A solution containing **9** (0.836 g, 1.45 mmol) in 35 mL of dry methanol was treated with 0.2 g (1.45 mmol) of dry potassium carbonate and the suspension was stirred under nitrogen for 60 h. Neutralization with Rexyn 102 (H^+), and processing of the filtered suspension gave a colorless syrup which was purified by preparative tlc (solvent B, R_f 0.52) to give 0.518 g (85%) of the lactone **10**. Crystallization from petroleum ether gave 0.43 g of material with mp 80.5–81.5°C; $[\alpha]_D$ +41.8° (*c* 1.05, $CHCl_3$). An additional 70 mg was obtained from the mother liquors but remained as a syrup; λ_{max}(KBr): 1780 (C=O) cm^{-1}; ms *m/e*: 409 ($M^+ - MeO$), 383 ($M^+ - Me_3C$), 351 ($M^+ - Me_3C - MeOH$), etc. *Anal.* calcd. for $C_{25}H_{32}O_6$ Si: C 68.15, H 7.32; found: C 68.46, H 8.00.

Synthesis of 11

A solution of DIBAH (3.65 mL, 5.1 mmol) in hexanes was added to a solution containing the lactone **10** (1.5 g, 3.4 mmol) in anhydrous toluene at −78°C under nitrogen. After stirring for 30 min at −78°C, the solution was diluted with ether (25 mL) and saturated aqueous ammonium chloride (20 mL) while gradually allowing it to warm to room temperature after the additions. The solution was filtered over Celite and the latter was washed successively with water (30 mL) and ethyl acetate (100 mL). The organic phase was processed as usual to give the lactol derivative corresponding to **10**.

A solution of 1.58 *M* *n*-butyl lithium (17.2 mL, 27 mmol) in pentane was added to bis(trimethylsilyl)amine (3.16 g, 27.2 mmol) in 30 mL of dry ether at 0°C, under nitrogen. The solvents were evaporated under a current of dry nitrogen during 1 h and the resulting crystalline lithium bis(trimethylsilyl)amide was dissolved in 30 mL of dry HMPT. The solution was transferred into a solution of (4-carboxybutyl)triphenylphosphonium bromide (6.03 g, 13.6 mmol dried at 110°C, 0.02 Torr, 6 h) in 15 mL of HMPT. The *dark red* solution of the corresponding ylid was stirred under nitrogen for 1 h, then slowly transferred (25 min) into a cooled (0°C) solution containing the lactol (1.5 g, 3.4 mmol) in 15 mL of HMPT using a double tip needle under nitrogen pressure. After stirring at room temperature for 20 min, the solution was diluted with ether (250 mL) and ice-water and was acidified to pH ~ 2 with a 0.2 *M* solution of sodium bisulfate (250 mL). The organic phase was processed as usual to give an oil (3.57 g) which was dissolved in 10 mL of dichloromethane and 5 mL of methanol and treated with an excess of diazomethane in ether. Unreacted reagent was destroyed by addition of small portions of silica gel and the solution was filtered and the filtrate was evaporated to a syrup. Purification by preparative tlc (solvent A, R_f 0.34) gave 1.27 g (67%) of the title compound as a syrup; $[\alpha]_D$ +62.5° (*c* 1.09, $CHCl_3$); λ_{max}(film): 1738 (C=O) cm^{-1}; ms *m/e*: 509 ($M^+ - MeO$), 508 ($M^+ - MeOH$), etc.

Synthesis of 12

To a cooled solution of **11** (0.92 g, 1.7 mmol) in 15 mL of dry pyridine was added benzoyl chloride (0.42 g, 3 mmol) dropwise and with stirring. After stirring at room temperature overnight, the solution was poured into ice-water and ether, and the organic layer was processed as usual to give, after preparative tlc (solvent A, R_f 0.5) the title compound (0.91 g, 89%) as a colorless syrup; $[\alpha]_D$ +92.6° (*c* 1.04, $CHCl_3$); λ_{max}(film): 1736 (CO_2Me), 1715 (OBz) cm^{-1}; ms *m/e*: 612 ($M^+ - MeOH$), 587 ($M^+ - Me_3C$), 555 ($M^+ - Me_3C - MeOH$), 491 ($M^+ - MeOH - PhCO_2$) etc.

Synthesis of 13

A solution containing **12** (0.885 g, 1.37 mmol) in 5 mL of dry tetrahydrofuran was treated with a 1 *M* solution of tetra-*n*-butylammonium fluoride (3 mL). After stirring at room temperature for 3 h, the solution was evaporated to dryness and the residue was purified by preparative tlc (solvent B, R_f 0.20) to give the title compound **12** as a syrup (0.5 g, 89.5%); $[\alpha]_D$ +130° (*c* 1.02, $CHCl_3$); λ_{max}(film): 1735 (CO_2Me), 1715 (OBz) cm^{-1}; M^+ 406; ms *m/e*: 375 ($M^+ - MeO$), 343 ($M^+ - MeO - MeOH$), etc.

Synthesis of 14

A solution containing **13** (0.5 g, 1.22 mmol) in 15 mL of dry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

dichloromethane was added rapidly to a solution of the Collins reagent prepared from chromium trioxide (1.46 g, 14.6 mmol) in pyridine (2.36 mL, 29.3 mmol) and dichloromethane (100 mL), under nitrogen. After stirring vigorously for 30 min the mixture was poured into ice-water and dichloromethane; the organic layer was processed as usual to give a syrup. The latter was dissolved in toluene (50 mL), the solution evaporated to dryness, the residue was taken up in ether, filtered, and the filtrate was evaporated to a syrup (0.446 g, 91%) which was used as such in the next step. The chromatographically homogeneous material showed λ_{max}(film): 1738 (CO_2Me, CHO), 1718 (OBz) cm^{-1}; R_f 0.4 (solvent B).

Synthesis of 15

A solution containing 1-tributylphosphoranylidene 2-heptanone (19) (0.42 g, 1.32 mmol) in dry ether (5 mL) was added to the aldehyde **14** (0.446 g, 1.1 mmol) in 20 mL of ether. The solution was stirred at room temperature for 3 h, it was then evaporated to dryness and the residue was purified by preparative tlc (solvent B, R_f 0.68) to give the title compound as a syrup (0.438 g, 79%); $[\alpha]_D$ +153.0° (*c* 1.14, $CHCl_3$); λ_{max}(film): 1736 (CO_2Me), 1718 (OBz), 1637 (C=C—*C*=*O*), 1636 (*C*=*C*—C=O) cm^{-1}; nmr data at 100 MHz, δ ppm: 2.26 ($H_{"16"}$, t, J = 7.5 Hz), 3.32 (s, OMe), 3.58 (s, CO_2Me), 4.68 ($H_{"12"}$, dd, $J_{"12,8"}$ = 10 Hz, $J_{"12,13"}$ = 6.25 Hz), 4.83 ($H_{"11"}$, d, $J_{"11"}$ = 3.73 Hz), 6.45 ($H_{"14"}$, d, $J_{"14,13"}$ = 15.6 Hz), 6.89 ($H_{"13"}$, dd, $J_{"13,14"}$ = 15.6 Hz, $J_{"13,12"}$ = 6.25 Hz), etc; M^+ 500; ms *m/e*: 468 (M^+ − MeOH), 437 (M^+ − MeOH − MeO), 399 (M^+ − $(CH_2)_3$ CO_2Me), 378 M^+ − $PhCO_2H$), 347 (M^+ − MeOH − $PhCO_2$), 315 (M^+ − 2MeOH − $PhCO_2$), 279 (M^+ − $PhCO_2H$ − $C_5H_{11}C$), etc.

Zinc Borohydride Reduction of 15. Isolation of the "C-15" Epimeric Alcohols 16 and 17

A 0.5 *M* solution of zinc borohydride (3 mL) in 1,2-dimethoxyethane was added to the enone **15** (0.37 g, 0.74 mmol) in 15 mL of anhydrous ether under nitrogen. The mixture was stirred for 3 h at room temperature, then it was diluted with ether (20 mL) and saturated ammonium chloride (20 mL). Processing the organic phase gave a 1:1 mixture of the epimeric alcohols **16** and **17** (0.354 g). Separation by preparative tlc (solvent C) gave the two products as syrups.

For the "15*S*" alcohol **16**: 0.15 g (40%), R_f 0.43; $[\alpha]_D$ +137.8° (*c* 1.19, $CHCl_3$); nmr data at 100 MHz, δ ppm: 3.34 (OMe), 3.60 (CO_2Me), 4.18 ($H_{"15"}$, m), 4.44 ($H_{"12"}$, dd, $J_{"12,8"}$ = 9.5 Hz, $J_{"12,13"}$ = 7.0 Hz), 4.79 ($H_{"11"}$, d, J = 3.75), 5.70 ($H_{"13"}$, dd, $J_{"13,14"}$ = 15.6 Hz, $J_{"13,12"}$ = 7.0 Hz), 6.08 ($H_{"14"}$, dd, $J_{"14,13"}$ = 15.6 Hz, $J_{"14,15"}$ = 5.6 Hz), etc; M^+ 502; ms *m/e*: 484 (M^+ − H_2O), 470 (M^+ − MeOH), 399 (M^+ − MeOH − C_5H_{11}), 348 (M^+ − MeOH − $PhCO_2H$), 330 (M^+ − $(CH_2)_3CO_2Me$ − C_5H_{11}), 304 (M^+ − C_5H_{11} − CH=CH$(CH_2)_3CO_2Me$), 227 (M^+ − MeOH − $PhCO_2H$ − C_5H_{11}), etc.

For the "15 *R*" isomer **17**: 0.125 g (33.7%); R_f 0.50; $[\alpha]_D$ +132.0° (*c* 0.91, $CHCl_3$); nmr data at 100 MHz, δ ppm: 3.36 (s, OMe), 3.60 (s, CO_2Me), 4.10 ($H_{"15"}$, m), 4.46 ($H_{"12"}$, dd, $J_{"12,8"}$ = 9.5 Hz, $J_{"12,13"}$ = 7 Hz), 4.70 ($H_{"11"}$, d, J = 3.75 Hz), 5.72 ($H_{"13"}$, dd, $J_{"13,14"}$ = 15.6 Hz, $J_{"13,12"}$ = 7 Hz), 5.92 ($H_{"14"}$, dd, $J_{"14,13"}$ = 15.6 Hz, $J_{"14,15"}$ = 5.6 Hz), etc; M^+ 502; ms *m/e*: 484 (M^+ − H_2O), 470 (M^+ − MeOH), 399 (M^+ − MeOH − C_5H_{11}), 348 (M^+ − MeOH − $PhCO_2H$). For the M^+ − MeOH fragment ($C_{27}H_{50}O_5Si_2$): calcd. 510.3197; observed, 510.3214.

Synthesis of 18

A solution of the ester **16** (0.15 g, 0.3 mmol) in anhydrous methanol (15 mL) containing potassium carbonate (0.14 g, 1 mmol) was stirred at room temperature in a nitrogen atmosphere for 96 h. The solution was then neutralized with Rexyn-102 (H^+) and processed in the usual way to give a residue which was chromatographed on silica gel (solvent D, R_f 0.38) to give **18** (0.094 g, 80%) as a colorless syrup; $[\alpha]_D$ +95.8° (*c* 1.09, $CHCl_3$); for the M^+ − MeOH − H_2O fragment ($C_{21}H_{32}O_4$): calcd. 348.2249; found 348.2246; ms *m/e*: 366 (M^+ − MeOH), etc; R_f 0.68 (solvent E). The corresponding bis-trimethylsilyl derivative (R_f 0.8, solvent C) had a mass spectral fragmentation pattern identical to the published report (2). For the M^+ − MeOH fragment ($C_{27}H_{50}O_9Si_2$): calcd. 510.3197; found 510.3214.

Synthesis of 19

A solution of the ester **17** (0.125 g, 9.25 mmol) was treated as described for the preceding compound to give **19** as a syrup (0.071 g, 71.5%); $[\alpha]_D$ +93.8° (*c* 1.1, $CHCl_3$); ms *m/e*: 380 (M^+ − H_2O), 366 (M^+ − MeOH), 348 (M^+ − MeOH − H_2O), etc; R_f 0.73 (solvent E).

(+)-Thromboxane B_2, (1): {2R-[2α(1E, 3S), 3β(Z), 4β, 6(α, β)]}-7-[tetrahydro-4,6-dihydroxy-2-(3-hydroxy-1-octenyl)-2H-pyran-3-yl]-5-heptenoic Acid

A solution of **18** (0.032 g, 0.08 mmol) in 1 mL of 0.1 *M* NaOH and 1 mL of methanol was stirred at room temperature for 8 h. The solution was evaporated to dryness below 35°C, the residue was dissolved in 4 mL of water and treated with Dowex-50 (H^+) (5 mL). After a few minutes the solution became somewhat opalescent, then gradually cleared during the course of 1 h. The formation of the "methyl glycoside" derivative of thromboxane B_2 could be easily monitored by tlc (solvent D or E). The resin was removed by filtration, the filtrate was extracted with a 2:1 mixture of ethyl acetate and ether (150 mL, total), and the extracts were processed as usual to give a syrup (0.025 g, 85%). Crystallization was effected by dissolving the syrup (0.025 g) in 4 drops of ethyl acetate, adding 2 mL of ether followed by 4 mL of petroleum ether or hexanes to give a turbid solution. After standing overnight, crystals of thromboxane B_2 were obtained (0.016 g), mp 91–93°C (lit. (3), mp 92–94°C). Recrystallization from the same solvent mixture gave material with mp 95–96°C, undepressed upon admixture with an authentic sample;[3] R_f 0.40 (solvent E); $[\alpha]_D$ +57.4° (*c* 0.26, EtOAc); λ_{max}(film): 1705 (C=O); ms *m/e*: 335 (M^+ − H_2O − HO), 317 (M^+ − $2H_2O$ − HO), 272 (M^+ − $3H_2O$ − CO_2), 246 (M^+ − $2H_2O$ − HO − C_5H_{11}), etc.

"15"-Epi Thromboxane B_2, 20

A solution of the "15 *R*" derivative **19** (0.03 g, 0.075 mmol) was treated as described for the preparation of **1** to give the title epi-derivative as a syrup (0.024 g, 86%); R_f 0.44 (solvent E); $[\alpha]_D$ +50.2° (*c* 1.0, EtOAc).

Oxidation and Reduction of Intermediate 11

To a solution containing **11** (0.061 g, 0.113 mmol) in 1 mL of DMSO were added successively 0.013 g of pyridine, 0.017 g of trifluoroacetic anhydride, and 0.067 g (0.37 mmol) of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDAC·HCl). After 3 h of stirring under nitrogen, the solution was diluted with ether (50 mL) and water. Processing the organic phase as usual gave a syrup which was purified by preparative tlc to give the ketone **21** as a syrup (0.052 g, 86%); R_f 0.43 (solvent A); $[\alpha]_D$ +51.4° (*c* 1.0, $CHCl_3$); λ_{max}(film): 1738 (CO_2Me), 1720 (C=O) cm^{-1}; M^+ 538; ms *m/e*: 507 (M^+ − MeO), 481 (M^+ − Me_3C), 450 (M^+ − Me_3C − MeO), 449 (M^+ − Me_3C − MeOH), 379 (M^+ − MeOH − CH=CH$(CH_2)_3CO_2Me$), etc.

Attempted epimerization of **21** (K_2CO_3, MeOH, pH 10, 5 h, N_2) showed some elimination (5–10%). Neutralization with Rexyn-102 (H^+) and processing gave a syrup which was identical to the starting ketone **21**; $[\alpha]_D$ +50.8°; ir, nmr, R_f.

[3]We thank Drs. N. A. Nelson, R. C. Kelly, and W. P. Schneider of the Upjohn Co. for a sample of thromboxane B_2.

Reduction of the above obtained material (0.036 g) with sodium borohydride (0.02 g) in methanol at 0°C gave, after work-up and preparative tlc, the alcohol **11** (0.027 g, 74%), identical with material obtained previously according to the synthetic scheme ($[\alpha]_D$, nmr, ir, R_f).

Acknowledgments

We thank the National Research Council of Canada and le Ministère de l'éducation du Québec for financial support and for a fellowship to P.L.

Synthesis of 3′,7′-anhydrooctose nucleosides related to the ezomycins and the octosyl acids

KWAN SOO KIM AND WALTER A. SZAREK

Carbohydrate Research Institute and Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received September 8, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

KWAN SOO KIM and WALTER A. SZAREK. Can. J. Chem. **59**, 878 (1981).

Several novel 3′,7′-anhydrooctose nucleosides, including a 3′,7′-anhydroocturonic acid nucleoside, namely 1-(3,7-anhydro-5,6-dideoxy-β-D-*allo*-octofuranosyluronic acid)-3-methyluracil (**40**), have been synthesized. The synthetic sequence leading to **40** consists of three key steps: preparation of an octose nucleoside by a chain extension of an uridine derivative using a Wittig reaction, conversion of the octose nucleoside into a bicyclic-octose nucleoside by an intramolecular cyclization, and elaboration of a carboxylic acid function at the C-8′ position of the bicyclic-octose nucleoside. The structures of the 3′,7′-anhydrooctose nucleosides have been established by their uv, ^{1}Hmr, ^{13}Cmr, and mass spectral data.

KWAN SOO KIM et WALTER A. SZAREK. Can. J. Chem. **59**, 878 (1981).

On a synthétisé plusieurs nucléosides du type anhydro-3′,7′ octose dont le nucléoside de l'acide anhydro-3′,7′ octuronique, soit (l'acide anhydro-3,7 didéoxy-5,6 β-D-*allo*-octofurannosyluronique)-1 méthyl-3 uracil (**40**). La synthèse comprend 3 étapes principales; la première étape consiste à préparer un nucléoside de type octose par élongation de la chaîne d'un dérivé de l'uridine en utilisant une réaction de Wittig. Dans la deuxième étape, on transforme l'octose en un nucléoside bicyclique en faisant appel à une cyclisation intramoléculaire. La troisième étape permet de fixer une fonction acide carboxylique en position C′-8 du nucléoside octose bicyclique. On a établi les structures des nucléosides anhydro-3′,7′ octose en se basant sur les données des spectres uv, rmn du ^{1}H et du ^{13}C et de la spectrométrie de masse.

[Traduit par le journal]

Introduction

The synthesis of carbohydrates containing carbon chains composed of more than six carbon atoms, carbohydrates which have been called higher-carbon sugars (1), has posed a considerable challenge. Such syntheses require the creation of C—C bonds together with control of the absolute stereochemistry at every carbon center. It is noteworthy that the concept of asymmetric synthesis was first realized by Emil Fischer's cyanohydrin reaction with carbohydrates (2). Added impetus has, in recent years, been given to this area of carbohydrate chemistry, by the development of new methods of chain extension (3) and by the discovery of various important antibiotics containing highly complex, higher-carbon sugars, such as lincomycin (4), celesticetin (5), apramycin (6), oxyapramycin (7), the ezomycins (8), mildiomycin (9), tunicamycin (10), and hikizimycin (11).

A major program in this laboratory has been concerned with the development of new methods of chain extension and with the synthesis of antibiotics containing higher-carbon sugars and of related systems; some methods (12) and the synthesis of lincomycin (13) were reported several years ago, and, recently, the synthesis of the octodiose related to apramycin has been also accomplished in this laboratory (14).

The present study is concerned with the ezomycins (15, 16) and the octosyl acids (17) which were obtained from two different strains of *Streptomyces* and which contain a unique type of higher-carbon sugar.

The sugar, a 3,7-anhydrooctonic acid in ezomycins A_1 (**1**), A_2 (**2**), B_1, B_2, C_1, and C_2 (**8**) and in octosyl acids A (**3**) and B (**4**) (17), is the first octose derivative containing a rigid bicyclic system in which a furanoid ring is *trans*-fused to a pyranoid ring. In spite of their structural similarities, the ezomycins and octosyl acids show marked differences in biological activities. Thus, whereas the

ezomycins are antifungal antibiotics (16), the octosyl acids are devoid of any such activity.

However, the adenine analog (**5**) of the octosyl acids, readily obtained from **3** by transglycosylation (18, 19), was found to be an inhibitor of cyclic-AMP phosphodiesterases from various animal tissues (19). In fact, octosyl acids **3** and **4** may be regarded as carboanalogs of 3′,5′-cyclic nucleotides. The unique structures and the biological activities of the ezomycins and the octosyl acids have inspired various studies related to these compounds during the last few years. For example, a biosynthesis of octosyl acid A has been accomplished by Sato *et al.* (20), and a synthesis of an octose derivative related to the octosyl acids has been attempted (21). A ^{13}Cmr spectroscopic study of the ezomycins has been also reported (22).

The present article describes the first synthesis of 3′,7′-anhydrooctose nucleosides and of a 3′,7′-anhydrooctonic acid nucleoside.

Results and Discussion

On the basis of a retrosynthetic analysis, it seemed most appropriate to prepare an octose nucleoside from a ribonucleoside by a three-carbon chain extension followed by cyclization of the octose nucleoside to afford a 3′,7′-anhydrooctose nucleoside. As the starting material, the readily available 2′,3′-isopropylidene-3-methyluridine (**6**) (23) was chosen. This compound could be prepared from 2′,3′-*O*-isopropylideneuridine in large quantities more easily by methylation with *N*,*N*-dimethylformamide dimethyl acetal. For the chain extension of **6**, the three Wittig reagents **7**, **8**, and **9** were chosen. Although the Wittig reagent **7** would not provide functionality at C-8′ of the 3′,7′-anhydrooctose nucleoside, nevertheless, because of its ready availability (24) and simple structure, **7** was employed, prior to the use of Wittig reagents **8** and **9**, for the synthesis of prototype compounds, especially in order to examine the formation of the *trans*-fused, bicyclic ring system.

14 R = Ts

The aldehyde **10**, obtained by oxidation of **6** and employed without isolation from the reaction mixture, was allowed to react with the Wittig reagent **7**. Chromatographic purification afforded the α,β-(*E*)-unsaturated ketone **11** in 77% yield from **6**. The ^{1}Hmr spectrum of **11** showed a doublet of doublets ($J_{5',6'}$ = 16 Hz, $J_{4',5'}$ = 6 Hz) at δ 6.89 for H-5′ and a singlet at δ 2.29 for H-8′. Compound **11** was reduced with sodium borohydride to give a chromatographically homogeneous, epimeric mixture, namely 1-[(*E*)-5,6,8-trideoxy-2,3-*O*-isopropylidene-β-D-*allo* (and α-L-*talo*)-oct-5-enofuranosyl]-3-methyluracil (**12**). The ^{1}Hmr spectrum of **12**, however, indicated that small amounts of the saturated alcohols **13**, which are the desired products of the next step, were also generated during the borohydride reduction of **11**. Catalytic hydrogenation of the allylic alcohols **12** in the presence of 10% palladium-on-charcoal afforded the saturated alcohols **13**. Treatment of **13** with *p*-toluenesulfonyl chloride gave **14**. The isopropylidene groups in **14** were cleaved using 90% formic acid at 0°C to afford the diols **15** in 78% yield. Cyclization was accomplished by treatment of the *p*-tolylsulfonates **15** with sodium hydride in *N*,*N*-dimethylformamide at room temperature. Two epimeric 3′,7′-anhydrooctose nucleosides were separated by column chromatography. The crystalline, faster-moving

17 R^1 = R^3 = H, R^2 = Me
18 R^1 = Me, R^2 = H, R^3 = Ac
19 R^1 = H, R^2 = Me, R^3 = Ac

isomer was identified as being 1-(3,7-anhydro-5,6,8-trideoxy-β-D-*allo*-octofuranosyl)-3-methyluracil (**16**) (25%). The slower-moving isomer, namely 1-(3,7-anhydro-5,6,8-trideoxy-α-L-*talo*-octofuranosyl)-3-methyluracil (**17**), was obtained as a syrup in 21% yield. Acetylation of **16** and **17** afforded monoacetates **18** and **19**, respectively.

The *trans*-fused bicyclic system of compounds **16** and **17** is supported by a sharp singlet ($J_{1',2'}$ = 0 Hz) owing to H-1′ protons in their ^{1}Hmr spectra. Usually the ^{1}Hmr spectra of uridine derivatives show a doublet for the anomeric proton. The $J_{1',2'}$ value of **15**, which is the immediate precursor of **16** and **17**, is 3.5 Hz. The zero value of $J_{1',2'}$ of **16** and **17** corresponds to a C-3′ *endo* conformation of the furanose ring and a *trans* relationship between H-1′ and H-2′. Small or zero values of $J_{1',2'}$ have been observed in the cases of 3′,5′-cyclic nucleotides (25), the ezomycins (8), and the octosyl acids (17). The mass spectra of **16** and **17** reflect very clearly the bicyclic nature of the molecules. The mass spectrum of **16** shows characteristic nucleoside-base peaks at *m/e* 155 (b + 30), *m/e* 127 (b + 2H), and *m/e* 126 (b + H) (26). In addition to these prominent ions, a major mode of fragmentation, not observed in other nucleoside spectra, is represented by the most intense peak at *m/e* 128, owing to the species formed from the molecular ion by the opening of the ribose ring, and a peak at *m/e* 98 owing to further decomposition of this species (see Scheme 1). Comparable fragmentation patterns have been observed in the spectra of 3′,5′-cyclic nucleotides (27). The intact sugar fragment is absent in this mass spectrum; however, the ion (*m/e* 139), formed from the molecular ion by the elimination of H_2O and subsequent cleavage of the glycosidic bond, is comprised of the entire bicyclic-sugar carbon skeleton.

The stereochemistry at C-7′ of **16** and **17** was assigned on the basis of their ^{13}Cmr and ^{1}Hmr chemical-shift data. The epimer, whose C-8′ signal resonated at δ 21.0 in its ^{13}Cmr spectrum, was assigned as being compound **16** bearing an equatorial methyl group, whereas the compound whose C-8′ signal was at δ 17.5 in its ^{13}Cmr spectrum was assigned as being compound **17** bearing an axial methyl group. In their ^{1}Hmr spectra, the resonance for the H-8′ protons of **16** (δ 1.32) appears at slightly higher field than that of **17** (δ 1.36). It has been well established that, whereas the carbon resonance of an equatorial methyl group in cyclohexane and 1,3-dioxane systems (28) shifts downfield relative to that of the corresponding axial one, the protons of an equatorial methyl group in cyclohexane, 1,3-dioxane, and 1,3,5-trioxane systems (29) resonate at higher field than do those of the corresponding axial one.

The initial studies established the feasibility of the synthesis of a 3′,7′-anhydrooctose nucleoside

by the approach described above. Attention was then directed to the functionalization of the C-5′, C-6′, and C-8′ positions, a process which is required for the eventual total synthesis of the ezomycins and the octosyl acids. Although the C-5′—C-6′ double bond in compounds **11** and **12** can be easily functionalized, the introduction of functionality at C-8′ is not feasible at any stage of the above synthetic sequence. This problem was solved by employing another Wittig reagent, namely **8** (30), which could be prepared in a reasonable quantity relatively easily using a modified procedure. Wittig reagent **9** (31) would be more suitable than **8** for the introduction of the carboxylic acid function at C-8′, however, the product of a Wittig reaction of **9** and **10** decomposed during the course of the reaction and subsequent processing.

A Wittig reaction of **8** and **10** afforded after chromatography the syrupy α,β-(*E*)-unsaturated ketone **20** in 72% yield from **6**. The ^{1}Hmr spectrum of **20** showed a large *trans*-ethylenic coupling constant ($J_{5',6'}$ = 16 Hz). Compound **20** was reduced with sodium borohydride in absolute ethanol at −20°C to afford a chromatographically homogeneous, epimeric mixture, namely 1-[(*E*)-8-*O*-acetyl-5,6-dideoxy-2,3-*O*-isopropylidene-β-D-*allo* (and α-L-*talo*)-oct-5-enofuranosyl]-3-methyluracil (**21**). The allylic alcohols **21** were converted by catalytic hydrogenation into the saturated alcohols **22**. The reaction of **22** with *p*-toluenesulfonyl chloride afforded **23**. Cleavage of the isopropylidene groups of **23** was accomplished with 90% formic acid at 0°C to give **24** in 75% yield.

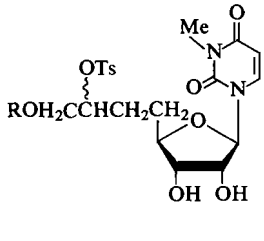
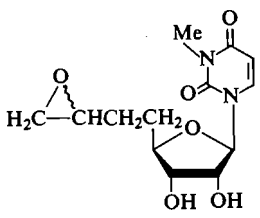
23 R^1 = Ac, R^2 = Ts
27 R^1 = $CH_2CH{=}CH_2$, R^2 = H
28 R^1 = $CH_2CH{=}CH_2$, R^2 = Ts



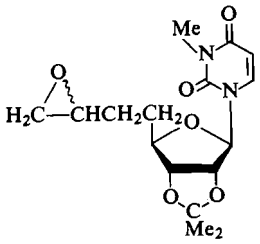
24 R = Ac
29 R = $CH_2CH{=}CH_2$

Treatment of **24** with sodium hydride in dry 1,2-dimethoxyethane or *N*,*N*-dimethylformamide unexpectedly gave a complex multiplicity of products. One of the major products was identified as being an oxirane derivative (**25**). However, the desired 3′,7′-anhydrooctose nucleoside was not detected. Although this attempted cyclization reaction was not fully investigated, the complication of the reaction might be attributable to the lability of the acetyl group under the reaction conditions. The acetyl groups in **23** were replaced by allyl groups (32) by a sequence of three steps: (*i*) conversion of **23** into a mixture of oxiranes using sodium methoxide in chloroform; (*ii*) ring opening of the oxiranes **26** with sodium alloxide in allyl alcohol at room temperature; (*iii*) treatment of the resulting secondary alcohols **27** with *p*-toluenesulfonyl chloride. The oxirane ring opening of **26** with alloxide was regioselective and provided the expected secondary alcohol **27** exclusively in 88% yield. The ^{1}Hmr spectrum of **27** showed a two-proton multiplet at δ 5.03–5.34 owing to two terminal vinylic protons and an one-proton multiplet at δ 5.58–6.39 attributable to another vinylic proton of the allyl group. The *p*-tolylsulfonates **28** obtained in this way were converted into **29** in 89% yield by treatment with 90% formic acid at 0°C.

The stage was again set for the elaboration of the bicyclic ring system. Cyclization was accomplished by treatment of **29** with sodium hydride in 1,2-dimethoxyethane at room temperature to afford a chromatographically homogeneous, epimeric mixture (**30**) in 50% yield. A sharp singlet at δ 5.65 owing to anomeric protons in the ^{1}Hmr spectrum of **30** indicated the *trans*-fused bicyclic structure. The allyl groups in **30** were isomerized to prop-1-enyl groups by treatment with $RhCl(PPh_3)_3$ in refluxing aqueous ethanol (33). At this stage the two epimers could be separated by careful column chromatography to afford pure **31** in 45% and **32** in 42% yield. The ^{1}Hmr spectrum of **31** showed a three-proton doublet of doublets at δ 1.56 attributable to the allylic-methyl protons of the prop-1-enyl group and a one-proton multiplet at δ 5.86–6.30 attributable to a vinylic proton on the carbon next to the oxygen atom of the prop-1-enyl group. The ^{1}Hmr spectrum of **32** also showed similar patterns of signals at δ 1.58 and at δ 5.91–6.32. The stereochemistry at C-7′ of the two epimers **31** and **32** was not assigned at this stage; however, it could be established later by the structural assignment of the two epimers **35** and **36** which were derived from **31** and **32**, respectively. Benzoylation of **31** and **32** gave monobenzoates **33** and **34**, respectively. Removal of the prop-1-enyl groups in **33** and **34** was



25



26

31 R^1 = CH=CHCH$_3$, R^2 = H
33 R^1 = CH=CHCH$_3$, R^2 = Bz
35 R^1 = H, R^2 = Bz
37 R^1 = R^2 = H

accomplished with 0.1 *N* hydrochloric acid in aqueous methanol at room temperature (32) to afford 1-(3,7-anhydro-2-*O*-benzoyl-5,6-dideoxy-β-D-*allo*-octofuranosyl)-3-methyluracil (**35**) and 1-(3,7-anhydro-2-*O*-benzoyl-5,6-dideoxy-α-L-*talo*-octofuranosyl)-3-methyluracil (**36**), respectively. Hydrolysis of the prop-1-enyl groups in **33** and **34** with mercuric chloride in the presence of mercuric oxide (34) resulted in the partial decomposition of products **35** and **36**. The stereochemistry at C-7′ of compounds **35** and **36** was readily assigned in a manner similar to that used for the assignments in the cases of the bicyclic octose nucleosides **16** and **17**. Thus, the C-8′ signal in the ^{13}Cmr spectrum of one epimer appeared at δ 65.0 and that of another epimer appeared at δ 60.9. The former was assigned as being compound **35** bearing an equatorial hydroxymethyl group and the latter as being compound **36**. The stereochemistry at C-7′ of compounds **31–34**, thereby, could be correctly assigned.

Thus, the synthesis of a 3′,7′-anhydrooctose nucleoside with a functional group at C-8′ has been accomplished. Finally, the hydroxymethyl group of compound **35** was further transformed into a carboxylic acid function. Oxidation of **35** with chromium(VI) reagents was not very satisfactory, mainly because the isolation of the product from the reaction mixture was difficult or very tedious owing to the solubility of the product. Better results could be obtained by employing catalytic oxidation. Thus, compound **37**, obtained from **35** by debenzoylation, was oxidized in the presence of 10% platinum-on-charcoal at pH 8–9 at 70°C to give 1-(3,7-anhydro-5,6-dideoxy-β-D-*allo*-octofuranosyluronic acid)-3-methyluracil (**39**) in 74% yield. Treatment of **39** with 3% hydrogen chloride in methanol afforded the methyl ester **40**. The ^{1}Hmr spectrum of **40** showed a three-proton singlet at δ 3.75 attributable to the methyl ester at C-8′. The ir spectrum of **40** showed a broad band at 3430 cm^{-1}.

The sequence leading to the 3′,7′-anhydroocturonic acid nucleoside as described in this paper can be adapted to the synthesis of the ezomycins, the octosyl acids, and their analogs. Further investigations into the functionalization at C-5′ and C-6′ of the 3′,7′-anhydrooctose nucleoside are currently underway, and a different approach to the synthesis of 3′,7′-anhydrooctose nucleosides will be reported separately.

Experimental

Evaporations were performed under reduced pressure at or below 40°C (bath temperature). Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 automatic polarimeter at 23 ± 3°C. Infrared spectra were recorded with a Perkin–Elmer 180 or a Perkin–Elmer 598 infrared spectrophotometer. Ultraviolet spectra were measured with a Unicam SP 800B or a Perkin–Elmer 552 spectrophotometer. The ^{1}Hmr spectra were determined with a Varian EM-360 or Bruker HX-60 spectrometer in chloroform-*d* with tetramethylsilane (TMS) as the internal standard, unless otherwise stated. The ^{13}Cmr were recorded in chloroform-*d* solution on a Bruker HX-60 spectrometer equipped with an FT60M Fourier transform accessory at 15.09 MHz; chemical shifts are given in parts per million downfield from TMS. Mass spectra were taken on a Jeolco model JMS-015C spectrometer using the direct-sample inlet system with a 70 eV ionization energy. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ont. Thin-layer chromatography (tlc) was performed on precoated glass plates (silica gel 60 F-254, 0.25 mm thickness) from EM Laboratories Inc., using the following solvent systems (v/v): (*A*) toluene–acetone, 1:1; (*B*) toluene – ethyl acetate, 1:1; (*C*) toluene–acetone, 2:1; (*D*) toluene – ethyl acetate, 2:1; (*E*) ethyl acetate; (*F*) ethyl acetate – methanol, 2:1; (*G*) *n*-butanol – methanol–water, 8:1:1. The developed plates were air dried and compounds located by irradiation of the plates with uv light and by heating the plates at 150°C after they had been sprayed with 10% aqueous sulfuric acid containing 1% cerium sulfate and 1.5% molybdic acid. Column chromatography was performed on Brinkmann silica gel 60 (70–230 mesh, E. Merck). E. Merck precoated glass plates (silica gel F-254, 20 × 20 cm, 2 mm thickness) were used for preparative tlc chromatography.

2',3'-O-Isopropylidene-3-methyluridine (6)

A suspension of 2',3'-*O*-isopropylideneuridine (35) (7.1 g, 20 mmol) and *N,N*-dimethylformamide dimethyl acetal (9.5 g, 80 mmol) in chloroform (80 mL) was heated at reflux temperature with vigorous stirring. The mixture became homogeneous within 30 min. After 8 h the solvent was evaporated to give a reddish syrup which slowly crystallized on standing. Recrystallization from ethanol–ether gave compound **6** (6.5 g, 87%) having R_f 0.57 (solvent *A*), mp 133–134°C (lit. (10) mp 133.5–134°C); ^{1}Hmr δ: 1.38 (3H, s, Me), 1.60 (3H, s, Me), 3.33 (3H, s, NMe), 3.55–3.92 (3H, m, H-4', 2(H-5')'s), 4.29 (1H, bs, OH, exchanged in D_2O), 4.74–5.02 (2H, m, H-2', H-3'), 5.73 (1H, d, $J_{1',2'}$ = 1.2 Hz, H-1'), 5.74 (1H, d, $J_{5,6}$ = 8 Hz, H-5), 7.60 (1H, d, H-6).

1-[(E)-5,6,8-Trideoxy-2,3-O-isopropylidene-β-D-ribo-oct-5-eno-1,4-furanosid-7-ulosyl]-3-methyluracil (11)

To a solution of **6** (2.39 g, 8 mmol) in dimethylsulfoxide (40 mL), stirred at room temperature under nitrogen, pyridine (0.64 mL), trifluoroacetic acid (0.30 mL), and *N,N'*-dicyclohexylcarbodiimide (4.96 g, 24 mmol) were added. After 12 h, the Wittig reagent **7** (3.31 g, 10.4 mmol) was added and stirring was continued for a further 24 h at room temperature. Oxalic acid dihydrate (2.9 g) and ethyl acetate (200 mL) were then added and the mixture was stirred for 10 min. This mixture was poured into saturated sodium chloride solution (100 mL), stirred for a few min, and filtered. The separated aqueous layer was extracted once more with ethyl acetate (80 mL). The combined ethyl acetate solutions were washed with dilute aqueous sodium hydrogen carbonate, saturated aqueous sodium chloride, and cold water, dried ($MgSO_4$), and evaporated to give a dark red syrup. The thick syrup was dissolved again in ethyl acetate and insoluble *N,N'*-dicyclohexylurea was removed by filtration. This procedure was repeated a few more times to remove *N,N'*-dicyclohexylurea. The resulting red syrup (5.5 g) was chromatographed on a column of silica gel by elution with toluene – ethyl acetate, 7:5 (v/v), to afford **11** as a colorless syrup (2.07 g, 77%) having R_f 0.23 (solvent *B*); $[\alpha]_D$ +54.8° (*c* 0.062, $CHCl_3$); ir (film) ν_{max}: 1710, 1680, 1665, 1630 cm^{-1}; uv λ_{max} (EtOH): 217 (ε 13 000), 259 (6800) nm; ^{1}Hmr δ: 1.38 (3H, s, isopropylidene-Me), 1.59 (3H, s, isopropylidene-Me), 2.29 (3H, s, H-8''s), 3.32 (3H, s, NMe), 4.51–5.17 (3H, m, H-2'–H-4'), 5.61 (1H, d, $J_{1',2'}$ = 1.2 Hz, H-1'), 5.78 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 6.22 (1H, d, $J_{5',6'}$ = 16.0 Hz, H-6'), 6.89 (1H, dd, $J_{4',5'}$ = 6.0 Hz, H-5'), 7.27 (1H, d, H-6). *Anal.* calcd. for $C_{16}H_{20}N_2O_6$: C 57.14, H 5.99, N 8.33; found: C 57.33, H 6.24, N 7.73.

1-[(E)-5,6,8-Trideoxy-2,3-O-isopropylidene-β-D-allo (and α-L-talo)-oct-5-enofuranosyl]-3-methyluracil (12)

To a stirred solution of **11** (1.62 g, 4.8 mmol) in ethanol (30 mL) was added sodium borohydride (0.19 g, 5.0 mmol) at 0°C in the dark. Thin-layer chromatography (solvent *C*) showed that after 5 min the reaction mixture contained only one component (R_f 0.33) but no starting material. The reaction mixture was carefully neutralized with 1 *N* hydrochloric acid and the neutral mixture was evaporated to a residue which was concentrated several times with methanol. The residue was extracted with hot ethyl acetate (4 × 30 mL) and the extract was filtered through a small amount of silica gel. Evaporation of the solvent gave **12** as a chromatographically homogeneous white foam (1.60 g, 98%). An analytical sample was obtained by preparative tlc using toluene–acetone, 1:1 (v/v), as eluent; ir (film) ν_{max}: 3430, 1710, 1670, 1630 cm^{-1}; uv λ_{max} (EtOH): 212 (ε 6800), 258 (9800) nm; ^{1}Hmr δ: 1.26 (3H, d, $J_{7',8'}$ = 6.0 Hz), 1.34 (3H, s, isopropylidene-Me), 1.58 (3H, s, isopropylidene-Me), 2.67 (1H, bs, OH, exchanged in D_2O), 3.30 (3H, s, NMe), 3.67–5.02 (4H, H-2'–H-4', H-7'), 5.49–5.90 (2H, m, H-5', H-6'), 5.64 (1H, d, $J_{1',2'}$ = 1.2 Hz, H-1'), 5.73 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.26 (1H, d, H-6).

1-[5,6,8-Trideoxy-2,3-O-isopropylidene-β-D-allo (and α-L-talo)-octofuranosyl]-3-methyluracil (13)

A solution of **12** (2.15 g, 6.3 mmol) in ethanol (150 mL) was shaken in a standard Paar bottle together with 10% palladium-on-charcoal catalyst (0.35 g) under a 1-atm hydrogen pressure at room temperature. As soon as the shaking was started, hydrogen was consumed very rapidly. After 10 min the hydrogen uptake had almost ceased. Thin-layer chromatography (solvent *C*) showed that the R_f value of the product was the same as that of the starting material. The reaction mixture was filtered through Celite twice and the filtrate was concentrated to a white foam which was chromatographed on a column of silica gel by elution with toluene – ethyl acetate, 5:6 (v/v), to give **13** as a white foam (1.81 g, 84%); ir (film) ν_{max}: 3430, 1710, 1670, 1640 cm^{-1}; uv λ_{max} (EtOH): 214 (ε 8000), 259 (12 600) nm; ^{1}Hmr δ: 1.21 (3H, d, $J_{7',8'}$ = 6.0 Hz, H-8'), 1.34 (3H, s, isopropylidene-Me), 1.43–2.03 (4H, m, 2(H-5')'s, 2(H-6')'s), 1.57 (3H, s, isopropylidene-Me), 2.45 (1H, bs, OH, exchanged in D_2O), 3.28 (3H, s, NMe), 3.64–4.61 (4H, H-3'–H-5', H-7'), 4.84 (1H, dd, $J_{2',3'}$ = 6.5 Hz, $J_{1',2'}$ = 2.0 Hz, H-2'), 5.58 (1H, d, H-1'), 5.72 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.19 (1H, d, H-6). *Anal.* calcd. for $C_{16}H_{24}N_2O_6$: C 56.46, H 7.11, N 8.23; found: C 56.06, H 7.42, N 7.97.

1-[5,6,8-Trideoxy-2,3-O-isopropylidene-7-O-p-tolylsulfonyl-β-D-allo (and α-L-talo)-octofuranosyl]-3-methyluracil (14)

To a solution of **13** (0.86 g, 2.5 mmol) in pyridine (4 mL) was added at 0°C *p*-toluenesulfonyl chloride (0.52 g, 2.8 mmol). The reaction mixture was kept at 0°C overnight to give only one product (R_f 0.21, solvent *D*). The reaction mixture was poured with vigorous stirring into ice-water (40 mL). The aqueous mixture was extracted with dichloromethane; the dichloromethane extract was washed successively with cold 1 *N* sulfuric acid, saturated aqueous sodium hydrogen carbonate, and cold water. Evaporation of the dried ($MgSO_4$) solution afforded **14** as a chromatographically homogeneous syrup (1.07 g, 85%). An analytical sample was obtained by preparative tlc using toluene–acetone, 2:1 (v/v), as eluent; ir (film) ν_{max}: 1710, 1670, 1630, 1360, 1180 cm^{-1}; uv λ_{max} (EtOH): 227 (ε 12 000), 259 (10 500) nm; ^{1}Hmr δ: 1.22 (3H, d, $J_{7',8'}$ = 6.0 Hz, H-8'), 1.32 (3H, s, isopropylidene-Me), 1.56 (3H, s, isopropylidene-Me), 1.65–1.84 (4H, m, 2(H-5')'s, 2(H-6')'s), 2.42 (3H, s, PhMe), 3.28 (3H, s, NMe), 3.82–4.76 (3H, H-3', H-4', H-7'), 4.80 (1H, dd, $J_{2',3'}$ = 6.5 Hz, $J_{1',2'}$ = 2.0 Hz, H-2'), 5.56 (1H, d, H-1'), 5.71 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.15 (1H, d, H-6), 7.17–7.78 (5H, m, aromatic H's). *Anal.* calcd. for $C_{23}H_{30}N_2O_8S$: C 55.86, H 6.11, N 5.67, S 6.48; found: C 55.49, H 6.34, N 5.48, S 6.19.

1-[5,6,8-Trideoxy-7-O-p-tolylsulfonyl-β-D-allo (and α-L-talo)-octofuranosyl]-3-methyluracil (15)

The product **14** (0.90 g, 1.8 mmol) was dissolved in cold 90% formic acid (5 mL) and the solution was kept at 0°C overnight. Cold water (15 mL) was added to the reaction mixture and evaporated. Addition of more water and evaporation were repeated to afford a pale yellow, solid residue which was fractionated on a column of silica gel by elution with toluene–acetone, 3:2 (v/v), to give **15** as a colorless glass (0.65 g, 78%) having R_f 0.10 (solvent *C*); ir (film) ν_{max}: 3420, 1710, 1660, 1630, 1360, 1180 cm^{-1}; uv λ_{max} (EtOH): 226 (ε 13 000), 259 (12 600) nm; ^{1}Hmr δ: 1.20 (3H, d, $J_{7',8'}$ = 6.0 Hz, H-8'), 1.69–1.89 (4H, m, 2(H-5')'s, 2(H-6')'s), 2.42 (3H, s, PhMe), 3.27 (3H, s, NMe), 3.87 (2H, bs, 2 OH), 4.02–4.78 (4H, H-2'–H-4', H-7'), 5.67 (1H, d, $J_{1',2'}$ = 3.5 Hz, H-1'), 5.77 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.15–7.81 (6H, H-6, aromatic H's).

Cyclization of 15

The product **15** (0.6 g, 1.3 mmol) in *N,N*-dimethylformamide

[a]In ppm downfield from tetramethylsilane in chloroform-*d*.
[b]Assignments may be changed.

(10 mL) was vigorously stirred with sodium hydride (0.13 g, 5.2 mmol, 50% oil dispersion) at room temperature for 3 h, after which time tlc (solvent *C*) showed the absence of starting material. The reaction mixture was poured with stirring into ice-water (100 mL) and the mixture was extracted exhaustively with dichloromethane. The combined organic solutions were washed with a small amount of cold water, dried ($MgSO_4$), and concentrated to a syrup. Column chromatography on silica gel (toluene–acetone, 5:2 (v/v)) gave crystalline 1-(3,7-anhydro-5,6,8-trideoxy-β-D-*allo*-octofuranosyl)-3-methyluracil (**16**) (0.095 g, 25%). Recrystallization from toluene afforded white crystalline **16** having R_f 0.30 (solvent *C*), mp 219.5–220°C; $[\alpha]_D$ +25.0° (*c* 0.14, $CHCl_3$); ir (KBr) ν_{max}: 3410, 1700, 1650, 1620 cm^{-1}; uv λ_{max} (EtOH): 214 (ε 7800), 261 (13 300) nm: ^{1}Hmr δ: 1.26 (3H, d, $J_{7',8'}$ = 6.0 Hz, H-8′), 1.56–2.31 (4H, m, 2(H-5′)'s, 2(H-6′)'s), 2.85 (1H, bs, OH, exchanged in D_2O), 3.07–4.29 (4H, H-2′–H-4′, H-7′), 3.30 (3H, s, NMe), 5.56 (1H, s, H-1′), 5.70 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.25 (1H, d, H-6). See Table 1 for ^{13}Cmr data. Mass spectrum *m/e*: 282 (M^+, 14%), 264 ($M^+ - H_2O$, 6), 155 (b + 30, 42), 139 (264 − b, 20), 128 [M^+ − (b + CHO), 100], 127 (b + 2H, 62), 126 (b + H, 16), 98 (128 − CHOH, 29), 69 [(b + H) − MeNCO, 31]. *Anal.* calcd. for $C_{13}H_{18}N_2O_5$: C 55.31, H 6.43, N 9.92; found: C 55.22, H 6.39, N 9.73.

1-(3,7-Anhydro-5,6,8-trideoxy-α-L-*talo*-octofuranosyl)-3-methyluracil (**17**) was isolated as a colorless syrup (0.082 g, 21%) having R_f 0.26; $[\alpha]_D$ +31.7° (*c* 0.30, $CHCl_3$); ir (film) ν_{max}: 3410, 1700, 1650, 1620 cm^{-1}; uv λ_{max} (EtOH): 214 (ε 7400), 261 (13 300) nm; ^{1}Hmr δ: 1.32 (3H, d, $J_{7',8'}$ = 6.0 Hz, H-8′), 1.67–2.39 (4H, m, 2(H-5′)'s, 2(H-6′)'s), 3.02 (1H, bs, OH, exchanged in D_2O), 3.28–4.51 (4H, H-2′–H-4′, H-7′), 3.30 (3H, s, NMe), 5.56 (1H, s, H-1′), 5.72 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.27 (1H, d, H-6). See Table 1 for ^{13}Cmr data. Mass spectrum *m/e*: 282 (M^+, 10%), 264 ($M^+ - H_2O$, 5), 155 (b + 30, 50), 139 (264 − b, 18), 128 [M^+ − (b + CHO), 100], 127 (b + 2H, 65), 126 (b + H, 22), 98 (128 − CHOH, 32), 69 [(b + H) − MeNCO, 33]. *Anal.* calcd. for $C_{13}H_{18}N_2O_5$: C 55.31, H 6.43, N 9.92; found: C 55.46, H 6.30, N 9.80.

[(Acetoxymethyl)carbonyl]methylenetriphenylphosphorane (8)

To a cold solution of 1,3-dichloro-2-propanone (5 g, 39 mmol) (**36**) in acetone (150 mL) was added powdered lithium bromide (50 g) with vigorous stirring using a mechanical stirrer. The reaction mixture was stirred at 18–20°C for 3 days. Evaporation of the solvent gave a brownish solid which was partitioned between water and dichloromethane. The aqueous solution was extracted once more with a small amount of dichloromethane. The combined dichloromethane solutions were washed with cold water, dried ($MgSO_4$), and evaporated to afford crude 1,3-dibromo-2-propanone as a syrup.

A solution of the crude 1,3-dibromo-2-propanone in toluene (25 mL) was added dropwise to a stirred solution of triphenylphosphine (10.2 g, 39 mmol) in toluene (30 mL) at room temperature. Stirring was continued overnight at room temperature. The solid was collected by filtration, washed with toluene, and dried. To a stirred solution of the dried salt in 60% aqueous methanol (250 mL) was added an excess of powdered sodium carbonate. Stirring was continued for 30 min and more water (50 mL) was added to the reaction mixture. After being stirred for another 30 min, the solid was collected by filtration, washed thoroughly with water, and dried in a desiccator to afford crude (bromoacetyl)methylenetriphenylphosphorane (7.5 g) as a white solid having R_f 0.18 (solvent *E*).

A mixture of the crude (bromoacetyl)methylenetriphenylphosphorane (7.5 g) and powdered sodium acetate (18 g) in *N,N*-dimethylformamide (200 mL) was stirred vigorously using a mechanical stirrer at 50°C for 3 days. The reaction mixture was poured into water and the mixture was extracted with dichloromethane a few times. The combined dichloromethane extracts were washed with water, dried ($MgSO_4$), and concentrated to a dark brownish solid. A solution of this solid in ethyl acetate was filtered through silica gel. Evaporation of the solvent afforded **8** as a yellow solid (4.1 g, 28% from 1,3-dichloro-2-propanone) having R_f 0.16 (solvent *E*); ^{1}Hmr δ: 2.12 (3H, s, OAc), 4.58 (2H, s, $COCH_2O$), 7.24–7.71 (16H, PCH, 15 aromatic H's). This material was suitable for use in the subsequent reaction.

1-[(E)-8-O-Acetyl-5,6-dideoxy-2,3-O-isopropylidene-β-D-ribo-oct-5-eno-1,4-furanosid-7-ulosyl]-3-methyluracil (20)

To a solution of **6** (1.79 g, 6.0 mmol) in dimethylsulfoxide (30 mL), stirred at room temperature under nitrogen, pyridine (0.48 mL), trifluoroacetic acid (0.23 mL), and *N,N′*-dicyclohexylcarbodiimide (3.72 g, 18 mmol) were added. After 18 h, the Wittig reagent **8** (2.94 g, 7.8 mmol) was added and stirring was continued for a further 24 h at room temperature. The product was isolated by the procedure which was used for **11** to give, after column chromatography (toluene–acetone, 6:1 (v/v)), **20** as a colorless syrup (1.7 g, 72%) having R_f 0.36 (solvent *B*); ir (film) ν_{max}: 1735, 1700, 1660, 1630 cm^{-1}; uv λ_{max} (EtOH) 226 (ε 10 100), 255 (8500) nm; ^{1}Hmr δ: 1.36 (3H, s, isopropylidene-Me), 1.57 (3H, s, isopropylidene-Me), 2.16 (3H, s, OAc), 3.28 (3H, s, NMe), 4.56–5.01 (4H, H-3′, H-4′, 2(H-8′)'s), 5.08 (1H, dd, $J_{2',3'}$ = 6.0 Hz, $J_{1',2'}$ = 1.2 Hz, H-2′), 5.56 (1H, d, H-1′), 5.76 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 6.27 (1H, d, $J_{5',6'}$ = 16.0 Hz, H-6′), 6.99 (1H, dd, $J_{4',5'}$ = 5.5 Hz, H-5′), 7.16 (1H, d, H-6).

1-[(E)-8-O-Acetyl-5,6-dideoxy-2,3-O-isopropylidene-β-D-allo (and α-L-talo)-oct-5-enofuranosyl]-3-methyluracil (21)

To a stirred solution of **20** (1.46 g, 3.7 mmol) in ethanol (20 mL) was added sodium borohydride (0.15 g, 3.9 mmol) at −20°C in the dark. Thin-layer chromatography (solvent *A*) showed that after 5 min the reaction mixture contained one major component (R_f 0.51) but no starting material. The product was isolated by the procedure which was used for **12** to give, after column chromatography (toluene–acetone, 5:2 (v/v)), **21** as a colorless syrup (1.25 g, 85%); ir (film) ν_{max}: 3430, 1735, 1710, 1660, 1630 cm^{-1}; uv λ_{max} (EtOH): 212 (ε 6700), 259 (9100) nm; ^{1}Hmr δ: 1.35 (3H, s, isopropylidene-Me), 1.57 (3H, s, isopropylidene-Me), 2.08 (3H, s, COMe), 3.29 (3H, s, NMe), 3.63–4.80

(5H, H-3′, H-4′, H-7′, 2(H-8′)'s), 4.99 (1H, dd, $J_{2',3'}$ = 6.0 Hz, $J_{1',2'}$ = 1.5 Hz, H-2′), 5.60 (1H, d, H-1′), 5.74 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 5.76–5.97 (2H, m, H-5′, H-6′), 7.21 (1H, d, H-6).

*1-[8-*O*-Acetyl-5,6-dideoxy-2,3-*O*-isopropylidene-*β*-D-*allo *(and α-L-talo)-octofuranosyl]-3-methyluracil (22)*

Catalytic hydrogenation of the allylic alcohols **21** (1.25 g, 3.4 mmol) was performed as described above for **12** and afforded, after column chromatography (toluene–acetone, 5:2 (v/v)), **22** as a glass (1.2 g, 90%) having R_f 0.51 (solvent *A*); ir (film) ν_{max}: 3430, 1730, 1710, 1665, 1630 cm^{-1}; uv λ_{max} (EtOH): 212 (ε 7600), 259 (11 800) nm; ^{1}Hmr δ: 1.36 (3H, s, isopropylidene-Me), 1.58 (3H, s, isopropylidene-Me), 1.48–1.95 (4H, m, 2(H-5′)'s, 2(H-6′)'s), 2.08 (3H, s, OAc), 2.89 (1H, bs, OH, exchanged in D_2O), 3.30 (3H, s, NMe), 3.63–4.67 (5H, H-3′, H-4′, H-7′, 2(H-8′)'s), 4.94 (1H, dd, $J_{2',3'}$ = 6.0 Hz, $J_{1',2'}$ = 2.0 Hz, H-2′), 5.67 (1H, d, H-1′), 5.78 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.30 (1H, d, H-6). *Anal.* calcd. for $C_{18}H_{26}N_2O_8$: C 54.26, H 6.58, N 7.03; found: C 54.57, H 6.87, N 6.88.

*1-[8-*O*-Acetyl-5,6-dideoxy-2,3-*O*-isopropylidene-7-*O*-p-tolylsulfonyl-*β*-D-*allo *(and α-L-talo)-octofuranosyl]-3-methyluracil (23)*

To a solution of **22** (1.1 g, 2.8 mmol) in pyridine (5 mL) was added at 0°C *p*-toluenesulfonyl chloride (0.58 g, 3.1 mmol). The product was isolated by the procedure which was used for **14** to give, after column chromatography (toluene – ethyl acetate, 5:2 (v/v)), **23** as a white foam (1.27 g, 83%) having R_f 0.51 (solvent *C*); ir (film) ν_{max}: 1710, 1670, 1630, 1360, 1180 cm^{-1}; uv λ_{max} (EtOH): 228 (ε 14 000), 259 (11 800) nm; ^{1}Hmr δ: 1.35 (3H, s, isopropylidene-Me), 1.56 (3H, s, isopropylidene-Me), 1.64–1.98 (4H, m, 2(H-5′)'s, 2(H-6′)'s), 1.90 (3H, s, OAc), 2.43 (3H, s, PhMe), 3.29 (3H, s, NMe), 3.78–4.92 (6H, H-2′–H-4′, H-7′ 2(H-8′)'s), 5.60 (1H, d, $J_{1',2'}$ = 2.0 Hz, H-1′), 5.73 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.15 (1H, d, H-6), 7.20–7.80 (5H, m, aromatic H's).

*1-[8-*O*-Acetyl-5,6-dideoxy-7-*O*-p-tolylsulfonyl-*β*-D-*allo *(and α-L-talo)-octofuranosyl]-3-methyluracil (24)*

Hydrolysis of **23** (0.18 g, 0.33 mmol) was performed as described above for **14** and afforded, after preparative tlc (toluene–acetone, 2:3 (v/v)), **24** as a glass (0.13 g, 75%) having R_f 0.36 (solvent *A*); ir (film) ν_{max}: 3410, 1710, 1670, 1630, 1360, 1180 cm^{-1}; uv λ_{max} (EtOH): 227 (ε 13 000), 259 (12 000) nm; ^{1}Hmr δ: 1.66–2.01 (4H, m, 2(H-5′)'s, 2(H-6′)s), 2.46 (3H, s, PhMe), 3.29 (3H, s, NMe), 3.60–5.11 (8H, H-2′–H-4, H-7′, 2(H-8′)'s, 2 OH's), 5.64 (1H, d, $J_{1',2'}$ = 3.5 Hz, H-1′), 5.82 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.27 (1H, d, H-6), 7.28–7.84 (5H, m, aromatic H's).

Treatment of 24 with Sodium Hydride

To a solution of **24** (0.101 g, 0.20 mmol) in dry 1,2-dimethoxyethane, stirred at room temperature under nitrogen, sodium hydride (0.014 g, 0.59 mmol) was added. Thin-layer chromatography (solvent *A*) showed that after 10 min the reaction mixture contained five new components (R_f 0.27, 0.48, 0.51, 0.66, and 0.78) and the starting material (R_f 0.36). After the reaction mixture had been stirred overnight tlc showed that three new components (R_f 0, 0.08, and 0.23) had been formed and that two of the components formed earlier (R_f 0.48 and 0.66) had almost disappeared. Cold water was added to the reaction mixture and the solution was carefully neutralized with 0.1 *N* hydrochloric acid. The neutralized solution was evaporated to dryness. The residue was extracted with methanol and the extract was evaporated to give a white solid which was fractionated on preparative tlc using toluene–acetone, 2:3 (v/v), as eluent. One (R_f 0.27) of the major components was identified as being 1-[7,8-anhydro-5,6-dideoxy-β-D-*allo* (and α-L-*talo*)-octofuranosyl]-3-methyluracil (**25**) (0.015 g, 25%); ir (film) ν_{max}: 3440, 1710, 1670, 1630 cm^{-1}; uv λ_{max} (EtOH): 212 (ε 7800), 259 (13 000) nm; ^{1}Hmr δ: 1.57–2.02 (4H, m, 2(H-5′)'s, 2(H-6′)'s), 2.45–3.08 (3H, m, H-7′, 2(H-8′)'s), 3.27 (3H, s, NMe), 3.65–4.38 (5H, H-2′–H-4′, 2 OH's), 5.66 (1H, d, $J_{1',2'}$ = 3.5 Hz, H-1′), 5.75 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.34 (1H, d, H-6).

When **24** was treated with sodium methoxide in chloroform only one product was obtained (92%), which was identical to the material (**25**) isolated in the above experiment.

*1-[7,8-Anhydro-5,6-dideoxy-2,3-*O*-isopropylidene-*β*-D-*allo *(and α-L-talo)-octofuranosyl]-3-methyluracil (26)*

To a solution of **23** (0.94 g, 1.7 mmol) in chloroform (25 mL) was added sodium methoxide (0.114 g, 2.0 mmol) with stirring at 0°C. After the reaction mixture had been stirred overnight at 0°C, tlc (solvent *C*) showed that the reaction mixture contained only one component (R_f 0.46) but no starting material. The reaction mixture was carefully neutralized with cold 1 *N* hydrochloric acid, diluted with water (15 mL), and extracted with dichloromethane (2 × 10 mL). The combined extracts were washed with water, dried ($MgSO_4$), and evaporated to give **26** as a syrup (0.57 g, 97%). An analytical sample was obtained by preparative tlc using toluene–acetone, 2:1 (v/v), as eluent; ir (film) ν_{max}: 1710, 1670, 1630 cm^{-1}; uv λ_{max} (EtOH): 212 (ε 7800), 259 (13 000) nm; ^{1}Hmr δ: 1.28 (3H, s, isopropylidene-Me), 1.52 (3H, s, isopropylidene-Me), 1.45–1.97 (4H, m, 2(H-5′)'s, 2(H-6′)'s), 2.38–2.99 (3H, m, H-7′, 2(H-8′)'s), 3.27 (3H, s, NMe), 3.81–4.63 (2H, m, H-3′, H-4′), 4.84 (1H, dd, $J_{2',3'}$ = 6.0 Hz, $J_{1',2'}$ = 2.0 Hz, H-2′), 5.56 (1H, d, H-1′), 5.70 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.17 (1H, d, H-6).

*1-[8-*O*-Allyl-5,6-dideoxy-2,3-*O*-isopropylidene-*β*-D-*allo *(and α-L-talo)-octofuranosyl]-3-methyluracil (27)*

To a stirred solution of **26** (0.57 g, 1.7 mmol) in allyl alcohol (7 mL) was added sodium alloxide (0.20 g, 2.5 mmol) at 0°C. The reaction mixture was stirred at 45–50°C. After 8 h tlc (solvent *C*) showed that the reaction mixture contained only one component (R_f 0.29) but no starting material. The reaction mixture was carefully neutralized with cold 1 *N* hydrochloric acid. The neutralized solution was diluted with water (10 mL) and the solution was extracted with dichloromethane (3 × 10 mL). The combined extracts were washed with cold water, dried ($MgSO_4$), and concentrated to a brownish syrup which was purified by column chromatography (toluene–acetone, 3:1 (v/v)) to afford pure **27** as a colorless syrup (0.61 g, 88%); ir (film) ν_{max}: 3480, 1710, 1660, 1630 cm^{-1}; uv λ_{max} (EtOH): 211 (ε 6800), 259 (9300) nm; ^{1}Hmr δ: 1.32 (3H, s, isopropylidene-Me), 1.50–1.90 (4H, m, 2(H-5′)'s, 2(H-6′)'s), 1.54 (3H, s, isopropylidene-Me), 2.66 (1H, bs, OH), 3.27–4.64 (7H, H-3′, H-4′, H-7′, 2(H-8′)'s, 2 vinylic H's), 3.30 (3H, s, NMe), 4.85 (1H, dd, $J_{2',3'}$ = 6.0 Hz, $J_{1',2'}$ = 2.0 Hz, H-2′), 5.03–5.34 (2H, m, terminal vinylic H's) 5.58–6.39 (1H, m, vinylic H), 5.64 (1H, d, H-1′), 5.75 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.23 (1H, d, H-6).

*1-[8-*O*-Allyl-5,6-dideoxy-2,3-*O*-isopropylidene-7-*O*-p-tolylsulfonyl-*β*-D-*allo *(and α-L-talo)-octofuranosyl]-3-methyluracil (28)*

To a solution of **27** (0.58 g, 1.4 mmol) in pyridine (3 mL) was added at 0°C *p*-toluenesulfonyl chloride (0.33 g, 1.7 mmol). Thin-layer chromatography (solvent *C*) showed that after the reaction mixture had been kept overnight it contained only one component (R_f 0.56) but no starting material. The product was isolated by the procedure which was used for **14** to give **28** as a syrup (0.75 g, 94%). An analytical sample was obtained by preparative tlc using toluene–acetone, 2:1 (v/v) as eluent; ir (film) ν_{max}: 1710, 1670, 1630, 1360, 1180 cm^{-1}; uv λ_{max} (EtOH): 227 (ε

For personal use only.

15 000), 259 (13 500) nm; ^{1}Hmr δ: 1.26 (3H, s, isopropylidene-Me), 1.48 (3H, s, isopropylidene-Me), 1.60–1.78 (4H, m, 2(H-5')'s, 2(H-6')'s), 2.45 (3H, s, PhMe), 3.23 (3H, s, NMe), 3.32–5.18 (10H, H-2'–H-4', H-7', 2(H-8')'s, 2 allylic H's, 2 terminal vinylic H's), 5.38–5.99 (1H, m, vinylic H), 5.54 (1H, d, $J_{1',2'}$ = 2.0 Hz, H-1'), 5.68 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.05–7.79 (6H, aromatic H's, H-6).

*1-[8-*O*-Allyl-5,6-dideoxy-7-*O*-p-tolylsulfonyl-β-D-allo (and α-L-talo)-octofuranosyl]-3-methyluracil (29)*

Deblocking of the isopropylidene groups of **28** (0.7 g, 1.2 mmol) was performed as described above for **14** and afforded, after column chromatography (toluene–acetone, 7:3 (v/v)), **29** as a colorless syrup (0.58 g, 89%) having R_f 0.17 (solvent *C*); ir (film) ν_{max}: 3430, 1710, 1660, 1355, 1180 cm^{-1}; uv λ_{max} (EtOH): 227 (ε 15 500), 259 (13 500) nm; ^{1}Hmr δ: 1.69–2.02 (4H, m, 2(H-5')'s, 2(H-6')'s), 2.44 (3H, s, PhMe), 3.30 (3H, s, NMe), 3.28–5.39 (10H, H-2'–H-4', H-7', 2(H-8')'s, 2 allylic H's, 2 terminal vinylic H's), 5.62 (1H, d, $J_{1',2'}$ = 3.5 Hz), 5.48–6.34 (1H, m, vinylic H), 5.76 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.08–7.83 (6H, H-6, 5 aromatic H's).

*1-[8-*O*-Allyl-3,7-anhydro-5,6-dideoxy-β-D-allo (and α-L-talo)-octofuranosyl]-3-methyluracil (30)*

Product **28** (0.57 g, 1.1 mmol) in 1,2-dimethoxyethane (20 mL) was stirred with sodium hydride (0.11 g, 4.4 mmol, 50% oil dispersion) at room temperature for 8 h. The reaction mixture was poured into ice-water (40 mL) and the mixture was exhaustively extracted with dichloromethane. The combined extracts were washed with a small amount of water, dried ($MgSO_4$), and concentrated to a syrup which was chromatographed on a column of silica gel (toluene–acetone, 5:2 (v/v)) to give **30** as a colorless syrup (0.22 g, 54%) having R_f 0.49 (solvent *A*); ir (film) ν_{max}: 3420, 1710, 1660, 1630 cm^{-1}; uv λ_{max} (EtOH): 214 (ε 6400), 262 (9850) nm; ^{1}Hmr δ: 1.55–2.05 (4H, m, 2(H-5')'s, 2(H-6')'s), 3.30 (3H, s, NMe), 3.14–4.40 (9H, H-2'–H-4', H-7', 2(H-8')'s, 2 allylic H's, OH), 5.02–5.39 (2H, m, 2 terminal vinylic H's), 5.65 (1H, s, H-1'), 5.59–6.23 (1H, m, vinylic H), 6.77 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.34 (1H, d, H-6).

Isomerization of the Allyl Groups in 30 with $RhCl(PPh_3)_3$

A mixture of **30** (210 mg, 0.56 mmol), 1,4-diazabicyclo[2.2.2]-octane (18 mg), and $RhCl(PPh_3)_3$ (52 mg, 0.056 mmol) in 60% aqueous ethanol was heated at reflux temperature. After 1.5 h tlc (solvent *A*) showed that the reaction mixture contained two components (R_f 0.55, 0.58) but no starting material. The reaction mixture was filtered, and the filtrate was concentrated to half-volume and then partitioned between water and dichloromethane. The aqueous layer was further extracted with dichloromethane a few times. The dried (K_2CO_3) organic solution was concentrated to a brownish foam which was fractionated on a column of silica gel (toluene–acetone, 3:1 (v/v)) to give 1-[3,7-anhydro-5,6-dideoxy-8-*O*-(prop-1-enyl)-β-D-*allo*-octofuranosyl]-3-methyluracil (**31**) as a colorless syrup (94 mg, 45%) having R_f 0.58, $[\alpha]_D$ +32.7° (*c* 0.26, CH_2Cl_2); ir (film) ν_{max}: 3430, 1710, 1660, 1630 cm^{-1}; uv λ_{max} (EtOH): 212 (ε 6500), 261 (12 500) nm; ^{1}Hmr δ: 1.56 (3H, dd, ^1J = 6.5 Hz, ^2J = 1.5 Hz, allylic Me), 1.58–2.02 (4H, m, 2(H-5')'s, 2(H-6')'s), 3.15–5.01 (8H, H-2'–H-4', H-7', 2(H-8')'s, =CH, OH), 3.29 (3H, s, NMe), 5.61 (1H, s, H-1'), 5.71 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 5.86–6.30 (1H, m, =HCO), 7.30 (1H, d, H-6).

1-[3,7-Anhydro-5,6-dideoxy-8-*O*-(prop-1-enyl)-α-L-*talo*-octofuranosyl]-3-methyluracil (**32**) was isolated as a colorless syrup (88 mg, 42%) having R_f 0.55; $[\alpha]_D$ +35.4° (*c* 0.26, CH_2Cl_2); ir (film) ν_{max}: 3430, 1710, 1660, 1630 cm^{-1}; uv λ_{max} (EtOH): 212 (ε 7000), 261 (12 500) nm; ^{1}Hmr δ: 1.58 (3H, dd, ^1J = 6.5 Hz, ^2J = 1.5 Hz, allylic Me), 1.58–2.02 (4H, m, 2(H-5')'s, 2(H-6')'s), 3.19–4.94 (8H, H-2'–H-4', H-7', 2(H-8')'s, =CH, OH), 3.30 (3H, s, NMe), 5.62 (1H, s, H-1'), 5.76 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 5.91–6.32 (1H, m, =HCO), 7.38 (1H, d, H-6).

1-(3,7-Anhydro-2-O-benzoyl-5,6-dideoxy-β-D-allo-octofuranosyl)-3-methyluracil (35)

To a cooled solution of **31** (92 mg, 0.25 mmol) in pyridine (2 mL) was added benzoyl chloride (42 mg, 0.30 mmol). The reaction mixture was kept at room temperature for 30 min and then poured into cold water (20 mL), and the mixture was extracted with dichloromethane (2 × 20 mL). Concentration and then co-evaporation with toluene of the dried ($MgSO_4$) dichloromethane solution afforded crude 1-[3,7-anhydro-2-*O*-benzoyl-8-*O*-(prop-1-enyl)-β-D-*allo*-octofuranosyl]-3-methyluracil (**33**) as a colorless syrup having R_f 0.72 (solvent *A*). To a solution of crude **33** in 60% aqueous methanol (8 mL) was added 0.1 *N* hydrochloric acid in 80% aqueous methanol (8 mL). The reaction mixture was stirred at room temperature for 8 h and then neutralized by addition of silver carbonate. The silver salts were removed by filtration. The filtrate was concentrated to half-volume and then extracted with dichloromethane several times. The dried ($MgSO_4$) organic solution was concentrated to a yellow solid which was fractionated by preparative tlc (toluene–acetone, 2:1 (v/v)) to afford **35** as a colorless syrup (87 mg, 88% from **31**) having R_f 0.46 (solvent *C*); $[\alpha]_D$ +28.8° (*c* 0.07, CH_2Cl_2); ir (film) ν_{max}: 3430, 1710, 1660, 1630 cm^{-1}; uv λ_{max} (EtOH): 231 (ε 15 100), 258 (10 300) nm; ^{1}Hmr δ: 1.54–1.88 (4H, m, 2(H-5')'s, 2(H-6')'s), 3.28 (3H, s, NMe), 3.52–3.86 (6H, H-3', H-4', H-7', 2(H-8')'s, OH), 5.62 (1H, d, $J_{2',3'}$ = 4.0 Hz, H-2'), 5.72 (1H, s, H-1'), 5.78 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.21–8.23 (6H, H-6, aromatic H's). See Table 1 for ^{13}Cmr data.

1-(3,7-Anhydro-2-O-benzoyl-5,6-dideoxy-α-L-talo-octofuranosyl)-3-methyluracil (36)

Compound **32** (85 mg, 0.23 mmol) was benzoylated as described above for compound **31** to give crude 1-[3,7-anhydro-2-*O*-benzoyl-5,6-dideoxy-8-*O*-(prop-1-enyl)-α-L-*talo*-octofuranosyl]-3-methyluracil (**34**) as a colorless syrup having R_f 0.72 (solvent *A*). Removal of the prop-1-enyl group of **34** was performed as described above for **33** to afford, after the preparative tlc (toluene–acetone, 2:1 (v/v)), **36** as a colorless syrup (80 mg, 88% from **32**) having R_f 0.43 (solvent *C*); $[\alpha]_D$ +32.7° (*c* 0.09, CH_2Cl_2); ir (film) ν_{max}: 3430, 1710, 1660, 1630 cm^{-1}; uv λ_{max} (EtOH): 230 (ε 14 000), 258 (10 000) nm; ^{1}Hmr δ: 1.75–1.96 (4H, m, 2(H-5')'s, 2(H-6')'s), 3.28 (3H, s, NMe), 3.66–4.15 (6H, H-3', H-4', H-7', 2(H-8')'s, OH), 5.62 (1H, d, $J_{2',3'}$ = 4.0 Hz, H-2'), 5.77 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 5.78 (1H, s, H-1'), 7.20–8.15 (6H, H-6, aromatic H's). See Table 1 for ^{13}Cmr data.

1-(3,7-Anhydro-5,6-dideoxy-β-D-allo-octofuranosyl)-3-methyluracil (37)

To a solution of **35** (80 mg, 0.20 mmol) in methanol (2 mL) was added 1 *N* sodium methoxide in methanol (0.07 mL) at room temperature. The reaction was complete almost immediately. The reaction mixture was filtered through ion-exchange resin (H^+) and the resin was washed with a small amount of methanol. Evaporation of the methanol solution afforded a brownish residue which was purified by preparative tlc (ethyl acetate–acetone, 3:1 (v/v)) to give **37** as an amorphous solid (58 mg, 98%) having R_f 0.63 (solvent *F*); $[\alpha]_D$ +21.2° (*c* 0.05, MeOH); ir (KBr) ν_{max}: 3350, 1700, 1660, 1620 cm^{-1}; uv λ_{max} (MeOH): 214 (ε 7500), 262 (12 800) nm; ^{1}Hmr δ (DMSO-d_6): 1.66–2.12 (4H, m, 2(H-5')'s, 2(H-6')'s), 3.27 (3H, s, NMe), 3.11–4.28 (6H, H-2'–H-4', H-7', 2(H-8')'s), 5.72 (1H, s, H-1'), 5.80 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.66 (1H, d, H-6). *Anal.* calcd. for $C_{13}H_8N_2O_6$: C 52.35, H 6.08, N 9.39; found: C 52.39, H 6.23, N 9.47.

1-(3,7-Anhydro-5,6-dideoxy-α-L-talo-octofuranosyl)-3-methyluracil (38)

Compound **36** (29 mg, 0.072 mmol) was debenzoylated in a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

manner similar to that used for compound **35** to afford, after preparative tlc (ethyl acetate – acetone, 3:1 (v/v)), **38** as an amorphous solid (21 mg, 98%) having R_f 0.61 (solvent *F*); $[\alpha]_D$ +25.6° (*c* 0.06, MeOH); ir (film) ν_{max}: 3350, 1700, 1650, 1620 cm^{-1}; uv λ_{max} (MeOH): 214 (ε 7500), 262 (13 000) nm; ^{1}Hmr δ (DMSO-d_6): 1.75–2.21 (4H, m, 2(H-5′)'s, 2(H-6′)'s), 3.27 (3H, s, NMe), 3.18–4.23 (6H, H-2′–H-4′, H-7′, 2(H-8′)'s), 5.72 (1H, s, H-1′), 5.82 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.71 (1H, d, H-6). *Anal.* calcd. for $C_{13}H_{18}N_2O_6$: C 52.35, H 6.08, N 9.39; found: C 52.59, H 6.08, N 9.20.

*1-(3,7-Anhydro-5,6-dideoxy-*β*-D-*allo*-octofuranosyluronic acid)-3-methyluracil (39)*

A mixture of **37** (50 mg, 0.17 mmol) in water (5 mL) and 10% platinum-on-charcoal catalyst (13 mg) were placed in a 30-mL test tube. The pH of the solution was adjusted to ~8.5 by addition of saturated aqueous sodium hydrogen carbonate solution. Oxygen was vigorously bubbled through the reaction mixture to provide sufficient agitation. The temperature of the reaction mixture was maintained at 70°C by means of a water bath throughout the course of the reaction. Every 30 min the pH of the reaction mixture was checked and adjusted to 8.5. The reaction was complete in 3 h. The reaction mixture was filtered through Celite twice and the filtrate was washed with dichloromethane. The aqueous solution was eluted through ion-exchange resin (H^+) and then freeze-dried to give a brownish foam which was carefully purified by preparative tlc (*n*-butanol – methanol–water, 8:1:1 (v/v)) to afford **39** as a colorless glass (39 mg, 74%) having R_f 0.18 (solvent *G*); $[\alpha]_D$ +14.4° (*c* 0.3, 0.1 *N* aqueous sodium hydroxide); ir (film) ν_{max}: 3420, 1710, 1660, 1620 cm^{-1}; uv λ_{max} (H_2O): 213 (ε 7800), 262 (13 500) nm; ^{1}Hmr δ (D_2O): 1.78–2.29 (4H, m, 2(H-5′)'s, 2(H-6′)'s), 2.97–4.45 (4H, H-2′–H-4′, H-7′), 3.26 (3H, s, NMe), 5.71 (1H, s, H-1′), 5.88 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.62 (1H, d, H-6). *Anal.* calcd. for $C_{13}H_{16}N_2O_7$: C 50.00, H 5.17, N 8.97; found: C 50.13, H 5.23, N 9.11.

*3-Methyl-1-(methyl 3,7-anhydro-5,6-dideoxy-*β*-D-*allo*-octofuranosyluronate)uracil (40)*

To a stirred solution of compound **39** (37 mg, 0.12 mmol) in methanol (1 mL) was added 5% hydrogen chloride in methanol (2 mL) at °C. After 2 h, the reaction mixture was neutralized with silver carbonate. Silver salts were removed by filtration and the filtrate was concentrated to a pale yellow syrup which was purified by preparative tlc (toluene–acetone, 1:1 (v/v)) to afford **40** as a colorless syrup (31 mg, 81%) having R_f 0.38 (solvent *A*); $[\alpha]_D$ +25.7° (*c* 0.05, $CHCl_3$); ir (film) ν_{max}: 3430, 1710, 1660, 1630 cm^{-1}; uv λ_{max} (MeOH): 214 (ε 7500), 262 (14 000) nm; ^{1}Hmr δ: 1.75–2.23 (4H, m, 2(H-5′)'s, 2(H-6′)'s), 3.27 (3H, s, NMe), 3.75 (3H, s, COOMe), 3.02–4.51 (4H, H-2′–H-4′, H-7′), 5.72 (1H, s, H-1′), 5.86 (1H, d, $J_{5,6}$ = 8.0 Hz, H-5), 7.62 (1H, d, H-6).

The preparation of amino sugars and branched-chain sugars by palladium-catalyzed, allylic substitution of alkyl hex-2-enopyranosides

HANS H. BAER AND ZAHER S. HANNA
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4
Received August 11, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

HANS H. BAER and ZAHER S. HANNA. Can. J. Chem. **59**, 889 (1981).

Ethyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside (**1**) in the presence of triphenylphosphine and a catalytic amount of tetrakis(triphenylphosphine)palladium(0) reacted with a variety of amines or with reactive methylene compounds to give high yields of products aminated or *C*-alkylated, respectively, in an allylic position. Some analogous experiments were performed using the β-D-*erythro* anomer (**2**) and the α-D-*threo* epimer (**3**) of **1**. The constitutions and configurations of the new products were established by means of mass spectra, ^{13}C- and ^{1}H-nmr spectra, and optical rotation data. The reactions of **1** were found to be highly regio- and stereoselective, giving almost exclusively 4-substituted 2-enopyranosides with retention of configuration, except in the case of dibenzylamine which produced a mixture of the corresponding enoside and its 2-substituted, 3,4-unsaturated isomer having the α-D-*threo* configuration. The reactions of **2** appeared slightly less selective although they, too, furnished mainly 4-substituted 2-enopyranosides with retention of configuration. Regioselectivity was low or lacking in two *C*-alkylations performed with **3**, which gave mixtures of 4-substituted 2-enosides and 2-substituted 3-enosides. Some aspects of conformation and optical rotation in enopyranosides are discussed.

HANS H. BAER et ZAHER S. HANNA. Can. J. Chem. **59**, 889 (1981).

Le composé éthyl-4,6-di-*O*-acétyl-2,3-didésoxy-α-D-*érythro*-hex-2-énopyranoside (**1**) en présence de triphénylphosphine et d'une quantité catalytique de tétrakis(triphénylphosphine)palladium(0) réagit avec différentes amines ou des composés ayant un groupement méthylène réactif et conduit avec d'excellents rendements aux produits aminés ainsi qu'aux dérivés *C*-alkylés en position allylique. On a réalisé des expériences similaires en utilisant l'anomère β-D-*erythro* (**2**) et l'épimère α-D-*thréo* (**3**) de **1**. Les spectres de masse et de rmn du ^{1}H et du ^{13}C ainsi que les données de rotation optique ont permis d'établir les structures et les configurations des nouveaux produits. Les réactions impliquant le composé **1** sont fortement régio- et stéréosélectives et donnent presqu'exclusivement les 2-énopyranosides substitués en position 4 avec rétention de configuration; la réaction avec la dibenzylamine fait exception puisqu'elle conduit a un mélange de l'énoside correspondant et de son isomère substitué en position **2**, insaturé en 3,4 et possédant la configuration α-D-*thréo*. Les réactions du composé **2** semblent être moins sélectives bien qu'elles conduisent principalement aux 2-énopyranosides substitués en position 4 avec rétention de configuration. La régiosélectivité est faible ou inexistante lors des deux *C*-alkylations réalisées avec le composé **3**; ces réactions donnent des mélanges de 2-énosides et 3-énosides substitués en position 4 et 2, réspectivement. Quelques aspects de la conformation et de la rotation optique des énopyranosides sont discutés.

Introduction

Recently we communicated (1) the first results of a study concerning the potential utility of organopalladium reagents for the functionalization of carbohydrates. The present article reports full details of the work and includes some additional results which have since been elaborated. In connection with our current interest in the development of methods for the synthesis of unusual amino, deoxy, unsaturated, and branched-chain sugars (2), we decided to examine whether the palladium-catalyzed substitution of allylic acetates by amines or reactive methylene compounds (3–6) might be employed to advantage in carbohydrate chemistry. In this reaction, which represents one of the numerous applications of organopalladium chemistry (7) that are currently in widespread use, an allylic acetate in the presence of a catalyst such as tetrakis(triphenylphosphine)palladium forms an intermediate π-allylpalladium complex that is then attacked by an added nucleophile, to give an allylically substituted product. The palladium species liberated upon collapse of the intermediary complex is reconverted into a catalytically active form by the action of the excess of triphenylphosphine which is provided. A high degree of regioselectivity and stereocontrol is normally observed in these substitutions (6), although certain exceptions to this welcome trend have been noted and discussed.

As our chief substrate for an evaluation of the utility of the method in the carbohydrate field,[1] we chose the crystalline ethyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside (**1**). This compound is readily prepared (9) from commercially available D-glucal triacetate. For some ancillary experiments, to be performed in the hope of

[1]To our knowledge, only one organopalladium reaction (of a different kind) with carbohydrates has been previously studied. Arai and Daves (8) effected regiospecific addition of a 1,3-dimethyl-2,4-pyrimidinedion-5-ylpalladium salt across the double bond of the enol ethers D-glucal triacetate and D-arabinal diacetate.

shedding light on stereochemical implications, the β-D-*erythro* anomer **2** and the α-D-*threo* epimer **3** of the pseudoglycal **1** were desired. Although the methyl glycoside analog (**2***a*) of **2** was known (10, 11), and was used in the present work for a confirmatory experiment, the ethyl glycoside **2** could not be found in the literature. However, we were able to synthesize it readily, also from D-glucal triacetate, by way of ethoxymercuration followed by elimination of the elements of mercuric acetate with sodium iodide, in a manner analogous to that described (11, 12) for the synthesis of **2***a*. The intermediate encountered in this synthesis, ethyl 2-acetoxymercuri-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranoside, was a highly crystalline compound (see Experimental). The α-D-*threo* epimer **3** was obtained by acetylation of the corresponding, crystalline diol.[2] A high-yielding procedure for its preparation from tri-*O*-acetyl-D-galactal has recently been described (14).

Results and Discussion

Formation of Unsaturated Amino and Branched-chain Sugars

The enopyranoside **1** was allowed to react, in tetrahydrofuran solution at reflux temperature, with a variety of nucleophiles in the presence of triphenylphosphine (0.7 molar equiv.) and a catalytic amount (0.07 molar equiv.) of tetrakis(triphenylphosphine)palladium. The use of diethylamine, piperidine, cyclohexylmethylamine, and benzylmethylamine led to the 4-aminated glycosides **4–7**, respectively, in yields of 70–87% after chromatographic purification. According to tlc and nmr spectroscopic evidence, the compounds **4–6** were formed as single isomers accompanied, at most, by traces of slow-moving impurities. In the case of **7**, a second but minor compound was seen to be present in the crude reaction mixture; it was removed by preparative tlc and could not be identified. By contrast, the reaction of **1** with dibenzylamine was less selective. It gave in 83% yield a separable mixture of two products that were present in a ratio of approximately 3:7 (by nmr). The minor component crystallized after chromatographic separation and proved to be the 4-aminated glycoside **8** whereas the major component failed to crystallize and was found to be the 2-aminated, 3,4-unsaturated isomer **9**.

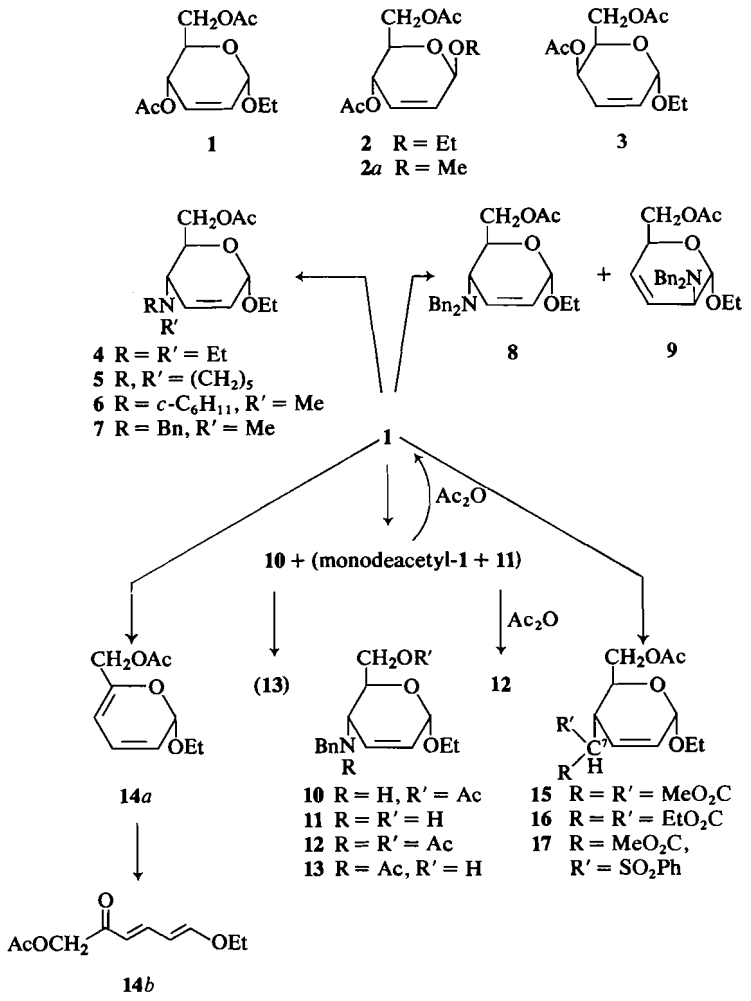
[2]For a gift of a sample of this diol we are indebted to Professor B. Fraser-Reid who informed us privately that it was prepared from the corresponding α-D-*erythro* diol by C-4 inversion through benzoylation in the presence of dialkyl azodicarboxylate and triphenylphosphine (13), followed by saponification.

Reaction of **1** with the primary amine, benzylamine, produced a more complex result. The expected 6-*O*-acetyl-4-benzylamino glycoside **10** could be isolated in only 31% yield, and the bulk of the reaction product was a chromatographically slow-moving mixture of two components which were difficult to separate. The nmr spectrum of this mixture suggested that the components were partially *O*-deacetylated **1** and the *O*-deacetylated derivative (**11**) of **10**. Acetylation of the mixture followed by chromatography led to the recovery of **1** (50%) and, in addition, furnished the syrupy but homogeneous *N*-acetyl-*O*-acetyl derivative **12** (15%) whereby the joint yield of isolated, aminated products (**10** + **12**) was raised to 46%. When syrupy **10** was stored for an extended period in the refrigerator, hydroxyl and amide bands developed in its ir spectrum, at the expense of the ester band. A sample stored at room temperature slowly crystallized in the course of a few weeks, and the crystals exhibited amide but no ester carbonyl bands. Although this transformation was not investigated further, it seems obvious that **10** underwent O → N acetyl migration to give **13**.

A preliminary examination of the reaction between **1** and some primary, aromatic amines has led to the conclusion, based on nmr spectra of the products obtained, that *p*-aminobenzophenone, *p*-aminoacetophenone, and 2,6-dimethylaniline are also incorporated into the glycoside. However, analysis of these reactions is still incomplete.

No amination was achieved with diisopropylamine, presumably because of the steric hindrance associated with this molecule. Instead, acetate elimination occurred to give the diene **14***a* which rearranged to **14***b*. The same happened on prolonged heating of **1** and catalyst in the presence of triethylamine or, indeed, in the absence of any amine. Details on the formation and properties of these dienic products are reserved for publication elsewhere.

C-Alkylations of **1** were performed in full analogy to the aminations just described, by use of several reactive methylene compounds that were administered as their sodio derivatives in tetrahydrofuran solution. Reactions with dimethyl malonate, diethyl malonate, and methyl phenylsulfonylacetate proceeded well, furnishing the branched-chain glycosides **15–17** in yields of 87, 83, and about 60%. Whereas **15** and **16** showed no evidence for isomeric inhomogeneity, crude **17** contained a small proportion of an unidentified by-product. However, **17** was obtained as a chromatographically and nmr-spectroscopically homogeneous

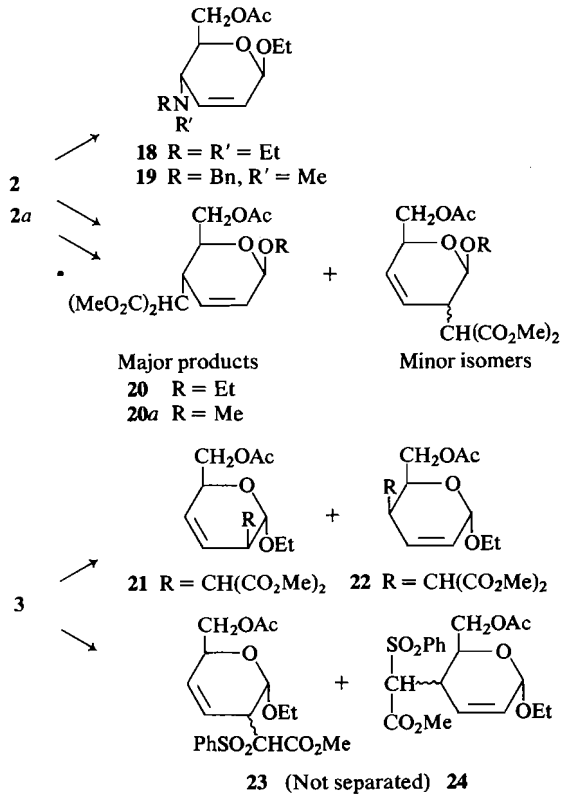


product by crystallization. Its configuration at C-7 in the side-chain remained unknown. Also tested with **1** were malononitrile and ethyl cyanoacetate. They too gave *C*-alkylated products, but the yields were poor in these instances and the products have not as yet been characterized definitively, nor have attempts been made to optimize reaction conditions.

In view of the high regioselectivity which was observed in all those aminations and alkylations of **1** that proceeded with good yields, with the noteworthy exception of the reaction with dibenzylamine, it appeared interesting to supplement the findings by some comparative experiments using stereoisomers of **1** as substrates. The β-enopyranoside **2** reacted equally well with diethylamine and benzylmethylamine, giving the aminated glycosides **18** and **19** in excellent yields. As was the case in the α-series (cf. **7**), a very small proportion of an unidentified by-product (presumably an isomer) was present in **19** as revealed by the nmr spectrum. The reaction of dibenzylamine with **2** gave a result even more abnormal than the reversal of regioselectivity encountered in its reaction with **1**. Apparently, no aminated ethyl glycoside was formed; instead, we found a major product that possessed a dibenzylamino group but had lost the glycosidic ethoxyl group. The exceptional behavior of dibenzylamine is the subject of ongoing studies.

The β-enopyranoside **2** and, likewise, its methyl analog **2***a* reacted with dimethylmalonate to give high yields of *C*-alkylated products. Although these appeared as single spots in tlc, they were revealed by nmr spectroscopy to be composed of strongly preponderant, major components and minor isomers. The chief components were the 4-substituted, 2-enosides **20** and **20***a*, respectively, whereas the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.



accompanying isomers were indicated by mass-spectral data to have the constitution of 2-substituted 3-enosides (*vide infra*).

For the α-D-*threo* enoside **3**, only two palladium-catalyzed substitutions have thus far been examined; in both instances, regioselectivity was found to be lower than in the analogous reactions with **1** or **2**. With dimethyl malonate, **3** gave in 66% yield an approximately 3:1 mixture of the 2-alkylated, 3,4-unsaturated α-D-*threo* glycoside **21** and its 4-alkylated, 2,3-unsaturated isomer **22**. In addition, small proportions of two chromatographically slow-moving products were isolated. Both of them originated from *C*-alkylation as they contained methyl ester groups of an incorporated malonate residue. However, they had lost both *O*-acetyl groups. Reacetylation of one of these minor fractions gave **21**, spectroscopically identified with the major component in the aforementioned mixture of main products. The other slow-moving by-product remained unaffected by acetylation and its ^{1}H nmr spectrum suggested the presence of three methyl ester groups. Hence the product had probably arisen from *O*-deacetylated **21** or **22** by transesterification with dimethyl malonate.

With methyl phenylsulfonylacetate, **3** gave also a mixture of two isomeric substitution products. Although separation could not be achieved, the ^{1}H nmr spectrum indicated a ratio of ~1:1. Formulas **23** and **24** are suggested as likely structures of these compounds. No information regarding the C-7 configuration is available.

Assignment of Structure

The gross structures of new compounds were supported by elemental analysis, fitting infrared spectra, the molecular ion peak present in the mass spectrum in most cases (Table 1), and the requisite substituent resonances displayed in the proton and carbon-13 nmr spectra. More detailed constitutional and configurational information was derived from spectral data and from optical rotations, as follows.

Mass Spectra

First of all, it was necessary to ascertain the position of the olefinic double bond in the pyranoside rings. This was made possible by mass spectrometry, which permits one to distinguish between 2,3- and 3,4-unsaturated hexopyranosides on the basis of different fragmentation patterns (15–17). For the former type of enosides, retrodienic fragmentation leads to two fragments (a and b) according to Scheme 1. In our compounds, since R″ = CH_3CO, M_b = 102 and hence $M_a = M - 102$. On the other hand, enopyranosides of the latter type are fragmented to give a diene (c) and alkyl formate (d) (Scheme 1). For ethyl glycosides, with M_d = 74, a fragment c having $M_c = M - 74$ is therefore diagnostic for 3,4-unsaturation. Table 1 shows that the amino glycosides **4–8**, **12**, **18**, and **19** gave prominent peaks of m/e $M - 102$, indicative of their 2,3-unsaturated structures. There were also peaks of m/e $M - 74$, but their intensities were only 1–6% of those of the $M - 102$ peaks. Although these minor peaks possibly may signify the presence of minute proportions of 3,4-unsaturated isomers that had escaped detection by tlc or nmr spectroscopy, they could well have resulted from thermal rearrange-

[a]The spectra were obtained with an A.E.I. MS 902 mass spectrometer fitted with a direct-inlet probe, at an ionizing potential of 50–55 eV. A full analysis of the fragmentation paths is in preparation for publication (J. Krause, Z. S. Hanna, and H. H. Baer).
[b]$M^+ - 60$ (loss of *methyl* formate).

ment of the compounds in the mass spectrometer prior to electron impact (17). On the other hand, the amine **9** gave only a feeble peak of *m/e* $M - 102$ but a peak 12 times as strong at *m/e* $M - 74$. Furthermore, **9** gave an intense daughter peak at *m/e* 262, believed to result from loss of OAc from the $M - 74$ fragment. By contrast, the positional isomer **8** showed only a weak peak at *m/e* 262 (with 12% of the intensity seen in **9**), whereas it produced a strong daughter peak at *m/e* 264 attributable to loss of C_2H_5 from its $M - 102$ fragment. Conversely, in **9**, this peak had an intensity of only 8% relative to that in **8**. These features clearly permitted allocation of the double bond positions as shown.

The *C*-alkylated compounds **15**, **16**, **20**, and **20*a*** were similarly revealed to possess 2,3-unsaturated structures, on account of the strong dominance of $M - 102$ over $M - 74$ peaks (or the analogous $M - 60$ peak in the case of the methyl glycoside **20*a***). It is noteworthy, though, that the $M - 102$ peaks generally were markedly lower in intensity relative to the base peak than in the cases of the aminated analogs, presumably because of a high instability associated with fragments that contain a malonic ester moiety. In support of this explanation, strong daughter peaks were observed, which arose from loss of CH_3CO_2 from the $M - 102$ fragments of **15**, **20**, and **20*a***, and from loss of $C_2H_5CO_2$ in the case of **16**.

As already mentioned, the β-glycosides **20** and **20*a*** were revealed by their ^{13}C nmr spectra to contain minor proportions of isomers that could not be isolated. The mass spectra exhibited minor peaks at *m/e* $M - 74$ and $M - 60$, respectively, whose intensities were somewhat greater (22 and 14%) relative to the major, $M - 102$ peaks, than in the preceding compounds where these intensities ranged from 1–6% (see above). These findings corroborated the assumption that the by-products accompanying **20** and **20*a*** were 2-substituted, 3,4-unsaturated analogs.

The mass spectrum of the phenylsulfonyl derivative **17** did not display peaks attributable to $M - 102$ or $M - 74$, such fragments apparently being too unstable to survive in this instance. Indeed, loss of $C_6H_5SO_2^+$ (*m/e* 141) was conspicuous, with concomitant formation of an intense ion peak at *m/e* 169 attributable to $M - 102 - 141$. The spectrum thus provided at least indirect evidence for the structure of **17**.

The spectrum of **21** failed to yield information to allocate the olefinic bond. Peaks for $M - 102$ and $M - 74$ were both weak and quite similar in intensity, and the same applied to daughter peaks expected to originate from loss of CH_3CO_2. However, the spectrum was useful at least insofar as it established the non-identity of **21** with the α-D-*erythro* isomer **15**. Furthermore, the spectrum of *isolated* **21** ($[\alpha]_D$ +100°) was extremely similar to that of the *mixture* ($[\alpha]_D$ +24°) of **21** and **22** originally obtained from **3**. This observation together with the ambiguous fragmentation pattern suggests that **21** is particularly prone to sigmatropic rearrangement which may occur in the spectrometer to some consider-

[a]Spectra were taken from chloroform solutions with a Varian CFT-20 instrument.
[b]In addition to the resonances listed, all compounds showed resonances as expected for the carbon atoms in the various substituents.
[c]The values for **1** are in good agreement with published (20) data.
[d]The signal was difficult to differentiate from nearby Ph signals; an alternative value is 129.3.
[e]The minor by-product present in **20**, believed to be a 3-enoside.
[f]The minor by-product present in **20***a*, believed to be a 3-enoside.

able degree. Ferrier *et al.* (16) have found such rearrangements to be especially facile when the migrating substituent was attached quasi-axially as in **21** and **22**, rather than quasi-equatorially as in **15** and most of the other compounds here considered. The mass-spectral peculiarity of **21** therefore tends to support its formulation as a *threo* compound. Finally, the spectrum of the mixture of phenylsulfonyl derivatives tentatively designated as **23** and **24** furnished little structural information other than admitting that one of the components (**24**) may have been identical with **17**.

^{13}C *Nuclear Magnetic Resonance Spectra*

The ^{13}C nmr signals were assigned to individual nuclei on the basis of multiplicities observed in proton-coupled spectra and in accordance with known chemical shift regularities (ref. 18 and literature cited therein). The chemical shifts of the pyranose carbon and some selected substituent carbon atoms are assembled in Table 2. It is seen that all of the compounds to which was assigned the 2,3-unsaturated α-D-*erythro* structure (**4–8**, **10**, **12**, and **15–17**) show the C-1 resonance in the narrow range of 93.8–94.3 ppm (relative to tetramethylsilane). The δ-effect upon C-1 associated with a configurational inversion at C-4 is expected to be small, and this is borne out in the starting compounds **1** and **3** whose C-1 resonances both occur in the same range. In the mixture of the two *C*-bis-(methoxycarbonyl)methyl derivatives obtained from **3**, only the minor component (**22**) showed a reasonably similar C-1 shift (94.6 ppm), and so did one of the components (provisionally termed **24**) of the mixture of methoxycarbonyl(phenylsulfonyl)methyl derivatives (94.3 ppm). These data appear consistent with the assignment of a 2,3-unsaturated constitution to **22** and **24**. By contrast, C-1 experienced a noticeable downfield shift, to 97.4 ppm, in the α-glycosides **9** and **21** for which the mass spectra had provided positive (**9**) or circumstantial (**21**) evidence for 3,4-unsaturation. By analogy it may be assumed that **23**, showing its C-1 resonance at 96.5 ppm, is 3,4-unsaturated also. Some further consistencies supporting the assignments may be noted. Thus, in each of the three pairs of regioisomers (**8/9**, **21/22**, and **23/24**), the carbon bearing the newly-introduced substituent resonates at lower field by 2.2 – 3.5 ppm when it is in position 2 than when it is in position 4. The pair of 4-epimers **15/22** shows a shielding difference in the expected direction for a quasi-equatorially vs. a quasi-axially substituted C-4, although the effect is quite small in this instance (0.5 ppm). A similar

insensitivity of the C-4 shift cannot be excluded for **17** and its 4-epimer; for this reason it was not possible to decide whether the non-isolated, mixture component **24** was identical with one or the other of the α-D-*erythro* compounds having the structure **17** (two C-7 epimers being possible), or whether it was an α-D-*threo* stereoisomer. As regards **9**, **21**, and **23**, the near coincidence of their C-1 shifts would obviously be consistent with an assumption that these compounds possess an identical configuration. However, it does not represent proof since the change from an axial C-2 substituent (α-D-*threo* configuration) to an equatorial one (α-D-*erythro* configuration) replaces one shielding factor by another one of similar magnitude, with little if any net effect upon the C-1 shift to be expected. This is exemplified in methyl α-D-mannopyranoside → α-D-glucopyranoside and other pairs of epimers having comparable features (18). On the basis of their optical rotations (*vide infra*), **9** and **21** could be assigned the α-D-*threo* configuration, and it is noteworthy in this context that the constitutionally analogous, α-D-*erythro* glycoside **35***a* also shows (19) a similar C-1 resonance (97.0 ppm).

In ordinary methyl β-hexopyranosides, excepting the mannosides, C-1 is generally deshielded by ca. 2–5 ppm relative to the corresponding α-anomers (18). The methyl 4,6-*O*-benzylidene-2,3-dideoxy-α- and -β-D-*erythro*-hex-2-enopyranosides, which are comparable to our compounds but for their rigid conformation due to the *trans*-fused acetal ring, were found (20) to obey this rule (Δδ −3.1 ppm). The difference is somewhat smaller (−1.5 to −1.8 ppm) in the 4,6-di-*O*-acetyl-2,3-dideoxy-D-hex-2-enopyranosyl dimethylphosphonates (**1–3** and β-D-*threo* isomer, with $P(O)(OMe)_2$ replacing OEt) recently studied by Paulsen and co-workers (21). The data in Table 2 indicate that the β-glycosides **2**, **18**, and **19** also give C-1 resonances to slightly lower field than do their α-anomers **1**, **4**, and **7** (Δδ −0.7, −1.3, and −0.7, respectively). The γ-effect of anomerization upon C-5, on the other hand, was distinctly larger in these pairs (Δδ −5.9, −5.2, and −4.9 ppm, respectively), exceeding the values observed (21) in the phosphonates just mentioned (−2.5 and −3.3 ppm) and coming closer to the value (−6.6 ppm) reported (20) for the benzylidene acetals. Summation of the chemical shifts for C-1 to C-6 in **4** and **7** (Σ_{1-6} 538.8 and 538.0 ppm) and their β-anomers **18** and **19** (Σ_{1-6} 544.7 and 543.1 ppm), and juxtaposition of these values with the sums for **1** (Σ_{1-6} 548.1 ppm) and **2** (Σ_{1-6} 553.0 ppm), respectively, is taken as a good indication (18) for structural equivalence. A similar exercise comparing Σ_{1-6} for the *C*-alkylated α-glycoside **15** (516.7 ppm) with the values for the β-glycosidic analogs **20** (516.0 ppm) and **20***a* (517.1 ppm) surprisingly did not yield any such difference of 5–6 ppm for anomerism. A possible reason for this apparent discrepancy may lie in differing conformational features as will be discussed below. As regards the minor by-products that accompanied **20** and **20***a*, their carbon atoms showed chemical shift relations, to the structurally analogous atoms in **20** and **20***a*, that were qualitatively similar to the relations seen in the pair of positional isomers **21/22**. Thus, C-1 and the alkyl-substituted carbon in particular, and to a lesser degree C-5 and C-6, all were significantly deshielded relative to their counterparts in **20** and **20***a*. These comparisons reinforced the suggestion, already intimated by the mass spectra, that the by-products were 2-substituted, 3,4-unsaturated isomers of **20** and **20***a*. Unfortunately, the configuration at C-2 could not be established definitively since the optical rotations of these products are unavailable for confirmation. From the ^{13}C nmr data alone it might tentatively be concluded that the β-D-*threo* configuration obtains, i.e., a 1,2-*cis* equatorial – axial substituent orientation. The C-1 and C-2 shifts in such an arrangement should differ little, for reasons discussed previously, from those in an α-D-*threo* arrangement, i.e., 1,2-*trans* diaxial, whereas deshielding by several ppm in C-1 and C-2 is expected for the β-D-*erythro* configuration (1,2-*trans* diequatorial). A comparison of the data for the by-product of **20** with those of the α-D-*threo* isomer **21** points to the former alternative, the relevant shift differences being only −1.3 and +1.4 ppm.

^1H *Nuclear Magnetic Resonance Spectra*

The ^1H nmr parameters are listed in Table 3. The spectra of the aminated, α-glycosidic derivatives **4–8** and **10**, as well as those of the *C*-alkylated derivatives **15–17**, were sufficiently resolved to permit first-order analysis which established the D-*erythro* configuration of these 2-enosides. The olefinic protons resonated in the δ 6.0 region and gave AB quartets showing $^3J_{2,3}$ = 10.0–10.5 Hz; each constituent part was split further, by small vicinal and allylic couplings with H-1 and H-4. The anomeric proton produced a broadened singlet or narrow multiplet near δ 5.0. Of diagnostic significance was the H-4 signal, which occurred at highest field as far as ring protons were concerned. It was a doublet ($J_{4,5}$ = 10 Hz) of narrowly-spaced multiplets. The large vicinal coupling constant required H-4 and H-5 to have an *anti* orientation and therefore proved the D-*erythro* configuration. The individual multiplets composing the H-4 doublet

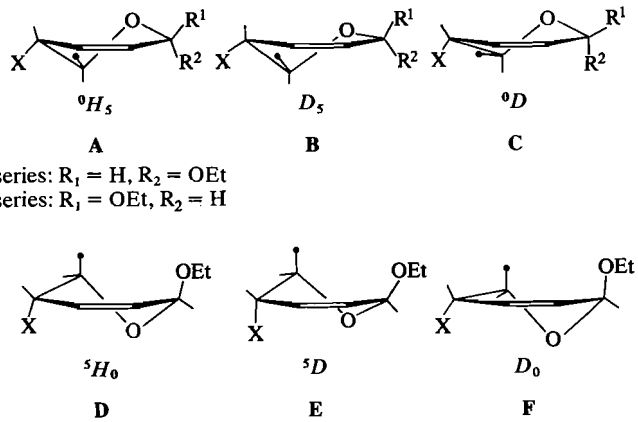
[a]From 100 MHz spectra of solutions in $CDCl_3$ containing tetramethylsilane as standard. In addition to the signals listed, all compounds showed substituent resonances as required by the structures.
[b]Signal multiplicities are indicated as cm (complex multiplet), d (doublet), nm (narrow multiplet), m (multiplet), o (octet), q (quartet), s (singlet), and t (triplet). Values refer to signal midpoints.
[c]Measured at 250 Hz sweep width.
[d]Estimated from observed splittings; see footnote 4 in the text.
[e]Splittings observed in the H-5 multiplet; these may not equal the coupling constants because of the proximity of the H-6,6′ signal.



contained small (1–2 Hz) vicinal ($J_{3,4}$), allylic ($J_{2,4}$), and homoallylic ($J_{1,4}$) couplings that were mirrored in the corresponding, downfield proton signals. An additional splitting of 4 Hz discernible in the H-4 signals of **15** and **16** was due to vicinal coupling with H-7, the methine proton in the side-chain.

A more detailed analysis of the signal fine-structure should make possible a correlation of the various small vicinal and allylic couplings just mentioned with the conformational shape of the molecules. It appeared reasonable to assume that the products would in this regard resemble the parent glycoside **1**, for which the $^0H_5$ half-chair conformation (formula **A**) had been proposed (9). Upon detailed spectral analysis of related molecules, Paulsen and co-workers (21) and Thiem *et al.* (22) recently came to the conclusion that α-D-*erythro*-hex-2-enopyranosides tend to adopt a noticeably flattened version of this half-chair, approaching the corresponding "sofa form" in which C-5 protrudes below the plane defined by C-1 to C-4 and the ring oxygen atom (formula **B**);[3] this geometry has been confirmed by X-ray crystallography in three cases (21–23). The spectra of our α-D-*erythro* products generally supported a similar molecular shape, rather than the alternate ^0D sofa form (formula **C**) advocated by Watanabe *et al.* (24) for some 4-amino hex-2-enosides closely related to our derivatives, which they synthesized by different methods. Thus, the allylic couplings $^4J_{1,3}$ and $^4J_{2,4}$ of −1 to −1.2 and −2 to −2.5 Hz, respectively, implied dihedral angles $\Phi_{1,2}$ and $\Phi_{3,4}$ in the ranges of 50–55 and 67–80°, according to Garbisch's relationship (25) given in eq.[1]

[1] $^4J = 1.3 \cos^2 \Phi - 2.6 \sin^2 \Phi \ (0° \leq \Phi \leq 90°)$

[2] $^3J = 6.6 \cos^2 \Phi + 2.6 \sin^2 \Phi \ (0° \leq \Phi \leq 90°)$

In an ideal D_5 sofa form, these angles are 60 and 90°, respectively; very small ring torsions in the direction towards a flattened $^0H_5$ form moves them into the indicated ranges. The homoallylic couplings, $^5J_{1,4}$ = 1.5–1.8 Hz, were in accord with those found (22, 26, 27) in other 2-enosides featuring comparable, mutual dispositions of H-1 and H-4. The vicinal couplings through sp^2 hybridized carbon ($^3J_{1,2}$ and $^3J_{3,4}$) require special comment. The relationship provided by Garbisch (25) for this situation (eq. [2]) fails to predict accurate values in the case of enopyranosides. It was first noted by Anet (28) that the parameter of +2.6 may be too large, and couplings smaller than the minimum value derivable from eq. [2], namely 2.6 Hz for Φ = 90°, have since been observed on numerous occasions (20–22, 24, 26, 27, 29–32). However, qualitatively the small coupling $J_{3,4}$ = 2 Hz, consistently shown by our products (Table 3), certainly was in line with a large dihedral angle $\Phi_{3,4}$ as required by the conformation discussed. For an angle $\Phi_{1,2}$ of 50–55°, eq. [2] predicts $^3J_{1,2}$ values of 3.9–4.3 Hz; taking into account the well-known weakening of vicinal coupling at the anomeric center, in addition to an inherent inaccuracy of the equation, the observed values of 2.5–2.8 Hz do appear reasonable. Finally it may be noted that, for all of the new 4-substituted α-D-*erythro*-2-enopyranosides, the vinylic proton signal occurring at higher field was assigned to H-2, while that at lower field was assigned to H-3. The same chemical shift relation was observed by Lemieux *et al.* (26, 27) in the 4,6-acetals **25**, **26**, **29**, and **30**, and in the methyl pent-2-enopyranosides **31** and **32**; corresponding assignments have since been made for numerous hex-2-enopyranose derivatives (14, 24, 30, 32). On the other hand, the relation is the *reverse* in pent-2-enofuranosides (27), in some of the aforementioned enopyranosyl phosphonates (21), and in certain disaccharidic analogs of **1** (22,

[3]The symbol *SO* has been used for sofa conformations, e.g., SO_5 for **B** (22). Inasmuch as single-letter conformational symbols are now in general use and *S* is already reserved for skew forms, we propose the letter *D* (from divan) for such conformations.

31, 33*a*). In compound **1** itself (and also in **2**) the vinylic signals happen to coincide,[4] a phenomenon encountered not infrequently in this series (Table 3 and refs. 20 and 29), and its is therefore clear that such shift differences as may be observable are quite sensitive to structural differences. A justification for our mode of assignment derives from the fact that the signal attributed to H-2 (δ 5.8 ± 0.1) incurred little change from the resonance position in **1** (δ 5.86), whereas a downfield shift to 6.15 ± 0.15 was evident for the other signal, which could therefore be allocated to H-3, the proton vicinal to the site of chemical modification.

An evaluation of the spectra of the β-glycosides **18**–**20***a* obtained from the β-D-*erythro* enoside **2** (or **2***a* in the case of **20***a*) must begin with a consideration of **2** itself. This deserves to be done in some detail as it is pertinent also to the discussion of optical rotations that will be presented in a subsequent section. For some 2-substituted analogs of **2**, namely, certain β-linked D-*erythro*-hex-2-enopyranose derivatives bearing an acetoxy group at C-2, the inverted, $^5H_0$ half-chair conformation (33*b*, 34) or a flattened version approaching the closely related ^5D sofa conformation (22) have been deduced from nmr data. No doubt the nonbonded interaction existing in such compounds, between the vinylic substituent and the neighboring, quasi-equatorial β-anomeric group (the $A^{(1,2)}$ strain (35)) contributes jointly with the anomeric effect to destabilization of the normal $^0H_5$ half-chair and favors inversion, overcoming opposition by a C-1,5 *syn*-diaxial-type substituent interaction (which in half-chair conformations is diminished anyway). No such opposing interaction is present in alkyl 4-*O*-acetyl-2,3-dideoxypent-2-enopyranosides, e.g. **28** and **32**, which on the strength of the anomeric effect alone prefer a conformation wherein the anomeric group is pseudoaxial rather than one wherein it is pseudoequatorial (**28′** and **32′**) (27, 29). Although in **2** the anomeric effect could be anticipated to favor a similar conformation, it was more difficult to predict whether 1,5-substituent interaction would significantly counteract. The spectrum of **2** showed the H-4 signal as a doublet of narrow multiplets at δ 5.21. The largest spacing (5.0 Hz) was mirrored in the upfield multiplet given by H-5 and hence represented $J_{4,5}$. This coupling immediately revealed a substantial deviation from the $^0H_5$ or D_5 forms (formulas **A** and **B**) in which the α-glycosides were found to reside, and for which $J_{4,5}$ = 9–10.5 Hz. On the other hand, the value appeared too large to be compatible with the inverted conformations $^5H_0$, ^5D, and D_0 (formulas **D**–**F**) where $\Phi_{4,5}$ is in the range 60–90° and $J_{4,5}$ should therefore be only 1–3 Hz. A possibility is the ^0D sofa form (formula **C**) with $\Phi_{4,5}$ = 150° but, as the sole representation of **2**, this is deemed unlikely for it does not have the benefit of the anomeric effect. Unfortunately, the small additional splittings observed in the H-4 signal and those present in the H-1 signal could not be used to decide the matter. However, the data were consistent with the assumption that **2** exists as a conformational equilibrium to which an inverted form such as $^5H_0$ or ^5D makes a large contribution.[4]

Now, the spectra of the β-glycosides **18**–**20***a* paralleled that of **2** in that they all displayed similar $J_{4,5}$ values, with those of the *C*-alkyl derivatives **20** and **20***a* being even somewhat smaller (~ 4 Hz). In view of the foregoing discussion this feature was compatible with the β-D-*erythro* configuration and suggested conformational similarity to **2**, with perhaps an increased preference for an inverted form in **20** and **20***a*. The assigned configuration was supported by the optical rotation of the products (see later), but definitive proof to exclude the β-D-*threo* configuration could not be obtained from the nmr data alone, mainly because the olefinic proton signals were ill resolved and pertinent *J* values could not be determined. However, one noteworthy observation relates to a comparison of the *C*-alkyl derivatives in the two anomeric series (**15** and **16** vs. **20** and **20***a*) with regard to the vicinal $J_{4,7}$ couplings found in the H-4 and sidechain methine proton signals. The most favored torsional orientation of the C-4 substituent about the C-4,7

[4]Because of this coincidence in **1**, the protons H-3, H-2, and H-1 constitute an AA′X system, as do H-2, H-3, and H-4. Hence, H-1 and H-4 are expected to give multiplets with splittings arising from averaging of the coupling constants involved. The two narrow parts of the wide H-4 doublet ($J_{4,5}$ = 9.2 Hz) each appeared as crude quartets with a line separation of ~0.7 Hz. Line separation in the H-1 multiplet (W_H = 3.6 Hz) was ~1.2 Hz. Calculation shows that these patterns can arise from estimated coupling constants as given in Table 3. These constants are compatible with the geometry of a flattened $^0H_5$ conformation approaching the D_5 form.

In compound **2**, the vinylic protons also coincided and the situation is, therefore, analogous. The two constituent parts of the H-4 doublet were quartets with a line separation of ~1.2 Hz, whereas H-1 gave a quartet with a line separation of 0.8 Hz. We have calculated approximate splittings as may be expected for the six conformations **A** – **F**, using estimated coupling constants that seemed reasonable for the respective, dihedral angles; eq, [1] was used for calculating $J_{1,3}$ and $J_{2,4}$, and values reported in this paper and elsewhere (14, 22, 26, 27, 33) were taken into account for choosing $J_{1,2}$, $J_{1,4}$, and $J_{3,4}$. The resultant splittings ranged from 0.3 to 1.7 Hz for H-1 and from 0.5 to 1.9 Hz for H-4, but none of the sets of values so derived for each individual conformation corresponded well with the actually observed pattern. However, the data were accommodated by a 1:1 equilibrium of the ^5D form (calculated splittings: H-1, 0.5; H-4, 1.9 Hz) and the D_5 form (calculated splittings: H-1, 1.0 Hz; H-4, 0.5 Hz).

bond should place H-7 antiperiplanar to H-4, allowing the bulky alkoxycarbonyl groups to point away from the sugar ring. In **15** and **16**, however, such an arrangement would imply a *syn*-parallel orientation of one of these groups with the acetoxymethyl group at C-5. To alleviate this, some rotation about the C-4,7 bond appears to take place, resulting in a diminished $J_{4,7}$ value (4 Hz). By contrast, there is no such steric encumbrance to be expected for **20** and **20***a* if indeed they are D-*erythro* compounds residing in an inverted conformation. In keeping with this assumption, their $J_{4,7}$ values of 9.0 Hz indicated a more nearly antiperiplanar orientation of H-4 and H-7.

The 3,4-unsaturated glycosides **9** and **21** displayed closely similar overall patterns of their respective ring proton signals, although H-1 to H-4 were slightly more deshielded in **9**. Specifically, they showed nearly identical patterns in their very narrow H-1 signals, their virtually coinciding olefinic proton signals (H-3 and H-4), and their complex multiplets for H-5. Also very similar in shape and width were the complex multiplets given by H-2, except that in **21** the multiplet was doubled by coupling with H-7. A splitting of 9.5 Hz indicated here, too, an H-2,7 *anti* situation. Very weak H-1,2 coupling ($\leq$ 1 Hz) as observed in **9** and **21** is characteristic for 3-enopyranosides having the α-D-*threo* configuration whereas corresponding α-D-*erythro* epimers show values of 3.5–4 Hz (36, 37, and refs. in Table 5). The optical rotations confirmed the assignment.

The parameters for **3** (Table 3) were in fair agreement with data recently given (14) for the same compound (but measured in a different solvent). They bear out a flattened $^0H_5$ half-chair conformation, which is in harmony with previous observations (33*b*) of similar conformational behavior in α-D-*threo* and α-D-*erythro*-hex-2-enopyranose systems. Finally, the data for compound **22**, whose H-1, H-2, and H-3 signals were clearly separated and visible in the spectrum of the crude mixture of **21** and **22**, allowed allocation of the α-D-*threo*-2-enoside structure to this minor product.

Optical Rotations

The configurational assignments made by spectroscopy were corroborated, and questions that remained open were settled, by the inclusion of arguments derived from comparison of optical rotations, with due consideration of conformational aspects (38) of optical superposition. Table 4 lists the molar rotations, $[M]_D = [\alpha]_D \times$ mol. wt./100, for chloroform solutions unless indicated otherwise. It

is seen that all of the α-D-*erythro* 2-enopyranosides, whose configurations are secure, are strongly dextrorotatory. This is fully in line with abundant data on analogous molecules found in the literature and conforms to a generality first stressed by Ferrier and co-workers (39). As has also been noted previously, it is apparent that the magnitude of $[M]_D$ depends to a considerable degree on the nature and size of the 4-substituent (compare, for example, ref. 27). The relatively low value of the primary amine **10**, as compared to the other amines, may perhaps be due to special effects of solvation or hydrogen bonding.

The β-glycosides **18**–**20***a* are less dextrorotatory than their α-linked counterparts; in either series the rotations are lower for *C*-alkylated than for aminated derivatives. However, in the parent diacetates **2** and **1** the difference is very small, and in benzene solution **2** is even *more* dextrorotatory than **1** (+383 vs. +276°), an anomaly that has been suspected (40) before. Deviations from Hudson's rule of isorotation have also been recognized in (nonacetylated) pairs of anomeric alkyl 2,3-dideoxypent-2-enopyranosides (27, 29) and in 2-acetylated 3-deoxy-hex-2-enopyranosides (33*b*). Likewise, the anomeric assignments for the aforementioned hexenopyranosyl phosphonates, originally made on the basis of optical rotations,

Values based on calculation are shown in italics.

SCHEME 2

later had to be revised (21, 41). The anomalies doubtless are rooted in the conformational behavior of β-D-glycosides in the enoside family (*vide supra*). In order to put the choice between the 4-epimeric alternatives for **18–20***a* on firm ground, and because there is a paucity of analogous β-D-*threo* derivatives for comparison, it became desirable to examine what sign and range of rotation could be predicted for each of the two configurational possibilities. Fortunately, this could be done with the aid of data, provided by Lemieux *et al.* (26, 27), on six securely characterized compounds (the benzylidene derivatives **25**, **26**, **29**, and **30**, and the pentosides **31** and **32**) in conjunction with our own data on **1**, **2**, and **3**. The argument is illustrated in Scheme 2. Compare the conformationally fixed acetal **25** with the 4-acetate **27** (the enantiomer of **32**) that is known to exist in the same, or nearly the same, conformation. The structural alteration entails a rotatory shift of −70° ($[M]_D$ values). An identical structural change in the conformationally rigid, β-anomeric acetal **26** may be expected to

cause the same shift, which leads to a *calculated* rotation of 43° for the conformer **28′** of **28**. However, compound **28** (the enantiomer of **31**) is known to exist predominantly in the conformation having pseudoaxial substituents as depicted, and the difference to its actual rotation of +232°, namely 189°, therefore represents the sum total of optical changes associated with this conformational equilibration. Now consider the structural alteration **27** → **1**, disregarding the optically insignificant replacement of OMe by OEt. Introduction of the 5-acetoxymethyl substituent increases the rotation by 49°. Use of this increment in applying the same manoeuvre to **28′** leads to a calculated rotation of +92° for **2′**, a conformer of **2** deduced by nmr spectroscopy to be unstable (*vide supra*). If one now makes the assumption that the equilibration **2′** ⇌ **2** is attended by a similar optical contribution as the process **28′** ⇌ **28**, and consequently uses the same value (+189°) for it, a calculated rotation of +281° in indicated for **2**, in remarkably good agreement[5] with the measured value of 285°. Performance of the same exercise starting with the D-*threo* acetals **29** and **30** involves the pentosides **31** and **32** as well as the hexenoside **3** and should lead to a good indication of the rotation to be expected for the latter's unknown β-anomer **33**. As the scheme shows, different parameters apply here for the various transformations. Thus, in **29** → **31**, replacement of the fused ring by 4-acetoxy, and in **31** → **3**, the introduction of a 5-acetoxymethyl group, produce rotatory changes opposite in sign and different in degree compared to the preceding series. The increment for conformational inversion (+75°) is also different. The final result of the exercise is the prediction that β-D-*threo* compounds of type **33** will be *highly levorotatory regardless of conformational preference*, and it is therefore evident that **18–20***a* must be β-D-*erythro* compounds. As an ancillary bonus, the calculations contribute to an understanding why it is inadvisable to rely on Hudson's rule of isorotation for anomeric (as opposed to epimeric) assignments in enopyranoside pairs which are not constrained in the same rigid conformation. Although the rotational differences in such pairs can be fairly large and in the expected direction (Table 4), substituent and solvent influences may cause them to become quite small (even reversed), as exemplified by **27**/**28**, **1**/**2**, and **3**/**33**.

For the 3,4-unsaturated α-D-glycosides **9** and **21** the *threo* configuration was buttressed, and the *erythro* configuration rejected, by comparing their specific rotations with those of model compounds found in the literature (Table 5). The product which was formed together with **21** and judged on the basis of ^{13}C nmr data to be a positional isomer rather than a stereoisomer, but differed from **15** and was therefore assigned formula **22**, showed strong levorotation as expected for an α-D-*threo* 2-enoside.

Summary

In summary, the palladium-catalyzed substitution of allylic acetates has proved to be a useful method for the preparation of unsaturated amino and branched-chain sugars. With the hex-2-enopyranoside 4,6-diacetates thus far employed as substrates, it leads chiefly, but not in every case exclusively, to 4-substituted 2-enopyranosides. As far as

[5]There may be an element of coincidence in this, since the equilibrium constants for **28′**⇌**28** and **2′**⇌**2** are not necessarily the same and, furthermore, application of the same increment (+189°) to both equilibrations may not be entirely sound. Nevertheless, a reasonable agreement was to be expected.

can be judged from present results, this substitution occurs essentially stereospecifically with retention of configuration at C-4. Evidently the palladium catalyst species, in forming the π-allyl complex, prefers to place itself on the side of the pyranose ring opposite to the acetoxy group it is displacing, which is in accord with the general understanding of this interaction (6, 7). The palladium is then in turn displaced by the nucleophile approaching from the opposite direction, with resultant net retention of configuration. As regards the regioselectivity of the nucleophilic attack, the preference for C-4 may in part be due to polarisation of the π-allyl complex by the electron-withdrawing effect of the anomeric center. For the reactions with **1**, steric hindrance to nucleophile approach at C-2 by the neighboring, quasi-axial glycosidic group can probably be invoked as a contributing factor since selectivity was indeed most pronounced in that series. However, selectivity was similar in the aminations of the β-glycoside **2**, although it was noticeably diminished in *C*-alkylations of **2** and **2***a*. The apparent lack or reversal of regioselectivity in the two reactions thus far studied with **3** is interesting, as is the exception provided by dibenzylamine in its reaction with **1**. As far as the latter is concerned, thermodynamic factors may play a role since allylic amination (but not *C*-alkylation) is believed to be reversible (7). However, it would clearly be premature to attempt, at this stage, an exhaustive assessment of the factors which govern the stereochemistry of these substitutions in enopyranoside systems.

From a practical point of view it may be noted that the aminations here described offer an attractive approach to syntheses of 4-aminopolydeoxy sugars related to such antibiotics constituents as forosamine (2,3,4,6-tetradeoxy-4-dimethylamino-D-*erythro*-hexose, ossamine (its D-*threo* epimer), tolyposamine (4-amino-2,3,4,6-tetradeoxy-L-*erythro*-hexose), and the sugar moiety (4-amino-2,3,4-trideoxy-D-*erythro*-hex-2-enopyranuronic acid) of blasticidin S (44).

Experimental

Optical rotations were measured at room temperature in a Perkin-Elmer 141 automatic polarimeter and refer to chloroform solutions unless otherwise stated. Infrared spectra of syrupy compounds were obtained from liquid films, and those of crystalline compounds from Nujol mulls. For tlc, precoated silica gel plates SIL G-25 UV_{254} were used, and for preparative tlc, glass plates were coated with MN-Kieselgel G/UV_{254} (both products of Macherey-Nagel and Co., West Germany). Spots were made visible by inspection under uv light and/or by use of a spray with 5% sulfuric acid in ethanol and subsequent heating. Column chromatography was performed with Silica Gel 60 (E. Merck AG, West Germany). Unless otherwise indicated, solvent systems employed for development were mixtures of ethyl acetate and petroleum ether in the proportions (A) 1:2, (B) 1:3, (C) 1:4, and (D) 1:10. Here and elsewhere in the text, petroleum ether refers to the fraction having bp 30–60°C.

Preparation of the Unsaturated Glycoside Diacetates 1, 2, and 3

Ethyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside (**1**) was prepared from 3,4,6-tri-*O*-acetyl-1,5-anhydro-2-deoxy-D-*arabino*-hex-1-enitol (tri-*O*-acetyl-D-glucal) by the method of Ferrier (9); it showed mp 79°C and $[\alpha]_D$ +107° (*c* 1, benzene) as reported; $[\alpha]_D$ +117.3° (*c* 2.2, chloroform).

For the preparation of the β-anomer **2**, tri-*O*-acetyl-D-glucal was first ethoxymercurated, in analogy to its methoxymercuration described by Inglis *et al.* (12). A solution of the glycal (5.0 g, 18.4 mmol) in absolute ethanol (20 mL, dried over and distilled from magnesium) was added to a stirred suspension of mercuric acetate (6.14 g, 19.2 mmol) in absolute ethanol (70 mL) whereupon the salt dissolved rapidly. Ethyl 3,4,6-tri-*O*-acetyl-2-acetoxymercuri-2-deoxy-β-D-glucopyranoside began to crystallize after an hour and was collected after overnight storage of the reaction mixture. (It thus proved unnecessary to convert the product into the chloromercuri compound as had been done in the methoxymercuration just cited.) The crystals (3.50 g, 33%) had mp 177°C after recrystallization from ethyl acetate; $[\alpha]_D$ −15.5° (*c* 2.3); ν_{max} (Nujol): 1735 and 1240 (OAc), 1620–1600 (AcO^-), 1300, 1140–1000, and 920 cm^{-1}. Two sharp, medium strong bands at 755 and 690 cm^{-1} were possibly due to Hg-O vibrations (45). Nuclear magnetic resonance (100 MHz, $CDCl_3$) δ: 5.17 (dd, $J_{2,3}$ = 11.3, $J_{3,4}$ = 9.3 Hz, H-3), 4.95 (t, J = 9.3 Hz, H-4), 4.71 (d, $J_{1,2}$ = 10 Hz, H-1), 4.34 (dd, $J_{5,6}$ = 4.7, $J_{6,6'}$ = 12 Hz, H-6), 4.09 (dd, $J_{5,6'}$ = 2.7, $J_{6,6'}$ = 12 Hz, H-6′), 3.95–3.4 (m, 3H, *Me*—CH_2 and H-5), 2.62 (dd, J = 10 and 11.3 Hz, H-2), 2.15, 2.06, 2.02 (3 s, total intensity 12H, 4 OAc), 1.22 (t, J = 7 Hz, ethyl CH_3). *Anal.* calcd. for $C_{16}H_{24}HgO_{10}$ (577): C 33.31, H 4.19; found: C 33.51, H 4.36.

A solution of this acetoxymercuri derivative (1.0 g) in aqueous, 75% ethanol (25 mL) was mixed with a solution of sodium iodide (1.5 g) in 25 mL of the same solvent. Complete conversion of the mercurial (R_f 0.0) into **2** (R_f 0.6) was indicated by tlc (solvent A) after 30 min. The mixture was concentrated *in vacuo* to one-third of its volume and then diluted with water to 50 mL. The organic product was transferred into ether by several extractions, and the extract was washed successively with sodium thiosulfate solution and water, dried over $MgSO_4$, and evaporated to give **2** as a colorless syrup (0.38 g, 85%); $[\alpha]_D$ +148.5° (*c* 3.6, benzene); ν_{max}: 1750 and 1240 (OAc), 1130–970, 910, 815, and 750 cm^{-1}. *Anal.* calcd. for $C_{12}H_{18}O_6$ (258.3): C 55.80, H 7.02; found: C 55.82, H 7.00.

The known (12, 40) *methyl* glycoside analog (**2***a*) of **2** was prepared by analogous methoxymercuration (11) followed by elimination (12). The nmr data (100 MHz, $CDCl_3$) of the intermediate methyl 3,4,6-tri-*O*-acetyl-2-chloromercuri-2-deoxy-β-D-glucopyranoside δ: 5.18 (dd, $J_{2,3}$ = 11.5, $J_{3,4}$ = 9 Hz, H-3), 4.93 (t, J = 9 and 9.5 Hz, H-4), 4.65 (d, $J_{1,2}$ = 9.7 Hz, H-1), 4.32 (dd, $J_{5,6}$ = 5, $J_{6,6'}$ = 12.5 Hz, H-6), 4.09 ($J_{5,6'}$ = 2.5, $J_{6,6'}$ = 12.5 Hz, H-6′), 3.67 (o, H-5), 3.52 (s, 3H, OMe), 2.55 (dd, J = 9.7 and 11.5 Hz, H-2), 2.08 and 2.04 (s, 6 and 3H, 3 OAc).

Ethyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*threo*-hex-2-enopyranoside (**3**) (14) was obtained by conventional acetylation with acetic anhydride in pyridine (1 h at 25°C), of a crystalline sample of ethyl 2,3-dideoxy-α-D-*threo*-hex-2-enopyranoside[2] kindly donated by Professor B. Fraser-Reid. The diacetate was a colorless syrup, R_f 0.8 (solvent A), $[\alpha]_D$ −171.5° (*c* 1.5, chloroform) (lit. (14) $[\alpha]_D$ −171° (dichloromethane); ν_{max}: 1750 and 1240 (OAc), 1110, 1050, 1020–970, 915, 850, 760 and 600 cm^{-1}.

General Procedure for Allylic Substitution

For Amination

The catalyst, tetrakis(triphenylphosphine)palladium(0), may be prepared according to Coulson (46) or purchased from Aldrich Chemical Company, Inc. Tetrahydrofuran used as a solvent was reagent grade and was purified further by drying over, and distillation from, lithium aluminum hydride. The other reactants were also reagent grade but used without pretreatment unless specially noted. Reactions were normally performed on a 0.5 mmol scale with respect to the glycoside employed (0.13 g). Deviations from this amount of starting glycoside are specifically indicated and imply proportionate changes in the amounts of solvent and other reactants. Typically the glycoside (0.13 g, 0.5 mmol), triphenylphosphine (93 mg, 0.35 mmol), and the catalyst (41 mg, 0.035 mmol) were stirred in tetrahydrofuran (10 mL) for 30 min at room temperature, under nitrogen, in a flask equipped with reflux condenser and gas inlet. An excess of the amine (3.3–3.5 mmol) was then added by syringe, and the mixture was boiled under reflux until monitoring by tlc indicated absence of the starting glycoside. (See individual sections for the various reaction times.) The cooled reaction mixture was then partitioned between ether and water. The aqueous phase was extracted with ether (4 × 30 mL), and the combined extracts and organic phase were dried ($MgSO_4$) and evaporated to give a yellow residue which contained the aminated sugar together with triphenylphosphine oxide, residual amine, and other impurities. Column chromatography or preparative tlc of the material, as indicated in the individual sections, furnished the desired product in homogeneous form, usually as a colorless, analytically pure oil.

For Alkylation

The mixture of glycoside, triphenylphosphine, and catalyst was prepared as described above, except that only 5 mL of tetrahydrofuran was used as the solvent. Separately and simultaneously, a solution of the sodio derivative of the reactive methylene component was prepared. For this purpose, sodium hydride (130 mg of a 61% dispersion in mineral oil; ca. 3.3 mmol) was washed twice with hexane and once with tetrahydrofuran by decantation and was then suspended in 5 mL of tetrahydrofuran. The methylene component (3.35 mmol or slightly more) was added dropwise with stirring, which caused the hydride to dissolve completely in the course of 15 min. The solution was added, in one portion, to the aforementioned solution of reactants when the latter had interacted for 30 min, and the mixture was then heated at reflux until tlc indicated completion of the reaction. The precautions and processing modes applied were the same as those in the aminations.

*Ethyl 6-O-Acetyl-2,3,4-trideoxy-4-diethylamino-α-D-*erythro-*hex-2-enopyranoside (4)*

Compound **4** was obtained from **1** and diethylamine (0.35 mL) after a reaction time of 48 h and preparative tlc (solvent C). The colorless oil (110 mg, 80%) showed R_f 0.9 (tlc with solvent A); $[\alpha]_D$ +169.8° (*c* 1); ν_{max}: 1745 and 1260 (OAc), 1150–1000 (C—N, C—O—C), and 730 (*cis* alkene) cm^{-1}. *Anal.* calcd. for $C_{14}H_{25}NO_4$ (271.4): C 61.97, H 9.29, N 5.16; found: C 62.11, H 9.18, N 4.97.

*Ethyl 6-O-Acetyl-2,3,4-trideoxy-4-piperidino-α-D-*erythro-*hex-2-enopyranoside (5)*

Prepared exactly like the preceding compound, but with piperidine (0.33 mL), **5** was a colorless oil (100 mg, 70%), R_f 0.9 (tlc in solvent A); $[\alpha]_D$ +164.3° (*c* 1); ν_{max}: 1745 and 1240 (OAc), 1160–1000 (C—N, C—O—C), and 730 (*cis* alkene) cm^{-1}. *Anal.* calcd. for $C_{15}H_{25}NO_4$ (283.4): C 63.58, H 8.89, N 4.94; found: C 63.41, H 8.97, N 4.67.

*Ethyl 6-O-Acetyl-4-(N-cyclohexyl)methylamino-2,3,4-trideoxy-α-D-*erythro-*hex-2-enopyranoside (6)*

From **1** (200 mg) and cyclohexylmethylamine (0.44 mL), compound **6** was obtained after a reaction time of 5 days; it was accompanied by traces of 2 slow-moving by-products (tlc with solvent A) which were readily removed by preparative tlc (solvent C). The colorless, homogeneous product (180 mg, 75%) had $[\alpha]_D$ +149.7° (*c* 1); ν_{max}: 1745 and 1240 (OAc), 1120–1000 (C—N, C—O—C), and 730 (*cis* alkene) cm^{-1}. *Anal.* calcd. for $C_{17}H_{29}NO_4$ (311.4): C 65.56, H 9.39, N 4.50; found: C 65.53, H 9.27, N 4.51.

*Ethyl 6-O-Acetyl-4-(N-benzyl)methylamino-2,3,4-trideoxy-α-D-*erythro-*hex-2-enopyranoside (7)*

Reaction of **1** with benzylmethylamine (0.5 mL) was complete after 24 h, and tlc (solvent A) showed a main spot (R_f 0.8) accompanied by a minor spot (R_f 0.7) which was presumably due to an isomer. Isolated by preparative tlc (solvent C), the major product **7** was a colorless syrup (140 mg, 87%) that tended to crystallize on strong cooling (mp below 0°C); $[\alpha]_D$ +165.4° (*c* 1); ν_{max}: 3100–3050, 1600, 1500, and 700 (Ph), 1745 and 1240 (OAc), 1120–970 (C—N, C—O—C), and 740 (*cis* alkene) cm^{-1}. *Anal.* calcd. for $C_{18}H_{25}NO_4$ (319.4): C 67.69, H 7.89, N 4.39; found: C 67.53, H 7.83, N 4.51.

*Ethyl 6-O-Acetyl-4-dibenzylamino-2,3,4-trideoxy-α-D-*erythro-*hex-2-enopyranoside (8) and Ethyl 6-O-Acetyl-2-dibenzylamino-2,3,4-trideoxy-α-D-*threo-*hex-3-enopyranoside (9)*

The reaction of **1** with dibenzylamine (0.64 mL) was nearly complete after 30 h. The tlc (solvent B) indicated the presence of 2 main products having $R_f \sim 0.8$ (major product) and ~ 0.7 (minor product), together with traces of slow-moving by-products. Integration of the sufficiently separated acetoxyl group signals in the nmr spectrum of the crude mixture (166 mg, 83%) suggested that the two main components were present in the ratio 7:3. The components were separated by preparative tlc using multiple irrigation with solvent D, which furnished either product free from the other (according to nmr spectra).

The syrupy, slower-moving, minor product proved to be the isomer **8**. It crystallized on storage in the refrigerator. Collected after trituration with petroleum ether and recrystallized from that solvent, it showed mp 78–79°C; $[\alpha]_D$ +171.4° (*c* 1.4); ν_{max}: 3100–3040, 1600, 1500, and 700 (Ph), 1745 and 1240 (OAc), 1120–975 (C—N, C—O—C), and 755–735 (*cis* alkene) cm^{-1}. *Anal.* calcd. for $C_{24}H_{29}NO_4$ (395.5): C 72.89, H 7.39, N 3.54; found: C 72.69, H 7.56, N 3.54.

The faster-moving, major product (**9**) failed to crystallize; $[\alpha]_D$ +155.3° (*c* 1.2). Its infrared spectrum was very similar to that of **8**, showing only minor differences in the fingerprint region. *Anal.* calcd. as for **8**; found: C 72.57, H 7.83, N 3.68.

*Ethyl 6-O-Acetyl-4-benzylamino-2,3,4-trideoxy-α-D-*erythro-*hex-2-enopyranoside (10) and Ethyl 6-O-Acetyl-4-(N-benzylacetamido)-2,3,4-trideoxy-α-D-*erythro-*hex-2-enopyranoside (12)*

After the reaction of **1** with benzylamine (0.36 mL) for 24 h, tlc with solvent A indicated the presence of 3 products ($R_f \sim 0.6$, 0.25, and 0.2) together with some remnant **1** ($R_f \sim 0.75$). An additional 10 mg of catalyst and 0.1 mL of benzylamine were introduced and refluxing was continued for another 9 h, which caused **1** to disappear completely. Upon processing, the mixture of products was applied to a silica gel column that was irrigated with solvent C. The fast-moving product (**10**) was isolated as a colorless oil (48 mg, 31%); $[\alpha]_D$ +115.5° (*c* 1.1); ν_{max}: 3200 (broad, NH), 3100–3050, 1600 and 1500 (weak), and 700 (Ph),

For personal use only.

1740 and 1240 (OAc), 1100–1000 (C—N, C—O—C), and 730 (*cis* alkene) cm^{-1}. On aging of the sample, an amide band at 1650 cm^{-1} developed owing to O→N acetyl migration.

The 2 slow-moving products were subsequently eluted from the column as a mixture. An attempt was made to separate this mixture by preparative tlc (solvent D), but separation was unsatisfactory in that each of the 2 bands isolated contained a substantial proportion of the other component (~ ⅓ according to nmr spectra). The spectra suggested that the components were the *O*-deacetylated derivative (**11**, R_f 0.25) of **10**, and partially *O*-deacetylated **1** (R_f 0.2). The fractions were individually acetylated with acetic anhydride and pyridine (16 h at room temperature), whereupon they gave similar tlc patterns showing a fast-moving spot (**1**) and a slow-moving spot (the *N*-acetyl-*O*-acetyl derivative **12**). Preparative tlc (solvent D) of these mixtures gave a total of 65 mg (50% recovery) of **1**, identified by its nmr spectrum and an undepressed mixture mp of 79–81°C; and oily but homogeneous **12** (27 mg, 15%) showing $[\alpha]_D$ +129° (*c* 1.1); ν_{max}: 3100–3050, 1610 and 1500 (weak), and 700 (Ph), 1740 (ester CO), 1650 (amide CO), 1250–970 (multiple bands), 900, and 735 cm^{-1}. *Anal.* calcd. for $C_{19}H_{25}NO_5$ (347.4): C 65.69, H 7.25, N 4.03; found: C 65.53, H 7.41, N 3.83.

Ethyl 6-O-*Acetyl-2,3,4-trideoxy-4-[bis(methoxycarbonyl)-methyl]*-α-D-erythro-*hex-2-enopyranoside (15)*

Reaction (10 h) of **1** and dimethyl malonate (0.40 mL) gave **15** as the sole product, according to tlc (R_f ~ 0.4, solvent A). The colorless syrup (145 mg, 87%) obtained after processing showed $[\alpha]_D$ +93.5° (*c* 1.3); ν_{max}: 1740 (ester CO), 1250–970 (C—O—C), and 730 (*cis* alkene) cm^{-1}. *Anal.* calcd. for $C_{15}H_{22}O_8$ (330.3): C 54.54, H 6.71; found: C 54.72, H 6.89.

Ethyl 6-O-*Acetyl-2,3,4-trideoxy-4-[bis(ethoxycarbonyl)-methyl]*-α-D-erythro-*hex-2-enopyranoside (16)*

Compound **1** and diethyl malonate (0.50 mL) were allowed to react for 24 h. In this instance, the product **16** had the same R_f value (0.8) as **1** and could only be distinguished by the light brown color of its spot, which differed from the black spot given by **1** (tlc with solvent A). Possibly the reaction was finished earlier. Processing gave **16** (150 mg, 83%) as a colorless syrup, $[\alpha]_D$ +93.4° (*c* 1.1); ν_{max}: 1750, 1730 (ester CO), 1250–1000 (C—O—C), and 730 (*cis* alkene) cm^{-1}. *Anal.* calcd. for $C_{17}H_{26}O_8$ (358.4): C 56.97, H 7.31; found: C 56.81, H 7.57.

Ethyl 6-O-*Acetyl-2,3,4-trideoxy-4-[methoxycarbonyl-(phenylsulfonyl)methyl]*-α-D-erythro-*hex-2-enopyranoside (17)*

Compound **1** (300 mg, 1.16 mmol) was allowed to react with a 0.117 *M* solution (65 mL) of methyl phenylsulfonylacetate sodium in tetrahydrofuran. Incomplete consumption of **1** was noted by tlc (solvent A) after 48 h; an additional 30 mg of catalyst and 4 mL of the solution of the sodio ester solution were introduced, whereupon **1** disappeared completely after a further 24 h of refluxing. There was formed one major product (R_f ~ 0.45) which was accompanied by a minor, slightly faster moving product. Column chromatography using solvent C as eluent gave 300 mg (63%) of the product as a syrup that still contained the minor by-product. Crystallization from ethyl acetate – petroleum ether furnished chromatographically pure **17**, mp 100–102°C; $[\alpha]_D$ +74° (*c* 2.8); ν_{max} (Nujol): 3100–3050, 1600, and 700 (Ph), 1750–1730 (ester CO), 1320 (S—O), 1250–950 (multiple bands, S=O, C—O—C), and 730 (*cis* alkene) cm^{-1}. *Anal.* calcd. for $C_{19}H_{24}O_8S$ (412.4): C 55.33, H 5.87, S 7.77; found: C 55.08, H 5.77, S 7.62.

Ethyl 6-O-*Acetyl-2,3,4-trideoxy-4-[bis(methoxycarbonyl)-methyl]*-β-D-erythro-*hex-2-enopyranoside (20)*

Reaction of **2** with dimethyl malonate (0.40 mL) was complete after 10 h; a single spot having R_f 0.55 was seen in tlc (solvent A). The product was isolated by use of a column which was eluted, first, with petroleum ether, and then with solvent D. Even though the oily product so obtained (145 mg, 87%) appeared chromatographically homogeneous, the presence of a small proportion (probably not more than 10%) of an isomer was revealed by the ^{13}C nmr spectrum; $[\alpha]_D$ +52.5° (*c* 3); ν_{max}: 1750–1730 (ester CO), 1300–1010 (multiple bands), 880–800, and 735 cm^{-1}. *Anal.* calcd. for $C_{15}H_{22}O_8$ (330.3): C 54.54, H 6.71; found: C 54.63, H 6.76.

Methyl 6-O-*Acetyl-2,3,4-trideoxy-4-[bis(methoxycarbonyl)-methyl]*-β-D-erythro-*hex-2-enopyranoside (20a)*

Compound **20***a* was obtained from **2***a* (120 mg) exactly as just detailed for **20**, after a reaction time of 20 h. The pale yellow syrup (125 mg, 83%) gave a single spot in tlc (R_f 0.6, solvent A) but contained, nevertheless, a small proportion of an isomer, according to the ^{13}C nmr spectrum; $[\alpha]_D$ +44° (*c* 0.5); ν_{max}: 1750 (ester CO), 1300–1050 (multiple bands), 970, 870–810, and 740 cm^{-1}. *Anal.* calcd. for $C_{14}H_{20}O_8$ (316.3): C 53.16, H 6.37; found: C 53.16, H 6.47.

Ethyl 6-O-*Acetyl-2,3,4-trideoxy-4-diethylamino*-β-D-erythro-*hex-2-enopyranoside (18)*

The reaction of **2** (130 mg) with diethylamine (0.85 mL) was not entirely complete after 20 h (tlc with solvent A); it was completed by adding further amounts of diethylamine (0.4 mL) and catalyst (20 mg) and continued refluxing for another 6 h. Processing included the passage of the crude product through a silica gel column which was eluted, first with petroleum ether and then with solvent D. Compound **18** was obtained as a colorless syrup (90 mg, 66%), R_f 0.3 (solvent A); $[\alpha]_D$ +133.6° (*c* 1.1); ν_{max}: 1745 and 1250 (OAc), 1200, 1120–1020 (C—N, C—O—C), 980, 900, 835, 800, 730, and 700 cm^{-1}.

Ethyl 6-O-*Acetyl-4-(*N-*benzyl)methylamino-2,3,4-trideoxy*-β-D-erythro-*hex-2-enopyranoside (19)*

The reaction between **2** (195 mg) and benzylmethylamine (0.75 mL) showed, after 24 h, a product that differed from **2** only in the color (light brown vs. black) of its tlc spot, but not in the R_f value (0.6 in solvent A). Refluxing was continued for another 24 h, which caused no change in the tlc picture. After processing (with use of dichloromethane instead of ether for extraction of the aqueous phase) and column chromatographic purification (elution with petroleum ether followed by solvent D), compound **19** was obtained as a colorless syrup (220 mg, 91%), $[\alpha]_D$ +118.2° (*c* 1.3); ν_{max}: 3100–3050, 1600, 1500, and 700 (Ph), 1745 and 1240 (OAc), 1120–970 (C—N, C—O—C), 900 and 810, and 755–730 (*cis* alkene) cm^{-1}. *Anal.* calcd. for $C_{18}H_{25}NO_4$ (319.4): C 67.69, H 7.89, N 4.39; found: C 67.47, H 8.13, N 4.26.

Ethyl 6-O-*Acetyl-2,3,4-trideoxy-2-[bis(methoxycarbonyl)-methyl]*-α-D-threo-*hex-3-enopyranoside (21) and Ethyl* 6-O-*Acetyl-2,3,4-trideoxy-4-[bis(methoxycarbonyl)methyl]-hex-2-enopyranoside (22)*

The reaction was performed with **3** (347 mg), triphenylphosphine (246 mg), and palladium catalyst (108 mg) in tetrahydrofuran (15 mL), to which was added dimethyl malonate (1.32 mL) and sodium hydride (61%; 343 mg) in tetrahydrofuran (10 mL). All of **3** had disappeared after 15 h of heating at reflux temperature. Thin-layer chromatography with solvent A showed a strong spot (R_f 0.6) together with a second, fairly strong, double spot (R_f ~ 0.1) and an intermediate trace spot. Column chromatography produced the fast-moving material (295 mg, 66%) which, although homogeneous in tlc, proved to be a ~3:1 mixture of **21** and **22**, according to ^1H and ^{13}C nmr spectra. This mixture of isomers showed $[\alpha]_D$ +24° (*c* 1.3) and an infrared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

spectrum that agreed with expectations. *Anal.* calcd. for $C_{15}H_{22}O_8$ (330.3): C 54.54, H 6.71; found: C 54.37, H 6.65.

The slow-moving material emerged from the column on continued elution with solvent D. There were obtained 2 fractions (55 and 65 mg), both of which showed methyl ester but lacked acetyl group resonances in the nmr spectrum. Acetylation with acetic anhydride and pyridine at room temperature left the first fraction unchanged whereas it converted the second fraction into a syrupy monoacetate, $[\alpha]_D$ +100° (*c* 0.24), whose ^{1}H nmr spectrum matched the signals belonging to the major component (**21**) in the spectrum of the aforementioned mixture of **21** and **22**. The infrared spectrum was also closely similar to that of the mixture; ν_{max}: 1750 and 1250 (ester), 1200–1000 (C—O—C), 930, 820, and 730 cm^{-1}.

*Mixture of Ethyl 6-O-Acetyl-2,3,4-trideoxy-2-[methoxycarbonyl(phenylsulfonyl)methyl]-α-D-hex-3-enopyranoside (**23**) and Ethyl 6-O-Acetyl-2,3,4-trideoxy-4-[methoxycarbonyl-(phenylsulfonyl)methyl]-α-D-hex-2-enopyranoside (**24**)*

Compound **3** (200 mg) was allowed to react with a 0.177 *M* solution (40 mL) of methyl phenylsulfonylacetate sodium in tetrahydrofuran. All of **3** was consumed after 5 days, and two product spots of comparable strength and similar mobilities (R_f ~ 0.4–0.5) were seen in tlc (solvent A). The products could not be separated; their presence in a ratio of ~ 1:1 was indicated by ^{1}H and ^{13}C nmr spectra. The mixture of **23** and **24** showed $[\alpha]_D$ +39.4° (*c* 2.8). *Anal.* calcd. for $C_{19}H_{24}O_8S$ (412.4): C 55.33, H 5.87, S 7.77; found: C 55.25, H 5.83, S 7.74.

Acknowledgments

Rotation optique et structure moléculaire. I. Cas des cyclitols et anhydro-1,6 sucres

MAURICE CHASTRETTE ET JEAN-CLAUDE MARTIN[1]

Université de Lyon I, Ecole Supérieure de Chimie Industrielle de Lyon, ERA 689 du C.N.R.S., BP 2002, 69603 Villeurbanne, France

Reçu le 28 mai, 1980

Ce papier est dédié au Prof. Raymond U. Lemieux à l'occasion de son 60ème anniversaire

MAURICE CHASTRETTE et JEAN-CLAUDE MARTIN. Can. J. Chem. **59**, 907 (1981).

Les relations entre rotation moléculaire et structure de composés à géométrie rigide (cyclitols et anhydro-1,6 sucres) sont étudiées en fonction des interactions entre les dipoles des liaisons carbone–oxygène et des contributions du cycle ou du squelette hydrocarboné. L'influence des interactions à longue distance (à travers 2 ou 3 atomes de carbones) n'est pas négligeable et un jeu de paramètres est proposé pour chacune des familles étudiées.

MAURICE CHASTRETTE and JEAN-CLAUDE MARTIN. Can. J. Chem. **59**, 907 (1981).

The relationships between molecular rotation and the structure of the rigid cyclitols and anhydro-1,6 sugars are studied as a function of the interactions between the carbon–oxygen bond dipoles and contributions from the ring or the hydrocarbon skeleton. The influence of long distance interactions (through 2 or 3 carbon atoms) is not negligible and a variety of parameters is suggested for each of the families of compounds studied.

[Journal translation]

La relation entre la structure d'un composé organique et son activité optique a fait l'objet d'études nombreuses notamment dans le domaine des sucres, depuis que Whiffen (1) a proposé le principe d'additivité des contributions de chaque élément conformationnel d'asymétrie. Ce principe a été repris dans un certain nombre de travaux (2–7) qui ont mis en évidence des corrélations empiriques pour différentes familles de dérivés. Ces travaux sont basés sur la définition d'un certain nombre d'interactions dipolaires simples à faible distance (une seule liaison entre les dipoles) et éventuellement sur la contribution globale d'un cycle ou d'un squelette hydrocarboné.

L'approche proposée dans ce mémoire consiste à envisager dans deux séries de composés bien connus et de structure rigide (cyclitols et anhydro-1,6 hexopyranoses) l'ensemble des interactions possibles dans la molécule sans faire aucune hypothèse ni sur leur valeur, ni sur leurs combinaisons mathématiques et à déterminer ensuite par une méthode de calcul par régression les paramètres nuls ou sans signification statistique.

Les dérivés choisis pour cette étude ont des structures déterminées par spectroscopie rmn, ir et par cristallographie aux rayons X (8–13). Leurs rotations moléculaires ont été plusieurs fois déterminées. Par ailleurs, la rigidité structurale de ces composés n'est pas affectée par les substitutions des cycles dans les exemples choisis.

La procédure utilisée consiste à envisager deux types d'interactions; la première concerne l'interaction du squelette avec un substituant. Elle est nulle dans le cas des cyclitols; dans le cas des anhydro-1,6 sucres, elle est désignée par $R/_nO_{ax}$ ou $R/_nO_{eq}$; n désignant le nombre de liaisons carbone–carbone séparant les supports des dipoles (n = 1, 2 ou 3). Les autres interactions caractérisent les substituants des cycles et sont désignées conventionnellement par $O_i/_nO_j$, les positions axiales ou équatoriales étant repérées par les indices i et j et n ayant la même signification que précédemment. Il faut remarquer cependant que les interactions du 3ème ordre (n = 3) $O_i///O_j$ sont nulles (substituants dans le plan de symétrie) pour les cyclitols et absentes dans le cas des anhydro-1,6 hexopyranoses. Le nombre maximum total de paramètres servant à décrire l'ensemble des structures est donc de douze.

Type d'interaction	n = 1 (1e ordre)	n = 2 (2e ordre)	n = 3 (3e ordre)
Squelette/ substituant	R/O_{ax}	$R//O_{ax}$	$R///O_{ax}$
	R/O_{eq}	$R//O_{eq}$	$R///O_{eq}$
Substituant/ substituant	O_{ax}/O_{ax}	$O_{ax}//O_{ax}$	—
	O_{ax}/O_{eq}	$O_{ax}//O_{eq}$	—
	O_{eq}/O_{eq}	$O_{eq}//O_{eq}$	—

Le calcul est réalisé avec un programme classique de régression multiple faisant intervenir au départ toutes les variables. On élimine ensuite les variables non significatives.

Résultats et discussion

Il est important de noter que notre objectif a été de rechercher dans chaque famille de dérivés, dont la structure et la géométrie sont bien connues, des relations permettant de prévoir au sein de ce groupe

de composés la valeur des rotations moléculaires. Il serait difficile de faire des comparaisons entre deux séries de produits différents, dont la géométrie et la conformation ne sont pas identiques.

Cyclitols

Les calculs préliminaires de régression montrent que les interactions $O_{eq}//O_{eq}$ pour le second ordre et O_{ax}/O_{ax} pour le premier ordre sont négligeables. Une régression linéaire sur les interactions restantes donne l'équation suivante

$$[M] = -3{,}31 + (40{,}88)n\,[O_{eq}/O_{eq}] + (41{,}47)n\,[O_{eq}/O_{ax}] + (9{,}14)n\,[O_{ax}//O_{eq}]$$

avec un coefficient de corrélation de $r = 0{,}999$ et un écart moyen de 2,83; n désigne le nombre d'interactions du type présentes dans la molécule et les incertitudes absolues pour les trois coefficients de l'équation précédente sont respectivement 2,68, 2,23 et 1,97.

Cette équation fournit un excellent accord entre les résultats calculés et les valeurs expérimentales (Tableau 1, Méthode 1).

Un second calcul, réalisé en imposant une condition supplémentaire (contribution nulle du cycle) conduit à l'équation suivante:

$$[M] = 43{,}76\,n\,[O_{eq}/O_{eq}] + 39{,}68\,n\,[O_{eq}/O_{ax}] + 8{,}82\,n\,[O_{ax}//O_{eq}]$$

Le coefficient de corrélation est de $r = 0{,}998$ et l'écart moyen de 3,30 (Tableau 1, Méthode 2).

On peut remarquer que dans ces deux calculs, les valeurs obtenues restent en accord avec celles proposées par Lemieux et Martin (5). Le calcul effectué par ces auteurs ne considérait qu'une seule interaction au premier ordre et négligeait celles du second ordre. Un calcul de régression effectué selon ces hypothèses conduit à un écart moyen de 5,88, nettement supérieur à ceux indiqués ci-dessus.

Les interactions qui n'ont pas d'influence marquante d'après le résultat du calcul sont celles qui font intervenir des liaisons coplanaires. Il nous a cependant paru préférable de ne pas les éliminer a priori.

Anhydro-1,6 hexopyranoses

Le problème posé faisait intervenir l'ensemble des douze paramètres proposés ci dessus. Il fallait donc tenter de simplifier le jeu des paramètres considérés. Une première approche a consisté à examiner si certaines interactions du squelette avec les substituants pouvaient être négligées. Aucun résultat acceptable n'a pu être obtenu selon cette hypothèse. Cependant, ces calculs ont montré que les interactions $R//O_{ax}$ et $R//O_{eq}$ étaient beaucoup plus faibles que les autres, de signes opposés et de valeurs absolues très proches (9 et 7 approximativement). Un calcul préliminaire considérant ces deux valeurs comme opposées peut alors être réalisé et montre que, de plus, comme dans le cas des cyclitols, l'interaction O_{ax}/O_{ax} est également négligeable. Un second calcul faisant intervenir les huit paramètres restants montre que la variable $O_{ax}//O_{eq}$ n'est pas significative; la valeur obtenue pour cette variable est en effet égale à −3,4 avec un écart type de ±6,7. On remarquera que dans le cas du *trans*-cyclohexane diol-1,3 une telle interaction a été estimée à environ 19 (14, 15) alors que dans les cyclitols, elle est de 9,1 (voir ci-dessus). Ces différences peuvent être provoquées par une modification conformationnelle d'une série à l'autre. Le présent travail ne prétend pas rationaliser dans une même corrélation l'ensemble des deux séries.

Le calcul définitif avec 7 variables seulement aboutit aux résultats consignés dans le tableau 2. Les valeurs calculées sont obtenues à partir de l'équation:

$$[M] = -117{,}1 - (49{,}0)n\,[R///O_{ax}] + (51{,}8)n\,[R///O_{eq}] + (8{,}2)n\,[R//O_{ax}]\ (\text{ou} - n\,R//O_{eq}) + (48{,}0)n\,[R/O_{ax}] - (68{,}4)n\,[R/O_{eq}] + 41{,}9\,n\,[O_{eq}/O_{eq}] + 59{,}3\,n\,[O_{ax}/O_{eq}]$$

Les écarts-types observés sur les coefficients des variables sont respectivement 4,4 pour $R///O_{ax}$; 5,0 pour $R///O_{eq}$; 2,1 pour $R//O_{ax}$; 4,4 pour R/O_{ax}; 5,0 pour R/O_{eq}; 5,3 pour O_{eq}/O_{eq} et 3,5 pour O_{ax}/O_{eq}.

Les valeurs prises par les différentes interactions sont rassemblées dans le tableau 3. On voit que les hypothèses retenues dans les calculs précédents (16, 17) ne sont pas toutes vérifiées.

TABLEAU 3. Paramètres calculés pour les diverses interactions présentes dans les anhydro-1,6 sucres

Interaction	Valeur calculée	Valeurs proposées (réf. 17)	
$R///O_{ax}$	−49,0	−36,9	−100
		ou	
$R///O_{eq}$	51,8	+36,9	+100
$R//O_{ax}$	8,2	+6,8	—
$R//O_{eq}$	−8,2	—	−6,8
R/O_{ax}	48,0	48,8	+113,6
R/O_{eq}	−68,4	−48,8	−113,6
O_{eq}/O_{eq}	41,9 (40,9)*	—	—
O_{ax}/O_{eq}	59,3 (41,5)*	—	—

*Valeurs obtenues pour les cyclitols.

En effet si on constate que l'hypothèse d'interactions égales et opposées est vérifiée pour $R///O_{ax}$ et $R///O_{eq}$ d'une part et $R//O_{ax}$ et $R//O_{eq}$ d'autre part, elle ne l'est pas pour le couple R/O_{ax} et R/O_{eq} dont les valeurs sont respectivement 48,0 et −68,4.

Nous avons donc montré qu'il est possible à l'intérieur d'une même famille, de géométrie et de conformation fixées, de n'utiliser qu'un seul jeu de paramètres et d'obtenir un écart moyen satisfaisant tant pour les dérivés substitués que pour les dérivés désoxy.

Néanmoins, il est possible de faire quelques remarques comparatives dans les deux séries cyclitols et anhydro-1,6 sucres. (*a*) La valeur O_{eq}/O_{eq} reste inchangée (41,9 et 40,9) et semble donc liée directement à la relation spatiale entre deux substituants équatoriaux. (*b*) La valeur O_{ax}/O_{eq} est en revanche nettement modifiée d'une série à l'autre, de même que la valeur $O_{ax}//O_{eq}$ précédemment discutée.

Le principe même de l'analyse de ces interactions et de leur calcul est de déterminer les paramètres importants qui lient dans chaque famille l'activité optique et la relation spatiale des substituants, sans chercher pour l'instant la généralisation et la rationalisation de l'ensemble des paramètres obtenus.

Solvolysis of 9-(*ortho*-substituted benzyl)fluorene-9-trimethylammonium ions. The effect of steric crowding

JYOTSNA PRADHAN AND PETER JAMES SMITH[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received November 3, 1980

JYOTSNA PRADHAN and PETER JAMES SMITH. Can. J. Chem. **59**, 911 (1981).

The solvolytic reaction of several 9-(*ortho*-substituted benzyl)fluorene-9-trimethylammonium salts in ethanol at 57.3°C has been found to give both the substitution and elimination products. The observed rate constant for alkene formation increases when both *ortho* positions have substituents, $k_{obs}(s^{-1}) = 2.35 \times 10^{-5}$ and 268×10^{-5} for 2-Me and 2,6-diMe compounds, respectively. As well, the magnitude of the observed hydrogen–deuterium isotope effect is dependent on ring substituents, $k_{obs}^{H}/k_{obs}^{D} = 1.22$ and 2.35 for 2-Me and 2,6-diMe substrates, respectively. The results are discussed in the light of steric acceleration favouring loss of the poor leaving group, which leads to only the second example of a trimethylammonium salt reacting via the E1 mechanism.

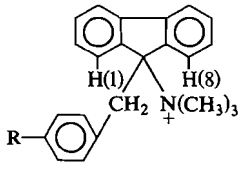
JYOTSNA PRADHAN et PETER JAMES SMITH. Can. J. Chem. **59**, 911 (1981).

On a trouvé que la réaction de solvolyse de plusieurs sels de (benzyl *ortho* substitués)-9 fluorényl triméthylammonium-9 dans l'éthanol à 57,3°C donne à la fois des produits de substitution et des produits d'élimination. La constante de vitesse observée pour la formation de l'alcène augmente quand les deux positions *ortho* sont substituées $k_{obs}(s^{-1}) = 2{,}35 \times 10^{-5}$ et 268×10^{-5} respectivement pour les composés méthyl-2 et diméthyl-2,6. L'importance de l'effet isotopique observé pour le deutérium dépend également des substituants sur le cycle, $k_{obs}^{H}/k_{obs}^{D} = 1{,}22$ et 2,35 respectivement pour les composés méthyl-2 et diméthyl-2,6. On discute des résultats en fonction d'une légère accélération stérique favorisant la perte d'un mauvais groupe nucléofuge; ceci constituerait seulement le second exemple de sels de triméthylammonium réagissant selon un mécanisme E1.

[Traduit par le journal]

Studies on the concerted one-step elimination from quaternary ammonium salts (1) and organic nitrate esters (2) have shown that electron-withdrawing substituents on the phenyl ring increase the rate of reaction with the corresponding transition state becoming more reactant-like, having decreased C—H and C—N (O—N) bond weakening. The effect of the substituent on the transition state geometry is in accord with Hammond's postulate (3) and also Thornton's (4) and More O'Ferrall's (5) theories.

In a recent investigation (6, 7) on the E2 reaction of 9-(4-substituted benzyl)fluorene-9-trimethylammonium ions (**1**) with ethoxide ion in ethanol, however, it was found that the variation of both the primary hydrogen–deuterium and nitrogen isotope effects with the 4-substituent on the phenyl ring were the opposite to those found in the earlier studies. As well, the Hammett ρ value of 1.33 for the reaction of **1** was very much less than 3.77 found for the reaction of the 2-arylethyl quaternary ammonium ions with ethoxide (8). It was concluded that for reactions in which the 4-substituent increases the rate of reaction, both the carbon–hydrogen and carbon–nitrogen bond rupture is more advanced in the transition state. This variance with Hammond's postulate was discussed in the light of a possible steric crowding at the transition state.



1

In order to test the proposal that interaction of the *ortho*-hydrogens on the phenyl ring with the 1,8 hydrogens of the fluorene nucleus results in the anti-Hammond behaviour, a series of *ortho*-substituted quaternary ammonium salts were prepared. These salts, unlike the 4-substituted compounds which were unreactive in ethanol, reacted in absolute ethanol in the absence of base to give both the alkene and ether products. The observed rate constants for the formation of the alkene from several *ortho*-substituted salts, k_{obs}, and their β,β-d_2 analogues, as well as the percent alkene, are given in Table 1. As well, the ratio k_E/k_S (Scheme 1) calculated from the percent alkene, together with the hydrogen–deuterium isotope effect, k_{obs}^{H}/k_{obs}^{D}, are included.

The observed rate constants for the formation of the alkene from the 2-Me and 2,4-diMe salts are similar and are approximately one hundred times less than the corresponding rate constants for the 2,6-diMe and 2,4,6-triMe substrates. It appears,

TABLE 1. Rate constants, percent alkene, and hydrogen–deuterium isotope effects for reaction of 9-(*ortho*-substituted benzyl)fluorene-9-trimethylammonium salts in absolute ethanol at 57.3°C

Substrate	$10^5 k_{obs}$ (s^{-1})	% alkene	$k_E/k_S = \frac{[alkene]}{[ether]}$	(k_E^H/k_E^D)*	k_{obs}^H/k_{obs}^D
2-Me	2.35	56.2	1.28	1.54	1.22
2-Me-β,β-d_2	1.92	42.8	0.748		
2,4-diMe	2.85	56.8	1.31	1.76	1.16
2,4-diMe-β,β-d_2	2.45	40.1	0.669		
2,6-diCl	9.60	28.6	0.401	2.10	1.45
2,6-diCl-β,β-d_2	6.60	14.7	0.172		
2,6-diMe	268.0	28.8	0.404	2.78	2.35
2,6-diMe-β,β-d_2	114.0	11.6	0.131		
2,4,6-triMe	248.0	25.4	0.340		

*Calculated with the assumption that $k_S^H/k_S^D = 0.9$.

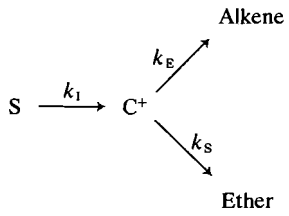
therefore, that since *ortho*-methyl groups accelerate the reaction[2] and the *para*-substituent has very little effect, the rate enhancement is due to steric acceleration. Dreiding stereomodels indicate considerable interaction between the *ortho*-methyl groups and the 1,8-hydrogens on the fluorene ring and, as well, the methyl groups of the trimethylammonium group. To our knowledge, this is only the second example (9) of a trimethylammonium salt (poor leaving group) undergoing solvolysis to give an alkene in an E1 process. The reaction is promoted by a relief of steric interactions and not only by the formation of a favourable carbocation.

The reaction of the 2,6-diCl substrate with ethanol is slower than the 2,6-diMe process, but is faster than the reaction of the 2,4-diMe compound. These observations can be accommodated by the steric argument since chlorine is smaller than methyl (Taft E_s values). As well, it is seen that the percent alkene decreases when both *ortho*-positions bear a substituent; e.g., % alkene = 56.2 and 28.8 for the 2-Me and 2,6-diMe compounds, respectively. This is also consistent since the presence of the *ortho*-substituents leads to an increase in the nonplanarity of the alkene due to interactions with the 1,8-hydrogens on the fluorene ring. As well, the presence of the *ortho*-groups provides steric hindrance to ethanol which acts as base to remove the β-hydrogen from the carbocation.

The carbocation mechanism for the formation of the alkene and ether products can be represented by Scheme 1. If it is assumed that all steps are irreversible then it can be shown that the observed rate constant for alkene formation is given by $k_{obs} = k_1 k_E/k_E + k_S$. If $k_E > k_S$ then $k_{obs}^H/k_{obs}^D \simeq k_1^H/k_1^D$ and the observed isotope effects will mainly be secondary β-deuterium effects, i.e. when $k_E/k_S = 1.28$ then $k_{obs}^H/k_{obs}^D = 1.22$ for the 2-Me substrate. When, however, $k_E < k_S$ then

$$k_{obs}^H/k_{obs}^D = (k_1^H/k_1^D)(k_E^H/k_E^D)$$

and a larger observed isotope effect is expected since the loss of a proton from the carbocation (k_E) is a primary effect; i.e. when $k_E/k_S = 0.404$ then $k_{obs}^H/k_{obs}^D = 2.35$ for the 2,5-diMe salt. The isotope effects for loss of hydrogen from the carbocation can be calculated from the observed percent alkene. The values for k_E^H/k_E^D ranging from 1.54 to 2.78 are reasonable primary effects. To our knowledge this is the first observation of a variable hydrogen–deuterium isotope effect for elimination under solvolytic conditions where substituents on a single substrate are varied. It is a consequence of steric interactions rather than electronic factors.



SCHEME 1

[2]The salts are completely stable in EtOH when there are no *ortho*-substituents.

A ^{125}Te Mössbauer study of hexahalotellurates, pentahalotellurates, and tetrahaloaryltellurates

NIGEL S. DANCE, PABLO DOBUD, AND COLIN H. W. JONES

Chemistry Department, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received August 26, 1980

NIGEL S. DANCE, PABLO DOBUD, and COLIN H. W. JONES. Can. J. Chem. **59**, 913 (1981).

The ^{125}Te Mössbauer spectra of a number of hexahalotellurates have been measured and no significant effects of the size or symmetry of the cation on the Mössbauer parameters were observed. The mixed hexahalotellurates, $M_2TeX_4Y_2$ (X, Y = Cl, Br, or I), do not exhibit a quadrupole splitting, Δ, and the trends in δ with variation in X and Y are discussed. The pentahalotellurates $MTeCl_5$, $MTeBr_5$, and $MTeBr_4Cl$ also yield single line spectra and this is interpreted as evidence of intermolecular bridging. The tetrahaloaryl tellurates $MArTeX_4$ and $MArTeX_3Y$ (X, Y = Cl, Br, or I) have been studied and the trends in Δ with variation X and Y are consistent with an additive model. The trends in δ are more complex.

NIGEL S. DANCE, PABLO DOBUD et COLIN H. W. JONES. Can. J. Chem. **59**, 913 (1981).

On a mesuré les spectres Mössbauer du ^{125}Te d'une série d'hexahalotellurates et on n'a pas observé d'effets significatifs de la taille ou de la symétrie du cation sur les paramètres de Mössbauer. Les hexahalotellurates mixtes $M_2TeX_4Y_2$ (X, Y = Cl, Br ou I) ne présentent pas de couplage quadrupolaire, Δ, et on discute des variations de δ en fonction de X ou Y. Les pentahalotellurates $MTeCl_5$, $MTeBr_5$ et $MTeBr_4Cl$ donnent également des spectres de raies simples et on interprète ceci comme une preuve de l'existence d'un pont intermoléculaire. On a étudié les tétrahalotellurates $MArTeX_4$ et $MArTeX_3Y$ (X, Y = Cl, Br ou I) et les variations de Δ avec celles de X et de Y sont en accord avec un modèle additif. Les variations de δ sont plus complexes.

Introduction

Among the first tellurium compounds to be studied by ^{125}Te Mössbauer spectroscopy were the hexahalotellurates (1). In these compounds the TeX_6^{2-} anion is octahedral, as evidenced by vibrational, X-ray, and nqr spectroscopy, and the lone-pair on the tellurium appears to be $5s^2$ in character. The bonding to the tellurium may then be viewed as involving $3c$–$4e$ bonds in which only the tellurium $5p$ orbitals participate. The ^{125}Te Mössbauer parameters for these compounds are quite consistent with this interpretation (1, 2). Thus the hexahalotellurates do not exhibit a quadrupole splitting, while the isomer shifts are positive and increase in the series $TeI_6^{2-} < TeBr_6^{2-} < TeCl_6^{2-}$. This suggests that the number of p-electrons removed in bonding from the tellurium increases with increasing electronegativity of the halogen and that the $5s^2$ electrons become increasingly deshielded from the nucleus. This would lead to an increase in the nuclear s-electron density and a more positive isomer shift (1, 2).

In a recent ^{35}Cl nqr study of the $TeCl_6^{2-}$, $SnCl_6^{2-}$, and $PbCl_6^{2-}$ salts (3), the effect on the anion of varying the size and symmetry of the cation was studied. While it might have been expected that for large cations of low symmetry significant distortion of the anion may have been observed, no evidence for such distortions in the form of inequivalent chlorine ligands was found for the hexachlorotellurates. Small changes in the ionicity of the Te—Cl bond were observed, although they did not appear to correlate with the size of the cation. In the present study we have re-examined this question using ^{125}Te Mössbauer spectroscopy to probe the lone-pair character of the $5s^2$ electrons as the size and symmetry of the cation is varied. It may be noted that the Mössbauer spectra of a number of hexahalides with large cations have been reported previously but that the reproducibility in the isomer shifts reported for those compounds was not very good (1, 4).

The above study was also of interest in another context. Donaldson and co-workers (5, 6) have proposed that in $CsSnBr_3$ and in the hexachlorides M_2EX_6 (M = K, Rb, Cs; E = Se, Te, Po; X = Cl, Br) there is a delocalisation of the ns^2 non-bonding lone-pair into delocalised low-energy bands in the solid involving halogen d orbitals. The population of such bands might be expected to vary as the size of the cation and the lattice parameters are changed and it was of interest to determine whether or not evidence for such changes were observed in the Mössbauer isomer shifts.

Mixed halotellurates of the kind $TeCl_nBr_{5-n}^-$ and $TeX_4Y_2^{2-}$ (X, Y = F, Cl, Br, or I) have been prepared by Ozin and Vander Voet (7) and characterised by ir and Raman spectroscopy. A number of these mixed halide anions have been prepared in this work and their Mössbauer spectra recorded. The objective here was to determine whether or not the five co-ordinate species $TeCl_nBr_{5-n}^-$ or the 6

co-ordinate anions would exhibit a quadrupole splitting or a significant diminution in isomer shift resulting from stereochemical activity of the lone-pair.

Finally, as an extension of the above and of our previous studies of organotellurium halides, we have studied the tetrahaloaryltellurates $RTeX_4^-$ and $RTeX_3Y^-$ (X, Y = Cl, Br, or I; R = p-$EtOC_6H_4$). These measurements provide an interesting comparison with the data for the mixed hexahalotellurates and also provide a further test of the applicability of a simple additive model in interpreting ^{125}Te quadrupole splittings in such molecules.

Results and Discussion

The ^{125}Te Mössbauer parameters are reported in Tables 1 and 2. Excellent spectra were obtained for these compounds at 4.2 K, with percent resonance absorptions of 5 to 10% being observed.

Hexahalotellurates, M_2TeX_6

The Mössbauer spectra of all the hexahalotellurates were single lines of relatively narrow linewidth. The absence of a quadrupole splitting, together with the fact that the isomer shifts for the hexachlorides, or for the hexabromides, were very similar, regardless of the size or symmetry of the cation, is further evidence of a lack of any appreci-

able distortion of the hexahalotellurate anion in these compounds. Such distortion would have been expected to result in an electric field gradient at the tellurium or, at least, in a diminution in the *s*-electron density at the nucleus and hence a smaller isomer shift. Thus this work supports the findings of Brill and Welsh (3) that the anion remains octahedral even in the presence of large unsymmetrical cations.

It must be noted, however, that $(Ph_4As)_2TeCl_6$, when prepared from TeO_2/HCl and $Ph_4As^+Cl^-$, yielded an isomer shift of 1.43 mm s^{-1}, significantly smaller than that for the same compound when prepared from $TeCl_4$ and $Ph_4As^+Cl^-$ in CH_2Cl_2 or benzene. The two samples also yielded different X-ray powder diffraction patterns (8). The two preparations may correspond to different polymorphic forms of the same compound and in the one of smaller isomer shift there may be some small distortion from regular octahedral symmetry.

Returning to the discussion of the main body of the data, the small change in the Te—Cl bond ionicity with change in the cation observed in the ^{35}Cl nqr experiments (3) by Brill and Welsh was not reflected in any significant change in the Mössbauer isomer shift. We have previously established an expression for the isomer shift in terms of the number of *p*-holes on tellurium, using the nqr data to estimate the tellurium *p*-orbital population in the hexahalotellurates (2):

$$\delta = 0.44hp - 0.14$$

where δ is the isomer shift in mm s^{-1} relative to an ^{125}I/Cu source and *hp* is the number of holes in the tellurium 5*p* shell.

Thus in $(NH_4)_2TeCl_6$, the ^{35}Cl coupling constant was 29.98 MHz, corresponding to a *p*-orbital imbalance on the chlorine of 0.3. In each Te—Cl bond, assuming that the bonding is predominantly *p* in character, there would be $1.7e^-$ on Cl and $0.3e^-$ on Te. The tellurium *p*-orbital occupancy would then be 1.8 and *hp* would be 6.0 − 1.8 = 4.2. This corresponds to an isomer shift of 1.7 mm s^{-1}. In $(4\text{-picH})_2TeCl_6$ and $(pyH)_2TeCl_6$ the ^{35}Cl coupling constants were 33.36 and 32.98 MHz, respectively, corresponding to a chlorine *p*-orbital imbalance of ca. 0.33, a tellurium *hp* value of 4.0 and an isomer shift of 1.62 mm s^{-1}. The experimentally observed δ's for these compounds were indeed a little lower than that for $(NH_4)_2TeCl_6$, although the agreement between the predicted and observed values is probably fortuitous given the large errors in δ. Certainly the Mössbauer isomer shifts are consistent with the explanation that the small variations in ^{35}Cl coupling constants arise from small differences in the tellurium *p*-orbital populations rather than through variations in the stereochemical activity of the lone-pair.

In connection with the work of Donaldson and co-workers (5, 6), there is no evidence from the Mössbauer data for any delocalisation of the $5s^2$ lone-pair into bands in the solid, at least at 4.2 K, in either the chlorides or bromides, since such delocalisation would have been expected to lead to variations in the isomer shift with changes in the size of the cation.

Mixed Hexahalotellurates, $M_2TeX_4Y_2$

In the series $M_2TeCl_4Y_2$, where Y = F, Cl, Br, or I, there is no resolvable quadrupole splitting in the Mössbauer spectra. The isomer shift for $TeCl_6^{2-}$ is observed to be the most positive in the series (1.74 mm s^{-1}), while $\delta \simeq 1.5$ mm s^{-1} when Y = F, Br, or I. The same results were observed for both the tetrabutyl- and tetraethylammonium compounds. In the bromide series, $M_2TeBr_4Y_2$, where Y = F, Cl, Br, or I, the spectra were again single lines and a δ value of 1.27 cm s^{-1} was observed for $TeBr_4F_2^{2-}$.

Two factors may be identified as influencing the Mössbauer parameters in these anions. Firstly, as the electronegativity of the halogen bonded to tellurium increases, there will be an increased removal of electron density from the tellurium and, where such electron density is predominantly *p* in character, as appears to be the case in the parent hexahalide anions, this would lead to an increased deshielding of the tellurium $5s^2$ electrons and, hence, an increase in the Mössbauer isomer shift. It is noted, however, that $TeCl_4F_2^{2-}$ and $TeBr_4F_2^{2-}$ have δ values smaller than the parent hexachloride or hexabromide, respectively. Secondly, on replacing two chlorine ligands in $TeCl_6^{2-}$ by two F, Br, or I ligands (and from ir and Raman studies this replacement appears to be *cis* in nature), this will necessarily lead to some distortion from regular octahedral geometry about the tellurium. Such distortion would imply that the $5s^2$ electrons are no longer stereochemically inactive and this would result in a decrease in the nuclear *s*-electron density and, hence a decrease in the isomer shift.

The relative insensitivity of δ to the nature of Y for $TeCl_4Y_2^{2-}$, and for $TeBr_4Y_2^{2-}$, Y = Cl, Br, or I, suggests that both the above effects are operative to some extent and that when Y = F the second factor appears to be more important. The effects are, in any event, small, as evidenced by the small changes in isomer shift. The direct removal of 5*s* electrons

from tellurium has a much larger effect on δ than the removal of *p*-electrons, since the latter only influences δ through the second order deshielding effect. Thus, even in $TeCl_4F_2^{2-}$ and $TeBr_4F_2^{2-}$, the stereochemical activity of the $5s^2$ electrons will only be small, consistent with the fact that there is no observable quadrupole splitting. In $TeBr_4F_2^{2-}$ the experimental linewidth was significantly broader than that for the other compounds and this could be explained by the presence of a very small, unresolved electric quadrupole interaction.

Pentahalotellurates, $MTeX_5$

The $TeCl_5^-$, $TeBr_5^-$, and $TeBr_4Cl^-$ tetraalkylammonium compounds were prepared as described in ref. 7 and in the Experimental section and gave ir spectra in good agreement with those of ref. 7.

The Mössbauer spectra did not exhibit a quadrupole splitting, although $[Et_4N][TeCl_5]$ had a significantly smaller isomer shift than $[Et_4N][TeCl_6]$. The absence of a quadrupole splitting here contrasts with the case of $KTeF_5$, where a quadrupole splitting of ca. 6.0 mm s^{-1} was observed (1). The latter compound is known to contain the discrete square pyramidal anion TeF_5^- (9). The vibrational spectra of $[Et_4N][TeCl_5]$ and $[Et_4N][TeBr_5]$ were interpreted by Ozin and Vander Voet (7) assuming that these compounds also contain TeX_5^- anions and that the Te—X bond lengths are the same as those in the parent TeX_6^{2-} anions, although in TeF_5^- the Te—F bond lengths for the apical and basal fluorines are 1.84 and 1.96 Å, respectively. The crystal structure (10) of $TeCl_4 \cdot PCl_5$, however, shows the presence of PCl_4^+ cations and chain-like polymeric $[TeCl_5^-]_n$ anions with distorted octahedral co-ordination about the tellurium. The polymeric chains consist of $TeCl_4$ groups with two short Te—$Cl_{equatorial}$ and two long Te—Cl_{axial} bonds, the $TeCl_4$ units being linked by two bridging chlorine atoms in *cis* position with the Te—Cl bridging contacts being somewhat longer than the Te—Cl_{axial} bonds. The ir and Raman spectra of the $[TeCl_5^-]_n$ polymeric anion in $TeCl_4 \cdot PCl_5$ show similarities to the spectra of $[Et_4N][TeCl_5]$, suggesting a similar environment about the tellurium in the two cases. The absence of a ^{125}Te quadrupole splitting in $[Et_4N][TeCl_5]$ is certainly consistent with a high co-ordination number and the presence of halogen bridges about the tellurium.

The fact that the isomer shift is smaller in $[Et_4N][TeCl_5]$ than in $[Et_4N]_2[TeCl_6]$ may be explained by the small amount of stereochemical activity associated with the lone-pair that would be expected in a distorted octahedral structure.

Tetrahaloaryltellurates, $RTeX_4^-$ and $RTeX_3Y^-$

In previous studies (11, 12) we have investigated the Mössbauer parameters of a wide range of organotellurium compounds, including tellurides R_2Te, dihalides R_2TeX_2, trihalides $RTeX_3$, and telluronium salts $R_3Te^+X^-$. We have also previously reported Mössbauer parameters for $RTeCl_4^-$. In the present work we have extended these studies to include $RTeBr_4^-$ and $RTeI_4^-$ and a number of mixed tetrahaloaryltellurates (Table 2).

The parent tetrahalotellurate anions $RTeX_4^-$ (X = Cl, Br, or I; R = *p*-$C_2H_5OC_6H_4$—) all exhibit a significant quadrupole splitting. These ions are square pyramidal with the organic ligand occupying the axial position (11). The bonding to the halogen ligands would again be viewed as $3c$–$4e$ involving only tellurium $5p$ orbitals. The electric field gradient derives from *p*-orbital imbalance between the *z*-axis, as defined by the Te—C bond, and the *x*–*y* plane in which the four halogen ligands lie. This *p*-orbital imbalance arises because of the difference in the ionicity of the Te—C and Te—halogen bonds and also because of the significant tellurium *s*-character associated with the Te—C bond, which confers significant *p*-character on the lone-pair. The stereochemically active lone-pair is then viewed as occupying the sixth co-ordinate position *trans* to the aryl group. The fact that the Te—C bond has significant *s*-character associated with it has been recognised in our previous Mössbauer studies (11, 12).

The above interpretation is supported by the observation that the quadrupole splittings decrease in the order $RTeCl_4^- > RTeBr_4^- > RTeI_4^-$. As the electronegativity of the halogen ligands decreases, the removal of *p*-electron density from the tellurium in the *x*–*y* plane decreases and the quadrupole splittings likewise decrease. The isomer shift of $RTeCl_4^-$ is significantly smaller than that of $TeCl_6^{2-}$ or $TeCl_5^-$, and this reflects the marked decrease in nuclear *s*-electron density as a result of removal of tellurium $5s$ electrons into the Te—C bond.

In the mixed tetrahaloaryltellurates $RTeX_3Y$, when X = Cl and Y = Cl, Br, or I, it is observed that Δ decreases in the series Y = Cl > Br > I. For the bromide series, i.e. X = Br, Y = Cl, Br, or I, the Δ values again decrease in the series Y = Cl > Br > I and a similar trend is again observed for the iodides, i.e., $RTeI_3Cl^- > RTeI_3Br^- > RTeI_4^-$ (Fig. 1). These trends again reflect a decrease in the removal of *p*-orbital electron density from the tellurium in the *x*–*y* plane as the electronegativity of the halogen ligand, Y, decreases. It would appear that in these compounds Δ is a simple additive property of

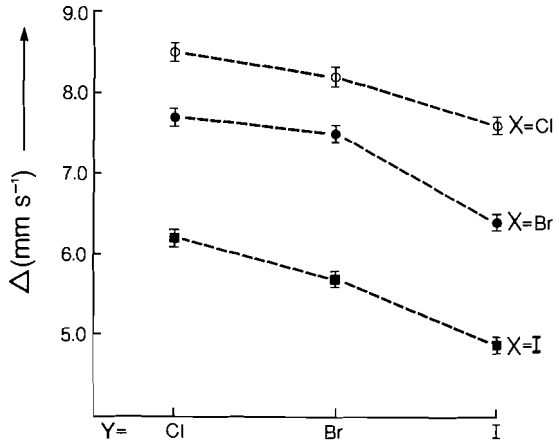

FIG. 1. Quadrupole splittings for ⊕ $RTeCl_3Y$, ● $RTeBr_3Y$, and ■ $RTeI_3Y$ where Y = Cl, Br, or I.

the ligands attached to the tellurium. To a first approximation, and ignoring any asymmetry in the $RTeX_3Y$ anions, the difference in quadrupole splitting between $RTeCl_4^-$ and $RTeBr_4^-$ should then just be twice that between $RTeCl_3Br^-$ and $RTeClBr_3^-$, and indeed that is the case. The agreement is not as good when comparing the chlorides and iodides or the bromides and iodides, but the trends are certainly in the right direction.

These findings are consistent with the previous work on the organotellurides, dihalides, and trihalides, where an additive model also appeared to work quite well in rationalising the Δ values (11, 12).

In contrast with the quadrupole splittings, the isomer shifts do not show any simple trends. This in part must reflect the fact that the range of δ values is small, while the errors in δ are large and, therefore, trends in δ are difficult to discern. However $RTeI_3Cl^-$ has a significantly smaller δ value than $RTeI_4^-$ while, on the basis of electronegativities and the removal of *p*-electron density from the tellurium, just the opposite would have been expected. Small changes in the *s*–*p* character of the lone-pair on Te may be important here and these would have a more marked effect on δ than on Δ.

Experimental

All compounds were prepared following literature procedures. Thus the hexahalotellurates were prepared by dissolving TeO_2 in 12 *M* HCl and adding the appropriate cation chloride salt in a minimum amount of water (3). In the case of $(Ph_4As)_2TeBr_6$ this produced an amorphous powder of anomalously low isomer shift. When the compound was prepared from $TeCl_4$ and Ph_4AsCl in CH_2Cl_2, a crystalline product was observed with the tellurium Mössbauer parameters shown in Table 1.

The mixed hexahalotellurates were prepared (7) by direct trituration in dry CH_2Cl_2 of $TeCl_4$ and $TeBr_4$ with the appropriate cation salt in the stoichiometry 1:2. The pentahalide salts were prepared in a similar way (7) employing a 1:1 stoichiometry. These preparations were carried out in a dry box using vacuum sublimed $TeCl_4$ and $TeBr_4$. The compounds were characterised by ir and Raman spectroscopy and by chemical analysis.

The tetrahaloaryltellurates were prepared (13) by reacting *p*-ethoxyphenyltellurium trihalides with the phosphium salts $(Ph_3{\cdot}PCH_2Ph^+)X^-$, where X = Cl, Br, and I, in chloroform and acetonitrile as solvents. The compounds were identified by chemical analysis and by melting points; in the latter case good agreement was found with the literature values except for $[p\text{-}EtOC_6H_4TeBr_3Cl][Ph_3PCH_2Ph]$, where a value of 171–173°C was found, in comparison with the literature value of 122–124°C.

The Mössbauer spectra were recorded (11) at 4.2 K on naturally abundant 100–200 mg cm^{-2} samples using an $^{125}Sb/Cu$ source (New England Nuclear). Both the source and absorber were immersed in liquid helium in a Harwell Instruments Dewar. A Harwell Instruments 200 series wave-form generator, attenuator, and transducer were used to drive the absorbers with constant acceleration. Spectra were accumulated in 256 channels of a Nuclear Data 2200 series 1024 channel analyser. A NaI(Tl) detector was used and the 35.56 keV Mössbauer γ-ray was monitored through the iodine escape peak. The spectrometer was routinely monitored at 4.2 K using internal tellurium standards, e.g. TeO_2 and $[Et_4N]_2TeCl_6$, and was calibrated using an iron foil and $^{57}Co/Pd$ source at room temperature. The spectra were computer fitted to independent Lorentzians (11).

^{129}I Mössbauer spectra of tellurium iodides. Part II

NIGEL S. DANCE AND COLIN H. W. JONES

Chemistry Department, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received August 26, 1980

NIGEL S. DANCE and COLIN H. W. JONES. Can. J. Chem. **59**, 918 (1981).

The ^{129}I Mössbauer spectra of PhTeI, p-EtOPhTeI$_2^-$, p-EtOPhTeI$_4^-$, Ph_3TeI, $(Me_2TeI_2)_2{\cdot}Ph_2Hg$, and Na_2HgI_4 have been measured and the data interpreted in terms of the bonding to tellurium in these compounds and ions. Evidence is presented that PhTeI is polymeric. The ^{129}I coupling constants in p-EtOPhTeI$_2^-$ and p-EtOPhTeI$_4^-$ are very similar and are the same as those observed in other compounds containing linear I—Te—I linkages, lending support to the use of an additive model in interpreting ^{125}Te quadrupole splittings. The compound Ph_3TeI is best formulated as an ionic species. The compound formed on reaction of α-Me_2TeI_2 with Ph_2Hg is concluded to be $(Me_2PhTe^+)_2HgI_4^{2-}$.

NIGEL S. DANCE et COLIN H. W. JONES. Can. J. Chem. **59**, 918 (1981).

On a mesuré les spectres de Mossbauer de ^{129}I des composés suivants: PhTeI, p-EtOPhTeI$_2^-$, p-EtOPhTeI$_4^-$, Ph_3TeI, $(Me_2TeI_2)_2{\cdot}Ph_2Hg$ et Na_2HgI_4, et on a interprété les résultats en fonction de la liaison du tellure dans ces composés et dans ces ions. On présente des données suggérant que le PhTeI existe sous forme de polymère. Les constantes de couplage de ^{129}I des ions p-EtOPhTeI$_2^-$ et p-EtOPhTeI$_4^-$ sont très semblables et sont identiques à celles observées dans d'autres composés où la liaison I—Te—I est linéaire; ce résultat tend à confirmer l'utilité d'une modèle additif pour interpréter les découplages quadrupolaires du ^{125}Te. La meilleure façon de représenter le composé Ph_3TeI est de le considérer comme étant un composé ionique. On conclut que le composé obtenu par la réaction de α-Me_2TeI_2 avec Ph_2Hg est le $(Me_2PhTe^+)_2HgI_4^{2-}$.

[Traduit par le journal]

Introduction

In an earlier paper (1) we reported the ^{129}I Mössbauer spectra of Cs_2TeI_6, α-Me_2TeI_2, α-TeI, TeI_4, and $PhTeI_3$. As a continuation of that work, and as part of an ongoing related study of the ^{125}Te Mössbauer spectra of organotellurium compounds (2), we have measured the ^{129}I Mössbauer spectra of PhTeI, $(Ph_3MeP^+)(p$-EtOPhTeI$_2^-)$, (Ph_3MeP^+)-$(p$-EtOPhTeI$_4^-)$, Ph_3TeI, and the adduct formed by reaction of α-Me_2TeI_2 with Ph_2Hg.

These compounds provide a measure of the ionicity of the Te—I bond in a number of different environments. In part they also provide a useful independent check of the basic assumptions, used in interpreting the ^{125}Te Mössbauer data of a number of organotellurium halides, that in a range of compounds a simple additive model may be used in interpreting ^{125}Te quadrupole splittings (2).

The adduct formed by reaction of Me_2TeI_2 with Ph_2Hg was of some interest since the nature of the bonding in this compound has been open to question (3).

Results and Discussion

The parameters computed from the ^{129}I spectra are given in Table 1 and the ^{125}Te parameters for these compounds are given in Table 2. A sample ^{129}I Mössbauer spectrum, that for PhTeI, is illustrated in Fig. 1.

PhTeI

Petragnani *et al.* (4) have reported that tellurenyl halides may be prepared by reaction of halogen with the ditelluride in solution in benzene at 0°C and that on further reaction with a phosphonium salt, $ArTeX_2^-$ salts can be isolated. We have used this route to prepare PhTeI, p-EtOPhTeI, and p-EtOPhTeI$_2^-$. While Petragnani *et al.* (4) did not attempt to isolate the tellurenyl halides, Schulz and Klar (5) have demonstrated that PhTeI can indeed be prepared this way. The black solid that precipitates on reaction of Ph_2Te_2 with I_2 in benzene analysed as PhTeI and no evidence for $PhTeI_3$, the other likely product of this reaction, was obtained.

The ^{125}Te and ^{129}I Mössbauer spectra of PhTeI indicated the presence of only one tellurium and one iodine site. The ^{129}I Mössbauer spectrum was clean and well resolved (Fig. 1) in contrast with that of $PhTeI_3$ which we have previously studied (1) and which gave a complex spectrum consistent with the presence of a number of inequivalent iodine sites.

The ^{125}Te quadrupole splitting for PhTeI of 6.5 mm s^{-1} is significantly smaller than that generally observed for Te(II) compounds, where Δ values of 10–15 mm s^{-1} are normally found (6). Thus, for example, Ph_2Te and $C_6H_5N{=}NC_6H_4TeCl$ have Δ values of 10.5 and 11.8 mm s^{-1} respectively (Table 2). The latter compound, a tellurenyl chloride, has the structure shown in Fig. 2 in which there is an intramolecular contact, the environment about the tellurium being essentially planar (7). The origin of the large quadrupole splitting lies in the considerable p-orbital imbalance between the p_z lone pair directed out of the bonding (xy) plane and the p_x and p_y orbitals.

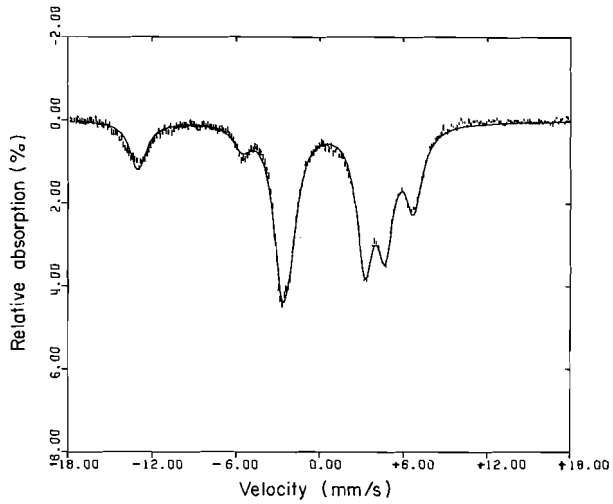

FIG. 1. The ^{129}I Mössbauer spectrum of PhTeI.

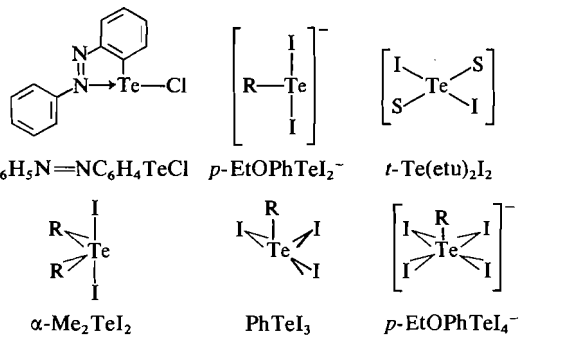

FIG. 2. A representation of the structures of a number of the compounds of interest.

The ^{129}I Mössbauer parameters for PhTeI are also somewhat unusual. The coupling constant of −894 MHz compares with those of −1308 and −1190 MHz for terminal iodine atoms in a α-TeI and TeI_4 respectively (1). The small ^{125}Te and ^{129}I quadrupole couplings suggest that PhTeI is polymeric. The presence of Te---I intermolecular contacts could lead to an increased co-ordination about the tellurium and hence a Δ value smaller than that observed in Ph_2Te, for example. Such bridging could also lead to a longer primary Te—I bond and a smaller iodine coupling constant than that observed for terminal Te—I bonds.

The ^{129}I Mössbauer data may be interpreted in terms of valence orbital populations on the iodine (1). The use of such a simple, valence bond approach must only be considered an approximation. However, its success in interpreting a large body of ^{129}I Mössbauer data in the past suggests that this approach has some validity. Thus, this isomer shift allows an estimation of h_p, the number of holes in the 5*p* shell of the iodine (Table 3) while the coupling constant allows an estimation of U_p, the *p*-orbital imbalance (1). The fact that h_p and U_p are the same in magnitude and that $\eta = 0$ for ^{129}I in PhTeI suggests that the iodine is utilising only a *p*-orbital in bonding to the tellurium and that any I---Te—I bridging units must be linear.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

The observation that PhTeI appears to be polymeric is not unexpected, given that α-TeI and TeI_4 are both polymeric (8, 9) and that intermolecular contacts are often observed in organotellurium iodides (10). Free tellurenyl halide molecules have only been observed in those cases where there is an intramolecular contact between the organic ligand and the tellurium as in the chloride noted above.

p-EtOPhTeI$_2^-$ *and p-EtOPhTeI*$_4^-$

The ^{129}I Mössbauer spectra of α-Me_2TeI_2 and Cs_2TeI_6 were reported previously and the present results for α-Me_2TeI_2 (Table 1) are in good agreement with that work. The tellurium in α-Me_2TeI_2 may be viewed as being in a distorted octahedral environment with bridging iodine atoms, although the bridging contacts are relatively long and weak (11). The I—Te—I linkage is nearly linear. The ^{129}I coupling constants in α-Me_2TeI_2 and Cs_2TeI_6 were found to be very similar. It was of some interest to measure the ^{129}I spectra of *p*-EtOPhTeI_2^- and *p*-EtOPhTeI_4^- and to compare the iodine coupling constants in these molecules with those in α-Me_2TeI_6 and Cs_2TeI_6. The *p*-EtOPhTeI_2^- anion will be T-shaped (Fig. 2) with the I—Te—I linkage again essentially linear. The crystal structure of the related compound C_6H_5Te-(ethylenethiourea)I shows this molecule to have this geometry with an essentially linear S—Te—I linkage (12). In contrast, the *p*-EtOPhTeI_4^- anion will be square based pyramidal (Fig. 2) with the organic ligand occupying the axial position and the TeI_4 grouping lying in a plane with linear I—Te—I bonds. Thus these two ions represent rather different geometries about the tellurium than those observed in Cs_2TeI_6 or α-Me_2TeI_2, yet all contain the linear I—Te—I linkage.

The compound (*p*-EtOPhTeI_2^-)(Ph_3MeP^+) was prepared (4) by adding Ph_3MePI to *p*-EtOPhTeI. The anion *p*-EtOPhTeI_2^- yields a large ^{125}Te quadrupole splitting consistent with the presence of a planar Te(II) species in which the p_z lone pair is directed out of the bonding plane. The ^{129}I coupling constant of *p*-EtOPhTeI_2^- is comparable with, although somewhat smaller than, that of α-Me_2TeI_2. Moreover, it compares very well with that of another Te(II) iodide which we studied sometime ago, namely *trans*-Te(ethylenethiourea)$_2$-$^{129}I_2$, in which the environment about tellurium is again planar (6) and the I—Te—I linkage is linear (Fig. 2).

The compound (*p*-EtOPhTeI_4^-)(Ph_2MeP^+) was made by addition of Ph_3MePI to *p*-EtOPhTeI_3. The *p*-EtOPhTeI_4^- anion yields a small ^{125}Te Mössbauer quadrupole splitting of 5.2 mm s^{-1} consistent with the presence of a square based pyramidal structure. The ^{129}I Mössbauer data indicated the presence of only one iodine site, in comparison with that of the triiodide, $PhTeI_3$, studied previously, which yields a complex spectrum arising from at least three inequivalent iodine sites (1, 10) (Fig. 2). The iodine coupling constant of −730 MHz in a *p*-EtOPhTeI_4^- is comparable with, but a little greater than, that of α-Me_2TeI_2.

Thus for the species *trans*-Te(ethylenethiourea)$_2I_2$, *p*-EtOPhTeI_2^-, TeI_6^{2-}, α-Me_2TeI_2, and *p*-EtOPh-TeI_4^- the iodine coupling constants span a small range from −585 to −731 MHz (Table 3). The I—Te—I linkage appears to remain relatively constant in bonding character in all of these compounds and ions as the number and character of the other ligands bonded to the tellurium changes and as the charge on the molecular species changes. There appears to be a small increase in the iodine coupling constant for iodine bonded to Te(IV) in comparison with that for iodine bonded to Te(II).

While the above discussion focussed attention on the ^{129}I coupling constants the isomer shifts are also reasonably constant for these compounds (Table 1). The h_p and U_p values estimated from δ and e^2qQ are given in Table 4 and are consistent with the bonding occurring to the iodine exclusively through an iodine *p*-orbital. The presence of any iodine *s*-character in the bond would lead to a value of U_p greater than the apparent h_p value.

The linear I—Te—I linkages in the molecules and ions listed in Table 3 may be viewed as three-centre bonds in which a single *p*-orbital on the tellurium atom overlaps with *p*-orbitals on the two iodine ligands, the bonds being relatively long and ionic. The iodine coupling constants are roughly one-half that observed for a terminal iodine atom bonded to tellurium in, for example, α-TeI, where the coupling constant is −1308 Hz, corresponding to a 2c—2e bond.

The constancy of the bonding character of the I—Te—I linkages for the compounds and ions of Table 3 is of some interest. In studying a wide range of organotellurium compounds of Te(II) and Te(IV)

it has been found that a simple additive rule can be used to rationalise the ^{125}Te quadrupole splittings. The present ^{129}I Mössbauer data further support the use of such a model since the I—Te—I linkage certainly remains relatively constant in bonding character.

Ph_3TeI

Here, no resolvable quadrupole coupling was observed in the iodine Mössbauer spectrum, while the isomer shift was found to lie in the range of the ionic iodides. There has been some discussion in the past of interionic interactions in the tellurium salts in the solid state (13). For example, in the structure of Ph$_3$Te(NCO)·½CHCl$_3$, Te---N and Te---O contacts were observed which, while significantly longer than those expected of single bonds, were shorter than the sums of the Van der Waal's radii. However, the ^{129}I isomer shift and the absence of measurable ^{129}I quadrupole coupling constant in Ph$_3$TeI suggests that there are no significant bonding interactions between tellurium and iodine and that the compound can be formulated as being ionic, i.e. Ph$_3$Te$^+$I$^-$.

$Me_2TeI_2 \cdot Ph_2Hg$

We have previously studied the product of the reaction of α-Me$_2$TeI$_2$ with Ph$_2$Hg (3) and proposed that the compound could be formulated as (Me$_2$PhTe$^+$)$_2$HgI$_4^{2-}$. The ^{125}Te Mössbauer parameters are consistent with the presence of a telluronium cation (3) and here we report the ^{129}I Mössbauer data. The ^{129}I Mössbauer parameters are reported in Table 1 and are compared with those of the HgI$_4^{2-}$ anion, prepared in aqueous solution by reacting Na^{129}I with HgI$_2$. It can be seen that Me$_2$TeI$_2$·Ph$_2$Hg has essentially the same ^{129}I Mössbauer parameters as HgI$_4^{2-}$, lending further support to the formulation of the former compound as (Me$_2$PhTe$^+$)$_2$HgI$_4^{2-}$.

The present ^{129}I data for (Me$_2$PhTe)$_2$HgI$_4$ and Na$_2$HgI$_4$ may be compared with that previously reported by Sakai *et al.* for HgI$_2$ as a crystalline solid and in frozen solution in dioxane (14). In HgI$_2$ the iodine is in a bridging environment and e^2qQ is positive in sign, η is 0.54, and consistent with some 4% s-character in the bonding to iodine. In the complex formed with dioxane it is assumed that HgI$_2$ is present as essentially isolated linear HgI$_2$ units with dioxane molecules forming distant contacts to the mercury in the plane at right angles to the bonding axis (15). The iodine coupling constant and isomer shift in this instance are −770 MHz and +0.18 mm s^{-1} respectively. In comparison, in HgI$_4^{2-}$ which is tetrahedral e^2qQ is −500 MHz and δ = −0.1 mm s^{-1}. Thus, not unexpectedly, the Hg—I bond is more ionic in the tetrahedral sp^3 complex ion HgI$_4^{2-}$ than in the linear sp HgI$_2$ isolated species.

Experimental

All compounds were prepared using literature methods with the exception of α-Me$_2$TeI$_2$ which was prepared directly from Me$_2$Te and elemental ^{129}I$_2$ in chloroform solution. Thus, PhTeI was prepared by reaction of Ph$_2$Te$_2$ with ^{129}I$_2$ in benzene (5). In a second preparation p-EtOPhTe^{129}I in benzene was treated with Ph$_3$MeP$^+$I$^-$ with the formation of p-EtOPhTeI$_2^-$·Ph$_3$MeP$^+$ (4). The compound p-EtOPhTeI$_4^-$ was prepared by first reacting p-EtOPh$_2$Te$_2$ with a small stoichiometric excess of ^{129}I$_2$ to form p-EtOPhTe^{129}I$_3$ (16) and then reaction with Ph$_3$MeP$^+$I$^-$ (17). The telluronium iodide Ph$_3$TeI was prepared by reaction of Ph$_3$TeCl with ^{129}I$_2$ in ethanol (18). The reaction of α-MeTe^{129}I$_2$ with Ph$_2$Hg in chloroform yielded (Me$_2$PhTe$^+$)$_2$Hg^{129}I$_4^{2-}$ (19). The sample of Na$_2$Hg^{129}I$_4$ was prepared by reacting Na^{129}I with HgI$_2$ in stoichiometric quantity in aqueous solution.

The ^{129}I used in these preparations was obtained from Oak Ridge National Laboratories as Na^{129}I in sodium sulphite solution and from this it was possible to prepare ^{129}I$_2$ and Na^{129}I to be used in the preparation noted above. The samples prepared contained 10–20 mg cm^{-2} of ^{129}I. Samples containing ^{129}I were not chemically analysed but non-active samples prepared using the same methods were identified by elemental analysis and, where appropriate, melting points, and ir spectra.

The general methods used in recording the ^{129}I and ^{125}Te Mössbauer spectra and in computer fitting the data have been described previously (1, 2). In brief, the ^{125}Te spectra were recorded on 100 mg naturally abundant samples at 4.2 K using an ^{125}Sb/Cu source (New England Nuclear). The ^{129}I spectra were recorded on ^{129}I labelled compounds, again at 4.2 K, using a Zn^{129m}Te source prepared in our laboratory from ^{129m}Te obtained from New England Nuclear as tellurite ion in aqueous solution. The tellurite was reduced to elemental tellurium and the dried powder heated with zinc under vacuum in a quartz capsule at 500°C.

Spectra were recorded using a Harwell Instruments 200 series drive and a Nuclear Data 2200 series analyser. The spectrometer was routinely calibrated using a ^{57}Co/Pd source and iron foil absorber at room temperature.

Spectra were computed to independent Lorentzians and in the analysis of ^{129}I spectra the approach taken by Pasternak (20) was used, taking Q^*/Q = 1.238 for ^{129}I (21).

Received June 23, 1980

KEITH VAUGHAN and MICHAEL T. H. LIU. Can. J. Chem. **59**, 923 (1981).

Kinetic parameters (E_a and ΔS^+) for the thermolysis of 3-methyl-1-*p*-tolyltriazene (**1**) in tetrachloroethylene have been determined. The near-zero value for ΔS^+ suggests a transition state with minimal stretching of the N—N bonds in tautomers **1***a* or **1***b*. The activation energy (E_a = 29.2 kcal/mol) and ΔS^+ for the decomposition of **1** are very similar to those of the azoarylalkanes (Ar—N=N—R), suggesting a similar mechanism of degradation. The major products of the thermolysis of **1** are *p*-toluidine, *N*-methyl-*p*-toluidine, and *p*-chlorotoluene, which are rationalized in terms of homolytic breakdown of both tautomers.

KEITH VAUGHAN et MICHAEL T. H. LIU. Can. J. Chem. **59**, 923 (1981).

On a déterminé les paramètres cinétiques (E_a et ΔS^+) de la thermolyse du méthyl-3 *p*-tolyl-1 triazène (**1**) dans le chlorure de méthylène. La valeur du ΔS^+ qui est voisine de zéro suggère un état de transition avec une élongation minimale des liaisons N—N des tautomères **1***a* ou **1***b*. L'énergie d'activation (E_a = 29,2 kcal/mol) et le ΔS^+ de la décomposition de **1** sont très voisines de celles des azoarylalkanes (Ar—N=N—R) suggérant ainsi que leurs mécanismes de dégradation sont analogues. Les produits principaux de la thermolyse du composé **1** sont la *p*-toluidine, la *N*-méthyl *p*-toluidine et le *p*-chlorotoluène dont on peut rationnaliser la formation en fonction d'un clivage homolytique des deux tautomères.

[Traduit par le journal]

Introduction

Alkyl aryl triazenes (Ar—N=N—NHR) have been widely studied and their synthesis, tautomerism, degradation, and biological properties have recently been reviewed (1). These monoalkyltriazenes exist as a tautomeric mixture of forms **A** and **B** (2, 3):

$$\underset{\mathbf{A}}{\text{R—NH—N=N—Ar}} \rightleftarrows \underset{\mathbf{B}}{\text{R—N=N—NHAr}}$$

The kinetics of the benzoic acid-catalyzed decomposition of 3-alkyl-1-aryltriazenes in aprotic solvents has been studied (3, 4) and it has been suggested that proton transfer and departure of the alkyl cation are synchronous and rate determining during the decomposition to give $ArNH_2$, N_2, and products from the alkyl fragment. The thermal decomposition of methylphenyltriazene in apolar hydrocarbon solvents follows first order kinetics (5), and the formation of methyl radicals was clearly demonstrated. In addition, a CIDNP investigation of the thermolysis of monoalkyltriazenes has demonstrated the formation of the aminyl radical pair ($\dot{A}rNH$ $\dot{R}$), which is presumed to arise via homolysis of the unconjugated tautomeric form **B** (6). The analogous tautomeric form has also been implicated in the decomposition of monoalkyltriazenes in aqueous solution; when Ar contains electron-withdrawing groups, a simple unimolecular heterolysis occurs involving the alkane diazonium ion (7):

$$\text{R—N=N—NHAr} \rightarrow \text{R—}\overset{+}{\text{N}}\equiv\text{N} + {}^-\text{NHAr}$$

We report here the measurement of the kinetic parameters for the unimolecular decomposition of 3-methyl-1-*p*-tolyltriazene (**1**) in tetrachloroethylene and an interpretation of the elementary processes involved in the degradation of this class of compounds.

Experimental

Materials

3-Methyl-1-*p*-tolyltriazene (**1**), obtained from Aldrich Chemical Company, was recrystallized from petroleum ether before use, and had mp 81–82°C. Tetrachloroethylene was spectroscopic grade.

Kinetics

Kinetic measurements were carried out by following the characteristic absorption of the triazene (**1**) with a Unicam SP 800A uv spectrophotometer. In all experiments, the decompositions were conducted in sealed Pyrex tubes containing an 0.1 *M* solution of **1** in tetrachloroethylene. Kinetic parameters were determined by following the change of absorbance with time at the wavelength of maximum absorption (337 nm in C_2Cl_4). First-order rate constants were determined graphically from the plot of log ($A_t - A_\infty$) against time.

Product Analysis

3-Methyl-1-*p*-tolyltriazene (**1**) in tetrachloroethylene (0.1 *M* solution) was heated at 100°C until starting material could not be detected (after approximately 2 h) by tlc on silica gel F-254 (Merck) with chloroform as eluent (the triazene **1** had R_f 0.32).

The solution was evaporated *in vacuo* to afford a dark red oil. The 60 MHz ^{1}H nmr spectrum of this residue was recorded in deuteriochloroform solution with a Varian EM360 spectrometer; assignments of ^{1}H signals were made by comparison with spectra of pure, authentic compounds and with published chemical shift data (6).

The product analysis was further refined by column chromatography on silica gel 30–70 mesh (Merck–Brinkman) with carbon tetrachloride as the initial eluent, followed successively by ether/CCl_4 (1:1), ether alone, chloroform, and finally 95% ethanol.

Results and Discussion

Table 1 lists the first-order rate constants for the decomposition of 3-methyl-1-*p*-tolyltriazene (1) in tetrachloroethylene. These data gave an excellent Arrhenius plot from which eq. [1] was obtained by least-squares analysis. R is taken as 0.00198 kcal mol^{-1} K^{-1}.

$$[1] \quad k = 10^{13.8 \mp 0.8} \exp(-29.2 \mp 1.4/RT)\ s^{-1}$$

An A factor of $10^{13.8}$ corresponds to a $\Delta S^{\ddagger}$ of 2.2 cal mol^{-1} K^{-1} at 104°C, the mean of the temperature range over which these measurements were made. The activation energy (E_a) and $\Delta S^{\ddagger}$ for the decomposition of the triazene (**1**) are very similar to those of the arylazoalkanes (Ar—N=N—R) (8) (see Table 2), suggesting a similar mechanism of degradation of these compounds. Unsymmetrical azoalkanes decompose with unequal stretching of the two C—N bonds; in the extreme case of arylazoalkanes the evidence (9) is overwhelmingly in favour of one-bond scission to give the radical pair Ar—N=N$^{\cdot}$ R$^{\cdot}$ (10). Lorand and co-workers (11) have shown that Ar—N=N$^{\cdot}$ is longer lived than the solvent cage. The similarity in the kinetic parameters of triazene and azo-compounds suggests that triazene fragmentation occurs by one-bond scission to give either of the radical pairs ArN=N$^{\cdot}$ $^{\cdot}$NHCH$_3$ or ArNH$^{\cdot}$ N$^{\cdot}$=N—CH$_3$ (Scheme 1). However, the kinetic parameters do not distinguish the pathways of decomposition from tautomer **1***a* or tautomer **1***b*.

TABLE 1. First-order rate constants for the decomposition of **1** in tetrachloroethylene

t (°C)	$k \times 10^4$ (s^{-1})
91.8	1.83
94.0	2.25
95.4	3.27
98.0	4.92
100.7	5.75
104.0	9.27
108.2	10.8
112.1	18.3
116.0	24.3

TABLE 2. Comparison of kinetic parameters of the triazene (**1**) and the azoarylalkanes (Ar—N=N—R)

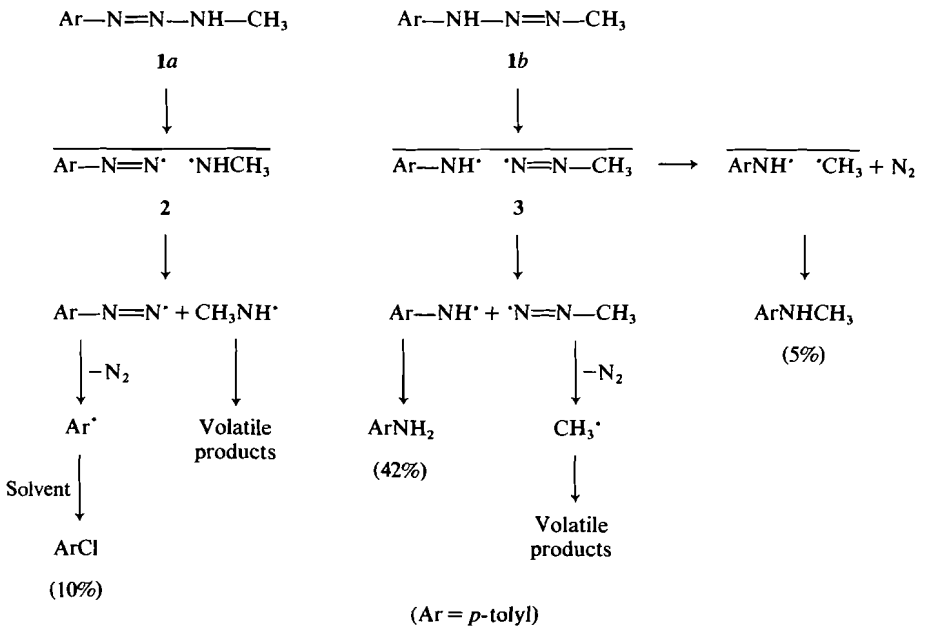
	E_a (kcal/mol)	$\Delta S^{\ddagger}$ (cal/mol^{-1} K^{-1})
Triazene (**1**)	29.2 ± 1.4	2.2 ± 3.0
Azoarylalkanes* (Ar—N=N—R)	27.0–34.0	3.9–5.2

*Reference 8.

The near zero $\Delta S^{\ddagger}$ value for the decomposition of **1** may indicate that the stretching of the N—N bond in **1***a* or **1***b* is minimal in the transition state. However, there may be other reasons for the small $\Delta S^{\ddagger}$, which may contain a contribution from loss of rotational freedom. For example, resonance stabilization of ArNH$^{\cdot}$ (from **1***b*) may freeze rotation about the C—N bond more fully than in the reactant; this may also be a factor in arylazoalkane decomposition.

Analysis of the product mixture suggests that decomposition of triazene (**1**) proceeds mainly via homolysis of **1***b*. The major component of the product mixture had *C*-methyl chemical shift at δ 2.18 and was identified as *p*-toluidine by comparison with authentic material; the yield of *p*-toluidine from the thermolysis of **1** was estimated to be 42%. A second component of the product mixture had *C*-methyl δ 2.33 as well as *N*-methyl chemical shift δ 2.68; these chemical shifts correlate with those reported for *N*-methyltoluidine (6). However, the yield of *N*-methyltoluidine from **1** was only 5%. A third component, which was the major compound in the first fraction from column chromatography, had a *C*-methyl chemical shift at δ 2.28; this component has a typical aromatic AA′BB′ pattern for a *p*-disubstituted benzene. The coupling constant (J = 8 Hz) in the AA′BB′ pattern is identical with that in authentic *p*-chlorotoluene, which has a measured *C*-methyl chemical shift of δ 2.27. The yield of *p*-chlorotoluene from the decomposition of **1** was less than 10%. These nmr assignments agree entirely with those made by Albert *et al.* (6). The moderate material balance (57% total recovery) in the product analysis reflects considerable tar formation in the reaction mixture. The 43% of radicals not accounted for probably underwent addition to tetrachloroethylene leading to some polymerization.

Scheme 1 shows the most probable mechanistic pathways consistent with these observations. One-bond scission of tautomer **1***b* gives the radical pair **3**, which can give rise to the major product,



(Ar = *p*-tolyl)

SCHEME 1

p-toluidine, after cage dissociation and H-abstraction by the arylaminyl radical, ArṄH. Alternatively, loss of nitrogen from the methyl diazenyl radical MeN=N· within the cage affords the pair ArṄH ĊH$_3$ which combine to give the observed minor product *N*-methyl-*p*-toluidine. Similar one-bond scission of tautomer **1***a* gives the radical pair **2**; since the aryldiazenyl radical ArN=Ṅ is relatively long-lived (11), dissociation of the radical pair will likely precede loss of N_2 to give the aryl radical Ar·. Abstraction of chlorine from the solvent by Ar· accounts for the formation of the observed product, *p*-chlorotoluene. Since ArN=Ṅ is long-lived, the pair Ar· ṄHCH$_3$ is unlikely to form and cannot be the source of *p*-toluidine.

Unless the relative amounts of the products are a reflection of the efficiency of H-abstraction by aminyl-radical over Cl-abstraction from the solvent by *p*-tolyl radical, the ratio of *p*-toluidine to *p*-chlorotoluene (>4:1) suggests that the major pathway of homolysis of **1** involves tautomer **1***b*. This preference probably reflects a greater reactivity associated with the unconjugated tautomer (**1***b*) rather than a greater concentration of **1***b* in the tautomeric mixture in accordance with the Curtin–Hammett principle (12). Indeed the tautomerism in **1** has been shown, by variable temperature nmr (2, 13), to favour the conjugated form **1***a*. The CIDNP investigation of monoalkyltriazene thermolysis (6) also showed the preferred fragmentation of the unconjugated tautomer and the formation of the arylaminyl–alkyl pair ArṄH ĊH$_3$.

Further studies of the thermolysis of monoalkyl triazenes will be aimed at the elucidation of the effect of substituents in the aryl group on the kinetics and course of the reaction. Tautomerism of the type (**1***a* ⇄ **1***b*) is greatly influenced by the nature of the aryl substituent and the latter might have a substantial effect on the thermal degradation. A preliminary study of a comparison of the *p*-tolyltriazene (**1**) with the *p*-nitrophenyl analogue suggests that the nitro-compound is much more stable to thermolysis. However, the determination of kinetic parameters for the nitrophenyltriazene by the spectrophotometric method proved impossible, due to the intense interference in the uv spectrum by the product of degradation, *p*-nitroaniline. Alternative methods of kinetic measurement are being examined.

Received July 22, 1980

DENNIS G. GARRATT, PIERRE L. BEAULIEU, and VERONIQUE M. MORISSET. Can. J. Chem. **59**, 927 (1981).

The reaction of benzeneselenenyl chloride with twenty-two propargyl alcohols in methylene chloride solution is reported. Products of both Markownikoff and anti-Markownikoff regiochemistry are formed in an *anti* stereospecific manner. The regioselectivity or specificity is found to be very dependent upon the nature of the substituents geminal to the alcoholic moiety. In general the presence of bulky substituents geminal to the alcoholic moiety tend to favour formation of the anti-Markownikoff adduct under conditions of kinetic control. The Markownikoff adducts are found to be favoured thermodynamically.

DENNIS G. GARRATT, PIERRE L. BEAULIEU et VERONIQUE M. MORISSET. Can. J. Chem. **59**, 927 (1981).

On rapporte la réaction du chlorure de benzènesélénenyle avec vingt-deux alcools propargyliques en solution dans le chlorure de méthylène. Des produits d'addition de type Markownikoff et anti-Markownikoff se forment d'une manière *anti* stéréospécifique. On a trouvé que la régiosélectivité ou la spécificité dépendent fortement de la nature des substituants géminaux de l'unité alcoolique. En général la présence de substituants géminaux encombrants sur la portion alcoolique tend à favoriser cinétiquement la formation d'adduits anti-Markownikoff. Les adduits du type Markownikoff sont thermodynamiquement favorisés.

Many investigators during the last few years have studied the utility of organoselenium compounds as reagents for cyclofunctionalizations (1–14). Our interest in allene chemistry had led us during this period to study electrophilically-induced cyclizations of α-allenic alcohols as a stereospecific synthesis of 2,5-dihydrofurans (15).

[1] $H_2C{=}C{=}CHCH_2OH \longrightarrow$ 
As precursors to these allenic alcohols and allenes in general, it was necessary for us to prepare a large number of propargyl alcohols. The very facile nature of the allenic cyclization reactions suggested to us that we might be able to force a cyclization of our propargyl alcohols (eq. [2]) to either oxacyclobutenes or methyleneepoxides. These experiments were, however, unsuccessful. Simultaneously, Filer and co-workers arrived at similar conclusions (16).[4] The only products observed and isolable were those of simple 1,2-addition. Several differences are, however, to be noted between our individual studies. Because of our prior interest in electrophilic additions to alkynes (17–21), we decided to complete our initial investigation. The results of this study are reported herein.

[2] 
Results and Discussion

The reaction of benzeneselenenyl chloride with propargyl alcohols, **1–22**, gives one or both of the two possible regioisomers of *anti* stereospecific addition (eq. [3]). Reaction times were found to vary greatly, from a few seconds or minutes for species **1–3** to a few weeks for species **4**, **21**, and **22**, when the reactions were carried out in methylene chloride solution at ambient temperatures (20–24°C). Isolated yields are normally essentially quantitative, although some adducts proved unstable after a few days. The initially observed product distributions are given in Table 1.

Assignment of alkene configuration as *E* has been made on the basis of vicinal carbon-13 –

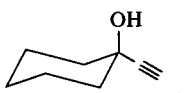
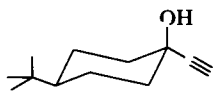
proton coupling constants, $^3J_{CC=CH}$. Previous studies in these laboratories and elsewhere (22–25) have shown that $^3J_{CC=CH}(trans)$ is greater than or equal to $^3J_{CC=CH}(cis)$ and that the *trans* couplings are normally in the range of 8 to 11 Hz, as observed during this study. Also of some diagnostic utility were vicinal selenium-77 – proton, $^3J_{SeC=CH}$, and selenium-77 – carbon-13, $^3J_{CC=CSe}$, couplings and allylic carbon-13 – proton couplings, $^4J_{HC=CCH}$ (26, 27).

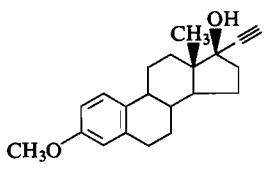
Assignment of adduct regiochemistry as Markownikoff, M, or anti-Markownikoff, aM, follows from an examination of their respective ^1H and ^{13}C nmr chemical shifts. In particular, it is noted that adducts derived from terminal propargyl alcohols, **1–10** and **16–21** have very diagnostic ^1H nmr spectra. The vinyl protons of the Markownikoff adducts are observed to resonate in the range δ 5.70–5.92 ppm, whereas the vinyl protons of the anti-Markownikoff adducts resonate in the range δ 6.20–6.47 ppm. Confirmation of these assignments is found in the analogous ^{13}C nmr chemical shifts for the olefinic methine carbon. For the Markownikoff adducts these carbons resonate between δ 110.1 and 116.1, whereas in the case of the anti-Markownikoff adducts the carbons resonate in the region 119.1–127.7.



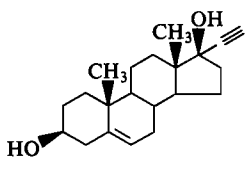
16



17



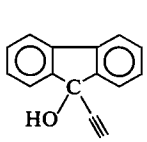
18



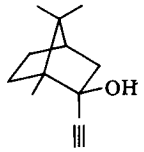
19

In making the assignments given in Table 1, we note that we have reversed the regiochemistry originally assigned by Filer *et al.* for the adduct of benzeneselenenyl chloride and alkyne **16**. Full spectral data are given in the Experimental.

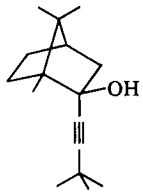
An examination of Table 1 shows the rather surprising result that twelve out of twenty-two of the propargyl alcohols give products of regiospecific Markownikoff addition, and that eight of the remaining ten give products of regiospecific anti-Markownikoff addition. ^1H nuclear magnetic resonance studies over a period of five to six months further showed that those adducts initially formed with the anti-Markownikoff orientation, isomerize slowly and stereospecifically to the corresponding Markownikoff isomer of *E* configuration. The Markownikoff species, in contrast, show no tendency to isomerize. These data therefore suggest that the anti-Markownikoff adducts are formed under conditions of kinetic control, and that the Markownikoff adducts are products of thermodynamic control.



20



21



22

Mechanistically such a scenario is readily interpretable. The observation of anti-Markownikoff addition under conditions of kinetic control clearly indicates that the alkyl groups exert a strong steric effect in the product determining transition state. If one assumes that the selenenylation of propargyl alcohols follows a reaction hypersurface similar to that proposed for simple alkynes (20), it is clear that

*Product composition determined when reaction reached 85% completion. This is neither a kinetic nor a thermodynamic product distribution.

the carbon of the substituent, the selenirenium ring, and the entering chloride ion must all lie in the same plane. Consequently the steric hindrance to attack at the terminal position is less than attack at the most substituted center, thus leading to the preferential formation of the anti-Markownikoff species.

Our hypothesis suggests that in those cases where regiospecific Markownikoff addition is observed, the observation of regiospecific addition might arise from a very fast isomerization of the form: aM → M. In order to test this concept we initially carried out nmr experiments using alkynes **1**, **3**, and **16**, wherein we were able to monitor the course of the reaction as a function of time. In all three cases only the Markownikoff adducts were observable. If one, at this point, makes the assumption that the products of kinetic control are indeed of the anti-Markownikoff regiochemistry, we are left with the conclusion that in these cases the rates of isomerization, aM → M, are much faster than the rates of addition.

In contrast to the above, a similar experiment using alkyne **4** showed, at approximately 5% reaction, only the presence of the anti-Markownikoff adduct. However, when the reaction had reached 85% completion, the ratio M:aM had increased to 32:68. While our data, in this case, are inconclusive due to the poor sensitivity of the ^{1}H nmr technique, it seems possible that the rate of isomerization of the anti-Markownikoff adduct is competitive with the initial rate of addition. A direct comparison of rates, however, is difficult since the first step (the addition reaction) is almost certainly a second-order process (eq. [4]), first-order in alkyne and first-order in selenenyl chloride (20), whereas the second step (the isomerization) is most likely a first-order process (eq. [5]). The formation of a single isomer of *E* configuration from this latter process suggests that the isomerization occurs with neighbouring group assistance by selenium, passing by way of a selenirenium ion-like intermediate, **23** (20, 21, 28).

A third situation is found in the additions to the steroidal alkynes, **18** and **19**. In these cases, the rates of isomerization are much slower than the rates of addition. For example, the reaction of 5-androsten-17α-ethynyl-3β,17β-diol, **19**, with benzeneselenenyl chloride under standard conditions (temperature, concentration) reaches completion after approximately 30 h. The subsequent isomerization, however, has a half-life of approximately 3 months.

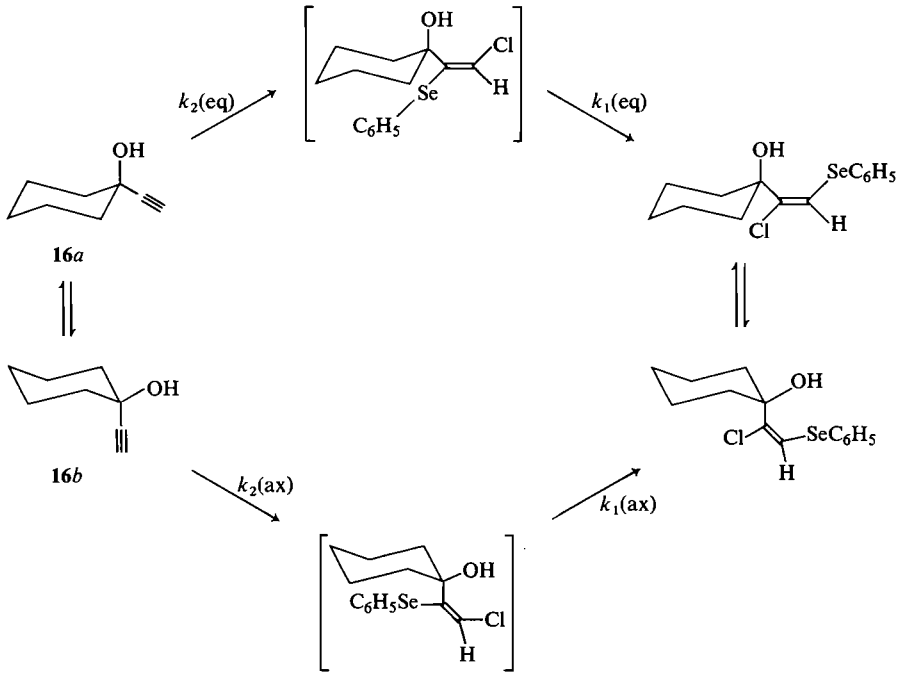
Perhaps the most surprising observation, as seen on examination of Table 1, concerns the two cyclohexylethynes, **16** and **17**. 1-Ethynylcyclohexanol, **16**, is observed to give the Markownikoff adduct regiospecifically, whereas its 4-*tert*-butyl derivative gives the anti-Markownikoff adduct regiospecifically. Two factors may be important in this situation. From a semi-quantitative point of view we note that $k_1' \ll k_1(\text{eq}) + k_1(\text{ax})$ and

[4] $C_6H_5SeCl + H{-}{\equiv}{-}C(OH)(C_4H_9) \rightarrow$ Cl, H, OH, SeC_6H_5

[5] Cl, OH, H, SeC_6H_5 → HO, H, Se^+, C_6H_5, Cl^- (**23**) → H, Cl, C_6H_5Se, HO

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

[6]



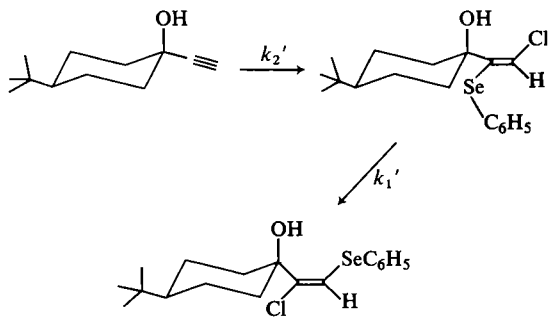
that $k_2' < k_2(\text{eq}) + k_2(\text{ax})$ (see eqs. [6] and [7]). For example, the reaction with **16** reaches completion within 2–3 min under conditions wherein the analogous reaction with **17** requires 12–15 h. Furthermore, while **16** yields immediately the Markownikoff isomer as the only observable product, **17** gives the anti-Markownikoff adduct which subsequently isomerizes completely to the Markownikoff species over a period of 3–4 weeks.

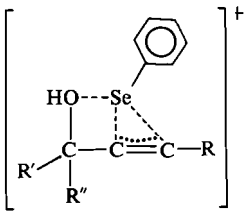
The only physical difference between the two systems is the presence of a *tert*-butyl group on C4 of alkyne **17**, a position which must be considered remote relative to the reaction site. The differences in reactivity must therefore be related to either a long range inductive effect or to conformation. In the case of **17**, the ethynyl group is held in an equatorial conformer by virtue of its *trans* relationship to the *tert*-butyl group (29). For **16**, however, it seems reasonable that an equilibrium exists between the two possible chair conformers, **16***a* and **16***b*. Clearly the ethynyl groups in **16***a* and **16***b* may have different reactivities (30). Since axial substituents are generally considered to be in a more crowded environment than equatorial substituents, and since the steric requirements of the transition state for this addition reaction may be considered greater than the steric requirements of the ground states, the conclusion is drawn that the axial ethynyl group in **16***b* should react more slowly than its equatorial analogue in **16***a*. On this basis one predicts that **17** will react faster than **16**, since **16** is a mixture of both conformers. Our results, however, show the opposite. We find that **16** reacts faster than **17**. Clearly some other factor is responsible.

One possibility is that selenirenium ion formation is stabilized by means of the adjacent hydroxy group by donation of an electron lone-pair from oxygen, **24** (31, 32). In support of this scenario, model studies using Dreiding molecular models indicate that an equatorial hydroxy group is better situated to interact with the developing selenirenium ion than its axial counterpart.

A stabilizing effect on the part of the hydroxy group may also account for the somewhat unprecedented regiochemical isomerizations (20). For example, the reaction of benzeneselenenyl chloride with ethynylcyclohexane under equivalent conditions to those used during this study leads to a 89:11 mixture of the respective anti-Markownikoff

[7]





24

25, and Markownikoff, 26, adducts (eq. [8]). These adducts, in contrast to those derived from 16 and 17, show no tendency, even after four months in methylene chloride solution at ambient temperature, to isomerize!

[8] 
If our hypothesis of a stabilizing interaction between oxygen and selenium is correct, the absence of products of internal cyclization, which both we and Filer *et al.* (16) sought, is readily explained. Additional studies are in progress in an effort to further ascertain the mechanism of this reaction.

Experimental

General

The ^1H and ^{13}C nmr spectra were run on Varian HA-100, T-60, and FT80-16K spectrometers and on a Bruker WP-80 spectrometer. Chloroform-*d* was used as an internal lock and reference for ^{13}C nmr experiments. All spectral parameters are referenced to TMS. Determination of carbon-13 – proton coupling constants and selenium – carbon-13 coupling constants is based upon first-order analysis of the fully coupled spectra, and may not thus represent true *J* values. Infrared spectra were recorded on a Unicam SP1100 spectrometer using neat liquid films or CCl_4 solutions in NaCl cavity cells. Melting points were recorded on a Fisher-Johns block and are reported uncorrected.

Terminal Propargyl Alcohols

General Procedure

Terminal propargyl alcohols were isolated from the reaction of ethynylmagnesium bromide with various ketones and aldehydes in THF solutions. Simple aldehydes and ketones were commercially available from Aldrich, Chemical Samples, and Eastman Kodak. 3-Methyl-2-pentanone was prepared according to known methods (33). 2,2-Dimethyl-3-propanal was obtained by alkylation of isobutyraldehyde using solid–liquid phase transfer catalysis according to the method of Purohit and Subramanium (34). Ethynylmagnesium bromide was prepared by the slow addition of ethylmagnesium bromide to a saturated solution of purified acetylene in THF under a vigorous stream of acetylene. The ketone or aldehyde was subsequently added and the mixture refluxed overnight. Hydrolysis with dilute aqueous HCl, extraction with ether, drying over $MgSO_4$, and distillation or recrystallization yielded the alcohols in 40–50% yields.

3-Isopropyl-2-methyl-4-pentyn-3-ol

Acetylene was purified by passing through a trap at −50°C, concentrated H_2SO_4, NaOH pellets, and anhydrous $CaSO_4$. It was then bubbled for 10 min in 200 mL of dried THF before the addition of 0.5 mol of ethylmagnesium bromide in 250 mL of THF. The Grignard reagent was added very slowly while a vigorous stream of acetylene was passed through the reaction mixture. The solution turned dark brown during the addition. Subsequently, 2,4-dimethyl-3-pentanone, 0.3 mol, was added and the mixture refluxed overnight. Normal acidic work-up and distillation at atmospheric pressure yielded the desired alcohol in 62% yield, bp 168–169°C.

Disubstituted Propargyl Alcohols

Monosubstituted acetylenes were treated with a 10% excess of *n*-butyllithium in THF at 0°C under nitrogen. The resulting mixture was stirred for 2 h and subsequently a 10% excess of an aldehyde or ketone in THF was added to the reaction mixture which was then refluxed for a further 2 h. Saturated aqueous NH_4Cl hydrolysis, extraction with ether, and distillation yielded the pure alcohols.

5-Cyclohexyl-2-methyl-4-pentyn-3-ol

Cyclohexylethyne (Chemical Samples Co.), 0.1 mol, was dissolved in 25 mL of dried THF under a nitrogen atmosphere. A 10% excess of 1.6 *M n*-BuLi in hexane was added at 0°C. The mixture was stirred for 2 h. Isobutyraldehyde, 0.11 mol, was added at room temperature and the mixture refluxed for 2 h. Normal work-up and distillation under reduced pressure gave the pure alcohol in 81% yield, bp 120–122°C/14 Torr.

Spectral Parameters and Physical Data for the Propargyl Alcohols

2-Methyl-3-butyn-2-ol, 1: bp 110–112°C/760 Torr, yield 47%; ir (cm^{-1}): 3370 (s, C≡CH), 3500 (mb, OH) 3680 (m, free OH); ^{13}C nmr δ: 64.6 (s), 89.2 (s), 69.9 (d), 31.4 (q).

3-Ethyl-1-pentyn-3-ol, 2: bp 50–55°C/10 Torr, yield 44%; ir (cm^{-1}): 3380 (s, C≡CH), 3500 (sb, OH), 3690 (m, free OH); ^{13}C nmr δ: 72.0 (s), 86.8 (s), 72.4 (d), 34.2 (t), 8.5 (q).

3-Isopropyl-4-methyl-1-pentyn-3-ol, 3: bp 168–169°C/760 Torr, yield 62%; ir (cm^{-1}): 3370 (s, C≡CH), 2140 (w, C≡C), 3550 (sb, OH), 3700 (m, free OH); ^{13}C nmr δ: 77.3 (s), 85.1 (s), 73.2 (d), 34.1 (d), 17.77 (q), 16.00 (q).

3-tert-Butyl-4,4-dimethyl-1-pentyn-3-ol, 4: bp 76–80°C/11 Torr, yield 17%; ir (cm^{-1}): 3370 (s, C≡CH), 2140 (w, C≡C), 3700 (s, free OH), no band for H-bonded OH was observed in this case; ^{13}C nmr δ: 80.9 (s, *C*OH), 87.1 (s, *C*≡CH), 73.4 (d, C≡*C*H), 41.1 (s, *t*Bu), 28.5 (q, *t*Bu).

1,1-Diphenyl-2-propyn-1-ol, 5: bp 150–160°C/0.25 Torr, yield 75%; ir (cm^{-1}): 3370 (s, C≡CH), 2145 (w, C≡C), 3600 (mb, OH), 3750 (m, free OH); ^{13}C nmr δ: 74.2 (s, *C*OH), 86.4 (s, *C*≡CH), 75.5 (d, C≡*C*H), 144.4 (s, C_x), 128.2 (d), 126.0 (d), 127.7 (d).

3-Methyl-1-pentyn-3-ol, 6: bp 120°C/760 Torr, yield 52%; ir (cm^{-1}): 3375 (s, C≡CH), 3500 (sb, OH), 3690 (m, free OH); ^{13}C nmr δ: 68.4 (s, *C*OH), 87.9 (s, *C*≡CH), 71.1 (d, C≡*C*H), 36.4 (t, Et), 8.9 (q, Et), 29.1 (q, Me).

3,4,4-Trimethyl-1-pentyn-3-ol, 7: bp 145–148°C/760 Torr, yield 62%; ir (cm^{-1}): 3365 (s, C≡CH), 3550 (mb, OH), 3690 (m, free OH); ^{13}C nmr δ: 73.6 (s, *C*OH), 87.6 (s, *C*≡CH), 71.7 (d, C≡*C*H), 37.8 (s, *t*Bu), 24.9 (q, *t*Bu), 24.7 (q, Me).

5-Androsten-17α-ethynyl-3β,17β-diol (Steraloids, Inc.), **19**: mp 242–245°C, rot. −124° (dioxane, 25°C); ^{13}C nmr δ: 39.0 (C1), 31.5 (C2), 71.8 (C3), 46.7 (C4), 140.9 (C5), 121.4 (C6), 32.6 (C7), 31.7 (C8), 50.8 (C9), 42.3 (C10), 20.8 (C11), 37.3 (C12), 50.7 (C13), 49.8 (C14), 23.2 (C15), 36.6 (C16), 80.0 (C17), 12.7 (C18), 19.5 (C19), 88.1 (s, *C*≡CH), 74.0 (d, C≡*C*H).

endo-*2-Ethynyl-1,7,7-trimethylbicyclo[2.2.1]heptan-2-ol*, prepared from *d*-camphor, **21**: mp 207.5–209°C, yield 47%; ir (cm^{-1}): 3375 (s, C≡CH), 3500 (wb, OH), 3690 (m, free OH); ^{13}C nmr δ: 53.7 (s, C1), 77.9 (s, C2), 48.5 (t, C3), 45.4 (d, C4), 32.6 (t, C5), 27.0 (t, C6), 47.9 (s, C7), 21.4 (q, MeC7), 21.0 (q, MeC7), 10.4 (q, MeC1), 87.6 (s, *C*≡CH), 77.9 (d, C≡*C*H).

endo-*3',3'-Dimethylbutynyl-1,7,7-trimethylbicyclo[2.2.1]-heptan-2-ol*, prepared from *d*-camphor, **22**: ^{13}C nmr δ: 53.1 (s, C1), 77.9 (s, C2), 48.6 (t, C3), 45.6 (d, C4), 32.7 (t, C5), 26.9 (t, C6), 47.8 (s, C7), 21.5 (q, MeC7), 21.1 (q, MeC7), 10.3 (q, MeC1), 92.0 (s, *C*≡C*t*Bu), 82.9 (s, C≡*C*t*Bu*), 27.4 (s, *t*Bu), 31.2 (q, *t*Bu).

Benzeneselenenyl chloride was purchased from Aldrich and recrystallized prior to use, mp 64.3°C.

Product Studies

General Procedure

To a solution of the respective propargyl alcohol (6.00 mmol) in 25 mL of anhydrous CH_2Cl_2 was added an equivalent (6 mmol) of benzeneselenenyl chloride as a solution in 5 mL of anhydrous CH_2Cl_2. The additions were carried out such that the propargyl alcohol was always retained in excess. After the solutions had become colourless or pale yellow the solvent was evaporated, and the residual oils analyzed by ^1H and ^{13}C nmr. Samples were further analyzed after purification on silica gel plates and/or columns. Control experiments run in CD_2Cl_2 and subjected to immediate ^1H nmr analysis showed the same product distributions as those found above, Table 1.

Anti-Markownikoff Adducts

*1,3,5(10)-Estratrien-17α-(*E*-1'-phenylseleno-2'-chloroethenyl)-3β,17β-diol 3-Methyl Ether*: prepared from **18** in 88% yield; ^1H nmr δ: 6.62 (s, 1H), 2.8 (bs, 1H, CO*H*), 0.97 (s, 3H, Me at C17), 3.72 (s, 3H, Me at C3); ^{13}C nmr δ: 141.0 (s, =*C*Se), 121.7 (d, =*C*HCl), 132.2 (s, C_{Se}), 132.0 (d, C_o), 129.5 (d, C_m), 127.6 (d, C_p), 126.1 (d, C1), 111.4 (d, C2), 157.5 (s, C3), 113.8 (d, C4), 137.9 (s, C5), 29.7 (t, C6), 27.5 (t, C7), 39.7 (d, C8), 43.3 (d, C9), 132.5 (s, C10), 26.5 (t, C11), 35.4 (t, C12), 50.6 (s, C13), 50.1 (d, C14), 23.8 (t, C15), 33.9 (t, C16), 87.9 (s, C17), 14.7 (q, C18), 55.1 (q, MeO at C3). *Anal.* calcd. for $C_{27}H_{31}O_2SeCl$: C 64.61, H 6.23, Cl 7.06, Se 15.73; found: C 64.64, H 6.41, Cl 7.28, Se 15.94.

Reveived October 21, 1980

GERALD OLIVER ASPINALL, HANY KAMAL FANOUS, NIMAL SAVITRI KUMAR, and VELUPILLAI PUVANESARAJAH. Can. J. Chem. **59**, 935 (1981).

Reaction of permethylated glycopyranosiduronic acids with lead tetraacetate furnishes epimeric 5-acetoxypentopyranosides as products of oxidative decarboxylation. Glycoside cleavage then occurs on treatment with sodium borohydride which affords the corresponding pentitols with exposure of aglyconic hydroxyl groups. The reaction sequence has been performed with permethylated derivatives of methyl β-melibiosiduronic acid, methyl β-gentiobiosiduronic acid, gum arabic, leiocarpan A, *Sterculia urens* gum, and citrus pectic acid. The scope of the reaction sequence in polysaccharide studies is discussed.

GERALD OLIVER ASPINALL, HANY KAMAL FANOUS, NIMAL SAVITRI KUMAR et VELUPILLAI PUVANESARAJAH. Can. J. Chem. **59**, 935 (1981).

Les acides glycopyrannosiduronique perméthylés réagissent avec le tétraacétate de plomb et conduisent par décarboxylation oxydante aux acéto-5 pentopyrannosides épimères. Un clivage du glycoside se produit lors de son traitement par le borohydrure de sodium et il se forme des pentitols correspondants avec une libération des groupes hydroxyles de l'acide aglyconique. On a réalisé cette série de réaction sur les dérivés perméthylés des composés suivants: l'acide méthyle β-mélibiosiduronique, l'acide méthyl β-gentiobiosiduronique, la gomme arabique, le leiocarpane A, la gomme du *Sterculia urens* et l'acide pectique des citrus. On discute des possibilités qu'offre cette série de réaction dans l'étude des polysaccharides.

[Traduit par le journal]

Kitagawa and his collaborators (1, 2) have studied several methods for the selective cleavage of glycosiduronic acid linkages in saponin derivatives and related model compounds. In one procedure oxidative decarboxylation of permethylated glycosiduronic acids with lead tetraacetate was shown to furnish an epimeric mixture of the corresponding 5-acetoxypentopyranosides. Treatment of these substances with sodium methoxide to effect deacetylation led to liberation of the aglyconic component in high yield. However, attempts to characterize the pentodialdose component which would be expected to be produced at the same time showed that the conditions for its liberation caused eliminations to occur, and acetylation of the products led to formation of a crystalline unsaturated compound which retained none of the chiral centres of the parent hexuronic acid residue. Nevertheless the intermediacy of pentodialdoses in the above reaction sequence was demonstrated by the formation of diastereomeric nitrocyclitols, each of which retained the stereochemistry of C-2, C-3, and C-4 of the parent glycosiduronic acid, when the 5-acetoxypentopyranosides were treated with sodium methoxide in the presence of nitromethane (2). Kitagawa *et al.* (1, 2) commented on the obvious application of this type of reaction to polysaccharide investigations. In continuation of our studies on the controlled depolymerization of acidic polysaccharides (3, 4) we now describe experiments on the selective cleavage by oxidative decarboxylation of glycosiduronic acid linkages in permethylated polysaccharides and related model compounds.

Model substrates for the oxidative decarboxylation reaction sequence were permethylated derivatives (**2** and **6**) of methyl β-melibiosiduronic acid (**1**) (5) and methyl β-gentiobiosiduronic acid (**4**). Compounds in the latter series were prepared by standard methods involving (*a*) condensation of (methyl 2,3,4-tri-*O*-acetyl-α-D-glucopyranosyluronate)bromide and methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside to give the peracetylated glycoside (**3**), (*b*) deacetylation and saponification, (*c*) permethylation by the Hakomori procedure (6) to give the fully methylated ester glycoside (**5**), and (*d*) saponification.

The permethylated aldobiouronic acids (**2** and **6**) with added internal reference compounds were each reacted with lead tetraacetate. Treatment of the reaction products with sodium borohydride caused deacetylation of the 5-acetoxypentopyrano-

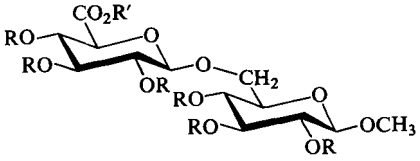
1 R = H, R′ = H
2 R = CH_3, R′ = H



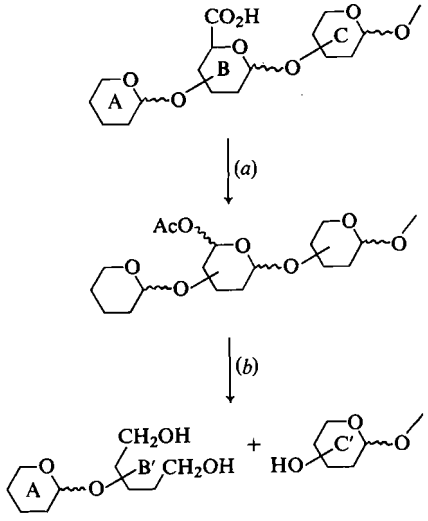
3 R = Ac, R′ = CH_3
4 R = H, R′ = H
5 R = CH_3, R′ = CH_3
6 R = CH_3, R′ = H

sides and thence, after ring opening of the resulting hemiacetal with liberation of the aglyconic component, reduction of the pentodialdose without detectable base-catalyzed elimination. Acetylation of these reaction mixtures afforded in each case methyl 6-*O*-acetyl-2,3,4-tri-*O*-methyl-β-D-glucopyranoside in at least 90% yield (based on the internal reference compound) and the 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methylpentitol (the arabinitol derivative from **2** and the xylitol derivative from **6**) in only slightly lower yield (~80%, possibly due to the volatility of these compounds). The identities of these compounds were confirmed by glc – mass spectrometry.

In order to show that the degradation could be performed with polysaccharide substrates (see Scheme 1), permethylated gum arabic was carefully saponified, methylated arabic acid (**7**) was reacted with lead tetraacetate, the resulting modified polysaccharide was treated with sodium borohydride, and the products were acetylated. The products from the net cleavage of glycosiduronic acid linkages were separated into fractions of low and high molecular weight. The fraction of low molecular weight was further fractionated to give a minor component identified as 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methylxylitol by glc – mass spectrometry, and a major component, whose ^1H and mass spectra were indistinguishable from those of 1,5-di-*O*-acetyl-2,3-di-*O*-methyl-4-*O*-(2,3,4-tri-*O*-methyl-α-L-rhamnopyranosyl)-D-xylitol (**8**) (4). The fraction of high molecular weight was a degraded methylated polysaccharide. Gas–liquid chromatographic examination of the mixture of methyl glycosides formed on methanolysis showed, within the limits of detection, that reaction had resulted in complete removal of methylated glucuronic acid residues and of the terminal rhamnose residues attached to some of them. Quantitative analysis of the constituent sugars in the methylated degraded polysaccharide by glc of the partially methylated alditol acetates formed on hydrolysis, reduction, and acetylation showed that the proportions of other sugar residues, namely, those of arabinose and galactose methyl ethers, were unaltered (Table 1).

Attention was next directed to the degradation of methylated leiocarpan A (7) which contains a main chain with alternating D-glucuronic acid and D-mannose residues with the latter carrying a variety of side-chains. Reaction of the permethylated polysaccharide with lead tetraacetate followed by treatment with sodium borohydride furnished a mixture of partially methylated oligosaccharide alditols. Although the components have yet to be separated and individually characterized, analysis of the sugar constituents in the oligosaccharide alditol mixture by glc of the products formed on methanolysis and acetylation showed that ~90% of the original 2,3-di-*O*-methylglucuronic acid residues had been modified and replaced by those of 2,3-di-*O*-methylxylitol.

In contrast to the degradation of β-D-glucopyranosiduronic acid residues, reactions of α-D-galactopyranosiduronic acid residues may proceed with difficulty. Kitagawa *et al.* (2) observed incomplete reaction when methyl 2,3,4-tri-*O*-methyl-α-



SCHEME 1. Selective fragmentation of glycosiduronic acid (B) linkages by (*a*) reaction with lead tetraacetate followed by (*b*) treatment with sodium borohydride to give pentitol units (B′) with attached substituents (A), when present, and exposure of aglyconic hydroxyl groups in the next inner residue (C′). (For simplicity other substituents are omitted.)

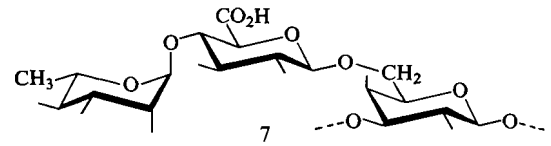
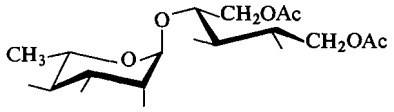
[d]The relative proportions of these two sugars were estimated separately by glc of the methyl glycosides formed on methanolysis of the methylated polysaccharides.



7

Terminal residues in methylated arabic acid: unless otherwise specified substituents are OCH_3.



8

D-galactopyranosiduronic acid was treated with lead tetraacetate, although in our hands reaction of the permethylated disaccharide (**2**) containing a configurationally similar α-D-galactopyranosiduronic acid residue had proceeded satisfactorily. However, reaction of such residues in permethylated polysaccharides was very slow, and repeated additions of lead tetraacetate were necessary in order to achieve substantial, but not yet complete, modification. *Sterculia urens* gum (**8**) contains terminal β-D-glucopyranosiduronic acid together with internal 2,4- and 3,4-di-*O*-substituted α-D-galactopyranosiduronic acid residues at branch points. The progress of reaction of the permethylated polysaccharide with lead tetraacetate was monitored by treatment of samples with sodium borohydride followed by glc analysis in the following ways: (*a*) direct acetylation to furnish 2,3,4-tri-*O*-methylxylitol diacetate liberated from terminal glucuronic acid residues; (*b*) methanolysis and acetylation to afford also *inter alia* partially methylated alditol acetates from modified glycosylically substituted uronic acid units and methyl ester methyl glycoside derivatives from unmodified uronic acid units; and (*c*) hydrolysis, reduction, and acetylation to give partially methylated alditol acetates from neutral sugar residues and modified uronic acid units. Using similar proportions of reagent to substrate to those used for methylated leiocarpan A, almost complete reaction of terminal glucuronic acid residues took place. After extended reaction with repeated additions of reagent the partially methylated alditol acetates derived from the modified methylated gum were examined by glc and the identities of the newly formed 2,3,4-tri-*O*-methylxylitol, and 2- and 3-*O*-methylarabinitol peracetates were confirmed by mass spectrometry. Comparison of the relative proportions of these partially methylated alditol acetates with those formed directly from the parent methylated gum (Table 2) showed in addition increases in the relative proportions of derivatives from 2,3,6-

tri-*O*-methylgalactose and 3-*O*-methylrhamnose, which components would be only partially liberated whilst carrying unmodified galactopyranosyluronic acid substituents.

Methylated citrus pectic acid (9) with added 1,6-anhydro-2,3,4-tri-*O*-methyl-β-D-galactopyranose as internal reference was reacted with lead tetraacetate, and subsequent treatment with sodium borohydride followed by acetylation gave 2,3-di-*O*-methylarabinitol triacetate in 25% yield. This figure represents less than the actual extent of uronic acid transformed since the neutral sugar residues in the parent pectic acid would furnish glycosylically substituted *O*-methylarabinitol derivatives. Furthermore, modification of one of a pair of galacturonic acid residues in the galacturonan portion of the chain would give rise to a disaccharide derivative containing a di-*O*-methylarabinitol residue. Qualitative comparison of the relative proportions of 2,3-di-*O*-methylgalacturonic acid derivatives formed on methanolysis and acetylation of the original and modified methylated pectic acids indicated that more than 50% of the galacturonic acid residues had been transformed.

Two general approaches have been used in the fragmentation of uronic acid-containing polysaccharides, namely, base-catalyzed β-eliminations from esterified hexuronic acids and those involving the net cleavage of glycosiduronic acid linkages (for further discussion see ref. 3). The former approach as developed by Lindberg and his collaborators (10), which has been widely used for methylated derivatives and may be extended to acetal-protected polysaccharides (11), has the great advantages of speed and ease of monitoring by methylated sugar analysis, but the reaction results in total loss of uronic acid residues and further degradation may take place from liberated reducing groups. In contrast, net cleavage of glycosiduronic acid linkages followed by reduction of the derived pentodialdoses results in product formation in which complete structural information is retained except for the configurations at the anomeric centers and C-5 of the uronic acid residues. This approach was first developed by Kochetkov *et al.* (12) in applying the Hofmann degradation of glycosiduronamides and was then extended to the cleavage of nonterminal linkages in methylated polysaccharides (3). The present studies show that similar results may be achieved by oxidative decarboxylation of per-*O*-methylated derivatives with lead tetraacetate followed by reductive scission with sodium borohydride (see Scheme 1) to give pentitol residues as recognizable derivatives from the parent hexuronic acid residues. Similar structural conclusions regarding the glucuronic acid units in gum arabic were drawn previously from the results of the Hofmann degradation of glucosiduronamide residues (3) and of the selective hydrolysis of hex-5-enopyranoside residues formed on modification of glucuronic acid residues (4) in the permethylated polysaccharide. Our results to date on the oxidative decarboxylation of polysaccharides containing α-D-galactopyranosiduronic acid residues have shown that prolonged reaction with repeated additions of reagent will be necessary to achieve complete modification of these hexuronic acid residues. Nevertheless, this sequence of reactions is the most direct procedure yet available for this selective cleavage of internal and external glucopyranosiduronic acid linkages with no detectable fragmentation of residues vulnerable to other reagents. The procedure has an advantage over the Hofmann glycosiduronamide degradation in avoidance of strongly basic conditions. It should therefore be possible to extend the procedure to the degradation of polysaccharides carrying removable protecting (e.g. acyl) groups and to distinguish between esterified (invulnerable to lead tetraacetate) and nonesterified uronic acid units, as in pectins.

Experimental

Evaporations were carried out under diminished pressure at temperatures of 40°C or less. Optical rotations were measured with a Perkin-Elmer model 141 polarimeter at 20 ± 2°. The ir spectra were measured on a Unicam SP 200 spectrophotometer. Unless otherwise stated, ^{1}H nmr spectra were recorded on a Varian EM 360 spectrophotometer in deuteriochloroform with tetramethylsilane as internal standard. Gas–liquid chromatography was performed with a Tracor 560 chromatograph using columns of Gas-Chrom Q coated with (*A*) 3% of silicone gum OV-225 or (*B*) 3% of silicone–polyester copolymer ECNSS-M; on a Pye 204 chromatograph using (*C*) a column of Superpak 20M (Analab) or (*D*) a W.C.O.T. column coated with silicone gum SE-30; or (*E*) on a Perkin-Elmer Sigma 3B chromatograph using a S.C.O.T. column coated with silicone gum OV-225. For glc – mass spectrometry, columns in a Pye 204 chromatograph were attached by a jet separator to a VG Micromass 16F mass spectrometer operated with an inlet temperature of 250°C, an ionization potential of 70 eV, and an ion-source temperature of ~250°C.

Methyl (Methyl Hexa-O-acetyl-β-gentiobiosid)uronate (3)

Methyl (2,3,4-tri-*O*-acetyl-α-D-glucopyranosyl)uronate bromide (13) (5.4 g, 13.6 mmol) and methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside (2.9 g, 9 mmol) were condensed in nitromethane (100 mL) and benzene (20 mL) containing mercuric cyanide (3.5 g, 14 mmol), and the mixture was stirred at 40°C for 24 h with exclusion of moisture. Further mercuric cyanide (3.5 g, 14 mmol) was added and stirring was continued for an additional 24 h at 40°C. The cooled solution was diluted with benzene, washed several times with cold aqueous sodium hydrogen carbonate and then with water, dried, and concentrated. The resulting syrup (4.7 g) was chromatographed on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

silica gel with dichloromethane–chloroform–acetone (10:10:1) as eluant. The major product was recrystallized from ethanol to give the acetylated glycoside ester (**3**) (3.4 g), mp 174–175°C; $[\alpha]_D$ −23.8° (*c*, 3.2 in chloroform); nmr ($CDCl_3$) δ: 2.03 (18H, 6 × OAc), 3.53 (s, 3H, OCH_3), 3.77 (s, 3H, CO_2CH_3). *Anal.* calcd. for $C_{26}H_{36}O_{18}$: C 49.06, H 5.70; found: C 48.93, H 5.66.

Methyl (Methyl Hexa-O-methyl-β-gentiobiosid)uronate (5) and the Derived Acid (6)

0.2 *M* Sodium methoxide in methanol (8 mL) was added to the acetylated glycoside ester (**3**) (2.55 g, 4 mmol) in methanol (30 mL) and the solution was stirred at room temperature for 20 min. The solution was stirred with Amberlite resin IR-120(H) to remove sodium ions and the filtrate was concentrated to give syrupy methyl (methyl β-gentiobiosid)uronate (1.3 g); nmr (D_2O) δ: 3.57 (s, 3H, OCH_3), 3.83 (s, 3H, CO_2CH_3). 1*M* Sodium hydroxide was added to the foregoing ester glycoside (1.32 g, 4 mmol) in water (50 mL) at 0°C to bring the solution to pH 12. The solution was kept at 0°C for 1 h with addition of further sodium hydroxide to maintain a pH of 12. The solution was treated with Amberlite resin IR-120(H) to remove sodium ions, and concentration of the filtrate afforded acid glycoside (**4**) (1.25 g), mp 128°C; nmr (D_2O) δ: 3.55 (s, 3H, OCH_3). The foregoing methyl β-gentiobiosiduronic acid (1 g) was dissolved in 0.67 *M* sodium methylsulfinylmethanide in methyl sulfoxide (75 mL), and methyl iodide (50 mL) was added to the cooled solution and the solution was stirred at room temperature for 1 h. Excess methyl iodide was removed under diminished pressure, the reaction mixture was poured into water (50 mL), and the aqueous solution was extracted 4 times with dichloromethane. The combined extracts were washed with water, dried, and concentrated to a syrup which was chromatographed on silica gel with dichloromethane–acetone (5:1) as eluant to give methyl (methyl hex-*O*-methyl-β-gentiobiosid)uronate (**5**) (1.23 g) mp (after recrystallization from ether – light petroleum) 174–175°C; $[\alpha]_D$ −44° (*c*, 0.85 in chloroform); ir ν_{max} (film): 1745 (ester C=O) cm^{-1}; nmr ($CDCl_3$) δ: 3.48–3.60 (m, 21H, ether and glycosidic OCH_3), 3.77 (s, 3H, CO_2CH_3). *Anal.* calcd. for $C_{20}H_{36}O_{12}$: C 51.27, H 7.75; found: C 51.27, H 7.73.

The methylated ester glycoside (**5**) (300 mg) was saponified in aqueous solution at pH 12 as described previously to methylated acid glycoside (**6**) (260 mg), mp 123–124°C (after recrystallization from ether – light petroleum); ir $\nu_{max}(H_2O)$: 1765 cm^{-1}; nmr ($CDCl_3$) δ: 3.43–3.56 (m, 21H, ether and glycosidic OCH_3), 7.83 (broad, 1H, CO_2H, exchanged with D_2O). *Anal.* calcd. for $C_{19}H_{34}O_{12}$: C 50.21, H 7.54; found: C 50.48, H 7.81.

Degradations of Permethylated Aldobiouronic Acids 2 and 6 with Lead Tetraacetate

Lead tetraacetate (100 mg) was added to methyl hexa-*O*-methyl-β-melibiosiduronic acid (**2**, formed on saponification of the ester **1** (5) as described for **6**) (29 mg) and 1,6-anhydro-2,3,4-tri-*O*-methyl-β-D-galactopyranose (**14**) (7 mg) in benzene (30 mL) containing pyridine (0.2 mL) and the solution was heated under reflux for 4 h. The cooled solution was diluted with benzene and filtered, the filtrate was washed with water, the aqueous solution was extracted with ether, and the combined extracts were dried and concentrated. Sodium borohydride (50 mg) was added to the residue in water (5 mL) and after 5 h at room temperature the solution was treated with Amberlite resin IR-120(H) to destroy excess of hydride and remove sodium ions, filtered, and concentrated by co-distillation with toluene and then methanol. The residue was acetylated in acetic anhydride – pyridine (1:1) (1 mL) and glc examination of the products on column *A* (150°C) showed the formation of compounds with the retention times of methyl 6-*O*-acetyl-2,3,4-tri-*O*-methyl-β-D-glucopyranoside (92%, based on the internal standard) and 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methyl-L-arabinitol (80%). Separate examination of the products by glc – mass spectrometry using column *C* (150°C) showed that the products gave mass spectra in conformity with the assigned structures.

In similar fashion methyl hexa-*O*-methyl-β-gentiobiosiduronic acid (25 mg) with added 1,6-anhydro-2,3,4-tri-*O*-methyl-β-D-galactopyranose (10 mg) was reacted with lead tetraacetate (100 mg) in benzene (30 mL) containing pyridine (0.2 mL). Analysis of the products after treatment with sodium borohydride and acetylation showed the formation of compounds with the retention times of methyl 6-*O*-acetyl-2,3,4-tri-*O*-methyl-β-D-glucopyranoside (96%) and 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methylxylitol (92%), whose identities were confirmed by glc – mass spectrometry.

Lead Tetraacetate Degradation of Methylated Arabic Acid

Methylated gum arabic (**4**) (300 mg) was saponified in water (30 mL) at 0°C by the dropwise addition of 1 *M* sodium hydroxide to maintain a pH of 12 and the solution was kept for 2 h with further addition of base as required. Sodium ions were removed by treatment with Amberlite resin IR-120(H) and concentration of the filtrate afforded methylated arabic acid (280 mg), whose ir spectrum showed absence of absorption at 1750 cm^{-1} (ester C=O) indicating completeness of reaction.

Methylated arabic acid (150 mg) in benzene (30 mL) containing pyridine (2 mL) and lead tetraacetate (500 mg) was heated under reflux for 4 h and, after addition of further lead tetraacetate (200 mg), for an additional 16 h. The cooled solution was diluted with benzene and filtered, the filtrate was washed with water, the aqueous solution was extracted with ether, and the combined extracts were dried and concentrated. Completeness of reaction was shown (*a*) by ir absorption at 1750 cm^{-1} (acetate C=O) but none at 1600 cm^{-1} (hexuronate —CO_2^-) on treatment with triethylamine, and (*b*) by the absence of peaks with retention times of methyl ester methyl glycosides of 2,3,4-tri- and 2,3-di-*O*-methylglucuronic acid on glc examination of the methanolysis products on column *A* (150°C). Sodium borohydride (50 mg) was added to the residue in water–methanol (3:2) (5 mL) and the solution was kept overnight, treated with Amberlite resin IR-120(H) to destroy excess of hydride and remove sodium ions, filtered, and concentrated by co-distillation with toluene and then methanol. The residue was acetylated with acetic anhydride – pyridine (1:1) (1 mL). After normal work-up, addition of light petroleum to the products in ether afforded degraded methylated arabic acid (115 mg), which was washed thoroughly until free of products of low molecular weight (detected by tlc) and then purified by chromatography on Sephadex LH-20 using dichloromethane as eluant.

The sugar components of methylated gum arabic and of the degraded methylated arabic acid were analyzed as partially methylated alditol acetates formed on hydrolysis, followed by reduction with sodium borohydride and acetylation, by glc on columns *A* and *B*, and average values from the two determinations are shown in Table 1. For separation of derivatives of 2,3,4-tri-*O*-methylrhamnose and 2,3,5-tri-*O*-methylarabinose, methylated polysaccharides were heated under reflux with methanolic 5% hydrogen chloride and the resulting methyl glycosides were examined by glc on column *A* (100°C, 5°/min to 180°C).

The supernatant liquid from the above precipitation of degraded methylated polysaccharide was chromatographed on silica gel using dichloromethane–methanol (10:1) as eluant. The main component of the minor fraction (5 mg) was identified as 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methylxylitol by glc – mass spectrometry on column *A* (150°C). The major fraction (16 mg) was identified as the partially methylated disaccharide alditol acetate (**8**) from the nmr spectrum ($CDCl_3$) (δ 1.27 (d, 3H $J_{5,6}$ = 6 Hz, H-6 of Me_3 rhamnopyranose residue), 2.10 (s, 6H, 2 × OAc),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

and 3.53 (m, 15H, 5 × OCH_3)) and by glc – mass spectrometry on column *C* (180°C), which showed a single component whose mass spectrum was indistinguishable from that previously reported (3) and included peaks of the same relative abundance at *m/e* 307, 247, 189, 157, and 117.

Lead Tetraacetate Degradation of Methylated Leiocarpan A

Methylated leiocarpan A (150 mg) was saponified as described for methylated gum arabic to give methylated gum acid (120 mg); ir ν_{max} (NaCl): 1740 cm^{-1} (shifted completely to 1600 cm^{-1} on treatment with triethylamine). Methylated gum acid (100 mg) in benzene (8 mL) containing pyridine (0.2 mL) and lead tetraacetate (400 mg) was heated under reflux for 15 h. The product, isolated as above, was treated with sodium borohydride (200 mg) in tetrahydrofuran–water (1:1) and normal work-up afforded a mixture of partially methylated oligosaccharide alditols. A portion of this material was methanolyzed and the products were acetylated. These products were compared with those similarly derived from the parent methylated polysaccharide by glc on column *A* (120°C, 10 min, 5°/min to 180°C and hold). The results showed that the methylated oligosaccharide alditols afforded the same derivatives of the neutral methylated sugar components, less than 10% of the quantity of the methyl ester methyl glycoside acetates of 2,3-di-*O*-methylglucuronic acid, but as a major new product, 2,3-di-*O*-methylxylitol triacetate, whose identity was confirmed by glc – mass spectrometry.

Lead Tetraacetate Degradation of Methylated Sterculia uren *Gum*

Methylated gum acid (100 mg), prepared by saponification of the methylated gum, was heated under reflux in benzene (8 mL) containing pyridine (0.2 mL) and lead tetraacetate (300 mg) for 5 h. Further lead tetraacetate (5 × 100 mg) was added at intervals during another 10 h. Precipitated lead salts were removed by centrifugation and a portion of the combined supernatant liquid and washings was withdrawn and treated with sodium borohydride. The products were analyzed by glc on column *A* (120°C, 10 min, 5°/min to 180°C) after (*a*) direct acetylation and (*b*) methanolysis and acetylation. The results indicated that ~90% of the 2,3,4-tri-*O*-methylglucuronic acid residues had been converted into 2,3,4-tri-*O*-methylxylitol diacetate but that only a small proportion of the *O*-methylgalacturonic acid residues had been modified. Lead tetraacetate (300 mg) was added to the remaining benzene solution which was heated under reflux for 15 h with periodic additions (5 × 100 mg) of further reagent. The cooled solution was filtered, and the filtrate was washed with water, dried, and concentrated to a syrup which was treated with sodium borohydride and analyzed as above (*a* and *b*). The results indicated that all of the 2,3,4-tri-*O*-methylglucuronic acid residues had been modified and that some of the *O*-methylgalacturonic acid residues had been converted into 2- and 3-*O*-methylarabinitol peracetates. A further portion of the reaction mixture was hydrolyzed, reduced with sodium borohydride, and acetylated. The resulting mixture of partially methylated alditol acetates was compared with that similarly formed from the parent methylated gum by glc on column *A* (170°C) (Table 2). The identities of 2,3,4-tri-*O*-methylxylitol, and 2- and 3-*O*-methylarabinitol peracetates were confirmed by co-chromatography with authentic samples on columns *A* and *E*, and by glc – mass spectrometry.

Lead Tetraacetate Degradation of Methylated Citrus Pectic Acid

Methylated pectic acid (100 mg), from saponification of methylated citrus pectin (9), with added 1,6-anhydro-2,3,4-tri-*O*-methyl-β-D-galactopyranose (20 mg) (11) was heated under reflux in benzene (10 mL) containing pyridine (0.2 mL), and lead tetraacetate (4 × 100 mg) was added at intervals during 5 h. Precipitated lead salts were removed by filtration and two further sets of addition of reagent were carried out. The reaction mixture was worked up as described for modified methylated *S. urens* gum and treated with sodium borohydride. A portion of the product was acetylated and glc on column *A* showed the formation of 2,3-di-*O*-methylarabinitol triacetate (25%) whose identity was confirmed by glc – ms. A further portion of the product was methanolyzed and acetylated and comparison of the derivatives with those formed from the parent methylated pectic acid by glc on column *A* showed that more than 50% of the 2,3-di-*O*-methylgalacturonic acid residues had undergone modification.

β-Lactams. VIII. The synthesis of iso-oxapenams from *N*-substituted-4-hydroxymethylazetidinones

GHOLAM HOSEIN HAKIMELAHI AND GEORGE JUST

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received August 22, 1980

GHOLAM HOSEIN HAKIMELAHI and GEORGE JUST. Can. J. Chem. **59**, 941 (1981).

The synthesis of 3,3-disubstituted iso-oxapenams is described.

GHOLAM HOSEIN HAKIMELAHI et GEORGE JUST. Can. J. Chem. **59**, 941 (1981).

On décrit la synthèse d'iso-oxapenam 3,3-disubstitués.

For personal use only.

We have recently shown (1) that 2,2-disubstituted tetrahydrofurans can be prepared from the corresponding 1,1-disubstituted butan-4-ols by reaction with trifluoromethanesulfonyl chloride – triethylamine, provided that the substituents stabilize an incipient carbanion ($pK_A = 11 \simeq 15$). In this paper, we describe the application of this method to the synthesis of iso-oxapenams of type **2** and **9**.

The cyclization reaction had originally been observed on the benzyl ester **1***b* (1) and its course elucidated using methyl ester **1***a* (1), where products obtained gave unambiguous mass spectra; *p*-nitrobenzyl ester **1***c*, prepared by adaptation of literature procedures (2), was eventually used to prepare free acid **2***f* since it could be cleaved in the presence of the highly labile (3) iso-oxapenam ring system.

Treatment of either diastereomer of hydroxymethylazetidinone **1***a* with trifluoromethanesulfonyl chloride (1 equiv.) and triethylamine (2 equiv.) in methylene chloride at 0°C gave, in 69% yield, the formal oxidation product of **1***a* having structure **2***a*. The nmr spectrum of **2***a* indicated the loss of two hydrogen atoms, and was consistent with the structure proposed, as were the ^{13}C nmr, uv, and the ir spectra. The latter showed the presence of azide (2105 cm^{-1}), ester (1730 cm^{-1}), and highly strained β-lactam (1790 cm^{-1}) functions. The C.I.-mass spectrum showed M + 1, M + 1 – $N_3CH{=}C{=}O$, and $PhCO^+$, and the E.I.-mass spectrum significant fragments for $M^+ - COOMe$, $M^+ - COOMe - N_2$, $M^+ - COOMe - N_3CH{=}C{=}O$, and $PhCO^+$ (100%). β-Lactam **2***a* could not be obtained in totally pure form and was extremely labile to acid, giving ketoester **10** (4), characterized as its dinitrophenylhydrazone.

The formation of an intermediate triflate **1***d* in the conversion of alcohol **1***a* to iso-oxapenam **2***a* could be ruled out by preparing triflate **1***d* from alcohol **1***a* with trifluoromethanesulfonic anhydride, and showing that triflate **1***d* was stable to triethylamine in methylene chloride. The most likely explanation for the cyclization is a sequence where trifluoromethanesulfonyl chloride acts as a chlorinating agent at the potential carbanionic site, followed by a replacement of the chlorine by the alcohol function (5). This hypothesis is further supported by the fact that treatment of either triflate **1***d* or styrylazetidinone **3***a* (3) with trifluoromethanesulfonyl chloride – triethylamine in methylene chloride at 0°C, followed by standard aqueous work-up, gave ketoester **10**, presumably via the highly labile chloroazetidinones of type **3***b*.

Iso-oxapenams **2***b* and **2***c* were prepared from alcohols **1***b* and **1***c* in a similar manner.

Catalytic reduction for one hour of azide **2***a* in ethyl acetate using palladium on charcoal as catalyst gave the very unstable amino β-lactam **2***d* in 20% yield only. Its instability was probably due to a bimolecular reaction of the amine function with a β-lactam group, since the β-lactam absorption at 1790 cm^{-1} disappeared over a period of a few hours, and was accompanied by the appearance of an amide absorption band at 1680 cm^{-1}.

The catalytic reduction was, therefore, carried out in the presence of acetic anhydride, and the relatively stable acetamido-β-lactam **2***e* was obtained in 47% yield. Having established a methodology for the conversion of the azide function to an amide group, the catalytic reduction in the presence of acetic anhydride was applied to azido *p*-nitrobenzyl oxapenam **2***c*, permitting the isolation of the free acid **2***f* in 35% yield. Its structure was proven by treatment with diazomethane, which gave **2***e* described above.

The stereochemistry of the phenyl group and the carbonyl function in compounds **2** was not determined. However, ^{13}C nmr and other spectroscopic data seemed to indicate that only one isomer was present.

We next studied the cyclization reaction using dialkyl aminomalonates as starting materials. Pre-

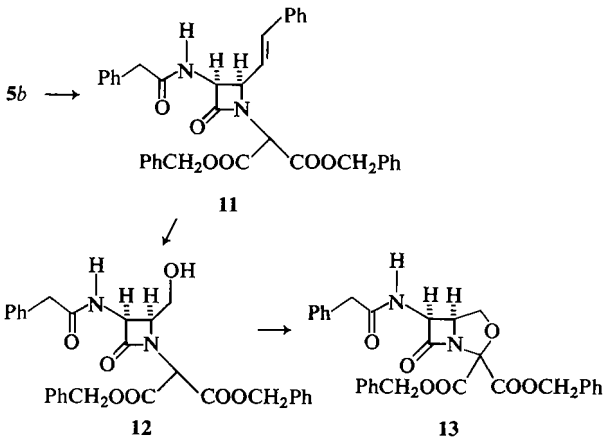
liminary studies were carried out on the commercially available diethyl aminomalonate **4***a*. Under precisely defined conditions, it was transformed to its cinnamylidene Schiff base, which could not be characterized, but was immediately transformed to azido β-lactam **5***a* in 24% yield only by the action of azidoacetyl chloride. Similarly, dibenzyl aminomalonate, prepared in good yield by a modification of the literature procedure (6), was converted to β-lactam **5***b* in 20% yield. It should be noted that dimethyl aminomalonate, when submitted to the same reaction conditions, gave no detectable β-lactam **5**. Di-*tert*-butyl aminomalonate, the most desirable starting material, could not be prepared using appropriate adaptations of literature (7) procedures. Ozonolysis of **5***a* or **5***b*, followed by sodium borohydride reduction (8), gave alcohols **6***a* and **6***b* in approximately 25% yield only, perhaps because of oxidation of the enolic form of **5**. Addition of acetic or trifluoroacetic acid to the ozonolysis solvent did not increase the yields. Treatment of **6***a* or **6***b* with one equivalent of trifluoromethanesulfonyl chloride and two equivalents of triethylamine gave iso-oxapenam **9***a* and **9***b* in approximately 60% yield.

Because of the extremely poor yields observed in most steps of this sequence, styryl lactam **5***b* was first chlorinated with CF_3SO_2Cl/NEt_3, and the mixture immediately submitted to the ozonolysis – borohydride reduction sequence described. Alcohol **8**, obtained in 57.6% yield, was cyclized quantitatively with triethylamine to iso-oxapenam **9***b*, identical to **9***b* obtained above. Attempts to transform the azide function to an amine or amide group by reaction with hydrogen sulfide – triethylamine (9), followed by quenching of the amine with phenylacetyl chloride, or by catalytic hydrogenation in the presence or absence of acetic anhydride failed, giving products which did not show the presence of a β-lactam function as evidenced by the disappearance of the 1780–1790 cm^{-1} band in the infrared.

We therefore introduced the amide group at an earlier stage by reducing the azide group of **5***b*, and acylating the resulting amine with phenylacetyl chloride – pyridine (9). Styryl amide **11** was then

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.



submitted to ozonolysis, followed by sodium borohydride reduction, and the resulting alcohol **12** was cyclized to **13** with trifluoromethanesulfonyl chloride – triethylamine. All attempts to hydrogenolyse the benzyl groups of **13** failed, and resulted in the destruction of the β-lactam ring.

Experimental

For general procedures, see (2).

Iso-oxapenams 2a, 2b, *and* 2c

Each diastereomer of **1***a*, **1***b*, and **1***c* was submitted to identical reaction conditions and purification procedures, which will be described for **1***a* only. Their spectra were similar except for their ester variations.

β-Lactam **1***a* (0.290 g, 1 mmol) was dissolved in 15 mL dry CH_2Cl_2. Triethylamine (0.202 g, 2 mmol) was added. Trifluoromethanesulfonyl chloride (0.169 g, 1 mmol) in 5 mL dry CH_2Cl_2 was added dropwise while the reaction mixture was stirring at room temperature. After 1 h, the solution was washed with water, dried, and evaporated to give the crude product, which was chromatographed on silica gel. Elution with CH_2Cl_2 gave 0.2 g (69%) **2***a* as an oil. Ultraviolet λ_{max} (EtOH): 255 nm (ε 220); ir (CH_2Cl_2): 2105 (N_3), 1790 (β-lactam), 1730 (ester) cm^{-1}; nmr ($CDCl_3$) δ: 3.90 (s, 3H, CH_3), 4.00–4.60 (m, 4H, $CHCHCH_2O$), 7.30–7.80 (m, 5H, Ph); ^{13}C nmr ($CDCl_3$ at 77.10 ppm) 171.50 (C=O), 164.77 (N—C=O), 135.04–127.90 (Ph), 69.23 (C(3)), 65.12 (CH_2O), 63.53 ($CHCH_2O$), 52.74 (CHN_3), 52.61 (OCH_3) ppm; ms E.I. 260 ($M^+ - N_2$), 229 (M^+ – COOMe), 201 (M^+ – COOMe – N_2), 146 (M^+ – COOMe – $N_3CH{=}C{=}O$), 105 (Ph^+CO), 77 (Ph^+); C.I. 289 ($M^+ + 1$), 261 ($M^+ + 1 - N_2$), 206 ($M^+ + 1 - N_3CH{=}C{=}O$) and Ph^+CO. *Anal.* calcd. for $C_{13}H_{12}N_4O_4$: C 54.16, H 4.20, N 19.44; found: C 53.65, H 4.01, N 19.18.

Acetamido β-*Lactam* 2e

Azido β-lactam **2***a* (0.2 g, 0.69 mmol) was dissolved in 30 mL dry ethyl acetate containing 5 mL acetic anhydride, and 10% Pd/C (0.05 g) was added. The mixture was hydrogenated at room temperature and 30 psi for 1.5 h. The solution was then filtered and evaporated, and the residue was chromatographed on silica gel using $CHCl_3$ as eluent to give **2***e* (0.1 g) in 47% yield. Infrared: 3410 (NH), 1789 (β-lactam), 1735 (ester), 1675 (amide) cm^{-1}; nmr ($CDCl_3$) δ: 2.22 (s, 3H, CH_3CO), 3.78 (s, 3H, CH_3), 3.82–4.63 (m, 4H, $CHCHCH_2O$), 6.50 (d, 1H, NH), 7.21–7.42 (m, 5H, Ph); ms C.I. 305 ($M^+ + 1$), 205 ($M^+ - CH_3CONHCH{=}C{=}O$). *Anal.* calcd. for $C_{15}H_{16}N_2O_5$: C 59.21, H 5.26, N 9.21; found: C 58.98, H 5.45, N 9.38.

β-*Lactam* 2f

β-Lactam **2***c* (0.2 g, 0.48 mmol) was dissolved in 30 mL ethyl acetate containing 10 mL acetic anhydride. 10% Pd/C (0.1 g) was added. The reaction mixture was hydrogenated at room temperature and 40 psi for 2 h. The solution was filtered and evaporated to dryness, 20 mL water was added, and the organic material was extracted with ethyl acetate, dried, and the solvent evaporated to give the crude product as a foam. Crystallization from diethyl ether gave 0.05 g (35%) β-lactam **2***f*, mp 101–104°C. Infrared (CH_2Cl_2): 3200–3500 (COOH, NH), 1780 (β-lactam), 1710 (acid), 1665 (amide) cm^{-1}; nmr ($CDCl_3$–D_2O) δ: 2.19 (s, 3H, CH_3), 3.82–4.2 (m, 3H, $CHCH_2O$), 4.41 (d, 1H, CHND, J = 5 Hz), 7.22–7.41 (m, 5H, Ph). Treatment of **2***f* with ethereal diazomethane gave the corresponding methyl ester **2***e* which was identical to that obtained before.

Azido-β-*lactams* 5a *and* 5b

Both β-lactams were prepared in an identical manner. Their spectra were similar except for their ester variations. Their chemical ionization mass spectra show $M^+ + 1$ and other appropriate fragments.

The following is a representative procedure.

To a solution of **4***a* (4 g, 0.022 mol) in 40 mL of dry CH_2Cl_2 was added cinnamaldehyde (3.1 g, 0.023 mol). Magnesium sulfate was added and the solution was stirred at room temperature for 6 h. The solution was filtered and triethylamine (2.5 g, 0.024 mol) was added. A solution of azidoacetyl chloride (3.6 g, 0.03 mol) in 30 mL dry CH_2Cl_2 was added dropwise over 10 min. The solution was stirred for 5 h and evaporated to dryness. The residue was dissolved in ether, treated with charcoal, filtered, and evaporated to give an oily product, which was chromatographed on silica gel. Elution with CH_2Cl_2 gave azido β-lactam **5***a* (2 g) in 24% overall yield. Infrared (CH_2Cl_2): 2100 (N_3), 1770 (β-lactam), 1750 (ester) cm^{-1}; nmr ($CDCl_3$) δ: 1.21 (t, 6H, $2CH_3$, J = 8 Hz), 4.21 (q, 4H, $2CH_2$, J = 8 Hz), 4.60–4.81 (m, 2H, $CHCHN_3$), 5.08 (s, 1H, CH), 5.91–6.81 (m, 2H, CH=CH), 7.19–7.41 (m, 5H, Ph); nmr (C_6D_6) δ: 0.50–1.11 (m, 6H, $2CH_3$), 3.51–4.12 (m, 4H, $2CH_2$), 4.38–4.60 (m, 1H, CHC=C), 4.64 (d, 1H, CHN_3, J = 5 Hz), 5.10 (s, 1H, CH), 5.90–6.71 (m, 2H, CH=CH), 7.01–7.21 (m, 5H, Ph); ms C.I. 373 ($M^+ + 1$), 345 ($M^+ + 1 - N_2$), 290 ($M^+ + 1 - N_3CH{=}C{=}O$), 328 ($M^+ + 1$ – OEt), 202 ($M^+ + 1 - \phi CH{=}CHCH{=}CHN_3$). *Anal.* calcd. for $C_{18}H_{20}N_4O_5$: C 58.06, H 5.37, N 15.05; found: C 58.12, H 5.29, N 15.10.

4-Hydroxy-azido-β-*lactams* 6a *and* 6b

Both β-lactams **5***a* and **5***b* were submitted to identical reaction conditions and separation procedures, which will be described for **5***a* only. Their spectra were similar, except for their ester variations. Their chemical ionization mass spectra showed ($M^+ + 1$) and appropriate fragments.

β-Lactam **5***a* (2 g, 5.4 mmol) in 50 mL dry CH_2Cl_2 was saturated with nitrogen gas at −78°C. Then a mixture of O_3–N_2 gas was bubbled in until KI starch paper showed excess ozone. The excess ozone was removed by a stream of nitrogen. Then 5 equiv. dimethyl sulfide was added. After 1 h, $NaBH_4/Al_2O_3$ (1 g:10 g, (8)) was added, and the reaction mixture was stirred for 1 h at room temperature. Filtration and evaporation gave the crude product, which was purified on silica gel using $CHCl_3$ as eluent to give 0.6 g (37%) hydroxy β-lactam **6***a*. Infrared (CH_2Cl_2): 2100 (N_3), 1760 (β-lactam), 1740 (ester) cm^{-1}; nmr ($CDCl_3$) δ: 1.25 (t, 6H, $2CH_3$, J = 6 Hz), 3.31 (b, 1H, OH), 3.61–3.80 (m, 3H, $CHCH_2O$), 4.20 (q, 4H, $2CH_2$, J = 6 Hz), 4.77 (d, 1H, CHN_3, J = 5 Hz), 5.20 (s, 1H, CH); ms C.I. 301 ($M^+ + 1$), 273 ($M^+ + 1 - N_2$), 218 ($M^+ + 1 - N_3CH{=}C{=}O$), 228 ($M^+ + 1$ – COOEt), 256 ($M^+ + 1$ – OEt). *Anal.* calcd. for $C_{11}H_{16}N_4O_6$: C 44.00, H 5.33, N 18.66; found: C 44.12, H 5.42, N 18.39.

Chloro-β-lactams 7a *and* 7b

Both β-lactams **5***a* and **5***b* were submitted to identical reaction conditions which will be described for **5***a* only. Their spectra were similar except for their ester variations.

β-Lactam **5***a* (1 g, 2.7 mmol) was dissolved in 50 mL dry CH_2Cl_2. Triethylamine (0.3 g, 2.9 mmol) was added. Trifluoromethanesulfonyl chloride (0.5 g, 2.9 mmol) in 5 mL dry CH_2Cl_2 was added dropwise over 5 min at 0°C. The reaction mixture was allowed to warm to room temperature while stirring (1 h). The solution was evaporated to dryness and diethyl ether was added. The ethereal solution was washed with water, dried, and treated with charcoal. Filtration and evaporation gave a quantitative yield of chloro-β-lactam **7***a* as an oil. Infrared: 2105 (N_3), 1790 (β-lactam), 1760 (ester) cm^{-1}; nmr ($CDCl_3$) δ: 1.01–1.30 (m, 6H, $2CH_3$), 3.93–4.39 (m, 4H, CH_2), 4.77 (dd, 1H, CHC=C, J_1 = 5 Hz, J_2 = 7 Hz), 5.05 (d, 1H, CHN_3, J = 5 Hz), 6.05 (dd, 1H, PhCH=*CH*, J_1 = 8 Hz, J_2 = 16 Hz), 6.61 (d, 1H, PhCH, J = 16 Hz), 7.20–7.31 (m, 5H, Ph); ms C.I. 407 ($M^+ + 1$, Cl-cluster).

Hydroxy-β-lactam 8

β-Lactam **7***b* (1.4 g, 2.6 mmol) in 40 mL dry CH_2Cl_2 was submitted to the identical reaction conditions which were described for the preparation of β-lactam **6***a*, except that $MgSO_4$ was used to dry the solution before adding the $NaBH_4/Al_2O_3$ complex. Chromatography on silica gel and elution with $CHCl_3$ gave 0.7 g (57.6%) β-lactam **8**. Infrared (CH_2Cl_2): 2100 (N_3), 1790 (β-lactam), 1750 (ester) cm^{-1}; nmr ($CDCl_3$) δ: 2.42 (b, 1H, OH, exchangeable with D_2O), 3.81 (b, 2H, *CH*$_2$OH), 4.20–4.51 (m, 1H, CH), 4.65 (d, 1H, CHN_3, J = 5 Hz), 5.10 (s, 4H, CH_2), 7.19 (s, 10H, Ph). *Anal.* calcd. for $C_{21}H_{19}N_4O_6Cl$: C 54.96, H 4.14, N 12.21, Cl 7.74; found: C 55.07, H 4.03, N 12.35, Cl 7.85.

Iso-oxapenams 9a *and* 9b

Both β-lactams **9***a* and **9***b* were prepared in the same manner, which will be described for **9***b* only. Their spectra were similar except for their ester variations.

(*a*) β-Lactam **6***b* (0.2 g, 0.47 mmol) was dissolved in 30 mL dry CH_2Cl_2. Triethylamine (0.101 g, 1 mmol) was added. A solution of trifluoromethanesulfonyl chloride (0.085 g, 0.5 mmol) in 5 mL dry CH_2Cl_2 was added dropwise at 5°C, during a period of 5 min. The temperature was permitted to rise to 30°C in 1 h. The solution was washed with water, dried, and evaporated to give an oily product, which was chromatographed on silica gel. Elution with CH_2Cl_2 gave 0.12 g (59.5%) of **9***b* as an oil. Infrared (CH_2Cl_2): 2105 (N_3), 1795 (β-lactam), 1750 (ester) cm^{-1}; nmr ($CDCl_3$) δ: 4.21–4.80 (m, 4H, $CHCHCH_2O$), 5.10 (s, 4H, $2CH_2$), 7.20 (s, 10H, Ph). *Anal.* calcd. for $C_{21}H_{18}N_4O_6$: C 59.71, H 4.26, N 13.27; found: C 60.01, H 4.20, N 13.19.

(*b*) Chloro-β-lactam **8** (0.5 g, 1.09 mmol) was dissolved in 20 mL dry CH_2Cl_2. Triethylamine (0.12 g, 1.2 mmol) was added, and the solution was stirred at room temperature for 1 h. The solution was washed with water, dried, and evaporated to give an oily product. Chromatography on silica gel and elution with CH_2Cl_2 gave 0.4 g (86%) β-lactam **9***b* which was identical to **9***b* obtained before.

Phenylacetamido-β-lactam 11

To a solution of azido β-lactam **5***b* (2.48 g, 0.005 mol) in 70 mL dry CH_2Cl_2 at 0°C was added triethylamine (0.6 g, 0.006 mol). A stream of H_2S gas was bubbled in for 20 min. The solution was allowed to stand for 2 h at room temperature. Evolution of nitrogen gas was observed. A stream of nitrogen gas was bubbled in for 30 min, then was added 1.5 g (0.018 mol) pyridine, followed by dropwise addition of 0.9 g (0.006 mol) phenylacetyl chloride in 10 mL CH_2Cl_2. The solution was stirred for 2 h at 25°C, then was washed with 5% HCl solution, 10% $NaHCO_3$ solution, and brine. It was then dried over $MgSO_4$, and evaporated to give impure amide, which was chromatographed on silica gel. CH_2Cl_2 eluted impurities, and $CHCl_3$ gave 2.5 g (84%) of β-lactam **11** as an oil. Infrared (CH_2Cl_2): 3400 (NH), 1770 (β-lactam), 1750 (ester), 1680 (amide) cm^{-1}; nmr ($CDCl_3$) δ: 3.41 (s, 2H, CH_2), 4.75 (dd, 1H, *CH*CH=C, J_1 = 5 Hz, J_2 = 8 Hz), 5.00–5.21 (m, 5H, $2CH_2O$ and CH), 5.5 (dd, 1H, C*H*NH, J_1 = 5 Hz, J_2 = 8 Hz), 5.85 (dd, 1H, *CH*=CHPh, J_1 = 8 Hz, J_2 = 16 Hz), 6.45 (d, 1H, CHPh, J = 16 Hz), 6.61 (d, 1H, NH, J = 8 Hz), 7.00–7.40 (m, 20H, Ph); ms C.I. 589 ($M^+ + 1$), 454 ($M^+ + 1$ − COOBn), 414 ($M^+ + 1$ − $PhCH_2CONHCH$=C=O). *Anal.* calcd. for $C_{36}H_{32}N_2O_6$: C 73.46, H 5.44, N 4.76; found: C 73.41, H 5.41, N 4.81.

4-Hydroxymethyl-β-lactams 12

β-Lactam **11** (2.94 g, 0.005 mol) in 50 mL dry CH_2Cl_2 was saturated with nitrogen gas at −78°C. Then a mixture of O_3/N_2 gas was bubbled in until KI starch paper showed excess ozone (16 min). The excess ozone was removed by passing a stream of N_2 for 10 min. Then dimethylsulfide (1.6 g, 5 equiv.) was added. The temperature of the solution was permitted to rise to 25°C over 1 h, following which 4 g $MgSO_4$ was added. After a few minutes, $NaBH_4/Al_2O_3$ (1 g:10 g) was added while stirring. After 1 h the solution was filtered and evaporated to give the impure product, which was chromatographed on silica gel. CH_2Cl_2 eluted impurities and 4-hydroxy-β-lactam **12** was eluted with $CHCl_3$, 2 g (76%). Infrared (CH_2Cl_2): 3250–3550 (NH, OH), 1769 (β-lactam), 1735 (ester), 1685 (amide) cm^{-1}; nmr ($CDCl_3$) δ: 3.50 (s, 2H, CH_2), 5.60–4.18 (bm, 4H, $CHCH_2OH$), 5.10 (s, 4H, CH_2O), 5.38 (s, 1H, CH), 5.58 (dd, 1H, *CH*NH, J_1 = 5 Hz, J_2 = 9 Hz), 7.00 (b, 1H, NH), 7.20 (s, 15H, Ph). *Anal.* calcd. for $C_{29}H_{28}N_2O_7$: C 67.44, H 5.42, N 5.42; found: C 67.34, H 5.49, N 5.44.

Iso-oxapenam 13

Preparation of β-lactam **13** from acetamide-β-lactam **12** was achieved by the same method which was described for preparation of **9***b* from **6***b*. Iso-oxapenam **13** was obtained in 70% yield. Infrared (CH_2Cl_2): 3410 (NH), 1790 (β-lactam), 1756 (ester), 1685 (amide) cm^{-1}; nmr ($CDCl_3$) δ: 3.52 (s, 2H, $COCH_2$), 4.31–4.82 (m, 4H, $CHCHCH_2O$), 5.20 (s, 4H, $2CH_2$), 7.30 (bs, 16H, Ph and NH).

MONCEF CHKIR, DANIEL LELANDAIS et CATHY BACQUET. Can. J. Chem. **59**, 945 (1981).

L'étude systématique de l'oxydation anodique d'ions β cétocarboxylates en milieu aqueux ou hydroorganique a permis de dégager les conditions dirigeant l'orientation de cette réaction. Il est ainsi possible, par le choix du milieu réactionnel et de la structure de l'ion de départ de synthétiser des produits aussi différents que les γ-dicétones, les cétones éthyléniques et les cétoamides.

Le schéma de formation de ces deux derniers composés fait intervenir un ion α-cétocarbénium habituellement difficile à obtenir.

MONCEF CHKIR, DANIEL LELANDAIS, and CATHY BACQUET. Can. J. Chem. **59**, 945 (1981).

A systematic study of the anodic oxidation of β-ketocarboxylate anions in aqueous or hydroorganic solvents allows to distinguish the factors directing this reaction. Thus, it is possible by the appropriate choice of reaction medium and the structure of the starting ion to synthesize products such as γ diketones, ethylenic ketones and ketoamides.

The mode of formation of these last two classes of compound involves an α-ketocarbonium ion which is usually difficult to obtain.

[Journal translation]

L'utilisation de l'oxydation anodique de carboxylates ω-fonctionnalisés pour l'obtention de composés de couplage suivant le schéma 1 est l'une des applications les plus importantes de la réaction de Kolbe.

L'analyse des cas où X est un groupement oxo a été envisagée par de nombreux auteurs. Cependant si les α-céto carboxylates ont donné lieu à un début d'étude systématique (1), la littérature, avant publication de nos notes préliminaires (2, 3, 4), ne relevait rien de tel pour les β-cétocarboxylates. Tout au plus Willstätter et Pfannenstiel (5) avaient utilisé une réaction de ce type pour la synthèse du dioxa-3,6 octanedioate-1,8 d'éthyle, réaction qu'ils avaient menée à bien avec un rendement de 12%.

Pourtant les deux principaux types d'évolution de la réaction de Kolbe, dimérisation du radical formé ou oxydation ultérieure de celui-ci en carbocation, laissaient espérer l'obtention de γ-dicétones d'une part, et la formation d'ions α-cétocarbénium, d'accès *à priori* difficile, d'autre part (Schéma 2).

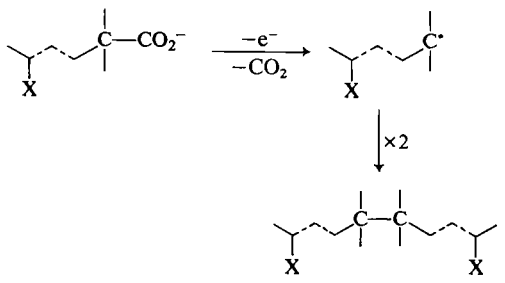

SCHÉMA 1

Nous avons donc entrepris ce travail en nous limitant dans un premier temps à l'électrolyse des β-cétocarboxylates en milieux aqueux ou hydroorganique. La solubilité de ces sels dans de tels solvants permet d'envisager la synthèse de produits en quantités acceptables en laboratoire.

Par ailleurs la littérature offre des méthodes faciles pour préparer des β-cétocarboxylates de structure très variée.

Cependant l'utilisation de β-cétocarboxylates impose certaines contraintes dans le choix des conditions expérimentales. En effet l'instabilité des β-céto-acides correspondants interdit l'emploi des milieux d'électrolyse acides habituellement utilisés dans les réactions de couplage radicalaire (6). De plus, la dégradation facile des sels sous l'effet de la chaleur, nécessite dans tous les cas le maintien de la solution d'électrolyse à une température inférieure à 30°C. Enfin notre but était la synthèse de composés organiques intéressants ou nouveaux avec une sélectivité et des rendements qui fassent de la méthode proposée un véritable mode de préparation de ces produits.

Il fallait donc choisir des conditions opératoires telles que l'oxydation anodique s'oriente vers la formation du radical suivie soit de la dimérisation, soit d'une oxydation électrochimique conduisant à

SCHÉMA 2

l'ion α-cétocarbénium susceptible de subir diverses réactions chimiques. Pour cela nous nous sommes basés sur les règles empiriques proposées classiquement (6), ainsi que sur des résultats que nous avons obtenus antérieurement (2).

Résultats

1. Orientation vers la voie radicalaire. Synthèse de γ-dicétones

Des études effectuées au laboratoire nous ont amenés à choisir un milieu eau–dioxanne (5:3) contenant environ une mole de β-cétocarboxylate de potassium; ce milieu s'est, en effet, révélé favorable à la duplication radicalaire. L'oxydation est réalisée sur une électrode de platine portée à une tension qui permette d'avoir une densité de courant supérieure à 0,25 A/cm². Dans tous les cas le potentiel a été supérieur à 2,2 V par rapport à l'électrode au calomel. Les produits de départ et les produits d'arrivée n'étant pas réductibles, l'électrolyse est conduite dans une cellule à compartiments non séparés. La réaction est arrêtée après consommation d'un Faraday par mole. Dans ces conditions, les résultats obtenus sont consignés dans le tableau 1.

Les γ-dicétones sont des éléments de base en synthèse, qu'il s'agisse par exemple de la préparation d'hétérocycles ou de cyclopenténones (7, 8), en témoignent le grand nombre de publications dont elles font l'objet (9 à 12).

Le tableau 1 permet de constater que ces composés sont obtenus aussi bien quand $R^2 = R^3 = H$, quand seul un groupement est un alkyle ou encore quand R^2 et R^3 sont tous les deux des alkyles. Lorsque R^2 est différent de R^3 il se forme une quantité égale de deux diastéréoisomères (*méso* et *dl*) que nous avons généralement pu séparer. L'attribution de la configuration résulte d'une étude développée par ailleurs.[2]

Les rendements de la réaction sont toujours de l'ordre de 30 à 40%. Ces rendements peuvent paraître modestes; néanmoins comparée aux autre méthodes d'obtention de γ-dicétones (13 à 15) cette réaction reste compétitive. Elle présente en particulier quelques avantages. Ainsi le seul produit secondaire observé est la cétone saturée R^1—CO—CHR^2R^3 ce qui rend la séparation des γ-dicétones particulièrement aisée. Par ailleurs, le mode de synthèse des sels de départ permet une grande variété de groupements R^1, R^2, R^3 d'où la possibilité de préparer un large éventail de γ-dicétones. Une application particulière a été faite pour la synthèse d'un composé deutérié difficilement accessible par deutériation directe.

2. Orientation vers la voie cationique. Obtention de cétones α,β-éthyléniques

L'eau pure étant connue pour être favorable à la voie cationique, de même qu'un milieu basique (6), nous avons électrolysé des solutions aqueuses de concentration environ molaire en carboxylate de potassium et en potasse. La facile électroréduction des cétones α,β-éthyléniques obtenues nécessite l'emploi d'une cellule à compartiments séparés. La libération d'un proton lors de la réaction:

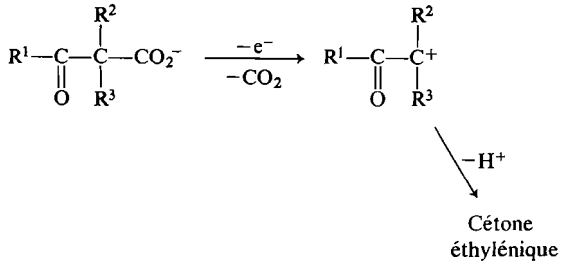

SCHÉMA 3

peut entraîner une acidification du milieu réactionnel ce qui risque d'une part, de favoriser la cétone saturée (voir 1), d'autre part de créer des conditions de pH défavorables à la voie cationique. Pour pallier cet inconvénient le pH du compartiment anodique est maintenu constant par addition de potasse.

L'anode utilisée est en platine; une anode en graphite, censée favoriser la formation du carbocation (6), n'a pas amélioré les résultats. Le potentiel imposé à l'anode est toujours supérieur à 2,2 V, la densité de courant est maintenue à 0,10–

0,15 A/cm² et l'électrolyse est arrêtée après passage de deux Faradays par mole.

Le tableau 2 résume les résultats obtenus lorsque R^2 et R^3 sont des groupements alkyles. Il apparait que, lorsque l'un des groupements R^2 ou R^3 (ou les deux) est un hydrogène, le seul produit isolé est la cétone saturée $R^1COCH_2R^2$. Les rendements observés font de cette réaction un bon mode de préparation de cétones éthyléniques, d'autant plus qu'elle présente l'avantage d'être simple et rapide à mettre en œuvre. En outre cette méthode permet dans certains cas, le passage en deux réactions, l'une chimique (16) l'autre électrochimique de la cétone saturée à la cétone éthylénique. Notons que la réaction de Kolbe, en ne modifiant pas d'autres fonctions présentes dans la molécule, rend possible l'obtention de composés telle la bromobutyl-2 cyclopentène-2 one, susceptible d'être utilisée dans les réactions ultérieures.

3. Orientation vers la voie cationique. Obtention de cétoamides

Ayant vérifié par cette synthèse de cétones α,β-éthyléniques qu'il est possible de créer des carbo-

cations $R^1COC^+R^2R^3$, nous avons pensé les faire réagir sur des nitriles RCN. Cette réaction analogue à celle de Ritter et Minieri (17) conduirait à des cétoamides selon:

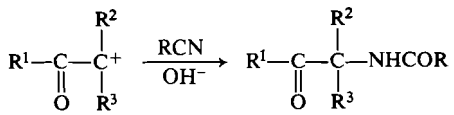

SCHÉMA 4

Ces cétoamides constituent en effet une famille originale d'amides *N*-substitués qui restent très recherchés en fonction de leurs applications diverses (18 à 22). Il est difficile de travailler en milieu nitrile pur à cause, en particulier, de la mauvaise solubilité des carboxylates dans ce solvant. Nous avons donc utilisé un milieu nitrile contenant un minimum d'eau. Ces conditions sont connues pour être assez favorables à l'obtention d'amides *N*-alcoylés par électrochimie (23, 24).

Les ions intermédiaires formés lors de la réaction étant susceptibles d'être réduits à la cathode, nous avons mené les électrolyses dans une cellule à compartiments séparés. L'anode utilisée est une lame de platine. Comme dans le cas des cétones α,β-éthyléniques, l'emploi d'une anode en graphite n'a pas amélioré les rendements. Les résultats obtenus sont rassemblés dans le tableau 3.

Les cétoamides n'ont été obtenus que lorsque R^2 et R^3 sont des groupements alkyles. Si l'un des deux est un hydrogène seule la cétone saturée $R^1COCH_2R^2$ se forme. Les rendements de la réaction décroissent de l'acétonitrile (50%) à l'isobutyronitrile (20%). Dans ce dernier cas se pose le problème de la solubilité dans l'eau, d'où la diminution du rendement. Par ailleurs, il apparait progressivement comme produit secondaire un peu de γ-dicétone $(R^1COR^2R^3)_2$. Enfin il faut signaler que ces produits sont dans leur grande majorité des produits nouveaux. L'un d'entre eux[3] a été soumis sous contrôle de l'ANVAR à des tests pharmacologiques préliminaires. Il ressort de cette étude que ce produit devrait être classé parmi les tranquillisants bien qu'il augmente, dans un certain intervalle des doses administrées, les phases motrices et exploratrices. Deux tranquillisants connus, le chlordiazépoxide et le diazépam présentent cette même dualité.

Ces premiers résultats montrent bien l'intérêt de synthétiser ce type de composé. En effet la substitution sur l'azote par un groupement carbonylé semble accroître l'activité psychotrope des produits ce qui n'est pas évident si la fonction carbonylée est introduite sur la chaîne carbonée.

Discussion

Cette étude montre l'importance de deux facteurs influant sur le déroulement de la réaction: (*1*) la structure de l'ion carboxylate; (*2*) la nature du milieu d'électrolyse .

Structure de l'ion carboxylate

Nous n'avons pas observé, même dans des

[3] *i*PrCOCMe$_2$NHCOMe.

milieux très favorables, de produits d'origine cationique dans les cas où R^2 et R^3 ne sont pas tous deux des alkyles. Nous retrouvons ainsi une règle empirique énoncée par Eberson: "les radicaux dont le potentiel d'ionisation est supérieur à 8 eV résistent généralement à une oxydation ultérieure en cation" (voir réf. 23).

Pour les radicaux α-carbonylés nous ne disposons que du potentiel d'ionisation du radical $^{\cdot}CH_2—COCH_3$ qui est de 7,95 eV. Mais par ailleurs, nous savons que le potentiel d'ionisation des radicaux α-cyanés varient de la façon suivante: $^{\cdot}CH_2CN$, 10,87 eV; $CH_3\dot{C}H—CN$, 9,76 eV et $(CH_3)_2\dot{C}—CN$: 9,15 eV (25, 26), Une évolution parallèle conduirait à environ 6,85 eV pour le radical carbonylé monométhylé et 6,25 eV pour le diméthylé.

Ces valeurs paraissent éloignées de la frontière des 8 eV proposée dans la règle d'Eberson. Cependant celle-ci ne peut s'appliquer rigoureusement puisque les potentiels d'ionisation sont déterminés en phase gazeuse par impact électronique ou photoionisation, alors que nous avons effectué les électrolyses en solution. De plus la règle d'Eberson avait été établie pour des radicaux alkylés électrolysés dans le méthanol. Nos résultats montrent néanmoins que la facilité d'oxydation du radical en carbocation va de pair avec un faible potentiel d'ionisation de ce radical.

Dans le cas des radicaux carbonylés électrolysés en milieu aqueux basique, nous remarquons un changement de comportement brutal: les β-cétocarboxylates monoalkylés conduisent uniquement à des produits issus d'une réaction radicalaire, alors que les composés dialkylés ne fournissent que des produits d'origine cationique. Ces résultats montrent néanmoins qu'il est facile de créer, par voie électrochimique, un ion α-cétocarbénium d'accès *à priori* difficile.

Milieu réactionnel

L'étude présentée met aussi en évidence l'importance du choix du milieu réactionnel pour orienter la réaction.

En effet, le milieu va non seulement déterminer le type d'intermédiaire qui va se former par électrolyse de β-cétocarboxylates dialcoylés (un radical en milieu dioxanne-eau, un carbocation en milieu basique aqueux, ou un mélange des deux espèces en milieu basique hydroorganique), mais encore orienter la réaction de l'intermédiaire (obtention de cétones éthyléniques en milieu aqueux ou obtention de cétoamides en milieu eau–acétonitrile). Le principal intérêt de ce travail, à côté des problèmes théoriques qu'il soulève, réside dans l'élaboration de composés aussi différents que les γ-dicétones, les cétones éthyléniques et les cétoamides à partir de matières premières d'accès aisé.

Partie expérimentale

Les spectres ir ont été effectués sur un appareil Perkin-Elmer 457G, les spectres rmn sur un appareil Varian EM360 en solution dans le tétrachlorure de carbone (référence interne hexaméthyldisiloxane).

Préparation des esters-β cétoniques

Plusieurs méthodes ont été utilisées pour préparer les β-cétocarboxylates suivants (Schéma 5); alcoylation de l'acétyl acétate d'éthyle selon Cournot (27) cas **1, 4, 5, 6, 7, 10**; alcoylation de la carbéthoxy-2 cyclopentanone selon la réf. 28, cas **13, 14**; double condensation du dibromo-1,4 butane sur l'acétyl acétate d'éthyle selon la réf. 16, cas **10**; condensation de cétones sur le diéthylcarbonate selon la réf. 29, cas **2, 3, 9**; condensation du dibromo-1,4 butane sur le sel de potassium de la carbéthoxycyclopentanone selon la réf. 30, cas 15.

Synthèse des carboxylates β-cétoniques

1. Saponification des esters β-cétoniques (mode opératoire général)

Une solution de 5,6 g de potasse en solution dans 50 mL d'eau est ajoutée à température ambiante à 0,1 mole d'ester β-cétonique; une agitation magnétique est maintenue pendant 16 h. Après extraction à l'éther, la phase aqueuse contenant le sel β-cétonique est électrolysée.

2. Synthèse directe de sels β-cétoniques

La synthèse des composés **8, 11** et **12** s'effectue par condensation des cétones saturées correspondantes sur le bioxyde de carbone (29).

Appareillage

Conditions d'électrolyse (mode opératoire général)

Les électrolyses sont menées à l'aide d'un potentiostat Tacussel modèle ASA 10A permettant d'imposer un potentiel fixe à l'anode. Les mesures coulométriques ont été faites sur un intégrateur Tacussel IG 4100 monté en série sur le circuit. L'in-

tensité du courant est mesurée par un ampèremètre monté sur le circuit de la cathode.

La cellule d'électrolyse est constituée par une cuve servant de compartiment cathodique au fond de laquelle se trouve une nappe de mercure (cathode). Un verre fritté servant de compartiment anodique est ajusté à l'intérieur de la cuve dans le cas d'électrolyse en compartiments séparés. L'anode est une lame de platine. Une agitation magnétique est maintenue au cours de la réaction et la tension imposée est toujours supérieure à 2,2 V par rapport à l'électrode de référence au calomel, de façon à obtenir une densité de courant de l'ordre de 0,10 à 0,15 A/cm^2 pour les réactions par voie cationiques et de 0,25 A/cm^2 pour les réactions par voie radicalaire. A la fin de l'électrolyse la solution est recueillie, neutralisée par une solution diluée d'acide chlorhydrique puis extraite plusieurs fois à l'éther. Les solvants et produits légers sont distillés sous pression ordinaire. Les résidus sont fractionnés sous pression réduite et analysés par chromatographie en phase vapeur. Nous avons utilisé trois types de colonne: silicone SE30, cyanosilicone XE60 et Carbowax 20M. La colonne de Carbowax donne généralement les meilleurs résultats et permet notamment de séparer les diastéréoisomères des composés bifonctionnels. Nous avons le plus souvent doublé la chromatographie en phase vapeur par une séparation des produits sur couche mince. Nous avons utilisé un support de silice légèrement platrée GF25H et un éluant composé de 50% d'éther de pétrole, 25% d'éther et 25% de chloroforme. Les produits sont révélés avec une lampe à ultraviolet puis fixés à l'aide d'une solution sulfurique de sulfate de cérium.

Obtention des γ-dicétones

1. Conditions d'électrolyse (mode opératoire général)

Dans une cellule non divisée, 50 mL d'une solution aqueuse contenant 0,1 mole de sel β-cétonique sont ajoutés à 30 mL de dioxanne. Une agitation magnétique est maintenue. L'électrolyse est arrêtée après consommation d'un Faraday par mole. La solution est traitée selon le mode opératoire général.

2. Produits isolés

Tous les rendements ont été calculés par rapport au β-cétocarboxylate de départ.

Hexanedione-2,5. Séparée en cpv sur colonne Carbowax à 150°C; rendement 38%. Identique à un échantillon commercial.

Diméthyl-2,7 octanedione-3,6 (31). Séparée en cpv sur colonne Carbowax à 180°C; rendement 40%; $Eb_{0,9}$ 100–102°C; dioxime F 172–173°C (litt (31) F 174–175°C); rmn (CCl_4): 2,6 (s, 2H), 2,5 (hept, 1H), 1,1 (d, 6H) ppm.

Tétraméthyl-2,2,7,7 octanedione-3,6 (32). Séparée en cpv sur colonne de silicone à 160°C; rendement 38%; Eb_{18} 106–107°C (litt. (32) Eb_{10} 106–107°C); rmn (CCl_4): 2,5 (s, 2H), 1,0 (s, 9H) ppm.

Diméthyl-3,4 hexanedione-2,5 (33). Séparée en cpv sur colonne Carbowax à 135°C; rendement 39%; rmn (CCl_4): 2,8 (m, 1H), 2,1 (s, 3H), 1,1 (m, 3H) ppm. Il s'agit d'un mélange de deux isomères.

Diéthyl-3,4-hexanedione-2,5 (34). Rendement 36%; Eb_{20} 112–115°C (litt. (34) Eb_{20} 112–115°C); rmn (CCl_4), isomère 1: 2,85 (m, 1H), 2,1 (s, 3H), 1,6 (m, 2H), 0,8 (t, 3H) ppm; isomère 2: 2,70 (m, 1H), 2,1 (s, 3H), 1,45 (m, 2H), 0,8 (t, 3H) ppm.

Tétraméthyl-3,3,4,4 hexanedione-2,5 (35). Séparée en cpv sur colonne de Carbowax à 135°C; rendement 37%; $Eb_{0,5}$ 40°C (litt. (35) $Eb_{0,5}$ 40°C); rmn (CCl_4): 2,1 (s, 3H), 1,2 (s, 6H) ppm.

Diéthyl-3,4 diméthyl-3,4 hexanedione-2,5 (36). Rendement 34%; Eb_1 95–97°C; rmn (CCl_4), isomère 1: 2,0 (s, 3H), 1,17 (s, 3H), 1,35 (q, 2H), 0,8 (t, 3H) ppm; isomère 2: 2,05 (s, 3H), 1,20 (s, 3H), 1,13 (q, 2H), 0,8 (t, 3H) ppm.

Hexaméthyl-2,4,4,5,5,7 octanedione-3,6 (37). Séparée en cpv sur colonne de silicone à 180°C. Rendement 33%; $Eb_{1,5}$ 75–77°C (litt. (37) $Eb_{5,5}$ 108–111°C); rmn (CCl_4): 3,1 (hept, 1H), 1,3 (s, 6H), 1,1 (d, 6H) ppm.

Tétraméthyl-2,2,7,7 diéthyl-4,5 octanedione-3,6. Séparée en cpv sur colonne de cyanosilicone à 160°C; rendement 32%; $Eb_{0,5}$ 105–107°C; F 44–45°C; ir v: 1720 cm^{-1}; rmn (CCl_4): 3,4 (m, 1H), 1,5 (m, 2H), 1,2 (s, 9H), 0,8 (m, 3H) ppm. Il s'agit d'un mélange de deux isomères. *Anal.* calc. pour $C_{16}H_{30}O_2$: C 75,53, H 11,89; trouvée: C 75,71, H 11,84.

Deutéro-4,5 tétraméthyl-2,2,7,7 diéthyl-4,5 octanedione-3,6. Séparée en cpv sur colonne de cyanosilicone à 160°C; rendement 32%; $Eb_{0,5}$ 105–107°C; ir v: 1720 cm^{-1}; rmn ($CDCl_3$), isomère 1: 1,6 (m, 2H), 1,15 (s, 9H), 0,8 (t, 3H) ppm; isomère 2: 1,4 (m, 2H), 1,15 (s, 9H), 0,8 (t, 3H) ppm.

Obtention des cétones éthyléniques

1. Conditions d'électrolyse (mode opératoire général)

Une solution contenant 0,1 mole de sel β-cétonique et 0,1 mole de potasse dans 50 mL d'eau est introduite dans le compartiment anodique. Dans le compartiment cathodique, une solution aqueuse de potasse de même concentration est versée de façon à égaliser les niveaux des deux compartiments. L'électrolyse est arrêtée après consommation de deux Faradays par mole. La solution est traitée selon le mode opératoire général.

2. Produits isolés

Méthyl-3 butène-3 one-2. Rendement 90%. Identique à un échantillon commercial.

Diméthyl-2,4 pentène-1 one-3 (38). Séparé en cpv sur colonne de Carbowax à 95°C. Rendement 90%; Eb_{40} 52–54°C (litt. (38) Eb_{60} 55°C); rmn (CCl_4): 5,9 (2m, 2H), 3,3 (hept, 1H), 1,9 (m, 3H), 1,1 (d, 6H) ppm.

Acétyl-1 cyclopentène (39). Séparé sur colonne de Carbowax à 160°C. Rendement 60%; F 206–208°C; rmn (CCl_4): 6,6 (m, 1H), 2,5 à 2 (m, 6H), 2,2 (s, 3H) ppm.

Diméthyl-2,6 cyclohexène-2 one-1 (40). Séparé sur colonne de Carbowax à 185°C. Rendement 55%; rmn (CCl_4): 6,7 (m, 1H), 2,6 à 1,9 (m, 5H), 1,8 (m, 3H), 1,15 (d, 3H) ppm.

Méthyl-2 cyclopentène-2 one-1 (41). Séparé sur colonne de Carbowax à 165°C. Rendement 80%; rmn (CCl_4): 7,3 (m, 1H), 2,7 à 2 (m, 4H), 1,8 (m, 3H) ppm.

Ethyl-2 cyclopentène-2 one-1 (42). Séparé sur colonne de Carbowax à 175°C. Rendement 70%; rmn (CCl_4): 7,2 (m, 1H), 2,7 à 1,9 (m, 6H), 1,1 (t, 3H) ppm.

Bromobutyl-2 cyclopentène-2 one-1. Séparée sur colonne de silicone à 200°C. Rendement 50%; ir v: 1710, 1630 cm^{-1}; rmn (CCl_4): 7,2 (m, 1H), 3,35 (t, 2H), 2,7 à 1,5 (m, 10H) ppm. *Anal.* calc. pour $C_9H_{13}OBr$: C 49,79, H 6,04, Br 36,81; trouvée: C 49,83, H 6,00, Br 36,78.

Obtention des cétoamides

1. Conditions d'électrolyse (mode opératoire général)

Une solution de 0,1 mole de sel β-cétonique dans 50 mL d'eau est introduite dans le compartiment anodique puis 30 mL d'acétonitrile, de propionitrile ou d'isobutyronitrile sont ajoutés. Dans le compartiment cathodique une solution de potasse de même concentration est versée de façon à égaliser les niveaux des deux compartiments. Les électrolyses sont conduites à pH légèrement alcalin, une solution de potasse est ajoutée au fur et à mesure que la réaction se poursuit. L'électrolyse est arrêtée après consommation de deux Faradays par mole. La solution anodique est traitée selon le mode opératoire général. Après évaporation des solvants, le résidu est abondonné au réfrigérateur. Les céto-amides cristallisent généralement au bout de quelques jours. Un lavage à zéro degré permet une première purification des produits.

Rydberg and valence-shell transitions in the quartz ultraviolet spectra of aliphatic thiones

A. E. BRUNO, D. J. CLOUTHIER, P. G. MEZEY, AND R. P. STEER[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received July 28, 1980

A. E. BRUNO, D. J. CLOUTHIER, P. G. MEZEY, and R. P. STEER. Can. J. Chem. **59**, 952 (1981).

The electronic absorption spectra of 3,3-dimethylbutane-2-thione and 3-methylbutane-2-thione in the gas phase have been measured and the observed transitions assigned with the aid of *ab initio* and semi-empirical calculations. In the quartz ultraviolet region four transitions are observed. A strong, broad, structureless band is assigned to the $\pi \rightarrow \pi^*$ transition and three weaker, narrower bands are assigned to Rydberg $n \rightarrow 4s$, $n \rightarrow 4p_y$ and $n \rightarrow 4p_z$ transitions on sulfur.

A. E. BRUNO, D. J. CLOUTHIER, P. G. MEZEY et R. P. STEER. Can. J. Chem. **59**, 952 (1981).

On a mesuré les spectres électroniques d'absorption de la diméthyl-3,3 butanethione-2 et de la méthyl-3 butanethione-2 en phase gazeuse et on a identifié les transitions à l'aide de calculs *ab initio* et semi-empiriques. Dans la région ultraviolette du quartz, on a observé 4 transitions: une bande large et intense non structurée que l'on attribue à la transition $\pi \rightarrow \pi^*$ et trois bandes plus faibles et plus étroites que l'on attribue aux transitions de Rydberg du soufre $n \rightarrow 4s$, $n \rightarrow 4p_y$ et $n \rightarrow 4p_z$.

[Traduit par le journal]

Introduction

Although clear distinctions have been made between Rydberg and valence-shell electronic transitions in organic molecules containing a wide variety of chromophores (1), the aliphatic thiones have not been examined from this point of view. The existing assignments (2–6) of higher energy absorption bands in the uv–visible spectra of aliphatic thiones are inconsistent and may be incorrect, in part, in light of recent work on thioformaldehyde (7–9). The photochemistry of the higher excited states of the thiones (10, 11) has been of great interest in recent years and a re-examination of thione uv spectra is also warranted from this standpoint.

Aliphatic thiones exhibit two weak, overlapping band systems in the visible which are unmistakably assignable to transitions involving $n \rightarrow \pi^*$ electron promotions which produce the lowest triplet and lowest excited singlet states of the molecule (12). The interpretation of the spectra in the quartz ultraviolet is less straightforward, however, since several band systems of comparable intensity overlap. Two strong, broad unstructured absorptions at $210\,nm < \lambda_{max} < 320\,nm$ have been observed previously in solution and have been assigned to $\pi \rightarrow \pi^*$ and $n \rightarrow \sigma^*$ transitions (2–5). Rydberg transitions in these solution spectra have not been identified but would tend to be obscured by solvent absorption in the expected absorption region. Moreover, the electronic spectra may be complicated by tautomerization which can occur in thiones possessing labile α-hydrogen atoms (13). Further difficulties are associated with the instability of many aliphatic thiones. No electronic spectra of aliphatic thiones in the gas phase have been reported.

In this paper we report the quartz ultraviolet spectra of two aliphatic thiones, 3,3-dimethylbutane-2-thione (**I**) and 3-methylbutane-2-thione (**II**), in the gas phase and assign the observed band systems to Rydberg and valence shell transitions with the aid of *ab initio* and semi-empirical calculations.

Experimental and Calculational Techniques

I and **II** were prepared by the acid-catalyzed reaction of H_2S with the corresponding ketones according to the method of Paquer and Vaille (14). After vacuum distillation the thiones were purified by preparative gas chromatography using a 3 m glass column containing 30% SE 30 on 60/80 acid-washed Chromosorb W. Samples were stored under vacuum in the dark at 77 K.

Absorption spectra were taken on a Cary 118 uv–visible spectrophotometer which had been flushed for 24 h with dry nitrogen. Matched 10 cm cells with Suprasil windows were used to obtain gas phase spectra using an evacuated cell as a reference. All measurements were made at a room temperature of 23 ± 2°C.

Because experimental structures of these thiones have not been reported, their ground state geometries were estimated by *ab initio* calculations using a modified version of the Gaussian 70 program in which an STO-3G minimal basis set is employed (15). This program is known to reproduce the measured ground state geometries of smaller thiocarbonyls with good accuracy (16). The most important bond angles and lengths were sequentially optimized in several iterations to obtain a final geometry. CNDO/2 calculations based upon these estimations were then used to obtain values of the oscillator strengths of the valence-shell transitions. The thiones were assumed to exhibit C_{2v} local symmetry about the $>C{=}S$ moiety in the ground electronic state. The z axis of the coordinate system was chosen to be coincident with the C—S bond axis, with the x axis perpendicu-

lar to the C—CS—C plane, in accordance with Mulliken's recommendation (17).

Results and Discussion

The gas phase spectra of **I** and **II** in the quartz ultraviolet are shown in Fig. 1. A weak, broad, structureless band with maximum intensity at 500 nm and a weaker shoulder to the red was found in the visible gas phase spectra of both compounds. The main band is assigned to the $\tilde{A} \leftarrow \tilde{X}$, $^1(n \rightarrow \pi^*)$ transition and the shoulder to the red to the corresponding triplet, in complete agreement with previous interpretations of similar aliphatic thione spectra in solution (2–5, 12). The quartz ultraviolet spectra of these and similar compounds in solution are poorly defined but provide evidence of the existence of at least two transitions. The gas phase spectra are much clearer. The spectrum of **I** at a pressure of 0.18 Torr is seen to consist of four overlapping but clearly resolvable bands in the 185 nm $< \lambda <$ 270 nm region. The spectrum of **II** is less well resolved in the $\lambda <$ 200 nm region and may be complicated by the presence of an unknown amount of enethiol (13). Nevertheless, the spectra of **I** and **II** are very similar, as expected. Because **I** is the simplest aliphatic thione which neither polymerizes nor tautomerizes significantly on the time scale of these experiments, it was chosen as a model compound for spectral assignment.

The strongest of the four overlapping bands in the uv spectrum of **I** is broad (fwhm ~ 5800 cm^{-1}) and structureless, is centered at 220 nm, and underlies a weaker, sharper band with maximum at 224 nm. Assuming that the broader band is Gaussian in shape, deconvolution of these two absorptions yields oscillator strengths of 0.15 and 0.016 for the two transitions. The broad, strong transition thus has features which are very similar to those of the well-documented $\pi \rightarrow \pi^*$ valence-shell transitions of smaller thiocarbonyl halides (18, 19) and of thioformaldehyde (8). Thiophosgene, for example, exhibits a strong (f = 0.059), broad (fwhm ~ 4000 cm^{-1}) transition with λ_{max} at 254 nm, assigned to a $\pi \rightarrow \pi^*$ electron promotion, whereas CF_3CSF has a similar band (20) with λ_{max} at 211 nm and fwhm of 5300 cm^{-1}. The intensity of this band in **I** is entirely consistent with an allowed ($\tilde{B}(^1A_1) \leftarrow \tilde{X}(^1A_1)$ in C_{2v} symmetry) transition involving a $\pi \rightarrow \pi^*$ intravalence electron promotion localized on the thiocarbonyl moiety. The breadth of the band is also consistent with the substantial elongation of the C—S bond associated with a reduction in the nominal C—S bond order from two to one and with the change in geometry from planar to pyramidal (about the C—CS—C linkage) on excitation. Equilibrium bond length increases of ca. 0.5 Å and excited state out-of-plane angles of up to 30° have been determined from the $\tilde{B} \leftrightarrow \tilde{X}$ spectra of those tetraatomic thiocarbonyls (18, 19, 21) which exhibit sufficient structure to permit detailed vibrational analysis. By analogy with the thiocarbonyl halides, the origin of this $\pi \rightarrow \pi^*$ transition likely lies near the long wavelength onset of measurable absorption near 270 nm.

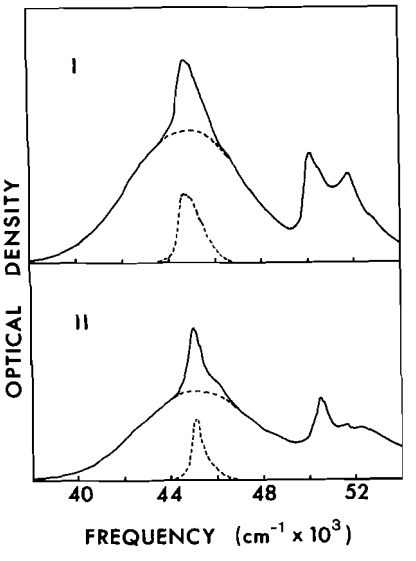

FIG. 1. Gas phase quartz ultraviolet spectra of **I** (3,3-dimethylbutane-2-thione) and **II** (3-methylbutane-2-thione). Dotted lines show the deconvolution of the overlapping $\pi \rightarrow \pi^*$ and $n \rightarrow 4s$ transitions.

These assignments are confirmed by measured solvent shifts. The visible band exhibits a hypsochromic shift with increasing solvent polarity which is characteristic of $n \rightarrow \pi^*$ transitions. The strong, broad band in the ultraviolet exhibits a small bathochromic shift, characteristic of $\pi \rightarrow \pi^*$ transitions.

The remainder of the quartz ultraviolet spectrum consists of three bands of about equal, moderate ($f \sim 0.02$) intensity and of the same general shape. In **I** these bands occur with λ_{max} at 224 nm (5.59 eV), 200 nm (6.21 eV), and 193 nm (6.42 eV). Each has a width of ca. 1200 cm^{-1} (fwhm) and exhibits some faint evidence of unresolved vibrational structure. All three bands are assigned to Rydberg transitions on the basis of the following evidence. First, in the parent thiocarbonyl, thioformaldehyde, three band systems assigned to $n \rightarrow 4s$, $n \rightarrow 4p_y$, and $n \rightarrow 4p_z$ Rydberg transitions, have been observed in the quartz ultraviolet (8). The aforementioned three transitions in **I** are observed in the same spectral region

TABLE 1. Comparisons of observed and calculated transition energies in several thiocarbonyls

[d]Onset of absorption (see text). All others from band maxima.

and with comparable spacing and intensity. The comparison is illustrated in Table 1. The thioformaldehyde Rydberg band systems are narrow and are about a factor of 10 less intense compared to the $\pi \rightarrow \pi^*$ valence-shell absorption. The present gas phase spectra of **I** and **II** exhibit similar properties.

The lowest energy of these Rydberg transitions has been observed previously at ca. 215 nm in hydrocarbon solution spectra of similar aliphatic thiones, but has been misassigned as $n \rightarrow \sigma^*$. The corresponding transitions in the gas phase spectra of **I** and **II** occur at 224 and 222 nm, respectively. Thus, the substantial increase in energy expected of a Rydberg transition on going from vapor to solution is observed (22).

Support for the assignment of these three bands to Rydberg transitions is also found in the *ab initio* SCF-CI calculations of the electronic spectrum of thioacetone by Bruna, Buenker, and Peyerimhoff (23) (cf. Table 1). Three allowed Rydberg transitions are predicted at 5.23, 5.93, and 6.04 eV for this molecule. The Rydberg transition of lowest energy in **I** and **II** (at 5.54 eV and 5.59 eV, respectively) corresponds well to the calculated lowest energy Rydberg state in thioacetone at 5.23 eV and is assigned as sulfur $n \rightarrow 4s$ ($^1B_2 \leftarrow {}^1A_1$ in C_{2v}) on this basis. This transition is also accurately predicted by a similar calculation on thioformaldehyde (24) (cf. Table 1). The two other allowed Rydberg transitions, which are calculated to lie at 5.93 eV and 6.04 eV in thioacetone, correspond to sulfur $n \rightarrow 4p_z$ and $n \rightarrow 4p_y$ electron promotions respectively. Two narrow, closely-spaced absorptions which lie within 0.5 eV of these predicted energies are found in the spectrum of **I**. It is impossible to distinguish between the $n \rightarrow 4p_y$ and $n \rightarrow 4p_z$ transitions in the absence of polarization data. However, by analogy with H_2CS, we tentatively assign the lower energy of these two to the $^1A_1 \leftarrow \tilde{X}(^1A_1)$ ($n \rightarrow 4p_y$) Rydberg transition and the one of higher energy to the $^1B_2 \leftarrow \tilde{X}(^1A_1)$ ($n \rightarrow 4p_z$) Rydberg transition. The $n \rightarrow 4p_x$ transition is predicted to occur at 5.90 eV in thioacetone but is electric-dipole forbidden and is therefore anticipated to be of much lower intensity than the three allowed transitions which are actually observed.

The quantum defect, Δ, for each Rydberg transition was calculated using the expression

$$[1] \quad E = I_p - R/(n - \Delta)^2$$

where E (eV) is the experimental transition energy, R is the Rydberg constant, n is the principal quantum number of the excited electron, and I_p is the ionization potential of the compound of interest. Ionization potentials of **I** and **II** have not been measured. However, using the value of I_p = 8.60 eV for thioacetone, determined from its photoelectron spectrum (25) and assuming $n = 4$, values of Δ given in Table 2 are obtained. Since **I** and **II** will likely have slightly lower ionization potentials than thioacetone, the values of Δ calculated in this way are probably slightly high. Nevertheless, reasonable correspondence is found with the quantum defects reported by Price *et al.* (26, 27) for H_2S and by McDiarmid (28) for $(CH_3)_2S$, particularly in view of the tendency of Δ for transitions to *ns* Rydberg states to decrease with increasing alkylation of the chromophoric group. The data are shown in Table 2. Such a comparison may not be unreasonable in view of the atomic-like nature of Rydberg transitions.

It has been argued that it is more appropriate to use a value of $n = 3$ than $n = 4$ to describe the lowest energy Rydberg transitions in H_2CS (29). There is theoretical evidence (30) that in formaldehyde the lowest energy Rydberg orbital centroids lie in the CH_2 region of that molecule. Use of $n = 3$ for H_2CS results in values of Δ which are similar to those of H_2CO. The implication of using $n = 3$ to describe these transitions in thiocarbonyls is that

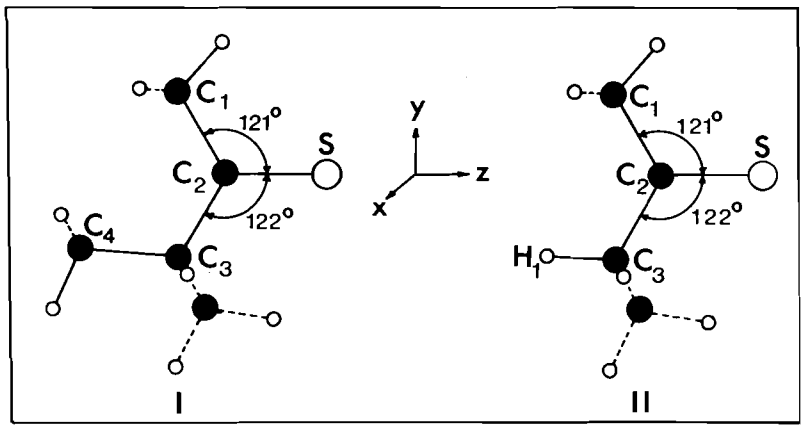

FIG. 2. Calculated geometry of ground state I and II. In both molecules C_2—S, C_1—C_2, C_2—C_3, and C_3—C_4 bond lengths are 1.60 Å, 1.54 Å, 1.54 Å, and 1.56 Å respectively. In II, the C_3—H_1 bond length is 1.086 Å. All C—C—H bond angles and all C—C_3—C bond angles are 109.5°. The two CH_3 groups attached to C_3 are located above and below the plane of the figure and are superimposed in the perspective shown.

the lowest energy Rydberg orbitals assume large measures of carbon 3*s* or 3*p* character. If a value of $n = 3$ is used in the present work, values of Δ are obtained for **I** and **II** which are substantially smaller than those determined for the corresponding transitions in H_2CS (29), but which nevertheless do not differ greatly from those of the lowest energy Rydberg transitions in the aldehydes and ketones. However, in view of the experimental uncertainties in Δ in the present work and the absence of orbital electron density calculations for these molecules, further speculation on the choice of *n* is unwarranted.

The calculated ground state geometries of **I** and **II** are shown in Fig. 2. The lowest energy conformation is one in which the C_1, C_2, C_3, C_4, and S atoms in **I** or the C_1, C_2, C_3, H_1, and S atoms in **II** are coplanar. The C—S bond length of 1.60 Å is nearly identical to both the calculated and experimentally measured C—S bond lengths in the ground states of several tetraatomic thiocarbonyl halides (16). The C_1—C_2 and C_2—C_3 bond lengths and the C—C—S bond angles are unremarkable. There is no evidence in these calculations which would indicate that **I** and **II** are atypical aliphatic thiones.

The results of CNDO/2 calculations of the oscillator strengths of the valence-shell transitions also support the above assignments. These calculations are based on the geometries given above and follow the method outlined by McGlynn *et al.* (31). A similar method was used successfully in the analysis of the electronic spectra of F_2CS, Cl_2CS, and H_2CS by Farnworth *et al.* (32). The results are shown in Table 3. In this calculation the one-center integrals were computed analytically using CNDO/2 molecular orbitals, the important (involving C_1, C_2, C_3, and S) two-center integrals were computed by the method of Yaranos (33), and the experimental transition energies were employed. The calculated oscillator strengths of the valence-shell transitions agree moderately well with those observed experimentally in the present study. Only lower limits are given for the measured oscillator strengths of **II** because of the unknown extent of tautomerization to the corresponding enethiol at the time of spectral measurement.

Conclusions

Four electronic transitions are observed in the quartz ultraviolet spectra of aliphatic thiones in the gas phase. The strongest transition is very broad

and unstructured and is assigned to a $\pi \rightarrow \pi^*$ valence-shell electron promotion. This assignment is supported by CNDO/2 calculations of the oscillator strength and by comparisons with several other thiocarbonyl-containing molecules. Three weaker and narrower Rydberg transitions, one of which ($n \rightarrow 4s$) overlaps the broad $\pi \rightarrow \pi^*$ band, are also observed. The two highest energy of these Rydberg bands have not been observed previously in aliphatic thiones. The lowest energy Rydberg transition had been misassigned as an $n \rightarrow \sigma^*$ electron promotion in previous solution spectra.

Studies in general acid and general base catalysis. Rate–acidity profiles for prototropic processes[1]

ROSS STEWART AND R. SRINIVASAN

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received August 1, 1980

ROSS STEWART and R. SRINIVASAN. Can. J. Chem. **59**, 957 (1981).

A theoretical study has been made of the effect of changing acidity on the rate of aqueous prototropic reactions. These processes, typified by ketone enolization, are catalyzed by general acids and bases and their log rate – pH profiles may take a number of different shapes. In the absence of buffer catalysis there are four reaction paths available to a substrate Z: $ZH^+ + HO^-$, $Z + HO^-$, $ZH^+ + H_2O$, and $Z + H_2O$. Equations have been derived that express the contributions each of these paths makes to the observed rate in terms of the experimental catalytic constants, the proton activating factor (*paf*), the deprotonating factor (*dpf*), and the basicity of the substrate as expressed by K_{ZH^+}. For ideal systems the relative rates of the kinetically equivalent paths $Z + H_2O$ and $ZH^+ + HO^-$ (though one does not know which is the larger) is given by the quantity $3.0 \times 10^{17}\, k^2_{H_2O}/(k_{H^+}k_{HO^-})$ where k_{H^+}, k_{HO^-}, and k_{H_2O} are the experimental catalytic constants. It is argued in the case of the real substrate acetone that (*a*) this quantity underestimates the rate difference, and (*b*) the more important path is $Z + H_2O$. Where *paf* is available from rate data determined in buffers an unequivocal choice can be made between the kinetically equivalent paths, provided *paf* is a constant for the particular substrate.

ROSS STEWART et R. SRINIVASAN. Can. J. Chem. **59**, 957 (1981).

On a étudié l'effet du changement d'acidité sur la vitesse des réactions prototropiques en solutions aqueuses. Ces réactions, dont l'exemple typique est l'énolisation d'une cétone, sont en général catalysées par les acides et les bases et leurs courbes de log de vitesse en fonction du pH peuvent être de formes différentes. En l'absence d'une catalyse tamponnée, il y a 4 chemins réactionnels probables pour un substrat Z: $ZH^+ + HO^-$, $Z + HO^-$, $ZH^+ + H_2O$ et $Z + H_2O$. On en a déduit des équations qui expriment les contributions de chacune de ces voies à la vitesse observée en fonction des constantes catalytiques expérimentales, du facteur activant du proton (*fap*), du facteur de déprotonation (*fdp*) et de la basicité du substrat tel qu'exprimé par K_{ZH^+}. Dans les systèmes idéaux, les vitesses relatives des voies cinétiquement équivalentes $Z + H_2O$ et $ZH^+ + HO^-$ sont données par la quantité $3{,}0 \times 10^{17} \times k^2_{H_2O}/(k_{H^+}k_{HO^-})$ ou k_{H^+}, k_{HO^-} et k_{H_2O} sont les constantes catalytiques expérimentales. Dans le cas d'un substrat réel, tel l'acétone, on pense que (*a*) cette quantité sous-estime la différence de vitesse et (*b*) la voie la plus importante est $Z + H_2O$. Quand le *fap* est disponible à partir des données de vitesse déterminées dans les tampons on peut faire un choix univoque entre les chemins réactionnels cinétiquement équivalents en admettant que le *fap* est constant pour un substrat particulier.

[Traduit par le journal]

The effect of changing acidity on the rates of acid and base catalyzed reactions is obviously a matter of great practical importance in organic chemistry. Early work in acid and base catalysis was concerned chiefly with establishing rate laws. Later as mechanistic studies begin to be pursued, the various steps in such reactions came to be described in some detail (1).

The activated forms of organic compounds are usually the protonated or deprotonated entities and studies over the past two decades have established p*K* values for such species for most kinds of organic compound. While our mechanistic understanding of the steps in most acid or base catalyzed reactions is now quite good (1), there has been lacking a general treatment of acid and base catalysis that would relate structural and other features to overall rate effects, particularly to rate–acidity profiles. The latter can assume a number of shapes (Fig. 1), even for simple prototropic reactions in the absence of buffer catalysis, as has been shown particularly by the work of Jones *et al.* (2, 4, 5). We have recently examined the effect on reactivity of protonating organic compounds and deprotonating reagent bases in terms of the quantities *paf* (proton activating factor) and *dpf* (deprotonating factor) (6). In this paper we develop the equations for the various routes that can lead from reactant to product in acid and base catalyzed processes, the sums of which give the rate–acidity profile. To simplify the treatment we consider only aqueous solution and only prototropic reactions, those in which a proton is relocated in the substrate – a not inconsequential set of reactions since these are the rate-controlling steps of many oxidation, condensation, and other processes. Furthermore, we consider only catalysis by H^+, H_2O, and HO^-. That is, we neglect the effect of buffers, which, in the case of general acid and general base catalyzed reactions, can significantly change the shapes of rate–acidity profiles, particularly in the regions near neutrality (1, 3). Finally, we ignore, as seems reasonable for aqueous solution (1), the possibility of proton loss and proton gain being simultaneous.

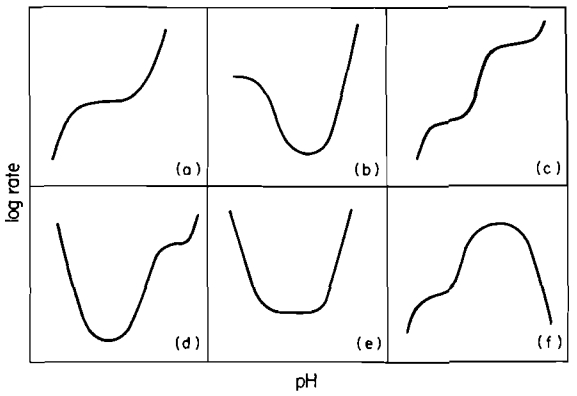

FIG. 1. A schematic portrayal of the rate–pH profiles for ionization or enolization of six selected compounds. In all cases water is the solvent and there is no buffer catalysis. The compounds, with literature references in parentheses, are (*a*) caffeine (2), (*b*) 1,4-dimethyl-2-pyrimidone (corrected for self-catalysis) (3), (*c*) paraxanthine (2), (*d*) 2-imino-1,4-dimethyl-1,2-dihydropyrimidine (3), (*e*) acetophenone (4), (*f*) xanthine (2). Only the curves in *a*, *b*, and *e* can be represented by the four terms [4]–[7] given herein; in *c*, *d*, and *f* additional protonation states intrude.

reaction via either its anion or a tautomeric form Z′. When a carbon–hydrogen bond is broken in forming the anion or tautomer the rate-controlling step involves attack on Z or ZH^+ by base, either water, hydroxide ion, or the basic component of any buffer that is present. The activating effect of protonating Z to give ZH^+ is expressed by the term *paf* (eq. [1]), which, when buffer systems are used can be determined (eq. [2]) from the catalytic constants k_{HA} and k_{A^-} of the buffer components determined in the standard way, and from the acidity constants K_{ZH^+} and K_{HA} of the substrate and the buffer acid (6, 7).

[1] $paf = k_{ZH^+ + B}/k_{Z+B}$

where B = H_2O, HO^-, or A^-

[2] $paf = k_{HA}K_{ZH^+}/k_{A^-}K_{HA}$

Activation by base is expressed in terms of *dpf*, in which the relative proton abstracting abilities of HO^- and H_2O are compared (eq. [3]) (6) (in most cases these are the only base pairs for which data are available).

[3] $dpf = k_{Z+HO^-}/k_{Z+H_2O}$

The magnitude of *paf* varies enormously depending on the structure of the substrate, but always seems to be less than *dpf*. Thus removing a proton from water, the base, is more effective than adding a proton to Z, the substrate.

Rate–Acidity Profiles

For the reaction of Z or ZH^+ with H_2O or HO^- there are four paths that contribute to reaction (reactions [4]–[7]). (The reactive intermediate might be, for example, the enol or enolate anion of a ketone.)

[4] $ZH^+ + HO^- \rightarrow$ reactive intermediate

[5] $Z + HO^- \rightarrow$ reactive intermediate

[6] $ZH^+ + H_2O \rightarrow$ reactive intermediate

[7] $Z + H_2O \rightarrow$ reactive intermediate

The rate contribution, V, of each of these paths is given by eqs. [8] to [11],

[8] $V_{ZH^+ + HO^-} = k_{ZH^+ + HO^-}[ZH^+][HO^-]$

[9] $V_{Z+HO^-} = k_{Z+HO^-}[Z][HO^-]$

[10] $V_{ZH^+ + H_2O} = k_{ZH^+ + H_2O}[ZH^+][H_2O]$

[11] $V_{Z+H_2O} = k_{Z+H_2O}[Z][H_2O]$

The rate–acidity profile, which is determined by the way the sum of the four rate contributions varies with acidity, turns out to depend on the magnitude of three variables: *paf*, *dpf*, and K_{ZH^+}. This point is illustrated for one of these variables in Fig. 2 where K_{ZH^+} is allowed to vary, while for simplicity's sake *paf* and *dpf* are kept fixed at 10^7 and 10^{10}, respectively.

The curves in Fig. 2, shown as log V_{rel} – pH rate profiles, have been generated by computer using the techniques described in the calculations section of this paper and the equations derived therein. V_{rel} is the relative rate of a pathway based on the rate constant k_{Z+HO^-} and the total substrate concentration being unity.

It can be seen in Fig. 2 that the way in which the observed rate responds to changing acidity depends on the basicity assigned to the substrate, the patterns of the three rate–acidity profiles being quite distinct.

A fourth pattern shown in Fig. 3 appears when pK_{ZH^+} is assigned a value of 5.7, with *dpf* being kept fixed at 10^{10}. Under these conditions the rate profile appears to consist of only two linear sections, one pH-dependent and the other pH-independent. The significance of the number 5.7 (15.7 − log *dpf*) arises as follows.

It can be seen from an examination of the curves in Fig. 2 that a profile of the type considered here can only arise when $V^{max}_{ZH^+ + HO^-} = V^{max}_{ZH^+ + H_2O}$ and it can be easily shown that under these conditions the quantities $V_{ZH^+ + HO^-}$ and $V_{ZH^+ + H_2O}$ become equal when the pH equals the pK_{ZH^+} of the substrate.

Referring to eqs. [8] and [9], it is clear that at the pK

$$k_{ZH^+ + HO^-}[ZH^+][HO^-] = k_{ZH^+ + H_2O}[ZH^+][H_2O]$$

and $k_{ZH^+ + HO^-}/k_{ZH^+ + H_2O}$, which is equal to *dpf*, becomes equal to $[H_2O]/[HO^-]$ or $[H^+]/K_{H_2O}$, where

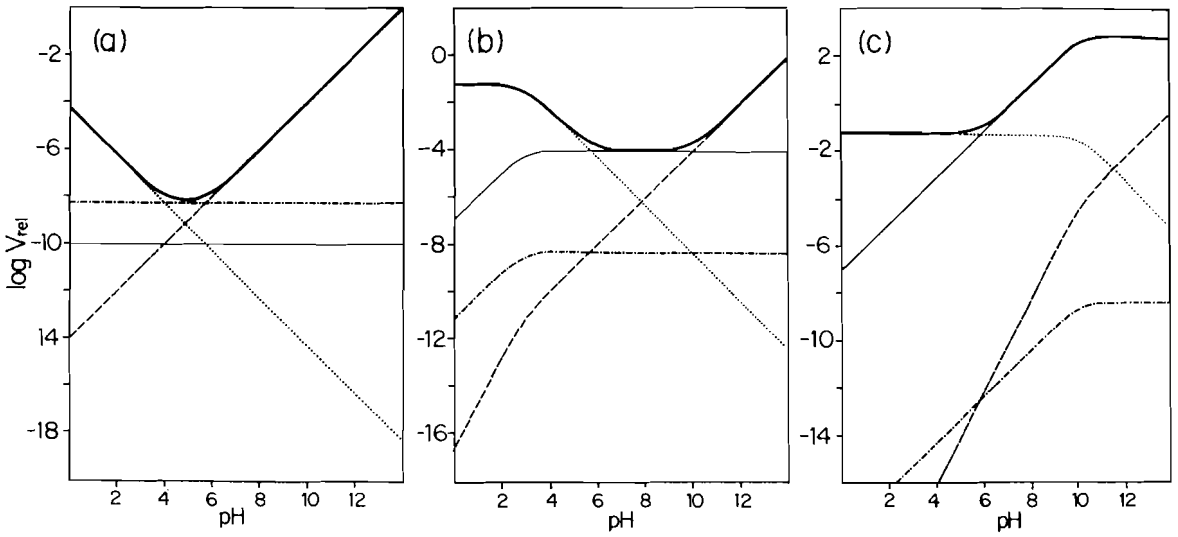

FIG. 2. Plots of logarithm of relative rate against pH showing the contribution of the four pathways that lead to reactive intermediates of a substrate Z. The heavy line represents the observed rate; the light solid line represents $V_{ZH^+ + HO^-}$; the dashed line represents V_{Z+HO^-}; the dotted line represents $V_{ZH^+ + H_2O}$; the dashed and dotted line represents V_{Z+H_2O}. (*a*) $paf = 10^7$, $dpf = 10^{10}$, $pK_{ZH^+} = -3.0$; (*b*) $paf = 10^7$, $dpf = 10^{10}$, $pK_{ZH^+} = +3.0$; (*c*) $paf = 10^7$, $dpf = 10^{10}$, $pK_{ZH^+} = 10.0$.

$$K_{H_2O} = [H^+][HO^-]/[H_2O] = 1.8 \times 10^{-16}$$

and $pK_{H_2O} = 15.7$.

Since $[H^+] = K_{ZH^+}$ at the pK,

$$dpf = K_{ZH^+}/K_{H_2O}$$

Therefore, eq. [12] holds for those reactions which show the simple rate–acidity profile given in Fig. 3.

[12] $$\log dpf + pK_{ZH^+} = 15.7$$

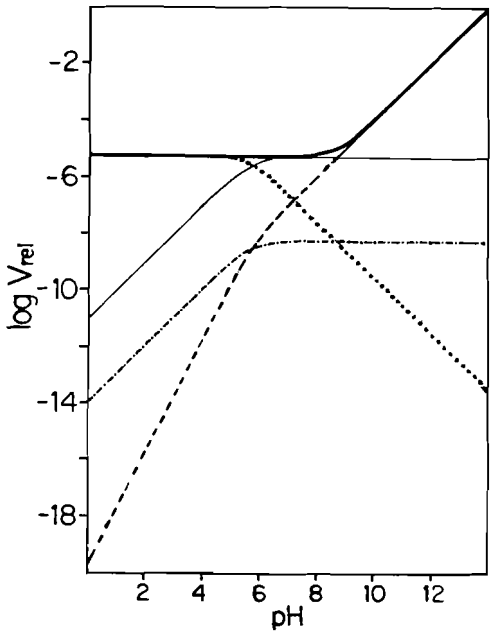

FIG. 3. Plot of logarithm of relative rate as a function of pH for a reaction identical to those shown in Fig. 2, except that the substrate has a pK_{ZH^+} of 5.7.

The magnitude of *paf* is of no importance in determining conditions for which such a curve will appear (provided that *paf* is greater than unity, which it must necessarily be). Thus, though Fig. 3 has been constructed by setting $\log paf = 3$, $\log dpf = 10$, and $pK_{ZH^+} = 5.7$, any value of *paf* greater than unity could be used to produce the same shape of curve. When $\log dpf$ and pK_{ZH^+} are varied but their sums kept equal to 15.7 the curves shown in Fig. 4 are generated.

Kinetically Equivalent Routes

The two reaction paths shown in reactions [4] and [7] represent kinetically equivalent paths. The difference in magnitude between their rates (though not which is the greater) can be calculated, providing the catalytic coefficients k_{H^+}, k_{HO^-}, and k_{H_2O} have been experimentally determined. Provided that the true values of *paf*, *dpf*, and K_{ZH^+} are known the difference in magnitude *and* which is the greater can be determined. There is an inherent ambiguity in the latter method, however, since only apparent *dpf* values can be determined from experimental data. These points will become clear as the pertinent equations are developed below.

The ratio of the two rates is given by eq. [13].

[13] $$\frac{V_{ZH^+ + HO^-}}{V_{Z+H_2O}} = \frac{k_{ZH^+ + HO^-}}{k_{Z+H_2O}} \frac{[ZH^+][HO^-]}{[Z][H_2O]}$$

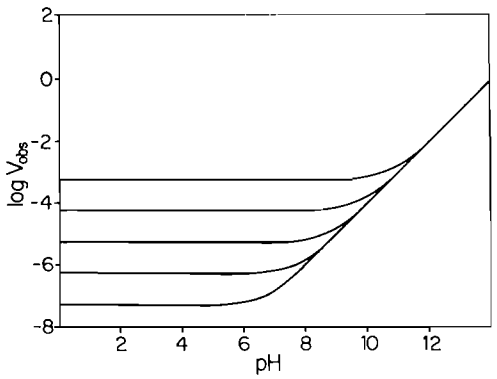

FIG. 4. Plots of logarithm of observed rate as a function of pH for various values of log *dpf* and pK_{ZH^+}, which in each case sum to 15.7. The respective values of log *dpf* and pK_{ZH^+} are from top to bottom, above: 8.0, 7.7; 9.0, 6.7; 10.0, 5.7; 11.0, 4.7; 12.0, 3.7. The *paf* is 10^3 in all cases.

Since

$$paf \cdot dpf = \frac{k_{ZH^+ + HO^-}}{k_{Z+HO^-}} \frac{k_{Z+HO^-}}{k_{Z+H_2O}} = \frac{k_{ZH^+ + HO^-}}{k_{Z+H_2O}}$$

then eq. [14] holds.

$$[14] \quad \frac{V_{ZH^+ + HO^-}}{V_{Z+H_2O}} = \frac{paf \cdot dpf \cdot K_{H_2O}}{K_{ZH^+}}$$

where $K_{H_2O} = 1.8 \times 10^{-16}$ as before. Equation [14] has been derived on the assumption that

$$dpf = k_{Z+HO^-}/k_{Z+H_2O}$$

That is, the more important pathway is assumed to be that shown in eq. [7], with the experimental catalytic constant k_{H_2O} being identical to the hidden rate constant k_{Z+H_2O}. An identical equation to [14], except for the left-hand term being inverted, can be derived by assuming the predominance of the path shown in eq. [4].

The acid HA and base A^- in eq. [2] can be taken as H^+ and H_2O, respectively, giving eq. [15].

$$[15] \quad paf = k_{H^+}K_{ZH^+}/k_{H_2O}K_{H^+}$$

where

$$K_{H^+} = [H_2O] = 55.5\ M$$

Furthermore,

$$dpf = k_{Z+HO^-}/k_{Z+H_2O} = k_{HO^-}/k_{H_2O}$$

Therefore eq. [14] becomes, after substitution and inversion, eq. [16].

$$[16] \quad \frac{V_{Z+H_2O}}{V_{ZH^+ + HO^-}} = \frac{k^2_{H_2O}(55.5)}{k_{H^+}k_{HO^-}(1.8 \times 10^{-16})}$$

$$= 3.0 \times 10^{17}\left(\frac{k^2_{H_2O}}{k_{H^+}k_{HO^-}}\right)$$

Again, an identical equation except for the left-hand term being inverted can be derived by assuming that $V_{ZH^+ + HO^-}$ is greater than V_{Z+H_2O}. Equations [14] and [16] and their analogs are useful only for assessing the relative importance of the two paths, not for distinguishing between them. This is as expected since a kinetic analysis cannot be expected to distinguish between kinetically equivalent pathways.

The theoretical treatment presented to this point is for ideal systems, those in which *paf* is independent of the base (H_2O or HO^-), and those in which *dpf* is independent of the ionic state of the substrate (Z or ZH^+). Indeed, if one of these conditions obtains, the other must do so also: if

$$(k_{ZH^+ + H_2O}/k_{Z+H_2O}) = (k_{ZH^+ + HO^-}/k_{Z+HO^-}) = paf$$

then

$$(k_{ZH^+ + HO^-}/k_{ZH^+ + H_2O}) = (k_{Z+HO^-}/k_{Z+H_2O}) = dpf$$

The application of the above ideas to the special case of acetone is considered in the next section.

Acetone

Acetone is an unusual ketone in that water catalysis, as expressed by the experimental catalytic coefficient k_{H_2O}, is significant over only a very narrow region of the pH spectrum. This can be seen in Fig. 5 where the acid and base catalyzed processes (undoubtedly $V_{ZH^+ + H_2O}$ and V_{Z+HO^-}) will make comparable contributions under such circumstances (see also Fig. 2*a*, in which the values

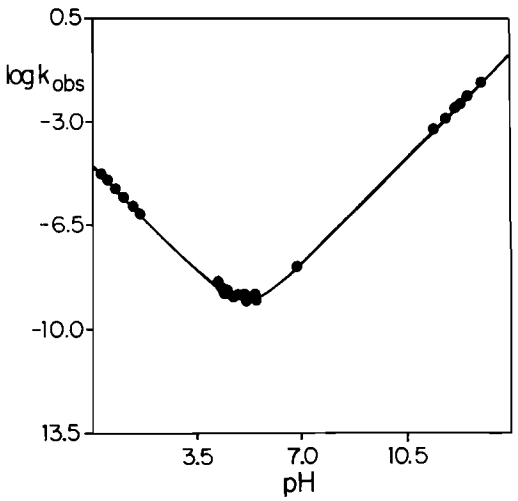

FIG. 5. Plot of logarithm of the rate of enolization of acetone in water in the absence of buffer catalysis at 25°C. The experimental points have been obtained by extrapolating to zero buffer concentration the rate data given in refs. 8, 9, and 10. The line was drawn by computer using the value of k_{H^+}, k_{HO^-}, and k_{H_2O} given in the text.

1,1-Dichloroacetone	—	450	13200	10.5

[a]Rate data of Bell and Lidwell (8) except for k_{H^+} and k_{HO^-} values for acetone, which come from ref. 9, $T = 25°C$.

there assigned to *paf*, *dpf*, and K_{ZH^+} are very close to those for acetone). The experimental values of Bell and Lidwell (8) and Hine, Kaufman, and Cholod (9) for k_{H_2O}, k_{H^+}, and k_{HO^-} are 8.3×10^{-12} M^{-1} s^{-1}, 2.54×10^{-5} M^{-1} s^{-1}, and 0.166 M^{-1} s^{-1}, respectively. When these values are substituted in eq. [16] a value of 4.4 is obtained for the ratio V_{Z+H_2O} and $V_{ZH^+ + HO^-}$.

As has been pointed out earlier, eq. [16] does not indicate which of the kinetically equivalent paths is the more important. We shall argue that for acetone and most other Type 1 compounds (6) V_{Z+H_2O} is greater than $V_{ZH^+ + HO^-}$. Furthermore, we believe that the rate ratio is actually greater for acetone than the theoretical value of 4.4, since eq. [16] is based on ideal behaviour, specifically that *paf* and *dpf* are independent of the ionic state of the base (H_2O or HO^-) and the substrate (Z or ZH^+).

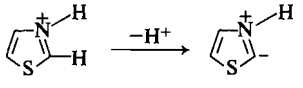
Table 1 lists the catalytic constants for a number of ketones and it can be seen that both k_{HO^-} and k_{H_2O} are sensitive to changes in structure of the ketone. Indeed, when log k_{HO^-} is plotted against log k_{H_2O} for these compounds a straight line of close to unit slope is obtained (slope = 1.03, correlation coefficient 0.983). The catalytic constant k_{H^+}, on the other hand, changes only slightly as the ketone structure is changed, presumably because of opposing substituent effects on the protonation of the substrate and on the rate-controlling deprotonation of its conjugate acid (11). Since the catalytic constants k_{HO^-} and k_{H_2O} are linearly related it is reasonable to assume that it is V_{Z+H_2O} rather than $V_{ZH^+ + HO^-}$ that is the major contributor to the water-catalyzed rate. Were $V_{ZH^+ + HO^-}$ the major component some correlation would have been expected between k_{H^+} and k_{H_2O}. (Earls and Jones have used a similar argument in the case of acetophenone (4).)

The slope of unity found for the plot of log k_{HO^-} against log k_{H_2O} indicates that the inductive effect of substituents modifies the rate of proton abstraction by HO^- and H_2O equally. Stated differently, the *dpf* values are little affected by substituents that influence the rate of enolization by the inductive effect. We regard this as a general principle in closely related systems. The *dpf* values, however, differ when the substituent is in conjugation with the reaction site. For example, acetylacetone, discussed below, has a *dpf* of 10^8 (12).

If $V_{ZH^+ + HO^-}$ is, indeed, the lesser of the two kinetically equivalent rates can we estimate its magnitude independently and then check the rate ratio that has been calculated using eq. [16]? It turns out that acetylacetone is a reasonable model for protonated acetone, as can be seen by comparing the reaction parameters given in Table 2. Taking 4.0×10^4 M^{-1} s^{-1} as the value of $k_{ZH^+ + HO^-}$ for acetone leads to a value of 600 for $V_{Z+H_2O}/V_{ZH^+ + HO^-}$, considerably greater than that calculated using eq. [16]. This discrepancy probably arises from the operation of the Reactivity–Selectivity Principle (RSP) (15), which predicts that $k_{ZH^+ + H_2O}/k_{Z+H_2O}$ will be greater than $k_{ZH^+ + HO^-}/k_{Z+HO^-}$. Equation [16], which was derived on the assumption that these two quantities are equal, gave a value of 4 for the reactivity ratio and we have argued that V_{Z+H_2O} is, indeed, greater than $V_{ZH^+ + HO^-}$. The RSP will operate in the direction to *increase* this factor, possibly to a value as high as the 600 estimated here. A second approach to resolving the ambiguity of the kinetically equivalent routes is considered in the next section.

Type I and Type II Systems: Buffer Catalysis

We have previously used the terms Type I and Type II to distinguish reactions in which deprotonation of the conjugate acid gives a neutral species, such as an enol (Type I), from those which give a mesoionic intermediate (Type II), such as that shown below (6).



Type II reactions frequently have rate–acidity profiles of the chair type (Fig. 1*a*) and this is a result of reaction $ZH^+ + HO^-$ being more important than

[a]Based on a pK_{ZH^+} value of −2.72 for acetone (13). Should this value, which has not been universally accepted (14), be found to be in error the individual rate constants would have to be changed, but all by the same amount and so the argument given in the text would be unaffected.

reaction $Z + H_2O$, unlike the situation with acetone and other Type I compounds. With such a log rate – pH profile there is no ambiguity, the ratio $V_{ZH^+ + HO^-}/V_{Z+H_2O}$ must be greater than unity and, indeed, it may be enormous. For example, in the case of thiazole it is roughly 10^{12} (6, 16).

Most Type I compounds exhibit concave-upward curves such as those shown in Fig. 1 *b*, *d*, and *e*, and for such compounds the ambiguities regarding the mechanism of the plateau were discussed in a previous section of this paper. For such compounds buffer catalysis can usually be measured and *paf* determined using eq. [2]. Provided the same *paf* holds for the two acid–base pairs, H^+/H_2O and HA/A^-, the log rate – pH profile would tell us which is the dominant path and to what extent. Consider the curve in Fig. 6. The right-hand side of the curve represents reaction of $Z + HO^-$, the left-hand side $ZH^+ + H_2O$. The plateau can represent either $Z + H_2O$, or $ZH^+ + HO^-$. It can be readily shown that hydroxide ion catalysis becomes manifest when $pH = pK_{H_2O} - \log dpf$; at this pH the dominant path changes from one in which water is the base to one in which hydroxide ion is the base.* This pH will correspond to one or the other termini of the plateau, $pH_{(a)}$ or $pH_{(b)}$ provided *paf* is not a function of the acid–base pair used but only of the substrate.[2] Thus in Fig. 6, if $pH_{(a)} = pK_{ZH^+} + \log paf$ then the dominant pathway at the plateau is $ZH^+ + HO^-$; if $pH_{(b)} = pK_{ZH^+} + \log paf$ then $Z + H_2O$ dominates. Furthermore, the length of the plateau, $pH_{(a)} - pH_{(b)}$, gives the logarithm of the ratio of the two rates, $V_{ZH^+ + HO^-}$ and V_{Z+H_2O}.

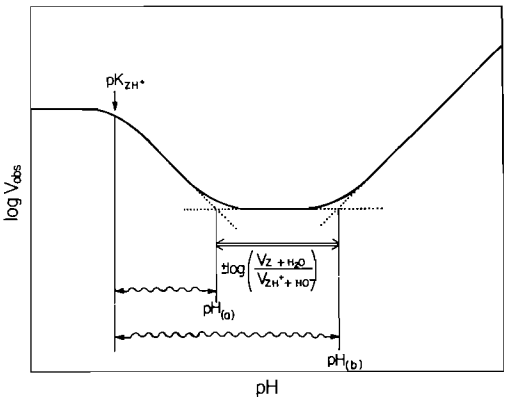

FIG. 6. A log rate – pH profile showing the relation between pK_{ZH^+}, log *paf*, and the length of the plateau. *One* of the two wavy lines represents log *paf*.

Calculations

The rate of ionization, V, of a carbon acid Z in water at any pH in the absence of buffers is given by eq. [17].

$$[17] \quad V = k_{ZH^+ + HO^-}[ZH^+][HO^-] + k_{Z+HO^-}[Z][HO^-] + k_{ZH^+ + H_2O}[ZH^+][H_2O] + k_{Z+H_2O}[Z][H_2O]$$

where [Z] and $[ZH^+]$ represent equilibrium concentrations. These concentrations can be expressed in terms of the total concentration of the substrate, $[Z]_t$ as follows

$$[Z] = \frac{[Z]_t K_{ZH^+}}{K_{ZH^+} + [H^+]}$$

$$[ZH^+] = \frac{[Z]_t [H^+]}{K_{ZH^+} + [H^+]}$$

The relative rate V_{rel} is thus determined by eq. [18], where the numerical value of $[Z]_t$ and k_{Z+OH^-} are arbitrarily kept at unity

$$[18] \quad V_{rel} = \{(k_{ZH^+ + HO^-} K_{H_2O}[H_2O]) + (K_{ZH^+} K_{H_2O}[H_2O]) + (k_{ZH^+ + H_2O}[H_2O][H^+]) + (k_{Z+H_2O} K_{ZH^+}[H_2O])\}/(K_{ZH^+} + [H^+])$$

Equation [18] can be expressed in terms of *paf* and *dpf*, since when k_{Z+HO^-} is unity, $paf = k_{ZH^+ + HO^-}$, $dpf = 1/k_{Z+H_2O}$, and $paf/dpf = k_{ZH^+ + H_2O}$.

[2]Use of an incorrect value of pK_{ZH^+} does not affect this determination since the error is cancelled by that in the determination of *paf* using eq. [2].

* Furthermore, when $pH = pK_{ZH^+} + \log paf$ the dominant path changes from one in which ZH^+ is the substrate to one in which Z is the substrate."

FOR ERRATA SEE v 59 #24 19 81 p 3318...

ERRATA ERRATA

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

$$[19]\quad V_{rel} = \left\{(paf\,K_{H_2O}[H_2O]) + \frac{K_{ZH^+}K_{H_2O}[H_2O]}{[H^+]} + \frac{paf\,[H^+][H_2O]}{dpf} + \frac{K_{ZH^+}[H_2O]}{dpf}\right\} \Big/ \left\{K_{ZH^+} + [H^+]\right\}$$

The four terms in parentheses in eq. [19] correspond to catalysis by mechanisms [4], [5], [6], and [7] respectively. The plot of log V_{rel} against pH was generated from the above equation for various values of *paf*, *dpf*, and K_{ZH^+} with the aid of a computer employing a value of 55.5 *M* for $[H_2O]$ and 1.8×10^{-16} for K_{H_2O}. The curves were drawn by connecting 500 data points distributed evenly over the pH range 0–14. The plot for any specific mechanism was likewise obtained by neglecting the three terms that do not pertain to the mechanism considered.

In the case of the plot shown in Fig. 6 the pH values at which the horizontal line (water catalysis) intersects the straight line of negative slope (H^+ catalysis) and that of positive slope (HO^- catalysis) in the plot of log V_{obs} against pH are given by $pH_{(a)}$ and $pH_{(b)}$ respectively. It is apparent that at $pH_{(a)}$ the rates of water-catalyzed and H^+-catalyzed reactions are equal, while at $pH_{(b)}$ the rates of water-catalyzed and HO^--catalyzed reactions are equal. The following equations, therefore, hold, where k_{H^+}, k_{HO^-}, and k_{H_2O} are the observed catalytic constants.

$$pH_{(a)} = \log k_{H^+} - \log k_{H_2O}[H_2O]$$

$$pH_{(b)} = \log k_{H_2O}[H_2O] - \log k_{HO^-}K_{HA}[H_2O]$$

Therefore

$$[20]\quad \frac{[H^+]_a}{[H^+]_b} = 3.0 \times 10^{17}\left(\frac{k^2_{H_2O}}{k_{H^+}k_{HO^-}}\right)$$

The right-hand side of eq. [20] is, in fact, the ratio of $V_{ZH^+ + HO^-}$ and V_{Z+H_2O}, or vice versa (see eq. [16]). Consequently, the relative importance of the two kinetically equivalent paths for water catalysis is given by the antilog of $pH_{(b)} - pH_{(a)}$.

On a obtenu les spectres Raman du cristal de violet deutéré $[p(CH_3)_2N{\cdot}C_6D_4]_3C^+Cl^-$ sous forme de solution aqueuse diluée. On discute de l'identification de quelques unes des caractéristiques marquantes observées dans les spectres du cristal de violet deutéré et non deutéré.

[Traduit par le journal]

Introduction

Crystal violet (CV) is an important analytical reagent in chemical and biological studies. It is used in the analysis of uranium (1, 2), thorium (2, 3) and other heavy metals and ions (4, 5) and has numerous applications in biological studies (6, 7). These applications of crystal violet result from its ability to exhibit characteristic spectral changes in the presence of other macromolecules and ions. Therefore, there is much interest in studying the spectral properties of crystal violet including its resonance Raman spectrum. Resonance Raman spectroscopy, due to its ability to give detailed molecular information at very low concentration of the sample, is being increasingly used to investigate systems with chromophoric moieties. Spectra of CV have been reported previously (8–14). All of these communications deal with the normal crystal violet and there is no published report on the resonance Raman spectrum of any of its deuterated derivatives according to the information available to us. Here we report the resonance Raman spectra of one of its deuterated derivatives $[p(CH_3)_2N{\cdot}C_6D_4]_3C^+Cl^-$ i.e., crystal violet-d_{12} or CV-d_{12}.

Experimental

Crystal violet-d_{12} was synthesized and generously supplied by Dr. L. Leitch of the National Research Council of Canada. The isotopic purity of the CV-d_{12} is better than 98% as indicated by its proton magnetic resonance spectrum. Raman spectra were obtained using a Spex-1400 double monochromator equipped with an EMI 6256 photomultiplier and photon counting electronics (15). An argon ion laser, Coherent Radiation model 52GA, was used to obtain the exciting radiation of 488 nm and 514.5 nm respectively. The laser output was filtered using a narrow band-pass spike filter and the laser power was adjusted so that the power of the exciting radiation was ~100 mW at the sample. The sample solution was contained in a rotating cell (16). Spectra were recorded using a 90° scattering geometry. The polarization of the scattered light going into the monochromator was selected by a polaroid analyzer placed between the collecting lens and the entrance slit and a polarization scrambler was placed between the polaroid analyzer and the entrance slit.

Visible absorption spectra were recorded using a Carey 14 spectrophotometer (15).

Results

The visible and uv absorption spectrum of CV-d_{12} as a dilute aqueous solution is very similar to that reported for the normal crystal violet (8, 13, 17) with a strong maximum around 590 nm in the visible region. The resonance Raman spectrum of CV-d_{12} is shown in Fig. 1. The Raman spectrum was excited using 488 nm radiation and the concentration of the CV-d_{12} in the aqueous solution was about 5×10^{-5} M. The frequency values of the observed features are listed in Table 1 and the frequency accuracy is estimated to be $\pm 2\,cm^{-1}$. The spectra were recorded at a resolution of $\sim 3\,cm^{-1}$. Table 1 also contains the depolarization ratio and the qualitative relative intensities of the observed spectral features. The spectra shown in Fig. 1 are photocopies of the original spectra. Here it may be mentioned that the monochromator employed was linear in wavelength and not in frequency. The spectra reported here are uncorrected for the frequency dependence of the instrumental response.

We have included in Fig. 1 the spectrum of normal crystal violet recorded under similar experimental conditions for the purpose of comparison. The spectrum of normal CV shown in Fig. 1

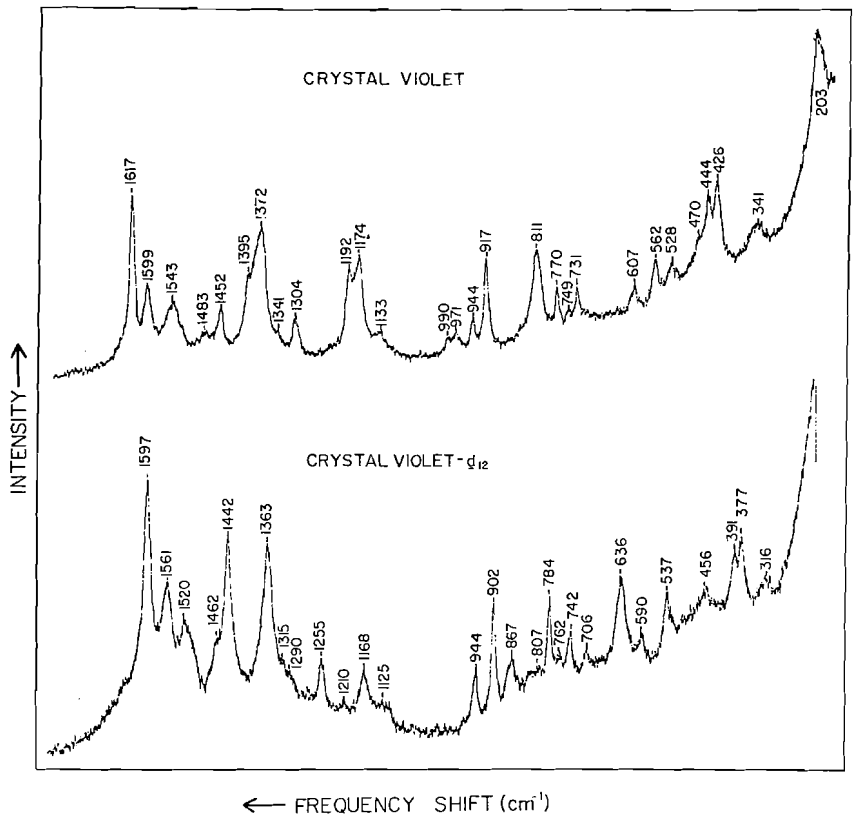

FIG. 1. Resonance Raman spectra of $\sim 5 \times 10^{-5} M$ aqueous solution of crystal violet (upper spectrum) and crystal violet-d_{12} (bottom spectrum) using 488 nm radiation from Ar^+ laser as the exciting line.

basically agrees with that reported in literature for this molecule (8, 13, 14). The spectrum of normal CV shown in Fig. 1 contains many well resolved doublets which were not clearly resolved in some of the earlier reports (9, 12). The notable examples of this are the doublets at about (*a*) 1174 cm^{-1} and 1192 cm^{-1}, (*b*) 426 cm^{-1} and 444 cm^{-1}, and (*c*) 971 cm^{-1} and 990 cm^{-1}.

Discussion

X-Ray data for the triphenyl carbonium ion suggest a propeller shaped structure with molecular symmetry D_3 (18). Analysis of the magnetic circular dichroism of the visible–uv absorption spectra also suggests a D_3 symmetry for crystal violet and related triphenyl carbonium derivatives (19). In this structure the phenyl rings of the molecule are at a dihedral angle of $\sim 30°$ with the central C_3C^+ plane and are symmetrically oriented with respect to each other. Resonance Raman spectra of crystal violet also suggest a D_3 symmetry for the molecule, as discussed by Angeloni *et al.* (13) and it turns out that no evidence from the resonance Raman spectra of CV-d_{12} described here is against this conclusion. The majority of the bands seen in the resonance Raman spectrum of CV have been assigned to the vibrations of the phenyl part of the molecule (9, 12, 13). Angeloni *et al.* have discussed the effect of lowering of symmetry on the vibrations arising from the phenyl rings. We studied the molecule with deuteration at the phenyl rings due to the predominance of the bands in the resonance Raman spectra arising from this part of the molecule.

Our tentative assignment for some of the strong bands seen in the spectrum of CV-d_{12} is given in Table 1. Before discussing the assignment of the deuterated crystal violet we would like to make a few brief comments on the literature assignments for normal CV. Three different groups of workers have suggested the assignments for the spectrum of CV (9, 12, 13). The strong Raman band seen around 1372 cm^{-1} has been assigned to the ^+C—C stretching vibration in ref. 12 while in refs. 9 and 13 it is assigned to the phenyl—N stretching vibrations. We agree with the latter assignments as the Raman

[a]As 5×10^{-5} *M* aqueous solution.
[b]Frequency in cm^{-1}, s, m, w, v, br, sh stand for strong, medium, weak, very, broad and shoulder, respectively.
[c]Polarization study done here using 514.5 nm exciting line; p, dp, and pp stand for polarized, depolarized, and partially polarized, respectively.
[d]Assignment of the bands is in terms of Wilson's notation (20, 21) for the benzene vibrations as used by previous workers for normal CV (9, 12, 13).

spectrum of dimethylaniline also shows a strong band around 1350 cm^{-1} (9). Although we agree with Angeloni *et al.* about the assignment of the 1372 cm^{-1} band to the ϕ—N stretch, the spectrum of CV-d_{12} reported here does not support their assignment of the polarized feature around 1395 cm^{-1} to the second vibration arising from the ϕ—N stretching. This feature is absent in the spectrum of CV-d_{12}, Fig. 1, which suggests that the vibration responsible for this band most probably involves the hydrogen atoms attached to the benzene ring. The suggested assignments for the strong depolarized band around 917 cm^{-1} also differ from one another as given in the three published papers (9, 12, 13). Gicquel *et al.* (12) have attributed this band to the C—H bending vibrations while Aleksandrov *et al.* (9) have attributed it to the benzene ring breathing (vibration ω_1 in Wilson's nomenclature), and Angeloni *et al.* have attributed it to the ring deformation vibration (i.e., vibration ω_{12} in Wilson's notation). A comparison of the spectra of CV and CV-d_{12} (Fig. 1) suggests that the band ~917 cm^{-1} in the spectrum of CV most probably corresponds to the band seen ~902 cm^{-1} in the spectrum of the deuterated derivative. Both are strong, depolarized, and appear similar in shape. If one accepts the suggestion that these two bands are due to similar vibrations in CV and CV-d_{12} respectively, then the absence of the expected deuterium shift, i.e., frequency ratio of 917/902 = 1.016, indicates that the normal mode responsible for these bands does not involve CH bends of benzene rings as suggested in ref. 12.

The assignment of the deuterated crystal violet given in Table 1 is based on the assignment of normal crystal violet, taking into account the lowering of the frequency for the modes involving hydrogen atoms attached to the benzene ring on deuteration. The strong band seen at about 811 cm^{-1} in the spectrum of CV can be readily correlated with the band at ~636 cm^{-1} in the spectrum of CV-d_{12}. The high frequency band is absent in the spectrum of CV-d_{12} and the low frequency band is absent in normal CV. Both bands appear with relatively strong intensity in their respective spectrum and are polarized. If one accepts the suggestion that the vibrations responsible for these two bands have nearly the same internal coordinate description, then the frequency ratio of the two bands, i.e., 811/636 = 1.275, suggests a strong involvement of the phenyl hydrogen atoms. This assignment is supported by the fact that the ω_{10} is seen at 849 cm^{-1} and 663 cm^{-1} in C_6H_6 and C_6D_6, respectively (22). Similar arguments can be used to correlate the depolarized band at ~1192 cm^{-1} in the spectrum of CV with the band at ~867 cm^{-1} in the spectrum of CV-d_{12}. The frequency ratio of these two bands is 1192/867 ~ 1.375, which suggests the involvement of the phenyl hydrogen atoms. In benzene and benzene-d_6 the ω_9 mode is seen at 1178 and 868 cm^{-1} respectively (22), which supports the correlation and assignment suggested above for the 1192 and 867 bands in CV and CV-d_{12} respectively. Table 1 also contains the assignment of a few strong bands based mainly on the spectra of normal CV and related molecules.

Les fragmentations de l'ion phényl-2 oxétane protoné dans un spectromètre de masse par ionisation chimique et de certains ions isomères ont été étudiées à l'aide de composés deutériés ou marqués au carbone 13. Avant sa fragmentation, l'ion phényl-2 oxétane protoné s'ouvre pour donner un carbocation hydroxylé susceptible de s'isomériser par transfert 1–2 ou 1–3 d'hydrures. L'ion phényl-3 propanal protoné ainsi formé élimine une molécule d'eau et donne un ion indène protoné. Le profil réactionnel et le mécanisme proposés sont en accord avec les résultats expérimentaux.

HENRI EDOUARD AUDIER, ARIELLE MILLIET, MARGARET MRUZEK, JEAN PIERRE DENHEZ, PIERRE DIZABO, and CATHERINE SCHAAL. Can. J. Chem. **59**, 968 (1981).

Fragmentations of the phenyl-2 oxetane ion by chemical ionization mass spectrometry, and of some isomeric ions, have been studied using deuterated and ^{13}C labelled compounds. The heterocyclic system of the protonated phenyl-2 oxetane ion is broken before fragmentation giving a hydroxylated carbocation which can isomerize by 1–2 or 1–3 hydride transfers. The protonated phenyl-3 propanal thus obtained eliminates a molecule of water and yields a protonated indene ion. The potential energy profile and the mechanism proposed are in agreement with the experimental results.

Introduction

L'étude de la fragmentation des éthers cycliques protonés (1) par ionisation chimique a montré que la première étape de cette fragmentation consiste en une isomérisation de l'ion moléculaire en carbocation hydroxylé (Schéma 1). Par transfert 1–2 d'hydrures (2–6) ou par transfert de méthylures (4–6), les ions aldéhydes ou cétones protonés conduisent à des carbocations du même type. Inversement de tels carbocations sont susceptibles de se cycliser en éthers protonés, qu'ils proviennent de composés carbonylés protonés ou qu'ils découlent de la perte d'eau d'un diol protoné (7, 8) (Schéma 1).

Dans tous ces dérivés, les compétitions entre les réactions de fragmentation et celles d'isomérisation dépendent non seulement des ΔH_f des états initiaux et finals, mais également des ΔH_f des formes isomères et des énergies d'activation nécessaires aux transferts 1–*n* d'hydrures.

La similitude des spectres ic (ionisation chimique) de phényl-2 oxétane **I**, du phényl-3 propane diol 1–3 **II**, du phényl-3 époxy 1–2 propane **III** et du phényl-3 propanal **IV** protonés avec du méthane, laisse présager que ces processus d'isomérisation interviennent aussi quand la chaîne est substituée par un noyau benzénique (Tableau 1).

Dans ce travail, l'examen des spectres des dérivés

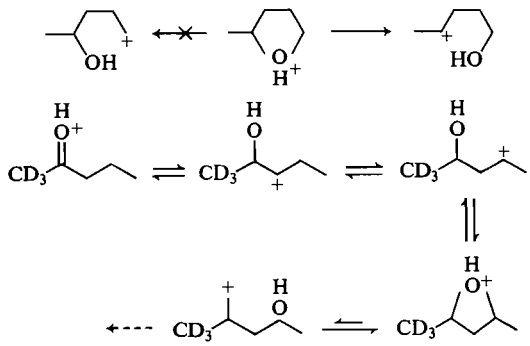

SCHÉMA 1

marqués par du deutérium du phényl-2 oxétane **I** a conduit à proposer un mécanisme de fragmentation qui a été confronté au profil réactionnel correspondant.

Résultats et discussion

Les spectres ic du phényl-2 oxétane protoné par du méthane ou de l'isobutane montrent, outre le pic moléculaire $[MH]^+$, trois fragments principaux $m/z = 117$ $[A]^+$, $m/z = 105$ $[B]^+$ et $m/z = 91$ $[C]^+$. Dans l'isobutane on peut détecter de plus un fragment mineur $m/z = 107$ et dans le méthane, un fragment $m/z = 57$.

L'intensité des pics dépend considérablement des conditions expérimentales, gaz protonant et

TABLEAU 1. Spectres ic des composés **1** à **4** (décomposition des ions dans la source; gaz protonant: méthane; rep. 6 V·cm^{-1}; T = 150°C)

Composé étudié		$[MH]^+$ m/z 135	$[A]^+$ m/z 117	$[B]^+$ m/z 105	$[C]^+$ m/z 91	m/z 57
	**I**	40	14	25	17	4
	**II**	55	18	14	11	2
	**III**	15	59	7	17	2
	**IV**	21	53	4	20	2

repousseur d'ions, donc de la distribution d'énergie interne de $[MH]^+$. A chacune de ces principales fragmentations en compétition est associé un pic métastable. Celui-ci est "applati" pour la transition $[MH]^+ \rightarrow [A]^+$ et "gaussien" pour les deux autres transitions. De ce fait la comparaison des hauteurs relatives de ces pics n'a que peu de sens. La comparaison des surfaces de ces pics métastables montre que la réaction $[MH]^+ \rightarrow [A]^+$ nécessite la plus faible énergie d'activation, la transition $[MH]^+ \rightarrow [B]^+$, a besoin de plus d'énergie, son pic métastable ayant une surface inférieure au précédent.

Les spectres d'ions métastables des composés marqués permettent de préciser le mécanisme et indiquent que l'ion $[A]^+$ m/z = 117 formé à basse énergie interne par perte d'eau a sans doute une structure bicyclique: (*i*) les hydrogènes portés par les carbones 2, 3 et 4 n'interviennent pas dans cette fragmentation à basse énergie; ils ne sont échangés ni avec l'hydrogène protonant, ni avec les hydrogènes du noyau aromatique (Tableau 3); (*ii*) la perte d'eau est précédée d'un échange de l'hydrogène protonant avec ceux du noyau benzénique (dérivé **1***a*, Tableau 3); (*iii*) un hydrogène du cycle aromatique est éliminé lors de la fragmentation. En effet, le spectre du dérivé **1***f* pentadeutérié sur le cycle aromatique présente des pics $[MH - D_2O]^+$ et $[MH - HDO]^+$ confirmant par ailleurs l'échange de l'hydrogène protonant.

TABLEAU 2. Spectres ic du composé **1** (décomposition des ions dans la source; gaz protonant: isobutane; T = 150°C)

	m/z				
Repousseur d'ions	135	117	107	105	91
6 V cm^{-1}	57	29	2	9	3
16 V cm^{-1}	26	32	2	13	27

La structure indanique **5** de l'ion m/z = 117 suggérée par les spectres des composés marqués est confirmée par les spectres d'activation par collision (ca); le spectre ca de cet ion provenant de la fragmentation de l'ion **1** est indentique à celui de l'indène protoné (8).

Le mécanisme de fragmentation proposé est en accord avec les résultats expérimentaux et le profil réactionnel (Fig. 1).

(*a*) La protonation s'effectue, soit sur le noyau aromatique, soit sur l'oxygène; les affinités protoniques (ap) de ces deux centres sont en effet très proches (toluène: ap = 193 kcal·mol^{-1}; oxétane: ap = 197 kcal·mol^{-1} (9)).

(*b*) La forme protonée sur le noyau benzénique peut s'isomériser en forme protonée sur l'oxygène. Cette dernière forme s'ouvre pour donner le carbocation hydroxylé le plus stable: l'ion **6** (1). Cette réaction est rapide dans la mesure où le ΔH_f de **6** est bien inférieur au ΔH_f de l'ion **1**.

(*c*) Le carbocation **6** s'isomérise par transferts

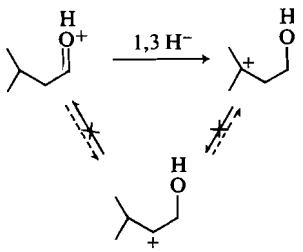

SCHÉMA 2

d'hydrure en ions **7** (ou **7**′) et **4** (2–4). La structure de l'ion **6** a été considérée comme "benzylique" et non "tropylique" à cause de la forte barrière d'isomérisation qui existe entre ces deux formes (10, 11). Par contre, il a été proposé, compte tenu des travaux relatifs à la stabilisation d'un carbocation en β d'un noyau benzénique (12, 13), que l'ion **7** pouvait s'isomériser en ion bicyclique **7**′. La réaction d'isomérisation de **6** en **4** par deux transferts successifs 1–2 d'hydrure et par l'intermédiaire de la forme **7**′ a une énergie d'activation maximale de 12 kcal·mol^{-1}. Le passage par l'intermédiaire **7** est très improbable. En effet, le passage direct de l'ion **6** à l'ion **4** par un transfert 1–3 d'hydrure est également possible; de tels transferts exigent des énergies d'activation de l'ordre de 6 à 8 kcal·mol^{-1} (6, 14) (Schéma 2).

(*d*) L'élimination d'eau s'effectue par attaque du carbocation **4** sur le cycle aromatique donnant le complexe intermédiaire **8** qui perd une molécule d'eau et donne l'ion indène protoné **5** (Fig. 1). Cet ion a un ΔH_f inférieur de 25 kcal·mol^{-1} environ à celui de l'ion phénylallyl isomère susceptible cependant de se former pour les ions $[MH]^+$ de plus haute énergie interne. La largeur du pic métastable de la transition $[MH]^+ \rightarrow [A]^+$ permet d'affirmer que le ΔH_f de l'état de transition de cette réaction est bien supérieur à celui de l'état final; la perte en énergie cinétique, calculée à partir de la largeur du pic métastable, est de 400 meV, soit 9,3 kcal·mol^{-1}. Cet état de transition ne peut être l'indanol protoné, puisque pour ce composé la largeur du pic métastable correspondant à la perte d'eau est bien inférieure (perte en énergie cinétique 70 meV, soit 1,6 kcal·mol^{-1}).

(*e*) Les ΔH_f des formes moléculaires protonées, soit sur le noyau aromatique, soit sur l'oxygène, étant très voisines, les échanges entre l'hydrogène protonant l'oxygène et les hydrogènes du noyau aromatique sont importants.

L'étude des fragments $[B]^+$ $m/z = 105$ et $[C]^+$ $m/z = 91$ permet de préciser plusieurs aspects du mécanisme. Tout d'abord le Tableau 3 montre que les ions $[B]^+$ et $[C]^+$ qui proviennent de $[MH]^+$ par élimination respectivement de CH_2O et de C_2H_4O contiennent intégralement le carbone 2 (dérivé **1***g*); il n'y a ni isomérisation, ni transposition de la chaîne conduisant à permuter les carbones 2 et 4.

Par ailleurs, l'hydrogène en position 2 se retrouve dans les ions $[B]^+$ et $[C]^+$ pour plus de 95%, par contre le groupement CH_2 en position 4 est totalement éliminé au cours de la formation du fragment $[B]^+$ (dérivés **1***c* et **1***d*, Tableau 3).

Les hydrogènes de l'hétérocycle ne s'échangent donc, ni entre eux, ni avec ceux du cycle aromatique, ni avec l'hydrogène protonant. Les réactions d'isomérisation des carbocations hydroxylés **6** → **7**′ → **4** ne sont donc pas réversibles dans les conditions expérimentales de cette étude.

La formation de l'ion $[B]^+$ s'accompagnant de l'élimination des deux hydrogènes portés par le carbone 4, nécessite le transfert de l'hydrogène protonant sur le carbone 2 (Fig. 1). De ce fait, l'échange préalable de l'hydrogène protonant avec ceux du cycle aromatique ne peut être décelé. L'ion $[B]^+$ $m/z = 105$ est déplacé à $m/z = 106$ pour le dérivé **1***a* et à $m/z = 110$ pour le composé **1***f*.

La participation de l'hydrogène protonant à la formation de l'ion $[C]^+$ est essentiellement liée à son échange préalable avec les hydrogènes benzéniques (comparaison des spectres de **1***a* et de **1***f*, Tableau 3).

Il ressort du Tableau 3 que l'hydrogène transféré contribuant à la formation de l'ion $[C]^+$ provient pour moitié de la position 3 et pour moitié de la position 4.

L'ion $[C]^+$ semble, comme le laisse prévoir le profil réactionnel, être le résultat soit d'un double transfert 1–2 d'hydrures (**6** → **7**′ → **4**) amenant un hydrogène du carbone 3 sur le carbone 2, soit d'un simple transfert 1–3 d'hydrure plaçant un hydrogène du carbone 4 sur le carbone 2.

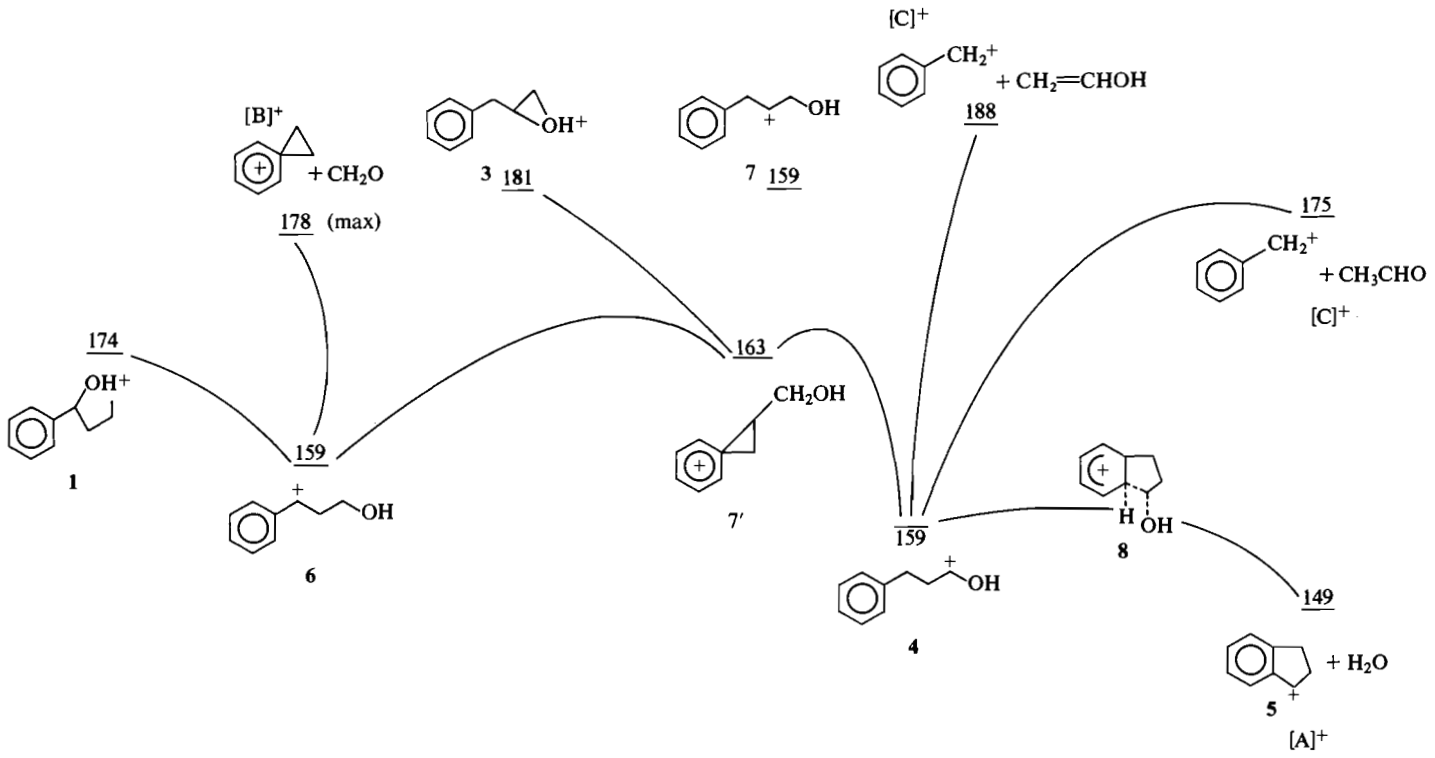

FIG. 1. Profil réactionnel; les ΔH^{0}_{f298} des niveaux sont donnés en kcal·mol^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Suivant la nature du fragment neutre formé, deux mécanismes peuvent être proposés pour former l'ion $[C]^+$ à partir de l'ion **4**: (*i*) rupture directe conduisant à la formation d'un énol; (*ii*) rupture accompagnée du transfert de l'hydrogène hydroxylique sur le carbone 3, donnant une molécule d'acétaldéhyde.

Ces données expérimentales montrent que les ΔH_f des états de transition des réactions **6** → **4** par transferts 1–2 ou 1–3 d'hydrures sont voisins.

La comparaison des spectres des composés **I**, **II**, **III** et **IV** est en accord avec les mécanismes et le profil réactionnel proposés.

Le Tableau 1 montre que, si les mêmes pics se retrouvent pour les 4 composés étudiés, l'intensité du pic $m/z = 105$ est toutefois plus faible pour les composés **III** et **IV**. Ce phénomène est plus accentué à basse énergie. En effet, alors que pour les composés **I** et **II** les surfaces des pics métastables $[MH]^+ \rightarrow [A]^+$ et $[MH]^+ \rightarrow [B]^+$ sont du même ordre de grandeur, pour les composés **III** et **IV** les pics métastables correspondant à la formation de l'ion $[B]^+$ ne peuvent être détectés.

La réaction **4** → **6** ne s'effectue donc pas plus pour ces dérivés que pour le phényl-2 oxétane protoné, pour lequel il a été montré que la réaction **6** → **4** n'était pas réversible. Par ailleurs, le Tableau 1 indique que les intensités des ions $[MH]^+$ correspondant aux composés **III** et **IV**, sont très voisines alors que leurs ΔH_f sont très différents.

En fait l'ion **3** s'isomérise très rapidement dans la source pour conduire à l'ion **4** plutôt qu'à l'ion **6**.

Le noyau aromatique favorise probablement un passage concerté direct à la forme **7'** qui s'isomérise ensuite en ion **4**. Cette isomérisation ayant lieu dans la source, les ions **4** formés, soit directement par protonation du phényl-3 propanal **IV**, soit par isomérisation du phényl-3 époxy 1–2 propane **III**, sont désactivés par chocs et ont des énergies internes comparables quelle que soit leur provenance; c'est pourquoi leurs spectres ic sont très voisins.

Par ailleurs, les données expérimentales montrent que le mécanisme de perte d'eau $[MH]^+ \rightarrow m/z = 117$ est identique pour tous les composés étudiés: (*a*) les spectres d'activation par collisions des ions m/z 117 sont identiques quel que soit le composé de départ (8). Ils sont superposables à celui de l'indène protoné; (*b*) les transitions $[MH]^+ \rightarrow m/z$ 117 sont accompagnées d'un pic métastable de même largeur (énergie cinétique 400 MeV ± 10).

Ces données sont en accord avec le mécanisme de perte d'eau proposé pour le phényl-2 oxétane protoné: **1** → **6** → **4** → $[MH - H_2O]^+$.

Conclusion

Les études relatives à la perte d'eau des aldéhydes et cétones protonés acycliques ont montré que les transferts 1–2 d'hydrure sont réversibles (6) lorsque ces réactions d'isomérisation ont des états de transition dont le ΔH_f est très inférieur à celui du dernier état de transition conduisant à la perte d'eau. Elles ne sont pas réversibles dans le cas contraire.

Dans l'exemple étudié ici, la barrière due à la réaction **4** → **6** est à l'origine de la non-réversibilité observée. Ce phénomène est à rapprocher de celui qui est observé pour le méthyl-3 butanal protoné (6), pour lequel la perte d'eau s'effectue avec un transfert d'hydrogène sélectif et sans échange préalable de l'hydrogène protonant: une énergie d'activation est nécessaire à l'isomérisation du carbocation stable initial en un carbocation tertiaire également stable (Schéma 2).

Par rapport au comportement des aldéhydes éthers ou diols alicycliques, l'introduction d'un cycle aromatique dans la chaîne influence considérablement les processus de rupture: (*a*) en modifiant les valeurs relatives des ΔH_f des différents carbocations formés, en particulier en stabilisant la charge positive sur le carbone adjacent au noyau; et (*b*) en induisant une réaction de cyclisation qui formellement s'apparente à la réaction de Friedel et Craft.

Partie expérimentale et calculs

Tous les ΔH_f cités sont des ΔH_{f298}^0.

Les ΔH_f des ions $[MH]^+$ provenant de la protonation d'une molécule neutre sont obtenus suivant la réaction [1]:

$$[1] \quad MH^+ \xrightarrow{ap} M + H^+$$

à partir du ΔH_f du proton, 366 kcal·mol^{-1}, du ΔH_f de la molécule neutre que l'on calcule en utilisant les incréments de Benson (15) et des affinités protoniques (ap) trouvées dans la littérature.

Toutes les valeurs sont données en kcal·mol^{-1}. Phényloxétane protoné **1**, $\Delta H_f = 174$, $\Delta H_{f_I} = 5{,}5$; ap (oxétane) = 197 (9); ap (toluène) = 193 (9). Phényl-3 époxy 1–2 propane protoné **3** $\Delta H_f = 181$, $\Delta H_{f_{III}} = 5{,}5$; ap (oxirane) = 190 (9). Phényl-3 propanal protoné **4**, $\Delta H_f = 155$, ΔH_f $CH_3CH_2\overset{+}{C}HOH = 132$ (16–18).[1] Indanol protoné $\Delta H_f = 144$, $\Delta H_{f_{indanol}} = -25$; ap (2-butanol) = 197 (19). Indène protoné **5**, $\Delta H_f = 206$, $\Delta H_{f_{indène}} = 40$; ap (styrène) = 202 (9).

Le ΔH_f de l'ion $[C]^+$ a été trouvé dans la littérature. Les ΔH_f des autres ions sont obtenus à partir des ΔH_f d'ions de structure voisine auxquels on fait subir une substitution isodesmique (20) dont l'incrément est calculé par la méthode de Benson (15). Ces valeurs ne sont qu'indicatives dans la mesure où le rôle d'un noyau benzénique dans la stabilisation de la charge positive portée par une chaîne n'a pas encore été étudié. Le ΔH_f de **6** = 159 est obtenu à partir du ΔH_f du styrène protoné = 200 auquel

[1]Une valeur de 130 kcal·mol^{-1} basée sur l'affinité protonique du propionaldéhyde a été attribuée à cet ion (4).

on ajoute l'incrément de substitution isodesmique − 41. Le ΔH_f de **7** est calculé à partir du ΔH_f de $C_6H_5CH_2\overset{+}{C}HCH_3$ (20): $\Delta H_f = 215$, l'incrément est −36. Le ΔH_f de l'ion $[B]^+$ est obtenu à partir du PA (potentiel d'apparition) d'un ion supposé identique obtenu, soit par perte de brome du 1-bromophényléthane, soit par perte d'un radical CH_3CO de la phényl-4 butanone 2, on obtient ainsi deux valeurs limites $205 < \Delta H_f < 217$. (21). Le ΔH_f de l'ion **7'** est obtenu par substitution isodesmique sur l'ion précédent, l'incrément étant −43.

Les spectres ont été effectués à l'I.C.S.N.–C.N.R.S. de Gif-sur-Yvette sur un appareil AEI MS 9 dont la source a été modifiée (22).

Les mesures relatives à la perte en énergie cinétique ont été effectuées sur l'appareil ZAB-2F de l'Ecole Polytechnique Fédérale de Lausanne avec un système AGHIS, $T = 180°C$, le gaz réactif étant l'isobutane (≃0,5 Torr). Les déterminations ont été faites dans la deuxième région libre de champ en mesurant la largeur à mi-hauteur du pic métastable et en effectuant la moyenne de trois mesures.

Nous remercions l'I.C.S.N. et Monsieur Pierre Varenne pour sa collaboration.

La préparation des composés étudiés a été décrite précédemment (23).

Photochemical reactions of charge-transfer complexes. III. Molecular orbital studies of the charge-transfer complexes between 1,2-dimethoxyethylenes and 1,2-dicyanoethylenes

PO CHEONG WONG[1] AND RUSSELL J. BOYD[2]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada, B3H 4J3

Received August 19, 1980

PO CHEONG WONG and RUSSELL J. BOYD. Can. J. Chem. **59**, 974 (1981).

Ab initio and PCILO molecular orbital (MO) calculations for the four $\pi-\pi^*$ charge-transfer complexes formed between maleonitrile (MN) and fumaronitrile (FN), and *cis* (CS) and *trans*-1,2-dimethoxyethylene (TR) are reported. The donor and the acceptor molecules are stacked in parallel planes. *Trans* and *cis*-1,2-dihydroxyethylene are used as the model compounds for TR and CS in the determination of the optimum geometries of the complexes. Both types of MO calculations indicate that the eclipsed geometry (with the two central double bonds parallel and the centres of the double bonds centred over one another) is relatively unstable. With limited geometry searching, we find that the slipped geometry (with the two central double bonds parallel but separated at a projected distance of 2.2 Å and the oxygen atoms above the cyanocarbon atoms) is the preferred structure. According to the *ab initio* calculations the relative order of the calculated heats of formation (ΔH^{θ}'s) for these complexes is: MN–CS > FN–CS > FN–TR > MN–TR.

PO CHEONG WONG et RUSSELL J. BOYD. Can. J. Chem. **59**, 974 (1981).

On rapport des calculs *ab initio* et PCILO d'orbitales moléculaires (OM) de quatre complexes $\pi-\pi^*$ de transfert de charge entre le maléonitrile (MN) et le fumaronitrile (FN) et les diméthoxy-1,2 éthylènes *cis* (CS) et *trans* (TR). Les molécules acceptrices et donneuses sont entassées dans des plans paralelles. On a utilisé les dihydroxy-1,2 éthylènes *cis* et *trans* comme composés modèles pour déterminer les géométries optimales des complexes de TR et de CS. Les deux types de calculs OM indiquent que la géométrie éclipsée (avec les deux doubles liaisons centrales paralelles et les centres des doubles liaisons centrées l'une sur l'autre) est relativement instable. A partir de recherches limitées sur la géométrie, nous avons trouvé que la structure préférée est la géométrie décalée (avec les deux doubles liaisons centrales paralelles mais séparées d'une distance projetée de 2,2 Å et les atomes d'oxygène au-dessus des atomes de carbone du groupement cyano). Selon les calculs *ab initio*, l'ordre relatif des chaleurs de formation calculées (ΔH^{θ}'s) de ces complexes est le suivant: MN–CS > FN–CS > FN–TR > MN–TR.

[Traduit par le journal]

Introduction

In spite of the fact that the binding energy of a charge-transfer (ct) complex in solution is of the order of a few kcal mol^{-1} (1), it has been very difficult to predict experimentally or theoretically the exact orientation of the donor and the acceptor in the complex. X-ray crystallographic structures provide the only reliable experimental information for ct complexes. However, caution must be taken in applying these solid phase results to the solution phase since there is uncertainty about the importance of crystal packing forces for the individual complex (2). Orientation effects in ct complexes have not been fully investigated by theoretical methods. Here, we define orientation effects as the effects of the orientation of the substituents on the geometry and stability of the ct complex. Several theoretical studies of the most stable geometries of ct complexes have been reported (see the references in later sections). However, the effects of the substituents of the subsystems on the geometry of the $\pi-\pi^*$ complexes have not been systematically investigated so far. It would be interesting to know how the substituents of the donor molecule align with those of the acceptor molecule in the complex in solution. A basic understanding of the orientation effects would help us to predict the geometry of the ct complex which in turn will be useful in (*1*) the rationalization of the 3-D structure of some biological macromolecules where ct interactions are important (1*c*), and (*2*) the selection of suitable donors and acceptors for the study of photochemical isomerization of olefins through the irradiation of the ct complexes. The latter is a potentially useful synthetic method for preparing stereospecific olefins (3). Selective irradiation of the ct complex formed by one olefin isomer with a proper donor (or acceptor) would lead to enrichment of the alternative olefin isomer. A successful example has been demonstrated in the irradiation of the ct complex between *trans*-stilbene (*t*-ST) and fumaronitrile (FN) where *cis*-stilbene (*c*-ST) can be obtained in up to 86% yield (3). Of course in this particular example, the difference in the absorption spectra and the stability of the *trans* and *cis*-stilbene complexes can be accounted for by merely considering the difference in their oxidation potentials ($E_{1/2}^{ox}$(Ag/$AgNO_3$) being 1.10 V[3] and 1.40 V[4] respec-

tively). The orientation effects in this case may in fact be overwhelmed by this major effect. Orientation effects are important in the case *t*-ST–FN and *t*-ST–MN complexes, where the equilibrium constant (K) of the former is larger (K = 1.7 and 1.0 M^{-1}, respectively) even though the acceptors have the same reduction potentials.

In the present study, we try to predict theoretically the most stable geometries as well as the heats of formation (ΔH^{θ}'s) of the four ct complexes formed between *trans* and *cis*-1,2-dimethoxyethylene (TR and CS), and fumaronitrile (FN) and maleonitrile (MN). These four complexes represent the smallest system for the study of orientation effects. This is because the ionization potentials (adiabatic) of the two donors are very similar (7.40 and 7.38 eV for *trans* and *cis*-1,2-diethoxyethylene respectively (4)), while the reduction potentials for the two acceptors are the same. According to the Mulliken theory (1), the difference in the strength of the complex will reflect the orientation effects for structurally similar systems.

In this paper *ab initio* molecular orbital (MO) calculations and Perturbation Configuration Interaction using Localized Orbitals (PCILO) (5) calculations have been used to predict the geometries and the heats of formation (ΔH^{θ}'s) of the π–π^* ct complexes. A comparison of the results from these two MO methods will be discussed in detail.

Method

All computations were performed on a Control Data CYBER 170-720 system. Two computational methods within the supermolecule approximation (6) were employed in this work to calculate the stabilization energies (ΔE equivalent to ΔH^{θ}) for the formation of charge-transfer complexes (eq. [1]).

$$[1] \quad \Delta E = E_C - (E_D + E_A)$$

E_D and E_A are the energies of the isolated donor and acceptor molecules respectively and E_C is the energy of the complex.

The standard single determinant *ab initio* calculations were performed using the GAUSSIAN 76 (G76) program (7) with the spin-restricted Hartree-Fock (RHF) procedure. The geometries of the subsystems employed in the complexes were assumed to be the same as the isolated molecules. This assumption is justified by the fact that there is no significant change in bond length of the central double bonds upon complex formation according to both X-ray crystallographic analysis on solid state ct complexes (2) and our calculations. The

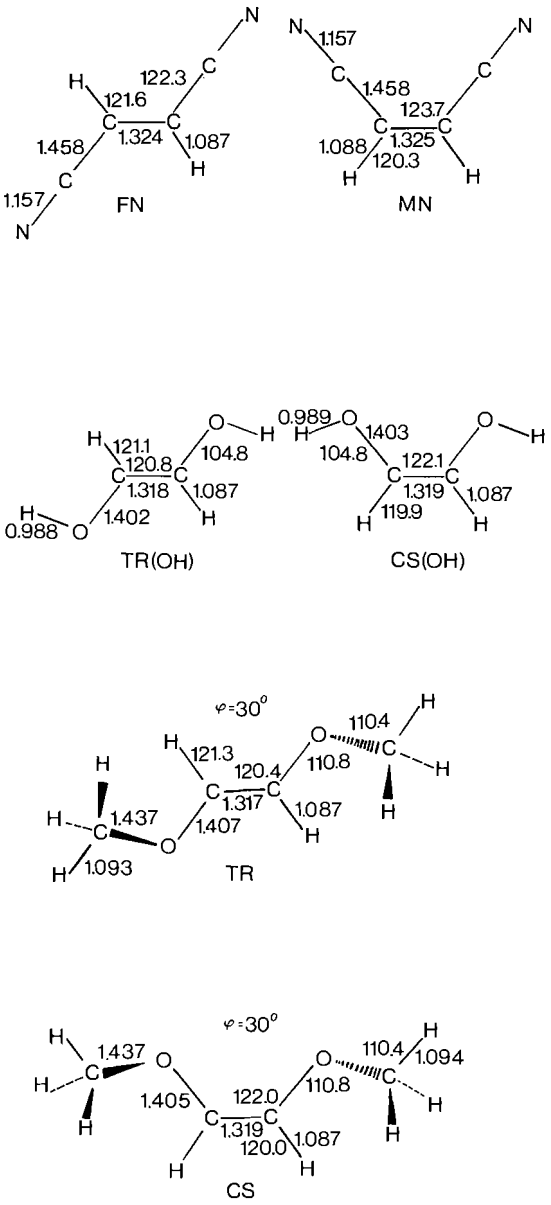

FIG. 1. STO-3G geometries of the olefins (bond lengths in Å, angles in degrees). ϕ refers to the $H_{Me}COC$ dihedral angles of TR (*trans*-1,2-dimethoxyethylene) and CS (*cis*-1,2-dimethoxyethylene).

geometries of the isolated donors and acceptors (Fig. 1) were fully optimized using the minimal STO-3G basis set.[5] The initial search for an optimum geometry used the models *trans* and *cis*-1,2-

[5]At the STO-3G level, the *trans* isomer of the olefins R—CH=CH—R is predicted to be more stable by 0.63 and 1.26 kcal/mol, whereas PCILO with third-order Epstein-Nesbet partitioning predicts the *cis* isomer to be more stable by 0.34 and 0.91 kcal/mol where R is CN and OCH_3, respectively.

[b]Using the model dihydroxymethylenes.

dihydroxyethylene as the donors. For computational convenience, the planar structures for both the dihydroxy and the dimethoxyethylene were used throughout although the optimized geometries of the latter (both *cis* and *trans*) have the methyl groups 30° off the molecular plane. The donor and the acceptor olefins were constrained to parallel planes in the search for the most stable geometry. The validity of this assumption is supported by both X-ray crystallographic analysis on $\pi-\pi^*$ ct complexes (2) and our calculations; that is, the complex becomes less stable when one of the planes is tilted in either direction. Calculations with larger split-valence basis sets, 3-21G and 4-31G, were performed for the dihydroxy complexes at selected geometries with an expanded version of the GAUSSIAN 76 program. Only one of the complexes with the 4-31G basis set was calculated due to limitations on high speed memory storage space.

The Cullen-Zerner version[6] which is a modified Daudey version (8) of the PCILO program was used in this work. Initial geometries for the complexes were taken from the STO-3G optimization results. The intermolecular distances were further optimized accordingly. The bond polarities of the subsystems and the complexes were optimized. The third order Epstein-Nesbet partitioning (EN) of the Hamiltonian has been used throughout. In some cases a comparison has also been made with the results obtained from the Møller-Plesset partitioning to third and fourth order.

Results

For the sake of brevity only selected results of the geometry searching are summarized in Table 1. A similar set of optimum structures is included for each complex, although it should be stressed that in all cases other structures less stable than the preferred ones were considered.

MN–CS Complex

According to the G76 calculation with the STO-3G basis set, the complex is not stable (repulsive) when the donor and acceptor are arranged as in structure **1***a* (Fig. 2), where the two central double bonds are parallel and the centres of the double bonds are centred over one another. The complex gains stability when the double bond of CS is rotated around the centre. A local minimum is obtained at $\phi = 150°$, structure **1***b* (ϕ is defined as the projected angle between the two double bonds with the zero taken to be the eclipsed geometry **1***a*). The optimum intermolecular distance (d) of **1***b* is $d = 3.8$ Å.

When the centre of CS is moved away from the centre over centre arrangement with $\phi = 180°$, ΔE becomes more negative (i.e. the complex becomes more stable). A minimum is found at $a = 2.2$ Å, structure **1***c* with ϕ being 180° and $d = 3.35$ Å where a is defined as the projected perpendicular distance between the two centres of the double bonds. The results for the dimethoxy complexes are essentially the same although the magnitude of ΔE is smaller. With the 3-21G calculations, ΔE becomes more negative in an analogous manner (Table 1).

The PCILO results are rather different as far as intermolecular distance and ΔE are concerned (Fig. 2). Nevertheless, the relative stabilities of **1***a*, **1***b* and **1***c* are consistent with the *ab initio* results.

FN–TR Complex

There are two possible arrangements for the centre over centre structures; the OH group can be placed either over the CN group, as in structure **2***a*, or on the other side of the double bond (Fig. 3). In either case, the G76 results for this complex are similar to the MN–CS complex in that the eclipsed

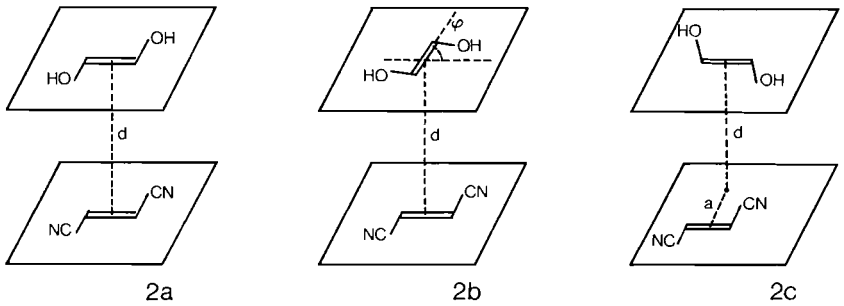
ΔH°_{calcd} (kcal mol^{-1})

G76(STO-3G)	+0.78 (d=3.8)	−1.06 (d=3.8, φ=150°)	−2.03 (d=3.35, a=2.2)
PCILO(EN)	−0.31 (d=2.8)	−0.67 (d=2.8, φ=150°)	−14.25 (d=2.0, a=2.2)

FIG. 2. The optimum structures of the MN–CS (OH) complex.



ΔH°_{calcd} (kcal mol^{-1})

G76(STO-3G)	+0.31 (d=3.8)	−1.06 (d=3.8, φ=45°)	−0.71 (d=3.35, a=2.2)
PCILO(EN)	−0.47 (d=2.8)	−1.87 (d=2.6, φ=60°)	−6.87 (d=2.0, a=2.2)

FIG. 3. The optimum structures of the FN–TR (OH) complex.

structure **2***a* is the least stable. A minimum can be obtained by rotating the double bond of TR about the centre with $\phi = 45°$ at $d = 3.8$ Å, structure **2***b*. Moving the centre of TR along the axes of the double bonds of both FN and TR (structure **2***b*) leads to a less negative ΔE. In contrast to the MN–CS complex, structure **2***c* is only a local minimum with $\phi = 0°$, $d = 3.35$,and $a = 2.2$ Å. The PCILO results, however, still favour structure **2***c* over structures **2***a* and **2***b*.

MN–TR Complex

As shown in Fig. 4, structure **3***a* is somewhat less stable than the other structures at the STO-3G level. Structure **3***b* represents a local minimum since moving the centre of TR of this structure off the centre along the direction of the double bonds of either TR or MN results in decreased stability. Structure **3***c*, which is similar to **1***c*, is the minimum. The PCILO results again support the relative stability of **3***a*, **3***b*, and **3***c*.

FN–CS Complex

As shown in Fig. 5, structure **4***a* is the least stable at the STO-3G level. Structure **4***b* corresponds to a local minimum while structure **4***c* is the minimum. The PCILO results again support the relative stability of the three structures of the FN–CS complex.

Discussion

Since the introduction of the classical theory for charge-transfer complex formation by Mulliken,

using a two-determinant charge-transfer resonance formalism (1*a*), several approaches have been developed to estimate the heat of formation (ΔH^{θ}) and the geometries of ct complexes (6, 9). Among these theories, there are two which have lead to considerable success: (*1*) the electrostatic-perturbation theory developed by Murrell *et al.* (9*d*) accounting for intermolecular forces, in the region of small overlap, by an extension of the theory for long range intermolecular interactions, and (*2*) the supermolecule approach, first introduced by Chesnut and Moseley (6), taking the whole complex as one molecular moiety for which general molecular orbital theories are applicable.

Using the electrostatic-perturbation approach, Lippert *et al.* (10) were able to calculate ΔH^{θ}'s for a number of ct complexes within close agreement with the observed values. Their calculations also predict the existence of rotational isomers for benzene–tetracyanoethylene (TCNE) and *p*-xylene–TCNE complexes, however, the relative stability to the two isomeric complexes of the latter was the opposite to that observed by Voigt and co-workers (11).

With the availability of large-scale computational facilities and advances in computational MO methods, the supermolecule approach has become significantly more popular and convenient for studying the properties of ct complexes. MO studies employing Extended Huckel Theory (EHT) (6, 12)

and semiempirical SCF methods (Pariser-Parr-Pople (13), CNDO and INDO (14)) demonstrated the potential of the supermolecule approach for predicting the most stable geometry of $\pi-\pi^*$ ct complexes. However, the quantitative values of ΔH^0's and interplane distances are generally poor. EHT calculations on some complexes failed to find any stable arrangement (15). The CNDO/2 and INDO methods overestimate ΔE while the minima are generally at too small a separation between the complex components (14). On the other hand, the MINDO/2 calculations have failed to find energy minima for some $\pi-\pi^*$ ct complexes (16).

There are three factors which cause the semiempirical methods to overestimate the binding energy: (*1*) the neglect of basis set superposition error (BSSE) (17), (*2*) underestimation of the electronic repulsion due to the neglect of differential overlap (14*b*), and (*3*) omission of geometry optimization. The first two factors are probably more important. The BSSE is more important in calculations using small basis sets. Improvements can be made by (*i*) increasing the basis set to the Hartree-Fock limit, or (*ii*) the introduction of configuration interaction (CI) with a reasonably large basis set, or (*iii*) the use of the counterpoise method (18). The PCILO method is therefore better, for calculating ΔE, than any of the other semiempirical methods since it does include CI over the localized molecular orbitals (19). The computing time for PCILO is almost the same as CNDO/2 even though all the single and double excited configurations are included. There are limitations to this method, however, since it starts with the minimal basis set and uses the CNDO approximations for evaluating the integrals. Therefore, uncertainties due to the BSSE and the underestimated electronic repulsion still exist. Generally speaking, PCILO normally gives good ΔE although there are exceptional cases (19). The intercomponent distance is also too short at minima as in the CNDO cases.

The *ab initio* MO method is the best choice although it requires substantially larger computing facilities and longer computational times. The improvement of the *ab initio* method is partly due to a better description of the electronic repulsion and partly due to smaller BSSE upon employing larger basis sets. In order to estimate the BSSE in our systems at the STO-3G level (see refs. 18 and 20 for relevant discussions) we have applied the counterpoise method (18). Our calculations suggest that the BSSE for the MN–CS complex is only -0.11 kcal mol^{-1} for structures **1***a* and **1***b*, and zero for **1***c*. In practice, the ΔE's calculated by use of the smaller basis sets are generally too small (21). The use of a larger basis set would improve ΔE relative to the observed value, but the theoretical value would still be too low since the single determinant SCF procedure does not account for the dispersion energy due to electron correlation (21*b*). A few procedures have recently been established to retrieve the dispersion energy (18*c*, 21*b*, 22), although this has not been included in the present study.

As shown in Table 1 and Figs. 2 to 5, the *ab initio* interplane distance for structures *a* and *b* is 3.8 Å which is somewhat longer than that usually observed from X-ray crystallographic analysis (2) of complexes in the solid state (3.1 to 3.6 Å). This result is consistent with the only two $\pi-\pi^*$ ct complexes (formaldehyde–ethylene and carbonyl cyanide – benzene complexes) studied previously by *ab initio* MO methods (18*c*, 21). The eclipsed geometry is relatively unstable. The instability is probably due to the unsubstituted ethylene–ethylene interaction which is repulsive according to the *ab initio* and valence-bond calculations on the ethylene dimer (20). Studies on the benzene–benzene system also support this conclusion. For instance, PCILO calculations (19*b*, *d*) suggest that the eclipsed benzene dimer is repulsive. This conclusion is easily visualized in terms of the Orientation and Overlap Principle (HOMO–LUMO interaction) introduced by Mulliken (9*a*). Moreover, CNDO/INDO calculations on the *p*-benzoquinone–aniline (toluene) complex (14*b*) favour the staggered form of both the benzenes and the substituents. The importance of steric effects and hydrogen bonding is, however, uncertain. The stability of the **1–4***c* and **2***b* structures may be explained in terms of electrostatic attraction between the oxygen atom and the cyanocarbon, at the same time avoiding overlap of the ethylene moieties. This explanation gains support from the study of the intramolecular ct complex (fixed geometries) of paracyclophanes with two e-donating substituents on one of the benzene rings and two e-withdrawing substituents on the other (23). The elipsed isomer is more stabilized by ct interaction than the anti isomer due to the closer proximity of the e-donating and e-withdrawing substituents.

The ΔE's calculated with the 4-31G basis are generally greater than those obtained at the STO-3G level. This tendency is probably due to an overestimation of charge effects with the 4-31G basis (21*a*, *b*, 24). The addition of d functions would be expected to move ΔE downward from the 4-31G values towards the STO-3G results (21*c*). However, this would be time consuming even with the decreased size of the model dihydroxyethylene complexes. Table 1 reveals that the split-valence 3-21G basis recently introduced by Binkley *et al.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

(25) would be a better choice to calculate the SCF ΔE. The computational time with the 3-21G basis is about 15% less than with the 4-31G basis. According to Morokuma's calculation on the formaldehyde–ethylene system (21*b*), the dispersion energy would be about the same magnitude as the SCF ΔE's. Therefore, an estimate for the gas phase ΔH^{θ}'s can be made by doubling the ΔE's calculated at 3-21G level (i.e., ΔH^{θ}_{calc} would be -3.9, -4.2, -10.0, and -6.4 kcal mol^{-1} for the MN–TR(OH), FN–TR(OH), MN–CS(OH), and FN–CS(OH) complexes, respectively). The magnitude of the ΔH^{θ}'s for the corresponding dimethoxy complexes will be slightly smaller (see Table 1 for the comparison of the ΔH^{θ}'s at the STO-3G level). The small ΔH^{θ}'s for the dimethoxy complexes are probably due to the steric effect of the methyl groups.

Another way to estimate the ΔH^{θ}'s is to use an empirical relation between the ΔH^{θ}'s and the difference in the oxidation potential of the donor and the reduction potential of the acceptor. A straight line can be obtained by plotting the ΔH^{θ}'s (gas) of a series of π–π^* complexes between tetracyanoethylene (TCNE) and methyl substituted benzenes (26) versus ($E^{ox}_{1/2}$(D) $-$ $E^{red}_{1/2}$(A)). The reduction potential of TCNE is -0.06 V vs. Ag/AgNO$_3$ (0.1 *M*) (27). The oxidation potentials of the methyl substituted benzenes have been summarized elsewhere (28). The oxidation potentials of *trans* and *cis*-1,2-dimethoxyethylene are 0.72 and 0.70 V[7] respectively. The reduction potentials of FN and MN are -1.63 V (3). From this relation, the ΔH^{θ}'s (gas) for all four of our complexes are predicted to be about 5 kcal mol^{-1} (Fig. 6).

The STO-3G minimum geometry is usually a good estimate for ct complexes (21). In our cases, assignment of the most stable geometry may be sensitive to the corresponding dispersion energies. Using a point charge model, structures **1**–**4***c* would possess smaller dispersion than **1**–**4***a*,*b* since the intercomponent distances for structure **1**–**4***c* are longer than for the others. Nevertheless, the PCILO results (containing a certain amount of dispersion energy) support the *ab initio* SCF results.

The PCILO energies calculated through to third order with Epstein-Nesbet partitioning are reasonably good for structures **1**–**4***a*,*b*. With structures **1**–**4***c* the equilibrium interplane distances appear to be too short (2.0 Å). Therefore, the ΔE's are probably overestimated. It has been suggested that a better estimate for ΔE would be at 2.5 Å (19*c*) (Table 1). The geometries from PCILO are comparable to those of the *ab initio* results although the

[7]Estimated from a relationship between IP and $E^{ox}_{1/2}$ ($E^{ox}_{1/2}$ = 0.827 IP $-$ 5.40 V) (see ref. 32).

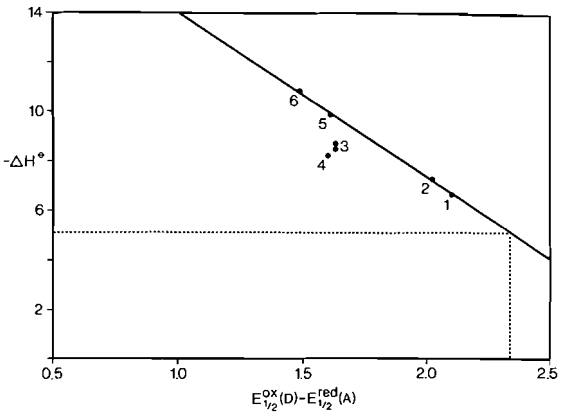

FIG. 6. The relation between ΔH^{θ} (gas)$_{expt}$ (in kcal/mol) and the redox potentials (in volts) of the acceptor (TCNE) and donor (methyl substituted benzenes). The donors represented are: (1) benzene; (2) toluene; (3) *o*-xylene; (4) *p*-xylene; (5) mesitylene; (6) durene.

TABLE 2. The calculated ΔH^{θ} (kcal mol^{-1}) of the MN–CS complex from the PCILO method[a]

Structure	EN (3°) $-\Delta H^{\theta}$ (*d*, Å)	MP (3°) $-\Delta H^{\theta}$ (*d*, Å)	MP (4°) $-\Delta H^{\theta}$ (*d*, Å)
1*a*	0.31 (2.8)	4.16 (2.4)	9.89 (2.2)
1*b*	0.67 (2.8)	3.66 (2.4)	7.14 (2.2)
1*c*[b]	14.25 (2.0)	28.11 (2.0)	43.11 (1.8)

[a]The notation is as follows: EN (3°), MP (3°), and MP (4°) refer to third-order Epstein-Nesbet partitioning, third-order Møller-Plesset, and fourth-order Møller-Plesset partitioning, respectively.
[b]*a* = 2.2 Å.

ΔE's appear to be overestimated. There are two situations where significant differences are found between the two methods: (*1*) ΔE for the MN–TR(OH) complex is too high, and (*2*) structure **1**–**4***c* seems significantly more stable than the other structures. These differences are probably due to the fact that PCILO underestimates the electronic repulsion to a lesser extent. Furthermore the geometries have not been optimized by the PCILO method in this work.

The ΔE's calculated through to 3rd and 4th order, especially to 4th order with Møller-Plesset partitioning, are generally larger (probably overestimated) than those of the 3rd order Epstein-Nesbet partitioning (Table 2). Therefore, the latter should be preferred for evaluating intermolecular forces.

Conclusion

The *ab initio* and PCILO MO calculations carried out on four ct complexes (FN–CS, FN–TR, MN–CS, MN–TR) indicate that the eclipsed geometries are relatively unstable. Since we feel that the PCILO method overestimates ΔE due to the use of the CNDO approximations, we have more confidence in the results from the *ab initio* calcula-

tions. The order of stability of the four complexes according to the *ab initio* calculations is MN–CS > FN–CS > FN–TR > MN–TR. Comparison of these predictions with the experimental results is reported in the following paper in this journal (29). And finally we wish to emphasize that this paper reports the first *ab initio* study of π–π^* ct complexes for which experimental heats of formation are available.

Acknowledgments

We are grateful for the assistance of Mr. K. W. Ling in expanding the G76 program to handle up to 127 basis functions. We also want to thank Dr. M. C. Zerner of the University of Guelph for providing us with an unpublished version of the PCILO program. The financial support of the Natural Sciences and Engineering Research Council of Canada in the form of a Postdoctoral Fellowship to P.C.W. and an Operating Grant to R.J.B. is gratefully acknowledged.

Photochemical reactions of charge-transfer complexes. IV. The orientation effects of charge-transfer complexes: theory and experiment

PO CHEONG WONG[1] AND DONALD R. ARNOLD[2]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received September 9, 1980

PO CHEONG WONG and DONALD R. ARNOLD. Can. J. Chem. **59**, 982 (1981).

In paper number III of this series (2) *ab initio* and PCILO molecular orbital calculations for the four $\pi-\pi^*$ charge-transfer (ct) complexes formed between maleonitrile (MN) and fumaronitrile (FN), and *cis* (CS) and *trans*-1,2-dimethoxyethylene (TR) were reported. This paper reports the ct transition absorption characteristics and association constants of these complexes as a function of temperature. From this data the heats of formation of the complexes are determined and these experimental results are then compared with the theoretical values; good agreement is obtained. The order of complex stability ($-\Delta H^\theta$ (kcal mol)) measured in chloroform solution is: MN–TR (0.55) < FN–TR (0.65) < MN–CS (0.78) < FN–CS (1.25).

We reach the conclusion that, for these complexes, orientation effects of the substituents are quite small in magnitude and that the dominant factor influencing complex stability follows the redox potential difference. The structures of the complexes are discussed in view of these results.

PO CHEONG WONG et DONALD R. ARNOLD. Can. J. Chem. **59**, 982 (1981).

Dans la troisième publication de cette série (2) on a rapporté les calculs d'orbitales moléculaires *ab initio* et PCILO des quatre complexes $\pi-\pi^*$ de transfert de charge (tc) entre la maléonitrile (MN), la fumaronitrile (FM) et les diméthoxy-1,2 éthylène *cis* (CS) et *trans* (TR). Dans cette publication on rapporte les caractéristiques de l'absorption de transition tc et les constantes d'association de ces complexes en fonction de la température. On a déterminé, à partir de ces données, les chaleurs de formation des complexes et on a comparé ces résultats expérimentaux aux valeurs théoriques; on a obtenu un parfait accord. L'ordre de stabilité du complexe ($-\Delta H^\theta$ (kcal mol)) mesuré dans une solution de chloroforme est le suivant: MN–TR (0,55) < FN–TR (0,65) < MN–CS (0,78) < FN–CS (1,25).

Nous avons conclu dans le cas de ces complexes que les effets d'orientation des substituants sont négligeables et que le facteur principal influençant la stabilité du complexe suit la différence de potentiel redox. On discute de la structure de ces complexes à la lumière de ces résultats.

[Traduit par le journal]

Introduction

We have recently reported a potentially useful photochromic system based upon the irradiation of charge-transfer (ct) complexes of olefins in solution (1). For example, the ct absorption band of the *trans*-stilbene – fumaronitrile (*t*-ST–FN) complex extends out to longer wavelengths than the ct absorption band of the *cis*-stilbene – fumaronitrile (*c*-ST–FN) complex. Irradiation of the *t*-ST–FN complex results in up to an 86% enrichment in *cis*-stilbene (1*a*). The position and absorption intensity of the ct absorption band is related to the strength of the complex. For structurally similar compounds, Mulliken has demonstrated that the strength of the complex depends mainly on the ionization potential (or oxidation potential $E_{1/2}^{ox}$ (D)) of the donor and electron affinity (or reduction potential $E_{1/2}^{red}$ (A)) of the acceptor. Therefore, the differences in the ct equilibrium constants (K) between the *t*-ST–FN complex and the *c*-ST–FN complex can be explained in terms of the difference between $E_{1/2}^{ox}$ (D) of *c* and *t*-ST. However, the contribution due to the differences in the geometries of the donor may also be important. For example, if the complex favours a geometry where the two central double bonds are parallel and the substituents are projected over one another (eclipsed form), then one might expect the *t*-ST–FN complex to have a higher binding energy than the *c*-ST–FN complex. Evidence supporting this hypothesis is obtained from the difference in the equilibrium constants of the *t*-ST–FN complex and the *t*-ST–MN complex (K being 0.17 and 0.10 M^{-1}, respectively) (1*b*). Since FN and MN have essentially the same reduction potentials (1*b*), the larger equilibrium constant for the *t*-FN complex may be due to orientation effects which arise from a favourable alignment of the olefin substituents.

Employing FN and MN as a probe for orientation effects in ct complexes, we have previously examined a series of dimethoxynaphthalene (DMN) donors where the methoxy substituents would presumably align better with either FN or MN (1*b*). For example, if the most favourable geometry is eclipsed, then MN would be expected to form stronger ct complexes with 2,3- and 1,4-DMN, while FN would form a stronger complex with 1,5-DMN. However, the observed association

constants and the heats of formation of these ct complexes are not consistent with this hypothesis. We found that maleonitrile complexes more strongly with 1,4- and 1,5-DMN than FN but not with 2,3-DMN. These results were interpreted in terms of there being more than one favourable geometry for the small π-acceptors to complex with the relatively larger π-donors. The observed stability of these complexes would then be a composite for all contributing geometries.

In this account, we examine orientation effects more closely by comparing the experimental K and the ΔH^0 of the ct complexes formed between FN and MN with three smaller π-donors i.e., 1,3-benzodioxole, and *trans*- and *cis*-1,2-dimethoxyethylene (TR and CS). It is important to emphasize that the 1,2-dicyanoethylene – 1,2-dimethoxyethylene system is one of the best systems for examining these orientation effects since (*i*) the sizes of the π-donors and the π-acceptors are small and comparable, (*ii*) the *trans*- and *cis*-donors have very similar oxidation potentials (0.72 and 0.70 V, respectively), and (*iii*) the *trans*- and *cis*-acceptors have essentially identical reduction potentials (−1.63 V) (1*b*).

Another interesting acceptor, bicyclo[2.2.2]-oct-2-ene-2,3-dinitrile, which we naively predicted would complex more strongly with CS than TR as the result of steric hindrance, was also examined.

Theoretical calculations of the optimum geometry and ΔH^0 for the four 1,2-dicyanoethylene – 1,2-dimethoxyethylene complexes have been carried out using two different molecular orbital (MO) methods (*ab initio* and PCILO). Details of the calculations are reported in a separate paper (2). The results from both the experimental and the theoretical work will be discussed here.

We have also investigated the photochemistry of the 1,2-dicyanoethylene – 1,2-dimethoxyethylene complexes. A preliminary account of this study will also be given.

Results

The ultraviolet–visible spectrophotometric (uv–vis) method (3) was used to measure the association constant (K) for the objective ct complexes. Determination of the K and ct extinction coefficient (ε_λ at wavelength λ) was performed using two methods, the Foster–Hammick–Wardley (F–H–W) method (4) and the Seal–Mukherjee–Mukherjee (S–M–M) method (5). There was good agreement between the two methods in all cases.

In the F–H–W method, a plot of $OD/[A]_0$ versus OD gives a straight line, of which the slope and the y-intercept correspond to $-K$ and $K.\varepsilon_\lambda\ [D]_0$ respectively; OD is the optical density (absorbance), and $[D]_0$ and $[A]_0$ refer to the total concentration of complexed and free donor and acceptor, respectively. A typical F–H–W plot is shown in Fig. 1.

The S–M–M method is an alternative method of solving the Rose–Drago equation (6). Taking $x = [D]_0 + [A]_0$, $y = [D]_0[A]_0/OD$ and $z = OD$, the plot of z versus x yields a straight line with the y-intercept = n and the slope = m. The plot of y versus x yields another straight line with the y-intercept = $M - M^2m$ and the slope = $L - M^2 - n$, where L and M are defined as $1/\varepsilon_\lambda$ and $1/(K.\varepsilon_\lambda)$. Figures 2 and 3 are typical plots of z vs. x and y vs. x.

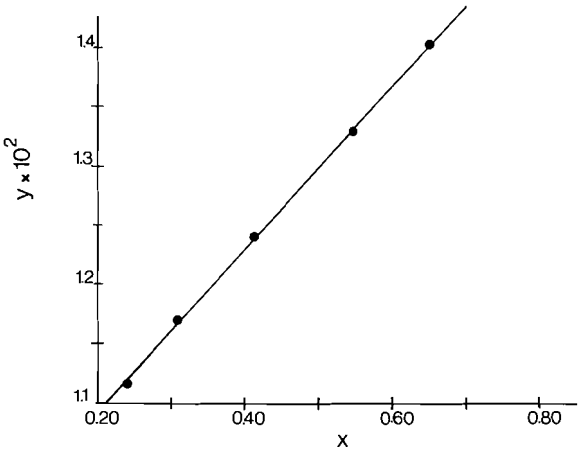

FIG. 3. S–M–M plot of y vs. x for the MN–CS complex in $CHCl_3$ at 2.2°C (λ = 315 nm).

(1,3-BDO) system, the K for the FN and MN complexes are identical (0.15 M^{-1}) while ε_{325} for the FN complex is slightly larger (500 and 455 for the FN and MN complex, respectively).

The experimental results for the 1,2-dicyanoethylene – 1,2-dimethoxyethylene system are listed in Table 1. It is well known that accurate separation of K and ε_{λ} from the spectrophotometric measurement is very difficult. Since ε_{λ} is nearly temperature-independent, evaluation of the ΔH^{θ} and ΔS^{θ} is possible from plots of log ($K.\varepsilon_{\lambda}$) versus $1/T$ (3). These results are shown in Fig. 4. The experimental heats of formation (ΔH^{θ}) are listed in Table 1 (the larger negative values correspond to more stable complexes). To our surprise, the most stable complex is the FN–CS complex while the least stable complex is the MN–TR complex.

Bicyclo[2.2.2]-oct-2-ene-2,3-dinitrile (BODN) forms very weak complexes with both TR and CS. The values of K and ε_{360} for the BODN complex are 0.06 M^{-1} and 50, respectively.

Irradiation of the MN–CS complex in acetonitrile solution leads to isomerization of both olefins. An accurate photostationary state composition was not obtained due to relatively rapid, competing consumption of the olefins through polymerization.

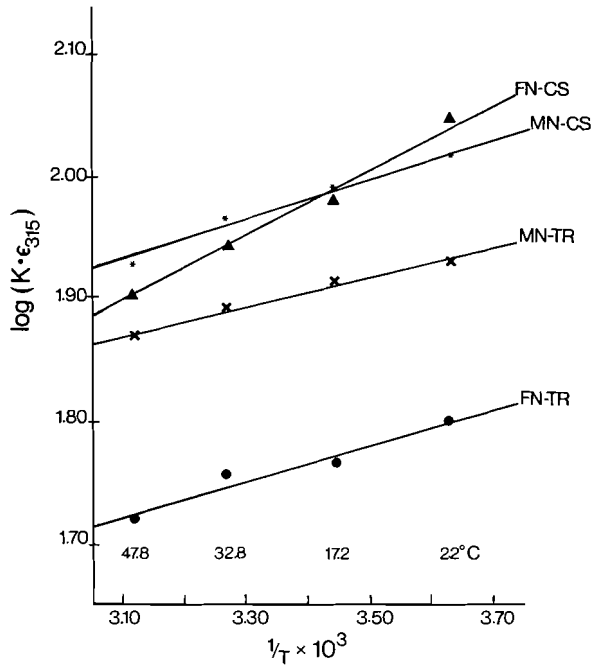

FIG. 4. Van't Hoff plots for the ct complexes.

Our preliminary results from the triplet-sensitized isomerization of *cis*- and *trans*-1,2-dimethoxyethylene indicate that the triplet energies for these two olefins are quite low. In fact, triplet sensitized isomerization proceeds at a reasonable rate even when acridine (E_T = 45.3 kcal mol^{-1}) is used as the sensitizer.

Molecular Orbital Calculations

Details of the molecular orbital calculations are reported elsewhere (2). A brief summary will be given here since these results are so important to the discussion that follows. Two computational methods (*ab initio* and PCILO (7)) were employed to calculate the heats of formation (ΔH^{θ}) for the 1,2-dicyanoethylene – 1,2-dimethoxyethylene ct complexes using the supermolecule approximation (8). The donor and the acceptor molecules are situated in parallel planes. Assuming that no

[b]The optimum geometries are the rotated geometries while all others are the slipped geometries (see text).

structural change in the components accompanies complex formation, the optimized geometry for each complex is obtained starting from the optimized geometries (STO-3G) of the individual components. The standard single determinant *ab initio* calculations were performed using the GAUSSIAN 76 program (G76) (9) with the spin-restricted Hartree–Fock (RHF) procedure. The initial search for the optimum geometries of ct complexes used the models *trans*- and *cis*-1,2-dihydroxyethylene as the donors. Calculations using the split valence basis sets, 3-21G (10) and 4-31G, were also performed for the model complexes at selected geometries. The calculated ΔH^θ of the ct complexes at optimum geometries[3] are listed in Table 2. At the STO-3G level, the calculated ΔH^θ values for the dimethoxy complexes are slightly smaller than for the corresponding dihydroxy complexes. This was attributed to steric effects due to the presence of the methyl groups.

The interplane distances (d's) calculated from G-76 at STO-3G level are reasonable. The optimum d's are 3.8 Å for the eclipsed and the rotated geometries, and 3.35 Å for the slipped geometries. These are quite close to the observed d's from X-ray crystallographic analysis for solid state ct complexes which are normally between 3.2 to 3.6 Å (11). The PCILO optimum d's, on the other hand, are too short (with the optimum d's equal to 2.6 Å for the eclipsed and rotated geometries and 2.0 Å for the slipped geometries) for the systems studied.

Discussion

Listed in Table 3 is a summary of the experimental spectroscopic constants for the series of ct complexes we have so far examined. The magnitude of the ct equilibrium constants is more or less inversely related to the donor oxidation potential. Donors having lower values of $E^{ox}_{1/2}$ generally form stronger ct complexes. There is no obvious way to predict which 1,2-dicyanoethylene isomer will form a stronger ct complex with a given donor. The relationships between K, ε_λ, ΔH^θ and ΔS^θ are not monotonic as has been peviously reported (12). A large value of K may not necessarily correspond to large values of ε_λ, ΔH^θ or ΔS^θ.

The ε_λ for the FN complexes tend to be larger than those for the corresponding MN complexes with only one exception (t-ST complexes). This behaviour was also observed in the benzene – 1,2-dicyanoethylene system (13). The magnitude of ε_λ also varies with the donor structures. Our results indicate that ε_λ should be larger for more highly conjugated donors.

ΔS^θ and ΔH^θ are linearly related within series of complexes which share a common component (D or A). The variation for the relationship between ΔH^θ and K can then be explained in terms of the difference due to the entropy term.

The best way to discuss the stability of ct complexes uses ΔH^θ since these values can be calculated theoretically. The calculated ΔH^θ of course corresponds to gas phase values which, experimentally, are quite close to those obtained in inert nonpolar solvents (3). In the following discussion, we will therefore concentrate on the ΔH^θ results.

As shown in Table 3, the stability of the complexes, in increasing order is: MN–TR < FN–TR < MN–CS < FN–CS. According to Mulliken theory, the first two complexes are expected to be less stable than the last two since TR has the higher $E^{ox}_{1/2}$. It is difficult to predict which of the complexes within the pairs would be more stable. Assuming that the eclipsed geometry would be the more stable structure, we would have predicted the relative stability of the complexes to be MN–TR < FN–TR and FN–CS < MN–CS. Since the ΔH^θ of the FN–CS complex is distinctly larger than those of the other complexes, the validity of this assumption is obviously questionable. Evidence against

[3]The rotated geometry is one with the two olefins in parallel planes and center over center, while the two central double bonds are separated at a rotational angle (4). The slipped geometry is one with the two olefins in parallel planes with the two central double bonds parallel and separated at a projected distance of 2.2 Å. Details of these geometries are shown in ref. 2.

the eclipsed structures being the most stable can also be inferred from the 1,2-dicyanoethylene – dimethoxynaphthalene system (1*b*), although the effect of the relative size of D and A is difficult to assess in this system.

According to both the *ab initio* and PCILO MO calculations, the eclipsed geometries for all four 1,2-dicyanoethylene–1,2-dimethoxyethylene complexes *are* relatively unstable. While there are some minor discrepancies between the results from these two MO methods and it is difficult to judge which method gives the more accurate estimates, we have more faith in the *ab initio* results since self consistent field (SCF) procedures are employed in this method.

The most stable (optimum) STO-3G geometries for the MN–CS, MN–TR, and FN–CS complexes are the slipped geometries, while the rotated geometry is preferred in the FN–TR complex. In the slipped geometries of all four complexes as well as the rotated geometry of the FN–TR complex, the oxygen atoms and the cyanocarbons are almost projected over each other. The reasons why the slipped and rotated geometries are preferred are probably: (*i*) the parent ethylene–dimer is repulsive in the eclipsed geometry (14) which is presumably due mainly to HOMO–LUMO interactions (15); (*ii*) the electrostatic attraction between the oxygen atoms (δ^-) and the cyanocarbons (δ^+) is relatively important.

The comparison of the experimental and the theoretical heats of formation of ct complexes is not a straightforward problem. There are some important considerations: (*i*) the experimental ΔH^θ should be obtained for the gas phase; (*ii*) in the *ab initio* calculation, one has to consider the effects of the choice of the basis set and the electron–electron correlation; and, (*iii*) the experimental ΔH^θ is an average value for all the geometries of the ct complex following the Boltzmann distribution, while the theoretical value is obtained from only a single pair of D and A at the optimum geometry.

Since the evaluation of gas phase ΔH^θ is not convenient, most of the experimental values in the literature (and all of the values in this study) have been obtained in inert, relatively nonpolar solvents. The ΔH^θ measured in hexane solution is, in general, reasonably close to that in the gas phase (3). In methylene chloride solution, the ΔH^θ is about one-half as large as in the gas phase (16). Therefore, in order to get an estimate of the gas phase ΔH^θ from our chloroform solution data, we can multiply our ΔH^θ (Table 1) by a factor of two which would give values at the upper limit. The ΔH^θ_{gas} would than be 1.10, 1.30, 1.56, and 2.5° kcal mol^{-1} for the MN–TR, FN–TR, MN–CS, and FN–CS complexes, respectively.

As shown in Table 2, the *ab initio* SCF ΔH^θ are consistently larger with larger basis sets. According to many authors (17), the 4-31G calculation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

tends to give high SCF ΔH^θ values. The use of polarization functions would bring ΔH^θ's down from 4-31G results (18). However, our complexes are too large for such calculations, even with the model dihydroxy derivative. In the single determinant *ab initio* SCF calculations, the electron correlation energies (representing dispersion energies in ct complexes) are neglected even when larger basis sets are employed (17*b*, 19). The contribution from dispersion energies in conjugated systems such as $\pi-\pi^*$ complexes is relatively important; it could be of the same order of magnitude as the SCF ΔH^θ's according to the only two $\pi-\pi^*$ ct complexes calculated using the *ab initio* method (17*b*). Verification of the accuracy of these two calculations is difficult due to the dearth of experimental data. The results reported here provide the first comparison of experimental and theoretical results for $\pi-\pi^*$ ct complexes.

A comparison of the ΔH^θ values from Tables 1 and 2 indicates that the STO-3G results will be the closest if one also includes the dispersion energies (multiply the calculated ΔH^θ by a factor of two) (17*b*). It appears now that the *ab initio* calculations with large basis sets and the PCILO calculations give values larger than the experimental ΔH^θ's. One possible source of the overestimation of the ΔH^θ's may come from the basis set superposition error (BSSE). We have examined this possibility at the STO-3G level using the counterpoise method (19*a*, 20). Our results for the MN–CS (OH) complex indicate that BSSE is relatively unimportant. We can rule out the BSSE as an error source here, since the calculations using larger basis sets than the STO-3G basis would presumably contain smaller BSSE. As we pointed out earlier, the comparison of the experimental and theoretical ΔH^θ's is not straightforward, and the results from calculations using large basis sets may in fact be valid since they correspond only to the optimum geometries of the ct complexes. Following the same argument, one can also explain why the calculated ΔH^θ of the MN–CS complex is larger than that of the FN–CS complex, which is the opposite of that observed (compare Tables 1 and 2).

We considered the possibility of observing a difference in stability between the bicyclo[2.2.2]oct-2-ene-2,3-dinitrile (BODN) – FN and the BODN–MN complexes due to possible steric hindrance in forming the former complex. Unfortunately, the additional carbon chain raises the reduction potential of BODN ($E^{red}_{1/2} = -2.02$ V, vs. $Ag/AgNO_3$ (0.1 *M*) in acetonitrile) significantly higher than MN so that BODN complexes are too weak to be accurately measured using the spectrophotometric method.

The irradiation of the MN–CS complex in acetonitrile results in isomerization of both olefins. The mechanism for the isomerization is probably the same as that reported for the stilbene and dimethoxynaphthalene systems (1*b*): (*i*) electron transfer from donor to acceptor within the excited complex to form a singlet radical ion pair; (*ii*) intersystem crossing to the triplet radical ion pair through hyperfine interaction; (*iii*) back electron transfer within the triplet radical ion pair to give the triplet excited donor or acceptor; (*iv*) the triplet olefins decaying to the ground state *trans*- and *cis*-olefins. We have not further investigated the detailed mechanism in this system since it would have limited applicability as a photochromic system due to the relatively fast rate of polymer formation. In any event, the first step (electron transfer) should be favourable (ΔG is negative) (21).

Since the rate of formation of TR is about one-third of that for FN, following our mechanism, the triplet energy of CS could be higher than that of MN by only a very small amount (~ 1 kcal mol^{-1}). This appears to be surprisingly low for dimethoxyethylene since the triplet energies of ethylene and *cis*-2-butene are 82 and 78.2 kcal mol^{-1}, respectively. However, our preliminary study of the triplet sensitized isomerization of CS indicates that the triplet energy is, in fact, quite low (efficient isomerization can be observed when acridine, $E_T =$ 45.3 kcal mol^{-1} (22) is used as the triplet sensitizer).

Conclusion

From the experimental ΔH^θ's measured for the ct complexes of MN and FN with a series of isomeric donors, we find that the orientation effects of the substituents are quite small in magnitude and the relative stabilities of the complexes are not always predictable by our present theoretical calculations.

Molecular orbital calculations using the *ab initio* method and the PCILO method indicate that the most stable geometries for the 1,2-dicyanoethylene – 1,2-dimethoxyethylene ct complexes are the slipped and the rotated geometries, which are presumably the result of electrostatic attraction between the oxygen atoms and the cyanocarbons, and the instability of the eclipsed geometries. The eclipsed geometries are relatively unstable, presumably because of the same repulsive forces which destabilize two of the parent molecules when they are in this orientation.

Experimental

General

1,3-Benzodioxole (Aldrich Chemical Co.) was distilled twice before use. Fumaronitrile (Aldrich Chemical Co.) was freshly sublimed under vacuum before use. Maleonitrile was prepared by the iodine-catalyzed thermal isomerization of fumaronitrile

For personal use only.

(23), and was purified by column chromatography on neutral alumina (Fisher) eluting with benzene–hexanes (1:1), followed by recrystallization from ether–pentane. Chloroform, benzene, and acetonitrile were purified as previously described (1*b*).

The ^{1}Hmr spectra were recorded on either a Varian T-60 or CFT-20 instrument with tetramethylsilane as the internal reference. The infrared spectra were run on a Perkin-Elmer 180 infrared spectrometer and calibrated against the 1602 cm^{-1} polystyrene absorption. Mass spectra were obtained from a Consolidated Electrodynamics Corporation 21-104 mass spectrometer. Half-wave oxidation and reduction potentials were measured by cyclic voltammetry as described elsewhere (24).

All irradiations were performed using a General Electric Co. 1 kW medium pressure mercury vapour arc lamp (unless otherwise specified) with a quartz cooling jacket (Photochemical Research Associates) at 10°C.

Bicyclo[2.2.2]oct-2-ene-2,3-dinitrile was prepared using a procedure modified from that reported by Scheiner *et al.* (25). Details are given below.

Dimethyl Bicyclo[2.2.2]oct-2-ene-2,3-dicarboxylate (I)

1,3-Cyclohexadiene (26) (3.2 g, 0.04 mol) was mixed with freshly distilled dimethyl acetylenedicarboxylate (4.55 g, 0.032 mol) and the solution was stirred at 60–65°C for 18 h, until all the acetylenedicarboxylate had reacted. The viscous liquid was dissolved in methanol (100 mL), 5% Pd/C powder (0.25 g) was added, and the mixture was stirred at room temperature. Hydrogen gas was bubbled through this solution at a slow rate and the progress of the reaction was monitored by the disappearance of the vinyl protons in the ^{1}Hmr. After the reaction was complete (ca. 6 h), the solution was filtered and concentrated. The solid product was recrystallized from hexanes to colourless needles, 6.45 g (90%); mp 45°C; ir (KBr): 2950 (m), 1720 (s), 1630 (w), 1430 (w), 1275 (w), and 1080 (w) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.52 (m, 8H), 3.02 (br s, 2H), 3.80 (s, 6H).

Bicyclo[2.2.2]oct-2-ene-diamide (II)

Sodium methoxide (0.35 g) was dissolved in methanol (300 mL) and the solution was saturated with ammonia at −10°C. A solution of I (4.48 g, 0.04 mol) in 50 mL methanol was added dropwise to the above solution. The mixture was stirred at −10°C for 20 min and then kept at room temperature in a stoppered flask for 4 days. The crystals which separated were filtered, washed with methanol, and dried. The mother liquid was concentrated and saturated with ammonia. This solution was kept at room temperature for 3 more days and the solid product isolated as before. The total yield of II was 2.50 g (64%); mp 238–240°C; ir (KBr): 3350 (s), 3300 (m), 3180 (s), 1635 (s), 1600 (s), 1430 (w), 1415 (w), 1380 (m), 1100 (w), 820 (w), 690 (m) and 650 (m) cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 1.25 (m, 8H), 3.20 (br s, 2H), 7.14 (br s, 2H), 7.50 (br s, 2H); ms *m/e*: 194.

Bicyclo[2.2.2]oct-2-ene-2,3-dinitrile

Bicyclo[2.2.2]oct-2-ene-2,3-diamide (II) (2.33 g, 0.012 mol) was mixed with an excess amount of freshly distilled phosphorous oxychloride (15 mL) and stirred at reflux temperature for 5 h. The resulting brown solution was cooled in an ice bath. The cold solution was then transferred to a beaker containing 30 g of crushed ice. The mixture was stirred well and then extracted with benzene (50 mL). The benzene layer was washed with ice-cold distilled water (5 × 20 mL) and 10% sodium bicarbonate solution (10 mL), followed by distilled water (3 × 20 mL). The solution was dried over anhydrous $MgSO_4$ and concentrated on a rotary evaporator. The resulting cream colored solid was sublimed under vacuum (95°C) to give a colorless solid which was recrystallized from benzene–hexanes (1:3) to needles, 1.2 g (63%); mp 120°C; ir (KBr): 2960 (s), 2875 (m), 2215 (m), 1458 (w), 1325 (w), 1240 (w), 1160 (w), 1120 (w) and 860 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.20 (m, 8H), 3.04 (br s, 2H); ms *m/e*: 158.

cis-*1,2-Dimethoxyethylene (27)*

Alumina (38 g, 8–14 mesh) was packed in a pyrolysis tube and preheated at 300°C in a tube furnace under a constant flow of nitrogen (90 mL/min) for 5 h to remove water. 1,1,2-Trimethoxyethane (20 g), prepared from vinyl acetate according to reported procedure (28), was introduced dropwise from an addition funnel into the nitrogen stream and the product mixture was collected in a receiving flask cooled in a Dry Ice – isopropanol bath. The reaction mixture was dried over 4A molecular sieves, filtered, and the *cis* isomer was isolated by preparative vapour phase chromatography (vpc) (10 ft × 1/2 in. column of 25% Theed on Chromosorb W at 90°C, He flow rate 70 mL/min, retention time 32 min). ^{1}Hmr ($CDCl_3$) δ: 3.52 (s, 6H), 5.12 (s, 2H).

trans-*1,2-Dimethoxyethylene*

A nitrogen purged solution of *cis*-1,2-dimethoxyethylene (300 mg) and acetophenone (80 mg) in *n*-hexane (600 mL) was irradiated in a Pyrex vessel for 48 h, yielding a photostationary state mixture of *trans–cis*, 65:35. A 450-W medium pressure mercury vapor lamp (Hanovia) was used in this case. The *trans*-isomer was isolated by preparative vpc using the same conditions as for the *cis*-isomer (retention time 21 min); ^{1}Hmr (CCl_4) δ: 3.40 (s, 6H), 6.15 (s, 2H).

*Determination of Association Constants (*K*) of Charge-transfer Complexes by the Uv–vis Method*

A chloroform solution of the donor (ca. 10 m*M*) was prepared. Then a series of five solutions were prepared by weighing various amounts of the acceptor (ca. 0.2 to 0.6 *M*) in 5 mL volumetric flasks before introducing 3 mL of the above solution through a pipette. The optical densities (OD) at selected wavelengths were recorded on a Cary 219 spectrophotometer equipped with a direct digital temperature readout device. The temperature of the solutions was maintained (±0.05°) by circulating coolant from a Polyscience 90 thermostated bath. In all cases studied, no chemical change of the solutions was encountered during the time required to make the measurements.

K and ε_λ were determined by both the FHW and SMM methods. The slopes and y-intercepts of the plots were computed using a standard linear least-squares program. The correlation coefficients were generally better than 0.96.

Irradiation of the Maleonitrile – cis-*1,2-Dimethoxyethylene Charge-transfer Complex*

An acetonitrile-d_3 solution of MN (0.3 *M*) and CS (0.3 *M*) was irradiated through a 1 cm filter solution composed of sodium bromide (120 g) and lead nitrate (0.75 g) in 250 mL water ($\lambda >$ 330 nm). After irradiating for 65 h, the reaction mixture contained MN (71%), FN (18%), CS (33%), TR (6%), and (presumably) polymeric material. Irradiation for a longer period (144 h) resulted in further consumption of the olefins; the solution contained MN (22%), FN (13%), CS (9%), and TR (2%). There was no change in either of the control experiments, irradiating MN or CS alone under the same conditions.

The Triplet-sensitized Isomerization of cis-*1,2-Dimethoxyethylene*

Nitrogen purged *n*-hexane solutions of *cis*-1,2-dimethoxyethylene (0.05 *M*) and the triplet sensitizer (< 0.01 *M*) were irradiated in Pyrex vessels. Progress of the isomerizations were monitored by vpc (10 ft 25% Theed on Chromosorb W at 90°C). Reasonably fast rates of isomerization were observed when the following sensitizers (triplet energies in kcal mol^{-1}) were employed: 1,3,5-triacetylbenzene (74.0), xanthen-9-one (74.0), thioxanthen-9-one (65.5), 2-acetonaphthone (59), fluoren-9-one (53), 3.3′-carbonyl-bis(7-diethylaminocoumarin) (52.0), phenanthrenequinone (49), and acridine (45.3).

Equilibrium decomposition pressures of the compounds Na_2ZrCl_6 and Na_2HfCl_6

G. J. KIPOUROS AND S. N. FLENGAS

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., M5S 1A4

Received August 5, 1980

G. J. KIPOUROS and S. N. FLENGAS. Can. J. Chem. **59**, 990 (1981).

The chemical equilibria representing the reactions

$$Na_2ZrCl_6(s \text{ or } l) \geq 2NaCl\ (s \text{ or } l) + ZrCl_4\ (vap, P, T)$$

and

$$Na_2HfCl_6\ (s \text{ or } l) \geq 2NaCl\ (s \text{ or } l) + HfCl_4\ (vap, P,T)$$

were investigated by direct vapour pressure measurements and thermodynamic data such as free energies and enthalpies of reaction have been calculated.

With reference to the separation of Hf from Zr by a recently developed process based on the selective reactivity of $ZrCl_4$ and $HfCl_4$ vapours with alkali chlorides, it is shown that the efficiency of alkali chlorides as separating agents increases in the order of LiCl → NaCl → KCl.

G. J. KIPOUROS et S. N. FLENGAS. Can. J. Chem. **59**, 990 (1981).

En utilisant des mesures directes de pression de vapeur, on a étudié les équilibres chimiques suivants:

$$Na_2ZrCl_6\ (s \text{ ou } l) \geq 2NaCl\ (s \text{ ou } l) + ZrCl_4\ (vap, P,T)$$

et

$$Na_2HfCl_6\ (s \text{ ou } l) \geq 2NaCl\ (s \text{ ou } l) + HfCl_4\ (vap, P,T)$$

et on a calculé les énergies libres et les enthalpies de réaction.

En relation avec la méthode récemment mise au point pour séparer le Hf du Zr qui est basée sur la réactivité sélective des vapeurs de $ZrCl_4$ et de $HfCl_4$ avec les chlorures alcalins, on a montré que l'efficacité des chlorures alcalins en tant qu'agents séparateurs augmente dans l'ordre suivant LiCl → NaCl → KCl.

[Traduit par le journal]

Introduction

In previous publications from this laboratory the vapour pressures of $ZrCl_4$ in equilibrium with its solutions containing alkali chlorides such as LiCl (3), NaCl, KCl (1, 2, 5), and CsCl (4), and of $HfCl_4$ in equilibrium with its solutions containing alkali chlorides such as LiCl (3), KCl (5), and CsCl (4), have been determined by direct experimental techniques involving the use of a spoon type Bourdon gauge (1, 2), a molten tin isoteniscope (3, 4) or a quartz spiral type Bourdon gauge (5).

In the present investigation, a quartz spiral type Bourdon gauge has been applied to the determination of the vapour pressures of $ZrCl_4$ and $HfCl_4$ in equilibrium with the two pure compounds Na_2ZrCl_6 and Na_2HfCl_6, respectively, over a temperature range extending below and above their melting points.

From the results of this study, the equilibrium dissociation constants, free energies, and enthalpies for the reactions

[1] $Na_2MCl_6\ (s) \rightleftharpoons 2NaCl\ (s) + MCl_4\ (vap)$

where M represents Zr or Hf, have been calculated.

The equilibrium constant for the exchange reaction

[2] Na_2ZrCl_6 (in solid solution) + $HfCl_4$ (vapour) $\rightleftharpoons$ Na_2HfCl_6 (in solid solution) + $ZrCl_4$ (vapour)

was also calculated.

From the above data, the theoretical efficiency for the separation of hafnium from zirconium by a previously developed process based on the selective reactivity of $ZrCl_4$ and $HfCl_4$ vapours with alkali halides (6, 7), has been calculated.

Experimental

At specific partial pressure and temperature pure $ZrCl_4$ and $HfCl_4$ vapours react with solid NaCl to form the stoichiometric solid complex compounds Na_2ZrCl_6 and Na_2HfCl_6 respectively. The corresponding reactions may be written as:

[3] $2NaCl\ (s) + ZrCl_4\ (v) \rightarrow Na_2ZrCl_6\ (s)$
at P,T P,T

and

[4] $2NaCl\ (s) + HfCl_4\ (v) \rightarrow Na_2HfCl_6\ (s)$
at P,T P,T

The $NaCl–Na_2ZrCl_6$ (1) and $NaCl–Na_2HfCl_6$ (8) binary systems are related by simple eutectic type phase diagrams which clearly indicate the stability of these congruently melting complex compounds.

The general method applied for the preparation of the pure stoichiometric compounds was developed in this laboratory earlier (1, 2) and involves the reaction of finely ground NaCl,

having a particle size of less than 325 mesh, with $ZrCl_4$ or $HfCl_4$ vapours at 1 atm pressure.

When the formation of the complex compounds is completed, the weight gain of NaCl, which is converted to either Na_2ZrCl_6 or Na_2HfCl_6, remains constant with time and it indicates mole ratios of NaCl to $ZrCl_4$ or NaCl to $HfCl_4$, respectively, equal to 2.

The optimum reaction temperature for both Na_2ZrCl_6 and Na_2HfCl_6 has been found to be 485°C. Reaction time was of the order of 80 to 100 h.

The $ZrCl_4$ and $HfCl_4$ salts were purchased from the Wah Chang Corporation of America, Albany, New York. As they were always received in a partially hydrolyzed condition, they were purified by repeated sublimations in vacuum through a molten tin plug, as reported earlier (3).

The NaCl used in the present investigation was reagent grade containing less than 0.01% total impurities, and supplied by Fisher Scientific. It was dried under vacuum, at 500°C.

Handling of materials, preparation of samples, and transfer to the reaction cells were conducted in a dry box filled with argon gas.

The apparatus for measuring the equilibrium vapour pressures of $ZrCl_4$ and $HfCl_4$ over the pure complex compounds Na_2ZrCl_6 and Na_2HfCl_6 respectively consisted of a hollow fused quartz Bourdon spiral pressure gauge connected to a quartz reaction cell as it has been described elsewhere (5).

For these measurements the temperature of the sample container was varied between 360 and 660°C while the upper part of the apparatus containing the Bourdon spiral was maintained at temperatures about 30°C higher than the corresponding normal sublimation points of pure $ZrCl_4$ and $HfCl_4$.

Specimens were introduced into the sample container of the apparatus in the form of powders. It was found that large quantities of absorbed gas were released from the salt upon heating. This introduced a systematic error into the measurements. Accordingly, an elaborate degassing procedure was employed in which the cell was repeatedly heated, cooled, reopened, and evacuated. When the residual gas was no longer present upon cooling, equilibrium vapor pressures were measured.

Experimental Results

The vapour pressures of $ZrCl_4$ and $HfCl_4$, in equilibrium with the pure compounds Na_2ZrCl_6 and Na_2HfCl_6 respectively, were determined. Pressures were measured in mm Hg, and corrections were made for mercury expansion and for gravity effects (9, 10) to convert to standard conditions, i.e. at 273.15 K and an acceleration of free fall of 9.80665 m/s^2. These corrected pressures are given in Table 1. Temperatures reported herein are based on the IPTS-68 (11). In Fig. 1 these data are plotted as $\ln P_{MCl_4}$ vs. $1/T$. The lines shown on the graphs are calculated by the least-squares method, while the points are experimental.

Some experimental points for the equilibrium decomposition pressures of Na_2ZrCl_6 obtained previously in the laboratory (1) using a quartz type spoon gauge are also shown in Fig. 1 and are in good agreement with the present work. These previous data were obtained only at higher temperatures near the melting temperature of Na_2ZrCl_6 as at lower temperatures the measurements became irreversible due to gases absorbed by the sample.

TABLE 1. Measured vapour pressures of $ZrCl_4$ and $HfCl_4$ over the pure compounds Na_2ZrCl_6 and Na_2HfCl_6, respectively.

$ZrCl_4$		$HfCl_4$	
T (°C)	P (mm Hg)	T (°C)	P (mm Hg)

531	45.8		
494	36.0		
460	27.0		
437	23.8		

As it was pointed out above the spiral type gauge used in the present work can withstand large pressure gradients and sudden decompression and is well suited for extensive degassing procedures, thus making possible accurate measurements at low pressures.

Also shown in Fig. 1 are equilibrium pressures reported by Morozoy and Sun-In-Chzhu (12) and Korshunov and Gregory (13) which are in disagreement with the values measured in the present study. In these studies transportation techniques have been employed and no mention was made of the problem of depleting $ZrCl_4$ or $HfCl_4$ from the condensed Na_2ZrCl_6 or Na_2HfCl_6 phases during the course of an experiment. The quantitative determination of transported $ZrCl_4$ and $HfCl_4$ was done colorimetrically and by flame photometry. Furthermore, the data of Morozov and Sun-In-Chzhu (12), which have been obtained at temperatures for which both solid and molten Na_2ZrCl_6 are present, have been represented by a single least-squares line (13).

The corresponding equations for the temperature dependence of the equilibrium pressures within the characteristic temperature ranges were calculated and are given in Table 2.

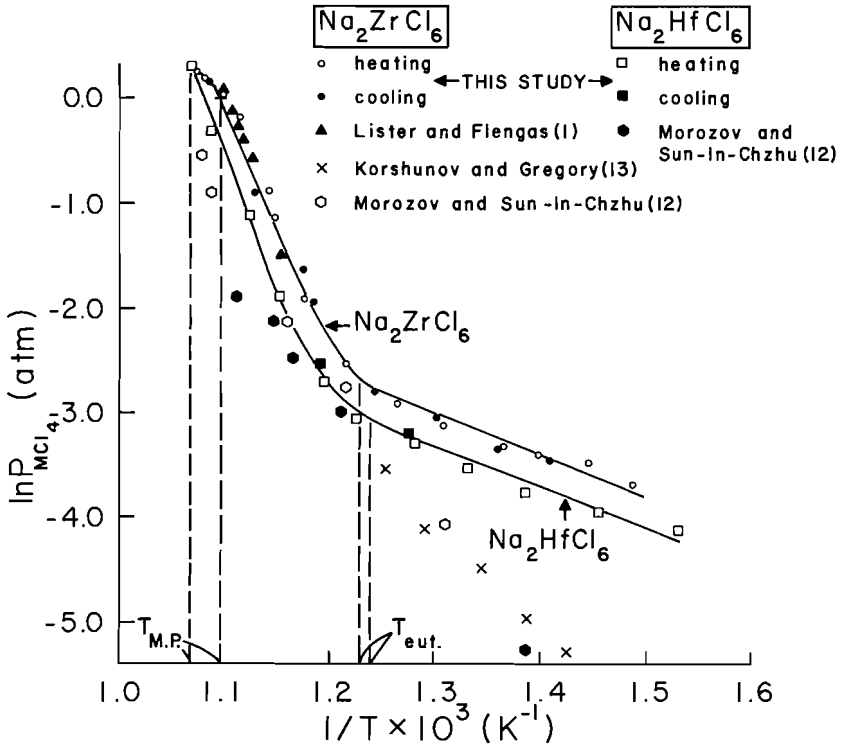

FIG. 1. $\ln P_{MCl_4}$ versus $1/T$ diagram for the pure complex compounds Na_2ZrCl_6 and Na_2HfCl_6.

TABLE 2. Equilibrium vapour pressures of $ZrCl_4$ and $HfCl_4$ over the pure compounds Na_2ZrCl_6 and Na_2HfCl_6 respectively

Equilibrium reactions	Na_2MCl_6 (mol%)	Temperature range (K)	$\ln P_{MCl_4}^{(atm)} = A + B/T$		
			A	B	St. error
[1] Na_2ZrCl_6 (solid) $\rightleftharpoons$ 2NaCl (solid) + $ZrCl_4$ (vap)	100	672–821	2.0259	−3 880	0.0691
[2] Na_2ZrCl_6 (solid) $\rightleftharpoons$ 2NaCl (in solution) + $ZrCl_4$ (vap)	100	821–919		Non-linear	
[3] Na_2ZrCl_6 (liquid) $\rightleftharpoons$ 2NaCl (in solution) + $ZrCl_4$ (vap)	100	919–931	11.5270	−10 538	0.0646
[4] Na_2HfCl_6 (solid) $\rightleftharpoons$ 2NaCl (solid) + $HfCl_4$ (vap)	100	653–813	1.5305	−3 749	0.0842
[5] Na_2HfCl_6 (solid) $\rightleftharpoons$ 2NaCl (in solution) + $HfCl_4$ (vap)	100	813–933		Non-linear	
[6] Na_2HfCl_6 (liquid) $\rightleftharpoons$ 2NaCl (in solution) + $HfCl_4$ (vap)	100	933–		High pressures	

Reaction [1] in Table 2 defines the equilibrium pressure of $ZrCl_4$ over pure solid Na_2ZrCl_6 and solid NaCl at temperatures lower than the eutectic temperature shown in Fig. 1.

Reaction [2] in Table 2 represents the equilibrium pressure of $ZrCl_4$ over pure solid Na_2ZrCl_6 at temperatures higher than the eutectic temperature and in the presence of a solution of NaCl and Na_2ZrCl_6 of liquidus composition, as given by the phase diagram (1). Due to the temperature and composition dependence of the activity of NaCl in this region, the $\ln P_{ZrCl_4}$ vs. $1/T$ plot exhibits the curvature shown.

Reaction [3] in Table 2 represents the equilibrium pressure of $ZrCl_4$ over pure molten Na_2ZrCl_6 at temperatures higher than its melting point.

Similar considerations apply to reactions [4], [5], and [6] for Na_2HfCl_6 given in Table 2. It should be noted that the non-linear and upper linear portions of the pressure curves for Na_2ZrCl_6 in Fig. 1 intercept at a temperature which is in agreement with the melting point of the compound Na_2ZrCl_6. As it is shown in Tables 1 and 2 vapour pressure measurements over pure liquid Na_2HfCl_6 have not been conducted since the pressures involved were too high to be measured safely with the pressure gauge.

Discussion

Below the corresponding eutectic temperatures of the pseudobinary systems NaCl–Na_2ZrCl_6 and NaCl–Na_2HfCl_6 respectively, the thermal decomposition of the chlorozirconate and chlorohafnate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

complex compounds are described by the reactions:

[5] Na_2ZrCl_6 (s) $\rightleftharpoons$ 2NaCl (s) + $ZrCl_4$ (vap)

[6] Na_2HfCl_6 (s) $\rightleftharpoons$ 2NaCl (s) + $HfCl_4$ (vap)

By choosing the standard states for the condensed phases as the pure solids at all temperatures and for the vapour phases, the pure vapours at 1 atm, the thermodynamic equilibrium constants for the decomposition reactions [5] and [6] can be written as:

[7] $K_5 = P_{ZrCl_4}$(vap)

[8] $K_6 = P_{HfCl_4}$(vap)

Actual pressures have been used, in these equations, instead of fugacities as the zirconium tetrachloride vapour is known to be unimolecular and ideal (14, 15), and hafnium tetrachloride vapour would be expected to be quite similar.

The standard heat ΔH_R^0 for the decomposition reactions may be obtained from the van't Hoff equation, written as:

[9] $d \ln K/dT = -\Delta H_R^0/RT^2$

while the standard free energy and the average standard entropy can be determined from the well known equations

[10] $\Delta G^0 = -RT \ln K$

[11] $\Delta G_R^0 = \Delta H_R^0 - T\Delta S_R^0$

The results of these calculations for pure Na_2ZrCl_6 and Na_2HfCl_6 are given in Table 3. From these data the equilibrium constant of the exchange reaction:

[12] $HfCl_4$ (vap) + Na_2ZrCl_6 (as a solid solution of Na_2ZrCl_6 in Na_2HfCl_6) = $ZrCl_4$ (vap) + Na_2HfCl_6 (as a solid solution of Na_2HfCl_6 in Na_2ZrCl_6)

is calculated as

[13] $$K_{ex} = \left(\frac{P_{ZrCl_4}}{P_{HfCl_4}}\right)_{\text{vapour}} \left(\frac{X_{Na_2HfCl_6}}{X_{Na_2ZrCl_6}}\right)_{\text{in solid solution}}$$

In this equation, mole fractions (X's) have been substituted for activities, because of the suggested ideal behaviour of the solid solutions (16).

Since [12] was derived by subtracting [5] from [6] given in Table 2, the temperature dependence of the equilibrium constant given by [13] may be calculated by combining [7] and [8] as:

[14] $\ln K_{ex} = 0.4954 - 131/T$

TABLE 3. Thermodynamic values for the decomposition of the pure compounds Na_2ZrCl_6 and Na_2HfCl_6

Compound	Temperature range (K)	ΔH_R^0 (dec.) (cal/mol)	ΔS_R^0 (dec.) (eu)
Na_2ZrCl_6	672–821	7 709	4.025
Na_2HfCl_6	653–813	7 449	3.041

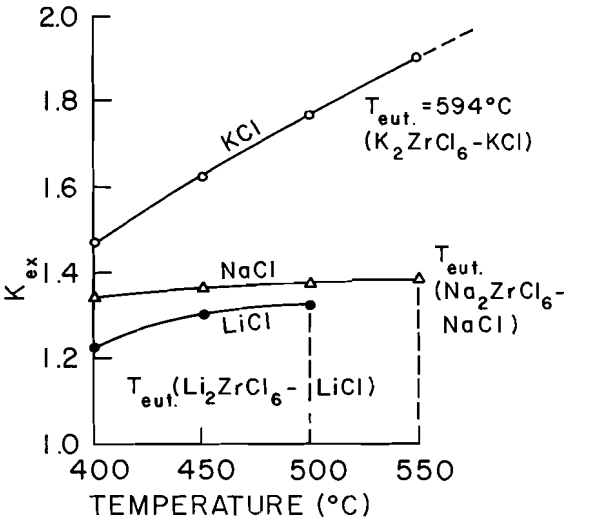

FIG. 2. Temperature dependence of the equilibrium constants K_{ex} for the exchange reactions:

$HfCl_4$(vap) + A_2ZrCl_6 (solid solution) $\rightleftharpoons$ A_2HfCl_6 (solid solution) + $ZrCl_4$(vap)

where A = Li^+, Na^+, or K^+.

A plot of K_{ex} vs T (in °C) is shown in Fig. 2. Data for the previously investigated systems employing LiCl (3) and KCl (5), respectively, are also included in this figure for comparison purposes.

It has been shown in a previous publication (6) that impure $ZrCl_4$ containing $HfCl_4$ may be purified in a closed two-compartment reaction cell in which the impure Zr(Hf)Cl_4 mixture is placed in the first compartment, which is kept at a temperature T_1 while the alkali chloride ACl is placed in the second compartment, which is kept at a temperature T_2.

The separation proceeds through the formation of the complex compounds A_2ZrCl_6 and A_2HfCl_6 which appear in the second compartment as a solid solution. The efficiency of the separation process depends upon the magnitude of the equilibrium constant for the exchange reaction [12].

The efficiency of separation η defined as:

[15] $$\eta = \frac{(\text{Wt\%HfCl}_4)_{\text{initial}} - (\text{Wt\%HfCl}_4)_{\text{final}}}{(\text{Wt\%HfCl}_4)_{\text{initial}}} \times 100$$

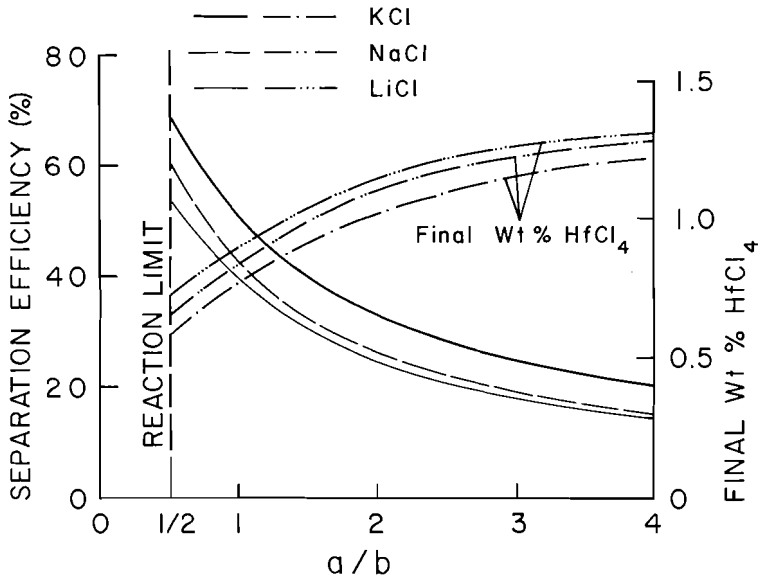

FIG. 3. Variation of the separation efficiency factor "η" and of the final wt% $HfCl_4$, with the molar ratio a/b of $Zr(Hf)Cl_4$ to LiCl, NaCl, or KCl, respectively. Calculations are based on $Zr(Hf)Cl_4$ initially containing 1.54 wt% $HfCl_4$. T_1 and T_2 temperatures are respectively 330°C and 450°C.

may be calculated from the previously derived relationship (7)

$$[16] \qquad K_{ex} = \frac{2(X'_{ZrCl_4})a - b + 2Z}{2(X'_{HfCl_4})a - 2Z} \cdot \left(\frac{P_{ZrCl_4}{}^0}{P_{HfCl_4}{}^0}\right)_{(T_1)} \cdot \frac{2Z}{b - 2Z}$$

where X'_{ZrCl_4} and X'_{HfCl_4} are the mole fractions of $ZrCl_4$ and $HfCl_4$ respectively in the $Zr(Hf)Cl_4$ mixture initially present in the first compartment of the separation cell prior to reaction; a represents the total number of moles of $Zr(Hf)Cl_4$ present in the first compartment of the reactor, prior to separation; b represents the number of moles of ACl present in the second compartment of the reactor; Z is the number of moles of $HfCl_4$ which have reacted with ACl and are retained in the second compartment of the reactor after equilibrium has been reached; $P_{ZrCl_4}{}^0$ and $P_{HfCl_4}{}^0$ are the sublimation pressures (17) of pure $ZrCl_4$ and $HfCl_4$ respectively, at the temperature T_1.

Considering a reactor containing NaCl and T_1 and T_2 temperatures of 330 and 450°C respectively the separation efficiency factor η may be calculated from the determined values of K_{ex} and for various ratios of a/b.

Figure 3 illustrates the variation of η with the a/b ratio for LiCl, NaCl, and KCl. As is seen, η increases as the a/b ratio decreases. Hence the separation becomes more efficient when the amount of the $Zr(Hf)Cl_4$ mixture placed in compartment I is close to that required by the stoichiometry for the formation of Na_2ZrCl_6 and Na_2HfCl_6. The reaction limit is reached at $a/b = 0.5$, at which point all the added tetrachloride vapours react with the NaCl. On the other hand, as the a/b ratio approaches the value of 0.5, most of the $Zr(Hf)Cl_4$ is present as a Na_2ZrCl_6–Na_2HfCl_6 solid solution in compartment II. Hence for practical purposes, the a/b ratio must be larger than 0.5, and a value of about 0.8 to 1.0 appears optimum. At $a/b = 0.8$ the calculated separation efficiency is about 52%.

By comparing LiCl, NaCl, and KCl as separating agents for Hf, it is evident that at 450°C the separation efficiency increases in the order LiCl → NaCl → KCl.

Allylic derivatives of nickel and palladium

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received September 10, 1980

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **59**, 996 (1981).

The synthesis of novel allylic derivatives of Ni and Pd incorporating the bispyrazolylgallate ligand $Me_2Ga(N_2C_5H_7)_2^-$ is described. Pyrazolyl-bridged homobinuclear and trinuclear nickel allyl systems are also presented. Crystal structures of $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ and $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$ are described. Crystals of the former are triclinic, $a = 8.265(1)$, $b = 10.487(1)$, $c = 11.755(2)$ Å, $\alpha = 72.60(1)$, $\beta = 87.28(1)$, $\gamma = 67.58(1)°$, $Z = 2$, space group $P\bar{1}$ and crystals of the latter are monoclinic, $a = 7.9172(3)$, $b = 10.6929(1)$, $c = 16.9118(6)$ Å, $\beta = 102.887(2)°$, $Z = 2$, space group $P2_1/c$. Both structures were solved by Patterson and Fourier syntheses and were refined by full-matrix least-squares procedures to $R = 0.026$ and 0.025 for 3329 and 2914 reflections with $I \geq 3\sigma(I)$ respectively. In both structures the M—(N—N)$_2$—M rings are in the boat conformation and the allyl groups display twofold orientational disorder. In $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ the nickel coordination may be regarded as square-planar with the allyl ligand occupying two coordination sites and the coordination about the gallium is distorted tetrahedral. Important bond lengths (corrected for libration) are: Ni—N, 1.926(2) and 1.929(2), Ni—C, 1.971(5)–2.025(3), Ga—N, 1.994(2) and 1.996(2), Ga—C, 1.966(3) and 1.988(3) Å. The trinuclear complex $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$ is centrosymmetric with the central Ni(1) atom bonded to four pyrazolyl nitrogen atoms in square-planar fashion. The outer Ni(2) atom is bonded to two pyrazolyl nitrogens and to an allyl group and also has square-planar coordination geometry. Important bond distances in this complex are: Ni(1)—N, 1.897(1) and 1.901(1), Ni(2)—N, 1.908(2) and 1.912(2), Ni(2)—C, 1.97(1)–2.022(3) Å.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **59**, 996 (1981).

On décrit la synthèse de nouveaux dérivés allyliques du Ni et du Pd dans lesquels on a incorporé le ligand bispyrazolylgallate, $Me_2Ga(N_2C_5H_7)_2^-$. On a aussi obtenu les systèmes allyliques homobinucléaire et trinucléaire du nickel ayant un pyrazolyle en position de pont. On décrit les structures du cristal de $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ et du $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$. Les cristaux du premier composé sont tricliniques avec $a = 8{,}265(1)$, $b = 10{,}487(1)$, $c = 11{,}755(2)$ Å, $\alpha = 72{,}60(1)$, $\beta = 87{,}28(1)$, $\gamma = 67{,}58(1)°$, $Z = 2$, groupe d'espace $P\bar{1}$ et les cristaux du deuxième composé sont monocliniques avec $a = 7{,}9172(3)$, $b = 10{,}6929(1)$, $c = 16{,}9118(6)$ Å, $\beta = 102{,}887(2)°$, $Z = 2$, groupe d'espace $P2_1/c$. On a résolu les deux structures par les synthèses de Patterson et de Fourier et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R de 0,026 et 0,025 pour 3329 et 2914 réflexions avec $I \geq 3\sigma(I)$. Dans les deux structures, les cycles M—(N—N)$_2$—M ont une conformation bateau et les groupes allyles montrent un double désordre d'orientation. On peut considérer la coordination du Ni du composé $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ comme plan carré avec le ligand allyle occupant deux sites de coordination alors que la coordination autour du gallium est tétraédrique déformée. Les longueurs de liaisons importantes (corrigées pour la libration) sont: Ni—N, 1,926(2), et 1,929(2), Ni—C, 1,971(1)–2,025(3), Ga—N, 1,994(2) et 1,996(2), Ga—C 1,966(3) et 1,988(3) Å. Le complexe trinucléaire $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$ est centrosymétrique avec l'atome de nickel central lié à 4 atomes d'azote du pyrazolyle de manière plan carré. L'atome de nickel extérieur est lié à deux atomes d'azote du pyrazolyle et à un groupe allyle et a également une géométrie de coordination plan carré. Les distances de liaison importantes de ce complexe sont: Ni(1)—N, 1,897(1) et 1,901(1), Ni(2)—N, 1,908(2) et 1,912, Ni(2)—C, 1,97(1)–2,022(3)Å.

[Traduit par le journal]

Introduction

Earlier reports have described the synthesis of bidentate chelating anionic pyrazolyl gallate ligands of the type $Me_2Ga(N_2C_3H_3)_2^-$ and their complexation with divalent transition metal ions (1–4). More recent studies have extended this work to include both symmetrical tridentate chelating ligands of the type $MeGa(N_2C_3H_3)_3^-$ (5), and unsymmetrical tridentate chelating ligands of the type $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]^-$ (ref. 6 and references therein). The present account describes the use of the above bidentate ligands in the preparation of some allylic derivatives of both Ni and Pd and also our attempts to complex the unsymmetrical tridentate gallate ligands to the Ni(allyl) moiety. The crystal structure determinations of the complexes $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_3)$ and $[(\eta^3\text{-}C_3H_3)Ni(N_2C_5H_7)_2]_2Ni$ are described.

Experimental

Starting Materials

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and was used immediately following distillation. Benzene was dried by refluxing over potassium followed by distillation. The bidentate gallium ligand $Na^+Me_2Ga(N_2C_5H_7)_2^-$ was prepared as described previously (4) and used as a THF solution. The tridentate ligand $Na^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]^-$ was prepared as a THF solution as described earlier (7). $(C_3H_5)_2Ni$ was prepared from $(C_3H_5)MgCl$ and $NiBr_2$ and subsequently converted to $[(C_3H_5)NiBr]_2$ by reaction with HBr (8). The $[(\text{"allyl"})PdCl]_2$ compounds ("allyl" = $\eta^3\text{-}C_3H_5$ and $\eta^3\text{-}C_4H_7$) were prepared via reaction of $PdCl_2$ with the appropriate "allyl"Cl in the presence of CO and MeOH (9).

Preparation of $[Me_2Ga(N_2C_5H_7)_2]Pd$"allyl" Compounds

$[(C_4H_7)PdCl]_2$ (0.394 g, 1.5 mmol) was dissolved in THF and $Na^+Me_2Ga(N_2C_5H_7)_2^-$ (3.0 mmol) in the same solvent added. The yellow solution slowly turned colorless and after stirring for

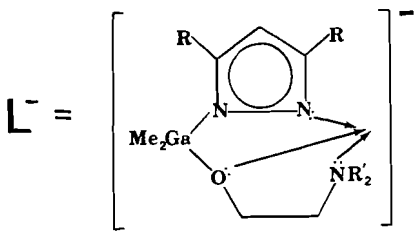
1 h, solvent was removed *in vacuo* and the residue extracted with benzene. Filtration of the extracts followed by slow evaporation of the filtrate gave white crystals of the product. Yield ~60%. *Anal.* calcd. for $Me_2Ga(N_2C_5H_7)_2Pd(C_4H_7)$: C 42.6, H 6.0, N 12.4; found: C 42.8, H 6.0, N 12.4. ^1H nmr (C_6D_6 solution): τ = 9.65s, 9.55s ($GaMe_2$), 8.28s (*Me* allyl), 7.92s, 7.78s, (pz-Me), 7.51s (*anti*-H), 6.71s (*syn*-H), 4.21s (pz-H(4)) ($\tau_{C_6H_6}$ = 2.84 ppm; s = singlet; pz = pyrazolyl).

The compound $[Me_2Ga(N_2C_5H_7)_2]Pd(C_3H_5)$ was prepared in an identical manner from $[(C_3H_5)PdCl]_2$ starting material. Yield ~75%. *Anal.* calcd. for $[Me_2Ga(N_2C_5H_7)_2]Pd(C_3H_5)$: C 41.2, H 5.8, N 12.8; found: C 41.3, H 5.8, N 13.2. ^1H nmr (C_6D_6 solution): τ = 9.67s, 9.62s ($GaMe_2$), 7.96s, 7.80s (pz-Me), 7.53d (J = 12 Hz, *anti*-H), 6.22d (J = 7 Hz, *syn*-H), 5.02tt (J = 7, 12 Hz, unique-H) 4.22s (pz-H(4)) (d = doublet, tt = triplet of triplets).

Preparation of $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$

A THF solution of $[(C_3H_5)NiBr]_2$ (0.287 g, 0.8 mmol) was cooled to −78°C and a solution of the ligand $Na^+Me_2Ga(N_2C_5H_7)_2^-$ (1.6 mmol) in the same solvent added dropwise over 30 min. The color of the solution gradually changed from red to yellow and after stirring for a further 30 min at 0°C, $MgSO_4$ (~5 g) was added and the mixture filtered. Removal of solvent from the filtrate gave yellow–brown crystals of the product in approximately 70% yield. *Anal.* calcd. for $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$: C 46.2, H 6.5, N 14.4; found: C 46.0, H 6.5, N 14.4. ^1H nmr (C_6D_6 solution): 9.66s, br, 9.19s, br ($GaMe_2$), 7.99d (J = 12 Hz, *anti*-H), 7.89s, 7.81s (pz-Me), 7.29d, br (J = 7 Hz, *syn*-H), 4.70tt, br (J = 7, 12 Hz, unique-H), 4.36s (pz-H(4)) (br = broad).

Reaction of Na^+L^- with $[(C_3H_5)NiBr]_2$



A THF solution of $[(C_3H_5)NiBr]_2$ was cooled to −78°C and a double molar amount of the ligand Na^+L^-, in the same solvent, was added dropwise. Slowly the red solution became yellow and a white precipitate formed. After stirring the reaction mixture for 1 h at 0°C, volatiles were removed *in vacuo*. In some cases, a yellow solid co-condensed in the cold trap and this material was identified as $(C_3H_5)_2Ni$ by mass spectrometry. The remaining yellow–brown residue was extracted with heptane to leave a green or blue residue (the color of the residue depended on the substituents on the ligand L). The heptane extracts were filtered and evaporation of the filtrate gave red crystals of $[Ni(N_2C_5H_7)(C_3H_5)]_2$ or $[Ni(N_2C_3H_3)(C_3H_5)]_2$. Finally, the green or blue residue was extracted with benzene. Filtration followed by evaporation of the filtrate gave crystals of the complexes L_2Ni (10, 11), $[LNi(N_2C_3H_3)]_2$ (7), or $LNi[(N_2C_5H_7)_2GaMe_2]$ (11) depending on the ligand L^-. These complexes have all been described previously.

Preparation of $[Ni(N_2C_5H_7)(C_3H_5)]_2$

$[(C_3H_5)NiBr]_2$ (0.180 g, 0.5 mmol) was dissolved in THF and a solution of $Na^+N_2C_5H_7^-$ (0.118 g, 1.0 mmol) in the same solvent added. The color of the solution changed from red to yellow and after the reaction mixture had been stirred for 24 h, the solvent was removed *in vacuo*. The remaining yellow residue was extracted with benzene and slow evaporation of the filtered extracts yielded a red crystalline product in approximately 40% yield. *Anal.* calcd. for $[Ni(N_2C_5H_7)(C_3H_5)]_2$: C 49.3, H 6.2, N 14.4; found: C 49.1, H 6.3, N 14.1. ^1H nmr (C_6D_6 solution): 7.89s, 7.89s, 7.81s, 7.64s (pz-Me), 7.71d, 7.79d (J = 14 Hz, *anti*-H), 7.18d, 6.96d ($J \approx$ 7 Hz, *syn*-H), 4.58m (unique-H), 4.21s (pz-H(4)) (m = multiplet).

Spectra

The mass spectra were collected on a Varian MAT CH4 spectrometer at 70 eV with an ion source temperature of 100–180°C and the ^1H nmr spectra on a Varian XL-100 spectrometer using FT techniques.

X-ray Crystallographic Analyses

[Dimethylbis(3,5-dimethyl-1-pyrazolyl)gallato(N',N')](η³-allyl)-nickel(II)

The crystal chosen was mounted in a general orientation and had dimensions of ca. 0.11 × 0.32 × 0.65 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data (at 22°C) are:

$C_{15}H_{25}GaN_4Ni$ f.w. = 389.82

Triclinic, a = 8.265(1), b = 10.487(1), c = 11.755(2) Å, α = 72.60(1), β = 87.28(1), γ = 67.58(1)°, V = 896.2(2) Å³, Z = 2, ρ_c = 1.445 gcm⁻³, $F(000)$ = 404, μ(Mo K_α) = 25.5 cm⁻¹. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2) from structure analysis.

Intensities were measured with graphite monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.91–10.06° min⁻¹ over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within ±1.5%. After data reduction, an absorption correction was applied using the Gaussian integration method (12, 13). Transmission factors ranged from 0.429 to 0.769 for 224 sampling points. Of the 5199 independent reflections measured, 3329 (64%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

Analysis was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the E-statistics. The coordinates of the Ga and Ni atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. Refinement of the non-hydrogen atoms with anisotropic thermal parameters gave R = 0.040. A difference map at this point indicated twofold disordering of the central allyl carbon atom. The C(4) and C(4′) atoms were included in the refinement with isotropic thermal parameters and fixed occupancy factors of 0.5 for each site. The resulting isotropic thermal parameters were employed to estimate the site occupancies at 0.6 for C(4) and 0.4 for C(4′). These atoms were then assigned anisotropic thermal parameters and the structure refined to R = 0.037. All hydrogen atoms (including disordered allyl hydrogens) were located from a subsequent difference map and were included in the refinement with isotropic thermal parameters. The occupancy factors for the disordered atoms were kept fixed at the previously determined values. The scattering factors of ref. 14 were used for non-hydrogen atoms and those of ref. 15 for hydrogen atoms. Anomalous scattering factors from ref. 16 were used for the Ni atoms. The weighting scheme, $w = 1/\sigma^2(F)$

*Prime denotes occupancy 0.6 or 0.8, double primes denote occupancy 0.4 or 0.2 (see text).

where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.026$ and $R_w = 0.031$ for 3329 reflections with $I \geq 3\sigma(I)$. For all 5199 reflections $R = 0.061$ and $R_w = 0.036$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.13 and 2.5σ (oscillating *x* for H(3c)) respectively. The mean error in an observation of unit weight was 0.9715. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 2,[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

[1]The structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Bis[bis(3,5-dimethylpyrazolyl)(η³-allyl)niccolato(II)(N′,N′)]-nickel(II)

Details of the structure analysis are the same as for $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ except where noted. Crystal dimensions were ca. 0.20 × 0.35 × 0.70 mm. Crystal data are:

$C_{26}H_{38}N_8Ni_3$ f.w. = 638.78

Monoclinic, $a = 7.9172(3)$, $b = 10.6929(1)$, $c = 16.9118(6)$ Å, $\beta = 102.887(2)°$, $V = 1395.65(7)$ Å^3, $Z = 2$, $\rho_c = 1.520$ gcm^{-3}, $F(000) = 668$, μ(Mo K$_\alpha$) = 20.4 cm^{-1}. Absent reflections: $h0l$, $l \neq 2n$ and $0k0$, $k \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

An ω–2θ scan at 1.06–10.06° min^{-1} over a range of (0.70 + 0.35 tan θ)° in ω was employed. Of 4030 reflections measured (to $2\theta = 60°$), 2914(72%) had intensities greater than $3\sigma(I)$ above background. An absorption correction was applied, transmission factors ranging from 0.503 to 0.663 for 264 sampling points.

The coordinates of the Ni atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. Refinement of the

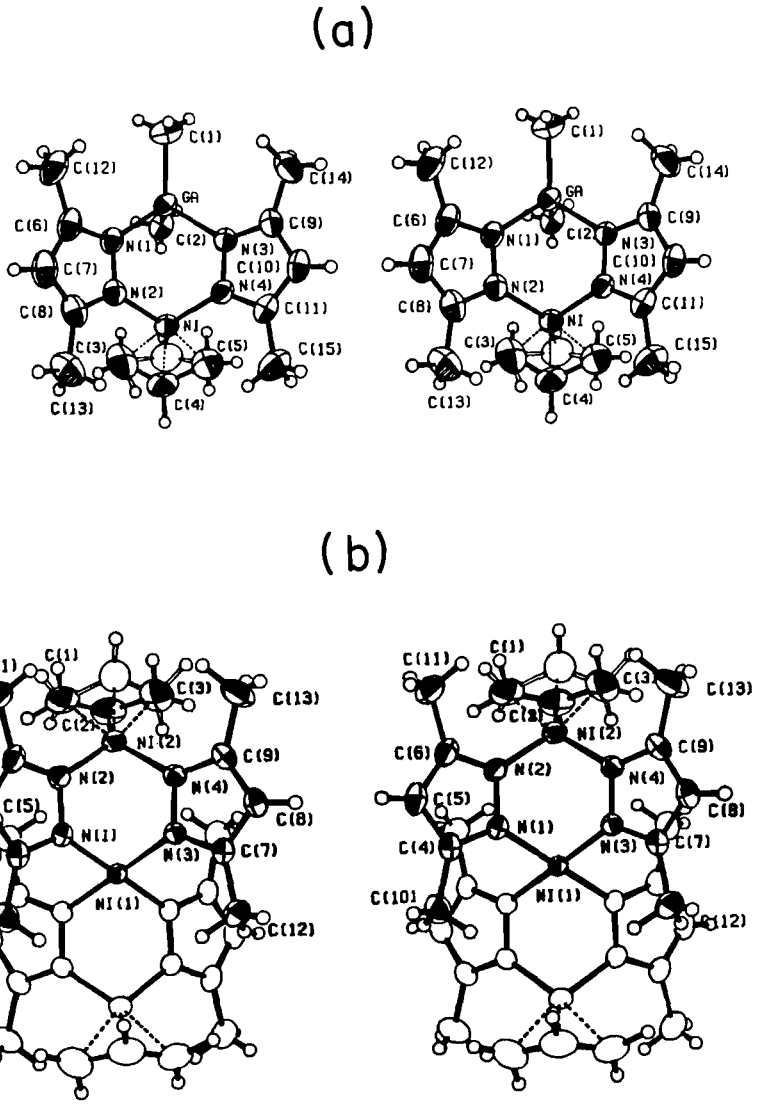

FIG. 1. Stereo views of [dimethylbis(3,5-dimethyl-1-pyrazolyl)gallato(N',N')](η^3-allyl)nickel(II) (*a*) and bis[bis(3,5-dimethylpyrazolyl)(η^3-allyl)niccolato(II) (N',N')]nickel(II) (*b*). 50% thermal ellipsoids are shown for the non-hydrogen atoms.

non-hydrogen atoms with anisotropic thermal parameters gave $R = 0.040$. The central allyl carbon atom was again disordered, this time the second site having a lower occupancy. The allyl disorder was treated as before, starting with occupancies of 0.75 for C(2) and 0.25 for C(2′) and adjusting to final values of 0.80 and 0.20. All hydrogen atoms except those associated with the 20% occupied allyl group were located from a difference map and were refined with isotropic thermal parameters. The hydrogen atom positions for the 20% occupied allyl were calculated and kept fixed in subsequent cycles of refinement. Convergence was reached at $R = 0.025$ and $R_w = 0.031$ for 2914 reflections with $I \geq 3\sigma(I)$, $R = 0.047$ and $R_w = 0.034$ for all 4030 reflections. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.09 and 1.1σ respectively. The mean error in an observation of unit weight was 1.023. A final difference map showed maximum fluctuations of -0.47 to 0.36 e Å^{-3} near the metal atoms and ± 0.2 e Å^{-3} elsewhere.

The thermal motion in both molecules (shown in Fig. 1) has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (17). For $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ (rms $\sigma U_{ij} = 0.0018$ Å^2) analysis of all non-hydrogen atoms except the terminal allyl carbons, C(3) and C(5), gave physically reasonable results and rms $\Delta U_{ij} = 0.0031$ Å^2. For $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$ (rms $\sigma U_{ij} = 0.0010$ Å^2) analysis was successful for all non-hydrogen atoms except the allyl and methyl carbon atoms (rms $\Delta U_{ij} = 0.0020$ and 0.0015 Å^2 with and without constraint to $\bar{1}$ symmetry, bond distances being essentially identical for both cases). The appropriate bond distances have been corrected for libration (18), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values and corrected bond angles are within one standard deviation of the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of the six-membered M_2N_4 rings are given in Table 5.

Results and Discussion

In a previous publication the preparation of several compounds of the general type DNi(NO) (where D is a tridentate pyrazolyl gallate ligand) were discussed (19). The formal replacement of the three electron NO ligand by the three electron "allyl" ligand leads to a marked difference in the stability of the resulting compounds. Thus when Na^+L^- was reacted with $[(C_3H_5)NiBr]_2$, the isolated gallium containing product was inevitably the same Ni(II) product obtained from the reaction of Na^+L^- with $NiBr_2$ (7, 10, 11). In addition when Na^+L^- (R = R′ = Me) was reacted with ["allyl"-$PdCl]_2$ (allyl = C_3H_5 or C_4H_7) the only "allyl" product isolated was $[Pd(N_2C_5H_7)$ "allyl"$]_2$. Thus with neither the nickel allyl nor the palladium allyl systems were we able to isolate complexes incorporating a tridentate gallate ligand. It is perhaps noteworthy that using the cyclopentadienyl ligand in this area the compounds $CpPd(C_3H_5)$ (9) and $CpNi(C_3H_5)$ (20) have both been prepared and the former compound has been structurally characterized (21). In addition the pyrazolyl borate compound $[HB(N_2C_3H_3)_3]Pd(C_3H_5)$ has also been prepared but ^1H nmr data for this compound suggest a bidentate pyrazolylborate ligand (22). In sharp contrast the reactions of $[(C_3H_5)NiBr]_2$ and ["allyl"$PdCl]_2$ with bidentate pyrazolyl gallate ligands did give the expected compounds. In the case of the Ni derivative the stability of the resulting compound (it can be sublimed under vacuum at 60°C without change) is again in marked contrast to the nickel nitrosyl system where compounds containing a bispyrazolyl gallate ligand could not be isolated.

The compounds $[Me_2Ga(N_2C_5H_7)_2]$Pd"allyl" and $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ were prepared by the reaction of $Na^+[Me_2Ga(N_2C_5H_7)_2]^-$ with ["allyl"$PdCl]_2$ and $[(C_3H_5)NiBr]_2$ respectively. The mass spectra of all three complexes showed weak signals due to the parent ions (~5%) with other strong signals due to the ions P—Me^+ (60%) and P—Me—"allyl"-H^+ (100%) (where P = parent).

The ^1H nmr spectra of the two palladium compounds $[Me_2Ga(N_2C_5H_7)_2]Pd(C_4H_7)$ and $[Me_2Ga$-

$(N_2C_5H_7)_2]Pd(C_3H_5)$ are shown in Fig. 2. In each case only one signal is observed for each of the *syn* and *anti* protons of the "allyl" group and this is indicative of either a rapidly rotating or symmetrically coordinated (with respect to the gallate ligand) "allyl" group. The observation of two signals for the Ga—Me protons is consistent with a boat conformation for the Ga—(N—N)$_2$—Pd ring, a configuration demonstrated for the nickel derivative $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ in the solid state through a crystal structure determination (see below).

The rt ^{1}H nmr spectrum of $[Me_2Ga(N_2C_5H_7)_2]$-$Ni(\eta^3\text{-}C_3H_5)$ was similar to that of the analogous Pd derivative shown in Fig. 2*b* but the signals due to the $GaMe_2$ and the allyl *syn* protons were fairly broad. Variable temperature ^{1}H nmr spectra for this Ni complex confirmed our expectations of a fluxional species in solution. On cooling an acetone-d_6 solution the $GaMe_2$ signals gradually sharpened until at 0°C the low temperature limiting spectrum was reached. Conversely, on warming the sample solution, the original broad $GaMe_2$ signals disappeared to be replaced by a single signal at ~60°C. A probable explanation for these observations is that at low temperatures the boat conformation for the Ga—(N—N)$_2$—Ni ring is static but at high temperatures this six-membered ring is rapidly inverting (see Fig. 3). A similar mechanism has been proposed for the fluxional behavior of the complex $[Me_2Ga(N_2C_3H_3)_2]_2Ni$ in solution. Two GaMe signals were again observed at low temperature but only one GaMe signal was observed at high temperature (2). In the present mechanism it has been assumed that the allyl group is rapidly rotating at higher temperatures.

The nickel compound was also found to undergo a novel disproportionation reaction in solution:

$$2[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5) \rightleftharpoons [Me_2Ga(N_2C_5H_7)]_2 + [Ni(N_2C_5H_7)(C_3H_5)]_2$$

The extent of this reaction was monitored by ^{1}H nmr spectroscopy. Freshly prepared solutions of $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ showed no extraneous signals. However, after 1 day at room temperature, substantial amounts of $[Me_2Ga(N_2C_5H_7)]_2$ and $[Ni(N_2C_5H_7)(C_3H_5)]_2$ were evident in the sample solution. (These were identified by comparison of the new signals with the ^{1}H nmr spectra of the pure materials.) The extent of the disproportionation increased gradually over approximately one week after which time the relative amounts of the three species appeared constant.

The compound $[Ni(N_2C_5H_7)(C_3H_5)]_2$ was readily prepared directly by the reaction of $Na^+(N_2C_5H_7)^-$ with $[(C_3H_5)NiBr]_2$. The predicted dimeric nature of this compound was confirmed by mass spectrometry and the ^{1}H nmr spectrum was found to be similar to that reported for the palladium analog $[Pd(N_2C_5H_7)(C_3H_5)]_2$ (23). The observation of four signals for the pyrazolyl methyl protons and fairly complicated patterns for the allyl protons suggest that a number of conformational isomers may exist in solutions of this Ni complex, a phenomenon invoked by Trofimenko to rationalize the ^{1}H nmr spectrum of the Pd analog (23). This conformational isomerism may also have thwarted our numerous attempts to produce high quality single crystals suitable for X-ray diffraction studies. An incomplete structure analysis of this compound[2] has provided some important information (see below). In our attempts to produce good quality crystals of $[Ni(N_2C_5H_7)(C_3H_5)]_2$ we inadvertantly produced very small quantities of excellent crystals of the trimetallic nickel complex $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$. The structure of this complex is described below and consists of the same type of double boat conformation about the central square-planar Ni atom observed in related molecules (1, 3, 24).

[2]Crystals of $[Ni(N_2C_5H_7)(C_3H_5)]_2$ are monoclinic, a = 6.677(1), b = 15.846(2), c = 8.870(1) Å, β = 107.01(1)°, Z = 2, space group $C2/m$, Cm or $C2$ (the noncentrosymmetric space groups being strongly indicated by the E-statistics). The nickel and pyrazolyl positions have been determined in both Cm and $C2$ but the allyl group appears to be severely disordered. No satisfactory solution has yet been found.

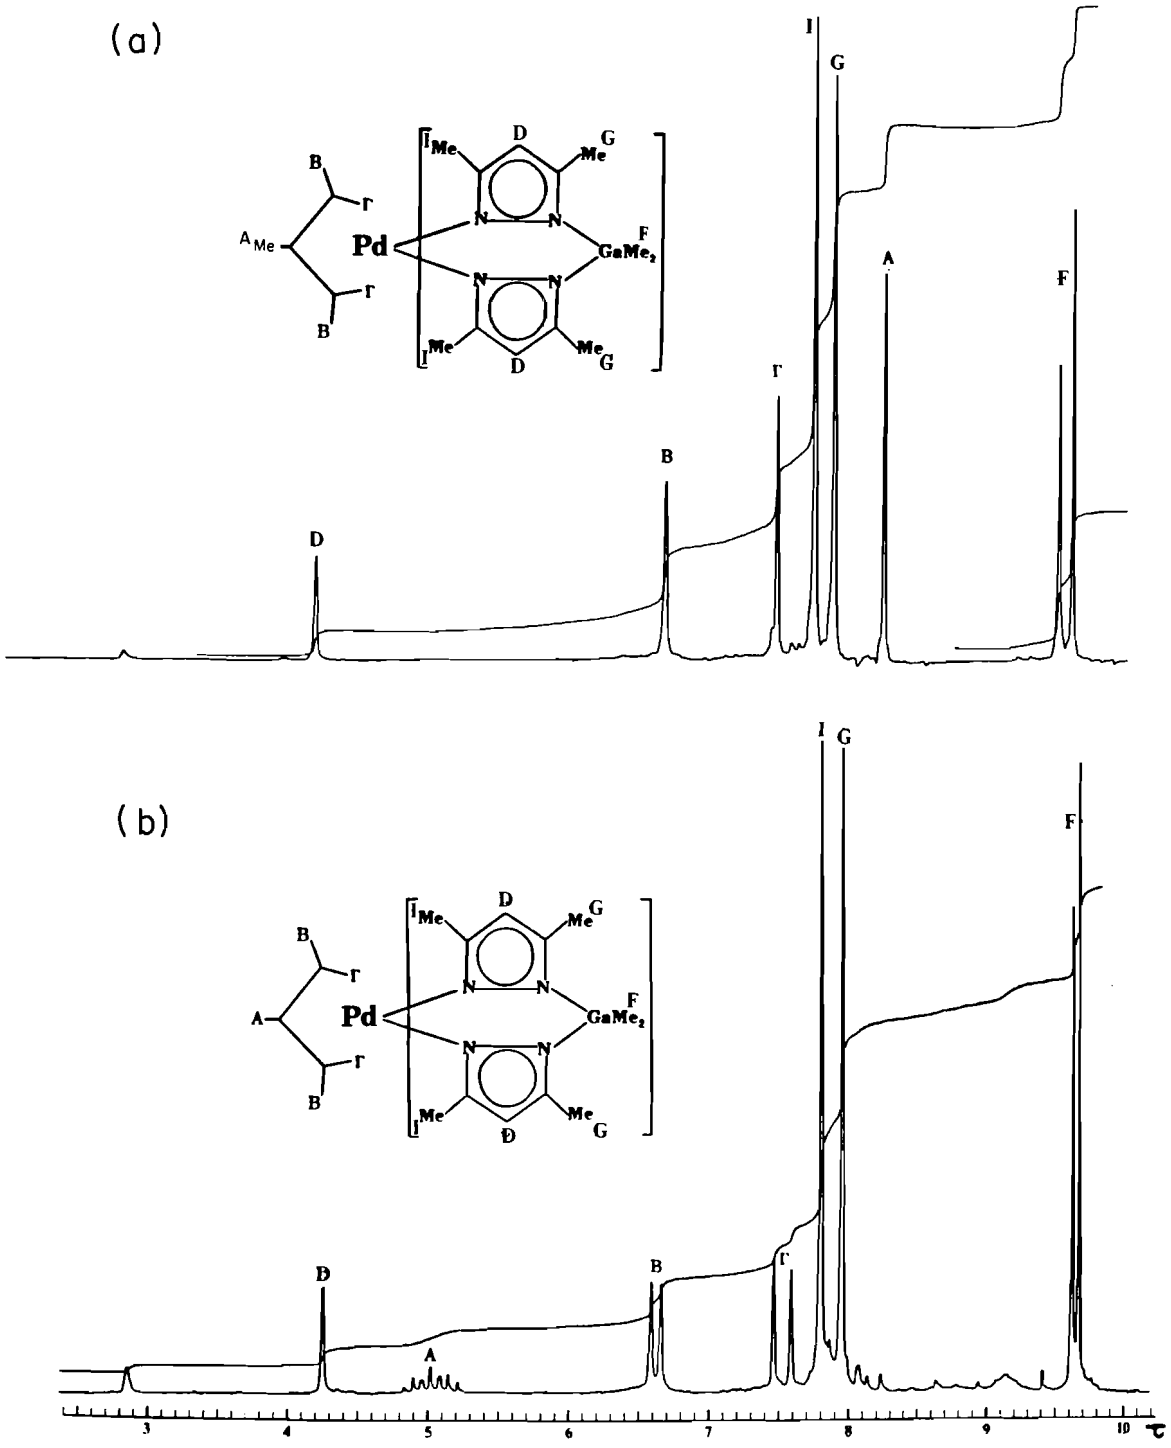

FIG. 2. 100 MHz ^{1}H nmr spectrum of (*a*) $[Me_2Ga(N_2C_5H_7)_2]Pd(C_4H_7)$ and (*b*) $[Me_2Ga(N_2C_5H_7)_2]Pd(C_3H_5)$ in C_6D_6 solution.

X-ray Crystallographic Analyses of $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ and $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$

Both crystal structures consist of discrete molecules separated by normal van der Waals distances. In both complexes the allyl groups display twofold orientational disorder. In $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$, the preferred orientation (60% to 40%) has the central allyl CH moiety directed toward the "outside" of the molecule (see Fig. 1)

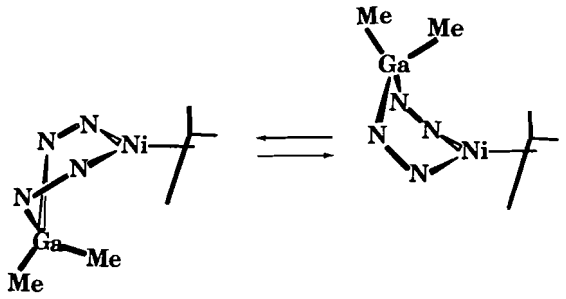

FIG. 3. Proposed conformational equilibrium for $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ in acetone-d_6 solution (C_3H_3 fragments of pyrazolyl groups omitted for clarity).

while in $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$, the opposite orientation is strongly preferred (80% to 20%). In the solid state the predominance of one orientation of the allyl group over the other results from steric interactions between the terminal CH_2 moieties of the allyl ligand and the pyrazolyl methyl groups, two of which are close to the allyl ligand in $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ and four in $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$. The disordering of the allyl groups is consistent with the ^1H nmr results for $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ discussed above and corresponds to the coexistence in the solid state at room temperature of both isomers depicted in Fig. 3. An analogous situation exists for $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$, for which there are four possible isomers.

The $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ molecule possesses approximate mirror symmetry; the mirror plane containing both metal atoms, the central allyl CH and the methyl carbon atoms bonded to gallium. With the exception of bonds involving the allyl ligand, all bond lengths related by the mirror plane agree within experimental error while mirror related bond and torsion angles are generally close but there are some statistically (but not chemically) significant differences. The central Ga—(N—N)$_2$—Ni ring has a distorted boat conformation with a Ga...Ni separation of 3.2748(4) Å and a dihedral angle of 111.3° between the pyrazolyl mean planes, the boat being steeper than those in $[Me_2Ga(N_2C_3H_3)_2]_2Ni$ (1) where the corresponding parameters are 3.432 Å and 116.4°. The N—Ni—N angle of 93.87(7)° is consistent with pseudosquare-planar coordination geometry about the Ni atom. The mean Ni—N distance is 1.928(2) Å and the Ni—C(allyl) distances are in the range 1.971(5)–2.025(3) Å (see below for further discussion). The gallium atom has distorted tetrahedral coordination geometry with bond angles ranging from 96.63(7) to 118.6(2)°. The mean Ga—N distance of 1.995(1) Å and the Ga—C bond lengths of 1.966(3) and 1.988(3) Å are normal.

Each centrosymmetric molecule of $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$ contains a square-planar central Ni(II) coordinated by four pyrazolyl nitrogen atoms and two pseudosquare-planar outer Ni(II) centres each coordinated by two pyrazolyl nitrogen atoms and an allyl group. The molecule has approximate C_{2h} symmetry, the mirror plane containing the three nickel atoms and the central allyl CH moieties. As for $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ there are no chemically significant deviations from the noncrystallographic symmetry. The slightly distorted boat conformation observed for the Ni—(N—N)$_2$—Ni rings (torsion angles in Table 5) and the overall molecular shape are similar to those observed in the related molecules $[Me_2Ga(N_2C_3H_3)_2]_2Ni$ (1), $[Me_2Ga(N_2C_3H_3)_2]_2Cu$ (3) and $[(NO)Ni(N_2C_5H_7)_2]_2Ni$ (24). There is a large variance in M...M cross-ring distances and torsion angles in the M_2N_4 rings (1, 3, 24), these parameters depending on the coordination geometry of both metal atoms as well as on steric factors arising from the ligands. The cross-ring distance in $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$ is 3.2314(2) Å and the dihedral angle between the pyrazolyl mean planes is 112.5°, similar to the corresponding values for $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ (see above). The M...M distances in the present structure are significantly shorter than those observed in related structures which range from 3.3770(3) Å in $[(NO)Ni(N_2C_5H_7)_2]_2Ni$ (24) to 3.790 for the nearly planar M_2N_4 ring in $[Me_2Ga(N_2C_5H_7)_2]_2Cu$ (3). The compound $[Ni(N_2C_5H_7)(C_3H_5)]_2$ has a very steep boat conformation for the central Ni_2N_4 ring with a Ni...Ni separation of only 3.00 Å^2. This is in sharp contrast to the Ni...Ni distance of 3.673(1) Å observed for the planar Ni_2N_4 ring in the closely related molecule $[(NO)Ni(N_2C_5H_7)]_2$ (24).

The central Ni(1) atom has nearly ideal square-planar coordination geometry with N—Ni—N angles of 89.67(6) and 90.33(6)°. The mean Ni(1)—N distance of 1.899(2) Å is intermediate between the corresponding values of 1.895(4) Å in $[Me_2Ga(N_2C_3H_3)_2]_2Ni$ (1) and 1.905(1) Å in $[(NO)Ni(N_2C_5H_7)_2]_2Ni$ (24). The mean Ni(2)—N distance of 1.910(2) Å is significantly shorter than the value of 1.928(2) Å observed in $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$. These values may be compared to the mean value observed for the trigonal planar Ni(I) in $[(NO)Ni(N_2C_5H_7)_2]_2Ni$ (24) of 1.922(3) Å. The Ni—C(allyl) distances of 1.97(1)–2.022(3) Å are in excellent agreement with those in $[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$ and in other Ni(II) allyls (21, 25).

As was noted previously (24), in each of the present structures one of the pyrazolyl groups is rigorously planar within experimental error while

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

the other is slightly, but significantly, non-planar (χ^2 = 4.8, 24.9, 18.6, and 4.4 for the N_2C_3 rings containing N(1) and N(3) for $[Me_2Ga(N_2C_5H_7)_2]$-$Ni(\eta^3\text{-}C_3H_5)$ and $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$ respectively). The metal atoms are significantly displaced from the pyrazolyl mean planes ($[Me_2Ga(N_2C_5H_7)_2]Ni(\eta^3\text{-}C_3H_5)$: Ga 0.1019(3), 0.2293(2); Ni 0.0429(3), −0.1166(3) Å for rings containing N(1) and N(3) respectively and for $[(\eta^3\text{-}C_3H_5)Ni(N_2C_5H_7)_2]_2Ni$: Ni(1) −0.0522(3), 0.1118(2); Ni(2) −0.0297(2), 0.0052(2) Å as above). All other bond distances in the ordered parts of both molecules assume expected values.

Crystal structure of raucubaine

RICHARD A. PAUPTIT AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received August 14, 1980

RICHARD A. PAUPTIT and JAMES TROTTER. Can. J. Chem. **59**, 1007 (1981).

Crystals of raucubaine, isolated from *Rauwolfia salicifolia*, $C_{20}H_{24}N_2O_3$, m.w. = 340.4, are monoclinic, $P2_1$, $a = 7.2179(3)$, $b = 12.8169(7)$, $c = 9.1996(2)$ Å, $\beta = 93.040(3)°$, $V = 849.87$ Å^3, $\rho_c = 1.33$ g cm^{-3}, $Z = 2$, $R = 0.046$ for 1699 reflections. The previously-unknown structure of this alkaloid was determined.

RICHARD A. PAUPTIT et JAMES TROTTER. Can. J. Chem. **59**, 1007 (1981).

Les cristaux de raucubaine, isolées de *Rauwolfia salicifolia*, $C_{20}H_{24}N_2O_3$, m.w. = 340.4, sont monocliniques, $P2_1$, $a = 7.2179(3)$, $b = 12.8169(7)$, $c = 9.1996(2)$ Å, $\beta = 93.040(3)°$, $V = 849.87$ Å^3, $\rho_c = 1.33$ g cm^{-3}, $Z = 2$, $R = 0.046$ pour 1699 réflexions. La structure auparavant inconnue de cet alcoloide a été determinée.

Introduction

The leaves of the plant *Rauwolfia salicifolia griseb.*, a species endemic to Cuba, yield a new alkaloid, raucubaine (1). Spectroscopic data suggested structures for various fragments, but did not allow elucidation of the complete structure, which has now been determined by X-ray crystal analysis.

Experimental

Crystal data as in the abstract. The intensity data were collected on an automatic Enraf-Nonius CAD-4 diffractometer using nickel-filtered CuKα radiation (λ = 1.54188 Å). An ω–2θ scan was used with an ω scan angle of $(0.90 + 0.15 \tan\theta)°$ extended on either side by 25% for background counts. The horizontal aperture width was $(2.00 + 0.5 \tan\theta)$ mm. The intensities of three standard reflections were measured every 1 h and used to scale the data. Three additional reflections were used as orientation control; reorientation occurred if the difference between observed and calculated scattering vectors was greater than 0.05°. In the θ range $2° < \theta \leq 75°$, 1700 out of 1822 reflections (93.3%) had $I/\sigma(I) \geq 3.00$, where $\sigma^2(I) = S + B + (0.04S)^2$ and S and B are the scan and time-corrected background counts, and were considered observed.

The structure was solved by direct methods. The E's were obtained by following the minimum profile of a K-curve and input into the MULTAN program (2). Considerable difficulty was encountered in trying to obtain a solution until four symbols in addition to the three origin-determining reflections were forced into MULTAN's symbolic addition routine. The resulting E-map revealed the positions of all 25 non-hydrogen atoms. After three isotropic full-matrix least-squares refinement cycles the atoms could easily be identified as C, N, or O from their temperature factors (all atoms were initially considered as carbons). Three more isotropic cycles and a difference map showed the number and atom-type of the non-hydrogen atoms to be correct. After an anisotropic refinement cycle a difference map produced all the hydrogen positions, and on refining all atoms (H isotropic; C, N, O anisotropic) the need for an extinction correction became apparent. R dropped from 0.054 to 0.049 on four least-squares cycles refining only an isotropic extinction parameter and the scale factor. The scattering factors of ref. 3 were used for non-hydrogens and those of ref. 4 for hydrogen atoms. The structure was refined to convergence using a polynomial weighting scheme updated after every cycle (5). The final isotropic extinction parameter g was 1.627×10^{-3} and the final R and R_w were 0.046 and 0.066, respectively. The atomic positional parameters of the non-hydrogen atoms are presented in Table 1.[1]

trates the cage-like framework. The central cage (i.e. not including the dihydroindole group) consists of three six-membered rings and a five-membered ring so connected as to form a "bowl" of which the open face is the nine-membered ring C(7)—C(15)—C(14)—N(2)—C(16)—C(17)—O(1)—C(18)—C(10). The C(10)—C(11)—C(12)—C(13)—C(8)—C(7) ring has a slightly distorted chair conformation, while the other two six-membered rings have slightly skewed boat conformations.

The five-membered ring has a skew conformation; C(10) and C(11) are both 0.24 Å away from the mean plane of the ring (including O(2)), but on opposite sides. The dihydroindole group is planar if C(8) and C(9) are not included. In this way the greatest deviation of any atom in the plane (C(1) to C(7), N(1)) from mean plane is 0.057 Å for C(4), whereas C(8) and C(9) are 0.66 and 0.73 Å away from the plane on the same side; i.e. the envelope of the dihydroindole five-membered ring is C(8).

All bond distances (Table 2) are within normal ranges, and bond angles[1] (Table 3) are as reasonable as could be expected given the constraints of

Received October 17, 1980

JOHN W. APSIMON, DAVID MOIR, and KAZUYUKI YAMASAKI. Can. J. Chem. **59**, 1010 (1981).

Investigations of the CDE ring construction of naturally occurring triterpenoids are described. The efficient synthesis of 3,3,10aβ-trimethyl-1,2,3,4,4aβ,5,8,9,10,10a-decahydrophenanthren-7(6*H*)-one (**25**) has been achieved. The D/E ring junction of the molecule, as well as that of related compounds, has been established by the use of ^{13}C nmr spectra. The synthetic intermediate **25** can be considered as a key substance for a synthetic entry to friedelin (**1**) in addition to β-amyrin (**23**).

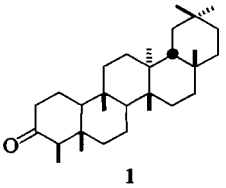
JOHN W. APSIMON, DAVID MOIR et KAZUYUKI YAMASAKI. Can. J. Chem. **59**, 1010 (1981).

On décrit les recherches sur la synthèse des cycles CD et E des triterpènes naturels. On a réalisé une synthèse appropriée de la 6*H* triméthyl-3,3,10aβ décahydro-1,2,3,4,4aβ,5,8,9,10,10a phénantrénone-7 (**25**). En utilisant la rmn du ^{13}C, on a identifié la stéréochimie de la jonction des cycles D/E de cette molécule ainsi que celle des composés apparentés. On peut considérer l'intermédiaire **25** comme une substance de base permettant d'accéder à la friedeline (**1**) ainsi qu'à la β-amyrine (**23**).

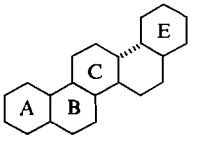
[Traduit par le journal]

Synthesis of pentacyclic triterpenoids is complicated by their structural complexity arising from the presence of a considerable number of contiguous asymmetric centres including a beautifully arranged array of angular methyl groups. During recent years several laboratories have made significant contributions in this area,[3] one of which is the first total synthesis of friedelin (**1**) by Ireland's group (2), and some progress related to the total synthesis of triterpenoids has also been reported from these laboratories.[4]

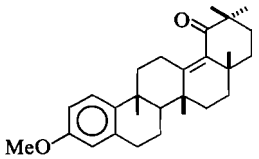
In particular, in the preceding papers (3) in this series we have discussed a synthetic strategy based on ABC + E ring construction (**2**) that has led us to the pentacyclic species **3** and **4**.



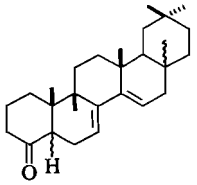
1



2



3



4

Among several different approaches currently being investigated in these laboratories, we now wish to report the completion of the first subgoal of an investigation concerning a variation on the above strategy, that is, a CDE + A ring construction as outlined in **5**. Since the bond formation indicated by the dotted line in **5** has been successfully demonstrated to generate the desired *trans*-fused B/C ring system present in friedelin when a proper ACDE ring unit is subjected to cycloalkylation (4), the foreseeable synthetic complexity associated with the approach is apparently reduced to the problem of construction of an appropriate CDE ring unit. Thus, the preparation of such a unit corresponding to that of the naturally occurring triterpenoids became our immediate concern, and tricyclic compound **6** was chosen as our prime synthetic objective since it provides not only the correct stereochemistry at the D/E ring junction but also the opportunity for further elaboration of the C ring to suitable precursors for pentacyclic species.

The initial phases of the synthetic route were

SCHEME 2

accomplished by alkylation of keto ester **7** (1) with **8**, using potassium *tert*-butoxide as a base to give **9** in 31% yield. Cyclization of this material was effected by refluxing in benzene containing a catalytic amount of *p*-toluenesulfonic acid, yielding the tricyclic ester **10** in 83% yield (Scheme 1). Next we attempted to reduce the double bond in **10** by catalytic hydrogenation. Previous studies from these laboratories (1) as well as literature precedents (5) suggest the strong directive effect of an angular hydroxymethyl group in catalytic hydrogenation. Therefore we predicted, a priori, that the catalytic hydrogenation of **10** with a carbomethoxy group at its angular position would produce a *trans*-D/E ring junction, whereas hydrogenation of the corresponding alcohol **11** could provide a *cis*-D/E ring junction predominantly by virtue of the attractive interaction between the catalyst surface and the hydroxyl group. Experimentally, the tricyclic alcohol **11** was prepared by lithium aluminium hydride reduction of **10** (97%), and hydrogenation of both tricyclic compounds **10** and **11** was investigated. Ester **10**, upon hydrogenation, (10% Pd–C, toluene), gave what appeared to be a single reduced ester **12** in 98% yield, and this ester was further reduced with lithium aluminum hydride to alcohol **13** (94%) to which we later assigned the *trans*-stereochemistry. By contrast, hydrogenation of **11** gave the alcohol of ambiguous stereochemical purity **14** which proved to be a mixture of the *cis*- and *trans*-alcohols (64% *trans*, 36% *cis* estimated by glc). These sequences are outlined in Scheme 2.

Although our surmise turned out to be at least partially true, the directive effect of a hydroxymethyl group in the hydrogenation of **11** was not as discriminating as we wished and certainly could not reverse the stereochemical course of hydrogenation. Furthermore, hydrogenation in a number of different solvents did not appreciably change the composition of the *cis*- and *trans*-isomers mixture.[5]

[5]The only exception was found when hydrogenation was conducted in acetonitrile, in which case a *very slow* formation of the *cis*-isomer only was noted. This route did not prove to be synthetically useful.

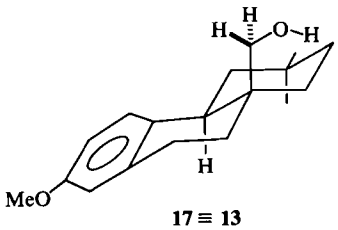
SCHEME 3

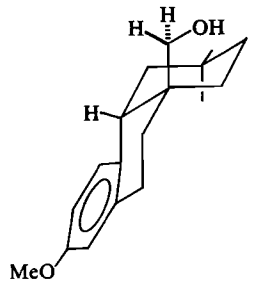
Following the observations of Thompson *et al.* (6), we then decided to investigate the metal–ammonia reduction of the unsaturated carboxylic acid **15** which would be expected, by analogy to their results, to produce the *cis*-ring junction. The required acid **15** was prepared by hydrolysis of ester **10** with potassium hydroxide in refluxing methoxyethanol. Acid **15** was reduced with lithium in liquid ammonia to give a single saturated carboxylic acid **16** in 74% yield, which was in turn converted to an alcohol **14** by lithium aluminum hydride reduction (see Scheme 3). This alcohol proved not to be identical with **13** obtainable from lithium aluminum hydride reduction of **12**.

Stereochemical assignments for **13** and **14**, and hence for **12** and **16**, are based on the following evidence. The ^{13}C chemical shift for the angular carbon atom bearing a hydroxyl group in **13** appears at 59.2 ppm, while the corresponding shift for **14** is at 69.2 ppm. If we assume that **13** possessed a *trans*-junction and **14** is the *cis* isomer, then the above ^{13}C chemical shifts are in complete agreement with the generalization that the angular methyl group in a *trans*-decalin is always shielded significantly when it is compared to its counterpart in a *cis*-decalin (7). The ^1H nmr spectra of a pair of alcohols **13** and **14** display a marked difference in the spectral pattern due to their C(10)-hydroxymethyl protons. The signals in **13** appear at δ 3.20 and 3.61 as a pair of doublets (J = 11 Hz), on the other hand the corresponding pair in **14** is located at δ 3.30 and 3.42 (J = 11 Hz).[6]

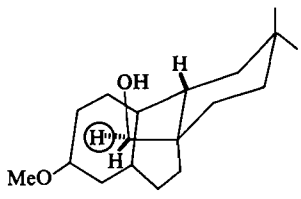
Dreiding models of both isomers show that the *trans*-alcohol can probably be conformationally described as **17** and the *cis*-alcohol as either **18** or **19**.[7] Considering the fact that one of the geminal dimethyl groups (δ 0.89) in **14** is shielded substantially more than either of those in **13** (δ 1.04, 1.07), it appears that the preferred configuration for **14** is probably **18** because in this configuration the methyl group is located in the shielding region of the benzene ring. It is also evident from the two projections **17** and **18** that one of the two protons belonging to the *cis*-hydroxymethyl group in the *trans*-isomer **17** experiences the anisotropic effect of the benzene ring by which the proton closer to the benzene ring is shielded considerably relative to the other one, while in **18** no such effect is clear. On this basis, the observed larger difference in the chemical shifts of the doublets in **13** (δ 3.20, 3.61, Δδ = 0.41) as opposed to the difference in **14** (δ 3.30, 3.42, Δδ = 0.12) can be explained. As the foregoing arguments imply, our stereochemical assignments, the *trans*-junction for **13** and *cis*- for **14**, seemed quite reasonable at this stage and were



17 ≡ 13



18 ≡ 14



19 ≡ 14

[6]Thompson *et al.* (6) have reported similar spectral patterns for their *cis*- and *trans*-alcohols without further comment.

[7]This is only one of the possible rotamers.

20

later confirmed when the ^{13}C data for a pair of hydrocarbons derived respectively from **13** and **14** became available.

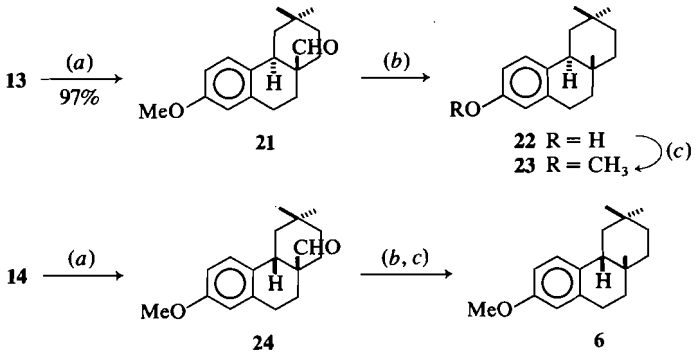
The stereochemical outcome of the lithium–ammonia reduction of **15**, leading to the generation of a *cis*-ring junction, is of particular interest and worthy of further comments. A number of examples in which a carboxyl grouping in the vicinity of a reducible double bond would probably be responsible for stereocontrolled reductions have been reported (6, 8) and McMurry *et al.* have commented on the role of the carboxylic acid function in this type of reduction. We believe that this role is general and are of the opinion that the carboxylic acid function would either direct the approach of a proton donor from its side of a reducible molecule or contribute to lowering of the energy level of an anionic intermediate such as **20** where the *cis*-relationship between the carboxyl group and the anionic center is maintained.

We have briefly investigated the role of angular substituents in directing the stereochemistry of the lithium–ammonia reduction in these cases. Thus, reduction of ester **10** yielded a mixture of 47% *cis* and 53% *trans* reduction products and alcohol **11** provided 82% *cis* (**14**) and 18% *trans* (**13**) reduction products. Comparing these data to the above highly stereoselective (>98%) formation of the *cis* compound **16** from acid **15** it is evident that acidic functional groups (CH_2OH or COOH) play a vital role in deciding the direction of protonation of intermediates analogous to **20** or are involved in stabilizing a particular conformation as already suggested.

Having thus established the routes to both alcohols **13** and **14**, we turned our attention to the preparation of the target molecule **6**. First, the tricyclic alcohol **13** was oxidized to the aldehyde **21** by Corey oxidation, which was then subjected to Wolff–Kishner reduction. During this reduction the consistent formation of phenol **22** was observed, besides the production of ethers **23**. Therefore, from a practical point of view, a mixture of **22** and **23** was treated with methyl iodide in the presence of sodium hydride at room temperature, and this remethylation procedure afforded only ether **23**. Analogously, alcohol **14** was transformed into the desired tricycle **6** via the aldehyde **24** (Scheme 4).

The obtention of both ethers **23** and **6** has provided us with further conclusive information regarding the stereochemistry of their ring junctions. Thus, upon comparison of the ^{13}C nmr spectra of both materials, it is seen that the angular methyl group in **23** appears at 27.5 ppm while the corresponding signal for **6** is at 15.2 ppm. These chemical shifts indicate that **23** has the *trans*-ring junction and **25** is *cis*-fused, and that our assignments for the structures of the parent alcohols **13** and **14** are correct. The synthetic objective **6** is thus available quite efficiently (overall yield from **10** = 39%).

Preliminary experiments on further elaboration of **6** have so far been encouraging. Reduction of the aromatic ring of **6** in lithium – liquid ammonia and direct mild acid treatment of the product provided the title compound, β,γ-enone **25** in 89% yield. This tricyclic compound appears to be a versatile synthon convertible to the CDE ring of friedelin **1** as



Reagents: (*a*) PCC; (*b*) Wolff–Kishner reduction, (*c*) NaH, CH_3I, THF.

25 26

well as that of β-amyrin **26**, since it is endowed with the requisite functionalities to incorporate (9) the variety of methyl groups and double bond isomers found in a variety of triterpenoids.

Experimental

General

All melting points were determined on a Fisher-Johns apparatus and are uncorrected. Boiling points are not corrected. Infrared spectra were recorded on a Perkin-Elmer Model 237B infrared spectrometer, ultraviolet spectra on a Perkin-Elmer 202 ultraviolet–visible spectrophotometer. Mass spectra were obtained on an AE1 MS12 instrument at Trent University. Nuclear magnetic resonance spectra were measured on a Varian T-60 (Carleton University) or Varian HA-100 (University of Ottawa), using tetramethylsilane as an internal standard. Chemical shifts are expressed in the δ scale with the following designations; s, singlet; d, doublet; t, triplet; m, multiplet, br, broadened. Combustion analyses were performed by Spang Microanalytical Laboratory, Ann Arbor, MI.

All reactions and chromatograms were routinely monitored by thin-layer chromatography (tlc) (Merck 60 PF-254 plates, 0.25 mm), using 1:5 hexane – ethyl acetate as eluent. Spots were developed by exposing to iodine vapour. Preparative thin-layer chromatography was carried out on Merck 60 F-254 precoated silica gel plates of 2.0 mm thickness. Bands were visualized by viewing under an ultraviolet source. Silica gel (Davison Chemical Co., grade 923, 100–200 mesh) was used for column chromatography.

The terms "dry benzene" and "dry toluene" refer to benzene or toluene which was distilled and stored over sodium. "Dry tetrahydrofuran" was obtained by distillation from lithium aluminum hydride. "Anhydrous ether" was available from Mallinckrodt Canada Ltd. Petroleum ether refers to the fraction boiling at 30–60°C.

2-Methoxycarbonyl-5,5-dimethylcyclohexanone (7)

Dry methyl carbonate (270 g, 3.00 mol) and sodium hydride (72 g, 3.00 mol) in 500 mL of dry tetrahydrofuran were heated at reflux temperature with mechanical stirring. To this suspension (1) was added dropwise 125 g (1.03 mol) of 3,3-dimethylcyclohexanone (1) in 200 mL of dry THF. Two minutes after the addition, about 1 g of potassium hydride was added to initiate the reaction. The solution was refluxed for an additional 1½ h. The mixture was then cooled in an ice bath for 30 min and hydrolyzed by the careful addition of 3 *M* aqueous acetic acid solution. The organic material was extracted with chloroform, then washed with saturated sodium bicarbonate solution and brine. Drying over anhydrous sodium sulphate and removal of solvent under reduced pressure gave a yellow oil from which the title keto ester **7** (115 g, 65%) was distilled under vacuum, bp 78–83°C/1.0 Torr; ir (neat): 1746, 1723, 1657, and 1623 (α-ketoester) cm^{-1}; nmr (CCl_4) δ: 0.97 (s, 6H, *gem*-dimethyl) and 3.70 (s, 3H, —COO-CH_3).

2-Methoxycarbonyl-5,5-dimethyl-2-(m-methoxyphenethyl)-cyclohexanone (9)

(*a*) The procedure of Daum *et al.* (10) was followed. Potassium (11.7 g, 0.30 mol) was dissolved in 250 mL of dry *tert*-butanol. To this was added dropwise 50.6 g (0.03 mol) of the above ketoester (**7**) diluted with 100 mL of *tert*-butanol. An additional 100 mL of *tert*-butanol was added, followed by the addition of 2-(*m*-methoxyphenyl)-ethyl bromide (**8**) diluted with 100 mL of *tert*-butanol. The reaction mixture was refluxed with mechanical stirring for 80 h. The cooled reaction mixture was poured into ice-water. Ether was added and the organic layer was separated. The ether layer was washed with dilute (3 *N*) hydrochloric acid, saturated sodium bicarbonate solution, and brine. After drying over sodium sulphate, the solvent was removed *in vacuo* to leave a yellow oil. This oil was distilled under high vacuum; the first fraction (13.2 g) contained the starting ketoester **7** and *m*-methoxystyrene; the second fraction (10.2 g) which boiled at 63–83°C contained the ester and the bromide **8**; the third fraction that boiled at 83–85°C was chiefly the bromide **8**, the final fraction that boiled at 168–172°C (0.3 Torr) was collected (a yellow viscous oil, 27.2 g, 31%); ir (neat): 1734 (ester), and 1712 (carbonyl) cm^{-1}; nmr ($CDCl_3$) δ: 0.89 (s, 3H, C-5 CH_3), 1.03 (s, 3H, C-5 CH_3), 3.70 (s, 3H, —COOCH_3), 3.76 (s, 3H, —OCH_3), and 6.62–7.30 (m, 4H, aromatics); ms *m/e* (relative intensity): 318 (M^+, 6), 184 (33), 152 (21), 135 (27), 134 (100), and 121 (23). *Anal.* calcd. for $C_{19}H_{26}O_3$: C 75.46, H 8.67; found: C 75.32, H 8.58.

(*b*) Potassium (5.0 g, 0.13 mol) was dissolved in 200 mL of dry benzene containing 20 mL of *tert*-pentyl alcohol under reflux. To the solution was added 19.5 g (0.106 mol) of the keto ester **7** diluted with 50 mL of dry benzene while ca. 50 mL of benzene was being removed through a Dean-Stark trap. Then, a solution of *m*-methoxyphenylethyl tosylate (32.7 g, 0.107 mol) in 100 mL of benzene was added dropwise with stirring under reflux. Reflux was continued for 24 h. The cooled reaction mixture was poured into ice-water and benzene was added. The benzene layer was separated and the aqueous layer was extracted with benzene (×2). The combined benzene extracts were washed with water, dilute (3 *N*) hydrochloric acid, saturated sodium bicarbonate solution, and brine. The solvent was removed *in vacuo* to leave a yellow oil. This oil was chromatographed on silica gel. Elution with hexane – ethyl acetate (10:1) separated the starting ketoester **7** (7.1 g) and yielded 10.2 g (30%) of **9** as a yellow viscous oil.

7-Methoxy-10a-methoxycarbonyl-3,3-dimethyl-1,2,3,9,10,10a-hexahydrophenanthrene (10)

Compound **9** (10 g, 0.31 mol) and 2.5 g of *p*-toluenesulphonic acid in 400 mL of dry benzene were refluxed under nitrogen for 12 h. Upon cooling, the reaction mixture was passed through a short column packed with neutral aluminium oxide (Woelm). Concentration of the solution under reduced pressure yielded the cyclized material (**10**) (7.8 g, 83%) as a yellow solid. An analytical sample of **10** was obtained by recrystallization from hexane as colourless crystals, mp 74–75°C; ir (KBr): 1712 (ester) cm^{-1}; nmr ($CDCl_3$) δ: 1.05 (s, 3H, C-3 CH_3), 1.10 (s, 3H, C-3 CH_3), 3.54 (s, 3H, COOCH_3), 3.72 (s, 3H, OCH_3), 5.94 (s, 1H, C-4 H), and 6.50–7.57 (m, 3H, aromatic); ms *m/e* (relative intensity): 300 (M^+, 100), 285 (100), 241 (31), and 225 (42). *Anal.* calcd. for $C_{19}H_{24}O_3$: C 75.97, H 8.05; found: C 75.98, H 8.08.

7-Methoxy-10aβ-methoxycarbonyl-3,3-dimethyl-1,2,3,4,4aα,9,10,10a-octahydrophenanthrene (12)

Ester **10** (382 mg, 1.27 mmol) was hydrogenated over 70 mg of 10% Pd/C in 50 mL of toluene. After 12 h, palladium–carbon was removed by filtration through a pad of Celite and the solution was concentrated to yield 376 mg (98%) of the hydrogenated product (**12**) as a white powder. A sample was recrystallized from hexane – ethyl acetate (3:1), mp 91–92°C; ir (KBr): 1739 (ester) cm^{-1}; nmr ($CDCl_3$) δ: 1.02 (s, 6H, C-3 *gem*-dimethyl), 3.54 (s, 3H, COOCH_3), 3.75 (s, 3H, OCH_3), and 6.50–7.23 (m, 3H, aromatic); ms *m/e* (relative intensity): 302 (M^+, 100), 242 (100), 186 (19), and 171 (19). *Anal.* calcd. for $C_{19}H_{26}O_3$: C 75.46, H 8.67; found: C 75.48, H 8.60.

10aβ-Hydroxymethyl-7-methoxy-3,3-dimethyl-1,2,3,4,4aα,9,10,10a-octahydrophenanthrene (13)

A slurry of 100 mg (2.50 mmol) of lithium aluminium hydride in 40 mL of dry ether was stirred under nitrogen while the ester **12** (670 mg, 2.22 mmol) in 50 mL of dry ether was added dropwise. The mixture was then refluxed for 4 h. Excess lithium aluminum hydride was destroyed by adding saturated sodium sulphate solution. The resulting suspension was diluted with dilute (3 *N*) hydrochloric acid and the ether layer was separated. The ether layer was washed with water (×2) and dried over sodium sulphate. Removal of ether under reduced pressure gave 569 mg (94%) of the alcohol **13** as a white powder. Recrystallization twice from hexane – ethyl acetate (4:1) afforded a sample of analytical purity: mp 119–120°C; ir (Nujol): 3270 (hydroxyl) cm^{-1}; nmr ($CDCl_3$) δ: 1.04 (s, 3H, C-3 CH_3), 1.07 (s, 3H, C-3 CH_3), 3.20 (d, 1H, J = 11 Hz, C-10a CH_2—OH), 3.61 (d, 1 H, J = 11 Hz, C-10a—OH), 3.79 (s, 3H, OCH_3), and 6.60–7.14 (m, 3H, aromatic); ms *m/e* (relative intensity): 274 (M^+, 100), 243 (34), 173 (19), and 147 (21). *Anal.* calcd. for $C_{18}H_{26}O_2$: C 78.79, H 9.55; found: C 78.84, H 9.48.

10a-Hydroxymethyl-7-methoxy-3,3-dimethyl-1,2,3,9,10,10a-hexahydrophenanthrene (11)

A slurry of 352 mg (8.8 mmol) of lithium aluminium hydride in 50 mL of dry ether was stirred under nitrogen during addition of a solution containing 2.80 g (9.3 mmol) of the ester **10** in 50 mL of dry ether. After addition was completed, the mixture was refluxed for 4 h and stirred overnight at room temperature. Excess lithium aluminium hydride was destroyed by adding saturated sodium sulphate solution. The resulting suspension was diluted with dilute (3 *N*) hydrochloric acid. The organic layer was separated, then washed with sodium bicarbonate solution and brine. Drying over sodium sulphate and removal of solvent *in vacuo* gave 2.55 g of semi-solids. The solids were purified by column chromatography (silica gel, eluted with hexane – ethyl acetate) to afford 2.49 g (97%) of the title alcohol (**11**) as a white powder. The material was recrystallized from hexane to give a sample of analytical purity, mp 55–56°C; ir (KBr): 3400 cm^{-1}; nmr ($CDCl_3$) δ: 1.03 (s, 3H, C-3 CH_3), 1.07 (s, 3H, C-3 CH_3), 3.46 (s, 2H, C-10a —CH_2—OH), 3.76 (s, 3H, OCH_3), 5.84 (s, 1H, C-4 H), and 6.50–7.42 (m, 3H, aromatic). *Anal.* calcd. for $C_{18}H_{24}O_2$: C 79.37, H 8.88; found: C 79.41, H 8.90.

Catalytic Hydrogenation of 11

A solution of 550 mg (2.00 mmol) of the alcohol **11** in 50 mL of toluene was hydrogenated at room temperature over 50 mg of 10% Pd/C for 20 h. Palladium–carbon was removed by filtration through Celite. Concentration of the solvent provided 564 mg of a white solid. Some material was recrystallized to give a sample that melted at 59–61°C. The mass spectrum of the sample showed a molecular ion peak at *m/e* 274. The nmr spectrum of this solid showed a complex pattern of peaks at 3.10–3.70 which was analyzed to be composed of two pairs of doublets, and on this basis the product was found to be a mixture of **13** and **14**.

The hydrogenation was repeated in the following solvents: ethanol, ethanol – 10% aqueous sodium hydroxide, acetic acid, and acetonitrile. After work-up, the residue was examined by nmr. The *cis*- and *trans*-mixtures were obtained in these solvents except acetonitrile, in which the *cis*-product (**14**) was produced predominantly, but the time for hydrogenation of 30 mg of **11** was ca. 150 h.

10a-Carboxy-7-methoxy-3,3-dimethyl-1,2,3,9,10,10a-hexahydrophenanthrene (15)

Ester **10** (1.03 g, 4.44 mmol) in 70 mL of methoxyethanol was refluxed with 2 g (36 mmol) of potassium hydroxide for 48 h under nitrogen. The cooled reaction mixture was acidified with dilute (3 *N*) hydrochloric acid and extracted with ether. The ether extract was washed with water (×2) and brine, and dried over sodium sulphate. Removal of ether under reduced pressure gave 695 mg (71%) of acid **15**. A sample was recrystallized twice from ethanol to afford a white powder, mp 180°C (dec.); ir (KBr): 3300–2400, 1735, and 1690 (carboxylic acid) cm^{-1}; nmr ($CDCl_3$) δ: 1.03 (s, 3H, C-3 CH_3), 1.10 (s, 3H, C-3, CH_3), 3.75 (s, 3H, OCH_3), 5.90 (s, 1H, C-4 H), 6.45–7.50 (m, 3H, aromatic), and 7.91 (s, 1H, COO*H*); ms *m/e* (relative intensity): 286 (M^+, 64), 271 (100), and 241 (15). *Exact Mass* calcd. for $C_{18}H_{22}O_3$: 286.1569; found: 286.1524.

10aβ-Carboxy-7-methoxy-3,3-dimethyl-1,2,3,4,4aβ,9,10,10a-octahydrophenanthrene (16)

The procedure of Thompson *et al.* (6) was followed. A solution of 300 mg (1.05 mmol) of the acid (**15**) in 20 mL of dry 1:1 tetrahydrofuran–ether was added to a stirred solution of 100 mg (19 mg-atoms) of lithium in 60 mL of distilled liquid ammonia. After 30 min the blue reaction mixture was quenched by adding solid ammonium chloride, and ammonia was allowed to evaporate. To this, dilute (3 *N*) hydrochloric acid was added and the organic substance was extracted with ether. The ether extract was washed with water (×2) and brine, and dried over sodium sulphate. Removal of the solvent under reduced pressure provided 274 mg of crude solid which was recrystallized from ethanol to give 222 mg (74%) of the title acid **16** as fine needles. The material was further recrystallized from ethanol to afford a sample for combustion analysis, mp 175–182°C with partial sublimation; ir (KBr): 3450, 3200, and 1723 (carboxylic acid) cm^{-1}; nmr ($CDCl_3$) δ: 0.90 (s, 3H, C-3 CH_3), 1.03 (s, 3H, C-3 CH_3), 3.74 (s, 3H, OCH_3), and 6.50–7.06 (m, 3H, aromatic); ms *m/e*: 288 (M^+, 100), 242 (63), and 186 (11). *Anal.* calcd. for $C_{18}H_{24}O_3$: C 74.97, H 8.39; found: C 74.79, H 8.46.

10aβ-Hydroxymethyl-7-methoxy-3,3-dimethyl-1,2,3,4,4aβ,9,10,10a-octahydrophenanthrene (14)

A slurry of 68 mg (1.7 mmol) of lithium aluminium hydride in 20 mL of dry tetrahydrofuran was stirred under nitrogen during dropwise addition of a solution containing 555 mg (1.9 mmol) of the acid (**16**) in 50 mL of dry THF. Upon completion of addition, the mixture was refluxed for 2 h. The cooled reaction mixture was titrated with saturated sodium sulphate solution and the solids formed were removed by filtration through Celite. The filtered solution was dried over sodium sulphate and the solvent was removed at reduced pressure to leave 498 mg (96%) of the alcohol (**14**) as an amorphous solid. Two recrystallizations from hexane afforded an analytical sample, mp 97–98°C; ir (KBr): 3350 (hydroxyl) cm^{-1}; nmr ($CDCl_3$) δ: 0.87 (s, 3H, C-3 CH_3), 1.00 (s, 3H, C-3 CH_3), 3.30 (d, 1H, J = 11 Hz, —CH_2—OH), 3.42 (d, 1H, J = 11 Hz, —CH_2—OH), 3.74 (s, 3H, OCH_3), and 6.54–6.96 (m, 3H, aromatic); ms *m/e* (relative intensity): 274 (M^+, 100), 256 (22), and 243 (22). *Anal.* calcd. for $C_{18}H_{26}O_2$: C 78.79, H 9.55; found: C 78.80, H 9.59.

10aβ-Formyl-7-methoxy-3,3-dimethyl-1,2,3,4,4aα,9,10,10a-octahydrophenanthrene (21)

Pyridinium chlorochromate (213 mg, 0.98 mmol) was suspended in 20 mL of dry methylene chloride, and the *trans*-alcohol **13** (181 mg, 0.66 mmol) was added rapidly at room temperature. The reaction mixture was stirred for 3 h. The resulting solution was diluted with ether, the solvent was decanted from the black mass, and the mass was washed with ether. The combined ether solutions were passed through a Florisil column and the solvent was removed at reduced pressure to give 174 mg (97%) of the aldehyde **21** as fine white crystals. Recrystallization of the material from aqueous methanol afforded a sample of analytical purity as fine needles, mp 86–87°C; ir (KBr) (CCl_4): 1714 (aldehyde) cm^{-1}; nmr ($CDCl_3$) δ: 1.03 (s, 6H, C-3 *gem*-dimethyl), 3.74 (s, 3H, OCH_3), 6.54–7.30 (m, 3H, aromatic), and 9.57 (s, 1H, aldehyde). *Anal.* calcd. for $C_{18}H_{24}O_2$: C 79.37, H 8.88; found: C 79.40, H 8.86.

7-Hydroxy-3,3,10aβ-trimethyl-1,2,3,4,4aα,9,10,10a-octahydrophenanthrene (22) and 7-Methoxy-3,3,10aβ-trimethyl-1,2,3,4,4aα,9,10,10a-octahydrophenanthrene (23)

Aldehyde **21** (1.10 g, 4.05 mmol), 50 mL of distilled diethylene glycol, and 7.5 mL (0.15 mol) of hydrazine hydrate were warmed to 120°C over a 1 h period and maintained at this temperature for 2 h. Upon cooling, 2.8 g (0.05 mol) of potassium hydroxide was added, and the mixture was brought to boiling point with concurrent removal of water by distillation over a period of 3 h. Reflux was continued for a further 6 h. After cooling, the mixture was acidified with dilute hydrochloric acid (3 *N*) and extracted with ether. The ether extract was washed with water (×5), then brine, and dried over magnesium sulphate. Concentration at reduced pressure left 894 mg of crystalline material that showed two spots on tlc. Some material (200 mg) was chromatographed on preparative tlc (hexane – 25% ethyl acetate) to separate 98 mg of less polar substance (R_f = 0.84, hexane – 10% ethyl acetate) and 75 mg of more polar substance (R_f = 0.64).

The more polar substance was recrystallized from methanol (twice) to afford a sample of the phenol **22** as an amorphous solid, mp 92–94°C; ir (CCl_4): 3640 (phenol) and 1510 (aromatic) cm^{-1}; nmr ($CDCl_3$) δ: 0.65 (s, 3H, C-10a CH_3), 0.98 (s, 3H, C-3 CH_3), 1.03 (s, 3H, C-3 CH_3), 5.74 (br, 1H, —O*H*), and 6.33–7.00 (m, 3H, aromatic). *Anal.* calcd. for $C_{17}H_{24}O$: C 83.55, H 9.90; found: C 83.49, H 9.90.

Recrystallization of the less polar substance from methylene chloride – methanol (1:3) gave a sample of the ether **23** as prisms with a yellow tinge, mp 43–44°C; ir (KBr): 1612 and 1501 (aromatic ring) cm^{-1}; uv_{max} (CH_3OH): 218 (ε = 7940), 278 (2340), and 287 nm (2060); nmr ($CDCl_3$) δ: 0.67 (s, 3H, C-10a CH_3), 0.97 (s, 3H, C-3 CH_3), 3.76 (s, 3H, OCH_3), and 6.55–7.20 (m, 3H, aromatic); ms *m/e* (relative intensity): 258 (M^+, 100). *Anal.* calcd. for $C_{18}H_{26}O$: C 83.67, H 10.14; found: C 82.60, H 10.06.

Phenol **22** was methylated according to the method of Stoochnoff and Benoiton (11). Thus, the phenol (50 mg, 0.2 mmol) was dissolved in 50 mL of dry tetrahydrofuran containing 10 mg (0.4 mmol) of suspended sodium hydride (98% dry). To this, was added 230 mg (0.9 mmol) of methyl iodide and the mixture was stirred at room temperature overnight. Water was added to destroy the remaining sodium hydride and the organic substance was extracted with ether. The ether extract was washed with water and brine, and dried over magnesium sulphate. Removal of the solvent at reduced pressure left 45 mg (85%) of chromatographically pure ether **23**.

Similarly, the remaining mixtures of the phenol **22** and the ether **23** were treated with 100 mg (4.2 mmol) of sodium hydride (98% dry) and 2.4 g (10 mmol) of methyl iodide. The solution was left at room temperature overnight with stirring. Work-up as above gave 667 mg of ether **23**. The combined yield of the two step WolfKishner methylation was 75%.

10aβ-Formyl-7-methoxy-3,3-dimethyl-1,2,3,4,4aβ,9,10,10a-octahydrophenanthrene (24)

Pyridinium chlorochromate (1.47 g, 6.80 mmol) was suspended in 70 mL of dry methylene chloride, and the *cis*-alcohol **14** (1.25 g, 4.53 mmol) was added quickly. The reaction mixture was stirred at room temperature for 5 h. The resulting black solution was diluted with ether, the solvent was decanted, and the black solid was washed with ether. The combined ether solutions were passed through a Florisil column and the solvent was removed under reduced pressure to leave 1.19 g (96%) of the aldehyde **24**. Recrystallization of the material twice from aqueous methanol afforded a sample of analytical purity as fine needles with a yellow tinge, mp 100–102°C; ir (CCl_4): 1718 (aldehyde) cm^{-1}; nmr ($CDCl_3$) δ: 0.93 (s, 3H, C-3 CH_3), 1.03 (s, 3H, C-3 CH_3), 3.74 (s, 3H, OCH_3), 6.50–7.10 (m, 3H, aromatic), and 9.40 (s, 1H, aldehyde proton). *Anal.* calcd. for $C_{18}H_{24}O_2$: C 79.37, H 8.88; found: C 79.30, H 8.86.

7-Methoxy-3,3,10aβ-trimethyl-1,2,3,4,4aβ,9,10,10a-octahydrophenanthrene (6)

Aldehyde **24** (2.88 g, 10.5 mmol), 70 mL of distilled diethylene glycol, and 25 mL (0.49 mol) of hydrazine hydrate (100%) were warmed to 100°C over a 2 h period and maintained at this temperature for 2 h. Upon cooling, potassium hydroxide (5.6 g, 0.10 mol) was added, and the mixture was boiled with concurrent removal of water by distillation over a period of 3 h. The solution was refluxed for a further 12 h. After cooling, the mixture was acidified with dilute (3 *N*) hydrochloric acid and extracted with ether. The ether extract was washed with water and brine, and dried over magnesium sulphate. Concentration at reduced pressure gave 2.38 g of crystalline material. This material was methylated in 50 mL of dry tetrahydrofuran using sodium hydride (200 mg, 8.33 mmol) and methyl iodide (4.00 g, 16.5 mmol). Work-up with ether afforded ether **6** (2.02 g, 75%). A sample of the material was twice recrystallized from methanol to give the ether as colourless needles, mp 65–66°C; ir (KBr): 1600 and 1510 (aromatic ring) cm^{-1}; uv_{max} (CH_3OH): 220 (ε = 5210), 280 (1740), and 285 (1610) nm; nmr ($CDCl_3$) δ: 0.89 (s, 6H, C-3 *gem*-dimethyl), 1.00 (s, 3H, C-10a CH_3), 3.76 (s, 3H, OCH_3), and 6.57–7.06 (m, 3H, aromatic); ms *m/e* (relative intensity): 258 (M^+, 100). *Anal.* calcd. for $C_{18}H_{26}O$: C 83.67, H 10.14; found: C 83.55, H 10.15.

3,3,10aβ-Trimethyl-1,2,3,4,4aβ,5,8,9,10,10a-decahydrophenanthren-7(6H)-one (25)

This procedure of Wiesner *et al.* (12) was followed. A solution of 600 mg (2.32 mmol) of the *cis*-ether (**6**) in 50 mL of dry 1:1 tetrahydrofuran – *tert*-butanol was added over 15 min to a stirred solution of lithium (320 mg, 45.7 mg-atoms) in distilled ammonia (ca. 100 mL). The mixture was stirred at acetone – Dry Ice temperature for 1 h. The blue reaction mixture was quenched by adding absolute methanol, and ammonia was allowed to evaporate. The residue was dissolved in water (100 mL) and extracted with ether (×4). The ether extract was dried by passing through a pad of magnesium sulphate and concentrated to afford a colourless oil. This oil was immediately dissolved in cold absolute ethanol (100 mL) and treated with 1 *M* aqueous oxalic acid solution (30 mL) for 30 min at 0°C. The mixture was neutralized by dropwise addition of saturated sodium carbonate solution. Normal work-up with ether gave 512 mg (89%) of the ketone **25** as a yellow oil which solidified upon refrigeration, but melted at room temperature. The material was distilled under vacuum to afford a colourless oil, bp 95–100°C/1.0 Torr; ir (neat): 1718 (carbonyl) cm^{-1}; uv_{max} (CH_3OH): transparent beyond 210 nm; nmr ($CDCl_3$) δ: 0.87 (s, 3H, C-10a CH_3) and 0.90 (s, 6H, C-3 *gem*-dimethyl); ms *m/e* (relative intensity): 246 (M^+, 100), 231 (100), 217 (86), 105 (38), 91 (41), 79 (31), 69 (31), and 55 (34). *Anal.* calcd. for $C_{17}H_{26}O$: C 82.87, H 10.64; found: C 82.90, H 10.68.

The iodination of azetidinone thio compounds. A convenient synthesis of 2-iodomethylpenams

RONALD G. MICETICH,[1] ROBERT A. FORTIER, AND PETER WOLFERT
Raylo Chemicals Limited, 8045 Argyll Road, Edmonton, Alta., Canada T6C 4A9

Received November 21, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

RONALD G. MICETICH, ROBERT A. FORTIER, and PETER WOLFERT. Can. J. Chem. **59**, 1018 (1981).

A practical method for the synthesis of 2β-iodomethyl-2α-methylpenams is described. These compounds undergo facile isomerization to the 3β-iodo-3α-methylcephams. A preliminary kinetic study of these reactions is reported. The isomerization of the 2β-iodomethylpenams to the 3β-iodocephams can be prevented by oxidation to the sulfoxide.

RONALD G. MICETICH, ROBERT A. FORTIER et PETER WOLFERT. Can. J. Chem. **59**, 1018 (1981).

On décrit une méthode pratique de synthèse des iodométhyl-2β méthyl-2α pénames. Ces composés s'isomérisent facilement en iodo-3β méthyl-3α céphames. On rapporte une étude cinétique préliminaire de ces réactions. L'isomérisation des iodométhyl-2β pénames en iodo-3β céphames peut être évitée par le biais d'une oxydation en sulfoxyde.

[Traduit par le journal]

The conversion of thiazolineazetidinones, **1**, and azetidinone disulfides, **2**, to 3-iodocephams, **4**, in high yields, with *trace* amounts of the corresponding 2-iodomethylpenams, **5**, has been reported (1, 2). Further studies have shown that with appropriate changes in reaction conditions the 2-iodomethylpenams, **5**, become the *major* products.

Compounds **1**, in a suitable organic solvent, react with iodine in the presence of moisture to give a mixture of **4** and **5**. The overall yield and the relative ratio of **4** and **5** depend on factors such as the purity of **1**, the nature of the group R, the presence or absence of air or oxygen, and on the reaction time. Convenient solvents for this reaction are methylene chloride, chloroform, or toluene. A reaction using purified (chromatographed and recrystallized from ether to constant mp, 85°C) **1***a*, showed only about 20% (from ^{1}Hmr spectral analysis) overall reaction after 7 h. By comparison, crude **1***a*, under otherwise identical conditions, underwent 90% conversion after 5 h. The iodination of **1** proceeded smoothly, under the conditions used, when R was phenoxymethyl (reactions employing commercial penicillin V as precursor), but when R was phenylmethyl (penicillin G as precursor), this reaction was slow and incomplete.[2] The reaction was catalyzed by air or oxygen, or by the presence of metal salts such as ferric chloride.

The reaction time is one of the most important factors in determining the yield of products and the ratio of **5** to **4** formed. A typical reaction (see Experimental) was monitored by removing aliquots from the reaction mixture at suitable intervals of time, and after work-up, analyzing the resulting product by its ^{1}Hmr spectrum in $CDCl_3$. The 3-iodocepham, **4**, C(3)—CH_3 singlet at about δ 1.99, the thiazolineazetidinone, **1**, CH_3 singlet at about δ 1.72, and the 2-iodomethylpenam **5**, C(2)—CH_3 singlet at about δ 1.38, are well separated, so that the integration of these signals provides a convenient measure of these three compounds in the product (no other compounds being detected in the reaction).

The results of this kinetic study can be summarized as follows.

1. The concentration of **1** drops rapidly to about 18% of its original value after 2 h, and then tapers off slowly to 15% in 5 h, 3.5% in 22 h, and 1.5% in 30 h.

2. The concentration of the 2-iodomethylpenam, **5**, rises rapidly and reaches a maximum of about 80% of the total material present in 1 to 3 h, and thereafter drops to about 12% in 22 h, and 9% in 30 h.

3. The concentration of the 3-iodocepham, **4**, increases fairly slowly to about 40% in 5 h, 84.5% in 22 h, and 89.5% in 30 h.

It is evident that the 2-iodomethylpenam, **5**, is the initial product of the reaction and is then slowly converted to the 3-iodocepham, **4**, via the thiiran-

ium intermediate, **3**.[3] Compounds **5** were in fact converted to **4** on storage (in solution or even in the solid state).[3] The concentration of **5***a* in a solid sample left at 23°C changed from 71% to 35% in 4 days, and to 14% in 2 weeks. Purification of **5** could be effected by rapid chromatography using silica gel, the compounds being obtained as amorphous white powders[4] which contained trace amounts of **4** (the amount of **4** increasing with time). The configuration of C(2) in **5** is as indicated.[5]

The reactions of compounds **2** with iodine were similar, in that the 2-iodomethylpenams, **5**, were the initial products and then underwent transformation to the 3-iodocephams, **4**.[3,6] These reactions did *not* require moisture, and proceeded easily and reproducibly at temperatures of about 25°C. A further advantage of this alternate route to **5** is that the reactions were independent of the nature of R. The ^{1}Hmr ($CDCl_3$) spectra (3) of the 2-iodomethylpenams, **5**, showed sharp singlets at δ 1.38 (3H, C(2)—CH_3) and 3.80 (2H, C(2)—CH_2I), while the 3-iodocephams, **4**, showed a singlet at δ 1.99 (3H, C(3)—CH_3) and a quartet (J = 14 Hz) at about 2.80 (2H, C(2)—CH_2).

Oxidation of **5** by peracids produced the 2β-iodomethyl-2α-methylpenicillin-1β-sulfoxides, **6**,[5] which are stable, since the formation of the thiiranium intermediate is now prevented. These compounds were purified by gradient elution chromatography on silica gel using methylene chloride – ether as eluant and were obtained as off-white amorphous solids[4] in over 70% yield (after chromatography) from **1**. The ^{1}Hmr ($CDCl_3$) spectra were, for **5***a*, δ: 1.00 (s, 3H, C(2)—CH_3), 3.77 (q, J = 10 Hz, 2H, C(2)—CH_2I), 4.5 (s, 2H, —OCH_2CO), 4.88 (s, 1H, C(3)—*H*), 4.93 (d, 1H, C(5)—*H*), 6.03 (dd, 1H, C(6)—*H*), 6.8 to 7.4 (m, 16H, $3C_6H_5$ and $CH\phi_2$), 8.10 (d, 1H, N*H*); for **5***b*, δ: 1.50 (s, 3H, C(2)—CH_3), 3.85 (s, 2H, C(2)—CH_2I), 4.50 (s, 2H, OCH_2CO), 4.7 to 5.2 (m, 4H, CH_2CCl_3, C(3)—*H*, and C(5)—*H*), 6.0 (dd, 1H, C(6)—*H*), 6.8 to 7.35 (m, 5H, C_6H_5), and 8.15 (d, 1H, N*H*).

[3]S. Kukolja *et al.* (see ref. 6 and earlier papers) have discussed the mechanism and stereochemistry of similar reactions involving thiiranium ions, and have also noted the spontaneous rearrangement of a 2-chloromethylpenam to a 3-chlorocepham.

[4]The analysis (elemental or high resolution mass spectral) of all new compounds described were within acceptable limits.

[5]The configuration is assigned on the basis of mechanistic considerations, from analogy with related reactions to produce the 2-halomethylpenams from **2**,[6] and from the results of thermolytic reactions of 2-substituted methylpenam sulfoxides to be described in publications to follow.

[6]T. Kamiya *et al.* (7) describe the preparation of 2-chloromethylpenams and 2-bromomethylpenams by a similar process. These compounds are reported to be relatively stable in the solid state.

Compounds **5**, and their sulfoxides, **6**, were readily converted by bases such as DBN or DBU, or even by sodium acetate into the 2,3-methylene-penams, **7**, or their sulfoxides, **8**, respectively (4).

Experimental

A typical reaction to convert **1***a* to **6***a* is described.

Crude **1***a* (20 g, 40 mmol) and iodine (17 g, 66 mmol) were dissolved in CH_2Cl_2 (300 mL) and stirred vigorously with water (300 mL) that had been previously saturated with air, the reaction being done with free access to air. After 35 min, the organic layer was separated and shaken with aqueous sodium thiosulfate (twice), and brine, and then dried ($MgSO_4$). (If **5** is required, concentration and rapid chromatography on silica gel will provide **5**. A ^{1}Hmr spectrum on the residue from an aliquot of the solution obtained above indicated a 78% overall yield of **5**.) The filtrate was cooled in an ice-bath and *m*-chloroperbenzoic acid (9.6 g of 85%, 48 mmol) added to the stirred solution. After 0.5 h at 0°C and 1 h at ambient temperature, the reaction mixture was extracted with aqueous sodium bicarbonate (twice), then brine, dried ($MgSO_4$), and concentrated to give 26.3 g (theoretical) of a yellow foam. Gradient elution chromatography on silica gel using methylene chloride to methylene chloride (20% ether) gave 18.6 g (71%) of **6***a*, as an off-white foam, and 4.6 g (17.5%) of the 3-iodocepham sulfoxide. Compound **6***a* precipitated from cold ether–hexane as an off-white amorphous powder with the ^{1}Hmr spectral characteristics reported above.

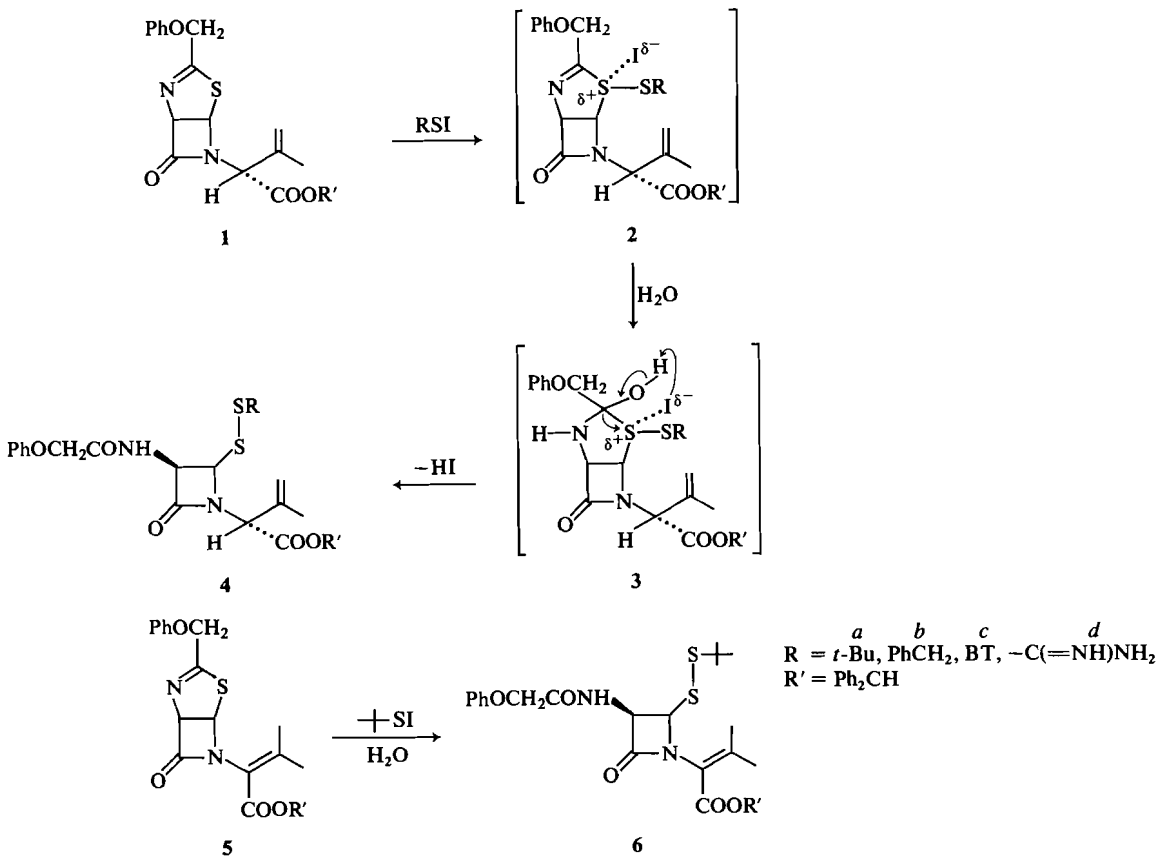

SCHEME 1

generates the thiosulfonium iodide, **2**, resulting in activation of the —C=N— bond to hydrolysis, **2** → **3** → **4**, which then reacts with excess iodine or sulfenyl iodide to form the 3-iodocepham as previously reported (1, 2).

In accordance with this suggested mechanism it is possible, by using the proper stoichiometry and reaction conditions (see Experimental), to prepare **4***a* (77%) and **4***b* (25%) by this reaction. Attempts to isolate **4***c* (BT = 2-benzothiazolyl) (4) and **4***d* (5), using 2-mercaptobenzothiazole and thiourea respectively as the sulfenyl iodide precursor, gave only trace amounts of these compounds. The products in these two cases were the 3-iodocepham and the thiazolineazetidinone, **1**. The data would suggest that the reactivity of the disulfide bond of **4** to iodination (and possibly other halogenation reactions) is dependent on the nature of the "R" group. When "R" is an aromatic (such as 2-benzothiazolyl), or an amidino (from thiourea) moiety, the disulfide bond in **4** is susceptible to halogenation, so that compounds **4** compete favourably with **1** in reactions with iodine or sulfenyl iodides. When "R" is an alkyl (such as *tert*-butyl), or an aralkyl (benzyl) group, the disulfide bond is deactivated and compounds **4***a* and **4***b* are hence isolated. In a recent patent, Underwood (6) has described the conversion of **1** to **4** utilizing isolated sulfenyl chlorides. In every example the "R" group was an alkyl moiety.

This novel method of opening the thiazoline ring can also be applied to other systems such as the α,β-double bond isomer, **5**. Reaction with *tert*-butylsulfenyl iodide (produced *in situ*) produces the *unsym*-azetidinone disulfide, **6**, in about 50% yield after chromatography.

Compounds **4** have been produced by the thermolysis of a penicillin sulfoxide in the presence of a suitable mercaptan. The sulfenic acid formed by heating the penicillin sulfoxide is trapped by the mercaptan to give **4**. Kamiya *et al.* (4) found that when stoichiometric amounts of heteroaromatic mercaptans such as 2-mercaptobenzothiazole were used high yields of **4** were obtained. Barton and co-workers (7) report that when excess of an alkylmercaptan was used the product was the α,β-

For personal use only.

unsaturated isomer of **4**, none of the β,γ-isomer, **4**, being isolated. In this case, double bond isomerization occurred during the reaction. The present method permits the preparation of the β,γ-isomers of these compounds. Compounds of type **4** are important synthetic intermediates for the preparation of modified cephalosporins (see for example refs. 4, 8, and 9).

Experimental

Iodine (2.60 g, 0.0102 mol) was added to an ice-cold, stirred solution of the thiazolineazetidinone, **1** (R′ = $CH\phi_2$, 5.0066 g, 0.0101 mol) and *tert*-butylmercaptan (1.2 mL, 0.0106 mol) in methylene chloride (40 mL) and the mixture stirred in an ice-bath for 30 min. Water (40 mL) was added, and stirring continued for 24 h at ambient temperature. The separated orange-red colored organic layer was extracted with aqueous sodium thiosulfate solution, then water, dried ($MgSO_4$), filtered, and concentrated to give 6.13 g of a green-yellow foam. Chromatography on silica gel using 5% ether in methylene chloride as eluant gave 4.7 g (77%) of **4***a* as a white foam; nmr ($CDCl_3$) spectrum, δ: 1.27 (s, 9H, $C(CH_3)_3$), 1.92 (s, 3H, —C—CH_3), 4.57 (s, 2H, —OCH_2—), 4.94 (d, 2H, —C=CH_2), 5.11 (s, 1H, —CHCOO—), 5.27 (d, 1H, C(4)—*H*), 5.52 and 5.67 (dd, 1H, C(3)—*H*), 6.87 to 7.49 (m, 17H, C_6H_5, $CHC\phi_2$, and N*H*).

When benzylmercaptan was used in place of *tert*-butylmercaptan, **4***b* (25%) was obtained as white foam after chromatography. The nmr ($CDCl_3$) spectrum, δ: 1.83 (s, 3H, —C—CH_3), 4.83 (s, 2H, $CH_2\phi$), 4.56 (s, 2H, —OCH_2—), 4.87 to 5.38 (m, 5H, —C=CH_2, —CHCOO, β-lactam *H*'s), 6.78 to 7.56 (m, 22H, C_6H_5, $CH\phi_2$, N*H*).

When *tert*-butyl mercaptan was reacted in a similar manner with compound **5** and iodine and water, **6** (50%) was obtained as a white foam after chromatography. The nmr ($CDCl_3$) spectrum, δ: 1.1 (s, 9H, $C(CH_3)_3$), 2.1 and 2.2 (ss, 6H, $=C(CH_3)_2$), 4.5 (s, 2H, OCH_2), 5.03 to 5.4 (m, 2H, β-lactam *H*'s), 6.8 to 7.4 (m, 16H, —$CH\phi_2$ and C_6H_5).

High resolution mass spectral data were consistent with the structures.

Hydrogen–deuterium exchange of heteroaromatics in neutral D_2O at elevated temperatures

Nick Henry Werstiuk and George Timmins

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 2, 1980

Nick Henry Werstiuk and George Timmins. Can. J. Chem. **59**, 1022 (1981).

Pyridine (**1**), 2-methylpyridine (**2**), 3-methylpyridine (**3**), 4-methylpyridine (**4**), and 1,10-phenanthroline undergo H—D exchange in neutral D_2O at elevated temperatures (180–300°C). With a suitable choice of temperature and reaction time it is possible to prepare selectively deuterated or perdeuterated substrates in good yield.

Nick Henry Werstiuk et George Timmins. Can. J. Chem. **59**, 1022 (1981).

La pyridine (**1**), la méthyl-2 pyridine (**2**), la méthyl-3 pyridine (**3**), la méthyl-4 pyridine (**4**) et la phénantroline-1,10 subissent un échange H—D dans du D_2O neutre à des températures élevées (180–300°C). En choisissant judicieusement la température et le temps de réaction, il est possible de préparer sélectivement et avec un excellent rendement des produits deutérés et perdeutérés.

Hydrogen–deuterium exchange of heteroaromatics in neutral D_2O at elevated temperatures

Nick Henry Werstiuk and George Timmins

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 2, 1980

Nick Henry Werstiuk and George Timmins. Can. J. Chem. **59**, 1022 (1981).

Pyridine (**1**), 2-methylpyridine (**2**), 3-methylpyridine (**3**), 4-methylpyridine (**4**), and 1,10-phenanthroline undergo H—D exchange in neutral D_2O at elevated temperatures (180–300°C). With a suitable choice of temperature and reaction time it is possible to prepare selectively deuterated or perdeuterated substrates in good yield.

Nick Henry Werstiuk et George Timmins. Can. J. Chem. **59**, 1022 (1981).

La pyridine (**1**), la méthyl-2 pyridine (**2**), la méthyl-3 pyridine (**3**), la méthyl-4 pyridine (**4**) et la phénantroline-1,10 subissent un échange H—D dans du D_2O neutre à des températures élevées (180–300°C). En choisissant judicieusement la température et le temps de réaction, il est possible de préparer sélectivement et avec un excellent rendement des produits deutérés et perdeutérés.

Digitoxigenin-3-alkyl ethers[1]

ROBERT GREENHOUSE
Syntex, S. A., Division de Investigacion, Apartado Postal 10-820, Mexico 10, D.F.
AND
JOSEPH M. MUCHOWSKI
Syntex Research, Institute of Organic Chemistry, 3401 Hillview Ave., Palo Alto, CA 94304, U.S.A.

Received November 4, 1980

ROBERT GREENHOUSE and JOSEPH M. MUCHOWSKI. Can. J. Chem. **59**, 1025 (1981).

The synthesis of the title compounds was accomplished by (*i*) boron trifluoride etherate catalysed alkylation of digitoxigenin with diazoalkanes, (*ii*) silver tetrafluoroborate assisted solvolysis of 3-desoxy-3α-iododigitoxigen **2***d* in an alcoholic medium, and (*iii*) *m*-chloroperbenzoic acid induced oxidative solvolytic displacement on the iodo compound **2***d* in the presence of alcohols. The third process was the most useful for the preparation of the mono ethers **2***e* and **2***f* of ethylene glycol and glycerol, respectively.

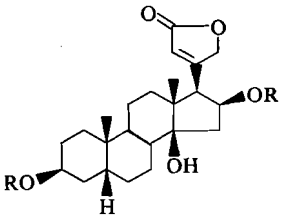
ROBERT GREENHOUSE et JOSEPH M. MUCHOWSKI. Can. J. Chem. **59**, 1025 (1981).

On a synthétisé les composés mentionnés dans le titre de la façon suivante: (*i*) une alkylation de la digitoxigénine par les diazoalcanes en présence de l'éthérate de trifluorure de bore, (*ii*) une solvolyse, assistée par le tétrafluoroborate d'argent, du désoxy-3 iodo-3*a* digitoxigène (**2***d*) en milieu alcoolique, et (*iii*) un déplacement solvolytique oxydant, induit par l'acide *m*-chloroperbenzoique, du composé iodé **2***d* en présence d'alcools. Cette trosième étape est la plus utile dans la préparation, par exemple, des mono éthers **2***e* et **2***f* de l'éthylène glycol et du glycérol.

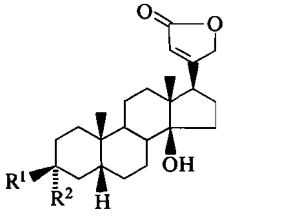
[Traduit par le journal]

Digitoxigenin-3-alkyl ethers were required in connection with our interest in modified cardenolides with a therapeutic ratio superior to that found in the cardiac glycosides currently in use.

Simple 3-alkyl ethers of digitoxigenin have heretofore not been described in the literature. Indeed, 3,16-di-*O*-methylgitoxigenin **1***b*, prepared by the boron trifluoride etherate catalysed alkylation of gitoxigenin **1***a* with diazomethane, appears to be the only example of a 3-alkoxy cardenolide which has been reported to date (1).



1*a* R = H
1*b* R = CH_3



2*a* R^1 = OH; R^2 = H
2*b* R^1 = OCH_3; R^2 = H
2*c* R^1 = $OCH_2C_6H_5$; R^2 = H
2*d* R^1 = H; R^2 = I
2*e* R^1 = $HOCH_2CH_2O$; R^2 = H
2*f* R^1 = $HOCH_2CHCH_2O$; R^2 = H
OH

The conversion of digitoxigenin **2***a* into the corresponding 3-alkyl ethers, a seemingly simple chemical operation, could not be accomplished using the more common methods of effecting such transformations. For example, the Williamson ether synthesis with various alkyl halides (methyl iodide, allyl bromide, benzyl bromide, or epibromohydrin) in the presence of a variety of bases (sodium hydride (2), barium oxide, sodium hydroxide under phase transfer conditions (3), thallium(I) ethoxide (4), proton sponge, 1,5-diazabicyclo[4.3.0]non-5-ene, 2,6-lutidine, etc.) in diverse solvents, consistently failed to give the expected products. In addition, the reaction of digitoxigenin with a large excess of an alkyl halide (see above), in the presence of silver tetrafluoroborate or mercuric perchlorate, in solvents such as acetonitrile, dimethylformamide, etc., did not occur in the desired sense. Of the large number of methods examined using digitoxigenin as the substrate, only the boron trifluoride etherate catalysed reaction of diazoalkanes (e.g. diazomethane and phenyldiazomethane) was successful, but this process did not take place with more complicated diazo compounds such as ethyl diazoacetate.

A much more useful point of embarkation for the synthesis of the desired compounds was 3-desoxy-3α-iododigitoxigenin **2***d*. This substance, which was prepared from digitoxigenin and triphenylphosphine diiodide (5),[2] gave the methyl ether **2***b*, in 55% yield, when solvolysed in methanol containing silver tetrafluoroborate.

[1]Contribution no. 566 from the Syntex Institute of Organic Chemistry.

[2]This compound, mp 175–177°C, was first prepared (and fully characterized) by E. Prisbe, Syntex Research, Palo Alto, CA.

Similarly, the l-glyceryl ether **2***f* was obtained in 25% and 28% yields when the reaction was effected in glycerol–tetrahydrofuran–dimethylformamide or glycerol – *tert*-butanol solutions, respectively. In all of these reactions an olefinic material, probably a mixture of the Δ^3- and Δ^4-isomers of anhydrodigitoxigenin, was formed as the principal by-product.

The most successful approach to the synthesis of the title compounds was based on the oxidative solvolytic displacement of hypervalent iodine (6) from the α-iodo compound **2***d*. Thus, the reaction of **2***d* with *m*-chloroperbenzoic acid in the presence of methanol, ethylene glycol, or glycerol, at room temperature, gave the ethers **2***b*, **2***e*, and **2***f*, respectively. Compound **2***f* was synthesized unambiguously, and in much better yield, by the acidic hydrolysis of the product derived from the oxidative displacement reaction using glycerol acetonide.

This ether synthesis obviously is of considerable utility. The mildness of the conditions under which the reaction is conducted suggest several other areas where it could be used advantageously.

The cardiotonic activities of the ethers of digitoxigen were evaluated in driven left atria of the guinea pig (7). In this assay compounds **2***e* and **2***f* were equipotent with digitoxigenin whereas the methyl and benzyl ethers, **2***b* and **2***c*, were ca. 0.3 and 0.1 times as active as digitoxigenin. The separation of cardiotonic activity and toxicity (arrhythmias, negative inotropic effects) was in no case, however, better than that observed for digitoxigenin.

Experimental

The melting points were determined in a Mel-Temp apparatus and are corrected. The infrared spectra were measured with a Perkin-Elmer Model 237 grating infrared spectrophotometer. The ultraviolet spectra were recorded with a Perkin-Elmer Model 402 ultraviolet visible spectrophotometer. The nmr spectra were taken with a Varian T-60 nmr spectrometer and are expressed as parts per million (δ) from internal tetramethylsilane. The mass spectra were measured with an Atlas CH-4 spectrometer. The high pressure liquid chromatographic separations were effected using a Dupont Model 841 apparatus equipped with a Waters Associates refractive index detector.

3β-Methoxy-14β-hydroxy-5β-card-20(22)-enolide 2(b)

(a) From Digitoxigenin and Diazomethane

Ethereal diazomethane (prepared from nitrosomethylurea (5 g)) was added in portions with stirring at 0°C to a solution of digitoxigenin (0.500 g) in dry dichloromethane (80 mL) containing boron trifluoride etherate (2 drops). If nitrogen evolution did not begin shortly after the addition of the first portion of the diazomethane solution an additional one drop of boron trifluoride etherate was added. When the addition was completed (ca. 50 min) the solution was stirred at 0°C until the yellow colour of the diazomethane had disappeared. The solution was diluted with an equal volume of ether and washed successively with 10% sodium carbonate solution and water; the organic phase was dried over sodium sulfate and evaporated *in vacuo*. The residue was subjected to thin layer chromatography (tlc) on silica gel (ethyl acetate – hexane, 2:3) to give a crystalline solid (0.345 g, 66%) which had mp 165.5°C after crystallization from dichloromethane–hexane; $[\alpha]_D$ +24.4° (*c* 0.242, $CHCl_3$), ir ($CHCl_3$) ν_{max}: 3520, 3490, 1792, 1749, 1625 cm^{-1}; uv (MeOH) λ_{max}: 223 nm (ε 12 600); nmr ($CDCl_3$)δ: 0.86 (s, 3H), 0.91 (s, 3H), 1.00–3.00(m, 23H), 3.23 (s, 3H), 3.45 (m, 1H), 4.88 (m, 2H), 5.83 (m, 1H); ms *m/e*: 388 (M^+). *Anal.* calcd. for $C_{24}H_{36}O_4$: C 74.19, H 9.34; found: C 73.90, H 8.96.

(b) By the Silver Tetrafluoroborate Assisted Solvolysis of 2d *in Methanol*

Silver tetrafluoroborate (0.025 g) was added to a stirred solution of the 3α-iodo compound **2***d* (0.050 g) in dry methanol (7 mL). After 40 min at room temperature the mixture was diluted with ether, the ether phase was washed with 5% sodium bicarbonate solution, dried, and evaporated. Thin-layer chromatographic analysis (silica gel, ethyl acetate – hexane, 3:7) of the residue showed that starting material was still present and therefore the mixture was resubmitted to the solvolysis conditions described above. After 2 h, the usual work-up gave a mixture which was subjected to tlc on silica gel using the above solvent system. A less polar product (0.018 g, presumably a mixture of Δ^{-3} and Δ^{-4} anhydrodigitoxigenin) and the more polar ether (0.023 g, 55%) were obtained. After crystallization from dichloromethane–hexane, it has mp 165–165.5°C, undepressed on admixture with a sample synthesized by method (*a*).

(c) By Oxidative Solvolysis of 2d

meta-Chloroperbenzoic acid (0.183 g) was added, in one portion, to a solution of the 3α-iodo compound **2***d* (0.200 g) in anhydrous methanol (15 mL) containing dry dichloromethane (5 mL). After 1 h at room temperature, the mixture was poured into ether (175 mL), the solution was washed with 5% sodium bicarbonate solution, dried, and evaporated *in vacuo*. The residue was filtered through a short column of silica gel using ether as the solvent. The mixture thus obtained was separated by high pressure liquid chromatography (hplc) on a 50 cm × ⅜ in. Lichrosorb column using ethyl acetate – hexane (1:3) as the developing solvent (flow rate 9 mL/min at 1100 psig). The major product (0.072 g, 45%) had a retention time of 26.5 min and was identical to the methyl ether obtained by methods (*a*) or (*b*).

3β-Benzyloxy-14β-hydroxy-5β-card-20(22)-enolide 2e

A solution of phenyldiazomethane, prepared from *N*(*N*^{1}-nitrosobenzylaminomethyl)benzamide (3.80 g) according to the method of Sekiya *et al.* (8), in dry dichloromethane (15 mL) was added in portions (0.5 mL) at 0°C, to a stirred solution of digitoxigenin (0.500 g) in dry dichloromethane (30 mL) containing boron trifluoride etherate solution (5 drops, prepared from boron trifluoride etherate (1 mL) and anhydrous dichloromethane (9 mL)). When the addition was completed, stirring was continued for an additional 10 min and the solution was diluted with dichloromethane. The mixture was washed with water, dried, and evaporated *in vacuo*. The oily residue was subjected to tlc on silica gel (ethyl acetate – hexane, 3:2) to give a solid (0.356 g, 57%). Crystallization of this material from hexane–dichloromethane followed by hexane–acetone gave the analytical specimen mp 145.5–146°C; $[\alpha]_D$ +24.6° (*c* 0.245, $CHCl_3$); ir (KBr) ν_{max}: 3530, 1785, 1755, 1740 sh, 1720 sh, 1627 cm^{-1}; uv (MeOH) λ_{max}: 219 nm (ε 15 100); nmr ($CDCl_3$) δ: 0.86 (s, 3H), 0.93 (s, 3H), 1.00–3.00 (m, 23H), 3.68 (m, 1H), 4.44 (s, 2H), 4.84 (m, 2H), 5.81 (s, 1H), 7.26 (s, 5H); ms *m/e*: 464 (M^+). *Anal.* calcd. for $C_{30}H_{40}O_4$: C 77.55, H 8.68; found: C 77.24, H 8.49.

3β-(2-Hydroxyethoxy)-14β-hydroxy-5β- card-20(22)-enolide **2e**

meta-Chloroperbenzoic acid (0.177 g) was added, in one portion, to a stirred solution of the iodo compound (0.196 g) in dioxan (9 mL) to which ethylene glycol (6 mL) had been added. After 1.5 h the reaction mixture was poured into water and the product was extracted with ether. The extract was washed successively with water and 5% sodium bicarbonate solution, dried over sodium sulfate, and evaporated *in vacuo*. The residue was subjected to tlc (hexane–acetone, 7:3) to give the major product (0.093 g, 55%) as a crystalline solid. Crystallization of this material from a small volume of ethyl acetate gave a powder, mp 174.5–182.5°C. On occasion, a solid, mp 165–166°C, was obtained, but the higher melting modification was the more stable one; $[\alpha]_D$ +25° (*c* 0.145, $CHCl_3$); ir ($CHCl_3$) ν_{max}: 3625, 3490, 1791, 1749, 1723 cm^{-1}, uv (MeOH) λ_{max}: 219 nm (ε 14 500); nmr ($CDCl_3$) δ: 0.90 (s, 3H), 0.94 (s, 3H), 1.15–2.96 (m, 24H), 3.40–3.80 (m, 5H), 4.90 (s, 2H), 5.87 (s, 1H). *Anal.* calcd. for $C_{25}H_{38}O_5$: C 71.74, H 9.15; found: C 71.74, H 9.20.

3β-(2,3-Dihydroxypropoxy)-14β-hydroxy 5β-card- 20(22)-enolide **2f**

meta-Chloroperbenzoic acid (0.900 g) was added, all at once, to a stirred solution of the iodo compound **2*d*** (1.00 g) in dry dichloromethane (25 mL) and glycerol acetonide (25 mL). After 1 h, methanol (100 mL) and 0.1 *N* sulfuric acid (50 mL) were added and the mixture was stirred for 3.25 h. The mixture was made neutral by the addition of solid sodium bicarbonate and was then concentrated *in vacuo* to remove most of the methanol. The mixture thus obtained was partitioned between water and ethyl acetate. The organic phase was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue (1.31 g) was taken up in dichloromethane (25 mL) and applied to a column of silica gel (50 g). Elution with ether (500 mL) removed nonpolar material and elution with ethyl acetate (500 mL) removed the partially purified product. This material was purified by hplc in the manner described above using ethyl acetate – hexane (8:1) as the eluting solvent at a flow rate of 12 mL/min at 1500 psig. The pure material (0.310 g, 36%), presumably a mixture of stereoisomers, on crystallization from ethyl acetate had mp 197°C; $[\alpha]_D$ +22.3 (*c* 0.274, $CHCl_3$); ir (KBr) ν_{max}: 3420, 1775, 1747, 1615 cm^{-1}; uv (MeOH) λ_{max}: 220 nm (ε 14 800); nmr ($CDCl_3$)δ: 0.88 (s, 3H), 0.93 (s, 3H), 1.00–3.00 (m, 25H), 3.66 (m, 6H), 4.88 (m, 2H), 5.85 (s, 1H); ms *m/e*: 430 ($M^+ - H_2O$). *Anal.* calcd. for $C_{26}H_{30}O_6$: C 69.61, H 8.99; found: C 69.47. H 8.96.

Lignin and related compounds. VIII. Lignin monomers and dimers from hydrogenolysis of aspen poplar wood using rhodium-on-charcoal catalyst

KENICHI SUDO,[1] DONALD J. MULLORD, AND JAMES M. PEPPER

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received October 14, 1980

KENICHI SUDO, DONALD J. MULLORD, and JAMES M. PEPPER. Can. J. Chem. **59**, 1028 (1981).

Aspen poplar wood meal has been subjected to catalytic hydrogenolysis in dioxane–water (9:1) at 500 psig initial pressure of hydrogen over a 5% rhodium-on-charcoal catalyst for five hours at 195 ± 5°C. The resulting chloroform-soluble lignin degradation products were separated by cellulose and silica gel column chromatography. The following compounds were isolated and identified: 4-hydroxybenzoic acid (**5**), 1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanone (propiosyringone) (**6**), 2,2′-dihydroxy-3,3′-dimethoxy-5,5′-dipropylbiphenyl (**7**), 2,3-bis(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol (**11**), and a mixture of 3-(4-hydroxy-3,5-dimethoxyphenyl)-2-(4-hydroxy-3-methoxyphenyl)-1-propanol (**9**) and 3-(4-hydroxy-3-methoxyphenyl)-2-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol (**10**).

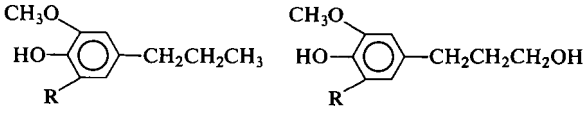
KENICHI SUDO, DONALD J. MULLORD et JAMES M. PEPPER. Can. J. Chem. **59**, 1028 (1981).

On a soumis de la sciure de bois de peuplier en suspension dans un mélange de dioxanne–eau (9:1) à une hydrogénolyse catalytique effectuée en utilisant une pression initiale d'hydrogène de 500 psig, du rhodium sur charbon à 5% comme catalyseur et une température de 195 ± 5°C pendant 5 heures. On a fait appel à la chromatographie sur colonne de cellulose et de silice pour séparér les produits de dégradation de la lignine qui sont solubles dans le chloroforme. On a isolé et identifié les composés suivants: l'acide hydroxy-4 benzoique (**5**), la (hydroxy-4 diméthoxy-3,5 phényl)-1 propanone-1 (propiosyringone) (**6**), le dihydroxy-2,2′ diméthoxy-3,3′ dipropyl-5,5′ biphényle (**7**), le bis(hydroxy-4 diméthoxy-3,5 phényl)-2,3 propanol-1 (**11**) et un mélange des (hydroxy-4 diméthoxy-3,5 phényl)-3 (hydroxy-4 méthoxy-3 phényl)-2 propanol-1 (**9**) et (hydroxy-4 méthoxy-3 phényl)-3 (hydroxy-4 diméthoxy-3,5 phényl)-2 propanol-1 (**10**).

[Traduit par le journal]

Introduction

In earlier publications (1, 2) the suitability of using a 5% rhodium-on-charcoal catalyst for the hydrogenolysis of wood was described. From the chloroform-soluble fractions high yields of the following monomeric lignin degradation products were obtained: compounds **1** and **3** from spruce wood and compounds **1–4** from aspen wood.



1 R = H
2 R = OCH_3

3 R = H
4 R = OCH_3

At that time attention was drawn to the significance of such a major potential source of phenolic chemicals. However, by the same procedure, other monomeric and oligomeric lignin products, whose identification would add to the knowledge of lignin structure, are produced in lesser amounts. We wish to report the isolation and characterization of compounds **5**, **6**, **7**, **11**, and a mixture of **9** and **10**.

Discussion

The same procedure for wood hydrogenolysis and lignin extraction as reported earlier (1, 2) was used but with a dioxane–water ratio of 9:1 instead of 1:1. Under these conditions only 75.5% of the original lignin was isolated as a chloroform-soluble fraction as compared to complete extraction in the earlier experiments. Under these modified conditions some selective bond cleavage may have occurred as is reflected in the nature of the isolated products. The chloroform extract was separated on a silica gel column using cyclohexane – ethyl acetate as the eluant, initially in a 3:1 ratio but with gradually increasing proportions of ethyl acetate

until a ratio of 1:1 was attained. A final elution (fraction P) was made using acetone. By this process, starting from 400 g of wood meal, the chloroform-soluble lignin degradation products (51.6 g) were divided among sixteen fractions (A–P) with recoveries of 0.259, 18.7, 1.62, 1.39, 3.20, 1.28, 1.24, 2.18, 0.687, 0.576, 0.796, 1.08, 1.91, 0.360, 0.990, and 8.61 g, respectively, for a total of 44.9 g (87%). Fraction B contained the monomeric lignin degradation products (**1–4**) whose isolation and characterization had been studied earlier (1, 2). Each other fraction was further separated using silica gel and/or cellulose column chromatography. Only from C, D, E, J, K, L, M, and P were amounts of pure compounds obtained that were adequate for characterization. Fractions C, D, and L are discussed herein; the others will be reported later. 4-Hydroxybenzoic acid (**5**) and 1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanone (**6**) isolated from fraction D, and 2,2′-dihydroxy-3,3′-dimethoxy-5,5′-dipropylbiphenyl (**7**) from fraction C were each identified by ir, ms, and by comparison with an authentic sample. Aspen lignin has been reported to contain large amounts of 4-hydroxybenzoate groups (3) so it is not surprising to find **5** in the products of this reaction. The isolation of **6** is more unusual under the hydrogenation conditions. It represents evidence for either the presence of an α-carbonyl group in the protolignin or possibly for the generation of 1-(4-hydroxy-3,5-dimethoxyphenyl)-1,2-propanediol (by alkyl – alkyl ether or glycosidic bond cleavage), followed by dehydration and tautomerization to give **6**. Considerable evidence is available for the 5–5 biphenyl linkage in lignin (3) and compound **7** was first isolated by Nahum in 1965 (4).

All available evidence suggests that a chromatographically "pure" substance obtained from fraction L was a mixture of compounds 3-(4-hydroxy-3,5-dimethoxyphenyl)-2-(4-hydroxy-3-methoxyphenyl)-1-propanol (**9**) and 3-(4-hydroxy-3-methoxyphenyl)-2-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol (**10**).[2] The mass spectrum showed

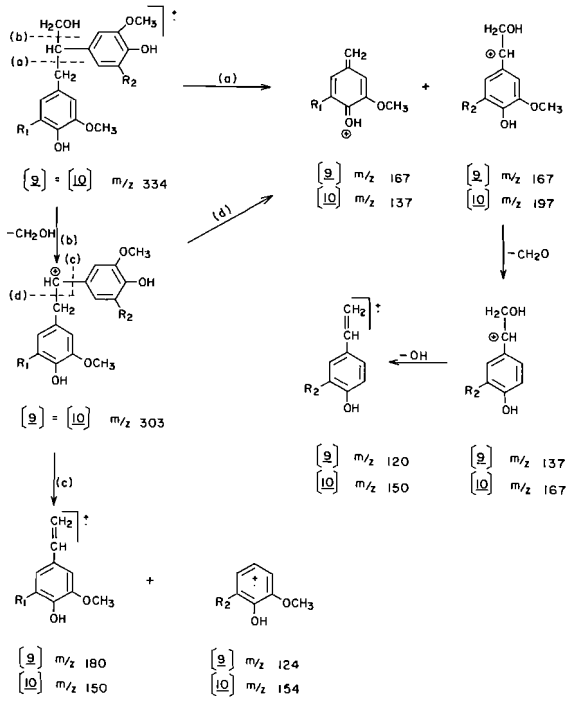

FIG. 1. Suggested fragmentation pattern of compounds **9** and **10**.

the molecular ion peak at *m/z* 334, a prominent base peak at *m/z* 167, and other main peaks at *m/z* 303, 197, 180, 167, 150, 137, and 122. The suggested fragmentation pattern as given in Fig. 1 shows that all the main peaks can only be accounted for on the basis of a mixture of **9** and **10**. Mass spectral patterns of pure **8** and **11** as reported by Sakakibara (5, 6), if considered additively, show a similar fragmentation pattern with the exception of the molecular ion peaks. Further support for the composition of the isolated fraction was provided by an examination of the ^{1}Hmr spectrum (Fig. 2) of the acetylated product and its comparison with the separate ^{1}Hmr spectra of compounds **8** and **11** as reported by Sakakibara and co-workers (5, 6). By this comparison the following assignments can be made: δ: 2.02 (s, 3H, alc-OAc), 2.28 (s, 3H, aryl-OAc), 2.29 (s, 3H, aryl-OAc), 2.70–3.02 (m, 2H, C_α—H), 3.02–3.33 (m, 1H, C_β—H), 3.69(s) and 3.74(s) (9H, aryl-OCH_3), 4.22 (d, 2H, C_α—H, J = 6.5 Hz), 6.17(s) and 6.28(s), (2H, aryl-H (syringyl)), and 6.40–7.03 (m, 3H, aryl-H (guaiacyl)). By comparing the relative peak areas of the two singlets at δ 6.17 and 6.28, corresponding to the syringyl ring protons, it was determined that the relative abundance of **9** to **10** was in the approximate molar ratio of 45:55.

[2]In earlier experiments (DJM) part of the dimeric lignin fraction from a Rh-C catalyzed hydrogenolysis of aspen poplar was converted into the trimethylsilyl ethers and separated on a 6 ft, 1/8 in. od stainless steel column packed with 15% SE-30 on Chromosorb W (AW-SMCS treated, 100/120 mesh) and temperature programmed from 200–300°C at 4°/min. Three fractions were collected at retention times of 18.5, 20.5, and 22.6 min. Mass spectral analysis showed molecular ion peaks at *m/z* 520, 550, and 580, respectively. Analysis of these spectra indicated that these fractions were the trimethylsilyl ethers of **8**, of a mixture of **9** and **10**, and of **11**, respectively.

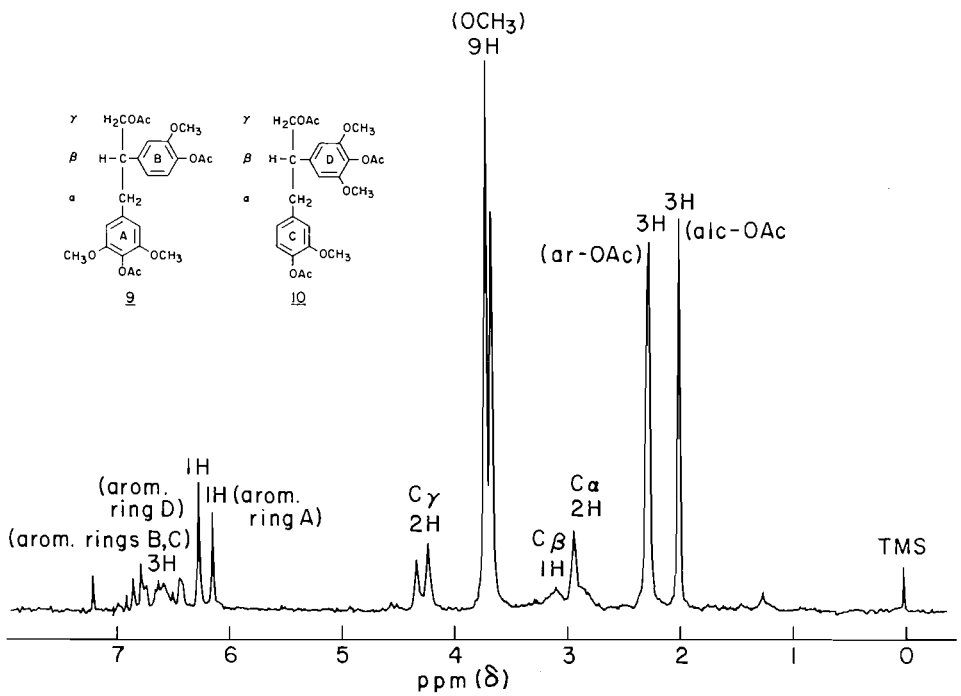

FIG. 2. ^{1}Hmr spectrum of mixture of compounds **9** and **10** (acetates).

2,3-Bis-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanol (**11**), isolated from fraction M, was characterized by ir, ms, and ^{1}Hmr. The mass spectrum showed a molecular ion peak at *m/z* 364, the base peak at *m/z* 167, and other prominent peaks at *m/z* 194, 180, and 137. The mechanism of fragmentation for this molecule would be similar to that illustrated in Fig. 1. The ^{1}Hmr pattern of the diacetate was similar to that reported for this compound by Sudo and Sakakibara (6).

Evidence for the existence of the C_β—C_1 type of linkage in lignin has been reported previously. From the hydrolysis products of beech wood, Nimz *et al.* (7, 8) isolated compounds analogous to **8**, **10**, and **11**, but retaining the α-hydroxy function. Using catalytic hydrogenation over a copper chromite catalyst, Sakakibara and co-workers (5, 6) obtained **8** from Ezomatsu wood and **11** from Yachidamo wood. The work reported here on the isolation of the mixed type of dimers, **9** and **10** (containing both guaiacyl and syringyl nuclei), along with **11** (two syringyl nuclei), is of particular significance and is most readily explained by Freudenberg's free radical theory of lignin formation (9).

Experimental

Aspen poplar (*Populus tremuloides*, Michx.) sapwood (20 mesh) was extracted in a Soxhlet extractor for 48 h with ethanol–benzene (1:1), then under reflux with acetone–water (9:1) for 24 h and air dried. Found: Klason lignin, 18.9%; moisture, 4.04%. The catalyst, 5% rhodium-on-charcoal was obtained from K & K Laboratories Inc., silica gel (Bio-sil A, 100–200 mesh) from BIO-RAD Laboratories, and cellulose powder from W & R Balston, Ltd.

General Reaction Procedure

A typical hydrogenolysis was as follows: wood meal (20 g), 5% Rh-C (2 g), dioxane–water (9:1) (300 mL) were placed in a 500 mL beaker inside a one litre Parr pressure reactor. After flushing twice with hydrogen, it was filled to an initial pressure of 500 psig. The temperature was raised and controlled at 195 ± 5°C for 5 h during which time the mixture was stirred using a magnetic stirrer. After cooling, the reactor contents were filtered, the pulp and catalyst washed with dioxane–water (9:1), and the combined filtrates extracted exhaustively with chloroform. After drying, the solvent was removed to leave the chloroform-soluble extract which, from a total of 400 g wood meal, weighed 51.6 g (68.3% of Klason lignin).

Separation of Lignin Degradation Products

Using a silica gel column (67 mm × 500 mm), the total chloroform-soluble material was separated by a gradient development technique. The column was eluted initially with cyclohexane – ethyl acetate (3:1) and then with gradually increasing proportions of ethyl acetate until a ratio of 1:1 was achieved. As a result fifteen fractions (A → O) were obtained. Residual material on the column was removed using acetone (fraction P). Total recovery was 44.9 g (87%). Further column chromatographic separation of each fraction was monitored using thin layer chromatography (developed with toluene – formic acid – ethyl formate (5:1:4), followed by spraying with 50% sulfuric acid and heating to 105°C).

Isolation of Compounds 5 and 6

Fraction D (1.38 g) was separated using a silica gel column (15 mm × 600 mm). Elution with cyclohexane–acetone (7:1) gave rise to two crude, separate, crystalline products. Recrystallization of one product from xylene–ethanol gave colourless

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

needles (21.2 mg), mp 213–214°C, no mp depression on mixing with authentic 4-hydroxybenzoic acid, **5**. The second product, after recrystallization from methylene chloride – petroleum ether (40–60°C), gave colourless needles (12.2 mg), mp 107–109°C, no mp depression on mixing with authentic 1-(4-hydroxy-3,5-dimethoxyphenyl)-1-propanone, **6**.

Isolation of Compound 7

Fraction C (1.62 g) was separated using a silica gel column (25 mm × 700 mm). Elution with cyclohexane–acetone (8:1) first removed some monomeric compounds, followed by a fraction which, after further chromatographic separation using a cellulose column (15 mm × 650 mm) and xylene–dimethylformamide (15:1) gave rise to a crude solid. Recrystallization from methylene chloride – petroleum ether (40–60°C) gave colourless crystals (5.2 mg), mp 147–150°C.

Isolation of Mixture of Compounds 9 and 10

Fraction L (1.08 g) was separated using a cellulose column (15 mm × 650 mm). Elution with xylene–dimethylformamide (10:1) yielded a component (87.5 mg) which required further purification using a silica gel column, eluting first with benzene–acetone (8:1) and rechromatographing using chloroform–methanol (100:1). This liquid product (49.4 mg) was used for mass spectral analysis. Acetylation of part of this material gave a product which was finally purified using a silica gel column (10 mm × 300 mm) and cyclohexane – ethyl acetate (5:1) as the eluting solvent. The product (32.1 mg) could not be crystallized. *Anal.* calcd. for $C_{24}H_{28}O_9$: C 62.60, H 6.13; found: C 62.49, H 6.15%.

Isolation of Compound 11

Fraction M (1.91 g) was separated using a cellulose column (20 mm × 600 mm) and gradient development elution starting with xylene and dimethyl formamide (10:1) with increasing dimethylformamide. A compound which gave a purple spot if monitored by tlc was collected and rechromatographed twice using silica gel columns (15 mm × 600 mm), first with benzene–acetone (7:1) and then with cyclohexane–acetone (3:1). After recrystallization from ethanol–water, compound **11** was obtained (45.2 mg), mp 169–171°C (lit. (6) mp 170–172°C).

Interaction électron–solvant dans la radiolyse-γ du *N*-methylacétamide et de ses mélanges à l'eau. Effet d'intercepteurs sélectifs

T. H. TRAN-THI, A. M. KOULKÈS-PUJO[1] ET J. SUTTON

CNRS et DPC/SCM, Centre d'Etudes Nucléaires de Saclay, 91190 Gif sur Yvette, France

Reçu le 18 septembre 1980

T. H. TRAN-THI, A. M. KOULKÈS-PUJO et J. SUTTON. Can. J. Chem. **59**, 1032 (1981).

L'étude des mécanismes de réactions de la radiolyse-γ du *N*-méthylacétamide (NMA) à 30°C (constante diélectrique 178) en présence d'intercepteurs d'électrons (N_2O; HCl,2NMA; $(CH_3)_2CO$) a permis de montrer que l'attachement d'un électron pré-solvaté sur NMA correspond à une réaction lente comparativement à celle de N_2O avec la même espèce. Cet attachement serait probablement dissociatif. Les constantes de vitesse de l'électron "sec" avec N_2O, $(CH_3)_2CO$, et NMA seraient dans l'ordre suivant:

$$k_{e^-+N_2O} \geq 70k_{e^-+(CH_3)_2CO} \geq 110k_{e^-+NMA}$$

T. H. TRAN-THI, A. M. KOULKÈS-PUJO, and J. SUTTON. Can. J. Chem. **59**, 1032 (1981).

A study of the reaction mechanism of the γ-radiolysis of *N*-methyl acetamide (NMA) at 30°C (dielectric constant 178) in the presence of various electron scavengers (N_2O; HCl·2NMA; $(CH_3)_2CO$) has shown that the attachment of a presolvated electron to NMA is a slow reaction compared to that of N_2O with the same species. This attachment probably is dissociative. The rate constants of the "dry" electron with N_2O, acetone (Ac), and NMA are in the following order

$$k_{e^-+N_2O} \geq 70k_{e^-+Ac} \geq 110k_{e^-+NMA}$$

1. Introduction

L'étude systématique du comportement des amides sous l'effet des rayonnements a été peu développée malgré l'importance de ces composés dans les réactions des biopolymères tels que les protéines et les polypeptides. En effet, les groupements amidiques dans les molécules de polypeptides semblent conserver dans une large mesure leur caractère de groupement amide isolé (1), ce qui justifie le développement actuel des recherches sur les amides à l'état monomère et en tant que solvant.

Le NMA à cet effet devrait permettre d'atteindre des rendements en ions libres élevés. Or nos résultats de radiolyse pulsée (2) ont permis de montrer que les électrons ne sont pas solvatés par les molécules de NMA dans le solvant pur. Dans les milieux mixtes NMA–H_2O une concentration 5,3 *M* en eau soit 10% en poids, est suffisante pour que le spectre d'absorption du mélange désaéré et irradié corresponde à celui de l'électron hydraté.

L'absence d'électron solvaté dans le NMA pur nous a amenés à suggérer que l'électron s'attache sur cette molécule selon un processus éventuellement dissociatif. La technique de radiolyse pulsée ne nous ayant pas permis de mettre en évidence de bande d'absorption pouvant être attribuée à l'anion NMA^- dans le domaine de l'uv et du visible (250–750 nm), nous avons poursuivi cette étude par la technique de radiolyse-γ continue, complémentaire de la radiolyse pulsée. En effet, le dosage des produits finals et l'utilisation d'intercepteurs sélectifs pourraient fournir des idées sur l'identité des espèces transitoires mises en jeu dans les mécanismes radiolytiques. Ainsi le protoxyde d'azote N_2O intercepteur connu d'électrons solvatés, d'anions, mais également d'électrons présolvatés pourrait réagir avec l'anion NMA^- ou l'électron présolvaté pour former de l'azote. La mesure du rendement en azote formé au cours de la radiolyse du système NMA + N_2O et sa variation avec l'addition de divers intercepteurs secondaires susceptibles de réagir différemment avec les électrons présolvatés ou NMA^- pourraient contribuer à élucider l'hypothèse de l'existence de l'anion NMA^-.

2. Partie expérimentale

A. Conditions opératoires

Irradiation

Des cellules de 6 mL contenant le solvant pur (NMA) désaéré, saturé de gaz (N_2O ou N_2O + Ar) ou en mélange avec d'autres solutés et cosolvants sont maintenues à 38 ± 1°C afin de conserver le NMA à l'état liquide. Les différents mélanges de gaz (N_2O + Ar) fournis par l'Air Liquide ont été utilisés afin d'avoir plusieurs concentrations de N_2O dans le NMA. La solubilité de N_2O dans le NMA déterminée à 38°C et à pression atmosphérique est de $7{,}2 \times 10^{-2}$ *M*. Nous avons contrôlé que la loi de Henry est vérifiée pour différentes pressions partielles de N_2O. Nous avons ainsi pu faire varier la concentration de N_2O dans le NMA de $7{,}2 \times 10^{-4}$ *M* à $7{,}2 \times 10^{-2}$ *M*.

Dosimétrie

Les échantillons sont irradiés à une source de ^{60}Co de 100 Ci. Le débit de la dose mesuré avec le dosimètre Fricke est $I_E = 2{,}84 \times 10^{18}$ eV h^{-1} cm^{-3} pour l'eau pure. On suppose que les rayonnements γ ou les électrons accélérés interréagissent avec tous les électrons du milieu, de sorte que le débit de dose I_{NMA} absorbée par le solvant peut être calculé à partir de

I_E en tenant compte des densités électroniques relatives de l'eau et du NMA.

Purification des solvants

Le NMA, produit Merck, a été purifié selon le procédé mis au point par Pucci, Vedel et Trémillon (3) qui consiste à éliminer les trois impuretés connues CH_3NH_2, CH_3COOH et H_2O, successivement par addition de H_2SO_4, K_2CO_3 et CaO, chacun de ces traitements étant suivi d'une distillation sous pression réduite. La principale impureté résiduelle demeure l'eau dont la concentration est de 63 ppm soit $3,9 \times 10^{-3}$ M. Le distillat recueilli est conservé sous atmosphère inerte dans une boîte à gants.

L'acétone R. P. Merck a été utilisé tel quel. L'eau est tridistillée. L'acide HCl,2NMA synthétisé suivant la réaction de Mannich et Heilner (4)[2] a été purifié par dissolution dans l'éther et par recristallisation dans l'acétone.

Analyse des produits finals

Les produits finals gazeux sont isolés par la technique du vide et analysés par chromatographie en phase gazeuse à l'aide d'un chromatographe Perkin-Elmer modèle F_6 à catharomètre. Les colonnes de 3 m de long remplies de tamis moléculaire 5 Å sont maintenues à 80°C. Le gaz vecteur est l'argon.

Le formaldéhyde a été dosé suivant la méthode colorimétrique et spectrophotométrique de Bricker et Vail (5), que nous avons adaptée à nos conditions opératoires (6).

B. Résultats expérimentaux

Les rendements en produits finals (H_2, CH_4, N_2 et CH_2O) formés au cours de la radiolyse des différents systèmes étudiés sont reportés dans le tableau 1.

NMA pur

Le NMA pur désaéré et irradié produit de l'hydrogène et du méthane avec les rendements respectifs:

$$G(H_2) = 0,90 \pm 0,05$$

$$G(CH_4) = 0,33 \pm 0,06$$

La valeur du $G(H_2)$ est à comparer à celle obtenue par irradiation du formamide par Matsumoto et coll. (7), $G(H_2) = 0,87$, et par Head et Walker (8), $G(H_2) = 0,94$. Elle est de beaucoup supérieure à celle trouvée pour le diméthylformamide $G(H_2) = 0,4$ par Kroh et Burzynska (9). De plus, le rendement en méthane que ces auteurs indiquent pour le formamide est négligeable ($G(CH_4) < 0,01$) et $G(CH_4) = 0$ pour le diméthylformamide. En revanche dans le cas du NMA, nous n'avons pas mis en évidence de CO contrairement aux deux autres amides.

NMA + N_2O

Les rendements en hydrogène et méthane ne sont pas affectés par la présence de N_2O quelle que soit sa concentration de 10^{-4} M à 10^{-2} M (tableau 1). Pour la concentration en N_2O la plus élevée, le rendement $G(N_2)$ égal à $3,3 \pm 0,3$ est encore loin de la valeur du rendement correspondant à l'ionisation totale estimée pour les liquides à $4,5 \pm 0,5$.

Effets de divers intercepteurs secondaires (HCl,2NMA; $(CH_3)_2CO$; H_2O)

Les résultats obtenus avec les différents intercepteurs secondaires laissent apparaître plusieurs points importants:

(*a*) L'acide HCl,2NMA entièrement dissocié dans le NMA (10) n'a pas d'effet sur les rendements initiaux en hydrogène, méthane et azote, quelle que soit la concentration en N_2O, malgré la grande réactivité connue du proton H^+ avec les anions et les électrons solvatés.

(*b*) L'effet de l'acétone (Ac) est plus complexe. En effet la présence de l'acétone dans les solutions NMA $7,2 \times 10^{-3}$ en N_2O, fait croître le rendement initial en azote. Ainsi pour le mélange NMA + Ac 1 M, $G(N_2) = 3,3 \pm 0,3$ au lieu de $1,8 \pm 0,2$

[2]Nous remercions J. C. Hallé qui a bien voulu nous fournir des échantillons de ce produit.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

en absence d'acétone. Cependant l'augmentation de la concentration en acétone à 2,5 *M* et à 5 *M* fait également croître $G(N_2)$ mais à des valeurs respectives plus faibles de 2,2 ± 0,3 et 2,5 ± 0,3.

En revanche, en présence de N_2O $7{,}2 \times 10^{-2}$ *M*, $G(N_2)$ reste constant et égal à 3,3 quelle que soit la concentration en acétone variant de 1 à 5 *M*. L'addition d'un second intercepteur secondaire (H_2O) au système NMA + N_2O $7{,}2 \times 10^{-2}$ *M* + Ac 1 *M* n'affecte pas le rendement initial en N_2 qui reste égal à 3,45 ± 0,3. Les variations complexes du rendement initial en N_2 suivant les concentrations de N_2O et des intercepteurs secondaires seront discutées ultérieurement, mais nous pouvons d'ores et déjà remarquer que le rendement en N_2 dans le milieu acétone seul est plus faible que celui obtenu pour ses divers mélanges au NMA.

D'autre part, pour les concentrations en N_2O supérieures à $7{,}2 \times 10^{-4}$ *M*, les rendements en H_2 et CH_4 ne sont pratiquement pas affectés par la présence de l'acétone.

(*c*) L'addition d'eau (de $3{,}9 \times 10^{-3}$ *M* à 17,22 *M*) au système NMA + N_2O provoque un abaissement lent du rendement en N_2, indiquant ainsi une action effective de l'eau sur les précurseurs conduisant à la formation de N_2. Ceci est également vrai pour le méthane dont le rendement diminue rapidement et devient négligeable pour H_2O 17,22 *M*. En revanche, l'hydrogène est formé avec un rendement à peu près constant ce qui laisserait supposer que son origine est moléculaire.

3. Discussion

Les nombreux termes employés dans la littérature pour distinguer les différents états de l'électron (électrons secs, piégés, présolvatés, solvatés), nous amènent à préciser le sens des termes que nous allons utiliser.

Le terme d'électron sec ou présolvaté (noté e^-) introduit par Hamill (11), désigne l'électron mobile, délocalisé, capable (avant de réorienter les molécules du solvant) de se recombiner avec l'ion positif ou de réagir soit avec le solvant lui-même en conduisant à un attachement électronique, soit avec certains intercepteurs à concentration suffisante.

L'absence d'électrons solvatés par NMA dans le milieu NMA pur ainsi que dans les mélanges avec l'eau (12) nous ont permis d'envisager l'hypothèse de l'attachement de l'électron présolvaté sur la molécule de NMA conduisant à un anion NMA^- transitoire dans un état fondamental ou excité, pouvant se dissocier. On aurait:

[1] $NMA \rightsquigarrow NMA^+ + e^-$

[2] $NMA + e^- \rightarrow NMA^-$
$\searrow$
$NMA^{-*} \rightarrow$ produits

Les intercepteurs pourraient alors réagir soit avec l'électron présolvaté soit avec les anions-radicaux du solvant. Par exemple dans le cas de N_2O, la formation d'azote pourrait provenir de l'une des réactions suivantes:

[3] $NMA^- + N_2O \rightarrow N_2 + O^- + NMA$

[4] $e^- + N_2O \rightarrow N_2 + O^-$

N_2O est connu d'ailleurs comme un bon capteur d'électrons tant solvatés que présolvatés (11, 13). Si la réaction [2] est rapide devant la réaction [4], l'azote proviendrait principalement de la réaction [3]. Un intercepteur efficace d'anion tel que le proton H^+, devrait avoir pour effet de faire décroître fortement le rendement en azote. En effet tous les anions organiques sont connus pour réagir rapidement avec H^+. Nous ne citerons pour mémoire que le cas de la benzophénone dont l'anion $(C_6H_5)_2\dot{C}O^-$ est rapidement transformé en radical $(C_6H_5)_2\dot{C}OH$ (14). En revanche le rendement en azote devrait demeurer inchangé s'il provenait des électrons présolvatés puisque ces derniers sont connus pour ne pas réagir avec H^+ (13). L'invariance du rendement en N_2 semble montrer que si l'attachement d'un électron présolvaté sur NMA est possible, cette réaction est plutôt lente comparativement à celle de l'attachement électronique sur N_2O. L'azote se forme principalement par la réaction [4] avec une constante de vitesse de réaction k_4 très grande devant k_2 étant donné le rapport de concentration des deux intercepteurs [NMA] = $\sim$200[N_2O].

Head et Walker (8) dans leur étude sur la radiolyse-γ du formamide (FA) saturé en N_2O ont trouvé un rendement en N_2 semblable au nôtre $G(N_2) = 3{,}2 \pm 0{,}3$. Contrairement au cas du NMA, ce rendement diminue rapidement en présence de H_2SO_4 ajouté comme intercepteur secondaire. L'absence d'électron solvaté dans ce milieu a amené ces auteurs à suggérer la présence d'anions FA^- formés par attachement des électrons secs sur les molécules de FA et à attribuer la diminution du $G(N_2)$ à une compétition entre H^+ et N_2O pour cet anion.

Dans le cas du NMA, la non réactivité de l'ion H^+ laisse supposer que l'attachement électronique s'il existe, est dissociatif. On aurait alors les réactions possibles suivantes:

[5] $NMA + e^- \rightarrow CH_3CO^{\cdot} + CH_3NH^-$ ou
$\searrow$ $CH_3CO^- + CH_3NH^{\cdot}$ ou
$\searrow$ autres produits

La réaction [5] en compétition avec la réaction [4] permettrait d'expliquer l'absence de plateau à la courbe de dilution que l'on pourrait tracer à partir des résultats portés dans le tableau 1. Le rendement en N_2 ne proviendrait donc que d'une partie des électrons formés au cours de la radiolyse.

Un autre intercepteur secondaire l'acétone (Ac) a été utilisé car il réagit tant avec les électrons secs que solvatés (15, 16). Son anion Ac^- est très réactif envers N_2O (17). L'addition de Ac pourrait entraîner une augmentation du rendement en azote

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

par compétition avec la réaction [5]. $G(N_2)$ devrait alors tendre vers le rendement total d'ionisation du solvant par le truchement des réactions suivantes:

[6] $e^- + Ac \rightarrow Ac^-$

[7] $Ac^- + N_2O \rightarrow N_2 + O^- + Ac$

L'augmentation du rendement en N_2 de $1,8 \pm 0,2$ à $3,3 \pm 0,3$ respectivement en absence et en présence d'acétone 1 *M* dans les solutions $7,2 \times 10^{-3}$ *M* en N_2O dans NMA, indique bien une compétition réelle entre N_2O, Ac et NMA pour l'électron sec en faveur de l'acétone. Cependant une augmentation de la concentration en acétone à 2,5 *M* et 5 *M* dans ce même milieu fait diminuer $G(N_2)$ respectivement à $2,2 \pm 0,3$ et $2,5 \pm 0,3$.

L'augmentation de la concentration d'acétone déplace bien la compétition entre les réactions [4]–[6] en faveur de [6], mais elle entraîne également une modification non négligeable des propriétés diélectriques du milieu. En effet nous avons déterminé les constantes diélectriques des mélanges NMA et Ac, et nous avons constaté qu'elle diminue de moitié quand la concentration en acétone augmente de 1 *M* à 5 *M* (tableau 2). L'abaissement de la constante diélectrique ne peut que favoriser les réactions de recombinaisons géminées de l'anion Ac^- entraînant ainsi une diminution du rendement en ions libres.

D'ailleurs pour l'acétone pur ($\varepsilon_{Ac}^{35°} = 20,7$), Chaudhri et Asmus (18) en utilisant la technique de radiolyse pulsée couplée à la conductimétrie, ont déterminé un rendement en ions libres $G(Ac^-) = 1,20 \pm 0,2$. En présence de solutés (acide perchlorique ($HClO_4$) anthracène (An) ou tétranitrométhane ($C(NO_2)_4$)), les rendements en ions libres secondaires, formés par transfert de la charge négative provenant de $(CH_3)_2CO^-$ tels que $G(Cl^-) = 1,4 \pm 0,1$; $G(An^-) = 1,7 \pm 0,2$ ou $G(C(NO_2)_3^-) = (2,15 \pm 0,10)$ sont tous supérieurs à celui de $(CH_3)_2CO^-$ lui-même. Cette différence est attribuée à la possibilité de ces anions d'échapper pendant une durée plus longue que l'anion Ac^- à la recombinaison géminée. Robinson et Rodgers (19) proposent pour ce même solvant une valeur encore plus faible du rendement en ions libres $G_{fi} = 0,75 \pm 0,05$ comparativement à celui des géminés $G_{gi} = 2,3 \pm 0,2$. L'étude en radiolyse pulsée de la cinétique de disparition de l'anion Ac^- absorbant à 550 nm et du cation Ac^+ à 860 nm les ont amenés à conclure à deux modes différents de disparition de l'anion: la première par recombinasion géminée avec Ac^+, et la seconde par réaction avec d'autres espèces transitoires formées au cours de la radiolyse. La valeur du rendement d'azote que nous avons déterminé par radiolyse-γ de l'acétone en présence de N_2O est $G(N_2) = 2,2 \pm 0,3$. Ce rendement n'est pas forcément égal à celui des ions libres si la réaction [7] intervient aussi dans les zones à forte densité d'ionisation et d'excitation. Cependant cette valeur est faible pour un rendement d'ionisation totale et on peut admettre que l'anion Ac^- disparait partiellement par une réaction de recombinaison géminée, cette dernière étant en partie inhibée par la présence de NMA. Cependant, la présence d'acétone ne joue plus pour une concentration en N_2O de $7,2 \times 10^{-2}$ *M*. $G(N_2)$ reste invariant et égal à $3,3 \pm 0,3$ quelle que soit la concentration en acétone de 1 *M* à 5 *M*. Ce résultat montre que dans ce cas, la vitesse de la réaction de l'électron sec avec N_2O est supérieur à celle avec l'acétone. En tenant compte des concentrations respectives de N_2O, Ac et NMA, on peut estimer que les constantes de vitesse varient suivant cet ordre

$$k_{e^-+N_2O} \geq 70k_{e^-+Ac} \geq 110k_{e^-+NMA}$$

En résumé, aussi bien dans les milieux NMA + N_2O que NMA + N_2O + HCl,2NMA la formation d'azote semble provenir exclusivement de la dissociation de l'anion N_2O^- formé à partir de l'attachement d'un électron sec sur N_2O.

En présence d'acétone elle peut cependant trouver une partie de son origine dans la réaction de l'anion Ac^- avec N_2O.

TABLEAU 2. Valeurs de la constante diélectrique des mélanges NMA–Ac

Milieu	*t* (°C)	ε	Réf.
NMA 13 *M*	31,4	178,9	24
NMA 12,02 *M* + $(CH_3)_2CO$ 1,00 *M*	25	162,2	*a*
NMA 10,62 *M* + $(CH_3)_2CO$ 2,50 *M*	25	127,65	*a*
NMA 8,25 *M* + $(CH_3)_2CO$ 5,00 *M*	25	86,45	*a*
$(CH_3)_2CO$ 13,7 *M*	25	20,7	24

Effet de l'eau

Dans les systèmes NMA + H_2O + N_2O où l'électron a une probabilité non négligeable de se solvater (par exemple à partir d'une concentration en eau de 5,3 *M* soit 10% en poids (2)) la présence d'eau fait abaisser le rendement en N_2. La constante diélectrique des mélanges eau–NMA (tableau 3) est toujours supérieure a celle de l'eau pur. Les différentes réactions possibles des électrons sont les suivantes:

[4] $e^- + N_2O \rightarrow N_2 + O^-$

[5] $e^- + NMA \rightarrow$ Produits

[8] $e^- + nH_2O \rightarrow e_{aq}^-$

[9] $e_{aq}^- + N_2O \rightarrow N_2 + O^-$ $\quad k_9 = 8,7 \times 10^9\ M^{-1}\ s^{-1}$ (20)

TABLEAU 3. Valeurs de la constante diélectrique des mélanges NMA–H_2O

Milieu	ε	Réf.
NMA 13 *M*	183,0	25
NMA 12,98 *M* + H_2O 0,138 *M*	181,0	
NMA 12,78 *M* + H_2O 1,00 *M*	170,0	
NMA 11,84 *M* + H_2O 5,00 *M*	136,5	
NMA 8,98 *M* + H_2O 17,22 *M*	100,0	
NMA 6,51 *M* + H_2O 27,8 *M*	91,0	

[10] $e_{aq}^- + H^+ \rightarrow H^\cdot$ $k_{10} = 2{,}3 \times 10^{10}\ M^{-1}\ s^{-1}$ (15)

[11] $e_{aq}^- + e_{aq}^- \rightarrow H_2 + 2OH^-$ $k_{11} = 6 \times 10^9\ M^{-1}\ s^{-1}$ (21)

[12] $e_{aq}^- + NMA \rightarrow$ Produits $k_{12} = 2{,}6 \pm 0{,}2 \times 10^6\ M^{-1}\ s^{-1}$[3]

[13] $e_{aq}^- + H_2O \rightarrow$ Produits $k_{13} = 1{,}0 \pm 0{,}2 \times 10^4\ M^{-1}\ s^{-1}$[3]

Nous suggérons que la baisse du rendement en N_2 provient de différentes compétitions possibles.

(*a*) Entre N_2O et H_2O pour l'électron sec (réactions [4] et [8]), le temps de solvatation de l'e^- a été estimée par Rentzepis et coll. (22) à 4 ps.

(*b*) Entre N_2O et H^+ pour l'électron hydraté e_{aq}^- par les réactions [9] et [10].

(*c*) Entre N_2O et e_{aq}^- selon [9] et [11].

La valeur de la constante de vitesse de réaction de l'e_{aq}^- avec H_2O ($k_{13} = 1{,}0 \times 10^4\ M^{-1}\ s^{-1}$) et celle que nous avons déterminée pour la réaction de e_{aq}^- avec NMA ($k_{12} = 2{,}6 \times 10^6\ M^{-1}\ s^{-1}$) nous permettent de négliger les réactions [12] et [13] devant les réactions [9]–[11].

Head et Walker (8) dans leur étude de la radiolyse du formamide (FA) ont également étudié l'effet de l'eau sur le rendement en azote dans les solutions de FA saturées en N_2O et n'ont pas trouvé d'effet jusqu'à une concentration en eau 0,19 *M* soit 0,86% en poids. Ce résultat n'est pas surprenant si l'on tient compte du fait que pour les mélanges H_2O–FA, la bande d'absorption correspondant à l'e_{aq}^- n'apparaît qu'à partir d'une concentration en eau égale à 20% en poids soit 11,1 *M* (23); pour le NMA, il suffit de 10% en eau (soit 5,3 *M*) pour que le spectre d'absorption de l'e_{aq}^- soit visible (2). D'ailleurs le rendement d'azote baisse déjà pour une concentration en eau de 1 *M*.

L'addition d'acétone 1 *M* au mélange NMA(11,8 *M*) + H_2O (1 *M*) + N_2O($7{,}2 \times 10^{-2}$ *M*) a permis par ailleurs de montrer que le rendement en azote dans ce mélange reste égal à celui déterminé en absence d'eau $G(N_2) = 3{,}45 \pm 0{,}3$. Il est supérieur à celui déterminé pour le même mélange exempt d'acétone ($G(N_2) = 2{,}9$). Ce résultat laisse présumer: soit que Ac^- formé à partir des électrons hydratés selon $e_{aq}^- + Ac \rightarrow Ac^-$ réagit avec N_2O pour augmenter le rendement de l'azote en favorisant une compétition avec les réactions de destruction de l'e_{aq}^- (réactions [10], [11]); soit que la vitesse de réaction de l'électron sec avec Ac est supérieure à celle de la solvatation de l'e^- avec H_2O de l'ordre de $2{,}5 \times 10^{11}\ s^{-1}$ (21) ce qui nous permettrait d'avoir une évaluation de k_{e^-+Ac} connaissant la concentration en Ac(1 *M*) $k_{e^-+Ac} \geq k = 2{,}5 \times 10^{11}\ M^{-1}\ s^{-1}$.

[3]Valeurs déterminées dans nos conditions expérimentales par radiolyse pulsée. Comme suggéré par l'un des referees, la vitesse de la réaction [13] est en fait la somme des vitesses des différentes réactions de disparition de e_{aq}^-.

The tryptophan fluorescence lifetime puzzle. A study of decay times in aqueous solution as a function of pH and buffer composition[1]

EVA GUDGIN, RICARDO LOPEZ-DELGADO,[2] AND WILLIAM R. WARE

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received April 23, 1980

EVA GUDGIN, RICARDO LOPEZ-DELGADO, and WILLIAM R. WARE. Can. J. Chem. **59**, 1037 (1981).

Tryptophan fluorescence decay kinetics have been systematically investigated in aqueous solutions as a function of pH as well as in a variety of buffer solutions. Below pH 7.0, the decay appears to be double exponential with a subnanosecond component confirming the previous findings of Rayner and Szabo (3). In the low pH region, where the proton concentration becomes kinetically significant, tryptophan fluorescence is collisionally quenched by $[H^+]$ with diffusion controlled rate and no experimental evidence is found regarding the appearance at low pH of a new tryptophan molecular species, namely the cationic form. At pH $\geq$ 7.0, the decay becomes triple-exponential with the appearance of a long component whose contribution to the total emission intensity increases rapidly with increasing pH at the expense of the other two. Lifetimes and relative intensities of each decay component depend in a complex way on pH and on the buffer chemical composition.

EVA GUDGIN, RICARDO LOPEZ-DELGADO et WILLIAM R. WARE. Can. J. Chem. **59**, 1037 (1981).

La cinétique du déclin de la fluorescence du tryptophane a été étudiée dans des solutions aqueuses en fonction du pH dans une serie de solutions tampons. En dessous du pH 7.0 le déclin est bi-exponentiel avec une composante de courte durée de vie, dans le domaine de temps de la subnanoseconde, ce qui confirme les resultats préalables de Rayner et Szabo (3). Dans la region du bas pH, où la concentration des protons commence à devenir importante du point de vue cinétique, la fluorescence du tryptophane est eteinte par $[H^+]$ avec une constante de vitesse controllée par la diffusion, et on ne trouve pas d'evidence expérimentale concernant l'apparition à pH bas d'une nouvelle espèce moléculaire du tryptophane, c'est-à-dire, de la forme cationique. Pour des pH $\geq$ 7.0 le déclin devient tri-exponentiel et on observe l'apparition d'une composante de longue durée de vie et dont la contribution à l'intensité totale d'emission augmente très rapidement avec le pH au détriment des deux autres composantes. Les durées de vie de fluorescence aussi bien que les intensitée relatives de chaque composante dépendent d'une manière complexe et du pH et de la composition chimique de la solution tampon.

"The short fluorescence lifetimes encountered for aqueous solutions of aromatic amino-acids lead to relatively large uncertainties in the values obtained. Within these limits the emission lifetimes for tryptophan ... from different laboratories are in satisfactory agreement" (2.6–3.0 ns; single exponential decay). This statement appeared in a review article by Weinryb and Steiner (1) in 1971.

However, from 1976 until very recently, a number of published reports (2–5) have introduced an amazing confusion into this particular subject, which has a certain interest since aromatic amino-acids have been extensively used as intrinsic fluorescent tags for protein structural and dynamical studies by spectrofluorometric methods. In all but one (5) of the above-mentioned publications, a double exponential decay is reported, which favours, according to the authors, the appealing model of two electronic excited states (^1L_a and ^1L_b) uncoupled to each other but independently coupled to the ground state through the radiation field (dual fluorescence). Nevertheless, in ref. 4, an idea, which is not essentially new (6, 7), of two different ground state conformers is cautiously advanced; also Rayner and Szabo in a very recent paper (8) have abandoned the idea of simultaneous $^1L_a \rightarrow {}^1A$ and $^1L_b \rightarrow {}^1A$ radiative transitions in favour of the coexistence of different populations of rotational conformers (rotamers) in the ground state. On the other hand, de Lauder and Wahl (9) studied the fluorescence decay of tryptophan as a function of pH and explained the observed variations of lifetimes in terms of mixtures of different ionic species present.

Although previous results of one of the authors (5) compare quite well (taking into account the fact (5) that only the red part of the emission was analyzed) with those of Rayner and Szabo (3), as well as with "classic" lifetime values (1), the bulk of the reported data is in strong contradiction; therefore, we think it is necessary to carefully reinvestigate the problem as a function of a number of pertinent experimental parameters in order to properly understand the tryptophan excited state relaxation mechanism.

In this preliminary work, we have re-examined the problem of the existence of a subnanosecond component in the tryptophan decay (3) as well as

the effect of pH on the molecular absorption and emission spectra and on the fluorescence decay parameters.

L-Tryptophan (Aldrich, 99%) was recrystallized from water–ethanol solutions and dried under vacuum. We have used three different kinds of buffer solutions made up in triple-distilled water in order to cover the pH region of interest: (*1*) 0.1 *M* citric acid – 0.2 *M* Na_2HPO_4 (2.5–7.6 pH region); (*2*) 0.2 *M* NaH_2PO_4 – 0.2 *M* Na_2HPO_4 (6.8–8.0 pH region); (*3*) sodium tetraborate (8.0–11.0 pH region). The ionic strength has been kept roughly constant.

Buffer solutions as well as tryptophan solutions were prepared immediately before each run in order to avoid as much as possible any unwanted aging effect. It has also been verified that the presence or absence of oxygen in the solutions does not, in the limit of our precision, show any noticeable effect on the measured lifetimes.

Absorption spectra were recorded in a Cary-219 spectrophotometer; fluorescence spectra were obtained by means of a Perkin-Elmer MPF-4 spectrofluorometer.

Fluorescence lifetime measurements were performed with a commerical PRA-3000 "Nanosecond Spectrofluorimeter". The system is directly interfaced to a DEC MINK-II computer allowing for fast data treatment. The Nanosecond Spectrofluorimeter is composed of three main elements: (*i*) PRA-510B low pressure thyratron triggered H_2 flash lamp with 10–45 kHz repetition rate; (*ii*) Jobin-et-Yvon H-10 type (high aperture, extremely high transmission power, very low optical noise, 8 nm/mm dispersion) excitation and emission monochromators; (*iii*) a Seven Stage (PRA model 1551) photomultiplier, cooled by Peltier Effect down to −30°C and coupled to an Elscint STD-N1 Snap-Off Timing Discriminator. This tube has less than one count per second dark counting rate.

The experimental decay data $I(t)$, stored in the Multichannel Analyzer, are the convolution

$$[1] \quad I(t) = g(t)*F(t)$$

where $F(t)$ is the true fluorescence decay profile. For the simplicity of the discussion, we have not taken into account parasitic effects such as scattered light or the dark counting background, that pertinent *blank* experiments easily check for.

$$[2] \quad g(t) = I_0(\lambda_{Ex},t)*R_{PM}(\lambda_{Em},t)$$

is a certain instrumental function; $I_0(\lambda_{Ex},t)$ represents the flash profile at the excitation wavelength λ_{Ex}, which is convoluted by the response function of the photodetector $R_{PM}(\lambda_{Em},t)$ at the fluorescence wavelength λ_{Em}. In general, R_{PM} is wavelength dependent (10) and we necessarily have to record another instrumental function

$$[3] \quad g'(t) = I_0(\lambda_{Em},t)*R_{PM}(\lambda_{Em},t)$$

with the lamp profile $I_0(\lambda_{Em},t)$ now measured at the fluorescence wavelength for the mathematical treatment of data in order to recover $F(t)$. However, in general, for conventional flash lamps

$$[4] \quad \frac{g(t)}{g'(t)} = \frac{I_0(\lambda_{Ex},t)}{I_0(\lambda_{Em},t)} = K(\lambda,t) \neq 1$$

and consequently a certain type of calibration is needed.

A flash lamp similar to the one used in the present work has been calibrated (11) using Synchrotron Radiation as a Standard of Excitation (12), in the 170–220 nm spectral region. It was found (11) that the lamp plasma decay is superexponential during the first two decades, with a fwmh ~ 1.8 ns and *wavelength independent*.

The light pulse profile of the lamp used in this work was studied in two different ways.

(*i*) A standard solution of anthracene in *n*-hexane has been excited with $I_0(\lambda,t)$, λ being varied systematically between 220 and 350 nm; $g'(t)$, eq. [3], has been recorded every time at constant λ_{Em} = 450 nm. After iterative convolution (see below) the lifetimes recovered for every excitation wavelength are identical within statistical error.

(*ii*) $g'(t)$ has been recorded every 10 nm in the 220–450 nm spectral range, with the surprising result that it is *wavelength invariant* within statistical error in the entire spectral region of interest. It is difficult to understand how $I_0(\lambda,t)$ could show a variance with λ that continuously cancels a concomitant variance with λ of $R_{PM}(\lambda,t)$, (see eq. [3]) in order to generate the observed λ-invariance of $g'(t)$. A plausible answer could be that both $I_0(t)$ and $R_{PM}(t)$ for this particular instrument are wavelength independent. This hypothesis could be easily checked using Synchrotron Radiation as a standard (11, 12). However, all we need for the purpose of this work is that

$$[5] \quad g(t) = g'(t) = \text{constant}$$

The true fluorescence decay is then recovered by iterative convolution of $g(t)$ by one, two, or three exponential decays with a weighted least-squares convolution procedure until the best fit is obtained with $I(t)$, as defined by a minimum χ^2 value and residuals randomly distributed at better than the 95% confidence limit. The entire decay curve has been analyzed in each case, paying particular attention to the leading edge, where contributions

TABLE 1. Tryptophan fluorescence lifetimes and relative emission intensities in aqueous solution in function of pH: citric acid – sodium phosphate buffer. $\lambda_{Exc} \sim 280$ nm; emission through 350 nm cut-off filter, $T = 20°C$

pH	τ_1 (ns)	I_1	τ_2 (ns)	I_2	[Citric acid] ($M \times 10^2$)
2.55	2.33±0.15	0.89	0.38±0.15	0.11	8.86
3.0	2.57±0.13	0.92	0.44±0.15	0.08	7.95
3.5	2.65±0.12	0.94	0.49±0.15	0.06	6.97
4.0	2.76±0.1	0.93	0.45±0.15	0.07	6.15
4.5	2.87±0.1	0.93	0.50±0.15	0.07	5.46
5.0	2.95±0.1	0.94	0.52±0.15	0.06	4.85
5.5	2.98±0.1	0.93	0.40±0.15	0.07	4.30
6.0	3.07±0.1	0.94	0.55±0.15	0.06	3.68
6.8	3.16±0.1	0.93	0.59±0.15	0.07	2.27

from very short components are likely to be most important.

Concerning the anomalously high lifetime values reported in ref. 2, it is plausible that the authors were simply measuring "electric noise" from the excitation source, for we have verified the appearance of long components in the fluorescence time distribution when the lifetime experiment is performed in the presence of strong "parasitic" radio-frequency fields.

Lifetime values of ref. 4 were obtained by powerful solid state laser excitation of aqueous solutions. Assuming the laser beam is focussed into 0.1 mm², the density of excitation will be of the order of a T W/cm²! If one assumes the likely appearance of self-focussing effects, then the result would be even more catastrophic. In these experimental conditions, with such a high density electric field, one is no longer probing the relaxation of a weakly dense population of excited species. On the one hand, it has already been shown (13) that high power solid state laser excitation of condensed media leads to quite different relaxation kinetics as compared to that obtained by relatively weak excitation. Also, we have verified in this laboratory that a few hours irradiation of fresh aqueous solutions of tryptophan at neutral pH, with a 150 W xenon lamp, leads to strong photodecomposition of the molecule. Very recently, Phillips and coworkers (14) have reached similar conclusions concerning the work reported in ref. 4.

We have recorded absorption and emission spectra that look very similar for all samples and compare quite well with those reported in the literature; however, a small monotonous red shift is observed in both emission and absorption with increasing pH.

In buffered aqueous solutions with pH < 7.0, we find (see Table 1) systematically a double exponential decay with lifetime values τ_1 and τ_2 which compare quite well with those of Rayner and Szabo (3). When fluorescence at all wavelengths (excitation at 280 nm; emission through 305 nm cut-off filter) is collected, the 3.1 ns component (τ_1) contributes (I_1) nearly 95% to the total intensity at neutral pH, in good agreement with "classic" data (1). When fluorescence lifetimes are measured as a function of emission wavelength, our results confirm the general trends already reported (3): the contribution (I_2) of the subnanosecond component (τ_2) increases with decreasing wavelength. However, we measure pre-exponential factor ratios rather smaller than those reported in ref. 3.

We have carefully investigated the possibility of an experimental artifact (such as Raman scattering from water or direct scattering of the exciting flash) being the origin of this subnanosecond component with negative results. Another possibility would be the contribution of rotational depolarization of the fluorescence during the lifetime of the excited state. This explanation was ruled out by the following experiment: fluorescence lifetimes were measured with a polarizer on the excitation side producing vertically polarized light and another on the emission side set at the "magic" angle. No changes either on τ_1 and I_1 or τ_2 and I_2 were observed within statistical error.

Also indicated in the right hand column of Table 1 is the total concentration of citric acid (as the neutral molecule and citrate anion) at the pH studied. There is an equilibrium between the two species depending on buffer composition, however it can be seen generally that increasing the total concentration of both species over $0.02M$ quenches τ_1 significantly.

We have also studied the tryptophan fluorescence decay behaviour in the low pH region under the same experimental conditions as those reported in ref. 9, i.e., aqueous solution where the pH is adjusted by adding increasing quantities of concentrated HCl.

Our results (see Table 2) do not compare well

TABLE 2. Tryptophan fluorescence lifetimes and relative emission intensities in HCl–water solutions as a function of pH. $\lambda_{Exc} \sim 280$ nm; emission through 305 nm cut-off filter, $T = 20°C$

pH	$[H^+]$ (M/L)	τ_1 (ns)	I_1	τ_2 (ns)	I_2
3.5	3.2×10^{-4}	3.2 ±0.1	0.94	0.52±0.15	0.06
2.0	10^{-2}	1.70±0.1	0.80	0.43±0.15	0.20
1.6	2.5×10^{-2}	1.20±0.15	0.65	0.40±0.15	0.35
1.45	3.5×10^{-2}	1.05±0.15	0.70	0.37±0.20	0.30
1.28	5.25×10^{-2}	0.80±0.15	0.80	0.31±0.25	0.20
1.21	6.2×10^{-2}	0.75±0.2	0.85	0.13±0.4	0.15
1.1	7.9×10^{-2}	0.51±0.2	1.00	—	—
1.0	10^{-1}	0.49±0.2	1.00	—	—
0.84	0.145	0.34±0.25	1.00	—	—

with de Lauder and Wahl's (9) data. Again, we find a two component decay, with lifetime values and relative emission intensities very similar to the ones observed in the citric acid – phosphate buffer at neutral pH (see Table 1). A plot of $1/\tau_1$ versus the proton concentration (see Fig. 1) yields an almost straight line; from the slope we found $K_q \sim 1.8 \times 10^{10} M^{-1}\,s^{-1}$, showing that protons quench one of the fluorescence components with a diffusion-controlled rate. The behaviour of the shortest component τ_2 is more difficult to describe because of the much lower precision of the lifetime values; the apparent increase in its relative intensity I_2 above pH $\sim$ 1.5 could be simply due to a differential quenching of τ_1 by protons. Around pH $\sim$ 1.25, τ_2 seems to be catastrophically quenched by the acid and below pH $\sim$ 1.2 the fluorescence decay becomes single exponential within our precision.

When pH is increased, beginning around pH = 7.0, a third longer component is observed whose lifetime τ_3 depends on the buffer composition (see Table 4); its contribution, I_3, to the total emission strongly increases with pH and is already overwhelming at pH $\geq$ 10.0 (see Table 3 and Fig. 2). A concomitant decrease in the contributions of the other two components (I_1 and I_2) is also observed. However, the striking observation is that in a large range (7.0–10.0) the pH does not seem to have an important effect on any of the three lifetime values, but only influences their relative contribution to the total intensity. It is also interesting to note that the buffer composition does not seem to affect the lifetimes of the two shorter components, τ_1 and τ_2, in this pH range.

In Fig. 3 we give a graphical demonstration of our method of fluorescence decay analysis showing that above pH 7.0 double exponential fits are not adequate. Table 5 gives the results of the analyses. Figure 3*a* illustrates the double-exponential analysis of early times where the influence of a subnano-

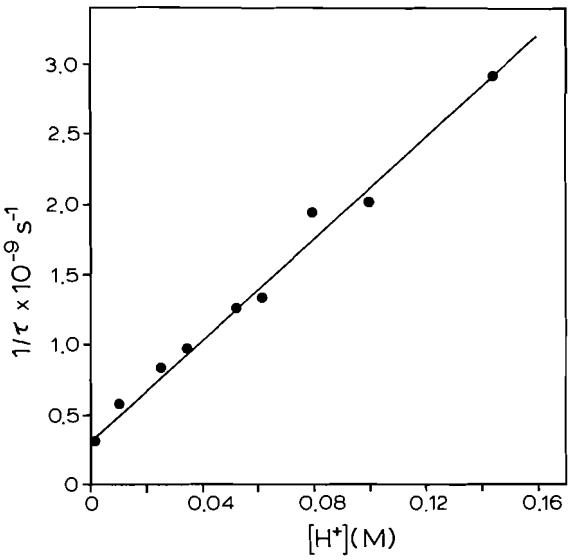

FIG. 1. Effect of HCl concentration on the tryptophan intermediate lifetime (τ_1) component (see Table 2); $[H^+]$ is the proton concentration. The slope yields a quenching rate constant $K_q \sim 1.8 \times 10^{10} M^{-1}\,s^{-1}$.

second component should be greatest; Fig. 3*d* through *f* show double-exponential analyses of the late time distribution where the contribution of long-lived components should be greatest; Fig. 3*c* shows the best double-exponential fit of the entire time distribution. The χ^2 value indicated in Table 5 for Fig. 3*c* is already relatively very large and the residuals are definitely not random, particularly around the early times (see also Fig. 4*a*); also the decay parameters are some sort of weighted average of those values found in analyses 3*a* and 3*f*. The last column of Table 5 shows that the computer has rejected analyses 3*b* and *c* as not meeting the requirement of random residuals within a 95% confidence limit. Using a triple-exponential analysis program in the PDP-11 computer we obtain a

convolution through the entire time distribution with a much lower χ^2 and randomly distributed residuals (see Fig. 4*b* and Table 5). The same three lifetimes are consistently retrieved in all our triple-exponential analyses between pH 7 and 10.5. We would like to point out that in this particular system the analysis is helped by the fact that the three fluorescence lifetimes are very different and therefore it is easy to differentiate between them.

We have, at the same time, reinvestigated the excitation wavelength effect; our results confirm the findings already reported by one of us (5): in aqueous solutions, for a given pH, tryptophan fluorescence lifetimes are independent of the excitation wavelength; moreover, at pH < 7.0, relative intensities I_1 and I_2 seem to remain constant with λ_{Exc} in the 240–300 nm spectral region. However, at pH ≃ 8.5, the relative intensity I_3 of the long component is very sensitive to λ_{Exc}: it contributes 24% to the total intensity when exciting at 280 nm; this contribution jumps to ~50%, when exciting at 310 nm.

In this preliminary communication, we have restricted ourselves to a phenomenological description of experimental results; nevertheless, on the basis of these results, we believe we can arrive at certain conclusions:

(*i*) It is necessary to conclude that the tryptophan fluorescence decay is double exponential below pH 7.0, with a subnanosecond component (3), although its contribution to the total intensity is only a few percent above pH 2.5, in good agreement with "classic" data (1). Since it contributes mainly to the leading edge of the fluorescence time distribution, it only becomes apparent with modern sophisticated methods of mathematical data treatment.

(*ii*) Our results in the low pH range are in contradiction with the data reported by de Lauder and Wahl (9) and they do not support their conclusion of the appearance of a new ionic species,

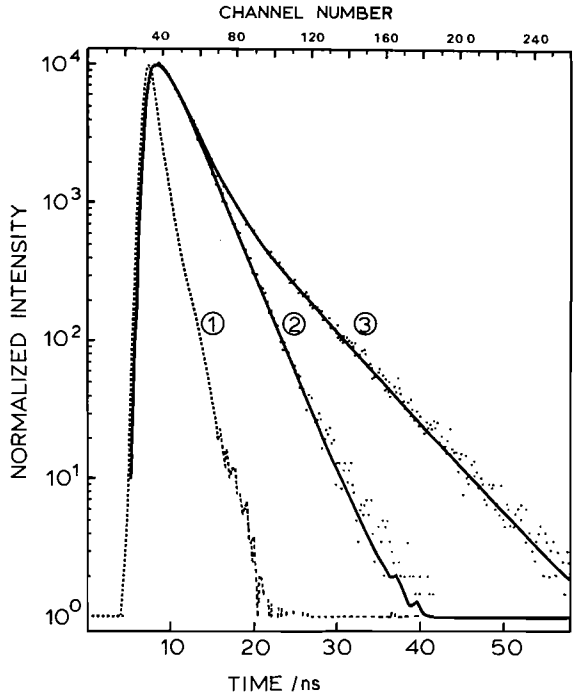

FIG. 2. Experimental decay curves. (*1*) Instrumental function $g'(t) = g(t)$. (*2*) Tryptophan in citric acid – sodium phosphate buffer pH = 6.8; double exponential decay (see Table 1): $\chi^2 = 1.155$. (*3*) Tryptophan in sodium tetraborate buffer, pH = 8.5; triple-exponential decay (see Table 3): $\chi^2 = 1.09$; $\lambda_{Exc} \simeq 280$ nm; fluorescence through 305 nm cut-off filter. $T = 20°C$.

namely the cationic form of tryptophan $R(NH_3^+)\cdot COOH$, induced by the pH. Our results are better understood in terms of a collisional quenching by H^+ with a diffusion controlled rate.

(*iii*) At pH $\geq$ 7.0, the tryptophan fluorescence decay becomes triple-exponential, increasing apparently the magnitude of the puzzle! This result, mainly the fact that the long component contribution I_3 becomes very quickly preponderant with increasing pH, jeopardizes the very recent tentative rationalization by Szabo and Rayner (8) of the tryptophan fluorescence lifetime puzzle in terms of rotational isomers, since their arguments to explain their decay times measured at pH $\sim$ 7.0 are based upon rotational isomer populations measured by nmr experiments in tryptophan in alkaline solutions (15). Our results show clearly that tryptophan decay kinetics are very different in the two media.

(*iv*) From our work, we have clear experimental evidence that tryptophan decay kinetics are strongly dependent upon the buffer composition; consequently, we firmly believe that any report on tryptophan fluorescence lifetimes should clearly describe the chemical composition of the solution, which is not the case most of the time.

(*v*) Finally, the triple-exponential decay we find at pH > 7.0 does not support the model (3) of dual fluorescence from two independent (^1L_a, ^1L_b) excited states.

In order to acquire more insight into the tryptophan fluorescence lifetime puzzle, more systematic research work is clearly needed, and mainly on solvent, temperature, and isotopic substitution effects. Also, a study of tryptophan pure crystal decay kinetics would be very helpful in the understanding of the problem of molecular conformations in the ground state. Work on these lines is presently in progress in this laboratory.

Synthesis of inorganic multilayers on chromatographic supports[1]

PALITHA P. WICKRAMANAYAKE, AMARES CHATT, and WALTER A. AUE[2]
Trace Analysis Research Centre, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received February 4, 1980[3]

PALITHA P. WICKRAMANAYAKE, AMARES CHATT, and WALTER A. AUE. Can. J. Chem. **59**, 1045 (1981).

Multilayers of various metal oxides have been produced on typical chromatographic supports such as diatomaceous earth and silica gel. The layer thickness was characterized for phases based on iron and chromium. These data, as well as chromatographic evidence obtained on chromium oxide, suggest that the layers are homogeneous. Similar, but less well characterized layers of aluminum and titanium oxides have been obtained.

PALITHA P. WICKRAMANAYAKE, AMARES CHATT et WALTER A. AUE. Can. J. Chem. **59**, 1045 (1981).

On a préparé des couches multiples d'oxydes métalliques sur des supports chromatographiques usuels tels la terre diatomée et le gel de silice. On a caractérisé l'épaisseur des couches dans le cas des phases préparées avec le chrome et le fer. Ces données ainsi que les preuves chromatographiques obtenues pour l'oxyde de chrome, suggèrent que les couches sont homogènes. On a obtenu des phases identiques, mais moins bien caractérisées avec les oxydes de titane et d'aluminium.

[Traduit par le journal]

Introduction

Gas–solid chromatography on inorganic surfaces is well known; in fact, this technique preceded the much more popular gas–liquid chromatography by a few years.

Gas–solid chromatography, however, is generally limited to the separation of gases and low-boiling liquids. Its application for purposes other than this straightforward one had therefore to contribute a large part of its current appeal for scientists. Nowadays it is often used to characterize various equilibria and to obtain kinetic information in catalysis research.

The chemical activity of a chromatographic surface may be a drawback for analytical purposes, but it has led to numerous studies in which such materials were used as catalysts and separation media at the same time. (For a review of this area, see ref. 1.)

Besides silica and alumina, a number of metal oxides – e.g. those of chromium, titanium, and iron (2–4) — have been used directly as adsorbents in gas–solid chromatography. Unsuitable pore structures or inferior mechanical stability may restrict such uses.

Hence, from early on, many attempts were made to coat metal oxides or salts on supports better suited to chromatographic use. For instance, aluminas modified by iron oxide (5–8) or chromia (9) have successfully separated hydrogen isotopes.

As pointed out by Aigner *et al.* (10), loading chromatographically active inorganics onto typical supports such as alumina or silica may lead to heterogeneous layers. One approach that would seem reasonable for obtaining homogeneous ones is the derivatization of amply present surface groups, e.g. the silanols. Such reactions are well known; they have been used most often to characterize the physical and chemical properties of various surfaces (for a review see ref. 11).

It should be noted here that the terms "homogeneous" and "heterogeneous" can have different meanings. A pure silica surface, for instance, is homogeneous in that only silicon is present (besides oxygen and hydrogen). But it is heterogeneous in that it contains a variety of surface features, for instance, different types of silanol groups. For the purpose of this paper, we shall use the former classification. In other words, a homogeneous layer of chromia on silica will be one that completely covers the silica support, on the inside of the pores as well as on the outside of the particle. Quite obviously, this "physical" homogeneity is not identical with "chromatographic" homogeneity (linear isotherm, symmetrical peaks, etc.).

Our group has recently attempted to investigate the chromatographic potential as well as the possibly detrimental effects, of various metal-containing surface species. Oxide and reduced-type structures were used by themselves and as carriers for "bonded" organic layers. Good gas chromatographic performance was obtained on several of these phases based on diatomaceous earth (12). A liquid-chromatography type silica gel was used to show that metal oxides bonded to its surface could drastically change lc retention patterns (13).

The main purpose of such prior studies was to define chromatographic utility. Multiple applica-

tions of metal-containing reagents were used in several cases. Yet it was not established whether such usage did in fact bring about the formation of multiple layers. It would appear interesting indeed, for chromatography as well as for surface chemistry, to know for a variety of select cases whether layers can be built on top of each other at will, or whether a "monomolecular" layer represents the limit. If multiple layers could be achieved, and if such layers were indeed "homogeneous" (cf. ref. 21), then chromatographic properties would be expected to stay reasonably constant once the monomolecular range had been exceeded. The current study was devised along these lines of interest.

Experimental

Figure 1 shows a schematic cross section of the set-up used to coat diatomaceous earth or silica gel support particles. These were filled into the vertical Pyrex tube which had Clearseal terminals and a fine frit located about 2/3 down its heated section.

The surrounding furnace was lab-made by drilling a block of aluminum. The block was heated by two cartridges (Watlow) and insulated by Marinite (Johns-Manville). Two sections of 1/4 in. copper tubing were used to pass tap water through the aluminum block for rapid cool-down.

Reagents were introduced from a little borosilicate vessel dangling inside the tube on a wire leading through a septum. This allowed positioning the reagent outside or inside the heated zone. Liquid reagents could also be introduced by injecting directly into the reagent vessel through another septum located on the side of the tube.

Synthesis of Multiple Layers

All supports were initially dried in vacuum at 110°C for 6 h.

Iron

About 4 g of Chromosorb W, NAW, 45/60 mesh, cleaned of metal contamination as described earlier (14), was filled into the reaction tube and covered by a quartz wool plug. An excess of anhydrous $FeCl_3$ was quickly filled into the reagent vessel and the apparatus assembled.

Then a 60 mL/min stream of dry nitrogen was turned on by opening valve A. Thirty minutes later the furnace was turned on and took another 30 min to reach the desired temperature of 280°C. After a further 30 min at 280°C, the cup containing $FeCl_3$ was lowered into the heated zone. The reaction was allowed to proceed for 90 min, during which excess $FeCl_3$ collected at the cold bottom outlet of the reaction tube.

Then the reagent vessel was raised and filled with 0.5 mL of water injected through the side port. Lowering the vessel into the heated zone introduced water vapor to the coated support; in addition, all of the nitrogen stream was bubbled through the "water doping tube" by closing valve A and opening valves B and C.

After 30 min in this condition, the apparatus was switched back to dry nitrogen. Traces of moisture that had condensed on the colder parts were driven off with a hot-air gun. The nitrogen purge was continued for 15 min; then the heater was turned off and the furnace cooled down by passing cold water through the copper tubing. This procedure was presumed to produce the "first layer"; it was precisely repeated for each additional "layer".

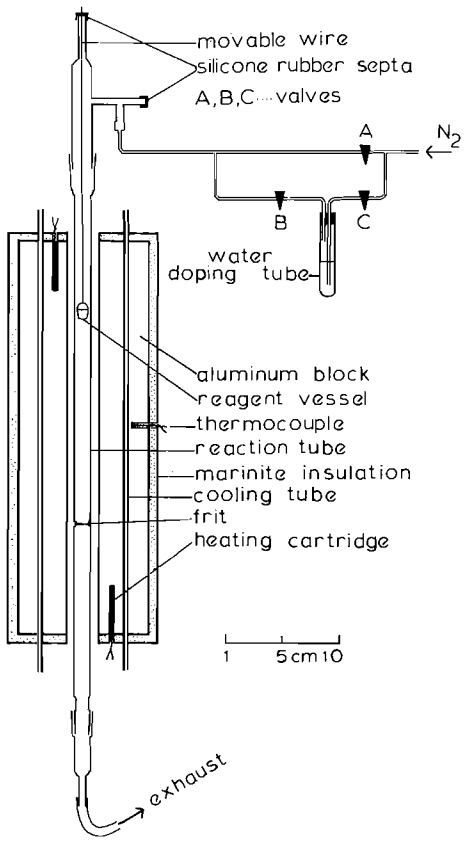

FIG. 1. Schematic of reaction tube, introduction system, and furnace.

Chromium

The coating of chromium was similar to that of iron with three exceptions. First, both Chromosorb W and silica gel 62, 80/100 mesh, were used. Second, the reagent CrO_2Cl_2 was introduced by injecting through the side port into the reagent vessel; ~0.2 mL for Chromosorb, ~0.5 mL for silica gel. Opening the reaction tube thus became unnecessary and the cool-down step was consequently omitted. Third, the reaction between support and chromyl chloride was allowed to proceed for 45 min.

Aluminum

The reagent was anhydrous $AlCl_3$, the support silica gel 62, 80/100 mesh. Otherwise the procedure was similar to that used for iron.

Titanium

Here the support was Chromosorb W, the reagent $TiCl_4$. Otherwise the procedure conformed to that given for chromium.

Analyses

Iron was extracted by boiling 6 *N* HCl and determined by atomic absorption flame spectrometry. Chromium was similarly extracted, but showed some resistance to complete extraction especially when multiple layers — and, consequently, longer heating periods — were involved. The extract was analysed by atomic absorption.

In addition, neutron activation analysis was used on the complete phases containing Cr, Al and Ti. The samples were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

placed into pre-cleaned polyethylene vials, which were heat-sealed and irradiated at the Dalhousie University SLOWPOKE reactor at a flux of 5×10^{11} n cm^{-2} s^{-1}. A high resolution Ge(Li) detector was used to record the γ-ray spectra.

Results and Discussion

The synthesis of chromatographic "bonded phases" via the presumed reaction of silanol groups has some controversial aspects; whether viewed from the organic side as now popular in liquid chromatography, or from the inorganic side as done in this study. To start with, the number and nature of silanol groups is usually in doubt. Full agreement is lacking even on the number of silanol groups on a "fully hydroxylated" silica surface.

When these silanol groups react, circular arguments easily arise. For instance, the stoichiometry of a particular reagent may be judged by the assumed number of silanol groups it is offered to react with. In other experiments, in turn, this or a similar reagent, with now assumed stoichiometry, may be used to determine the number of silanol groups. Aside from the potential involvement of such a circular argument, the choice of reagents and reaction conditions has a strong influence on the apparent result.

The difficulties inherent in this area are clearly illustrated, for instance, by an early publication of Boehm and co-workers (15). In the work of Peri *et al.* (16), who proposed a surface structure for silica based on its reaction with aluminum trichloride and silicon tetrachloride, it is suggested that often two silanol groups react with one halide molecule. Obviously, such stoichiometries strongly influence expectations of how thick a nominally monomolecular layer ought to be.

The situation becomes even more complicated with multiple reagent exposures. For instance, Hair and Hertl (17) reacted silica with PCl_3 and BCl_3 and subsequently hydrolysed the products to produce P—OH and B—OH groups for their ir study. In order to maximize the concentration of these surface groups, they had to repeat the reaction with halide and water as often as four and five times. (From the fact that they had to do this one would assume that, there, homogeneous multilayers were *not* produced by multiple reactions; however, such was also not the objective of their study.) A few of the variables involved in producing a particular layer thickness in multi-reaction experiments have been discussed in a previous paper (12).

Here, the nominal "number of layers", i.e., the number of reactions with metal halide and subsequent hydrolyses, is correlated with the number of metal atoms per 100 Å^2 of the original support. This is shown in Fig. 2 for iron. The number of iron atoms after the first coating corresponds approximately to the (most commonly assumed) number of available hydroxyl groups.

In the case of chromium shown in Fig. 3, however, the number of chromium atoms in the first coating is between two to three times that of the iron atoms in the case above. Chromium forms multilayers with apparent ease and even though the two methods of analysis, AA and NA, differ considerably in the higher concentration range, this trend nevertheless emerges clearly from the graph.

Why chromium should form heavier layers than iron is not immediately apparent. However, the presumed initial reaction with silanol groups is just one of a variety of processes that can occur on the surface. For instance, a reagent may not only "bond" but also "decompose" there. The former reaction is likely dependent on the presence of silanols, the latter likely not. Furthermore, deposition of a layer may start with the former but continue with the latter process.

This would complicate a mechanistic description of the synthesis, but in terms of the final product it may be an advantage. To wit, the problem here is

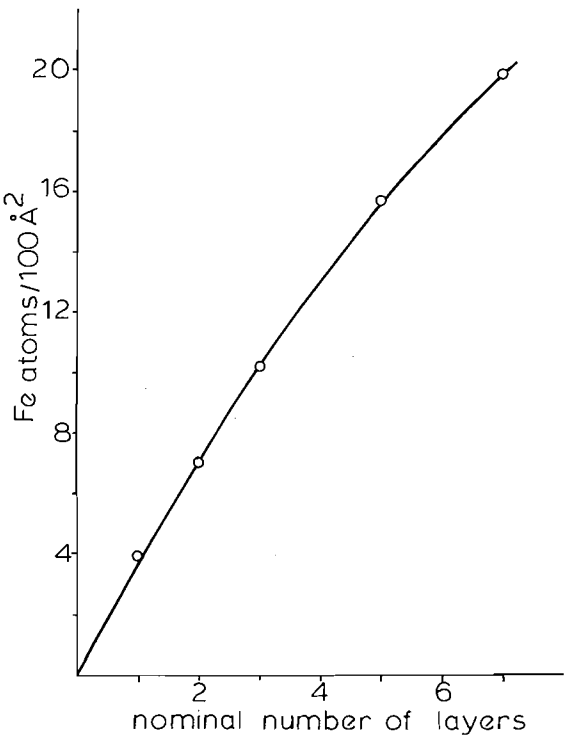

FIG. 2. Iron content of Chromosorb W treated with $FeCl_3$ and H_2O; as determined by AA. See text for details.

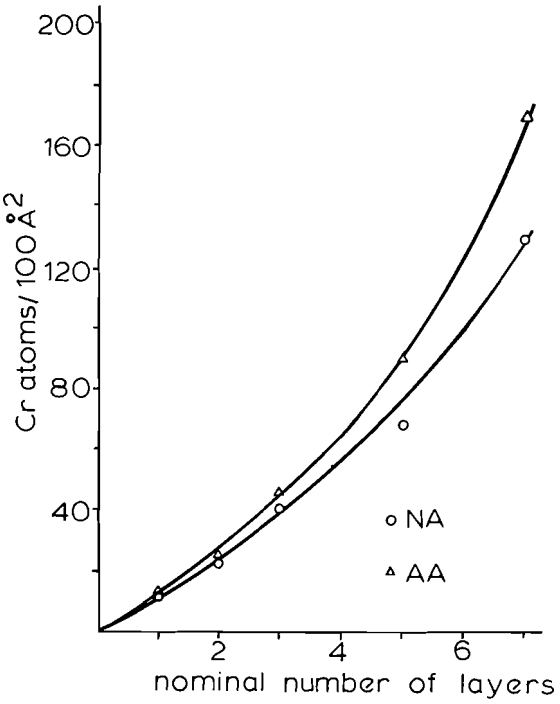

FIG. 3. Chromium content of Chromosorb W treated with CrO_2Cl_2 and H_2O; as determined by AA and NA. See text for details.

to produce a *homogeneous* layer — and a starting reaction involving densely and evenly distributed surface groups (the silanols) would be a helpful first step. Once a monolayer has been formed in this manner, reagent degradation may help to thicken it.

This scenario compares favorably with one in which a decomposing reagent would be the *lone* contributor. More likely than not, such a process would result in isolated agglomerations of metal oxide on a partially covered silica surface — in other words, in a heterogeneous layer.

Aside from tests of layer homogeneity, the question of mechanism could be resolved by experimental means. For instance, the kinetics of "surface reaction" and "reagent decomposition" are different. Once the accessible silanol groups have reacted in the former manner, the reaction should cease. The latter process, however, should be characterized by a fairly constant deposition rate (after, perhaps, a differently behaved initial phase). Other tests could involve the presumably larger contribution of a reagent decomposition process at higher temperatures or longer exposure times.

A further possible test of deposition mechanism utilizes the introduction of water between applications of metal halide (see Experimental). Water is presumably necessary to hydrolyze halide and provide bound hydroxyl groups to form the next layer.

If this presumption were entirely correct (and if the first application of metal halide were to saturate all available silanol groups), then the second and any further halide treatment *without* intermittent introduction of water should not significantly increase layer thickness. If, on the other hand, reagent decomposition were the prevailing mechanism, then the layers should build up in regular fashion with or without water treatment.

On a rather superficial basis, we have done some experiments that indicate the presence of both mechanisms. For instance, four applications of ferric chloride with intermittent water treatments lay down 13 Fe atoms on 100 Å^2 (Fig. 2). The same procedure but *without* water yields about 8 iron atoms on the same area. What is achieved by the second application of $FeCl_3$ after exposure to water vapor, requires (roughly) a second, third, and fourth halide treatment in its absence. The assumption of more than one mechanism seems therefore justified in the case of iron.

However, the evidence is far from making an ironclad case. A variety of questions would still need to be investigated. These include adsorption vs. reaction of halide and water molecules, the effects of temperature and time of exposure, and the behavior of different metal species. Desirable as such investigations may be, they were beyond the limited framework of this study. Questions other than of a mechanistic nature needed attention.

The chromium layers of Fig. 3 are bonded to a diatomaceous earth support with average pore size well above 10^3 Å. In analogy to the "bonding" of organic polymers (18) or organosilicon monomers (19) to the surface of supports of different pore sizes, one could have suspected that the number of chromium atoms bonded to 100 Å^2 of a silica gel like grade 62 with a surface area of approximately 300 m^2/g, would turn out to be less than those bonded to the diatomaceous earth of nominally 1 m^2/g.

This was indeed the case — as can be seen, for instance, from the analytical data for one and three layers. Instead of holding 12 and 40 Cr atoms as the Chromosorb did, the silica gel held only 4 and 10 chromium atoms per 100 Å^2, respectively. Silica gel 62 as a support was interesting for us to investigate; not only because of the potential extension to liquid chromatography but also because this material produces efficient gas–solid chromatography with aliphatics and aromatics.

TABLE 1. Retention temperatures t_R in °C of various gas chromatographic solutes in a standard program

Solute	Silica gel	Silica gel + 4 Cr/100 Å²	Silica gel + 10 Cr/100 Å²
Benzene	140	125	120
Naphthalene	225	212	210
Toluene	162	155	150
m-Xylene	185	178	173
n-Heptane	109	125	130
n-Undecane	173	200	210
Cyclohexane	88	105	108
Decalin	155	185	190
Average of absolute differences[a]	16.5	5	

[a] $\Sigma|\Delta t_R|/8$, where Δt_R is the difference in retention temperature for each of the eight solutes on silica gel and one-layer chromia, and on one-layer and three-layer chromia, respectively.

Thus we had the chance to test chromia homogeneity in a gas chromatographic experiment, using a one-layer material that was close to "monomolecular", and a three-layer one definitely beyond this ill-defined state.

What is one to expect from chromatographic retention experiments on these two materials of 4 and 10 Cr/100 Å²? If the layers are non-homogeneous (isolated chromia deposits strewn about the silica surface), then solute interactions involve both chromia and silica in both cases. That would suggest greater differences between the one- and three-layer phases. If the layers, on the other hand, are homogeneous, then there should be relatively little difference between the 4 and 10 Cr/100 Å² materials, since the former should be already close to covering the silica surface. What is presumed here, of course, is that the precise nature (really the chromatographic behavior) of "chromia" is the same in both cases, and that one can find chromatographic solutes that interact differently, though still on a comparable scale, with chromia and silica.

Fortunately, the chromatographic behavior of a chromium oxide layer differs distinctly from that of silica. On chromia, aliphatics are more and aromatics are less retained than on silica gel — the best possible situation for a test of surface homogeneity. Table 1 lists the results, and they are similar both for solutes that increase and for solutes that decrease in retention with the introduction of chromia. Once the first layer has been laid down, most of the change in retention has been accomplished. Thus both chromatographic and analytical data suggest (though neither of them proves) that it is possible in this case to synthesize successive, homogeneous metal oxide layers.

It can be added that the general performance of chromia layers, in gas as well as in liquid chromatography, is equivalent to that of silica in terms of efficiency (HETP) and peak symmetry, but that the retention characteristics of the two materials, fortunately, are different. A short chromatographic characterization of chromia layers has just appeared (20).

It would come as no surprise if the chromia layer were to exhibit catalytic activity — as, in fact, most chromatographic supports do. A typical catalysis study was never performed on the bonded inorganics, even though that could be interesting in its own right. Most chromatographers experience only the undesirable effect of a catalytic surface: its detrimental influence on solute integrity. In this context, and under our conditions and with our test compounds, overt degradation of migrating molecules was never apparent.

Thus the primary test of catalytic activity as well as of layer homogeneity was chromatographic in nature. This appeared to make sense, since our main interest is in chromatography and the synthesis of bonded phases for use by that technique. However, as one of the reviewers of this manuscript has pointed out, chromatographic testing alone is a bit unusual from the general viewpoint of surface characterization. To discuss the situation, we are adding the following few comments.

Chromatographic separation depends on the sorption of solute molecules on available surfaces. These surfaces are formally of two types: the outside of particles (in contact with the fast-flowing mobile phase) and the inside (in contact with slow-flowing or stagnant carrier). A rough calculation may help to appreciate the relative contributions of these two types of surfaces.

Typical silica gel 62 has a surface area of 300 m^2/g; as a gc packing its average particle diameter may be, say, 150 μm. If we consider the particles as spheres for purposes of calculation, and assume an apparent density of 0.2 g/cm^3, then the outside

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

surface is close to one tenth of one percent of the totally available one. Or, if we think in terms of a surface technique like ESCA, which would sample, say, about 50 Å deep, then, again, a volume negligible in terms of the total particle would be scrutinized. When extrapolating the results of such a technique to the chromatographic behavior of a particular packing, one has therefore to assume that the particle outside resembles the porous interior in terms of surface chemistry.

Unfortunately, this did not seem to have been the case with our materials covered by iron or chromium oxide. When sent for ESCA to Hewlett-Packard in Palo Alto, CA, the values for iron and chromium came back much lower than presumed from the overall content of these metals. Why the values were low has not been established. The effect could arise from synthesis conditions but, more likely, simply represents abrasion during handling, and transport across the continent. After all, the layers are only a few angstroms thick. Chromatographically, abrasion of the particle periphery is of course unimportant, since retention is essentially accomplished by the protected interior surfaces. A correlation of ESCA data with chromatographic characteristics would thus have been misleading. It is realized, of course, that particles can be treated with more caution — but we like to mention this disappointing attempt as a case-in-point for the difficulties and potential pitfalls that can arise in analyzing chromatographic packings.

The problem of porous particles surfaced again in infrared spectroscopy. For transmission ir spectroscopy, the sample has to be brought at least to a translucent form. Although plain silica becomes translucent when suspended in solvents such as chloroform, it turned out that the modified materials did not. This attempt having failed, other ir approaches were considered not more likely to succeed. A thin disc, reacted in analogy to a support with metal halide, may have turned out translucent — but, even then, it would have been extremely difficult to ascertain the surface homogeneity by transmission ir spectroscopy as some of the disc interior, closed to the metal halide, could have interfered. The other option, reflectance ir spectroscopy, was beyond the scope of this work.

To return to the synthesis of inorganic layers, the coating of one and three layers of alumina and titania was attempted on silica gel 62 and Chromosorb W, respectively. Neutron activation analysis showed that, for one layer, five aluminum atoms and nine titanium atoms were held onto 100 Å^2. These numbers increased to 9 and 24, respectively, after three coatings. These results are in essential accord with earlier data obtained on Porasil (13) and follow similar trends as those of Fe and Cr. Even though gas chromatography on alumina or titania turned out to be much poorer than on bare silica, it appears that here, too, multilayer formation was possible.

Dielectric relaxation of lithium and sodium perchlorates in 1,2-dimethoxyethane and propylene carbonate

HUBERT CACHET, MOHAMED FEKIR, AND JEAN-CLAUDE LESTRADE

Groupe de Recherche n°4 du C.N.R.S., Physique des Liquides et Electrochimie, associé à l'Université Pierre et Marie Curie, 4 place Jussieu, 75230 Paris Cedex 05, France

Received May 5, 1980

HUBERT CACHET, MOHAMED FEKIR, and JEAN-CLAUDE LESTRADE. Can. J. Chem. **59**, 1051 (1981).

The complex permittivity of $LiClO_4$ and $NaClO_4$ solutions in 1,2-dimethoxyethane (DME) has been measured in the frequency range 0.140–123.2 GHz. The data have been analysed according to a model for the reorientation of ion pairs given in a previous paper. The dielectric data are supplemented by conductivity measurements in a broad concentration range (10^{-4}–1 mol/L) which evidence the large extent of salt association. The main result is that the solvation of Li^+ and Na^+ by DME cannot be described as simply as in the case of other solvents, such as tetrahydrofuran or ethyl acetate, as far as the dielectric properties are concerned: while the assumption of rigidly bound solvating molecules was acceptable for the latter solvents, some freedom in the reorientation of these molecules has to be taken into account for the case of DME. $LiClO_4$ solutions in propylene carbonate (PC) + benzene and PC + DME mixtures have also been studied. The data, for the latter, can be qualitatively interpreted under the assumption that PC molecules take the place of DME molecules in the solvation sheath, even at low PC concentration.

HUBERT CACHET, MOHAMED FEKIR et JEAN-CLAUDE LESTRADE. Can. J. Chem. **59**, 1051 (1981).

La permittivité complexe de solutions de $LiClO_4$ et $NaClO_4$ dans le 1,2-diméthoxyéthane a été mesurée entre 0,140 et 123,2 GHz. Les résultats ont été analysés selon un modèle de réorientation de paires d'ions exposé dans un précédent article.

Les données diélectriques sont complétées par des mesures de conductivité dans un large domaine de concentration (10^{-4}–10 mol/L) qui mettent en évidence l'importance de l'association du sel. Le principal résultat est que la solvatation de Li^+ et Na^+ par le DME ne peut pas être décrite de manière aussi simple que dans le cas d'autres solvants, tels le tétrahydrofuranne et l'acétate d'éthyle, en ce qui concerne les propriétés diélectriques: tandis que l'hypothèse de molécules solvatantes rigidement liées était acceptable pour ces derniers solvants, il faut tenir compte d'une certaine liberté d'orientation de ces molécules dans le cas du DME. Des solutions de $LiClO_4$ dans les mélanges carbonate de propylène (PC) + benzène et PC + DME ont aussi été étudiées. Pour ces derniers, les données expérimentales peuvent être expliquées qualitativement en supposant que des molécules de PC prennent la place de molécules de DME dans la couche de solvatation même aux basses concentrations de PC.

Introduction

In a recent paper (1), we have shown that the dielectric relaxation of $LiClO_4$ in tetrahydrofuran (THF) and ethyl acetate solutions could be interpreted by a model in which the salt is assumed to be associated into ion pairs. The ion pairs are simultaneously the rotating dipoles and the diffusing defects which perturb the rotation of the dipoles; this model is derived from Glarum's (2) and Hunt and Powles' (3) theory, with a new feature consisting of the assumption that the ion pairs can be considered as a hard sphere fluid when calculating their radial distribution function. A parallel study of the conductivity vs. concentration curves, up to about 1 *M*, yielded (1) an anion–cation closest distance of approach, not very different from the radius of the ion pair deduced from the dielectric study. The dipole moment of the ion pair was also discussed in terms of this radius, and the discussion showed that Li^+ was solvated. A solvation number was also deduced from that part of the overall relaxation spectrum which can be assigned to the reorientation of the solvent molecules.

In this work, we present data about $LiClO_4$ solutions in 1,2-dimethoxyethane (DME) and propylene carbonate (PC). These solvents are used as components of the electrolyte solutions in high energy density batteries with lithium as anode. The data are analysed in the same way as those previously reported (1), but it will be shown that the solvation of Li^+ (and Na^+) by DME has to be taken into account in a different way.

Experimental

Conductivity measurements have been performed exactly in the same way as previously described (1), using a parallel-plate cell and the General Radio 1608-A impedance bridge between 10^3 and 2×10^4 Hz, and a coaxial cell with the General Radio 1615-A transformer ratio bridge between 10^3 and 10^5 Hz, for the less conducting systems. The complex permittivity measurements have been performed (4) with a slotted line and a coaxial cell between 0.15 and 3 GHz, with waveguide interferometers at 9.4 and 34 GHz. Additional measurements at 123.2 GHz, using a Michelson interferometer (5), have been performed in the Centre Hyperfréquence et Semi-Conducteurs (Université des Sciences et Techniques de Lille, France) by courtesy of Professor Constant.

The perchlorates are dried in vacuum, at 240°C for at least 36 h. The solvents are dried by contact on molecular sieves. The water content of the solutions, determined by coulometric titration, is typically 50 ppm before use, 200 ppm after use in the dielectric cells. All experiments have been performed at 25°C.

Conductivity

As previously explained (1), the salt is assumed to be in the form of single ions ($\alpha_1 c$), ion-pairs ($\alpha_2 c$), triple ions ($\alpha_3 c$), and quadrupoles ($\alpha_4 c$), where c is the overall concentration. The formations of ion-pairs, triple ions, and quadrupoles are governed by chemical equilibria with constants K_2, K_3, and K_4:

$$[1]\quad \begin{aligned} A^+ + B^- &\rightleftarrows AB & K_2\\ A^+ + AB &\rightleftarrows ABA^+ & K_3\\ AB + B^- &\rightleftarrows BAB^- & K_3\\ AB + AB &\rightleftarrows ABBA & K_4 \end{aligned}$$

where K_2 and K_3 depend on the dielectric constant ε_s of the solution (higher than that of the solvent) through the following equations

$$[2]\quad K_2 = (4\pi N_A a_2^3/3000) \exp (e^2/a_2\varepsilon_s kT - 1/2)$$

$$[3]\quad K_3 = (\pi N_A a_3^3/1000] \exp (e^2/2a_3\varepsilon_s kT - 3/2)$$

N_A is Avogadro's number, e the charge of the ions, k Boltzmann's constant, T the absolute temperature, a_2 the closest distance of approach of A^+ and B^-, a_3 a characteristic distance for the formation of triple ions. The equivalent conductivity Λ is assumed to depend only on α_1 and α_3:

$$[4]\quad \Lambda = \Lambda_0(\alpha_1 + \alpha_3/3)$$

where Λ_0 is the limiting equivalent conductivity of the salt in the form of single ions. Previously (1), we had corrected this equation by multiplying Λ_0 by η/η_0 where η is the viscosity of the solution and η_0 the viscosity of the solvent. Such a correction is active in the high concentration region, and it yielded a maximum in the theoretical Λ vs. c curve of $LiClO_4$ in ethyl acetate solutions. The same was found with $NaClO_4$ solutions in DME, which are about to be discussed in the present paper. Repeating the calculations without this corrective term, i.e. with eq. [4], showed the data were better reproduced and the maximum disappeared. The best values of the parameters (a_2, a_3, K_4) were changed, but this change was important only for K_4, moderate for a_3, and negligible for a_2. This reinforces the opinion that in such an analysis, K_4 strongly depends on the model, so that we cannot rely on the distinction between "free" ion pairs AB and ion-pairs engaged in a quadrupole ABBA; on the other hand a_2 does not depend too much on the model. In what follows, we thus adopt eq. [4] without any correction for the change of viscosity with concentration.

The data for $LiClO_4$ and $NaClO_4$ solutions in DME are shown in Fig. 1. The solid and dashed lines are the Λ vs. c curves calculated with the following sets of parameters.

$$LiClO_4 \begin{cases} a_2 = 4.70 \times 10^{-8}\,\text{cm} \\ a_3 = 11.0 \times 10^{-8}\,\text{cm} \end{cases} \quad K_4 = 8.8\,M^{-1}$$

$$NaClO_4 \begin{cases} a_2 = 4.70 \times 10^{-8}\,\text{cm} \\ a_3 = 11.8 \times 10^{-8}\,\text{cm} \end{cases} \quad K_4 = 8.7\,M^{-1}$$

Λ_0 is chosen as 176.4 ohm^{-1} cm^2 mol^{-1} for $LiClO_4$, 189.5 ohm^{-1} cm^2 mol^{-1} for $NaClO_4$. These values are derived from the values found in tetrahydrofuran (156.1 ohm^{-1} cm^2 mol^{-1} for $LiClO_4$ (6), 167.7 ohm^{-1} cm^2 mol^{-1} for $NaClO_4$ (7)) and application of the Walden rule which states the product $\Lambda_0\eta_0$ is constant.

The more striking feature of this result is that nearly the same set of parameters is found for both series of solutions. It can be seen in the raw data since at any concentration Λ does not depend very much on which salt ($LiClO_4$ or $NaClO_4$) is in solution. This fact is in contrast with the difference in the solubilities: $LiClO_4$ is not soluble in DME at a concentration higher than 0.2–0.25 M at 25°C. This is true in a dry solvent, because this solubility increases rapidly if a small amount of water is added. For instance, we had already given dielectric data on a 0.5 M solution of $LiClO_4$ in DME (8), with a water content of 6.3 g/L, i.e. 0.35 M. The second point to be noticed about these data is that the distance a_2 is significantly higher than for the solutions in tetrahydrofuran and ethyl acetate: the values 3.95 and 3.92 $\times$ 10^{-8} cm found with the viscosity correction

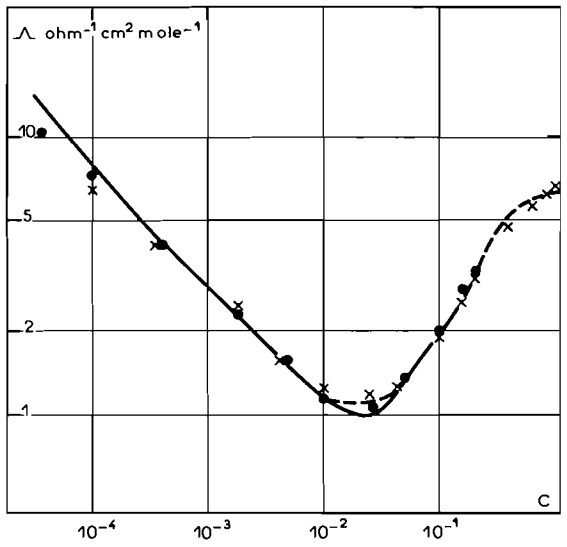

FIG. 1. Equivalent conductivity of $LiClO_4$ (●) and $NaClO_4$ (×) solutions in DME vs. salt concentration (mol/L). The solid ($LiClO_4$) and dashed lines ($NaClO_4$) have been drawn according to the model given in the text, with fitted values of a_2, a_3, and K_4.

(1) are changed into 3.97 and 3.93 $\times$ 10^{-8} cm with eq. [4].

Dielectric Relaxation

The overall measured complex permittivity can be written as:

$$\varepsilon(\omega) = \varepsilon_m(\omega) + \Delta\varepsilon(\omega) + \sigma/i\omega\varepsilon_0$$

where $\varepsilon_m(\omega)$ is the contribution of the solvent molecules and σ the static conductivity; $\Delta\varepsilon(\omega)$ is thus the contribution of the ions apart from the losses arising from the frequency independent conductivity σ. This splitting of $\varepsilon(\omega)$ into different terms has been discussed elsewhere (9), the discussion being summarized in ref. 1, where expressions are also given for the calculation of $\Delta\varepsilon(\omega)$. The latter read:

$$[5] \quad \Delta\varepsilon(\omega) = \frac{\varepsilon_s - \varepsilon_m}{1 + i\omega\tau_0}\left\{1 + i\omega\tau_0 \int_0^\infty 3r(x + r) \times \exp\left[-(x + r)^3 + r^3 - \lambda x\right] dx\right\}$$

where

$$[6] \quad r = R_s/L_0; \qquad (4\pi/3)\rho L_0{}^3 g(R_s) = 1$$

$$[7] \quad \lambda^2 = (L_0{}^2/D\tau_0)(1 + i\omega\tau_0)$$

These expressions correspond to a model of ion-pairs, whose numerical density is ρ, which reorient with a characteristic time τ_0 and which diffuse with a coefficient D. Their radial distribution function is that of hard spheres with a diameter R_s. Upon a collision, the time correlation function of the dipole moment vanishes instantly. The diffusion coefficient D can be related to the viscosity η of the solution and to a characteristic diameter R_0 through the Stokes–Einstein formula:

$$[8] \quad D = kT/6\pi\eta(R_0/2)$$

The (macroscopic) relaxation time τ_0 can be related to the same quantities by the Debye formula with the Powles–Glarum equation (10) for a micro/macroscopic correction:

$$[9] \quad \tau_0 = (3\varepsilon_s/(2\varepsilon_s + \varepsilon_m))4\pi(R_0/2)^3\eta/kT$$

In eqs. [5] and [9], ε_s is the low frequency limit of ε', the real part of $\varepsilon(\omega)$; ε_m is the same quantity for $\varepsilon_m(\omega)$, i.e. the contribution of the solvent molecules to the static permittivity. More details on the model and the calculations are given in ref. 1.

Solvation can be dealt with through a discussion of $\varepsilon_m(\omega)$. In ref. 1, as in previous papers, we had considered that $\varepsilon_m(\omega)$ could be deduced from the spectrum of the pure solvent, $\varepsilon_{m0}(\omega)$ with the transformation

$$[10] \quad (\varepsilon_m(\omega) - \varepsilon_\infty)/(\varepsilon_m - \varepsilon_\infty) = (\varepsilon_{m0}(\omega) - \varepsilon_\infty)/(\varepsilon_{m0} - \varepsilon_\infty)$$

the only change being in the static permittivity (ε_{m0} for the pure solvent, ε_m for the solvent contribution in the solution). The formula is deduced from the following model of solvation: a part of the solvent molecules reorients freely, i.e. in the same way, with the same characteristic time, in the pure solvent and in the solution; another part of the molecules does not reorient at all because they belong to a rigid solvation sheath built in such a way that the overall dipole moment of this aggregate is zero. Let qc be the concentration of the latter, $\rho_{ms} = \rho_m - qc$ the concentration of the former; ρ_m is the overall concentration of the solvent molecules in the solution, c the salt concentration; ρ_{ms}, hence q, can be deduced from the Fröhlich–Kirkwood formula written as:

$$[11] \quad \frac{(\varepsilon_m - \varepsilon_\infty)(2\varepsilon_m + \varepsilon_\infty)}{q\varepsilon_m} = \frac{N_A\rho_{ms}}{9000\varepsilon_0 kT} \times g_m\mu_m{}^2\left(\frac{\varepsilon_\infty + 2}{3}\right)^2$$

where the product $g_m\mu_m{}^2$ (Kirkwood correlation factor multiplied by the square of the dipole moment of the solvent molecules) can be deduced from the same formula applied to the pure solvent.

As shown further, this model does not apply to the DME solutions studied in the present work. In order to make the comparison of these solutions with previous ones easier, we performed the calculations on THF and ethyl acetate solutions of $LiClO_4$ solutions in a slightly different way, without any assumption on the value of q, formerly supposed to be equal to 4. In fact, this value is not very well determined by experiment and 4 is not significantly better than, say, 6 for a dilute solution. In the present case, a first run was performed without any constraint upon ε_m, then the function $\varepsilon_m(c)$ was smoothed and the calculations performed a second time with these smoothed values for ε_m; the fitting is not significantly worse for any system, and the result is given in Fig. 2 as a $q(c)$ curve. We have also reported the change in R_0 and R_s with c, because we dropped the condition $R_s \leq R_0$, used in ref. 1. The limiting values of q, for $c = 0$, are 5.9 $\pm$ 1.3 for THF solutions and 5.8 $\pm$ 1.1 for ethyl acetate solutions. Though higher than 4, these values remain small enough for a model involving a rigid solvation sheath to be acceptable. Moreover, the apparent dipole moment of $LiClO_4$ deduced from the difference $\varepsilon_s - \varepsilon_m$ leads to μ = 11.4 $\pm$ 0.4 D for both series,

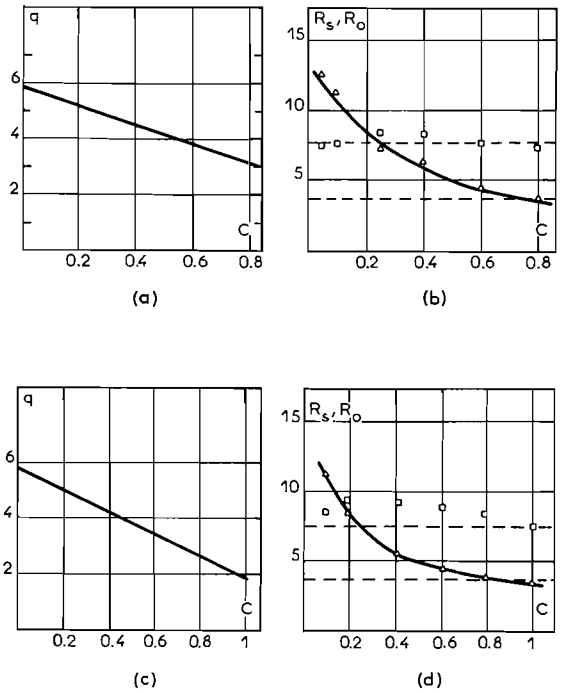

FIG. 2. $LiClO_4$ solutions in THF (upper part) and ethyl acetate (lower part). Salt concentration c in mol/L. Left (a and c), solvation number q in a rigid solvation sheath model defined in text. Right (b and d), collision distance R_s (△) and diameter R_0 (□) of the equivalent diffusion and rotation sphere, in the model of ion pairs. These lengths are given in Angströms. The horizontal dashed lines in b and d correspond to a_2 and $2a_2$ (characteristic distance of ion-pairing from conductivity data).

as a low concentration limit of μ_a; this value is slightly higher than in ref. 1 (10.5 ± 0.5 D) but the discussion remains unchanged, because the value of μ cannot be predicted with accuracy (it is difficult to take into account the solvating molecules in this calculation).

Solutions in DME

We have already reported dielectric measurements with $LiClO_4$ solutions in DME and dioxolane (8). The water content of these solutions was too large to be negligible, as shown by more recent measurements reported in the present paper. Though a correction can be made on the spectra to take water into account (11), we shall limit our study in the present case to the dried samples already considered above in the discussion of conductivity. The complex permittivity data are given in Table 1. Two samples of solvent have been used, with slightly different results. The difference can probably be ascribed to a difference in the residual water content. Anyway, each solution, in what follows, is compared to the appropriate sample of solvent. The dielectric relaxation of DME can be described by the Cole–Cole formula (12):

$$[12]\quad \varepsilon_{m0}(\omega) = \varepsilon_\infty + (\varepsilon_{m0} - \varepsilon_\infty)/(1 + (i\omega\tau)^{1-h})$$

with $0 < h < 1$. The infinite frequency permittivity has been estimated as 2.16, adding 20% to the electronic polarization α_e deduced from the optical refractive index $n_D = 1.38$, using the Clausius Mosotti formula. The set of equations reads:

$$[13]\quad (\varepsilon_\infty - 1)/(\varepsilon_\infty + 2) = (4\pi/3)\rho_m\alpha \qquad \alpha = 1.20\,\alpha_e$$
$$(n_D^2 - 1)/(n_D^2 + 2) = (4\pi/3)\rho_m\alpha_e$$

The parameters ε_{m0}, τ, and h which describe the relaxation of the solvents are given in Table 2 for both samples together with their water content. The influence of water can be seen from the difference with the same analysis performed on a third sample; the corresponding data of the latter, which had not been dried but used as received, have already been published (8). The autoassociation of DME can be discussed from the variations of the dielectric constant with temperature and dilution in a nonpolar component; the conclusion was that DME is not an associated liquid, as far as its dielectric properties are concerned (11).

A first analysis of the dielectric data of the solutions has been performed in exactly the same conditions as for the solutions in THF and ethyl acetate, i.e. with the assumption of a rigid, nonpolar aggregate of solvent molecules around the cation. As can be seen from Fig. 3, the value of q extrapolated at zero concentration is higher than 30 for both salts. So high a value had been observed only for associated solvents such as ethanol or methanol ($q = 25$ to 35) (13), whereas in nonassociated solvents, it is always lower than 6 to 8, whatever the analysis may be (9). In the present case, it can hardly be accepted that an ion could freeze so large a number of solvent molecules in their freedom of reorientation, when these molecules are able to reorient independently one from another. This difficulty can be circumvented if we drop the assumption that solvating molecules are rigidly bound to an ion, and if we accept that they are able to rotate with a characteristic time τ_p, longer than the reorientation time τ in pure solvent. The complex permittivity $\varepsilon_m(\omega)$ which originates from the solvent, in a solution, can thus be written as:

$$[14]\quad \varepsilon_m(\omega) = (\varepsilon_m - \varepsilon_p)/(1 + i\omega\tau_p) + \varepsilon_p(\omega)$$
$$(\varepsilon_p(\omega) - \varepsilon_\infty)/(\varepsilon_p - \varepsilon_\infty)$$
$$= (\varepsilon_{m0}(\omega) - \varepsilon_\infty)/(\varepsilon_{m0} - \varepsilon_\infty)$$

where ε_m is equal to ε_{m0} corrected for the change in the overall number of solvent molecules from pure solvent to the solution. The difference with the other model is that every molecule present in the solution con-

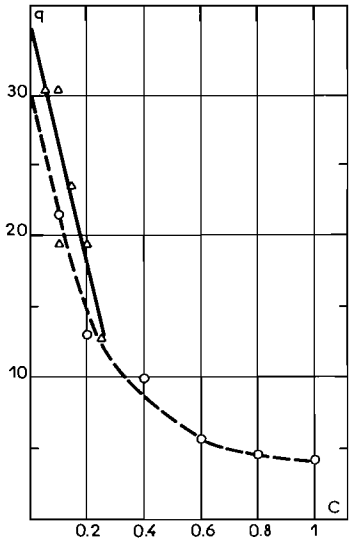

FIG. 3 $LiClO_4$ (△, solid line) and $NaClO_4$ (○, dashed line) in DME: solvation number in a rigid solvation sheath model.

tributes to the polarization since it reorients, though very slowly. The solvation number $q = (\rho_m - \rho_p)/c$ is then the number of molecules which interact with an ion in such a way that it reorients slower than in pure solvent. Of course such a splitting of the solvent molecules in two classes is arbitrary; ρ_p can be calculated from ε_p, using the Fröhlich–Kirkwood formula (eq. [11]) where ε_{ms} is changed into ε_p, ρ_{ms} into ρ_p. A common value of τ_p can be used in the analysis for each salt. The best choice is 350×10^{-12} s for $LiClO_4$, 300×10^{-12} s for $NaClO_4$, about 100 times as long as in pure solvent. The results of the analysis are given in Table 3. A smoothing over ε_p vs. c has also been performed, as above over ε_m vs. c The q values thus found can be given as

$$q = 8.54 - 6.47c \qquad \text{for } LiClO_4$$

$$q = 11.2 - 15.6c + 8.1c^2 \qquad \text{for } NaClO_4$$

In this model, there is no reason for the limiting (zero concentration) values of q to be lower than 6–8, but they are actually lower than in the first analysis. However the main point which is evidenced is that solvation in DME is qualitatively different from what it is in THF, ethyl acetate, and other non-associated solvents previously studied (9) since the simple model used before cannot apply.

The μ_a values of Table 3 can also be extrapolated to zero concentration and yield the dipole moment of the ion pair: 12.5 D for $LiClO_4$, 12.2 D for $NaClO_4$. The polarisability α_+ of the solvated cation can be deduced from the cation–anion distance $r = 2a_2$ using the Böttcher formula which gives the dipole moment μ of two polarisable charge points

$$[15] \quad \mu = er\,\frac{1 - (\alpha_+ + \alpha_-)/r^3 - 8\alpha_+\alpha_-/r^6}{1 - 4\alpha_+\alpha_-/r^6}$$

with $\alpha_- = 5.30 \times 10^{-24}$ cm^3 for ClO_4, under the assumption that the anion is not solvated. The value of α_+ thus found is 32×10^{-24} cm^3, much higher than the value found in THF or ethyl acetate, which was about 13×10^{-24} cm^3. This reinforces the idea that a larger number of molecules interact with the cation in DME than in other solvents, since the molecular polarisability of these solvents is not so different (about 10×10^{-24} cm^3 for THF, 14×10^{-24} cm^3 for DME).

The values of R_s decrease with increasing concentration of salt, but always remain larger than a_2, as in THF solutions. As previously discussed in the latter case (1), this can be explained by the fact that considering the ion-pairs as hard spheres is too crude an approximation, and that nevertheless, their closest distance of approach is always larger than the corresponding distance for two ions. But, whereas for THF solutions R_0 was about twice a_2, we find here $R_0 < 2a_2$; this might be taken as an argument in favor of a solvating sheath which is not made of tightly bound molecules, in agreement with the model: the reorientation and the diffusion of the ion pair are faster, and thus correspond to smaller equivalent spheres.

An open question is the difference between $LiClO_4$ and $NaClO_4$ since their solubilities in DME are quite different, whereas no difference can be observed for the dielectric properties of the solutions.

Solutions in PC + Benzene Mixtures

$LiClO_4$ solutions in pure PC solutions are highly conducting, but information about ion–solvent molecule and ion–ion interaction can be obtained if such solutions are diluted in a nonpolar solvent. Complex permittivity data of 0.2 M $LiClO_4$ solutions in PC + benzene mixtures are given in Table 4, along with the data for the corresponding solvents.

The dielectric property of pure PC has been studied up to 34 GHz by Cavell (14). His data have been supplemented in this work by a measurement at 125 GHz ($\varepsilon = 4.05 - i2.84$). These data have been analysed according to the Cole–Davidson formula (15).

$$[16] \quad \varepsilon_{m0}(\omega) = \varepsilon_\infty + (\varepsilon_{m0} - \varepsilon_\infty)/(1 + i\omega\tau)^\beta$$

with $0 < \beta < 1$. The same equation has been used for the PC + benzene mixtures. The data have been analysed with the condition that the polarization $(\varepsilon_\infty - 1)/(\varepsilon_\infty + 2)$ is a linear function of the corres-

ponding quantity for each component:

$$[17]\quad (\varepsilon_\infty - 1)/(\varepsilon_\infty + 2) = \frac{\rho_b\,\varepsilon_b - 1}{\rho_{b_0}\,\varepsilon_b + 2} + \frac{\rho_{PC}\;\varepsilon_{\infty,PC} - 1}{\rho_{0,PC}\,\varepsilon_{\infty,PC} + 2}$$

where the subscript b refers to benzene, ρ_b and ρ_{PC} are the partial densities of each component in the solution, as opposed to ρ_{0b} and $\rho_{0,PC}$ which refer to the pure liquid. The parameters of the dielectric relaxation of pure PC and mixed solvents are given in Table 5. This table also gives the Kirkwood correlation factor g of PC, calculated from the Fröhlich–Kirkwood formula (eq. [11]) with μ_{PC} = 4.94 D (16). The g factor can also be calculated at various temperatures from the data of Gores (17) between −45°C and 40°C. The Clausius Mosotti formula is used to evaluate ε_∞ at each temperature, the density being given in ref. 17; g increases from 0.79 to 0.92 in the above temperature range These values indicate that PC is not a highly associated liquid, as far as the dielectric properties are concerned.

The solutions themselves have been analysed with the same model of association as above. Solvation has been dealt with as in THF solutions, i.e. with the assumption of a nonpolar rigid aggregate of q molecules around each cation. The number thus found, as shown in Table 6, is higher than in THF, but lower than in DME with the same assumption and at the same concentration. In the present case, it can probably be explained by the high dipole moment of PC which probably strongly interacts through electrostatic forces with Li^+. This high solvation number is in agreement with the high value found for R_s and R_0, especially at the lower PC content.

Solutions in PC + DME Mixtures

The complex permittivity data for each solvent and each solution are given in Table 7. The salt concentration is kept constant, at the highest value possible in pure dry DME (0.2 *M*, $LiClO_4$); the concentration of PC corresponds to 1–2–4–6 molecules of PC per cation. The spectra of the solvents can be analysed with the assumption that the contribution of PC is a simple Debye relaxation, while that of DME is the same as in pure DME apart from a change of magnitude $(\varepsilon_{DME} - \varepsilon_\infty)$ related to the change in the partial density of DME from $\rho_{DME,0}$ (pure liquid) to ρ_{DME} (mixture). The complex permittivity of the mixed solvent thus reads:

$$[18]\quad \varepsilon_m(\omega) = \varepsilon_{DME}(\omega) + \Delta\varepsilon_{PC}/(1 + i\omega\tau_{PC})$$

where $\varepsilon_{DME}(\omega)$ results from eqs. [10] and [11] where the subscript m should be changed into the subscript DME. Table 8 gives the parameters of the spectra. The relaxation time of PC is about 4 times as long as that of DME, so that the decomposition just performed is not meaningless. Because of the high dipole moment of PC, its dielectric contribution is about the same as that of DME at the highest concentration used (1.2 *M*).

The spectra of the solutions involve many parameters if we adopt the model of non-rigid solvation sheath which we found necessary to develop for the case of pure DME as solvent. It is not a problem of numerical analysis, as the program used proved to be able to find out these parameters. The difficulty comes from the fact that the data themselves are not accurate enough for such information to be extracted. The analysis has then been performed under the assumption that only the magnitudes $(\varepsilon_{DME} - \varepsilon_\infty)$ and $\Delta\varepsilon_{PC}$ change in the presence of salt. The latter is assumed to contribute as in pure DME, according to eqs. [5] to [9]. Two solvation numbers

are thus found,

$$q_{DME} = (\rho_{DME} - \rho_{DME,s})/c$$

and

$$q_{PC} = (\rho_{PC} - \rho_{PC,s})/c$$

where the second subscript, s, refers to the concentration, in the electrolyte solutions, of the molecules which contribute the relaxation. For the case of DME, this concentration results from eq. [11], with m standing for "DME". For the case of PC, the Fröhlich–Kirkwood equation is written for a mixture of PC and DME so that, taking into account eq. [11], $\rho_{PC,s}$ is deduced from:

$$[19]\quad \frac{(\varepsilon_M - \varepsilon_\infty)(2\varepsilon_M + \varepsilon_\infty)}{9\varepsilon_M} = \frac{N_A \rho_{PC,s}}{9000\varepsilon_0 kT} q_{PC}\mu_{PC}^2 \times \left(\frac{\varepsilon_\infty + 2}{3}\right)^2 + \frac{(\varepsilon_{DME} - \varepsilon_\infty)(2\varepsilon_{DME} + \varepsilon_\infty)}{9\varepsilon_{DME}}$$

where $q_{PC}\mu_{PC}^2$ corresponds to the quantity given in Table 9, which refers to PC in the mixed solvent. The results of the analysis are given in Table 9, along with the same analysis (corresponding to a rigid solvation sheath) for the case of the 0.2 *M* $LiClO_4$ solution in pure DME. The solvation numbers thus found have no real physical significance themselves, as they have for the solutions in pure DME, but the interesting point demonstrated by these experiments is the drastic decrease in q_{DME} when PC is added to the solution. This is accompanied by an increase in q_{PC}, and can be taken as indicating a strong influence of PC, even at low concentration with respect to the salt concentration, in the solvation phenomenon of Li^+ by DME.

TABLE 8. Dielectric relaxation of PC + DME mixtures

ρ_{PC} (mol/L)	ρ_{DME} (mol/L)	$\Delta\varepsilon_{PC}$	$10^{12}\tau_{PC}$ (s)	ε_{DME}

Conclusion

Complex permittivity data of $LiClO_4$ and $NaClO_4$ solutions in DME have been analysed according to a model for the reorientation of ion-pairs, which had been shown to apply to a variety of systems in a previous work (1). In contrast with the case of

$LiClO_4$ in other solvents, such as THF and ethyl acetate, the assumption of tightly linked solvating molecules leads to unrealistic values of the solvating number, so that the data have been analysed with the assumption that these molecules retain some freedom of reorientation. This assumption is also supported by the fact that the radius of the equivalent rotating and diffusing sphere which represents the ion-pair in the model is smaller than the closest distance of approach between cation and anion, as deduced from the conductivity data. $LiClO_4$ solutions in PC + benzene and PC + DME mixtures have also been investigated, and analysed according to the same model of ionic relaxation. While PC + benzene solutions exhibit trivial behaviour, some qualitative information can be drawn from PC + DME solutions: it seems that PC takes the place of DME in the solvation sheath, even at low PC concentration. This might explain why the solubility of $LiClO_4$ in DME drastically increases when a small amount of PC is added to the solvent.

The intramolecular Cannizzaro reaction of phthalaldehyde

ROBERT S. MCDONALD[1] AND CHRISTINE E. SIBLEY[2]

Department of Chemistry, Mount Saint Vincent University, Halifax, N.S., Canada B3M 2J6

Received August 6, 1980

ROBERT S. MCDONALD and CHRISTINE E. SIBLEY. Can. J. Chem. **59**, 1061 (1981).

Phthalaldehyde undergoes an intramolecular Cannizzaro reaction in aqueous base to produce the *o*-hydroxymethylbenzoate ion. The kinetics of the reaction have been measured over a range of sodium hydroxide concentration at 40°C. The reaction is considerably slower than that of the analogous reaction of phenylglyoxal since it proceeds exclusively via the cyclic hydrate dianion which must undergo a very unfavorable ring opening before internal hydride transfer can occur.

ROBERT S. MCDONALD et CHRISTINE E. SIBLEY. Can. J. Chem. **59**, 1061 (1981).

La phtaldéhyde subit une réaction de Cannizzaro intramoléculaire en présence d'une base en solution aqueuse et produit l'ion *o*-hydroxyméthylbenzoate. On a mesuré la cinétique de la réaction en faisant varier la concentration en hydroxyde de sodium à 40°C. La réaction est considérablement plus lente que la réaction analogue du phénylglyoxale puisqu'elle se fait exclusivement par l'intermédiaire d'un dianion hydraté cyclique qui doit subir une ouverture de cycle très défavorable avant que le transfert interne d'hydrure ne se produise.

[Traduit par le journal]

Introduction

Intramolecular reactions have been frequently studied as models for reactions occurring within an enzyme–substrate complex (1, 2). Thus systems have been investigated which mimic the chemistry at the active site of several proteases and lysozyme and which involve amide, ester, or acetal hydrolysis catalyzed by various proximate functional groups. However, few model systems have been proposed to mimic the behavior of the oxidoreductases which catalyze hydride transfer between substrate and coenzyme. An intramolecular Cannizzaro reaction might provide such a model.

The Cannizzaro reaction of aldehydes with no α-H has been extensively studied and reviewed (3) and the mechanism of the reaction is now well understood (4).[3] Kinetic studies of the homogeneous reaction (usually in mixed aqueous–organic solvents) show the reaction to be second order in aldehyde and may be both first and second order in hydroxide. These latter kinetic terms have been taken (7) to represent rate-determining hydride transfer from the hydrate monoanion and dianion, respectively, to a second aldehyde molecule.

Although several intramolecular Cannizzaro reactions have been reported (6, 8, 9) only that of phenylglyoxal has been investigated in any mechanistic detail (6, 10, 11). We chose initially to investigate the behavior of the *o*-dialdehyde, phthalaldehyde (**1**), in aqueous base to see if it also undergoes this intramolecular hydride transfer (to produce *o*-hydroxymethylbenzoate ion). This reaction has not been reported previously and we hoped, if reaction did occur, to extend investigation of catalysis to a series of amine-thiols as Franzen (12) has done for phenylglyoxal. This paper reports only the results of the base-catalyzed reaction.

Experimental

General

Routine ultraviolet spectra were recorded on a Beckman 24 spectrophotometer. Kinetic runs were carried out on a Hitachi (Perkin-Elmer) 139 instrument equipped with a Haake FG circulating thermoregulator. An Orion 601A pH meter with a combination electrode was used to measure all pH values. The meter was standardized with Fisher certified buffers at pH 7.00 and 10.00. Routine nuclear magnetic resonance spectra were recorded on a Varian EM 360A 60 MHz spectrometer. Peak positions were measured in ppm (δ) relative to tetramethylsilane (TMS) as internal reference in $CDCl_3$.

Materials

The purification of phthalaldehyde and the preparation of buffer solutions has been described previously (13). Water distilled through an all-glass apparatus (Corning Mega-Pure) was used in the preparation of all solutions. Stock 1.0 and 0.10 *M* NaOH solutions were prepared by diluting the appropriate Fisher concentrate with boiled, then cooled, distilled water (in the case of the 0.10 *M* solution, KCl was added to maintain an ionic strength of 1.0). All dilutions of these stock solutions were made with 1.0 *M* KCl. The 1.0 and 0.2 *M* NaOH solutions were standardized against primary standard potassium acid phthalate and found to be 0.9957 and 0.1983 *M* in NaOH respectively. The concentrations of all other base solutions were assumed to be within 1% of the specified value and no corrections to rate constants were made. The 2.0 *M* NaOH solution was prepared by diluting the 1.0 *M* concentrate to half the specified volume with water. The 1.50 *M* solution was prepared by dilution of this solution with water.

For comparison with the uv spectrum of **1** under conditions in which it is present primarily in one of the cyclic forms (see Scheme 1), the cyclic acetal, 1,3-dimethoxyphthalan, was prepared.

Phthalaldehyde (5.0 g) was refluxed for three hours in 40 mL methanol (a large excess) in the presence of a catalytic amount of *p*-toluene sulfonic acid. The cooled solution was poured into 100 mL of 5% Na_2CO_3 and extracted (4 × 50 mL) with ether. The combined ether extracts were dried ($MgSO_4$), filtered, and concentrated to yield a colourless liquid (6.4 g, 93%) which by nmr analysis proved to be a mixture of *cis*- (54%) and *trans*- (33%) 1,3-dimethoxyphthalan accompanied by 13% of the noncyclic *bis*-acetal. Simple distillation (bp 59–61°C at 1 Torr) reduced to 6% the amount of *bis*-acetal, leaving the *cis*- and *trans*-isomers in the unchanged ratio 1.7:1. This method provides a much simpler route to the acetals than that previously reported (14) and the *cis*:*trans* ratio observed is similar to that (1.5) measured by Aso and Tagami (15). This product was used directly for the uv spectral measurements.

Kinetics

Kinetic runs were initiated by injecting 10–20 μL of a 0.03 *M* stock solution of phthalaldehyde in dioxane into 3.0 mL of the aqueous base solution which had been temperature pre-equilibrated for at least 30 min in the cell compartment of the Hitachi instrument. The reaction was monitored at 230 nm on the high wavelength shoulder of the λ_{max} of the product which appears to be near 200 nm. Typically, for a 1.50×10^{-4} *M* solution of substrate, the absorbance changed from 0.18 to 0.67 at this wavelength during a kinetic run. Normally, 25 absorbance readings were made over the extent of 90% reaction and an "infinity" value taken after at least ten half-lives. Pseudo-first-order rate constants (k_{obs}) were calculated from the slopes of the semi-logarithmic plots of $(A_\infty - A)$ vs. time using a standard linear regression analysis on a computer. All kinetic plots were strictly linear ($r \geq 0.999$) over at least three half-lives of the reaction. The quoted rate constants are the average of at least duplicate determinations; agreement between replicate runs was normally within 3%.

Product

The final uv spectrum of the reaction mixture after a kinetic run was virtually superimposable on that of an equal concentration of phthalide in aqueous base. The ring opening of phthalide with hydroxide producing *o*-hydroxymethylbenzoate is known to be a very rapid reaction under these conditions (k_{OH} = 0.87 $M^{-1}s^{-1}$ at 25°C (16)).

Product isolation was carried out as follows. A solution of phthalaldehyde (317 mg; 2.36 mmol) in 25 mL of 0.25 *M* NaOH (6.25 mmol) was stirred for 8 h at 40°C. The solution was acidified with HCl to pH 2 and stirred for a further three hours at room temperature. The aqueous solution was then poured into an equal volume of saturated NaCl and extracted with CH_2Cl_2 (3 × 75 mL). The combined extracts were dried ($MgSO_4$), filtered, and concentrated to yield 295 mg (93% yield) of a white crystalline solid which proved to be pure phthalide by nmr analysis and mp after recrystallization (73–74°C; lit. (17) mp 75°C). We chose to isolate the lactone rather than the hydroxy-acid since preliminary product runs gave mixtures of the two compounds (the acid-catalyzed lactonization reaction has been studied (18)).

To determine whether the base-catalyzed reaction indeed involves an intramolecular hydride transfer, a product isolation run was carried out as above but using 0.25 *M* NaOD in D_2O. The solution was acidified with DCl and extracted with CH_2Cl_2. After removal of solvent, the solid was taken up in $CDCl_3$ for nmr analysis. On our machine, the relative integral of the aromatic to methylene protons of a commercial phthalide sample was in the ratio 4.0:1.95. The ratios for two separate product runs in D_2O were 4.0:1.94 and 4.0:1.96. Clearly no deuterium (< 1%) is incorporated into product from solvent and hydride transfer is intramolecular.

Results and Discussion

pK_a Measurement of Hydrate (2)[4]

The uv spectrum of **1** in dioxane is that expected for an aromatic aldehyde (λ_{max} nm (ε): 222(26 700), 256(8460), 297(2190)). However, spectra in aqueous solution show significantly weaker absorptions in this region indicative of extensive hydration to form **2**; K_{H_2O} is 7.7 at 25°C and 4.0 at 40°C (13). These absorptions remain essentially constant in intensity in a series of phosphate buffers over the pH range 5.7–10 but become progressively weaker as the pH increases further. This is illustrated in Fig. 1(a) where the extinction coefficient at 259 nm (the apparent λ_{max} values for aqueous solutions of **1** occur at 259 and 299 nm) is plotted as a function of the pH of the solution (phosphate buffer or sodium hydroxide). Much of the absorption in the neutral or weakly basic solutions at this wavelength is due to the 11–12% of **1** which is not hydrated under these conditions. However, as the pH increases above 10, the absorption intensity decreases as remaining **1** is siphoned out via **2** to monoanion **3** and eventually to dianion **4** (see Scheme 1). The spectrum in 1.0 *M* NaOH (λ_{max} nm (ε): 259 (448)) is reminiscent of that for a nonconjugated benzenoid system and is similar to that observed for 1,3-dimethoxyphthalan (in 1.0 *M* KCl at 25°C, λ_{max} nm (ε): 251(423), 256(419), sh 280(65)).

The inflection point of the sigmoidal curve in Fig. 1(a) reveals the pK_a of the hydrate to be in the range 11.5–11.6. Alternatively (and rather more accurately), a plot of $\log(\varepsilon - \varepsilon_\infty)/(\varepsilon_0 - \varepsilon)$ vs. pH where ε_0 and ε_∞ are limiting values[5] of the extinction coefficients at low and high pH respectively, should be linear with an intercept at $\log(\varepsilon - \varepsilon_\infty)/(\varepsilon_0 - \varepsilon) = 0$ of pH = pK_a. This plot is illustrated in Fig. 1(b); least-squares analysis yields a value of the pK_a of 11.44(±0.05); slope = −0.91 ± 0.04, r = 0.993. The data at 299 nm gave plots of similar shape and yielded a pK_a value of 11.56(±0.06); slope = −0.91 ± 0.06, r = 0.985. Thus, we assign a value of 11.50(±0.10) to the first pK_a of **2** at 25°C, μ = 1.0. This value may be compared to that (12.2) observed by McClelland and co-workers[6] for 1-phthalanol. Apart from the statistical correction to the pK_a for the two identical acidic centres in **2** (0.3), the

[4]The structures of all compounds referred to by numbers are shown in Scheme 1.

[5]Limiting values for the extinction coefficients used to construct Fig. 1(*b*) were: at low pH (ε_0), 1163; at high pH (ε_∞), 437.

[6]R. A. McClelland, private communication.

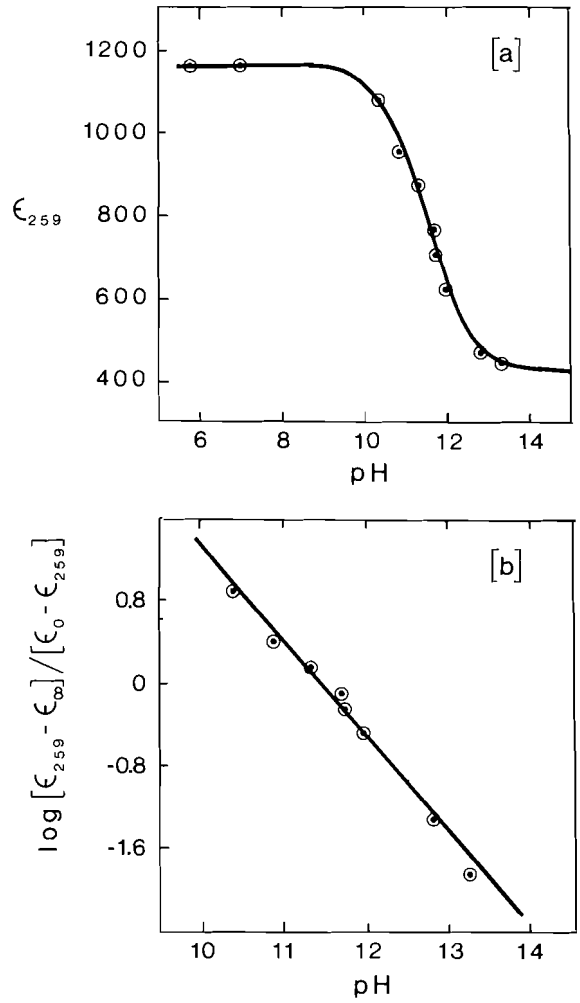

FIG. 1. (*a*) The pH dependence of the extinction coefficients at 259 nm of aqueous solutions of **1** at 25°C, μ = 1.0; (*b*) The plot for the graphical determination of the pK_a of **2** at 25°C, μ = 1.0. The intercept of this plot at Y = 0 gives the pK_a.

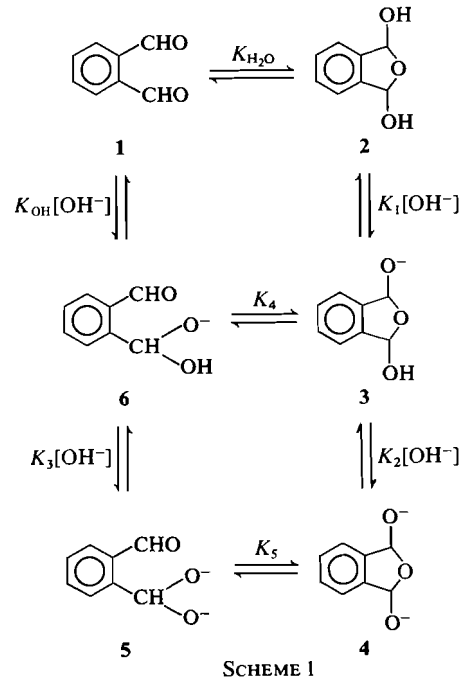
effective acid-strengthening inductive effects of both the aromatic and ethereal substituents in **2** should be larger than those in 1-phthalanol. Thus our value for the first pK_a of **2** is quite reasonable.

The Cannizzaro Reaction

It is clear from uv spectral and product isolation results (see Experimental) that **1** undergoes a base-catalyzed intramolecular hydride transfer to form the *o*-hydroxymethylbenzoate ion. The product contains no deuterium when the reaction is carried out in NaOD–D_2O.

The pseudo-first-order rate constants (k_{obs}) for appearance of product under various conditions are collected in Table 1 and the data at 40.3°C are plotted vs. [NaOH] in Fig. 2.



SCHEME 1

Kinetic runs carried out in NaOH solutions greater than 1.0 *M* are no longer at an ionic strength of 1.0. However, the k_{obs} value in 1.0 *M* NaOH which is also 1.0 *M* in KCl (μ = 2.0) is identical within experimental error to that observed in the absence of KCl (μ = 1.0) illustrating that these kinetic data have negligible rate contributions due to variable ionic strength over this range. These results have been analyzed with the rest of the kinetic data.

A change of solvent from water to 50% by volume methanol–water caused an 8.8-fold rate reduction in 0.20 *M* NaOH, a result not unexpected for the polar reaction. However, this particular solvent mixture was chosen to allow calculation of the "effective concentration" of the second aldehyde group in the substrate acting as an internal hydride acceptor. This is done by dividing the second-order rate constant, k_2, for our reaction ($1.33 \times 10^{-4} M^{-1}s^{-1}$) by the third-order rate constant for the intermolecular Cannizzaro reaction of benzaldehyde under identical conditions of solvent and temperature. This latter value at 40.3°C in 50% methanol–water can be calculated from the data of Tommila (5*b*) to be $1.03 \times 10^{-5} M^{-2}s^{-1}$ which leads to an "effective concentration" of the second CHO group in **1** of 13 *M*.

Also collected in Table 1 are the second-order rate constants k_2 (= k_{obs}/[NaOH]), for the reaction. It is clear that k_2 is reasonably constant at 40.3°C ($1.19 \pm 0.03 \times 10^{-3} M^{-1}s^{-1}$) up to 0.25 *M* NaOH

TABLE 1. Collected kinetic data for the intramolecular Cannizzaro reaction of **1** in aqueous NaOH

[NaOH] (M)	Conditions[a]	k_{obs} ($\times 10^4$ s^{-1})[b]	k_2 ($\times 10^3$ M^{-1} s^{-1})[c]
0.05		0.586(±0.008)	1.17
0.10		1.205(±0.008)	1.21
0.15		1.84 (±0.02)	1.23
0.20		2.34 (±0.08)	1.17
	50% (v/v)CH_3OH/H_2O	0.266(±0.005)	0.133
	30.5°C	0.906(±0.013)	0.453
	46.5°C	4.49 (±0.04)	2.24
	52.0°C	7.83 (±0.08)	3.92
0.25		2.90 (±0.02)	1.16
0.50		4.61 (±0.03)	0.922
0.75		5.63 (±0.07)	0.751
1.00		6.78 (±0.10)	0.678
	1.0 M KCl (μ = 2.0)	6.85 (±0.07)	0.685
1.50	μ = 1.50	8.16 (±0.08)	0.544
2.00	μ = 2.00	9.38 (±0.08)	0.469

[a] Unless noted otherwise, the conditions are 40.3 (±0.5)°C, ionic strength = 1.0 with KCl in aqueous solution.
[b] Average of 2–4 runs; the errors quoted are standard deviations.
[c] $k_2 = k_{obs}/[NaOH]$.

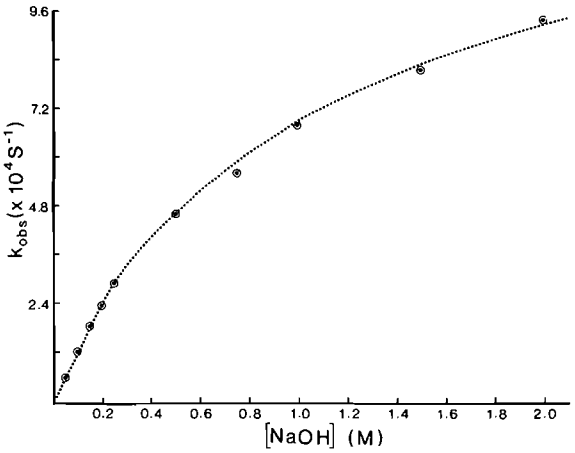

FIG. 2. The hydroxide ion-dependence of the pseudo-first-order rate constants for appearance of product in aqueous solutions of **1** at 40.3°C, μ = 1.0. (Data from Table 1).

(Fig. 2 is essentially linear over this range with a zero intercept) but decreases considerably at higher concentrations. Since we believed initially that k_2 was a true second-order (bimolecular) rate constant, the effect of temperature on k_2 was examined over the range 30–52°C at a base concentration where Fig. 2 is essentially linear (0.20 M NaOH). The activation parameter plot (of ln k_2T^{-1} vs. T^{-1}) yielded values for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ of 19.0 ± 0.5 kcal mol^{-1} and −11.4 ± 1.6 cal K^{-1} mol^{-1}, respectively. We hesitate to interpret these data since it is now clear that k_2 is a composite of rate and equilibrium constants which will be variously affected by temperature (see Scheme 1 and Appendix).

The data in Table 1 and Fig. 2 at 40.3°C fit an equation of the form [1] from 0.05 to 2.0 M NaOH.

A weighted nonlinear regression

$$[1] \quad k_{obs} = \frac{a[OH^-]}{1 + b[OH^-]}$$

of the data to eq. [1] yields values for a and b of 1.38 ± 0.02 × 10^{-3} M^{-1}s^{-1} and 0.99 ± 0.02 M^{-1}, respectively. The solid curve in Fig. 2 is a graph of this equation and predicts the k_{obs} values with an overall standard deviation of 5.1%. At sufficiently high [OH^-], k_{obs} should reach a limiting value, k_∞ (= a/b) of 1.39 × 10^{-3} s^{-1}.

We propose the mechanism found in eqs. [2] and [3] for the Cannizzaro reaction of **1** leading to

$$[2] \quad \mathbf{3} \underset{}{\overset{K_2[OH^-]}{\rightleftharpoons}} \mathbf{4} \overset{K_{-5}}{\rightleftharpoons} \mathbf{5}$$

$$[3] \quad \mathbf{5} \xrightarrow[\text{Slow}]{k} \text{o-}C_6H_4(CH_2O^-)(CO_2^-) \xrightarrow[\text{Fast}]{H_2O} \text{o-}C_6H_4(CH_2OH)(CO_2^-)$$

o-hydroxymethylbenzoate. The initial hydration of **1** and subsequent ionization of **2** to **3** should be very rapid and essentially complete within a few milliseconds of mixing **1** with any of the base solutions used in this study (13). The effective starting point for the subsequent reaction then is **3**. We assume that essentially all unreacted **1** is present as **3** or **4** over the range of [NaOH] used here (i.e. $[\mathbf{1}]_s$ = [**3**] + [**4**]).[7] No significant reaction of the monoanion

[7] Inspection of the equilibrium constants relating these species in aqueous base (see Appendix) reveals that even in 0.05 M NaOH about 92% of the substrate is immediately converted to **3** and **4**. This proportion increases to 97% in 0.1 M NaOH and to 99% in 0.20 M base. Above 0.20 M NaOH, only the relative proportions of **3** and **4** vary significantly; the ratio [**3**]/[**4**] being given by K_2[OH^-]. No significant amounts (≤1%) of **1**, **5**, or **6** are present at any base concentration used in this study.

(see Scheme 1) can be detected under our conditions.[8] If the internal hydride transfer step in **5** is rate-limiting (with a first-order rate constant, k), then the rate of appearance of product is given by eq. [4] where K_{-5} is the equilibrium constant for the very unfavorable ring opening of the cyclic hydrate

[4] $\text{Rate} = d[P]/dt = k[\mathbf{5}] = kK_{-5}[\mathbf{4}]$

dianion. The rate is also given by equation [5] where k_{obs} is the pseudo-first-order rate constant

[5] $\text{Rate} = k_{obs}[\mathbf{1}]_s$

and since $[\mathbf{1}]_s = [\mathbf{3}] + [\mathbf{4}]$, the expression for k_{obs} becomes:

[6] $k_{obs} = kK_{-5}K_2[OH^-]/(1 + K_2[OH^-])$

where $K_2[OH^-] = [\mathbf{3}]/[\mathbf{4}]$. Equation [6] has the form required for k_{obs} (see eq. [1]) and thus values for K_2, k_2, and kK_{-5} are 0.99 M^{-1}, 1.38×10^{-3} M^{-1} s^{-1}, and 1.39×10^{-3} s^{-1}, respectively.

The K_2 value gives rise to a value of 13.53 for the second pK_a of the cyclic hydrate at 40°C and if we make no temperature correction to K_2 (11, 19), a value for pK_{a_2} for **2** at 25°C of 14.00 can be calculated. It is interesting to note that the difference between successive pK_a values for **2** at 25°C of 2.50 is similar to that observed for malonic acid ($\Delta pK_a = 2.86$ (20)) in which the acidic hydrogens are the same number of atoms apart.

In the Appendix estimates for many of the equilibrium constants relating species derived from **1** in aqueous base have been collected. These include a value for K_5 (1.2×10^5) which allows calculation of K_{-5} to be 8.3×10^{-6}. Now k, the rate constant for internal hydride transfer in **5**, may be estimated to be 170 s^{-1}. Considering the number of calculations and approximations required in the estimation of K_5 in the Appendix, the cumulative error in K_5 (and therefore k) may be considerable (up to several hundred percent).

For comparison purposes, the kinetics of the analogous intramolecular Cannizzaro reaction of phenylglyoxal were reinvestigated under conditions similar to those of the above study (in aqueous solution at 40°C, ionic strength 1.0, and over the range of [NaOH] from 0.05 to 1.0 M). From 0.05 to 0.50 M NaOH, the rate of disappearance of starting material is strictly first-order in substrate and first-order in hydroxide, the second-order rate constant, k_2', being 0.211 ± 0.006 M^{-1} s^{-1} at 40°C, $\mu = 1.0$.[9] The predominant form of phenylglyoxal under these conditions is the monoanion of the aldehyde hydrate and the reaction proceeds almost entirely via the dianion (11). We are unable to effect any significant ionization to the dianion even up to 1.0 M NaOH in contrast to the behavior of **1**.[10] This is not unexpected since the second pK_a of the hydrate can be estimated to be 16.0 at 40°C (see below). The rate constant, k_2', is a composite of the equilibrium constant for dianion formation from monoanion, K_2', and the first-order rate constant, k', for intramolecular hydride transfer. Hine and Koser (11) have determined the equilibrium constant for monoanion formation from the hydrate (K_1') for phenylglyoxal to be 276 M^{-1} at 35°C. Making no temperature correction to 40°C, and assuming the relation: $K_2' = 10^{-5} \times K_1'$ used by Hine and Koser (19) for *gem*-diols of this type, K_2' may be estimated to be 2.76×10^{-3} M^{-1} (corresponding to a pK_{a_2} of 16.0 at this temperature). This then allows calculation of k' ($= k_2'/K_2'$) on the phenylglyoxal pathway to be 76 s^{-1} at 40°C.

Thus, although the rate of product formation in the Cannizzaro reaction of phenylglyoxal is at least 150-fold that for the phthalaldehyde reaction, the actual hydride transfer steps are quite similar in rate (within a factor of 3 by our calculations). This is clearly attributable to the very unfavorable ring opening of the cyclic hydrate dianion (**4**) to **5** which must precede hydride transfer in the reaction of **1**. The similarity in rate for the elementary hydride transfer steps in the two pathways is somewhat surprising since one might expect the three-membered cyclic transition state required in the phenylglyoxal pathway to be energetically (and entropically) more favorable than the five-membered one required in the reaction of **1**. In this latter reaction, the formyl acceptor group must also be rotated out of coplanarity with the aromatic ring as hydride transfer occurs. Nevertheless, the free energy barriers for the hydride transfer steps must be within 1 kcal mol^{-1} of one another.

Although the study of hydride transfer mechanisms which require hydroxide-catalysis provides limited information concerning such mechanisms in biological systems, the chemist working on model systems for enzymic catalysis often finds such background information on the chemical behavior of these models useful. Current studies in this laboratory are concerned with the collection of

[8]Hine and Koser (11) were able to detect a small contribution to the rate due to reaction of the monoanion for the intramolecular Cannizzaro reaction of phenylglyoxal only by working in very dilute (down to 0.001 M) NaOH solutions. The predominant reaction pathway above 0.003 M base is via the dianion.

[9]Average of 13 runs; the error quoted is the standard deviation.

[10]In fact at [NaOH] greater than 0.50 M, k_2' actually increases, to 0.236 M^{-1} s^{-1} in 0.75 M base and to 0.245 M^{-1} s^{-1} in 1.0 M base. This is presumably a small specific salt effect.

detailed kinetic data for the internal hydride transfer of phenylglyoxal in the presence of amine-thiols of general structure: $HSCH_2CH_2NR_2$ (12). These compounds promote formal hydride transfer in aqueous solution in a pH region of some biological relevance (from 6–9).

Acknowledgements

We are pleased to thank Mr. E. V. Martin for carrying out the kinetic work on phenylglyoxal and Dr. O. S. Tee for valuable discussions. We also wish to thank the Natural Sciences and Engineering Research Council of Canada for continued financial support in the form of an operating grant (to R.S.M.).

Appendix

Equilibrium Involving 1 in Aqueous Base

Species derived from **1** in aqueous base are related by the equilibria shown in Scheme 1 in the Results and Discussion.

Equilibria on the horizontal involve formation of the five-membered ring and should progressively favor the cyclic form as one proceeds from the neutral species through the monoanion to the dianion. Equilibria on the vertical all involve hydroxide (addition or ionization); K_1, K_2, and K_3 can be related to pK_a values using the relation: $pK_a = pK + pK_w$.

In the preceding discussion, a value for K_5 (actually K_{-5}) was required to separate a composite rate–equilibrium constant. The following represents an attempt to evaluate it. The data used refer to 25°C where most of the measurements or estimates are based.

The hydration equilibrium constant, K_{H_2O} is 7.7 at 25°C (13). The first pK_a of **2** is 11.50 at this temperature which corresponds to a value for K_1 of $320\,M^{-1}$. Estimation of K_{OH} for hydroxide addition to **1** is more difficult since it cannot be observed directly (the predominant forms of **1** in aqueous base are **3** and **4**). However, Greenzaid (21) and Sedon and Zuman (22) have observed a linear correlation between log K_{OH} for a series of *o*-substituted benzaldehydes and the pK_a of the corresponding benzoic acid (log $K_{OH} = 4.0 - 1.25\ pK_a$). A value for the pK_a of *o*-formylbenzoic acid has been reported to be 4.56 (23) but this value does appear to be anomalous since the pK_a of benzoic acid is 4.20 (ref. 20, p. J-194) and an *o*-formyl substituent should be acid-strengthening. It is now clear from the ^1H nmr spectrum in D_2O that *o*-formylbenzoic acid exists predominantly (≥95%) as 3-hydroxyphthalide in aqueous solution. However, an examination of the pK_a values of a series of benzoic acids bearing *o*-substituents of similar electronic and steric effects to a formyl group (i.e. the halogens, cyano, carboxyl, nitro) lead us to assign a pK_a of 2.84 (±0.3) to *o*-formylbenzoic acid. This leads to a K_{OH} value of $5.6\,M^{-1}$ after statistical correction for the two identical aldehyde groups. This value may be compared to values observed for the 2-chloro, 2,4-dichloro, and 2-nitro substituted benzaldehydes of 2.5, 6.8, and $10.0\,M^{-1}$, respectively (24). This now permits calculation of K_4 ($K_{H_2O} \cdot K_1/K_{OH}$) to be 440.

Our kinetic results have yielded a value for K_2 of $0.99\,M^{-1}$ at 40°C and we make no temperature correction at 25°C. The second ionization constant for the *gem*-diol hydrate of *o*-formylbenzaldehyde

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

(K_3) is now required. Hine and Koser (19) have estimated that the second pK_a of a *gem*-diol of this type is related to the first by the equation: $pK_{a_2} = pK_{a_1} + 5.0$. The first p$K_a$ of the hydrate of benzaldehyde has been estimated to be 12.8 (21) and we assume that the *o*-formyl group will have the same effect on the pK_a of this hydrate as it does on the pK_a of benzoic acid (i.e. acid-strengthening by 1.36 pK_a units). This leads to successive pK_a values for *o*-formylbenzaldehyde hydrate of 11.44 and 16.44. Thus K_3 is 3.6×10^{-3} ($10^{14-16.44}$) M^{-1} at 25°C and K_5 ($= K_2 \cdot K_4/K_3$) can be estimated to be 1.2×10^5. Clearly the cyclization equilibria are in the expected order: K_5 (1.2×10^5) > K_4 (440) > K_{H_2O} (7.7).

Thermodynamics of acid dissociation of aqueous bisulfite ion: ΔH^0, $\Delta C_p{}^0$, and ΔV^0 at 298.15 K

GREGORY C. ALLRED, JOHN W. LARSON,[1] AND LOREN G. HEPLER

Department of Chemistry and Oil Sands Research Laboratory, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4

Received September 8, 1980

GREGORY C. ALLRED, JOHN W. LARSON, and LOREN G. HEPLER. Can. J. Chem. **59**, 1068 (1981).

Calorimetric measurements of the enthalpy of protonation of sulfite ion and the enthalpy of proton transfer from bisulfite ion to carbonate ion have led to two independent values for the standard enthalpy of the acid dissociation reaction represented by $HSO_3^-(aq) = H^+(aq) + SO_3^{2-}(aq)$. Further calorimetric and density measurements have led to apparent and partial molar heat capacities and volumes for sulfite and bisulfite ions. Results of all of these measurements are summarized by $\Delta H^0 = -3.59 \pm 0.10$ kJ mol^{-1}, $\Delta C_p{}^0 = -262 \pm 7$ J K^{-1} mol^{-1}, and $\Delta V^0 = -28.7 \pm 1.0$ cm^3 mol^{-1} for the acid dissociation of $HSO_3^-(aq)$ at 298.15 K. These results are used for thermodynamic calculations of the temperature and pressure dependence of the equilibrium constant for acid dissociation of $HSO_3^-(aq)$.

GREGORY C. ALLRED, JOHN W. LARSON et LOREN G. HEPLER. Can. J. Chem. **59**, 1068 (1981).

Des mesures calorimétriques de l'enthalpie de protonation de l'ion sulfite et de l'enthalpie du transfert du proton de l'ion bisulfite à l'ion carbonate ont permis d'obtenir deux valeurs indépendantes de l'enthalpie standard de la réaction de dissociation acide représentée par l'équation $HSO_3^-(aq) = H^+(aq) + SO_3^{2-}(aq)$. Des mesures additionnelles de calorimétrie et de densité ont conduit aux capacités calorifiques et aux volumes molaires partiels apparents des ions sulfites et bisulfites. On peut résumer les résultats de toutes ces mesures par: $\Delta H^0 = -3{,}59 \pm 0{,}10$ kJ mol^{-1}, $\Delta C_p{}^0 = -262 \pm 7$ J K^{-1} mol^{-1} et $\Delta V^0 = -28{,}7 \pm 1{,}0$ cm^3 mol^{-1} pour la dissociation de l'acide $HSO_3^-(aq)$ à 298,15 K. On a utilisé ces résultats pour les calculs thermodynamiques de l'effet de la température et de la pression sur la constante d'équilibre de dissociation de $HSO_3^-(aq)$.

[Traduit par le journal]

Introduction

Although aqueous solutions of sulfur dioxide and the related bisulfite and sulfite ions are of considerable general scientific interest and also have substantial technological importance, useful thermodynamic properties are either unavailable or are of unsatisfactory accuracy. We have therefore undertaken the calorimetric and density measurements to be described here.

The first acid ionization or dissociation of "sulfurous acid" can be represented by

[1] $H_2SO_3(aq) = H^+(aq) + HSO_3^-(aq)$

where we use $H_2SO_3(aq)$ to represent all of the un-ionized species formed in aqueous solutions of sulfur dioxide. The second acid dissociation is represented by

[2] $HSO_3^-(aq) = H^+(aq) + SO_3^{2-}(aq)$

In this paper our particular focus is on the thermodynamics of this second acid dissociation reaction. More specifically, we have made calorimetric measurements leading to values for $\Delta H_2{}^0$ and $\Delta C_{p,2}{}^0$ for this reaction at 298.15 K. Measurements of densities have led to $\Delta V_2{}^0$ for this same reaction, also at 298.15 K. All of these values have been used for thermodynamic calculations of the effects of temperature and pressure on the equilibrium constant (K_2) for this reaction.

[1]Visiting Scientist from Marshall University, Huntington, WV, U.S.A.

Experimental

Enthalpy measurements were made using an LKB 8700 Precision Calorimetry System and a modified LKB 8721 titration calorimeter. Our modified glass calorimetric vessel (~100 cm^3) is a combination of the standard LKB 8721-1 (ampoule) and LKB 8721-2 (titration) vessels that permits us to make both ampoule and titration measurements. The titrant delivery system is a Metrohm E-415 automatic piston buret with a 10 cm^3 buret, operated in the fixed increment mode. The temperature of the thermostatted bath, and therefore of the titrant solution entering the calorimeter, was monitored with a quartz crystal thermometer. Electrical calibrations were made after each calorimetric titration.

Heat capacity measurements were made with a Picker flow calorimeter of a type that has been described previously (1). A small systematic error in the heat capacity measurements made with this calorimeter has been identified and corrected as also described previously (2, 3).

Densities were measured with a Picker flow densimeter of a kind that has been described before (4).

Results of all measurements refer to 298.15 K.

Perchloric acid solution was prepared from reagent grade 70% perchloric acid and freshly boiled double distilled water. For the first set of enthalpimetric titrations, calibration of the buret and standardization of the perchloric acid solution were performed together, using Fisher primary standard tris(hydroxymethyl)-aminomethane (TRIS), which had been crushed and then dried at 363 K for 2 h. A weighed sample of TRIS was partially neutralized with 4.00 cm^3 of perchloric acid titrant delivered from the piston buret under conditions similar to those of an enthalpimetric titration. The portion of TRIS remaining (about 10%) was then further titrated to the endpoint with a more dilute solution of $HClO_4$, which had been standardized previously. Combination of results of these titrations with the density permitted calculation of both the molality and molarity of the stock solution of perchloric acid. Duplicate experiments established that the quantity of acid delivered was constant to 0.03%.

Fisher certified reagent grade anhydrous sodium sulfite was used without further treatment in the enthalpimetric titrations with perchloric acid. This material was weighed into glass ampoules (1.0 cm^3), which were sealed with silicone rubber stoppers and wax. Each ampoule contained 1.060 ± 0.002 g of Na_2SO_3. Iodometric titration of material in three ampoules taken at random showed that the contents were 99.2 ± 0.2% by mass sodium sulfite.

One of the difficulties encountered in any attempt to determine ΔH_2 is that of oxidation of sulfite to sulfate by dissolved oxygen, which proceeds at an appreciable rate (5). In order to minimize oxidation, sodium sulfite solutions were prepared in the calorimetric reaction vessel by breaking an ampoule into 89.70 cm^3 of freshly boiled double distilled water, which had been cooled under and saturated with N_2. Nitrogen gas, saturated with water vapor, was bled into the vapor space of the calorimetric vessel during the course of each run.

Following dissolution of Na_2SO_3 in the reaction vessel, 0.5 cm^3 of $HClO_4$ solution was injected to protonate about 10% of the sulfite present. After thermal equilibration and an initial rating period, the main titration, comprising a single injection of 4.00 cm^3 of 1.696$_4$ *M* $HClO_4$ titrant, was begun when the temperature of the vessel matched that of the bath in such a way as would produce no detectable thermal effect when the titrant was the same as the solution in the vessel.

To evaluate the corrected temperature change, all measured thermistor resistances were converted to temperatures and the data for the initial and final rating periods were fitted by least squares analysis to the integrated form of Newton's cooling law. The corrections for heat exchange with the surroundings and thermal contributions from stirring and Joule heating of the thermistor were evaluated by computer assisted integration of the time–temperature curves according to the Regnault–Pfaundler method.

The chemicals used in the second approach to the enthalpy determination were reagent grade sodium carbonate (BDH AnalaR) dried at 543 K for 1 h, Baker analyzed reagent grade sodium bicarbonate, recrystallized Fisher certified sodium sulfite, and Fisher certified sodium bisulfite ($Na_2S_2O_5$). Titration of all compounds with either HCl or NaOH indicated high purity. Both the Na_2SO_3 and the $Na_2S_2O_5$ gave negative sulfate spot tests with acidic $BaCl_2$.

Buffer solutions were made by dissolving known masses of these solutes in a known mass of degassed distilled water. The decrease in mass of the water due to hydration of $Na_2S_2O_5$ to form $NaHSO_3$ was allowed for in the calculation of molalities. The solutions were prepared just prior to the calorimetric runs and were kept under a nitrogen atmosphere. Water-saturated nitrogen gas was bled into the vapor space of the calorimeter during the runs.

The temperature rises in the enthalpimetric titrations involving carbonate/bicarbonate and sulfite/bisulfite solutions were evaluated according to Dickinson's method.

Stock solutions used in the determination of the apparent molar heat capacities and volumes were prepared in the same way and from the same sodium sulfite and sodium bisulfite used in the second set of enthalpy measurements. The solutions contained molalities of Na_2SO_3 and $NaHSO_3$ in the ratios 9:1, 1:1, and 1:9.

Results

We represent the reaction between sulfite/bisulfite buffer solutions and perchloric acid by

[3] $HClO_4(aq, I = 1.696) + Na_2SO_3(aq, I = 0.269) = NaHSO_3(aq, I = 0.186) + NaClO_4(aq, I = 0.186)$

The average result of 7 determinations of the enthalpy of this reaction, ΔH_3, is given in Table 1. In order to obtain the desired ΔH_2^0, the enthalpies of the following reactions must also be evaluated:

[4] $HClO_4(aq, I = 1.696) = HClO_4(aq)$

[5] $Na_2SO_3(aq, I = 0.269) = Na_2SO_3(aq)$

[6] $NaHSO_3(aq, I = 0.186) = NaHSO_3(aq)$

[7] $NaClO_4(aq, I = 0.186) = NaClO_4(aq)$

In order to reduce the uncertainty in the corrections applied to ΔH_3 to derive ΔH_2^0, the enthalpy of dilution of perchloric acid to 0.0725 molal was determined under conditions similar to those used to determine ΔH_3. The enthalpy of dilution from 0.0725 molal to infinite dilution was taken from the compilation by Parker (6) to give the value of ΔH_4 reported in Table 1. It was necessary to estimate values for ΔH_5 and ΔH_6 as these do not appear in the literature.

The enthalpy of dilution of Na_2SO_4 has been determined over a range of concentrations by Wallace and Robinson (7). We estimate ΔH_5 by making the assumption that the enthalpies of dilution of Na_2SO_3 in the buffer solution where hydrolysis is nearly completely suppressed, and of Na_2SO_4, which does not hydrolyze to an appreciable extent, will be similar.

To estimate the value of ΔH_6 we assume that the enthalpy of dilution of sodium bisulfite in the buffer solution will be similar to that of some other strong 1:1 electrolytes at the same ionic strength. We chose as model electrolytes $NaClO_3$, $NaNO_3$, and $NaBrO_3$, for which enthalpies of dilution have been tabulated (6); ΔH_6 was taken as the average of the heats of dilution for these three model electrolytes.

The enthalpy of dilution of $NaClO_4$ in the product mixture is assumed to be equal to the value for a pure $NaClO_4$ solution of the same ionic strength, and was taken from Parker's compilation (6).

All of these values were combined according to

[8] $$\Delta H_2^0 = -\Delta H_3 + \Delta H_4 + \Delta H_5 - \Delta H_6 - \Delta H_7$$

to give $\Delta H_2^0 = -3.52\ kJ\ mol^{-1}$. We estimate the total uncertainty in this result, due to chemicals,

TABLE 1. Measured enthalpies of reactions [3] and [4] and estimated enthalpies of dilution

Reaction	ΔH / kJ mol^{-1}	Estimated uncertainty / kJ mol^{-1}

[a]See text following eq. [9] for information about compositions and quantities of solutions.

calorimetric measurements, and enthalpies of dilution, to be less than 0.10 kJ mol^{-1}.

In the second set of measurements the enthalpy of the reaction

[9] $$NaHSO_3(aq) + Na_2CO_3(aq) = Na_2SO_3(aq) + NaHCO_3(aq)$$

was determined by titrating an aqueous sodium bicarbonate/carbonate buffer with an aqueous sodium bisulfite/sulfite buffer. In order to minimize the corrections for heats of dilution, hydrolysis, and extent of reaction, buffer solutions of equal ionic strength with a 9:1 ratio of Na_2CO_3 to $NaHCO_3$ and a 1:9 ratio of Na_2SO_3 to $NaHSO_3$ were used. The heat evolved with each of three successive additions of 10.22 cm^3 of the sulfite buffer to 75.0 cm^3 of the carbonate buffer was determined, with results given in Table 2. The enthalpy of reaction [9], ΔH_9, is that calculated from the equation

[10] $$\Delta H_9 = -(Q + Q_h)/\alpha n$$

where Q is the measured heat evolved, Q_h is the heat due to the hydrolysis of the carbonate, α is the fraction of the added bisulfite reacting according to eq. [9], and n is the number of moles of $NaHSO_3$ added. The values of Q_h were calculated by multiplying the enthalpy of hydrolysis of CO_3^{2-}(ΔH_h^0 = 41.12 kJ mol^{-1}) (8) by the calculated change in the number of moles of OH^-(aq) present in the solution. The latter values were calculated using $K_h = 2.13 \times 10^{-4}$, and Davies' modification (9) of the extended Debye–Hückel equation for calculating the activity coefficients. Values of K_a for HSO_3^-(aq) and HCO_3^-(aq) were combined to give $K_9 = 1.17 \times 10^3$. This value was used to calculate the extent of reaction, α.

A linear extrapolation of these results to $I = 0$ yields $\Delta H_9^0 = -18.50$ kJ mol^{-1}, which is then combined with $\Delta H^0 = 14.70$ kJ mol^{-1} for the dissociation of HCO_3^-(aq) (8) to give $\Delta H_2^0 = -3.80$ kJ mol^{-1} for the dissociation of HSO_3^-(aq). The total estimated uncertainty in this value is about 0.30 kJ mol^{-1}.

We take as a best value for ΔH_2^0 a weighted average of the two experimentally determined quantities, the weighting factors being proportional to the reciprocals of the uncertainties quoted. This procedure leads to $\Delta H_2^0 = -3.59 \pm 0.10$ kJ mol^{-1}.

Results of measurements with the Picker flow calorimeter are heat capacities per unit volume of solution. Combination of these heat capacities with the densities that we have also measured leads to heat capacities per unit mass of solution. Further combination of these latter heat capacities with the already known (10) heat capacity of pure water (4.1793 J K^{-1} g^{-1}) leads to apparent molar heat capacities. Similarly, densities of solutions in combination with the already known density of pure water (0.997044 g cm^{-3}) leads to apparent molar volumes. Because the measurements of heat capacities and densities to be reported here were made on buffer solutions, it is useful to define our apparent molar properties according to

[11] $$\phi_Y = [Y(\text{solution}) - n_1 Y_1^0]/(n_2 + n_3)$$

in which Y is the extensive property (heat capacity or volume) of a specified quantity of solution, n_1 is the number of moles of water in the specified quantity of solution, Y_1^0 is the molar property of the pure solvent water, and n_2 and n_3 represent the numbers of moles of $NaHSO_3$ and Na_2SO_3 in this specified quantity of solution.

Apparent molar properties of reasonably dilute solutions of electrolytes are accurately represented by equations of the form

[12] $$\phi_Y = \phi_Y^0 + A_Y(d_1^0)^{1/2}\omega^{3/2}m^{1/2} + B_Y\omega m$$

in which A_Y values come from the Debye–Hückel theory and B_Y values are adjustable parameters. The "valence factor" ω is defined as

TABLE 3. Parameters for eq. [12] applied to apparent molar heat capacities and volumes of $NaHSO_3/Na_2SO_3$ buffer solutions

F_2	ϕ_C^0 / J K^{-1} mol^{-1}	B_C / J K^{-1} mol^{-2} kg	ϕ_V^0 / cm^3 mol^{-1}	B_V / cm^3 mol^{-2} kg
0.1	−154.6	36.8	6.5	1.9
0.5	−70.2	30.5	18.0	2.2
0.9	20.6	20.3	30.4	0.8

[13] $\omega = I/m = 0.5 \Sigma \nu_i z_i^2 m_i/m$

in which I is the ionic strength, m_i is the molality of a particular solute, and m is the total molality.

For application of eq. [12] to apparent molar volumes we use $A_V(d_1^0)^{1/2} = 1.865\,\text{cm}^3\,\text{mol}^{-3/2}\,\text{kg}^{1/2}$ from Millero (11) and for application to apparent molar heat capacities we use $A_C(d_1^0)^{1/2} = 28.95\,\text{J K}^{-1}\,\text{mol}^{-3/2}\,\text{kg}^{1/2}$ from Desnoyers (12). In connection with our use of this latter value, which is adopted here partly for consistency with some related earlier investigations, we note that there is some evidence (13, 14) for a slightly larger value for $A_C(d_1^0)^{1/2}$. We also define solute mole fractions according to

[14] $F_2 = n_2/(n_2 + n_3)$ and $F_3 = n_3/(n_2 + n_3)$

in which subscripts 2 and 3 refer to $NaHSO_3$ and Na_2SO_3, respectively. For F_2 values of 0.9, 0.5, and 0.1 (corresponding to compositions of buffer solutions we have investigated) we have ω values of 1.2, 2.0, and 2.8, respectively.

Following application of small corrections for hydrolysis, ionization, and (in the case of heat capacities) chemical relaxation as described elsewhere (15–18) in detail, we have obtained desired ϕ_Y^0 values by way of linear least-squares fitting of $\phi_Y - A_Y(d_1^0)^{1/2}\omega^{3/2}m^{1/2}$ against ωm, with results that are summarized in Table 3.

The apparent molar properties at infinite dilution of the buffer solutions are related to the corresponding apparent molar properties of the constituent electrolytes by

[15] $\phi_Y^0 = F_2\phi_Y^0(NaHSO_3) + F_3\phi_Y^0(Na_2SO_3)$

Using $F_2 + F_3 = 1$ and least-squares fitting of eq. [15] to the results in Table 3 we have obtained the following:

$$\phi_C^0(NaHSO_3) = 41.2\,\text{J K}^{-1}\,\text{mol}^{-1}$$
$$\phi_V^0(NaHSO_3) = 33.2\,\text{cm}^3\,\text{mol}^{-1}$$
$$\phi_C^0(Na_2SO_3) = -177.8\,\text{J K}^{-1}\,\text{mol}^{-1}$$

and

$$\phi_V^0(Na_2SO_3) = 3.3\,\text{cm}^3\,\text{mol}^{-1}$$

As previously demonstrated in many investigations, it is useful to assign values for the thermodynamic properties of individual ions in aqueous solution at infinite dilution. The customary procedure for doing so is based on $\phi_Y^0(H^+) = 0$, which leads (11, 19) to $\phi_C^0(Na^+) = 43\,\text{J K}^{-1}\,\text{mol}^{-1}$ and to $\phi_V^0(Na^+) = -1.2\,\text{cm}^3\,\text{mol}^{-1}$. We now combine these values for Na^+(aq) with those given in the paragraph above for $NaHSO_3$(aq) and Na_2SO_3(aq) to obtain the following:

$$\phi_C^0(HSO_3^-) = -2\,\text{J K}^{-1}\,\text{mol}^{-1}$$
$$\phi_V^0(HSO_3^-) = 34.4\,\text{cm}^3\,\text{mol}^{-1}$$
$$\phi_C^0(SO_3^{2-}) = -264\,\text{J K}^{-1}\,\text{mol}^{-1}$$

and

$$\phi_V^0(SO_3^{2-}) = 5.7\,\text{cm}^3\,\text{mol}^{-1}$$

Discussion and Thermodynamic Calculations

Selections of several earlier reviews (10, 20–22) are in accord with $K_2 = 5.6 \times 10^{-8}$ and $\Delta G^0 = 41.4\,\text{kJ mol}^{-1}$ for the acid dissociation of HSO_3^-(aq) at 298.15 K. We accept (Table 4) and use these values for further calculations.

The first two groups of reviewers (10, 20) chose $\Delta H_2^0 = -9.3$ and $-12.1\,\text{kJ mol}^{-1}$, with large uncertainties in both values. The two more recent reviews (21, 22) have both chosen $\Delta H_2^0 = -5.2\,\text{kJ mol}^{-1}$, based on the calorimetric enthalpy of neutralization reported by Zambonin and Jordan (23). Although this latter value is almost certainly better than the earlier values just cited, it is not in good agreement with $\Delta H_2^0 = -3.59\,\text{kJ mol}^{-1}$ based on our measurements and therefore requires further consideration as follows.

The ΔH_2^0 from Zambonin and Jordan (23) differs from our value by 44%, but this is not a meaningful indication of the difference between results of the calorimetric measurements made in the two labora-

tories. Zambonin and Jordan (23) measured the enthalpy of neutralization (-61.0 kJ mol^{-1}), which must be combined with the enthalpy of ionization of water (55.8 kJ mol^{-1}) to yield the desired ΔH_2^0. We can bring the results of Zambonin and Jordan (23) into perfect accord with our present result by assuming that their measured enthalpy of neutralization was too exothermic by only 2.6%. On the other hand, our measured enthalpy of protonation of SO_3^{2-} would have to be in error by 44% to make our derived ΔH_2^0 be in agreement with the value from Zambonin and Jordan (23). We also note that any air oxidation to sulfate that might have occurred in connection with the measurements by Zambonin and Jordan (23) would have had the effect of making their derived ΔH_2^0 be too exothermic, which is in the right direction to account for the difference between their $\Delta H_2^0 = -5.2$ kJ mol^{-1} and our $\Delta H_2^0 = -3.59$ kJ mol^{-1}. On the basis of all of these considerations and also because we have obtained nearly the same values for ΔH_2^0 by two independent routes (direct protonation of SO_3^{2-} and proton transfer from HSO_3^- to CO_3^{2-}), we select (Table 4) our ΔH_2^0 as the best available value and use it for subsequent calculations.

Changes in heat capacity ($\Delta C_{p,2}^0$) and volume (ΔV_2^0) for the acid dissociation of HSO_3^-(aq) as in reaction [2] can be calculated from conventional ionic heat capacities and volumes by way of

$$[16] \quad \Delta Y_2^0 = \phi_Y^0(SO_3^{2-}) - \phi_Y^0(HSO_3^-)$$

Using the ionic ϕ_C^0 and ϕ_V^0 values for HSO_3^-(aq) and SO_3^{2-}(aq) from our investigations as reported earlier in this paper in equation [16] leads to $\Delta C_{p,2}^0 = -262$ J K^{-1} mol^{-1} and to $\Delta V_2^0 = -28.7$ cm^3 mol^{-1}, both referring to 298.15 K.

We do not know of any earlier results that permit us to make any useful comparisons with our $\Delta C_{p,2}^0$, $\phi_C^0(HSO_3^-)$, or $\phi_C^0(SO_3^{2-})$. We can, however, compare our $\phi_V^0(SO_3^{2-}) = 5.7$ cm^3 mol^{-1} with $\phi_V^0(SO_3^{2-}) = 8.9$ cm^3 mol^{-1} selected by Millero (11) and also compare our $\Delta V_2^0 = -28.7$ cm^3 mol^{-1} with $\Delta V_2^0 = -22.7$ cm^3 mol^{-1} selected by Hamann (24) in his thorough review of effects of pressure on acid–base reactions in aqueous solutions. Both of these earlier values appear to be less accurate than our values; we list our ΔV_2^0 in Table 4 and use it for subsequent thermodynamic calculations.

Before going on with some thermodynamic calculations based on quantities listed in Table 4, we discuss and estimate uncertainties to be associated with our results that have been reported in this paper. We have already explained and cited ± 0.1 kJ mol^{-1} as our estimate of the total uncertainty to be associated with ΔH_2^0. Further considerations of uncertainties related to our measurements of heat capacities and densities, compositions of solutions, and data treatment (hydrolysis and ionization corrections, and values used for $A_Y(d_1^0)^{1/2}$ in eq. [12]) lead us to estimate that total uncertainties in our values for $\Delta C_{p,2}^0$ and ΔV_2^0 are about ± 7 J K^{-1} mol^{-1} and ± 1.0 cm^3 mol^{-1}, respectively.

Integration of the van't Hoff equation

$$[17] \quad d \ln K/dT = \Delta H^0/RT^2$$

with ΔH^0 taken to be independent of temperature leads to

$$[18] \quad \ln K_2 = 432/T - 18.146$$

for the acid dissociation of HSO_3^-(aq) as in eq. [2]. A better approach is to allow for the temperature dependence of ΔH^0 by way of

$$[19] \quad d\Delta H^0/dT = \Delta C_p^0$$

Integration of eq. [19] with $\Delta C_{p,2}^0$ taken to be independent of temperature leads to

$$[20] \quad \Delta H_2^0 = -262T + 74530 \qquad (\text{kJ mol}^{-1})$$

Further integration of [17] with [20] leads to

$$[21] \quad \ln K_2 = -8964/T - 31.51 \ln T + 192.899$$

for the acid dissociation of HSO_3^-(aq). Equations [18] and [21] are both illustrated in Fig. 1, which clearly shows the value of considering $\Delta C_{p,2}^0$ as well as ΔH_2^0 (at 298.15 K) in relation to the temperature dependence of K_2. Equation [20] shows that $\Delta H_2^0 = 0$ at 284 K, which is consistent with the maximum in $\ln K_2$ calculated from eq. [21] and

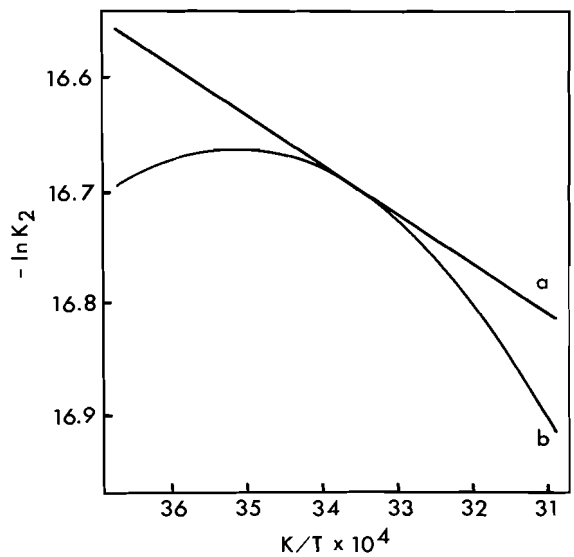

FIG. 1. Plot of $-\ln K_2$ vs. K/T for reaction [2]: (*a*), eq. [18]; (*b*), eq. [21].

displayed in Fig. 1. Equation [21] can be improved and made applicable over a still wider range of temperature by consideration of the temperature dependence of $\Delta C_{p,2}^0$ in equation [19], but these further heat capacities are not now available.

Integration of

$$[22] \quad \mathrm{d} \ln K/\mathrm{d}P = -\Delta V^0/RT$$

with ΔV_2^0 taken to be independent of pressure leads to

$$[23] \quad \ln K_2 = 0.001173P - 16.697$$

for the acid dissociation of HSO_3^-(aq) at 298.15 K, when P is expressed in atmospheres. Equation [23] could be improved and made applicable to a wider range of pressures by consideration of compressibilities and thence of the pressure dependence of ΔV_2^0, but this additional information is not now available.

Charge distributions and chemical effects. XXV. On the homogeneity of total molecular energies and the relationships between electronic, orbital, and total energies[1]

SÁNDOR FLISZÁR, MARIELLE FOUCRAULT, MARIE-THÉRÈSE BÉRALDIN, AND JACQUES BRIDET

Department of Chemistry, University of Montreal, Montreal, P.Q., Canada H3C 3V1

Received November 21, 1980

SÁNDOR FLISZÁR, MARIELLE FOUCRAULT, MARIE-THÉRÈSE BÉRALDIN, and JACQUES BRIDET. Can. J. Chem. **59**, 1074 (1981).

With the definition of a "screening factor" σ_k transforming the nuclear charge Z_k of an atom k into an "effective" nuclear charge $Z_k^* = Z_k\sigma_k$, the total energy $E = E(Z_k^*, Z_l^*, \ldots)$ of a molecule at equilibrium can be expressed as a homogeneous function of degree γ/α in $Z_k^*, Z_l^*, \ldots$, i.e. $E = -\Sigma_k Z_k^{*\gamma/\alpha}$, where α is the average of the α_k's ($\alpha_k = \partial \ln Z_k\sigma_k/\partial \ln Z_k$) and $\gamma = (V_{ne} + 2V_{nn})/E$ is a function of the nuclear–electronic, nuclear–nuclear, and total energies. Molecular energies calculated in this manner agree within 0.045% (average deviation) with their SCF counterparts. The sums of the orbital energies are correctly predicted from the equation $\Sigma_i \nu_i \varepsilon_i^{orb} = (3 - \gamma)E$. A separation of the individual nuclear–electronic and nuclear–nuclear contributions to the total potential energy $V(k, \text{mol})$ of each nucleus k indicates that the K_k^{mol} factors of the energy formula $E = \Sigma_k K_k^{mol} V(k, \text{mol})$ are constant for each type of atom, thus stressing the basic homogeneity of the total energy rather than of the electronic energy only. The γ function, which is the inverse of the molecular average of the K_k^{mol}'s, can be estimated in a simple way from atomic data.

SÁNDOR FLISZÁR, MARIELLE FOUCRAULT, MARIE-THÉRÈSE BÉRALDIN et JACQUES BRIDET. Can. J. Chem. **59**, 1074 (1981).

L'utilisation d'un "facteur d'écran" σ_k pour définir une charge nucléaire "effective" $Z_k^* = Z_k\sigma_k$ à partir de la charge nucléaire Z_k d'un atome k permet d'exprimer l'énergie totale $E = E(Z_k^*, Z_l^*, \ldots)$ d'une molécule à l'équilibre comme une fonction homogène de degré γ/α en $Z_k^*, Z_l^*, \ldots$, c'est-à-dire $E = -\Sigma_k Z_k^{*\gamma/\alpha}$, où α est la moyenne des α_k atomiques ($\alpha_k = \partial \ln Z_k\sigma_k/\partial \ln Z_k$) et où $\gamma = (V_{ne} + 2V_{nn})/E$ dépend de E ainsi que des énergies potentielles noyau–électron et noyau–noyau. Les énergies moléculaires calculées ainsi diffèrent de 0.045% (en moyenne) des valeurs SCF. La somme des énergies d'orbitales est correctement déduite de l'équation $\Sigma_i \nu_i \varepsilon_i^{orb} = (3 - \gamma)E$. La séparation des contributions noyau–électron et noyau–noyau à l'énergie potentielle totale $V(k, \text{mol})$ de chaque noyau k révèle que les facteurs K_k^{mol} de la formule $E = \Sigma_k K_k^{mol} V(k, \text{mol})$ sont des constantes pour chaque espèce atomique, en confirmant ainsi l'hommogénéité de l'énergie totale plutôt que celle de l'énergie électronique seulement. La fonction γ, qui est l'inverse de la moyenne moléculaire des facteurs K_k^{mol}, peut être facilement déduite à partir de données atomiques.

Introduction. Basic Formulas

The relationships between the various contributions to the total molecular energy which are investigated here play a major role in local density functional theory, which is of interest because the exact functional (1) would appear to contain a substantial local component (2). The local contribution involved in a description of molecular energies is conveniently introduced by means of the derivative $(\partial E/\partial Z_k)_{Z_l \neq k}$ of the total (kinetic + potential) energy E with respect to the nuclear charge Z_k of the kth atom. For atom k, the nuclear–electronic attraction energy $V_{ne}(k, \text{mol})$ arises from all electrons in the molecule and the total potential energy involving nucleus Z_k is

$$[1] \quad V(k, \text{mol}) = V_{ne}(k, \text{mol}) + Z_k \Sigma_{l \neq k} Z_l / r_{lk}$$

where the sum over l runs over all nuclei but k and r_{lk} is the distance from nucleus k to nucleus l. This quantity is central in the present theory because, applying the Hellmann–Feynman theorem, it results that[2]

$$[2] \quad Z_k(\partial E/\partial Z_k) = V(k, \text{mol})$$

and

$$[3] \quad \Sigma_k Z_k(\partial E/\partial Z_k) = V_{ne} + 2V_{nn}$$

On the other hand, the total energy E of a molecule in its equilibrium geometry can be expressed in terms of the electron–nucleus attraction energy V_{ne}, the electron–electron repulsion energy V_{ee}, and the nucleus–nucleus repulsion energy V_{nn} by applying the virial theorem, i.e.

$$[4] \quad 2E = V_{ne} + V_{ee} + V_{nn}$$

Consequently, one obtains from eqs. [3] and [4] that

$$[5] \quad 2E - \Sigma_k Z_k(\partial E/\partial Z_k) = V_{ee} - V_{nn}$$

Next, if the ε_i^{orb} are Hartree–Fock orbital energies with occupations ν_i, we obtain from the Hartree–Fock formula

$$E = \Sigma_i \nu_i \varepsilon_i^{orb} - (V_{ee} - V_{nn})$$

and from eq. [5] that

$$[6] \quad 3E - \Sigma_k Z_k(\partial E/\partial Z_k) = \Sigma_i \nu_i \varepsilon_i^{orb}$$

which is an identity in Hartree–Fock theory provided, of course, that all quantities are evaluated at equilibrium geometry. Equation [6] led Parr and

Gadre to formulate the theorem (3) that "a necessary and sufficient condition for the validity of the equality

$$[7] \quad (3-\gamma)E = \sum_i \nu_i \varepsilon_i^{orb}$$

is that $E(Z_k, Z_l, ...)$ is a homogeneous function of degree γ in Z_k, Z_l, ...". This theorem provides an interesting basis for the understanding of approximate energy formulas of the form

$$E = \text{constant} \times \sum_i \nu_i \varepsilon_i^{orb}$$

which are implied in Hückel and extended Hückel descriptions of molecular energies. Indeed, for $\gamma = 7/3$, which is the characteristic homogeneity of both Thomas–Fermi (4) and local density functional theory (2), eq. [7] yields the Ruedenberg approximation (5)

$$E = (3/2)\sum_i \nu_i \varepsilon_i^{orb}$$

Finally, it is readily deduced from eqs. [3], [6], and [7] that

$$[8] \quad E = (1/\gamma)(V_{ne} + 2V_{nn})$$

which gives the original Politzer equation (6)

$$E = (3/7)(V_{ne} + 2V_{nn})$$

if γ is taken at its Thomas–Fermi value of 7/3. Equation [8] is instrumental in the forthcoming calculations of γ.

The object of the present work is to investigate the nature of the homogeneity parameter γ defined by eq. [7] and to study energy formulas derived in the spirit of the Parr–Gadre theorem.

Numerical Applications of Equations [7] and [8]

Present GTO $(9s5p|6s) \rightarrow [5s3p|3s]$ calculations, using Dunning's exponents (7) and optimum contraction vectors (8), are in satisfactory agreement with eq. [7], in which the γ values are those given by eq. [8], notwithstanding the fact that the virial $-V/T$ ratios slightly differ from the theoretical value of 2. The $E/\sum_i \nu_i \varepsilon_i^{orb}$ ratios, which are very sensitive to small changes in γ, clearly vary too widely from case to case to be replaced by an "average" constant value, at least for the accuracy required in this type of energy calculations (Table 1).

Postponing temporarily the detailed discussion concerning the variations of γ, the point which is now made numerically clear is that the homogeneity parameter γ cannot be regarded as a constant when going from one molecule to another.

In the following, we use the γ values given by eq. [8] and, to begin with, examine an interesting aspect related to the Parr–Gadre theorem mentioned above. Indeed, the total molecular energy

$$E = E(Z_k, Z_l, ...)$$

can be written[3]

$$[9] \quad E = \text{"constant"} \times \sum_k Z_k^{\gamma}$$

(This can be shown simply by differentiating eq. [9], assuming that the "constant" and γ are not functions of Z_k, Z_l, ..., and using eq. [8] to give eq. [3].) Now, of course, the consistency of eqs. [3] and [8] with

[3] A more general solution satisfying the equation

$$\gamma E = \sum_k Z_k(\partial E/\partial Z_k)$$

implied in writing eq. [7] is

$$E = \text{constant} \times \sum_k Z_k^{\gamma}(1 + \sum_l a_{kl} Z_k^{-\omega(k,l)} Z_l^{\omega(k,l)})$$

where a_{kl} and $\omega(k,l)$ are Z-independent parameters. The neglect of the

$$\sum_k Z_k^{\gamma} \sum_l a_{kl} Z_k^{-\omega(k,l)} Z_l^{\omega(k,l)}$$

terms represents a simplification which does not obscure the main conclusions resulting from this study. Quite on the contrary, the use of the present approximation ultimately reveals both the relative smallness of the neglected part and its physical importance at levels of numerical accuracy which, however, are beyond what can be reached within the limits of precision set by the present type of analysis.

*Additional examples can be extracted from the compilation of our SCF results (Table 5).

eq. [9], i.e., ultimately, the validity of the Parr–Gadre theorem, does not require that the "constant" in eq. [9] be necessarily the same for all molecules. This point is examined by means of the $E/\sum_k Z_k^{\gamma}$ results presented in Table 2.

The answer is clear: the value of the $E/\sum_k Z_k^{\gamma}$ ratio differs from molecule to molecule (within extreme limits of the order of $\sim 12\%$) when the γ values given by eq. [8] are used. It is also true, on the other hand, that with an appropriate empirical choice of a single γ for all molecules, and of an accordingly determined constant $E/\sum_k Z_k^{\gamma}$ ratio, it still remains possible to use eq. [9] as a reasonable simple first approximation. The merits of such an approach are discussed elsewhere (3). In this work, however, we prefer to carry on with the γ's of eq. [8] and submit the following argument for treating the variable $E/\sum_k Z_k^{\gamma}$ ratio.

An examination of the results given in Table 2 reveals, indeed, that the hydrocarbons having the same H:C (atom:atom) ratio (e.g. 2 for the ethylenes and cyclopropane) also exhibit nearly the same $E/\sum_k Z_k^{\gamma}$ ratio and, moreover, that this ratio varies regularly with the H:C composition. This observation suggests that the "constant" of eq. [9] possibly represents in each case an appropriate "average" depending on the composition of the molecule, an idea which is exploited as follows in a simple way.

New Energy Formulas

Let us define a "screening factor" σ_k for each atom k of the molecule which transforms the nuclear charge Z_k to give an "effective" nuclear charge Z_k^*, i.e.

$$[10] \quad Z_k^* = Z_k\sigma_k$$

and examine, to begin with, the consequences of introducing this multiplier. Using

$$\partial Z_k = (1/\sigma_k)\partial Z_k^* + Z_k^*\partial(1/\sigma_k)$$

(from eq. [10]) for calculating $Z_k(\partial E/\partial Z_k)$ it is found that

$$[11] \quad Z_k(\partial E/\partial Z_k) = \alpha_k Z_k^*(\partial E/\partial Z_k^*)$$

where

$$[12] \quad \alpha_k = 1 + Z_k(\partial \ln \sigma_k/\partial Z_k) = \partial \ln Z_k\sigma_k/\partial \ln Z_k$$

In carrying out the sum over all k's of the terms given in eq. [11], we use the weighted molecular average of all atomic α_k's, i.e.

$$[13] \quad \alpha(\text{average}) = \frac{\sum_k \alpha_k Z_k^*(\partial E/\partial Z_k^*)}{\sum_k Z_k^*(\partial E/\partial Z_k^*)}$$

and obtain, from eqs. [11] and [13],

$$[14] \quad \sum_k Z_k(\partial E/\partial Z_k) = \alpha\sum_k Z_k^*(\partial E/\partial Z_k^*)$$

Finally, we deduce from the equation

$$\gamma E = \sum_k Z_k(\partial E/\partial Z_k)$$

(see eqs. [6] and [7]), which does not imply constancy of γ, and from eq. [14] that

$$[15] \quad (\gamma/\alpha)E = \sum_k Z_k^*(\partial E/\partial Z_k^*)$$

This equation does not imply any approximations and remains consistent with eq. [7] for molecules in their equilibrium geometry. Applying now the argument developed by Parr and Gadre on the basis of the equation

$$\gamma E = \sum_k Z_k(\partial E/\partial Z_k)$$

it appears from eq. [15] that the total molecular energy

$$E = E(Z_k^*, Z_l^*, \ldots)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

is a homogeneous function of degree γ/α in Z_k^*, Z_l^*, ..., i.e.[3]

[16] $E = -\sum_k Z_k^{*\gamma/\alpha}$

In this approach, the quantity corresponding to the absolute value of the "constant" appearing in eq. [9] is given by the weighted average

$$\langle \sigma_k^{\gamma/\alpha} \rangle = \sum_k \sigma_k^{\gamma/\alpha} Z_k^{\gamma/\alpha} / \sum_k Z_k^{\gamma/\alpha}$$

of the individual atomic $\sigma_k^{\gamma/\alpha}$'s. Indeed, eq. [16] can also be written as follows:

[17] $E = -\langle \sigma_k^{\gamma/\alpha} \rangle \sum_k Z_k^{\gamma/\alpha}$

This is the type of equation which has been successfully applied by Parr and Gadre to the study of diatomics. In terms of the present equations, the Parr–Gadre calculations correspond to an approximation implying constancy of $\langle \sigma_k^{\gamma/\alpha} \rangle$ (evaluated at 0.51130). Moreover, γ/α (identified as γ) was taken at an empirically determined constant value of 2.40073 suggesting that, just like γ, α remains fairly constant from molecule to molecule. Equation [7], however, is not satisfied in this approach. Our formalism now permits us to evaluate E and $\sum_i \nu_i \varepsilon_i^{orb}$ at more refined levels of approximation. In a first approximation, dropping the constraint of constant γ and $\langle \sigma_k^{\gamma/\alpha} \rangle$ parameters, we have examined a number of polyatomic molecules tentatively assuming that each chemical species can be adequately described by a constant $Z_k^{*1/\alpha}$ value. Using the appropriate γ's (eq. [8]), a fit of eq. [16] with our SCF results gives $Z_H^{*1/\alpha} = 0.94715$, $Z_C^{*1/\alpha} = 4.75059$, $Z_N^{*1/\alpha} = 5.48845$, and $Z_O^{*1/\alpha} = 6.17329$. The back-calculation of the molecular energies by means of eq. [16] agrees, in this approximation, within 0.087% (average deviation) with the corresponding SCF energies. Similar calculations using an extended GTO(9*s*5*p*2*d*|6*s*2*p*) → [5*s*3*p*1*d*|3*s*1*p*] basis set yield $Z_H^{*1/\alpha} = 0.95333$ and $Z_C^{*1/\alpha} = 4.74756$ and a satisfactory agreement with the SCF energies of methane, ethane, ethylene, acetylene, cyclopropane, and C_2 (0.087% average deviation).

While these results are certainly encouraging, we shall now examine in what way the constraint of a constant average α can be dropped and, moreover, how γ can be estimated without having recourse to eq. [8].

The γ Function

At this stage we introduce the defining equation (9–11)

[18] $E_k(\text{mol}) = K_k^{\text{mol}} V(k, \text{mol})$

for the energy E_k(mol) of an atom k being part of a molecule, without making any a priori assumption regarding the possible value(s) of the K_k^{mol} factors of the individual atoms. With eq. [18] the total molecular energy becomes

[19] $E = \sum_k K_k^{\text{mol}} V(k, \text{mol})$

i.e., noting that $\sum_k K_k^{\text{mol}} V(k, \text{mol}) / \sum_k V(k, \text{mol}) = K_{Av}^{\text{mol}}$ is just a weighted average of the individual K_k^{mol}'s,

[20] $E = K_{Av}^{\text{mol}} \sum_k V(k, \text{mol}) = K_{Av}^{\text{mol}} (V_{ne} + 2V_{nn})$

Consequently, comparing this result with eq. [8], it appears that

[21] $\gamma = 1/K_{Av}^{\text{mol}}$

We examine now the K_k^{mol} coefficients of eq. [18]. Indeed, K_k^{mol} multiplies a total potential energy which consists of two distinct contributions, i.e. (see eq. [1]) a nuclear–electronic and a nuclear–nuclear part. It may be regarded questionable that the same factor should apply to these two distinct parts. The answer is that one can always consider two independent multipliers, K_k^{el} and K_k^{nucl}, so that

[22] $E_k(\text{mol}) = K_k^{el} V_{ne}(k, \text{mol}) + K_k^{nucl} Z_k \sum_{l \neq k} Z_l / r_{lk}$

In doing so, eq. [18] remains valid provided that

[23] $K_k^{\text{mol}} = [K_k^{el} V_{ne}(k, \text{mol}) + K_k^{nucl} Z_k \sum_{l \neq k} Z_l / r_{lk}] / V(k, \text{mol})$

which is simply the weighted average of K_k^{el} (for the nuclear–electronic part) and K_k^{nucl} (for the nuclear–nuclear part).

Let us now study a number of molecules containing C, H, N, and O in order to determine the appropriate independent coefficients K_k^{el} and K_k^{nucl} for each of these atoms. This is done, firstly, by calculating the potential energies appearing in eq. [22] for each individual atom in the molecule. Secondly, we add separately the nuclear–electronic and the nuclear–nuclear terms to give sub-sums which collect only the contributions of atoms of the same chemical species. For example, V_{ne}(C) represents the sum of all the $V_{ne}(k, \text{mol})$ terms where the k's refer to carbon nuclei. Similarly, V_{nn}(C) is the sum of all the $Z_k \sum Z_l / r_{lk}$ terms in which the k's are carbon nuclei. Similar sub-sums, e.g. V_{ne}(H), V_{nn}(H), etc., are calculated for each chemical species which is present in the molecule and the total molecular energy is written, according to eq. [19], as

[24] $E = K_C^{el} V_{ne}(C) + K_C^{nucl} V_{nn}(C) + K_H^{el} V_{ne}(H) + K_H^{nucl} V_{nn}(H) +$ similar terms for all other atoms

Equation [24] enables thus a separation of the nuclear–electronic from the nuclear–nuclear contributions for each chemical species contained in the molecule. The results are presented in Table 3.

A multiple regression analysis was carried out using the potential energy terms of Table 3. The individual multipliers derived in this fashion from eq. [24] for the nuclear–electronic and nuclear–nuclear contributions are given in Table 4.

The present results indicating that $K_k^{el} = K_k^{nucl}$ now settle an important question, namely that of the constancy of the K_k^{mol} factor introduced in the defining of eq. [18]. Indeed, had it been $K_k^{el} \neq K_k^{nucl}$, then K_k^{mol} would have changed to some extent from molecule to molecule, depending on the relative weights of $V_{ne}(k, \text{mol})$ and $Z_k\sum_{l\neq k}Z_l/r_{lk}$ (eq. [23]). The observed constancy of K_k^{mol} for each chemical species, at least within the limits set by the accuracy of the present type of analysis, adds considerable support to earlier work (10, 11) in which this constancy has been postulated, namely in applications of eq. [19] (13). Finally, this result discriminates in favor of homogeneity of the total energy, as opposed to homogeneity of the electronic energy only,[4] i.e., ultimately, fully supports the arguments based on the Parr–Gadre theorem leading to eq. [16].

TABLE 4. The K_k^{el}, K_k^{nucl}, and K_k^{mol} coefficients of eqs. [22]–[24]*

Atom	K_k^{el}	K_k^{nucl}	K_k^{mol}
H	0.500	0.500	0.500
C	0.429	0.429	0.429
N	0.423	0.413	0.426
O	0.422	0.423	0.4216

*Alternatively, by means of eqs. [7] and [21], using the Hartree–Fock ε_i values and the equilibrium geometries given in ref. 12, we find for the diatomics C_2, N_2, and O_2 that $K_k^{mol} = 0.4291$, 0.4260, and 0.4211, respectively. Similarly, one obtains $K_k^{mol} = 0.4318$ (Li), 0.4321 (B), and 0.4169 (F).

The constancy of K_k^{mol} for each chemical species now enables us to derive approximate but still accurate molecular γ values. Let us examine the energy of atomization, ΔE_a^*, of a vibrationless molecule at 0 K, i.e.

$$\Delta E_a^* = \sum_k \langle\psi_k|H_k|\psi_k\rangle - \langle\psi_{mol}|H_{mol}|\psi_{mol}\rangle$$

where H_k and H_{mol} are the appropriate Hamiltonians

[4]A detailed discussion of related questions is offered in ref. 3.

and ψ_k and ψ_{mol} the corresponding ground-state wave functions. Applying the Hellmann–Feynman theorem, it is

[25] $V(k, \text{mol}) = V_{ne}(\text{free atom } k) - Z_k(\partial \Delta E_a^*/\partial Z_k)$

It is well known (9) that

$$Z_k(\partial \Delta E_a^*/\partial Z_k) \ll V(k, \text{mol})$$

Consequently, we may write, to a good approximation,

[26] $V(k, \text{mol}) \simeq V_{ne}(\text{free atom } k)$

Therefore, applying this approximation in the exact definition of K_{Av}^{mol} and using eq. [21]

$$\gamma = 1/K_{Av}^{mol}$$

it is

[27] $$\gamma \simeq \frac{\sum_k V_{ne}(\text{free atom } k)}{\sum_k K_k^{mol} V_{ne}(\text{free atom } k)}$$

from which γ can be deduced from the composition of the molecule and the appropriate K_k^{mol} values indicated in Table 4. The V_{ne}(free atom k) values are conveniently derived from experimental ground-state atomic energies and calculated E/V_{ne} ratios for the isolated atoms, giving V_{ne}(free atom) = −1.0000 (H), −88.4879 (C), −128.6872 (N), and −178.7457 au (O). The precision of these V_{ne}(free atom k) values is not too critical in the evaluation of γ by means of eq. [27].

Discussion and Numerical Tests of Equation [16]

In writing eq. [16] on the basis of eq. [15], the new homogeneity parameter γ/α is treated as a constant. It follows from eq. [16] that

$$Z_k^*(\partial E/\partial Z_k^*) = -(\gamma/\alpha)Z_k^{*\gamma/\alpha}$$

This expression, combined with eqs. [2] and [11], gives

$$-Z_k^{*\gamma/\alpha} = (\alpha/\gamma\alpha_k)V(k, \text{mol})$$

From a comparison of this result with those expressed by eqs. [16] and [19] it appears that

$$K_k^{mol} = \alpha/\gamma\alpha_k$$

and, consequently, that

[28] $$-Z_k^{*\gamma/\alpha} = K_k^{mol} V(k, \text{mol})$$

Finally, using the defining equation

$$Z_k^* = Z_k\sigma_k$$

it is concluded that

[29] $$\sigma_k^{\gamma/\alpha} = -K_k^{mol} Z_k^{-\gamma/\alpha} V(\text{k, mol})$$

Concerning eq. [28], which unifies the energy formulas [16] and [19], it is noteworthy that its validity is not linked to any particular choice for γ/α as long as the σ_k's are adjusted to give the $Z_k^{*\gamma/\alpha}$ values required by this expression. The following numerical tests are therefore made directly on the basis of the best possible $Z_k^{*\gamma/\alpha}$ values. Equation [29], on the other hand, is instructive because it reveals something about the "constancy" of the σ_k factors. It is now clear that these multipliers differ slightly, but significantly, from atom to atom and, moreover, that they are not strictly constant for each type of atom. Indeed, eqs. [25] and [29] show that

$$\sigma_k^{\gamma/\alpha} = -K_k^{mol} Z_k^{-\gamma/\alpha}[V_{ne}(\text{free atom } k) - Z_k(\partial \Delta E_a^*/\partial Z_k)]$$

meaning that $\sigma_k^{\gamma/\alpha}$ depends in part on a "local" portion of the molecular binding energy, a problem which has been thoroughly studied elsewhere (11) in terms of local electron densities affecting chemical binding.[5] Energy differences between isomers are reflected in subtle changes of $\sigma_k^{\gamma/\alpha}$ and, hence, of $Z_k^{*\gamma/\alpha}$. Our choice of a set of constant $Z_k^{*\gamma/\alpha}$'s remains nevertheless a valid first approximation because of the relatively narrow range of variation of $V(k, \text{mol})$ (eqs. [25], [26]).

With these premises, we have calculated total energies from eq. [16] with $Z_k^{*\gamma/\alpha}$ = 0.60309 (H), 37.79858 (C), 54.40009 (N), and 74.82589 (O), parameters which best satisfy eq. [28] when used with our SCF potential energies. The calculated total energies (eq. [16]) agree within 0.045% (average error) with their SCF counterparts. Moreover, it is also interesting to use these $Z_k^{*\gamma/\alpha}$ parameters for a numerical evaluation of the derivative

[30] $$\partial \ln Z_k^{*\gamma/\alpha}/\partial \ln Z_k = 1/K_k^{mol}$$

which follows from eqs. [10], [12], and

$$\gamma\alpha_k/\alpha = 1/K_k^{mol}$$

Using the power series

$$a_0 + a_1 \ln Z_k + a_2(\ln Z_k)^2$$

for a numerical fit of the $\ln Z_k^{*\gamma/\alpha}$ results for C, N, and O (which is a reasonable approximation in this short range of variations),[6] we find from eq. [30] that K_k^{mol} = 0.493 (H), 0.432 (B), 0.426 (C), 0.421 (N), 0.417 (O), and 0.413 (F), values which are systematically about ~1% smaller than those given in

[5] At this level, one should also consider the terms described in footnote 3 which were neglected in writing the approximations [9] and [16].

[6] The coefficients are $a_0 = -0.290676$, $a_1 = 2.030605$, and $a_2 = 0.088647$.

Table 4. These results certainly justify our approximate energy partitioning in terms of atomic-like contributions which is reflected by eqs. [16] and [18].

There is another point deserving attention. The σ_k's of the individual atoms k, which are likely not to be the same for H, C, etc., depend to some extent on the molecular environment (eq. [29]), although an approximation implying their constancy is certainly a good one (eq. [26]). On the other hand, if eq. [16] is used with fixed atomic σ_k's, its validity is linked to that of the assumed "constancy" of the σ_k's. Here we submit that if some value of γ/α minimizes the differences between the σ_k's of different atoms (C, N, etc.), the range of variation of the σ_k's of each type of atom would also be minimized, thus approaching the requirements for internal consistency of eq. [16] involving constant atomic σ_k values. By means of the $Z_k^{*\gamma/\alpha} = (\sigma_k Z_k)^{\gamma/\alpha}$ values given above, it is found that the differences between σ_C, σ_N, and σ_O are minimized for $\gamma/\alpha = 2.3733$, giving

$$\sigma_C = 0.7701,\ \sigma_N = 0.7695,\ \sigma_O = 0.7701,$$
$$\text{and } \sigma_H = 0.8081$$

Including H in this analysis, it appears that

$$\sigma_H = 0.8038,\ \sigma_C = 0.8004,\ \sigma_N = 0.8029,$$
$$\text{and } \sigma_O = 0.8063$$

for $\gamma/\alpha = 2.3149$. Finally, assuming now $\gamma/\alpha = 7/3$, it results that

$$\sigma_H = 0.8052,\ \sigma_C = 0.7905,\ \sigma_N = 0.7920,$$
$$\text{and } \sigma_O = 0.7945$$

While this type of analysis does not provide a clear-cut answer about the "true" value of γ/α, it is clear that the Thomas–Fermi or local density functional homogeneity constraint of $\sim 7/3$ corresponds to a situation in which the σ_k's of the various atoms are quite similar one to another.

The fact that γ/α is taken at a constant value does not imply that γ itself is a constant. Hence, using the γ values given by our approximation (eq. [27]) and the K_k^{mol} values of Table 4, we obtain an estimate of the sum $\sum_i \nu_i \varepsilon_i^{\text{orb}}$ of the orbital energies (eq. [7]). Finally, using the appropriate V_{nn} values, we obtain V_{ne} from eq. [8] and V_{ee} (eq. [4]). The results are given in Table 5, together with their SCF counterparts.

The results are self-explanatory and vividly support the views having led to eq. [16] as well as the approximations used for estimating γ. They suggest the following conclusions.

Conclusions

The proportionality relationship

$$E \propto \sum_k Z_k^{\gamma}$$

in which γ is a characteristic constant for the molecule under study and where the proportionality factor is left undetermined, satisfies the equation

$$\gamma E = \sum_k Z_k (\partial E/\partial Z_k)$$

This expression describes an energy partitioning in terms of atomic-like contributions. Introducing a multiplier σ_k for defining an "effective" nuclear charge

$$Z_k^* = Z_k \sigma_k$$

we find that

$$(\gamma/\alpha)E = \sum_k Z_k^* (\partial E/\partial Z_k^*)$$

(in which γ/α is now a new characteristic constant) and, moreover, that

$$E = -\sum_k Z_k^{*\gamma/\alpha} = -\langle \sigma_k^{\gamma/\alpha} \rangle \sum_k Z_k^{\gamma/\alpha}$$

The ratio $E/\sum_k Z_k^{\gamma/\alpha}$ is thus defined in terms of the multipliers σ_k which differ from atom to atom. A first approximation with

$$\langle \sigma_k^{\gamma/\alpha} \rangle = 0.51130 \text{ and } \gamma/\alpha = 2.40073$$

is known to give reasonable results in calculations of total energies (3). This type of approach, which has the merits of its simplicity, meets, however, with a major difficulty. The constant γ/α exponent, simply identified as γ, fails, indeed, to satisfy the equation

$$(3 - \gamma)E = \sum_i \nu_i \varepsilon_i^{\text{orb}}$$

Our approach, on the contrary, not only satisfies the approximation

$$E = -\sum_k Z_k^{*\gamma/\alpha}$$

but equally well that giving the sum $\sum_i \nu_i \varepsilon_i^{\text{orb}}$ of the orbital energies. The reason is that even though γ/α is constant, it is γ itself which determines the relationship between total and orbital energies. It is seen that the use of the σ_k multipliers restores in a simple way the required internal consistency among energy formulas which play a central role not only in Hartree–Fock theory but also in exact and local density functional theory.

The calculation of γ, using either the appropriate $V(k, \text{mol})$ values or valid approximations thereof, rests on the validity of the energy formula

$$E = \sum_k K_k^{\text{mol}} V(k, \text{mol})$$

This equation, which has been thoroughly tested on previous occasions (10, 11, 13), reproduces the present SCF energies (Table 5) with an average error of 0.106%. We feel presently unable to go beyond this level of accuracy, partly because the SCF virial $-V/T$ ratio is usually not exactly 2 and, moreover, because it is uncertain whether the present GTO basis set describes the molecules containing nitrogen and oxygen with the same degree of accuracy as the hydrocarbons. Our analysis which has explicitly considered a separation of the individual nuclear–electronic and nuclear–nuclear contributions to the potential energies, rather than merely forcing a fit of the sum $\sum_k K_k^{\text{mol}} V(k, \text{mol})$ with SCF total energies, concludes that the K_k^{mol}'s are, indeed, constants for the individual atoms. This result, as well as the way it has been deduced, is important not only because it lends strong support to earlier work which was based on this energy formula but also because it discriminates in favor of homogeneity of the total energy over that of the electronic energy only. Homogeneity of the total energy is a basic aspect in the present theory.

The assumption of a constant σ_k for each type of atom is supported, as a first approximation, by the present results which also suggest that $\gamma/\alpha \sim 7/3$. The K_k^{mol} coefficients are now defined in terms of the σ_k's and of γ/α by the formula

$$1/K_k^{\text{mol}} = (\gamma/\alpha)\partial \ln (Z_k \sigma_k)/\partial \ln Z_k$$

which provides the link between the two alternate descriptions of molecular energies which have been analysed in this work. While the present results illustrate the merits and the limitations of the description of molecular energies in terms of atomic-like $Z_k^{*\gamma/\alpha}$ contributions, they leave room for refine-

ments by a consideration of the subtle influence of local properties on σ_k, thus creating a bridge between the present views and the concept of a molecule regarded as a collection of "atoms" or, alternatively, of "chemical bonds" (11).

Etude rmn (^{1}H et ^{13}C) des interactions entre les nucléosides et les bleus de platine obtenus à partir du méthyle-1 nicotinamide

JEAN-PIERRE LAURENT ET PAULE LEPAGE

Laboratoire de Chimie de Coordination du CNRS associé à l'Université Paul Sabatier, 205 route de Narbonne, 31400 Toulouse, France

Reçu le 29 février 1980[1]

JEAN-PIERRE LAURENT et PAULE LEPAGE. Can. J. Chem. **59**, 1083 (1981).

Les interactions entre deux "bleus de platine" obtenus à partir du méthyle-1 nicotinamide et divers nucléosides (guanosine, cytidine, uridine et adénosine) ont été étudiées à l'aide de la spectrographie de rmn (^{1}H et ^{13}C). Les résultats obtenus montrent que les sites d'interaction sont identiques à ceux qui sont généralement observés pour les complexes "classiques" du platine(II), le *cis*-$Pt(NH_3)_2Cl_2$ par exemple.

JEAN-PIERRE LAURENT and PAULE LEPAGE. Can. J. Chem. **59**, 1083 (1981).

The interactions between two "platinum blues", obtained from 1-methylnicotinamide, and various nucleoside (guanosine, cytidine, uridine, and adenosine) have been studied by ^{1}H and ^{13}C nmr spectroscopy. The results obtained show that the interaction sites are identical to those usually observed for normal Pt(II) complexes, e.g. *cis*-$Pt(NH_3)_2Cl_2$.

De nombreux travaux ont été consacrés à l'étude des interactions entre les ions des métaux lourds et les constituants des acides nucléiques (1, 2). Les études en solution ont ainsi fait largement appel à la spectrographie de résonance protonique mais le petit nombre de protons non échangeables, intervenant dans la structure des bases purines ou pyrimidiques, limite la portée des résultats obtenus. La résonance du noyau ^{13}C, au contraire, permet d'atteindre des informations plus précises sur la localisation des sites d'interaction par suite du nombre important de carbones observables.

L'intérêt de tels travaux s'est accru dans le cas du platine à la suite de la découverte des propriétés antitumorales de certains complexes de type classique (tel *cis*-$Pt(NH_3)_2Cl_2$) ou appartenant au groupe des espèces dites "bleus de platine" (3–5). Ces derniers composés, dont la coloration bleue est la caractéristique commune la plus évidente, ont donné lieu, depuis leur découverte, à un nombre important de travaux (cf. par exemple les réfs 6 à 13). Ils posent encore de nombreux problèmes, en particulier pour ce qui est de leur mode d'action. Disposant de deux espèces originales (14), nous avons entrepris d'étudier leur réaction avec quelques nucléosides, dans la perspective retenue par de nombreux auteurs (15–19) et suivant laquelle l'activité antitumorale de ces produits serait liée à des interactions spécifiques avec l'ADN. Si par suite de leur caractère polymère et de la présence d'un certain paramagnétisme, la résonance nucléaire n'est pas l'outil de choix pour étudier les complexes bleus eux-mêmes, cette technique permet cependant de préciser la nature des sites d'interaction avec les nucléosides.

Résultats et discussions

1. Les complexes bleus

Les complexes bleus du platine sont généralement obtenus à partir des produits d'hydrolyse[2] du complexe *cis*-$Pt(NH_3)_2Cl_2$ et d'un ligand présentant une fonction amide ou lactame. La classe la plus étudiée actuellement fait intervenir l'uracile et ses dérivés (4, 5). Nous avons pu obtenir une espèce originale en utilisant K_2PtCl_4 comme précurseur et le méthyle-1 nicotinamide (cf. fig. 1) comme ligand (14). La réaction conduit à une espèce neutre de type chloro (A) qui, par action du nitrate d'argent en milieu aqueux permet d'atteindre une espèce cationique de type aquo ou hydroxo (B).

Ces espèces sont amorphes et, de ce fait, difficiles à caractériser. Sur la base des seules données analytiques, il n'est pas possible de proposer une formulation entièrement satisfaisante mais ce résultat peut être atteint en envisageant l'ensemble des propriétés physico-chimiques de ces espèces. A partir des résultats d'analyse, il apparaît que dans (A) et (B), une seule molécule de méthyle-1 nicotinamide intervient par atome de platine et que, dans (A), le rapport atomique Cl/Pt est toujours légèrement supérieur à 2. La solubilité de (B) dans l'eau a permis la mise en œuvre d'un dosage oxydant (20) réalisé en milieu sulfurique dilué à l'aide de sulfate cérique et suivi par la décroissance de la bande d'absorption caractéristique à 715 nm. Dans l'hypothèse où le produit final

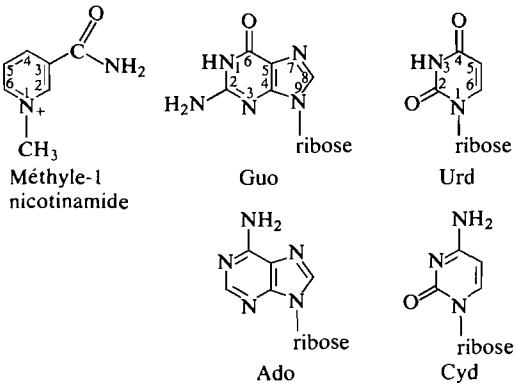

FIG. 1. Les composés étudiés: numérotation retenue pour la présentation des données rmn.

serait du platine(IV), ce dosage accorde au platine présent dans (B) un degré d'oxydation formel égal à $2{,}2_5 \pm 0{,}0_5$.

Ce résultat est en quelque sorte confirmé par l'observation de signaux RPE, faibles mais parfaitement discernables. Les spectres obtenus sont de symétrie axiale ($g_{\|} = 1{,}98$; $g_{\perp} = 2{,}40$) et présentent de très grandes analogies avec le spectre du complexe bleu obtenu à partir de 1′ α-pyridone (13).

La spectrographie infra-rouge enfin établit que le ligand intervient, dans les deux espèces, sous forme déprotonée et que la coordination se ferait à la fois par l'oxygène et le groupement NH de la fonction amide. Dans ces conditions, il semble raisonnable de représenter les espèces (A) et (B) par les formules respectives:

$$Pt_n(L\text{–}H)_nCl_{2n+1}(H_2O)_m$$

et

$$Pt_n(L\text{–}H)_n(NO_3)_{2n+1}(H_2O)_{2n}$$

avec $n = 4$ ou 5. m est variable suivant les échantillons mais reste compris entre 5 et 7. (L–H) désigne la forme déprotonée du méthyle-1 nicotinamide.

En définitive on peut dire que les complexes (A) et (B) présentent les caractéristiques habituelles des "bleus de platine": absorption dans le visible, production de signaux RPE. Ceci, joint aux faits que le platine se trouve dans un état d'oxydation fractionnaire et que le ligand se coordine par la fonction amide déprotonée, suggère que la structure de (A) et (B) doit présenter de nombreuses analogies avec celles qui ont été déjà proposées ou établies pour certains complexes de ce type (11–13).

Les spectres de résonance nucléaire confirment bien ces données, mais n'apportent que peu de renseignements supplémentaires. L'espèce (A), pratiquement insoluble dans l'eau, n'est que peu soluble dans le diméthylsulfoxyde et il n'a pas été possible d'obtenir de spectre de résonance ^{13}C. D'une façon générale, les spectres obtenus présentent des pics larges, mais dont il est possible d'évaluer la position. Les résultats sont rassemblés dans le tableau 1. Ils permettent de conclure que, dans les espèces (A) et (B), l'identité du ligand n'est pas altérée, si ce n'est que le groupement amide est déprotoné. Dans les spectres ^1H obtenus sur des solutions dans le DMSO, on observe en effet à la complexation un déplacement important du signal NH (de 8,6 à 4,4 ppm), cohérent avec la déprotonation du motif NH_2, alors que les autres signaux ne sont que très peu affectés. Au niveau des spectres ^{13}C, le passage du ligand libre à l'espèce (B) s'accompagne de modifications faibles sauf pour les noyaux C(3) et C(7) qui se trouveraient ainsi au voisinage du site de complexation.

2. *Interaction des complexes bleus avec les nucléosides*

D'une façon très générale, nous avons considéré les spectres de résonance (^1H et ^{13}C) de plusieurs mélanges présentant des proportions variées de complexe et de nucléoside en solution aqueuse. Les nucléosides envisagés sont la guanosine (guo), la cytidine (Cyd), l'uridine (Uri) et l'adénosine (Ado) (cf. fig. 1). Les mélanges sont examinés après une période de repos (12 h à 40°C, pD = 6) au terme de laquelle une filtration permet d'écarter l'excès éventuel de réactifs qui apparaît généralement quand le rapport [Nucl]/[Pt] est différent de deux.

Pour un rapport égal à deux, on obtient une dissolution totale des deux constituants, même si, pris séparément, ceux-ci sont insolubles (ou très faiblement solubles) dans l'eau au voisinage de la neutralité (cas de la guanosine et de l'espèce A par exemple). Cette observation suggère qu'une interaction privilégiée correspondrait à une stoechiométrie mettant en jeu deux molécules de nucléoside par atome de platine. En fait, l'examen des spectres de résonance confirme cette conclusion, sauf dans le cas de l'adénosine.

En ce qui concerne les signaux du méthyle-1 nicotinamide, un seul ensemble a pu être détecté dans tous les échantillons examinés de composition [Nucl]/[Pt] = 2/1.[3] Ces signaux sont facilement repérables, à l'exception de ceux qui correspondent aux carbones C(3) et C(7) qui, dans certains cas, n'ont pas été décelés. Quoi qu'il en soit, les signaux observés apparaissent toujours à ces posi-

[3]La largeur des pics de résonance ne permettrait pas de distinguer deux signaux présentant des déplacements différant de moins de 1 ppm.

tions extrêmement voisines de celles qu'ils ont dans les complexes bleus initiaux, soit: 169 pour C(7), 151 C(6), 148 C(2), 146 C(4), 137 C(3), 129 C(5) et 52 ppm. Il en est de même pour les spectres de résonance ^1H.

Au niveau des noyaux ^1H et ^{13}C des nucléosides, nous considérerons tout d'abord le cas des échantillons de composition 2/1. Les résultats obtenus sont rassemblés dans les tableaux 2 et 3. Les valeurs retenues pour les déplacements (δ^1H et $\delta^{13}C$) des nucléosides résultent de nos propres déterminations; elles sont en accord avec les données de la littérature (10, 18, 19, 21–27). Les déplacements des noyaux ^{13}C de l'ose ne sont pas rapportés ici, les modifications liées à l'introduction des espèces bleues restant inférieures ou au plus égales à 1,2 ppm.

A pH 6, la guanosine est sous forme neutre et la base présente un seul proton, H(8), non échangeable et nettement décelable dans le spectre (δ = 8,00 ppm) ainsi que le proton H(1′) de l'ose. Ce dernier n'est que peu affecté par l'addition du complexe (A), contrairement à H(8) dont le déplacement évolue fortement (0,72 ppm). Si le mélange réactionnel (2/1) est évaporé sous vide puis repris dans le diméthylsulfoxyde, on obtient un spectre d'aspect semblable à celui de la guanosine libre mais faisant apparaître un déplacement important de H(8) (8,64 pour 8,00 ppm dans la guanosine isolée) et des variations faibles pour les autres noyaux; H(1′) (5,82 pour 5,92), NH_2 (6,43 pour 6,31) et NH (10,05 pour 9,88 ppm). Il faut noter ici que ces solutions dans le diméthylsulfoxyde s'altèrent très rapidement, les spectres comportant plusieurs types de signaux attribuables au solvant. Les résultats obtenus à partir des spectres ^1H tendent à localiser l'interaction platine–guanosine au niveau de l'azote N(7), ce qui semble confirmé par l'étude de la résonance ^{13}C qui crédite le carbone C(8) de la plus forte perturbation.

Pour ce qui est de la cytidine, la base présente deux protons non échangeables H(5) et H(6), qui sont affectés dans des proportions très voisines par l'addition de (A) ou de (B). Les modifications enregistrées dans les spectres ^{13}C sont plus significatives. Elles privilégient très nettement les carbones C(2) et C(4) et désignent ainsi l'azote N(3) comme site d'interaction.

A pH 6, l'uridine se trouve essentiellement sous la forme déprotonée en N(3). Comme dans le cas de

TABLEAU 3. Déplacements chimiques $\delta^{13}C$ dans les mélanges 2/1 (solutions aqueuses, pH 6)

	C(2)	C(4)	C(5)	C(6)	C(8)
Guo	154,6	152,4	117,6	157,8	137,0
Guo/(A)	155,2	151,2	119,7	156,6	142,2
Cyd	158,0	166,8	96,3	142,2	
Cyd/(A) (2/1)	153,3	162,9	97,1	142,9	
Cyd/(B) (2/1)	154,8	163,7	96,8	142,5

Uri/(B) (2/1)	157,8	174,7	101,4	139,6	
Ado	153,0	150,1	120,4	156,8	140,7
Ado/(A)	156,1 (158,5;154,3)	150,1 (n.o.)	129,9 (n.o.)	160,8 (n.o.)	149,8 (146,7;142,2)
Ado/(B)	155,4	150,3	127,1	158,2	145,6

la cytidine, la base possède deux protons non échangeables H(5) et H(6). Aucune réaction n'a pu être mise en évidence à partir des spectres (^1H et ^{13}C) caractérisant des mélanges 2/1 et 1/1 d'uridine et de l'espèce chlorée (A). Au contraire, les mélanges 2/1 formés par l'espèce (B) sont le siège d'une forte baisse de pH (jusqu'à la valeur 1,5). Les spectres obtenus après avoir ramené le pH à la valeur 6 présentent des modifications significatives. Ceci est particulièrement net pour les spectres ^{13}C dans lesquels les noyaux C(4) et C(2) sont le plus fortement affectés. Ces effets désignent l'azote N(3) comme site d'interaction.

Dans le cas de l'adénosine, les spectres ^1H ne conduisent pas à des résultats totalement dépourvus d'ambiguïté. Sous forme neutre, ce nucléoside présente, au niveau de la base, deux protons non échangeables H(2) et H(8) dont les déplacements sont voisins (8,11 et 8,28 ppm). Cette proximité rend délicat l'établissement d'une filiation entre les spectres du ligand libre et complexé, et ce d'autant plus que plusieurs jeux de signaux se manifestent dans les spectres des mélanges. Pour les mélanges 2/1 constitués à partir de l'espèce (A), un de ces jeux (8,26; 8,71 ppm) se distingue des deux autres (8,94; 8,78 et 8,66; 8,59 ppm) par une intensité nettement plus marquée.On observe également plusieurs signaux aux environs de 6,16 ppm. Ces remarques peuvent être étendues aux spectres ^1H des mélanges formés par l'espèce (B) et aux spectres ^{13}C. Pour ces derniers, l'ensemble principal de signaux fait apparaître des perturbations maximales pour les noyaux C(5) et C(8). Ces effets seraient cohérents avec l'existence d'une interaction en N(7).

En définitive, les résultats obtenus pour des mélanges 2/1 permettent de penser que, vis-à-vis du platine engagé dans les espèces bleues (A) et (B), les nucléosides se comportent préférentiellement comme des ligands monodentates par l'intermédiaire des sites N(7) (Guo et Ado) et N(3) (Cyd et Uri).

Ces sites d'interaction sont ceux qui sont le plus généralement retenus dans la littérature (10, 18, 19, 21–28). Des interactions secondaires sont suggérées dans le cas de l'adénosine. Nous les envisagerons plus loin.

Les spectres correspondant à des mélanges de compositions différentes de 2/1 sont, le plus souvent, identiques à ceux des mélanges 2/1.

Les constituants en excès n'apparaissent pas dans les spectres (cas des constituants insolubles ou peu solubles tels que l'espèce (A) ou la guanosine) ou donnent des signaux facilement repérables (constituants solubles comme, par exemple, l'espèce (B)).

Dans deux cas cependant les modifications de composition se traduisent par des changements significatifs dans l'allure des spectres: apparition de nouveaux signaux (guanosine et défaut de (A)) ou variation des intensités relatives des différents ensembles de signaux (adénosine et excès ou défaut de (A) ou (B)).

C'est ainsi que, dans le premier cas, on note dans les spectres ^1H l'apparition, à côté du pic principal précédemment observé (8,72 ppm), d'un pic secondaire à 8,51 ppm. De la même façon, les spectres ^{13}C présentent de nouveaux signaux à 128,5;186,8 et 155,5 ppm. Ces nouveaux signaux pourraient correspondre à une interaction secondaire mettant en jeu les sites O(6) et N(7) de la guanosine (26, 29, 30).

Dans le cas de l'adénosine, les modifications du rapport [Nucl]/[Pt] provoquent des changements dans les intensités relatives des trois ensembles de signaux qui sont déjà présents dans les spectres des mélanges 2/1.

Il faut noter ici qu'en résonance de ^{13}C, on n'observe qu'une partie des signaux attendus dans l'hypothèse de la coexistence de trois formes. Ceci

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

peut être dû au fait que deux de ces formes sont toujours présentes en faibles quantités et que, dans ces conditions, certains signaux, ceux des carbones quaternaires en particulier, ont une intensité très faible. En effet, l'espèce majoritaire dans les spectres des mélanges 2/1 l'emporte toujours sur les deux autres. L'observation de plusieurs ensembles de signaux peut être rapprochée des remarques déjà formulées (21, 25, 31) et concernant les possibilités d'interaction de l'ion métallique avec l'adénosine au niveau de N(7), mais aussi de N(1) et même, simultanément, de N(1) et N(7), le nucléoside jouant alors le rôle de pont entre deux centres métalliques pour conduire à un complexe dinucléaire. Ces hypothèses seraient compatibles avec les valeurs des déplacements observés ici, ainsi qu'avec les modifications d'intensité des signaux en fonction de la composition des mélanges étudiés.

Conclusions

Pour conclure cette étude, nous retiendrons tout d'abord que si la rmn (^1H et ^{13}C) n'est pas un outil de choix pour étudier les complexes bleus du platine, cette spectroscopie peut être utilisée pour préciser la nature des sites d'interaction des nucléosides avec ces espèces bleues. Dans les conditions expérimentales utilisées (pD = 6, solutions aqueuses relativement concentrées (de l'ordre de 0,1 M)) les espèces bleues (A) et (B) obtenues à partir du méthyle-1 nicotinamide réagissent avec les nucléosides suivant des processus extrêmement voisins de ceux observés pour les complexes plus "classiques" du platine(II) ou du palladium(II). Il apparaît en effet que les interactions se situent essentiellement au niveau des sites N(7) (Guo et Ado) et N(3) (Cyd et Uri), les nucléosides se comportant en ligands monodentates et l'uridine réagissant sous forme déprotonée.

L'intervention d'interactions secondaires au niveau des sites O(6) (Guo) et N(1) (Ado) pourrait être également envisagée, en particulier quant le rapport des concentrations [Nucl]/[Pt] devient inférieur à 2. L'intensité des signaux qui leur correspondent reste cependant toujours faible.

Il est intéressant de noter qu'aucune modification importante de la position ou de la largeur des signaux attribuables au méthyle-1 nicotinamide n'intervient quand on passe des espèces bleues initiales (A) et (B) aux mélanges renfermant les nucléosides. Par ailleurs, ces mélanges conservent, pendant un certain laps de temps (de l'ordre de plusieurs jours) après leur préparation, une coloration bleue et continuent à donner des signaux RPE complexes mais décelables. Ces deux observations suggèrent que la structure des espèces (A) et (B) n'est pas profondément modifiée par l'interaction avec les nucléosides. Dans la mesure où les propriétés de (A) et de (B) permettent de les rapprocher des autres bleus connus et de leur attribuer une structure semblable, il semblerait que l'enchaînement d'atomes de platine dans un état d'oxydation fractionnaire soit conservé et que l'interaction avec les nucléosides ne fasse pas intervenir une forme mononucléaire comme cela a été suggéré pour les systèmes bleus de platine – protéines (32).

Partie expérimentale

La préparation des espèces bleues (A) et (B) a été décrite par ailleurs (14). Les nucléosides utilisés sont des produits commerciaux.

Les mélanges réalisés dans l'eau lourde à partir des constituants en proportions variables ne sont étudiés qu'après une période de repos (12 h à 40°C, pH = 6) à l'obscurité.

Les spectres rmn ont été réalisés sur un appareil Bruker WH 90 opérant à 90,00 MHz pour ^1H et à 22,62 MHz pour ^{13}C en mode pulsé avec transformation de Fourier. De 30 000 à 50 000 signaux de libre précession ont été accumulés dans 8K mémoire pour la résonance de ^{13}C. On a utilisé un temps de répétition de 3 s et une impulsion voisine de 60°.

Hydrolyse des dérivés de cyclopropylidène-3 propyle. Structure et stéréochimie des alcools précurseurs et des produits résultant de l'hydrolyse

ROBERT FAURE

Laboratoire de Chimie Organique Physique, Université d'Aix-Marseille III, Rue H. Poincaré, 13397 Marseille Cedex 4, France

ET

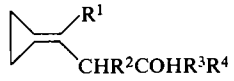
GILBERT LEANDRI ET ALAIN MEOU

Laboratoire Associé au C.N.R.S. no 109, Université d'Aix-Marseille III, Rue H. Poincaré, 13397 Marseille Cedex 4, France

Reçu le 3 octobre 1980

ROBERT FAURE, GILBERT LEANDRI et ALAIN MEOU. Can. J. Chem. **59**, 1089 (1981).

Nous avons enregistré les spectres de rmn du carbone-13 de 14 alcools β-cyclopropylidéniques **1**, de structure



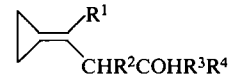
(R¹, R², R³ et R⁴ = H ou CH_3)

Tous les déplacements chimiques ont été attribués et les effets de substituant sont discutés en fonction de la conformation moléculaire. La stéréochimie des deux diastéréoisomères des alcools **1***e* ($R^1 = R^3 = H$; $R^2 = R^4 = CH_3$) et **1***k* ($R^3 = H$; $R^1 = R^2 = R^4 = CH_3$) a été établie à partir des résultats de spectroscopie infrarouge et de résonance magnétique nucléaire du proton.

Nous avons également enregistré les spectres de carbone-13 des produits résultant de l'hydrolyse des tosylates de cyclopropylidène-3 propanol **1***a* et de cyclopropylidène-4 butanol-2 **1***b*. L'analyse de ces données permet d'établir sans ambiguité la structure et la stéréochimie des produits d'hydrolyse.

ROBERT FAURE, GILBERT LEANDRI, and ALAIN MEOU. Can. J. Chem. **59**, 1089 (1981).

The ^{13}C nmr spectra of 14 β-cyclopropylidenic alcohols **1** have been determined:



(R¹, R², R³ and R⁴ = H or CH_3)

All the chemical shifts were assigned and the substituent effects are discussed as a function of molecular conformation. The stereochemistry of two diastereoisomers of alcohols **1***e* ($R^1 = R^3 = H$; $R^2 = R^4 = CH_3$) and **1***k* ($R^3 = H$; $R^1 = R^2 = R^4 = CH_3$) was established from ir spectroscopy and ^1H nmr results.

The ^{13}C nmr spectra of products arising from hydrolysis of 3-cyclopropylidene propanol **1***a* and 4-cyclopropylidene 2-butanol **1***b* tosylates have been also recorded. The analysis of these data enables us to establish unambiguously the structure and the stereochemistry of the hydrolysis products.

Introduction

Dans un récent travail (1), nous avons montré l'aptitude qu'avaient les tosylates de cyclopropylidène-3 propyle **I** à se réarranger au cours de réactions de solvolyse. Les premiers résultats expérimentaux sont en faveur d'une participation du doublet π de la liaison éthylénique au départ du groupement partant, le cation cyclopropyl-cyclopropyle ainsi formé pouvant évoluer et conduire aux composés **2** à **4** (figure 1). Les structures de ces composés ont été déduites des résultats de spectroscopie infrarouge et de résonance magnétique nucléaire du proton à 60 MHz. Ces méthodes analytiques n'ont toutefois pas permis de déterminer la stéréochimie des dérivés de la série *b* (R = CH_3).

Pour confirmer l'hypothèse d'une participation du doublet π au départ du processus d'hydrolyse, les études cinétiques et stéréochimiques sont actuellement en cours;[1] de telles études nécessitent une connaissance précise de la stéréochimie des produits d'hydrolyse et des alcools β-cyclopropylidéniques **1** précurseurs des tosylates **I**. La résonance magnétique nucléaire du carbone-13 qui est une méthode dont les avantages en analyse conformationnelle sont reconnus (2, 3), convient tout à fait à ce genre d'études. En associant à ces résultats de ^{13}C d'autres données spectroscopiques, infrarouge ou rmn du proton à haut champ, nous allons montrer qu'il est possible d'une part de confirmer ou d'infirmer les structures précédemment proposées pour les composés **2** à **4** (1), d'autre part de déterminer la stéréochimie des alcools β-cyclopropylidéniques **1** et des différents produits d'hydrolyse de la série *b*.

Partie expérimentale

Les spectres de carbone-13 ont été enregistrés sur un spectromètre Varian FT-80 à la température de 28 ± 2°C. Les déplacements chimiques mesurés sur les spectres totalement découplés par bruit sont rapportés au signal du TMS pris comme référence interne. Pour chacun des composés un spectre en découplage partiel a été enregistré afin de déterminer la multipli-

1

R^1, R^2, R^3 et R^4 = H ou CH_3

cité des différents signaux de résonance. Les spectres de proton ont été obtenus en balayage de fréquence sur un spectromètre Cameca opérant à 250 MHz (T = 20°C). Ces différentes études spectroscopiques ont été réalisées en solution dans le chloroforme deutérié à l'exception des spectres de ^{13}C des composés **1***a* à **1***c* qui ont été enregistrés dans l'acétone deutériée. Enfin les diverses méthodes utilisées pour la préparation des alcools β-cyclopropylidéniques **1** ont déjà été décrites dans un récent mémoire (4).

Structure et stéréochimie des alcools β-cyclopropylidéniques

Les déplacements chimiques du carbone-13 des alcools β-cyclopropylidéniques **1** sont présentés dans le tableau 1.

Stéréochimie des alcools **1***e et* **1***k*

Les alcools secondaires **1***e* et **1***k* qui possèdent deux centres asymétriques sont obtenus sous forme de couples de diastéréoisomères (**A** et **B**); l'isomère **A**, élué le premier en chromatographie en phase vapeur sur colonne polaire, est toujours majoritaire: 56% dans le cas de **1***e* et 79% dans le cas de **1***k* (4). La stéréochimie de ces alcools peut aisément être établie par spectroscopie infrarouge; en effet, comme cela a déjà été mis en évidence dans le cas des alcools β-éthyléniques (5, 6) dans les alcools du type **1** le groupement hydroxyle doit être lié intramoléculairement avec les électrons π de la liaison éthylénique pour former une liaison hydrogène. Puisque la bande d'absorption $\nu_{(OH)}$ relative à cette chélation est insensible aux effets de dilution (7), une étude en fonction de la concentration permet alors de déterminer la force d'une telle liaison et, par conséquent, d'accéder à la stéréochimie des alcools étudiés.

En ce qui concerne **1***e* et **1***k*, l'examen des spectres infrarouge (4) montre que cette association intramoléculaire est plus importante pour l'isomère **A**. Si l'on considère les différents rotamères des formes *érythro* et *thréo* des alcools **1***e* et **1***k* (figure 2), on constate que, compte tenu des interactions *gauches* déstabilisantes entre groupements volumineux, l'association par liaison hydrogène est particulièrement favorisée pour le rotamère T1. On peut donc affirmer que **A** est l'isomère *thréo*.

Cette chélation est beaucoup plus intense pour **1***k***A** que pour **1***e***A**; cela s'explique, d'une part par une nucléophilie accrue du système π (effet donneur du méthyle), et, d'autre part, par une déstabilisation plus importante des rotamères T2 et T3 (perturbations supplémentaires apportées par le groupement méthyle).

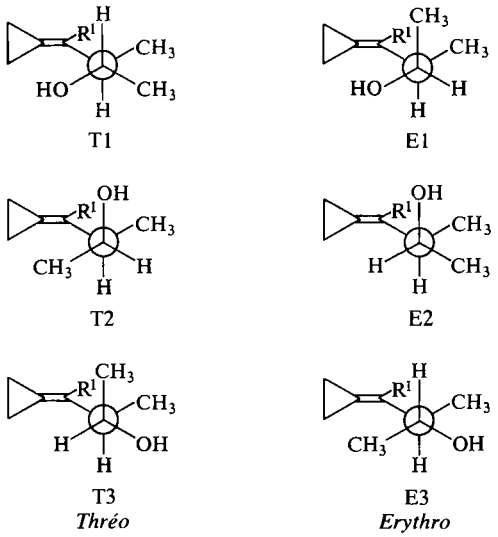

FIG. 2. Représentation de Newman des différents rotamères des formes *érythro* et *thréo* de **1***e* (R^1 = H) et de **1***k* (R^1 = CH_3).

La mesure de la constante de couplage[2] entre les deux protons portés par les carbones asymétriques confirme en partie les conclusions précédentes. Selon Karplus (8), le couplage entre protons vicinaux doit être plus élevé pour les rotamères dont les liaisons CH se trouvent en position antipériplanaire. Dans ces conditions on devrait observer une

[2]Cette valeur est déterminée par une analyse de la figure de couplage du proton H(6); on simplifie cette analyse par une irradiation des protons du groupement méthyle R^3 (ou R^4).

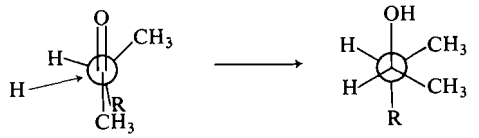
*Ces composés ont été étudies en solution dans l'acétone deutériée.
†La stéréochimie de ces structures sera précisée par ailleurs (voir texte).
‡Déplacements dont l'attribution peut être inversée.

valeur plus grande pour l'isomère *thréo* du fait de la stabilité préférentielle du rotamère T1. Cette proposition est vérifiée pour **1***k* (**A**, $J_{H(5)H(6)} = 9.7_5$ Hz; **B**, $J_{H(5)H(6)} = 7.2_5$ Hz). Par contre, en ce qui concerne **1***e*, les deux couplages sont identiques (6 Hz), ce qui empêche toute conclusion sur la stéréochimie des deux diastéréoisomères. Cependant ces résultats traduisent la grande stabilité du rotamère E3, qui est, notons le, le plus apte à donner des associations intermoléculaires.

Enfin, compte tenu du mode de préparation de ces alcools (4), la prépondérance de l'isomère *thréo* est conforme à la règle de Cram et Abd Alhafez (9) qui prévoit une attaque privilégiée sur la face la moins encombrée du carbonyle.

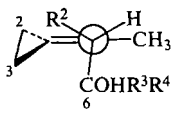


Isomère *thréo*

Attribution des déplacements chimiques et analyse des effets de substituant

En tenant compte de la multiplicité des différents signaux de résonance et des résultats de la littérature (2, 10) concernant des molécules de structure voisine, nous pouvons attribuer sans ambiguité les déplacements chimiques des différents carbones exceptés ceux relatifs aux carbones C-2 et C-3. Cette dernière attribution, qui dépend de la substitution de la position 4, nécessite de ce fait une discussion plus détaillée.

Dans le cas des composés **1***a* à **1***f* ($R^1 = H$), le carbone C-3 résonne à champ plus fort que C-2 (effet γ gauche (11)). Toutefois, en ce qui concerne **1***f*, il n'en est plus ainsi puisque les raies de résonance de ces deux atomes sont pratiquement confondues. Nous proposerons ultérieurement une explication à ce phénomène. Considérons maintenant les dérivés **1***g* à **1***k* ($R^1 = CH_3$): la méthylation en position 4 est à l'origine de nouvelles interactions qui n'étaient pas prises en compte dans la première série. En conséquence certaines conformations, moins encombrées d'un point de vue stérique, vont être favorisées, en particulier celles dans lesquelles le carbone C-6 se trouve à proximité de C-3, et ce comme le montre la figure suivante:



Notons que ce type de conformation est également stabilisé par la liaison hydrogène existant entre ce groupement hydroxyle et les électrons de la liaison éthylénique (voir le précédent chapitre). De l'interaction entre les carbones C-3 et C-6 (interaction δ stérique (12)) il s'ensuit un déblindage de C-3. L'ordre des déplacements chimiques est alors inversé par rapport à la première série d'alcools. Dans le cas de **1***k* on peut également invoquer l'existence de conformations privilégiées dans lesquelles C-6 se trouve dans le voisinage de C-3. Toutefois l'effet de déblindage est moins prononcé, compte tenu des plus faibles interactions stériques ($R^1 = H$).

Structure et stéréochimie des produits d'hydrolyse

Les alcools **1***a* et **1***b* sont convertis en tosylates puis hydrolysés. Les produits formés et présents en quantité suffisante pour pouvoir être séparés par chromatographie en phase vapeur sont alors analysés.

*Cas du cyclopropylidène-3 propanol 1*a

En plus de **1***a* non transposé, on isole deux alcools **2***a* et **3***a* (figure 3) dont les structures respectives ont été déduites des résultats de spectroscopie infrarouge et de résonance magnétique nucléaire du proton (1). En ce qui concerne l'hydroxy-1 cyclopropyl-1 cyclopropane **2***a* et le cyclopropyl-2 propène-2 ol-1 **3***a*, leurs données spectroscopiques sont cohérentes avec celles de la littérature (13–15). Les structures proposées pour **2***a* et **3***a* sont confirmées par les résultats de la rmn du ^{13}C. Les déplacements chimiques de ces composés sont donnés dans le tableau 2.

*Cas du cyclopropylidène-4 butanol-2 1*b

Les structures des différents produits isolés sont présentées en figure 4. Dans notre précédent travail, la stéréochimie de ces composés n'avait pas été précisée; seul le pourcentage global des différents isomères avait été donné, excepté pour **3***b* où les formes *cis* et *trans* avaient été séparées par

chromatographie préparative en phase vapeur mais non identifiées.

Détermination de la stéréochimie de **2**b *et* **3**b

Stothers *et al.* (16) ont montré que la stéréochimie de systèmes rigides peut être simplement déterminée par comparaison entre les déplacements chimiques expérimentaux et ceux calculés par additivité des effets de substituant. En ce qui concerne des substituants vicinaux, les écarts à l'additivité sont plus importants pour l'isomère *cis* (effets stériques) que pour l'isomère *trans*. Ces déviations représentent des interactions de second ordre (interactions croisées) qui ne sont pas prises en compte dans le cas des dérivés monosubstitués. En série cyclopropanique nous avons déjà montré l'importance de telles interactions dans le cas des isomères *cis* (17).

Les déplacements chimiques des formes *cis* et *trans* des composés **2***b* et **3***b* sont présentés dans le tableau 2. Dans le tableau 3 sont rassemblées les valeurs théoriques et expérimentales des déplacements chimiques des carbones cyclopropaniques

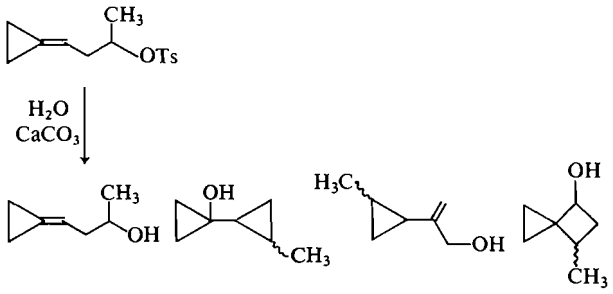

FIG. 4. Produits isolés lors de l'hydrolyse du tosylate de cyclopropylidène-4 butanol-2 **1***b*.

de **2***b* et **3***b* ainsi que les valeurs des déviations. Les données relatives au méthyl cyclopropane sont issues de la référence 17.

En ce qui concerne **2***b*, le pourcentage de forme *trans*, calculé par intégration de pics devant présenter une relaxation similaire est d'environ 15%.

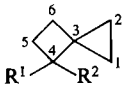
TABLEAU 4. Déplacements chimiques du ^{13}C. Dérivés du spiro [2,3] hexane



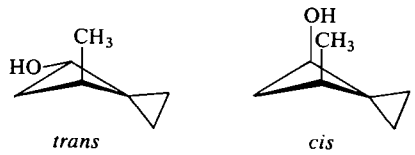
Composé	R^1	R^2	C-1	C-2	C-3	C-4	C-5	C-6	Autres
6*	H	H	12.4	12.4	20.2	31.2	17.3	31.2	
7	H	OH	7.2	9.3	28.1	71.0	30.4_5	23.5	
8	CH_3	OH	7.6	8.9	31.3	74.1	36.2	23.1	CH_3 : 24.6

*Valeurs de la référence 18.

Contrairement à **3***b* (pour lequel la forme *trans* est prépondérante) le groupement méthyle est plus blindé en position *trans* qu'en position *gauche*. De plus la non-équivalence des méthylènes cyclopropaniques (carbones C-2 et C-3) des formes *cis* et *trans* de **2***b* suggère une rotation empêchée autour de la liaison C1—C4; ce phénomène n'est pas observé pour le dérivé non substitué **2***a*.

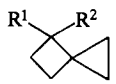
Détermination de la structure de **4**b

L'analyse du spectre de ^{13}C de ce composé montre l'existence de deux formes, présentes en proportions équivalentes, et de déplacements chimiques très proches. La structure précédemment proposée (1) pour **4***b*, à savoir l'hydroxy-4 méthyl-6 spiro [2,3] hexane n'est pas compatible avec les données de ^{13}C. En effet, d'une part les méthyles sont équivalents dans chacune de ces deux formes, alors qu'on s'attendrait à des valeurs différentes des déplacements chimiques si les structures étaient du type ci-dessous (*trans* ou *cis*); d'autre part, les



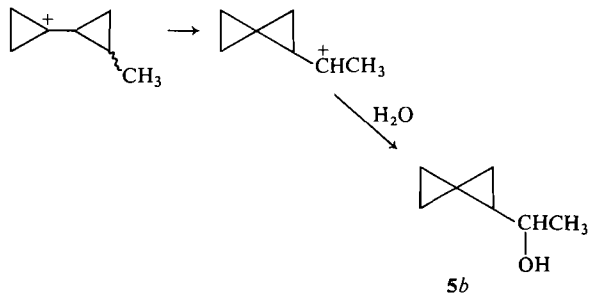
trans *cis*

déplacements chimiques de **4***b* ne sont pas en accord avec les valeurs observées pour le spiro [2,3] hexane **6** (18) et ses dérivés **7** et **8**. Ces deux derniers composés ont été spécialement synthétisés pour cette étude selon des méthodes déjà décrites dans la littérature (19). Les déplacements chimiques des composés **6** à **8** sont présentés dans le tableau 4.



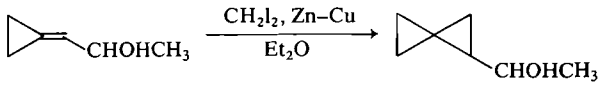
6 $R^1 = R^2 = H$
7 $R^1 = H; R^2 = OH$
8 $R^1 = CH_3; R^2 = OH$

Compte tenu des remarques précédentes il est nécessaire de considérer une évolution différente du cation cyclopropyl-cyclopropyle (cf. figure 1) primitivement formé lors de l'hydrolyse. On peut ainsi envisager la formation d'un composé possédant la structure **5***b*: la présence de deux centres asymétriques expliquant l'existence des deux formes, en l'occurrence des diastéréoisomères, précédemment mises en évidence par rmn du carbone-13.



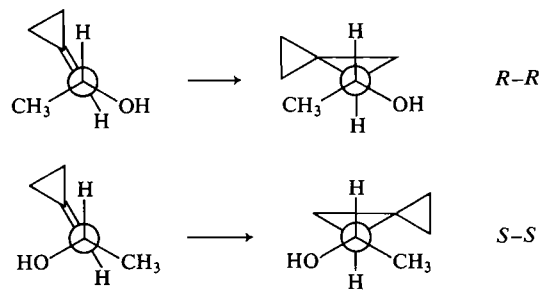
5*b*

Une manière élégante de vérifier notre hypothèse, et, dans le même temps, de réaliser une attribution univoque des déplacements chimiques des deux diastéréoisomères, consiste en une synthèse stéréospécifique de **5***b*. Il a déjà été montré (20, 21) que la cyclopropanation d'alcools allyliques[3] selon la méthode de Simmons-Smith conduit à un seul diastéréoisomère.



Racémique Un seul diastéréoisomère

Le conformère le plus apte à réagir est celui dont le groupement cyclopropylidénique est éclipsé par le proton du carbone fonctionnel, ce qui permet



R–R

S–S

[3]Ces alcools doivent nécessairement posséder un groupement en *cis* de la chaîne portant l'hydroxyle.

TABLEAU 5. Déplacements chimiques du ^{13}C. Spiro [2,2]pentyl-1 éthanol

	Composés		
	S–R ou *R–S*	*R–R* ou *S–S*

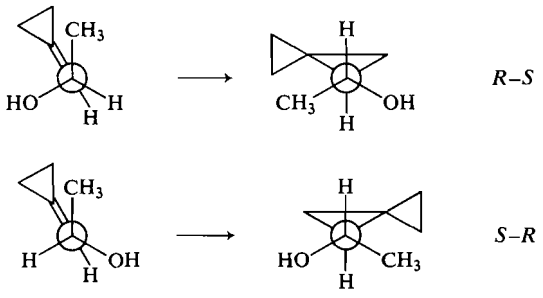
CH_3	22.6	22.6	22.7

l'attaque du réactif iodozincique et sa complexation par le groupement hydroxyle. Deux conformères présentent cette disposition et conduisent aux deux énantiomères *R–R* ou *S–S*.

La formation de l'autre diastéréoisomère (*R–S* ou *S–R*) est empêchée par l'encombrement stérique dû au groupement méthyle. Notons toutefois que les résultats de rmn du carbone-13 mettent en évidence sa présence à l'état de traces (~1 à 2%).



Les déplacements chimiques du ^{13}C du produit formé dans cette réaction (tableau 5) confirment d'une part l'hypothèse faite sur la structure de **5***b* et, d'autre part, permettent une attribution univoque des déplacements des deux diastéréoisomères. Notons enfin que les constantes physiques de ce produit sont cohérentes avec les données de la littérature (22).

The transfer of alkanoic acids from dodecane to water[1,2]

NORMAN H. SAGERT, MICHAEL J. QUINN, AND ROBERT S. DIXON

Research Chemistry Branch, Atomic Energy of Canada Research Company, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received July 17, 1980

NORMAN H. SAGERT, MICHAEL J. QUINN, and ROBERT S. DIXON. Can. J. Chem. **59**, 1096 (1981).

A rotating diffusion cell was used to study the transfer of five alkanoic acids from dodecane to water under conditions of known interfacial area and hydrodynamics. The acids studied were acetic, butanoic, hexanoic, 2-methylbutanoic and 2,2-dimethylpropanoic acids. Small interfacial resistances to mass transfer were noted, the mass transfer coefficients for interfacial transfer being in the range 2.6 to 4.7 μm/s at 25°C. This small range means that the effects of the length and structure of the alkane chain on the resistance to mass transfer are minimal. A study of the temperature dependence of the resistance to mass transfer at the interface showed that the resistance is largely entropic rather than enthalpic.

NORMAN H. SAGERT, MICHAEL J. QUINN et ROBERT S. DIXON. Can. J. Chem. **59**, 1096 (1981).

On a utilisé une cellule de diffusion rotative pour étudier le transfert de cinq acides alcanoiques, du dodécane à l'eau dans des conditions où la surface interfaciale et l'hydrodynamique sont connus; on a étudié les acides suivants: butanoique, hexanoique, méthyl-2 butanoique et diméthyl-2,2 propanoique. On a noté de faibles résistances interfaciales au transfert de masse; les coefficients de transfert de masse lors du transfert interfacial sont de l'ordre de 2,6 à 4,7 μm/s à 25°C. Ce faible écart signifie que les effets de la longueur des chaînes et la structure de l'alcane influencent très faiblement la résistance au transfert de masse. Une étude de l'effet de la température sur la résistance au transfert de masse à l'interface à montré que la résistance est plutôt de nature entropique que de nature enthalpique.

[Traduit par le journal]

Introduction

In separating the components of irradiated nuclear fuel, solvent extraction processes are usually involved (1). In such processes, species are transferred between aqueous and organic phases across the aqueous–organic interface. It would be useful to be able to study the chemical processes occurring at the interface but to do this, the hydrodynamics must be known exactly (2).

The rotating disc has been an invaluable tool for studying kinetics, electrochemical and otherwise, at solid–liquid interfaces (3). The thickness of the boundary layer is constant over the surface of the disc and this thickness can be calculated exactly (3, 4). Unfortunately a liquid–liquid interface cannot support the shear stress necessary to allow it to be rotated in isolation and thus to establish rotating disc hydrodynamics at both sides of the interface. Albery *et al.* (5, 6) have partially solved this problem by introducing a porous filter disc into the interface. The filter disc is filled with one of the two fluids, and the fluid interface is located at one of its surfaces. The filter disc can then be rotated to establish rotating disc hydrodynamics at both surfaces of the disc. Although the mass transfer resistance in the disc must now be allowed for, Albery *et al.* (5) used thin Millipore filters (~150 μm) of high porosity (~80%) to ensure small resistances. They used this method to investigate mass transfer for a number of systems, and carried out some studies of the transfer of hexanoic acid across the hexane–water interface.

The purpose of this work is to extend the studies of the transfer of alkanoic acids at the alkane–water interface. First, dodecane was used as the alkane since it is a relatively non-volatile solvent. Secondly, the transfer was studied as a function of temperature to distinguish between enthalpic and entropic effects. Finally a number of alkanoic acids were examined to determine whether the structure of the alkane chain played any role in the rate of transfer.

Experimental

Apparatus

The diffusion cell was built according to the design of Albery *et al.* (5). For the experiments described here, dodecane containing dissolved alkanoic acids was placed in a rotating cylinder whose end was closed with a porous filter disc. The acids diffused through the disc and into the aqueous phase. This aqueous phase was kept at a constant pH (generally 8.0) with a Mettler Titration System operating as a pH stat, and the volume of base required to maintain the set pH was displayed as a function of time on an X–Y recorder.

Details of the cell are shown in Fig. 1. The outer aqueous phase, A, was contained in a thermostatted water bath whose temperature was controlled to ±0.1°C. The air space above the aqueous phase was purged with purified nitrogen, N, to eliminate absorption of atmospheric CO_2. The pH of the aqueous phase was monitored using the glass electrode, E, and a sodium

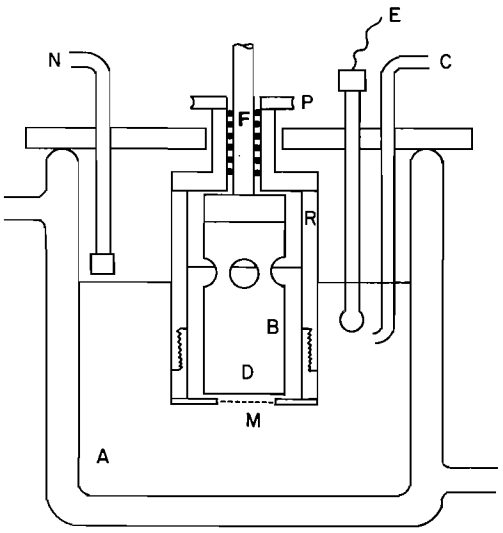

FIG. 1. Schematic diagram of rotating diffusion cell. A, aqueous phase; B, stationary baffle; C, inlet for base; D, dodecane phase; E, glass electrode; F, fixed inlet supporting stationary baffle; M, filter; N, nitrogen purge inlet; P, pulley system; R, rotating perspex reservoir.

hydroxide solution was introduced through the inlet C under the control of the pH stat.

The dodecane phase, D, usually with 0.1 mol/dm^3 of alkanoic acid, was contained in a perspex reservoir R, which was rotated on the hollow fixed rod F. A pulley system P, connected to a DC servomotor was geared to allow rotation speeds up to 16 Hz. The bottom of the reservoir was a thin perspex plate with provision for cementing a 25 mm diameter filter flush with the bottom of the plate. For convenience the bottom third of the reservoir was detachable. The filter, a Millipore RAWP, with pores of 1.2 μm diameter, was rendered hydrophobic with Fisher "Dricote" preparation.

Rotation of this reservoir would have given good rotating disc hydrodynamics only at the bottom surface of the filter disc. The innovation of Albery *et al.* (5) was to provide good rotating disc hydrodynamics at the inner surface of the filter by introducing a stationary hollow cylindrical baffle B. This stationary baffle protects the organic liquid inside it from the shear of the rotating reservoir. The baffle extends to within 2 mm of the bottom of the reservoir, a distance large enough not to affect centrifugal flow across the filter face. The organic liquid returns to the center region of the baffle through large holes drilled in the side at the top of the liquid level.

Methods

To begin a run, the filter was impregnated with the dodecane solution and the apparatus was assembled. The aqueous solution of 10^{-3} mol/dm^3 KCl was added until it almost reached the filter. Then dodecane solution and the aqueous solution were added simultaneously, keeping the level of the dodecane a little higher than that of the water. About 55 cm^3 of dodecane solution was added, and a record of elapsed time was started when the water first reached the filter. At this point the filling equipment was removed, rotation started, and the volumes of base necessary to keep the pH constant were recorded continuously.

Distribution coefficients were obtained by equilibrating aqueous and dodecane phases for several hours, separating, and analyzing both phases by titration. The aqueous phase was titrated with standard alkali. For the dodecane phase, an excess of aqueous alkali was equilibrated with this phase, and this was back-titrated with standard acid.

Materials

The dodecane was Phillips Pure Grade which was passed through a column of activated alumina, and the water was triple distilled from Pyrex. Its conductivity was 190 μS/m. The alkanoic acids were all reagent grade and were used without further purification. The acetic acid was Fisher reagent grade, butanoic and hexanoic acids were from Matheson, Coleman and Bell, and the isomeric pentanoic acids were from Aldrich.

Results and Discussion

The rate constant for the transfer of an alkanoic acid to water, k, may be defined (6, 7) by eq. [1]

$$[1] \quad J = kA\Delta C$$

where J is the flux in mol/s, A is the area of the filter over which transfer takes place, and ΔC is the effective concentration difference of alkanoic acid between dodecane and water. Since the acid concentration in the water is very small (pH = 8.0), ΔC is given by the concentration of acid in the dodecane, C_β, the dodecane phase being designated the β phase and the aqueous phase the α phase. In these experiments, the number of moles of base added to maintain the pH at 8.0 is equal to the number of moles of acid crossing the interface. Thus the flux is given by the slope of the experimental plot of base solution added against time. These plots were linear over the time scales used. Figure 2 shows a typical example, using hexanoic acid at various rotation speeds. From the measured fluxes, rate constants can be calculated. Corrections were made to ΔC (C_β) to allow for the decrease in ΔC with time as the experiment progressed.

Mass transfer resistances (total resistance, $1/k$)

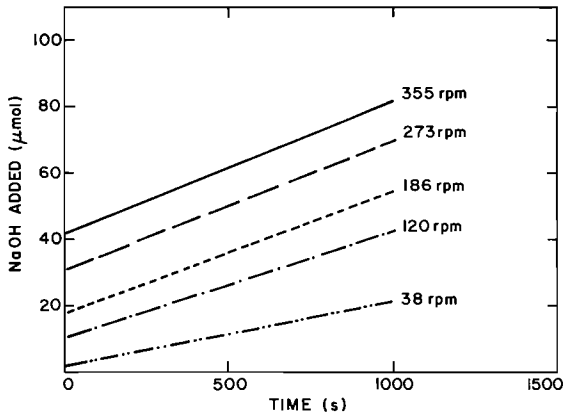

FIG. 2. Flux measurements for transfer of 0.1 mol/dm^3 hexanoic acid from dodecane to water at the indicated rotation speeds. T = 25°C.

add linearly (7). Thus it is advantageous to describe the separate resistances encountered by the acid as it is transferred from the dodecane to the water, bearing in mind that the filter contains dodecane and the dodecane–water interface is located at the bottom surface of the filter. Distribution coefficients, K, are defined by the ratio C_β/C_α as required by IUPAC convention. The acid first crosses the laminar diffusion layer in the dodecane and encounters a resistance δ_β/D_β where δ_β and D_β are the thickness of the diffusion layer in dodecane and the diffusion coefficient of the acid in dodecane, respectively. A further resistance is encountered in the dodecane-filled pores of the filter and this is given by l/aD_β where l is the effective path length and a the porosity of the filter. Any resistance to mass transfer at the interface will be given by $1/ak_i$ where k_i is the rate constant for interfacial transfer. Finally the resistance to mass transfer across the diffusion layer in the water would be given by $K\delta_\alpha/D_\alpha$. The total resistance to mass transfer would thus be given by eq. [2]

$$[2]\quad \frac{1}{k} = \frac{\delta_\beta}{D_\beta} + \frac{l}{aD_\beta} + \frac{1}{ak_i} + \frac{K\delta_\alpha}{D_\alpha}$$

The thickness of the diffusion layer is given by the Levich equation, eq. [3] (3, 4), where W is the rotation speed in Hz and v the kinematic viscosity in m^2/s.

$$[3]\quad \delta = 0.643\, \nu^{1/6} D^{1/3} W^{-1/2}$$

Thus, combining eq. [2] with eq. [3], a relationship between k and W is obtained.

$$[4]\quad \frac{1}{k} = \frac{l}{aD_\beta} + \frac{1}{ak_i} + 0.643\left(\frac{\nu_\beta^{1/6}}{D_\beta^{2/3}} + \frac{K\nu_\alpha^{1/6}}{D_\alpha^{2/3}}\right)\frac{1}{W^{1/2}}$$

A plot of $1/k$ against $1/W^{1/2}$ should be linear with an intercept of $l/aD_\beta + 1/ak_i$ and with a theoretically predictable slope, provided distribution, diffusion, density, and viscosity data are available.

Viscosity and density data for water up to 100°C are readily available. Viscosities for dodecane were taken from Hogenboom *et al.* (8). With some exceptions (9, 10), diffusion coefficients were not generally available. They were therefore calculated by the Wilke–Chang method using the molal volume increments listed by Sherwood, Pigford, and Wilke (11) and an association parameter for water of 2.60 (12). Allowance was made for dimerization in the dodecane. Distribution coefficients for butanoic and hexanoic acids were taken from Aveyard and Mitchell (12) and those for acetic, 2,2-dimethylpropanoic, and 2-methylbutanoic acids were measured. The values applicable for 0.1 mol/dm^3 in dodecane were used. Values of the distribution coefficients and diffusion coefficients used are shown in Table 1.

Plots of $1/k$ against $1/W^{1/2}$ are shown in Figs. 3 and 4 for hexanoic and butanoic acids respectively. The slopes shown are calculated from eq. [4]. These theoretical slopes fit the data reasonably well except at the lowest rotation speeds and lowest temperatures. At the lowest speeds, it is possible that the conditions for the derivation of eq. [3] are not obeyed, as the thickness of the hydrodynamic layer approaches the radius of the disc (3, 4).

Finally, it is necessary to correct for the effect of dimerization of the alkanoic acids in the dodecane. Albery *et al.* (5) have considered this problem and have set up and solved the transport equations. If K_2 is the equilibrium constant for dimerization in the organic phase, their analysis shows that the flux is given by eq. [5]

$$[5]\quad J = \frac{D_1(C_1 + 2C_2)_{x=\delta}}{\delta}\left(\frac{1 + 2D_2K_2C_1/D_1}{1 + 2K_2C_1}\right)_{x=\delta}$$

where x is the distance from the interface, C is the concentration, as before, and subscripts 1 and 2 refer to monomer and dimer respectively. For a simple dimerization $K_2C_1 = C_2/C_1$. In this case, where dimerization is highly favoured (13), the bracketed last term in eq. [5] is nearly equal to D_2/D_1 which, in turn, from the Wilke–Chang expression (11), is given by 0.660.

From the intercepts in plots such as those shown in Figs. 3 and 4, k_i may be evaluated if l, a, and D_β are known (eq. [4]). Values of D_β were, of course, calculated from the Wilke–Chang expression. Thus it is necessary to know only the effective path length, l, and the porosity, a, of the filter. In their original paper, Albery *et al.* (5) chose the effective path length as the measured thickness of the filter and obtained a porosity of 82% from the manufacturer's data and from a study of the electrochemical reduction of *p*-nitrophenol at a filter-covered electrode by Chien *et al.* (14). Later electrochemical work by Albery, in which the rotating reservoir was filled with mercury and the reduction of Cu(II) was followed, showed that an effective porosity of 78% was more appropriate.[3] The measured filter thickness of 140 μm was used as the effective path length.

The values obtained for k_i at 25°C are shown in Table 2. Also shown are the rate constants for transfer in the reverse direction, k_{-i}, calculated from the distribution coefficients. The values of k_i are quite constant, being in the range 3.8 ± 1.2

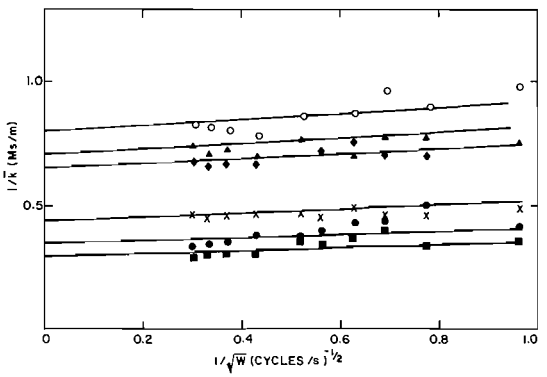

FIG. 4. Levich plots for the transfer of 0.1 mol/dm³ butanoic acid from dodecane to water. The legend for temperatures is as in Fig. 3.

μm/s. On the other hand the rate constants in the reverse direction vary by a factor of about 300.

The rate constant k_i may be expressed by eq. [6]

$$[6] \quad k_i = Z \exp(\Delta G_i^{\ddagger}/RT)$$

where $\Delta G_i^{\ddagger}$ is the free energy of activation and Z is a frequency factor, usually taken as $(RT/2\pi m)^{1/2}$ where m is the reduced mass (15, 16). Thus Z has a value close to 100 m/s at 25°C. Free energies of activation can thus be calculated from eq. [6]; these are shown in Table 2. The free energies for the complete transfer process, $\Delta^\alpha_\beta G^{\ominus}$, can, of course, be calculated from the distribution coefficients, and thus the free energies of activation for the reverse reaction, $\Delta G_{-i}^{\ddagger}$, can be calculated. These values are also given in Table 2. The energy barriers in the forward direction are very similar, suggesting a common transfer process. It is tempting to suggest that the peak of the barrier occurs in splitting the dimer and ionizing the acid group before the acid passes into the aqueous phase. Dimerization has been postulated as the rate determining step in the transfer of alkanoic acids from water to carbon tetrachloride in a series of experiments using the rising drop technique (17–19). Certainly, the length and degree of branching of the alkane chain of the acid has little effect on the height of the free energy barrier.

Equation [6] may be expressed in a slightly expanded form

$$[7] \quad k_i = Z \exp(\Delta S_i^{\ddagger}/R) \exp(-\Delta H_i^{\ddagger}/RT)$$

The frequency factor, Z, taken as 100 m/s at 25°C is assumed proportional to $\sqrt{T}$ (15). Thus, follow-

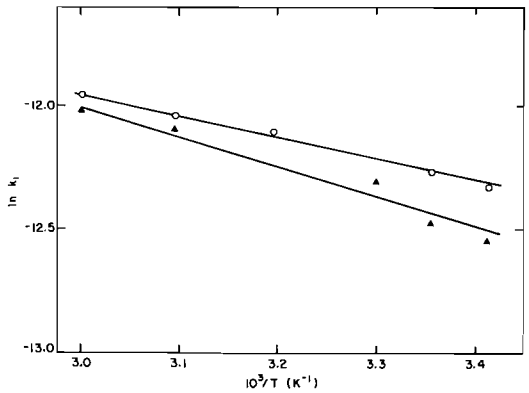

FIG. 5. Arrhenius plots of rate constant for interfacial transfer for acetic (▲) and hexanoic acids (○).

ing Laidler (20), the experimental Arrhenius activation energy E_a, is given by $\Delta H_i^{\ddagger} + (1/2)RT$.

Studies of the interfacial resistance to transfer were made as a function of temperature for all systems. Some typical results are shown in Fig. 5, plotted in the Arrhenius fashion with $\ln k_i$ plotted against the reciprocal of the absolute temperature. From the slope of the line the experimental activation energy, E_a, and thus the enthalpy of activation, $\Delta H_i^{\ddagger}$, can be obtained. Entropies of activation may then be calculated. The enthalpies and entropies of activation so obtained are listed in Table 3.

The free energies of activation are independent of the concentration units of the standard states used for defining the distribution coefficient since this coefficient is taken as a simple ratio of concentrations. The assignment of $Z = 100$ m/s allows the free energy of activation to be calculated independent of the choice of the standard states. Thus, from Table 3, it is apparent that entropic effects are much more important in defining the height of the free energy barrier. With the possible exception of butanoic acid, the entropies of activation are all large and negative. Their similarity suggests again that we are dealing primarily with effects of the carboxylic acid group, and that the size and structure of the hydrocarbon chain has relatively little effect on the kinetics of transfer. Albery *et al.* (5) reported an entropic barrier for the hydrolysis of methyl nicotinate, where a carboxylate group is involved, whereas they reported an enthalpic barrier for the hydrolysis of *p*-methylbenzyl chloride. It is interesting to note that the entropy barrier we obtained is roughly equal to the entropy of ionization of carboxylic acids (21), suggesting a charge separation in the transition state. Further speculation is probably unwarranted at the present time.

TABLE 3. Entropies and enthalpies of activation for the transfer of alkanoic acids from dodecane to water at 25°C

Alkanoic acid	E_a (kJ/mol)	$\Delta H_i^{\ddagger}$ (kJ/mol)	$\Delta S_i^{\ddagger}$ (J/mol·K)
Acetic	10.0	8.8	−112
Butanoic	23.9	22.7	−69
2-Methylbutanoic	12.9	11.7	−102
2,2-Dimethylpropanoic	15.8	14.0	−95
Hexanoic	7.3	6.1	−120

Stereospecific total synthesis of (±)-cassipurine, an alkaloid from rhizophoraceae

JERZY TADEUSZ WRÓBEL AND JAN ADAM GLIŃSKI
Department of Chemistry, University of Warsaw, 02-093 Warsaw, Pasteura 1, Poland

Received June 9, 1980

JERZY TADEUSZ WRÓBEL and JAN ADAM GLIŃSKI. Can. J. Chem. **59**, 1101 (1981).

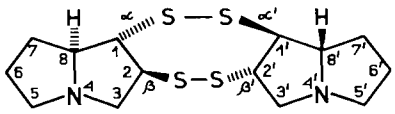
Two isomeric 1α,2α-epoxy- and 1β,2β-epoxypyrrolizidines have been obtained from 1,2-dehydropyrrolizidine. The structure of both isomers has been determined enabling a study of the stereochemistry of their reactions with a number of sulfur-containing nucleophilic reagents. The BzS^- anion has been shown to stereospecifically attack the C2 carbon atom of both compounds. In the three-stage process 1β,2β-epoxypyrrolizidine was transformed into 1α,2α-epithiopyrrolizidine, which reacts stereospecifically with benzylthiol to yield 1α-(2β-thiobenzylpyrrolizidine)-thiol. This, in turn, oxidizes in air to give a mixture of three diastereomeric 1α,1′α-dithio-2β,2′β-dithiobenzyldipyrrolizidines. These diastereomers were chromatographically separated into the racemic mixture and the *meso* diastereomer. Treatment of the racemic mixture with Na/liquid NH_3 induced debenzylation without cleavage of the disulfide bond. The resulting enantiomeric 1α,1′α-dithio-2β,2′β-dimercaptodipyrrolizidines were oxidized in air to give racemic cassipurine.

JERZY TADEUSZ WRÓBEL et JAN ADAM GLIŃSKI. Can. J. Chem. **59**, 1101 (1981).

A partir de la déhydro-1,2 pyrrolizidine, on a obtenu les époxy-1α,2α et -1β,2β pyrrolizidines isomères. On a déterminé la structure des deux isomères par l'étude de la stéréochimie de leurs réactions avec une série de réactifs nucléophiles contenant du soufre. L'anion BzS^- attaque de façon stéréospécifique l'atome de carbone en position 2 des deux composés. On a transformé, par une série de 3 réactions l'époxy-1β,2β pyrrolizidine en époxy-1α,2α pyrrolizidine qui réagit de façon stéréospécifique avec le benzylthiol en donnant le (thiobenzyl-2β pyrrolizidine)-1α thiol. Ce dernier composé à son tour par oxydation à l'air donne un mélange de trois diastéréoisomères des dithio-1α,1′α 2β,2′β-benzyldipyrrolizidines. On a séparé ces diastéréoisomères par chromatographie en un mélange racémique et le diastéréoisomère *méso*. Le mélange racémique traité par du Na/NH_3 liq. est débenzylé sans clivage de la liaison disulfure. Les dithio-1α,1′α 2β,2′β-dimercaptodipyrrolizidines ainsi obtenues donnent, par oxydation à l'air, la cassipurine racémique.

[Traduit par le journal]

Alkaloid cassipurine, **1**, has been isolated by Wright and Warren (1), and chemically studied by Cooks *et al.* (2). The X-ray study carried out by Gafner and Admiraal (3) has shown that the stereochemistry of cassipurine corresponds to the 1α,1′α:2β,2′β-(bisdithiodipyrrolizidine) isomer. They have reported the absolute configuration of the naturally occuring enantiomer to be "very probably" (3) of the type S,S′ as referred to the N atoms.



1

In the present paper the total synthesis of racemic cassipurine is described. The basic approach involves the synthesis of the 1α,2β-dithio-substituted pyrrolizidine skeleton under conditions of full stereochemical control followed by coupling two such disulfide bonds bridging C1 with C1′ and C2 with C2′ carbon atoms. The procedure leading to the desired 1α,2β configuration of sulfur atoms in the pyrrolizidine skeleton has been developed by studying the stereochemistry of the oxirane ring cleavage in both isomeric 1,2-epoxypyrrolizidines. 1α,2α-Epoxypyrrolizidine, **2**, and 1β,2β-epoxypyrrolizidine, **3**, have been obtained from racemic 1,2-dehydropyrrolizidine (4), and then examined in reactions with sulfur nucleophilic reagents. Benzylthiol, thiolacetic acid, and sodium hydrosulfide have been found to attack isomer **2** exclusively at the C2 carbon atom. The mechanism of the reaction with isomer **3** depends on the size of the attacking reagent. Relatively small molecules of thiolacetic acid and SH^- anions preferentially attack the C2 carbon atom, but the product of the attack at the C1 carbon atom also has been observed.

Reactions with benzylthiol were stereospecific:

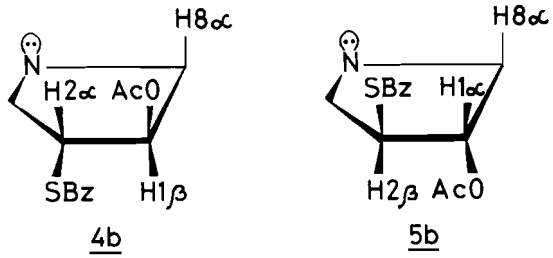
1α-hydroxy-2β-thiobenzylpyrrolizidine, **4***a*, and 1β-hydroxy-2α-thiobenzylpyrrolizidine, **5***a*, were obtained from epoxides **2** and **3** respectively. This has been shown by the ^{1}Hmr spectra of the acetylated derivatives **4***b* and **5***b*. Analysis of the proton signal of the diagnostic hydrogen atom linked to the same carbon atom as the acetyl group indicates that in both products the attack of the thiobenzyl group occurs at the C2 carbon atom.



The ^{1}Hmr spectrum of the derivative **4***b* shows a triplet at δ = 4.86 ppm attributed to the H1β proton. The equality of both coupling constants is due to the two symmetrically situated vicinal protons. Hence, $J_{1\beta,2\alpha}$ = 2.5 Hz and $J_{1\beta,8\alpha}$ = 2.5 Hz. In the spectrum of the **5***b* derivatives the doublet of doublets corresponding to the H1α proton appears at δ = 5.06 ppm. The coupling constant of 5 Hz results from H1α—H8α protons coupling. The out-of-plane H1α and H2β protons have a coupling constant of 2.5 Hz. The larger chemical shift of the H1β proton results from the fact that the C—H1α hydrogen bond is situated in a plane in a position parallel to the free electron pair on the nitrogen atom.

In analogy to the reaction of 1,2-epoxypyrrolizidines with sulfur nucleophilic reagents, 1α,2α-epithiopyrrolizidine, **6**, (of epoxide **3** configuration) was reacted with benzylthiol. The reaction product, 1α-(2β-thiobenzylpyrrolizidine)-thiol, **9**, has the same configuration of sulfur atoms as cassipurine.

1α,2α-Epithiopyrrolizidine, **6**, was obtained in three steps from 1β,2β-epoxypyrrolizidine, **3**, (with an overall yield of 65%) using the method of Goodman *et al.* (5). A stereoselective reaction of **3** with thiolbenzoic acid yields 1β-hydroxy-2α-thiobenzoylpyrrolizidine, **7**, and 2β-hydroxy-1α-thiobenzoylpyrrolizidine, **7***a*, in a 9:1 ratio. The hydroxyl groups in compounds **7** and **7***a* were esterified with $MeSO_2Cl$ to give 1β-(2α-thiobenzoylpyrrolizidine)-methanesulfonate, **8**, and 2β-(1α-thiobenzoylpyrrolizidine)-methanesulfonate, **8***a*, which were equally good precursors of **6**. Compounds **7***a* and **8***a* have not been separated but they were detected by tlc and by the characteristic H2α signals in ^{1}Hmr spectra (**7***a*: δH2α = 4.40 ppm, **8***a*: δH2α = 5.00 ppm). Nucleophilic cleavage of the thiirane ring in episulfide **6** was stereospecific. In addition to 1α-mercapto-2β-thiobenzoylpyrrolizidine, **9**, adduct **10** has also been obtained (about 15%).

Coupling the two pyrrolizidine skeletons by two disulfide bridges between C1—C1′ and C2—C2′ carbon atoms, respectively, was carried out using 1-hydroxy-2-benzylthiopyrrolizidines **4***a* and **5***a*.

Compound **5***a* was reduced with sodium in liquid ammonia. Under these conditions the S—C bond cleavage occurs exclusively between the sulfur atom and the benzyl group, to yield 1β-hydroxy-

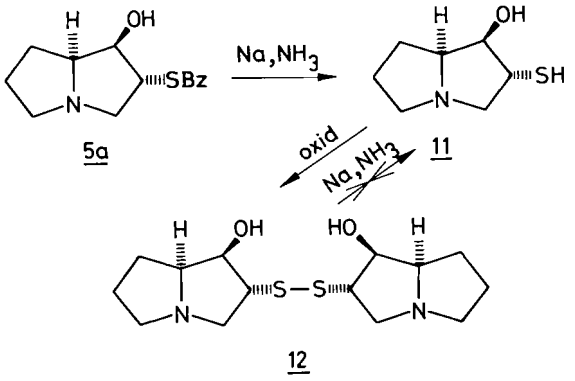
For personal use only.



2α-mercaptopyrrolizidine, **11**. Iodine oxidation of the latter results in three diastereomers of 2α,2′α-dithio-1β,1′β-dihydroxydipyrrolizidine, **12**, obtained in excellent yield. It has been shown that the S—S bond joining two pyrrolizidine skeletons is resistant to sodium in liquid ammonia. This very unusual behavior of the disulfide bond has been known hitherto only in the case of cassipurine. The selective removal of the benzyl group using sodium in liquid ammonia leaves the disulfide bond intact and enables the reduction of 1α,1′α-dithio-2β,2′β-dithiobenzyldipyrrolizidines, **13**.

The diastereomeric 1α,1′α-disulfides **13** were obtained by oxidation in air of the racemic thiol **9**. The mixture of the diastereomers **13** was chromatographically separated into two fractions of equal weight. One of these fractions contains a racemic mixture of the two enantiomers. The second fraction consists of the *meso* diastereomer. The racemic mixture of the enantiomers **13** was debenzylated with Na/liquid NH_3 to give a racemic mixture of 1α,1′α-dithio-2β,2′β-dimercaptodipyrrolizidines, **14**, which without isolation were oxidized by bubbled oxygen. From the resulting mixture thin white crystals were obtained. Their molecular weight as determined by high resolution mass spectroscopy is 346.0660 (calcd. 346.0664). The mass fragmentation ions coincide with data reported for cassipurine.

The *meso* diastereomer **13** treated in a similar way yields no product of the same (346) molecular weight.

Experimental

All melting and boiling points are uncorrected. Spectra were obtained as follows: ^{1}Hmr at 100 MHz on a Jeol JNM-4H-100 spectrometer in $CDCl_3$ using TMS as internal standard (δ = 0.0 ppm); symbols s, d, t, q, m stand for singlet, doublet, triplet, quartet, multiplet, respectively; ms on a LKB-2091 gc–ms low resolution instrument with a direct inlet system operating at 70 eV. High resolution and FD (field desorption) measurements were performed using a Varian MAT-771 instrument. Merck Al_2O_3 plates type E were used for tlc and preparative chromatography. For column chromatography Merck Al_2O_3-60 Activ was used.

1α,2α-Epoxypyrrolizidine, 2, and 1β,2β-Epoxypyrrolizidine, 3

A solution of 1,2-dehydropyrrolizidine (0.14 mol) in 250 mL of sulfuric acid 1:4 was treated with sucessive portions of *N*-bromoacetamide (0.16 mol). The solution was stirred for 4 h, then made alkaline with K_2CO_3 and stirred for another hour. Precipitated KCl was filtered off and the solution was extracted with $CHCl_3$ (8 × 100 mL) to finally yield 9 g of the mixture of the epoxides **2** and **3**. Stereomers **2** and **3** were separated on an alumina column; **3** was eluted with Et_2O + 5% MeOH, then Et_2O + 30% MeOH was used to elute compound **2**. Upon distillation 0.025 mol of **2** and 0.044 mol of **3** were obtained. Total yield of **2** + **3** was 44%.

Compound **2**, a colourless oil, bp 70°C/10 Torr; ^{1}Hmr: 3.5–3.9 (m, 3p), 2.9–3.5 (m, 3p), 2.7 (m, 1p), 1.8–2.1 (m, 4p); ms: 41(100), 68(66), 80(12), 96(90), 108(18), 125(67). *Anal.* calcd. for $C_7H_{11}NO$: C 67.2, H 8.9, N 11.2%; found: C 66.6, H 9.0, N 11.2%.

Compound **3**, a colourless oil, bp 66°C/10 Torr; ^{1}Hmr: 3.3–4.0 (m, 4p), 2.4–3.3 (m, 3p), 1.5–2.3 (m, 4p); ms: 41(100) 68(57), 70(30), 96(82), 108(16), 125(51). *Anal.* found: C 66.5, H 8.7, N 11.0%.

*1α-Hydroxy-2β-thiobenzylpyrrolizidine, 4*a

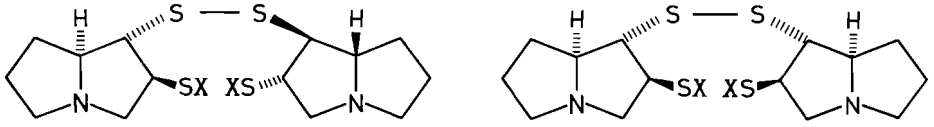
An ethanolic solution of **2** (10 mmol), benzylthiol (11 mmol), and a catalytic amount of KOH was kept for 36 h at room temperature to complete the reaction. After a routine processing of the solution, crude **4***a* was obtained. Crystallization from acetone resulted in white needles (75% yield), mp 124°C; ^{1}Hmr ($CDCl_3$ + D_2O): 7.3 (C_6H_5), 3.8 (s, $C_6H_5CH_2$), 3.57 (t, 1p), 2.2–3.4 (m, 6p), 1.5–2.0 (m, 4p); ms: 70(97), 83(21), 91(27), 126(100), 158(11), 249(1). *Anal.* calcd. for $C_{14}H_{19}NOS$: C 67.4, H 7.7, N 5.6%; found: C 67.2, H 7.80, N 5.7%.

*1β-Hydroxy-2α-thiobenzylpyrrolizidine, 5*a

Compound **5***a* was obtained from **3** similarly to compound **4***a* from **2**. White crystals (from acetone), mp 103°C, 75% yield; ^{1}Hmr ($CDCl_3$ + D_2O): 7.3 (C_6H_5), 3.98 (t, 1p), 3.77 (s, $C_6H_5CH_2$), 3.63 (m, 1p), 3.1–3.2 (m, 4p), 2.4 (m, 1p), 1.6–2.0 (m, 4p); ms: 70(100), 83(15), 91(25), 126(75), 158(25), 249(1). *Anal.* found: C 67.1, H 7.5, N 5.5%.

*1α-Acetoxy-2β-thiobenzylpyrrolizidine, 4*b

Compound **4***b* was obtained from **4***a* using an excess of Ac_2O in $CHCl_3$. The mixture was stored at room temperature for 36 h.



One of the enantiomers

13 : X = Bz
14 : X = H

(meso) Diastereomer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

After routine processing compound **5***b* was isolated from solution as a viscous colourless oil (95% yield); ^{1}Hmr: 7.3 (C_6H_5), 4.86 (t, H1β), 3.80 (s, $C_6H_5CH_2$), 3.15–3.5 (m, H8α, H2β, H3α), 2.95 (m, H5α), 2.5–2.8 (m, H3β, H5β), 2.05 (s, CH_3CO), 1.65–2.03 (m, H6α, H6β, H7α, H7β); ms: 43(60), 7(100), 83(25), 91(49), 108(40), 168(99), 200(7), 291(3). *Anal.* found: C 67.1, H 7.5, N 5.7%.

1β-Acetoxy-2α-thiobenzylpyrrolizidine, **5**b

Compound **5***b* was obtained from **5***a* similarly to compound **4***b* from **4***a* with a 95% yield of noncrystallizing oil; ^{1}Hmr: 7.3 (C_6H_5): 5.06 (dd, H1α), 3.97 (t, H8α), 3.83 (s, $C_6H_5CH_2$), 3.2 (m, H2β), 2.7–3.2 (m, H3α, H3β, H5α), 2.46 (m, H5β), 2.08 (s, CH_3CO), 1.5–2.0 (m, H6α, H6β, H7α, H7β); ms: 43(58), 70(100), 91(48), 108(16), 168(90), 200(14), 291(6). *Anal.* found: C 67.0, H 7.5, N 5.5%.

1α,2α-Epithiopyrrolizidine, **6**

A three-necked flask was connected with a dropping funnel containing 3.8 mmol of **8** dissolved in 30 mL of an Et_2O–MeOH mixture. To the flask was added 8.5 mmol KOH dissolved in 60 mL of water. Argon was bubbled through the magnetically stirred solution. The bubbling was periodically interrupted and a water vacuum pump was connected to the reaction flask in order to evaporate the ethereal layer. After dropping was completed (about 20 min), the solution was stirred for an additional 15 min. Residual Et_2O and MeOH were evaporated *in vacuo*. The aqueous solution was filtered and extracted with $CHCl_3$. The extract was dried and evaporated to give pure **6** as a light yellow oil (98%) yield), which did not require distillation; ^{1}Hmr: 3.68 (t, 1p), 3.35–3.55 (m, 3p), 2.6–3.32 (m, 3p), 1.4–2.3 (m, 4p); ms: 41(23), 80(36), 81(13), 108(100), 141(25). *Anal.* calcd. for $C_7H_{11}NS$: C 59.5, H 7.9, N 9.9%; found: C 59.2, H 7.7, N 9.8%.

1β-Hydroxy-2α-thiobenzylpyrrolizidine, **7**

In a stoppered flask a mixture of epoxide **3** (16 mmol) and thiobenzoic acid (24 mmol) in $CHCl_3$ solution was stored at room temperature for 36 h. Then the mixture was processed to give crude **7**, which after crystallization from acetone gave 72% of pure compound **7**. White crystals had mp 133°C; ^{1}Hmr ($CDCl_3 + D_2O$): 7.95 (2p), 7.4 (3p), 4.02–4.3 (H1α, H2β), 3.75 (dt, H8α), 2.9–3.4 (m, H3α, H3β, H5α), 3.65 (m, H5β), 1.5–2.2 (m, H6α, H6β, H7α, H7β); ms: 70(10), 75(10), 77(18), 83(9), 105(15), 126(89), 158(1), 263(0.2). *Anal.* calcd. for $C_{14}H_{17}NO_2S$: C 63.8, H 6.5, N 5.3%; found: C 63.6, H 6.5, N 5.3%.

1β-(2α-Thiobenzoylpyrrolizidine)-methanesulfonate, **8**

Methanesulfonic chloride (6.7 mmol) was added to a solution of 5.7 mmol of **7** in 20 mL of dry pyridine. The mixture was kept for 36 h at 10°C and then pyridine was removed *in vacuo*. After routine processing the dry residue gave a viscous oil, which crystallized after a few days in a refrigerator. Recrystallization from acetone gave 91% of pure **8** as colourless plates having mp 83°C; ^{1}Hmr: 7.9 (2p), 7.48 (3p), 4.85 (dd, H1α), 4.27 (t, H2β), 3.95 (dt, H8α), 3.3 (CH_3), 3.16–3.3 (m, 2p), 2.9–3.17 (m, 1p), 2.45–2.8 (m, 1p), 1.7–2.1 (m, 4p); ms: 105(100), 108(63), 135(12), 140(9), 148(9), 204(64), 262(13), 341(0.2). *Anal.* calcd. for $C_{15}H_{19}NO_4S_2$: C 52.7, H 5.6, N 4.1%; found: C 52.5, H 5.6, N 4.0%.

1β-Hydroxy-2α-mercaptopyrrolizidine, **11**

Compound **5***a* (5.6 mmol) was dissolved in 50 mL of liquid ammonia and then 24 mmol of sodium were added. After a few seconds the reaction was completed and only a light blue colour of the solution remained. Ammonia was allowed to evaporate and the dry residue was dissolved in a small amount of water. The aqueous solution was extracted with benzene. The organic layer was discarded, the aqueous layer was evaporated, and the residue was extracted with $CHCl_3$ + 10% MeOH mixture. Colourless crystals, readily oxidizable to compound **12**, were obtained from the extract with 94% yield. The crystals decomposed above 120°C. Mass spectra: 41(13), 55(15), 70(100), 83(12), 126(37), 159(0.8).

2α,2′α-Dithio-1β,1′β-dihydroxydipyrrolizidine, **12**

The thiole **11** was oxidized by air bubbled through the MeOH solution. White crystals were recrystallized from Et_2O + 5% MeOH mixture to give 80% of **12**, mp 187°C; ^{1}Hmr ($CDCl_3 + D_2O$): 4.47 (dd, H1α), 3.92 (q, H8α), 3.76 (m, H2β), 3.0–3.25 (m, H3α, H3β, H5α), 2.6 (m, H5β), 1.6–2.3 (m, H6α, H6β, H7α, H7β); ms: 55(15), 70(100), 108(9), 126(35), 158(8), 191(9), 317(0.3). *Anal.* calcd. for $C_{14}H_{24}N_2O_2$: C 53.8, H 7.8, N 17.9%; found: C 53.6, H 7.6, N 17.7%.

1α,1′α-Dithio-2β,2′β-dithiobenzylpyrrolizidine, **13**

An ethanolic solution of episulfide **6** (6 mmol) and benzylthiol (12 mmol) was refluxed with a catalytic amount of EtONa. Argon was passed through the solution. After 75 min the reaction was completed. Ethanol was evaporated and then aqueous H_2SO_4 was added to the residue. An excess of benzylthiol was removed with C_6H_6 and the aqueous layer was made alkaline and extracted with $CHCl_3$. The resulting mixture of 1α-mercapto-2β-thiobenzylpyrrolizidine, **9**, and 1α,2′β-(1′α-mercaptopyrrolizidine-2β-thiobenzylpyrrolizidine)-sulfide, **10**, was oxidized in air to give a mixture of disulfides. After preparative chromatography on alumina (Et_2O + 4% MeOH + 2% H_2O) two fractions were obtained. One of them contained a racemic mixture of the enantiomers **13** (17% yield, R_f 0.81), while the other consisted of the **13** *meso* diastereomer (17% yield, R_f 0.85). The two fractions were noncrystallizing viscous oils.

For the racemic mixture, ^{1}Hmr ($CDCl_3$–C_6D_6, 1:1): 7.26 (C_6H_5), 3.75 (s, $C_6H_5CH_2$), 3.05–3.65 (m, 3p), 2.65–3.04 (m, 2p), 2.21–2.63 (m, 2p), 1.39–2.14 (m, 4p); ms: 70(56), 91(100), 108(77), 142(58), 174(3), 232(50), 264(16), 297(10), 298(14), 406(3), 528(0.1), 529(0.8); FD: M + 1 = 529. *Anal.* calcd. for $C_{28}H_{36}N_2S_4$: C 63.6, H 6.9, N 5.3%; found: C 63.1, H 6.7, N 5.1%.

For the *meso* diastereomer, ^{1}Hmr ($CDCl_3$– C_6D_6, 1:1): 7.27 (s, C_6H_5), 3.68 (s, $C_6H_5CH_2$), 3.48 (m, 1p), 3.05–3.38 (m, 2p), 2.62–2.98 (m, 2p), 2.18–2.58 (m, 2p), 1.37–2.02 (m, 4p); ms: 70(13), 91(100), 108(20), 142(43), 174(6), 232(37), 264(10), 297(17), 298(8), 406(2), 528(0.3), 529(1.2); FD: M + 1 = 529. *Anal.* found: C 63.0, H 6.6, N 5.2%.

(±)-Cassipurine

To a flask 50 mL of liquid NH_3, 0.2 mmol of **13** (racemic mixture), and 0.5 mmol of sodium wee added. After a few seconds the reaction was completed and NH_3 was allowed to evaporate. The dry residue was extracted with a mixture of $CHCl_3$ + 5% MeOH. The resulting solution of the racemic 1α,1′α-dithio-2β,2′β-dimercaptodipyrrolizidine, **14**, was oxidized (without separation of pure compound **14**) in air. After routine processing, the solution gave crystals of racemic cassipurine (10% yield). Recrystallization from acetone resulted in white thin needles, mp 191°C; ms: 41(15), 70(25), 80(13), 106(8), 108(100), 140(25), 141(41), 173(17), 174(45), 205(6), 346(22); FD: M^+ = 346. *Exact Mass* calcd.: 346.0664; found: 346.0660.

1,7-Dioxaspiro[5.5]undecanes. An excellent system for the study of stereoelectronic effects (anomeric and *exo*-anomeric effects) in acetals[1] ERRATA

PIERRE DESLONGCHAMPS, DARYL D. ROWAN, NORMAND POTHIER, GILLES SAUVÉ, AND JOHN K. SAUNDERS

Laboratoire de Synthèse Organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received September 3, 1980

PIERRE DESLONGCHAMPS, DARYL D. ROWAN, NORMAND POTHIER, TILLES SAUVÉ, and JOHN K. SAUNDERS. Can. J. Chem. **59**, 1105 (1981).

Several isomeric compounds derived from the spiro systems **5** to **9** (Scheme 4) were obtained from the acid cyclization of the appropriate dihydroxy ketone precursor.

The configuration and the conformation of the products obtained was determined by ^{13}C nmr analysis and equilibration studies. The experimental results can be rationalized by taking into account the anomeric and the *exo*-anomeric effects and the usual steric interactions.

PIERRE DESLONGCHAMPS, DARYL D. ROWAN, NORMAND POTHIER, TILLES SAUVÉ et JOHN K. SAUNDERS. Can. J. Chem. **59**, 1105 (1981).

Plusieurs composés isomères dérivés des systèmes spiranniques **5** à **9** (Schéma 4) furent obtenus par cyclisation en milieu acide des précurseurs dihydroxycétoniques appropriés.

La configuration et la conformation des produits obtenus ont été déterminées par la rmn du ^{13}C et par des études d'équilibration. Les résultats expérimentaux sont expliqués en tenant compte de l'effet anomère, de l'effet *exo*-anomère et des interactions stériques habituelles.

Stereoelectronic effects have been recognized for a long time to influence the configuration and the conformation of acetals, particularly in carbohydrates where these effects were first discovered and discussed in terms of the anomeric and *exo*-anomeric effects (1).[2,3]

α- And β-glycosides can theoretically take conformations A_1, A_2, A_3 and E_1, E_2, E_3 respectively (Scheme 1). The relative proportions of these various conformers in α and β-glycosides should be influenced by the usual steric interactions and by stereoelectronic effects. For instance, if stereoelectronic effects (anomeric and *exo*-anomeric effects) are important, the following predictions can be made: (*a*) conformer A_2 has only one anomeric effect and conformers A_1 and A_3 have two each,[4] and since A_3 must be eliminated because of strong steric interactions, A_1 must correspond to the most stable conformer of an α-glycoside; (*b*) conformer E_3 has no anomeric effect whereas E_1 and E_2 have one each, and since E_2 has an extra steric interaction (one *gauche* form of butane ≈0.9 kcal/mol) by comparison with E_1, β-glycosides should exist as a mixture of conformers E_1 and E_2 in which E_1 should predominate.

The validity of the above conclusion depends on the importance of the anomeric effect. Efforts have been made to evaluate the anomeric effect by undertaking equilibration studies between equatorial and axial isomers at the anomeric center in carbohydrates (4), and in monosubstituted 2-alkoxytetrahydropyrans (5) as well as in more rigid systems (6). The anomeric effect has been evaluated to be of the order of 1.2 to 1.8 kcal/mol from these studies. These evaluations cannot, however, be very precise because the orientation of the OR group in the axial and in the equatorial isomer was not considered, and the influence of the *exo*-anomeric effect was consequently neglected.

The evaluation of the anomeric effect could be achieved by determining the relative proportions of conformers in equatorial (E_1, E_2, and E_3) and axial (A_1 and A_2) 2-alkoxytetrahydropyrans respectively. This analysis, which could be done in principle by a study at low temperature by nmr spectroscopy, does not seem to be realizable because the energy barrier of rotation between conformers is presumably too small.[5]

[1]This work has been presented at the 8th Natural Products Symposium, University of West Indies, Mona, Jamaica, January 1980, and at the 1st International Symposium on Stereoelectronic Effects, University of St. Andrews, Scotland, July 1980.

[2]The preference for an alkoxy group to be axially oriented is due to the anomeric effect, whereas the preference for the R group of the side chain at the anomeric center to be in the A_1 or the E_1 conformation in α and β-glycosides respectively is due to the *exo*-anomeric effect (Scheme 1).

[3]The anomeric (or the *exo*-anomeric) effect is considered to be a stabilizing effect which occurs when an electron pair of an oxygen atom is oriented antiperiplanar to a C—OR bond. The stabilization would be gained through an electronic delocalization due to the overlap of an electron lone pair orbital of an oxygen with the antibonding orbital of a C—OR sigma bond (2, 3).

[4]In this article, we use the term anomeric effect to describe either an anomeric or an *exo*-anomeric effect, assuming that both effects are of the same order of magnitude.

[5]This analysis is also impossible if equatorial and axial isomers exist in only one preferred conformation.

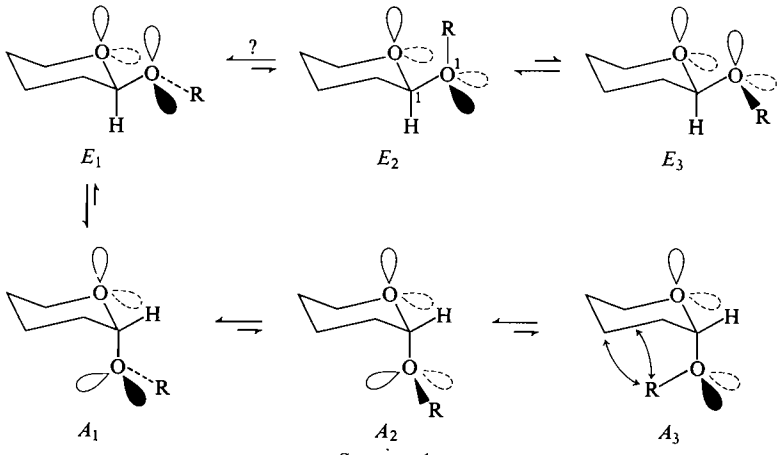

SCHEME 1

The analysis could also be done by nmr at room temperature provided that the various conformers have sufficiently different coupling constants. This method has the disadvantage that small percentages of some conformers will be difficult to detect. Using this method, in an attempt to assess the relative abundance of conformers E_1 and E_2 in β-glycosides, Lemieux (7) was unable to detect conformer E_2. Thus, E_1 and E_2 would be separated by over 2 kcal/mol. It was suggested that this rather unexpected situation would be mainly the result of a short C(1)—O(1) bond which would amplify the steric interaction in E_2. Also, by comparison of bond length (X-ray) in α and β-glycosides, Lemieux *et al.* (8) further suggested that the *exo*-anomeric effect would be stronger in the β-anomer. The fact remains that there exists no experimental evidence, including X-ray (9) and dipole moment studies (10), that α and β-glycosides exist in conformations other than A_1 and E_2 respectively.

The above results indicate that 2-alkoxytetrahydropyrans are not very appropriate models for a precise evaluation of the anomeric and the *exo*-anomeric effect. There is, however, a very interesting experiment on the evaluation of the anomeric effect which has been described by Descotes *et al.* (11). They have studied the acid catalyzed isomerization of *cis* and *trans* bicyclic acetals **1** and **2** (Scheme 2) and found, at equilibrium, a mixture of 57% *cis* and 43% *trans*. The *cis* isomer **1** corresponds to conformer E_2 (or A_2) which has one anomeric effect, whereas the *trans* isomer **2** corresponds to conformer E_3 which has none. It was possible to estimate the steric effects in *cis* acetal **1** (one *gauche* interaction = 0.85 kcal/mol and one interaction for an axial OR group to cyclohexane = 0.8 kcal/mol) and, by taking into account an entropy factor (0.42 kcal/mol at 80°C) caused by the fact that *cis* acetal **1** exists as a mixture of two conformations (*cis* decalin system), they arrived at

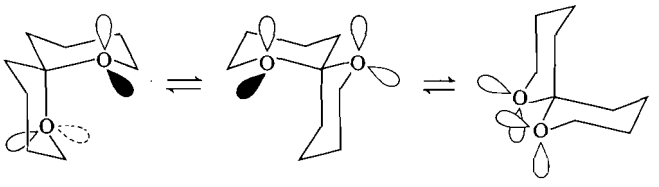
9 R = CH_3



5*a* (0 kcal/mol) 5*b* (2.4 kcal/mol) 5*c* (4.8 kcal/mol)

SCHEME 4

a value of 1.4 kcal/mol for the anomeric effect. We have recently studied the equilibration of *cis* and *trans* tricyclic acetals **3** and **4** and have arrived at a value of 1.5 kcal/mol (12), which confirms the result of Descotes *et al.* The value of 1.4–1.5 kcal mol must, however, be considered a minimum value because, as suggested by Lemieux *et al.* (8), the value for the steric interactions might be larger, being amplified by a shortened C—O bond.[6]

We have undertaken a study on the conformational analysis and on the acid hydrolysis of the 1,7-dioxaspiro[5.5]-undecane system **5** (Scheme 3) in order to obtain results on the evaluation of both the anomeric and the *exo*-anomeric effects. We wish to report these results.

We envisaged that the spiro system **5** would be a very convenient one for the study of stereoelectronic effects in the acetal function for the following reasons: (*a*) **5** can take three different conformations which correspond to either conformer E_1 (or A_2), E_3, or A_1 of α and β-2-alkoxytetrahydropyrans; (*b*) with **5**, it appeared possible to undertake a conformational analysis by low temperature nmr spectroscopy, because the energy barrier for each conformational change which involves a chair inversion should be high enough; (*c*) analogously to the system of Descotes *et al.*, the steric effects should also be easily evaluated; and (*d*) by adding appropriate alkyl substituents to the spiro system **5**, it appeared possible to isolate isomeric compounds which would differ by existing in one of the above conformations.

We have studied the parent compound **5**, the methyl substituted derivatives **6** and **7**, the tricyclic system **8**, as well as the corresponding methyl substituted derivatives **9** (Scheme 4).

[6]Jeffrey *et al.* (13) were the first to carry out molecular orbital calculations on the anomeric effect, and suggested that as much as 4 to 6 kcal/mol of stabilization can be involved.

Results and Discussion

Spiro System 5

Compound **5** can exist theoretically in the three conformations **5***a*, **5***b*, and **5***c* (Scheme 4). Conformation **5***a* has two oxygens having each an electron pair oriented antiperiplanar to a polar C—O bond, conformation **5***b* has only one, whereas conformation **5***c* has none. Consequently, **5***a* has two anomeric effects, **5***b* has only one, whereas **5***c* has none. Accepting the value of 1.4 kcal/mol for one anomeric effect, conformations **5***a* and **5***b* should be more stable than conformation **5***c* by 2.8 and 1.4 kcal/mol respectively on that basis.[7]

The next task concerns the evaluation of steric effects in these three conformations. In conformation **5***a*, the two oxygens are oriented axial to a ring. In conformation **5***c*, there are two methylene groups oriented axial to a ring. In conformation **5***b*, there are one oxygen and one methylene group axially oriented to a ring. When a methylene group is axially oriented, it corresponds to two *gauche* forms of butane evaluated at 0.9 kcal/mol each (14). When an oxygen is axially oriented, it corresponds to two *gauche* forms of *n*-propylether ($O—CH_2—CH_2—CH_2$) which we have evaluated at 0.4 kcal/mol each (15). On that basis, the steric effect for conformations **5***a*, **5***b*, and **5***c* should correspond to 1.6 (4 × 0.4), 2.6 (2 × 0.4 + 2 × 0.9), and 3.6 (4 × 0.9) kcal/mol respectively (Table 1).

If the stabilizing anomeric and the destabilizing steric effects are taken together, conformation **5***a* should be more stable than conformations **5***b* and **5***c* by 2.4 and 4.8 kcal/mol respectively (Table 1). *This analysis leads to the prediction that the spiro compound 5 must exist essentially in conformation* 5a *only.*

[7]We make the assumption that when there are two anomeric effects in the same conformation, they are additive.

* 1 *ae* = one anomeric effect; 1 *co* = one *gauche* form of $OCH_2CH_2CH_2$; 1 *cc* = one *gauche* form of *n*-butane; 1 δ*co* = CH_3 and oxygen in a 1,3 diaxial arrangement; 1 δ*cc* = two CH_3's in a 1,3 diaxial arrangement.

The spiro compound **5** was prepared by the method (**10** + **11** → **12** → **13** → **5**) described in Scheme 5.[8] The ^{13}C nmr spectra of **5** at room temperature or at low temperature (≃ −130°C, $CHFCl_2$) are virtually identical and they show five peaks only.[9] This result indicates that **5** exists in only one conformation which can either be **5***a* or **5***c*. Due to symmetry, conformations **5***a* and **5***c* should show five peaks only, whereas conformation **5***b* should exhibit eleven peaks. Conformation **5***b* is therefore eliminated. Conformation **5***a* has two anomeric effects whereas **5***c* has none, and on that basis, **5***c* must be eliminated. Rigorous evidence confirming this conclusion has been obtained by X-ray analysis (*vide infra*). Consequently, **5***a* corresponds to the stable conformation of **5** as predicted.

Interestingly, compound **5** does not yield the corresponding dihydroxyketone precursor upon acid hydrolysis; however, in the presence of deuterated water, it incorporated four deuterium atoms (at C(5) and C(11)). This result shows that **5** undergoes hydrolysis, but the equilibrium lies toward the spiro ketal **5** in preference to the dihydroxyketone precursor.

Spiro System **6**

The spiro system **6** was considered next. With **6**, two isomers, **14** and **15** (Scheme 6), are possible and each can exist in principle in four different conformations (**14***a*–*d* and **15***a*–*d* respectively). Furthermore, the two isomers **14** and **15** are theoretically interconvertible under acidic conditions (**14** can be converted into the mirror image of **15** by opening and reclosure of the acetal function).

The evaluation of the anomeric and the steric effects in the eight conformations of isomers **14** and **15** is described in Table 1. When a methyl group was found to be in a 1,3-diaxial arrangement with another methyl (or methylene) group (δ C, C) or with an oxygen atom (δ C, O) we have taken the values of 4.0 and 2.4 kcal/mol respectively for the corresponding steric interactions (17, 18).

The relative stability of the four conformers (**14***a*–*d* and **15***a*–*d*) for each of the two isomers **14** and **15** is shown in Scheme 6. This analysis shows that isomer **14** should exist in conformation **14***a* (0 kcal/mol) only, whereas isomer **15** should exist as a mixture of a major (**15***d*, 2.4 kcal/mol) and a minor (**15***a*, 2.9 kcal/mol) conformer. However, since isomers **14** and **15** are interconvertible, and since conformer **14***a* is more stable than conformer **15***d* by 2.4 kcal/mol, this analysis leads to the prediction that under thermodynamically controlled conditions, only isomer **14** should be formed and that it should exist in conformation **14***a* only.

The preparation of the spiro system **6** (**10** + **16** → **17** → **18** → **6**) is described in Scheme 5. We have isolated only one isomer (**14**) and analysis by ^{13}C nmr shows that **14** exists in only one conforma-

[8] A shorter synthesis of **5** has been recently published, see ref. 16.

[9] A detailed account of the ^{13}C nmr spectral analysis is reported in the accompanying publication.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

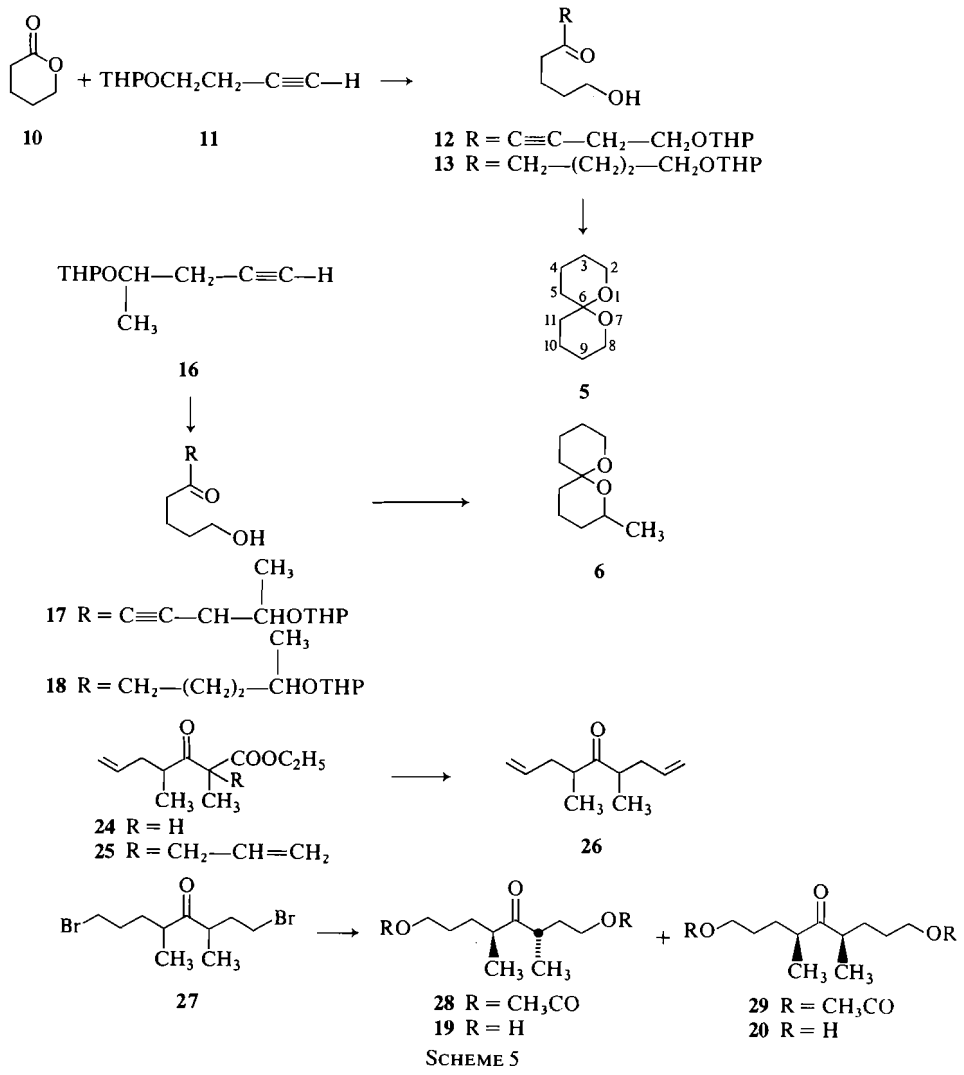

SCHEME 5

tion which corresponds to **14***a*.[9] Upon hydrolysis (2.3 *M* DCl in 60% D_2O/DME), compound **14** did not hydrolyse but incorporated four deuterium atoms. This result shows that hydrolysis of **14** takes place but the equilibrium lies toward the cyclic form **14** in preference to the corresponding dihydroxyketone. This result further proves that under thermodynamic conditions, the isomer **15** should not be observed, a result in accord with our prediction.

Spiro System 7

We will now consider the spiro system **7** which has two methyl groups. With this system, there are three possible isomers; two of them, **21** and **22**, are formed from the cyclization of the *dl* dihydroxyketone **19** (Scheme 7), whereas the third isomer **23** comes from the cyclization of the isomeric *meso* dihydroxyketone **20**. Under acidic conditions, **21** and **22** should be readily interconvertible and if these acidic conditions are strong enough to allow epimerization of the two dihydroxyketones **19** and **20**, the three isomeric compounds **21**, **22**, and **23** should be interconvertible.

Molecular models show that isomer **21** can exist in the three conformations, **21***a–c* (Scheme 8), isomer **22** in the three conformations, **22***a–c*, and isomer **23** in the four conformations, **23***a–d*. The relative stabilities of these various conformers of the three isomers **21**, **22**, and **23** are indicated in Scheme 8 and the detailed analysis is described in Table 1.

Isomer **21** should therefore exist in conformation **21***a* only (0 kcal/mol), isomer **22** should also exist in only one conformation (**22***a*, 1.8 kcal/mol), whereas isomer **23** should exist as a mixture of a

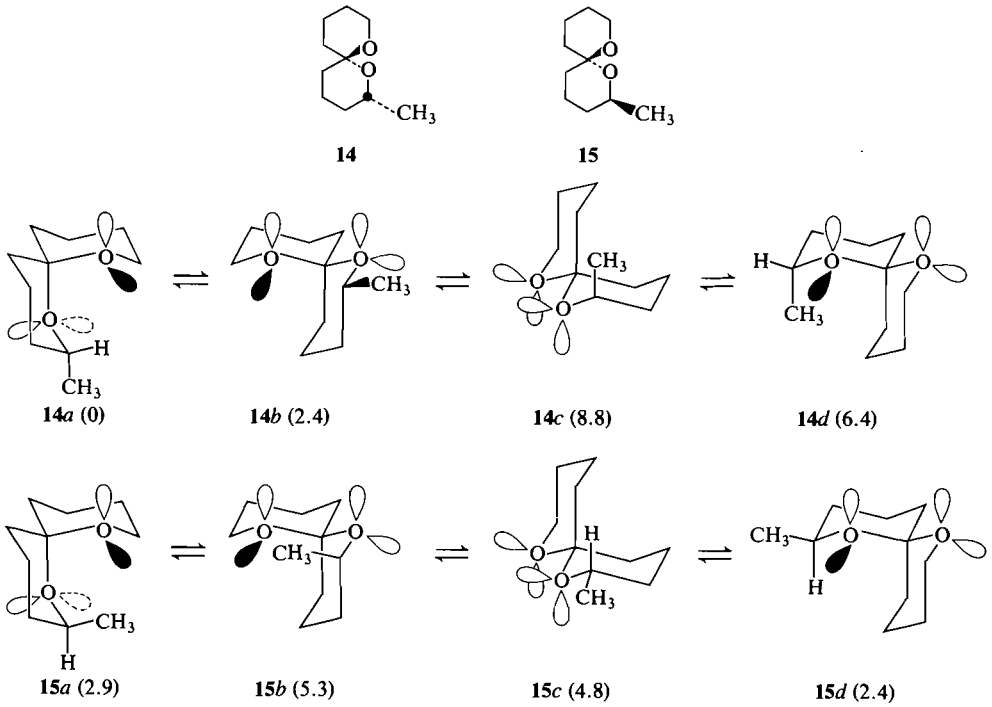
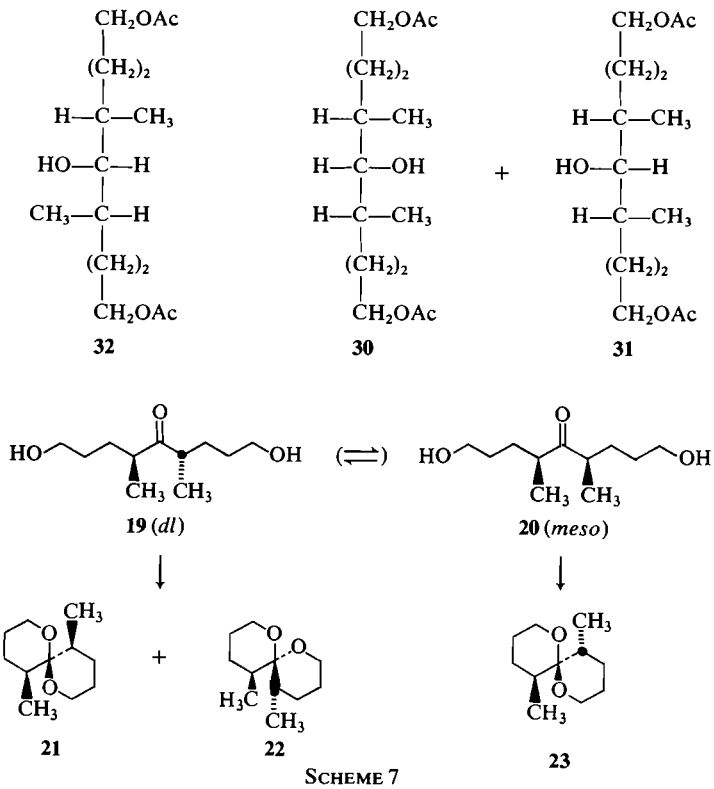
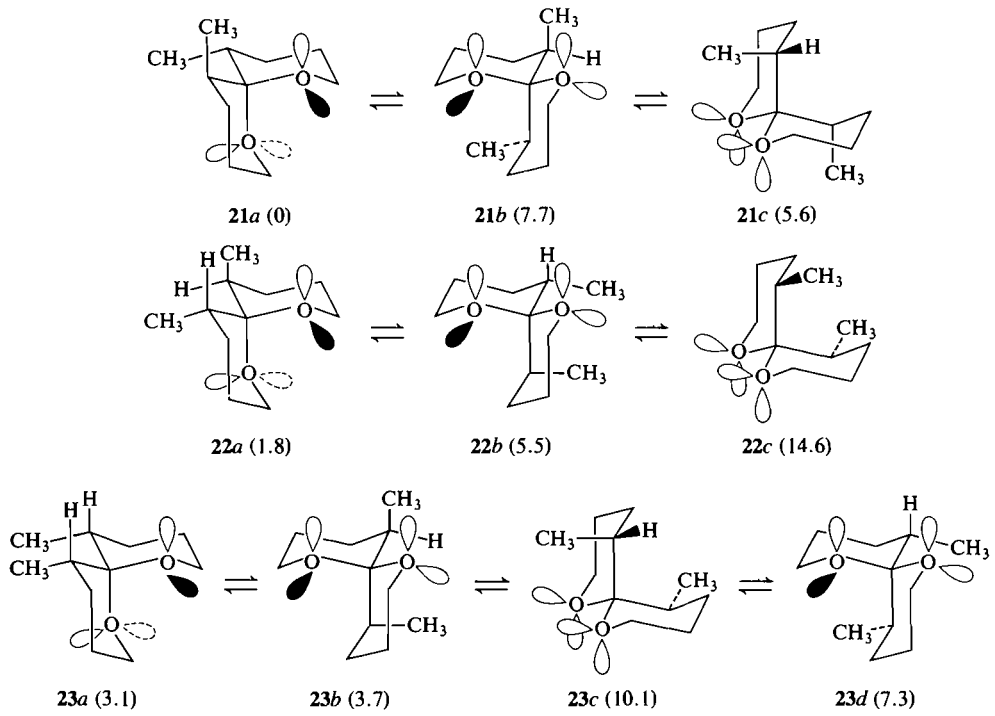


SCHEME 6



SCHEME 7



SCHEME 8

major (**23***a*, 3.1 kcal/mol) and a minor (**23***b*, 3.7 kcal/mol) conformer. This analysis leads to the prediction that, under thermodynamic conditions, the *dl* precursor **19** should yield a ≃97:3 mixture of isomers **21** and **22** which will exist in conformations **21***a* and **22***a* respectively, whereas the *meso* precursor **20** should yield **23** existing as a mixture of conformers **23***a* and **23***b*.

However, if the acidic conditions used allow the equilibration of the isomeric precursors **19** and **20**, isomer **23** which is at least 3.1 kcal/mol less stable than isomer **21** should not be observed, and a ≃97:3 mixture of isomers **21** and **22** should be isolated.

The preparation of a mixture of *dl* and *meso* dihydroxyketones **19** and **20** (**24** → **25** → **26** → **27** → **28** + **29** → **19** + **20**) is described in Scheme 5. Cyclization of this mixture under mild acidic conditions (PTSA/$CHCl_3$) gave a mixture of the three isomeric spiroketals **21**, **22**, and **23** which were separated. These products were identified by their spectral data, equilibration experiments, and behavior under hydrolysis conditions; ^{13}C nmr spectroscopy further showed that **21** and **22** exist in conformations **21***a* and **22***a* respectively. We have also been able to show by low temperature study ($CHFCl_2$, 160 K, 250 MHz), that **23** exists as a mixture of conformations **23***a* and **23***b*, as predicted.[9]

Treatment of **21** under aqueous acid conditions (0.1 *N* HCl in H_2O/acetone) did not yield the precursor *dl* dihydroxyketone **19**, but gave a ≃97:3 mixture of **21** and **22**. Repeating the above experiment with deuterated water, compound **21** was shown to incorporate two deuterium atoms. Treatment of **23** under the same acidic conditions gave also a 97:3 mixture of **21** and **22**. Under milder acidic conditions (0.01 *N* HCl in 20% H_2O/acetone) **23** produced a mixture of **21**, **22**, and the *meso* dihydroxyketone **20**, which was isolated as the corresponding *meso* ketodiacetate **29**.[10]

These results are again completely consistent with our predictions based on the evaluation of the steric and the anomeric effects.

Spiro System 8

With the tricyclic spiro system **8**, two isomers, **34** and **35**, are possible from the cyclization of the dihydroxyketone **33** (Scheme 9) and they can exist

[10]The structure of *meso* ketodiacetate **29** was proven in the following way. Upon reduction of the ketone function, **29** can give the two isomers **30** and **31** whereas the *dl* ketodiacetate **28** can give the isomer **32** only. The ketodiacetate obtained (**29**) was reduced ($NaBH_4$, MeOH); ^{13}C nmr analysis showed the presence of two signals for a carbon bearing a secondary alcohol indicating that a mixture of **30** and **31** was obtained. The product of the reduction of a 1:1 mixture of **28** and **29** showed three different signals for a carbon bearing a secondary alcohol, indicating that a mixture of **30**, **31**, and **32** was obtained.

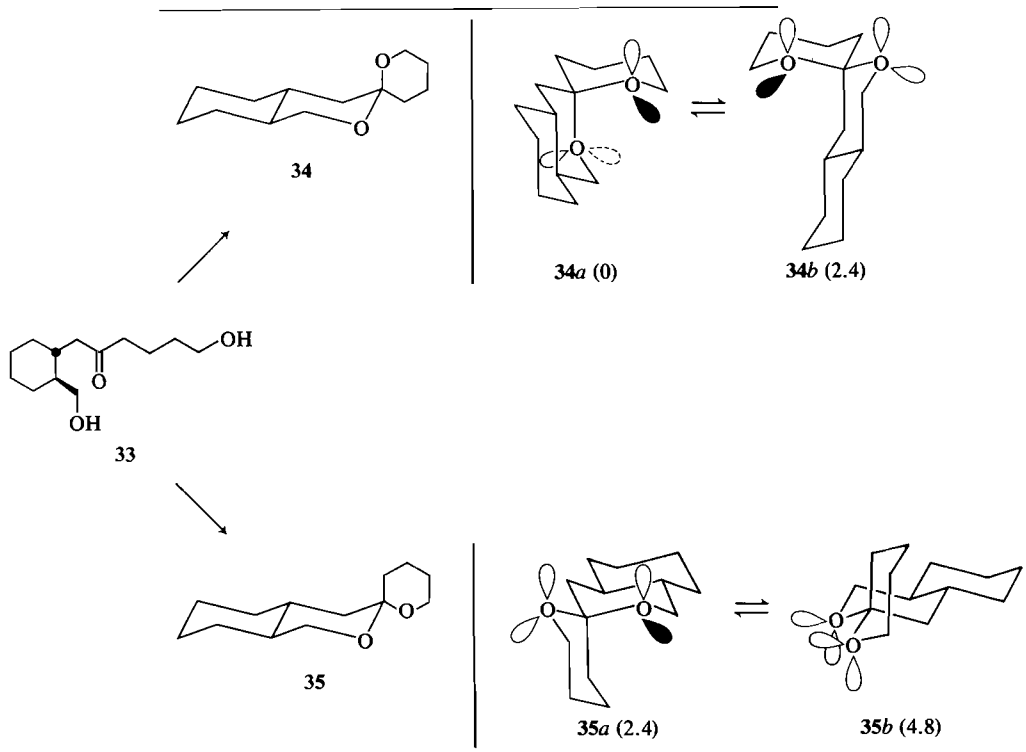

SCHEME 9

in two conformations each, which are **34***a*–*b* and **35***a*–*b* respectively. The detailed analysis of the relative stability of these four structures is described in Table 1. Conformer **34***a* (0 kcal/mol) is more stable than **34***b* (2.4 kcal/mol); isomer **34** should therefore exist in conformation **34***a* only. Similarly, conformer **35***a* (2.4 kcal/mol) is more stable than **35***b* (4.8 kcal/mol); isomer **35** should exist in conformation **35***a* only. However, since conformer **34***a* is more stable than conformer **35***a* by 2.4 kcal/mol, and since the isomers **34** and **35** can be interconverted by equilibration under acidic conditions, only isomer **34** should be observed under thermodynamically controlled conditions.

The preparation of the tetrahydropyranyl derivative **38** of monocyclic dihydroxyketone **33** (**36** + **11** → **37** → **38**) is described in Scheme 10. Treatment of **38** under acidic conditions (0.1 *N* HCl/CH_3OH) gave only the tricyclic ketal product **34** which was shown by ^{13}C nmr to exist in conformation **34***a* only.[9] Under aqueous acidic conditions (1 *N* DCl, acetone), compound **34** did not hydrolyse or equilibrate with **35** but incorporated four deuterium atoms. We have also prepared the monocyclic dihydroxyketone **33** (**38** → **39** → **40** → **41** → **33**, Scheme 10) and this product was cyclized under mild acid conditions (catalyst *p*-TSOH in $CHCl_3$); the reaction was stopped before completion and the reaction mixture was acetylated ($(CH_3CO)_2O$, pyridine) before isolation. This procedure gave a mixture of tricyclic acetal **34** and ketodiacetate **41** as well as a very small quantity of tricyclic acetal **35**. Compound **35** was obtained pure (≃1.5 mg) and characterized by infrared, ^1H nmr, and mass spectrometry. Upon treatment under acidic conditions (1 *N* HCl in acetone), tricyclic acetal **35** was irreversibly transformed into the more stable isomer **34**. These results are again in complete agreement with our prediction.

Spiro System 9

This spiro system can theoretically give the four isomers **43**, **44**, **46**, and **47** (Scheme 11). The two isomers **43** and **44** come from the cyclization of the dihydroxyketone precursor **42**, whereas the two isomers **46** and **47** come from the cyclization of the isomeric dihydroxyketone precursor **45**. In this case, **42** and **45** cannot be interconverted by epimerization. The isomers **43** and **44** which are interconvertible under acidic conditions can exist in two conformations each, which are **43***a*, *b* and **44***a*, *b*, respectively (Scheme 12). Similarly, the isomers **46** and **47** which are also interconvertible under acidic conditions can exist in two conformations each which are **46***a*, *b* and **47***a*, *b*, respectively.

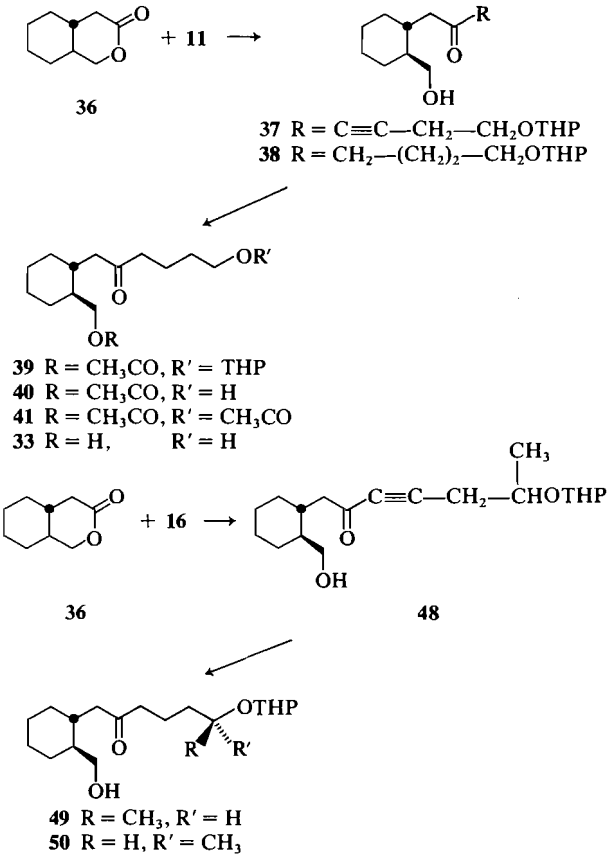

SCHEME 10

The analysis of the relative stabilities of the eight conformers of the four isomeric compounds **43**, **44**, **46**, and **47** is described in detail in Table 1 and shown in Scheme 12.

Isomer **43** should exist as a mixture of a major (**43***b* 0 kcal/mol) and a minor conformer (**43***a*, 0.5 kcal/mol). Isomer **44** should exist only in conformation **44***a* (0 kcal/mol). However, isomers **43** and **44** are interconvertible under acid conditions; a $\simeq 1:1$ mixture of isomers **43** and **44** should therefore be isolated from the cyclization of the precursor **42**. The isomer **43** should, however, slightly predominate at equilibrium due to an entropy factor, because **43** can exist in two conformations (**43***a* and **43***b*) whereas **44** can exist in only one (**44***a*).

Isomer **46** should exist in conformation **46***a* (0 kcal/mol) only, whereas isomer **47** should exist as a mixture of conformers **47***a* (6.9 kcal/mol) and **47***b* (4.8 kcal/mol). However, since isomers **46** and **47** are interconvertible under acidic conditions, only isomer **46** existing in conformation **46***a* should be isolated under thermodynamically controlled conditions.

Thus, under thermodynamically controlled conditions, the acid cyclization of a mixture of the isomeric dihydroxyketones **42** and **45** should yield a mixture of the three isomers **43**, **44**, and **46**. The preparation of a mixture of the tetrahydropyranyl derivatives **49** and **50** of the dihydroxyketones **42** and **45** (**36** + **16** → **48** → **49** + **50**) is described in Scheme 10. Cyclization of **49** and **50** under acidic conditions (1 *N* HCl, acetone), yielded as expected a mixture of **43**, **44**, and **46** which were separated by chromatography. Low temperature ^{13}C nmr study confirms that isomers **44** and **46** are conformationally rigid and exist in conformations **44***a* and **46***a* respectively.[9] Contrary to our analysis, isomer **43** exists in conformation **43***b* only; steric effects might have been underestimated in **43***a*, especially the 1,3 diaxial interaction between the oxygen and the methyl group.

Furthermore, under acidic conditions, isomer **43** (or **44**) was converted into a $\simeq 1:1$ mixture of isomers **43** and **44**. It was also shown that isomer **46** does not isomerize under acidic conditions, indicating that under thermodynamically controlled conditions the formation of **47** cannot compete with that of **46**.

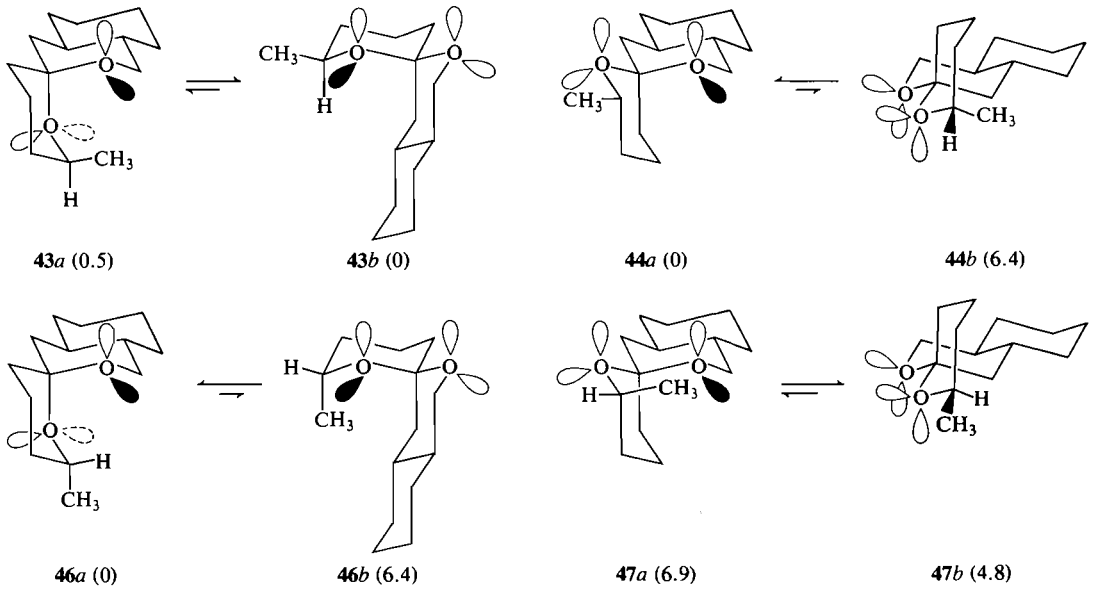
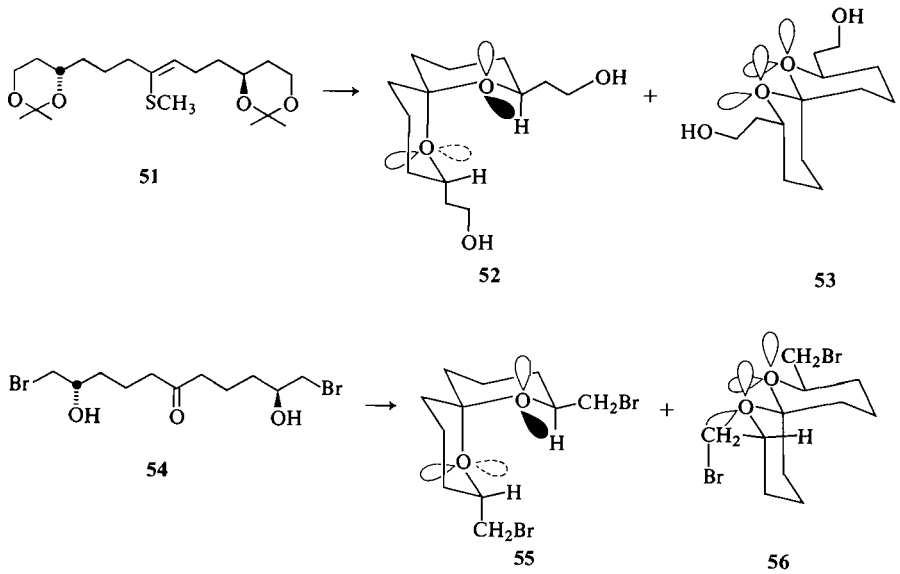


SCHEME 12



SCHEME 13

Results from the Literature

Compound **51**, a masked tetrahydroxyketone (Scheme 13), which can theoretically give the isomers **52** and **53**, was found to yield the isomer **52** exclusively (19). The structure of **52** was proven by X-ray analysis. Similarly, dibromodihydroxyketone **54** can theoretically give either isomer **55** or **56**. Upon cyclization, the isomer **55** was the product formed (20), and its structure was also established by X-ray analysis (21). The recently reported total synthesis of ionophore A-23187 (22), a polyether antibiotic which can be considered as a substituted 1,7-dioxaspiro[5.5]undecane system, i.e. **5**, confirms these results. Thus, these results described in the literature rigorously established that conformer **5***c* of **5** is much less stable than conformer **5***a*, as predicted.

Conclusion

These results constitute very strong evidence concerning the importance of the anomeric (and the *exo*-anomeric) effect. The value of 1.4 kcal/mol for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12

For personal use only.

an anomeric effect must, however, be considered as a minimum value, because the steric interactions might be larger than those observed in a simple cyclohexane (8).

These results demonstrate clearly that the basic spiro system **5** exists in conformation **5***a* only; **5** can therefore be considered as a conformationally rigid system.[11]

Experimental

Vapor-phase chromatographic (vpc) analyses and separations were carried out on a Varian Aerograph instrument, model 2800 equipped with a thermal conductivity detector. The infrared (ir) spectra were recorded in chloroform on a Perkin-Elmer 257 spectrophotometer. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded in deuterochloroform on a Bruker WP-60 instrument with TMS as an internal standard. The ^{13}C nmr spectra were recorded on a Bruker HX-90 spectrometer equipped with a Nicolet 1083 computer (8K memory for data) operating in the Fourier transform mode. Spectra were recorded in deuterochloroform with a sweep width of 5000 Hz. Mass spectra were obtained on Hitachi-Perkin-Elmer RMU-6-A and Micromass ZAB-2F machines. Microanalyses were carried out by Guelph Chemical Laboratories Ltd., Guelph, Ontario. Bicyclic lactone **36** was obtained by Baeyer–Villiger oxidation (23) of *trans*-hydrindanone (24).

The abbreviation plc (x% E/H) refers to preparative thin layer chromatography eluting with x% ether in hexane. The following abbreviations are also used: RT (room temperature); s (singlet); bs (broad singlet); d (doublet); t (triplet); q (quartet); quin (quintet); m (multiplet); $W/2$ (peak width at half peak height).

*Acetylene **11***

To dihydropyran (84 g, 1.0 mol) cooled in an ice bath was added 3-butyn-1-ol (50 g, 0.70 mol) and then concentrated hydrochloric acid (2 drops). After 3 h at RT, potassium carbonate (1 g) was added and after 15 min stirring the solution was filtered and distilled to give pure compound **11** (99 g, 90%); bp 72–78°C/20 Torr; ir: 3280, 1124, 1108, 1053, and 1017 cm^{-1}; ^{1}H nmr δ: 1.63 (6H, m), 1.95 (1H, t, J = 2.5 Hz, HC≡C), 2.48 (2H, t of d, J = 7.0 Hz, 2.5 Hz, CH_2C≡C), 3.30–4.15 (4H, m, CH_2O), 4.64 (1H, bs, OCHO).

*Acetylene **16***

A small quantity of propargyl bromide was added to magnesium (9.2 g, 0.38 mol) and mercuric chloride (catalytic quantity) under ether (50 mL). Once the reaction had been initiated by gentle heating, the solution was cooled to 0°C and the remainder of the propargyl bromide (47.6 g, 0.40 mol) in ether (100 mL) was slowly added. After 30 min, acetaldehyde (19.8 g, 0.45 mol) in ether (100 mL) was slowly added and the reaction stirred at room temperature for a further 30 min. The solution was acidified with 1 *N* hydrochloric acid and the organic phase was removed. The aqueous phase was extracted with ether (3 × 50 mL) and the combined ether phases were then washed with brine (1×), dried (Na_2SO_4), and evaporated. The residue was added to dihydropyran (42 g, 0.50 mol) maintained at 0°C. Two drops of concentrated hydrochloric acid were then added and the solution was left at RT for 3 h. Potassium carbonate (1 g) was added and after 15 min stirring, the reaction was filtered and distilled to give pure compound **16** (19 g, 30%); bp 90–95°C/20 Torr; ir: 3310, 1110, 1053, 1000, and 973 cm^{-1}; ^{1}H nmr δ: 1.24 and 1.32 (3H, d, J = 10.5 Hz, isomeric CH_3), 1.62 (6H, m), 2.00 (1H, m, HC≡C), 2.20–2.60 (2H, m, CH_2C≡C), 3.30–4.20 (3H, m, CHOR), 4.75 (1H, bs, OCHO).

*1,7-Dioxaspiro[5.5]undecane (**5**)*

To a solution of compound **11** (3.08 g, 20 mmol) in tetrahydrofuran (25 mL) at −78°C was added slowly *n*-butyllithium (1.6 *M* in hexane, 20 mmol). After 30 min, δ-valerolactone (2.00 g, 20 mmol) in tetrahydrofuran (25 mL) was rapidly added and the reaction was allowed to warm to RT. The solution was poured into water (50 mL) and the organic phase was separated. The aqueous phase was extracted with ether (3 × 50 mL) and the combined organic phases were then dried (Na_2SO_4) and evaporated. The oily residue was taken up in dry methanol (50 mL) and hydrogenated (40 psi over PtO_2). After filtration through silica gel, concentrated hydrochloric acid (2 drops) was added and the solution was left at RT overnight. Evaporation of the methanol gave a residue which was taken up in ether and dried (Na_2SO_4 and some K_2CO_3). Evaporation, followed by chromatography on silica gel gave, on elution with 5% E/H, spiroketal **5** (1.10 g, 33%) as a clear oil; ir: 1164, 1076, 1046, and 966 cm^{-1}; ^{1}H nmr δ: 1.60 (12H, m), 3.3–4.0 (4H, m, CH_2O); ^{13}C nmr δ: 18.6 (t), 25.4 (t), 35.8 (t), 60.3 (t), 94.9 (s); ms *m/e*: 156 (M^+).

*2-Methyl-1,7-dioxaspiro[5.5]undecane **14** (**6**)*

To a solution of acetylene **16** (3.53 g, 20 mmol) in tetrahydrofuran (20 mL), cooled to −78°C, was slowly added *n*-butyllithium (21 mmol of 1.6 *M* solution in hexane). After 30 min, a solution of δ-valerolactone (2.0 g, 20 mmol) in tetrahydrofuran (40 mL) was rapidly added and the solution was then allowed to warm to RT. The reaction was quenched in water (50 mL), the organic phase was removed, and the aqueous phase was ether extracted (3×). The combined organic phases were dried (Na_2SO_4) and evaporated to give an oily residue which was hydrogenated (40 psi) over platinum oxide in methanol (50 mL). The catalyst was removed by filtration through silica gel, concentrated hydrochloric acid (2 drops) was added and the solution was left at RT overnight. The solvent was removed under reduced pressure and the residue was taken up in ether and dried ($MgSO_4/K_2CO_3$). Evaporation and chromatography on silica gel gave, on elution with 5% E/H, methyl spiroketal **14** (900 mg, 26%) as a clear oil; ir: 1384, 1216, 1093, 1064, and 994 cm^{-1}; ^{1}H nmr δ: 1.14 (3H, d, J = 10.5 Hz, CH_3), 1.54 (12 H, m), 3.60 (3H, m, CHOR); ^{13}C nmr δ: 18.6 (t), 19.0 (t), 21.8 (q), 25.4 (t), 32.7 (t), 35.1 (t), 35.9 (t), 60.2 (t), 65.1 (d), 95.5 (s); ms *m/e*: 170 (M^+).

*Deuteration of Spiroketals **5** and **14***

The spiroketals (100–300 mg) in dimethoxyethane (3.0 mL), deuterium oxide (3.0 mL), and 35% deuterium chloride/D_2O (1.5 mL) were maintained at RT overnight. The reaction was diluted with water (10 mL) and ether extracted (3 × 20 mL). Drying ($MgSO_4$) and evaporation of solvent gave the deuterated ketals; d_4-acetal **5**: ^{13}C nmr δ: 18.3, 25.3, 60.4, anomeric carbon not observed; d_4-acetal **14**: ^{13}C nmr δ: 18.4, 18.7, 21.8, 25.4, 32.7, 60.3, 65.2, anomeric carbon not observed.

*Keto-ester **24***

A suspension of sodium hydride (4.22 g, 50% dispersion, 88 mol, washed with pentane (2×)) in tetrahydrofuran (200 mL) was cooled in an ice/salt bath under nitrogen and ethyl-α-propionyl propionate (12.6 g, 9.64 mL, 80 mmol) was added dropwise with rapid stirring. Ten minutes after gas evolution ceased, *n*-butyllithium (81 mmol, 1.6 *M* in hexane) was added and, after a further 10 min, allyl bromide (8.0 mL, 92 mmol). The

[11] The basic spiro system **5** can therefore be used to develop a new strategy for the synthesis of aliphatic chains containing several asymmetric centers and functional groups. Work is now in progress in our laboratory to demonstrate the validity of this new strategy.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

cooling bath was removed and, after 10 min, the reaction was quenched (10% hydrochloric acid, 50 mL) and diluted with ether (≈200 mL). The aqueous phase and a first brine washing of the organic phase were combined and further extracted with ether. The combined ether phases were then washed with brine, brine – sodium bicarbonate to remove colour, and then brine again until neutral. Drying ($MgSO_4$) and evaporation of the solvent gave the keto-ester **24** (14.8 g, 94%) sufficiently pure for the next reaction. Distillation (86–88°C/4 Torr) and vpc (5 ft × ¼ in; 10% SE-30 on Chromosorb W, 160°C) gave an analytical sample; ir: 3070, 1745, 1716, 1643, 1222, 1180, 973, and 898 cm^{-1}; ^1H nmr δ: 1.11 (3H, d, J = 7 Hz, γCH_3), 1.25 (3H, t, J = 7 Hz, CH_2CH_3), 1.32 (3H, d, J = 8 Hz, αCH_3), 1.9–3.1 (3.5 H, m), 3.63 and 3.67 (1H, 2 q, J = 7 Hz, isomeric αH), 4.17 (2H, q, J = 7 Hz, OCH_2), 4.80–6.10 (3H, olefinic m); ms *m/e*: 198 (M^+), 152, 129, 97.

Keto-ester 25

A solution of dimethylformamide (70 mL) and benzene (40 mL) was dried in a Dean-Stark apparatus (17 ml removed), cooled under nitrogen, and the major part added to sodium hydride (3.66 g, 50% dispersion, 76.3 mmol, washed with pentane (2×)) and stirred in an ice/salt bath under nitrogen. Keto-ester **24** (13.7 g, 69.2 mmol) was added dropwise followed by the remainder of the solvent. After 15 min, allyl bromide (7.1 mL, 82 mmol) was added and the system was allowed to warm to RT over 15 min. After 50 min at 40°C, the reaction was quenched (10% hydrochloric acid, 40 mL), diluted with water (600 mL), and extracted with ether (3×). The combined organic fractions were washed with water until neutral, dried ($MgSO_4$), and evaporated to give keto-ester **25** (14.2 g, 86%) sufficiently pure for the next reaction. An analytical sample was prepared by vpc (5 ft. × ¼ in., 10% SE-30 on Chromosorb W, 170°C); ir: 3065, 1735, 1713, 1642, 1220, 1135, 977, and 897 cm^{-1}; ^1H nmr δ: 1.06 (3H, d, J = 7 Hz, CH_3), 1.26 (3H, t, J = 7 Hz, CH_3), 1.32 and 1.34 (3H, two s, isomeric CH_3's), 2.0–3.1 (6H, m), 4.17 (2H, q, J = 7 Hz), 4.80–6.07 (6H, olefinic m); ms *m/e*: 238 (M^+), 210, 193, 142.

Ketone 26

Keto-ester **25** (14.2 g, 59.7 mmol) in methanol (200 mL) and water (10 mL) was refluxed with sodium hydroxide (5.0 g, 125 mmol) with vigorous stirring for 3¼ h. The solvent was largely removed under reduced pressure and the residue was diluted with water and adjusted to neutral pH. Ether extraction (3×), drying ($MgSO_4$), and evaporation of the solvent followed by distillation (76–80°C/6 Torr) gave ketone **26** (7.08 g, 71.5%). An analytical sample was prepared by vpc (5 ft. × ¼ in., 10% SE-30 on Chromosorb W, 130°C); ir: 3065, 1713, 1642, 977, and 893 cm^{-1}; ^1H nmr δ: 1.04 and 1.07 (6H, two d, J = 7 Hz, isomeric CH_3), 1.73–3.02 (6H, m), 4.75–6.02 (6H, olefinic m); ^{13}C nmr δ: 16.1 and 16.2 (q, isomeric CH_3), 37.0 and 37.2 (t), 45.0 (d), 116.8, 135.9, 216.5; ms *m/e*: 166 (M^+), 97, 69.

Dibromide 27

The ketone **26** (2.39 g, 14.4 mmol) in pentane (500 mL) was placed in a water-cooled uv apparatus, cooled with ice, and purged with nitrogen for 15 min. Anhydrous hydrogen bromide was then bubbled gently into the solution with irradiation from a 450 W Hanovia mercury lamp for 15 min. The solution was again purged with nitrogen and the pentane solution was washed with 5% sodium bicarbonate containing some sodium thiosulfate (2×), then water (1×). Drying ($MgSO_4$) and evaporation gave the dibromide **27** (4.21 g, 85%) as a rapidly blackening oil which was used directly for the next step; plc (50% E/H) gave an analytical sample; ir: 1713, 1243, and 995 cm^{-1}; ^1H nmr δ: 1.08 and 1.09 (6H, two d, J = 7 Hz, isomeric CH_3), 1.4–2.1 (8H, m), 2.63 (2H, deformed quin, J = 6.5 Hz), 3.39 (4H, t, J = 6 Hz); ms *m/e*: 330, 328, 326 (M^+, 1:2:1), 249, 247 (M^+ – Br, 1:1), 179, 177 ($M^+ - C_5H_{10}Br$, 1:1).

Diacetates 28 and 29

Sodium acetate (2.70 g, 32.9 mmol) was dissolved in hexamethylphosphoramide (60 mL) and water (12 mL). To this warm solution was added the dibromide **27** (3.87 g, 11.8 mmol) and hexamethylphosphoramide (5 mL). After 21 h at 35°C the solution was diluted with water (600 mL) and ether extracted (3×). The combined ethereal phases were washed with brine (2×), dried ($MgSO_4$), and evaporated. Chromatography on silica (140 g) with increasing proportions of ether in hexane gave keto-diacetates **28** and **29** (2.27 g, 70.7%) as an inseparable mixture; plc (60% E/H) gave an analytical sample; ir: 1735, 1237, and 1017 cm^{-1}; ^1H nmr δ: 1.06 and 1.08 (6H, two d, J = 7 Hz, isomeric CH_3), 1.3–1.8 (8H, m), 2.04 (6H, s, OAc), 2.4–2.9 (2H, m), 4.04 (2H, deformed t); ^{13}C nmr δ: 16.6, 20.9, 26.5, 28.9, 29.1, 44.6, 64.2, 170.9, 216.7, 216.8; ms *m/e*: 226, 186, 166, 157. *Anal.* calcd. for $C_{15}H_{26}O_5$: C 62.91, H 9.15; found: C 62.81, H 9.35.

Spiroketals 21, 22, and 23

Diacetates **28** and **29** (3.31 g, 11.6 mmol) in methanol (90 mL), triethylamine (10 mL), and water (5 mL) were maintained at 50°C for 3 days. Evaporation of the solvent gave the diols **19** and **20** (3.06 g, 100%); ir: 3420, 1710, 1040, and 973 cm^{-1}; ^1H nmr δ: 0.96 (6H, d, J = 7 Hz), 2.30–2.85 (2H, m), 3.40 (4H, deformed t, $W/2$ = 4 Hz, CH_2O), 4.51 (2.5 H, variable s, OH); ms *m/e*: 184, 115.

Cyclization was effected in chloroform (12 mL) with consecutive additions of *p*-toluenesulfonic acid (total ≈50 mg) as the reaction was followed by nmr and vpc (5 ft × ¼ in., 5% FFAP on Chromosorb W, 105°C). The reaction occurred suddenly giving spiroketals **21**, **23**, and **22** in a ratio of 100:59:4 (R_f 3.6, 6.0, and 7.2 min respectively). The reaction was quenched with saturated sodium bicarbonate and the aqueous phase was extracted with chloroform. The combined organic phases were washed with sodium bicarbonate, dried (Na_2SO_4), and evaporated to give the product (2.13 g 115%). Chromatography on Florisil (200 g), eluting with 2% E/H, gave a partial separation of the isomeric spiroketals. From these fractions, pure material was prepared by vpc, to give (from highest R_f) the following.

Spiroketal 21: ir: 1067, 1000, 958, and 913 cm^{-1}; ^1H nmr δ: 0.86 (6H, d, J = 6 Hz), 1.3–2.0 (10H, m), 3.38–3.70 (4H, m, $W/2$ = 10 Hz); ^{13}C nmr δ: 16.2, 26.4, 27.3, 34.5, 59.9, and 99.8; ms *m/e*: 184 (M^+). *Anal.* calcd. for $C_{11}H_{20}O_2$: C 71.69, H 10.94; found: C 71.94, H 11.39.

Spiroketal 23: ir: 1062, 998, and 915 cm^{-1}; ^1H nmr δ: 0.96 (3H, d, J = 6 Hz), 1.08 (3H, d, J = 7 Hz), 1.17–2.10 (10H, m), 3.59 (4H, m, $W/2$ = 8 Hz); ^{13}C nmr δ: 16.8 (q), 17.5 (q), 20.6 (t), 24.9 (t), 26.6 (t), 29.2 (t), 35.9 (d), 36.0 (d), 59.4 (t), 60.6 (t), 100.0; ms *m/e*: 184 (M^+).

Spiroketal 22: ir: 1053, 1015, 988, 910, and 865 cm^{-1}; ^1H nmr δ: 1.01 (6H, d, J = 7 Hz), 1.13–2.42 (10H, m), 3.50–3.80 (4H, m, $W/2$ = 11 Hz); ^{13}C nmr δ: 13.6, 19.6, 25.4, 32.0, 60.7, and 99.4; ms *m/e*: 184 (M^+).

Equilibration of Spiroketal 21

To spiroketal **21** (264 mg, 1.43 mmol, >99.5% by vpc) in acetone (2 mL) was added hydrochloric acid (1 *N*, 0.50 mL) and then sufficient acetone to give a homogeneous system. The reaction was complete within 2 days by vpc. After 8 days, the reaction was quenched with sodium carbonate, diluted with ether, and concentrated under reduced pressure. Dilution with ether, drying (Na_2SO_4), and evaporation gave the product (242 mg, 91.7%) which by vpc, consisted of spiroketals **21** (96.8%), **23** (≤0.1%), and **22** (3.2%). Infrared and ^1H nmr confirmed the presence of acetal **21**. The presence of acetal **22** was confirmed by ^{13}C nmr.

Deuteration of Spiroketal 21

Spiroketal **21** (106 mg, 0.58 mmol) in d_1-methanol (0.9 mL)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

and 1 *M* deuterium chloride in deuterium oxide (0.1 mL) were maintained at RT for 6 days when ^{1}H nmr showed the exchange to be 50% complete. Additional 35% deuterium chloride solution (10 μL) and d_1-methanol (0.1 mL) were added and after a further 8 days the reaction was almost complete. Complete deuteration was effected by dilution of the system with d_1-methanol (≃2 mL) and addition of further acid (20 μL, 35% solution). After 3 more days, the system was quenched with saturated sodium bicarbonate solution, diluted with ether, and the organic phase dried (Na_2SO_4). Evaporation of the solvent gave d_2-acetal (**21**) (70 mg, 66%); vpc gave an analytical sample; ir: 1090, 1052, 1035, and 995 cm^{-1}; ^{1}H nmr δ: 0.86 (6H, s, CH_3), 1.24–1.86 (8H, m), 3.44–3.76 (4H, m); ^{13}C nmr δ: 16.1, 26.4, 27.2, 59.9, anomeric carbon not observed; ms *m/e*: 186 (M^+).

Hydrolysis of Spiroketal 22

To spiroketal **22** (4.0 mg) in acetone (0.3 mL) and water (0.15 mL) was added a solution of 1 *M* hydrochloric acid (50 μL). By tlc, the isomerization was almost complete in 1 h. Work-up, as for the isomerization of spiroketal **21**, gave spiroketal **21** by vpc, tlc, ^{1}H nmr, and ir; vpc analysis gave a ratio **21**:**22** ≃ 97:3.

Hydrolysis of Spiroketal 23

Spiroketal **23** (7.9 mg) in acetone (250 μL) was treated with 1 *N* hydrochloric acid (100 μL) and the reaction was followed by vpc (≃15 min). After 18 h, the acetone was removed under reduced pressure at RT and the acid was quenched with sodium bicarbonate. Dilution with ether and adsorption of the aqueous phase with sodium sulfate gave, after evaporation, the product (11.7 mg) of composition **21** (97%), **22** (3%), **23** (≃0.09%) byvpc. Drying with EtOH–benzene azeotrope gave acetal **21** (5.5 mg, 70%) by ir, ^{1}H nmr, and tlc.

Mild Acid Hydrolysis of Spiroketal 23

To spiroketal **23** (178 mg, 0.97 mmol, composition by vpc **21** (2%), **23** (95%), **22** (3%)) in acetone (2.4 mL) and water (0.57 mL) was added 1 *M* hydrochloric acid (30 μL) and the hydrolysis was followed by vpc. After 160 min, the reaction was quenched with sodium bicarbonate and then diluted with ether. After drying (Na_2SO_4) and evaporation of the solvent, the residue was acetylated with pyridine (0.5 mL) and acetic anhydride (0.4 mL) for 2 h at room temperature. Saturated sodium bicarbonate and ether were added. The ethereal phase was washed with sodium bicarbonate (1×) and then water (2×), dried, and evaporated to give the product (0.57 g). Chromatography with ether–hexane on Florisil (30 g) gave, on elution with 2% ether–hexane (*i*) spiroketal **21** (33.6 mg, 18.9%) by ir and nmr; vpc analysis gave **21** (95%) and **23** (5%); (*ii*) a mixture of spiroketals (66.8 mg, 37.5%) consisting by vpc of **21** (67%), **23** (30%), and **22** (3%); (*iii*) a fraction of starting material (9.9 mg, 5.6%) by ir and nmr and consisting, by vpc analysis, of **21** (3%), **23** (75%), and **22** (23%).

Elution through to ether gave diacetate **29** (50 mg, 18%) as a clear oil; ir: 1735, 1234, and 1040 cm^{-1}; ^{1}H nmr δ: 1.08 (6H, d, J = 7 Hz), 1.30–1.90 (8H, m), 2.04 (6H, s), 2.37–2.90 (2H, m), 4.04 (4H, t, J = 6 Hz); ^{13}C nmr δ: 16.6, 20.9, 26.4, 29.0, 44.6, 64.3, 171.1, 217.1; ms *m/e*: 226, 166, 157.

Sodium Borohydride Reduction of Keto-acetate 29

To diacetate **29** (70 mg, 0.24 mmol) in methanol (5 mL) was added sodium borohydride (10 mg). After 95 min, the reaction was concentrated cold under reduced pressure whereupon thin layer chromatography showed incomplete reduction. Additional sodium borohydride (≃10 mg) and methanol (2 mL) were added and after 60 min the reaction was complete. The solution was again concentrated under reduced pressure, ether was added, and the organic phase was washed with saturated ammonium chloride (1×) and the brine (1×). Drying (Na_2SO_4) and evaporation gave alcohols **30** and **31** (54 mg, 77%). An analytical sample (18 mg, 26%) was obtained after plc (50% ethyl acetate – hexane); ir: 3510, 1733, 1240, and 1022 cm^{-1}; ^{1}H nmr δ: 0.92 (6H, d, J = 6 Hz), 1.30–2.87 (11H, m), 2.05 (6H, s), 3.00–3.30 (1H, m), 4.06 (4H, t, J = 6 Hz); ^{13}C nmr δ: 14.1, 16.5, 21.0, 26.2, 26.3, 27.0, 29.9, 35.1, 64.7, 64.8, 78.3, 80.6, 171.2; ms *m/e*: 159, 99.

Sodium Borohydride Reduction of Ketodiacetates 28 and 29

To diacetates **28** and **29** (90 mg, 0.31 mmol) in methanol (10 mL) was added sodium borohydride (22 mg). After 80 min, saturated ammonium chloride and ether were added. The aqueous phase was diluted with enough water to dissolve precipitated salts and extracted with ether (1×). The combined ether layers were washed with brine (1×), evaporated, and then azeotroped with benzene–ethanol to give alcohol diacetates **30**, **31**, and **32** (92 mg, 102%); plc (80 mg, 50% ethyl acetate – hexane) gave a sample (52 mg, 65%) pure by vpc (5 ft × $\frac{1}{4}$ in., Apiezon L 10% on Chromosorb W, 230°C); ir: 3500, 1733, 1240, and 1020 cm^{-1}; ^{1}H nmr δ: 0.85 and 0.91 (6H, two d, J = 6 Hz, *meso* and *dl* isomers respectively), 1.13–1.90 (11H, m), 2.04 (6H, s), 3.00– 3.30 (1H, m), 4.06 (4H, t, J = 6 Hz); ^{13}C nmr δ: 12.5, 14.1, 15.9, 16.6, 21.0, 26.2, 26.3, 26.4, 27.0, 28.8, 29.9, 30.6, 34.5, 35.1, 35.9, 64.7, 64.8, 78.2, 80.6, 171.2; ms *m/e*: 159, 99.

Spiroketal 34

To acetylene **11** (1.40 g, 9.1 mmol) in tetrahydrofuran (25 mL) at −78°C was added *n*-butyllithium (9.1 mmol of 1.6 *M* hexane solution). After 30 min, bicyclic lactone **36** (1.40 g, 9.1 mmol) in tetrahydrofuran (30 mL) was quickly added and the system was allowed to warm to RT. The reaction was quenched in water (50 mL), the organic phase was separated, and the aqueous phase was ether extracted (3×). The combined organic phases were dried (Na_2SO_4) and evaporated and the resulting residue was taken up in methanol (50 mL) and hydrogenated (40 psi over PtO_2). After filtration through silica gel, concentrated hydrochloric acid (2 drops) was added and the solution was left at RT overnight. The solvent was evaporated and the residue was taken up in ether, dried ($MgSO_4/K_2CO_3$), and again evaporated. Chromatography on silica gel gave on elution with 5% E/H, spiroketal **34** (1.18 g, 62%) as a clear oil; ir: 1164, 1150, 1132, 1020, 997, and 964 cm^{-1}; ^{1}H nmr δ: 1.32 (18H, m), 3.3–4.0 (4H, m, CH_2O); ^{13}C nmr δ: 18.6, 25.4, 26.0, 26.2, 27.7, 32.8, 35.4, 35.6, 41.8, 43.1, 60.4, 65.5, 96.0; ms *m/e*: 210 (M^+).

Deuteration (as for spiroketals **5** and **14**, but for 30 days reaction time) gave d_4 spiroketal **34**. *Exact Mass* calcd. for $C_{23}H_{28}D_4O$: 214.1871; found (ms): 214.1872.

THP-hydroxyketone 38

Compound **38** was produced, as described above for spiroketal **34**, and purified by chromatography on Florisil. Eluting with 40% E/H gave compound **38** (60–70%) as a clear oil which crystallized on standing (mp 53–55°C crystallized from hexane); ir: 3595, 3440, 1707 (weak), 1121, 1060,1048,1006 cm^{-1}; ^{1}H nmr δ: 1.58 (24H, m), 2.10 (1H, variable s, OH), 3.15–4.03 (6H, m, CH_2O), 4.56 (1H, m, OCHO).

THP-keto-acetate 39

Compound **38** (597 mg, 1.69 mmol) was treated with pyridine (2.0 mL) and acetic anhydride (2.0 mL) for 24 h at RT. Dilution with water (100 mL) and saturated sodium bicarbonate (100 mL) was followed by extraction with dichloromethane (3 × 30 mL). Washing with brine (1×), drying ($MgSO_4$), and evaporation gave THP-keto-acetate **39** (658 mg, 97.2%) as a yellow oil. Chromatography on Florisil, eluting with 20% ethyl acetate – hexane gave analytical material; ir: 1728, 1237, 1010 cm^{-1}; ^{1}H nmr δ: 1.0–1.9 (20H, m), 2.04 (3H, OAc), 2.42 (4H, m, $W/2$ = 20 Hz, CH_2COR), 3.56 (4H, m, $W/2$ = 33 Hz, CH_2O), 3.97 (2H, deformed d, J = 6 Hz, CH_2OAc), 4.56 (1H, m, OCHO); ms *m/e*: 354 (M^+), 294 (M^+ − HOAc), 270, 269, 253.

Alcohol 40 and Diacetate 41

Crystals of *p*-toluenesulfonic acid were added successively to a solution of the THP-keto-acetate **39** (467 mg, 1.32 mmol) in 10% water–methanol (25 mL) and the reaction followed by tlc. After 4 h, sodium bicarbonate was added and the solution concentrated under reduced pressure. After the addition of ether (50 mL) and removal of the aqueous phase, drying ($MgSO_4$) and evaporation gave compound **40** as a clear oil (370 mg, 104%). Pure hydroxy-acetate **40** (70% yield) could be obtained as a clear oil by chromatography on Florisil, eluting with 40% E/H; ir: 3480, 1733, 1240, and 1017 cm^{-1}; ^1H nmr δ: 1.1–1.9 (14H, m), 2.05 (3H, s, OAc), 2.45 (4H, m, $W/2 = 20$ Hz, CH_2COR), 3.63 (2H, t, $J = 6$ Hz, CH_2OH), 3.97 (2H, d, $J = 4$ Hz, CH_2OAc); ms *m/e*: 252.1685 ($M^+ - H_2O$, $C_{15}H_{24}O_3$ requires 252.1725), 210 ($M^+ -$ HOAc).

Alternatively the crude hydroxy-acetate **40** was acetylated with acetic anhydride (2.0 mL) and pyridine (2.0 mL) at RT for 17 h. Dilution with 3% sulfuric acid (150 mL), ether extraction (3×), and washing of the combined ether extracts with saturated sodium bicarbonate (1×) and brine (1×), followed by drying ($MgSO_4$) and evaporation of the solvent gave a pale oil (556 mg). Chromatography on silica gel gave, on elution with 80% E/H, keto-diacetate **41** (190 mg, 46.1% as a clear oil. A midfraction, pure by tlc and vpc (5 ft × ¼ in., Apiezon 10% on Chromosorb W, 230°C, R_t 32 min) gave ir: 1733, 1238, 1016 cm^{-1}; ^1H nmr δ: 1.0–1.8 (14H, m), 2.03 (6H, s, OAc), 2.42 (4H, m, $W/2 = 20$ Hz, CH_2COR), 3.99 (4H, m, $W/2 = 9$ Hz, CH_2OAc); ms *m/e*: 252.1724 ($M^+ -$ HOAc, $C_{15}H_{24}O_3$ requires 252.1725), 192 ($M^+ - 2$ HOAc), 158, 155, 137.

Spiroketal 35

Keto-diacetate **41** (148 mg, 0.47 mmol) in a mixture of methanol, triethylamine, and water (4:2:1; 7 mL) was warmed at 70°C for 8 days, additional solvent (3.5 mL) being added after 5 days. Removal of the solvent gave keto-diol **33** as a brown oil which crystallized on standing; mp 67–69°C; ir: 3400,1710 (weak), 1222, and 1040 cm^{-1}; ms *m/e*: 210 ($M^+ - H_2O$), 165, 155, 152, 137, 101.

This material was immediately cyclized in chloroform (2 mL) by the successive addition of small crystals of *p*-toluenesulfonic acid, the reaction being followed by tlc and vpc (5 ft × ¼ in., 3% SE-30 on Chromosorb W, 175°C). Spiroketals **34** and **35** were initially present in a ratio of 7:3 (R_t 5.0 and 5.7 min respectively) which fell to 9:1 after 5.5 h. Quenching with sodium carbonate, dilution with ether, and drying (Na_2SO_4) gave, after evaporation, a yellow oil (117 mg) which was immediately acetylated in pyridine (0.5 mL) with acetic anhydride (0.5 mL). After standing overnight at RT, the solution was diluted with ether (50 mL) and washed with saturated sodium bicarbonate (2×), brine (1×), then dried (Na_2SO_4). Evaporation gave a yellow oil (155 mg) which was chromatographed on Florisil. Elution with 5% E/H gave spiroketal **34** (27 mg, 27% from **41**) pure by vpc, tlc, nmr, and ir. Elution with ether gave keto-diacetate **41** (74 mg, 50%). Recovery of intermediate fractions gave a sample of spiroketal **35** (14 mg, 14%) containing 9% of spiroketal **34** by vpc. Preparative vpc gave an analytical sample (≃1.5 mg); ir: 1166, 1090, 1042, 1021, and 970 cm^{-1}; ^1H nmr δ: 0.8–1.9 (17 H, m), 2.10–2.43 (1H, m), 2.88–4.33 (4H, m); ms *m/e*: 210 (M^+), 155, 152, 137, 110, 101.

Isomerization of Compound 35

A sample of spiroketal **35** (≃1.5 mg, **56**:**55** = 74:26, spontaneous isomerization on sample recovery) in acetone (0.45 mL) was treated with 1 *N* hydrochloric acid (0.05 mL) at RT. Conversion to spiroketal **34** was complete within 5 min by vpc. Evaporation of the solvent gave pure spiroketal **34** by ir, nmr, tlc, and vpc.

Spiroketals 43, 44, and 46

To acetylene **16** (18.5 g, 110 mmol) in tetrahydrofuran (100 mL) at −78°C was slowly added *n*-butyllithium (100 mmol of 1.6 *M* hexane solution). After 30 min, bicyclic lactone **36** (13.9 g, 90 mmol) in tetrahydrofuran (50 mL) was quickly added and the system was allowed to warm to RT. The reaction was quenched in water (50 mL), the organic phase separated,and the aqueous phase was ether extracted (3×). The combined organic phases were dried (Na_2SO_4), evaporated, and the resulting oil was taken up in methanol (50 mL) and hydrogenated (40 psi over PtO_2). After filtration through silica gel, concentrated hydrochloric acid (2 drops) was added and the solution was left at RT overnight. The solvent was evaporated and the residue was taken up in ether, dried ($MgSO_4/K_2CO_3$), and again evaporated. Chromatography on silica gel gave, on elution with 5% E/H, (*i*) spiroketal **46**: (6.80 g, 33.5%); ir: 1383, 1229, 1092, 1087, 1048, and 992 cm^{-1}; ^1H nmr δ: 1.14 (3H, d, $J = 10.5$ Hz, CH_3), 1.19 (18H, m), 3.1–4.1 (3H,m, C*H*OR); ^{13}C nmr δ: 19.0, 21.9, 26.0, 26.2, 27.7, 32.7, 32.8, 35.1, 35.4, 41.9, 43.2, 65.2, 65.4, 96.6; ms *m/e*: 224 (M^+); (*ii*) spiroketal **44**: (2.60 g, 12.8%); ir: 1052 and 992 cm^{-1}; ^1H nmr δ: 1.12 (3H, d, $J = 10.5$ Hz, CH_3), 1.30 (18H, m), 2.8–4.5 (3H, m, CHOR); ^{13}C nmr δ: 18.4, 22.2, 25.9, 26.1, 27.7, 28.0, 32.2, 33.0, 37.2, 41.9, 44.2, 66.4, 68.3, 97.9; ms *m/e*: 224 (M^+); (*iii*) spiroketal **43**: (3.40 g, 16.7%); ir: 1068 and 1006 cm^{-1}; ^1H nmr δ: 1.21 (3H, d, $J = 10.2$ Hz, CH_3), 1.52 (18H, m); 2.8–4.3 (3H, m, CHOR); ^{13}C nmr δ: 19.3, 21.9, 26.0, 26.3, 27.7, 32.4, 32.9, 35.0, 36.0, 37.3, 41.9, 66.3, 68.6, 97.8; ms *m/e*: 224 (M^+).

Isomerization of Spiroketals 43, 44, and 46

Spiroketal **43** (224 mg, 1 mmol) in anhydrous methanol (25 mL) containing one drop of concentrated hydrochloric acid was left at RT for 20 h. The solvent was evaporated, ether was added, and the solution was dried ($MgSO_4$), filtered, and evaporated to dryness. ^1H and ^{13}C nmr analysis showed that a ≃1:1 mixture of spiroketals **43** and **44** was obtained.

The same experiment was repeated starting with spiroketal **44** and an identical result was obtained. However, spiroketal **46** was recovered unchanged when submitted to the same experimental conditions.

Deuteration of a mixture of spiroketals **43** and **44** under the conditions described previously gave the spiroketals **43** and **44** containing two deuterium atoms in ring B as shown by ^{13}C nmr analysis.

1,7-Dithia and 1-oxa-7-thiaspiro[5.5]undecanes. Excellent systems for the study of stereoelectronic effects (anomeric and *exo*-anomeric effects) in the monothio and the dithioacetal functions[1]

PIERRE DESLONGCHAMPS, DARYL D. ROWAN, NORMAND POTHIER, AND JOHN K. SAUNDERS

Laboratoire de Synthèse Organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received September 3, 1980

PIERRE DESLONGCHAMPS, DARYL D. ROWAN, NORMAND POTHIER, and JOHN K. SAUNDERS. Can. J. Chem. **59**, 1122 (1981).

1,7-Dithiaspiro[5.5]undecane (**2**), 1-oxa-7-thiaspiro[5.5]undecane (**4**), and the tricyclic systems **3**, **5**, and **6** have been prepared by the acid cyclization of the appropriate ketone dithiol or hydroxy ketone thiol precursors.

The configuration and the conformation of the products obtained was determined by ^{13}C nmr analysis and equilibration studies. The experimental results can be rationalized by taking into account the anomeric and the *exo*-anomeric effects and the usual steric interactions.

PIERRE DESLONGCHAMPS, DARYL D. ROWAN, NORMAND POTHIER et JOHN K. SAUNDERS. Can. J. Chem. **59**, 1122 (1981).

On a préparé le dithia-1,7 spiro[5.5]undécane (**2**), le oxa-1 thia-7 spiro[5.5]undécane (**4**) et les systèmes tricycliques **3**, **5** et **6** par cyclisation en milieu acide des précurseurs dimercaptocétonique ou mercaptohydroxycétonique approprié.

La configuration et la conformation des produits obtenus ont été déterminées par la rmn du ^{13}C et par des études d'équilibration. Les résultats expérimentaux sont expliqués en tenant compte de l'effet anomère, de l'effet *exo*-anomère et des interactions stériques habituelles.

In the accompanying publications,[2] we have shown that the 1,7-dioxaspiro[5.5]undecane system exists in conformation **1***a* in preference to the other conformations **1***b* and **1***c* (Scheme 1). The relative stability of **1***a–c* was rationalized by taking into account the stereoelectronic (anomeric (3) and *exo*-anomeric (4) effects) and the classic steric effects. It can be concluded from this study that 1,7-dioxaspiro[5.5]undecane is an excellent system for the evaluation of the stereoelectronic effects in the acetal function. This work also showed that both the anomeric and the *exo*-anomeric effects correspond to a minimum value of about 1.4 kcal/mol, a value in accord with that of Descotes *et al.* (5) for the anomeric effect and which we have recently confirmed (6).

We wish to report an analogous study on the stereoelectronic effects of the monothio and the dithioacetal functions (7–9). We have studied the parent compounds, 1,7-dithiaspiro[5.5]undecane (**2**), 1-oxa-7-thiaspiro[5.5]undecane (**4**), and the three tricyclic systems **3**, **5**, and **6**.

Results and Discussion

Dithiaspiro Acetals

1,7-Dithiaspiro[5.5]undecane **2** was prepared by the method described in Scheme 2 (**7** → **8** → **2**). The ^{13}C nmr spectra of **2** at room temperature and at low temperature (≃ −130°C, $CHFCl_2$) are virtually identical and they show five peaks only.[3] This result shows that **2** is essentially a conformationally rigid system.

Compound **2** can exist theoretically in the three conformations **2***a*, **2***b*, and **2***c* (Scheme 1), which must show 5, 9, and 5 lines respectively in their ^{13}C nmr spectra. Consequently, conformer **2***b* can be eliminated on that basis and compound **2** should exist in either of the two conformations **2***a* or **2***c*.

The classic steric interactions in these three conformers can be analyzed as follows. In conformer **2***a*, the two sulfurs are axially oriented to a ring, in conformer **2***c* the two sulfurs are equatorially oriented, whereas in conformer **2***b* one sulfur is axial while the other is equatorial to a ring. If we accept that when a methylene group is axially oriented, it corresponds to two *gauche* forms of *n*-butane (2 × 0.9 = 1.8 kcal/mol),[4] and that when a sulfur is axially oriented, it corresponds to two *gauche* forms of S—CH_2—CH_2—CH_2 (2 × 0.4 = 0.8 kcal/mol (10)), then the steric effects for **2***a*, **2***b*, and **2***c* should correspond to 1.6 (4 × 0.4), 2.6 (2 × 0.4 + 2 × 0.9), and 3.6 (4 × 0.9) kcal/mol respectively. Thus, the conclusion from this study is that compound **2** should exist as a mixture of a major (**2***a*, 0 kcal/mol) and a minor (**2***b*, 1 kcal/mol) conformer. It is therefore not possible to rational-

[1]This work has been presented at the First International Symposium on Stereoelectronic Effects, University of St. Andrews, Scotland, July 1980.

[2]See refs. 1 and 2.

[3]A detailed account of the ^{13}C nmr spectral analysis is reported in the accompanying publication, see ref. 2.

[4]We make the assumption that the *gauche* form of CH_2—S—CH_2—CH_2 is equivalent to that of *n*-butane.

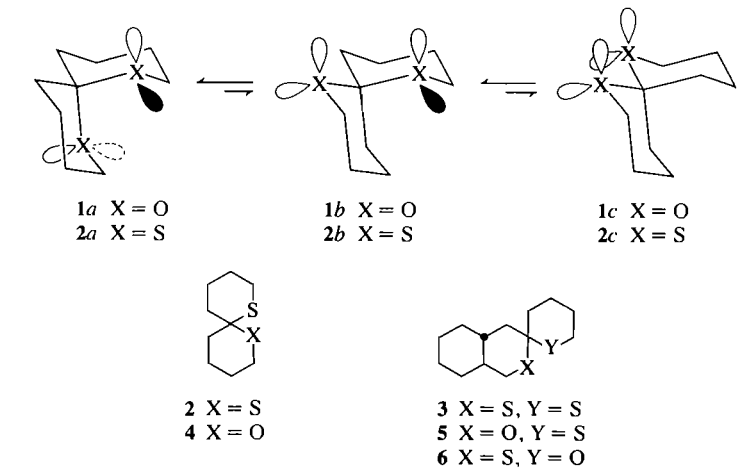
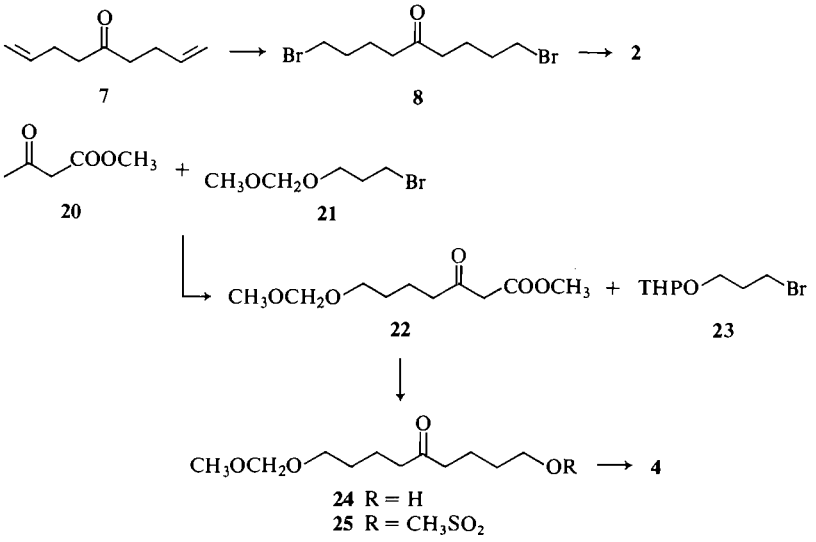


SCHEME 1



SCHEME 2

ize the experimental results on the basis of steric effects only. This indicates that stereoelectronic effects must also play a role.

Conformer **2***a* has two sulfurs each having an electron pair oriented antiperiplanar to a polar C—S bond, conformer **2***b* has only one, whereas conformer **2***c* has none. Consequently, **2***a* has two anomeric effects, **2***b* only one, and **2***c* none. If we accept that the anomeric effect is a stabilizing effect (10, 11), it must be of the order of −1.4 kcal/mol in order to arrive at a theoretical rationalization which agrees with the experimental result. Indeed with such a value, the relative energies of conformers **2***a*, **2***b*, and **2***c* become 0, 2.4, and 4.8 kcal/mol respectively (Table 1). Thus, compound **2** is a conformationally rigid system which exists in conformation **2***a* which has the least steric interactions and two anomeric effects.

The results obtained with the dithia tricyclic system **3** confirm the above conclusion. With **3**, two isomers **10** and **11** are possible from the cyclization of the ketone dithiol precursor **9** (Scheme 3) and they can exist in two conformations each, which are **10***a*–*b* and **11***a*–*b*, respectively. The detailed analysis of the relative stability of these four structures is described in Table 1. Conformer **10***a* (0 kcal/mol) is more stable than **10***b* (2.4 kcal/mol), isomer **10** should therefore exist in conformation **10***a* only. Similarly, conformer **11***a* (2.4 kcal/mol) is more stable than **11***b* (4.8 kcal/mol), isomer **11**

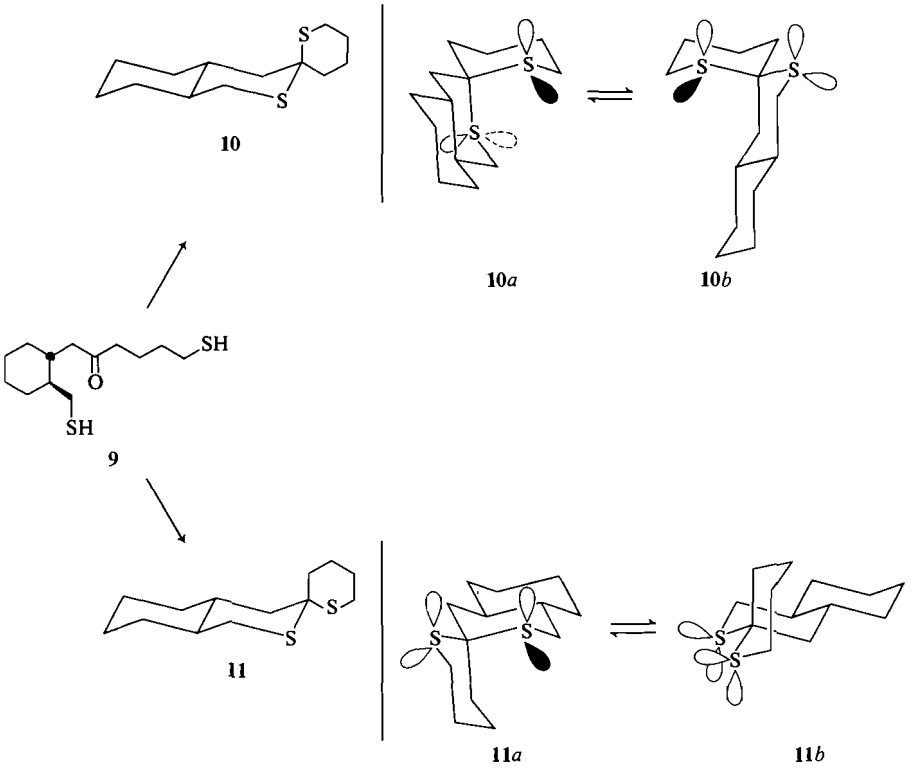

SCHEME 3

should exist in conformation **11***a* only. However, since conformer **10***a* is more stable than conformer **11***a* by 2.4 kcal/mol, and since isomers **10** and **11** can be interconverted by equilibration under acidic conditions, only isomer **10** should be observed under thermodynamically controlled conditions at low temperature.

The preparation of the diacetate derivative **19** of ketone dithiol **9** is described in Scheme 4 (**12** + **13** → **14** → **15** → **16** → **17** → **18** → **19**). Treatment of **19**

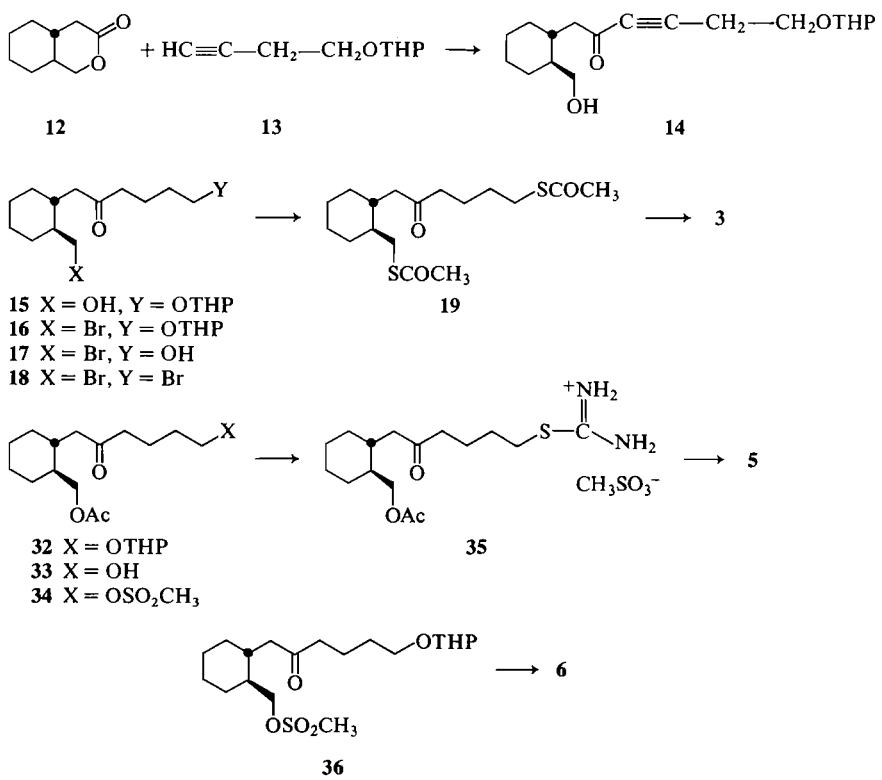
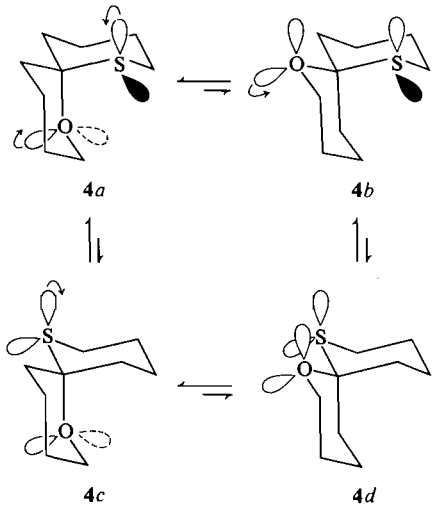


SCHEME 4

under acidic conditions (25% H_2SO_4/THF) gave a mixture of a major and a minor isomer which were separated by chromatography and identified as isomers **10** and **11**, respectively. Equilibration (concentrated HCl/benzene) of **10** gave a mixture of **10** and **11** in a 98:2 ratio. Deuteration of **10** (D_2SO_4/CH_2Cl_2) yielded a partially di- and trideuterated **10** and again the formation of a small percentage of **11** was detected. The ^{13}C nmr analysis showed that the major isomer corresponds to **10** and that it exists in conformation **10***a*.[5] The fact that a small percentage (2%) of **11** was detected at room temperature shows that, at low temperature, less than 0.1% of **11** would have been present, which confirms that, at low temperature, 1,7-dithiaspiro[5.5]undecane (**2**) is a compound which exists essentially in conformation **2***a* only.



SCHEME 5

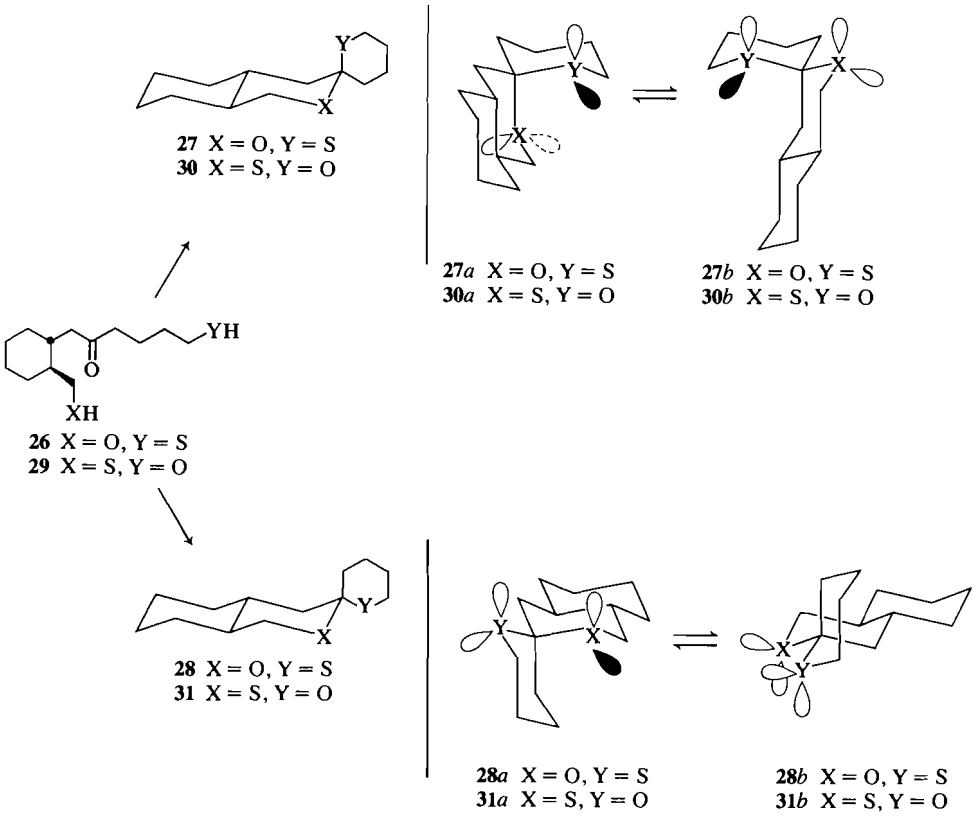
The above results show conclusively that the anomeric effect for sulfur in the dithioacetal function must be near 1.4 kcal/mol.

Monothiaspiro Acetals

1-Oxa-7-thiaspiro[5.5]undecane (**4**) can exist theoretically in four conformations (**4***a–d*, Scheme 5). The steric interactions in the four conformations **4***a–d* must be approximately 1.6, 2.6, 2.6, and 3.6 kcal/mol, respectively. Conformer **4***a* has two anomeric effects (the sulfur and the oxygen have each an electron pair oriented antiperiplanar to a polar bond), conformer **4***b* has one anomeric effect (the oxygen), conformer **4***c* has also one anomeric effect (the sulfur), and conformer **4***d* has none. If we take a value of −1.4 kcal/mol each for the

[5]Due to the small quantity obtained, the ^{13}C nmr spectra of **11** was not obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.



SCHEME 6

oxygen and the sulfur anomeric effect, we can predict that compound **4** will exist in conformation **4***a* only (Table 1).

1-Oxa-7-thiaspiro[5.5]undecane (**4**) was prepared by the method described in Scheme 2 (**20** + **21** → **22** + **23** → **24** → **25** → **4**) and its ^{13}C nmr spectral analysis showed that it exists in conformation **4***a* only. This conclusion was further confirmed by the study of the tricyclic spiro systems **5** and **6**.

The hydroxyketone thiol **26** (Scheme 6) can cyclize to yield the two isomers **27** and **28** which can take each two different conformations (**27***a–b* and **28***a–b*). An analysis of the steric and stereoelectronic effects leads again to the prediction that under equilibrating conditions, only isomer **27** should be formed and that it should exist in conformation **27***a* only (Table 1).

The isomeric hydroxyketone thiol **29** can also cyclize to yield two isomers (**30** and **31**) which can also take two different conformations (**30***a–b* and **31***a–b*) each. However, we can predict again that under equilibrating conditions, essentially only isomer **30** existing in conformation **30***a* should be observed (Table 1).

The preparation of the isomeric tricyclic monothio spiro systems **5** and **6** is described in Scheme 4 (**15** → **32** → **33** → **34** → **35** → **5** and **15** → **36** → **6**). An identical result was obtained in both series. With the spiro system **5**, the isomer **27** was the only product observed and ^{13}C nmr spectral analysis showed that it exists in conformation **27***a* only. Upon equilibration under acidic conditions (0.1 *N* DCl in 10% D_2O/CH_3OH, reflux), isomer **27** incorporated deuterium but the formation of isomer **28** was not observed. With the spiro system **6**, the isomer **30** was the only product observed and it was shown to exist in conformation **30***a* only. Similarly, isomer **30** does not equilibrate with isomer **31** under acidic conditions which allow deuterium incorporation.

The fact that a small percentage of isomers **28** and **31** was not observed during the deuteration experiments of isomers **27** and **30** indicates that the anomeric effect for oxygen and for sulfur must be slightly larger than 1.4 kcal/mol in the monothioacetal function.

Conclusion

These results constitute very strong evidence concerning the importance for the stereoelectronic

(anomeric and *exo*-anomeric) effects of the oxygen and the sulfur atoms in the monothio and the dithioacetal functions.

Experimental

Vapor-phase chromatographic (vpc) analysis and separations were performed on a Varian Aerograph instrument, model 2800 equipped with a thermal conductivity detector. The infrared (ir) spectra were obtained in chloroform, unless otherwise stated, on a Perkin-Elmer 257 spectrophotometer. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded in deuterochloroform on a Bruker WP-60 instrument with TMS as an internal standard. The ^{13}C nmr spectra were recorded on a Bruker HX-90 spectrometer equipped with a Nicolet 1083 computer (8K memory for data) and operating in the Fourier transform mode. Spectra were recorded in deuterochloroform with a sweep width of 5000 Hz. Mass spectra were obtained on Hitachi-Perkin-Elmer RMU-6-A and Micromass ZAB-2F machines.

The following abbreviations are used. % E/H: % of ether in hexane; % EA/H: % of ethyl acetate in hexane; RT: room temperature; s: singlet; d: doublet; t: triplet; quin: quintet; m: multiplet; b: broad.

Ketone 7

α-Alkylation of methyl acetoacetate (11) with allyl bromide gave methyl 3-oxohept-6-enoate (84%, bp 72°C/2 Torr). α-Alkylation (12) with allyl bromide followed by decarboxylation by refluxing with aqueous sodium hydroxide gave ketone **7** (48%, bp 70–72°C/6 Torr); ir: 3075, 1715, 1640, 970, and 888 cm^{-1}; ^{1}H nmr δ: 2.34 (8H, m), 4.73–6.04 (6H, m).

Dibromide 8

Ketone **7** (1.592 g, 11.5 mmol) in pentane (500 mL) was cooled in an ice–salt bath and purged with nitrogen (≃10 min) in a photochemical apparatus. Anhydrous hydrogen bromide was bubbled in and the solution was irradiated (450 W Hanovia Hg lamp) for 15 min. After purging with nitrogen, the solution was washed with saturated sodium bicarbonate containing some sodium thiosulfate (1×), then with brine (1×), before it was dried (Na_2SO_4) and evaporated to give a black oil (3.36 g). Medium pressure chromatography on silica gel, eluting with 25% E/H gave dibromide **8** (1.97 g, 56.9%) as a clear oil; ir: 1716, 1403, 1367, 1243, and 1078 cm^{-1}; ^{1}H nmr δ: 1.76 (8H, m), 2.43 (4H, t, J = 6 Hz), and 3.38 (4H, t, J = 6 Hz); ms *m/e*: 221/219 (M^+ − Br), 165/163 (M^+ − C_4H_8Br), and 137/135 (M^+ − C_5H_8OBr).

1,7-Dithiaspiro[5.5]undecane (2)

A solution of dibromide **8** (1.239 g, 4.13 mmol) in 95% ethanol (30 mL) and thiourea (0.69 g, 9.06 mmol) was refluxed for 3 h. Solvent (10 mL) was distilled off and sodium hydroxide (10%, 10 mL) was added. After 4 h of reflux, hydrochloric acid (10%, 10 mL) was added, followed, after cooling, by ether. The mixture was left stirring overnight. The aqueous phase was diluted with brine and extracted with ether (1×). The ethereal phase was washed with brine (1×), dried (Na_2SO_4), and the solvent was evaporated. Elution with 10% E/H from a short column of silica gel gave 1,7-dithiaspiro[5.5]undecane (**2**) (685 mg, 88%) as a pale oil. Preparative vpc (R_f 9.3 min, 5% FFAP on Chromosorb W, 5 ft × ¼ in., 155°C) gave an analytical sample; ir: 1259, 1250, 1230, 978, and 924 cm^{-1}; ^{1}H nmr δ: 1.36–2.15 (12H, m), and 2.23–3.27 (4H, m); ^{13}C nmr δ: 2.16, 27.5, 42.4, C6 was not observed; ms *m/e*: 188.0694 ($C_9H_{16}S_2$ requires 188.0693), 154, and 127.

Bromoalcohol 17

The THP-hydroxyketone **15** was prepared from the bicyclic lactone **12** by the method described in ref. 1. THP-hydroxyketone **15** (846 mg, 2.71 mmol) in pyridine (5.0 mL) was cooled in an ice–salt bath and mesyl chloride (0.25 mL, 1.2 equiv.) was added dropwise. After 21 h at 0°C, tetra-*n*-butylammonium bromide (1.00 g, 3.11 mmol) was added and the mixture was warmed to 50°C with hexamethylphosphoramide (2.0 mL) for 5 h. The reaction was quenched with 5% sulfuric acid and the aqueous phase was extracted with ether (3×). The combined ether phases were washed sequentially with 5% sulfuric acid (1×), saturated sodium bicarbonate (2×), and brine (2×). Drying (Na_2SO_4) and evaporation gave bromo-THP **16** (843 mg, 87%) as an orange oil containing still some hexamethylphosphoramide; ir: 1713, 1105, 1053, 1003, and 960 cm^{-1}; ^{1}H nmr δ: 1.62 (20H, m), 2.45 (4H, m, CH_2COR), 3.51 (2H, d, J = 3 Hz, CH_2Br), and 3.67 (4H, bm, CH_2O), and 4.55 (1H, s, OCHO).

Hydrolysis of bromo-THP **16** was accomplished in methanol (10 mL) and water (1 mL) with *p*-toluenesulfonic acid. After 5 h at RT, the bulk of the solvent was removed under reduced pressure and the residue was diluted with ether. After washing with saturated sodium bicarbonate (1×) and brine (1×), the solution was dried (Na_2SO_4) and evaporated to give a yellow oil (651 mg). Chromatography on silica gel (60 g) gave on elution with 50% EA/H the bromoalcohol **17** (480 mg, 61%) as a clear oil; ir: 3445, 1706, and 1062 cm^{-1}; ^{1}H nmr δ: 0.8–2.1 (15H, m), 2.46 (4H, m), 3.51 (2H, d, J = 3 Hz, CH_2Br), and 3.62 (2H, t, J = 6 Hz, CH_2OH); ms *m/e*: 193.1592 (M^+ − Br − H_2O; $C_{13}H_{21}O$ requires 193.1593).

Dibromide 18

To a stirred solution of bromoalcohol **17** (336 mg, 1.15 mmol) in pyridine (1 mL) in an ice–salt bath was added mesyl chloride (95 μL, 1.23 mmol). After 4 h at 0°C, tetra-*n*-butylammonium bromide (540 mg, 1.68 mmol) was added and the solution was protected from light and stirred at RT for 13 h. The reaction was diluted with ether and washed sequentially with 5% sulfuric acid (2×), brine (1×), saturated sodium bicarbonate (1×), and brine (1×). Drying (Na_2SO_4) and evaporation gave dibromide **18** (401 mg, 98%) as a pale oil pure by tlc; ir: 1708 and 1285 cm^{-1}; ^{1}H nmr δ: 1.75 (14H, m), 2.46 (4H, deformed quin, J = 6 Hz), 3.52 (2H, d, J = 2.5 Hz), and 3.54 (2H, t, J = 6 Hz); ms *m/e*: no characteristic peak observed.

Dithioacetate 19

To dibromide **18** (300 mg, 8.47 mmol) in hexamethylphosphoramide (1.5 mL) was added potassium thioacetate (314 mg, 27.5 mmol) and water (0.25 mL) and the resulting red solution was stirred in the dark at RT for 10 h. Dilution with water (100 mL) and ether extraction (3×) gave, after washing with water (1×), brine (1×), and drying (Na_2SO_4), a yellow oil (366 mg). Chromatography on silica gel gave, on elution with 20% E/H, the dithioacetate **19** (299 mg, 77%) as a clear oil pure by tlc; ir: 1680 (shoulder at 1700), 1355, 1132, 1112, and 902 cm^{-1}; ^{1}H nmr δ: 2.32 (6H, s, $SCOCH_3$), and 2.22–3.25 (8H, m); ms *m/e*: 301.1309 (M^+ − CH_3CO; $C_{15}H_{25}S_2O_2$ requires 301.1304), 269 (M^+ − CH_3COS), 241, 209, and 171.

Tricyclic Spiro Dithioacetals 10 and 11

To dithioacetate **19** (266 mg, 0.77 mmol) in tetrahydrofuran (20 mL) under nitrogen was added degassed sulfuric acid (25%, 2 mL). After 24 h of reflux under nitrogen, the reaction was quenched with saturated sodium bicarbonate and the organic phase was removed and evaporated. The aqueous phase was extracted with ether (1×), and the combined organic fractions were washed with brine (1×), dried (Na_2SO_4), and evaporated

to give a pale oil (213 mg). Chromatography on Florisil gave the following, on elution with 2% E/H.

(*i*) Dithioacetal **10** (93.4 mg, 50%) as white crystals on standing, mp 43–45°C; ir (CH_2Cl_2): 1216, 1146, and 956 cm^{-1}; ^1H nmr δ: 1.72 (18H, m), and 2.20–3.06 (4H, m, CH_2S); ^{13}C nmr δ: 21.7, 26.2, 26.4, 27.1, 27.5, 32.6, 33.2, 34.0, 37.3, 42.7, 44.8, 50.4, and 55.7; ms *m/e*: 242.1164 (M^+; $C_{13}H_{22}S_2$ requires 242.1163) and 209.

(*ii*) Dithioacetals **10** and **11** (50 mg, 27%). Preparative layer chromatography (3% E/H) gave, at higher R_f, compound **10** (37 mg) and, at lower R_f, dithioacetal **11** (9.6 mg, 5%) as white crystals, mp 101–103°C; ir (CH_2Cl_2): 1235, 1142, and 961 cm^{-1}; ^1H nmr δ: 1.76 (18H, m) and 2.18–3.16 (4H, m, CH_2S); ms *m/e*: 242.1164 (M^+; $C_{13}H_{22}S_2$ requires 242.1163) and 209.

(*iii*) Elution through to 10% EA/H gave a fraction of dithioacetate **19** (22.8 mg, 8.6%).

By vpc (5 ft × ¼ in, 3% SE-30 on Chromosorb W, 220°C) compounds **10** and **11** showed R_t 6.5 and 8.0 min, respectively.

Isomerization of Dithioacetal 10

Dithioacetal **10** (8 mg) in benzene (0.5 mL) was stirred with hydrochloric acid (concentrated, one drop) for 3 days. The mixture was diluted with ether and saturated sodium bicarbonate was added. The organic phase was dried ($NaHCO_3$ and Na_2SO_4) and evaporation gave a yellow oil (6.4 mg) which was identified as dithioacetal **10** (tlc, ^1H nmr, and ir). Vapor-phase chromatography showed a mixture of **10**:**11** in a 98:2 ratio.

Deuterium Incorporation in Dithioacetal 10

Treatment of dithioacetal **10** with deuterium chloride (7% in 20% D_2O/CH_3OD, 12 h, reflux) gave dithioacetal **10** (vpc, tlc) showing $M^+ + 2$ and $M^+ + 3$ in ms; vpc indicated the presence of dithioacetal **11** (≈2%). Treatment of **10** with deuterated sulfuric acid in dichloromethane at room temperature gave also dithioacetal **10** showing $M^+ + 2$ and $M^+ + 3$ peaks in ms; vpc indicated again the presence of dithioacetal **11**.

Ketoester 22

To sodium hydride (1.43 g, 29.8 mmol, 50% dispersion) in tetrahydrofuran (25 mL) under nitrogen, stirred at 0°C, was added methyl acetoacetate (3.13 g, 27.0 mmol) dropwise. After 10 min, *n*-butyllithium (1.6 *M* in hexane, 17.0 mL, 27.2 mmol) was added to give a yellow solution. After 10 min at 0°C, the methoxymethyl ether derivative **21** of 3-bromopropanol (5.18 g, 28.2 mmol) was added to give a deep crimson solution which was allowed to warm to RT over 2.5 h. Addition to saturated ammonium chloride, and extensive ether extraction followed by washing until neutral, drying, and evaporation gave a crude product. Distillation (124–125°C/5 Torr) gave pure ketoester **22** (1.91 g, 33%); ^1H nmr δ: 1.70 (4H, m), 2.65 (2H, m), 3.34 (3H, s, CH_3OR), 3.50 (4H, m), 3.73 (3H, s, COOMe), 4.59 (2H, s, OCH_2O).

Methoxymethylbromoacetal 21

To a stirred suspension of phosphorous pentoxide (25 g) in chloroform (200 mL) and dimethoxymethane (350 mL) was added dropwise 3-bromopropanol (12 g) in chloroform (50 mL). After 5 h, the solvent was decanted and washed with saturated sodium carbonate solution. The solid residue was also dissolved in saturated sodium carbonate and extracted with chloroform (1×). The combined organic phases were further washed with saturated sodium carbonate (1×), dried (Na_2SO_4), and evaporated to give acetal **21** sufficiently pure by vpc (10% SE-30 on Chromosorb W, 5 ft × ¼ in., 100°C) for subsequent reactions. Distillation (34–35°C/4 Torr) gave pure material (4.1 g, 26%) but also extensive polymerization; ^1H nmr δ: 2.07 (2H, quin, J = 6 Hz), 3.26 (3H, s, OCH_3), 3.45 (2H, t, J = 6 Hz), 3.58 (2H, t, J = 6 Hz), 4.48 (2H, s, OCH_2O).

THP-bromide 23

To 3-bromopropanol (13.0 g, 93 mmol) in dihydropyran (9.0 g, 107 mmol) and benzene (60 mL) was added *p*-toluenesulfonic acid (10 crystals). After stirring for 12 h at 65°C, the solution was washed with saturated sodium bicarbonate (1×). The aqueous phase was extracted with ether (3×) and the combined organic phases were washed with brine (1×), dried ($MgSO_4$), and evaporated. Distillation gave **23** (14.2 g, 68.2%); bp 85–90°C/4 Torr, pure by vpc (10% SE-30 on Chromosorb W, 5 ft × ¼ in., 165°C, R_t 7.2 min); ^1H nmr δ: 1.42 (4H, m), 2.13 (2H, quin, J = 6 Hz), 3.32–4.07 (4H, m, CH_2O), 3.52 (2H, t, J = 6.6 Hz, CH_2Br), 4.59 (1H, m, OCHO).

Methoxymethyl Ether Hydroxyketone 24

To a stirred solution of sodium (220 mg, 9.57 mmol) in ethanol (30 mL) at RT under nitrogen was added dropwise the ketoester **22** (1.91 g, 8.76 mmol), and then the tetrahydropyranyl ether derivative **23** of 3-bromopropanol (2.15 g, 9.64 mmol). The resulting solution was refluxed for 12.5 h when tlc indicated a complete reaction. Sodium hydroxide (10%, 20 mL) was added and, after 3 h of reflux and standing overnight at RT, the system was saturated with sodium chloride and extracted with ether (2×). Washing with saturated ammonium chloride (1×), drying (Na_2SO_4), and evaporation gave a yellow oil (2.50 g).

Hydrolysis of the tetrahydropyranyl ether was accomplished in methanol (40 mL) and water (2 mL) with a catalytic amount of *p*-toluenesulfonic acid over 3 h at RT. Sodium bicarbonate was added and the solvent was evaporated.

The residue was diluted with ether and the aqueous phase was discarded. Further washing with saturated sodium bicarbonate (1×) and brine (1×), drying (Na_2SO_4), and evaporation gave the crude product (1.54 g) as a yellow oil. Medium pressure liquid chromatography (30% E/H to pure E) produced a number of high R_f products which were discarded. The polar fraction (≈0.5 g) was further purified on silica gel. Elution with 40% EA/H gave pure methoxymethyl ether hydroxyketone **24** (317 mg, 17%); ir: 3480, 1715, 1135, 1094, and 1020 cm^{-1}; ^1H nmr δ: 1.65 (m), 2.45 (4H, deformed t, CH_2COR), 3.45 (3H, s, CH_3O), 3.52 (4H, m, CH_2O), and 4.60 (2H, s, OCH_2—O); ms *m/e* (CI, CH_4): 219 ($M^+ + 1$), 200 ($M^+ - H_2O$), 185 ($M^+ - H_2O - CH_3$), 169, and 155; ms *m/e*: 200.1434 ($M^+ - H_2O$; $C_{11}H_{20}O_3$ requires 200.1412).

Methoxymethyl Ether Ketomesylate 25

To a stirred solution of methoxymethyl ether hydroxyketone **24** (240 mg, 1.10 mmol) in pyridine (0.44 mL) at 0°C was added dropwise mesyl chloride (0.10 mL, 1.2 equiv.). After 3.5 h, the reaction was quenched with 0.5% sulfuric acid and ether. Ether extraction (3×), followed by washing with sulfuric acid (0.5%, 1×), brine (1×), saturated sodium bicarbonate (1×), and brine (2×), drying (Na_2SO_4), and evaporation gave methoxymethyl ether ketomesylate **25** (306 mg, 94.2%) as a clear oil; ir: 1717, 1348, 1160, 1015, and 910 cm^{-1}; ^1H nmr δ: 1.64 (8H, m), 2.43 (4H, deformed t, CH_2COCH_2), 2.99 (3H, s, CH_3SO_2), 3.33 (3H, s, CH_3O), 3.49 (2H, t, CH_2O), 4.20 (2H, t, $CH_2OSO_2CH_3$), and 4.58 (2H, s, OCH_2O).

1-Oxa-7-thiaspiro[5.5]undecane (4)

To methoxymethyl ether ketomesylate **25** (306 mg, 1.03 mmol) in dry ethanol (5 mL) was added thiourea (157 mg, 2.06 mmol) and the resulting solution was refluxed under nitrogen for 4.5 h. Evaporation of the solvent and dissolution of the resulting oil in chloroform gave a white precipitate of thiourea which was filtered. Evaporation of the filtrate gave a pale viscous oil (348 mg) which was dissolved in sulfuric acid (0.5%) and washed with ether (1×). The ethereal layer was washed with sulfuric acid (0.5%) and the combined aqueous phases were made alkaline with sodium hydroxide (10%, 5 mL). Ethanol (10 mL)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

was added and the mixture was refluxed for 3 h. Sulfuric acid (5%, 10 mL) was added and the solution was left at RT for 24 h. The solution was neutralized with sodium bicarbonate and was continuously extracted overnight with dichloromethane. Evaporation of the dichloromethane gave 1-oxa-7-thiaspiro[5.5]undecane (**4**) (107 mg, 57%) as a pale oil which showed one peak in vpc. Chromatography on silica gel (elution with 2% E/H) gave an analytical sample homogeneous by tlc and vpc (R_f 6.3 min, 5% FFAP on Chromosorb W, 5 ft. × ¼ in., 120°C); ir: 1269, 1095, 1078, 1068, 1042, 991, and 955 cm^{-1}; ^1H nmr δ: 1.35–1.90 (12H, m), 2.30–2.98 (2H, m, CH_2S), and 3.50–4.18 (2H, m, CH_2O); ^{13}C nmr δ: 19.2, 21.1, 25.1, 25.9, 27.2, 38.1, 41.6, 61.6, and 82.6; ms *m/e*: 172.0918 ($C_9H_{16}SO$ requires 172.0922).

Ketone Acetate Mesylate 34

Acetylation of THP-hydroxyketone **15** to give the acetate derivative **32** followed by hydrolysis to yield the hydroxyketone acetate **33** is described in ref. 1. To a stirred solution of hydroxyketone acetate **33** (212 mg, 0.79 mmol) in pyridine (0.50 mL) at 0°C was added dropwise mesyl chloride (0.08 mL, 1.3 equiv.). After 2.5 h, the reaction was poured into sulfuric acid (0.5%, 50 mL) and extracted with ether (3×). The combined ethereal layers were washed with phosphate buffer (pH 6.0, 1×) saturated sodium bicarbonate (1×), buffer (1×), and brine (1×). Drying (Na_2SO_4) and evaporation gave ketone acetate mesylate **34** (237 mg, 87%) as a clear oil; ir: 1730, 1350, 1220 (b), 1161, and 913 cm^{-1}; ^1H nmr δ: 0.83–1.93 (14H, m), 2.03 (3H, s, $OCOCH_3$), 2.44 (4H, m. $W/2$ = 14 Hz, CH_2COCH_2), 2.99 (3H, s, OSO_2CH_3), 3.94 (2H, d, J = 4 Hz, CH_2OCOCH_3), and 4.21 (2H, t, J = 6 Hz, $CH_2OSO_2CH_3$); ms *m/e*: 288 ($M^+ - CH_3CO_2H$), 252 ($M^+ - CH_3SO_3H$).

Tricyclic Monothioacetal 27

To ketone acetate mesylate **34** (232 mg, 0.67 mmol) in dry ethanol (10 mL) was added thiourea (119 mg, 1.56 mmol) and the resulting solution was refluxed for 3 h. Evaporation and dissolution of the resulting oil in chloroform gave a precipitation of thiourea which was filtered and removal of the solvent yielded the acid thiouronium salt **35** (305 mg) as a clear oil; ^1H nmr ($CDCl_3/D_2O$) δ: 2.05 (3H, s, $OCOCH_3$), 2.50 (4H, m, CH_2COCH_2), 2.77 (3H, s, $CH_3SO_2O^-$), 3.16 (2H, deformed t, CH_2SR), 3.96 (2H, b s, CH_2OCOCH_3), and 4.75 (HOD).

The thiouronium salt **35** was dissolved in sulfuric acid (0.5%, 20 mL) and extracted with ether (1×). The ethereal phase was washed with water and the combined aqueous phases were made alkaline with sodium hydroxide (10%, 5 mL). Ethanol (10 mL) was added and the mixture was refluxed for 3 h. Sulfuric acid (10%, 5 mL) was added, then ether, and the mixture was left standing at RT for 2 days. The solution was saturated with sodium chloride and extracted with ether (2×). The ethereal extracts were washed with saturated sodium bicarbonate, dried (Na_2SO_4), evaporated, and filtered through silica gel (50% E/H). Evaporation gave tricyclic monothio acetal **27** (88 mg, 58%) as a clear oil. Complete purification (162 mg) was achieved on elution from silica gel with 2% E/H which gave pure **27** as a clear oil which solidifies on cooling and melts just below RT. This compound was homogeneous by tlc and vpc (R_f 5.9 min, 3% SE-30 on Chromosorb W, 5 ft. × ¼ in., 190°C); ir: 1120, 1107, 1038, 1001, 945, and 940 cm^{-1}; ^1H nmr δ: 0.9–2.22 (18H, m), 2.28–2.98 (2H, m, CH_2S), and 3.58 (2H, m, CH_2O); ^{13}C nmr δ: 21.2, 25.4, 26.0, 26.1, 27.3, 27.6, 32.8, 36.1, 41.6, 42.5, 45.4, 66.6, and 83.4 ms *m/e*: 226.1388 ($C_{13}H_{22}SO$ requires 226.1391).

Attempted Isomerization and Deuteration of Tricyclic Monothioacetal 27

Tricyclic monothioacetal **27** (74 mg, 0.33 mmol) in methanol (1.8 mL) and hydrochloric acid (1 N, 0.2 mL) were refluxed under nitrogen for 8 h. After a further 11 h at RT, the solution was concentrated under reduced pressure and the reaction was quenched with saturated sodium bicarbonate solution. After dilution with ether, the aqueous phase was adsorbed into anhydrous sodium sulfate and the ethereal layer was removed and evaporated to give unchanged tricyclic monothioacetal **27** (vpc, tlc, ir, ^1H, and ^{13}C nmr).

Similarly, treatment of compound **27** (9.8 mg) with 0.1 N deuterium chloride in 10% deuterium oxide in monodeuterated methanol (reflux, 2.5 h and RT, 2 h) gave deuterated tricyclic monothioacetal **27** (9.4 mg, 95%); ms *m/e*: 227 ($M^+ + 1$, 9%), 228 ($M^+ + 2$, 27%), 229 ($M^+ + 3$, 39%), and 230 ($M^+ + 4$, 26%).

Tricyclic Monothioacetal 30

Mesyl chloride (0.20 mL, 2.58 mmol) was added dropwise to a solution of THP-hydroxyketone **15** (658 mg, 2.11 mmol) at 0°C. The reaction was complete after 2.5 h. Work-up consisted of filtration (washing with ether), addition of phosphate buffer (5%, pH 6, 150 mL), and extraction with ether (3×). The combined ether extracts were washed with buffer (1×), saturated sodium bicarbonate (3×), buffer (1×), and then brine (2×). Drying (Na_2SO_4) and evaporation gave crude THP-ketonemesylate **36** (752 mg, 92%) as a clear oil; ir: 1715, 1350, 1160, 1008, and 920 cm^{-1}; ^1H nmr δ: 2.36 (4H, m, CH_2COCH_2), 2.89 (3H, s, CH_3SO_2O), 3.47 (4H, b m, CH_2OR), 4.01 (2H, d, J = 3.8 Hz, $CH_2OSO_3CH_3$), and 4.46 (1H, b s, OCHO).

THP-ketonemesylate **36** (598 mg, 1.53 mmol) and thiourea (240 mg, 3.15 mmol) were refluxed in dry ethanol (15 mL) for 2.5 h. After standing at RT for 2 days, the solvent was evaporated and the resulting oil was taken up in chloroform from which crude thiourea (203 mg) precipitated. After filtration, the filtrate was concentrated (633 mg), and ether (20 mL) followed by sulfuric acid (0.5%) was added. The ether phase was washed with sulfuric acid (5%). The combined aqueous phases were washed once with ether and were then made alkaline with sodium hydroxide (10%, 5 mL). Ethanol (10 mL) was added and the solution was refluxed for 4 h. Sulfuric acid (5%, 5 mL) was added, and after standing at RT overnight, the solution was saturated with sodium chloride and extracted with ether (3×). The combined ether extracts were washed with saturated sodium bicarbonate (1×), dried (Na_2SO_4), and evaporated to give a pale oil (184 mg, 53%). Chromatography on silica gel, eluting with 2% E/H, gave crystalline tricyclic monothioacetal **30** (92 mg, 27%); mp 59.5–60.5°C (recrystallized from ethyl acetate) and homogeneous by tlc and vpc (R_f 6.1 min, 3% SE-30 on Chromosorb W, 5 ft. × ¼ in., 190°C); ir: 1058, 1018, and 954 cm^{-1}; ^1H nmr δ: 1.64 (18H, m), 2.22 (2H, m, CH_2S), and 3.48–4.34 (2H, m, CH_2O); ^{13}C nmr δ: 19.2, 26.0, 26.4, 26.7, 30.9, 33.3, 34.2, 37.0, 38.0, 44.3, 49.7, 61.6, and 83.4; ms *m/e*: 226.1383 (M^+; $C_{13}H_{22}SO$ requires 226.1391).

Attempted Isomerization and Deuteration of Tricyclic Monothioacetal 30

To tricyclic monothioacetal **30** (73 mg) dissolved in methanol (9.0 mL) was added hydrochloric acid (1 N, 1.0 mL) and the solution was refluxed for 2.5 h, then left at RT for a further 15 h; vpc and tlc showed only starting material. Saturated sodium bicarbonate was added, and the solution was diluted with ether. The aqueous phase was adsorbed into anhydrous sodium sulfate and the cloudy ethereal phase was filtered through Florisil and then evaporated to give crystalline tricyclic monothioacetal **30** (72 mg, 98%) unchanged and pure by vpc, tlc, ir, ^1H, and ^{13}C nmr.

Tricyclic monothioacetal **30** (10.8 mg) in monodeuterated methanol (1.80 mL) and deuterium oxide (0.02 mL) with deuterium chloride in deuterium oxide (1.13 M, 0.18 mL) were heated to reflux for 2.5 h. After 2 h at RT, work-up gave crystalline tricyclic monothioacetal **30** (9.4 mg, 87%), pure by vpc and tlc. Preparative thin layer chromatography gave material with ms

peaks 228 ($M^+ + 2$, 5%), 229 ($M^+ + 3$, 33%), and 230 ($M^+ + 4$, 62%).

^{13}C chemical shift data for 1,7-dioxaspiro[5.5]undecanes and related compounds

NORMAND POTHIER, DARYL D. ROWAN, PIERRE DESLONGCHAMPS, AND JOHN K. SAUNDERS
Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received September 3, 1980

NORMAND POTHIER, DARYL D. ROWAN, PIERRE DESLONGCHAMPS, and JOHN K. SAUNDERS. Can J. Chem. **59**, 1132 (1981).

The carbon-13 chemical shift data for a series of 1,7-dioxa-, 1-oxa-7-thia-, and 1,7-dithiaspiro[5,5]undecanes and related compounds are presented. Analysis of this data led to structural and stereochemical assignments. The results show that the unsubstituted spiro bicyclic compounds exist in the conformation shown as conformation *a*. It is shown that the ^{13}C chemical shift parameters developed for cyclohexane derivatives can be applied to the sulfur but not to the oxygen heterocycles.

NORMAND POTHIER, DARYL D. ROWAN, PIERRE DESLONGCHAMPS et JOHN K. SAUNDERS. Can. J. Chem. **59**, 1132 (1981).

Les déplacements chimiques en rmn de ^{13}C de plusieurs dérivés de dioxa-1,7, oxa-1-thia-7 et dithia-1,7 spiro[5,5]undécanes sont présentés ainsi que ceux de quelques composés modèles. Les structures et la stéréochimie des composés ont été attribuées à partir de l'analyse de ces données. L'analyse conformationnelle démontre que les composés spiro-bicyclique non substitués existent dans la conformation *a*. On démontre que les paramètres de déplacement chimique de ^{13}C développés pour les dérivés du cyclohexane peuvent être appliqués aux hétérocycles sulfurés mais ils ne peuvent pas être utilisés pour les composés oxygénés.

The determination of the value of the anomeric effect using the bicyclic acetals and thioacetals described in the accompanying publications required determination of the preferred conformations and conformer populations of the various molecules. Carbon-13 chemical shifts are now accepted as one of the most valuable spectroscopic means for such determination although correlation of chemical shift with molecular geometry is generally obtained by empirical means (1–3). The idea then, for a conformationally mobile system, is to predict the chemical shift of each carbon in each conformer and then to compare these values with those obtained experimentally to ascertain the preferred conformation and in the limit, conformer populations. The empirical methods for 6-membered carbocyclic compounds in the chair conformation are reasonably well developed (3). However, the derived parameters in these systems may or may not hold true for heterocyclic compounds. For example, the effect at the β-carbon, upon introduction of a methyl group in cyclohexane, is 8.9 ppm whereas it is 5.8 or 7.3 ppm in 1,3-dioxans depending on whether the methyl group is introduced at C-4 or at C-5 (4). One is in somewhat of a quandary then, to know what value to use when the necessary parameters have not been determined for the molecule under study. In this paper we will use the parameters derived for 6-membered carbocyclic molecules (3). As will be seen, comparison of ^{13}C chemical shift values between the various compounds studied together with low temperature ^{13}C nmr led to the determination of conformational properties.

Armed with the conformational assignments, it was then of interest to examine the observed shifts to obtain more information on the effect on ^{13}C chemical shifts of introducing electronegative heterosubstituents, particularly at the β- and γ-carbons. One of the apparent anomalies in substituent effects on chemical shifts is the effect at the γ-carbon when the $C_\gamma—C_\beta$ bond is antiperiplanar to the C-substituent bond. In most examples when the α- and γ-carbons are primary or secondary, the effect is of shielding (5), whereas if either of these carbons is quaternary then deshielding is normally observed (6). The acetals and thioacetals possess heteroatoms in known, relatively rigid, orientations and should thus furnish information on substituent effects.

Results

The chemical shifts for all compounds[1] (Schemes 1 and 2) studied are given in Table 1. Spectra were assigned using the standard techniques such as single frequency off-resonance decoupled spectra, chemical shifts of model compounds, and comparison of shifts between compounds studied. For a number of compounds, the assignment of resonances to C-5 and C-11 was confirmed by deuteration since these resonances disappeared on deuteration. The presence of the spiro bicyclic function for compounds **9–25** is readily confirmed from the observation of a quaternary anomeric carbon at about 95 ppm (acetal), 80 ppm (monothioacetal), and 42 ppm (dithioacetal) respectively.

Compound **8** exists in two conformations of

[1]The chemical shifts for model compounds **3**, **6**, and **7** are taken from the Ph.D. thesis of F. Sauriol, Université de Montréal, with permission of the author and Professor St. Jacques. Their values obtained for **1** and **2** are the same as those given in Table 1.

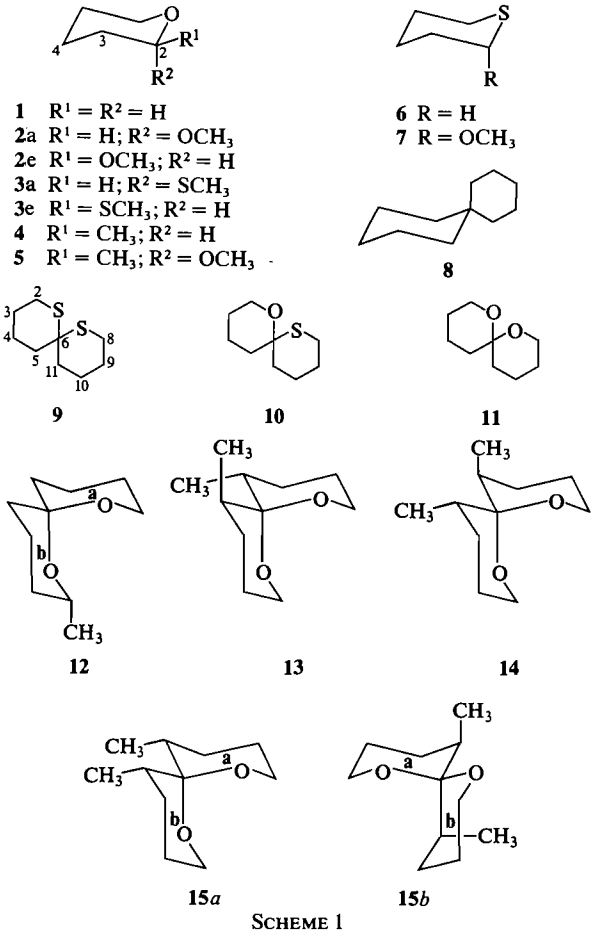

SCHEME 1

equal populations whereas there are 4 possible conformations for compounds **9–11** as illustrated in Scheme 3. The shifts for **8** and **9–11** were predicted using the chemical shifts of cyclohexane and compounds **2**, **3**, and **7**, respectively, for reference shifts and adding the increments for the various extra substituents. For example δ for C(1) of **8** is predicted to be 43 ppm which is calculated from[2] δ = reference + 3 HC + 1 CC which numerically gives 27.7 + 9 + 6.3 = 43 ppm. There are two HC interactions from C-7 and one from C-11. The CC term is for the C(11)—C(6); C(1)—C(2) *gauche* interaction. The spectra for **2**, **3**, and **7** were obtained at −130°C and the dominant, if not the exclusive, conformer of the OCH_3 group at this temperature is that in which the O—CH_3 (or S—CH_3) bond is *gauche* relative to the O(1)—C(2) (or the S(1)—C(2)) bond. This is the same orientation as in conformer *a* (Scheme 3) and thus the predicted shift for C-5 in **11***a* is 30.6 (value observed for C-3 in **2a**) + 9 (2 HC interactions from the introduction of C-11) = 39.6 ppm. By comparison the chemical shift of C-5 in conformer *d* of **11** is predicted to be 30.6 + 4.5 (1 HC from C-11) − 4.5 (the C(8)—O(7) bond is *gauche* to the C(6)—C(5) bond) = 30.6 ppm. The predicted shifts, given in Table 2, show that the only carbons which have significant conformational dependence are carbons 5 and 11. The differences in predicted shifts for the various compounds in a given conformation result from differences in the observed shifts of the reference compounds. For example, the shift induced at C-3 in the monocyclic compounds by introduction of an OCH_3 group depends on the atom at position 1 and this difference is then incorporated in the predicted shifts.

For **9**, the comparison of predicted and observed shifts infers that conformer *a* predominates. The spectrum at 160 K[3] indicates no evidence of a second conformer and is virtually identical[4] with that obtained at room temperature. We believe that our analytical method would have detected 0.5% of a second isomer if present (see Experimental). The low temperature spectrum confirms that **9** exists predominately (>95% at 25°C) as conformation *a*.

The spectrum of **10** at low temperature is essentially the same as that at room temperature. The comparison of predicted and observed shifts for C-11 suggests that either conformer *a* or *c* is predominant and that possibly a small percentage of *b* and/or *d* is also present. However, since **7** exists exclusively (or almost)[1] with the OCH_3 group in the axial orientation, conformations *c* and *d* must be neglected. Therefore **10** also exists at least predominately as conformer *a* with the shift of C-5 being more shielded than predicted.

The low temperature spectrum (160 K) of **11** shows only one symmetric conformer present since only 5 peaks are observed. Conformers *b* and *c* are equivalent and thus carbon 5 and 11 would resonate at 34.5 ppm if these were the only conformers present. This value gives the best correlation with the observed value although a significant proportion of *a* is necessary for observed and predicted values to coincide. If we take into account (*a*) that conformers *b* and *c* would give 11 peaks at low temperature whereas *a* only gives 5, (*b*) that 2-methoxy-

[2]For definitions of HC, CC, etc. see ref. 3.

[3]Assumed to be well below the coalescence temperature since separate conformers for **15** are observed at this temperature.

[4]Each carbon in **1** is more shielded at −130°C relative to 25°C by 0.4 to 0.8 ppm. Thus, any small change in chemical shift for the compounds of interest may be due to either conformational changes or changes in carbon shielding.

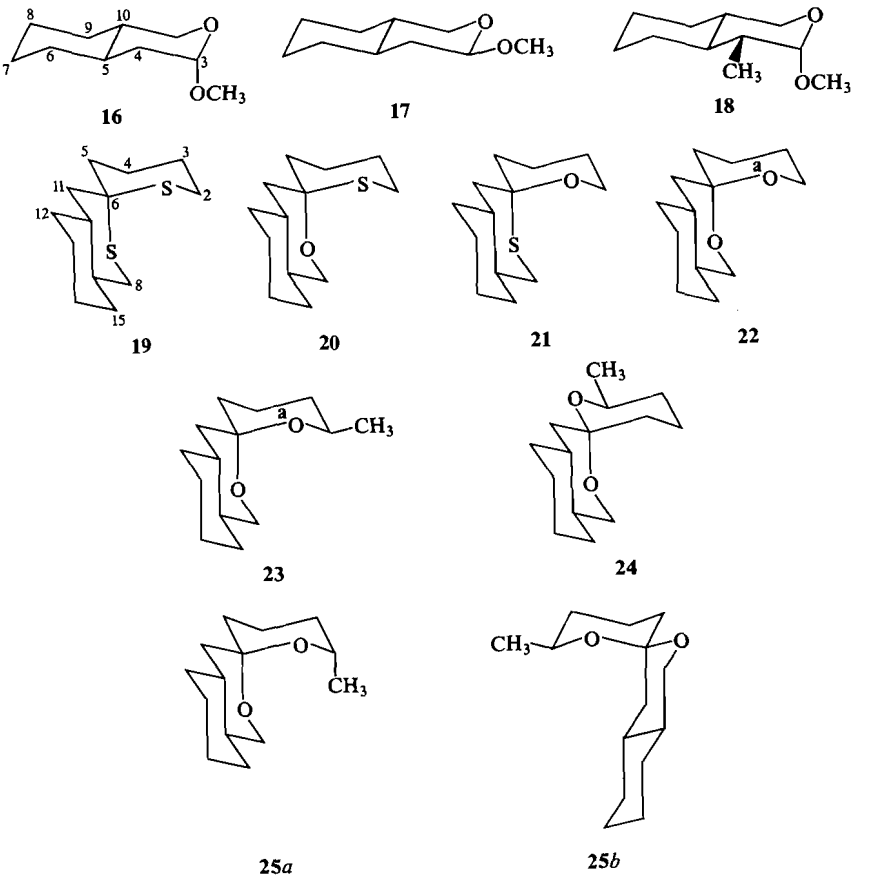

SCHEME 2

tetrahydropyran exists preferentially as **2**a (60% at 160 K), (*c*) that the observed shifts correlate better with *a* than with *d*, and (*d*) that in most oxygenated compounds, nonquaternary carbons are more shielded (5) than predicted, then it is reasonable to conclude that **11** exists predominately as conformer *a*. The X-ray data (8) discussed in the preceding paper confirm this statement. There is therefore a relatively large error in the prediction of δ(C-5) for this molecule. It should be noted at this point that the shift of C-5 in **11** is predicted by taking the observed shift for **2**a and adding the effective difference between shifts of decalin and cyclohexane, an operation which was quite successful for **8**. However, the β-effect for the introduction of a methyl group at C-4 of 1,3-dioxan is 5.8 ppm (5) and if we use this value then δ(C-5) of **11** has a predicted value of 36.0 ppm, which corresponds to that obtained experimentally.

The structure, stereochemistry, and spectra of **12** were assigned by consideration of the ^{13}C chemical shifts and SFORD spectrum. The presence of the spiro system is evident from the quaternary anomeric carbon signal at 95.5 ppm, the position of the CH_3 group follows from the methine carbon resonance at 65.2 ppm and the orientation of the methyl group follows from its chemical shift and that of C-10. The spectrum of **12** at low temperature is virtually identical with that obtained at room temperature. The chemical shifts for ring **a** of **11** and **12** are essentially the same and thus the two molecules must exist in the same conformation, and

[a]Reference shifts for **8**, cyclohexane; reference shifts for **9–11**, **1–3**, **6**, and **7**; reference shifts for **12–14**, compound **11**; reference shifts for **15**, compounds **13** and **14**; reference shifts for **16–17**, compound **2**; reference shifts for **19–25**, the corresponding bicyclic compound.

since introduction of a CH_3 group in ring **b** resulted in virtually no shift changes in ring **a** carbons it is evident that both **11** and **12** exist exclusively in conformation *a* even at room temperature. There is a downfield shift of C-3 by introduction of the methyl group which is not observed in **4** nor in cyclohexanes, nor in 1,3-dioxans (4).

The next compounds studied were the dimethyl bicyclic compounds **13–15**. Two of these compounds gave 6 signals whereas the third gave 11. The two former compounds must then, from symmetry arguments, have both methyl groups either axial or equatorial. For **13**, carbons 3, 4, 5, and 12 all absorb at lower field than the corresponding carbons in **14** and this must therefore be the compound with the CH_3 groups equatorial. Lowering the temperature for both compounds did not significantly alter their spectra and therefore the two exist as conformer *a*.

The third dimethyl compound gave 11 resonances including a quaternary anomeric carbon, 2 tertiary carbon, 6 secondary carbon, and 2 primary carbon resonances. Coalescence behaviour for each resonance was observed upon lowering the temperature in the following order of decreasing temperature: $35.9 > 16.8 \simeq 24.9 > 36.0 > 29.3 > 20.6 > 26.6 \simeq 59.4 > 16.8 > 60.6$. The coalescence temperatures are in a similar range as those observed for **2** and it is thus reasonable to presume that the inversion is between two chair conformations. The predicted shifts for **15***a* were obtained from **13** and **14** for rings **a** and **b**, respectively. The only carbons whose shifts should differ significantly from those in **13** and **14** are carbons 5, 11, and the methyl groups. The former have 1 less γ-*gauche* interaction than in their respective model compounds, and the methyl groups have a mutual δ-*syn*-diaxial interaction. In conformer **15***b* the shifts of carbons 2–4 and 8–10 were predicted to be the same as those in **14**. The resonance for C-5 in **15***b* should be at higher field by about 10 ppm relative to that observed in **15***a* since a γ-gauche interaction has been introduced and the methyl has changed from equatorial to axial. The difference for C-11 between the two conformations should be about 9 ppm since two γ-*gauche* interactions are present in **15***b* which are absent in **15***a*. The methyl carbon, C-13, is predicted to be shielded by 3 ppm in *b* relative to *a* since there is no δ interaction in this conformation. The CH_3 group, C-12, is axial in *b* and the change from equatorial to axial together with the lack of a δ interaction leads to a prediction

that this carbon will be shielded by approximately 8 ppm in *b* relative to *a*. The assignments given in Table 1 for **15***a* and **15***b* were made by taking into account predicted shifts, the room temperature shifts, and the coalescence behaviour. They must, however, be taken as tentative. The correlation between predicted and observed shifts is not good. The most disturbing shift is that for C-9 in **15***b* (25.4 ppm). This carbon should show very little chemical shift difference between the two conformations since it has a γ-*gauche* orientation relative to the CH_3 group in both and yet a $\Delta\delta$ value of 5.4 ppm is observed. The observed difference would in fact be best explained by placing the methyl group axial in *a* and equatorial in *b*. The conformers *c* and *d* were not considered since both have two of the very severe *syn*-diaxial interactions. The correlation between predicted and observed for the other carbons in **15***b* is acceptable. The deviation between predicted and observed for **15***a* is somewhat larger which could be indicative of a small deformation to alleviate the CH_3–CH_3 interaction. The assignments for C-5 and C-11 could be interchanged.

The assignment of *a* as the predominant conformer is based principally on the chemical shifts of C-5 and C-11. It is evident from the room temperature chemical shifts and the relative intensities at low temperature that the predominant conformer is the one in which the two methine carbons are more deshielded. It is virtually inconceivable that these carbons be more shielded in *a* than in *b* (see shifts of C-5 and C-11 in **24** and **25**). The shifts of C-2 and C-8 also infer that *a* predominates. The only doubt that persists is the shift of C-9 in *b*. Inversion of the assignments for C-3 and C-9 would infer that *b* predominates and that C-9 in *a* is more deshielded than predicted due to molecular deformation to alleviate the δ interaction. This argument does not counterbalance those for C-2, C-5, C-8, and C-11 and is therefore discarded. It should be pointed out that the difference at C-3 between **13** and **14**, 7.9 ppm, is significantly larger than that observed normally (4.5 ppm (3)). The weight of evidence indicates that the compound **15** has the structure as shown, with the conformer **15***a* being predominant by a ratio of 3:1.

The compounds **16–18** represent good models for the tricyclic compounds. The results for these compounds confirm that C-6 is deshielded relative to C-9.

For the tricyclic compounds **19–22** the predicted shifts were obtained by adding the parameters which correspond to the addition of the third ring to the spirobicyclic compounds. The correlation between predicted and observed shifts is satisfactory with the exception of C-8 in **20** and **22**. These compounds all exist in the same conformation, *a*, since the chemical shifts of ring **a** are virtually identical with those obtained for the bicyclic compounds. The structure and stereochemistry of **23** was assigned by comparison with **12**. Equilibration of **24** yields an approximate 1:1 mixture of **24** and **25** which led to the proposed structures. Confirmation of the structure for **24** was obtained from chemical shift data particularly for the methyl group (equatorial), C-5 (axial), and C-11. The spectrum of **25** at 160 K gave signals corresponding to only one conformer, **25***b*, with no trace of *a* being observed. The conformation **25***b* was assigned from the methyl carbon resonance (equatorial), the absorption of C-11 (shielded by 8.2 ppm relative to **24** and therefore axial), and C-5 (about the same as in **11**). Equilibration of **24** in deuterated medium led to an approximately 50:50 mixture of **24** and **25** with the resonances assigned to C-5 and C-11 absent in both compounds.

The conclusion that can be drawn for the chemical shift data is, with the exception of **15**, **24**, and **25**, that all spiro compounds exist almost exclusively even at room temperature in one conformation, that illustrated as *a*. At low temperature, no evidence for a second conformer was found in these compounds. Comparison of the chemical shifts of the hydrogen bearing carbons of **11** with unsubstituted ring carbons in **12** and **22** shows that the introduction of a methyl group or a third ring has not altered the chemical shift of these carbons (experimental error of ± 0.1 ppm). The conformational mobility in **12** and **22** is restricted relative to **11** yet the chemical shift is invariant. The chemical shifts of hydrogen bearing ring carbons of the methyl substituted ring of **12** and **23** are the same. Comparison of the chemical shifts of **9** with those of **19**, and **10** with either **20** or **21**, shows similar results. In light of this invariance in chemical shift upon restriction of conformational mobility, it is reasonable to conclude that the compounds **9–11** exist in one conformation.

The principal aim of developing an empirical method for predicting chemical shift is to predict chemical shifts for a large number of molecules based on a limited number of parameters. As mentioned above, a method which gives satisfactory correlation between calculated and observed shifts for six membered carbon rings in the chair conformation has been developed (3). Application of this method to compounds where sulfur replaces one of the CH_2 entities appears reasonable at least for the compounds presented herein. However, once oxy-

For personal use only.

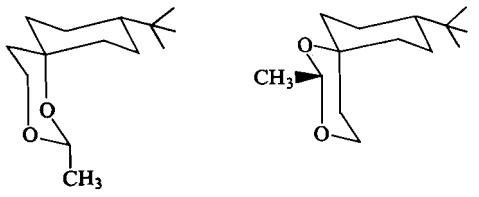
gen is introduced, the correlation between predicted and calculated shifts is no longer satisfactory.

Examination of the model compounds reveals a number of interesting facts. First of all the β-effect at C-3 for the introduction of an OCH_3 group is 2.8 ppm (axial) and 4.5 ppm (equatorial) for tetrahydropyran, 1.1 ppm for 2-methyltetrahydropyran, 5.4 ppm (axial) for the tetrahydrothiopyran, and 4.4 ppm (axial) and 6.3 ppm (equatorial) for 2-methoxymethylenecyclohexane (9). Thus this effect is significantly smaller for an oxygen heterocyclic compound. The β-effect for introducing a CH_3 group at C-2 varies between 7.3 ppm (**12-11**) and 7.9 ppm (**4-1**) which is somewhat smaller than that observed in cyclohexanes (9 ppm) but larger than that observed in 1,3-dioxans (5.8 ppm when substituted at C-4 (5)). Secondly, the magnitude of the γ-effect at C-6 by the introduction at C-2 of an OCH_3 (or CH_3) axial in oxygen heterocyclics is significantly larger than that observed at C-4. The latter shift is similar to that observed in cyclohexane derivatives (3).

There is a reasonably large discrepancy between predicted and observed shifts for C-5 of **11**. The difference between C-5 of **11** and C-3 of **2**a is only 5.2 ppm, which is much smaller than that using cyclohexane parameters (9 ppm) or the difference between C-3 in **4** and **1** (7.9 ppm). We assumed that the OCH_3 group in ***2a*** exists with the O—CH_3 bond *trans* with respect to the C(2)—C(3) bond, conformation A_1.[5] The other orientation possible would have the O—CH_3 bond *gauche* to this bond (conformation A_2)[5] which would lead to shielding of C-3 by the well known γ-*gauche* effect. This would at least partially explain the small β-effect at C-3 between ***2a*** and **1**. However since **11** exists in conformation *a*, the difference at C-5 between **11** and ***2a*** would be greater than predicted if ***2a*** existed in conformation A_2. The chemical shift of C-3 in 2-methyl-2-methoxytetrahydropyran is 35.8 ppm which is virtually identical to that observed for **11**. This compound will exist almost exclusively (if not exclusively) with the OCH_3 group axial since **2** exists predominately with the OCH_3 group axial and since attempts to observe the axial conformer of 2-methyltetrahydropyran proved fruitless. The shift of C-3 infers that 2-methoxy-2-methyltetrahydropyran exists with the O—CH_3 bond *gauche* with respect to the O(1)—C(2) bond, conformation A_1.

The other discrepancy between predicted and observed shifts is that for C-1 of **16–18** and C-8 of **22** and **24**. In these compounds the β-effect for the introduction of a CH_2 is about 5 ppm as compared to the normal value of 8 to 9 ppm. It is of interest to note that for **16** and **17**, C-9 is significantly shielded relative to C-6, and C-15 is significantly shielded relative to C-12 in **20** and **22**. The carbons C-9 and C-15, are γ-*trans* with respect to the oxygen and represent excellent examples of the relative shielding of this carbon when placed in this orientation relative to an electronegative substituent. However, both carbons 1 and 9 of **16** and **17** and carbons 8 and 12 of **20** and **22** are all significantly more shielded than predicted. The methyl carbons of *cis*-3,5-dimethyl tetrahydropyran are shielded by 5.9 ppm relative to that of methylcyclohexane (5), another example of the shielding effect at the γ-*trans* carbon. Carbons 2 and 4 of this compound are shielded by 5 and 18 ppm relative to **1** respectively. The effect at C-2 is similar to that discussed above whereas that at C-4 is similar to cyclohexane derivatives. The methyl carbons of **13** appear at 16.5 ppm which represents a shielding of only 1 ppm relative to those of 3,5-dimethyl tetrahydropyran. The former have two γ-*gauche* interactions which are absent in the latter and we would thus predict a difference of the order of 9 ppm, not 1 ppm. Obviously the so-called γ-*trans* shielding effect is no longer present when the α-carbon becomes quaternary. The observed shift of 16.5 ppm is comparable with that observed for the 2-methyl carbon in 1,1,2-trimethylcyclohexane. The shifts of the methyl carbons of **14** are more deshielded than predicted using cyclohexane parameters which is no doubt another example of a deshielding effect at the γ-*trans* carbon when the α-carbon is quaternary. The discussion in this paragraph infers that hydrogen–hydrogen interactions play an important role in determining carbon shieldings.

The chemical shifts for several bicyclic 1,3-dioxans have been reported (10). For compound **26** the predicted shifts for C-5, C-7, and C-11 are 42, 33, and 42 ppm, respectively. The corresponding observed shifts are 36, 30, and 41 ppm. For **27**, the predicted shifts for the same carbons are 33, 33, and 42 ppm which correspond to the observed shifts of 31, 31, and 42 ppm respectively. In both com-



26 **27**

SCHEME 4

pounds C-7 is more shielded than predicted which is most likely due to the γ-*gauche* interaction, when oxygen is present in the ring, being larger than for a CH_2 as already discussed. The correlation between observed and predicted shifts is reasonable for C-11 whereas that for C-5 is not. The chemical shifts for the carbocyclic ring are predicted satisfactorily whereas in the oxygen-containing ring, the carbon is more shielded than predicted. Compound **26** exists as conformation *a* and the chemical shift of C-5 is very close to that for C-5 in **9**.

The results from the study of these compounds demonstrate that the parameters derived from cyclohexane derivatives can be applied to sulfur but not to oxygen heterocyclics. For tetrahydropyrans, the β-effect for introduction of a methyl group equatorial at C-2 depends on the axial substituents. If the substituent is hydrogen or sulfur, the β-carbon is deshielded by 7.6 ± 0.3 ppm whereas if it is oxygen, the carbon is deshielded by 5.2 ppm. Introduction of the CH_3 at C-3 deshields C-2 by 5 ppm and C-4 by 9 ppm. It is apparent that the shielding effect at the carbon γ-*trans* to an electronegative substituent is also reflected at the α-carbon. This relative shielding effect at the γ-carbon is not present if the α-carbon is quaternary. The γ-*gauche* effect is larger if the β-atom is an oxygen rather than a carbon and this effect is even more pronounced for an oxygen than a carbon or sulfur substituent.

Experimental

The carbon-13 spectra were recorded on a Bruker HX-90 spectrometer equipped with a Nicolet 1083 computer (8K data points). Sweep widths of 5000 Hz were usually employed with TMS being used as reference. The room temperature spectra were recorded in $CDCl_3$ whereas those at low temperatures were recorded in $CHFCl_2$ with about 10% of CD_2Cl_2 added for locking purposes. The spectra of **9**, **11**, **15**, **20**, and **25** were also recorded at 160 K on a Bruker WM 250 operating at 64 MHz for carbon-13. In **9** and **11**, several peaks of very weak intensity were observed which were assigned to impurities (for example, **9** exhibited 2 of these peaks below 70 ppm which are obviously assignable to oxygen bearing carbons). These peaks varied in intensity from 0.2 to 0.5% of the intensity of the compound peaks. Since peaks were observed in the region of interest, and since these peaks could not be unequivocally assigned to impurities, the conformer purity is thus assigned to **9** and **11** as being a minimum of 99.5% at 160 K. It should be pointed out that there are very few analytical techniques capable of detecting less than 0.5% impurities.

The preparation of most of these compounds is reported in the accompanying publications. The compound **2** was obtained from the addition of methanol to dihydropyran (11). Compounds **4** and **5** were obtained from the reduction of, and the addition of methanol to, 2-methylene tetrahydropyran (12), respectively.

Separation of short fibers from bulk chrysotile asbestos fiber materials: analysis and physico-chemical characterization.[1]

CARMEL JOLICOEUR, PIERRE ROBERGE, AND JEAN-LUC FORTIER

Centre d'Application en Calorimétrie et Thermodynamique and Département de Chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received July 21, 1980

CARMEL JOLICOEUR, PIERRE ROBERGE, and JEAN-LUC FORTIER. Can. J. Chem. **59**, 1140 (1981).

The aqueous sedimentation behavior of commercial chrysotile asbestos fibers has been investigated and a simple method for separating short fibers (90% < 2 μm) could be devised based on selective sedimentation. Chemical, X-ray structural, and differential thermal analyses show that the short fibers have chrysotile composition and structure, with lower brucite ($Mg(OH)_2$) and iron contents than the bulk fibers. The length distribution of these short fibers exhibits a maximum at 0.3 μm and a width-at-half-height of ~0.5 μm. Surface adsorption studies yield specific areas of 20 and 28 m^2/g for N_2 and H_2O respectively. Because of their finely divided state and narrow length distribution, such fibers should be well suited for a variety of physico-chemical, chemical, and biological investigations on chrysotile fibers.

CARMEL JOLICOEUR, PIERRE ROBERGE et JEAN-LUC FORTIER. Can. J. Chem. **59**, 1140 (1981).

Une étude de la sédimentation de fibres d'amiante chrysotile en suspension aqueuse a permis la mise au point d'un procédé pour la séparation de fibres courtes (90% < 2 μm) à partir d'échantillons de fibres commerciales. L'analyse chimique, la diffraction de rayons-X et l'analyse thermique différentielle effectuées sur ces fibres courtes ont démontré qu'elles possèdent la composition et la structure du chrysotile, bien que contenant moins de brucite ($Mg(OH)_2$) et de fer que l'échantillon de départ. L'étude de l'adsorption de N_2 et H_2O par les fibres courtes a donné des surfaces spécifiques respectivement de 20 et 28 m^2/g. La distribution de longueur de ces fibres a un maximum à 0.3 μm et une largeur à demi-hauteur de ~ 0.5 μm. Il est proposé que ces fibres, vu leur état finement divisé et leur homogénéité dimensionnelle, sont bien adaptées à une variété d'études concernant les propriétés physico-chimiques, chimiques ou biologiques des fibres d'amiante chrysotile.

Introduction

The interest in the structural and surface properties of asbestos minerals has been sharply revived in recent years, because of potential health hazards resulting from human ingestion of fibrous minerals (1–4). The biological consequences of the interactions between fibrous silicates and biochemical materials (proteins, membranes, nucleic acids, etc.) remain largely unknown, but clearly the elucidation of such effects at the molecular level will require a detailed knowledge of the chemical and physico-chemical behavior of these fibrous compounds.

Among the various asbestos minerals of industrial interest, chrysotile is by far the most important. Its morphology and main structural and chemical features have been established through investigations using a variety of analytical and physical methods, for example, electron microscopy (5), infrared spectroscopy (6–8), X-ray diffraction (9–11), and surface adsorption (12–16).

Chrysotile asbestos belongs to the category of serpentine minerals (with antigorite and lizardite) having chemical composition $3MgO \cdot 2SiO_2 \cdot 2H_2O$ (17). Its basic structure consists of a sheet of silica tetrahedra which is overlayed with a sheet of magnesium hydroxide (brucite). The latter is joined to the silica layer by two out of three —Mg—O groups as illustrated in Fig. 1. Because of differences in the lattice parameters of the silica and brucite layers, the composite layer adopts a curvature (18) with the Mg—OH groups on the external surface. The growth of these curved sheets, in concentric or spiral arrangements, has lead to the naturally occurring fibrils which are found in the form of cylinders with internal and external diameters of approximately 10 nm and 25 nm respectively (17).[2] The central cavity of these cylinders has been suggested to contain amorphous minerals (12, 19) the composition of which varies depending on the origin of the chrysotile.

Attempts to perform refined studies of the physico-chemical properties of chrysotile fibers are generally difficult because of composition variations and size heterogeneity of the material. The composition variations due to substitutional elements are intrinsic to the particular material of interest and cannot be avoided. However, the situation with regards to interstitial impurities (e.g., excess brucite, amorphous minerals trapped between fibers) might be improved by using finely divided fibers, ideally monofibers (fibrils). With

[1]Part of M.Sc. Thesis of P. R., Sherbrooke 1978; work presented at A.C.F.A.S. Conference, Montreal, May 1979.

[2]Chrysotile may be found in three crystallographic varieties labelled *clino*, *ortho*, and *para*-chrysotile (9, 10); the most naturally abundant variety is *clino*-chrysotile.

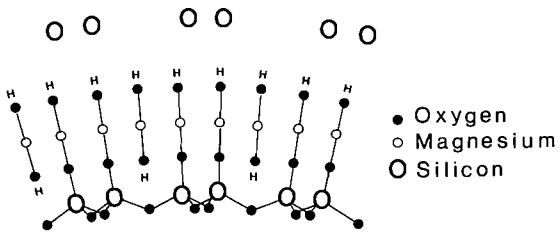

FIG. 1. Partial cross-section of a chrysotile asbestos fiber showing the composite silica–brucite layer.

such materials, the size heterogeneity should also be decreased since, in the limit, monofibers will all have comparable diameters. Finely divided fibers are also intrinsically better suited for a number of physico-chemical studies, for example, infrared absorption and surface adsorption. Investigation on fine chrysotile particles would also appear relevant to environmental and health studies, since the small fibers will be more readily airborne or transported in streams.

For one or more of the above reasons, it would thus seem highly desirable to develop methods for preparing representative samples of finely divided chrysotile fibers in a reproducible way. The present investigation was therefore undertaken with the specific aim of preparing and characterizing such samples. After various attempts with mechanical separation and size reduction procedures[3] (wet and dry), we have turned to investigate aqueous sedimentation methods. These studies have yielded a simple procedure for separating short fibers from bulk commercial samples. The separated fibers were found to have a relatively narrow length distribution and lower levels of the main interstitial impurities (brucite and iron oxides) than the starting materials. Details of the separation procedure and the results of various characterization studies including chemical and structural analysis, sedimentation rates, surface area, and differential thermal analysis are reported below. A combined thermogravimetric and infrared absorption study on the sedimented fibers will be reported in a subsequent paper (20).

Experimental

(a) Materials

The chrysotile asbestos samples used in this study were provided by Canadian Johns-Manville Ltd. through the A.M.A.Q. (Asbestos Mining Association of Quebec) laboratory. The results given in later sections were collected systematically for fibers classified as 4-T-30.[4] The water used in the various experiments was distilled and deionized on a mixed resin (Continental Deionizer). Electrolytes employed in some experiments (NaCl, $CaCl_2$) were certified reagent grade.

(b) Methods

(i) Sedimentation Rates

Two methods were adopted to measure sedimentation rates, depending on the type of fibers. With bulk 4-T-30 samples, measurements of sedimentation velocities were obtained by following the level of the solution–suspension boundary as a function of time. These measurements were carried out in Pyrex glass cylinders (diameter 7.5 cm, height 75 cm), thoroughly washed with detergents and rinsed repeatedly with deionized water. The aqueous fiber suspension was prepared at 1.00 wt%, and 50 glass beads (0.5 cm diameter) were added to assist the initial mixing. The latter was performed by inverting the stoppered cylinder 20 times in 10 min.

With short fibers the sedimentation rates were measured using a technique described, for example, by Mironov and Churaev (21). The basis of this method consists in following the weight of a horizontal glass disc, suspended from an analytical balance in the aqueous suspension. The diagram of the controlled temperature apparatus used for these measurements is illustrated in Fig. 2; the temperature was regulated to better than 0.01°C.

In the sedimentation experiments, the rates observed depended on a number of variables (standing time before experiment, stirring time, amount of material used, temperature, etc.). However, for a controlled set of experimental conditions and procedures, the half-times for sedimentation were found reproducible within 5%.

(ii) Chemical Analysis

The Mg and Fe content of samples of the 4-T-30 and of the short fibers (obtained as described in the result section, ref. 2) were determined by atomic absorption (Mg, Fe) and EDTA titration (Mg). Since prolonged acid treatment is know to leach out the metal ions of chrysotile leaving mostly amorphous silica (23, 24), the chrysotile samples were stirred vigorously in excess HCl 2.0 *M* (100 mL HCl/g chrysotile) for a period of 10 days; the resulting suspensions were centrifuged, filtered, and diluted for analysis. The Mg-EDTA titration was performed according to standard procedures using the calmagite indicator, after precipitation and removal of the iron (22).

(iii) X-ray Analysis

The diffraction pattern of sedimented short fiber samples and other materials dried at 110°C for 48 h were obtained with a Debye–Scherrer camera using the Cu, K_α line (Ni filter). The samples were confined in thin wall Pyrex capillaries having typical internal diameters of 0.5 mm. The uncertainty on the lattice parameters obtained is respectively 0.1 Å and 0.01 Å for the largest and smallest *d* spacings.

(iv) Differential Thermal Analysis (DTA)

The DTA curves of several chrysotile samples were recorded between room temperature and ~1000°C on a SETARAM thermal analyser, model Micro ATD-M4. Because of the low thermal conductivity of loose fibers, the samples (e.g. ~10 mg)

[3]There is now ample evidence that dry mechanical processes (grinding, milling) can induce profound structural modifications of the native chrysotile structure (19); such methods must therefore be avoided for the preparation of finely divided chrysotile samples.

[4]Asbestos fibers designated as 4-T-30 contain fibers with a broad distribution of lengths which may be specified from dry screening procedures. The latter show ~80% of the fibers between 1 and 4 mm with ~40% near 2 mm. Details of the procedures may be obtained from section B-2, Ro Tab Screen Analysis of Chrysotile Asbestos Test Manual (39).

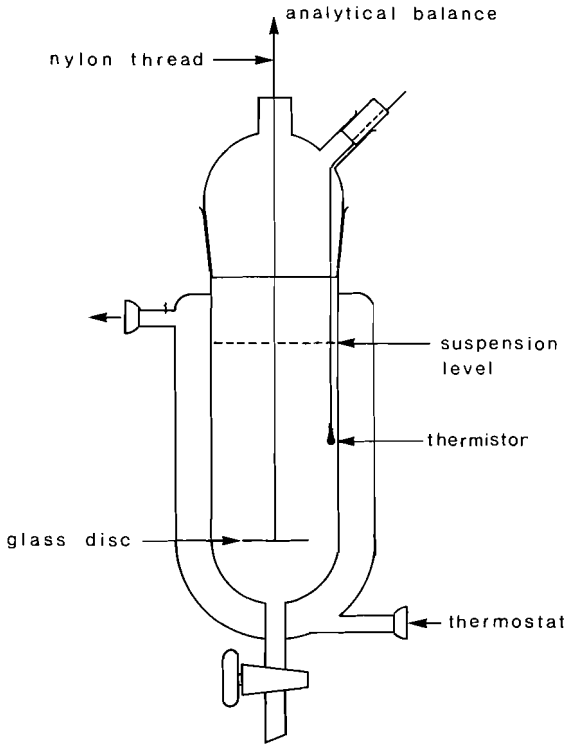

FIG. 2. Horizontal disc apparatus for the measurement of sedimentation rates.

were gently compacted in the DTA cups and the scanning rate was kept sufficiently low to avoid broadening of the transition peaks.

(v) Surface Adsorption Measurements

The specific area of chrysotile fibers was determined from nitrogen adsorption using a commercial BET apparatus (Micrometrics, Model 2200). Fibers used in these experiments and others described below were previously heated to 110°C for at least 24 h. This was sufficient to achieve constant weight and provided a reliable reference state for the various physicochemical measurements; structural modifications and dehydration of the brucite do not occur, however, until much higher temperatures.

Water adsorption measurements for short fiber samples were carried out as a function of water activity (relative humidity) using the isopiestic technique described for example by Robinson and Stokes (25) and Platford (26). The apparatus used consisted of a vacuum desiccator which housed a copper plate holding seven platinum crucibles. A solution of the isopiestic standard ($CaCl_2$ or H_2SO_4 (25)) was placed at the bottom of the desiccator and the apparatus was evacuated slowly to 2 Torr; the system was left to equilibrate, from 3 days to 1 week depending on the water partial pressure, in a constant temperature bath at 25.00 ± 0.01°C. The desiccator was then opened to a stream of dry nitrogen, the samples were quickly sealed and weighed, and the isopiestic standard solution was titrated to obtain the equilibrium water activity (25). The reproducibility in the weight of equilibrated samples (~0.5 g) for the entire operation was within ±0.0005 g.

Results and Discussion

(1) Sedimentation Studies on 4-T-30 Fibers

The sedimentation rates of 1.0 wt% aqueous suspensions of 4-T-30 fibers were investigated in electrolyte-free suspensions and in solutions of NaCl and $CaCl_2$. The time dependence of the height of the sedimentation boundary is very nearly exponential with a half-time ($t_{1/2}$) of 125 s. The latter was noted, however, to be markedly dependent on the presence of small amounts of electrolytes; for example leaching of ions from a new glass tube changed the observed rate significantly.

The measurement of sedimentation rates as a function of NaCl or $CaCl_2$ concentration yielded the results illustrated in Fig. 3. Both electrolytes retard the sedimentation of the coarse fibers with a saturation effect at ~13 m*M*. Although electrolytes have been shown to have a marked influence on the stability of chrysotile fiber suspensions (27), the behavior shown in Fig. 3 is contrary to that expected on the basis of results from ζ potential studies (28). In electrolyte-free suspensions, the ζ potential of chrysotile fibers is positive, decreasing with added salt concentration. In the absence of specific interactions as, for example with sodium silicate (28), the main influence of electrolytes should be to decrease the electrostatic repulsion between fibers (reducing the double layer thickness) and this should enhance the sedimentation rates. While the influence of various electrolytes on the sedimentation of 4-T-30 fibers was not investigated in further detail, it was noted that the sedimentation behavior with and without electrolytes differed qualitatively in an important fashion. In electrolyte-free suspensions, the supernatant liquid is a cloudy suspension of fine particles (presumably short fibers and foreign materials), whereas in the presence of sufficient electrolyte, the fine particles settled as well. From the sedimentation behavior of the fibers, it could later be concluded that the influence of electrolytes on the

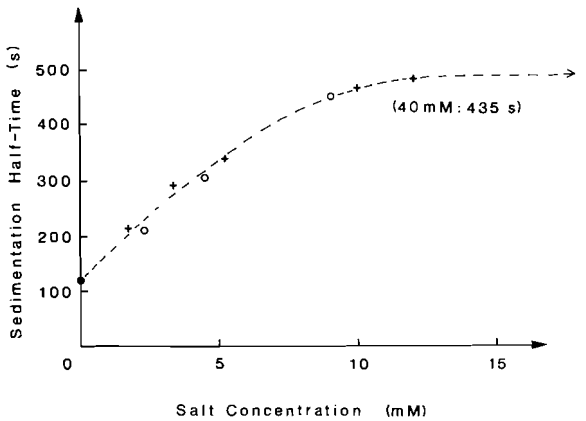

FIG. 3. Half-time for the sedimentation of aqueous suspensions of bulk 4-T-30 chrysotile fibers (1.0 wt%), as function of electrolyte concentration; +: NaCl; O: $CaCl_2$.

sedimentation rates of the coarse fibers (4-T-30) is in fact due to the properties of the short fibers; in the presence of electrolytes, the latter aggregate into a macroscopic floc and this process hinders the coarse fiber sedimentation.

(2) Method for Separation of Short Chrysotile Fibers

The experimental observations described above suggest a simple way of separating short fibers and other fine particles from bulk commercial fibers. The latter (1–2 wt%) are dispersed by gentle agitation in a column containing distilled deionized water; when sedimentation of the coarse particles is completed, the supernatant suspension is pumped out and the fine particles are precipitated by addition of low levels of electrolytes, typically NaCl 20 m*M*. If electrolyte contamination is to be avoided, the suspended material may, of course, be recovered by filtration.

The sedimentation behavior of the fine particles was examined using the suspended disc method described earlier. The influence of NaCl concentration on the sedimentation rates may be seen in Fig. 4 from the time-dependence of the disc weight in a suspension containing 0.063 wt% solids. While the disc weight is invariant in the absence of electrolyte (no sedimentation), addition of NaCl at low concentrations ($c < 2$ m*M*) leads to very slow sedimentation and an apparent weight decrease; the latter can only be understood as the result of a density gradient in the column, before a significant amount of material settles on the disc. At higher NaCl concentrations ($c > 3$ m*M*), the particles aggregate into a floc which sediments more rapidly; with an NaCl concentration of 13 m*M* (cf. the concentration required for saturation of electrolyte effects with the 4-T-30 fibers), a sedimentation half-time of ~450 s is observed, and the latter is not strongly dependent on the solid content of the suspension. This sedimentation half-time closely corresponds to that observed for the sedimentation of coarse fibers under similar conditions, an observation which is readily explained as follows: in electrolyte-free suspensions, the coarse fibers sediment with $t_{1/2} \sim 2$ min, while the fine particles remain in suspension; in the presence of electrolytes, the coarse and fine particles settle simultaneously, but the rate is now dominated by the slow ($t_{1/2} \sim 450$ s) flocculation–sedimentation process of the fine particles.

Following the method described by Michaels and Bolgers (29) in sedimentation studies of kaolin suspensions, an estimate of the average size of the floc can be obtained from the sedimentation rates. The rate determined from the positive slope of the

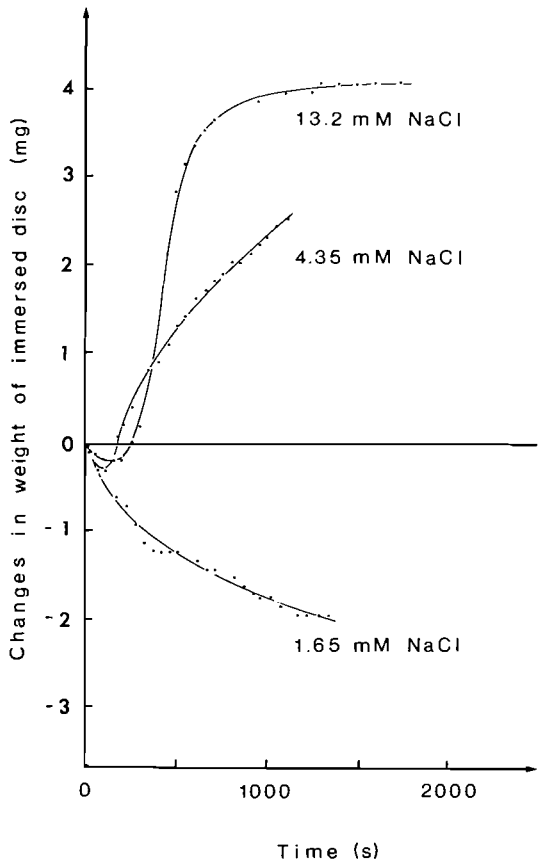

FIG. 4. Sedimentation behavior of supernatant fine particles (0.063 wt%) from the variation of immersed disc weight.

data with 13.2 m*M* NaCl (Fig. 4) leads to a floc size of 1.1 ± 0.2 mm which is compatible with the physical size of the observed aggregates.

Several experiments were carried out to determine the influence of pH on the sedimentation rate of the fine particles. In the absence of other electrolytes, addition of HCl to pH 3 does not induce significant sedimentation over a period of 2 h; sedimentation occurring at much longer times was not investigated further because of acid attack of the chrysotile fibers. On the other hand, addition of NaOH induced sedimentation, at a rate increasing with pH. The maximum sedimentation rate was found near pH 11.0 which corresponds approximately to the pH of zero-charge of chrysotile fibers for which values have been reported in the range 10.1–11.8 (30).

Finally, to determine the amount of short fibers and fine particles which could be extracted from a given bulk material, the sedimentation–separation procedure was performed repeatedly on the same sample, and this was carried out for several 60.0 g samples of 4-T-30 fibers. The total separation

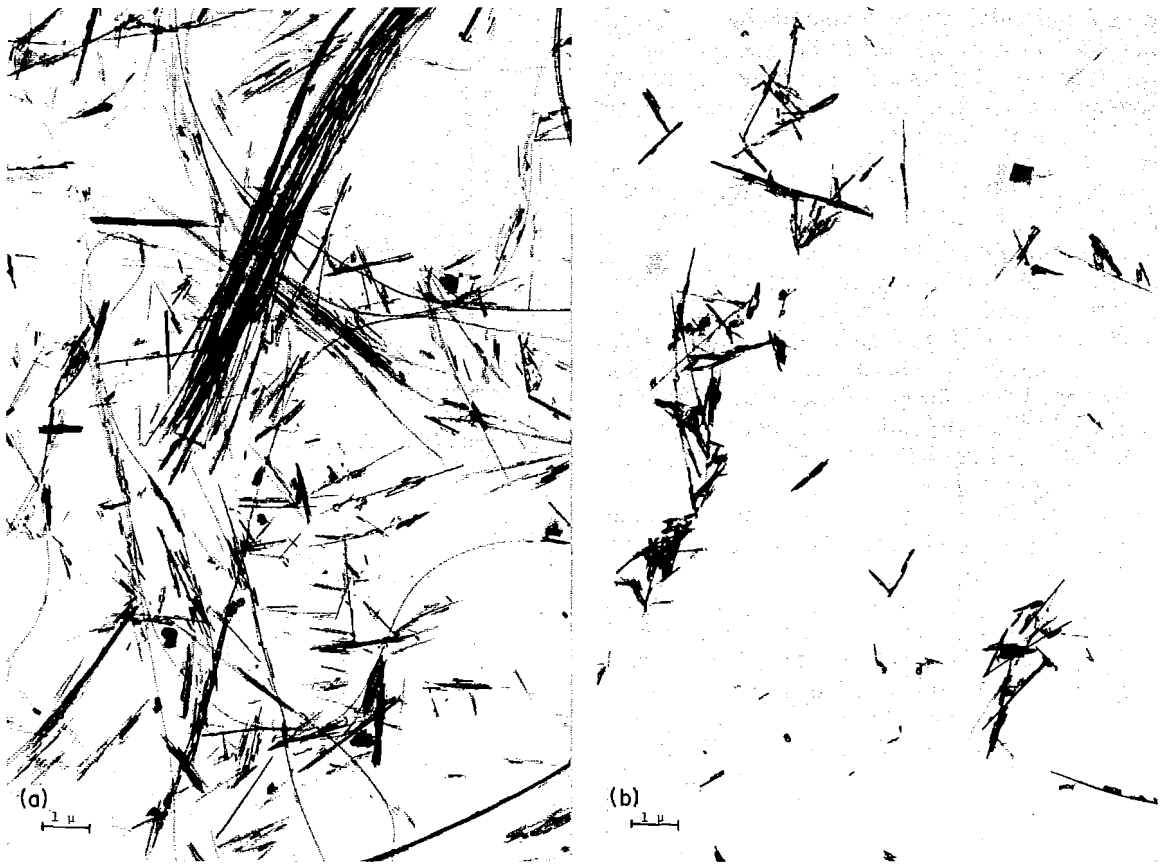

FIG. 5 (*a*) Electron micrograph of 4-T-30 chrysotile asbestos at 11 900×. (*b*) Electron micrograph of fine particles separated from the 4-T-30 chrysotile sample shown in (*a*).

yields were found as high as 10 wt% and, since the separation procedure does not involve sufficient mechanical stress to produce defibrilation, these short fibers and fine particles must be present in the starting bulk materials. The remainder of this work was concerned with the assessment of the nature and properties of these fine particles.

(3) Size Distribution Analysis

Samples obtained from consecutive extractions of fine particles on a given batch of coarse 4-T-30 fibers were examined under transmission electron microscopy and compared with the starting material. Typical electron micrographs (11 900 ×) of 4-T-30 chrysotile fibers, and of the sedimented fines are reproduced in Fig. 5 *a* and *b*, respectively. These, and a large number of other similar results, consistently showed that the fine particles are mainly short fibers rather than powdered minerals. The average diameter of these fibers could not be estimated reliably, but their length distribution was determined through fiber counting procedures using a Zeiss optical counter. The length histogram illustrated in Fig. 6 (for the 1st, 2nd, and 9th samples of consecutive extractions on a given sample) shows a sharp peak in the length distribution near 0.3 μm, more than 90% of the fibers being shorter than 2.0 μm (the peak shown at 2.5 μm is the instrument count for all fibers with lengths greater than 2.5 μm; the maximum fiber length observed was 8 μm). While these parameters are expected to vary with the type of bulk material investigated, it is interesting to note that the length distributions obtained for samples of successive separations are very similar. This shows that under the present conditions, there is no sedimentation selectivity which could allow further separation according to fiber lengths.

(4) X-ray Structural Analysis

The X-ray diffraction pattern of several chrysotile bulk and short fiber samples were obtained in thin-wall capillaries using a powder camera. The various derived lattice parameters are reported in

[a]Natural brucite-free chrysotile.
[b]*Clino*-chrysotile (16% *ortho*-chrysotile).
[c]Most intense lines for brucite.

Table 1 with reference data for $Mg(OH)_2$ (brucite, ASTM-7-239), a brucite-free chrysotile fiber (Cassiar) and the ASTM recommended parameters for chrysotile analysis (ASTM 10-380) (31). Within the experimental error, the data for the 4-T-30 material match those of the Cassiar chrysotile and the ASTM reference data. The main chrysotile parameters are also found with the sedimented short fibers, so there can be little doubt that these fibers have chrysotile structure. Although no reliable quantitative intensity measurements could be carried out, the two most intense lines of brucite which are readily observed with the 4-T-30 sample, could not be detected in the short fiber material studied under the same conditions. This indicates a lower brucite content in the sedimented short fibers compared to the bulk initial sample; similar findings are also apparent in other analyses described below.

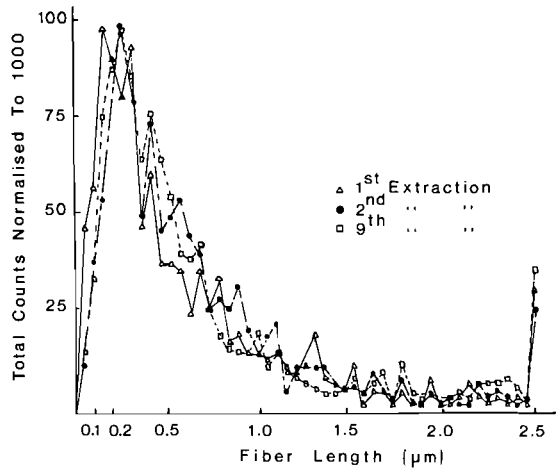

FIG. 6. Length distribution in short fibers sedimented from bulk 4-T-30 chrysotile; data obtained for 600–800 fibers and normalized to 1000.

(5) Chemical Analysis of Short Fibers

The composition of the sedimented short fibers relative to that of the bulk starting material was determined with respect to two important components: Mg and Fe. Magnesium is, of course, a key component in the chrysotile lattice, but it may also be present in excess as hydroxide (brucite) and carbonate. On the other hand, iron is one of the main substitutional and interstitial (as oxides) impurity of the chrysotile 4-T-30 material investigated. The results of Mg and Fe analysis are given in

Table 2 along with various other chrysotile asbestos compositions reported earlier.

The elemental analysis data from different investigations illustrate typical composition variations, with Mg contents usually lower than that calculated from the chemical formula due to substitutional impurities. The same is true for the bulk and short fiber chrysotile samples studied here, and both exhibit high total Fe content. However, comparison of the results for bulk and short fibers indicate lower Mg and Fe concentrations in the latter. The significance of the lower Fe content in short fibers is difficult to assess because of the occurrence of Fe_3O_4 (magnetite) particles in the bulk material which would be partly removed in the sedimentation process. However, the lower Mg content of the short fibers confirms the lower amount of brucite in this material compared to the original 4-T-30 sample (if the difference found in entirely due to excess brucite, this means an ~2.5% difference in $Mg(OH)_2$ content).

(6) Thermal Analysis

The thermogravimetric behavior and the temperature dependence of the infrared absorption spectrum of the sedimented short fibers have been investigated in some detail and will be reported in a subsequent paper (20). The differential thermal analysis (DTA) curves provide additional evidence on the nature and composition of the sedimented short fibers as illustrated in Fig. 7. The DTA curve recorded for 4-T-30 fibers is typical of bulk chrysotile materials showing the endothermic dehydration of brucite near 400°C and dehydration of the chrysotile structure in the temperature range 600–800°C; the exothermic peak above 800°C corresponds to a rearrangement into forsterite and amorphous silica (17, 36). The DTA curve obtained with the sedimented short fibers exhibits the same features although the brucite dehydration peak is substantially lower than with 4-T-30 fibers. The ratio of the normalized brucite peak areas of short fibers and 4-T-30 fibers is ~1:10, while the ratio for the high temperature peaks is unity within experimental error.[5] The short fibers washed once with 25 vol% aqueous acetic acid exhibit no brucite peak, as expected, due to the leaching of the Mg from both the free brucite and the external brucite layer of the fibers.

The DTA curves further show that the chrysotile decomposition peak (about 780°C) is much narrower with the short fibers compared to the bulk 4-T-30 material. This may be a result of different physical properties of the samples (19), but it could also be related to differences in their decomposition mechanisms. Such effects have been observed in the thermal decomposition of loose fibers compared to fibers embedded in KBr matrices (20).

(7) Specific Area and Water Sorption Isotherm

The specific area of bulk chrysotile fibers determined from nitrogen adsorption can vary between 5–30 m^2/g, depending on the average size of the fibers (14, 16, 37, 38); specific areas up to 50 m^2/g have been obtained for mechanically dispersed fibers (14, 16) or thermally activated fibers (15). A first order calculation, taking a fiber diameter of 25 nm and a density of 2.5 g cm^{-3}, yields a specific surface area (of cylinders) of 32 m^2/g (neglecting end adsorption).

For chrysotile asbestos fibers of grade 7-R (Johns Manville),[6] Young and Healey (16) reported a nitrogen specific area of 9.7 m^2/g using a molecular

[5]The relative areas of the brucite peaks may not be taken as a measure of relative excess brucite contents until a quantitative relationship between these variables can be demonstrated.

[6]Fibers of this commercial grade are much shorter than the 4-T-30 fibers, i.e. ~75% < 0.1 mm.

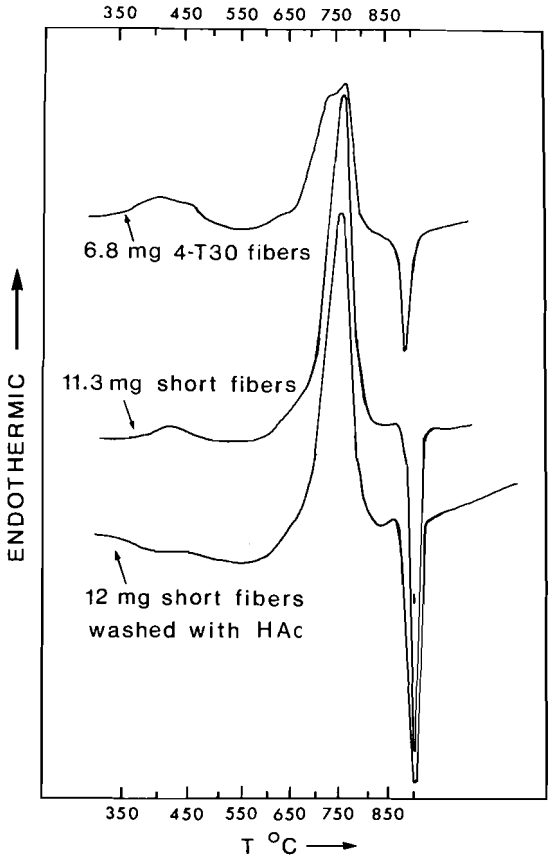

FIG. 7. Differential thermal analysis (DTA) curves for 4-T-30 fibers and short fibers before and after leaching with 25 vol% acetic acid.

adsorption area of 16.2 $(Å)^2$/molecule; data for water adsorption yielded a specific area of 17.6 m^2/g using a molecular area of 10.6 $(Å)^2$/molecule.

The specific area, determined from nitrogen adsorption, lies in the range 5–8 m^2/g for various samples of 4-T-30 fibers, and is 20 m^2/g for the sedimented short fibers. Data on water adsorption by short fibers are illustrated in Fig. 8 and compared with similar results for coarse (4-R) fibers reported by Pidgeon and Van Winsen (37). The fractional weight of sorbed water plotted against the water partial pressure yields typical BET isotherms for both types of fibers, though the short fibers exhibit substantially higher water sorption at high humidity. The origin of this difference is uncertain, but it cannot be attributed to artifacts of the isopiestic method, since Pidgeon and Van Winsen (37) had used the isopiestic and high vacuum techniques with identical results. Possibly, differences in excess brucite contents could also affect the water sorption behavior.

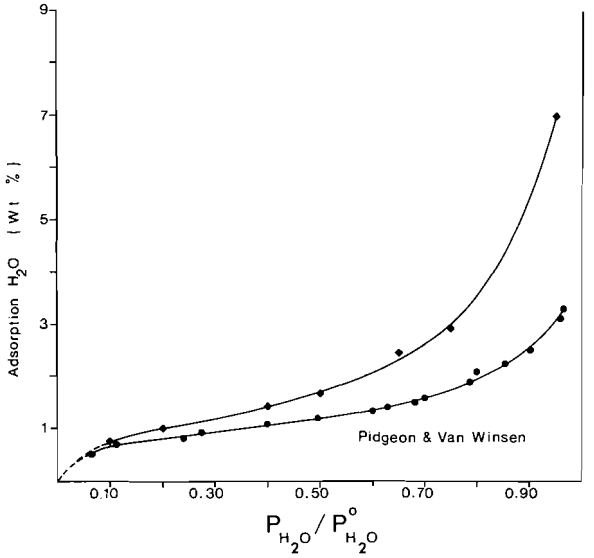

FIG. 8. Water adsorption isotherm of short fibers (25°C) compared with similar data from Pidgeon and Van Winsen (37) for coarse fibers (4-R). ◆, This work, short fibers; ●, Pidgeon and Van Winsen (37).

From the data at low water activity, monolayer coverage of the short fibers occurs at 0.8 ± 0.1 wt%; taking the H_2O molecular area as 10.6 $(Å)^2$, this yields a specific area of 28 m^2/g. Thus, from either nitrogen or water adsorption, the specific area of the sedimented short fibers appears in the upper range of values available for fibers which have not been subjected to extensive mechanical dispersion.

Conclusion

The results of the investigation described here provide a simple means for separating short chrysotile fibers from bulk commercial fibers. The selective sedimentation procedure enables rapid separation of fibers shorter than 2.0 μm, and this can be performed quantitatively by successive sedimentation–separation cycles. While the process may be of potential interest for removal of short fibers from bulk chrysotile materials, the purpose of this work was mainly to (*a*) define separation conditions, (*b*) explain the selective sedimentation behavior, and (*c*) provide some basic physico-chemical characterization of the short fibers separated in this way. Although some aspects could not be elucidated quantitatively (particularly the difficult question of excess $Mg(OH)_2$), it could be demonstrated satisfactorily that the separated short fibers are essentially native chrysotile in a form which is more homogeneous than bulk commercial fibers; in many instances, it should thus be more suitable for

further physico-chemical, biochemical, or biological investigations.

Acknowledgements

The authors gratefully acknowledge financial support of this research by the "Programme de Recherche sur l'Amiante (PRAUS)" (through Professor J. M. Lalancette) and the "Ministère de l'Education du Québec". The assistance of Marc-André Simard and Renée Hallée with some of the measurements is also acknowledged with pleasure. We also thank Mr. Marcel Cossette for providing the chrysotile samples and helpful advice, and Professor F. Kimmerle for discussion and comments on the manuscript. Finally, the assistance of Dr. R. F. Platford (Canada Center for Inland Waters) in lending the equipment for isopiestic measurements is gratefully acknowledged.

Crystal structures of racemic and optically active 4,4′-dimethyl-1,1′-binaphthyl

RICHARD A. PAUPTIT AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received August 14, 1980

RICHARD A. PAUPTIT and JAMES TROTTER. Can. J. Chem. **59**, 1149 (1981).

The structures of the title compounds were determined to aid in understanding spontaneous resolution in binaphthyl derivatives. Crystals of the racemate, $C_{22}H_{18}$, are monoclinic, $C2/c$, $a = 13.225(8)$, $b = 10.768(4)$, $c = 11.572(7)$ Å, $\beta = 114.04(2)°$, $Z = 4$. The structure was solved by direct methods and refined to $R = 0.074$ for 886 reflections with $I \geq 3\sigma(I)$. The crystals of the optically active form are tetragonal, $P4_12_12$ or $P4_32_12$, $a = 8.3031(8)$, $c = 23.706(7)$ Å, $Z = 4$. This structure was also solved by direct methods and refined to $R = 0.060$ for 723 reflections with $I \geq 3\sigma(I)$.

RICHARD A. PAUPTIT et JAMES TROTTER. Can. J. Chem. **59**, 1149 (1981).

Les structures des composés du titre ont été déterminées pour aider la compréhension du dédoublement spontané dans les derivatives de binaphthyle. Les cristaux racémiques, $C_{22}H_{18}$, sont monocliniques, $C2/c$, $a = 13.225(8)$, $b = 10.768(4)$, $c = 11.572(7)$ Å, $\beta = 114.04(2)°$, $Z = 4$. On a déterminé la structure par les méthodes directes et l'a affinée jusqu'à une valeur de $R = 0.074$ pour 886 réflexions avec $I \geq 3\sigma(I)$. Les cristaux des antipodes optiques sont tetragonals, $P4_12_12$ ou $P4_32_12$, $a = 8.3031(8)$, $c = 23.706(7)$ Å, $Z = 4$. Cette structure a été déterminée aussi par les méthodes directes, et on l'a affinée jusqu'à une valeur de $R = 0.060$ pour 723 réflexions avec $I \geq 3\sigma(I)$.

Introduction

In contrast to 1,1′-binaphthyl (1–4), racemic 4,4′-dimethyl-1,1′-binaphthyl does not undergo spontaneous resolution upon heating from room temperature to just below the melting point (5). Optically active dimethylbinaphthyl may be obtained by seeding the racemic melt with optically active naphthidine (6). The crystal structures of both the racemic and optically active dimethylbinaphthyls were investigated in the hope of understanding these observations.

Experimental

The data for both crystals, prepared by Pincock *et al.* (6), were collected on a Datex-automated GE XRD-6 diffractometer with CuKα radiation by use of a θ–2θ scan technique. The 2θ scan was performed at 4 deg min^{-1} over a range of $(1.80 + 0.86 \tan\theta)°$ with 10 s background counts at each end of the scan.

I. Racemate

Crystal data are as follows:

$C_{22}H_{18}$, mp = 145°C fw = 282.4

Monoclinic, $C2/c$, $a = 13.225(8)$, $b = 10.768(4)$, $c = 11.572(7)$ Å, $\beta = 114.04(2)°$. $V = 1505(1)$ Å^3, $Z = 4$, $\rho_c = 1.246(1)$ g cm^{-3}.

The intensity of one check reflection was measured every 50 reflections. The first data collection showed large variations in the check reflection count (due to electronic difficulties) and although the structure was solved with this data set, another set of data was collected for the refinement. In this set the check reflection counts were used to scale the data, and 886 out of the 1497 unique reflections in the range $0 < \theta \leq 60°$ had $I/\sigma(I) \geq 3.0$, where $\sigma^2(I) = S + B + (0.06S)^2$ and S and B are the scan and background counts, respectively, and were considered observed. Lorentz and polarization corrections were applied.

The structure was solved by direct methods; the E-map revealed all 11 carbon atoms. After three isotropic and two anisotropic full-matrix least-squares refinement cycles, all but one of the hydrogens could be located on a difference map; the remaining hydrogen was placed in a calculated position. Three more refinement cycles with unit weights followed by four cycles with a polynomial weighting scheme (7) reduced R and R_w to their final values of 0.078 and 0.074, respectively. The coefficients for the polynomial weighting scheme were adjusted after every cycle and had final values $a = -0.0079$, $b = 0.08165$, $c = -0.01791$, $d = 0.001391$. The scattering factors of ref. 8 were used for the carbon atoms and those of ref. 9 for the hydrogen atoms in both structure determinations.

II. Optically Active Form

Crystal data are as follows:

$C_{22}H_{18}$, mp 158°C fw = 282.4

Tetragonal, $P4_12_12$ or $P4_32_12$, $a = 8.3031(8)$, $c = 23.706(7)$ Å, $V = 1634.3(5)$ Å^3, $Z = 4$, $\rho_c = 1.1478$ g cm^{-3}.

The intensity of a check reflection measured every 50 reflections showed very little variation and no data scaling was required. 723 out of 1117 unique reflections in the range $0 < \theta \leq 80°$ had $I/\sigma(I) \geq 3.0$.

The structure was solved by direct methods, and again the E-map revealed the positions of all 11 carbon atoms. After three isotropic and three anisotropic full-matrix least-squares refinement cycles, a difference map was calculated, but the position of only one methyl hydrogen was used and all other hydrogens were placed in calculated positions. Several more refinement cycles with use of a weighting scheme where $w = 1/\{1 + [(|F_o| - F^*)/G^*]^2\}$, $F^* = 6.0$, $G^* = 15.0$, reduced R to its final value of 0.060. Attempts at determining the absolute configuration by inclusion of the small anomalous dispersion effects were unsuccesful.

The atomic positional parameters for the two structures are presented in Table 1.[1]

Results and Discussion

Figure 1 shows the molecular drawings and numbering schemes for both molecules. The asym-

[1]Thermal parameters, mean planes, bond lengths and angles involving hydrogen atoms, and the structure factor table for both structures are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

metric unit is one half the molecule; in each case the other half is generated by rotation about a twofold axis which bisects the C(1)—C(1′) bond. The naphthalene residues are *cis*-oriented in both molecules with a dihedral angle of 68.4° in the racemate and 80° in the optically active form.

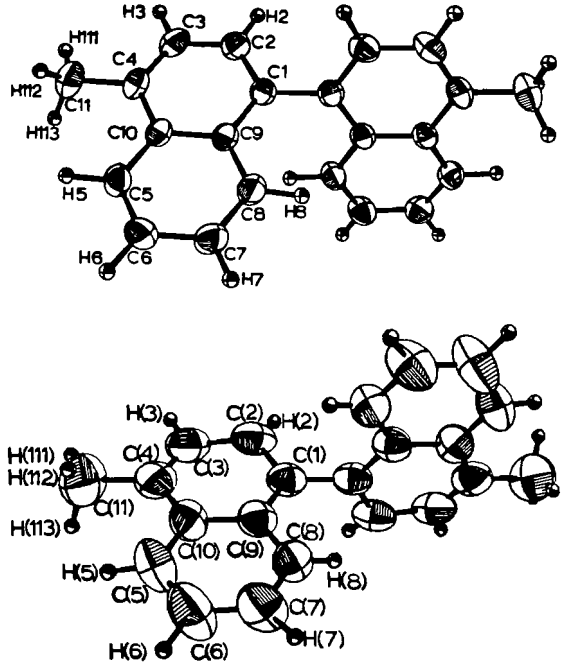

FIG. 1. Molecular views of the racemate (above) and the optically active form (below) showing 50% thermal ellipsoids.

Mean plane calculations[1] show that there is a slight bend in the asymmetric unit along the C(9)—C(10) bond: 3.1° in the racemate and 2.7° in the optically active form. For a similar distortion of 1° in 1,1′-binaphthyl the close contacts between the two halves of the molecule, e.g. C(8)...C(8′), have been suggested as possible reasons for this bending (10), but in the dimethyl compounds these contacts seem slightly too large for such an argument (e.g. C(8)...C(8′) is 3.45, 3.63, and 3.32 Å and C(9)...C(9′) is 3.34, 3.36, and 3.27 Å in the racemate, optically active form, and 1,1′-binaphthyl, respectively). At any rate, there appears to be no correlation between the proximity of these contacts and the degree of bending.

Bond lengths and angles with their standard deviations are listed in Table 2[1] and have normal values.

Packing diagrams for both compounds are shown in Fig. 2. The racemate consists of alternating layers of *R* and *S* molecules parallel to the (001) planes. Within each layer all molecules have the same orientation with respect to the crystal axes, i.e. there are only two orientations (which are enantiomorphic) with which a molecule might add to the lattice during crystallization. The optically active form packs with four orientations of molecules spiralling around a fourfold screw-axis, giving rise to quite an elongated (along *c*) unit cell. The two packing modes seem quite different.

The racemate is somewhat denser (1.25 vs. 1.15 g cm^{-3}) and hence more tightly packed and probably

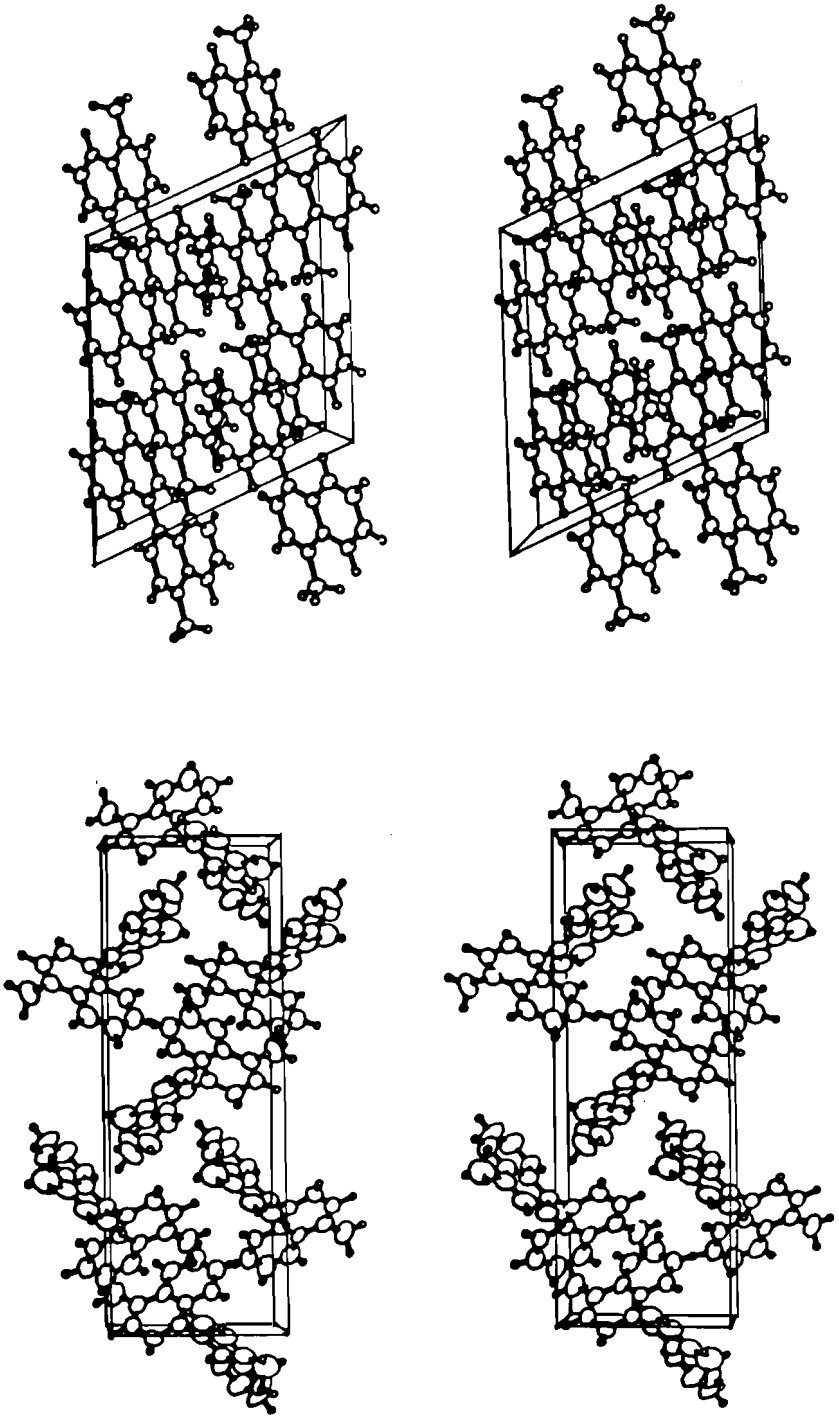

FIG. 2. Packing diagrams of the racemate (above) and the optically active form (below).

with a slightly greater lattice energy, i.e. more stable in the solid state than the optically active form. This might explain why the racemate does not undergo spontaneous resolution upon heating, but it offers no reasons for differences in behaviour between the methylated compounds and 1,1′-binaphthyl.

These results will be compared to the crystal structures of optically active naphthidine and 1,1′-binaphthyl in another paper (11).

TABLE 2. Bond lengths and angles of racemic and optically active dimethylbinaphthyl

Determination of absolute transfer free energies of hydroxyl ion from water to aqueous 2-methoxy ethanol

ABHIJIT BHATTACHARYA, ASIM K. DAS, AND KIRON K. KUNDU[1]

Physical Chemistry Laboratories, Jadavpur University, Calcutta–700 032, India

Received April 9, 1980

ABHIJIT BHATTACHARYA, ASIM K. DAS, and KIRON K. KUNDU. Can. J. Chem. **59**, 1153 (1981).

Absolute standard free energies of transfer ΔG_t^0 of OH^- from water to aqueous mixtures of 2-methoxy ethanol (ME) have been evaluated at 298.15 K by combining the apparent transfer free energies of the lyate ion that were obtained from the standard emf's of the double cell:

Hg–HgO/KOH(m), solvent/K(Hg)/KOH(m) water/HgO–Hg

and that from the autoionization constants of these mixed solvents determined by use of the cell comprising H_2– and Ag–AgCl electrodes. The required ΔG_t^0 values of K^+ and H^+ were determined earlier using the well-known tetraphenyl arsonium tetraphenyl boride (TATB) reference electrolyte method. These values and their non-Born type contributions in particular, are found to be increasingly positive in water-rich compositions, indicating that the relative stabilization of OH^- and the acidity of the mixed solvents decrease with increasing cosolvent composition. These, when compared with those in aqueous mixtures of ethylene glycol and 1,2-dimethoxy ethane, are found to lie intermediate between the latter solvent systems conforming to what is expected from the structural and electronic features of the cosolvents.

ABHIJIT BHATTACHARYA, ASIM K. DAS et KIRON K. KUNDU. Can. J. Chem. **59**, 1153 (1981).

On a évalué, à 298,15 K, les énergies standards absolues de transfert, ΔG_t^0, de l'ion OH^- à partir de l'eau jusqu'à des mélanges aqueux de méthoxy-2 éthanol (ME) en combinant les énergies libres apparentes de transfert de l'ion lyate obtenues à partir des fem standard de la double cellule:

Hg–HgO/KOH(m), solvant/K(Hg)/KOH(m) eau/HgO–Hg

et à partir des constantes d'auto-ionisation de ces solvants mixtes déterminés en utilisant une cellule formée d'électrodes H_2– et Ag–AgCl. Les valeurs nécessaires de ΔG_t^0 pour K^+ et H^+ ont été déterminées antérieurement en utilisant la méthode électrolytique de référence bien connue du tétraphényl arsonium borure de tétraphényle (TABT). On a trouvé que ces valeurs ainsi que leurs contributions de types différents de ceux prévues par Born sont de plus en plus positives dans des compositions riches en eau, indiquant ainsi que la stabilisation relative du OH^- et l'acidité des solvants mixtes décroîssent lorsque la composition du co-solvant augmente. Lorsqu'on compare ces valeurs à celles des mélanges aqueux d'éthylèneglycol et de diméthoxy-1,2 éthane, on trouve qu'elles se situent à un point intermédiaire entre celles des derniers systèmes de solvant, conformément à ce qu'on attend compte tenu des caractéristiques structurales et électroniques des co-solvants.

[Traduit par le journal]

Introduction

The knowledge of solvation behaviour of OH^- is an important prerequisite to the understanding of solvent effects on the rates of base-catalyzed reactions or equilibria involving OH^-. This is particularly true in the cases of dipolar aprotic solvents which usually cause dramatic enhancement of the rates of OH^--catalyzed reactions, H_--acidity function, and the proton transfer equilibria involving OH^- (1–6). Although all these effects are usually attributed to the well recognized "desolvation" and the accompanying enhancement of the OH^- activity caused by dipolar aprotic solvents (1–6), the thermodynamic basis of these are yet to be resolved in many cases.

It is well known that the usual source of transfer free energies ΔG_t^0, of OH^-_{app} or OH^- from water to the aquo-organic (protic as well as dipolar aprotic) solvents is the autoionization constants (K_s) of the mixed solvents (7–9) or the apparent ionization constants $(K_a)_{app}$ of water in the mixed solvents, which help determine ΔG_t^0 of $[H^+(OH^-)_{app}]$. Consider an H_2O + ROH solvent system, where ROH is a protic cosolvent. The autoionization of the aqueous mixtures of this cosolvent may be presented by the general expression [1]

$$[1] \quad SOH(s) + SOH(s) \rightleftharpoons SOH_2^+(s) + SO^-(s)$$

where SOH is a solvent molecule in the mixed solvents being either water or the cosolvent, and SOH_2^+ and SO^- are the lyonium and lyate ions, respectively, and (s) denotes that the species are in the standard state in the respective mixed solvent. In pure water the corresponding ionization process can be represented as

$$[2] \quad H_2O(w) + H_2O(w) \rightleftharpoons H_3O^+(w) + OH^-(w)$$

where (w) denotes that the species are in the standard state in pure water. Consequently, the standard free energy change $\delta(\Delta G^0)$ accompanying the ionization of the components of the mixed solvents relative to that of water i.e. of the process [3]

[3] $H_3O^+(w) + SOH(s) + SOH(s) + OH^-(w) \rightleftharpoons H_2O(w) + SOH_2^+(s) + SO^-(s) + H_2O(w)$

which is equivalent to the sum of the free energy changes of the processes [4] and [5]:

[4] $H_3O^+(w) + SOH(s) \rightleftharpoons H_2O(w) + SOH_2^+(s)$

[5] $SOH(s) + OH^-(w) \rightleftharpoons SO^-(s) + H_2O(w)$

If we denote the free changes due to the processes [4] and [5] by $\Delta G_t^0(H^+)$ and $\Delta G_t^0(OH^-)_{app}$ respectively, it follows that

[6] $\delta(\Delta G^0) = \Delta G_t^0(H^+) + \Delta G_t^0(OH^-)_{app}$

If $\Delta G_t^0(H^+)$ is known for the system, $\Delta G_t^0(OH^-)_{app}$ could be evaluated. But $\Delta G_t^0(OH^-)_{app}$ being a composite quantity, estimation of the absolute free energies of transfer of OH^-, $\Delta G_t^0(OH^-)$ i.e. of the process [7]

[7] $OH^-(w) \rightarrow OH^-(s)$

is difficult, especially for cosolvents whose acidity is comparable to that of water. Consequently, auxiliary measurements are in order.

Another possible source of transfer free energy of OH^- in these mixed solvents is the study of emf's of suitable cells (say, cell A) containing Hg–HgO electrode – the well known OH^- reversible electrode.

[A] Hg–HgO/KOH(m), solvent/K(Hg)/KOH(m), water/HgO–Hg

The free change $\Delta G^0_{\text{cell A}}$, accompanying the overall reaction of the double cell A:

[8] $2K^+(s) + OH^-(s) + SO^-(s) + H_2O(w) = 2K^+(w) + 2OH^-(w) + SOH(s)$

as computable from the standard emf (ΔE^0) of the double cell [A] will be related as follows:

[9] $\Delta G^0_{\text{cell A}} = -2F[\Delta E^0]$

where F = Faraday. Also, from reaction [8] it follows that

[10] $\Delta G^0_{\text{cell A}} = -2\Delta G_t^0(K^+) - \Delta G_t^0(OH^-)'_{app}$

where $\Delta G_t^0(OH^-)'_{app}$ is the free energy change accompanying the process [11]

[11] $2OH^-(w) + SOH(s) \rightleftharpoons SO^-(s) + OH^-(s) + H_2O(w)$

Again, if $\Delta G_t^0(K^+)$ values are known, $\Delta G_t^0(OH^-)'_{app}$ could be evaluated. Moreover, since $\Delta G_t^0(OH^-)'_{app}$ and $\Delta G_t^0(OH^-)_{app}$ are related as follows

[12] $\Delta G_t^0(OH^-)'_{app} = \Delta G_t^0(OH^-)_{app} + \Delta G_t^0(OH^-)$

$\Delta G_t^0(OH^-)$ can be estimated, if $\Delta G_t^0(OH^-)_{app}$ is obtained from the studies of autoionization of the solvents, as indicated above. Thus it appears that the combination of the data obtainable from the studies of autoionization as well as of the cell [A], offers, for the first time, a suitable method for determining absolute transfer free energies of OH^-, $\Delta G_t^0(OH^-)$, provided ΔG_t^0 values of H^+ and K^+ are determined by use of a suitable extra-thermodynamic assumption (11, 12).

In the aqueous solutions of dipolar aprotic cosolvents, however, since SOH(s) and SO^-(s) are in fact HOH(s) and HO^-(s) respectively, it follows from eqs. [5] and [11] that

[13] $\Delta G_t^0(OH^-)_{app} = \Delta G_t^0(OH^-) - \Delta G_t^0(H_2O) = \Delta G_t^0(OH^-) + RT \ln a_w^s$

and

[14] $\Delta G_t^0(OH^-)_{app} = 2\Delta G_t^0(OH^-) - \Delta G_t^0(H_2O) = 2\Delta G_t^0(OH^-) + RT \ln a_w^s$

where a_w^s is the activity of water in the mixed solvents referred to pure water as the standard state. Thus, if a_w^s is known for the system, either autoionization constants or the ΔE^0's of the cell A would yield $\Delta G_t^0(OH^-)$. In addition to this, if $\Delta G_t^0(OH)$ is known from the combined results of both sets of measurements. eqs. [13] or [14] would provide a method for determining a_w^s in these mixed solvents.

Now, it is often observed that determination of the primary thermodynamic quantity viz. autoionization constant of water by use of suitable galvanic cells comprising either H_2 and Ag–AgCl electrodes or less preferable glass and calomel/Ag–AgCl electrodes proves difficult, especially at higher compositions of some dipolar aprotic cosolvents. Consequently, the use of cell A or the like is likely to serve as a suitable method for determining $\Delta G_t^0(OH^-)$, provided a_w^s values are known for such solvent systems.

The object of the present paper is to demonstrate the suitability of cell A or the like for evolving ΔG_t^0 values of $(OH^-)'_{app}$ in aqueous mixtures of an organic cosolvent, the nature of which lies in the borderlines of protic and dipolar aprotic characters. One such cosolvent is 2-methoxy ethanol (ME), commonly known as methyl cellosolve (MCS). Although it is basically a protic solvent, the inductive effect of methyl group is likely to facilitate intramolecular hydrogen bonding thus imparting some aprotic character to the molecule. Con-

sequently, the behaviour of cell A or the like in this solvent system, it is hoped, will be indicative of the suitability of its potential use in some aqueous dipolar aprotic solvents. Moreover, since it is a protic solvent, it is also expected that the autoionization constant of water could be easily determined by use of suitable cells referred to above. In fact, Wooley *et al.* (10*a*) have already reported the apparent ionization constant $(K_a)_{app}$ of water in this solvent system up to 65 wt% cosolvent, but by use of glass and Ag–AgCl electrodes. However, as Smits *et al.*'s (13) ΔG_t^0(HCl) values based on glass and Ag–AgCl electrodes are found to differ appreciably from those of Sadek *et al.* (14) based on H_2 and Ag–AgCl electrodes, and as similar differences are quite usual for dipolar aprotic cosolvent systems (13) we have considered it useful to determine the autoionization constant (K_s) of these solvents by use of H_2 and Ag–AgCl electrodes. Thus, in this paper we are reporting ΔG_t^0 values of $[K^+(OH^-)'_{app}]$ as well as $[H^+(OH^-)_{app}]$ in aqueous mixtures of 10, 30, 50, and 70 wt% ME as obtained by determining respectively the standard emf (ΔE^0) of the double cell A and the autoionization constants (K_s) of these mixed solvents by use of cell B

[B] H_2(g,1 atm)/KOH(m_1)KCl(m_2), solvent/AgCl–Ag

Experimental

2-Methoxy ethanol (Merck, Pure) was purified in a manner described earlier (14, 15); water used for the preparation of the mixed solvents and the electrolyte solutions was distilled thrice and made free from CO_2 and O_2 first by boiling and then by flushing pure H_2. For the studies of cell A the concentrations of the stock solutions of KOH (Merck, G.R.) were determined by standard HCl solution using phenolphthalein as indicator. Solutions of different molalities of KOH were prepared by weight dilution. As before (16), to avoid the effects of corrosion of K(Hg) the concentrations of KOH solutions used were kept above 0.02 *m*. All the manipulations and handling of the solutions were done in a chamber flushed with N_2, so as to avoid the exposure of the solutions to atmosphere as far as possible.

The methods of purification of mercury and preparation of potassium amalgam, [K(Hg)] have been described (16, 17). The amalgam reservoir and the cell design were also similar to those described earlier (17, 18).

Hg–HgO electrode consists of a j-shaped glass tube fitted with a B-19 standard joint at the upper end of the larger limb which allows placing of the electrode in the amalgam cell. The shorter limb is separated from the longer limb by a glass seal and connected electrically through a Pt-wire fused through the glass seal. The open end of the shorter limb, called the "cup" of the electrode and serving as the holder of the electrode materials, was dipped into the cell solutions. In the "cup" a small portion of triple distilled Hg was first introduced, then a paste of triturated mixture of Hg and HgO, formed by adding the respective cell solutions, was added to cover up the free surface of Hg in the "cup". Before using the HgO (red variety, Merck, G.R.) was pretreated (19) by thoroughly washing with hot water, filtering and then drying *in vacuo*. It has been observed that the asymmetry potential was reduced practically within the range of experimental uncertainty of ±0.5 mV, when a thick layer of HgO-paste was used. The electrodes were kept overnight in the respective solutions in a specially designed closed container for the attainment of equilibrium in the mixed solvents, although in aqueous solutions ageing for 2 h proved sufficient. Adequate care was taken to remove the air film often formed at the paste–solution interface, particularly in aqueous solutions. Fresh pairs of electrodes were used for each set of the cell solutions.

All studies were made at 298.15 K. Completely O_2-free atmosphere was maintained by passing pure H_2 gas through the cell solutions. The H_2 gas was presaturated with the respective solvent vapour by passing it through a train of gas saturator containing the respective cell solutions. The general experimental procedure was essentially similar to that described earlier (16, 17). Electromotive force measurements were made with the help of a Leeds and Northrup K_4-potentiometer along with a moving-coil galvanometer (Cambridge Inst. Co.) as a null point detector. Constancy of emf values within ±0.2 mV between three successive emf readings taken at 10 min intervals was taken as the criterion of equilibrium.

For the studies of cell B, the experimental set up and procedures adopted were exactly similar to those described earlier (8).

Results

Cell [A]

The observed emf's (ΔE) of cell A for different molalities (m) of KOH in each of the mixed solvents are given in Table 1. These values in each solvent mixture were used to construct an extrapolation function (17) given by eq. [15]

$$[15]\quad \Delta E' = \Delta E - 2k'[{}_sf(m) - {}_wf(m)_-] = \Delta E^0 - 2k'({}_sb - {}_wb)m$$

where

$$f(m) = -A_0B_0m^{1/2}(1 + a_0B_0m^{1/2})^{-1} - \ln(1 + 0.002\,Mm)$$

subscripts s and w indicate the mixed solvent and water respectively, $k' = RT/F$, M = molar or mean molar mass of water or of the mixed solvents respectively, a_0 is the ion-size parameter, A_0B_0 and B_0 are the familiar Debye-Hückel constants (14, 15), values of which for this solvent system were taken from a previous paper (15), and b is the empirical constant depending upon the nature of the solvent, temperature, and also the ion-size parameter used for computing $f(m)$. As in earlier studies (15, 17), since alteration of a_0 values does not impart any significant change in the extrapolated values of ΔE^0 beyond experimental error of ±0.5 mV, $a_0 = 0$ has been used. As the $\Delta E'$ function in each case was found fairly linear against mol kg^{-1} (m) of KOH solution, ΔE^0 was found by extrapolating the plots of $\Delta E'$ against m to $m = 0$. The values so obtained are presented in Table 1. The corresponding values when obtained by least squares agree within the experimental error and the

average standard deviation lies well within the same limits.

Following the arguments cited earlier (see Introduction), standard free energy changes accompanying the overall reaction of cell A, $\Delta G^0_{\text{cell A}}$ were computed on mole fraction scale (20) by using eq. [16]

$$[16] \quad -\Delta G^0_{\text{cell A}} = 2\Delta G_t{}^0(\text{K}^+) + \Delta G_t{}^0(\text{OH}^-)'_{\text{app}} = 2F\Delta E^0 - 4RT \ln M_s/M_w$$

Since $\Delta G_t{}^0(\text{K}^+)$ values for this solvent system are known from a previous measurement (15) based on the most widely used tetraphenylarsonium tetraphenylboride (TATB) reference electrolyte assumption (11, 12), eq. [16] helped yield the values of $\Delta G_t{}^0(\text{OH}^-)'_{\text{app}}$. All these values are presented in Table 3.

Cell [B]

The observed emf's E (corrected to $p_{H_2} = 1$ atm) of cell B for cell solutions of different ionic strength μ in each of the solvents are presented in Table 2. These values were used to compute an extrapolation function ($_pK_s'$) defined (8) by eq. [17]

$$[17] \quad pK_s' = \frac{F[(E - E^{0,m}_{\text{AgCl-Ag}})]}{RT \log 10} + \log \frac{m_{\text{Cl}^-}}{m_{\text{OS}^-}} = pK_s{}^m - \log \frac{\gamma_{\text{Cl}^-} a_{\text{SOH}}}{\gamma_{\text{OS}^-}} = pK_s{}^m - f(\mu)$$

where the symbols have usual meanings (8) and the required $E^{0,m}_{\text{AgCl-Ag}}$ values referred to respective solvents as the standard states were taken from the paper of Sadek *et al.* (14). The standard states are so chosen that at infinite dilution in a given solvent the molal activity coefficients of the ions, and also the mole fraction of the solvent x_{SOH}, are unity. As in pure water (20*a*) and dioxane–water mixtures (20*b*) etc., since the term, $\log \gamma_{\text{Cl}^-} a_{\text{SOH}}/\gamma_{\text{OS}^-}$ is likely to be proportional to μ in dilute solutions, a plot of the function pK_s' against μ would yield pK_s value on molal scale, pK_s^m. In fact, the values of the function pK_s' for each of these solvent mixtures when plotted against μ, are found to be fairly linear. And pK_s^m values were obtained from the least-squares linear plots of pK_s' against μ. These values are given in Table 2, their standard deviations lying within ± 0.01 unit in all the cases.

Notably, these pK_s^m values are found to differ from the corresponding values $K_{a/1}$ (molal scale) of Wooley *et al.* (10*c*) by about 0.1 unit up to 65 wt% cosolvent composition. Although, the corresponding data in aqueous ethylene glycol (EG) (10*a*, 21) and glycerol (8*c*, 10*c*) agree fairly well at least up to 50 wt% cosolvents, they differ somewhat appreciably at about 70 wt% in the case of glycerol. Moreover, as mentioned earlier, since $\Delta G_t{}^0(\text{HCl})$ values obtained by glass and Ag–AgCl electrodes (13) differ appreciably from those based on H_2 and Ag–AgCl electrodes (14) in this solvent system, it leads us to wonder if the observed differences stem from the untoward behaviour of glass electrode in this cosolvent system of "semi-aprotic" character, as is usually the case in most protic – dipolar aprotic solvent systems (13).

The standard free energy changes accompanying the autoionization of the mixed solvents relative to that of water, $\delta(\Delta G^0)_{\text{cell B}}$, which stand for $\Delta G_t{}^0[\text{H}^+(\text{OH}^-)_{\text{app}}]$, have been computed on mole fraction scale by use of eq. [18]

$$[18] \quad \delta(\Delta G^0_{\text{cell B}}) = \Delta G_t{}^0[\text{H}^+(\text{OH}^-)_{\text{app}}] = 2.3026RT[p(_sK_s^m)] - p(_wK_s^m)] + 2RT \ln M_w/M_s$$

Since $\delta(\Delta G^0_{\text{cell B}})$ is the sum of $\Delta G_t{}^0(\text{H}^+)$ and $\Delta G_t{}^0(\text{OH}^-)_{\text{app}}$ (see eq. [6]), and also $\Delta G_t{}^0(\text{H}^+)$ values for this solvent system are known from a previous study (15), these $\delta(\Delta G^0_{\text{cell B}})$ values helped compute $\Delta G_t{}^0(\text{OH}^-)_{\text{app}}$ values for the system. All these values are presented in Table 3.

Combining these values of $\Delta G_t{}^0(\text{OH}^-)_{\text{app}}$ and those of $\Delta G_t{}^0(\text{OH}^-)'_{\text{app}}$ estimated from the results of cell A we have obtained $\Delta G_t{}^0(\text{OH}^-)$ values with the help of eq. [12] and listed in Table 3. The figure illustrates their variation with cosolvent composition. For the sake of comparison, the corresponding values in aqueous 1,2-dimethoxy ethane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

(DME)[2] and in aqueous EG solvent systems are also shown in the figure. It should be noted that these values in DME + water system, which is an aqueous dipolar aprotic solvent system, were obtained from $\Delta G_t^0[H^+(OH^-)_{app}]$ values[2] based on autoionization constants determined by use of H_2 and Ag–AgBr electrodes and $\Delta G_t^0(H^+)$ values based on TATB method reported recently (22). And as per eq. [13] the required values of $RT \ln a_w^s$ were taken approximately equal to $RT \ln x_w^s$. Similarly, $\Delta G_t^0(OH^-)$ values for the EG–water system which is an aqueous-protic system were also obtained from literature data of $\Delta G_t^0[H^+(OH^-)_{app}]$ (8*c*) based on autoionization constants (21*a*) and $\Delta G_t^0(H^+)$ based on TATB method (21*b*). It should be particularly noted, however, that the proper correction for the ionization of EG has been made by Basu Mullick *et al.* (8*c*) following Woolley *et al.*'s method (10*c*) to make $(OH^-_{app})_{protic}$ equivalent to $(OH^-_{app})_{aprotic}$ from which $\Delta G_t^0(OH^-)$ values were obtained by adding $\Delta G_t^0(H_2O)$, i.e. $-RT \ln a_w^s$ (23) as per eq. [13]. The dotted portion in the curve for the EG–water system in Fig. 1 is to indicate the approximate nature (8*c*) of Woolley-type correction.

Discussion

It is interesting to note that while $\Delta G_t^0(OH^-)$ – composition profile (Fig. 1) in EG–water mixtures remains almost invariant, that for the other two solvent systems become increasingly positive with increased cosolvent composition in the range studied. And for any cosolvent composition $\Delta G_t^0(OH^-)$ values in the ME–water system lie in between those of the two other solvent systems, their relative order being DME > ME > EG.

As is well known, the solvation behaviour of OH^- in the mixed solvents is likely to be dictated chiefly by the combined effects of varying dielectric constant and the acidity of the solvents. So, when Born-type electrostatic effects resulting from the varying dielectric constants of the solvents (23), were computed tentatively by use of simple Born equation (24) using $r_{OH^-} = 0.156$ nm (25) and the dielectric constant values from literature (14, 20*a*, 26), and subtracted from $\Delta G_t^0(OH^-)$ values, the resulting $\Delta G_{t,ch}^0(OH^-)$ values should essentially reflect the effects of relative acidity of the mixed solvents. The observed $\Delta G_{t,ch}^0(OH^-)$ – composition profile (Fig. 1) therefore suggests that with increasing addition of the cosolvent, while the acidity of EG–water mixtures increases somewhat slowly, that of DME–water mixtures decreases quite sharply. In ME–water mixtures, as well, the

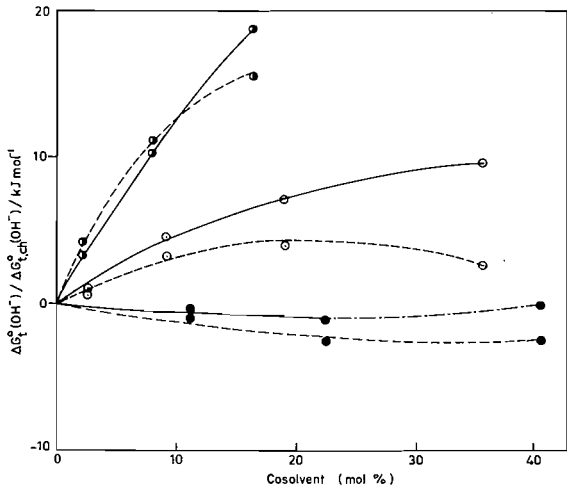

FIG. 1. Variation of $\Delta G_t^0(OH^-)$ (solid lines) and $\Delta G^0_{t,ch}(OH^-)$ (dotted lines) with cosolvent composition in ME–water mixtures (⊙), DME-water mixtures (◑), and EG–water mixtures (●).

acidity decreases, but to a much smaller extent. In fact, this is also expected from the relative acidities of the cosolvent molecules as governed by their structural features indicated below.

Simple consideration of the molecular structures of the cosolvent molecules shows that (*1*) EG is more acidic than water because the positive charge on the hydroxylic H-atom of the intramolecularly hydrogen bonded EG is enhanced by the electron withdrawing effect of the remote O-atom transferred through H-bond and (*2*) ME is less acidic than EG due to the presence of an electron releasing *O*-methyl group and also less acidic than water due to the restricted availability of the H-bonded acidic H-atom, which imparts some aprotic character to the molecule, while (*3*) DME is wholly dipolar aprotic by nature, having no acidic H-atom. Since this acidity of the cosolvents is likely to be relayed through co-operative structure of H-bonding between the cosolvent and H_2O molecules (27) in the aqueous solutions, the possible H-bonded cosolvent–water complexes should make EG–water solutions increasingly more acidic and DME–water mixtures increasingly less acidic. But the ME–water solutions should be less acidic than EG–water mixtures as well as water due to the partial aprotic character of the ME molecule but at the same time more acidic than DME–water mixtures because of its partial protic character. And this explains why the extent of stabilization of OH^- in ME–water mixtures is lying in between that in the other two cosolvent systems.

The foregoing discussions underline the importance of the absolute values of $\Delta G_t^0(OH^-)$ in obtaining information regarding solvent acidity. It will thus be useful to determine this quantity in various solvents by the method described in this work to gain better understanding of the acid–base nature of such solvents.

Conformational dynamic investigation of 1,5-benzodioxepin and its dimethyl derivative by ^1H and ^{13}C nmr

D. MENARD AND M. ST-JACQUES

Département de Chimie, Université de Montréal, Montreal (Qué.), Canada H3C 3V1

Received September 26, 1980

D. MENARD and M. ST-JACQUES. Can. J. Chem. **59**, 1160 (1981).

The conformational and dynamic properties of 1,5-dioxa-6,7-benzocycloheptene (**2**; 1,5-benzodioxepin) and its dimethyl derivative (**7**) have been investigated by dynamic ^1H and ^{13}C nmr methods. Analysis of the spectra at low temperatures (below coalescence) indicates that the most stable seven-membered ring conformations detected for solutions in CHF_2Cl are a mixture of the chair (C, 80%) and the twist-boat (TB, 20%) for **2** and a mixture of TB (64%) and C (36%) for **7**. Free energy barriers were determined for the chair inversion of **2** (6.5 kcal/mol) and **7** (7.5 kcal/mol) as well as for the twist-boat pseudorotation of **7** (6.8 kcal/mol). The conformational properties of these seven-membered heterocycles are discussed and compared to those known for 2,4-benzodioxepins.

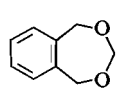
D. MENARD et M. ST-JACQUES. Can. J. Chem. **59**, 1160 (1981).

Les propriétés conformationnelles et dynamiques du dioxa-1,5 benzocycloheptène-6,7 (**2**; benzodioxépine-1,5) et de son dérivé diméthylé (**7**) ont été étudiées par rmn dynamique des noyaux ^1H et ^{13}C. L'analyse des spectres à basse température (en-dessous de la coalescence) de ces composés en solution dans le CHF_2Cl révèle que les conformations les plus stables adoptées par le cycle à 7 chaînons sont la chaise (C, 80%) et le bateau-croisé (TB, 20%) dans le cas de 2 et un mélange de TB (64%) et C (36%) dans le cas de **7**. On a déterminé l'énergie libre d'activation de l'inversion de la chaise de **2** (6,5 kcal/mol) et de **7** (7,5 kcal/mol) de même que la barrière de pseudorotation de la forme bateau-croisé de **7** (6,8 kcal/mol). Les propriétés conformationnelles de ces hétérocycles à 7 chaînons sont discutées et comparées à celles déjà connues des benzodioxépines-2,4.

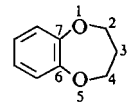
The recent observation of interesting and surprising conformational features for 1,3-dioxa-5,6-benzocycloheptene (**1**; 2,4-benzodioxepin) and its 2-substituted derivatives (**1**) as well as our continuing interest in the conformations of seven-membered ring systems led us to focus our attention on the 1,5-dioxa analogs of this family of molecules (i.e. **2** and its derivatives).

A study of the conformational characteristics of 1,5-benzodioxepins is particularly pertinent in view of the pharmaceutical activity associated with some compounds from this class of heterocyclic molecules. A number of 3-substituted aminomethyl-3-hydroxy-1,5-benzodioxepins (**3**) have been shown to possess interesting bronchial dilator activity (2) while various 3,3-disubstituted 1,5-benzodioxepin derivatives (**4**) have recently been recognized as analgesics, antiarrythmics, and sedatives (3). A precise knowledge of the conformational properties of this type of molecule therefore appears desirable in order to fully understand their biological mode of action.

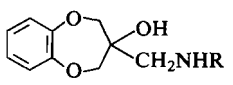
At present, very few studies of the conformational properties of this class of compounds have been published. Results reported from an ultraviolet study of 1,5-benzodioxepin and its derivatives (4) have provided only partial and qualitative information on the conformations adopted by these molecules in solution. Depending on the substitution pattern, the compounds studied were often thought to exist as mixtures of conformations for



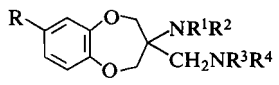
1



2



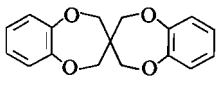
3



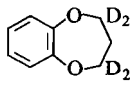
4

which no quantitative measurement could be made. Furthermore, a variable temperature ^1H nmr study of several compounds down to −80°C is reported to have failed to provide information on the conformational processes involved (4). On the other hand, X-ray diffraction data for 3,3′-spirobi[3H-2,4-dihydrobenzo[1,4]dioxepin] (**5**) showed that the seven-membered ring exists exclusively in the twist-boat conformation (5).

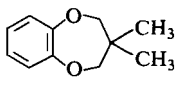
We therefore report the results of our study of the conformation of 1,5-benzodioxepin (**2**) and its 3,3-dimethyl derivative (**7**). Our nmr observations



5



6



7

provide more complete insight into the conformational and dynamic features characterizing this class of heterocyclic molecules.

						7.13 (−140°C) (C → TB interconversion)
			4.01 (TB)			
			3.42 (C)	−11.7		6.84 (−140°C (TB inversion)
			3.90 (C)			

[a]At 100 MHz in CHF_2Cl containing internal Me_4Si.
[b]The letters C and TB in parentheses refer to conformations described in the text.
[c]At 250 MHz in CHF_2Cl containing internal Me_4Si and CD_2Cl_2 (about 13%) for lock.
[d]Because a transmission coefficient of 1/2 was used in the calculation of this value, the number given refers to the C ⇌ B step of the inversion pathway.
[e]These values were obtained from a computer simulation of the H-2,4 spectral change. The $\Delta G^{\ddagger}$ values correspond to k_{14}, k_{12}, and k_{23} respectively, which characterize the conformational processes given in parentheses. The estimated error is about ±0.3 kcal/mol.

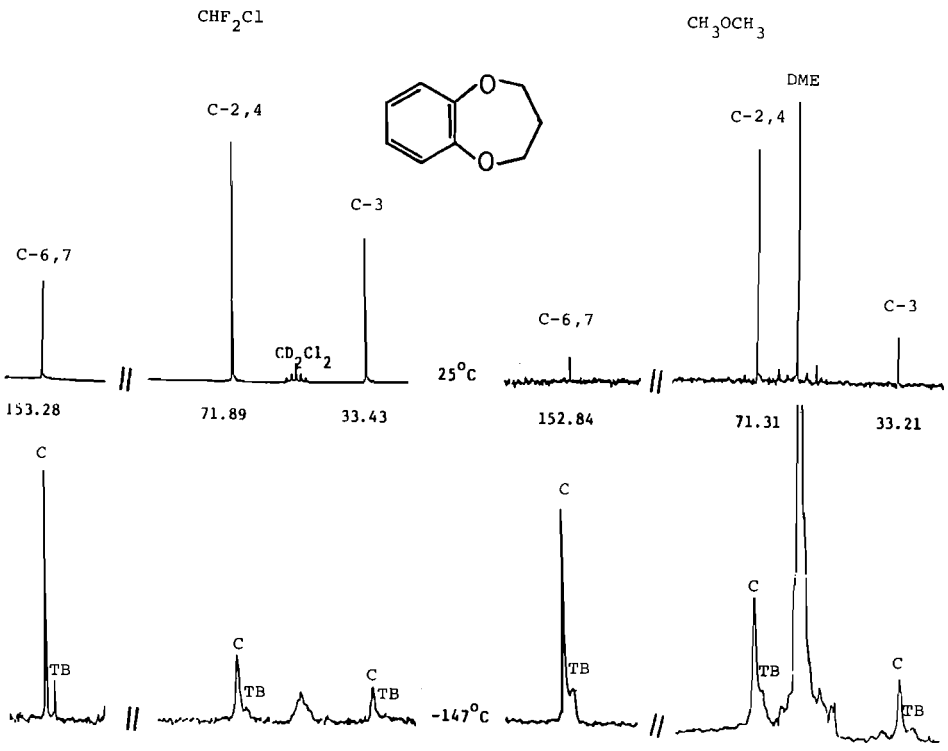

FIG. 1. The 20.15 MHz ^{13}C nmr spectra of the seven-membered ring carbons of **2** in CHF_2Cl and CH_3OCH_3 (DME identifies the CH_3 signal of the CH_3OCH_3 solvent). The symbols C and TB are defined in the text.

Results

Both compounds **2** and **7** gave dynamic proton and carbon-13 magnetic resonance (^{1}H and ^{13}C nmr) spectral changes on going to low temperatures. For spectral simplification, the variable temperature ^{1}H nmr study of **2** was performed on its 2,2,4,4-tetradeutero isomer **6**. Spectral and dynamic parameters for these compounds are listed in Tables 1 and 2.

Figure 1 illustrates the 20.15 MHz ^{13}C spectral

[a]Solutions containing internal Me_4Si and CD_2Cl_2 (19%) for field lock purpose.
[b]The letters C and TB in parentheses refer to conformations described in the text.
[c]The chemical shifts of the less intense signals were not determined accurately at low temperature and consequently are not reported in this table.

modifications observed for **2** in CHF_2Cl. Most of the ring carbon signals have split into doublets of unequal intensities at −147°C. The more intense lines account for 80% while the less intense lines account for 20% of the total intensity. A similar spectral change was observed for this compound in dimethyl ether in which signal integration revealed 23% for the less intense lines and 77% for the major ones.

Figure 2 shows that the methylene proton singlet of the 100 MHz ^1H nmr spectrum of **6** in CHF_2Cl changes into an AB pattern below −131°C. The free energy of activation calculated from the coalescence of the AB pattern (6) is found to be 6.5 kcal/mol (at −131°C) using a transmission coefficient of one-half (*vide infra*).

The changes observed in the ^{13}C nmr spectrum of **7** as the temperature is lowered are illustrated in Fig. 3 where all ring carbons are shown to have split into doublets of unequal intensities at −128°C. For a solution of **7** in CHF_2Cl, the more intense lines account for 64% and the less intense lines account for 36% of the total intensity. A free energy of activation of 7.8 ± 0.3 kcal/mol was estimated at −113°C (the coalescence temperature) using a two site approximation (7) and a transmission coefficient of one (*vide infra*). Similar changes were observed in the ^{13}C nmr spectrum of **7** in CH_3OCH_3 with the exception that the singlet at δ 22.55 splits into three lines instead of two in CHF_2Cl at −141°C (see inset in Fig. 3). Thus, the upfield methyl line observed in CHF_2Cl constitutes an unresolved doublet and the solvent effect produced by dimethyl ether leads to better resolution of the two components of equal intensity. Integration of the signals in CH_3OCH_3 revealed 75% for the most intense lines and 25% for the minor ones.

The 250 MHz ^1H nmr spectrum of **7** in CHF_2Cl (Fig. 4) shows that the methylene singlet observed at room temperature splits into a seven line pattern below −130°C while the methyl singlet splits into a triplet below −120°C for which the center line accounts for 64% of the total intensity and the less intense lines on each side account for 18% each of the total intensity.

This figure also illustrates a series of changing spectra calculated for the methylene protons by means of the DNMR-2 computer program (8). Thus it was possible to confirm the spectral analysis reported diagrammatically under the methylene proton spectrum at −140°C (Fig. 4) where two overlapping AB patterns are identified by the solid and broken lines. The kinetic results derived from the computer spectral simulation are summarized in Table 1.

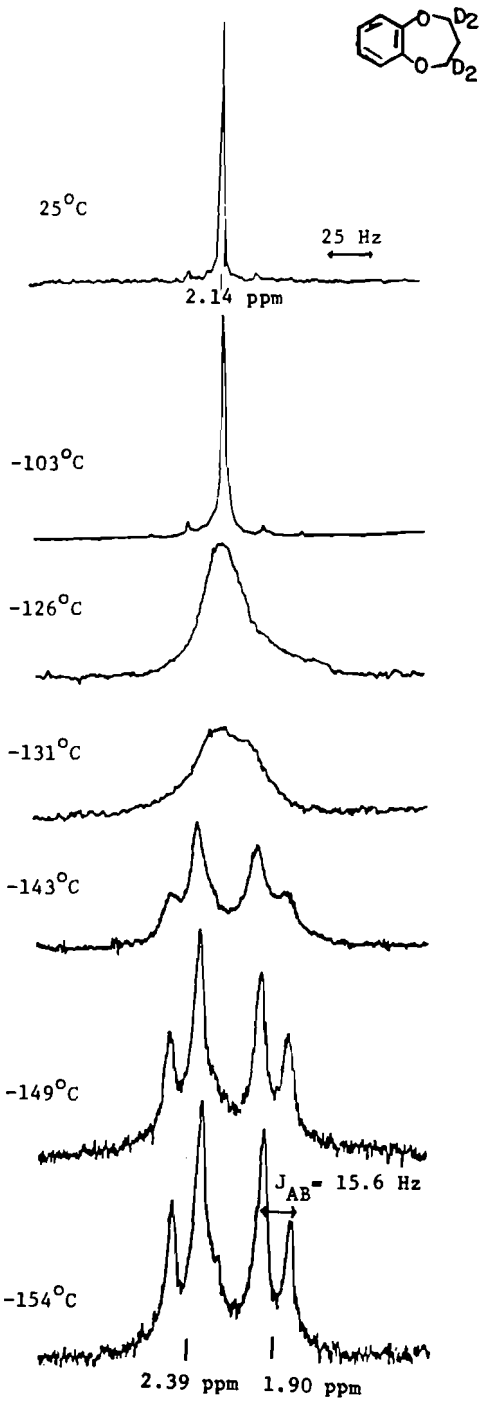

FIG. 2. The ^2H decoupled 100 MHz ^1H nmr spectra of the methylene protons of **6** in CHF_2Cl at several temperatures.

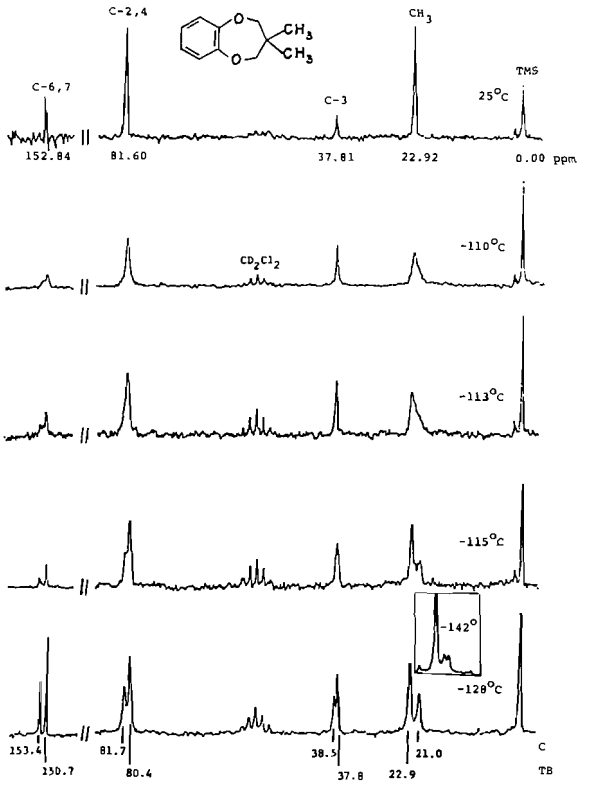

FIG. 3. The 20.15 MHz ^{13}C nmr spectra of the seven-membered ring carbons of **7** in CHF_2Cl at several temperatures. The inset shows the methyl carbon signals of **7** in dimethyl ether at −142°C.

The spectral simulation was actually carried out by means of a slightly modified version of the DNMR-2 program capable of handling four different spin systems of unequal populations instead of three in the initial version (8). The exchange model selected for the simulation is illustrated below in Scheme 1 where the numbers constitute four configurations of which 1 represents the minor conformer and 2 the major one, while 4 is the inverted form of 1 and 3 the inverted form of 2. Thus four configurations are considered whose populations in CHF_2Cl are: 1 (18%); 2 (32%); 3 (32%); 4 (18%). Each of these configurations contains two non-equivalent protons which are labelled A_1 and B_1 for 1 and 4 and A_2, B_2 for 2 and 3 and whose chemical shifts are shown in Fig. 4. Thus Scheme 1 illustrates that, for example, the transformation from 1 to 4 only exchanges the environments of A_1 and B_1. This approach therefore assumes that the methylene groups are independent of one another, as is expected from the fact that long range coupling should be small.

In addition, the following relationships were respected: $k_{12} = k_{13} = k_{43} = k_{42}$, $k_{14} = k_{41}$, $k_{23} = k_{32}$, $k_{21} = k_{34} = k_{24} = k_{31}$, and k_{21} = population ratio ([1]/[2]) k_{12}. Furthermore, the initial guess value for $k_{1,4}$ was taken as $\frac{1}{2}(k_{21})$. Best values for the rate constants at each temperature were then

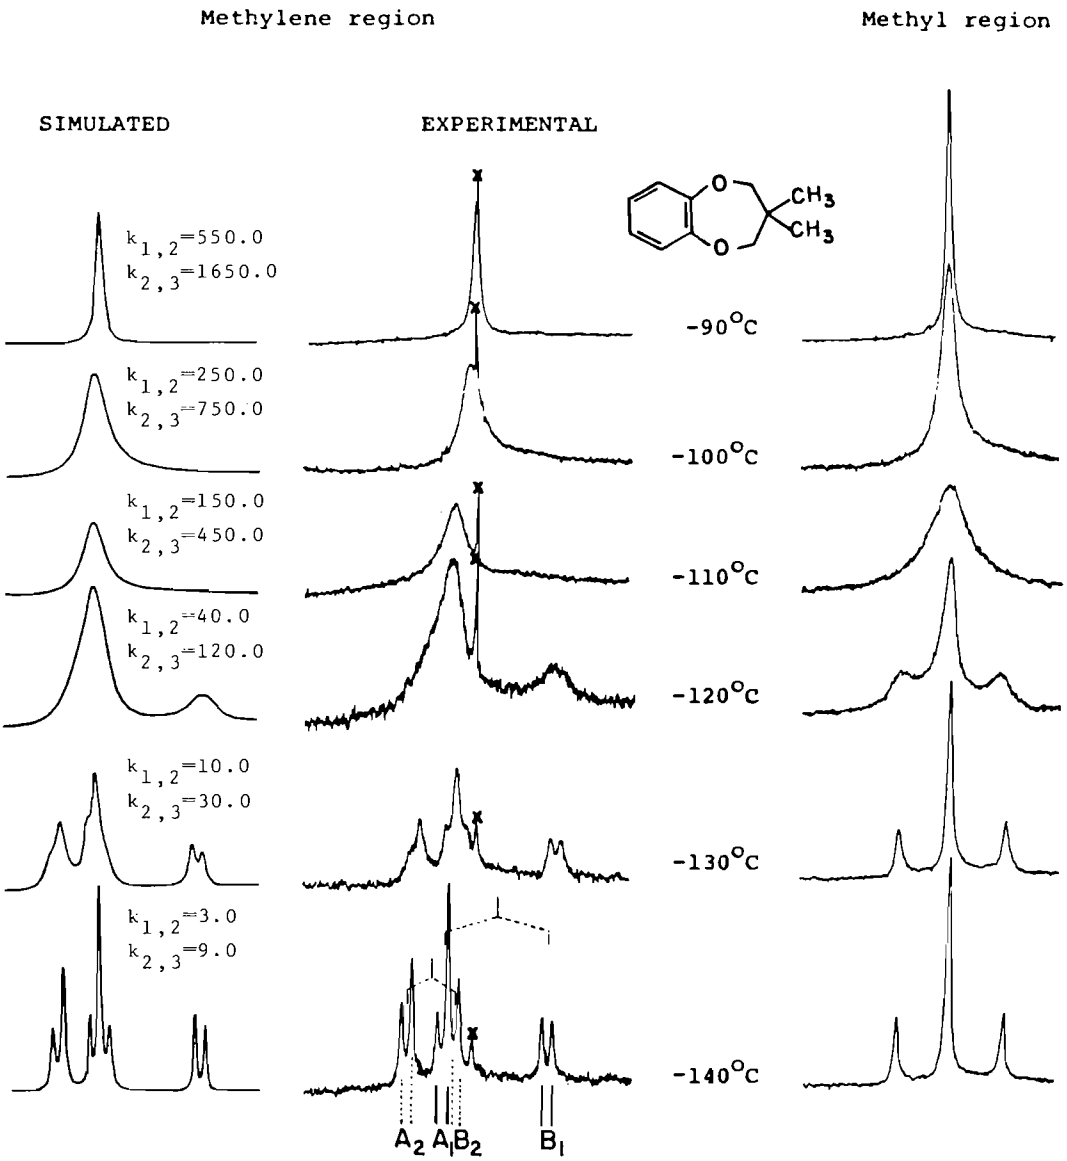

FIG. 4. The 250 MHz ^{1}H nmr spectra of the methylene and methyl protons of **7** in CHF_2Cl at several temperatures (x denotes impurity). Calculated spectra are shown on the left. The symbols A_1, B_1, A_2, B_2 identify the components of the two AB patterns observed at −140°C.

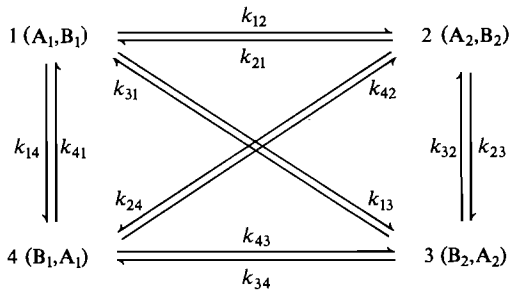
obtained by a trial and error empirical method using visual comparison as test. The values for k_{12} and k_{23} are given on Fig. 4 while that of k_{14} was found to be equal to $0.28k_{12}$.

Discussion

Conformations of the Seven-Membered Rings

The spectral modifications observed in the ^{13}C spectrum of **2** (Fig. 1) reveal the existence of a mixture of two conformers (80:20 in CHF_2Cl). Furthermore, the observation of a single AB pattern in the ^{1}H spectrum of **6** below −131°C (Fig. 2) suggests that the signals of the minor conformation are hidden under those of the major form. Examination of the symmetry properties of the three conformations possible for the seven-membered ring, namely the chair (**8***a*, C), the boat (**8***b*, B), and the twist-boat (**8***c*, TB), reveals that in both C and B, the two protons (or identical substituents) on C-3 are not chemically equivalent, whereby one proton (or substituent) occupies an axial position and the other occupies an equatorial position. On the other hand, the C_2 axis of symmetry in the twist-boat conformation makes both protons (or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.



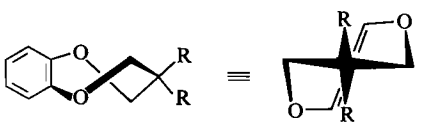
SCHEME 1

identical substituents) at the 3-position chemically equivalent. It then follows from these considerations and from the observed nonequivalence of the two H-3 in **6** that TB is ruled out as the major conformation of 1,5-benzodioxepin, whereas either the C or the B forms are compatible with this observation. Since C is generally less energetic than B (9) for unsubstituted molecules, it is expected to be the most stable conformation adopted by **2**. Later, ^{13}C chemical shift considerations will indicate that the minor conformer of **2** is TB.

The spectral modifications observed in the ^{13}C spectrum of **7** indicate that we are again in the presence of a mixture of two conformers (64:36 in CHF_2Cl or 75:25 in CH_3OCH_3). The observation of a three line pattern in the high field methyl region (Fig. 3 inset, intensity distribution 75:12.5:12.5) clearly shows that these two conformers are TB and C, whereby the most intense methyl signal is due to the two equivalent methyl carbons in the TB conformation, while the two smaller upfield signals of equal intensities are due to the nonequivalent methyl carbons in the C conformation (axial and equatorial positions). Thus, unlike the parent compound **2**, TB is the major conformation adopted by the dimethyl derivative **7** and C is the minor one.

The above conclusion is confirmed by the ^1H spectrum of **7** in CHF_2Cl (Fig. 4); the center line observed in the methyl region accounts for 64% of the total intensity and is due to the chemically equivalent methyl protons in the TB conformation, while the less intense lines on each side account for 18% each of the total intensity and are due to the methyl protons in the axial and equatorial positions of the C conformation.

8a *8b*



8c

Because the C-2 and C-4 methylene groups should give distinct nmr signals for the C and TB forms, it follows that the two AB patterns comprising the seven line spectrum of the methylene protons of **7** (Fig. 4 at −140°C) each belong to one conformer. Thus, the most intense AB pattern at lower field (dotted lines) corresponds to TB, while the second, less intense one, at higher field corresponds to the C form.

It has been noted that while equatorial protons generally appear at lower field than axial protons (cyclohexane : $\Delta\delta = \delta H_e - \delta H_a = 0.46$ ppm (10)), electronic polarization by a *trans* coplanar oxygen atom moves the equatorial proton of a methylene group β to an oxygen atom at higher field than the axial proton. Hence, the chemical shift difference Δδ between geminal axial and equatorial protons β to oxygen is −0.074 ppm in tetrahydropyran (11) and about −0.80 ppm in 1,3-dioxan (12). Our results seem to show that the same trend exists in seven-membered rings. A previous report (13) has shown that while Δδ for the benzylic methylene protons is −0.106 ppm in benzocycloheptene, introduction of a β oxygen atom moves the equatorial proton at 0.504 ppm upfield from the axial proton. Assuming that the same trend applies qualitatively to **2** (or **6**) we would expect the two oxygens β to the protons on C-3 to shift the equatorial proton at about 0.4 ppm upfield from the axial proton since in benzocycloheptene Δδ for the corresponding protons in 0.41 ppm (14). Results obtained from the low temperature spectrum of **6** show that the absolute value of Δδ is 0.49 ppm. The good agreement with the above prediction suggests that $\Delta\delta = -0.49$ ppm.

An important Δδ difference is observed for H-2,4 in the C and TB forms of the dimethyl derivative **7**. The Δδ value in C is 0.48 ppm while it is only 0.16 ppm in the TB form. The Δδ value for the analog H-4,6 protons of 5,5-dimethyl-1,3-dioxane, which exists as a chair, is 0.22 ppm (15). The higher field signal of the C form of **7** is therefore assigned to the axial protons on C-2,4 and the lower field signal to the equatorial protons. Lack of systems existing in the TB form, however, prevents us from further assigning the ^1H signals of this form.

The comparison of the low temperature ^{13}C spectra of **2** and **7** shows that the C-2,4, C-3, and C-6,7 signals exhibit characteristic intensities, whereby for **7** the more intense lines (those of the TB form) are upfield, while for **2** the more intense lines (those of C) are at lower field. This

observation together with the very similar chemical shifts for C-6,7 (carbons remote from the site of substitution) in both compounds identify TB as the minor conformation of **2**.

The observed differences between ^{13}C chemical shifts of the C and TB forms of **2** are 3.17 ppm for the C-3 signals, 2.93 ppm for the C-2,4 signals, and 2.34 ppm for the C-5,6 signals. Similarly differences of 0.66, 1.25, and 2.70 ppm respectively are observed for solutions of **7** in CHF_2Cl.

It is customary to analyze substituent effects on ^{13}C chemical shifts in terms of the α, β, γ, and δ shifts (16). Therefore the introduction of two methyl groups on C-3 produces an α shift of 3.74 ppm for C and 5.92 ppm for TB, while β shifts are 6.39 ppm for C and 7.59 ppm for TB. The δ shifts produced on the C-6,7 signals are very small (less than 0.6 ppm). Similarly an α shift of 3.8 ppm is observed for dimethyl substitution on the 5-position of 1,3-dioxane (which exists as a chair (17)); the β shift, being 10.0 ppm, follows the same trend although is significantly higher.

Our conformational results are in general agreement with the findings of Archer *et al.* (4) who had concluded from their uv study that **2** should exist in the chair conformation while its dimethyl derivative should exist as a mixture of C and TB conformations. Their method, however, did not allow the detection of the minor TB conformer in the case of **2** and did not provide any quantitative measurement for each conformer in the case of mixtures. Furthermore, it is not surprising that the above authors did not observe changes in the ^1H spectrum of **7** at −80°C since these occur only below −120°C.

Thus, as was the case for the 2,4-benzodioxepin family, the parent compound of the 1,5-benzodioxepin family exists predominantly in the C conformation with about 20% of the TB conformer. However, while the amount of TB for 2,4-benzodioxepin increases significantly as the polarity of the solvent is decreased, the solvent effect is small for 1,5-benzodioxepin.

The observation of an important amount of C conformer for **7** compared to the 2,4-benzodioxepin analog which exists exclusively in the TB conformation (1) can be rationalized as follows: whereas, in the case of disubstituted 2,4-benzodioxepin derivatives, the chair conformation is destabilized by nonbonding interactions between the axial methyl group and the axial benzylic protons, the fact that these protons have been replaced by the free electron pairs of the oxygen atoms in **7** leads to weaker nonbonding interactions. Thus, the chair conformation is less destabilized than in the 2,4-benzodioxepin family. A similarly attenuated nonbonding steric repulsion was observed in the case of 5-substituted 1,3-dioxanes (18, 19).

A more important solvent effect is observed for **7** than for **2**; it suggests that TB is somewhat less polar (20) than C for **7**.

Conformational Averaging Processes

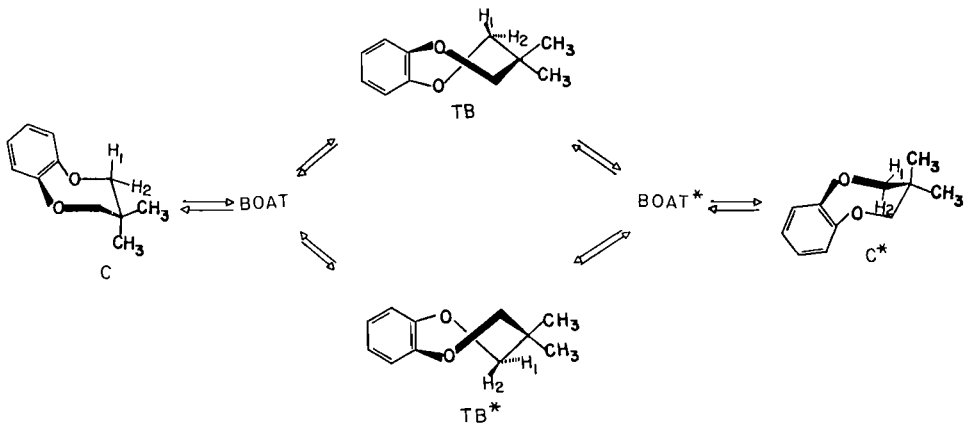
The chair inversion process of benzocycloheptene (21) involves a rate-determining chair-to-boat step characterized by a free energy of activation of 10.7 kcal/mol (22). The presence of one oxygen atom in 5-oxabenzocycloheptene lowers the ΔG^* value to 9.5 kcal/mol (13), whereas the value of 8.0 kcal/mol observed for 2,4-benzodioxepin (1) indicates easier ring deformation along the inversion pathway. The even lower inversion barrier (6.5 kcal/mol) estimated from the ^1H spectral change of **6** (Fig. 2) therefore shows that chair inversion for 1,5-benzodioxepin is the most facile of these oxygenated seven-membered heterocyclic molecules.

Our inability to observe the ^1H signals of TB of **2** limited further kinetic investigation of the parent compound. Fortunately, the situation is more favorable in the case of **7** where a line shape simulation of the spectral modifications observed in the methylene region of the ^1H spectra enabled us to determine the free energies of activation of several of the conformation processes involved.

The conformational interconversion pathways applicable to **7** are shown in Scheme 2 where it is seen that the various exchange processes involve only two independent molecular transformations, namely C ⇌ B and B ⇌ TB, where the population of B is extremely small and undetermined. In other words, the C–TB interconversion involves the C ⇌ B ⇌ TB pathway while the TB inversion involves the TB ⇌ B ⇌ TB* pathway (the symbol * indicates inverted conformations), which is usually designated as a pseudorotation.

It then follows that of the various rate constants obtained from the computer spectral simulation, k_{12} corresponds to the C → TB conversion and k_{23} to the TB inversion. (i.e. 1 ≡ C; 2 ≡ TB; 3 ≡ TB*; 4 ≡ C*). The results summarized in Table 1 therefore show that at −140°C, the first process characterized by a free energy of activation of 7.13 kcal/mol is slightly more energetic than the second one (6.84 kcal/mol). A calculation of these parameters at −113°C raises the ΔG^* value for the C → TB conversion to 7.8 kcal/mol which turns out to be identical to that estimated from the ^{13}C spectrum of **7** at the coalescence temperature using the two-site approximation.

Because the B ⇌ TB step is common to both conformational processes, the higher ΔG^* value for the C → TB conversion indicates that it is the C ⇌



SCHEME 2

B step which is rate determining. Furthermore, the $\Delta G^{\ddagger}$ value given above for this process is about one kcal/mol higher than the corresponding value of 6.5 kcal/mol (−131°C) determined for **2** (or **6**). It is interesting to note that a similar *gem*-dimethyl substitution of benzocycloheptene also increased the chair inversion barrier by about one kcal/mol (22) (i.e. from 10.7 to 11.8 kcal/mol). This trend therefore suggests that a similar ring deformation probably takes place in the rate determining C ⇌ B step for both families of molecules, namely a flip of the benzo part of the molecule (23).

A comparison of the dynamic parameters of **7** with other seven-membered cyclic molecules is made difficult by the limited number of systems amenable to as complete an investigation as was carried out in this work. Nevertheless it is possible to compare the pseudorotation $\Delta G^{\ddagger}$ of **7** (6.8 kcal/mol) to that of 2,2-dimethyl-1,3-dioxabenzocycloheptene, for which a value of 10.0 kcal/mol was reported (1). The rather high $\Delta G^{\ddagger}$ value for the latter molecule was attributed to a *syn*-1,3 nonbonded repulsive interaction between one of the methyl groups and a benzylic hydrogen in the transition state for pseudorotation. In the case of **7**, the benzylic protons are replaced by oxygen lone pairs and consequently the methyl – lone pair interaction, being weaker (18, 19), results in a smaller pseudorotation barrier.

Experimental

Melting points are uncorrected and were determined using a Büchi melting point apparatus. The vpc analyses and separations were carried out on a Varian-aerograph model 920 instrument using helium as carrier gas.

The variable temperature ^{1}H nmr spectra of **6** at 100 MHz were obtained using a JEOL JNM-4H-100 spectrometer equipped with a temperature control unit Model JES-VT-3. Temperatures were measured accurately with a calibrated copper–constantan thermocouple placed inside a solvent containing a dummy nmr tube. A precision of ±1°C is expected. The sample was studied as a solution in chlorodifluoromethane (35 mg in 0.55 mL of solution) containing a small quantity of tetramethylsilane (TMS) in standard 5 mm tubes which had been degassed and sealed.

The variable temperature ^{1}H nmr spectra of **7** at 250 MHz were obtained in the FT mode using a Bruker WM-250 spectrometer (located at the Centre d'Etudes Nucléaires de Grenoble, France) equipped with a standard Bruker temperature control unit. Temperatures were read off the control unit and are most probably accurate to ±3°. The sample was studied as a solution in chlorodifluoromethane (11 mg in 0.55 mL of solution) containing a small quantity of TMS and about 13% of CD_2Cl_2 (for locking purposes) in a standard 5 mm tube which had been degassed and sealed. The following instrumental parameters were used: flip angle = 90°; SW = 2403 Hz; data size = 16K; AQ = 3.4 s.

The variable temperature ^{13}C nmr spectra of **2** and **7** were recorded in the FT mode with a Bruker WP-80 spectrometer operating at 20.15 MHz and equipped with the Bruker variable temperature accessory. All ^{13}C spectra were recorded with proton noise decoupling for solutions in chlorodifluoromethane or dimethyl ether (180–200 mg in 2.2 mL of solution) containing TMS and about 19% of CD_2Cl_2 (for locking purposes) in standard 10 mm tubes which had been degassed and sealed. The following instrumental parameters were used: flip angle = 35°; SW = 6000 Hz; data size = 8K; AQ = 0.679 s; pulse delay, none, except when integration of the signals was performed; a pulse repetition rate of 10 s was then used. Temperatures were measured accurately with a thermocouple as described above for the 100 MHz ^{1}H spectra.

The rate constants were estimated at the coalescence temperature using the equation $k = \pi\Delta\nu/\sqrt{2}$ for singlet to doublet splitting (in the ^{13}C spectra of **7**) (6) and the equation $k = \pi(\Delta\nu^2 + 6J^2)^{\frac{1}{2}}/\sqrt{2}$ for singlet to AB splitting (in the ^{1}H spectra of **6**) (6). The free energies values ($\Delta G^{\ddagger}$) were calculated from standard equations (24) using a transmission coefficient of one, except for the ^{1}H spectral changes of **6** for which a transmission coefficient of one half is most appropriate to describe the chair-to-boat step of the chair inversion.

Simulations were carried out using a slightly modified version of the DNMR-2 program (*vide infra*) on an CDC Cyber 173 computer. Spectra were traced by means of a Printronix plotter. Free energies of activation were calculated from a $\ln k/T$ vs. $1/T$ plot using the Eyring equation (6).

Calculations of $\Delta S^{\ddagger}$ and $\Delta H^{\ddagger}$ were not expected to be sufficiently reliable because of the uncertainty in temperature (±3°C), uncertainties in $T_2°$ arising from possible small long range coupling, as well as the fact that the conformational

populations and chemical shifts were kept constant through the whole temperature interval. As a consequence, the values of -15 ± 5 eu obtained for $\Delta S^{\neq}$ cannot be regarded as sufficiently reliable for discussion.

1,5-Benzodioxepin (2) (25)

o-Dihydroxybenzene (10.1 g, 0.092 mol), 1,3-dibromopropane (19.0 g, 0.094 mol), anhydrous potassium carbonate (12.9 g), and glycerol (0.5 g) were heated under reflux for 24 h. The mixture was cooled, diluted with water (30 mL), and made faintly alkaline with sodium hydroxide. It was then steam distilled and the distillate was extracted with chloroform. The chloroform layer was then dried ($MgSO_4$) and evaporated. There was obtained 3.45 g (24.8%) of **2** which was further purified by gas chromatography using a U.C.W. 98 column (2 m × 1 cm, T = 165°C). The product was characterized by its ^{1}H nmr spectrum which was identical with that reported (26). The ^{13}C nmr spectrum of the product (Table 2) confirmed the assigned structure.

1,3-Propanediol-1,1,3,3-d_4 *(27)*

Diethylmalonate (8.3 g, 0.052 mol) dissolved in 15 mL of anhydrous ether was added dropwise to a suspension of 29 g of $LiAlD_4$ (0.064 mol) in 100 mL of anhydrous ether. The mixture was refluxed for 6 h and then stirred magnetically at room temperature overnight. The excess of hydride was decomposed with 15 mL of a 1 *N* sodium hydroxide solution and the mixture was filtered. The yellow precipitate was washed with ether and returned to the reaction flask. Tetrahydrofuran (50 mL) was added and the mixture was brought to reflux for 30 min. The precipitate was again filtered and washed. The process of refluxing with THF was repeated twice more. The organic fractions were concentrated to give 2.56 g (1.032 mol, 61.5%) of 1,3-propanediol-1,1,3,3-d_4 which was characterized by its ^{1}H nmr spectrum; $\delta(CDCl_3)$: 1.65 (2H, s, CH_2) ppm, and was used without further purification in the next reaction.

1,3-Dibromopropane-1,1,3,3-d_4 *(27)*

Phosphorous tribromide (1.8 mL, 5.13 g, 0.019 mol) and 1,3-propanediol-1,1,3,3-d_4 (1.12 g, 0.014 mol) were mixed at 0°C and permitted to react slowly as the temperature rose. The mixture was stirred at 125°C for 3 h, then allowed to cool; 10 mL of water were added and a small amount of orange precipitate was removed by filtration. The filtrate was extracted 4 times with 20 mL of methylene chloride and the combined organic fractions were dried over magnesium sulfate; 1,3-dibromopropane-1,1,3,3-d_4 (0.84 g, 29%) was isolated and used without further purification.

1,5-Benzodioxepin-2,2,4,4-d_4 *(6)*

This compound was prepared in the same manner as **2** using 0.55 g (0.005 mol) of *o*-dihydroxybenzene and 0.84 g (0.004 mol) of 1,3-dibromopropane-1,1,3,3-d_4. The mixture was extracted with chloroform (3 × 25 mL) and the combined organic fractions were treated with charcoal, filtered, and dried over magnesium sulfate. The product was then purified by gas chromatography using a U.C.W. 98 column; 60 mg of **6** (9.5%) were obtained. The 1,5-benzodioxepin-2,2,4,4-d_4 was characterized by its retention time (which was identical to that of **2**) and by its ^{13}C nmr spectrum which was the same as **2** except for isotope effect and the lower intensity and multiplicity of the CD_2 signal.

Ditosylate of 2,2-dimethyl-1,3-propanediol

This compound was prepared by a procedure already published (28). It was characterized by its melting point, 118–121°C (lit. (28) mp 121–123°C) and its ^{1}H nmr spectrum; $\delta(CDCl_3)$:0.88 (6H, d, CH_3), 2.46 (6H, d, CH_3—Ar), 371 (4H, d, OCH_2), 7.54 (4H, AB multiplet, Ar) ppm. Yield: 86%.

3,3-Dimethyl-1,5-benzodioxepin (7)

Compound **7** was prepared by a procedure already published (4) and was characterized by its ^{1}H nmr spectrum which was identical with that reported. The ^{13}C nmr spectrum of the product (Table 2) also confirmed its structure.

The tetrahedral intermediate of a lactonization reaction

ROBERT A. MCCLELLAND AND MASUMA ALIBHAI

Department of Chemistry, Scarborough College, University of Toronto, West Hill, Ont., Canada M1C 1A4

Received September 29, 1980

ROBERT A. MCCLELLAND and MASUMA ALIBHAI. Can. J. Chem. **59**, 1169 (1981).

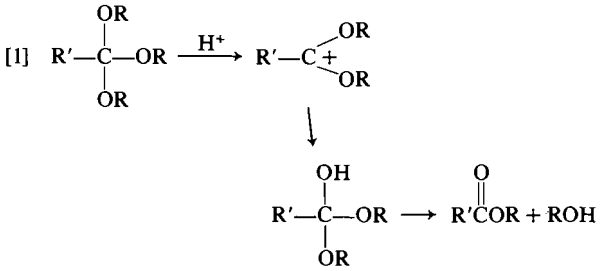
The hydrolysis of the ortho ester 1,1-diethoxy-1,3-dihydroisobenzofuran (**1**) is described. This hydrolysis proceeds with initial expulsion of an exocyclic ethoxy group, producing upon hydration of the oxocarbonium ion 1-hydroxy-1-ethoxy-1,3-dihydroisobenzofuran (**7**), the tetrahedral intermediate of the lactonization of ethyl (2-hydroxymethyl)benzoate (**6**) to phthalide (**8**). Based on the kinetic behavior of the ortho ester hydrolysis, the pH variation in the ratio of **6**:**8** initially formed from the ortho ester, and the kinetic behavior of the lactonization reaction, rate constants for the breakdown of the tetrahedral intermediate **7** have been determined, along with the equilibrium constant for its formation from the hydroxy ester **6**. The breakdown occurs in an extremely rapid hydroxide-ion-catalyzed reaction, with the rate being at the diffusion limit. Hydronium ion catalysis is also observed; this breakdown is also rapid although considerably less so than the hydroxide ion reaction. The changeover from H^+ to OH^- catalysis occurs at pH 3.5. The rate of breakdown is a minimum at this point, and corresponds to a half-life for the tetrahedral intermediate of about 0.1 s. It is concluded that this allows sufficient time for conformational changes in the tetrahedral intermediate prior to breakdown; this factor must be taken into account in stereoelectronic considerations.

ROBERT A. MCCLELLAND et MASUMA ALIBHAI. Can. J. Chem. **59**, 1169 (1981).

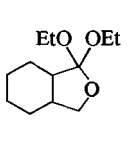
On décrit l'hydrolyse de l'ortho ester diéthoxy-1,1 dihydro-1,3 isobenzofuranne (**1**). Cette hydrolyse se fait avec une expulsion initiale d'un groupe éthoxy exocyclique conduisant après hydratation à l'ion oxocarbonium hydroxy-1 éthoxy-1 dihydro-1,3 isobenzofuranne (**7**), l'intermédiaire tétraédrique de la lactonisation du (hydroxyméthyl)-2 benzoate d'éthyle (**6**) en phtalide (**8**). On a déterminé la constante de vitesse de rupture de l'intermédiaire tétraédrique **7** ainsi que la constante d'équilibre conduisant à sa formation à partir de l'hydroxy ester **6** en se basant sur le comportement cinétique de l'hydrolyse de l'ortho ester, sur la variation du pH dans le rapport du produits **6**:**8** qui se forment initialement à partir de l'ortho ester et sur le comportement cinétique de la réaction de lactonisation. La rupture se produit au cours d'une réaction extrêmement rapide catalysée par l'ion hydroxyde dont la vitesse est limitée par la diffusion. On observe également la catalyse par l'ion hydronium; cette rupture est également rapide quoique considérablement plus faible que celle de la réaction catalysée par l'ion hydroxyde. Le changement de catalyseur de H^+ à OH^- se produit à un pH de 3,5. La vitesse de rupture est minimale à ce point et correspond à une demie-vie de l'intermédiaire tétraédrique d'environ 0,1 s. On en conclut que ceci accorde suffisamment de temps à des changements conformationnels de l'intermédiaire tétraédrique avant sa rupture. On doit tenir compte de ce facteur dans les considérations stéréoélectriques.

[Traduit par le journal]

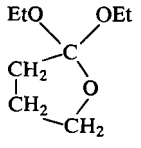
Experiments have recently been reported of the direct observation of the two types of intermediates of the hydrolysis of ortho esters (1–7). These experiments obviously verify the three-stage reaction mechanism commonly accepted for this hydrolysis (8). Moreover they provide a direct measure of the kinetic behavior associated with the later two stages and, in certain cases (7), are capable of furnishing the free energy of the intermediates.



In this paper we report an analysis of the later stages in the hydrolysis of 1,1-diethoxy-1,3-dihydroisobenzofuran (**1**), an ortho ester derived from the lactone phthalide. The hydrolysis of cyclic dialkoxy ortho esters related to **1** (for example, **2**)



1



2

has been studied by Deslongchamps and coworkers (9, 10). Such investigations have played a major role in the development of the theory of stereoelectronic control of the breakdown of tetrahedral intermediates (11). The studies of Deslongchamps focused mainly on the nature of the products of the hydrolysis, and we felt it of interest to see if quantitative kinetic data could also be obtained for such a system. It can also be noted that one of the two possible hydrogen ortho ester intermediates of the hydrolysis of **1**, the one that is in fact formed (*vide infra*), is the tetrahedral intermediate of a lactonization reaction, the lactonization of ethyl 2-(hydroxymethyl)benzoate. Although lactonization reactions have seen considerable investigation in a number of cases (12–16), including the above hydroxy ester (15), no direct

information regarding the tetrahedral intermediate has been reported.

Experimental

1-Ethoxy-1,3-dihydroisobenzofuran-1-ylium (3) borofluorate was prepared by the ethylation of phthalide with triethyloxonium borofluorate following a general procedure described by Deslongchamps and co-workers (10). The ^1H nmr spectrum of the salt in 100% H_2SO_4/external $(CH_3)_4Si$ had peaks at δ: 7.9–8.6 (m, 4H), 6.77 (s, 2H), 5.56 (q, J = 8 Hz, 2H), and 2.12 (t, J = 8 Hz, 3H).

1,1-Diethoxy-1,3-dihydroisobenzofuran (1) was prepared by addition of a suspension of the above salt in CH_2Cl_2 to a stirred solution at 0°C of sodium ethoxide in ethanol. Standard work-up (10) gave **1** as a clear liquid, yield 55% based on starting phthalide; bp 65°C/0.1 Torr; ^1H nmr ($CDCl_3$) δ: 7.2–7.5 (m, 4H), 5.08 (s, 2H), 3.53 (*aa'* multiplet, 4H), and 1.17 (t, 6H). *Anal.* calcd. for $C_{12}H_{16}O_3$: C 69.20, H 7.74; found: C 69.6, H 7.83.

Products of Hydrolysis

The ortho ester **1** (0.1 g) was dissolved in 500 mL of an appropriate buffer or acid and the solution allowed to stand for a period of time corresponding to 5–10 half-lives of $k_H[H^+]$ (see Results). The solution was extracted with carbon tetrachloride (100 mL), the bulk of the solvent immediately removed on a rotary evaporator, and the ^1H nmr spectrum of the residual material recorded. This spectrum contained peaks due to phthalide, δ: 7.8–8.1 (m, 1H), 7.2–7.4 (m, 3H), and 5.18 (s, 2H), and peaks due to a second material identifiable as ethyl 2-hydroxymethylbenzoate, δ: 7.8–8.1 (m, 1H), 7.3–7.4 (m, 3H), 4.70 (s*, 2H), 4.29 (q, J = 7 Hz, 2H), 3–4 variable (s*, 1H), and 1.34 (t, J = 7 Hz, 3H). (In certain samples the peaks marked with an asterisk also showed some coupling). The ratio of the two products was determined by the nmr integration of the methylene peaks at δ 5.18 and 4.70.

A solution of the ortho ester **1** dissolved in 100% H_2SO_4 exhibited an nmr spectrum identical to that of the borofluorate salt of **2** in the same acid, with additional peaks appearing from the ortho ester at δ: 4.95 (q, J = 7 Hz, 2H) and 1.87 (t, J = 7 Hz, 3H). These last two peaks are also found on dissolving ethanol in 100% H_2SO_4.

Kinetics

The procedures employed for the hydrolysis of the ortho ester (3), the detection of the oxocarbonium ion intermediate (3, 4), and the hydrolysis in H_2SO_4 solutions of the oxocarbonium ion **2** (17) have been described previously. The lactonization of ethyl 2-hydroxymethylbenzoate was followed spectroscopically at 285 nm (see Fig. 1). For measurements at pH < 4 this experiment was carried out by dissolving the ortho ester in the acid or buffer of interest, and waiting for a period of time sufficient for complete reaction of the ortho ester. For measurements at pH > 4 the ortho ester was dissolved in 0.001 M HCl, and after complete reaction of the ortho ester the solution was adjusted to the desired pH. Rate constants were determined from the slopes of plots of ln $(A_\infty - A)$ or ln $(A - A_\infty)$ versus time. Except where noted these plots were excellently linear. The error in the observed rate constants is ±2%.

Results

Kinetics of Hydrolysis of Ortho Ester 1

The hydrolysis of **1** was followed spectroscopically, from the increase in uv absorbance at 232 nm (Fig. 1). In phosphate buffers, pH 5–7, excellent first-order kinetic behavior is observed, and the

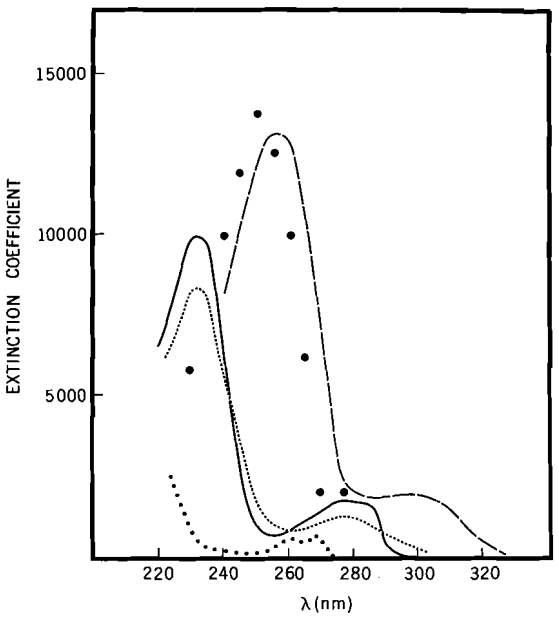

FIG. 1. Absorption spectra; (....) ortho ester **1**; (—) phthalide; (----) initial product of hydrolysis of **1** in 0.001 M HCl; (– – –) oxocarbonium **2**, spectrum taken in 90% H_2SO_4; (●) transient signal generated on hydrolysis of **1** in 0.6 M $HClO_4$; 2.4 M $NaClO_4$.

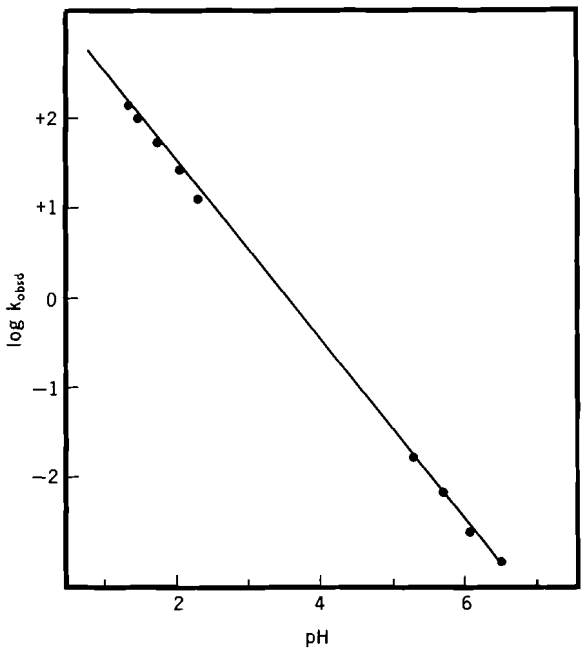

FIG. 2. Observed rate constants for the hydrolysis of **1**. The values in phosphate buffer (pH 5–7) are based on extrapolation to zero buffer concentration. The values in HCl solutions are based on the linear portion of the experimental curves. The line drawn is based on $k_H = 3.1 \times 10^3\ M^{-1}s^{-1}$.

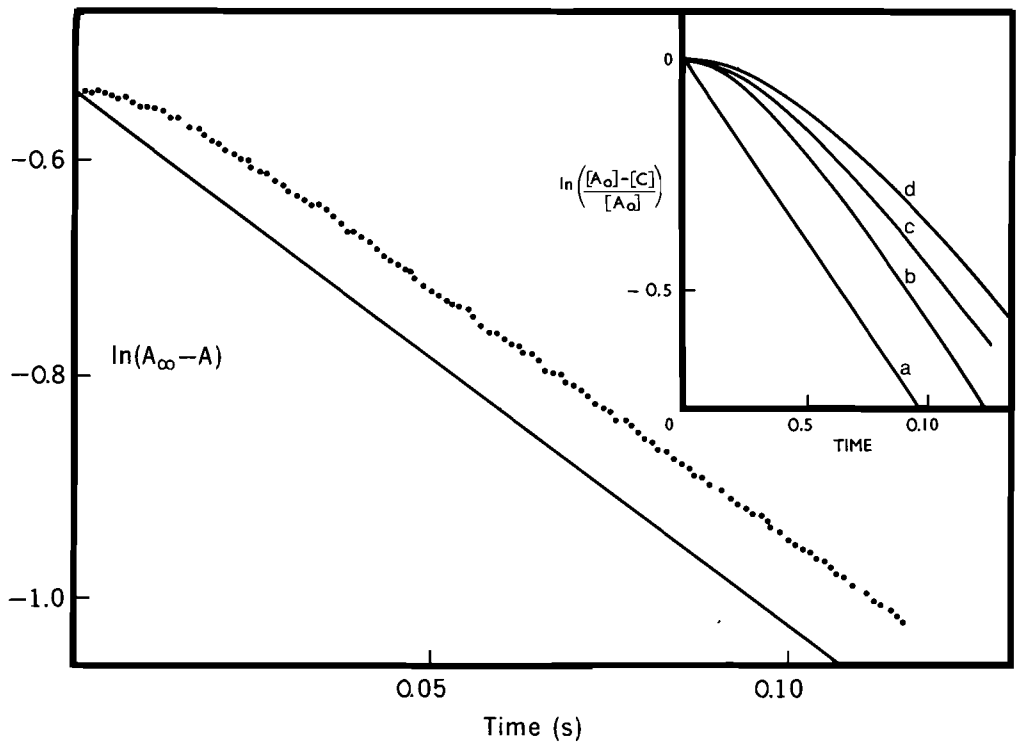

FIG. 3. First-order plot obtained for the hydrolysis of the ortho ester **1** in 0.0015 *M* HCl. The points are observed (see Experimental). The linear portion of the experimental curve ($t > 0.025$) has a least-squares slope of 4.17 s^{-1} ($2.78 \times 10^3 \times [H^+]$). The line drawn in the major figure has a slope of 4.65 s^{-1} ($3.1 \times 10^3 \times [H^+]$) and an intercept corresponding to the intercept of the experimental curve. The insert depicts the first-order plots which would be observed following the formation of the product C of two consecutive first-order reactions A → B → C, with $k_{AB} = 4.65\ s^{-1}$ and (a) $k_{BC} = \infty$ (b) $5k_{AB}$ (c) $3k_{AB}$ and (d) $2k_{AB}$.

observed first-order rate constants show the presence of both an H^+ catalyzed reaction (Fig. 2) and a general acid catalyzed reaction. The value of the second-order rate constant for H^+ catalysis is $3.1 \times 10^3\ M^{-1}s^{-1}$.

In HCl solutions, pH 1–3, the first-order kinetic plots take a form illustrated in Fig. 3. These are characterized by an initial induction period, followed by a region of reasonable linearity. The initial behavior is reproducible and is seen in all HCl solutions, although it does tend to become somewhat obscured at higher acidities where the rate becomes very large. The first-order rate constants evaluated from the linear portions of the plots are proportional to the hydronium ion concentration (Fig. 2), and give a second-order rate constant of $2.8 \times 10^3\ M^{-1}s^{-1}$. Similar behavior is also observed in dilute $HClO_4$ solutions. This observation rules out the possibility that the chloride ion in HCl is somehow responsible for the induction period.

The Oxocarbonium Ion

The cation **3** can be isolated as its borofluorate salt by treatment of phthalide with triethyloxonium borofluorate (18), and is also formed quantitatively on dissolving the ortho ester **1** in concentrated sulfuric acid. This cation has an absorption spectrum with λ_{max} near 255 nm in concentrated acid solutions (Fig. 1), where it is stable to hydrolysis. Similar spectral behavior is also observed with the related cations **4** (19) and **5** (3). The hydrolysis of **3** does occur in more dilute sulfuric acid solutions; rate constants for the hydrolysis in three acids are listed in Table 1. An approach was recently described (17) whereby such rates could be extrapolated to 0% H_2SO_4 to obtain an estimate of the rate in pure water. The average value of these estimates (Table 1) is $1.4 \times 10^2\ s^{-1}$.

Hydrolysis of the ortho ester **1** in solutions where the acid concentration is greater than 0.3 *M* reveals the presence of a transient intermediate. The uv spectrum of this transient (Fig. 1) bears a close

TABLE 1. First-order rate constants (25°C) for the hydrolysis of the oxocarbonium ion **2** in H_2SO_4 solutions and estimated rate constants for its hydrolysis in water

$\%H_2SO_4$	k_{obsd}, s^{-1}	$k_{H_2O}{}^2$, s^{-1} [a]
63.9	0.0064	1.4×10^2
67.9	0.00132	1.3×10^2
72.0	0.00035	1.5×10^2

[a] $\log k_{H_2O}{}^2 = \log k_{obsd} - \log (f_R + a_{H_2O}/f_+)$. Values of the last term taken from ref. 17.

resemblance to the spectrum in concentrated acid of the authentic sample of **3**, particularly when the different solvents are taken into account (20). The first-order rate constant for the disappearance of this transient in 0.5 *M* HCl is 3×10^2 s^{-1}.

Products of Hydrolysis of Ortho Ester 1

Both phthalide and the ethyl ester of 2-hydroxymethylbenzoic acid are formed as initial products of the hydrolysis of **1**, and their relative proportion as a function of pH is provided in Fig. 4. It should be noted that these ratios do represent the products of kinetic control of the hydrolysis. The hydroxy ester does slowly convert to lactone (next section), but over the pH region of Fig. 4 this process is much slower than the hydrolysis of the ortho ester.

Lactonization of Hydroxy Ester

First-order rate constants for the conversion of the hydroxy ester to phthalide were measured. This reaction is susceptible to buffer catalysis (15), but after extrapolation to zero buffer concentration, the rate law of eq. [2] is found (Fig. 5), with k_H(lact) $= 1.4 \times 10^{-3}$ $M^{-1}s^{-1}$ and k_{OH}(lact) $= 4.4 \times 10^3$ $M^{-1}s^{-1}$.

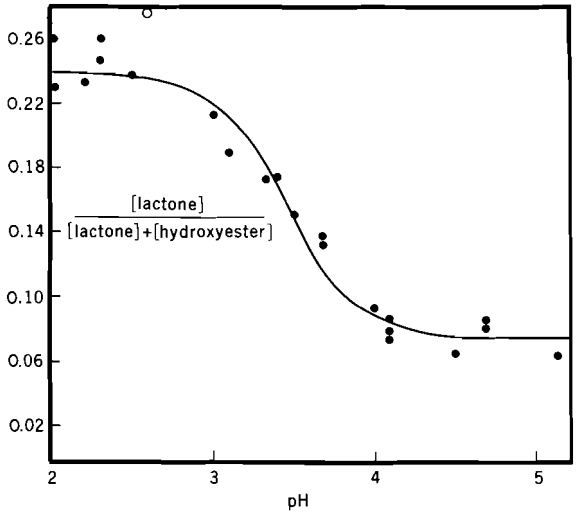

FIG. 4. Composition of the products of the hydrolysis of the ortho ester **1** as a function of pH. The curve is based on eq. [6] and values of constants listed in eqs. [7]–[9]. The point (○) represents the products obtained by addition of the borofluorate salt of the oxocarbonium ion **2**.

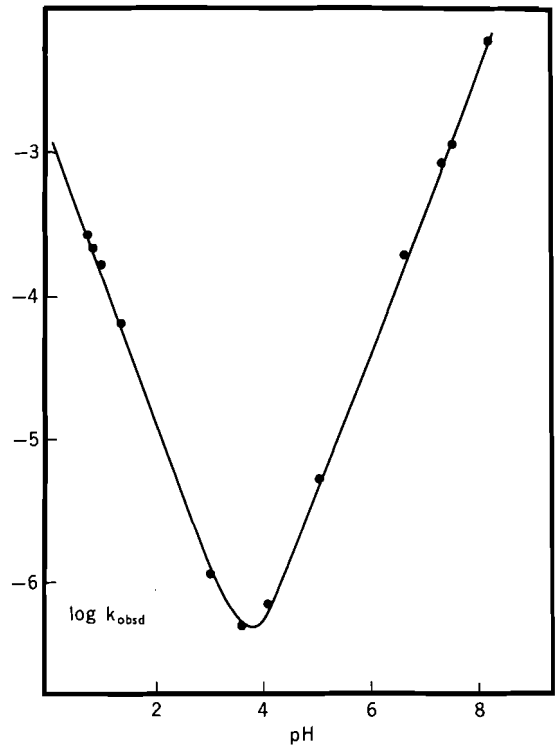

FIG. 5. First-order rate constants for the lactonization of the hydroxy ester **3**. Numbers at pH > 3 are based on extrapolation to zero buffer concentration. The curve is drawn according to eq. [2] using constants defined in the text.

[2] $k_{obsd}(lact) = k_H(lact)[H^+] + k_{OH}(lact)[OH^-]$

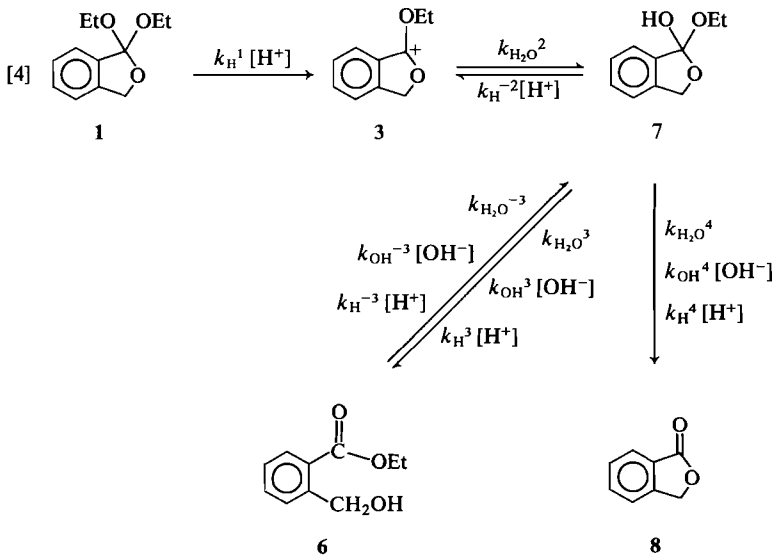
Fife and Benjamin (15) report $k_{OH} = 10^4$ $M^{-1}s^{-1}$ and $k_H = 3.4 \times 10^{-3}$ $M^{-1}s^{-1}$ for the same system at 30°C and ionic strength 0.5. Our rate–pH profile (Fig. 5) shows no contribution to the lactonization rate constant from a water or pH independent reaction.

Discussion

In their study of lactone derived ortho esters, Deslongchamps and co-workers presented evidence that the initial stage in the hydrolysis proceeds with loss of an exocyclic alkoxy group and not ring opening (10). The same interpretation (eq. [3]) can be made with the ortho ester **1**. This

[3] 
9 **1** **3**

is supported in the present case by two pieces of evidence.



A transient uv signal attributable to an oxocarbonium ion intermediate is observed, and is more reasonably assigned to the cation **3** than to the cation **9**. The rate constant for the disappearance of this transient is close to that estimated for **3** by extrapolation of rates of an authentic sample of this cation. The cation **9** is a phenyl dialkoxy carbonium ion and, unless there is a large rate retarding effect associated with the ortho group, should be considerably more reactive (4, 17).

The products of hydrolysis of the authentic cation **3** have also been determined (Fig. 4) and are very similar to the products from the ortho ester. If the ortho ester were to be hydrolyzing to a significant extent through the cation **9**, it would have formed considerably more hydroxy ester.

The general scheme of eq. [4] can therefore be written to describe the system. The products of the ortho ester hydrolysis are both derived from the cyclic hydrogen ortho ester **7**, the same intermediate that must be involved in the subsequent lactonization of the hydroxy ester.

There can be little uncertainty in assigning the kinetic behavior observed with the ortho ester in phosphate buffers to the oxocarbonium ion-forming stage, so that we can set $k_H{}^1 = 3.1 \times 10^3\ M^{-1}s^{-1}$. This is apparent in the nature of the kinetic data which show only acid catalysis, and is confirmed by our kinetic analysis (*vide infra*). It is in fact generally true that regardless of the nature of the rate-limiting stage in acid solutions, as the acidity is decreased the oxocarbonium-ion-forming stage which requires H^+ catalysis must eventually become rate limiting.

In its oxocarbonium-ion-forming stage **1** behaves fairly similarly to a 2-phenyl-2-alkoxy-1,3-dioxolane (3, 21). Both systems exhibit general acid catalysis and react at fairly similar rates. These rates are moreover considerably greater than that associated with the acyclic trimethyl orthobenzoate. The reason for this difference has been discussed previously (21) in a comparison of the dioxolane and the acyclic ortho esters.

For the 2-aryl-2-alkoxy-1,3-dioxolanes in HCl solutions, the breakdown of the hydrogen ortho ester becomes rate-limiting for product formation (3), and the measured rate constants in HCl solutions refer to this later stage. One of the principal pieces of evidence pointing to the change between low pH and high pH is that the values of k_H obtained in HCl solutions are considerably smaller than values measured in phosphate buffers (3). This change is clearly not seen with the ortho ester **1** where, neglecting the first portion of the kinetic plots, a value of k_H is obtained in HCl solutions which is the same, within experimental uncertainty, as the value measured in phosphate buffers. Thus stage 1 must remain rate determining with **1** in acid[1] and $k_H{}^1 < k_H{}^3 + k_H{}^4$.

The curved initial regions are reminiscent of those seen with simple benzaldehyde acetals in acid solutions (22) and suggest the following analysis. The kinetic system can be described in terms of two consecutive first order reactions (eq. [5]),

[1]It can be noted that the rate constant of 3×10^2 for the decomposition of the ion **3** is actually equal to $k_{H_2O^2}(k_H{}^3 + k_H{}^4)/(k_H{}^{-2} + k_H{}^3 + k_H{}^4)$, but this must in fact be fairly close to $k_{H_2O^2}$. The argument relies on the close similarity between the reverse of the hydration stage and the oxocarbonium-ion-forming stage, such that $k_H{}^{-2}$ must be about the same as $k_H{}^1$ (3). Thus if $k_H{}^1 < k_H{}^3 + k_H{}^4$, so is $k_H{}^{-2}$.

[5] 
with $v1 = k_H^1[H^+] = 3.1 \times 10^3[H^+]$ and $v2 = (k_H^3 + k_H^4)[H^+]$. This neglects the hydroxide-ion-catalyzed and pH independent reactions of the hydrogen ortho ester. The step involving hydration of the oxocarbonium is also ignored, although it must become important in strongly acidic solutions. The analysis of the previous paragraph suggests that v2 is greater than v1. The insert to Fig. 3 plots theoretical curves (23) for the formation of product for several cases where the difference is not great. These curves do resemble the observed one, showing the induction period followed by the reasonably linear region whose slope is close to v1. The scatter in the experimental data makes the assignment of an exact value for v2 difficult; a number of the order of 3–6 times v1 does satisfy the observed curve reasonably well. This provides the estimate $k_H^3 + k_H^4 = (1\text{–}2) \times 10^4\ M^{-1}s^{-1}$.

It is of course possible that the initial nonlinear portion is an artifact, associated perhaps with the mixing in a stopped-flow apparatus.[2] The following analysis, however, provides support that it is real. The analysis is based on the change with pH in the ratio of products formed in the ortho ester hydrolysis, a change which is due to a variation in the partitioning of the intermediate **7**. The experimental data (Fig. 4) can be fit by eq. [6].

$$[6]\quad \frac{[\text{lactone}]}{[\text{lactone}] + [\text{hydroxy ester}]} = P = \frac{P^+[H^+]^2 + P^-(K_{app})^2}{[H^+]^2 + (K_{app})^2}$$

This equation provides a pH independent region in acid solutions (pH < 2.5 experimentally) which corresponds to breakdown of **7** by H^+ catalyzed reactions, and a pH independent region in base solutions (pH > 4.5 experimentally) which corresponds to breakdown by hydroxide ion catalyzed reactions (eqs. [7] and [8]).

$$[7]\quad P^+ = \frac{k_H^4}{k_H^3 + k_H^4} = 0.24$$

$$[8]\quad P^- = \frac{k_{OH}^4}{k_{OH}^3 + k_{OH}^4} = 0.075$$

The changeover occurs between pH 3 and 4 with an inflection point at $pH = 3.45 = pK_{app}$. The constant K_{app} is squared in eq. [6], and its value (squared) is given by eq. [9].

$$[9]\quad (K_{app})^2 = \left(\frac{k_{OH}^3 + k_{OH}^4}{k_H^3 + k_H^4}\right)K_w = 1.3 \times 10^{-7}$$

Equations [6]–[9] are derived from the general scheme of eq. [4] with the assumption being made that the decomposition of **7** occurs only by H^+ catalyzed and OH^- catalyzed reactions or, in other words, that the pH independent reactions $k_{H_2O}^3$ and $k_{H_2O}^4$ are never important. Justification for this lies in the fact that such a treatment does fit the experimental data, although admittedly the scatter in the experimental points may obscure a minor contribution from the water reactions. Corroboration can be seen in the kinetic behavior associated with the lactonization of the hydroxy ester, which must proceed by cyclization to **7**, the microscopic reverse of its breakdown. This also shows no sign of a pH independent reaction (Fig. 5).

Equations [7]–[9] can be combined with the value of $k_H^3 + k_H^4$ previously estimated to provide the absolute values of all four constants (Table 2). This operation results in very large values for k_{OH}^3 and k_{OH}^4, the former value in fact being indicative of a reaction which is proceeding at the diffusion limit (24).[3] The assignment of these rate constants relies of course on the absolute value of $k_H^3 + k_H^4$ estimated on the basis of the initially curved first-order kinetic plots observed with the ortho ester. Our argument that this region must be real is based on the consideration that if it were an artifact $k_H^3 + k_H^4$ would in fact have a larger value than $(1\text{–}2) \times 10^4\ M^{-1}s^{-1}$. The consequence of this, however, would be that k_{OH}^3 would also be required to be larger to satisfy the product data and would exceed the diffusion limit.

As seen in Table 2 large values of k_{OH} are not unexpected. The hydrogen ortho ester 2-phenyl-2-hydroxy-1,3-dioxolane also reacts with hydroxide ion at a rate near the diffusion limit, and the number in this case is actually measured when this intermediate is generated from a highly reactive precursor amide acetal (6). Rates of breakdown (and formation) of a hemiacetal analog of **7** have also been measured (27), and k_{OH} is again large, although not up to the diffusion limit.

[2]Evidence that such an artifact does not exist with our apparatus is provided by experiments carried out with trimethyl orthobenzoate, where v2 is known to be 10^4 v1 in acid solutions (5). We find excellently linear first-order traces in acid solutions, starting right from zero time.

[3]Since the hydroxide-ion-catalyzed reactions probably proceed by prior ionization (25), this could mean that a proton transfer step could be rate-limiting, an implication which we are currently investigating in other systems which also exhibit large values of k_{OH} (3, 6, 26).

The subsequent lactonization of the initially formed hydroxy ester can be analyzed by making a stationary state assumption in the tetrahedral intermediate **7**, producing the following equations for the rate constants of eq. [2].

$$[10] \quad k_H(\text{lact}) = P^+ k_H^{-3}$$

$$[11] \quad k_{OH}(\text{lact}) = P^- k_{OH}^{-3}$$

The terms P^+ and P^- have the same meaning as in eqs. 7 and 8, providing that the partitioning of **7** is independent of its source. This was established experimentally in the case of coumarin derivatives (16) and should be true here (*vide infra*). Values of k_H^{-3} and k_{OH}^{-3} can be obtained from the observed rate constants and partitioning ratios. These can then be used in conjunction with the values of k_H^3 and k_{OH}^3 to calculate the equilibrium constant for tetrahedral intermediate formation from the hydroxy ester. The value listed in Table 2 is k_H^3/k_H^{-3}. The value of k_{OH}^3/k_{OH}^{-3} is a factor of two larger, the agreement between the two estimates pointing to the self-consistency of our analysis.

It can be noted that unlike the case with coumarinic acids (14) or esters (16) there is no dramatic change in partitioning here between high pH and low pH. To be exact, the first-order rate constants for lactonization should be expressed as in eq. [12],

$$[12] \quad k_{obsd}(\text{lact}) = (k_H^{-3}[H^+] + k_{OH}^{-3}[OH^+])\,P$$

where P is the full partitioning ratio of eq. [6]. The variation in this ratio, however, has little effect on the shape of the rate–pH profile and in particular causes no "break" of the type observed with the coumarinic acid systems (14). In fact the difference between a theoretical curve based on eq. [12] using the constants of Table 2 and the simple empirical rate law of eq. [4] is not outside experimental error.

It can also be noted according to the partitioning ratio that the rate-determining step in the lactonization must be the breakdown of the tetrahedral intermediate to lactone.[4] This has often been assumed (12, 13) for simple lactonizations, although it appears not to have been rigorously established. The same suggestion can also be made on the basis of Deslongchamp's results (9, 10).

Table 2 compares rate and equilibrium constants in several related systems. The three hydrogen ortho esters, all of which form a benzoate ester derivative, exhibit fairly similar rates of breakdown. The rates of formation are considerably slower; this is associated of course with the instability of the hydrogen ortho ester or tetrahedral intermediate relative to the ester product. As expected, these formation rate constants are significantly larger in the case of intramolecular reactions. The first and last columns offer a comparison of a hydrogen ortho ester and a closely related hemiacetal. These show a very large difference, the cyclic hemiacetal being slightly more stable than its free aldehyde form. If one assumes that the free energies of the cyclic forms are similar, the difference in equilibrium constants with these two systems corresponds to an energy difference of about 10 kcal/mol between the ring-opened hy-

[4] Although the difference in energy between the transition states for formation and breakdown is not very great.

TABLE 3. Life-time (half-life) of the tetrahedral intermediate 7 as a function of pH

pH	Half-life (s)
−1.5	2×10^{-6}
1.0	7×10^{-4}
3.5	0.1
6.0	7×10^{-4}
8.5	2×10^{-6}
11.0[a]	7×10^{-9}

[a]The calculation here is based on the assumption that 7 is not significantly ionized at pH 11.

droxy aldehyde and hydroxy ester. In the kinetic behavior the free energy difference is seen in both directions, the breakdown rates being significantly smaller for the hemiacetal, while its formation rates are larger.

We can also comment on the question of the importance of stereoelectronic control. The system of this study follows the general pattern of behavior exhibited by this type of ortho ester (10), namely a predominance of ring-opened hydroxy ester product. This result was originally explained (10) by invoking stereoelectronic arguments, although it was recognized (10, 11) that a necessary condition for these to apply was that the breakdown of the hydrogen ortho ester occur prior to any conformational change. More recent results (11*c*) have, however, indicated that this condition is not always met, particularly in the case of a hydrogen ortho ester generated in relatively neutral solutions.

The results obtained in the present study fully support this later conclusion. Table 3 lists the life-times of the tetrahedral intermediate **7** as a function of pH. This intermediate has a maximum half-life of about 0.1 s near pH 3.5; this decreases significantly in acid and base solutions. Similar life-times are obtained for the other tetrahedral intermediates of Table 2. These life-times, in the weakly acidic solutions, particularly at pH 3–4, are certainly large enough to allow the tetrahedral intermediate to undergo conformational change prior to breakdown. In fact conformational equilibrium should probably be established. In more acidic solutions and even in weakly basic solutions, the life-times do become short, and the question of conformational change prior to breakdown may arise. In strongly basic solutions the life-time is very short. It is possible in fact that the anionic form of the tetrahedral intermediate breaks down even faster than it is reprotonated.

Reçu le 9 juillet 1980

GUY SCHMITZ et HENRI ROOZE. Can. J. Chem. **59**, 1177 (1981).

La proportion de dioxyde de chlore produit par la dismutation du chlorite de sodium augmente avec la concentration du chlorite et des ions chlorures. Elle passe par un minimum lorsque la concentration de l'acide perchlorique varie de 2 *M* à 0.01 *M*. La réaction rapide entre le chlorite et l'acide hypochloreux fait partie du mécanisme de cette dismutation et sa stoechiométrie a également été étudiée. La proportion de dioxyde de chlore produit dépend du mode de mélange des réactifs et de l'acidité. Elle augmente avec la concentration du chlorite et peut dépasser la quantité prévue par:

$$HClO + 2HClO_2 \rightarrow 2ClO_2 + Cl^- + H^+ + H_2O$$

L'*ortho*-tolidine réagit très rapidement avec le chlore et avec le dioxyde de chlore mais pas avec l'acide chloreux. En milieu perchlorique (pH < 2,5) le produit de son oxydation présente une bande d'adsorption intense avec un maximum à 440 nm (ε = 59 700 M^{-1} cm^{-1}). Le chlore réagit plus vite avec l'*ortho*-tolidine qu'avec l'acide chloreux. L'étude cinétique de la dismutation de l'acide chloreux est ainsi simplifiée par l'utilisation de l'*ortho*-tolidine. En présence de chlorure ajouté initialement l'étape déterminante est $HClO_2 + Cl^- + H^+ \rightarrow 2HClO$ avec une constante cinétique

$$k = 1{,}8 \times 10^{-3}\ M^{-2}\ s^{-1}$$

Les valeurs les plus probables des enthalpies libres de formation des composés oxygénés du chlore sont déduites de la littérature.

GUY SCHMITZ and HENRI ROOZE. Can. J. Chem. **59**, 1177 (1981).

The relative amount of chlorine dioxide produced by the disproportionation of sodium chlorite increases as the concentrations of chlorite and chloride ions increase. It passes through a minimum when the concentration of perchloric acid varies from 2 *M* to 0.01 *M*. The fast reaction between chlorite and hypochlorous acid is a part of the mechanism of this disproportionation and its stoichiometry was also investigated. The relative amount of chlorine dioxide produced depends on the method of mixing the reactants and on the acidity. It increases if the concentration of chlorite increases and can exceed the amount predicted by:

$$HClO + 2HClO_2 \rightarrow 2ClO_2 + Cl^- + H^+ + H_2O$$

Ortho-tolidine reacts very rapidly with chlorine and with chlorine dioxide but not with chlorous acid. In perchloric acid solutions (pH < 2.5) the product of its oxidation has a considerable absorption with a maximum at 440 nm (ε = 59 700 M^{-1} cm^{-1}). Chlorine reacts more rapidly with *ortho*-tolidine than with chlorous acid. The kinetic investigation of the disproportionation of chlorous acid is thus simplified by the use of *ortho*-tolidine. With added chloride ions the rate determining step is $HClO_2 + Cl^- + H^+ \rightarrow 2HClO$ with a rate constant

$$k = 1.8 \times 10^{-3}\ M^{-2}\ s^{-1}$$

The most reliable values for the free enthalpy of formation of oxychlorine compounds are selected from the literature.

Introduction

Les réactions du chlorite de sodium et du dioxyde de chlore présentent un intérêt particulier dans le cadre général de l'étude du mécanisme des réactions d'oxydo-réduction des halogènes et de leurs dérivés oxygénés. Celles du type [1], avec X = Cl, Br ou I, constituent un sujet classique d'études cinétiques en solution.

$$[1] \quad XO_3^- + 5X^- + 6H^+ = 3X_2 + 3H_2O$$

Il existe neuf réactions de ce type, chacun des trois halogénates pouvant réagir avec les trois halogénures. Les lois cinétiques expérimentales sont différentes suivant les cas et ont été le sujet de nombreuses études (1–3), en particulier celles de Bray et de Skrabal. Il en résulte clairement que les réactions du type [1] font intervenir les intermédiaires HXO_2 et HXO suivant un mécanisme complexe dont certains aspects restent controversés. Un des aspects importants de celui que nous adopterons est le rôle du complexe asymétrique et probablement hydraté que nous représenterons par X_2O_2. Différentes structures de ce complexe ont été proposées par Barton et collaborateurs (4, 5). Conformément aux idées de Bray et de Skrabal, on ne peut considérer un processus du type $HXO_3 + HX \rightarrow HXO_2 + HXO$ comme une étape élémentaire impliquant un transfert d'atomes d'oxygène.[1] Un tel processus doit être décomposé en une réaction de formation du complexe X_2O_2 suivie de son hydrolyse:

$$HXO_3 + HX \rightarrow X_2O_2 + H_2O \rightarrow HXO_2 + HXO$$

[1]Intéressés par l'aspect d'oxydo-réduction des réactions étudiées nous considérons comme équivalentes celles qui ne diffèrent que par un équilibre acido–basique et ne distinguons pas toujours explicitement les molécules de leurs ions.

Nous verrons que de nombreux faits expérimentaux sont alors interprétés aisément en considérant les autres réactions possibles de X_2O_2. Soulignons également les résultats de Taube et Dodgen (6) qui constituent un argument de poids pour considérer le Cl_2O_2 asymétrique comme un intermédiaire des réactions que nous étudierons.

Le cas du chlore se distingue des autres par la relative stabilité du chlorite et de l'acide hypochloreux ainsi que par la formation de dioxyde de chlore pouvant accompagner la réaction [1]. L'élaboration d'un mécanisme des réactions d'oxydo-réduction dans le système chlore peut être basée sur des faits expérimentaux d'origines plus diverses que dans le cas des autres halogènes. Nous commencerons par étudier les réactions du chlorite et la formation du ClO_2 en milieux acides. Nous envisagerons ultérieurement les réactions du ClO_2 en solutions neutres ou basiques.

Thermodynamique

Une étude critique de la littérature nous a conduit à adopter les enthalpies libres de formation reprises dans le tableau 1.

Nous avons vu antérieurement (7) pourquoi nous adoptons pour le chlorite une valeur assez différente de celle que l'on trouve généralement. Le potentiel d'oxydo-réduction de la réaction $ClO_2(aq.) + e = ClO_2^-$ a été mesuré dans des conditions diverses (8–11) et la valeur que nous avons utilisée (E_0 = 0,950 V) est probablement exacte à 0,005 V près.

Différentes méthodes de détermination de la constante d'acidité de l'acide chloreux ont donné des valeurs assez concordantes (12–15).

[2] $HClO_2 = ClO_2^- + H^+; \quad K_2 = 1{,}10 \times 10^{-2}$

La valeur de la constante d'acidité de l'acide hypochloreux déterminée par Morris (16) est quasi égale à celle adoptée antérieurement (12).

[3] $HClO = ClO^- + H^+; \quad K_3 = 3{,}0 \times 10^{-8}$

La valeur de la constante K_4 obtenue par Connick et Chia (17) par extrapolation à force ionique nulle est en accord avec les valeurs d'autres auteurs (13, 18–20) à condition de les corriger en tenant compte du coefficient d'activité de HCl.

[4] $Cl_2(aq.) + H_2O = HClO + Cl^- + H^+; \quad K_4 = 3{,}9 \times 10^{-4}$

Pour l'enthalpie libre de formation du chlorate nous avons adopté la valeur de Wagman et coll. (21). Johnson et coll. (22) ont proposé −7,95 kJ/mol. Avec les valeurs du tableau 1 on obtient pour la réaction [5] une variation d'enthalpie libre de −32 kJ/mol en bon accord avec les mesures de Olson (23).

[5] $ClO_3^- + 5Cl^- + 6H^+ = 3Cl_2(aq.) + 3H_2O; \quad K_5 = 4 \times 10^5$

TABLEAU 1. Enthalpies libres de formation à 25°C

	ΔG_f^0 (kJ/mol)	Références et valeurs utilisées pour le calcul
ClO_3^-	−3,4	(21)
$ClO_2(aq.)$	119	(7)
ClO_2^-	27,3	ΔG_f^0 (ClO_2 aq.) et E_0 (ClO_2/ClO_2^-) = 0,950 V
$HClO_2$	16,1	ΔG_f^0 (ClO_2^-) et $K_2 = 1{,}10 \times 10^{-2}$
HClO	−79,8	(12, 21) ou K_4
ClO^-	−36,9	ΔG_f^0 (HClO) et $K_3 = 3{,}0 \times 10^{-8}$
$Cl_2O(g)$	98	(21)
$Cl_2(aq.)$	6,9	(12, 21)
Cl^-	−131,9	(12, 21)

Compte tenu de la valeur de K_6 et des données de Roth (24) pour la solubilité du Cl_2O, nous ne le considérerons pas dans nos équations stoechiométriques, sa concentration étant toujours extrêmement faible. Il peut cependant intervenir comme produit intermédiaire de certaines réactions.

[6] $2HClO(aq.) = Cl_2O(g) + H_2O; \quad K_6 = 3 \times 10^{-4}$

Au point de vue thermodynamique, l'évolution d'une solution de chlorite doit conduire finalement à la formation de chlorure et d'oxygène. Expérimentalement on constate cependant qu'en l'absence d'effets photochimiques la production d'oxygène est négligeable. Nous ne considérons donc que les dismutations donnant les composés oxygénés du chlore.

A partir des valeurs du tableau 1 on peut calculer la composition d'équilibre obtenue au départ d'une solution acide de chlorite. On constate que si le pH est supérieur à 1 elle correspond à la formation de chlorate et de chlorure suivant [7] avec disparition totale du chlorite. En milieu plus acide on a également une formation non négligeable de chlore suivant [9]. Par exemple à pH = 0 et pour une concentration initiale en chlorite valant 10^{-2} M, on obtient à l'équilibre $[Cl_2]/[Cl^-] = 0{,}24$.

Les études expérimentales de la dismutation du chlorite ne conduisent généralement pas à la composition d'équilibre et l'on observe simultanément les réactions [7] et [8]. Le dioxyde de chlore formé subsiste en milieu acide pour des raisons cinétiques.

[7] $3HClO_2 = 2ClO_3^- + Cl^- + 3H^+$

[8] $5HClO_2 = 4ClO_2 + Cl^- + H^+ + 2H_2O$

[9] $5HClO_2 = 3ClO_3^- + Cl_2 + 3H^+ + H_2O$

En milieu neutre ou basique le dioxyde de chlore se dismute. On n'observe pas de production d'oxygène en solutions à l'abri de la lumière. Il a été

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

montré (25) que celle signalée par certains auteurs résulte en fait d'une réaction en phase gazeuse. Comme dans le cas du chlorite, on obtiendrait à l'équilibre un mélange de chlorate et de chlorure, ce qui correspond à la réaction [10], ainsi que du chlore en milieux très acides suivant [11]. La réaction [10] est extrêmement lente. Elle a été étudiée par Bray (26) en présence d'ions chlorures agissant comme catalyseur. En milieux basiques, on observe [12] au lieu de [10]. La constante d'équilibre K_{12} calculée avec les valeurs du tableau 1 vaut 9×10^{-5}, valeur beaucoup plus faible que celle calculée par Taube et Dodgen (6). La différence provient principalement de l'enthalpie libre de formation du chlorite (7). Cette réaction serait donc limitée par la réaction inverse vers pH = 2. La confirmation expérimentale directe de cette conclusion n'est cependant pas possible (6).

[10] $6ClO_2 + 3H_2O = 5ClO_3^- + Cl^- + 6H^+$

[11] $5ClO_2 + 2H_2O = 4ClO_3^- + \frac{1}{2}Cl_2 + 4H^+$

[12] $2ClO_2 + H_2O = ClO_3^- + ClO_2^- + 2H^+$

Stoechiométrie

Technique expérimentale

Le chlorite de sodium commercial à 80% est purifié par trois recristallisations successives. Ses solutions à pH naturel sont standardisées par iodométrie et peuvent être conservées plusieurs jours dans le noir. Le dioxyde de chlore est préparé par réduction du chlorate de sodium par l'acide oxalique (26). Il est dissous dans l'eau distillée et conservé dans le noir à pH naturel. Les solutions d'acide hypochloreux sont obtenues à partir de solutions de chlore où l'on précipite les ions chlorures par l'oxyde mercurique (27). Elles sont conservées dans un réfrigérateur. L'acidité des mélanges réactionnels est fixée soit avec de l'acide perchlorique, soit par un mélange tampon acide citrique–hydrogénophosphate de sodium (concentration totale = 0,1 *M*). Les produits de la qualité "pour analyses" sont utilisés sans purification supplémentaire.

Les productions de ClO_2 sont mesurées par spectrophotométrie à 360 nm. Le coéfficient d'absorption molaire obtenu expérimentalement vaut 1158 L/mol cm. En présence de grandes quantités de chlorite une petite correction doit être apportée aux mesures d'absorbances. La détermination par iodométrie en milieu acide du pouvoir oxydant des solutions étudiées permet, après déduction de la contribution du ClO_2, de calculer selon les cas le chlorite ou l'acide hypochloreux résiduel.

Dismutation du chlorite

La dismutation du chlorite en solutions acides doit être décrite par deux équations stoechiométriques, par exemple [7] et [8]. En désignant par $\Delta(HClO_2)$ la quantité de chlorite ayant réagi, on voit que les rapports stoechiométriques expérimentaux peuvent varier dans les limites suivantes.

$$0 < [ClO_2]/\Delta(HClO_2) < 0{,}80$$

$$0 < [ClO_3^-]/\Delta(HClO_2) < 0{,}66$$

De nombreux travaux (28) sont en accord avec ces relations et confirment qu'il ne faut tenir compte ni d'autres composés du chlore, ni d'une production d'oxygène. L'équation [13] souvent trouvée dans la littérature correspond à la somme de [7] et [8].

[13] $4HClO_2 = 2ClO_2 + ClO_3^- + Cl^- + 2H^+ + H_2O$

Parmi les études consacrées à l'effet des conditions expérimentales sur les rapports stoechiométriques la plus précise et la plus détaillée est celle de Kieffer et Gordon (29). Les résultats que nous avons obtenus sont en parfait accord avec cette étude. Le rapport $[ClO_2]/\Delta(HClO_2)$ augmente avec la concentration du chlorure et dépend de façon complexe de l'acidité. Entre pH = 2 et pH = 5, on trouve dans la littérature des valeurs généralement voisines de 0,5 et quasi indépendantes du pH. Hefti (30) a cependant obtenu des valeurs supérieures et augmentant avec le pH. A pH = 2,5 Kieffer et Gordon (29) ont obtenu 0,64. Ces différences résultent de l'intervention d'autres facteurs, l'un d'eux étant probablement la nature du tampon utilisé. En dessous de pH = 2 et en l'absence de chlorure ajouté initialement, ce rapport passe par un minimum aux environs de pH = 0,5 (29). Nos résultats ont confirmé cette observation. En présence de suffisamment d'ions chlorures, il augmente avec l'acidité et la stoechiométrie tend vers [8].

Un fait expérimental mérite d'être souligné car il n'apparaît pas explicitement dans la littérature. Le rapport $[ClO_2]/\Delta(HClO_2)$ diminue si l'on diminue la concentration du chlorite (cf. tableau 2). On explique ainsi la diminution de ce rapport en fonction du degré d'avancement de la réaction, observée par Kieffer et Gordon (29) à pH = 2,5. En solution 2 *M* en $HClO_4$ ce rapport augmente au cours du temps car, en milieux très acides, l'effet précédent est masqué par celui des ions chlorures produits par la réaction.

Un mécanisme permettant d'interpréter ces observations sera détaillé ultérieurement sur base des études cinétiques. Un de ses éléments importants est le rôle du complexe Cl_2O_2 proposé par Taube et Dodgen (6). Lors de la dismutation du chlorite on forme de l'acide hypochloreux qui réagit extrêmement rapidement suivant [14].

[14] $HClO + HClO_2 \rightarrow Cl_2O_2 + H_2O$

TABLEAU 2. Effet de la concentration du chlorite sur la stoechiométrie de sa dismutation à 25°C

$[HClO_4]$ (M)	$[NaClO_2]_0$ (10^{-3} M)	$\frac{[ClO_2]}{\Delta[HClO_2]}$
0,2[a]	4,08	0,40
	3,06	0,37
	2,04	0,33
0,6[b]	10,1	0,78
	6,53	0,77
	2,99	0,76
	1,79	0,72
1,0[c]	42,2	0,80
	1,05	0,76
	0,105	0,47

[a]Sans addition de chlorure, conversions = 50%.
[b]Chlorure initial = 0,08 M, conversions quasi totales.
[c]Chlorure initial = 1 M, conversions quasi totales.

Le Cl_2O_2 ainsi formé peut réagir de deux façons différentes, l'une donnant du chlorate, l'autre du dioxyde de chlore. L'étude de la stoechiométrie de la réaction entre le chlorite et l'acide hypochloreux, en vue de préciser l'effet des conditions expérimentales sur l'importance relative des réactions du Cl_2O_2, est donc le complément logique de celle de la dismutation du chlorite.

Réactions du chlorite avec le chlore et avec l'acide hypochloreux

Les vitesses des réactions du chlorite avec le chlore et avec l'acide hypochloreux sont extrêmement grandes en milieux très acides et diminuent si le pH augmente (28, 31–33). Elles semblent d'ordre un par rapport à chacun des deux réactifs. Il est généralement admis que la stoechiométrie de ces réactions peut être décrite par [15] et [16] ou leurs équivalents pour le chlore.

[15] $HClO + HClO_2 = ClO_3^- + Cl^- + 2H^+$

[16] $HClO + 2HClO_2 = 2ClO_2 + Cl^- + H^+ + H_2O$

Les études antérieures de l'importance relative de [15] et [16] ont donné des résultats discordants. Ceci peut être attribué notamment à deux aspects particuliers de ces réactions, l'effet du mode de mélange des réactifs signalé par Emmenegger et Gordon (33) et confirmé par nos expériences, et l'effet du temps écoulé entre le mélange des réactifs et les mesures. En milieu acide et en présence d'un excès de chlorite les réactions étudiées sont suivies de la dismutation du chlorite. En milieu neutre et en présence d'un excès d'hypochlorite, elles sont suivies de la réaction entre le ClO_2 et l'hypochlorite. Pour isoler la production de ClO_2 propre aux réactions chlorite–hypochlorite, il faut alors mesurer sa variation en fonction du temps et déterminer la contribution des autres réactions, ce qui est généralement possible celles-ci étant plus lentes.

Quelques exemples de nos résultats expérimentaux sont donnés par les figs 1 et 2. La variation du rapport $[ClO_2]/[HClO]_0$ en fonction de l'acidité n'est pas monotone. Dans l'acide perchlorique, il augmente si le pH varie de 0 à 2, dans le tampon citrate–phosphate, il diminue si le pH varie de 2 à 6. Ce rapport augmente avec la concentration du chlorite (fig. 1), il varie peu ou diminue si l'on augmente la quantité d'hypochlorite (fig. 2). Pour interpréter ces observations, nous admettons que le Cl_2O_2 formé suivant [14] peut réagir suivant [17] et [18], ce qui correspond respectivement aux équations stoechiométrique [15] et [16].

[17] $Cl_2O_2 + H_2O \rightarrow ClO_3^- + Cl^- + 2H^+$

[18] $Cl_2O_2 + HClO_2 \rightarrow 2ClO_2 + Cl^- + H^+$

L'augmentation du rapport $[ClO_2]/[HClO]_0$ avec la concentration du chlorite s'explique facilement, l'importance de [18] par rapport à [17] étant proportionnelle à cette concentration. Ceci explique également la diminution de ce rapport lorsque l'on augmente la quantité d'acide hypochloreux en remarquant que la concentration instantanée du chlorite dans la solution dépend de cette quantité. Pour une concentration initiale du chlorite donnée, sa concentration au cours de la réaction est plus faible si l'on introduit plus d'hypochlorite. La contribution relative de [18] est alors moins importante. Cet effet doit être d'autant plus marqué que l'excès de chlorite est plus faible. C'est effectivement ce que nous avons observé. Si au lieu de [18] on considérait la réaction $2Cl_2O_2 \rightarrow 2ClO_2 + Cl_2$,

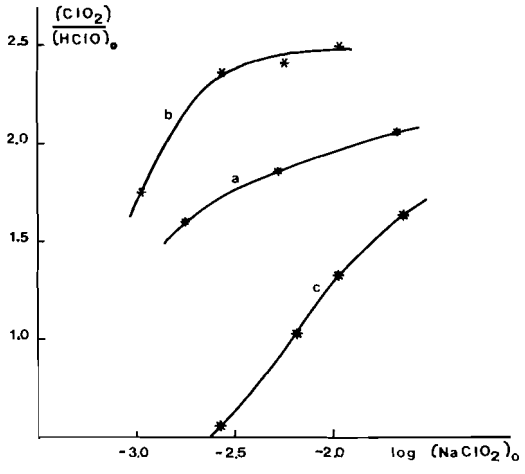

FIG. 1. Productions relatives de ClO_2 obtenues par addition de HClO à un excès de $NaClO_2$; (*a*) $[HClO_4] = 1\ M$, $[HClO]_0 = 5{,}6 \times 10^{-4}\ M$; (*b*) $[HClO_4] = 10^{-2}\ M$, $[HClO]_0 = 4{,}4 \times 10^{-4}\ M$; (*c*) tampon, pH = 6, $[HClO]_0 = 4{,}7 \times 10^{-4}\ M$.

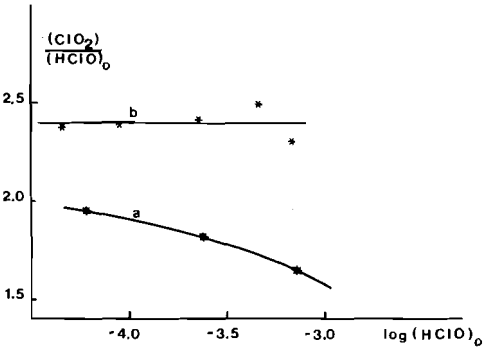

FIG. 2. Productions relatives de ClO_2 obtenues par addition de HClO à un excès de $NaClO_2$; (*a*) $[HClO_4] = 1\,M$, $[NaClO_2]_0 = 2{,}20 \times 10^{-3}\,M$; (*b*) $[HClO_4] = 10^{-2}\,M$, $[NaClO_2]_0 = 5{,}75 \times 10^{-3}\,M$.

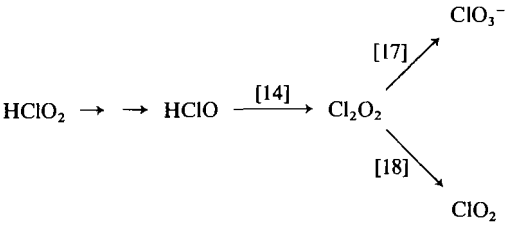
proposée par Taube et Dodgen (6), on pourrait justifier l'effet du chlorite mais pas celui de l'hypochlorite.

Le modèle proposé explique également l'effet du mode d'addition des réactifs. On obtient moins de ClO_2 si l'on verse la solution de chlorite dans celle d'hypochlorite que si l'on suit l'ordre inverse, les autres conditions expérimentales étant identiques. En effet, si l'on verse le chlorite dans la solution d'hypochlorite où il réagit très rapidement, sa concentration instantanée reste faible, ce qui limite la contribution de [18].

Les éqs [14], [17] et [18] ne sont cependant pas suffisantes pour décrire le système. On constate que le rapport $[ClO_2]/[HClO]_0$ peut être supérieur à 2, c'est-à-dire que l'on obtient plus de dioxyde de chlore que la quantité maximale prévue par [16]. Cet excès n'est pas dû à la dismutation du chlorite en l'absence d'acide hypochloreux, réaction beaucoup plus lente que celles étudiées et généralement négligeable. De plus nos résultats en tiennent compte lorsque cela est nécessaire. Ce problème a été évoqué par Emmenegger et Gordon (33) qui ont suggéré que l'acide hypochloreux catalyse la dismutation du chlorite. Le mécanisme qui sera proposé après notre étude cinétique permettra de compléter la discussion des résultats présentés ici.

Conclusions et introduction à l'étude cinétique

La dismutation du chlorite en solutions acides donne du dioxyde de chlore et du chlorate en proportions variables. Le dioxyde de chlore, thermodynamiquement instable, apparaît pour des raisons cinétiques. Sa formation n'est cependant pas en contradiction avec les valeurs du tableau 1, la réaction [8] correspondant à une grande diminution d'enthalpie libre. Le mécanisme de la dismutation du chlorite est compliqué et sera discuté ultérieurement. Il fait intervenir un complexe asymétrique, probablement hydraté, que nous avons représenté par Cl_2O_2 et dont on peut schématiser la formation et la disparition comme suit:



Nous avons montré que la deuxième partie de ce schéma rend compte de plusieurs faits expérimentaux relatifs à la stoechiométrie de la réaction très rapide entre le chlorite et l'acide hypochloreux. L'étude de sa première partie, la formation de l'acide hypochloreux, fait immédiatement apparaître de nombreuses complications d'origines stoechiométriques et cinétiques. En particulier, les lois admises par Gordon et coll. (28) pour les solutions $1{,}2\,M$ en acide perchlorique ne sont pas valables pour les solutions moins acides. Nous allons montrer que beaucoup de ces complications peuvent être évitées en étudiant la vitesse de dismutation du chlorite en présence d'*ortho*-tolidine (biphenyl 4,4′ diamino 3,3′ diméthyl). Il réagit très rapidement avec le chlore, l'acide hypochloreux et le dioxyde de chlore, mais pas avec le chlorite, pour donner en milieu acide une forme oxydée présentant une bande d'absorption intense dans le visible. Son coéfficient d'absorption molaire élevé constitue un des avantages de la méthode en permettant de mesurer facilement des vitesses initiales de réactions et d'élargir le domaine des mesures aux faibles concentrations en chlorite. Ses autres avantages apparaîtront au cours de l'étude cinétique.

Réaction de l'*ortho*-tolidine

Réactions avec le chlore et le dioxyde de chlore

L'*ortho*-tolidine est un réactif classique pour le dosage colorimétrique du chlore et de l'acide hypochloreux (34, 35). La coloration du produit de son oxydation dépend de l'acidité. Pour des valeurs du pH inférieures à 3, on obtient une seule espèce oxydée à laquelle Verbestel et Berger (34) ont attribué la formule $NH = C_6H_3(CH_3) = C_6H_3(CH_3) = NH$ et que nous représenterons par NHRNH. Les réactions de l'*ortho*-tolidine avec le chlore et avec l'acide hypochloreux s'écrivent ainsi sous la forme condensée [19].

[19] $NH_2RNH_2 + HClO \rightarrow NHRNH + Cl^- + H^+ + H_2O$

[19′] $NH_2RNH_2 + Cl_2 \rightarrow NHRNH + 2Cl^- + 2H^+$

Classiquement le dosage du chlore par l'*ortho*-

tolidine se fait en milieu chlorhydrique. Nous avons constaté que l'on peut également utiliser l'acide perchlorique et tous les résultats présentés ici ont été obtenus avec cet acide. Nos mesures préliminaires ont montré que plusieurs conditions relatives aux concentrations doivent être respectées. La solution d'oxydant doit être diluée; avec plus de 10^{-4} mol/L de Cl_2 on obtient des résultats par défaut. Si d'autre part la concentration de l'*ortho*-tolidine est trop grande, on observe une décroissance de l'absorbance en fonction du temps, d'autant plus rapide que le pH est élevé. Il semble qu'il y ait une réaction lente entre l'*ortho*-tolidine et sa forme oxydée. Nous avons généralement utilisé une concentration d'environ $5 \times 10^{-4}\,M$ pour laquelle cette réaction est négligeable. Il faut également que le pH soit inférieur à 2,5. La forme du spectre d'absorption est alors indépendante des concentrations avec un maximum à 440 nm. A partir de pH = 3 l'*ortho*-tolidine oxydée prend une coloration verte et il apparaît une bande d'absorption ayant son maximum à 370 nm. Dans les conditions de mesures ainsi définies, la coloration est obtenue instantanément, reste stable pendant au moins 30 min et est parfaitement reproductible. La fig. 3 montre que la loi de Beer–Lambert est satisfaite et que le coéfficient d'absorption molaire vaut $59\,700\,M^{-1}\,cm^{-1}$. Nous avons vérifié qu'il n'y a pas d'interférences des différents ions pouvant être présents lors de nos mesures cinétiques: $[ClO_3^-] \leq 0.1\,M$, $[Cl^-] \leq 1\,M$, $[Fe^{2+}] \leq 10^{-5}\,M$, $[Fe^{3+}] \leq 10^{-5}\,M$. L'effet du Fe(III) qui a parfois été signalé est uniquement d'origine spectrale (36) et n'apparaît pas aux concentrations utilisées. Il n'y a aucun effet de chlorite. L'oxydation lente de l'*ortho*-tolidine par le chlorite signalée antérieurement (35) correspond en fait au système que nous allons étudier: la dismutation du chlorite et l'oxydation de l'*ortho*-tolidine par le chlore ou le dioxyde de chlore produits.

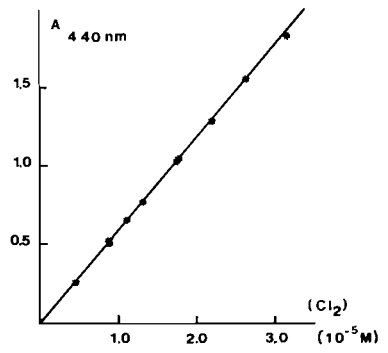

FIG. 3. Dosage du chlore par l'*ortho*-tolidine. $[HClO_4] = 0{,}1\,M$: $[NH_2RNH_2]_0 = 2{,}5 \times 10^{-4}\,M$.

L'*ortho*-tolidine est également utilisée pour le dosage du dioxyde de chlore (35). Les conclusions de nos mesures préliminaires sont identiques à celles obtenues avec le chlore. En solutions diluées dans l'acide perchlorique et pour des valeurs du pH inférieures à 2,5, on obtient le même spectre d'absorption. La coloration est obtenue instantanément, est reproductible et reste stable pendant au moins 30 min. Nos solutions de ClO_2 sont préparées par la méthode de Bray (26), préférable à la méthode standard (35), et standardisées par iodométrie. Les résultats de la fig. 4 correspondent à la réaction [20] et donnent un coéfficent d'absorption molaire de l'*ortho*-tolidine oxydée pratiquement identique à celui obtenu avec le chlore: $\varepsilon = 59\,800\,M^{-1}\,cm^{-1}$.

[20] $NH_2RNH_2 + 2ClO_2 \rightarrow NHRNH + 2HClO_2$

Pour doser le dioxyde de chlore dans des solutions contenant du chlore, on élimine ce dernier par de l'acide oxalique (35). Celui-ci ne réagit pas avec le dioxyde de chlore. Sa réaction avec le chlore apparaît lors des expériences suivantes. Dans une solution d'acide perchlorique donnant un pH final de 1,8 on a introduit $1{,}74 \times 10^{-5}$ mol/L de chlore, $2{,}5 \times 10^{-4}$ mol/L d'*ortho*-tolidine et 10^{-2} mol/L d'acide oxalique dans un ordre variant d'une expérience à l'autre. On a obtenu les absorbances suivantes.

$H_2C_2O_4 + Cl_2 + NH_2RNH_2$	$A_1 = 0$
$NH_2RNH_2 + H_2C_2O_4 + Cl_2$	$A_2 = 0{,}98$
$NH_2RNH_2 + Cl_2 + H_2C_2O_4$	$A_3 = 1{,}04$
$NH_2RNH_2 + Cl_2$	$A_4 = 1{,}04$

La comparaison de A_3 et A_4 montre que l'acide oxalique ne réduit pas l'*ortho*-tolidine oxydée. La comparaison de A_2 et A_3 montre que le chlore réagit plus vite avec l'*ortho*-tolidine qu'avec l'acide oxalique. Nous utiliserons cette propriété ultérieurement.

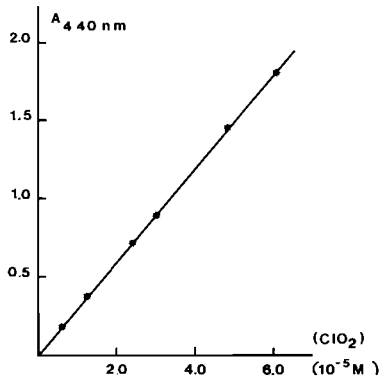

FIG. 4. Dosage du dioxyde de chlore par l'*ortho*-tolidine. $[HClO_4] = 0{,}03\,M$; $[NH_2RNH_2]_0 = 2{,}5 \times 10^{-4}\,M$.

*La réaction chlorite–chlore en présence d'*ortho-*tolidine*

La technique expérimentale est essentiellement la même que celle décrite antérieurement. Dans les conditions du tableau 3, mais en l'absence d'*ortho*-tolidine, on obtient les réactions [15] et [16], la proportion de chlorate formé étant d'autant plus importante que la concentration du chlorite est plus faible. Si par contre on ajoute du chlore ou de l'acide hypochloreux dans un mélange d'acide perchlorique, d'*ortho*-tolidine et de chlorite, on obtient uniquement la réaction [19] comme le montrent les résultats du tableau 3. Les concentrations de l'*ortho*-tolidine oxydée sont déduites des mesures d'absorbance à 440 nm corrigées pour tenir compte de la dismutation du chlorite. Si les mesures sont faites rapidement cette correction est inférieure à 5%. Les résultats sont indépendants de la concentration initiale de l'*ortho*-tolidine comprise entre 2×10^{-4} et 10^{-3} *M*.

Le rapport $[NHRNH]/[HClO]_0$ valant 1 quelle que soit la concentration du chlorite et le chlorate n'oxydant pas l'*ortho*-tolidine, il est ainsi établi que le chlore ou l'acide hypochloreux ne réagissent pratiquement pas suivant [15]. Nous admettons par conséquent que la réaction avec l'*ortho*-tolidine est encore plus rapide que celle avec le chlorite.[2] Le schéma du mécanisme de la dismutation du chlorite en est simplifié.

$$HClO_2 \rightarrow\rightarrow HClO \xrightarrow{NH_2RNH_2} NHRNH$$

La vitesse initiale de la dismutation du chlorite correspond ainsi à celle de la formation de l'*ortho*-tolidine oxydée. Par contre, en l'absence d'*ortho*-tolidine elle n'est liée à la vitesse de formation du dioxyde de chlore que par un coéfficient stoechiométrique variable. C'est un des avantages de notre méthode.

Cinétique de la dismutation du chlorite en présence de chlorure et d'*ortho*-tolidine

Technique expérimentale

Les solutions de chlorite de sodium sont préparées et standardisées comme précisé antérieurement. Elles donnent des résultats parfaitement reproductibles à condition de n'être pas trop anciennes. Les autres réactifs sont de la qualité "pour analyses" et sont utilisés sans purification supplémentaire. L'acidité est ajustée avec de l'acide perchlorique et la force ionique est fixée à 1 *M* avec du perchlorate de sodium. Toutes les mesures cinétiques sont faites à 25 ± 0,1°C. On mélange les réactifs, le chlorite étant introduit en dernier lieu, et l'on enregistre en fonction du temps l'absorbance à 440 nm mesurée par un spectrophotomètre Beckman DBGT. On obtient des droites dont la pente donne la vitesse initiale de la réaction.

$$v_0 = \frac{d}{dt}[NHRNH] = \frac{1}{59\ 700}\frac{dA}{dt}$$

Ces vitesses initiales sont obtenues très facilement, la grande sensibilité de la méthode permettant de se limiter à des taux de conversion de chlorite extrêmement faibles.

Résultats

Il n'y a aucun effet de la force ionique ni de la concentration en *ortho*-tolidine sur la valeur de v_0. Quelques résultats sont repris dans le tableau 4. Il faut éviter les temps de réaction trop longs et les mesures d'absorbances trop élevées la variation de celles-ci en fonction du temps cessant alors d'être parfaitement linéaire. Les écarts résultent probablement d'une réaction de l'*ortho*-tolidine oxydée, totalement négligeable dans les conditions de mesures que nous avons adoptées.

La fig. 5 montre que la vitesse v_0 peut être représentée par une somme de deux termes.

$$v_0 = v_I + k_{II}[Cl^-]$$

Dans la zone des concentrations en chlorure utilisées ceci est conforme aux résultats de Kieffer et Gordon (29) ainsi qu'à ceux de Hong et Rapson (37). Nous expliquerons ultérieurement les écarts

[2]On pourrait admettre également que l'on forme du Cl_2O_2 et que celui-ci réagit plus vite avec l'*ortho*-tolidine qu'il ne s'hydrolyse. Pour la suite de notre étude, cette hypothèse est strictement équivalente à celle adoptée.

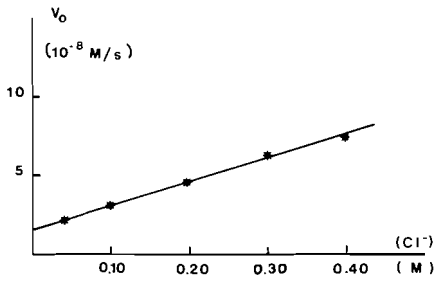

FIG. 5. Vitesses de réaction en présence d'*ortho*-tolidine $2 \times 10^{-4}\ M$. $[HClO_2] = 0{,}104\ M$; $[NaClO_2] = 5{,}02 \times 10^{-4}\ M$.

à cette relation linéaire, observés par ces auteurs pour les très faibles concentrations en ions chlorures, par un effet de ces ions sur le processus réactionnel correspondant à v_I.

Dans l'acide perchlorique $1{,}2\ M$, le terme v_I correspond à une réaction d'ordre deux par rapport au chlorite (29). En milieu moins acide la loi cinétique est beaucoup plus compliquée et sera l'objet de notre prochain article. Une étude précise de k_{II} implique d'éliminer la contribution de v_I. Pour cela, nous avons mesuré v_0 en fonction de (Cl^-) pour différentes concentrations en chlorite et en acide et déterminé k_{II} par la relation

$$k_{II} = \frac{\Delta v_0}{\Delta[Cl^-]}$$

Les résultats sont repris sur les figs 5 à 7 ainsi que dans le tableau 5.

Nous avons représenté par $[NaClO_2]$ la concentration totale du chlorite. On a donc:

$$[NaClO_2] = [HClO_2] + [ClO_2^-]$$

Pour le calcul de la concentration $[HClO_2]$ nous avons utilisé la constante d'équilibre de la réaction [2] ainsi que $\gamma_\pm = 0{,}8$ pour une force ionique fixée à $1\ M$. Le choix d'une valeur un peu différente n'aurait pas eu d'influence sur le résultat du calcul de la constante cinétique.

Le tableau 5 montre que k_{II} varie proportionnellement à la concentration de l'acide chloreux et à celle de l'acide perchlorique. Le deuxième terme de la loi donnant v_0 prend ainsi la forme.

$$v_{II} = k[HClO_2][Cl^-][H^+]$$

avec

$$k = 3{,}50 \times 10^{-3}\ M^{-2}\ s^{-1}$$

Discussion

La loi cinétique expérimentale comporte deux termes dont le second peut être interprété par le mécanisme suivant:

[21] $HClO_2 + Cl^- + H^+ \rightarrow 2HClO$

[19] $HClO + NH_2RNH_2 \rightarrow Cl^- + H^+ + NHRNH + H_2O$

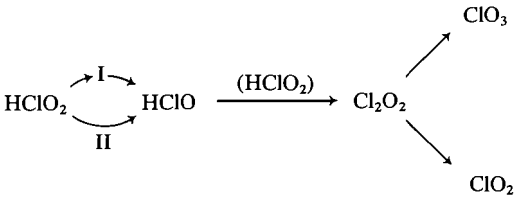
L'étape [21] étant déterminante[3] la vitesse de la réaction est indépendante de la concentration de l'*ortho*-tolidine.

$$\frac{d[NHRNH]}{dt} = 2k_{21}[HClO_2][Cl^-][H^+]$$

$$k_{21} = \tfrac{1}{2}k = 1{,}75 \times 10^{-3}\ M^{-2}\ s^{-1}$$

*Comparaison avec des mesures en l'absence d'*ortho-*tolidine*

L'étude cinétique de la dismutation du chlorite en l'absence d'*ortho*-tolidine est compliquée par des problèmes stoechiométriques. Reprenons, en le complétant, le schéma considéré antérieurement.



Les processus I et II correspondent aux deux termes de la loi cinétique.

Si le mécanisme de la dismutation du chlorite correspondait simplement à [21] suivi de [15], sa stoechiométrie serait donnée par [7] et sa loi cinétique par:

$$\frac{d[ClO_2]}{dt} = 0; \qquad -\frac{d[HClO_2]}{dt} = 3v_{21}$$

Si son mécanisme correspondait à [21] suivi de

[3]Pour des raisons étrangères à ce travail nous pensons que [21] n'est pas une étape élémentaire mais résulte de $HClO_2 + Cl^- + H^+ \rightarrow Cl_2O + H_2O$ suivi de $Cl_2O + H_2O \rightarrow 2HClO$. On obtient la même loi cinétique quelle que soit l'étape déterminante.

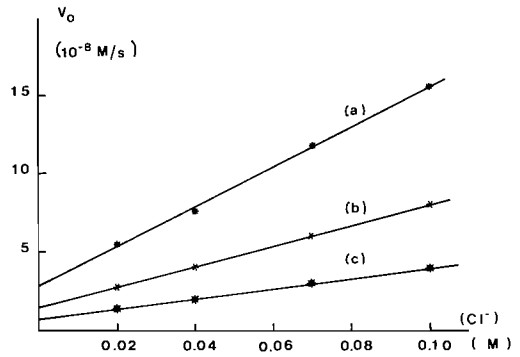

FIG. 6. Vitesses de réaction en présence l'*ortho*-tolidine 2×10^{-4} *M*. $[HClO_4] = 0{,}208$ *M*; $[NaClO_2] = 1{,}97 \times 10^{-3}$ (*a*), $9{,}86 \times 10^{-4}$ (*b*) et $4{,}93 \times 10^{-4}$ *M* (*c*).

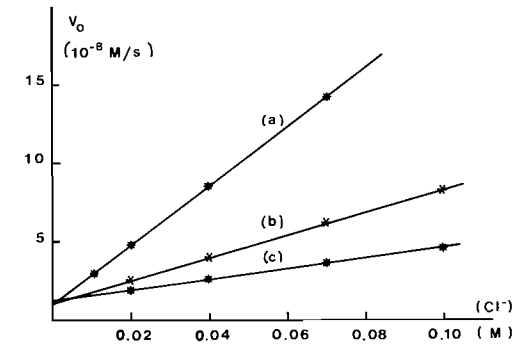

FIG. 7. Vitesses de réaction en présence d'*ortho*-tolidine 2×10^{-4} *M*. $[NaClO_2] = 1{,}07 \times 10^{-3}$ *M*; $[HClO_4] = 0{,}521$ (*a*), 0,208 (*b*) et 0,104 *M* (*c*).

TABLEAU 5. Constantes cinétiques en présence de chlorure et d'*ortho*-tolidine; 25°C; $\mu = 1$ *M*

$[HClO_4]$ (*M*)	$[NaClO_2]$ (10^{-3} *M*)	$10^6 k_{II}$ (s^{-1})	$10^3 k$ (M^{-2} s^{-1})
0,208	1,970	1,280	3,38
0,208	0,986	0,650	3,43
0,208	0,493	0,334	3,53
0,104	0,502	0,157	3,50
0,521	1,071	1,892	3,50
0,208	1,071	0,725	3,52
0,104	1,071	0,336	3,52

[16], sa stoechiométrie serait donnée par [8] et sa loi cinétique par:

$$[22] \quad \frac{d[ClO_2]}{dt} = 4v_{21}; \qquad -\frac{d[HClO_2]}{dt} = 5v_{21}$$

En général [21] est suivi de [15] et [16] simultanément. En exprimant la stationnarité de HClO ($v_{15} + v_{16} = 2v_{21}$) et en posant $v_{16} = \alpha v_{21} (0 < \alpha < 2)$, on obtient:

$$\frac{d[ClO_2]}{dt} = 2\alpha v_{21}; \qquad -\frac{d[HClO_2]}{dt} = (3 + \alpha)v_{21}$$

Pour obtenir v_{21} à partir des courbes cinétiques, il faut donc non seulement isoler la contribution du processus II, comme nous l'avons fait en présence d'*ortho*-tolidine, mais également connaître l'effet des conditions expérimentales sur α.

Dans les milieux très acides et très riches en ions chlorures le problème est plus simple. Kieffer et Gordon (29) ont montré que la stoechiométrie correspond alors quasi exclusivement à [8] ce qui implique $\alpha \simeq 2$. De plus l'importance relative du processus I est fortement réduite.

Quelques résultats expérimentaux sont repris sur la fig. 8. Ils ont été obtenus en suivant la production de dioxyde de chlore en fonction du temps par absorptiométrie à 360 nm. Pour les faibles taux de conversion du chlorite on obtient des droites dont la pente donne la vitesse initiale de la réaction. En milieux moins acides, on n'obtient plus des droites même pour les faibles taux de conversion et la mesure des vitesses initiales devient très imprécise. La raison en apparaîtra lors de notre étude du processus I.

Signalons que pour obtenir des mesures reproductibles, nous avons du recristalliser le chlorure utilisé. Cette précaution est rendue nécessaire par la présence de bromure qui, même à des concentrations extrêmement faibles, peut avoir un effet sur la vitesse de la réaction. Cet effet n'apparaît pas en présence d'*ortho*-tolidine et sera étudié ultérieurement.

La fig. 8 montre qu'en l'absence d'*ortho*-tolidine la vitesse est également donnée par une somme de deux termes dont l'un est proportionnel à la concentration en ions chlorures.

$$\frac{d[ClO_2]}{dt} = v_1' + 7{,}3 \times 10^{-3}[HClO_2][Cl^-][H^+]$$

Nous avons vu que dans ces conditions le mécanisme correspond à [21] suivi de [16] ce qui donne compte tenu de [22],

$$k_{21} = 1{,}82 \times 10^{-3}\ M^{-2}\ s^{-1}$$

La concordance avec la valeur obtenue en présence d'*ortho*-tolidine est remarquable.

La loi cinétique proposée par Kieffer et Gordon (29) correspond à celle obtenue ici lorsque la concentration en ions chlorures est suffisamment grande. Pour une solution 1,2 molaire en acide perchlorique, elle se réduit à

$$-\frac{d[HClO_2]}{dt} = 1{,}57 \times 10^{-2}[HClO_2][Cl^-]$$

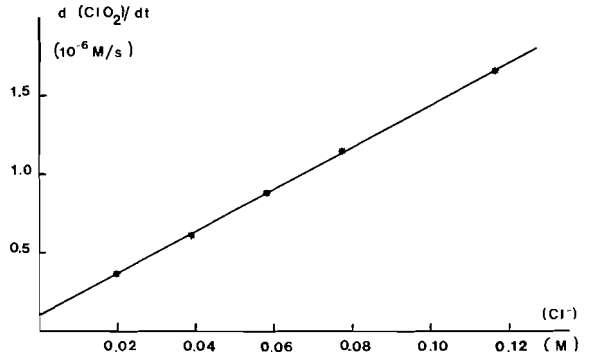

FIG. 8. Vitesses de réaction en l'absence d'*ortho*-tolidine. $[NaClO_2] = 2{,}99 \times 10^{-3}\,M$; $[HClO_4] = 0{,}624\,M$.

Ces auteurs constatent cependant que leur constante cinétique augmente avec l'acidité et admettent une variation linéaire. Leur loi devient ainsi:

$$-\frac{d[HClO_2]}{dt} = 1{,}31 \times 10^{-2}[HClO_2][Cl^-][H^+]$$

ce qui correspond, pour $\alpha \simeq 2$, à

$$k_{21} = 2{,}6 \times 10^{-3}\,M^{-2}\,s^{-1}$$

Cette valeur est compatible avec la nôtre compte tenu des différences de méthodes expérimentales, du fait qu'elle a été déduite de mesures globales de la vitesse de disparition de l'acide chloreux, sans isoler la contribution du processus II, et des complications stoechiométriques qui apparaissent en l'absence d'*ortho*-tolidine. Les résultats de Hong et Rapson (37) sont également en accord avec les nôtres moyennant des remarques similaires.

Conclusions

La loi cinétique de la dismutation du chlorite peut être représentée par une somme de deux termes dont l'un, proportionnel à la concentration des ions chlorures, peut être interprété par le mécanisme suivant:

[21] $HClO_2 + Cl^- + H^+ \rightarrow 2HClO$

[14] $HClO + HClO_2 \rightarrow Cl_2O_2 + H_2O$

[17] $Cl_2O_2 + H_2O \rightarrow ClO_3^- + Cl^- + 2H^+$

[18] $Cl_2O_2 + HClO_2 \rightarrow 2ClO_2 + Cl^- + H^+$

Ce mécanisme doit être complété pour tenir compte d'au moins deux groupes de faits expérimentaux. D'une part, nous avons vu qu'il explique l'essentiel de nos résultats relatifs à la réaction entre le chlorite et l'acide hypochloreux, mais pas leur intégralité. D'autre part, il existe un autre processus de dismutation du chlorite. En milieux 1,2 molaire en acide perchlorique ce processus est d'ordre 2 par rapport au chlorite et n'est pas influencé par le ClO_2 (29). Kieffer et Gordon ont cependant constaté que la loi qu'ils ont établie ne reste pas valable en milieux moins acides. Ce sera l'objet de notre article suivant où nous montrerons notamment que le ClO_2 peut alors inhiber la dismutation du chlorite.

L'*ortho*-tolidine simplifie grandement ces études de mécanismes en réagissant très rapidement avec l'acide hypochloreux et avec le dioxyde de chlore. En particulier il remplace les réactions [14], [17] et [18] par [19]. Grâce à la grande valeur du coéfficient d'absorption molaire de sa forme oxydée il a également l'avantage de permettre une mesure précise des vitesses initiales de réaction.

Remerciements

Les fructueuses discussions que nous avons eues avec Monsieur le Professeur C. Herbo sont à l'origine de ce travail. Nous lui adressons nos plus vifs remerciements.

Phosphorus-31 nuclear magnetic resonance studies of phosphido-bridged dinuclear complexes of palladium and platinum

JAMES BRADLEY BRANDON AND KEITH ROGER DIXON[1]

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received September 15, 1980

JAMES BRADLEY BRANDON and KEITH ROGER DIXON. Can. J. Chem. **59**, 1188 (1981).

Proton decoupled ^{31}P nmr spectra are reported for a series of dinuclear metal complexes containing bridging dialkyl- or diarylphosphido groups: $[M_2Cl_2(\mu\text{-}PR'_2)_2(PR_3)_2]$, M = Pd, R′ = Ph, $R_3 = Et_3$ or HPh_2; M = Pd, R′ = Me, $R_3 = Et_3$, Ph_3, or HMe_2; M = Pt, R′ = Ph, $R_3 = Et_3$ or HPh_2; and $[M_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$, M = Pd, or Pt, dppe = $Ph_2P(CH_2)_2PPh_2$. Detailed analysis and computer simulation of the spectra in the AA′XX′, AA′XX′M, AA′A″A‴XX′, and AA′A″A‴XX′M spin systems leads to the following ranges and *relative* signs for coupling constants involving the bridging phosphorus atoms: $^2J(R_3P\text{—}cis\ PR'_2)$, M = Pt, −1 to +5 Hz, M = Pd, +20 to +32 Hz; $^2J(R_3P\text{—}trans\ PR'_2)$, M = Pt, +291 to +396 Hz, M = Pd, +311 to +443 Hz; $^2J(R_2P\text{—}cis\ PR_2)$, M = Pt, −162 to −208 Hz, M = Pd, −261 to −350 Hz (the assignment of negative signs to these couplings is not completely certain); $^1J(Pt\text{—}PR_2)$, *trans* to Cl, +2364 to +2635 Hz, *trans* to PR_3, +1690 to +1992 Hz. Resonances due to the bridging phosphido groups occur at very high field (−267 to −322 ppm upfield of $P(OCH_3)_3$), in strong contrast to literature reports of phosphido bridges in palladium cluster complexes where the bridged metal atoms are linked by a metal–metal bond and the bridging phosphorus occurs +57 to +82 ppm downfield of $P(OCH_3)_3$.

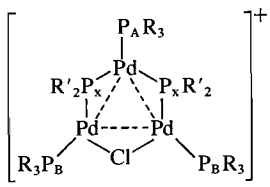
JAMES BRADLEY BRANDON et KEITH ROGER DIXON. Can. J. Chem. **59**, 1188 (1981).

On rapporte les spectres rmn du ^{31}P desquels on a découplé les protons d'une série de complexes métalliques binucléaires ayant en position de point des groupements dialkyle ou diaryle phosphido: $[M_2Cl_2(\mu\text{-}PR'_2)_2(PR_3)_2]$ M = Pd, R′ = Ph, $R_3 = Et_3$ ou HPh_2; M = Pd, R′ = Me, $R_3 = Et_3$, Ph_3 ou HMe_2; M = Pt, R′ = Ph, $R_3 = Et_3$ ou HPh_2; et $[M_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$, M = Pd ou Pt, dppe = $Ph_2P(CH_2)_2PPh_2$. Une analyse détaillée et une simulation à l'ordinateur des spectres des systèmes de spin AA′XX′, AA′XX′M, AA′A″A‴XX′ et AA′A″A‴XX′M conduisent aux intervalles et aux signes *relatifs* suivants des constantes de couplage impliquant l'atome de phosphore en position de pont: $^2J(R_3P\text{—}cis\ PR'_2)$, M = Pt, −1 à +5 Hz, M = Pd, +20 à +32 Hz; $^2J(R_3P\text{—}trans\ PR'_2)$, M = Pt, +291 à +396 Hz, M = Pd, +311 à +443 Hz; $^2J(R_2P\text{—}cis\ PR_2)$, M = Pt, −162 à −208 Hz, M = Pd, −261 à −350 Hz (l'attribution des signes négatifs à ces constantes de couplage n'est pas absolument certaine); $^1J(Pt\text{—}PR_2)$, *trans* à Cl, +2364 à +2635 Hz, *trans* à PR_3, +1690 à +1992 Hz. Les résonances dues au groupe phosphido en position de pont se produisent à très haut champ (−267 à −322 ppm à plus haut champ que $P(OCH_3)_3$) ce qui contraste fortement avec les données de la littérature au sujet des ponts phosphido dans les complexes du palladium où les atomes de métal en position de pont sont liés par une liaison métal–métal et le phosphore du pont apparaît de +57 à +82 ppm plus bas que le $P(OCH_3)_3$.

[Traduit par le journal]

Introduction

One of the objectives of our recent work has been the structural and chemical characterisation of the novel trinuclear palladium cluster cations $[Pd_3(\mu\text{-}X)(\mu\text{-}PR'_2)_2(PR_3)_3]^+$ (**1**). These clusters



1

are unusually stable and offer opportunities for development of an extensive chemistry (1, 2). The primary technique for following their reactions is ^{31}P nuclear magnetic resonance spectroscopy (nmr) and for comparison purposes there is a need for reliable ^{31}P parameters in simple (i.e. non-metal bonded) platinum and palladium complexes containing terminal tertiary phosphines and bridging phosphido ligands. Many palladium complexes of the general type, $[Pd_2X_2(\mu\text{-}PR'_2)_2(PR_3)_2]$, were prepared in the early 1960's, initially by Issleib and Wenschuk (3) and then by the more extensive work of Hayter and co-workers (4–6). These workers utilised reactions involving elimination of HCl from secondary phosphine complexes and later Chatt and Davidson (7) extended the work to syntheses of platinum complexes using both the HCl elimination reaction and reactions of lithium diphenylphosphide with chloro-bridged complexes.

Despite the large range of known palladium and platinum species containing bridging phosphido ligands, no ^{31}P nmr data were available in the literature for these complexes. This situation prompted us to undertake a detailed ^{31}P nmr study of two groups of complexes:

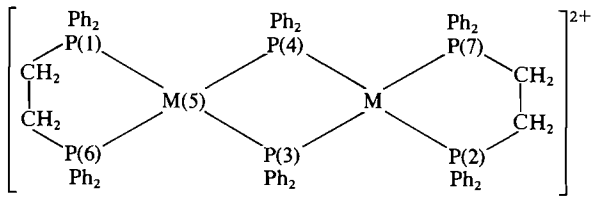
2: $[M_2Cl_2(\mu\text{-}PR'_2)_2(PR_3)_2]$, M = Pd, R' = Ph, $R_3 = Et_3$ or HPh_2; M = Pd, R' = Me, $R_3 = Et_3$, Ph_3, or HMe_2; M = Pt, R' = Ph, $R_3 = Et_3$ or HPh_2.



3

3: $[M_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$, M = Pd, or Pt, dppe = $Ph_2P(CH_2)_2PPh_2$.

The results of this ^{31}P nmr study are described in the present paper and we also note that during the preparation of our work, some parameters for the group of complexes; $[Pt_2X_2(\mu\text{-}PPh_2)_2L_2]$, X = Cl, L = PPr^n_3, PEt_3, PMe_2Ph, $AsEt_3$; X = H, L = PEt_3; X = $SiHPh_2$, L = PEt_3; have been briefly reported (8). These latter results are generally consistent with the parameters reported below except for some variations in the assigned signs of coupling constants. The brevity of the literature report (8) precludes a more detailed evaluation at the present time.

NOTE ADDED IN PROOF: We have recently learned that a more detailed report of these results is available in a Ph.D. thesis (K. J. Odell, University of Sussex, 1975).

Results

The following discussion is concerned with the proton decoupled phosphorus-31 nmr spectra of the two general types of species represented by structures **2** and **3**. The structures also show the numbering scheme (in parentheses) adopted for identification of chemical shifts and coupling constants. For the complex cations **3**, this scheme has been chosen to be consistent with that used for the neutral molecules, **2**, and to retain the same labelling for directly comparable chemical shifts and coupling constants throughout the paper. As a result the scheme for the cations is not the most logical one for these species considered independently but this should not cause any problems.

For palladium complexes, the species **2** and **3** will belong respectively to the AA'XX' and AA'A"A'"XX' spin systems as a first approximation.[2] There is a small amount of non-first order ("AB") character, as the detailed analyses given below will show, but this can be ignored in the preliminary analysis to obtain approximate parameters. For platinum complexes, a further subdivision of these spin systems is necessary since the species contain two platinum atoms and ^{195}Pt (with $I = 1/2$) is 33.8% abundant. Thus 43.8% (approximately 4/9) of the dinuclear molecules will contain no magnetically active platinum and will belong to the same spin systems as the palladium complexes; 44.8% (approximately 4/9) will contain one platinum-195 and belong to the spin systems AA'XX'M (Type **2**) and AA'A"A'"XX'M (Type **3**); and 11.4% (approximately 1/9) will contain two platinum-195 and belong to the spin systems AA'XX'MM' (Type **2**) and AA'A"A'"XX'MM' (Type **3**).[2]

Our general approach has been to analyse first spectra of Type **2** compounds of palladium in order to establish typical values for the inter-phosphorus coupling constants. We then analysed Type **2** compounds of platinum to provide platinum–phosphorus coupling constants before proceeding to the much more difficult spin systems of the Type **3** cations. As the detailed analyses will show, absorptions attributable to the approximately 1/9 of the platinum species containing two magnetically active platinum were too weak and difficult to identify for meaningful analysis. However, the only additional parameter which such an analysis could provide is ^2J(Pt,Pt) and computer simulations show that these particular spectra are not sensitive to the actual value of this coupling constant. They only depend on its approximate magnitude.

It should be noted that in all of the following discussions, identical coupling constants which are members of symmetry related sets are specified by reference to only one member of the set. For example, in Type **2** complexes a reference to $^2J(1,3)$ implies both of the identical couplings $^2J(1,3)$ and $^2J(2,4)$, or in Type **3** complexes a reference to $^2J(1,4)$ would imply the whole set $^2J(1,4)$, $^2J(4,7)$, $^2J(3,6)$, and $^2J(2,3)$.

$[Pd_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$

As noted above, the proton decoupled ^{31}P spec-

[2]In the alternative notation proposed by Haigh (35), these various spin systems would be designated $[AX]_2$, $[AX]_2M$, and $[AXM]_2$ for Type **2** species; $[[A]_2X]_2$, $[[A]_2X]_2M$, and $[[A]_2XM]_2$ for Type **3** species.

trum of this complex is, to a first approximation, an example of the AA'XX' spin system. The wave functions and transition energies for this spin system have been calculated previously in terms of four composite parameters (see ref. 9, note that this reference describes the AA'XX' spin system as A_2X_2). Using the nucleus labelling shown in structure **2** and redefining the parameters so as to be consistent with the AA'A"A'"XX' case discussed below, we obtain the following expressions for the composite parameters:[3]

$$K = \tfrac{1}{2}({}^2J(1,3) + {}^2J(1,4))$$

$$L = \tfrac{1}{2}({}^2J(1,3) - {}^2J(1,4))$$

$$P = \tfrac{1}{2}({}^4J(1,2) + {}^2J(3,4))$$

$$R = \tfrac{1}{2}({}^4J(1,2) - {}^2J(3,4))$$

The spectrum consists of identical A (terminal phosphine, downfield) and X (bridging phosphido, upfield) regions, centred on the chemical shifts δ_A and δ_X respectively, and each may be divided into two components:

(*a*) a strong doublet, separation $2K$

(*b*) two symmetrical quartets with line positions (relative to δ_A or δ_X) given by the equations:

$$+S + (S^2 + L^2)^{1/2}$$

$$-S + (S^2 + L^2)^{1/2}$$

$$+S - (S^2 + L^2)^{1/2}$$

$$-S - (S^2 + L^2)^{1/2}$$

In the first quartet $S = P$ and in the second $S = R$.

In the present example, inspection of the molecule suggests that $|{}^4J(1,2)| \ll |{}^2J(3,4)|$. Hence $|P| \simeq |R|$ and the two quartets will be almost coincident. Preliminary analysis of the A or X regions then assigns the peaks marked D in Fig. 1 to the strong doublet and the peaks marked Q to the almost coincident quartets. Closer inspection shows resolution of some of the quartet peaks and it is then possible to assign these (assuming for convenience that $P > R$ and both are positive) and to arrive at preliminary magnitudes of K, L, P, and R and hence for the coupling constants. Since only magnitudes are obtained and it is also not possible to distinguish P and R, no sign information is available except that because we find $|K| > |L|$ it follows that ${}^2J(1,3)$ and ${}^2J(1,4)$ must have the same sign. The indistinguishability of P and R also means that we cannot tell which of the two couplings ${}^4J(1,2)$ and ${}^2J(3,4)$ is which. However, couplings between phosphorus atoms in mutually *trans* positions are known to be large and positive (10, 11) and it also seems probable that the two bond coupling ${}^2J(3,4)$ will be very much larger in magnitude than the four bond coupling ${}^4J(1,2)$. With these assumptions we obtained the preliminary assignment: ${}^2J(1,3) = +407.9$ Hz, ${}^2J(1,4) = +31.2$ Hz, ${}^4J(1,2) = \pm 0.9$ Hz, and ${}^2J(3,4) = \pm 287.2$ Hz.

The actual spectrum shows significant non-first order character and so these preliminary parameters were then used as the basis for iterative computer refinements using all possible combinations of the two unknown signs. Whenever ${}^4J(1,2)$ and ${}^2J(3,4)$ were given the same sign, iteration resulted in a change of sign of ${}^4J(1,2)$ during refinement. Moreover, although the differences are subtle the plots of observed and simulated spectra shown in Fig. 1 support the assignment of ${}^2J(3,4)$ as negative. The parameters used for the plots in Fig. 1 are the result of refinement to convergence with both possible sets of signs, i.e. they are not the result of refining one set of parameters and then simply changing the signs of ${}^4J(1,2)$ and ${}^2J(3,4)$. This latter procedure is potentially very misleading

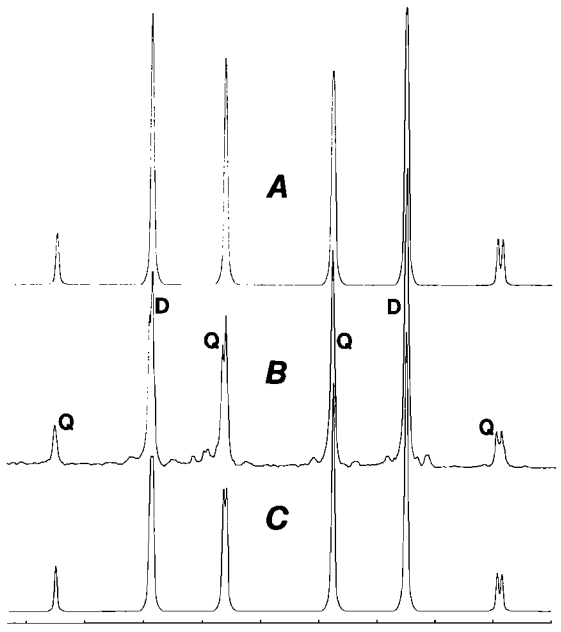

FIG. 1. Proton decoupled ^{31}P nmr spectrum of $[Pd_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$. The figure shows the terminal phosphine (lower field) region only and an identical mirror image spectrum occurs to higher field for the bridging phosphorus: (*A*) computer simulated spectrum with ${}^4J(1,2) = -2.7$, ${}^2J(1,3) = +406.7$, ${}^2J(1,4) = +29.8$, ${}^2J(3,4) = +289.0$ Hz; (*B*) observed spectrum at 24.3 MHz; (*C*) computer simulated spectrum with ${}^4J(1,2) = +2.9$, ${}^2J(1,3) = +405.9$, ${}^2J(1,4) = +31.9$, ${}^2J(3,4) = -289.5$ Hz. The significance of the doublet (D) and quartet (Q) labels is explained in the text. Each major division on the chemical shift/frequency axis represents 100 Hz.

[3]In ref. 9 the corresponding parameters are N, L, K, and M which in terms of our parameters are given by $2K$, $2L$, $2P$, and $2R$ respectively.

with complex spectra. On the basis of the plots shown in Fig. 1, the final refined parameters given in Table 1 were selected as the best fit to the observed spectrum. The signs given in Table 1 are relative to the assumption of a positive value for $^2J(1,3)$.

In the analysis of the spectrum of $[Pd_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$, and in the other cases discussed below, the preliminary assignment of the downfield resonances (δ_A in Table 1) to the terminal phosphines and the upfield (δ_X in Table 1) to the bridging phosphides, was made on the basis of known chemical shifts in terminal phosphine complexes. Thus, tabulated values (10) for a wide variety of tertiary phosphines and metals range from −66 to −166 ppm with the vast majority falling in a much smaller range, approximately −100 to −150 ppm (10). In our complexes the chemical shift assignments were confirmed by the observation in platinum compounds of two very different ^{195}Pt couplings ($^3J(2,5)$ and $^1J(1,5)$) in the low-field resonances. This unambiguously establishes these resonances as due to the terminal phosphines.

Other $[Pd_2Cl_2(\mu\text{-}PR'_2)_2(PR_3)_2]$ Spectra

These were analysed by procedures similar to that described above for $[Pd_2Cl_2(PPh_2)_2(PEt_3)_2]$ and the final refined parameters are collected in Table 1. The spectra of $[Pd_2Cl_2(\mu\text{-}PPh_2)_2(PHPh_2)_2]$ and $[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PHMe_2)_2]$ showed very small magnitudes for $^4J(1,2)$ and in consequence the two quartets were not resolved from each other and it was not possible to determine the signs of $^4J(1,2)$ and $^2J(3,4)$. In Table 1 they are assumed to be similar to the other examples. Spectra of $[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PEt_3)_2]$ and $[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PPh_3)_2]$ showed subtle evidence that $^4J(1,2)$ is positive and $^2J(3,4)$ negative, similar to the $[Pd_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$ case discussed above.

$[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$

Observed and calculated spectra for this molecule at 24.3 MHz are shown in Fig. 2. For the purposes of analysis the spectrum must be divided into contributions from two separate species; a "centre-band" spectrum (43.8%) due to molecules having no magnetically active platinum and a "side-band" spectrum (44.8%) due to molecules containing one ^{195}Pt atom. The remaining 11.4% of the molecules (containing two magnetically active platinums) can be neglected in the preliminary analysis. The centre-band spectrum is similar to the $[Pd_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$ spectrum discussed above and was analysed in the same way using either the A (low-field, terminal) or X (high-field, bridging) to provide preliminary values for

For personal use only.

the chemical shifts and phosphorus–phosphorus coupling constants. The side-band spectrum in the A region consists of two parts: (*i*) a pair of subspectra (labelled S1 in Fig. 2), associated with the spin transitions of nucleus 1 (see structue **2**) separated by the one-bond phosphorus–platinum coupling constant, $^1J(1,5)$, and (*ii*) sets of lines (labelled S2 in Fig. 2) associated with the spin transition of nucleus 2, flanking the principal lines of the centre band spectrum and having a separation of the same general magnitude (but *not* equal to) the three-bond phosphorus–platinum coupling constant, $^3J(2,5)$. It is also useful to note that $^4J(1,2)$ may be directly measured as a doublet separation of each of the principal lines of these side-band spectra. The side-band spectrum in the bridging region is more complex but consists basically of two subspectra separated by the approximate mean of the two platinum–phosphorus coupling constants, $^1J(3,5)$ and $^1J(4,5)$. Thus preliminary analysis gave direct measurement of $^1J(1,5)$, an approximate magnitude of $^3J(2,5)$ and the mean of $^1J(3,5)$ and $^1J(4,5)$.[4] Using this information together with that derived from the centre-band spectrum, the side-band spectrum was computer simulated and refined. Next the centre-band spectrum was simulated using the refined data from the side-bands and the two spectra were then combined in the correct intensity ratio to produce the plot shown in Fig. 2. The final refined parameters are collected in Table 1. As a final check on the correctness of the assignment, spectra were recorded at 101.2 MHz and the 24.3 MHz data were used, with appropriate chemical shift adjustment, to simulate the high-field results. Excellent agreement was obtained.

Careful inspection of Fig. 2 shows that only a few weak peaks are observed in addition to those accounted for in the simulated spectrum. These peaks may be attributed to the 11.4% of molecules containing two magnetically active platinums. It is clear that an analysis of these additional peaks is not necessary or indeed possible! In principle such an analysis could yield $^2J(Pt,Pt)$ but in practice the spectrum is expected to be insensitive to the precise value of this coupling.

During the refinement of the $[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$ spectra we considered that $^2J(1,3)$, $^1J(1,5)$, $^1J(3,5)$, and $^1J(4,5)$ could be assumed positive on the basis of previous sign determinations for mutually *trans* phosphorus atoms (10,11) and for one bond phosphorus–platinum couplings (12). $^2J(1,4)$ was shown by the preliminary analysis to have the same sign as $^2J(1,3)$. All possible sign combinations of $^4J(1,2)$, $^3J(2,5)$, and $^2J(3,4)$ were explored and the results showed the high-field bridging region of the spectrum to be essentially independent of the signs of these three coupling constants. The low-field terminal region was similarly non-productive as far as $^2J(3,4)$ was concerned and it appears that in this particular case this sign cannot be determined. In Table 1 it is assumed to be the same as in the palladium complexes. Changing the sign of $^4J(1,2)$ causes a reversal of the asymmetry in the outer side-bands (labelled S1 in Fig. 2) associated with spin transitions of nucleus 1 and this parameter is thus established as positive. Similarly, the inner side-bands (labelled S2 in Fig. 2), associated with spin transitions of nucleus 2, can only be satisfactorily fitted if $^3J(2,5)$ is positive.

$[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PHPh_2)_2]$

Analysis of the spectrum of this complex and exploration of the possible signs of coupling constants were carried out exactly as described above for the PEt_3 analogue and the results are collected in Table 1.The only exception was that spectra at 101.2 MHz were not recorded.

$[Pd_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$

As noted above, the cation in this complex is a representative of the AA′A″A‴XX′ spin system (see structure **3**). This system is relatively rare in nmr literature and the analyses which have been carried out have mostly involved heteronuclear species where A and X are different magnetically active nuclei. The principal examples are P_2H_4 (13), P_2F_4 (14), $(^{13}C)_2H_4$ (15), 1,3-difluoroacetone (16), and a group of diazadiphosphetidines (17). One case which does involve a homonuclear spin system is a ^{19}F study of some hexafluorocyclopentenes (18) but these spectra are dominated and simplified by large geminal F–F couplings (i.e. couplings within the AA′A″A‴ set) and are quite different from the present example.

Theoretical approaches to the AA′A″A‴XX′ spin system have been worked out by several authors (15, 19, 20) and we have followed the work of Lynden-Bell (15) who tabulated the wave functions in C_{2v} symmetry (for P_2H_4). The $[Pd_2(\mu\text{-}PPh_2)_2(dppe)_2]^{2+}$ cation has D_{2h} symmetry but it can be shown that this has no effect on the overall analysis (15). Because certain combinations of coupling constants are repeated throughout the analysis, it is convenient to define a number of secondary parameters. Adopting the basic approach used by Lynden-Bell, and relabelling the

[4]As a starting point for the refinement an approximate magnitude for $^1J(3,5)$ was derived from the value in $[Pt_2(\mu\text{-}PPh_2)_2(dppe)_2]^{2+}$ where the assignment is unambiguous.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

secondary parameters to conform to the symmetry in structure **3**, we obtain:

$$K = \tfrac{1}{2}({}^2J(1,3) + {}^2J(1,4))$$

$$L = \tfrac{1}{2}({}^2J(1,3) - {}^2J(1,4))$$

$$N = \tfrac{1}{2}({}^4J(1,2) + {}^2J(1,6))$$

$$M = \tfrac{1}{2}({}^4J(1,2) - {}^2J(1,6))$$

$$G = \tfrac{1}{2}{}^4J(1,7)$$

$$X = \tfrac{1}{2}{}^2J(3,4)$$

The indistinguishability of $^4J(1,2)$ and $^2J(1,6)$ compared to the unique nature of $^4J(1,7)$ is most easily seen by considering the effects of interchanging labels in structure **3**. Thus a change such as $2 \leftrightarrow 6$ results only in the interchange of the couplings $^4J(1,2) \leftrightarrow {}^2J(1,6)$ and the symmetry related pair $^4J(6,7) \leftrightarrow {}^2J(2,7)$. All other couplings are unchanged. However, a label change such as $2 \leftrightarrow 7$ will change not only the symmetry related pairs $^4J(1,2) \leftrightarrow {}^4J(1,7)$ and $^4J(6,7) \leftrightarrow {}^4J(2,6)$ but also the couplings to the bridging phosphorus; $^2J(2,3) \leftrightarrow {}^2J(3,7)$ and $^2J(2,4) \leftrightarrow {}^2J(4,7)$.

The lines in the A (low-field, terminal phosphine) region of the spectrum are symmetrical about δ_A,

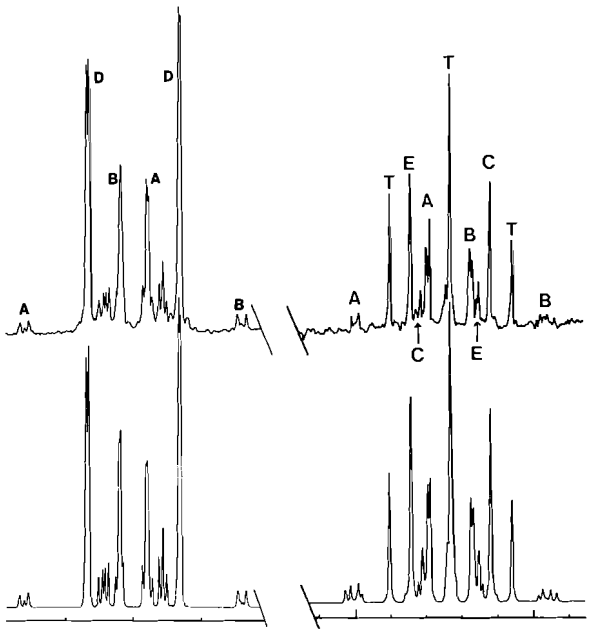

FIG. 3. Proton decoupled ^{31}P nmr spectrum of $[Pd_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$. The upper plot is the observed spectrum at 24.3 MHz and the lower plot is computer simulated using the parameters given in Table 1. The low-field (left) and high-field (right) regions are centred ca. −92 and −321 ppm respectively and each major division on the chemical shift/frequency axis represents 50 Hz in the low-field region and 200 Hz in the high-field region. The significance of the labelling (A, B, etc.) is explained in the text.

the chemical shift of the terminal tertiary phosphine ligands. The most prominent feature is an intense doublet with separation $2K$, and this separation also occurs in a triplet in the X (high-field, bridging) region. These features are labelled D and T respectively in Fig. 3. As in Type **2** systems described above, in the preliminary analysis we ignore complications (in this case a slight extra splitting of the doublet) caused by slight AA′A″A‴BB′ character in the basically AA′A″A‴XX′ spin system. The next most prominent feature is a set of 8 lines symmetrically disposed about $\delta_A + X$ and a corresponding mirror image set about $\delta_A - X$. The positions of these lines are given by

$$\delta_A + X + N \pm (L^2 + (X + N)^2)^{1/2}$$

$$\delta_A + X + M \pm (L^2 + (X + M)^2)^{1/2}$$

$$\delta_A + X - N \pm (L^2 + (X - N)^2)^{1/2}$$

$$\delta_A + X - M \pm (L^2 + (X - M)^2)^{1/2}$$

and

$$\delta_A - X - N \pm (L^2 + (X + N)^2)^{1/2}$$

$$\delta_A - X - M \pm (L^2 + (X + M)^2)^{1/2}$$

$$\delta_A - X + N \pm (L^2 + (X - N)^2)^{1/2}$$

$$\delta_A - X + M \pm (L^2 + (X - M)^2)^{1/2}$$

These equations contain all the terms necessary to estimate 5 of the 6 coupling constants with only the G term ($\frac{1}{2}{}^4J(1,7)$) being omitted. Thus the main interpretive problem is the assignment of these 8 lines to their corresponding algebraic expressions. The high-field bridging phosphorus region ("X" spectrum) may also be used in this assignment since in this region the two 8 line systems are repeated twice, centred on $\delta_X \pm K$ respectively (i.e. there are four 8 line systems centred on $\delta_X \pm K \pm X$ respectively). In the present case this assignment problem was solved by tabulating the A lines relative to δ_A and the X lines relative to $\delta_X + K$ and relative to $\delta_X - K$ and then searching for repeating patterns. It should be noted that exact symmetry of the repeating patterns only occurs in a true AA′A″A‴XX′ system with no AA′A″A‴BB′ character. In this tabulation it was immediately apparent that only a 4 line repeating pattern is present in the observed spectra. In the low-field region of Fig. 3, the first 4 line set is labelled A, the second B, and in the high-field region the labels A, B, C, and E are used. Reduction of the 8 line to 4 line sets is expected if $|M| \simeq |N|$, i.e. if either or both of $^4J(1,2)$ and $^2J(1,6)$ are very small. This is reasonable in the present case since the former

For personal use only.

coupling is close to zero in the other diphenylphosphido bridged palladium complexes discussed above (see Table 1). Assuming for convenience that N and X are both positive and that N is small relative to X and L,[5] it is then possible to make an assignment of the sets of lines and to derive magnitudes for the coupling constants; $^2J(3,4)$, $^2J(1,3)$, $^2J(1,4)$, and for the parameter N.

These are approximate magnitudes because of the partial AA'A"A'"BB' character of the spectrum. Computer refinement of the spectrum was then carried out by assuming $^4J(1,2) = 0$, thereby enabling $^2J(1,6)$ to be set equal to $2N$, and also by assuming $^4J(1,7) = 0$. The refinement proceeded perfectly satisfactorily with $^4J(1,2)$ and $^4J(1,7)$ held at zero and with $^2J(1,6)$, and all other parameters, allowed to vary. The refined value of $^2J(1,6)$ is included in Table 1 with $^4J(1,2)$ set to zero but since these two parameters cannot be distinguished in this spin system (see above) and we have in any case insufficient spectral resolution to determine the parameter M, the values of $^2J(1,6)$ and $^4J(1,2)$ must be regarded as essentially undetermined, although definitely of small magnitude. Similarly $^4J(1,7)$ is undetermined although of small magnitude.

During the refinement all signs of the various coupling constants were explored. Since $|K| > |L|$ it is evident that $^2J(1,3)$ and $^2J(1,4)$ have the same sign and since couplings between mutually *trans* phosphorus atoms are known to be large and positive (10,11), it is likely that both these parameters are positive. Correct fitting of the weak lines in the central region of the A spectrum (low-field, terminal phosphines) required that a negative value of $^2J(1,6)$ be used although, as noted above, this is not a well determined parameter. Figure 3 shows the experimental spectrum together with computer simulations. The excellent fit with experiment shows the overall correctness of the analysis and, as in the Type **2** complexes described above, the detail indicates a slightly better fit when $^2J(3,4)$ is negative. As in the other cases, the evidence is suggestive only and cannot be regarded as a final proof.

$[Pt_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$

As in the case of $[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$ discussed above, spectra of the cation in the present complex must be divided into contributions from two separate species: (*a*) about 4/9 of the molecules contain no magnetically active platinum and give rise to a "centre-band" spectrum, (*b*) about 4/9 contains one ^{195}Pt and give rise to a "side-band" spectrum. The remaining ~1/9 of the molecules contain two ^{195}Pt and can be neglected in the preliminary analysis.

The "centre-band" spectra are similar to those described above for $[Pd_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$ and were analysed in basically the same way by determination of $2K$ as the separation of the large doublet in the low-field A region due to phosphorus in the dppe ligands, followed by location of the repeating 8 line patterns. In Fig. 4 the components of the centre-band spectrum are labelled in the same way as for the Pd analogue discussed above. As in the case of the palladium complex the small values of some parameters reduce the sets to 4 lines and in some cases even to two lines. These assignments yielded preliminary values for $^2J(1,3)$, $^2J(1,4)$, $^2J(3,4)$, and N, the principal difference from the palladium case being that, since $|K| \simeq |L|$, it follows that $^2J(1,4)$ is near zero. Once the centre-band spectrum is clearly identified it is easy to pick out the platinum side-bands arising from the various components and to obtain preliminary values for the coupling constants to platinum. These then permit computer simulation and refinement of the side-band spectra. Whereas, in the palladium complex it is not possible to distinguish between $^4J(1,2)$ and $^2J(1,6)$, this is possible in the side-band spectra of the platinum complex because these belong to the AA'A"A'"XX'M spin system and the principal side-band peaks due to spin transitions of nuclei 1 and 2 are doubled when $^4J(1,2) \sim 7$ and $^2J(1,6) \sim 0$ Hz but not in the reverse case. The observed spectrum shows this doubling and establishes the parameters as listed in the table. It is difficult to distinguish between the situations $^4J(1,2) \sim 7$, $^2J(1,6) \sim 0$, $^4J(1,7) \sim 0$ and $^4J(1,2) \sim 0$, $^2J(1,6) \sim 0$, $^4J(1,7) \sim 7$ Hz since both of these lead to doubling of the principal side-band peaks but examination of other spectral detail supports the former assignment.

Once refinement of the side-band spectrum was complete the refined parameters were used to simulate the centre-band spectrum and the two simulations are shown in Fig. 4. The simulated spectra of the two isotopomers were also combined in a 1:1 ratio (4/9:4/9) to produce a composite simulation (not illustrated) which showed excellent agreement with the observed spectrum. The observed spectrum in Fig. 4 contains some weak extra peaks which may be assigned to the ~1/9 of the molecules containing two magnetically active platinums. There are also 3 peaks, labelled I in Fig. 4,

[5]The assumption regarding the magnitude of N is fully justified by the likely coupling constants to be found in these molecules (see structures **2** and **3**). The assumption of positive signs is arbitrary but only interchanges line assignments without changing the final magnitudes of the derived parameters.

which are clearly due to a simple impurity with ^{195}Pt side-bands. As in the case of $[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$ discussed above, attempted analysis of the weak "two ^{195}Pt" spectrum was not considered profitable.

Discussion

The nmr parameters for all of the complexes are collected in Table 1 using the labelling schemes shown in structures **2** and **3**. Derivation of the relative signs of the various coupling constants has already been discussed in detail in the Results section. Absolute signs for the P—P coupling constants given in Table 1 are all based on the assumption that the large coupling, $^2J(1,3)$, between mutually *trans* phosphorus atoms is positive. This has been the case in all previous examples where absolute sign has been determined (10, 11) and, although these involved phosphine or phosphite ligands rather than bridging phosphido groups, the present couplings are of very similar magnitude and it is likely that they also are positive. However, it should be noted that all of the sign information is *relative* to the assumption of a positive value for $^2J(1,3)$ and in the absence of a definitive sign determination for any phosphido system the absolute signs remain tentative assignments.

Given $^2J(1,3)$ positive, the sign of $^2J(1,4)$ is then established as positive by the relative magnitudes, $|K| > |L|$. $[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PHPh_2)_2]$ is a minor exception to this statement but the negative value is of very small magnitude. The positive values for $^2J(1,4)$ are somewhat unusual in that the majority of previous sign determinations have found negative couplings between mutually *cis* phosphorus atoms (10, 11). However, none of the previous examples involved bridging phosphido and, unlike the situation with the large *trans* couplings, the small magnitudes of the *cis* couplings make sign reversals quite possible as the nature of the phosphorus groups and substituents are changed.

Continuing to discuss P—P coupling constants, the refinements suggest that the signs of the remote, $^4J(1,2)$, couplings are reliable. However, their magnitudes (especially the very small ones) are probably less accurate than those of the other couplings because these determinations depend upon resolution of the quartets which in our spectra were often almost coincident. The difficulties of distinguishing $^4J(1,2)$ from $^2J(1,6)$ in $[Pd_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$ and $^4J(1,2)$ from $^4J(1,7)$ in $[Pt_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$ have already been discussed in the Results section. A more serious problem concerns the sign of $^2J(3,4)$, the coupling between the two bridging phosphido groups. As we noted above, the majority of previous determinations for couplings between mutually *cis* phosphorus atoms have given negative signs (10, 11). However, those couplings were of relatively small magnitude and there seems to be no precedent in studies of phosphine and phosphite metal complexes for a negative coupling as large as $^2J(3,4)$. Moreover, the assignment of $^2J(3,4)$ as negative depends on some rather subtle features of the observed/simulated spectra (see figures and Results section) and it is clear that further work is needed to confirm the assignment. For the present it must be regarded as suggestive and not conclusive.

Examination of Table 1 shows that, for the exactly similar pairs of platinum and palladium complexes ($[M_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$, $[M_2Cl_2(\mu\text{-}PPh_2)_2(PHPh_2)_2]$, and $[M_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$), the two bond phosphorus–phosphorus coupling constants $^2J(1,3)$, $^2J(1,4)$, and $^2J(3,4)$ are always of larger magnitude in the palladium complex. The trends to be expected in J(PMP) coupling constants as M is varied down a transition triad are not well established but our observations are generally consistent with previous results. For example, in the Ni, Pd, and Pt triad the limited data available for *cis*-^2J(P—M—P) have been summarised by Carty, Johnson, and Jacobson (21). These authors show that in most cases the magnitude of *cis*-^2J(P—M—P) decreases in the sequence Ni > Pd > Pt, although the general trend is contradicted by data on $[MX_2(PMe_3)_2]$, M = Pd or Pt, X = Cl or Br. In *trans* complexes the same general trend appears to hold (i.e. decrease in magnitude of *trans*-^2J(P—M—P) down the triad) although the data are limited to platinum and palladium complexes, $[MX_2(L)_2]$, X = Cl or Br, L = PMe_3, PEt_3, or PMe_2H (10, 11). The only other well studied triad is the Cr, Mo, W group where a variety of data is available to show that *cis*-^2J(P—M—P) in *cis*-$M(CO)_4L_2$ complexes decreases in magnitude in the sequence Cr > Mo > W (10, 22). For *trans*-$M(CO)_4L_2$ complexes the data are much more limited but indicate the reverse order (10). Clearly much more data, especially with sign determinations, are needed before meaningful generalizations about these trends can be made.

One bond, platinum–phosphorus couplings are known to have positive sign (12) and this sign has been assumed for $^1J(1,5)$, $^1J(3,5)$, and $^1J(4,5)$ in Table 1. The magnitudes of $^1J(3,5)$ and $^1J(4,5)$ are consistent with the well known *trans* influence order $R_3P \gg Cl$ (23) and the relatively small values of $^1J(1,5)$, compared for example with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

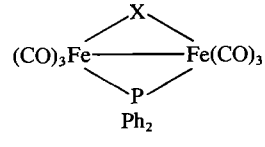
values for ^1J(Pt,P) of 2400 and 3520 Hz in *trans*- and *cis*-$[PtCl_2(PEt_3)_2]$ respectively (24), indicate a very high *trans* influence for the bridging diphenylphosphido group. Overall the data show the *trans* influence order

$$\mu\text{-}PPh_2 > PEt_3 > Cl$$

and this appears to represent the first determination of *trans* influence for a bridging phosphido group in platinum complexes.

Given the assumption of positive signs for the directly bonded Pt—P couplings, the detailed spectral refinements fix the indirect Pt—P coupling, ^3J(2,5) as positive. Comparatively little literature data are available for comparison with this coupling but some ^3J(Pt—P) values have been reported from ^{195}Pt spectra of a group of chloro-bridged complexes; $[Pt_2(\mu\text{-}Cl)_2(PR_3)_2]$, ^3J(Pt—P) = −21 to −27 Hz, and $[Pt_2(\mu\text{-}Cl)_2(PPr^n_3)_4][BF_4]_2$, ^3J(Pt—P) = −11 Hz (25). ^3J(Pt—P) has also been determined in $[Pt_2(\mu\text{-}Cl)_2(COEt)_2(PMe_2Ph)_2]$, *cis* isomer ±11 Hz, *trans* isomer −5.6 Hz (26) and in the sulphur bridged species $[Pt_2Cl_2(\mu\text{-}SCH_2Ph)_2(PBu^n_3)_2]$, −16 Hz, and $[Pt_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SCH_2Ph)(PBu^n_3)_2]$, 0 Hz (27). The variation of ^3J(Pt—P) between zero and small negative magnitudes indicates that the coupling is sensitive to the nature of the bridging groups and other substituents on the metal. With this background our observation of positive couplings is interesting but not necessarily surprising.

As noted in the Introduction, a principal motivation for this work was to obtain nmr parameters for phosphido bridged complexes in order to assess the effect of the metal–metal bonds in our cluster complexes (see structure **1**). The most dramatic difference between the clusters and the non-metal–metal bonded systems described in the present paper is in the chemical shifts of the bridging diphenylphosphido groups. In the clusters (1, 2) these occur ca. 60–80 ppm downfield of trimethylphosphite, a sharp contrast to the ca. 270–320 ppm upfield observed in the present complexes. In their work on phosphido bridged iron carbonyl systems:



Carty and co-workers (28, 29) have shown that variation of the bridging group X causes marked shifts in the chemical shift of the PPh_2 phosphorus and have suggested that these variations are associated with changes in the Fe—P—Fe angle. The complexes give δ_P from about 0 to +60 ppm downfield of trimethylphosphite with Fe—P—Fe angles in the range 70–75° and with a tendency for δ_P to become more positive as angle increases (28, 29). In contrast, the complexes $[M_3(\mu\text{-}PPh_2)(\mu\text{-}C{\equiv}CR)(CO)_9]$, M = Ru and Os where there is no metal–metal bond between the atoms bridged by PPh_2, show M—P—M angles >90° and phosphorus chemical shifts upfield of 85% H_3PO_4 (i.e. > −140 ppm upfield from trimethylphosphite) (30). The overall effect is thus similar to the palladium case. In the clusters (structure **1**) where there is metal–metal bonding, the Pd—P—Pd angle is 81.4° (31) and the PPh_2 shift is downfield (1). For the complexes studied in the present paper the PPh_2 shifts are upfield. There is unlikely to be metal–metal bonding and comparison with the results on iron compounds leads to the expectation of large angles at the bridging phosphorus. These expectations are confirmed by very recent structure determinations (32) for $[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PHPh_2)_2]$ and $[Pt_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$ which show Pt—PPh_2—Pt angles of 102.85(0)° and 103.9(1)° respectively and Pt....Pt separations of 358.5 and 369.9 pm. Clearly more structural information on both iron and palladium systems would be very valuable in investigating the generality of these trends.

Another important consideration is the effect of metal–metal bonds on the phosphorus–phosphorus coupling constants. Thus $J(P_A,P_B)$ in structure **1** is a 4-bond coupling if metal–metal bonding is ignored but a 3-bond coupling if it is included. $J(P_A,P_B)$ is directly comparable with the 4-bond couplings, ^4J(1,2), in Table 1 and the large difference in magnitude (~90 Hz and <10 Hz respectively) clearly shows the importance of the metal–metal bonds in the cluster.

Experimental

Phosphorus-31 nmr spectra were recorded in dichloromethane solution at 24.29 MHz on a Nicolet TT14 Fourier transform spectrometer using a Varian HA60 magnet. Protons were decoupled by broad band ("noise") irradiation at appropriate frequencies. $[P(OCH_3)_3]$ was used as external reference and C_6D_6 as external lock. Negative chemical shifts are upfield from the reference. Most spectra were recorded using 4096 real time data points in sweep widths of 6000 – 12 000 Hz and the data are thus subject to errors of the order of 1–3 Hz. Spectra of $[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$ were also recorded at 101.2 MHz using a Bruker WP250 Fourier transform spectrometer.

Simulated nmr spectra were calculated on an IBM 3031 computer and plotted on Calcomp 563 and 1039 plotters. The programmes used were a locally constructed package based on the UEAITR (33) and NMR PLOT (34) programmes from the literature.

$[Pd_2Cl_2(\mu\text{-}PPh_2)_2(PHPh_2)_2]$, $[Pd_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$, and $[Pd_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$ were prepared by established literature procedures (4) except that, in our hands the published

recrystallization of the PEt_3 derivative from aqueous acetone did not give satisfactory results. Our samples of this complex were purified by washing with pentane and recrystallization from acetone by addition of diethyl ether and pentane. Preparation of $[Pt_2(\mu\text{-}PPh_2)_2(dppe)_2]Cl_2$ was similar to that of the palladium analogue (4) except that the reaction mixture was heated under reflux for 30 min and the product recrystallized as pale yellow plates from methanol by addition of diethyl ether.

$[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$ has been prepared previously by reaction of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PEt_3)_2]$ with $[SiMe_3(PPh_2)]$ (8). We preferred to prepare this complex by reaction of $[PtCl_2(PhCN)_2]$ with $PHPh_2$ followed by displacement of $PHPh_2$ by PEt_3.

$$2PtCl_2(PhCN)_2 + 4PHPh_2 \xrightarrow[-2PhCN]{-2HCl} Pt_2Cl_2(PPh_2)_2(PHPh_2)_2$$

$$Pt_2Cl_2(PPh_2)_2(PHPh_2)_2 + 2PEt_3 \xrightarrow{-2PHPh_2} Pt_2Cl_2(PPh_2)_2(PEt_3)_2$$

Palladium derivatives with PMe_2 bridges were prepared by similar routes based on reactions of $PHMe_2$.

$[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PHPh_2)_2]$

A solution of *cis*-$[PtCl_2(PhCN)_2]$ (0.75 g, 1.6 mmol) in benzene (50 mL) was heated under reflux in a nitrogen atmosphere and $PHPh_2$ (0.56 mL, 3.2 mmol) was slowly added. After reflux for 30 min, cooling to 10°C gave $[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PHPh_2)_2]$ (0.90 g, 0.75 mmol) as a white precipitate which was recrystallized from dichloromethane by addition of diethyl ether.

$[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$

PEt_3 (0.056 mL, 0.38 mmol) was added to a stirred suspension of $[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PHPh_2)_2]$ (0.23 g, 0.19 mmol) in acetone (7 mL) in a nitrogen atmosphere. Stirring was continued for 30 min before the reaction mixture was evaporated under reduced pressure, washed with pentane, and the residue recrystallized from acetone by the addition of pentane to yield $[Pt_2Cl_2(\mu\text{-}PPh_2)_2(PEt_3)_2]$ (0.12 g, 0.11 mmol) as colourless crystals.

$[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PHMe_2)_2]$

$[PdCl_2(PhCN)_2]$ (0.23 g, 0.59 mmol) and benzene (10 mL) were placed in a thick-walled Pyrex tube and $PHMe_2$ (0.072 g, 1.16 mmol) added *in vacuo*. The tube was sealed, shaken at ambient temperature for 4 h, cooled to −196°C and opened *in vacuo*. As the contents warmed to ambient temperature the most volatile products were removed *in vacuo* and the resulting solution was removed from the vacuum line and filtered to give $[PdCl_2(PHMe_2)_2]$ (0.17 g, 0.56 mmol) as a white solid smelling strongly of $PHMe_2$. This solid was then heated under reflux in a nitrogen atmosphere with *p*-toluidine (0.063 g, 0.59 mmol) for 20 min. The reaction mixture was evaporated under reduced pressure and extracted with dichloromethane leaving impure *p*-toluidine hydrochloride (0.089 g, ~0.6 mmol) as residue. Evaporation of the filtrate under reduced pressure gave oily yellow crystals which were partially dissolved in benzene and re-precipitated with hexane to give $[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PHMe_2)_2]$ (0.12 g, 0.23 mmol).

$[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PPh_3)_2]$

PPh_3 (0.6 g, 2.3 mmol) and $[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PHMe_2)_2]$ (0.067 g, 0.13 mmol) were dissolved in CH_2Cl_2 (10 mL) and the mixture evaporated to dryness under reduced pressure. The solution/evaporation process was repeated 4 times to completely displace $PHMe_2$. The residues were recrystallized from dichloromethane by addition of hexane to yield $[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PPh_2)_2]$ (0.10 g, 0.11 mmol) as yellow crystals.

$[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PEt_3)_2]$

PEt_3 (0.15 mL, 1.0 mmol) was added to a solution of $[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PHMe_2)_2]$ (0.27 g, 0.5 mmol) in dichloromethane (5 mL) under a nitrogen atmosphere. After stirring for 1 h the reaction mixture was evaporated *in vacuo* to a dark red oil. Pumping *in vacuo* was continued for several hours before the residue was dissolved in dichloromethane and the solution poured into a large volume of stirred pentane to give $[Pd_2Cl_2(\mu\text{-}PMe_2)_2(PEt_3)_2]$ (0.11 g, 0.17 mmol) as an orange powder.

Mechanism of 2-quinizarinsulphonic acid reduction on a mercury electrode

F. CAPITAN,[1] A. GUIRAUM, AND J. L. VILCHEZ
Department of Analytical Chemistry, Faculty of Sciences, Granada, Spain
Received September 24, 1980

F. CAPITAN, A. GUIRAUM, and J. L. VILCHEZ. Can. J. Chem. **59**, 1201 (1981).

The reduction of the 1,4-dihydroxyanthraquinone-2-sulphonic acid (quinizarinsulphonic acid) at a dropping mercury electrode has been investigated. The reduction takes place in two monoelectronic steps and show $E_{1/2}$ values vs. sce $(E_{1/2})_1 = -0.380$ V and $(E_{1/2})_2 = -1.045$ V at pH 4.60. The first wave is diffusion controlled, while the second wave is kinetically controlled. The reagent captures one electron and one proton to form the semiquinonic system. The semiquinone is dimerized. The dimer captures one electron and one proton, per molecule, to form the hydroquinone. The reaction orders, together with Tafel's slopes, have been calculated.

F. CAPITAN, A. GUIRAUM et J. L. VILCHEZ. Can. J. Chem. **59**, 1201 (1981).

On a étudié la réduction de l'acide dihydro-1,4 xianthraquinone sulfonique-2 (acide quinizarinsulfonique) au niveau d'une électrode à goutte de mercure. La réduction a lieu en deux étapes monoélectroniques et a des valeurs de $E_{\frac{1}{2}}$ par rapport à sce de $(E_{\frac{1}{2}})_1 = 0{,}380$ V et $(E_{\frac{1}{2}})_2 = 1{,}045$ V à un pH de 4,60. La première onde est contrôlé par diffusion tandis que la deuxième est sous contrôle cinétique. Le réactif capte un électron et un proton en formant un système semiquinonique. La semiquinone est dimérisée. Le dimère capte un électron et un proton par molécule et donne l'hydroquinone. On a calculé l'ordre des réactions ainsi que les pentes de Tafel.

[Traduit par le journal]

Introduction

The polarographic reduction of anthraquinonic molecules has been studied by several authors (1–5). It may take place through various mechanisms (dimerization, dismutation, catalysis, etc.). The reduction product is the respective semiquinone or hydroquinone depending on the functional groups existing in the molecule, the pH of the medium and the nature of the solvent (5).

Previous to this paper the polarographic behaviour of 1,2,7-trihydroxyanthraquinone-3-methylamino-*N*,*N*-diaceticacid (anthrapurpurin complexan, reagent with anthraquinonic structure of analytical interest) has been described (4). In this paper the reduction of 1,4-dihydroxyanthraquinone-2-sulphonic acid (2-quinizarinsulphonic acid) at the DME is studied. This reagent has been previously studied with respect to some of its analytical applications; thus it has been proposed for the spectrophotometric determination of F^- (6), Zr^{4+} (7), and Th^{4+} (8), for the spectrofluorimetric determination of Al^{3+} (9) and Be^{2+} (10), and as an acid–base indicator (11).

Experimental

The *i*–*E* curves were registered either automatically or traced point by point using a 471 AMEL multipurpose unit with the damping circuit completely suppressed. The cyclic voltammetry curves were recorded on a Tectronix SSP 3 polarograph. The potentials were measured vs. sce with a Beckman Research Potentiometer, which was also used as a pH-meter.

The polarographic measurements were done using a thermostated AMEL 494 cell. A saturated calomel reference electrode was used. The working electrode was a mercury capillary with the following characteristics: rate of mercury flow $m = 1.87$ mg/s, drop time $t = 5.65$ s, open circuit, in a buffered solution at pH 4.60 and the height of the mercury column $h = 40$ cm. The cyclic voltammetry curves were carried out using an amalgamated gold electrode as a working electrode.

All the reagents used were Merck P.A. grade. As a supporting electrolyte solution, a buffered solution was used; it was composed of 0.8 *M* acetic acid and 0.8 *M* sodium acetate which were mixed in varying proportions according to the pH desired. The ionic strength was adjusted with $NaClO_4$ to 0.2 *M*. All the measurements were done in an atmosphere of nitrogen and at a temperature of 25.0 ± 0.1°C.

Results and Discussion

The 2-quinizarinsulphonic acid reduced on the DME produces two polarographic waves from aqueous solutions at concentrations smaller than 5×10^{-4} *M*. Both waves were always observed throughout the complete pH range studied (3.60–8.20). Figure 1 shows a representative polarogram at pH 4.60, $(E_{1/2})_1 = -0.380$ V, and $(E_{1/2})_2 = -1.045$ V. First of all, we investigated the dependence of the limiting current on the height of the mercury column. The results were obtained for a 5×10^{-4} *M* solution at pH 4.60. The plot of i_{lim} vs. $h^{1/2}$ (corrected for the back pressure) shows a linear dependence for the first wave. This proves that the wave height is diffusion controlled (Fig. 2). For the second wave i_{lim} is independent of the height, proving the kinetic nature of such a wave. The temperature coefficients of i_{lim} have been investigated in the range between 20 and 85°C with 10^{-4} *M* solutions at pH 4.60. The temperature coefficient is found to be $d(\log i_d)/dT = 0.0075$ for the first wave (close to the theoretical value 0.007), confirming

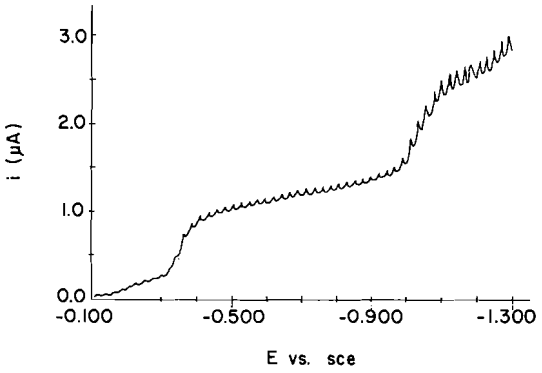

FIG. 1. Polarogram of 10^{-3} M 2-quinizarinsulphonic acid at pH 4.60 (acetate buffer).

the diffusion-controlled nature of the first wave. For the second wave $d(\log i_{lim})/dT = 0.035$, so that the kinetic nature of the wave is again confirmed. The dependence of the half-wave potential on pH was studied as well, to determine how many hydrogen ions are involved in the reduction. Polarograms were recorded for 5×10^{-4} M solutions in the pH range between 3.60 and 8.20. The dependence $E_{1/2}$ vs. pH for both waves is linear, the slopes being 57 mV and 55 mV respectively. Accordingly, the number of hydrogen ions involved in the reduction must be $p = 1$ in both cases. Likewise, the order of reaction with respect to the H^+ is 1 in both reductions. Note that the limiting currents are independent of the pH.

On the other hand, we checked whether the limiting currents are proportional to the concentration of the 2-quinizarinsulphonic acid in the bulk of the solution, in the range between 5×10^{-3} M and 10^{-4} M at pH 4.60. The value of the slope of the linear segments is: 1.6 μA L/mM and 1.2 μA L/mM for the first and the second wave respectively. Hence, the diffusion current constant is $I = i_d/m^{2/3}t^{1/6}C = 607D^{1/2}n = 0.79$, and the diffusion coefficient $D = 1.7.10^{-6}$ cm^2/s, where $n = 1$, $m = 1.87$ mg/s and $t = 5.65$ s. Such values for I and D agree with those previously published for some anthraquinones (4, 5).

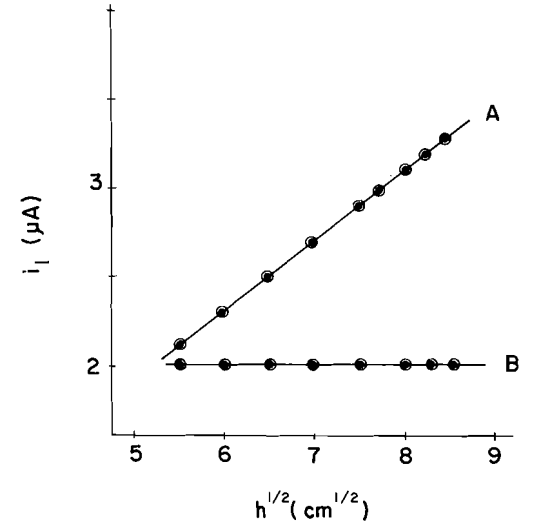

FIG. 2. Dependence of the limiting current on the height of the mercury column. A, first wave; B, second wave.

The half-wave potential $E_{1/2}$ shifts to more negative potentials with an increase in concentration. The plot $E_{1/2}$ vs.log C is linear in both waves with slopes of 13 mV and 18 mV respectively.

The transfer coefficient determined from Tafel's slope is $\alpha = 0.7$ and the orders of reaction with respect to the concentration are

$$\left(\frac{d \log i}{d \log C}\right)_E = 1$$

for the first wave and 0.53 for the second wave.

We carried out controlled-potential coulometry to determine n, i.e., the number of electrons involved in the reduction. A mercury pool was used as the cathode and a platinum wire as the auxiliary electrode; the reference electrode was a sce. The concentration of the sample before and after the electrolysis was measured polarographically to ensure that reduction reached completion. The electrolyzed samples contained 0.0348 g of solute in 100 mL of solution and a continuous stream of nitrogen was passed during the electrolysis. It appears that the reduction of 2-quinizarinsulphonic acid involves one electron in every wave.

The cyclic stationary electrode voltammetric curves for both waves at different scan rates were registered (Fig. 3). If the scan rate is medium, both systems are reversible. When the scan rate is lower both curves become irreversible. This behaviour agrees with the diagnostic criteria proposed by Wopschall and Shain (12) for reversible electrode processes followed by an irreversible chemical reaction.

Conclusions

The polarographic curves show that the reduction of the 2-quinizarinsulphonic acid proceeds by two monoelectronic steps, diffusion and kinetically controlled respectively. The reagent requires one electron and one proton in each step, to produce the semiquinone and hydroquinone consecutively.

The shape of the cyclic voltammetry curves is, in both cases, in agreement with the diagnostic criteria proposed for systems in which a single chemi-

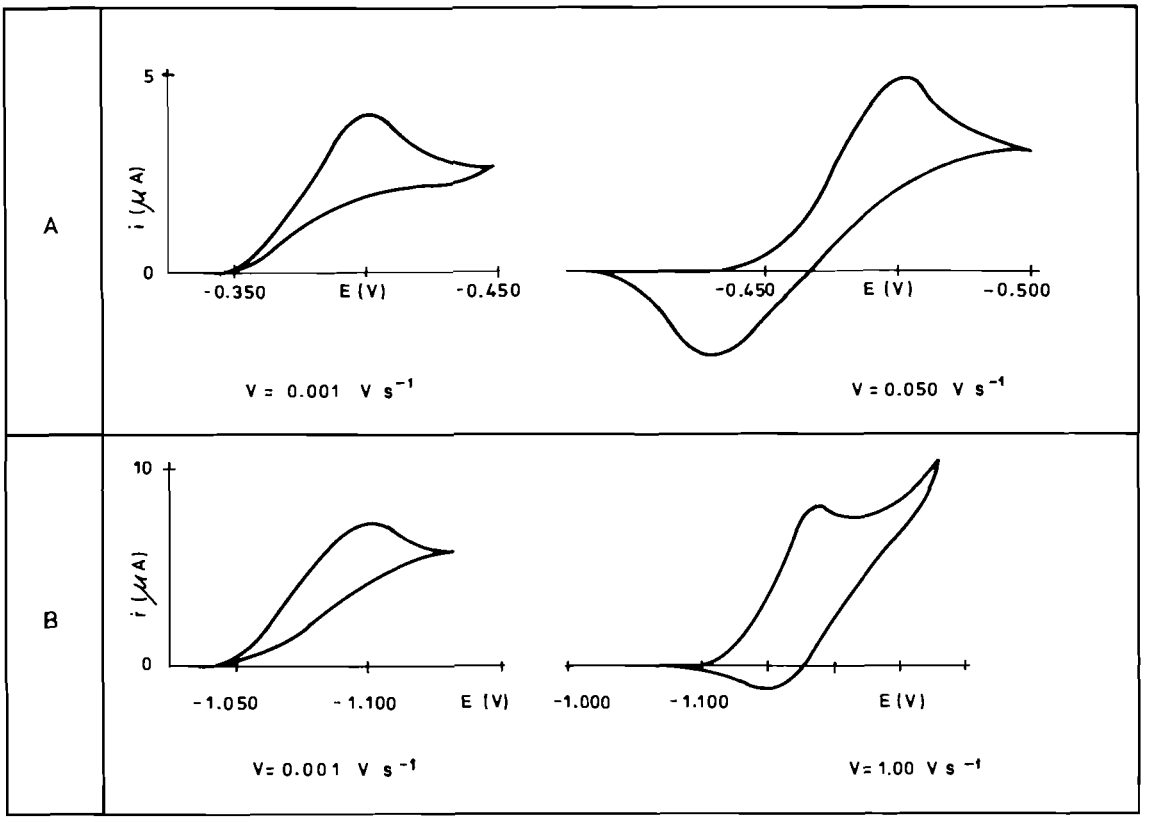

FIG. 3. Cyclic voltammetry curves of 10^{-4} *M* 2-quinizarinsulphonic acid at pH 4.60. *A*, first wave; *B*, second wave.

cal reaction follows at a reversible charge transfer (EC mechanism) (12).

On the other hand, the value $d(E_{1/2})_2/d \log C = -28$ mV agrees with the theoretical value calculated for the dimer discharge (13).

The analysis of peak voltammetry curves of the first wave lead to values $(E_p - E_{p/2}) = 36$ mV and $(E_p - E_{1/2}) = -20$ mV. This is in close agreement with the theoretical values (40.2 mV and −18 mV respectively) deduced by Shuman (14) for a discharge process followed by the hydrodimerization (15) of the reagent.

From the results and conclusions obtained, we propose for the reduction of 2-quinizarinsulphonic acid, a mechanism with the following reaction kinetic pathways:

A simple ^{1}H nmr conformational study of some heterocyclic azomethines

FRANCESCO A. BOTTINO, MARIA L. LONGO, DOMENICO SCIOTTO,[1] AND MICHELE TORRE

Istituto Dipartimentale di Chimica e Chimica Industriale, Università di Catania, Viale Andrea Doria 6, 95125 Catania, Italy

Received August 6, 1980

FRANCESCO A. BOTTINO, MARIA L. LONGO, DOMENICO SCIOTTO, and MICHELE TORRE. Can. J. Chem. **59**, 1205 (1981).

The variable temperature 60 MHz ^{1}H nmr spectra of some heterocyclic azomethines exclude the presence of rotational isomerism. Chemical shift values and stereospecific long-range couplings are used to establish that *s-trans* is the existing conformation. In the case of the pyrrole derivatives a chelated *s-trans* rotamer is indicated, depending on the presence of an intramolecular hydrogen bond.

FRANCESCO A. BOTTINO, MARIA L. LONGO, DOMENICO SCIOTTO, et MICHELE TORRE. Can. J. Chem. **59**, 1205 (1981).

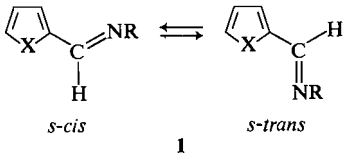
Le spectre rmn du proton à 60 MHz à température variable de quelques azométhines hétérocycliques excluent la présence d'une isomérie rotationnelle. On a utilisé les valeurs des déplacements chimiques et les couplages stéréospécifiques à longue distance pour prouver que la conformation *s-trans* est la seule qui existe. Dans le cas des dérivés du pyrole, on constate qu'un rotamère *s-trans* chélaté se forme en conséquence de l'existence d'une liaison hydrogène intramoléculaire.

[Traduit par le journal]

Introduction

In connection with previous studies on 2-carbonyl substituted heterocyclic systems (1) and some (*E*)-1,2-diarylethylenes (2–4), we carried out a short investigation on the conformational preferences of some heterocyclic azomethines **1**.

These molecules may populate both *s-cis* and *s-trans* rotamers.



s-cis *s-trans*

1

X = N—H, N—CH_3, O; R = CH_3, *n*-C_4H_9

An electrostatic interaction between the heterocyclic heteroatom and the azomethinic nitrogen could affect the energy of the favoured *s-trans* conformation, thus allowing the existence of the *s-cis* rotamer. A similar effect was postulated to account for the conformational preferences of some diaryl ethylene derivatives (2–3) and some heterocyclic 2-carbonyl compounds (5).

Results and Discussion

In order to provide insight on the population ratio of the two planar rotational isomers we have undertaken a ^{1}H nmr variable temperature study of azomethines **1**. The ^{1}H nmr spectra of azomethines **1** show only a small line broadening or sharpening but no substantial changes of the spectral features in the range of −90°C to +100°C. The linewidth changes with the temperature were in all cases of the same order of magnitude of those observed for the TMS signal (less than 7%).

Because of the conjugation between the heterocyclic nucleus and the —C=N—R group, the rotational barrier may reasonably be considered quite similar to the one observed in the 2-carbonyl derivatives (6–8), a higher value consequently than the one required on the nmr time scale for the occurence of a process that averages the signals of the two rotational isomers. Free rotation then is excluded at lowest temperatures and the presence of only one conformational isomer is evidenced.

From ^{1}H nmr data it is possible to establish whether the *s-trans* or the *s-cis* is the existing conformation.

In the case of the molecules **1** (X = NH), ^{1}H nmr spectra ($CDCl_3$) exhibit a strong deshielding of the broad resonance of the N—H proton, which may be better evidenced by comparison with the observed value of the corresponding proton of pyrrole (see Table 1).

No significant differences are observed, in the chemical shifts of both the N—H proton and the heterocyclic protons, between the azomethines **1** (X = NH) and pyrrole-2-carboxaldehyde (see Table 1), which exists almost exclusively in the *s-trans* conformation, as supported by nmr studies (9–11) and dipole moment measurements (12). Whether an intramolecular hydrogen bond in this aldehyde is present is, however, a problem which has been investigated (9–12), but not yet unambiguously settled. In any case the ^{1}H nmr spectrum ($CDCl_3$) exhibits all the spin–spin couplings of the N—H proton with the heterocyclic ones. On the contrary no spin–spin coupling of the N—H proton

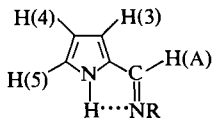
[a]The J values were measured directly from the spectra run at the maximum of the scale width.

of the compounds **1** with the heterocyclic protons is evidenced in $CDCl_3$ solution.

The N—H proton chemical shift values of **1** (X = N—H) are quite insensitive to both temperature and concentration changes. Moreover ir spectra of neat **1** (X = N—H) as well as those of dilute solutions show a broad N—H stretching band in the region 3500–3000 cm^{-1}. On the basis of all these results the presence of an intramolecular hydrogen bond can be suggested in the molecules **1** (X = N—H), and the *s-trans* chelated rotamer must therefore be the populated one.



According to this hypothesis a high value of the stereospecific coupling (W_5-plan) between the a zomethinic proton H(A) and H(5) is observed (see Table 2). No spin–spin coupling occurs between H(A) and H(4), because of the *cis* coplanar disposition (dihedral angle 0°) of the two atoms. In these molecules **1** a *trans* coplanar disposition is required for the stereospecific coupling (J^5_W) to occur, as observed for aromatic (13, 9) and heterocyclic aldehydes (9, 11) and for 1,2-diarylethylenes (3, 4).

In the case of **1** (X = N—CH_3), the same value of the stereospecific spin–spin coupling between H(A) and H(5) is observed, in addition to an identical ^{1}H nmr spectral behaviour (see Tables 1 and 2). We can suggest then that the molecules **1** (X = N—CH_3) also occur exclusively in the *s-trans* conformation.

In the case of molecules **1** (X = O), from the H(A) signal of the ^{1}H nmr spectrum, a lower value of the stereospecific spin–spin coupling ($J^5_{H(A)-H(5)}$) is pointed out (see Table 2). The H(5) signal appears as an unresolved multiplet because of the presence of three small coupling constants, as typically occurs in the furan derivatives (14).

No coupling between H(A) and H(4) is observed, the H(4) signal being a clean quartet (doublet of doublet) that is the X part of an AMX system which arises from the spin–spin interaction with H(3) and H(5). The *s-trans* conformation can then be suggested also for the compounds **1** (X = O).

This behaviour is different from the corresponding 2-carbonyl-furan derivatives, where both rotamers are populated (5, 7, 9, 10, 15–19). The lower electron density on the azomethinic nitrogen of molecules **1** (X = O) with respect to the carbonyl oxygen seems to be inadequate to reduce the stability of the *s-trans* conformation because of

electrostatic repulsion with intracyclic oxygen, thus allowing the existence of the alternative *s-cis* rotamer.

Experimental

The samples of the azomethines **1** were prepared by condensation of the appropriate heterocyclic aldehyde with methylamine or *n*-butylamine following the general procedure described in ref. 20. Melting points or boiling points are reported in Table 3.

The ^{1}H nmr spectra were measured in 15% solution with ca. 1% of tetramethylsilane as internal standard using $CDCl_3$ as solvent. Low temperature ^{1}H nmr spectra were obtained in a mixture of acetone-d_6 and deuterochloroform (2:1). High temperature ^{1}H nmr spectra were obtained in 5% dimethylformamide-d_7 solutions. A Varian A-60 D spectrometer with variable temperature accessories was used.

The ir spectra were recorded on a Perkin-Elmer 237 spectrophotometer. Compound **1** (X = NH, R = n-C_4H_9) was investigated as the pure liquid. For compound **1** (X = NH, R = CH_3) a KBr disk was used. Dilute solution ir spectra were obtained in CCl_4 (concentration range 0.1–5%).

Received August 19, 1980

EL-HUSSIENY M. DIEFALLAH, MOHAMED A. ASHY, and AHMED O. BAGHLAF. Can. J. Chem. **59**, 1208 (1981).

The kinetics of the alkaline solvolysis of dichloroacetate ion in water–methanol solutions have been studied in the temperature range of 50.0 to 65.0°C and the influence of solvent variation on reaction rate has been examined in terms of changes in the activation parameters. The activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for the solvolysis reaction showed a minimum at about 0.8 water mole fraction. The significance of the results was discussed in view of the electrostatic theory and the changing of solvent structure.

EL-HUSSIENY M. DIEFALLAH, MOHAMED A. ASHY et AHMED O. BAGHLAF. Can. J. Chem. **59**, 1208 (1981).

On a étudié la cinétique de la solvolyse alcaline de l'ion dichloroacétate dans des solutions de méthanol–eau dans l'intervalle de température allant de 50,0 à 65,0°C et on a examiné l'effet de la variation du solvant sur la vitesse de réaction en fonction des variations des paramètres d'activation. Les paramètres d'activation $\Delta H^{\ddagger}$ et $\Delta S^{\ddagger}$ de la réaction de solvolyse atteignent un minimum lorsque la fraction molaire de l'eau est d'environ 0,8. On discute de la signification de ce résultat par rapport à la théorie électrostatique et au changement de la structure du solvant.

[Traduit par le journal]

Introduction

Mixed solvents, in which water was frequently one component, provided a graded series of solvolytic media in which to explore the relation between rates, mechanism, and the effect of changing solvent properties (1–4). In alcohol–water binary solvent systems, an extremum in the activation parameters towards the pure water end of the composition scale has been observed (5–13). The extremum behaviour seems to reflect a common solvent behaviour (12–14) and has been related to the accompanying solvent reorganization attending the activation process in binary alcohol–water systems (13). In the present investigation, we report the results of the study of the kinetics of the alkaline solvolysis of dichloroacetate ion in water–methanol solutions. Studies of the alkaline solvolysis of mono- and trichloroacetate ions in binary alcohol–water systems were recently published (5–8). Comparisons between the mono-, di-, and trichloroacetates have shown that there are large differences in order, specific rate constant, and mechanisms of the solvolysis reactions of these ions.

Experimental

The rate of reaction was determined in the temperature range 50.0 to 65.0°C, using a titrimetric method by following the release of chloride ions according to Volhard's technique (6–8). The initial concentrations of dichloroacetic acid were in the range 0.2 to 0.5 mol/L, while the initial concentrations of the base were in the range 0.05 to 0.4 mol/L. In each reaction mixture, the concentration of the base was always less than about twice that of dichloroacetate ion in the reaction solution.

Results and Discussion

Dilute alkaline solutions of sodium dichloroacetate turn acidic on standing due to the hydrolysis of dichloroacetate ion to yield glyoxylate and hydrochloric acid (15). The rate of the reaction follows the second-order rate law:

$$[1] \quad kt = \left(\frac{1}{2A_0 - B_0}\right) \ln \frac{AB_0}{A_0B}$$

where A_0 is the initial concentration of dichloroacetate ion, B_0 is the initial concentration of base, A and B are the concentrations of dichloroacetate ion and hydroxide ion at a time t during the reaction, and k is the specific reaction rate constant. The rate constants were evaluated from the slopes of the straight lines obtained when $\ln (AB_0/A_0B)$ is plotted against t. Figure 1 shows typical plots in water–methanol solutions at 55.0°C. The mechanism of the reaction would thus involve the initial formation of the unstable chlorohydroxyacetate intermediate which, in turn, eliminates hydrochloric acid to yield glyoxylate:

$$[2] \quad CHCl_2 \cdot COO^- + OH^- \xrightarrow{-Cl^-} H{-}\underset{\displaystyle Cl}{\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}}{-}COO^- \qquad \text{(slow)}$$

$$[3] \quad H{-}\underset{\displaystyle Cl}{\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}}{-}COO^- \xrightarrow{-HCl} H{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}COO^- \qquad \text{(fast)}$$

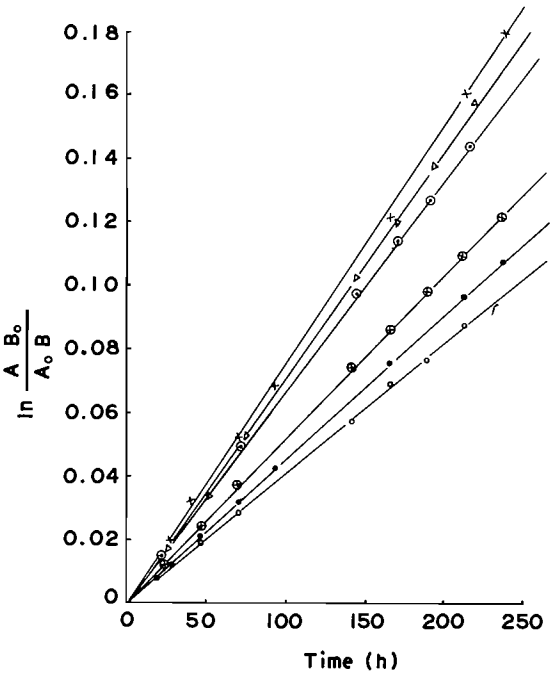

FIG. 1. Second-order plots at 55.0°C in water–methanol solutions. Water mole fraction: ●, 1.00; ⊙, 0.941; ×, 0.806; △, 0.727; ⊗, 0.542; ○, 0.308.

Table 1 lists the values of the rate constants obtained at the specified temperatures and the medium dielectric constant (D) of the various solvent mixtures investigated. The rate constants represent the average of at least three determinations and the reported errors are average errors. In each solvent mixture, D was taken from the experimental data of Akerlöf (16) or calculated from these values by interpolation between different temperatures or between different solvent mixtures. The results show that the rate of reaction first increases as the methanol content of the solution increases up to a maximum at about 0.8 water mole fraction, and then decreases. The behaviour of the solvolysis rates shows similarity to that of monochloroacetate ion in the same medium (6) but is different from those of the decarboxylation reaction of trichloroacetate ion (8). This would be due to the fact that the rate of the alkaline solvolysis in the mono- and dichloroacetates is determined by the attack of the hydroxide ion on the respective ion, whereas the rate of the alkaline decarboxylation of the trichloroacetate ion is independent of the concentration of the hydroxide ion and the rate-determining step is the breaking of the carbon–carbon bond with the concomitant release of CO_2 and the formation of trichloromethyl carbanion intermediate (7, 8). In solvent mixtures with compositions in the range 0 to 30% by weight methanol (1.0 to 0.8 water mole fraction), the results are not in the same order as that predicted by the simple electrostatic theory (17) and indicate that there is no simple correlation between the dielectric constant and the rate constant (18).

The energy of activation of the reaction was calculated from the temperature coefficient of the reaction rates by the least-squares method. The enthalpy and entropy of activations were calculated from the rate constants using absolute rate theory equations (19) and the results (calculated at 50.0°C) are tabulated in Table 2. Entropy of activation values are all negative in all solvent mixtures investigated indicating that in all of these mixtures the activated complex structure is relatively more ordered than the structure of the separated reactants. It is seen that when the concentration of methanol in the solvent mixture is increased, the enthalpy and entropy of activation first decrease to a minimum at about 0.8 water mole fraction, and then increase. The positions of the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ minima appear to coincide, which is characteristic of binary solvent mixtures in which both components are hydroxylic. The depth of the $\Delta H^{\ddagger}$ minimum relative to pure water is about 4 kcal/mol and that for $\Delta S^{\ddagger}$ is 12 cal deg^{-1} mol^{-1}. These values are the same as those observed for the solvolysis of monochloroacetate ion (6) and the trichloroacetate ion (7) in the same media. The calculated values of the free energy of activation, $\Delta G^{\ddagger}$ (listed in Table 2), show that they do not change much with solvent composition. This must be due to the linear compensation between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. The plot of $\Delta H^{\ddagger}$ versus $\Delta S^{\ddagger}$ gave rise to a straight line (Fig. 2), the slope of which, known as the isokinetic or isoequilibrium temperature, equals 320 K. Linear $\Delta H^{\ddagger}$–$\Delta S^{\ddagger}$ relationships were also observed for the solvolysis of monochloroacetate (5, 6) and trichloroacetate ions (7, 8) and for other systems (12, 19). This behaviour is expected if the solvents in a series perform closely similar roles in the reaction (18).

The solvolysis of dichloroacetate ion in water–methanol solutions showed that for solvent mixtures with compositions in the range 1.0 to 0.8 water mole fraction, the principal contribution toward increasing rate is from the decrease in $\Delta H^{\ddagger}$ which outweighs the decrease in rate caused by a decrease in $\Delta S^{\ddagger}$. However, at water mole fractions less than about 0.8, $\Delta S^{\ddagger}$ increases by about 15 cal deg^{-1} mol^{-1} between 0.8 and 0.3 water mole fraction, but its effect on the rate of reaction is far outweighed by the increase in $\Delta H^{\ddagger}$ (which is about

0.308	23.9	23.2	15.0	28.1

5 kcal mol^{-1} in the same composition range), which causes a net decrease in reaction rate for solvent mixtures with less than about 0.8 water mole fraction. Comparison of the results obtained for the solvolysis of mono-, di-, and trichloroacetates indicated that in the same solvent system the activation parameters may show similar variations irrespective of the reaction substrates, order, and mechanism. The results reflect a common solvent behaviour and emphasize the previously stated necessity of taking structural properties of the solvent into consideration.

The behaviour of the activation enthalpy and entropy towards solvent change observed here is similar to that observed for many solvolytic reactions in aqueous–organic solvent mixtures under a variety of conditions (2–6, 10). Arnett *et al.* (14) have shown that the appearance of the minimum in aqueous–organic solvent mixtures is readily explained on the basis of the behaviour of heats of

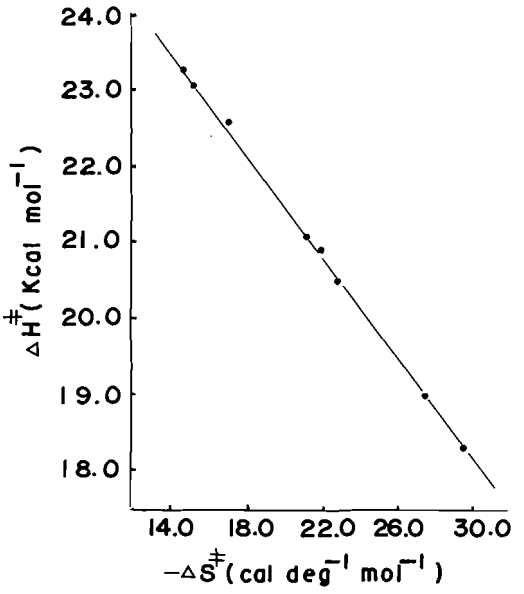

FIG. 2. A plot of $\Delta H^{\ddagger}$ versus $\Delta S^{\ddagger}$ for the alkaline solvolysis of dichloroacetate ion in a series of water–methanol solutions.

solution in aqueous alcohols. It was concluded that both heats of solution and the enthalpy of activation were related to the same kind of changes in solvent structure with changing composition. The results reported here indicate that the activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ pass through a minimum at about the same composition range where other tests showed extreme behaviour, which could be attributed to a change in structural stability with composition (12–14). Hence, the behaviour of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ is interpreted on the basis that the breakdown of solvent structure, as a consequence of charge separation in the activation process, parallels the sensitivity to changes in the solvent composition (13, 14).

Studies of molecular complexes of some π- and *n*-donors with iodine by the constant activity method

RAM ADHAR SING[1] AND SUBRAY N. BHAT[2]

Chemistry Department, North Eastern Hill University, Shillong - 793003, India

Received August 22, 1980

RAM ADHAR SING and SUBRAY N. BHAT. Can. J. Chem. **59**, 1212 (1981).

The iodine complexes of naphthalene, biphenyl, hexamethylbenzene, aniline, and *o*-toluidine in carbon tetrachloride were studied by using the constant activity method. The association constants and the heats of formation of the complexes were determined and the results are compared with those obtained by using conventional spectral methods. The blue-shifted iodine band maxima were determined directly.

RAM ADHAR SING et SUBRAY N. BHAT. Can. J. Chem. **59**, 1212 (1981).

On a étudié les complexes de l'iode avec le naphtalène, le biphényle, l'hexaméthylbenzène, l'aniline et la *o*-toluidine dans le tétrachlorure de carbone, en utilisant la méthode de la constante d'activité. On a déterminé les constantes d'association et les chaleurs de formation des complexes et on a comparé les résultats à ceux obtenus en utilisant les méthodes spectrales conventionnelles. On a déterminé directement les déplacements maxima vers le bleu de la liaison impliquant l'iode.

[Traduit par le journal]

Introduction

Ever since Benesi and Hildebrand (1) reported the interaction of iodine with aromatics, iodine complexes have been most extensively studied (2–6). However, it is not easy to obtain sufficiently accurate spectral measurements (particularly in the case of weak complexes) and to interpret spectral data in terms of parameters characteristic of molecular complexes of iodine. Although one can obtain a reasonably good value of $K_c\varepsilon$ from the spectral studies, the reliable separation of K_c and ε is not an easy task, particularly in the case of weakly interacting systems. So the validity of many of the published spectral and thermodynamic constants, obtained by the spectroscopic method alone has been questioned by many investigators (7–10).

Childs *et al.* (11, 12) have developed a procedure called the "spectral-solubility" or "constant activity" method which can be used to obtain the values of K_c and ε directly. In the present study, the applicability of the constant activity method in the case of iodine complexes of naphthalene, biphenyl, hexamethylbenzene (π-donors) and aniline, *o*-toluidine (*n*-donors) is investigated.

Materials and Methods

Solid tetramethylammonium pentaiodide, $TMAI_5$, was prepared as described by Chattaway and Hoyle (13). All the donors, namely, naphthalene, biphenyl, hexamethylbenzene, aniline, *o*-toluidine, and the acceptor, iodine, were purified by standard procedures (14–16). Spectral grade (BDH) carbon tetrachloride was used as such.

[1]Present address: Chemistry Department, Banaras Hindu University, Varanasi, India.

[2]To whom all correspondence should be addressed.

The procedure used to obtain the value of K_c is that developed by Childs *et al.* (11, 12). It is based on using a mixture of tetramethylammonium polyiodides to maintain a constant activity of iodine, e.g.,

[1] $(CH_3)_4NI_5(s) \rightleftarrows (CH_3)_4NI_3(s) + I_2$

Addition of a donor to this system establishes a second equilibrium (and eq. [1] is displaced to the right, to replace the iodine complexed by the donor),

[2] $D + I_2 \rightleftarrows DI_2$

and the concentration of iodine in the second equilibrium is determined directly from the increase in absorbance at the isosbestic point of iodine in the visible region. Since the extinction coefficients of the complexed and of the free (uncomplexed) iodine are equal at this wavelength (i.e. at the isosbestic point), the concentration of the complex (assuming it to be 1:1) can be calculated directly.

The equilibrium constant, K_c, for the interaction of a donor, D, with an acceptor, I_2, to form a 1:1 complex is,

[3] $K_c = C_{DI_2}/C_D C_{I_2}^t$

or

[4] $K_c = C_{DI_2}/(C_D^0 - C_{DI_2})C_{I_2}^t$

where C_{DI_2} is the equilibrium concentration of the complex (DI_2), $C_{I_2}^t$ is the equilibrium concentration of free iodine at temperature t(°C), C_D^0 is the initial donor concentration, and $(C_D^0 - C_{DI_2}) = C_D$ is the equilibrium concentration of donor. For a cell of unit path length, the increase in absorbance (assuming that the system obeys Beer's law) at the isosbestic point, ΔA_{isos}, is related to the complex concentration, C_{DI_2} as,

[5] $\Delta A_{isos} = \varepsilon_{isos} C_{DI_2}$

where ε_{isos} is the molar extinction coefficient of iodine at the isosbestic point. From eqs. [4] and [5] we get,

[6] $K_c = \Delta A_{isos}/(\varepsilon_{isos} C_D^0 - \Delta A_{isos})C_{I_2}^t$

Thus the equilibrium constant, K_c, can be calculated by knowing ΔA_{isos}, C_D^0, and $C_{I_2}^t$. In this method, a prior knowledge of the molar extinction coefficient of the complex is not needed.

The molar extinction coefficient of the charge-transfer band,

ε_{CT}, or of the blue-shifted iodine band, ε_{BS}, can also be evaluated directly without a prior knowledge of K_c, if simultaneous measurements of absorbance are made at the isosbestic point, the charge-transfer band, or the blue-shifted iodine band for the same solution. It can be easily seen that

[7] $\Delta A_{CT}/\Delta A_{isos} = \varepsilon_{CT}/\varepsilon_{isos}$

and

$$\Delta A_{BS}/\Delta A_{isos} = \varepsilon_{BS}/\varepsilon_{isos}$$

For obtaining the isosbestic point as well as ε_{iso}, the spectra of pure iodine and complexed iodine in carbon tetrachloride were recorded by keeping the iodine concentration constant (~0.8 mM) and varying the donor concentrations (0.005–0.9 M). Pure $TMAI_5$ was equilibrated with carbon tetrachloride (~3 days) at constant temperature (in a thermostat) and the spectrum of iodine in the equilibrated solution was recorded. Then a series of several solutions of donors in carbon tetrachloride were similarly equilibrated with $TMAI_5$ (~150 mg) and spectra were recorded for all those solutions at constant temperature.

The spectra at 25, 30, 35, and 40°C were recorded in the uv and visible regions using a Cary-14 recording spectrophotometer fitted with thermostat jackets for temperature control of the cell. The temperature of the solutions could be controlled to within ±0.1°C.

For locating the blue-shifted iodine band of the donor–iodine complex, the spectrum of the complex was recorded with the donor and the constant activity source of iodine in the sample cell and only the constant activity source of iodine in the reference cell (17).

Results and Discussion

Heat of Dissociation of $TMAI_5$ in CCl_4

The dissociation constant, K_d for the dissociation of $TMAI_5$ into $TMAI_3$ and I_2 is given by

$$K_d = [TMAI_3][I_2]/[TMAI_5]$$

or

$$K_d = [I_2]$$

The heat of dissociation of $TMAI_5$ is obtained from Van't Hoff's plot of the absorbance of iodine at 517 nm from the $TMAI_5/TMAI_3$ equilibrium in carbon tetrachloride, and the value is 8.10 kcal/mol. This value compares well with the most recent value of Tse and Tamres (8.18 kcal/mol) (18).

Naphthalene–Iodine System

Figure 1 shows the isosbestic point of the naphthalene–iodine complex (at 497 nm). The molar extinction coefficient of iodine in carbon tetrachloride at 497 nm is 819 M^{-1} cm^{-1} (Table 1). The isosbestic point does not vary with the concentration of donor (in the experimental range of 0.11 to 0.4 M). It can be seen from Fig. 2 that as the concentration of naphthalene increases the absorbance at the isosbestic wavelength increases. It has been pointed out earlier that measurement of the increase in absorbance at the isosbestic point gives the concentration of the complex. The equilibrium

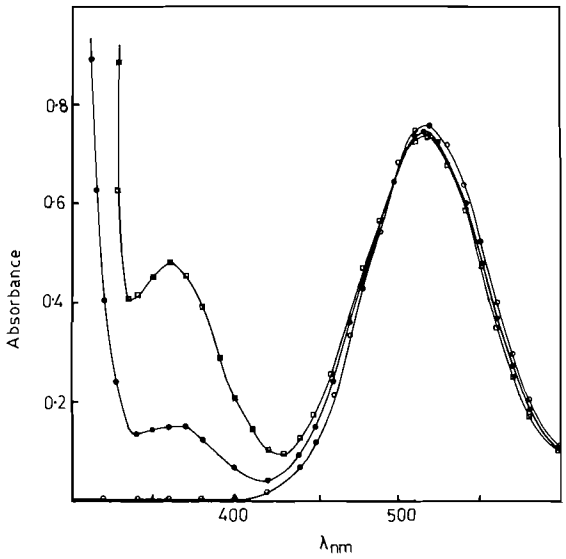

FIG. 1. Isosbestic point of the naphthalene–iodine complex in CCl_4 at 25°C; cell path = 1.00 cm; $[I_2]_0 = 8.0 \times 10^{-4}$ M; $[D]_0$ = 0.0–0.4 M.

constants, K_c^s (calculated by using eq. [6]) at only two temperatures and two concentrations have been listed in Table 2 for the sake of brevity. The average K_c^s and ε_{CT} at 25°C are 0.54 M^{-1} and 4850 M^{-1} cm^{-1} respectively. The value of K_c^s is slightly higher than the literature data (0.25 M^{-1}) (19); similar higher values of K_c^s have been reported by Childs *et al.* for aromatic–iodine systems (12). It has been pointed out by Christian *et al.* (11, 12) that K_c^s actually includes both the specific interaction (complex formation) and non-specific interactions between donor and iodine. If the correction term due to non-specific interactions is near zero, then the K_c^{th} value may be equal to the K_c^s value (18, 20). The enthalpy $-\Delta H^0$, (1.91 kcal/mol) calculated from a study of the temperature dependence of the absorbance of the complex using a single solution of donor with excess of $TMAI_5$ and also by the usual procedure (i.e. by knowing

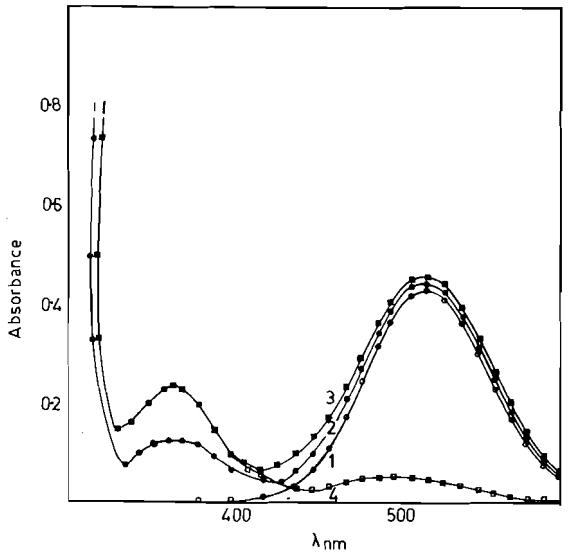

FIG. 2. Visible spectra of the naphthalene–iodine complex in CCl_4 by the constant activity method at 25°C, cell path = 1.00 cm; *1*, $[I_2]_0 = 4.53 \times 10^{-4}$, ○; *2*, $[D]_0 = 0.0994$ M, ●; *3*, $[D]_0 = 0.1989$ M, ■; *4*, Differential spectrum of *3* vs. *1*, □.

the values of K_c at different temperatures) agrees well with the literature value (1.80 kcal/mol) (21).

The concentrations of donor (range 0.05–0.2 M) used are such that we can assume that the solutions are reasonably dilute and in the low concentration region, ΔA_{CT} (the change in A_{CT} corrected for free iodine and donor) varies linearly with ΔA_{isos} and the limiting slope of the plot of ΔA_{CT} vs. ΔA_{isos} is equal to the ratio of $\varepsilon_{CT}/\varepsilon_{isos}$ (Fig. 3). The value of ε_{isos} thus calculated is 4850 M^{-1} cm^{-1} which is lower than that reported in the literature (7250 M^{-1} cm^{-1}) by the conventional spectral methods. Here it is worth mentioning that the association constant obtained by this method is higher and ε is lower but the $K\varepsilon$ product is nearly the same as that of the literature data.

The visible spectrum of the naphthalene–iodine system obtained by the constant activity method (using a differential procedure) is shown in Fig. 2. The blue shifted iodine band has a maximum at 498 ± 2 nm. An examination of the spectra at different concentrations of donor indicates that the blue-shifted iodine band position does not vary with the concentration of the donor. The molar extinction coefficient of the blue-shifted iodine band maximum, ε_{BS}, is calculated from the ratio of the change in absorbance of the blue shifted band, ΔA_{BS}, to the change in absorbance at the isosbestic point ΔA_{isos}. The molar extinction coefficient, ε_{BS}, thus obtained is 915 ± 20 M^{-1} cm^{-1}.

Biphenyl–Iodine System

The isosbestic point of the biphenyl–iodine complex is 504 nm and the molar extinction coefficient of iodine in carbon tetrachloride at 504 nm is 875 M^{-1} cm^{-1} (Table 1). The isosbestic point does not vary with the concentration (concentration range 0.1–0.9 M) of the donor. As the concentration of biphenyl in $TMAI_5$–biphenyl increases, the absorbance at the isosbestic point increases. The relevant data and the equilibrium constants for the iodine–biphenyl system are given in Table 3. The average equilibrium constant at 25°C is 0.51 M^{-1} which is slightly higher than the literature value of 0.39 M^{-1} (22) which may be due to the inclusion of

non-specific interactions in the K_c^s. The enthalpy, $-\Delta H^0$, for biphenyl–iodine is 3.45 kcal/mol.

The molar extinction coefficient of the biphenyl–iodine complex at the charge-transfer band (335 nm) calculated from the limiting slope of the plot of ΔA_{CT} vs. ΔA_{isos} is 2600 M^{-1} cm^{-1}, which is very much lower than the literature value (4000 M^{-1} cm^{-1}) (23). However, as in the case of naphthalene–iodine, the $K_c\varepsilon$ value calculated from the constant activity method is comparable to that obtained by the spectral method. It is noteworthy that Lane *et al.* (24) have rightly pointed out that, in the case of weak molecular complexes, values of ε determined using different concentration scales can differ widely.

The blue-shifted iodine band maximum (which is independent of the concentration of the donor) for the biphenyl–iodine system is at 480 ± 5 nm.

The iodine absorption band at 517 nm in CCl_4 is due to electron excitation from the antibonding π_g* molecular orbital to the antibonding σ_u* molecular orbital. Mulliken and Person (3) had pointed out that the strongly antibonding σ_u* molecular orbital must be larger in size than the outer occupied molecular orbitals in the ground state of the iodine molecule. On excitation of the iodine molecule in a complex, its swollen size introduces an exchange repulsion between it and the partner molecule. This repulsion energy, and thus the blue-shift in absorption frequency, should be greater the stronger the complex. In the present case, the shift in the visible iodine band is much more in biphenyl–iodine system compared to that in the naphthalene–iodine system and the enthalpy of the former is also higher. These results indicate that biphenyl–iodine is definitely a stronger complex than naphthalene–iodine. This observation parallels the electron-donating properties (or ionization potentials) of the donors.

Hexamethylbenzene–Iodine System

The hexamethylbenzene–iodine complex has an isosbestic point at 519 nm in CCl_4 and the molar extinction coefficient of the iodine (ε_{isos}) is 950 M^{-1} cm^{-1}. As the concentration of hexamethylbenzene (in the hexamethylbenzene–$TMAI_5$ system) in-

*Error limit in K_c^s is ± 0.5.
†Value in parentheses refer to literature data (26).

creases, the absorbance at the isosbestic point also increases. The equilibrium constant for the hexamethylbenzene–iodine system in CCl_4 is 2.09 M^{-1} at 25°C (lit. 1.35 M^{-1}; Table 4). However, the enthalpy is 4.33 kcal/mol which is comparable to the literature value of 3.75 kcal/mol (25).

The molar extinction coefficient of hexamethylbenzene–iodine at the charge-transfer band (375 nm) is 8200 M^{-1} cm^{-1}. This value is in very good agreement with the literature value of 8200 M^{-1} cm^{-1} (25). However, the $K_c\varepsilon$ value is higher than the literature data. In the absence of detailed information in the literature, it is not possible to comment on this.

The blue-shifted iodine band appears at 480 ± 5 nm and ε_{BS} is 1375 M^{-1} cm^{-1}. Judging from the position of the blue-shifted iodine band, it appears that hexamethylbenzene–iodine is a stronger complex than naphthalene–iodine but that its strength is comparable to that of biphenyl–iodine.

Aniline–Iodine System

The isosbestic point of the aniline–iodine system in carbon tetrachloride is located at 498 nm and ε_{isos} is 837 M^{-1} cm^{-1}. The isosbestic point neither changed with donor concentration (0.005–0.05 M) nor with time. As the concentration of aniline (in aniline–$TMAI_5$) is increased, the absorbance at the isosbestic point increases. We did not notice any change in absorbance during the experiment. This indicates that the complex is reasonably stable in CCl_4 during that time interval. The equilibrium constants K_c^s at 26.5°C is 20.5 M^{-1}, which is higher than the literature value of 12 M^{-1} (26) (Table 5). Here it may be recalled that in the literature it has been mentioned that the complex is not stable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

(which may be due to some chemical reactions at high concentration of aniline). Due to this, the equilibrium constant reported may be lower compared to the present data (where the concentration of donor is low). The other possibility is that the contribution due to the non-specific interactions may be quite high, resulting in K_c^s being higher than K_c^{th}. The blue-shifted iodine band maximum is 500 ± 10 nm and the molar extinction coefficient is $\sim 830\, M^{-1}\, cm^{-1}$.

o-*Toluidine–Iodine System*

The isosbestic point of the *o*-toluidine–iodine system in carbon tetrachloride is 493 nm and ε_{isos} is $766\, M^{-1}\, cm^{-1}$. The equilibrium constant calculated by the constant activity method is $25.0\, M^{-1}$ at 26.5°C (lit. $11\, M^{-1}$) (26). This value is slightly higher than that of aniline–iodine which indicates that *o*-toluidine is a stronger complex. Here it is interesting to note that the equilibrium constant in the present case as well as in the aniline–iodine system is very much higher even though the enthalpies are nearly equal. The blue-shifted iodine band appears at 500 ± 10 nm and ε_{BS} is $\sim 770\, M^{-1}\, cm^{-1}$.

The constant activity method (sometimes known as the polyiodide-solubility method or simply solubility method) is a convenient alternative procedure for determining K_c and ε_{CT}, especially for weak molecular complexes of iodine. Secondly the blue-shifted iodine band maximum can be obtained directly. In addition to this, the heat of complexation can be determined by studying the temperature dependence of the absorbance of the complex using only a single solution of donor with excess of polyiodide.

Consideration on rotational isomerism in connection with its influence on some electrical properties of an interface

EDWARD DUTKIEWICZ AND STANISŁAW LAMPERSKI

Department of Electrochemistry, Institute of Chemistry, A. Mickiewicz University, ul. Grunwaldzka 6, 60-780 Poznań, Poland

Received February 25, 1980

EDWARD DUTKIEWICZ and STANISŁAW LAMPERSKI. Can. J. Chem. **59**, 1218 (1981).

The rotational isomerism contribution to some electric properties of an interface region has been considered. The mean electric dipole $\langle\mu\rangle$, the mean equilibrium constant $\langle K\rangle$ expressing the ratio of *gauche* and *trans* conformers, surface charge density σ, electric permittivity ε, differential capacity C were calculated as a function of electric field for 1,2-dichloroethane, 1-chloro-2-bromoethane, and 1,2-dibromoethane.

The results obtained suggest that in the case of adsorbed molecules exhibiting rotational isomerism, their structure and behaviour in the electrical double layer field have to be taken into account.

EDWARD DUTKIEWICZ et STANISŁAW LAMPERSKI. Can. J. Chem. **59**, 1218 (1981).

On a considéré la contribution de l'isomérie rotationnelle à quelques propriétés électriques d'une région de l'interface. On a calculé, en fonction du champ électrique, le dipôle électrique moyen $\langle\mu\rangle$ exprimant le rapport des conformères gauche et *trans*, la densité de la charge de surface σ, la permittivité électrique ε et la capacité différentielle C des dichloro-1,2, chloro-1 bromo-2 et dibromo-1,2 éthanes.

Les résultats obtenus suggèrent que dans le cas des molécules adsorbées qui montrent une isomérie rotationnelle, on doit tenir compte de leur structure et de leur comportement dans le champ électrique de l'interface.

[Traduit par le journal]

Introduction

Molecules exhibiting rotational isomerism have repeatedly been studied with interest, both experimentally and theoretically. This is, in particular, the case of the 1,2-dihalogenoderivatives of ethane, the molecule of which occurs in three stable forms, two *gauche* and one *trans*. The population ratio of *gauche* and *trans* states is referred to as the equilibrium constant of the forms and is directly dependent on the energies of the latter. This energy can be affected by many factors which, thus, modify the equilibrium constant perceptibly. Obviously, in the first place, the latter is dependent on temperature which, if raised, enhances the number of molecules in the *gauche* state (1). Also, a change in polarity of the solvent affects the equilibrium constant (2); for 1,2-dichloroethane in carbon tetrachloride it amounts to 0.9, whereas in chloroform it equals 1.0 and takes the value 1.4 for the pure liquid (3). In strongly polar solvents like acetonitryl, nitrobenzene, and nitrotoluene, it increases with increasing dilution (4, 5). An external electric field raises the equilibrium constant, as proved by the positive value of the nonlinear dielectric effect. The latter effect is characteristic for many molecular species showing rotational isomerism (5, 6). This field dependence of the electric permittivity has been considered theoretically (7, 8) with quite good results. Rotational isomerism of adsorbed molecules has been also the object of studies. Thus, for example, 1,2-dichloroethane, adsorbed on cationized zeolyte, exhibits an equilibrium constant fivefold that of the pure liquid (9). When adsorbed on a methoxylated surface, the constant decreases to 0.5 but increases even up to 2.4 on a hydroxylated surface (9). The effect can be attributed to the strong field, of the order of 10^8–10^9 V m^{-1}, existing at the phase boundary.

The above-mentioned electric field (6) and "adsorption" field effects stimulated studies of the influence of rotational isomerism in the metal/electrolyte solution interphase region (10, 11) where a strong electric field, the strength of which can be varied by applying externally a potential polarizing the electrode, exists.

On the other hand, the molecular models proposed till now in the literature (12) take into account orientational and non-orientational contributions to the electric permittivity of the surface layer of solvent. The latter contributions may be considered in terms of electric polarisation, dipole–dipole interactions, formation of associates, breaking of bonds in associates, bond formation with the metal or with the bulk, partial charge transfer, chemisorption, electrostriction, and temperature.

As can be seen, the rotational isomerism contribution connected with the increase in the number of polar molecules due to the electric field in the double layer region was not considered. Therefore, in our paper an attempt is made to estimate the role of this effect on the electric permittivity of the surface layer of solvent only. Thus the other contributions mentioned above will not be considered here.

Theory

Model of the Rotational Isomer

In this paper we present a different approach to the rotational isomers of 1,2-dihalogenoderivatives of ethane than that in the method of infrared spectroscopy. The ir region vibrational modes of these molecules have a considerably greater frequency than the frequency associated with transitions among the stable isomers. In this situation the molecule analysed by means of infrared spectroscopy occurs always in one of the possible isomeric forms. Therefore, according to this method, information can be obtained about each stable form of the isomer.

The situation is otherwise in the case of dielectric methods. Here we obtain a certain "mean picture" of the molecule represented by the mean dipole moment. It is, as is well known, a fundamental quantity in the field of dielectric investigations. Therefore, it is advisable to assume a model of the rotational isomer, from which can be determined easily the mean dipole moment of the molecule. Let us assume that the molecule is at first in the state *gauche* "1" (Fig. 1) with the dipole moment μ_g. It can be assumed next that in the case of a transition to the state *trans* both halogenmethylene groups make the rotation by the same angle but in a reverse direction. The dipole moment in this state, when the halogen substituents are identical, is equal to zero. Further rotary motion of the halogenmethylene groups causes the transition of the molecule to the state *gauche* "2" in which the molecule has the dipole moment μ_g in the reverse direction.

It is obvious that the mean dipole moment calculated on the basis of the above model, for instance for 1,2-dichloroethane, amounts to zero. But the same compound will have a mean dipole moment different from zero if it is placed in an electric field F (except in the case that $F \perp \mu_g$), because, due to the interaction of the dipole moments of the *gauche* form with the electric field, one of these forms will be energetically more stable than the other.

The Electric Dipole Moment of a Molecule with Rotational Isomers

The electric moment under consideration is a function of the dihedral angle α (1), defined by the following atoms: halogen substituent – carbon – carbon – halogen substituent, as given by eq. [1]:

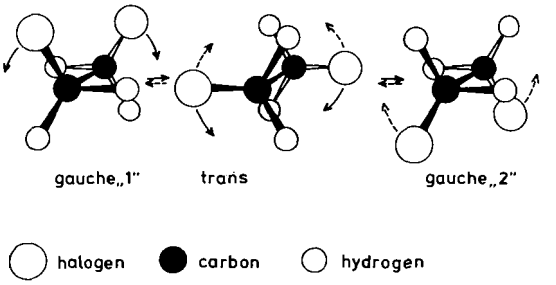

FIG. 1. Model of intramolecular rotation of 1,2-dihalogenoderivatives of ethane.

$$[1] \quad \mu(\alpha) = \pm[(\mu_1 - \mu_2)^2 + 4\mu_1\mu_2 \cos^2(\alpha/2) \sin^2\beta]^{1/2}$$

For ideal sp^3 hybridization of carbon orbitals, $\beta = 70°31'44''$. In the above equation, μ_1 and μ_2 are the dipole moments of the carbon–halogen bonds. Obviously, if the substituents are identical, $\mu_1 = \mu_2$, and we have (10):

$$[2] \quad \mu(\alpha) = 2\mu \cos(\alpha/2) \sin\beta$$

At $\alpha > \pi$, a change in sign of the dipole moment takes place. Once the function $\mu(\alpha)$ and the dependence of the potential energy on the dihedral angle $U(\alpha)$ are available, one can determine the mean dipole moment of the molecule from the Boltzmann distribution. A "6-exp" type potential can be used to describe $U(\alpha)$, applying the parametrisation proposed by Scott and Scheraga (13).

When describing the behaviour of a molecule with rotational isomers in an electric field one has still to consider the interaction energy of its dipole moment and the field F:

$$[3] \quad U(F,\Theta) = -\mu F \cos\Theta$$

F is the cavity field strength and Θ, the angle between the vectors of the dipole moment and electric field; the mean dipole moment of the isomeric molecule, called the dipole moment of the isomer, is:

$$[4] \quad \bar{\mu}(F,\Theta) = \frac{\int_0^{2\pi} \mu(\alpha) \exp\{[-U(\alpha) + \mu(\alpha)F\cos\Theta]/kT\}\, d\alpha}{\int_0^{2\pi} \exp\{[-U(\alpha) + \mu(\alpha)F\cos\Theta]/kT\}\, d\alpha}$$

$U(\alpha)$ is the potential energy per molecule.

The mean value $\langle\mu\rangle$ of the molecular dipole moment in the direction of the field allows the calculation

of the electric permittivity of an interfacial region in a strong field. Boltzmann's distribution for the mean value of the dipole moment of a rotational isomeric molecule gives:

$$[5] \quad \langle \mu(F) \rangle_{\text{rot isom}} = \frac{\int_0^\pi \bar{\mu}(F,\Theta) \exp\left[\bar{\mu}(F,\Theta) F \cos\Theta / kT\right] \cos\Theta \sin\Theta \, d\Theta}{\int_0^\pi \exp\left[\bar{\mu}(F,\Theta) F \cos\Theta / kT\right] \sin\Theta \, d\Theta}$$

Applying the definition of dipole polarizability we similarly define the dipole polarizability of the rotational isomer:

$$[6] \quad \alpha(F)_{\text{rot isom}} = \frac{\langle \mu(F) \rangle_{\text{rot isom}}}{F}$$

Influence of the Electric Field on the Equilibrium Constant

As initially stated, the field lowers the population of the *trans* state and favours the *gauche* state, thus causing an increase of the equilibrium constant K. The influence of the field is thus described by the following equation:

$$[7] \quad K(F,\Theta) = e^{-\Delta U/kT} \cos h(\mu_g F \cos\Theta / kT)$$

where μ_g is the moment of the *gauche* form and ΔU the difference in energy between the *gauche* and *trans* states.

At constant Θ, the value of K increases with increasing field strength, the sharpest change occurring if $\Theta = 0$ or π. If $\Theta = \pi/2$, K is field-independent. In the field, the molecules can assume any orientation, albeit with unequal probability. As shown above, for a given field strength K is still dependent on Θ, so that it appears useful to introduce a mean value of K defined as:

$$[8] \quad \langle K(F) \rangle = \frac{\int_0^\pi K(F,\Theta) \exp\left[\bar{\mu}(F,\Theta) F \cos\Theta / kT\right] \sin\Theta \, d\Theta}{\int_0^\pi \exp\left[\bar{\mu}(F,\Theta) F \cos\Theta / kT\right] \sin\Theta \, d\Theta}$$

Electric Permittivity

We determined the electric permittivity applying the Onsager model (14), assumed to be valid for very strong fields also. We employed for this purpose the following equation:

$$[9] \quad \varepsilon(F) = \frac{3\varepsilon(F)}{2\varepsilon(F) + 1} \frac{N g \alpha_{\text{rot isom}}(F,g)}{\varepsilon_0} + n^2$$

where g comes from Onsager's reaction field

$$[10] \quad g = \frac{[2\varepsilon(F) + 1](n^2 + 2)}{3[2\varepsilon(F) + n^2]}$$

N is the number of molecules per unit of volume, n the refractive index, and ε_0 the electric permittivity of vacuum. With the obtained permittivity and assumed distance between the condenser plates one can calculate classically the capacity per unit area of the condenser, the potential difference between its plates, and the surface charge density. We hence derive the differential capacity, defined as follows:

$$[11] \quad C_{\text{diff}} = d\sigma/dE$$

with σ being the electric charge density, and E the potential difference.

Results of Calculations

Since eqs. [4], [5], and [8] cannot be solved algebraically for strong fields, we had recourse to a numerical technique, calculating the integrals by steps of $\pi/90$ and assuming the dipole moment of C—Cl bonds to be 4.86×10^{-30} C m, C—Br, 4.6×10^{-30} C m, and H—C, 1.33×10^{-30} C m (15).

The calculated dependence of the dipole moment of the isomer (for $\Theta = 0$) as well as the mean projection in the field direction versus the field strength for 1,2-dichloroethane, 1-chloro-2-bromoethane, and 1,2-dibromoethane are presented in Fig. 2 and Fig. 3, respectively. The mean value of the equilibrium constants versus the electric field are plotted in Fig. 4. The course of the variability of the permittivity for the molecules considered as a function of the field strength is displayed in Fig. 5.

The calculated differential capacities as a function of the electrode potential (for a distance of 10 Å

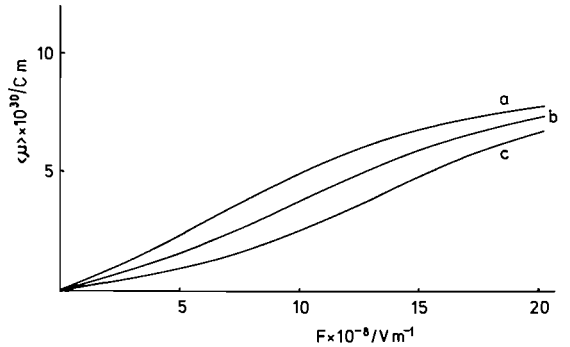

FIG. 3. Computed mean projection of dipole moment in the field direction $\langle\mu\rangle$ vs. electric field F curves obtained from eq. [5] for the following rotational isomers: *a*, 1,2-dichloroethane; *b*, 1-chloro-2-bromoethane; *c*, 1,2-dibromoethane.

between the plates of the condenser) for 1,2-dichloro-1-chloro-2-bromo-, and 1,2-dibromoethane is shown in Fig. 6. The character of these curves is due to the dependence of the electric permittivity on the electric field. Differences which occur among the curves for the investigated compounds are the result of the intramolecular hindered rotation. The hindered rotation depends on the steric effect of substituents (16).

In Table 1 there are presented some calculated values characterizing the properties of 1,2-dihalogenoderivatives of ethane in the liquid phase and they are compared with experimental data.

Discussion

In this paper the influence of a strong electric field on the behaviour of rotational isomers has been considered. Molecules can occur in a very strong electric field, when they are adsorbed, for instance, at the electrode/electrolyte solution interface. In the case of the electrode/electrolyte solution interface,

there exists furthermore the possibility of an increase in the intensity of the electric field at the interface with the external voltage applied to the electrode, as it has been mentioned in the Introduction.

It has been stated in the theoretical part that the change of the mean dipole moment of the rotational

isomer $\langle\mu\rangle$ due to the electric field F is rather complex and differs from the Langevin function (Fig. 3). The mean dipole moment versus electric field is described initially by a linear function. It follows that the polarizability of the rotational isomer is approximately constant and, therefore, that the permittivity is not subjected to great changes (Fig. 5). The value of the field intensity for such a behaviour of the molecules to be observed must be small enough. The energy corresponding to the molecule being in the *gauche* state in the electric field cannot exceed the difference in energy between the *gauche* and *trans* states. We can therefore state that the approximately linear dependence of the mean dipole moment of the rotational isomer on field is valid for field intensities smaller than 1.4×10^8 V m^{-1} for 1,2-dichloroethane, 4.5×10^8 V m^{-1}, for 1-chloro-2-bromoethane, and 8.9×10^8 V m^{-1} for 1,2-dibromoethane. It must also be stated that the mean value of the equilibrium constant $\langle K\rangle$ practically does not change (Fig. 4) in this range of electric fields. The above discussed electric fields exert a small influence on the orientation of molecules and on the transition from the *trans* to *gauche* form.

A further increase of the field intensity causes a rapid increase of the equilibrium constant $\langle K\rangle$ as well as the dipole moment $\langle\mu\rangle$. This results in an increase of the electric permittivity. This increase is due to the transition of molecules from *trans* to *gauche*.

The higher electric field intensity causes a very great increase of the equilibrium constant $\langle K\rangle$, but exerts a small influence on the value of dipole moment $\langle\mu\rangle$. The greater number of molecules is already now in the *gauche* form and the vectors of

For personal use only.

their dipole moments are oriented parallel to the line of the electric field. As a result, the electric permittivity decreases.

The dielectric permittivity ε has been calculated on the basis of Onsager's model. From Fig. 5 one can see that the dependence of the electric permittivity of 1,2-dihalogenethane on electric field shows a maximum in a given field region before dielectric saturation is reached. A similar dependence occurs for the capacity as a function of electric potential difference (Fig. 6). These results are the main achievements of this work.

Now, the question arises whether rotational isomerism contributes to the electric permittivity of a metal/electrolyte solution interface. As was pointed out in the Introduction there is some experimental evidence for an increase in polarity of adsorbed solvent rotamers. Hence, an increase of the electric permittivity of an interface region is to be expected. Recently, Ikeda *et al.* (24) explained the change in the capacity of the inner layer in the presence of 2-methylthioethanol by means of rotation of the hydroxyl group. Adding to these facts the results presented in this paper, we suppose that a change in the electric permittivity of the metal/electrolyte solution interface in the presence of adsorbed rotamers could be partially a result of the role of rotational isomerism. Hence the differential capacity as a function of electrode potential (or surface charge) will be a more complex function as a result of various molecular and intramolecular interactions in the interface region.

The fact that molecules in adsorbed states may form a solid-like surface does not exclude the possibility of the rotation of one group within the molecule. Investigations of the dielectric properties of organic compounds have shown that, in some solid crystals, the rotation of certain groups in the molecules can also occur (25). Therefore, we assume that, in adsorbed layers, intramolecular rotation under the influence of the electric field can also take place.

Finally we would like to stress that in describing a molecular model for adsorbed solvent which consists of rotamers one has to take into account, besides the orientational and non-orientational contributions, also an intramolecular rotation contribution to the dielectric properties of the interface region.

La nitration par le peroxyde d'azote des styrylcétones conduit avec de bons rendements aux cétones α-nitroéthyléniques correspondantes. Toutefois, lorsque des groupes méthoxyles sont présents sur le noyau, la nitration s'effectue sur celui-ci.

La réduction par $LiAlH_4$ des α-nitrostyrylcétones fournit les aminoalcools *érythro* et *thréo* racémiques correspondants. Après acylation puis cyclisation, on obtient une dihydroisoquinoléine ou une oxazoline-2.

La réduction électrochimique de ces nitrostyrylcétones engendre sélectivement les α-cétoximes, elles-mêmes électroréductibles en α-aminocétones. Ces dernières conduisent en milieu neutre, par condensation de deux molécules, aux dihydro-2,5 pyrazines qui s'aromatisent en pyrazines correspondantes. En milieu acide on isole un α-cétol.

Un mécanisme de réduction faisant intervenir un intermédiaire énaminol est proposé.

BERNARD MARÇOT, ALAIN RABARON, CLAUDE VIEL, CHRISTIAN BELLEC, STÉPHANE DESWARTE, and PIERRE MAITTE. Can. J. Chem. **59**, 1224 (1981).

Nitration of styryl ketones with nitrogen peroxide leads to the corresponding α-nitroethylenic ketones in good yield. However, the presence of methoxy groups involves a nitration on the aromatic nucleus.

$LiAlH_4$ reduction of α-nitrostyrylketones yields the corresponding racemic *erythro*- and *threo*-aminoalcohols; after acylation and cyclisation a dihydro-quinoline or a 2-oxazoline is obtained.

Electrochemical reduction of these nitrostyryl-ketones selectively provides the α-ketoximes, which are themselves reduced electrolytically to α-aminoketones. These latter compounds dimerise in neutral medium to dihydro-2,5-pyrazines which aromatise to the corresponding pyrazines. In acid medium an α-ketol is obtained.

A mechanism for the reduction is proposed implicating an enaminol intermediate.

[Journal translation]

Introduction

Les dérivés styréniques substitués sur le carbone β par un groupement électroattracteur sont nitrés sélectivement par le peroxyde d'azote en β-nitrostyrènes β-substitués (1–3). Ainsi s'obtiennent les α-nitrobenzylidèneacétones et les α-nitrochalcones. Nous avons pensé que la réduction de ces composés par l'hydrure de lithium et d'aluminium fournirait aisément les aminoalcools correspondants susceptibles de subir une cyclodéshydratation soit en isoquinoléines substituées en position-3, soit en oxazolines-2.

Il est particulièrement difficile de transformer en isoquinoléines les β-phényl éthylamides si le noyau aromatique est dépourvu de substituant donneur en *para* du site de cyclisation; il était donc important d'envisager la nitration de styrylcétones méthoxylées en bonne position sur le noyau.

D'autre part, et dans le cadre de nos études sur la réduction électrochimique de dérivés nitrostyréniques (4, 5) nous avons réalisé l'électroréduction de quelques β-nitrostyrylcétones.

Les résultats obtenus font l'objet du présent mémoire.

1. Nitration de styrylcétones — limites de la méthode (schémas 1 et 2)

La nitration de la benzylidène acétone (**1***a*), de la chalcone (**1***b*) et d'analogues non méthoxylés, par le peroxyde d'azote, conduit bien aux α-nitrocétones correspondantes **2** (2, 3), mais la méthode ne peut être généralisée aux styrylcétones méthoxylées sur le noyau.[1] Ainsi, pour les diméthoxy-3,4 benzylidèneacétone (**3***a*), diméthoxy-3,4 chalcone (**3***b*) et diméthoxy-3,4 chloro-4′ chalcone (**3***c*), nous constatons une nitration exclusive sur le noyau aromatique en position-6.

La structure des nitro-6 styrylcétones obtenues (**5***a*, **5***b*, **5***c*) est déterminée sans ambiguité par résonance magnétique nucléaire du proton et du

[1]Les diméthoxy-3,4 et diméthoxy-3,4 chloro 4′-chalcones décrites précédemment (2) sont par conséquent nitrées en 6 et non en α du carbonyle comme il avait été proposé.

^{13}C pour la nitrovératrylidèneacétone (**5***a*).[2] Les spectres protoniques de ces cétones nitrées montrent la présence de deux protons éthyléniques *trans* (J = 16 Hz) ainsi que celle de deux protons aromatiques en *para* l'un de l'autre. De même le spectre de ^{13}C de **5***a* confirme la nitrosubstitution en-6 et montre la présence d'une liaison éthylénique disubstituée. D'autre part, sur le spectre protonique de cette même cétone le déplacement à très bas champ (8,05 ppm) du signal d'un des protons éthyléniques est en faveur d'une liaison hydrogène entre ce proton et le groupe NO_2. L'effet électroattracteur de ce groupement influe également sur les protons aromatiques, le proton *ortho* sortant à champ nettement plus bas que le proton *méta* (respectivement 7,60 et 7,00 ppm). Des constatations identiques peuvent être effectuées pour les nitro-6 chalcones (**5***b* et **5***c*).

L'interprétation du spectre rmn du ^{13}C de **5***a* est effectuée par comparaison des constantes de couplage résiduel des carbones aromatiques et des hydrogènes aromatiques d'une part, des carbones éthyléniques et des hydrogènes éthyléniques d'autre part.

En ce qui concerne les carbones aromatiques, le signal à 110,2 ppm présente une constante de couplage résiduel plus faible que celle du signal à 108,2 ppm, ce qui permet d'attribuer ce dernier au carbone aromatique situé en *ortho* du groupe NO_2. De même pour les carbones éthyléniques, le signal à 131,6 ppm qui présente une constante de couplage résiduel plus grande que celui à 97,6 ppm peut être attribué au carbone éthylénique en β du carbonyle, lié à l'hydrogène chélaté avec le NO_2. Les spectres de rmn ^{13}C ont été interprétés sur la base de travaux récents relatifs aux chalcones (6), compte-tenu des incréments apportés par la nitrosubstitution en-6.

On trouve, pour les protons éthyléniques et les carbones de **1***a* et **1***b* (cf. Partie expérimentale) les déplacements chimiques attendus ce qui confirme l'existence d'une liaison hydrogène dans le cas des nitro-6 styrylcétones. On constate donc que les styrylcétones non substituées sur le noyau aromatique subissent une nitration exclusive sur la double liaison éthylénique, tandis que celles qui sont, en plus, éther de phénol sont nitrées exclusivement en position-6 sur le noyau.

Si l'on rapproche ceci du fait que des composés tels que l'anisole (7) le vératrole, l'acide vératrique et le vératraldéhyde (8) sont aisément nitrés par N_2O_4, il est logique d'admettre que l'entité réactive est l'ion NO_2^+. Dans le cas des styrylcétones, l'addition élimination doit aussi débuter par une attaque de NO_2^+ sur la double liaison éthylénique (9) puisque seul le produit de nitration dans le noyau et non sur la double liaison est obtenu dans le cas des dérivés méthoxylés. Pour ces derniers, on n'observe pas la compétition théoriquement possible entre deux sites réactionnels pour NO_2^+: noyau et double liaison. En effet, le noyau est ici activé et se nitre préférentiellement; la double liaison est ainsi appauvrie en électrons et ne peut subir l'attaque électrophile.

2. Réduction chimique des nitrostyrylcétones (schémas 1 et 2)

L'hydrure de lithium et d'aluminium transforme les α-nitrostyrylcétones (**2**) en α-aminoalcools saturés correspondants **7**; dans la série des styrylcétones diméthoxylées et nitrées dans leur noyau **5**, les aminoalcools **6** sont fragiles, et seul **6***c* issu de la diméthoxynitrochalcone chlorée a pu être cristallisé (10). Les amino-2 diphényl-1,3 propanol-1: (**7***a*) et amino-3 phényl-4 butanol-2: (**7***b*) ont été obtenus sous forme d'un mélange *érythro* et *thréo* racémiques, ainsi que le montre l'examen de leur spectre de résonance protonique: deux doublets dus au méthine du groupe —CHOH— de chaque isomère couplé au proton tertiaire adjacent (de —CH—NH_2) pour **7***b*; deux doublets dus au groupe méthyle de chaque isomère couplé au proton tertiaire adjacent (de —CHOH—) pour **7***a*.

Pour chaque aminoalcool, il a été possible de définir les proportions respectives d'isomères *érythro* et *thréo* présents dans le mélange: après transformation de ces aminoalcools en chlorhydrate, nous avons constaté dans chaque cas la cristallisation préférentielle de l'un des chlorhydrates isomères. Les constantes de couplage pour les couples de protons méthine de —CHOH—[3] (respectivement 4 Hz pour le sel de **7***a*, 4,16 Hz pour celui de **7***b*) ont été comparées aux valeurs observées pour les méthines dans l'éphédrine (4,07 Hz) et la pseudoéphédrine (8,23 Hz) (11). Elles conduisent à proposer la configuration *érythro* pour les chlorhydrates cristallisés des deux aminoalcools **7***a* et **7***b*.

A partir de chaque chlorhydrate, nous avons régénéré l'aminoalcool *érythro* pur. Ceci a permis de faire dans les spectres rmn, les attributions aux

[2]Seule cétone nitrée dans le noyau soluble à concentration suffisante pour permettre l'enregistrement du spectre de rmn ^{13}C.

[3]Après découplage du méthyle dans le cas du phénylaminobutanol.

For personal use only.

composés *érythro* et *thréo* et de déterminer les pourcentages: compte-tenu de la précision des mesures, le rapport *érythro/thréo* pour chaque aminoalcool est de l'ordre de 50%.

3. Hétérocyclisations (schéma 2)

Vis-à-vis du chlorure d'acétyle, le comportement des aminoalcools (**7***a* et **7***b*) est différent. Alors qu'avec **7***b* seule la *N*-acylation est observée (45% en amide-alcool (**8***c*)), avec **7***a*, la double acylation des fonctions amine et alcool est prépondérante (57% en amide-ester (**8***b*); 13% en amide-alcool (**8***a*)).

Les amides **8***a*, **8***b* et **8***c* peuvent subir une cyclodéshydratation par action de l'anhydride phosphorique ou de l'oxychlorure de phosphore. Pour l'acétamido-3 acétoxy-2 phényl-4 butane (**8***b*) l'action de $POCl_3$ ou de P_2O_5 conduit à l'(α-hydroxyéthyl)-3 méthyl-1 dihydro-3,4 isoquinoléine (**9**) comme produit majeur, et seul identifiable après chromatographie du mélange réactionnel et transformation en chlorhydrate. Par contre, la cyclisation des hydroxyamides (**8***a* et **8***c*) par l'anhydride phosphorique conduit aux *cis* oxazolines-2 (**10** et **20**)[4] seuls produits identifiables après chromatographie du mélange réactionnel.

On trouve effectivement dans la littérature (13, 14) des exemples où une oxazoline-2 se forme préférentiellement à une isoquinoléine lors de la cyclisation de β-hydroxy β-phényléthylacétamides à noyau non activé; mais il est surprenant d'avoir obtenu la dihydroisoquinoléine (**9**) et non l'isoquinoléine (**11**) lors de la cyclisation de l'ester-amide (**8***b*).

Une hypothèse peut être formulée pour expliquer la formation dans un cas des oxazolines, dans l'autre celle d'une dihydroisoquinoléine. Avec les hydroxyamides (**8***a* et **8***c*), un ester phosphate peut transitoirement se former dans la réaction, et à partir de celui-ci, la formation d'une oxazoline-2 s'explique aisément. Dans le cas du bis-amide (**8***b*), la formation d'un tel intermédiaire ne pouvant avoir lieu, l'amide ester (**8***b*) subit une cyclodéshydratation isoquinoléique selon Bischler et Napieralski, suivie d'une hydrolyse de la fonction ester avec formation de la dihydroisoquinoléine (**9**).

[4]La configuration *cis* de ces composés a été attribuée à partir de la benzyl-4 méthyl-2 phényl-5 oxazoline-2 (**10**): pour ce dérivé, la valeur de la constante de couplage, 6,5 à 7 Hz, des protons CH portés par les carbones 4 et 5 a permis, par application de la règle de Karplus (12) et l'examen comparé des modèles moléculaires des oxazolines isomères, d'attribuer la configuration *cis* à l'oxazoline obtenue.

4. Réduction électrochimique des nitrostyryl-cétones

4.1. Etude polarographique

En solution hydro-organique tamponnée, la stabilité des composés **2***a* et **2***b* suivie par spectrophotométrie uv décroit par élévation du pH. Nous avons donc limité leur étude aux milieux acide et neutre.

Pour des pH inférieurs à 4–4,5, **2***a* et **2***b* présentent à l'électrode à goutte de mercure deux vagues, chacune de hauteur proche de 4 faradays. Leur potentiel de demi-vague varie linéairement avec le pH; la seconde vague est perturbée par des phénomènes d'adsorption. Au delà de pH 4,5 apparait une troisième vague dont le potentiel de demi-vague, plus négatif, reste sensiblement constant lorsque le pH croit.

Les courbes $E_{1/2} = f(\text{pH})$ pour **2***a* et **2***b* sont représentées sur la fig. 1.

4.2. Electrolyses en milieu acide (schéma 3)

4.2.1. Au niveau du palier de la première vague

Lors des *électrolyses en solution diluée* de **2***a* pH = 1,08 (50% d'acétonitrile; $c = 2 \times 10^{-3}$ *M*, $E = -0{,}5$ V) ou de **2***b*: pH = 0,75 (50% d'acétonitrile, $c = 2 \times 10^{-3}$ *M*, $E = -0{,}4$ V), on observe une décroissance de la première vague proportionnelle au nombre de coulombs consommés. A la fin de l'électrolyse, après passage de 4 électrons par molécule, subsiste une vague de hauteur 4 faradays dont le potentiel de demi-vague est identique à celui de la seconde vague de **2***a* et **2***b*.

Des électrolyses préparatives de **2***a* et **2***b*, ef-

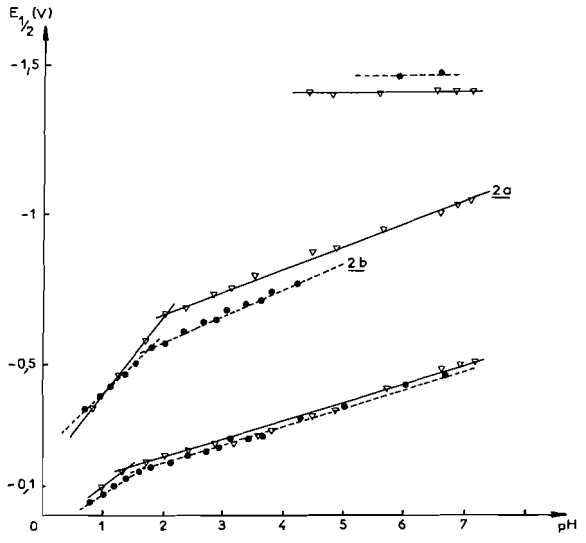

FIG. 1. Courbes $E_{1/2} = f(\text{pH})$ pour **2***a* et **2***b* en solution hydro-organique (25% de CH_3CN).

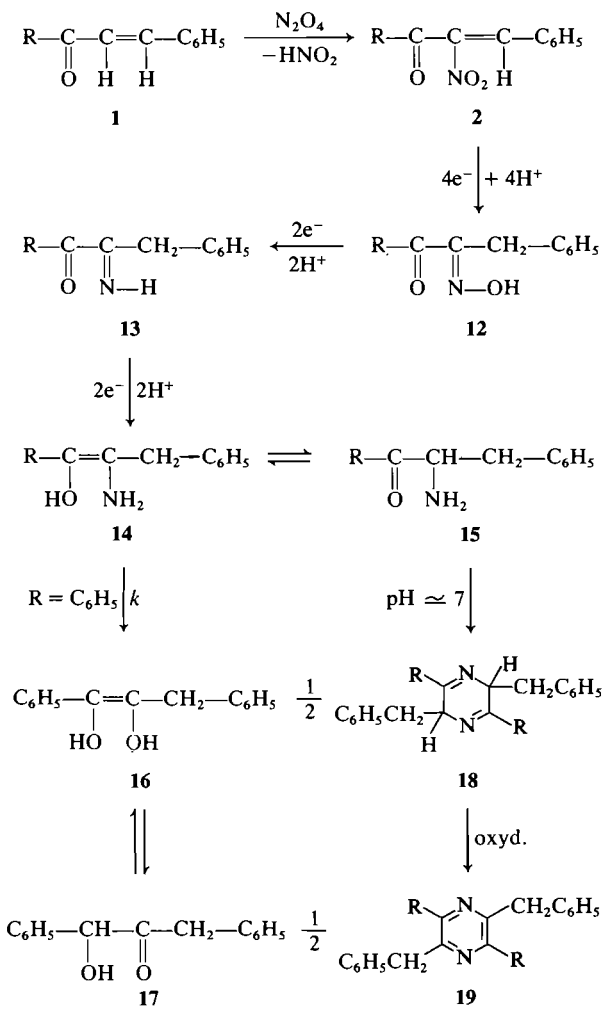

SCHÉMA 3: *a*: R = CH_3; *b*: R = C_6H_5.

fectuées dans les mêmes conditions, permettent d'isoler avec de bons rendements les α-cétoximes (**12***a* et **12***b*).

Ces résultats montrent que le premier stade de réduction de **2***a* et **2***b* correspond au schéma classique de réduction des dérivés nitrés éthyléniques en oxime selon un processus à 4 électrons. La fonction carbonyle n'est pas affectée.

Nous pouvons donc attribuer la première vague polarographique de **2***a* et **2***b*, à la réduction du motif nitré éthylénique. La hauteur (voisine de 4 faradays) et le potentiel de demi-vague à pH = 1,30: −0,15 V pour **2***a*, −0,14 V pour **2***b* sont comparables à ceux du β-nitrostyrène dans des conditions très proches (−0,16 V à pH = 1,36).

La seconde vague est attribuable à la réduction des oximes (**12***a* ou **12***b*) protonées. Le $E_{1/2}$ de cette vague (−0,55 V à pH = 1,3 pour **2***b*) est à rapprocher par exemple de celui de la phényl-1 oximino-2 propanone: −0,57 V à pH = 1 (16). De plus les échantillons authentiques de **12***a* et **12***b* obtenus par électrolyse préparative, présentent une vague cathodique de hauteur et de potentiel de demi-vague très proches de ceux de la seconde vague de **2***a* et **2***b* dans les mêmes conditions.

La troisième vague, présente au delà de pH = 4 sur le polarogramme de **2***b*, possède un $E_{1/2}$ identique à celui de la seconde vague de l'α-cétoxime (**12***b*) au même pH. Cette vague peut être attribuée à la réduction de la diphényl-1,3 propanone-1 qui résulte de l'hydrogénolyse de l'aminocétone (**15***b*) (17). Le potentiel de demi-vague: $E_{1/2}$ = −1,42 V à pH = 7,5 peut être comparé à celui de l'acétophénone: −1,4 V à pH = 7,5 (18).

4.2.2. Au niveau du palier de la seconde vague

4.2.2.1. Etude de 2a. *En solution diluée*, des électrolyses de **2***a*: pH = 1,24; (50% d'acétonitrile, E = −0,95 V; $c \simeq 2{,}5 \times 10^{-3}$ M) montrent la décroissance, proportionnelle au nombre de coulombs consommés, des deux vagues polarographiques. Après passage d'environ 8 électrons par molécule, il n'y a plus de espèce réductible en solution.

Des *électrolyses préparatives* effectuées dans des conditions très voisines permettent d'isoler le chlorhydrate de l'amino-2 phényl-1 butanone-3 (**15***a*).

Le schéma de réduction proposé est indiqué sur le schéma 3. Le premier stade de la réduction à quatre électrons de la nitrocétone éthylénique conduit à l'α-oximinocétone (**12***a*). En milieu acide il est admis que la réduction des oximes de cétones simples en amine se fait via l'imine correspondante (19). D'autre part, Armand et coll. (20) ont montré que les monoimines d'α-dicétones sont réduites en aminocétones par l'intermédiaire d'un énaminol. Au vu de ces résultats, et bien que dans le cas de **2***a*, ni l'α-cétoimine (**13**), ni l'énaminol (**14***a*) n'aient pu être décelés, le schéma de réduction proposé semble néanmoins le plus plausible. Nous verrons qu'il est justifié par les résultats exposés ultérieurement.

4.2.2.2. Etude de 2b. Au cours *d'électrolyses en solution diluée* de **2***b* à pH = 1,02 (E = −0,8 V; c = $1{,}2 \times 10^{-3}$ M; 50% d'acétonitrile), outre la décroissance des vagues 1 et 2 toujours proportionnelle au nombre de coulombs consommés, on note, au cours du temps, l'apparition d'une vague anodique de $E_{1/2}$ = −0,06 V dont la hauteur atteint son maximum aux quatre cinquièmes de l'électrolyse; en fin d'électrolyse (passage de 8 électrons par molécule), elle est encore présente mais décroit progressivement pour disparaître après environ 1 h 30 (fig. 2), la solution étant maintenue constamment sous atmosphère d'argon.

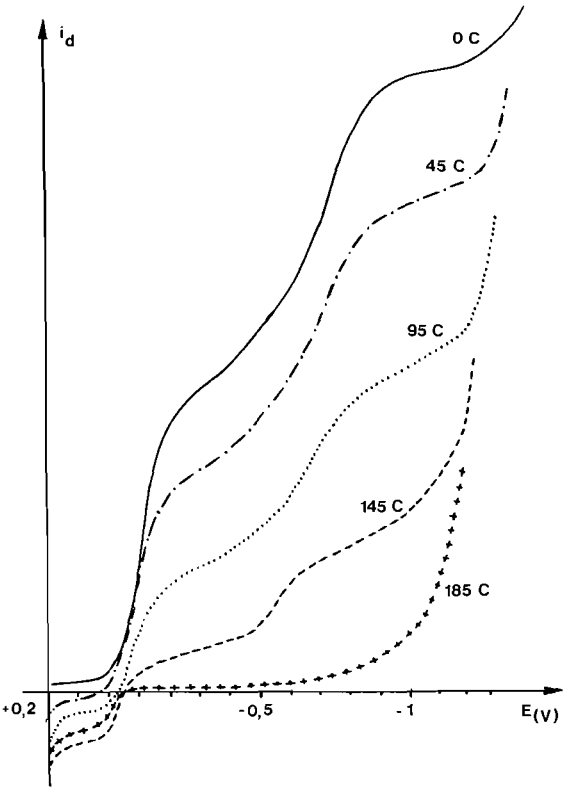

FIG. 2. Electrolyse de **2***b* en solution diluée. pH = 1,02; c = 1,2 × 10^{-3} M; CH_3CN 50%; E = −0,8 V SCE; V = 200 mL. Polarogrammes enregistrés avant (OC) pendant (45 C, 90 C, 145 C) et à la fin de l'électrolyse (185 C).

Ces résultats ne peuvent s'expliquer simplement par la réduction de **2***b* en α-cétoxime (**12***b*), puis en aminocétone (**15***b*). On devrait dans ce cas observer en fin d'électrolyse une vague cathodique due à **15***b*. La vague de l'amino-2 phényl-2 acétophénone possède en effet un $E_{1/2}$ = −0,89 V à pH = 1,2 (17).

Les faits observés montrent l'apparition d'un composé aisément oxydable évoluant lentement en solution pour conduire à une entité non réductible dans les conditions opératoires.

Des électrolyses préparatives ont été effectuées afin d'éclaircir le mécanisme de réduction. Elles permettent d'isoler avec un bon rendement l'α-cétol (**17**).

4.2.2.3. Discussion. Quatre schémas de réduction sont possibles. Les trois premiers, représentés sur le schéma 4, peuvent être éliminés:

En premier lieu, on doit rejeter l'hypothèse d'une hydrolyse de **12** en α-dicétone et la réduction de cette dernière en **17** par l'intermédiaire de l'ène-diol (**16**) (21). Nous avons en effet vérifié par ultraviolet la stabilité de l'oxime (**12***b*) dans les conditions opératoires utilisées.

Peut être exclue également la réduction de **12***b* en oxime-alcool suivie de l'hydrolyse de cette dernière en **17**. La réduction de **2***b* en **17** ne nécessiterait que 6 électrons par molécule et d'autre part, pour des composés possèdant l'enchaînement —C(=O)—C(=N)— la liaison —C=N est toujours réduite avant la fonction carbonyle (22).

Enfin, nous pouvons écarter l'hydrolyse de **13***b* en dicétone, réduite ultérieurement en **17**. En effet, on peut attendre pour cette α-cétoimine un $E_{1/2}$ proche, à pH ≃ 1,4 de 0 V. A titre de comparaison, le potentiel de demi-vague du monoanile du benzile est de −0,4 V à pH = 6 (22). Dans ces conditions, il est difficile d'envisager pour **13** une vitesse d'hydrolyse supérieure à sa vitesse de réduction à l'électrode.

Le seul schéma de réduction compatible avec les résultats expérimentaux est donc celui représenté sur le *schéma 3*.

La vague anodique observée lors des électrolyses de **2***b* à −0,8 V et qui indique la présence d'un composé aisément oxydable peut être due à l'énaminol (**14***b*) ou à l'ène-diol (**16**). Cependant, la disparition relativement lente de cette vague anodique exclut de l'attribuer à **16** l'équilibre tautomère **16** ⇌ **17** devant être beaucoup plus rapide que la réaction d'hydrolyse **14***b* → **16**.

La vague anodique est donc attribuée à **14***b*. Cet intermédiaire est par ailleurs mis en évidence par voltamétrie cyclique à balayage linéaire de tension. Pour une solution de **2***b* à pH = 1,34 (c = 10^{-3} M; 30% de méthanol, v = 0,25 V/s) on observe au balayage vers les potentiels négatifs entre 0 et −0,8 V deux pics cathodiques de potentiel de pic, E_p, proches des $E_{1/2}$ des deux vagues polarographiques de ce composé, respectivement −0,15 V et −0,56 V. Au balayage retour de −0,8 V à + 0,2 V, on note la présence d'un pic anodique de E_{pa} = −0,07 V due à l'oxydation de **14***b* (fig. 3). La décroissance de la vague anodique observée lors des électrolyses est due à l'hydrolyse de l'énaminol **14***b* en **17** via l'ène-diol **16**.

La différence de comportement observée entre **2***a* et **2***b* s'explique par les stabilités relatives des énaminols **14***a* et **14***b*. **14***a* est moins conjugué que **14***b* donc moins stable, et l'équilibre tautomère **14***a* ⇌ **15***a* est alors totalement déplacé vers la forme aminocétone **15***a*: ceci exclut une éventuelle hydrolyse de **14***a* comme nous l'observons dans le cas de **14***b*.

4.3. Electrolyses en milieu neutre (schéma 3)

Les polarogrammes enregistrés en cours d'électrolyse en solution diluée de **2***a* ou **2***b* au niveau du

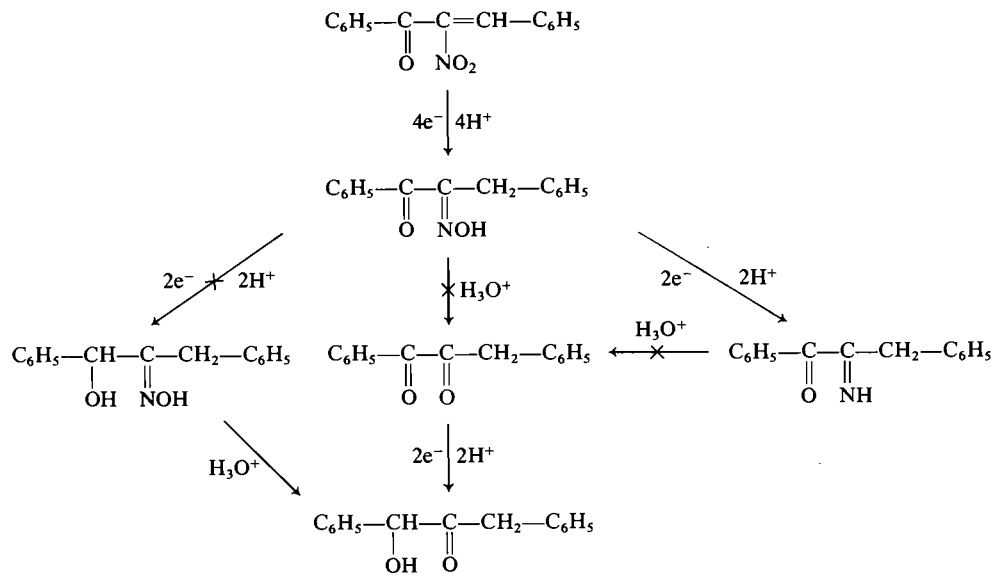

SCHÉMA 4

palier de la seconde vague et à pH ≃ 7 sont complexes. Lors des électrolyses en solution diluée, la dégradation de **2***a* et **2***b* à ce pH est négligeable. Par contre elle devient importante lors des électrolyses préparatives, beaucoup plus longues, et celles-ci ne peuvent être effectuées dans de bonnes conditions. Nous avons vérifié que la réduction primaire à quatre électrons respectivement de **2***a* et **2***b* conduisait toujours à **12***a* et **12***b* ce qui nous a permis de réaliser les électrolyses sur ces cétoximes.

Au cours d'*électrolyses en solution diluée* de **12***b* par exemple, à pH = 7,5 (50% d'acétonitrile; $c = 2 \times 10^{-3}$ *M*; $E = -1{,}05$ V), on observe une décroissance de la première vague polarographique ($E_{1/2} = -0{,}9$ V) proportionnelle au nombre de coulombs consommés tandis que la hauteur de la seconde vague ($E_{1/2} = -1{,}14$ V) attribuable à l'aminocétone **15***b* (amino-2 phényl-2 acétophénone: $E_{1/2} = -1{,}15$ V à pH = 7,4 (17)) croit avec le temps jusqu'à la demi-électrolyse. Une troisième vague de $E_{1/2}$ plus négatif apparait également. Elle peut être attribuée à la diphényl-1,3 propanone provenant de l'hydrogénolyse de la liaison C—N lors de la réduction de **15***b* (17). Ces résultats laissent penser que le produit de réduction en milieu neutre ou très faiblement basique est l'aminocétone **15***a* ou **15***b*.

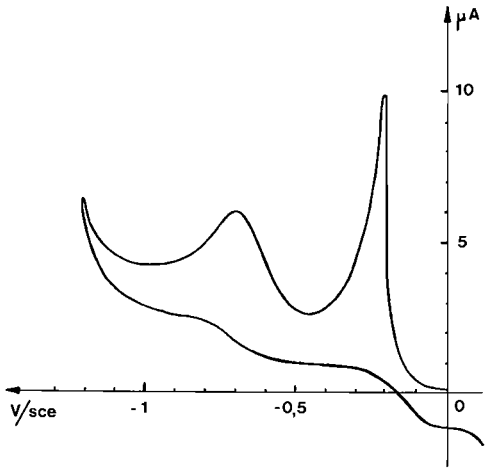

FIG. 3. Voltamogramme de **2***b* pH = 1,34; $c = 10^{-3}$ *M*; MeOH 30%; $v = 0{,}25$ V/s.

Des *électrolyses préparatives* de **12***a* et **12***b* à des pH voisins de 7: par exemple pH = 7,5–7,6 pour **12***a*; (50% d'acétonitrile, $c = 3 \times 10^{-2}$ *M*; $E = -1{,}05$ V) ou pour **12***b* pH = 7,20 (50% d'acétonitrile; $c = 2{,}8 \times 10^{-3}$ *M*; $E = -1{,}1$ V) permettent d'isoler respectivement après passage d'environ quatre électrons par molécule la dibenzyl-2,5 diméthyl-3,6 pyrazine (**19***a*) et la dibenzyl-2,5 diphényl-3,6 pyrazine (**19***b*), identifiée, par leur analyse pondérale, leurs caractéristiques physicochimiques et leur point de fusion.

Le schéma de la réduction de **2***a* et **2***b* vers pH = 7 (schéma 3) propose le passage par les α-cétoximes **12***a* et **12***b* puis les α-aminocétones **15***a* et **15***b*. Ces deux derniers composés, à ce pH, conduisent, par condensation de deux molécules (23) aux dihydropyrazines correspondantes **18***a* et **18***b*. Ces dihydropyrazines ne sont isolables qu'en prenant des précautions particulières (atmosphère inerte ...) sinon elles s'oxydent très facilement en pyrazines tétrasubstituées **19***a* et **19***b*, elles mêmes électroréductibles (24). On note par exemple pour **19***a*

une vague cathodique de hauteur proche de 2 faradays $E_{1/2}$ (V) = −0,44–0,073 pH.

Partie expérimentale

Les chromatographies en couche mince ont été réalisées sur plaques de gel de silice Riedel – De Haen. Les points de fusion sont, soit des points de fusion instantanée pris sur banc Kofler (F_K), soit des points de fusion lente pris en tubes capillaires sur appareil Buchi-Tottoli (F_T). Les microanalyses élémentaires ont été effectuées par le service central de microanalyses du CNRS. Tous les composés ont fourni des résultats analytiques correspondant à la formule à ±0,3% près.

Les spectres ultraviolets ont été enregistrés en solution éthanolique sur appareil Unicam SP 1800 (les longueurs d'onde sont exprimées en nm et les ε sont reportés entre parenthèses). Les spectres infra-rouges ont été pris en pastilles de KBr ou en solution dans $CHCl_3$ sur appareil Perkin-Elmer 177 (les nombres d'onde sont exprimés en cm^{-1}). Les spectres de rmn du proton ont été enregistrés à 60 MHz sur Varian T 60 A et les spectres de rmn ^{13}C sur Varian CFT 20 à transformées de Fourier. Dans tous les cas le tétraméthylsilane a été utilisé comme référence interne et les déplacements chimiques sont exprimés en ppm. Les abréviations s pour singulet, d pour doublet, t pour triplet, q pour quadruplet et m pour multiplet sont utilisées. Les polarogrammes sont enregistrés sur polarographe Radiometer PO_4 ou Tacussel type EPL 1B; les potentiels de demi-vague sont donnés par rapport à l'électrode à calomel saturée en chlorure de potassium. La hauteur des vagues est mesurée par rapport au β-nitrostyrène. Nous avons utilisé les tampons suivants: H_2SO_4; H_3PO_4–NaH_2PO_4; CH_3COOH–CH_3COONa; Na_2HPO_4–NaH_2PO_4. La concentration des tampons assure une force ionique comprise entre 0,1 *M* et 0,15 *M*. Les pH sont mesurés avec un pH-mètre Tacussel pH N 75 et une électrode de verre combinée verre–calomel. Les électrolyses à potentiel contrôlé sont effectuées sur cathode de mercure sous balayage d'argon ou d'azote. Le volume de la solution est généralement 200 cm^3; la solution anodique est de même composition que la solution cathodique mais sans dépolarisant. Des polarogrammes sont enregistrés en cours d'électrolyses en solution diluée en utilisant une électrode à goutte de mercure plongeant dans le compartiment cathodique et l'électrode de référence du dispositif d'électrolyse. Le potentiel est fixé par un potensiostat Tacussel ASA 4F2, la valeur exacte du potentiel est lue sur un millivoltmètre Exaprécis. Le nombre de coulombs est mesuré à l'aide d'un intégrateur Tacussel IG 31A, l'intensité du courant est lue au milliampèremètre.

Certaines abréviations ont été utilisées dans la partie expérimentale: LAH pour hydrure de lithium et d'aluminium; THF pour tétrahydrofuranne; Et_3N pour triéthylamine; N_2O_4 pour peroxyde d'azote; P_2O_5 pour pentoxyde de phosphore.

D_2O); 2,70 (d, 2, CH_2); 2,8–3,3 (massif 1, CH—N); 4,55 (d, 1, CHOH, *J* = 4,16 Hz); 7,10 (m, 5, H arom.); 7,30 (s, 5, H arom.); ^{13}C-rmn ($CDCl_3$) δ: C_6H_5—CH_2—: *i* 138,9; *o*, *m*, 128,1, 128,2; *p* 127,4; 37,7; —CH(NH_2)—CH(OH)—C_6H_5: 57,9; 75,8; *i* 141,4; *o*, *m* 129,1, 126,4; *p* 126,2; *aminoalcool thréo*: la connaissance des valeurs des déplacements chimiques des carbones de l'alcool *érythro* permet dans le mélange d'aminoalcools isomères d'attribuer les valeurs des carbones non aromatiques (à l'exception des carbones *ipso*) de la base *thréo*: ^{13}C-rmn ($CDCl_3$) δ: C_6H_5—CH_2—: *i* 138,7; 39,5; —CH(NH_2)—CH(OH)—C_6H_5: 58,3; 75,7; *i* 142.5.

Acétamido-2 diphényl-1,3 propanol-1 (8c)

A 10 g (0,03 mol) d'aminoalcool **7***b* dissous dans 400 cm^3 de Et_2O anhydre, on ajoute 17,1 g (0,17 mol; 24 cm^3) de Et_3N séchée sur KOH. A cette solution refroidie par un bain de glace on ajoute lentement 7 g (0,09 mol; 6,5 cm^3) de chlorure d'acétyle. Après addition le mélange est maintenu sous agitation à température ambiante pendant 2 h. On hydrolyse par 200 cm^3 d'H_2O puis extrait la solution au toluène; la phase organique est séchée sur Na_2SO_4 puis évaporée sous pression réduite. L'huile résiduelle cristallise par addition d'un minimum de Et_2O. Après recristallisation dans MeOH: 5,30 g (45%); *F* = 150°C; ir ($CHCl_3$); 3600, 3360 (bande large, OH), 3440 (NH), 1652 (C=O), 1605 (C=C).

cis-*Benzyl-4 méthyl-2 phényl-5 oxazoline-2 (10)*

A 6 g (0,02 mol) de **8***c* dissous dans 50 cm^3 de toluène anhydre on ajoute 15 g de P_2O_5. Le mélange réactionnel est porté à reflux pendant 5 h puis refroidi par un bain de glace et traité par H_2O glacée pour décomposer l'excès de P_2O_5. La phase organique est basifiée par K_2CO_3, extraite à $CHCl_3$, lavée à H_2O jusqu'à neutralité, séchée sur Na_2SO_4 puis évaporée sous pression réduite. L'huile résiduelle est chromatographiée sur 30 fois son poids de SiO_2 G Merck. L'élution par $CHCl_3$ donne 2,5 g (45%) d'oxazoline (**10**) (R_f = 0,35, éluant CH_2Cl_2 + 20% EtOH, révélation par le réactif de Dragendorff) que l'on transforme en *chlorhydrate* par addition d'éther chlorhydrique à une solution éthérée de base; F_T = 175°C après recristallisation dans Me_2CO; uv (EtOH) 215 (496), 250 (217), 256 (271), 264 (256), 266 (210); ^1H-rmn (DMSO d_6), δ: 2,10 (s, 3, CH_3); 2,82 (m, 2, CH_2); 3,80–4,20 (massif, 1, H de CH—CH_2); 5,70 (d, 1, H de C*H*—C_6H_5, *J* = 7 Hz), 7,40 et 7,50 (2s, 10, 2 C_6H_5); ^{13}C-rmn (DMSO d_6), δ: N—CH—CH_2—C_6H_5; 55,0; 34,9; arom.: voir ci-après;

For personal use only.

CH_3—C—O—CH—C_6H_5: 20,9; 169,4; 74,3; arom.: voir ci-après; 2 singulets arom. à 135,7 et 136,1; doublets arom.: 126,8 à 129,3.

(2)(α-Hydroxyéthyl)-3 méthyl-1 dihydro-3,4 isoquinoléine (9)
Z α-Nitrobenzylidène acétone (2a)

Selon (2) par nitration de la benzylidène-acétone par N_2O_4; 72%; F_K = 108°C (2), F = 108°C; ir ($CHCl_3$) 1690 (C=O) 1580, 1600, 1615, 1630 (C=C), 1520, 1348 (NO_2); ^{1}H-rmn ($CDCl_3$), δ: 2,47 (s, 3, CH_3), 7,47 (s large, 6, H vinylique + arom.); ^{13}C-rmn ($CDCl_3$), δ: —CH=C(NO_2)—CO—CH_3: 132,3; 147,8; 187,9; 24,9; phényle; *i* 128,7; *o* 129,7; *m* 129,3; *p* 132,2.

Amino-3 phényl-4 butanol-2 (7a)

A partir de 15 g (0,39 mol) de LAH et 15 g (0,08 mol) de **2***a* selon un mode opératoire identique à celui décrit pour **7***b* on obtient 7 g (54%) d'aminoalcool ($E_{0.5}$ = 130°C) à raison de 42% d'*érythro* et 58% de *thréo* (sur un autre essai 43 et 57%); ir ($CHCl_3$): 3300 (bande large, OH et NH_2).

Chlorhydrate érythro: 3 g du mélange d'amino alcools en solution méthanolique traités dans des conditions identiques à celles de **7***b* conduisent à froid à 0,6 g de chlorhydrate *érythro*, F_T= 162°C; ^{1}H-rmn (DMSO d_6+ D_2O), δ 1,17 (d, 3, CH_3); 2,75 à 3,37 (massif, 3, CH—N et CH_2—C_6H_5); 3,53 à 3,9 (massif, 1, CHOH; après irradiation sur le CH_3: d, J = 4 Hz); 7,33 (s, 5, H arom.); ^{13}C-rmn (DMSO d_6): δ C_6H_5—CH_2—: *i* 136,3; *o* ou *m* 130,04 ou 130,26; *p* 128,43; 36,03; —CH(NH_2)—CH(OH)—CH_3: 59,33; 67,25; 20,04. De la même façon que pour **7***b*, les eaux mères sont encore constituées par un mélange d'aminoalcools isomères (2 g) avec net enrichissement en isomère *thréo*. *L'aminoalcool* érythro *pur* est obtenu par basification d'une solution aqueuse du chlorhydrate et extraction par CH_2Cl_2; ^{1}H-rmn ($CDCl_3$), δ: 1,27 (d, 3H, CH_3); 2,17 (s, large, OH et NH_2, éch. D_2O); 2,33 à 3,03 (massif, 3, CH_2—C_6H_5 et CH—N); 3,30 à 3,85 (massif, 1, CHOH); 7,22 (s, 5, H arom.); ^{13}C-rmn ($CDCl_3$), δ: C_6H_5—CH_2—: *i* 138,84; *o* ou *m* 128,39 ou 129,06; *p* 126,18; 40,49; —CH(NH_2)—CH(OH)—CH_3: 58,33; 69,54; 20,15; *aminoalcool* thréo: la connaissance des valeurs des déplacements chimiques des carbones de la base *érythro* permet dans le mélange d'amino alcools isomères d'attribuer les valeurs des carbones non aromatiques de la base *thréo*: ^{13}C ($CDCl_3$), δ, C_6H_5—CH_2—: 38,5; —CH(NH_2)—CH(OH)—CH_3: 57,4; 65,70; 17,7.

Acétamido-3 phényl-4 butanol-2 (8a) et acétamido-3 acétoxy-2 phényl-4 butane (8b)

On ajoute goutte à goutte 20,8 g (0,26 mol, 19 cm³) de chlorure d'acétyle à une solution refroidie dans un bain de glace de 21 g (0,13 mol) de **7***a* dans 500 cm³ d'Et_2O anhydre. On ajoute alors 40 cm³ (28,8 g; 0,28 mol) de Et_3N séchée sur KOH. On poursuit l'agitation pendant 2 h à température ambiante. L'hydrolyse du mélange réactionnel par 400 cm³ d'eau puis son traitement de façon identique à celui décrit pour **8***c* conduit à 3,5 g (13%) d'acétamido-3 phényl-4 butanol-2 (**8***a*); F = 132°C; ir ($CHCl_3$): 3440 (bande large, OH et NH), 1652 et 1660 (C=O amide *érythro* et *thréo*). L'huile résiduelle après cristallisation de **8***a* est distillée sous pression réduite et donne 18 g (57%) d'acétamido-3 acétoxy-2 phényl-4 butane (**8***b*); E_5 = 165–170°C; ir ($CHCl_3$): 3280 (NH) 1730 (C=O ester), 1645–1650 (C=O amide).

En opérant la réaction d'amidification mole à mole entre le chlorure d'acétyle et l'aminoalcool (**7***a*) on obtient 20% de dérivé monoacétylé (**8***a*) et 20% de dérivé diacétylé (**8***b*).

cis Benzyl-4 diméthyl-2,5 oxazoline-2 (20)

A partir de 5 g (24 mmol) d'amide (**8***a*) dissous dans 100 cm³ de toluène anhydre et de 15 g de P_2O_5, et suivant le mode opératoire rapporté ci-dessus pour la préparation de l'oxazoline (**10**), on obtient après traitement 4 g d'une huile que l'on chromatographie sur 100 g de SiO_2 G Merck. L'élution par $CHCl_3$ + 10% EtOH donne 3,5 g (76,6%) d'oxazoline (**20**), huile qui cristallise par trituration avec de l'éther; F_T = 102°C; ^{1}H-rmn ($CDCl_3$), δ: 1,17 (d, 3, CH_3 en 5; J = 6,4 Hz); 1,92 (s, 3, CH_3 en 2); 2,85 (d élargi, 2, CH_2); 3,78 à 4,18 (m, 1, H de CH—CH_2); 5,92 à 6,15 (m, 1, H de CH—CH_3); 7,24 (s, 5, C_6H_5); ^{13}C-rmn ($CDCl_3$) δ: N—CH—CH_2—C_6H_5: 55,81; 38,05; arom.: 3 doublets: 126,27 (*p*); 128,32 et 129,11 (*o* et/ou *m*); 1 singulet à 138,20 (*i*); CH_3—C—O—CH—CH_3: 20,68; 170,60; 66,76; 23,10.

(α-Hydroxyéthyl)-3 méthyl-1 dihydro-3,4 isoquinoléine (9)

Le traitement de 7 g (0,028 mol) d'amide-ester (**8***b*) dans 60 cm³ de toluène anhydre et de 20 g de P_2O_5 de façon identique à celle décrite pour la préparation de **10** conduit après élution par $CHCl_3$ à 2,8 g (53%) d'isoquinoléine (**9**) (R_f = 0,65, éluant CH_2Cl_2 + 20% EtOH, révélation par le réactif de Dragendorff) que l'on transforme de la même façon en *chlorhydrate*; F = 150°C après recristallisation dans Me_2CO; uv (EtOH) 209 (19 100), 276 (9900); ir (KBr): 3460, 3290 (OH), 1650 (C=$\overset{+}{N}$H) 1600, 1570 (C=C); ^{1}H-rmn (DMSO d_6), δ: 1,20 (d, 3, CH_3 de CH_3—CHOH—); 2,90 (s, 3, CH_3 de CH_3—C=N^+); 3,2 (d, 2, CH_2 isoq. en 4); 3,65–4,2 (massif, 3, OH, CH isoq. en 3, CH de CH(OH)CH_3); 7,4–8,2 (m, 4, H isoq. en 5, 6, 7, 8); ^{13}C-rmn (D_2O), δ: CH(OH)—CH_3: 67,2, 18,9; CH_3—$C_{(1)}$=$N^+_{(2)}$: 20,6, 155,1: isoquinoléine: 58,7 (C_3), 25,5 (C_4), 129–131 (C_5, C_6, C_8), 138,4 (C_7), 137,7 (C_9), 125,9 (C_{10}).

II. Nitration des diméthoxy-3,4 benzylidène-acétone (3a), diméthoxy-3,4 chalcone (3b) et diméthoxy-3,4, chloro-4' chalcone (3c); alcools de réduction

Diméthoxy-3,4 nitro-6 benzylidène-acétone (5a)

On dissout 15 g (0,07 mol) de diméthoxy-3,4 benzylidène-acétone (**3***a*) (15) dans 600 cm³ de CCl_4 anhydre. Sous agitation vigoureuse on ajoute 127 g (1,38 mol) de N_2O_4 dissous dans 50 cm³ du même solvant. Après 5 mn de contact on chasse à froid et sous pression réduite l'excès de N_2O_4 et le HNO_2 formé. On ajoute 30 cm³ de MeOH à l'huile résiduelle: (**5***a*) précipite alors. Après recristallisation dans MeOH: 5,12 g (42%) de nitrocétone; F_K = 164–165°C; ir ($CHCl_3$): 1696 (C=O), 1640, 1610, 1575 (C=C), 1510, 1335 (NO_2); ^{1}H-rmn ($CDCl_3$) δ: 6,45 (d, 1, H vinylique, CH en α du CO; J = 16 Hz), 7,0 (s, 1, H arom. en *méta* du NO_2), 7,6 (s, 1, H arom. en *ortho* du NO_2), 8,05 (d, 1, H vinylique, CH en β du CO; J = 16 Hz); ^{13}C-rmn ($CDCl_3$), δ: —CH=CH—CO—CH_3: 131,6; 97,6; 187,5; 25,4; phényle: 119,8 (C_1); 110,2 (C_2); 153,8 (C_3; CH_3O); 150,5 (C_4; CH_3O); 108,2 (C_5); 139,8 (C_6; NO_2); méthoxyles: 56,6.

Diméthoxy-3,4 nitro-6 chalcone (5b)

A 10,6 g (0,02 mol) de diméthoxy-3,4 chalcone (2) dissoute dans 250 cm³ de CCl_4 anhydre, sont ajoutés 30 g (0,33 mol) de N_2O_4 dissous dans 150 cm³ du même solvant. Un abondant précipité, que l'on essore aussitôt, se forme rapidement. La chalcone nitrée est recristallisée dans MeOH: 8,67 g (77%); F_K = 184°C (2[1]) F = 182°C; ir ($CHCl_3$) 1668 (C=O), 1590, 1610, 1645 (C=C), 1508, 1338 (NO_2); ^{1}H-rmn ($CDCl_3$), δ: 4,05 (s, 6, $2CH_3O$—), 7,05–8,35 (massif, 9, 2 H vinyliques + 7 H arom.); ^{13}C-rmn.[5]

Diméthoxy-3,4 nitro-6 chloro-4' chalcone (5c)

Préparée comme la chalcone précédente à partir de 25 g (0,08 mol) de diméthoxy-3,4 chloro-4' chalcone (2) dissoute dans 400 cm³ de CCl_4 anhydre et de 45 g (0,49 mol) de N_2O_4 dans 250 cm³ du même solvant. Après recristallisation dans MeOH: 13,8 g (48%) de **5***c*; F_K = 212°C (2[1])F = 208°C; ir ($CHCl_3$): 1665 (C=O), 1645, 1608, 1590 (C=C), 1505, 1335 (NO_2); ^{1}H-rmn ($CDCl_3$), δ: 4,0 (s, 6, $2CH_3O$), 7,05 (d, 1, H vinylique, J = 17 Hz), 8,15 (d, 1, H vinylique, J = 17 Hz), 6,96–7,9 (massif, 6, H arom.); ^{13}C-rmn.[5]

[5]Composé trop peu soluble à concentration suffisante pour en effectuer le spectre de ^{13}C rmn ($CDCl_3$, DMSO d_6, $(CD_3)_2CO$).

(Amino-6 diméthoxy-3,4 phényl)-3 (chloro-4' phényl)-1 propanol-1 (6c)

Selon (10): dans la capsule d'un Soxhlet, on place 10 g (0,02 mol) de **5***c* et on introduit dans le ballon 8 g (0,21 mol) de LAH et 100 cm³ de THF anhydre. L'extraction par le solvant à reflux dure 36 h. Après refroidissement l'excès d'hydrure est détruit avec précaution par H_2O glacée et NaOH à 10%. Après essorage, on extrait l'amine avec $CHCl_3$; la phase organique est séchée sur Na_2SO_4 puis évaporée sous pression réduite. L'huile résiduelle reprise par Et_2O cristallise. Après recristallisation dans MeOH: 2 g (45%); F_K = 121–122°C; (10) F = 122°C; ir ($CHCl_3$) 3670, 3600, 3370 (bande large, OH et NH_2) 1615, 1580 (C=C); ^{1}H-rmn ($CDCl_3$), δ: 1,90 (m, 2, CH_2 de CH_2—CHOH—); 2,60 (t, 2, CH_2 de C_6H_5—CH_2—); 3,45 (s, 3, OH et NH_2, éch. D_2O); 3,80 (s, 6, $2CH_3O$); 4,55 (CH de —CHOH—); 6,25 (s, 1, CH en *ortho* de NH_2); 6,55 (s, 1, CH en *méta* de NH_2); 7,25 (s, 4, arom. de —C_6H_4—Cl).

III. Réductions électrochimiques préparatives

Phényl-1 oximino-2 butanone-3 (12a)

On prépare 250 cm³ de solution contenant 100 cm³ d'acétonitrile, 25 cm³ d'acide sulfurique N et de l'eau. On place 200 cm³ de cette solution (pH = 1,05) et 573 mg de **2***a* ($1,5 \times 10^{-2}$ *M*) dans le compartiment cathodique; la solution restante est mise dans le compartiment anodique. On fixe le potentiel à −0,4 V. Après passage de 980 C (1160 C = 4 F), i < 5 mA, l'électrolyse est arrêtée. Après évaporation de l'acétonitrile le précipité formé est lavé, séché; 487 mg (85%) puis recristallisé dans un mélange hexane–benzène 70/30 en volume. On recueille l'α-céto-oxime (**12***a*). F = 77–78°C; (25) F = 80–81°C; ^{1}H-rmn (DMSO d_6) δ: 3,35 (s, 3, CH_3); 3,93 (s, 2, CH_2); 7,3–7,4 (m, 6, arom. + N—OH).

Diphényl-1,3 oximino-2 propanone-1 (12b)

On prépare 250 cm³ de solution contenant 125 cm³ d'acétonitrile, 100 cm³ d'acide sulfurique N et de l'eau. On introduit 200 cm³ de cette solution et 910 mg de **2***b* ($1,8 \times 10^{-2}$ *M*) dans le compartiment cathodique; le reste de la solution est placé dans le compartiment anodique. Le potentiel est fixé à −0,25 V. Après passage de 1490 C (1740 C = 4 F), l'intensité résiduelle est inférieure à 5 mA et le pH de la solution est égal à 1,05. L'électrolyse est arrêtée et l'acétonitrile évaporé. Le précipité formé, lavé puis séché est l'α-céto-oxime (**12***b*): 738 mg (80%) qui est recristallisé dans un mélange hexane–benzène, 70/30 en volume, F = 122°C; (26), F = 123°C; ^{1}H-rmn (DMSO d_6), δ: 4,12 (s, 2, CH_2); 7,2–7,9 (m, 10, H arom.) 8,5 (s, éch. avec D_2O, 1, N—O*H*); uv (acétonitrile) λ_{max} = 252 nm (10 200).

Amino-2 phényl-1 butanone-3 (15a)

On prépare 250 cm³ d'une solution contenant 125 cm³ d'acétonitrile, 50 cm³ d'acide sulfurique N et de l'eau. On introduit 200 cm³ de cette solution et 1,15 g (3×10^{-2} *M*) de **2***a* dans le compartiment cathodique. Le reste est placé dans le compartiment anodique. Le potentiel est fixé à −0,95 V. Après passage de 4420 C (4630 C = 8 F) l'électrolyse est arrêtée. Le pH de la solution est alors 1,16. On évapore l'acétonitrile puis neutralise la solution par de la soude N jusqu'à pH ≃ 6. La phase aqueuse est extraite par 3 fois 30 cm³ d'éther et les phases éthérées sont séchées sur Na_2SO_4. On sature alors la solution en HCl gazeux. Le chlorhydrate de l'amino-2 phényl-1 butanone (**15***a*) précipite: F = 129–130°C; (27) F = 130°C; ^{1}H-rmn (D_2O) δ: 2,05 (s, 3, CH_3), 2,93 (d, 2, CH_2); 5,21 (t, 1, —C*H*—NH_2); 7,3–7,4 (m, 5 arom.).

Diphényl-1,3 hydroxy-1 propanone-2 (17)

On prépare 250 cm³ d'une solution contenant 125 cm³ d'acétonitrile, 50 cm³ d'acide sulfurique N et de l'eau. On place 200 cm³ de cette solution et 900 mg de **2***b* dans le compartiment cathodique; le reste de la solution est mis dans le compartiment anodique. On fixe le potentiel à −0,95 V. L'intensité résiduelle est inférieure à 10 mA après passage de 3140 C (3470 C = 8 F). L'électrolyse est arrêtée, le pH de la solution est alors 1,15. L'acétonitrile est évaporé et le précipité formé, lavé séché (702 mg: 82%) et recristallisé dans un mélange hexane–benzène 70/30 en volume conduit à l'α-cétol (**17**). F = 115°C; (28) F = 114–116°C; ^{1}H-rmn (acétone d_6): δ: 3,22 (s, 2, CH_2); 4,08 (s, éch. avec D_2O, 1, OH); 4,72 (s, 1, C*H*OH); 6,3–7 (m, 10, arom.).

Dibenzyl-2,5 diméthyl-3,6 pyrazine (19a)

On prépare 250 cm³ d'une solution contenant 100 cm³ d'acétonitrile, 50 cm³ d'acide phosphorique 0,5 *M*, 30 cm³ de soude 1 N et de l'eau. On place 200 cm³ de cette solution (pH = 7,21) et 1 g de **12***a* ($2,8 \times 10^{-2}$ *M*) dans le compartiment cathodique. La solution restante est introduite dans le compartiment anodique. On fixe le potentiel à −1,1 V. Après passage de 1920 C (2180 C = 4 F) on arrête l'électrolyse (i < 5 mA). L'acétonitrile est évaporé. Le solide obtenu est recristallisé dans un mélange méthanol–éther de pétrole 50/50. On recueille 220 mg (45%) de pyrazine (**19***a*); F = 100–102°C; (29), F = 100–101°C; uv (méthanol) λ_{max} = 282 nm. ^{1}H-rmn ($CDCl_3$), δ: 2,55 (s, 6, CH_3); 4,19 (s, 4, CH_2); 7,25 (s, 10, arom.); polarographie: vague cathodique, hauteur 2F; $E_{1/2}$(V) = 0,44–0,073 pH.

Dibenzyl-2,5 diphényl-3,6 pyrazine (19b)

On prépare 250 cm³ de solution contenant 100 cm³ d'acétonitrile, 50 cm³ d'acide phosphorique 0,5 *M*, 30 cm³ de soude N et de l'eau. On introduit 200 cm³ de cette solution (pH = 7,52) et 1,16 g de **12***b* dans le compartiment cathodique. Le reste de la solution est placé dans le compartiment anodique. Le potentiel est fixé à −1,05 V. A intervalles réguliers au cours de l'électrolyse, sont ajoutés cm³ par cm³, 5 cm³ d'acide phosphorique 0,5 *M* pour maintenir le pH à sa valeur initiale. Après passage de 1533 C (1600 C = 4 F) l'électrolyse est arrêtée, l'acétonitrile évaporé et la solution extraite par trois fois 20 cm³ d'éther. Les phases éthérées sont regroupées puis séchées sur Na_2SO_4. On obtient, après évaporation de l'éther, une gomme visqueuse orangée qui, lavée avec un minimum de chloroforme cristallise et conduit à 225 mg (40%) de pyrazine (**19***b*) qui est alors recristallisée dans l'acétonitrile; F = 151–153°C (30) F = 152°C; uv (méthanol): λ_{max} = 245 et 300 nm ^{1}H-rmn ($CDCl_3$); δ: 4,33 (s, 4, $2CH_2$); 7,23 (s, 10, arom. de C_6H_5—CH_2); 7,55 (s, 10, H arom.).

Localized excess electrons in H_2O glasses and ice[1]

GERALD J. TRUDEL,[2] HUGH A. GILLIS, NORMAN V. KLASSEN, AND GEORGE G. TEATHER
Division of Physics, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received November 4, 1980

GERALD J. TRUDEL, HUGH A. GILLIS, NORMAN V. KLASSEN, and GEORGE G. TEATHER. Can. J. Chem. **59**, 1235 (1981).

The yields and decay rates of two types of localized excess electrons, absorbing in the visible (e^-_{vis}) and in the infrared (e^-_{ir}), have been compared in four pulse-irradiated H_2O glasses and their D_2O analogues, and in irradiated H_2O and D_2O ice crystals, all at 73 K. If it is assumed that extinction coefficients of e^-_{vis} and e^-_{ir} at 650 nm and 1800 nm, respectively, are independent of isotopic substitution for both glasses and ice, the G's for both types of localized electrons are lower in all the H_2O solids studied than in the corresponding D_2O solids. The largest effect of isotopic substitution was found in the lifetime of e^-_{vis} in the crystal; at 73 K the inital half-life for decay of e^-_{vis} is approximately 14 times longer in D_2O than in H_2O ice. Even at 6 K the decay of e^-_{vis} in H_2O ice is very rapid with an initial half-life of about 75 ns.

GERALD J. TRUDEL, HUGH A. GILLIS, NORMAN V. KLASSEN et GEORGE G. TEATHER. Can. J. Chem. **59**, 1235 (1981).

Opérant à 73 K, on a comparé les rendements et les vitesses de disparition de deux types d'électrons en excès localisés qui absorbent dans le visible (e^-_{vis}) et dans l'infrarouge (e^-_{ir}) et qui se forment dans quatre verres à H_2O ainsi que dans leurs analogues à D_2O irradiés par pulsation de même que dans des cristaux de glace de H_2O et de D_2O irradiés. Si on fait l'hypothèse que les coefficients d'extinction de e^-_{vis} et e^-_{ir} à 650 nm et 1800 nm respectivement sont indépendants de la substitution isotopique des deux verres et des deux glaces, les valeurs de G pour les deux types d'électrons localisés sont plus bas dans tous les H_2O solides étudiés que dans les D_2O solides correspondants. On a trouvé que l'effet de substitution isotopique est maximal dans le temps de vie e^-_{vis} dans le cristal; à 73 K, la période de demie-vie initiale de la disparition de e^-_{vis} est approximativement 14 fois plus longue dans la glace à D_2O que dans la glace à H_2O. Même à 6 K, la disparition de e^-_{vis} dans la glace à H_2O est très rapide avec une demie-vie initiale d'environ 75 ns.

[Traduit par le journal]

Introduction

In pulse radiolysis studies of some deuterated aqueous solids at low temperature, two well separated absorption bands due to excess electrons are seen (1–4). The better known of these, e^-_{vis}, has an optical absorption with a maximum around 650 nm. The more recently discovered e^-_{ir} has a maximum >2500 nm, and has been studied almost exclusively in deuterated systems because of their greater transparency in the 1200–3200 nm range; matrix absorption bands in this region in solid H_2O arising from combinations of the fundamental vibrational modes are shifted to higher wavelengths by deuterium substitution. One expects to find e^-_{ir} also in protiated systems but heretofore the possibility has remained that e^-_{ir} is peculiar to aqueous systems that are deuterated. An infrared electron band has been seen in an irradiated protiated ethylene glycol – H_2O glass (5), but there is a possibility that it is due to a presolvated electron in an alcohol environment, similar to the species which causes the infrared absorption seen in the pulse radiolysis of some pure alcohol glasses (6, 7). Hase and Kawabata (8) looked for e^-_{ir} in γ-irradiated H_2O ice at 4 K but did not find it, whereas they did find e^-_{ir} in pure D_2O ice under the same conditions. They reported that 10% by volume of H_2O in D_2O ice was sufficient to suppress the appearance of e^-_{ir}.

In this work e^-_{ir} was looked for in several protiated aqueous solids corresponding to deuterated solids in which it was found in significant yield. In all cases e^-_{ir} was found also in the protiated system. Some differences in the behaviour of e^-_{ir} and e^-_{vis} in the corresponding protiated and deuterated systems are noted.

Experimental

Most of the experimental techniques used in this work have been described earlier (1–4). The light detector for $\lambda \geq 900$ nm was a Barnes A-100 room temperature InAs photodiode. For 450 nm $\leq \lambda \leq$ 1000 nm an EG&G SHS-100 silicon photodiode was normally used, but the faster HP-4207 silicon photodiode was used in this wavelength region for measurements of e^-_{vis} in H_2O ice at 73 K.

The D_2O and DCl were used as supplied by Merck, Sharp and Dohme. All other solutes were reagent grade and were also used without further purification. Ice crystals were 5 mm thick. Glasses were irradiated in windowless cells to avoid corrections for radiation-induced absorptions in windows which can be significant for thin samples. Sample thicknesses were 1, 2, or 5 mm. Each solution was deaerated by bubbling with argon (Superpurified grade from Liquid Air Ltd.) for 15 min and was then injected into a sample holder with demountable sides. The holder was sometimes coated with a film of paraffin wax, which reduced the extent of cracking. The filled holder was immersed in liquid nitrogen to form the glass, and the polished stainless steel plates on either side were removed to leave the windowless sample. Glasses were often slightly cracked. Corresponding

H_2O and D_2O glasses were done on the same day to reduce as much as possible errors involved in comparing their yields.

Dosimetry was done with an oxygen saturated solution of 5×10^{-3} *M* KSCN, irradiated in a windowless holder to which two Suprasil plates were attached. Methanol was used in the irradiation Dewar to simulate liquid nitrogen. $G\varepsilon(SCN)_2^-$ at 475 nm was taken as $2.2 \times 10^4\ M^{-1}\ cm^{-1}$ $(100\ eV)^{-1}$. The dose per pulse was about 2 krad for a 10 ns pulse and 6–10 krad for a 40 ns pulse.

Results

Aqueous Glasses

The absorption spectra in four pairs of glasses as measured 100 ns after the start of a 40 ns pulse are shown in Fig. 1. The ethylene glycol glasses were made from 50% by volume of ethylene glycol-h_6 with either D_2O or H_2O. The yields of e^-_{vis} and e^-_{ir} for the D_2O glasses of ethylene glycol and 9.5 *M* LiCl were reported earlier (1) and we find approximately the same values in this work. For all four pairs both $G\varepsilon(e^-_{vis})$ and $G\varepsilon(e^-_{ir})$ at 100 ns are greater in the D_2O glasses than in those made with H_2O. The decays of e^-_{vis} and e^-_{ir} between 100 ns and about 10 μs for each glass are also shown in Fig. 1. The rates of growth or decay of e^-_{vis} are the same for the H_2O and D_2O glasses of each pair, so that the initial values of $G\varepsilon_{max}$ for e^-_{vis} are very likely higher for the D_2O glasses. The decay rates of e^-_{ir} seem to be a little faster in the H_2O glasses than in their D_2O counterparts, so that it is possible that the lower values of $G\varepsilon(e^-_{ir})$ at 100 ns in the H_2O glasses are due in part to the faster decay and not just to lower initial values. No noticeable differences in decay rates were found at different wavelengths in the e^-_{ir} band for any glass.

H_2O Ice at 73 K

Figure 2 shows the spectra found at 51 and 142 ns after irradiation of H_2O ice at 73 K with a 40 ns pulse. Absorption beyond 1000 nm could not be measured accurately at the shorter time because of the slow rise-time of the InAs detector that must be used at these wavelengths. Measurements were possible only at three wavelengths beyond 1000 nm because of the limited transparency of the sample, but these clearly indicate the high energy tail of an infrared absorption band. The visible band decays much more quickly than that in D_2O ice at the same temperature, as is seen in Fig. 3. In this figure OD_0 is the OD at mid-pulse, estimated from an extrapolation on a plot of 1/OD against time which happens to be approximately linear at short times. Estimated half-lives from mid-pulse are 25 ns for e^-_{vis} in H_2O ice, and 350 ns in D_2O ice (2). The decays of e^-_{vis} in H_2O (Fig. 3) and D_2O ice (2) give reasonably linear plots of OD against log *t*, which suggests a tunnelling mechanism of recombination. In water at room temperature ε_{700} for e^-_{aq} in D_2O is reported to be $2.02 \times 10^4\ M^{-1}\ cm^{-1}$ (9), as compared to $1.85 \times 10^4\ M^{-1}\ cm^{-1}$ in H_2O (10).[3] Here we simply assume that ε_{650} for H_2O ice at 73 K is the same ($2 \times 10^4\ M^{-1}\ cm^{-1}$) as the value used previously for D_2O ice at this temperature (2). On this basis $G(e^-_{vis})$ for H_2O ice at 73 K is approximately 0.27, as compared to 0.41 for D_2O ice (2).

The rate of decay of e^-_{ir} in H_2O ice could not be followed with much precision because the optical density at 1800 was so low (about 1.6×10^{-3} for a 40 ns pulse). However from a plot of 1/OD against time we calculate $k = 1.2 \times 10^{13}\ M^{-1}\ s^{-1}$ at 73 K by assuming (*a*) that second-order kinetics are obeyed, as they are for the e^-_{ir} in D_2O ice (2), (*b*) that the ratio $\varepsilon_{1800}/\varepsilon_{2350}$ is the same for H_2O ice as for D_2O ice, and (*c*) that $\varepsilon_{2350} = 3.8 \times 10^4\ M^{-1}\ cm^{-1}$ as for D_2O ice (2). For D_2O ice we had calculated $k = 4 \times 10^{12}\ M^{-1}\ s^{-1}$ at the same temperature (2), which is rather similar in view of the assumptions and imprecision involved. From the above assumptions about ε's for e^-_{ir}, $G(e^-_{ir})$ for H_2O ice at 73 K at mid-pulse is calculated to be 0.06, as compared to 0.11 for D_2O ice.

In order to provide further evidence that the weak infrared absorption seen in Fig. 2 is due to e^-_{ir}, the effect of accumulated dose was measured for pure H_2O ice and for samples doped with NH_4F; some results are shown in Fig. 4. The NH_4F causes a large increase in the initial yield of infrared absorption (about a factor of 8 at $7 \times 10^{-3}\ M$), and yields in the doped samples increase with accumulated dose whereas in the pure H_2O ice accumulated dose causes a small decrease in 1800 nm absorption at 100 ns. The decay rate of the absorption at 1800 nm was greatly reduced by the added NH_4F; for the conditions used to obtain the results of Fig. 4, the half-life for decay at 1800 nm from the time of maximum absorption was 170 ns in pure H_2O ice, whereas in the sample doped with $7 \times 10^{-3}\ M$ NH_4F there was about 5% decay in this time. These effects were found earlier for e^-_{ir} in D_2O ice, so there is no doubt that the infrared absorption seen in Fig. 2 is also due to e^-_{ir}.

H_2O Ice at 6 K

The spectra of irradiated H_2O ice at 6 K at 72 and 640 ns after a 40 ns pulse are shown in Fig. 5. A significant increase in infrared absorption with accumulated dose (about 25% for 10 pulses of 8 krad each) was noted; the spectra of Fig. 5 have been corrected for this effect by assuming the increase is linear with dose. Notable features of the spectra are that the ratio of infrared to visible absorption is

[3]Dr. G. Nilsson recently informed us that the value $\varepsilon_{max}(e^-_{aq})_{D_2O}/\varepsilon_{max}(e^-_{aq})_{H_2O} = 1.28$ given in Nilsson *et al.* (21) should have been 1.09 as calculated from the values given in the above text. This error is also present in our paper (22).

much larger than at 73 K, the visible band decays very quickly considering the temperature ($t_{\frac{1}{2}}$ from mid-pulse ≃ 75 ns) and much more rapidly than the infrared band, and the shape of the accessible part of the infrared band is very different from the Lorentzian shape found for e^-_{ir} in D_2O ice at 73 K. The mid-pulse (pulse length of 40 ns) yields found for H_2O ice at 6 K are: for $\lambda = 650$ nm, $G\varepsilon = 5.1 \times 10^3$, very similar to the 5.3×10^3 found at 73 K; for $\lambda = 1800$ nm, $G\varepsilon = 3.3 \times 10^3$, as compared to 0.85×10^3 at 73 K. It is worth noting that our $G\varepsilon$ at 1800 nm for H_2O ice is much lower than that of 2.3×10^4

recently published for D_2O ice at 6 K (11), but not very different from our results for D_2O ice at 6 K (23).

Discussion

Aqueous Glasses

If we assume that the values of ε_{650} and ε_{1800} are the same for D_2O glasses as for the corresponding H_2O glasses, then yields of both e^-_{vis} and e^-_{ir} are higher in all four D_2O glasses. If an effect of

For personal use only.

deuterium substitution is to increase ε_{max} for e^-_{vis} by 9%, as it does in liquid water (9, 10), then the values of $G(e^-_{vis})$ are the same in protiated and deuterated ethylene glycol glasses, and remain higher in the D_2O glasses of the other pairs. As stated in the Results section, the lower yields ($G\varepsilon$'s) of e^-_{ir} at 100 ns in H_2O glasses could be due in part to slightly faster decay rates, rather than to smaller initial yields, but the 100 ns yields of e^-_{vis} are not subject to this reservation. In general substitution of H_2O by D_2O does not bring about the same percentage changes in yields of e^-_{vis} and e^-_{ir}. Thus in the ethylene glycol – D_2O glass values of $G\varepsilon$ of e^-_{vis} (at 650 nm) and e^-_{ir} (at 1900 nm) are larger by 12% and 87%, respectively, than the values in the corresponding H_2O glasses.

Stradowski and Hamill (12) found somewhat higher yields of e^-_{vis} in 8 *M* $NaClO_4$–D_2O glasses than in the corresponding H_2O glasses. They concluded that the initial yield of dry electrons in H_2O is slightly larger than in D_2O (13) but there is a significant isotope effect in the frequency of localization of dry electrons. They proposed that localization involves transferring to the lattice the binding energy of the dry electron as a vibrational excitation, probably through formation of H_2O^- or D_2O^-, and the cross-section for this process is smaller for D_2O. Thus localization would take place at a larger charge-pair radius in D_2O and Coulombic recombination of the localized electron, before relaxation, would be less significant than in H_2O systems. An alternative explanation they offer is that H_2O^+ and D_2O^+ have large ranges, but localization of D_2O^+ (to form D_3O^+) is slower than that of H_2O^+ so that again localization takes place at a larger charge-pair radius in D_2O (12). Evidence has been presented which indicates that both e^-_{vis} and e^-_{ir} decay geminately in LiCl and $MgCl_2$ glasses (1, 14) and the mechanism is probably tunnelling, at least for e^-_{ir} (14). The rate of decay by tunnelling is very sensitive to the distance between reactive species (15, 16). The fact that the decay rates of e^-_{ir} in corresponding H_2O and D_2O glasses are very similar (Fig. 1) argues against localization taking place at different distances from spur centers. Decays of e^-_{vis} were not followed to a large enough extent to permit any conclusion about relative localization distances for this species. (The probable reason for the rapid decay of e^-_{vis} in HCl, DCl glasses is reaction with homogeneously distributed H_3O^+ and D_3O^+.)

Our apparently higher G's of localized electrons in D_2O glasses as compared to their H_2O analogues may be due to the same mechanism that causes $G(e^-_{aq})$ to be 12% larger in liquid D_2O than in liquid H_2O (17). Various possibilities have been suggested as that mechanism. Some time ago it was suggested that the longer relaxation time and higher viscosity of D_2O as compared to H_2O would mean a greater charge-pair radius and hence a smaller amount of fast recombination (18). Anbar and Meyerstein (17) argued against this hypothesis and instead proposed the production of excited states by the reaction of subexcitation electrons, with the isotope effect arising from deuterium substituted excited states having a higher probability of undergoing non-dissociative ionization as compared with dissociative processes. More recently Singh *et al.* (19) also proposed large isotope effects in reactions of vibrationally excited states, though their proposed reactions are different from those suggested by Anbar and Meyerstein. Our results do not enable us to comment on these mechanisms for the isotope effect on yields which involve excited states.

H_2O Ice

At 73 K the yields of both e^-_{vis} and e^-_{ir} in H_2O ice, though not determined very accurately, seem to be lower than in D_2O ice. Lowering the temperature to 6 K increases considerably the yield of e^-_{ir} in H_2O ice, just as it does in D_2O ice (11, 23). The failure of Hase and Kawabata (8) to find e^-_{ir} in H_2O ice at 4 K in γ-radiolysis must have been due to its disappearance before their earliest observation time, as they suggested (8).

The biggest isotope effect we have seen in ice is in the lifetime of e^-_{vis}; at 73 K the initial half-life for decay of e^-_{vis} is approximately 14 times longer in D_2O than in H_2O ice. Lowering the temperature to 6 K increases the lifetime slightly; for e^-_{vis} in H_2O ice we find $t_{\frac{1}{2}}$'s from mid-pulse of ~25 ns at 73 K (pulse length of ~20 ns) and ~75 ns at 6 K (pulse length of ~40 ns), though these are not strictly comparable because of the difference in pulse lengths. Such a small effect of temperature strongly suggests that e^-_{vis} decays by tunnelling. Kawabata *et al.* (11) found a first observable half-life of about 5 μs after a 0.6 μs pulse for e^-_{vis} in D_2O ice at 6 K, which indicates that at this temperature also, decay is much slower than in H_2O ice.

Earlier we suggested that e^-_{vis} in D_2O ice is produced by a quasi-free electron (e^-_{qf}) dropping into a radiation-produced vacancy (□) in the same spur, with the vacancy-producing reaction being either a spur neutralization:

$$(2\,D_2O^+ + 2\,e^-_{qf}) \longrightarrow (D + OD + D_2O^+ + e^-_{qf} + \square)$$

or decomposition of an excited molecule (2). The energy of neutralization or excitation would be converted into sufficient kinetic energy of the D

plus OD fragments to expel them some distance from the lattice site. Because of conservation of momentum, the hydroxyl radical would have 1/18 of the available energy in the case of H_2O and 1/10 of the energy in D_2O ice, so that in D_2O ice the OD would be further away from the vacancy (and hence e^-_{vis}) than would OH for H_2O ice. The difference would not be large, but if it is assumed that e^-_{vis} decays by reaction with hydroxyl radical by tunnelling (2), only a small difference is required to explain the difference in lifetimes of e^-_{vis} in H_2O and D_2O ice at 73 K. If there is no inefficiency in the reaction, the distance a an electron can tunnel in time t is given by:

$$a = a_0 + 2.26\,(15 + \log t)\,B^{-1/2}$$

where a is in Å, B is the binding energy of the electron in eV, and the constant a_0 accounts for the finite radii of the electron and its reaction partner (20). We take $B = 1.2$ eV, as has been assumed for 6 M NaOH glass at 77 K (20), and $a_0 = 5$ Å. For $t =$ 25 ns and 350 ns, $a = 20.2$ Å and 22.6 Å, respectively. Thus at 73 K if half the yield of e^-_{vis} is produced within 20.2 Å and 22.6 Å of the hydroxyl radical in H_2O and D_2O ice respectively, our observed difference in half-lives is accounted for.

Received July 15, 1980

GUIDO BANDITELLI, ANNA LAURA BANDINI, GIOVANNI MINGHETTI, and FLAVIO BONATI. Can. J. Chem. **59**, 1241 (1981).

Ligand displacement by a pyrazole on Me_2SAuCl afforded L_nAuCl (n = 1 or 2, and L = 3,5-Me_2pzH, 3(5)-Me-5(3)-PhpzH; n = 1, and L = pyrazole or 3,5-Me_2-4-(p-tolylazo)pyrazole), while Ph_3PAuCl, silver fluoborate, and ligand gave both $[(Ph_3P)Au(3,5\text{-}Me_2pzH)]BF_4$ and $[(Ph_3PAu)_2(\mu\text{-}3,5\text{-}Me_2pz\text{-}N,N')]BF_4$. With iodine the last compound underwent reaction on the bridging μ-azolato ligand yielding $[(Ph_3PAu)_2(\mu\text{-}3,5\text{-}Me_2\text{-}4\text{-}Ipz\text{-}N,N')]BF_4$. The possible structures are discussed on the basis of spectral data (ir; ^1H, ^{13}C, and ^{31}P nmr).

GUIDO BANDITELLI, ANNA LAURA BANDINI, GIOVANNI MINGHETTI et FLAVIO BONATI. Can. J. Chem. **59**, 1241 (1981).

Le déplacement du ligand par un pyrazole sur Me_2SAuCl conduit aux composés L_nAuCl (n = 1 ou 2, et L = 3,5Me_2pzH, 3(5)Me-5(3)PhpzH; n = 1 et L = pyrazole ou 3,5Me_2-4-(p-tolylazo)pyrazole); d'autre façon la reaction de Ph_3PAuCl avec $AgBF_4$ et le ligand conduit soit à $[(Ph_3P)Au(3,5\text{-}Me_2pzH)]BF_4$ soit à $[(Ph_3PAu)_2(\mu\text{-}3,5\text{-}Me_2pz\text{-}N,N')]BF_4$. Par l'action de iode sur le dernier composé se produit une reaction du ligand ponté, avec formation de $[(Ph_3PAu)_2(\mu\text{-}3,5\text{-}Me_2\text{-}4\text{-}Ipz\text{-}N,N')]BF_4$. Les possibles structures sont examinés d'aprés des données spectroscopiques (i.r.; ^1H, ^{13}C et ^{31}P rmn).

Introduction

During our investigation in the field of pyrazole[1] complexes and of pyrazolates, several gold derivatives of the pyrazolato anion were obtained, including the tri-, di-, and mononuclear species **A**, **B**, and **C**, where the ligand is either bi- or monodentate (1). The first type of compound, **A**, was obtained, *inter alia*, through reaction [1]

[1] $Me_2SAuCl + pzH + KOH = (1/n)[Au(pz)]_n + KCl + H_2O + Me_2S$

A reasonable intermediate of the reaction might be a complex of the neutral pyrazole, such as $(pzH)_nAuCl$, formed by displacement of the rather volatile Me_2S ligand. In the case of gold, however, no complex of a neutral pyrazole has been reported up to now, while much work has been carried out on the related copper and silver derivatives.

Indeed, in the case of copper, the published results are abundant, and include complexes with several copper(I) and copper(II) salts (2). Other papers report the copper(II) derivatives of various anionic or neutral substituted pyrazoles, such as polypyrazolylborates (3), bis-(1-pyrazolyl)methane (4), indazole and 5-aminoindazole (5), and even the ligand $(Ph_2PCH_2)_2Pt(3,5\text{-}Me_2pz\text{-}N)_2$ (6).

Many other data are available and include: spectra (7, 8), X-ray data (9), stability constants (10), enthalpies of dissolution and of formation (11), polarographic studies (12), the thermal behaviour of $Cu(PzH)_4(SO_4)\cdot H_2O$ (13), magnetic data (14), and the extraction of the metal by pyrazoles from acid solutions (15).

Much less work is available on silver derivatives of pyrazoles (2*b*, 2*c*, 5, 16–18) which include species such as $(pzH)_2Ag^+$ (19) or $[Ag(pz)]_n$ (20); some electrochemical investigations were also published (17, 19).

In the case of gold, the only published work concerns the use of 1-phenyl-3-methyl-4-fluoroacetylpyrazol-5-one in the extraction of gold(III) from irradiated platinum (21).

In this paper we report the first gold derivatives having neutral pyrazoles as ligands and some related compounds.

Results and Discussion

The complexes reported in this paper belong to three types: (*a*) neutral complexes with one pyrazole ligand, $[(pzH)AuCl]_m$ (**I**, **II**, **III**, and **IV**); (*b*) complexes with two molecules of pyrazoles, $(pzH)_2AuCl$ (**V** and **VI**), and (*c*) ionic, bicoordinated derivatives $[(Ph_3P)Au(pzH)]BF_4$ (**VII**). In addition, two new pyrazolato complexes of the type $[(Ph_3P)Au(\mu\text{-}pz)Au(PPh_3)]^+$ (**VIII** and **IX**), where the said anion is bridging, were identified during this investigation.

The complexes of the first type were obtained

[1]1-Unsubstituted pyrazole ($C_3H_4N_2$) is indicated by PzH, while pzH represents a pyrazole on which substituents may be present (e.g.: 3,5-Me_2pzH is 3,5-dimethylpyrazole).

A B C

according to reaction [2]:

[2] $Me_2SAuCl + pzH = Me_2S + (1/m)[(pzH)AuCl]_m$

A few hours reflux in methylene chloride was required to displace the volatile dimethylsulphide. The reaction occurred with pyrazole, 3,5-Me_2-, 3,5-Me_2-4-(*p*-tolylazo)-, and 3(5)-Me-5(3)-PhpzH, yielding the complexes **I**, **II**, **III**, and **IV**, respectively, while when an electron-withdrawing substituent was present on the pyrazole ring, e.g. 3,5-Me_2-4-NO_2pzH (pK_{acid} 10.65 (22)), no adduct could be isolated, at least in the same conditions. In the case of 3(5)-Me-5(3)-PhpzH, the formation of the 1:1 adduct **IV** was accompanied by that of a 2:1 adduct, $(pzH)_2AuCl$, **V**. The latter, as well as the compound **VI**, could properly be obtained alone by carrying out the reaction with a ligand/Au ratio of two.

All the compounds (Table 1) are white solids (except **III**, yellow) which can be crystallized from organic solvents when freshly prepared. After standing for a few weeks, the 1:1 adducts may become insoluble, although, at least in the case of **I**, no change is observed in the infrared spectrum (4000–250 cm^{-1}). The analytical, spectroscopic, and conductivity data are reported in Tables 1–5 and at the end of the Experimental section.

The ionic compound containing two different neutral ligands, $[(Ph_3P)Au(3,5\text{-}Me_2pzH)]BF_4$, **VII**, was isolated as a by-product upon addition of the pyrazole to the CH_2Cl_2 extract obtained, after removal of AgCl, from the reaction of Ph_3PAuCl with silver fluoborate in methanol. The main product of the reaction was found to be $[(Ph_3P)Au(\mu\text{-}3,5\text{-}Me_2pz)Au(PPh_3)]BF_4$, **VIII**, i.e. a derivative of the bridging pyrazolato anion. In agreement with the behaviour of the species $[Au(\mu\text{-pz-}N,N')]_3$, **A**, previously observed (1), the sequence Au(μ-pz-*N*,*N*′)Au seems to be remarkably stable: indeed, the reaction of the complex **VIII** with iodine affords the corresponding 4-iodosubstituted derivative, **IX**, through an unusual reaction of a bridging ligand. In the phosphine containing compounds **VII** and **VIII** the coordination of the gold atoms is two: the complexes are 1:1 electrolytes in acetone solution, and both the ir spectrum in the solid state and the ^{19}F nmr spectrum (complex **VIII**) are in agreement with an uncoordinated tetrafluoborate anion (T_d). The ^1H (and ^{31}P) spectrum of the complex **VIII** shows unambiguously the presence of a symmetrically substituted exobidentate (i.e. bidentate and bridging) pyrazolato ligand.

The isolation of the compound **VIII** in the absence of any added alkali requires some comment. A scrutiny of the literature has revealed other cases where a (coordinated) pyrazole loses the 1-proton in apparently neutral conditions. Thus pyrazolato derivatives were obtained from the reaction of a diglyme solution of pyrazole complexes of copper(II) and elemental copper (2*c*), or from the reaction (23) between palladium(II) acetate and 3,5-Me_2pzH (pz′H). Furthermore, even in an acid medium, that is during attempted protonation with fluoboric acid of $Ph_3PAu(pz'')$ (pz″H = 3,5-Me_2-4-NO_2-pyrazole) a proton-free dimeric cation resulted, namely $[(Ph_3P)Au(\mu\text{-}pz'')Au(PPh_3)]^+$ (1). In the absence of contrary evidence, these reactions may be written as follows:

$$Cu(pzH)_4^{2+} + Cu = (2/n)[Cu(pz)]_n + 2pzH_2^+$$

$$2Pd(OAc)_2 + 4pz'H = [(pz'H)(AcO)Pd(\mu\text{-}pz')]_2 + 2AcOH$$

$$2Ph_3PAu(pz'') + 2H^+ = [(Ph_3P)Au(\mu\text{-}pz'')Au(PPh_3)]^+ + pz''H_2^+$$

The easy occurrence of deprotonation might be related to an increase, upon coordination, of the acidity of the N–H group. The donor bond from the nitrogen to the metal removes electron density from the ligand: the extent of the electron shift could be measured by the variation of the chemical shift in the ^{14}N nmr spectrum of the free and metal-coordinated pyrazole. Although such an experiment is out of our reach at the moment, recent data (24) on the ^{14}N nmr spectra of free and protonated pyrazole (i.e. coordination of H^+ instead of M^+) support this view.

The monomeric complexes of the type *b*, $(pzH)_2AuCl$, are an uncommon example of gold(I)

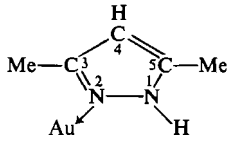
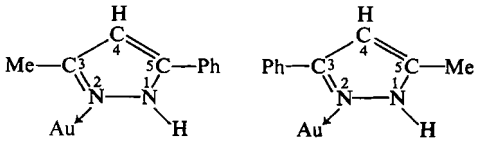
compounds stabilized by two neutral nitrogen ligands. Since they are non-electrolytes and are monomers in chloroform, they are likely to be three coordinated, at least in this solvent. Although their ir spectra (solid state) in the NH stretching region might suggest the presence of uncomplexed pyrazole, and although one of the two coordinated azoles is easily removed by donor solvents (see Experimental), the ^1H and ^{13}C nmr spectra in chloroform solution rule out a relevant amount of dissociation according to reaction [3]:

[3] $(pzH)_2AuCl = (1/m)[(pzH)AuCl]_m + pzH$

On the other hand the complexes do not display any tendency to coordinate further molecules of ligands to afford species such as $(pzH)_3AuCl$, as shown by the ^{13}C nmr spectrum of the mixture (1:1) of the compound **V** and of the ligand, where signals due to each component — and no averaged spectrum — are observed. In the ^1H and ^{13}C spectra of the complex **VI**, different signals are observed for the 3-Me and the 5-Me protons and for the C-3 and C-5 nuclei, respectively.



By analogy with the assignments made possible by $J(^{195}Pt\text{-}H)$ in the $[(Ph_2PCH_2)_2Pt(3,5\text{-}Me_2pzH\text{-}N)_2]^{2+}$ cation (25), in the ^1H nmr spectrum the signal at higher field is likely to be due to the 3-Me, the other one to the 5-Me group. In the case of the complex **V**, $(3,5\text{-}MePhpzH)_2AuCl$, the ^1H nmr spectrum shows two different methyl signals (partially overlapping, ca. 7:1), suggesting that both the possible coordination modes are present:



Thus, both the three coordinated species, **V** and **VI**, do not exhibit in the nmr time scale a dynamical behaviour, which, on the contrary, is observed in the case of the phosphine containing complex $[(Ph_3P)Au(3,5\text{-}Me_2pzH)]BF_4$, **VII**, as well as in pyrazole derivatives of other elements (26).

The 1:1 adducts of the type *a*, $[(pzH)AuCl]_m$, are likely to contain two coordinate gold(I), in agreement with the presence of a band at ca. 340 cm^{-1}, assigned to the terminal Au—Cl stretching vibration. However, the molecular weight determi-

nations in chloroform solution show that the molecules do associate, independent support coming from the presence of two equally intense N—H signals in the proton nmr spectrum of **II** ($CDCl_3$ or CD_2Cl_2). The obvious possibility is that association occurs through hydrogen bond between N—H and a chlorine atom, but a simple intermolecular hydrogen bond to give extended chains is not supported by change upon dilution either in the infrared (3500–3000 cm^{-1}) or in the proton nmr spectrum. The nmr spectra of the compounds **II–IV** cannot be used in order to draw conclusions about the ways of attachment of the coordinated pyrazoles owing to the unknown nature of the intermolecular association established in solution. In the absence of additional data, such as an X-ray structure determination or Mössbauer spectra, it is not possible to state which is the structure of the complexes belonging to type *a*. It is remarkable that X-ray structural determinations of complexes of 1-unsubstituted pyrazoles have shown, in all cases (9*a*, 27), the presence of hydrogen bonding, sometimes of a rather uncommon type (28).

Experimental

General techniques and spectroscopic methods have been described previously (25). Analytical and other data are given in Table 1, ^1H and ^{13}C nmr data in Tables 2 and 3, infrared data in Table 4, and conductivity data in Table 5. All the analytical samples were pumped to constant weight (ca. 0.1 Torr, 20°C). Evaporation was always carried out under reduced pressure (water aspirator).

Freshly prepared Me_2SAuCl (29) should preferably be used because aged samples may cause catalytical decomposition with separation of a purple precipitate most likely to be colloidal gold.

While pyrazole was a commercial product, 3,5-dimethyl- (30), 3(5)-methyl-5(3)-phenyl- (31), and 3,5-dimethyl-4-(*p*-tolylazo)-pyrazole (32) were prepared according to the literature methods.

Preparation of the Compounds

(3,5-Dimethylpyrazole) chlorogold(I), II. A dichloromethane solution (50 mL) of (dimethylsulphide)chlorogold(I) (465 mg; 1.58 mmol) and 3,5-Me_2pzH (164 mg; 1.71 mmol) was refluxed for 2 h. The filtered solution was evaporated to dryness; the residue was washed with petroleum ether (50 mL; overnight; under stirring) and the solid (510 mg) was dissolved in diethyl ether (150 mL). Upon concentration to ca. 30 mL the colourless compound **II** (250 mg; 48%) was obtained. Additional compound (151 mg) was obtained upon addition of petroleum ether and concentration of the mother liquor.

The compounds **I**, **III**, and **V** were prepared analogously. The crude compound **III** was obtained by adding petroleum ether (60 mL) to the concentrated reaction mixture (15 mL) and was crystallized by concentration of its chloroform solution. The compound **I** was crystallized from CH_2Cl_2/petroleum ether. The compound **V** (or the compound **VI**) was prepared using a 2:1 ligand/Au ratio, and was isolated by precipitation with petroleum ether; if the precipitation was carried out with diethyl ether, compound **IV** was obtained. The same compound **IV** could also be obtained in the same way as **II** using a ligand/Au 1:1 ratio, but the yield was low because both **V** and unreacted Me_2SAuCl were also present.

(Triphenylphosphine)(3,5-dimethylpyrazole)gold(I) tetra-

VIII	24	MeOH	0.77	91.4

[a]The resistance of a CH_2Cl_2 solution of the compound **II** or of an acetone solution of the compound **III** was too high to be measured.
[b]The acetone solution of the compound is not stable but, in any case, it is not conducting.

fluoroborate, **VII**, and bis[triphenylphosphinegold(I)](μ-3,5-dimethylpyrazolato-*N*,*N'*) tetrafluoroborate, **VIII**. Solid triphenylphosphinechlorogold(I) (460 mg; 0.93 mmol) was added to a methanol solution of silver fluoroborate (181 mg; 0.93 mmol). After 75 min of stirring, the filtered solution was evaporated to dryness. The oily residue was extracted with dichloromethane (80 mL) and 3,5-Me_2pzH (91 mg; 0.95 mmol) was added to the solution. After standing overnight, the solution was concentrated to ca. 20 mL and, upon addition of diethyl ether (50 mL), a precipitate formed slowly (190 mg) which was crystallized from CH_2Cl_2/Et_2O (5 + 50 mL) affording the compound **VIII** (154 mg). The first mother liquor was evaporated to dryness, and the residue was stirred under Et_2O till the oily part disappeared; the crystals (130 mg) present in the resulting solid were hand-picked under a microscope, thus affording the compound **VII**.

Compound ***IX***. To a chloroform solution (20 mL) of the compound **VIII** (73 mg; 0.066 mmol) iodine (16.8 mg; 0.066 mmol) in the same solvent (2 mL) was added. The residue after evaporation was washed with diethyl ether (2 × 50 mL), and filtered, affording **IX** (32 mg), which showed a strong ir absorption at 1050 cm^{-1}, typical of tetrahedral BF_4^- anion.

Additional nmr Data

In addition to the data reported in Tables 2 (^1H) or 3 (^{13}C), compound **VIII** showed in the ^{31}P nmr spectrum one signal at 31.55 ppm downfield from external 85% H_3PO_4, and in the ^{19}F nmr spectrum a signal at 154.8 ppm upfield from internal $CFCl_3$; both spectra were recorded in $CDCl_3$ solution at room temperature and were decoupled.

Reactions of phthalans with dienophiles. III. Formation of homoquinones by reaction of 1,1-diethoxyphthalans with quinones

LUIS CONTRERAS, DAVID B. MACLEAN, ROMOLO FAGGIANI, AND COLIN J. L. LOCK

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 26, 1980

LUIS CONTRERAS, DAVID B. MACLEAN, ROMOLO FAGGIANI, and COLIN J. L. LOCK. Can. J. Chem. **59**, 1247 (1981).

Treatment of 1,1-diethoxyphthalan with 1,4-benzoquinone gave the homoquinone, ethyl 2-[(1′R*,6′S*,7′S*)-2′,5′-dioxo-3′-norcaren-7′-yl]benzoate, **3**, instead of an anthracene derivative expected of a normal cycloaddition reaction. The structure of the homoquinone was deduced from an examination of its spectroscopic properties (ir, ^{1}H nmr, and ^{13}C nmr) and verified by an X-ray crystallographic study. The homoquinone, **3**, is triclinic, $P\bar{1}$, with $a = 10.601(2)$, $b = 10.434(3)$, $c = 6.491(3)$ Å, $\alpha = 105.53(3)$, $\beta = 95.21(2)$, $\gamma = 100.66(2)°$ and has two formula units per unit cell. The crystal structure was determined by direct methods and refined to $R_1 = 0.059$, $R_2 = 0.048$, based on 2378 independent reflections. The data set was obtained using a Syntex $P2_1$ diffractometer and MoKα radiation. Bond angles and distances within the molecule are normal. Homoquinones were also isolated as major products of reaction of 1,1-diethoxyphthalan and 5,6-dimethoxy-1,1-diethoxyphthalan with 1,4-benzoquinone and 1,4-naphthoquinone. A mechanism for the formation of homoquinones is offered that involves the same type of transient intermediates proposed for the reactions of 1,1-diethoxyphthalans with activated acetylenes and ethylenes.

LUIS CONTRERAS, DAVID B. MACLEAN, ROMOLO FAGGIANI et COLIN J. L. LOCK. Can. J. Chem. **59**, 1247 (1981).

La diéthoxy-1,1 phtalane réagit avec la benzoquinone-1,4 en donnant l'homoquinone, soit le [(1′*R**,6′*S**,7′*S**)dioxo-2′,5′-norcarène-3′ yl-7′]-2 benzoate d'éthyle (**3**) au lieu du dérivé de l'anthracène attendu dans une réaction normale de cycloaddition. On a déduit la structure de l'homoquinone à partir de ses spectres (ir, rmn du ^{1}H et du ^{13}C) et on l'a vérifié par diffraction de rayons-X. L'homoquinone **3** est triclinique, $P\bar{1}$, avec $a = 10{,}601(2)$, $b = 10{,}434(3)$, $c = 6{,}491(3)$Å, $\alpha = 105{,}53(3)$, $\beta = 95{,}21(2)$, $\gamma = 100{,}66(2)°$ et deux unités par maille. On a déterminé la structure du cristal par des méthodes directes et on l'a affinée jusqu'à des valeurs de $R_1 = 0{,}059$ et de $R_2 = 0{,}048$ en se basant sur 2378 réflexions indépendantes. On a obtenu l'ensemble des données en utilisant un diffractomètre de type Syntex $P2_2$ et une radiation MoKα. Les angles et les longueurs de liaison de la molécule sont normaux. L'homoquinone est également le produit principal de la réaction du diéthoxy-1,1 phtalane et des diméthoxy-5,6 diéthoxy-1,1 phtalane avec la benzoquinone-1,4 et la naphtaquinone-1,4. On propose un mécanisme de la réaction de formation de l'homoquinone qui fait intervenir des intermédiaires semblables à ceux dont l'existence a été proposée dans les cas des réactions des diéthoxy-1,1 phtalanes avec les acétylènes et éthylènes activés.

[Traduit par le journal]

In two previous papers in this series (1, 2) phthalans have been shown to react with acetylenic and ethylenic dienophiles to yield substituted naphthalenes or dihydronaphthalenes. In its reaction with activated acetylenes and ethylenes it has been proposed that 1,1-diethoxyphthalan **1** yields, on heating, an isobenzofuran as a transient intermediate which undergoes cycloaddition reactions with dienophiles (Scheme 1). In an extension of this study to carbocyclic dienophiles we treated 1,1-diethoxyphthalan with *p*-benzoquinone. Instead of the anthracene derivative expected from a cycloaddition reaction we isolated a new compound which proved to be a homoquinone derivative (3–5). The structure of this compound (**3**, $C_{16}H_{14}O_4$, formed in 30% yield) was assigned on the basis of its spectroscopic properties (ir, ^{1}H nmr, ^{13}C nmr) and confirmed by an X-ray crystallographic investigation (*vide infra*).

The ir spectrum of **3** showed two carbonyl bands, one at 1715 cm^{-1} assigned to a conjugated ester, and the second at 1685 cm^{-1}, assigned to the two carbonyl groups in the enedione system (6). The presence of an ester function was the first indication that the reaction product was not an anthracene derivative.

The ^{1}H nmr spectrum of **3** showed peaks at 1.37 δ (t, 3H) and 4.38 δ (q, 2H) corresponding to the methyl and methylene groups, respectively, of an ethoxy group in an ester function. The absorption of the methine protons, H-1′ and H-6′, was assigned to a doublet at 2.83 δ ($J = 5.4$ Hz). The methine proton at H-7′ appears as a triplet at 4.02 δ ($J = 5.4$ Hz) because of coupling to the equivalent protons, H-1′ and H-6′. The equivalence of H-1′ and H-6′ is attributed to the fact that the molecule has a symmetry plane that bisects the cyclopropane ring when the aromatic ring adopts a conformation that is at right angles to the homoquinone system. The configuration of the cyclopropane ring was assigned on the basis of the value of the coupling constant between the equivalent protons H-1′ and H-6′ and the proton of H-7′. In analogous systems, Yogev *et al.* (5) have reported values for J_{cis} in the range 9.3–10.0 Hz, and J_{trans} in the range 5.0–5.4 Hz. Clearly the coupling observed in **3** is consistent only with a *trans* relationship between the equivalent protons, H-1′ and H-6′, on the one

0008-4042/81/081247-10$01.00/0

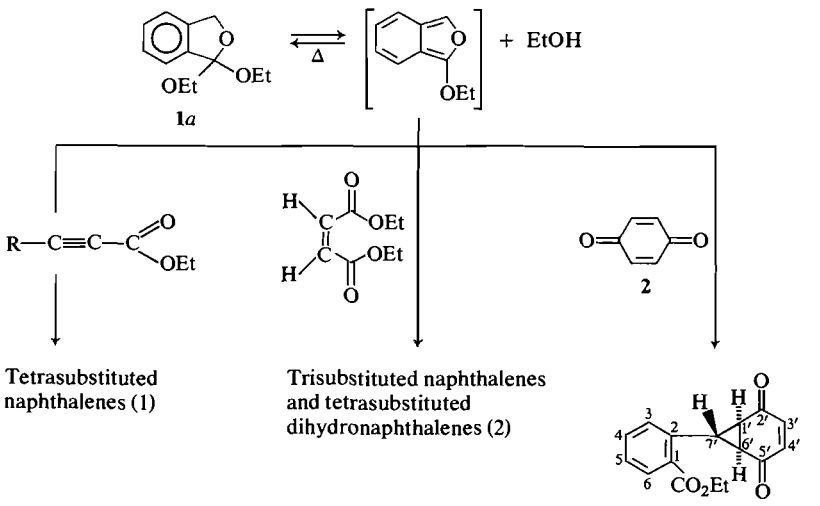

SCHEME 1

hand, and H-7′ on the other. The olefinic protons of the enedione appeared as a singlet at 6.60 δ. The aromatic protons showed two multiplets, the first centred at 7.40 δ of area 3 attributed to H-3, H-4, and H-5 and the second of area one at 8.05 δ attributed to H-6.

In the ^{13}C nmr spectrum of **3** there were four signals in the aliphatic region. The resonances at 61.5 (t) and 14.3 (q) δ, were assigned, respectively, to the methylene and methyl carbons of the ethoxy group. Two other signals at 35.8 and 36.6 δ were assigned to C-1′ and C-6′ and C-7′, respectively. The lower field signal was the more intense and assigned therefore to the two equivalent carbon atoms at C-6′ and C-7′. The signal at 138.0 δ (d) was attributed to the two ethylenic carbon atoms at C-3′ and C-4′ and that at 193.5 δ to the two carbonyl groups of the enedione. The ester carbonyl resonated at 166.4 δ. Other signals, attributed to aromatic carbon atoms appeared at 127.0 (d), 128.0 (d), 131.5 (d), 131.5 (s), 132.5 (d), and 137.3 (s) but have not been definitively assigned.

The spectroscopic data indicated strongly that **3** has the structure illustrated in Scheme 1 and this was verified through an X-ray crystallographic study described later.

The reactions of other quinones with phthalans have been investigated. Thus, when **2** was treated with **1*b*** the major product of reaction was homoquinone **4** accompanied by a small amount of its isomer **5**. Next we examined the reaction of 1,4-naphthoquinone **6** with both **1*a*** and **1*b*** and again homoquinones were formed as major products of the reaction. Two isomeric homoquinones **7** and **8** were obtained from the reaction of **1*b*** and **6** while homoquinone **9** and 2-(2′-carboethoxybenzyl)-1,4-naphthoquinone **10** were isolated from the reaction of **1*a*** with **6**. The structures of the homoquinones were deduced from a knowledge of their compositions and by comparison of their spectroscopic properties with those of **3** of established structure and relative configuration.

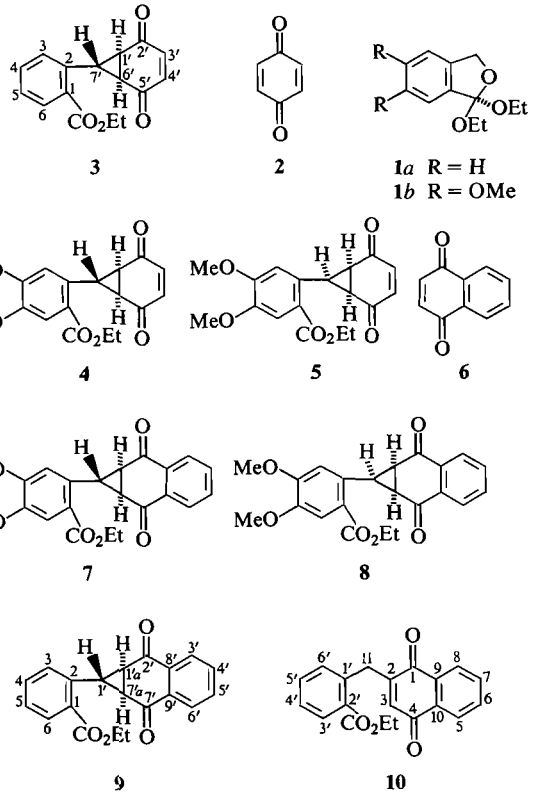

TABLE 1. ^{1}H nmr chemical shifts and coupling constants of the cyclopropyl protons of *p*-homoquinones

Compound	H-1′,6′	H-7′	H-1′a,7′a	H-1′	Coupling constant (Hz)

5	2.87	3.55			$^3J_{1',7'}$	9.0*
7			2.96	3.83	$^3J_{1',7'a}$	5.3†
8			3.10	3.70	$^3J_{1',7'a}$	9.8†
9			3.01	3.85	$^3J_{1',7'a}$	5.3†

*$J_{1',7'} = J_{6',7'}$
†$J_{1',7'a} = J_{1'1'a}$

The infrared spectra of compounds **4**, **5**, **7**, **8**, and **9**, like the spectrum of **3**, showed two characteristic bands in the carbonyl region, the first in the range 1710–1725 cm^{-1}, attributed to the ester group, and the second in the range 1675–1685 cm^{-1}, ascribed to the two carbonyl groups of the enedione system (6). The ^{1}H nmr spectrum of **3** has already been discussed in detail and is used as a reference compound in making assignments to the new homoquinones. The resonances of the cyclopropyl protons of **3** are recorded in Table 1 along with those of other homoquinones prepared in this study. It is evident from examination of this table that compounds **4**, **7**, and **9** have the same relative configuration of protons about the cyclopropane ring and that this corresponds to the *trans* arrangement of the benzylic proton to the bridgehead protons as already established for **3**. Compounds **5** and **8** on the other hand have the *cis* arrangement. The coupling constants of similar systems have been examined previously (5, 7, 8) and are in accord with these assignments. The ^{13}C nmr spectra in the cyclopropyl region and in the carbonyl region were also examined and the resonances are recorded in Table 2. Again it is evident that there is a high degree of correspondence among the five compounds examined. Other ^{1}H and ^{13}C resonances of the compounds are listed in the Experimental and assignments made where justified. From these data it is evident that the five new compounds of this study are phenyl substituted homoquinones that carry an *ortho* carboethoxy group on the phenyl ring. Two of them, **5** and **8**, differ from the others in the stereochemistry of the cyclopropane ring. Other differences are a consequence of the starting materials employed.

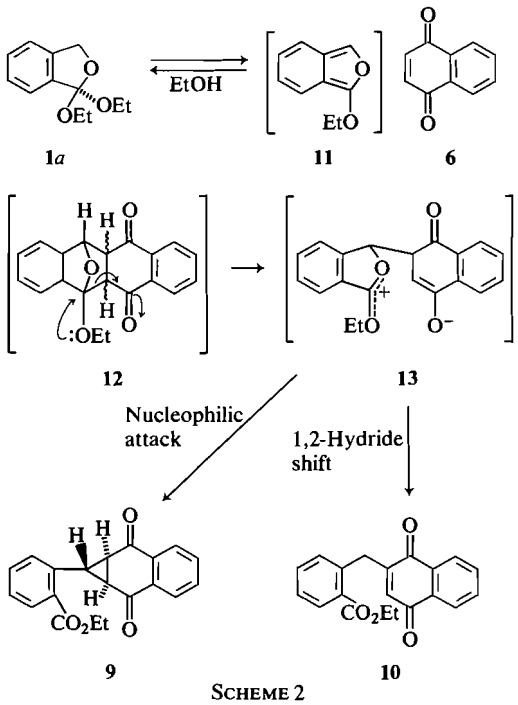
TABLE 2. ^{13}C nmr chemical shifts of *p*-homoquinones*

	Compound				
Carbon	**3**	**4**	**7**	**8**	**9**
*CO*OEt	166.4	166.2	166.8		166.8
C-2′,5′	193.5	193.5			
C-2′,7′			193.3	193.0	192.2
C-1′,6′	35.8	36.0			
C-7′	36.3	36.8			
C-1′a,7′a			36.7	34.0	36.4
C-1′			36.4	34.4	36.0

*The two bridgehead carbons were differentiated from the benzylic carbon in all cases on the basis of signal intensity.

Compound **10** shows an ir absorption in the carbonyl region similar to the homoquinones but is readily differentiated from them on the basis of nmr data. The ^{1}H nmr spectrum of **10** has a number of signals which are similar to those of **9**. The methyl and methylene protons of the carboethoxy group appear at 1.28 and 4.26 δ, respectively. The aromatic region has three multiplets, the first is centered at 7.41 δ for 3H, the second at 7.73 δ for 2H, and the third centered at 8.10 δ for 3H. The major difference between **10** and **7**, **8**, and **9** is the absence of signals associated with the cyclopropane ring and the appearance of two new signals. The first is at 4.30 δ of area 2 and the other at 6.28 δ of area 1H, both of which showed a small coupling. Irradiation of the 4.30 peak produced a sharpening of the signal at 6.28. This suggests the presence of allylic coupling between the olefinic proton at 6.28 δ and the benzylic methylene protons at 4.30 δ. The presence of a methylene carbon atom was confirmed by the ^{13}C nmr spectrum of **10** which showed a signal at 34.3 ppm. This signal appeared as a triplet in the off-resonance spectrum. The aliphatic region also showed signals for the methyl and methylene carbon atoms of the ethoxy group at 14.2 and 61.0 ppm, respectively, but no other signals were present. The low field region had three signals; the first at 166.8 ppm corresponding to the carbonyl carbon atom of the ester group, and the other two at 185.0 and 185.2 ppm attributed to the nonequivalent naphthoquinone carbonyl carbon atoms. The remaining signals for the aromatic and the vinyl carbon atoms are listed in the Experimental but not assigned.

The formation of the products discussed above can be rationalized on the basis of the reactions outlined in Scheme 2 in which the reaction between



1*a* 11 6

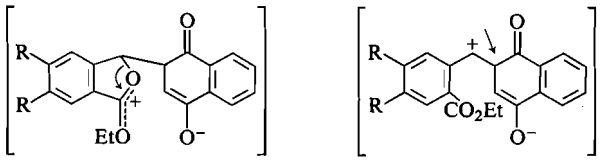
12 13

9 10

SCHEME 2

1*a* and **6** is depicted. Intermediate **11** is considered to add to the quinone in a normal manner yielding **12**. The intermediate **12** may then undergo simultaneous C—C bond cleavage and enolization to form the zwitterion **13**. This may collapse to **10** by a 1,2 hydride shift with simultaneous C—O bond cleavage. Alternatively, this zwitterion may undergo intramolecular nucleophilic substitution by attack of the enol at the benzylic carbon atom to give *cis* ring fused *p*-homoquinone **9**. The major isomer in these reactions has the benzylic hydrogen *trans* to the bridgehead hydrogens. This would be the result expected if the adduct **12** had the *endo configuration. A cis* arrangement of all hydrogens would be the result from an *exo* adduct undergoing a similar series of reactions.

Another possible route to products beginning from **13** is outlined in Scheme 3. In this case, it is proposed that **13** is transformed to zwitterion **14***a* or **14***b*. The intermediate **14***a* may then collapse by



13*a* R = H
13*b* R = OMe

14*a* R = H
14*b* R = OMe

14*a* → **9** + **10**
14*b* → **7** + **8**

SCHEME 3

1,2 hydride shift and ketonization to **10** or by attack of the enolic carbon at the benzylic carbon to homoquinone **9**. In the case of **14***b*, collapse to a mixture of **7** and **8** would occur. The *trans* isomer is sterically less crowded than the *cis* isomer and would be expected to predominate. Thus, there would be no dependence of the isomer ratio on the original *endo–exo* ratio in the addition of **11** to **6**.

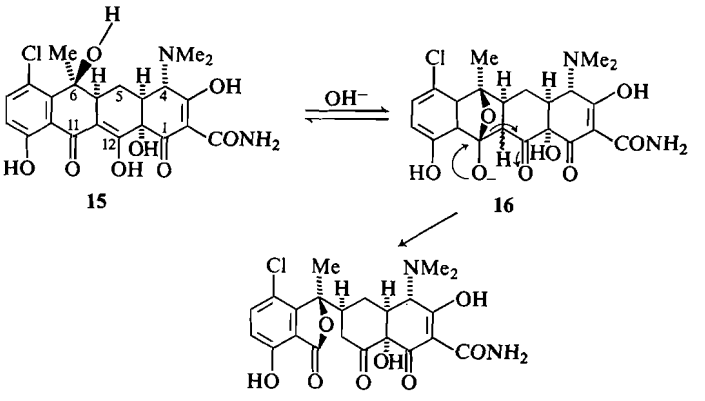
Similar types of C—C bond cleavage, followed by enolization as shown in Scheme 2, have been reported before. For example, it is known that compounds in the tetracycline family such as chlorotetracycline **15** (Scheme 4) undergo rearrangement to phthalide derivatives called isotetracyclines, e.g. isoaureomycin **17**, when they are treated with aqueous base under mild conditions (9). The rearrangement is initiated by nucleophilic attack of the C-6 hydroxy group on the C-11 ketone to give the hemiketal intermediate **16**. This intermediate now undergoes C—C bond cleavage and enolization to isoaureomycin **17**.

Another example comes from the work of Eugster and Bosshard (10) who have reported that the addition of furan to acetyl-1,4-benzoquinone yields an unexpected product **18**. The formation of **18** can be explained by a rearrangement of normal adduct in its enol form as shown in Scheme 5.

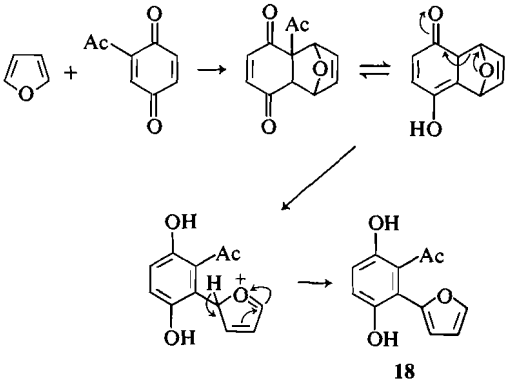
From the two examples given above, it is apparent that the intermediates proposed for the two reactions of Scheme 4 and 5 are related to the intermediate **12**. All the intermediates are unstable and undergo C—C bond cleavage accompanied by enolization in a retroaldol manner.

The possibility that the formation of the compounds **3**, **4**, **5**, **7**, **8**, **9**, and **10** might involve a carbene intermediate was also considered. Hamaguchi and Ibata (11) had already proposed an interrelationship between a carbene and an isobenzofuran. In this case, intermediate **19**, in equilibrium with **11**, might undergo C=C bond insertion to yield the *p*-homoquinones or C—H bond insertion, to give the compound **10**. In order to test for the presence of **19**, trapping experiments with cyclooctene and 1-phenyl-1-propyne were carried out. However, no reaction was found to occur when **1***a* and cyclooctene or **1***a* and 1-phenyl-1-propyne were heated together under a variety of conditions.

The reactions described here provide a new route to phenyl substituted homoquinones carrying an *ortho* carboethoxy group. Such compounds would be difficult to obtain by routes previously described. Because of the unusual nature of this reaction it was considered desirable to verify the structure of **3** through an X-ray study.



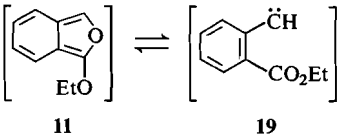
SCHEME 4



SCHEME 5

The structure of **3** derived from the X-ray study is illustrated in Fig. 1 and selected interatomic distances and angles are given in Table 3. The *trans* relationship between H(7a) and both H(1a) and H(6a) predicted from nmr spectroscopy is clearly shown. The aromatic ring is not at right angles to the homoquinone system in the crystal. Instead the angle between the aromatic ring and the C(1a)C(6a)C(7a) plane is only 53° (Table 4) and that between the aromatic ring and the C(*i*a) (*i* = 1–6) ring is 34°.

Bond lengths and angles within the ethyl benzoate portion of the molecule compare well with previous results (12–16). The C(11)O(3)O(4) plane is at a dihedral angle of 23° to the aromatic ring. This angle is quite large although values up to 18° (14, 17) have been observed previously. The twist appears to be caused by intramolecular interactions. O(3) is only 3.0 and 3.2 Å from C(1a) and C(2a), respectively, and O(4) is 2.34(5) Å from H(6), and any twist to make the CO_2 unit more nearly coplanar with the aromatic ring will decrease these distances. The short O(4)–H(6) distance may imply a weak intramolecular bonding interaction, C(6)–H(6)–O(4) is 102°. A further weak intermolecular interaction may exist as H(6a) of another molecule is only 2.5 Å from O(3) and the O(6a)–H(6a)–O(3) angle of 161° is consistent with a weak hydrogen bond. The ethyl group is almost coplanar with the CO_2 unit (7.5°) which is the usual arrangement (16).



Distances and angles within the homoquinone part of the molecule also agree well with previously reported values (18, 19). The torsional distortions of the rings are very similar as well (Table 4). The quinone ring adopts a folded book conformation about the C(2a)–C(5a) axis and the dihedral angle (19.4°) is very similar to that observed in homonaphthaquinone (20.0°) (19). Similarly the angles between the cyclopropane ring and the best plane through the quinone ring are identical (83.7°, 83.8°). These angles are greater, however, than was ob-

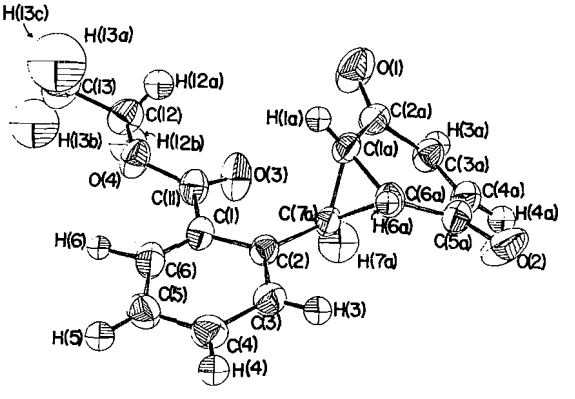


FIG. 1. The molecular structure of ethyl-2-[(1′*R**,6′*S**,7′*S**)-2′,5′-dioxo-3′-norcaren-7′yl] benzoate, $C_{16}H_{14}O_4$.

served in the *anti* form of a homoduroquinone (75.3, 77.3°) (18). Even though the greatest difference between **3** and homonaphthaquinone is shown in the dihedral angle between the planes involving the oxygen atoms (32.7(3)° vs. 37.8(3)°) the actual distance the oxygen is out of the best plane through the quinone ring is very similar (0.500(4) 0.476(4) vs. 0.50(5) Å).

The packing of the molecules is shown in Fig. 2.

In the *c* direction the molecules are arranged such that the basic shapes (defined by the aromatic and quinone rings) are stacked like tiles on a roof. Important contacts between molecules related by the *c* translation are H(6a)....O(3) and H(12b).... phenyl ring. In the *b* direction contacts between molecules related by the *b* translation are between interleaved aromatic and quinone rings, but a further important contact at $y = \frac{1}{2}$ is between ethyl groups of molecules related by the inversion centre at $\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$. In the *a* direction contacts consist of interleaved ethyl groups and quinone rings from adjacent molecules near $x = \frac{1}{2}$, and H(7a) – aromatic ring contacts near $x = 0$. All contact distances are at, or greater than, the van der Waals distances.

Experimental

Apparatus, Methods and Materials

Spectroscopic methods and procedures used in this study are the same as those described in the first paper of this series (1). The X-ray work is described below.

Collection of the X-ray Data

A parallelepiped crystal, homogeneous under the polarizing microscope, was chosen for X-ray studies and mounted roughly along [100]. Precession photographs showed the crystals were triclinic and a Delaunay test showed no hidden symmetry. Unit cell parameters were obtained from a least-squares fit of χ, ϕ, and 2θ for 15 reflections for each compound in the range $21° < 2\theta < 36°$ recorded on a Syntex $P2_1$ diffractometer using graphite-monochromated MoKα radiation (λ 0.71069 Å at 22°C). Crystal

Triclinic, $P\bar{1}$, a = 10.601(2), b = 10.434(3), c = 6.491(1) Å, α = 105.53(3), β = 95.21(2), γ = 100.66(3)°, V = 676.6(4) Å^3, Z = 2, ρ_{calc} = 1.33 g cm^{-3} at 22°C, ρ_{obs} = 1.30(1) g cm^{-3}. Crystal size, 0.20 × 0.15 × 0.25 mm, μ(MoKα) = 1.0 cm^{-1}. Max 2θ = 55° h, $\pm k$, $\pm l$. Standard reflections (esd) $\bar{3}\,2\,\bar{1}$ (1.99%), $\bar{4}\,2\,\bar{2}$ (2.76%). Number of independent reflections 2378, $I > 3\sigma(I)$, 1251, $3\sigma(I) < I < \sigma(I)$, $F_c > F_o$ 445, $3\sigma(I) < I < \sigma(I)$, $F_c < F_o$ 682, R_1 = 0.064, R_2 = 0.054 ($R_1 = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$; $R_2 = \{\Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2\}^{1/2}$. Final shift/error: max 0.23, ave. 0.02; g(secondary extinction) 2.45 × 10^{-6}. Final residual peak: 0.33 e/Å^3, valley: −0.18 e/Å^3. Weighting scheme $\omega = (\sigma_F^2 + (0.020|F_o|)^2)^{-1}$, error in an observation of unit weight 1.238.

Densities were obtained by flotation in an aqueous zinc bromide solution. Intensity data were also recorded on the Syntex $P2_1$ diffractometer using a coupled θ(crystal)–2θ(counter) scan. The methods of selection of scan rates and initial data treatment have been described (20, 21). Corrections were made for Lorentz polarization effects but not absorption. This will make a maximum error in F of < 1.5%.

Solution of the Structure

The phase problem was solved by direct methods using 50 reflections with $|E| > 1.20$ and 12 sets of starting phases. A subsequent E map with 418 most reliable phases yielded all the

*Anisotropic temperature factors U_{ij} were obtained from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where the β_{ij}'s appear as a temperature effect for $\exp[-(\beta_{11}h^2 + \ldots + 2\beta_{12}hk + \ldots.)]$ and b_i and b_j are the reciprocal lattice vectors.

carbon and oxygen atoms. A series of full matrix least-squares refinements followed by three-dimensional difference syntheses revealed all the atoms. In subsequent refinements, the temperature factors of the carbon and oxygen atoms were made anisotropic. Tests were made to show the use of increased number of parameters was justified (22). Refinement using full matrix least squares and minimizing $\Sigma\omega(|F_o| - |F_c|)^2$ was terminated when the maximum shift/error was 0.23. Secondary extinction was applied using the method of Larson (23). Scattering factors were from Cromer and Waber (24). The final positional parameters and temperature factors are given in Table 5.[1] All calculations were carried out on a CYBER 170/730 computer.[2]

*Reaction of 1,1-Diethoxyphthalan 1*a *with 1,4-Benzoquinone 2*

Phthalan **1***a* (1.04 g, 5 mmol) and **2** (540 mg, 5.5 mmol) were heated together for 45 min at 146–148°C under an argon atmosphere. The brown oil was cooled, dissolved in methylene chloride, and filtered through alumina (neutral) to give 380 mg (29%) of colorless crystals that were recrystallized from ethanol (mp 121–122°C). The compound proved to be ethyl 2-[(1′*R**,6′*S**,7′*S**)-2′,5′-dioxo-3′-norcaren-7′-yl]benzoate, **3** and had the following spectroscopic properties. Infrared (ir) ν_{max}: 1715 and 1685 cm^{-1}; ^1H nmr δ: 1.37 (t, 3H, OCH_2CH_3, J = 7.5 Hz), 2.83 (d, 2H, H-1′ and H-6′, J = 5.4 Hz), 4.02 (t, 1H, H-7′, J = 5.4 Hz), 4.38 (q, 2H, OCH_2CH_3, J = 7.5 Hz), 6.60 (s, 2H, H-3′ and H-4′), 7.40 (m, 3H, aromatic), and 8.05 (m, 1H, aromatic). *Exact Mass* calcd. for $C_{16}H_{14}O_4$: 270.089; found (ms): 270.090. *Anal.* calcd. for $C_{16}H_{14}O_4$: C 71.09, H 5.22; found: C 70.87, H 5.28%.

*Reaction of 1*b *with 1,4-Benzoquinone 2*

Phthalan **1***b* (1.3 g, 5 mmol) and **2** (540 mg, 5.5 mmol) were heated together for 10 min at 155°C under an argon atmosphere. The dark oil was cooled, dissolved in methylene chloride, and filtered through neutral alumina to give yellow crystals that were recrystallized from benzene–pentane (800 mg, 42%) mp 191–192°C. The compound was identified as ethyl 4,5-dimethoxy-2[(1′*R**,6′*S**,7′*S**)-2′,5′-dioxo-3′-norcaren-7′-yl]benzoate, **4**, and had the following spectroscopic properties: ir ν_{max}: 1685 and 1710 cm^{-1}; ^1H nmr δ: 1.34 (t, 3H, OCH_2CH_3, J = 7.5 Hz), 2.77 (d, 2H, H-1′ and H-6′, J = 5.3 Hz), 3.97 (s, 6H, 2 × OCH_3), 4.02 (overlapping t, 1H, H-7, J = 5.3 Hz), 4.32 (q, 2H, OCH_2CH_3, J = 7.5 Hz), 6.55 (s, 2H, H-3′ and H-4′), 6.60 (s, 1H, aromatic), and 7.35 (s, 1H, aromatic); ^{13}C nmr[3] δ: (C-1) 123.2, (C-2) 131.3, (C-3) 109.8, (C-4) 152.3, (C-5) 148.3, (C-6) 114.3, (C-1′) and (C-6′) 36.0, (C-2′) and (C-5′) 193.5, (C-3′) and (C-4′) 137.9, (C-7′) 36.8, ($CO_2CH_2CH_3$) 166.2, ($CO_2CH_2CH_3$) 61.4, ($CO_2CH_2CH_3$) 14.3, (2 × OCH_3) 56.2. *Exact Mass* calcd. for $C_{18}H_{18}O_6$: 330.110; found (ms): 330.109. *Anal.* calcd. for $C_{18}H_{18}O_6$: C 65.45, H 5.45; found: C 65.14, H 5.60%.

The mother liquor was evaporated to dryness and the residue (10 mg, 0.5%) was crystallized from ether. The separated solid melted at 115–116°C. It proved to be ethyl 4,5-dimethoxy-[(1′*R**,6′*R**,7′*S**)-2′5′-dioxo-3′-norcaren-7′-yl]benzoate **5**. Infrared ν_{max}: 1680 and 1715 cm^{-1}; ^1H nmr δ: 1.41 (t, 3H, OCH_2CH_3, J = 7.5 Hz), 2.87 (d, 2H, H-1′ and H-6′, J = 9.0 Hz), 3.55 (t, 1H, H-7′, J = 9.0 Hz), 3.80 (s, 3H, OCH_3), 3.87 (s, 3H, OCH_3), 4.39 (q, 2H, OCH_2CH_3, J = 7.5 Hz), 6.18 (s, 2H, H-3′ and H-4′), 6.54 (s, 1H, aromatic), and 7.37 (s, 1H, aromatic). *Anal.* calcd. for $C_{18}H_{18}O_6$: C 65.45, H 5.45; found C 65.07, H 5.65%.

*Reaction of 1*a *with 1,4-Naphthoquinone, 6*

The phthalan (1.04 g, 5 mmol) and **6** (790 mg, 5 mmol) were heated together at 140°C for 20 min under an argon atmosphere. The resulting brown oil (1.6 g) was subjected to column chromatography (silica gel, 160 g) using methylene chloride as eluant. The first fraction (450 mg, 28%) was purified on a Lobar reversed phase chromatography column (acetonitrile–water = 70:30) and crystallized from pentane (mp 82–83°C). It proved to be 2-(2′-carboethoxybenzyl)-1,4-napthoquinone **10** and had the following spectroscopic properties. Infrared ν_{max}: 1675 and 1725 cm^{-1}; ^1H nmr δ: 1.28 (t, 3H, OCH_2CH_3, J = 6.0 Hz), 4.26 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 4.30 (s, 2H, H-11), 6.28 (t, 1H, H-3), 7.41 (m, 3H, aromatic), 7.73 (m, 2H, aromatic), and 8.10 (m, 3H, aromatic); ^{13}C nmr δ: (C-1 and C-4) 185.0 and 185.2, (C-11) 34.3, ($CO_2CH_2CH_3$) 166.8, ($CO_2CH_2CH_3$) 61.0, ($CO_2CH_2CH_3$) 14.2. Other signals observed but not assigned: 126.1, 126.8, 127.4, 130.3, 131.5, 132.5, 133.7, 134.3, 134.9, 138.5. *Exact Mass* calcd. for $C_{20}H_{16}O_4$: 320.104; found (ms): 320.104. *Anal.* calcd. for $C_{20}H_{16}O_4$: C 74.97, H 5.03; found: C 75.07, H 5.20%.

The second fraction from the column was filtered through neutral alumina to remove coloured impurities and crystallized from ether to give colorless crystals that melted at 126–127°C. It was identified as ethyl 2-[(1′*R**,1′a*S**,7′a*R**)-1′a,2′,7′,7a′-tetrahydro-2′,7′-dioxo-1*H*-cyclopropa[*b*]naphthalen-1′-yl]benzoate, **9**. Infrared ν_{max}; 1685 and 1725 cm^{-1}; ^1H nmr δ: 1.28 (t, 3H, OCH_2CH_3, J = 7.0 Hz), 3.01 (d, 2H, H-1′a, and H-7′a, J = 5.3 Hz), 3.85 (t, 1H, H-1′, J = 5.3 Hz), 4.29 (q, 2H, OCH_2CH_3, J = 7.0 Hz) and 7.20–8.20 (m, 8H, aromatic); ^{13}C nmr[4] δ: (C-1′) 36.0, (C-1′a and C-7′a) 36.4, (C-2′ and C-7′) 192.2, (C-3′ and C-6′) 127.2, (C-4′ and C-5′) 134.3, (C-8′ and C-9′) 132.8, ($CO_2CH_2CH_3$) 166.8, ($CO_2CH_2CH_3$) 61.5, ($CO_2CH_2CH_3$) 14.1. Other signals observed but not assigned: 127.9, 131.4, 132.5, 137.2. *Exact Mass* calcd. for $C_{20}H_{16}O_4$: 320.104; found (ms): 320.104. *Anal.* calcd. for $C_{20}H_{16}O_4$: C 74.97, H 5.03; found: C 74.74, H 5.30%.

*Reaction of 1*b *with 1,4-Naphthoquinone 6*

Phthalan **1***b* (1.3 g, 5 mmol) and **6** (790 mg, 5 mmol) were heated together for 10 min at 150°C under an argon atmosphere. The dark oily product was filtered through neutral alumina to give a brown oil (1.4 g) that showed three spots on tlc (silica gel). Crystallization of the oil from acetone–hexane yielded 377 mg (20%) of ethyl 4,5-dimethoxy-2-[(1′*R**,1′a*S**,7′a*R**)-1′a,2′,7′,7′a-tetrahydro-2′,7′-dioxo-1*H*-cyclopropa[*b*]naphthalen-1′-yl]benzoate **7**. It melted at 151–152°C and had the following spectroscopic properties. Infrared ν_{max}: 1680 and 1710 cm^{-1}; ^1H nmr δ:

[1]The table of structure factors has been deposited and is available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[2]Initial data treatment used the programs DATCO5, DATRDN from the XRAY 76 system (25). Most data treatment used programs from the SHELX package (26). Final data treatment used the full matrix least-squares program, CUDLS, and Fourier program, SYMFOU, written internally by J. S. Stephens and J. S. Rutherford, respectively. The least-squares plane program NRC-22 (27) was used. Diagrams were prepared using ORTEP II (28).

[3]It is known from the off-resonance spectrum that the signals at 109.8, 114.3, and 137.9 are doublets and that the signals at 123.2, 131.3, 148.3, and 152.3 are singlets. The signals at 109.8 and 114.3 are shielded by the *o*-methoxy groups and assigned to C-3 and C-6, those at 148.3 and 152.3 are deshielded by the methoxy groups and assigned to C-4 and C-5, while those at 123.2 and 131.3 are assigned to C-1 and C-2. Definitive assignments within the three pairs are not possible but those given are favoured because of observable long range coupling and known substituent effects.

[4]The assignment of signals in the quinone moiety is based on examination of the off-resonance spectrum and on comparison with the published spectrum of 1,4-naphthoquinone (29).

1.26 (t, 3H, OCH_2CH_3, J = 7.5 Hz), 2.96 (d, 2H, H-1′a and H-7′a, J = 5.3 Hz), 3.83 (t, 1H, H-1′, J = 5.3 Hz), 3.90 (s, 3H, OCH_3), 3.96 (s, 3H, OCH_3), 4.23 (q, 2H, OCH_2CH_3, J = 7.5 Hz), 6.68 (s, 1H, aromatic), 7.50 (s, 1H, aromatic), 7.75 (m, 2H, aromatic), and 8.06 (m, 2H, aromatic); ^{13}C nmr[5] δ: (C-1) 123.4, (C-2) 131.3, (C-3) 114.4, (C-4) 152.3, (C-5) 148.3, (C-6) 110.0, (C-1′) 36.4, (C-1′a and 7′a) 36.7, (C-2′ and 7′) 192.3, (C-3′ and 6′) 127.2, (C-4′ and 5′) 134.2, (C-8′ and 9′) 133.0, ($CO_2CH_2CH_3$) 166.3, ($CO_2CH_2CH_3$) 61.4, ($CO_2CH_2CH_3$) 14.3, (2 × OCH_3) 56.2. *Exact mass* calcd. for $C_{22}H_{20}O_6$: 380.125; found: 380.124. *Anal.* calcd. for $C_{22}H_{20}O_6$: C 69.53, H 5.30; found: C 69.73, H 5.54%.

The mother liquors were evaporated to dryness and the residue was subjected to column chromatography (silica gel, 100 g). Starting materials, 64 mg of 1,4-naphthoquinone and 73 mg of 5,6-dimethoxyphthalide, were eluted with methylene chloride, and products (856 mg) with methylene chloride – ether (50:50). Recrystallization of the mixture (856 mg) from acetone–hexane gave 229 mg (12%) of the compound previously described. The mother liquor from this crystallization was removed and the residue (627 mg) showed two spots on tlc (reversed phase, acetonitrile–water = 60:40). A portion of the mixture (3 × 10 mg) was subjected to Lobar reversed phase chromatography using acetonitrile–water (60:40) as eluant. The first fraction (15 mg, 50%) which was crystallized from acetone–pentane had mp 131–133°C. It proved to be ethyl 4,5-dimethoxy-2[(1′*R**,1′a*R**,7′a*S**)-1′a,2′,7′,7′a-tetrahydro-2′,7′-dioxo-1*H*-cyclopropa[*b*]naphthalene-1′-yl]benzoate, **8**, and had the following spectroscopic properties. Infrared ν_{max}: 1675 and 1710 cm^{-1}; ^{1}H nmr δ: 1.45 (t, 3H, OCH_2CH_3, J = 7.5 Hz), 3.10 (d, 2H, H-1′a and H-7′a, J = 9.8 Hz), 3.70 (overlapping t, 1H, H-1, J = 9.8 Hz), 3.70 (s, 6H, 2 × OCH_3), 4.36 (q, 2H, OCH_2CH_3, J = 7.5 Hz), 6.68 (s, 1H, aromatic), 7.08 (s, 1H, aromatic), 7.41 (m, 2H, aromatic), and 7.71 (m, 2H, aromatic); ^{13}C nmr δ: (C-3) 114.5, (C-4) 150.8, (C-5) 148.0, (C-6) 113.5, (C-1′) 34.4, (C-1′a and 7′a) 34.0, (C-2′ and 7′) 193.2, (C-3′ and C-6′) 125.8, (C-4′ and 5′) 133.7, (C-8′ and 9′) 134.0, ($CO_2CH_2CH_3$) 61.6, ($CO_2CH_2CH_3$) 14.3, (2 × OCH_3) 56.0. Signals were not observed for C-1, C-2, and the ester carbon because of low intensity of the spectrum. *Exact Mass* calcd. for $C_{22}H_{20}O_6$: 380.125; found: 380.126. *Anal.* calcd. for $C_{22}H_{20}O_6$: C 69.53, H 5.30; found: C 69.06, H 5.52%.

The second fraction (10 mg, 33%) showed spectroscopic properties similar to those of **7**.

Treatment of **1**a *with Cyclooctene or 1-Phenyl-1-propyne*

The reactions were carried out in sealed nmr tubes using $CDCl_3$ or DMSO-d_6 as solvent. In each case equivalent amounts of **3***a* and cyclooctene or 1-phenyl-1-propyne were used. The solutions were heated in an oil bath at temperatures over the range 120–190°C over a 10 h period. The tubes were examined periodically by nmr but no reaction was found to occur.

Excess enthalpies of aqueous solutions of biuret at 25°C. Interaction with urea

GUIDO BARONE, PASQUALE CACACE, GIUSEPPINA CASTRONUOVO, AND VITTORIO ELIA
Istituto Chimico, University of Naples, Via Mezzocannone 4, 80134 Naples, Italy

Received June 18, 1980[1]

GUIDO BARONE, PASQUALE CACACE, GIUSEPPINA CASTRONUOVO, and VITTORIO ELIA. Can. J. Chem. **59**, 1257 (1981).

The heats of dilution in water of biuret and the heats of mixing of biuret with urea have been determined by flow microcalorimetry at 25°C. The excess enthalpies obtained from the experimental data can be expressed as virial expansions of the molalities.

The value of the cross interaction coefficient h_{UB} is compared to that calculated through the empirical relation $h_{UB}^2 = (h_{UU}h_{BB})$. The agreement between the two values outlines the strict analogy in the behaviour of these two solutes. The cited combining rule, verified up to now for pairs of solutes having both h_{ii}, $h_{jj} > 0$, is here applied for the first time to a pair having h_{ii}, $h_{jj} < 0$.

GUIDO BARONE, PASQUALE CACACE, GIUSEPPINA CASTRONUOVO et VITTORIO ELIA. Can. J. Chem. **59**, 1257 (1981).

Les chaleurs de dilution dans l'eau du biurete et les chaleurs de mélange de biurete avec l'ureé ont été déterminées à 25°C par un calorimétre en flux. Les enthalpies d'excés obtenues par les données expérimentales peuvent être exprimées par une expansion du viriel en molalité. La valeur du coéfficient de l'intéraction croisée, h_{UB}, est comparée à celle évaluée par la règle empirique: $h_{UB}^2 = (h_{UU}h_{BB})$. L'accord trouvé entre les deux valeurs souligne l'analogie du comportement de ces deux solutés.

La régle combinatoriale sus-citée, verifiée jusqu'à présent seulement pour les paires de solutés ayant à la pair h_{ii} et h_{jj} positif, a été appliquée ici pour la premiére fois à une paire ayant h_{ii} et $h_{jj} < 0$.

Introduction

The study of the excess thermodynamic properties is useful to make hypotheses and to test models concerning interactions in solution. In the case of aqueous solutions of nonelectrolytes containing more than one solute, it is convenient to refer to 1 kg of solvent.

The excess enthalpy, then, is defined as:

$$[1] \quad H^E = H - H_w^{\ominus} - \sum_i m_i \bar{H}_i^0$$

where H is the enthalpy of a solution containing 1 kg of water, $H_w^{\ominus}$ is the enthalpy of 1 kg of water, and $\bar{H}_i^0$ is the standard (infinite dilution) partial molar enthalpy of each solute species. The other excess quantities, as for instance the entropy, are defined analogously.

Nonelectrolytes in water can be classified in two groups (1). The first class ($T|S^E| > |H^E|$) groups mainly hydrophobic solutes in water, while the second ($T|S^E| < |H^E|$) deals with hydrophilic solutes. The excess thermodynamic properties of predominantly hydrophobic substances of the amide or urea class have been studied extensively. On the contrary only urea, among the hydrophilic solutes of this group, has been studied in detail (2–6). Recently we studied the aqueous solutions of the predominantly hydrophilic, urea-like substances, monomethylurea (MMU) (7) and thiourea (TU) (8).

In the present paper, the heats of dilution in water of biuret (B), $NH_2CONHCONH_2$, and the heats of mixing of the same substance with aqueous solutions of urea (U) are reported. From the experimental data, the excess enthalpies, referred to 1 kg of water, are obtained. For the binary and ternary solutions they can be expressed through the following virial expansions:

$$[2] \quad H^E(m_i) = h_{ii}m_i^2 + h_{iii}m_i^3 + \ldots$$

$$[2'] \quad H^E(m_i, m_j) = h_{ii}m_i^2 + 2h_{ij}m_im_j + h_{jj}m_j^2 + h_{iii}m_i^3 + 3h_{iij}m_i^2 m_j + 3h_{ijj}m_im_j^2 + h_{jjj}m_j^3 + \ldots$$

The coefficients h_{ij}, h_{iij} characterize the interactions among pairs, triplets, etc., of molecules of the same or different species, according to the McMillan–Mayer approach (9–13). The virial expansions [2] and [2′] can be transformed to analogous expressions, as functions of the molar concentration, which are more appropriate for statistical calculations. The values of h_{BB}, h_{UU}, and h_{BU} outline the strict analogy of the molecular interactions characterizing their aqueous solutions, as a result, in our opinion, of the close similarity between the perturbations induced in water by these two solutes.

Experimental

Biuret (B) and urea (U), C. Erba (Milan) products, were crystallized twice from ethanol and dried *in vacuo* at room temperature. The solutions were prepared by weight using freshly distilled and degassed water. All the dilution and mixing experiments were performed at 25.00 ± 0.02°C. The measurements of the heats of dilution and mixing were performed by an LKB 10700-1 flow microcalorimeter equipped with a pair of gold cells, a Keithley amplifier, and two peristaltic pumps. The experimental procedure was described in preceding papers (7, 8,

[1]Revision received December 30, 1980.

13). The values of ΔH^{dil} from the initial molality m_i to the final molality m_f, expressed in J kg^{-1} of water, can be obtained as follows:

$$[3]\quad \Delta H^{dil}(m_i \rightarrow m_f) = -\frac{(dQ/dt)}{P_1}$$

where dQ/dt is the heat absorbed per time unit in steady state conditions and P_1 is the total mass flow rate of water.

Mixing experiments were carried out by mixing aqueous solutions of B and U at different concentrations in different amounts. The mixing of equimolal solutions might have been employed to simplify the experimental part, but the above described procedure was preferred because of the limited solubility of B, given its relatively large heat of dilution in comparison with that of urea. The heat of mixing, ΔH^{mix}, relative to 1 kg of water in the final solution is given by:

$$[4]\quad \Delta H^{mix}[(m_B)_i, (m_U)_i \rightarrow (m_B, m_U)_f] = -\frac{dQ/dt}{P_1}$$

where m_i and m_f are the initial and final aquamolalities.

Results

The heats of dilution ΔH^{dil}, in J kg^{-1} of solvent and $\Delta\phi_L = \Delta H^{dil}/m_f$ expressed as J mol^{-1} of solute, for biuret in aqueous solutions, are reported in Table 1. Polynomial expansions of $\Delta\phi_L$ as a function of the molalities were used to interpolate the experimental data (14):

$$[5]\quad \Delta\phi_L(m_i \rightarrow m_f) = (1/m_f)\,H^E(m_f) - (1/m_i)\,H^E(m_i) = h_{BB}(m_f - m_i) + h_{BBB}(m_f^2 - m_i^2) + \ldots$$

The degree of the interpolating polynomial, obtained by a least-squares analysis, is chosen as the one for which all the coefficients exceed their own 95 percent confidence limit. According to this criterion, only h_{BB} is significant in the concentration range explored.

The heats relative to the mixing of two binary solutions of B and U, $\Delta H_{UB}{}^{mix}$, are reported in Table 2. To simplify the evaluation of the cross interaction coefficients, the auxiliary function $\Delta H^* = \Delta H_{UB}{}^{dil} - \Delta H_U{}^{dil} - \Delta H_B{}^{dil}$ is used (11, 12).

The enthalpies of dilution for the binary solutions were calculated from eq. [5], by multiplying for the appropriate m_f and using the parameters h_{ii} reported in Table 1 for B and in Table 2 for U. It is possible to correlate ΔH^* and the enthalpic coefficients through the following expression:

$$[6]\quad \Delta H^* = H^E(m_B, m_U) - H^E(m_B) - H^E(m_U) = 2\,h_{UB}m_U m_B + 3\,h_{UUB}m_U{}^2 m_B + 3\,h_{UBB}\,m_B{}^2 m_U + \ldots$$

Equation [6] can be interpolated by a least-squares method. The analysis of the relative confidence limits shows that only the pair interaction coefficient h_{UB} is significant in the concentration range studied. The limited solubility of biuret and, at the same time, its relatively large heat of dilution allowed the exploration of a range of concentration unusually low for nonelectrolytes, without loss of accuracy.

[a]Enthalpic pair interaction coefficient evaluated according to eq. [6] and using $h_{UU} = -350$ (refs. 6, 12): $h_{UB} = -796 \pm 84$ J mol^{-1} (mol kg^{-1})$^{-1}$. The error corresponds to the 95% confidence limit in the value of the coefficient.

Discussion

For aqueous solutions of urea and urea-like solutes, two groups of models have been proposed. The first of them (3, 15–18) assumes the formation of reversible dimers (in some cases, polymers) of

urea. However, the close similarity between the thermodynamic excess properties of urea and thiourea (8) shows that they are not realistic. The second group of approaches focuses the attention on the perturbations induced into the solvent, more than on the direct solute–solute interactions. The first model of this group was a statistical one, developed for dilute solutions. It assumes that the main effect of urea is that of a "statistical structure breaker" (19) of water. It is supported by spectroscopic (20, 21) and nmr (22) evidence. In preceding papers (7, 8), making some hypotheses on the hydration state, we proposed an overall qualitative explanation of the thermodynamic properties of concentrated and moderately concentrated aqueous solutions of urea-like solutes. The main process in these solutions should be the coalescence of the hydration cospheres upon the concentration process. The relaxation of water from the hydration layers to the bulk state, less rich in enthalpy and in entropy, should define the signs of the excess properties.

Among the urea-like solutes, biuret is very interesting. The partial double bond character of C—N and N—C bonds makes the biuret molecule essentially planar (in the monohydrate crystals the angle between the two NH_2–CO–NH– frameworks is about 5° (23)) and partially rigid, even though it is possible to hypothesize a concerted internal rotation around the two mentioned bonds in solution. As in the case of urea, however, the excess thermodynamic properties at 25°C may be interpreted in more than one way. Even for biuret the value of h_{BB} can be due either to a relaxation of water from the cospheres coalescing during the concentration process, or to the formation of one or a pair of H-bonds. The first mechanism does not exclude completely the second one but it seems the most convincing. Friedman and Krishnan have shown, on the other hand, that if the solute–solvent interaction makes the solvent–solvent forces less attractive, the result is a net weak attraction between two solute particles (24). Anyway, the larger values of the pair interaction coefficients for biuret seem to indicate that the degrees of advancement of the involved molecular processes are more extended with respect to urea and other urea-like solutes.

The similarity of the properties of biuret and urea solutions is confirmed by the behaviour of the ternary solutions, which suggests that the same qualitative effects determine the values of all the self and cross parameters. In Table 3 the enthalpic coefficients of the pair interactions for B, U, and their mixtures are reported. Also reported is the

value of h_{UB} predicted by the empirical rule:

$$[7] \quad h_{ij} \simeq -(h_{ii}\, h_{jj})^{1/2}$$

This is a case of the empirical rule $h_{ij}^2 = h_{ii}h_{jj}$ discussed in a preceding paper (25). This rule was first found by Franks (26) for alcohols and seems applicable to all the simple pairs of organic solutes, having both $h_{ii}, h_{jj} > 0$. The pair urea–biuret is, vice versa, a case for which both the coefficients are negative. We pointed out that the rule works better when the solutes i and j are similar and bear groups all perturbing water in the same manner. The close prediction of the value of h_{UB} (the agreement is within 8%) outlines, in our opinion, the strict analogy between the interactions determining the properties of the binary and ternary aqueous solutions of urea and biuret. Also given in Table 3 are the values of h_{ij} evaluated according to the group contribution method, following the same procedure used by Savage and Wood (6) and considering biuret as the sum of an "amide" and of a "urea group". Table 3 also contains the value for the "urea group" recalculated more recently by Wood and Hiltzik (27). Even considering biuret as the sum of two "urea groups" the disagreement was beyond the limits of uncertainty (± 220 J mol^{-1} (mol kg^{-1})$^{-1}$) found by those authors for other substances. We think that this happens because of the partial failure of the additivity principle (which is the base for the validity of the approach). For the excess enthalpy we introduced (25) a relative effectiveness coefficient $b_{i/j} = (h_{ii}/h_{jj})^{1/2}$. This coefficient accounts for the contribution of one mole of solute i in determining the value of H^E with respect to one mole of solute j. On this basis biuret seems to be 2.45 times more effective than urea in determining H^E of aqueous solutions. In our opinion, the value 2.45 found for the coefficient $b_{B/U}$ indicates, for biuret, the existence of a cooperative, intramolecular effect, which enhances its capability of undergoing interactions in these solutions, whatever the actual mechanism. At the same time, the good prediction given by eq. [7] excludes any

specific interaction in the biuret–urea solutions with respect to other urea-like solutions.

Reçu le 2 juillet 1980

Y. UMETSU, D. L. PIRON et G. BÉLANGER. Can. J. Chem. **59**, 1261 (1981).

L'examen microscopique des alliages de NbCo a été réalisé et a permis l'identification des différentes phases. Ces alliages furent évalués vis-à-vis leur comportement pour la réaction du dégagement de l'hydrogène (RDH) à 25°C dans une solution de 25% KOH. On observe une activité accrue par rapport au Nb ou Co pur pour les alliages entre 20 et 70% Co. Cependant cette activité pour la RDH se situe en dessous de l'activité électrocatalytique du Ni pur. Comme pour les alliages NbNi, les alliages NbCo montrent une dégradation importante de leur surface sous une polarisation cathodique prolongée (6 h) à des densités de courant variant entre 400 et 700 mA cm^{-2}. Cette dégradation se manifeste surtout pour les alliages où la teneur en Co est inférieure à 50% en poids. Pour les alliages supérieurs, la surface demeure stable vis-à-vis la RDH. La dégradation de la surface est associée à la présence de la phase δ dans l'alliage: cette phase est la solution solide de Nb.

Y. UMETSU, D. L. PIRON, and G. BÉLANGER. Can. J. Chem. **59**, 1261 (1981).

NbCo alloys were prepared and their composition characterized by optical microscopy. These alloys were evaluated for their electrochemical activity towards the hydrogen evolution reaction (HER) at 25°C in a 25% KOH solution. The alloys between 20 and 70wt% Co showed an increased activity compared to their parent metals. However the activity is below the one observed for pure Ni. As for the NbNi alloys, the NbCo undergo some surface degradation under prolonged (6 h) cathodic polarization at 400–700 mA cm^{-2}. This disintegration of the surfaces is observed for alloys below 50% in Co. Above this proportion, the alloys remain stable towards the RDH. This degradation is associated with the presence of the δ phase in the alloy: this phase is the solid solution of Nb in the alloy.

I. Introduction

Dans la quête de nouveaux matériaux pour l'électrolyse de l'eau en milieu alcalin, le niobium a été étudié par notre groupe (1–5). Le mécanisme du dégagement de l'hydrogène sur le métal pur en milieu alcalin a été démontré (1, 2) et la réaction semble obéir au mécanisme d'Heyrovsky où l'étape déterminante de la réaction est la désorption électrochimique. A la suite de ces travaux, les caractéristiques du niobium (Nb) (3, 4) et des alliages niobium–nickel (Nb–Ni) (5, 6) ont été déterminées vis-à-vis le dégagement de l'hydrogène en milieu alcalin fortement concentré (25% KOH) et à différentes températures.

Afin de continuer notre exploration des alliages du Nb et de tenter de stabiliser la surface, nous avons déterminé l'activité électrocatalytique et la stabilité des alliages Co–Nb. L'activité a été déterminée par les courbes de polarisation de différents alliages et leur stabilité par l'examen microscopique de leur surface avant et après ces polarisations.

II. Technique expérimentale

(a) Préparation des alliages

Les alliages Co–Nb furent préparés à partir de billes de cobalt de 99.9% et de poudre de niobium de même pureté. Les quantités requises furent fondues dans un four à arc sous vide utilisant une électrode de tungstène et un creuset de cuivre refroidi à l'eau. Après refroidissement et solidification, le bouton d'alliage ainsi formé a été retourné et refondu pour assurer une homogénéité complète à l'état solide de l'alliage. Ce procédé de fontes successives fut répété de 2 à 3 fois selon la composition de l'alliage. Après cette première étape les boutons furent chauffés à 1000°C sous vide pendant 24 h et pour ensuite être refroidis dans l'air. De ces spécimens, des électrodes de 5 × 5 × 3 mm furent taillées à la scie diamantée; après la taille, ces électrodes furent recuites à 1000°C sous vide (environ 10^{-6} mm Hg) pendant 10 min.

L'analyse chimique d'échantillons prélevés des boutons a montré que les alliages étaient homogènes et qu'aucune contamination soit de tungstène ou de cuivre n'avait été introduite. L'examen microscopique de la microstructure des alliages n'a pas révélé de ségrégation décelable ni l'existence de constituants non mélangés.

La surface de 5 × 5 mm fut polie sur papier de verre jusqu'à 600 et le polissage fin réalisé avec une suspension d'alumine de 0.05 μ. L'échantillon poli fut monté dans un support de Teflon et les contours isolés avec la colle époxy. Aucun polissage chimique ou électrochimique ne fut tenté pour éviter la dissolution sélective d'une des composantes de l'alliage. Avant chaque courbe de polarisation, la surface de 5 × 5 fut repolie avec la suspension de 0.05 μ d'alumine et lavée à l'eau distillée.

(b) Procédures électrochimiques

L'électrolyte utilisé a été une solution de KOH à 25% par poids. La solution a été désoxygénée avant chaque polarisation pendant 4 h par le barbotage d'hydrogène.

Un montage conventionnel à trois électrodes séparées fut utilisé: l'électrode calomel saturée fut employée comme élec-

trode de référence avec un potentiostat Tacussel PRT20-2X. Une électrode auxiliaire de platine fut utilisée. La procédure potentiostatique à pseudo-équilibre fut utilisée: elle consiste essentiellement à polariser l'électrode de travail à une valeur déterminée pendant 2 min et à enregistrer le courant essentiellement constant à la fin de cet intervalle. La plage de potentiels ainsi balayée a été à partir du potentiel de repos de l'électrode dans le milieu jusqu'à −1.6 V (vs. ECS). La variation de potentiel entre chaque point a été soit 50 ou 25 mV. Les potentiels rapportés dans le texte ont été ramenés vis-à-vis l'électrode normale d'hydrogène (ENH).

Les courbes ainsi obtenues furent corrigées pour la chute ohmique entre l'électrode de travail et l'extrémité du capillaire Luggin à l'aide de la technique d'interruption de courant. L'examen microscopique des surfaces après polarisation fut réalisé pour les alliages de 30, 50 et 70% de Co par rapport à la masse.

III. Résultats

(a) Examen microscopique des alliages préparés

Le diagramme de phases du système binaire NbCo est illustré à la fig. 1 (7). Les alliages préparés furent solidifiés à partir des masses en fusion dans un creuset en cuivre refroidi à l'eau: la vitesse de solidification ne fut pas contrôlée. A la fig. 2, les photos des microstructures des alliages préparés sont présentées: les échantillons ont été attaqués par une solution HF + HNO_3 ($HF:HNO_3:H_2O$: 15:30:55 par volume) après un polissage avec une suspension de 0.05 μ d'alumine. La partie noire de la photo représente la partie riche en Co car cet élément est attaqué par la solution. Les différents échantillons furent analysés par diffraction des rayons-X, la sonde microscopique d'analyse électronique et la microscopie optique. L'alliage 1% Co et le composé intermétallique NbCo furent préparés et utilisés comme échantillons de comparaison standard pour les profils de diffraction des rayons-X. Aucune différence notable n'a été observée entre la surface des échantillons ainsi analysés et le coeur de l'alliage.

(i) Alliage 10% Co–Ni

Cet alliage est composé essentiellement de grains de phase δ (la solution solide de Nb) et une petite quantité de l'eutectique δ–γ (γ étant le composé NbCo). La seconde phase a été décelée à la frontière des grains de la phase γ. Le profil de diffraction des rayons-X laisse apparaître des fortes raies associées au Nb ou à l'alliage 1% CoNb et de faibles raies de la phase γ.

(ii) Alliage 20% Co–Nb (fig. 2a)

Cet alliage est un mélange en quantité comparable de phases δ et γ et d'une faible quantité de l'eutectique NbCo.

(iii) Alliage 30% Co–Nb (fig. 2b)

Cet alliage est constitué principalement de la phase γ et d'une faible partie de phase δ. Cette dernière phase est détectée par le spectre de diffraction des rayons-X.

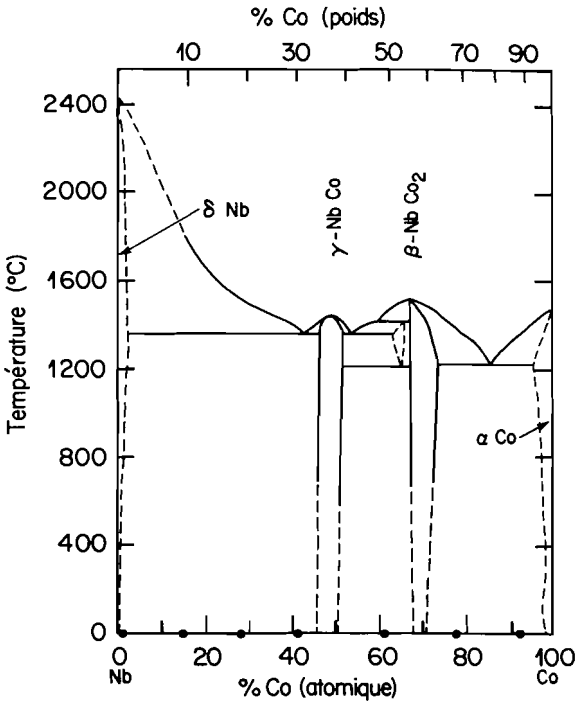

FIG. 1. Diagramme de phase du système Nb–Co d'après Shunk (7); les alliages utilisés dans cette étude sont illustrés en abscisse.

(iv) Alliage 50% Co–Nb (fig. 2c)

De longs grains de la phase γ furent observés; entre ceux-ci, la phase β ($NbCo_2$) a pu être mise en évidence. Aucune raie de la phase δ ne fut décelée.

(v) Alliage 70% Co–Nb (fig. 2d)

Cet alliage est un mélange de grains fins des phases β et α; cette dernière est la solution solide de Co.

(vi) Alliage 90% Co–Nb (fig. 2e)

Cet alliage est constitué essentiellement de la phase α; sur certains endroits de la surface on a pu observer certaine structure orientée de la phase β.

(b) Polarisation cathodique

Les courbes de polarisation du Nb, Co et certains des alliages étudiés sont illustrées à la fig. 3; en plus on inclut la courbe du Ni pour fin de comparaison. Ces courbes sont déjà corrigées pour tenir compte de la chute ohmique. Chaque courbe couvre des densités de courant s'échelonnant entre 10^{-1} à 5×10^2 mA cm^{-2}.

La courbe de polarisation du Co pur se situe entre celle de Nb et de Ni (5); le cobalt est un meilleur électrocatalyseur pour la RDH que le niobium mais moins efficace que le nickel. La fig. 3 montre que certains alliages présentent des surtensions inférieures pour la RDH que le niobium ou le cobalt pur mais sans atteindre le rendement du

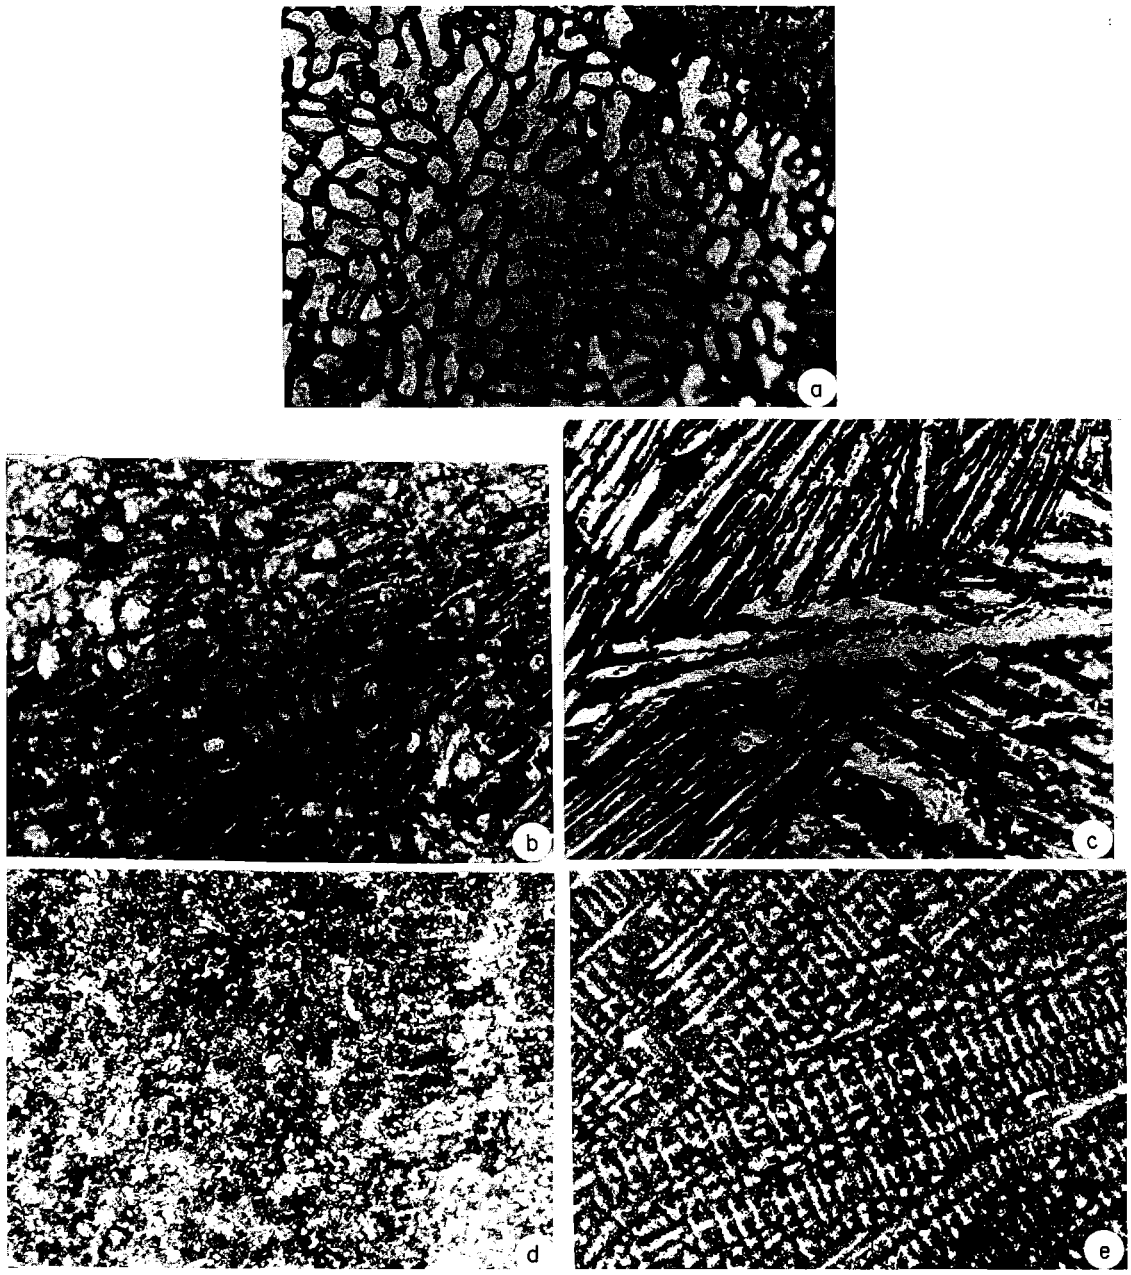

FIG. 2. Photographies microscopiques (grossissement 200 ×) des surfaces des alliages NbCo attaquées par une solution HF, HNO_3: les parties noires sont associées aux phases riches en Co. (*a*) 20% Co; (*b*) 30% Co; (*c*) 50% Co; (*d*) 70% Co; (*e*) 90% Co.

nickel. L'amélioration d'efficacité de la RDH observée précédemment (5) pour l'alliage 30% Ni–Nb ne se retrouve pas avec le cobalt.

Les pentes de Tafel furent évaluées; jusqu'à 20% de Co, les pentes demeurent inchangées à 120 mV par décade. Lorsque la proportion de cobalt augmente, cette pente s'accroît pour atteindre une valeur constante d'environ 140 mV par décade.

La surtension de la RDH pour une densité de courant de 10 mA cm^{-2} a été mesurée et tracée en fonction de la composition des alliages à la fig. 4. La surtension subit une chute importante pour l'alliage 30% Co comme cela avait été observé précédemment dans le cas des alliages Ni–Nb.

Le changement de surface apporté par la polarisation cathodique fut étudié pour les alliages de 30, 50 et 70% Co par la microscopie optique ainsi que la microscopie électronique à balayage. Chaque

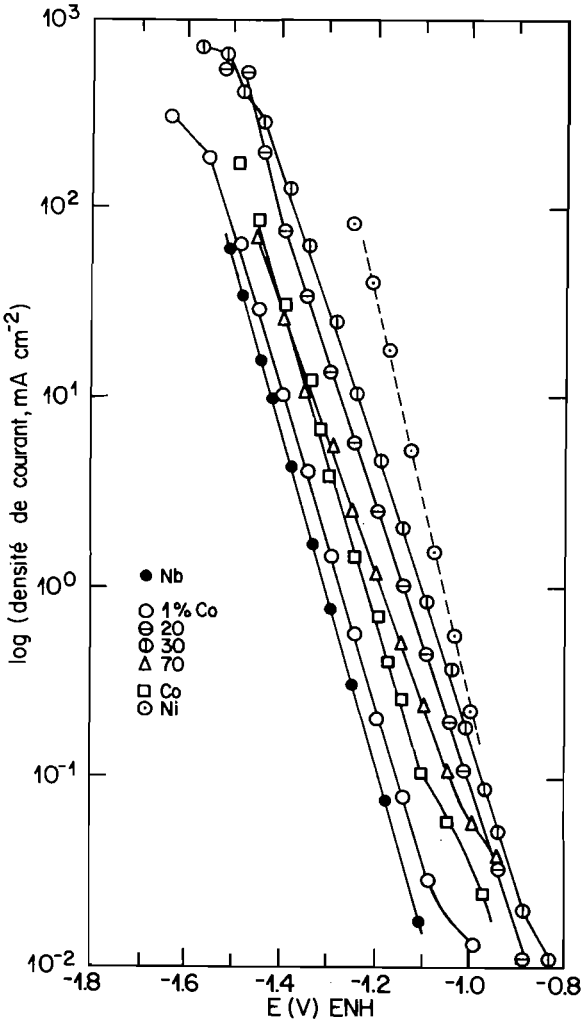

FIG. 3. Courbes de polarisation potentiostatique à l'équilibre du Nb, Ni, Co et des alliages NbCo; 25°C; sous atmosphère d'hydrogène.

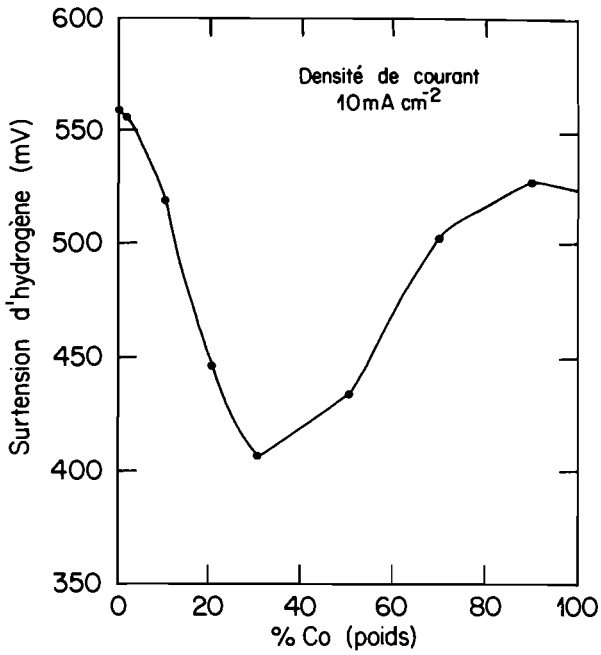

FIG. 4. Variation de la surtension de la réaction du dégagement d'hydrogène (η) en fonction de la composition de l'alliage NbCo à une densité de courant de 10 mA cm^{-2}; $\eta = E_{\text{observé}} - E_{\text{réversible}}$.

spécimen fut porté à une polarisation de -1.55 V vs. ENH pendant 6 h; les densités de courant initiales à ces tensions cathodiques variaient de 400 à 700 mA cm^{-2} selon les alliages.

A la fig. 5, nous présentons les photographies des surfaces ainsi traitées pour l'alliage 30% Co. La surface au cours de l'électrolyse est devenue uniformément noirâtre et après quelques heures, des fissures se sont révélées. A partir des photos micrographiques de la surface (figs 5*a* et *b*), on a observé un film noir sous lequel une couche brune (grise sur les photos) a été décelée. Le film de surface pouvait se détacher facilement. Les figs 5*c*, *d* et *e* sont des images de la microscopie électronique à balayage où des marches sont observées (fig. 5*c*) à la surface et le long de ces marches des fissures apparaissent et se propagent. On remarque que l'extrémité des bordures est retroussée vers l'extérieur (fig. 5*d*). Cette observation peut être associée à une expansion volumétrique importante sous la surface durant la polarisation cathodique. La forme hachurée des fragments des bordures indique la fragilité des films formés à la surface. La fig. 5*e* illustre la surface sous-jacente des films de surface à un endroit où ce film s'est décollé. Compte tenu de la nature amorphe des produits de surface, l'analyse aux rayons-X s'est avérée impuissante à identifier la composition de ces différents produits de désintégration.

Jusqu'à 30% de Co, l'addition de cet élément au niobium induit une fragilisation importante des alliages durant la polarisation cathodique. Au-delà de cette concentration, la génération et la propagation des fissures sont à toute fin pratique supprimées. Les surfaces des alliages 50 et 70% Co soumises à la polarisation cathodique décrite plus haut passent d'un fini lustré métallique à une apparence noire mate mais sans fissure. La couche de surface consiste en un produit poudreux et fin. Aux endroits où cette poudre a été balayée, on retrouve la surface métallique d'origine.

Des coupes transversales des alliages de 20% et 30% polarisés cathodiquement sont illustrées à la fig. 6. L'alliage à 20% montre une structure très

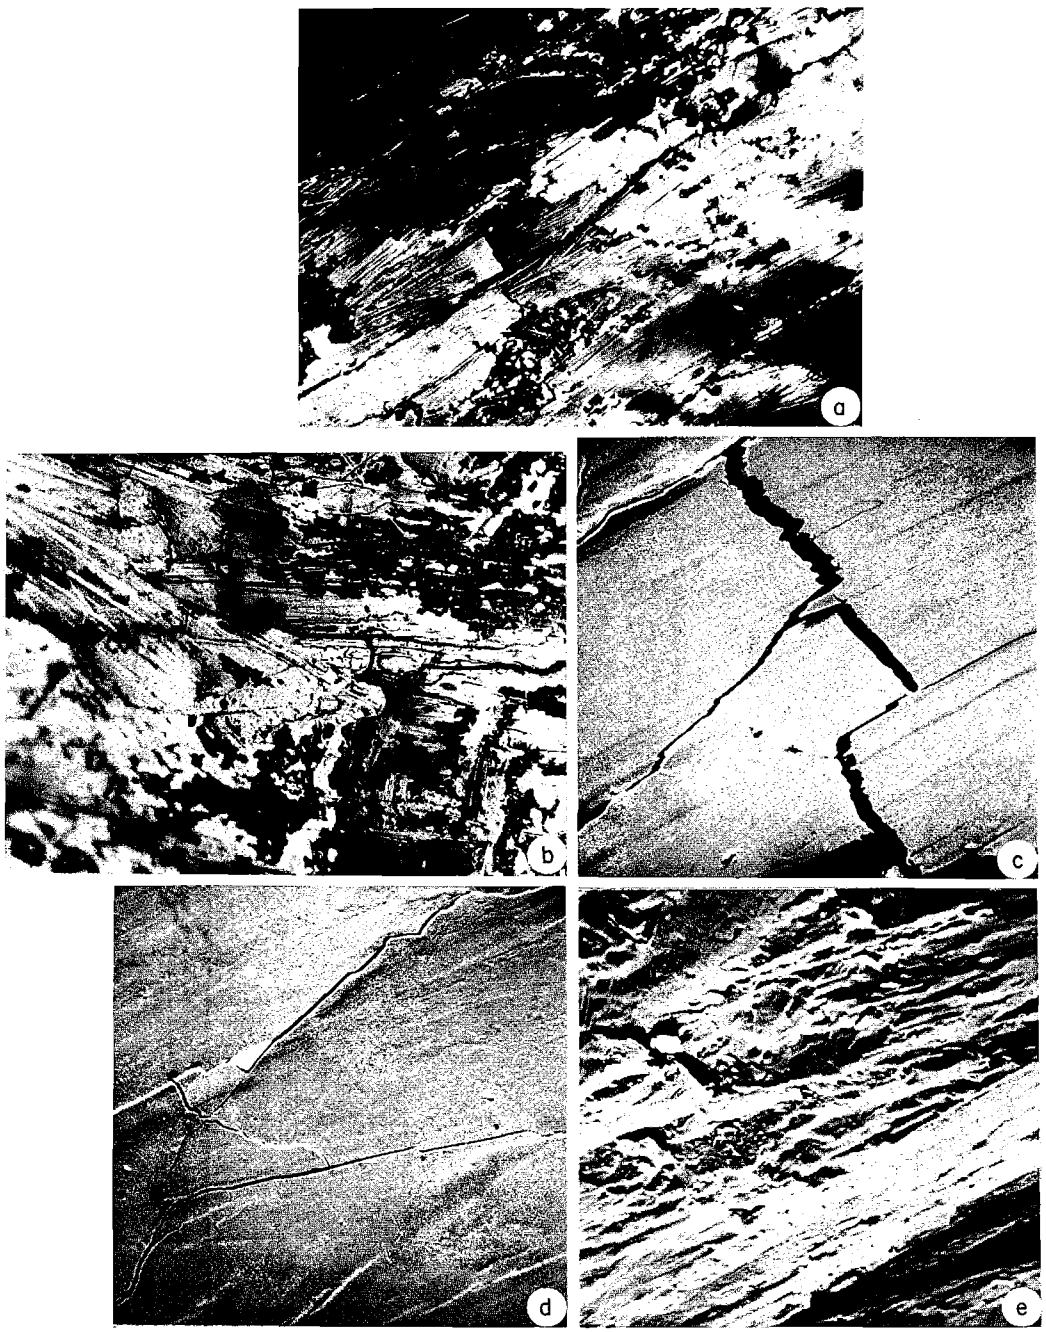

FIG. 5. Photographies microscopiques optiques (*a*, *b*) et électroniques à balayage (*c*, *d* et *e*) des surfaces de l'alliage 30% Co après une polarisation de 6 h à −1.55 V vs. ENH; (*a*) et (*b*) grossissement 200 ×; (*c*), (*d*), et (*e*) grossissement 550 ×.

modifiée par cette polarisation cathodique. Les fissures pénètrent profondément dans le métal. Pour l'alliage de 30% Co, la surface est aussi déformée par l'expansion volumétrique mais les dommages demeurent plus superficiels. Ces déformations ne furent pas observées pour les alliages de plus de 50% Co. Ces dommages ou déformations ne se manifestent pas de façon significative au cours des mesures réalisées dans l'obtention des courbes potentiostatiques illustrées à la fig. 3. Seule une polarisation prolongée (2 à 6 h) à des potentiels de −1.55 V révèlent ces dommages.

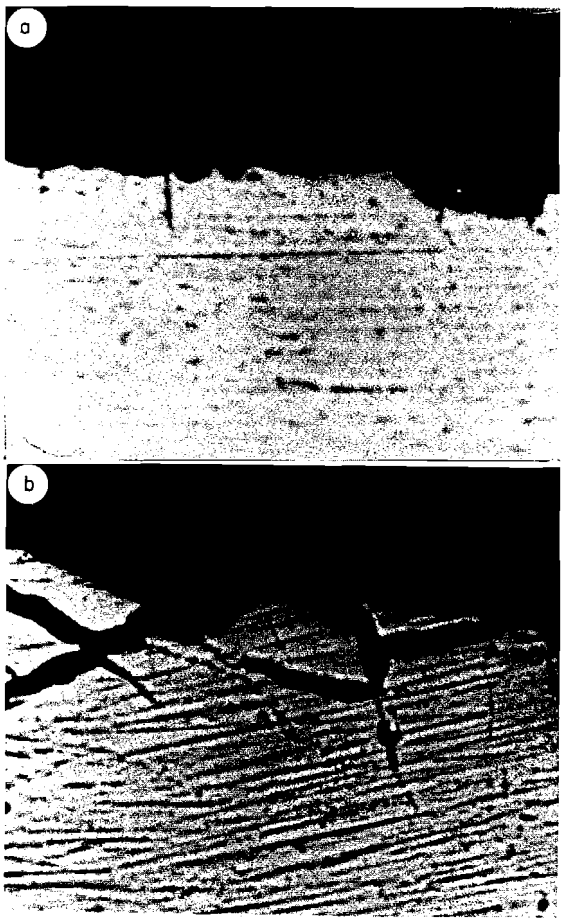

FIG. 6. Photographies microscopiques optiques (grossissement 50 ×) de coupes d'électrodes polarisées pendant 6 h à −1.55 V vs. ENH; (*a*) 20% Co; et (*b*) 30% Co.

IV. Discussion et conclusion

Comme nous l'avions observé précédemment dans le cas du nickel (5), l'alliage du cobalt et du niobium résulte en une amélioration sensible des propriétés catalytiques du nouveau matériau. En fait, pour une série d'alliages de 20 à 70% Co, le rendement dépasse celui du cobalt pur. Cependant, même le meilleur alliage ne réussit pas à surpasser le rendement du nickel pur.

Le principal problème que l'on rencontre avec les alliages du niobium est la dégradation de la surface pour les matériaux entre 20 et 30% de Co ou Ni (5, 6). Pour les alliages de plus forte teneur en Co, la stabilité s'accroît mais au détriment de l'activité électrocatalytique.

Dans le diagramme des phases à l'équilibre pour le système Co–Nb (fig. 1), il existe deux solutions solides (les phases δ et α respectivement riches en niobium et en cobalt) ainsi que deux composés intermétalliques soit le NbCo (phase γ) et le $NbCo_2$ (phase β). Le Nb et la phase δ possèdent un réseau cubique centré (c.c.) du type du tungstène, le NbCo un réseau cristallin similaire au W_6Fe_7 et enfin le $NbCo_2$ un empilement de phase de Laves (8–10). Le réseau du $NbCo_2$ passe du type $MgZn_2$ au type $MgCu_2$ lorsque la concentration de Co passe de 53 à 55.8% (poids). Les alliages utilisés dans la présente étude n'étaient pas monophasés mais bien des mélanges des phases α et β ou β et γ ou enfin γ et δ selon la composition des mélanges.

L'absence de données thermodynamiques pertinentes pour le système NbCo vis-à-vis les réactions avec l'hydrogène nous empêche de quantifier le comportement de chaque phase vis-à-vis cette molécule.

Cependant, comme la phase δ est une solution solide riche en Nb avec une faible concentration de soluté (Co), cette phase peut être associée au comportement du niobium vis-à-vis l'hydrogène. La dégradation de la surface pour les alliages où le Co est inférieur à 40% peut donc être reliée à la présence de la phase δ. Cette conclusion semble s'imposer car au-dessus de 40% où la phase δ ne se retrouve plus, la surface sous l'action de la RDH demeure relativement stable et ne présente plus de fissures. Donc en alliant le niobium avec le cobalt, la concentration de Co doit être supérieure à 40% pour obtenir une surface stable vis-à-vis la RDH.

Remerciements

L'un de nous (Y.U.) tient à remercier Hydro-Québec pour le support financier accordé pour la réalisation de cette étude.

Spectroscopic confirmation of orientational disorder of the cyanide groups in sodium cyanide dihydrate, $NaCN{\cdot}2H_2O$[1]

MICHAEL FALK

Atlantic Research Laboratory, National Research Council of Canada, 1411 Oxford Street, Halifax, N.S., Canada B3H 3Z1

Received October 1, 1980

MICHAEL FALK. Can. J. Chem. **59**, 1267 (1981).

Occurrence of orientational disorder involving the CN groups in $NaCN{\cdot}2H_2O$, suggested by van Rij and Britton on the basis of a refinement of X-ray diffraction data, has been confirmed by the doubling of CN stretching fundamentals. The ratios of doublet band areas are consistent with the energy of the orientation NC···Na being higher than that of the "normal" orientation, CN···Na by 800 ± 300 cal mol^{-1}.

MICHAEL FALK. Can. J. Chem. **59**, 1267 (1981).

En faisant appel à un affinement des données obtenues à partir d'une étude de diffraction des rayons-X, van Rij et Britton ont suggéré que l'orientation des groupes CN du $NaCN{\cdot}2H_2O$ est désordonnée. On a confirmé l'existence d'un tel désordre par l'observation d'un doublement des bandes fondamentales des vibrations de valence du groupe CN. Les rapports des aires des doublets sont en accord avec la conclusion que l'énergie de l'orientation NC···Na est plus élevée que celle de l'orientation normale, CN···Na, de 800 ± 300 cal mol^{-1}.

[Traduit par le journal]

The crystal structure of $NaCN{\cdot}2H_2O$ was first determined by Le Bihan (1), who found the cyanide groups to be oriented with their carbon atoms towards sodium, NC···Na. On the basis of subsequent refinement, using X-ray diffraction data collected at 150 K, Bats (2) found the cyanide groups to be oriented with their nitrogen atoms toward sodium, CN···Na, inverted with respect to the structure proposed by Le Bihan. A further refinement by van Rij and Britton (3), based on X-ray diffraction data collected at 295 K, led these authors to suggest that, at room temperature at least, the CN ions are partially disordered, with approximately 80% CN···Na and 20% NC···Na. Such orientational disorder should, in principle, produce a doubling of the vibrations involving the cyanide group. Upon an examination of the infrared spectrum of $NaCN{\cdot}2H_2O$ in the region of the fundamental CN stretching vibration we have, indeed, found spectroscopic confirmation of the orientational disorder postulated by van Rij and Britton.

Experimental

The dihydrate was prepared by recrystallizing sodium cyanide (BDH reagent grade) from aqueous solution at room temperature. The polycrystalline material was mulled with fluorocarbon oil and the mulls were sandwiched between calcium fluoride plates. Spectra were recorded on a Perkin Elmer model 180 spectrophotometer, fitted with a closed-cycle helium refrigerator (Displex model 202, Air Products and Chemicals Co.). Temperature readings (chromel/iron-doped-gold thermocouple) were checked against low-temperature transitions and found to be accurate to ± 1 K over most of the accessible range, 300–10 K. Spectral resolution was 2 cm^{-1}.

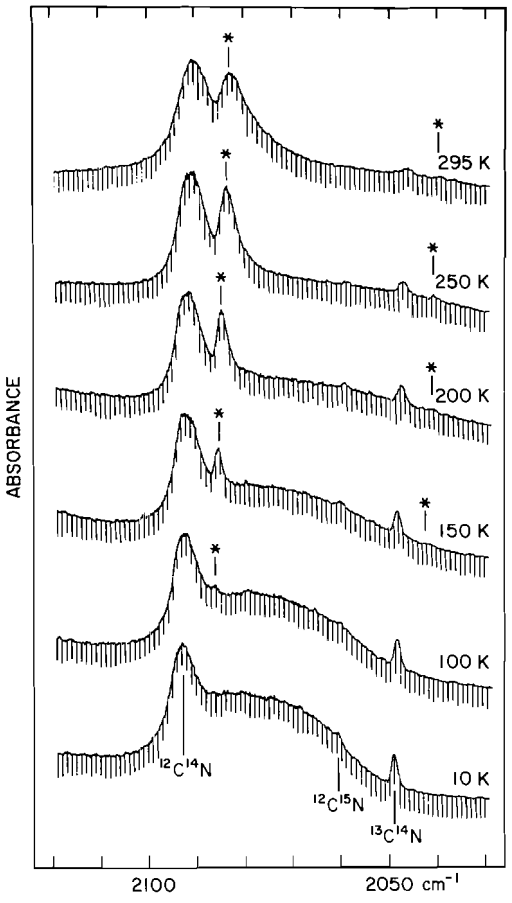

FIG. 1. The region of the CN stretching fundamental in the infrared spectrum of polycrystalline $NaCN{\cdot}2H_2O$ (fluorocarbon mull) at different temperatures. The peaks due to inverted CN groups are marked with asterisks.

Results

In the 10 K spectrum, a broad absorption region extending from 2050 to 2100 cm^{-1} underlies the much sharper absorption peaks due to CN stretching vibrations (Fig. 1). The broad band is probably due to the combination $\nu_2 + \nu_L$ (involving the bending mode and one of the librational modes) of the water molecules in $NaCN \cdot 2H_2O$. It rapidly loses intensity with increasing temperature. At 10 K, the main CN stretching fundamental, due to the dominant isotopic species $^{12}C^{14}N$, gives rise to the band at 2092.8 cm^{-1}, while the minor isotopic species $^{13}C^{14}N$ (natural abundance 1.11%) and $^{12}C^{15}N$ (natural abundance 0.36%) give rise, respectively, to the small, sharp bands at 2060.9 and 2049.2 cm^{-1}. The calculated positions of these isotopic bands are, under a harmonic diatomic approximation, 2060.4 and 2049.1 cm^{-1}, respectively.

As the temperature increases, the $^{12}C^{14}N$ stretching band as well as its two isotopic satellites shift gradually toward lower wavenumbers (Fig. 2). At about 100 K a new absorption band becomes visible, about 7.0 cm^{-1} below the $^{12}C^{14}N$ peak, its band area rapidly increasing with temperature, until at 295 K it is about half the size of the main peak. The extra peak appears to be due to CN ions of reversed orientation.

In confirmation of this assignment, a similar doubling is observed for the $^{13}C^{14}N$ satellite band. At temperatures above 150 K a new peak emerges, 6.5 cm^{-1} below the $^{12}C^{14}N$ peak, its relative intensity increasing with temperature (Fig. 1). The barely observable $^{12}C^{15}N$ satellite band was too weak for its doubling to be seen.

Assuming that the intensity of the CN stretching fundamental is independent of orientation, the ratio of CN ions in the two orientations can be estimated from the areas of the two components of the $^{12}C^{14}N$ doublet. The results are plotted in Fig. 3, with error bars corresponding to twice the estimated standard error. Most of the experimental uncertainty arises from uncertain baseline, caused by the underlying broad absorption mentioned above. The $^{13}C^{14}N$ doublet is somewhat less affected by sloping baseline, but its very low intensity leads to even larger uncertainties in band areas.

At temperatures above 150 K the observed

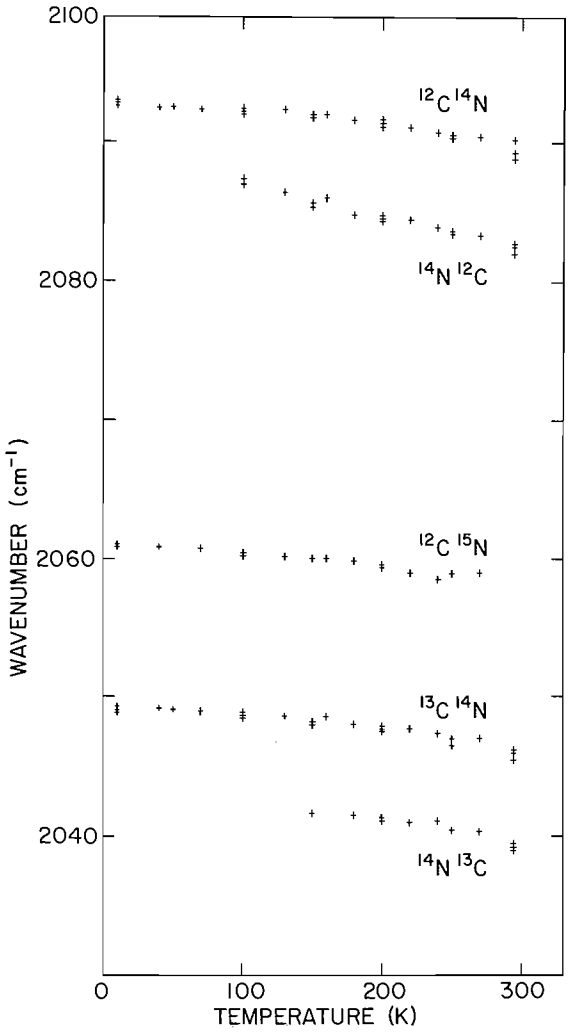

FIG. 2. Variation of peak wavenumbers of the bands in Fig. 1 with temperature.

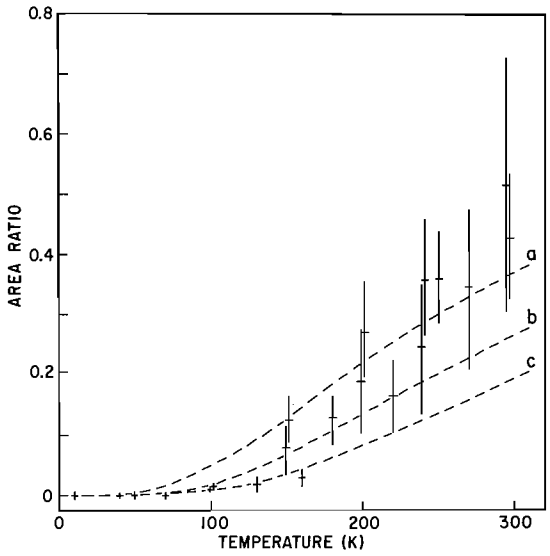

FIG. 3. Plot of the ratio of band areas of the $^{12}C^{14}N$ doublet as a function of temperature. Curves *a*, *b*, and *c* correspond to the function $\exp(-\Delta E/RT)$ where $R = 1.98$ cal deg^{-1} mol^{-1} and $\Delta E = 600$, 800, and 1000 cal mol^{-1}, respectively.

values fall within experimental error on the curve exp $(-600/RT)$, which corresponds to an order–disorder process in which there is no entropy difference between the two orientations and the energy difference is 600 cal mol^{-1}. Below 150 K the data are distinctly better fitted by exp $(-1000/RT)$, corresponding to an energy difference of 1000 cal mol^{-1}. A simple model based on CN ions with two orientations and a constant energy difference between them does not fit the data. This indicates that the disorder process is cooperative, the energy depending on the relative orientations of neighbouring CN ions, as well as on their orientation with respect to the site.[2]

[2]This type of cooperativity has been suggested by Professor Doyle Britton (personal communication).

Conclusions

The observed doubling of $^{12}C^{14}N$ and $^{13}C^{14}N$ stretching fundamentals confirms the occurrence of orientational disorder in $NaCN \cdot 2H_2O$. The ratios of the band areas are consistent with an energy difference of 800 ± 300 cal mol^{-1} between the two possible orientations. The fraction of reversed CN groups at 295 K is estimated to be 0.33 ± 0.06, greater than the estimate of 0.20 of van Rij and Britton (3). At 150 K this fraction is only 0.07 ± 0.04, which could have easily escaped detection in the study of Bats.

Echange isotopique hydrogène–deutérium subi par les groupements méthyles de la triméthyl-4,5,6 pyrimidone-2

ERIC PICQUENARD ET PIERRE DIZABO

Laboratoire de Spectrochimie Moléculaire, Université Pierre et Marie Curie, 4 place Jussieu, 75230 Paris, Cedex 05, France

Reçu le 27 juin 1980

ERIC PICQUENARD et PIERRE DIZABO. Can. J. Chem. **59**, 1270 (1981).

L'échange isotopique hydrogène–deutérium des méthyles en positions 4 et 6 de la triméthyl-4,5,6 pyrimidone-2 dans D_2O à des acidités allant de pD 0,4 à 7,7 est suivie par rmn du proton. La vitesse d'échange passe par un maximum correspondant à l'équimolécularité de la pyrimidone avec son acide conjugué. Le maximum de vitesse est dû à l'arrachement par la molécule neutre d'un hydrogène du groupement méthyle de l'acide conjugué. Ce mécanisme est confirmé par l'étude de l'échange des méthyles de la tétraméthyl-1,4,5,6 pyrimidone-2.

ERIC PICQUENARD and PIERRE DIZABO. Can. J. Chem. **59**, 1270 (1981).

The rate of deuterium exchange of 4 and 6 methyl protons in 4,5,6-trimethyl-2-pyrimidone has been followed in D_2O over a range of acidity from pD 0.4 to 7.7 by means of proton magnetic resonance spectroscopy. The maximum of exchange rate represents equimolar proportions of the pyrimidone and its conjugate acid. The maximum is due to the neutral molecule acting as a base and removing a proton from one of the methyl groups of its conjugate acid. The exchange study of methyl protons in 1,4,5,6-tetramethyl-2-pyrimidone corroborates this mechanism.

Introduction

Dans des études antérieures concernant des alkyl- et aminoalkylpyrimidines (1–3), nous avons constaté, par rmn du proton, que dans les groupements alkyles en position 4 et 6, les hydrogènes portés par les carbones en α du cycle s'échangeaient en milieu acide. Nous avons proposé un mécanisme de réaction et déterminé les constantes cinétiques et isotopiques de cet échange.

Rappelons qu'en milieu acide, une double protonation est nécessaire pour déclencher le processus d'échange qui met en jeu la coupure d'une liaison C—H en α du cycle. La confrontation des résultats expérimentaux avec le traitement mathématique nous a permis de retenir un mécanisme dit séquentiel dans lequel la deuxième protonation est rapide, la coupure de la liaison C—H est lente.

Nous avons effectué une étude analogue sur des méthylpyrimidone-2. Comme pour les alkyl- et aminoalkylpyrimidines, un groupement méthyle en position 5 ne subit aucun échange isotopique, seuls les hydrogènes des méthyles en 4 et 6 s'échangent. Nous avons donc fait une étude sur la triméthyl-4,5,6 pyrimidone-2 (**1**), le méthyle en 5 servant de référence dans notre méthode expérimentale.

L'échange isotopique étudié a lieu dans l'eau lourde, soit pure, soit additionnée d'acide chlorhydrique ou de soude. A 60°C, la vitesse V de réaction varie selon l'acidité du milieu:

$$V_{\text{milieu acide}} > V_{\text{milieu basique}} > V_{\text{eau lourde pure}}$$

En milieu acide, la vitesse d'échange passe par un maximum. Dans ce mémoire, nous ne présenterons que les résultats obtenus en milieu acide. La vitesse d'échange à 60°C étant trop élevée dans ce milieu pour pouvoir, selon notre méthode expérimentale, obtenir des résultats facilement mesurables et reproductibles, nous avons effectué cette étude à 40°C.

Pour vérifier certaines hypothèses de mécanisme, nous avons été amenés à étudier l'échange isotopique hydrogène–deutérium des méthyles de la triméthyl-4,5,6 pyrimidone-2-urée (**1**-urée) et de la tétraméthyl-1,4,5,6 pyrimidone-2 (**2**).

Résultats et discussion

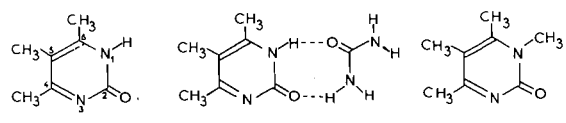
Triméthyl-4,5,6 pyrimidone-2

Nous avons porté sur la figure 1 le taux relatif de la réaction en fonction du temps pour différentes acidités. Le taux relatif de la réaction est défini par la relation:

$$\omega = \frac{\text{Aire du massif correspondant aux méthyles 4 et 6}}{2 \times (\text{Aire du pic correspondant au méthyle 5})}$$

Les différents mélanges sont caractérisés par le rapport ρ = [acide]/[pyrimidone], rapport des concentrations analytiques de départ, que nous avons fait varier de 0 à 2.

La vitesse de réaction passe par un maximum quand le rapport ρ est égal à 0,5, c'est à dire pour un mélange contenant deux moles de pyrimidone pour une mole d'acide.



1 **1-urée** **2**

SCHÉMA 1. Composés étudiés: **1** = triméthyl-4,5,6 pyrimidone-2; **1**-urée = triméthyl-4,5,6 pyrimidone-2-urée; **2** = tétraméthyl-1,4,5,6 pyrimidone-2.

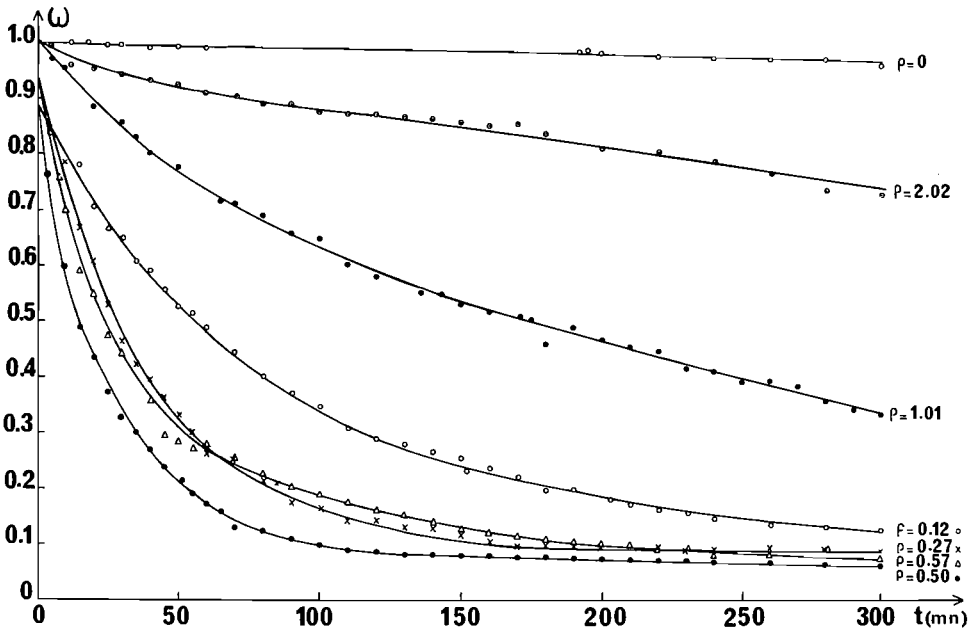

FIG. 1. Influence de la proportion d'acide présent en solution sur la vitesse d'échange de **1**.

Nous étudierons successivement la cinétique d'échange quand ρ est supérieur ou égal à 1, puis quand ρ est inférieur à 1. Nous accorderons une analyse plus détaillée à ce dernier cas.

$\rho \geq 1$: La vitesse d'échange est du même ordre de grandeur que celle des alkyl- et aminoalkylpyrimidines. De même, la réaction est du pseudo-premier ordre, toutefois, une seconde protonation ici n'est pas nécessaire pour déclencher le processus d'échange, le mécanisme de réaction est différent et le traitement mathématique établi lors des études antérieures (3) n'est pas transférable à notre cas.

Nous pouvons considérer que la réaction est principalement régie par l'attaque de l'eau sur l'acide conjugué ($\mathbf{1}D^+$) de la pyrimidone. Lorsque l'acidité augmente, la vitesse de réaction diminue, ceci est certainement dû à une baisse de l'activité de l'eau comme dans le cas de la diméthyl-1,4 pyrimidone-2 (4).

$\rho < 1$: La vitesse est plus rapide. En opérant une régression sur les valeurs expérimentales, de type $\omega = Ae^{-kt}$ et $\omega = 1/(kt + b)$ et en appliquant le test t de Student sur les déviations obtenues entre les points expérimentaux et les points calculés,[1] nous avons retenu les valeurs de k_{obs} obtenues pour une loi du pseudo-premier ordre.

La vitesse passe par un maximum pour $\rho = 0{,}5$, ce qui correspond à un pD mesuré de 4,5 (fig. 2, tableau 1). La valeur du pK_a de l'acide conjugué $\mathbf{1}H^+$ de cette pyrimidone, déterminée par rmn du carbone-13 en mesurant les déplacements chimiques des carbones en fonction du pH est de 4,4. Nous observons donc, à l'erreur expérimentale près, une vitesse maximum quand $(\mathbf{1}) = (\mathbf{1}D^+)$. Des maxima identiques ont été observés au cours d'échanges isotopiques hydrogène–deutérium pour d'autres composés (4–7). Dans tous les cas, les maxima sont expliqués par une réaction d'attaque du composé neutre sur son acide conjugué. Or lors de la synthèse de la triméthyl-4,5,6 pyrimidone-2, nous avons mis en évidence un complexe stable défini 1:1 entre la pyrimidone et l'urée (cf. partie expérimentale). La structure de ce complexe a été étudiée par spectrométrie de vibration (8). Le spectre infrarouge est compatible avec l'existence d'une double liaison hydrogène entre la pyrimidone et l'urée (**1**-urée: schéma 1). Cette constatation nous a fait envisager en premier lieu, malgré les autres résultats cités plus haut (4–7), un mécanisme où les espèces **1** et $\mathbf{1}D^+$ interviennent par formation d'un complexe intermédiaire favorisant l'échange isotopique hydrogène–deutérium:

$$1 + 1D^+ \underset{2}{\overset{1}{\rightleftharpoons}} (1D1)^+$$

[1]Apparemment, la meilleure corrélation est obtenue entre ω et le temps pour une loi du 2ième ordre, les coefficients de corrélation n'étant que peu différents de ceux obtenus pour une loi du 1er ordre pour certaines compositions initiales de mélange, c'est pourquoi nous avons dû faire une régression et utiliser le test t de Student.

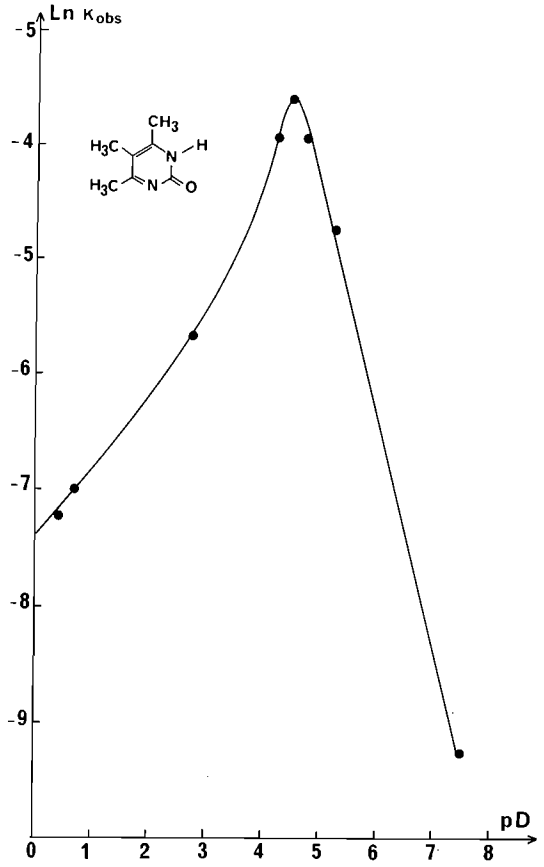

FIG. 2. Effet de l'acidité sur la vitesse d'échange de **1**.

TABLEAU 1. Constantes de vitesse observées pour l'échange de la triméthyl-4,5,6 pyrimidone-2

ρ	pD	k_{obs} mn^{-1}
2,01	0,70	$7{,}30\cdot10^{-4}$
2,00	0,40	$8{,}82\cdot10^{-4}$
1,00	2,75	$3{,}38\cdot10^{-3}$
0,57	4,25	$2{,}21\cdot10^{-2}$
0,50	4,50	$2{,}39\cdot10^{-2}$
0,27	4,80	$1{,}98\cdot10^{-2}$
$0{,}11_5$	5,25	$8{,}46\cdot10^{-3}$
0	7,70	$9{,}47\cdot10^{-5}$

Dans ce mécanisme, nous pouvons faire l'hypothèse que la pyrimidone **1** et la pyrimidone protonée $\mathbf{1D}^+$ forment un complexe identique au complexe pyrimidone–urée. Dans ce complexe, même s'il reste en faible proportion en solution, les groupements méthyles en 4 et 6 peuvent par prototropie perdre un proton, puis la recombinaison avec un deutérium du solvant conduit à l'échange. Si cette hypothèse est exacte, en milieu eau lourde le complexe **1**-urée devrait s'échanger plus rapidement que **1** seul. C'est

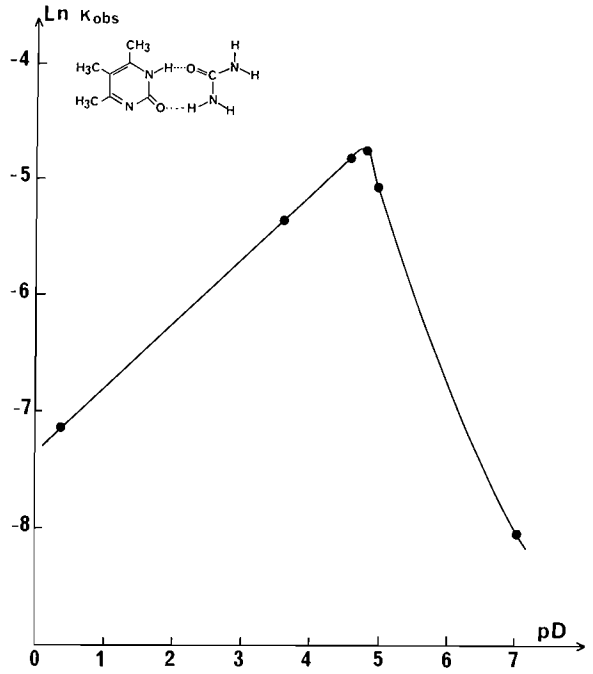

FIG. 3. Effet de l'acidité sur la vitesse d'échange du complexe **1**-urée.

pourquoi, nous avons étudié l'échange des méthyles de la triméthyl-4,5,6 pyrimidone – urée en fonction de la quantité d'acide ajoutée.

Triméthyl-4,5,6 pyrimidone-2-urée (1-urée)

Pour des raisons de solubilité, nous avons dû travailler à des concentrations plus faibles en complexe pour les solutions où ρ est inférieur à 1. Afin de mieux comparer les vitesses d'échange du complexe avec celles de la pyrimidone dans ce domaine, nous avons étudié les échanges de la pyrimidone et du complexe aux mêmes concentrations pour chaque valeur de ρ.

Nous observons que la vitesse d'échange du complexe passe par un maximum pour ρ = 0,5 (fig. 3, tableau 2). Les vitesses d'échange des deux composés **1** et **1**-urée aux mêmes concentrations pour une valeur de ρ proche de 0,5 sont les mêmes. En milieu eau lourde seule (ρ = 0), la vitesse d'échange du complexe n'est que légèrement supérieure à celle de la pyrimidone, ainsi que dans le domaine où ρ > 1.

Pour confirmer que le mécanisme proposé n'est pas vérifié, nous avons étudié l'homologue *N*-méthylé de **1** (tétraméthyl-1,4,5,6 pyrimidone-2).

Tétraméthyl-1,4,5,6 pyrimidone-2 (2)

Pour ce dernier composé, nous observons des vitesses d'échange différentes pour les groupements méthyles en position 4 et 6. Les hydrogènes du méthyle en 6 s'échangent beaucoup plus rapidement

que ceux du méthyle en 4, phénomène déjà observé par Batterham *et al.* (9) et Stewart *et al.* (10). Par rapport à l'échange des méthyles du composé **1**, l'échange du méthyle en 6 du composé **2** est plus rapide, par contre, celui du méthyle en 4 de **2** est plus lent.

Dans la région où ρ est inférieur à 1, le composé **2** présente pour l'échange des deux méthyles un maximum de vitesse pour ρ = 0,5 (fig. 4, tableau 3).

TABLEAU 3. Constantes de vitesse observées pour l'échange de la tétraméthyl-1,4,5,6 pyrimidone-2

		k_{obs} mn^{-1}	
ρ	pD	Me-4	Me-6
2,00	1,07	$2,22 \cdot 10^{-4}$	$2,66 \cdot 10^{-3}$
1,00	1,35	$7,60 \cdot 10^{-4}$	$3,79 \cdot 10^{-3}$
0,71	4,51	$1,10 \cdot 10^{-2}$	$4,29 \cdot 10^{-2}$
0,51	4,75	$1,16 \cdot 10^{-2}$	$4,90 \cdot 10^{-2}$
0,25	5,29	$9,78 \cdot 10^{-3}$	$2,41 \cdot 10^{-2}$
0	8,08	$2,30 \cdot 10^{-5}$	$2,30 \cdot 10^{-4}$

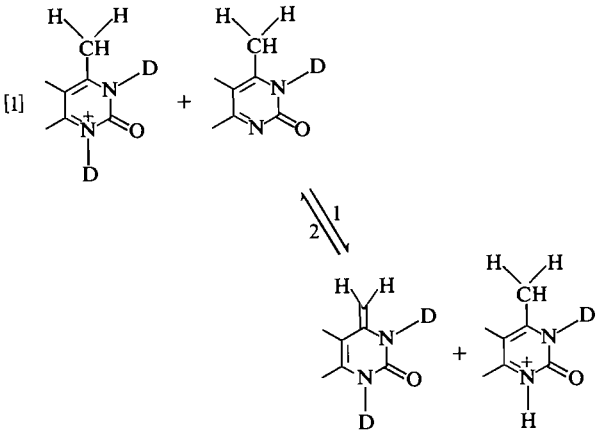
L'hypothèse du complexe intermédiaire $\mathbf{1D1}^+$ s'avère donc fausse. Même en de faibles proportions en solution, ce complexe ne contribue pas à l'échange. Le complexe **1**-urée se dissocie donc dans l'eau et l'échange se résume à l'attaque de **1** sur $\mathbf{1D}^+$.

Mise en équation du mécanisme

Examinons maintenant l'échange du composé **1** dans la région où ρ est inférieur à 1. La pyrimidone existe principalement sous forme de base libre **1** quand pD > 4,5 et sous forme d'acide conjugué $\mathbf{1D}^+$ pour pD < 4,5. L'échange est dû à l'arrachement par **1** d'un proton d'un groupement méthyle de $\mathbf{1D}^+$.

Par simplification, nous ne nous intéresserons qu'à l'échange d'un seul proton d'un groupement méthyle, les conclusions sont inchangées par cette simplification, si l'on néglige les effets isotopiques secondaires qui peuvent intervenir lors de l'arrachement d'un proton d'un groupement méthyle, qu'il soit sous forme $—CH_3$, $—CH_2D$, $—CHD_2$, ou que les azotes du cycle soient liés à des hydrogènes ou des deutériums. L'arrachement d'un proton se résume donc à l'équilibre [1]:

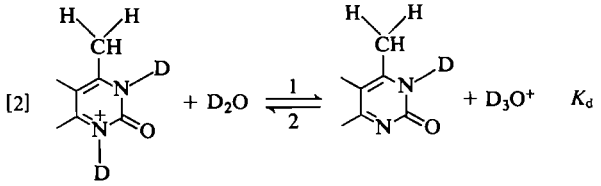
[1]



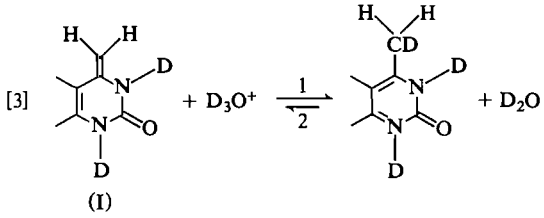
Etant donné la faible proportion d'hydrogène sous forme H_2O, H_3O^+, HDO, etc, le milieu étant à

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

forte teneur en deutérium, nous pouvons négliger les réactions d'équilibre acido-basique où l'hydrogène intervient. Il nous reste donc pour l'équilibre acido-basique [2]:



Considérons l'équilibre de recombinaison qui conduit à l'échange [3]:



L'espèce intermédiaire I ne se recombine qu'avec D_3O^+ puisque nous négligeons H_3O^+. L'espèce I étant très réactive, l'équilibre [3] est fortement déplacé dans le sens 1.

Soit en résumé:

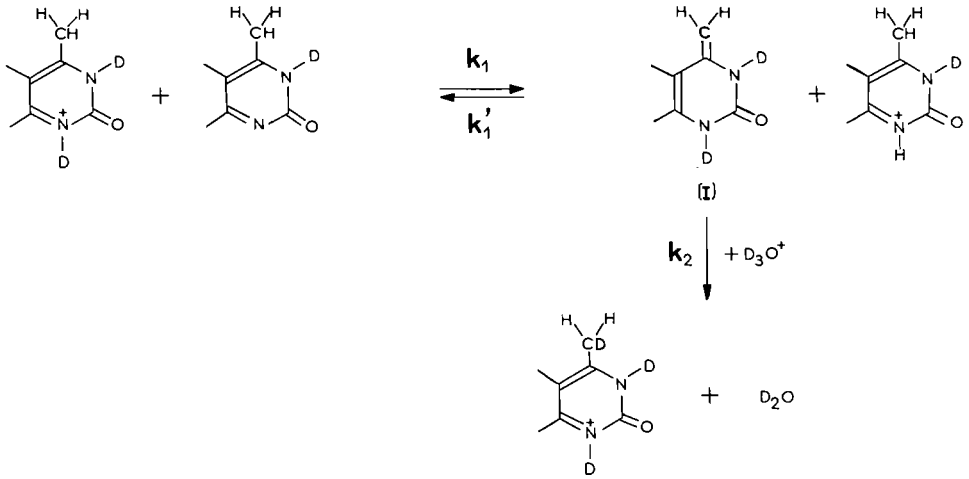


SCHÉMA 2. Mécanisme d'échange de **1** pour $0 < \rho < 1$.

Appelons $[D^+]$ la concentration en ion deutérium, [B] la concentration en pyrimidone neutre contenant l'hydrogène à échanger, [B'] la concentration en pyrimidone neutre deutériée, $[B_T]$ concentration totale en pyrimidone neutre $[B_T] = [B] + [B']$; $[BD^+]$, $[B'D^+]$ et $[B_TH^+]$ concentrations en pyrimidone protonée correspondant respectivement à B, B', B_T; X_0 concentration analytique de départ en pyrimidone et X celle correspondante aux produits non deutériés.

Si nous appliquons à l'espèce I l'hypothèse de l'état stationnaire, exprimons la vitesse de disparition des produits hydrogénés:

$$[4] \quad -\frac{dX}{dt} = k_2 \frac{k_1[BD^+][B_T][D^+]}{k_1'[B_TH^+] + k_2[D^+]}$$

Si de plus, nous considérons que la vitesse de recombinaison avec D_3O^+ est très rapide par rapport à l'établissement de l'équilibre [1] nous obtenons:

$$[5] \quad -\frac{dX}{dt} = k_1[BD^+][B_T]$$

car $k_1'[B_TH^+] \ll k_2[D^+]$. Les équilibres [2] nous donnent:

$$[6] \quad [BD^+] = X\frac{[D^+]}{[D^+] + K_d}$$

et

$$[7] \quad [B_T] = X_0\frac{K_d}{[D^+] + K_d}$$

avec $X = [B] + [BD^+]$ et $X_0 - X = [B'] + [B'D^+]$. Nous obtenons:

$$[8] \quad -\frac{dX}{dt} = k_1\frac{[D^+]K_d}{([D^+] + K_d)^2}X_0X$$

Nous mesurons le taux $\omega = X/X_0$ d'où:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

$$[9] \quad -\frac{d\omega}{dt} = k_1 \frac{[D^+]K_d}{([D^+] + K_d)^2} X_0\omega$$

La réaction étant du premier ordre, nous obtenons pour

$$k_{obs} = k_1 \frac{[D^+]K_d}{([D^+] + K_d)^2} X_0$$

expression déjà établie par Stewart *et al.* lors de l'échange de la créatinine (7) où la condition k_{obs} maximum est obtenue pour $K_d = [D^+]$.

Lorsque l'on trace la courbe k_{obs} en fonction de l'expression $[D^+]K_d/([D^+] + K_d)^2$ nous obtenons une relation linéaire satisfaisante. Nous avons pris pour valeur de K_d la valeur obtenue à $\rho = 0,5$ ($pK_d = 4,5$) et de $[D^+]$ celles calculées à partir des

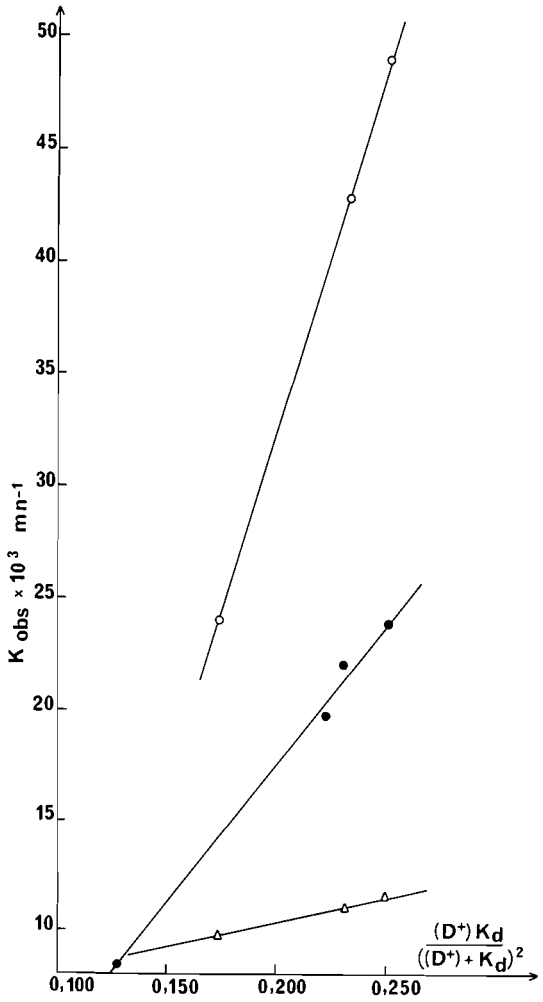

FIG. 5. Relation entre k_{obs} et $[D^+]K_d/([D^+] + K_d)^2$ pour **1**(–●–) et pour **2** (Me-6 = –○–, Me-4 = –△–).

TABLEAU 4. Constantes de vitesse k_1 obtenues à l'aide de la relation de Stewart

Composé		k_1 L mol^{-1} mn^{-1}
1		0,235
2	Me-4	0,046
	Me-6	0,649

valeurs expérimentales (fig. 5). La valeur de k_1 calculée à partir de la pente de la droite est de 0,235 mol^{-1} L mn^{-1}.

Pour le composé **2**, la comparaison des deux régressions montre que la réaction d'échange pour les méthyles en 4 et en 6 est du pseudo-premier ordre. Nous obtenons pour les deux cinétiques une relation linéaire satisfaisante (fig. 5); les valeurs de k_1 ainsi obtenues sont rassemblées dans le tableau 4.

Ces résultats nous amènent à conclure que les échanges des méthyles en position 4 et 6 sur le cycle pyrimidique des pyrimidone-2 sont dûs, dans le domaine d'acidité encadrant le pK_a de l'acide conjugué, à l'arrachement par la molécule neutre agissant comme une base, d'un proton du groupement méthyle de son acide conjugué. Ceci se traduit expérimentalement par un maximum de réactivité à l'équimolécularité de la pyrimidone avec son acide conjugué. Ce mécanisme se trouve confirmé par l'étude de l'échange des méthyles de la tétraméthyl-1,4,5,6 pyrimidone-2.

Partie expérimentale

Technique de mesure

Les réactions d'échange sont suivies par rmn du proton à l'aide d'un spectromètre Varian HA 100, équipé d'une sonde à température variable. Le deutérium ne résonnant pas dans les conditions expérimentales envisagées, nous pouvons aisément préciser de façon qualitative le site d'échange et quantitative le taux relatif de réaction. Le pic correspondant au méthyle en 5, qui ne s'échange pas, sert de référence interne à l'intégration. Nous mesurons le taux relatif de réaction ω défini dans le texte. Nous avons utilisé le signal du pic H_3O^+ ou OH^- selon le milieu, comme asservissement champ-fréquence. Dans le cas où le composé est seulement dissous dans l'eau lourde, nous avons utilisé le signal des méthyles de la pivalone, placée dans un capillaire.

Préparation des échantillons

Chaque solution est préparée par pesée en fiole jaugée, puis introduite dans un tube rmn, placé dans la sonde à 40°C. La réaction est suivie en continu en enregistrant les spectres toutes les 10 mn pendant 300 mn, jusqu'à une valeur constante, pour les réactions où $\rho < 1$, $\omega_{equilibre}$ correspondant à une deutération allant de 92 à 95% selon la composition initiale du mélange. Nous avons travaillé à concentration constante en pyrimidone (0,5 mol L^{-1}) dans l'eau lourde, provenance C.E.A. (99,84 at.% D), avec des quantités variables d'acide chlorhydrique.

Mesures d'acidités

Les mesures de pD des solutions ont été effectuées à l'aide d'un pH-mètre Orion, muni d'une électrode combinée verre–calomel. Nous avons appliqué l'équation générale pD = pH_{lu} + 0,4 (11).

Synthèse de la triméthyl-4,5,6 pyrimidone-2

Nous avons adapté pour notre composé la méthode de préparation de la diméthyl-4,6 pyrimidone-2 décrite par Kosolapoff et Roy (12). Cette méthode donne un composé blanc qui, après sublimation sous vide, a un point de fusion de 210°C; nous l'avons identifié comme étant un complexe stable pyrimidone–urée par analyse élémentaire et spectrométrie de vibration (8). *Anal.* calc.: C 48,48, H 7,07, N 28,28, O 16,26; trouvé: C 48,43, H 6,91, N 27,28, O 16,36%. Nous avons extrait la pyrimidone de la solution aqueuse du complexe en continu, avec le chloroforme, pendant 48 h. Le produit obtenu, triméthyl-4,5,6 pyrimidone-2, après recristallisation et sublimation sous vide a un point de fusion de 243°C.

A ce stade, le rendement de la réaction par rapport à la méthyl-3 pentanedione-2,4 est de 33%. *Anal.* calc.: C 60,85, H 7,29, N 20,28, O 11,58; trouvé: C 60,76, H 7,06, N 20,23, O 11,94%.

Nous avons préféré l'adaptation de la méthode de Kosolapoff à celle de Jones et Rees et celle de Brown et England qui, pour un résultat identique et un rendement équivalent, sont beaucoup plus lentes (13).

Synthèse de la tétraméthyl-1,4,5,6 pyrimidone-2

Nous avons adapté la méthode de Brown et Foster (14). Dix grammes de *N*-méthylurée (0,135 mol) sont dissous dans 60 cm^3 d'éthanol absolu. On ajoute sous agitation 14,2 g (0,125 mol) de méthyl-3 pentanedione-2,4 puis 23 cm^3 d'acide chlorhydrique concentré. La solution est laissée au repos à la température ambiante pendant 85 h. Après avoir chassé les solvants, le résidu dissous dans l'eau est neutralisé par K_2CO_3 jusqu'à pH 9 environ. Par extraction au chloroforme puis recristallisation dans l'éthanol et sublimation sous vide, nous obtenons des cristaux blancs (5 g) de tétraméthyl-1,4,5,6 pyrimidone-2; point de fusion 88–89°C. Le rendement de la réaction par rapport à la méthyl-3 pentanedione-2,4 est de 26,5%. *Anal.* calc.: C 63,13, H 7,95, N 18,41, O 10,51; trouvé: C 63,11, H 7,85, N 18,38, O 10,66%. Les cristaux obtenus sont très hygroscopiques et il est nécessaire de les conserver sous vide partiel, en présence de P_2O_5 et de les sublimer sous vide avant utilisation.

La tétraméthyl-1,4,5,6 pyrimidone-2 peut aussi être obtenue par méthylation de la pyrimidone correspondante (composé **1**) cependant cette méthode donne un produit plus difficile à purifier.

Remerciements

Nous tenons à remercier le Dr. D. Baron et Mademoiselle C. Coupry pour la détermination du pK_a de l'acide conjugué du composé **1** par rmn du carbone-13. Nous tenons également à remercier le Dr. O. S. Tee, Concordia University, Montreal, pour ses critiques constructives et ses conseils pour la mise au point de ce mémoire.

AVYGDOR MOISE and HUW O. PRITCHARD. Can. J. Chem. **59**, 1277 (1981).

A numerical study of the vibrational relaxation at 500 K of a mixture of ortho-H_2 and para-H_2 is described. The required state-to-state rate constants were calculated from the quantum results of Rabitz and co-workers, and missing pieces of data were estimated by interpolation.

It is concluded that only one relaxation time will be observed in any mixture of ortho-H_2 and para-H_2 and that (except at very high dilutions in a third inert gas) the relaxation rate constant will be close to the mean of the individual rate constants for relaxation, weighted according to the respective mole fractions of ortho-H_2 and para-H_2 present in the mixture.

We find that the relaxation process can be modelled very accurately as an electrical RC network, whose time constants can be written down quite easily as sums of the appropriate microscopic rate constants, and by using this model, it is a simple matter to explore the conditions required for a mixture of two gases to exhibit two distinct vibrational relaxation times.

AVYGDOR MOISE et HUW O. PRITCHARD. Can. J. Chem. **59**, 1277 (1981).

On décrit une étude numérique de la relaxation vibrationnelle à 500 K d'un mélange de H_2 ortho et para. On a calculé les constantes de vitesse entre états nécessaires en se basant sur les résultats quantiques de Rabitz et ses collaborateurs et on a évalué les données manquantes par interpolation.

On conclut qu'un seul temps de relaxation pourra être observé pour tous les mélanges de H_2 ortho et para et que (à l'exception des cas de très fortes dilutions dans un troisième gaz inerte), la constante de vitesse de relaxation sera voisine de la moyenne des constantes individuelles des vitesses de relaxation pondérées selon les fractions molaires respectives de H_2 ortho et para présentes dans le mélange.

Nous avons trouvé que le processus de relaxation peut être représenté d'une façon très précise par un réseau électrique RC dont on peut très facilement représenter les constantes de temps par la somme des constantes de vitesse microscopiques appropriées. L'utilisation de ce modèle permet d'explorer facilement les conditions requises pour qu'un mélange de deux gaz présente deux temps distincts de relaxation vibrationnelle.

[Traduit par le journal]

Introduction

In a recent group of papers from this laboratory, we have examined the fundamental nature of vibrational and rotational relaxation in diatomic molecules by a series of numerical experiments (1–3). To simplify matters, H_2 was considered the model molecule, and in the absence of sufficient quantum-mechanical data for individual state-to-state rate constants, such rates for the model calculations were constructed by a mixture of empiricism and guesswork. However, recent investigations, principally by Alexander (4–6) and by Rabitz and co-workers (7–9), have now reached the point where it is possible to make reasonable estimates for any state-to-state rate constant for H_2 in collision with He, among the first two or three vibrational states, and perhaps the lowest ten or twelve rotational states; most of this effort has been devoted to the even J states of H_2, i.e. para-H_2, although Alexander has also examined transitions among a few of the odd J states, i.e. ortho-H_2.

The problem we wish to address in this paper is that of the vibrational relaxation of a mixture of two diatomic gases, and the major new phenomenon to be probed here is whether the two molecules will equilibrate their vibrational energies separately or together: this problem has been addressed previously by Foster and Simpson (10) in relation to the relaxation of mixtures of N_2O and CO_2.

A feasible calculation from the point of view of consumption of computer time and computer storage space at the present time limits the number of rotation–vibration states of each molecule to an order of about ten; thus, in fact, it is only for mixtures of ortho-H_2 and para-H_2 that a full calculation of the relaxation of a mixture of two gases can be contemplated. Consequently, we describe in the following pages a calculation of the relaxation of mixtures of ortho-H_2 and para-H_2, both diluted and undiluted, using state-to-state rate constants synthesised from the tabulations of Rabitz and Zarur (7, 11). This calculation, we believe, fulfils a two-fold purpose: a reasonable description of the relaxation of ortho–para hydrogen mixtures in particular, and a realistic modelling of the relaxation of mixtures of diatomic gases in general.

State-to-state Transition Rate Constants

We begin by enumerating the kinds of processes involved in the relaxation of a mixture of ortho-H_2 with para-H_2 in the presence of a diluent M.

(1) T–VR Processes

[1] $H_2^{p,o}(v, J) + M \rightleftarrows H_2^{p,o}(v', J') + M$

These are the standard atom–diatom rate processes which have been the subject of most theoretical studies in the past (4–9). We may also project out of the manifold of diatom–diatom collision processes the two sets

[1*a*] $H_2^{p,o}(v, J) + H_2^{p,o}(i) \rightleftarrows H_2^{p,o}(v', J') + H_2^{p,o}(i)$

[1*b*] $H_2^{p,o}(v, J) + H_2^{o,p}(i) \rightleftarrows H_2^{p,o}(v', J') + H_2^{o,p}(i)$

These processes are equivalent to the processes [1] in the sense that the quantum state (i) of the second H_2 on each side of the equation remains unchanged; for the present purposes, we follow our earlier model calculations (3) and make the simplification that for a given pair $(v, J) \leftrightarrow (v', J')$, all three types of process [1], [1*a*], and [1*b*] are equivalent.

(2) Self-relaxation Processes

[2] $H_2^{p,o}(v, J) + H_2^{p,o}(v', J') \rightleftarrows H_2^{p,o}(v'', J'') + H_2^{p,o}(v''', J''')$

These processes represent the exchange of vibrational and rotational excitation, with attendant dissipation because of energy mismatching, between molecules of the same species; there have been many fewer theoretical studies of these processes.

(3) Exchange Processes

[3] $H_2^{p,o}(v, J) + H_2^{o,p}(v', J') \rightleftarrows H_2^{p,o}(v'', J'') + H_2^{o,p}(v''', J''')$

Again, these processes have been the subject of a limited range of theoretical studies, but are relatively amenable to experimental study by laser fluorescence techniques. We shall see below that eq. [3] as it stands is insufficient, and that it will be necessary to subdivide [3] into two sets of processes in order to describe properly the relaxation of the mixed gases.

Our prime source of data for the construction of the required state-to-state rate constants of type [1] is an extensive tabulation (Table II) in the paper by Rabitz and Zarur (7); here, they list cross-sections for state-to-state transitions, induced by collision with He, among even states of H_2. For our purposes, we require all state-to-state rate constants among the set of levels $H_2(v, J)$ for $v, J = 0, 0; 0, 2; 0, 4; 0, 6; 0, 8; 0, 10; 1, 0; 1, 2; 1, 4;$ and $1, 6$. The cross-sections for the endothermic transitions within this group were plotted as shown in Figs. 4 and 6 of the paper of Rabitz and Zarur, and a self-consistent set of "best fit" plots was obtained using their eq. [7]. These functions of cross-section versus energy were then transformed into thermally averaged rate constants for a specific temperature T by following the development, eqs. [4.1]–[4.4] of Augustin and Rabitz (8); and finally, detailed balancing for the temperature in question was used to generate the corresponding rate constants for the reverse (exothermic) processes. For the reason that the thermal averaging procedure is extremely sensitive to small variations in the cross-section fitting procedure at low temperature, and because we cannot consider too high a temperature if we wish to truncate the energy-level system at about ten levels, we chose to perform these calculations at a single representative temperature, that of $T = 500$ K. This procedure, then, yielded a set of T–VR transition rate constants sufficient to describe the relaxation among the ten lowest states of para-H_2 at 500 K, at infinite dilution in He.

In order to extend the calculation to non-dilute mixtures of para-H_2 with He, it is necessary to know the rate constants for all the VR–VR processes of type [2] within this group of states. Here, theoretical information is much less extensive, and we used our previous parameterisation (3) of the results of Zarur and Rabitz (11), namely that for any *exothermic* VR–VR process in para-H_2 at 500 K,

[4] $$k_{ij \rightarrow kl} = 0.006Z \exp\left[-0.002\Delta\varepsilon - 2.5|\Delta J|\right]$$

where Z is the collision number for unlike particles, $\Delta J = J_i + J_j - J_k - J_l$; for processes between like reactants, reactions between $i + i'$ and $i' + i$ were each counted once.

For the analogous ortho-H_2 calculation, we require the set of state-to-state rate constants among the levels $v, J = 0, 1; 0, 3; 0, 5; 0, 7; 0, 9; 0, 11; 1, 1; 1, 3; 1,5;$ and $1, 7$. A few of these have been estimated by Alexander (4–6) for the cases where $|\Delta v| = 1$, but there are too few values from which to deduce a rule by which all the required rates may be estimated. Consequently, we examined the functions constructed from the data of Rabitz and Zarur for even J, and found that at any particular value of the total energy, rotational transfer for J, $J + 2$, and $J + 4$ states were roughly related to each other in a geometric manner. Thus, we interpolated the original tabulated data of Rabitz and Zarur (7) according to the equation

[5] $$\sigma_{v,J \rightarrow v',J'}(E) = [\sigma_{v,J-1 \rightarrow v',J'-1}(E) \times \sigma_{v,J+1 \rightarrow v',J'+1}(E)]^{1/2}$$

in order to estimate cross-sections among the odd states of H_2; thermally averaged rate constants for $T = 500$ K were then constructed as described above.

These data show one major difference from those of Alexander (c.f. Tables IX and X of ref. 4) in that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

he concludes there is a larger cross-section for the transition from $v = 1, J = 1 \rightarrow v = 0, J = 1$ than for that from $v = 1, J = 0 \rightarrow v = 0, J = 0$, whereas we interpolate the data in the opposite sense. This eventually leads Alexander to the conclusion that the rate of relaxation of ortho-H_2 by He is slightly faster than that of para-H_2 (5, 6), whereas the numbers we use make it slightly slower; in fact, it appears that although ortho-H_2 is relaxed by He more quickly than is para-H_2 at low temperatures, the two rates are very nearly the same at room temperature and above (12). For our purposes, this discrepancy is of minor importance: all we require is that the relaxation times for ortho-H_2 and para-H_2 shall be different, so that we may examine meaningfully their individual behaviours in mixtures of the two gases; if we make any arbitrary adjustment to our cross-sections which makes the two relaxation rates too similar, then we will lose the ability to examine departures from the linear mixture rule, or to obtain information about the separation of relaxation times, for mixtures of gases in general.

In the absence of any theoretical data about VR–VR processes of type [2] in ortho-H_2, we again use our earlier parameterisation for the para-states, i.e. eq. [4]. Finally, for the calculations on mixtures of ortho-H_2 and para-H_2, we need to know the rate constants for the exchange processes of type [3] between the unlike species, and we also assume that these can be represented by eq. [4].

With this set of assumptions, we are now in a position to make a sequential analysis of the individual relaxation behaviours of pure ortho-H_2 and pure para-H_2, first at infinite dilution, then as a function of mole fraction in admixture with He, and finally in various mixtures of He with both ortho-H_2 and para-H_2. These calculations were performed using a slightly modified version of the numerical integration routine EPISODE, as described by Koda, McRae, and Seinfeld (13).

As in our earlier work (2, 3), the starting population for the relaxation in single species systems was taken to be a Boltzmann distribution for $T = 500$ K, but with the lowest rotational level of the $v = 1$ manifold overpopulated by a factor of 100 at the expense of the corresponding state in the $v = 0$ manifold; the reasons for using this starting distribution have been fully explained previously (2). In those cases where both H_2 species were present, we investigated starting distribution in which *either* $v = 1, J = 0$ *or* $v = 1, J = 1$ was excited, or else both were simultaneously excited: however, for reasons outlined below, the nature of the initial excitation in these systems is not important, except in highly dilute admixtures with He.

Relaxation of a Single Species at Infinite Dilution

We have made extensive investigations of single species systems involving only processes of type [1] previously (1, 2) using eigenvalue methods which, of course, are valid only at infinite dilution (3). Nevertheless, they are useful in ensuring the correct performance of the numerical integration routines, and in both the ortho-H_2 and the para-H_2 cases, we established that the two methods gave identical results to within the error criterion specified in the numerical integration routine. At this stage, we were able to confirm the exact agreement between the rate constant for energy loss calculated by integration methods and the approximate formula (5, 8)

$$[6] \qquad k_1 \equiv k_{1\rightarrow 0}(T) = \frac{\sum_J \sum_{J'} (2J + 1)[\exp(-\varepsilon_{1J}/\not{k}T)]k_{1J\rightarrow 0J'}(T)}{\sum_J (2J + 1)\exp(-\varepsilon_{1J}/\not{k}T)}$$

This is because the normal modes of relaxation for these two relaxations are very similar to those predicted previously (1) and the rotational relaxation is essentially complete (at this temperature) before the decay of the vibrational energy becomes significant.

We will find it convenient to plot the data in the form of λ, the rate constant for relaxation in the model mixture: this was always taken to comprise 3.5×10^{19} molecules $cm^{-3} \equiv [M]$, whence

$$[7] \qquad \lambda_i = k_i[M] \equiv k_i \times 3.5 \times 10^{19}\ s^{-1}$$

Relaxation of Single Species in Non-dilute Mixtures

Calculations similar to those reported previously (3) for mixtures of ortho-H_2 with He, and para-H_2 with He, for all mole-fraction ratios were performed with these new transition rate data, and the results are shown in Fig. 1. In both cases, the linear mixture rule holds quite well, but there is some downward curvature in the plots of the relaxation rate constants as the mole fraction of H_2, $x \rightarrow 0$; this curvature is of similar magnitude to that we had observed before (3), as is shown in the insets to Fig. 1 where the results for dilute mixtures are plotted on an enlarged scale.[1]

Ignoring this slight curvature, we can write that

$$[8] \qquad \lambda^{o,p}(x) \simeq \lambda_1{}^{o,p} + x\lambda_2{}^{o,p}$$

where λ_1 is given by eqs. [6] and [7], and following

[1]The values of $d\lambda/dx$ shown in Fig. 1 are much greater than that we showed previously (3). This is because, although all the processes of type [2] have the same rates as before, processes of type [1] are now a lot slower, so that $\lambda_1{}^o = 6.8 \times 10^3\ s^{-1}$ instead of $7.9 \times 10^5\ s^{-1}$; thus, type [2] processes have a relatively much larger effect on the dissipation rate in the present calculation.

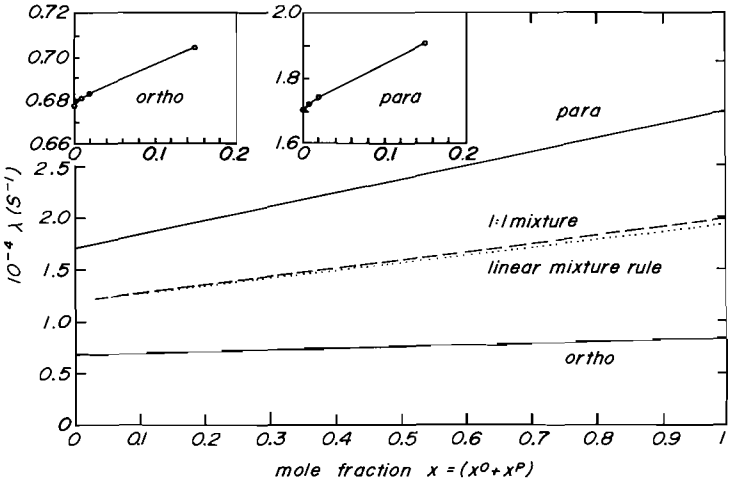

FIG. 1. Relaxation time constants λ for mixtures of H_2 and He containing a total of 3.5×10^{19} molecules cm^{-3} at 500 K. Solid lines: mixtures of He with only ortho-H_2 or only para-H_2; dashed line: 1:1 ortho-H_2:para-H_2 mixtures; dotted line: linear or mixture rule, eq. [10*b*] for the 1:1 mixture. Insets: data for ortho-H_2/He and para-H_2/He mixtures, at $x = 0, 0.01, 0.02$, and 0.15 to illustrate the magnitude of the curvature as $x \to 0$.

the reasoning by which [6] was evolved, we find that

$$[9] \qquad k_2 = \frac{\sum_J \sum_{v'} \sum_{J'} \sum_{J''} \sum_{J'''} (2J+1)(2J'+1)\{\exp[-(\varepsilon_{1J} + \varepsilon_{v'J'})/kT]\}k_{(1J+v'J')\to(0J''+v'J''')}(T)}{\left[\sum_J (2J+1)\exp(-\varepsilon_{1J}/kT)\right]\left[\sum_{v'}\sum_{J'}(2J'+1)\exp(-\varepsilon_{v'J'}/kT)\right]}$$

Equation [9] is the direct analogue of eq. [6], summing over all type [2] processes which transform a $v = 1$ state into a $v = 0$ state: thus, by using eq. [8] with $\lambda_1^{o,p}$ and $\lambda_2^{o,p}$ calculated via eqs. [6] and [9] respectively, the curves shown in Fig. 1 can be reconstructed with an accuracy of better than 0.5% for all x.

Relaxation of Mixtures of Ortho-H_2 and Para-H_2

Although we had originally intended to perform these calculations for a series of ortho-H_2 to para-H_2 mixture ratios, the simplicity of the resulting behaviour enabled us to confine our attention to equimolar mixtures of the two gases, at various dilutions in He. The results for the 1:1 ortho–para mixture at various degrees of dilution in He are shown, also in Fig. 1, as the dashed line: as long as the mole fraction x of H_2 is greater than about 1%, it can be seen that the resulting relaxation rate conforms quite closely to the form

$$[10] \qquad \lambda(x) = \lambda_1 + x\lambda_2$$

where

$$[10a] \qquad x = x^o + x^p$$

and (5)

$$[10b] \qquad \lambda_i = \frac{x^p\lambda_i^p + x^o\lambda_i^o}{x^o + x^p} \qquad i = 1, 2$$

The latter linear mixture relation is shown as the dotted line in Fig. 1; the true relaxation rate is slightly faster than the traditional average, but again the departure from the linear mixture rule is not large. Moreover, in this range of mixtures ($x > 0.01$), the vibrational energies in the ortho-H_2 and in the para-H_2 manifolds always relax together: this is because the exchange processes [3] equilibrate the excess energy between the two species so quickly that they are always virtually in equilibrium with each other.

However, in very dilute mixtures, the situation is quite different, as shown in Fig. 2. The relaxation rate constant for the mixture begins to fall below the arithmetic mean value, eq. [10], and at infinite dilution reaches the relaxation rate of the ortho-H_2/He system. Basically what is happening is that at very high dilutions, the exchange processes [3] die out, and the two manifolds tend to relax separately. However, with the rate constants we have in this calculation, this does not mean that we actually see

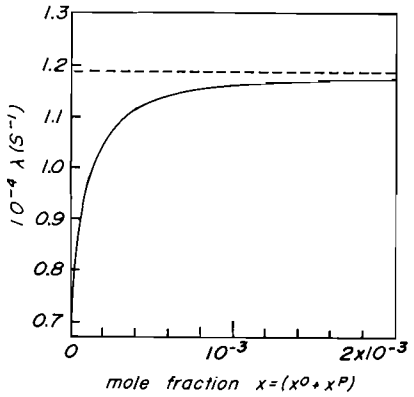

FIG. 2. Comparison of linear mixture rule, eq. [10*b*] (dashed line), with actual relaxation of a 1:1 mixture of ortho-H_2 and para-H_2 at high dilution in He (solid line). Other details as in Fig. 1.

two separate relaxation times — only that by the time either manifold reaches the stage where its energy is decaying exponentially, there is no measurable energy left in the para-H_2 manifold.

Exchange Processes

We have devoted little attention to the initial transient behaviour because there is little new information to be gleaned over and above that presented previously (2). There is however, one qualification to be made to those conclusions: we had found previously that in the simulated laser-schlieren experiment (corresponding roughly to the kinds of initial population distribution we use here), there was an initial *absorption* of energy needed to bring the $v = 1$ rotational manifold into thermal equilibrium with the initially overpopulated $v = 1$, $J = 0$ or $v = 1, J = 1$ state. In non-dilute mixtures, this does not happen: the equilibration of the $v = 1$ rotational manifold still takes place, but not by absorption from the surroundings; instead, these states are fed by $(v = 1 + v' = 0) \rightarrow (v = 0 + v' = 1)$ processes which are implicitly contained within types [2] and [3], with the result that the total energy of excitation decreases from the very beginning.

Exchange processes of this kind are very fast, and although we included them formally in defining processes [2] and [3], we have excluded them in calculating k_2 by eq. [9]. Likewise k_3 is also given by eq. [9], with the constraint that J, J'' refer to one species, J', J''' to the other. We require to project out the set of processes which lead to an exchange of vibrational energy, i.e. $(v = 1 + v' = 0) \rightarrow (v = 0 + v' = 1)$ since these lead to a rapid exchange of energy between the species, with only a small dissipative contribution (due to energy mismatch). The rate constant for such processes will be, extending the previous argument,

$$[11]\quad k_4 = \frac{\sum_J \sum_{J'} \sum_{J''} \sum_{J'''} (2J+1)(2J'+1)\{\exp[-(\varepsilon_{1J}+\varepsilon_{0J'})/kT]\}k_{(1J+0J')\rightarrow(0J''+1J''')}(T)}{\left[\sum_J (2J+1)\exp(-\varepsilon_{1J}/kT)\right]\left[\sum_{J'}(2J'+1)\exp(-\varepsilon_{0J'}/kT)\right]}$$

The numerical magnitude of k_4 is very much greater than that of k_3, because the $k(T)$ terms in the numerator are large.

As we noted above, these exchange processes are implicitly included in the type [2] self-relaxation processes, but their explicit consideration is unnecessary in order to describe the self-relaxation behaviour at long times; however, it is these particular exchange processes which are responsible for reversing the initial rise in energy observed at the beginning of the relaxation in infinitely dilute systems (2).

An Electrical Analogy

In the preceding two sections, we have defined, in terms of specific state-to-state processes, a set of relaxation rates $\lambda_1^{o,p}$, $\lambda_2^{o,p}$, $\lambda_3^{o,p}$, and λ_4, the latter being symmetrical in the species ortho-H_2 and para-H_2; we now show how it is possible to model the relaxation process (once the initial transients have died out) for any mixture of ortho-H_2, para-H_2, and He to an accuracy which for practical purposes is exact: discrepancies between the exact results found by numerical integration and those given by the following procedure never exceeded 0.5% in any of the systems we examined.

Ignoring the minor non-linearities shown in the insets in Fig. 1, we can write the rates of relaxation of the energies in the following form

$$[12]\quad \frac{dE^o}{dt} = -\left[\lambda_1^o + x^o\lambda_2^o + x^p\lambda_3^o + x^p\lambda_4\left(\frac{E^o - E^p}{E^o}\right)\right]E^o$$

$$[12a]\quad \frac{dE^p}{dt} = -\left[\lambda_1^p + x^p\lambda_2^p + x^o\lambda_3^p + x^o\lambda_4\left(\frac{E^p - E^o}{E^p}\right)\right]E^p$$

where $E^{o,p}$ are the instantaneous values of the internal energy relative to their equilibrium values. The structure of these equations arises because the processes with relaxation rates $\lambda_1^{o,p}$, $\lambda_2^{o,p}$, and $\lambda_3^{o,p}$ operate directly on the departure of the internal energy from the equilibrium value, i.e. on $E^{o,p}$, whereas the exchange process with rate constant λ_4 redistributes the energy excess between the ortho-H_2 and the para-H_2 manifolds at a rate which is proportional to the difference $E^o - E^p$ or $E^p - E^o$ depending upon the direction of the energy flow. Writing

$$[13] \quad \lambda^o = \lambda_1^o + x^o\lambda_2^o + x^p\lambda_3^o + x^p\lambda_4$$

$$[13a] \quad \lambda^p = \lambda_1^p + x^p\lambda_2^p + x^o\lambda_3^p + x^o\lambda_4$$

$$[14] \quad \lambda_\varepsilon^o = x^p\lambda_4$$

$$[14a] \quad \lambda_\varepsilon^p = x^o\lambda_4$$

These two equations may be rewritten as

$$[15] \quad dE^o/dt = -\lambda^o E^o + \lambda_\varepsilon^o E^p$$

$$[15a] \quad dE^p/dt = -\lambda^p E^p + \lambda_\varepsilon^p E^o$$

If we replace E by electric charge, these are the equations which govern the discharge of a pair of capacitances connected as shown in Fig. 3, whence it becomes clear immediately that if R_ε is very large, the two capacitances will discharge independently at rates determined by the products R_1C_1 and R_2C_2 respectively, whereas if R_ε is small, the whole system will discharge with a single relaxation time.

The exact solution to the pair of eqs. [15] and [15*a*] is given by

$$[16] \quad E^o(t) = [E^o(0) - \varepsilon^o]\exp(\lambda^+ t) + \varepsilon^o \exp(\lambda^- t)$$

$$[16a] \quad E^p(t) = [E^p(0) - \varepsilon^p]\exp(\lambda^+ t) + \varepsilon^p \exp(\lambda^- t)$$

where

$$\lambda^\pm = -\tfrac{1}{2}[\alpha \pm (\alpha^2 - 4\beta)^{1/2}]$$

$$\alpha = (\lambda^o + \lambda^p)$$

$$\beta = (\lambda^o\lambda^p - \lambda_\varepsilon^o\lambda_\varepsilon^p)$$

and

$$\varepsilon^o = \frac{\lambda^o E^p(0) - (\lambda^o + \lambda^+)E^o(0)}{\lambda^- - \lambda^+}$$

$$\varepsilon^p = \frac{\lambda^p E^o(0) - (\lambda^p + \lambda^-)E^p(0)}{\lambda^+ - \lambda^-}$$

Relaxation Together or Separately?

The values of the various relaxation rates, constructed from the state-to-state cross-sections via eqs. [6], [9], and [11], and which reproduce the relaxation behaviour calculated by numerical integration to within 0.5% when substituted into eq. [16], are as follows

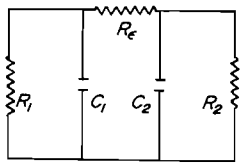

FIG. 3. Electrical circuit equivalent to the vibrational relaxation of ortho-H_2 and para-H_2 mixtures at long time, i.e. after the initial transients have ceased.

$$\lambda_1^o = 6.78 \times 10^3\ s^{-1};\quad \lambda_1^p = 1.70 \times 10^4\ s^{-1}$$
$$\lambda_2^o = 1.62 \times 10^3\ s^{-1};\quad \lambda_2^p = 1.37 \times 10^4\ s^{-1}$$
$$\lambda_3^o = 7.91 \times 10^3\ s^{-1};\quad \lambda_3^p = 8.80 \times 10^3\ s^{-1}$$
$$\lambda_4 = 9.22 \times 10^7\ s^{-1}$$

or, on a per-collision basis, with $Z = 3.68 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} taken to be the collision number for all distinguishable pairs of particles, the values of $P = \lambda/Z[M]$ are

$$P_1^o = 5.27 \times 10^{-7};\quad P_1^p = 1.32 \times 10^{-6}$$
$$P_2^o = 1.26 \times 10^{-7};\quad P_2^p = 1.06 \times 10^{-6}$$
$$P_3^o = 6.14 \times 10^{-7};\quad P_3^p = 6.83 \times 10^{-7}$$
$$P_4 = 7.16 \times 10^{-3}$$

The value of λ_1^p is very close to that calculated by Rabitz and co-workers — interpolating from Fig. 5 of ref. 9 they calculated values near 500 K in the region of 2–4 $\times 10^8$ cm^3 mol^{-1} s^{-1} compared with the value of 2.9 $\times 10^8$ cm^3 mol^{-1} s^{-1} which we find at 500 K using the same primary data. Our value of λ_1^o is somewhat smaller than λ_1^p, in contrast with Alexander's conclusion that it is slightly greater (5, 6), as we have already noted. We cannot compare our calculated values of λ_2 with experiment, although experiments do exist (14, 15), since experimentally, $d\lambda/dx = \lambda_2$ contains a contribution of the kind $[x\lambda_{1,H_2}^{o,p} + (1 - x)\lambda_{1,He}^{o,p}]$ which we have assumed to be independent of x (note that in modelling practical systems, the λ_1 components in eq. [12] would have to be expanded in this fashion). Finally, the calculated value of λ_4, which corresponds to an exchange of internal energy every 140 collisions is reasonable, c.f. a measured value of every 125 collisions for the analogous process between ^{12}CO and ^{13}CO (16).

Going back to our electrical analogy, the exchange of internal energy via λ_4 is very much faster than the decay of that energy via $\lambda_1^{o,p}$, $\lambda_2^{o,p}$, and $\lambda_3^{o,p}$ combined, and so both species relax together; obviously, we could only expect them to relax separately if $\lambda_4 < \lambda_i^{o,p}$, $i = 1, 2, 3$. However, eq. [16] shows that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

if $\lambda_\varepsilon^{o,p} \ll \lambda^{o,p}$, $\lambda^{\pm}$ will be either λ^o or λ^p, in which case the two systems will relax separately: consequently, the criterion for separation of the two relaxations is not simply the intuitive one that the exchange rate constant is smaller in magnitude than the deactivation rate constants, but that the product of the mole fraction with the exchange rate constant is smaller than the deactivation rate constants. Obviously, if λ_4 is very small, the relaxations will separate, but even if λ_4 is large, it may be possible to observe a separation at high dilution in a third inert gas.

From a practical point of view, Foster and Simpson (10) studied the relaxation of N_2O and CO_2 with a view to looking for the separation of the relaxation processes. From the construction of λ_4 by eq. [11] in terms of state-to-state processes, it is clear that λ_4 will always be greater than $\lambda_{1,2,3}^{A,B}$ for any pair of molecules A and B, although as the energy mismatch becomes greater, as for example in the exchange between CO and N_2 (17), the disparity will be less marked. Then, it would seem feasible to observe a separation of relaxation times at high dilution, provided that λ_1^A and λ_1^B were not too different: if they are too different, we will find (as in our model calculation here) that all the energy has relaxed from one molecule in a non-exponential manner before the decay of the energy from the other molecule becomes exponential.

Details of the derivation of eq. [16] and an expanded set of numerical results will be made available later in thesis form (18).

Boron trihalide adducts of 1,1-bis(piperidinyl)ethylene. ^{13}C and ^{11}B nmr studies of a model system for β-carbon donation in enamine adducts

J. STEPHEN HARTMAN[1] AND ERIC C. KELUSKY

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received September 9, 1980

J. STEPHEN HARTMAN and ERIC C. KELUSKY. Can. J. Chem. **59**, 1284 (1981).

1,1-Bis(piperidinyl)ethylene coordinates to the boron trihalides through the CH_2 carbon, but the covalent adducts $D.BX_3$ undergo rearrangement to give predominantly the ionic adducts $D_2BX_2^+.BX_4^-$. Striking variations in ^{11}B and ^{13}C nmr peak widths support our proposed structures. The disappearance of peaks due to excessive broadening can be misleading in the interpretation of such systems.

J. STEPHEN HARTMAN et ERIC C. KELUSKY. Can. J. Chem. **59**, 1284 (1981).

Le bis(pipéridinyl)-1,1 éthylène se coordonne aux trihalogénures de bore au moyen de l'atome de carbone du CH_2, mais les adduits covalents obtenus, $D.BX_3$, se transposent en donnant majoritairement les adduits ioniques $D_2BX_2^+.BX_4^-$. Les fortes variations observées dans les spectres de rmn du ^{13}C et du ^{11}B semblent confirmer les structures que nous proposons. La disparition des pics, due à un étalement excessif, peut conduire à une interprétation erronée de ces systèmes.

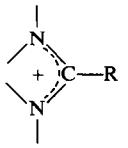
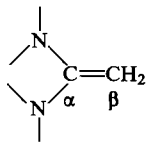
Introduction

The well-known stability of the amidinium ion structure **1** (1) leads to the expectation of exclusive β-carbon protonation and complexation in 1,1-enediamines (**2**). This is well established for protonation (2). The few available studies of complexation of 1,1-enediamines to simple Lewis acids (boron trihalides (3) and Group IV tetrahalides (4)) also show that complexation is at the β-carbon site. In the boron trihalide adducts of 1,1-bis(dimethylamino)ethylene (**3**), there is restricted rotation about the central C—N bonds as a result of the amidinium-ion partial double bond character (3).



1



2

In our current nmr studies of enamine adducts (5), we are attempting to detect ambidentate behaviour of the enamine ligands, in which both nitrogen and the β-carbon are potential donor sites (6). Interpretation of results in the enamine adduct systems, in particular confirmation that β-carbon donation occurs, has been hampered by the scarcity of nmr data on carbon-donor boron trihalide adducts (7, 8). We now report ^{13}C and ^{11}B nmr studies of boron trihalide coordination of 1,1-bis(piperidinyl)ethylene (**4**), a 1,1-enediamine and a model compound for β-carbon donation to Lewis acids.

Results and Discussion

^{13}C Spectra

^{13}C nmr parameters of **4** and its boron trihalide adducts are given in Table 1. The β-carbon of uncomplexed **4** absorbs exceptionally far to high field for an olefinic carbon, and this can be attributed to the importance of the mesomeric forms ***4b*** and ***4c***, with the buildup of appreciable negative charge on this carbon. Similar but less pronounced effects occur in enamines (5, 9). Changes in chemical shift on complex formation are consistent with the β-carbon being the donor atom. Structures ***4b*** and ***4c*** should be the only mesomeric forms contributing to the adducts, due to the localization of a lone pair at the donor position on adduct formation. The pronounced shift to high field of the β-carbon on complexation to BF_3 is consistent with the required hybridization change to sp^3. The shift back to lower field in the heavier-halogen boron trihalide adducts is consistent with the increasing Lewis acid strength of these compounds and the nearness of the BX_3 moiety. The 6 ppm chemical shift difference between the BF_3 and BCl_3 adduct β-carbon resonances is consistent with the 2.6 ppm difference between the ^{13}C resonances of $Me_3N.BF_3$ and $Me_3N.BCl_3$ (10), and the 3–7 ppm between

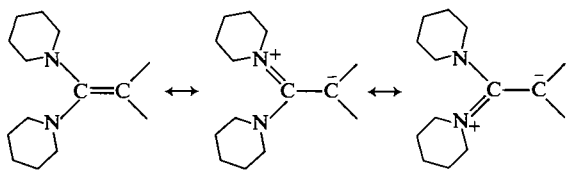
α-carbon resonances of BF_3 and BCl_3 adducts of ethers (11).

The α-carbon resonance shifts to low field in the adducts and in protonated **4** (Table 1). The chemical shift of 168.7 ppm for protonated **4** is consistent with values for other amidinium ions ($[(Me_2N)_2CH]^+$, 156.4 ppm (12), $[(Me_2N)(C_6H_5NH)CCl]^+$, 159 ppm (13)). However correlations of $C{=}N^+$ ^{13}C chemical shifts are generally poor, the nature of the anion having a strong influence, which can be as much as 10 ppm (12). The α-carbon shifts in the adducts (172–178 ppm, and temperature-dependent) are close to the amidinium ion range. Doubling of the adduct α-carbon resonance at low temperatures in some cases indicates additional complexity in the adduct systems, as is discussed below. The small shift to low field of the piperidinyl C-2 and C-6 carbons is consistent with adduct formation at a donor site remote from these carbons.



4*a* **4***b* **4***c*

Peak widths of the resonances assigned to the β-carbons are given in Table 1. The resonances are broad or even unobservable at ambient temperature, but become sharper as the temperature is lowered. This is consistent with coupling to ^{11}B which is undergoing quadrupole relaxation. Quadrupole relaxation is more effective at lower temperatures, due to slower molecular tumbling. This causes a more complete collapse of the splittings due to ^{11}B–^{13}C coupling, and of any residual peak broadening due to such coupling, at lower temperatures in the spectrum of the spin-1/2 nucleus coupled to the quadrupolar nucleus (14). Thus spectra of spin-1/2 nuclei coupled to boron are often simplified at low temperatures (7). In a

[a]Chemical shifts are in ppm to low field of external trimethoxyboron. (To convert to ppm to low field of boron trifluoride etherate, add 18.1 ppm.) Values in brackets are peak widths at half-height. The BX_4^- peak remains quite sharp at all temperatures.
[b]Not visible.
[c]Broad and badly overlapping peaks.
[d]Insufficient resolution.
[e]Broad resonance, likely a composite of D.BX_3 and $D_2BX_2^+$.
[f]Spectrum is complex, apparently due to decomposition.
[g]Obscured by the BF_4^- peak and by poorly-resolved fine structure which is probably due to boron–fluorine coupling.

number of cases a carbon directly bonded to boron is undetectable at ambient temperature due to excessive broadening from coupling to ^{11}B, but does give a peak at low temperatures (15). Thus our ^{13}C peak widths support our β-carbon peak assignments and the proposed adduct structure.

Splittings due to ^{11}B–^{13}C coupling can usually be seen in ^{13}C nmr spectra of tetrahedral boron compounds with C—B bonds, but these splittings are often not visible in three-coordinate boron compounds (7). This is in accord with the expectation that quadrupole relaxation of boron should be less effective in tetrahedral boron compounds due to their higher symmetry (14). The absence of such splittings in the ^{13}C spectra of the present series of adducts is thus somewhat unusual. ^{11}B chemical shifts are not consistent with three-coordinate boron. The effect of the bulky enediamine donor in slowing molecular tumbling is probably responsible for the effectiveness of ^{11}B quadrupole relaxation in these adducts, leading to ^{13}C and ^{11}B peak widths more typical of trigonal boron than of tetrahedral boron.

^{11}B Spectra

Solutions of **4** with the boron trihalides in a 1:1 molar ratio or with excess **4** give more than one ^{11}B nmr signal, and the signals have a very wide range of peak widths (Table 2 and Fig. 1). Uncomplexed boron trihalide peaks, which would absorb at low

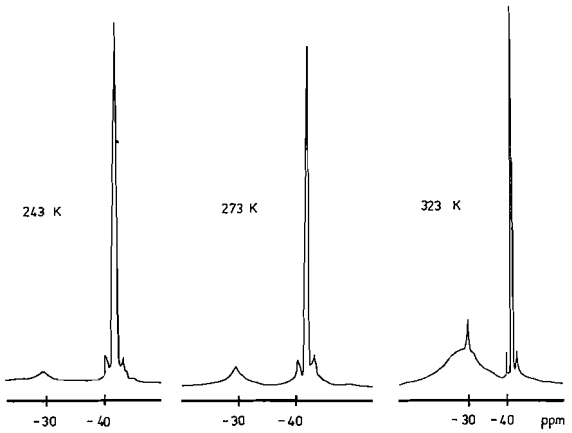

FIG. 1. ^{11}B nmr spectra of **4**.BBr_3 at various temperatures. The spectra were transformed with 5 Hz of line broadening, slightly increasing the apparent width of the BBr_4^- signal.

field, are absent, as are resonances in the RBX_2 region which is at even lower field (8). The spectra are consistent with adduct formation followed by redistribution of donor for halogen to give the ionic form of the adducts, $D_2BX_2^+.BX_4^-$.

[1] $2D.BX_3 \rightleftharpoons D_2BX_2^+ + BX_4^-$

Comparison with literature values (16–18)[2] of ^{11}B chemical shifts of adducts and related species

[a]In ppm to low field of trimethoxyboron.

(Table 3) shows that the sharpest peak in the ^{11}B spectra of the **4**/BX_3 samples corresponds to the tetrahaloborate anion BX_4^-. From the size of the peak, BX_4^- is a major species. Boron cations such as $D_2BX_2^+$ are well-known species (19, 20) but ^{11}B chemical shifts have been reported for few haloboron cations (8).

In the **4**/BBr_3 and **4**/BI_3 systems, one broad resonance has a chemical shift consistent with the values for known simple boron trihalide adducts (Table 3) and is assigned to **4**.BX_3. An additional, even broader resonance occurs at lower field, and we have assigned this to $D_2BX_2^+$. One further very broad resonance is present in the **4**.BI_3 system and might arise from a species such as D_3BI^{2+}. Precedent exists for such species, which are most easily formed when iodines, having the weakest boron–halogen bonds, are available to be displaced (19). Supporting evidence for our assignments comes from addition of tetramethylammonium iodide to solutions of **4** and BI_3. The size of the initially-small −78 ppm peak, assigned to **4**.BI_3, is greatly increased relative to both of the lower-field peaks, in accord with reactions such as [2].

[2] $D_2BI_2^+ + I^- \rightleftharpoons D.BI_3 + D$

In the ^{11}B spectrum of the **4**/BBr_3 system (Fig. 1) the resonance of intermediate chemical shift and peak width that is assigned to D.BBr_3 is small, consistent with equilibrium [1] being far to the right. The very slight chemical shift difference between the broad resonances assigned to D.BBr_3 and $D_2BBr_2^+$, together with the small range of chemical shifts of B–Br compounds when compared to analogous B–I compounds (Table 3), makes it unlikely that any further broad resonance signals, such as might arise from D_3BBr^{2+}, would be detectable. The broadest resonance could be a composite signal, rather than solely due to $D_2BBr_2^+$.

^{11}B peak areas are not consistent with $D_2BX_2^+$ and BX_4^- as the only ions in solution. The peaks assigned to cations are considerably larger than those assigned to BX_4^- ions. Halide ion is another possible counterion for $D_2BX_2^+$ (19, 20) and would not be detected in this study.

The small ^{11}B chemical shift ranges in the **4**/BCl_3 and **4**/BF_3 systems do not allow adequate resolution of peaks in addition to BX_4^-. However, there is definitely a large broad resonance underlying the BX_4^- peak in each system. It becomes less broad at higher temperatures, but resolution into separate signals has not been possible. The existence of the broad, poorly resolved resonance does indicate that reactions analogous to those in the heavier boron trihalide adduct systems are occurring.

Peak widths and their variation with temperature are the most striking feature of the ^{11}B spectra. In contrast to the ^{13}C spectra, some peaks became too broad to detect at the *lowest* temperatures, in keeping with very short lifetimes of the ^{11}B spin states due to more effective quadrupole relaxation at these temperatures (14). The variations of ^{11}B peak widths support our assignments. The tetrahaloborate ions, with full tetrahedral symmetry, give quite sharp peaks to the lowest temperatures studied, because the high electric field symmetry about boron decreases the effectiveness of quadrupole relaxation. The adducts D.BX_3, with only C_{3v} symmetry about boron and also with molecular tumbling slowed due to the attachment of a bulky donor group, undergo more effective quadrupole relaxation and hence give much broader resonances. Since the boron is in a somewhat-flexible C—CH_2—BX_3 unit, considerable local tumbling should still be possible. $D_2BX_2^+$ ions, with only C_{2v} symmetry, should give the broadest peaks. The effect should be accentuated by the much slower tumbling of the boron-containing part of the molecule due to anchoring between two very bulky donor groups. These are indeed the broadest peaks.

Boron trihalide adduct systems can be far more complex than is frequently assumed; reaction [1] is one of several possible complications (21). ^{11}B chemical shifts of the tetrahaloborates confirm reaction [1], in accord with a recent suggestion (8). Nuclear magnetic resonance studies involving only donor-molecule nuclei can be misleading in that they give no direct evidence of this reaction. ^{11}B chemical shift and peak width studies should have

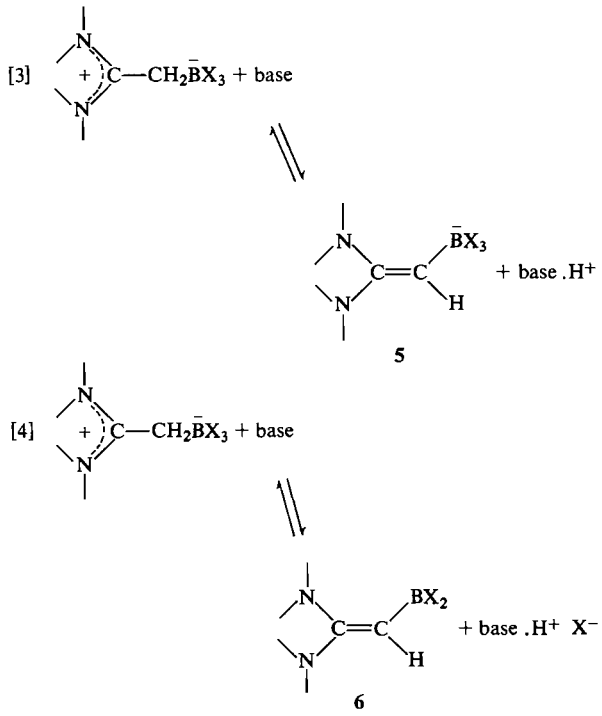
similar value in other adduct systems in which such complications may occur.

Further Aspects

1,1-Enediamines have low stabilities, especially in the presence of Lewis acids, and this severely limits their usefulness as ligands. The present study has been limited by the tendency of many nmr samples to give precipitates on standing, and a few features of the spectra have not been fully explained. Thus ^{13}C spectra show that protonated **4** is present in variable amounts in our samples. Possible reactions of the initially-formed adducts include loss of an acidic β-hydrogen to give an organoboron enediamine, **5** or **6**:



When the base in eqs. [3] and [4] is excess uncomplexed enediamine, protonated **4** would be formed. Such reactions have been reported for enediamine-group IV Lewis acid complexes by Weingarten and Wagar (4), and some evidence for similar reactions has been found for the adduct **3** (X = F) by ^{1}H and ^{19}F nmr (3). Such reactions apparently occur to a significant extent on standing in methylene chloride solution at ambient temperature for a few hours (22), consistent with the behaviour of carbon acids which often undergo relatively slow proton transfer (23). However, absence of the olefinic-carbon resonances expected for **5** or **6** argues against this reaction being the source of protonated **4**. Protonation might also arise from traces of hydrogen halide present in the boron trihalide (24) or from DCl which is often present in deuterochloroform, but this normally gives only traces of the protonated species.

Doubling of the ^{13}C α-carbon resonances in some of the adduct spectra at low temperatures could be the result of ion pairing effects, since $C{=}N^+$ shifts are quite anion-dependent (12). The absence of an equivalent doubling of the β-carbon resonances, together with the coalescence of the α-carbon resonances as the temperature is raised, excludes the possibility that the donor environments in $D.BX_3$ and $D_2BX_2^+$ give rise to the separate α-carbon resonances. The boron–carbon bonds must be long-lived to account for the broadening of the adduct β-carbon resonances at higher temperatures, and hence α-carbon resonances from $D.BX_3$ and $D_2BX_2^+$ would not coalesce. Ion pairing, on the other hand, would have the greatest effects on the α-carbon, and changes involving the counterion would be fast, consistent with the data. However, confirmation of such ion pairing effects awaits further work.

A 1,1-enediamine complex with platinum(II) has recently been reported (25). Two isomers, an η^2 (metal–olefin) complex and an η^1 (β-carbon-donor) complex analogous to our adducts, were postulated on the basis of ^{1}H and ^{13}C nmr data. ^{13}C chemical shifts for the η^1 complex are very similar to ours (Table 1) and an especially large ^{13}C–^{195}Pt coupling constant provides further evidence for the structure. The inherent interest of 1,1-enediamines as carbon-donor "ylide" ligands merits further studies of their coordination behaviour, in spite of difficulties arising from their high reactivity.

The readiness of boron trihalide adducts of 1,1-enediamines to rearrange according to eq. [1] throws light on our current studies of possible ambidentate behaviour of enamines as ligands to the boron trihalides. Initially-formed nitrogen-donor adducts of certain enamines convert to a second species, which ^{13}C nmr indicates is the β-carbon-donor adduct (5). However, ^{11}B nmr, showing only BX_4^- resonances for the second species, seemed inconsistent with the ^{13}C results. Our present study, showing that carbon-donor BX_3 adducts are especially susceptible to reaction [1], resolves the apparent inconsistency. We have apparently been unable to detect ^{11}B nmr signals of the enamine $D.BX_3$ and $D_2BX_2^+$ species due to excessive peak broadening. We will report our enamine coordination studies in a further paper.

Experimental

1,1-Bis(piperidinyl)ethylene (**4**) was synthesized by reacting

1,1,1-triethoxyethane and piperidine in the presence of toluene-4-sulfonyl chloride, according to the method of Baganz and Domaschke (26). Freshly distilled **4** is clear and colorless but it discolors on standing. The nmr samples were prepared in a nitrogen-filled glove box and made up as 20% solutions of the enediamine in deuterochloroform.

Boron tribromide and boron triiodide (Alfa Inorganics), which had been transferred and sealed into ampoules on a high-vacuum system, were opened in the glove box and added to the enediamine solutions which were cooled to −50°C. BF_3 and BCl_3 (Matheson) were added directly from the cylinder to some samples. For other samples, BF_3 and BCl_3 were purified on the high-vacuum system and condensed onto a solution of the enediamine at −196°C, and allowed to warm and react; the excess boron trihalide and the solvent were pumped off, leaving the adduct as a colorless oil.

^{13}C and ^{11}B nmr spectra were obtained on a Bruker WP-60 Fourier Transform nmr spectrometer operating at 15.08 MHz and at 19.25 MHz, respectively; 10 mm sample tubes were used. For ^{13}C spectra a 3759 Hz sweep width was used, with a 1.09 s acquisition time for 8K of data memory, using quadrature detection. A 30° pulse was used, with the Phase Alternating Pulse Sequence, and up to 5000 pulses were accumulated. The FID's were transformed with 0.5 Hz of line broadening. Off-resonance decoupled spectra were obtained to confirm peak assignments and used a proton frequency set at 250 Hz to high field of tetramethylsilane. For ^{11}B spectra various sweep widths and memory sizes were used in order to optimize spectra containing both sharp and broad resonances. Transformation of FID's with extreme line broadening (> 100 Hz) was found to be helpful in confirming the presence of very broad peaks which were difficult to detect above the noise when zero or small line broadening was applied.

n–π Electron donor–acceptor complexes. I. Aliphatic amines with benzonitrile

J. ANUNZIATA, J. SINGH, AND J. J. SILBER[1]

Universidad Nacional de Río Cuarto, Departamento de Química y Física, C.C. 135-5800 Río Cuarto, Córdoba, Argentina

Received September 26, 1979[2]

J. ANUNZIATA, J. SINGH, and J. J. SILBER. Can. J. Chem. **59**, 1291 (1981).

Interaction of diethyl, triethyl, *n*-butyl, di-*n*-butyl and tri-*n*-butyl amines as n-donor with benzonitrile as π-acceptor has been studied in *n*-hexane. The formation of weak electron donor–acceptor (EDA) complexes is proposed to explain the spectroscopic behavior of the mixtures. An iterative procedure was used to obtain values of stability constants (K) and extinction coefficients (ε). The fact that from the new absorption observed for these systems a value of K and a finite constant value of ε could be determined gives proof of the existence of EDA complexes. This conclusion is further supported by the temperature effect observed. Correlations of the experimental data with amine structure and other types of amine complexes were found.

J. ANUNZIATA, J. SINGH et J. J. SILBER. Can. J. Chem. **59**, 1291 (1981).

On a étudié l'interaction entre le diethyle, le triethyle, le *n*-butyle, le di-*n*-butyle et le tri-*n*-butyle amines comme donneurs n et le benzonitrile comme accepteur π dans le *n*-hexane. Pour expliquer le comportement spectroscopique des solutions de ces amines avec benzonitrile, on propose la formation de complexes faibles electron donneur–accepteur (EDA). On a employé une méthode itérative pour l'obtention de valeurs des constantes de stabilité (K) et des coefficients d'extinction (ε). En effet, á partir de la nouvelle absorption observeé dans ce systéme on a pu remarquer des valeurs de K et des valeurs limitées et constantes de ε, ce qui prouve l'existence de complexes EDA. L'effet de temperature observé renforce encore toutes ces conclusions. On a fait, des correlations parmi les éléments obtenus des expériences effectuées et la structure des amines et d'autres sortes de complexes d'amines.

Introduction

The existence of n–π type molecular complexes has been widely postulated (1). It seems characteristic of a particular n-donor to form weaker complexes with π-acceptors than with any other kind of acceptor (1*b*, 2). Thus, although the ionization potentials of aliphatic amines are mostly less than 9 eV, small enough for them to be good electron donors, their complexes with π-acceptors appear to fall in the category of weak charge-transfer complexes (3). The contribution of the charge-transfer interaction to the ground state stabilization is relatively small in these complexes, and it is appropriate to speak of them as molecular electron donor–acceptor (EDA) complexes.

The most studied π-acceptors in their interaction with aliphatic amines have been polynitroaromatic compounds (4–9). These interactions are strongly dependant on the solvent and the amine structure.

From the physicochemical properties of liquid binary systems of aliphatic amines and polar mono-substituted benzenes, the formation of EDA complexes has been inferred (10, 11), and they are considered the initially formed intermediates of nucleophilic aromatic substitution and other reactions (12–14).

The involvement of these complexes in the mechanism of general carbonyl reactions has been established (14) as well as the important biological implications of these types of interactions in protein chemistry (15).

Recently, excited charge-transfer complexes were proposed as intermediates in photochemical reactions of dicyanobenzenes and saturated amines (16–18). Furthermore intramolecular, n–π, charge-transfer interactions have been confirmed for 1-(*p*-nitrophenyl) alkanes bearing a dimethylamino group on the ω-carbon (19).

Summarizing the literature, the interaction of aliphatic amines with π-acceptors seems to follow a general pattern. In ionizing solvents, the intermediate n–π complex goes to products, making it difficult to study the complex itself; in nonpolar solvents these complexes appear to be stable but there is little information about their stabilities and thermodynamic properties. The lack of these data could be attributed to the fact that these are weak complexes and such studies, by the usual spectrophotometric methods (20), are difficult.

In order to assert most of the proposals given in the literature, a systematic study of amine complexes with π-acceptors is necessary to obtain quantitative data about stability constants and other thermodynamic properties. Also, these properties should be related to the structures of the amines and acceptors and to solvent effects.

In this work, as part of a series, the interaction of some aliphatic amines with benzonitrile as π-acceptor has been studied in the inert solvent (21)

Solvent: *n*-hexane. Temperature: 27 ± 0.1°C.

n-hexane. Correlations of the data with amine structure and other types of amine complexes were performed.

Experimental

n-Hexane (Carlo Erba R. P.) was purified by treatment with fuming sulfuric acid several times, washed to neutrality, dried over anhydrous $CaCl_2$, and fractionally distilled over metallic sodium. The distillate was kept over 4 Å molecular sieves (Merck). The solvent was then thoroughly degassed and distilled in a high vacuum line before use. Ultraviolet cut off point: 210 nm.

Diethylamine, triethylamine, *n*-butyl, di-*n*-butyl, and tri-*n*-butyl amines (Aldrich Chemical Co.) were purified and dried just before use by the following procedure. The amine was left over KOH pellets for several days, then refluxed, and later distilled in a dry nitrogen atmosphere over metallic sodium, collecting the middle fraction.

Benzonitrile (Fluka) was distilled over P_2O_5 under dry nitrogen atmosphere collecting the middle fraction. This distillation was repeated as many times as necessary until the residue remained colorless.

All the reagents were degassed and distilled in a high vacuum line just before use to ensure anhydrous conditions.

Spectra were measured in a thermostatted 10 mm cell in a Cary 17 spectrophotometer.

Data processing was performed in a Monroe 1860 computer and a Hewlett-Packard 9810 programable calculator.

Solutions were prepared by weighing the liquids and diluting with *n*-hexane as solvent. The complete range of concentrations used was of 0.5 to 6 *M* for benzonitrile and from 0.5 to 3.5 or 6 *M* for the amines, depending on their molecular weight. All solutions were freshly prepared prior to use.

Results

Spectral Characteristics of Solutions of Aliphatic Amine – Benzonitrile in n-*Hexane*

Typical spectral results are shown in Fig. 1. Although no new band assignable to complex formation is observed, there is an appreciable deviation from additivity of the optical density with respect to that of the amine and benzonitrile alone.

The change in the spectrum can be most likely interpreted in two ways: (*i*) a solvent shift of an absorption band of one component of the solution in the presence of the other, (*ii*) the formation of an EDA complex. For case (*i*) it is reasonable to consider that a high concentration of amine in a dilute hexane solution of benzonitrile would produce a red shift of the longer wave-length absorption of the latter, as predicted by dielectric theory (22). This is a pure electrostatic effect, which would lead to observation of an enhanced absorption in the tail of the band which has been experimentally measured, shown as full lines in Figs. 1(a) and 1(b). However, it is highly improbable that such a shift would

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

occur when the ratio of concentrations is reversed: i.e. excess of benzonitrile in a dilute hexane solution of amine (as is observed in Figs. 1(a) and 1(b), broken line). Furthermore it is widely recognized that solvents capable of acting as lone pair n-donors may produce anomalous shifts with respect to those expected from a purely electrostatic effect (23). The fact that amines are good n-donors, and that the deviation from additivity reaches an equivalent value with either an excess of benzonitrile or of amine suggests that the effect is caused by an alternate mechanism. The formation of EDA complexes is considered to be this mechanism. In fact, formation of EDA complexes is considered as a specific solvent effect, in addition to the electrostatic ones, and as Davis (23) has pointed out, this effect when present is likely to dominate the solvent–solute interaction.

In light of these arguments, the absorbance of the mixture (A_T) is interpreted as the sum of three components (eq. [1]).

$$[1] \quad A_T = A_A + A_D + A_{AD}$$

where A_A, A_D, and A_{AD} stand for the absorbance of the acceptor (benzonitrile), the donor (amine), and the complex at equilibrium concentration, respectively.

Assuming that Beer's Law holds for every species involved (24) and considering the formation of only a 1:1 complex, eq. [2] can be defined

$$[2] \quad A_c = A_T - (A_{Ao} + A_{Do})$$

where $A_{Ao} = \varepsilon_A$ [Ao], $A_{Do} = \varepsilon_D$ [Do], and where [Ao] and [Do] represent the initial molar concentrations of acceptor and donor; ε_A and ε_D are the molar extinction coefficients of these components.

The values of A_c calculated from A_T by eq. [2] give a measure of a deviation from additivity in the mixtures. Since no new band could be defined, A_c was obtained in the range between 295 and 305 nm where the experimental values were most accurately determined. The range of λ was restricted due to the high absorption of both donor and acceptor at shorter λ than 290 nm.

For every amine–benzonitrile system A_c values were determined by varying the concentration of either the donor or acceptor in excess with the concentration of the minor component kept constant. Some values were obtained for equal concentrations of both. Typical plots of A_c vs. concentration of the component in excess are illustrated in Fig. 2. The values of A_c obtained were independent of which component was in excess. This independence of the A_c values from the nature of the component in excess is evidence in favor of

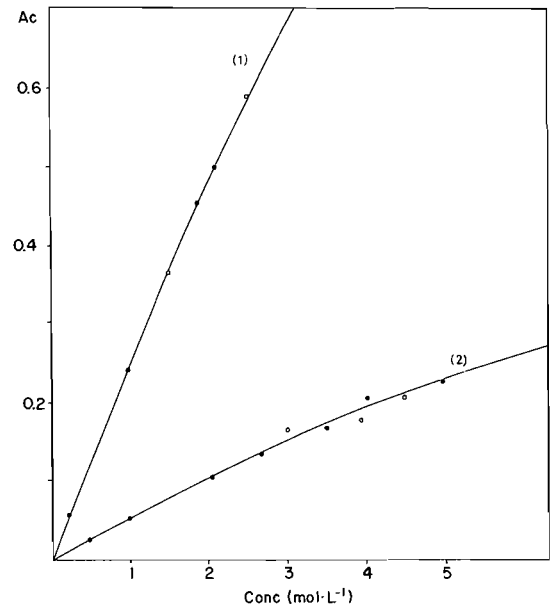

FIG. 2. Values of A_c for the systems: (1) tri-*n*-butylamine – benzonitrile, (2) di-*n*-butylamine – benzonitrile. Solvent: *n*-hexane. Temperature: 27 ± 0.1°C, λ = 300 nm. (●) Excess of amine (0.25–5 *M*); (○) excess of benzonitrile (0.25–5 *M*). Concentration of the low concentration component 0.08 *M* in all cases.

the formation of 1:1 EDA complexes. Moreover the curvature of these plots is characteristic of a particular amine, giving a qualitative picture of the equilibrium conditions. (The larger the deviation from a straight line, the greater the stability constant *K*.)

Determination of K *and* ε

By the results hitherto presented, if constancy of the ratio of activity coefficients is proposed (25), *K* can be expressed in terms of molar concentrations of benzonitrile [Ao] and amines [Do] as eq. [3];

$$[3] \quad K = [AD]/([Ao] - [AD])([Do] - [AD])$$

[AD] being the equilibrium molar concentration of the complex. If $A_{AD} = \varepsilon_{AD}$ [AD] is assumed, the following expression can be derived

$$[4] \quad \frac{[Ao]}{A_{AD}} = \frac{1}{K\varepsilon_{AD}}\frac{1}{[Do]} + \frac{[Ao]}{[Do]\varepsilon_{AD}} + \frac{1}{\varepsilon_{AD}} - \frac{[AD]}{[Do]\varepsilon_{AD}}$$

To solve eq. [4] for *K* and ε_{AD} a variety of graphical methods have been developed depending upon the system and experimental conditions (1*a*, *c*).

In the case where the absorption of the complex overlaps with the one of the donor and the acceptor, and considering

$$[5] \quad \varepsilon_c = \varepsilon_{AD} - (\varepsilon_A + \varepsilon_D)$$

[d]Reference 33.

the following expression can be derived (26).

$$[6]\quad \frac{[Ao][Do]}{A_c([Ao]+[Do])} = \frac{1}{K\varepsilon_c}\frac{1}{([Ao]+[Do])} + \frac{1}{\varepsilon_c}$$

For every system studied, the values of A_c measured at different [Do] and [Ao], were plotted as in eq. [6]. A good straight line is obtained when some experimental points are neglected. From the intercept ($1/\varepsilon_c$) and the slope ($1/K\,\varepsilon_c$), the values of K and ε_c can be determined. However, the uncertainty in the determination of $1/\varepsilon_c$ is high depending upon which values of A_c are considered.

The values of the intercept change drastically if points for [Ao] = [Do] are included in the plot. Furthermore values of A_c for high values of [Ao] + [Do] seem to align better than for low donor or acceptor concentration. Therefore, calculations of K become completely unreliable. Several critical reviews about potential errors in the use of this type of graphical method for weak complexes have been published (1*c*, 20, 24, 27). Also Person (28) has shown that, for weak complexes it is very difficult experimentally to obtain concentrations of the complex which are high enough to give a good number of points sufficiently separated in the graph to allow a reliable calculation of K. In fact, this difficulty is at the root of the problems in proving the existence of weak complexes.

In order to overcome these problems, an iterative procedure was developed, where every experimental value of A_c was used independent of the initial donor or acceptor concentrations.

The method takes an approximate value of K obtained by plots of eq. [6], and then the corresponding value of [AD] is calculated by solving eq. [3] for each experimental point. Then, by using relation [7],

$$[7]\quad 1/[AD] = \varepsilon_c\, 1/A_c$$

and the usual least-squares procedure, a value of ε_c is obtained. The fit to eq. [7] obtained is measured by the correlation coefficient. An arbitrary change of K is then made and the whole process is repeated. The fit obtained is compared with the one obtained previously. The value of K is varied to obtain a better fit until there is no further improvement. In this way, the best values of both K and ε_c according to the least-squares criterion are found.

It should be noted that this method works with any ratios of [Do] to [Ao], the only restriction being that the values of A_c be sufficiently high to be measured accurately. Taking into account Person's (28) and Derenleau's (29) criteria, the best experimental points were chosen from graphs of the type shown in Fig. 2 (data corresponding to saturation fractions between 0.09 and 0.9). The same criteria (29) were used to calculate the error in the determination of K. The results obtained for measurements at λ = 300 nm are shown in Table 1.

Variation of K with λ was not appreciable; nevertheless, the range of λ that could be measured was so small that it is not possible to eliminate the possible existence of such an effect.

Since the values of ε_A and ε_D at 300 nm are very low (of the order of 10^{-2} L mol^{-1} cm^{-1}), the value of ε_c corresponds very closely to the value of ε_{AD} at this λ.

Temperature Dependance of K

The behaviour of K with temperature was studied for the system diethylamine–benzonitrile. K was determined by the described method at three temperatures; 16°C, 27°C, and 40°C ± 0.2°C. From the slope of the plot of log K vs. $1/T$ (Fig. 3) a value of -2 kcal mol^{-1} was found for the enthalpy change. This procedure assumes that ε_{AD} does not change with temperature, which is thought to be a reasonable approximation for the small range of temperature involved (30). The small negative value of ΔH encountered is consistent with the value expected for the formation of a weak EDA complex (1).

Discussion

To interpret the results from the interaction between aliphatic amines and benzonitrile, some structural properties of the molecules must be con-

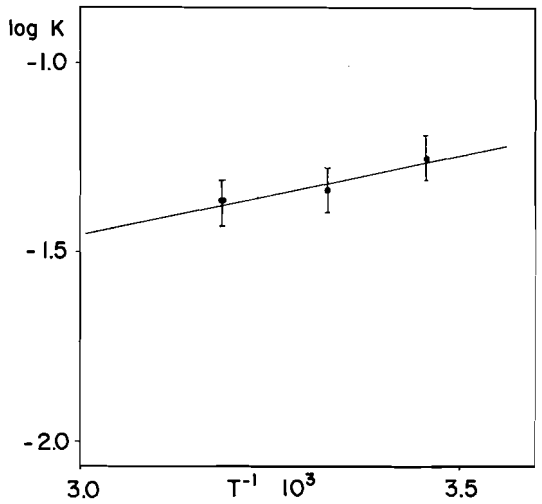

FIG. 3. Behavior of log K vs. T^{-1} for the system benzonitrile–diethylamine in n-hexane.

sidered. The presence of a cyano group in the aromatic ring, causing it to become electron deficient, makes benzonitrile a π-type of acceptor for the nonbonding electrons of a heteroatom (O, N, etc.). From these properties the formation of weak EDA complexes of benzonitrile with aliphatic amines has been proposed to explain the unusual deviation from additivity of refractive index and density of binary solutions of these compounds (10, 11). At the same time it must be recognized that, in interaction of an electron donor and acceptor to form a complex, interactions other than the charge-transfer type (such as electrostatic or dipolar) may play an important role in the ground state stabilization (22). However, the fact that from the new absorption observed in this study, a value of K and a finite constant value of ε could be determined, confirms the proposal of formation of an EDA complex between aliphatic amines and benzonitrile. Moreover, possible "contact complexes' (31) which avoid this kind of determination may be discarded as the unique cause of the spectral changes observed. These conclusions are further supported for the temperature effect observed, which is consistent with the known behaviour of weak EDA complexes.

The complexes of aliphatic amines with benzonitrile are undoubtedly very weak as judged by the small values of K. Nevertheless, the effect of the donor structure is reflected in these results. There is little correlation between the pK_a values of amines and their respective K values with benzonitrile (Table 1); this is hardly surprising, as the pK_a value is a measure of the Brönsted basicity, while the K is presumably a measure of the Lewis basicity of alkyl amines (32). It has been found that the electron donor strength of $R_3N > R_2NH > RNH_2$ predicted from the inductive effect of alkyl groups is expected to change when bulky substituent groups exert steric hindrance in the case of complex formation (33, 34). Considering that the value of the stability constant reflects the donor strength of the amine toward benzonitrile, it is possible to conclude that the same steric effects are present in these n–π complexes as in the n–v (R_3N: BMe_3) (34) and n–σ (R_3N: I_2) (35) complexes. Thus, secondary amines form stronger complexes than tertiary and primary.

The failure to observe a new maximum from the complex formed may be attributed to the fact that there is broadening of a component band, due to admixture of a component excited state with a charge transfer state (36). However, a likely possibility is that the difference in absorption of the mixture with respect to either component alone corresponds to overlap with a new band of the EDA complex. It is expected that for this type of system the new band would lie in a region of the uv spectrum which is unreachable experimentally due to the strong absorption of both donor and acceptor at the concentrations that must be used to detect such weak complexes. A maximum for such a band in aliphatic amine complexes with a stronger π-acceptor, namely 1,3,5-trinitrobenzene (6), has been found. These maxima vary with the ionization potential (I_p) of the amine in a very similar way to the variation of λ_{max} of the corresponding aliphatic amine complexes with iodine (35). In this matter, and considering that the values of ε_{AD} calculated for the amine–benzonitrile systems represent the extinction coefficient of the tail of the new absorption band at 300 nm, they would vary with the I_p of the amine, if there is a shift of λ_{max} with it. It is evident, as is shown in Table 1, that this is so. Assuming that $\varepsilon_{AD(max)}$ is not drastically different for different amines (32), the increase in ε_{AD} at 300 nm reflects the shift in λ_{max} with the order $R_3N > R_2NH > RNH_2$, as is observed for the cited n–π complexes (6).

Work is in progress to assess these conclusions from further thermodynamic data such as ΔH and ΔS measurements. Stronger π-acceptors such as nitro-substituted benzenes will be chosen in order to avoid some of the experimental difficulties found for the benzonitrile systems.

It is believed, however, that for the systems studied, the data obtained gives good evidence of complex formation which correlates with donor strength as expected and which can be used as a starting point for the elucidation of the chemical

properties of n–π complexes in reaction mechanisms.

The addition of simple aromatic hydrocarbons to condensed aromatic thiophenes promoted by aluminum chloride. Part II. Naphtho[1,2-*b*]thiophene

PETER DAVID CLARK AND DAVID M. MCKINNON

Department of Chemistry, The University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 6, 1980

PETER DAVID CLARK and DAVID M. MCKINNON. Can. J. Chem. **59**, 1297 (1981).

The reaction of naphtho[1,2-*b*]thiophene with an aromatic hydrocarbon in the presence of aluminum chloride at 20°C gave either a 3-aryl-2,3-dihydronaphtho[1,2-*b*]thiophene by addition to the 2,3-bond or 2,3-dihydronaphtho[1,2-*b*]thiophene as a result of hydride abstraction.

Occasionally 2-aryl-2,3-dihydronaphtho[1,2-*b*]thiophenes were obtained. At higher temperatures 2-arylnaphtho[1,2-*b*]thiophenes and 2,3-dihydronaphtho[1,2-*b*]thiophene were isolated. Attempts are made to rationalize the formation of these products in terms of protonation of naphtho[1,2-*b*]thiophene by moist aluminum chloride and reaction of the resulting electrophile with an aromatic substrate.

PETER DAVID CLARK et DAVID M. MCKINNON. Can. J. Chem. **59**, 1297 (1981).

Le naphto[1,2-*b*] thiophène réagit avec un hydrocarbure aromatique en présence de chlorure d'aluminium à 20°C et conduit soit à l'aryl-3 dihydro-2,3 naphto[1,2-*b*] thiophène par une addition sur la double liaison 2,3 soit au dihydro-2,3 naphto[1,2-*b*] thiophène par suite de l'enlèvement d'un hydrure.

On obtient occasionnellement des aryl-2 dihydro-2,3 naphto[1,2-*b*] thiophènes. On a isolé, à température plus élevée, des aryl-2 naphto[1,2-*b*] thiophènes et le dihydro-2,3 naphto[1,2-*b*] thiophène. On a essayé de rationaliser la formation de ces produits en fonction d'une protonation du naphto[1,2-*b*] thiophène par le chlorure d'aluminium humide suivie de la réaction de l'électrophile ainsi obtenu avec un substrat aromatique.

[Traduit par le journal]

Introduction

Recent studies (1) have revealed that aluminum chloride promotes the addition of simple aromatic compounds to the 2,3-bond of benzo[*b*]thiophene (**1***a*) to give either 3-aryl-2,3-dihydrobenzo[*b*]thiophenes (**2***a*) or 2-arylbenzo[*b*]thiophenes (**1***b*), depending on the reaction conditions. Since the dihydro products could be dehydrogenated readily to 3-arylbenzo[*b*]thiophenes (**1***c*), a synthesis of 2- or 3-arylbenzo[*b*]thiophenes from the parent heterocycle was achieved. This work was extended to naphtho[2,1-*b*]thiophene (**3***a*) providing a general synthesis of 1- and 2-arylnaphtho[2,1-*b*]thiophenes (**3***b*, *c*) (2). For the isomeric arylnaphtho[1,2-*b*]-thiophenes (e.g., **4***b*, *c*), very few examples have been reported (3) and the general synthetic procedures for the preparation of substituted naphtho-[1,2-*b*]thiophenes are either not applicable (4) to the synthesis of arylnaphtho[1,2-*b*]thiophenes (**4***b*, *c*) or can result in mixtures (5). Consequently we have examined the addition of aromatic compounds to naphtho[1,2-*b*]thiophene (**4***a*) with aluminum chloride.

Results and Discussion

In a typical experiment naphtho[1,2-*b*]thiophene (**4***a*) was dissolved in excess of an aromatic hydrocarbon, two mol equivalents of aluminum chloride[1] were added, and the reaction mixture was

[1]The reactions proceed more slowly with one mol equivalent of aluminum chloride.

stirred either at 0° or 25°C or heated under reflux. An intense deep red color which always developed on addition of the aluminum chloride disappeared on addition of dilute acid during the isolation of the products. The results of these reactions are summarized in Table 1.

At 25°C naphtho[1,2-*b*]thiophene (**4***a*) reacted with simple aromatic hydrocarbons and aluminum chloride to form mainly either 3-aryl-2,3-dihydronaphtho[1,2-*b*]thiophenes (**5***c*) or 2,3-dihydronaphtho[1,2-*b*]thiophene (**5***a*). These results may be contrasted to similar reactions with benzo[*b*]thiophene (**1***a*) and with naphtho[2,1-*b*]thiophene (**3***a*) which gave the corresponding aryldihydro products almost exclusively (1, 2). The formation of 2,3-dihydronaphtho[1,2-*b*]thiophene (**5***a*) depends on the aromatic hydrocarbon being used. While toluene and 1,2-dimethylbenzene reacted to give 3-aryl-2,3-dihydronaphtho[1,2-*b*]thiophenes (**5***f*, *h*), ethylbenzene gave a mixture of the 3-aryldihydro product (**5***g*) and 2,3-dihydronaphtho[1,2-*b*]thiophene in a ratio of 2:3. Examination of probable mechanisms (Scheme 1)[2] of these reactions shows how **5***a* may arise. It is probable that protonation of naphtho[1,2-*b*]thiophene (**4***a*) by moist aluminum chloride[3] (i.e., species such as $[H^+][AlCl_4^-]$ or $[H^+][AlCl_3OH^-]$) occurs at either the 2- or 3-positions to give the carbonium ions **7** and/or **8**. It is likely that protonation at C-2 is favored since products derived from the carbonium ion **7** predominate. Also, studies (4) made on the electrophilic substitution reactions of naphtho[1,2-*b*]-thiophene indicate that attack at C-2 predominates with C-5 being the next most reactive centre.

The carbonium ion **7** may undergo two reactions, either abstraction of a hydride ion to form **5***a* or electrophilic attack on an aromatic carbon atom to form a 3-aryl-2,3-dihydronaphtho[1,2-*b*]thiophene (**5***c*). The most likely sources of hydride ions are the alkyl substituents of the aromatic hydrocarbons (8). In the reactions with toluene and 1,2-dimethylbenzene at 20°C the energy of activation for abstraction of a hydride ion seems to be unfavorable compared to reaction of the carbonium ions at an aromatic carbon atom, resulting in the production of 3-aryl-2,3-dihydro products **5***f*, *h*. However, in the reaction with ethylbenzene at 20°C, hydride abstraction by the carbonium ions becomes the dominant process and **5***a* is the major product. This

[2]Discussions of probable mechanisms for reactions with benzo[*b*]thiophene and naphtho[2,1-*b*]thiophene were given in refs. 1 and 2.

[3]Carefully dried aluminum chloride slows these reactions considerably.

SCHEME 1. Mechanisms for the addition of aromatic hydrocarbons to naphtho[1,2-*b*]thiophene.

is reasonable, since hydride abstraction from the methylene group of ethylbenzene should be easier than abstraction from the methyl groups of toluene or 1,2-dimethylbenzene.

Interestingly, when the reaction with ethylbenzene was carried out at 0°C very little 2,3-dihydronaphtho[1,2-*b*]thiophene (**5***a*) was formed and 2,3-dihydro-3-(4-ethylphenyl)naphtho[1,2-*b*]thiophene (**5***g*) was the major product. Conversely, when the same reaction was carried out under reflux, 2,3-dihydronaphtho[1,2-*b*]thiophene (**5***a*) was the only heterocyclic product isolated. 1-Phenyl-2-(4-ethylphenyl)ethane (**10**) was also obtained. It is likely that **10** arises by attack of the α-phenethylcarbonium ion (**9**) on another molecule of ethylbenzene (Scheme 1). This reaction constitutes a more direct synthesis of both **5***a* and **10** than the syntheses already described (6, 7).

Unexpectedly, the reaction of naphtho[1,2-*b*]-thiophene with benzene gave 2,3-dihydronaphtho-[1,2-*b*]thiophene (**5***a*), along with 2,3-dihydro-3-phenylnaphtho[1,2-*b*]thiophene (**5***d*) and 3-phenylnaphtho[1,2-*b*]thiophene (**4***d*) in approximately equivalent quantities. Analysis of this mixture is described in the Experimental. Although it appears that reaction of the carbonium ion **7** with benzene is slow, after a significant quantity of **5***d* has formed, hydride abstraction from **5***d* by the carbonium ion **7** becomes significant and **5***a* results. The newly formed carbonium ion **11** loses a proton to form **4***c*.

The reactions with 1,2- and 1,4-dimethylbenzene at 25°C were unusual since only in these reactions were 2-aryl-2,3-dihydronaphtho[1,2-*b*]thiophenes (**5***i*, *k*) observed. In fact the 2-aryl product **5***k* was the major product in the reaction with 1,4-dimethylbenzene. Examination of molecular models indicates that when either 1,2- or 1,4-dimethylbenzene attacks the carbonium ion **7** there are steric interactions between the methyl groups of the benzenes and the C—H bond at C-4 of **7**. As a result products derived from the carbonium ion **8** are observed.

An interesting mechanistic feature of these reactions is that the formation of aryl-2,3-dihydronaphtho[1,2-*b*]thiophenes from the carbonium ions **7**, **8** is reversible (Scheme 1). Evidence for this was obtained as when 2,3-dihydro-3-(3′,4′-dimethylphenyl)naphtho[1,2-*b*]thiophene (**5***h*) was stirred with aluminum chloride in toluene solution 2,3-dihydro-3-(4-methylphenyl)naphtho[1,2-*b*]thiophene (**5***f*) was obtained (87% isolated yield). Similarly reactions with benzo[*b*]thiophene and naphtho-[2,1-*b*]thiophene were found to be reversible (1, 2).

[a]Values are ± 0.02 ppm.
[b]Values are ± 0.2 Hz.
[c]Unobtainable from degenerate spectrum.

In many of the reactions described a small quantity of the dimer **6** was obtained (see Table 1). Its structure was confirmed by Raney-nickel hydrodesulfurization. Nevertheless when naphtho-[1,2-*b*]thiophene (**4***a*) was treated with aluminum chloride in dichloromethane the reaction proceeded very slowly. A very complex reaction mixture was obtained from which the dimer **6** could be isolated.

Because of the formation of mixtures in the reactions of naphtho[1,2-*b*]thiophene with aromatic compounds and aluminum chloride at 25°C, their usefulness as a general procedure for the synthesis of arylnaphtho[1,2-*b*]thiophenes is limited. However, when 3-aryl-2,3-dihydronaphtho-[1,2-*b*]thiophenes (**5***c*) could be isolated, it was found that dehydrogenation of these compounds with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone gave 3-arylnaphtho[1,2-*b*]thiophenes (**4***c*) in excellent yield. Also reactions carried out at the boiling point of the aromatic hydrocarbon, which were expected (cf. results described in refs. 1 and 2) to give 2-arylnaphtho[1,2-*b*]thiophenes (**4***b*), in fact gave mixtures of **4***b* and 2,3-dihydronaphtho[1,2-*b*]-thiophene (**5***a*) (Table 1). Often **5***a* predominated, again limiting the method as a general synthesis of 2-arylnaphtho[1,2-*b*]thiophenes.

Product Analysis

Using ^{1}H nmr spectroscopy it was possible to differentiate between 2- and 3-aryl-2,3-dihydrobenzo[*b*]thiophenes, (**2***a*, *b*) on the basis of a difference in the value of the coupling constants (J_{AB}) for the geminal protons located at either C-2 or C-3 (1). J_{AB} values for the 3-aryl products **2***a* were always in the range -11.0 ± 0.2 Hz and, for 2-aryl products **2***b*, -15 ± 0.2 Hz. Also, while oxidation of 3-aryl products to their *S*,*S*-dioxides changed the value of J_{AB} to -13.0 ± 0.2 Hz, oxidation of the 2-aryl products did not alter the value of J_{AB}. The same technique was applied to studies on the naphtho[2,1-*b*]thiophene (**3***a*) and values of J_{AB} were almost identical for the corresponding derivatives (1, 2). In the present work, study of the ^{1}H nmr spectra of 2- and 3-aryl-2,3-dihydronaphtho-[1,2-*b*]thiophenes (**5***b*, *c*) showed analogous behaviour for the values of J_{AB} (Table 2), so enabling structural assignment. In one case (compound **5***f*) Raney-nickel hydrodesulfurization was used to confirm the structural assignment. This technique was also used to confirm the structures of 2-arylnaphtho-[1,2-*b*]thiophenes **4***b*. Full details are given in the Experimental.

Experimental

The ^{1}H nmr spectra were obtained in deuteriochloroform solution, unless stated otherwise, on a Varian model EM360 spectrometer using tetramethylsilane as an internal standard. Mass spectra were obtained on a Finnegan 1015 spectrometer. Melting points are uncorrected.

Naphtho[1,2-b]thiophene

This was prepared by the method of Clarke *et al.* (4) and had bp 125–127°C at 0.25 Torr.

Addition Reactions of Naphtho[1,2-b]thiophene at 0°C and 20°C to Form 2- and 3-Aryl-2,3-dihydronaphtho[1,2-b]-thiophenes (5b, 5c) and 2,3-Dihydronaphtho[1,2-b] thiophene (5a)

(a) General Procedure

Aluminum chloride (Fisher technical grade) (2.88 g, 0.020 mol) was added to a solution of naphtho[1,2-*b*]thiophene (2.0 g, 0.010 mol) in the appropriate aromatic hydrocarbon (100 mL). The resulting deep red mixtures were stirred for 1–4 h (see Table 1) and poured into ice-cold aqueous 20% hydrochloric acid (100 mL). The organic material was isolated by extraction with ethyl acetate. The solutions were washed with water and dried

over anhydrous magnesium sulfate. Evaporation of the solutions gave the products as oils, which either yielded crystalline material from hexane solution or were pruified further by chromatography on silica (Merck 60) and elution with hexane – ethyl acetate (20:1). Individual experiments are described below.

(b) With Toluene

The oily product was dissolved in hexane (50 mL) at 20°C and after 1 h pale yellow microcrystals of the dimer (**6**) (0.21 g, 10%), mp 257–259°C, which separated, were collected. The nmr spectrum δ: 7.0–8.2 (m, the aromatic protons). The mass spectrum: M^+ 366, calcd. 366. *Anal.* calcd. for $C_{24}H_{14}S_2$: C 78.70, H 3.85, S 17.50; found: C 78.55, H 3.90, S 17.25%.

After keeping the filtrate at −5°C for 24 h colorless plates (2.6 g, 86%), mp 76–77°C, of 2,3-dihydro-3-(4′-methylphenyl)-naphtho[1,2-*b*]thiophene (**5***f*), which were deposited, were collected. The nmr spectrum δ: 2.27 (s, Me) and 6.9–7.95 (m, the aromatic protons). The mass spectrum: M^+ 276, calcd. 276. *Anal.* calcd. for $C_{19}H_{16}S$: C 82.60, H 5.80, S 11.60; found: C 82.60, H 5.85, S 11.65%.

The structure of the dimer (**6**) was confirmed by hydrodesulfurization with Raney-nickel. A mixture of (**6**) (0.5 g) and Raney-nickel (1 g) in 95% aqueous ethanol was heated under reflux for 18 h. The reaction mixture was filtered and the filtrate was evaporated leaving an oily residue of 1,4-di-2′-naphthylbutane.[4] The nmr spectrum δ: 1.6–3.1 (m, —$(CH_2)_4$—) and 6.9–8.1 (m, the aromatic protons). The mass spectrum: M^+ 310, $C_{24}H_{22}$ requires 310. *Anal.* calcd. for $C_{24}H_{22}$: C 92.90, H 7.10; found: C 92.85, H 7.10%.

Similarly hydrodesulfurization of **5***f* gave 1-(4′-methylphenyl)-1-(2′-naphthyl)ethane as a colorless oil, bp 110–115°C at 0.6 Torr. The nmr spectrum δ: 1.65 (d, CH—*Me*), 2.15 (s, Me), 4.72 (q, *CH*—Me), and 6.9–8.1 (m, the aromatic protons). The mass spectrum: M^+, 246, $C_{19}H_{18}$ requires 246. *Anal.* calcd. for $C_{19}H_{18}$: C 92.70, H 7.32; found: C 92.90, H 7.05%.

(c) With Ethylbenzene at 0°C

Chromatography of the crude product gave an oil which was redissolved in hexane (50 mL) at 20°C. On standing at 10°C, a pale yellow microcrystalline solid (0.18 g, 9%), mp 255–259°C, corresponding to the dimer (**6**), was obtained. Cooling of the mother liquors to −5°C gave 2,3-dihydro-3-(4′-ethylphenyl)-naphtho[1,2-*b*]thiophene (**5***g*) as colorless plates (2.3 g, 73%), mp 76–77°C, which were collected. The nmr spectrum δ: 1.21 (t, Me), 2.62 (q, CH_2), and 6.8–8.0 (m, the aromatic protons). The mass spectrum: M^+ 290, calcd. 290. *Anal.* calcd. for $C_{20}H_{18}S$: C 82.75, H 6.20, S 11.05; found: C 82.55, H 6.35, S 11.05%.

(d) With Ethylbenzene at 20°C

The dimer (**6**) (0.16 g, 16%) and **5***g* (0.88 g, 28%) were isolated as described in the reaction at 0°C. Evaporation of the mother liquors gave an oil and distillation of this oil gave 2,3-dihydronaphtho[1,2-*b*]thiophene (**5***a*) (6) as a colorless oil (1.06 g, 53%), bp 110–115°C at 0.25 Torr. The nmr spectrum δ: 3.38 (s, CH_2—CH_2) and 6.8–8.2 (m, the aromatic protons). The mass spectrum: M^+ 186, calcd. for $C_{12}H_{10}S$ 186. *Anal.* calcd. for $C_{12}H_{10}S$: C 77.40, H 5.40, S 17.20; found: C 77.45, H 5.30, S 17.45%.

(e) With 1,2-Dimethylbenzene at 0°C or 20°C

The crude product was dissolved in hexane and on cooling this solution to −5°C, 2,3-dihydro-3-(3′,4′-dimethylphenyl)-naphtho[1,2-*b*]thiophene (**5***h*) was deposited as colorless prisms (1.95 g, 62%), mp 113–114°C. These were removed by filtration. The nmr spectrum δ: 2.21 (s, 2Me) and 6.9–8.0 (m, the aromatic protons). The mass spectrum: M^+ 290, calcd. 290. *Anal.* calcd. for $C_{20}H_{18}S$: C 82.75, H 6.20, S 11.05; found: C 82.80, H 6.30, S 11.10%.

[4]This compound has been reported (10) but no physical or spectroscopic data were given.

After concentration of the mother liquors and storage of this solution at −5°C for 14 days the 2-isomer (**5***i*) was collected as colorless plates, (0.88 g, 28%), mp 110–111°C. The nmr spectrum δ: 2.17 (s, 2Me) and 7.0–8.0 (m, the aromatic protons). The mass spectrum: M^+ 290, cald. 290. *Anal.* calcd. for $C_{20}H_{18}S$: C 82.75, H 6.20, S 11.05; found: C 82.60, H 6.20, S 11.05%.

(f) With 1,4-Dimethylbenzene

The crude product was dissolved in hexane (50 mL). On standing at 20°C the dimer (**6**) crystallized out as a pale yellow solid (0.31 g, 16%) which was collected. Evaporation of the mother liquors gave a clear oil (2.4 g) which could not be induced to crystallize. The ^1H nmr spectrum and the mass spectrum of the oil indicated three compounds were present: (*i*) 2,3-Dihydro-2-(2′,5′-dimethylphenyl)naphtho[1,2-*b*]thiophene (**5***k*), (*ii*) its 3-isomer (**5***j*), and (*iii*) 2,3-dihydronaphtho[1,2-*b*]thiophene (**5***a*). The nmr spectrum δ: 2.18 and 2.34 (Me's), 3.38[5] (s, due to CH_2—CH_2 of **5***a*), 3.2–4.0 (m, due to CH_2's of **5***j* and *k*), 5.10[5] (t, due to CH of **5***j*), 5.40[5,6] (t, due to CH of **5***k*), and 6.8–8.2 (m, the aromatic protons). The mixture could not be resolved by standard techniques. The mass spectrum showed peaks at 186 (due to **5***a*) and 290 (due to **5***j* and **5***k*).

(g) With Benzene

Spectroscopic studies indicated that the product was a mixture of 2,3-dihydronaphtho[1,2-*b*]thiophene (**5***a*), 2,3-dihydro-3-phenylnaphtho[1,2-*b*]thiophene (**5***d*), and 3-phenylnaphtho-[1,2-*b*]thiophene (**4***d*). Attempts to resolve this mixture were unsuccessful. The nmr spectrum δ: 3.38 (s, CH_2—CH_2 of **5***a*), 3.35–3.75 (m, CH_2 of **5***d*, 4.75 (t, CH— of **5***d*), and 7.0–8.2 (m, the aromatic protons of **5***a*, **5***d*, and **4***d*); J_{AB} for CH_2 (**5***d*) is −10.8 Hz, thus indicating a 3-aryl product. The mass spectrum: M^+, 186, 260, 262 (corresponding to **5***a*, **4***d*, and **5***d*).

Although the presence of **5***a* and **5***d* in the mixture could be determined directly by analysis of the ^1H nmr and the mass spectrum, it was not possible to determine if the remaining product was 2- or 3-phenylnaphtho[1,2-*b*]thiophene. The problem was resolved by Raney-nickel hydrodesulfurization of the reaction mixture using the procedure described earlier. The product was obtained as a clear oil and contained a mixture of 2-ethylnaphthalene and 1-(2′-naphthyl)-1-phenylethane.[7] The mixture was not resolved. The nmr spectrum, for 2-ethylnaphthalene, δ: 1.16 (t, Me), 2.57 (q, CH_2), and 7.0–8.0 (m, the aromatic protons); for 1-(2′-naphthyl)-1-phenylethane, δ: 1.72 (d, CH—Me), 4.76 (q, CH—Me), and 7.0–8.1 (m, the aromatic protons). The mass spectrum: M^+ 156, 232.

*Aryl-2,3-dihydronaphtho[1,2-*b*]thiophene-S,S-dioxides*

The aryl-2,3-dihydronaphtho[1,2-*b*]thiophenes (**5***b*, *c*) described were characterized as their *S*,*S*-dioxides (9) as an aid to structural elucidation (see Discussion). The relevant ^1H nmr data for these compounds are given in Table 2. The compounds were prepared by oxidation with hydrogen peroxide in glacial acetic acid (9) and were crystallized from ethanol. Their properties are summarized in Table 3.

[5]By integration of these signals it was determined that the mixture contained **5***k* (50%), **5***j* (30%) and **5***a* (20%).

[6]This signal was assigned to the methine proton of the 2-isomer **5***k* rather than to the methine proton of the 3-isomer **5***j* since for the isomers **5***h*, *i* the methine proton of the 2-isomer **5***i* occurred at lower field (Table 2). Also when comparing 2- and 3-aryl-2,3-dihydrobenzo[*b*]thiophenes (**2***a*, *b*), the methine signals due to the 2-aryl isomers (**2***b*) always occured to lower field (1).

[7]If the original reaction mixture had contained 2-phenylnaphtho[1,2-*b*]thiophene, 1-(2′-naphthyl)-2-phenylethane would have been formed. ^1H nmr data gave no evidence for this compound. The presence of 2-ethylnaphthalene was confirmed by comparison to an authentic sample.

*The Preparation of 3-Arylnaphtho[1,2-*b*]thiophenes (**4**c)*
General Procedure

A mixture of a 3-aryl-2,3-dihydronaphtho[1,2-*b*]thiophene (**5***c*) (1 g) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (1.25 mol equiv.) in benzene (50 mL) was heated under reflux for 2 h. The reaction mixture was cooled and filtered through a short (ca. 5 cm) alumina (tlc grade) column. The colorless filtrate was evaporated to dryness and the residue was crystallized from hexane with cooling to −5°C. The results are summarized in Table 4.

*Addition Reactions of Naphtho[1,2-*b*]thiophene Above 20°C to Form 2-Arylnaphtho[1,2-*b*]thiophenes (**4**b) and 2,3-Dihydronaphtho[1,2-*b*]thiophene (**5**a)*
General Procedure

These reactions were carried out as described for the reactions at 20°C except that each experiment was carried out at the boiling point of the aromatic hydrocarbon. All products were isolated by column chromatography on silica and elution with hexane – ethyl acetate (20:1), followed by crystallization from hexane (for products of type **4***b*) and distillation for **5***a*. The results of these experiments are presented in Table 4. The ^{1}H nmr data for the 2-arylnaphtho[1,2-*b*]thiophenes (**4***b*) are not detailed since each compound gave complex signals due to the aromatic protons and the usual resonances expected for the alkyl substituents. Likewise the infrared spectra for **4***b* are complex and uninformative[8].

[8]Full ^{1}H nmr and ir data are available on request.

JEAN-CLAUDE RICHER, MARC-ANDRÉ POIRIER, YVETTE MARONI et GEORGES MANUEL. Can. J. Chem. **59**, 1303 (1981).

On décrit la synthèse des diméthyl-5,5 *tert*-butyl-2 (**1***a*), triméthylsilyl-2 (**1***b*) et triméthylgermyl-2 (**1***c*) cyclohexanones ainsi que celle des diméthyl-2,2 *tert*-butyl-5 (**2***a*), triméthylsilyl-5 (**2***b*) et triméthylgermyl-5 (**2***c*) cyclohexanones. On examine la stéréochimie de la réaction de réduction de ces cétones par divers hydrures. Dans le cas des cétones substituées en β par un Si ou un Ge, la réduction est en compétition avec la réaction de clivage de la liaison C—M, (M = Si, Ge).

JEAN-CLAUDE RICHER, MARC-ANDRÉ POIRIER, YVETTE MARONI and GEORGES MANUEL. Can. J. Chem. **59**, 1303 (1981).

The synthesis of 5,5-dimethyl-2-*tert*-butyl- (**1***a*), -2-triméthylsilyl- (**1***b*), and -2-trimethylgermyl- (**1***c*) cyclohexanones is described as well as those of 2,2-dimethyl-5-*tert*-butyl- (**2***a*), -5-trimethylsilyl- (**2***b*), and -5-trimethylgermyl- (**2***c*) cyclohexanones. The stereochemistry of the reduction of these ketones by different hydrides is examined. This latter reaction competes with the cleavage reaction of the C—M bond in the case of β-substituted ketones (M = Si, Ge).

Introduction

Au cours de travaux antérieurs (1–3), on a mis en évidence l'influence stérique prépondérante des groupes *tert*-butyle, triméthylsilyle et triméthylgermyle sur la stéréochimie de réactions d'addition sur des cyclohexènes et lors de l'ouverture d'époxydes qui en dérivent. Dans le cadre de nos travaux sur la stéréochimie des réductions des cétones cycliques (4), nous avons donc préparé les cétones

1 et **2** et examiné la stéréochimie de leur réduction par des hydrures complexes.

Résultats et discussion

Préparation des cétones

La cétone **1***a* a été obtenue par oxydation, par le mélange sulfochromique (5), du *tert*-butyl-2 diméthyl-5,5 cyclohexanol *trans* (**4***a*) obtenu au cours d'un travail antérieur (1), par hydroboration de l'alcène vinylique **7***a*.

Dans les mêmes conditions, l'oxydation du diméthyl-5,5 triméthylsilyl-2 cyclohexanol *cis* (**3***b*), obtenu par ouverture de l'époxyde silylé **8***b* par $LiAlH_4$ (2), conduit toutefois à la diméthyl-3,3 cyclohexanone (**9**) à la suite d'une scission de la liaison C—Si (5, 6). Cette réaction est bien connue (7, 8); la fonction carbonyle étant en β du silicium, cet arrangement représente un modèle parfait pour le clivage de la liaison C—Si (9–11). Cette réaction peut être interprétée par le schéma 1. Ce mécanisme implique la formation transitoire de la cétone β silylée (**1***b*) suivie par une attaque de l'eau sur l'atome de silicium pour conduire, avec un bon rendement, à la cétone **9**. On a pu vérifier que la cétone **1***b*, dont la préparation est décrite plus bas, conduit bien à la cétone **9** lorsqu'elle est plaçée en milieu acide.

La cétone β **1***b* a été obtenue grâce à une oxydation par un mélange oxyde de chrome – pyridine dans le chlorure de méthylène (12, 13).

0008-4042/81/091303-04$01.00/0

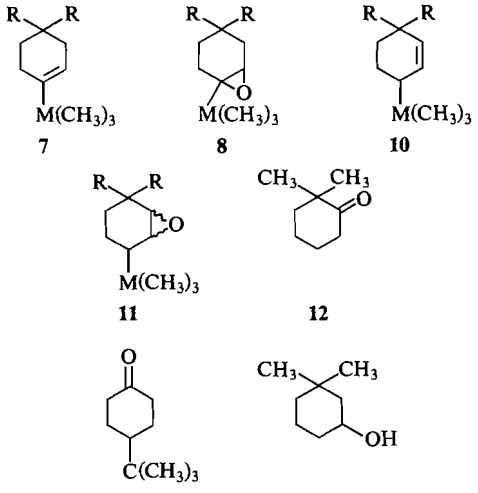
SCHÉMA 1

Cette méthode a d'ailleurs été utilisée par Hudrlik et Peterson (14, 15) pour l'obtention de cétones β silylées.

L'oxydation de l'alcool germylé **3***c* par le complexe oxyde de chrome – pyridine dans le chlorure de méthylène (12) ne nous a pas permis d'isoler la cétone **1***c* attendue. Le produit obtenu (**9**) résulte du clivage de la liaison C—Ge. On a remarqué un comportement semblable en série germylée, lors de l'époxydation de l'alcène **10***c* par l'acide *m*-chloroperbenzoïque (**3**). Il semble que les composés germylés **11***c* et **1***c* soient plus sensibles à l'effet β que leurs homologues silylés.

La synthèse de la cétone carbonée **2***a* est décrite dans un travail antérieur (1). Cette cétone **2***a* peut être obtenue soit à partir de la diméthyl-2,2 cyclohexanone (**12**) soit à partir de la *tert*-butyl-4 cyclohexanone (**13**).



L'obtention, à l'état pur, de la cétone γ **2***b* fait appel à la propriété qu'ont les cétones β silylées de se cliver en milieu acide. L'oxydation en milieu acide du mélange d'alcools, riche en isomère γ, obtenu par réduction des époxydes silylés **11***b* (*cis*/*trans*) par $LiAlH_4$ (3), conduit à environ 88% de diméthyl-2,2 triméthylsilyl-5 cyclohexanone (**2***b*) et à de la diméthyl-3,3 cyclohexanone (**9**) résultant du clivage de la cétone β **1***b* (schéma 1) en milieu acide. La cétone γ **2***b* est ensuite obtenue à l'état pur par distillation du mélange.

TABLEAU 1. Comparaison des valeurs d'absorption du C=O (cm^{-1}) des cétones β et γ

Composés		M = C; R = CH_3	1710	1710
M = Si; R = CH_3	1680	1700
M = Ge; R = CH_3	—	1700

Les études spectroscopiques sur les cétosilanes ont fait l'objet de nombreux travaux (11, 16–18). Brook et Pierce (17) ont étudié l'absorption en infrarouge du groupe carbonyle de cétones α, β et γ trialkylsilylées et ils ont fait une comparaison avec leurs homologues carbonés. Conformément aux résultats de ces auteurs, on note une augmentation de la fréquence d'absorption ν(C=O) lorsqu'on passe des β aux γ cétosilanes (tableau 1). Ces résultats sont interprétés par des interactions entre les électrons *p* de l'oxygène du carbonyle et les orbitales $3d^0$ vacantes du silicium ou germanium. La valeur de l'absorption ν(C=O) pour les γ-cétosilanes se rapproche de la position normale (soit de 1700 cm^{-1}).

La cétone germylée **2***c* est obtenue par la méthode décrite pour la série silylée. L'oxydation en milieu acide du mélange d'alcools résultant de l'hydroboration de l'alcène **10***c* (1) conduit à environ 66% de cétone γ **2***c* et à la cétone **9**. La cétone **2***c* est ensuite purifiée par distillation.

Stéréochimie de la réduction des cétones par $LiAlH_4$, $NaBH_4$ et $LiAlH(OtBu)_3$

Les études concernant la stéréochimie de la réduction de cyclohexanones différemment substituées ont fait l'objet de nombreux travaux (19–21). Les résultats concernant la réduction des cétones β (type 1) par $LiAlH_4$, $NaBH_4$, $LiAlH(OtBu)_3$ sont consignés dans le tableau 2.

Comme l'indique le tableau 2, la réduction de la cétone carbonée **1***a* par l'hydrure double de lithium et d'aluminium conduit à 98% d'alcool *cis* (**3***a*) et 2% d'isomère *trans* (**4***a*). Ces résultats suggèrent que la stéréochimie de la réduction est gouvernée par des facteurs stériques intervenant dans l'état de transition (4, 22). En effet, la comparaison de ces résultats avec ceux obtenus lors de la réduction,

TABLEAU 2. Pourcentages relatifs des différents produits obtenus par réduction des cétones β

Produit	Réducteur*	 **1**	 **9**	 **14**	 **3**	 **4**
1a	$LiAlH_4$	—	—	—	98	2
1a	$NaBH_4$	100	—	—	0	0
1a	$LiAlH(OtBu)_3$	100	—	—	0	0
1b	$LiAlH_4$	—	1	17	74	8
1b	$NaBH_4$	—	42	0	48	0
1b	$LiAlH(OtBu)_3$	—	100	0	0	0

*Toutes les réductions ont été effectuées dans l'éther anhydre.

par $LiAlH_4$, de la *tert*-butyl-2 cyclohexanone (**1***d*) alors qu'on obtient un mélange 50/50 des isomères *cis* et *trans* (23), met en évidence l'importance du groupe méthyle axial supplémentaire en position 3.

Dans le cas de la réduction par $LiAlH_4$ de la cétone silylée (**1***b*), on remarque une augmentation du pourcentage en isomère *trans* (**4***b*) par rapport à la série carbonée (**1***a*–**4***a*). Cet accroissement en composé **4***b* pourrait être due à l'élongation de la liaison C—Si. La face *cis* de la cétone **1***b* deviendrait alors moins encombrée par suite de la diminution de l'interaction 1–3 diaxiale entre le réactif et l'un des méthyles du groupe triméthylsilyle et il en résulterait un accroissement d'entrée *cis* par rapport à la série carbonée.

En plus des produits normaux de réduction, on note la présence de 18% de produits **9** et **14** résultant du clivage de la liaison C—Si par un mécanisme similaire à celui représenté dans le schéma 1. Ce pourcentage de clivage est accru lors de la réduction de **1***b* par $NaBH_4$ et on note la disparition de l'isomère *trans* (**4***b*); ces résultats suggérant que le réducteur $NaBH_4$ réagit comme s'il était plus volumineux que $LiAlH_4$ s'expliquent probablement par l'insolubilité du $NaBH_4$ dans l'éther. Dans ce cas, la réaction de réduction est donc concurrencée par la réaction de clivage. Cette dernière est d'autant plus importante que le réducteur est plus volumineux. Parallèlement, en série carbonée, la réduction de la cétone **1***a* par $NaBH_4$ n'a pas lieu.

Avec un réducteur plus volumineux, tel que $LiAlH(OtBu)_3$, la réaction de clivage en série silylée est univoque et conduit uniquement à la diméthyl-3,3 cyclohexanone **9**; ce réactif ne réduit pas la cétone carbonée.

Les résultats concernant la stéréochimie de la réduction des cétones γ (**2**) par l'hydrure double de lithium et d'aluminium sont présentés dans le tableau 3.

TABLEAU 3. Pourcentages relatifs des isomères obtenus par réduction des cétones γ par $LiAlH_4$

		M = C; R = CH_3 (**2***a*)	85 (**5***a*)	15 (**6***a*)
M = Si; R = CH_3 (**2***b*)	85 (**5***b*)	15 (**6***b*)
M = Ge; R = CH_3 (**2***c*)	87 (**5***c*)	13 (**6***c*)

Ils mettent en évidence que les groupes *tert*-butyle, triméthylsilyle et triméthylgermyle en position 3 du groupement carbonyle à réduire n'affectent pas la stéréochimie de sa réduction.

Partie expérimentale

Les points de fusion ont été pris sur un appareil Cole-Parmer de la compagnie Instrument and Equipment.

Les spectres ir ont été pris sur un spectrophotomètre Beckman modèle IR-8 à double faisceau et, sauf indication contraire, tous les spectres ont été pris entre deux plaques de NaCl.

Les spectres de résonance magnétique nucléaire ont été déterminés sur un spectromètre modèle C-60-H de la compagnie Jeol. Le solvant choisi est le chloroforme deutéré pour la série carbonée et le tétrachlorure de carbone pour les séries silylée et germylée. Les déplacement chimiques sont exprimés en ppm et se réfèrent au tétraméthylsilane utilisé comme référence interne pour la série carbonée; le chloroforme est utilisé comme référence pour les séries silylée et germylée.

Les indices de réfraction ont été déterminés à l'aide d'un réfractomètre du type Abbe. La pureté de tous les nouveaux produits décrits dans ce travail a été déterminée par chromatographie en phase gazeuse et leur identité confirmée par spectrométrie de masse à l'aide d'un spectromètre Hitachi-Perkin-Elmer modèle RMU6-D opérant avec une énergie de faisceau d'électrons ionisants de 70 eV.

Préparation de la tert-*butyl-2 diméthyl-5,5 cyclohexanone (1a)*

Dans un ballon de 50 mL à trois tubulures, muni d'un réfrigérant et d'une ampoule à addition, on introduit 1,0 g (5,4 mmol) d'alcool **4***a* (1) en solution dans 6 mL d'éther (5). Deux millilitres d'une solution composée de 3,65 g de bichromate de sodium, de 7 mL d'eau, puis de 2,8 mL d'acide sulfurique concentré, est ajouté à 0°C par une ampoule à brome dans le ballon contenant l'alcool.

L'agitation est maintenue pendant 3 heures; le mélange réactionnel est extrait à l'éther selon la méthode habituelle. La phase organique, séchée sur du sulfate de sodium anhydre, filtrée, puis concentrée sous vide, fournit 0,93 g de cétone **1***a* (95% du rendement théorique) possédant les caractéristiques suivantes: pf: 32–33°C; pé 110°C/14 Torr; ir (pur): 1710 cm^{-1}; rmn ($CDCl_3$): 1,00 (*tert*-butyle), 0,87 et 1,05 (groupe *gem*-diméthyle) ppm.

Préparation de la diméthyl-5,5 triméthylsilyl-2 cyclohexanone (1b)

L'anhydride chromique (3,0 g; 30 mmol) est ajouté à une solution de 4,75 g de pyridine anhydre dans 20 mL de chlorure de méthylène. La solution colorée est agitée 15 min à la température de la pièce. Après cette période, une solution d'alcool **3***b* (1,0 g; 5 mmol) dans 10 mL de chlorure de méthylène est ajoutée d'un seul coup. Une suspension noire se sépare aussitôt. On laisse sous agitation pendant 2,5 heures. La solution est décantée, filtrée et la phase organique extraite à l'éther est lavée avec une solution de nitrate cuivrique, puis à l'eau. La phase éthérée est séchée sur du K_2CO_3, filtrée et concentrée sous vide. La distillation permet d'obtenir 0,8 g de cétone **1***b* (84% du rendement théorique) ayant les caractéristiques suivantes: pé 96–98°C/5 Torr; n_D^{29} 1,4615; ir: 1680, 1245 cm^{-1}; rmn (CCl_4): 0,86 et 0,79 (groupe *gem*-diméthyle), −0,07 (groupe triméthylsilyle) ppm.

Préparation de la tert-*butyl-5 diméthyl-2,2 cyclohexanone (2a)*

La synthèse de cette cétone ainsi que ses caractéristiques physiques sont décrites dans une publication antérieure (1).

Préparation de la diméthyl-2,2 triméthylsilyl-5 cyclohexanone (2b)

Cette cétone **2***b* a été préparée selon la méthode déjà décrite pour la cétone **1***a* par oxydation chromique du mélange d'alcools (1,0 g; 5 mmol) résultant de l'ouverture des époxydes *cis* et *trans* (**11***b*) par $LiAlH_4$ (3). La distillation permet d'obtenir 0,7 g de produit (85% du rendement théorique) dont les caractéristiques physiques sont les suivantes: pé 109°C/7 Torr; n_D^{21} 1,4605; ir: 1700, 1380, 1360, 1240 cm^{-1}; rmn (CCl_4): 1,09, 0,96 (groupe *gem*-diméthyle) et 0,00 ($SiMe_3$) ppm.

Préparation de la diméthyl-2,2 triméthylgermyl-5 cyclohexanone (2c)

Cette cétone **2***c* a été préparée par la méthode décrite pour la préparation de la cétone silylée **2***b* et conduit avec un rendement voisin de 80% à la cétone **2***c* et dont les caractéristiques physiques sont les suivantes: pé 110°C/5 Torr; n_D^{23} 1,4725; ir: 1700, 1380, 1360, 810 cm^{-1}; rmn (CCl_4): 1,06 et 0,96 (groupe *gem*-diméthyle), 0,06 ($GeMe_3$) ppm.

Réduction des cétones par $LiAlH_4$, $NaBH_4$, $LiAlH(OtBu)_3$

La réduction des cétones par les différents hydrures a été réalisée sur des échantillons de 5,0 mmol de cétones ajoutés à une suspension de 25,0 mmol d'hydrures dans 15 mL d'éther anhydre. Après 20 h d'agitation au reflux du solvant, l'hydrolyse par une solution de soude à 5% suivie d'une extraction à l'éther conduit au mélange d'alcool avec des rendements moyens de 95%.

Analyse des produits

Les mélanges d'alcools provenant des réactions de réduction des cétones **1** et **2** ont été analysés par chromatographie en phase gazeuse à l'aide d'un chromatographe à ionisation de flamme Research Chromatograph 700 de la compagnie F & M muni d'une colonne de 6 pi × 1/8 de po remplie de Diatoport 5750 (80–100) supportant 6% de son poids de LAC 728. Les temps de rétention (en min) des alcools dans ces conditions sont résumés dans un tableau figurant dans une publication antérieure (1).

Remerciements

Les auteurs remercient vivement le Conseil National de Recherches du Canada, le C.N.R.S. français et les autorités chargées d'administrer les accords Franco–Québécois pour l'aide financière apportée sous forme d'octroi de recherches, de bourses d'études et de frais de mission. Les auteurs tiennent à remercier le Dr. Pierre Maroni pour l'accueil chaleureux réservé à Marc-André Poirier durant son stage à Toulouse. Les auteurs tiennent aussi à exprimer leur reconnaissance aux Dr. Mazerolles et Lesbre pour leur compréhension et leurs discussions utiles.

Product distributions and isotopic selectivities in ir multiphoton dissociation of pentafluoroiodoethane[1]

E. WEINBERG,[2] M. GAUTHIER, P. A. HACKETT, AND C. WILLIS

Laser Chemistry Group, Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received October 15, 1980

E. WEINBERG, M. GAUTHIER, P. A. HACKETT, and C. WILLIS. Can. J. Chem. **59**, 1307 (1981).

Infrared multiphoton dissociation of pentafluoroiodoethane leads to a complex array of reaction products. For photolysis in the ν_4 band the reaction mechanism involves C_2F_5—I bond cleavage followed by thermal dissociation of C_2F_5 radicals. For irradiation within the ν_3 band at high fluence, efficient secondary photolysis of C_2F_5 radicals is postulated. At lower fluences the dissociation is isotopically selective leading to C_4F_{10} enriched in carbon-13.

E. WEINBERG, M. GAUTHIER, P. A. HACKETT et C. WILLIS. Can. J. Chem. **59**, 1307 (1981).

Si on soumet le pentafluoroiodoéthane à une dissociation multiphotonique infrarouge il se forme une série complexe de produits de réaction. Dans le cas de la photolyse dans la bande ν_4, le mécanisme de la réaction fait intervenir un clivage de la liaison C_2F_5—I qui est suivi par une dissociation thermique des radicaux C_2F_5. Lors de l'irradiation avec une forte intensité de la bande ν_3, on croit qu'une photolyse secondaire efficace des radicaux C_2F_5 intervient. A des intensités plus faibles, la dissociation est sélective du point de vue isotopique et elle conduit à du C_4F_{10} qui est enrichi en carbone-13.

[Traduit par le journal]

Introduction

Isotopically selective infrared multiphoton dissociation of molecules is now a common experimental procedure. This is especially true for CO_2 laser induced dissociation of fluorocarbons, a consequence of particularly favourable spectral overlaps. Early work was directed at demonstrating isotopic selectivity and towards understanding the infrared multiple photon absorption and induced dissociation processes. While research in these latter areas is far from complete, other groups have pursued active research in areas where infrared multiple photon dissociation is used as a tool, e.g. synthesis of specifically isotopically enriched (labelled) compounds (1), elucidation of detailed reaction mechanisms by isotopically selective dissociation of substrates at natural isotopic abundance (2), or generation of free radicals for kinetic studies (3). It is in this vein that we have carried out the present investigation of the infrared multiple photon dissociation of pentafluoroiodoethane.

Experimental

Irradiations were carried out in a Pyrex cell (4.7 cm od × 17.5 cm long) equipped with sodium chloride windows. A Lumonics model 101 TEA-CO_2 laser, modified for closed system gas flow for use with rare isotopes of CO_2, was used for irradiations involving product analysis by gas chromatography. A second TEA-CO_2 laser (Lumonics model 103) was used for carbon-13 enrichment studies. Both lasers were equipped with high efficiency gratings (PTR Optical 135 lines/mm master ruling). Sample irradiations were performed in both parallel (2 m f.l. germanium lens) and focused beam (10 cm f.l. germanium lens) geometry with incident or exit energy monitored by a calibrated pyroelectric detector.

Pentafluoroiodoethane was obtained from PCR Inc. and purified by distillation at −131°C. Analysis by gas chromatography (9 ft Porapak S; 15 ft Chromosorb G, NAW 80–100 mesh, 3/8 in. od copper tubing, 10% silicone fluid, 90 or 120°C) (4) failed to reveal impurities, however, mass spectrometry indicated trace amounts of decafluorobutane.

Products were analysed by gas chromatography (9 ft Porapak S, 80–100 mesh, 1/4 in. od copper tubing, 100° or 140°C) or by mass spectrometry. The gc response (thermal conductivity detector) was calibrated with authentic aliquots of tetrafluoroethylene, hexafluoroethane, decafluorobutane, and pentafluoroiodoethane. No authentic sample of octafluoropropane was available to us; a response intermediate to that for the ethane and butane was assumed.

Isotopically selective dissociation was confirmed by measuring the carbon-13/carbon-12 ratio in the decafluorobutane product ($C_3F_5^+$ ion at 131, 132, 133 and $C_4F_9^+$ ion at 219, 220, 221, and 222 monitored) in the presence of substrate (reaction mixture held at −96°C) with suitable background corrections being made. A Hitachi RMU-6D mass spectrometer was used for these initial analyses.

Results and Discussion

The experimental results are summarized in Fig. 1 and in Table 1. All experiments were carried out with C_2F_5I pressure of 0.5 Torr. The distribution of products appears to be sensitive to incident fluence, irradiation geometry, and to irradiation frequency, with decafluorobutane becoming the dominant product at low fluence, in parallel beam geometry at frequencies to the red of the predominant absorption bands. Possible explanations for this are discussed below.

There is little reliable thermochemical data for fluorocarbon molecules, however, the heat of formation of C_2F_5I has recently been measured as

[e] $A = \Sigma$(products + substrate)/-(substrate).

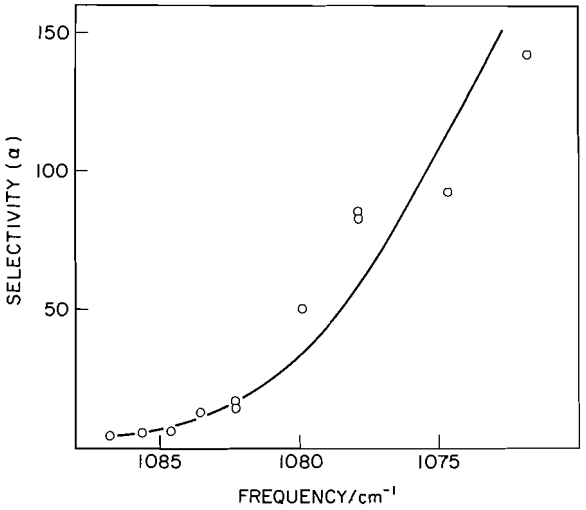

FIG. 1. Isotopic selectivities (γ) observed in the infrared multiple photon dissociation of 0.5 Torr pentafluoroiodoethane as a function of irradiation frequency. Parallel beam geometry, 1.5 J cm^{-2} fluence, temperature 22°C. γ was measured for the $C_3F_5^+$ fragment ion and is defined as γ = (carbon-13/carbon-12)

−240.0 ± 1 kcal mol^{-1} (all heats of formation and bond dissociation energies given for gas phase, 298 K) (5). This, coupled with Okafu and Whittle's recent value of $D(C_2F_5—I)$ (6), leads to a value of the heat of formation of C_2F_5 of −214.5 kcal mol^{-1} and allows the calculation of the following threshold energies:[3]

[1] $C_2F_5I \rightarrow C_2F_5 + I(^2P_{3/2})$ 51.2 kcal mol^{-1}

[2] $C_2F_5I \rightarrow CF_2 + CF_3I$ 55.7 kcal mol^{-1}

[3] $C_2F_5I \rightarrow C_2F_4 + IF$ 60.0 kcal mol^{-1}

[4] $C_2F_5 \rightarrow CF_3 + CF_2$ 58.5 kcal mol^{-1}

Of particular note is both the weakness of the $CF_3—CF_2$ bond, a result first reported by Fisher *et al.* (8), who noted the thermal decomposition of the pentafluoroethyl radical at temperatures >950°C, and the small difference in threshold energy for the molecular elimination process [3] compared to the free radical process [1]. The present value, 8.8 kcal mol^{-1}, may be contrasted to the value 21.8 kcal mol^{-1} calculated for the equivalent reactions involving CF_3I (7). This energy difference is less than the energy of three CO_2 laser photons above the first dissociation threshold. For smaller molecules the spontaneous dissociation rate rises rapidly with excess internal energy so that photon absorption is terminated at energy levels close to the first dissociation limit (9, 10). For larger molecules this rate constant is smaller and increases less rapidly so that higher levels of internal energy may be reached (11, 12). Although multiphoton absorption through the vibrational quasicontinuum depends upon the laser fluence, the degree of excess energy and hence the primary dissociative processes will depend upon laser intensity. It is certain that excess energies greater than the threshold energy of reaction [3] are achieved in the present case; what is less certain is whether one has then reached the activation energy for process [3], i.e. what is the activation energy for the addition of iodine monofluoride to tetrafluoroethylene, and also whether the rate of process [3] will compete with the rate of process [1] because of different pre-exponential (frequency) factors. These arguments apply even more stringently to the postulated difluorocarbene elimination. Thus, although our expectation is that C—I bond scission would be the dominant process, indeed it is the only process observed in multiphoton dissociation of CF_3I, we cannot reject *a priori* contributions from processes [3] and [2]. They are, however, unlikely. We are presently considering direct detection ex-

[3]Estimated energies based upon selected data from ref. 7.

periments using CF_2 $\tilde{A}(^1B_1) \rightarrow \tilde{X}(^1A_1)$ (13) and IF $\tilde{B}(^3\Pi\ 0^+) \rightarrow \tilde{X}(^1\Sigma^+)$ (14) transitions to fully elucidate the role of these intermediates in the present system.

One other observation is instructive: after infrared multiphoton irradiation with conventional gain switched TEA-CO_2 laser pulses, much vibrational energy is stored in vibrational energy levels of molecules with internal energies below the dissociation threshold (15). The collisional relaxation of this energy often leads to a high temperature thermal reaction. Thus, the purely thermal decomposition of pentafluoroiodoethane and of any perfluoroalkyl radicals (e.g. $D(C_2F_5—CF_2) \approx 49$ kcal mol^{-1}) (7) is a likely event whenever the infrared laser frequency can interact homogeneously with the ensemble of molecules, i.e. resonant excitation. When only a subset of molecules is excited, e.g. far from resonance, or when carbon-13 molecules are selectively excited, *vide infra*, we do not expect to observe this secondary thermal dissociation. Our remarks concerning the stability of the pentafluoroethyl radical are strengthened by the expectation that any excess internal energy in excited substrate will be carried away in internal excitation of the radical (16). This is because there is no exit barrier to the C—I bond cleavage and hence small probability for translational excitation (11).

Thus, an internally self consistent, but by no means unique, explanation for the results presented in the table is

$$[5]\quad C_2F_5I \xrightarrow{nh\nu} C_2F_5 + I$$

$$[6]\quad 2C_2F_5 \rightarrow C_4F_{10}$$

$$[7]\quad C_2F_5 + I \rightarrow C_2F_5I$$

$$[8]\quad I + I \rightarrow I_2$$

$$[9]\quad C_2F_5 \rightleftharpoons CF_3 + CF_2$$

$$[10]\quad C_2F_5 + CF_3 \rightarrow C_3F_8$$

$$[11]\quad CF_3 + (I, I_2, C_2F_5I) \rightarrow CF_3I + (I, C_2F_5)$$

$$[12]\quad CF_3 + CF_3 \rightarrow C_2F_6$$

$$[13]\quad C_2F_5 + CF_2 \rightleftharpoons C_3F_7 \rightarrow \text{Higher products}$$

$$[14]\quad CF_2 + CF_2 \rightarrow C_2F_4$$

A key aspect of this mechanism is the instability of the perfluoroalkyl radicals which allows $[C_2F_4] > [C_2F_6]$ as CF_3 radicals are effectively scavenged by pentafluoroethyl or iodine donors. However, another possible explanation would be the involvement of primary process [3]. We note that at suitably defined irradiation conditions the reactions [5]–[8] are sufficient to describe the production of the only product detected, namely decafluorobutane.

The sole observation outside the explanation discussed above is the product distribution due to focused beam irradiations at 1082 cm^{-1}. Although the laser interacts only with a small subset of molecules (small rate of loss of C_2F_5I), products derived from the CF_3 radical dominate those from the C_2F_5 radical. Decafluorobutane absorbs infrared radiation at this frequency (ν_{max} 1070 cm^{-1}) and hence we checked the possibility of its photolysis. Although the process

$$[15]\quad C_4F_{10} \xrightarrow{nh\nu\ (1082\,cm^{-1})} C_2F_6 + C_2F_4$$

was observed, its rate was negligible compared to the production rates reported in the table. These observations strongly support the reaction

$$[16]\quad C_2F_5 \xrightarrow{nh\nu\ (1082\,cm^{-1})} CF_3 + CF_2$$

i.e. the secondary photolysis of C_2F_5 during the 5 μs laser pulse. Similar processes have been inferred in the infrared multiphoton dissociation of CF_3Br (10), CF_3Cl (17), and C_3F_7I (18) in this same spectral region. For the trifluoromethyl compound the observation is supported by the known frequency for the ν_1 stretch of CF_3 of 1090 cm^{-1} (*7a*). Vibrational frequencies are not known for the larger radicals but both contain CF_3 groups; moreover, the carbon–carbon bond dissociation energies are certainly less than $D(CF_2—F) \approx 88$ kcal mol^{-1} (7). We conclude this discussion by noting that reaction [16] or its analogue for C_3F_7 almost certainly accounts for the product distribution observed in multiphoton dissociation of decafluorobutane.

The results of experiments investigating the isotopic selectivity of the dissociation are shown in Fig. 1. The value reported (γ) is given by:

$$\gamma = (\text{carbon-13/carbon-12})\ C_3F_5^+\ \text{ion}/0.0112$$

where 0.0112 is the carbon-13/carbon-12 ratio of the natural abundance substrate. The infrared absorption spectrum of pentafluoroiodoethane has been previously reported and a vibrational analysis has been made (19). The two strong bands within the gain profile of the CO_2 laser are ν_3 at 1114 cm^{-1}, assigned to a CF_2 stretch, and ν_4 at 922 cm^{-1} assigned to a CF_2—I stretch. This latter frequency has also been assigned to a C—C stretch (20). It is also underlain by a hot band $\nu_{13} - \nu_{10}$ at 900 cm^{-1}; for this reason we have concentrated our investigation of isotopic selectivity at frequencies to the red of the ν_3 band.

The spectral dependence of these isotopic selectivities is consistent with data obtained from dissociation of trifluoromethyl halides (21). We plan to

investigate the selective dissociation further using gc – mass spectrometry to investigate more fully the isotopic substitution of the C_4F_{10} and to observe any small amouts of C_2F_4, C_3F_8, and CF_3I in terms of carbon-13 enrichment in order to more fully define the reaction mechanisms discussed above.

In conclusion, the infrared multiphoton chemistry of C_2F_5I involves C_2F_5, CF_2, and CF_3 intermediates. At frequencies close to 9 μm the dissociation is isotopically selective and the gas phase photolysis of C_2F_5 to yield CF_2 and CF_3 seems to be a likely process. This observation suggests further pulsed laser experiments to investigate the homogeneous gas phase *photochemistry* of C_2F_5 and other free radicals.

Reactions of the methylmercury(II) ion with adenine and crystal structure of (adeninato-N9)methylmercury(II) monohydrate

LEONARDO PRIZANT, MARC J. OLIVIER, ROLAND RIVEST, AND ANDRÉ L. BEAUCHAMP[1]

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada, H3C 3V1

Received October 9, 1980

LEONARDO PRIZANT, MARC J. OLIVIER, ROLAND RIVEST, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. 59, 1311 (1981).

Adenine (HAd) reacts with CH_3HgX (X = NO_3, ClO_4) in basic aqueous solution to form a compound $[CH_3HgAd]\cdot H_2O$, which crystallizes in the monoclinic space group $C2/c$, with a = 19.796, b = 7.119, c = 16.471 Å, β = 128.83°, and Z = 8. The CH_3Hg^+ group is linearly bonded to N(9) of deprotonated adenine and the molecules are held in pairs by two N(6)–H(6)···N(1) hydrogen bonds. With excess adenine, higher complexes of the formula $[(CH_3Hg)_nAd]X_{n-1}$ (where n = 2, 3) are formed, in which positions N(9) (deprotonated), N(7), and N(3) are successively filled. Compounds $[(CH_3Hg)_3(Ad\text{-}H)]X$ have been obtained at high pH by substitution of H(9) and an amino hydrogen, and with coordination of a third CH_3Hg^+ group probably to N(7). Complexation leads to significant changes in the infrared spectra and the 1750–1250 cm^{-1} regions are correlated with the substitution patterns. The structures are discussed in connection with the basicity of the donors in adenine and the basicity changes of the remaining donors when other atoms are already involved in coordination.

LEONARDO PRIZANT, MARC J. OLIVIER, ROLAND RIVEST et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **59**, 1311 (1981).

L'adénine (HAd) réagit avec CH_3HgX (X = NO_3, ClO_4) en solution aqueuse basique pour former un composé $[CH_3HgAd]\cdot H_2O$, qui cristallise dans le groupe monoclinique $C2/c$ et dont les paramètres de maille sont a = 19,796, b = 7,119, c = 16,471 Å, β = 128,83° et Z = 8. Le groupe CH_3Hg^+ est lié linéairement à l'atome N(9) de l'adénine déprotonée et les molécules sont associées en paires par deux liaisons hydrogène N(6)–H(6)···N(1). En présence d'adénine en excès, il se forme des complexes supérieurs de formule $[(CH_3Hg)_nAd]X_{n-1}$ (où n = 2, 3), dans lesquels les sites N(9) (déprotoné), N(7) et N(3) sont successivement occupés. On obtient à pH élevé des composés $[(CH_3Hg)_3(Ad\text{-}H)]X$ par déplacement de H(9) et d'un atome d'hydrogène du groupe amino, et coordination d'un troisième groupe CH_3Hg^+ probablement en N(7). La complexation engendre des changements importants dans les spectres infrarouges et on relie les domaines 1750–1250 cm^{-1} de ces spectres au motif de substitution. On discute des structures de ces composés en rapport avec les basicités des atomes donneurs et les variations que subissent ces basicités lorsque certains de ces atomes donneurs sont liés au métal.

Introduction

Because of its ability to act as a unifunctional Lewis acid with minimum steric effects, the CH_3Hg^+ cation is a convenient ligating species to probe the basicities of the donor atoms in multidentate ligands such as the purine and pyrimidine molecules found in nucleic acids. Crystallographic work on complexes with 9-methlyadenine (1, 2) have confirmed the complexation sites deduced from spectroscopic work on aqueous solutions of adenosine (3–5). Under similar conditions, adenine was found to react quite differently (1, 6) and a systematic investigation of its CH_3Hg^+ complexes was undertaken in order to understand these differences.

The present paper reports on the interaction of CH_3Hg^+ with adenine (HAd) in water, as deduced from the compositions and structures of the isolated solid compounds. Complexes of various stoichiometries have been characterized and attempts have been made to relate their structures, generally known from X-ray diffraction work, with information more readily accessible, such as routine infrared spectra. The crystal structure of the neutral 1:1 complex $[CH_3HgAd]\cdot H_2O$ is also described.

Experimental

Preparation

Adenine (Aldrich) was used without further purification. CH_3HgI (Alfa) was the starting material to prepare water solutions of CH_3HgNO_3 and CH_3HgClO_4 as described elsewhere (7).

Preparations were usually run with 2 mmol (0.27 g) of ligand dissolved in 20–30 mL of hot water. A suitable volume of 1 *M* CH_3HgNO_3 or CH_3HgClO_4 solution was added to obtain the needed metal-to-ligand ratio. When necessary, 1 *M* NaOH, HNO_3, or $HClO_4$ were added in required amount or until a predetermined pH value was reached. Equilibria are normally rapid in homogeneous water solutions of CH_3Hg^+ and prolonged heating of reaction mixtures proved unnecessary. The final mixtures were allowed to stand at room temperature for 1–2 days before precipitates were collected. More soluble compounds were left uncovered for longer periods to reduce volume. The samples were usually washed with ethanol and ether. They usually decomposed when recrystallized or washed with water. The solids are colorless, generally crystalline, and stable in air, although some of them become yellowish after standing in closed bottles for several weeks.

The compounds prepared are listed below, together with the quantities of methylmercury salt, acid or base reacted with 2 mmol of ligand. All analyses were carried out by Schwarzkopf Laboratories, NY.

$[CH_3HgAd]\cdot H_2O$: CH_3HgNO_3 2 mmol, NaOH added to pH 9. *Anal.* calcd. for $C_6H_9HgN_5O$: C 19.60, H 2.47, N 19.04, Hg 54.54; found: C 19.77, H 2.35, N 18.79, Hg 54.67.

Crystal Data

$C_6H_9HgN_5O$ fw = 367.8

Monoclinic, space group $C2/c$, a = 19.796(6) Å; b = 7.119(3) Å, c = 16.471(4) Å, β = 128.83(2)°, V = 1808.3 Å, D_c = 2.70 g cm^{-3}, Z = 8, μ(MoKᾱ) = 169.9 cm^{-1}, λ(MoKᾱ) = 0.71068 Å (graphite monochromator), t = 23°C.

Crystallographic Measurements and Structure Resolution

The crystal selected for data collection had dimensions 0.09 × 0.14 × 0.70 mm^3. A set of precession photographs showed monoclinic Laue symmetry and indicated space group Cc or $C2/c$ (systematic absences hkl, $h + k \neq 2n$ and $h0l$, $l \neq 2n$). The crystal was mounted on an Enraf-Nonius CAD-4 diffractometer and the cell parameters were obtained from least-squares fit of the setting angles for 25 reflections centered in the counter aperture. The intensity data were collected using the ω/2θ scan technique. A fixed slit of 4 × 4 mm^2 was used and the scan range (ω) was (1.0 + 0.35 tan θ)° extended 25% on either side for backgrounds. Scan speed between 10 and 0.67 deg min^{-1} was automatically selected to make $I/\sigma(I)$ = 100, but a maximum scan time of 135 s was imposed. Prescans at 10° min^{-1} were done and all reflections having $I/\sigma(I) < 1$ were labelled "weak" and not remeasured. Three standard reflections, used as a check on instrument and crystal stability, showed only random fluctuations (esd 2.3–3.8%). Crystal orientation was checked every 100 reflections by centering three reflections. Crystal reorientation proved unnecessary.

A total of 2088 independent hkl and $\bar{h}kl$ reflections with $h + k = 2n$ were measured within a sphere $2\theta \leq 55°$. Net intensity I and esd $\sigma(I)$ were calculated as described elsewhere (8). A set of 1520 reflections with $I \geq 2.5\ \sigma(I)$ was retained for structure determination. An absorption correction was applied (Gaussian integration, grid 10 × 10 × 10, transmission coefficient 0.057–0.279). The data were finally corrected for the Lorentz and polarization effects.

The structure was solved by the heavy-atom method and refined on $|F_o|$ by full-matrix least squares. The statistical distribution of the normalized structure factors clearly favored the centric space group $C2/c$. From a Patterson map, the eight Hg atoms were positioned on a general equipoint. A Fourier map easily revealed the positions of all nonhydrogen atoms. Isotropic refinement with unit weights converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.123$. Refinement was continued using the block-diagonal approximation. Anisotropic temperature factors were refined for all nonhydrogen atoms. H(2), H(8), H(61), and H(62) were fixed at their calculated positions (sp^2 hybridization, C—H = 0.95 Å, N—H = 0.87 Å) with temperature factors B of 4.0 Å^2. The parameters of those hydrogens were not refined. The hydrogen atoms of the methyl group were not located. Individual weights based on counting statistics $w = 1/\sigma(F)^2$ were applied in the last least-squares cycles. Anisotropic refinement of all nonhydrogen atoms and of the scale factor converged to R = 0.051 and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.063$. The final difference Fourier map had a general background < ±0.7 e Å^{-3}, except for a few peaks of 1.1–2.0 e Å^{-3} within 1 Å from Hg. The refined parameters are listed in Table 1. A list of structure factors is part of the unpublished material.[2]

The form factors used were those of Cromer and Waber (9), except for hydrogen (10). Anomalous dispersion terms f' and f'' were used for Hg (11). The computer programs used are listed elsewhere (8).

Infrared Measurements

The spectra (4000–300 cm^{-1}) were recorded as Nujol mulls (CsI windows) and KBr pellets using a Beckman IR4520 spectrophotometer.

Results

Adenine is a potential pentadentate ligand. Three sites, i.e. N(1), N(3), and N(7) have available lone pairs in the undissociated ligand. Atom N(9) can become a reactive site by displacement of the weakly acidic H(9) proton (pk_a = 9.9) (12). The 6-amino group does not react as such because its lone pair participates in the ring π system, but substitution of an amino hydrogen by CH_3Hg^+ has been shown to take place under mild conditions with 9-methyladenine (1).

A number of adenine complexes containing various numbers of hydrogen and metal atoms have been structurally characterized. As the anionic form Ad^-, adenine is either monodentate through N(9) (13–16) or bridging-bidentate through N(9) and N(3) (13). The neutral form (HAd) reacts by the same donor atoms as the anion, the proton originally bonded to N(9) being displaced to N(7) (13). In the complexes with the adeninium cation H_2Ad^+, coordination usually takes place with N(3) and N(9), whereas protons are found at N(1) and N(7) (13, 17). The only exception to the latter generalization is the zwitterionic compound $[ZnCl_3(H_2Ad)]$, in which Zn is bonded to N(7), the extra proton is found at N(1), and H(9) is undissociated (18).

[2]The supplementary material includes a list of anisotropic temperature factors, a table of observed and calculated structure factors, and details of least-squares plane calculations. Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada, K1A 0S2.

*Parameters not refined.

Interactions of CH_3Hg^+ with Adenine

The simplest solid compound is obtained from a 1:1 solution of CH_3HgNO_3 and HAd in which pH is raised to ~9 with NaOH:

[1] $CH_3Hg^+ + HAd + OH^- \rightarrow CH_3HgAd + H_2O$

Extra CH_3Hg^+ groups are introduced into the ring without proton exchange by increasing the amount of CH_3HgX. For instance $[(CH_3Hg)_2Ad]X$ is obtained either by adding 1 equiv. of NaOH to a 2:1 mixture of CH_3HgX and HAd (eg. [2]), or by reacting a 1:1 mixture without NaOH (eq. [3]):

[2] $2CH_3Hg^+ + HAd + OH^- \rightarrow [(CH_3Hg)_2Ad]^+ + H_2O$

[3] $2CH_3Hg^+ + 2HAd \rightarrow [(CH_3Hg)_2Ad]^+ + H_2Ad^+$

In the latter case, half of adenine acts as a base to accept the liberated proton. Using one extra mole of CH_3HgX yields $[(CH_3Hg)_3Ad]X_2$. When pH is raised to ~7 in solutions containing excess CH_3HgX, complexes of composition $[(CH_3Hg)_3(Ad-H)X$ are isolated. Two hydrogen atoms, presumably H(9) and an amino proton, are displaced in that reaction:

[4] $3CH_3Hg^+ + HAd + 2OH^- \rightarrow [(CH_3Hg)_3(Ad-H)]^+ + 2H_2O$

The proton attached to N(9) in solid HAd is involved in a tautomeric equilibrium between N(9) and N(7) in water solutions (19). Hence, CH_3Hg^+ coordination to N(7) in $[CH_3HgAd]\cdot H_2O$ could not be ruled out. The X-ray work described hereafter shows, however, that mercury is bonded to the more common N(9) site (13, 15, 16). The three remaining types of compounds obtained with this system have not been reported for other metals. Coordination was found to take place with N(9) and N(7) in both $[(CH_3Hg)_2Ad]^+$ compounds (1, 20). In both salts of $[(CH_3Hg)_3Ad]^{2+}$, the third mercury atom is bonded to N(3) (6, 8). No X-ray diffraction data are available for the compounds obtained at high pH. According to the formula, two protons have been substituted, an indication that mercury bonds to N(9) and N(6). The site used by the third CH_3Hg^+ group is still uncertain, but we suggest N(7) on the basis of our present interpretation of the infrared spectra (*vide infra*).

When this work was undertaken, it was expected that low pH could reverse equilibrium [1] and lead to a series of complexes without H(9) substitution, as found in $[ZnCl_3(H_2Ad)]$ (18). Although formation of such species in solution is not ruled out, whenever pH was lowered to the point that none of the above complexes would precipitate, the solid phase isolated was adeninium nitrate or perchlorate.

Crystal Structure of $[CH_3HgAd]\cdot H_2O$

Interatomic distances and bond angles are represented in Fig. 1. The CH_3Hg group is bonded to N(9), the site formerly occupied by the displaced proton. The Hg—N (2.07(1) Å) and Hg—C (2.06(2) Å) bond lengths are similar to those found in previous studies (1, 2, 6–8). The coordination of mer-

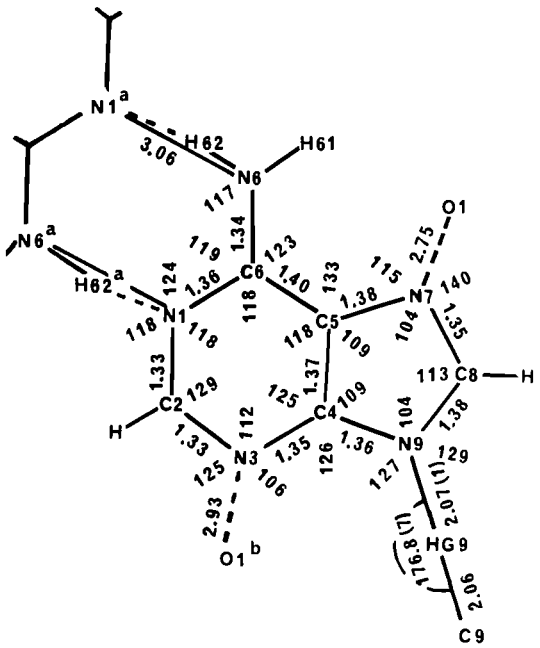

FIG. 1. Interatomic distances (Å) and bond angles (deg) in (adeninato-N9)methylmercury(II) monohydrate. Unless otherwise stated, the standard deviations on distances are 0.02 Å and on bond angles, 1°. Superscript a denotes $\frac{1}{2}-x, -\frac{1}{2}-y, 1-z$; b, $\frac{1}{2}+x, \frac{1}{2}-y, \frac{1}{2}+z$.

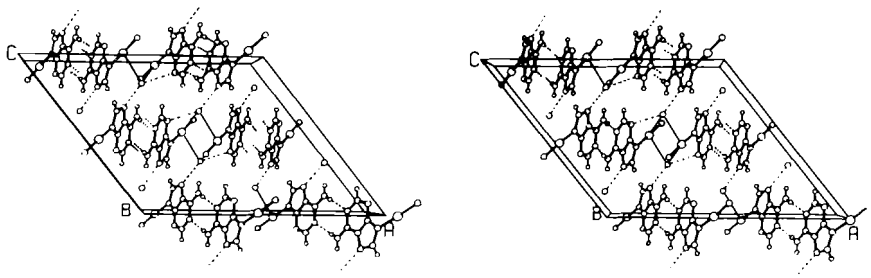

FIG. 2. Stereo view of the crystal packing. The smaller and larger spheres correspond to hydrogen and mercury atoms respectively. The hydrogen bonds are shown as dashed lines and the Hg···O contacts as thin bonds. Some of the molecules in the *ab* plane at $z = 0$ have been shifted along c to illustrate base pairing.

TABLE 2. Environments of O(1) and Hg(9) in the crystal structure*

Bond	Distance (Å)	Bond	Distance (Å)
Hg(9)—O(1)^a	3.00(1)	O(1)—N(7)	2.75(2)
Hg(9)—O(1)^b	2.97(1)	O(1)—N(3)^c	2.93(2)
		O(1)—Hg(9)^c	3.00(1)
		O(1)—Hg(9)^d	2.97(1)
Bonds	**Angle (°)**	**Bonds**	**Angle (°)**
C(9)–Hg(9)–O(1)^a	88.8(6)	N(7)–O(1)–N(3)^c	127.9(6)
C(9)–Hg(9)–O(1)^b	101.4(6)	N(7)–O(1)–Hg(9)^c	156.1(6)
N(9)–Hg(9)–O(1)^a	88.3(5)	N(7)–O(1)–Hg(9)^d	108.8(5)
N(9)–Hg(9)–O(1)^b	80.7(5)	N(3)^c–O(1)–Hg(9)^c	71.0(4)
O(1)^a–Hg(9)–O(1)^b	103.5(4)	N(3)–O(1)–Hg(9)^d	102.4(5)
		Hg(9)^c–O(1)–Hg(9)^d	76.5(3)

*Superscript a denotes $\frac{1}{2} + x, \frac{1}{2} - y, \frac{1}{2} + z$; b, $\frac{1}{2} - x, \frac{1}{2} + y, \frac{1}{2} - z$; c, $-\frac{1}{2} + x, \frac{1}{2} - y, -\frac{1}{2} + z$; d, $\frac{1}{2} - x, -\frac{1}{2} + y, \frac{1}{2} - z$.

cury is linear (N(9)–Hg(9)–C(9) = 176.8(7)°) as expected. The geometry of the ligand does not significantly differ from what has been observed for other N(9)-bonded complex (13, 15, 16) and the large standard deviations preclude any conclusions as to changes in ligand geometry (21) produced by complexation. The adenine ring, including the exocyclic N(6) atom, is planar within 1σ (0.02 Å). The CH_3Hg group is significantly out of that plane, with atom-to-plane distances of 0.177(1) Å for Hg(9) and 0.35(3) Å for C(9).

The packing diagram (Fig. 2) shows that two centrosymmetrically-related complex molecules are associated in pairs by two N(6)–H(62)···N(1′) hydrogen bonds of moderate strength: N(6)—N(1′) = 3.06(2) Å, C(6)–N(6)–N(1′) = 117(1)°, C(2′)–N(1′)–N(6) = 118(1)°, C(6′)–N(1′)–N(6) = 124(1)°.

Layers parallel to the *ab* plane at $z = 0$ and $\frac{1}{2}$ contain flat "dimers" stacked parallel with the usual separation of ~3.4 Å. The interlayer region is occupied by the water molecule O(1), which is hydrogen-bonded to N(7) in one layer, whereas it interacts with N(3) and two Hg atoms in the adjacent layer (Table 2). The N(7)···H–O(1) hydrogen bond is strong (N(7)···O(1) = 2.75(2) Å) and O(1) is close to the molecular plane, although not along the expected direction of the lone pair (the O(1)–N(7)–C angles differ by 25°, Fig. 1). The other hydrogen of O(1) interacts with N(3), but this time, the H-bond is much weaker (N(3)—O(1) = 2.93(2) Å) and O(1) is far from the molecular plane where best H-bonding is expected. The unhindered side of the water molecule bridges two mercury atoms with which it forms weak secondary bonds of 2.97(1) and 3.00(1) Å. In the resulting arrangement, each Hg atom has two such secondary bonds established as usual near the equatorial plane (assuming C(9) and N(9) as axial).

Infrared Spectroscopy

This technique has been widely used to distinguish between complexation sites in multidentate ligands. With adenine, reliable correlations between structure and spectral information are still missing. Since we had at our disposal unambiguous structural information on a series of related compounds, we carefully examined their ir spectra, hoping to detect characteristic features for each structural type. The most interesting region (1750–1250 cm^{-1}) will be discussed below.

With the exception of the weak ν C–H stretching band around 2925 cm^{-1}, the only vibration of the CH_3Hg group (22) which was clearly recognized is the Hg–C stretch showing at ~565 cm^{-1}. The band is not single when the molecule contains more than one CH_3Hg group, but the number of such groups in the compounds cannot be reliably deduced therefrom because the components are overlapping. Likewise, band position does not seem to be sensitive to the sites of attachment on the ring.

The anions present in most of our compounds produce broad and very intense bands (NO_3^-, ~1360; ClO_4^-, ~1080 cm^{-1}) (23). Except for these absorptions and other weaker anion bands, pairs of corresponding complex salts show very similar spectra and are assumed to have the same structure, a conclusion that is borne out by X-ray work for two of the three pairs of compounds (1, 6, 8, 20).

Figure 3 shows the 1750–1250 cm^{-1} portions of the ir spectra, which appear to be sensitive to the substitution pattern. This region includes mostly ring stretching vibrations, together with some in-plane deformation modes of exocyclic atoms (δ NH_2, δ NH, and δ CH). Our results for adenine are in good agreement with those reported by Lautié and Novak (24). Band assignments have been proposed by these workers for adenine and its Na salt. A normal-coordinate analysis has been carried out for the adenine ring in-plane vibrations (25).

X-ray diffraction work has been done on all the compounds in which the amino group is not substituted. Their spectra will be discussed first (Fig. 3, B, C, and D).

The scissoring motion of the 6-NH_2 group leads to a strong absorption at 1673 cm^{-1} in adenine (24). The shift to 1655 cm^{-1} observed in the complexes undoubtedly results from a change in H-bonding rather than from direct effects of complexation. The crystal structure of adenine is not known yet, but Lautié and Novak (24) have suggested a reasonable model in which each molecule is surrounded by three pairs of H-bonds (N(6)–H(62)···N(1), N(6)–H(61)···N(7), and N(9)–H(9)···N(3)) of the type found in DNA base pairing (21). Obviously, mercury binding to heterocyclic nitrogen atoms destroys most of those H-bonds. Interestingly, the N(6)–H(62)···N(1) pairing is found in all our complexes and it is the only type of base pairing observed. Even in $[CH_3HgAd]\cdot H_2O$, where N(7) is not blocked by mercury, this position is involved in H-bonding with water instead of pairing with another CH_3HgAd molecule. Consequently, the constant position of the δ NH_2 band is likely to simply reflect the similarity in H-bonding.

A set of three bands at 1604, 1570, and 1507 cm^{-1} in adenine are displaced to 1593, 1555, and 1485 cm^{-1}, respectively, in CH_3HgAd, but they return to their original positions in higher complexes. The latter vibration involves predominantly the imidazole ring (24, 25) and the shift to 1485 cm^{-1} may be characteristic of a singly N(9)-metalated ring.

The ligand band at 1449 cm^{-1} appears around 1468 cm^{-1} in all our compounds. It probably indi-

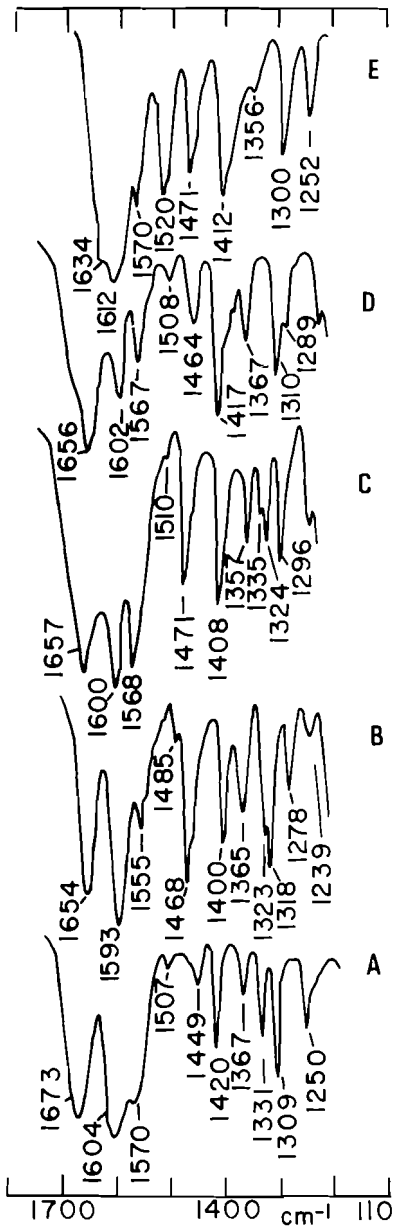

FIG. 3. The 1750–1250 cm^{-1} regions of the infrared spectra; A = adenine (HAd), B = $[CH_3HgAd]\cdot H_2O$, C = $[(CH_3Hg)_2Ad]\text{-}ClO_4\cdot H_2O$, D = $[(CH_3Hg)_3Ad](ClO_4)_2$, E = $[(CH_3Hg(Ad\text{-}H)]\text{-}ClO_4$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

cates coordination through N(9), but it is not sensitive to further reaction with N(7), or N(7) and N(3).

The position of the band around 1420 cm^{-1} in adenine is differently shifted depending on the substitution pattern.

The pair at 1331 and 1309 cm^{-1} in adenine shifts to 1323 and 1318 cm^{-1} in CH_3HgAd, to 1335 and 1324 cm^{-1} in $[(CH_3Hg)_2Ad]ClO_4$, and a single absorption at 1310 cm^{-1} is found for $[(CH_3Hg)_3Ad](ClO_4)_2$.

A band at 1250 cm^{-1} and a shoulder at 1235 cm^{-1} have been assigned to the δ NH and δ CH modes, respectively (24). The latter assignment is probably correct (25). The former vibration undoubtedly involves a large amount of ring stretching mixed with N–H bending or there may be another component (25) under the 1250 cm^{-1} peak, since the band does not disappear in the complexes, even though H(9) is no longer present. It is shifted to 1278 cm^{-1} in the 1:1 complex, it undergoes further displacement to 1296 cm^{-1} in the 2:1 complex, and probably to 1289 cm^{-1} in $[(CH_3Hg)_3Ad](ClO_4)_2$.

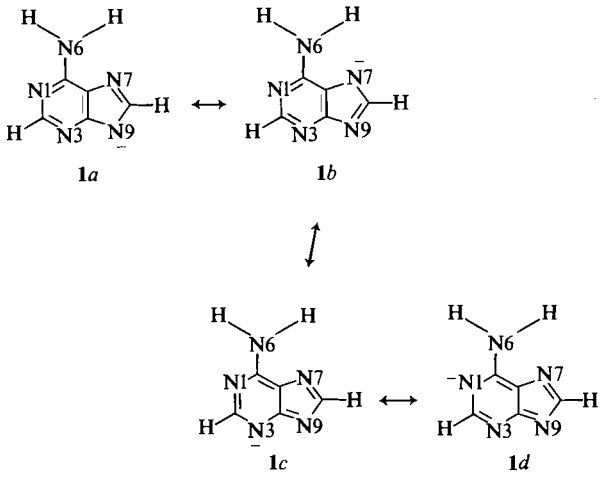
The structure of $[(CH_3Hg)_3(Ad\text{-}H)]X$ is not known from X-ray work. Substitution of an amino hydrogen by a CH_3Hg^+ group is consistent with the disappearance of the strong δ NH_2 band at 1673 cm^{-1} (Fig. 3, curve E). The spectrum of the nitrate shows a sharp peak at 1117 cm^{-1} (not shown). With 9-methyladenine, such a peak has been found (~1135 cm^{-1}) only in $[(CH_3Hg)_2(MAd\text{-}H)]NO_3$ (26), a compound in which mercury has displaced an amino hydrogen (1). Tobias and co-workers (5) have also reported a similar absorption at 1122 cm^{-1} in the Raman spectrum of adenosine 5′-monophosphate when reaction takes place with the amino group. Evidence for H(9) substitution comes from the band at 1471 cm^{-1}, which is common to all the N(9)-coordinated complexes above. The present complex also shows bands at 1612, 1570, and 1520 cm^{-1}, respectively. This probably rules out single occupancy of the imidazole ring, since those bands would have shifted to lower wavenumbers as in the 1:1 complex. Consequently, we suggest that the third CH_3Hg^+ group is bonded to N(7). In that case, the presence of a single band at 1300 cm^{-1} would result from perturbations in the ring caused by amino substitution. It must be stressed that the structure of $[(CH_3Hg)_3(Ad\text{-}H)]X$ is not firmly established, since this work provided unambiguous information only on three substitution patterns and the spectral changes on metal-binding elsewhere, with N(1), for example, are not easily predictable.

Discussion

This work brings out interesting aspects of CH_3Hg^+ complexation with adenine ligands. First, mercury competes favorably with the proton, since as noted by other workers (3, 5), protons are displaced by mercury at a pH much lower than that at which spontaneous dissociation would take place. For instance, an amino proton that does not dissociate in water was easily displaced in the $[(CH_3Hg)_3(Ad\text{-}H)]X$ compounds. Similarly, N(9)-mercurated compounds precipitated even at pH 2 in spite of a pk_a of 9.9 for H(9) of adenine (12). Another interesting point is the influence of substitution on the basicity of the remaining donor atoms. For example, N(9)-alkylated adenine reacts through N(1), while N(9)-mercurated adenine reacts through N(7). These peculiarities can be rationalized in terms of charge distribution.

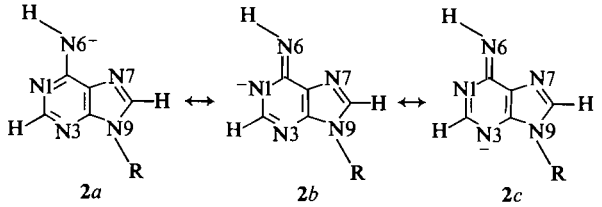
There is no generally accepted basicity order for the donors in the adenine ring. Electrostatic potential energy calculations (27) on neutral adenine indicate that pyrimidine nitrogens N(1) and N(3) have comparable charge densities, whereas N(7) is significantly less electron-rich. This would be in agreement with the fact that adenine protonates at N(1) (12) and that N(9)-blocked adenines accept CH_3Hg^+ at the same position (2). When H(9) has been substituted by CH_3Hg^+, the theoretical considerations above have to be modified in order to explain the formation of higher complexes. Because CH_3Hg is less electron-attracting than H or CH_3, but more than nothing at all (free lone pair), the electronic distribution in CH_3HgAd should be intermediate between that of neutral adenine HAd and that of the adeninate anion Ad^-. The anion can be represented by resonance structures **1***a–d*, which are expected to contribute in the order **1***a* > **1***b* > **1***c* > **1***d*. Structures in which the charge appears on the pyrimidine ring (**1***c*, *d*) are likely to contribute less because the benzenoid structure is lost. On the other hand, N(3) is close to N(9) and is expected to receive more charge than the remote N(1) site. The net result of H(9) substitution by CH_3Hg^+ is a large basicity enhancement of N(7), a lesser effect at N(3), and probably very little effect at N(1). This work suggests that N(7) has become the best residual binding site in CH_3HgAd. Coordination to the free lone pair on N(7) will now reduce the availability of both N(1) and N(3), but probably to the same extent. Further reaction with N(3) shows either that N(3) was already more basic than N(1) in neutral adenine, or that H(9) substitution has raised its basic character above that of N(1).

In connection with the possible structures for $[(CH_3Hg)_3(Ad\text{-}H)]X$, it is interesting to speculate on the best residual binding site of an adenine ring in which H(9) and one amino hydrogen have already been substituted by CH_3Hg^+. Substitution of



1*a* 1*b* 1*c* 1*d*

an amino hydrogen by CH_3Hg^+ should initiate a charge redistribution approaching that of the anion, for which the three predominant resonance structures are shown (**2** *a–c*). They probably contribute in the order **2***a* > **2***b* > **2***c*. Thus, initial mercuration



2*a* 2*b* 2*c*

on the amino group should enhance the donor basicities in the order N(1) > N(3) > N(7). On the other hand, initial mercuration at N(9) should lead to the reverse order N(7) > N(3) > N(1). Consequently, depending on the relative importance of those effects, any of the three sites would be possible. If our suggestion based on ir spectra that the compounds are N(9), N(7), N(6)-bonded is correct, it would mean that H(9) substitution directly on the imidazole ring releases more charge into the ring system than substitution on the exocyclic amino group.

Ab initio MRD-CI calculations have been carried out to nearly full-CI accuracy for several large AO basis sets (including *f* functions) for the potential curves of the BH_2 molecule in its X^2A_1 and A^2B_1 electronic states. A two-dimensional vibrational treatment of the bending modes in this system has been performed employing a variational method which takes account of both Renner–Teller coupling and large-amplitude motion. The resulting structural data agree to within 0.002 Å and 2° of measured bond distance and angles and the computed bending frequencies are found to be in error by less than 30 cm^{-1}; in addition predictions of the as yet unobserved stretching frequencies are also reported for both electronic states. In the best theoretical treatment the $v_2'' = 0 \rightarrow v_2' = 1$ transition energy to the linear upper state is calculated to be 4145 cm^{-1}, in excellent agreement with the corresponding value of 4190 cm^{-1} obtained by extrapolation of the three higher-energy band frequencies actually observed by Herzberg and Johns provided a renumbering of these levels (namely as $v_2' = 9$, 11, and 13) is undertaken relative to the originally preferred experimental interpretation. It is also pointed out that some of the earlier reported discrepancies between calculation and experiment regarding transition energies in this band system are actually due to a misinterpretation of the definition of the experimental fitting parameter T_{00} in previous theoretical work.

MILJENKO PERIĆ, SIGRID D. PEYERIMHOFF et ROBERT J. BUENKER. Can. J. Chem. **59**, 1318 (1981).

Utilisant plusieurs ensembles de OA avec des bases élargies (y compris les fonctions *f*), on a effectué des calculs *ab initio* MRD-CI jusqu'à une pression CI presque parfaite pour les courbes de potentiel de la molécule BH_2 dans ses états électroniques excités X^2A_1 et A^2B_1. On a effectué un traitement vibrationnel en deux dimensions des modes de déformation de ce système en utilisant une méthode de variation qui tient compte du couplage de Renner–Teller et du mouvement de grande amplitude. Les données structurales qui en résultent s'accordent à 0,002 Å et 2° avec les distances et les angles de liaison mesurés, et les fréquences calculées accusent une erreur de moins de 30 cm^{-1}. De plus on rapporte les prédictions relatives aux fréquences d'élongation qui n'ont pas encore été observées jusqu'ici, des deux états électroniques. Selon le meilleur traitement théorique, on a calculé que l'énergie de transition $v_2'' = 0 \rightarrow v_2' = 1$ vers l'état supérieur linéaire est de 4145 cm^{-1} et cette valeur est en parfait accord avec la valeur de 4190 cm^{-1} obtenue par extrapolation des trois bandes de fréquence de haute énergie observées de fait par Herzberg et Johns; cette concordance conduit à changer la numérotation de ces niveaux (soit $v_2' = 9$,11 et 13) par rapport à l'interprétation expérimentale retenue originalement. On montre également que quelques-unes des différences rapportées antérieurement entre les calculs et l'expérience relatives aux énergies de transition de ce système de bandes sont dues en fait à une mauvaise interprétation de la définition du paramètre expérimental d'accord T_{00} dans le travail théorique antérieur.

I. Introduction

The triatomic radical BH_2 possesses only 7 electrons and is thus the smallest polyatomic molecule for which an electronic spectrum has yet been observed. Because of the small number of electrons the theoretical *ab initio* results should be very reliable for this species and hence very good agreement between measured and calculated data for the BH_2 structure and electronic spectrum is expected. Nevertheless up to the present when such comparison is attempted, considerable discrepancy appears to exist between the experimental and theoretical descriptions of the lowest-energy electronic transition in this spectrum.

On the experimental side an extensive study of the absorption spectrum of BH_2, observed in the flash photolysis of borine carbonyl, was undertaken by Herzberg and Johns (1). It consists of a progression of bands in the 6400–8700 Å region and is very similar to that observed for both NH_2 and CH_2. The transitions occur between the bent X^2A_1 and the upper (linear) $^2B_1$ state, whereby both states correlate with the same electronic species $^2\Pi$ in the linear nuclear arrangement (Renner–Teller effect). The progression is attributed to the bending mode, and on the basis of an extrapolation procedure, carried out under the assumption that anharmonicity effects can be neglected, it was concluded that the observed frequencies could best be fit in a polynomial series in $(v_2' + 1)$ with a constant value of $T_{00} = 4194$ cm^{-1}. No stretching frequency could be determined but on the basis of the isotope shift results between corresponding BH_2 and BD_2 bands it was concluded that one or possibly both stretch-

ing frequencies are appreciably larger in the upper than in the X^2A_1 ground state.

Among the first *ab initio* studies of the two BH_2 states is the work of Bender and Schaefer (2), who employed a double-zeta type contracted gaussian AO basis in their natural orbital CI calculations and obtained structural data for both states which agree within 0.03 Å and 2° with the corresponding measured equilibrium quantities. Nevertheless they report a difference in the equilibrium electronic energies of the $^2A_1$ and $^2B_1$ ($^2\Pi$) species of only 2260 cm^{-1} compared to a result for this quantity given by Herzberg and Johns of 4300 cm^{-1}, and they have assumed that the resulting discrepancy arises from shortcomings in the above calculations. Staemmler and Jungen (3) have since made a very careful theoretical study of both BH_2 states in a large AO basis of 65 gaussian lobe functions contracted to 38 groups, including *d* polarization functions on boron and *p* species on hydrogen, whereby some of the original 5*p* boron exponents were reoptimized in the molecular calculation. The correlation energy is accounted for in an independent electron pair approach (IEPA) combined with the direct determination of pair natural orbitals (PNO). The calculated molecular structure constants are again in very good agreement with the experimental results (deviations of 0.006 and 0.024 Å in equilibrium bond lengths and 2.4° in X^2A_1 bond angle) in this work, but in this case the calculated energy difference (2740 cm^{-1}) between the two electronic states is only slightly greater than that obtained by Bender and Schaefer. Upon correcting for zero-point vibrational effects, Staemmler and Jungen find a value for T_{00} of 3035 cm^{-1}, and state their belief that this theoretical result is more reliable than the corresponding experimental value of 4194 cm^{-1}, suggesting that the remaining discrepancy comes about as a consequence of an incorrect numbering of the observed vibrational levels. Further theoretical work (4–6) on BH_2 has concentrated on the calculation of other molecular properties than the above transition energy or has employed a less extensive theoretical treatment, and hence has not helped to clarify this apparent discrepancy between computed and measured results.

On the basis of this literature survey it must be concluded that there is either an incorrect interpretation of the experimental results, such as an error in the assignment of the observed bands, or that the previous theoretical treatments underestimate the energy difference between the lowest vibrational levels of the two electronic states by an unexpectedly large amount. The present work attempts to clarify this situation by employing a large AO basis set in the multi-reference double-excitation CI technique (MRD-CI), which has been very successful in the study of a number of similar systems such as PH_2, H_2S^+, and NH_2, for example (7–9).

2. Technical Details of the Calculations

A. Potential Surface Treatment

The AO basis set employed in the present calculations consists of 38 contracted cartesian gaussian functions: five *s* and three *p* groups in the contraction (4,2,1,1,1/3,1,1) given by Dunning (10), in addition to a set of cartesian *d* functions with exponent $\alpha = 0.6$, located at the boron atom, and two *s* groups in the contraction (4,1) with scaling factor $\eta^2 = 2.0$ augmented by one set of *p* functions ($\alpha = 0.7$) for the hydrogen atoms; furthermore one *s* and one *p* function ($\alpha_s = 1.3$, $\alpha_p = 0.5$) located in each of the BH bonds are included. Finally for a few additional calculations at representative geometrical points a cartesian *f* function ($\alpha = 1.0$) is also employed on the boron basis set.

The calculation of the electronic energies is carried out by means of the MRD-CI method (12, 13), with configuration selection and energy extrapolation. In the present case all MO's except the highest a_1 species have been considered for variable occupation (37 total) in the construction of the configuration basis, and all electrons including those in the boron 1*s* shell are correlated. The orbital basis consists of the parent-configuration SCF MO's in each case, i.e. X^2A_1 SCF orbitals for the treatment of the X^2A_1 state and $^2B_1$ SCF MO's for the $^2B_1$ CI calculations.

The set of reference configurations employed for all nuclear conformations is listed in Table 1. All single- and double-excitation species with respect to this reference set are generated, resulting in 46 252 symmetry-adapted configuration state functions (SAF's) for the X^2A_1 and 31 988 SAF's for the $^2B_1$ state; a selection threshold of $T = 5$ μh is employed so that the actual secular problem to be solved at each nuclear conformation is in the order of 2200, while the contribution of the remaining generated configurations is accounted for by the usual extrapolation procedure (12, 13). The effect of still higher excitations is estimated by means of the perturbation formula

$$\Delta E = \left(1 - \sum_i^{\text{ref}} C_i^2\right)(E_{\text{ref}} - E_{\text{MRD-CI}})$$

so that this energy contribution, when added to the

MRD-CI value, yields a reasonable estimate (14, 15) for the full CI energy in the AO basis employed.

B. Vibrational Treatment

The vibrational treatment is carried out under the assumption that all three vibrational modes are independent of one another, i.e. the potential is represented in polynomial expansions in the vibrational coordinates including higher than second-order terms but no cross terms. Such an approach is justified since one can assume that excitation into high-lying stretching vibration levels during the electronic transition are improbable, and hence that the molecule undergoes only small-amplitude stretching vibrations, in which case it is possible to separate the bending and stretching motions from each other (16–18).

The Schrödinger equation for the symmetric and the antisymmetric vibrations is solved with the help of the variation method, involving expansion of the vibrational states in harmonic oscillator functions and employing a polynomial fit for the electronic potential, as described in more detail elsewhere (18). In the correct treatment of bending vibrations it is necessary to consider both the effect of large-amplitude vibrations as well as of the Renner–Teller vibronic interaction. A set of two-dimensional harmonic oscillator functions of the form

$$R_{v,k}(\rho) = N_{v,k} \exp(-\alpha\rho^2/2)(\alpha\rho^2)^{k/2} L^k_{(v+k)/2}(\alpha\rho)$$

is thereby employed as the functional basis ($\rho = \pi - \alpha$), just as in the related study of PH_2 (7) or NH_2 (9), and the vibronic energy levels and wavefunctions are then obtained by diagonalization of the corresponding Hamiltonian matrix.

Of the various suggestions for the kinetic energy operators allowing a treatment of the large-amplitude bending vibration (16, 17, 20), the form of Freed and Lombardi (17) as modified by Barrow *et al.* (21) is chosen for the present treatment. The operator formula 1 of ref. 21 is thereby cast in the form $T = T_0 + T'$, whereby $T_0 = \lim_{\rho\to 0} T$ (ρ denotes the bending coordinate), i.e. T_0 is the kinetic energy operator for a two-dimensional harmonic oscillator while T' has the form

$$T' = T_1'(\rho)\frac{\partial^2}{\partial\rho^2} + T_2'(\rho)\frac{\partial}{\partial\rho} + T_3'(\rho)\frac{\partial^2}{\partial\phi^2} + T_4'$$

The coefficients T_i' are expanded in a McLaurin series in ρ as described in more detail elsewhere (22), so that Hamiltonian matrix elements of the form

$$\left\langle \left| \rho^n \frac{\partial^2}{\partial\rho^2} \right| \right\rangle, \quad \left\langle \left| \rho^n \frac{\partial}{\partial\rho} \right| \right\rangle, \quad \text{and} \quad \langle|\rho^n|\rangle$$

have to be evaluated for the secular equation in the corresponding variational procedure.

If only Σ vibronic levels are of interest, there is no Renner–Teller coupling and the procedure described so far suffices. In a general treatment it is necessary to take account of the coupling between the electronic and vibrational motion which can be achieved, for example (23), by diagonalizing the total Hamiltonian in a basis consisting of products of electronic and vibrational wavefunctions obtained in the Born–Oppenheimer approximation. The coupling elements require the evaluation of the first and second derivatives of the electronic CI wavefunction with respect to the nuclear coordinate (24), which in this case is the rotation angle ϕ. An alternative procedure is the more conventional approach by Dixon (25) which has been refined (26) (and successfully applied to C_3) by taking a polynomial expansion of the Born–Oppenheimer potentials for both components of the Π electronic states under the assumption of a simple form for the electronic wavefunctions proportional to $\sin(\theta - \phi)$ and $\cos(\theta - \phi)$. Both treatments will give the same results if carried to sufficiently high order, as has been numerically demonstrated for the vibronic levels in NH_2 (19), but in the present work only the second approach (26) is actually employed.

3. Results and Discussion

A. Potential Energy Curves

The calculated potential energy curves (generally the energy corresponding to the full CI estimate) are given in Fig. 1*a*, *b* for symmetric and antisymmetric BH stretching motion respectively, and in Fig. 2 for the bending coordinate at a fixed value of the BH bond length. The total energy values of the ground state are contained in Table 2,

For personal use only.

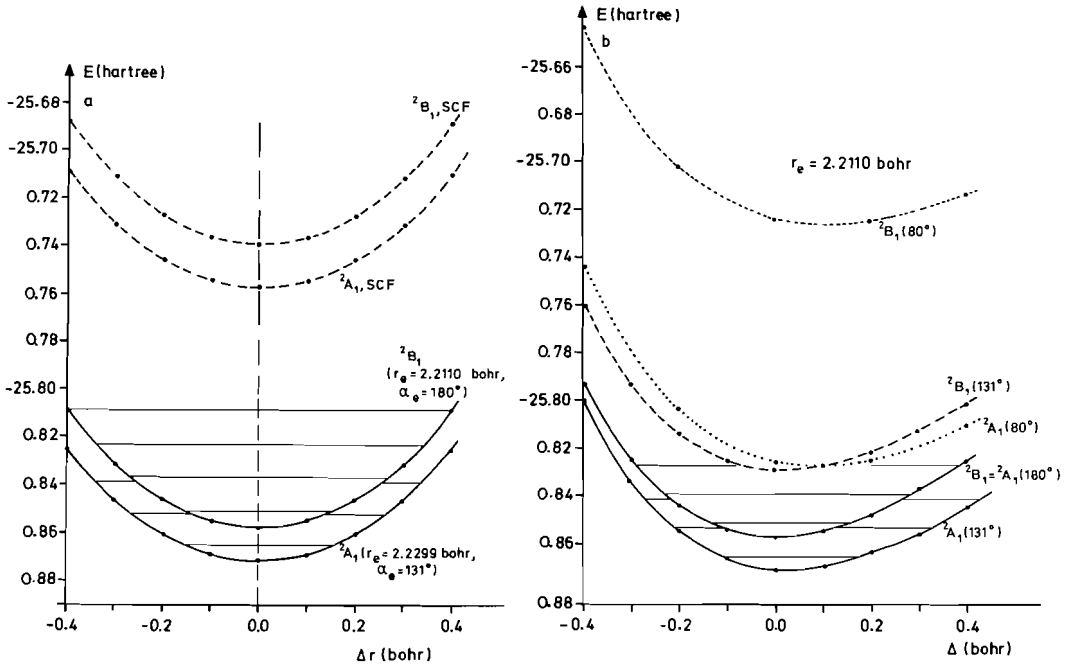

FIG. 1. Potential curves for the lowest-lying electronic states of BH_2 for the (*a*) symmetric and (*b*) antisymmetric vibrational modes obtained in the present CI treatment; corresponding SCF results are also indicated for the antisymmetric stretch motion. The values for bond lengths and angles held fixed in these calculations are given in parentheses in the figure. The lowest computed vibrational energies are also indicated in a number of instances.

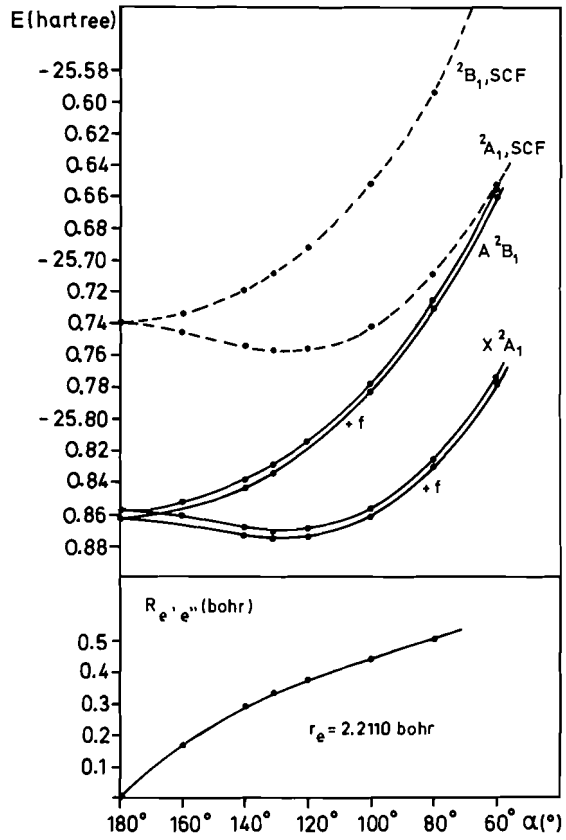

FIG. 2. Bending potential curves obtained in the SCF (dashed lines) and CI (solid lines) treatments for the A^2B_1 and X^2A_1 electronic states of BH_2; a second set of CI curves obtained for the AO basis including f functions is also indicated. In the bottom portion of the figure is given the corresponding variation in the electronic transition moment between these states.

and comparison is also made with corresponding results of previous work.

It is seen that the total energies obtained in the present work are somewhat lower than those reported previously because of the more flexible AO basis set employed. The lowering due to inclusion of f functions is only 0.00019 hartree at the SCF level but is more substantial, namely 0.00426 hartree (0.00447 hartree, full-CI estimate), at the CI level. Calculations including the f functions have only been carried out for the angular potential curve at fixed BH bond length (Fig. 2), but these results indicate that the energy lowering obtained thereby remains fairly constant for both electronic states (0.0045 hartree for $^2A_1$ and 0.0050 hartree for $^2B_1$) over a large range of internuclear angles. There is a tendency for the f functions to be somewhat more effective at very large angles, however, so that the barrier to linearity in the X^2A_1 ground state (or energy splitting between the equilibrium conformations of both states) is reduced by approximately 340 cm^{-1} as a result of this AO basis set extension. This pattern is wholly consistent with the experience for other systems such as NH_2, for example (9). It is also important to note that electron correlation is more effective in the linear geometry (Fig. 2), so that the CI potential well in the X^2A_1 state is considerably more shallow than its SCF counterpart (Table 2 and Fig. 2).

The potential energy curves for symmetric stretch (Fig. 1*a*) have been calculated for three different internuclear angles in both states to assess the dependence of the BH distance on the bending angle. The optimal values are 1.172 Å, 1.183 Å, and 1.225 Å for X^2A_1 at the angles 180°, 131°, and 80° respectively, while the $^2B_1$ counterparts for the same angles are 1.172 Å, 1.183 Å, and 1.228 Å. Hence a change of approximately 0.055 Å results in going from the equilibrium conformation to the small-angle structure.

The $^2A_1$ and $^2B_1$ curves for asymmetric distortion displayed in Fig. 1*b* run quite parallel to each other, but a definite deviation from the SCF counterparts as a result of inclusion of electron correlation is also apparent. The structural data obtained from polynomial fits to the calculated potential data are summarized in Table 3 and are seen to be in excellent agreement with the corresponding data inferred from experiment (1). A more accurate change in bond length between X^2A_1 and $^2B_1$ is also given by the present calculation, this quantity having been slightly overestimated in both previous theoretical treatments.

B. Vibrational Pattern in the X^2A_1–$^2B_1$ *Transition*

The calculated lowest vibrational levels for the two stretching modes are also indicated in Fig. 1*a*, *b*; the polynomial fit for the potential contained terms up to power 5 (symmetric) and 6 (antisymmetric mode) while a set of 15 vibrational basis functions was employed in the corresponding variational calculations in each case. The calculated frequencies are collected in Table 4 for the four common isomers of BH_2, while the corresponding Franck–Condon factors are given in Table 5*a* and *b* for the two stretching modes.

[a]The reduced masses employed are μ(X) = 1.9576, μ(A) = 2.0157 for $^{10}BH_2$, μ(X) = 1.9620, μ(A) = 2.01565 for $^{11}BH_2$, μ(X) = 3.82947, μ(A) = 4.0282 for $^{10}BD_2$ and μ(X) = 3.84268 and μ(A) = 4.0282 for $^{11}BD_2$.
[b]The notation *n.m-a* stands for *n.m.* × 10^{-a}.

(*b*) Calculated Franck–Condon factors for the asymmetric stretching modes in the X^2A_1–A^2B_1 transition[a]

		$v_3' = 0$	$v_3' = 1$	$v_3' = 2$	$v_3' = 3$	$v_3' = 4$	$v_3' = 5$
$^{11}BH_2$	$v_3'' = 0$	0.9998	0	2.4–4	0	4.9–7	0
	1	0	0.9993	0	7.3–4	0	2.0–6
	2	2.4–4	0	0.9983	0	1.4–3	0
$^{11}BD_2$	$v_3'' = 0$	0.9996	0	3.6–4	0	7.6–7	0
	1	0	0.9989	0	1.1–3	0	3.5–6
	2	3.6–4	0	0.9974	0	2.2–3	0

[a]The reduced masses employed are μ(X) = 1.7503, μ(A) = 1.7037 for $^{11}BH_2$ and μ(X) = 3.09156 and μ(A) = 2.94914 for $^{11}BD_2$.

The calculated stretching frequencies are in reasonable accord with corresponding results from previous theoretical treatments (3). There are no experimental data available so far and this fact is quite understandable from the data in Table 5*a*, *b*, which show that the O—O stretching transitions are by far the most intense while excitation to $v_1' = 1$ is roughly 100 times less likely in $^{11}BD_2$ and almost 10^4 times weaker in $^{11}BH_2$.

The calculated vibrational levels are given in Fig.

3 for the rotational species $K = 0$ and $K = 1$ together with the expected intensity pattern. In this case the Franck–Condon factors $|\langle\psi_{v''}|\psi_{v'}\rangle|^2$ alone are not representative for the intensity distribution because the electronic transition moment $\boldsymbol{R}_{e'e''}$ changes drastically over the range in which the nuclear motion occurs, as seen in Fig. 2. Hence the entire integral

$$R_{e'v'e''v''} = \langle\psi_{v''}|R_{e'e''}(\rho)|\psi_{v'}\rangle$$

must be evaluated whereby for $\boldsymbol{R}_{e'e''}(\alpha)$ a polynomial fit in powers of the internuclear angle α is employed.[2] A large progression in the bending mode is apparent from these calculations, as must be expected qualitatively on the basis of the considerable difference in the internuclear angles of the X^2A_1 and $^2B_1$ electronic states.

The calculated ground state frequency of $\omega_e'' = 1057\ \text{cm}^{-1}$ is in very good accord with the measured value of $1030\ \text{cm}^{-1}$ (Table 4). The frequency of the excited state $\omega_2' = 954.65\ \text{cm}^{-1}$ has been obtained experimentally (1) via an extrapolation with the formula,

$$[1]\quad G(v_2') = \omega_2'(v_2' + 1) + x_{22}'(v_2' + 1)^2 + T_{00}$$

as will be discussed in the next section. In this connection it is important to point out that the lowest vibrational level in the two-dimensional harmonic oscillator treatment is $v_2' = 1$ in this notation, and thus the corresponding zero-point vibrational energy is not $\frac{1}{2}\omega_2'$, as in the more common one-dimensional stretching treatment, but rather $G(v_2' = 1) = 2\omega_2'$. The present calculations (Fig. 3) place $G(v_2' = 1)$ at $1935\ \text{cm}^{-1}$ and hence lead to a value for ω_2' of $967.5\ \text{cm}^{-1}$, which should be compared directly with the experimental finding of $954\ \text{cm}^{-1}$, also given in Table 4. Alternatively ω_2' can be defined as one-half of the $v_2'(1 \rightarrow 3)$ transition energy, which in the present calculations is $978\ \text{cm}^{-1}$, also in good agreement with what is inferred experimentally.

The calculated levels for states with $K > 2$ are given graphically in Fig. 4*a* and 4*b* for $^{11}BH_2$ and $^{11}BD_2$ respectively. For $^{11}BH_2$ the calculated $\Pi(K'' = 1)$, $\Delta(K'' = 2)$, $\Gamma(K'' = 3)$, and $\Phi(K'' = 4)$ levels of $v_2'' = 0$ lie higher by 34, 160, 363, and $632\ \text{cm}^{-1}$ respectively than the $K'' = 0$ energy, while the lowest levels in the excited electronic state are

[2]Since only transitions corresponding to $\Delta K = \pm 1$ are allowed the correct treatment would require the ($v_2'' = 0$, $K'' = 1$) and (v_2', $K' = 0$) functions in the evaluation of the integral for transitions to upper state levels. In the present case the radial dependance of the $K'' = 1$ and $K'' = 0$ functions is assumed to be quite similar, however, and the ground state radial function for ($v_2'' = 0$, $K'' = 0$) is employed exclusively in obtaining the intensity distributions shown in Fig. 2.

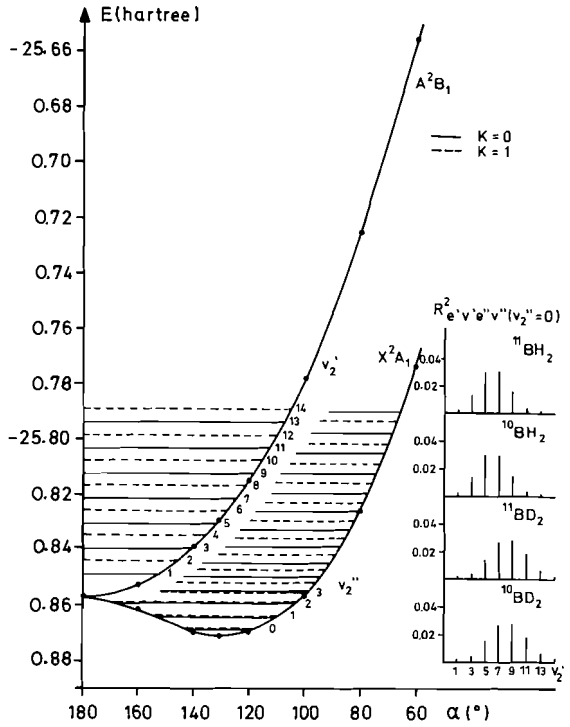

FIG. 3. Calculated bending vibrational levels and intensity distributions for the A^2B_1–X^2A_1 electronic transition of BH_2 obtained in the CI treatment without *f* functions.

above the A^2B_1 minimum by 1935 ($K' = 0$), 2894 ($K' = 1$), 3698 ($K' = 2$), 4936 ($K' = 3$), and $5701\ \text{cm}^{-1}$ ($K' = 4$).

C. *Comparison with Experiment and Revised Vibrational Assignment*

Herzberg and Johns (1) were able to fit their three measured Σ^- bands at $\bar{\nu} = 11\,767.3\ \text{cm}^{-1}$, $13\,640.6\ \text{cm}^{-1}$, and $15\,505.9\ \text{cm}^{-1}$ for $^{11}BH_2$ (Table 5 in ref. 1) in the form of eq. [1], whereby the numbering $v_2' = 7, 9, 11$ leads to $\omega_2' = 954.65\ \text{cm}^{-1}$, $x_{22} = -1.00\ \text{cm}^{-1}$, and $T_{00} = 4194.1\ \text{cm}^{-1}$. These authors prefer the above assignment even though they point out that it implies that ω_1' or ω_3', or both, are appreciably larger in the upper than in the lower state. According to Fig. 1*a*, *b* this increase in frequency is *not* to be expected, and Table 4 shows explicitly that these frequencies are not very different in the ground and excited states. In their original assignment (1) the first upper bending level ($v_2' = 1$) would then lie at $6099.4\ \text{cm}^{-1}$ above the X^2A_1 ($v_2'' = 0$) ground state energy, in considerable discrepancy (i.e. much higher) with the values calculated in the present work (Fig. 4*a*). The electronic energy difference, assuming the harmonic approximation, would then amount to

$$T_e = T_{00} + \tfrac{1}{2}\omega_2'' = 4194.1 + 515 = 4709\ \text{cm}^{-1}$$

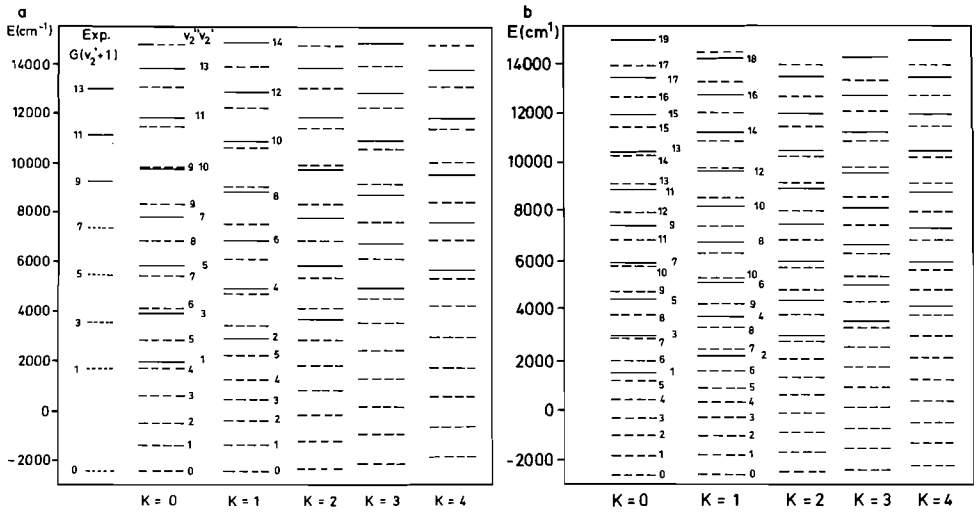

FIG. 4. Computed bending vibrational levels in the CI treatment without f functions for various values of the rotational quantum number K in the X^2A_1 ground (dashed lines, v_2'') and A^2B_1 excited (solid lines, v_2') electronic states of the (*a*) $^{11}BH_2$ and (*b*) $^{11}BD_2$ isotopes; because of the Renner–Teller coupling the distinction between ground and excited levels respectively is only clearly drawn for the $K = 0$ (Σ) levels, and hence in all other cases this designation is based on the identity of the dominant electronic component in each instance. For $^{11}BH_2$ comparison is made with the experimental results of Herzberg and Johns (1) for the Σ levels based on eq. [1] with a T_{00} value of 2285 cm^{-1} (solid lines observed, dashed lines computed from eq. [1]). The zero of energy corresponds to the location of the linear nuclear conformation of this system. Note that inclusion of f functions lowers the A^2B_1 energy results by 350 cm^{-1} relative to those of X^2A_1.

also in large disagreement with the results of all previous theoretical treatments (Table 2).[3]

If the alternative numbering for the observed lines, namely $v_2' = 9, 11, 13$ is chosen instead, i.e. an assignment which is less preferred by Herzberg and Johns (1) because it would be in apparent contradiction to their interpretation of the ^{10}B–^{11}B isotope shifts, the T_{00} value in the extrapolation formula would be 2285 cm^{-1} (1). This value, on the other hand, taken together with $\frac{1}{2}\omega_2''$ leads to $T_e = 2285 + 515 = 2800\ cm^{-1}$, again under the assumption of harmonic approximations in upper and lower states (and the same frequencies for the stretching motion), is in quite good agreement with the theoretical values for T_e given in Table 2. This fact has not been pointed out in the earlier theoretical papers (2, 3), since both sets of authors employed an incorrect definition of the T_{00} parameter in their arguments, and furthermore employed the "$\frac{1}{2}\omega$"-formula for the zero-point energy of all modes in going from T_e to the lowest possible 0–0 transition (3).

Comparison with the theoretical work thus definitely speaks in favor of the assignment $v_2' = 9, 11, 13$ for the observed bands. A direct calculation of these levels according to the Herzberg formula[4] (1) yields the levels also given in Fig. 4*a*, and the agreement between calculated and experimentally extrapolated and measured levels is excellent, especially when it is realized that the energies of the calculated levels are shifted downward by 300–400 cm^{-1} upon inclusion of f functions in the theoretical treatment (Table 2). The actual values obtained in the best theoretical treatment for the transition energies to the first three levels of the $^2B_1$ upper state agree to within 50–100 cm^{-1} with the corresponding extrapolated results obtained by fitting the experimental data according to eq. [1] when the observed bands are assigned as $v_2' = 9$, 11, and 13 (Table 6). In addition the results for higher K' values are also in good agreement with one another once this experimental interpretation is taken.

Finally, it remains to show that the results of the isotope shifts are also consistent with the revised assignment. In Fig. 5 the isotope shift for the calculated $^{10}BH_2$ and $^{11}BH_2$ lines are plotted as a function of the wavenumbers of the $^{11}BH_2$ bands. It is seen that the slope is not 0.0077 as assumed in the original work (1), i.e. by neglecting anharmonicity

[3]Note that according to eq. [1], T_{00} is the energy difference between the (0,0,0) level of the X^2A_1 state and the potential minimum ($v_2' = -1$) of A^2B_1).

[4]The new fitting with $v_2' = 9, 11, 13$ yields slightly different constants, namely $\omega_2' = 957.5\ cm^{-1}$, $x_{22} = -0.96\ cm^{-1}$, and $T_{00} = 2288\ cm^{-1}$.

TABLE 6. Comparison of the lowest calculated A^2B_1–X^2A_1 transition energies with those obtained by formula (1) from the experimental spectrum using $T_{00} = 2285\ cm^{-1}$, i.e. the alternative value for this quantity and not 4194.1 cm^{-1} as originally preferred in ref. 1

Lower state X^2A_1	($v_2'' = 0$, $K'' = 1$)	Correction for zero-point energy of ω_1 and ω_3	Correction for f-function basis augmentation	Present best calculated value	$G(v_2')$ eq. [1]
$A^2B_1(v_2' = 1, K = 0)$	4394	+101	−350	4145	4190
$A^2B_1(v_2' = 3, K = 0)$	6351	+101	−350	6102	6088
$A^2B_1(v_2' = 5, K = 0)$	8317	+101	−350	8068	7977

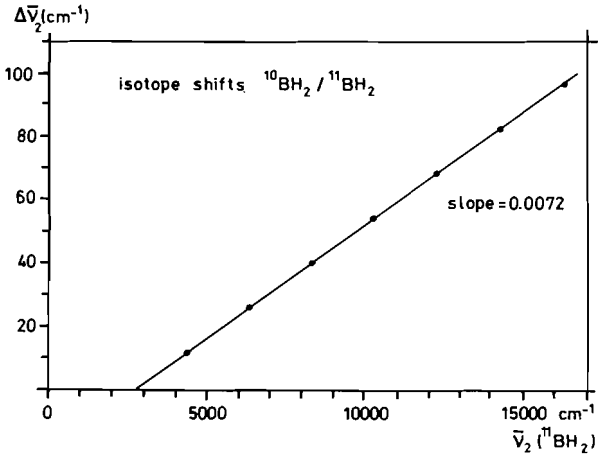

FIG. 5. Calculated $^{10}BH_2/^{11}BH_2$ isotope shifts for corresponding bending vibrational species in the A^2B_1–X^2A_1 band system plotted as a function of the $^{11}BH_2$ frequency $\bar{\nu}_2$.

effects entirely, but rather 0.0072. The latter slope can also be realistically employed to fit the measured three points, whereby a crossing of the abscissa is thereby not found around 4500 cm^{-1} as found originally, but rather below 3000 cm^{-1}, i.e. consistent with the alternative experimental choice for the value of T_{00} as 2285 cm^{-1}.[5]

In summary, then, when the above arguments are taken into account it is found that there is excellent agreement between the present calculated and the experimental structural data of BH_2 in its two lowest electronic states. The frequencies for the two stretching modes in both states have been calculated as well and are expected to constitute good predictions, awaiting experimental verification. Furthermore there is a very good correspondence in the calculated and measured energy levels in the bending progression of the A^2B_1–X^2A_1 transition and very good agreement is obtained between the lowest accessible excitation $A^2B_1(010)$–$X^2A_1(000)$ and the level extrapolated from three observed high-lying vibrational lines if they are assigned as $v_2' = 9$, 11, and 13 rather than 7, 9, and 11 as assumed originally. This reassignment, together with a correct interpretation of the T_{00} value employed in the literature as the energy difference between the lowest $v_2'' = 0$ level and the *potential minimum* of the upper state, also brings previous theoretical results in good agreement with the experimental inferences on this point, so that each of the apparent discrepancies between the experimental and theoretical description of the lowest-energy electronic transition in the BH_2 spectrum would appear to have been removed as a result of the present investigation.

[5]The intensity distribution calculated for the BH_2 isotopes (Fig. 3) indicate maxima for $v_2' = 5$ and 7, thus perhaps raising an additional argument against the $v_2' = 9$, 11, 13 assignment for the observed bands of Herzberg and Johns. It is not clear why lower energy bands were not actually seen, however, i.e. whether because of intrinsic weakness of such transitions or rather because of apparatus insensitivity in the wavelength region above 8700 Å (1), and thus in reality it is not possible to make comparison between the calculated and measured intensity distributions.

Acknowledgements

The authors wish to thank Dr. R. Marian-Runau for his assistance in carrying out some of the calculations discussed in this paper. One of us (M.P.) expresses his gratitude to the Deutsche Forschungsgemeinschaft for financial support extended during the course of this work. The services and computer time made available by the University of Bonn Computing Center (RHRZ) are also hereby gratefully acknowledged.
