic voltammogram of 5.0×10^{-4} *M* dibiphenylene-ethene registered in ethylenediamine solution containing 0.10 *M* $(C_2H_5)_4NClO_4$ at scan rate 10 V s^{-1}.

It was of particular interest in this study to obtain information on the environmental effects on $\Delta E_{1/2}$ values of DBPE. As clearly seen from the data presented in Table 1 these values are dependent both on the properties of solvent and on the nature of electrolyte cation. The possible reason can be that the difference between the formal potentials of DBPE is influenced by the effects of solvation and by ion pairing phenomena. We suppose that the role of ion pairs $DBPE^{-\cdot}...M^+$ (M^+ stands for a counter ion) may be neglected. It follows from the observation that $E^{I}_{1/2}$ values are identical within experimental error both in the presence of $(C_2H_5)_4NClO_4$ and $NaClO_4$ in a given solvent. These values are also indendent of electrolyte concentration (in the range 0.02–0.15 *M*). On the other hand, the half-wave potentials of the second reduction step are, in many solvents, dependent on the nature of cations (Table 1) and on their concentration in solutions. Thus, in the case of $DBPE^{2-}$ the solvent–anion interaction is overlapped by cation–anion interactions.

At present, it is not easy to discuss in detail the structural aspects of $DBPE^{2-}...(M^+)_n$ systems; anyway this is not important in our present work. Therefore, we only suppose that the ionic associates $DBPE^{2-}...(M^+)_n$ have most probably loose structure, because $E^{II}_{1/2}$ values of DBPE are generally shifted towards negative direction when sodium perchlorate is used instead of $(C_2H_5)_4NClO_4$. This problem requires, however, additional investigations.

In the light of the facts described above, it was of interest to investigate whether $\Delta E_{1/2}$ values of DBPE can be correlated with solvent parameters. Plots of these values versus the dielectric permittivity or the dipole moments showed no correlations, indicating that the simplest electrostatic models do not satisfy our experimental results.

[2]Very recently Sock *et al.* demonstrated that (amino-2-ethyl) carbamic acid is produced by the fixation of CO_2 gas from the air dissolved in ethylenediamine (16). Obviously, this acid can also react as an effective proton source.

TABLE 2. Application of the equation $\Delta E_{1/2} = \alpha DN + \beta AN + \gamma$ to $\Delta E_{1/2}$ values of dibiphenylene-ethene[a]

Supporting electrolyte	$\alpha \times 10^3$	$\beta \times 10^3$	γ	r^b
$(C_2H_5)_4NClO_3$	2.16±0.27[c]	−2.47±0.89	0.417±0.016	0.975
$NaClO_4$	3.18±0.48	−6.70±0.15	0.467±0.028	0.974

[a] Multiparametric equation for calculating the solvent dependence of chemical systems using DN and AN values has been introduced by Mayer (21).
[b] Correlation coefficient.
[c] Errors are standard deviations.

Thus, we have analyzed the relations between $\Delta E_{1/2}$ and the parameters approximating Lewis basicity and acidity of solvents. Accordingly, we have applied an empirical model proposed by Krygowski and Fawcett (17, 18) in which the solvent effect on a given physicochemical property is a linear function of the Gutmann donor number (DN) (19) and of the Dimroth and Reichardt parameter (E_T) (20). In our case, the appropriate expression of this relationship is

$$\Delta E_{1/2} = \alpha DN + \beta E_T + \gamma$$

where α and β describe (after normalization) the sensitivity of the half-wave potential to changes in solvent basicity and acidity, respectively. Applying this relation to the results collected in Table 1, we have found that the correlation coefficients are 0.945 and 0.902 for the values determined in solutions containing tetraethylammonium and sodium perchlorates, respectively. The correlations were much better if instead of E_T, corresponding Gutmann's acceptor numbers (19) were used. The results of calculations in this case are listed in Table 2. It must be pointed out that DN and AN values are not collinear, in the case investigated by us the correlation coefficient between between them is $r = 0.165$.

As can be seen from Table 2, α is positive whereas β is negative in solutions containing both $(C_2H_5)_4NClO_4$ and $NaClO_4$ as electrolytes. This means that the separation between two successive electron transfers decreases with the decrease of Lewis basicity and with the increase of Lewis acidity of a solvent. This observation can easily be explained in terms of ion pairing and solvation phenomena.

Generally, ion pairing is expected to favor the disproportionation of $DBPE^{-\cdot}$ radical ions, and, consequently, to diminish the $\Delta E_{1/2}$ value, similarly as in many cases decribed in literature (for review see e.g. ref. 22). Obviously, the donicity plays the major role in ion pair formation (23), a high DN value of the solvent increases the degree of dissociation of $DBPE^{2-}...(M^+)_n$ into free ions owing to the solvation of M^+. On the other hand, the solvation of anionic species, particularly of $DBPE^{2-}$, drives disproportionation, according to the donor–acceptor concept (19), the free energies of the solvation of anions increase with an increase in AN. On this basis, the positive sign of α and negative sign of β in the correlations we obtained is fully comprehensible.

Evidently, the thermodynamical aspects of successive electron transfers should be analyzed in consideration of enthalpy and entropy terms for ion pairing and solvation. Such a treatment was described in the case of electrochemistry of some dinitrocompounds but only in dimethylformamide solutions (24). How is it in a series of various solvents? Are ΔH and ΔS collinearly changed with their Lewis basicity and acidity? Further investigations will be to explain these questions.

Formylation en série arylpyrrolique

JEAN-PAUL BOUKOU-POBA, MICHEL FARNIER ET ROGER GUILARD

Laboratoire de Synthèse et d'Electrosynthèse organométallique associé au C.N.R.S., Faculté des Sciences "Gabriel", 21100 Dijon, France

Reçu le 23 janvier 1981

JEAN-PAUL BOUKOU-POBA, MICHEL FARNIER et ROGER GUILARD. Can. J. Chem. **59**, 2962 (1981).

La formylation d'aryl-2 pyrroles et d'aryl-5 pyrrolecarboxylates-2 de méthyle (avec aryl = benzyl, thiényl-2′, thiényl-3′, furyl-2′, furyl-3′) est décrite par la méthode de Vilsmeier. L'orientation de cette substitution électrophile est discutée. La structure des aldéhydes obtenus est précisée à l'aide des données de rmn protonique.

JEAN-PAUL BOUKOU-POBA, MICHEL FARNIER, and ROGER GUILARD. Can. J. Chem. **59**, 2962 (1981).

The formylation of 2-arylpyrroles and methyl 5-arylpyrrole-2-carboxylates (with aryl = benzyl, 2′-thienyl, 3′-thienyl, 2′-furyl, and 3′-furyl) is performed by the Vilsmeier reaction. The orientation of this electrophilic substitution is discussed. The structure of the aldehydes obtained is established by proton nmr data.

Introduction

Dans une précédente publication (1), nous avons indiqué une méthode générale pour la synthèse d'aryl-2 pyrroles. Ces systèmes hétérocycliques peuvent être le siège de divers types de réactions et en particulier de substitutions électrophiles. Or, dans ce domaine, aucune étude systématique de l'effet de la présence d'un groupe aryle sur la réactivité d'un hétérocycle donné n'a été signalée.

Pour préciser cette influence, nous avons examiné l'une des diverses substitutions possibles et nous avons fait choix de la formylation. Ce choix a été dicté par les deux considérations suivantes: d'une part les formyl aryl-2 pyrroles peuvent être des précurseurs d'analogues de prodigiosines (2); d'autre part, si on peut obtenir des diformyl-αα′ aryl-2 pyrroles, ceux-ci opposés à des diacides dérivés du dipyrrolylméthane doivent permettre l'accès à des isostères de corrines (3).

Résultats

Nous décrivons ici la synthèse de formyl aryl-2 pyrroles selon la méthode de Vilsmeier.

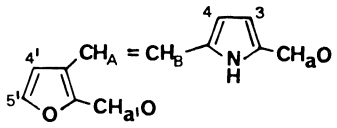
Formylation des aryl-2 pyrroles eux-mêmes

Nous avons examiné le comportement des phényl-2 **1**, (thiényl-2′)-2 **2**, (thiényl-3′)-2 **3**, (furyl-2′)-2 **4** et (furyl-3′)-2 **5** pyrroles. A l'exception du phényl-2 pyrrole **1**, le lien valentiel unissant le reste pyrrolyl-2 à l'autre noyau hétérocyclique intéresse des sommets de réactivité très différente et on pouvait s'attendre à ce que les résultats varient, non seulement d'un hétérocycle à l'autre, mais également pour un même hétérocycle selon que le reste arylique est en position α ou β. Les résultats que nous avons observés sont indiqués sur le schéma 1 et le rendement global des réactions est de l'ordre de 80%.

La formylation du (furyl-2′)-2 pyrrole **4** conduit aux aldéhydes **9** et **10** dans les proportions relatives de 81 et 19%. Lors de la formylation du dérivé **5**, outre les aldéhydes **11** et **12**, on isole un composé **13** pour lequel les caractéristiques analytiques et rmn sont en accord avec la structure suivante:



13

Par ailleurs, le spectre de masse de ce dérivé **13** montre une nette similitude avec celui du dialdéhyde **12**, les fragments correspondants différant de 26 unités. Ainsi, outre le pic moléculaire à 215 (100%), on relève les principaux fragments suivants M^+ 186 (72), 158 (22), 130 (21), 104 (18), 103 (28) et 77 (28). Ces fragments correspondent aux coupures des fonctions aldéhydiques (par perte de CHO$^\bullet$ et de CO), des cycles furannique et pyrrolique (par perte de CO et de HCN) et à la perte de C_2H_2 pour conduire vraisemblablement à l'ion phényle $C_6H_5^+$. A noter que les dérivés **11**, **12** et **13** sont obtenus dans les proportions relatives de 73, 16 et 11%.

De l'ensemble des résultats observés se dégagent les remarques suivantes:

(*1*) Le groupe formyle se fixe électivement ou très majoritairement sur le cycle pyrrolique et uniquement en α. Ce résultat est conforme à celui attendu: en effet, on retrouve le fait bien connu (4) que parmi les hétérocycles fondamentaux, thiophène, furanne, pyrrole, c'est le pyrrole qui est le plus sensible aux attaques électrophiles, puis le furanne, enfin le thiophène; le benzène non substitué est quant à lui peu sensible au réactif utilisé lors de la formylation selon Vilsmeier. Par ailleurs, la position α est toujours plus réactive que la position β.

(*2*) C'est d'ailleurs sur cette position α la plus réactive que se fixe le second groupe formyle dans le cas des dialdéhydes **10** et **12**; dans le cas du (furyl-3′)-2 pyrrole **5** pour lequel les deux positions α furanniques sont libres, la fixation du second groupe formyle en position 2′ est conforme à l'orientation généralement observée (4).

Formylation d'aryl-5 pyrrolecarboxylates-2 de méthyle

La formylation d'un ester α pyrrolique a été étudiée (5); le groupe formyle s'introduit très majoritairement en position β′ et α′ (les proportions relatives des isomères obtenus dépendant largement des modalités opératoires). Compte tenu de l'effet électro-attracteur d'un groupe ester et des résultats de l'étude précédente, on pouvait prévoir que la formylation des esters précurseurs des arylpyrroles intéresserait et le noyau pyrrolique et le reste aryle qui lui est lié; c'est effectivement ce qui est observé, les divers synthèses réalisées figurant au schéma 2.

Les résultats obtenus s'interprètent là-aussi assez aisément en tenant compte des diverses réactivités des hétérocycles fondamentaux vis à vis d'une substitution électrophile. La position α pyrrolique étant occupée par un groupe carboxylate de méthyle, par suite de l'effet orientant de ce substituant, le groupe formyle doit être introduit en position β′ sur le cycle pyrrolique; c'est ce qui se passe de façon très préférentielle pour les phényl et thiényl pyrroles. Cependant dans le cas des thiénylpyrroles **15** et **16** on observe conjointement, mais minoritairement, la formylation en α du cycle thiophénique (proportions relatives des dérivés **20** et **21** d'une part, **22** et **23** d'autre part: 95 et 5%).

Les dérivés minoritaires obtenus en série thiénylpyrrolique sont en fait les produits uniques en série furannique; en effet, l'on sait (4) que la différence de réactivité entre le pyrrole et le furanne vis-à-vis d'une substitution électrophile est la plus faible; il est alors plus aisé de formyler en α du furanne qu'en β′ du pyrrole.

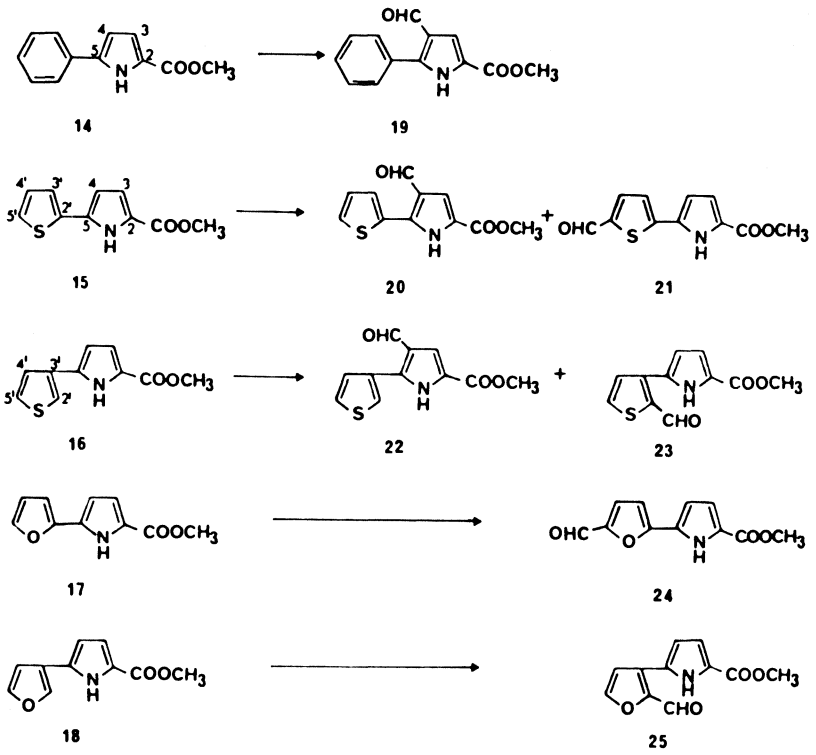
Spectres de résonance magnétique nucléaire

La structure de chacun des produits obtenus a pu être généralement établie par analyse des spectres de rmn protonique.

(a) Aldéhydes dérivés des aryl-2 pyrroles

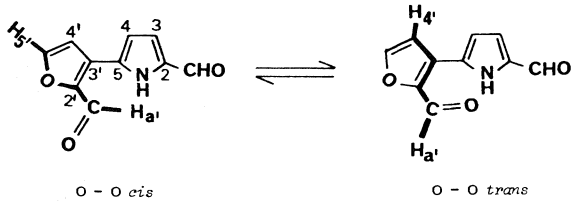
Les caractéristiques rmn observées pour les mono et dialdéhydes arylpyrroliques obtenus ont été regroupées dans le tableau 1.

Pour tous les produits étudiés, la constante de couplage des protons pyrroliques correspond à



SCHEMA 2

celle signalée pour des protons ββ′ pyrroliques (5, 7). Dans le cas des monoaldéhydes, les positions des signaux et les constantes de couplage correspondent à celles de protons αββ′ ou αα′β′ thiophéniques (8) ou furanniques (9). Pour les dialdéhydes, les valeurs des constantes de couplage des protons furanniques impliquent que ces protons soient respectivement en position ββ′ pour le dérivé **10** et αβ pour le dérivé **12**. Pour ce dialdéhyde **12**, le proton du groupe formyle en 2′ est également couplé (^5J) avec $H_{5'}$ et (^5J) avec $H_{4'}$; aussi à température ambiante et dans le diméthylsulfoxyde hexadeutérié comme solvant, la molécule présente l'équilibre conformationnel suivant:



O - O *cis* O - O *trans*

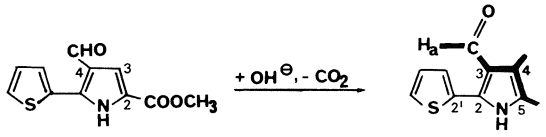
En se référant aux constantes de couplage observées pour les conformères *cis* et *trans* du furfural (10) on aurait les proportions suivantes: environ 60% de conformère *trans* et 40% de *cis*.

Enfin le spectre rmn du dialdéhyde **13**, vinylogue du composé **12**, présente les caractéristiques suivantes: δ: 7.10 (d, $J_{4'5'}$ = 1.7 Hz, $H_{4'}$), 8.05 (2d, $J_{4'5'}$ = 1.7 et $J_{a'5'}$ = 0.6 Hz, $H_{5'}$), 7.05 (d, J_{34} = 3.6 Hz, H_3), 6.59 (d, J_{34} = 3.6 Hz, H_4), 9.47 (s, H_a), 9.90 (d, $J_{a'5'}$ = 0.6 Hz, $H_{a'}$), 7.15 et 7.81 (deux doublets, J_{AB} = 16.4 Hz, H_A et H_B).

(b) Aldéhydes dérivés des aryl-5 pyrrolecarboxylates-2 de méthyle

Dans le tableau 2 ont été rassemblées les caractéristiques rmn des esters aldéhydes **19** à **25**.

Pour les composés **19**, **20** et **22**, le singulet situé entre 7.2 et 7.3 ppm est attribuable au proton pyrrolique. En considérant l'effet orientant du groupe carboxylate de méthyle, le groupe formyle doit occuper la position 4. Nous avons vérifié la validité de cette conclusion dans le cas de l'ester aldéhyde **20**; soumis à une hydrolyse suivie d'une décarboxylation, il donne naissance à un aldéhyde **26**:



20 **26**

La constante de couplage des protons pyrroliques de l'aldéhyde **26** correspond à un couplage αβ. De plus on observe le couplage du proton aldéhydique

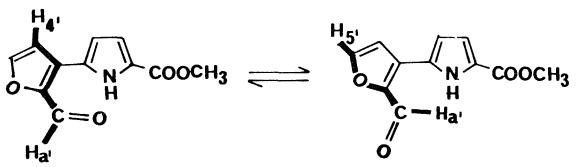
[a]A, chloroforme; B, acétone; C, benzène; D, hexane; E, dichloro-1,2 éthane; F, toluène; G, méthanol; H, eau.
[b]Litt. (6), pf 99–101°C.

avec à la fois le proton H_4 (^4J) et le proton H_5 (^5J) du noyau pyrrolique; or ces deux couplages ne peuvent apparaître simultanément (11) que dans la mesure où le groupe formyle est en position 3; l'aldéhyde **26** est donc le (thiényl-2′)-2 pyrrolecarbaldéhyde-3 (son groupe formyle a été représenté dans l'état conformationnel majoritaire).

Pour le dérivé thiophénique **23**, le proton aldéhydique n'apparaît couplé qu'avec le proton $H_{5'}$ ($J_{a'5'}$ = 1.1 Hz); le groupe formyle est donc pratiquement totalement conformé en S—O *cis*. Nous avons étudié le [(formyl-2′) furyl-3′]-5 pyrrolecarboxylate-2 de méthyle **25** en solution dans le diméthylsulfoxyde hexadeutérié et dans le deutériochloroforme. Dans le premier solvant le couplage intéresse à la fois $H_{5'}$ (^5J = 0.15 Hz) et $H_{4'}$ (^5J = 0.65 Hz); dans le second, seul $H_{4'}$ est couplé (^5J = 0.9 Hz). A température ambiante on peut donc envisager l'existence de l'équilibre conformationnel suivant:



O – O *trans* O – O *cis*

Dans le deutériochloroforme, le groupe formyle est pratiquement totalement conformé en O—O *trans*, conformation vraisemblablement privilégiée en raison de l'existence d'une liaison intramoléculaire NH—O (aldéhydique). Par contre, dans un solvant polaire (type DMSO-d_6), la liaison

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

est partiellement rompue; le groupe formyle, bien que toujours préférentiellement en conformation O—O *trans*, existe alors en proportion non négligeable sous la conformation O—O *cis*.

Partie expérimentale

Les analyses élémentaires ont été effectuées par le Laboratoire Central de Microanalyse du C.N.R.S. Les spectres rmn ont été relevés sur un appareil JEOL FX 100 en utilisant le TMS comme référence interne et, sauf indication contraire, le DMSO-d_6 comme solvant. Le couplage des protons pyrroliques avec l'hydrogène iminique a été supprimé par ajout d'eau lourde.

La synthèse des aryl-2 pyrroles et aryl-5 pyrrolecarboxylates-2 de méthyle utilisés a été décrite précédemment (1).

Formylation des aryl-2 pyrroles et aryl-5 pyrrolecarboxylates-2 de méthyle

Toutes les formylations ont été conduites selon la même méthode exposée ci-dessous de façon générale.

Dans 1.7 cm³ (0.022 mol) de diméthylformamide on verse, à 0°C, goutte à goutte et sous agitation, 2 cm³ (0.022 mol) d'oxychlorure de phosphore. On laisse revenir à température ambiante tout en maintenant l'agitation puis, à 0°C, 40 cm³ de dichloro-1,2 éthane anhydre sont ajoutés. On introduit alors 0.02 mol d'aryl-2 pyrrole ou d'ester en solution dans 100 cm³ de dichloro-1,2 éthane. L'addition terminée (1 h environ), on porte à reflux 1 h. On laisse revenir à température ambiante et ajoute lentement et avec précaution 15 g d'acétate de sodium trihydraté en solution dans 40 cm³ d'eau tout en maintenant une agitation efficace. Le mélange réactionnel est porté à reflux 1 h. A température ambiante, la phase organique est séparée. La phase aqueuse est extraite deux fois par 100 cm³ de chloroforme. Les phases organiques réunies sont traitées par une solution saturée d'hydrogénocarbonate de sodium, puis à l'eau jusqu'à neutralité. Les solvants sont évaporés et le résidu obtenu est chromatographié sur colonne d'acide silicique.

Les modalités opératoires utilisées et les caractéristiques des produits obtenus sont indiquées dans le tableau 3.

Préparation du (thiényl-2')-2 pyrrolecarbaldéhyde-3 ***26***

(a) Hydrolyse du (thiényl-2')-5 formyl-4 pyrrolecarboxylate-2 de méthyle ***20***

On porte à reflux durant 30 min une solution de 1.175 g (0.005 mol) de (thiényl-2')-5 formyl-4 pyrrolecarboxylate-2 de méthyle **20** et 0.57 g (0.01 mol) de potasse dans 10 cm³ d'eau. Après retour à la température ambiante, on acidifie à 0°C par de l'acide chlorhydrique 5 *N*. Le précipité obtenu est essoré, lavé à l'eau froide jusqu'à neutralité. On récupère 0.85 g (77%) d'acide (thiényl-2')-5 formyl-4 pyrrolecarboxylique-2, pf 278°C.

(b) Décarboxylation de l'acide (thiényl-2')-5 formyl-4 pyrrolecarboxylique-2

On chauffe à 90°C 10 cm³ de quinoléïne et 0.796 g de l'acide précédent et maintient cette température jusqu'à dissolution totale de l'acide. On ajoute alors 0.120 g de chromite de cuivre (activé par du baryum), puis on porte la température à 158–162°C jusqu'à ce que l'on n'observe plus de dégagement de CO_2. On refroidit brutalement dans un mélange eau–glace, ajoute 80 cm³ de chloroforme et filtre le catalyseur. On élimine la quinoléïne par lavage à l'acide chlorhydrique 5 *N* jusqu'à pH 2. La phase chloroformique est lavée à l'eau bicarbonatée jusqu'à neutralité. On recueille après chromatographie sur acide silicique (éluant chloroforme–acétone (9:1)) et recristallisation dans un mélange benzène–hexane (1:1), 0.250 g (40%) de (thiényl-2')-2 pyrrolecarbaldéhyde-3 **26**, pf 120–122°C; rmn (DMSO-d_6, D_2O) δ: 6.56 (2d, J_{45} = 3.0 et J_{a4} = 0.37 Hz, H_4), 6.96 (2d, J_{45} = 3.0 et J_{a5} = 0.73 Hz, H_5), 7.19 (2d, $J_{3'4'}$ = 3.7 et $J_{4'5'}$ = 5.1 Hz, $H_{4'}$), 7.50 (2d, $J_{3'4'}$ = 3.7 et $J_{3'5'}$ = 1.2 Hz, $H_{3'}$), 7.67 (2d, $J_{3'5'}$ = 1.2 et $J_{4'5'}$ = 5.1 Hz, $H_{5'}$), 9.94 (2d, J_{a4} = 0.37 et J_{a5} = 0.73 Hz, H_a). *Anal.* calc. pour C_9H_7NOS: C 60.99, H 3.98, N 7.90, O 9.03, S 18.10; trouvé: C 61.08, H 3.92, N 7.82, O 9.10, S 17.95.

Volume fraction statistics and the surface tensions of non-electrolyte solutions

DOUGLAS E. GOLDSACK AND CARMEN DESIRRIE SARVAS

Department of Chemistry, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received November 14, 1980[1]

DOUGLAS E. GOLDSACK and CARMEN DESIRRIE SARVAS. Can. J. Chem. **59**, 2968 (1981).

Explicit and implicit surface tension equations have been derived using both mole fraction and volume fraction statistics and have been applied to a variety of binary polar–polar, non-polar–non-polar, and non-polar–polar organic systems with good success. Average errors of less than 1% are found for a large variety of such systems with the assumption of ideal chemical potential equations and molar surface areas calculated from bulk density values. These equations are found to be valid for those systems with surface tension differences of 20 ergs/cm^2 or less. Systems with surface tension differences larger than this value would require the inclusion of activity coefficient effects.

DOUGLAS E. GOLDSACK et CARMEN DESIRRIE SARVAS. Can. J. Chem. **59**, 2968 (1981).

Faisant appel aux statistiques de la fraction molaire et de la fraction volumique on a déduit les équations de tensions de surface implicites et explicites et on les a appliqué avec succès à une série de systèmes organiques binaires: polaire–polaire, non-polaire–non-polaire et non-polaire–polaire. On a trouvé que la moyenne des erreurs est inférieure à 1% pour une grande variété de ces systèmes en supposant que les équations de potentiel chimique idéal et les domaines de surface molaire sont calculées à partir des valeurs de densité de volume. On a trouvé que les différences de tension de surface sont de 20 ergs/cm^{-1}. Les systèmes ayant des différences de tension de surface plus grandes que cette valeur nécessitent l'inclusion des effets de coefficient d'activité.

Introduction

At present there are no simple explicit formulae for calculating the surface tension of mixtures of organic compounds of a wide range of polarity from the bulk parameters of the individual components (1). The thermodynamics of the surface tension of such systems has been treated in a variety of fashions in the literature in an attempt to formulate such an explicit equation for the concentration dependence of the surface tension of these solutions with a minimum number of adjustable parameters (2–6). These approaches have generally involved arbitrary assumptions of equal or average molar surface areas of the components and use of regular solution theory to approximate activity coefficient effects. In some cases (7, 8), other arbitrary assumptions in the formulation of the thermodynamics have led to incorrect equations for the concentration dependence of the surface tension of these mixtures (9).

In all of these attempts mole fraction statistics have been applied to both the surface and bulk phases. The effect of molecular size on the surface tension of mixtures has been tentatively explored (ref. 4, chapt. 13, ref. 10) and has also been shown to have a significant effect on adsorption isotherms (11, 12). Hence a detailed comparison of mole fraction and volume fraction statistics on the surface tension of binary solutions of nonelectrolytes over a wide range of polarity would seem to be warranted.

Theory

The starting point for obtaining any relation involving the surface tension of a mixture is to assume (4, 9, 13, 14) that the surface layer can be treated thermodynamically as a phase separate from the bulk phase.

The chemical potential of a component i in the bulk liquid phase (B) of a solution is given by:

$$[1] \qquad \mu_{i,B} = \mu^0_{i,B} + RT \ln (a_{i,B})$$

where $\mu^0_{i,B}$ is the standard state chemical potential of component i in the bulk phase, $a_{i,B}$ is the activity of component i in the bulk phase, and R and T are the gas constant and absolute temperature respectively. In the surface phase (S), the chemical potential of component i is similarly given by:

$$[2] \qquad \mu_{i,S} = \mu^0_{i,S} + RT \ln (a_{i,S}) - \sigma A_i$$

where σ is the surface tension of the mixture of activity $a_{i,S}$ and A_i the molar surface area of component i. For a pure component

$$[3] \qquad \mu^0_{i,S} - \mu^0_{i,B} = \sigma_i A_i$$

At equilibrium

$$[4] \qquad \mu_{i,S} = \mu_{i,B}$$

Combining eqs. [1] through [4] leads to the Butler equation (13):

$$[5] \qquad \sigma = \sigma_i + \frac{RT}{A_i} \ln \left(\frac{a_{i,S}}{a_{i,B}}\right)$$

This equation can also be written as

$$[6] \qquad a_{i,S} = a_{i,B} \exp \left[(\sigma - \sigma_i)\frac{A_i}{RT}\right]$$

[1]Revision received June 26, 1981.

where exp stands for the Napierian base e. If the surface and bulk phases over the whole concentration range are similar in properties, e.g. the heat of mixing of the components are similar as a function of concentration, then to a first approximation, the activity coefficients, f_i, in the surface and bulk phases are approximately equal over the whole concentration range and as a result the following relation is approximately valid:

$$[6a] \quad \frac{a_{i,S}}{a_{i,B}} = \frac{f_{i,S}X_{i,S}}{f_{i,B}X_{i,B}} \simeq \frac{X_{i,S}}{X_{i,B}}$$

and therefore [6] can be rewritten as

$$[6b] \quad X_{i,S} = X_{i,B} \exp\left[(\sigma - \sigma_i)\frac{A_i}{RT}\right]$$

Since the sum of the mole fractions of all components in the surface phase is unity, then

$$[7] \quad \sum X_{i,S} = \sum X_{i,B} \exp\left[(\sigma - \sigma_i)\frac{A_i}{RT}\right] = 1$$

This general equation has been obtained previously by a variety of authors (9, 14). It can also be rearranged in a different fashion to obtain the concentration dependence of the surface tension. For a binary solution

$$[8] \quad X_{1,B}\left\{\exp\left[(\sigma - \sigma_1)\frac{A_1}{RT}\right]\right\} + X_{2,B}\left\{\exp\left[(\sigma - \sigma_2)\frac{A_2}{RT}\right]\right\} = 1$$

Since the sum of the mole fractions in the bulk phase is unity, this equation can also be rearranged into:

$$[9] \quad \sigma = \sigma_1 - \frac{RT}{A_1}\left\{\ln\left\{1 + X_2\left[\exp\left(\frac{\sigma(A_2 - A_1)}{RT} + \frac{\sigma_1 A_1 - \sigma_2 A_2}{RT}\right) - 1\right]\right\}\right\}$$

If $A_2 = A_1 = A$, which is an approximation often used in the literature, then an equation of a form similar to the Szyszkowski equation (4) results.

$$[10] \quad \sigma = \sigma_1 - \frac{RT}{A}\left\{\ln\left\{1 + X_2\left[\exp\left(\frac{(\sigma_1 - \sigma_2)A}{RT}\right) - 1\right]\right\}\right\}$$

This latter equation has one adjustable parameter and has been used to fit the concentration dependence of the surface tension of binary mixtures of non-electrolytes. The values of A so found have sometimes been unreasonable (15), and this is not unexpected since [9] is an implicit equation for which some approximate value for σ on the right-hand side must be given before it can be used.

Schuchowitsky (2) first showed how it was possible to obtain an explicit equation for σ using the Butler equation [5] as the starting point. We will therefore show how, taking his approach, one can derive both explicit and implicit equations for the surface tension of a binary mixture on both the mole fraction and volume fraction scales and indicate both theoretically and practically the limits of applications of both the explicit and implicit forms.

In order to use the Butler equation one must first have an estimate of the molar surface area, A_i, of each component. If it is assumed that the surface phase is a monolayer (1), then the individual molar surface areas of each component, A_i, can be related to bulk molar volumes V_i. To do so requires the further assumption that the molecules of each component can be approximated as spheres and that the cross sectional area of each molecule is the appropriate geometrical area presented at the surface. In that case

$$A_i = \pi\left(\frac{3}{4\pi}\right)^{2/3} N^{1/3} V_i^{2/3} = 1.02 \times 10^8 V_i^{2/3}$$

where N is Avogadro's number. This relation also assumes that the bulk density and the surface density of component i are equal — an assumption which may bear further investigation since it may not necessarily, and is most probably not, valid in general (16). But, for a first approximation, this assumption is useful since it enables the surface tension of mixtures to be calculated from known bulk properties of each component.

It is also useful to note that the value of RT/A_i for most organic components with molar volumes in the range of 50 to 150 cm^3/mol is of the order of 10 to 20 ergs/cm^2. This factor is of importance in limiting the usefulness of the explicit equations to be derived for σ.

Explicit Equations for σ on Mole Fraction Scale

The Butler equations on the mole fraction scale for components 1 and 2 of a binary mixture are:

$$[11a] \quad \sigma = \sigma_1 + \frac{RT}{A_1} \ln \left(\frac{X_{1,S}}{X_{1,B}}\right)$$

$$[11b] \quad \sigma = \sigma_2 + \frac{RT}{A_2} \ln \left(\frac{X_{2,S}}{X_{2,B}}\right)$$

Multiplying [11*a*] by $X_{1,B}$ and [11*b*] by $X_{2,B}$ and adding results in an equation yielding an ideal surface tension term and a term involving the free energy of mixing per unit area, one gets

$$[12] \quad \sigma = \sigma_1 X_{1,B} + \sigma_2 X_{2,B} + X_{1,B} \frac{RT}{A_1} \ln \left(\frac{X_{1,S}}{X_{1,B}}\right) + X_{2,B} \frac{RT}{A_2} \ln \left(\frac{X_{2,S}}{X_{2,B}}\right)$$

Equation [12] cannot be used to calculate the surface tension of a mixture unless the surface mole fractions $X_{1,S}$ and $X_{2,S}$ are known. Prigogine *et al.* (ref. 4, p. 202 *ff*) have introduced a difference function which enables a relation between the surface and bulk mole fractions to be established under certain conditions. If we define a dimensionless difference term Δ such that:

$$[13] \quad X_{1,S} = X_{1,B} + X_{1,B}X_{2,B}\Delta$$

and since

$$[14] \quad X_{1,S} + X_{2,S} = X_{1,B} + X_{2,B} = 1$$

$$[15] \quad X_{2,S} = X_{2,B} - X_{1,B}X_{2,B}\Delta$$

Applying these equations to the Butler equations for each component gives

$$[16a] \quad \sigma = \sigma_1 + \frac{RT}{A_1} \ln (1 + X_{2,B}\Delta)$$

$$[16b] \quad \sigma = \sigma_2 + \frac{RT}{A_2} \ln (1 - X_{1,B}\Delta)$$

Subtracting [16*a*] from [16*b*], and expanding the logarithmic terms to their first term under the conditions that $X_{2,B}\Delta$ and $X_{1,B}\Delta$ are much less than one, yields the following relation for Δ:

$$[17] \quad \Delta = -\frac{(\sigma_2 - \sigma_1)A_1A_2}{(A_1X_1 + A_2X_2)RT}$$

where the mole fractions now apply to the bulk phase only. If this equation for Δ is now put into eq. [12] then the following explicit equation for the surface tension of a binary mixture is obtained (the mole fractions refer to the bulk phase only):

$$[18] \quad \sigma = \sigma_1X_1 + \sigma_2X_2 + \frac{X_1RT}{A_1} (\ln (1 + X_2\Delta)) + \frac{X_2RT}{A_2} (\ln (1 - X_1\Delta))$$

The same restriction on the derivation of the equation for Δ should apply to this general equation for the surface tension, however, i.e. that $X_2\Delta$ or $X_1\Delta$ must be less than one. As noted previously, because of the size of the molecular volumes of most molecules, the term RT/A_i is of the order of 10–20 cm^2/ergs and hence the use of the Δ function approach should be restricted to systems with $(\sigma_2 - \sigma_1)$ generally less than 10 ergs/cm^2 in order that the expansion approximation used in deriving [17] be valid.

For such systems, however, [18] can be simplified by expanding the logarithmic terms. To the second approximation the surface tension then becomes:

$$[19] \quad \sigma = (\sigma_1X_1 + \sigma_2X_2) + RTX_1X_2\Delta\left[\frac{(A_2 - A_1)}{A_1A_2}\right] - \frac{RT}{2} X_1X_2\Delta^2\left[\frac{A_1X_1 + A_2X_2}{A_1A_2}\right]$$

Equation [19] has not been derived previously and shows that for unequal molar surface areas, a first order deviation term can either add to or cause a negative deviation from the ideal surface tension relation. Gener-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

ally it is found on application of [19] to real systems, as will be discussed later, that the second order term in Δ^2 dominates over the first order term causing an overriding negative deviation from the simple linear relation for surface tension as is observed for real systems.

Schuchowitsky (2) also showed how a different weighting for the ideal term could be obtained on the mole fraction scale. If the Butler equations are written as:

$$[20a] \quad \sigma A_1 = \sigma_1 A_1 + RT \ln \left(\frac{X_{1,S}}{X_{1,B}}\right)$$

$$[20b] \quad \sigma A_2 = \sigma_2 A_2 + RT \ln \left(\frac{X_{2,S}}{X_{2,B}}\right)$$

and are multiplied by $X_{1,B}$ and $X_{2,B}$ respectively, added, the Δ notation introduced to eliminate the surface mole fractions and the logarithmic terms expanded as before, then the first term approximation in the logarithmic expansion yields:

$$[21] \quad \sigma = \sigma_1 \left(\frac{A_1 X_1}{A_1 X_1 + A_2 X_2}\right) + \sigma_2 \left(\frac{A_2 X_2}{A_1 X_1 + A_2 X_2}\right)$$

This equation implies that the ideal surface tension relation is affected strongly by the ratio of the molar surface area A_2/A_1. The second term approximation will be given by

$$[22] \quad \sigma = \sigma_1 \frac{A_1 X_1}{A_1 X_1 + A_2 X_2} + \sigma_2 \frac{A_2 X_2}{A_1 X_1 + A_2 X_2} - \frac{RTX_1 X_2}{A_1 X_1 + A_2 X_2} \frac{\Delta^2}{2}$$

These equations should also be expected to apply to systems with $(\sigma_2 - \sigma_1)$ less than 20 ergs/cm^2.

Volume Fraction Statistics and Explicit Surface Tension Equations

So far only mole fraction statistics have been used to derive equations for the surface tension of binary mixtures. Volume fraction statistics can be applied to the surface and bulk phases assuming that the entropy of mixing for each phase is given by:

$$[23] \quad \Delta S_{mix} = -R[N_1 \ln \phi_1 + N_2 \ln \phi_2]$$

where N_1 and N_2 are the number of moles of components 1 and 2 and ϕ_1 and ϕ_2 are the volume fractions of each component as defined by:

$$[24a] \quad \phi_1 = \frac{X_1 V_1}{X_1 V_1 + X_2 V_2}$$

$$[24b] \quad \phi_2 = \frac{X_2 V_2}{X_1 V_1 + X_2 V_2}$$

where V_1 and V_2 are the molar volumes of components 1 and 2 respectively. The chemical potentials for components 1 and 2 in the bulk and surface phases then become (13):

$$[25a] \quad \mu_{1,B} = \mu^0_{1,B} + RT \left[\ln \phi_{1,B} + \left(1 - \frac{V_1}{V_2}\right)\phi_{2,B}\right]$$

$$[25b] \quad \mu_{2,B} = \mu^0_{2,B} + RT \left[\ln \phi_{2,B} + \left(1 - \frac{V_2}{V_1}\right)\phi_{1,B}\right]$$

$$[25c] \quad \mu_{1,S} = \mu^0_{1,S} + RT \left[\ln \phi_{1,S} + \left(1 - \frac{V_1}{V_2}\right)\phi_{2,S}\right] - \sigma A_1$$

$$[25d] \quad \mu_{2,S} = \mu^0_{2,S} + RT \left[\ln \phi_{2,S} + \left(1 - \frac{V_2}{V_1}\right)\phi_{1,S}\right] - \sigma A_2$$

Equating the chemical potentials in each phase and recognizing that the surface free energies of each component are given by the difference in chemical potentials of the pure components in the surface and bulk phases, then the surface tension equations can be written as:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$$[26a]\quad \sigma = \sigma_1 + \frac{RT}{A_1}\left[\ln\left(\frac{\phi_{1,S}}{\phi_{1,B}}\right) + \left(1 - \frac{V_1}{V_2}\right)(\phi_{2,S} - \phi_{2,B})\right]$$

$$[26b]\quad \sigma = \sigma_2 + \frac{RT}{A_2}\left[\ln\left(\frac{\phi_{2,S}}{\phi_{2,B}}\right) + \left(1 - \frac{V_2}{V_1}\right)(\phi_{1,S} - \phi_{1,B})\right]$$

We can now proceed in a fashion similar to that carried out for the mole fraction statistics in order to eliminate the unknown surface volume fractions in [26*a*] and [26*b*]. Defining the difference function Δ (13) as:

$$[27a]\quad \phi_{1,S} = \phi_{1,B} + \phi_{1,B}\phi_{2,B}\Delta$$

$$[27b]\quad \phi_{2,S} = \phi_{2,B} - \phi_{1,B}\phi_{2,B}\Delta$$

and introducing these definitions into [26*a*] and [26*b*] yields (dropping the B subscript since all volume fractions are now bulk volume fractions):

$$[28a]\quad \sigma = \sigma_1 + \frac{RT}{A_1}\left[\ln(1 + \phi_2\Delta) - \phi_1\phi_2\Delta\left(1 - \frac{V_1}{V_2}\right)\right]$$

$$[28b]\quad \sigma = \sigma_2 + \frac{RT}{A_2}\left[\ln(1 - \phi_1\Delta) + \phi_1\phi_2\Delta\left(1 - \frac{V_2}{V_1}\right)\right]$$

Expanding the logarithms to a first term and subtracting [28*a*] from [28*b*] yields the following expression for Δ on the volume fraction scale:

$$[29]\quad \Delta = \frac{(\sigma_2 - \sigma_1)A_1A_2}{\left\{\phi_1A_1\left[1 - \phi_2\left(1 - \frac{V_2}{V_1}\right)\right] + \phi_2A_2\left[1 - \phi_1\left(1 - \frac{V_1}{V_2}\right)\right]\right\}RT}$$

For many systems, as will be shown in the Discussion section, the denominator of this expression for Δ can be approximated as $(\phi_1A_1 + \phi_2A_2)$ to within 2 to 3% or less over the whole range of composition. This can be readily seen from the denominator expression which can be rearranged as:

$$[30]\quad (\phi_1A_1 + \phi_2A_2) - \phi_1\phi_2\frac{(V_2 - V_1)(A_2V_1 - A_1V_2)}{V_1V_2}$$

Since the molar volumes of most organic molecules are generally within 10 to 20% of each other and since the last term of eq. [30] is the product of two difference terms and a concentration variable, $\phi_1\phi_2$, whose maximum value is 0.25, then for most organic mixtures the Δ function on the volume fraction basis is given by

$$[31]\quad \Delta \simeq \frac{(\sigma_2 - \sigma_1)A_1A_2}{(\phi_1A_1 + \phi_2A_2)RT}$$

For either Δ function, however, explicit equations for the surface tension of a binary mixture on the volume fraction scale can be derived similar to [19] and [22] for the mole fraction scale. Multiplying [28*a*] and [28*b*] by ϕ_1 and ϕ_2, respectively, and expanding logarithmic terms yield the following equations for the surface tension of a binary mixture:

$$[32]\quad \sigma = (\sigma_1\phi_1 + \sigma_2\phi_2) + RT\phi_1\phi_2\left\{\frac{\left[\phi_2\left(1 - \frac{V_2}{V_1}\right) - 1\right]}{A_2} - \frac{\left[\phi_1\left(1 - \frac{V_1}{V_2}\right) - 1\right]}{A_1}\right\}\Delta - RT\frac{\phi_1\phi_2}{2}\left(\frac{A_1\phi_1 + A_2\phi_2}{A_1A_2}\right)\Delta^2$$

It may be noted that the ideal term $(\sigma_1\phi_1 + \sigma_2\phi_2)$ is effectively weighting the surface tension, i.e. the surface free energy per unit area, linearly with the volume fraction. On the other hand, if the revised Butler equations [26*a*] and [26*b*] are weighted according to molar surface free energies, i.e., σ_1A_1 and σ_2A_2, by multiplying [26*a*] and [26*b*] by ϕ_1A_1 and ϕ_2A_2 respectively, and if the logarithmic term is then expanded after the Δ notation has been introduced, then the following equation results:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

$$[33]\quad \sigma = \sigma_1\left(\frac{A_1\phi_1}{A_1\phi_1 + A_2\phi_2}\right) + \sigma_2\left(\frac{A_2\phi_2}{A_1\phi_1 + A_2\phi_2}\right) + \frac{RT\phi_1\phi_2}{(A_1\phi_1 + A_2\phi_2)} \times \left\{\left[\phi_2\left(1 - \frac{V_2}{V_1}\right) - \phi_1\left(1 - \frac{V_1}{V_2}\right)\right]\Delta - \frac{\Delta^2}{2}\right\}$$

It is to be noted that the ideal term of this equation now reflects the difference in molar surface areas through the molar surface area ratio A_2/A_1 and furthermore that this total expression should be limited to those systems for which the explicit Δ equation derivation is applicable, viz. those systems with $\sigma_2 - \sigma_1 < 10$ to 20 ergs/cm^2.

Implicit Surface Tension Equations on Mole and Volume Fraction Scales and Their Application to Systems of Large Polarity Difference

It has been mentioned several times that the Δ function approach to obtaining explicit surface tension equations for binary systems is inherently limited to systems of low polarity differences, i.e. for those systems with $(\sigma_2 - \sigma_1) < 10$ ergs/cm^2. This is due to the need for expansion of the logarithmic expression to its first order term in Δ in order to derive an explicit expression for Δ in terms of the bulk system parameters. A second approach to overcome this limitation is to use the implicit equation [9] with first or second order approximations to the implicit σ term on the right-hand side of equation, which were derived from the explicit Δ function approach, such as [19] and [21]. Since [9] has been derived using mole fraction statistics, by analogy a volume fraction statistic implicit equation should also be readily generated for comparison and the appropriate implicit σ term in this new implicit equation can be approximated by the first or second approximations for σ on the volume fraction scale.

To obtain this implicit equation on the volume fraction scale [26*a*] and [26*b*] are rewritten in terms of the volume fractions in the surface phase as:

$$[34a]\quad \phi_{1,S} = \phi_{1,B}\left\{\exp\left[(\sigma - \sigma_1)\frac{A_1}{RT}\right]\exp\left[(\phi_{2,S} - \phi_{2,B})\left(\frac{V_1}{V_2} - 1\right)\right]\right\}$$

$$[34b]\quad \phi_{2,S} = \phi_{2,B}\left\{\exp\left[(\sigma - \sigma_2)\frac{A_2}{RT}\right]\exp\left[(\phi_{1,S} - \phi_{1,B})\left(\frac{V_2}{V_1} - 1\right)\right]\right\}$$

We have previously defined the differences $(\phi_{i,S} - \phi_{i,B})$ as $|\phi_i\phi_j\Delta|$. The parameter Δ is generally of the order of 1 or less and $\phi_i\phi_j$ has a maximum of 0.25. Furthermore, $(V_2/V_1 - 1)$ and $(V_1/V_2 - 1)$ are generally of the order of 0.1 to 0.2 for most systems. Hence the second exponential in [34*a*] and [34*b*] are of the character e^x where x is much smaller than 1 over the whole range of composition. Expanding this term of e^x to $(1 + x)$ and defining the following terms for ease of derivation,

$$[35]\quad \exp\left[(\sigma - \sigma_1)\frac{A_1}{RT}\right] = B_1 \quad \text{and} \quad \exp\left[(\sigma - \sigma_2)\frac{A_2}{RT}\right] = B_2$$

and noting that $(\phi_{2,S} - \phi_{2,B})$ equals $-(\phi_{1,S} - \phi_{1,B})$, then [34*a*] and [34*b*] become:

$$[36a]\quad \phi_{1,S} = \phi_{1,B}B_1\left[1 + (\phi_{1,S} - \phi_{1,B})\left(1 - \frac{V_1}{V_2}\right)\right]$$

$$[36b]\quad \phi_{2,S} = \phi_{2,B}B_2\left[1 + (\phi_{2,S} - \phi_{2,B})\left(1 - \frac{V_2}{V_1}\right)\right]$$

These two equations enable explicit functions for $\phi_{1,S}$ and $\phi_{2,S}$ to be obtained by rearrangement and since the sum of these volume fractions in the surface phase is unity, we obtain the following explicit relation for the surface tension of the mixture in terms of bulk parameters alone:

$$[37]\quad \phi_{1,B}B_1\frac{\left[1 - \phi_{1,B}\left(1 - \frac{V_1}{V_2}\right)\right]}{\left[1 - \phi_{1,B}B_1\left(1 - \frac{V_1}{V_2}\right)\right]} + \phi_{2,B}B_2\frac{\left[1 - \phi_{2,B}\left(1 - \frac{V_2}{V_1}\right)\right]}{\left[1 - \phi_{2,B}B_2\left(1 - \frac{V_2}{V_1}\right)\right]} = 1$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Dropping the bulk subscripts since all volume fractions now refer to the bulk phase, it can be shown that [37] can be rearranged into the following form:

$$[38]\quad \phi_1 B_1\left[1+\phi_2\left(1-\frac{V_1}{V_2}\right)\right]+\phi_2 B_2\left[1+\phi_1\left(1-\frac{V_2}{V_1}\right)\right]-\phi_1\phi_2 B_1 B_2\left[\left(1-\frac{V_1}{V_2}\right)+\left(1-\frac{V_2}{V_1}\right)\right]=1$$

For most organic systems $(1 - V_1/V_2)$ is of the order of 0.1 to 0.2 and is approximately equal to $(V_2/V_1 - 1)$. Furthermore the last term of this equation is the product of several terms all of which are less than 1. To a good approximation therefore, this term is smaller than the first two terms. Neglecting this term yields:

$$[39]\quad B_1\left[\phi_1+\phi_1\phi_2\left(1-\frac{V_1}{V_2}\right)\right]+B_2\left[\phi_2+\phi_1\phi_2\left(1-\frac{V_2}{V_1}\right)\right]=1$$

Again we note that the terms $\phi_1\phi_2(1 - V_1/V_2)$ and $\phi_1\phi_2(1 - V_2/V_1)$ are of the order of 0.025. Neglecting these terms as a further approximation and replacing the B_1 and B_2 terms with their definitions yields:

$$[40]\quad \phi_1 \exp\left[(\sigma-\sigma_1)\frac{A_1}{RT}\right]+\phi_2\exp\left[(\sigma-\sigma_2)\frac{A_2}{RT}\right]=1$$

This last equation is the volume fraction equivalent to [8] and is applicable only to systems for which the above detailed approximations are valid. Just as [8] can be rearranged into its implicit form, so can [40], [39], and [38].

The following equations are the implicit forms of these last three equations and can be tested for those systems with $(\sigma_2 - \sigma_1)$ greater than 10 ergs/cm^2 by using an approximate value (on the volume fraction scale) for the σ on the right-hand side of each equation to obtain an explicit function in each case. The approximate σ is indicated by σ' in these formulae.

$$[41]\quad \sigma=\sigma_1-\frac{RT}{A_1}\left\{\ln\left\{1+\phi_2\left\{\exp\left[\frac{\sigma'(A_2-A_1)}{RT}\right]\exp\left[\frac{(\sigma_1A_1-\sigma_2A_2)}{RT}\right]-1\right\}\right\}\right\}$$

$$[42]\quad \sigma=\sigma_1-\frac{RT}{A_1}\left\{\ln\left\{\phi_1\left[1+\phi_2\left(1-\frac{V_1}{V_2}\right)\right]+\phi_2\left[1+\phi_1\left(1-\frac{V_2}{V_1}\right)\right]\exp\left[\frac{\sigma'(A_2-A_1)}{RT}\right]\times\exp\left[\frac{(\sigma_1A_1-\sigma_2A_2)}{RT}\right]\right\}\right\}$$

$$[43]\quad \sigma=\sigma_1-\frac{RT}{A_1}\left\{\ln\left\{\phi_1\left[1+\phi_2\left(1-\frac{V_1}{V_2}\right)\right]+\phi_2\left[1+\phi_1\left(1-\frac{V_2}{V_1}\right)\right]\exp\left[\frac{\sigma'(A_2-A_1)}{RT}\right]\times\exp\left[\frac{\sigma_1A_1-\sigma_2A_2}{RT}\right]-\phi_1\phi_2\left[\left(1-\frac{V_1}{V_2}\right)+\left(1-\frac{V_2}{V_1}\right)\right]\exp\left[(\sigma'-\sigma_2)\frac{A_2}{RT}\right]\right\}\right\}$$

These implicit and explicit equations for the surface tensions of binary mixtures have been tested to determine the practical usefulness of these equations for a large variety of binary organic systems for large and small polarity differences.

Discussion and Conclusions

A variety of binary systems were chosen from the literature with increasing $(\sigma_2 - \sigma_1)$ values. Table 1 details the average percentage error found using different explicit functions to account for the concentration dependence of the surface tension of these binary solutions. There is generally some improvement in accuracy using the volume fraction ideal equation G over the corresponding ideal mole fraction statistics form A. With increasing $(\sigma_2 - \sigma_1)$ difference, there is an increasing deviation from ideal equations behaviour no matter what form of ideal equation is used, i.e., mole fraction statistics, area fraction statistics or volume fraction statistics (columns A, B, G, and H respectively). Columns J and K (volume fraction statistics) indicate what effect the first and second order perturbation terms (eqs. [19] and [22] and eqs. [32] and [33]) have when added to the linear ideal surface tension equation. As is observed, the resultant equations are able to account for the concentration dependence of the surface tension of binary solutions with a wide range of polarity (polar–polar, non-polar–non-polar, and non-polar–polar) to within an average error of less than 1%.

For some systems, however, (e.g. $BrCH_2CH_2Br$ +

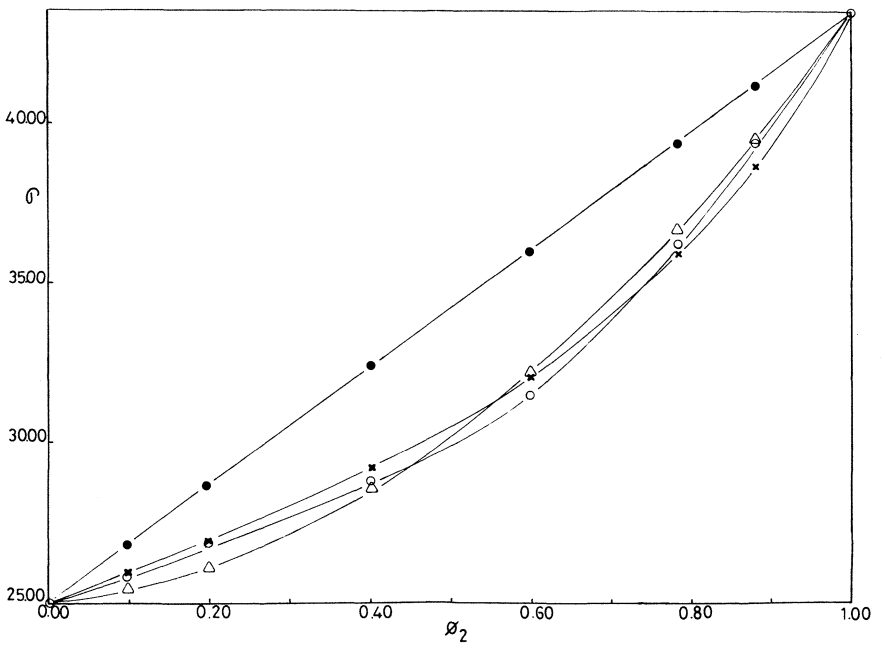

FIG. 1. Test of surface tension equations for cyclohexane–nitrobenzene (data of Table 3*b*) on volume fraction scale ϕ: Experimental ○, G, ●, △, L; ×, L, d. Letters refer to equations detailed in footnote to Table 1.

C_6H_6; $C_6H_5OH + C_6H_6$), the average error is substantially larger. This most probably is due to surface orientation effects which would require molar area values A_i much different (generally smaller) than those calculated using the assumption that the bulk density gives a good first estimate of these molar area values. The other possible explanation of this deviation is that the mixtures do not form ideal solutions to a first approximation. Activity coefficient effects could be invoked to account for this, possibly by using regular solution behaviour. For over 90% of the binary systems studied, however, the ideal solution approximation coupled with the use of bulk densities for calculating molar area values has been shown to be useful.

For those systems with $(\sigma_2 - \sigma_1)$ values greater than 20 as indicated in the theory section, substantial errors are found when using the explicit forms of these surface tension equations. Furthermore, the higher order expansion terms generally show diverging values. For such systems the implicit surface tension equations were tested and examples of this test are given in Table 2. On comparing the average error for calculating surface tensions of the same system either by the explicit or implicit methods, it is generally found that a decrease in error is found by using the less complex implicit equations (e.g. $C_6H_6 + C_6H_{12}$; $C_6H_{12} + C_6H_5Cl$; $C_6H_6 + C_6H_5NO_2$). Furthermore, it is generally found that equations based on volume fraction statistics give

better fits to the observed surface tension data than do equations based on mole fraction statistics.

For those systems where the explicit higher order terms in the equations for the surface tension showed divergence, it was found that the implicit forms of the surface tension equations gave excellent fits to the data, i.e. less than 1% average error.

Table 3 *a* and *b* illustrate a detailed set of calculations for two systems for all the explicit and implicit formulae derived in the theory section (the large capital letters indicate explicit surface tension functions and the small capital letters indicate implicit surface tension functions). The cyclohexane–nitrobenzene systems illustrate for a non-polar–polar system how well the simple explicit functions as well as the more complex implicit functions are able to account for the data with the elementary assumptions made about the system. These same data are displayed in Fig. 1.

The system glycerin–ethanol was chosen to illustrate the fact that for very large differences in $(\sigma_2 - \sigma_1)$ e.g. greater than 30, neither the explicit nor the implicit equations are able to account for the data. This is particularly true of aqueous systems. Obviously for such systems the assumption of ideal or near-ideal solutions is not valid and activity coefficients in the surface and bulk chemical potential equations would have to be taken into account in deriving surface tension equations for such mixtures. A systematic approach to this problem is presently underway. These data are displayed in Table 3 *a* and *b* as well as in Fig. 2.

In conclusion, the surface tension equations which have been derived both in their implicit and explicit forms are able to account for the composition dependence of the surface tension of a wide variety of binary organic systems with $(\sigma_2 - \sigma_1)$ values 20 or less. This includes polar–non-polar mixtures which have not been accounted for previously (1). Surface orientation effects seem to be insignificant for most systems studied, although a small percentage of the systems, where larger errors persist no matter what form of the surface tension is used, may indicate the presence of such orientation factors. A detailed study of surface entropy effects in such systems is also underway in order to elucidate this factor.

Received January 22, 1981

GEORGE JUST, YOULA S. TSANTRIZOS, and ANTONIO UGOLINI. Can. J. Chem. **59**, 2981 (1981).
The synthesis of the title compound is described.

GEORGE JUST, YOULA S. TSANTRIZOS et ANTONIO UGOLINI. Can. J. Chem. **59**, 2981 (1981).
La synthèse du produit nommé est décrite.

[Traduit par le journal]

As part of a continuing program to prepare nonclassical β-lactam antibiotics (for rationale, see ref. 1), in which a phenolic group replaces the carboxylic function of penicillins and cephalosporins, we wish to describe the synthesis of title compound **18** and its nitro analogues. Recently, Doyle (2) has described a similar compound differing from **18** only in the nature of the side-chain and the position of the phenolic hydroxy group, which was attached *para* to the ether function.

o-Aminophenol **1** and 2-aminoresorcinol **4** were transformed to their dimethyl-*tert*-butylsilyl ethers **2** and **5**. Amines **2** and **5** were converted to their cinnamylidene Schiff bases **3** and **6**, and, without purification, treated with azidoacetyl chloride and triethylamine at −20°C.

β-Lactams **7**, mp 84–85°C, and **8**, mp 95–96°C, were obtained in good yield after column chromatography and crystallization. The presence of the azide and β-lactam functions was confirmed by ir absorption bands at 2100, and 1760 and 1770 cm^{-1} respectively. The stereochemistry could not be assigned at this point because of overlapping signals in the ^{1}Hmr spectrum. However, all ^{1}Hmr spectra of compounds **9**–**21** showed $J_{3,4} \simeq 5$ Hz, indicating that the substituents on the β-lactam ring were *cis* (3).

Ozonolysis of **7** in methanol at −78°C, followed by sodium borohydride reduction (−40° → +20°C), gave alcohol **9**, mp 77°C. Alcohol **9** was converted with little difficulty to the corresponding mesylate **11**, and, by means of thionyl chloride – pyridine in boiling benzene, to chloride **13**.

In order to study the cyclization reaction, mesylate **11** and chloride **13** were used as model compounds. Treatment of a tetrahydrofuran solution of either mesylate **11** or chloride **13** with freshly prepared tetra-*n*-butylammonium fluoride (4) gave instantaneously a quantitative yield of tricyclic azide **15**, mp 77–78°C.

This sequence was then applied to the disilylazido-β-lactam **8**. Ozonolysis of **8** in methanol at −78°C as described for monosilyl-β-lactam **7** proceeded in very poor yield. However, when the reaction was carried out in ethanol – methylene chloride (4:1) at −78°C, and the crude ozonide reduced with sodium borohydride (−40° → +20°C), alcohol **10** was obtained in good yield. Treatment of **10** with methanesulfonyl chloride and triethylamine in methylene chloride at −78°C gave mesylate **12**.

Reaction of mesylate **12** with exactly one equivalent of tetra-*n*-butylammonium fluoride in dry tetrahydrofuran gave tricyclic azide **16**, mp 69–70°C. Since the amount of fluoride added turned out to be extremely critical, and the reaction was virtually a titration with no easily determined end-point except by tlc, a more controllable set of reaction conditions was sought. Treatment of an acetonitrile solution of disilylether **12** with 1.2 equiv. of potassium fluoride and 0.3 equiv. of 18-crown-6 effected the same transformation to **16** in about 6 hours, permitting easy monitoring of the reaction. The reaction conditions turned out not to be critical, and the amounts of 18-crown-6 and potassium fluoride could be varied with impunity.

Tricyclic azido-β-lactam **15** exhibited a clean, nearly first-order ^{1}Hmr spectrum in deuterobenzene at 100 MHz for protons A–D. Proton A appeared at 4.18 ppm (J_{AB} = 5.0 Hz). Proton B (3.10 ppm) was coupled to A (J_{BA} = 5.0 Hz), C (J_{BC} = 3.5 Hz), and D (J_{BD} = 10 Hz). Protons C (3.36 ppm) and D (3.87 ppm) showed geminal coupling of 10 Hz, giving the spectrum a deceptively simple appearance reproduced below (Fig. 1). Hydrogen

sulfide – triethylamine reduction of **16** followed by acylation with phenylacetyl chloride, gave amide **17** in 54% yield, based on **8**. Removal of the silyl group gave tricyclic amide **18**, mp 194–195°C. The same compound could be obtained using the alternate route **12** → **21** → **17** → **18**. It should be noted that the potassium fluoride/18-crown-6 cyclization method could not be used for the transformation **21** → **17**, and the tetra-*n*-butylammonium fluoride method had to be employed.

For comparison purposes, alcohol **9** was silylated, and the resulting silyl ether **14** transformed by the methods described to the phenylacetamido-β-lactam **19**, which was hydrolyzed to **20**. Whereas bicyclic β-lactam **20** showed no biological activity, when tested against a variety of microorganisms in concentrations up to 256 μg/mL (MIC), tricyclic β-lactam **18** inhibited the growth of *S.aureus* (Q74-1) and *S.lutea* (PCI-1001) at 128 and 64 μg/mL respectively.

High anti-bacterial activity has usually been associated with chemical reactivity of the β-lactam ring, which is normally induced by steric strain. In a system such as **18**, increased reactivity of the β-lactam ring can, in principle, be induced by substituting the phenyl ring with an electron-withdrawing substituent such as a nitro group. In order to obtain a tricyclic β-lactam in which a nitro group is substituted *para* to the β-lactam nitrogen (see **15**), one would have to use as starting material an *o*,*o*′-disilyloxy-*p*-nitroaniline. We have shown

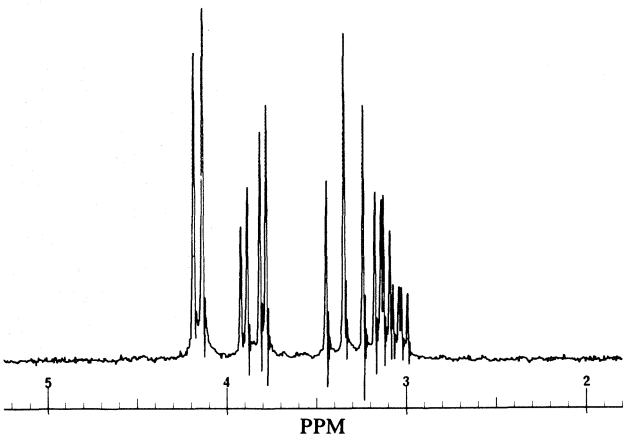

FIG. 1

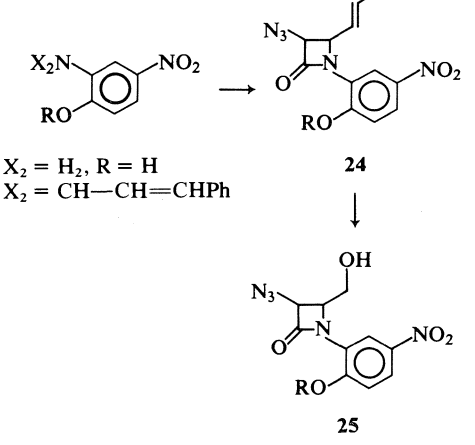


22 $X_2 = H_2$, R = H
23 X_2 = CH—CH=CHPh

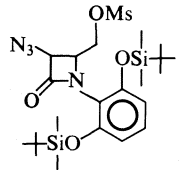
24

25

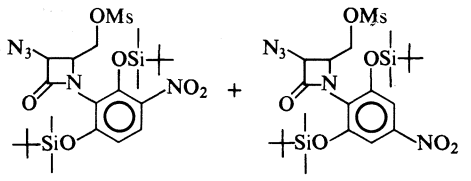
a, R = *t*-BuSiMe_2
b, R = *t*-BuSiPh_2

that *o*-dimethyl-*tert*-butylsilyloxy-*p*-nitroaniline is converted to the corresponding *trans*-fused β-lactam only (5).

We therefore used 2-hydroxy-5-nitroaniline **22** as model. Silylation with either *tert*-butyldimethyl or *tert*-butyldiphenylsilyl chloride gave silyl ethers **22***a* and **22***b*, which were converted via their cinnamylidene derivatives **23***a* and **23***b* to β-lactams **24***a* and **24***b*. Both **24***a* and **24***b* were extremely labile to reductive ozonolysis reaction conditions, and little **25** could be isolated, the side-products being silanol and other unidentified products. Because of the lability of the *p*-nitrosilyl ethers to reductive ozonolysis conditions, we next investigated the nitration of the relatively unstrained β-lactam **12**, and cyclization of the resulting nitro derivatives, **26** and **27**.



12



26 **27**

β-Lactam **12** was treated with nitronium tetrafluoroborate at −20°C and, as expected, two compounds (**26** and **27**) were detected in the reaction mixture. Attempts to purify the mixture, which was well separated on thin layer chromatography, proved unsuccessful, resulting in complete decomposition of **27** and extensive desilylation of **26**.

It is known that *p*-nitrophenols ($pK_A = 7.2$) (7) behave almost like carboxylic acids, and it is therefore to be expected that the *p*-nitrosilyl ether **26** would be extremely unstable to hydrolysis, as are silyl esters. In **27**, the nitro substituent *para* to the β-lactam ring introduces so much chemical reactivity that the amide linkage is easily hydrolyzed on contact with silica gel.

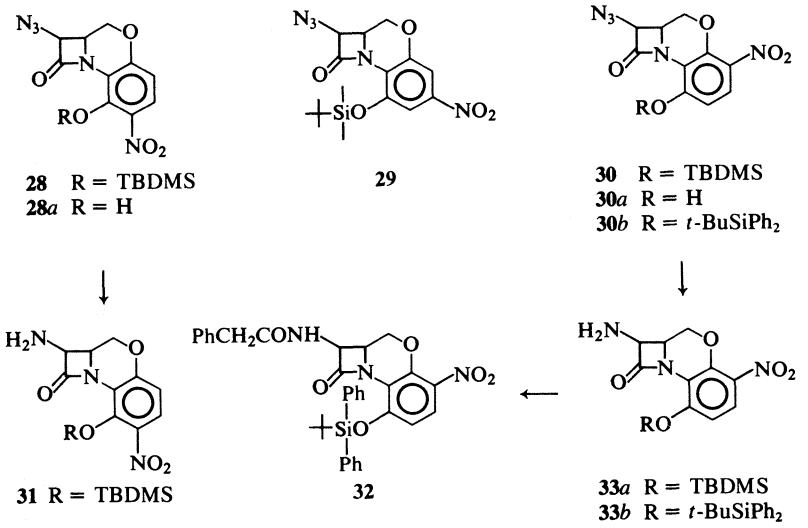
Nitration of silyloxy azido-β-lactam **16** showed very similar complications. The ^{1}Hmr spectrum of the crude reaction mixture clearly showed the presence of three compounds (**28**, **29**, and **30**), characterized by three sets of doublets, two having a large coupling constant ($J = 9$ Hz), as would be expected for *ortho* protons (**28**, **30**), and one set at about 7.4 ppm with the two doublets overlapping and a small coupling constant of 3 Hz indicating *meta* protons (**29**). Attempts to separate the three compounds by chromatography lead to complete decomposition of **29** and some desilylation of **28** and **30**. The latter were found to be sensitive to moisture and traces of acid, even after crystallization. The ^{1}Hmr spectra of **28** and **30** in deuterobenzene were virtually identical. However, in deuterochloroform the two methyl groups attached to silicon appeared in **28** as two 3H singlets at approximately 0.2 ppm downfield from the corresponding 6H singlet in **30**, indicating hindered rotation of the silyloxy group in **28**. This assignment was further corroborated by mass spectrometric data: *o*-nitro substituted phenyl ethers and amines are characterized by intense ions of mass $M^{+\cdot} - OR^{\cdot}$ (6).

The very intense peak at *m/e* 260 ($M^{+\cdot}$ − $OSiMe_2$-*tert*-butyl$^{\cdot}$) seen in the mass spectrum of compound **28** is almost completely absent from the spectrum of **30**.

Both compounds show intense ions at *m/e* 334 (base peak, $M^{+\cdot}$ − *tert*-butyl$^{\cdot}$), 306 (334 − $N_2^{\cdot}$, from the azide group), 251 (334 − 83, 83 = COCH—N_3), and 205 (251 − $NO_2^{\cdot}$).

A mixture of **28** and **30** was reacted with hydrogen sulfide – triethylamine to obtain the unstable amines **31** and **33***a* in good yield. Further reaction of **31** or **33***a* with phenylacetyl chloride was unsuccessful, initially leading to hydrolysis of the silyl ether, followed by hydrolysis of the β-lactam ring, as evidenced by ^{1}Hmr, which showed the presence of silanol, and ir, which showed a decrease in intensity of the β-lactam absorption with time.

We then thought that protection of the phenol group with diphenyl-*tert*-butylsilyl chloride would give a more stable β-lactam. It was found that treatment of phenol **30***a* with diphenyl-*tert*-butylsilyl chloride – triethylamine gave compound **30***b* which was well characterized by its ^{1}Hmr spectrum. However, phenol **28***a* was unreactive under the same conditions, further confirming that the phenolic group was sterically hindered by the presence of an *ortho* nitro substituent. The azide function of diphenyl-*tert*-butylsilyl ether **30***b* was then reacted with hydrogen sulphide – triethylamine and the progress of the reaction was followed by the disappearance of the infrared absorption of the azide. Upon complete formation of amine **33***b*,



an equivalent of triethylamine was added along with an equivalent of phenylacetyl chloride to form final product **32**.

The ^{1}Hmr spectrum of **32** clearly showed the presence of all expected proton resonances: a singlet at 3.5 ppm (—COCH_2Ph), a multiplet at 3.3–3.6 ppm due to H_B, two sets of doublets at 3.8 to 4.6 ppm, coupled to each other and each integrating to one proton (H_C and H_D). H_A was found as a doublet of doublets at 5.1 to 5.3 ppm with one of its coupling constants equal to that of the broad doublet (due to NH) at 8.0 ppm. Finally, two doublets (6.6 and 8.7 ppm) were seen coupled to each other by a large coupling constant of 9 Hz, characteristic of the *ortho* protons on the nitrobenzene ring.

The infrared spectrum of **26** was also consistent with the structure given, with an absorption of 1790 cm^{-1} for the carbonyl group of the β-lactam.

Unfortunately, mass spectrometry and elemental analysis could not be used to further support the structure of **32** due to the extreme instability of this compound. It was observed through ^{1}Hmr and ir studies that even the traces of moisture or acid found in DMSO-d_6 would cause rapid decomposition of the silyl ether, followed by hydrolysis of the β-lactam ring, within half an hour.

Biological studies of these compounds were inconclusive due to complete decomposition of these compounds within a short time. We therefore showed that a nitro substituent introduces greater reactivity than desired and perhaps replacement of this group with a less electron withdrawing substituent such as an ester might lead to more stable and perhaps biologically active products.

Experimental

Thin-layer chromatography (tlc) was performed on Merck Silica Gel 60 F_{254} aluminum-backed plates. Flash chromatography was done on Woelm Silica (32–63 μ). Melting points (mp) were measured on a Gallenkamp block and are uncorrected, unless specified otherwise. The nmr spectra were recorded on Varian T-60, T-60A, and where noted, HA-100 and XL-200 spectrometers. Infrared (ir) spectra were recorded on Pye Unicam SP-1000, Perkin Elmer 257 and 297 spectrophotometers. Mass spectra (ms) were obtained on HP 5984A or LKB 9000 spectrometers, in the direct inlet mode unless indicated otherwise. Elemental analyses were performed by Midwest Microlab Ltd., Indianapolis.

*Di-*tert*-butyldimethylsilyl-2-aminoresorcinol 5*

A suspension of 2-nitroresorcinol (15 g, 97 mmol) and PtO_2 (1 g) in absolute ethanol (250 mL) was hydrogenated in a Parr apparatus at 40 psi. Filtration through Celite and evaporation of the rapidly darkening filtrate afforded 12 g of amine **4** as a brown solid. This amine was added to *tert*-butyldimethylsilyl chloride (32 g, 211 mmol) and imidazole (33 g, 485 mmol) in dry DMF (75 mL), and let stir overnight at room temperature. Then water (300 mL) was added and the solution extracted thrice with ether (300, 50, 50 mL). The ether extract was washed with water (3 × 100 mL), then brine (100 mL), then dried ($MgSO_4$) and evaporated. Chromatography of the residue on SiO_2 (250 g) afforded 20 g (59%) of amine **5** as a brownish oil; ^{1}Hmr ($CDCl_3$) δ: 0.2 (s, 12H, $SiMe_2$), 1.0 (s, 18H, *t*-BuSi), 3.47 (bs, 2H, NH_2), 6.27 (s, 3H, C_6H_3).

β-Lactam Azide 8

Amine **5** (14.2 g, 40 mmol) and cinnamaldehyde (5.6 g, 42 mmol), in benzene (150 mL), with a trace of *p*-TsOH, were refluxed overnight using a Dean–Stark trap. Evaporation of the solvent afforded Schiff base **6** as a thick brown oil. To this Schiff base, in CH_2Cl_2 (250 mL) containing triethylamine (5.3 g, 52 mmol), at −20°C was added dropwise azidoacetyl chloride (6.2 g, 52 mmol) in CH_2Cl_2 (50 mL), over 1 h. The red-brown solution was stirred for an additional hour at −20°C, and then allowed to warm up. Washing with water (2 × 150 mL) and brine (150 mL), then drying ($MgSO_4$) and evaporation of the solvent afforded, after chromatography on SiO_2 (300 g, $CHCl_3$), 13 g (59%) of β-lactam **8** as a thick brown oil, which crystallized upon trituration with

petroleum ether, mp 95–96°C; ir (film) ν_{max}: 2900, 2100 (N_3), 1770 (β-lactam), 1580 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.24, 0.3 (2s, 12H, $SiMe_2$), 1.03 (s, 18H, *t*-BuSi), 4.8–5.0 (m, 2H, CH—CHN_3), 6.4–7.3 (m, 10H, C_6H_3 and CH=CH—C_6H_5).

β-Lactam Azide **7** was prepared as described for **8**; 63% yield, mp 84–85°C; ir ($CHCl_3$) ν_{max}: 2100 (N_3), 1760 (β-lactam) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.28 (s, 6H, $SiMe_2$), 1.03 (s, 9H, *t*-BuSi), 4.88 (d, 1H, CHN_3), 5.02 (dd, 1H, C*H*—CHN_3), 6.1 (dd, 1H, C*H*=CH—Ph, *J* = 7, 15 Hz), 6.57 (d, 1H, C*H*—Ph, *J* = 15 Hz), 6.6–7.5 (m, 9H, C_6H_5 and C_6H_4).

Azido Alcohol ***10***

Ozone was bubbled through a solution of β-lactam **8** (7 g, 12.7 mmol) in EtOH (200 mL) and CH_2Cl_2 (50 mL) at −78°C. Excess ozone was flushed out with N_2 and $NaBH_4$ (0.95 g, 25 mmol) was added at −40°C. After warming to room temperature, pH 4.5 buffer (200 mL) was added and the ethanol removed under reduced pressure. The aqueous residue was extracted with ether (3 × 100 mL) and the ether washed with brine (100 mL), dried ($MgSO_4$), and evaporated to a yellow oil, which was chromatographed on SiO_2 to give 4.5 g (74%) of a viscous pale yellow oil. Crystallization was induced, by addition of a little pentane, giving β-lactam **10** as white needles, mp 99.5–100°C; ir (film) ν_{max}: 3500 (OH), 2100 (N_3), 1765 (β-lactam), 1590 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.26, 0.30 (2s, 12H, $SiMe_2$), 1.05 (s, 18H, *t*-BuSi), 2.5 (bs, 1H, OH), 3.8 (bs, 2H, CH_2), 4.1 (dt, 1H, C*H*—CH_2—OH, *J* = 5, 5 Hz), 4.7 (d, 1H, CH—N_3, *J* = 5 Hz), 6.4–7.2 (m, 3H, C_6H_3).

Azido Alcohol **9** was prepared as described for **10**; 88% yield, mp 77–77.5°C; ^{1}Hmr ($CDCl_3$) δ: 0.25 (s, 6H, $SiMe_2$), 0.98 (s, 9H, *t*-BuSi), 2.30 (bt, 1H, OH), 3.83 (bdd, 2H, CH_2), 4.46 (dt, 1H, C*H*—CH_2, *J* = 4, 5 Hz), 4.87 (d, 1H, CHN_3, *J* = 5 Hz), 6.7–7.7 (m, 4H, C_6H_4).

Azido Mesylate ***12***

To alcohol **10** (4 g, 8.4 mmol) in CH_2Cl_2 (100 mL) and Et_3N (1 g, 10 mmol) at −78°C was added dropwise MsCl (1.1 g, 10 mmol) in CH_2Cl_2 (10 mL). The solution was stirred for 0.5 h at −78°C and allowed to warm to room temperature. After 1 h the solution was washed with water (2 × 75 mL), then brine (75 mL), dried ($MgSO_4$), and evaporated to give a pale yellow oil, which crystallized *in vacuo*. Trituration with petroleum ether yielded 4.4 g (95%) of mesylate **12** as white crystals, mp 69–70.5°C; ir (film) ν_{max}: 2900, 2100 (N_3), 1780 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.24, 0.27 (2s, 12H, 2$SiMe_2$), 1.0 (s, 18H, 2*t*-BuSi), 2.86 (s, 3H, SCH_3), 4.45 (bm, 3H, CH—CH_2), 4.94 (m, 1H, CHN_3), 6.4–7.2 (m, 3H, C_6H_3).

Azido Mesylate β-Lactam **11** was prepared as described for **12**; 85% yield; ir (film) ν_{max}: 2110 (N_3), 1770 (β-lactam) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.28 (s, 6H, $SiMe_2$), 1.02 (s, 9H, *t*-BuSi), 2.87 (s, 3H, SO_2CH_3), 4.47 (m, 2H, CH_2), 4.80 (m, 1H, C*H*—CH_2), 5.10 (d, 1H, CHN_3, *J* = 4.5 Hz), 6.8–7.8 (m, 4H, C_6H_4).

Chloro β-Lactam ***13***

Alcohol **9** (0.5 g, 1.4 mmol) was refluxed for 2 h in benzene (25 mL), containing thionyl chloride (0.2 g, 1.7 mmol) and pyridine (0.14 g, 1.7 mmol). This mixture was added to ether (25 mL) and then washed with water (2 × 30 mL) and brine (30 mL). Treatment with charcoal and drying ($MgSO_4$), followed by filtration and evaporation of the solvent afforded 0.46 g (87%) of chloride **13** as a white solid, mp 77–78°C (Et_2O–hexane); ir (film) ν_{max}: 2110 (N_3), 1765 (β-lactam) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.32 (s, 6H, $SiMe_2$), 1.03 (s, 9H, *t*-BuSi), 3.75 (m, 2H, CH_2), 4.75 (m, 1H, C*H*—CH_2), 5.05 (d, 1H, CHN_3, *J* = 4.5 Hz), 6.8–7.8 (m, 4H, C_6H_4).

Disilyl Ether **14** was prepared according to the procedure described by Corey and Venkoteswarlu (8); ^{1}Hmr ($CDCl_3$) δ: −0.10, −0.15 (2s, 6H, $SiMe_2$), 0.20 (s, 6H, $SiMe_2$), 0.75, 0.92 (2s, 18H, 2*t*-BuSi), 3.75 (d, 2H, CH_2, *J* = 5 Hz), 4.40 (dt, 1H, C*H*—CH_2, *J* = 5,5 Hz), 4.65 (d, 1H, C*H*N_3, *J* = 5 Hz), 6.6–7.6 (m, 4H, C_6H_4).

β-Lactam Amide **19** was prepared as described for **21**; ir ($CHCl_3$) ν_{max}: 3400 (NH), 1755 (β-lactam), 1680 (amide) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: −0.37, −0.23 (2s, 6H, $SiMe_2$), 0.20, 0.24 (2s, 6H, $SiMe_2$), 0.80, 0.95 (2s, 18H, 2*t*-BuSi), 3.52 (s, 2H, CH_2Ph), 3.72 (broad *ABX*, 2H, CH_2O), 4.47 (bd, 1H, C*H*—CH_2, *J* = 5.5 Hz), 5.60 (dd, 1H, C*H*—NH, *J* = 5.5, 10 Hz), 6.5–7.9 (m, 10H, C_6H_4, C_6H_5, NH).

Tricyclic β-Lactam **15** was prepared from **11** or **13** as described for **16**, mp 77–78°C; ir (KBr) ν_{max}: 2120 (N_3), 1780 (β-lactam) cm^{-1}; ^{1}Hmr 100 MHz (C_6D_6) δ: 3.10 (ddd, 1H, C*H*—CH_2, *J* = 3.5, 5.0, 10 Hz), 3.36 (dd, 1H, CH—C*H*H, *J* = 10,10 Hz), 3.87 (dd, 1H, CH—CH*H*, *J* = 3.5, 10 Hz), 4.18 (d, 1H, CHN_3, *J* = 5.0 Hz), 6.6–7.4 (m, 4H, C_6H_4); ms (70 eV, 30°C), *m/e* (‰): 216 (330, $M^{+\cdot}$), 188 (250, $M^{+\cdot} - N_2$), 135 (1000), 133 (455, $M^{+\cdot}$ − O=C=CH—N_3), 84.4 (M*, 216 → 135).

Tricyclic β-Lactam ***16***

To mesylate **12** (400 mg, 0.72 mmol) in dry THF (30 mL) at 0°C was added dropwise *n*-Bu_4NF (0.76 mmol) in dry THF (10 mL), over 15 min. Dilution with pH 4.5 buffer (KH_2PO_4, 40 mL) and extraction with ether (3 × 50 mL) afforded, after chromatography of the residue on SiO_2 (CH_2Cl_2), 226 mg (91%) of tricyclic β-lactam **16** as a pale yellow oil which crystallized on standing, mp 69–70°C; ir (film) ν_{max}: 2900, 2100 (N_3), 1775 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.22, 0.30 (2s, 6H, $SiMe_2$), 1.0 (s, 9H, *t*-BuSi), 3.95 (m, 2H, CH_2), 4.56 (m, 1H, C*H*—CH_2), 5.24 (d, 1H, CHN_3, *J* = 5 Hz), 6.55–6.94 (m, 3H, C_6H_3).

Procedure B

To mesylate **12** (3.42 g, 6.2 mmol) in dry CH_3CN (80 mL) was added anhydrous KF (0.43 g, 7.4 mmol) and 18-crown-6 (0.49 g, 1.9 mmol). Upon completion of the reaction, as indicated by tlc (6–8 h), the solution was diluted with water (100 mL) and extracted with CH_2Cl_2 (3 × 80 mL), which was then washed with brine (100 mL), dried ($MgSO_4$), and evaporated to give 2.0 g (95%) of tricyclic β-lactam **16**, after chromatography.

Amino β-Lactam ***16a***

Into azide **16** (2.1 g, 6.1 mmol) dissolved in CH_2Cl_2 (80 mL) and Et_3N (0.61 g, 6.1 mmol) at 0°C was bubbled H_2S for 10 min. The solution was allowed to warm, and after stirring for 1 h at room temperature, nitrogen was bubbled through the solution for 0.5 h. The solution was then washed with H_2O (2 × 50 mL) and brine (50 mL), then dried ($MgSO_4$), and evaporated. The oily residue was flash chromatographed on silica gel, using ethyl acetate – petroleum ether (3:1), affording 1.65 g (85%) of amine **16*a*** as a white solid, mp 135–136°C (recrystallized from ether); ir (film) ν_{max}: 3400 and 3330 (NH_2), 2900, 1765 (C=O) cm^{-1}; ^{1}Hmr (C_6D_6) δ: 0.22, 0.30 (2s, 6H, $SiMe_2$), 0.9 (bs, 2H, NH_2), 1.13 (s, 9H, *t*-BuSi), 3.15 (ddd, 1H, O—CH_2—C*H*, *J* = 3.5, 4.6, 10 Hz), 3.5 (dd (apparent triplet), 1H, O—C*H*H—CH, *J* = 10, 10 Hz), 3.95 (bs, 1H, C*H*NH_2), 4.1 (dd, 1H, O—CH*H*—CH, *J* = 3.5, 10 Hz), 6.4–6.9 (m, 3H, C_6H_3); ms (70 eV, 51°C), *m/e* (‰): 320 (22, $M^{+\cdot}$), 305 (54, $M^{+\cdot} - CH_3$), 292 (428), 263 (1000, $M^{+\cdot} - 57$), 248 (290, $M^{+\cdot} - 15 - 57$), 235 (314), 216.2 (M*, 320 → 263), 189.1 (M*, 292 → 235). *Anal.* calcd. for $C_{16}H_{24}N_2O_3Si$: C 59.97, H 7.55, N 8.74; found: C 59.59, H 7.61, N 8.74.

β-Lactam Amide ***17***

To amine **16*a*** (640 mg, 2 mmol) and Et_3N (242 mg, 2.4 mmol)

in CH_2Cl_2 (20 mL) at 0°C was added dropwise phenylacetyl chloride (370 mg, 2.4 mmol) in CH_2Cl_2 (5 mL), over a period of 5 min. The solution was allowed to warm and, after stirring for 1 h at room temperature, was washed with pH 4.5 buffer (20 mL) and H_2O (20 mL), dried ($MgSO_4$), and evaporated. Chromatography of the residue on SiO_2, eluting successively with CH_2Cl_2, $CHCl_3$, and ether, afforded 750 mg (86%) of amide **17** as fine needles from ether, mp 161–162°C; ir (film) ν_{max}: 3300 (NH), 2900, 1780 (β-lactam), 1670 (amide) cm^{-1}; ^{1}Hmr 200 MHz ($CDCl_3$) δ: 0.15, 0.22 (2s, 6H, $SiMe_2$), 0.96 (s, 9H, *t*-BuSi), 3.56 (s, 2H, CH_2Ph), 3.62 (dd, 1H, C*H*H—CH, J = 10, 10 Hz), 3.93 (ddd, 1H, CH_2CH, J = 3.5, 5.0, 10 Hz), 4.38 (dd, 1H, CH*H*—CH, J = 3.5, 10 Hz), 5.46 (dd, 1H, C*H*NH, J = 5, 7 Hz), 6.4 (2 dd, 2H, C*H*—CH—C*H* on C_6H_3, J = 1, 8 Hz), 6.53 (bd, 1H, NH, J = 7 Hz), 6.83 (dd, 1H, CH—C*H*—CH, on C_6H_3, J = 8, 8 Hz), 7.25 (m, 5H, C_6H_5); ms (70 eV, 91°C), *m/e* (‰): 438 (311, $M^{+\cdot}$), 423 (26, $M^{+\cdot} - CH_3^{\cdot}$), 381 (130, $M^{+\cdot} - t$Bu$^{\cdot}$), 264 (1000), 206 (732), 159.1 (M*, 438 → 264), 111.4 (M*, 381 → 206).

Phenol β-*Lactam* ***18***

To silyl ether **17** (240 mg, 0.55 mmol) in dry THF (15 mL) at 0°C was added *n*-Bu_4NF (0.61 mL, 1 *M*), in dry THF (4 mL), dropwise over 10 min. After stirring for 15 min, pH 4.5 buffer (15 mL) was added, and half the THF removed under reduced pressure. Extraction with ethyl acetate (30 mL) followed by evaporation afforded 92 mg (52%) of phenolic β-lactam **18** as fine needles, mp 194–195°C, from ethyl acetate – petroleum ether; ir (Nujol) ν_{max}: 3280 (NH, OH), 1760 (β-lactam), 1655 (amide) cm^{-1}; ^{1}Hmr 200 MHz ($OC(CD_3)_2$) δ: 3.62 (s, 2H, CH_2Ph), 4.07 (dd, 1H, C*H*HCH, J = 10, 10 Hz), 4.18 (ddd, 1H, CH_2CH, J = 3.3, 4.5, 10 Hz), 4.47 (dd, 1H, CH*H*CH, J = 3.3, 10 Hz), 5.66 (dd, 1H, C*H*NH, J = 4.5, 8 Hz), 6.50 (2dd, 2H, C*H*—CH—C*H* on C_6H_3, J = 1, 8 Hz), 6.92 (dd, 1H, CH—C*H*—CH on C_6H_3, J = 8, 8 Hz), 7.32 (m, 5H, C_6H_5), 7.99 (bd, 1H, NH, J = 8 Hz); ms (70 eV), *m/e*(‰): 324 (103, $M^{+\cdot}$), 205 (12, $M^{+\cdot} - PhCH_2CO^{\cdot}$), 175 (30), 149 (54), 150 (1000), 91 (398).

Hydroxy Phenol β-*Lactam* **20** was prepared as described for **18**, 97% yield, mp 174–175°C dec. (corr.); ir (CH_3CN) ν_{max}: 3400 (OH, NH), 1720 (β-lactam), 1680 (amide) cm^{-1}; ^{1}Hmr ($OC(CD_3)_2$) δ: 3.1 (b, 2H, 2 OH), 3.80 (s, 2H, CH_2Ph), 4.07 (*ABCX*, 2H, CH_2OH, J = 2.5, 3.0, 12.5 Hz), 4.75 (ABC*X*, 1H, C*H*—CH_2, J = 2.5, 3.0, 5.0 Hz), 5.72 (ABC*X*, dd, 1H, C*H*—NH, J = 5.0, 10 Hz), 6.8–7.7 (m, 10H, C_6H_4, C_6H_5, NH); gc–ms (TMS derivative) (70 eV), *m/e* (‰): component 1: 542 (4, $M^{+\cdot}$, tri-TMS derivative), 527 (17, $M^{+\cdot} - CH_3^{\cdot}$), 439 (30, $M^{+\cdot}$ – TMS—O—$CH_2^{\cdot}$), 335 (210, $M^{+\cdot}$ – TMS—O—Ar—N=C=O); component 2: 470 (56, $M^{+\cdot}$, di-TMS derivative), 455 (24, $M^{+\cdot} - CH_3^{\cdot}$), 296 (1000, $M^{+\cdot} - 174$).

Amide Mesylate 21

Hydrogen sulfide was bubbled through a solution of azido mesylate **12** (796 mg, 1.4 mmol) and Et_3N (0.2 mL, 1.4 mmol) in CH_2Cl_2 (75 mL) at 0°C for 10 min. The cooling bath was removed and stirring continued for 1 h, then nitrogen was flushed through the solution for 0.5 h. To this solution at 0°C was added Et_3N (0.26 mL, 1.8 mmol) followed by dropwise addition of phenylacetyl chloride (287 mg, 1.8 mmol) over 5 min. After stirring for 1 h at ambient temperature, the solution was washed with H_2O (3 × 50 mL) and brine (50 mL), then treated with $MgSO_4$ and charcoal, filtered, and evaporated to give 735 mg (79%) of crystalline amide **21**, upon trituration with hexane, mp 129–130°C; ir (CH_2Cl_2) ν_{max}: 3310 (NH), 1775 (β-lactam), 1685 (amide) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.20 (s, 12H, $SiMe_2$), 0.95 (s, 18H, *t*-BuSi), 2.80 (s, 3H, CH_3SO_2), 3.68 (s, 2H, CH_2Ph), 4.15–4.60 (m, 3H, CH_2CH), 5.35 (dd, 1H, C*H*NH, J = 4.4, 7 Hz), 6.0 (bd, 1H, NH, J = 7 Hz), 6.4–7.2 (m, 3H, C_6H_3), 7.37 (s, 5H, C_6H_5); ms (70 eV, 116°C), *m/e* (‰): 537 (8), 512 (23, $M^{+\cdot} - t$Bu$^{\cdot} - SO_2CH_3^{\cdot}$), 495 (131), 322 (1000).

Azido β-*Lactam* ***24***a

2-*tert*-Butyldimethylsiloxy-5-nitroaniline (7.5 g, 28 mmol) and cinnamaldehyde (4.1 g, 31 mmol), in benzene (100 mL) containing a trace of *p*-TsOH, were refluxed for 2 days using a Dean–Stark trap. The solvent was then evaporated and replaced by CH_2Cl_2 (250 mL). To this solution, at −20°C, was added triethylamine (3.7 g, 36 mmol) followed by dropwise addition of azidoacetyl chloride (4.3 g, 36 mmol), in CH_2Cl_2 (50 mL), over 1 h. The red-brown solution was stirred for an additional hour at −20°C, then allowed to warm up. Washing with water (2 × 200 mL), brine (200 mL), and drying ($MgSO_4$), then treating with charcoal and evaporating the solvent afforded 6.9 g (53%) of β-lactam ***24a*** as a pale yellow solid; mp 109–110°C (ether – petroleum ether); ir (film) ν_{max}: 2100 (N_3), 1770 (β-lactam) cm^{-1}; ^{1}Hmr (C_6D_6) δ: 0.10 (s, 6H, $SiMe_2$), 0.93 (s, 9H, *t*-BuSi), 4.35 (d, 1H, CH—N_3, J = 5.5 Hz), 4.58 (dd, 1H, C*H*—CHN_3, J = 5.5, 7.0 Hz), 5.9–6.7 (m, 2H, CH=CH), 6.42 (d, 1H, C_6H_3), 7.16 (m, 5H, C_6H_5), 7.60 (dd, 1H, C_6H_3), 8.46 (d, 1H, C_6H_3).

Azido β-*Lactam* ***24***b

tert-Butyldiphenylsilyl ether β-lactam ***24b*** was obtained, using the same procedure as for ***24a***, in 58% yield as fine white crystals, mp 159.5–160°C corr. (ether – petroleum ether); ir (film) ν_{max}: 2100 (N_3), 1780 (β-lactam) cm^{-1}; ^{1}Hmr (C_6D_6) δ: 1.22 (s, 9H, *t*-BuSi), 4.50 (m, 2H, CH—CHN_3), 6.33 (m, 3H, CH=CH, and C_6HH_2), 7.16 and 7.76 (2m, 16H, 3 C_6H_5 and C_6HH_2), 8.16 (d, 1H, C_6H_3).

Nitro Derivatives: 28 and 30

To a solution of **16** (574 mg, 1.6 mmol) in dry acetonitrile (20 mL) under nitrogen atmosphere at −20°C, nitronium tetrafluoroborate (3.2 mL, 0.5 *M* solution in sulfolane) was added dropwise. After 1 h, dry benzene (10 mL) was added and the mixture was stirred for 10 more minutes. The reaction mixture was then poured (while still very cold) into 30 mL of pH 4.5 buffer and extracted twice, dried ($MgSO_4$), and evaporated. The *ortho*-, *nitro*-, and *para*-nitrosilyl ether compounds were isolated and crystallized, after flash chromatography. The remaining mixture of nitrophenols was separated from sulfolane via Kugelrohr distillation, resilylated, and purified by flash chromatography to afford more of the desired products.

ortho-Silyl ether **28**, mp 109–110°C; ir (film) ν_{max}: 2100 (N_3), 1795 (β-lactam) cm^{-1}; ^{1}Hmr (C_6D_6) δ: 0.2 (s, 3H, $SiCH_3$), 0.3 (s, 3H, $SiCH_3$), 1.1 (s, 9H, *t*-Bu), 2.6–2.9 (ddd, 1H, CH_2—C*H*), 2.9–3.3 (dd, 1H, CH*H*—CH, J = 10, 10 Hz), 3.8–4.0 (dd, 1H, C*H*H—CH, J = 3, 10 Hz), 4.05 (d, 1H, CHN_3, J = 4.5 Hz), 6.15 (d, 1H, C_6HH, J = 9 Hz), 7.43 (d, 1H, C_6HH, J = 9 Hz); ms, *m/e*: 334 ($M^{+\cdot} - t$-Bu$^{\cdot}$), 306 ($M^{+\cdot} - t$-Bu$^{\cdot} - N_2^{\cdot}$), 260 ($M^{+\cdot} - OSi(CH_3)_2C(CH_3)_3^{\cdot}$), 251 ($M^{+\cdot} - t$-Bu$^{\cdot}$ – O=C=CHN_3).

para-Silyl ether **30**, mp 122–123°C; ir (film) ν_{max}: 2100 (azide), 1785 (β-lactam) cm^{-1}; ^{1}Hmr (C_6D_6) δ: 0.03 (s, 3H, $SiCH_3$), 0.15 (s, 3H, $SiCH_3$), 1.7 (s, 9H, *t*-Bu), 2.66–3.0 (ddd, 1H, CH_2—C*H*, J = 4, 5, 10 Hz) 3.15–3.45 (dd, 1H, C*H*H—CH, J = 10, 10 Hz), 3.7–3.9 (dd, 1H, CH*H*—CH, J = 4, 10 Hz), 4.1 (d, 1H, CHN_3, J = 5 Hz), 6.15 (d, 1H, C_6HH, J = 9 Hz), 7.35 (d, 1H, C_6HH, J = 9 Hz); ms *m/e*: 334 ($M^{+\cdot} - t$-Bu$^{\cdot}$), 306 ($M^{+\cdot} - t$-Bu$^{\cdot} - N_2^{\cdot}$), 251 ($M^{+\cdot} - t$-Bu$^{\cdot}$ – O=C=CHN_3). *Anal.* calcd. for $C_{16}H_{21}N_5O_5Si$: C 49.10, H 5.37, N 17.90; found: C 48.91, H 5.50, N 17.72.

p-*Nitro Silyl Ether* ***30***b

A mixture of *ortho*- and *para*-nitrophenols ***28a*** and ***30a*** (138 mg, 0.5 mmol), *tert*-butyldiphenylsilyl chloride (165 mg, 0.6 mmol), and imidazole (82 mg, 1.2 mmol), in dry dimethylformamide (5 mL) was stirred at room temperature for 15–20 h.

The reaction mixture was then added to ethyl ether (100 mL), washed with water and brine, dried ($MgSO_4$), and evaporated to dryness to give crude product **30***b* which was crystallized from CH_2Cl_2 – petroleum ether (100 mg, 45%), mp 153–154°C. The water–brine layer was further extracted with ethyl acetate in order to isolate *ortho*-nitrophenol **28***a* and decomposition products; ^{1}Hmr (C_6D_6) δ: 1.1 (s, 9H, $C(CH_3)_3$), 3.15–3.5 (ddd, 1H, CH_2—C*H*, *J* = 4, 5, 10 Hz), 3.65–4.0 (dd, 1H, C*H*H—CH, *J* = 10, 10 Hz), 4.3–4.55 (dd, 1H, CH*H*—CH, *J* = 4, 10 Hz), 4.65 (d, 1H, CHN_3, *J* = 5 Hz), 6.47 (d, 1H, C_6HH, *J* = 9 Hz), 7.2–7.7 (m, 11H, C_6HH, 2Ph).

β-*Lactam Amines 31 and 33*a

Hydrogen sulphide was bubbled into a solution of azides **28** and **30** (mixture) (170 mg, 0.45 mmol) and triethylamine (49 mg, 0.5 mmol) in dry methylene chloride (10 mL) at 0°C. After 1 h of stirring at room temperature the solution was purged with nitrogen, washed with water (2 × 10 mL), dried, and evaporated to give a crude yellow oily product (140 mg); ir (film) ν_{max}: 3350 (amine), 1780 (β-lactam) cm^{-1}; ^{1}Hmr (acetone-d_6) δ: 0.3 (2s, 6H, $Si(CH_3)_2$), 1.0 (s, 9H, $C(CH_3)_3$), 2.9 (bs, 2H, NH_2), 4.0–4.3 (m, 2H), 4.7–4.9 (m, 1H), 5.5–5.6 (dd, 1H, C*H*NH_2), 6.5–6.7 (2d, 1H, C_6HH), 7.6 (d, 1H, C_6HH).

Phenylacetamido Silyl Ether 32

Hydrogen sulphide was bubbled into a solution of azide **30***b* (140 mg, 0.3 mmol) and triethylamine (0.05 mL) in methylene chloride (10 mL) at 0°C for 3–5 min. After 1 h, the solution was purged with nitrogen. To the crude product **33***b*, in methylene chloride (10 mL) and triethylamine (0.05 mL) at 0°C, was added dropwise phenylacetyl chloride (0.06 g, 0.4 mmol). After stirring for 1 h the solution was washed with pH 4.5 buffer (10 mL), water (10 mL), dried ($MgSO_4$), and concentrated. The crude product **32** was crystallized from ethyl acetate – petroleum ether several times to obtain 100 mg (60%) of pale yellow crystalline product, mp 190–191°C; ir (film) ν_{max}: 1790 (β-lactam), 1710 (amide) cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 1.1 (s, 9H, $C(CH_3)_3$), 3.5 (s, 2H, $COCH_2Ph$), 3.3–3.7 (m, 1H, CH_2—C*H*), 3.8–4.2 (dd, 1H, C*H*H—CH, *J* = 10, 10 Hz), 4.3–4.6 (dd, 1H, CH*H*—CH, *J* = 4, 10 Hz), 5.1–5.3 (dd, 1H, C*H*—NHCO, *J* = 5, 8 Hz), 6.6 (d, 1H, C_6HH, *J* = 9 Hz), 7.2 (s, 10H, $SiPh_2$), 7.2–7.7 (m, 5H, —CH_2Ph), 8.0 (bd, 1H, NH, *J* = 8 Hz), 8.7 (d, 1H, C_6HH, *J* = 9 Hz).

Cation mobilities in C_1–C_4 hydrocarbon gases at densities up to the critical

NORMAN GEE AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 5, 1981

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

NORMAN GEE and GORDON R. FREEMAN. Can. J. Chem. **59**, 2988 (1981).

The temperature coefficient of cation mobility, $d\mu/dT$, at constant gas density n, is positive and increases with increasing n. The increase of temperature coefficient is attributed to the clustering of molecules about the ion. However, the temperature coefficient is positive even for the mass-identified, unclustered CO_3^- ion in N_2 gas (Eisele, Perkins, and McDaniel. J. Chem. Phys. 1980). The energy dependence of the cross section for the scattering of CO_3^- by N_2 was deconvoluted from the $(\mu n, T)$ data. The cross section decreases with increasing energy in a manner that implies sticky collisions (associative interactions) at energies < 0.1 eV, and essentially hard core collisions at higher energies. The scattering of CH_5^+(?) ions by CH_4 behaves similarly. The cross section in methane is larger than that predicted by the simple polarization potential at all energies. In the low density gas the ion mobility is controlled by collision with one molecule at a time, and $\mu n \approx$ constant. In the dense liquid the mobility is governed mainly by viscosity, and $\mu\eta \approx$ constant. The transition region is $0.3 \lesssim n/n_c \lesssim 2.0$, which corresponds to $0.5 \lesssim \eta/\eta_c \lesssim 3$. A plot of $\mu\eta$ against η for several hydrocarbons ranging from methane to n-hexane is nearly independent of molecular size in both the liquid and gas phases.

NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **59**, 2988 (1981).

Le coefficient de température de la mobilité du cation, $d\mu/dT$, pour une densité constante n de gaz est positif et augmente avec n. On attribue l'augmentation du coefficient de température à l'entassement des molécules autour de l'ion. Cependant le coefficient de température est positif même pour l'ion CO_3^- dans l'azote gazeux qui d'après la masse ne subirait pas d'entassement des molécules (Eisele, Perkins, and McDaniel. J. Chem. Phys. 1980). A partir des données $(\mu n, T)$, on a déduit l'effet de l'énergie sur la section droite lors de la dispersion du CO_3^- par l'azote. On déduit de la relation entre la diminution de la section droite avec une augmentation de l'énergie qu'il existe des collisions avec association (interactions associatives) à des énergies $< 0{,}1$ eV et ces collision sont essentiellement fortes qu'aux énergies plus grandes. La dispersion des ions CH_5^+(?) par le CH_4 présente un comportement semblable. La section droite dans le méthane est plus grande que celle prévue par le potentiel de polarisation simple à toutes les énergies. Dans les gaz à faible densité, la mobilité de l'ion est contrôlée par la collision avec une molécule a la fois et à un $\mu n \approx$ constante. Dans le cas des liquides denses la mobilité dépend principalement de la viscosité et de $\mu n \approx$ constante. La région de transition est de $0{,}3 \lesssim n/n_c \lesssim 2{,}0$ qui correspond à $0{,}5 \lesssim \eta/\eta_c \lesssim 3$. Une courbe de $\mu\eta$ en fonction η pour plusieurs hydrocarbures allant du méthane au n-hexane est presqu'indépendante de la taille des molécules dans les phases liquide et gazeuse.

[Traduit par le journal]

Introduction

The mobility μ of cations is chiefly limited by the viscosity η in the liquid phase (1–9) and by the density n in the dilute gas (6, 7, 10, 11). Relatively few attempts have been made to connect the liquid and gas phase behaviors (10, 12). We had recently examined the variation of $\mu\eta$ over the entire liquid range up to the critical region for eight C_1 to C_4 hydrocarbons (9). The $\mu\eta$ values were only slightly dependent on the nature of the molecules. Plots of $\mu\eta$ against η^{-1} usually contained a broad maximum with $\mu\eta \approx 3 \times 10^{-3}$ cm^2 mP/V s in the vicinity of 1 mP^{-1}. With increasing temperature and concomitant decreasing liquid density and viscosity, $\mu\eta$ first increases due to increasing ion mean free path, then decreases as the critical region is approached, due to increasing liquid compressibility and consequent electrostriction about the ion (9). The study has now been extended through the critical fluid into the dense gas and to progressively lower densities.

Measurements of mobility were also made as a function of temperature at several constant densities.

Experimental

The experimental procedures have been previously reported (5–7, 9). The electrodes in the present cells were always in the gas phase.

Briefly, the fluid in a parallel plate cell was irradiated by a 100 ns pulse of 1.7 MeV X rays ($\approx 1 \times 10^{10}$ eV/g). Data collection was controlled by a Texas Instruments 980A minicomputer. The electrons were swept from the gas by the electric field in a time about 1000-fold less than the ion time. Both the electron and ion currents were integrated, giving a charge vs. time signal. The signal was amplified with a Princeton Applied Research 113 preamplifier. From 4 to 32 signals were averaged using a Fabritek 1062 or Nicolet 1170 signal averager. The final result was drawn on a Zeta Research Incorp. 1200 plotter. Representative traces are given in Fig. 1. The initial sharp rise is due to collection of the electrons. The collection time of the ions equals the drift time of the ions. The ion mobility is given by the drift distance (cell gap) divided by the product of drift time t_D and electric field strength. Both the drift distance and electric field strength have errors of less than 1%. The major source of error is the determination of t_D from the charge vs. time plots.

Gas densities were obtained from ref. 13, except for cyclopropane which were obtained as described in ref. 14. Viscosities were obtained from ref. 15, except for ethene which were taken

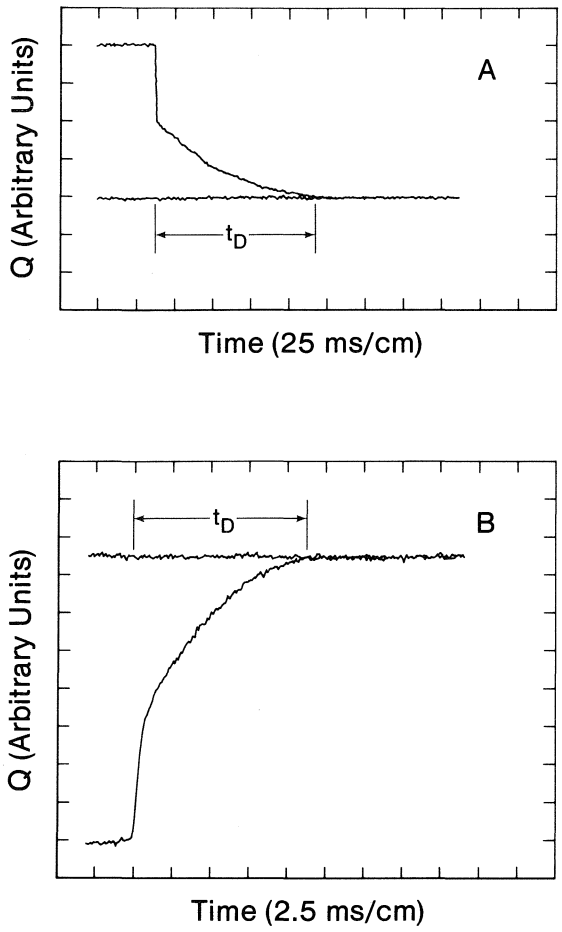

FIG. 1. Collected charge as a function of time. The densities (10^{20} molecules/cm^3), temperatures (K), and applied voltages (V) were: *A*, 3.4, 365, −20; *B*, 8.2, 349, +500. The sample *A* was *n*-butane and *B* was propene. The drift distance was 0.322 ± 0.003 cm.

from ref. 16, and liquid *i*-butane which were obtained as described in ref. 9. Only viscosities based on experimental measurements were used. The critical temperatures, densities, and viscosities are listed in Table 1.

Results

The cation mobilities in each of the eight gases at all densities were independent of applied electric field strength up to the highest field used, ~ 1 Td. Examples of the data are shown in Fig. 2. Each point is the average of the positive and negative applied voltage results. The average deviation of μ for the ~ 6 data points at a given n and T was usually ~ 3%, but ranged from 1–6%.

Arrhenius plots of the mobilities at different densities are displayed for methane and ethane (Fig. 3), ethene and propene (Fig. 4), propane and cyclopropane (Fig. 5), *n*-butane and *i*-butane (Fig. 6). The number beside each constant density curve is n (10^{20} molecules/cm^3). The highest density for each system is the critical. The triangles represent mobilities in the coexistence vapors, the densities of which increase with temperature.

At constant density $d\mu/dT$ was positive in all systems. The coefficient increases with density (Figs. 3–6). This density effect was previously observed for cations in benzene and toluene vapors and was attributed to clustering of molecules about the cations (7).

The upper half of the coexistence curve (triangles) for each compound in Figs. 3–6 corresponds to a negative Arrhenius parameter ($-E$ = 8.4 kJ/mol for methane, ~ 15 kJ/mol for the C_2's, ~ 20 kJ/mol for the C_3's, and 24 kJ/mol for the C_4's) that is 5–20% larger than the heat of vaporization of the compound at the corresponding temperature. If there were no clustering of molecules about the ion, the positive $d\mu/dT$ at constant n would have caused the negative Arrhenius parameter from the triangles in Figs. 3–6 to be slightly smaller than the heat of vaporization of the corresponding compound.

The density normalized mobility μn is plotted against n for the coexistence vapors and liquids (9) in Fig. 7. The slightly negative slopes at low densities are consistent with the clustering, but the concomittant increase of temperature with n keeps the overall effect on μn small. At $n/n_c \gtrsim 0.3$ the value of μn increases. There is no special effect at

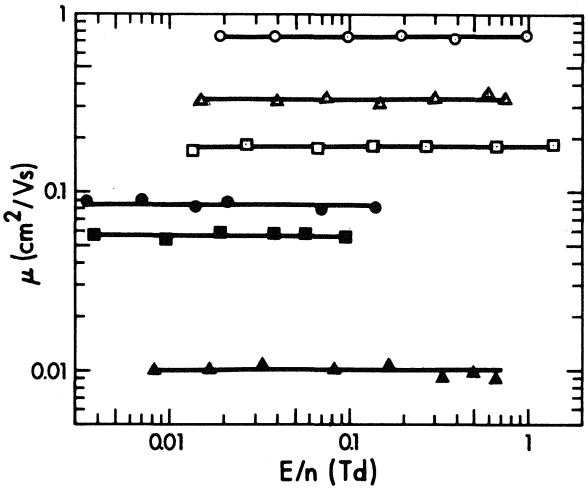

FIG. 2. Cation mobilities μ as functions of density normalized electric field strength E/n in gaseous hydrocarbons. The densities (10^{20} molecules/cm^3) and temperatures (K) were as follows: CH_4: ○, 0.53, 108; ●, 4.66, 144; C_2H_6: △, 0.68, 197; ▲, 19.0, 296; *n*-C_4H_{10}: □, 0.76, 370; ■, 1.64, 333. The average % deviations are (top to bottom): 1.2, 1.9, 2.0, 4.8, 2.7, and 5.6.

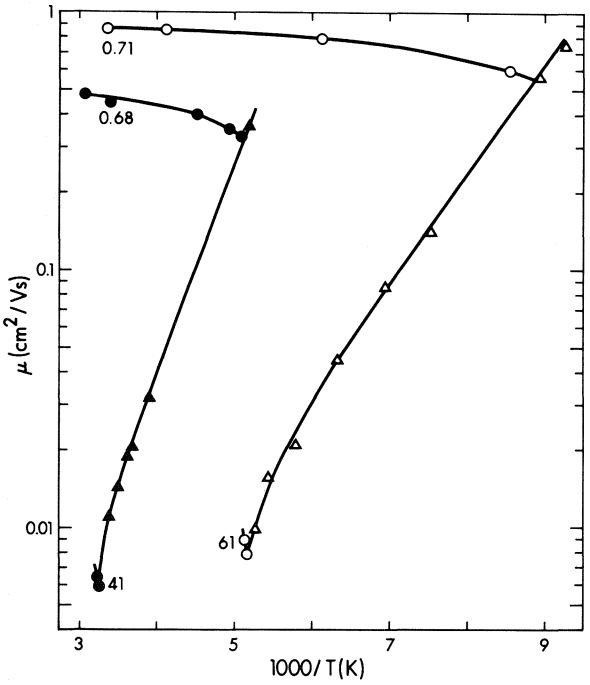

FIG. 3. Arrhenius plots of cation mobilities in methane (open symbols) and ethane (solid symbols). Triangles represent vapor in equilibrium with liquid. Circles represent constant density gas; the numbers labelling the curves give the density n in units of 10^{20} molecules/cm^3.

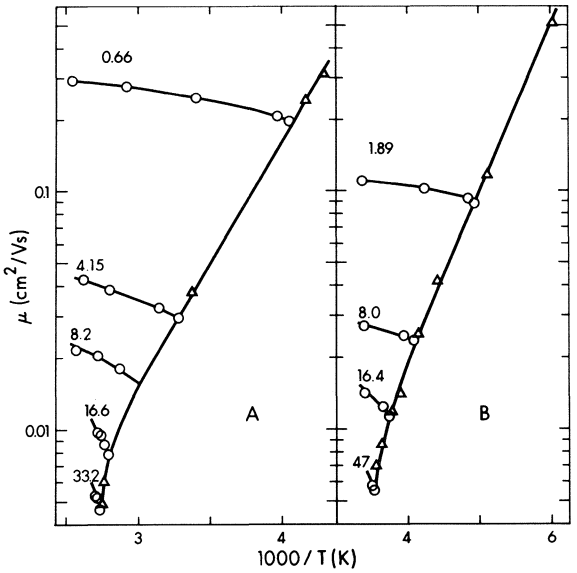

FIG. 4. Arrhenius plots of cation mobilities in propene (A) and ethene (B). The symbols have the same meanings as in Fig. 2.

the critical point (7, 17), in agreement with theory (18).

The density variation of μn at constant temperature (T_c + 2) K is shown in Fig. 8. The curves are similar to those in Fig. 7, but the low density ends are raised somewhat.

The uncertainty in n is ~6% at $n < 1 \times 10^{20}$ molecules/cm^3, and is smaller at higher n for all the gases. The uncertainty in μn is therefore ~9%.

Discussion

(A) Low Density Gas

Previous measurements indicated that the mobility was independent of field strength below about 600 Td in methane (19) and below about 130 Td in ethane (20) at 293 K and $n < 10^{19}$ molecules/cm^3. The present measurements (Fig. 2) were at fields two orders of magnitude lower than those used

earlier and were far below the field dependence threshold. The previously reported low field mobilities correspond to μn (10^{19} molecules/cm V s) values of 6.9 (19), 6.0 (21*a*), and 5.9 (21*b*) in methane, compared to the present 6.1, 2.5 (20) in ethane compared to the present 3.1, and 1.6 (21*a*) in isobutane compared to the present 1.3, in the low density gases at 294 ± 1 K. The differences between the sets are ±2 to 23%. The high value for methane in ref. 19 is attributed to the high field used (see later). The gas densities used in ref. 21*a* were two orders of magnitude lower than our lowest, so clustering in our isobutane sample at 295 K probably contributed to the lower value of μn for that compound.

The present ion drift times were $\sim 10^{-3}$ s. Ion–molecule reaction cross sections in hydrocarbons are typically 10^{-15}–10^{-14} cm² (22), so at $n \approx 10^{20}$ molecules/cm³ and $T \approx 10^2$ K the initial ions would be altered by reaction in $\sim 10^{-10}$ s. Clustering would also reach equilibrium at a time $\ll 10^{-3}$ s. One may therefore assume that the mobilities

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

measured were those of ions that could not undergo charge exchange, but whose masses and sizes changed several times according to [1] during the drift period:

[1] $M_m^+ + M \rightleftharpoons M_{m+1}^+$

where $m = 1, 2, \ldots$. The mass and size changes caused by ion–molecule reactions such as [2] may be neglected, while reactions such as [3] simply affect the value of m.

[2] $CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3$

[3] $C_2H_4^+ + C_2H_4 \rightarrow C_4H_8^+$

Scattering cross sections extracted from the mobilities are average values for the clusters present at the particular n and T.

(1) Scattering Cross Sections

Scattering by the polarization potential would give (23):

[4] $n\mu_{pol} = 3.73 \times 10^{20}/(\alpha M_r)^{1/2}$ molecules/cm V s

where α is the polarizability of the gas molecules M in units of 10^{-24} cm^3 (24, 25), M_r is the reduced mass of the drifting ion and a gas molecule in units of g/mol. The observed values of $n\mu$ are approximately half those predicted by [4], as illustrated in Table 1. It was assumed that the ions were heavily clustered, with M_r = molecular mass. If the ions are less heavily clustered the reduced mass is less than the molecular mass, for example, $M_r = 0.67 \times$ molecule mass when $m = 2$, then the ratio (expt/pol) is somewhat lower than the values listed in Table 1. The simple polarization potential is too small to explain the ion scattering, as had been noted in many other systems (6, 7, 23). The ratio $(n\mu_{expt}/n\mu_{pol})$ equals 0.53 ± 0.02 for nine of the thirteen alkanes, alkenes, cycloalkanes, and aromatics listed in Table 1. The exceptions were methane, cyclopentane, and cyclohexane for which (expt/pol) = 0.65 ± 0.02, and benzene for which the ratio equalled 0.47. The polarization interaction makes a major contribution to ion scattering in hydrocarbon vapors, but something else makes an approximately equal contribution.

Calculated mobilities can be brought into closer agreement with experimental values by adding a hard core to the polarization potential (23). This adjusts mainly for the facts that the ion is not a point charge and the molecule is not a perfectly polarizable sphere. The correction is especially important for polyatomic ions and molecules. However, when the cross section has been doubled by adding a hard core to the polarization potential the model predicts a negative temperature coefficient for the mobility (Fig. 1, ref. 23, $\mu/\mu_{pol} \approx 0.5$), which is the opposite of that observed experimentally (Figs. 3–6 and refs. 6, 7). Positive temperature coefficients have also been observed for certain simple ions such as CO_3^- (26), Rb^+ (27), and H_3^+ (28) in gases such as N_2, Ar, and H_2, respectively. The positive temperature coefficients might be interpreted in terms of short-lived association complexes (sticky collisions).

In low density gases the normalized mobility may be represented by the Chapman–Enskog equation (29, 30):

$$[5a] \quad n\mu = \frac{\frac{3e}{8M_r}\sqrt{\pi}\left(\frac{2kT}{M_r}\right)^{5/2}}{\int_0^\infty v^5\sigma_v \exp\left(-\frac{M_r v^2}{2kT}\right) dv}$$

or

$$[5b] \quad n\mu = \frac{\frac{3e}{8}(kT)^{5/2}\left(\frac{2\pi}{M_r}\right)^{1/2}}{\int_0^\infty \varepsilon^2\sigma_\varepsilon \exp\left(-\frac{\varepsilon}{kT}\right) d\varepsilon}$$

where e is the charge on the ion, M_r is the reduced mass, k is Boltzmann's constant, T is the absolute temperature, v is the relative velocity of the ion with respect to the molecule, and σ_v (or σ_ε) is the ion–molecule scattering cross section for velocity v (or energy ε). Equation [5] is equivalent to using an average cross section σ_{av} represented by [6].

[6] $\sigma_{av} = \langle v^3\sigma_v\rangle/\langle v^3\rangle = \langle \varepsilon^{3/2}\sigma_\varepsilon\rangle/\langle\varepsilon^{3/2}\rangle$

Sets of experimental ($n\mu$, T) values in the lowest density gases were used to extract apparent values of σ_v as functions of v in the trial and error manner described for electrons (31, 32). Data for the mass identified, unclustered CO_3^- ion in N_2 gas (ref. 26 and Fig. 9) were first analyzed to see the shape of a cross section curve for ions. The value of σ_v decreases with increasing v up to about 1.0 km/s (ε = 0.1 eV), then is relatively constant up to about 2.5 km/s or 0.6 eV (Fig. 10). The simple polarization potential leads to (ref. 33, eq. [42], $S^{(1)}$):

$$[7] \quad \sigma^{pol} = (2.2\pi/v)(e^2\alpha/M_r)^{1/2} = \pi\,(2.42e^2\alpha/\varepsilon)^{1/2} = 1.86 \times 10^{-15}\,(\alpha/\varepsilon)^{1/2} \quad \text{cm}^2$$

where α is in units of 10^{-24} cm^3 and ε is in eV. For CO_3^- in N_2 one obtains

[8] $\sigma^{pol} = 2.47 \times 10^{-15}\varepsilon^{-1/2}$ cm^2

Equation [8] cuts through the empirical cross

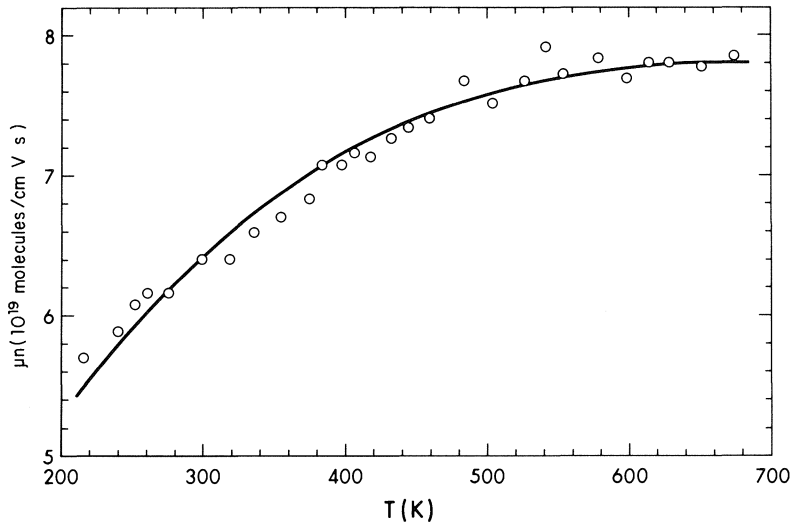

FIG. 9. Temperature dependence of μn for unclustered CO_3^- ions in N_2 gas (26). $n = (1.2 \pm 0.4) \times 10^{18}$ molecules/cm^3. The line was calculated from the cross sections in Fig. 10, using eq. [5].

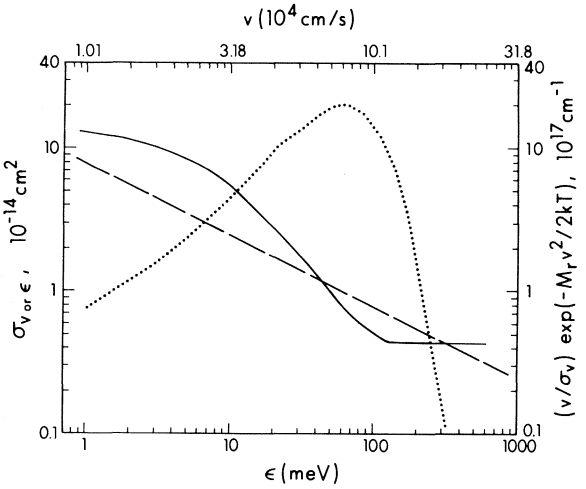

FIG. 10. Momentum transfer cross sections for CO_3^- collisions with N_2, as a function of energy ε and relative velocity v. —, obtained from Fig. 9 and eq. [5]. ---, σ^{pol}, eq. [8], obtained from polarization potential; ···, (v/σ_v) exp $(-M_r v^2/2kT)$, at 446 K, using σ_v from the full curve.

sections (Fig. 10). The sensitivity of the empirical fitting of $(n\mu, T)$ data to eq. [5] is greatest in the vicinity of the maximum of the transport distribution. The latter may be approximated as

$$[9] \quad \text{Maxwellian}/v\sigma_v = (v/\sigma_v) \exp(-M_r v^2/2kT)$$

The sensitivity of the data in Fig. 9 to σ_v is greatest between about 0.010 and 0.16 eV (Fig. 10). The empirical cross sections are progressively less accurate as the distance from this central energy region increases.

The interpretation of the hydrocarbon ion mobilities is complicated by clustering and its effect on M_r and σ_v. The Maxwellian energy distribution is independent of M_r, whereas the velocity distribution is not, so eq. [5*b*] is the more convenient form for examining the effect of clustering on the mobility. Clustering increases M_r and therefore decreases $n\mu$. The reduction of n would be negligible at the low ion concentrations used. Increasing the cluster size would increase the stiff core portion of the scattering potential, but the polarization portion might decrease due to shielding, so the effect of clustering is not simple. The net effect is probably to increase σ_ε and thereby further decrease $n\mu$. Changing from a monomer ion to a dimer would decrease $n\mu$ by a factor of about 1.5. In a mixture the smaller clusters make a proportionately larger contribution to the mobility than do the larger clusters. We assume that the exchange time of reaction [1] is much smaller than the drift time and that the measured time is the average drift time of the distribution.

For a given set of $(n\mu, T)$ data the *apparent* values of the cross sections vary as $M_r^{-1/2}$. Thus if the ions are assumed to be monomeric (M_r = 0.5 molecular mass) the apparent values of σ_ε are 1.4 times those that would be obtained by assuming that the ions are heavily clustered (M_r = molecular mass).

In the temperature studies of the hydrocarbons at constant low density, the methane sample had the lowest value of n/n_c (0.012) and highest value of T/T_c (up to 1.6). The extent of clustering should

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

therefore be smaller in methane than in the other hydrocarbons under the conditions used. The low density methane results were analyzed in two stages: (*a*) the main ion was assumed to be CH_5^+ at all temperatures; (*b*) clustering was assumed to have a significant effect on $n\mu$ at 117 K, which is near the coexistence curve at this density, and a minor effect at $T \geq 143$ K. The apparent cross sections obtained from these treatments are displayed in Fig. 11. The calculated and experimental values of $n\mu$ are compared in Fig. 12. The full line in Fig. 11 represents the more realistic cross sections; at 117 K the ratio of μ calculated from this curve to the experimental value is 1.20, which is equivalent to about half of the ions being dimers if the rest are monomers.

It is curious that the dash–dot curve in Fig. 11 is similar in shape to the full curve in Fig. 10. The former is thought to be distorted by ion–molecule clustering at low temperatures. The latter represents ions that were identified by mass and no clustering was observed (26). In both cases a better fit to the experimental mobilities could have been obtained by putting a minimum in the cross section near the energy where the present curves become flat, then having σ_ε increase at higher ε.

The cross sections extracted from the mobilities in methane are greater than σ^{pol} at all energies (Fig. 11). This implies that the contribution of sticky collisions to ion scattering in the methane system is greater than in the scattering of CO_3^- by N_2. The latter system had a much lower value of n/n_c (1.8×10^{-4}) and larger T/T_c (1.7–5.4), which might explain the lower contribution of associative interactions. We do not understand the shape of the cross section curve in Fig. 10 relative to those in Fig. 11.

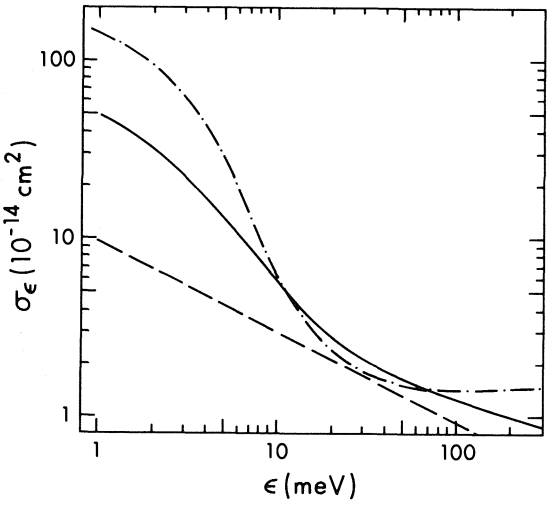

FIG. 11. Momentum transfer cross sections in methane, assuming the ions to be CH_5^+, -·-·-, estimated by ignoring an effect of clustering; —, estimated after discarding the point at 117 K in Fig. 12; ---, $\sigma^{pol} = 3.00 \times 10^{-15}\ \varepsilon^{-1/2}$ cm^2, where ε is in eV.

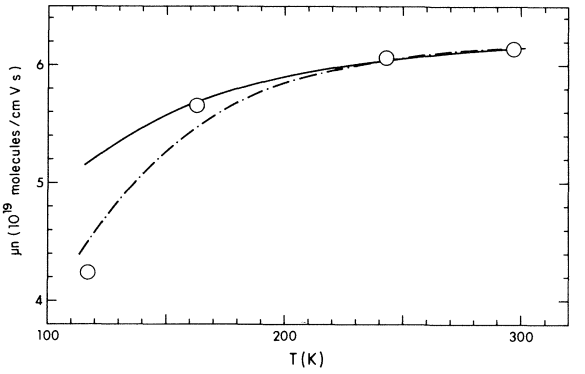

FIG. 12. Comparison of calculated and experimental (○) values of ion mobilities in methane. $n = 7.1 \times 10^{19}$ molecules/cm^3. The lines were calculated from eq. [5], assuming the ions to be CH_5^+: -·-·- and —, using the corresponding curves in Fig. 11.

All the other hydrocarbons were studied at larger relative densities, $n/n_c \geq 0.02$, and lower relative temperatures, T/T_c up to only 1.04 ± 0.04. Fitting the ($n\mu$, T) data to eq. [5] in each case gave a minimum in the *apparent* σ_ε at $\varepsilon = 0.05 \pm 0.01$ eV. The minima are artifacts attributed to the effects of clustering on the temperature dependence of μ. In each hydrocarbon gas at the lowest density the change of mobility with temperature is approximately equivalent to that expected if the average value of m in M_m^+ were reduced by half on going from the coexistence curve to 1.1 T_c. Assuming $m < 10$ a few K above the coexistence curve at the lowest gas density, the average association energy of a molecule to an ion is roughly 3 kJ/mol, within a factor of about two.

(2) Field Dependence

When the drift velocity of the ions is equal to or greater than the random velocities of the molecules, v_{mol}, it is no longer reasonable to assume that the temperature of the ions equals that of the gas. An upper limit to the threshold field, above which the mobility should be field dependent if the thermal ion mobility is temperature dependent, may be estimated from eq. [10].

$$[10] \quad (E/n)_{thr} \lesssim v_{mol}/\mu n \text{ (thermal)}$$

where $v_{mol} = (3kT/M_{mol})^{1/2}$ and M_{mol} is the molecular mass. To connect eq. [10] with earlier comments on this matter (34), v_{mol} is approximately equal to the speed of sound in the gas. One obtains for ethane at 293 K, $(E/n)_{thr} \lesssim 4.9 \times 10^4/3.1 \times 10^{19} = 1.60 \times 10^{-15}$ V cm^2/molecule, or 160 Td. This is

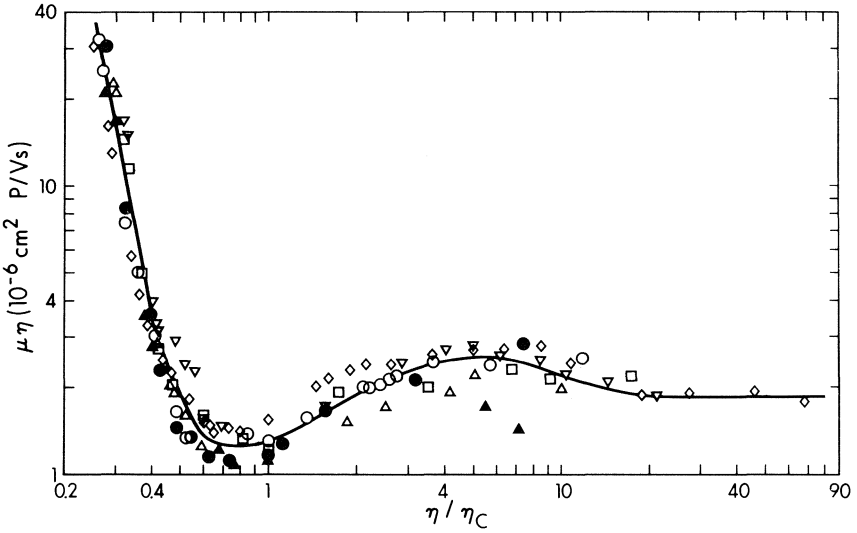

FIG. 13. Cation mobilities normalized for differences in fluid viscosities η, plotted against η/η_c, where $\eta_c \approx 0.2$ mP refers to the critical fluid. The fluid is a gas at $\eta/\eta_c < 1.0$ and a liquid at $\eta/\eta_c > 1.0$. ○, methane; ●, ethene; △, ethane; ▲, propene; ▽, propane; □, *n*-butane; ◇, *n*-hexane, ref. 6. The liquid phase data are from ref. 9. The vapor and liquid are coexistent fluids.

consistent with the observed threshold at 120 Td (20). The threshold predicted from the speed of sound, 311 m/s, would be 100 Td.

For methane at 293 K, eq. [10] predicts $(E/n)_{thr} \lesssim 6.8 \times 10^4/6.1 \times 10^{19} = 1.1 \times 10^{-15}$ V cm²/molecule, or 110 Td. In the study where the threshold in methane was reported to be 600 Td the lowest field used was 170 Td (19), and $d\mu/dE$ was negative above the reported threshold. We predict that the true threshold lies at ~80 Td and that $d\mu/dE$ is positive just above it. This could explain why Schlumbohm's (19) value for μn for methane is 13% larger than ours. The values of μn obtained at less than 20 Td (21) were within 3% of ours.

(B) Effect of Density Along the Coexistence Curve

At $n/n_c \geq 0.3$ the value of μn increases (Fig. 7), due to the mutual interference of the long range interactions of an ion with more than one molecule at the same time. The increase continues through the critical fluid and into the low density liquid. At $n/n_c \approx 1.7$ the value of μn passes through a maximum, and decreases rapidly at $n/n_c \geq 2.2$ (Fig. 7). The decrease of μn at the higher densities is due to transition to a different mechanism of ion transport. At low densities, where the ion mean free path is much greater than the molecular diameter, the drift of the ion in the direction of the electric field is disturbed by collisions with single molecules. Under these conditions $\mu n \approx$ constant. At high densities, where the mean free path is less than a molecular diameter, the ion interacts continuously with one or more molecules. Under these conditions the *viscosity* η dominates and $\mu\eta \approx$ constant. In Fig. 13, μη is plotted against η/η_c for the liquids and gases, where η_c is the viscosity of the critical fluid. The general behavior is similar for the alkanes from methane to *n*-hexane. Ethene and propene also fall near the alkane curve (Fig. 13). As noted earlier (9), at high viscosities in the liquids μη is approximately constant. The viscosity was reduced by heating the liquid under its vapor pressure. The value of μη passed through a slight maximum at $\eta/\eta_c \approx 5$ and decreased gently until the critical fluid was reached. Upon passing to the coexistence vapor the viscosity was decreased by decreasing the temperature and concomittant density. The value of μη passed through a shallow minimum at $\eta/\eta_c \approx 0.8$ and increased rapidly at $\eta/\eta_c < 0.6$. At the lowest densities the curve becomes vertical, because for an ideal gas η is independent of density.

Thus in the region where $\mu n \approx$ constant the value of μη varies rapidly (compare Figs. 7 and 13), and where $\mu\eta \approx$ constant the value of μn varies rapidly. The analogous regions in fluid mechanics are sometimes called the kinetic (low density) and hydrodynamic (high density) regimes (35). The transition region in our work is $0.3 \lesssim n/n_c \lesssim 2.0$, or $0.5 \lesssim \eta/\eta_c \lesssim 3$.

In ref. 8 it was suggested that μη was constant for cations in liquid ethane up to the critical point. However, they used η values from Gallant (36), which are too high for ethane and many other compounds near the critical region (15). Insertion of correct viscosities shows that μη decreases as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

the critical region is approached, in agreement with our result (9).

There is no systematic dependence of $\mu\eta$ on molecular size (Fig. 13). This had been noted earlier for the liquid phase (9, 37) and attributed to electrostriction being greater around smaller ions. Electrostriction increases the local viscosity around the ions and tends to make $\eta R \approx$ constant, where R is the ion radius. By contrast, in the low density gases μn is strongly dependent upon molecular size (Table 1).

The Diels–Alder adducts of 2-acetoxyfuran and maleic anhydride and 2-acetoxyfuran and chloromethylmaleic anhydride have been obtained and their dihydro derivatives manipulated in high yield to various 2,3-functionalized 4-hydroxycyclohexanones. In all cases the hemiketal acetate bridge of the oxabicyclo[2.2.1] derivatives was cleaved smoothly using sodium methoxide in methanol at 0°C; however, in the case of the chloromethyl compounds the reaction proceeds further to give an almost quantitative yield of the corresponding fused cyclopropane derivatives. These sequences, starting from the readily accessible but seldom used 2-acetoxyfuran, are therefore extremely advantageous to gain rapid and efficient access to a number of 2,3-functionalized 4-hydroxycyclohexanones. In the case of the adduct involving chloromethylmaleic anhydride, stereochemistry and regiochemistry were established by X-ray diffraction on the dihydro derivative.

D. GRAVEL, R. DEZIEL, F. BRISSE et L. HECHLER. Can. J. Chem. **59**, 2997 (1981).

Les adduits de Diels–Alder de l'anhydride maléique et de l'anhydride chlorométhylmaléique avec l'acétoxy-2 furanne ont été obtenus et leur dérivé dihydro transformé en excellent rendement en diverses hydroxy-4 cyclohexanones fonctionnalisées aux positions-2,3. Dans chaque cas l'acétate du pont hémicétal des dérivés oxabicyclo[2.2.1] a été facilement scindé en utilisant le méthylate de sodium dans le méthanol à 0°C. Toutefois, dans le cas des composés chlorométhylés la réaction progresse plus loin pour donner un rendement presque quantitatif des dérivés cyclopropaniques fusionnés correspondants. Ces séquences à partir du réactif très accessible mais peu utilisé qu'est l'acétoxy-2 furanne sont donc très avantageuses pour préparer rapidement et efficacement certaines hydroxy-4 cyclohexanones fonctionnalisées en -2,3. Dans le cas de l'adduit impliquant l'anhydride chlorométhylmaléique, la stéréochimie et la régiochimie furent établies par diffraction des rayons X sur le dérivé dihydro.

Introduction

Over the years, the Diels–Alder reaction has been developed to the state of being probably the greatest tool available to organic chemists to quickly and efficiently assemble relatively complex synthons, be they bridged polycyclics, aromatics, or cyclohexane derivatives (1). Recent important developments on this topic have been in the areas of understanding and predicting regioselectivity (2), reversing regioselectivity by using Lewis acid catalysis (3), improving rate of reaction by the use of Lewis acids (4) or very high pressures (5), and broadening the spectrum of functionalities available on the enophile (6).

The problem at hand in the present case was the need for a simple, efficient, and selective method to generate various 2,3-functionalized 4-hydroxycyclohexanones required as potential starting material in a synthetic problem currently under study in our laboratory. Of the different methods envisaged or explored, it appeared that the Diels–Alder reaction might provide an advantageous solution.

Currently, the most frequently employed diene to generate 1,4-dioxygenated 2,3-functionalized cyclohexanes is *trans-trans*-1,4-diacetoxybutadiene (**1**) in conjunction with suitable dienophiles (7). An alternate, slightly less reactive but also less expensive, diene is 2-acetoxyfuran (**2**) which in the presence of suitable dienophiles leads to the usual [4 + 2] adduct which by opening of the hemiketal acetate bridge should lead *directly* to 2,3-disubstituted 4-hydroxycyclohexanones as required in the present study (see Scheme 1). As is readily apparent, both types of dienes could possibly be applicable to the synthetic objective pursued and both are under study. The results we wish to report in the present paper pertain to the use of 2-acetoxyfuran (**2**) as starting diene.

An examination of the literature reveals that 2-acetoxyfuran (**2**) was first reported by Clauson-Kaas and Elming (8) in 1952 who described its preparation and formation of an adduct **3** with maleic anhydride. A few years later, Cava *et al.* (9) reported a study of its preparation and its behavior

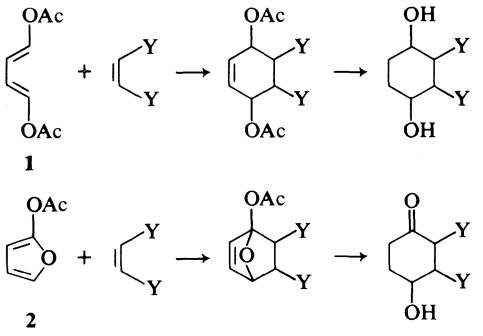
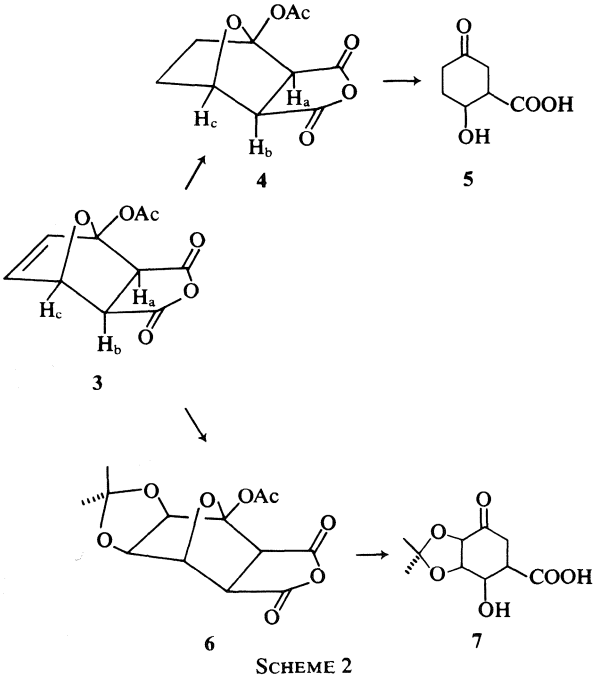


SCHEME 1

as a diene with the conclusion that: "The reactivity of 2-acetoxyfuran as a diene in the Diels–Alder reaction is as great as, though not noticeably greater than, that of furan itself".

To our knowledge, there is only one report in the literature (10) describing the use of a Diels–Alder adduct of 2-acetoxyfuran (**2**) to generate a 4-hydroxycyclohexanone derivative and this is the base induced hydrolysis of the dihydro adduct **4** of maleic anhydride and 2-acetoxyfuran (**2**). As depicted in Scheme 2, the reaction leads to hydrolysis of the anhydride, saponification of the hemiketal acetate, and decarboxylation of the resulting β-ketoacid moiety to yield 2-hydroxy-5-oxocyclohexane carboxylic acid (**5**). According to the authors (10*a*) the latter experiment was performed as a model to devise conditions to carry out the same sequence of transformations on the isopropylidene derivative



SCHEME 2

6 to obtain **7**; unfortunately, aromatization was invariably present to a large extent, forcing the authors to modify their strategy and to use *trans-trans*-1,4-diacetoxybutadiene (**1**) as starting diene.

Since then there appears to have been no other report of the use of 2-acetoxyfuran (**2**) as diene in Diels–Alder reactions although 2-methoxyfuran, which is commercially available, and 2-trialkylsilyloxyfuran, which has been reported recently (11), have both been used as dienes a number of times (11, 12) but only to generate aromatic synthons.

Results and Discussion

For strategic, practical, and economic reasons we chose to investigate the potential of 2-acetoxyfuran (**2**) first. In our initial study we repeated the preparation of the known (8, 9) adduct **3** with maleic anhydride and verified by nmr the *exo* configuration which had correctly been assigned by McCrindle *et al.* (10*a*) on the basis of analogy with the furan – maleic anhydride adduct reported by Woodward and Baer (13).[4] In the adduct **3** the *endo* protons H_a and H_b appear (acetone-d_6) as a pair of AB doublets ($\Delta\nu \simeq 8$ Hz) centered at δ 3.95 with $J =$ 8 Hz and no evidence of vicinal coupling with H_c, the bridgehead proton, as expected in such bicyclo[2.2.1] systems (15). The same observation holds for the dihydro adduct **4** where H_a and H_b again appear (acetone-d_6) as a pair of AB doublets ($\Delta\nu \simeq 20$ Hz) centered at δ 4.0 with $J = 8.0$ Hz and no evidence of vicinal coupling with H_c, the bridgehead proton (see Scheme 2).

As stated earlier, our synthetic objective was to develop access to various 2,3-substituted 4-hydroxycyclohexanones and therefore, contrary to McCrindle *et al.* (10), opening of the anhydride had to be achieved without decarboxylation of the β-ketoacid. In a first sequence of reactions (see Scheme 3), the anhydride **4** was heated in water at 70°C for 1 h and the crude diacid esterified with ethereal diazomethane to yield 91% overall of the bicyclotriester **8**. The delicate step of opening the bicyclotriester **8** to the corresponding cyclohexanone derivative was achieved in methanolic sodium methoxide at 0°C to yield 96% of the desired *trans*-2,3-dicarbomethoxy-*cis*-4-hydroxycyclohexanone **9**, as evidenced by the nmr spectrum which shows the 2, 3,

[4]In a recent paper Herndon and Lee (14) showed that, in accord with the typical kinetic and thermodynamic pattern for Diels–Alder reactions, maleic anhydride and furan react to give the *endo* adduct as the kinetically preferred product, but since the reaction is reversible and since the *exo* adduct (**3**) is 1.9 kcal/mol more stable than the *endo* adduct, the former is eventually the final product isolated.

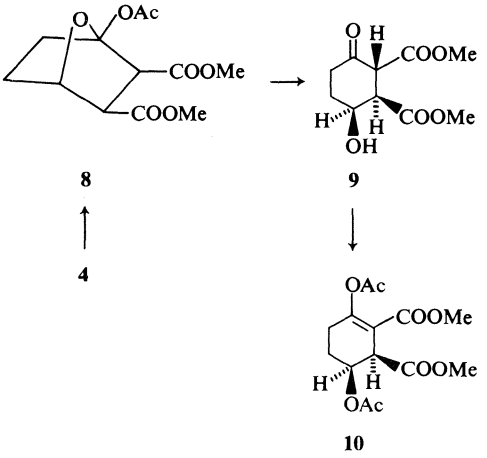
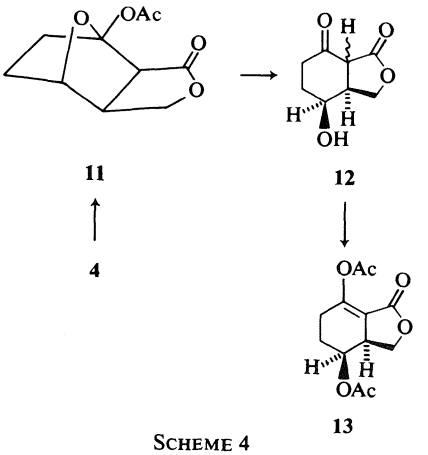


SCHEME 3

and 4 protons in the form of an ABX portion where J_{AB} = 12.3 Hz and J_{AX} = 2.6 Hz. Acetylation of **9** under the usual pyridine – acetic anhydride conditions yielded 81% of diacetate **10**, providing additional evidence for the proposed structure **9**.

In a second sequence of reactions (see Scheme 4) we aimed at regioselectively manipulating the fused anhydride ring prior to hemiketal acetate cleavage in order to have chemically differentiated functional groups at the 2,3-positions. There was of course the possibility of opening the anhydride by a nucleophile such as an alcohol or an amine in order to achieve differentiation, but our objective here was to generate two groups differing in their oxidation state. There are many reports in the literature pertaining to the regioselective reduction of nonsymmetrical fused anhydrides by sodium borohydride (16, see also 10*b*), and although regioselection is almost invariably observed, explanations differ as to its origin (16*a*). Be that as it may, at this early stage of the work, our strategy could



SCHEME 4

accommodate itself to either mode of regioselection so long as it were complete.

In the event, reduction of the fused anhydride **4** with sodium borohydride in absolute ethanol yielded 85% of a single (tlc, nmr) crystalline fused lactone of known (10*b*) structure **11**, as shown unambiguously by the formation of a diacetate **13** after base cleavage of the hemiketal acetate bridge (*vide infra*). As in the former case, opening of the hemiketal acetate **11** was carried out in methanolic sodium methoxide at 0°C and the expected hydroxyketolactone **12** isolated in 85% yield as an epimeric mixture. Acetylation in pyridine – acetic anhydride yielded a single crystalline diacetate **13** in a 94% yield. The formation of a diacetate (**13**) in the reaction shows conclusively that reduction of the fused anhydride **4** had taken place *only* at the carbonyl *opposite* the hemiketal acetate moiety. In the nmr, diacetate **13** shows clearly the two acetate methyl singlets at δ 2.10 and 2.27 and in the infrared, two characteristic carbonyl absorptions appear at 1750 and 1725 cm^{-1}.

Having thus found anhydrous basic conditions to efficiently open the hemiketal acetate ring, and thus avoiding loss of functionality at the 2-position by decarboxylation, and also having observed total regioselectivity in the reduction of the fused anhydride, we decided to attempt to increase the complexity of the dienophile in order to achieve a more elaborate synthon. An interesting such dienophile is chloromethyl maleic anhydride (**14**), the synthesis of which was reported by Eschenmoser *et al.* (17). Again, as in the case of maleic anhydride, the conditions to be met were (*i*) stereoselective adduct formation, (*ii*) regioselective manipulation of the anhydride function, and (*iii*) efficient opening of the hemiketal acetate plus a new condition due to the nonsymmetrical nature of the dienophile, namely, regioselective adduct formation.

Diels–Alder addition of chloromethylmaleic anhydride (**14**) to 2-acetoxyfuran (**2**) took place smoothly in refluxing dichloromethane to yield 76%[5] of a single (tlc, nmr) adduct which was shown by chemical correlation (*vide infra*) to have structure **15**, i.e. a *meta* adduct where the fused anhydride has the *exo* configuration, which by analogy with the former case should be the thermodynamically most stable product (see Scheme 5).

The nmr of the adduct **15**, although quite simple, is of little help to determine regio- and stereochemistry in this case; indeed, the key proton H_a appears as a sharp singlet which means it is not coupled

[5]Lower yields were obtained when the reaction was scaled up.

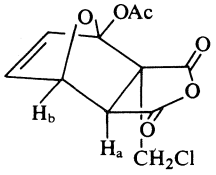
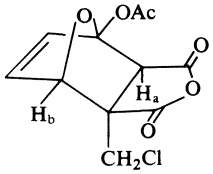
SCHEME 5

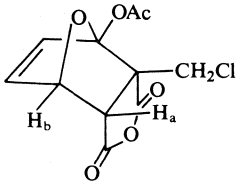
appreciably to any other proton in the molecule. Of the four possible adducts (*exo-ortho*, *exo-meta*, *endo-ortho*, and *endo-meta*) it therefore results that only one, the *endo-ortho* structure, can safely be eliminated as H_a and H_b form a dihedral angle of approximately 45° and therefore should be coupled by 3–4 Hz.



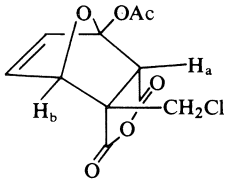
exo-ortho



exo-meta **15**



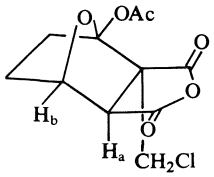
endo-ortho



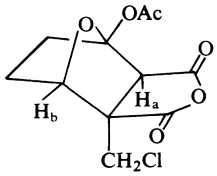
endo-meta

Hydrogenation of the adduct over 10% palladium on charcoal in ethyl acetate gave 87% of the crystalline dihydroadduct **16** (*exo-meta*) whose structure was conclusively established by X-ray diffraction as described below (*vide infra*).

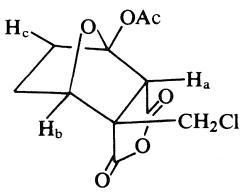
As in the former case, the nmr spectrum is of little help in establishing the structure since the H_a proton again appears as a sharp singlet and therefore, of the three remaining possible structures for the dihydro adduct, only the *endo-meta* dihydro adduct may possibly be eliminated since H_a and H_c should normally show a long-range W coupling of 1–2 Hz as in the norbornyl systems. Be that as it may, there nevertheless remain two possible structures, perhaps three, and since the carbon-13 spectra of these compounds which were recorded did not allow us to unambiguously solve the problem, we resorted, as mentioned earlier, to the method of X-ray diffraction (*vide infra*).



exo-ortho



exo-meta **16**



endo-meta

Again, in analogy with the first adduct discussed, a few sequences of reactions were carried out in order to assess the possibilities of the intermediate for further elaboration. Firstly, heating anhydride **16** in water for 30 min at 70°C and then leaving it at room temperature for 12 h yielded the corresponding crystalline diacid which was characterized as its dimethyl ester by treating it with diazomethane. The crystalline diester **17** was obtained in an overall yield of 72% (see Scheme 6). As in the previous cases, the *endo* proton, α to carbomethoxy, appears as a sharp singlet at δ 3.3. Cleavage of the hemiketal acetate group of dimethylester **17** took place smoothly as in the previous case but, however, yielded 95% of the undesired hydroxyketodiester **18**, i.e. where the desired chloromethyl group had been transformed into a fused cyclopropane ring by internal displacement of chlorine by the β-ketoester anion even under the mild conditions (0°C) used. Such behavior for somewhat similar systems has been exploited by Eschenmoser *et al.* in their synthesis of colchicine (17*a*) and by Greenlee and Woodward in their synthesis of marasmic acid (17*b*); in these cases, however, more basic conditions were used (*t*-BuOK – benzene). Acetylation of the product (**18**) in pyridine – acetic anhydride at room temperature for 24 h yielded 94% of the corresponding crystalline monoacetate **19**, thus corroborating the proposed structure **18** for the hydroxyketodiester. It is important to note at this point that, regarding the ultimate objective pursued in this work, loss of the chloromethyl side chain renders the intermediate useless.

It therefore becomes imperative that the bicyclic derivative **17** be elaborated further before hemiketal acetate opening and/or that an alternative method of hemiketal acetate cleavage be found which avoids cyclopropanation (*vide infra*).

In a second sequence, dihydro adduct **16** was reduced with sodium borohydride in ethanol to yield 80% of the corresponding crystalline fused lactone **20** where a sharp singlet at δ 3.10 is typical of the *endo* proton α to carbonyl; also, an AB system (J = 9.7 Hz) centered at δ 4.36, and which shows no vicinal coupling, both demonstrate conclusively that reduction took place in a totally regioselective manner on the chloromethyl side of the anhydride (see Scheme 7). Interestingly, reduction of dihydroadduct **16** using lithium tri-*tert*-butoxyaluminium hydride in tetrahydrofuran gave 83% of an epimeric mixture of lactols **21** as evidenced by nmr; however, the sharpness of the melting point suggests that in the crystalline form only one diastereoisomer of the lactol is present. In the nmr, the epimeric mixture of lactols shows a singlet at δ 2.07 for the *endo* proton α to carbonyl and two singlets at δ 3.22 and 3.27 integrating for one hydrogen and attributable to the lactol carbinol. However, the final and conclusive evidence showing that the site of reduction is identical to that observed with sodium borohydride was obtained by reducing the epimeric lactol mixture **21** to obtain the fused lactone **20** described above.

Finally, cleavage of the hemiketal acetate group of fused lactone **20** in methanolic sodium methoxide at 0°C and acetylation at room temperature of the crude product afforded the crystalline 4-acetoxycyclohexanone derivative **22** in 80% yield. As in the previous case, chlorine was displaced by the β-ketolactone anion resulting in the formation of a fused cyclopropane ring, thus again imposing the condition of elaborating bicyclic intermediate **20** further prior to hemiketal acetate opening and/or of finding an alternative method of hemiketal acetate cleavage which avoids cyclopropanation. Such a method was indeed found simply by treating anhydride **16** with methanolic hydrogen chloride which yields 71% of the desired 2,3-disubstituted 4-hydroxycyclohexanone **23**. Further work is therefore in progress on this and related series.

X-Ray Structure Determination of the Dihydro Adduct of 2-Acetoxyfuran and Chloromethylmaleic Anhydride (16)

Final atomic coordinates and their standard deviations are given in Table 1.[6] The molecular structure is represented by the pair of stereoscopic drawings in Fig. 1. The molecule consists of a six-membered ring A (atom C(1) through C(6)) in the boat conformation *cis* fused to a five-membered ring B made up of the anhydride group of atoms. In addition, an oxygen atom O(7) bridges atoms C(1) and C(4) of ring A. Finally the acetate group is on the bridgehead at C(1) while the chloromethyl group is *endo* at C(3).

Bond Distances and Angles

The interatomic distances and angles calculated from the final refined coordinates are summarized in Fig. 2. The estimated standard deviations are of the order of 0.004 Å and 0.3° for bond distances and angles between nonhydrogen atoms. When one H atom is implied, these values become 0.03 Å and 2° respectively. The two bridging C—O bond lengths are significantly different 1.447(3) and 1.422(3) Å. Although no explanation is given, a similar situation has been found for an analogous oxabicyclo-[2.2.1]heptane derivative where the corresponding distances have the values of 1.442(3) and 1.425(3) Å (22).

The C(sp^3)—C(sp^3) bond distances, ranging from 1.504 to 1.550 Å, average 1.530 Å, and the C(sp^3)—Cl distance of 1.782(3) Å are all normal. Except for angles C(2)–C(1)–C(6) = 109.5(3)° and C(3)–C(4)–C(5) = 110.9(3)°, the other bond angles in the bicyclo[2.2.1] system are smaller than usual; they

[6]The structure factor table and the anisotropic temperature factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Canada, K1A 0S2.

range in values from 100.3 to 102.0° and average 101.2°.

Mean Planes

The least-squares plane computed for the anhydride group reveals that C(2) deviates from the plane by about 10σ; when C(2) is omitted the groups of atoms are planar (Table 2). The acetate group including C(1) is also planar. Other various planes have been defined and the angles between them are compared in Fig. 3 with the corresponding dihedral angles in the *anti*-8-tricyclo[3.2.1.$0^{2,4}$] octyl derivative (23).

TABLE 2. Mean planes*

*The esd's are of the order of 0.4° except for the torsion angle involving a H atom for which the esd is of 3°.

Torsion Angles

The torsion angles of interest are listed in Table 3. In the six-membered ring the torsion angles do correspond to the boat conformation but with deviations of up to 17° from the theoretical values. Two other torsion angles, C(6)–C(1)–C(2)–C(7) and C(5)–C(4)–C(3)–C(8), nearly 180°, indicate that all light atoms C(1) to C(8) are very nearly coplanar. The torsion angle H(4)–C(4)–C(3)–C(9) has a value of 80° which supports nicely the fact that no coupling is observed in the nmr between protons H_b and H_c in structures **3** and **4** (*vide supra*).

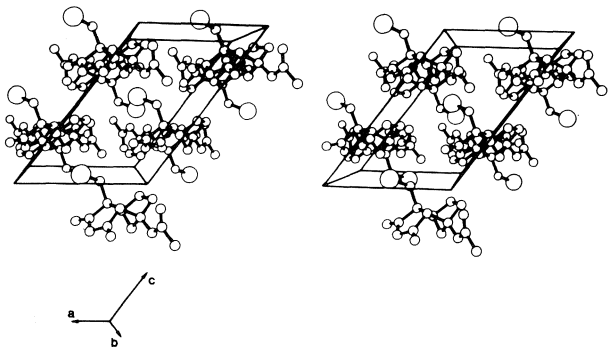

FIG. 4. Stereoscopic view of the packing of the molecule of dihydro adduct **16**.

Packing of Molecules

The organisation of the molecules in the crystal is shown in Fig. 4. There are no contacts shorter than 3.30 Å, hence the molecules are held in the crystal by van der Waals forces only.

Experimental

Melting points (mp) were taken on a Büchi apparatus and are uncorrected. The nmr spectra were recorded on a Bruker WH-90 apparatus and tetramethylsilane used as internal standard; deuterated solvents used are indicated in the experimental. The chemical shifts (δ) are expressed in parts per million (ppm) and the coupling constants (*J*) in Hertz (Hz). The following notation has been used throughout: s for singlet, d for doublet, t for triplet, m for multiplet, dd for doublet of doublets, br s for broadened singlet and unres. m for unresolved multiplet. The infrared spectra (ir) were recorded on a Perkin-Elmer 710A apparatus using the 1601 cm^{-1} band of a polystyrene film as reference. The EI mass spectra were taken on a AEI MS902 spectrometer and the CI spectra taken on a AEI MS25 apparatus. Finally, the combustion analyses were done by Guelph Chemical Laboratories Ltd., Guelph, Ont.

exo-*1-Acetoxy-7-oxabicyclo[2.2.1]heptane-2,3-dicarboxylic Anhydride (4)*

Catalytic hydrogenation of **3** (8, 9) (7.2 g, 33.6 mmol) in ethyl

acetate over 10% Pd/C catalyst gave, after filtration through Celite and recrystallization from mixtures of dichloromethane–hexane, 7.2 g (94%) of colourless crystals **4**, mp 143–144°C (lit. (10) mp 165–166°C (AcOEt)).[7] Infrared ($CHCl_3$): 1870, 1790 and 1760 cm^{-1}; nmr (acetone-d_6), δ: 2.2 (s, 3H), 1.7–2.3 (m, 4H), 3.85 (A of AB, d, 1H, J_{AB} = 8 Hz), 4.20 (B of AB, 1H), and 5.0 (unres. m, 1H); ms, CI, *m/e*: 227 (M + 1).

Dimethyl exo-*1-Acetoxy-7-oxabicyclo[2.2.1]heptane-2,3-dicarboxylate (8)*

A suspension of anhydride **4** (10) (210 mg, 0.93 mmol) in 4 mL of water was heated at 70°C for 1 h. After the reaction mixture had cooled to room temperature, the white crystalline diacid was filtered and dried *in vacuo* at room temperature. The crude diacid was esterified with an excess of ethereal diazomethane at room temperature to afford diester **8** (230 mg, 91%) as colourless crystals, mp 128–129°C; ir ($CHCl_3$): 1760–1750 cm^{-1}; nmr $CDCl_3$), δ: 2.1 (s, 3H), 1.6–2.4 (m, 4H), 3.4 (AB, 2H, J_{AB} = 9.4 Hz, Δν = 58 Hz), 3.6 (s, 3H), and 5.0 (br d, 1H); ms, CI, *m/e*: 273 (M + 1).

2,3-Dicarbomethoxy-4-hydroxycyclohexanone (9)

To a solution of triester **8** (1.7 g, 6.25 mmol) in 25 mL of dry methanol at 0°C were added 40 mL of 0.61 *N* methanolic sodium methoxide. The solution was stirred for 60 min under argon at 0°C and then quenched by the addition of an excess of acidic resin (Dowex 50W-X8). The resulting mixture was stirred for 10 min, filtered, and the resin washed with 100 mL of methanol. After drying ($MgSO_4$) and removal of the methanol *in vacuo*, the residual colourless oil was crystallized from mixtures of ether–hexane to afford 1.37 g (96%) of colourless crystals **9**, mp 108–109°C; ir ($CHCl_3$): 3500, 1760, 1735, and 1260 cm^{-1}; nmr $CDCl_3$), δ: 1.9–2.9 (m, 4H), 3.0 (s, 1H, —OH), 3.30 (A of ABX, dd, 1H, J_{AB} = 12.3 Hz, J_{AX} = 2.6 Hz), 3.74 (s, 3H), 3.77 (s, 3H), 4.10 (B of ABX, d, 1H), and 4.6 (unres. m, 1H); ms, CI, *m/e*: 231 (M + 1). *Anal.* calcd. for $C_{10}H_{14}O_6$: C 52.17, H 6.13; found: C 52.45, H 6.31.

1,4-Diacetoxy-2,3-dicarbomethoxycyclohexene (10)

Ketoester **9** (450 mg, 1.96 mmol) was dissolved in 5 mL of dry pyridine and 1 mL of acetic anhydride added. After stirring for 12 h at room temperature the volatile components were removed *in vacuo* and the residual oil chromatographed on 28 g of silica gel. Elution with ethyl acetate afforded 550 mg of diacetate **10** as a white solid. Recrystallization from mixtures of ether–hexane gave 500 mg (81%) of colourless crystals **10**, mp 106–107°C; ir (CH_2Cl_2): 1780, 1730, 1650, and 1220 cm^{-1}; nmr ($CDCl_3$), δ: 1.9 (m, 2H), 2.05 (s, 3H), 2.22 (s, 3H), 2.42 (m, 2H), 3.68 (s, 3H), 3.72 (s, 3H), 3.98 (m, 1H), and 5.2 (m, 1H); ms, *m/e*: 314 (M^+).

Sodium Borohydride Reduction of Anhydride 4

A suspension of anhydride **4** (16*b*) (1 g, 4.44 mmol) in 5 mL of absolute ethanol at 0°C was treated, in small portions, with sodium borohydride (200 mg, 5.28 mmol). The reaction mixture was allowed to warm slowly to 20°C by permitting the ice to melt (2 h). The solution was then cooled to 0°C and acidified with 10% hydrochloric acid to pH 5. The resulting solution was extracted with dichloromethane (3 × 50 mL) and the combined extracts dried ($MgSO_4$). Removal of the volatile components *in vacuo* gave an oil which easily crystallized in ether to afford 800 mg (85%) of white crystalline lactone **11**, mp 139–140°C (lit. (10*b*) mp 142–143°C); ir (CH_2Cl_2): 1770, 1750, and 1220 cm^{-1}; nmr ($CDCl_3$), δ: 1.6–2.5 (m, 4H), 2.20 (s, 3H), 2.9 (A of AB, m, 1H), 3.50 (B of AB, d, 1H, J_{AB} = 8.5 Hz), 4.14 (A of AB, m, 1H, J_{AB} = 9.4 Hz), 4.37 (d, 1H), and 4.51 (B of AB, d, 1H); ms, *m/e*: 169 ($M^+ - CH_3CO\cdot$).

[7]Recrystallization of our material in ethyl acetate did not raise the mp.

Base Cleavage of Hemiketal Acetate 11

To a solution of lactone **11** (900 mg, 4.28 mmol) in 15 mL of dry methanol at 0°C were added 27 mL of 0.61 *N* methanolic sodium methoxide. The solution was stirred for 40 min under argon at 0°C and then quenched by the addition of an excess of acidic resin (Dowex 50W-X8). The mixture was worked up as before and the resulting clear oil crystallized easily from chloroform to yield 610 mg (85%) of white crystalline lactone **12** as an epimeric mixture; ms, CI, *m/e*: 171 (M + 1).

Acetylation of Hydroxy Keto Lactone 12

Lactone **12** (500 mg, 2.94 mmol) was dissolved in 10 mL of dry pyridine and 1.2 mL of acetic anhydride added. After stirring for 8 h at room temperature the volatile components were removed *in vacuo* and the residual oil chromatographed on 80 g of silica gel. Elution with ethyl acetate afforded 700 mg (94%) of diacetate **13** as a white solid, mp 139–140°C; ir (CH_2Cl_2): 1750, 1725, 1690, and 1220 cm^{-1}; nmr ($CDCl_3$), δ: 1.6–2.5 (m, 4H), 2.10 (s, 3H), 2.27 (s, 3H), 3.44 (X of ABX, m, 1H), 3.92 (B of ABX, m, 1H), 4.44 (A of ABX, m, 1H), and 5.25 (m, 1H); ms, *m/e*: 254 (M^+).

exo-*1-Acetoxy-3-chloromethyl-7-oxabicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic Anhydride (15)*

To a solution of chloromethylmaleic anhydride (**14**) (17) (580 mg, 4 mmol) in 25 mL of dry dichloromethane was added 500 mg (4 mmol) of 1-acetoxyfuran (**2**) (8, 9) and the solution was heated to reflux for 18 h. Removal of the volatile components *in vacuo* gave a crude crystalline adduct which was recrystallized from mixtures of dichloromethane–hexane to afford 820 mg (76%) of colourless crystals **15**, mp 125–126°C; ir (CH_2Cl_2): 1860, 1790, 1760, and 1200 cm^{-1}; nmr ($CDCl_3$), δ: 2.18 (s, 3H), 3.22 (A of AB, d, 1H, J_{AB} = 11.4 Hz), 3.62 (s, 1H), 4.01 (B of AB, d, 1H), 5.13 (d, 1H), 6.66 (A of AB, dd, 1H, J_{AB} = 5.9 Hz), and 6.90 (B of AB, 1H); ms, *m/e*: 272 (M^+).

exo-*1-Acetoxy-3-chloromethyl-7-oxabicyclo[2.2.1]heptane-2,3-dicarboxylic Anhydride (16)*

Application of the same hydrogenation procedure as described above for the preparation of **4** gave 350 mg (87%) of **16** (recrystallized from mixtures of dichloromethane–hexane) as colourless crystals, mp 175–176°C; ir (CH_2Cl_2): 1860, 1780, 1760, and 1220 cm^{-1}; nmr ($CDCl_3$), δ: 1.6–2.3 (m, 4H), 2.22 (s, 3H), 3.60 (A of AB, d, 1H, J_{AB} = 11.5 Hz), 3.79 (s, 1H), 3.85 (B of AB, 1H), and 4.75 (d, 1H, *J* = 4.7 Hz); ms, *m/e*: 274 (M^+). *Anal.* calcd. for $C_{11}H_{11}O_6Cl$: C 48.10, H 4.04, Cl 12.91; found: C 48.10, H 4.19, Cl 12.10.

Dimethyl exo-*1-Acetoxy-3-chloromethyl-7-oxabicyclo[2.2.1]-heptan-2,3-dicarboxylate (17)*

A suspension of anhydride **16** (600 mg, 2.18 mmol) in 4 mL of water was heated at 70°C for 30 min and then left at room temperature for 12 h. The reaction mixture was cooled to 0°C and the white crystalline diacid filtered, dried, and esterified with ethereal diazomethane to afford diester **17** (500 mg, 72%) as colourless crystals, mp 122–123°C; ir ($CHCl_3$): 1760 and 1750 cm^{-1}; nmr ($CDCl_3$), δ: 1.6–2.4 (m, 4H), 2.08 (s, 3H), 3.24 (s, 1H), 3.51 (A of AB, d, 1H, J_{AB} = 11.4), 3.66 (s, 3H), 3.76 (s, 3H), 4.28 (B of AB, 1H), and 5.15 (br d, 1H); ms, CI, *m/e*: 321, 323 (M + 1, M + 3).

Base Cleavage of Hemiketal Acetate 17[8]

To a solution of diester **17** (300 mg, 0.94 mmol) in 10 mL of dry methanol at 0°C were added 8 mL of 0.61 *N* methanolic sodium methoxide. The solution was stirred for 30 min under argon at 0°C, then quenched by the addition of an excess of acidic resin (Dowex 50 W-X8). The mixture was worked up as above, giving

[8]The reaction time is crucial in this case as the product evolves further with longer reaction times.

For personal use only.

pure alcohol **18** as a clear oil (247 mg, 95%); ir ($CHCl_3$): 3600, 1750, 1720, 1700, and 1260 cm^{-1}; nmr ($CDCl_3$), δ: 1.86 (A of AB, d, 1H, J_{AB} = 6.4 Hz), 2.30 (B of AB, 1H), 1.6–2.7 (m, 4H), 3.73 (s, 3H), 3.75 (s, 3H), 3.90 (s, 1H, —OH), and 4.70 (t, 1H); ms, *m/e*: 228 (M^+).

Acetylation of Hydroxyketodiester 18

Alcohol **18** (50 mg, 0.18 mmol) was dissolved in 1 mL of dry pyridine and 1 mL of acetic anhydride added. After stirring for 24 h at room temperature, the volatile components were removed *in vacuo* and the residual oil chromatographed on 10 g of silica gel. Elution with ethyl acetate afforded 55 mg (94%) of acetate **19** as a white solid, mp 153–155°C; ir ($CHCl_3$): 1740, 1730, and 1700 cm^{-1}; nmr ($CDCl_3$), δ: 1.82 (A of AB, d, 1H, J_{AB} = 6.5 Hz), 2.10 (s, 3H), 2.21 (B of AB, 1H), 2.0–2.5 (m, 4H), 3.71 (s, 3H), 3.78 (s, 3H), and 5.91 (t, 1H); ms, *m/e*: 284 (M^+).

Sodium Borohydride Reduction of Anhydride 16

A suspension of anhydride **16** (750 mg, 2.72 mmol) in 10 mL of absolute ethanol at 0°C was treated, in small portions, with sodium borohydride (140 mg, 3.7 mmol). The reaction mixture was allowed to warm slowly to 20°C (2 h). The solution was then cooled to 0°C and acidified with 10% hydrochloric acid to pH 3. The resulting solution was extracted with dichloromethane (3 × 20 mL) and the combined extracts dried ($MgSO_4$). Removal of the volatile components *in vacuo* gave a crude crystalline lactone which was recrystallized from mixtures of ether–dichloromethane to afford 600 mg (80%) of colourless crystals **20**, mp 194–195°C; ir ($CHCl_3$): 1770 and 1750 cm^{-1}; nmr ($CDCl_3$), δ: 1.6–2.5 (m, 4H), 2.18 (s, 3H), 3.10 (s, 1H), 3.73 (A of AB, d, 1H, J_{AB} = 11.7 Hz), 3.84 (B of AB, 1H), 4.23 (A of AB, d, 1H, J_{AB} = 9.7 Hz), 4.46 (d, 1H), and 4.49 (B of AB, 1H); ms, *m/e*: 262 and 260 (M + 2, M^+).

*Lithium Tri-*tert*-butyoxyaluminium Hydride Reduction of Anhydride 16*

To a suspension of lithium tri-*tert*-butoxyaluminium hydride (7 g, 27.5 mmol) in 100 mL of dry tetrahydrofuran at −20°C was added a solution of anhydride **16** (6 g, 21.9 mmol) in 100 mL of dry tetrahydrofuran at −20°C. The solution was stirred for 8 h under argon at −20°C, then 50 mL of water–tetrahydrofuran (1:1) were added followed by the addition of 100 mL of hydrochloric acid (1.2 *N*). The resulting solution was extracted with methylene chloride (3 × 20 mL) and the combined organic layers dried ($MgSO_4$) and filtered through Celite. The volatile components were removed *in vacuo* and the residual colourless oil dissolved in 50 mL of methylene chloride and then cooled at −10°C to afford 5.0 g (83%) of an epimeric mixture of lactols **21** as colourless crystals, mp 183–185°C; ir (CH_2Cl_2): 3600, 1775, and 1755 cm^{-1}; nmr (acetone-d_6), δ: 1.6–2.5 (m), 2.07 (s superimposed over residual nondeuterated acetone), 3.22 and 3.27 (2s, 1H), 3.77–4.95 (m, 2H), 4.95 (m, 1H), 5.80 (m, 1H), and 7.0 (m, 1H, —OH); ms, *m/e*: 278 and 276 (M + 2, M^+). The mixture of lactols **21** can be converted to lactone **20** under conditions identical to those described for the reduction of anhydride **16** to lactone **20**.

Base Cleavage of Hemiketalacetate 20

To a solution of lactone **20** (120 mg, 0.461 mmol) in 5 mL of dry methanol at 0°C were added 3 mL of 0.61 *N* methanolic sodium methoxide at 0°C. The solution was stirred for 30 min[8] under argon at 0°C followed by the addition of an excess of acidic resin (Dowex 50W-X8). The mixture was worked up as above and the resulting clear oil dissolved in 2 mL of dry pyridine and treated with 0.3 mL of acetic anhydride. The resulting mixture was stirred for 18 h at room temperature after which 0.2 mL of methanol was added. The volatile components were removed *in vacuo* and the residual oil chromatographed on 20 g of silica gel. Elution with ethyl acetate afforded 96 mg (80%) of colourless crystals of acetate **22**, mp 194–195°C; ir ($CHCl_3$): 1780, 1740, and 1700 cm^{-1}; nmr ($CDCl_3$), δ: 1.67 (A of AB, d, 1H, J_{AB} = 6.2 Hz), 2.05 (B of AB, 1H), 2.15 (s, 3H), 1.96–2.5 (m, 4H), 4.25 (s, 2H), and 5.64 (t, 1H); ms, *m/e*: 224 (M^+). *Anal.* calcd. for $C_{11}H_{12}O_5$: C58.92, H 5.39; found: C 58.76, H 5.43.

Acidic Methanolysis of Hemiketal Acetate 16

To a suspension of anhydride **16** (500 mg, 1.82 mmol) in 10 mL of dry methanol at 0°C was added 10 mL of 5% methanolic hydrogen chloride. The reaction mixture was allowed to warm slowly to 25°C and then stirred 30 min at this temperature. The solution was then cooled to 0°C and neutralized with aqueous sodium bicarbonate. The resulting mixture was extracted with ether (3 × 30 mL) and the combined extracts dried ($MgSO_4$). Removal of the volatile components *in vacuo* gave a white solid which was recrystallized from mixtures of chloroform–hexane to afford 360 mg (71%) of colourless crystals **23**, mp 165–166°C; nmr ($CDCl_3$), δ: 1.6–1.8 (m, 2H), 2.26 (s, 1H, —OH), 2.3–2.6 (m, 2H), 2.96 (s, 1H), 3.51 (s, 3H), 3.80 (A of AB, d, 1H, J_{AB} = 11.7 Hz), 3.79 (s, 3H), 4.23 (B of AB, d, 1H), and 4.15 (m, 1H); ms, CI, *m/e*: 279, 281 (M + 1, M + 3). *Anal.* calcd. for $C_{11}H_{15}O_6Cl$: C 47.41, H 5.43, Cl 12.72; found: C 47.69, H 5.58, Cl 12.36.

X-Ray Structure Determination of Dihydro Adduct 16

Well developed clear prismatic crystals were obtained by slow evaporation from a chloroform–hexane (80:20) solution. Precession photographs revealed that the crystals belonged to the monoclinic system, space group $P2_1/c$ (systematic absences for $0k0$, $K \neq 2n$; $h0l$, $l \neq 2n$). The unit cell dimensions were obtained by a least-squares refinement of the angular measurements of 25 reflections centered on the Nonius CAD4 diffractometer using graphite monochromatized MoKα radiation.

Crystal data:

$C_{11}H_{11}ClO_6$ f.w. = 274.66

Monoclinic, a = 8.059(3), b = 15.079(3), c = 12.474(4) Å, β = 126.66(3)°, V = 1216.0 $Å^3$, ρ_0 = 1.49 Mg/m^3, ρ_c = 1.500 Mg/m^3, Z = 4, $F(000)$ = 568 e, μ(MoKα) = 0.326 mm^{-1}, λ(MoKᾱ) = 0.71068 Å, mp = 447–448 K.

Three dimensional intensity data were collected on the Nonius CAD4 diffractometer using a graphite monochromator and MoKα radiation. The reflection intensities were measured with an ω − 2θ scan, Δω = (0.80 + 0.35 tan θ) degrees, and an aperture 4 mm high and 2 mm wide. Each reflection was measured with a prescan acceptance limit such that $\sigma(I)/I$ = 0.010 at a minimum scanning speed, S, of 6.67 deg min^{-1}, and a maximum scanning time of 120 s. The intensities of three standard reflections were monitored every hour; these did not vary to any significant degree during the entire period of the data collection. No trend was detected although the crystal had turned orange by the end of the measurement. The fluctuations of the reference reflections remained constant to within ±1.5% over the duration of the measurements. Of the 2138 reflections measured out to $2\theta \leq 50°$ (hkl and $hk\bar{l}$), 1556 of them (72%) were such that $I/\sigma(I) > 1.90$, with $\sigma^2(I) = (I_T + 4B)S^2 + (0.04\ I_N)^2$ where I_T is the total intensity, I_N the net intensity, and B the background. Lorentz and polarization corrections were applied but, since the crystal was of small dimensions (0.22 × 0.30 × 0.50 mm) and the linear absorption coefficient was low, no absorption correction was applied.

A set of normalized structure factors $|E|$ was obtained after isotropic temperature factor correction. The statistical averages of the normalized structure factors indicated a centrosymmetrical distribution in agreement with the space group determination. The signs of 305 reflections with $|E| \geq 1.50$ were determined using the MULTAN multisolution programme (18). The E-map, calculated with the set of phases having the highest combined figures of merit coordinates and isotropic temperature

factor led to an R-value of 0.205, ($R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$). The function minimized was $\Sigma w(|F_o| - |F_c|)^2$. Following anisotropic temperature factor refinement of Cl, O, and C atoms, which was concluded when R reached 0.086, the H atoms were located on a Fourier difference map. The refinement of the atomic coordinates, anisotropic temperature factors for Cl, O, and C atoms, and isotropic temperature factors for H atoms proceeded normally using the block diagonal approximation and unit weights for all reflections. When the refinement process was terminated $R = 0.039$ and the mean error in an observation of unit weight $\sigma_F = [\Sigma w \Delta F^2/(m - n)]^{1/2} = 2.01$, where m is the number of reflections and n, the number of refined parameters. When all measured reflections were included, $R = 0.060$. The mean shift/error in the final least-squares cycle was 0.3. The difference Fourier synthesis following the last cycle showed electron density fluctuations in the range -0.18 + to 0.23 Å^{-3}. Weighting analyses confirmed the suitability of unitary weights over those derived from counting statistics. Scattering factors for the H atoms were taken from Stewart *et al.* (19) and all others from Cromer and Waber (20). The anomalous dispersion for the chlorine atom was taken from Cromer and Liberman (21).

^{13}C lithiation shifts in aldimines and ketimines. Evidence on the configuration of lithiated *N-tert*-butylimines

ROBERT R. FRASER AND NOEMI CHUAQUI-OFFERMANNS

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received April 15, 1981

ROBERT R. FRASER and NOEMI CHUAQUI-OFFERMANNS. Can. J. Chem. **59**, 3007 (1981).

The ^{13}C shieldings for a series of aldimines and ketimines have been measured along with the shifts for their 1-lithio derivatives. For those aldimines with a primary or secondary alkyl group attached to nitrogen, the "lithiation shifts" for the attached carbon (C-4) were all upfield due to the change from *anti* to *syn* configuration on lithiation. In the ketimines and in the *N-tert*-butyl aldimines and ketimines, the lithiation shifts for the C-4 carbon failed to provide stereochemical information. The shifts at C-1 and C-2 proved similar to those previously observed for lithiated alkenes.

ROBERT R. FRASER et NOEMI CHUAQUI-OFFERMANNS. Can. J. Chem. **59**, 3007 (1981).

On a mesuré les blindages du ^{13}C d'une série d'aldimines et de cétimines ainsi que les déplacements chimiques de leurs dérivés lithiés en position 1. Pour les aldimines ayant un groupe alkyle primaire ou secondaire fixé sur l'azote, les déplacements conduits par la lithiation du carbone (C-4) se font tous vers les champs forts par suite d'un changement de configuration de *anti* à *syn* lors de la lithiation. Dans le cas des cétimines, des *N*-butylaldimines et cétimines, les déplacements provoqués par la lithiation sur le carbone en position 4 n'ont pas apporté d'information sur la stéréochimie. Les déplacements chimiques des carbones en positions 1 et 2 sont identiques à ceux observés antérieurement pour les dérivés lithiés des alcènes.

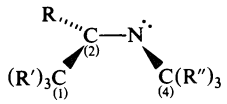
In a series of studies of the stereochemistry of lithiation and alkylation of aldimines and ketimines, we have described evidence for a very marked energetic preference for the formation of a *syn*[1] lithiated intermediate on the basis of formation of *syn* alkylation products (1, 2), *ab initio* calculations (3), and the observation of extraordinarily large barriers to rotation about the N—C-4 single bond of several 1-lithio-3-azapent-2-enides (4). Distinction between configurations at the C=N bond of these imines having the formulae shown below is readily provided by the large *syn–anti* differential shielding which appears as preferential upfield shifts of 5 to 11 ppm (5) for either C-1 or C-4 when *syn* to each other.

In this paper we wish to describe the ^{13}C shielding parameters for a variety of lithiated imines. Comparison with the shieldings of their neutral precursors provides a measure of the "lithiation shifts" whose magnitudes appear to be significantly influenced by substituent effects and by the stereochemistry at the C=N bond. A more unique class of sterically congested aldimines and ketimines bearing an *N-tert*-butyl substituent was also studied. One of these, acetone *N-tert*-butylimine was observed to undergo lithiation and methylation to give only *syn* product, indicative of



a *syn* lithiated intermediate. Unfortunately, similar alkylation experiments on *N-tert*-butylaldimines were inconclusive.[2] Measurement of the ^{13}C spectra of these aldimines and lithio derivatives gave "lithiation shift" data which failed to provide any clear stereochemical evidence.

Experimental

Imines **1–10** were synthesized from the parent aldehyde or ketone and primary amine as described previously (5). For the ketimine derived from *tert*-butyl amine (60 mmol scale) pentane (10 mL) was used in place of ether and two drops of pyridine were added to shorten the reaction time to 16 h. Yields of distilled imine varied from 30 to 50%. For the *N-tert*-butyl aldimines only one hour of reaction time was required to produce similar yields. Much of the loss in yield is thought to be manipulative, resulting from the high volatility of these imines. Compound **11** was synthesized (in 62% yield) by the method of Etienne and Correia (6). The product, bp 64°C (18 Torr) exhibited proton and ^{13}C nmr properties (5) consistent with structure. Imine **14** has been described previously (7).

The solutions of all anions, 1 *M* in THF, were prepared as reported previously for 1-lithio-4-methyl-3-azapent-2-enide (4).

The ^{13}C spectra were recorded on a Varian FT-80 nmr spectrometer operating at a frequency of 20 MHz and at a temperature of 29°C. The assignments were made on the basis of

[1]The use of *syn–anti* nomenclature to describe the configuration at the C=N function will be continued herein as it serves to pinpoint the location at the C—N bond while *E–Z* nomenclature can be employed to delineate stereochemistry at the C-1—C-2 bond in lithiated derivatives.

[2]The single product observed in the alkylation of lithiated aldimines had the *anti* configuration. However, it is possible that a *syn* alkylation product was formed which then rapidly isomerized to *anti*. This isomerization would be expected to be faster in the *tert*-butyl series than in the isopropyl series ($t_{1/2}$ = 1 h at −20°C (2)).

off-resonance decoupling experiments and known substituent effects. To verify the signal assignment in **1** by an unambiguous method, a sample of 2-deutero-2-aminobutane was prepared by the reduction of 2-butanone oxime with lithium aluminum deuteride. Reaction of this amine with acetaldehyde gave 4-deutero-4-methyl-3-azahex-2-ene, **1**-d_1. The change in the appearance of the ^{13}C absorption of C-4 due to coupling with deuterium verified its signal assignment in the spectra of this imine and its lithio derivative.

Results and Discussion

Before discussing the nmr data of imines **1** to **15** and their lithio derivatives, one point must be emphasized. The formulae given to represent the lithiated imines are simply a formal representation of their gross structure. They are not meant to indicate a definitive position of the lithium counterion. Whether it is C-coordinated, N-coordinated, π-coordinated, or fully solvated cannot be determined at this time.

The ^{13}C shielding parameters, listed in Table 1, represent imines belonging to four classifications, each of which we will consider in sequence. The shieldings presented are those for carbons C-1, C-2, and C-4 of the common structural unit of all the imines which possess the C-1—C-2=N—C-4 or 3-azabut-2-ene fragment. These are the only absorptions which are consistently free from overlap with the peaks of solvent or other reaction components.

A. Aldimines

Compounds **1** to **4** are aldimines, all of which possess the more stable *anti* configuration. Previously we have found a consistent difference in the shifts for C-1 in several closely related *syn* and *anti* aldimines (5). The signal for C-1 in the *syn* form appeared 6 ppm to higher field. Assuming comparable shift differences in **1** to **4**, we have listed the estimated shifts for C-1 of each *syn* isomer in brackets.

The lithiation shifts at C-1 can be seen to be downfield shifts which show an increasing magnitude with the change from primary site (50 ppm) to a secondary (55 ppm) or a tertiary one (62 ppm). It is possible that this decrease in shielding at the lithiated carbon reflects a decrease in electron density and thus greater double bond character between C-1 and C-2. House *et al.* (8) proposed the same explanation to account for similar trends in

the chemical shifts of lithium enolates. The shifts at C-2 are consistent with this explanation, moving progressively upfield with substitution and also showing behavior parallel to the enolates (8). In the structurally related enamines, methyl substitution effects at C-1 and C-4 are also remarkably similar (9). The most consistent change in the aldimines occurs at C-4 which in each case shifts upfield by 8 to 9 ppm on lithiation. The major cause for this upfield shift is undoubtedly the change from the *anti* configuration in the aldimine to the *syn* configuration in the organolithium derivative. This change at the C-2—N bond introduces a γ-effect of steric origin. Shifts smaller in size can be seen in the data for C-4 of the carbon analogs given in Table 1. For example, comparing C-4 in **17**-Li versus **18** and **19**-Li versus **20** shows upfield lithiation shifts of 3.3 and 4.5 ppm respectively.

B. Acyclic Ketimines

The lithiation shifts at C-1, the primary carbon in **5**, **6**, and **7**, behave similarly to that of primary aldimine **1**, and the lithiation shifts for **8** and **9** at their secondary carbon, C-1, are comparable to that in **2**. The C-2 carbons of the imines **5** and **6** shift on lithiation, but by only a small amount (±3 ppm) as also found in **1**. Again C-2 undergoes a substantial upfield shift upon lithiation at the secondary α carbon in **9** just as occurs for C-2 in **2**. A striking difference in ketimine lithiation shifts vs. aldimines

[a] Shifts for the related hydrazonium iodides of 2-butanone were recently reported (14).
[b] Shifts in ppm from TMS. All shifts measured in THF except for **17** and **18** which were measured in chloroform-*d*.

is seen at C-4 where all ketimines give negligible shifts (±1 ppm) in contrast to the 9 ppm upfield shifts of aldimines. This is of course a result of the lack of any *anti* to *syn* configurational change in the ketimine series and therefore no introduction of a γ-shielding factor.

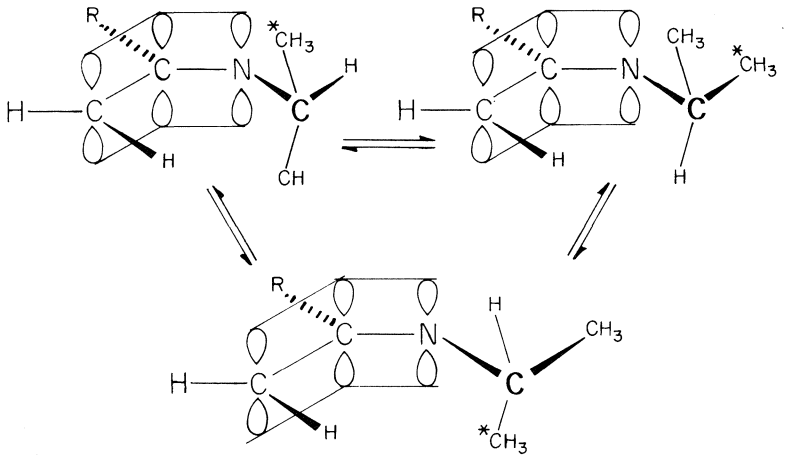

SCHEME 1

C. Cyclic Ketimines

The lithiation shifts for the exocyclic imine, **10**, do not differ significantly from those of either the open ketimine, **9**, or the endocyclic imine, **11**. One might attempt to utilize the fact that the shift for the *anti* lithiated α carbon in **11** is at higher field (δ 78) than would be expected for a *syn* lithiated carbon (i.e., the *syn*-lithiated carbon of **9** shifted 51 ppm downfield in **9**-Li), while the *anti*-lithiated carbon of **11**-Li is only shifted 41 and 45 ppm downfield in the two lithiation products (which differ in configuration at the C-1—C-2 bond). The magnitude of the downfield shift could be considered as diagnostic of the stereochemistry. However, the mobility of **9**, which surely changed on lithiation, precludes its use as a model for comparison with the data of the rigid imine **11**.

D. N-tert-*Butylimines*

Only one configuration in this category, that for **15**-Li has been established as *syn* by means of chemical evidence. Methylation of **15**-Li gave a single product **16** which was assigned the *syn* configuration on the basis of its slow subsequent isomerization to a mixture dominant in its *anti* configurational isomer, *anti* being expected to be the more stable isomer on the basis of steric interactions. Examination of the ^{13}C spectral data for **12–15** in comparison with **1**, **2**, **4**, and **5**, which are the *N*-isopropyl or *N-sec*-butyl imines of the same carbonyl compounds, provides little firm evidence regarding the configuration about the C-2—N bond in the lithiated *tert*-butyl imines. A comparison of the *syn* **15**-Li with **5**-Li reveals similar shielding parameters for both. Only at C-4 is the effect of the extra methyl group (an α effect) different in the ketimines (5.2 ppm) versus the lithiated species (2.9 ppm). Gamma effects at C-2 and δ effects at C-1 are both small. Indeed, δ effects in sterically crowded environments have generally been found to vary in an unpredictable fashion, up to ±3 ppm (13), so that their potential for providing stereochemical evidence is small. Comparing the lithiation shifts in **1**, **2**, and **4** with those of **12**, **13**, and **14** reveals differences in the upfield shift at C-4 on lithiation. They are smaller in the *tert*-butyl (4 ppm) series than in the isopropyl series (8 ppm) but no conclusion can be made since the lithiation shifts for **15** → **15**-Li (*syn*) and **11** → **11**-Li (*anti*) are also similar (2–4 ppm). Even the similarities at C-1 at lithiated **1**, **2** and **4** (all *syn*) in comparison with C-1 in lithiated **12**, **13**, and **14**, though suggestive, are not conclusive evidence of like configuration. Additional evidence will be required to prove the configurations in these lithiated *N-tert*-butylaldimines. An independent argument can be made for the *syn* configuration in all these species. We have described elsewhere the detection of two rotamers of equivalent energy for **12**-Li as shown in Scheme 1 (4). Since location of one methyl or two methyls "inside" or close to C-1 does not affect the relative energies of the two conformers, it would suggest that replacement of the remaining hydrogen at C-4 by a methyl would not introduce any steric destabilization of the *syn* configuration. This lack of change in steric effect in the lithiated *tert*-butyl imines versus isopropyl imines can in part be attributed to the very large N–C-2–C-1 bond angle of about 133° (3). It is also important to recognize that the smaller N–C-2–C-1 angle calculated to be 128° in the neutral *syn* imine should cause the *syn* isomer of the neutral *tert*-butyl imines to be strained more than their isopropyl counterparts as suggested in footnote 2.

Complexing and exchange of boron, aluminum, and gallium chlorides with some Lewis bases[1]

BORIS GLAVINCEVSKI AND SYDNEY K. BROWNSTEIN
Division of Chemistry, National Research Council, Ottawa, Ont., Canada K1A 0R9

Received March 31, 1981

BORIS GLAVINCEVSKI and SYDNEY K. BROWNSTEIN. Can. J. Chem. **59**, 3012 (1981).

Boron trichloride and dimethyl sulfide form a 1:1 complex. It exchanges with excess boron trichloride by a displacement mechanism with an activation energy of 5.0 ± 0.5 kcal/mol and with excess dimethyl sulfide by a dissociation mechanism which has an activation energy of 20 ± 1 kcal/mol. The 1:1 complex of $AlCl_3$ and dimethyl sulfide exchanges very rapidly with excess dimethyl sulfide. Equilibria and exchange reactions of $AlCl_3[(CH_3)_2O]$, $AlCl_3[(CH_3)_2O]_2$, and $(CH_3)_2O$ are described. Rapid exchange is always found in the analogous gallium systems. BCl_3 reacts with chloride ion to give BCl_4^- and $B_2Cl_7^-$, which exchange rapidly with excess BCl_3. $AlCl_3$ reacts with Cl^- and BCl_4^- to give $AlCl_4^-$ which does not exchange with $AlCl_3$.

BORIS GLAVINCEVSKI et SYDNEY K. BROWNSTEIN. Can. J. Chem. **59**, 3012 (1981).

Le trichlorure de bore donne un complexe 1:1 avec le sulfure de méthyle. En présence d'un excès de trichlorure de bore, il y a un échange suivant un mécanisme de déplacement avec une énergie d'activation de 5,0 ± 0,5 kcal/mol et en présence d'un excès de sulfure de méthyle suivant un mécanisme de dissociation avec une énergie d'activation de 20 ± 1 kcal/mol. Le complexe 1:1 formé entre $AlCl_3$ et le sulfure de méthyle échange très rapidement avec le sulfure de méthyle en excès. Des équilibres et des réactions d'echange de $AlCl_3$ $[(CH_3)_2O]$ et $AlCl_3[(CH_3)_2O]_2$ avec $(CH_3)_2O$ sont décrits. On a toujours trouvé un échange rapide dans les systèmes semblables du gallium. BCl_3 réagit avec l'ion chlorure pour donner BCl_4^- et $B_2Cl_7^-$, complexes qui échangent rapidement avec le BCl_3 en excès. $AlCl_3$ réagit avec Cl^- et BCl_4^- pour donner $AlCl_4^-$ qui n'échange pas avec $AlCl_3$.

Introduction

Lewis acid–base interactions involving boron trihalides have been widely studied and a variety of exchange rates and mechanisms have been reported (1–6). Exchange of the acid–base complex with excess of Lewis acid has only been reported for boron trifluoride and occurs by a displacement mechanism. Exchange of the complex with an excess of Lewis base has been found to occur via a dissociation mechanism with acetonitrile and trimethylamine as bases and BCl_3 and BBr_3 as Lewis acids (4, 5). Thus far, studies of aluminum halide complexes have been limited to the solid state and to solutions of the halide in acetonitrile, a strongly coordinating solvent (7–14). In acetonitrile both cationic and anionic aluminum species have been identified. It is possible that different results might be obtained if the aluminum halide and Lewis base are allowed to react in an inert solvent. Sulfur dioxide, a good solvent for $AlCl_3$ and its complexes, was chosen for this study. This solvent is not truly inert since it forms a molecular complex with aluminum trichloride (15). The structure of the complex has not been determined although a dimer with SO_2 coordinated to chlorine at each end of the Al_2Cl_6 chain has been suggested.

The tetrachloroborate anion is well known but thus far no evidence has been reported for $B_2Cl_7^-$ although the existence of the analogous $B_2F_7^-$ is well established (16). With aluminum as central atom equilibria have been reported between $AlCl_3$, Cl^-, $AlCl_4^-$, and $Al_2Cl_7^-$ (17, 18). The positions of the equilibria depend upon the solvent.

Experimental

Boron trichloride and aluminum trichloride were purified by fractional distillation and stored in containers on the vacuum system used for sample preparation. Sulfur dioxide and tetramethylammonium chloride were purified and manipulated as previously reported (19).

Proton, ^{11}B, ^{27}Al, and ^{71}Ga resonance spectra were obtained on a Varian Associates XL100 spectrometer equipped with Nicolet Fourier Transform and multinuclear attachments. All spectra are referenced with respect to internal tetramethylsilane (20). For cross-comparison with existing compilations of boron resonance spectra (21), we find Ξ BCl_3 of 32,085,482 (lit. 32,085,486)[2] and Ξ $B(OCH_3)_3$ of 32,084,591 (lit. 32,084,565),[2] well within the variation which may be caused by solvent effects. The most common reference for ^{27}Al has been $Al(H_2O)_6^{3+}$. In order to compare our results with previous literature values Ξ $Al(H_2O)_6^{3+}$ was measured and found to be 26,056,780 (lit 26.057 × 1(

Infrared spectra of potassium bromide pellets of some products were obtained on Beckman Acculab 4 and Perkin–Elmer 283 spectrometers. Raman spectra of solids and sulfur dioxide solutions were obtained by excitation with the 514.5 nm line of a Coherent Radiation argon ion laser and recorded with a Jarrell–Ash 25–100 double monochromator equipped with photon counting detection. Lifetimes in the exchanging systems were determined by comparison of experimental spectra with those calculated by a stochastic method (22).

Tetramethylammonium (TMA) chloroborate: 227.2 mg (2.073 mmol) of well dried TMACl were dissolved in sulfur dioxide and

[1]NRCC No. 19604.

[2]These values are calculated from the various types of results reported in ref. 21.

2.073 mmol of BCl_3 were added to the solution. All volatile materials were removed under vacuum to give 458.5 mg (2.073 mmol) of product. *Anal.* calcd: B 4.77, Cl 62.5; found: B 4.58, Cl 61.2%.

Results and Discussion

Sulfur dioxide and methylene chloride solutions with a ratio of boron trichloride to dimethyl sulfide from 3:1 to 1:2 and a mole fraction of complex from 0.022 to 0.149 were studied by proton, ^{11}B, and ^{13}C resonance spectroscopy over a temperature range from 245 to 299K. The rate constants as a function of temperature are shown in Fig. 1. The relationships between reaction rates, rate constants, and lifetimes via nuclear magnetic resonance studies have been known for many years (1, 2). Exchange between a free and complexed species, as in eq. [1], can occur either by dissociation of the complex or by displacement of one species in the complex by excess of the free species. In the former case the activation enthalpy for exchange equals the heat of dissociation and the lifetime of the complex is independent of the concentration of the free species. For exchange by displacement the activation enthalpy will be less than the heat of dissociation and the lifetime of the complex will be inversely proportional to the concentration of the free species.

[1] $A^* + A{:}B \rightleftharpoons A^*{:}B + A$

In the present study, we have determined the energetics and exchange mechanisms for exchange of both excess Lewis acid and base upon the same complex, boron trichloride – dimethyl sulfide. From ^{11}B resonance spectroscopy it was possible to obtain the lifetimes of free and complexed boron trichloride as a function of temperature and concentration. At a given temperature the lifetime of complexed BCl_3 varied with concentration of free BCl_3 and a constant value for the rate constant could only be obtained for the kinetics of a displacement reaction. Results for three samples are shown in Fig. 1. The Arrhenius activation energy for BCl_3 exchange was calculated to be 5.0 ± 0.5 kcal/mol.

The second exchange reaction for this system, exchange of free and complexed dimethyl sulfide, was studied by ^1H and ^{13}C spectroscopy. It was found that the lifetime of complexed dimethyl sulfide was independent of the concentration of free dimethyl sulfide and a constant value of the rate constant for exchange was obtained by assumption of a dissociation mechanism. These kinetic results, also shown in Fig. 1, yield an Arrhenius activation energy for dimethyl sulfide exchange of

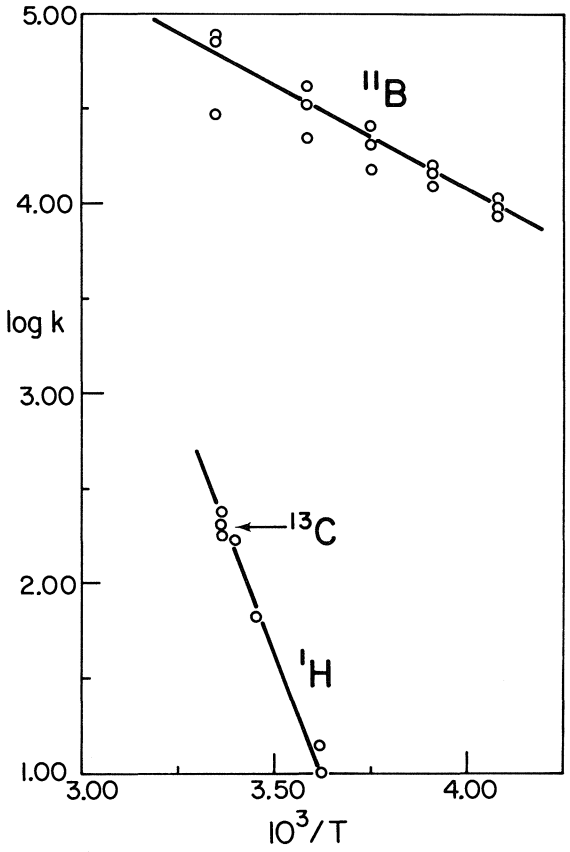

FIG. 1. Temperature dependence for exchange rates with the complex $(CH_3)_2S{\cdot}BCl_3$.

20 ± 1 kcal/mol. The order of activation energies also agrees with the proposed mechanisms.

It therefore appears that exchange of excess Lewis acid by a displacement mechanism and excess Lewis base by a dissociation mechanism may be the usual mechanisms for complexes of boron trihalides. A possible route for exchange with excess boron trichloride is via tetra-coordinate sulfur with the incoming BCl_3 coordinating to the remaining lone pair of electrons on sulfur followed by departure of BCl_3. This possibility would allow a low energy pathway for exchange via displacement. It is difficult to visualize two molecules of dimethyl sulfide coordinated to a single boron trichloride. The higher energy dissociation mechanism of exchange with excess dimethyl sulfide indicates that a lower energy pathway via a displacement reaction is not available. Thus the mechanistic results for dimethyl sulfide exchange are also consistent with chemical intuition.

It would be useful to determine if the mechanisms for exchange with BCl_3 as Lewis acid were

also followed by $AlCl_3$ and $GaCl_3$. For the aluminum chloride – dimethyl sulfide system in sulfur dioxide solution and for the systems $GaCl_3$–$(CH_3)_2S$ and $GaCl_3$–$(CH_3)_2O$ exchange was too fast to be measured by the nmr technique. The shielding parameters are listed in Table 1. It is to be noted that a complex $2(CH_3)_2S \cdot AlCl_3$ has been reported (21), suggesting that a low energy displacement pathway for exchange of dimethyl sulfide may be available in this system.

Although exchange in the system $AlCl_3$–$(CH_3)_2S$ was too fast to study, in the system $AlCl_3$–$(CH_3)_2O$ the rates were in a convenient range. The geometry of 2:1 complexes of an ether with $AlCl_3$ was found to be a trigonal bipyramid with the ethers at the axial sites (23). Only a 1:1 complex between diethyl ether and $AlCl_3$ was reported for a mixture of the reactants (13). We found both 2:1 and 1:1 complexes of dimethyl ether with $AlCl_3$ in sulfur dioxide solution. Their nuclear magnetic resonance parameters are listed in Table 1.

Samples were prepared with from 4.0 to 1.5 equivalents of $(CH_3)_2O$ for each $AlCl_3$. In those samples containing more than two equivalents of dimethyl ether, signals are observed only for the 2:1 complex and for free ether. There is no evidence for the 1:1 complex. Therefore the kinetics of the exchange between at least one of the dimethyl ether species in the 2:1 complex and free dimethyl ether can be measured directly. The exchange rates for $(CH_3)_2O$ in the 2:1 complex are listed in Table 2. Since they are independent of the

TABLE 2. Exchange rates for dimethyl ether in the 2:1 complex with free dimethyl ether and that in the 1:1 complex

0.018	0.011	−60	10
		−50	180
0.042	0.018	−60	12

concentration of free dimethyl ether this implies that exchange occurs via a dissociation of at least one bound ether from the 2:1 complex. From an Arrhenius plot of the average rate for these samples an activation energy of 29.3 ± 0.5 is obtained. The limited temperature range and number of data points precludes an accurate measure but an activation energy of about 30 kcal/mol is reasonable for a dissociation process. It compares reasonably well with the value of 20 kcal/mol for the dissociation mechanism found for $BCl_3 \cdot (CH_3)_2S$.

In those samples containing less than two equivalents of ether per $AlCl_3$ only signals of the 2:1 and 1:1 complexes are observed. The exchange between these species can then be determined without interference. The exchange rates for $(CH_3)_2O$ in the 2:1 complex with that in the 1:1 complex are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

also listed in Table 2. Within the rather large limits of error the rates are the same for exchange of the 2:1 complex with either free ether or the 1:1 complex. This is also strong confirmation that the exchange occurs via dissociation of one dimethyl ether from the 2:1 complex.

Disproportionation and ionization to yield $AlCl_4^-$ and $AlCl^{2+}$, both solvated, have been reported when $AlCl_3$ is dissolved in acetonitrile (7). Very recent results present evidence for some $CH_3CN \cdot AlCl_3$ and various solvated CH_3CN species (24). Since the behaviour of neat acetonitrile is rather different from that found for dimethyl ether and dimethyl sulfide in sulfur dioxide as solvent, the system $AlCl_3$–acetonitrile was investigated in SO_2 solvent. With an excess of aluminum trichloride only the complex $CH_3CN \cdot AlCl_3$ and uncomplexed $AlCl_3$ were observed via ^1H, ^{13}C, and ^{27}Al resonance spectroscopy. The shielding parameters are listed in Table 1. With approximately equal concentrations of $AlCl_3$ and CH_3CN both the 1:1 complex and the ionized species previously reported were observed via their ^{27}Al resonances. The shielding parameters for $AlCl_4^-$ and $AlCl^{2+}$ are also listed in Table 1 and agree with the previously reported values (7). With ratios of two or three CH_3CN for each $AlCl_3$ only the ionized species were observed. At −60°C in the proton resonance spectra of these solutions considerable fine structure was observed for the coordinated acetonitrile, suggesting different environments for these species. These results show that CH_3CN, in an inert solvent, with an excess of $AlCl_3$, behaves similarly to $(CH_3)_2S$ and $(CH_3)_2O$ as a Lewis base. The rather different behaviour when acetonitrile is in excess is presumably due to its strong coordinating tendency for the aluminum ion.

It is possible to study exchange and competitive complexing of the Group III chlorides BCl_3, $AlCl_3$, and $GaCl_3$ with the common Lewis base, chloride ion. The reaction of chloride ion and BCl_3 to give BCl_4^- is long established but further reaction to give $B_2Cl_7^-$ has not been previously reported. There is rapid boron exchange on the nmr time scale between BCl_4^- and BCl_3. The chemical shift for the boron resonance in a solution of composition $B_2Cl_7^-$ is not the weighted average of those for BCl_3 and BCl_4^-. With an excess of BCl_3 the chemical shift of the single line observed is that of a weighted average for $B_2Cl_7^-$ and BCl_3. The shielding parameters are listed in Table 1. These results suggest, but do not prove, the existence of $B_2Cl_7^-$ in solution. It was not possible to isolate $TMAB_2Cl_7$ since a reaction with the solvent occurred upon concentration, or standing at room temperature, to yield an insoluble product with a very different elemental composition.

In sulfur dioxide as solvent $AlCl_3$ and $AlCl_4^-$ are observed as separate ^{27}Al resonances with no evidence of reaction or exchange. Perhaps the complex of $AlCl_3$ with the SO_2 solvent is stronger than that which might be formed with $AlCl_4^-$. In a competition experiment for chloride ion it was found that for an initially equimolar mixture of Cl^-, BCl_3, and $AlCl_3$ only BCl_3 and $AlCl_4^-$ were observed at equilibrium. There was no evidence for BCl_4^- nor $BAlCl_7^-$. Shielding parameters for these and the corresponding gallium species are given in Table 1.

The effect of the leaving group on the nature of the E2 transition state for reaction of 2-aryl-1-phenylethylammonium ions with ethoxide in ethanol

SHUNE-LONG WU AND PETER JAMES SMITH[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received May 29, 1981

SHUNE-LONG WU and PETER JAMES SMITH. Can. J. Chem. **59**, 3016 (1981).

The reaction of 2-aryl-1-phenylethylammonium salts with ethoxide in ethanol at 40°C for five different amine leaving groups has been investigated. A significant dependence of the rate of reaction on the basicity of the leaving group was found. The variation of the primary hydrogen–deuterium isotope effect and pK_a of the leaving group was not linear and it is concluded that the proton is less than one-half transferred to base at the transition state for reactions involving the best two leaving groups. In support of this conclusion is the observed opposite variation of k^H/k^D with ring substituents for the various leaving groups, i.e., for *N*-methylpyrrolidine, $k^H/k^D = 4.58$, 4.72, and 5.01 for *p*-Me, H, and *p*-Cl, respectively; for *N*-methylmorpholine, $k^H/k^D = 6.13$, 5.73, and 5.50 for *p*-Me, H, and *p*-Cl, respectively.

SHUNE-LONG WU et PETER JAMES SMITH. Can. J. Chem. **59**, 3016 (1981).

Opérant à 40°C, on a étudié la réaction des sels d'aryl-2 phényléthyl-1 ammonium portant cinq groupes amino nucléofugues différents sous l'influence de l'ion éthanolate dans l'éthanol. On a trouvé que la basicité du groupe nucléofugue affecte de façon marquée la vitesse de la réaction. L'effet isotopique primaire hydrogène-deutérium ne varie pas d'une façon linéaire avec le pK_a du groupe nucléofugue; on en conclut que le proton est transferré très partiellement à la base pendant l'étape de transition de la réaction qui fait intervenir les deux meilleurs groupes labiles. A l'appui de cette conclusion, on a observé une variation contraire de k^H/k^D avec les substituants du cycle pour différents groupes nucléofugues, ainsi avec la *N*-méthylpyrolidine, le k^H/k^D varie de 4,58 à 4,72 et à 5,01 pour les groupes *p*-Me, H et *p*-Cl. Dans le cas de *N*-méthylmorpholine, ces valeurs sont respectivement de 6,13, 5,73 et 5,50.

[Traduit par le journal]

Elimination reactions have been investigated in considerable detail. The effect of β and α substituents as well as changes in the abstracting base and solvent on the nature of the E2 transition state have been extensively studied. However, detailed studies on the effect of changes in the leaving group on the E2 transition state have been limited (1, 2).

Alunni and Jencks (2) studied the reaction of 2-phenylethylammonium salts with ethoxide in ethanol for various substituted quinuclidines as leaving group and found $\beta_{lg} = -0.28$. The results of Schmid and Bourns (1) in a study on the same system with substituted anilines as leaving groups give $\beta_{lg} = -0.26$ to -0.31. As well, we have recently investigated the same reaction for nine different amine leaving groups where the pK_a was varied over 6 units and found a value of $\beta_{lg} = -0.28$.[2]

Due to the dependence of the rate of reaction on the pK_a of the leaving amine a transition state with significant carbon leaving-group rupture is indicated. In order to investigate in more detail the effect of the leaving group on the nature of the E2 transition state we have studied the reaction of 2-aryl-1-phenylethylammonium ions with five different amine leaving groups with ethoxide at 40°C to give the more stable stilbene product as compared with styrene obtained in the earlier studies (1, 2). In all cases elimination was the sole reaction and only *trans* 4-substituted stilbenes were formed. The rate constant (measured by the spectrophotometric procedure), primary hydrogen–deuterium isotope effects, rho (ρ), and the pK_a for the different amine leaving groups are shown in Table 1.

A plot of log k_2 versus pK_a (determined in H_2O) was made in order to determine the Bronsted β for the leaving group. There was no apparent correlation, in contrast to the 2-phenylethyl series (1, 2), and this observation will be discussed in a subsequent publication. It is seen that the ρ values are the same within experimental error for the first three leaving groups, but they are significantly greater than the values obtained for the two best leaving groups, *N*,*N*-dimethylbenzylamine and *N*-methylmorpholine. The fact that ρ decreases as the pK_a of the leaving group decreased suggests that the better

	Cl	79.2±0.3	5.50±0.08

[a] Deviation = $\pm k^H/k^D[(r^H/k^H)^2 + (r^D/k^D)^2]^{\frac{1}{2}}$ where r is the standard deviation in k.

leaving groups lead to an E2 transition state where there is less carbon–hydrogen bond weakening.

The variation of k^H/k^D with the pK_a of the leaving group is of particular significance. It is seen that k^H/k^D *increases* initially when the leaving group becomes less basic, but a further decrease in pK_a leads to a *decrease* in the magnitude of the hydrogen–deuterium isotope effect. This behaviour suggests that at least when the leaving group is *N*-methylmorpholine the proton is less transferred to base at the transition state (3). The theoretical treatments of both Winey and Thornton (4) and More O'Ferrall (5) predict less C—H bond rupture for an E2 transition state when the leaving group is made better.

In order to investigate further the degree of proton transfer, a series of 2-aryl-1-phenylethylammonium salts and their β,β-d_2 analogues were prepared and the rate constants and k^H/k^D were determined for reaction with ethoxide in ethanol at 40°C, Table 2. It is noted that for reactions involving the two poorest leaving groups, *N*-methylpyrrolidine and trimethylamine, the magnitude of k^H/k^D increases when the ring substituent is changed from electron-donating to electron-withdrawing. This behaviour is expected for a transition state where the proton is more than one-half transferred to base (6).

On the other hand, however, for the better leaving group, *N*-methylpiperidine, the magnitude of k^H/k^D increases when the ring substituent is changed from MeO to H, but *decreases* when electron-withdrawing chlorine is the substituent. This behaviour suggests that the proton is approximately one-half transferred to base, slightly more for the *p*-MeO reaction and slightly less for the *p*-Cl process.

For the best two leaving groups, where the consideration of ρ and k^H/k^D indicated the least degree of C—H bond weakening for the various leaving groups studied, the trend of k^H/k^D with variation of ring substituent is exactly the opposite

to that found for the two poorest leaving groups (k^H/k^D is the least for electron-withdrawing substituents). The conclusion is reached that for the two best leaving groups, the proton is *less* than one-half transferred to base at the transition state.

[Traduit par le journal]

Ravidomycin, isolated from the fermentation broth of *Streptomyces ravidus*, possesses strong inhibitory effect on gram positive organisms and potent antitumor activity (1). We propose structure **1***a* for ravidomycin[1] based on chemical and spectral information.

Ravidomycin, $C_{31}H_{33}NO_9$ (M^+ 563.2148), mp 248–250°C, $[\alpha]_D^{26}$ −105.5°, has an infrared (ir) spectrum which shows the presence of two carbonyls (1740, 1720 cm^{-1}), an aromatic system (1620, 1600, 1580 cm^{-1}), and hydroxyl groups (3380 cm^{-1}). Its ultraviolet (uv) spectrum λ_{max}(MeOH) nm (log ε): 244 (4.68), 263 (4.54, sh), 277 (4.60), 285 (4.65), 308 (4.33), 320 (4.30), 335 (4.20), 350 (4.08), 392 (4.24) reveals the presence of a substituted naphthalene system (2). The ^1H nmr spectra of ravidomycin **1***a* and its diacetate **1***b* (see Table 1) attest to the presence of *ortho* (one pair), *meta* (one pair), and isolated (one) aromatic protons, which features can only be accommodated by inclusion of two tetrasubstituted and one pentasubstituted aromatic rings. Fusion of ravidomycin with alkali affords the aglycone **2***a* which features in its ^1H nmr ($CDCl_3$) spectrum six aromatic hydrogens, three of which (H-6, δ 7.00, dd, J = 8.0/0.8; H-7, δ 7.50, dd, J = 8.0/8.0; H-8, δ 8.04, dd, J = 8.0/0.8) are in a 1,2,3 relationship clearly demonstrating the position of the *C*-glycosidic moiety relative to the *ortho* hydrogens. This aglycone can be hydrogenated (Pt/glacial acetic acid) to a desoxohexahydro derivative **3** in which the original aglycone-containing ring has suffered reduction and has also been the site of hydrogenolysis of the phenolic hydroxyl. Alkali fusion of ravidomycin also furnishes diastereomeric hemiacetal carboxylic acids (~ 1:1) **4***a*, which provides compelling evidence for the relationship of the *C*-glycosidic bond and the

tion and hydrogenolysis of **2***a* to **3** and confirms the fact that the hemiacetal ring in **4***a* utilizes the phenolic oxygen derived from opening of the lactone. The lactone aldehyde **2***b* is obtainable by heating **4***b* in quinoline at 180°C in the presence of copper affording corroboration of the relationship of lactone and sugar in **1***a*.

The lactone ring in ravidomycin must unite the tetrasubstituted phenyl ring bearing the *meta* hydrogens to the pentasubstituted naphthalene ring and placement of the substituents on this ring D follows from the juxtaposition of groups on the known anisole-2,3,5-tricarboxylic acid obtainable by hot alkaline permanganate treatment of **1***a*, together with analysis of ^{1}H nmr chemical shift data on various compounds. For example, in compound **3** the solvent-induced chemical shift for the *meta* protons, $\Delta_{C_6H_6}(CDCl_3) = -0.23$ ppm for H-5′ and +0.46 ppm for H-3′ is as predicted by the "carbonyl plane rule" (3). Mutual proton decoupling experiments on ravidomycin diacetate **1***b* give rise to a significant narrowing of the resonance lines due to H-3′ (δ 7.42) and the OCH_3-2′ (δ 4.13) which indicates an *ortho* relationship between the respective carbons. In a similar manner it was shown that the isolated aromatic proton H-3 is *ortho* to the remaining methoxyl group. Furthermore, when the lactone ring is opened, as in **4***a*, the isolated aromatic proton and one methoxyl are shifted 1.58 ppm and 0.32 ppm upfield, respectively, relative to the corresponding signals in **2***a* and this can only be explained if the isolated aromatic proton and one methoxyl are located at C-3 and C-2′, respectively, where both are deshielded when the lactone ring is closed and shielded when it is open and the angle between the planes of the two aromatic systems is changed substantially.

The structure of the amino sugar moiety follows from consideration of ^{1}H nmr data on ravidomycin and its diacetate, together with a full set of appropriate decoupling experiments which confirmed the presence of the 3,6-dideoxy-3-*N*,*N*-dimethylamino pseudo altropyranose in the conformation (with H-7 and H-1″ *S-trans*) indicated in **1***a*. The absolute configuration of the molecule has yet to be determined.

The structures of all compounds are fully supported by infrared, ultraviolet, and mass spectral data and are consistent with ^{13}C nmr chemical shift, multiplicity data and selective ^{13}C–{^{1}H} decoupling experiments.

Information from stereospecific spin–spin couplings about the relative absorptivities of the hydroxyl stretching bands in 2-iodophenol solutions

TED SCHAEFER, RUDY SEBASTIAN, and TIMOTHY A. WILDMAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 15, 1981

TED SCHAEFER, RUDY SEBASTIAN, and TIMOTHY A. WILDMAN. Can. J. Chem. **59**, 3021 (1981).

The stereospecific spin–spin coupling constants between the hydroxyl proton and the ring protons for 2-iodophenol in various solvents yield some free energy differences between the *cis* and *trans* conformations of this molecule at 305 K. Comparison with areas of the hydroxyl stretching bands in the same or similar solvents shows that the ratio of the absorptivity coefficients for the two conformers is sensitive to solvent. It is suggested that this ratio is temperature dependent and therefore apparent enthalpy differences must be considered tentative for at least some solutions. Molecular orbital calculations are consistent with the arguments concerning the absorptivity coefficients.

TED SCHAEFER, RUDY SEBASTIAN et TIMOTHY A. WILDMAN. Can. J. Chem. **59**, 3021 (1981).

Les constantes de couplage stéréospécifique entre le proton hydroxylique et les protons du cycle de l'iodo-2 phénol dans divers solvants donnent quelques différences d'énergie libre entre les conformations *cis* et *trans* de cette molécule à 305 K. La comparaison avec les bandes d'élongation de l'hydroxyle dans les mêmes solvants ou dans des solvants identiques montre que le rapport des coefficients d'absorption des deux conformères est sensible au solvant. On suggère que ce rapport dépend de la température et que par conséquent on doit considérer les différences d'enthalpie apparente comme des valeurs expérimentales du moins pour quelques solutions. Les calculs d'orbitales moléculaires sont en accord avec les faits relatifs aux coefficients d'absorption.

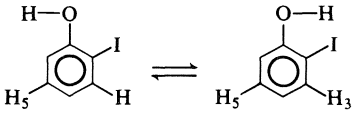
Introduction

Infrared spectroscopy is still used for the conformational analysis of intramolecular hydrogen bonding in dilute solutions. A recent review is available (1). In particular, the *trans–cis* equilibrium in 2-iodophenol has been investigated extensively by infrared spectroscopy (1–8), both in the gas phase and in a variety of solvents. The equilibrium constant, K, is given by $(A_c/A_t)(\alpha_t/\alpha_c)$, where A is the area of the hydroxyl stretching band for a conformer and α is its integrated absorption coefficient. This relationship is correct if Beer's law holds.



trans, **1***a* *cis*, **1***b*

If α_t/α_c is temperature independent, then the enthalpy difference between the conformers, ΔH, is obtainable from the usual van't Hoff plot. ΔH values were measured in this way for twelve solvents (4). It was also argued that K was given reasonably well by the ratio of band areas (4), thereby yielding free energy differences, ΔG, at 298 K.

In addition, if α_c and α_t are each independent of temperature, then a plot of A_c against A_t is linear and gives α_c/α_t and therefore ΔG (9). The precise data (4) for a CCl_4 solution indicated (9) that α_c/α_t is 13 and that ΔG is very nearly zero for this solution.

In this paper, stereospecific spin–spin couplings are used to derive some ΔG values for the equilibrium in a number of solvents. Comparison with the thermodynamic parameters obtained from the infrared data suggests that α_c/α_t is probably less than one in relatively polar solvents and that it is temperature dependent. These criticisms of the infrared method, as applied to 2-iodophenol, need not apply to the gas phase nor to 2,6-dihalo-substituted phenol derivatives.

Experimental

Solutions of 2-iodophenol (K and K Laboratories) in various solvents contained some tetramethylsilane (TMS) and were transferred to 5 mm od nmr sample tubes. The samples were degassed by the freeze–pump–thaw procedure and were then flame-sealed. ^1H nmr spectra were recorded at a probe temperature of 305 K on an HA100 spectrometer. Calibrations of peak positions were made in the frequency-sweep mode at a center-band frequency of 100.001 MHz (10). Sweep rates were 0.02 and 0.01 Hz/s. Intermolecular proton exchange was retarded in the manner described previously. Linewidths at half height were 0.10 Hz and were no doubt determined by the residual magnetic field inhomogeneity.

Results and Discussion

Spectral Analysis

The spectra for the CCl_4, C_6F_6, CD_2Cl_2, CH_2Br_2, and C_6H_{12} solutions were analyzed precisely with the computer program LAME (11, 12). Spectral parameters appear in Table 1. The $^5J_m^{H,OH}$ obtained by analysis is indistinguishable from the splitting of the OH peaks, no doubt because of the relatively large chemical shift dispersion for the

[a]In Hz at 100.001 MHz to low field of internal TMS, numbers in parentheses being standard deviations in the last significant figure.

ring protons. Accordingly, for the other solutions $^5J_m{}^{H,OH}$ was found directly from the OH resonance and from splittings in the peaks from H-5.

Because $^5J_m{}^{OH,H_3}$ is clearly very small (when not zero), showing that the *cis* form, **1***b*, is preponderant in all solutions, decoupling experiments were used to investigate the existence of hydroxyl proton couplings other than $^5J_m{}^{OH,H_5}$. It was expected that some coupling to H-6 would be present, $^4J_0{}^{OH,H}$ in phenol being ± 0.07 Hz (13).

The smallest $\Delta\nu_{1/2}$ obtainable in all solutions was 0.10 Hz. In Fig. 1*a*, the OH resonance is displayed for a 2 mol% solution in CCl_3CF_3, showing $\Delta\nu_{1/2}$ as $0.10 + 0.01$ Hz. This was also the linewidth for the ring proton transitions. Decoupling the OH resonance did not decrease the linewidth of any ring proton peaks. By way of comparison, Fig. 1*b* displays the OH doublet for the CCl_4 solution. The width, a $\Delta\nu_{1/2}$ of 0.13 Hz, indicates additional coupling to ring protons other than H-5. As shown, in Fig. 1 *c* and *c'* a multiplet from H-3 shows no change in $\Delta\nu_{1/2}$ when the OH resonance is irradiated; $\Delta\nu_{1/2}$ is 0.10 Hz in both single and double resonance conditions. However, a multiplet from H-6 in Fig. 1 *d* and *d'* displays a change in $\Delta\nu_{1/2}$ from 0.13 to 0.10 Hz under such conditions. Therefore $^4J_0{}^{OH,H_6}$ appears to be a maximum of $\pm 0.03 \pm 0.01$ Hz.

A series of such experiments yielded the data in Table 2. In C_6D_6, CH_2Br_2, and CD_2Cl_2 solutions there was evidence for coupling between H-3 and the hydroxyl proton. A series of simulations of spectral peaks, assuming $\Delta\nu_{1/2}$ as 0.10 Hz in the absence of extra coupling, were useful in the estimation of the magnitudes of the very small couplings.

Because $^5J_m{}^{H_3,OH}$ is so very small, when present at all, the present method is not suitable for a reliable study of the temperature dependence of the equilibrium constant.

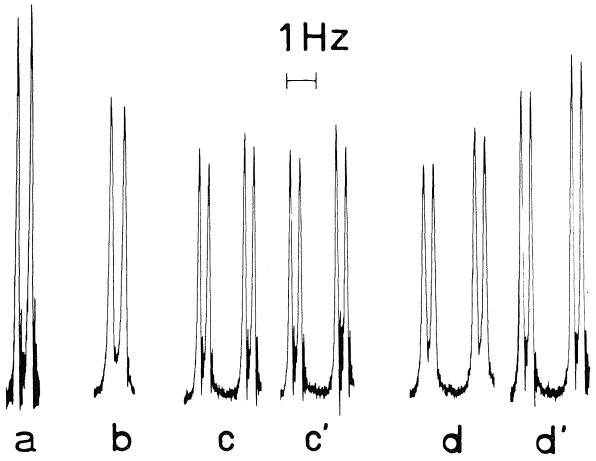

FIG. 1. (*a*) A display of the hydroxyl proton resonance at 100.001 MHz (centerband) and 305 K of a 2.0 mol% solution of 2-iodophenol in CCl_3CF_3. The linewidth at half height is 0.10 Hz. In (*b*) the same resonance is shown for a 4.7 mol% solution in CCl_4. In (*c*) and (*c'*) a multiplet from H-3 is recorded in single resonance and when the hydroxyl proton is decoupled. From (*d*) and (*d'*) it is clear that a multiplet from H-6 changes its linewidth from 0.13 to 0.10 Hz when the hydroxyl proton is irradiated.

Thermodynamic Parameters

(a) Equilibrium Constants

The ΔG values in Table 3, determined from the $^5J^{H,OH}$ magnitudes in Table 2, depend on the experience (13–16) that $^5J_m{}^{OH,H_3} \equiv {}^5J_c$ in the *cis* form is indistinguishable from zero and that $^5J_m{}^{OH,H_5} \equiv {}^5J_t$ is finite; and that a similar statement holds for the *trans* form. Accordingly,

$$\Delta G = G_c - G_t = -RT \ln {}^5J_t/{}^5J_c$$

[a] 1 kcal ≡ 4.184 kJ.
[b] From band areas.
[c] Assuming α_t/α_c to be temperature independent (4).
[d] From the same data, where α_c/α_t is 13 (9).
[e] From ΔG and ΔH.
[f] Reference 5, using peak heights of the infrared bands.

This relationship has led to consistent equilibrium constants for a wide variety of phenol derivatives.

The ΔG values in Table 3 also assume that the sum of the $^5J_m^{OH,H}$ numbers in Table 2 are independent of solvent or, perhaps less stringently, that an intrinsic solvent-induced increase or decrease in one coupling is accompanied by a proportional increase or decrease, respectively, in the other coupling. If the standard deviations in $^5J_m^{OH,H_5}$ (numbers in parentheses in Table 2) are multiplied by 2 to obtain the 95% confidence limits and the errors in $^5J_m^{OH,H_3}$ are taken as 0.01 Hz also, then the sum of the two couplings ranges from $0.43_9 \pm 0.01_9$ to $0.46_9 \pm 0.01_9$ Hz.

The errors in ΔG for the C_6D_6, CH_2Br_2, and CD_2Cl_2 solutions are estimated by writing, for the CD_2Cl_2 solution for example

$$\Delta G = -RT \ln (0.42 \pm 0.01)/(0.02 \pm 0.01)$$
$$= -1850 \pm 400 \text{ cal/mol}$$

Were it to be argued that the small magnitudes of $^5J_m^{OH,H_3}$ are overestimated, then the magnitudes of ΔG in Table 3 would all be too small, and the disagreement with the magnitudes from infrared band areas would become larger than indicated. Again, in order to obtain agreement between the nmr data and the infrared data for the CH_2Br_2 solution, for example, $^5J_m^{OH,H_3}$ would have to be 0.12 Hz, easily resolvable in spectra of the present quality. If the coupling were this large, the sum of the two $^5J_m^{H,OH}$ values would become 0.55_5 Hz, in stark contrast to the other solutions in Table 2.

The solute concentrations (Table 2) in the nmr samples are much higher than those employed in the infrared measurements. Note, however, that a change in concentration from 1.3 to 0.2 mol% in C_6H_{12} entails an upfield shift of only 0.022 ppm. Because the dimerization of 2-iodophenol is expected to be largest in C_6H_{12} (17), and because the shift for the dimer would certainly be as large as 7.0 ppm

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

(17), comparison with the observed shift of 5.04 ppm clearly indicates that dimerization is not an important consideration in a discussion of the data in Table 2.

Table 3 also contains the ΔG values as given in ref. 4 and obtained from band areas. Comparison of the ΔG numbers demonstrates the inadequacy of the underlying assumption that α_t/α_c is near unity in all solvents. In fact, in CH_2Br_2 near 300 K, α_t/α_c must be approximately 4 (K_{nmr} is 14 and K_{area} is 3.5). Rough values of α_t/α_c near 300 K are ~ 4 for $CDCl_3$, >2.5 for C_6F_6, >1.5 for CCl_4, and ≥ 1 for *iso*-C_8H_{12} (*c*-C_6H_{12}).

(b) The Enthalpy Differences, ΔH

The enthalpy differences in Table 3 assume that α_t/α_c is temperature independent and that they can therefore be derived from a van't Hoff plot involving apparent K values.

Consider, however, that the absolute intensity of the hydroxyl stretching band of phenol is dependent on solvent (18, 19), being twice as intense in CCl_4 as in hexane, for example. Furthermore, intensities of a number of hydroxyl bands decrease roughly linearly with an increase in temperature (20, 21) and the solvent dependence of the intensity of a *trans* band is greater than for a *cis* band (18). If, therefore, the temperature dependence of α_t for 2-iodophenol in solution is larger than that of α_c and if the temperature dependence of α_t/α_c is roughly linear over a limited temperature range; then it follows that a van't Hoff plot using band areas may be linear but the slope includes a contribution from the decrease in α_t/α_c. The magnitude of ΔH deduced from the plot will be less than the true magnitude.

It is interesting that the smallest ΔH magnitudes in Table 3 correspond to the largest magnitudes of α_t/α_c deduced from the nmr and infrared ΔG data near 305 K.

Previous corrections to ΔH values by means of estimates of α values at 298 and 348 K in CCl_4 solution (6) were about 0.1 kcal/mol and were not applied in the detailed study of 2-iodophenol (4).

It is concluded that, at least for a number of the solvents (4), both ΔG and ΔH are unreliable.

In consequence, nothing very reliable can be stated about ΔS for the *trans–cis* equilibrium in many of the solvents. If ΔS were zero, as is apparently true for 2-alkylphenols in CCl_4 (18), then the J data would suggest a maximum solvent stabilization of the *trans* form by ca. 1 kcal/mol (enthalpy) in CH_2Br_2 solution, because in the vapor phase the *cis* form is favoured by 2.7 kcal/mol in enthalpy. The high dielectric constant of CH_2Br_2 would favor the more polar *trans* conformer.

In C_6D_6, hydrogen bonding to the π electrons would account for the increased population of the *trans* form. Enthalpies for the interaction of phenolic hydroxyl groups with π bases can evidently be as large as 1.7 kcal/mol (22, 23). The shift to high field of the hydroxyl proton in C_6D_6 solution is consistent with such an interaction. In C_6F_6 solution the solute protons do not experience high field shifts (compare C_6F_6 and C_6H_{12} solutions in Tables 1 and 2). These results are in keeping with the charge distribution in C_6D_6 and C_6F_6 deduced from the signs of their quadrupole moments (24).

(c) Plots of A_c *versus* A_t *for* CCl_4 *Solutions*

If α_c and α_t are *not* dependent on temperature, a plot of A_c versus A_t should be linear with a slope equal to α_c/α_t. The precise data in ref. 4 yield (9) α_c/α_t as 13 for the CCl_4 solution and therefore a ΔG of 0.02 kcal/mol. Yet we have $\Delta G < -1.86$ kcal/mol (Table 3). It must be concluded that, in fact, none of ΔG, ΔH, ΔS is known for 2-iodophenol in CCl_4 solution. We know only that ΔG is smaller than -1.86 kcal/mol at 305 K. Unfortunately, the present method is not suitable for a *reliable* determination of ΔH.

Molecular Orbital Calculations of α

The CNDO/2 and INDO MO methods (25) available in this laboratory are not parameterized for iodine. However, calculations on an Amdahl 470/V7 system for 2-chlorophenol gave $\delta\mu_{OH}/\delta r_{OH}$ as 0.91 D/Å for the *cis* and as 0.66 D/Å for the *trans* form; implying 1.9 for α_c/α_t in the free molecule. Approach of a CH_3F molecule along the O—H direction of the *trans* conformer to give a linear F ··· H—O arrangement led to a dipole derivative of 1.1 D/Å; larger than for the *cis* form.

Although the E versus r_{OH} plots were parabolic near the minimum and μ_{OH} versus r_{OH} plots were nicely linear (correlation coefficients of 0.999 for 13 points), the calculations suggest only that α_t/α_c is sensitive to solvent and that ΔG is not available from band areas for 2-halophenols. The calculations do support the suggestion (18) that the intrinsic intensity of the *trans* band in such compounds in the vapor is lower than in solution.

A referee does not believe the CNDO MO calculations are useful in this type of problem, emphasizing the caution with which we view the numbers quoted in this section.

The σ–π transmitted coupling over five and six bonds in pyridine–borane complexes. MO calculations on structure and spin–spin couplings

TED SCHAEFER, RUDY SEBASTIAN, AND SALMAN R. SALMAN[1]

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 26, 1981

TED SCHAEFER, RUDY SEBASTIAN, and SALMAN R. SALMAN. Can. J. Chem. **59**, 3026 (1981).

The spin–spin coupling over six bonds between borane and ring protons in the borane complexes of pyridine and 2,6-lutidine has the same magnitude as in toluene. This σ–π transmitted coupling suggests that the hyperfine parameters Q_{CCH} and Q_{NBH} have the same magnitude. Comparison of INDO MO FPT calculations of ^6J for these compounds and the methyl borazines with experiment indicates the relative degree of electron delocalization in these systems. An STO-3G structure is calculated for pyridine–borane. Almost free rotation about the B—N bond is predicted (sixfold barrier). The calculated $^6J^{H,BH_3}$ depends exponentially on the B—N bond length. Solvent effects on the proton chemical shift are in qualitative agreement with the reaction field model.

TED SCHAEFER, RUDY SEBASTIAN et SALMAN R. SALMAN. Can. J. Chem. **59**, 3026 (1981).

La constante de couplage spin–spin à travers six liaisons entre le borane et les protons du cycle dans les complexes du borane avec la pyridine et la lutidine-2,6 est du même ordre de grandeur que dans le toluène. Ce couplage σ–π suggère que les paramètres hyperfins Q_{CCH} et Q_{NBH} ont le même ordre de grandeur. La comparaison des calculs INDO MO FPT des ^6J de ces composés et des méthylborazines avec les résultats expérimentaux indiquent le degré de délocatisation relative des électrons dans ces systèmes. En utilisant les calculs STO-3G on a calculé une structure pour la pyridine–borane. On a prédit une rotation presque libre autour de la liaison B—N (barrière du sixième ordre). Les constantes $^6J^{H,BH_3}$ calculées varient d'une façon exponentielle avec la longueur de la liaison B—N. Les effets de solvant sur le déplacement chimique du proton sont qualitativement en accord avec le modèle de champ réactionnel.

[Traduit par le journal]

Introduction

Theory and experiment agree that the spin–spin coupling constant over six bonds between the methyl protons and the ring proton in the *para* position of toluene is transmitted via a σ–π electron mechanism. The experimental value of −0.62 Hz for $^6J_p^{H,CH_3}$ in toluene (1) is reproduced by INDO MO FPT computations (2), which also predict a $\sin^2\theta$ dependence; θ is the angle by which the methyl C—H bond is rotated out of the benzene plane. Accordingly, $^6J^{H,CH_3}$ is proportional to $Q_{CH}Q_{CCH}$, the hyperfine interaction constants between unpaired spin in the π electron system and the aromatic C—H and aliphatic C—H bonds, respectively. The fact that $^6J_p^{H,CH_3}$ in toluene equals $-{}^7J_p^{CH_3,CH_3}$ in *p*-xylene (3, 4) suggests that $Q_{CH} \sim -Q_{CH}$.

$^7J_p^{CH_3,CH_3}$ is insensitive to ring substituents and indeed to the presence of heteroatoms in the ring (4). For example, it is 0.59 ± 0.02 Hz in 2,5-dimethylpyridine and sinks only to 0.53 ± 0.02 Hz in 1,4-dimethylpyridinium iodide. However, it is 0.0 ± 0.04 Hz in 2,5-dimethyl-*p*-benzoquinone, showing that ^7J is also a good test of electron delocalization in these six-membered rings.

In fact, for borazine such tests suggest very small if not negligible delocalization (aromaticity), in agreement with INDO MO FPT calculations of $^6J^{H,CH_3}$ for *N*-methyl and *B*-methyl borazines (4), giving an average of ^7J of 0.06 Hz in *p*-dimethylborazine. The possibility that Q_{BH} and Q_{NH} or Q_{NCH} and Q_{BCH} are very small, thereby accounting for the very small observed and calculated ^6J and ^7J, can be partly negated by the ^7J (4) and ^6J observed in pyridine derivatives (5) and by the known Q_{NH} from esr data (6).

Little is known about σ–π interactions for B—H bonds. The present measurements of $^6J_p^{H,BH_3}$ in the borane complexes of pyridine and 2,6-lutidine are therefore of interest because delocalization in the pyridine fragment of the complexes must still occur. Calculations at the STO-3G (7) and INDO (8*a*) levels of molecular orbital theory are reported, yielding a partially optimized structure of the pyridine complex and spin–spin couplings.

Experimental

The complexes were insoluble in CCl_4 or CS_2. Approximately 5 mol% solutions of the borane complexes of pyridine and 2,6-lutidine (Aldrich) in $CDCl_3$, containing some tetramethylsilane, were degassed by the freeze–pump–thaw technique and were then sealed into 5 mm od nmr sample tubes. The ^{1}H nmr spectra were recorded in the frequency sweep mode on an HA100 spectrometer at a probe temperature of 305 K. Calibrations were performed by reading sweep and manual oscillator frequencies of markers placed at ca. 5 Hz intervals. Repetition of this procedure at sweep rates of 0.02 Hz/s and a dispersion of 1 Hz/cm yielded peak frequencies by an interpolation procedure. The precision of the frequencies was about 0.02 Hz for

$^4J_{24}$	1.56	1.6	—	—
$^6J_p^{H,CH_3}$	$(-)0.59_7$[d]	(−)0.6	-0.62_3[e]	—

[a] 5.0 mol% solutions.
[b] In Hz at 100.00 MHz to low field of internal TMS.
[c] Shifts of the methyl protons.
[d] $^5J_m^{H,BH_3}$ is (+)0.24 ± 0.03 Hz.
[e] $^5J_o^{BH_3,CH_3}$ is 0.22 ± 0.02 Hz.

those peaks not broadened by partially relaxed couplings to ^{14}N or ^{11}B nuclei (T_2 effects on H-2 and *B*-H protons).

The borane protons of the pyridine complex displayed strong broadening (about 40 Hz) of the quartet arising from $^1J(^{11}B{-}H)$, so that ^1J could not be deduced accurately (see, for example, Fig. 7 of ref. 8*b*). However, a 5 mol% solution in acetone-d_6, having a lower viscosity, displayed no overlap of these peaks ($\Delta\nu_{1/2} \sim 18$ Hz) and yielded $^1J(^{11}B{-}H)$ as 97.4 ± 1.0 Hz, close to the value of 98 Hz reported for a benzene solution (9).

STO-3G and INDO MO FPT computations were made on an Amdahl 470/V7 system.

Results and Discussion

Spectral Analysis

The width of the H-2 transitions in the pyridine complex (partially relaxed coupling to ^{14}N) precluded a thorough analysis of the ring proton spectrum. The parameters extractable with some accuracy are given in Table 1 and involved the use of the computer program LAME (10, 11). The sign of $^6J_p^{H,BH_3}$ could not be determined but is no doubt negative.

Decoupling of the methyl protons in the 2,6-lutidine complex allowed extraction of the parameters in Table 1. The value of $^5J_o^{CH_3,BH_3}$ could then be obtained by simulation of the methyl proton resonance, using $^nJ^{H,CH_3}$ parameters reliably determined for some 2,6-lutidine derivatives (5).

STO-3G and INDO MO Computations on Structures

The most striking parameter is $^6J_p^{H,BH_3}$, whose magnitude is the same as $^6J_p^{H,CH_3}$ in toluene, to within experimental error. The latter is reproduced by INDO MO PFT procedures (2) and therefore MO calculations were performed on the structure and *J* values as follows.

The microwave geometry of pyridine (12) was assumed for the ring skeleton. Minimization procedures with respect to all other bond lengths and angles yielded the two STO-3G structures in Scheme 1. Local threefold symmetry was maintained for the BH_3 group. The structure with a B—H bond in a plane perpendicular to the ring plane (90°) had an energy (−269.7749994 au) lower by 24.5 J/mol than the other structure in Scheme 1. It may probably be concluded that the sixfold barrier to internal rotation about the B—N bond is very small and similar to the 59 J/mol in toluene (13). The calculated dipole moment is 7.06 D for both structures, somewhat larger than the benzene solution value of 5.86 D (14). The B—N bond length of 1.647 Å appears rather large, when compared to the X-ray value of 1.56 Å in $NH_3{\cdot}BH_3$ (15) or to the microwave value of 1.609 Å in $(CH_3)N{\cdot}BH_3$ (16). In the latter the B—H length is 1.21 Å and the NBH angle is 105.3°.

The minimization procedures also suggested that the B—N bond makes an angle of 2° with the ring plane so as to move the unique B—H bond closer to the ring in the 90° structure.

The INDO//STO 3G computations agree that the 90° structure is the most stable, but by 543 J/mol and with a dipole moment of 7.36 D. That this rather significant barrier is an artifact, is indicated by INDO calculations for the averaged STO 3G geometry (average of all bond lengths and angles in the two structures of Scheme 1), which yield a preference of only 25 J/mol for the 90° structure. Variation of the B—N bond length in the INDO// STO 3G calculations gave a minimum at 1.56_5 Å.

For all these calculations it must be noted that the ring skeleton was that of pyridine and that further, rather expensive, STO 3G or, better, 4-31G computations are needed.

INDO MO FPT Calculations of J

These were performed for various B—N bond lengths and θ, where θ is the angle by which a B—H bond is rotated out of the ring plane.

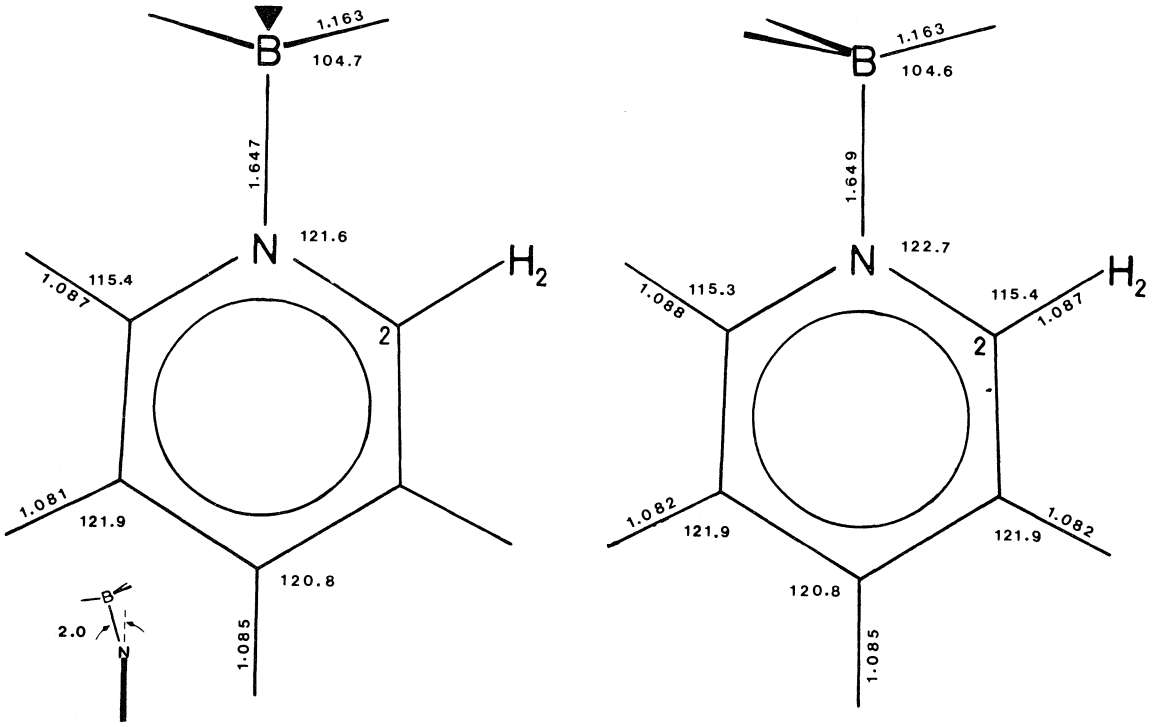

SCHEME 1

The most interesting results are perhaps those for ${}^6J_p^{H,BH_3}$. They can be written as

[1] $${}^6J^{H,BH_3} = {}^6J_o{}^r + {}^6J_{90}{}^r \sin^2\theta$$

where ${}^6J_o{}^r$ is the value at $\theta = 0°$ (B—H in ring plane) for a given value of r, the B—N bond length. Table 2 summarizes the calculated data for four r values. Note that ${}^6J_o{}^r$ is very small and that a σ–π mechanism is indicated, as for toluene (2). In Table 2, $\langle J \rangle$ is the average of J over θ. The observed ${}^6J^{H,BH_3}$ of -0.59_7 Hz is reproduced at $r = 1.600$ Å, probably a reasonable number (of course, this r value need not correspond to a minimum in the energy, being dependent on the FPT parameterization).

It is also true that $|{}^6J_o{}^r + J_{90}{}^r|$ in Hz is reproduced by the function 1266.5 exp $-4.366r$ (correlation coefficient of 0.99998) where r is in Å. This fact may indicate the way in which Q_{NBH} depends on overlap between the B—H orbitals and the π orbitals of the ring. The magnitude of ${}^6J^{H,BH_3}$ implies that Q_{CCH} in toluene is very nearly the same as Q_{NBH} in pyridine–borane. Recent esr data (17) on pyridinyl radicals are compatible with $Q_{NCH} \sim Q_{CCH}$. The present results do not alter our previous conclusions (4) about the very low degree of electron delocalization in borazine.

The calculations on ${}^5J_m{}^{H,BH_3}$ are not reproduced here. Qualitatively they follow previous results (2) for toluene. $\langle J_m{}^{H,BH_3} \rangle$ is calculated as 0.78 $\langle J_m{}^{H,CH_3} \rangle$. Then the observed value of 0.36 Hz in toluene perhaps implies a ${}^5J_m{}^{H,BH_3}$ of 0.28 Hz in pyridine–borane, in acceptable agreement with experiment. If it is remembered that ${}^5J^{H,BH_3}$ is expected to have a substantial σ component, in addition to a σ–π component apparently as large as in toluene (see above), then it follows that the σ component is smaller in the complex than in toluene.

${}^4J_o{}^{H,BH_3}$ could not be measured in the pyridine complex. In the 2,6-lutidine complex, ${}^5J_o{}^{BH_3,CH_3}$ is (+)0.22 Hz as compared to 0.45 Hz in *o*-xylene (3, 4). In addition to σ and σ–π components, these couplings contain contributions from direct or through-space mechanisms (2) very sensitive to interproton distances.

Because the INDO calculations of J for boron are apparently reliable in other systems (18), some such values are given in Table 3 for two B—N distances. The computed numbers are insensitive to θ. ${}^1J({}^{11}B–H)$ is overestimated by 10%. The small ${}^1J({}^{11}B–{}^{14}N)$ of near +5 Hz is compatible with the surmise (19) that a positive coupling occurs between nuclei if the electronegativity difference between the corresponding atoms is less than 1.5,

TABLE 2. INDO MO FPT values[a] for $^6J^{H,BH_3}$ in the pyridine–borane complex[b,c]

r_{BN}, Å	$^6J_o{}^r$	$^6J_{90}{}^r$	$\langle {}^6J \rangle$
1.648	−0.02	−0.93	-0.48_5
1.600	−0.02	−1.15	-0.59_5

[a] In Hz at two values of the B—N length.

and is negative if the difference is greater than 1.5. The other couplings to ^{11}B alternate in sign with the number of formal intervening bonds.

Other Parameters

The available couplings between ring protons in the pyridine complex (Table 1) fall between those in pyridine (20) and the pyridinium ion (21), as expected (22) on the basis of electronegativity of the *N*-substituent.

The ^{14}N spin lattice relaxation rate is lower in the complex than in the free base, yielding broader H-2 resonances, and therefore the other ring proton parameters are not reliably available.

The ^{11}B and ^{14}N shifts fall between those of the free base and the pyridinium ion (23). They indicate no steric hindrance to the addition of BH_3 to the lutidine, as is confirmed by $^6J^{H,BH_3}$ for the complexes. According to these numbers (Table 1) and those in Table 2, the B—N bond lengths in the two complexes should be the same to within 0.01 Å.

Solvent Shifts

Their striking aspect is the (small) shift to high field of the BH_3 and CH_3 peaks as the dielectric constant of the solution increases and the corresponding, rather larger, low-field shift for H-3 and H-4. These observations are in qualitative agreement with a reaction field model (24). From geometrical considerations, however, it is clear that quantitative agreement with this model cannot be had for these solvents.

Standard electrode potentials of the silver – silver phosphate and silver – silver arsenate electrodes in formamide at different temperatures

UPENDRA NATH DASH[1] AND SURENDRA KUMAR NAYAK
Department of Chemistry, G.M. College, Sambalpur (Orissa), India

Received January 12, 1981

UPENDRA NATH DASH and SURENDRA KUMAR NAYAK. Can. J. Chem. **59**, 3030 (1981).

For the emf measurements of cells of the type Ag, AgCl/NaCl(m)|Na_3X(m/3)/Ag_3X, Ag where X is PO_4 or AsO_4, the standard potentials of the silver – silver phosphate and silver – silver arsenate electrodes have been determined in formamide at five different temperatures ranging from 5 to 45°C. The standard molal potentials of the electrodes have been expressed through the equations

$$E_m^0(Ag,Ag_3PO_4) = (2.0565 \pm 0.0001) - (5.1627 \pm 0.0001) \times 10^{-2}T + (88.974 \pm 0.039) \times 10^{-4}T \ln T - (29.892 \pm 0.054) \times 10^{-6}\, T^2/2$$

$$E_m^0(Ag,Ag_3AsO_4) = (2.0771 \pm 0.0001) - (5.3252 \pm 0.0013) \times 10^{-2}T + (91.743 \pm 0.016) \times 10^{-4}\, T \ln T - (31.116 \pm 0.029) \times 10^{-6}\, T^2/2$$

The standard thermodynamic quantities, ΔG^0, ΔH^0, ΔS^0, and $\Delta C_p{}^0$ for the respective electrode reactions have been evaluated from the $E_m{}^0$'s of the electrodes at these temperatures. The solubility products of silver phosphate and silver arsenate have also been calculated in formamide at these temperatures.

UPENDRA NATH DASH et SURENDRA KUMAR NAYAK. Can. J. Chem. **59**, 3030 (1981).

On a déterminé les potentiels normaux des électrodes de phosphate d'argent/argent et d'arsénate d'argent/argent dans le formamide à 5 températures différentes allant de 5 à 45°C pour mesurer la fem des cellules du type Ag, AgCl/NaCl(m)| Na_3X(m/3)/Ag_3X, Ag, où X = PO_4 ou AsO_4. On exprime les potentiels molaires normaux des électrodes par les équations:

$$E_m^0(Ag,Ag_3PO_4) = (2.0565 \pm 0.0001) - (5.1627 \pm 0.0001) \times 10^{-2}T + (88.974 \pm 0.039) \times 10^{-4}T \ln T - (29.892 \pm 0.054) \times 10^{-6}\, T^2/2$$

$$E_m^0(Ag,Ag_3AsO_4) = (2.0771 \pm 0.0001) - (5.3252 \pm 0.0013) \times 10^{-2}T + (91.743 \pm 0.016) \times 10^{-4}\, T \ln T - (31.116 \pm 0.029) \times 10^{-6}\, T^2/2$$

On a évalué les quantités thermodynamiques normales ΔG^0, ΔH^0, ΔS^0 et $\Delta C_p{}^0$ des diverses réactions aux électrodes, à partir des $E_m{}^0$ des électrodes à ces températures. On a également calculé les produits de solubilité du phosphate d'argent et de l'arsenate d'argent dans la formamide à ces températures.

[Traduit par le journal]

Introduction

No work seems to have been done on the determination of the standard potentials of the silver – silver phosphate and silver – silver arsenate electrodes in aqueous and non-aqueous media. However, from this laboratory Dash and Padhi (1) have reported the standard potentials of these electrodes in aqueous and aqueo-organic solvent systems over a range of temperature. The present work has been undertaken as a part of our programme of the determination of standard potentials of some electrodes of the second kind of the inorganic tribasic acids in formamide.

As in previous communications (2), the cells with liquid junction

[A] Ag,AgCl/NaCl(m)|Na_3X(m/3)/Ag_3X,Ag

where X is PO_4 or AsO_4, have been studied in formamide for the determination of standard potentials of the silver – silver phosphate and silver – silver arsenate electrodes.

Experimental

Sodium chloride (BDH, AnalaR) was dried above 100°C for 2 h before use. Formamide (BDH, LR) was purified as described earlier (3). Sodium phosphate (E. Merck) and sodium arsenate (BDH, AnalaR) were dried at 120°C, and kept in vacuum desiccator before use.

Silver phosphate and silver arsenate were prepared from silver nitrate (BDH, AnalaR) and sodium phosphate or

arsenate, and the precipitates were repeatedly washed with conductivity water, and were kept in conductivity water in amber coloured bottles for use.

The preparation of silver – silver chloride electrodes has been described earlier (4). Silver – silver phosphate and silver – silver arsenate electrodes were prepared by a method similar to that of the silver – silver oxalate, malonate, succinate, adipate, or chromate electrodes (5) by applying a paste of silver phosphate or arsenate on the spongy silver obtained by the thermal decomposition of silver oxide (6). The electrodes thus prepared were stored in 0.05 *M* aqueous sodium phosphate or arsenate solution for 24 h and then rinsed with sodium phosphate or arsenate solution in formamide before use. Only those electrodes which showed a potential difference of 0.01 mV or less on mutual comparison were used.

Solutions for emf measurements were prepared by dissolving the appropriate weighed amounts of salts in known weights of formamide.

Setting up of the cells and emf and conductance measurements was essentially similar to that described earlier (2, 7). The cells were kept in the water thermostat at the required temperature with a precision of ±0.1°C. The reproducibility of emf measurements was of the order of ±0.2 mV.

Results and Discussion

The emf, E, of cell [A] is given by the expression

$$[1]\quad E = E^0_{cell} + (2RT/3F)\ln(3m) + (RT/3F)\ln[\gamma^3(Cl^-)/\gamma(X^{3-})] + E_j$$

where the symbols have their usual significance.[2]

The standard molal potential, E_m^0 of the silver – silver phosphate or arsenate electrodes was obtained by the method of extrapolating (2) the auxiliary function, $E_m^{0\prime}$ given by

$$[2]\quad E_m^{0\prime} = E - \tfrac{2}{3}k\log(3m) - k[(3A\sqrt{2m}/1 + \sqrt{2m}) - (A\sqrt{m}/1 + \sqrt{m})] + E_m^0(Ag/AgCl) - E_j = E_m^0(Ag/Ag_3X) + bm$$

to the molality, $m = 0$, (Figs. 1 and 2) where $E_m^0(Ag/AgCl)$ is the standard potential of the silver – silver chloride electrode and A is the Debye–Hückel constant, and are known (8) over the temperature range under investigation. In eq. [2] $k = (2.3026RT/F)$ and $b = k\{\beta_{Cl^-} - \tfrac{2}{3}\beta_{X^{3-}}\}$ where β is the usual constant ($2b$) in the Debye–Hückel expression for the activity coefficient, i.e.,

$$-\log\gamma_i = \frac{AZ_i^2\mu^{1/2}}{1 + \mu^{1/2}} - \beta_i\mu$$

where i is Cl^- or X^{3-}.

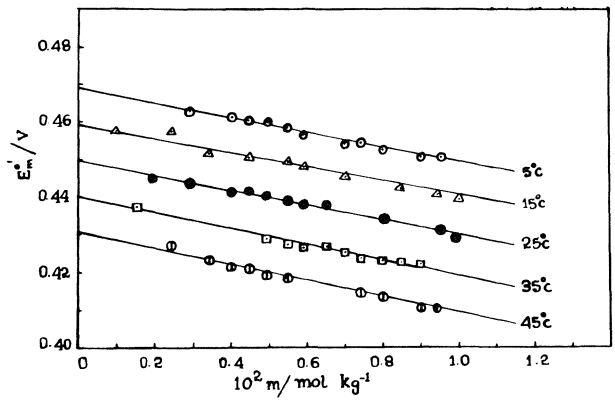

FIG. 1. Plot of $E_m^{0\prime}$ of Ag/Ag_3PO_4, PO_4^{3-} electrode vs. molality in formamide at different temperatures.

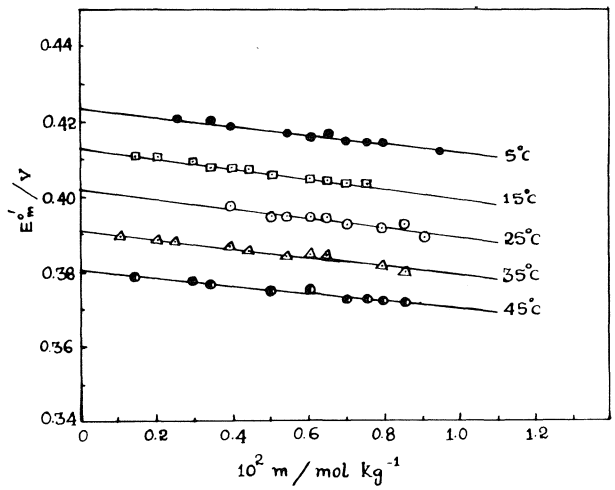

FIG. 2. Plot of $E_m^{0\prime}$ of Ag/Ag_3AsO_4, AsO_4^{3-} electrode vs. molality in formamide at different temperatures.

As usual (2), the values of the liquid junction potentials, E_j, were calculated from the equivalent conductance of sodium phosphate or arsenate and sodium chloride by means of the Henderson equation. The values of E were found to be in the range 0.02–0.03 V at all temperatures.

From the E_m^0 values of the silver – silver phosphate or arsenate electrodes the values for the standard potential on the molar (E_c^0) and mole-fraction (E_N^0) scales have also been calculated at experimental temperatures by the usual equations (9). The variation of the standard potential in molal (E_m^0), molar (E_c^0), and mole-fraction (E_N^0) scales with temperature has been expressed through the equations of the type (7),

$$[3]\quad E_x^0 = A + BT + CT\ln T + DT^2/2$$

*Uncertainties in ΔG^0, ±0.6 kJ mol^{-1}; ΔS^0, ±2 J mol^{-1} K^{-1}; ΔH^0, ±0.9 kJ mol^{-1}; and $\Delta C_p{}^0$, ±2 J mol^{-1} K^{-1}.

where x is m, c, or N, and T is the temperature in K. The parameters A, B, C, and D in eq. [3] on different scales are presented in Table 1 along with their standard deviations calculated by the least-squares method.

The thermodynamic quantities, ΔG^0, ΔH^0, ΔS^0, and $\Delta C_p{}^0$ for the electrode reaction

[4] $Ag_3X(s) + 3\ e \rightleftharpoons 3\ Ag(s) + X^{3-}$ (solvated)

have been calculated by the usual relations (7), and are given in Table 2 at different temperatures.

A comparison of the standard potentials of these electrodes ($E_m{}^0(Ag/Ag_3PO_4)$ = 0.4498 V and $E_m{}^0(Ag/Ag_3AsO_4)$ = 0.4019 V) at 25°C in formamide with those reported in water (1) ($E_m{}^0(Ag/Ag_3PO_4)$ = 0.4524 V and $E_m{}^0(Ag/Ag_3AsO_4)$ = 0.4079 V) shows that the $E_m{}^0$ values are higher in water than in formamide, lending support to the earlier studies on the determination of standard potentials of the electrodes of the second kind in formamide (6, 10). The lowering of $E_m{}^0(Ag/Ag_3PO_4)$ may be explained by the lower basicity of formamide which increases $\Delta G^0(\Delta G^0(Ag_3PO_4)$ = −130.2 kJ and $\Delta G^0(Ag_3AsO_4)$ = −116.3 kJ at 25°C in comparison with $\Delta G^0(Ag_3PO_4)$ = −131 kJ and $\Delta G^0(Ag_3AsO_4)$ = −118.1 kJ at 25°C in water) of the cell reaction [4] by increasing the Gibbs free energy of $PO_4{}^{3-}$ (solvated) or $AsO_4{}^{3-}$ (solvated) in formamide. As expected the ΔH^0 and ΔS^0 values for the cell reaction [4] are negative in both water and formamide but they are less negative in formamide than in water (1) ($\Delta S^0(Ag_3PO_4)$ = −450.1 J mol^{-1} K^{-1} and $\Delta S^0(Ag_3AsO_4)$ = −483.3 J mol^{-1} K^{-1}) pointing to the fact that the net amount of order created by $PO_4{}^{3-}$ or $AsO_4{}^{3-}$ ions is less in formamide than in water. In other words, the formamide molecules become more associated than water suggesting that $PO_4{}^{3-}$ or $AsO_4{}^{3-}$ ions "break down more structure" in formamide than in water.

The solubility products, $K_s{}^0$, of silver phosphate and silver arsenate in formamide have been calculated from the values of standard potentials of the silver – silver phosphate or arsenate, and of the silver electrodes by means of the equation

$$[5]\quad \ln K_s{}^0 = (E_m{}^0\,(Ag/Ag_3X) - E_m{}^0(Ag/Ag^+))(3F/RT)$$

where $E_m{}^0(Ag/Ag^+)$ is the standard molal potential of silver electrode and is given by the equation (11)

$$[6]\quad E_m{}^0(Ag/Ag^+) = (1.7073 \pm 0.0019) - (3.5171 \pm 0.0026) \times 10^{-2}T + (62.486 \pm 0.017) \times 10^{-4}\,T \ln T - (25.492 \pm 0.013) \times 10^{-6}\,T^2/2$$

over the temperature range under investigation. The values for $K_s{}^0$ in the molality ($K_s{}^{0m}$) and molarity ($K_s{}^{0c}$) scales are shown in Table 3 at the experimental temperatures. The data for $K_s{}^{0c}$ calculated from $K_s{}^{0m}\ \rho^2$ where ρ is the density of

The kinetics of proton and deuteron transfer from 4-nitrophenylnitromethane and 1-(4-nitrophenyl)-1-nitroethane to 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene in acetonitrile solvent[1]

KENNETH T. LEFFEK AND PRZEMYSLAW PRUSZYNSKI[2]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4H6

Received April 3, 1981

KENNETH T. LEFFEK and PRZEMYSLAW PRUSZYNSKI. Can. J. Chem. **59**, 3034 (1981).

4-Nitrophenylnitromethane reacts with 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene in acetonitrile in a bimolecular proton transfer, which shows a primary deuterium isotope effect, $k_H/k_D = 12.2$ at 25°C. The large isotope effect on the enthalpy of activation, $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}) = 4.6 \pm 0.3$ kcal mol^{-1} is consistent with a significant contribution of proton tunnelling to the reaction rate of the protium substrate.

The analogous reaction of 1-(4-nitrophenyl)-1-nitroethane with the same base in acetonitrile gives contrasting kinetics and reaction parameters. The reaction is first order, showing no dependence on base concentration. While the isotope effect $k_H/k_D = 9.3$ at 25°C, the enthalpy of activation difference $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})$ is only 0.5 ± 0.1 kcal mol^{-1}. It is concluded that the 1-(4-nitrophenyl)-1-nitroethane undergoes a slow dissociation, with a very small dissociation constant, followed by a fast association with the base to yield the carbanion ion-pair.

KENNETH T. LEFFEK et PRZEMYSLAW PRUSZYNSKI. Can. J. Chem. **59**, 3034 (1981).

Le nitro-4 phenylnitrométhane réagit avec le diméthoxy-2,7 bis(diméthylamino)-1,8 naphtalène dans l'acétonitrile selon un transfert de proton bimoléculaire avec un effet isotopique primaire du deutérium de $k_H/k_D = 12{,}2$ à 25°C. Le grand effet isotopique sur l'enthalpie d'activation $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}) = 4{,}6 \pm 0{,}3$ kcal mol^{-1} est en accord avec une contribution importante de l'effet tunnel du proton à la vitesse de réaction de l'hydrogène du substrat.

La réaction analogue du (nitro-4 phényl)-1 nitro-1 éthane avec la même base dans l'acétonitrile donne des cinétiques et des paramètres de réaction qui s'opposent. La réaction est d'ordre un et est indépendante de la concentration de la base. L'effet isotopique k_H/k_D est égal à 9,3 à 25°C tandis que la différence d'enthalpie d'activation $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})$ est seulement de $0{,}5 \pm 0{,}1$ kcal mol^{-1}. On en conclut que le (nitro-4 phényl)-1 nitro-1 éthane subit une dissociation lente avec une très faible constante de dissociation, suivie d'une association rapide avec la base pour conduire au carbanion sous forme de paire d'ions.

[Traduit par le journal]

Introduction

An earlier study of the proton transfer from 4-nitrophenylnitromethane to 1,8-bis(dimethylamino)naphthalene in isopropyl alcohol and *tert*-butyl alcohol solvents showed only small primary isotope effects and fairly high enthalpies of activation (1). Subsequent calculations in which the results were fitted to Bell's equation (2–4) for quantum mechanical tunnelling of the proton through a parabolic potential energy barrier yielded a wide barrier of 3.3 Å and indicated no significant proton tunnelling (5).

In aprotic solvents, in which larger isotope effects may be expected, the base abstracts a proton from 4-nitrophenylnitromethane and 1-(4-nitrophenyl)-1-nitroethane to yield a coloured carbanion in measurable yield only at high concentration; i.e. the reactions have very low equilibrium constants. Therefore, in order to study this type of reaction it is necessary to use 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene, which is one of the strongest neutral bases (6) and also very sterically hindered. The high steric hindrance should make the reaction very sensitive to steric crowding in the acid molecule and perhaps give a reaction with a narrow potential energy barrier. This would give a large tunnelling contribution to the proton transfer relative to the deuteron transfer and hence a high primary isotope effect. The nitroethane substrate has been used to test this hypothesis.

Results and Discussion

The reactions of 4-nitrophenylnitromethane (4-NPNM) and 1-(4-nitrophenyl)-1-nitroethane (4-NPNE) with 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene (2,7-DMDAN) in acetonitrile give single absorption peaks in the visible region at 500 nm and 520 nm respectively. Caldin and Mateo (7) found $\lambda_{max} = 493$ nm for 4-NPNM reacting with tetramethylguanidine in acetonitrile. The intensity of the absorbance varied very little with base concentration indicating that the equilibrium constants for the reactions were large.

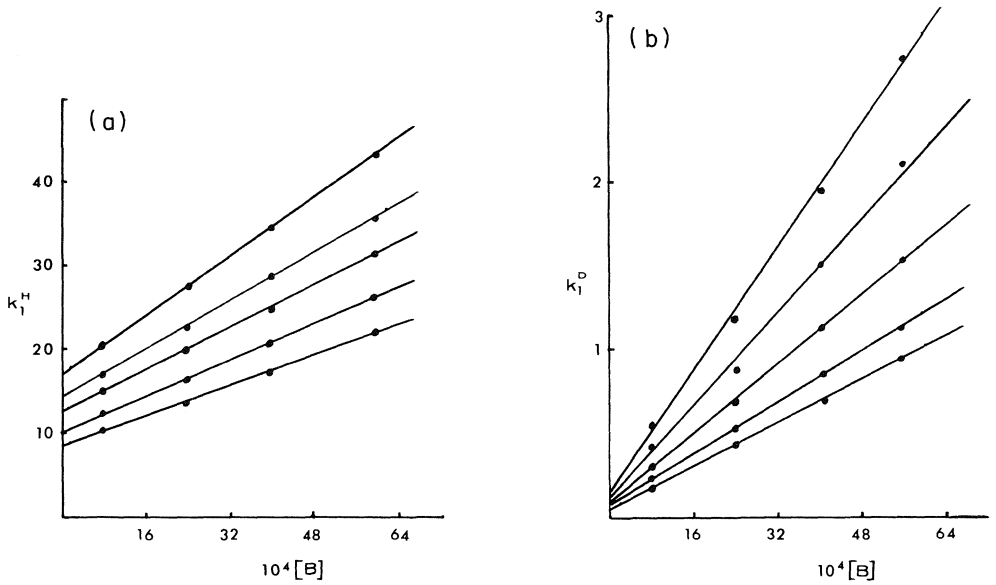

FIG. 1. Pseudo-first order rate constants (a) k_H and (b) k_D in s^{-1} vs. base concentration for the proton and deuteron transfer from *p*-nitrophenylnitromethane and its α-deuterated analogue to 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene. Rate constant measurements were made at 15, 20, 25, 30, and 35°C.

The 4-Nitrophenylnitromethane Reaction

For the 4-NPNM and 4-NPNM-d_2 reactions, pseudo first-order rate constants were determined using an acid concentration of 2×10^{-5} *M* and a series of base concentrations ranging from 8×10^{-4} *M* to 6×10^{-3} *M*. Figures 1(a) and (b) show these first-order rate constants plotted against base concentration. The slopes of these lines are the second-order rate constants and are collated in Table 1, together with the isotopic rate ratios. These values yield the activation parameters shown in Table 2.

The isotopic rate ratio of 12.2 at 25°C is the same within experimental error as that found by Caldin and Mateo (7) for the reaction of 4-NPNM with tetramethylguanidine in acetonitrile, and isotope effects of this magnitude have been observed for a number of other proton transfer reactions of this acid (8–13). This value may be indicative of proton tunnelling in that it is considerably greater than the value of ~7 which is obtained by the assumption of the complete loss of one C—H stretching vibration during the activation process. The activation parameter differences are considerably larger than the maximum values which can be accounted for without assuming a large contribution to the reaction by proton tunnelling. The enthalpy of activation difference of more than 4 kcal mol^{-1} and log A_D/A_H in excess of 2 are very similar to such values recorded by Caldin and Mateo (7) for the 4-NPNM reaction with tetramethylguanidine, although these workers obtained such results mostly in nonpolar solvents where the equilibrium constants were fairly small. Furthermore, their values were associated with very high isotopic rate ratios.

TABLE 1. Second order rate constants for the reaction of 4-nitrophenylnitromethane and its deuterated analogue and 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene in acetonitrile

Temperature (°C)	$10^{-2} k_{2H}$ ($L\ mol^{-1}\ s^{-1}$)	$10^{-2} k_{2D}$ ($L\ mol^{-1}\ s^{-1}$)	k_{2H}/k_{2D}
15	22.6±1	1.56±0.05	14.5
20	26.1±1	1.90±0.07	13.7
25	31.0±1	2.55±0.09	12.2
30	35.1±1.5	3.54±0.15	9.9
35	40.5±2	4.61±0.18	8.8

The results have been fitted to Bell's equation (2–4) using the technique of Caldin and Mateo (7) and the tunnelling parameters are shown in Table 3, together with the values reported (7) for the reaction 4-NPNM with TMG. Thus, although the isotope effect on the second-order rate constants is not exceptionally large, tunnelling of the proton appears to contribute to the proton transfer reaction to a significant extent.

The 1-(4-Nitrophenyl)-1-nitroethane Reaction

Pseudo first-order rate constants were determined in the same manner as for the 4-NPNM reaction. The 4-NPNE initial concentration was 1×10^{-5} *M* and the base concentration was varied

between 1.2×10^{-4} and 6.1×10^{-3} M. The first-order rate constants showed no change when the base concentration was changed by a factor of 50. At 20°C measurements at eight different base concentrations gave $k_{1H} = 2.6 \pm 0.2 \times 10^{-2}$ s^{-1} and for the deuteron transfer five determinations gave $0.32 \pm 0.01 \times 10^{-2}$ s^{-1}. This insensitivity of the first-order rate constant could arise in a second order reaction with a very small equilibrium constant. For such a reaction the observed first-order rate constant k_{obs} is given by eq. [1], where k_2 and k_{-2} are the second-order rate constants for the forward and reverse reactions respectively and b is the base concentration. If the equilibrium constant, k_2/k_{-2}, is very small, the k_{obs} is approximately equal to k_{-2}. However, if the equilibrium constant were very small an increase in the base concentration would give a proportionate increase in the carbanion concentration at equilibrium and hence a proportionate increase in the intensity of the absorbance at 520 nm. In our reaction, an increase in the base concentration by a factor of 10 increased the intensity of the absorbance by only about 4% indicating that the equilibrium constant is large, about 5000 dm^3 mol^{-1}. This value would give a very marked dependence of k_{obs} on base concentration if the reaction were indeed second order. It is concluded, therefore, that the reaction of 2,7-DMDAN with 4-NPNE is a first-order reaction.

$$[1] \quad k_{obs} = k_2 b + k_{-2}$$

Table 4 shows the temperature dependence of k_{obs} and the isotopic rate ratios. These values yield the activation parameters in Table 5.

The results show that, although the values of k_H/k_D are not very different for the two acids 4-NPNM and 4-NPNE, the activation parameters and the isotope effects on the activation parameters show no similarity at all and reinforce the conclusion dictated by the difference in the kinetics that the two reactions have different mechanisms. The p-nitrophenylnitromethane reaction is not markedly different from proton transfer from this substrate to other bases (7) and may, therefore, be assumed to follow the same mechanism, a bimolecular reaction. The p-nitrophenylnitroethane reaction, on

For personal use only.

the other hand, shows a significant isotope effect on the rate of the reaction and also an isotope effect on the enthalpy of activation about equal to the maximum effect associated with the loss of one C–H stretching vibration. Despite this, the concentration of the base does not appear in the kinetic equation. The proton transfer must, therefore, be a two-step process in which the step involving the base is not rate determining.

There are two possibilities. In the first, the base associates with the acid in a rapid step with a large equilibrium constant to yield a hydrogen-bonded complex which subsequently undergoes a proton transfer from acid to base to yield the colored anion in a second rate-determining step. In the second possible mechanism, the acid dissociates in an initial slow step to give an ion-pair which then is captured by the base in a second rapid proton transfer.

The second of these two mechanisms fits the data better than the first because the two-step mechanism is not observed with the methane substrate. This may be accounted for by the fact that the methane substrate is less sterically hindered in its reaction with the base, hence the direct bimolecular reaction can be observed. For the ethane substrate, the bimolecular reaction is blocked by the additional steric hindrance, allowing the slower dissociation to be observed.

In the first possible mechanism, if it is assumed that the base associates rapidly with the ethane substrate, it would also associate rapidly with the less crowded methane substrate and hence the same kinetics would be found for both acids.

It is, therefore, concluded that the 4-nitrophenylnitroethane undergoes a slow dissociation followed by a fast association with the base to yield the carbanion ion-pair. The isotope effect on the dissociation, $\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger} = 0.9$ kcal mol^{-1} shows no contribution from tunnelling. This result contrasts markedly with the bimolecular proton transfer from 4-nitrophenylnitromethane which shows a narrow energy barrier for reaction of 0.75 Å and an isotope effect enhanced by proton tunnelling.

The fact that 4-nitrophenylnitroethane transfers a proton to the solvent faster than it does to 2,7-DMDAN is a dramatic demonstration of the observation by Alder *et al.* (6) that, despite the very high base strength of 2,7-DMDAN, proton transfers to and from it are exceptionally slow.

Experimental

Materials

4-Nitrophenylnitromethane and its deuterated analogue were prepared as described previously (14). 1-(4-Nitrophenyl)-1-nitroethane was prepared from *p*-nitroacetophenone via the oxime as described by Boyle (15) and earlier workers (16, 17). The 1-deuterated material was made by the same procedure as that used for the methane.

2,7-Dimethoxy-1-8-bis(dimethylamino)naphthalene was obtained from 2,7-dihydroxynaphthalene by methylation with dimethylsulphate (18) to give the 2,7-dimethoxy derivative, followed by nitration at the 1 and 8 positions with 90% nitric acid in acetic acid. The nitro groups were reduced to amino groups with stannous chloride (19) and these were methylated by refluxing the material with excess methyl iodide and potassium hydride in tetrahydrofuran (16). The crude base was purified by repeated crystallization from *n*-hexane at low temperature; mp 67–68.5°C. The nmr spectrum showed two doublets each from two protons at 2.52 τ and 2.94 τ ($J = 9.0$ Hz), a singlet for 6 protons from the methoxy groups at 6.11 τ, and a singlet for 12 protons from the four methyl groups at 7.11 τ. The values are in good agreement with those of Alder *et al.*[3]

Acetonitrile, reagent grade, was purified by the method of O'Donnell *et al.* (20) and fractionally distilled over P_2O_5.

Kinetic Measurements

The reaction rates were measured with a Durrum–Gibson stopped-flow spectrophotometer using the standard technique previously described (21). Some of the rate measurements with deuterated substrates were made both with the stopped-flow spectrophotometer and a standard uv–vis spectrophotometer and the results showed good agreement between the two instruments. A sample run is given in Table 6.

TABLE 6. Run #185; temperature 15.0°C; initial concentration $NO_2C_6H_4CH_2NO_2 = 2 \times 10^{-5}$ *M*; initial concentration 2,7-dimethoxy-1,8-bis(dimethylamino)naphthalene $= 4.05 \times 10^{-3}$ *M*

Rearrangements during deamination of 4-amino-4-des(oxymethylene)anhydrolycoctonam[1,2]

O. E. EDWARDS

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received April 21, 1981

O. E. EDWARDS. Can. J. Chem. **59**, 3039 (1981).

The diterpenoid alkaloid lycoctonine was transformed into 4-amino-4-des(oxymethylene)anhydrolycoctonam. Nitrous acid deamination of this led to two unexpected products, an aldehydo-lactam acid and a hydroxy-keto lactam, both involving skeletal rearrangement. The origin of these products is discussed on the basis of structures determined by X-ray crystallography.

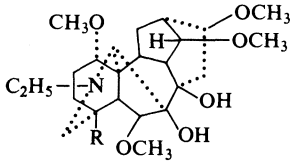
O. E. EDWARDS. Can. J. Chem. **59**, 3039 (1981).

On a transformé la lycoctonine, un alkaloide diterpénique, en amino-4 des(oxyméthylène)-4 anhydrolycoctoname. La désamination nitreuse de ce composé conduit à deux produits inattendus, un acide aldéhydo-lactame et une hydroxy-céto lactame impliquant tous deux une transposition du squelette. On discute de l'origine de ces produits en fonction des structures déterminées par cristallographie de rayons-X.

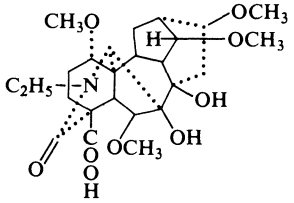
[Traduit par le journal]

Introduction

The first determination of the structure of a polyoxygenated diterpene alkaloid was made possible by the X-ray analysis of the structure of des(oxymethylene)lycoctonine hydriodide **1** (1). In our search, prior to this analysis, for methods which might help to define the skeleton of the parent alkaloid lycoctonine (**2**)[3] we explored reactions of its derivative lycoctonamic acid **3** (2).

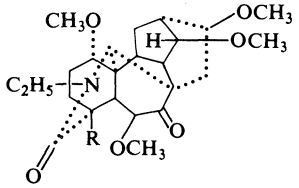


1 R = H
2 R = CH_2OH



3

An improved method of preparing the product of its pinacolic dehydration, anhydrolycoctonamic acid **4**, involved the action of very dilute sulfuric acid in acetic acid on **3**. Acid **4** was converted into 4-amino-4-des(oxymethylene)anhydrolycoctonam **5** by Curtius or Hofmann degradation. Nitrous acid deamination of **5** gave as main products a hydroxy-keto lactam (50%) and a crystalline acid (20%). The skeletal rearrangements involved in their formation, and the nature of the oxidation leading to the acid are of considerable interest.

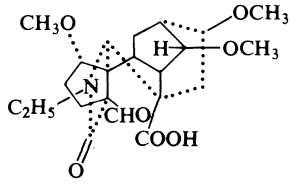


4 R = COOH
5 R = NH_2

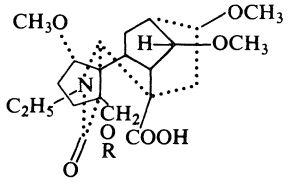
Structures

Because of a number of difficulties in interpreting the structural evidence, recourse was had to X-ray crystallographic analysis of the derivatives of the two major products. The exposition is simplified by assuming the correct structures.

The acid from the deamination proved to be an aldehydo-lactam acid (δ 9.9, 1H singlet, doublet at 201 ppm in its ^{13}C nmr spectrum), with empirical formula $C_{22}H_{31}NO_7$. Since it contained no C—C double bond (^{13}C nmr) it was pentacyclic. It only contained three methoxyl groups, hence it appeared probable that ring B had undergone fission with loss of C-6 and its attached methoxyl. This and the facts that the aldehyde group was attached to a quaternary carbon and that a γ-lactam (ν_{max} 1686 cm^{-1}) was probably present, coupled with mechanistic considerations, made structure **6** one of the likely possibilities.



6



7

The aldehyde function of **6** hydrated or formed hemiacetals on handling, resulting in the, at first puzzling, disappearance of the group. The mass spectrum of the methyl ester of **6**, prepared using

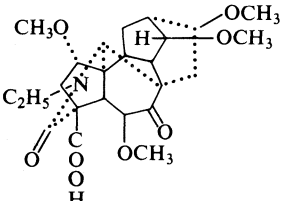
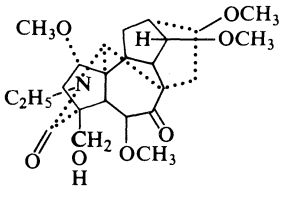
diazomethane in methanol–ether, gave an apparent molecular ion of *m/e* 449. This could possibly be due to small amounts of homologous aldehyde or epoxide formed by reaction with diazomethane. This, and ambiguity of many analyses, hampered structural work.

The aldehyde group was reduced to the primary alcohol, then this acetylated, giving an acetoxy acid. An X-ray analysis (3) showed that the acetoxy acid had structure **7** (R = OAc) and that **6** was the correct representation of the aldehydo acid.

The neutral deamination products contained some very polar components, nitrite esters (slow release of oxides) and at least three similar components separated by preparative thin layer chromatography. The main one (51% yield) was a hydroxy-keto-lactam (ν_{max}: 3470, 1729, and 1633 cm^{-1}) with formula $C_{24}H_{35}NO_7$. Since it had a saturated skeleton (^{13}C nmr) it was hexacyclic. The hydroxyl was readily acetylated, hence was primary or secondary. Jones' reagent oxidized it into a mixture of neutral and acidic products. The main acid (up to 52% yield) was a crystalline keto-lactam acid with formula $C_{24}H_{33}NO_8$. X-ray analysis[4] showed that it had the surprising structure **8** and hence that the hydroxy-keto lactam was **9**.



8



9

The ^{13}C spectrum of **9** had a triplet at 66 ppm, now attributable to the CH_2OH group. However the main neutral product from the Jones' oxidation (14%) appeared to be a diketo γ-lactam (ν_{max}: 1732, 1711, and 1693 cm^{-1}, no aldehyde proton in its ^1H nmr spectrum). This proved to be a stumbling block to interpretation. Despite the clean spectra of **9**, it may have contained an impurity which gave rise to this product.

The keto-lactam acid **8** showed strong internal hydrogen bonding (lactam carbonyl at 1604 cm^{-1}) as expected for a malonamic acid (see lycoctonamic and anhydrolycoctonamic acids (2)). Unlike these malonamic acids, however, it did not decarboxylate below 255°C.

Discussion

The X-ray analyses of **7** (3) and **8**[4] gave totally unexpected information that the C-1 configuration in lycoctonine was opposite to what had been assumed on the basis of the X-ray analysis of "des(oxymethylene)lycoctonine" hydriodide (1). This point will be discussed in a separate communication. The skeletal rearrangement involved in formation of the aldehyde was expected to be the main one observed, since the bond antiparallel to the departing nitrogen migrates, giving a secondary cation. However, the cleavage to the aldehydo acid was unexpected. One possible explanation is the formation of an intermediate nitrite ester, which fragments (eq. [1]). Subsequent oxidative cleavage

[1] 
by nitrous acid or oxides of nitrogen could give **6**. Fragmentation giving hyponitrous acid has been demonstrated in nitrosamide photolysis in acid (4*a*).

We are grateful to a referee for suggesting an alternate mechanism outlined in eq. [2]. This would require formation of the secondary alcohol from the rearranged cation, then retroaldol fission of the rather rigid ring B. This might relieve strain and increase entropy. The nitrosation of the resulting enol also seems possible. However, the second order Beckmann reaction of α-oximino ketones normally requires the action of strong acid (sulfuric, trifluoroacetic), or the action of base on the oxime esters (4*b*). The actual medium for the deamination was partially neutralized (amine, $NaNO_2$) 2 *N* sulfuric acid. Hence the fragmentation under such mild conditions would be unusual.

The formation of the primary alcohol **9** as a major

[2] 
product of the deamination is surprising. In model studies related to this work, we demonstrated ring contraction of α-aminocyclohexanones to hydroxy-

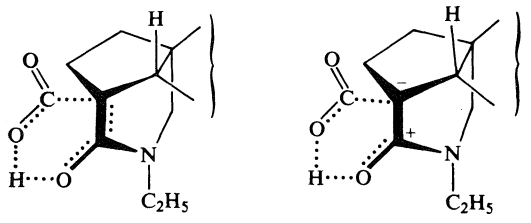
[4]M. Cygler and M. Przybylska, unpublished work.

cyclopentanones and the related enones (5, 6). But the process was clearly a downhill one energetically, since the secondary cations were involved (eq. [3]).

[3] 
The driving force for the ring contraction was the avoidance of a high energy cation adjacent to the positive end of the carbonyl dipole (6). Even though the bridgehead cation at C-4 would probably be more destabilized than the cations adjacent to the ketone carbonyls of our model compounds, it seems improbable that a high energy primary cation[5] would form from it. Hence, as in our model studies (6) we invoke formation of a specific edge-protonated cyclopropane as a less energetic intermediate. This would form by C2—C3 bond participation in the ionization followed by proton migration to give **10** with the proton on the more basic bond of the cyclopropane (6). This would then be preferentially attacked by water at C-3 for steric reasons and the proximity of solvent molecules to the face near the departing nitrogen and the lactam carbonyl (eq. [4]).

[4] 
10

The failure of the malonamic acid **8** to decarboxylate below 250°C, in contrast to the behaviour of lycoctonamic (**3**) and anhydrolycoctonamic (**4**) acids (2) could be interpreted as due to the very high energy of a transition state with bridgehead double bond character (see **11**) in this rigid fused system. However, Ferris and Miller (8) suggested that the transition state resembles a zwitterion such as **12** in these cases, and that the energy of this state diminishes to the extent that overlap of the anion with the π orbitals of the carbonyl becomes possible.



11 **12**

[5]A primary cation is around 27 kcal/mol less stable than a simple tertiary cation, and around 10 kcal/mol less stable than an isolated secondary cation (7).

Experimental

Unless otherwise mentioned, infrared spectra were of chloroform solutions and nmr spectra of deuterochloroform solutions containing TMS as reference. All plate separations were done on silica gel plates with fluorescent indicator. Spectra were obtained on a Perkin–Elmer model 157 infrared spectrometer, and Varian EM-360 and CFT-20 spectrometers.

Anhydrolycoctonamic Acid 4

An improved method of preparing this acid (2) follows. The trihydrate of lycoctonamic acid (**3**) (1.01 g) in 15 mL of glacial acetic acid containing 0.015 mL of concentrated sulfuric acid was heated at 85–90°C for 5.5 h. The sulfuric acid was neutralized by the addition of solid sodium carbonate, then the acetic acid removed under reduced pressure. The residue was taken up in water and the acid extracted into chloroform. The acid crystallized when 1 mL of methanol was added. A first crop of crystals (600 mg) melted at 181°C (dec.) and gave no mixture mp depression with the product prepared using acetyl chloride (2). Its ^{1}H nmr spectrum had signals at δ 4.02 (1H, d?, J = 3 Hz), 3.48 (3H, s), 3.38 (3H, s), 3.26 (6H, s), 2.96 (1H, s), 2.78 (1H, s), 1.17 (3H, t, J = 7 Hz), and its ^{13}C nmr spectrum had signals at δ 203.4, 174.1, 172.9, 88.3(d), 82.6(d), 82.0(d), 80.4(d), 64.7(d), 59.9(q), 58.6(s), 57.1(s), 56.7(q), 56.6(q), 55.5(t or s), 48.7(s), 47.6(d), 46.9(d), 43.9(t), 42.2(d), 38.8(d), 32.3(t), 25.6(t), 23.1(t), and 11.5(q).

Anhydrolycoctonamide

Anhydrolycoctonamic acid (910 mg) was added to 15 mL of thionyl chloride containing 0.2 mL of pyridine. The solution was refluxed for 45 min, the reagents removed under reduced pressure, then the residue cooled to 0°C. Ice-cold concentrated ammonia (28%, 15 mL) was added rapidly. A white gum formed, which gradually crystallized. After 30 min this was extracted into chloroform and the chloroform washed with dilute ammonia. The 757 mg of neutral product from the chloroform crystallized from ether giving 716 mg of amide, mp 190–200°C. Some unchanged acid was recovered from the ammonia solutions.

The amide was recrystallized from methanol–ether. After drying 3.5 h at 100°C *in vacuo* it had mp 210–214°C. It had ν_{max}: 3480, 3320, 1728, 1675, 1632, and 1553 cm^{-1}. Its ^{1}H nmr spectrum gave signals at δ 8.66 (1H, broad), 5.85 (1H, broad), 3.98 (1H, d, J = 3 Hz), 3.50 (3H, s), 3.40 (3H, s), 3.30 (6H, s), 3.08 (1H, s), 2.85 (1H, s), 1.13 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{25}H_{36}N_2O_7$: C 63.00, H 7.61; found: C 63.09, H 7.64.

4-Amino-4-des(oxymethylene)anhydrolycoctonam 5

Anhydrolycoctonamide (680 mg) was added to 15 mL of an ice-cold solution of potassium hypobromite (2 g of potassium hydroxide, 260 mg of bromine). The bulk of the amide dissolved rapidly. The solution was allowed to warm gradually until only a trace of undissolved solid remained (15 min), then heated at 75°C for 50 min. Sodium bisulfite was added to the solution, which was then acidified using sulfuric acid. Extraction of the solution with chloroform removed 36 mg of neutral material. The aqueous layer was basified and the base extracted into methylene chloride. The 580 mg of base crystallized from ether giving 550 mg, mp 194–202°C. It had ν_{max} (CH_2Cl_2): 3380 (very weak), 1726, and 1648 cm^{-1} and $[\alpha]_D$ 16° (*c* 1.03, absolute ethanol). Its ^{1}H nmr spectrum had signals at δ 4.36 (1H, s), 3.93 (1H, s), 3.52 (3H, s), 3.36 (3H, s), 3.26 (3H, s), 3.25 (3H, s), 1.1 (3H, t, J = 7 Hz), and its ^{13}C nmr spectrum had signals at δ 204.2, 173.0, 84.3, 83.4, 82.8, 64.0, 60.4, 59.2, 57.9, 56.9, 56.5, 56.2, 54.2, 49.9,

For personal use only.

47.9, 43.7, 43.4, 38.8, 33.2, 26.4, 25.5, and 12.3. Its pK_a in 50% aqueous methanol was 5.5. *Anal.* calcd. for $C_{24}H_{36}N_2O_6$: C 64.26, H 8.09, N 6.25; found: C 64.19, H 8.21, N 6.32.

The amine was also prepared by converting anhydrolycoctonamic acid into its chloride using thionyl chloride, then its azide (ν_{max} 2145 cm^{-1} in methylene chloride) using a cold saturated solution of sodium azide in 50% aqueous acetone. The azide was converted to isocyanate by heating in refluxing benzene for 1 h. The isocyanate had ν_{max}: 2235, 1731, and 1656 cm^{-1}. This was hydrolysed, using 1 *N* sulfuric acid in 50% aqueous acetone, to give a crystalline amine identical to **5**.

Deamination of 5

Five hundred milligrams of the amino-lactam were dissolved in 15 mL of 2 *N* sulfuric acid. After addition of 400 mg of sodium nitrite the flask was loosely stoppered. After 40 min and 70 min two further 100 mg portions of nitrite were added. At the end of 95 min total reaction time the mixture was concentrated under reduced pressure to remove nitrogen oxides. The neutral and acidic products were extracted into methylene chloride, then the acids removed from the methylene chloride by two sodium carbonate washes. The neutral product weighed 400 mg and the acids 115 mg (1). Only a trace of base was recovered.

Aldehydo Acid 6

After purification by preparative tlc on silica gel plates, using 15% methanol in chloroform for development, the main acid from deamination of **5** crystallized from methanol as needles, mp 230°C. It had ν_{max}: 1711 and 1656 cm^{-1} with intermediate shoulders. Its ^1H nmr spectrum had signals at δ 9.9 (1H, s), 4.4 (1H, s), 3.36, 3.24 (singlets), and a distorted triplet centered at δ 1.13 (3H, J = 7 Hz). Its ^{13}C nmr spectrum had signals at δ 201.1(d), 177.1(s), 174.6(s), 84.6(d), 83.8(d), 81.8(d), 71.5(d), 69(s), 63.5(s), 57.5(q), 56.7(q), 56.3(q), 54.5(s), 48.9(d), 43.1(d), 40.14(d), 38.6(t), 33.8(t), 30.1(t), 28.8(t), 27.5(t), and 12.3(q). *Anal.* calcd. for $C_{22}H_{31}NO_7$: C 62.69, H 7.41, N 3.32, OCH_3 22.09; found (average of three analyses): C 63.43, H 7.66, N 3.44, OCH_3 21.68. Occasionally a hydrated form of the aldehyde was obtained (lactol?) distinguished by the absence of the ^1H nmr signal at δ 9.9. It could be reconverted to the aldehydo acid by recycling through the sodium salt.

Aldehydo Acid Methyl Ester (and its homologue?)

This was prepared by action of an ether solution of diazomethane on a solution of the acid in methanol. After purification by preparative tlc on silica gel plates, using 5% methanol in chloroform as developing solvent, it crystallized from ether–hexane mixture as thin rectangular plates, mp 118°C. It had ν_{max}: 1727 and 1683 cm^{-1}. Its ^1H nmr spectrum gave signals at δ 9.95 (1H, s), 4.36 (1H, s), 3.68, 3.34, 3.20 (3H singlets), 1.07 (3H, t, J = 6 Hz). *Anal.* calcd. for $C_{23}H_{33}NO_7$: C 63.43, H 7.64, N 3.32; found: C 63.90, H 7.72, N 3.18. Its mass spectrum gave peaks at *m/e*: 449 (calcd. for $C_{24}H_{35}NO_7$ = 449; $C_{23}H_{33}NO_7$ = 435), 417, 408, 407 (intense). However, a later determination on an MS-9 instrument gave *m/e* 449 and 435 in the ratios of 1 to 1.8.

Hydroxy and Acetoxy Acids 7

Sodium borohydride (60 mg) was added in five portions to a solution of 32 mg of aldehydo acid in 2 mL of methanol over the course of 20 min. The solution was evaporated to dryness on a rotating evaporator. After addition of dilute sulfuric acid, the product was recovered by extraction with methylene chloride, giving crystalline hydroxy acid **7** (R = H). This gave ^1H nmr signals at δ 7.75 (2H, br), 4.3 (1H, s), 3.35, 3.3, 3.26 (OCH_3 singlets), 1.08 (3H, t, J = 7 Hz). This was not further characterized. It was acetylated overnight in 1 mL of 1:1 pyridine – acetic anhydride at room temperature, giving 4 mg of neutral product and 35 mg of acetoxy acid **7** (R = Ac) which crystallized readily from ether–hexane mixture. It was purified by preparative tlc on silica gel plates using 15% methanol in chloroform for development. After three recrystallizations from ether–hexane (small prisms) it had mp 199–202°C. Its ^1H nmr spectrum in C_6D_6 had signals at δ 9.95 (1H, br), 4.8 (2H, s), 4.49 (1H, s), 3.2 (6H, s), 2.93 (3H, s), 1.91 (3H, s), 1.07 (3H, t). Its ^{13}C nmr spectrum had signals at δ 177.0, 176.0, 170.8, 85.5, 84.3, and 81.2, 71.9, 63.8, 61.0, 58.2, 57.65, 56.4, 54.6, 49.2, 42.9, 40.3, 38.5, 34.4, 29.6, 27.9, 27.5, 20.9, and 12.0. *Anal.* calcd. for $C_{24}H_{35}NO_8$: C 61.92, H 7.58, N 3.01; found: C 62.36, H 7.68, N 2.97.

Methyl Ester of Acetoxy Acid 7

Excess ethereal diazomethane was added to a solution of the acetoxy acid in methanol. After a few minutes the solvent was removed on a rotating evaporator. After purification by preparative tlc on a silica gel plate, using 5% methanol in chloroform, it crystallized as lustrous prisms from ether–hexane mixture, mp 111–114°C. It had ν_{max}: 1726 and 1681 cm^{-1} and gave ^1H nmr signals at δ 4.38 (2H, s), 4.28 (1H, s), 3.64 (3H, s), 3.35 (3H, s), 3.32 (3H, s), 3.22 (3H, s), 2.08 (3H, s), 1.03 (3H, t, J = 7 Hz). Its mass spectrum had peaks at *m/e*: 479 (M^+), 447, and 392 (M^+ calcd. for $C_{25}H_{37}NO_8$: 479). *Anal.* calcd. for $C_{25}H_{37}NO_8$: C 62.61, H 7.78, N 2.92; found: C 62.39, H 7.87, N 2.80.

Hydroxy-keto Lactam 9

The neutral product from the deamination was a mixture that was separated by preparative tlc on silica gel plates using 10% methanol in chloroform for development. The main band with R_f near 0.6 represented 68% of the neutral product (50% yield). After replating for final purification the substance was still amorphous. It had ν_{max}: 3470, 1729, and 1633 cm^{-1}. Its ^1H nmr spectrum had signals at δ 3.9 (1H, s), 3.48 (3H, s), 3.39 (3H, s), 3.27 (6H, s), and 1.07 (3H, t, J = 7 Hz). In C_6D_6 it gave signals at δ 3.90 (1H, s), 3.40 (3H, s), 3.18 (3H, s), 3.12 (3H, s), 2.90 (3H, s), and 1.06 (3H, t, J = 7 Hz). Its ^{13}C nmr in deuterobenzene had signals at δ: 204.2(s), 175.8(s), 83.3(d), 83.2(d), 80.0(d), 66.4(t), 62.0(d), 59.9(q), 57.6(q), 57.4(q), 57.3(q), 56.8(s), 56.0(s), 53.7(d), 53.4(s), 45.8(d), 45.2(d), 41.2(t), 40.0(d), 38.8(t), 30.2(t), 26.9(t), and 12.3(q). This fits structure **9** if there is accidental superposition of two methine carbons carrying methoxyl groups (ca. 83 ppm).

The amorphous solid did not give satisfactory analysis, but a sample distilled at 170°C, 1×10^{-4} Torr did. Its electron impact mass spectrum had peaks at *m/e*: 449 (M^+), 434, 417, 406, 402, 390, 389, 373, 359, 358, and 357 (M^+ calcd. for $C_{24}H_{35}O_7N$: 449). *Anal.* calcd. for $C_{24}H_{35}O_7N$: C 64.12, H 7.85; found: C 63.98, H 8.08.

Acetoxy-keto Lactam

The hydroxy-keto lactam **9** was completely acetylated overnight at room temperature in 1:1 acetic anhydride – pyridine. The amorphous product had ν_{max}: 1735 and 1651 cm^{-1} and gave ^1H nmr signals at δ 4.38 (2H, s), 3.88 (1H, s), 3.45 (3H, s), 3.37 (3H, s), 3.25 (3H, s), 3.22 (3H, s), 2.07 (3H, s), and 1.05 (3H, t, J = 7 Hz). When heated in a bath at 250°C under 0.1 Torr the acetate refluxed but did not significantly decompose.

Keto-lactam Tosylate

Sixty milligrams of **9** were added to a solution of 159 mg of *p*-toluenesulfonyl chloride in 1 mL of dry pyridine. After 40 h at room temperature, 0.5 mL of water was added, then the mixture left for 1 h. The solvents were then removed on a rotating evaporator, the residue taken up in methylene chloride and this washed with dilute sulfuric acid, then saturated sodium bicarbonate solution. The 80 mg of product was purified by preparative tlc on silica gel using 5% methanol and chloroform. The main band (R_f 0.7) contained 53 mg. A chloroform solution of this was filtered through a short bed of activity I neutral alumina

giving 47 mg of colorless amorphous product. An ether solution of this was filtered for analysis, giving on evaporation a colorless froth. This had ν_{max}: 1731 and 1649 cm^{-1} and gave ^1H nmr signals (C_6D_6) at δ 7.72 (2H, d, J = 8 Hz), 6.75 (2H, d, J = 8 Hz), 4.78 (1H, d, J = 11 Hz), 4.25 (1H, d, J = 11 Hz), 3.88 (1H, s), 3.28 (3H, s), 3.18 (3H, s), 3.08 (3H, s), 2.82 (3H, s), 1.88 (3H, s), and 0.98 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{31}H_{41}NO_9S$: C 61.67, H 6.84, N 2.32; found: C 61.50, H 6.72, N 2.49.

A solution of the 80 mg of tosylate in 1 mL of toluene containing 107 mg of DBN was refluxed under argon for 2 h. Relatively pure starting material (70 mg) was recovered.

Oxidation of Hydroxy-keto Lactam **9**

A solution of 150 mg of **9** in 2 mL of acetone was titrated with a dilute solution of Jones' reagent (9) in acetone until excess reagent persisted for 10 min. The solvent was decanted from precipitate, then evaporated. The residue was taken up in methylene chloride and the acids removed by two extractions with sodium carbonate solution. The aqueous layers were back-washed with methylene chloride. The methylene chloride gave 60 mg of neutral products while the sodium carbonate solution gave 106 mg of acid.

Combined neutral products from 334 mg of hydroxy-keto lactam (123 mg) were purified by separation on a 1000 μm tlc plate using 10% methanol in chloroform under argon. Only 46 mg were recovered in the main zone. After replating this, 25 mg were recovered, which gave sharp spectra: ν_{max}: 1732, 1711, and 1693 cm^{-1}; ^1H nmr signals in C_6D_6 at δ 4.08 (1H, d, J = 12 Hz), 3.37 (3H, s), 3.07 (6H, s), 2.77 (3H, s), and 0.97 (3H, t, J = 7 Hz). Addition of $Eu(dpm)_3$ shift reagent resulted in separation of the methoxyl signals, but gave no more information about the medium-field hydrogens.

No further work was done on this material.

Keto-lactam Acid **8**

The acid from the Jones' oxidation of **9** crystallized from ether as thin plates, mp 154°C, with no gas evolution below 255°C; $[\alpha]_D$ +39° (*c* 0.89, ethanol); ν_{max}: 1736 and 1604 cm^{-1}; for a Nujol mull, ν_{max}: 1747, 1734, and 1606 cm^{-1}. Its ^1H nmr spectrum had signals at δ 3.98 (1H, s), 3.48 (3H, s), 3.38 (3H, s), 3.26 (6H, s), 1.10 (3H, t). In C_6D_6 the signals were shifted to δ 3.86 (1H, s), 3.38 (3H, s), 3.16 (3H, s), 3.09 (3H, s), 2.73 (3H, s), 0.91 (3H, t, J = 7 Hz). *Anal.* calcd. for $C_{24}H_{33}NO_8$: C 62.19, H 7.18, N 3.02 (mol. wt. 463.5; $4OCH_3$ 26.77); found: C 62.07, H 7.43, N 2.97; equivalent wt. by titration 465; OCH_3 27.58. Its pK_a in 50% aqueous methanol was 5.0.

The same acid was produced less efficiently by oxidation of **9** with chromium trioxide in wet acetic acid, or by potassium permanganate in acetone containing a small amount of acetic acid.

Methyl Ester of Keto-lactam Acid **8**

This was prepared by addition of excess diazomethane in ether to a methanol solution of acid **8**. After purification on silica gel plates (5% MeOH in chloroform), it crystallized from ether as sheaves of fine needles with mp 196°C. It had ν_{max}: 1728 and 1657 cm^{-1} and gave ^1H nmr signals at δ 4.14 (1H, s), 3.78 (3H, s), 3.52 (3H, s), 3.26 (6H, s), 1.03 (3H, t, J = 7 Hz). In pyridine-d_5 the signals were at δ 4.61 (1H, s), 4.14 (1H), 3.92 (1H), 3.72 (3H, s), 3.63 (3H, s), 3.33 (3H, s), 3.26 (3H, s), 3.14 (3H, s), 1.13 (3H, t, J = 7 Hz). Its ^{13}C nmr spectrum in C_6D_6 had signals at δ: 203.9, 170.9, 169.5, 82.8(d), 78.6(d), 61.5(d), 59.9(q), 59.7(s), 56.9(d), 56.7(q), 56.3(q), 55.5(t?), 54.5(d), 51.9(q), 45.4(d), 44.5(d), 41.2(t), 39.6(d), 38.1(t), 29.8(t), 26.3(t), and 11.7(q). *Anal.* calcd. for $C_{25}H_{35}NO_8$: C 62.87, H 7.39, N 2.93 (mol. wt. 477.54); found: C 62.06, H 7.45, N 2.93. Its mass spectrum gave M^+ 477, with the next significant peak at *m/e* 462. The analysis was repeated several times on different samples with no better agreement.

A theoretical study on the bimolecular hydrogen exchange aminonitrene → *trans*-diimide. Comparison with formaldehyde photochemistry

M. J. H. KEMPER AND H. M. BUCK

Laboratory for Organic Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

Received April 22, 1981

M. J. H. KEMPER and H. M. BUCK. Can. J. Chem. **59**, 3044 (1981).

Ab initio calculations on the rearrangement aminonitrene → *trans*-diimide are reported. It is shown that a bimolecular hydrogen exchange is much easier than a unimolecular 1,2 hydrogen shift: the reactions have activation energies of 4 and 94 kcal/mol, respectively. The hydrogen exchange starts from dimers which have a fairly large stabilization energy. Infrared and Raman frequencies of these dimers are calculated in order to facilitate experimental studies. Some striking similarities are indicated between diimide chemistry and the photochemistry of formaldehyde. It is shown that results from one field are transferable to the other one. From this, some new experiments are suggested.

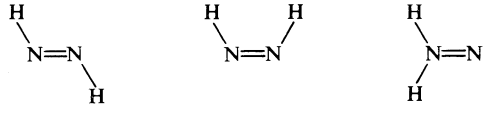
M. J. H. KEMPER et H. M. BUCK. Can. J. Chem. **59**, 3044 (1981).

On rapporte les calculs *ab initio* relatifs à la transposition aminonitrène → diimide *trans*. On a montré que la réaction bimoléculaire d'échange d'hydrogène est plus facile que le glissement d'hydrogène-1,2 unimoléculaire: les énergies d'activation de ces deux réactions sont respectivement de 4 et de 94 kcal/mol. L'échange d'hydrogène se fait à partir des dimères qui ont une énergie de stabilisation assez élevée. On a calculé les fréquences ir et Raman de ces dimères en vue d'en faciliter les études expérimentales. On indique des similarités frappantes entre la chimie des diimides et la photochimie de la formaldéhyde. On montre que ces résultats sont transférables d'un champ à l'autre. On suggère de nouvelles expériences à partir de ces données.

[Traduit par le journal]

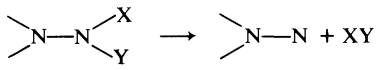
I. Introduction

There are three different equilibrium structures of N_2H_2: *trans*-diimide (**1**), *cis*-diimide (**2**), and the nitrene-structure (**3**) (aminonitrene or 1,1-diazine).



1 **2** **3**

The thermochemistry of these isomers has been the subject of intense theoretical and experimental interest (1). A reason for this is the fact that diimide, generated *in situ*, is widely used as a reagent in the hydrogenation of double bonds. The observation that this reduction of alkenes and alkynes occurs in a highly stereoselective *syn* manner resulted in a concerted mechanism, via a six-centered transition state, which requires *cis*-diimide. However, only *trans*-diimide has been definitely observed by spectroscopic means (2). The probable stereochemistry of the molecules produced in the various reactions giving diimide is not clarified. The thermal cycloreversion of diimide–anthracene adducts (3) produces directly *cis*-diimide. The stereochemistry of the products from microwave discharges (4) or oxidation (5) of hydrazine, however, is unclear, although energetic considerations suggest that *trans*-diimide should be the dominant isomer formed. It can also be argued (6), that a nitrene is the expected product of the decomposition of unsymmetrically substituted hydrazine derivatives:



The same holds for reactions involving the decomposition of hydrazine derivatives containing the R_1R_2—N—N—Z fragment. The nitrene rearranges then to the azo compound:

$$R_1R_2\text{—N—N} \rightarrow R_1\text{—N—N—}R_2$$

So, a very central point in the chemistry of N_2H_2 is the question how an easy interconversion between the isomers **1**, **2**, and **3** is possible. The most stable isomer is singlet *trans*-diimide, which lies 6–7 kcal/mol below the *cis* structure (7, 8). Much calculational attention has been paid to the *trans*–*cis* isomerization which is considered to be the rate-controlling step in gas phase reactions of diimide. An experimental activation energy of 4.2 kcal/mol has been reported for this process (9). Unimolecular isomerizations, however, including both concerted and dissociation–recombination mechanisms, have much too high energy barriers (1). Therefore, Casewit and Goddard III (1) proposed a bimolecular radical-chain mechanism, initiated by:

$$\textit{trans}\text{-HNNH} + \textit{trans}\text{-HNNH} \rightarrow \text{H}\cdot + \text{N}_2 + \text{H}_2\text{N}\dot{\text{N}}\text{H}$$
$$\Delta H = -15.0\ \text{kcal/mol}$$

The experimentally observed activation energy for the diimide reactions is consistent with the rate-

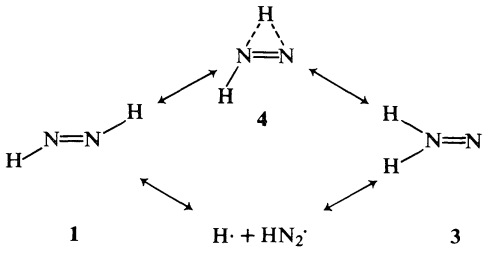
determining step in their scheme:

$$H_2N\dot{N}H + \textit{trans}\text{-}HNNH \rightarrow \textit{cis}\text{-}HNNH + H_2N\dot{N}H \qquad \Delta H = 4.7\,\text{kcal/mol}$$

A similar problem occurs for the unimolecular rearrangement aminonitrene → *trans*-diimide:



Sophisticated calculations including electron correlation give rather ultimate values for the barrier (relative to **1**) of the 1,2 hydrogen shift: 83.0 (7) and 82.6 (8) kcal/mol. The dissociation–recombination is a little easier: the N—H bond energy of **1** is predicted (1) to be (at 298 K) 71.5 kcal/mol. So, also in this case the unimolecular barriers are too high to agree with the easy nitrene–azo rearrangement.

We will show in Section II that there is, just as for the *trans–cis* isomerization, a bimolecular mechanism which easily produces *trans*-diimide from aminonitrene. We also give in that section calculated infrared and Raman frequencies of **1**, **3**, and dimers of these isomers. Details of the calculation are described in Section III. In Section IV we offer some comments on the similarities between the systems H_2N_2–HNNH and H_2CO–HCOH.

II. Results

Figure 1 gives the structures and relative energies of **1**, **3**, and the two cyclic dimers of these isomers, which are important here. The dimers are considerably stabilized, relative to two non-interacting monomers:

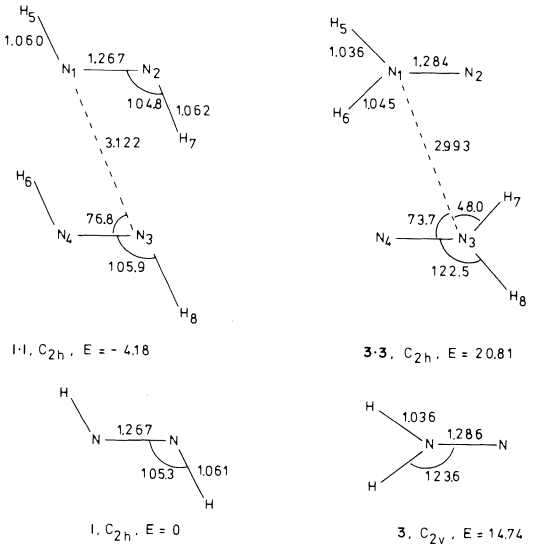


FIG. 1. STO-3G monomers and dimers of trans-diimide and aminonitrene. Geometries are in Å and deg. Energies are in kcal/mol; the dimer energies are relative to two non-interacting *trans*-diimides.

4.18 and 8.67 kcal/mol for **1·1** and **3·3**, respectively. This stabilization energy is caused by the formation of —N···H— hydrogen bonds. This is seen from the equilibrium geometries: the hydrogens H_6 and

TABLE 1. Calculated infrared and Raman frequencies (cm^{-1}) for *trans*-diimide (**1**), aminonitrene (**3**), and their dimers

		Frequency

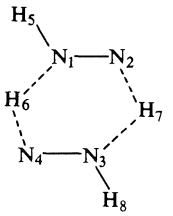
H_7 interact with the directed nitrogen lone pairs. This interaction is reflected in the small, but significant electron densities[1] between the hydrogen bonded atoms (N_1H_6 and N_3H_7 in **1·1**; N_4H_6 and N_2H_7 in **3·3**).

The most promising way to study, in an experimental manner, dimer formation is infrared and Raman spectroscopy. Therefore, we calculated the in-plane vibrational frequencies of the structures in Fig. 1. The results are shown in Table 1. We used some empirical corrections in our method, which were calibrated on the formaldehyde molecule (13, 14) (see also Section III). This method reproduces the experimental frequencies of *trans*-diimide with an average deviation of 5%. A more refined calibration on diimide itself is not possible, because the experimental values are nitrogen matrix frequencies. What is more important is the calculated difference between monomeric and dimeric spectra. As a consequence of dimer formation the frequencies of **1** and **3** shift. The largest change occurs for the asymmetric bonding modes. This is by far the strongest *trans*-diimide absorption (11). Also, every vibration is split into two bands: one infrared and one Raman band. So, **1·1** might be detectable because of the appearance (near 1360 cm^{-1}) of the Raman-active component of the asymmetrical band. This statement needs, of course, the reservation that the spectra are not perturbed by *cis*-diimide, that should have frequencies (both infrared and Raman active), close to the *trans* isomer (15).

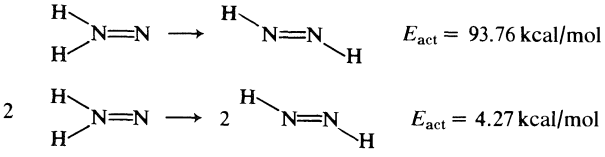
As might be clear already from the dimers given in Fig. 1, the reaction

aminonitrene → *trans*-diimide

involves a bimolecular hydrogen exchange via the transition state (TS):



In Fig. 2 we give the STO-3G energetics of this process. We calculated the potential energy surface as a function of the N_1H_6 and N_3H_7 distances. All the other parameters were optimized with respect to the total energy of the supermolecule. The system retains C_{2h} symmetry; relaxation of this symmetry constraint is not expected to give a considerable lowering of TS. This will be discussed in Section III, together with possible changes due to larger basis sets. The interatomic electron densities (10) show that in TS the migrating hydrogens are equally shared by the two nitrogens; the six-centered transition state has an "aromatic" character, in the sense that the migration of 6 electrons is involved in it. We also compare in Fig. 2 the bimolecular energetics with the concerted unimolecular 1,2 hydrogen shift (**3** → **4** → **1**), as calculated with the same method. The hydrogen exchange mechanism is clearly in favour:



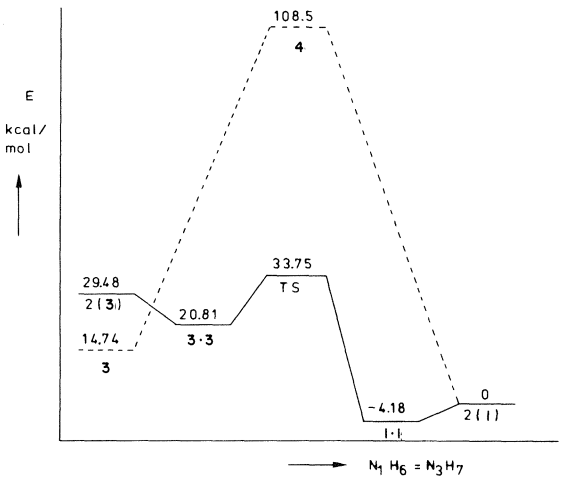


FIG. 2. STO-3G energetics of 2 aminonitrene → (aminonitrene)$_2$ → TS → (HNNH-*trans*)$_2$ → 2 HNNH-*trans*. The broken line gives the energy of the unimolecular 1,2 hydrogen shift (**3** → **4** → **1**).

III. Methods of Calculation

Ab-initio structures and energies were calculated with the widely used GAUSSIAN 70 program (16) and the STO-3G (17) basis set. These methods are well described and documented (18) in the literature and need no further comment here. We do not expect that larger basis sets will give a qualitative change of the picture given in Fig. 2. We extensively studied (13, 14) the analogous hydrogen exchange in the isoelectronic formaldehyde system:

2HCOH-*trans* → $2H_2CO$

The results were virtually the same in going from minimal STO-3G up to complete optimization with 6-31 G* (19). We also found in the case of formaldehyde that the hydrogen exchange is nearly symmet-

[1]The electron density indicates the strength of a bond between two atoms and is calculated similar to the so-called Reduced Overlap Population as defined in ref. 10.

ric. Relaxation of the C_{2h} symmetry constraint resulted in almost the same reaction path and barrier.

To obtain vibrational frequencies, we calculated the STO-3G force constants. We used internal coordinates (bond distances and angles). Diagonal constants are obtained from:

$$F_{xx} = \frac{\partial^2 E}{\partial x^2} \simeq E(x_0 + \Delta x) - 2E(x_0) + E(x_0 - \Delta x)/\Delta x^2$$

The interaction constants are calculated from:

$$F_{xy} = \frac{\partial^2 E}{\partial x \partial y} \simeq E(x_0 + \Delta x, y_0 + \Delta y) + E(x_0 - \Delta x, y_0 - \Delta y) - E(x_0 + \Delta x, y_0 - \Delta y) - E(x_0 - \Delta x, y_0 + \Delta y)/4\Delta x \Delta y$$

Here, x_0 and y_0 are the values of the internal coordinates in the equilibrium structure. The displacements Δ are chosen (by some trial and error) neither too large for anharmonicity to matter nor too small for numerical inaccuracies to appear. The force constants are transformed to frequencies using the conventional **FG** method (20). The obtained symmetry of the normal mode movement shows whether the vibration is infrared and/or Raman active. As shown by Pulay (21), the prediction of diagonal force constants to experimental accuracy is not easily possible from single determinant Hartree–Fock wave functions. Fortunately, however, the errors are near-systematic and allow for correction factors to improve significantly the agreement with experiment. The method that was used here was calibrated on formaldehyde (13). We scaled down the diagonal stretching constants by a factor 0.65; for the diagonal bendings we used 0.9. The interaction constants were left unchanged. Another important improvement is made by using spectroscopic masses defined by (22, 23):

$$M_{sp} = M + 0.0795M^{1/2}$$

This partially corrects for anharmonicity and improves primarily H-stretching modes.

IV. Some Similarities with Formaldehyde Photochemistry

It will be clear from the foregoing that this study on the reaction

aminonitrene → *trans*-diimide

was heavily inspired from our studies on formaldehyde. There, the hydroxycarbene molecule (HCOH) is supposed to be a good candidate for the long searched intermediate state in formaldehyde photochemistry (13, 14, 24). HCOH has a much higher energy than H_2CO and can only be produced via the excited formaldehyde S_1 state. A direct experimental verification of the existence of this intermediate has not yet been published in the literature. Indirect evidence comes from matrix experiments (25, 26). The addition products, which are formed out of formaldehyde dimers, can be explained with the HCOH intermediate (13, 14). A hydrogen exchange mechanism was shown to explain the rearrangement

trans-HCOH → H_2CO

In this section we want to point out some other striking similarities between these two fields. Pasto and Chipman (27, 28) calculated reactions of ethene with diimide species, and disproportionation reactions of N_2H_2. Diimide and ethene are isoelectronic with formaldehyde, so it might not be too surprising that the reactions are completely analogous to our formaldehyde results. For instance:

$$\left.\begin{array}{l} H_2C{=}CH_2 + \textit{cis}\text{-HNNH} \rightarrow H_3C - CH_3 + N_2 \\ H_2C{=}O \quad + \textit{cis}\text{-HCOH} \rightarrow H_3COH \quad + CO \end{array}\right\}$$

or:

$$\left.\begin{array}{l} H_2C{=}CH_2 + \textit{trans}\text{-HNNH} \rightarrow \text{1-ethyl-1,1-diazine} \\ H_2C{=}O \quad + \textit{trans}\text{-HCOH} \rightarrow \text{glycoaldehyde} \end{array}\right\}$$

So, it is seen that the results from one field are transferable to the other one; this study is, in fact, the first example. Pasto's (28) theoretical results on disproportionation reactions of N_2H_2 species ($2N_2H_2 \rightarrow N_2H_4 + N_2$) can be a guide for analogous reactions between two hydroxycarbenes. Perhaps more important (and it is the main purpose of this section to indicate this), is the fact that these results might stimulate two kinds of experiments. Firstly, suited photochemical studies of diimide can give information about the behaviour of the mysterious hydroxycarbene. Secondly, photoinduced gas-phase reactions between formaldehyde and alkenes should be studied; such experiments can give valuable information concerning the involvement of HCOH in addition reactions.

Heat capacities and volumes of NaCl, $MgCl_2$, $CaCl_2$, and $NiCl_2$ up to 6 molal in water

GÉRALD PERRON, ALAIN ROUX[1], AND JACQUES E. DESNOYERS[2]
Department of Chemistry, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received April 2, 1981

GÉRALD PERRON, ALAIN ROUX, and JACQUES E. DESNOYERS. Can. J. Chem. **59**, 3049 (1981).

It has been claimed by Enderby and co-workers that changes in long-range order occur in $NiCl_2$ aqueous solutions at high concentrations. To investigate the possibility of a transition, the partial molar heat capacities and volumes of $NiCl_2$, $CaCl_2$, $MgCl_2$, and NaCl were measured and compared in water at 25°C up to 6 mol kg^{-1}. In the case of NaCl, data were also measured at 5 and 45°C. A slight change in slope of $\bar{C}_{p,2}$ is observed for $NiCl_2$ around 4 mol kg^{-1} which may suggest a third or higher order transition. However, the change is too small to support unambiguously any particular model for the high concentration region.

GÉRALD PERRON, ALAIN ROUX et JACQUES E. DESNOYERS. Can. J. Chem. **59**, 3049 (1981).

Enderby et ses collaborateurs ont prétendu qu'il se produit des changements très importants dans des solutions aqueuses très concentrés de $NiCl_2$. Afin d'étudier la possibilité d'une transition, on a mesuré les capacités calorifiques molaires partielles et les volumes molaires partiels du $NiCl_2$, du $CaCl_2$, du $MgCl_2$ et du NaCl et on les a comparés dans l'eau à 25°C jusqu'à 6 mol, kg^{-1}. Dans le cas du NaCl, on a également mesuré les données à 5°C et à 45°C. On a observé un léger changement dans la pente de $\bar{C}_{p,2}$ pour le $NiCl_2$ à environ 4 mol kg^{-1} ce qui suggère une transition d'ordre trois ou une transition d'ordre plus élevée. Cependant le changement est trop faible pour servir de preuve formelle à tout modèle particulier dans la région de forte concentration.

[Traduit par le journal]

Introduction

Enderby and co-workers (1, 2) reported in 1974 data on the neutron scattering of aqueous solutions of $NiCl_2$ and concluded that, at high concentration, the Ni ions were arranged in a quasi-lattice and that the solutions possessed a substantial degree of long-range order. This unexpected conclusion has prompted numerous investigations, namely, Raman scattering (3, 4), thermodynamic measurements (5), viscosity (6), diffusion (7), and X-ray scattering (8). However, the interpretation of many of these data is subject to criticism and other explanations can be offered to explain the anomalous neutron scattering (9).

Of all the thermodynamic properties, heat capacity is probably the most sensitive to transitions in the condensed state. On a suggestion from Professor H. L. Friedman, we therefore decided to make a careful investigation of this property up to the region where the transitions are said to occur. Our flow microcalorimeter measures heat capacities per unit volume, and densities of comparable precision are required to calculate apparent and partial molar heat capacities. The densities were therefore measured with a flow densimeter on the same solutions.

It will be necessary to compare the data on $NiCl_2$ with other systems where such transitions are not expected to occur. $CaCl_2$ seems to be a good reference for this purpose. If the hydration of Ni^{++} is responsible for any anomalous behavior, then similar trends would be expected for $MgCl_2$. Data on these two electrolytes are available in the literature. For example, data in our own laboratory were reported on these two salts at low concentration (10). However, it is important to compare the properties of all these electrolytes under very similar experimental conditions.

Volumes and heat capacities of NaCl have been measured as a function of temperature up to 3 mol kg^{-1} (11). Many authors interested in the data of this salt have asked us to extend our measurements to higher concentration. We therefore measured these properties up to 6 mol kg^{-1} at 5, 25, and 45°C. A comparison with the 1:2 electrolytes might also prove to be informative.

Experimental

The techniques for measuring heat capacities and densities by flow microcalorimetry (12, 13) and flow densimetry (14) have been well described, and the method of calculating apparent molar heat capacities (ϕ_C) and volumes (ϕ_V) are given therein.

The origin and purification procedure of the chemicals are the following. NaCl (Fisher Certified) was used as such after drying under vacuum at 150°C. $NiCl_2$ (Ultra-pur Alfa Product), $MgCl_2$ (Analar, BDH Chemicals), and $CaCl_2$ (Fisher Certified) were recrystallized in water at a pH of 5. $NiCl_2$ was analyzed by precipitation with EDTA and also by conductometric titration with $AgNO_3$ with a concentrated and with two dilute samples. $MgCl_2$ and $CaCl_2$ were analyzed gravimetrically and conductometrically with $AgNO_3$. In all cases the analyses agreed within 0.05%. All solutions were prepared by weight dilution of the same stock solution. The uncertainty in the concentration plus the 0.5% uncertainty in the relative change in heat capacity per unit volume limits the precision in ϕ_C to ± 0.8 J K^{-1} mol^{-1}. At low concentration this uncertainty may increase.

Results

The measured densities and heat capacities per unit volume and the derived ϕ_V and ϕ_C are given in Table 1.

The volumes and heat capacities of $MgCl_2$, $CaCl_2$, and NaCl have been well investigated at low concentration and need not be discussed here. On the other hand, only one set of reliable data seems to exist for $NiCl_2$ (15). This electrolyte was therefore studied to fairly low concentration. The values of $\phi_V - A_V m^{1/2}$ and $\phi_C - A_C m^{1/2}$, where A_V and A_C are the theoretical slopes of the limiting Debye–Hückel theory, are plotted against m and compared with the data of Hepler *et al.* (15*a*) in Fig. 1.

Two sets of measurements, corresponding to two different stock solutions of $NiCl_2$, agree well inside the expected uncertainty. Our data are also in reasonably good agreement with those of Hepler *et al.*, especially at their higher concentrations. An extrapolation of the straight lines at low concentration to infinite dilution will give the standard partial molal values at 25°C.

$$\bar{V}_2^0 = 6.20 \pm 0.05\ \text{cm}^3\ \text{mol}^{-1}$$
$$\bar{C}_{p,2}^0 = -306 \pm 1\ \text{J K}^{-1}\ \text{mol}^{-1}$$

The data of all the electrolytes up to 6 mol kg^{-1} were fitted with eq. [1]:

$$[1]\quad \phi_Y = \phi_Y^0 + A_Y m^{1/2} + B_Y m + C_Y m^{3/2} + D_Y m^2 + \ldots$$

where Y stands for V or C_p. In eq. [1] ϕ_Y^0 should be equal to $\bar{Y}_2^0$, the standard value, and A_Y should be the Debye–Hückel limiting slope. However, ϕ_Y varies significantly at low concentration and much less at high concentration. As a result, if ϕ_Y^0 and A_Y are fixed before the least-squares analysis, many parameters are required to fit the data. A better extended form of the Debye–Hückel theory would probably give a better fit. However, since in the present case we are not interested in the high dilution region, it was found simpler to treat ϕ_Y^0 and A_Y as adjustable parameters like the other coefficients since this allowed a very good representation of all our high concentration data with a minimum of parameters. Parameters such as A_Y then include any specific interactions such as a small degree of association.

The coefficients of eq. [1] are given in Table 2. Again we stress that no physical significance should be given to the parameters ϕ_Y^0 and A_Y.

The uncertainty in the data and a comparison with the literature are best illustrated through deviation plots $\Delta(\phi_Y^{obs} - \phi_Y^{calc})$, where ϕ_Y^{calc} is obtained from eq. [1] and the parameters in Table 2.

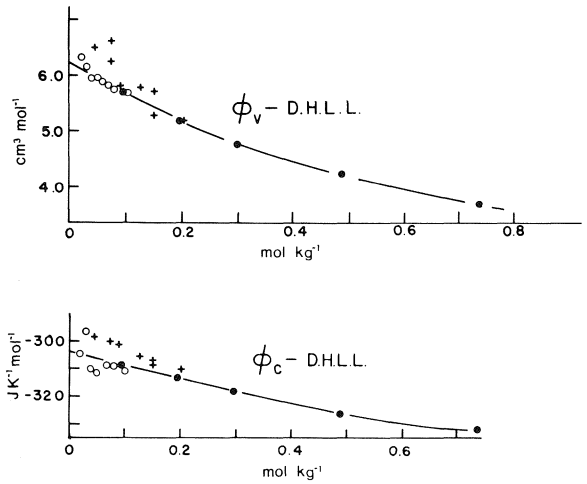

FIG. 1. Apparent molal volumes and heat capacities of $NiCl_2$ at low concentrations at 25°C; ○: present data, low concentration stock solution; ●: present data, high concentration stock solution; +: ref. 15*a*.

These plots are shown in Fig. 2 for ϕ_V and in Fig. 3 for ϕ_C. These functions will be discussed separately.

The scatter of data points for ϕ_V of NaCl is about 0.01 cm^3 mol^{-1} at 5 and 45°C and somewhat higher at 25°C. At 5° and 25°C the present data agree with our earlier ones within 0.02 cm^3 mol^{-1}. At 45°C the difference is more of the order of 0.10 cm^3 mol^{-1}. Recently, Rogers and Pitzer (15*b*) have analyzed the literature data of volumetric properties of NaCl over a large range of temperature and pressure. They proposed parametric equations to represent ϕ_V as a function of concentration up to about saturation. These predicted ϕ_V are systematically lower than ours, the mean deviation being 0.046 cm^3 mol^{-1}. Our weights were not corrected for vacuum. This can cause an error of about 0.06% in m and of about 0.02 cm^3 mol^{-1} in ϕ_V. Assuming the predicted ϕ_V data are the correct ones then the probable source of error in our data would be in the calibration of the densimeter. Dry nitrogen and distilled water were used for this purpose (14). Probably aqueous NaCl solutions should be used as a standard instead. For the present purpose a recalculation of our data is not warranted since a maximum error of 0.05 cm^3 mol^{-1} in ϕ_V causes a negligible error in ϕ_C.

Our volume data for $MgCl_2$ and $CaCl_2$ are in very good agreement with most literature values (16–19). The data of Wirth and Bangert for $MgCl_2$ (19, 20) (not shown) show a scatter of 0.20 cm^3 mol^{-1} but overlap our data. The data of Vasilëv *et al.* (21) for $MgCl_2$ diverge by as much as 1.4 cm^3 mol^{-1} and cannot be considered reliable. Their data for $CaCl_2$ are better but still show much scatter.

It was shown in Fig. 1 that our low concentration data for ϕ_V of $NiCl_2$ were in good agreement with those of Hepler *et al.* (15). At high concentration (see Fig. 2) a systematic difference of 0.10 cm^3 mol^{-1} is observed with the data of Stokes *et al.* (22). The agreement would be worse if corrections such as those discussed for NaCl were made on our data. It is therefore more probable that the observed difference could be accounted for by the uncertainty in the analyses of the $NiCl_2$ stock solutions in both laboratories. The data of Karapet'yants *et al.* (23) are quite different from ours and those of Stokes *et al.*

The heat capacities are shown in Fig. 3. The present data for NaCl are in excellent agreement with our earlier data (11) at all temperatures and also with the recent data of Tanner and Lamb (24) at 25 and 45°C. A difference of about 2 J K^{-1} mol^{-1} is observed at 5°C. For $CaCl_2$ the agreement with the literature (21, 25) is acceptable. With $MgCl_2$ the

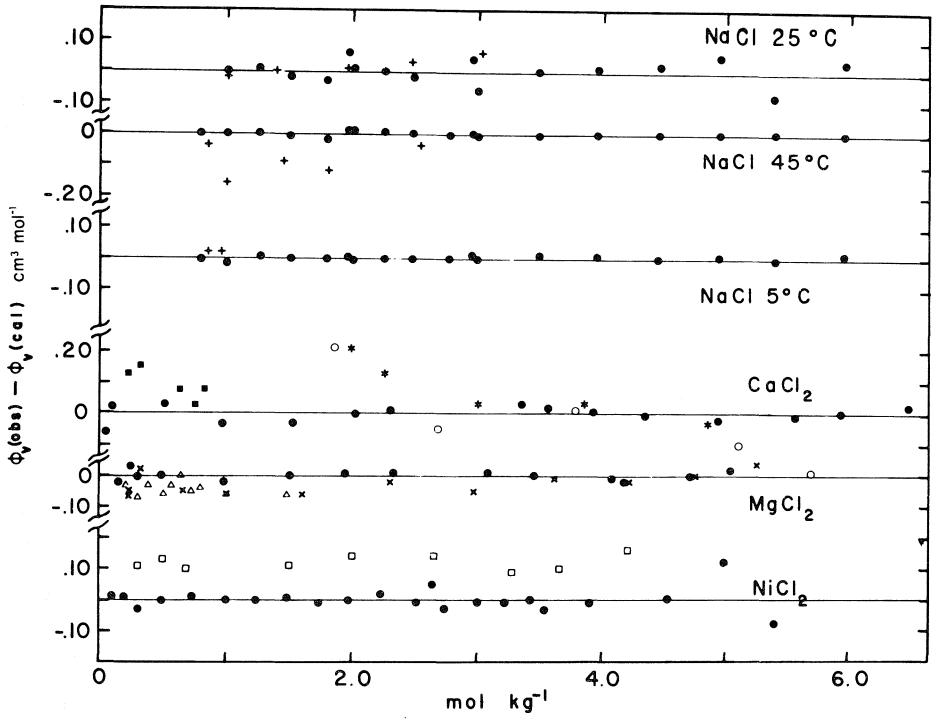

FIG. 2. Apparent molal volumes of various electrolytes in water. Deviation plots from eq. [1]: ●: present data; +: ref. 11; ○: Vasilëv *et al.* (21); *: I.C.T. (18); ×: Phang and Stokes (16); △: Chen *et al.* (17); □: Stokes *et al.* (22); ■: Dunn (20).

agreement is less satisfactory since the data of Fedyainov *et al.* (25) and of Rutskov (26) diverge by as much as 6 J K^{-1} mol^{-1}. Since the densities from the same laboratory (21) showed large differences, such disagreement is not unexpected. We could not find any reliable data for $NiCl_2$ at high concentration for comparison. Our scatter of points is of the order of 0.5 J K^{-1} mol^{-1}.

Discussion

Transitions in aqueous solutions have been well investigated by heat capacity measurements, especially in the case of the micellization process (27). If the partial molar heat capacities of the initial and final states are different and if there is a corresponding enthalpy change, then the transition can be considered of first order and $\bar{C}_{p,2}$ will go through a

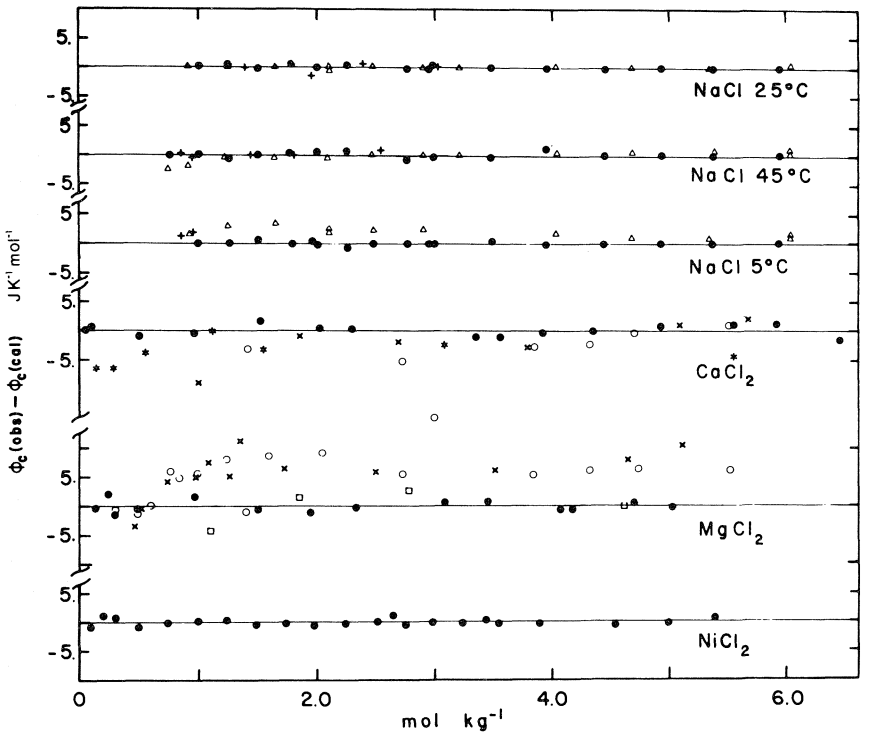

FIG. 3. Apparent molal heat capacities of various electrolytes in water. Deviation plots from eq. [1]: ○: present data; △: Tanner and Lamb (24); +: Perron *et al.* (11); ○: Fedyainov *et al.* (25); ×: Vasilëv *et al.* (21); *: Ruskov (26); □: Ruskov (26).

hump or maximum before dropping rapidly to its final value as the concentration crosses the transition zone. If there is no corresponding enthalpy change, $\bar{C}_{p,2}$ will still change rapidly in the transition concentration but no hump (relaxational contribution) will be observed. This would be a second order transition. A break in a $\bar{C}_{p,2}$ curve would therefore indicate a transition of a higher order.

The partial molar volumes $\bar{V}_2$ and heat capacities $\bar{C}_{p,2}$ of the solutes were calculated in two ways: from eq. [1] knowing that $d(\phi_V m)/dm = \bar{V}_2$ and from a plot of $\Delta(\phi_V m)/\Delta m$ against the mean molality. The first technique is the simplest but may lead to erroneous results at the concentration limits since the least-squares analysis may not be reliable at these edges unless many data points were available. For example, the $\bar{C}_{p,2}$ of rare earth chlorides of Spedding *et al.* (28), obtained by this technique, give very pronounced curvature at high concentrations which may not be real. In our case both approaches to the calculation of $\bar{V}_2$ gave the same results except at very high concentrations where the graphical procedure was better. The values of $\bar{V}_2$ and $\bar{C}_{p,2}$ are shown in Figs. 4 and 5.

The trends in $\bar{V}_2$ of $NiCl_2$, $MgCl_2$, and $CaCl_2$ are quite similar at intermediate concentrations as seen from Fig. 4. At concentrations above 3 mol kg^{-1} the data for $NiCl_2$ and $MgCl_2$ level off more rapidly than those for $CaCl_2$. However, no break in these $\bar{V}_2$ curves can be seen. NaCl shows less curvature than the 1:2 electrolytes.

The $\bar{C}_{p,2}$ data are shown in Fig. 5. The trends with NaCl, $MgCl_2$, and $CaCl_2$ are all quite smooth while $\bar{C}_{p,2}$ of $NiCl_2$ levels off at about 4 mol kg^{-1}. The derivative of this curve, $d\bar{C}_{p,2}/dm$ suggests that there might be a change in slope with $NiCl_2$ at about that concentration. However, this may also be true of $CaCl_2$ near 6 mol kg^{-1}.

The present data therefore exclude the possibility of a sharp transition in aqueous $NiCl_2$ near 4 mol kg^{-1} but not a transition of a high order. It would be of course possible to find methods of plotting our data so as to show a definite break with our heat capacities (6), but unless the function has a sound scientific justification such plots are meaningless. The heat capacity is very sensitive to local average structure but the effect of long-range ordering is small. The structures proposed by Enderby *et al.* (1, 2) are long range and the transitions could be gradual. Under such circumstances heat capacities, or any other thermodynamic properties, would not be expected to change significantly. There are

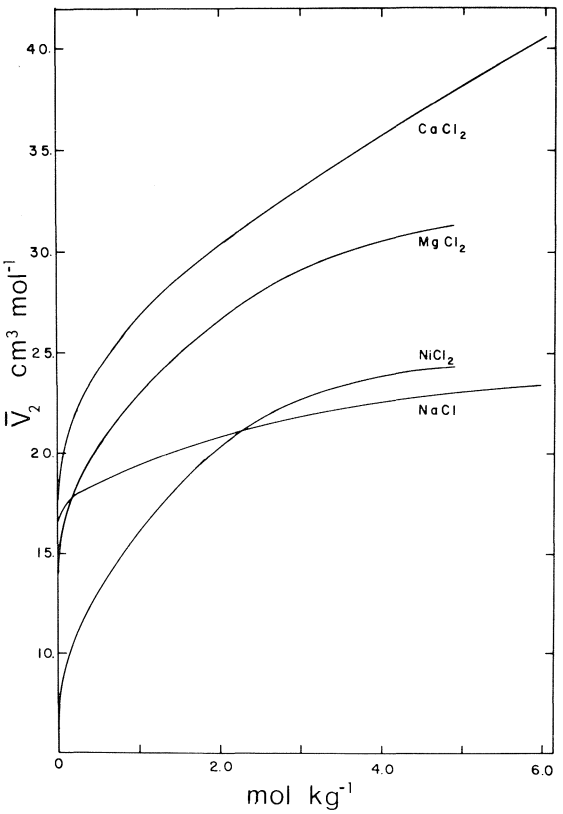

FIG. 4. Partial molal volumes of various electrolytes in water at 25°C.

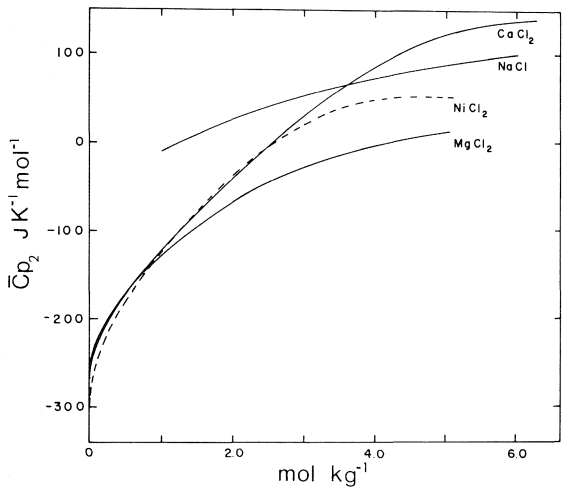

FIG. 5. Partial molal heat capacities of various electrolytes in water at 25°C.

also many ways of interpreting the changes in $\bar{C}_{p,2}$ of these electrolytes at high concentration, including a partial dehydration of the ions, complex formation, and ionic association. We can therefore conclude that while heat capacity data do not exclude the possibility of a smooth transition in aqueous $NiCl_2$, they do not offer strong evidence for such changes.

Synthesis of phthalideisoquinolines from 3-halophthalides and 3,4-dihydroisoquinolinium salts[1]

CLARKE E. SLEMON,[2] LOUISE C. HELLWIG, JEAN-PIERRE RUDER, ERIC W. HOSKINS, AND DAVID B. MACLEAN[3]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 20, 1981

CLARKE E. SLEMON, LOUISE C. HELLWIG, JEAN-PIERRE RUDER, ERIC W. HOSKINS, and DAVID B. MACLEAN. Can. J. Chem. **59**, 3055 (1981).

Phthalideisoquinoline alkaloids have been synthesized by coupling appropriately substituted 3-halophthalides and 2-methyl-3,4-dihydroisoquinolinium salts in the presence of Zn(Cu) couple or metallic Zn. Both *erythro* and *threo* isomers are formed in the reaction. The nmr spectra of the (±)-*erythro*- and (±)-*threo*-isocordrastines have been reinvestigated. The results, which differ from those previously reported, lead to a different conclusion regarding the conformation of the molecules.

CLARKE E. SLEMON, LOUISE C. HELLWIG, JEAN-PIERRE RUDER, ERIC W. HOSKINS et DAVID B. MACLEAN. Can. J. Chem. **59**, 3055 (1981).

On a synthétisé des alkaloides du type phtalideisoquinoleines en faisant réagir des halo-3 phtalides convenablement substitués avec les sels de méthyl-2 dihydro-3,4 isoquinolinium en présence du couple Zn(Cu) ou du Zn métallique. Il se forme les deux isomères *érythro* et *thréo* au cours de la réaction. On a étudié de nouveau les spectres de rmn des isocordrastines (±) *érythro* et (±) *thréo*. Les résultats, qui diffèrent de ceux rapportés antérieurement, conduisent à une conclusion différente en ce qui a trait à la conformation des molécules.

The first successful synthesis of a phthalideisoquinoline alkaloid was realized by Perkin and Robinson (1) in 1911 by direct coupling of an isoquinoline moiety and a suitably activated phthalide moiety. In the interim, but particularly in the past decade, many new but less direct approaches to the construction of this ring system have been reported (2–18). In the past year, two syntheses using the strategy of Perkin and Robinson have been reported in which improved methods of joining the two moieties have been developed. Shono *et al.* (19) have shown that bromophthalides and *N*-methyl-3,4-dihydroisoquinolinium salts may be coupled electrochemically, while Mooney *et al.* (20) have shown that phthalide anions add to isoquinolinium salts. In a similar vein we report here the coupling of 3-halophthalides **1** with *N*-methyl-3,4-dihydroisoquinolinium salts **2** in the presence of Zn(Cu) couple or metallic Zn to give a mixture of *erythro*- and *threo*-*N*-methylphthalidetetrahydroisoquinolines, **3** and **4**, respectively (Scheme 1). In a different context Granelli and Leander (21) found that Zn(Cu) couple could be used to couple an α-bromoester and an iminium salt.

We have used this method successfully in the preparation of the following racemic diastereomeric pairs, β-hydrastine **5** and α-hydrastine **6**, corlumine **7** and adlumine **8**, bicuculline **9** and adlumidine **10**, and the *erythro* **11** and *threo* **12** isocordrastines.[4] However, we have studied the reaction in detail only in the case of the isocordrastines. In this instance we have found that optimum yields were obtained when the ratio of halophthalide **1** to iminium salt **2** to Zn(Cu) was 2:1:2. In the preparation of other compounds different reactant ratios were used and no attempt was made to find conditions for optimum yields. It is likely that better yields might be obtained in the latter cases by altering the reactant ratio but these experiments were not attempted.

In the condensation of **1***a* and **2***a* the optimum yield of *erythro* and *threo* isomers was 35% and 28% respectively. Reaction periods longer than those normally used had no effect on yield but higher temperatures caused a decrease. Yields were equally good when Zn metal was used instead of Zn(Cu) couple but Cu metal was ineffective in promoting condensation. An increase in the amount of metal used above the stoichiometric quantity had no effect. When **1***a* was treated with Zn under Reformatsky conditions, followed by introduction of **2***a*, coupling of the two components did

not occur. From these observations we conclude that the reaction proceeds on the metal surface through formation of a phthalide anion which reacts directly with the iminium salt at the surface. However, a radical mechanism for the reaction cannot be excluded on the basis of the present data. The only by-products isolated and identified were *m*-meconin **13** and compound **14** but their formation in no way helps to clarify the mode of coupling.

In the course of these studies we examined the ^1H nmr spectra of the isocordrastines, **11** and **12**. The compounds had been previously studied by Shamma and St. Georgiev (8, 11) who assigned the resonances of the aromatic protons using conformational arguments. However, they provided no experimental justification for their assignments. We have reached a different conclusion regarding the aromatic resonances based upon double irradiation experiments. As a result we are led to a different conclusion concerning the favoured conformation of the molecules from that proposed earlier.

The coupling constants between H-1 and H-1′ are 4.2 Hz for **11** and 3.5 Hz for **12**, indicating dihedral angles of approximately 45°, 135°, 225°, or 315° for **11** and 50°, 130°, 230°, or 310° for **12**. The absorptions of the aromatic protons were assigned unambiguously by double irradiation experiments. Thus in **11**, irradiation at δ 5.57, assigned to H-1′ in analogy to other phthalideisoquinoline alkaloids (7, 12), collapses the H-1 doublet at δ 4.10 and sharpens the signal of H-7′ at δ 6.22 from $w_{\frac{1}{2}}$ = 1.6 Hz to $w_{\frac{1}{2}}$ = 1.3 Hz. Irradiation of the H-1 resonance at δ 4.10 collapses the H-1′ doublet at δ 5.57 and sharpens the aromatic singlet at δ 6.46 from $w_{\frac{1}{2}}$ = 1.6 Hz to $w_{\frac{1}{2}}$ = 1.4 Hz, attributed therefore to H-8. In addition, irradiation at δ 2.49 causes a sharpening of the proton at δ 6.62 from $w_{\frac{1}{2}}$ = 1.8 Hz to $w_{\frac{1}{2}}$ = 1.3 Hz which must therefore be assigned to H-5.

In **12**, irradiation at δ 5.64, attributed to H-1′, collapses the doublet at δ 4.12 to a singlet and also sharpens the aromatic singlet at δ 7.14 ($w_{\frac{1}{2}}$ = 1.5 Hz before irradiation and $w_{\frac{1}{2}}$ = 1.2 Hz during irradiation), which may now be assigned to H-7′. Irradiation at δ 4.12 collapses the doublet at δ 5.64 and affects the aromatic singlet at δ 6.67 ($w_{\frac{1}{2}}$ = 1.5 Hz before irradiation and $w_{\frac{1}{2}}$ = 1.3 Hz during irradiation), which is assigned to H-8. Assignment of the resonance at δ 6.34 to H-5 was confirmed by another double irradiation experiment in which the signal at 6.34 sharpened from $w_{\frac{1}{2}}$ = 1.8 Hz to $w_{\frac{1}{2}}$ = 1.2 Hz when the sample was irradiated at δ 2.68, presumably at the protons at C-4 (Table 1).

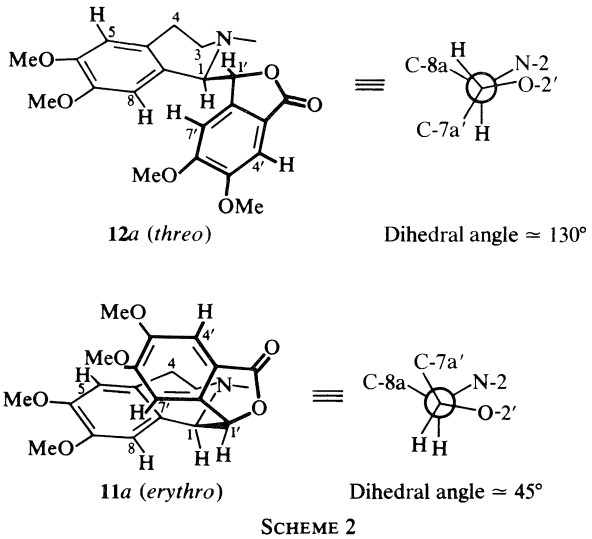
[a] It is noteworthy that the nmr of **11** is very susceptible to Zn(Cu) impurities present.
[b] H's at C-4 from decoupling experiment: δ 2.49.
[c] H's at C-4 from decoupling experiment: δ 2.68.
[d,e] Assignments may be interchanged.

The aromatic proton resonances of **11** and **12** may be compared with those of 2-methyl-1,2,3,4-tetrahydroisoquinoline **15** and *m*-meconin **13** in Table 1. Whereas the protons at H-5, H-8, and H-4′ of the alkaloids **11** and **12** are not affected very much relative to the models, the protons at H-7′ show a big change in chemical shift. In **11**, H-7′ is shielded more than 0.7 ppm to δ 6.22, indicating that it must be located somewhere above the plane of the aromatic ring of the isoquinoline moiety. This is the case only with a dihedral angle of approximately 45°, and qualitative calculations using a Dreiding model and the method of Johnson and Bovey (22) suggest conformation **11***a*. In the case of **12** a dihedral angle of ca. 130° between H-1 and H-1′ leads to conformation **12***a* where there is minimum interaction between the two aromatic rings and, as expected, little change in chemical shift in the alkaloids relative to the corresponding signals in **13** and **15** (See Scheme 2).

The general procedure for the preparation of the alkaloids **5** to **10** is given in the Experimental. In these preparations chlorophthalides prepared by standard methods were sometimes used instead of bromophthalides. In cases where both phthalides were available the reactions were carried out with each halide but there was no appreciable difference in yield. The choice of chloro or bromophthalide is therefore a matter of preparative convenience. In all cases mixtures of the *erythro* and *threo* isomers were isolated. The isomers were easily separated from one another and from by-products by flash chromatography. These yields (30–35%) are comparable to those of the isocordrastines (combined yield 34%) when prepared under similar conditions.

This preparative method provides a convenient route to alkaloids of this family from readily available starting materials. In the one case where optimum reaction conditions for the condensation were established the yields are comparable to those obtained in the electrochemical coupling reaction (19).



SCHEME 2

Experimental

Apparatus, Materials, and Methods

Continuous wave ^{1}H nmr spectra were run on a Varian EM 390 or T-60 spectrometer and Fourier transform nmr spectra on either a Bruker WP 80 or WH 90 spectrometer. Unless otherwise specified, the samples were dissolved in chloroform-*d* using tetramethylsilane (TMS) as the internal standard. Chemical shifts, quoted as δ values, were measured in relation to TMS. The symbols s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, and br = broad are used in reporting spectra.

Mass spectra were recorded on a V.G. Micromass 7070 F mass spectrometer, at 70 eV. Infrared spectra were recorded on a Perkin Elmer 283 spectrometer in chloroform solution.

Melting points were determined on a Kofler micro hot stage and are uncorrected.

Column and thin layer chromatography (tlc) were performed using silica gel 60 as the adsorbent. Gravity columns were run using Baker 60–200 mesh silica, and "flash" columns prepared as described in the literature (23). Zn(Cu) couple (Ventron, Alfa Products) was activated by washing with 10% aqueous HCl, rinsed with water until neutral, flushed with acetone, and dried at 120°C at reduced pressure. Zn dust (Matheson, Coleman, and Bell) was activated by washing with dilute aqueous NaOH, water, dilute acetic acid, water, ethanol, acetone, and ether in this sequence, and dried at 100°C under reduced pressure (24).

The following compounds were prepared by standard methods and gave satisfactory physical and spectral data: *m*-meconin (25), meconin (26), 6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium iodide (27), 2-formyl-5,6-methylenedioxybenzoic acid (28), and opianic acid, prepared from lithiated 2,3-dimethoxy-*N*,*N*-diethylbenzamide and dimethyl formamide using the procedure of Snieckus and co-workers (29).

Preparation of Hydrastinine Iodide, **2**b

(a) 3,4-Methylenedioxydihydrocinnamoyl Chloride

3,4-Methylenedioxydihydrocinnamic acid (30) prepared by standard methods from piperonal (12.9 g, 66.5 mmol) was treated with excess thionyl chloride on a steam bath for one hour. The excess thionyl chloride was removed on the rotary evaporator and the residue was distilled at 100–110°C/0.15 Torr to give 12.2 g (86%) of the acid chloride as a viscous yellow liquid.

(b) 2-(3,4-Methylenedioxyphenyl)-ethyl Isocyanate

3,4-Methylenedioxydihydrocinnamoyl chloride (12.116 g, 57 mmol) was dissolved in mesitylene (50 mL) and brought to reflux. Trimethylsilyl azide (11.2 mL, 84.5 mmol) was added and refluxing continued for 40 h. The reaction solution was cooled, the excess trimethylsilyl azide and mesitylene were distilled off at reduced pressure, and the residue was distilled at 82–100°C/0.15 Torr to give 9.93 g (91%) of the isocyanate: ir (neat): 2900, 2260, 1610, 1503, 1490, 1440, 1250, 1040 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.58–6.83 (3H, m, arom), 5.90 (2H, s, OCH_2O), 3.45 (2H, t, J = 7.0 Hz), 2.78 (2H, t, J = 7.0 Hz).

(c) Homopiperonyl Formamide

2-(3,4-Methylenedioxyphenyl)-ethyl isocyanate (5.6 g, 29.4 mmol) was dissolved in dry ether (34 mL) and cooled to −78°C. Diisobutylaluminum hydride (32.6 mL, 20% in hexane, 95% active, 1.5 equiv.) was added via syringe, and the solution was allowed to warm to 0°C over 4 h. The mixture was quenched with water (5 mL). After the vigorous reaction had subsided aqueous hydrochloric acid (100 mL) was added to dissolve the aluminum salts. The solution was extracted with ether (2 × 50 mL) and the aqueous layer basified to pH 10 with solid potassium carbonate and extracted with diethyl ether (5 × 50 mL). The combined ether extract (350 mL) was dried to give 4.24 g (75%) of the formamide as a white solid which was recrystallized from ether–acetone to give white crystals, mp 60–62°C (lit. (31) mp 62–63°C); ir ($CHCl_3$): 3450, 2860, 1685 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.05 (1H, d, J = 2.0 Hz, CHO), 7.26 (1H, br s, NH, exchangeable in D_2O), 6.53–6.83 (3H, m, arom), 5.80 (2H, s, OCH_2O), 3.39 (2H, "quintet", J = 6 Hz, CH_2NH), 2.70 (2H, t, J = 6 Hz, benzylic).

(d) 6,7-Methylenedioxy-3,4-dihydroisoquinoline (Norhydrastinine)

To a refluxing solution of homopiperonyl formamide (2.46 g, 12.7 mmol) in acetonitrile (18 mL, freshly distilled from calcium hydride) was added phosphorus oxychloride (1.23 mL, 13.38 mmol, 1.05 equiv.) After two hours, the dark solution was cooled in an ice bath and washed with petroleum ether. The acetonitrile layer was diluted with water (20 mL), and this acidic layer (pH 1) was washed with benzene (3 × 30 mL) before being basified to pH 11 with 10% sodium hydroxide solution, and then extracted with benzene (3 × 50 mL). The combined basic organic extract was dried and evaporated to give 1.02 g (46%) of norhydrastinine as a beige solid; ^1H nmr ($CDCl_3$) δ: 8.14 (1H, br s, CH=N), 6.70 (1H, s, arom), 6.60 (1H, s, arom), 5.90 (2H, s, OCH_2O), 3.67 (2H, triplet split into doublets, J = 7.0 and 2 Hz, HC=NCH_2), 2.6 (2H, t, J = 7.0 Hz, benzylic).

(e) Hydrastinine Iodide

A solution of norhydrastinine (3.2 g, 18.3 mmol) in benzene (50 mL) was swirled with methyl iodide (3 mL) and left overnight. Filtration yielded 5 g (86%) of hydrastinine iodide, mp 220–230°C. A sample was recrystallized from EtOH to give shiny yellow plates, mp 232–237°C (lit. (32) mp 234°C); ^1H nmr (CD_3OD) δ: 8.90 (1H, s, CH=N), 7.27 (1H, s, arom), 7.03 (1H, s, arom), 6.19 (2H, s, OCH_2O), 4.03 (2H, t, J = 8.0 Hz, CH_2N), 3.27 (2H, t, J = 8.0 Hz benzylic), 3.78 (3H, s, N—CH_3).

5,6-Dimethoxy-3-bromophthalide, **1**a

A mixture of *m*-meconin (2.0 g, 10.3 mmol) and *N*-bromosuccinimide (1.73 g, 9.7 mmol) in dry benzene (40 mL) was treated with a few mg of dibenzoyl peroxide and the solution heated under reflux for 3.5 h under a nitrogen atmosphere. The mixture was cooled to 5°C, the succinimide removed by filtration, and the filtrate washed with water (2 × 25 mL). The benzene solution was dried (anhydrous $MgSO_4$) and evaporated to give a crystalline residue which was used directly in subsequent steps. Yield: 80%. Recrystallization from CCl_4 gave a sample melting at 108–109°C; ^1H nmr ($CDCl_3$) δ: 7.39 (1H, s), 7.34 (1H, s), 7.07 (1H, s), 4.05 (3H, s, OMe), 3.95 (3H, s, OMe).

6,7-Dimethoxy-3-bromophthalide, **1**b

A solution of meconin (0.458 g, 2.36 mmol) and *N*-bromosuccinimide (0.448 g, 2.52 mmol) in carbon tetrachloride (39 mL) was refluxed with a catalytic amount of dibenzoyl peroxide under the illumination of a 100-W light bulb for 4 h. The suspension was cooled in an ice bath, filtered, and the filtrate evaporated to give a quantitative yield of the bromophthalide as a brownish solid which was used without further purification; ^1H nmr ($CDCl_3$) δ: 7.31 (1H, s), 7.26 (2H, s), 4.12 (3H, s, OMe), 3.93 (3H, s, OMe).

6,7-Methylenedioxy-3-chlorophthalide, **1**c

2-Formyl-5,6-methylenedioxybenzoic acid (0.39 g, 2 mmol) was heated with excess thionyl chloride on a steam bath for 10 min. When all the acid had gone into solution, the excess thionyl chloride was removed at reduced pressure to give a quantitative yield of the chlorophthalide as a brownish white solid which was used without further purification; ^1H nmr ($CDCl_3$) δ: 7.10 (1H, s), 7.07 (1H, s), 7.03 (1H, s), 6.20 (2H, s, OCH_2O).

6,7-Dimethoxy-3-chlorophthalide, **1**d

This compound was prepared in the same manner as the above from opianic acid; ^1H nmr ($CDCl_3$) δ: 7.25 (2H, s), 6.98 (1H, s), 4.05 (3H, s, OMe), 3.90 (3H, s, OMe).

Preparation of the Isocordrastines, **11** *and* **12**

3-Bromo-*m*-meconin (255 mg, 0.93 mmol) and 6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium iodide (154 mg, 0.46 mmol) were dissolved in dimethylformamide (7 mL, distilled from CaH_2). To the clear yellow solution 61 mg of Zn or 67 mg Zn(Cu) (0.94 mmol) were added yielding a greenish-black mixture. The mixture was stirred at room temperature yielding first a yellow green solution and after 3 days a clear solution. The solution was filtered to remove any solid impurity, the solvent removed under reduced pressure, and the residue taken up in $CHCl_3$ (15 mL). The chloroform solution was extracted first with water (1 × 15 mL) and then with 10% aqueous HCl (5 × 7 mL). The now light yellow chloroform layer was evaporated and the brownish-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

yellow residue was dissolved in dry benzene (10 mL). This solution was washed with 10% aqueous HCl, 5 × 7 mL, leaving behind a slightly beige benzene layer. The combined greenish-yellow acidic aqueous layers from the chloroform and the benzene extractions were basified with concentrated NH_4OH (to pH 9) after cooling to 0–5°C. The now alkaline solution was extracted with 10 × 10 mL dry ether and the yellow combined ethereal layers were dried over $MgSO_4$ overnight, filtered, and evaporated, leaving behind 135 mg of a yellow oil, which showed 4 spots on tlc (R_f in EtOAc: 0.45, 0.41, 0.38, 0.07).

Flash chromatography (23) (12 mm column, 15 cm silica gel 37–53 μm, eluants CH_2Cl_2–Et_2O (15:1) 90 mL, EtOAc 45 mL, EtOAc–acetone (1:1) 30 mL, and acetone 50 mL (in this sequence), speed 5 cm/min, fraction size 1 mL) yielded 4 pure compounds: *m*-meconin **13** (4 mg, R_f 0.45), *m*-meconin dimer **14** (3 mg, R_f 0.41), *threo*-isocordrastine **12** (51 mg, 28%, R_f 0.38), and *erythro*-isocordrastine **11** (65 mg, 35%, R_f 0.07). *m*-Meconin **13** was identified by comparison with an authentic sample. *m*-Meconin dimer **14** had the following physical properties: ^{1}H nmr ($CDCl_3$) δ: 3.83 (6H, 2 × OMe); 3.90 (6H, 2 × OMe); 5.94 (2H, s, H-3 and H-3′), 6.93 (2H, s, H-4 and H-4′), 7.07 (2H, s, H-7 and H-7′); ms (70 eV, probe) *m/e*: 386 M^+, 193, 165, 149, 122. (±)-*erythro*-Isocordrastine **11** had the following physical properties: mp 169–170°C (from EtOH) (lit. (8) mp 157–159°C, (13) mp 166–167°C); ir ν_{max} ($CHCl_3$): 1755 cm^{-1}; ^{1}H nmr, see Table 1. (±)-*threo*-Isocordrastine **12** had the following physical properties: mp 144–146°C (from EtOH) (lit. (8, 13)[5] mp 115–117°C); ir ν_{max} ($CHCl_3$): 1758 cm^{-1}; ^{1}H nmr, see Table 1.

Preparation of the Alkaloids, 5 to 10

(a) General Procedure

The halophthalide (2 mmol) and the imminium iodide (1.69 mmol) were dissolved in dimethylformamide (10 mL, freshly distilled from calcium hydride). The Zn(Cu) couple (0.2 g, ca. 3 mmol) was added and the reaction was left stirring in a stoppered flask overnight. The solvent was removed at reduced pressure. The solid residue was taken up in chloroform and washed with 10% hydrochloric acid (5 × 50 mL). The combined aqueous layers were basified to pH 10 with ammonium hydroxide and extracted with ether (5 × 25 mL). The combined ethereal layers were dried to give a mixture of *erythro* and *threo* compounds, hereafter referred to as "the product of the first work-up". The chloroform layer was evaporated and the residue taken up in benzene and 10% hydrochloric acid (50 mL of each). The benzene layer was further washed with 10% hydrochloric acid (4 × 50 mL). The combined aqueous layers were basified to pH 10 with ammonium hydroxide and extracted with ether (5 × 25 mL). The combined ethereal layers were dried to give a mixture of *erythro* and *threo* compounds, hereafter referred to as "the product of the second work-up".

(b) Preparation of (±)-β-Hydrastine 5 and (±)-α-Hydrastine, 6

The product of the first work-up, 0.320 g (47%), was subjected to column chromatography (silica gel, 10 g, column diameter 5/8 in., eluting with methylene chloride gradually changing to 30% ether – methylene chloride) to give 0.086 g (13%) of (±)-α-hydrastine identical by nmr with an authentic sample. Recrystallization from methanol gave a sample melting at 150–154°C (lit. (2, 33) mp 150–152°C) identical with an authentic sample[6] by ir and tlc. The product of the second work-up (0.134 g, 20%) was essentially pure (±)-β-hydrastine. It was recrystallized from methanol yielding a sample melting at 136–140°C (lit. (2, 34) mp 138–139°C) identical with authentic sample by nmr, ir, and tlc.

(c) Preparation of (±)-Corlumine 7 and (±)-Adlumine 8

The product of the first work-up, 0.282 g (43%), was subjected to flash chromatography (column diameter 25 mm, eluting with 2% acetone – ethyl acetate) to yield 0.127 g (20%) of pure (±)-adlumine as a pale yellow foam, identical with an authentic sample by nmr. Crystallization from chloroform–methanol yielded pale yellow crystals melting at 191.5–193.5°C (lit. (35) mp 190°C), identical by tlc and ir with authentic adlumine. The product of the second work-up, 0.063 g (10%) of (±)-corlumine, was identical with an authentic sample of corlumine by nmr. Recrystallization from methanol yielded yellow crystals, mp 178–181°C (lit. (27) mp 193.5–195°C dec.) identical with an authentic sample by ir and tlc.

(d) Preparation of (±)-Bicuculline 9 and (±)-Adlumidine 10

This preparation was done using 3 mmol of the imminium iodide, 3.55 mmol of the halophthalide, and 5 mmol of the Zn(Cu) couple. The product of the first work-up, 0.616 g (56%), was subjected to flash chromatography (column diameter 25 mm, eluting with ethyl acetate – acetone, then acetone) to yield 0.240 g (22%) of (±)-adlumidine as a yellow foam which was crystallized from chloroform–methanol to yield colorless crystals melting at 200–203°C (lit. (35) mp 205°C), identical with authentic adlumidine by nmr, ir, and tlc. A second fraction contained 0.134 g (12%) of (±)-bicuculline as a white foam which was crystallized from chloroform–methanol to give colorless crystals melting at 217–220°C (lit. (36) mp 215°C) identical with authentic bicuculline by nmr, ir, and tlc.

The product of the second work-up (0.06 g, 5%) was discarded.

[5]The melting point was consistently higher than values reported in the literature whereas the spectroscopic data were in accord with reported values (8, 13). We conclude therefore that (±)-*threo*-isocordrastine must be dimorphic.

[6]In this and in subsequent cases comparisons were made with samples of the natural alkaloids. All spectra were recorded in solution.

Merostabilization in radical ions, triplets, and biradicals. 6. The excited state behaviour of *para*-substituted tetraphenylethylenes

WILLIAM J. LEIGH AND DONALD R. ARNOLD[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received April 3, 1981

This paper is dedicated to Prof. G. Hammond on the occasion of his 60th birthday

WILLIAM J. LEIGH and DONALD R. ARNOLD. Can. J. Chem. **59**, 3061 (1981).

The half-wave oxidation and reduction potentials, measured by cyclic voltammetry, of tetraphenylethylene and a series of *para*-substituted (cyano, methyl, and methoxy) derivatives are found to correlate with σ^+ and σ^- values respectively. The deviations from these correlations that are observed for one of the derivatives (unsymmetrically substituted) are attributed to merostabilization.

The nature of the first excited singlet state of these compounds is investigated by spectroscopic and photochemical means. Quantum yields for the direct *cis–trans* photoisomerization demonstrate that this provides the dominant pathway for decay of the singlet state. The π,π^* triplet energies are estimated from a qualitative investigation of the relative efficiencies of triplet-sensitized *cis–trans* isomerization as a function of sensitizer triplet energy.

WILLIAM J. LEIGH et DONALD R. ARNOLD. Can. J. Chem. **59**, 3061 (1981).

On a trouvé que les potentiels d'oxydation et de réduction à demi-onde, mesurés par voltométrie cyclique, du tétraphénylethylène et d'une série de dérivés (cyano, méthyle et méthoxy) substitués en position *para*, sont respectivement en accord avec les valeurs σ^+ et de σ^-. On attribue à la mérostabilisation les écarts observés par rapport à ces corrélations dans le cas des dérivés dissymétriquement substitués.

On a étudié la nature du premier état singulet excité de ces composés par la photochimie et la spectroscopie. Les rendements quantiques de la photoisomérisation directe *cis–trans* démontrent le mécanisme principal de la désintégration de l'état singulet. On a évalué les énergies du triplet π,π^* à partir d'une recherche qualitative sur l'efficacité relative de l'isomérisation *cis–trans* sensibilisée par un triplet en fonction de l'énergie du triplet sensibilisateur.

[Traduit par le journal]

Introduction

We have recently reported the synthesis, separation, characterization, and kinetics of the thermal *cis–trans* isomerization of a series of uniquely substituted tetraphenylethylenes (**1***a–d*) (1). These results were significant in many respects. The variation in the rates and energetics of thermal isomerization of the three disubstituted derivatives (**1***a–c*) is consistent with the transition state having distinct biradical character; the rates of isomerization in benzene solution correlate with a series of parameters $\sigma^\cdot$, which reflect the effect of the substituents on benzylic radical stabilities (2). While it is commonly accepted that the transition state for thermal isomerization of symmetrically substituted (1,2- across the double bond) olefins is 1,2- biradical-like in nature (3, 4), this study provides experimental evidence of the validity of this idea.

The rate of isomerization of **1***d* was found to be significantly faster than what would be expected based on the normal radical-stabilizing effects of the substituents (i.e. their $\sigma^\cdot$ values). This was attributed to increased stability of the biradical-like transition state due to merostabilization (5, 6). The effect of merostabilization was also evident in the Arrhenius activation energies for the isomerization of **1***a–d*. While the activation energies for thermal isomerization of **1***a–c* were identical (35.3 kcal mol^{-1}) within experimental error, that of **1***d* was found to be about 2 kcal mol^{-1} lower. This value provides an assessment of the contribution from merostabilization to the ground state rotational barrier in the cyano, methoxy substituted tetraphenylethylene derivative **1***d*.

Further support for the biradical nature of the transition state was provided by the agreement between these experimental values and an empirical calculation of the rotational barrier using radical stability arguments. The resonance stabilization energy of the radicals was estimated from esr spin density data (7). The rotational barrier of tetraphenylethylene, for example, was calculated by simply subtracting twice the difference between the resonance stabilization energies of the benzyl and diphenylmethyl radicals from the activation energy for thermal isomerization of *cis*-stilbene. This calculated rotational barrier agreed quite closely with the value (35.5 kcal mol^{-1}) estimated by extrapolation from the activation energies found for **1***a–c*. Good agreement was also found in similar comparisons of calculated and experimental rotat-

ional barriers in the related compounds 9,9′-bisfluorenylidene and bixanthylidene.

We were also interested in characterizing the first excited states (singlet and triplet) of this series. In contrast to the stilbenes, which have been well characterized (8), very little work has been done by way of mapping out the excited state behaviour of tetraphenylethylene, in spite of considerable interest in the thermo- and photochromic properties of related, heavily arylated olefin systems (9). Previous investigations of the first excited singlet state of tetraphenylethylene have focussed on the minor pathways for decay of the excited state, i.e. fluorescence emission (10) and electrocyclic ring closure (11). Substitution as in **1***a–d* enables an investigation of the direct *cis–trans* photoisomerization process, which is believed to be the dominant pathway for decay of the first excited singlet state of tetraphenylethylene (11). The π,π^* triplet state has been neglected, with the exception of one early experimental estimate of its energy (12).

In this paper, we describe our initial attempts to characterize the first excited (singlet and triplet) states of tetraphenylethylene and the *para*-substituted derivatives **1***a–f*. The nature of the singlet state is characterized by absorption and fluorescence emission spectroscopy and determinations of the photostationary states and quantum yields for *cis–trans* isomerization. The half-wave oxidation and reduction potentials of this series provide further information about the HOMO and LUMO in this system, as well as providing further examples illustrating the effect of merostabilization on the stabilities of radical-like species, i.e., the radical ions. A preliminary examination of the nature of the π,π^* triplet state of tetraphenylethylene is also described. These results are used in conjunction with our previous report (1) to characterize the nature of the ground and the excited state surfaces of tetraphenylethylene.

Results and Discussion

Half-wave Oxidation and Reduction Potentials

The electrochemical behaviour of tetraphenylethylene (TPE) has been reasonably well studied with respect to both its oxidation (13) and reduction (14) processes. The oxidative cyclic voltammogram of TPE in acetonitrile solution exhibits two closely-spaced separate anodic waves, each corresponding to irreversible one-electron transfer. A cathodic wave associated with the first anodic wave is evident at high scan rates (13). The reduction of TPE has been investigated by cyclic voltammetry in dimethylformamide solution (16). The single "reversible" wave that was observed was interpreted as being due to two reversible one-electron transfers at potentials separated by less than 0.1 V. A similar rationale has been extended to account for the reversible oxidative cyclic voltammetric behaviour of tetraanisylethylene (**1***e*) in acetonitrile (15). The radical cations of TPE (16) and **1***e* (17) and the radical anion of TPE (18) have been observed by esr spectroscopy.

In this study, the half-wave oxidation and reduction potentials of TPE and the substituted derivatives **1***a–f* were measured in acetonitrile solution using a platinum working electrode and a Ag/0.1 *M* $AgNO_3$ reference electrode. The cyclic voltammetric behaviour of these compounds varied within the series.

Since we are interested primarily in the variation in stability of the radical cation and anion with substituent, we will confine our attention to the first oxidative and reductive waves in the cyclic voltammograms of the series (**1***a–f*). For those derivatives which exhibited reversible electrolytic behaviour, redox potentials were calculated as the midpoints of the forward and reverse waves and are thermodynamically significant (19). Redox potentials of those derivatives exhibiting irreversible behaviour were estimated as 0.03 V less than the peak position of the voltammogram using a 0.1 V s^{-1} sweep rate. Although redox potentials calculated in this way have no strict thermodynamic significance (19), it has been shown that they can, in fact, provide reasonable estimates of the thermodynamic redox potentials and are therefore useful for comparison within a closely related series (20). The voltammetric behaviour and oxidation–reduction potentials of TPE and **1***a–f* are summarized in Table 1.

The radical cation of tetraphenylethylene can be represented by the parent valence bond structure **2**. The substituent effect on the stability of this species is naively expected to be roughly the composite of a polar effect on the stability of the diphenylmethyl cation and a radical-stabilizing effect on the stability of the diphenylmethyl radical. Since, as is well known, the stability of an ion is much more profoundly affected by substituents

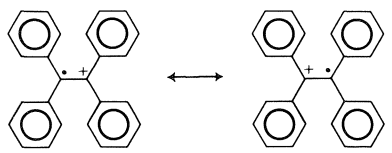
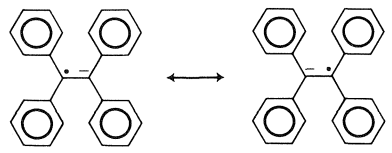
than the stability of the corresponding radical (21, 22), polar factors are expected to dominate the observed substituent effect on radical cation stability.

We can similarly represent the radical anion of tetraphenylethylene by the parent valence bond structures **3**. The substituent effect in this case is expected to be dominated by a polar effect on the stability of the diphenylmethyl anion.

We have plotted the half-wave oxidation and reduction potentials of TPE and 1*a*–*f* versus $\Sigma\sigma^+$ and $\Sigma\sigma^-$, respectively, in Figs. 1 and 2. The reasonable correlations observed in both cases illustrate the additive nature of the effect of substituents on the stabilities of **2** and **3**, and as expected,



2



3

polar factors are seen to dominate in both cases. The points for 1*d* in Figs. 1 and 2 deviate significantly from the best lines drawn for the other derivatives, $E_{\frac{1}{2}}^{ox}$ and $E_{\frac{1}{2}}^{red}$, both being lower than what would be expected based on the normal effects of the substituents on the stabilities of the radical cation and the radical anion as defined by σ^+ and σ^- values. It is tempting to attribute these deviations of 0.1–0.15 eV (2–3 kcal mol^{-1}) from normal behaviour to merostabilization of the radical-like species. Our interpretation, however, is tempered by the known effect of substituents on the rate of solvolysis of

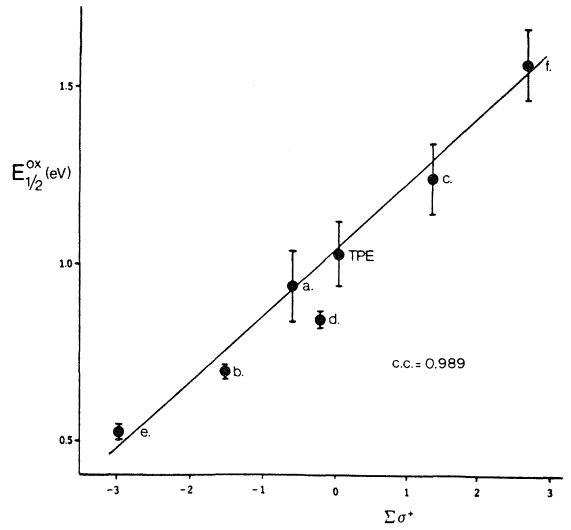


FIG. 1. Hammett correlation: $E_{\frac{1}{2}}^{ox}$ vs. σ^+ for substituted tetraphenylethylenes. The correlation coefficient was derived excluding point 1*d*.

diphenylmethyl chloride (23). The effects of substituents on the stability of the diphenylmethyl cation are *not* strictly additive; a plot of relative rate of solvolysis versus $\Sigma\sigma^+$ for a variety of substituents gives a series of lines, each characteristic of a given electron-donating group (23). It is clear that the solvolysis of those diphenylmethyl

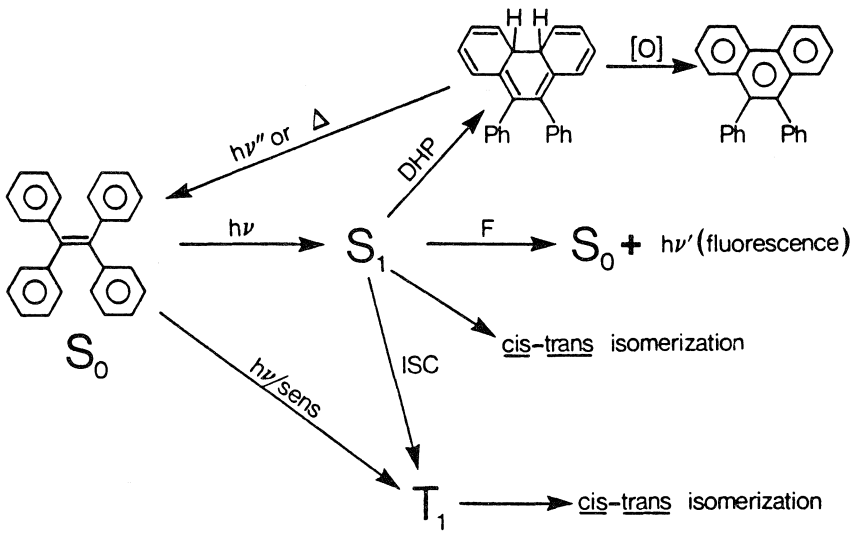

FIG. 3. Summary of the decay processes available to the excited states of tetraphenylethylene.

chlorides substituted in the *para*- and *para'*-position with electron donating and electron withdrawing groups (e.g., *para*-methoxy-*para'*-nitrobenzhydrylchloride) proceed with an anomalously fast rate. Since the substituent effects on the stabilities of the radical cation and anion of TPE are clearly dominated by polar factors, it may be that the anomalous behaviour of **1***d* is the result of some factor other than merostabilization, analogous to the situation with the diphenylmethyl cation.

The Excited Singlet State; Spectroscopic Singlet Energies

The behaviour of the stilbenes upon direct irradiation has been investigated thoroughly (8), and the character of the excited states in this system is well understood. The excited state behaviour of *cis*-stilbene is considerably different from that of the *trans* isomer, and it is widely accepted that this difference is primarily the result of steric factors. It is reasonable to expect that the excited state behaviour of tetraphenylethylene will parallel that of *cis*-stilbene in many respects. The various processes by which the excited states of these olefins can decay are shown in Fig. 3.

The ultraviolet absorption spectra of tetraphenylethylene (Fig. 4) and the stilbenes have been discussed in some detail by Suzuki (24). According to his nomenclature, the three absorption bands in these spectra are designated the A, B, and C bands in order of decreasing wavelength. The A-band, or the so-called conjugation band, corresponds to the transition to the first excited singlet state in these molecules. The absorption spectrum of TPE shows marked similarities to that of *cis*-stilbene, and it has

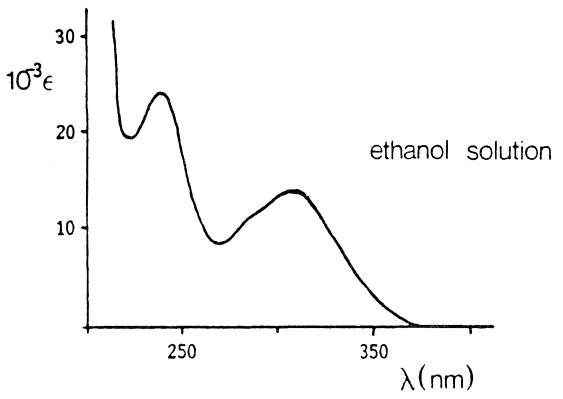

FIG. 4. The ultraviolet absorption spectrum of tetraphenylethylene.

been concluded that the preferred conformation is one in which all the phenyl groups are rotated out of the plane of the ethylenic bond (24). This is in agreement with X-ray crystallographic data (25),[2] and accounts for the relative intensities of the A- and B-bands in the spectrum.

In Fig. 5 are shown the ultraviolet (uv) absorption spectra of the *para*,*para'*-disubstituted derivatives **1***a*–*c*. Substitution by methyl or methoxy groups in the *para*-positions has little effect on the general appearance of the spectrum (Fig. 5a, b). These substituents do shift the positions of the A- and B-bands to slightly longer wavelengths, the shift being greatest for methoxy substitution. There are no significant differences between the spectra of the *cis* and *trans* isomers of either **1***a* or **1***b*.

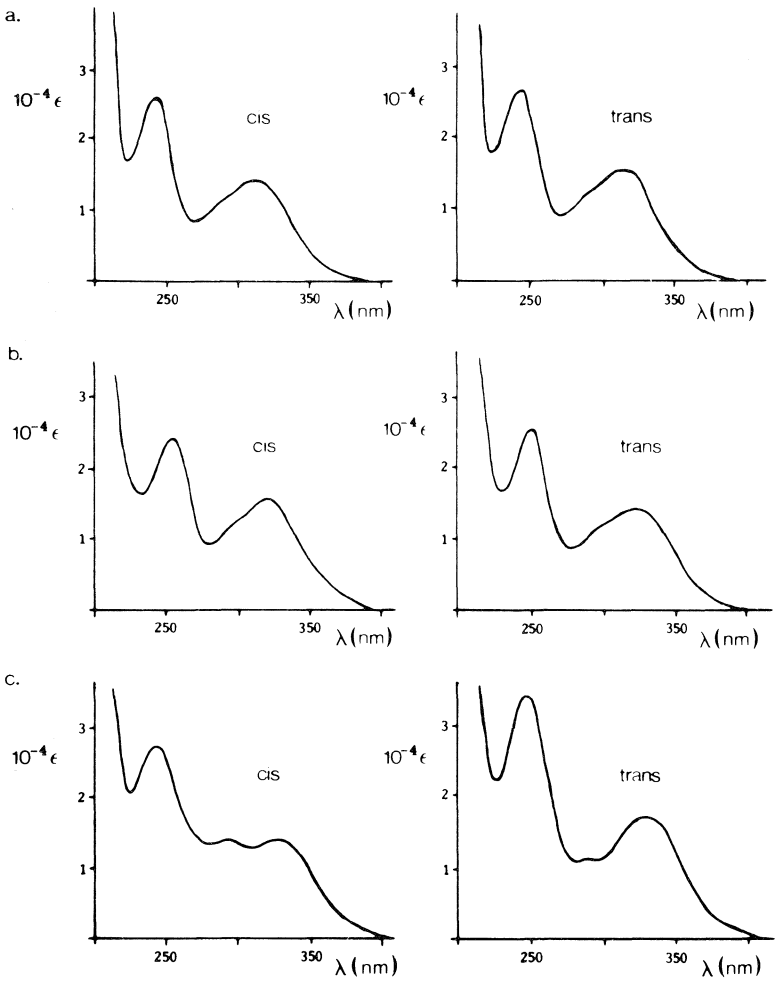

FIG. 5. Ultraviolet absorption spectra (ethanol solution) of disubstituted tetraphenylethylene derivatives 1*a*(a), 1*b*(b), and 1*c*(c).

Furthermore, the spectra of *cis*- and *trans*-1*b* are closely similar to that of tetraanisylethylene (1*e*, Fig. 6b), except the positions of the absorption bands in the latter are shifted to slightly longer wavelengths.

Interesting differences become evident in the spectra of the isomeric dicyano-derivatives 1*c* (Fig. 5c); a new absorption band, positioned between the A- and B-bands, appears. This band may correspond to the shoulder on the short wavelength side of the A-bands in the spectra of 1*a*, *b*, *e*, and TPE, in which case its position would appear to be insensitive to substitution. Its appearance in the spectra of 1*c* as a distinct absorption band is a result of the fact that the A-band has been shifted considerably from its position in the spectra of the other derivatives. There are now distinct differences between the spectra of *cis*- and *trans*-1*c*, in that the intensities of the A- and B-bands in *trans*-1*c* are significantly greater than those for *cis*-1*c*. The opposite effect is noted for the intermediate band. The spectrum of *cis*-1*c* is very similar to that of 1*f* (Fig. 6c), both in the positions and relative intensities of the bands.

The uv absorption spectra of the tetrasubstituted tetraphenylethylene derivatives 1*d*–*f* are shown in Fig. 6. The A-bands in the spectra of *cis*- and *trans*-1*d* (Fig. 6a) are identical in position and intensity, but are shifted to considerably longer wavelengths than in the other derivatives. The big difference between the two isomers appears in the short wavelength region of the spectra. There is very little fine structure in the spectrum of *trans*-1*d*, and the B-band has shifted to considerably longer wavelengths from its position in the spectrum of *trans*-1*c*. This band appears to be masking the intermediate band which was noted in the spectra of *cis*- and *trans*-1*c*. In *cis*-1*d*, the B-band is similar

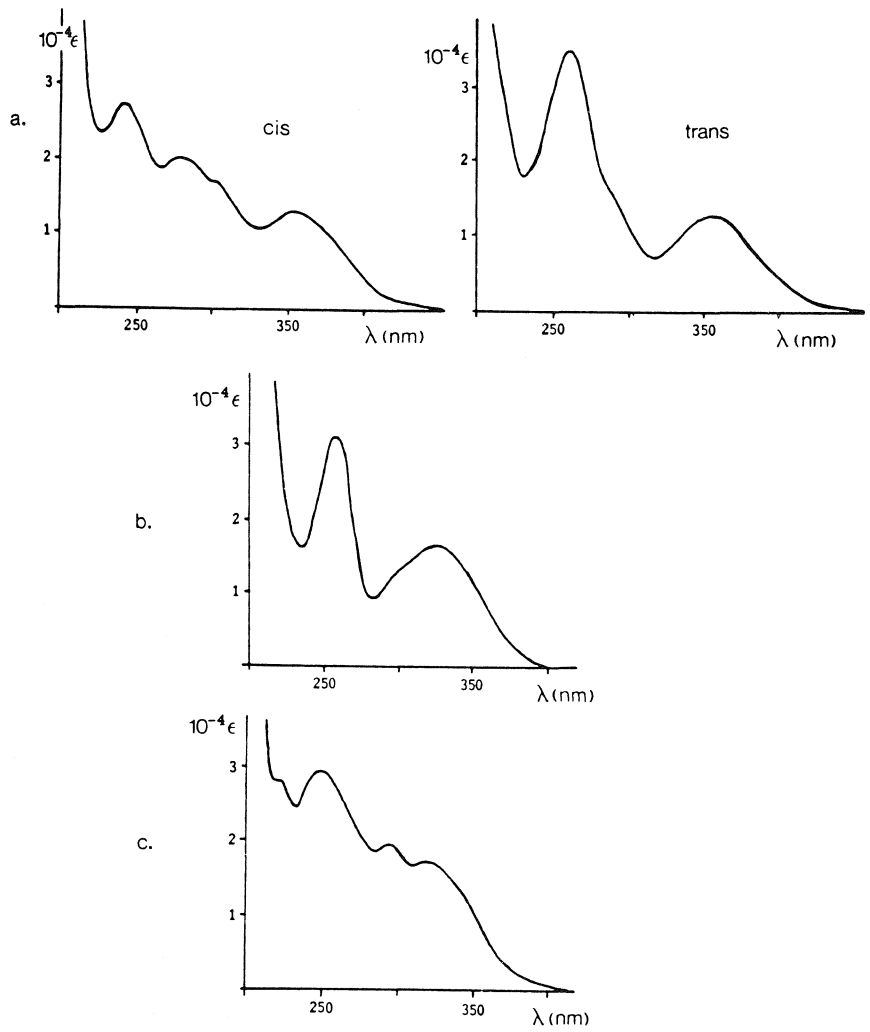

FIG. 6. Ultraviolet absorption spectra (ethanol solution) of tetrasubstituted tetraphenylethylene derivatives 1*d*(a), 1*e*(b), and 1*f*(c).

in both position and intensity to that in the spectrum of *cis*-1*c*. There are now two bands situated at intermediate wavelengths, one of which presumably corresponds to the band observed in the spectra of *cis*- and *trans*-1*c*. The effect of substituents on the absorption spectrum of TPE provides evidence for the existence of two closely spaced transitions within the long wavelength A-band. A similar conclusion has been reached for *trans*-stilbene on the basis of absorption and fluorescence emission studies with a series of substituted derivatives (26).

The use of benzene as a solvent is known to have a remarkable effect on the absorption spectra of stilbene derivatives, causing the A-band to shift to longer wavelengths and blurring its vibrational fine structure in the case of *trans*-stilbene (24). This has been attributed to an interaction between the π-orbitals of the olefin and those of the solvent. The magnitude of the shift appears to be related to the preferred conformation of the molecule, being considerably smaller for nonplanar derivatives such as *cis*-stilbene and TPE than for planar ones (24). This solvent shift amounts to about +3 nm for TPE. The A-bands in the spectra of 1*a–f* in benzene are shifted to a similar extent relative to the spectra in ethanol.

The fluorescence emission spectrum of *cis*-1*d* was measured in alcohol solution at room temperature, and this is shown in Fig. 7, along with the fluorescence excitation spectrum. The appearance of the excitation spectrum does not match that of the absorption spectrum in the short wavelength

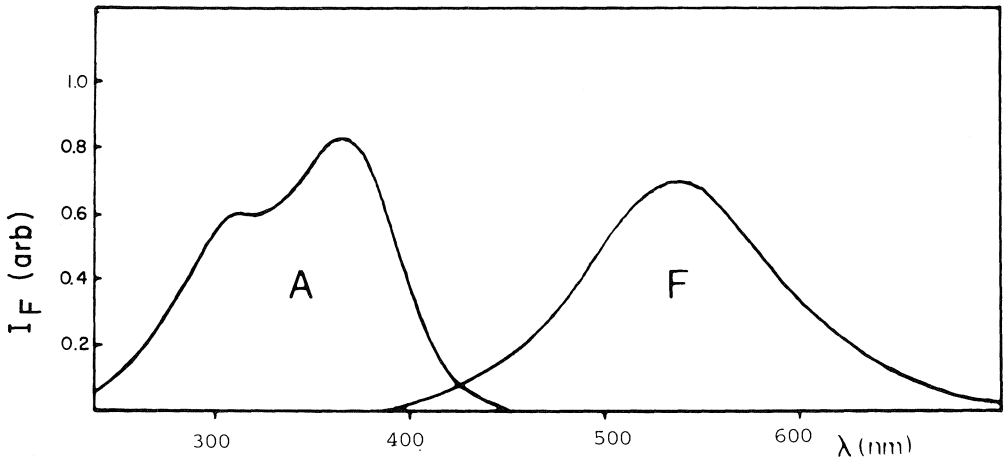

FIG. 7. Fluorescence emission (F) and excitation (A) spectra of *cis*-**1***d* (alcohol, 25°C; uncorrected).

region due primarily to the spectral distribution of the excitation source. The large Stokes shift ($\bar{\nu}_{max}^{ex.} - \bar{\nu}_{max}^{F} \sim 9000\,cm^{-1}$) is similar to that observed for TPE itself (10*a*), and indicates a substantial difference in the preferred geometries of S_0 and S_1. From these spectra, the position of the 0–0 band is estimated to be 425 ± 5 nm. Noting that the extinction coefficient (ε) at 425 nm in the absorption spectrum of *cis*-**1***d* is ca. 100, we estimate the positions of the 0–0 band in the other derivatives as the wavelength at which ε ~ 100. This data is collected in Table 2. The energies listed in Table 2 are believed to correspond to the energies of the vertical (Franck–Condon) transitions between the stable ground state, slightly nonplanar S_0 and the corresponding S_1, (i.e. ${}^0t \rightarrow {}^1t$, ${}^0c \rightarrow {}^1c$) (8).

Included in Table 2 for comparison are the π- and π*-orbital energy differences calculated from the half-wave oxidation and reduction potentials of these compounds. Singlet excitation energies are related to the redox potentials by eq. [1] (27), where J_{12} is the Coulomb repulsion integral and K_{12} is the exchange integral. The term $(-J_{12} + 2K_{12})$ represents the difference between the energy of the lowest unoccupied molecular orbital when it is occupied by an electron after excitation and when it is empty in the closed shell (i.e. ground state) configuration. The close agreement between the spectroscopic singlet energies and $(E_{\frac{1}{2}}^{ox} - E_{\frac{1}{2}}^{red})$ for this series indicates that this term is very small. A similar result was obtained by Loutfy and Loutfy (27*b*) for an extensive series of polynuclear aromatic hydrocarbons.

Fluorescence Emission

Trans-stilbene fluoresces at room temperature (φ ~ 0.05) (8), and this competes with *cis–trans* isomerization. The fluorescence quantum yield increases considerably in viscous media and at low temperatures. This is known to be due both to hindrance to rotation by the rigidity of the medium and to the presence of a small activation barrier (~ 3 kcal mol^{-1}) for twisting to the ${}^1p$ conformer, from which *cis–trans* isomerization occurs.

Cis-stilbene, on the other hand, is nonfluorescent at room temperature owing to rapid (unactivated) rotation to the ${}^1p$ conformer. Electrocyclic ring closure to dihydrophenanthrene also occurs (ϕ_{DHP} ~ 0.1). In rigid media, *cis*-stilbene fluoresces efficiently due to an inhibition of bond rotation. The fluorescence exhibits a large Stokes shift ($\bar{\nu}_{max}^{ex} - \bar{\nu}_{max}^{F} \sim 12\,000\,cm^{-1}$), which implies that the geometry of the fluorescent state is much different from the preferred ground state geometry.

The situation is a bit different for the case of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12

tetraphenylethylene, although many parallels with *cis*-stilbene can be drawn. Tetraphenylethylene is visibly fluorescent at room temperature, though this process is not very efficient ($\phi_F < 0.01$) (10) and the Stokes shift is only about 9000 cm^{-1} (10*a*). The fluorescence is shifted to shorter wavelengths (10*a*) and ϕ_F increases considerably in more viscous solvents (10*b*). From studies of the fluorescence quantum yield as a function of temperature and solvent viscosity, it has been concluded that bond rotation in S_1 is an unactivated process (10*b*). Dihydrophenanthrene formation ($\phi_{DHP} = 0.022$) competes with fluorescence at room temperature (11), and by analogy with *cis*-stilbene, this is expected to be subject to a modest activation barrier. It has furthermore been suggested that *cis–trans* isomerization is the most efficient decay process in fluid media (11).

The dependence of $\bar{\nu}_{max}{}^F$ and ϕ_F on solvent viscosity has led to the suggestion that the geometry of the luminescent species is different in viscous and nonviscous media (10*a*). According to the "classical" explanation, bond rotation can occur within the lifetime of S_1 in solvents of low viscosity, and emission therefore occurs from the favoured (lowest energy) twisted conformation. On the other hand, bond rotation is hindered considerably in viscous solvents, so that fluorescence occurs mainly from conformations close to those originally populated during excitation, and with considerably higher efficiency. This explanation is apparently supported by the observation that the fluorescence spectrum of tetraphenylethylene in highly viscous solvents is strongly dependent on the excitation wavelength (10*c*). Also, in solvents of intermediate viscosities (where the time required for double bond rotation is presumably of the same order of magnitude as the fluorescence) the fluorescence lifetime is longer in the lower energy end of the emission spectrum (10*d*).

Two recent studies, utilizing picosecond absorption (28) and fluorescence emission (29) spectroscopy, point to a different explanation for these results. Rentzepis and co-workers argue that the viscosity dependent spectral shift of the fluorescence is a result of rotation of the phenyl rings in tetraphenylethylene, and *not* to rotation about the carbon–carbon double bond in S_1. They do, however, favor the classical explanation for the dependence of the fluorescence quantum yield and total lifetime on solvent viscosity (29). Greene has observed two transient absorptions after picosecond excitation of tetraphenylethylene in solution at room temperature (28). The long wavelength absorption ($\lambda_{max} = 640$ nm) is characterized by a lifetime of 5 ps, and is attributed to absorption by a nearly planar S_1 geometry, which decays as rotation about the double bond proceeds. The lifetime of this absorption corresponds rather closely with the fluorescence lifetime of TPE in solution at room temperature (6 ps (29)). The short wavelength absorption ($\lambda_{max} = 417$ nm) decays with a lifetime of 3 ns, and is attributed to absorption from a long-lived twisted geometry. These results seem to indicate that the twisted singlet (^1p) of TPE, although a factor of ca. 500 longer-lived than the planar singlet, is nonfluorescent.

We have attempted to measure fluorescence quantum yields for **1***c*, *d* (*cis* and *trans*), **1***e*, and **1***f* in benzene solution at room temperature. The emission spectra were measured under standard conditions with solutions whose concentrations were adjusted so that their optical densities matched at the excitation wavelength (370 nm). The relative fluorescence quantum yields (measured by determining the areas beneath the emission spectra) varied by less than a factor of two within the series: **1***e* > **1***f* > **1***c* > **1***d*. The *cis* and *trans* isomers of both **1***c* and **1***d* fluoresce with equal efficiencies. On an absolute scale, $\phi_F \sim 0.001$ for these compounds since 9,10-diphenylanthracene fluorescence[3] (measured under comparable conditions) was more than a factor of 10^3 more intense.

cis–trans *Isomerization*

Direct irradiation of *cis*- or *trans*-**1***a–d* in benzene solution (10°C) results in rapid *cis–trans* isomerization. The photostationary states obtained upon irradiation of the long wavelength absorption tail of these derivatives are collected in Table 3. In all cases, attainment of the photostationary state was ensured by approaching it from both directions. By analogy with the stilbenes (8), the photostationary states obtained upon direct irradiation will be given by eq. [2], where the partitioning constant, β, defines the fraction of twisted singlets that decay to the *trans* isomer (8). The major simplifying assumption made here is that isomerization proceeds from an excited singlet state and does not involve intersystem crossing to the triplet, prior to decay to the ground state. The validity of this assumption will be discussed later.

$$[2]\quad (t/c)_{pss} = \frac{\varepsilon_c}{\varepsilon_t} \cdot \frac{\phi_{c \to t}}{\phi_{t \to c}} = \frac{\varepsilon_c}{\varepsilon_t} \cdot \frac{(1 - \phi_F{}^c)}{(1 - \phi_F{}^t)} \times \frac{(1 - \phi_{DHP}{}^c)}{(1 - \phi_{DHP}{}^t)} \cdot \frac{\beta}{1 - \beta}$$

[3]Using the value of $\phi_F = 0.85$ for 9,10-diphenylanthracene in benzene (30).

1*d*[c]	0.24±0.02	0.03±0.01

[a] Benzene solution, 25°C.
[b] Average of two determinations.
[c] Average of three determinations.

Enough data are now available to further simplify eq. [2]. The A-bands in the absorption spectra of the isomeric pairs are virtually identical in each case and therefore $\varepsilon_c/\varepsilon_t \sim 1$. We have seen that ϕ_F for tetraphenylethylene is very small at room temperature (~ 0.001) (10), as is also the case for **1***c*. Furthermore, $\phi_F^c \sim \phi_F^t$ for **1***c*, *d*, and if we assume this to be the case as well for **1***a*, *b*, the term involving fluorescence quantum yields drops out of eq. [2]. Olsen and Buckles have shown that dihydrophenanthrene formation proceeds with a very low quantum yield (~ 0.02) for TPE and several substituted derivatives (11). This term in eq. [2] will therefore also be very close to unity, even if $\phi_{DHP}^c \neq \phi_{DHP}^t$. The photostationary states obtained upon direct irradiation of **1***a*–*d* can thus be almost totally accounted for by the partitioning ratio describing the decay of ^1p to the ground state:

$$[3] \quad (t/c)_{pss} = \frac{\phi_{c \rightarrow t}}{\phi_{t \rightarrow c}} \sim \frac{\beta}{1 - \beta}$$

The partitioning constants (β), calculated according to eq. [3], are collected in Table 3.

The value of β is essentially constant for **1***a*–*c* (0.55–0.57). The indication that ^1p decays to give almost equal amounts of *cis* and *trans* olefins is expected, since the geometry of ^1p should be approximately perpendicular and decay to the ground state should be vertically down (i.e. to the point on the S_0 surface corresponding to the transition state for thermal isomerization). The behaviour of **1***d* upon direct excitation is obviously very different from that of the other derivatives, since in this case the photostationary state consists of 90% of the *trans* isomer.

In order to test the validity of eq. [3], we have determined quantum yields for the direct photoisomerization of **1***b*–*d* in benzene solution at 25°C, with 370 nm excitation (31). These data, collected in Table 4, further illustrate the anomalous behaviour of **1***d* upon direct excitation. *cis*–*trans* Isomerization does indeed prove to be the major pathway for decay of the first excited singlet state of **1***b* and **1***c*. In these cases, the sum of the quantum yields for *cis* → *trans* and *trans* → *cis* interconversion are only slightly less than unity, and the photostationary state is hence described adequately by eq. [3]. On the other hand, *cis*–*trans* isomerization appears to account for less than one-third of the total light absorbed at 370 nm in the case of **1***d*. Hence, the assumptions leading to the simplification of eq. [2] are not justifiable in this case, and eq. [3] does not adequately describe the photostationary state. Obviously, some other nonradiational decay process is responsible for the reduced efficiency of *cis*–*trans* isomerization in this derivative.

Two possibilities are vibrational deactivation, taking place before complete twisting to ^1p can occur, and dihydrophenanthrene formation. These processes are expected to be of increased importance when rotation in S_1 is an activated process. Although it is believed that, in S_1, bond rotation in TPE itself is unactivated (11), we cannot rule out the possibility of an activation barrier for twisting in the first excited singlet state of **1***d*.

Theory predicts the first excited singlet state of olefins to have zwitterionic character (4). A zwitterionic configuration in tetraphenylethylene will be especially stabilized when the molecule bears *both* cyano and methoxy substituents, through the contribution of resonance structures such as those illustrated below in **1***d*′. This may also account for the significantly lower singlet energy observed for **1***d* than the other derivatives. The barrier to rotation in S_1 may then arise as a result of a stabilizing charge-transfer-like interaction across the rings, the barrier being higher, of course, for *trans* ^1p than *cis* ^1p rotation. This sort of interaction may also constrain the most stable conformation of ^1p to have an angle of twist less than 90° (i.e. transoid), which would result in an anomalously high value of β, the partitioning constant.

Although we have not determined the quantum yields for dihydrophenanthrene formation from *cis*- and *trans*-**1***d*, qualitative experiments indicate that they are relatively low. Thus, irradiation (370 nm) of oxygen-saturated benzene solutions of either *cis*- or *trans*-**1***d* (10^{-5} *M*) does not result in any detectable change of the uv absorption spectrum during the time required to achieve partial (ca.

[c] The cutoff wavelength is taken as the wavelength at which the extinction coefficient has fallen to ~ 100.

10%) *cis–trans* photoequilibration. Therefore, it does not appear that the decreased efficiency of *cis–trans* photoisomerization of **1***d* relative to the other derivatives can be attributed to dihydrophenanthrene formation. It must be stressed, however, that this interpretation is based on the assumptions that oxygen serves only to trap the initially formed dihydrophenanthrene and, furthermore, that it would do so with high efficiency.

The Triplet-sensitized cis–trans *Isomerization of* 1a–d

Since one of our primary interests in the investigation of the excited state behaviour of **1***a–d* was an examination of the effect of substituents (and merostabilization) on the π,π^* triplet energy of tetraphenylethylene, our initial efforts were directed toward spectroscopic determination of the triplet energy of **1***d*.

A low intensity $S_0 \rightarrow T$ absorption band could not be found in the absorption spectrum of a saturated solution of **1***d* in ethanol, even with cells of path-length as high as 15 cm. The use of a heavy atom solvent (ethyl iodide) was also fruitless. Phosphorescence emission could not be detected from **1***d* in either an ethanol/methanol or ethanol/ethyl iodide glass at 77 K. Sensitized phosphorescence was also undetectable upon irradiating a benzophenone glass containing ca. 10^{-4} *M* **1***d* at 77 K.

We therefore turned to indirect methods of determining the triplet energies of this series. The simplest method involves examination of the triplet-sensitized isomerization of the olefin using a series of sensitizers of varying triplet energy (32) and this is the approach we have used to estimate the triplet energies of **1***a–d*. It should be emphasized, however, that this method affords only a qualitative indication of an olefin's triplet energy.

A major problem in this study was that our choice of sensitizers was severely restricted by the fact that the absorption spectra of **1***a–d* (**1***d* in particular) tail out to quite long wavelengths. In order to ensure that the sensitizer absorbs at least 99% of the incident light, the relative concentrations of sensitizer/olefin would have to be as high as 200:1 for many of the common, well characterized triplet sensitizers in frequent use (33, 34). This presented analytical problems in most cases. Particular attention was therefore paid to choosing a series of sensitizers which each absorb at fairly long wavelengths. These are listed in Table 5, along with their triplet energies, absorption maxima, long wavelength cutoffs, and intersystem crossing efficiencies (where known).

We can use the well-defined stilbene system (8) to aid in the analysis of our results. We assume that the behaviour of the triplet states of **1***a–d* will correspond more closely to that of *cis*-stilbene than *trans*-stilbene. Thus, the twisted triplet (^3p) is expected to be lower in energy than both planar triplets (^3t and ^3c), and conversion of ^3t and ^3c to ^3p will be irreversible in both cases. Furthermore, nonvertical endothermic energy transfer is expected to occur for both isomers.

The photostationary states obtained upon triplet-sensitized isomerization will be given by eq. [4], by analogy with the stilbenes (8),

$$[4] \quad (t/c)_{pss} = \frac{k_{et}^c}{k_{et}^t} \frac{\alpha}{1-\alpha}$$

where the partitioning constant, α, represents the percentage of twisted triplets that decay to the *trans* isomer. With high energy sensitizers, energy

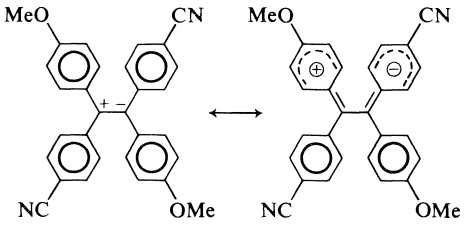
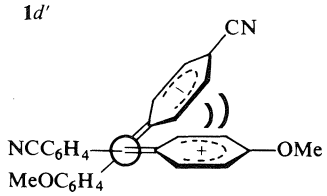
transfer to both isomers should be diffusion-controlled, and the photostationary state (pss) ratio will be given by the decay ratio $\alpha/(1-\alpha)$.

Exploratory photolyses revealed that the $(t/c)_{pss}$ ratios for **1***a–d* are *invariant* as a function of



1*d′*



sensitizer triplet energy in every case. This implies that the rates of energy transfer to the *cis* and *trans* isomers are equal regardless of the sensitizer's triplet energy, and hence that the spectroscopic triplet energies of the *cis* and *trans* isomers are very nearly the same. The result of this observation is that a Saltiel plot ($(t/c)_{pss}$ vs. E_T^{sens}) will contain no fine structure, and hence yield no information regarding the olefins' triplet energies.

We therefore turned to a qualitative examination of the relative efficiencies of triplet-sensitized isomerization of **1***a–d* as a function of sensitizer triplet energy. This was done by simply comparing the times required to effect photoequilibrium for each olefin with a given sensitizer, and these results are collected in Table 6. While little significance can be attached to the variation in irradiation time for a particular olefin with the different sensitizers (i.e. proceeding down the columns in Table 6), the irradiation times required for each olefin to reach the photostationary state with a given sensitizer (i.e. proceeding across the rows in Table 6) do reflect the relative quenching efficiencies. Assuming that the quenching process responsible for isomerization is indeed triplet energy transfer, the data then provide estimates of the triplet energies of **1***a–d*. We assume that nonvertical excitation transfer should be observable by this method when triplet energy transfer is endothermic by ca. 5 kcal mol^{-1} or less; triplet (^3p) energies are then obtained by simply adding 5 kcal mol^{-1} to the triplet energy of the lowest energy sensitizer that effects isomerization.

Examining Table 6, we see that energy transfer is efficient in all cases with the high energy sensitizer (**4**, E_T = 56 kcal mol^{-1}), isomerization being complete in less than 0.5 h in all cases. A drop in the relative isomerization efficiencies of **1***a*, *b* becomes evident with **6** (E_T = 47 kcal mol^{-1}), and this becomes even more pronounced with **7** (E_T = 43.4 kcal mol^{-1}). Energy transfer from Michler's thioketone (**8**, E_T = 43.4 kcal mol^{-1}) to **1***a–c* is very inefficient compared to **1***d*, and we thus estimate the triplet (^3p) energies of **1***a–c* to be about 48 kcal mol^{-1}. This estimate is in excellent agreement with the value of 47 kcal mol^{-1} which was estimated for tetraphenylethylene (12). Energy transfer to **1***d*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

appears to be inefficient with **9** (E_T = 41.9 kcal mol^{-1}), although we have nothing to compare it to. However, since the $(t/c)_{pss}$ ratio obtained in this case is intermediate between the high energy limit (1.14) and the direct irradiation value (8.35), we are reasonably certain that triplet energy transfer is indeed occurring.[4] Since triplet sensitized isomerization of **1***d* does not occur (detectably) with **10** (E_T = 40.6 kcal mol^{-1}) as sensitizer (the photostationary state was the same as that obtained upon direct irradiation[4]), we estimate the triplet (^3p) energy of **1***d* to be about 46 kcal mol^{-1}.

This study provides only qualitative estimates of the triplet (^3p) energies of **1***a–d*, as was emphasized earlier. Although these estimates provide only upper limits for the triplet energies of **1***a–d*, it does seem safe to conclude that the triplet energies of **1***a–c* are in fact similar (±1 kcal mol^{-1}) while that of **1***d* is about 2 kcal mol^{-1} lower. This difference between the estimated triplet energies of **1***a–c* and **1***d* compares favourably with the difference in the activation energies for thermal isomerization of these compounds (1). We attribute this difference to additional stabilization of the twisted, biradicaloid triplet state as a result of merostabilization.

Summary and Conclusions

We are now in a position to define the potential energy curves for twisting about the double bond in the ground and first excited singlet and triplet states of tetraphenylethylene, and the effect of substituents on these energy surfaces. Mulliken diagrams for the 1,2-diphenyl-1,2-ditolylethylenes (**1***a*) and the 1,2-dianisyl-1,2-di(4-cyanophenyl)ethylenes (**1***d*) are shown in Fig. 8.

The most stable ground state conformation in tetraphenylethylene is twisted about the double bond by about 8° (25). The difference in thermodynamic stability between *cis* and *trans* isomers of **1***a–d* is less than 0.5 kcal mol^{-1}, the *trans* isomer being more stable in every case (1). The transition state for thermal isomerization, which presumably occurs at an angle of twist of about 90°, lies 35–36 kcal mol^{-1} for **1***a–c*, and about 33 kcal mol^{-1} for **1***d*, above the energies of the stable S_0 conformers (1).

We were not able to determine the spectroscopic triplet energies of *cis*- and *trans*-**1***a–d*, so these points in Fig. 8 are uncertain. We assume, however, that like *cis*-stilbene (8), the planar triplets are higher in energy than the twisted triplet (^3p). The

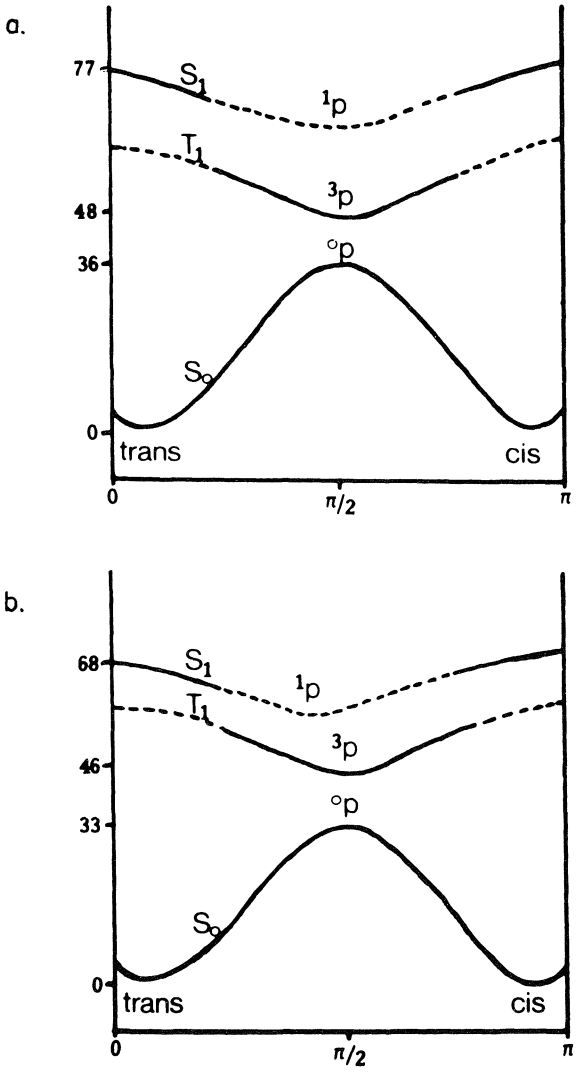


FIG. 8. Mulliken diagrams for **1***a* (a) and **1***d* (b).

angle of twist in ^3p is presumably about 90° in **1***a–d*, since the photostationary states obtained upon triplet-sensitized isomerization indicate that the partitioning ratio $\alpha/(1-\alpha)$ is about unity in each case. The energy of ^3p in TPE and **1***a–c* is estimated to be about 48 kcal mol^{-1} (12). The effect of substituents on the energy of ^3p in tetraphenylethylene parallels that on the ground state rotational barrier, which supports the notion that the triplet state of symmetrical olefins is biradical-like in nature. Merostabilization contributes about 2 kcal mol^{-1} additional stabilization of ^3p in **1***d* relative to the other derivatives. *Cis–trans* isomerization is the major pathway for decay of the triplet state.

The relative energies of the twisted triplet (^3p)

[4]Direct irradiation of **1***d* could not be avoided in this case. It is estimated that the sensitizer absorbed at least 90% of the incident light.

and the twisted ground state (^0p) conformers are a cause of concern. We were not expecting ^3p to be so much higher in energy than ^0p (12 kcal mol^{-1}). Theory predicts the triplet to be the ground state for simple olefins in the twisted geometry (4). In the stilbenes, however, ^3p and ^0p are known to be nearly isoenergetic, with ^0p slightly lower in energy than ^3p (8), and the difference is apparently even greater in tetraphenylethylene. Radical stability arguments (1) would lead to the prediction that ^3p in tetraphenylethylene should be 8–10 kcal mol^{-1} lower in energy than the corresponding state in the stilbene system. The apparent similarity between the energies of the ^3p states in stilbene and TPE thus appears to be incompatible with the biradical nature of these species. We do not understand this relatively major discrepancy, however, we hasten to stress that the triplet energies of **1***a–d* estimated in this way are *upper limits*, so the true values may actually be considerably less.

The spectroscopic singlet energy of tetraphenylethylene is about 79 kcal mol^{-1}. Substituents in the *para* positions lower this value somewhat, although isomeric pairs are not different enough electronically to cause their singlet energies to differ appreciably in the cases studied thus far. The singlet energy of **1***d* is considerably lower than those of the other derivatives studied. Twisting in S_1 is apparently unactivated (28, 29) (at least for TPE and **1***a–c*), and leads to a lower-energy, nonfluorescent twisted singlet from which *cis–trans* isomerization occurs. Although we have identified this low energy twisted singlet as ^1p (i.e. part of the S_1 potential energy surface), it is now accepted that this state in the stilbene system is, in fact, a doubly excited one, populated by internal conversion from S_1 as twisting proceeds (8, 38). In any case, we are not able to estimate the energy of this conformer from our data. In **1***a–c*, the angle of twist in ^1p is presumably about 90°, since decay to the ground state results in the formation of both *cis* and *trans* isomers in almost equal amounts.

Minor pathways of decay from the first excited singlet state of TPE and **1***a–f* are fluorescence and electrocyclic ring closure (DHP formation). At room temperature, fluorescence presumably occurs mainly from a conformer in which the phenyl rings have rotated somewhat from their arrangement in S_0, but in which very little rotation about the double bond has occurred (29).

Cis–trans isomerization occurs as a result of decay of ^1p to the ground state. This decay must not involve intersystem crossing to the triplet state, since the photostationary states obtained upon direct and triplet-sensitized excitation conditions are different, particularly in the case of **1***d*. Although *cis–trans* isomerization accounts for essentially all the decay of the singlet states of **1***a–c* (and, by analogy, tetraphenylethylene), it is much less important in **1***d*. This may be due to the presence of an activation barrier to twisting in the first excited singlet state of this derivative.

Much remains to be done in this area. Although the singlet state decay processes of TPE and **1***a–c* are now completely accounted for, further investigation is required in order to fully understand the unusual behaviour of **1***d*. An examination of the temperature and viscosity dependence of the quantum yields for *cis–trans* isomerization of **1***a–d* would obviously go a long way towards a full understanding of the first excited singlet state of TPE. A more careful study of the triplet state is also necessary. Quenching rate studies and sensitized isomerization quantum yields will give a more accurate indication of the triplet energies of this compound. Although the triplet energies of **1***a–d* are apparently not as low as we had originally expected, these compounds may nevertheless prove to be useful as triplet counters for sensitizers whose triplet energies are too low for them to be conveniently investigated with the widely used stilbene system.

Experimental

All melting points are corrected. The ^{1}Hmr spectra were recorded on Varian T60 or CFT20 nmr spectrometers and are reported in parts per million downfield from TMS. Infrared spectra were recorded on a Perkin–Elmer 180 grating infrared spectrometer and are reported in wavenumbers, calibrated against the 1601.8 cm^{-1} polystyrene absorption. Ultraviolet absorption spectra were recorded on a Cary–Varian 219 ultraviolet spectrometer and reported in nanometers. Fluorescence emission and excitation spectra were recorded on an Aminco–Bowman Model 4-8202 spectrophotofluorometer. All spectra were calibrated with a Pen-ray low pressure mercury vapour lamp. Suprasil optical cells (1 cm path length) were used for room temperature measurements, while evacuable Suprasil tubes (4 mm od) were used with a quartz Dewar for those at 77 K.

Half-wave oxidation and reduction potentials were measured by cyclic voltammetry using the apparatus and method described previously (2). Substrate concentrations were typically 20 mg/25 mL 0.1 *M* tetraethylammonium perchlorate (TEAP) in acetonitrile. The voltammograms were scanned at 20, 50, 100, and 200 mV s^{-1}. For reversible waves the half-wave redox potentials were calculated as the average of the midpoints between the forward and reverse waves for the 50, 100, and 200 mV s^{-1} scans. For irreversible waves, the half-wave potentials were calculated as 0.03 V less than the peak potential of the forward scan at 100 mV s^{-1}.

Acetonitrile was refluxed with calcium hydride under dry nitrogen for three days and distilled as required. Benzene was stirred with concentrated sulfuric acid for 24 h, washed thrice with distilled water, once with saturated aqueous bicarbonate, refluxed over sodium for 8 h, distilled, and stored over 4A molecular sieves. Absolute ethanol was obtained by refluxing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

95% ethanol over magnesium turnings and iodine for 24 h followed by distillation. Ethyl iodide was Fisher reagent grade, and was passed down an alumina column and stored over copper wire.

Silver nitrate was Engelhard A.C.S. grade and was recrystallized three times from aqueous ethanol and stored in the dark. Tetraethylammonium perchlorate (TEAP; Aldrich) was recrystallized three times from 90% ethanol.

Tetraphenylethylene (mp 224–225°C) was obtained from Aldrich and recrystallized twice from chloroform–ethanol. The preparation, purification, and characterization of **1***a–d* have been previously described (1). Tetraanisylethylene (**1***e*) was prepared in a similar manner and was recrystallized four times from chloroform–methanol to yield colourless plates (mp 189–190°C; lit. (39) mp 179–180°C).

1,1,2,2-Tetra(4-cyanophenyl)ethylene (**1***f*) was prepared by the same procedure used for **1***a–e* (1). The crude product, a brown, oily solid (3 g), was chromatographed on a silica gel (150 g) column with ether (0 → 10%)–benzene. Elution with pure benzene brought unreacted 4,4′-dicyanobenzophenone (0.9 g) off the column. The olefin was eluted with 10% ether. Evaporation of solvent yielded the product as a yellow solid (0.7 g), which was recrystallized three times from chloroform–methanol to yield **1***f* as light yellow needles (mp 363–366°C); ir (KBr): 2230(s), 1500(s), 1401(m), 1172(w), 1108(w), 1010(m), 826(m, br), 806(m), 750(m), 675(m, br); uv λ_{max} (ethanol): 220(sh, 28 300), 254(29 600), 305(19 500), 319(17 100); ^{1}Hmr ($CDCl_3$): 7.09(d, 1H), 7.53(d, 1H). *Anal.* calcd. for $C_{30}H_{16}N_4$: C 83.31, H 3.73; found: C 83.35, H 3.83.

3,3′-Carbonyl-bis*(5,7-diethoxycoumarin)* (**4**) was prepared by the method of Farid and Specht (35*b*), and recrystallized twice from chloroform–ethanol (1:1) to yield bright yellow crystals (mp 237–239°C).

3,3′-Carbonyl-bis*(7-diethylaminocoumarin)* (**5**) was prepared in a similar fashion (35*b*), and recrystallized twice from acetonitrile–ethanol (1:3) to yield orange needles, mp 213–214°C (lit. (35*b*) mp 213°C).

Benzanthrone (**6**, K & K, 15 g) was treated with Norite (3 g) in refluxing 1,1,2,2-tetrachloroethane for 15 min and filtered. Hot ethanol (200 mL) was added and the solution was allowed to cool slowly. The dark yellow crystals were collected by vacuum filtration and the process was repeated. A portion of this material (5 g) was then chromatographed on a silica gel (125 g) column, using benzene (80%) – hexane as the eluant, and finally recrystallized twice from ethanol, mp 169.5–170°C.

Phenazine (**7**, Aldrich) was recrystallized once from ethanol, mp 180–180.5°C.

Michler's thioketone (**8**, Fisher) was recrystallized thrice from chloroform–methanol, mp 203–204°C.

3,4-Benzopyrene (**9**, Sigma) was sublimed (150°C, 0.1 Torr), chromatographed on alumina (benzene (70%) – hexane), and recrystallized from benzene, mp 183–184°C.

9-Methylanthracene (**10**, Aldrich) was recrystallized once from methanol and sublimed (85°C, 0.1 Torr), mp 81–81.5°C.

All sensitizers were shown to be pure by tlc or hplc.

Direct and Triplet-sensitized Photoisomerization of **1**a–d

All irradiations were carried out in degassed (bubbling N_2, 15 min) benzene solution in 5 or 7 mm Pyrex tubes, using the appropriate Corning glass filter. The tubes were clamped in a water bath (10°C) 2 in. away from the light source, which was a 1 kW GE medium pressure mercury vapour lamp. The photostationary states were approached from both directions, progress of the isomerization being monitored by ir spectroscopy (**1***a*) or hplc (**1***b–d*) (see ref. 1 for analytical procedures). Each sample was analysed at least twice, and the results were averaged. Further experimental details are listed as footnotes in Tables 3 and 6.

Quantum Yield Determinations

Quantum yields were determined with an apparatus which is conceptually similar to that described by Zimmerman *et al.* (40), the major difference being that the photomultiplier tubes used to measure the intensities of the main and reference beams are replaced with phototransistors (41). The light source is an Osram 450 W high pressure xenon lamp, powered by a PRA Model 302 power supply. A Spex Minimate monochromator, fitted with 1.25 mm entrance and exit slits is used to isolate excitation light of the desired wavelength. After entering the sample/phototransistor compartment, the light passes through a Corning CS7-37 glass filter to remove the long wavelength component, and then passes through the beam splitter. The apparatus was calibrated daily by ferrioxalate actinometry.

A 10 mL volume of a benzene solution of the olefin was pipetted into a 2 cm Suprasil optical cell, the cell was sealed with a rubber septum, and the solution was degassed by bubbling dry nitrogen through a syringe for at least 30 min. The concentration of the solution was chosen such that its optical density would be between 1 and 2. After degassing, the optical density of the solution at 370 nm was measured, the cell was placed in the main beam of the quantum yield apparatus, and irradiated. At suitable time intervals, irradiation was stopped, the number of accumulated counts (from the reference phototransistor) was recorded, the photolysis cell was shaken vigorously, and a 70 μL aliquot of the solution was removed by syringe for hplc analysis. The cell was then replaced and irradiation was continued. After a suitable number of aliquots (usually ten) had been taken, irradiation was continued to evaluate the photostationary state.

Analysis of the data is based on the treatment developed by Zimmerman *et al.* (31). Since $\varepsilon^{370}_{trans} = \varepsilon^{370}_{cis}$,

$$[5] \quad \ln (X_c^e - X_c) = \ln (X_c^e - X_c^0) - \frac{\theta \phi_{t \rightarrow c} D}{V c_0 X_c^e \left(1 + \frac{D}{2} + \frac{D^2}{12}\right)} I$$

where X_c = mole fraction of the *cis* isomer, θ = light intensity in einsteins/count, D = optical density of the solution, I = accumulated counts absorbed = $SI_{ref} - I_{main}$, where S = splitting ratio, V = initial volume in photolysis cell, and C_0 = total olefin concentration. Plots of $\ln (X_c^e - X_c)$ vs. I were linear, and the correlation coefficients better than 0.990 in all cases. $\phi_{t \rightarrow c}$ and $\phi_{c \rightarrow t}$ were then calculated from the slope of the plot and the photostationary state composition, and are collected in Table 4. For **1***b* and **1***c*, both *trans* → pss and *cis* → pss were examined and the results averaged, while for **1***d*, only *cis* → pss was examined. The quantum yields in this case are the average of three determinations.

The least-squares triangle: a new method for evaluation of solid phase compositions from solubility measurements

JOHN W. LORIMER

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 5, 1981

JOHN W. LORIMER. Can. J. Chem. **59**, 3076 (1981).

A least-squares method is described for calculating compositions of equilibrium solid phases from data on solubilities and either wet residues or initial compositions for systems of three or more thermodynamic components. The method minimizes the squares of areas of triangles formed by the solubility, wet residue (or initial composition), and solid composition points. Full descriptions of error analyses and hypothesis tests are given, along with an illustrative example and detailed comparisons with the traditional extrapolation method.

JOHN W. LORIMER. Can. J. Chem. **59**, 3076 (1981).

On décrit une méthode impliquant les moindres carrés qui permet de calculer des compositions de phases solides à l'équilibre à partir de données de solubilité ainsi que des restes ou des compositions initiales des systèmes thermodynamiques à trois composants ou plus. La méthode minimise les carrés des aires des triangles formés par les points de solubilité, de reste (ou de composition initiale) et de composition solide. On donne une description complète des erreurs d'analyse et des vérifications, des hypothèses ainsi qu'un exemple et des comparaisons détaillées avec la méthode d'extrapolation directe.

Introduction

In determinations of solubilities of solids in liquids, it is important, but not always easy, to establish accurately the composition of the equilibrium solid phase or phases. A general way of finding the composition of a solid phase while it is in contact with a saturated solution was devised by Schreinemakers (1) in 1893, and his "method of wet residues" has found wide use up to the present. Bancroft (2) rediscovered the method independently in 1902. In Fig. 1a, A, B, and C are three components whose compositions (as mass or mole fractions at constant temperature and pressure) are represented on the triangle ABC. The curves ab, bc are the solubility curves, respectively, of the binary compound A' and the ternary compound B'. If x' is a point on the solubility curve bc, then all points on tie-line $x'B'$ represent systems containing solid B' and solution x' saturated with B'. If a sample of solution is removed and analyzed to give the composition x', then the remaining solid and solution (the "wet residue") will have a composition x'' lying on the tie-line. This composition may be determined by analysis of the complete wet residue, and the tie-line $x'x''$ may be drawn. Other tie-lines such as $z'z''$ can be found in a similar way, and their intersection gives the composition B'. The points x'', z'' can equally well be the initial overall compositions of the system, and Hill and Ricci (3) have recommended using these compositions, called by them the "initial complexes", to avoid errors due to loss or gain of solvent in transferring the wet residues from the solubility bottles to the containers used for analysis. It is also possible to determine two wet residue compositions by successive sampling of different proportions of solid and liquid or to use one wet residue and the initial composition. The three points obtained thus for a given tie-line should improve the precision of the extrapolation, but the method has been used infrequently; for examples, see Delyon (4) and Filipescu and Filipescu (5). Other points such as p'' lie on tie-lines within three-phase regions, and these tie-lines intersect at the eutonic (isothermally invariant) point b. In principle, such tie-lines can be used to obtain a more precise value for the eutonic composition, but no instances of this application have been found in the literature.

Extrapolation of tie-lines is usually done graphically, even in modern work, but Hill and Ricci (3) have used an algebraic method. The two points x', x'', with coordinates x_A', x_B' and x_A'', x_B'' for coordinate axes A, B are used to find the equation of the tie-line. The intersection of the tie-line with a line through a vertex and the assumed composition of the compound, such as lines CA or CB', is then calculated. These reference lines fix the relative proportions of components A and B in the compound; component B is absent along line CA. The points of intersection of all p tie-lines constitute a univariate population of random variables with mean $\bar{x}_x$ (the relative amount of the one independent component X in the compound) and standard deviation σ. If x_x^0 is a theoretical value for x_x, the hypothesis $x_x = x_x^0$ can be tested by computing the statistic $|\bar{x}_x - x_x^0|p^{\frac{1}{2}}/\sigma$. If this value exceeds the

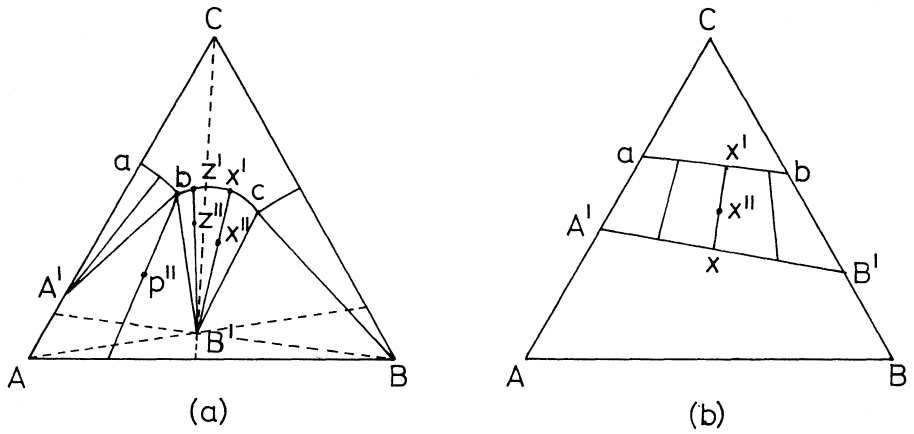

FIG. 1. Schematic solubility curves for ternary systems of A, B, and C where: (a) binary compound A' with solubility curve ab and ternary compound B' with solubility curve bc appear; (b) isomorphic solid solutions $A'B'$ appear, with solubility curve ab. Lines such as aA', $x'x''$ are tie-lines.

tabulated value of Student's t for $p - 1$ degrees of freedom, the hypothesis can be rejected (6). The existence of this simple statistical test does not appear to have been realized previously. It is also possible to find the point of intersection of pairs of tie-lines without making any assumption concerning the ratio of components in the compound. The data for the $p(p-1)/2$ pairs of tie-lines give rise to a set of nonlinear conditions which can be linearized and used to find least-squares estimates of the point of intersection by an iterative procedure (7). This approach is being investigated.[1] The point of intersection will be more precise if the points x' and x'' are widely separated as possible (1, 3), whatever method of extrapolation, graphical or analytical, is used.

It is also possible to extrapolate the tie-lines to intersect line BB', along which the ratio of components C to A is fixed, or to intersect line AB', along which the ratio of components B to C is fixed. Only two of these lines will give independent estimates of the composition of the solid phase, because the intersection of any two of the lines AB', BB', CB' is sufficient to determine point B'. If C is a solvent component, then the usual practice is to use line CB'. If, as shown in Fig. 1a, the tie-lines are roughly parallel to CB', intersections with AB' or BB' will tend to give a more precise estimate of the solid composition than intersections with CB'. Similar considerations hold for point A', except that only two reference lines, CA' and BA', are possible. These considerations of precision appear not to have been recognized.

A variation of the analytical extrapolation procedure which uses projections of the points x' and x'' on the coordinate axes has been proposed independently by Smith (8) and by Schott (9), but Heric (10) has pointed out that nothing is gained by this method. Filipescu and Filipescu (5) fitted least-squares equations of the form $\hat{y}_{ij} = n_i + m_i x_{ij}$ to tie-lines i defined by three points x_{ij}, y_{ij} (one solubility, one initial composition, one wet residue) with parameters n_i, m_i. The point of intersection x_s, y_s was then found by minimizing $\Sigma_i(y_s - \hat{y}_{si})^2 = \Sigma(y_s - n_i - m_i x_s)^2$ with respect to x_s and y_s. The method was also applied to two-dimensional projections of four-component reciprocal salt systems. The statistical properties of the method were not investigated, but the assumption that the variance of x_{ij} is negligible compared to that of y_{ij} is implied in the theory. In practice, both variances are of comparable magnitude, so the statistical basis of the procedure is unsatisfactory.

The various procedures outlined above (with the probable exception of the iterative least-squares procedure) are all deficient in one or more respects. What is required is a method which: (a) allows for equal or pre-assigned weights for each coordinate; (b) makes no assumptions about the composition of a solid phase, and thereby permits estimation of n coordinates of the point of intersection in an $n + 1$ component system; (c) permits estimation of the variance–covariance matrix for the point of intersection; (d) permits statistical tests for the significance of the point of intersection; and (e) can be

[1]The author wishes to thank a referee for pointing out the relevance of Mikhail's book.

generalized to multicomponent systems. The method described below satisfies all these criteria, and does not require iterations. It has proved of value in analyzing critically the large body of solubility data which exists for the alkaline earth sulfates (11). In practice, it is restricted to three-component systems in which continuous series of solid solutions do not occur, or to ternary sections or ternary projections of higher-component systems. If isomorphic solid solutions occur ($A'B'$ in Fig. 1b), tie-lines such as $x'x''$ have no common intersection, but can be extrapolated algebraically (12, 13) to find the composition x of the conjugate solid solution. In four-component systems, tie-lines may exist between points on a three-dimensional solubility surface and the composition point of a solid phase. However, most solubility experiments on four-component systems are conducted by adding the fourth component to a three-component eutonic system. The tie-lines for these isothermally univariant four-component systems are not collinear. Similar considerations hold for systems of five or more components.

Theory

(a) *The Least-squares Triangle*

In Fig. 2, A, B, and C are three points in n-dimensional space which represent, respectively, the compositions (as mass or mole fractions) of the solid phase ($\boldsymbol{x}$), the saturated solution ($\boldsymbol{x}_k'$) and the wet residue ($\boldsymbol{x}_k''$) for an $(n + 1)$-component system. The coordinates of the points in terms of their components x_{ik} $(i = 1, \ldots, n)$ and a set of n orthogonal unit basis vectors $\boldsymbol{e}_i$ are

$$[1] \quad \boldsymbol{x} = \sum_{i=1}^{n} \boldsymbol{e}_i x_i, \boldsymbol{x}_k' = \sum_{i=1}^{n} \boldsymbol{e}_i x_{ik}'$$

and similarly for $\boldsymbol{x}_k''$. The line segments AB, AC form two sides of a triangle the area of which is the length of the vector

$$[2] \quad \boldsymbol{a}_k = \tfrac{1}{2}(\boldsymbol{x}_k' - \boldsymbol{x}) \wedge (\boldsymbol{x}_k'' - \boldsymbol{x})$$

where $\wedge$ is the exterior (vector) product. Define

$$[3] \quad \boldsymbol{y}_k \equiv \boldsymbol{x}_k' - \boldsymbol{x}_k''$$

Then, eq. [2] can be written as

$$[4] \quad 2\boldsymbol{a}_k = (\boldsymbol{x} - \boldsymbol{x}_k') \wedge \boldsymbol{y}_k$$

or, in terms of its components,

$$[5] \quad 2\boldsymbol{a}_k = \sum_{i<j=1}^{n} \boldsymbol{e}_i \wedge \boldsymbol{e}_j\{(x_i - x_{ik}')y_{jk} - (x_j - x_{jk}')y_{ik}\}$$

Now consider the set of lines $k = 1, \ldots, p$ each of which is determined uniquely by two points $\boldsymbol{x}_k'$ and $\boldsymbol{x}_k''$; the set is approximately collinear through point $\boldsymbol{x}$. If $p > n$, the coordinates of $\boldsymbol{x}$ are overdetermined, and it is desired to find estimates of these coordinates. If $\boldsymbol{a}_k = 0$, points $\boldsymbol{x}_k'$, $\boldsymbol{x}_k''$, and $\boldsymbol{x}$ are exactly collinear. If B lies as shown in Fig. 2, $\boldsymbol{a}_k$ is negative; if B lies on the opposite side of AC, $\boldsymbol{a}_k$ is positive. The coordinates $\boldsymbol{x}$ can then be estimated by minimizing the sum of squares of the areas $\boldsymbol{a}_k$, a procedure suggested to the author by Prof. M. M. Ali.

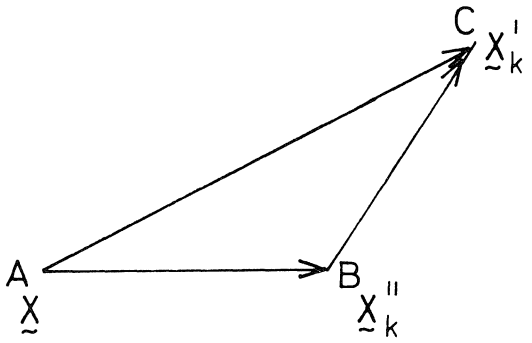

FIG. 2. Vector relations among a solubility coordinate $\mathbf{x}_k'$, a wet residue coordinate $\mathbf{x}_k''$, and a solid phase coordinate $\mathbf{x}$.

(b) *The Least-squares Normal Equations*

Vector notation (bold face italic type) is now abandoned, and the problem is recast in matrix terms. (Matrices are in bold face Roman type.) The skew symmetric matrix

$$[6] \quad 2\mathbf{A}_k = (\mathbf{x}\mathbf{y}_k^t - \mathbf{y}_k\mathbf{x}^t) - (\mathbf{x}_k'\mathbf{y}_k^t - \mathbf{y}_k\mathbf{x}_k''), \quad k = 1, \ldots, p$$

contains as its elements all components of the area given by eq. [5]. Here, the superscript t after a matrix indicates the transpose; lower case letters represent column matrices, upper case letters square matrices. Thus, $\mathbf{x}$, $\mathbf{x}_k'$, $\mathbf{y}_k$ are $n \times 1$ matrices (n rows, 1 column), $\mathbf{x}^t$, etc. are $1 \times n$ row matrices, and $\mathbf{A}_k$ is a $n \times n$ matrix. There are only $n(n-1)/2$ distinct components of area, but their signs are undefined, so that each component appears twice with a different sign in eq. [6]. The quantity

$$[7] \quad \alpha_k = \pm\{\tfrac{1}{2} \operatorname{tr} \mathbf{A}_k^t\mathbf{A}_k\}^{1/2}, \quad k = 1, \ldots, p$$

is the square root of the sum of squares of all components of area, and thus its magnitude is that of the area $\boldsymbol{a}_k$ in eq. [2]. The sign of α_k is undefined, so that the matrix $\boldsymbol{\alpha}$ with elements α_k is a matrix of random variables with zero means and finite variances. The corresponding variance–covariance matrix of $\boldsymbol{\alpha}$ is

$$[8] \quad \mathbf{M}_\alpha = \langle \boldsymbol{\alpha}\boldsymbol{\alpha}^t \rangle$$

where angular brackets indicate the expectation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

value. In practice, this matrix is diagonal, with elements $\sigma_{A_k}^2$, because individual areas are uncorrelated. In addition, only relative variances are known, so that

[9] $\mathbf{M}_\alpha = \sigma^2\mathbf{P}^{-1}$

where σ^2 is the variance of unit weight, and $\mathbf{P}$ is the weight matrix, which may itself be the unit matrix $\mathbf{I}$. The weighted sum of squares of all areas is given by the scalar

[10] $S = \boldsymbol{\alpha}^t\mathbf{M}_\alpha^{-1}\boldsymbol{\alpha} = \sum_{k=1}^{p} \frac{1}{2}\,\mathrm{tr}\,\mathbf{A}_k^t\mathbf{A}_k/\sigma_{A_k}^2$

where a diagonal weight matrix has been assumed in the second term. This quantity can be expanded using eq. [6] and simplified by multiplying out such products as

$$\mathrm{tr}\,(\mathbf{x}\mathbf{y}_k^t)^t(\mathbf{x}\mathbf{y}_k^t) = \mathrm{tr}\,(\mathbf{y}_k\mathbf{x}^t\mathbf{x}\mathbf{y}_k^t) = \mathbf{x}^t\mathbf{y}_k^t\mathbf{y}_k\mathbf{x}$$

to give finally

[11] $4S = \mathbf{x}^t\mathbf{B}\mathbf{x} - 2\mathbf{x}^t\mathbf{C} + D$

where

[12] $\mathbf{B} = \mathbf{B}^t = \left[\sum_{k=1}^{p} (\lambda_k^2\delta_{ij} - y_{ik}y_{kj})/\sigma_{A_k}^2\right]$

with

[13] $\lambda_k^2 = \sum_{i=1}^{n} y_{ik}^2$

[14] $\mathbf{C} = \left[\sum_{j=1}^{n}\sum_{k=1}^{p} (\lambda_k^2\delta_{ij} - y_{ik}y_{jk})x_{kj}/\sigma_{A_k}^2\right]$

[15] $D = \sum_{i,j=1}^{n}\sum_{k=1}^{p} (\lambda_k^2\delta_{ij} - y_{ik}y_{jk})x_{ik}'x_{jk}'/\sigma_{A_k}^2$

with δ_{ij} the Kronecker delta. Matrix $\mathbf{B}$ has dimensions $n \times n$, $\mathbf{C}$ has dimensions $n \times 1$, and D is a scalar.

The least-squares estimator $\hat{\mathbf{x}}$ for matrix $\mathbf{x}$ is found in the usual way by setting a variation in scalar S equal to zero:

$$4\delta S = \delta\mathbf{x}^t\mathbf{B}\hat{\mathbf{x}} + \mathbf{x}^t\mathbf{B}\delta\mathbf{x} - 2\delta\mathbf{x}^t\mathbf{C} = 0$$

or

[16] $4\delta S = 2\delta\mathbf{x}^t(\mathbf{B}\hat{\mathbf{x}} - \mathbf{C}) = 0$

from which

[17] $\mathbf{B}\hat{\mathbf{x}} = \mathbf{C}$ or $\hat{\mathbf{x}} = \mathbf{B}^{-1}\mathbf{C}$

Equations [17] are the required least-squares normal equations, and give estimates of the point of intersection $\hat{\mathbf{x}}$ in terms of the matrices $\mathbf{B}$ and $\mathbf{C}$, which are known if the $\sigma_{A_k}^2$ are known. If $\mathbf{P} = \mathbf{I}$ in eq. [9], then the weights $\sigma_{A_k}^2$ in eqs. [12] to [15] may all be set equal to unity, as they cancel in eq. [17]. An estimate $\hat{S}$ of the weighted sum of squares can now be found by substituting eq. [17] into eq. [11] to give

[18] $4\hat{S} = D - \mathbf{C}^t\mathbf{B}^{-1}\mathbf{C} = D - \hat{\mathbf{x}}^t\mathbf{B}\hat{\mathbf{x}}$

For a 3-component system, the specific equations are as follows, where all sums are over the p pairs of experimental points with coordinates (x_{1k}', x_{2k}'), (x_{1k}'', x_{2k}''), and $\sigma_{A_k}^2 = 1$.

[19] $\mathbf{B}^{-1}\Delta = \begin{bmatrix} \sum y_{1k}^2 & \sum y_{1k}y_{2k} \\ \sum y_{1k}y_{2k} & \sum y_{2k}^2 \end{bmatrix}$

[20] $\Delta = \sum y_{1k}^2 \sum y_{2k}^2 - (\sum y_{1k}y_{2k})^2$

[21] $\mathbf{C} = \begin{bmatrix} \sum y_{2k}(y_{2k}x_{1k}' - y_{1k}x_{2k}') \\ \sum y_{1k}(y_{1k}x_{2k}' - y_{2k}x_{1k}') \end{bmatrix}$

The correlation coefficient between the coordinates (x_1, x_2) of the point of intersection is

[22] $\hat{\rho}_{12} = \sum y_{1k}y_{2k}/\{\sum y_{1k}^2 \sum y_{2k}^2\}^{1/2}$

(c) *Errors in the Estimated Parameters*

The variance–covariance matrix of the parameter estimates $\hat{\mathbf{x}}$ is

[23] $\mathbf{M}_x = \langle(\mathbf{x} - \hat{\mathbf{x}})(\mathbf{x} - \hat{\mathbf{x}})^t\rangle = 4\langle\mathbf{B}^{-1}\rangle$

where angular brackets indicate the expectation value. It has not been possible to find a direct proof of eq. [23], but an indirect proof can be given readily by making use of the theorem that (6), if $\mathbf{X}$ is the matrix of a set of random variables with zero means, finite variances, and variance–covariance matrix $\mathbf{M}$ of rank q, then

[24] $\langle\mathbf{X}^t\mathbf{M}^{-1}\mathbf{X}\rangle = q$

Subtract eq. [11] from eq. [18] and use eq. [17]:

[25] $4(S - \hat{S}) = \mathbf{x}^t\mathbf{B}\mathbf{x} + \hat{\mathbf{x}}^t\mathbf{B}\hat{\mathbf{x}} - 2\mathbf{x}^t\mathbf{B}\hat{\mathbf{x}}$

Because the product $\mathbf{x}^t\mathbf{B}\hat{\mathbf{x}}$ is a scalar,

[26] $\mathbf{x}^t\mathbf{B}\hat{\mathbf{x}} = (\mathbf{x}^t\mathbf{B}\hat{\mathbf{x}})^t = \hat{\mathbf{x}}^t\mathbf{B}\mathbf{x}$

and thus

[27] $4\langle\hat{S}\rangle = 4\langle S\rangle - \langle(\mathbf{x} - \hat{\mathbf{x}})^t\mathbf{B}(\mathbf{x} - \hat{\mathbf{x}})\rangle$

Now,

[28] $\langle S\rangle = \langle\boldsymbol{\alpha}^t\mathbf{M}_\alpha^{-1}\boldsymbol{\alpha}\rangle = p$

since $\boldsymbol{\alpha}$ is a matrix of random variables with zero means and variance–covariance matrix $\mathbf{M}_\alpha$ of rank p. Similarly, if $4\ \mathbf{B}^{-1}$ is the variance–covariance

matrix for the random variables $\mathbf{x} - \hat{\mathbf{x}}$ with zero means, its rank is n, and thus

$$[29] \quad \langle \hat{S} \rangle = p - n = \left\langle \sum_k \tfrac{1}{2} \mathrm{tr}\,(\mathbf{A}_k{}^t\mathbf{A}_k) \right\rangle \Big/ \sigma^2$$

An estimate of the variance of an observation of unit weight is therefore

$$[30] \quad \hat{\sigma}^2 = \sum_k \tfrac{1}{2}\,\mathrm{tr}\,(\mathbf{A}_k{}^t\mathbf{A}_k)/(p - n)$$

and an unbiased estimate of $\mathbf{M}_x$ is

$$[31] \quad \hat{\mathbf{M}}_x = 4\hat{\sigma}^2\mathbf{B}^{-1}$$

Equations [23] and [29] are what one would expect by comparison with other least-square problems (6). It should be noted that p is the number of *pairs* of points $\mathbf{x}_k'$, $\mathbf{x}_k''$, or the number of tie-lines, and n is the number of dimensions, or one less than the number of thermodynamic components.

(d) *Multivariate Linear Hypothesis*

The theory of the least-squares triangle, as formulated above, is formally similar to general linear least-squares theory (6). The only differences are in the actual form of the defining equation for the parameters. This formal similarity means that all the results concerning the multivariate distribution function and the distribution properties of quadratic forms can be taken over directly. Only one result is of interest here, the test of the null hypothesis

$$[32] \quad \mathbf{x} = \mathbf{x}^0$$

where $\mathbf{x}^0$ is a set of theoretical parameters. The quantity to be tested is (6)

$$[33] \quad u = (\hat{\mathbf{x}} - \mathbf{x}^0)^t\hat{\mathbf{M}}_x{}^{-1}(\hat{\mathbf{x}} - \mathbf{x}^0)/n$$

and this quantity is distributed as $F_{n,\,p-n,\,\alpha}$ the F-distribution (14) for a significance level α. If the computed value of u exceeds $F_{n,p-n,\alpha}$ the hypothesis that the set $\hat{\mathbf{x}}$ is equal to the set $\mathbf{x}^0$ may be rejected at significance level α; otherwise, it may be accepted.

If a given value of F is chosen, then (cf. ref. 6, sect. 4–2)

$$[34] \quad (\mathbf{x} - \hat{\mathbf{x}})^t\hat{\mathbf{M}}_x{}^{-1}(\mathbf{x} - \hat{\mathbf{x}}) = nF_{n,p-n,\alpha} \equiv w$$

defines a hyperellipsoid of constant probability centred on $\mathbf{x} = \hat{\mathbf{x}}$. Setting $x_i - \hat{x}_i = \delta_i$ gives

$$[35] \quad \delta_1{}^2/\hat{\sigma}_1{}^2 + \delta_2{}^2/\hat{\sigma}_2{}^2 - 2\hat{\rho}_{12}\delta_1\delta_2/\hat{\sigma}_1\hat{\sigma}_2 = w(1 - \hat{\rho}_{12}{}^2)$$

as the equation of the projection of the hyperellipsoid on the (δ_1, δ_2) coordinate plane, where $\hat{\sigma}_1$, $\hat{\sigma}_2$ are the estimated standard deviations for parameters $\hat{x}_1$, $\hat{x}_2$ and $\hat{\rho}_{12}$ is the parameter correlation coefficient. The following properties of this ellipse are easy to establish, and permit a sketch to be made (compare ref. 6, p. 133). The ellipse is inscribed in a rectangle

$$[36] \quad \delta_1 = \pm w^{1/2}\hat{\sigma}_1,\ \delta_2 = \pm w^{1/2}\hat{\sigma}_2$$

The axis α of the ellipse makes an angle β with the δ_2-axis, where

$$[37] \quad \tan 2\beta = 2\hat{\rho}_{12}\hat{\sigma}_1\hat{\sigma}_2/(\hat{\sigma}_1{}^2 - \hat{\sigma}_2{}^2)$$

If $\hat{\rho}_{12} = 0$, $\beta = 0$; if $\hat{\sigma}_1 = \hat{\sigma}_2$ and $\hat{\rho}_{12} \neq 0$, $\beta = \pm 45°$. The sign of the angle in [37] is given by the sign of $\hat{\rho}_{12}\hat{\sigma}_2/\hat{\sigma}_1$, which is the slope of the ellipse at $\delta_1 = 0$, or the slope of the regression line of δ_2 on δ_1. Alternatively, the slope of the ellipse at $\delta_2 = 0$, or the slope of the regression line of δ_1 on δ_2, is $\hat{\sigma}_2/\hat{\rho}_{12}\hat{\sigma}_1$. The semi axes a and b of the ellipse are given by

$$[38] \quad a^2 = w(\hat{\sigma}_1{}^2\cos^2\beta + \hat{\sigma}_2{}^2\sin^2\beta + \hat{\rho}_{12}\hat{\sigma}_1\hat{\sigma}_2\sin 2\beta)$$

and

$$[39] \quad b^2 = w(\hat{\sigma}_1{}^2\sin^2\beta + \hat{\sigma}_2{}^2\cos^2\beta - \hat{\rho}_{12}\hat{\sigma}_1\hat{\sigma}_2\sin 2\beta)$$

where β is given by eq. [37]. The ellipse defined by these equations will be called the 100(1-α)% confidence ellipse. The probability that the true values x_1, x_2 lie within this ellipse is 100(1-α)%. The ratio of the axes of the confidence ellipse is $a/b = \hat{\sigma}_1/\hat{\sigma}_2$ if $\hat{\rho}_{12} = 0$ (when $\beta = 0$) and zero or infinite if $\hat{\rho}_{12} = 1$ (when $\tan\beta = -\hat{\sigma}_1/\hat{\sigma}_2$ or $\hat{\sigma}_1/\hat{\sigma}_2$). Thus for no correlation between the coordinates of the point of intersection, one axis of the ellipse is parallel to a coordinate axis, and the axial ratio is simply the ratio of the standard deviations. From eq. [22], zero correlation is highly unlikely, because for values of y_{1k} near a coordinate axis (and thus small), the correlation coefficient remains finite. Perfect correlation between the coordinates of the point of intersection occurs only if y_{1k} and y_{2k} are proportional, i.e., when the points $\mathbf{x}'$ and $\mathbf{x}''$ lie on a reference line. In general, finite correlation coefficients are therefore to be expected, and the confidence ellipse will be more elongated if all tie-lines are nearly parallel to a reference line.

For the extrapolation method, the coordinates of the points of intersection for a two-component system are proportional: $\hat{x}_2 = r_i M_i \hat{x}_1/M_1$ where r_i is the mole ratio of components i and 1 in the solid and M_i is the molar mass, and

$$[40] \quad \tan\beta = r_i M_i/M_1 \quad \text{or} \quad -M_1/r_i M_i$$

The confidence limits for the theoretical point of

intersection x_i constitute a straight line segment with slope β and extending between $\hat{x}_i - \hat{\sigma}_i\, t_{p-1,\alpha}/p^{\frac{1}{2}} < x_i < \hat{x}_i + \hat{\sigma}_i\, t_{p-1,\alpha}/p^{\frac{1}{2}}$, $i = 1, 2$. The experimental point of intersection lies on this line or on its extension.

(e) *Errors in and Distribution of Individual Data Points*

It is of interest to investigate how the variance–covariance matrix, eq. [23], depends on the separation of the solubility and wet residue points. To simplify the problem, consider the case where the ratio, L, of the distance between any pair of solubility and wet residue points to the distance between the solubility point and the theoretical point of intersection is constant. Thus, $\mathbf{y}_k = L\,(\mathbf{x}_k' - \mathbf{x})$, an equation that also holds for each coordinate component, but implies that all three points are collinear. To represent experimental data it is necessary to add a random error $\delta\mathbf{y}_k$ whose magnitude is determined by the errors in $\mathbf{x}_k'$ and $\mathbf{x}_k''$, but is independent of L:

$$[41] \quad \mathbf{y}_k = L(\mathbf{x}_k' - \mathbf{x}) + \delta\mathbf{y}_k$$

If $\delta\mathbf{y}_k \ll L\,(\mathbf{x}_k' - \mathbf{x})$, substitution of eq. [41] in eq. [23] shows that $\mathbf{M}_x$ is inversely proportional to L^2, while eq. [17] shows that $\hat{\mathbf{x}}$ is independent of L. Similar conclusions are found for the estimated variance–covariance matrix, $\hat{\mathbf{M}}_x$, eq. [31]. In particular, the contribution of the first term of eq. [41] to S (and also to $\hat{S}$; see eqs. [11], [18]) is zero, and there is a finite contribution to S which involves the products $\delta y_i \delta y_j$, $i, j = 1, \ldots, n$. It is expected, therefore, that the standard deviations of the parameter estimates are inversely proportional to L.

For the extrapolation method, the standard deviation in $\hat{x}_i$ can be calculated in terms of $\mathbf{x}_k'$ and $\mathbf{y}_k$, and it is also found, by use of eq. [41], to be approximately inversely proportional to L, while $\hat{x}_i$ itself is independent of L, under the condition $|\delta y_{2k} - r\delta y_{1k}| \ll L|x_{2k}' - r\,x_{1k}'|$, where r is the mole ratio of components 2 to 1 in the solid.

These predictions were all confirmed by computer simulations based on two different sets of six solubility points and a theoretical point of intersection which corresponded approximately to the experimental data used in the application section below. Values of $\delta\mathbf{y}_k$ were chosen as random numbers in the range ± 0.1, a choice which was found to simulate typical experimental data. Values of $\mathbf{y}_k$ were then calculated from eq. [41], and points of intersection were calculated using both the least-squares triangle and extrapolation methods for a series of values of L between 0.025 and 0.975. For $L \leq 0.1$, the parameter estimates themselves became unreliable. This behaviour is expected, since such small values of L cause both terms in eq. [41] to be of comparable magnitude. Again as predicted, standard deviations were independent of the distribution of data points relative to a reference line for the least-squares triangle method, but not for the extrapolation method.

Zero correlation among individual points $\mathbf{x}_k'$, $\mathbf{x}_k''$ is in accord with the way in which experiments are carried out, but correlations among the components of these points can arise. In a three-component system, if analyses in terms of masses of components 1 and 2 are carried out on the same weighed sample, there is a correlation (usually small) between the two mass fractions w_i. If mole fractions x_i are now calculated from these mass fractions, strong correlations automatically appear because of the occurrence of both w_1 and w_2 in the denominator of

$$[42] \quad x_i = w_i/M_i\{1/M_3 + w_1(1/M_1 - 1/M_3) + w_2(1/M_2 - 1/M_3)\}$$

where M_i is the molar mass of thermodynamic component i. For this reason, data analysis should be based on mass fractions rather than derived mole fractions (cf. ref. 10).

(f) *The Formula of the Solid*

For a three-component system, the data for the point of intersection can be used to calculate the formula of the solid in the form $A{\cdot}r_2B{\cdot}r_3C$ where

$$[43] \quad r_2 = x_2M_1/x_1M_2,\ r_3 = (1 - x_1 - x_2)M_1/x_1M_3$$

Using standard methods, the estimated variances in r_2 and r_3 are found to be:

$$[44] \quad \hat{\sigma}^2(r_2)/r_2^2 \simeq \hat{\sigma}_1^2/x_1^2 + \hat{\sigma}_2^2/x_2^2 - 2\hat{\sigma}_1\hat{\sigma}_2\hat{\rho}_{12}/x_1x_2$$

and

$$[45] \quad \hat{\sigma}^2(r_3)/r_3^2 \simeq \hat{\sigma}_2^2/x_3^2 + \hat{\sigma}_1^2(1/x_3 + 1/x_1)^2 + 2\hat{\rho}_{12}\hat{\sigma}_1\hat{\sigma}_2(1/x_3 + 1/x_1)/x_3$$

if component 1 has a coefficient of unity in the formula, or

$$[46] \quad \hat{\sigma}^2(r_3)/r_3^2 \simeq \hat{\sigma}_1^2/x_3^2 + \hat{\sigma}_2^2(1/x_3 + 1/x_2)^2 + 2\hat{\rho}_{12}\hat{\sigma}_1\hat{\sigma}_2(1/x_3 + 1/x_2)/x_2$$

if component 2 has a coefficient of unity in the formula, where $\hat{\sigma}_1$, $\hat{\sigma}_2$, and $\hat{\rho}_{12}$ are the least-square estimates of the standard deviations in the coordinates of the point of intersection and of the correlation coefficient.

Application and Discussion

Recent measurements (15) of solubilities and wet

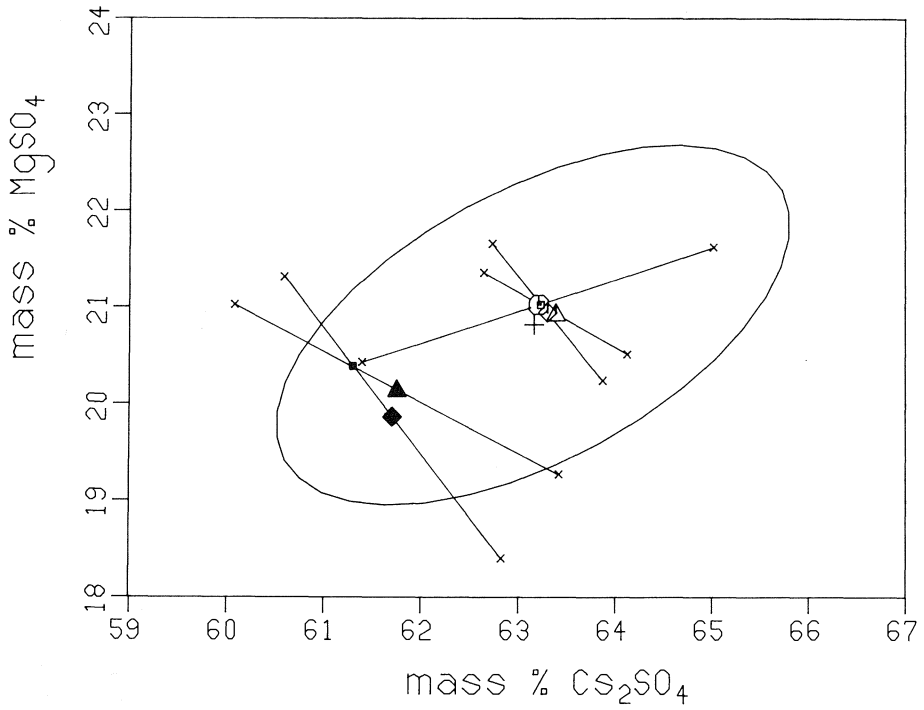

FIG. 3. The 95% confidence ellipses and confidence limits for formation of the compound $Cs_2SO_4 \cdot MgSO_4 \cdot r\ H_2O$ at 100°C. Theoretical solid compositions: ■, $r = 6$; □, $r = 5$. Calculated solid compositions: by least squares, +; by extrapolation, (a) assuming $Cs_2SO_4/MgSO_4 = 1{:}1$, ○; (b) assuming $H_2O/MgSO_4 = 6{:}1$, ▲; (c) assuming $H_2O/Cs_2SO_4 = 6{:}1$, ◆; (d) assuming $H_2O/MgSO_4 = 5{:}1$, △; (e) assuming $H_2O/Cs_2SO_4 = 5{:}1$, ◇. The 95% confidence lines for the extrapolation method each point to a vertex of the composition triangle, terminate in the points marked ×, and are centred on the extrapolated values. The confidence ellipse is centred on the least-squares value.

residue compositions for the system Cs_2SO_4–$MgSO_4$–H_2O will be used to illustrate use of the theory given above. The authors have tabulated data for 19 compositions of this system at 100°C. A plot of these data on a triangular diagram indicates four compositions which, from graphical intersection of tie-lines, appear to correspond to solutions saturated with respect to the solid phase $Cs_2SO_4 \cdot MgSO_4 \cdot 6H_2O$. All subsequent calculations are based on these original data (14) (given as mass fractions of Cs_2SO_4 and $MgSO_4$), and have been carried out using the author's computer program SOLUB, which is a general BASIC/MAXBASIC program for processing solubility data.

Matrices **B**, **C**, and scalar D are computed first, using eqs. [12]–[15], and have the values

$$\mathbf{B} = \begin{bmatrix} 234.227 & -216.085 \\ -216.085 & 1028.58 \end{bmatrix}$$

$$\mathbf{C} = \begin{bmatrix} 10296.2 \\ 7763.42 \end{bmatrix} \qquad D = 812060$$

Components 1, 2 are Cs_2SO_4, $MgSO_4$ respectively. The coefficients of the point of intersection of the tie-lines are, from eq. [17], $\hat{x}_1 = 63.16\ (0.53)$; $\hat{x}_2 = 20.82\ (0.25)$ mass%, with estimated standard deviations in parentheses, correlation coefficient $\hat{\rho}_{12} = 0.4402$ and overall standard deviation 3.643 (mass%)^2 (eqs. [30], [31]). The individual contributions to the area, eq. [6], are $2A_k = 5.540, -8.356, 2.141, 1.039$ (mass%)^2. If the theoretical point of intersection corresponds to $Cs_2SO_4 \cdot MgSO_4 \cdot 6H_2O$, then $x_1^0 = 61.30$, $x_2^0 = 20.39$ mass%, and the quantity $u = 6.186$ can be calculated from eq. [33]. From tables (14), the critical value of $F_{2,2,0.05} = 19.00$, so the hypothesis that the calculated point of intersection coincides with the theoretical point is acceptable at the 95% confidence level. The semi-axes of the 95% confidence ellipse are $a = 1.402$, $b = 2.923$ (eqs. [38], [39]), and a lies at an angle 28.8° with coordinate axis 2 (eq. [37]). Figure 3 shows this confidence ellipse centred on the calculated point of intersection. The calculated formula of the solid, with standard deviations in parentheses and component 2 as a reference, is 1.009 (0.011) $Cs_2SO_4 \cdot MgSO_4 \cdot$ 5.14 (0.27) H_2O, and suggests that a pentahydrate double salt would represent the solid phase equally well. This is in fact the case. The parameters are $x_1^0 = 63.23$, $x_2^0 = 21.03$, $u =$

0.396 (see Fig. 3). The authors have also analyzed a synthetic sample of the double salt, and found 45.32 mass% Cs, 4.120 Mg, 11.01 S (theory for hexahydrate: 45.03 Cs, 4.117 Mg, 10.86 S; for pentahydrate; 46.45 Cs, 4.247 Mg, 11.20 S). The analyses correspond more closely to the hexahydrate, and thus provide independent evidence for its existence.

If the same data are now analyzed by algebraic extrapolation, two cases are possible. (a) If the ratio $Cs_2SO_4/MgSO_4$ is fixed at unity, $\hat{x}_1 = 63.21$ (1.14), $\hat{x}_2 = 21.03$ (0.38) mass% (eq. [40]), and $t = 3.358$ using $x_1^0 = 61.30$, or $t = 0.027$ using $x_1^0 = 63.23$ mass%. The critical value of $t_{3,\,0.05} = 3.182$, so the pentahydrate is an acceptable formula at a 95% confidence level, but the hexahydrate is not. The calculated formula of the salt is $Cs_2SO_4 \cdot MgSO_4 \cdot 5.01$ (0.057) H_2O, and the 95% confidence limits on the theoretical values are $\pm$ 1.81 mass%. (b) If the ratio $H_2O/MgSO_4$ is fixed at 6, $\hat{x}_1 = 61.76$ (1.05), $\hat{x}_2 = 20.15$ (0.55) mass%, and $t = 0.863$ using $x_1^0 = 61.30$. If the ratio is 5, $\hat{x}_1 = 63.39$ (0.47), $\hat{x}_2 = 20.94$ (0.27), and $t = 0.668$ using $x_1^0 = 63.23$ mass%. Thus, both pentahydrate and hexahydrate are acceptable formulae at the 95% confidence level. The formula of the salt is 1.019 (0.045) $Cs_2SO_4 \cdot MgSO_4 \cdot 6H_2O$ or 1.007 (0.020) $Cs_2SO_4 \cdot MgSO_4 \cdot 5H_2O$.

Figure 3 illustrates the data given above, and includes as well the nonindependent points found by extrapolation, the 95% confidence limits for all extrapolated values, and the 95% confidence ellipse. The figure shows clearly that, in this case, much the same information can be obtained from either least squares or extrapolation. However, in all generality, the least-squares triangle gives a unique point of intersection and one confidence ellipse for each theoretical point of intersection. By contrast, the extrapolation method gives three independent points of intersection and three sets of confidence limits for the two theoretical values, and it is useful to examine all five different points of intersection and the corresponding confidence limits to obtain a complete picture of the results.

In summary, the least-squares triangle provides a convenient and unambiguous method of finding compositions of solid phases from solubility and wet residue or initial composition data which is free from the ambiguities and assumptions inherent in the extrapolation method. More generally, the least-squares triangle can be used to find the point of intersection of any family of straight lines, each member of which is determined by two points.

Ultrasonic dispersion studies in 3-methylcyclohexanone

BUDIDETI ANANDA REDDY AND NAGINENI PRABHAKARA RAO
Sri Venkateswara University Physical Laboratories, Tirupati 517 502, India

Received February 13, 1981

BUDIDETI ANANDA REDDY and NAGINENI PRABHAKARA RAO. Can. J. Chem. **59**, 3084 (1981).

Using a variable path interferometer, ultrasonic velocity dispersion in 3-methylcyclohexanone was studied in the temperature range 323.15 K to 363.15 K and in the frequency range 0.5 MHz to 5.0 MHz. The relaxation parameters were evaluated from the experimental data. These values were utilised to evaluate the energy parameters; the differences in the enthalpy (ΔH_0), the free energy (ΔG_0), and the entropy (ΔS_0) are 2.79 kcal/mol, 0.88 kcal/mol, and 5.9 cal/mol K, respectively. The enthalpy (ΔH_r) for the backward reaction was 7.63 kcal/mol.

BUDIDETI ANANDA REDDY et NAGINENI PRABHAKARA RAO. Can. J. Chem. **59**, 3084 (1981).

Utilisant un interféromètre à trajectoire variable on a étudié la vitesse ultrasonique de dispersion de la méthyl-3 cyclohexanone dans l'intervalle de temperature allant de 323,15 K à 363,15 K et à des fréquences variant de 0,5 à 5,0 MHz. A partir des données expérimentales, on a évalué les paramètres de relaxation. On a utilisé ces valeurs pour évaluer les paramètres énergétiques tels les variations d'enthalpie (ΔH_0), l'énergie libre (ΔG_0) et l'entropie (ΔS_0) qui sont respectivement 2,79 kcal/mol, 0,88 kcal/mol et 5,9 cal/mol/K. L'enthalpie (ΔH_r) de la réaction inverse est de 7,63 kcal/mol.

[Traduit par le journal]

Introduction

Ultrasonic relaxation phenomena have been studied in alicyclic compounds, mainly substituted cyclohexanes, by many workers (1–6) who suggested that the mechanism involved the perturbation of equilibrium by ultrasonic wave.

Physico-chemical (7) evidence indicates that the substituted cyclic compounds take mainly a chair configuration with the substituted atom in the equatorial position. This isomer is believed to be in equilibrium with another having a chair configuration and an axial substituent, the two isomers being rapidly interconvertible by a process often called ring inversion in which no bonds are broken. The energy difference between the two isomers could be evaluated from the measured variation with temperature of the magnitude of the dispersion. The barrier hindering rotation could be found from the associated variation of the relaxation frequency with temperature.

In the present work, the dispersion and the relaxation frequency for 3-methylcyclohexanone at different temperatures were calculated using ultrasonic velocity measurements. These values are used to evaluate the energy parameters.

Experimental

Ultrasonic velocities were measured using a variable path interferometer technique (8). To obtain the velocities at frequencies 0.5, 1, 2, 3, and 5 MHz, a tri-tet (9) crystal controlled rf oscillator was used to excite the quartz transducers of fundamental frequencies of 0.5, 1, and 2 MHz.

To obtain the measurements at different temperatures, the interferometer was immersed in a thermostatic water bath whose temperature could be maintained with an accuracy of ± 0.1°C. The accuracy in measurement of velocity is $\pm 0.003\%$.

3-Methylcyclohexanone was supplied by Riedel-Dehaen Ag seelze-Hanover and was of purity 97%.

Theory

The equilibrium between the equatorial and axial conformers is equivalent to a two state process of the kind $A \rightleftharpoons B$ with A having the lower energy. Such a two-state process is characterized by a single relaxation time and at any given temperature the ultrasonic relaxation arising from the perturbation of the above equilibrium is accompanied by a variation in velocity given by [1],

$$[1] \quad \frac{C_\infty^2 - C^2}{C_\infty^2 - C_0^2} = \frac{1}{1 + (f/f_r)^2}$$

where C is the velocity at frequency f, C_0 is the velocity at low frequency ($f \ll f_r$), C_∞ is the velocity at high frequencies ($f \gg f_r$) and f_r is the relaxation frequency.

If C_1, C_2, and C_3 are the velocities at 1, 2, and 3 MHz, respectively, substituting these values in [1] we get

$$[2] \quad C_\infty^2 = \frac{5C_2^2C_3^2 - 8C_1^2C_3^2 + 3C_1^2C_2^2}{8C_2^2 - 5C_1^2 - 3C_3^2}$$

Using the above equation C_∞ was calculated from the experimental data.

The equilibrium parameters ΔH_0, ΔG_0, ΔS_0, and ΔV_0, the differences in enthalpy, Gibbs free energy, entropy and volume, respectively, between 1 mol of axial and equatorial isomers are related to C_0 and C_∞ as follows (10).

$$[3] \quad F = (2C_p^2J(C_\infty - C_0)/\theta^2C_i^2RTM)^{1/2}$$

$$[4] \quad = \left(\frac{\Delta H_0}{RT} - \frac{\Delta V_0 C_p}{\theta V_0 RT}\right)\left[\frac{\exp(\Delta G_0/2RT)}{1 + \exp(\Delta G_0/RT)}\right]$$

Assuming ΔV_0 equals zero, [4] becomes

$$[5] \quad F = \frac{\Delta H_0}{RT}\frac{\exp(\Delta G_0/2RT)}{1 + \exp(\Delta G_0/RT)}$$

In these equations C_p is the molar specific heat capacity at constant pressure, J the conversion factor from joules to ergs, θ the thermal expansion coefficient, R the gas constant, T the absolute temperature, M the molecular weight, V_0 the molar volume, and C_i is equal to $(C_\infty + C_0)/2$. If ΔH_0 and ΔS_0 are both independent of the temperature, the algebraic solution of [5] is

$$[6] \quad \frac{\Delta G_0}{RT} = 2 \ln\left[\frac{(\xi_1 + 1) + [F_1^2 + (\xi_1 + 1)^2]^{1/2}}{F_1}\right]$$

and

$$[7] \quad \frac{\Delta H_0}{RT} = 2[F_1^2 + (\xi_1 + 1)^2]^{1/2}$$

where

$$\xi_1 = \frac{T_1}{F_1}\left[\frac{dF}{dT}\right]_1$$

In the above equation subscript 1 refers to the value for a given temperature T_1. The value of ΔS_0 was obtained from the relation

$$[8] \quad \Delta S_0 = (\Delta H_0 - \Delta G_0)/T$$

The slope of the plot of $1/T$ vs. $\log f_r$ yields the value of activation enthalpy for the backward reaction.

Results

For a single relaxation process at a given temperature and pressure, the shape of $\log(C_\infty^2 - C^2)$ vs. $\log f$ is independent of the numerical values of the relaxation parameters; i.e. f_r and $(C_\infty^2 - C_0^2)$. Hence a template of this theoretical curve with the relaxation frequency marked on it was made on transparent material. This template was moved parallel to the axis and the theoretical curves fitting the experimental data are shown in Fig. 1. The relaxation frequency was read directly from the graph. The value of the ordinate asymptote attained at $f \ll f_r$ as read from the graph gave values of $(C_\infty^2 - C_0^2)$. C_∞^2 was calculated using [2].

The velocity data measured at different frequencies from 0.5 MHz to 5.0 MHz and at different temperatures from 323.15 K to 363.15 K are presented in Table 1 and the relaxation parameters evaluated are

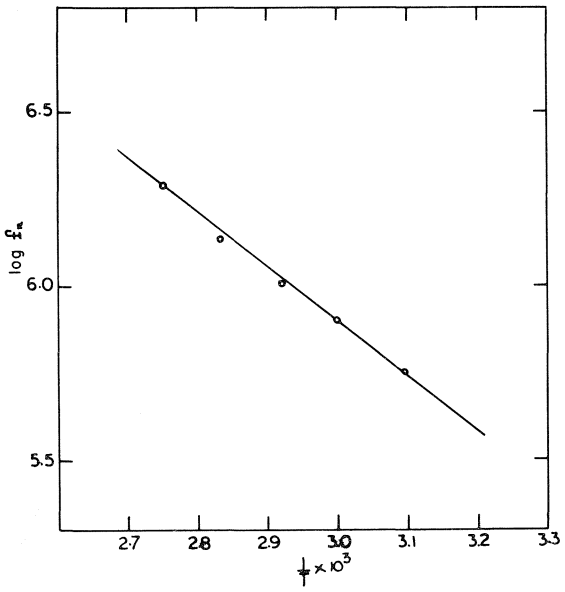

FIG. 2. Variation of $1/T$ vs. log f_r for 3-methylcyclohexanone.

given in Table 2. The plots of log $(C_\infty{}^2 - C^2)$ vs. log f at different temperatures and the plot of $1/T$ vs. log f_r for 3-methylcyclohexanone are shown in Figs. 1 and 2, respectively. The energy parameters ΔG_0, ΔH_0, and ΔS_0, the change in free energy, enthalpy and entropy between two isomers, evaluated from [6]–[8], are 0.88 kcal/mol, 2.79 kcal/mol, and 5.9 cal/mol K, respectively. The activation enthalpy for the backward reaction, calculated from the slope of the plot of $1/T$ vs. log f_r, was 7.63 kcal/mol.

Discussion

Replacement of the equatorial hydrogen atom by a methyl group at C_3 in cyclohexanone would set up additional steric repulsion, as a result of which the difference in energy between 3-methylcyclohexanones with equatorial and axial methyl should be less than the normal difference of 1.7 kcal/mol (11) between equatorial and axial methyl groups in cyclohexane. This supposed reduction in ΔG_0 was called the 3-methyl ketone effect (12) and was estimated to amount to about 0.85 kcal/mol (11). Therefore, in the present relaxation process the free energy of 0.88 kcal/mol between two isomers is in agreement with the above result. The relaxation frequency observed in 3-methylcyclohexanone is of the same order as that observed in substituted cyclohexanes (1, 2, 4). Hence the molecular mechanism in the present relaxation process may be attributed to ring inversion.

Photolysis of 5,5-dimethyl-4-phenyl-Δ^1-1,2,4-triazolin-3-one. Fragmentation to nitrogen, carbon monoxide, and isopropylidene phenyl amine

LUBOMIRA M. CABELKOVA-TAGUCHI AND JOHN WARKENTIN

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 2, 1980[1]

LUBOMIRA M. CABELKOVA-TAGUCHI and JOHN WARKENTIN. Can. J. Chem. **59**, 3087 (1981).

Photolysis of 5,5-dimethyl-4-phenyl-Δ^1-1,2,4-triazolin-3-one (**2**) produces the same products as thermolysis; namely, nitrogen, carbon monoxide, and isopropylidene phenyl amine (acetone anil). The quantum yield for direct photolysis of **2** in methanol with 313 nm light is 0.066. Sensitization with benzophenone in the same solvent, and quenching with 1,3-cyclohexadiene, revealed that photolysis of **2** involves a triplet excited state. The most likely photo processes are thought to involve initial cleavage of the C3—N4 bond or the C3—N2 bond (Norrish, type 1 cleavage).

LUBOMIRA M. CABELKOVA-TAGUCHI et JOHN WARKENTIN. Can. J. Chem. **59**, 3087 (1981).

La photolyse de la diméthyl-5,5 phényl-4 Δ^1 triazoline-1,2,4 one-3 (**2**) conduit aux mêmes produits que la thermolyse; soit en particulier, l'azote, le monoxyde de carbone et l'isopropylidene phénylamine (acétone anil). Le rendement quantique de la photolyse directe du composé **2** dans le méthanol à 313 nm est de 0,066. La sensibilisation avec la benzophénone dans le même solvant et le piégeage par le cyclohexadiène-1,3 indiquent que la photolyse du composé **2** implique un état excité triplet. On pense que les procédés photolytiques les plus communs font intervenir la rupture initiale de la liaison C3—N4 ou de la liaison C3—N2 (rupture de type I de Norrish).

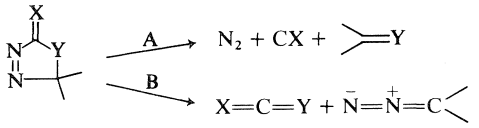
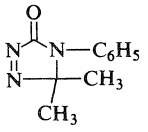
Introduction

The thermolysis behaviour of a number of 5-membered heterocyclic rings (**1**) has been reported (1–7). Some of them undergo competitive fragmentations according to paths A and B, eq. [1],[2] and the



[1]

1*a* X = Y = O
b X = N—N=CR_2, Y = O
c X = NAr, Y = O
d X = S, Y = NAr
e X = O, Y = NAr



2

diazoalkane fragment from path B can undergo subsequent reactions which have some synthetic utility (2, 3, 4).

Others fragment largely or exclusively by path A only[3] while still others fragment exclusively according to path B.[4] In view of this intriguing and potentially exploitable chemistry we became interested in finding out which pathway, A or B, is followed during photolysis or if photolysis actually involves a third set of products. To this end we chose to study 5,5-dimethyl-4-phenyl-Δ^1-1,2,4-triazolin-3-one (**2**).

Experimental

Compound **2**, prepared by oxidative cyclization of acetone-4-phenylsemicarbazone on alumina (7, 8), melted at 142–143°C (lit. (8) mp 143–144°C); uv (95% EtOH, λ_{max}, log ε): 275 nm (3.35), 375 nm (2.63); ^{1}H nmr (δ, $CDCl_3$) : 1.58 (s, 6H), 7.0–7.6 (m, 5H).

For product studies, **2** (0.15 g, 0.77 mmol) in methanol (50 mL, spectroscopic grade) was irradiated through quartz in a Srinivasan–Griffin Photochemical Reactor (Rayonet) fitted with 12 lamps (253.7 nm). The solution was purged with argon before and during irradiation and 1 mL aliquots were withdrawn at 1 h intervals to monitor the reaction. To an aliquot was added 1 mL of a stock solution of 1,3,5-trimethoxybenzene (**3**) in methanol, most of the solvent was evaporated with a rotary evaporator, and the height of the methyl singlet in the ^{1}H nmr spectrum of **2** was compared to that of the internal standard (**3**). After 5 h irradiation, when **2** could no longer be detected, the solution was divided into two parts, one of which was analyzed by glpc, which showed only acetone and aniline. The liquid residue left after removal of the volatile components, under vacuum, from the second portion, was examined by ^{1}H nmr, ir, and uv. All three spectra were those of aniline.

Quantum yield experiments were done with an optical bench and a Bausch and Lomb Model 33-86-01 high intensity monochromator fitted with an achromatic condenser lens and coupled to an Osram HBO 200 W super pressure mercury lamp[5] (9). The slits of the grating were set to give a band pass of 15 nm at 313 nm. Absorbances of ferrioxalate actinometry solutions

[1]Revision received July 16, 1981.

were determined with a Bausch and Lomb Precision Spectrophotometer, Model 33-26-50. The latter was calibrated by the procedure of Hatchard and Parker (10).

The concentration of **2** in aliquots was determined by ^{1}H nmr, using **3** as internal standard, by measuring peak heights. The latter were converted to concentrations using calibration charts prepared from standard solutions containing both **2** and **3**. Thus, irradiation for 10 h at 313 nm, with absorption of 7.3×10^{-4} Einstein of light, led to disappearance of 9.0 mg (4.8×10^{-5} mol) from a solution containing initially 39 mg (2.1×10^{-4} mol) of **2** in 13 mL of methanol, corresponding to a quantum yield of 0.066. A duplicate run gave the same value.

For benzophenone-sensitized photolysis, the solution cell contained 39 mg (2.1×10^{-4} mol) of **2** and 234 mg (1.29×10^{-3} mol) of benzophenone (Anal. Reagent, BDH) in a solution prepared with 13 mL of methanol. The quantum efficiency of conversion of ferrioxalate was taken to be 1.23.

Duplicate quantum yield determinations using ^{1}H nmr to monitor consumption of **2**, as described above, gave apparent values of 0.20 and 0.22. Correction of these for the fraction (ca. 1/3) of light absorbed by **2** under the experimental conditions gave a quantum yield of 0.3 for benzophenone-sensitized photolysis of **2**.

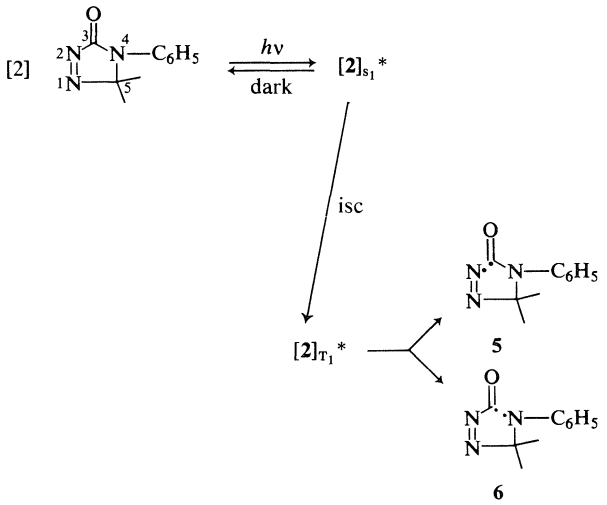
Analogous photolysis of **2** (39 mg, 2.1×10^{-4} mol) in the presence of freshly-distilled 1,3-cyclohexadiene (84 mg, 1.0×10^{-2} mol) and methanol (13 mL) for 10 h did not result in any detectable consumption of **2**.

Discussion

Previous work on the thermolysis of **2** showed that it fragments cleanly to nitrogen, carbon monoxide, and isopropylidene phenyl amine (7). However, the latter is very sensitive to hydrolysis and it was obtained free from acetone and aniline only if carefully dried hydrocarbon solvents were used (7). It was partly hydrolyzed during handling; for example, during analysis by glpc (7). Freshly prepared **4** was converted to acetone and aniline when small amounts of **4** were added to the methanol used in the present study. Since there is no straightforward mechanism for the clean formation of acetone and aniline as primary photoproducts from **2**, we conclude that **2** is converted to **4**, which is then hydrolyzed to the products observed.

The higher quantum yield for triplet-sensitized photolysis of **2**, compared to that for direct photolysis, and the suppression of direct photolysis by a known triplet quencher (1,3-cyclohexadiene) (11), indicates that **2** fragments from a triplet excited state. Since that triplet state can be populated by energy transfer from benzophenone triplets (E_t = 69 kcal mol^{-1}), it probably lies less than 69 kcal mol^{-1} above the energy of the ground state of **2**. Moreover, intersystem crossing (isc) (S → T) appears to be inefficient for **2**, since the quantum yield for triplet-sensitized fragmentation of **2** is between 4 and 5 times as large as that for direct photolysis.

Other conclusions are more tentative. The most likely intermediates, by analogy to the known



Norrish Type 1 cleavage of carbonyl compounds[6] are diradicals **5** and **6** (eq. [2]). A choice between **5** and **6** on the basis of the present results does not seem possible. Initial cleavage of the N1—C5 bond cannot be excluded either, but a fully-concerted process, involving simultaneous rupture of three bonds from the triplet state of **2**, is symmetry forbidden and can presumably be ignored as a possible mechanism.

From the standpoint of synthetic application, the photolysis of **2**, like its thermolysis, holds little promise. We plan to examine the photolysis of other members of the family **1**, in a search for sources of photogenerated heterocumulenes (eq. [1], path B).

Isotope effects in the diphenylpicrylhydrazyl-inhibited thermal polymerization of 2,6-dideuteriostyrene[1]

KARL R. KOPECKY AND MICHAEL C. HALL
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 6, 1981

KARL R. KOPECKY and MICHAEL C. HALL. Can. J. Chem. **59**, 3090 (1981).

There is an inverse isotope effect in the reaction between 2,2-diphenyl-1-picrylhydrazyl DPPH and 2,6-dideuteriostyrene of 0.75 ± 0.07 at 75°C in degassed neat styrene. This result is consistent with the proposal that the reaction involves hydrogen transfer to DPPH from a Diels–Alder dimer of styrene. The rate constant for dimerization of styrene to this dimer is calculated to be 1.8×10^{-10} L mol^{-1} s^{-1} at 75°C.

KARL R. KOPECKY et MICHAEL C. HALL. Can. J. Chem. **59**, 3090 (1981).

Lors de la réaction entre le diphényl-2,2 picryl-1 hydrazyle (DPPH) et le dideutéro-2,6 styrène dégasé agissant comme solvant il y a un effet isotopique inverse de $0,75 \pm 0,07$ à 75°C. Ce résultat est en accord avec la proposition qui stipule que la réaction fait intervenir un transfert d'hydrogène du dimère de Diels–Alder du styrène au DPPH. On a calculé que la constante de vitesse de dimérisation du styrène est de $1,8 \times 10^{-10}$ L mol^{-1} s^{-1} à 75°C.

[Traduit par le journal]

Introduction

The rate of initiation of the polymerization of styrene can be calculated (1) from eq. [1]

[1] $$R_p^2 - R_{p,th}^2 = k_p^2[M]^2R_i/2k_t$$

where R_p is the total rate of polymerization, $R_{p,th}$ is the rate of thermal polymerization, k_p and k_t are the rate constants for propagation and termination, respectively, [M] is the monomer concentration, and R_i is the rate of initiation due to monoradical producing catalysts (initiators). For moderate concentrations of initiators $R_{p,th}$ may be neglected and eq. [1] reduces to eq. [2].

[2] $$R_p^2 = k_p^2[M]^2R_i/2k_t$$

DPPH

In the presence of the stable free radical 2,2-diphenyl-1-picrylhydrazyl, DPPH, there is an induction period during which no polymerization occurs and DPPH is consumed. The rate of disappearance of DPPH, R_{DPPH}, is equal to the value of R_i determined from eq. [2] (2). In the absence of added initiator DPPH still inhibits the thermal polymerization of styrene (3) and is consumed in a zero order process above a concentration of $\sim 1 \times 10^{-4}$ *M* at 60°C. Under these conditions R_{DPPH} is 1.1×10^{-8} *M* s^{-1} (3*a*). This is 85 times greater than the calculated rate of the thermal initiation of radicals, $R_{i,th} = 1.3 \times 10^{-10}$, which can be obtained from eq. [3] (3*a*).

[3] $$R_{p,th} = k_p^2[M]^2R_{i,th}/2k_t$$

The tentative explanation for this discrepancy proposed that a small fraction of the 1,4-diphenyl-1,4-butadiyl diradical **1**, reaction [4], which had

[4] 
1

been suggested earlier (1) to be responsible for the thermal initiation, is intercepted by DPPH. However, **1** cyclizes too rapidly to be involved in the formation of high polymer (4) and it is unlikely that it could be scavenged by the low concentration of DPPH used.

The inhibition by DPPH of the thermal polymerization might be accounted for in terms of the currently accepted mechanism for the thermal initiation, reactions [5]–[7] (5), where $M_n\cdot$ is a growing polymer chain.

In this mechanism hydrogen atom transfer from the reversibly formed styrene Diels–Alder dimer **2** to a third styrene molecule results in the formation of a pair of radicals, some of which initiate polymer chains. On the basis of this mechanism for the thermal initiation the inhibition by DPPH occurs as the result of hydrogen atom abstraction from the Diels–Alder adduct **2**, reaction [8] (6), to produce the radical **3**

[8] DPPH + **2** → **3** + DPPH—H

[9] DPPH + **3** → products

and the hydrazine DPPH—H. The radical **3** would then consume a second DPPH, reaction [9].

The present study was undertaken to test this proposal by determining the isotope effect in the thermal reaction between DPPH and styrene using 2,6-dideuteriostyrene. The accompanying paper reports the products of the reaction (7).

Results

The rates of disappearance of DPPH in both normal styrene and in 2,6-dideuteriostyrene (91.7 mol% styrene-d_2, 8.3 mol% styrene-d_1, prepared as previously described (8)), Table 1, were initially zero order with respect to DPPH, Fig. 1. The point at which the rates deviated from zero order dependence varied with the initial concentration of DPPH and was $\sim 7 \times 10^{-5}\,M$ DPPH in ordinary styrene when the initial DPPH concentration was $1.8 \times 10^{-4}\,M$, and $\sim 2 \times 10^{-4}\,M$ DPPH in the styrene-d_2 when the initial concentration of DPPH was $7 \times 10^{-4}\,M$. The rates were monitored by following the decrease in absorption of DPPH at 525 nm in degassed, neat styrene at 75°C. The rate of disappearance of DPPH in a sample of synthetic styrene prepared by the route used for the preparation of the deuterated material was the same as that in purified commercial styrene. The rate is quite reproducible and the average value, 2.42×10^{-8} mol $L^{-1}\,s^{-1}$, compares with a value 30% greater than this 3.19×10^{-8} mol $L^{-1}\,s^{-1}$ at 75°C, as estimated from a figure given in the original study (3*a*). The reason for this discrepancy is not known, but the rate of disappearance of DPPH is sensitive to oxygen (3*a*) and presumably to other impurities.[2]

In the deuterated styrene the rate was found to be significantly greater, $R'_{DPPH} = 3.19 \times 10^{-8}$ mol $L^{-1}\,s^{-1}$, than in normal styrene. Correcting (9) for isotopic purity, the isotope effect R_{DPPH}/R'_{DPPH} is 0.75 ± 0.07.

Discussion

The isotope effect found here for the disappearance of DPPH in styrene in the absence of added initiators lends support to the proposal (6) that reactions [5] and [8] are involved in which the first formed Diels–Alder dimer of styrene **2** suffers hydrogen atom transfer to DPPH to produce the radical **3** and DPPH—H as initial products. Further support results from a product study of the reaction (7). The order of the reaction with respect to styrene was not determined in this work but the original report (3*a*) that the reaction is second order with respect to styrene has been confirmed (10). In this sequence of reactions hydrogen atom transfer to DPPH will be the fast step since the rate of disappearance of DPPH obeys a zero order dependence on the concentration of DPPH. The formation of the Diels–Alder adduct **2** will then be the rate determining step, and the isotope effect observed is the isotope effect for formation of **2**. The inverse isotope effect that is found for this reaction is consistent with what is expected for the effect of deuterium substitution on a carbon atom which is undergoing sp^2 rehybridization during the

[2]A referee has suggested that a possible reason for this discrepancy is the fact that the earlier work was done before it was recognized that DPPH complexes with solvents and that DPPH was not purified nor freed from complexed solvent.

course of the reaction (9, 11). While the magnitude of the inverse isotope effect found here is greater than usually observed for cycloaddition reactions, $k_H/k_D \sim 0.85$–0.95 per deuterium (10), it is still well within the maximum predicted for an inverse secondary isotope effect of 0.46 (12).

Since two DPPH radicals are consumed each time a molecule of **2** is intercepted the rate of formation of **2** is $(1/2)R_{DPPH}$ or 1.2×10^{-8} mol L^{-1} s^{-1} at 75°C. The rate constant k_5 for the dimerization of styrene to **2** is then 1.8×10^{-10} L mol^{-1} s^{-1} (calculated using a value of 0.855 for the density of styrene at 75°C (12)).[3] This value is in good agreement with the value of 7×10^{-11} L mol^{-1} s^{-1} at 64°C which was obtained by monitoring the increase at 320 nm of an absorption in neat styrene that was attributed to the dimer **2** (13).

The factor of 85 between R_{DPPH} and $R_{i,th}$ at 60°C can be explained in terms of reactions [5] to [9] (10). In the presence of sufficient DPPH all the molecules of **2** are consumed by reaction [8] as soon as they are formed. In the absence of DPPH only a small fraction of the **2** molecules formed will initiate polymerization. Several reactions occur that make **2** a very inefficient initiator. In the mechanism considered here $R_{i,th}$ is given by eq. [10],

$$[10] \quad R_{i,th} = 2k_5k_6f[M]^3/(k_{-5} + \Sigma k_s)$$

[3]This should be a minimum number for the value of k_5. There will be some reaction in the original solvent cage between **3** and DPPH—H to produce DPPH and 1-phenyl-1,2,3,4-tetrahydronaphthalene. Thus less than 1 mole of DPPH is consumed for each mole of **2** that is intercepted. When the concentration of DPPH—H is great enough it can compete with DPPH for **3** outside the solvent cage as well. This results in a decrease in the rate of disappearance of DPPH after a time which depends upon the initial concentration of DPPH.

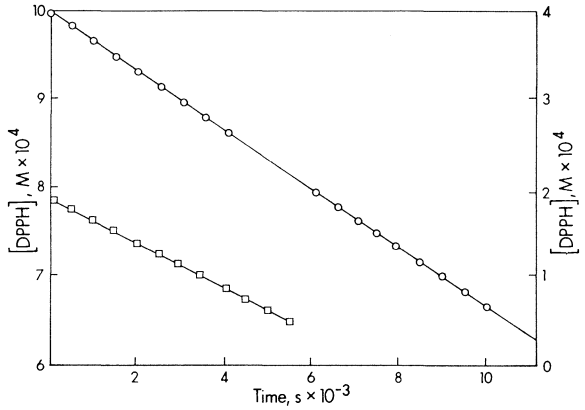

FIG. 1. Disappearance of DPPH in normal (□) and in 2,6-dideuteriostyrene (○).

where k_5 and k_{-5} are the rate constants for formation of **2** and for reversion of **2** to styrene, respectively, k_6 is the rate constant for hydrogen atom transfer from **2** to styrene, Σk_s is the sum of the rate constants for other reactions that consume **2** and f is the fraction of the radicals which are formed according to reaction [6] that reacts with styrene to form growing polymer chains, reaction [7*a*]. With the radical initiator azoisobutyronitrile only 50–55% of the radicals produced react with styrene to initiate polymerization (14). The remainder undergoes coupling and disproportionation within the solvent cage. The radical pair produced according to reaction [6] will undergo coupling and disproportionation reactions to a greater extent than that from azoisobutyronitrile because the former is born without an intervening nitrogen molecule. This leaves a smaller fraction left to initiate polymerization. An alternate route to the trimer of

For personal use only.

reaction [7*c*] is an ene reaction between styrene and **2** (15) which would, of course, divert some more of **2** from initiation. Another contributor to the inefficiency of **2** as an initiator is the reversal of the reaction that forms **2**. The overall rate of initiation is third order in styrene which requires that most **2** formed must revert to monomer (6). Another reaction which will divert **2** from initiating polymerization is hydrogen atom transfer to a growing polymer chain (16). Although it is not possible to assess quantitatively the effect of these reactions on the efficiency of **2** as an initiator it is clear qualitatively that only a small fraction of **2** formed will initiate polymer chains.

A more quantitative assessment may be made as follows. The consumption of two molecules of DPPH for each molecule of **2** formed in the presence of DPPH accounts for 50% of the discrepancy between R_{DPPH} and $R_{i,th}$. This leaves a factor of 42 which is the difference between the rate of formation of **2** and $R_{i,th}$ at 60°C. Thus, only about 1.2% of the molecules of **2** that are formed actually initiate polymerization (two radicals are formed from each molecule of **2**). This is in excellent agreement with the value of 1.1% which was obtained recently using a different analysis (17). In this analysis the fraction of **2** that reacts to produce polymer chains was calculated from the ratio of the rate of thermal initiation of polymerization (3*a*) over the rate of disappearance of **2**. The latter value was based on the steady-state concentration of **2** as determined from the steady-state absorption at 320 nm (attributed to **2**) in the thermal polymerization. This absorption builds up in the initial stages of the polymerization and on this basis it was calculated (17) that the instantaneous rate of polymerization should increase during the first few hours of reaction. The values of $R_{p,th}$ at 0.25, 0.5, 1.0, and 1.5 h were calculated to be about 0.5, 0.75, 1.03, and 1.22×10^{-6} mol L^{-1} s^{-1}, respectively, at 60°C. As was pointed out, this change in rate should be detectable experimentally. However, this was not observed in a study of the rate of the thermal polymerization of styrene and some deuterated styrenes (8). The rates were measured accurately using a dilatometer. Although a changing rate of polymerization during the initial stages of polymerization was not sought at that time a review of the data shows that all rates were followed from 0.25 or 0.5 h after the dilatometer was placed in the constant temperature bath for a total of 8 to 12 h. In several runs measurements were made initially at 0.25 h intervals and at 0.5 h intervals in all other runs. There was no change in the rate of polymerization in the initial 1 to 2 h period in any of the 40 runs that were made (except for several runs in which the rate appeared to be variable for several hours) and the rates were linear for the entire time during which they were followed. The reason for the discrepancy between the predicted and observed initial rates is not clear.

While the evidence that **2** is the critical intermediate in the thermal initiation seems compelling it must be pointed out that 5-methylene-1,3-cyclohexadiene, prepared as a model for **2**, does not initiate styrene polymerization (15, 17) although it does react rapidly with styrene in an ene reaction. A possible explanation for the discrepancy in the behaviour of **2** and the model compound has been offered (17), and other model compounds do initiate styrene polymerization (18).[4]

Experimental

General

Mass spectra were obtained on an A.E.I. model MS-9 mass spectrometer using an ionizing voltage of 10.5 eV.

All glassware used in the distillation of monomer and in kinetic measurements was cleaned in a mixture of concentrated nitric and sulfuric acids, 1:3, washed thoroughly with distilled water, placed in ammonium hydroxide solution for several hours, washed with distilled water, and finally dried at 110°C. The cuvette used for kinetic measurements was washed with benzene and rinsed with acetone after each run prior to the neutralization procedure.

The method previously described (8) was used to prepare 2,6-dideuteriostyrene. It was stored under nitrogen at 0°C.

Commercial styrene was freed from inhibitor by washing three times with an equal volume of 10% sodium hydroxide and then with saturated aqueous sodium chloride until free from alkali. The styrene was dried with magnesium sulfate and distilled through a 12 in Vigreux column at 41°C (14 Torr) in a current of nitrogen. A middle cut was collected and stored under nitrogen at 0°C. For the kinetic runs samples of normal and deuterated styrene that had been freshly distilled through a 12 in. Vigreux column in a stream of nitrogen were used.

DPPH was recrystallized by dissolving 50 mg in a minimum amount of benzene, adding a few drops of purified ($KMnO_4$) ligroin and allowing the resulting solution to stand in an open flask. After a day the crystals were filtered and dried under vacuum for 8 h to give 45 mg bright, violet crystals, mp 128–129°C (lit. (20) mp 127–129°C for a 1:1 DPPH-benzene complex).

---

[4]Citing unpublished work it is reported in an excellent review article (19) that there is a normal isotope effect, R_{DPPH}/R'_{DPPH}, of 2 when the rate of disappearance of DPPH in 2,3,4,5,6-pentadeuteriostyrene was compared with that in styrene. It was concluded that this isotope effect resulted from the abstraction of a hydrogen atom from a position originally in the phenyl ring in the rate-determining step and supported the proposal that the reaction involves hydrogen atom abstraction from **2** by DPPH. However, this result is not compatible with the results of the present study. Also, since the reaction is zero order in DPPH it is impossible for the hydrogen abstraction step to be rate determining, as is pointed out in the present paper. Thus, the dimerization of styrene to give **2** must be rate determining and a primary isotope effect is not to be expected. An inverse secondary isotope effect should result as is reported in the present paper.

Kinetics

A solution of DPPH in spectro grade benzene was placed in a reservoir that was attached to a glass tube which also had attached to it a 0.1 mm cuvette and another reservoir for styrene. This apparatus was then sealed onto a high vacuum rack and the benzene was evaporated under 0.2 Torr pressure. The styrene reservoir was removed, filled with 2.0 mL styrene, and resealed to the apparatus. The styrene was degassed by three freeze–thaw cycles under 0.01 Torr pressure and then distilled into the DPPH reservoir. The styrene reservoir was sealed off and the resulting solution was degassed once more, allowed to warm to 22°C, and inverted into the cuvette. The cuvette was placed into a Bausch and Lomb dual cell constant temperature cell holder kept at 75.0°C in a Bausch and Lomb Spectronic 600 Spectrophotometer. The reaction was followed by the decay in the absorbance at 525 nm of DPPH. The rate of decomposition of DPPH is less than 0.1%/h under these conditions (7). Small corrections were made to the rates for the absorption of DPPH—H type molecules formed in the reaction. It was assumed that no DPPH—H was present initially and that all the DPPH which reacted was converted into DPPH—H type molecules. At 525 nm ε = 500 and 11 900 for DPPH—H and DPPH, respectively. Initial concentrations of DPPH were determined from the initial absorbance readings.

Products of reaction between styrene and some radicals with 2,2-diphenyl-1-picrylhydrazyl[1,2]

KARL R. KOPECKY AND MICHAEL C. HALL

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 6, 1981

KARL R. KOPECKY and MICHAEL C. HALL. Can. J. Chem. **59**, 3095 (1981).

Addition of 2,2-diphenyl-1-picrylhydrazyl DPPH to styrene at 75°C results in little change in the amounts of *cis*- and *trans*-1,2-diphenylcyclobutane and 1,2,3,4-tetrahydro-1-phenylnaphthalene, in a slightly smaller amount of 1-phenylnaphthalene, and in a considerable increase in the amount of 1,2-dihydro-1-phenylnaphthalene that are formed. Formation of the styrene trimer 1,2,3,4-tetrahydro-1-phenyl-4-(1-phenylethyl)naphthalene is eliminated completely. Products derived from DPPH are 1-(4-nitrophenyl)-1-phenyl-2-picrylhydrazine **9** and 1-[2,6-dinitro-4-(1,2,3,4-tetrahydro-4-phenyl-1-naphthyl)phenyl]-2,2-diphenylhydrazine, **10**. DPPH intercepts the thermally formed Diels–Alder dimer of styrene as soon as it is formed to give the 1,2,3,4-tetrahydro-4-phenyl-1-naphthyl radical.

Thermolysis of bis(1,2,3,4-tetrahydro-4-phenyl-1-naphthyl)diazene in the presence of DPPH yields 20% of **10**, 10% of 1-[2,6-dinitro-4-(1,2,3,4-tetrahydro-4-phenyl-1-naphthyl)phenyl]-2-(4-nitrophenyl)-2-phenylhydrazine and **9** while thermolysis of 1,2-bis(1-phenylethyl)diazene in the presence of DPPH yields **9** and 44% of 1-[2,6-dinitro-4-(1-phenylethyl)phenyl]-2,2-diphenylhydrazine showing that substituted benzyl radicals efficiently displace the 4-nitro group of DPPH. The nitro group is transferred to an unsubstituted phenyl group of DPPH.

KARL R. KOPECKY et MICHAEL C. HALL. Can. J. Chem. **59**, 3095 (1981).

L'addition du diphényl-2,2 picrylhydrazyle (DPPH) au styrène à 75°C ne change que faiblement les quantités de diphényl-1,2 cyclobutane *cis* et *trans* et de tétrahydro-1,2,3,4 phényl-1 naphtalène, mais conduit à une quantité légèrement plus faible de phényl-1 naphtalène et à une augmentation considérable de dihydro-1,2 phényl-1 naphtalène. On élimine complètement la formation du trimère du styrène, le tétrahydro-1,2,3,4 phényl-1 (phényl-1 éthyl)-4 naphtalène. Les produits obtenus à partir du DPPH sont la (nitro-4 phényl)-1 phényl-1 picryl-2 hydrazine (**9**) et la [dinitro-2,6 (tétrahydro-1,2,3,4 phényl-4 naphtyl-1)-4 phényl]-1 diphényl-2,2 hydrazine (**10**). Le DPPH intercepte le dimère du styrène, formé thermiquement selon une réaction de Diels–Alder au fur et à mesure qu'il se forme en donnat le radical tétrahydro-1,2,3,4 phényl-4 naphtyl-1.

La thermolyse du bis(tétrahydro-1,2,3,4 phényl-4 naphtyl-1) diazène en présence du DPPH conduit à 20% du composé **10** et à 10% de [dinitro-2,6 (tétrahydro-1,2,3,4 phényl-4 naphtyl-1)-4 phényl]-1 (nitro-4 phényl)-2 phényl-2 hydrazine et au composé **9** tandis que la thermolyse du bis(phényl-1 éthyl)-1,2 diazène en présence de DPPH conduit au composé **9** et à 44% de [dinitro-2,6 (phényl-1 éthyl)-4 phényl]-1 diphényl-2,2 hydrazine montrant ainsi que le radical portant un substituant benzyle déplace efficacement le groupe nitro du DPPH. Le groupe nitro est transféré au group phényl non substitué du DPPH.

[Traduit par le journal]

Introduction

The generally accepted mechanism for the thermal initiation of the polymerization of styrene is given by reactions [1]–[3] (1), where $M_n^{\cdot}$ is a growing polymer chain. According to this mechanism hydrogen atom transfer from the reversibly formed Diels–Alder dimer **1** of styrene to a third molecule of styrene yields a pair of radicals, a fraction of which initiate styrene polymerization. The radical pair also undergoes coupling and disproportionation reactions. The products **3**, **4**, and **5** of these reactions have been isolated from thermolysis of styrene as have the isomeric 1,2-diphenylcyclobutanes, *cis*- and *trans*-**6** and 1-phenylnaphthalene (1, 2).

The stable free radical 2,2-diphenyl-1-picrylhydrazyl DPPH inhibits the thermal polymerization and is consumed during the inhibition period (3). The rate of disappearance of DPPH is ~ 85 times the rate of the thermal initiation of polymer chains at 60°C (3*a*), is zero order with respect to DPPH in styrene, and is second order with respect to styrene in benzene or toluene (3*a*, 4). It has been proposed that DPPH intercepts the dimer as soon as it is formed (1*b*, 5). Presumably the initial products of this reaction would be those resulting from hydrogen atom transfer, 1,1-diphenyl-2-picrylhydrazine DPPH—H and **2**, reaction [4]. Consistent with this proposal is the finding of an inverse isotope effect, $k_H/k_D = 0.75$, on the rate of disappearance of DPPH in 2,6-dideuteriostyrene (6). The radical **2** would then consume a second molecule of DPPH, reaction [5].

The present study was undertaken to determine the effect of DPPH on the distribution of the dimers and trimers formed during the thermal polymerization (2, 7), and to identify the products from the DPPH that has been consumed. Products of the reaction between DPPH and the two radicals

1-phenylethyl and **2**, generated by thermolysis of the appropriate diazenes, were also identified.

Results

DPPH in Styrene

The relative yields, Table 1, of dimeric compounds that were formed on heating pure styrene and styrene containing 1% DPPH, both degassed, at 75°C for 72 h were determined by gas chromatography (gc). Not all the DPPH was consumed under these conditions. Styrene dimers were separated from DPPH and its derivatives by column chromatography on silica gel. The relative amounts of *cis*- and *trans*-**6** were essentially the same and these compounds were formed in qualitatively the same yield in the presence as in the absence of DPPH. In the presence of DPPH relatively much more **3** and somewhat less **7** were produced than in the absence of DPPH. This effect of DPPH on the formation of **3** has been observed before (*7b*, *c*, *d*). Very similar amounts of **4** were formed in the two experiments. A small amount of an unknown material, possibly 1,3-diphenyl-1-butene (*7a*), that eluted from the gc just before *cis*-**6** was formed in the uninhibited

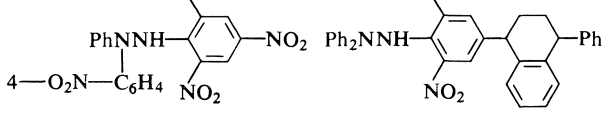
reaction, but was not formed at all in the presence of DPPH. Also, material, presumably the styrene trimer **5** (2*d*), with a much longer retention time than those of the dimeric products was formed in the absence of DPPH, but could not be detected among the products formed in the presence of DPPH.

It has been found in previous studies, Table 1, that *trans*-**6** predominates over *cis*-**6** and that the formation of these compounds is not suppressed in the presence of DPPH (7). The relative amounts of **4** formed vary considerably among the various studies and has been found to be as low as 2% (2*d*), as in the present work, to as high as 70% (2*a*) of the total dimeric fraction. The greater amounts of **4** formed in some experiments must result from isomerization of the initial dimer **1** by adventitious acid. A model of **1**, 5-methylene-1,3-cyclohexadiene **8**, has been found to be extremely sensitive to acid and is isomerized to toluene, reaction [6] (8).

[6] 
8

The finding that similar amounts of **4** are formed in the presence and in the absence of DPPH is in contrast to an earlier report that the formation of **4** is completely suppressed by DPPH (7*b*, *c*, *d*).

The products derived from DPPH were isolated from a larger scale run by column chromatography followed by preparative tlc. Three main fractions were isolated: 21% of 1-(4-nitrophenyl)-1-phenyl-2-picrylhydrazine, **9**, 5% of 1-[2,6-dinitro-4-(1,2,-3,4-tetrahydro-4-phenyl-1-naphthyl)-phenyl]-2,2-diphenylhydrazine, **10**, and 50% DPPH—H. The



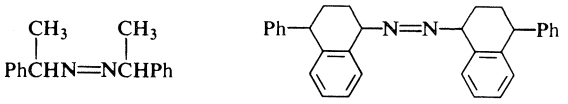
9 **10**

yields are based on starting DPPH and the products isolated represent 76% of the initial DPPH. The amount of **10** isolated from heating 100 mL of styrene with DPPH for 30 h at 75°C was 0.04 g. Compounds **9** and **10** were identified as described below. A large number of other compounds derived from DPPH was formed as evidenced by colored bands on the chromatogram but all were present in very small amounts and were not identified.

The Radicals 2 and 1-Phenylethyl with DPPH

To aid in the identification of the products derived from reaction of DPPH in styrene the product analyses of the decomposition of the diazenes **11** and **12** in the presence of DPPH were carried out.

Degassed benzene solutions 0.4 *M* in **11** and 1.6 *M* in DPPH or 0.6 *M* in **12** and 1.2 *M* in DPPH were heated at 84°C for 72 h, about 4 half-lives of decomposition for **11** (9). Initial product studies were made on the products derived from **11** which generates the 1-phenylethyl radical which might give products that are easier to identify than the products derived from **12** which generates the radical **2**.



11 **12**

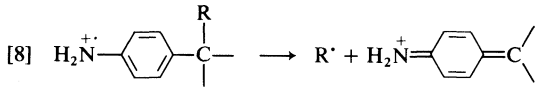
The determination of the structures of the DPPH—1-phenylethyl products was greatly facilitated by the fortuitous discovery that appreciable amounts of volatile N—N cleavage products were formed at high temperature in the gc. In a preliminary attempt to measure the scavenger efficiency of DPPH under these conditions and to estimate the cage effect in the thermolysis of **11** by this method a sample of the reaction mixture from thermolysis of **11** was analyzed by gc at 220°C column temperature. Four compounds designated **A**, **B**, **C**, and **D** in order of increasing retention time, were eluted after the radical coupling products *meso*- and *dl*-2,3-diphenylbutane. Injection of a benzene solution of DPPH into the gc also resulted in formation of **A**, **B**, and **C**, but not **D**, indicating that **D** might be derived from a DPPH—1-phenylethyl radical adduct. The thermal decomposition of DPPH has not been reported, but it has long been known that tetraphenylhydrazine decomposes to diphenylamine **13** among other products (10). By analogy thermolysis of DPPH and of DPPH—H might yield **13** and 2,4,6-trinitroaniline, reaction [7].

[7] 
13 **14**

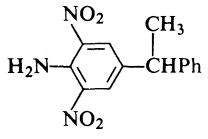
Compounds **A** and **B** were identified as **13** and **14**, respectively, **A** by coinjection of authentic **13** with the reaction mixture, and **B** by isolation from the effluent of the gc and comparison of this with authentic **14**. The compounds **C** and **D** were analyzed by mass spectrometry as they eluted from the gc. The mass spectrum of **C** has a parent peak at *m/e* 214 and was identical with that (11) of 4-nitrodiphenylamine. The mass spectrum of **D** has a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

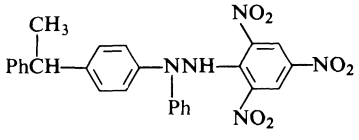
parent peak at *m/e* 287 and prominent peaks at *m/e* 272 ($M^{+\cdot} - 15$), 180 ($M^{+\cdot} - 107$) and 152 ($M^{+\cdot} - 135$). The odd molecular weight indicates that **D** contains an odd number of nitrogen atoms. The peak at *m/e* 180 is attributed to a fragment that has lost a methyl and two nitro groups. The most intense peak is at *m/e* 272 which indicates loss of a methyl group. Other small peaks correspond to ($M^{+\cdot} - 17$) and ($M^{+\cdot} - 48$) which, by analogy to the cracking pattern of 2,4,6-trinitroaniline, suggests that **D** has an amino group with two *ortho* nitro groups on an aromatic ring. The ready loss of methyl indicates the presence of a benzylic carbon, perhaps *para* to the amino group, which bears a methyl group. Such compounds readily undergo loss of benzylic substituents to give a quinoid species (12), reaction [8].



This prompted the assignment of the structure of 2,6-dinitro-4-(1-phenylethyl)aniline **15** to **D**. The mass spectrum of authentic **15**, prepared as shown in Scheme 1, was identical with that of **D**.



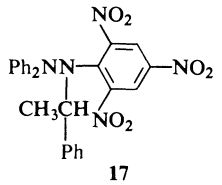
15



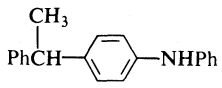
16

These results indicate that 1-phenylethyl radicals couple with DPPH at the 4-position of the picryl ring with displacement of a nitro group which then becomes attached to the 4-position of the phenyl group of DPPH or a substituted DPPH. However, capture of a variety of radicals by DPPH had previously been proposed to take place either at the 4-position of the phenyl ring or at the radical nitrogen atom in every instance studied (13). If this occurred with the 1-phenylethyl radical the hydrazines **16** or **17** would be formed which would cleave under the gc conditions to yield either the diphenylamine **18** or the N-substituted picramine **19**. Authentic samples of **18** and **19** were prepared but no materials with similar retention times could be detected by gc of the reaction mixture of the thermolysis of **11** in the presence of DPPH. Thus, the DPPH–radical adducts formed from thermolysis of **11** and **12** should have the structures **20** and **10**, respectively.

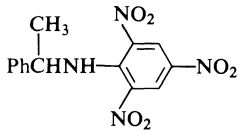
Authentic samples of **10** and **20** were prepared as shown in Schemes 1 and 2. The reactions were all straightforward and will not be discussed here. However, the compounds in the sequence leading



17



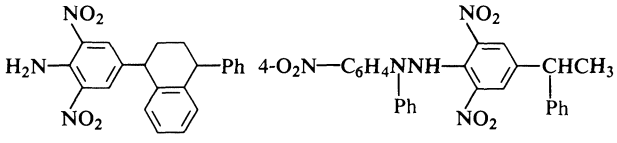
18



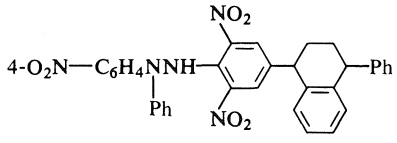
19

to **10** were all syrups which could not be crystallized and a satisfactory analysis was not obtained for any of these. Also **10** was an amorphous solid which could not be crystallized and a satisfactory analysis was not obtained either. The presence of two chiral carbon atoms in these compounds results in diastereomeric mixtures which may be responsible for the failure to obtain crystalline materials. The structures of these compounds are assigned on the basis of the similarity of the reactions used to make them to those of Scheme 1, and on the basis of their nmr spectra. These spectra showed no evidence of impurities and were consistent with the structures. The mass spectrum of **10** was also consistent with its proposed structure.

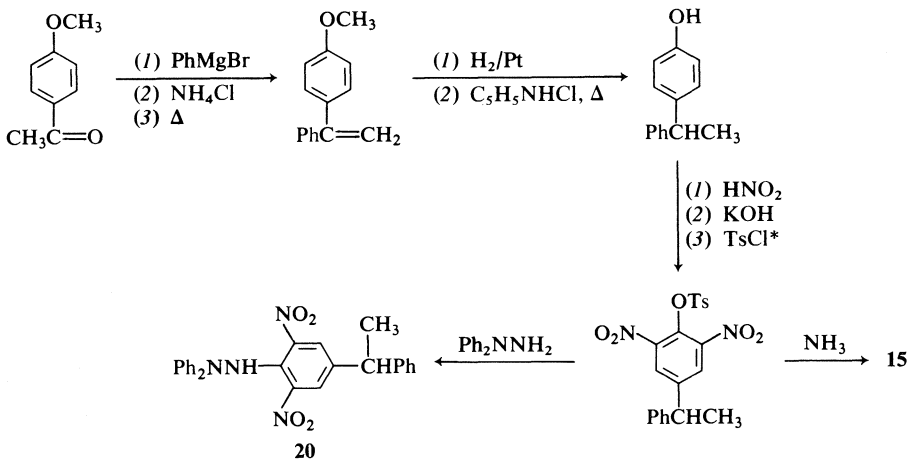
The electron impact mass spectra of **10** and **20** did not contain the molecular ion peaks, but only peaks due to fragments of the molecular ions. The chemical ionization (CH_5^+) mass spectra did contain the parent ($M^+ + 1$) peaks at *m/e* 557 for **10** and *m/e* 455 for **20**. In both spectra peaks at ($M^+ + 1$) − 46 and ($M^+ + 1$) − 63, resulting from loss of NO_2 and NO_2 + OH, respectively, from the parent ion were present. The most intense peaks in both spectra were those due to the ions resulting from N—N bond cleavage at *m/e* 390 from **10** and *m/e* 288 from **20**. These correspond to the protonated forms of **15** and **21**, respectively.



21 **22**



23



SCHEME 1

The products from the thermolysis of **11** in the presence of DPPH were isolated by a combination of column chromatography on cellulose and preparative tlc on silica gel. There was obtained 23% of **20**, 11% of **9**, both yields based on DPPH, and 22% recovered DPPH, accounting for 56% of the initial DPPH. Based on **11** the yield of **20** was 44%. The structure of **9** was determined by comparison with an authentic sample (13*b*), and **20** isolated from the reaction mixture was identical with synthetic material.

A number of other products derived from DPPH was formed but each was present in very small amount, except for a few mg of material tentatively identified as **22** on the basis of its nmr spectrum.

The products from the thermolysis of **12** in the presence of DPPH were separated by preparative tlc on silica gel. There was obtained 20% of **10** and 27% of **9**, based on DPPH, and 35% recovered DPPH. Also isolated was ~10%, based on DPPH, of a compound tentatively assigned structure **23** on the basis of its nmr and mass spectra. These products account for 92% of the initial DPPH. The total yield, based on **12**, of **10** and **23** is 30%. Again, a number of other products derived from DPPH was formed but all these were present in very small amounts.

The structure of **10** was determined by comparison with synthetic material. The nmr spectrum of **23** is almost identical with that of **10** except that the

aromatic region contains an A_2B_2 system that is identical with that observed for the 4-nitrophenyl group in the nmr spectrum of **9**. The chemical ionization (CH_5^+) mass spectrum of **23** has the highest mass peak of *m/e* 556 which is assigned as $(M^+ + 1) - 46$, resulting from loss of NO_2 from the molecular ion. The most intense peak was at *m/e* 390, as in the mass spectrum of **10**, which is due to the protonated form of **21**.

A ~25% yield of a mixture of **3** and **4**, identified by gc, and a ~25% yield of viscous material, presumably the products of coupling of the radicals **2** in the original solvent cage, were isolated as well from the thermolysis of **12** in the presence of DPPH.

Discussion

The main effect of the addition of DPPH to styrene on the distribution of styrene dimers and trimers is the three-fold increase in the relative amount of **3** formed and the elimination of the formation of the trimer **5** and of a presumed styrene dimer of undetermined structure. The formation of other products is relatively unaffected. The results are consistent with the mechanism of the thermal initiation of polymerization given by reactions [1]–[3]. Interception of the initial styrene dimer **1** by DPPH, reaction [4], as soon as it is formed would prevent hydrogen transfer to a third molecule of styrene, reaction [2] and thereby eliminate formation of **5**. Subsequent rapid reaction between **2** and DPPH would prevent any addition of **2** to styrene to initiate polymer chains. This mechanism for the inhibitory effect of DPPH is supported by the isolation of **10**, the product of coupling of DPPH with the radical **2**. Reaction between **2** and DPPH—H could also lead to the disproportionation products **3** and DPPH. Although the relative amount of **3** formed is greater by a factor of ~3 in the presence of DPPH the coupling reaction must predominate. If disproportionation were the predominant reaction the amount of **3** formed would be increased by as much as 40-fold in the presence of DPPH. This number is obtained in the following way. In the absence of DPPH most of **1** that is formed reverts to styrene and some undergoes chain transfer (2*a*) with growing polymer chains. A portion of the molecules of **1** that are formed undergo hydrogen atom transfer with styrene to give a pair of radicals, reaction [2], and only a fraction of these radicals initiate polymerization. DPPH intercepts all the molecules of **1** as they are formed. This accounts for the much greater rate of disappearance of DPPH as compared with the rate of initiation of polymerization, a factor of 85 at 60°C. Half the DPPH that is consumed is converted to DPPH—H by hydrogen atom transfer from **1**, reaction [4]. The remainder reacts by disproportionation or coupling with **2**.

The results of the thermolysis of **11** and **12** in the presence of DPPH confirm that half or more of 1-phenylethyl radicals and of **2** react with DPPH by coupling. The coupling products were isolated in 44 and 30% yields, respectively. The cage effect in the thermolysis of **11** at ca. 110°C is over 30% (14) and must be at least as great for **12**, so that the majority of the radicals which escape the cage must couple with DPPH.

The maximum amount of **10** that could have been formed in styrene if **2** and DPPH gave only **10** can be calculated. The rate of disappearance of DPPH in styrene at 75°C is $2.2 \times 10^{-8} M\ s^{-1}$ (6). A maximum of half the DPPH consumed can be converted to **10**, so that from 100 mL of styrene at 75°C after 30 h the theoretical yield of **10** would be ~0.06 g. This compares well with the 0.04 g which was isolated under these conditions, considering that about half the molecules of **2** and DPPH that react with each other form **10** as found from thermolysis of **12** in the presence of DPPH.

In neat styrene **4** can be formed by a disproportionation reaction, [3*b*], and by isomerization of **1** by adventitious acid. With care the latter route to **4** can be minimized, and in the presence of DPPH reaction [3*b*] cannot occur. **4**, which is formed in the presence of DPPH, likely results from a hydrogen atom transfer from DPPH—H to **2**, which are the initial products of reaction [4], in the original solvent cage in which they are formed. Such a reaction between DPPH—H and radicals is known to occur (15).

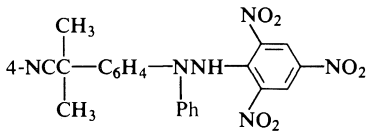
The finding that **2** and 1-phenylethyl radicals react with DPPH at the 4-position of the picryl ring stands in contrast to all studies of reactions between radicals and DPPH which had been carried out when this work was completed (13). For every system studied the radical was claimed to become bound to the nitrogen containing the free valence or to an unsubstituted phenyl group. In each instance in which reaction at the unsubstituted phenyl ring was claimed the only evidence available was the observation that the products could be oxidized to hydrazyls. This oxidation reaction is also available to products of reaction at the picryl ring and does not distinguish between reaction at the two different positions.

Since the present work was completed there have been three reports of displacement of a nitro group from an aromatic ring: from DPPH by the thiyl radical derived from 2,4,6-tri-*t*-butylbenzenethiol (16*a*, *b*), and by bromine (16*c*) and from

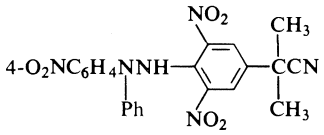
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

a series of *p*-substituted nitrobenzenes by 1-adamantyl radicals (17).

However, 2-cyano-2-propyl radicals and ethylthiyl radicals are reported to react with DPPH at the 4-position of an unsubstituted phenyl group (18). The evidence for the structure of the 2-cyano-2-propyl—DPPH adduct **24** is based on the mass spectrum of the product. A peak at *m/e* 462 was present, but this is also consistent with the isomeric structure **25**, a secondary product formed after

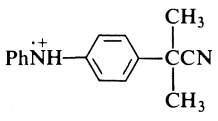


24

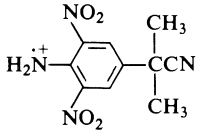


25

attack of the 2-cyano-2-propyl radical at the picryl ring. In the present study adducts corresponding to **25** were formed in the reactions between both **2** and 1-phenylethyl radical and DPPH. A fragment with *m/e* 236, attributed to the product **26** of the N—N cleavage of the molecular ion obtained from **24** was also detected in the mass spectrum (18). However, an ($M^{+\cdot}$ + 1) peak is present in the mass spectrum of 2-nitroaniline (19). N—N cleavage of the corresponding ion derived from **25** might form **27** which would lose CH_3 to give **28** which has *m/e* 235. A



26



27

corresponding fragmentation of the (M^+ + 1) ion from **25** would produce a fragment with *m/e* 236. Thus the mass spectral evidence is ambiguous.

The structure of the ethylthiyl–DPPH adduct seems to be more secure as it was degraded chemically to 4-ethylthiodiphenylamine.

Coupling of radicals at the unsubstituted phenyl group of DPPH is certainly a feasible reaction and does occur with nitrogen dioxide, at least, as evidenced by the formation of **9** (13*b*) and **23** in the present work. It is possible that nitrogen dioxide reacts preferentially with DPPH at the picryl ring, a process undetectable in the absence of suitably labelled materials, and more slowly at the unsubstituted phenyl group to form **9**.

There are thus at least three sites in DPPH at which radical attack may occur and careful characterization of the products is required to distinguish between reaction at the picryl ring and the unsubstituted phenyl group.

Experimental

General

Melting points and boiling points are uncorrected. Refractive indices were measured on a Bausch and Lomb Abbe-3L refractometer. Infrared spectra were recorded on a Beckman IR-7 recording spectrophotometer. Ultraviolet spectra were recorded on a Bausch and Lomb Spectronic 600 spectrophotometer. Nuclear magnetic resonance spectra were recorded on Varian Analytical Spectrometers, Models A-60 and HR-100 with tetramethylsilane as internal standard. Mass spectra were recorded on A.E.I. Models MS-2, MS-9, and MS-12 mass spectrometers. Gas chromatographic – mass spectra were obtained using a Varian Series 1200 gc connected to the MS-12 mass spectrometer. Gas–liquid chromatographic analyses were carried out on an Aerograph-202 Gas Chromatograph. Elemental analyses were performed in the microanalytical laboratories in the Chemistry Department under the supervision of Mrs. Darlene Mahlow.

Solutions were dried with magnesium sulfate.

All reactions involving the heating of styrene were conducted in apparatus that had been soaked several hours in ammonium hydroxide solution and then baked at 120°C for several hours.

cis- and *trans*-**6** (20), **4** (20), and **11** (9) were prepared as described in literature, while **7** was obtained commercially. Styrene and DPPH were purified as described (6).

1,2,3,4-Tetrahydro-4-phenyl-1-naphthol

A mixture of 10 g of 4,4-diphenyl-3-butenoic acid and the corresponding lactone (21) in 150 mL methanol was hydrogenated over 500 mg palladium on charcoal at 710 Torr. Hydrogenation was complete in 3 h. The solid remaining after removal of catalyst and solvent was recrystallized from benzene to give 9.2 g large prisms, mp 107°C (lit. (22) mp 107°C), of 4,4-diphenylbutanoic acid. This material was preheated to 70°C and added in one lot to 40 g polyphosphoric acid at 90°C and the resulting mixture was kept at 90°C for 3 min and stirred vigorously for 4 min more. Then 40 g polyphosphoric acid preheated to 90°C was added with stirring and the resulting mixture was kept at 90°C for 1 h. After cooling to 60°C ice water was added and the product was taken up in ether. Further workup yielded a solid which was recrystallized to give 7.6 g of 1,2,3,4-tetrahydro-4-phenylnaphthalen-1-one, mp 76–77°C (lit. (23) mp 75.5–76°C). Reduction of 5.0 g of this material with excess sodium borohydride in ethanol provided 4.8 g white powder after workup which was recrystallized from carbon tetrachloride, mp 96–100°C. A portion of this material was recrystallized from pentane to give long white needles, mp 121.5–123°C; nmr ($CDCl_3$: τ 2.72 (m, 9 H), 5.16 (m, 1 H), 5.91 (m, 1 H), 7.75 (s, O—*H*), 8.0 (broad m, 5 H). *Anal.* calcd. for $C_{16}H_{16}O$: C 85.68, H 7.19; found: C 85.98, H 7.11.

1,2-Dihydro-1-phenylnaphthalene, ***3***

A mixture of 4.8 g of the above alcohol and 10 g phosphoric acid was heated at 120–130°C for 2 h and then poured into ice water. The product was taken up in ether and the ether solution washed with sodium bicarbonate solution, with water, and then dried. Ether was removed and the residue distilled to give 3.4 g (70%) of a viscous oil, bp 87°C/0.08 Torr, n_D^{25} 1.6225. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

infrared spectrum matched that reported (1*b*). *Anal.* calcd. for $C_{16}H_{14}$: C 93.16, H 6.84; found: C 93.45, H 6.94.

Bis(1,2,3,4-tetrahydro-4-phenyl-1,1-naphthylene)diazane

A mixture of 2.5 g (0.011 mol) of 1,2,3,4-tetrahydro-4-phenylnaphthalen-1-one, 0.32 g (0.011 mol) of 85% hydrazine hydrate and a drop of acetic acid in 25 mL 98% ethanol was heated under reflux for 3.5 h during which time the product precipitated. This was filtered, washed with ethanol, and dried to yield 2.35 g (84%) of fine yellow powder, mp 207–210°C; ir ($CHCl_3$): 1690 (C=N) cm^{-1}; nmr ($CDCl_3$): τ 1.80 (m, 2 H), 2.90 (m, 16 H), 5.87 (m, 2 H), 7.25 (m, 4 H), and 7.80 (m, 4 H). *Anal.* calcd. for $C_{32}H_{28}N_2$: C 87.24, H 6.41, N 6.36; found: C 87.06, H 6.49, N 6.54.

Bis(1,2,3,4-tetrahydro-4-phenyl-1-naphthyl)diazene

A mixture of 1.7 g of the above diazane and 500 mg 5% palladium on charcoal in 300 mL benzene was stirred under hydrogen at 710 Torr until hydrogen uptake ceased. Catalyst and solvent were removed to give a sticky white solid which was immediately taken up in 125 mL ether. The resulting solution was stirred under oxygen for 24 h. The white solid which had formed was filtered and the ether cooled to 0°C to give more precipitate. A total of 0.78 g (46%) of white powder was obtained, mp 121–124°C; nmr ($CDCl_3$): τ 2.87 (m, 18 H), 5.82 (m, 2 H), and 7.80 (broad m, 8 H); uv (ether): 362 (110) nm. *Anal.* calcd. for $C_{32}H_3ON_2$: C 86.84, H 6.83, N 6.33; found: C 86.79, H 6.50, N 6.09.

The infrared spectrum showed no absorptions due to NH or to C=N. Addition of a drop of hydrochloric acid to the ether solution used for the uv spectrum rapidly gave a new absorption at 286 (11000) nm.

1-(4-Hydroxyphenyl)-1-phenylethane

Hydrogenation of 1-(4-methoxyphenyl)-1-phenylethene (24) gave 1-(4-methoxyphenyl)-1-phenylethane (25) and 39.5 g of this material was added to molten pyridinium hydrochloride at 140°C for the cleavage reaction (26). The mixture was heated under reflux under nitrogen for 3 h and then cooled. To the warm solution was added 80 mL water and this mixture was poured into 600 mL water. The product was taken up in ether. The ether solution was dried, the solvent removed, and the residue distilled to give 33 g (91%) of a viscous liquid that solidified at 0°C, bp 133–134°C/0.5 Torr, mp 54–56°C (lit bp 185–190°C/10 Torr (27), mp 64°C (28)); nmr (CCl_4): τ 2.92 (s, 5 H), 7.07 (d, J = 9 Hz, 2 H), 7.36 (d, J = 9 Hz, 2 H), 3.95 (broad, 1 H, O—*H*), 6.05 (q, J = 7 Hz, 1 H) and 8.50 (d, J = 7 Hz, 3 H). *Anal.* calcd. for $C_{14}H_{14}O$: C 84.81, H 7.12; found: C 84.88, H 6.90.

2,6-Dinitro-4-(1-phenylethyl)phenyl-p-*toluenesulfonate*

Nitration of 9.75 g of 1-(4-hydroxyphenyl)-1-phenylethane with nitrous acid in buffered solution (29) followed by shaking the benzene extract of the diluted reaction mixture with 10% potassium hydroxide produced 7.8 g orange–red precipitate. This was recrystallized from boiling water to give 7.6 g (50%) potassium 2,6-dinitro-4-(1-phenylethyl)phenoxide as long orange needles. A mixture of 1.6 g (0.005 mol) of this salt, 1.0 g (0.005 mol) *p*-toluenesulfonyl chloride, and 15 mL acetone was stirred under reflux for 4 h. The dark red solution gradually lost its color and became light yellow. The reaction mixture was filtered and solvent removed from the filtrate. The residual solid was treated with charcoal in methanol and recrystallized from methanol to give 1.8 g (81%) white needles, mp 114–115°C; nmr ($CDCl_3$): τ 0.41 (s, 2 H), 0.68 (d, J = 8.5 Hz, 2 H), 1.12 (d, J = 8.5 Hz, 2 H), 1.23 (m, 5 H), 4.84 (q, J = 7.3 Hz, 1 H), 7.03 (s, 3 H), and 7.97 (d, J = 7.3 Hz, 3 H). *Anal.* calcd. for $C_{21}H_{18}N_2O_7S$: C 57.01, H 4.10, N 6.33, S 7.25; found: C 57.20, H 4.11, N 6.05, S 7.33.

2,6-Dinitro-4-(1-phenylethyl)aniline, ***15***

Anhydrous ammonia was bubbled through a solution of 1.8 g of the above tosylate in 20 mL diglyme kept at 160°C. After 3 h the solution had turned dark red and fine white needles had precipitated. The reaction mixture was filtered and solvent removed from the filtrate. The residue was recrystallized from methanol to give 0.94 g (81%) bright orange prisms, mp 115°C; ir ($CHCl_3$): 3485 and 3370 cm^{-1}; nmr ($CDCl_3$): τ 1.58 (s, 2 H), 1.60 (broad, 2 H), 5.89 (q, J = 7.5 Hz, 1 H), and 8.33 (d, J = 7.5 Hz, 3 H); ms (70 eV) *m/e*: 287 ($M^{+\cdot}$), 272, 180, 152. *Anal.* calcd. for $C_{14}H_{13}N_3O_4$: C 58.53, H 4.56, N 14.63; found: C 58.40, H 4.75, N 14.50.

1-[2,6-Dinitro-4-(1-phenylethyl)phenyl]-2,2-diphenylhydrazine, ***20***

To a stirred mixture of 0.5 g (0.0023 mol) of 1,1-diphenylhydrazine hydrochloride in 10 mL ethanol was added 0.5 g (0.006 mol) sodium bicarbonate. When gas evolution ceased 1.0 g (0.0023 mol) of 2,6-dinitro-4-(1-phenylethyl)phenyl-*p*-toluenesulfonate was added and the resulting mixture heated under reflux for 2.5 h. The mixture was cooled, filtered, the filtrate concentrated and the residue recrystallized from 98% ethanol to give 0.72 g red prisms, mp 133°C (char 131°C); ir ($CHCl_3$): 3310 cm^{-1}; nmr ($CDCl_3$): τ 0.52 (s, 1 H), 2.18 (s, 2 H), 2.80 (m, 17 H), 5.93 (q, J = 7 Hz, 1 H) and 8.42 (d, J = 7 Hz, 3 H); ms (CH_5^+) *m/e*: 455 (M^+ + 1), 409, 392, 288. *Anal.* calcd. for $C_{26}H_{22}N_4O_4$: C 68.71, H 4.88, N 12.11; found: C 68.81, H 4.83, N 12.11.

1,2-Dihydro-1-phenyl-4-(4-methoxyphenyl)naphthalene

A solution of 6.2 g (0.028 mol) of 1,2,3,4-tetrahydro-4-phenylnaphthalen-1-one in 100 mL ether was added to the Grignard reagent made from 2.4 g (0.1 mol) magnesium and 18.7 g (0.1 mol) 4-bromo-1-methoxybenzene. The reaction was carried out in the usual way, hydrolyzed with saturated ammonium chloride, and worked up in the usual way. Removal of solvent left an oily residue which was heated at 210°C under 60 Torr for 30 min to leave a viscous oil, 8.5 g (89%) which could not be crystallized, nmr (CCl_4): τ 2.85 (m, 9 H), 2.95 (d, J = 8.5 Hz, 2 H), 3.18 (d, J = 8.5 Hz, 2 H), 4.10 (t, J = 4.5 Hz, 1 H), 5.90 (t, J = 8.5 Hz, 1 H), 6.26 (s, 3 H), and 7.35 (d of d, J = 4.5 Hz, 8.5 Hz, 2 H). A satisfactory analysis was not obtained. At least a three-fold excess of Grignard reagent was required to consume all the ketone.

1,2,3,4-Tetrahydro-4-(4-methoxyphenyl)-1-phenylnaphthalene

The above material was hydrogenated in ethyl acetate using platinum oxide and the reaction worked up in the usual way, except that the product was warmed to 80°C under 20 Torr for 0.5 h, to give 100% of a viscous oil that could not be crystallized, nmr (CCl_4): τ 3.0 (broad m, 13 H), 5.90 (broad m, 2 H), 6.28 (s, 3 H), and 8.0 (m, 4 H). A satisfactory analysis was not obtained.

1,2,3,4-Tetrahydro-4-(4-hydroxyphenyl)-1-phenylnaphthalene

Cleavage of 7.5 g of the above ether with pyridinium hydrochloride (26) yielded 6.2 g (86%) of a viscous oil that could not be crystallized, ir (CCl_4): 3350 cm^{-1}; nmr (CCl_4): τ 3.0 (broad m, 13 H), 5.90 (broad m, 2 H), 6.70 (s, 1 H), and 8.0 (m, 4 H). A satisfactory analysis was not obtained.

1-[2,6-Dinitro-4-(1,2,3,4-tetrahydro-4-phenyl-1-naphthyl)-phenyl]-2,2-diphenylhydrazine, ***10***

Nitration (29) of 3.05 g (0.01 mol) of the above phenol with nitrous acid in buffered solution gave, after work up and conversion of the product to the potassium salt, 0.8 g (18%) of a sticky red solid. This was dissolved in 10 mL acetone containing 0.4 g (0.02 mol) *p*-toluenesulfonyl chloride and the resulting solution was heated under reflux until the red color disappeared. The reaction mixture was filtered and the filtrate concentrated to give a tan syrup which could not be crystallized. The material was added to a mixture of 0.45 g (0.02 mol) of 1,1-diphenylhydrazine hydrochloride and 0.45 g sodium carbonate in 10 mL ethanol. The mixture was heated under reflux for 2.5 h, filtered,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

and the solvent removed. The residue was applied to a 20 × 20 cm plate coated with 2 mm of silica gel. The plate was developed six times with 1:8 acetone–hexane which resulted in a well separated red–brown band. This was removed and extracted with benzene. Removal of the benzene left 73 mg of a brittle orange–red solid, which could not be crystallized, mp 69–72°C; nmr (CCl_4): τ 0.50 (s, 1 H), 2.35 (overlapping s, 2 H adjacent to NO_2), 2.90 (m, 19 H), 5.85 (broad m, 2 H), and 8.10 (broad m, 4 H); ms (CH_5^+) *m/e*: 557 ($M^+ + 1$), 511, 494, 390. A satisfactory analysis was not obtained.

2,4,6-Trinitro-N-(1-phenylethyl)aniline, ***19***

A mixture of 2.0 g (8 mmol) of picryl chloride, 1.0 g (8 mmol) 1-phenylethylamine, and 1 g sodium carbonate in 50 mL chloroform was heated under reflux for 30 min. The dark red reaction mixture was shaken with water, dried, and concentrated. The residue was recrystallized from ethanol to give 2.45 g (89%) bright yellow needles, mp 108–109°C, nmr ($CDCl_3$): τ 1.10 (s, 2 H), 2.75 (s, 5 H), 5.70 (q, J = 6.5 Hz, 1 H), 7.25 (broad s, 1 H, N*H*), and 8.30 (d, J = 6.5 Hz, 3 H). *Anal.* calcd. for $C_{14}H_{12}N_4O_6$: C 50.45, H 3.64, N 16.86; found: C 50.47, H 3.69, N 17.02.

4-(1-Phenylethyl)diphenylamine

The method used is a modification of that described (30) for the preparation of 4-benzyldiphenylamine. A mixture of 11.2 g (0.08 mol) of 1-chloro-1-phenylethane, 13.6 g (0.04 mol) of diphenylamine, and 13.6 g zinc chloride was heated at 100°C for 80 min when gas evolution ceased. The dark brown reaction mixture was mixed twice with 100 mL boiling water, cooled, and taken up in ether. The resulting solution was dried and concentrated to a viscous oil which was distilled to give 3 g of an oil, bp 190–220°C/1 Torr, which deposited white crystals of diphenylamine. The crystals were separated and a portion of the oil chromatographed on a 3 × 30 cm column of silica gel using 1:8 acetone–hexane as eluent. Concentration of the first fraction, 150 mL, left a clear oil, nmr (CCl_4) τ 2.8–3.5 (broad, 14 H), 5.05 (broad s, 1 H, N—*H*), 5.82 (q, J = 7 Hz, 1 H) and 8.40 (d, J = 7 Hz, 3 H). This material was not analyzed further.

*Thermolysis of **11** in the presence of DPPH*

A solution of 0.207 g (9 mmol) of **11** and 1.34 g (34 mmol) of DPPH in 20 mL benzene was degassed with four freeze–thaw cycles under 0.001 Torr and then kept at 84°C for 72 h. Analysis by gc on a 5 ft × 0.25 in. column of 15% SF 96 on 60/80 Chromosorb W at 220°C, 60 mL/min helium flow rate, and injector temperature of 275°C indicated four components with retention times of 6.0, 14.4, 25.4, and 43.5 min. The retention time of the first component coincided with those of diphenylamine and of *meso-* and *dl*-2,3-diphenylbutane. The second compound was isolated by preparative gc, mp, and mixed mp with 2,4,6-trinitroaniline 187°C. The third and fourth components were analyzed by mass spectrometry of the effluent of the gc. The ms of the third component matched that of 4-nitrodiphenylamine and the ms of the fourth component matched that of **15**.

Diphenylamine, *meso-* and *dl*-2,3-diphenylbutane were separated on a 5 ft × 0.25 in. column of 20% PDEAS on 60/80 Chromosorb W temperature programmed from 90 to 225°C over 20 min. The retention times were 36.0, 17.2, and 17.7 min, respectively, and the compounds were identified by coinjection with authentic materials.

Removal of benzene left 1.6 g residue, 0.800 g of which was chromatographed on a 5 × 38 cm column of microcrystalline cellulose. Washing with heptane eluted a brown–red and, overlapping with it, a violet band. Removal of solvent left 0.40 g dark solid which was taken up in the minimum amount of benzene and applied to four 20 × 20 cm plates coated with 2 mm silica gel. The plates were developed six times at 5°C with 1:10 acetone–hexane to separate two strong bands, the first red–brown, the second violet, and a number of minor, highly colored, more slowly moving bands. The materials from the bands were extracted into chloroform. The first gave 178 mg of red–brown solid whose nmr spectrum showed only broad signals. Addition of a drop of a solution of hydroquinone resulted in a spectrum with sharp lines that was identical with that of authentic **20**. The second band gave 146 mg of violet solid whose nmr spectrum, after addition of a little hydroquinone, was identical with that of authentic DPPH—H.

Further elution of the cellulose column with 1:1 benzene–heptane removed further material which was collected in 250 mL fractions. The first three fractions contained 0.105 g material which was shown by tlc to consist mainly of DPPH and **20** along with a small amount of an unidentified indigo colored material. The next three fractions contained 77 mg material which was separated on a preparative tlc plate using 1:8 acetone–hexane as eluent. After six developments three bands were separated. The major band was extracted with chloroform to give 16 mg solid whose nmr spectrum, after addition of some hydroquinone, indicated that it was a mixture of **9** and 1-[2,6-dinitro-4-(1-phenylethyl)phenyl]-2-(4-nitrophenyl)-2-phenylhydrazine, **22**. The nmr spectrum of the mixture contained peaks that were present in the spectra of both **9** and **20**, but **20** was shown by tlc not to be present.

Fractions 7–11 contained 0.285 g material 0.085 g of which was chromatographed on a preparative tlc plate. After six developments with 1:6 acetone–hexane a brown band and a violet band were separated. Extraction with chloroform and removal of solvent gave 48 and 33 mg, respectively, of **9** and the corresponding hydrazyl. These were identified by their nmr spectra, after the addition of some hydroquinone, which matched that of authentic **9** (13*b*).

*Thermolysis of **12** in the Presence of DPPH*

A solution of 0.076 g (1.7 mmol) **12** and 0.134 g (3.4 mmol) DPPH in 3 mL benzene was degassed as described above and heated at 84°C for 72 h. The benzene was removed, the residue taken up in the minimum volume of acetone, and the resulting solution was applied to three 20 × 20 cm plates coated with 2 mm silica gel. The plates were developed six times with 1:8 acetone–hexane at 5°C. Four well defined colored bands and two closely spaced colorless bands which were near the solvent front were resolved at this time. The organic material of each band was taken up in chloroform and analyzed in order of decreasing R_f value as follows:

Fraction 1, 20 mg oil shown to contain **3** and **4** by gc.

Fraction 2, 20 mg viscous oil, presumably products of coupling of **2**.

Fraction 3, 38 mg orange brown solid whose nmr and mass spectra matched those of authentic **10**.

Fraction 4, 47 mg orange red solid whose nmr and mass spectra matched those of DPPH—H.

Fraction 5, 23 mg orange red solid assigned structure **23** on the basis of its nmr spectrum (CD_3COCD_3): τ 0.75 (s, 1 H, N*H*), τ 1.90 (d, J = 9 Hz, 2 H, half of A_2B_2 of 4-O_2N—C_6H_4) 2.08 (s, 2 H), 2.80 (broad, 16 H), 5.75 (broad, 2 H), 8.05 (broad, overlapping with solvent); and mass spectrum (CH_5^+): *m/e* 556 (P − 46), 415, 390, 386, 360, 206.

Fraction 6, 40 mg red–brown solid whose nmr spectrum matched that of authentic **9**.

Fraction 7, 8 mg material remaining at the base line which was not identified.

Thermolysis of Styrene

(a) With DPPH

A 250 mL long-necked round-bottomed flask with a side arm reservoir containing 0.8 g DPPH–benzene complex was filled with 100 mL freshly distilled styrene which was then degassed with three freeze–thaw cycles under 0.02 Torr. The DPPH was

taken up in styrene and the sidearm sealed off. The flask was then immersed in a 75°C bath for 30 h in the dark. Styrene was then removed at 80°C/23 Torr to leave 1.35 g residue which was chromatographed on a 3 × 60 cm column of silica gel using 1:4 acetone–hexane as eluent. Fractions were collected in 20 mL portions and analyzed by tlc. Those containing similar products were combined and rechromatographed, if necessary, using a ratio of 1:100 compound – silica gel. The following materials were obtained: 0.520 g of a hydrocarbon mixture whose nmr spectrum indicated it to be 90% styrene and which was analyzed by gc as described in *b*, below; 0.04 g of **10** identified on the basis of its nmr spectrum; 0.048 g of DPPH—H, and 0.190 g **9**, identified on the basis of their nmr spectra.

(b) Without DPPH

A 100 mL portion of freshly distilled styrene was heated under the conditions as given in (*a*), except that no DPPH was present, and then poured into 250 mL benzene. The resulting solution was poured into 500 mL methanol. The sticky polymer was filtered and leached several times with methanol. The leachings and filtrate were combined and concentrated under 23 Torr to a yellow viscous residue which was chromatographed on 100 g silica gel. Elution with 1:4 acetone–hexane and removal of the eluent gave 0.36 g of a pale yellow viscous oil whose nmr spectrum indicated it was ~90% styrene.

This material and the hydrocarbon fraction from (*a*) were analyzed by gc using a 10 ft × 0.125 in. column of 10% Apiezon L on 60/80 Firebrick at 202°C with 85 mL/min helium flow rate. The products were identified by comparison of their retention times and mass spectra with those of authentic materials. Several mass spectra were recorded as each component eluted to ensure that no other materials were eluted at the same time.

Thermolysis of DPPH

A solution of 134 mg DPPH in 3 mL benzene was degassed and then heated at 84°C for 72 h. The resulting solution was applied to two 20 × 20 cm plates coated with 2 mm silica gel and the plates developed six times with 1:10 acetone – petroleum ether at 5°C to give three resolved bands. The most intense was extracted into chloroform and the solvent removed to give 127 mg (95%) DPPH. The other two bands were identified as **9** and the corresponding hydrazyl by comparison of their R_f values with those of authentic samples.

Some chemical and analytical aspects of polysaccharide modifications. I. Nitroxide spin-labelling studies of alginic acid, cellulose, and xanthan gum[1]

MANSUR YALPANI[2] AND LAURANCE D. HALL

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received May 7, 1981

MANSUR YALPANI and LAURANCE D. HALL. Can. J. Chem. **59**, 3105 (1981).

Nitroxide spin labels have been employed as model reagents for evaluating several aspects of the synthesis of covalently modified polysaccharide derivatives using alginic acid **1**, xanthan gum **19**, and cellulose **23** as exemplars. Modifications were accomplished both nonspecifically, by the alkylation of hydroxyl groups, and specifically, either by direct transformation of the carboxylate function of **1** and **19** or after introduction of appropriate prominent functions, such as aldehydes or amines. Thus, the acetamido ether **3** was obtained from **1** and chloroacetamide **2**. The carboxylate functions of **1** and **19** were condensed with amines to yield the corresponding amides **8**, **10**, **20**, **21**, and **22** either by direct reaction, by carbodiimide-mediated coupling, or by transesterification. The amine derivatives **12**, **13**, **25**, and **18** were obtained either from dialdehyde derivatives via periodate oxidation or from *s*-triazine intermediates, using sodium cyanoborohydride. Similarly, the keto spin label **15** reacted with hydrazide intermediates **14** and **29** in the presence of sodium cyanoborohydride to afford the hydrazide derivatives **16** and **30**. The cellulose urethane derivative **27** was obtained via the cyclic carbonate precursor. The products were characterized by esr and other spectroscopic techniques.

MANSUR YALPANI et LAURANCE D. HALL. Can. J. Chem. **59**, 3105 (1981).

On a utilisé des marqueurs de spin de type nitroxyde comme réactifs modèles pour évaluer plusieurs aspects de la synthèse de dérivés de polysaccharides modifiés de façon covalente en utilisant comme exemples l'acide alginique (**1**), la gomme xanthane (**19**) et la cellulose (**23**). On a réalisé ces modification de façon non spécifique en alkylant les groupes hydroxyles et de façon spécifique soit par la transformation directe de la fonction carboxylate des composés **1** et **19** soit après l'introduction de fonctions appropriées telles les aldehydes ou les amines. Dans ces conditions, on obtient l'éther acétamido **3** à partir du composé **1** et du chloroacétamide (**2**). Les fonctions carboxylates des composés **1** et **19**, par condensation sur les amines, donnent les amides correspondants **8**, **10**, **20**, **21** et **22** soit par réaction directe soit par couplage en présence de carbodiimide ou par transestérification. On a obtenu les dérivés d'amines **12**, **13**, **25** et **18** soit à partir des dérivés dialdéhydes au moyen d'une oxydation par le periodate ou à partir des intermédiaires *s*-triazines en utilisant le cyanoborohydrure de sodium. D'une manière analogue, le marqueur de spin de type cétone (**15**) réagit avec les hydrazines intermédiaires **14** et **29** en présence du cyanoborohydrure de sodium en donnant les dérivés de l'hydrazide **16** et **30**. On a obtenu le dérivé uréthane de la cellulose **27** par l'intermédiaire d'un précurseur cyclique. On a caractérisé les produits par la rpe et par d'autres techniques spectroscopiques.

[Traduit par le journal]

Introduction

Polysaccharides are increasingly being recognized for their immense value in many areas of academe, industry, and medicine (1). With their rich abundance, low cost, and general versatility, natural polysaccharides can be expected to be of even greater significance in future, particularly in view of possible discoveries of new types of polymers from bacterial sources. At the same time, there is a growing demand for the preparation of modified polysaccharides which display specific properties such as viscosity (2), gelling ability (3), metal-chelating capacity (4), or drug-releasing potential (5). However, despite the substantial amount of work which has been directed at evaluating both native and modified polysaccharides (6), the predictive understanding of the important relationship between their structure and function is still rather imperfect (7). This is partially a consequence of the limitations both of the "traditional" analytical methods and of the chemical methodology used for modification (8); developments in both of these areas would clearly advance such an understanding.

There are several distinct protocols for the chemical modification of polysaccharides: (*i*) "statistical chemistry", until recently the prevailing trend, which involves the use of nonselective chemical reagents for random derivatizations (8); and (*ii*) specific modifications which can be accomplished either (*a*) by derivatizing polysaccharide sites which have intrinsic selective chemical reactivities (e.g. —COOH, —NH_2, etc.) (9), or, (*b*) in the absence of such sites, by selectively introducing reactive functions using either chemical or enzymic methodology (10).

The reagents commonly used in category (*i*) include strong alkalis and alkylating or acylating agents, as, for example, in the preparation of carboxyalkyl derivatives; these can lead to partial degradation of the polysaccharide (3), which is undesirable.

[1]Aspects of this work were presented at the 63rd Canadian Chemical Conference, Ottawa, June 3–9, 1980.

Characterization and detailed structural determinations of the modified products by the conventional methods of monosaccharide chemistry are in most cases complicated, if not precluded, by the intrinsic properties of polysaccharides, such as high solution viscosity, gel formation, polydispersity, or polymolecularity. There is, consequently, a need for the development of new analytical techniques whereby the chemistry of these complex systems can be followed.

In this study we have chosen to emphasize the use of nitroxide spin-labelling for evaluating various aspects of polysaccharide derivatizations. The basic concept involves the use of nitroxide probes as model reagents either to monitor the course of a particular reaction, or to optimize the reaction conditions, in order to establish criteria for processes involving diamagnetic analogues. Among the important advantages of this approach is the facility with which products in either the solid state or in the hydrated forms (solution, gel) can be investigated, and "covalently-bound" species can be distinguished from even relatively low concentrations of "adsorbed" or "trapped" spin-labelled reagents.

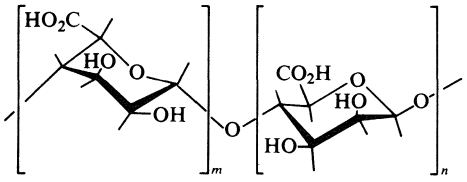
In the present paper we attempt to survey various aspects of some selective and nonselective modification procedures. In view of the substantial versatility and efficiency of the reductive amination reaction (11), most of the modifications described herein were designed to introduce either carbonyl or amine functionalities into the polysaccharides for subsequent derivatizations. The choice of synthetic procedures was further guided by the following main considerations: (*i*) to maintain the polysaccharide chain largely, if not completely, intact and to avoid acid hydrolysis of the nitroxide spin labels; and (*ii*) to form covalent linkages between the nitroxide labelled reagents and the polymers in the simplest and most direct way. As a consequence, strongly acidic or basic conditions were avoided and the reactions were conducted at ambient temperature and pressure.

Three important polysaccharides were used as exemplars: cellulose, the most abundant neutral polymer; alginic acid, a linear uronic acid derivative; and xanthan gum, a branched, high-molecular-weight acidic species. The reactions reported herein afforded in all cases covalently-linked derivatives, confirmation of which was obtained by esr and other spectroscopic methods.

Results

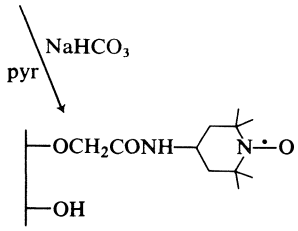
A. *Alginic Acid*

Of the three polysaccharides discussed here, alginic acid **1**, provided the greatest challenge for modifications because of its susceptibility to degradation and low reactivity; as a result mild reaction conditions were employed to preserve structural integrity. Various workers (12) had earlier noted that the acetylation of alginic acid never proceeded to completion, introducing no more than one acetyl group per uronic acid residue. However, Schweiger (13) discovered that a peracetylated product could be obtained with minimal polymer degradation if alginic acid was first partially (80–90%) dehydrated. This procedure reduces the extensive hydrogen-bonding in **1** thereby rendering the hydroxyl groups available for reactions, whereas complete dehydration leads to inactivation of **1**. Thus, following



1

1 **2**



3

Schweiger's method (13), partially dehydrated alginic acid was obtained by treatment of **1** with cold, glacial acetic acid, and used for subsequent reactions.

Alkyl ether

Stable acetamido ethers **3** were prepared from activated alginic acid **1** using 4-chloroacetamido-2, 2,6,6-tetramethylpiperidine-1-oxyl **2** in either pyridine or aqueous acetone (65%), with solid sodium bicarbonate as base. The mild conditions which were employed to minimize degradation of **1** led to very low degrees of substitution, ds (0.03–0.04).

The esr spectrum of **3** in aqueous solution (Fig. 1a) reveals a very mobile nitroxide moiety (τ_c 1.1×10^{-11} s); at least part of this relatively high mobility can be ascribed to the rotational freedom associ-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

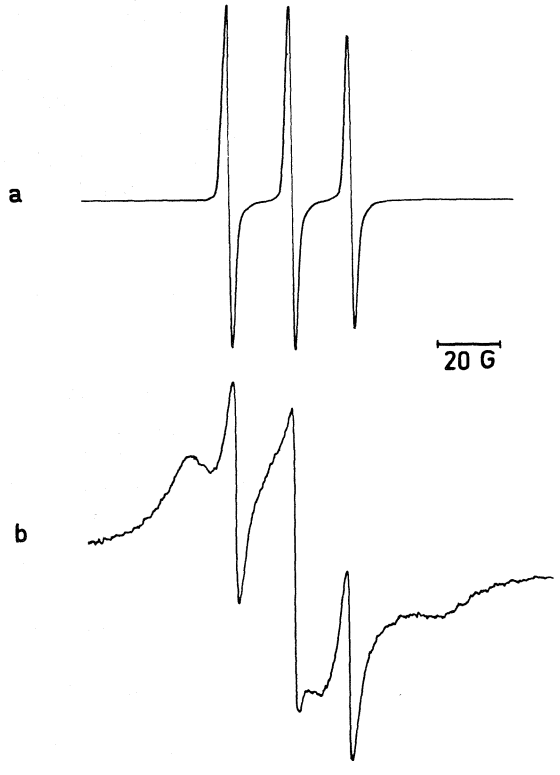

FIG. 1. Room temperature esr spectra of **3**: (a) aqueous solution; (b) powder.

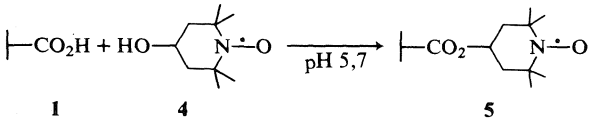
ated with the four-bond linkage between the polymer and probe.

The powder spectrum of **3** (Fig. 1b) resembles that of a polycrystalline sample and also indicates presence of a small percentage of free label which could not be removed by dialysis. The amount of free label did not vary with time, i.e. no "leakage" could be detected after periods of several weeks.



1 **4** **5**

Alkyl ester

The esterification of partially dehydrated alginic acid **1** was accomplished using 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl **4** in aqueous acetone, to afford the ester **5** (ds 0.05). The τ_c value of **5** in aqueous solution was 20 ns (Fig. 2a). Evidence[3] for the formation of **5** was derived from the esr spectrum of the powder under methanol (Fig. 2b) which revealed a broad "bound" component together with a superimposed signal arising from

[3]Attempts to verify the formation of **5** by ir were unsuccessful.

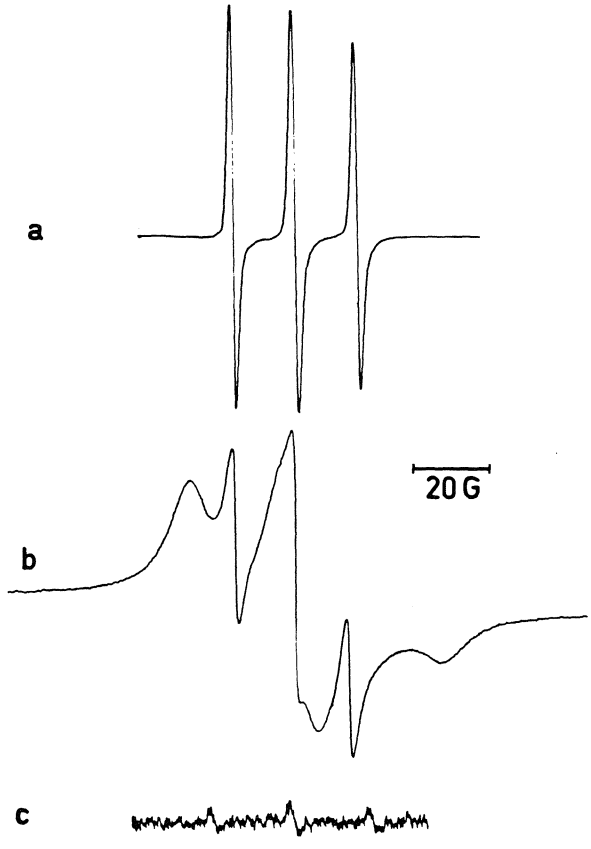


FIG. 2. Room temperature esr spectra of **5**: (a) aqueous solution; (b) powder; (c) control experiment: **1** treated with **6** under identical conditions.

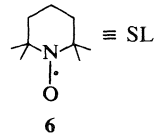
"free" label (despite extensive dialysis of the product!). This "free" label may be present as the salt to which previous workers have alluded (14, 15). Additional evidence for the occurrence of esterification was derived from a control experiment in which the spin label **4** was replaced by the unreactive analogue **6**. Only a very small proportion of **6** remained in the sample after dialysis, as indicated in Figure 2c.

The above reaction appears to provide a viable alternative to the known esterification procedures for alginic acid which involve the use of alkyne oxides (16) or the alginic acid chloride intermediate proposed by Wypych (17).



6

Amides

(a) Via Carbodiimide Coupling

Amide derivatives of alginic acid could be readily

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

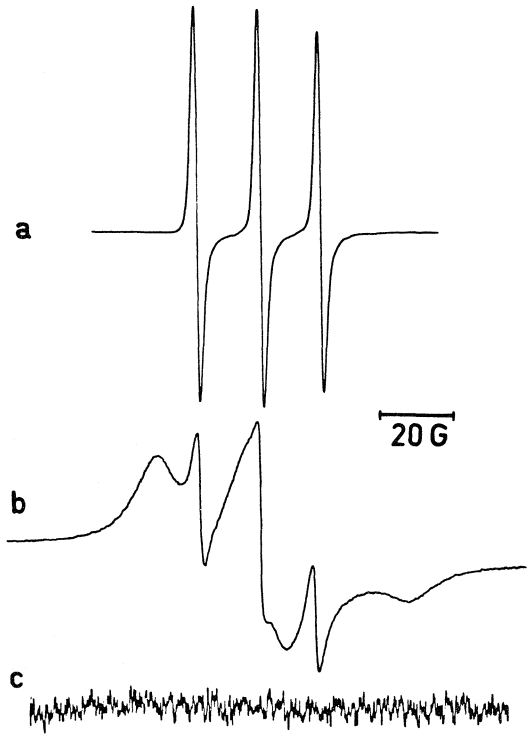


FIG. 3. Room temperature esr spectra of **8**: (a) aqueous solution; (b) powder; (c) control experiment: **1** treated with **6** under identical conditions.

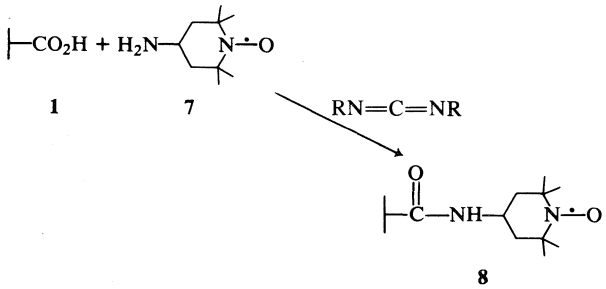
prepared by carbodiimide-mediated coupling in organic, or mixed aqueous–organic media. As in the previous reactions, however, alginic acid is only reactive in its partially dehydrated form (18). Amidation could be achieved using *N*,*N*′-dicyclohexylcarbodiimide (DCC) in dimethylformamide (DMF), or with *N*-ethyl-*N*′-dimethylaminopropylcarbodiimide (EDC) in 65% aqueous acetone to afford the amide **8** with ds 0.10 and 1.00, respec-

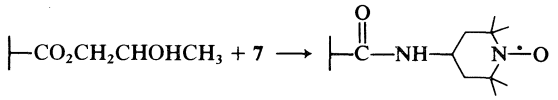


1 **7** **8**

tively; clearly, EDC is the preferred reagent for high ds products. The esr spectra of **8** provide evidence for the covalent nature of the linkage (Fig. 3); in the control experiment with label **6** no signal was detectable after identical treatment (Fig. 3c). The nitroxide moiety of **8** is moderately immobile in aqueous solution, (τ_c 15 ns) (Fig. 3a).

(b) Via Nucleophilic Substitution of Alginic Esters

Propylene glycol esters of alginate **9** have been reported to react with amines to form amides in high yields at ambient temperature (14, 15, 19). Two commercial samples of propylene glycol alginate (PGA) with different degrees of esterification (ds 0.80–0.85 and ds 0.50–0.60, respectively)



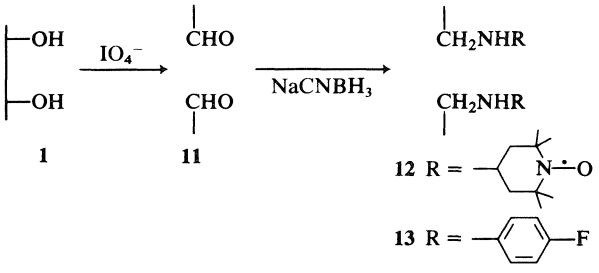
9 **10**

were condensed with amine spin label **7** in DMF in the presence of small amounts of water to yield the amide **10**. Reactions of this type are of considerable utility since they can be reportedly (15) performed with a wide range of amines such as primary or secondary aliphatic, cycloaliphatic, aromatic, and diamines. The resulting products are of interest for their gel-forming properties.

The esr spectra of amides of the type **10** in aqueous solution (Fig. 4a) indicate moderately immobile nitroxide moieties (τ_c 33 ns) and the corresponding powder spectra reveal not only the covalent nature of the linkages to the polymer, but also strong dipolar interactions (Fig. 4b). Similar information can be derived from rapidly frozen (77 K) samples (Fig. 4c). The control experiment with label **6** revealed no detectable esr signal (Fig. 4d).

Amines

Following the methods of Painter and coworkers (20), dialdehyde alginates **11** with varying degrees of oxidation (do) were prepared by periodate oxidation. These were subsequently converted to the corresponding amine derivatives **12** using reductive amination with label **7**; typically, amines with ds 0.05 (**12***a*) and 0.13 (**12***b*) were obtained from dialdehyde precursors with do 0.10 and 0.44, respectively. The esr spectra of **12***a* and **12***b* in aqueous solution (Fig. 5a) revealed substantial line broadening and τ_c values of 51 ns and 57 ns, respectively. When these solutions were frozen, dipolar broadening was again apparent (Fig. 5c). The powder spectra of the respective materials at 298 K



1 **11**

For personal use only.

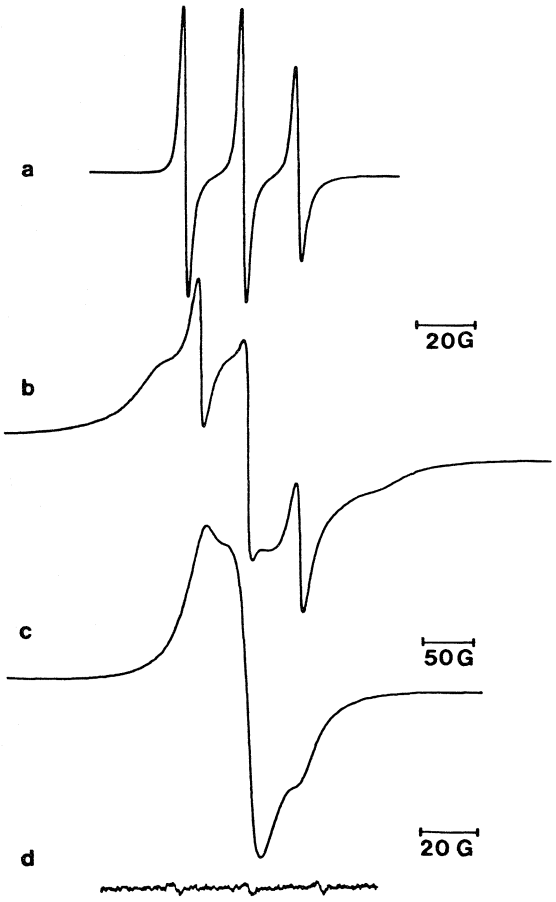

FIG. 4. The esr spectra of **10**: (a) aqueous solution (298 K); (b) powder (298 K); (c) powder (77 K); (d) control experiment: **9** treated with **6** under identical conditions.

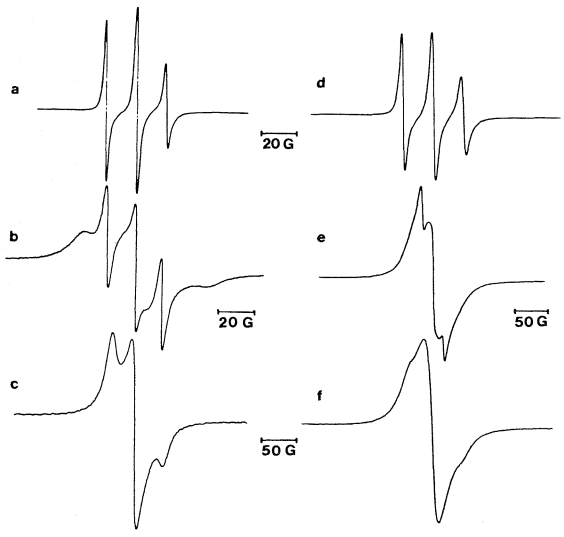

FIG. 5. The esr spectra of **12***a*: (a) aqueous solution (298 K); (b) powder (298 K); (c) powder (77 K); and **12***b*: (d) aqueous solution (298 K); (e) powder (298 K); (f) powder (77 K).

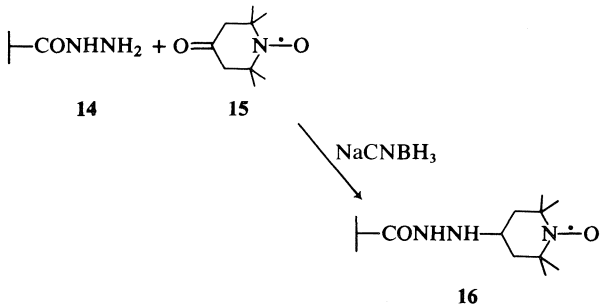
show the presence of small proportions of free label (Fig. 5b). The above findings seem to implicate the presence of two spin-label units per periodate-cleaved hexuronic acid residue of **12** since, even at low ds, dipolar interactions are evident. Possible contributions to the observed lineshapes from interactions between nitroxides attached to different chains or to neighbouring uronide residues should be negligible, at least for derivatives of **12** with low overall ds. If the above inference is correct, it would be in contrast to several observations of other dialdehyde reaction products for which incorporation of only one amine-bearing unit per dialdehyde has been found (see for example ref. 21). The reaction of equivalent dialdehyde cellulose derivatives will be discussed in section C.

A sample of periodate-oxidized alginate (do 0.10) was treated with *p*-fluoroaniline under identical conditions as above, to produce a derivative **13**, the 100.6 MHz ^{13}C nmr spectrum of which showed the aromatic resonances at 117 ppm. Fluorine-19 nmr studies of this derivative at 96.4 MHz indicated that ^{19}F is well suited for distinguishing covalently-bound material from reactant; thus, when *p*-fluoroaniline was added to an aqueous solution of the fluoroaniline-alginate derivative, the free and bound species were found to have resonances separated by ca. 1 ppm in chemical shift.

Hydrazide

Pfannemüller *et al.* (22) have recently reported a series of polysaccharide-hydrazide derivatives which they employed for the synthesis of branched-chain derivatives. In the present work, alginic acid hydrazide **14** was prepared, in adaptation of their method, from propylene glycol alginate **9** and hydrazine hydrate. Reductive amination of **14**, using 4-oxy-2,2,6,6-tetramethylpiperidine-1-oxyl **15** afforded the spin-labelled derivative **16** (ds 0.21),



whose aqueous solution spectrum is shown in Fig. 6a. This method is potentially useful for the preparation of polysaccharide intermediates since it introduces a very short spacer group between the polymer and other molecules to be attached to it.

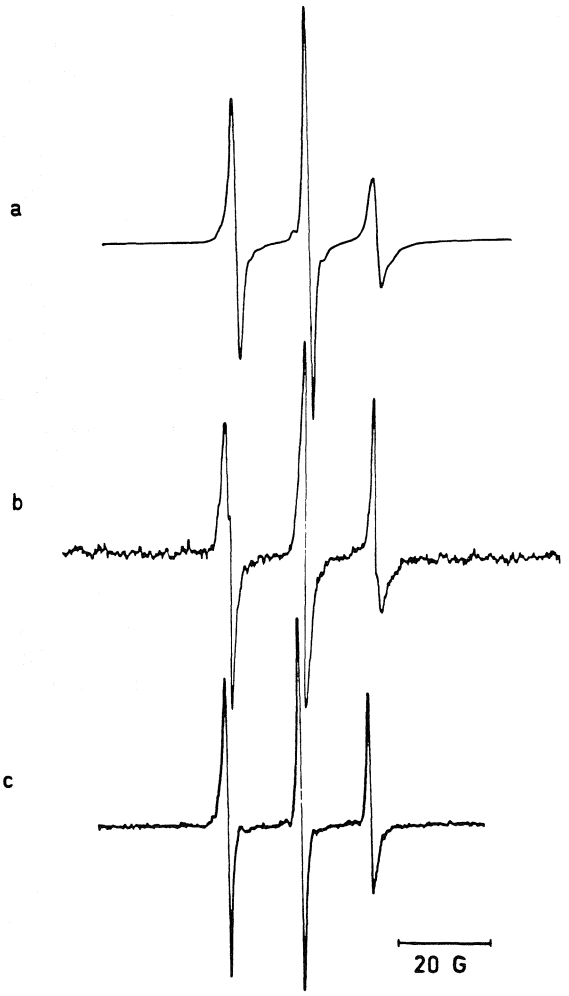

FIG. 6. Room temperature esr spectra of: (a) **16** in aqueous solution (b) **18** in aqueous solution; (c) **30** in aqueous solution.

s-*Triazine Derivative*

Lee and Maekawa (23) have reported a method for incorporating the carboxyl groups of polyuronides into *s*-triazine rings using dimethylbiguanidine hydrochloride. Following their method, **17** (ds 0.12) was prepared from propylene glycol alginate **9** and subsequently labelled using **15** to afford a product **18** (ds 0.02) whose aqueous solution spectrum (Fig. 6b) revealed a relatively slow tumbling nitroxide moiety (τ_c 31 ns). The *s*-triazine type derivative may be of interest for applications in which a partial masking of the carboxylate groups of polyuronides is desired.

B. *Xanthan Gum*

The carboxyl functions of the glucuronic acid and pyruvic acid residues are the most prominent candidates for specific derivatizations of xanthan gum, and should undergo the same reactions as their counterparts in alginate; this is demonstrated here by the carbodiimide-mediated preparation of the carboxamide derivative.

Amide

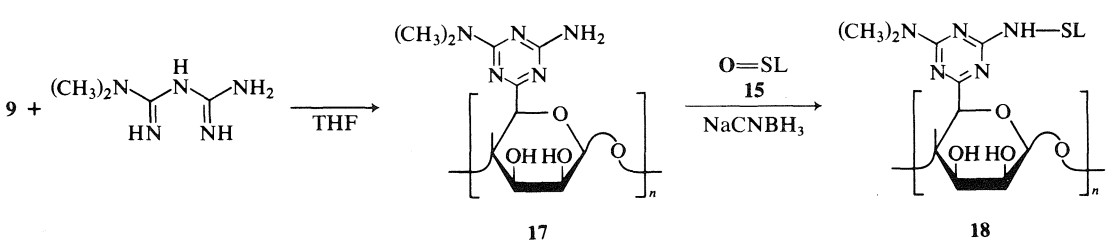
(a) Via Carbodiimide Coupling

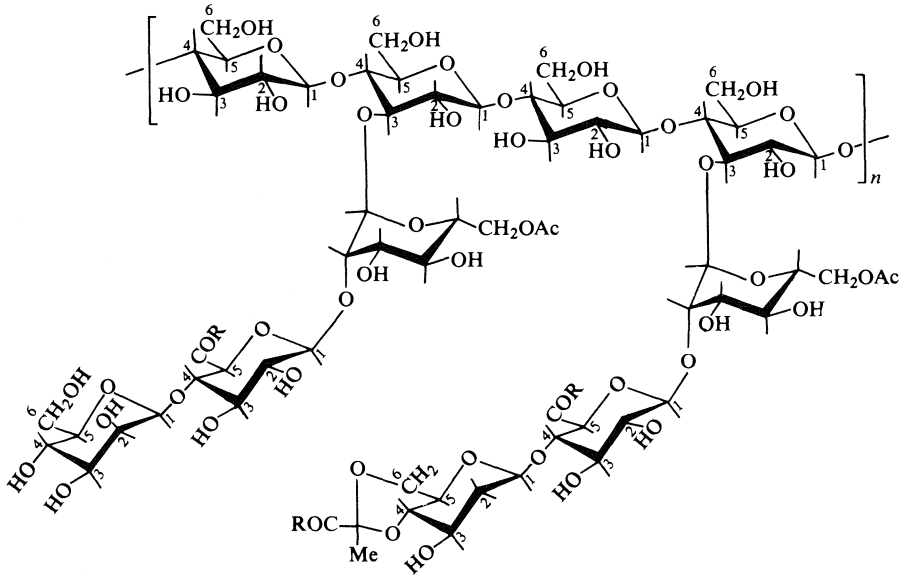
Purified xanthan gum **19** was activated via the carbodiimide procedure using EDC, and subsequently condensed with amine label **7** to afford the amide **20** in which 43% of the carboxyl groups had been transformed. In light of the mild reaction conditions employed, it is likely that derivatization of the pyruvic acid acetal groups has also occurred.

The esr spectrum of **20** in aqueous solution (Fig. 7a) reveals a fast tumbling (τ_c 6.1×10^{-11} s) nitroxide moiety, the motion of which is presumably attributable to the motional freedom enjoyed by the sidechains.

(b) Via Direct Condensation

A procedure has been described (24) for the preparation of "amine" alginates which involves the condensation of amines with solid alginate in the presence of small amounts of water. Since no further information was provided it is unclear, however, from this report what the term "amine alginates" actually implies in terms of the structure of such derivatives; assuming the formation of covalent linkages between the amines and hexuronide carboxylates, such products should be more appropriately classified as amides. Nevertheless, the procedure appeared to be interesting enough to warrant investigation using xanthan gum as substrate. Thus, xanthan gum **19** was condensed with amine label **7** following this procedure to yield a product **21** whose esr spectrum (Fig. 8b) revealed the presence of both "bound" and some "free" label, after purification by dialysis.





19 R = OH

20, 21 R = NH—

22 R = $NH(CH_2)_{17}CH_3$

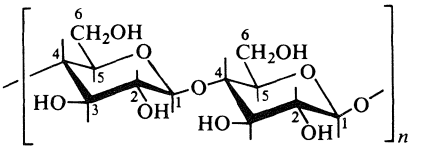
Encouraged by this evidence for the formation of a covalent derivative, the reaction was performed using a diamagnetic analogue, *n*-octadecylamine. Carbon-13 nmr measurements of the resulting product **22**, both in the solid state as well as in aqueous solution, confirmed the presence of the amide substituent (25). The ds of **22** could not, however, be accurately established; the C/N ratio found by combustion analysis corresponded approximately to a fully substituted product.

C. *Cellulose*

Amines via Reductive Amination of Dialdehyde Cellulose

Following Nevell's procedure (26), cellulose **23** was oxidized with periodate to the dialdehyde derivative **24** to obtain products with three different degrees of oxidation (do), 0.05, 0.19, and 0.34, respectively. Subsequent reductive amination of these materials produced the spin-labelled derivatives **25**. As in the case of alginate, the conversion into spin-labelled amines **25** did not seem to linearly correspond to the increasing do of the precursors. Degree of substitution values of 0.01, 0.063, and 0.065 were obtained for **25** from the dialdehyde samples with do 0.05, 0.19, and 0.34, respectively. The low overall spin-label incorporations can probably be attributed to the fact that the cellulose samples exhibit differential accessibility to the bulky nitroxide probes. Such reasoning seems justifiable in light of a recent esr study of the accessibility of cellulose which came to similar conclusions (18, 27). Interestingly, the esr spectra of **25** in aqueous suspension (Fig. 9a), indicate two distinct nitroxide populations of which one enjoys a substantially greater freedom of motional reorientation than the other; this finding gives further credence to the above "accessibility" arguments.

As for the corresponding alginate derivatives



23

(**12**), the esr powder spectra (Fig. 9b) of the cellulose derivatives **25** reveal dipole–dipole interactions between neighbouring spins from which it may again be inferred that structures containing two nitroxides per periodate-cleaved glucose residue **25***a* predominate over those bearing only one label, as exemplified (from a series of other possibilities) by **25***b*. The strongest evidence for this inference derives from the observation of dipolar interactions for cellulose derivatives with low ds. Assuming random oxidation and subsequent label-

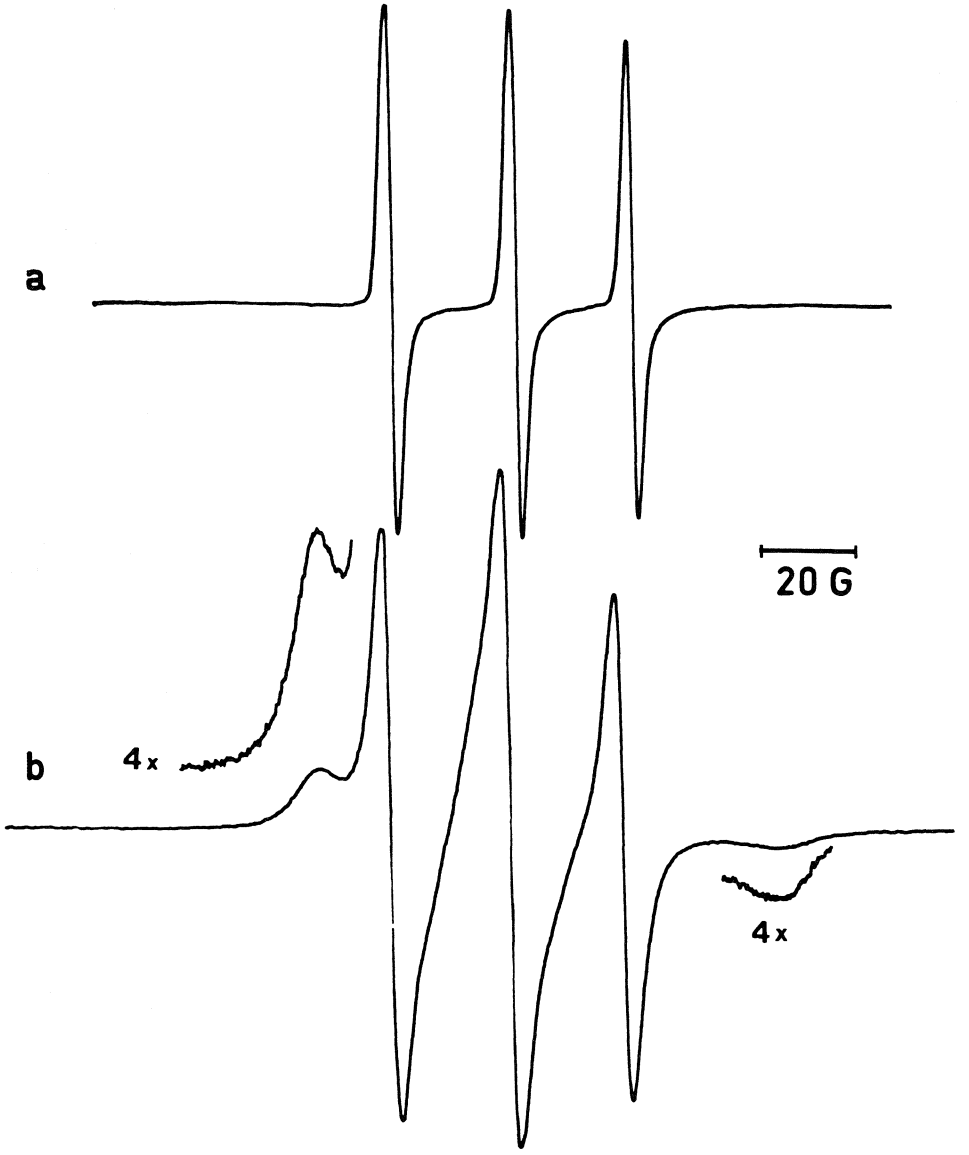

FIG. 7. Room temperature esr spectra of **20**: (a) aqueous solution; (b) powder (insert: receiver gain × 4).

ling of the polymer and with due consideration of the aforementioned "accessibility" factor, it is reasonable to expect the separation between single nitroxides attached to different hexose units to be too great for significant contributions to the dipolar interactions to arise from this source. Thus, it would seem that these findings are best accommodated by structural units of the type **25***a*.

Urethanes

Five-membered cyclic carbonate derivatives, obtained from the reaction of ethylchloroformate with vicinal diols, have been reported for a number of carbohydrates including polysaccharides (28). These derivatives form stable urethane products upon reaction with amine nucleophiles. Commercial cellulose carbonate (ds 0.21) **26** was derivatized in aqueous medium to afford the spin-labelled derivative **27** (ds 0.08).

It is interesting to note that (as for **25**) an aqueous suspension of **27** produced a complex spectrum consisting of a partially resolved broad component and a more mobile (τ_c 9.1×10^{-11} s) one (Fig. 10a). Differences in the morphology of **27** are therefore again indicated; indeed, the properties of **27** varied with its history: when prepared from methanol, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

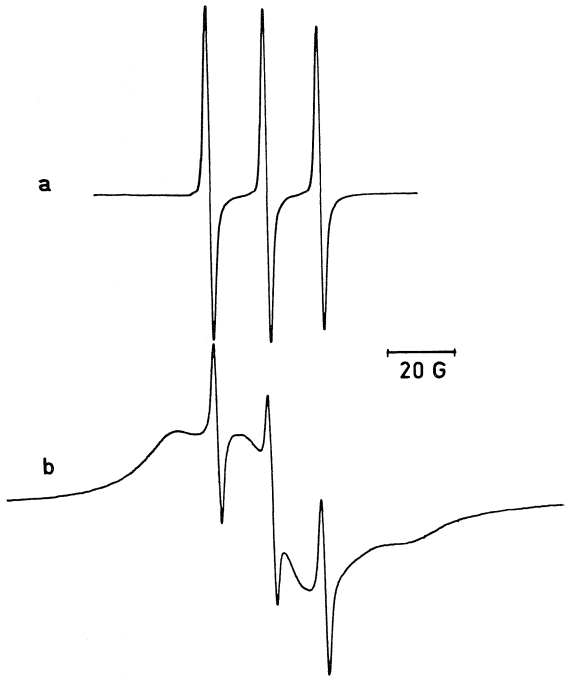

FIG. 8. Room temperature esr spectra of **21**: (a) aqueous solution; (b) powder.

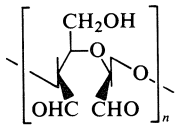
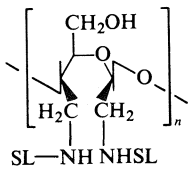
product had a lower ds and its esr spectrum (Fig. 10b) resembled that of a polycrystalline sample, whereas the product obtained from reaction in aqueous medium revealed strong dipolar interactions (Fig. 10c). It can therefore be suggested that these differences are attributable to the greater accessibility of **26** to aqueous solvent. A control experiment in which **26** was treated with the unreactive label **6**, proved that no adsorption phenomena were present in this set of experiments (Fig. 10d).

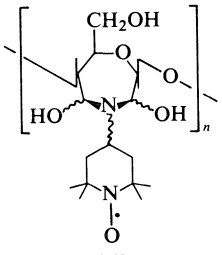
Finally, it should be noted that in methanol **26** may possibly undergo side-reactions (formation of



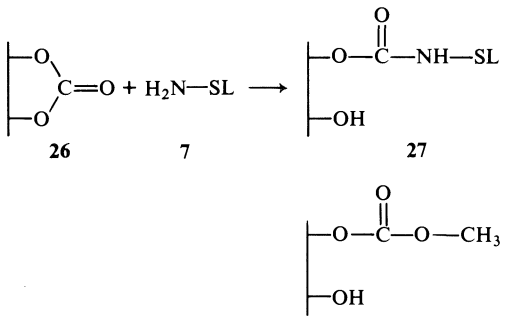
24



25*a*



25*b*



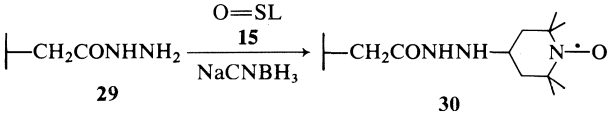
26 **7** **27**

28

O-methoxycarbonyl derivatives **28**) which could be partially responsible for the lower ds of **27** obtained from this medium.

Hydrazide

Cellulose hydrazide derivatives have found various applications as reactive intermediates (22) for enzyme immobilization (30), or for metal collection (31). Their synthesis can be achieved via the *C*-6-chlorodeoxy derivative (31) or, more conveniently, via commercially available carboxymethyl cellulose (32). Using the latter method, cellulose hydrazide **29** (ds 0.5) was prepared and subsequently reductively aminated, using **15**, to yield the hydrazide derivative **30** (ds 0.003) whose aqueous solution spectrum is shown in Fig. 6c. The nitroxide moiety of **30** displayed a relatively slow motional reorientation time (τ_c 17 ns).



29 **30**

Discussion

In view of the fact that some of the reactions described here, for example the amidation or esterification of alginate derivatives, occur under conditions which have no formal analogy in monosaccharide chemistry, it is appropriate to summarize the criteria used herein to establish the existence of covalent linkages. The esr spectra of nitroxide-labelled derivatives are highly informative in this regard for the following reasons.

1. The spectral lineshapes and widths from derivatives (in most cases, in aqueous solution) at ambient temperature are a well-established measure of the degree of motional immobilization of nitroxide moieties attached to polymers (33), allowing for facile distinction between these species and unbound spin label which is tumbling freely in solution. Whereas the latter species gives rise to three sharp lines of essentially equal intensity, the

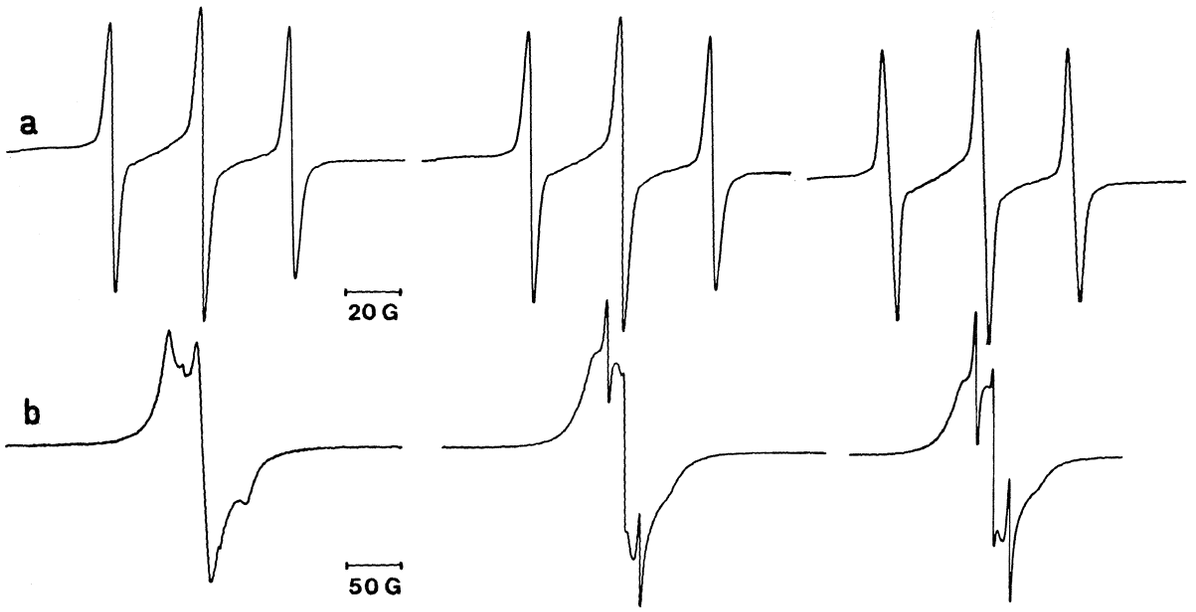


FIG. 9. Room temperature esr spectra of **25** with ds 0.03 (left), 0.063 (centre), and 0.065 (right): (a) aqueous suspension; (b) powder.

former exhibit varying intensity ratios and degrees of linewidth. This differential is important because even after extensive washing or dialysis, the esr spectra of several derivatives revealed the presence of small quantities of adsorbed species (see also item 4 below).

2. Similarly, the spectral lineshapes obtained from powder samples at 77 K facilitate distinction of "bound" and "free" labels (in the former case). Additional information regarding interactions between attached, proximate spin labels can, as we have described elsewhere (10, 18, 27, 34), be extracted from these spectra.

3. The τ_c values of nitroxide moieties provide, of course, another useful indication for the presence of covalent linkages, since values differing by several orders of magnitude are commonly found between species which are covalently associated as compared with species tumbling freely in solution. Due to the apparent complexity of many of the esr spectra (e.g. Fig. 6b) the corresponding τ_c values derived here merely serve for comparative purposes.

4. Control experiments in which an "unreactive" spin label was employed under identical reaction conditions as its reactive counterparts demonstrated that very few, if any, noncovalent associations or other phenomena such as trapping within a polysaccharide matrix occur for the various derivatives studied here. The absence of esr signals in experiments involving label **6** does, of course, not necessarily preclude ionic interactions in reactions involving amine- and hydroxy-bearing nitroxides and polyelectrolytes, such as alginate. Evidence for such phenomena derives from the relatively small, albeit significant, contribution of "free" label to the esr spectra (e.g. Figs. 2 and 4) of several derivatives where the corresponding control experiments produced only very weak esr signals. Thus, nitroxide labels can also be employed, as we will describe elsewhere, to probe polyelectrolyte interactions.

5. Whenever "free" nitroxide was suspected to coexist with bound label the leakage of such species from the polymer systems was monitored with time.

While fulfilment of only one of the above criteria may not always be considered sufficient proof for the existence of a polymer-bound nitroxide probe, a combination of several criteria, in conjunction with other spectroscopic evidence (such as nmr, ir, etc.) establishes such species unambiguously. Our attempts to use (standard) ir spectroscopy were generally unsuccessful mainly because the levels of probe incorporation were often too small to be detected.

Our confidence in the reliability of the esr technique for the purposes outlined above derives from a series of studies of polysaccharide derivatizations using spin labels (10, 18, 27, 35), in addition to the host of esr literature on a variety of other polymer systems (33).

Although some reactions proceeded in essentially quantitative fashion, for many others the

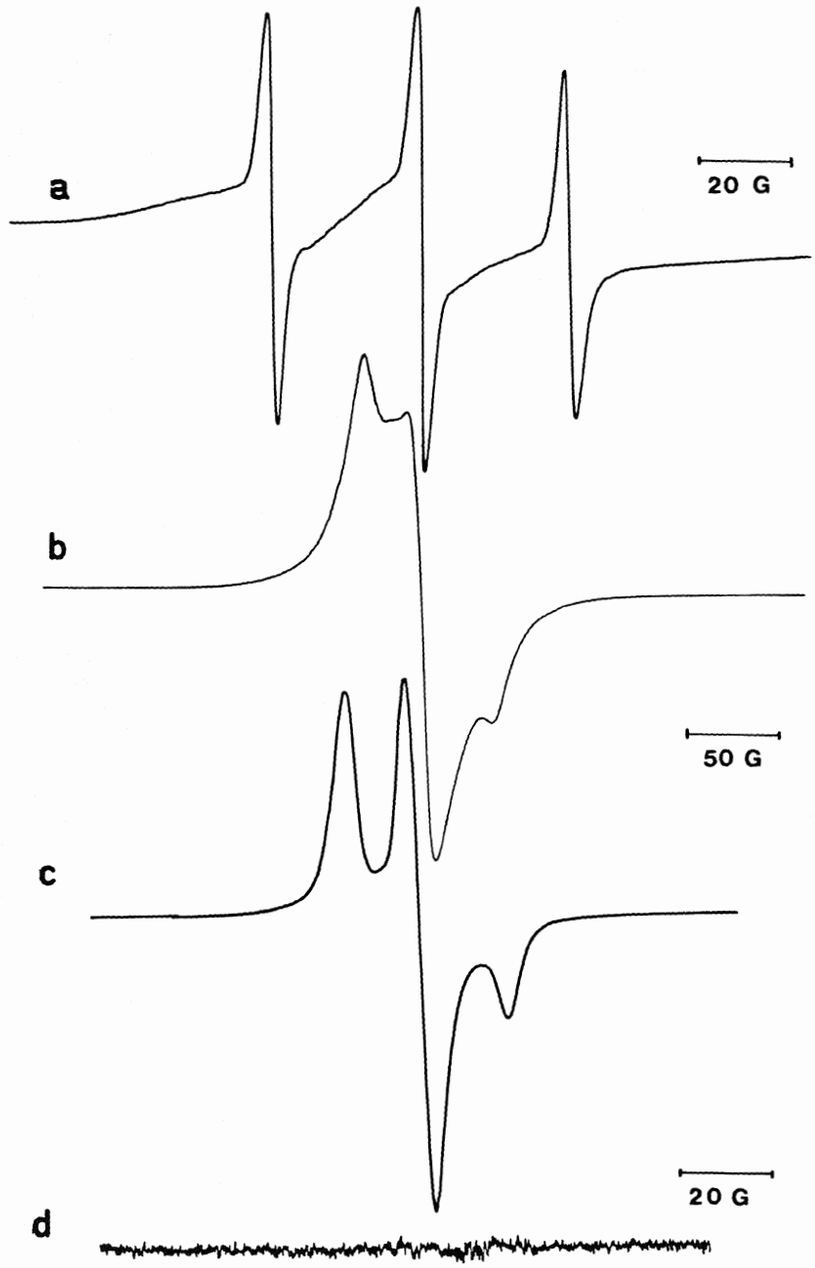

FIG. 10. The esr spectra of **27**: (a) aqueous suspension (298 K); (b) powder (298 K); (c) powder (77 K); (d) control experiment: **26** reated with **6** under identical conditions.

:onversion yields were relatively low. For two easons no attempts were made here to fully ptimize the reaction conditions in such cases: on ıe one hand, these studies were intended largely to rove the formation of covalent derivatives, and, ı the other hand, industrial procedures (36) for the eparation of high ds polysaccharide derivatives ere not followed to avoid factors, such as a certain degree of polymer degradation or additional chemical species, which might complicate the interpretation of our data.

In view of the low ds values obtained in many reactions, esr double integration was used to determine the levels of spin-label incorporation. Although this method is satisfactory for water-soluble polysaccharide derivatives, we have generally ob-

personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

tained (with the instrumentation available to us) somewhat less reliable results from double integration of *solid* samples. From calibration studies we estimate the accuracy of the esr double integration to range from a few percent for solutions, to approximately 10–15 percent for powder samples, depending on the ds values of the derivatives.

For the case of derivatives with higher ds values, particularly for those containing nitrogen, routine microanalysis offers, of course, a highly reliable method for ds determinations; a certain small (generally less than one percent) uncertainty in the ds values is, however, usually encountered here, as a consequence of the extremely hygroscopic character of polysaccharides (37).

It is evident from the above that a number of reactions satisfied the requirements for specific and medium- to high-efficient conversion of polysaccharides. The carbodiimide-mediated amidation falls into this category, as does the formation of reactive intermediates via the hydrazide derivatives. The modification of vicinal diols via periodate oxidation or cyclic carbonate formation is less specific; however, the former procedure may, if performed under controlled conditions, be a useful method. Among the other methods examined, the esterification of alginic acid with alcohols seems to be promising and deserves investigation for some other polysaccharide systems; the same holds true for the amidation reactions of alginic esters.

In conclusion, we wish to note that the particular merit of the spin-labelling approach derives not solely from the fact that it provides information regarding polymer bound versus free species. As will be demonstrated in future publications, the esr method can also be employed for probing important molecular parameters, such as surface homogeneity and area, as well as the proximity of spin probes tethered to polysaccharide substrates.

Experimental

General Methods and Materials

All polysaccharide modification reactions were conducted at ambient temperature. All concentrations were performed on a Büchi rotary evaporator. Polysaccharide reaction products were purified by dialysis (unless indicated otherwise) using Spectropore #1 or #2 tubing from Spectrum Medical Inc. (Los Angeles, CA), against 0.01 *M* EDTA/0.01 *M* NaCl solutions or distilled water with 0.02% NaN_3 for 4–6 days, and subsequently lyophilized. All samples were stored refrigerated with desiccation.

C, H, N microanalyses were carried out by Mr. P. Borda of the Microanalytical Laboratory, Department of Chemistry, University of British Columbia, following careful and extensive (1–2 days) drying of the samples *in vacuo* (56°C, 0.01 Torr) over sodium hydroxide.

The following alginate samples were a gift from Kelco Co., San Diego, CA: sodium alginate (Keltone), alginic acid (Kelacid), and propylene glycol alginate esterified 50–60% (Kelcoloid-HVF) and 80–85% (Kelcoloid-O). Sodium alginate was purified following Schweiger's method (38). Cellulose carbonate was purchased from Sigma Chemical Co., cellulose powder (Whatman CF11) from W. & R. Balston Ltd., U.K. Carboxymethylcellulose (12M31P) was a gift from Hercules Inc., Wilmington, DE. Xanthan gum samples were gifts from Kelco Co. (Keltrol) and Tate & Lyle Ltd, London ($77A_3$). The former samples were purified according to the method of Holzwarth (39) while the latter were supplied in purified form.

1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide HCl (EDC) was purchased from Sigma Chemical Co., and *N,N'*-dicyclohexylcarbodiimide (DCC) from Eastman Chemical Co. Dimethylbiguanidine HCl was from Aldrich Chemical Co., sodium periodate was from Fisher Scientific Co. Hydrazine hydrate was purchased from Mallinckrodt Co. Sodium cyanoborohydride, 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl, 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl, and the spin label analogue, 4-amino-2,2,6,6-tetramethylpiperidine were purchased from Aldrich Chemical Co. The other spin labels, 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl and 4-chloroacetamido-2,2,6,6-tetramethylpiperidine-1-oxyl, were synthesized by Ms. L. Evelyn of this lab using the method of McConnell and co-workers (40).

Electron Spin Resonance

The esr spectra were recorded at *X*-band using a Varian E-3 instrument in the derivative adsorption mode, and integrated using a Pacific Precision Co. MO-1012A integrator. The second integration was performed by peak cutting and weighing and comparison with freshly prepared, standard solutions of 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl. Spectral lineshape distortions were avoided by careful choice of spectrometer settings (modulation amplitude, filter time constant, and scan rate); nonsaturating power levels were used. Linewidths and correlation times for rotational reorientation (τ_c) were measured using the smallest possible scan range (generally not that shown in the diagrams) and at least two to three scans in each case. τ_c values were calculated from the quadratic term of the ratio-of-heights method of McConnell and co-workers (41). No computer simulation of spectra was used since only estimates for relative comparisons were required here. A flat high-quality quartz cell (73 μL) with ground glass joints at both ends (J. Scanlon Co.) was used for aqueous solutions; aqueous suspensions and gels of polysaccharides were measured using a Teflon insert which was designed by Dr. F. G. Herring of this Department.

Nuclear Magnetic Resonance

Carbon-13 nmr spectra of aqueous and solid polysaccharide samples were recorded with a Bruker WH-400 and CXP 200 spectrometer at 100.6 MHz and 50.3 MHz, respectively, at ambient temperature (25). Fluorine-19 nmr spectra were obtained with a Varian XL-100 spectrometer (at 96.4 MHz).

Preparation of (4-Acetamido-2,2,6,6-tetramethylpiperidine-1-oxyl) Alginic Acid (3)[4]

Alginic acid was partially dehydrated following Schweiger's

[4]The application of systematic nomenclature to most of the polysaccharide derivatives reported here is not feasible due to the heterogeneity in the structure of the original polymers or in the substitution pattern of the reaction products; in a number of cases, such as for the products derived from periodate-oxidized materials, the exact structure of the product is unknown (see text). The nomenclature system adapted here attempts to indicate the substituent(s) introduced followed by the name of the native polysaccharide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

method (13) but with some modifications. Alginic acid (1 g) was swelled in glacial acetic acid (5 mL) and then centrifuged in a desk-top centrifuge. The supernatant was decanted, and the procedure repeated several times. The wet material thus obtained was used for subsequent reactions.

A solution of chloroacetamide label **2** (130 mg, 5.3 mmol) in pyridine (4 mL) was added to partially dehydrated alginic acid (40 mg, 0.23 mmol) and the dispersion was adjusted with solid $NaHCO_3$ to pH 7.5. The reaction mixture was gently shaken for 18 h. The resulting product **3** had ds 0.04. When 65% aqueous acetone was used as solvent instead of pyridine the ds of **3** was lowered to 0.01.

Preparation of [4-(2,2,6,6-Tetramethylpiperidine-1-oxyl)] Alginate (5)

Partially dehydrated alginic acid (150 mg, 0.85 mmol) was suspended in 65% aqueous acetone (5 mL). After addition of hydroxy label **4** (300 mg, 1.7 mmol) the pH was adjusted to 6 using $NaHCO_3$ and the mixture was shaken for 18 h. The product **5** had ds 0.05.

Preparation of [4-(2,2,6,6-Tetramethylpiperidine-1-oxyl)] Alginamides (8, 10)

(i) Carbodiimide Coupling

(a) EDC coupling. To partially dehydrated alginic acid (150 mg, 0.85 mmol) was added a 65% aqueous acetone solution of EDC (240 mg, 1.25 mmol, 5 mL), and after adjustment of the pH to 6.5 using Na_2CO_3, a solution of amine label **7** (270 mg, 1.6 mmol, 2 mL). The mixture was shaken for 18 h and the resulting product **8** had ds 1.00.

(b) DCC coupling. The reaction conditions were the same as in the EDC coupling procedure with the exception of using DCC (100 mg, 0.48 mmol), and DMF (3 mL) as solvent. This reaction, however, proceeded in lower (ca. 10%) yields than the EDC coupling.

(ii) Via Propylene Glycol Esters

A solution of amine label **7** (276 mg, 1.6 mmol) in DMF (2 mL) was added to a suspension of propylene glycol alginate (PGA) with a degree of esterification 0.80–0.85 (193 mg, 0.86 mmol) in DMF (2 mL). The mixture was shaken for 14 h to yield a product **10** with ds 0.15 (18% conversion of available ester groups). For PGA with a lower degree of esterification (0.5–0.6) a product with ds 0.10 (18% conversion) was obtained.

Preparation of [4-N-(2,2,6,6-Tetramethylpiperidine-1-oxyl)] Alginamine (12)

Sodium alginate was periodate-oxidized according to the procedure of Painter and co-workers (20). In a typical experiment, a 0.78% aqueous solution of sodium alginate was oxidized with 0.25 *M* $NaIO_4$ in the presence of 1-propanol at 4°C in the dark for 24 h. The oxidation was terminated by addition of ethylene glycol. Reductive amination was performed by addition of an aqueous solution of amine spin label **7** (3- to 5-fold molar excess) and sodium cyanoborohydride (7- to 10-fold molar excess). The reaction mixture was shaken for 24 h. For alginate samples oxidized 10%, products with ds 0.05 (52% conversion of available aldehyde groups) were obtained, while for samples oxidized 44% the products **12** had ds 0.13 (30% conversion).

Preparation of N-[4-(2,2,6,6-Tetramethylpiperidine-1-oxyl)] Algin Hydrazide (16)

(a) The method of Andresz *et al.* (22) was modified to prepare the hydrazide derivatives. Samples of propylene glycol alginate (Kelcoloid-O, 0.5 g, 2.2 mmol) were mixed with hydrazine hydrate, (10 mL, 0.2 *M*), in a 50 mL Erlenmeyer flask. The reaction mixture was gently shaken overnight at 22°C, affording a viscous solution which was diluted with water (25 mL). The product was precipitated in methanol (300 mL), the precipitate was collected after centrifugation (9000 rpm, 50 min), and dialyzed against 0.01 *M* EDTA for 2 days before lyophilization. Elemental analysis showed a product **14** with ds 0.76, i.e., 92% conversion of the ester. *Anal.* calcd. for $[(C_6H_8O_6)_{0.17}(C_9H_{14}O_7)_{0.07}(C_6H_{10}N_2O_5)_{0.76}]\cdot 0.88\ H_2O$: C 36.25, H 5.74, N 10.35 (C/N 3.53); found: C 36.01, H 5.37, N 10.36 (C/N 3.48).

Similarly, for PGA with lower degrees of esterification, products **14** with ds 0.45 (i.e., 80% conversion) were obtained (C/N 5.71). These ds obtained here correspond well with those of Andresz *et al.* (22) (ds 0.67).

(b) Reductive amination of hydrazide alginate **14** (ds 0.76) was carried out by dissolving it (27 mg, 0.13 mmol) in water (10 mL) and adding a solution (7 mL) of keto spin label **15** (102 mg, 0.58 mmol) and $NaCNBH_3$ (140 mg, 2.2 mmol). The reaction mixture was left on a shaker overnight. The hydrazide product **16** had ds 0.21.

Preparation of [(2-Amino-4-N-dimethylamino)-s-triazin-6-yl] Alginate (17) and [4-(N-Dimethylamino)-2-(4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl)-s-triazin-6-yl] Alginate (18)

(a) The *s*-triazinyl derivate was prepared according to Lee and Maekawa (23) using propylene glycol alginate (Kelcoloid-O) instead of the methyl ester of alginate. Kelcoloid-O (1 g, 5.44 mmol) was suspended in MeOH (100 mL) at 0°C and dimethylbiguanidine hydrochloride (1 g, 6.1 mmol) in THF/MeOH (1:1) (60 mL) was added with stirring to the suspension over a 20 min period. After one hour, the reaction mixture was allowed to warm to room temperature and left stirring for four days. The mixture was concentrated to dryness, and distilled water (20 mL) was added affording a gel, which was purified by dialysis. The product had ds ca. 0.12 (i.e., 15% conversion of esters) as determined by microanalysis. *Anal.* calcd. for $[(C_6H_8O_6)_{0.2}(C_9H_{14}O_7)_{0.68}(C_{10}H_{15}N_5O_4)_{0.12}]\cdot 2.01\ H_2O$: C 38.88, H 6.50, N 3.20 (C/N 12.2); found: C 38.59, H 5.70, N 3.05, (C/N 12.7).

(b) The *s*-triazinyl alginate **17** was labelled by dissolving 40 mg (0.18 mmol) in water (10 mL) and adding a solution of keto label **15** (80 mg, 0.47 mmol) and $NaCNBH_3$ (100 mg, 1.5 mmol) to the mixture, which was shaken for 13 h. The product **18** had ds 0.02.

Preparation of [4-N-(2,2,6,6-Tetramethylpiperidine-1-oxyl)] Xanthan Amide 20

To xanthan gum (150 mg, 0.16 mmol) dissolved in water (10 mL) was added EDC (100 mg, 0.78 mmol) and the reaction mixture (pH 5) was cooled to 5°C for 10 min before the amine label **7** (80 mg, 0.47 mmol) was added with stirring. The reaction was continued for 12 h, yielding a product **20** with ds 0.43 (based on carboxyl groups) after dialysis (4 days).

Preparation of [4-N-(2,2,6,6-Tetramethylpiperidine-1-oxyl)] Xanthan Amide (21)

Following a method reported for the synthesis of "amine alginates" (24), xanthan gum (50 mg, 0.05 mmol) was mixed in a 25 mL Erlenmeyer flask with solid amine spin label **7** (57 mg, 0.33 mmol) using a spatula. Three drops of water were added and mixed in to produce a heavy paste, which was shaken for 11 h, and then dialysed (4 days). The product **21** had ds 0.05 (based on carboxyl groups).

Preparation of [18-N-(n-Octadecyl)] Xanthan Amide (22)

Following the above procedure, octadecylamine (60 mg, 0.22 mmol) was admixed with xanthan gum (75 mg, 0.08 mmol) to afford (22), after precipitation from ethanol (twice), and dialysis (3 days), **22**. The microanalytical results (C 48.04, H 7.99, N 2.27) could not be matched with a corresponding molecular formula but the C/N ratio corresponds roughly to a ds 1.0.

*Preparation of [4-*N*-(2,2,6,6-Tetramethylpiperidine-1-oxyl)] Cellulose Amine (25)*

(a) The periodate oxidation method of Nevell (26) was used. Three samples (500 mg, 3.1 mmol) of cellulose powder were each reacted with $NaIO_4$ (0.01 *M*, 0.05 *M*, and 0.10 *M*) in distilled water (25 mL) in the dark for 60 h at 20°C in a constant temperature shaker to afford products which had a degree of oxidation (do) of 5%, 19%, and 34%, respectively. The reaction was quenched by mixing the dispersions with distilled water (250 mL) and decanting the supernatant. This process was repeated 6–7 times. The samples were left in distilled water overnight, then washed with water (100 mL) and subsequently dried *in vacuo* at 56°C.

(b) Periodate-oxidized cellulose samples (1 mmol) were labelled in MeOH (7 mL) by adding 2.6 equivalents of amine spin label **7** and 6.4 equivalents $NaCNBH_3$ and a few drops of water. After gentle shaking (28 h) the samples were successively washed on a fritted glass filter with 100 mL each of water, ethanol, acetone, and ether, and subsequently dried under vacuum for 24 h at 56°C. The following ds were obtained (do): (A) ds 0.03 (5%); (B) ds 0.063 (19%); (C) ds 0.065 (34%). *Anal.* calcd. for (A) $[(C_6H_{10}O_5)_{0.93}(C_6H_8O_5)_{0.04}(C_{13}H_{27}N_2O_5)_{0.03}]\cdot 0.13\ H_2O$: C 44.30, H 6.43, N 0.50; found: C 44.01, H 6.38, N 0.51. *Anal.* calcd. for (B) $[(C_6H_{10}O_5)_{0.81}(C_6H_8O_5)_{0.127}(C_{13}H_{27}N_2O_5)_{0.063}]\cdot 0.14\ H_2O$: C 44.81, H 6.49, N 1.02; found: C 44.70, H 6.49, N 1.03. *Anal.* calcd. for (C) $[(C_6H_{10}O_5)_{0.66}(C_6H_8O_5)_{0.275}(C_{13}H_{27}N_2O_5)_{0.065}]\cdot 0.21\ H_2O$: C 44.61, H 6.37, N 1.05; found: C 44.33, H 6.25, N 1.04.

*Preparation of [4-*N*-(2,2,6,6-Tetramethylpiperidine-1-oxyl)] Cellulose Urethane (27)*

A solution of the amine label **7** (366 mg, 2.1 mmol) in phosphate buffer (0.5 *M*, pH 7, 2 mL) was added to a suspension of cellulose carbonate (ds 0.21, 80 mg, 0.48 mmol) in the buffer (10 mL). The reaction mixture was stirred overnight at 5°C, and then dialyzed (5 days) at the same temperature to afford a product **27** with ds 0.08. *Anal.* calcd. for $[(C_6H_{10}O_5)_{0.74}(C_7H_8O_6)_{0.18}(C_{16}H_{27}N_2O_6)_{0.08}]\cdot 0.75\ H_2O$: C 43.22, H 6.50, N 1.16; found: C 43.08, H 6.54, N 1.10.

When the reaction was carried out in methanol a product with lower ds (0.05) was obtained. *Anal.* calcd. for $[(C_6H_{10}O_5)_{0.8}(C_7H_8O_6)_{0.15}(C_{16}H_{27}N_2O_6)_{0.05}]\cdot 0.34\ H_2O$: C 44.06, H 6.25, N 0.77; found: C 43.86, H 6.16, N 0.75.

Preparation of N*-[4-(2,2,6,6-Tetramethylpiperidine-1-oxyl)] Cellulose Hydrazide (30)*

(a) The cellulose hydrazide derivative **29** was prepared following the method of Andresz *et al.* (22) using sodium carboxymethylcellulose (ds 1.2–1.4) as starting material. The product had a ds value of ca. 0.5 (lit. (22) ds 0.68) as calculated from elemental analysis. *Anal.* calcd. for $[(C_8H_{12}O_7)_{0.5}(C_8H_{14}N_2O_6)_{0.5}]\cdot 2.9\ H_2O$: C 34.37, H 6.78, N 5.01 (C/N 6.86); found: C 34.20, H 5.87, N 4.90 (C/N 6.98).

(b) Cellulose hydrazide (40 mg, 0.16 mmol) was labelled in phosphate buffer (0.5 *M*, ph 7, 10 mL) using keto spin label **15** (97 mg, 0.6 mmol) and $NaCNBH_3$ (100 mg, 1.6 mmol). The mixture was shaken for 15 h and then dialyzed (4 days), to afford **30**, ds 0.003 (from esr double integration).

COMMUNICATION

A thermal [1,3] sigmatropic rearrangement: thermolysis of 2,2-bis(ethylthio)-3,3-dimethyl-4-pentenal

GORDON S. BATES[1] AND S. RAMASWAMY

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received June 12, 1981

GORDON S. BATES and S. RAMASWAMY. Can. J. Chem. **59**, 3120 (1981).

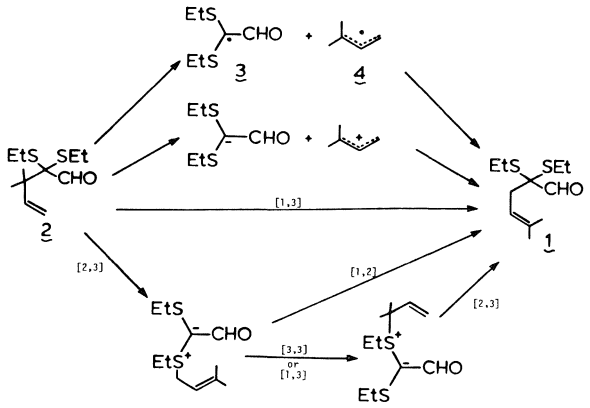
2,2-Bis(ethylthio)-3,3-dimethyl-4-pentenal was found to quantitatively isomerize to 2,2-bis(ethylthio)-5-methyl-4-hexenal over a wide temperature range (130–170°C). This rearrangement can formally be regarded as a [1,3] sigmatropic shift. The reaction, which could be conveniently monitored by ^{1}Hmr spectroscopy, was found to obey first order kinetics. The substantial positive entropy of activation (+ 61.5 J deg^{-1} mol^{-1}) for the reaction and the negligible solvent effect (decane vs. DMF) are both consistent with a proposed diradical pathway.

GORDON S. BATES et S. RAMASWAMY. Can. J. Chem. **59**, 3120 (1981).

On a trouvé que le bis(éthylthio)-2,2 diméthyl-3,3 pentène-4 al s'isomérise quantitativement en bis(éthylthio)-2,2 méthyl-5 hexène-4 al à des températures allant de 130 à 170°C. On peut considérer formellement cette transposition comme étant un glissement sigmatropique [1,3]. Cette réaction qu'on peut suivre convenablement par la spectroscopie de rmn, est d'ordre un. La forte entropie positive d'activation (+61,5 J deg^{-1} mol^{-1}) de la réaction et l'effet négligeable du solvant (décane vs. DMF) sont en accord avec le mécanisme biradicalaire proposé.

[Traduit par le journal]

The alkylation of the anions of various enamines of bis(ethylthio)acetaldehyde (1) with 2-methyl-4-bromo-2-butene gives exclusively, after hydrolysis of the enamine, the S_N2 product **1**, whereas alkylation of the anion of the aldehyde yields the S_N2' product **2**. This latter compound is likely formed by initial S_N2 alkylation of one of the sulphur atoms of the anion followed by a [2,3] sigmatropic rearrangement of the resulting ylide.[2] Compound **2** appeared to be an ideal substrate to provide an example of a rare thermal carbon–carbon [1,3] alkyl shift (5) in an *acyclic* system. Rearrangement of **2** into **1** should be favoured since the transformation would be accompanied by relief of the steric strain associated with the two adjacent quaternary centres in **2**, as well as by formation of the more highly substituted alkene in **1**. Indeed, upon heating an *n*-decane solution of **2** at 170°C for one hour, the desired rearrangement occurred to provide **1** in virtually quantitative yield.[3] This rearrangement may be rationalized in terms of several different mechanisms as shown in Scheme 1.



SCHEME 1

Any of the concerted processes must involve ordered transition states which should be reflected in a relatively large negative entropy of activation ($\Delta S^{\ddagger}$).[4] The $\Delta S^{\ddagger}$ for the ionic pathway could vary greatly. If there is considerable freedom in the transition state then $\Delta S^{\ddagger}$ would be positive. However, a negative $\Delta S^{\ddagger}$ is also possible due to electrostriction of the solvent around the ions produced (11). The diradical process should have a substantial positive $\Delta S^{\ddagger}$ (12). If the rearrangement proceeds by way of an ionic, or indeed, via any process involving significant charge development

[2]For similar transformations see refs. 2, 3, and 4 and references cited therein.

[3]Thermal [1,3] rearrangements of several 4-dimethylaminobutenes have been reported. See refs. 6 and 7.

[4]For example, the Cope rearrangement has $\Delta S^{\ddagger}$'s ranging from −46.4 to −58.6 J deg^{-1} mol^{-1} (8–10).

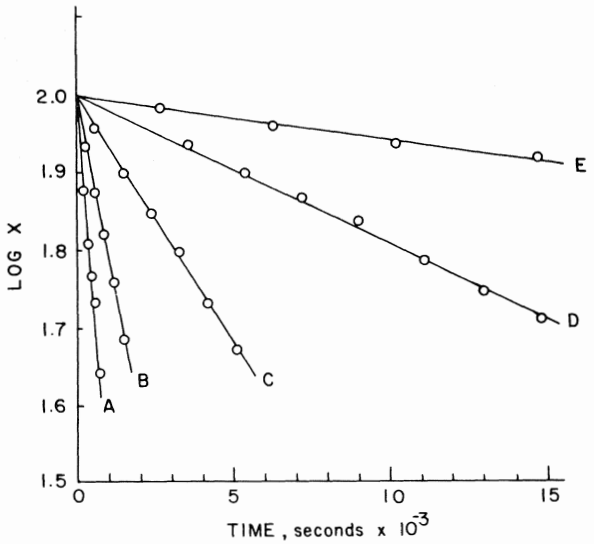

FIG. 1. Rate of rearrangement of **2**: X = 100 ([2]/[1 + 2]) as determined by ^{1}Hmr spectroscopy. A, t = 170°C, $k = 1.10 \times 10^{-3}$ s^{-1}; B, t = 160°C, $k = 4.73 \times 10^{-4}$ s^{-1}; C, t = 150°C, $k = 1.46 \times 10^{-4}$ s^{-1}; D, t = 140°C, $k = 4.51 \times 10^{-5}$ s^{-1}; E, t = 130°C, $k = 1.35 \times 10^{-5}$ s^{-1}.

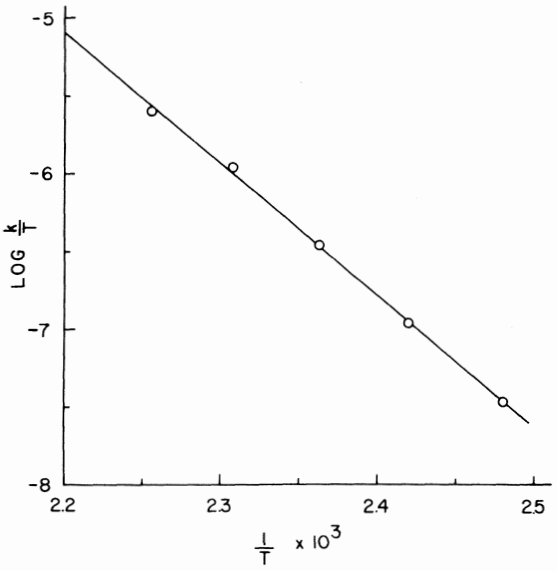

FIG. 2. Dependence on temperature of rate constants for rearrangement of **2**.

in the transition state, there should be a definite solvent effect. The rate of a concerted or of a diradical process should be relatively independent of solvent (13). A determination of the activation parameters of the reaction as well as the presence or absence of a solvent effect will thus allow a mechanistic choice to be made.

The ^{1}Hmr spectra of **1** and **2** are very different.[5] The progress of the rearrangement was conveniently monitored by observing the change in the relative intensities of the singlets in the ^{1}Hmr spectrum due to the aldehyde protons of **1** (δ 9.10) and **2** (δ 9.20). The thermolyses were carried out in degassed, spectral grade *n*-decane under an argon atmosphere. The reactions were quenched at various intervals by immersing the samples in an ice–water slurry. Figure 1 clearly indicates that the rearrangement follows first order reaction kinetics. The enthalpy (162.3 kJ mol^{-1}) and entropy (+ 61.5 J deg^{-1} mol^{-1}) of activation for the reaction were calculated from the Eyring equation (14) using the data obtained from Fig. 2. The rearrangement was also carried out in *N*,*N*-dimethylformamide (DMF) (t = 140°C, $k = 6.59 \times 10^{-5}$ s^{-1}). Since the rate of the rearrangement changes by a factor of less than 1.5 with the drastic change in solvent from *n*-decane to DMF, we feel that the rearrangement is not accompanied by any charge separation and thus the ionic process may be ruled out.[6] The substantial positive $\Delta S^{\ddagger}$ for the reaction appears to be inconsistent with a concerted mechanism. On the basis of the sign and magnitude of the $\Delta S^{\ddagger}$ for the reaction and the lack of any significant solvent effect we propose that **2** undergoes homolytic cleavage to form two stabilized radicals, the tertiary allylic fragment **3** and capto-dative stabilized (16) radical **4**. These two radicals then undergo smooth recombination to give **1**.

Preliminary studies have shown that 3,3-dimethyl-2,2-(1,3-dithiane)-4-pentenal (3) undergoes a similar [1,3] rearrangement. Further work on this and several other related systems will be reported in due course.

Received March 27, 1981

SHARON E. ANSLOW, KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **59**, 3123 (1981).

The synthesis of a number of six-coordinate manganese, molybdenum, and tungsten carbonyl compounds incorporating both the bidentate bispyrazolyl gallate ligand, $[Me_2Ga(N_2C_3H_3)_2]^-$, and a neutral pyrazole ligand in a facial coordination arrangement are described. Variable temperature ^1H nmr studies have revealed interestingly different behaviours in solution for the valence isoelectronic species $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ and $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3^-$. X-ray structural analyses of crystalline samples of the two compounds have been carried out in an effort to shed light on these behavioural differences. Crystals of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ are monoclinic, $a = 31.053(2)$, $b = 8.0503(4)$, $c = 15.8629(8)$ Å, $\beta = 108.164(2)°$, $Z = 8$, space group $C2/c$ and crystals of $[(C_2H_5)_4N]^+\{[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3\}^-$ are monoclinic, $a = 10.058(1)$, $b = 20.6488(5)$, $c = 13.533(1)$ Å, $\beta = 93.800(5)°$, $Z = 4$, space group $P2_1/n$. Both structures were solved by Patterson and Fourier syntheses and were refined by full-matrix least-squares procedures to final R values of 0.028 and 0.023 for 2613 and 4388 observed reflections for the Mn and Mo complexes, respectively. The neutral Mn complex and the complex Mo anion both have approximate mirror symmetry and both metal atoms have trigonally distorted octahedral coordination geometry. Important bond distances (corrected for thermal vibration) are: Mn—N, 2.074(3)–2.086(3), Mn—C, 1.795(4)–1.809(5), Mo—N, 2.291(2)–2.295(2), and Mo—C, 1.918(3)–1.936(3) Å. Although structural differences between these two species do offer plausible explanations for the differences observed in solution, it appears that other factors are more important.

SHARON E. ANSLOW, KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **59**, 3123 (1981).

On décrit la synthèse d'une série de composés carbonylés hexacoordonnés du manganèse, du molybdène et du tungstène, incorporant le ligand bidentate bispyrazolyl gallate $[Me_2Ga(N_2C_3H_3)_2]^-$ et un ligand neutre pyrazole coordonné de façon faciale. Les études de rmn du ^1H à température variable ont révélé de façon intéressante les comportements différents de la valence des espèces isoélectroniques $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ et $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3^-$ en solution. On a étudié les cristaux par cristallographie de rayons-X afin de comprendre ces différences de comportement. Les cristaux de $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ sont monocliniques et appartiennent au groupe d'espace $C2/c$ avec $a = 31,053(2)$, $b = 8,0503(4)$, $c = 15,8629(8)$ Å, $\beta = 108,164(2)°$, $Z = 8$. Les cristaux de $[(C_2H_5)_4N]^+\{Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3\}^-$ sont monocliniques avec $a = 10,058(1)$, $b = 20,6488(5)$, $c = 13,533(1)$ Å, $\beta = 93,800(5)°$, $Z = 4$, groupe d'espace $P2_1/n$. On a résolu les deux structures par les synthèses de Patterson et de Fourier et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R = 0,028$ et 0,023 pour 2613 et 4388 réflexions observées pour les complexes de Mn et de Mo respectivement. Le complexe neutre de Mn et le complexe anionique de Mon sont approximativement l'image l'un de l'autre dans un mirroir et les deux atomes métalliques ont une géométrie de coordination octaédrique déformée de façon trigonale. Les longueurs importantes de liaison (corrigés pour la vibration thermique) sont Mn—N, 2,074(3)–2,086(3), Mn—C, 1,795(4)–1,809(5), Mo—N, 2,291(2)–2,295(2) et Mo—C, 1,918(3)–1,936(3) Å. Bien que les différences structurales entre ces deux espèces offrent des explications plausibles des différences observées en solution, il semble que d'autres facteurs sont plus importants.

[Traduit par le journal]

Introduction

Earlier reports have detailed the synthesis of bidentate chelating anionic pyrazolyl gallate ligands of the type $[Me_2Ga(N_2C_3H_3)_2]^-$ and their complexation with divalent transition metal ions (1–4). More recently a series of allylic derivatives of Ni and Pd incorporating these ligands has been characterized (5). The present account describes the use of these bidentate ligands in the preparation of a number of manganese, molybdenum, and tungsten carbonyl complexes. The properties of the compounds prepared are compared with and contrasted to the properties of similar pyrazolyl borate complexes. X-ray structural studies have been carried out on two of the complexes in an attempt to explain their variable temperature ^1H nmr spectra.

Experimental

Starting Materials

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. Pyrazole (Aldrich), molybdenum and tungsten hexacarbonyls, (Strem) and tetraethylammonium chloride (Eastman) were used as supplied. $Mn(CO)_5Br$ (6), $(MeCN)_3M(CO)_3$, M = Mo or W (7), $(C_7H_7)Mo(CO)_2I$ (8) and $(C_7H_7)W(CO)_2I$ (9) were prepared as described in the literature. The bidentate gallium ligand $Na^+[Me_2Ga(N_2C_3H_3)_2]^-$ was prepared as described previously (4) and used as a THF solution. Analytical and ir data for the complexes described below are given in Table 1. Proton nmr data are given in Table 2.

Preparation of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$

To a stirred solution of $Mn(CO)_5Br$ (1.07 g, 3.9 mmol) in THF

was added a solution of $Na^+[Me_2Ga(N_2C_3H_3)_2]^-$ (3.9 mmol) in the same solvent. Pyrazole (0.27 g, 3.9 mmol) was added immediately and the reaction mixture stirred overnight. The solvent was then removed *in vacuo* and the remaining yellow residue recrystallized from benzene to give bright yellow crystals of the product. Yield 0.91 g (53%). The corresponding compound incorporating the 3,5-dimethylpyrazole molecule, $[Me_2Ga(N_2C_3H_3)_2](N_2C_5H_8)Mn(CO)_3$, was prepared in a similar manner.

Preparation of $Et_4N^+[Me_2Ga(N_2C_3H_3)_2M(CO)_4]^-$ where M = Mo, W

To a THF solution of the appropriate hexacarbonyl $M(CO)_6$ was added an equimolar amount of the ligand $Na^+[Me_2Ga(N_2C_3H_3)_2]^-$ in the same solvent. The reaction mixture was refluxed overnight. After cooling the reaction mixture to room temperature a CH_2Cl_2 solution of $Et_4N^+Cl^-$ was added. The resultant mixture was filtered and slow evaporation of the filtrate produced bright yellow crystals of the product (yield 80–90%).

Preparation of $Et_4N^+[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)M(CO)_3^-$ where M = Mo, W

An equimolar amount of $Et_4N^+Cl^-$ dissolved in CH_2Cl_2 was added to a 1:1:1 mixture of $(MeCN)_3M(CO)_3$, $Na^+[Me_2Ga(N_2C_3H_3)_2]^-$, and $N_2C_3H_4$ in THF. The reaction mixture was stirred for approximately 1 h and then filtered. Slow evaporation of the filtrate gave golden yellow crystals of the product in 80% yield.

Preparation of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)M(CO)_2(C_3H_5)$ where M = Mo, W

To a 1:1:1 mixture of $(MeCN)_3M(CO)_3$, $Na^+[Me_2Ga(N_2C_3H_3)_2]^-$ and $N_2C_3H_4$ in THF was added an excess of allyl bromide. After stirring the reaction mixture for 2 h, the solvent was removed *in vacuo*. The yellow residue was recrystallized from benzene to give yellow crystals of the product in 20% yield. These compounds may also be prepared by the reaction of $Na^+[Me_2Ga(N_2C_3H_3)_2]M(CO)_4^-$ with allyl bromide but this alternate route gives even lower yields of the desired product.

Preparation of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)M(CO)_2(C_7H_7)$ where M = Mo, W

An equimolar amount of $Na^+[Me_2Ga(N_2C_3H_3)_2]^-$ in THF was added to $(C_7H_7)M(CO)_2I$ in the same solvent. An equimolar amount of pyrazole was then added immediately. The reaction mixture was stirred overnight and the solvent then removed *in vacuo*. The resultant solid was extracted with and recrystallized from benzene. The desired product was isolated as red–brown crystals (yield 60%).

Spectra

Mass spectra were recorded on a Varian MAT CH4 mass spectrometer at 70 eV with an ion source temperature of 100–180°C. Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer and ^1H nmr spectra on a Varian XL-100 spectrometer using FT techniques.

X-ray Crystallographic Analyses

[Dimethylbis(1-pyrazolyl)gallato(N,N)](pyrazole)-tricarbonylmanganese(I)

A crystal ca. 0.18 × 0.50 × 0.53 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data at 22°C are:

$C_{14}H_{16}GaMnN_6O_3$ fw = 440.98
Monoclinic, a = 31.053(2), b = 8.0503(4), c = 15.8629(8) Å, β = 108.164(2)°, V = 3767.9(3) Å^3, Z = 8, ρ_c = 1.555 g cm^{-3}, $F(000)$ = 2016, μ(Mo K_α) = 20.93 cm^{-1}. Absent reflections: hkl, $h + k \neq 2n$ and $h0l$, $l \neq 2n$, space group $C2/c$ (C_{2h}^6, No. 15) from structure analysis.

Intensities were measured with graphite-monochromated Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.18–10.26° min^{-1} over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 60°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, decreased uniformly during the data collection to final values about 3% less than the initial values. An isotropic decay correction was applied. After data reduction, an absorption correction was applied using the Gaussian integration method (10, 11). Transmission factors ranged from 0.342 to 0.575 for 200 sampling points. Of the 5476 independent reflections measured, 2613 (47.7%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

The systematic absences allow space groups Cc or $C2/c$, the latter being chosen on the basis of the E-statistics and the number of molecules in the unit-cell. The coordinates of the metal atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.044, a difference map gave the coordinates of all 16 hydrogen atoms which were included in subsequent cycles of refinement with isotropic thermal parameters. The scattering factors of ref. 12 were used for non-hydrogen atoms and those of ref. 13 for hydrogen atoms. Anomalous scattering factors from ref. 14 were used for the Ga and Mn atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (15–17). The final value of g was 2.5(2) × 10^4. Convergence was reached at R = 0.028 and R_w = 0.034 for 2613

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

reflections with $I \geq 3\sigma(I)$. For all 5476 reflections $R = 0.102$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.02 and 0.21σ respectively. The mean error in an observation of unit weight was 1.050. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 3 and 4[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

Tetraethylammonium [dimethylbis(1-pyrazolyl)gallato-(N,N)](pyrazole)tricarbonylmolybdate(0)

Experimental details are as above except where noted. Crystal dimensions were ca. 0.24 × 0.53 × 0.55 mm. Crystal data are:

$C_{22}H_{36}GaMoN_7O_3$ fw = 612.24

Monoclinic, $a = 10.058(1)$, $b = 20.6488(5)$, $c = 13.533(1)$ Å, $\beta = 93.800(5)°$, $V = 2804.4(4)$ Å^3, $Z = 4$, $\rho_c = 1.450$ g cm^{-3}, $F(000) = 1256$, μ(Mo K$_\alpha$) = 14.27 cm^{-1}. Absent reflections: $h0l$, $h + l \neq 2n$ and $0k0$, $k \neq 2n$ uniquely indicate the space group $P2_1/n$ (non-standard setting of $P2_1/c$, C_{2h}^5, No. 14).

An ω–2θ scan at 1.12–10.06° min^{-1} over a range of (0.60 + 0.35 tan θ)° in ω was employed. Corrections were made for an isotropic decay of ~6% during data collection. Of 8120 independent reflections measured (to 2θ = 60°), 4388 (54.0%) had intensities greater than 3σ(*I*) above background. An absorption correction yielded transmission factors ranging from 0.521 to 0.734 for 244 sampling points.

The coordinates of the metal atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent Fourier synthesis. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.043$, a difference map revealed disordering of the α-carbons of the Et_4N^+ cation and positions of all hydrogen atoms except those associated with the low occupancy methyl groups of the cation (although the methyl carbon atoms themselves are not disordered, the methyl hydrogens are). Site occupancies for the disordered carbon atoms were initially estimated from relative peak heights on a Fourier map and were later adjusted to yield comparable isotropic thermal parameters for corresponding atoms. Final occupancies were fixed at 0.78 and 0.22. In the final stages of refinement the low-occupancy carbon atoms and all hydrogen atoms were refined with isotropic thermal parameters. Anomalous scattering terms were included for the Mo and Ga atoms. No extinction correction was applied. Convergence was reached at $R = 0.023$ and $R_w = 0.029$ for 4388 reflections with $I \geq 3\sigma(I)$, for all 8120 reflections $R = 0.080$. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.08 and 0.97σ respectively and the mean error in an observation of unit weight was 0.8756. A final difference map showed no unusual features.

Analysis of Thermal Motion

The thermal motion in $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$, in the $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3^-$ anion and in the Et_4N^+ cation (shown in Figs. 1 and 2) has been analysed in terms of the rigid-body modes of translation, libration, and screw-motion (18). The rms errors in the U_{ij} (derived from the least-squares analysis) are 0.0023 and 0.0019 Å^2 respectively for the Mn and Mo complexes. For the Mn complex and the molybdate anion two successful analyses were carried out, one rigid group consisting of all non-hydrogen atoms except the methyl carbon atoms and carbonyl oxygen atoms and the second consisting of the Ga atom and the four atoms bonded to it (rms $\Delta U_{ij} = 0.0047$ and 0.0013 for Mn, 0.0045 and 0.0025 Å^2 for Mo). The Et_4N^+ cation was analysed as a five atom group consisting of the N and four high-occupancy α-carbon atoms (rms $\Delta U_{ij} = 0.0017$ Å^2). The appropriate bond distances have been corrected for libration (19), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 5 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 6. Intra-annular torsion angles defining the conformations of six-membered chelate rings are listed in Table 7.

[1]The structure factor table and Table 4 (anisotropic thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and Discussion

Manganese Compounds

The two manganese tricarbonyl derivatives prepared in this study, $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ and $[Me_2Ga(N_2C_3H_3)_2](N_2C_5H_8)Mn(CO)_3$, were characterized as monomeric octahedral complexes having the three CO groups in a facial arrangement. Mass spectral analysis of the complexes displayed the monomer parent ion signal as the highest mass peak with the most intense signal arising from the parent ion minus the three CO groups and the "pyrazole" ligand. Other signals observed could be assigned to ions arising from predictable fragmentation patterns. The ir spectra of both compounds in cyclohexane solution showed three strong bands of equal intensity in the ν_{CO} region of the spectrum. This pattern indicates that the three CO groups are facially coordinated in the octahedral complexes since a meridional arrangement of the carbonyl groups would lead to two weak and one strong ν_{CO} bands in the ir spectra (20). The ^{1}H nmr spectra of the two complexes in C_6D_6 solution are also consistent with a *fac* arrangement of the three CO groups. The ^{1}H nmr spectrum of the complex $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ is shown in Fig. 3. The signals due to the two equivalent pyrazolyl groups of the chelating gallate ligand can easily be distinguished from those of the pyrazole ligand by virtue of their relative intensities (2:1). A *mer* arrangement of the three CO groups would lead to a different ^{1}H nmr pattern since the two pyrazolyl moieties of the gallate ligand would no longer be equivalent. The N—H proton on the pyrazole ring gives rise to a broad singlet at low field in the spectrum. It is noteworthy that the C—H protons of the coordinated pyrazole in this, and all of the complexes studied, show an additional coupling above the expected J_{HCCH} interaction. A triplet–triplet–quartet pattern is observed, presumably caused by an interaction with the N—H proton. The octahedral structure proposed for the complexes in the vapor phase and in solution has been demonstrated unequivocally in the solid state through a crystal structure analysis

TABLE 3. Final positional (fractional × 10^5, H and low-occupancy C × 10^4) and isotropic thermal parameters ($U \times 10^3$ Å^2) with estimated standard deviations in parentheses

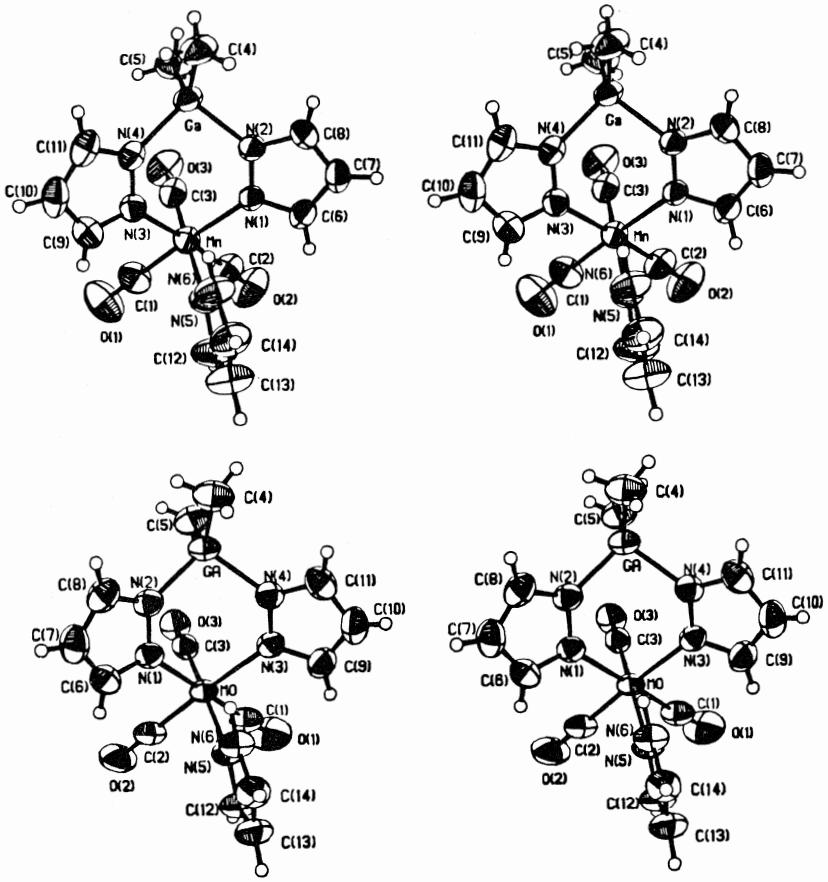

FIG. 1. Stereo views of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ (top) and the $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3^-$ anion (bottom). 50% probability thermal ellipsoids are shown for non-hydrogen atoms. Hydrogen atoms have been assigned artifically small thermal parameters for the sake of clarity.

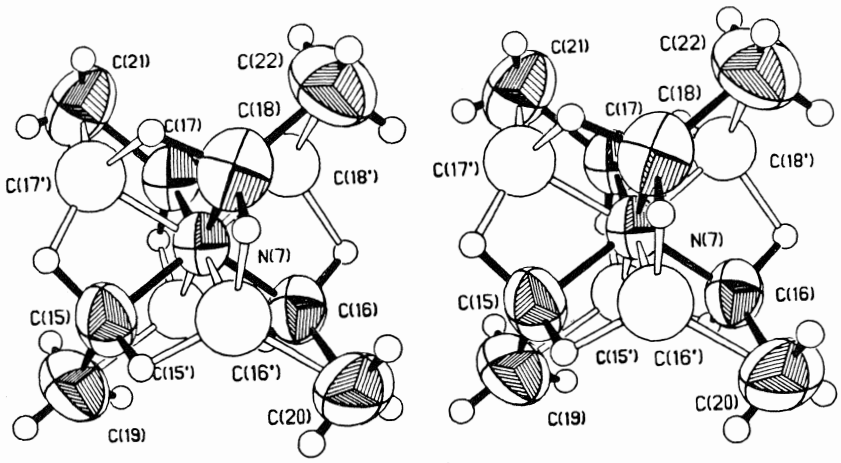

FIG. 2. Stereo view of the disordered Et_4N^+ cation in $[(C_2H_5)_4N]^+\{[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3\}^-$.

of the complex $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ (see below). It is noteworthy that in earlier studies it was found that the complex $[H_2B(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ was formed by the reaction of the ligand $H_2B(N_2C_3H_3)_2^-$ with $Mn(CO)_5Br$ in the absence of pyrazole (21). In the present study reaction of $[Me_2Ga(N_2C_3H_3)_2]^-$ with $Mn(CO)_5Br$ in the absence of pyrazole did yield the complex

$[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ but the yield was considerably lower than that obtained from the preparative route above. In addition, isolation of the desired complex was complicated by the formation of $Mn_2(CO)_{10}$ and other carbonyl containing products. The desired product obtained from the reaction involving pyrazole as a reactant was the only carbonyl-containing product formed.

Molybdenum and Tungsten Compounds

The tetracarbonyl anions, $[Me_2Ga(N_2C_3H_3)_2]M(CO)_4^-$, M = Mo and W, were isolated as their tetraethylammonium salts. The room temperature proton nmr spectra (Table 2) of the complexes displayed one signal for the $GaMe_2$ moiety suggesting that the octahedral species possess either a planar M—(N—N)$_2$—Ga six-membered chelate ring or a rapidly inverting boat conformation for this part of the molecule. Even at −80°C there is no indication of the $GaMe_2$ singlet separating into a doublet, so either inversion of the boat conformation is very fast even at low temperature or the planar arrangement is preferred. The ir spectra (Table 1) of the two anions in the ν_{CO} region show a four band pattern typical of a *cis* tetracarbonyl octahedral species (20).

The tricarbonyl anions, $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)M(CO)_3^-$, M = Mo and W, isolated as their tetraethylammonium salts, were shown to possess the three CO groups facially coordinated. Thus the ir spectrum of the complexes showed three strong bands in the ν_{CO} region of the spectrum. In addition a sharp singlet ν_{NH} band gave evidence for the presence of a coordinated pyraz-

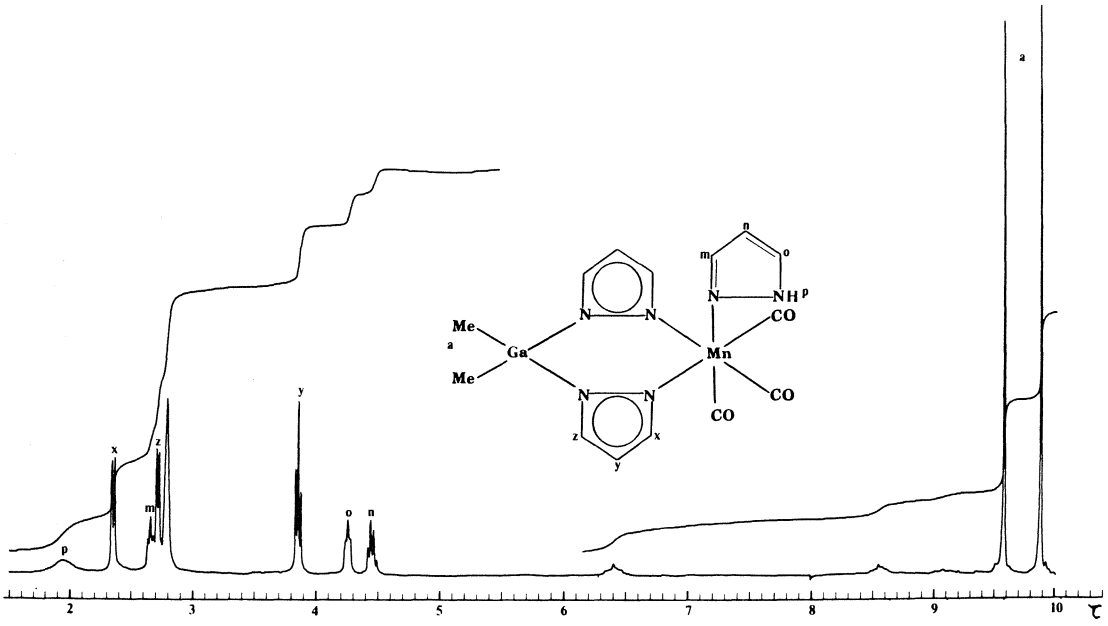

FIG. 3. Room temperature 100 MHz ^{1}H nmr spectrum of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ in C_6D_6 solution.

ole ligand. However, the ^{1}H nmr spectra of these complex anions were somewhat surprising in that they showed only one GaMe signal and one set of signals due to both the pyrazolyl groups and the pyrazole group (see Fig. 4). No signal could be found in the region where the NH proton of the pyrazole group might be expected. A possible explanation for these observations is that there is a rapid exchange of roles between the pyrazolyl groups and pyrazole group which makes all three of these groups equivalent and the methyl groups on the gallium equivalent on the nmr time scale. A proposed mechanism is shown in Fig. 5. In this mechanism the structure displayed in the solid state (Fig. 1) must initially undergo an inversion of the GaN_4M six-membered ring to bring the two pyrazolyl moieties and the coordinated pyrazole group in close proximity. The "Ga" and "M" portions of the molecule could then remain relatively fixed while the pyrazolyl units breathe in and out while the H atom exchanges among the three nitrogen atoms. It is interesting that the neutral $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ compound does not show this type of fluxionality since it is valence isoelectronic with the Mo and W tricarbonyl anions, the only difference being the charge on the latter species. The ^{1}H nmr spectrum of the Mn compound was run in d_6-acetone to establish the absence of a solvent effect and indeed the spectrum obtained displayed the same type of pattern as shown in Fig. 3 for the C_6D_6 solution of the complex. Even at −80°C the $GaMe_2$ singlet in the spectra of the Mo and W tricarbonyl anions showed no signs of splitting into the doublet pattern observed in the room temperature spectrum of the Mn derivative. It was thought that a structural difference in the two complexes might be responsible for the observed difference in solution behaviour. Consequently X-ray structural analyses of the manganese compound $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ and the corresponding Mo tricarbonyl anion $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3^-$ were carried out and the results are discussed below. The Mo and W tricarbonyl anions of the present study are closely

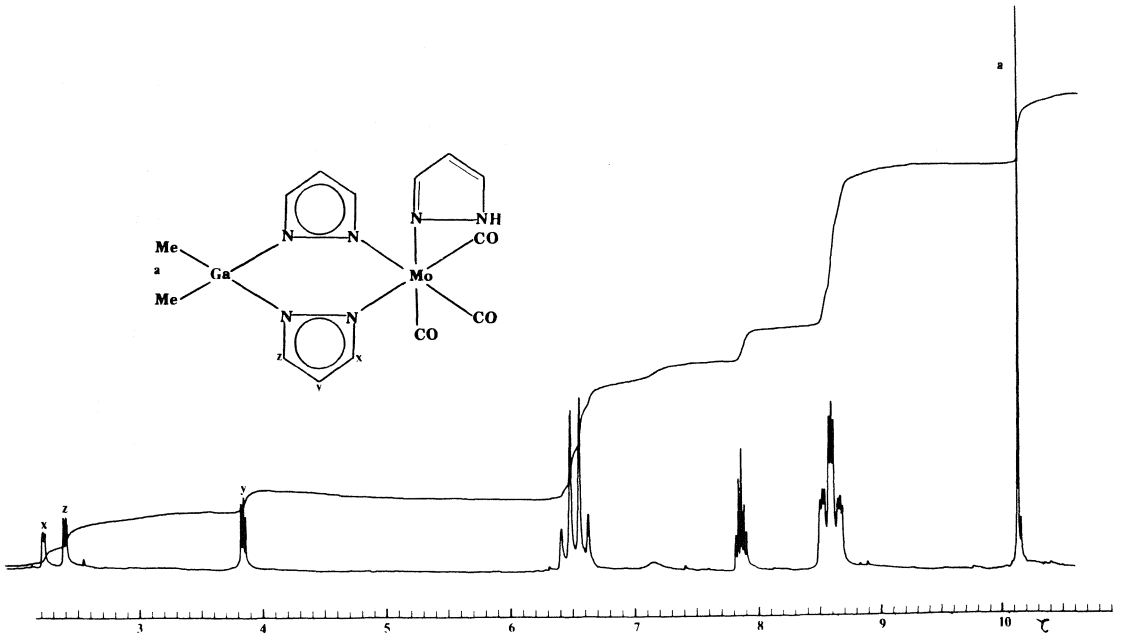

FIG. 4. Room temperature 100 MHz ^{1}H nmr spectrum of $[(C_2H_5)_4N]^+\{[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3\}^-$ in d_6-acetone solution.

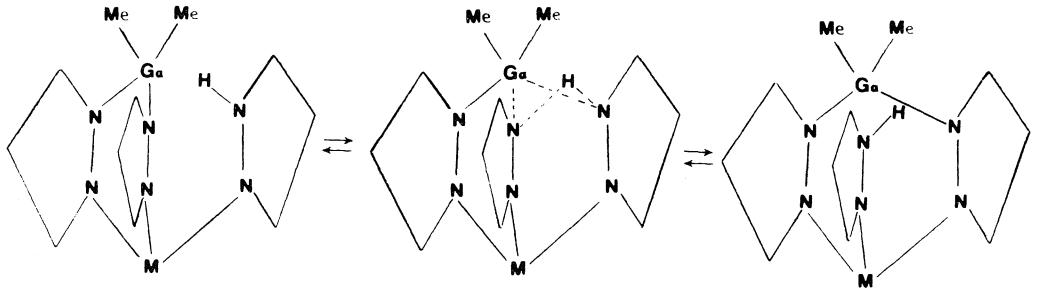

FIG. 5. Proposed mechanism for exchange of pyrazole and pyrazolyl groups in solutions of $[(C_2H_5)_4N]^+\{[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3\}^-$.

related to the anions incorporating the trispyrazolylborate and trispyrazolylgallate ligands, viz. $RE(N_2C_3H_3)_3M(CO)_3^-$ (where R = H, E = B; R = Me, E = Ga; M = Mo and W). It has already been shown that these symmetrical anions react with allyl bromide or diazald to give the corresponding neutral species $RE(N_2C_3H_3)_3M(CO)_2D$ (where D = η^3-C_3H_5 or NO) (22, 23). Consequently it was not surprising that the reaction of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3^-$ with allyl bromide in THF produced the monomeric six-coordinate complex $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_2(\eta^3\text{-}C_3H_5)$ in good yield. The ^{1}H nmr of this complex in C_6D_6 solution is shown in Fig. 6. Assuming that the facial configuration of the $[Me_2Ga(N_2C_3H_3)_2]$ and $N_2C_3H_4$ ligands is retained during the substitution reaction the allyl group may be positioned either opposite the pyrazole ligand or opposite one of the pyrazolyl moieties of the chelating gallate ligand. The ^{1}H nmr pattern shown in Fig. 6 shows two sets of signals for the pyrazolyl and pyrazole protons in the ratio 2:1. This means that the pyrazolyl groups of the gallate ligand must be equivalent and hence the allyl group must be positioned opposite to the pyrazole ligand as shown. The ^{1}H nmr signals due to the allyl protons also indicate this positioning for the allyl groups since there is one signal only for the two *anti* protons and one signal only for the two *syn* protons. In this position the allyl group must be either symmetrically attached or undergoing a rapid rotation about the molybdenum–allyl bond axis. If the allyl group were positioned opposite to

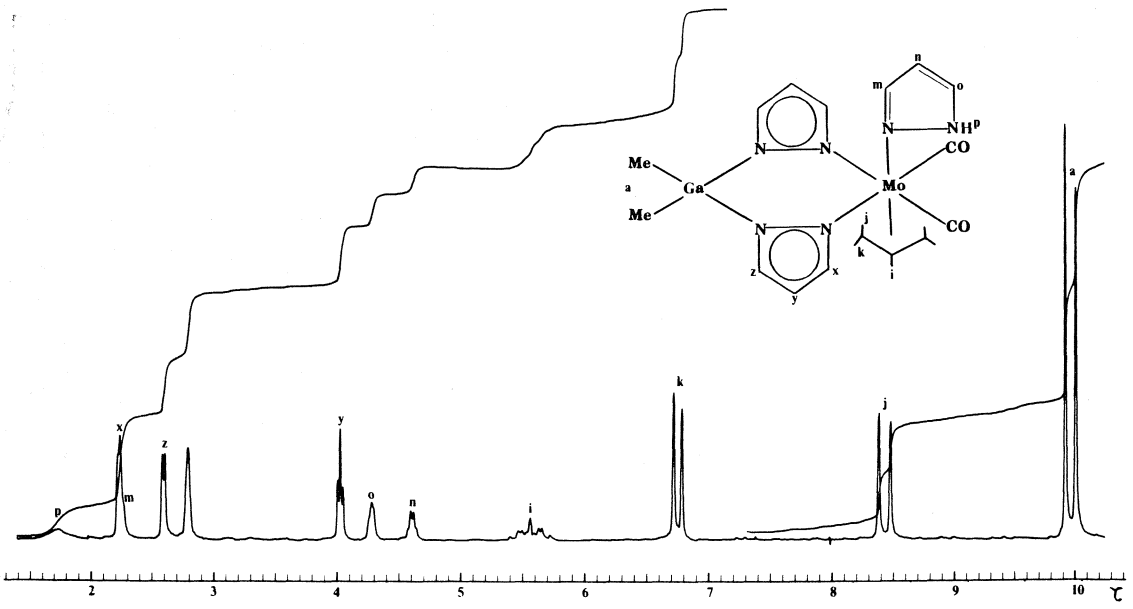

FIG. 6. Room temperature 100 MHz ^{1}H nmr spectrum of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_2$ (η^3-C_3H_5) in C_6D_6 solution.

one of the pyrazolyl moieties two signals should be seen for the *syn* protons and for the *anti* protons even if a rapid rotation of the allyl group is occurring.

In contrast to the allylating experiments, attempts to nitrosylate the tricarbonyl anions met with only marginal success. Reactions of the Mo tricarbonyl anion with Diazald in THF resulted in the evolution of CO and a color change from yellow to orange. A small amount of orange solid (<1% yield) was obtained on workup of the reaction mixture and this was shown by mass spectrometry to contain the desired nitrosyl compound $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_2NO$. However, attempts to prepare the nitrosyls on a larger scale were unsuccessful.

The related cycloheptatrienyl compounds $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)M(CO)_2(\eta^3\text{-}C_7H_7)$, M = Mo and W, were prepared by the reaction of $[Me_2Ga(N_2C_3H_3)_2]^-$ with $(C_7H_7)M(CO)_2I$ in the presence of pyrazole in THF solution. As with the allyl compound discussed above, two structural isomers are possible but again the ^{1}H nmr spectra (Table 2) of the complexes establish that the position of substitution of (C_7H_7) is *trans* to the pyrazole ligand. The room temperature spectra also display but one signal for the C_7H_7 group indicating that this ligand is involved in a rapid fluxional process, a phenomenon observed recently in another series of η^3-C_7H_7 complexes (24). It should be noted that in earlier studies involving the bispyrazolylborate ligands it was found that the $H_2B(N_2C_3H_3)_2^-$ anion frequently acted as a tridentate ligand in molybdenum complexes by utilizing a 3c–2e B—H—Mo bonding interaction in addition to coordination via the two pyrazolyl groups. For example, the reaction of the ligand $H_2B(N_2C_3H_3)_2^-$ with $(C_7H_7)Mo(CO)_2I$ gave the complex $[H_2B(N_2C_3H_3)_2]Mo(CO)_2(\eta^3\text{-}C_7H_7)$ which contains a trihapto cycloheptatrienyl ligand and a B—H—Mo bond (25, 26). In addition, substitution of ethyl groups for hydrogens on the B atom of the ligand gave a novel B—CH···H···Mo 3c–2e bonding interaction in the complex $Et_2B(N_2C_3H_3)_2Mo(CO)_2(\eta^3\text{-}C_7H_7)$ (27–29). In the present study there was no evidence for a similar type of interaction involving the gallate ligand. Indeed, when $(C_7H_7)Mo(CO)_2I$ was reacted with the gallate ligand $[Me_2Ga(N_2C_3H_3)_2]^-$ in THF, in the absence of pyrazole, an intractable black tar resulted. As pointed out by a referee, a much closer analogy to the "Et_2B" complex would be possible if the $Et_2Ga(N_2C_3H_3)_2^-$ ligand were utilized in the above reaction. Even with this ligand, however, the longer Ga—N bond, compared to the B—N bond lengths, might well preclude the formation of such a 3c–2e interaction.

Crystal Structures of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ and $[(C_2H_5)_4N]^+\{[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3\}^-$

The crystal structure of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mn(CO)_3$ consists of discrete neutral molecules (Fig. 1) separated by normal van der Waals distances. The structure of $[(C_2H_5)_4N]^+\{[Me_2Ga-$

$(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3\}^-$ consists of discrete cations (Fig. 2) and anions (Fig. 1), all anion–cation and cation–cation contacts corresponding to normal van der Waals interactions while screw-related anions interact via possible weak C—H···O hydrogen bonds (C(14)—H(14)···O(3) ($1/2 - x$, $1/2 + y$, $1/2 - z$), H···O = 2.51(3), C···O = 3.275(4) Å, C—H···O = 156(3)°).

The metal atoms in both structures are coordinated by three mutually *cis* carbonyl ligands, two pyrazolyl nitrogen atoms of the $[Me_2Ga(N_2C_3H_3)_2]^-$ ligand and by the non-protonated nitrogen of the pyrazole ligand. The resulting coordination geometry is trigonally distorted octahedral, the distortion from "ideal" octahedral geometry being greater for the Mo complex anion. The inner coordination group in each case has approximate C_{3v} symmetry while both the Mn complex and the Mo complex anion have approximate mirror symmetry. The distortions from mirror symmetry in both structures involve a twist of the pyrazole ligand such that the N—H is closer to one of the two pyrazolyl groups of the $[Me_2Ga(N_2C_3H_3)_2]^-$ ligand. The chemically equivalent pyrazolyl groups also differ slightly, one having a larger torsional twist about the N—N bond than the other. On this basis the C(1) and C(2) carbonyl groups and the N(1) and N(3) pyrazolyl groups of the Mn complex correspond to the C(2) and C(1) carbonyl groups and the N(3) and N(1) pyrazolyl groups respectively in the Mo complex anion as shown in Fig. 1. Average bond angles about the central metal atoms are: C—M—C, 87.7 and 85.0, N—M—N, 87.5 and 83.4, *cis*-N—M—C, 92.3 and 95.7, *trans*-N—M—C, 176.9 and 176.1° for M = Mn and Mo respectively. In the Mn complex the Mn—N distances involving the gallate ligand are equal within experimental error and their mean[2] of 2.085(2) Å is longer by about 3σ than the Mn—N distance of 2.074(3) Å to the pyrazole ligand. A corresponding trend is observed for the Mn—CO distances, that *trans* to the pyrazole ligand being slightly longer than the two others (1.809(5) compared to a mean of 1.797(2) Å). In the Mo anion all three Mo—N distances are equal within experimental error (mean Mo—N = 2.293(2) Å) and the trend in the Mo—CO distances is opposite to that observed in the Mn complex with Mo—C(3), 1.918(3) Å, being shorter than the others (mean 1.931(5) Å). The carbonyl C—O distances in the Mn complex are equal within experimental error (mean C—O = 1.148(3) Å) while in the Mo anion the extreme values are significantly different, the longest involving O(3) which is involved in the postulated weak hydrogen bond. All of the C—O distances in the Mo complex (mean C—O = 1.170(10) Å) are significantly longer than in those in the Mn structure in accord with the markedly different ν_{CO} values for these species in solution (see Table 1).

The gallium atoms in both structures have distorted tetrahedral coordination geometry with bond angles in the range 97.3(1)–119.5(2)°. The bonds to gallium in the Mo complex are longer than those in the Mn analog by an average of 0.01 Å even though all other intraligand bond distances and angles are essentially equal. This observation as well as the differences in the C—O distances mentioned above indicate stronger binding of all ligands in the Mo structure and may result, at least in part, from the greater steric crowding about the smaller Mn centre. The Ga—C(4) distances are longer than the Ga—C(5) distances in both cases (by 0.018(7) and 0.020(4) Å respectively for Mn and Mo), bond angles at Ga indicating that this is primarily a result of σ-hybridization effects. The chemically equivalent Ga—N distances also differ by a small but possibly significant amount, Ga—N(4) being longer than Ga—N(2) by 0.008(4) Å in the Mn complex and the corresponding bonds in the Mo anion differing in the same sense by 0.007(3) Å. The longer Ga—N bond is associated in both structures with the nitrogen atom involved in the larger Ga—N—N—M torsion angle (see Table 7).

The pyrazolyl and pyrazole rings in both structures are planar within experimental error (χ^2 values range from 0.5 to 3.8) and in each case the metal atoms are significantly displaced from the mean planes. The six-membered chelate rings have slightly twisted asymmetric boat conformations, that in the Mo complex being somewhat steeper (corresponding intra-annular torsion angles are presented side-by-side in Table 7). The angles between normals to the pyrazolyl mean planes of the gallate ligand (180° for a planar chelate ring) are 139.8 and 128.1° respectively for the Mn and Mo structures. Corresponding values for the square-planar metal complexes $[Me_2Ga(N_2C_3H_3)_2]_2M$ (M = Ni (1) or Cu (3)) are 116.4 and 117.1° respectively, indicating that the GaN_4M rings in the present octahedral complexes are less steep. This is as expected in view of the greater steric hindrance in the octahedral complexes. The cross-ring M···Ga distances are 3.818 and 3.929 Å for M = Mn and Mo respectively.

The structures of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)$-$Mn(CO)_3$ and $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Mo(CO)_3^-$ are remarkably similar, especially in view of the

[2]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

fact that the local environments of these species in the solid state are quite different. The major structural differences noted above arise from the different sizes of the central metals. It may be argued that in the case of the more sterically crowded Mn complex the exchange mechanism of Fig. 5, which requires an initial inversion of the six-membered chelate ring (see Fig. 1) through a planar (or nearly planar) transition state, is inhibited by short (2.7 Å) intramolecular contacts between the atom pairs C(1)···H(9) and C(2)···H(6) which are increased to at least 2.93(3) Å in the Mo complex. However, an impure sample of $[Me_2Ga(N_2C_3H_3)_2](N_2C_3H_4)Cr(CO)_3^-$ (the Cr being comparable to Mn in size) gave a ^1H nmr spectrum which indicated fluxional behaviour in solution, an observation which tends to discount the steric argument presented above.[3] The ^1H nmr data in Table 2 show that all fluxional species reported here are anionic, a feature which may be of overriding importance. It should be noted in this regard that the neutral Mo and W complexes reported in Table 2 are not fluxional.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada for financial support and the University of British Columbia Computing Centre for assistance. We are grateful to Mr. P. Borda for C, H, N analyses, Mr. J. Nip for mass spectra, and to Ms. L. Evelyn for the ^1H nmr spectra.

Received March 19, 1980[1]

T. Stanley Cameron, Ruth E. Cordes, B. Mario Pinto, and Walter A. Szarek. Can. J. Chem. **59**, 3136 (1981).

The products of photodimerization of *N*-benzoylazacyclohex-2-ene-4-one (**1**) have been investigated by X-ray crystallography. Irradiation of a benzene solution of compound **1** leads to a mixture of head-to-head and head-to-tail, *cis,anti,cis* adducts, namely, *cis,anti,cis*-*N,N'*-dibenzoyl-3,12-diazatricyclo[6.4.0.0^{2,7}]dodecan-6,12-dione and *cis,anti,cis*-*N,N'*-dibenzoyl-3,9-diazatricyclo-[6.4.0.0^{2,7}]dodecan-6,9-dione, compounds **2** and **3** respectively.

T. Stanley Cameron, Ruth E. Cordes, B. Mario Pinto et Walter A. Szarek. Can. J. Chem. **59**, 3136 (1981).

On a étudié par cristallographie de rayons-X les produits résultant de la photodimérisation de la *N*-benzoylcyclohexène-2 one-4 (**1**). L'irradiation du composé **1** en solution dans le benzène conduit à un mélange d'adduits *cis*, *anti*, *cis* tête à tête et tête à queue soit la *N,N'*-dibenzoyldiaza-3,12 tricyclo[6,4,0,0^{2,7}]dodécanedione-6,12-*cis*, *anti*, *cis* (**2**) et la *N,N'*-dibenzoyldiaza-3,9 tricyclo[6,4,-0,0^{2,7}]dodécanedione-6,9 *cis*, *anti*, *cis* (**3**).

[Traduit par le journal]

Introduction

Numerous reports have appeared in the literature on the photochemical [2 + 2] cycloaddition dimerization reactions of α,β-unsaturated carbonyl compounds both in solution (1, 2) and in the solid state (3–5). The photochemical reactions of enamides and dienamides have also been extensively studied (6). In particular dienamides have been shown to undergo 6π-electron photocyclization to form polycyclic heterocycles when irradiated (6) with ultraviolet light. However, the photodimerization of *N*-substituted enaminones (R_1R_2N—C=C—C=O) has not been the subject of much investigation. We report here the photodimerization of an *N*-acyl enaminone, *N*-benzoylazacyclohex-2-ene-4-one (**1**), and the determination of the regiochemistry and the stereochemistry of the products by X-ray crystallography.

Results and Discussion

N-Benzoylazacyclohex-2-ene-4-one (**1**) was prepared from the saturated amide, *N*-benzoylazacyclohexan-4-one by an adaptation of the peroxyester reaction of Kharasch and Sosnovsky (6).

Irradiation of a 0.005 *M* solution of compound **1** in benzene with light of wavelengths greater than 3000 Å leads to a mixture of two possible cyclobutane dimers, namely the head-to-head and the head-to-tail adducts **2** and **3** respectively.

Crystal structure of 2

Crystal data

$C_{24}H_{22}N_2O_4$ fw = 402.24

Monoclinic $P2_1/c$, a = 18.568(4), b = 11.396(4), c = 19.374(5) Å, β = 150.75(2)°, V = 2003 Å^3, Z = 4, ρ_c = 1.334 g cm^{-3} (22 ± 1°C; MoKα_1, λ = 0.71069 Å (graphite monochromator) μ = 0.53 cm^{-1}), F(000) = 848.

A crystal about 0.3 × 0.3 × 0.8 mm was mounted along its long axis. The cell dimensions were refined from 25 general reflections with the Bragg angle θ in the range of 14–15° on a CAD4 diffractometer. 3113 independent reflections were measured in the range θ = 2–25° of which 1188 had $I > \sigma(I)$. The data were reduced to a standard scale by routine procedures (7) and were corrected for Lorentz and polarisation, but not for extinction or absorption, factors. Reflections with $|E| > 1.2$ were used to solve the structure by an application of the tangent formula that examined 4096 (2^{12}) sets of starting phases and eliminated successively all but the most likely. This procedure is part of an X-ray system written by Sheldrick (8). The positions of all but the hydrogen atoms were found on the resultant E map.

The structure was refined by least-squares pro-

cedures, minimising $\Sigma w\{\Delta F\}^2$ with isotropic temperature factors on all the atoms. The H atom positions were located from a difference Fourier synthesis when R was 0.09. Refinement was continued with anisotropic temperature factors on all but these hydrogen atoms, and it converged with $R = 0.026$. Weights were calculated from $w = (\sigma|F_0| + 0.003252F_0^2)^{-1}$ where σ is the standard deviation for each reflection and is determined from the diffractometer counting statistics.

Table 1 gives the final atomic coordinates.[2] The atomic scattering factors are taken from International Tables for X-ray Crystallography (1974), and the scattering factors of all but the hydrogen atoms were corrected for the real part of the anomalous dispersion effect. The interatomic distances and interbond angles are given in Table 2, while the torsional angles are given in Table 3.[2] Figure 1*a* shows a view of the molecule projected onto the least-squares best plane through the four-membered ring, and Fig. 2 shows the packing of the molecules in the unit cell viewed along the *a* axis.[2]

The crystal is constructed from isolated molecules of **2** with the head-to-head configuration. Within the molecule there are two types of C—C bonds. Those in the phenyl rings exhibit typical bond lengths for a conjugated system; the lengths are in the range 1.374(7) to 1.396(10), with a mean of 1.383(3) Å, and are not significantly different. The other type of C—C bond is in the heterocyclic and four-membered rings and these are all saturated. The C—C bond lengths, unique to the heterocyclic rings, C(12) to C(15) and C(22) to C(25), are equivalent with a mean value of 1.510 (3) Å. The lengths of the C—N bonds at N(1) and N(2) are also equivalent and have a mean value of 1.456 (5) Å. The C—C bonds C(11)—C(12) and C(21)—C(22) which are common to both the six- and the four-membered rings have a mean length of 1.555 (6) Å. This four-membered ring is sterically strained and in these circumstances C—C bond lengths of bonds common to several rings are often somewhat longer (10, 11). The other two bonds in the four-membered ring, C(11)—C(21) and C(12)—C(22), are shorter (mean 1.542 (6) Å) but the difference is not significant. The four-membered ring itself is not quite planar, C(21) for example is 0.045 (3) Å out of the plane of the other three atoms. There are four

$> \sigma (I)$ and only 278 reflections had $I > 3\sigma (I)$. The data were reduced to a common scale and were corrected for Lorentz and polarisation, but not for extinction or absorption, effects. The structure was solved in a way similar to that for compound **2**. The positions of the C, N, and O atoms were located from an E Map and the structure was refined by full-matrix least-squares with isotropic temperature factors on these atoms; it converged with $R = 0.09$.

The X-ray data for this compound are few in number and weak in intensity so the resultant atomic resolution is poor. However, enough detail of the structure can be seen to establish that the molecule has the head-to-tail configuration **3** (Fig. 1*b*) and that there is a crystallographic inversion centre in the middle of the four-membered ring. The ring is apparently planar though disorder remains a possibility. The interatomic distances and interbond angles do not differ significantly in

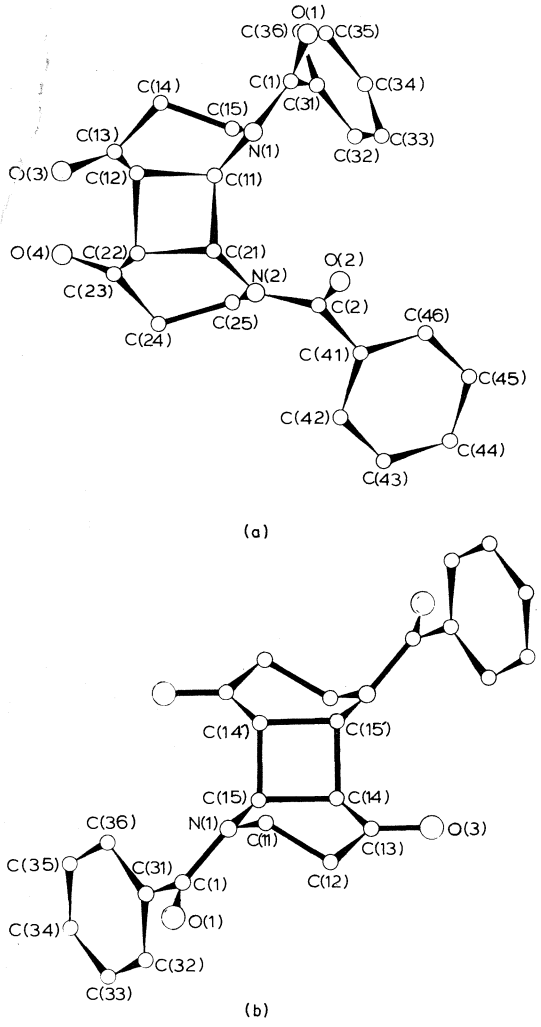

FIG 1. The assymmetric unit viewed perpendicular to the least-squares best plane through (*a*) atoms C (11), C (12), C (21), and C (22), compound **2** and (*b*) atoms C (14), C (15), C (14'), and C (15') compound **3**.

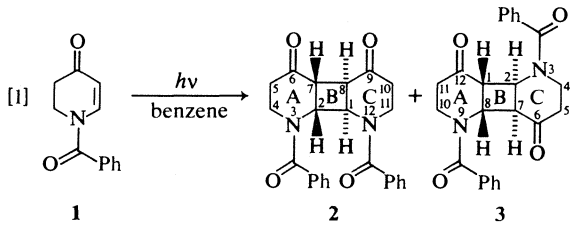
this compound from those observed in compound **2**; the atomic parameters are given in Table 5, and distances and angles are given in Table 6.[3]

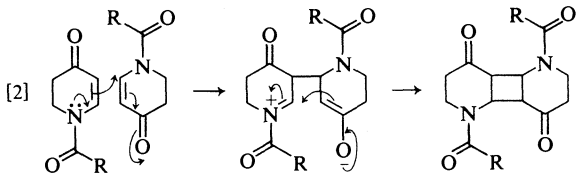
The reaction that produced compounds **2** and **3** (reaction [1]) is analogous to the photodimerization reaction of 2-cyclohexenone which also gives only the *cis*-fused products (1). The observed ratio of the head-to-head and head-to-tail products (1.5:1)

[3]A complete list of atomic parameters (Table 5), a list of interatomic distances and interbond angles (Table 6), selected torsional angles (Table 7), a view of the unit cell projected down *b*, and a list of the structure factors (Table 8) are available at a nominal charge from the Depository of Unpublished Data CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.



suggests that there is little preference for the direction of photodimerization of compound **1** in a 0.005 *M* benzene solution.

A process, analogous to the intramolecular photocyclization reactions of dienamides (6), in which compound **1** would undergo an intermolecular 6π-electron photocyclization reaction, is shown in reaction [2].



This reaction would, however, only give rise to the head-to-tail products. It is therefore likely that the photodimerization reaction of compound **1** is analogous to the photodimerization reactions of enones and not to the photocyclization reactions of dienamides. The reaction is a rare example of the photodimerization of an *N*-acyl enaminone. Since the photodimerization of *N*-benzoylazacyclohex-2-ene-4-one (**1**) proceeds in excellent yield, it is conceivable that the more general photocycloaddition reactions of *N*-acyl enaminones will be of potential synthetic utility.

Experimental

Melting points were determined with a Fisher–Johns melting point apparatus and are uncorrected. Thin layer chromatography was performed with silica gel G as the adsorbent in the following solvent systems (v/v): (*A*) benzene – ethyl acetate, 1:1; (*B*) 1:2. The developed plates were air dried and exposed to uv light and/or sprayed with a solution of cerium sulfate (1.0%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at ~ 150°C. Column chromatography was performed on Brinkmann silica gel 60 (E. Merck). Preparative thin layer chromatography was performed on plates pre-coated with silica gel F-254 (E. Merck). Solvents were evaporated under reduced pressure below 40°C.

Proton (^{1}H nmr) spectra were recorded on a Varian HA-100 spectrometer in toluene-d_8 with TMS as internal standard. The mass spectra were recorded on a CEC 21-104 mass spectrometer operating at 70 eV ionizing voltage.

The irradiation was performed in a borosilicate glass reaction vessel in which a 450-W Hanovia medium-pressure mercury-arc lamp was mounted. It was contained in a water-cooled quartz immersion-well fitted with a Pyrex filter-sleeve. Nitrogen gas was passed over the solution throughout the course of the irradiation.

N-*Benzoylazacyclohex-2-ene-4-one* (*1*)

Tert-butyl peracetate (0.8 equiv.) in benzene (15 mol) was added over a period of 3 h to a stirred solution of *N*-benzoylazacyclohexan-4-one (1.0 g, 4.9 mmol) in benzene (40 mL) containing cuprous chloride (20 mg), under an atmosphere of nitrogen at 81°C. The mixture was stirred at 81°C for an additional 3.5 h, then cooled, diluted with benzene (30 mL), washed successively with aqueous sodium hydrogen carbonate (2 × 25 mL) and water (25 mL), and dried over anhydrous sodium sulfate. The solvent was evaporated to give a syrup. Thin layer chromatography (solvent B) indicated the presence of a component with an R_F value of 0.51 together with unreacted starting material (R_F 0.34). After column chromatography with solvent B as eluant, the component with the R_F value of 0.51 was isolated as a syrupy solid and was identified as *N*-benzoylazacyclohex-2-ene-4-one (**1**) (0.278 g, 74%). Compound **1** was obtained from ethanol as white plates; mp 121–122°C; ^{1}H nmr data (195.5 K): δ 1.55 min, 2.04 maj (m's, 2H, H5, 5′), 2.82 min, 3.44 maj (m's, 2H, H6, 6′), 4.88 maj, 5.31 min (d's, 1H, H3), 6.45 maj, 7.77 min (d's, 1H, H2), 7.1 (m, 5H, Ph); *m/e* calcd. for $C_{12}H_{11}NO_2$: 201; found: 201. The second component (R_F 0.34) was isolated as a syrup and was identified as unreacted starting material (0.621 g).

Irradiation of N-*benzoylazacyclohex-2-ene-4-one* (*1*)

Compound **1** (0.066 g, 0.33 mmol) was dissolved in dry benzene and the solution was irradiated for 5 h under nitrogen. Thin layer chromatography (solvent A) showed that starting material had been consumed and also showed the presence of two slower moving components with R_F values of 0.28 and 0.14; the mixture was concentrated and the two components were isolated by preparative thin layer chromatography with solvent A as eluant. Compound **2** (R_F 0.28) was isolated as a white solid (0.035 g, 53%); it was recrystallized from ethyl acetate, and has mp 259.5–260.5°C (decomp.). Compound **3** (R_F 0.14) was isolated as a white solid (0.024 g, 36%). It was recrystallized from ethyl acetate, and has mp 276.5–278.5°C (decomp.). The crystals of compounds **2** and **3** used for X-ray crystallographic analysis were obtained by repeated recrystallization of the compounds from ethyl acetate.

Thermodynamics of autoionization of aqueous tetrahydrofuran and 1,2-dimethoxyethane and the structuredness of solvents

JAYATI DATTA[1] AND KIRON K. KUNDU[2]

Department of Chemistry, Jadavpur University, Calcutta-700 032, India

Autoionization constants (K_s) of aqueous mixtures of tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME) containing 10, 30, and 50 wt.% cosolvent in each case have been determined from emf measurements of the cell: Pt, H_2 (g, 1 atm)|KOH (m_1), KBr (m_2), solvent|AgBr, Ag at seven equidistant temperatures ranging from 5 to 35°C. The standard free energies (ΔG^0), entropies (ΔS^0), and enthalpies (ΔH^0) of autoionization of the solvents were also evaluated from these data. Relative free energy data, $\delta\Delta G^0(\equiv {}_s\Delta G^0 - {}_w\Delta G^0)$, for these solvents as well as those for dioxane (D) – water mixtures taken from the literature, when coupled with the previously determined transfer free energies of H^+, $\Delta G_t^0(H^+)$, yielded $\Delta G_t^0(OH^-)_{app}$ ($\equiv \Delta G_t^0(OH^-) - \Delta G_t^0(H_2O)$) values in the mixed solvents. Relative magnitudes of $\Delta G_t^0(H^+)$ and $\Delta G_t^0(OH^-)_{app}$ and their non-Born parts, $\Delta G_{t,ch}^0(H^+)$ and $\Delta G_{t,ch}^0(OH^-)_{app}$ in particular, suggest that the "basicity" of these aqueous cosolvents decreases in the order DME > THF > D and their "acidity" in the reverse order, as expected from structural and electronic consideration of these cosolvent molecules. Analysis of the relative entropic contributions, $T\delta$ (ΔS^0) ($\equiv T({}_s\Delta S^0 - {}_w\Delta S^0)$, for the autoionization of these aqueous cosolvents and in particular $\Delta S_t^0(H_2O)$ values derived therefrom, suggests that while THF promotes three dimenstional (3D) ice-like water structures at initial compositions and D induces breakdown of the 3D structures right from the beginning, DME breaks down water structures at initial compositions, but induces some order around 4–14 mol% DME by forming the possible H-bonded bidentate DME–water complexes. And beyond certain compositions, depending upon the relative size and shape, all the cosolvents break down water structure due to packing imbalance.

JAYATI DATTA et KIRON K. KUNDU. Can. J. Chem. **59**, 3141 (1981).

A partir de mesures de la fem de la cellule: Pt, H_2 (g, 1 atm)|KOH (m_1), KBr (m_2) solvant|AgBr, Ag à sept températures équidistantes allant de 5 à 35°C, on a déterminé les constantes d'auto-ionisation (K_s) des mélanges aqueux de tétrahydrofuranne (THF) et de diméthoxy-1,2 éthane (DME) contenant dans chaque cas 10, 30 et 50% en poids de cosolvant. A partir de ces données on a également évalué les énergies libres (ΔG^0), les entropies (ΔS^0) et les enthalpies (ΔH^0) standards d'auto-ionisation des solvants. Les données d'énergie libre relative, $\delta\Delta G^0(\equiv {}_s\Delta G^0 - {}_w\Delta G^0)$ de ces solvants aussi bien que celles des mélanges de dioxanne–eau existantes, combinées aux énergies libres de transfert déterminées antérieurement pour H^+, $\Delta G_t^0(H^+)$, conduisent aux valeurs de $\Delta G_t^0(OH^-)_{app}$ ($\equiv \Delta G_t^0(OH^-) - \Delta G_t^0(H_2O)$ des solvants mixtes. Les grandeurs relatives de $\Delta G_t^0(H^+)$ et de $\Delta G_t^0(OH^-)_{app}$ et leurs éléments qui ne sont pas du type Born, $\Delta G_{t,ch}^0$ (H^+) et $\Delta G_{t,ch}^0(OH^-)_{app}$ en particulier, suggèrent que la basicité de ces co-solvants aqueux décroît dans l'ordre DME > THF > D et que leur acidité est dans l'ordre inverse conformément aux considérations structurales et électroniques des molécules de cosolvant. L'analyse des contributions entropiques relatives, $T\delta$ (ΔS^0) ($\equiv T({}_s\Delta S^0 - {}_w\Delta S^0)$, d'auto-ionisation des cosolvants aqueux et en particulier les valeurs de $\Delta S_t^0(H_2O)$ qui en dérivent suggèrent que le THF favorise des structures tridimensionnelles (3D) comme celle de l'eau glacée pour les compositions initiales tandis que D induit une rupture de ces structures 3D au moment où elles s'établissent. Le DME au contraire rompt les structures de l'eau au départ mais favorise un agencement ordonné pour une composition allant de 4 à 14 mol% de DME en formant possiblement les complexes bidentates de DME–eau liés par des liaisons hydrogène. Au-delà de certaines compositions compte tenu de la taille relative et de la forme, tous les cosolvants rompent la structure de l'eau par suite d'un entassement désordonnée.

[Traduit par le journal]

Introduction

The autoionization constants (K_s) of aquo-organic solvents at different temperatures and the related thermodynamic parameters not only help give the thermodynamic measures of acidity but also help throw some important reflections on their structural features (1). The basis of these structural reflections stems from the fact that while the ionization of water accompanying the production of order-producing H_3O^+ and OH^- ions imparts negative magnitudes to $T\Delta S^0$(ΔS^0 = entropy of ionization), the required configurational changes, including depolymerization of the three dimensional (3D) ice-like structure prior to self-ionization, contribute positive magnitudes to $T\Delta S^0$. These render the observed overall magnitude of $T\Delta S^0$ for water less negative than that for alcohols or glycols (2), where the 3D H-bonded structures are likely to be absent. The observed decreased order of the maximum in $T\delta$ (ΔS^0) ($\equiv T({}_s\Delta S^0 - {}_w\Delta S^0)$) – composition profiles (subscripts s and w refer to the solvent and water respectively) for the aqueous *t*-BuOH, 2-propanol, ethanol etc. (1), which results from the relative effects of the initial promotion and subsequent breakdown of 3D hydrogen-bonded (H-bonded) networks of water (3), also corroborates the same conclusion. Unlike alcohols, as aprotic cosolvents

like dioxane (D), tetrahydrofuran (THF), 1,2-dimethoxyethane (DME), etc. will not contribute to autoionization of the mixed solvents, similar studies in aqueous mixtures of these aprotic cosolvents should be of particular interest and utility. The present paper therefore deals with similar studies in aqueous mixtures of two ethereal cosolvents, namely THF and DME, as the corresponding data for the closely related D–water mixtures are already known (4).

As in previous studies (1, 2, 5–7) the thermodynamics of autoionization of these mixed solvents have been evaluated from the autoionization constant (K_s) of these mixed solvents as determined by measuring the emf's (E) of the cell [A]

[A]: Pt, H_2 (g, 1 atm)|KOH (m_1), KBr (m_2), solvent|AgBr, Ag

at seven equidistant temperatures ranging from 5 to 35°C. The solvents used contained 10, 30, and 50 wt.% of the cosolvents in each case.

Since the autoionization of aqueous solutions of these aprotic cosolvents involves the ionization of water alone, the general expression of the equilibrium in the different mixed solvents can be written as [1]

[1] $H_2O\ (s) \rightleftharpoons H^+\ (s) + OH^-\ (s)$

where (s) denotes that the respective species are in the standard state in each of the solvent mixtures. H^+ (s) counts all H^+ (solvated) including H_3O^+ and otherwise that are "seen" (2) by the H_2-electrode in the mixed solvents. In the case of pure water, (s) in the process [1] will be replaced by (w) meaning that the species will be in the standard state in pure water.

Experimental

Both THF (Reidel) and DME (Reidel) were first purified by refluxing successively with metallic sodium (Merck) and $LiAlH_4$ (Merck) for about 10–12 h followed by distillation after each refluxing. The twice-distilled solvents were then stored in a desiccator and used within 10 days, redistilling every time from $LiAlH_4$ before the preparation of the cell solutions. The bp, density, and refractive index of the solvents compared fairly well with the corresponding values in the literature (8, 9). Water used was triple distilled and made free from CO_2 by collecting the final distillate under N_2 atmosphere. Solvents of different compositions were made by weight. KBr (Merck, G.R.) was used after drying at 200–300°C and cooling in a vacuum desiccator. Stock KOH solutions were prepared by adding carbonate-free KOH (Merck, G.R.) to the weighed amounts of the solvent and the molalities were determined by titration using phenolphthalein as indicator. The method of preparation of the cell solutions was essentially similar to that described earlier (10). Adequate care was taken to avoid exposure of the solutions to the atmosphere by using a chamber flushed with N_2 whenever possible.

General experimental procedures, including the preparation of the electrodes and the measurements of emf, were similar to those described earlier (1, 2, 5, 7, 10). The equilibrium was attained in about 5–6 h. The constancy of emf readings to about ± 0.1 mV for 1 h was taken as the criterion of equilibrium. The emf's of the cell were measured by a Leeds and Northrup K_4 potentiometer using a moving coil galvanometer (Cambridge Instrument Co.) as the null point detector. Readings at 5°C were taken first and then at successively higher temperatures. Readings at lower temperatures, when checked, were found to agree within the experimental error of ± 0.3 mV. The alkali concentrations were often checked after the experiments and no significant changes were detected.

Results

The emf data (E) of cell [A] at different temperatures and the corresponding molalities of KOH and KBr for each of the solvent mixtures are given elsewhere.[4] The required corrections of the observed emf's corresponding to $p_{H_2} = 1$ were made using the partial pressures reported by Roy *et al.* (11, 12). The pK_s values (molal scale) in these mixed solvents were obtained by extrapolating the observed linear plots of pK_s' values defined by eq. [2] (1, 2, 5, 10).

$$[2] \quad pK_s' = F\,[E - (E_m^0)_{Ag,AgBr}]/2.3026\,RT + \log m_{Br^-}/m_{OH^-} = pK_s - \log a_{H_2O}\,\gamma_{Br^-}/\gamma_{OH^-} = pK_s + f(\mu)$$

against the ionic strength μ to $\mu = 0$. Here a, m, and γ denote activity, molality, and molal activity coefficient of the species subscripted. As in previous studies (1, 2, 4, 5, 10*a*), the standard state is so chosen that at infinite dilution in a given solvent $\gamma_{Br^-} = \gamma_{OH^-} = a_{H_2O} = 1$. And as in aqueous D (4), since the term $-\log \gamma_{Br^-} a_{H_2O}/\gamma_{OH^-}$ in dilute solutions of each solvent is likely to be proportional to μ, the pK_s' function would be linear with μ, as has been observed. Also in the standard state the autoionization constant of the solvent, defined by $K_s = a_{H^+}\,a_{OH^-}/a_{H_2O}$, becomes equal to $m_{H^+}\,m_{OH^-}$.

Assuming that the electrolytes KOH and KBr are completely dissociated in these mixed solvents, m_{OH^-} and m_{Br^-} were taken as equal to m_1 and m_2 respectively and $\mu = (m_1 + m_2)\,d_s$, where d_s is the density of the mixed solvent. The required values of density and E_m^0 of the Ag–AgBr electrode in the solvents were obtained from the literature (11, 12). The pK_s values at different temperatures for all the mixed solvents are listed in Table 2. The average standard deviation in pK_s values is of the order of ± 0.005 unit.

[4] A complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a] Reference 22, p. 759. Assuming that maximum uncertainty in pK_s values in all the solvents used is of the order ± 0.005 unit, the estimated (45) maximum uncertainties in the values of ΔG^0, ΔH^0, and ΔS^0 at 25°C are of the order: ± 0.03 kJ mol^{-1}, ±0.4 kJ mol^{-1}, ±1 J K^{-1} mol^{-1} respectively.

Notably, pK_s values of THF–water mixtures at 25°C compare fairly well at low cosolvent compositions but deviate significantly at higher compositions from the corresponding values reported by Woolley *et al.* (13), as obtained by use of a glass electrode (cf. the data in parentheses of Table 1). Similar discrepancies were also observed between the H_2-electrode data of Harned and Fallon (4) and the glass electrode data of Wooley *et al.* (6) in D–water mixtures. The same is true of the results obtained by H^+/Rb^+-sensitive glass electrodes (14) and those obtained by H_2- (15, 16) and Rb(Hg)- (17, 18) electrodes respectively, especially at higher cosolvent compositions of some aqueous dipolar aprotic cosolvents (14, 19). Now considering the observed larger liquid junction potentials (20), especially across water and dipolar aprotic solvents compared to those across water and alcohols, it is perhaps reasonable to doubt that if the ion-sensitive glass electrodes containing aqueous solutions inside and a large proportion of aprotic cosolvents outside the glass membrane should be free from complications.

The pK_s values at different temperatures were fitted to the Harned–Robinson expression (21).

$$[3] \quad pK_s = A/T - B + CT$$

by the method of least squares. The values of the coefficients A, B, and C for the solvents are given in Table 2. Computed pK_s values using eq. [3] are found to be reproducible within ± 0.005 unit in each solvent mixture.

The thermodynamic quantities, namely ΔG^0, ΔS^0, and ΔH^0 accompanying the autoionization of 1 mol of each of the solvent mixtures, were evaluated by using the standard relations (22) comprising the coefficients of eq. [3]. These values (molal scale) are presented in Table 2.

[a] $\Delta G_t^0(H^+)$ values in THF–water and D–water mixtures have been taken from ref. 25*b* and those for DME–water mixtures from ref. 25*a*.
[b] Values in parentheses have been obtained by interpolation and conversion of the corresponding data of Harned *et al.* (ref. 22, p. 759), as the values for H^+ have been determined at these compositions.

Free Energy Changes

The standard free energy changes accompanying the autoprotolytic reaction [1] in the mixed solvent, ${}_s\Delta G_N^0$, relative to that in pure water, ${}_w\Delta G_N^0$, have been computed on the mole fraction scale using [4]

$$[4]\quad \delta(\Delta G_N^0) = {}_s\Delta G_N^0 - {}_w\Delta G_N^0$$
$$= 2.3026\,RT\,[p({}_sK_s)_N - p({}_wK_s)_N]$$
$$= 2.3026\,RT\left[(p_sK_s + 2\log 1000/M_s) - \left(p_wK_s + 2\log\frac{1000}{M_w}\right)\right]$$

The subscript s refers to the solvent, w to water, and N to the mole fraction scale. M_w and M_s are the molar and mean molar mass of water and the mixed solvent respectively. The values of $\delta(\Delta G_N^0)$ are presented in Table 3.

Figure 1 illustrates the variations of $\delta(\Delta G_N^0)$ values with mol% of the cosolvent for these solvent systems. For the sake of comparison the corresponding profile for the D–water system is also shown. The required data were obtained from Harned and Fallon (4) after due interpolation and conversion. As for aqueous mono-ols (6), $\delta(\Delta G_N^0)$ values for all these mixed solvents are found to be increasingly positive and at any cosolvent composition these are in the order D > DME > THF. It is well known that $\delta(\Delta G_N^0)$ values are the result of the combined effects of dielectric constant as well as the acidity and basicity of the mixed solvents (1). Since the dielectric constant of DME increases up

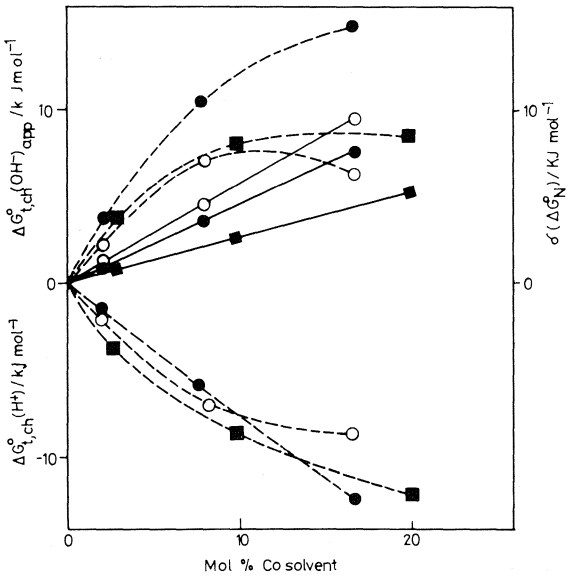

FIG. 1. Variation of $\delta(\Delta G_N^0)$ (solid line), $\Delta G_{t,ch}^0(H^+)$ and $\Delta G_{t,ch}^0(H^-)_{app}$ (dotted line) in aqueous ethers (■ THF, ● DME, and ⊙ dioxane).

to 30 wt.% and then decreases (12), whilst that for D (23) and THF (11) decreases monotonically, the relative positions of $\delta(\Delta G_N^0)$ suggest that the effects of acidity and basicity are apparently more predominant than that of the dielectric constant. So, derivation of these effects should be more informative.

As indicated in previous studies (1, 10) the quantity $\delta(\Delta G_N^0)$ represents the standard free energy changes accompanying the reaction [1] rela-

tive to that in pure water, i.e. of the process [5]

[5] $H^+(w) + OH^-(w) + H_2O(s) = H^+(s) + OH^-(s) + H_2O(w)$

Since this process is equivalent to the sum of the processes [6] and [7]

[6] $H^+(w) = H^+(s)$

[7] $OH^-(w) + H_2O(s) = OH^-(s) + H_2O(w)$

$\delta(\Delta G_N^0)$ would be given by

[8] $\delta(\Delta G_N^0) = \Delta G_t^0(H^+) + \Delta G_t^0(OH^-)_{app}$

where $\Delta G_t^0(H^+)$ denotes the transfer free energy accompanying the process [6] and $\Delta G_t^0(OH^-)_{app}$ that for the process [7]. As indicated in earlier papers (2, 10*a*), $\Delta G_t^0(OH^-)_{app}$ referred to above is equivalent to $\Delta G_t^0(OH^-)$, the standard free energy change accompanying the transfer of OH^- alone from water to the mixed solvent, i.e. the transfer process OH^- (w) $\rightarrow$ OH^- (s). This is because $\Delta G_t^0(H_2O)$ embedded in $\Delta G_t^0(OH^-)_{app}$ referred to here is formally zero due to the involved assumption that a_{H_2O} in the standard state of each solvent mixture $(a_{H_2O})_s^s$ is unity. If, however, the said activity of water $(a_{H_2O})_w^s$ be referred to that in pure water, $(a_{H_2O})_w^w$ as unity, then $-RT \ln (a_{H_2O})_w^s$ would give a measure of $\Delta G_t^0(_{H_2O})$. Obviously, while $\Delta G_t^0(H^+)$ gives a thermodynamic measure of basicity of the mixed solvent relative to that of water, $\Delta G_t^0(OH^-)_{app}$ gives the corresponding measure for the relative acidity of the mixed solvents. Consequently dissection of $\delta(\Delta G_N^0)$ to $\Delta G_t^0(H^+)$ and $\Delta G_t^0(OH)_{app}$ is in order.

Utilizing the $\Delta G_t^0(H^+)$ values based on the widely used reference electrolyte assumption (24): $\Delta G_t^0(Ph_4As^+) = \Delta G_t^0(Ph_4B^-) = \frac{1}{2}\Delta G_t^0(Ph_4AsBPh_4)$ reported earlier for these solvent systems (25), we have evaluated $\Delta G_t^0(OH^-)_{app}$ for all these mixed solvents. The values of $\Delta G_t^0(H^+)$ and $\Delta G_t^0(OH^-)_{app}$ are given in Table 3. Moreover, in order to make these data free from Born-type electrostatic effects (26) $\Delta G_{t,el}^0(i)$, these values were computed tentatively by use of the simple Born equation (26) taking $r_{H^+} \approx r_{H_3O^+} = 0.276$ nm (27), $r_{OH^-} = 0.156$ nm (28), and ε values as given in the literature (11, 12, 23). These values when subtracted from the respective $\Delta G_t^0(i)$ values yielded the chemical or non-Born type contributions (26): $\Delta G_{t,ch}^0(H^+)$ and $\Delta G_{t,ch}^0(OH^-)_{app}$, which are plotted against the cosolvent composition in Fig. 1.

Notably, in all the solvent systems, while $\Delta G_{t,ch}^0(H^+)$ are increasingly negative the corresponding values of $\Delta G_{t,ch}^0(OH^-)_{app}$ are increasingly positive. This implies that the "basicity" of the mixed solvent increases and the "acidity" decreases with the increased proportion of the cosolvents. Moreover, while the order of increased "basicity" especially at higher compositions is D < THF < DME, that of decreased "acidity" is D > THF > DME. Structural and electronic consideration of the cosolvent molecules also indicates that these three ethers, unlike water, are incapable of acting as electron acceptor or donating H^+, and hence aprotic. But, because of the electron-releasing tendency of the $(-CH_2-)$ or $(-CH_3)$ groups, the molecules are capable of acting as stronger electron donors and H^+ acceptors or "bases" than water. Also, the negative charge density will be much more intense on the single O-centre of the THF molecule than on the two O-centres of the D molecule. And, the DME molecule being effectively a 1,4 dioxane with the ring opened up, each of the electron donating $(-CH_3)$ groups induces large negative charge density on the respective O-centre to which it is attached so that the flexible chain so produced imparts more H-bond donating propensity compared to D and THF. As a result, the "basicity" or "cation–O-centre" interacting capacities of the cosolvents (28) are likely to increase in the order: D < THF < DME and their "acidity" or "anion–H-centre" interacting capacities (28) in the reverse order, as observed. Besides, since the "basicity" and "acidity" of the cosolvents are likely to be relayed through cooperative H-bonding between the cosolvents and H_2O molecules (28*a*, *b*) in their aqueous solutions, the possible H-bonded cosolvent–water complexes and their aqueous solutions should be more "basic" and less "acidic" than water. At low compositions of the DME–water system the contrary behaviour of H^+ seemingly stems from the possible structural changes due to the formation of H-bonded bidentate intercomponent complexes peculiar to this cosolvent, as indicated by Roy *et al.* (12) to explain the observed increased dielectric constant up to 30 wt.% DME.

Entropy Changes

Since entropy changes rather than enthalpy changes are a better indicator of the structural implications of a process in any aquo-organic solvents (29), analysis of the entropy changes in the present study should be useful. The values of entropy of autoionization on the mole fraction scale, ΔS_N^0, were computed at 25°C by use of eq. [9]

[9] $\Delta S_N^0 = \Delta S^0 - 2R \ln 1000/M_s$

The variations of the values of $T\Delta S_N^0$ at 25°C relative to that in water, $T\delta(\Delta S_N^0)$ ($\equiv T\ (_s\Delta S_N^0 - {}_w\Delta S_N^0)$), for these solvent systems are shown in Fig. 2 in which the corresponding profile for D–

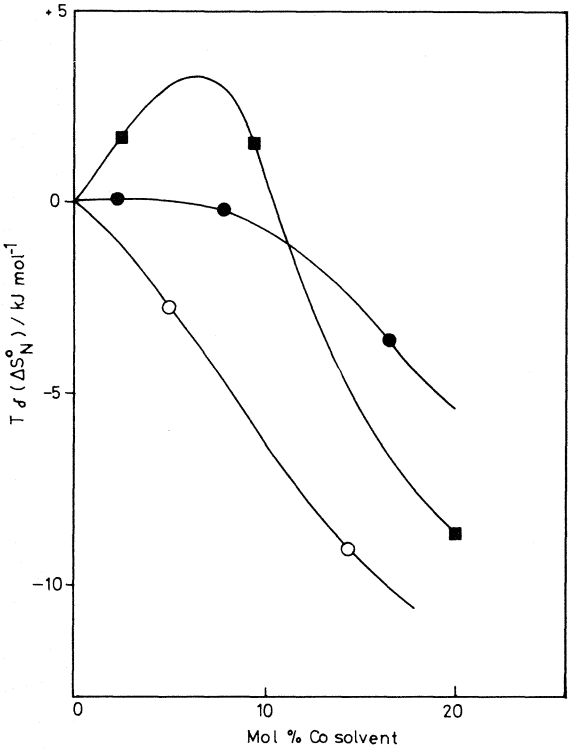

FIG. 2. Variation of $T\delta(\Delta S_N^0)$ accompanying the autoionization of water in aqueous ethers (■ THF, ● DMe, and ⊙ dioxane).

water mixtures has also been shown. The required data were obtained from Harned and Fallon's work on pK_s values at different temperatures (4).

Since the depolymerization of water molecules prior to self-ionization contributes positive entropy changes to the overall entropy of autoionization, the larger the extent of 3D ice-like water structures in the aquo-organic solvents, the larger is this contribution. Consequently, the appearance of a maximum in $T\delta(\Delta S_N^0)$–composition profiles would imply that the mixed solvents are more structured than pure water and a downward trend would imply less structured. Evidently the observed profile for THF–water mixtures implies that the addition of THF initially promotes the 3D-structure of water, possibly due to the strong hydrophobicity of 4 ($-CH_2-$) groups, but breaks down the same beyond 10 mol% THF due to packing imbalance. This contention is also in fair agreement with that arrived at from various other studies (30–33) in this solvent system.

In the case of D–water mixtures, as the $T\delta(\Delta S_N^0)$–composition (x) profile (Fig. 2) takes a sharply downward trend from $x_D = O$, it appears to suggest that the addition of D, unlike THF, breaks down the 3D-water structure even at the water-rich composition, as has been concluded from various other studies (34–39). The genesis of this destabilizing effect is possibly the effect of H-bonded intercomponent interactions, as has been indicated by ir and nmr studies (40, 41). The symmetrically placed ethereal O atoms with pronounced H-bond-donating propensity, caused by the cooperative inductive effect of the $-CH_2-$ groups (42), and also the high quadrupole moment of D (43) possibly help in such interactions. These, in effect, shift the $(\text{water})_{\text{bulky}} \leftrightarrow (\text{water})_{\text{dense}}$ equilibrium towards the right.

In the case of DME–water mixtures, the observed slight hump followed by a sharp negative trend of $T\delta(\Delta S_N^0)$ (Fig. 2) with increased cosolvent composition apparently suggests that the small addition of DME to water possibly does not alter water structure to a significant extent, unlike both THF and D, although like both of these cosolvents DME at higher composition breaks down 3D structure due to the packing imbalance. However, as the H-bonding capability of the DME molecule (because of its two flexible methoxy O-centres) exceeds that of D, the observed slight hump possibly stems from the unusual dielectric behaviour (12) and its reverse temperature dependence (12) compared to the D–water system (23).

Moreover, in view of the fact that $T\delta(\Delta S_N^0)$ is more involved by having a contribution of $\Delta S_t^0(H_2O)$ as well (cf. eq. [10]), if pK_s values for all the solvents be referred to $(a_{H_2O})_w^w = 1$ instead of $(a_{H_2O})_s^s = 1$, it would be of interest to see the structural implications of $T\delta(\Delta S_N^0)$ from another angle. Since $\delta(\Delta S_N^0)$ is given by

$$[10] \quad \delta(\Delta S_N^0) = {}_s\Delta S_N^0 - {}_w\Delta S_N^0 = \Delta S_t^0(H^+) + \Delta S_t^0(OH^-) - \Delta S_t^0(H_2O)$$

and the contributions of $\Delta S_t^0(H^+) + \Delta S_t^0(OH^-)$ could be tentatively obtained from another source which is free from a_{H_2O}, it would be possible to estimate $\Delta S_t^0(H_2O)$ by subtracting the contributions of the sum: $(\Delta S_t^0(H^+) + \Delta S_t^0(OH^-))$ from $\delta(\Delta S_N^0)$. In fact, in the following paper (44) we have collected the values of the sum: $(\Delta S_t^0(H^+) + \Delta S_t^0(X^-))$ where $X^- = Cl^-$, Br^-, and I^-, for these solvent mixtures. So, plotting $(\Delta S_t^0(H^+) + \Delta S_t^0(X^-))$ values against $(r_{x^-})^{-1}$ and reading out the values corresponding to $(r_{OH^-})^{-1}$ (by slight extrapolation of the smooth plots) yielded the tentative values of $(\Delta S_t^0(H^+) + \Delta S_t^0(OH^-))$. The values of $\Delta S_t^0(H_2O)$ so obtained for all these solvent mixtures are given in Table 3 and their variations with cosolvent compositions are shown in Fig. 3.

Simple consideration of order–disorder phenomena indicates that the negative trend of the $\Delta S^0(H_2O)$ – composition profile would imply more

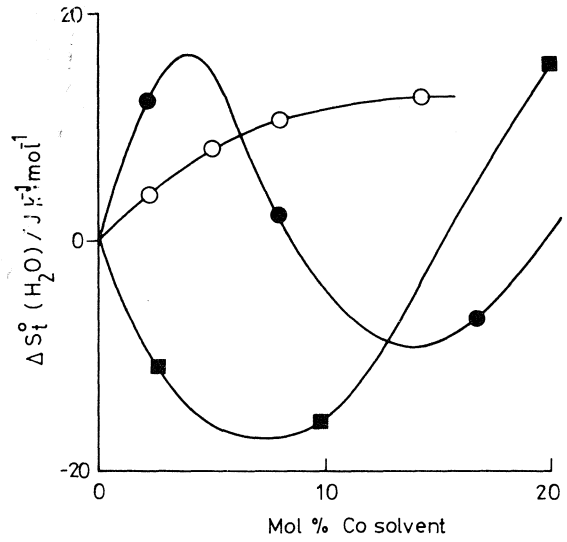

FIG. 3. Variation of ΔS_t^0 (H_2O) in aqueous ethers (■ THF, ● DMe, and ⊙ dioxane).

order and hence more "structure" or "cluster" in the mixed solvents than in water. But the reverse is true when the $\Delta S_t^0(H_2O)$–composition profile has a positive trend. The observed results in Fig. 3 therefore suggest that addition of THF initially enhances the 3D structure of water while at higher composition breaks down the same, conforming to what has been indicated earlier. On the other hand, addition of D to water induces breaking down of the 3D water structure right from the beginning as has also been indicated earlier. But in the case of the DME–water system the observed sharp increases of $\Delta S_t^0(H_2O)$ with the addition of DME are indicative of the effect of the predominant structure-breaking propensity of DME. And the observed downward trend of $\Delta S_t^0(H_2O)$ around 4–14 mol% DME is possibly the result of the increased order accompanying the formation of relatively more stable H-bonded bidentate DME–water complexes peculiar to this cosolvent, as referred to earlier. Lastly, the observed upward trend at still higher composition is the reflection of increased disorder due to the packing imbalance as common to all other cosolvents.

Free energies and entropies of transfer of hydrogen halides from water to aqueous solutions of tetrahydrofuran, dioxane, and 1,2-dimethoxyethane and the structuredness of the solvents

JAYATI DATTA[1] AND KIRON K. KUNDU[2]

Physical Chemistry Laboratories, Jadavpur University, Calcutta – 700 032, India

Received July 24, 1980[3]

JAYATI DATTA and KIRON K. KUNDU. Can. J. Chem. **59**, 3149 (1981).

Standard free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer of hydrogen iodide from water to some aqueous solutions of tetrahydrofuran (THF), dioxane (D), and 1,2-dimethoxyethane (DME) have been determined by measuring the emf's of the cell: Pt, H_2 (g, 1 atm)|KOH (m_1), KI (m_2), solvent|AgI, Ag at seven equidistant temperatures ranging from 5 to 35°C. In each of these ethereal solvent systems ΔG_t^0 values of HI, as well as of HCl and HBr obtained from the literature, and particularly of the individual ions, suggest that while H^+ is increasingly stabilized, halide ions are increasingly destabilized due to the influence of cosolvent-induced larger "basicity" and smaller "acidity" of the mixed solvents compared to that of water, and both conformed to the expected order: D < THF < DME. Moreover, the relative order: $Cl^- > Br^- > I^-$ in all the solvent systems is ascribable to the combined effects of "acid–base" and "soft–soft" interactions and the superimposed quadrupolar interactions in the case of D and the charge transfer to solvent (CTTS) complexation effect, especially on I^- in the case of THF. Analysis of the entropic contributions, $T\Delta S_t^0$, and particularly of the relative order of ΔY ($\equiv T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$) for X = Cl, Br, and I, in the light of the semi-quantitative theory proposed earlier by Kundu *et al.*, reveals that at initial compositions, while THF promotes 3D structures of water, both D and DME break down the same; at higher compositions all the cosolvents disrupt the structure as usual due to packing imbalance. The nature and relative positions of ΔY–composition profiles also suggest that while increase of hydrophobic groups of the cosolvents increases the stabilization, increase in hydrophilicity or H-bonding sites decreases the stabilization of the 3D structure of water.

JAYATI DATTA et KIRON K. KUNDU. Can. J. Chem. **59**, 3149 (1981).

A partir de mesures de la fem de la cellule: Pt, H_2 (g, 1 atm)|KOH (m_1), KI (m_2), solvant|AgI, Ag à sept températures équidistantes allant de 5 à 35°C, on a déterminé les énergies libres (ΔG_t^0) et les entropies (ΔS_t^0) standards de transfert, de l'iodure d'hydrogène, de l'eau aux solutions aqueuses de tétrahydrofuranne (THF), de dioxanne (D) et de diméthoxy-1,2 éthane (DME). Dans chacun de ces systèmes de solvants les valeurs de ΔG_t^0 de HI aussi bien que celles de HCl et de HBr déjà existantes, et en particulier celles des ions individuels, suggèrent que tandis que H^+ est stabilisé de façon accru, les ions halogénures sont déstabilisés par suite de l'influence de la plus grande "basicité" induite du cosolvant et d'une plus faible "acidité" des solvants mixtes comparés à celles de l'eau, les deux propriétés étant dans l'ordre prévu: D < THF < DME. De plus, l'ordre relatif: $Cl^- > Br^- > I^-$ dans tous les systèmes de solvants est attribuable aux effets combinés d'interactions de type "acide–base" et "doux–doux" et d'interactions quadrupolaires additionnées dans le cas de D et à l'effet de complexation du transfert de charge au solvant (CTTS), spécialement avec I^- dans le cas du THF. L'analyse des contributions entropiques $T\Delta S_t^0$ et en particulier l'analyse de l'ordre relatif de ΔY ($\equiv T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$) pour X = Cl, Br et I, à la lumière de la théorie semi-quantitative de Kundu *et al.* proposé antérieurement, révèle que pour des compositions initiales le THF favorise les structures 3D de l'eau tandis que le D et le DME au contraire détruisent cette structure 3D pour des compositions plus élevées, tous les cosolvants rompent la structure comme d'habitude par suite d'un entassement déséquilibré. La nature et les positions relatives des profils de composition–ΔY suggèrent également que, tandis que l'augmentation des groupes hydrophobes des cosolvants augmente la stabilisation, l'augmentation de l'hydrophilicité ou des sites de liaisons hydrogène diminue la stabilisation de la structure 3D de l'eau.

[Traduit par le journal]

Introduction

As part of evolving some knowledge on solvating and structural characteristics of certain aqueous ethers we have reported in the preceding paper (1) the autoionization constants of tetrahydrofuran (THF) – water and 1,2-dimethoxyethane (DME) – water mixtures at different temperatures. The related thermodynamic parameters gave some insight into the acidity and basicity as well as the structural aspects of these aqueous ethers.

Recent studies by Kundu and co-workers (2) have shown that standard potentials (E^0) of the Ag–AgX electrodes at different temperatures in different aquo-organic solvents are not only valuable in various electrochemical studies involving these electrodes in the solvents, but the related transfer free energies of HX from water to those solvents, ΔG_t^0 (HX), also furnish useful measures of the relative ion–solvent interactions, and the transfer entropies, ΔS_t^0 (HX), serve as an effective probe for the structural aspects of the solvents relative to that of water. In fact, the observed characteristic "maximum" of $T\Delta S_t^0$(HX)–composition profiles and the relative order of the

function ΔY ($\equiv T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$) (2): HI > HBr > HCl in the water-rich compositions of aqueous *t*-BuOH, 2-propanol, and ethanol, the well known promoters of three-dimensional (3D) ice-like structure of water (3), and the observed downward trends of ΔY values and their reverse order at higher cosolvent compositions where the 3D structures collapse due to packing-imbalance (3), led Kundu *et al.* (2) to propose a semi-quantitative theory relating $T\Delta S_t^0(HX)$ or rather ΔY as a structural probe for aquo-organic solvents. According to that theory (*a*) when solvent structure > pure water structure, $\Delta Y > 0$, and ΔY (X = I) > ΔY (X = Br) > ΔY (X = Cl), and (*b*) when solvent structure < pure water structure, $\Delta Y < 0$, and ΔY (X = I) < ΔY (X = Br) < ΔY (X = Cl).

Applying the above-noted tenets as the structural probe Kundu and co-workers also derived important conclusions regarding the structural features of some other solvents, viz. glycol–water (2), glycerol–water (4), etc. which are in fair agreement with those derived from various other studies in the respective solvents. So it should be highly interesting and useful to apply the said probe in elucidating the structural features of these aqueous ethers as well.

As the E^0 values of the Ag–AgX (X = Cl or Br) electrodes at different temperatures are already known in these solvents (5, 6), we are reporting the same for X = I. Since I^- is highly susceptible to oxidation at low pH solutions of these cosolvents, cell [A]

[A] Pt, H_2 (g, 1 atm)|KOH (m_1), KI (m_2), solvent| AgI, Ag

has been used. The required autoionization constants (K_s) of the solvents are of course already known (1). Moreover, although E^0 values of the Ag–AgX (X = Cl, Br, and I) at different temperatures are already known (7–9) in the aqueous mixtures of dioxane (D), another widely used and closely related ethereal cosolvent, the values of the Ag–AgI electrode are, however, based on emf measurements of cells with liquid junction (8*c*). So it would be useful to extend the present study to D–water mixtures as well. In all these aqueous ether solvents E^0 values have been determined at seven equidistant temperatures ranging from 5° to 35°C. The compositions studied for DME are 10, 30, and 50 wt.% DME and for THF are restricted to 10, 20, and 30 wt.% THF, while those for D are restricted to 20 and 45 wt.% D, as the required pK_s data available from Harned and Fallon's work (10) are restricted to these compositions only where the compositions of ion-association are likely to be absent.

Experimental

The quality and the method of purification of the solvents DME and THF have been described (1). Dioxane (Merck, G.R.) was purified by refluxing over pieces of Na for about 24 h and then distilling twice. The physical properties, viz. bp, density, and refractive index, compared fairly well with those given in the literature (6, 11, 12). The solvents so purified were stored in a desiccator not more than 10 days and redistilled every time before use after refluxing with Na for some time. Water used was, as before (1), triple distilled. KI (Merck, G.R.) was used after drying at about 150°C and then over a vacuum desiccator for about 12 h. The purity of the sample was checked by gravimetric estimation of I^-. Ag–AgI electrodes were of the thermal type and prepared by the method described by Ives and Janz (13). Other experimental details including the preparation of solvents, solutions, and the platinized electrodes and also the methods of measurements were exactly as described in the preceding paper (1). The behaviour of the electrodes, the time for attainment of the equilibrium, and criteria of equilibrium of the cells were also essentially similar to that described in the said paper.

Results

The emf (E) of the cell [A] at any solvent mixture is given by

$$[1] \quad E = E^0 - 2.303\frac{RT}{F}\log(a_{H^+}a_{I^-})$$

where the terms have the usual significance. Replacing a_{H^+} in terms of K_s by $K_s\, a_{H_2O}/a_{OH^-}$ (1, 10), a_i of the ionic species by the product of molality (m_i) and the molal activity coefficient (γ_i), and $2.303RT/F$ by k, we have an extrapolation function, $E^{0\prime}$ defined by [2]

$$[2] \quad E^{0\prime} \equiv E + k\log m_{I^-}/m_{OH^-} + k\log K_s = E^0 - k\log a_{H_2O}\gamma_{I^-}/\gamma_{OH^-} = E^0 + f(\mu)$$

As in the previous cases (1, 10, 11*b*), the standard states are so chosen that at infinite dilution in each solvent mixture the activity coefficients of the ions concerned as well as the activity of water (a_{H_2O}) are unity. Also, as the term $\log a_{H_2O}\gamma_{I^-}/\gamma_{OH^-}$ in dilute solution in each solvent mixture is, as before (1, 10, 11), likely to be proportional to the ionic strength, μ, extrapolation of the function $E^{0\prime}$ to $\mu = 0$ would yield the E^0 values on the molal scale, henceforth denoted as E_m^0. It may be noted that since the effect of the a_{H_2O} term in eq. [2] gets cancelled by that contained in the K_s term, the E^0 value is effectively free from the involved assumption that $a_{H_2O} = 1$.

The E values of cell [A] at different temperatures and the corresponding molalities of KOH and KI for each of the solvent mixtures are given else-

[a]Computed from the data reported in ref. 27.

where.[4] The required partial pressures of the mixed solvents for correcting P_{H_2} = 1 atm were taken from data of Roy *et al.* for THF–water (5*b*) and DME–water (6*c*) mixtures and from Akerlof's paper (14) for D–water mixtures. The required values of pK_s for computing $E^{0\prime}$ values were obtained from the previous paper for most of the compositions of DME and THF and by interpolating the appropriate data at 20 wt.% THF, and those for D–water mixtures were taken from Harned and Fallon's data (10).

Assuming as before (1, 10, 11) that KOH and KI are completely dissociated in all these mixed solvents, m_{OH^-} and m_{I^-} were taken as equal to m_1 and m_2 respectively, and $\mu = (m_1 + m_2)d_s$, where d_s is the density of the mixed solvent. The values of d_s were obtained from the literature (5*b*, 6*c*, 10). The values of $E^{0\prime}$ computed by use of eq. [2] at any temperature for any composition were then fitted to linear plots by the method of least squares and the values of E_m^0 so obtained are given in Table 1. The uncertainties in the values of E_m^0 as obtained from the standard deviations lie within ±0.3 mV. The E_m^0 values of D–water mixtures at 25°C compare fairly well with the data of Feakins *et al.* (15*a*), as shown in parentheses beside the respective data in the table.

The E_m^0 values at different temperatures for each solvent mixture were then fitted into the E_m^0–temperature quadratic equation

$$[3] \quad E_m^0 = a + b(t - 20) + c(t - 20)^2$$

by the method of least squares where t is the temperature in degree Celsius. The coefficients a, b, and c for each of the solvent mixtures are listed in Table 2. The coefficients of eq. [3] for water were also obtained by use of data of Bates and coworkers (27) and are included in Table 2.

The free energy change ΔG_t^0 accompanying the transfer of 1 mole of HI from the standard state in water (w) to that in each of the mixed solvents (s), i.e. of the process HI (w) → HI (s), were computed on the mole fraction scale at t = 25°C, using the relation

$$[4] \quad \Delta G_t^0(\mathrm{HI}) = -F[(E_m^0)_s^{25°} - (E_m^0)_w^{25°}] - 2RT \log M_s/M_w$$

where T = 298.15, and M_s and M_w are the average and pure molar mass of the mixed solvent and

water respectively. The corresponding entropy changes ΔS_t^0(HI) at 25°C were obtained by use of eq. [5]

$$[5]\quad \Delta S_t^0(\mathrm{HI}) = F(b_s - b_w) + 2F(t - 20)(c_s - c_w) + 2R \ln M_s/M_w$$

The values of ΔG_t^0 and ΔS_t^0 so obtained for HI for all these solvents are presented in Table 3. The average estimated uncertainties in ΔG_t^0 and ΔS_t^0 at 25°C for these mixed solvents are respectively $\pm$ 0.03 kJ mol^{-1} and $\pm$ 3 J K mol^{-1}.

For the sake of comparison, the corresponding values for HBr were also computed in a similar manner. As E_m^0 values of the Ag–AgBr electrodes in THF–water (5*b*) and DME–water (6*c*) mixtures reported by Roy *et al.* are based on a polynomial curve-fitting technique, these might differ from those based on an extrapolation procedure. We have therefore first reevaluated E^0 values from the primary emf data of Roy *et al.* by the usual extrapolation procedure. The observed E_m^0 values at seven equidistant temperatures in the range 5–35°C were then fitted into eq. [3], the coefficients of which were used to calculate ΔG_t^0 and ΔS_t^0 values for HBr. In the case of D–water mixtures, as values of Mussini *et al.* (9) are already based on an extrapolation procedure, these values were fitted into eq. [3] and the coefficients so obtained yielded the ΔG_t^0 and ΔS_t^0 values. All these values are given in Table 3. Notably, these values agree with Roy's data (Table 3) within the limits of experimental error, namely $\pm$3 J K^{-1}. But the E^0 values of the Ag–AgCl electrode in THF–water (5*a*) and DME–water (6*a*, *b*) systems are, however, given at equidistant temperatures from 15 to 35°C and at 10° intervals, and also at other compositions. So, similar treatment of the data would involve interpolations and hence is likely to incur extra uncertainties. In view of these intrinsic limitations, data of Johnson and Sen (6*a*), though based on a polynomial curve-fitting technique, were not reevaluated by extrapolation procedure. Instead, E_m^0 values at intermediate temperatures at 20° and 30°C were first obtained by careful interpolation of the large scale plots of E_m^0 between 15° and 35°C. E_m^0 values at these 5 temperatures were then fitted into eq. [3] for the reported compositions and also for water. The coefficients so obtained were used for computing ΔG_t^0 and ΔS_t^0 values for HCl. And the values at desired compositions were then collected by interpolation and are given in Table 3. In the case of D–water mixtures, however, corresponding values were obtained by treating Harned *et al.*'s extrapolation data (7) at seven equidistant temperatures in the range 5–35°C.

In Fig. 1 $T\Delta S_t^0$(HX)–composition profiles for HCl, HBr, and HI in D–water mixtures as obtained from the data of Harned *et al.* (7), Mussini *et al.* (9), and the present study respectively have been compared with the corresponding profiles obtained from data of Das and co-workers (8). Notably, the former set of profiles are increasingly negative and their order HCl > HBr > HI conforms to what is expected from Kundu and co-workers' theory (2) if D has the structure-breaking propensity implied by various other studies referred to in the preceding paper (1). But curiously enough, the latter set of profiles are not only widely divergent from the respective profiles of the former set but their order: HI > HBr > HCl at any composition is also not akin to their behaviour in the cosolvents studied so far. This questions the reliability of the entropy data of Das and co-workers.

Discussion

Free Energies of Transfer

A perusal of ΔG_t^0(HX) values in Table 3 reveals that the variation of ΔG_t^0(HX) with cosolvent composition of the three aquo-ether systems is essentially similar to that of aqueous alcohols (2), glycol (2), glycerol (4), etc., and at any composition $\Delta G_t^0(\mathrm{HCl}) > \Delta G_t^0(\mathrm{HBr}) > \Delta G_t^0(\mathrm{HI})$. This is expected if the halide ions become destabilized on passing from water to any of these mixed solvents, being influenced by decreased dielectric constant and the decreased acidity (15*b*, 16) of the solvents. For better understanding of the involved ion–sol-

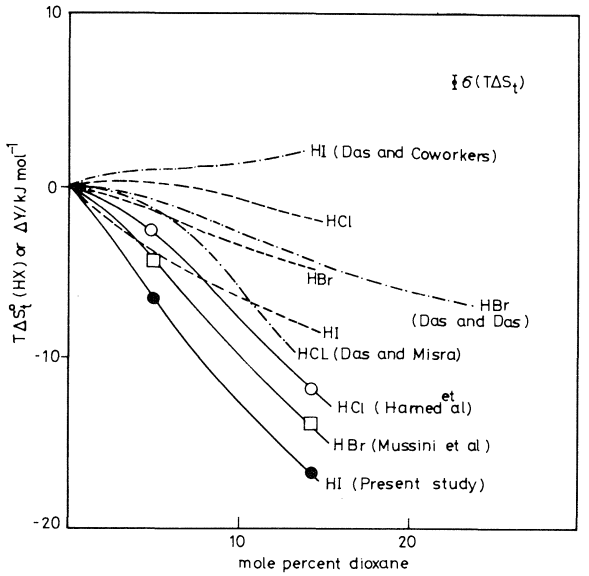

FIG. 1. Variation of ΔS_t^0 (HX) (solid lines) and ΔY ($\equiv T\Delta S_t^0$ (H^+) + $T\Delta S_{t,ch}^0$ (X^-)) (dotted lines) of hydrogen halides in dioxane + water mixtures at 25°C (Das *et al.*'s data refer to ΔS_t^0 (HX)).

For personal use only.

vent interactions, $\Delta G_t^0(HX)$ values were broken down into individual ion contributions by the use of the tetraphenyl arsonium tetraphenyl boride reference electrolyte data for these solvent systems reported earlier (11, 16) and are given in Table 3. In all these cosolvent systems, while $\Delta G_t^0(H^+)$ values are more or less increasingly negative, indicating increased "basicity" or "cation – O-centre" type interactions with the possible H-bonded aquo-ether complexes (15, 16) in the mixed solvents, $\Delta G_t^0(X^-)$ values are increasingly positive, reflecting the decreased "acidity" or "anion–H-centre" type interactions with the aquo-ether complexes (15, 16) in the mixed solvents. These increased "basicity" and decreased "acidity" values of the mixed solvents compared to that of water, and their relative orders: D < THF < DME, are in conformity with what is expected from structural and electronic consideration of these aprotic ethereal cosolvents, as discussed in the preceding paper (1). And the relative order of destabilization of the halide ions in each of the cosolvent systems is the combined result (16–18) of the decreasing strength of anion – H-centre type interactions and the possible increasing strength of soft–soft interactions (17–19) between the increasingly polarizable anions and the softer cosolvent or their aquo-complex bases than water. The observed trend of less destabilization of I^- compared to Br^- and Cl^- at higher compositions of THF (Table 3) is possibly indicative of the superimposed effect of charge transfer to solvent (CTTS) (20) complexation of I^- with THF molecules or their aquo-complexes. On the other hand, the observed downward trend of $\Delta G_t^0(X^-)$ for all the halide ions in D–water mixtures (Table 3) is possibly the result of the effect of enhanced quadrupolar interactions arising from the high quadrupole moment of D (21).

Entropies of Transfer

Since $T\Delta S_t^0(HX)$ rather than $\Delta H_t^0(HX)$ should be more informative regarding the structuredness of the solvents (22), we have illustrated the variation of $T\Delta S_t^0(HX)$ values at 25°C with cosolvent composition for all three solvent systems in Figs. 1–3. In the case of THF–water mixtures the observed $T\Delta S_t^0(X)$–composition profiles (Fig. 2) exhibit the characteristic maxima at initial compositions and their downward trends at higher cosolvent compositions. Also, while the relative order of the maxima is the regular one: HI > HBr > HCl, that at the higher compositions is, as usual, the reverse one. In DME–water mixtures, however, $T\Delta S_t^0(HX) - T\Delta S_{t,el}^0(X^-)$ (2) for this system, as well as ing small maxima at the initial composition, take

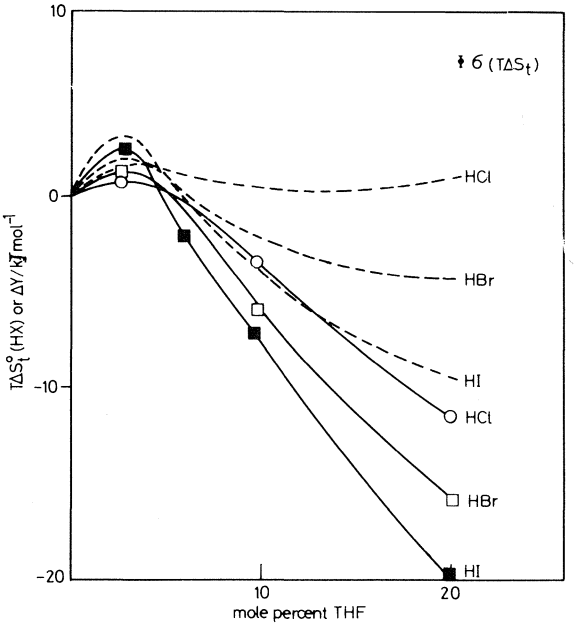

FIG. 2. Variation of $T\Delta S_t^0$ (HX) (solid lines) and ΔY ($\equiv T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$) (dotted lines) of hydrogen halides in THF + water mixtures at 25°C.

sharply downward trends at higher compositions. But their relative order being HCl > HBr > HI throughout the whole composition, the observed small maxima are possibly due to the effect of increased dielectric constant of the mixtures at that region, compared to water (6*c*). That this is particularly true becomes all the more evident when we consider the partly rationalized quantities ΔY ($\equiv T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$) presented in Table 3 and depicted in Fig. 3. These values of ΔY ($\equiv T\Delta S_t^0(HX) - T\Delta S_{t,el}^0(X^-)$) (2) for this system, as well as those for other cosolvent systems, were obtained by subtracting the Born-type electrostatic contributions of the halide ions, $\Delta S_{t,el}^0(X^-)$, which were tentatively computed in a manner described earlier (23). The required values of $\theta^{-1} = -d \ln \varepsilon/dT$ for water and the mixed solvents were obtained from data of Roy *et al.* on DME–water (6*c*) and THF–water (5*b*) mixtures and from Akerlof's paper (14) on D–water mixtures. Figures 1 and 2 illustrate the variation of ΔY–composition profiles for the other two solvent systems.

Notably, while ΔY–composition profiles for both THF–water and D–water mixtures are simply raised without undergoing an essential change in their nature, those for DME–water mixtures move sharply downward in the scale and undergo a significant change by being concave upward in place of the convex-downward nature of the $T\Delta S_t^0(HX)$–composition profiles. Evidently θ^{-1} values

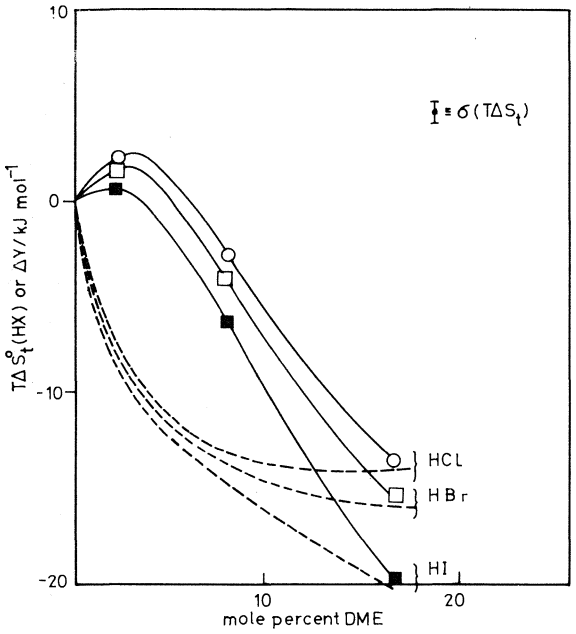

FIG. 3. Variation of $T\Delta S_t^0$ (HX) (solid lines) and ΔY ($\equiv T\Delta S_t^0$ (H^+) + $T\Delta S_{t,ch}^0$ (X^-)) (dotted lines) of hydrogen halides in DME + water mixtures at 25°C.

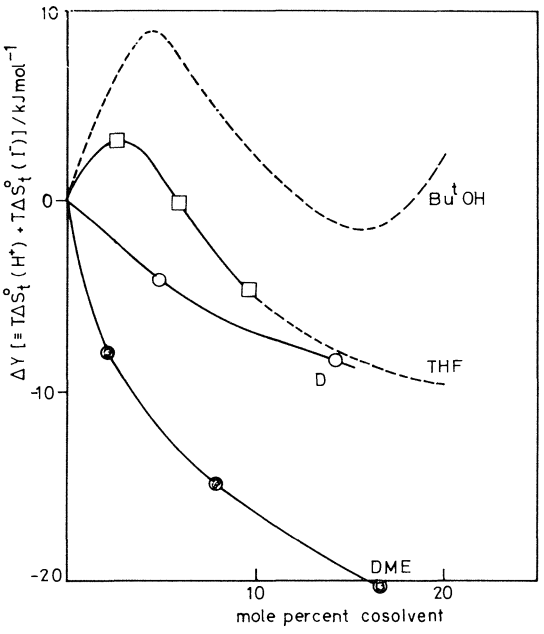

FIG. 4. Variation of ΔY ($\equiv T\Delta S_t^0$ (H^+) + $T\Delta S_{t,ch}^0$ (X^-)) of HI in aqueous ethers (□, THF; ●, DME; ○, dioxane) (solid lines) and *t*-BuOH + water mixtures (dotted line).

in the latter case, which are in reverse order to those for other cosolvent systems, are responsible for this.

Referring to Fig. 4, where we have illustrated ΔY–composition profiles for HI for all these cosolvent systems as well as for *t*-BuOH–water mixtures (24) for drawing meaningful implications of the results, we find that as in *t*-BuOH–water mixtures, the profile for THF–water mixtures exhibits a maximum around 2–4 mol% of THF and then a sharply downward trend at higher compositions. But the profiles for both D–water and DME–water systems move downward right from the beginning, with the relative position for the former system being above that for the latter.

Following the dictates of the semi-quantitative theory proposed by Kundu and co-workers (2) referred to earlier, it may be concluded that like *t*-BuOH and also other mono-ols, the well known promoters of the 3D-structure of water (3), the THF molecule promotes the same at initial compositions but beyond 3–4 mol% it starts breaking down the same due to onset of packing imbalance, as is usual in the cases of other nonelectrolytes (3). Moreover, the relative order of ΔY viz. HI > HBr > HCl (Fig. 2) in the region of the maximum and the reverse order at the structure-breaking region also substantiate the above contention. Evidently, like *t*-BuOH and other mono-ols, the structure-inducing hydrophobicity of four (—CH_2—) groups of the THF molecule overcomes the structure-breaking hydrophilicity of the ethereal O-atom. Similarly, the observed downward trends of ΔY values for HX and their relative order: HCl > HBr > HI right from zero cosolvent composition in both D + water and DME + water solvent systems (Figs. 1, 2) imply that the addition of D or DME induces the breakdown of the 3D structure of water right from their initial compositions. Evidently, in D–water mixtures the hydrophilic effect of two symmetrically placed ethereal O-centres with a pair of free orbitals on each D molecule overcomes the structure-making propensity of the two hydrophobic (—CH_2—CH_2—) groups in between. But in DME–water mixtures the observed relatively sharp downward trends of ΔY compared to that of D–water mixtures reflect the stronger structure-breaking effect of DME compared to that of D. Seemingly, the inductive effect of two (—CH_3) groups attached to the two flexible ethereal O-atoms of the DME molecule makes it more hydrophilic than the D molecule. Moreover, as in THF or other cosolvent systems, the downward trends of ΔY values and their relative order: HCl > HBr > HI at higher compositions also reflect the structure-breaking effect of these cosolvents due to packing imbalance.

Thus, the contentions of the present study are in
