AJIT K. CHAKRAVARTY, SATYESH C. PAKRASHI, and JUN UZAWA. Can. J. Chem. **59**, 1328 (1981).

The ^{13}C nmr spectra of some 23-hydroxy spirostane sapogenins from *Solanum hispidum* Pers., mostly as their acetates, have been studied. The effect of different orientations of the substituents at C-23 and C-25 as well as that due to change in the stereochemistry at C-22 have been discussed. The unexpected absence of the γ_g effect of the axial 23-OH on C-25 in hispigenin (**5**), a 22β*O*-spirostane derivative, presumably results from ring F deformation brought about by the steric interaction between 20-Me and 23-OH groups.

AJIT K. CHAKRAVARTY, SATYESH C. PAKRASHI et JUN UZAWA. Can. J. Chem. **59**, 1328 (1981).

On a étudié principalement sous forme d'acétates, les spectres rmn du ^{13}C de quelques sapogénines hydroxy-23 spirostanes provenant du *Solanum hispidum* Pers. On discute des effets des différentes orientations des substituants en C-23 et C-25 ainsi que de ceux provenant du changement de la stéréochimie en C-22. L'absence inattendue d'effet γ_g du OH-23 axial sur le C-25 de l'hispigénine (**5**), un dérivé 22β*O* spirostane, provient probablement de la déformation du cycle F provoquée par l'interaction stérique entre les groupes Me et OH présents respectivement en positions 20 et 23.

[Traduit par le journal]

Introduction

We have recently isolated and characterized (1, 2) five spirostane sapogenins, namely, neochlorogenin (**1**), paniculogenin (**2**), solaspigenin (**3**), neosolaspigenin (**4**), and hispigenin (**5**), from the leaves of *Solanum hispidum* Pers. Except for **1**, all the others are 23-hydroxy derivatives differing in the stereochemistry at one or more chiral centres in ring F. Furthermore, hispigenin (**5**) is the first 22β*O*-spirostane sapogenin encountered in nature.

Though the ^{13}C nmr spectra of a number of typical spirostane derivatives have been reported (3), no compound hydroxylated in ring F, except (25*S*)-5α-spirostane-25-ol, has so far been studied. It was, therefore, considered desirable to investigate the ^{13}C nmr spectra of the 23-hydroxy spirostane derivatives (**2–5**), particularly to ascertain the effect of different orientations of 23-OH and 25-Me groups as well as that due to change in stereochemistry at C-22 (as in **5**) on the chemical shifts of D, E, and F ring carbons.

Experimental

The isolation and characterization of the sapogenins and the preparation of their acetates have already been reported (1, 2). In view of the poor solubility of most of the sapogenins themselves, the spectra of the corresponding acetates, **1***a*–**5***a*, were studied.

The ^{13}C nmr spectra of the acetates were recorded in a Jeol FX-100 FT spectrometer at 25.05 MHz in $CDCl_3$ solutions at 25°C with autostacking programme. The conditions for FT measurements were as follows: spectral width, 5 KHz; data points 8K; repetition time, 0.9 or 1.2 s; flip angle, 45–60°. The spectra of paniculogenin (**2**) and hispigenin (**5**) were recorded in CD_3OD solutions in a Bruker instrument at 67.89 MHz. The chemical shifts are expressed on the δ scale from TMS as internal standard.

The methyl, methylene, and methine carbons were assigned on the basis of the multiplicities in the gated decoupled spectra. The quaternary carbon signals were identified on the basis of low-power noise-modulated decoupled spectra. Unambiguous assignment of the methyl carbon signals, particularly of 13-Me, 20-Me, and 25-Me, was done by selective proton decoupling.

Results and Discussion

The ^{13}C chemical shift data are given in Table 1. The assignments of the individual chemical shift values to specific carbons were based on the reported values for spirostane sapogenins (3), cholestanols and their acetates (4), and 3β,6α-dihydroxy cholestane (5–7).

The results showed consistent chemical shifts for the carbons of rings A, B, and C of all the acetates (**1***a*–**5***a*) as expected. Now, the chemical shifts of D, E, and F ring carbons of **1***a*, lacking the 23-substituent, were found to be in excellent agreement with the values reported (3) for a (25*S*)-spirostane, viz. sarsasapogenin. Taking **1***a* as the model, the chemical shifts for compounds **2***a*–**5***a*, however, showed significant variation with regard to D, E, and F ring carbons due to substitution at

7

C-23 as well as the difference in stereochemistry at C-22, C-23, and C-25.

Thus, the equatorial 23-OAc of **2***a* exerted a γ_g effect on C-20 by 5.7 ppm. The observed deshielding of C-25 and C-27 by 3.7 and 1.2 ppm respectively in **2***a* may be ascribed to an antiperiplanar γ effect (4, 8) and the δ_2 effect (4) of equatorial 23-OAc, which also exerted an expected shielding δ_5 effect (4) on C-26 by 1 ppm. The comparatively larger deshielding (5.3 ppm) of C-25 in the alcohol **2** (spectrum measured in CD_3OD) may partly be due to the solvent effect.

On the other hand, the axial 23-OAc (as in **3***a*, **4***a*, and **5***a*) exhibited a deshielding δ_1 effect (4) on the 20-Me carbon by 1.6–1.8 ppm indicating a *skew*-pentane type interaction between the two functions. A very strong δ_1 effect (3.3 ppm) was also observed in respect of axial 25-Me carbon in **4***a* due to its *syn*-1,3-diaxial interaction with the axial 23-OAc group. The latter also caused an upfield displacement of the C-25 signal of **3***a* by 5.5 ppm due to the γ_g effect as evidenced (3) from the chemical shift (δ 30.3 ppm) of the corresponding carbon in tigogenin, a (25*R*)-23-unsubstituted spirostane sapogenin.

Contrary to expectation, however, the axial 23-OAc group of **5***a* did not apparently exert any γ_g effect on C-25. The ^{13}C nmr spectrum (Table 1) of the corresponding alcohol **5** in CD_3OD also showed similar abnormality. Although the reason for this anomaly is not very clear, a plausible explanation may be put forward as follows.

Though the ^{13}C nmr data of 23-deacetoxy-22β*O*-spirostane is not available for rationalizing the chemical shifts of D, E, and F ring carbons of **5***a*, analogy could be drawn from its 22β*N*-analogue, tomatidine (**6**). The 20-Me in the latter has been shown (9) to interact strongly with 23-methylene hydrogens since the signal of C-23 suffers an upfield shift by 7.5 ppm compared to that of the corresponding carbon of the 22α*N*-analogue, solasodine (**7**). The same type of interaction would also be expected in 23-unsubstituted 22β*O*-spirostanes. Now, introduction of an axial 23-OAc therein is likely to produce a severe *skew*-pentane type interaction with 20-Me. This interaction, however, might partially be relieved by the preferred inward bending of the 23-OAc function with concomitant outward bending of the axial 25-H, leading to such a deformation (4) of ring F as to virtually annul the γ_g effect of 23-OAc on C-25.

The assumed geometrical deformation of ring F in **5***a* received further support from the observed significant downfield shift of the signals for C-15 (1.7 ppm), C-16 (2.5 ppm), C-20 (2.0 ppm), C-22 (3.3 ppm), C-23 (0.7 ppm), C-25 (5.4 ppm), and C-26

(2.0 ppm) compared to those of the corresponding carbons in **3***a* which is enantiomeric with **5***a* at C-22.

Regarding the α-substitution effect on introduction of an acetoxyl/hydroxyl substituent at C-23, a general trend of downfield chemical shift of the carbinyl carbon in compounds with axial substituent as against the equatorial one has been observed. This may be due to a *skew*-pentane interaction existing in the axial isomer in analogy with some 10-methyl-*trans*-decalols (6) even though the two systems are not readily comparable.

Finally, besides the effects discussed above, the upfield shift of C-22, a β-carbon, and C-20, as well as a downfield displacement of C-17 signals by ca. 2 ppm compared to those for the corresponding 23-unsubstituted compounds, have been noted in 22α*O*-spirostanes with axial 23-OAc.

Received November 4, 1980

KENNETH S. CHONG and ALAN STORR. Can. J. Chem. **59**, 1331 (1981).

The synthesis and complexation of the novel tridentate chelating anionic organogallate ligands $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SR)]^-$ (R = Et or Ph) have been investigated. A variety of octahedral molybdenum, tungsten, and manganese carbonyl compounds have been studied in which the organogallate ligand (R = Et) is in the *fac* coordination mode. In addition tetrahedral "Cu·PPh_3" and "Ni(NO)" complexes have been characterized which display fluxional behaviour in solution. The dearth of derivatives available using the ligand where R = Ph is attributed to steric factors.

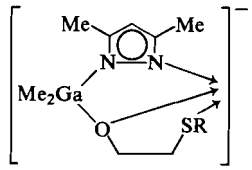
KENNETH S. CHONG et ALAN STORR. Can J. Chem. **59**, 1331 (1981).

On a étudié la synthèse et la complexation du nouveau ligand organogallate anionique chélaté de façon tridentate $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SR)]^-$ (R = Et ou Ph). On a étudié divers composés carbonylés octaédriques du molybdène, du tungstène et du manganèse dans lesquels le ligand organogallate (R = Et) est coordonné de manière *fac*. De plus, on a caractérisé les complexes tétraédriques "Cu·PPh_3" et "Ni(NO)" qui exhibent un comportement fluxionnaire en solution. On attribue à des facteurs stériques le fait qu'il existe peu de dérivés incorporant le ligand ou R = Ph.

[Traduit par le journal]

Introduction

Anionic tridentate chelating organogallate ligands incorporating "ethanolamino" and "pyrazolyl" moieties have been the subject of a number of recent publications (1, and references therein). The many novel aspects displayed by compounds containing these ligands prompted us to extend our investigations into related systems in which the "$OCH_2CH_2NR_2$" (R = H or Me) moiety is replaced by the "OCH_2CH_2SR" (R = Et or Ph) grouping. This has led to tridentate chelating ligands of the type **1**,



1

where R = Et or Ph, in which the three donor atoms NOS replace the NON donor atom set of the dimethylpyrazolylethanolaminogallate ligand systems (1). The new ligand where R = Et has been found to yield a wide variety of transition metal complexes but for the ligand where R = Ph the only compound fully characterized to date is the "$Mn(CO)_3$" derivative.

Experimental

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen, in a nitrogen-blanketed apparatus, or on a high-vacuum line. Tetrahydrofuran (THF) was dried by refluxing over Na/benzophenone and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. Phenyl-2-hydroxyethyl sulphide, $HOCH_2CH_2SPh$ (2), and ethyl-2-hydroxyethyl sulphide, $HOCH_2CH_2SCH_2CH_3$, (3) were prepared by literature methods. Trimethyl gallium was prepared as described previously (4). Ni(NO)I was prepared by the method of Haymore and Feltham (5) and $Mn(CO)_5Br$ was prepared from $Mn_2(CO)_{10}$ (Strem) by a standard route (6). $(MeCN)_3M(CO)_3$ (M = Mo or W) compounds were prepared from the $M(CO)_6$ hexacarbonyls (Strem) by a literature method (7). $(C_7H_7)Mo(CO)_2I$ (6) and $(C_7H_7)W(CO)_2I$ (8) were prepared as described previously and Ph_3PCuBr was synthesized from Ph_3P and CuBr (9).

Ligand Syntheses, $Na^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SR)]^-$ (R = Et or Ph)

Both ligands were prepared as standard THF solutions using the method established for the corresponding ligands incorporating "ethanolamino" moieties (10, 11). In the last stage of the ligand syntheses the appropriate sulphide in THF solution was added to a THF solution of $Na^+[Me_3Ga(N_2C_5H_7)]^-$ and the mixture refluxed until evolution of methane ceased (~24 h):

$$Na^+[Me_3Ga(N_2C_5H_7)]^- + HOCH_2CH_2SR \xrightarrow[\text{reflux}]{\text{THF}} Na^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SR)]^- + MeH$$

1

Preparation of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]$"M" Complexes

In general the transition metal complexes listed in Tables 1 and 2 were prepared by adding a slight excess of the ligand **1** (where R = Et), in 25 mL THF to the appropriate transition metal precursor compounds (~2 mmol) in 25 mL of the same solvent (see Table 1). The mixture was then stirred at room temperature for a few hours. In the preparations of the Mo and W nitrosyl derivatives, an equimolar amount of diazald was

added at this point and stirring continued for a further hour. In the preparation of the "$(\eta^3$-$C_3H_5)$Mo" complex, a slight excess of allyl bromide was added in the second stage of the reaction sequence and the resulting mixture stirred for ~30 min at room temperature. In all cases, at the completion of the synthesis, the THF solvent was removed under vacuo and the resulting residue extracted with benzene. The filtered extracts were then left to evaporate slowly and yielded pure crystalline products. Elemental analysis results together with ν_{CO} and ν_{NO} stretching frequencies are listed in Table 1 for all the complexes prepared.

Preparation of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SPh)]Mn(CO)_3$

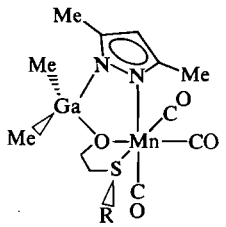
$Mn(CO)_5Br$ (0.60 g; 2.2 mmol) in THF solution was added to 20 mL of ligand (**1**, where R = Ph) solution (2.2 mmol) and the reaction mixture stirred for 2 h. The solvent was then removed under vacuum and the solid remaining extracted with benzene. The filtered extracts yielded yellow–orange crystals of the desired product on slow evaporation of the solvent. *Anal.* calcd. for $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SPh)]Mn(CO)_3$: C 44.4, H 4.5, N 5.8; found: C 44.3, H 4.5, N 5.8. ^{1}H nmr (C_6D_6 solution): τ = 10.26s, 9.72s ($GaMe_2$); 7.93s, 7.52s (pz—Me) 4.18s (pz—H(4)). ($\tau_{C_6H_6}$ = 2.84 ppm; s = singlet; pz = pyrazolyl.) Infrared spectra: ν_{CO} (cm^{-1}) 2036, 1947, 1916 (cyclohexane); 2026, 1916 br (Nujol) (br = broad).

Spectra

Mass spectra were recorded on a Varian MAT CH4 mass spectrometer at 70 eV with a source temperature of 120–200°C. Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer and ^{1}H nmr spectra on a Varian XL-100 spectrometer using FT techniques.

Results and Discussion

Analysis of mass spectral, ir, and ^{1}H nmr data for the complexes listed in Table 1, and also for the compound $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SPh)]Mn(CO)_3$, points to monomeric structures for the whole range of compounds studied. An octahedral structure is proposed for the molybdenum, tungsten, and manganese compounds with the tridentate gallate ligand occupying three facial positions. A schematic representation of the two manganese tricarbonyl species is shown in **2**, where R =



2

Et or Ph. The suggested octahedral structure of the compounds and the *fac* arrangement for the organogallate ligands has been established conclusively for the two compounds $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]Mo(CO)_2(C_7H_7)$ and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SPh)]$ $Mn(CO)_3$ through crystal structure determinations.[1]

[1]Manuscript in preparation.

The nickel nitrosyl and triphenylphosphine copper complexes are believed to possess tetrahedral transition metal centres although if this is indeed the case then fluxional behaviour in solution must be invoked to explain their ambient temperature ^{1}H nmr spectra. The tetrahedral distribution of ligand atoms about the Ni centre in the crystalline complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]Ni(NO)$ has been firmly established by a crystal structure determination.[1]

Infrared Spectra

The infrared spectral data reported in Table 1 for the octahedral complexes are consistent with a *fac* tridentate gallate ligand in these molecules. In the spectrum of the manganese tricarbonyl compound three strong ν_{CO} bands are seen, an observation which discounts the possibility of a *mer* configuration for the three CO ligands since such an arrangement would lead to two weak ν_{CO} bands and one strong ν_{CO} band (12). For the molybdenum and tungsten compounds two strong ν_{CO} bands are observed in the ir spectra indicating a *cis* arrangement of the two CO ligands. This does not in itself distinguish between a *mer* or *fac* arrangement for the gallate ligand about the central metal but molecular models indicate that the *fac* mode of coordination is the sterically preferred conformation. Further, a *fac* conformation of the gallate ligand is indicated by the appearance of two strong ν_{CO} bands in the ir spectra of THF solutions of the intermediate anions $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]M(CO)_3^-$ (M = Mo or W), the lower frequency band being much broader (unresolved *e* mode) than the higher frequency band (a_1 mode). Again, a *mer* conformation of the gallate ligand in these precursor anions would give rise to two weak ν_{CO} bands and one strong ν_{CO} band in the ir spectra (12). Finally, the *fac* type of chelation has been proven in the solid state for the complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]Mo(CO)_2(C_7H_7)$ through a crystal structure determination.[1]

As noted previously the ν_{CO} and ν_{NO} bands for similar tungsten and molybdenum complexes are 10–20 cm^{-1} different, the lower frequency bands appearing in the spectra of the tungsten compounds (1).

Mass Spectra

With the exception of the Cu(I) compound all of the complexes prepared in this study displayed a parent ion signal in their mass spectra. No higher mass peak was observed in any of the spectra suggesting a monomeric structure for the complexes in the vapour phase. The highest *m/e* signal observed for the $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt]Cu{\cdot}PPh_3$ complex corresponded to the parent ion minus the

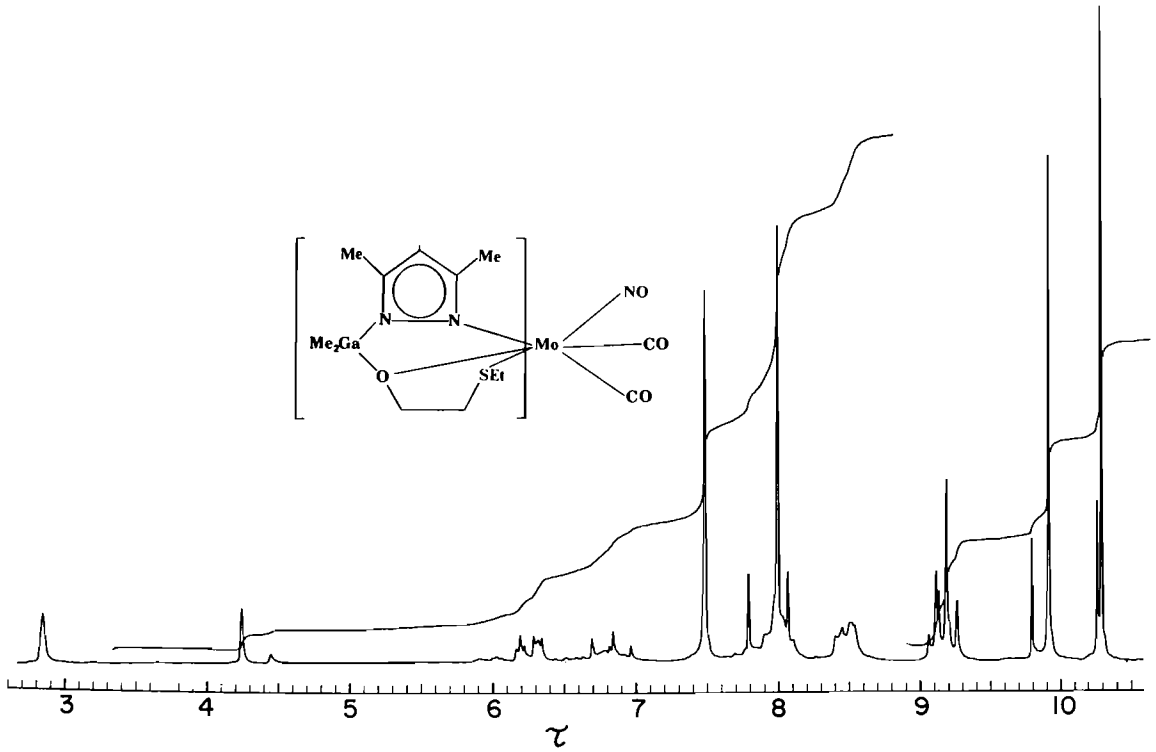

FIG. 1. Room temperature 100 MHz ^{1}H nmr spectrum of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]Mo(CO)_2(NO)$ in C_6D_6 solution.

triphenylphosphine ligand. The appearance of signals due to other ions in all of the spectra indicated predictable fragmentation patterns for the various complexes and the intensity ratios of the individual peaks in multipeak signals agreed closely with theoretical predictions based on the percentage isotope compositions of the contributing metal atoms. The spectra of the two "$Mn(CO)_3$" derivatives were dominated by the very intense signal due to the parent ion minus the 3CO ligands, the parent ion signal being about 2% of this intensity. In all the other spectra the parent ion signal was $\geq$20% the intensity of the strongest signal in the spectrum.

^{1}H Nuclear Magnetic Resonance Spectra

Selected ^{1}H nmr data for the complexes in C_6D_6 solution are listed in Table 2. Of the five octahedral complexes where isomerism is possible only the spectra of the two nitrosyl derivatives reveal the presence of two positional isomers in solution. Thus, there are three possible positions of substitution for the incoming C_3H_5, C_7H_7, or NO groups in the decarbonylation stage of the syntheses, viz. opposite any one of the atoms of the NOS donor set. Molecular models indicate that, with a *fac* conformation for the organogallate ligand, the positions most favoured sterically for incoming substituents are those opposite the pyrazolyl nitrogen and the sulphur atoms. It is evident that the small NO group can occupy either of these positions. However, one site of substitution is distinctly preferred since the two isomers in both the Mo and W complexes occur in an approximate 5:1 ratio (see Fig. 1). The ^{1}H nmr spectra of the "C_3H_5" and "C_7H_7" compounds (see Fig. 2), on the other hand, indicate that but one positional isomer is formed in the syntheses of these complexes. Additionally, in the case of the complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]Mo(CO)_2(C_7H_7)$ a crystal structure determination[1] has shown the "C_7H_7" ligand to be substituted opposite to the S atom in the pseudo octahedral molecule. The asymmetric nature of the octahedral compounds is also clearly illustrated by these ^{1}H nmr spectra. In the spectrum of the η^3-C_3H_5 complex all five allyl protons give rise to separate signals. The two *anti* proton signals appear as two doublets at high field and the *unique* proton signal appears at low field as a triplet of triplets. The two *syn* proton signals occur as two doublet of doublets in an intermediate field position, the lower field *syn* proton signal being partially obscured by one of the $-CH_2-CH_2-$ proton signals. The ^{1}H nmr spectra of the "C_7H_7" compounds display a number of noteworthy features (the spectrum of the Mo complex is shown in

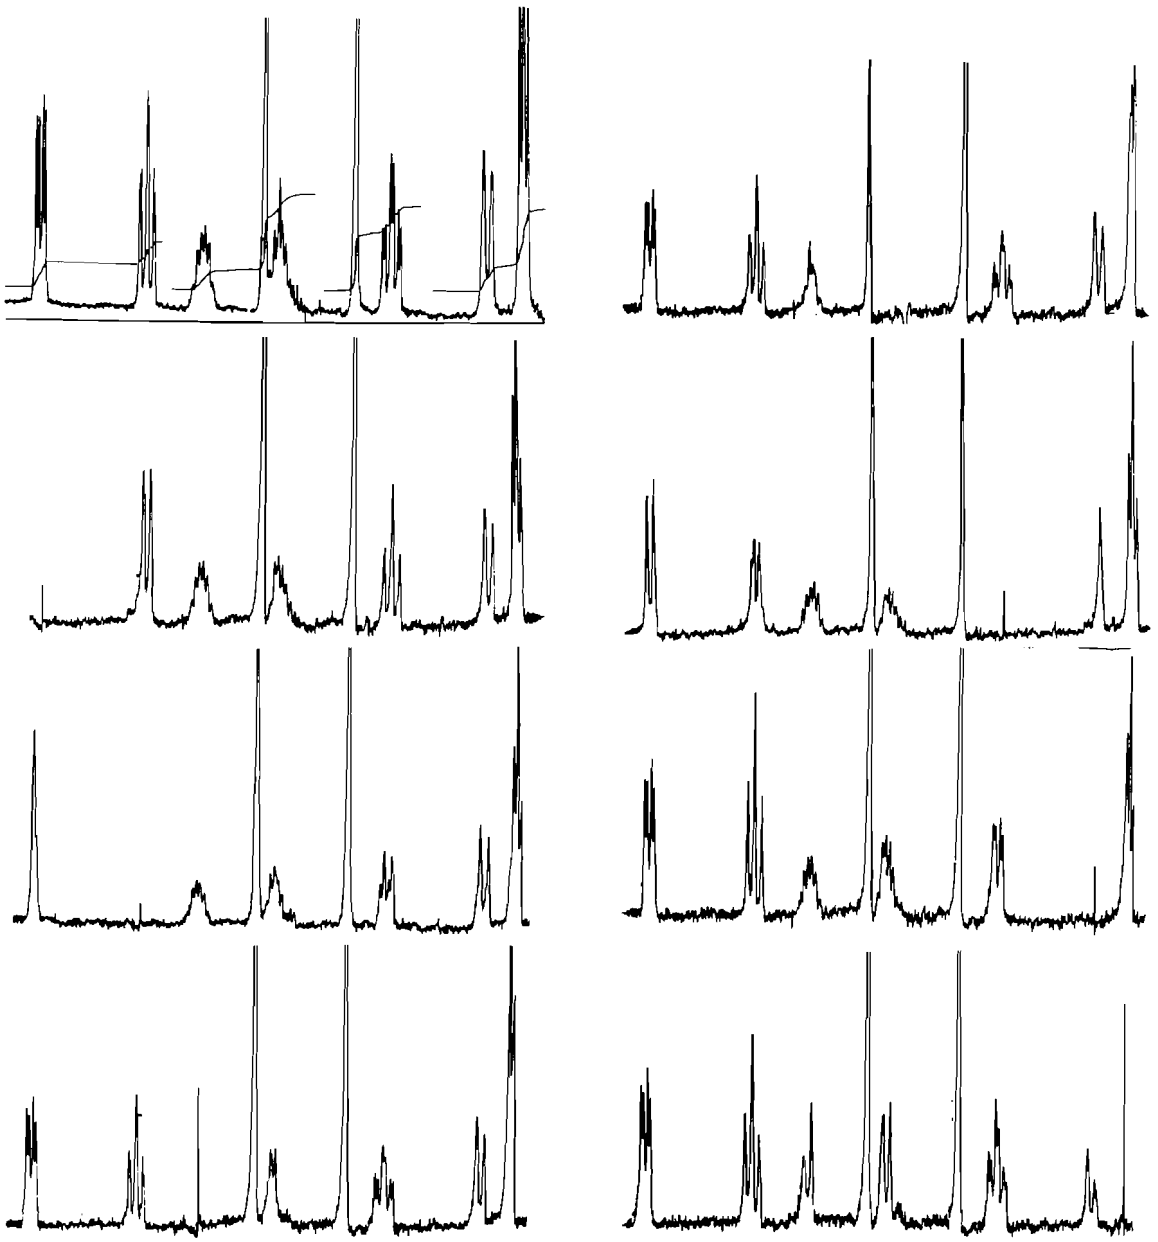

FIG. 3. Effect of double resonance experiments on the proton signals of the "$OCH_2CH_2SCH_2CH_3$" moiety in the room temperature 270 MHz spectrum of the complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]W(CO)_2(C_7H_7)$ in C_6D_6 solution.

Fig. 2). Firstly, the observation of one signal due to the η^3-C_7H_7 group indicates that this group is involved in a rapid fluxional process at room temperature. However, the "C_7H_7" signals are quite broad in the two spectra, especially for the W compound, and on cooling a d_6-acetone solution of this latter complex to −80°C the "C_7H_7" signal was split into a number of components. The pattern of signals observed at this lower temperature was characteristic of a rigid "η^3-C_7H_7" moiety in an asymmetric environment and was similar to the pattern reported for the C_7H_7 group in the low temperature ^1H nmr spectrum of the $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]W(CO)_2(C_7H_7)$ complex (1). Secondly, the six methylene protons of the

—O—CH_2—CH_2—S—CH_2—CH_3

moiety are particularly clearly distinguishable in these spectra. This distinguishability again arises from the asymmetric and rigid nature of this part

of the molecule. Double irradiation experiments have allowed the assignment of the S—CH_2—CH_3 methylene protons. Thus the two central multiplets (Fig. 3) both collapse to doublets when the S—CH_2—CH_3 methyl group high field triplet is irradiated. Conversely irradiation of either of these two central multiplets caused the S—CH_2—CH_3 triplet to collapse to a doublet and the other multiplet to collapse to a pseudo quartet. The remaining four multiplets can be assigned by comparison with the ^{1}H nmr spectrum of the $HOCH_2CH_2SEt$ compound. Thus the two low field multiplets can be assigned to the methylene group adjacent to the O atom and the two high field multiplets adjacent to the S—CH_2—CH_3 triplet can be assigned to the O—CH_2—CH_2—S methylene protons. The experimental ^{1}H nmr spectrum for the "$OCH_2CH_2SCH_2CH_3$" grouping is shown again in Fig. 4 together with a near-identical computer simulated spectrum based on the parameters given in Table 3.

The room temperature ^{1}H nmr spectra of both the "Ni(NO)" and "$CuPPh_3$" derivatives were very similar and both were simple first-order spectra. The spectrum of the copper complex is shown in Fig. 5. The appearance of only one signal due to the —$GaMe_2$ protons in the ^{1}H nmr spectra of both these metal complexes is compatible with a meridionally coordinated gallate ligand and a square-planar arrangement about both the Ni and Cu centres. A tetrahedral arrangement about these metal centres in solution would lead to two signals for the —$GaMe_2$ protons. However, a square-planar geometry in Cu(I) complexes is very unusual and a square-planar "Ni(NO)" complex has to date proven elusive. Further, our studies involving the analogous complexes using the ligand $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]^-$ have revealed fluxional behaviour for the two complexes in solution and tetrahedral structures about the metal centres in the solid state (13, 14). For the present complexes the room temperature ^{1}H nmr spectra may be explained on the basis of a rapid fluxional process which interconverts tetrahedral molecules via either a square-planar or three-coordinate intermediate (14) thus giving rise to a single averaged —$GaMe_2$ signal. Again, the tetrahedral environment about the Ni atom in the solid state has been confirmed by a crystal structure determination of the "Ni(NO)" complex.[1] In addition, low temperature ^{1}H nmr spectra of both complexes in d_6-acetone solutions display two —$GaMe_2$ proton signals, one to either side of the single room temperature signal. Thus at low temperatures in solution "static" tetrahedrally coordinated Ni and Cu centres are likely attained. Fluxional behaviour for the "Ni(NO)" and "$CuPPh_3$" complexes in solution at room temperature is also indicated by the proton signals due to the "$OCH_2CH_2SCH_2CH_3$" moiety in the ^{1}H nmr spectra. Thus these protons give rise to simple first order triplets and a quartet arrangement (see Fig. 5), much simplified from the pattern observed for these protons in the octahedral complexes (see Fig. 4).

Conclusion

It was initially puzzling that the ligand **1**, where R = Ph, was so reluctant to yield a parallel series of

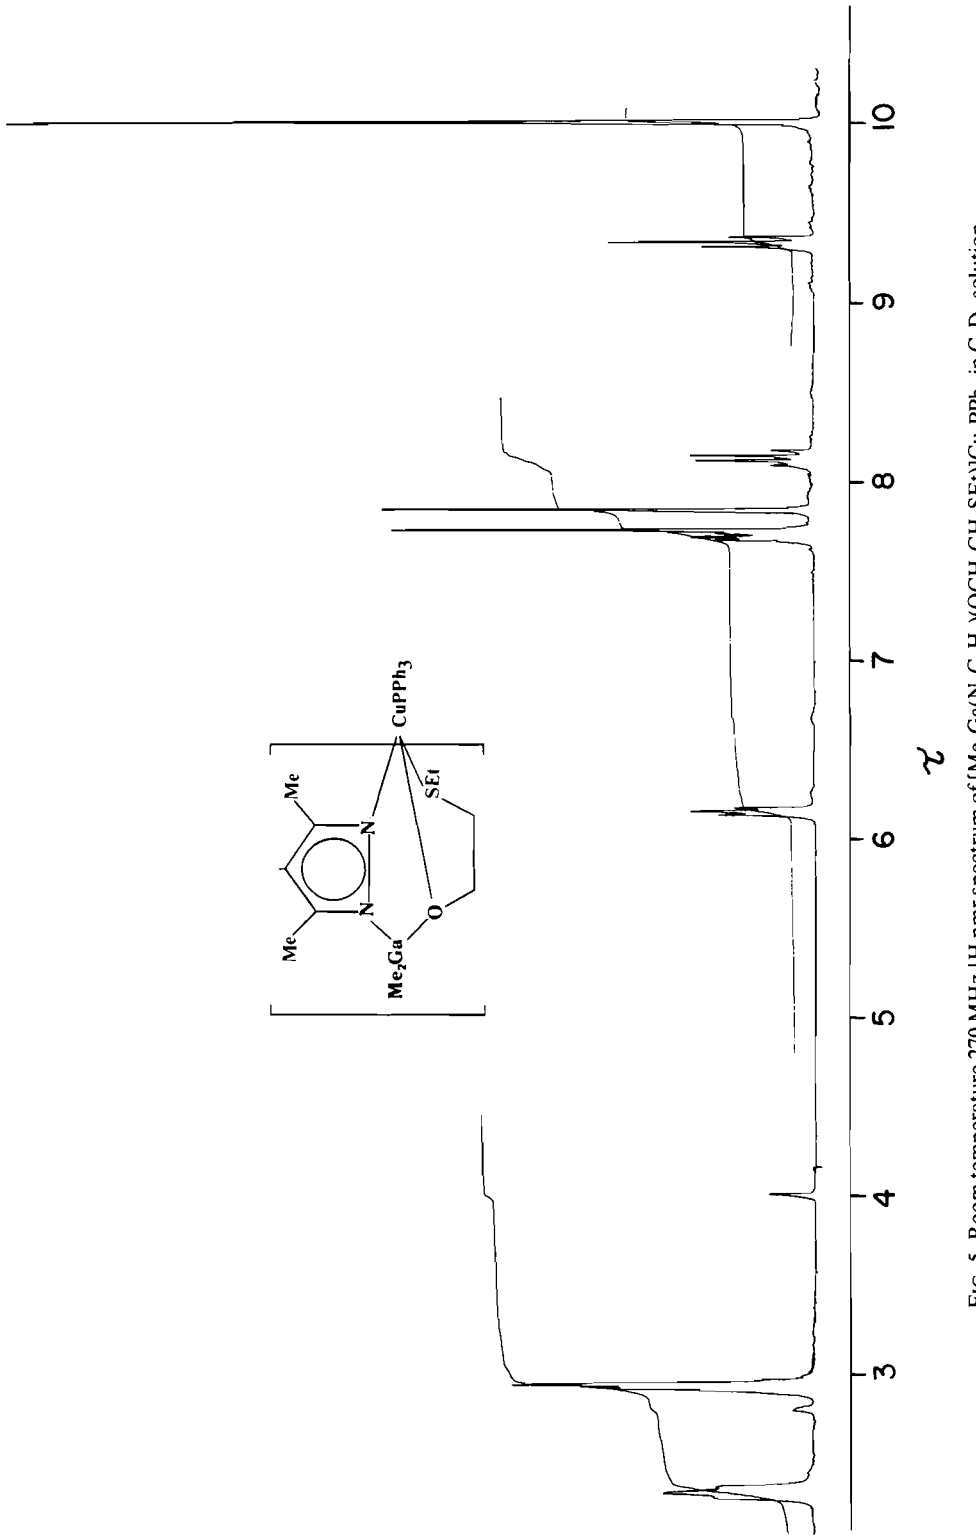

FIG. 5. Room temperature 270 MHz ^{1}H nmr spectrum of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]Cu{\cdot}PPh_3$ in C_6D_6 solution.

compounds to the one described above for the ligand **1**, where R = Et. The only complex characterized to date is the "$Mn(CO)_3$" derivative, although evidence for a "$Mo(CO)_2(NO)$" species was obtained in one attempt to prepare this nitrosyl compound. It is conjectured that the bulky phenyl substituent on the S atom is responsible for this reluctance of the ligand **1** (R = Ph) to form complexes. The steric requirements of this ligand are discussed further in connection with the crystal structure of its "$Mn(CO)_3$" derivative.[1]

It is relevant in this regard to report that our explorations into the ligating properties of the potentially tridentate chelating ligand $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2PPh_2)]^-$ have so far proven fruitless. Again the bulky "PPh_2" grouping may prohibit the tridentate chelation necessary to stabilize the various metal complexes. Our endeavours in this area of multidentate organogallate ligands are continuing with other 3-atom donor sets, and also with ligands of potentially higher denticity.

The thermal and photochemical decomposition of maleic anhydride in the gas phase[1]

R. A. BACK AND J. M. PARSONS

Division of Chemistry, National Research Council of Canada, 100 Sussex Drive, Ottawa, Canada K1A 0R6

Received October 9, 1980

R. A. BACK and J. M. PARSONS. Can. J. Chem. **59**, 1342 (1981).

The thermal decomposition of maleic anhydride has been studied in the gas phase in a static system at temperatures from 645 to 760 K and pressures from 0.7 to 20 Torr. The first-order rate constant for the homogeneous unimolecular reaction,

Maleic anhydride $\rightarrow C_2H_2 + CO + CO_2$

is described by the Arrhenius parameters $\log A\ (s^{-1}) = 14.33\ (\pm 0.3)$, and $E = 60.9\ (\pm 1)$ kcal/mol. The reaction appears to proceed through a concerted mechanism rather than a biradical one.

The photochemical decomposition, studied at wavelengths from 220 to 350 nm, yielded the same products. At 300 nm and below, the decomposition was unaffected by pressure, but at longer wavelengths collisional quenching was observed. Weak light emission was observed on excitation between 350 and 380 nm. The absorption spectrum was measured from 250 to 400 nm, and three overlapping transitions, $\pi^* \leftarrow \pi$, $\pi^* \leftarrow n_+$, and $\pi^* \leftarrow n_-$, can be distinguished. The mechanism of the photolysis is discussed and it is concluded that it probably proceeds through internal conversion to a vibrationally excited ground state.

R. A. BACK et J. M. PARSONS. Can. J. Chem. **59**, 1342 (1981).

Utilisant un système statique et opérant à des températures de 645 à 760 K et à des pressions allant de 0,7 à 20 Torr, on a étudié la décomposition thermique de l'anhydride maléique en phase gazeuse. On décrit la constante de vitesse d'ordre un de la réaction unimoléculaire homogène

Anhydride maléique $\rightarrow C_2H_2 + CO + CO_2$

par les paramètres d'Arrhénius $\log A\ (s^{-1}) = 14{,}33\ (\pm 0{,}3)$ et $E = 60{,}9\ (\pm 1)$ kcal/mol. La réaction semble se dérouler selon un mécanisme concerté de préférence à un mécanisme biradicalaire.

On obtient les mêmes produits quand on étudie la décomposition photochimique à des longueurs d'ondes allant de 220 à 350 nm. A des longueurs d'onde allant jusqu'à 300 nm, la pression n'affecte pas la décomposition mais à des longueurs d'onde plus grandes, on observe des extinctions par collision. Lorsqu'on excite entre 350 et 380 nm, on observe une faible émission de lumière. On a mesuré le spectre d'absorption à partir de 250 jusqu'à 400 nm et on peut distinguer trois transitions de recouvrement: $\pi^* \leftarrow \pi$, $\pi^* \leftarrow n_+$ et $\pi^* \leftarrow n_-$. On discute du mécanisme de la photolyse et on en conclut qu'il se fait par l'intermédiaire d'une conversion interne en un état fondamental vibrationnellement excité.

[Traduit par le journal]

Introduction

Few studies have been reported of the thermal or photochemical decomposition of the cyclic anhydrides of dicarboxylic acids in the gas phase. Krull and Arnold (1) briefly described the mercury-photosensitized decomposition of several anhydrides, while Brown and Ritchie reported qualitative results of "hot tube" pyrolysis of a number of anhydrides, both cyclic and noncyclic (2). Rice and Murphy briefly examined the pyrolysis of several cyclic anhydrides in the vapor phase in a flow system at temperatures from 750 to 900°C (3). The present paper describes a study of the thermal and photochemical decomposition of maleic anhydride (2,5-furandione) in the gas phase.

Experimental

Reaction vessels and the vacuum line for handling maleic anhydride vapor were totally enclosed in an air thermostat usually held at 100°C, well above the condensation temperature at the highest pressure employed, yet below the temperature at which thermal decomposition becomes significant. Stopcocks were greased with silicone grease, and pressure was measured by a heated quartz spiral nulled by an oil manometer outside the thermostat.

The thermal decomposition was studied in a static system using a cylindrical quartz vessel 5 cm in diameter and 7 cm long of 236 cc volume, mounted in a tube furnace controlled to ± 1°C. A similar reaction vessel packed with quartz tubing was used to test for surface effects.

The photolysis vessel was cylindrical, 5 cm in diameter and 10 cm long fitted with plane quartz windows. The light source was a 1000 W mercury–xenon arc fitted with a matching monochromator with a bandwidth that could be varied from 3.3 to 23 nm. Fluorescence was measured in a conventional quartz cell with a window at right angles to the exciting light beam and fitted with blackened Wood's horns to minimize scattered light. Emission was measured with a RCA 1P21 photomultiplier mounted behind a sharp-cutoff filter to remove most of the exciting radiation.

Product analysis was by simple low-temperature fractionation and measurement in a gas burette, followed by gas chromatography to confirm the identification and analysis. Maleic anhydride (of purity ≥99.5%) was obtained from BDH chemicals and used without further purification; it was rigorously degassed and stored as a solid in a trap cooled to about 20°C which was warmed to give the desired vapor pressure when required.

Results and Discussion

The Thermal Decomposition

The decomposition was studied at pressures from about 0.7 to 20 Torr and temperatures from 645 to 760 K. The only products observed were CO, CO_2, and C_2H_2, formed in equimolar quantities, in agreement with the brief observations of Rice and Murphy (3) in experiments at 1093 K. There is no evidence for the formation of the propiolaldehyde or propiolic acid at 703 K suggested by Brown and Ritchie (2) even though our experiments were extended to lower temperatures and were at much lower conversions (always <5%) than theirs. No systematic search was made for products less volatile than the parent anhydride. At the higher temperatures, the change in pressure during the reaction was approximately in agreement with that expected from dissociation into the observed products. At the lowest temperatures, however, a small decrease in pressure was observed, indicating the occurrence of some condensation reactions, perhaps dimerization; this was not investigated further.

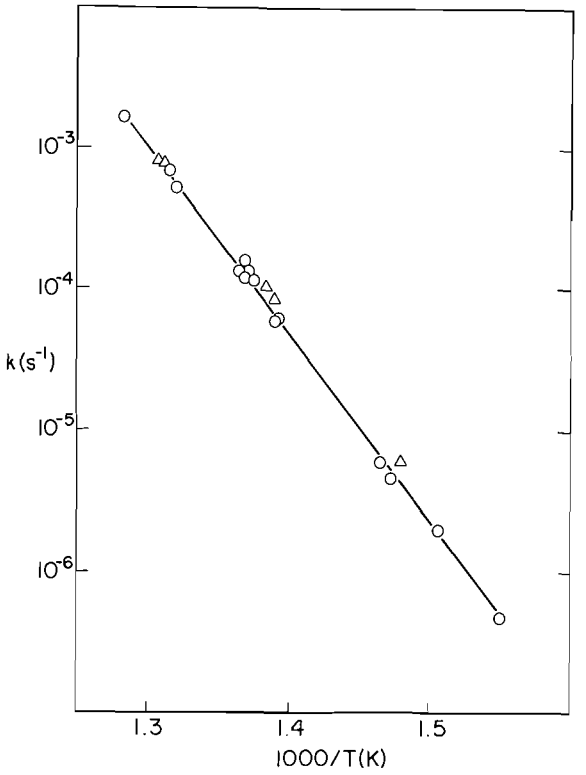

FIG. 1. Arrhenius plot for the first-order rate constant for the thermal decomposition of maleic anhydride. O = unpacked reaction vessel; Δ = packed reaction vessel, S/V increased by factor of 9.

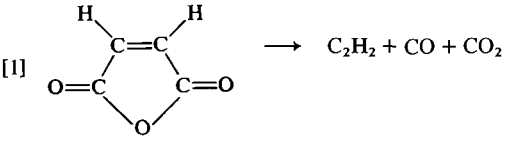
In Fig. 1, first-order rate constants based on CO formation are shown in an Arrhenius plot; the straight line corresponds to the equation $\log k\ (s^{-1}) = 14.19 - 60.5/4.58\,T$. Experiments in the packed reaction vessel, in which the surface to volume ratio was increased by a factor of 9, showed an appreciable enhancement (Fig. 1). A small correction was made based on these data, assuming surface and homogeneous reactions to be simply additive, and surface reaction proportional to area, leading to an Arrhenius equation for the homogeneous unimolecular reaction of $\log k\ (s^{-1}) = 14.33 - 60.9/4.58T$, with uncertainties of ±0.3 in log A and ±1 in E. Between about 8 and 20 Torr, values of k were independent of pressure, and all the data in Fig. 1 were obtained in that range. At lower pressures, k decreased significantly, falling to about 60% of its high-pressure value at 0.7 Torr at 731 K. The pressure and values of k at which this occurs suggest that this is simply the normal pressure dependence of a unimolecular reaction.

The simplicity of the reaction products, the pressure dependence of k, and the values of the Arrhenius parameters indicate that the measured first-order rate constant is that for the simple homogeneous unimolecular reaction,



($\Delta H^0 = +34$ kcal/mol)

Biradical mechanisms are operative in the decomposition of many cyclic compounds (4). It can be estimated, however, that formation of a biradical by simple ring opening of maleic anhydride would require at least 75 kcal/mol, far above the observed activation energy. Formation of secondary biradicals or intermediates such as cyclopropenone or oxiren-2-one by molecular elimination of CO_2 or CO would also appear to be too endothermic. We conclude therefore that reaction [1] probably proceeds through a simple direct concerted mechanism. The fact that the activation energy only exceeds the endothermicity of the reaction by about 27 kcal/mol indicates a relatively loose or expanded transition state which permits CO_2 and C_2H_2 to approach their linear equilibrium configurations much more closely than is possible for maleic anhydride itself.

The Photochemical Decomposition

Products of the photolysis at all wavelengths

from 220 to 350 nm were CO, CO_2, and C_2H_2 in equimolar quantities, as in the thermal and the mercury photosensitized (1) decompositions. Relative quantum yields at 300 nm and below were independent of pressure of maleic anhydride or added CO_2. At 350 nm, quantum yields decreased with increasing pressure of maleic anhydride or of added CO_2, as shown in Stern–Volmer plots in Figs. 2 and 3; the ratio of the slopes of the two lines indicates that maleic anhydride is about 5.5 times more efficient than CO_2 in quenching the decomposition.

Weak light emission was also observed from maleic anhydride irradiated betweeen 350 and 380 nm. An excitation spectrum for this emission is shown in Fig. 4, obtained using a bandwidth of 16 nm, and normalizing the data to constant incident intensity. A spectrum of the emission excited at 366 nm was photographed on a small Hilger spectrograph with a 22 h exposure, and showed continuous emission extending from about 420 to 480 nm. The emission intensity at 366 nm was found to be a linear function of pressure, (i.e., of the light absorbed) thus indicating no collisional quenching of the emitting species.

Because of its low volatility, the absorption spectrum of maleic anhydride vapor has only been reported for wavelengths below 230 nm where the strong $\pi^*-\pi$ absorption begins; weaker absorption was observed in solution and low-temperature glasses extending to about 360 nm (5). The spectrum was therefore measured in a heated 10 cm cell at 147°C and 100 Torr pressure in a Cary spectrophotometer, and is shown in Fig. 5. Three overlapping absorption systems can be distinguished, and following McGlynn's assignments (5, 6) can be attributed to the $\pi^* \leftarrow n_-$, $\pi^* \leftarrow n_+$, and $\pi^* \leftarrow \pi$ transitions. The first two are symmetry forbidden and are quite weak with ε_{max} around 10; the dashed curves in Fig. 5 indicate only very approximately the positions of these systems. The much stronger allowed $\pi^* \leftarrow \pi$ transition was studied by Seliskar and McGlynn (5); it shows strong but diffuse vibrational bands with an origin at 213.8 nm. The tail of this absorption system, presumably an unresolved complex of hot bands, extends at least 60 to 80 nm to the red, strongly overlapping the much weaker $\pi^* \leftarrow n_+$ system and obscuring its structure. The latter shows one strong progression of diffuse vibrational bands with a spacing of about 1530 cm^{-1}, marked in Fig. 5, and a second weaker progression

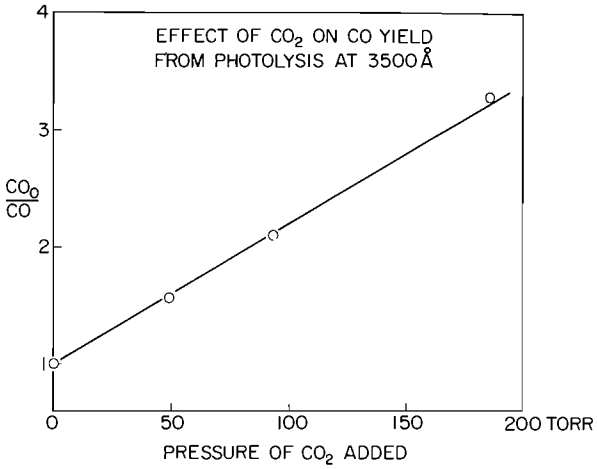

FIG. 3. Stern–Volmer plot showing the effect of CO_2 on the photolysis at 350 nm.

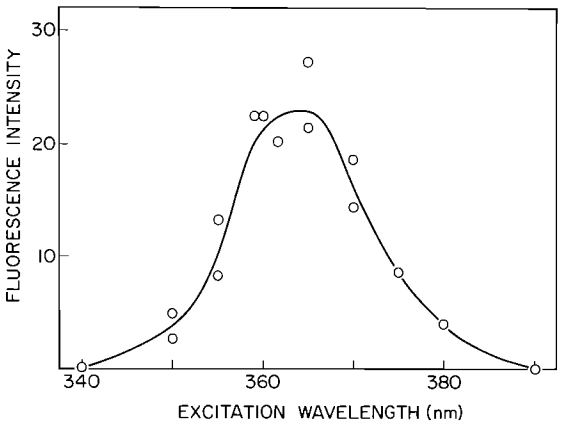

FIG. 4. Excitation spectrum for emission from maleic anhydride, normalized to constant incident intensity.

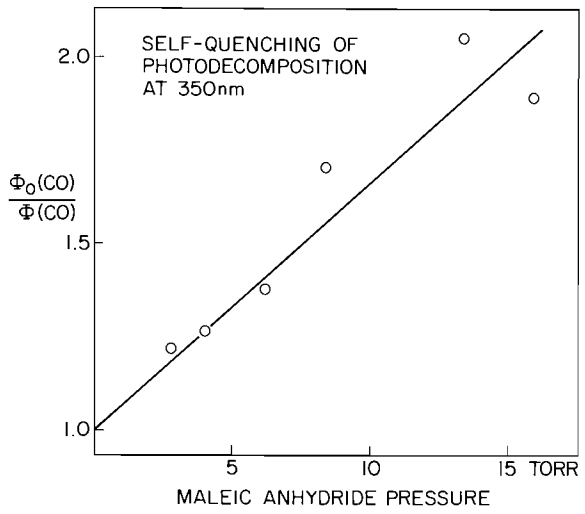

FIG. 2. Stern–Volmer plot of quantum yield of CO formation vs. pressure of maleic anhydride for the photolysis at 350 nm.

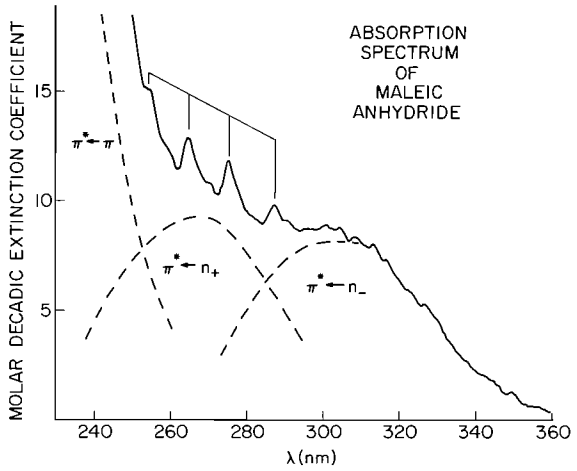

FIG. 5. Absorption spectrum of maleic anhydride vapor taken with a Cary spectrophotometer at 147°C, 100 Torr pressure, and 10 cm path length.

displaced about 700 cm^{-1} to the blue. These are presumably the same progressions observed by Seliskar and McGlynn (5) in a low-temperature glass, and probably arise from excitation of a C=O stretching vibration in the upper state. Between 290 and 320 nm a further group of diffuse vibrational bands is seen, probably belonging to the $\pi^* \leftarrow n_-$ system. Photographic spectra taken at moderately high resolution in a multi-pass 2 m cell showed that these bands are part of a complex system extending beyond 360 nm.[2] At longer wavelengths, the bands become very much sharper, showing well-resolved K-structure and rotational band contours, but spectra taken at higher resolution show that even at the longest wavelength observed (358 nm) they are ultimately diffuse, with no resolved rotational fine structure.

The Mechanism of the Photochemical Decomposition

The following generalized mechanism accounts for the observed behaviour:

[2] $MA + h\nu \rightarrow MA^*$

[3] $MA^* \rightarrow MA^{\#}$

[4] $MA^* \rightarrow h\nu' + MA$

[5] $MA^{\#} \rightarrow CO + CO_2 + C_2H_2$

[6] $MA^{\#} + X \rightarrow MA + X$

where MA = maleic anhydride and X = a collision partner. The broad diffuse bands of the $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n_+$ transitions indicate very short lifetimes for these states. The $\pi^* \leftarrow n_-$ spectrum is much sharper but at high resolution is still diffuse, and the excited state must have a lifetime no more than a few picoseconds. None of the three excited singlet states, MA*, are expected from their electronic structure to be dissociative themselves, and their short lifetime and the broadening of the spectra must be attributed to a rapid internal conversion or intersystem crossing. The corresponding triplet states are also unlikely to dissociate directly, and it seems probable that dissociation occurs from the vibrationally excited ground state ($MA^{\#}$ in the mechanism). The conversion from the initially formed singlet to the ground state might or might not proceed through a triplet state; the only experimental conclusion is that this process must be fast.

The collisional quenching of the decomposition at 350 nm is compatible with its proceeding through the vibrationally excited ground state. If no energy were lost by collision prior to internal conversion, excitation at this wavelength would yield molecules excited by about 82 kcal of vibrational energy, about 21 kcal/mol in excess of the dissociation energy measured in the thermal decomposition. Pressures of 15 Torr of maleic anhydride or 84 Torr of CO_2 were required to reduce the decomposition yield by one half (Figs. 2 and 3). This may be compared with a similar excitation of cyclobutanone by internal conversion, where a half-pressure of 600 Torr of propylene was reported for molecules with excess energy of 39 kcal/mol (7). The much lower half-pressures in the present system are a reasonable reflection of the lower excess energy.

The excitation spectrum of the emission (Fig. 4) must arise from the convolution of a decreasing extinction coefficient and an increasing quantum yield of emission with increasing wavelength. This behaviour, and the increasing diffuseness of the absorption spectrum with decreasing wavelength, suggests that only the $\pi^* \leftarrow n_-$ state is sufficiently longlived to give detectible emission, and that its lifetime decreases sharply with decreasing wavelength. Similar behaviour has been observed in many other systems, e.g., cyclobutanone (8). The observed fluorescence was very weak and while a quantum yield was not measured it must be very low. The absence of collisional quenching and the diffuseness of the absorption spectrum indicates a very short lifetime for the emitting species ($<10^{-11}$ s), while the radiative lifetime for such a weak transition must be much longer, 10^{-8} s or more, fixing the quantum yield of fluorescence at 10^{-3} or lower.

[2]We are grateful to Mr. M. Barnett of the Herzberg Institute for photographing these spectra.

Synthesis of 3(2-haloethyl)aryltriazenes and study of their reactions in aqueous solution

J. WILLIAM LOWN AND RANJIT SINGH
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 14, 1980

J. WILLIAM LOWN and RANJIT SINGH. Can. J. Chem. **59**, 1347 (1981).

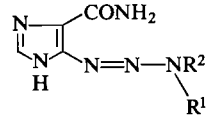
Several 1-aryl-3-(2-haloethyl)triazenes have been synthesized and characterized spectroscopically as well as by their esterification of 3,5-dinitrobenzoic acid. Their rates of decomposition in aqueous media at pH 7 were determined polarographically employing the electrochemically active triazene moiety. In two selected cases the rates of decomposition increase markedly with lowered pH in the range 9.3 to 4.65. The products of aqueous decomposition, both volatile and involatile, were identified and quantitated by gc and gc–ms. Discrimination between alternative decomposition pathways was possible by the preparation and use of selectively deuterated triazenes. The data are consistent with initial protonation of the triazene and generation therefrom of a 2-haloethyl cation (or its kinetic equivalent) which is subject to rearrangements detected by deuterium scrambling. A second competing pathway involves cyclization of the triazene to a 1-aryl-1,2,3-triazoline intermediate which is then subject to nucleophilic opening at two sites with attendant loss of nitrogen. The effects of structural changes in the triazenes on their modes of decomposition and generation of electrophiles should assist in the interpretation of their antitumor effects.

J. WILLIAM LOWN et RANJIT SINGH. Can. J. Chem. **59**, 1347 (1981).

On a synthétisé plusieurs aryl-1 (halo-2 éthyl)-3 triazènes et on les a caractérisés par spectroscopie et en les transformant en leurs dinitro-3,5 benzoates. On a déterminé leur vitesse de décomposition en milieu aqueux à un pH = 7 en faisant appel à la polarographie et en utilisant la portion triazène électrochimiquement active. Dans deux cas sélectionnés, les vitesses de décompositions augmentent fortement lorsque le pH diminue de 9,3 à 4,65. Faisant appel à la cpg et à la cpg reliée à la sm, on a identifié les produits de décomposition volatils et non-volatils qui se forment en milieu aqueux et on a déterminé les quantités de produits formés. On peut choisir parmi les diverses voies de décomposition possibles en préparant et en utilisant des triazènes sélectivement deutérés. Les donnés sont en accord avec une protonation initiale du triazène conduisant par la suite à la formation d'un cation halo-2 éthyl (ou son équivalent cinétique) qui peut subir des transpositions qui peuvent être différenciées sur la base des produits deutérés obtenus. Une autre voie qui est en compétition avec la précédente fait intervenir la cyclisation du triazène en un intermédiaire aryl-1 triazoline-1,2,3 qui peut ensuite subir une ouverture nucléophile par attaque en deux points avec une perte concomittante d'azote. Les effets de changements structuraux dans le triazène sur leurs modes de décomposition et sur la formation d'électrophiles devraient faciliter l'interprétation de leurs effets antitumoraux.

[Traduit par le journal]

Synthetic attempts to design antagonists of 4-aminoimidazole-5-carboxamide, the ribotide of which is a precursor in purine biosynthesis, led to the development of 5(3,3-dimethyl-1-triazene)imidazole-4-carboxamide (DIC), **1***a*, which is probably the most effective agent used clinically in the treatment of melanoma (1). Among the substituted triazenes that were subsequently evaluated, 5-[3,3-bis(2-chloroethyl)-1-triazenyl]imidazole-1-carboxamide] (BIC), **1***b*, was found to be effective against brain tumors, malignant melanoma, and lymphomas (2, 3). Studies of the metabolism of DIC (5–7) and related triazenes (8) showed that oxidative *N*-demethylation gives rise to the ultimate alkylating species 5(3-methyl-1-triazene)imidazole-4-carboxamide (MIC), **1***c* (3), prior to its decomposition in water to give electrophiles which are thought to react with biological macromolecules. Mono-*N*-alkylated triazenes based on MIC, e.g. [5-[3-(2-chloroethyl)-1-triazenyl]-1*H*-imidazole-4-carboxamide], **1***d*, have exceeded MIC in activity (4). Subsequent structure–activity relationships of triazenes showed that the anticancer activity arose from the alkyltriazene portion and that the imidazole group could be replaced by an aryl ring without materially affecting activity (6, 8).



1*a* $R^1 = CH_3$, $R^2 = CH_3$
b $R^1 = CH_2CH_2Cl$, $R^2 = CH_2CH_2Cl$
c $R^1 = CH_3$, $R^2 = H$
d $R^1 = CH_2CH_2Cl$, $R^2 = H$

Studies on the chemical properties and the types of products obtained from aqueous decomposition of 2-haloethylnitrosoureas have contributed significantly to an understanding of their reactivity and mode of action (9–13). There have been few reports of a similar examination of 2-haloethyltriazenes and most studies in this field have dealt with monoalkyltriazenes (14, 15) and dialkyltriazenes (16, 17). We wish to report the synthesis, characterization, and identification of the pathways of decomposition of 2-haloethyltriazenes using specifically deuterium labelled compounds.

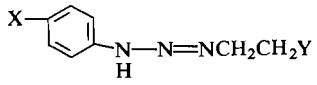
Syntheses and Properties of Protium and Deuterium Labelled Triazenes

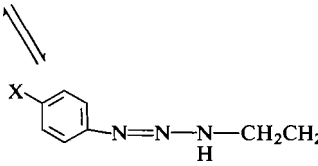
The aryl triazenes required in this study were prepared by coupling of the aryl diazonium cation with the 2-haloethylamine (15). The observation that the presence of an electron-withdrawing group in the phenyl ring, particularly at the *p*-position, increases the stability of the triazene and prevents formation of the pentaazadiene during the reaction of the aryldiazonium ion with the primary amine (18) was exploited in these preparations. In general it was found that a *p*-CN substituent in the phenyl ring conferred the desired stability characteristics. A special comment may be made in the case of the 2-bromoethyltriazene **8**. It was recently reported that when the *p*-nitrophenyldiazonium salt **2** was condensed with 2-bromoethylmethylamine **3** the product was that of intramolecular cyclization to the triazolinium salt (19). A similar triazolinium salt has been observed as a primary metabolite of BIC (20). No such cyclization took place in the preparation of the 2-bromoethyltriazene **8** that was obtained as a mixture of tautomers similar to the other triazenes. However, cyclization to a 1-aryl-Δ^2-1,2,3-triazoline may be significant in the aqueous decomposition of triazenes (see Discussion).

The purification of the 2-haloethyltriazenes required special care and was carried out by recrystallization at low temperatures. Purification by standard chromatographic methods was not possible owing to the rapid degradation on solid adsorbents as observed previously (21). The composition, structures, and purity of the triazenes were established by exact mass spectral measurements and by ^{1}Hmr and infrared spectroscopy. In several cases individual triazenes were characterized by their formation of ester derivatives from 3,5-dinitrobenzoic acid. The 2-haloethyltriazenes are thermally as well as chemically more labile than monoalkyl triazenes. Their instability increases in the sequence F < Cl < Br. It was also observed that the stability and reactivity are influenced by the number of methylene units intervening between the azide moiety and the halogen atom.

In common with other aryl triazenes, the 2-haloethyltriazenes were observed to exist in solution as mixtures of tautomers. Since the position of equilibrium has a direct bearing on the mechanism of decomposition, it was studied for each compound by nmr.



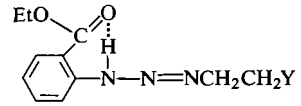
A



B

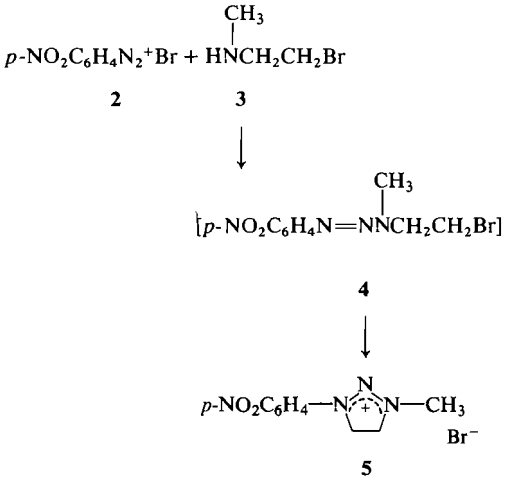
X = NO_2, CN, $COCH_3$, $CO_2C_2H_5$; Y = F, Cl, Br

An electron-withdrawing group X in the *para* position strongly favors tautomeric form A, whereas such a substituent in the *ortho* position gives tautomer A exclusively, results which are similar to those for other types of triazenes (22). 2-Haloethyltriazenes with an electron-withdrawing group in the *ortho* position (and therefore in tautomeric form A) are much more labile than their *para* substituted counterparts. For example triazene **14** was isolable as a stable solid whereas its *ortho* isomer decomposed as soon as it was formed. A possible explanation in accord with the proposed mechanism of decomposition is that the *ortho* triazene is fixed in tautomeric form A by hydrogen bonding:

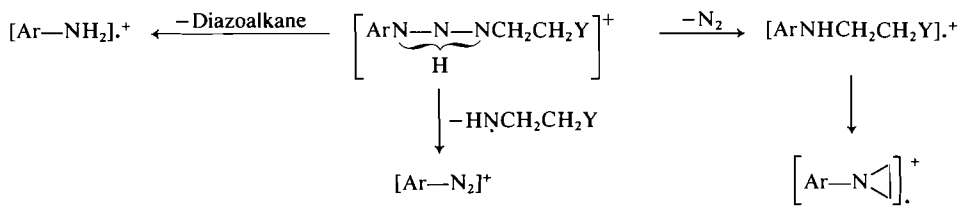


The resulting partial displacement of charge on to the aniline nitrogen should facilitate its protonation, leading to decomposition.

The presence of either tautomer in the equilibrium mixtures was detected by its characteristic bands in the infrared and ^{1}Hmr spectra. For example, the NH proton nmr signals corresponding to both tautomers are visible at −15°C. The NH proton absorbing at higher field could be assigned to



2 3 4 5



SCHEME 1

tautomer B on the basis of its coupling with the protons on the adjacent carbon at low temperature and the assigned couplings were confirmed by double resonance experiments. The mass spectra of the 2-haloethyltriazenes showed several fragmentation patterns (15) which were useful in characterizing the new compounds as shown in Scheme 1.

One new representative of the family of imidazole triazenes namely 5-[2-(2-fluoroethyl)-1-triazenyl]imidazole-4-carboxamide **28** was synthesized for a comparison of its chemical properties with those of the 2-fluoroethylaryltriazenes. Triazene **28** was light sensitive and chemically labile. It was characterized by its spectral properties and by its reaction with 3,5-dinitrobenzoic acid to form 2-fluoroethyl 3,5-dinitrobenzoate.

Certain specifically deuterated 2-haloethyltriazenes were required in order to establish the mechanistic pathways of formation of certain products. Accordingly triazenes **21** and **22** specifically deuterated on carbons C-1 and C-2, respectively, were synthesized from the corresponding deuterated amines which were in turn prepared following the procedures of Brundrett *et al.* (23).

Results

Triazenes **9**, **21**, **22**, **23**, and **28** were allowed to decompose at 37°C in phosphate buffered (0.1 *M*, pH 7.2) aqueous solution in gas-tight vials and the volatile products were analyzed by gc and identified by gc–ms (Table 1). Each product was identified by its retention time compared with a standard and by its characteristic mass spectrum (see Table 1). The involatile products were separated by chromatography and identified spectrophotometrically. 1-(*p*-Cyanophenyl)-3-(2-chloroethyl)triazene (**10**) afforded acetaldehyde (11.5% of volatiles), 1,2-dichloroethane (11.5% of volatiles), and 2-chloroethanol (77% of volatiles). In addition the following involatile products were identified: *p*-cyanoaniline (52% of involatiles), *N*-(2-chloroethyl)-*p*-cyanoaniline (30%), 1,2-di(*p*-cyanoanilino)ethane (10%), and *N*-(2-hydroxyethyl)-*p*-cyanoaniline (8%). When this triazene (**10**) was allowed to decompose in the presence of sodium bromide an additional product was 1-bromo-2-chloroethane.

Aqueous decomposition of the corresponding specifically deuterium labelled triazene 1-(*p*-cyanophenyl)-3-(2-chloro-1,1-dideuterioethyl)triazene (**21**) afforded acetaldehyde, 1,2-dichloro-1,1-dideuterioethane, a mixture of the isomeric deuterium labelled 2-chloroethanols bearing the deuterium predominantly on the carbon bearing hydroxyl (92:8), a mixture of isomeric deuterium labelled *N*-(2-chloroethyl)-*p*-cyanoanilines bearing deuteriums predominantly on carbon adjacent to chlorine (52:48), a mixture of isomeric deuterium labelled *N*-(2-hydroxyethyl)-*p*-cyanoaniline bearing deuteriums predominantly on carbon adjacent to hydroxyl (70:30), and deuterium labelled 1,2-di(*p*-cyanoanilino)ethane. Reaction of **21** in the presence of potassium bromide gave in addition labelled 1-bromo-2-chloroethane bearing deuterium mainly on the carbon bonded to bromine.

The isomeric deuterium labelled triazene 1-(*p*-cyanophenyl)-3-(2-chloro-2,2-dideuterioethyl)triazene (**22**), when allowed to decompose in pH 7 phosphate buffer, gave acetaldehyde with deuterium in the formyl group, 1,2-dichloro-1,1-dideuterioethane, a mixture of the isomeric deuterium labelled 2-chloroethanols bearing deuterium predominantly on the carbon bearing chlorine, (92:8), a mixture of isomeric deuterated *N*-(2-chloroethyl)-*p*-cyanoaniline bearing two deuteriums predominantly on carbon adjacent to nitrogen (53:47), a mixture of isomeric deuterium labelled *N*-(2-hydroxyethyl)-*p*-cyanoaniline bearing two deuteriums predominantly on carbon adjacent to nitrogen (70:30), and deuterium labelled 1,2-di(*p*-cyanoanilino)ethane. Reaction of **22** in the presence of potassium bromide gave, in addition, labelled 1-bromo-2-chloroethane bearing deuterium mainly on the carbon bonded to chlorine.

When 1-(*p*-cyanophenyl)-3-(2-chloro-2,2-dideuterioethyl)triazene **22** was allowed to react with 3,5-dinitrobenzoic acid the product was 2-chloro-2,2-dideuterioethyl 3,5-dinitrobenzoate **31** exclusively.

Aqueous decomposition of 1-(*p*-cyanophenyl)-3-

		$ClCH_2CD_2Cl$	100 (7.7, M^+ ^{35}Cl); 102 (4.1, M^+ ^{37}Cl); 64, 66 (99.8, 29.6, $M^+ - HCl$); 63, 65 (25.4, 25.4, $M^+ - DCl$); 29 (100, C_2HD_2)
		$ClCH_2CD_2OH$	82 (1.4, M^+ ^{35}Cl); 84 (non visible, M^+ ^{37}Cl);
		$ClCD_2CH_2OH$	31 (100, CH_2OH); 33 (3.4, CD_2OH)
	Buffer + KBr	$BrCH_2CD_2Cl$	144 (4.4, M^+ ^{35}Cl); 146 (5.5, M^+ ^{37}Cl)
		$BrCD_2CH_2Cl$	65 (100, $M^+ - Br$, ^{35}Cl); 67 (31.4, $M^+ - Br$, ^{37}Cl)
23	Phosphate buffer	CH_3COCH_3	58 (24.9, M^+); 43 (100, $M^+ - 15$);
		$CH_3CCl{=}CH_2$	76 (43.7, M^+ ^{35}Cl); 78 (14.8, M^+ ^{37}Cl); 39 (63.8, M^+ ^{37}Cl); 41 (100, M^+ ^{35}Cl)
		$CH_3CHClCH_2Cl$	112 (4.9, M^+ ^{35}Cl); 114 (3.0, M^+ ^{37}Cl); 76, 78 (37.4, 12.7, $M^+ - HCl$); 63, 65 (100, 29.8, $M^+ - CH_2Cl$)
		$CH_3CHClCH_2OH$	65 (3.7, M^+ ^{35}Cl—CH_2OH); 67 (0.4, M^+ ^{37}Cl —CH_2OH); 58 (11.7, $M^+ - HCl$)
		CH_3COHCH_2Cl	31 (100, CH_2OH)
9 or **28**	Phosphate buffer	FCH_2CH_2F	66 (8.6, M^+); 46 (22.7, $M^+ - HF$); 33 (100, CH_2F)
		FCH_2CH_2OH	64 (12.4, M^+); 45 (15.7, $M^+ - F$); 31 (100, CH_2OH)
		$CH_3CHOHCH_2Cl$	44 (40.2, M^+); 43 (19.4, CH_3CO); 29 (100, CHO)

(2-chloropropyl)triazene at pH 7 and 37°C afforded acetone, 2-chloro-1-propanol and 1-chloro-2-propanol (3:2), 1,2-dichloropropane and 2-chloropropene, as well as *p*-cyanoaniline.

Representative examples of two 2-fluoroethyl derivatives were allowed to decompose in buffered aqueous solution and their products identified and quantitated. 5-[3-(2-Fluoroethyl)-1-triazenyl]imidazole-4-carboxamide **28** afforded 2-fluoroethanol (79% of volatiles), acetaldehyde and 1,2-difluoroethane (together constituting 21% of volatiles), 5-aminoimidazole-4-carboxamide (90% of involatiles), and 5-(2-fluoroethylamino)imidazole-4-carboxamide (~1%).

Decomposition of 1-(*p*-cyanophenyl)-3-(2-fluoroethyl)triazene **9** gave 2-fluoroethanol (76% of total volatiles), acetaldehyde and 1,2-difluoroethane (together constituting 24% of volatiles), and *p*-cyanoaniline (86%).

The kinetic half-lives of the 2-chloroethyltriazenes in buffered aqueous solution could be conveniently determined electrochemically by following the disappearance of the polarographic wave characteristic of the triazene moiety which appears in the range −0.910 to −1.038 V (Table 2). The observed half lives range from ca. 2 min to ca. 38 min. In the 1-(*p*-cyanophenyl)triazenes the sequence of stabilities depending on the halogen substituent is F > Cl > Br. For a given halogen in the 2-haloethyltriazenes the sequence of stabilities depending on the nature of the *p*-aryl substituent is CH_3CO > CH_3CH_2COO > CN. There was also observed to be a marked dependence of the decomposition half-life on the length of the alkyl chain bearing the halogen in the series of 1-(*p*-cyanophenyl)-3-(ω-chloroalkyl)triazenes such that butyl > propyl > pentyl > ethyl.

In the case of 1-(*p*-cyanophenyl)-3-(2-fluoroethyl)triazene **9** a marked pH dependence on the rate of decomposition at 26°C was observed (Table 3). The rate of decomposition increased rapidly as the pH was lowered, such that $t_{1/2}$ at pH 8, 7, and 6 was 10080 s, 7560 s, and 3180 s respectively. The rate of the more rapid decomposition of 1-(*p*-cyanophenyl)-3-(2-chloroethyl)triazene **10** at 26°C also showed a marked and progressive increase on lowering the pH in the wider range of 9.3 to 4.65.

Discussion

The types of volatile products formed from aqueous decomposition of the 2-haloethylaryltriazenes are consistent with the general Scheme 2. The observed increase in the rate of decomposition of the triazenes with lowered pH suggests a protonation step on the major tautomer first. This is followed by cleavage to produce the observed aromatic amine and the 2-chloroethyldiazonium ion or (its kinetic equivalent) the 2-chloroethyl cation. Analogy with the reactions of 2-haloethylnitrosoureas suggests hydride transfer and hydrolysis of the latter can give rise to acetaldehyde (23, 24). Alternatively, nucleophilic attack by chloride ion or water on the diazonium ion or the 2-chloroethyl cation gives rise to 1,2-dichloroethane and 2-chloroethanol, respectively. The results with the corresponding specifically deuterated 2-chloroethylaryltriazenes provided further insight into these pathways and the possible participation of the chloronium ion species.

TABLE 3. Variation of half-life ($t_{\frac{1}{2}}$) of haloalkylaryltriazenes determined polarographically as a function of solution pH at 26°C

Triazene	pH	$t_{\frac{1}{2}}$ (s)

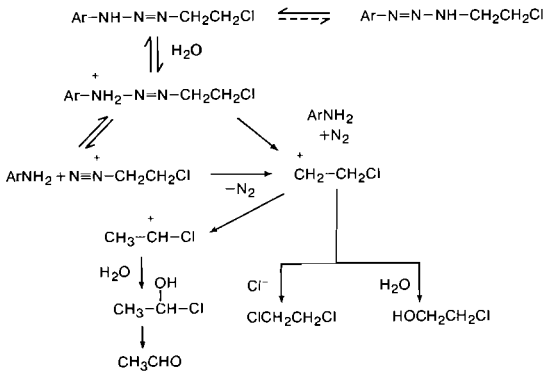
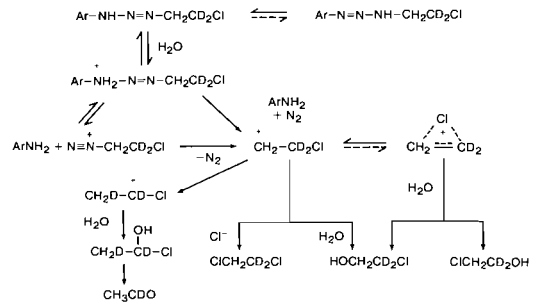
	5.95	355
	6.0	378
	6.95	420
	8.0	516
	9.3	718
9	6.0	3175
	7.0	7549
	8.0	10080



SCHEME 2

The deuterium labelled products obtained from the 2,2-dideuterio-2-chlorotriazene may be interpreted in terms of Scheme 3. The retention of the deuterium label in the formyl group of the acetaldehyde is consistent with generation of a transient 2-chloroethyl cation, a subsequent hydride shift to



SCHEME 3

For personal use only.

give the 1-chloroethyl cation, and hydrolysis of the latter. While either S_N2 by chloride ion attack on the conjugate acid of the triazene or S_N1 reaction via the 2-chloroethyl cation accounts for the 1,2-dichloroethane, the observed formation of a mixture of labelled 2-chloroethanols requires the intermediacy of another reactive species. The mixture of 2-chloroethanols contains predominantly (ca. 10:1) the isomer with deuterium adjacent to chlorine. As is the case with the corresponding 2-chloroethylnitrosoureas (23), the small amount (5–10%) of deuterium scrambling is consistent with a small contribution of the chloronium ion species in the overall decomposition.

Entirely complementary results are obtained in the decomposition of the 1,1-dideuterio-2-chlorotriazene. In this case, and as predicted from a pathway corresponding to Scheme 3, only unlabelled acetaldehyde is obtained. In this case, however, the two labelled 2-chloroethanols are obtained in a ratio of 10:1, containing predominantly the isomer with deuterium adjacent to hydroxyl, again in accord with a small contribution from the chloronium ion. Capture of the latter species by added bromide ion accounts for the formation of 1-bromo-2-chloroethane. Alternative decomposition pathways may be envisaged for the 2-haloethylaryltriazenes which would be indistinguishable from the main pathways outlined in Schemes 2 and 3, e.g. via the formation of a diazohydroxide.

$$ArNH{-}N{=}NCH_2CH_2Cl \xrightarrow{H_3O^+} ArNH_3^+ + HON{=}NCH_2CH_2Cl$$

The deuterium labelling experiments do, however, preclude the intermediacy of a diazoalkane since this requires the loss of one deuterium from the 2-chloroethanol and 1,2-dichloroethane isolated from the 1,1-dideuterio-2-chloroethyltriazene.

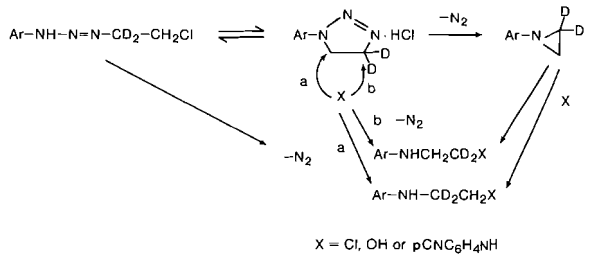
$$Ar\overset{+}{N}H_2N{=}NCH_2CH_2Cl \downarrow$$

$$ArNH_2 + N{\equiv}\overset{+}{N}CD_2CH_2Cl \not\downarrow$$

$$\bar{N}{=}\overset{+}{N}{=}CDCH_2Cl \downarrow H_2O$$

$$HOCDHCH_2Cl$$

Four involatile products were identified and quantitated from aqueous decomposition of triazene **10**. The use of specific deuterium labelling was especially informative in determining the origin of these products. While there are precedents for the direct loss of nitrogen from **10** to yield the 2-chloroethyl-*p*-cyanoaniline (15), the observation of deuterium scrambling favoring the rearrangement product (52:48) demands the intermediacy of a cyclic intermediate, but not a symmetrical one. The facts are in accord with the intermediate formation of the aryl 1,2,3-triazolinium salt (for which precedents exist, see refs. 13, 19, 25) as shown in Scheme 4. The much more marked preference for the formation of the rearrangement product with the 2-hydroxyethyl-*p*-cyanoanilines (70:30) confirms an unsymmetrical cyclic intermediate with, in this case, preferential attack by water at position 4 of the aryl 1,2,3-triazoline. Whereas the aziridine may participate as an intermediate, it alone cannot explain the observed results. Attack



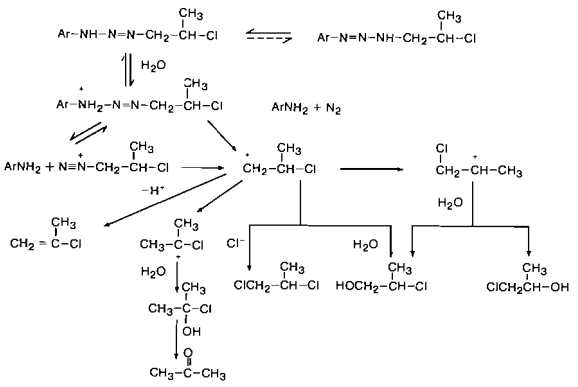
SCHEME 4

by *p*-cyanoaniline on the intermediate aryltriazenium salt (or aziridine) accounts for the formation of 1,2-*p*-cyanoanilinoethane. The results with the isomeric 1-(*p*-cyanophenyl)-3-(2-chloro-2,2-dideuterioethyl)triazene **22** are entirely consistent with Scheme 4.

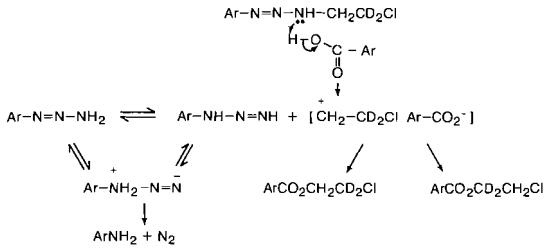
The effects of a substituent α to the halogen were observed in the decomposition of 1-(*p*-cyanophenyl)-3-(2-chloropropyl)triazene. The formation of acetone is rationalized by initial formation of the diazonium ion (from protonation of the preferred tautomer) and then a formation of the 2-chloropropyl-3-cation leads to acetone by the steps indicated in Scheme 5. This requires a hydride transfer from the 2-chloropropyl cation to form the more stable 2-chloropropyl-2-cation.

In this case proton loss from the initially formed cation to give 2-chloropropene is favored by the additional methyl substituent in contrast to the 2-chloroethylaryltriazene case where no detectable quantities of vinyl chloride were produced (Schemes 2 and 3).

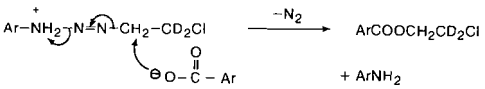
Nucleophilic attack by chloride ion (either S_N2 via the diazonium ion or by S_N1 reaction via the 2-chloropropyl-1-cation) accounts for 1,2-dichloropropene. Since both possible isomeric chloropropanols were identified as products, this



SCHEME 5



SCHEME 6



SCHEME 7

requires a rearrangement of the intermediate 2-chloro-1-propyl cation to the more stable 1-chloro-2-propyl cation. Thus in this example we employ a methyl group as a label rather than deuterium in Scheme 3. The observed ratio of 3:2 of 2-chloro-1-propanol:1-chloro-2-propanol is in accord with the expected greater contribution of this pathway compared with the approximately 10% contribution of the chloronium ion (26, 27) in Scheme 3. The fact that a greater yield of the chloropropanol product of the less stable cation is obtained suggests a substantial contribution of direct S_N2 attack on the precursor diazonium ion in Scheme 5 (such pathways have not been included in the schemes to simplify them.)

The observed order of decomposition of the homologous series of ω-haloalkyl-(*p*-cyanophenyl)-triazenes **10** > **26** > **24** > **25**, i.e. chloroethyl > chloropentyl > chloropropyl > chlorobutyl, deserves a comment. The fact that the chloroethyl homologue decomposes fastest is in accord with the intermediacy in this case only of the triazoline species. Analogous cyclization for **26**, **24**, and **25** is presumably precluded for entropic reasons. Moreover, only in the case of **10** can the chloronium ion contribute. The intervention of other pathways, involving a 1,2-hydride shift leading to a number of possible cationic intermediates in the 3, 4, and 5 carbon homologues, may account for the observed rate sequences which require detailed individual examination.

In connection with chloronium ion species, the observation of deuterium label scrambling in the decomposition of the 2-chloroethyltriazenes afforded an opportunity to investigate the mechanism of alkylation by these triazenes. Such a reaction has direct bearing on the cytotoxicity of triazenes which has been attributed in part to the alkylation of biological macromolecules. Alkylation of 3,5-dinitrobenzoic acid with 1-(*p*-cyanophenyl)-3-(2-chloro-2,2-dideuterioethyl)triazene afforded only the 2-chloro-2,2-dideuterioethyl 3,5-dinitrobenzoate, i.e. no detected label scrambling had occurred. This result is clearly at variance with one mechanism that has been suggested for this reaction (Scheme 6) (28). This mechanism requires the formation of a solvent caged ion pair which, since it permits Wagner–Meerwein rearrangement of the intermediate cation, would predict a certain degree of label scrambling as shown. A more likely pathway is by S_N2 displacement which correctly predicts the lack of label scrambling which is observed (Scheme 7). This result is then in accord with the previous conclusion of a substantial contribution from S_N2 mechanisms in the formation of products from the intermediate diazonium ions in Schemes 2, 3, and 5.

In conclusion, the above findings on the synthesis and details of the decomposition pathways of new 2-haloethylaryltriazenes may assist in the interpretation of their antitumor action. It may be noted in this connection that their observed tendency to decompose more rapidly under more acidic conditions may contribute to their selectivity of action owing to the characteristic of neoplastic tissue to exhibit somewhat lower pH than normal tissue (29, 30).

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer grating infrared spectrophotometer Model 421 and generally only the principal peaks are reported. Absorption spectra were measured in either distilled water or "spectrograde" solvents and were run on either a Beckman DB spectrophotometer, a Gilford 250 spectrophotometer, or a Unicam SP1700 UV spectrophotometer. Proton magnetic resonance spectra were recorded on Varian HA-100 or Bruker WH-200 instruments and were generally measured on a 10–15% (w/v) solution of the compound in the appropriate deuterated solvent. The reference compound was tetramethylsilane (TMS). Line positions are reported in ppm from the reference. Mass spectra

were determined with Associated Electrical Industries MS2, MS9, MS12, or MS50 (DS50) mass spectrometers. In general the ionization energy was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 1500. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for thin layer chromatography. Microanalyses were carried out by Mrs. D. Mahlow of this department.

General Procedure for 1(3)-Aryl-3(1)-2-haloalkyltriazenes

A solution of the aromatic amine (10 mmol) in concentrated hydrochloric acid (2.5 mL), diluted with water (12 mL) was diazotized at 0°C with sodium nitrite (0.80 g), dissolved in the minimum amount of water, and the resulting solution was stirred for 30 min or until clear. Excess acid was neutralized by addition of calcium carbonate (1.6 g). 2-Haloalkylamine hydrohalide (10 mmol) was dissolved in 5 mL water and deprotonated with potassium bicarbonate (11 mmol) (added solid) by stirring at 0°C until effervescence stopped. The diazonium salt solution was filtered cold and quickly transferred to the flask containing 2-haloalkylamine free base and then the reaction mixture was stirred for 5–10 min at 0°C. A precipitate of the triazene usually appeared immediately and was washed with cold water, air dried for 1 min, and transferred to a precooled test tube. The product was dissolved in a minimum amount of methylene chloride at room temperature whereupon an aqueous layer separated. The methylene chloride layer was carefully pipetted out and transferred to another precooled container. The triazene was precipitated out by cooling the methylene chloride solution to −30°C and adding cold petroleum ether dropwise. The precipitate was filtered, washed with cold petroleum ether, and air dried for 1–2 min.

Special precaution was exercized during the condensation of 2-bromoethylamine with the diazonium salt as well as in handling the product. The condensation was usually carried out at −10°C and the precipitate was transferred to a precooled test tube immediately after filtration in order to avoid decomposition. 2-Haloalkyltriazenes can be stored in Dry Ice for an indefinite period. The general procedure afforded the following triazenes.

1-(p-Nitrophenyl)-3-(2-fluoroethyl)triazene (6) (2.0 g, 95%), mp 98–100°C; ν_{max}: 3184, 3142, 1608, 1595, 1515, and 1340 cm^{-1}; δ (CD_2Cl_2, −20°C): 4.06 (2t, J_H = 5 Hz, J_F = 30 Hz, 2H, N—CH_2), 4.81 (2t, J_H = 5 Hz, J_F = 47 Hz, 2H, CH_2—F), 7.19–8.36 (m, 4H, aromatic), 8.5 and 9.55 (br 2s, exchangeable, 1H, NH); M^+: 212.0715 (45.90%) (calcd. for $C_8H_9FN_4O_2$: 212.0710); *m/e*: 184.0655 (M − N_2, calcd. for $C_8H_9FN_2O_2$: 184.0648), 164.0589 (2.38%) M − N_2 − HF, calcd. for $C_8H_8N_2O_2$: 164.0586), 150.0305 (68.78%) (M − NH − CH_2CH_2F, calcd. for $C_6H_4N_3O_2$: 150.0303), 138.0431 (27%) (M − N_2CHCH_2F, calcd. for $C_6H_6N_2O_2$: 138.0415), 122.0246 (100%) (calcd. for $C_6H_4NO_2$: 122.0228).

1-(p-Nitrophenyl)-3-(2-chloroethyl)triazene (7) (1.8 g, 79%) mp 64–66°C; ν_{max}: 3180, 3140, 1605, and 1595 cm^{-1}; δ ($CDCl_3$, −20°C): 3.9 (t, 2H, CH_2—Cl), 4.1 (t, 2H, N—CH_2), 7.2–8.35 (m, 4H, aromatic), 8.5 and 9.6 (1H, exchangeable, N—H); M^+: 228.0420 (2.45%) (calcd. for $C_8H_9ClN_4O_2$: 228.0414); *m/e*: 200.0361 (23.02%) (M − N_2, calcd. for $C_8H_9ClN_2O_2$: 200.0353), 164.0588 (18.12%) ((M − N_2) − HCl, calcd. for $C_8H_8N_2O_2$: 164.0586), 150.0346 (4.12%) (M − $NHCH_2CH_2Cl$, calcd. for $C_6H_4N_3O_2$: 150.0304), 138.0434 (37.79%) (M − N_2CHCH_2Cl, calcd. for $C_6H_6N_2O_2$: 138.0429).

1-(p-Nitrophenyl)-3-(2-bromoethyl)triazene (8) (1.2 g, 44%), mp 30–31°C; ν_{max} (due to rapid thermal decomposition the absorptions were too broad to be assigned to definite frequencies); δ ($CDCl_3$, −50°C): 3.8 (t, 2H, CH_2—Br), 4.25 (t, wH, N—CH_2), 7.2–8.3 (m, 4H, aromatic), 8.7 and 9.7 (br, 2s, 1H, N—H); *m/e*: 164.0599 (1.25%) ((M − N_2) − HBr, calcd. for $C_8H_8N_2O_2$: 164.0586), 138.0434 (100%).

1-(p-Cyanophenyl)-3-(2-fluoroethyl)triazene (9) (1.8 g, 93%), mp 95–96°C; ν_{max}: 3183, 3161, 2228, and 1609 cm^{-1}; δ ($CDCl_3$, −20°C): 4.08 (2t, J_H = 5 Hz, J_F = 30 Hz, 2H, N—CH_2), 4.8 (2t, J_H = 5 Hz, J_F = 47 Hz, 2H, CH_2—F), 7.2–7.75 (m. 4H, aromatic), 8.5 and 9.55 (br, 2s, exchangeable, 1H, N—H); M^+: 192.0804 (26.09%) (calcd. for $C_9H_9FN_4$: 192.0811); *m/e*: 164.0744 (1.39%) (M − N_2, calcd. for $C_9H_9FN_2$: 164.0750), 144.0683 (4.02%) ((M − N_2) − HF, calcd. for $C_9H_8N_2$: 144.0688), 130.0403 (33.87%) (M − $NHCH_2CH_2F$, calcd. for $C_7H_4N_3$: 130.0405), 118.0518 (32.11%) (M − N_2 − CH_2CH_2F, calcd. for $C_7H_6N_2$: 118.0531), 102.0342 (100%).

1-(p-Cyanophenyl)-3-(2-chloroethyl)triazene (10) (1.0 g, 48%), mp 68°C; ν_{max}: 3181, 3159, 2228, and 1608 cm^{-1}; δ (CD_2Cl_2, −45°C): 3.9 (t, 2H, CH_2—Cl). 4.1 (t, 2H, N—CH_2), 7.2–7.75 (m, 4H, aromatic), 8.55 and 9.6 (br, 2s, 1H, exchangeable, N—H); *m/e*: 182.0424 (7.23%) (M − N_2, calcd. for $C_9H_9ClN_2$: 182.0424), 144.0682 (9.74%) ((M − N_2) − HCl, calcd. for $C_9H_8N_2$: 144.0688), 132.0638 (11.06%), 131.0638 (100%), 118.0530 (62.79%).

1-(p-Cyanophenyl)-3-(2-bromoethyl)triazene (11) (yield 10–40%), mp 39°C. Compound **11** decomposed during ir scan; δ (CD_2Cl_2, −45°C): 3.7 (t, 2H, CH_2Cl), 4.9 (t, 2H, N—CH_2), 7.2–7.8 (m, 4H, aromatic), 8.7 (br, 1s, integrated for less than one proton, normally observed second broad singlet could not be traced, N—H); *m/e*: 225.9925 (20.26%) (M − N_2, calcd. for $C_9H_9N_2Br$: 225.9929), 144.0675 (9.74%) (M − N_2) − HBr, calcd. for $C_9H_8N_2$: 144.0688), 132.0638 (25.25%), 118.0531 (26.52%).

1-(p-Acetylphenyl)-3-(2-fluoroethyl)triazene (12) (0.8 g, 38%), mp 92–93°C; ν_{max}: 3192, 3161, and 1600 cm^{-1}; δ (CD_2Cl_2, − 45°C): 2.6 (s, 3H, Me), 4.08 (2t, J_H = 5 Hz, J_F = 30 Hz, 2H, N—CH_2), 4.84 (2t, J_H = 5 Hz, J_F = 47 Hz), 7.15–8.15 (m, 4H, aromatic), 8.94 and 10.0 (br, 2s, N—H); M^+: 209.0964 (35.12%) (calcd. for $C_{10}H_{12}FN_3O$: 209.0964); *m/e*: 182.0952 (41%) (M − N_2, calcd. for $C_{10}H_{13}FNO$: 182.0981), 148.0734 (16.55%), 135.0682 (44.49%), 120.0460 (87.20%) 119.0490 (100%).

1-(p-Acetylphenyl)-3-(2-chloroethyl)triazene (13) (0.6 g, 27%), mp 48–49°C; ν_{max}: 3188, 3158, and 1600 cm^{-1}; δ (CD_2Cl_2, − 45°C): 2.62 (s, 3H, Me), 3.9 (t, 2H, CH_2Cl), 4.12 (t, 2H, N—CH_2), 7.15–8.1 (m, 4H, aromatic), 8.7 and 9.75 (br, 2s, N—H); *m/e*: 197.0607 (21.67%) (M − N_2, calcd. for $C_{10}H_{12}ClNO$: 197.0607), 161.0851 (2.01%) ((M − N_2) − HCl, calcd. for $C_{10}H_{11}NO$: 161.0841), 148.0760 (77.08%), 120.0450 (100%).

1-(p-Ethoxycarbonylphenyl)-3-(2-fluoroethyl)triazene (14) (1.6 g, 56%), mp 85–87°C; ν_{max}: 3194, 3174, 1714, and 1610 cm^{-1}: δ (CD_2Cl_2, 200 MHz, − 55°C): 1.35 (t, 3H, Me), 4 (2t each accompanied by a multiplet at the base, J_H = 5 Hz, J_F = 47 Hz, 2H, N—CH_2), 4.27 (q, 2H, O—CH_2), 4.78 (2t, each accompanied by a triplet at the base, J = 5 Hz, J_F = 47 Hz, 2H, CH_2—F), 7.1–8.05 (m, 4H, aromatic), 8.6 (t, N—H, tautomer), 9.85 (br, s, N—H tautomer); M^+: 239.1077 (49.67%) (calcd. for $C_{11}H_{14}FN_3O_2$: 239.1070); *m/e*: 211.1017 (4.78%) (M − N_2, calcd. for $C_{11}H_{14}FNO_2$: 211.1008), 194.0737 (12.58%) (M − CH_2CH_3, calcd. for $C_9H_9FN_3O_2$: 194.0730), 191.0953 (6.93%) ((M − N_2 − HCl, calcd. for $C_{11}H_{13}NO_2$: 191.0947), 165.0795 (64.65%), 149.0599 (100%).

1-(p-Ethoxycarbonylphenyl)-3-(2-chloroethyl)triazene (15) (1.8 g, 70%), mp 58–60°C; ν_{max}: 3193, 3171, 1715, and 1605 cm^{-1}; δ ($CDCl_3$, − 30°C): 1.38 (t, 3H, Me), 3.84 (t, 2H, CH_2—Cl), 4.06 (t, 2H, N—CH_2), 4.34 (q, 2H, O—CH_2), 7.1–8.1 (m, 4H, aromatic), 8.55 and 9.58 (br, 2s, N—H); *m/e*: 227.0716 (21.16%) (M − N_2, calcd. for $C_{11}H_{14}ClNO_2$: 227.0713), 191.0949 (19.85%), ((M − N_2) − HCl, calcd. for $C_{11}H_{13}NO_2$: 191.0446), 165.0793 (71.29%), 120.0449 (100%).

1-(o-Nitrophenyl)-3-(2-fluoroethyl)triazene (16) (1.5 g, 70%), mp 30–31°C; ν_{max}: 3322, 1613, 1515, and 1338 cm^{-1}; δ ($CDCl_3$, −20°C): 4.08 (2t, J_H = 5 Hz, J_F = 30 Hz, 2H, N—CH_2), 4.84 (2t, J_H = 5 Hz, J_F = 47 Hz, 2H, CH_2—F), 6.94–8.34 (m, 4H, aromatic), 11.74 (s, 1H, NH); M^+: 212.0712 (67.61) (calcd. for $C_8H_9FN_4O$: 212.0710); *m/e*: 184.0650 (2.18%) (M − N_2, calcd. for $C_8H_9FN_2O_2$: 184.0648), 164.0589 (1.78%) ((M − N_2) − HF, calcd. for $C_8H_8N_2O_2$: 164.0586), 138.0430 (100%).

1(3)-(o-Nitrophenyl)3(1)-(2-chloroethyl)triazene (16a) (1.8 g, 79%), mp 55°C; ν_{max}: 3329, 1610, 1513, and 1338 cm^{-1}; δ ($CDCl_3$, −20°C): 3.92 (t, 2H, CH_2—Cl), 4.12 (t, 2H, N—CH_2), 6.94–8.34 (m, 4H, aromatic), 11.76 (s, 1H, NH); M^+: 228.0414 (21.74%) (calcd. for $C_6H_9ClN_4O_2$: 228.0414); *m/e*: 200.0353 (0.76%) (M − N_2, calcd. for $C_8H_9ClN_2O_2$: 200.0353), 164.0592 (1.02%) (calcd. for $C_8H_8N_2O_2$: 164.0586), 138.0429 (44.07%), 63.0121 (100%) (calcd. for C_2H_4Cl: 63.0001).

2-Amino-2,2-dideuterioethanol (17)

This compound was prepared by reducing glycolonitrile with lithium aluminum deuteride following the procedure of Brundrett *et al.* (23), bp 40–41°C/~0.15 Torr (lit. (23) bp 85–90°C/~10 Torr).

2-Chloro-2,2-dideuterioethylaminehydrochloride (18)

A solution of **17** (2 g, 21.6 mmol) in $CHCl_3$ (10 mL) was saturated with hydrogen chloride gas at 0°C. To the solution was added thionyl chloride (10 mL) diluted with $CHCl_3$ (10 mL) at 0°C and the solution was allowed to warm slowly to 70°C. The stirring was continued for 5 h. The solvent and the excess of the thionyl chloride were removed under vacuum. The residue was purified by recrystallization from absolute ethanol. Yield 1.5 g, 60%, mp 141–143°C (lit. (33) undeuterated, mp 143–146°C).

2-Amino-1,1-dideuterioethanol (19)

Compound **19** was prepared by reducing glycine ethyl ester with lithium aluminum deuteride following the procedure of Brundrett *et al.* (23), bp 35–38°C/~0.15 Torr (lit. (23) bp 83–88°C/~10 Torr).

1-Chloro-1,1-dideuterioethylaminehydrochloride (20)

The aminoethanol **19** was chlorinated following the procedure described for the chlorination of **17**, mp 144–146°C.

The following triazenes were also prepared by the general procedure. The diazonium salt solutions were allowed to react with the corresponding chloro-alkylamines and the products were purified by recrystallization at low temperature.

1-(p-Cyanophenyl)-3-(2-chloro-1,1-dideuterioethyl)triazene (21), mp 66–67°C; ν_{max}: 3181, 3160, 2224, and 1608 cm^{-1}; δ (CD_2Cl_2, − 10°C): 3.84 (s, 2H, CH_2—Cl), 7.2–7.75 (m, 4H, aromatic), 8.56 and 9.15 (br, 2s, exchangeable, N—H); M^+: 210.0644 (3.03%) (calcd. for $C_9H_7D_2ClN_4$: 210.0641), 182.0578 (18.69%) (M − N_2, calcd. for $C_9H_7D_2ClN_2$: 182.0580), 146.0810 (23.62%) ((M—N_2) − HCl, calcd. for $C_9H_6D_2N_2$: 146.0813), 118.0532 (100%).

1-(p-Cyanophenyl)-(3)-(2-chloro-2,2-dideuterioethyl)triazene (22), mp (67–68°C); ν_{max}: 3181, 3159, 2224, and 1608 cm^{-1}; δ (CD_2Cl_2, − 15°C): 4.03 (s, 2H, N—CH_2), 7.2–7.70 (m, 4H, aromatic), 8.5 and 9.45 (br s, exchangeable, N—H); M^+: 210.0661 (0.50%) (calcd. for $C_9H_7D_2ClN_4$: 210.0641); *m/e*: 182.0581 (63.95%) (M − N_2, calcd. for $C_9H_7D_2ClN_2$: 182.0580), 146.0811 (33.91%) ((M − N_2) − HCl, calcd. for $C_9H_6D_2N_2$: 146.0813), 133.0724 (100%).

1-(p-Cyanophenyl)-3-(2-chloropropyl)triazene (23), (1.5 g, 72%), mp 74–75°C; compound **23** decomposed during ir scan; δ (CD_2Cl_2, −20°C): 1.56 (2d, 3H, CH_3), 3.95 (2d, 2H, N—CH_2), 4.4 (m, 1H, CHCl), 7.2–7.8 (m, 4H, aromatic), 8.6 and 9.5 (br, 2s, exchangeable, N—H); M^+: 222.0672 (12.10%) (calcd. for $C_{10}H_{11}ClN_4$: 222.0672), 194.0613 (0.57%) (M − N_2, calcd. for $C_{10}H_{11}ClN_2$: 194.0611), 158.0844 (1.55%) ((M − N_2) − HCl calcd. for $C_{10}H_{10}N_2$: 158.0844), 118.0530 (30.08%), 102.0344 (100%).

1-(p-Cyanophenyl)-3-(3-chloropropyl)triazene (24), (1.5 g, 67%), mp 64–65°C; ν_{max}: 3186, 3162, 2228, and 1610 cm^{-1}; δ (CD_2Cl_2, −15°C): 2.18 (t, 2H, —CH_2—), 3.65 (t, 2H, CH_2—Cl), 6.85 (t, 2H, N—CH_2), 7.2–7.8 (m, 4H, aromatic), 8.5 and 9.5 (br, 2s, exchangeable, N—H); M^+: 222.0673 (7.79%) (calcd. for $C_{10}H_{11}ClN_4$: 222.0673), 194.0609 (3.62%) (M − N_2 calcd. for $C_{10}H_{11}ClN_2$: 194.0611), 158.0841 (7.93%) ((M − N_2) − HCl, calcd. for $C_{10}H_{10}N_2$: 158.0843), 132.0639 (2.55%), 131.0438 (1.26%), 118.0531 (100%).

1-(p-Cyanophenyl)-3-(4-chlorobutyl)triazene (25), (1.6 g 67%), mp 82°C; ν_{max}: 3186, 3163, 2220, and 1608 cm^{-1}; δ (CD_2Cl_2, −15°C): 1.85 (br, m, 4H, —CH_2CH_2—), 3.4–3.85 (br, m, 4H, N—CH_2 and CH_2—Cl), 7.2–7.8 (m, 4H, aromatic), 8.35 and 9.4 (br, 2s, exchangeable, N—H); M^+: 236.0829 (12.05%) (calcd. for $C_{11}H_{13}ClN_4$: 236.0829); *m/e*: 208.0768 (1.53%) (M − N_2, calcd. for $C_{11}H_{13}ClN_2$: 208.0768), 172.0921 (0.24%) ((M − N_2) − HCl, calcd. for $C_{11}H_{12}N_2$: 172.1010), 131.0573 (16.39%), 118.0529 (56.77%), 102.0343 (100%).

1-(p-Cyanophenyl)-3-(5-chloropentyl)triazene (26), (2.16 g, 84%), mp 66°C; ν_{max}: 3182, 3160, 2220, and 1610 cm^{-1}; δ (CD_2Cl_2, −15°C): 1.7 (br, m, 6H), 3.65 (br, sextet, N—CH_2 and CH_2—Cl), 7.2–7.8 (m, 4H, aromatic), 8.4 and 9.5 (br, 2s, exchangeable, N—H); M^+: 250 (6.12%) (calcd. for $C_{12}H_{15}ClN_4$: 250.0985); *m/e*: 222.0926 (1.33%) (M− N_2, calcd. for $C_{12}H_{15}N_2$: 222.0924), 131.0569 (12.78%), 118.0529 (100%).

1-(p-Acetylphenyl)-3-(3-chloropropyl)triazene (27), (1.2 g, 50%), mp 50–51°C; ν_{max}: 3186, 3157, 1674, and 1600 cm^{-1}; δ (CD_2Cl_2, −45°C): 2.2 (br, 2H, —CH_2—), 2.62 (s, 3H, Me), 3.67 (t, 2H, CH_2—Cl), 3.92 (t, 2H, N—CH_2), 7.15–8.1 (m, 4H, aromatic), 8.5 and 9.65 (br, 2s, N—H); M^+: 239.0825 (1.70%) (calcd. for $C_{11}H_{14}ClN_3O$: 239.0826), 211.0765 (1.09%), (M—N_2, calcd. for $C_{11}H_{14}ClNO$: 211.0766), 175.0996 (3.56%) ((M − N_2) − HCl, calcd. for $C_{11}H_{13}NO$: 175.0997), 120.0450 (83.85%).

5-[3-(2-Fluoroethyl-1-triazenyl]-imidazole-4-carboxamide (28)

Compound **28** was prepared following the procedure of Shealy *et al.* (2). 2-Fluoroethylamine free base (400 mg, 6.3 mmol) was taken in dry ethyl acetate (30 mL) and stirred under nitrogen. To the stirred solution was added thoroughly dried 5-diazoimidazole-4-carboxamide (800 mg, 4.6 mmol) in one portion. The reaction mixture was protected from light and the stirring was continued for 1 h. The resulting white solid was collected by filtration, washed with ethyl acetate, and dried *in vacuo* at room temperature, yielding 850 mg (92%) of the triazene, mp 119°C (dec); δ_{max}: 3478, 3249, 3079, 1645, 1585, 1430, and 1380 cm^{-1}; *m/e*: 138.0396 (11.75%) (M − $NHCH_2CH_2F$, calcd. for $C_4H_4N_5O$: 138.0398), 137.0341 (100%). *Anal.* calcd. for $C_6H_9N_6O$: C 36.0, H 4.5, N 42.0; found: C 35.6, H 4.5, N 41.6%.

General Procedure for the Esterification of 3,5-Dinitrobenzoic Acid by Phenyl-2-haloalkyltriazenes

The triazene (4 mmol) was suspended in ether (15 mL) at −20°C. To the stirring suspension was added dropwise 3,4-dinitrobenzoic acid (700 mg, 3.3 mmol) dissolved in ether (20 mL). After the addition was completed, the reaction mixture was allowed to warm up to room temperature and the stirring was continued for another 2 h. The reaction mixture was filtered and the solvent was evaporated leaving a syrupy residue which on tituration with chloroform deposited most of the unreacted acid. The ester was purified by chromatography on silica using benzene as eluant. When the imidazole triazene **28** was used, the reaction mixture was stirred for two days at room temperature protected from light at all times. This procedure afforded the following esters in varying yield.

2-Fluoroethyl-3,5-dinitrobenzoate (29)

From **9** and **28**, yield 60% and 30% respectively, mp 84–85°C (lit. (31) mp 86°C); ν_{max}: 1735, 1625, 1545, and 1340 cm^{-1} (in CH_2Cl_2); δ ($CDCl_3$, 200 MHz): 4.7 (m, 2H, O—CH_2), 4.99 (2m, 2H, CH_2—F), 9.18–9.3 (m, 3H). Aromatic compound **29** was identical in every respect with a sample obtained from reaction of 3,5-dinitrobenzoyl chloride with 2-fluoroethanol.

2-Chloroethyl-3,5-dinitrobenzoate (30)

From **10**, yield 40%, mp 89–90°C (lit. (32) mp 92°C); ν_{max}: 1735, 1625, 1545, and 1340 cm^{-1}; δ (CD_2Cl_2): 3.88 (t, 2H, CH_2—Cl), 4.72 (t, 2H, OCH_2), 9.14–9.28 (m, 3H, aromatic); M^+: 273.9981 (2.98%) (calcd. for $C_9H_7N_2O_6Cl$: 273.9992); *m/e*: 239.0299 (5.78%) (M − Cl, calcd. for $C_9H_7N_2O_6$: 239.0304). Compound **30** was identical with a sample obtained from reaction of 3,5-dinitrobenzoylchloride with 2-chloroethanol.

2-Chloro-2,2-dideuterioethyl-3,5-dinitrobenzoate (31)

From **22**, yield 40%, mp 89°C; ν_{max}: 1735, 1625, 1535, and 1340 cm^{-1}; δ ($CDCl_3$): 4.6 (s, 2H, O—CH_2), 9.1–9.3 (m, 3H, aromatic); M^+: 276.0117 (8.53%) (calcd. for $C_9H_5D_2ClN_2O_6$: 276.0117). *Anal.* calcd. for $C_9H_5D_2ClN_2O_6$: C 39.05, N 10.12; found: C 39.18, N 9.83%.

2-Bromoethyl-3,5-dinitrobenzoate (32)

From **11**, yield 10%, mp 82°C (lit. (33) mp 85–86°C); ν_{max}: 1740, 1625, 1540, and 1340 cm^{-1}; δ ($CDCl_3$): 3.70 (t, 2H, CH_2—Br), 4.66 (t, 2H, O—CH_2), 9.1–9.3 (m, 3H, aromatic). Compound **32** was identical with a sample obtained from reaction of 3,5-dinitrobenzoylchloride with 2-bromoethanol.

Acknowledgements

Solvent induced frequency shifts of the C—H stretching bands of *n*-octane. A Fourier transform infrared study[1]

D. G. CAMERON, S. C. HSI,[2] J. UMEMURA,[3] AND H. H. MANTSCH

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received December 10, 1980

D. G. CAMERON, S. C. HSI, J. UMEMURA, and H. H. MANTSCH. Can. J. Chem. **59**, 1357 (1981).

Using a Fourier transform spectrometer the frequencies and bandwidths of the infrared active C—H stretching modes of *n*-octane were determined in a variety of solvents with refractive indices from 1.63 (carbon disulfide) to 1.28 (*n*-perfluorooctane), and dielectric constants from 37.5 (acetonitrile) to 1.8 (*n*-perfluorooctane). The frequency shifts were correlated with the refractive indices and dielectric constants of the solvents, and fitted with the equation of David and Hallam (Spectrochim. Acta, Part A, **23**, 593 (1967)). Generally, solution results in shifts to frequencies lower than those observed in the gas phase. However, solution in *n*-perfluorooctane resulted in a shift to a higher frequency, behavior in accord with the above equation but not previously observed.

D. G. CAMERON, S. C. HSI, J. UMEMURA et H. H. MANTSCH. Can. J. Chem. **59**, 1357 (1981).

Utilisant un spectromètre à transformation de Fourier et opérant dans des solvants dont l'indice de réfraction varie de 1,63 (sulfure de carbone) à 1,28 (*n*-perfluorooctane) et la constante diélectrique varie de 37,5 (acétonitrile) à 1,8 (*n*-perfluorooctane), on a déterminé les fréquences et les largeurs des bandes de vibration du C—H, du *n*-octane actives dans l'infrarouge. On a établi une corrélation entre les déplacements des fréquences et les indices de réfraction et les constantes diélectriques des solvant et on les a ajustés avec l'équation de David et Hallam (Spectrochimica Acta, Part A, **23**, 593 (1967)). Généralement la mise en solution provoque des déplacements de fréquence qui sont plus faibles que ceux observés en phase gazeuse. Cependant la mise en solution dans le *n*-perfluorooctane provoque un déplacement vers les hautes fréquences; ce comportement, en accord avec l'équation mentionnée ci-dessus, n'avait pas encore été observé jusqu'à maintenant.

Introduction

In a recent study (1) of micelle formation in aqueous solutions of sodium *n*-alkanoates the C—H stretching bands of the acyl chains were observed at frequencies substantially higher than those reported in the literature. These high frequencies were found at low concentrations at which the alkanoates are present in the monomeric form, and we tentatively attributed the shifts to solvent induced effects.

Solvent induced frequency shifts have been extensively studied since the initial applications of Onsager's theory (2–4). However, the studies have generally been restricted to localized vibrations of small molecules in order to approximate a diatomic oscillator (5–7). We were unable to locate a report on solvent effects on the C—H stretching bands of acyl chains. Consequently, we have investigated the solvent induced frequency shifts of *n*-octane using a Fourier transform infrared spectrometer, and report the results herein.

Experimental

Materials were of spectroscopic or analytical reagent grade and their purities were checked by gas–liquid chromatography prior to their use.

The gas phase spectrum was recorded in a 100 cm pathlength cell at a pressure of 10 Torr. For solution spectra, demountable 25 μm pathlength calcium fluoride cells were used. The spectrum of pure *n*-octane was recorded in a 2.5 μm calcium fluoride cell. As the peak absorbances in the solutions used in the study (1% by volume) were about 0.01, frequency errors due to anomalous dispersion effects were negligible (8). Slight frequency errors can be expected in the case of pure *n*-octane. However, as the bands are quite broad (20–30 cm^{-1} half bandwidth) the effect is expected to be small. This was confirmed by plotting frequency versus concentration over the concentration range 1% v/v to 100% v/v. Linear plots were obtained with both CS_2 and CCl_4 as solvents, whereas nonlinearities would be expected if there were appreciable anomalous dispersion effects.

Spectra were recorded at 25°C on a Digilab FTS-11 Fourier transform infrared spectrometer equipped with a 15 μm low frequency cutoff high sensitivity mercury cadmium telluride detector (Infrared Associates, New Brunswick, NJ). Typically, 400 interferograms recorded with an optical velocity of 1.2 cm s^{-1} and maximum optical retardation of 0.25 cm were co-added, apodized with a triangular function, and Fourier transformed with 4 levels of zero filling resulting in a spectral resolution of 4 cm^{-1}.

Frequencies were determined by computing the center of area of the topmost segment of a band employing data points within ±1 cm^{-1} of the frequency of the maximum encoded data point. As the frequency scale of this instrument is reproducible to within ≤ ±0.005 cm^{-1} this technique yields frequencies accurate and reproducible to better than ±0.1 cm^{-1} (9). Bandwidths were determined by subtracting a baseline interpolated between 2990 and 2820 cm^{-1} from the spectrum and computing the width at nine-tenths height of the resultant band.

Refractive indices were determined at 25°C at the sodium

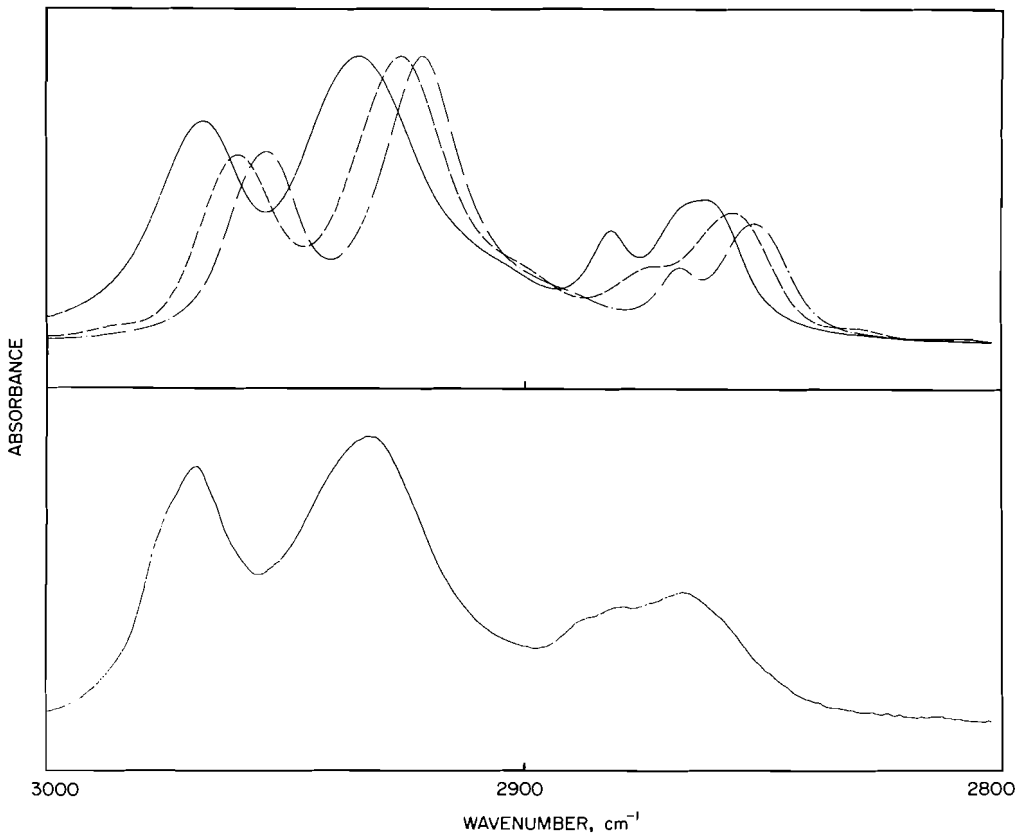

FIG. 1. C—H stretching region of the infrared spectrum of *n*-octane. Top: pure liquid (---); 1% v/v solution in carbon disulfide (——·——); 1% v/v solution in *n*-perfluorooctane (—). Bottom: vapour phase, 40 Torr in 1 m cell.

wavelength using an Abbé refractometer and agreed with literature values. The refractive index of perfluoromethylcyclohexane was determined by linear extrapolation of a plot of refractive index versus concentration of a series of solutions of perfluoromethylcyclohexane in hexafluorobenzene. Experimental values were linear over the range 1% v/v to 70% v/v. Dielectric constants were taken from the literature (10).

Results and Discussion

Figure 1 shows the C—H stretching region of the infrared spectrum of *n*-octane as a gas, liquid, and 1% v/v solutions in carbon disulfide and *n*-perfluorooctane. Four fundamentals are present in each spectrum. They result from the asymmetric and symmetric methyl and methylene stretching modes although in the vapour phase spectrum the symmetric bands can not be distinguished due to overlap of the bands and the superposition of rotational structure.

The changes on going from the gas to the liquid phases are typical of those observed on condensation. The rotational structure is lost and all bands shift to lower frequency. Solution in carbon disulfide, which has the highest refractive index ($n_D = 1.632$) of the solvents employed in this study, results in further shifts to lower frequency and some reduction of the bandwidth. Solution in *n*-perfluorooctane ($n_D = 1.282$) results in shifts to frequencies close to those of the gas phase, and broadening of the bands.

These spectra and spectral changes represent the largest variations observed in the study. The detailed results observed with these and the other solvents are discussed below.

Frequency Shifts

Table 1 lists the frequencies of the asymmetric C—H stretching bands in the infrared spectra of gaseous and liquid *n*-octane, and 1% v/v solutions of *n*-octane in a variety of solvents. Also listed are the refractive indices and the dielectric constants of the solvents.

Attempts were made to relate the frequency shift on solution to the refractive indices and dielectric constants of the solvents. Of the various equations used (3, 5, 11) only that of David and Hallam (11) resulted in a satisfactory fit of the data. The equation has the form

$$[1] \quad \Delta\nu = C_1 + C_2(n^2 - 1)/(n^2 + 2) + C_3(\varepsilon - 1)/(\varepsilon + 2)$$

TABLE 1. Solvent induced frequency shifts (in cm^{-1}) of the asymmetric C—H stretching bands of *n*-octane

	Asymmetric CH_3 stretch		Antisymmetric CH_2 stretch			
	ν	Δν	ν	Δν	n_D	ε
Vapour	2969.2		2932.6

TABLE 2. Differences (in cm^{-1}) between calculated and observed frequency shifts, and bandwidths at nine-tenths peak height of the C—H stretching bands of *n*-octane

	Asymmetric CH_3 stretch		Antisymmetric CH_2 stretch	
	$\nu_{obs} - \nu_{calc}$	$\Delta\nu_{0.9}$	$\nu_{obs} - \nu_{calc}$	$\Delta\nu_{0.9}$
Carbon disulfide	−0.1	7.2	−0.9	6.8
Tetrachloroethylene	+0.4	7.5	+0.6	8.4
Carbon tetrachloride	−0.6	7.2	−0.4	7.9
Chloroform-*d*	−0.3	7.5	+0.3	8.5
Hexafluorobenzene	+1.0	9.0	+2.0	10.3
Acetone-d_6	−0.5	7.3	−0.1	9.4
Acetonitrile	+0.6	6.5	—	—
n-Perfluorooctane	+0.3	7.9	+0.7	10.9
Perfluoromethylcyclohexane	−0.8	8.9	−2.1	12.9

where Δν is the difference in frequency between the gas and solution phase spectra, and C_1, C_2 and C_3 are constants. Using the data in Table 1, the coefficients of the equations for the asymmetric methyl and methylene stretching bands obtained by least-squares solution are:

CH_3 asymmetric stretch

$$C_1 = -10.7, C_2 = 68.8, C_3 = 3.62$$

CH_2 antisymmetric stretch

$$C_1 = -13.4, C_2 = 63.1, C_3 = 3.64$$

In these equations the refractive index term dominates and the effects of the dipolar interactions are an order of magnitude smaller. Nonetheless the latter term is critical; even in the case of low dielectric constant solvents, neglect of the term results in a less satisfactory fit of the data.

The degree to which the data are fitted is shown in Table 2, which lists the differences between the observed (ν_{obs}) and calculated (ν_{calc}) frequency shifts. The maximum differences for the methyl and methylene bands are 1.0 and 2.1 cm^{-1}, respectively. The fit of the methyl frequencies is slightly better than that of the methylene frequencies. The most probable cause is that the methyl band of *n*-octane is not affected by differences in conformational distribution in the various solvents, while the methylene band is (12).

We also note that in *n*-perfluorooctane solution the methylene stretching band is at a higher frequency than in the gas phase. That this can occur when $\varepsilon - 1$ is small, C_1 is negative, and $|C_1| > C_2(n^2 - 1)/(n^2 + 2)$, is apparent from eq. [1]; furthermore, Buckingham (7) has suggested the possibility of a blue frequency shift from his theoretical treatment. However, as far as we can ascertain, a shift to higher frequency of the C—H stretching band has not been previously reported. The situation in another example of such a shift, the nitroxyl chloride stretching band (13), is quite different from the present case, in that the band shifts to higher frequencies as the polarity or the dielectric constant of the solvent increases.

Bandwidths

Table 2 also lists the widths at nine-tenths height of the asymmetric CH_3 and CH_2 stretching bands of *n*-octane in 1% v/v solutions. There is no simple correlation between refractive index and bandwidth. However, it is evident that in the fluorinated solvents the bandwidths are substantially greater. As this effect is observed in both the aromatic and aliphatic fluorocarbon solvents, it appears to be associated with the presence of fluorine. Broadening is indicative of either increased rotational relaxation or increased vibrational relaxation, and these are generally incompatible with each other. Fluorocarbons are known to have very low surface tensions which are another expression of the low intermolecular forces present (14). Therefore, the solute–solvent interaction is expected to be substantially smaller in the fluorocarbon solvents than in others, resulting in greater motional freedom of the solute molecule and hence rapid rotational relaxation in fluorocarbons, thus suppressing the vibrational relaxation.

Summary

The frequencies of the C—H stretching bands of acyl chains have been shown to be sensitive to solvent–solute interactions and behave as predicted by the David and Hallam equation. A shift to higher frequency has been demonstrated on going from the gas phase to an *n*-perfluorooctane solution. In addition, fluorinated solvents produce a substantial broadening of the C—H stretching bands compared to the other solvents studied.

In general, although the frequency shifts are not large, their precise determination is well within the capability of modern infrared instrumentation. Acyl chains are found in a wide variety of systems, such as polymers, fatty acids, surfactants, and lipids. As vibrational spectroscopic techniques are increasingly used to monitor the acyl chain properties in such systems, it is apparent that as more complex systems are more precisely studied, solvent induced shifts must be carefully considered in the interpretation of the data.

Effect of short-chained sodium alkylsulfate micelles on the kinetics of metal complex formation

PAUL D. I. FLETCHER[1] AND VINCENT C. REINSBOROUGH

Department of Chemistry, Mount Allison University, Sackville, N.B., Canada E0A 3C0

Received November 10, 1980

PAUL D. I. FLETCHER and VINCENT C. REINSBOROUGH. Can. J. Chem. **59**, 1361 (1981).

The kinetics of the reaction between Ni_{aq}^{2+} and the bidentate ligand pyridine-2-azo-*p*-dimethylaniline (PADA) have been investigated in micellar solutions of sodium decyl-, octyl-, and hexylsulfates using the stopped-flow technique. The rate of enhancement decreased with decreasing alkyl-chain length and from the Berezin or Robinson model could be quantitatively related to the independently measured binding constants of Ni^{2+} ion and PADA to the micelle surface. The dramatic effect of micelles upon the reaction rates in different directions of the Ni^{2+}/PADA and the Ni^{2+}/ murexide reactions served as sensitive indicators of the cmc even at the very limit of micelle formation which relatively concentrated sodium hexylsulfate solutions represent.

PAUL D. I. FLETCHER et VINCENT C. REINSBOROUGH. Can. J. Chem. **59**, 1361 (1981).

En utilisant la technique de flux stoppé, on a étudié la cinétique de la réaction entre le Ni_{aq}^{2+} et le ligand bidentate, pyridine azo-2 *p*-diméthylaniline (PADA), dans des solutions micellaires de décylsulfate, d'octylsulfate et d'hexylsulfate de sodium. Le taux d'augmentation de la vitesse diminue avec la longueur de la chaîne alkylée et, à partir du modèle de Berezin ou de Robinson, on peut le relier quantitativement aux constantes de liaison entre l'ion Ni^{2+} et la PADA à la surface de la micelle que l'on peut mesurer indépendamment. L'effet dramatique des micelles sur les vitesses de réaction dans les différentes directions des réactions de Ni^{2+}/PADA et du Ni^{2+}/murexide servent d'indicateurs sensibles de cmc même à la limite de la formation de la micelle ce qui est le cas pour des solutions relativement concentrées d'hexylsulfate de sodium.

[Traduit par le journal]

Introduction

The mechanism whereby sodium dodecylsulfate (SLS) micelles increase the rate of complex formation between Ni_{aq}^{2+} and neutral bidentate ligands such as pyridine-2-azo-*p*-dimethylaniline (PADA) has been adequately characterized (1–4). The kinetic model successfully predicts the effect of changes of pH, of ligand, and of reactant concentrations. The reaction occurs in the surface region of the micelle and the rate increase depends upon the independently measured extent of binding of ligand to the micelle.

In SLS micellar solutions at concentrations greater than twice the critical micelle concentration (cmc), both the nickel ion and PADA are strongly adsorbed into the surface region of the micelle so that any effects of partitioning of the reactants at low ionic strength into the bulk water upon the apparent rate are negligible. With ligands less hydrophobic than PADA, where an appreciable amount of the ligand is in the bulk water, the rate enhancement of the SLS micelles upon the Ni^{2+}–ligand complex formation is less dramatic (2). The kinetic model successfully accounts for the observed kinetic constant by allowing for this distribution of ligand between the micellar surface region and the bulk water.

The effect of significant partitioning of the other reactant, Ni^{2+}, into the bulk water from the micellar surface upon the enhancement of the rate of these reactions has not hitherto been reported. White[2] had noted in a preliminary study that decreasing the length of the carbon chain in the members of the sodium alkylsulfate series had led to a decrease in the rate enhancing effect of the micelles for this particular reaction.

In the case of both reactants partitioning significantly between the micelle surface and the bulk water, the more complex kinetic expression can still be readily interpreted. It was for this reason that the reaction between Ni_{aq}^{2+} and the ligand PADA was studied kinetically in sodium decylsulfate (SDS) solutions, in sodium octylsulfate (SOS) solutions, and in sodium hexylsulfate (SHS) solutions. We wished also to gain more information on the micellization phenomenon as it occurs with short-chained surfactants with which little work has been done.

Experimental

The stopped-flow instrumentation and technique did not differ significantly from that described previously (2, 5); the deadtime was less than two milliseconds. The nickel ion concentrations were varied from 5×10^{-4} to 1.5×10^{-3} mol dm^{-3} while the PADA concentration, to maintain pseudo-first order conditions, was kept constant at 5×10^{-6} mol dm^{-3}. The pH of

all solutions was manually adjusted with a glass electrode to 8.2 ± 0.2 to prevent protonation of the ligand and hydrolysis of the nickel ion (1) on the micelle surface. Analysis of the experimental transients was performed from Polaroid photographs of the storage oscilloscope traces. When the micellar reaction rate was much faster than the bulk solution rate, exponential traces were obtained. In SHS solutions especially, where the rates were within an order of magnitude of each other, the initial region of the observed trace was used to obtain the observed kinetic constant (k_{obs}) for the micellar reaction.

The solubilities of PADA in the various micellar solutions were measured at 25°C by means of a Cary 219 spectrophotometer. The electrical conductivities of SOS solutions were measured using a dip-cell and a RC-18A Beckman conductivity bridge. The sharp break in the plot of the conductivity vs. concentration was interpreted as the cmc. The presence of 5×10^{-4} mol dm^{-3} Ni_{aq}^{2+} did not alter the cmc in SOS solutions within experimental error. This was presumably due to the large excess of Na_{aq}^{+} ions (approx. 0.2 mol dm^{-3}) largely present as surfactant counter ions. In contrast, for very pure SLS, the cmc is $\sim 8 \times 10^{-3}$ mol dm^{-3} and is strongly dependent on the concentration of added electrolyte.

PADA was supplied by Sigma Chemicals, SDS by Schwarz-Mann, and SOS and SHS by Eastman Kodak. All of the reagents were of the highest purity except SHS (practical grade), where it was felt that purifying the surfactant would not improve the results. Only an approximate value of k_{obs} could be obtained with SHS because, as mentioned above, coupling of the fast and slow reactions could not be eliminated.

Results and Discussion

The overall reaction between Ni_{aq}^{2+} and PADA may be represented as

$$Ni_{aq}^{2+} + PADA \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} NiPADA^{2+}$$

for which the kinetic equation is

$$[1] \quad k_{obs} = k_1 [Ni^{2+}]_T + k_{-1}$$

where k_{obs} is the observed first-order rate constant for metal-complex formation and $[Ni^{2+}]_T$ is the total nickel ion concentration in mol dm^{-3} (2). Equation [1] is valid when $[Ni^{2+}]_T \gg [PADA]$.

When the reaction occurs in the micelle surface region as well as in the bulk water, the reaction scheme is enlarged as follows (2):

$$\begin{array}{ccc} Ni_w^{2+} + PADA_w & \underset{k_{-1}^{w}}{\overset{k_1^{w}}{\rightleftharpoons}} & NiPADA_w^{2+} \\ \Big\downarrow\Big\uparrow K_{Ni} \quad \Big\downarrow\Big\uparrow K_{PADA} & & \Big\downarrow\Big\uparrow K_c \\ Ni_M^{2+} + PADA_M & \underset{k_{-1}^{M}}{\overset{k_1^{M}}{\rightleftharpoons}} & NiPADA_M^{2+} \end{array}$$

The subscript or superscript M denotes the micellar surface region and w, the bulk water. K_{Ni}, K_{PADA}, and K_c are the equilibrium constants for the distribution between the bulk water and micellar surface regions for Ni^{2+} ion, PADA ligand, and metal–ligand complex, respectively. The equilibrium constants are defined for the general case as

$$K_A = [A_M]/C[A_W]$$

where C is (C_T − cmc) with C_T being the total surfactant concentration. C is a measure of the concentration of the micellar surfactant and is proportional to the micellar surface area.

The metal–ligand complex should be the most strongly adsorbed species of the three into the micellar surface region since both hydrophobic and coulombic interactions are operative. Thus, it is reasonable to neglect the K_c contribution to the overall rate of reaction.

When this pathway is neglected, the kinetic expressions, which result from a treatment analogous to that of Berezin (6), for the apparent forward rate constant for a pseudo-first order reaction in the micellar surface region, become

$$[2a] \quad {}^{M}k_1^{app} = k_1{}^{M}/[CV\{1 + (CK_{Ni})^{-1}\} \times \{1 + (CK_{PADA})^{-1}\}]$$

and

$$[2b] \quad {}^{w}k_1^{app} = k_1{}^{w}/[(1 + CK_{Ni}) \times (1 + CK_{PADA})(1 - CV - C_T\bar{V}]$$

where V is the reaction volume per mole of micellar surfactant and $\bar{V}$ is the partial molar volume of surfactant.

The surface and bulk water reactions can couple together to produce a composite overall rate under certain partitioning conditions. Since the kinetic trace was analyzed only for the faster pseudo-first order rate constant, eq. [2*a*] only need be considered, i.e.

$$[3] \quad k_1{}^{app} = k_1{}^{M}/CV\{1 + (CK_{Ni})^{-1}\} \times \{1 + (CK_{PADA})^{-1}\}$$

It must be noted that eqs. [2] and [3] are valid only when the partitioning equilibria are established rapidly relative to the reaction rate.

If the alternative analysis of Robinson and coworkers (1, 2) is followed, then a similar expression is obtained with the same assumptions:

$$[4] \quad k_1{}^{app} = k_1{}^{M}/CAN\{1 + (CK_{Ni})^{-1}\} \times \{1 + CK_{PADA})^{-1}\}$$

where A is the effective surface area per head group at the micelle surface and N is Avogadro's Number. The two $k_1{}^{M}$ values cannot be compared since they are dimensionally different, reflecting the different conceptual approaches of the two models. Berezin defines the surface reaction as occurring within a certain volume V which probably amounts

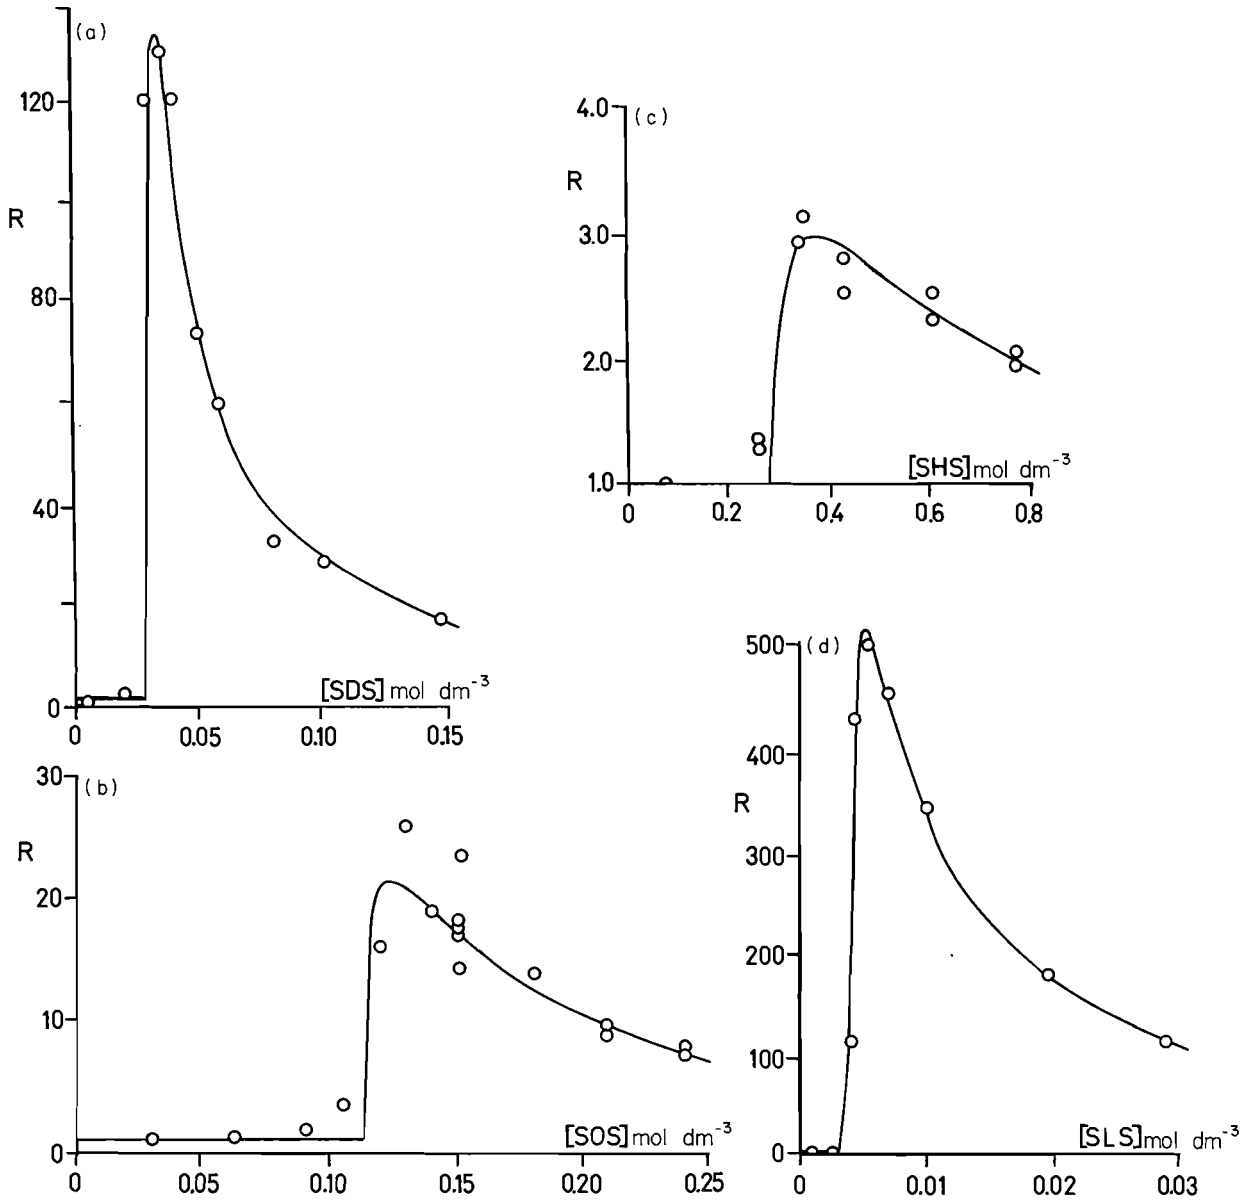

FIG. 1. Dependence of k_1^{app}/k_1^0 or R upon surfactant concentration at 25°C for (a) SDS, (b) SOS (c) SHS, and (d) SLS solutions. The open circles are data points while the curves have been fitted according to eq. [3].

to the combined volumes of the Stern layer and the shell of deepest penetration of the reactants. Berezin estimated V to be 3/4 of the total volume for the SLS micelle and approximated V by the molar volume of the surfactant (6). As yet, V cannot be independently measured and remains an adjustable parameter. Robinson and co-workers (1, 2) view the reaction as occurring on the outer skin of the micelle thus reducing the reaction volume to a reaction area defined by the effective cross-sectional area of the polar group of the surfactant.

The relationship between k_{obs} and k_1^{app} is given by the equation

$$[5] \quad k_{obs} = k_1^{app}[Ni^{2+}]_T + k_{-1}^M$$

Values of k_{-1}^M were obtained as the intercepts of the linear plots of k_{obs} against $[Ni^{2+}]_T/C\{1 + (CK_{Ni})^{-1}\}\{1 + (CK_{PADA})^{-1}\}$. Since k_{-1}^M was normally much less than $k_1^{app}[Ni^{2+}]_T$, values of k_1^{app} were not strongly dependent on the relatively inaccurate values obtained for k_{-1}^M. The ratio $R(= k_1^{app}/k_1^w)$, where k_1^w is the forward rate constant

for the metal–ligand complex formation in water at 25°C ($k_1^w = 1.2 \pm 0.1 \times 10^3$ dm^3 mol^{-1} s^{-1} (1)), gives a direct measure of the forward rate enhancement and these ratios for the SDS, SOS, and SHS systems are shown in Figs. 1(a), (b), and (c), respectively. Corresponding data from the literature for SLS (3) are given in Fig. 1(d). The curves are all similar and the four zones of Holzwarth *et al.* (3) are clearly delineated. On approaching the cmc region from the dilute concentration side in very short-chained surfactant solutions, the slight increase in the rate of reaction that occurs can be explained simply as a concentrative effect as the volume fraction of the solution due to surfactant monomer becomes appreciable. This increase cannot be interpreted as evidence for micellar precursors.

The maximum rate enhancement occurs in the region of the cmc for each surfactant with the maximum ratios being estimated as 520 for SLS, 130 for SDS, 22 for SOS, and 2.9 for SHS solutions. In Fig. 2, where these values are plotted against the number of carbon atoms in the alkyl chain of the surfactant, an extrapolation suggests that shorter members of the series will have no rate enhancing effect.

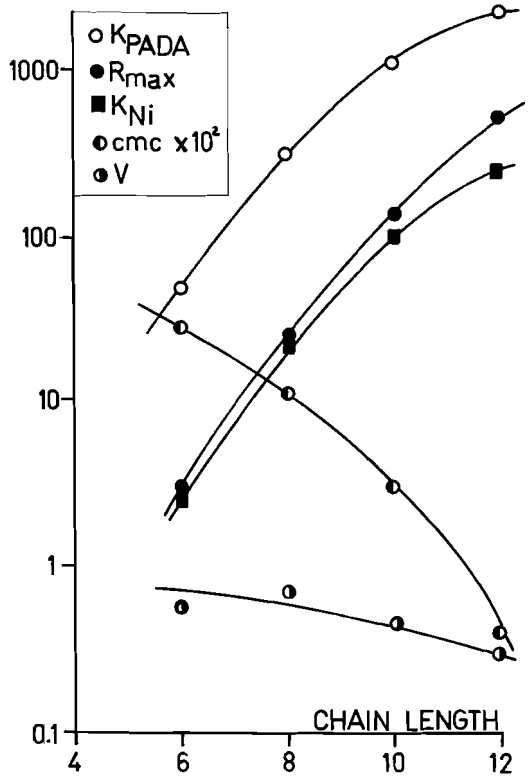

FIG. 2. Variation of various micellar parameters with chain length for the sodium alkylsulfates.

This dramatic decrease in rate enhancing activity with decrease in chain length of the surfactant could mean that either one or both of the reactants

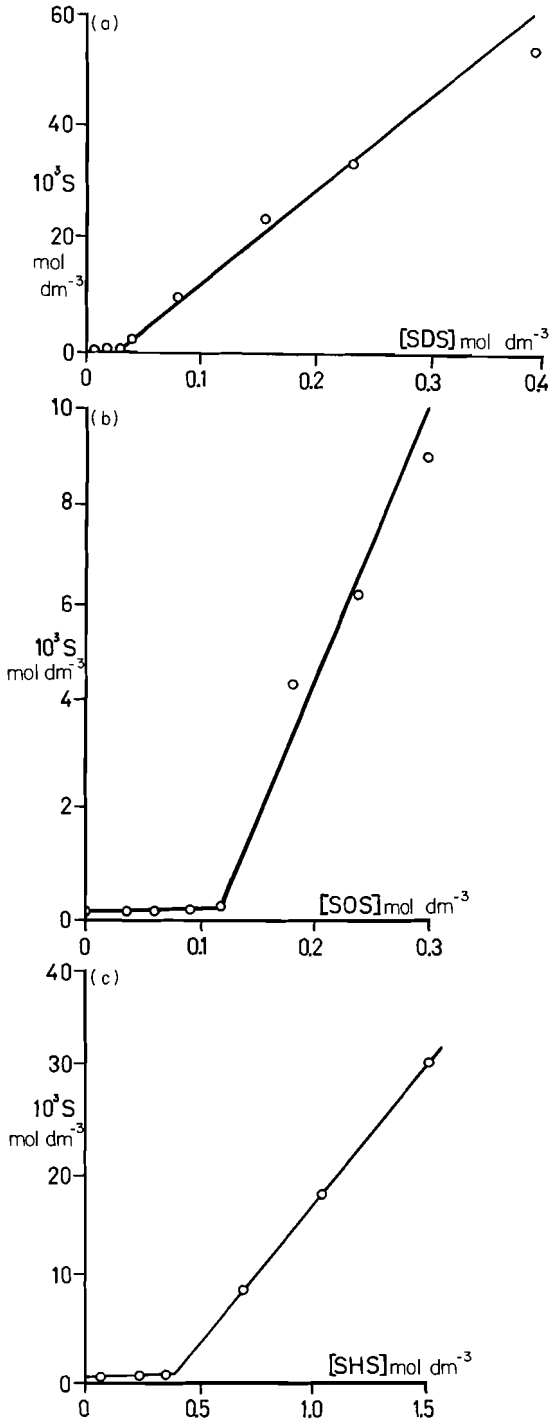

FIG. 3. Solubility (S) of PADA in (a) SDS, (b) SOS, and (c) SHS solutions at 25°C.

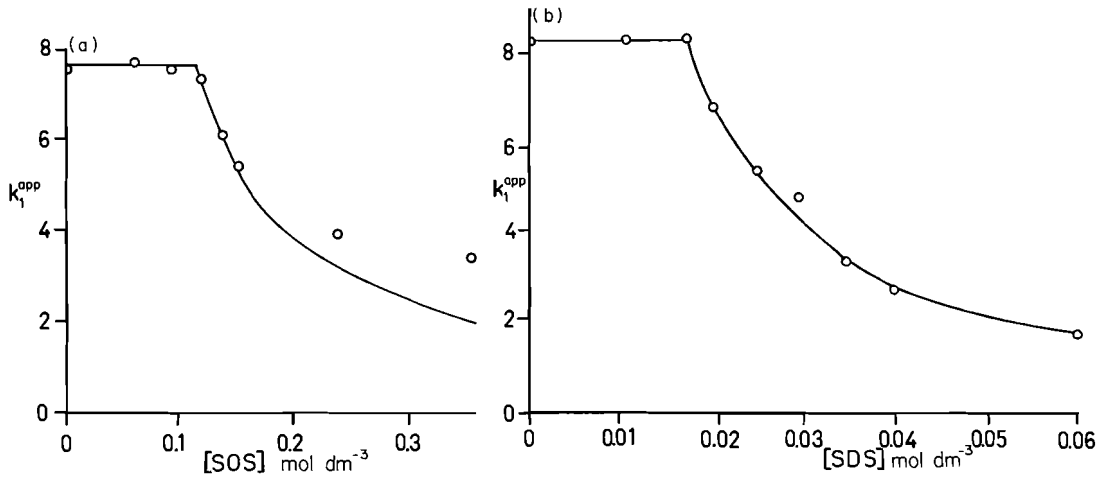

FIG. 4. Apparent forward rate constants (k_1^{app} in 10^3 dm^3 mol^{-1} s^{-1}), for the Ni^{2+}/murexide reaction in (a) SDS and (b) SOS solutions at 25°C. The open circles are data points while the solid line represents the best fitted curve. In the case of SOS, the first few data points beyond the cmc have been more heavily weighted.

are less available for reaction on the micelle surface, i.e. in terms of eq. [3] or [4], K_{Ni} or K_{PADA} or both are much lower in value than for SLS micelles. Both these quantities can be independently measured. Alternatively, the factor k_1^M/V could be changing.

The distribution constant for the PADA ligand between bulk water and the micelle surface, K_{PADA}, was obtained from solubility measurements. Figures 3(a), (b), and (c) show the variation of the solubility of PADA with surfactant concentration for SDS, SOS, and SHS solutions at 25°C. Again there is a clear indication of the cmc from the two linear portions of the curves, even for SHS solutions. K_{PADA} was calculated as $[PADA]_M/[PADA]_w C$ with $[PADA]_w$ being equated to the solubility of PADA at the cmc since, below the cmc, a slight increase in solubility was noted. The values of K_{PADA} at 25.0°C determined by this method were 50 dm^3 mol^{-1} for SHS, 300 dm^3 mol^{-1} for SOS, and 1050 dm^3 mol^{-1} for SDS (2800 dm^3 mol^{-1} for SLS (2)) (see Fig. 2). The degree of binding of the PADA ligand to the micelle decreases as the chain length is decreased reflecting weaker hydrophobic interaction.

K_{Ni} was determined using the murexide complexation technique (7, 8) for SDS and SOS solutions. The negatively-charged murexide ion avoids the anionic micelles so that, when Ni^{2+} ion is also present in solution, any complex formation between Ni^{2+} and murexide will occur only in the bulk water. The rate constant for $NiMu^+$ complex formation is conveniently obtained by the stopped-flow technique using optical detection. Thus, the ratio of the amount of Ni^{2+} ion in the bulk water ("free" Ni^{2+}) to the amount of Ni^{2+} ion in the surface region ("bound" Ni^{2+}) is readily determined from the decrease in observed rate constant with increasing surfactant concentration. The data were corrected for ionic strength according to the Davies equation (7) and plotted as values of apparent rate constants k_1^{app} for complex formation. The Davies equation is not satisfactory above approximately 0.2 mol dm^{-3} so that no attempt was made to measure K_{Ni} in SHS solutions by this method. A value of k_1^w of 2.1 s^{-1} was used in the calculation of k_1^{app} since this was the appropriate value for the experimentally used pH of 4.0 (7). The best fitted curves to the corrected data points for SDS and SOS solutions are shown in Figs. 4(a) and (b). In the SOS situation, the first few points above the cmc were more heavily weighted. The K_{Ni} values thus determined were 90 dm^3 mol^{-1} for SDS and 12 dm^3 mol^{-1} for SOS. The literature value for K_{Ni} for SLS solutions by this method is 650 dm^3 mol^{-1} when data from ref. 12 of that paper is recalculated according to its modified eq. [7], i.e., ${}^wk_1^{app} = k_1^w/(1 + K_{Ni}C)$.

At first glance, it is surprising that Ni^{2+} ions are so weakly bound, especially to the anionic SOS micelles. At 0.2 mol dm^{-3} above the cmc, about half the Ni^{2+} ions are bound, whereas with SLS micellar solutions they are almost totally bound. However, the much greater Na^+ counter ion concentration in micellar SOS solutions must nullify the charge density advantage that the Ni^{2+} ion would have in dilute micellar SLS solutions. Hence, the decrease of K_{Ni} with decreasing chain length is due to the ionic strength changes caused by the increasing cmc values. The much weaker binding

TABLE 1. Rate enhancement parameters

Surfactant	Experimental[a] K_{PADA} dm^3 mol^{-1}	Experimental[a] K_{Ni} dm^3 mol^{-1}	Best-fit K_{Ni} dm^3 mol^{-1}	Best-fit V dm^3 mol^{-1}
SLS	2800	650	250	0.29
SDS	1050	90	100	0.45
SOS	300	12	25	0.70

[a]The experimental values of K_{PADA} were used in obtaining the fitted K_{Ni} and V values.

of the Ni^{2+} ion to the micelle as compared with the PADA ligand binding to the micelle largely accounts for the reduced rate enhancement with short-chained surfactants.

The curves of the forward rate enhancement ratio R against surfactant concentration were computer fitted. Figures 1(a), (b), (c), and (d) show the experimental data together with the "best-fit" solid curve. The curves were fitted using the experimental values of K_{PADA} and the values of K_{Ni} and k_1^M/V were adjusted until a best fit was obtained. The values of K_{Ni} determined experimentally using the Ni^{2+}/murexide indicator system do not necessarily correspond to the Ni^{2+}/PADA reaction and hence were adjusted independently. This point is discussed in more detail below. It was further assumed that $k_1^M = k_1^w$ and hence the two adjustable parameters were reduced to K_{Ni} and V. This assumption is reasonable in that the activation enthalpy of this reaction is unchanged in SLS micellar solutions (1). The values of the "best fit" parameters are shown graphically in Fig. 2 and listed for purposes of comparison with the experimental values of K_{Ni} in Table 1. Considering that the kinetics can be confidently calculated only within a factor of 2 over almost 3 orders of magnitude, the agreement between the parameters is remarkably good.

The small apparent divergence between "best-fit" and experimental values of K_{Ni} can be rationalized in this manner. The "best-fit" values apply to partitioning of the nickel ion between the bulk water and the surfactant surface region defined by CV. The experimental values apply to partitioning between the bulk water pseudophase as "seen" by the murexide ion and a surface region "not seen" be the murexide ion which can be defined by CV'. The value of V' could be different from V leading to different values of K_{Ni}.

The increase of the parameter V with decreasing chain length may reflect an increase in the effective surface area of sulfate head groups, indicating in turn a looser packed micelle structure with decreasing chain length. Since only the ratio k_1^M/V can be determined, an alternative explanation is that k_1^M decreases with decreasing chain length. Combinations of these two factors must also be possible.

Another conclusion from this study is that C_8 and even C_6 surfactant solutions show well defined cmc's which agree well between the different methods used. The cmc values for SOS at 25°C as determined by four methods were 0.117 mol dm^{-3} (PADA solubility), 0.114 mol dm^{-3} (Ni–murexide), 0.11 to 0.12 mol dm^{-3} (onset of micellar rate enhancement), and 0.115 mol dm^{-3} (electrical conductivity). These agree well with cmc values of 0.118 and 0.115 mol dm^{-3} from two different ultrasonic absorption studies (9, 10). The nickel murexide experiment was particularly impressive (Fig. 4(b)) as the abrupt fall-off of the forward rate signalled the sudden emergence of micelles to which some Ni^{2+} ion had been adsorbed. The two estimates for the cmc of SHS solutions were 0.40 mol dm^{-3} from PADA solubility measurements and 0.28–0.32 mol dm^{-3} from the onset of micellar rate enhancement (0.43 mol dm^{-3} at 40°C from ultrasonic absorption data (9)). Even with this presumably last micelle former of the sodium alkylsulfate series, the appearance of these solution aggregates is dramatic, especially from the sudden increase in the rate enhancement factor, and occurs over a narrow concentration range.

In conclusion, the kinetic behaviour of these systems can be very well characterized from a simple model that is successful even with the extreme case of micellization that sodium hexylsulfate solutions represent (perhaps less than 10 monomers per aggregate). The indicator methods provide simple, sensitive, and flexible probes of micellar solution structure.

The relative rates of transfer of the cyclopentyl radical with molecular bromine and hydrogen bromide (k_2'/k_{-1}') and with hydrogen tribromide and hydrogen bromide (k_3'/k_{-1}') have been determined. The relative transfer rates are compared with the analogous values previously reported for the reactions of cyclohexyl radicals (k_2/k_{-1} and k_3/k_{-1}). Utilizing the values of k_2'/k_{-1}' and k_2/k_{-1} the competitive vapor phase rates of bromine atom abstraction of hydrogen from the two substrates could be obtained. An expression using a combination of the five sets of relative rate constants was used to determine the effect of competitive cage reversal which occurs in the solution phase bromination of the two substrate radicals with caged hydrogen bromide. For two structurally similar radicals, cage reversal (internal return) was found to affect the relative rates of bromination by 30%, while the relative transfer rates, although differing each by a factor of two, fortuitously nearly cancel each other's effect.

The effect of both internal and external reversal reactions on the relative rates of bromination of structurally dissimilar substrates, halogenated alkanes and their parent hydrocarbons, is discussed.

DENNIS D. TANNER, TOMOKO C-S. RUO, HIDEKI TAKIGUCHI et ANDRE GUILLAUME. Can. J. Chem. **59**, 1368 (1981).

On a déterminé les vitesses relatives de transfert du radical cyclopentyle avec le brome moléculaire et le bromure d'hydrogène (k_2'/k_{-1}') et avec le tribromure d'hydrogène et le bromure d'hydrogène (k_3'/k_{-1}'). On a comparé les vitesses relatives de transfert aux valeurs analogues rapportées précédemment pour les réactions des radicaux cyclohexyles (k_2/k_{-1}) et (k_3/k_{-1}). En utilisant les valeurs de k_2'/k_{-1}' et k_2/k_{-1}, on peut obtenir les vitesses compétitives en phase gazeuse de l'enlèvement d'un atome d'hydrogène par l'atome de brome à partir des deux substrats. On a utilisé une expression faisant intervenir une combinaison des 5 ensembles des constantes relatives de vitesse pour déterminer l'effet de l'inversion compétitive de cage qui a lieu au cours de la bromation en solution des deux radicaux avec du bromure d'hydrogène encagé. On a trouvé que, pour deux radicaux ayant des structures identiques, l'inversion de cage (renversement interne) modifie de 30% les vitesses relatives de bromation; par ailleurs, dans le cas des vitesses relatives de transfert qui diffèrent l'une de l'autre par un facteur de deux, elles annulent par hasard leurs effets respectifs.

On discute de l'effet des réactions d'inversion interne et externe sur les vitesses relatives de bromation des substrats ayant des structures différentes soit les alcanes et leurs dérivés halogénés.

[Traduit par le journal]

Introduction

Recently the kinetics of the solution phase free radical bromination of alkanes has been shown to be complicated by transfer of the radicals formed with hydrogen bromide in the solvent cage (internal return) and transfer of the radicals external to the solvent cage with both hydrogen bromide and hydrogen tribromide (external return) (1–3), see Scheme 1.

From studies of the relative rates of bromination of alkanes and substituted alkanes it has become apparent that the above mentioned reversal reactions seriously affect the magnitude of the values of the relative rates obtained for competitive bromination reactions (4).[4] Studies on the bromination of several model compounds, cyclohexane (1), 1-chlorobutane (5), and 1-bromobutane (6) in the vapor phase, where neither the cage reaction nor the transfer reaction with hydrogen tribromide are important, gave values of k_2/k_{-1} of 2.81, 12.3, and 28.2, respectively. Transfer reactions with unsubstituted alkyl radicals with the polar species hydrogen bromide appear to show less polar deactivation than do their substituted analogs (4). Competitive rates of bromination between substituted and unsubstituted alkanes will be the more seriously affected by

$$\mathrm{Br_2} \xrightarrow{h\nu} 2\,\mathrm{Br^\cdot}$$

reversal. The substituted, deactivated radicals will reverse less frequently, to reform starting material, than the unsubstituted radicals. The kinetic results of this process lead to the erroneous conclusion that the substituted reactant undergoes a relatively greater amount of reaction during the competitive brominations. The values for the relative rates of bromination in solution of pairs of unsubstituted alkanes can be strongly affected by reversal. These effects, however, may be fortuitously diminished or cancelled out by competitive sets of reversible reactions. One such set of competitive reversal reactions has been reported in the study of the relative rates of bromination of cyclohexane and cyclopentane (7). Under conditions favoring reversible abstraction, the relative rate obtained at 60°C, $k_{C_5H_{10}}/k_{C_6H_{12}}$, was determined to be 6.8 (C_5H_{10}:C_6H_{12}:Br_2, 10:10:1) whereas under conditions favoring no reversal, $k_{C_5H_{10}}/k_{C_6H_{12}} = 8.0$ (C_5H_{10}:C_6H_{12}:Br_2, 1:1:100). Since under the condition favoring reversibility the kinetics of the bromination of cyclohexane itself has been shown to be greatly influenced by hydrogen bromide reversal (1), the similarity between the two competitive reactions reported for cyclohexane vs. cyclopentane could be interpreted as being due to the concomitant cancellation of the effects of reversibility for the two substrates.

Kinetic data is now available for the bromination reactions of cyclohexane in the vapor phase and in solution (1). If similar data for the bromination of cyclopentane were also available, a method could be designed to combine these results and obtain the solution phase relative rates of abstraction for these two cycloalkanes. The objective of this study is to devise such a method and test the bromination scheme (Scheme 1) proposed for the competitive solution phase bromination of these two unsubstituted alkanes.

Discussion and Results

The rate of bromination of cyclohexane (RH) in solution, as depicted in Scheme 1, can be derived using the steady state assumption for the caged radical – hydrogen bromide pair and the cyclohexyl radicals free of the solvent cage, eq. [1].[5]

$$[1] \quad \frac{-d[RH]}{dt} = \frac{k_1[RH][Br\cdot]k_2[Br_2]k_d}{(k_d + k_{-1}[HBr]^c)(k_2[Br_2] + k_3[HBr_3] + k_{-1}[HBr])}$$

A similar derivation for the bromination of cyclopentane, R′H, can be obtained. Dividing these two equations gives eq. [2], the relative rates of bromination of cyclohexane vs. cyclopentane.

$$[2] \quad \frac{d[RH]/dt}{d[R'H]/dt} \cdot \frac{[R'H]}{[RH]} = \frac{k_1}{k_1'} \frac{k_2}{k_{-1}} \frac{k_{-1}'}{k_2'} \frac{k_d}{k_d'} \frac{k_d' + k_{-1}'[HBr]^c}{k_d + k_{-1}[HBr]^c} \frac{\left(\frac{k_2'}{k_{-1}'}\right)\left(\frac{[Br_2]}{[HBr]}\right) + \left(\frac{k_3'}{k_{-1}'}\right)\left(\frac{[HBr_3]}{[HBr]}\right) + 1}{\left(\frac{k_2}{k_{-1}}\right)\left(\frac{[Br_2]}{[HBr]}\right) + \left(\frac{k_3}{k_{-1}}\right)\left(\frac{[HBr_3]}{[HBr]}\right) + 1}$$

The relative rates of disappearance of the two substrates in solution can be evaluated when the reactions are carried out using high concentrations of hydrogen bromide and molecular bromine, when the concentrations of these reactants remain essentially constant, if the relative transfer rates k_2/k_{-1} and k_3/k_{-1} and the cage contribution k_d ($k_d + k_{-1}[HBr]^c$) are known for both substrates, and if the equilibrium concentration of hydrogen tribromide is known.

The relative transfer rate constants for the bromination of cyclohexane (23°C), k_2/k_{-1}, k_3/k_{-1}, and the equilibrium constant, K, for the formation of hydrogen tribromide have previously been determined (k_2/k_{-1}, 2.81; k_3/k_{-1}, 21.8; K, 2.8) (1, 3). Similar determinations of the relative transfer rate constants for cyclopentane were carried out by determining the relative rates of transfer of perdeuteriocyclopentyl radicals after their formation in the presence of an excess of hydrogen bromide and molecular bromine, see Table 1.

$$C_5D_{10} + Br^\cdot \longrightarrow C_5D_9^\cdot + DBr$$

$$C_5D_9^\cdot + HBr \xrightarrow{k_{-1}'} C_5D_9H + Br^\cdot$$

$$C_5D_9^\cdot + Br_2 \xrightarrow{k_2'} C_5D_9Br + Br^\cdot$$

[5]Caged species are treated as bimolecular and the same rate constant, k_{-1}, is used for reaction within the solvent cage and outside the solvent cage. For a more detailed explanation of this treatment, first proposed by Flory for initiator efficiency, see ref. 12.

[a]Superscripts 0 refers to initial concentrations and f to final concentrations.
[b]Material balances are based on hydrocarbon and bromination products accounted for.
[c]Calculated using eq. [3]; the values for the average concentration of Br_2 and HBr during the reactions were used. This correction is only significant when the conversion is greater than 10% (reactions 2 and 4). The value of $[C_5D_9Br]$ in eq. [3] was taken as the sum of $[C_5D_9Br]$ and $[C_5D_8Br_2]$.
[d]Gas phase 12 L reaction bulb.
[e]Freon 113 solution.

The relative rates of formation of the two products are given by eq. [3].

$$[3] \quad \{d[C_5D_9Br]/dt\}/\{d[C_5D_9H]/dt\} = k_2'[Br_2]/k_{-1}'[HBr]$$

The ratio of rate constants, $(k_2'/k_{-1}')^{vp}$, in the vapor phase was determined by carrying out the reaction of perdeuteriocyclopentane with excess bromine and added hydrogen bromide to low conversion and the products were analyzed by glpc and mass spectrometry in the same manner as was reported for cyclohexane (1). The values obtained are reported in Table 1, reactions 1–4. The ratio of transfer rate constants in solution (Freon 113), k_3'/k_{-1}', was calculated from the data (Table 1, reactions 5–8) obtained from the photobromination of perdeuteriocyclopentane with excess bromine and added hydrogen bromide using the integrated form of eq. [4], derived from the reactions listed in Scheme 1 (see ref. 1).

$$[4] \quad (d[C_5D_9Br]/dt)/(d[C_5D_9H]/dt) = \frac{k_2'([Br_2]^0 - [HBr_3])}{k_{-1}'([HBr]^0 - [HBr_3]) + k_3'[HBr_2]}$$

Equation [4] could be integrated, eq. [5], when the reactions were carried out to low conversion where the concentrations of bromine and hydrogen bromide were essentially unchanged.[6]

$$[5] \quad \frac{[C_5D_9Br]^f}{[C_5D_9H]^f}\left(\frac{k_{-1}'}{k_2'}\right)^{vp} = \frac{[Br_2]^0 - [HBr_3]}{[HBr]^0 - [HBr_3] + (k_3'/k_{-1}')[HBr_3]}$$

The equilibrium concentration of hydrogen tribromide was calculated using the previously determined equilibrium constant (3), $K = 2.8 \pm 0.3$, at 23°C.

The relative rate constants for abstraction of hydrogen from cyclopentane and cyclohexane could be determined in the vapor phase by carrying out the competitive bromination of the two substrates using high concentrations of bromine and hydrogen bromide (see Table 2, reactions 9–10). Since in the vapor phase the reactions of the radicals formed are exclusive of the cage and do not include the reaction of the radicals with hydrogen tribromide, the relative rate constants for abstraction, k_1'/k_1, can be calculated from the integrated form of eq. [2], eq. [6].[7]

$$[6] \quad \frac{\log \frac{(R'H)^0}{(R'H)^f}}{\log \frac{(RH)^0}{(RH)^f}} = \frac{k_1'}{k_1}\frac{k_2'}{k_{-1}'}\frac{k_{-1}}{k_2}\frac{1 + k_2/k_{-1}[Br_2]/[HBr]}{1 + k_2'/k_{-1}'[Br_2]/[HBr]}$$

Likewise the value k_1'/k_1 could be obtained by an analysis of the products formed during the competitive vapor phase bromination of the two substrates (low conversion) using excess bromine and hydrogen bromide, eq. [7] (see Table 2, reactions 11–13), or using high concentrations of excess bromine with no added hydrogen bromide (see Table 2, reactions 14–15), eq. [8].

$$[7] \quad \frac{[R'Br]}{[RBr]} \approx \frac{[R'H]}{[RH]}\frac{k_1'}{k_1}\frac{k_2'}{k_{-1}'}\frac{k_{-1}}{k_2}\frac{1 + k_2/k_{-1}[Br_2]/[HBr]}{1 + k_2'/k_{-1}'[Br_2]/[HBr]}$$

$$[8] \quad \frac{[RH]}{[R'H]}\frac{[R'Br]}{[RBr]} = \frac{k_1'}{k_1}$$

The agreement between the determination of the relative rates of abstraction, k_1'/k_1 (9.66 ± 0.26), by the three methods used lends support to the validity of the mechanistic scheme (Scheme 1) and substantiates the values obtained for the relative transfer rate constants.

The cage contribution, the kinetic result of competitive cage reversal (k_{-1}) and diffusion (k_d) of two different hydrogen bromide – radical pairs, (C), was calculated (eq. [9]) using all of the relative rate constants and the data obtained for the relative rates of product formation obtained from the competitive, low conversion, solution phase brominations of cyclopentane and cyclohexane in the presence of excess bromine and added hydrogen bromide.

[6]The validity of using the values of relative rate constants obtained in the vapor phase for the calculation of relative rates for a solution phase reaction has previously been substantiated, see refs. 1–3.

[7]It has previously been established that the relative rates of transfer obtained for deuterated radicals could be considered as equivalent to the same relative rate constants obtained for the protiated species, see refs. 1, 3, 5, 6.

[c]The values listed for $[C_5H_9Br]$ and $[C_6H_{11}Br]$ are the sum of $[C_5H_9Br]$ + $[C_5H_8Br_2]$ and $[C_6H_{11}Br]$ + $[C_6H_{10}Br_2]$.
[d]Calculated using eq. [10].
[e]Calculated using eq. [7].
[f]Calculated using eq. [8].

$$[9]\quad \frac{[C_5H_9Br]\,[C_6H_{12}]^0}{[C_6H_{11}Br]\,[C_5H_{10}]^0} = \frac{k_1'}{k_1}\frac{k_2'}{k_{-1}'}\frac{k_{-1}}{k_2}\,C\,\frac{\left(\frac{k_2}{k_{-1}}\right)\left(\frac{[Br_2]}{[HBr]}\right) + \left(\frac{k_3}{k_{-1}}\right)\left(\frac{[HBr_3]}{[HBr]}\right) + 1}{\left(\frac{k_2'}{k_{-1}'}\right)\left(\frac{[Br_2]}{[HBr]}\right) + \left(\frac{k_3'}{k_{-1}'}\right)\left(\frac{[HBr_3]}{[HBr]}\right) + 1}$$

$$C = \left(\frac{k_d'}{k_d}\right)\left(\frac{k_d + k_{-1}[HBr]^c}{k_d' + k_{-1}'[HBr]^c}\right)$$

The data obtained from these reactions (reactions 16–18) as well as a summary of the rate constants used for the calculation of C are listed in Table 3.

The magnitude of the cage contribution, $C = 1.43 \pm 0.02$, demonstrates that even in the case of structurally similar substrates such as cyclohexane and cyclopentane, differential cage reversal can affect the apparent relative rates of abstraction by as much as 30%. A further analysis of the cage contribution is not justified, however, since although the function is mathematically correct its physical significance is unclear. In the previous observations of differential cage reversal (2, 3) the cage contribution was simplified by assuming that k_d/k_d' was equal to unity. The approximation was justified on the basis of the assumption that the relative rates of diffusion of a perdeuteriocyclohexyl radical and a cyclohexyl radical were the same or that the same simplification could be made for the isomeric radicals formed during the bromination of 1-chlorobutane. The relative rates of diffusion of the cyclohexyl and cyclopentyl radicals are not necessarily expected to be as similar (8) and therefore this approximation was not made.

The observation, that the relative rates of bromination of two substrates in the absence of external return (high concentrations of bromine and low conversion of substrates) were not the same as the values obtained in their vapor phase brominations carried out under the same reaction conditions, has been attributed to competitive internal return reactions of the geminate radical – hydrogen bromide pairs (2, 3). It was demonstrated (2, 3) that in solvent liquid bromine the radicals, both external and internal to the solvent cage, could be effectively scavenged by molecular bromine and that both the vapor phase bromination of a substrate (carried out in absence of external return) and the reactions run in neat bromine give the same relative rates of bromination. This scheme could be further tested in the study of the competitive bromination of cyclopentane and cyclohexane.

When the competitive bromination was carried out in solvent liquid bromine (14–18 M) and the reaction mixture was analyzed for the relative disappearance of the two substrates, the relative rate of abstraction of hydrogen (per molecule), k_1'/k_1, was found to be 9.20 ± 0.28 (see Table 4), well within the experimental limits found for the vapor phase reactions, 9.66 ± 0.26 (see Table 4, reactions 19–22). These values are in excellent agreement with the value, 8.0, previously reported by Traynham and Lee (7) for the bromination of the two substrates at 60°C using high concentrations of molecular bromine.

Conclusions

The relative rates of bromination of hydrocarbon substrates in solution, whether they be deactivated

by electronegative substituents or be hydrocarbon pairs of a similar structure, are affected by both internal and external reversal. In the case of the substrates cyclohexane and cyclopentane these reversal reactions fortuitously nearly cancel each other.

Competitive brominations carried out to obtain information on structure reactivity relationships between chlorinated or brominated substrates and their parent unsubstituted hydrocarbons will lead to serious errors in mechanistic interpretation (9) unless these effects are considered (4).

Although detailed evidence for internal and external reversal has been obtained in the case of bromination reactions only, these processes should similarly affect the interpretation of structure reactivity relationships in other substitution processes which have comparable energetics.

Experimental

Materials

Perdeuteriocyclopentane (Merck, Sharp and Dohme, Canada) was used without further purification. Gas–liquid partition chromatography (glpc) (10 ft × 1/4 in. 10% SE-30 on Chromosorb P AW) showed it to be >99.9% pure, and mass spectral analysis (AEJ MS 50, 12 eV) showed it to contain 99.47 at.% D.

Cyclopentane (Philips 66, research grade) and cyclohexane (Aldrich Chemical) were heated to reflux over P_2O_5 and fractionally distilled using an 18 in. Vigreux column; the middle fractions were collected; glpc analysis (10% SE-30) showed them to be >99.9% pure.

Freon 112 (PCR) and Freon 113 (Matheson of Canada Ltd.) were fractionally distilled (18 ft Vigreux column) from P_2O_5; the middle fractions were collected.

Bromine (Fisher Scientific) was washed twice with concentrated sulfuric acid, decanted, and fractionally distilled (18 ft Vigreux column) from P_2O_5. The middle fraction was collected.

Analysis

The glpc area ratios were determined using either a HP digital integrator or a HP disk integrator. Concentrations determined by glpc analysis were calculated using standard calibration curves obtained from plots of area ratios vs. mole ratios of known mixtures.

The protium in perdeuteriocyclopentane was determined as previously described (1) using an AEI MS 9 mass spectrometer (12 eV) and the percentage ^1H was calculated by the method of Biemann (10).[8]

Vapor Phase Bromination of Perdeuteriocyclopentane

Perdeuteriocyclopentane (about 0.2 g) was accurately weighed into a Pyrex break seal, and this was degassed by the freeze–thaw method three times and finally sealed. Bromine (about 0.7 g) was similarly weighed, degassed, and sealed in a separate break seal. Hydrogen bromide was degassed and distilled in a vacuum line, measured manometrically, and distilled into a break seal. The three break seals were attached to the reaction vessel (12 L), and the system was evacuated. The

[8]For details of the analytical procedure see ref. 1.

break seals were broken in the absence of light (in the order C_5D_{10}, HBr, Br_2, with 20 min intervals between each break seal), the mixture of the three substrates was allowed to equilibrate (30 min, 23°C), and then the vessel was irradiated (one 100 W incandescent lamp). The contents of the bulb were condensed into a tube attached to the reaction vessel in the absence of light. The tube was cooled (−198°C), opened, and a CCl_4 solution of an internal standard (chlorobenzene) was added, and the excess bromine and hydrogen bromide was destroyed with cold (0°C) sodium bisulfite. The organic phase was washed with a solution of sodium bicarbonate (0°C) and then with water, and dried (anhydrous $MgSO_4$). The mixture was analyzed by glpc (10 ft × 0.25 in. 10% Carbowax 20 M on Chromosorb P AW, glass column) for remaining starting material and products and the unbrominated deuterated cyclopentane was collected and submitted for mass spectral analysis. As controls, known mixtures of the three substrates and their products were placed in the reaction vessel, in the absence of light, and isolated and reanalyzed in the same manner. The control experiments gave material balances within the experimental errors quoted. The concentrations and results of the analyses of the reaction mixtures are listed in Table 1, reactions 1–4.

Bromination of Perdeuteriocyclopentane in Freon 113

A Freon 113 solution of bromine and hydrogen bromide was allowed to equilibrate at 23°C. An aliquot of the solution was titrated iodometrically for both bromine and hydrogen bromide (11). A Freon 113 solution of perdeuteriocyclopentane was added and the mixture was irradiated (2 × 200 W incandescent lamps) after equilibration at 23°C. Several aliquots of the mixture were again analyzed for both bromine and hydrogen bromide, after adequate irradiation. The mixture, in the absence of light, was freed from the excess bromine and hydrogen bromide by washing with a cold (0°C) solution of $NaHSO_3$. The organic phase was washed with aqueous sodium bicarbonate, then water, and dried over anhydrous Na_2SO_4. The mixture was then analyzed by glpc (10 ft × 0.25 in. 10% SE 30 and Chromosorb P AW, glass column) for starting material and products. The deuterated cyclopentane was collected by preparative glpc (10% SE 30) and subjected to mass spectral analysis (reaction 5, Table 1) or concentrated by preparative glpc and subjected to glpc–ms (10% SE 30, AEI-MS12 mass spectrometer) analysis directly (reactions 6–8, Table 2). The concentrations and results used are listed in Table 1, reactions 5–8. Control experiments on known mixtures of reactants and products gave analytical results within the experimental values quoted.

Competitive Bromination of Cyclohexane and Cyclopentane in the Vapor Phase

The reactions were carried out with mixtures of cyclohexane and cyclopentane as substrates in the manner described previously for the gas phase brominations of perdeuteriocyclopentane, except that Freon 112 was used as an internal standard and a 24 ft × 0.25 in. 7% SE 30 on Chromosorb P AW, glass column was used to analyze the mixture. The results are listed in Table 2, reactions 9–10.

When the reaction mixture was analyzed for the disappearance of reactants (Table 2, reactions 9–10), the reaction mixture was condensed in the isolated compartment of a break seal attached to the reaction vessel. The break seal contained one mL of toluene and 10 mL of an aqueous solution containing excess Na_2SO_3. The collecting tube was sealed and after the break seal was opened and the materials mixed, the tube was opened and the organic phase was subjected to analysis by glc (7% SE 30 on Chromosorb P AW, glass column). The concentrations and results, calculated using eqs. [6] and [10], are listed in Table 2, reactions 9–10.

$$[10]\quad \frac{\log \dfrac{[C_5H_{10}]^0/[\text{Freon 112}]^0}{[C_5H_{10}]^f/[\text{Freon 112}]^f}}{\log \dfrac{[C_6H_{12}]^0/[\text{Freon 112}]^0}{[C_6H_{12}]^f/[\text{Freon 112}]^f}} = \frac{\log [C_5H_{10}]^0/[C_5H_{10}]^f}{\log [C_6H_{12}]^0/[C_6H_{12}]^f}$$

When the reaction was analyzed for the appearance of products (reactions 11–15, Table 2), the same method was used as that described for the product analysis used in the bromination of perdeuteriocyclopentane.

Competitive Brominations of Cyclohexane and Cyclopentane in Freon 113

The reactions were carried out and analyzed in the manner described for the bromination of perdeuteriocyclohexane in Freon 113 (1) except that the reaction mixture was concentrated by distillation using a 24 in. Teflon spinning band column, and the concentrated mixture was analyzed by glpc (24 ft × 0.25 in. 7% SE 30 on Chromosorb P AW glass column). Control experiments showed the analytical method to be accurate. The concentrations and results are listed in Table 3.

Competitive Brominations of Cyclohexane and Cyclopentane in Liquid Bromine

Aliquots of a pre-analyzed mixture of cyclohexane, cyclopentane, and Freon 112, as an internal standard, were placed in reaction tubes containing molecular bromine, degassed, and sealed in the absence of light. The mixtures were allowed to equilibrate at 23°C and were then irradiated with 4 × 200 W incandescent lamps. The tubes were cooled, opened, and an aliquot of toluene and an aqueous solution of $NaHSO_3$ were added. The organic layer was washed with a cold aqueous solution of Na_2CO_3, then water, dried over anhydrous Na_2SO_4, and analyzed by glpc (24 ft, 7% SE 30). The concentrations and results, calculated using eq. [11], are listed in Table 4, reactions 19–22.

$$[11]\quad \frac{\log \dfrac{[C_5H_{10}]^0/[\text{Freon 112}]^0}{[C_5H_{10}]^f/[\text{Freon 112}]^f}}{\log \dfrac{[C_6H_{12}]^0/[\text{Freon 112}]^0}{[C_6H_{12}]^f/[\text{Freon 112}]^f}} = k_1'/k_1$$

Le potentiel chimique d'excès dans des systèmes binaires: acides dicarboxyliques – acides monocarboxyliques ou esters. L'énergie libre d'interéchange entre groupes aliphatiques et carboxyliques

GIANFRANCESCO BERCHIESI, GIANCARLO GIOIA-LOBBIA, GIOVANNI VITALI ET MARIA A. BERCHIESI

Istituto Chimico dell'Università, Via S. Agostino 1, 62032 Camerino, Italie

Reçu le 6 octobre 1980

GIANFRANCESCO BERCHIESI, GIANCARLO GIOIA-LOBBIA, GIOVANNI VITALI et MARIA A. BERCHIESI. Can. J. Chem. **59**, 1375 (1981).

Les auteurs rapportent des donnés experimentales concernant les températures d'équilibre solide–liquide et liquide–liquide de systèmes binaires entre acides aliphatiques dicarboxyliques et l'hexadecanoate d'éthyle. Le potentiel chimique d'excès est deduit à partir de la courbe de crystallization soit pour ces systèmes soit pour des systèmes étudiés précédemment et publiés seulement sous forme graphique. Cette quantité thermodynamique est comparée avec la valeur correspondante calculée selon la théorie d'interaction des groupes.

GIANFRANCESCO BERCHIESI, GIANCARLO GIOIA-LOBBIA, GIOVANNI VITALI, and MARIA A. BERCHIESI. Can. J. Chem. **59**, 1375 (1981).

We report experimental data concerning the solid–liquid and liquid–liquid equilibrium temperatures for some binary systems composed of ethyl hexadecanoate and some bicarboxylic aliphatic acids. The crystallization curves of these systems and of others, previously published only in a graphical form, are used in order to obtain the excess chemical potential of the bicarboxylic acid along its crystallization curve. This thermodynamic quantity is compared with that calculated from the theory of group interaction, by means of the areas of the contact surfaces and of three interchange energy parameters.

Introduction

Les propriétés thermodynamiques des mélanges de composés organiques peuvent être traitées théoriquement selon la théorie d'interaction des groupes developpée par Kehiahian (1). Depuis quelques années nous avons étudié (2–8)[1] les mélanges binaires entre acides dicarboxyliques (composé **1**) et acides monocarboxyliques ou esters (composé **2**) par la méthode cryoscopique, qui permet de calculer le potentiel chimique d'excès (9–12). Dans cette note les valeurs expérimentales des équilibres de phase dans les systèmes binaires $CH_3(CH_2)_{14}-COOC_2H_5-COOH(CH_2)_nCOOH$ ($2 \leq n \leq 7$) sont données. Les composés ont été choisis pour étudier l'interaction entre groupes carboxyliques et aliphatiques, à cause de l'importance de ces groupes dans le domain industriel et biologique. L'interpretation du potentiel chimique d'excès dans les systèmes étudiés jusqu'à présent est essayée sur la base de la théorie proposée récemment par Kehiahian (1).

Méthode expérimentale

La méthode expérimentale employée est décrite en detail dans une note précédente (13): le mélange fondu, contenu dans une éprouvette en Pyrex, est placé dans un four thermoréglé au moyen d'une thermocouple Chromel Alumel jointe à un système CAT Leeds & Northrup. La température du four est reglée quelques dégrés au dessous de la température de fusion et une resistence auxiliaire, enroulée autour de l'éprouvette, permet de fondre le mélange partiellement crystallisé et de régler la vitesse de refroidissement à une valeur approximative de 0,25 K/min. La température du mélange est mesurée par une seconde thermocouple (Chromel Alumel) placée dans la cavité interne de la canne en verre du vibrobrouilleur et jointe à un potentiomètre Leeds & Northrup K-3. La thermocouple de mesure est étalonnée par comparaison avec un thermomètre à résistance de platine (avec garantie NBS). Les mélanges étudiés sont thermiquement stables pendant 3 ou 4 h à la température du composé plus haut-fondant. Pour un temps plus long les mesures de température de crystallisation d'une même composition ne sont plus reproductibles entre ±0,1 K et, en plus, le mélange brunit. Chaque mésure est répétée deux ou trois fois et l'accord est toujours meilleur que 0,1 K. A plus hautes températures (p.e. dans les courbes d'équilibre L–L), les mélanges sont moins stables et ont été employés pour une période plus courte. Des produits Fluka ou Ega ont été employés (purété 99%), après une recristallisation d'alcool.

Théorie et calculs

Les courbes cryoscopiques sont employées dans les études thermodynamiques et cette méthode est largement décrite en littérature (14) et a été employée dans des études précédentes (10–12). La courbe T/x peut être représentée mathematiquement par une des équations suivantes (9, 10, 14):

$$[1] \quad T = (H_{f1} + \Sigma H_{t1} + \mu_{E1})/(S_{f1} + \Sigma S_{t1} - R \ln x_1)$$

$$[2] \quad T = (H_{f1} + \Sigma H_{t1} + \bar{H}_1)/(S_{f1} + \Sigma S_{t1} + \bar{S}_1)$$

qui peuvent être déduites de l'équation $\mu_{1s} =$

[1] A cause d'une erreur de presse dans le tableau 1 de ref. 3 x_2 est écrit au lieu de x_1 et dans le tableau 3 de ref. 7 le terme A_3 du système binaire acide adipique + diphenyl ether a été écrit 956,0 au lieu de −956,0.

μ_{1L} à condition que les crystaux en équilibre avec le mélange liquide soient une phase pure. Dans cette note nous employons l'éq. [1] qui permet d'obtenir μ_{E1}, quand H_{f1} et H_{t1} seulement sont connus. μ_{E1} est exprimé par un polynôme $\sum_1^n A_i x_2^i$ et la limite est n choisie de façon à avoir une valeur de rms comparable à l'erreur expérimentale. Dans la statistique employée la fonction de partition configurationnelle est calculée sur un modèle de liquide quasi-réticulaire, en employant l'approximation quasi-chimique et l'hypothèse que les molécules sont en contact sur toute leur surface. Le potentiel chimique d'excès deduit est donné par la formule suivante:

$$[3]\quad \mu_{E1}/RT = \mu_{E1}^*/RT + zq_1 \Sigma_s \alpha_{s1} \ln (X_s\alpha_{s1}/X_{s1}\alpha_s)$$

où le terme combinatoire est exprimé dans la forme de Guggenheim:

$$[4]\quad \mu_{E1}^*/RT = \ln \varphi_1/x_1 + (zq_1/2) \ln \xi_1/\varphi_1$$

et X_s, égale à $\sqrt{2A_{ss}/A}$ est obtenu à l'aide d'un système d'équations de Barker (1):

$$[5]\quad X_s(X_s + \Sigma_t X_t \eta_{st}) = \alpha_s$$

où η_{st} est en relation avec l'énergie libre d'interéchange g_{st}

$$[6]\quad \eta_{st} = \exp(-g_{st}/zRT)$$

Les volumes et l'aire des surfaces des molécules sont obtenus selon la méthode de Bondi (15) et sont donnés au tableau 1.

Analyse des erreurs expérimentales

μ_{E1} calculé selon la méthode cryoscopique le long de la courbe de cristallisation est affecté par l'influence de ces causes d'erreur: (*1*) l'erreur expérimentale en T; (*2*) l'erreur expérimentale en H_f et S_f; (*3*) le fait que, si la capacité calorifique partielle des composés dans le mélange n'est pas connue, en général H_f et S_f sont considérés constants le long de la courbe de cristallisation. L'expression pour ces causes d'erreurs peut être obtenue à partir de l'éq. [1].

L'erreur relative au point *1* est: $\delta\mu_{E1} = (S_f - R \ln x_1)\delta T$, qui peut être estimé en employant la valeur S_f relative à l'acide hexanedioique publiée précédemment (16). Dans l'intervalle de concentration $0{,}9 > x_1 > 0{,}1\mu_{E1}$ change entre 2,0 et 2,4 cal/mol.

L'erreur relative au point *2* est: $\delta\mu_{E1} = T\delta S_f - \delta H_f$; dans l'intervalle de concentration entre le composé **1** pur et le mélange eutectique $\delta\mu_{E1}$ change entre 0 et 23 cal/mol (calcul effectué sur l'acide hexanedioique).

Le point *3* donne une erreur:

$$[7]\quad \delta\mu_{E1} = T\int_{T_f}^{T} (\Delta\bar{c}_p/T)\,dT - \int_{T_f}^{T} \Delta\bar{c}_p\,dT \simeq T\Delta\bar{c}_p \ln (T/T_f) + \Delta\bar{c}_p(T_f - T)$$

A cause du fait que $\bar{c}_p$ n'est pas connu pour l'acide hexanedioique ou pour les autres acides employés, une évaluation approximative peut être effectuée en employant une valeur $\Delta\bar{c}_p = 10$ cal/K mol, valable pour d'autres substances aliphatiques (17–19). $\delta\mu_{E1}$ change entre 0,0 et 195 cal/mol dans l'intervalle de concentration entre le composé **1** pur et le mélange eutectique. Pour cette raison une incertitude de 10 ou 15% est attendue pour les valeurs de μ_{E1}.

Résultats et discussion

Les températures expérimentales d'équilibre L–L et L–S sont données au tableau 2 avec les

coordonnées des points invariants. La courbe de cristallisation du composé **1** est étendue jusqu'à des valeurs très faibles de x_1 et, comme observé souvent précédemment (3–8), il n'a pas été possible de mettre en évidence le point eutectique. Ce fait peut être attribué à la grande différence de point de fusion des deux composés (20). Les systèmes binaires avec les acides butanedioique, pentanedioique et hexanedioique présentent la region d'immiscibilité à l'état liquide, qui n'a pas été étudiée complètement à cause des raisons de stabilité thermique. Les autres systèmes binaires présentent

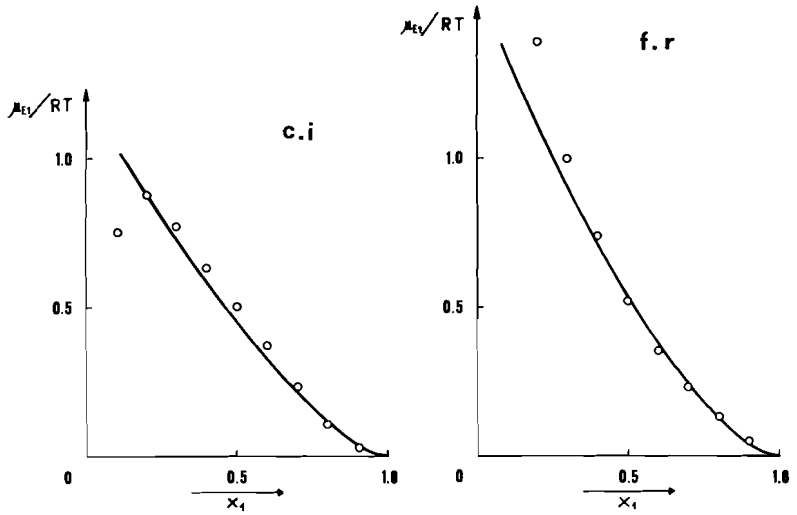

FIG. 1. Comparaison entre le potentiel chimique d'excès expérimental (points) et théorique (ligne) pour les systèmes suivants: b–i; b–h; d–m; g–m; f–m; e–m; c–m; c–i; c–l; c–h; d–p; f–p; f–q; f–n; f–r; e–r; f–o; d–o; e–n; e–p; e–q; d–n; dans cette note les systèmes c–i et f–r sont publiés, les autres figures sont placées dans le dépôt.[2]

une courbe de cristallisation T/x en forme de S, comme dans les systèmes avec "region d'immiscibilité submergée" (20).

Dans les systèmes étudiés jusqu'à présent (2–8) et dans ceux rapportés dans cette note il est assez probable que les équilibres L–S soient entre phase liquide et phase solide pure: en effet dans une note précédente (2) nous avons mis en évidence le fait que la constante cryoscopique $\Delta T/m$ s'approche à la valeur thermodynamique $RT_f^2M_1/1000H_f$ pour des solutions diluées de 2 en 1. Même les acides nonanedioique, octanedioique et heptanedioique présentent un comportement cryoscopique regulier avec l'hexadecanoate d'éthyle; en effet les mesures effectuées jusqu'à une concentration 1,2 m du composé **2** donnent les valeurs $\Delta T/m$ suivantes, extrapolées à $m = 0$: 6,0, 8,3, 6,0 K/molalité qui sont en accord avec les valeurs thermodynamiques (16): 6,9, 8,6, 6,9 K/molalité.

Ce fait, comme aussi le nombre remarquable de systèmes qui présentent la region d'immiscibilité dans cette famille de systèmes binaires supporte l'hypothèse que la déviation positive des courbes T/x est due au potentiel chimique d'excès plutôt que à une solubilité partielle du composé **2** dans le composé **1** solide.

Après ces considérations et au moyen des données calorimétriques publiées précedemment (16), μ_{E1} a été calculé pour les mélanges étudiés et exprimé en polynômes $\sum_1^n A_i x_2^i$, dont les coefficients concernant les systèmes en hexadécanoate d'éthyle et en nonadécanoate de methyle ont été donnés au tableau 3 avec les valeurs rms.[2] Les valeurs des coefficients des autres systèmes étudiés ont été données dans une note précédente (5). Les valeurs g_{st} d'énergie libre d'interéchange ont été déterminées sur les systèmes b–h et f–q et elles sont: 6480 J/mol, pour le contact (CH_3, CH_2)–COOH(**1**); 4800 J/mol pour le contact (CH_3, CH_2)–COOH(**2**); 400 J/mol pour le contact COOH(**1**)–COOH(**2**); 4400 J/mol pour le contact (CH_3, CH_2)–COO; 3600 J/mol pour le contact COOH(**1**)–COO; z étant 4 dans cette note. Les valeurs de μ_{E1} expérimentales et calculées sont comparées en fig. 1, montrant un accord satisfaisant. Les groupes carboxyliques COOH(**1**) et COOH(**2**) ne semblent pas équivalents. Précédemment nous avons mis en évidence du point de vue expérimentale (2) que l'interaction COOH(**2**)–COOH(**2**) prévaut sur l'interaction COOH(**1**)–COOH(**2**) quand la concentration du composé **2** augmente. La présence de deux groupes identiques dans une molécule semble changer les propriétés du groupe, comme rapporté en littérature pour les diols (21). Les valeurs g_{st} élevées et la valeur z faible peuvent expliquer les déviations positives de l'idéalité comme dues à une déviation du mélange casuel.

Etant $X_sX_t\eta_{st}$ la surface de contact entre les surfaces s et t dans le système, le produit $g_{st}X_sX_t\eta_{st}/A$

[2]On peut obtenir les données mises en dépôt, à un prix nominal, en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa (Ont.), Canada K1A 0S2.

peut être considéré égal à l'énergie libre d'interéchange totale dans le mélange. La fonction $F = \Sigma g_{st} X_s X_t \eta_{st}$ étendue à tous les contacts montre un maximum (fig. 2) dans la zone riche en composé **1**, probablement comme conséquence de la constitution géométriques et cimique des composés. En fig. 2 on peut aussi remarquer que F augmente avec la longueur de la chaîne aliphatique du composé **2**; du point de vue expérimentale on a remarqué une tendance plus forte à la separation en deux phases liquides au fur et à mesure que la chaîne du composé **2** augmente.

La composition des deux phases liquides en équilibre à une température T sont en relation, dans l'intervalle de température étudié, selon la formule suivante, tel que remarqué précédemment (8)

$$[8] \quad \ln x_2/x_2' = a - b(T - T_m)$$

où $x_2 > x_2'$ et T_m est la température monotectique. D'une façon empirique on peut montrer que a et b dependent des groupes présents dans les composés. En effet les paramètres

$$[9] \quad \delta = (n_{COOH}/n_C)_{dicarb} - (n_{COO(H)}/n_C)_{ester,\ (monocarb)}$$

et b sont en relation linéaire (fig. 3); tandis que le paramètre a dépend de la température monotectique selon la relation $a/\gamma T_m \simeq 0{,}0011\ K^{-1}$ ($\sigma = 0{,}0003$). γ est définie: $\gamma = (n_{COOH}/n_C)_{dicarb}/(n_{COO(H)}/n_C)_{ester(mon)}$. La valeur 0,0011 K^{-1} est la moyenne sur 25 systèmes (8) et a varie entre 1,58 et 4,78, γ entre 5,70 et 10,00, T_m entre 369,2 et 455,2 K.

Ces considérations empiriques montrent que la region d'immiscibilité peut être traitée par une théorie des groupes et qu'il est nécessaire de developper une convenable statistique pour les systèmes binaires de composés polaires et associés. L'utilité pratique de la fig. 3 à été expliqué précédemment (8).

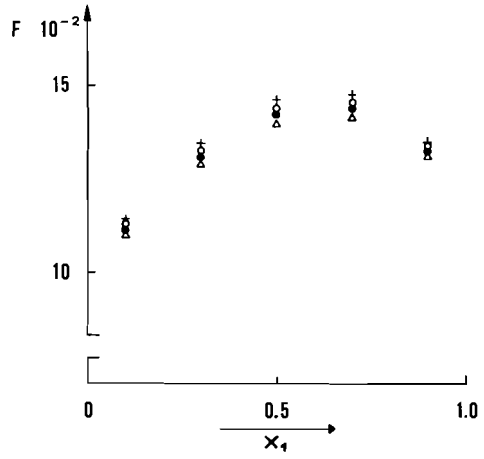

FIG. 2. Comportement de la fonction F contre x_1 dans les systèmes: c–i ●; c–l ○; c–h △; c–m +. F est exprimé en J/mol.

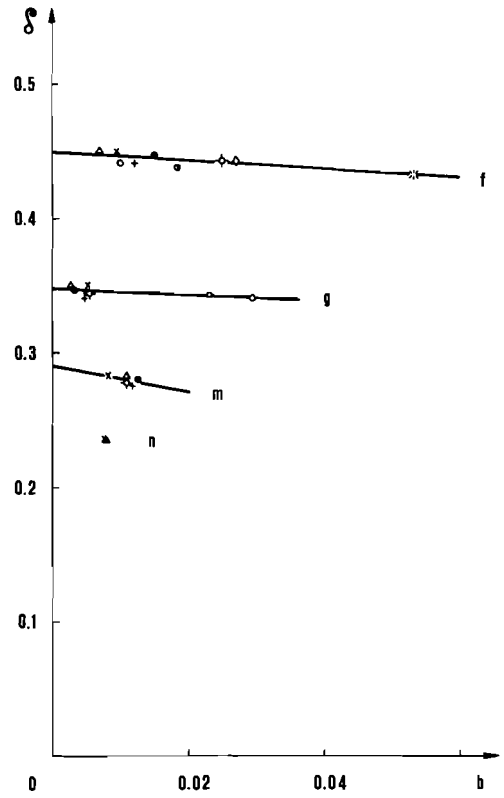

FIG. 3. Comportement δ/b (K^{-1}) dans les systèmes binaires entre: *a* et (à partir de gauche) q, r, l, o, n, p, i, u, h; *b* et (à partir de gauche) q, p, n, o, r, m, l; *c* et (à partir de gauche) r, q, o, n, p; *d* et (à partir de gauche) r, q.

Remerciements

Nous remercions le Dr. Ing. A. Polzonetti, directeur du Centro di Calcolo dell'Università di Camerino, pour nous avoir mis à disposition le programme pour la resolution des systèmes d'équations de Barker et nous remercions aussi le CNR (Rome) pour l'aide financière.

SÁNDOR FLISZÁR and J.-L. CANTARA. Can. J. Chem. **59**, 1381 (1981).

A simple equation has been derived for calculating accurate ZPE + $H_T - H_0$ (zero-point and heat content) energies of saturated hydrocarbons from their enthalpies of formation and carbon-13 nuclear magnetic resonance spectra. Applications to conformational analysis indicate a near invariance of vibrational energies with respect to chair–boat conformational changes of the cyclohexane ring, the loss in molecular stability arising then from a weakening of the chemical binding due to a reorganization of the electronic charges. The origin of the destabilizing effect of butane *gauche* interactions is found, in the cyclohexane series, in a weakening of the chemical binding (~1.85 kcal/mol) which is partially compensated by a lowering (~0.85 kcal/mol) vibrational energy, thus offering an explanation for the loss in molecular stability of ~1.00 kcal/mol for one *gauche* interaction without invoking Coulomb-type repulsions between non-bonded atoms. Calculated enthalpies of formation are presentd for a number of cycloalkanes.

SÁNDOR FLISZÁR et J.-L. CANTARA. Can. J. Chem. **59**, 1381 (1981).

On a déduit une équation simple pour calculer avec précision les énergies ZPE + $H_T - H_0$ (point zéro et contenu de chaleur) des hydrocarbures saturés à partir de leurs enthalpies de formation et de leurs spectres rmn du ^{13}C. Les applications à l'analyse conformationnelle indiquent une quasi invariance des énergies vibrationnelles par rapport aux changements de conformation chaise-bateau du cycle cyclohexane, la perte de la stabilité moléculaire provient alors de l'affaiblissement des liaisons chimiques provoquées par une réorganisation des charges électroniques. En série cyclohexanique l'origine de l'effet déstabilisant des interactions butane gauche réside dans un affaiblissement des liaisons chimiques (~1,85 kcal/mol) qui est partiellement compensé par un abaissement (~0,85 kcal/mol) de l'énergie vibrationnelle, apportant ainsi une explication de la perte de stabilité moléculaire de ~1,00 kcal/mol pour une interaction gauche sans invoquer des répulsions de type Coulombien entre les atomes non liés. On présente des enthalpies de formation calculées pour un certain nombre de cycloalcanes.
[Traduit par le journal]

The atomization

$$\text{Molecule} \rightarrow n_1A_1 + n_2A_2 + \ldots$$

of a molecule into its constituent n_1 atoms A_1, n_2 atoms A_2, ... provides a direct insight into fundamental aspects of molecular energies. The relevant thermodynamic information is usually expressed in terms of enthalpy of formation, ΔH_f, or enthalpy of atomization, ΔH_a, of the molecule under consideration, i.e.

$$[1] \quad \Delta H_a = \Sigma n_i \Delta H_f(A_i) - \Delta H_f$$

where the $\Delta H_f(A_i)$'s are the enthalpies of formation of the gaseous atoms A_i. A number of schemes viewing the molecule as an assembly of chemical bonds or groups and the " molecular energy" as a sum of appropriately defined contributions has been proposed for calculating ΔH_a (1). In the study of isolated molecules, however, we refer more conveniently (2) to the *energy* of atomization ΔE_a, i.e.

$$[2] \quad \Delta E_a = \Delta H_a - (\Sigma n_i - 1)RT$$

Both ΔE_a and ΔH_a are considered at some temperature, say 25°C, i.e. under working conditions which are of real practical interest. This situation may be compared with that referring to molecules in their hypothetical vibrationless state at 0 K, whose atomization energy is ΔE_a^*. The relation between ΔE_a and ΔE_a^* is described by eq. [3]

$$[3] \quad \Delta E_a = \Delta E_a^* - \Sigma F(\nu_i,T) + 3(\Sigma n_i - 2)RT/2$$

which states that the energy of atomization at, say, 25°C is that of the hypothetical vibrationless molecule at 0 K *less* the sum $\Sigma F(\nu_i,T)$ (over $3\Sigma n_i - 6$ degrees of freedom) of vibrational energy corresponding to the fundamental frequencies ν_i, which is already present in the molecule at 25°C. The term $3(\Sigma n_i - 2)RT/2$ accounts for the formation of Σn_i atoms with translational energy and the disappearance of one nonlinear molecule with 3 translational and 3 rotational $RT/2$ contributions. It follows from eqs. [1]–[3] that

$$[4] \quad \Delta E_a^* = \Sigma n_i[\Delta H_f^0(A_i) - 5RT/2] + \Sigma F(\nu_i,T) + 4RT - \Delta H_f^0$$

where all enthalpies are now referred to standard conditions (gas, $T = 298.16$ K). The vibrational energy may be separated into a zero-point energy term (ZPE) and a thermal energy term (E_{vibr}). It is, therefore,

$$\Sigma F(\nu_i, T) + 4RT = \text{ZPE} + E_{vibr} + 4RT$$

On the other hand, $E_{vibr} + 4RT$ is the increase in enthalpy $(H_T - H_0)$ of nonlinear molecules due to their warming up from $T = 0$ to $T = T$. Consequently, eq. [4] can now be written as follows.

$$[5] \quad \Delta E_a^* = \Sigma n_i[\Delta H_f^0(A_i) - 5RT/2] + \text{ZPE} + (H_T - H_0) - \Delta H_f^0$$

This analysis of the energy components illustrates that there is a long way to go from the knowledge of the behavior of hypothetical motionless molecules to the understanding of their actual behavior at some temperature T. Postponing the questions about the derivation of accurate ΔE_a^*'s, it appears that the real problem is one of estimating the vibrational contributions in a simple manner. The object of this paper is to report some information about vibrational energies of saturated hydrocarbons, thus opening a way towards the construction of a simple empirical scheme for their evaluation. Saturated hydrocarbons $C_nH_{2n+2-2m}$ containing m (≥ 0) six-membered rings are selected because it is presently the only class of compounds for which we possess sufficient experimental information, namely both thermochemical and spectroscopic data.

Outline of calculations

For the $C_nH_{2n+2-2m}$ hydrocarbons under study, it is possible to calculate accurate ΔE_a^* energies from carbon-13 nuclear magnetic resonance shifts δ (ppm from ethane) by means of eq. [6] (3)

$$[6] \quad \Delta E_a^* = (1 - m)\Delta E_a^*(C_2H_6) + (n - 2 + 2m) \times [\Delta E_a^*(C_2H_6) - \Delta E_a^*(CH_4)] + \lambda_1 \Sigma N_{CC}\delta + \lambda_2[(n - 2 + 2m)\delta(CH_4) + \Sigma\delta]$$

in which $\Delta E_a^*(C_2H_6)$ and $\Delta E_a^*(CH_4)$ are, respectively, the appropriate values for ethane and methane. N_{CC} is the number of CC bonds formed by the C atom whose shift is δ. The parameters λ_1 and λ_2, which are derived from theory (3), are constants for this class of compounds. Equation [6] enables a simple and remarkably accurate calculation of the ΔE_a^*'s, considerably outperforming in rapidity and precision their quantum chemical evaluation. Indeed, eq. [6] was shown to agree with experimental ΔE_a^* values (eq. [5]) within experimental uncertainty, the average deviation being ~0.23 kcal/mol (3, 4). On the physical side, eq. [6] contains the information that, for vibrationless molecules, the prime factors governing molecular stabilities are found in the behavior of the charge dependent energy contributions associated with the chemical bonds indicating, namely, that 1 millielectron (= 10^{-3} e) of electronic charge added to hydrogen stabilizes a CH bond by 0.632 kcal/mol, whereas 1 me added to carbon has a stabilizing effect of 0.247 on a CH bond and of 0.488 kcal/mol on a CC bond (3).

At this stage we have two expressions for ΔE_a^*, i.e. eqs. [5] and [6]. Inserting the experimental values (3–5) (kcal/mol at $T = 298.16$ K) $\Delta H_f^0(C) = 170.89$, $\Delta H_f^0(H) = 52.09$, $\Delta E_a^*(C_2H_6) = 710.54$, $\Delta E_a^*(CH_4) = 419.27$, $\lambda_1 = 0.03244$, $\lambda_2 = 0.05728$, and $\delta(CH_4) = -8$ ppm, the following new energy formula is obtained from eqs. [5] and [6] (in kcal/mol at 298.16 K)

$$[7] \quad \text{ZPE} + H_T - H_0 = 27.692(1 - m) + 20.184n + 0.03244\Sigma N_{CC}\delta + 0.05728\Sigma\delta + \Delta H_f^0$$

which enables a rapid calculation of ZPE + H_T − H_0 energies from standard enthalpies of formation and C-13 nmr spectra. Of course, eq. [7] is as accurate as eq. [6] which has been tested earlier (3). The possibility of deriving ZPE + H_T − H_0 energies in a simple manner by means of eq. [7] offers now a new way of recognizing possible structure-related regularities from an examination of numerous cases. The results are as follows.

Results

Non-cyclic Alkanes

To begin with, we apply eq. [7] to all the non-cyclic alkanes (through C_9) which are either linear or contain only CH_3 branching but no quaternary C atoms. The idea is to avoid any case involving an *a priori* visible steric hindrance of internal rotations. The results obtained in this way are well reproduced by the simple new additivity scheme, eq. [8].

$$[8] \quad \text{ZPE} + H_T - H_0 = 11.479 + 18.213n_1 + 17.870n_2$$

where n_1 = number of CH_2 groups forming the linear chain and n_2 = number of CH_3 branchings.

Indeed, Table 1 indicates, firstly, that the ZPE + H_T − H_0 energies derived from eq. [7] are in excellent agreement with their experimental counterparts and, secondly, that these results are well reproduced by eq. [8], which gives the ZPE + H_T − H_0 values with a standard error of 0.176 kcal/mol (average deviation = 0.125 kcal/mol) and a multiple correlation coefficient of 0.99997. The change in ZPE + H_T − H_0 associated with methyl substitutions giving quaternary carbon atoms, however, can only be estimated as a rough average (17.55 kcal/mol) suggested by the experimental incre-

[a]Zero-point energies were calculated in the harmonic oscillator approximation (ZPE = $N_{Av}\Sigma h\nu/2$) using the frequencies taken from ref. 6. The $H_T - H_0$ values are from ref. 7.
[b]The experimental ^{13}C and ΔH_f^0 data used in eq. [7] are indicated in Table 2.

ments in going from 2-MeC_3 to 2,2-Me_2C_3 (17.41), from 2-MeC_4 to 2,2-Me_2C_4 (17.37), from 2,3-Me_2C_4 to 2,2,3-Me_3C_4 (17.66), and from 2,2,3-Me_3C_4 to 2,2,3,3-Me_4C_4 (17.77), and should, therefore, be used with due care. The practical aspects of eq. [8] are clear: together with the ΔE_a*'s derived from carbon-13 nmr spectra (eq. [6]) they give access to accurate enthalpies of formation (eq. [5], Table 2).

Of course, the construction of an additivity scheme involving vibrational energies is, in itself, not free from conceptual difficulties and is considered here only on an empirical basis. It is also true, however, that the problems raised in this manner are no more acute than those hidden in additivity schemes involving directly ΔH_a or ΔE_a, because any such scheme implicitly distributes vibrational energies by treating them *de facto* as if they were additive. This point can be shown as follows. Let us temporarily assume that one single value (e.g., 18.213 kcal/mol) describes the increment in ZPE + $H_T - H_0$ for one added CH_2 group, regardless of the point of methyl substitution, i.e.,

$$\text{ZPE} + H_T - H_0 = 11.479 + 18.213n$$
$$= 47.905 + 18.213(n - 2)$$

where 47.905 is the value for ethane. Then, using eqs. [1], [5], and [6], we obtain the following expressions

$$[9] \quad \Delta H_a = \Delta H_a(2) + (n - 2)\,[\Delta H_a(2) - \Delta H_a(1)] + \lambda_1 \Sigma N_{CC}\delta + \lambda_2[(n - 2)\delta(1) + \Sigma\delta]$$

$$[10] \quad \Delta H_f^0 = \Delta H_f^0(2) + (n - 2)\,[\Delta H_f^0(2) - \Delta H_f^0(1)] - \lambda_1 \Sigma N_{CC}\delta - \lambda_2[(n - 2)\delta(1) + \Sigma\delta]$$

in which the indices 1 and 2 refer to methane and ethane, respectively. These equations describe in fact a bond-enthalpy additivity scheme, $\Delta H_a = \Sigma\Delta H_a$(bond) with individual bond contributions depending on the charges of the bond-forming atoms, implying exact additivity not only of non-bonded interactions, but also of the vibrational energy contributions. Now we know that the latter do depend on structural features. It so happens that the terms $\Sigma N_{CC}\delta$ and $\Sigma\delta$ are also structure-dependent. Equations [9] and [10] give generally satisfactory results (Table 2) because a readjustment of the parameters λ_1 and λ_2 compensates for the error introduced in assuming exact additivity of the vibrational energy terms. Hence, the success of eqs. [9] and [10] is in part due to fortunate compensations and should not be interpreted as a proof for postulated intrinsic qualities of bond-enthalpy additivity schemes. Of course, *marked* departures from "quasi-additivity" of the interactions between non-bonded atoms occurring in situations of extreme steric crowding represent a source of errors which should not be overlooked (14).

Cycloalkanes

We can now turn to the study of cyclic hydrocarbons and examine to what extent the additivity scheme describing ZPE + $H_T - H_0$ energies in acyclic compounds (eq. [8]) is applicable to cyclic structures. To begin with, we select molecules which are free from steric effects, such as butane *gauche* or *skew* pentane interactions.

Firstly, we note that a CH_2 group contributes 18.213 kcal/mol if no tertiary C atom is formed and 17.870 kcal/mol when branching occurs to give a tertiary C atom. We construct tentatively the ZPE + $H_T - H_0$ energies of cycloalkanes by counting 18.213 kcal/mol for each C atom of the molecule (rule 1) and subtract 18.213 − 17.870 = 0.343 kcal/mol for each tertiary C atom that is formed (rule 2). A number of H atoms is removed in the formation of polycyclic compounds, e.g., 2H atoms in *trans* decalin. The 11.479 kcal/mol term of eq. [8] represents roughly the contribution of two H atoms. Accordingly, we approximate the decrease in ZPE + $H_T - H_0$ due to the loss of one H atom by subtracting 11.479/2 = 5.740 kcal/mol per H atom that is removed (rule 3). These rules express clearly

TABLE 2. Comparison of ΔH_f^0's calculated from eqs. [7] and [8] or eq. [10], with experimental results[a]

Molecule	$\Sigma N_{CC}\delta$	$\Sigma\delta$	$-\Delta H_f^0$, kcal/mol

[a]The ^{13}C data were taken from ref. 8 (C_1, C_2), ref. 9 (C_3–C_6), and ref. 10 (C_7–C_9). Except as noted below, the experimental ΔH_f^0 values are from ref. 7. The values for C_2, C_3, C_4, and 2-MeC_3 are taken from ref. 11, and that of 2,2-Me_2C_3 from ref. 12. The value for 2,3-Me_2C_6 and for the C_9 alkanes are taken from ref. 13. The present selection of experimental ΔH_f^0 values is not intended to represent a critical collection of "best values". Slightly different results are reported in ref. 13*a* for C_2 (−20.24), C_3 (−24.82), and C_4 (−30.15 kcal/mol), all other values being those given in this table. Similarly, one finds (13*b*), in kcal/mol, −35.07 for C_5, −36.55 (2-MeC_4) and −40.09 (2,2-Me_2C_3). Experimental uncertainties of this magnitude do not affect the general conclusions drawn in the present work. The parameters of eq. [10] are $\lambda_1 = 0.04531$ and $\lambda_2 = 0.05338$.

the fact that so far cyclic compounds are considered on the same basis as the acyclic ones, following strictly the description given by eq. [8]. Considering now that eq. [8] describes non-cyclic compounds in which internal rotations are as free as possible and, moreover, that internal rotations are hindered in cyclic compounds, we subtract tentatively $\frac{1}{2}RT = 0.296$ kcal (at 298.16 K) for each C—C bond in the cycle (rule 4). The results are presented in Table 3.

The comparison of the ZPE + $H_T - H_0$ energies derived from eq. [7] with their experimental counterparts clearly confirms the validity of eq. [7] for this class of compounds. The remarkable agreement between ZPE + $H_T - H_0$ energies constructed from the admittedly crude rules 1–4 and their "experimental" counterparts deduced from eq. [7] suggests that these cycloalkanes behave in essence like acylic alkanes inasmuch as vibrational energies are concerned, provided that the suppression of internal rotations is adequately taken into account. The fact that the $RT/2$ correction appears to be adequate further suggests that in acyclic hydrocarbons the contributions from internal rotations seem to be fairly close to $RT/2$, within experimental accuracy, even in relatively long chains.

TABLE 3. ZPE + $H_T - H_0$ energies of selected cycloalkanes

Molecule	ZPE + $H_T - H_0$, kcal/mol		
	Exptl.[a]	Eq. [7][b]	Rules 1–4
Cyclohexane	107.54	107.58	107.50
Methylcyclohexane	125.73	125.37	125.37
Ethylcyclohexane		144.17	143.59
n-Butylcyclohexane		180.30	180.01
cis-1,3-Dimethylcyclohexane		143.46	143.24
trans-1,4-Dimethylcyclohexane		143.46	143.24
1-*cis*-3-*cis*-5-Trimethylcyclohexane		161.54	161.11
trans-Decalin	166.90	166.96	166.71
trans-syn-trans-Perhydroanthracene		225.64	225.90
trans-anti-trans-Perhydroanthracene		225.96	225.90
Adamantane	153.54	153.64	154.25
Bicyclo[2.2.2]octane	130.83	131.17	130.87

[a]The value for bicyclo[2.2.2]octane is given in ref. 15. The other results are given in ref. 4 and were deduced from the spectroscopic data of ref. 6 and the $H_T - H_0$ values reported in ref. 7.
[b]The experimental ^{13}C and ΔH_f^0 data used in eq. [7] are indicated in Table 4.

Now, of course, there is no reason to assume that the individual energy contributions in cycloalkanes are necessarily *exactly* the same as in noncyclic paraffins. To begin with, the comparison of ZPE + $H_T - H_0$ energies derived by means of eq. [7] for isomer pairs differing by the number of butane *gauche* interactions (e.g., *cis*- vs. *trans*-decalin) indicates a lowering of the ZPE + $H_T - H_0$ energy by 0.853 kcal/mol for one *gauche* interaction. A multiple regression analysis carried out using ZPE + $H_T - H_0$ energies derived for sixteen cycloalkanes containing no quaternary C atoms indicated, firstly, a contribution of 18.249 kcal/mol for each carbon atom and, secondly, a decrease of 0.322 kcal/mol for each tertiary C atom of the molecule. Moreover, the removal of one H atom in the formation of polycyclic structures reduces the ZPE + $H_T - H_0$ energy by 5.925 kcal/mol. Finally, this energy is further lowered by 0.296 ($= \frac{1}{2}RT$) kcal/mol for each CC bond of the cycle(s). These results are expressed by eq. [11], where n_C and $n_C + m - 1$ are, respectively, the numbers of C atoms and CC bonds in the cycle(s) and $2(m - 1)$ is the number of H atoms removed in the formation of polycyclic compounds.[1] The number of butane *gauche* interactions is n_g.

$$[11]\quad \text{ZPE} + H_T - H_0 = 11.850(1 - m) + 18.249n - 0.322n_{\text{tert}} - (n_C + m - 1)RT/2 - 0.853n_g$$

This approximation yields accurate estimates of ZPE + $H_T - H_0$ energies and involves only the knowledge of the molecular structures. Indeed, enthalpies of formation calculated from eq. [7] (or eqs. [5] and [6]) using the results given by eq. [11] and the appropriate ^{13}C nmr data are accurate within 0.168 kcal/mol (average deviation) when compared with their experimental counterparts. The results are given in Table 4.

This verification by means of experimental ΔH_f^0 values includes two compounds (**9** and **34**) which were not considered in the parameterization of eq. [11] because of the quaternary C atoms contained in their structures. Here, quaternary C atoms were tentatively treated like tertiary carbons. While the present results clearly support the validity of this approximation, additional verifications would be desirable. The enthalpy differences between **9**, **10**, and **11** calculated in this fashion can nevertheless be regarded as being reasonably reliable, as well as the difference of 1.41 kcal/mol between the *trans*- and *cis*-9-methyldecalins. For the latter compounds, the experimental ΔH_f^0 difference in the liquid phase is 1.39 ± 0.64 kcal/mol (24).

It is noteworthy that the change from chair to boat cyclohexane has no effect (or only a very minor one) on ZPE + $H_T - H_0$. This is clearly indicated by the results obtained for *trans-anti-trans*-perhydroanthracene (**26**) and bicyclo[2.2.2]-octane (**32**) and is further supported by the ZPE + $H_T - H_0$ energy determined for **32** by Boyd *et al.* (15), 130.83 kcal/mol, which is precisely the value derived from eq. [11].

As regards the perhydroanthracenes, our calculated ΔH_f^0 values can be compared with the results derived from Allinger's equilibration experiments in the liquid phase (25). Of course, liquid and gas phase results are not identical. *cis*-Decalin, for example, is less stable than its *trans* isomer by

[1]Not too much importance should be attached to the precise values of these parameters as they are subject to slight changes depending upon whether or not one or another compound is left out of the regression analysis. Inclusion of a constant term in the correlation yields an insignificant improvement (~0.02 kcal/mol in average deviation) and cannot be justified within the precision of this type of analysis.

[a]The carbon-13 nmr are extracted from ref. 16 (**1**, **2**, **5**–**13**), ref. 17 (**3**, **4**), ref. 18 (**14**–**24**, **34**), ref. 19 (**25**–**31**), ref. 20 (**32**), and ref. 21 (**33**). The experimental enthalpies of formation are taken from ref. 1*a* (**1**–**8**, **14**, **15**, **25**, **26**), ref. 7 (**9**), ref. 22 (**12**, **13** from equilibration experiments), ref. 15 (**32**, **33**), and ref. 23 (**34**).

2.69 kcal/mol in the liquid and by 3.36 kcal/mol in the gas phase (26). Relative to **25**, the compounds **27**, **26**, and **28** are less stable, in that order, by 2.76, 4.15, and 5.58 kcal/mol in the liquid phase and by 3.42, 5.07, and 7.05 kcal/mol, as calculated for the gas phase.

In Table 4 we have only considered molecules for which the structural dependence of the ZPE + $H_T - H_0$ energies has been substantiated by an adequate body of experimental data, thus leaving out structural features (e.g., *skew* pentane, or interactions between methyl substituents in a 1,2 position) for which no, or too little, experimental information is presently available. Because of this selection, our predicted ΔH_f^0 values should represent reasonably good estimates.

Conclusions

The energetic factors governing molecular stabilities are conveniently classified into, firstly, a part which relates to molecules in their hypothetical vibrationless state at 0 K and, secondly, a contribution arising from vibrational energies.

In the part not involving vibrational energies, the prime factors are found in the behavior of the charge dependent bonded contributions, whereas interaction energies between non-bonded atoms are little affected by structural features and do not account for the bulk of the energy differences between isomers or conformers (14). The atomization energy ΔE_a^*, covering both bonded and non-bonded interactions, is a measure of the molecular energy component referring to vibrationless molecules.

Combining the description given for ΔE_a^* in terms of an additivity scheme explicitly involving atomic charges with the thermochemical definition of ΔE_a^*, we obtain a new formula for ZPE + $H_T - H_0$ energies, which can now be calculated accurately in a very simple way from ^{13}C nmr data and the appropriate enthalpies of formation. The examination of numerous ZPE + $H_T - H_0$ energies

derived in this fashion has led to simple empirical formulas for their evaluation from structural features. Noteworthy aspects are (*i*) the decrease in ZPE + $H_T - H_0$ energy by $\sim RT/2$ for each hindered internal rotation in cycloalkanes, (*ii*) its invariance with respect to the change from the chair to the boat conformation of the cyclohexane ring, and (*iii*) the decrease in vibrational energy by ~0.85 kcal/mol for one *gauche* interaction involving H atoms of the cycle.

The thermochemical stabilities are a blend of both ΔE_a* and vibrational energy components. Isomer pairs differing by the number of *gauche* interactions (e.g., *trans*- vs. *cis*-decalin) usually reveal a decrease of ~1.85 kcal/mol in ΔE_a* energy for one *gauche* interaction, i.e., a weakening of the chemical bonds. Because of the concurrent decrease in vibrational energy by ~0.85 kcal/mol, which is a stabilizing effect, the total destabilization due to one *gauche* interaction is ~1.0 kcal/mol. This analysis of the *gauche* effect clearly shows that it has nothing to do with Coulomb-type repulsions between non-bonded atoms. In comparisons between isomers, the order of stability indicated by the ΔE_a* energies is in most cases also reflected in the ΔH_f^0's. An interesting exception is the *cis-trans*-perhydroanthracene[2] which is 0.91 kcal/mol less stable in ΔE_a* energy than its *trans-anti-trans* isomer but more stable in terms of ΔH_f^0 by 1.65 kcal/mol because of its low content in vibrational energy. This point is confirmed by Allinger's equilibration experiments (25).

While this last example further stresses the important role of the vibrational contributions in determining molecular stabilities, it is clear that the present analysis is incomplete as it would not account for a number of possible structural features. In turn, the possibility of deriving ZPE + $H_T - H_0$ energies in a simple manner by means of eq. [7] offers a new way of recognizing the occurrence of other possible regularities from an examination of numerous cases.

Absorption and magnetic circular dichroism (mcd) spectra of toluene solutions of zinc octamethyltetrabenzporphyrin, Zn(OMBP), exhibit marked concentration and temperature dependence. Monomeric Zn(OMBP), **1**, characterized by a 429 nm Soret band, dominates at low concentrations (10^{-7} *M*, 300 K) and higher temperatures (10^{-5} *M*, 320 K) in toluene solution. Decreasing temperatures (320 to 235 K for a 10^{-5} *M* solution) and increasing concentrations (10^{-7} *M* to 10^{-4} *M*, 300 K) result in 8–10 nm red shifts in this band. These spectral changes are attributed to the concurrent formation of a species **2** with a low extinction coefficient and another compound, **3**, with λ_{max} at 439 nm. At the highest concentrations (10^{-3} *M*) and lowest temperatures (225–190 K) used, a dramatic blue shift (439 to 422 nm) due to a fourth species (**4**) is observed. All the spectral changes observed are completely reversible. In addition, and consistent with self-association, species **2**, **3**, and **4** are formed at higher temperatures as the concentration is increased. Possible aggregate structures are proposed and evidence is presented for a novel Zn—N (pyrrole) intermolecular bond.

KENNETH J. REIMER, MONICA M. REIMER et MARTIN J. STILLMAN. Can. J. Chem. **59**, 1388 (1981).

Les spectres d'adsorption et de dichroïsme circulaire magnétique (dcm) de solutions d'octaméthyltétrabenzporphyrine de zinc, Zn(OMBP), dans le toluène varient d'une façon importante avec la concentration et la température. Le monomère Zn(OMBP), **1**, caractérisé par une bande de Soret à 429 nm, domine aux faibles concentrations (10^{-7} *M*, 300 K) et aux températures élevées (10^{-5} *M*, 320 K) en solution dans le toluène. Si on diminue la température (de 320 à 235 K, pour des solutions 10^{-5} *M*) et si on augmente la concentration (de 10^{-7} à 10^{-4} *M* à 300 K) il se produit des déplacements de 8 à 10 nm de cette bande vers le rouge. On attribue ces changements spectraux à la formation simultanée d'une espèce, **2**, avec un faible coefficient d'extinction et d'un autre composé, **3**, caractérisé par un λ_{max} à 439 nm. Si on utilise des concentrations plus élevées (10^{-3} *M*) et des températures plus basses (225–190 K), on observe un déplacement dramatique vers le bleu (439 à 422 nm) provoqué par une quatrième espèce (**4**). Tous les changements observés dans les spectres sont réversibles. De plus et en accord avec l'auto-association, les espèces **2**, **3** et **4** se forment à des températures plus élevées quand on augmente la concentration. On propose des structures associées possibles et on présente des données relatives à une nouvelle liaison intermoléculaire Zn—N (pyrrole).

Introduction

Self-association of metalloporphyrins (1) and related compounds (2) has been known for some time. Because of their biological significance, and potential catalytic importance (3), current interest has focussed on the structures and intermolecular bonding of such aggregates (4). Dimers have been characterized in aqueous media and organic solvents at concentrations of 10^{-2}–10^{-3} *M* by nmr and epr spectroscopy (1, 4), and observed at 10^{-6} *M* by optical methods (5), but higher aggregates, particularly at low concentration ($< 10^{-4}$ *M*) are essentially unknown (1, 4).

This paper describes the facile self-association of zinc octamethyltetrabenzporphyrin (Fig. 1). Although benzporphyrins are known to have unique optical (6) and redox characteristics (7) there have been no reports of concentration dependent phenomena (for a preliminary report see ref. 8). Particularly unusual in the present instance is the formation of several aggregate species in dilute solutions. These observations can be attributed to

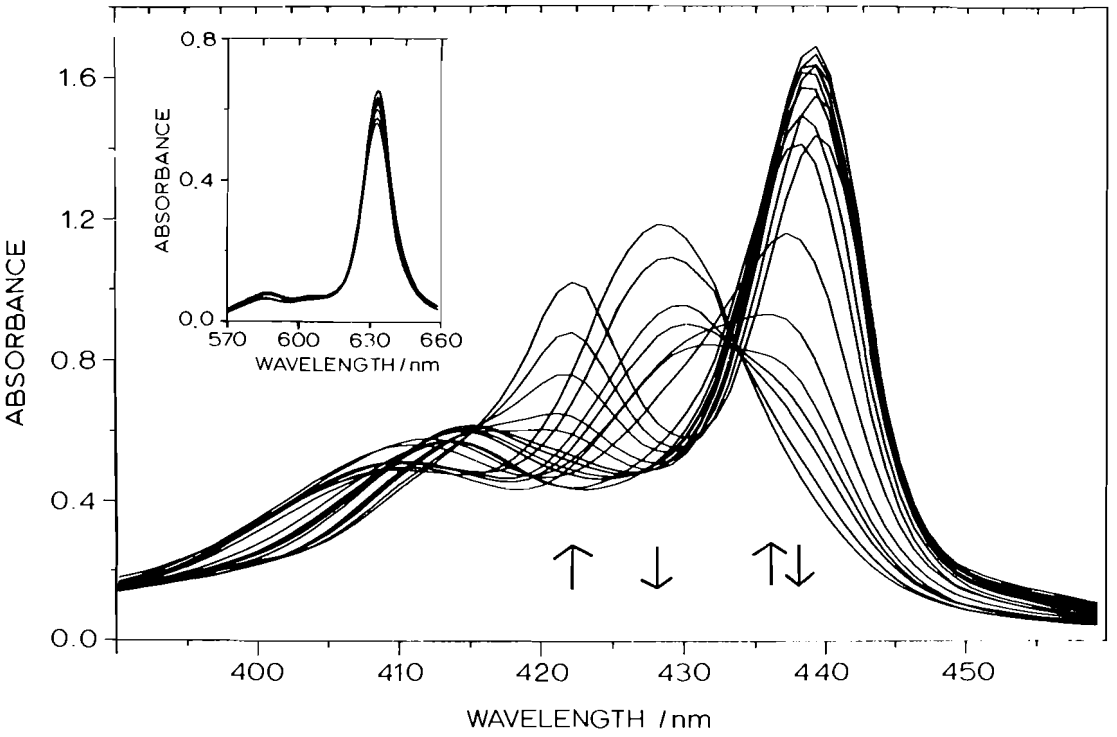

FIG. 2. Temperature dependence of the absorption spectrum of a 10^{-5} *M* toluene solution of Zn(OMBP). The major portion shows the Soret region for spectra recorded between 320 and 190 K. The arrows indicate the spectral changes that occur upon cooling the solution from 320 K. The intensity in the 439 nm region first increases and then decreases at the lowest temperatures. The inset shows the *Q* band region at all temperatures.

the special donor properties of the $OMBP^{2-}$ ligand described herein.

Experimental

A sample of Zn(OMBP), prepared by a modification (9) of the original procedure, was generously supplied by J. R. Sams and T. B. Tsin. Solutions freshly prepared without exclusion of air using Fisher "spectroscopy grade" toluene gave identical results to anaerobic control experiments employing toluene distilled from calcium hydride.

A Cary 14 spectrometer was used to record all of the absorption data. Each trace was simultaneously digitized using equipment designed and constructed at the U.W.O. The spectra presented here are computer plots of these original data. An Oxford Instruments exchange gas cryostat, CF204, coupled to a digital temperature controller, DTC2, was used to maintain the temperature of each sample within ±0.1 K. The absolute temperature is correct to ±1 K. Magnetic circular dichroism (mcd) spectra were recorded with a Jasco J5 spectrometer modified to Sproul SS20 specifications, and using an Oxford Instruments SM2 superconducting magnet operating at 5.5 T. The mcd data were digitized as above. The spectrometer was calibrated by measuring the negative band of aqueous $CoSO_4$, which gave a value of $[\theta]_M = -61.0$ deg cm^2 dmol^{-1} T^{-1}.

Results

Temperature Dependence

Figure 2 is a composite of all of the spectra obtained from a 10^{-5} *M* Zn(OMBP) toluene solution from 320–190 K. In contrast to the relative invariance of the 630 nm band (inset), the Soret spectral region displays extremely complex behavior. Several distinctive features may be discerned within this data set and for greater clarity representative spectra are plotted in Figs. 3–5.

Figure 3 shows that the 429 nm absorption which dominates the spectrum at 320 K undergoes a red shift with decreasing temperature, 320–295 K; cooling below 295 K results in a further red shift at the expense of the 429 nm absorption. In the range 255–235 K, subsequent to the complete disappearance of the 429 nm band, an isosbestically related series of spectra (Fig. 4) is defined by an increase in intensity at 439 nm due to a further red shift from a very weak absorption. A new isosbestic set of spectra (Fig. 5) results from the loss of the 439 nm species and the formation of a new blue-shifted band at 422 nm. This band continues to grow to 190 K (near the fp of toluene). All spectral features are reproducible at different Zn(OMBP) concentrations and are completely reversible with temperature.

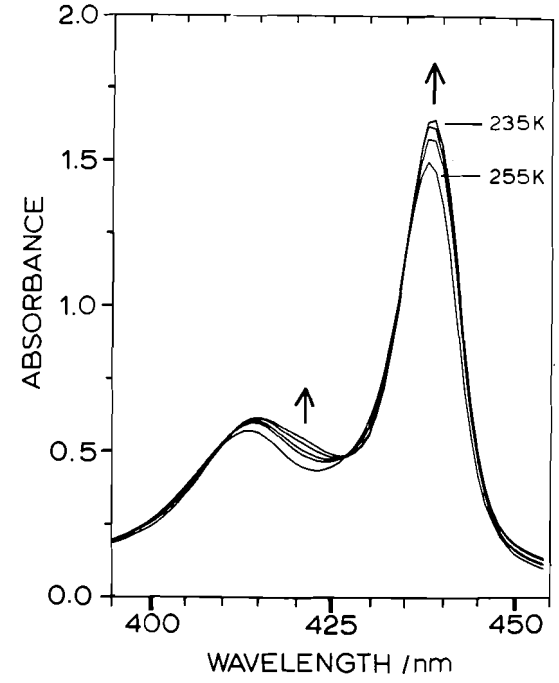

FIG. 4. Mid temperature data set, 255–235 K.

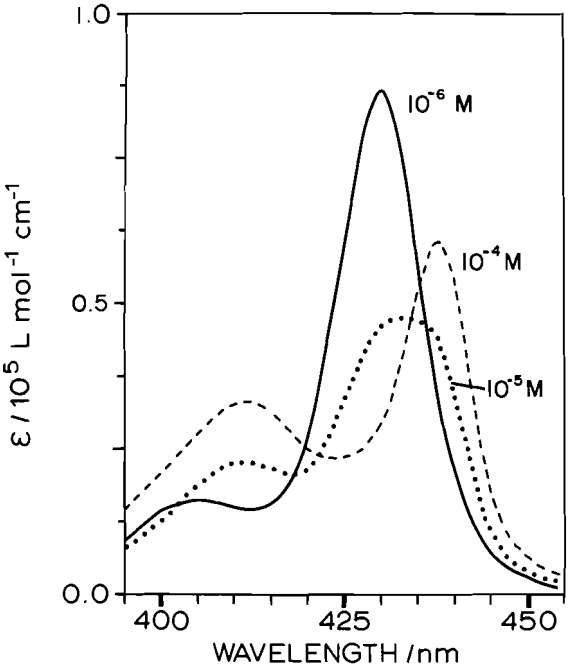

FIG. 6. Concentration dependence of the absorption spectrum of Zn(OMBP). Extinction coefficient calculated on the basis of the total monomeric porphyrin concentration.

Concentration Dependence

Unlike the temperature dependence data, isosbestic points were not seen in the related room temperature concentration dependence results despite considerable experimental effort. Representative data from one experiment are summarized in Fig. 6, for a range of concentrations from 10^{-6} (a similar band is observed for 10^{-7} *M* solutions) to 10^{-4} *M*. Red shifts accompany increasing concentration as does an increase in the intensity of the 439 nm band. There is only a slight increase in

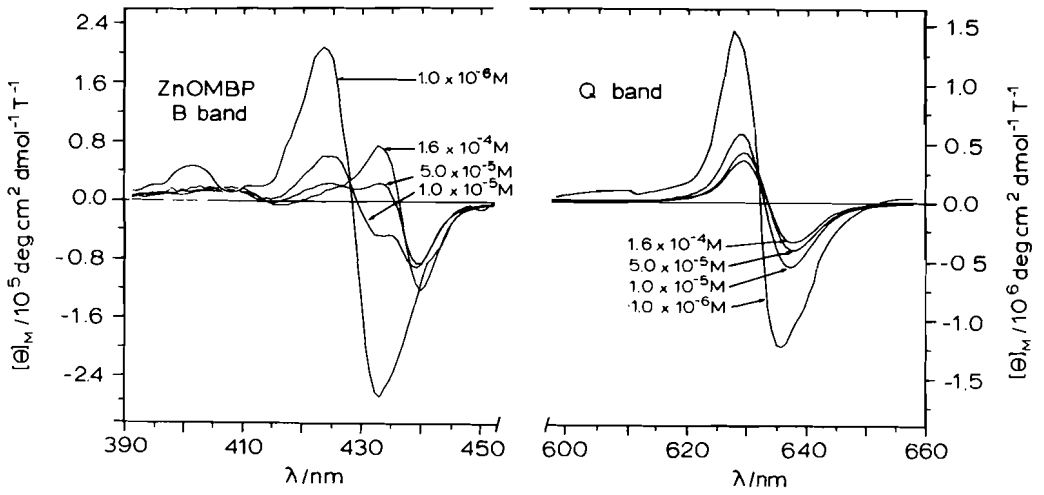

FIG. 7. Concentration dependence of the mcd spectra of Zn(OMBP). Ordinate values were calculated on the basis of the total monomeric porphyrin concentration.

absorbance at 422 nm at the highest concentrations ($\sim 10^{-3}\,M$) suggesting that this might be the next species to develop as it is found at the lowest temperatures used.

It is notable that the extinction coefficient of the 439 nm band, calculated on a monomer basis, is far less than that of the initial monomer, contrasting the considerable increase in absorbance observed for the 439 nm band at low temperatures.

Magnetic Circular Dichroism Concentration Dependence

Figure 7 shows a series of mcd spectra recorded for Zn(OMBP) solutions ranging in concentration from 1×10^{-6} to $1.6 \times 10^{-4}\,M$, a range similar to that in Fig. 6. The ordinate units were calculated using the nominal monomer porphyrin concentration with no account taken for aggregation.

Following the absorption spectrum, the mcd of the most concentrated solution shows a Soret band that is weaker and has a slightly smaller half-width than the spectrum of the most dilute solution. Although an initial analysis of the mcd data in Fig. 7 suggests that a two-species system may be present, the lack of isosbestic points in each of several concentration experiments requires a more complicated system. Two species must be formed with increasing concentration but one (with a 439 nm maximum) dominates at the highest concentration.

It is also apparent that the mcd intensity of the other species is very low, as no clear spectral features can be identified, apart from the lack of isosbestic points. The visible region Q band envelope similarly loses intensity as the solution concentration increases, the band centre being slightly red-shifted at the highest concentration.

Figure 8 shows the absorption and mcd spectra of the most concentrated solution used ($1.6 \times 10^{-4}\,M$). From the sequence of the absorption data in Fig. 6 it can be seen that the dominant species is an aggregate. Surprisingly the spectra in Fig. 8 have all the characteristics of a monomeric species (10). The Q_{00} region is clearly resolved, especially in the mcd spectrum where individual components of the Q_{vib} envelope can be discerned, and the band half-widths are almost the same as the most dilute solution ($10^{-6}\,M$), see the insert in Fig. 2.

In the Soret region, we observe a well resolved positive A term under the 439 nm band, clearly identifying the degeneracy of the second $\pi \rightarrow \pi^*$ transition, followed, to higher energy, by a weak shoulder at about 424 nm. It is rather easier to see the shoulder in the mcd spectrum, and it is likely that this band is the B_{01} transition normally buried in a broader Soret band envelope. In spectra where the B_{00} band is very sharp, for example ZnTPP, a weak and fairly well resolved shoulder is seen to higher energy. For ZnTPP, CuOEP, and CoOEP, the mcd shows (10*c*) a weak positive band at this wavelength, quite similar to the overlapping positive mcd signal at 425 nm in the ZnOMBP spectrum.

The prominent resolved band at 411 nm is associated with a weak mcd signal that appears to be a positive A term centred on the absorption band centre. Although it is common for Q band envelopes to exhibit a series of well resolved vibrational components, often extending some 2000–3000 cm^{-1} from Q_{00}, and of significant intensity in both absorption and mcd spectra, it would be unusual for the B_{01} bands to be as intense and well separated from the B_{00} transition as would be the

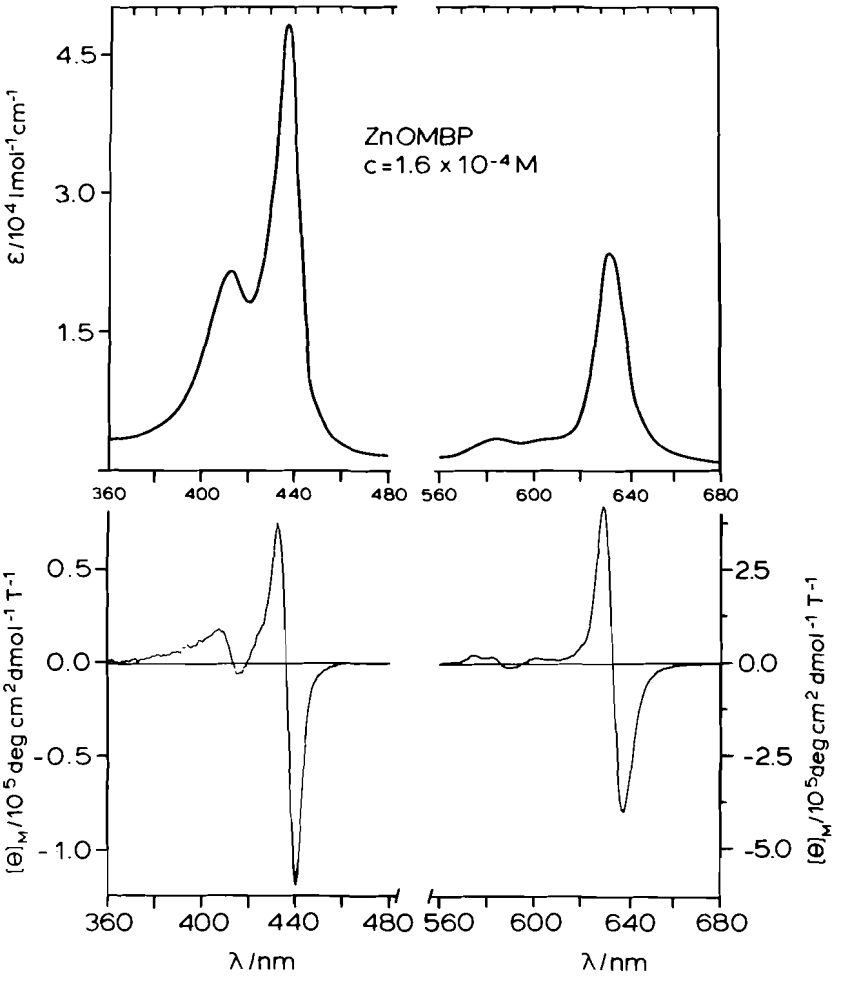

FIG. 8. Absorption and mcd spectra of a concentrated (1.6×10^{-4} *M*) toluene solution.

case if the 411 nm band was a vibronic band. It is more reasonable to suggest that this is the *N* band of the porphyrin, i.e., the third $\pi \rightarrow \pi^*$ transition (10, 11). A similar band is also clearly visible in the spectra of many zinc porphyrins (10*a*, *c*) and phthalocyanines (12).

Discussion

Aggregation phenomena reported to date are not nearly as complicated as those exhibited by Zn(OMBP) in toluene. Typically, the observed spectral changes are isosbestically related and have been interpreted in terms of a monomer $\rightleftharpoons$ dimer equilibrium (1, 4, 5). The data presented in this paper show unambiguously that more than one species is formed with Zn(OMBP). Of even greater significance, it is clear that the type of association found at intermediate concentrations ($\sim 10^{-5}$ to 10^{-6} *M*), close to room temperature (295 K, 10^{-5} *M*), and which is characterized by red shifts of the Soret band, is completely different from the association observed at the lowest temperatures (<225 K for 10^{-5} *M*) where a 17 nm (439 to 422 nm) blue shift is seen.

Species **1**, with a 429 nm Soret band, is undoubtedly monomeric as it is observed for all low concentration solutions (10^{-7} *M*) and at the highest temperatures (320 K) used. This is additionally verified by an analysis of separate ligand binding data (13). We assume that the toluene solvates the porphyrin under these conditions, however, it is not clear whether the interaction is through the metal or the porphyrin π system.[2] As the solution temperature is lowered, or as the concentration of the porphyrin is increased, the Soret band shifts some 8–10 nm to higher wavelength.

[2]Both types of interaction have been observed in the solid state (14). No spectral changes are observed when hexamethylbenzene is added to dilute dichloromethane solutions of Zn(OMBP).

It is tempting to interpret the 320–295 K spectral changes shown in Fig. 3 in terms of a simple equilibrium between the monomer and a single compound characterized by this red-shifted Soret band. However, a closer examination of the composite temperature dependence spectra (Fig. 2), and the 410 nm region in particular, indicates that the apparent isosbestic point at 435 nm is fortuitous. It is lost at temperatures below 295 K and no isosbestic point is ever found in the concentration dependent spectra (including the mcd data). These concentration data argue strongly against successive compound formation (with overlapping equilibria) but are consistent with the simultaneous formation of two species, **2** and **3**, at concentrations $< 10^{-5} M$. Similarly, both species are probably present at most temperatures between 320 and 255 K. As the spectral changes are dominated by the 439 nm absorption due to **3**, species **2** must have a low extinction coefficient and is also mcd inactive. It is therefore difficult to assign a peak position to this compound, but it must lie in the range 435–439 nm. This is verified by the 255–235 K spectral set (Fig. 4) which is indicative of a **2** to **3** transformation. In the concentration data, the low intensity of the 439 nm band relative to 429 nm at $10^{-4} M$ (Fig. 6) suggests that this band is still a composite of absorptions due to both species **2** and **3**. Finally, at the lowest temperature studied, a fourth species, **4**, (λ_{max} at 422 nm) replaces compound **3** (Fig. 5). The combination of temperature and concentration data, and the reversibility of all spectra, can only be explained by the formation of aggregated species.

Three main modes of aggregation have been described (15) for dimers reported in the literature: (*i*) an electrostatic metal $d\pi$ – porphyrin π interaction (4), (*ii*) a donor–acceptor complex involving a porphyrin π–π interaction (16), and (*iii*) a peripheral substituent-to-metal coordination of the type found in chlorophyll dimers (2). The extent of aggregation through modes (*i*) and (*ii*) is enhanced by asymmetric substitution (particularly with electron-withdrawing groups) of the porphyrin ring; indeed it appears that an asymmetric electronic distortion may be a necessary condition for dimer formation through (*i*) or (*ii*) (4, 16). The complicated aggregation observed for Zn(OMBP) is unusual because $OMBP^{2-}$ is a symmetric porphyrin.

Structural assignments in the present case are complicated by the relatively few optical studies available, as aggregation is usually only significant at concentrations more accessible by nmr and epr measurements (1, 4). The only related example of a symmetrical porphyrin is zinc octaethylporphyrin, Zn(OEP), which undergoes discrete dimer formation accompanied by a blue shift (5).

Red shifts in zinc porphyrin Soret bands are associated with axial ligand coordination to the zinc, the extent of the red shift being directly related to the nature of the donor atom (17). Zinc must therefore play an important role in species **2** and **3**. The coincidence of the spectrum of **3** recorded (13) for monomeric Zn(OMBP) in the presence of pyridine or any neutral nitrogen donor ($\lambda_{max} = 439$ nm) provides compelling support for a geometrical arrangement of **3** that involves the coordination of zinc to one of the ring nitrogens on an adjacent porphyrin. The structure depicted in Fig. 9 is consistent with the above data and the (maximum) five-coordinate stoichiometry observed for all (13, 17) zinc porphyrin complexes including Zn(OMBP).

An alternative explanation involving coordination of adventitious water can be dismissed on the following grounds. First, spectra of toluene solutions of Zn(OMBP) prepared under rigorously anhydrous conditions are identical to those obtained using water-saturated toluene. (Similarly weak binding of water to Zn(TPP) has been reported (17).) Secondly, O-donor ligands such as dimethylacetamide induce small (~3 nm) red shifts and intense ($\varepsilon \sim 10^5 M^{-1}cm^{-1}$) Soret bands, behavior which is inconsistent with the spectroscopic properties of both **2** and **3**. Finally, the concentration of adventitious water should be constant, yet the same red shifts are observed with increasing concentration of Zn(OMBP) as are noted with decreasing temperature. Thus, the concentration dependence experiments demonstrate unequivocally the involvement of a donor group other than water.

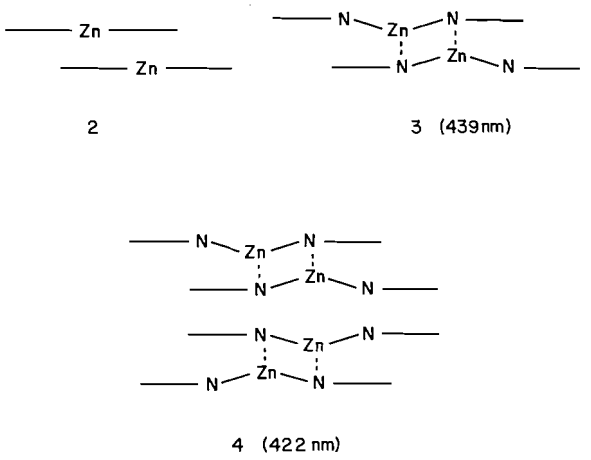

FIG. 9. Proposed aggregate structures for species **2**, **3**, and **4**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

Further support for a Zn—N coordinative interaction comes from related experiments with CH_2Cl_2 solutions. Only slight red shifts (<2 nm) and increasing absorbance are observed with increasing concentration of Zn(OMBP); identical effects are again noted on pyridine addition to solutions of the monomer. Although the extent of Zn(OMBP) aggregation is less in CH_2Cl_2, it is notable that it occurs at all (1) in this polar solvent.

While the above data support a model for **3** that involves a zinc—N (pyrrole) intermolecular bond, we find little direct evidence for the geometrical arrangement of **2**. However, it is not inconsistent that mode (*i*) may obtain a weak electrostatic interaction between the zinc and the porphyrin π orbitals (Fig. 9).

Finally, at the lowest temperatures (<225 K) a new species, **4**, (λ_{max} = 422 nm) forms at the expense of **3**. Similar large blue shifts (ca. 20 nm) have been observed for cofacial porphyrins (18) and with the dimerization of Zn(OEP) (5). These two examples suggest that the blue shift arises from $\pi-\pi$ interactions of the porphyrins rather than metal specific interactions (especially as the same shifts occur for metal-free cofacial porphyrins (18)). In the present case polymerization of the **3** dimers through $\pi-\pi$ interactions provides a reasonable model (Fig. 9). Thus units of **3** begin to associate through a weaker interaction to form dimers or higher aggregates.

Conclusion

The spectra of toluene solutions of Zn(OMBP) indicate that at least three aggregates form at high concentrations or low temperatures. The unusual behavior of the Soret band in exhibiting both red and blue shifts is only consistent with a scheme that involves axial coordination to the central metal for the red-shifted species. This result follows the general trend of an extremely electron deficient central metal in M(OMBP) species. The equilibrium constant for Zn(OMBP) + py $\rightleftharpoons$ Zn(OMBP)py is the largest yet reported (13) (log K = 5.63 compared with 3.76 for the analogous reaction with zinc tetraphenylporphyrin (17)) and similar trends are found for ligand binding to Co(OMBP) and Mn(OMBP).[3] The blue shifted species is an aggregate comprised of more typical, weaker $\pi-\pi$ association.

Aluminum chloride promoted reaction of 2,5-dimethylfuran with ethyl cyanoformate affords, depending on the experimental conditions, *cis* and *trans* ethyl 5-cyano-2,5-dimethyl-2,5-dihydrofuran-2-carboxylates, **3** and **4**, ethyl 2,5-dimethylfuran-3-carboxylate **5**, 4,8-dicyano-1,2,4,8-tetramethyl-3,9-dioxatricyclo-[5.2.1.$0^{2,6}$]decane **6**, and ethyl 3-(2,5-dimethyl-3-furyl)-5-cyano-2,5-dimethyltetrahydrofuran-2-carboxylate **7**. Structures were elucidated from spectral evidence and chemical transformations.

ARCHIBALD W. MCCULLOCH, A. GAVIN MCINNES et DONALD G. SMITH. Can. J. Chem. **59**, 1395 (1981).

Le chlorure d'aluminium initie la réaction du diméthyl-2,5 furanne avec le cyanoformate d'éthyle et conduit, selon des conditions expérimentales, aux cyano-5 diméthyl-2,5 dihydro-2,5 furanne carboxylates-2 d'éthyle *cis* et *trans*, **3** et **4**; au diméthyl-2,5 furanne carboxylate-3 d'éthyle, **5**; au dicyano-4,8 tétraméthyl-1,2,4,8 dioxa-3,9 tricyclo[5.2.1.$0^{2,6}$] décane, **6**, et au (diméthyl-2,5 furyl-3)-3 cyano-5 diméthyl-2,5 tétrahydrofurannecarboxylate-2 d'éthyle **7**. On a déterminé les structures des produits obtenus à partir de données spectroscopiques et de transformations chimiques.

[Traduit par le journal]

Introduction

We have recently studied the $AlCl_3$-promoted reaction of 2,5-dimethylfuran **1** with ethyl cyanoformate **2**. This study was prompted in part by the reported isolation of azanorbornadiene adducts **18** from highly dienophilic sulfonyl cyanides (1), and also by our own experience with the influence of Lewis acids on certain Diels–Alder reactions of acetylenic dienophiles (e.g. ref. 2). Although no Diels–Alder addition was observed between **1** and **2**, a number of interesting heterocyclic products were obtained; these are described in the present communication.

Results and Discussion

The reaction of **1** with **2** in the presence of $AlCl_3$ in CH_2Cl_2 yielded a mixture of products, amongst which we have identified the *cis*- and *trans*-2-carbethoxy-5-cyano-2,5-dimethyl-2,5-dihydrofurans **3** and **4**, the 3-carbethoxyfuran **5**, the tricyclic derivative **6**, and the 2:1 adduct **7**. No Diels–Alder adduct **19** was detected.

Under all reaction conditions used, polymerization of **1** was a major factor, resulting in low yields of **3–7**. When the reaction was carried out at 10–15°C for 60 s only, the major products were **3** (11%) and **4** (5%), while reaction at 25°C for 1 h

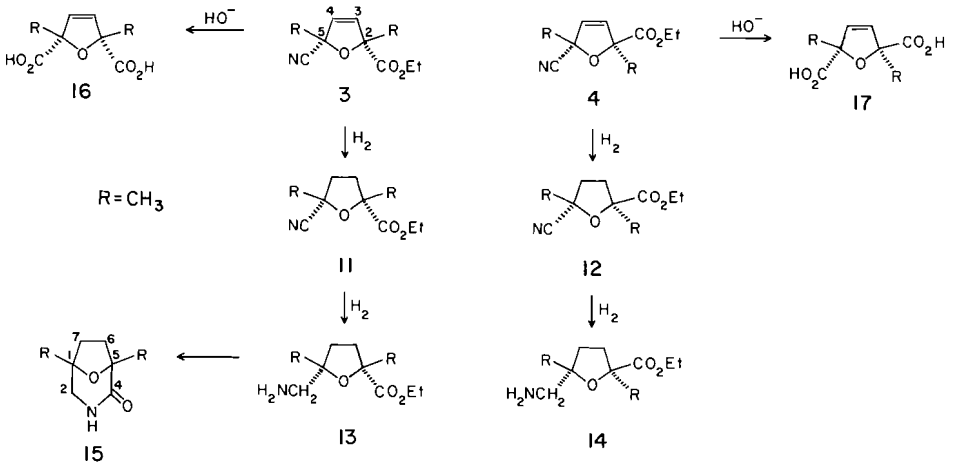
[e]The high-field proton was coupled (2.9 Hz) to the NH.

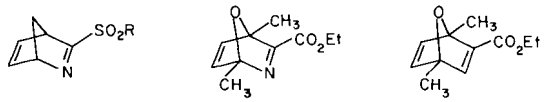


favored **5** (11%) and **7** (8%). Independent experiments established that at 25°C both **3** and **4** react (*a*) with $AlCl_3$ to give **5**, and (*b*) with **1** and $AlCl_3$ to give **6** and **7**.

Structures

The structures of all products were elucidated chiefly on the basis of their spectral properties (see Experimental and Tables 1 and 2). Mass measurement of the molecular ions of **3** and **4** established that each possessed the molecular formula $C_{10}H_{13}NO_3$, indicating 1:1 adducts formed by reaction of **1** and **2**. Mass spectral fragmentation of each isomer involved facile cleavage of a $—CO_2C_2H_5$ moiety. The ^1H nmr spectrum (Table 1) in each case showed an AB quartet for two olefinic hydrogens with a coupling (J_{AB} = 5.8 Hz) consistent with a 2,5-dihydrofuran system (3), two nonequivalent *C*-methyl singlets, and signals corresponding to the protons of a carbethoxyl substituent. The ^{13}C nmr spectra (Table 2) showed corresponding signals for the carbons of two olefinic methine, two nonequivalent methyl, and one carbethoxyl group. Signals near 82 and 92 ppm for the two quaternary carbons bonded to methyl groups were consistent with deshielding by oxygen. The remaining resonance was identified as a nitrile carbon by its characteristic chemical shift (ca. 119 ppm). (This was supported by weak ir absorption at ca. 2230 cm^{-1}.) The combined evidence is compatible only with the dihydrofuran structures **3** and **4**. The quaternary carbon resonances (C-2 and C-5) of each compound could be clearly differentiated on the basis of the known shielding effects of attached nitrile and carbethoxyl substituents (4). The methyl and olefinic carbons could be similarly assigned.

Catalytic reduction of **3** and **4** gave the corresponding tetrahydrofurans **11** and **12**. The ^1H nmr spectrum of each of the latter showed four ring methylene, but no olefinic, hydrogens. Their high-resolution ^{13}C nmr spectra confirmed that the two olefinic carbons of **3** and **4** had in each case been replaced by two methylene carbons, while characteristic resonances (and also ir absorptions) for cyano groups established that the nitrile functions of **3** and **4** were retained in **11** and **12**.



18 **19** **20**

The cyano groups of **11** and **12** could be reduced on exhaustive hydrogenation. The products, amino-esters **13** and **14**, were unstable, and attempts to isolate pure samples were unsuccessful. In each instance ^1H and ^{13}C nmr spectra of the freshly-prepared material were consistent with the amino-ester structure. The most important features of the ^{13}C spectra were the absence of the CN resonance and the presence of new signals near 59 ppm which could be assigned to methylene carbons deshielded by an attached nitrogen.

The products of exhaustive hydrogenation of **3** also included the lactam **15**, establishing that the cyano and carbethoxyl groups in **3** have a *cis* orientation. No lactam was formed after reduction of **4**, which must therefore have the corresponding *trans* stereochemistry. Mass measurement of **15** established the molecular formula $C_8H_{13}NO_2$. The combined ^1H and ^{13}C nmr evidence confirmed that the ethyl group of the carbethoxyl function of **3** had been lost and that new methylene (δ_C 54.2, carbon deshielded by the attached N) and —NH—(δ_H 7.05) groups had been formed. Characteristic carbonyl and NH absorptions for a cyclic amide were observed in the ir.

Finally, saponification of **3** and **4** afforded the corresponding *cis* and *trans* diacids **16** and **17**, which for symmetry reasons gave signals for pairs

of chemically equivalent methyl groups and olefinic hydrogens (Table 1).

Identification of the 3-carbethoxyfuran **5** posed no problem since we had previously isolated this compound as a product of Diels–Alder retrogression of the oxanorbornadiene **20** (5).

The mass, ir, ^{1}H nmr, and ^{13}C nmr spectra of compound **6** suggested a product comprised of two 2-cyano-2,5-dimethyltetrahydrofuran moieties linked together. Structure **6** was established through X-ray analysis of its crystalline derivative **8** (6).

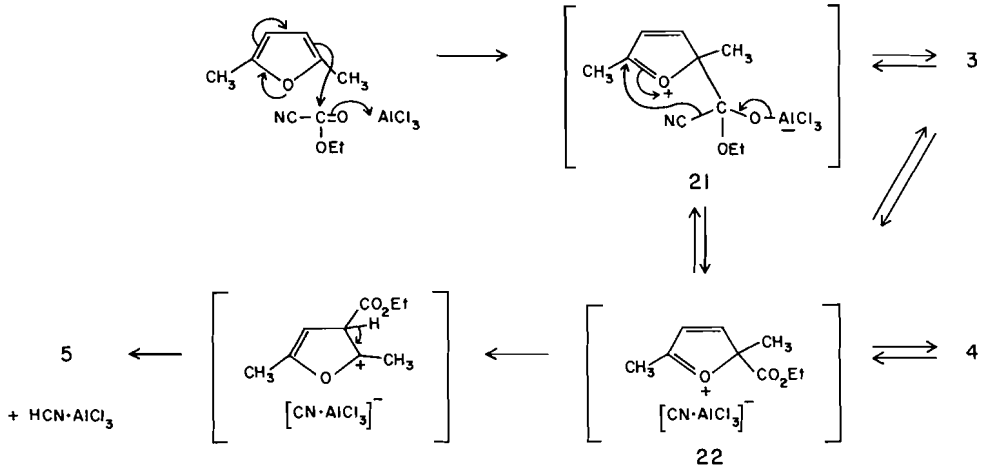
In the case of **7**, mass measurement established the molecular formula $C_{16}H_{21}NO_4$, suggesting a 2:1 product of **1** with **2**. The ir spectrum confirmed the presence of ester (1720 cm^{-1}) and nitrile (2235 cm^{-1}) groups. The ^{1}H nmr spectrum showed two broadened *C*-methyl signals at 2.19 and 2.26 ppm, both coupled to a single hydrogen at 5.65 ppm. In addition, the ^{13}C nmr spectrum showed resonances for two *C*-methyl carbons at 11.79 and 13.26 ppm, a single ring CH at 104.79 ppm, and three quaternary ring carbons at 113.53, 147.62, and 149.90 ppm. These combined data indicated the presence of a 3-substituted 2,5-dimethylfuryl ring system (cf. ref. 7 and also ref. 4, p. 253). Furthermore, ^{13}C signals for two quaternary carbons linked to oxygen (76.12 and 88.67 ppm), and a nitrile (122.06 ppm), and ^{1}H and ^{13}C resonances for a carbethoxyl, a —CH_2CH—, and two chemically nonequivalent methyl groups, indicated that the second ring of **7** is a β-substituted 2-carbethoxy-5-cyano-2,5-dimethyltetrahydrofuryl moiety. The two rings can be linked together at either β-position of the tetrahydrofuran ring. The ester-substituted (88.67 ppm) and cyano-substituted (76.12 ppm) ring carbons of **7** can be readily distinguished on the basis of substituent effects (4). The fact that the carbon bearing the carbethoxyl in **7** is deshielded (by about 3 ppm) compared to the corresponding carbon in **11** and **12**, while the nitrile substituted carbon is virtually unaffected, indicates that the furyl substituent in **7** is located on the carbon (C-3) adjacent to the ester-bearing carbon. This was confirmed by selective decoupling experiments. Irradiation of the methine hydrogen (H-3) had a significant effect on the carbonyl carbon resonance (causing the doublet of quartets to collapse to a broad quartet), but negligible effect on the nitrile resonance. Similarly, irradiation of the methylene ring hydrogens (H-4) caused a significant change in the nitrile carbon resonance (causing the triplet of quartets to collapse to a quartet), but had little effect on the carbonyl signal.

The relative stereochemistry of **7** was deduced on the basis of (*a*) nuclear Overhauser enhancement (13%) of the ^{1}H nmr signal for H-3 upon irradiation of the adjacent methyl hydrogens, establishing their *cis* relationship, and (*b*) failure to form either an anhydride from diacid **9** (obtained by saponification) or a lactam from the amino-ester **10** (obtained by catalytic reduction), showing that the ester and nitrile functions of **7** must be *trans*.

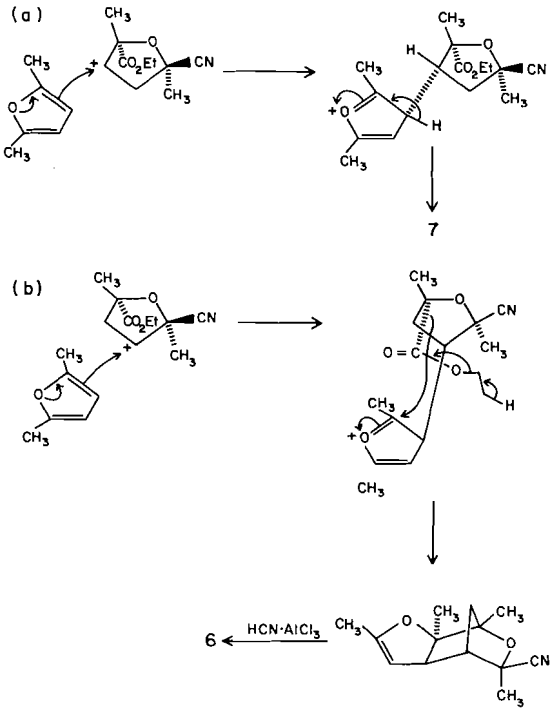
Mechanisms

Electrophilic attack of the cyanoformate – $AlCl_3$ complex at position 2 of the 2,5-dimethylfuran ring (to give **21**) followed by intramolecular attack at position 5 by cyanide results in formation of the favored isomer **3**. Elimination of cyanide (from **21**) to give **22** and its reinsertion may result in either **3** or **4** (Scheme 1).

Intermediate **22** is also likely in the formation of **5**. Thus, migration of the carbethoxyl group of **22** accounts for the observed formation of **5** from



SCHEME 1



SCHEME 2

either **3** or **4** (Scheme 1); analogous ester migrations are well documented (8).

Any explanation of the formation of **6** and **7**, which are co-products of **5** in the $AlCl_3$-promoted reaction of **3** or **4** in the presence of **1**, must explain the observed stereochemistry of each product. Additional experiments showed that **6** was not formed through $AlCl_3$-promoted reactions of (*a*) **1** with HCN, (*b*) **7** with HCN, or (*c*) **7** with **2**. Pathways involving **4** as a common intermediate, and initiated in each case by protonation of the double bond (presumably by $H^+AlCl_3CN^-$ formed during production of **5**), are outlined in Schemes 2a and 2b.

The second step in each pathway is nucleophilic attack by **1**. Examination of molecular models indicates that there is less steric hindrance to approach of **1** on the face of the molecule substituted by the carbethoxyl group. (Presumably such approach can indeed only occur when the two methyl groups are *trans*, and hence is confined to **4**).

Protonation at C-4, attack by **1** at C-3, and elimination of a proton leads directly to compound **7** (Scheme 2a). Protonation at C-3 and attack by **1** at C-4, followed by a decarboxylative ring-closure affords a tricyclic derivative; addition of HCN to the latter gives **6** (Scheme 2b).

Experimental

The ^1H nmr spectra were obtained on a Varian A-60A spectrometer using $CDCl_3$ as solvent (unless otherwise stated) and tetramethylsilane as internal standard. Nuclear Overhauser enhancement measurements were made on a degassed solution of **7** in dimethyl sulfoxide-d_6, using a Varian HA-100D spectrometer. Carbon-13 nmr spectra were recorded in $CDCl_3$ on a Varian XL-100-15 or Varian FT-80 spectrometer. The operating conditions, including those used in the selective decoupling experiments on **7**, were similar to those detailed previously (9). High-resolution mass spectra were recorded using a Dupont-CEC 21-110B instrument with electrical detection being used for mass measurements. Infrared spectra were measured with Perkin-Elmer 180, 521, or 237 spectrometers. Column chromatographic separations were carried out on Mallinckrodt silicic acid (100 mesh) and preparative thin-layer chromatography (plc) on 2.0 mm Merck silica gel F-254 precoated plates. In all cases $CHCl_3$ was used for elution.

Reaction of 2,5-Dimethylfuran 1 with Ethyl Cyanoformate 2

No reaction occurred when a mixture of equimolar amounts of **1** and **2** was refluxed for 48 h.

$AlCl_3$-Promoted Reaction

(*a*) To a stirred suspension of $AlCl_3$ (6.65 g, 0.05 mol) in CH_2Cl_2 (175 mL) was added a solution of **2** (4.95 g, 0.05 mol) in CH_2Cl_2 (50 mL). To the resultant yellow-green solution was then added a solution of **1** (4.80 g, 0.05 mol) in CH_2Cl_2 (25 mL). There was an exothermic reaction, the mixture turned red, and some gummy material precipitated. Stirring was continued for 1 h at room temperature, during which the mixture became dark red and further tarry material was deposited. The mixture was poured into ice-water and the tarry residue in the reaction flask dissolved in a CH_2Cl_2/H_2O mixture. The combined organic and aqueous solutions were separated (after shaking vigorously) and the aqueous layer extracted twice with CH_2Cl_2. The combined CH_2Cl_2 solutions were then dried (Na_2SO_4) and evaporated to give a red-brown oil (7.85 g) which was chromatographed. In order of their elution from the column the following were obtained.

(*i*) *Ethyl 2,5-dimethylfuran-3-carboxylate* **5** as a yellow oil (723 mg, 8.6%). Repeated chromatography gave a pale yellow oil, n_D^{23} = 1.4690, whose spectral properties were identical with those of an authentic sample (5). (*ii*) A yellow oil (242 mg) composed of **5** and **7** in a molar ratio of 5:2. (*iii*) A semi-solid fraction (965 mg), crystallization of which from a small amount of ethyl acetate/petroleum ether gave cream colored prisms (420 mg). Preparative thin-layer chromatography afforded a solid fraction and final crystallization from petroleum ether gave pure **7** as colorless prisms (193 mg), mp 74–75°C; ν_{max} ($CHCl_3$):2235(w), 1720 cm^{-1}; λ_{max} (EtOH):217 nm (ε 7400). Molecular ion (55%) at *m/e* 291.1462 ($C_{16}H_{21}NO_4$ requires 291.14706), base peak at *m/e* 151, strong ions at *m/e* 218 (73%), 175 (80%), and 160 (37%). (iv) Oily material (585 mg), containing some **7**. (*v*) A yellow-brown oil (633 mg). Repeated column chromatography gave a solid fraction; crystallization from ethyl acetate/petroleum ether gave **6** as colorless prisms (102 mg, 1%), mp 117.5–118.5°C; ν_{max} ($CHCl_3$):2234 cm^{-1}, no absorption in carbonyl region. Molecular ion (2%) at *m/e* 246.1371 ($C_{14}H_{18}N_2O_2$ requires 246.13683); base peak at *m/e* 188.0946 ($C_{11}H_{12}N_2O$ requires 188.09496); strong ion (50%) at *m/e* 123.0684 (C_7H_9NO requires 123.06841). Estimated total yields (from ^1H nmr): **5** (11%), **6** (3%), and **7** (8%).

(*b*) To a mixture of $AlCl_3$ (13.30 g, 0.10 mol) and **2** (9.90 g, 0.10 mol) in CH_2Cl_2 (450 mL), cooled to 10–15°C, was added with stirring a similarly cooled solution of **1** (9.60 g, 0.10 mol) in CH_2Cl_2 (50 mL). The mixture was stirred for 60 s only, and was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

then worked up as in (*a*) above to give a red oil. The crude product was distilled under vacuum. The initial distillate contained mainly unreacted **2**. The intermediate fractions (5.44 g) were combined. High-boiling fractions contained mainly polymeric material and were discarded. The intermediate distillate was then chromatographed. In order of their elution, the following were obtained.

(*i*) A fraction (564 mg), containing approximately equal amounts of **4** and **7**. (*ii*) Pure trans *ethyl 5-cyano-2,5-dimethyl-2,5-dihydrofuran-2-carboxylate* **4** as a pale yellow oil (104 mg), $n_D^{24} = 1.4391$; ν_{max} (liq. film):2230 (w), 1750 (sh), 1735 cm^{-1}. Molecular ion (<1%) at *m/e* 195.0899 ($C_{10}H_{13}NO_3$ requires 195.08954); base peak at *m/e* 122.0603 (C_7H_8NO requires 122.06059). (*iii*) A fraction (1.056 g) containing equal amounts of **3** and **4**. (*iv*) A fraction (702 mg) containing **3**, contaminated by ca. 5% **4**. (*v*) Pure cis *ethyl 5-cyano-2,5-dimethyl-2,5-dihydrofuran-2-carboxylate* **3** as a pale yellow oil (522 mg), $n_D^{23} = 1.4448$; ν_{max} (liq. film):2230 cm^{-1} (w), 1750 (sh), 1732 cm^{-1}. Molecular ion (<1%) at *m/e* 195.0895 ($C_{10}H_{13}NO_3$ requires 195.08954); base peak at *m/e* 122.0606 (C_7H_8NO requires 122.06059). (*vi*) A final fraction (607 mg) consisting chiefly of **3**, together with ca. 20% **6**. Estimated total yields (from ^1H nmr): **3** (11%), **4** (5%), **6** (1%), and **7** (1%).

Reaction of 3 or 4 with $AlCl_3$

A 1:1 mixture (105 mg, 0.00054 mol) of **3** and **4** in CH_2Cl_2 (2 mL) was added to a stirred suspension of $AlCl_3$ (157 mg, 0.00118 mol) in CH_2Cl_2 (3 mL). The mixture was stirred at room temperature for 1 h, then worked up in the usual way to give a yellow oil (96 mg); ^1H nmr analysis indicated almost quantitative conversion to **5**; plc afforded pure **5** (46 mg, 51%). (Low recovery is due to volatility of **5**.)

A similar result was achieved with pure **3** or **4**.

Reaction of 3 (or 4) with 1 and $AlCl_3$

A mixture of **3** (155 mg, 0.0008 mol) and **1** (96 mg, 0.001 mol) in CH_2Cl_2 (3 mL) was added to a stirred, cooled suspension of $AlCl_3$ (215 mg, 0.0016 mol) in CH_2Cl_2 (2 mL). The mixture was stirred at 25°C for 1 h and then worked up as above to give a brown oil; plc of this product afforded **5** (45 mg, 34%), **7** (34 mg, 15%), and slightly impure **6** (20 mg, estimated 7%).

Similar reaction of **4** (52 mg, 0.00027 mol), **1** (41 mg, 0.00043 mol), and $AlCl_3$ (76 mg, 0.00057 mol) in CH_2Cl_2 (5 mL) gave **5** (15 mg, 34%), **7** (17 mg, 22%), and slightly impure **6** (7 mg, estimated 7%).

A comparable product was obtained from a corresponding reaction of **3** (390 mg, 0.002 mol), **1** (192 mg, 0.002 mol), $AlCl_3$ (532 mg, 0.004 mol), and HCN (generated from 500 mg NaCN) in CH_2Cl_2 (12 mL).

Attempted Reaction of 1 with HCN and $AlCl_3$

A solution of **1** (200 mg) in CH_2Cl_2 (3 mL) was added to a stirred suspension of $AlCl_3$ (266 mg) in CH_2Cl_2 (3 mL). The resultant solution was treated with HCN (liberated from 300 mg NaCN). After stirring in a stoppered flask for 1 h at 25°C, the usual work-up gave a yellow oil (194 mg); ^1H nmr indicated no **6**.

Attempted Conversion of 7 to 6

An almost quantitative recovery of **7** was made after 1 h treatment of a 0.2 *m* solution of this compound in CH_2Cl_2 at 25°C (stoppered flask) with (*a*) up to three molar equivalents of $AlCl_3$, (*b*) a mixture of $AlCl_3$ (two molar equivalents) and HCN (generated from 250 mg NaCN), or (*c*) $AlCl_3$ (two molar equivalents) and **2** (one molar equivalent). In no case could **6** be detected in the product.

cis-*Ethyl 5-Cyano-2,5-dimethyltetrahydrofuran-2-carboxylate 11*

A solution of **3** (278 mg) in 100% EtOH (35 mL) was hydrogenated over 5% Pd/C (35 mg). The reduction was stopped after uptake of one mole of H_2 (10 min). Filtration and evaporation gave a product, plc of which afforded **11** as a mobile pale yellow oil (185 mg, 66%), $n_D^{26} = 1.4381$; ν_{max} (liq. film):2235 (w), 1732 cm^{-1}. Molecular ion not detected; base peak at *m/e* 124.0759 ($C_7H_{10}NO$ requires 124.07624, corresponding to loss of $CO_2C_2H_5$ from $C_{10}H_{15}NO_3$).

cis-*Ethyl 5-Aminomethyl-2,5-dimethyltetrahydrofuran-2-carboxylate 13 and 3-Aza-1,5-dimethyl-8-oxabicyclo-[3.2.1] octan-4-one 15*

A solution of **11** (413 mg) in 100% EtOH (40 mL) was hydrogenated over 5% Pd/C (60 mg). After uptake ceased (2 h) filtration and evaporation gave a product which partially crystallized on standing overnight. Trituration with petroleum ether gave **15** as a colorless crystalline solid (114 mg, 35%). Crystallization from ethyl acetate/petroleum ether gave colorless prisms, mp 131–133°C; ν_{max} (KBr):3450, 3320, 3200, 1675 cm^{-1}. Molecular ion (100%) at *m/e* 155.0946 ($C_8H_{13}NO_2$ requires 155.09463); other ions at *m/e* 126 (19%), 112 (20%), 98 (69%), and 97 (75%).

The petrol-soluble portion of the product was a colorless oil. All attempts to obtain a completely pure sample were unsuccessful, although ^1H and ^{13}C nmr data were obtained, consistent with this fraction being predominantly **13**.

trans-Ethyl 5-Cyano-2,5-dimethyltetrahydrofuran-2-carboxylate 12

A solution of **4** (156 mg) in 100% EtOH (20 mL) was hydrogenated over 5% Pd/C (16 mg). The reaction was stopped after one mole of H_2 had been taken up (3 h); plc of the crude product afforded **12** as a pale yellow oil (92 mg, 59%), $n_D^{25} = 1.4438$; ν_{max} (liq. film):2230 (w), 1732 cm^{-1}. Molecular ion not detected; base peak at *m/e* 124.0769 ($C_7H_{10}NO$ requires 124.07624, corresponding to loss of $CO_2C_2H_5$ from $C_{10}H_{15}NO_3$).

trans-*Ethyl 5-Aminomethyl-2,5-dimethyltetrahydrofuran-2-carboxylate 14*

A solution of **12** (172 mg) in 100% EtOH (25 mL) was hydrogenated over 5% Pd/C (80 mg). When uptake of H_2 ceased the reaction was worked up in the usual way to give a colorless oil (166 mg). All attempts to obtain pure **14** were unsuccessful, although consistent ^1H and ^{13}C nmr data were obtained on the freshly prepared material.

Ethyl 5-Aminomethyl-2,5-dimethyl-3-(2,5-dimethyl-3-furyl)-tetrahydrofuran-2-carboxylate 10

Compound **7** (235 mg) in 100% EtOH (25 mL) was hydrogenated over 5% Pd/C (100 mg) for 24 h at room temperature. The usual work-up gave **10** as a viscous yellow oil (217 mg). The nature of the product was established by characteristic ^1H and ^{13}C nmr signals, although attempts to obtain a pure sample by chromatography or crystallization were unsuccessful.

cis-*2,5-Dimethyl-2,5-dihydrofuran-2,5-dicarboxylic Acid 16*

A solution of **3** (364 mg) in 95% EtOH (3 mL) and 30% NaOH (10 mL) was refluxed for 3 h. The dark red-brown mixture was cooled and diluted with water (10 mL). The aqueous solution was filtered, extracted with ether, and then acidified with 50% H_2SO_4. The acid solution was thoroughly extracted with ether. After drying (Na_2SO_4), evaporation of solvent from the extract afforded **16** as a colorless crystalline residue (302 mg, 87%). Crystallization from water gave cream-colored prisms, mp 178–179°C; ν_{max} (KBr):3500–2500 (br. env.), 1700 (b) cm^{-1}. Molecular ion not detected; base peak at *m/e* 141.0551 ($C_7H_9O_3$ requires 141.05517, corresponding to loss of CO_2H from $C_8H_{10}O_5$).

trans-*2,5-Dimethyl-2,5-dihydrofuran-2,5-dicarboxylic Acid 17*

A solution of **4** (197 mg) in 95% EtOH (2 mL) and 30% NaOH

(6 mL) was refluxed for 3 h. The red-brown solution was then worked up as for **16** above to give a solid residue. Crystallization from ethyl acetate/petroleum ether gave **17** as colorless prisms (110 mg, 60%), mp 148–149°C; ν_{max} (KBr):3500–2500 (br. env.), 1700 (b) cm^{-1}. Molecular ion not detected; base peak at m/e 141.0549 ($C_7H_9O_3$ requires 141.05517, corresponding to loss of CO_2H from $C_8H_{10}O_5$).

4-Carboxy-1,2,4,8-tetramethyl-3,9-dioxatricyclo[5.2.1.0^{2,6}] decane-8-carboxamide 8

A solution of **6** (120 mg) in 95% EtOH (2 mL) and 30% NaOH (10 mL) was refluxed for 3 h. Work-up as for **16** above gave a solid residue (132 mg). Crystallization from ethyl acetate gave **8** as colorless prisms, mp 240–242°C; ν_{max} (KBr):3600–2800 (br. env., with bands superposed at 3460 and 3220 cm^{-1}), 1723, 1642 cm^{-1}. Molecular ion (8%) at *m/e* 283.1412 ($C_{14}H_{21}NO_5$ requires 283.14197); base peak at *m/e* 239.1278 ($C_{13}H_{19}O_4$ requires 239.12834).

3-(2,5-Dimethylfuryl)-2,5-dimethyltetrahydrofuran-2,5-dicarboxylic Acid 9

A solution of crude **7** (450 mg) in 95% EtOH (3 mL) and 30% NaOH (20 mL) was refluxed for 3 h. The dark brown solution was worked up as for **16** above to give a brown solid (400 mg). Crystallization from ethyl acetate gave pure **9** (163 mg), mp (dec.) 230–232°C; ν_{max} (KBr):3600–2300 (br. env.), 1712 (b) cm^{-1}. Molecular ion (66%) at *m/e* 282.1108 ($C_{14}H_{18}O_6$ requires *m/e* 282.11034); base peak at *m/e* 149.0966 ($C_{10}H_{13}O$ requires 149.09664).

Reaction of 9 with Acetyl Chloride

A solution of **9** (90 mg) in acetyl chloride (10 mL) was refluxed for 24 h. Evaporation gave a dark brown residue. Attempts to isolate an anhydride from this product by recrystallization or chromatography resulted only in recovery of **9**.

Acknowledgments

We gratefully acknowledge the excellent technical assistance of Mrs. M. G. Flack, and the useful contributions made to this work by J. Walker (N.R.C.C. summer student, 1973) and D. Appleton (technical assistant 1976–1977). Our thanks go also to D. J. Embree for all mass measurements and to P. F. Seto for ir spectra.

Received January 19, 1981

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

RINALDO MARINI-BETTOLO, PETR FLECKER, THOMAS Y. R. TSAI, and KAREL WIESNER. Can. J. Chem. **59**, 1403 (1981).
A new and efficient synthesis of Digitalis cardenolides via methoxyfuryl intermediates is described.

RINALDO MARINI-BETTOLO, PETR FLECKER, THOMAS Y. R. TSAI, et KAREL WIESNER. Can. J. Chem. **59**, 1403 (1981).
Une nouvelle synthèse efficace des cardenolides de Digitalis à partir des intermediaires methoxyfuryle est décrit.
[Traduit par le journal]

Some time ago we reported a short and efficient synthesis of digitoxigenine via the furyl intermediate **I**. This material was converted by oxidation and reduction to the 15β-hydroxy cardenolide **II** and hence in three simple steps to digitoxigenine (2).

We now wish to disclose an even more effective (second generation (4)) variant of this method which dispenses with the oxidation and reduction.

We describe first the preparation of the new organometallic reagent 2-methoxy-4-furyl lithium **1**.[2]

The dibromo carboxylic ester **2** (5) was heated to 120°C in a pressure bottle with methanolic sodium methoxide for 30 min. The methoxy derivative **3** (mp 93–95°C) was obtained in a yield of 58% besides starting material.[3] (Infrared ($CHCl_3$): 1720 ($-CO.OCH_3$) cm^{-1}; ^{1}Hmr ($CDCl_3$): τ = 4.45 (s, 1H, aromatic H), 6.03 (s, 3H, $-OCH_3$), 6.10 (s, 3H, $-CO.OCH_3$).) Saponification of the ester **3** to the carboxylic acid **4** (mp 185°C (dec.)) and decarboxylation of this material at 185°C gave 2-methoxy-4-bromofuran **5** in a yield of 50%. For purification compound **5** was simply distilled without fractionation (100°C bath temperature, 14 Torr). (^{1}Hmr ($CDCl_3$): τ = 3.12 (d, J = 1 Hz, 1H, C5H), 4.69 (d, J = 1 Hz, 1H, C3H), 6.18 (s, 3H, $-OCH_3$).)

The methoxy bromofuran **5** was converted to the lithium derivative **1** by stirring with *n*-butyllithium (2.3 mol) in ether at −78°C for 1 h. The steroid ketone **III** (2)[4] (0.3 mol) was added in benzene solution and stirring was continued for 1 h. The crude compound **6** was obtained practically pure in a quantitative yield. On purification by chromatography on silica gel about 20% of the material was hydrolyzed to the corresponding lactone, which is useless for the continuation of the synthesis. (^{1}Hmr ($CDCl_3$): τ = 3.3 (d, J = 1 Hz, 1H, α-furyl H), 4.75 (d, J = 1 Hz, 1H, β-furyl H), 6.18 (s, 3H, $-OCH_3$), 8.94, 8.97 (2s, 3H each 2-CH_3).)

To avoid losses of compound **6** due to its facile hydrolysis on purification, the crude material **6** was acetylated with acetic anhydride and pyridine and a catalytic amount of *p*-dimethylaminopyridine for 48 h at room temperature. The crude acetyl derivative was refluxed in aqueous acetone in the presence of calcium carbonate for 48 h. On purification by chromatography, the allylic rearrangement product **7** was again partially hydrolyzed to the lactone **8**. The pure compound **7** remained oily. (^{1}Hmr ($CDCl_3$): τ = 3.00 (broad s, 1H, α-furyl H), 4.67 (broad s, 1H, β-furyl H), 6.15 (s, 3H, $-OCH_3$), 4.12 (d, J = 4 Hz, 1H, C16H).)

The hydrolysis of compound **7** to the lactone **8**

[1]References 1, 2, and 3 are considered the first three communications of this series.

[2]The method is actually not shorter in absolute terms. It is, however, shorter and more efficient with respect to the far more expensive steroid starting material **III**. Experiments to prepare the reagent **1** by a much simpler method are in progress.

[3]All compounds gave molecular ions in mass spectrometry and ir and ^{1}Hmr spectra compatible with the structures assigned to them. All crystalline compounds gave satisfactory C/H analyses.

[4]The preparation of **III** has now been made fully stereospecific by substituting reduction of the C3 ketone with "Selectride" for hydrogenation at the appropriate stage of the synthesis (cf. 2).

8

was accomplished quantitatively by stirring with dilute hydrochloric acid in aqueous THF for 5 h at room temperature. Compound 8 was recrystallized from ether and melted at 129–131°C. (Infrared ($CHCl_3$): 3600, 3475 (OH), 1790, 1750 (lactone) cm^{-1}; uv λ_{max}(EtOH): 268 nm (ε = 13 170); ^{1}Hmr ($CDCl_3$): τ = 3.75 (d, J = 4 Hz, 1H, C16H), 3.84 (s, 1H, C22H), 5.06 (broad s, 2H, C21H), 5.35 (m, 1H, C15H).)

The lactone **8** was obtained in a yield of 75% from the starting steroid **III** if the entire operation was performed without purification of the intermediates **6** and **7**. Hydrogenation of compound **8** with $Pd/CaCO_3$ in ethanol gave quantitatively the already described intermediate **II** (2). We have originally described this material as oily, but it crystallized after several months in the refrigerator and was recrystallized from ethanol (mp 147–148°C). Identity was established by mixture mp and spectral and chromatographic data.

A number of crosslinked polymers containing primary or secondary amine functional groups were prepared by chemical modification of styrene–divinylbenzene or styrene–acrylonitrile–divinylbenzene resins. The polymers were tested in the binding of α-methylene-γ-butyrolactone allergens via Michael addition of their nucleophilic ends with the conjugated system of the lactones. Best results were obtained using 1% crosslinked poly(aminoethylstyrene) in ethanol; polymers with higher crosslinking or other functional groups were somewhat less reactive. This technique for the removal of α,β-unsaturated lactones from solution was applied successfully to the selective removal of the allergenic components of costus oil, a natural oil of plant origin used in the cosmetics industry. After purification of the costus extracts, the allergens which were retained by the polymer could be cleaved by permethylation followed by base treatment, and characterized. The polymer-treated natural oil had lost its allergenic properties while the polymer-retained materials were found to be powerful allergens.

ANNIE CHEMINAT, CLAUDE BENEZRA, M. JEAN FARRALL et JEAN M. J. FRÉCHET. Can. J. Chem. **59**, 1405 (1981).

On a préparé des polymères réticulés contenant des amines primaire ou secondaire comme groupes fonctionnels en modifiant chimiquement des résines de styrène–divinylbenzène ou de styrène–acrylonitrile–divinylbenzène. On a vérifié les possibilités que pourront avoir ces polymères à se lier à l'allergène α-méthylène γ-butyrolactone par le biais d'une addition de Michael de leurs extrémités nucléophiles sur le système conjuguée des lactones. On obtient les meilleurs résultats en utilisant le poly(aminoéthylstyrène) réticulé à 1% dans l'éthanol; les polymères plus fortement réticulés ou porteurs d'autres groupes fonctionnels sont un peu moins réactifs. On a appliqué avec succès cette technique de fixation des lactones-α,β non saturées pour enlever sélectivement des composés allergènes de l'huile de costus, une huile végétale naturelle utilisée dans l'industrie des cosmétiques. Après la purification des extraits de costus, les allergènes qui se sont fixés sur le polymère peuvent être clivés par une perméthylation suivie d'un traitement basique, et être ensuite caractérisés. L'huile naturelle ainsi traitée perd ses propriétés allergènes alors que les produits retenus par le polymère sont des allergènes puissants.

[Traduit par le journal]

Introduction

Synthetic functional polymers have been used in a number of very varied applications in organic chemistry (1). For example, polymers have been used as regenerable reagents (2) or supports (3) in organic synthesis or chiral column packings for the resolution of racemates (4). Another potentially important application of polymers is derived from their ability to "fish out" selectively one type of functionality from a complex mixture (5). Thus we have recently experimented with the use of poly(*p*-2-aminoethyl styrene) in the removal of an α-methylene-γ-butyrolactone from solution (6). This reaction was the test of a system for the removal of certain allergy-causing compounds from natural oils.

Many plants, especially those of the very common Compositae family, contain sesquiterpene α-methylene-γ-butyrolactones (7). These substances are extremely reactive and their biological activity has been reviewed recently (8). Among their numerous properties, they are capable of inducing allergic contact dermatitis. Since numerous plant extracts are used in cosmetology, perfumery, or pharmacy, it is desirable to devise a method for the selective removal of these undesirable allergy-causing compounds from the complex mixtures which make up these extracts. Two main benefits would accrue from the development of a specific removal procedure: first the mixtures would become anallergic; second the compounds which have been removed could be isolated, characterized, and tested, thus providing a better insight into the complex mechanism of allergenic reactions.

Results and Discussion

Studies of the mechanism of action (8) of α-methylene-γ-butyrolactone allergens have suggested that Michael additions of thiol or amine

nucleophiles to the unsaturated lactones are involved. Our method for the removal of these lactones is patterned after this supposed *in vivo* reaction and makes use of an insoluble but very reactive nucleophilic polymer which can bind the conjugated lactones by a Michael addition and thus is able to remove them from solution (Fig. 1).

We have described recently the preparation of several polymeric nucleophiles (6, 9, 10) by chemical modification of styrene–divinylbenzene copolymers. Among these, the resins containing amine or thiol groups have the greatest potential in the role of polymeric nucleophiles for the binding of α-methylene-γ-butyrolactones.

Our first tests were centered on the use of aminated polymers for the extraction from solution of a single sesquiterpene lactone, isoalantolactone, which is isolated from a plant of the Compositae family: *Inula helenium L.* Our results have then been extended to the much more demanding problem of extracting selectively several α-methylene-γ-butyrolactones from a complex plant extract, costus oil, which is obtained from the dried roots of another member of the Compositae family, *Saussurea Lappa C.*

Synthesis of the Polymers

Copolymers of styrene and divinylbenzene were chosen as substrates because their properties are well known and their chemical modification is readily carried out. For example, polymers containing thiol or phenol groups on a 1% crosslinked polystyrene matrix can be prepared easily by bromination of the aromatic rings, followed by lithiation and reaction with elemental sulfur or oxygen (9). We have observed that this reaction sequence results in the introduction of some additional crosslinks in the polymer beads. However, this increase in the degree of crosslinking does not affect noticeably the performance of the polymers. Another route to similar polymers involved the copolymerization of *m*-mercapto- (11) or *o*-hydroxystyrene (12) with divinylbenzene.

In an attempt to ascertain whether small differences in polymer structure had an influence on the binding of unsaturated lactones, a series of resins containing amine functional groups was prepared. Variations in structure included the degree of functionalization, the extent and type of crosslinking (micro or macroporous), the nature of the amine (primary or secondary), and the length of the spacer arm between the polymer backbone and the amino group.

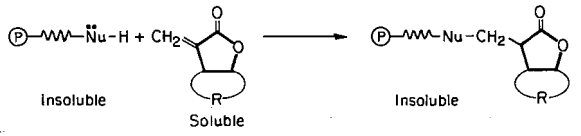

FIG. 1. Insolubilization of α-methylene-γ-butyrolactones by Michael addition with a nucleophilic polymer.

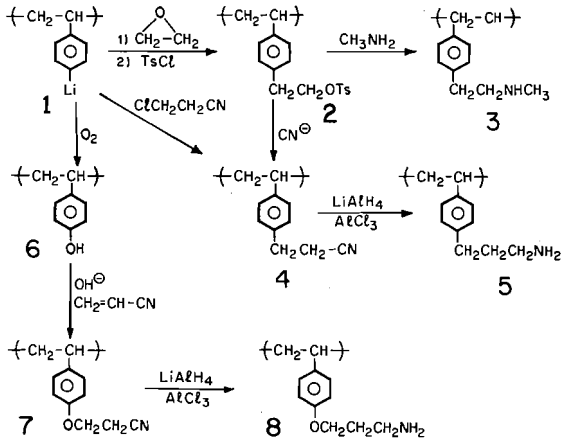
A first type of polymer in which the amino group is linked through a short 1–3 carbon chain to some of the aromatic rings of polystyrene was prepared from partially chloromethylated or partially lithiated polystyrene. Poly(aminomethylstyrene) is obtained (13) by reaction of the chloromethylated polymer with potassium phthalimide followed by treatment with hydrazine hydrate. Poly(aminoethylstyrene) is prepared by cyanation (6, 14) of poly(chloromethylstyrene) followed by reduction of the polymeric nitrile with lithium aluminium hydride – aluminium chloride. We have prepared poly(aminopropylstyrene) **5** via two different routes (Scheme 1). One involves the reaction

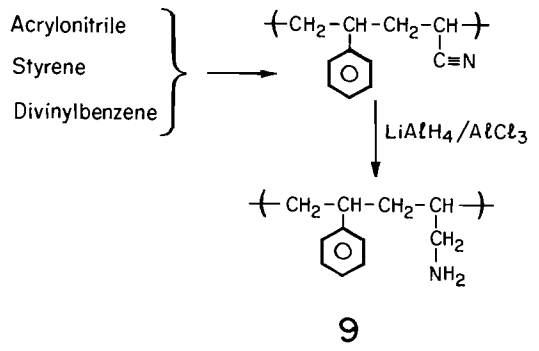


SCHEME I

of the lithiated polymer **1** with 3-chloropropionitrile to yield **4** which can then be reduced to **5**; the second route is somewhat longer but also gives the nitrile **4** in good functional yield. The lithiated polymer **1** is quenched with ethylene oxide, then tosylated to afford **2**, which can either be treated with cyanide to produce a polymer with propionitrile pendant groups **4** or with methylamine to give a polymer with secondary amine functionalities **3**. The polymers prepared through the intermediate tosylate **2** had capacities of up to 2.5 mequiv./g.

Another preparation by chemical modification makes use of the cyanoethylation of the hydroxylated polymer **6** with acrylonitrile in the presence of base. This simple reaction affords a nitrile polymer **7** which can be reduced to the corresponding primary amine **8**.

A different approach to the synthesis of a



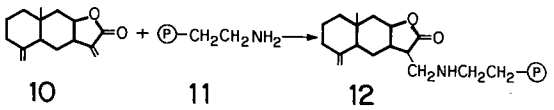
SCHEME 2

polymer containing amino groups (Scheme 2) involves the preparation of a terpolymer containing styrene, acrylonitrile, and divinylbenzene and its subsequent reduction to **9**. Although the final composition of the terpolymer can be varied by changing the polymerization conditions, monomer feed ratio, etc., we have concentrated on the preparation of polymers with a capacity of approximately 3 mequiv. of functional group per gram to maintain the desirable physical characteristics (porous bead formation, mechanical stability, etc.) of the more classical styrene–divinylbenzene copolymers.

Use of Aminated Polystyrenes for the Removal of Isoalantolactone From Solution

The ability of aminated polymers to bind allergenic lactones by Michael addition to their α,β-unsaturated system was first tested in the insolubilization of isoalantolactone **10** using poly(aminoethylstyrene) (Scheme 3). The reaction was carried out simply by stirring a solution containing a known concentration of **10** in the presence of polymer **11** while monitoring the soluble phase by gas chromatography. Comparison of the chromatograms with those obtained for calibrated solutions afforded a fairly accurate measurement of the uptake of lactone by polymer **11**. This was confirmed by gravimetric measurements both on the soluble phase after evaporation of the solvent and on the solid phase after washing and drying.

In order to optimize the reaction conditions we have studied the influence of the nature of the solvent, lactone concentration, lactone-to-polymer



SCHEME 3

ratio, and nature of the polymer on the binding of **10**.

Influence of Solvent

Reactions involving insoluble functional polymers are usually extremely solvent sensitive (1, 3). In particular, when microporous resins are used, it is desirable to use good swelling solvents such as halogenated hydrocarbons, cyclic ethers, or aromatic solvents, to ensure that most of the reactive sites located within the polymer beads are fully exposed to the reagents in solution. Macroporous resins having a more rigid and very porous structure are usually much less affected by the nature of the reaction solvent; however, their reactivity is often less than that of swollen microporous polymers. Another important point to be considered in choosing a solvent for the reaction of polymer **11** with isoalantolactone is that Michael additions are usually best carried out in polar solvents such as alcohols. Thus it appears that it might be difficult to reconcile the solvent requirements of both the Michael addition and the microporous polymer, although a careful survey of the literature shows that in some cases good results can be obtained even in nonswelling solvents. For example, Leznoff and Wong (15) succeeded in the preparation of chalcones in quantitative yields using a microporous polymer support with ethanol as solvent.

Table 1 summarizes the results we obtained using an excess of polymer **11** with a capacity of 3.1 mequiv. of amino groups per gram. Best results were obtained in ethanol with essentially complete removal of isoalantolactone from solution in approximately seven hours. Mixtures of ethanol with dichloromethane or dioxane were almost as efficient while nonpolar solvents gave poor results. A kinetic study of the reaction carried out under similar conditions but in homogeneous phase with primary amines (*n*-butylamine and phenethylamine) in ethanol, showed that the reaction rates were comparable whether the amine was in solution or polymer-bound. Binding of the lactone to the polymer was confirmed both by the gain in weight of the polymer **12**, which indicated attachment of all the lactone originally present in the solution, and by the infrared spectrum of **12**, which included a broad peak at 1770 cm^{-1} and a weaker one at 1640 cm^{-1}, consistent with the presence of a γ-lactone and a disubstituted double bond on **12**.

Influence of Concentration

As can be seen in Table 2, a large excess of amino reactive sites on the polymer results in complete removal of the lactone from solution, while at constant resin sites to lactone ratio (exp. 9 and 12). best

results are obtained with a higher concentration of lactone. It should be noted, however, that even with a low resin sites to lactone ratio, most of the lactone can be removed from solution provided sufficient reaction time is allowed. Table 1 shows clearly that the rate of addition decreases as binding increases, a result which can be explained easily by the decrease in concentration of the reactive species and by increasing hindrance about the remaining sites of the polymer. A saturation test using a large excess of isoalantolactone showed that for resins with capacities of 3–4 mequiv./g up to 80% of the amine sites of the polymer were available for binding of the lactone.

Although all of the experiments described in Tables 1 and 2 were performed using a stirred suspension of the aminoethyl resin in a solvent, removal techniques involving the use of columns packed with resin **11** were also tested. Complete retention of the isoalantolactone on the column could be achieved by changing such variables as the size of the column, concentration, and rate of elution, or by passing the eluate several times over the column.

Influence of Polymer Structure

Table 3 summarizes the results which were obtained with nucleophilic polymers containing amine functional groups. Although best results were obtained using 1% crosslinked aminoethyl polystyrene **11**, most of the polymers which were tested performed satisfactorily. Neither the length of the spacer between the aromatic ring of the styrene units and the amino group, nor the primary or secondary nature of the nucleophile seemed to have a drastic effect on coupling provided the contact time was long enough (Fig. 2). Surprisingly perhaps, since ethanol is not a good swelling solvent for microporous polymers, the 1% crosslinked swellable resin performed better than the macroporous one. This seems to confirm the general trend to higher reactivity of microporous polymers. Also, better results were obtained with the less crosslinked resins and therefore microporous 1% crosslinked **11**, having shown the best performance, was used in almost all of the experiments described below. However, it is worthwhile noting that polymer **9**, obtained by reduction of crosslinked styrene–acrylonitrile beads, is the cheapest and most easily prepared aminated resin and may be the reagent of choice in larger scale applications.

Cleavage of Isoalantolactone From Polymer 12

Cleavage of the polymer-bound isoalantolactone was carried out by permethylation with methyl iodide followed by base treatment to regenerate the conjugated exocyclic double bond (Scheme 4). Unfortunately, with polymer **12** the yield of this reaction was usually only 40–50% and two or three

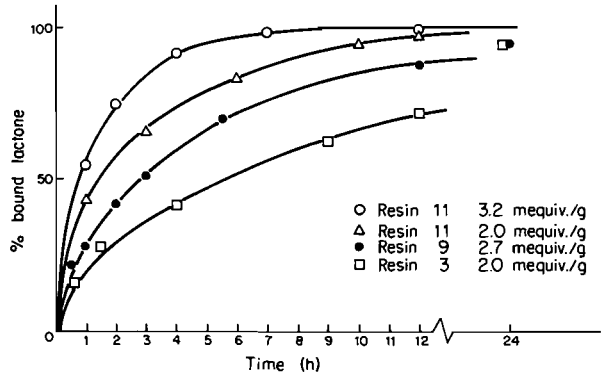

FIG. 2. Influence of the nature and loading of the polymer on lactone binding. The measurements were made on 0.5 g polymer with 0.05 g isoalantolactone in 5 mL ethanol at room temperature.

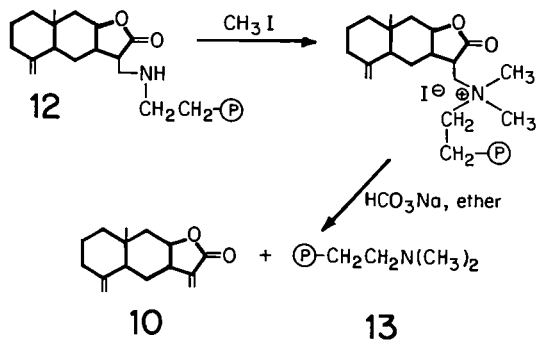
successive sequential permethylation–bicarbonate treatments were required to liberate up to 80% of the bound lactone. Attempts were made to improve the reaction by increasing the permethylation time or by using other methylating agents such as methylfluorosulfonate or Meerwein's reagent but these were unsuccessful. The only improvement which could be made was the addition of ether during the bicarbonate cleavage step. This served to remove the isoalantolactone from the reaction medium as it was formed and prevented its involvement in side reactions. The recovered isoalantolactone was identical (ir, nmr, gc, tlc) to an authentic sample.

Somewhat better results were obtained in the cleavage of isoalantolactone bound to the secondary amine polymer **3** with a 65% yield in a single treatment. This may be due to a more efficient permethylation step.

An obvious drawback of polymer **11** and indeed of all the aminated polymers we have tested to date is that they cannot be regenerated in simple fashion. The permethylation step causes the deactivation of all the amine sites of the polymer, whether they are involved in the binding of lactone or not. Although a fully regenerable polymer would be highly desirable, it should be emphasized that the unique advantages inherent to the use of insoluble nucleophiles are amply sufficient to justify their use.



SCHEME 4

Application to Other Unsaturated Lactones

To ensure that the results obtained for isoalantolactone would be applicable to similar compounds, the binding of two other α,β-unsaturated lactones, alantolactone **14** and dehydrocostuslactone **15**, was attempted using polymer **11**. Figure 3 shows that the three lactones react with the polymer at approximately the same rate. Cleavage of the lactones from the polymer by permethylation–bicarbonate treatment gave results identical to those reported above.

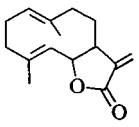
15

Application of Poly(aminoethylstyrene) to the Treatment of Costus Oil

Costus oil is a natural oil which is extracted from the roots of *Saussurea Lappa C.* (Costus), a plant of the Compositae family growing in the western Himalayas. This oil, which has a very characteristic and persistent odor, has been used extensively in perfumery. Unfortunately, costus oil contains some α-methylene-γ-butyrolactones which can cause allergic contact dermatitis (16); to prevent potential undesirable reactions to products containing plant extracts such as costus oil, it is useful to effect the selective removal of the α-methylene-γ-butyrolactones from the natural oils.

Costus extracts are available in two forms, costus essential oil, a light yellow viscous liquid which is obtained by steam distillation of the dried roots of *Saussurea Lappa C,* and costus oil, which is obtained by solvent extraction of costus roots. Both of these extracts contain at least two α-methylene-γ-butyrolactones: costunolide **16** and dehydrocostuslactone, DHC **15**.



16

Both extracts were treated with poly(aminoethylstyrene) **11** suspended in a minimum amount of ethanol (Table 4). Binding of the lactones onto the polymer was followed by gas–liquid chromatography. As can be seen in Table 4, significant amounts of material were retained by the polymer: 13% of the essential oil and 40% of the oil. Examination of the chromatograms before (Fig. 4a) and after (Fig. 4b) polymer treatment of the essential oil show that most of the components of the oil remain untouched. One main component, identified as dehydrocostuslactone, is essentially completely removed by the polymer (peak 16, Fig. 4a). Two other minor components (peaks 11 and 15, Fig. 4a) were also removed. These were later identified as α- and β-cyclocostunolide, **17** and **18**. Similarly, the chromatograms of costus oil before and after treatment with polymer **11** show that two major components are removed by reaction with the

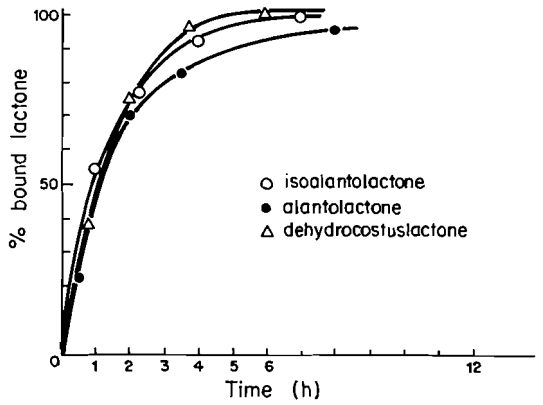


FIG. 3. Influence of lactone structure on coupling. The measurements were made on 0.5 g polymer (3.2 mequiv./g) with 0.05 g lactone in 5 mL ethanol at room temperature.

polymer: dehydrocostuslactone **15** and a product tentatively identified as costunolide **16**.[3]

The polymer-bound products were cleaved from their supports using the procedure which was developed with isoalantolactone. Analysis of the cleaved products was carried out by gc–ms and also by nmr spectrometry of the various components after separation by preparative thin layer chromatography. In the case of the polymer-retained products recovered after treatment of costus essential oil, the chromatogram (Fig. 5a) shows several products, including 80% of dehydrocostuslactone **15** (peak 4, Fig. 5a) and some small amounts of α-cyclocostunolide (peak 2, Fig. 5a) and β-cyclocostunolide (peak 3, Fig. 5a). Another 10% of the mixture are unidentified products.[4] In the case of the products liberated from the polymer after treatment of costus oil, the chromatogram shows four different peaks (Fig. 5b). The major peak (4, 65% of total) corresponds to dehydrocostuslactone, with sizeable peaks for α-cyclocostunolide (2, 14%) and β-cyclocostunolide (3, 21%). A very small peak (1) has tentatively been assigned to arbusculin-B **19**. Table 5 summarizes the composition of the lactone mixtures cleaved from the polymer.

It is noteworthy that no costunolide is found among the products which are cleaved from the polymer although costus oil is known to contain costunolide. In contrast, α- and β-cyclocostunolide

[3]The product decomposes thermally on the glc column. However, analysis of the product cleaved from the polymer after reaction suggests that it is indeed costunolide.

[4]One of these, peak 1 with $M^+ = 230$ has a mass spectrum consistent with that of an unsaturated lactone. A smaller peak with $M^+ = 232$ could not be analyzed satisfactorily.

and arbusculin-B have never been reported in costus oil, yet they have been identified as important components of the cleavage mixture. Since it is well known (17) that costunolide can cyclize readily in acidic medium (Scheme 5) to yield both cyclocostunolides and arbusculin-B, it is likely that our treatment of costus oil has resulted in the cyclization of costunolide, probably during the cleavage step. To verify this hypothesis pure costunolide was bound to the poly(aminoethylstyrene) in the usual fashion and the cleavage reaction was carried out with gc–ms analysis of the cleaved material. As expected, α- and β-costunolide, as well as arbusculin-B were found in the cleaved material. The composition of the mixtures recovered from the polymers after cleavage is given in Table 5.

Allergy-Testing of the Polymer-Purified Costus Extracts

animals sensitized to crude costus extracts with appropriate control experiments, confirmed that the polymer-treated extracts were anallergic. In contrast, the mixtures recovered by cleavage of the polymer-retained materials were shown to contain powerful allergens. The complete results of this animal testing are being reported elsewhere.[5]

Conclusion

These results confirm clearly the great potential of polymers containing amino groups for the removal of α,β-unsaturated lactones from complex mixtures. Complete selectivity of the polymers cannot be claimed since the α,β-unsaturated aldehydes and ketones which are reported (18) to be present in small amounts in costus essential oil might also have been retained by the polymer. These compounds are present in such small amounts that they are likely to escape detection by our method. However, since one of the aims of this project is to remove all potential allergens from natural extracts, their removal would in fact be a benefit. We are currently studying the selectivity of poly(aminoethylstyrene) with test mixtures of various α,β-unsaturated compounds. We are also testing the reactivity of polymers containing thiol groups since much of the biological activity of α-methylene lactones seems to derive from their affinity for the thiol side-groups of sulfhydryl enzymes. Our preliminary work has indicated that almost instantaneous binding is achieved when thiolate reactive ends are present on the polymer.

Several improvements to our procedure are also under investigation. These include the development of a better and more quantitative cleavage procedure which would be free of side reactions such as the cyclization of costunolide and the preparation of fully regenerable polymers which could be used repeatedly in the removal of allergy-causing substances.

Experimental

Infrared spectra were recorded on a Pye-Unicam SP 1100 spectrophotometer using KBr pellets or NaCl discs. The nmr spectra were obtained on a 250 MHz spectrometer in $CDCl_3$ using approximately 1 mg samples. The gc–ms results were obtained on a LKB 900 S with LKB 2130 interface, and a PDP 11/10 Digital Equipment computer using a 25 m SE-30 capillary column with temperature programming 110–280°C, 3°/min. The gc chromatograms were obtained on a Girdel 300 gas chromatograph with FID on a 2 m, 1/8 in. column of 10% OV 17 on Chromosorb. Analytical thin-layer chromatography was carried out on silica gel without binder with three successive migrations using 1:1 ether–hexane. The polymers used were Bio-Beads SX-1 or SX-2 from Bio-Rad Laboratories, or Amber-

lite XE-305 from Rohm and Haas. Elemental analyses were performed by MHW Laboratories (Phoenix, AZ) or at the University of Ottawa. Isoalantolactone was isolated from Helenin (Sigma Chemical Co.). Costus oil and costus essential oil were obtained through Roure and Bertrand (Grasse, France). All other chemicals were obtained from commercial sources and used without further purification except when otherwise stated.

Preparation of Ⓟ $-CH_2CH_2NH_2$ *11*

Bio-Beads SX-1 (103 g) were chloromethylated using 260 mL of chloromethyl ethyl ether and 20 mL of $SnCl_4$ in 600 mL $CHCl_3$ as previously described (9, 14, 19) to give 130 g of polymer containing 4.1 mequiv./g of Cl. This polymer (100 g) was then transformed into the nitrile by treatment with 70 g of sodium cyanide in 1 L DMF at 60°C (6, 14) to give 98 g of Ⓟ $-CH_2CN$ which was reduced as follows. To a cooled and stirred solution of 18 g of $LiAlH_4$ in 1 L of dry THF were added slowly 60 g of anhydrous $AlCl_3$ followed by 97 g of the nitrile polymer. After refluxing overnight, the reaction was stopped by addition of excess dilute HCl which dissolved all of the aluminium salts. After filtration the polymer was washed with H_2O (3×), THF/2 *N* NaOH (3:1), H_2O (3×), THF, acetone, CH_2Cl_2, and CH_3OH, and dried to give polymer **11**. The infrared spectrum showed no remaining nitrile absorption at 2200 cm^{-1} and had a large NH_2 band centered at 3450 cm^{-1}. Elemental analysis showed that the polymer contained 4.42% N, indicating a capacity of 3.2 mequiv./g or a degree of functionalization of 0.38.

This procedure was also used to prepare poly(aminoethylstyrene) using Eastman 2% crosslinked polystyrene and macroporous Amberlite XE-305.

Preparation of Ⓟ $-CH_2CH_2OTs$ *2*

Ⓟ –Li **1** was prepared as described in the literature (20) from 15 g of brominated polystyrene (3 mequiv./g) and 75 mL *n*-BuLi (1.1 *N*) in 200 mL of dry benzene. After three hours of reaction at 65°C, the polymer was filtered, washed 2× with benzene, then 150 mL anhydrous THF, and 14 mL of ethylene oxide were added and allowed to react 15 h at room temperature. The polymer was filtered, washed, and dried as previously described (20), to give 13 g of Ⓟ $-CH_2CH_2OH$. The ir spectrum showed a large OH absorption at 3400 cm^{-1}. Ⓟ $-CH_2CH_2OH$ (7 g) was then treated with 8 g of tosyl chloride in 75 mL of pyridine at 4°C for 5 days followed by washing with water, THF, and ether, and drying to give 9.7 g of Ⓟ $-CH_2CH_2OTs$ **2**. The ir spectrum of **2**, showed large bands at 1160 and 1350 cm^{-1}.

Preparation of Ⓟ $-CH_2CH_2NHCH_3$ *3*

Polymer **2** prepared above (2.45 g) was suspended in 30 mL THF and 30 mL methylamine and the suspension was refluxed 6 h, then left at room temperature 18 h. After filtration and washing with H_2O, 1 *N* NaOH, H_2O, THF, acetone, CH_2Cl_2, CH_3OH, and ether, the polymer was dried (1.85 g). The infrared spectrum of **3** still showed very small bands at 1160 and 1350 cm^{-1}. Analysis, found: N 2.85%; 2.0 mequiv./g.

Preparation of Ⓟ $-CH_2CH_2CN$ *4*

Method A: Ⓟ –Li **1** prepared from 10 g of Ⓟ –Br (3.0 mequiv./g) and 35 mL of *n*-BuLi (2 *N*) as described previously was treated with 11 mL of 3-chloropropionitrile in 150 mL THF at room temperature for 18 h. The polymer was filtered, washed with H_2O (3×), THF/2 *N* HCl (3:1), H_2O (3×) THF, acetone, CH_2Cl_2, and CH_3OH, and dried to give 10 g of polymer **4**. The ir spectrum showed a CN absorption at 2240 cm^{-1}. Analysis, found: N 4.38%; 3.1 mequiv./g.

Method B: Ⓟ $-CH_2CH_2OTs$ **2** (3.0 g) suspended in 60 mL of DMF was reacted with 1 g of NaCN at 60°C for 5 h, then 18 h at room temperature. The polymer was then filtered, washed with DMF, H_2O (3×), THF/H_2O (3:1), THF, acetone, CH_2Cl_2, and CH_3OH, and dried to give 2.33 g of polymer **4**. The ir spectrum showed a CN peak at 2240 cm^{-1} and no residual tosylate absorptions. Analysis, found: N 3.43%; 2.45 mequiv./g.

Preparation of Ⓟ $-CH_2CH_2CH_2NH_2$ *5*

Ⓟ $-CH_2CH_2CN$ **4** (9.8 g, 3.1 mequiv./g) was treated with 4 g of $LiAlH_4$ and 13.4 g of $AlCl_3$ in 150 mL anhydrous THF as described above for Ⓟ $-CH_2CH_2NH_2$ **11**. After washing and drying, 10.0 g of polymer **5** was obtained. The ir spectrum showed the disappearance of the CN absorption and appearance of a $-NH_2$ band at 3400 cm^{-1}.

Preparation of Ⓟ *–OH 6*

Ⓟ –OH was prepared as described in the literature (9) from 15 g of SX-1 resin, 37 mL of *n*-BuLi (2.6 *N*), 15 mL of tetramethylethylenediamine, and O_2. After washing and drying, 15.5 g of polymer **6** were obtained. Analysis, found: O 2.52%; 1.6 mequiv./g.

Preparation of Ⓟ $-OCH_2CH_2CN$ *7*

Ⓟ –OH **6** (10 g, 1.6 mequiv./g) was suspended in 70 mL of acrylonitrile and 2 mL of 5% aqueous NaOH. After 18 h of reflux, the polymer was filtered, washed with THF, THF/2*N* HCl (3:1), CH_3CN (2×), H_2O (3×), THF, acetone, CH_2Cl_2, and CH_3OH, and dried to give 10.5 g of polymer **7**. The infrared spectrum showed a CN absorption at 2260 cm^{-1}. Analysis, found: N 1.86%; 1.33 mequiv./g.

Preparation of Ⓟ $-OCH_2CH_2CH_2NH_2$ *8*

Ⓟ $-OCH_2CH_2CN$ **7** (9.0 g, 1.33 mequiv./g) was reduced with 2 g of $LiAlH_4$ and 7 g of $AlCl_3$ in 250 mL of dry THF as described above. After washing and drying, 9.0 g of polymer **8** was obtained. The ir spectrum showed complete disappearance of the CN band. Analysis, found: N 1.70%; 1.21 mequiv./g.

Preparation of Ⓟ $-CH_2NH_2$

Ⓟ $-CH_2NH_2$ was prepared as described by Sparrow (13) from 50 g of Ⓟ $-CH_2Cl$ (4.28 mequiv./g) by reaction with 50 g of potassium phthalimide in 400 mL DMF followed by 17 g of hydrazine hydrate in 300 mL ethanol. After washing and drying, 50 g of polymer were obtained, containing 3.73 mequiv./g of N.

Preparation of an Acrylonitrile–Styrene–Divinylbenzene Terpolymer and Reduction to 9

To a solution of 1 g of sodium oleate in 400 mL deoxygenated water was added 13 g of acrylonitrile, 37 g of styrene, and 2 g of divinylbenzene (50%) followed by 0.2 g of benzoyl peroxide. The reaction mixture was stirred vigorously at 60°C for 12 h. The product was filtered, washed with H_2O, CH_3OH, and ether and dried to yield 37 g of fine white polymer beads. The ir spectrum showed a strong CN band at 2240 cm^{-1}. Analysis, found: N 4.23%; 3.0 mequiv./g.

The polymer (10 g, 3.0 mequiv./g) was then treated with 2.5 g of $LiAlH_4$ and 9.0 of $AlCl_3$ in 350 mL of anhydrous THF as described above. After washing and drying 9.0 g of polymer **9** were obtained. The ir spectrum contained a NH_2 band at 3480 cm^{-1} and no residual CN absorption. Analysis, found: N 3.8%; 2.7 mequiv./g.

General Procedure for the Binding of Isoalantolactone on an Aminated Polymer

All the preliminary tests for the study of the influence of solvent on the binding of isoalantolactone were carried out using 0.5 g of polymer **11** in 5 mL of a solution containing 0.030 g of isoalantolactone in the solvent tested. Tests to determine the influence of the nature of the polymer were carried out in similar fashion but with 5 mL of a solution containing 0.050 g of isoalantolactone in ethanol. The polymer suspensions were stirred at room temperature and the liquid phase was monitored by

gas chromatography on 10% OV 17 at 220°C. Final uptake of isoalantolactone by the polymer was confirmed by gravimetry both on the soluble phase and the polymer phase. In some cases the reaction was also monitored by uv spectrophotometry. An infrared spectrum of the polymer after reaction showed a strong band at 1770 cm^{-1} with no remaining absorption at 1660 cm^{-1}.

Determination of the Capacity of Polymer 11: Saturation Test

To a solution of 0.1091 g isoalantolactone in 4 mL ethanol was added 0.1137 g of polymer **11** (3.2 mequiv./g). The mixture was stirred at room temperature for 7 days. After thorough washing and Soxhlet extraction, the polymer weighed 0.1840 g while the combined liquid phases after evaporation yielded only 0.0380 g of isoalantolactone. This saturation test indicated that 83% of the sites of the polymer reacted with isoalantolactone. Duplicate tests gave results ranging from 74 to 84%.

General Procedure for the Cleavage of the Polymer-Retained Products from Their Support

A suspension of 1 g of a polymer containing bound lactones in 5 mL DMF (or ethanol) was treated with a large excess (1–2 mL) of CH_3I. The mixture was stirred in the dark at room temperature for 2 days. After filtration the polymer was washed repeatedly and dried *in vacuo*. The permethylated polymer was then suspended in 5 mL dioxane and 10 mL of a 10% aqueous $NaHCO_3$ solution were added. After addition of 20 mL ether, the polymer remained in the aqueous phase. The mixture was then stirred vigorously for 3–10 h while appearance of the lactone in the ether phase was monitored by gas chromatography. Once no further progress of the reaction was observed, the ether phase was separated from the aqueous phase, washed with dilute aqueous HCl, with aqueous $NaHSO_3$, and finally with water. After extraction of the aqueous wash water, the combined ether phases were dried and evaporated to yield a light yellow oily material which was characterized.

Purification of Costus Extracts

To a suspension of 1.470 g of **11** (1% crosslinked, 3.2 mequiv./g) in 2.5 mL ethanol was added 1.190 g costus oil (Roure and Bertrand). The mixture was stirred in the dark at room temperature and the disappearance of dehydrocostuslactone from the liquid phase was followed by gas chromatography. Once the reaction appeared to be complete (1–3 days), the polymer was filtered, washed with ethanol, then extracted in a Soxhlet for 24 h with CH_2Cl_2. The combined soluble phases were evaporated *in vacuo* to yield the purified costus oil (0.70 g). After drying *in vacuo* the polymer weighed 1.956 g indicating that 0.486 g (40%) of the original extract had been retained by the polymer.

A similar experiment carried out on 2 g of costus essential oil with 1 g of **11** in 2.5 mL ethanol resulted in the retention of 0.270 g (13.5%) of material by the polymer. The bound products were cleaved from their support as described above.

Acknowledgements

The authors thank N.A.T.O. for grant no. 1678. Additional support of this work through a Natural Sciences and Engineering Research Council of Canada operating grant (to J.M.J.F.) and a postdoctoral fellowship (to M.J.F.) is also acknowledged. Finally, thanks are due to I.N.S.E.R.M. for financial support (contrat libre 77-1-097-3) and to Dr. P. Teisseire from Roure and Bertrand for the generous gift of costus oil and costus essential oil.

Received July 30, 1980

JOHN M. DECESARE, BERNARD CORBEL, TONY DURST, and JOHN F. BLOUNT. Can. J. Chem. **59**, 1415 (1981).

γ-Epoxy sulfones in which the epoxide function is terminal yield cyclopropylmethanol derivatives on reaction with methyllithium or lithium diisopropylamide. In contrast, treatment of these epoxides with two equivalents of CH_3MgI gives only *cis*-3-phenylsulfonylcyclobutanols. The *cis*-relationship between the OH and sulfonyl groups was proven in one instance by an X-ray structure determination. Internal γ-epoxy sulfones yield cyclopropylmethanols with all bases studied. All δ-epoxy sulfones studied furnished *cis*-3-phenylsulfonylcyclopentanols upon reaction with the Grignard reagent. These same epoxides gave either cyclopentanols or noncyclic products upon reaction with LDA; no cyclobutane ring containing products were obtained contrary to the expectations based on Stork's results with the corresponding epoxy nitriles (ref. 2). The mechanism of the Grignard-mediated reaction involves epoxide opening by iodide ion, α-sulfonyl Grignard formation, and, finally, cyclization. When LDA or CH_3Li is used the products are formed by an intramolecular S_N2 opening of the epoxide by an α-lithio sulfone.

JOHN M. DECESARE, BERNARD CORBEL, TONY DURST et JOHN F. BLOUNT. Can. J. Chem. **59**, 1415 (1981).

Les γ-époxysulfones ayant la fonction époxyde en position terminale réagissent avec le méthyllithium ou le diisopropylamidure de lithium en donnant des dérivés du cyclopropylméthanol. Par contre, ces mêmes époxydes réagissent avec deux équivalents de CH_3MgI en donnant uniquement des phénylsulfonyl-3 cyclobutanols *cis*. Dans un cas, on a établi la relation *cis* entre les groupes OH et sulfonyle par une détermination de structure par diffraction de rayons-X. Sous l'influence de toutes les bases utilisés les γ-époxy sulfones internes conduisent aux cyclopropylméthanols. Toutes les δ-époxy sulfones étudiées fournissent les phénylsulfonyl-3 cyclopentanols *cis* après réaction avec le réactif de Grignard. Ces mêmes époxydes réagissent avec le DAL en donnant des cyclopentanols ou des produits non cycliques; on n'a pas obtenu de produit contenant un cycle cyclobutane, contrairement à ce qui etait attendu selon les résultats de Stork relatifs aux époxy nitriles correspondants (ref. 2). Le mécanisme de la réaction induite par le réactif de Grignard fait intervenir une ouverture de l'époxyde par l'ion iodure, la formation d'un réactif de Grignard avec le groupement α-sulfonyle et finalement une cyclisation. Avec le DAL ou le CH_3Li, la formation des produits implique une ouverture intramoléculaire du type S_N2 de l'époxyde par une α-lithio-sulfone.

[Traduit par le journal]

Introduction

Examples of intramolecular attack by a carbanion on an epoxide as a method of ring formation have been known for some time (1). However, the general synthetic potential of this type of reaction was not appreciated or systematically investigated until 1974 when Stork and co-workers (2) studied the base-induced cyclization of a series of epoxy nitriles. These workers generalized that the epoxy nitriles **1** always cyclized to yield preferentially the smaller ring when both ends of the epoxide were equally substituted (path **a** rather than **b** in structure **1**). The regioselectivity was due to a more ready attainment of the necessary co-planar arrangement of the attacking group, epoxide carbon, and oxide leaving group, thus resulting in the smaller of the two ring sizes. (See structures **2** and **3** for 4- vs. 5-membered ring formation.)

The preference for cyclobutyl vs. cyclopentyl ring formation was later reinvestigated by Lallemand and Onanga (3) who noted that the epoxide stereochemistry also played a role in the regioselectivity of the epoxide opening. *cis*-δ-Epoxy nitriles bearing equal degrees of substitution on the epoxide ring continued to give cyclobutanes, selectively, whereas similarly substituted *trans*

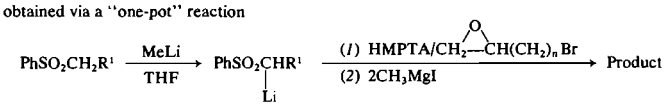
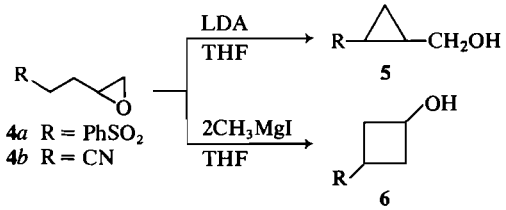
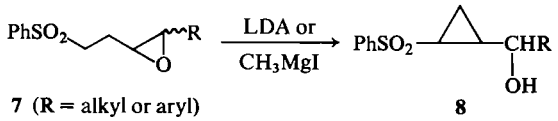
[a]Yield obtained via a "one-pot" reaction



epoxides yielded mixtures of 4- and 5-membered ring products. Cyclopropanes were formed from γ-epoxy nitriles irrespective of the epoxide substitution pattern (2).

We have recently reported in preliminary form that a variety of γ-epoxy sulfones **4***a* and γ-epoxy nitriles **4***b* can be converted into either cyclopropyl methanols **5** or cyclobutanols **6** upon treatment with lithium diisopropylamide (LDA) and CH_3MgI respectively (4). The ability to generate at will two different ring sizes from the same starting material greatly increases the value of these epoxy sulfones and nitriles as synthetic intermediates.



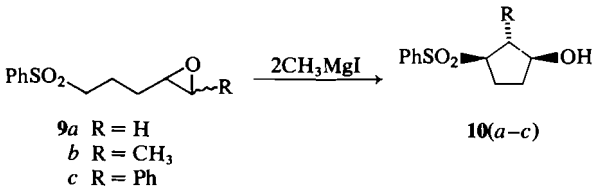


7 (R = alkyl or aryl) 8

Discussion and Results

In our previous publications (4, 5) we reported the reactions of a number of γ- and δ-epoxy sulfones with both LDA (or CH_3Li) and CH_3MgI (Table 1). Also included in Table 1 are the cyclization results of several new nonterminal epoxides. In general, the terminal epoxides in the γ-epoxy sulfone and γ-epoxy nitrile series yield cyclopropyl derivatives when treated with LDA and cyclobutanols upon reaction with CH_3MgI. Gaoni (6) had earlier reported several examples of the reaction of γ-epoxy sulfones with *n*-butyllithium, each yielding cyclopropane derivatives. In contrast to these results, internal γ-epoxy sulfones such as **7** gave only cyclopropyl derivatives with either LDA or CH_3MgI as the cyclizing reagents.

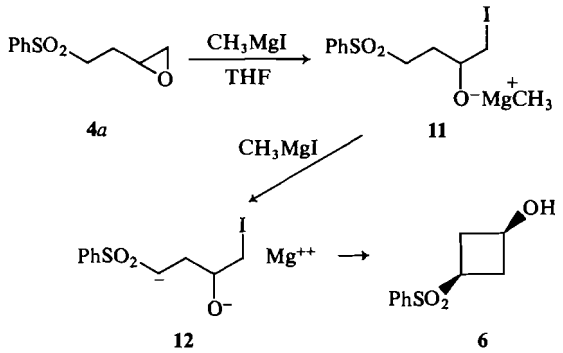
In the δ-epoxy sulfone series, the three examples investigated, **9***a–c*, gave only 3-phenylsulfonyl cyclopentanols **10***a–c* when reacted with CH_3MgI. Unfortunately, the reaction of these epoxy sulfones with LDA failed to give the expected cyclobutylmethanols (2). The parent γ-epoxy sulfone **9***a* and the methyl derivative **9***b* gave few or no monomeric products while the styrene oxide **9***c* afforded, upon reaction with LDA, the same cyclopentanol as was



9*a* R = H
b R = CH_3
c R = Ph

10(*a–c*)

obtained with CH_3MgI. The response of the various epoxides to CH_3MgI can be explained in terms of the mechanism shown in Scheme 1.



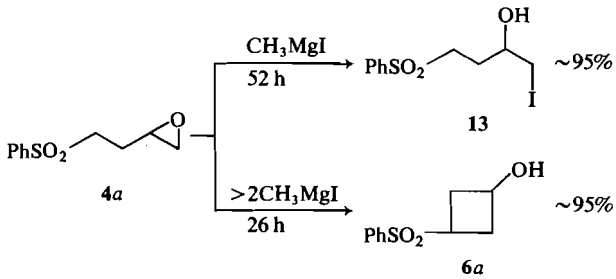
4*a* **11** **12** **6**

SCHEME 1. Mechanism of conversion of γ-epoxy sulfones to cyclobutanols.

Some evidence for this mechanism has been described in our initial publication (4). This involved isolation of the iodohydrin **13** derived from **11** when the reaction mixture was hydrolyzed before warming to above −20°C. The epoxide **4** was also opened to a bromohydrin corresponding to **13** upon reaction with $MgBr_2$. Both these bromo- and iodohydrins were converted to **6** upon exposure to two or more equivalents of CH_3MgI or CH_3MgBr (4).

The opening of the epoxide ring in **4***a* was shown to be faster than abstraction of a hydrogen α to the sulfonyl group. Hydrolysis of the reaction mixture at low temperature with D_2O (see above) furnished **13** bearing 30% D α to the sulfonyl group (nmr). If α-sulfonyl Grignard formation had been complete prior to the epoxide opening monodeuterated **13** should have resulted. The isolation of **13** containing some deuterium suggests that the cyclization of the dimagnesium derivative **12** is not instantaneous, thus allowing some buildup of **12**, hydrolysis of which with D_2O would give mono-deuterated iodohydrin.

We have now shown that the cyclization **4***a* to **6***a* requires two equivalents of Grignard reagent. Thus reaction of **4***a* with 1 equivalent of CH_3MgI at −70°C followed by warming to room temperature for as long as 52 h gave only the iodohydrin derived from **13**, no cyclobutanol **6***a* could be detected by ^1H nmr. In contrast, when two equivalents of CH_3MgI were utilized, **6***a* was formed in approximately 95% yield after 26 h. It appears that the methylmagnesium alkoxide **11** is not sufficiently basic to cause abstraction of a hydrogen α to the sulfone group; thus a second equivalent of CH_3MgI is required.



4*a* **13** **6***a*

In contrast to the conversion of **4** to **6**, compounds such as **14**, in which the epoxide function is internal, furnished only cyclopropylmethanols, **15**, irrespective of the base employed. The formation of only cyclopropane derivatives from all γ-epoxy sulfones and CH_3Li or LDA has been explained in terms of stereoelectronic requirements (see above); the CH_3MgI mediated reaction may best be rationalized as follows. In contrast to **4**, the opening of the epoxides in **14** by iodide is not expected to be regioselective and both the iodoalkoxides **16** and **17** should be formed, deprotonation of which would yield **18** and **19**, respectively. Cyclization of **18** to **15** should be rapid relative to the conversion of **19** to **20** since cyclopropanes are formed up to 10^6 times more rapidly than cyclobutanes in this type of cyclization (*exo*-tetrahedral) (7). If the conversion of **19** to **20** is indeed slow, reepoxidation to **21** and subsequent rapid intramolecular epoxide opening, thereby again yielding the cyclopropane **15**, may become the dominant route.

As mentioned above, the δ-epoxy sulfones afforded 3-phenylsulfonylcyclopentanols upon treatment with excess CH_3MgI. This was expected since the relative rates of cyclization of the α-sulfonyl derivatives of the two possible iodoalkoxides **22** and **22***a* should greatly favour **22** and hence the cyclopentanol product **10**. A pathway similar to the type discussed above for the reactions of **14** could also come into play and thus help form **10** rather than **23** from **22***a*.

Reaction of **9***c* (R = Ph, 85% *trans*-epoxide) with LDA afforded in 75% yield the cyclopentanol **10***c* (R = Ph), identical in all respects with that obtained using CH_3MgI as base. This result is reminiscent of those of Lallemand and Onanga (3) who showed that *trans*-δ-epoxy nitriles gave mainly cyclopentanol rather than cyclobutylmethanol derivatives.

Based on the stereochemistry of the in-

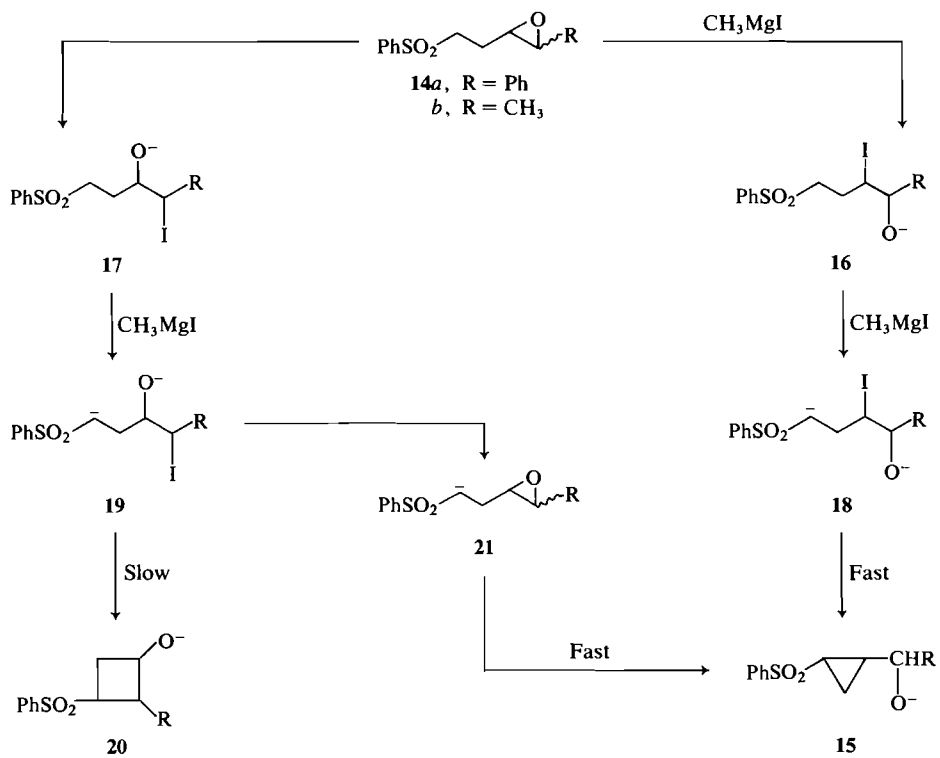

SCHEME 2. Possible mechanism of the reaction of 1,2 disubstituted γ-epoxy sulfones with CH_3MgI.

tramolecular epoxide opening by the α-lithiosulfone, the epoxide stereochemistry in the starting material, and the 75% yield of a single isomeric product, we have assigned the stereochemistry of **10***c* as shown below. The relative configuration of the $PhSO_2$ and OH as *cis* is based on an X-ray structure determination in the 3-phenylsulfonylcyclobutanol series (see below). The product **10***c*, mp 105–106°C, was oxidized with CrO_3 to 3-phenylsulfonylcyclopentanone (ir 1750 cm^{-1}), which on further treatment with triethylamine afforded a 2-phenylcyclopent-2-enone (8).

The formation of **10***c* in 67% yield from **9***c* with CH_3MgI probably results from an iodide-catalyzed epimerization at the benzylic carbon of the intermediate iodoalkoxide **24**, since a simple S_N2 opening of the epoxide by iodide (formation of **24***a*) followed by intramolecular cyclization would give **10***c* having the OH and phenyl groups *cis* to each other. Cyclization of the intermediate **24***b* leading to **10***c* should be much faster than that of **24***a* lead-

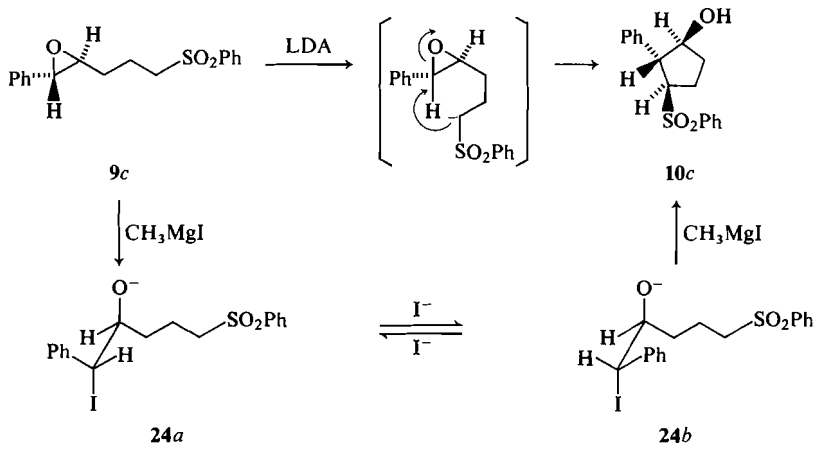

SCHEME 3

ing to the isomer of **10***c* in which all substituents are *cis* (Scheme 3).

In the cyclization of γ- and δ-epoxysulfones of the type **27** to **28** only one isomeric product was obtained. This was ascertained by comparing the nmr spectra of both the crude and purified reaction products with that of diastereomeric mixtures prepared by C-alkylation of the dianion of 3-phenylsulfonylcyclobutanol (5). The mixtures obtained showed two distinct areas of absorption for C*H*—OH at δ = 4.0–4.3 and 4.3–4.6. The cyclization products showed only the absorption at the higher field and thus it seems likely that all cyclization products belong to the same stereochemical series. The stereochemistry of one of the cyclization products was unambiguously shown to have the OH and $PhSO_2$ groups *cis* to each other by an X-ray structure determination (Fig. 1). This *cis* relationship is proposed to result from chelation of the magnesium(II) in the intermediate **29** by both the alkoxide and sulfonyl groups thus holding these two groups *cis* to each other. Admittedly, the basicity of a typical sulfone is not very high (9). It would, however, be expected to increase due to the adjacent Grignard function. Marquet[2] and coworkers have noted a decrease of approximately 60 cm^{-1} in both the symmetric and asymmetric S—O stretching frequencies in going from sulfones to α-lithio sulfones. This change indicates that the S—O bond in the α-lithio sulfones, and hence in the α-sulfonyl Grignards, is becoming somewhat like that in sulfoxides in which the oxygen acts as a strong Lewis base.

Highly stereoselective cyclizations were also observed for appropriately substituted δ-epoxy sulfones; presumably in these compounds the OH and the phenylsulfonyl group are also *cis* to each other.

If the formation of the parent compound **6***a* from **4***a* was carried out for a minimum amount of time, the isomer having its C*H*—OH absorption at higher field was obtained. Prolonged reaction times caused isomerization, presumably via an O,C dianion.

We attempted to investigate the importance of

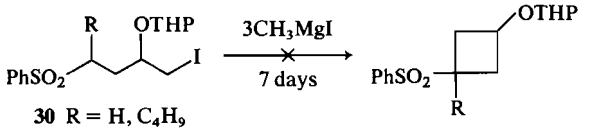
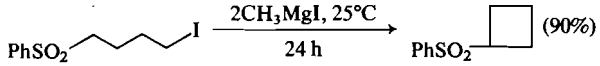
the proposed chelation in controlling the stereochemistry of the cyclization. To this end the tetrahydropyranyl ethers **30** were prepared. Reaction of these with up to 3 equivalents of CH_3MgI under the usual conditions for up to 7 days failed to give any reaction other than halogen exchange. Inadvertent quenching of the CH_3MgI was ruled out as a possible cause for the lack of reactivity since quenching of one reaction trial with benzophenone resulted in an 85% yield of 1,1-diphenylethanol. The lack of reactivity of **30** is not obvious, especially since the iodo sulfone **31** furnished cyclobutyl phenyl sulfone **32** in 90% isolated yield upon reaction with 2 equivalents of CH_3MgI for 24 h. One is left with the suggestion that failure to observe cyclization in **30** is due to adverse steric effects.



30 R = H, C_4H_9

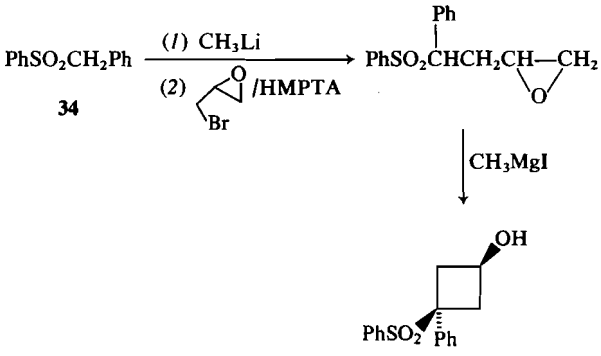


31 **32**

(Reaction of one equiv. of CH_3MgI with **31** produced **32** in 60% yield after 24 h; 20% of **31** was also recovered).

X-ray Structure Determination of 3-Phenyl-3-phenylsulfonylcyclobutanol (33) (Fig. 1)

The cyclobutanol **33** was prepared in 60% yield via a one-pot reaction according to



34 **33**

Replacement of epibromohydrin by 4-bromo-1,2-epoxybutane in the above reaction furnished the 5-membered ring homologue, 3-phenyl-3-phenylsulfonylcyclopentanol (75%). The parent 3-phenylsulfonylcyclobutanol and -cyclopentanol were similarly obtained in 46 and 35% yield respectively by alkylation of the lithio salt of methyl phenyl sulfone with the appropriate bromo epoxide followed by CH_3MgI treatment.

Suitable crystals of **33**, mp 132°C, were grown from methanol. The crystal data are:

$C_{16}H_{16}O_3S$ fw 288.36

Monoclinic, space group $P2_1/n$, a = 18.399(2), b = 10.607(2), c = 15.384(3) Å, β = 107.24(1)° and d_{calcd} = 1.335 g cm^{-3} for Z = 8. The intensity data were measured on a Hilger-Watts diffractometer (Ni filtered CuKα radiation, θ–2θ scans, pulse height discrimination). A crystal fragment measuring approximately 0.15 × 0.5 × 0.6 mm was used for data collection; the data were corrected for absorption (μ = 19.9 cm^{-1}). A total of 3727 reflections were measured for $\theta < 57°$, of which 3322 were considered to be observed ($I > 2.5\sigma(I)$). The structure was solved by a multiple solution procedure (10). The final refinement was carried out by block-diagonal least squares in which the matrix was partitioned into two blocks. In the final refinement anisotropic thermal parameters were used for the heavier atoms and isotropic temperature factors were used for the hydrogen atoms. The hydrogen atoms were included in the structure factor calculations but their parameters were not refined. The final discrepancy indices are R = 0.057 and wR = 0.075 for the 3322 observed reflections. The final difference map has no peaks greater than ±0.3 Å^{-3}.

The conformations of the two independent molecules of **33** into the unit cell are essentially the same except for a rotation of about 15° around the S—C(3) bond. The dihedral angles between the plane C(1)–C(2)–C(3) and the plane C(1)–C(4)–C(3) are 32.8 and 32.2° in the unprimed and primed molecules, and the dihedral angles between the planes C(2)–C(3)–C(4) and C(2)–C(1)–C(4) are 33.2 and 32.8° (Fig. 1).

Conclusions

Treatment of a variety of γ- and δ-epoxy sulfones with different bases (CH_3Li, LDA, or CH_3MgI) results in products whose ring size depends on both the structure of the epoxide and the base used. The results are summarized in Table 2.

Experimental

General Comments (See also ref. 5)

The synthesis of the epoxy sulfones involved in entries 1–18 (Table 1) and the preparation of 3-phenylsulfonylcyclobutanols (entries 3, 5–8, 10) and 3-phenylsulfonylcyclopentanol (entry 17) have been described. The reactions of the various epoxy sulfones with different bases are described below and are referenced with respect to their entry number in Table 1.

Reaction of Epoxy Sulfones with LDA or CH_3Li. General Procedure

To a solution of LDA in THF at −78°C was added via syringe the epoxy sulfone as a concentrated THF solution. The reaction mixture was then allowed to warm to room temperature and

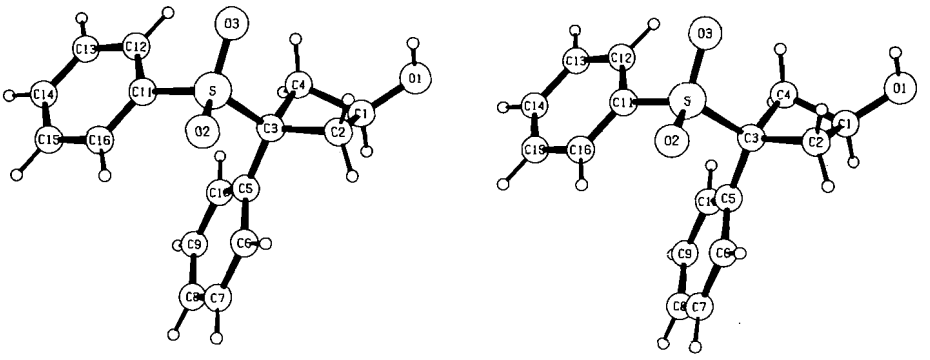


FIG. 1. X-ray structure of 3-phenyl-3-phenylsulfonylcyclobutanol.

TABLE 2. Products obtained in γ- and δ-epoxy sulfone "cyclizations"

Epoxy sulfone structure	Base	Product
	CH_3Li or LDA	Cyclopropylmethanols
	$2CH_3MgI$	Cyclobutanols
	LDA or CH_3Li or $2CH_3MgI$	Cyclopropylmethanols
	LDA	Cyclopentanols or noncyclic products
	$2CH_3MgI$	Cyclopentanols

[a] R, R^1, R^2 = alkyl or aryl.

stored for the indicated times. Work-up was accomplished by quenching with a saturated ammonium chloride solution, extracting with CH_2Cl_2, drying the organic extracts with anhydrous $MgSO_4$, and evaporating the solvent. The products were purified by silica gel chromatography. The yields in Table 1 refer to purified materials. When CH_3Li was used as base, it was added to the epoxy sulfone dissolved in THF at −78°C and the reaction was allowed to proceed as above.

Reactions of 4-Phenylsulfonyl-1,2-epoxybutane

(a) With LDA (Entry 1)

Epoxide (2.12 g, 10 mmol) was added to 30 mL of dry THF containing 10 mmol of LDA at −78°C. The reaction mixture was allowed to warm to room temperature over a 15 min period. Work-up followed by chromatography (ethyl acetate – hexane) yielded 1.8 g, 85%, of 2-hydroxymethyl-1-phenylsulfonylcyclopropane as a clear oil; nmr (after D_2O):1.1–1.5 (m, 1H), 1.5–2.2 (m, 2H), 3.0–3.5 (m, 2H), 3.6–4.1 (m, 1H), 7.5–8.2 (m, 5H).

(b) With CH_3Li (Entry 2)

Epoxy sulfone (0.244 g, 1.15 mmol), dissolved in 30 mL of THF at −78°C was reacted with 0.9 mL of 1.3 *M* CH_3Li in ether. The reaction mixture was stirred for 15 min at −78°C, warmed to 25°C, and quenched with saturated NH_4Cl solution. Work-up and chromatography gave 198 mg (81%) of 2-hydroxymethyl-1-phenylsulfonylcyclopropane as a mixture of *cis–trans* isomers; nmr (after D_2O): 0.7–1.5 (m, 2H), 1.6–2.6 (m, 2H), 3.0–4.0 (m, 2H), 7.4–8.1 (m, 5H). *Anal.* calcd. for $C_{10}H_{12}O_3S$: C 56.60, H 5.66; found: C 56.92, H 5.63.

Reactions of 4-Phenyl-4-phenylsulfonyl-1,2-epoxybutane

(a) With LDA (Entry 4)

Epoxy sulfone (0.23 g, 0.8 mmol), dissolved in 2 mL of THF, was added to 20 mL of THF containing 0.9 mmol of LDA. The reaction mixture was kept at low temperature for 15 min, warmed to 25°C, and then worked up. Chromatography on silica gel with 1:2 ethyl acetate – hexane gave 104 mg (48%) and 91 mg (43%) respectively of the less and more polar isomers of 2-hydroxymethyl-1-phenyl-1-phenylsulfonylcyclopropane. More polar isomer (mp 92–93°C), nmr: 1.1–1.3 (m, 1H), 1.7–2.1 (m, 2H including O*H*), 2.3–2.8 (m, 1H), 3.43 (d, J = 6 Hz, 2H), 7.1–7.7 (m, 10H). *Anal.* calcd. for $C_{16}H_{16}O_3S$: C 66.64, H 5.60; found: C 66.51, H 5.70. Less polar isomer (mp 84–86°C), nmr: 1–2.1 (m, 3H), 3.0 (O*H*), 4.33 (d, J = 6 Hz, 2H), 7.1–7.7 (m, 10H). *Anal.* found: C 66.62, H 5.65.

The more polar isomer is tentatively assigned the structure in which the phenyl and CH_2OH groups are *trans*, since the chemical shift of the CH_2OH group is considerably shielded, 3.43 vs 4.33, when CH_2OH and $PhSO_2$ are *cis* (less polar isomer).

5-Phenylsulfonyl-2,3-epoxypentane

(a) Reaction with LDA (Entry 11)

Epoxy sulfone (39.5 mg, 1.76 mmol) was added to 25 mL of THF containing 1.9 mequiv. of LDA at −78°C. The reaction mixture was stirred at low temperature for 1 h, then warmed to room temperature and quenched with saturated NH_4Cl. The organic product was purified on chromatography to yield 223 mg of isomeric product as a clear oil; nmr (after D_2O exchange): CH_3 (2 doublets at 1.05 and 1.03, J = 6 Hz), 1.0–2.0 (m, 3H), 2.2–2.6 (m, 1H), 3.3–3.7 (m, 1H), 7.5–8.1 (m, 5H). *Anal.* calcd. for $C_{11}H_{14}O_3S$: C 58.38, H 6.23; found: C 58.12, H 6.14.

(b) Reaction with CH_3MgI (Entry 12)

Epoxy sulfone (353 mg, 1.56 mmol) was reacted in the usual manner with 1.72 mmol of CH_3MgI. Work-up gave several products including 30% of 1-hydroxyethyl-2-phenylsulfonylcyclopropane, having a different isomer mixture than in (*a*) above. The other products were not identified.

Reactions of 1-Phenyl-4-phenylsulfonyl-1,2-epoxybutane

(a) With LDA (Entry 13)

Epoxy sulfone (284 mg, 0.99 mmol) was added to 20 mL of THF at −78°C containing 1.05 mmol of LDA. The reaction mixture was kept at −78°C for 20 min, then warmed to room temperature. Work-up gave 280 mg (98%) of a single alcohol, 1-hydroxyphenyl-2-phenylsulfonylcyclopropane, as a white solid, mp 126°C (ether–hexane); nmr: 1.1–1.7 (m, 2H), 1.8–2.2 (m, 1H), 2.3–2.9 (m, 2H, including O*H*), 4.43 (d, J = 5 Hz, 1H),

7.1–7.9 (m, 10H). *Anal.* calcd. for $C_{16}H_{16}O_3S$: C 66.64, H 5.60; found: C 66.81, H 5.75.

(b) With CH_3Li (Entry 14)

Reaction of 107 mg of epoxy sulfone in 20 mL THF at −78°C with 1.1 equiv. of CH_3Li furnished, in 90% yield, the same product as described in (*a*) above.

(c) With CH_3MgI (Entry 15)

To 203 mg of epoxy sulfone in THF (20 mL) at −78°C was added 2 equiv. of CH_3MgI. The reaction mixture was allowed to warm to room temperature and stirred overnight. Work-up, followed by chromatography on silica gel, furnished 142 mg (70%) of the alcohol described in (*a*) above.

"One-pot" Reactions

(a) Preparation of 3-Phenyl-3-phenylsulfonylcyclopentanol (Entry 18)

Benzyl phenyl sulfone (786 mg, 3.3 mmol) was dissolved in 25 mL of THF containing 1 mL of HMPTA. The solution was cooled to −70°C, reacted with 3.6 mmol of CH_3Li for 5 min, followed by 543 mg (3.6 mmol) of 4-bromo-1,2-epoxybutane. The reaction mixture was warmed to room temperature and kept until the starting sulfone had disappeared as evidenced by tlc. The reaction mixture was then cooled again to −70°C, reacted with 6.9 mmol of CH_3MgI, warmed to room temperature, and kept for 48 h. Work-up followed by chromatography (1:2 ethyl acetate – hexane) gave 750 mg of viscous oil identified as the title compound; ir: 3500 (broad), 1300(s) and 1130(s) cm^{-1}; nmr: 2.0–3.4 (m, 6H), 3.4–3.8 (O*H*), 4.2–4.6 (m, 1H), 7.0–7.6 (m, 10H). *Anal.* calcd. for $C_{17}H_{18}O_3S$: C 67.55, H 5.96; found: C 67.33, H 6.10.

(b) 3-Phenylsulfonylcyclopentanol (Entry 17)

Using the above procedure, methyl phenyl sulfone (4.9 g, 31.5 mmol) was converted to its carbanion with 35 mmol of CH_3Li, treated with 4.72 g (32 mmol) of 4-bromo-1,2-epoxybutane, and then 65 mmol of CH_3MgI. The yield of 3-phenylsulfonylcyclopentanol (**5**) was 2.5 g (35%).

*(c) 3-Phenyl-3-phenylsulfonylcyclobutanol (**33**) (Entry 5)*

To the α-lithio derivative derived from 3.5 g (15 mmol) of benzyl phenyl sulfone was added 2.4 mL (excess) of epibromohydrin followed, as in (*a*) above, by 35 mmol of CH_3MgI. Work-up followed by chromatography provided 2.6 g (60%) of the title cyclobutanol as white granules, mp 132°C (CH_2Cl_2–CCl_4); ir: 3500 (broad), 1305(s), 1150(s) cm^{-1}; nmr: 2.9–3.3 (m, 5H; 4H after D_2O treatment), 4.18 (J = 6 Hz, 1H), and 6.8–7.7 (m, 10H). *Anal.* calcd. for $C_{16}H_{16}O_3S$: C 66.64, H 5.60; found: C 66.58, H 5.64.

(d) 3-Phenylsulfonylcyclobutanol (5) (Entry 3)

This compound (**5**) was obtained in 46% isolated yield from 711 mg (4.6 mmol) of methyl phenyl sulfone, 4.7 mmol of CH_3Li, 1.0 mL of epibromohydrin, and 10 mmol of CH_3MgI using the procedure outlined in (*a*) above.

Syntheses of New Epoxy Sulfones

Epoxy Sulfone 9c (R = Ph)

To a solution of 32.3 g (0.29 mol) of thiophenol dissolved in 200 mL of methanol containing 16.8 g (0.3 mol) of KOH was added dropwise 42.3 g (0.28 mol) of 1-acetoxy-4-chlorobutane. The mixture was stirred overnight and then saponified by addition of a further 26 g of KOH. After the saponification was complete the mixture was diluted with 200 mL of H_2O, extracted with 2 × 100 mL of CH_2Cl_2, and worked up further in the usual manner. The yield of 4-phenylthiobutan-1-ol was 84%.

The above alcohol (5.0 g, 27.5 mmol) dissolved in 5 mL of CH_2Cl_2 was added over 15 min to a mixture of 226 mmol pyridinium chlorochromate (12 g, 56 mmol) and sodium carbonate (24 g), suspended in 25 mL of dry CH_2Cl_2. After stirring for an additional 10 min the granular precipitate was filtered and washed with 50 mL of CH_2Cl_2. The crude organic product was purified by column chromatography on 100 g of silica gel using hexane as eluent. The yield of 4-phenylthiobutanal (clear oil) was 70%; ir: 1710 cm^{-1}; nmr: 1.3–1.9 (m, 2H), 2.1–2.6 (m, 2H), 2.83 (t, J = 7 Hz, 2H), 6.8–7.2 (m, 5H), 10.0 (s, 1H).

4-Phenylthiobutanal (7.5 g, 41.6 mmol) was dissolved in 30 mL of CH_2Cl_2 containing 8.5 g (46 mmol) of benzyldimethylsulfonium chloride and 300 mg of benzyltriethylammonium chloride. To this mixture, well stirred and cooled in an ice-bath, was added dropwise 40 mL of a 50% NaOH solution. After 1 h of reaction time the mixture was diluted with 50 mL each of H_2O and CH_2Cl_2. Further work-up afforded, after silica gel chromatography (ethyl acetate – hexane, 1:20), 8.0 g of 1-phenyl-5-phenylthio-1,2-epoxypentane as a clear oil; nmr: 1.4–2.0 (m, 4H), 2.5–3.0 (m, 3H), 3.40 (d, J = 2 Hz), and 3.83 (d, J = 4 Hz, combined 1H), 6.7–7.1 (m, 10H).

The above epoxide was refluxed overnight with 2 equiv. of MCPBA in CH_2Cl_2. Work-up followed by chromatography (1:2 ethyl acetate – hexane) afforded the epoxy sulfone **9***c* (R = Ph) in 87% yield. Infrared: 1310(s), 1150(s) cm^{-1}; nmr: 1.5–2.1 (m, 4H), 2.8–3.4 (m, 3H), 3.56 (d, J = 2 Hz), and 4.04 (d, J = 4 Hz, combined 1H), 7.1–8.0 (m, 10H); ms: M^+ = 302 (0.01%); other key fragments at m/e = 105(100), 91(74), 77(62).

Epoxy Sulfone 9b (R = CH_3)

To 75 mL of dry THF containing 33 mmol of ethylidenetriphenylphosphorane was added at room temperature 4.0 g (22 mmol) of 4-phenylthiobutanal (see above). The light orange reaction mixture was stirred for an additional 5 min and then worked up. The yield of 6-phenylthiohex-2-ene was 90% after purification on silica gel chromatography using hexane as eluent; nmr: 1.0–2.3 (m, 7H), 2.80 (t, J = 6 Hz, 2H), 4.7–5.4 (m, 2H), 6.7–7.1 (m, 5H). This olefin-sulfide was refluxed overnight in CH_2Cl_2 with 3 equiv. of MCPBA to furnish, after chromatography (1:2 ethyl acetate – hexane), 4.2 g (85%) of epoxy sulfone **9***b* (R = CH_3) as a light yellowish oil; ir: 1310(s), 1150(s) cm^{-1}; nmr: 1.18 (d, J = 5 Hz) and 1.30 (d, J = 5 Hz, total 3H), 1.0–2.1 (m, 4H), 2.3–3.4 (m, 4H), 7.4–8.0 (m, 5H).

Reaction of Epoxy Sulfone 9c with CH_3MgI (Entry 22)

Epoxy sulfone **9***c*, 2.0 g (6.6 mmol) dissolved in 50 mL of THF at −78°C was treated with 16.5 mmol of CH_3MgI. The resultant white suspension was allowed to warm to room temperature and stirred for an additional 24 h. Work-up followed by chromatography on 100 g of silica gel (2:8 ethyl acetate – hexane) furnished 1.35 g, 67%, of **10***c*, white crystals, mp 105–106°C (methylene chloride – hexane). Infrared: 3500 (broad), 1310(s), 1145(s) cm^{-1}; nmr: 1.7–2.6 (m, 5H; 4H, following D_2O treatment), 3.2–3.4 (m, 1H), 3.5–3.8 (m, 1H), 3.9–4.2 (m, 1H), and 6.8–7.8 (m, 10H). *Anal.* calcd. for $C_{17}H_{18}O_3S$: C 67.55, H 5.96, S 10.60; found: C 67.47, H 6.08, S 10.99.

Reaction of 22a with LDA (Entry 21)

Reaction of **9***c* (1.41 g, 4.7 mmol) with 5.1 mmol of LDA in 50 mL of THF at −78 to 25°C (1 day), gave 1.10 g (75%) of **10***c*.

Oxidation of 10c

Alcohol **10***c* (660 mg, 2.2 mmol) was dissolved in 10 mL of "Spectrograde" acetone and reacted with 2.5 mmol of Jones' reagent for 30 min. Excess oxidizing agent was destroyed by addition of 10% $Na_2S_2O_3$ solution. Chromatography, followed by recrystallization, yielded 260 mg (75%) of 2-phenylcyclopent-2-enone, mp 67–68°C (lit. (8) mp. 71°C).

2-Methyl-3-phenylsulfonylcyclopentanol (Entry 20)

Epoxy sulfone **9*b***, (1.0 g, 4.2 mmol) was dissolved in 50 mL of THF at −78°C and reacted with 10 mmol of CH_3MgI (in ether solution). The resultant white suspension was allowed to warm to ambient temperature and then quenched with saturated NH_4Cl solution. Further work-up and chromatography of the crude product yielded 0.5 g (50%) of the title compound; nmr: 1.02 (d, J = 6 Hz, 3H), 1.6–2.5 (m, 5H), 2.5–2.9 (O*H*), 3.0–3.3 (m, 1H), 3.6–3.9 (m, 1H), 7.4–7.9 (m, 5H). *Anal.* calcd. for $C_{12}H_{16}O_3S$: C 60.00, H 6.66; found: C 59.93, H 6.83.

2-Methyl-3-phenylsulfonylcyclopentanone

Cyclopentanol **10*b*** (110 mg, 0.45 mmol) was oxidized with 0.50 mmol of Jones' reagent in 10 mL of "Spectrograde" acetone for 5 min. The reaction mixture was treated with 5 mL of 10% $Na_2S_2O_3$ solution and then worked up to yield 88 mg of the title compound, mp 82–83°C. Infrared: 1750, 1310, 1150 cm^{-1}; nmr: 1.13 (d, J = 6 Hz, 3H), 2.0–2.8 (m, 5H), 3.3–3.5 (m, 1H), 7.5–8.0 (m, 5H). *Anal.* calcd. for $C_{12}H_{14}O_3S$: C 60.50, H 5.88, S 13.44; found: C 60.50, H 6.01, S 13.22.

Reaction of Epoxy Sulfone 9b *with LDA (Entry 19)*

Epoxy sulfone **9*b*** (600 mg, 2.5 mmol) was added to 75 mL of THF at −78°C containing 3.0 mmol of LDA. The solution was allowed to warm to room temperature and stirred for 24 h. Work-up followed by chromatography gave 450 mg of a slightly yellow oil whose nmr showed peaks at 1.0–1.2 (m, 6H), 1.5–2.5 (m, 11H), 2.7–3.2 (m, 3H; 2H after D_2O treatment), 3.6–3.9 (m, 2H), 7.5–8.1 (m, 10H); the infrared showed bands at 3400 (OH), 1155, and 1320 (SO_2) cm^{-1}. The material was not further characterized.

Mechanistic Studies

Iodohydrin 13

Epoxy sulfone **4*a*** (4.0 g, 18.8 mmol) was added to 20 mmol of CH_3MgI dissolved in 100 mL of dry THF at −78°C. The reaction mixture was allowed to warm to room temperature and then quenched with 20 mL of saturated ammonium chloride solution. Usual work-up provided, after recrystallization from CH_2Cl_2–hexanes, 5.4 g (85%) of iodohydrin **13**, mp 88–89°C. Infrared: 3480 (broad), 1310(s), 1150(s) cm^{-1}; nmr: 1.6–2.3 (m, 2H), 2.6 (O*H*), 3.2–3.4 (m, 2H), 3.5–3.9 (m, 1H), 7.4–8.0 (m, 5H). *Anal.* calcd. for $C_{10}H_{13}IO_2S$: C 37.09, H 4.04, S 9.89; found: C 36.51, H 4.03, S 9.58.

Reaction of Epoxy Sulfone 4a *With One or Two Equivalents of CH_3MgI*

To two flasks, each containing 500 mg (2.4 mmol) of epoxy sulfone **4*a*** dissolved in 25 mL of THF at −78°C, were added 2.4 and 6.0 mmol, respectively, of CH_3MgI solution which had been standardized just prior to use. The reaction mixtures were warmed to room temperature and stirred for up to 52 h and the progress of the reactions was monitored by tlc. In the case where a 1:1 epoxide to CH_3MgI ratio was employed, work-up gave a 95% yield of the iodohydrin **13**, whereas formation of **6*a*** (~95%) was observed in the second reaction. Gas evolution, presumed to be methane, was observed from each mixture on addition of saturated NH_4Cl solution.

Tetrahydropyranyl Derivative 30

To a solution of 5.11 g of iodohydrin **13** in 50 mL of CH_2Cl_2 was added 2.52 g of dihydropyran and 200 mg of TsOH. The reaction mixture was stirred for 30 h, diluted with 50 mL of H_2O, worked up, and chromatographed on silica gel. Elution furnished 5.0 g (78%) of THP derivative as a yellowish oil. Infrared: no OH; nmr: 0.8–2.7 (m, 8H), 2.9–4.2 (m, 7H), 4.3–4.9 (m, 1H), 7.0–7.9 (m, 5H).

To 50 mL of freshly distilled THF was added 1.33 g (3.13 mmol) of the above THP. The solution was cooled to −78°C and reacted with 6.3 mmol of CH_3MgI. A white precipitate formed immediately. The reaction mixture was stirred for 24 h and then worked up. Nuclear magnetic resonance and tlc analysis of the reaction mixture indicated the presence of only **30**. When the crude product was exposed to 5% methanolic HCl for several hours the iodohydrin **13** was obtained in 80% yield.

The above reaction was repeated with 3 and 4 equivalents of Grignard reagent per equivalent of **30** and for reaction times varying from 1–4 days. No **6*a*** was ever detected by nmr or tlc. Finally, at the end of one of the above runs, an equivalent of benzophenone was introduced prior to work-up. The product, besides recovered **30** (90%), was 1,1-diphenyl ethanol (85%).

Cyclobutyl Phenyl Sulfone 32

An ethanol solution (100 mL) containing 20 g of 1,4-dibromobutane and 16 g of $PhSO_2Na$ was refluxed for 24 h, diluted with 200 mL of H_2O, and extracted twice with 100 mL of CH_2Cl_2. The crude organic-soluble product was chromatographed on silica gel (1:3 ethyl acetate – hexane) to furnish 4.6 g (18%) of 1-bromo-4-phenylsulfonylbutane, mp 58–59°C (CH_2Cl_2–hexanes); nmr: 1.7–2.1 (m, 4H), 3.12 (t, J = 6 Hz, 2H), 3.36 (t, J = 6 Hz, 2H), 7.4–7.9 (m, 5H); M^+ calcd: 276. 278; found (ms): 276. 278.

The above bromo sulfone (3.0 g) was dissolved in 30 mL of acetone containing 1.8 g of NaI. The solution was stirred for 12 h at room temperature, diluted with 100 mL of H_2O, and further worked up. The crude product was recrystallized from CH_2Cl_2–hexanes to give 83% of **31** as colorless needles, mp 74–75°C; nmr: 1.7–2.1 (m, 4H), 3.0–3.3 (m, 4H), 7.5–8.0 (m, 5H). *Anal.* calcd. for $C_{10}H_{13}IO_2S$: C 37.04, H 4.03, I 39.17; found; C 36.78, H 4.21, I 38.81.

The above iodo sulfone (1.34 g, 4.1 mmol) dissolved in 25 mL of THF at −78°C was reacted with 10 mmol of CH_3MgI. The solution was warmed to room temperature, stirred for 24 h, and worked up. Chromatography of the crude product on 40 g of silica gel using 1:9 ethyl acetate – hexane afforded 700 mg (90%) of cyclobutyl phenyl sulfone as a viscous slightly yellowish oil; nmr: 1.8–2.6 (m, 6H), 3.56 (quintet, J = 8 Hz, 1H), 7.4–7.9 (m, 5H); ^{13}C nmr: 16.8(t), 22.8(t), 56.9(d), in addition to the aromatic carbons.

1-Iodo-4-phenylsulfonylbutane, **31**, was reacted as above with about 1.2 equiv. of CH_3MgI. Nuclear magnetic resonance inspection of the crude reaction product indicated approximately 45% of **32**, 45% of recovered **31**, and 5–10% of 1-phenyl sulfonyl pentane.

Investigation of a Ziegler–Natta catalyst system derived from a mixture of lithium tetraalkylaluminate, aluminum chloride, and titanium tetrachloride and its usefulness in polymerizations involving styrene

ANU MISHRA

Uniroyal Research Laboratories, Guelph, Ont., Canada N1E 5L7

Received September 29, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

ANU MISHRA. Can. J. Chem. **59**, 1425 (1981).

Vinyl ethers, 1-olefins, and styrene were homo- and copolymerized by the use of catalyst derived from a mixture of lithium tetraalkylaluminate ($LiAlR_4$), aluminum chloride ($AlCl_3$), and titanium tetrachloride ($TiCl_4$), in order to determine the nature of the active components present.

It is postulated that the active catalyst in the stereospecific polymerization of vinyl ethers is ether-coordinated $TiCl_3 \cdot LiCl$, while in the polymerization of 1-olefins and styrene, it is the alkylated derivatives of $TiCl_3 \cdot LiCl$.

For homo- and copolymerization of styrene, AlR_3 seems to be the preferred alkylating agent. About 3 to 4 equivalents of AlR_3 are needed for complete alkylation of $TiCl_3 \cdot LiCl$, probably due to heterogeneity of the system.

Highly isotactic polystyrene and copolymers of styrene with 1-olefins can be prepared in good yields by the use of this catalyst.

ANU MISHRA. Can. J. Chem. **59**, 1425 (1981).

Dans le but de déterminer la nature des composants actifs présents, on a utilisé un catalyseur provenant d'un mélange de tétraalkylaluminate de lithium ($LiAlR_4$), de chlorure d'aluminium ($AlCl_3$) et de tétrachlorure de titane ($TiCl_4$) pour polymériser et copolymériser des éthers vinyliques, des oléfines-1 et le styrène.

On pense que le catalyseur actif lors de la polymérisation stéréospécifique des éthers vinyliques est le $TiCl_3 \cdot LiCl$ coordonné à l'éther alors que les dérivés alkylés du $TiCl_3 \cdot LiCl$ seraient les catalyseurs actifs pour la polymérisation des oléfines-1 et du styrène.

Il semble que la AlR_3 soit l'agent alkylant privilégié lors de la polymérisation et de la copolymérisation du styrène. Il faut environ 3 à 4 équivalents de AlR_3 pour alkyler complètement le $TiCl_3 \cdot LiCl$; ce phénomène est probablement dû à l'hétérogénéité du système.

L'utilisation de ce catalyseur permet de préparer, avec d'excellents rendements, du polystyrène et des copolymères du styrène avec les oléfines-1 qui sont fortement isotactiques.

Introduction

In our study of polymer electrets (1), we wanted to evaluate the copolymers of styrene and 1-olefins for their electret behaviour. Since such copolymers are not commercially available, we decided to prepare them by the use of Ziegler–Natta type catalysts (2). Ziegler–Natta catalysts are susceptible to oxygen, moisture, and other electron-rich compounds. The catalyst components, generally aluminum alkyls and halides of lower valent titanium and vanadium are pyrophoric and thus difficult to handle. However, a simple system comprised of a lithium tetraalkylaluminate and titanium tetrachloride as described by Campbell and Haven (3) seemed easier to handle.

Although Campbell and Haven discovered this catalyst system over twenty years ago, not much work has since been carried out to elucidate the nature and efficiency of this system. We believe that we have determined the nature of the active catalyst present by following its action on vinyl ethers, 1-olefins, and styrene. As a result, we have been able to modify this catalyst to prepare isotactic polystyrene and copolymers of styrene with various 1-olefins in reasonably good yields.

Experimental

All temperatures are in degrees Celsius.

Reagents

Monomers

Commercial vinyl ethers from GAF Corporation were washed several times with distilled water, dried over potassium hydroxide pellets, and finally distilled under reduced pressure over calcium hydride.

Commercial styrene from Fiberglass, Canada, was washed several times with 1% sodium hydroxide solution and distilled water, then dried over anhydrous magnesium sulfate and fractionally distilled under reduced pressure just before use. The 1-olefins used were high purity commercial materials obtained from Aldrich or Gulf Chemicals.

Solvents

Normal hexane was of spectroscopic grade, from Caledon Laboratory, Georgetown, Ontario. Toluene was purified by treatment with concentrated sulfuric acid, followed by aqueous sodium hydroxide solution and distilled water, dried over anhydrous magnesium sulfate, and distilled over metallic sodium, under nitrogen.

Catalyst Components

Titanium tetrachloride, lithium aluminum hydride, and anhydrous aluminum chloride were purchased from Anachemia, and *n*-butyl lithium from Alpha Inorganics.

Catalyst Preparation

The catalysts were all prepared in a clean three-necked round bottom flask which was oven-dried (140°) overnight and flushed with nitrogen while cooling. The flask was equipped with a

thermometer, condenser, and a nitrogen inlet tube. Stirring, which took place during the preparation, was achieved by a magnetic stirrer and Teflon-coated magnetic stirring bar.

Vinyl Ethers

The catalyst for the polymerization of vinyl ethers was prepared by mixing lithium aluminum hydride (500 mg, 13.1 millimol) and 1-hexadecene (20 mL, 70.1 millimol) under a nitrogen atmosphere in the three-necked round bottom flask described above. The reaction mixture was heated at 160° with stirring for four hours. The temperature was lowered to 120°, a given amount of anhydrous aluminum chloride added, and stirring continued at that temperature for one hour. Then, heat was turned off and the reaction mixture was allowed to cool, after 50 mL toluene or *n*-hexane had been added. When the temperature was about 50°, a given amount of titanium tetrachloride was injected into the mixture through a hypodermic syringe. The black suspension of catalyst particles thus formed in the reaction mixture was aged for 30 min while it slowly cooled down to room temperature. At this point, the catalyst was ready for use.

To obtain a catalyst without using aluminum derivatives, a mixture of *n*-butyl lithium (5 mL of 4.25 *m* in *n*-hexane, 21.3 millimol) and toluene (50 mL) was stirred for 5 min at room temperature in a dry three-necked flask, kept under nitrogen. Titanium tetrachloride (1.2 mL, 12 millimol) was added through a syringe and the mixture exothermed to 45°. After ageing for 30 min, the catalyst was ready for use.

Styrene and 1-Olefins

The catalyst used in the polymerization and copolymerization of styrene and 1-olefins was prepared in a manner similar to that used in the vinyl ether polymerization.

Polymerization

The polymerizations took place in the same three-necked flask in which the catalysts were prepared. A flow of nitrogen was maintained during the polymerization reaction as was also rapid stirring with a magnetic stirrer.

Vinyl Ethers

The flask containing the catalyst (prepared from 7 millimol of $LiAlH_4$) was placed in a water bath at 25°. A vinyl ether (50 mL) was added dropwise so that the temperature of the reaction mixture was maintained between 25 and 35°. After the addition, the polymerization was allowed to continue overnight for a period of about 17 h.

A mixture of methanol (100 mL) and concentrated hydrochloric acid (5 mL) was added to the polymerization mixture to decompose the catalyst and precipitate the polymer. The supernatant liquid which was quite dark was decanted. The precipitated polymer was washed several times with additional methanol until it was decolourized. The polymers were isolated and dried in a vacuum oven at 60° for 10 h.

Styrene and 1-Olefins

After the catalyst (prepared from 26 millimol of $LiAlH_4$) had aged, a vinyl monomer (200 mL) was added to the flask at room temperature and the polymerization continued overnight.

The polymerization reaction was stopped by adding a mixture of isopropanol (150 mL) and hydrochloric acid (5 mL). After a few hours, the contents of the flask were transferred to a beaker and additional isopropanol added until the polymer completely precipitated. The polymer was washed several times with isopropanol until most of the dark colour of the catalyst had disappeared. The polymer was filtered under suction, washed further with isopropanol, and dried in a vacuum oven at 60° for 10 h.

Determination of Stereospecificity

Percentage isotacticity of a polyvinyl ether was determined by measuring the percent of that material insoluble in boiling acetone (5). For polystyrene, percentage of isotacticity was similarly determined by using boiling methyl ethyl ketone. Infrared spectra of these materials were used as further checks of isotacticity content. Infrared spectra were also used to determine the composition of copolymers of styrene and 1-olefins.

Results and Discussion

Lithium Alkylaluminates as Reducing Agents

Lithium aluminum hydride is a widely used reducing agent for organic synthesis (4), usually in ether as solvent. However, in Ziegler–Natta polymerizations, electron-rich compounds such as ethers cannot be used as solvents because they coordinate with the transition metals and render them ineffective as catalysts.

Alkylation of lithium aluminum hydride makes the derivatives soluble in hydrocarbon solvents so that they can be used as reducing agents for the transition metal halides. Thus, with $LiAlR_xH_y$ where R = alkyl group, $x + y = 4$ and $x = 1$ to 4, reduction of titanium tetrachloride occurs readily in hexane and toluene, as evidenced by the production of dark coloured lower valent compounds. In contrast, no reaction occurs when titanium tetrachloride is added to a suspension of lithium aluminum hydride in toluene even at 80°, although in diethyl ether these compounds react vigorously at room temperature.

Campbell and Haven (3) have shown that the catalyst prepared from lithium tetraalkylaluminate and titanium tetrachloride is not very active for styrene polymerization. Actually, for steric reasons, styrene is not very reactive towards Ziegler–Natta catalysts in general. Therefore, one can judge the relative reactivities of Ziegler–Natta catalysts belonging to a particular group by the amount of polystyrene obtained when styrene is polymerized by these catalysts under exactly the same conditions. Table 1 shows the results of varying R and x in $LiAlR_xH_y$, $(x + y = 4)$ on the amount of polystyrene obtained employing the catalyst prepared by the action of $LiAlR_xH_y$ on $TiCl_4$.

Varying R from ethyl to 1-hexadecyl increases the yield of polystyrene. Actually, when R = ethyl, over-reduction of $TiCl_4$ is indicated by production of metallic mirrors on the side of the reaction flask. Longer chain-length in R makes the final product a mild reducing agent. There was no effect due to variation in x from 2 to 4 (R = 1-hexadecyl) showing that this is not as important. However, when $x = 0$, exothermic cationic polymerization due to unreduced $TiCl_4$ took place, indicating again that $LiAlH_4$ is insoluble in toluene and does not react with $TiCl_4$ in this solvent.

For further work, $LiAlR_4$, where R = 1-hexadecyl, was adopted as the reducing agent be-

TABLE 1. Effect of varying R and x on polymerization of styrene by $LiAlR_xH_y$ ($x + y = 4$)*

R ($x = 3$)	Yield of polystyrene (%)	x (R = 1-hexadecyl) from stoichiometry	Yield of polystyrene (%)
Ethyl	0	0 ($LiAlH_4$)	Cationic polymerization
1-Octyl	5	2 ($LiAlR_2H_2$)	20
1-Decyl	15	3 ($LiAlR_3H$)	20
1-Hexadecyl	20	4 ($LiAlR_4$)	20

*Polymerization condition: toluene, 50 mL; $LiAlR_xH_y$, 27 mmol; $TiCl_4$, 13 mmol; styrene, 200 mL. Room temperature, 16 h.

cause of its mild reducing nature. Since this compound does not contain any hydride ion, production of hydrogen gas during the isolation of the polymer product would not occur.

The Nature of the Reduced Titanium Species

The nature of the reduced titanium species can be deduced from the study of polymerization of isobutyl vinyl ether and decyl vinyl ether with these catalysts. It has been reported by Joh *et al.* (5) that substantially different kinds of polymers are obtained from vinyl ethers due to difference in the structure of VCl_3 and $TiCl_3$ catalysts employed.

In Table 2, the nature of polyvinyl ethers prepared by us with various titanium catalysts is shown.

From Tables 2 and ref. 5, it is clear that when the VCl_3 and $TiCl_3$ used are free of other metallic salts, because they are prepared by reduction with hydrogen or by thermal decomposition, they give rise to mostly atactic polyvinyl ethers (5). In sharp contrast, however, when VCl_3 and $TiCl_3$ are produced by reaction with *n* BuLi, Al, or $LiAlR_4$ (R = 1-hexadecyl), they are in association with LiCl and $AlCl_3$ (5*c*) and these catalysts are isospecific.

According to Joh *et al.* (5*c*), the isospecific catalysts produced by reduction of VCl_4 and $TiCl_4$ with *n* BuLi may be $VCl_3 \cdot LiCl$ and $TiCl_3 \cdot LiCl$ (eq. [1])

[1] $VCl_4 + n\ BuLi = VCl_3 \cdot LiCl + n\ BuCl$

$TiCl_4 + n\ BuLi = TiCl_3 \cdot LiCl + n\ BuCl$

In Table 2, it can be seen that the polyvinyl ethers produced are about 50 to 70% isotactic. Therefore, the action of $TiCl_3$, produced from $TiCl_4$ by $LiAlR_4$, should be very similar to that produced by *n*-BuLi and the following equation may be valid (eq. [2]):

[2] $LiAlR_4 + TiCl_4 = TiCl_3 \cdot LiCl + AlR_3 + \frac{1}{2}R{-}R$

The above equation also explains why an equimolar mixture of $LiAlR_4$ and $TiCl_4$ is a good polymerization catalyst for 1-olefins, because 1 equivalent of AlR_3 is produced in this reaction and this alkylates $TiCl_3 \cdot LiCl$ to produce an active Ziegler–Natta catalyst.

TABLE 2. Polymerization of vinyl ethers by titanium halide catalysts*

Vinyl ether	Catalyst	Conversion (%)	Isotacticity (% insoluble in boiling acetone)
Decyl	$TiCl_3$[a]	76	68
Decyl	$TiCl_3$[b]	90	56
Decyl	$TiCl_3$[c]	100	64
Decyl	$TiCl_3$[d]	100	66
Isobutyl	$TiCl_3$[b]	90	50

*Polymerization conditions: toluene, 50 mL; monomer, 50 mL; catalyst, 10 mmol; 30°C, 17 h. (*a*) $TiCl_4$/*n*-BuLi = 1/2; (*b*) $TiCl_4/LiAlR_4$ = 1/1; (*c*) $TiCl_4/LiAlR_4/AlCl_3$ = 1/1.75/.25; (*d*) $TiCl_4/LiAlR_4/AlCl_3$ = 1.0/4.75/1.25 R = 1-hexadecyl.

Alkyl Lithium, Lithium Alkylaluminate, and Aluminum Alkyls as Organic Bases and Reducing Agents

It is known (4*b*) that aluminum alkyls react with alkyl lithium compounds to produce lithium alkyl aluminates (eq. [3]).

[3] $LiR + AlR_3 = LiAlR_4$

Because lithium alkyls are strong bases, they can initiate anionic polymerization of vinyl monomers such as styrene (6). Neither AlR_3 nor $LiAlR_4$ alone can polymerize styrene. We have found that in toluene at 80° for 20 h no polymer was obtained from styrene by the action of $LiAlR_4$ (R = 1-hexadecyl). This shows that, in toluene, $LiAlR_4$ does not dissociate appreciably into LiR and AlR_3.

These three classes of organometallic compounds (RLi, $LiAlR_4$, and AlR_3, R = alkyl) behave quite characteristically towards titanium tetrachloride. It is known (7) that the reduction of $TiCl_4$ with *n*-butyllithium is complicated by complex formation. Complete reduction is not achieved and the extent of reduction depends on the order of reagent addition, Li/Ti ratio, and concentration of the reagents. Maximum reduction to about 55% Ti^{3+} occurs at a Li/Ti ratio of 2.0. At Li/Ti <1.5,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

sufficient free $TiCl_4$ is present in the system to initiate cationic polymerization of *N*-vinyl carbazole. At Li/Ti >4, almost all the titanium is in the tetravalent state but complexed with *n*-BuLi, so it no longer retains its Lewis acidity. This is another example of the highly basic nature of *n*-BuLi that prefers salt formation with acidic $TiCl_4$ rather than effecting its reduction.

The reduction of $TiCl_4$ with alkyl aluminum compounds such as triethyl aluminum (Et_3Al) has been described in a simplified form as a succession of alkyl–chlorine group exchanges, followed by a reductive dealkylation of unstable alkyltitanium halide (eq. [4]):

[4] $TiCl_4 + Et_3Al = EtTiCl_3 + Et_2AlCl$
$TiCl_4 + Et_2AlCl = EtTiCl_3 + EtAlCl_2$ etc.
$EtTiCl_3 \rightarrow TiCl_3 + Et$
or $2EtTiCl_3 \rightarrow 2TiCl_3 + Et—Et$

Beerman and Bestian (8) have shown a strong solvent effect on the mechanism of decomposition of CH_3TiCl_3. In hydrocarbon solvents, no evidence for the intermediate formation of free radicals could be found whereas, in diethyl ether, methyl radicals were the primary decomposition products. It seems that aluminum alkyls preferably alkylate titanium trichloride rather than reduce it to Ti^{2+} or lower valent species. Therefore, most active and stereoselective catalysts are prepared from $TiCl_3$ and aluminum alkyls (2).

The reduction of $TiCl_4$ by $LiAlR_4$ can similarly occur (eq. [5]).

[5] $2LiAlR_4 + 2TiCl_4 \rightarrow 2RTiCl_3 \cdot LiCl + 2AlR_3$
$2RTiCl_3 \cdot LiCl \rightarrow 2TiCl_3 \cdot LiCl + R—R$

On the basis of the above discussion, we can readily explain the observation made by Ludlum *et al.* (9) in the polymerization of ethylene by catalysts derived from titanium tetrachloride through the reductive action of *n*-hexyl lithium, lithium tetra-1-heptylaluminate, and triisobutyl aluminum or triethyl aluminum. This is illustrated in Fig. 1. The maximum yield of polyethylene is apparently produced by a catalyst formed by reaction of the stoichiometric amount of the reducing agent required to reduce titanium tetrachloride to its trivalent state followed by alkylation. Thus in the case of *n*-hexyl lithium, the ratio of $C_6H_{13}Li$:$TiCl_4$ is 2:1 and in the case of lithium tetra-1-heptylaluminate, $LiAl(C_7H_{15})_4$:$TiCl_4$ is 1:1. In the case of aluminum alkyls, reduction and subsequent alkylation require a ratio of alkylaluminum:$TiCl_4 \gg 1$.

It can be easily seen that *n*-hexyl lithium does not produce a very active catalyst but lithium tetra-1-heptylaluminate does. In this example, actions of

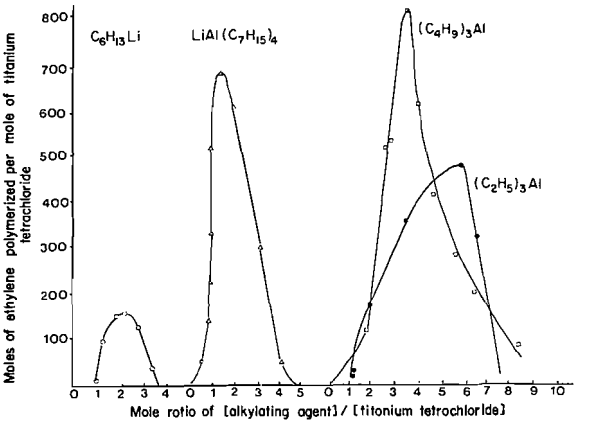

FIG. 1. Catalytic activity versus catalyst composition at 100°C (9), for ethylene polymerization.

$LiAlR_4$ and aluminum alkyls appear to be very similar.

The Nature of the Active Catalyst in the $LiAlR_4$ (R = Alkyl) and $TiCl_4$ System

From the above results, it seems that when equimolar amounts of $LiAlR_4$ and $TiCl_4$ are mixed together, an active catalyst is produced, according to the following scheme (Fig. 2).

With the above catalyst, copolymerization between vinyl ether and 1-olefin or styrene cannot be accomplished. It seems that vinyl ethers coordinate initially with the catalyst and this can polymerize only vinyl ethers but not styrene or 1-olefins. It is known (5) that styrene can be polymerized by $VCl_3 \cdot LiCl$ but not by VCl_3LiCl,THF where THF = tetrahydrofuran. Production of atactic polystyrene and isotactic poly(1-olefin) by this catalyst is interesting. It shows that 1 mole of AlR_3 produced cannot completely alkylate the $TiCl_3 \cdot LiCl$ and because 1-olefins are very reactive, they can be polymerized easily by the alkylated $TiCl_3 \cdot LiCl$ species present. Styrene, however, is polymerized preferentially by $TiCl_3 \cdot LiCl$ to an atactic polymer. It should not be cationic by nature because the rate of polymerization is very low at room temperature, resulting in low yields. It is characteristic of Ziegler–Natta catalysts to be sensitive to steric factors.

A Truly Isotactic Specific Ziegler–Natta Catalyst in $LiAlR_4/AlCl_3/TiCl_4$ System

It is known (4) that anhydrous $AlCl_3$ reacts with $LiAlR_4$ (eq. [6]):

[6] $3LiAlR_4 + AlCl_3 = 3LiCl + 4AlR_3$

It is clear from Table 3 that activity of $TiCl_3$ depends on its relative concentration with respect to the alkylating agent AlR_3. However, at a ratio of AlR_3:$TiCl_3 \simeq 3:1$, saturation is achieved in the rate

of polymerization, yield, and isospecificity in styrene polymerization. At this particular catalyst concentration, the amount of polystyrene obtained depends on styrene concentration (Table 4 and Fig. 3).

A few interesting observations can be made from Table 4. Higher temperature, e.g. 60°C, dramatically decreases the isotacticity of the polymer without much change in yield. This indicates that the catalyst is sensitive to temperature to lose much of its isospecific character. At room temperature (22°C) the catalyst is highly isospecific and, in dilute solution and at lower conversions, the amount of polystyrene obtained is proportional to the product $V \times t$ (Table 4) as it can be seen from Fig. 3. This shows that the polymerization of styrene is of first order in styrene at lower conversions and the order tends to be zero at higher values of $V \times t$.

Proof of Copolymerization between Styrene and 1-Olefins

To prove that styrene is copolymerizing with 1-olefins in the presence of $TiCl_3 \cdot LiCl + 3AlR_3$ catalyst, we chose 1-hexene as the olefin, because it is known (2) that poly(styrene-co-1-hexene) is soluble in *n*-hexane and polystyrene is not. Table 5 shows the analysis of the copolymers obtained from these monomers by the action of the above catalyst. The portion of the copolymer mixture insoluble in *n*-hexane was found to be polystyrene by infrared analysis. Thus, from Table 5, it is clear that copolymerization between styrene and 1-hexene occurs to a very significant degree.

Generally, styrene polymerizes at a yield of 25–30% and 1-hexene at 95–100% yield under the polymerization conditions given in Tables 4 and 5. Under the same conditions, the copolymer yield is

also 25–30% and the unreacted monomers, even 1-hexene, could be recovered. This shows that the catalyst preferentially coordinates with styrene and although 1-hexene polymerizes faster than styrene in the copolymerization reaction, the overall reaction rate is controlled by styrene.

Effect of Varying the Catalyst Composition on the Copolymerization Behaviour of Styrene and 1-Hexene

Table 6 shows that when a mixture of styrene and 1-hexene (2:1 molar) is copolymerized in the presence of a catalyst system, derived from a fixed amount of $LiAlR_4$ (R = 1-hexadecyl) but varying amounts of $AlCl_3$ and $TiCl_4$, a pattern develops that enables us to determine the right catalyst composition for optimum yield.

The nature and amount of the various catalyst components may be explained by the following reactions (eq. [7]):

[7] $3LiAlR_4 + AlCl_3 = LiCl + 4AlR_3$
$LiAlR_4 + TiCl_4 \equiv TiCl_3 \cdot LiCl + AlR_3 + \frac{1}{2}RR$
$AlR_3 + TiCl_4 \equiv TiCl_3 + AlR_2Cl + \frac{1}{2}RR$

Addition of $AlCl_3$ converts $LiAlR_4$ into AlR_3. Thus for complete conversion of $LiAlR_4$ to AlR_3 in Table 6, only 88 × 10^{-4} moles of $AlCl_3$ is necessary. Figure 4 shows that the maximum activity of the catalyst occurs well before addition of 88 × 10^{-4} moles of $AlCl_3$, indicating that for the production of

TABLE 7. Copolymerization of styrene and 1-olefins having branched sidechains*

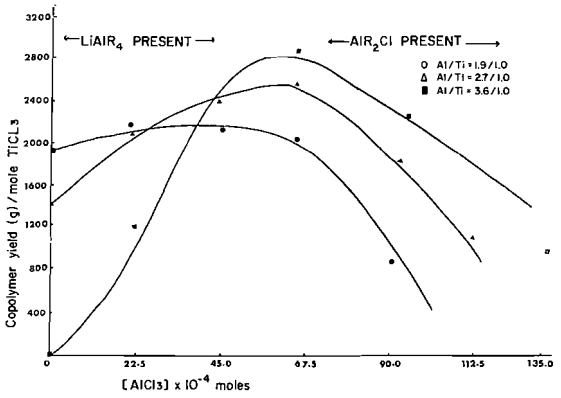

FIG. 4. Effect of varying catalyst compositions on copolymer yield for styrene/1-hexene (2:1 molar) system.

active $TiCl_3$, $LiAlR_4$ is a much better reagent than AlR_3 when R = 1-hexadecyl.

In all three cases (Table 6, Fig. 4), at the point of maximum activity, the concentration of $LiAlR_4$ equals that of $TiCl_4$. Presence of excess of $LiAlR_4$ is deleterious. Presence of not enough $LiAlR_4$ results in the reduction of $TiCl_4$ by AlR_3 producing AlR_2Cl and this is also deleterious. In all three cases, presence of excess $LiAlR_4$ is more harmful than the presence of excess AlR_2Cl. At the point of maximum polymerization activity, the catalyst corresponds to $TiCl_3 \cdot LiCl + xAlR_3$ with no $LiAlR_4$ and AlR_2Cl present. This shows that copolymerization of styrene proceeds best in the presence of catalysts prepared by the alkylation of $TiCl_3$ by simple aluminum alkyls.

Copolymerization of Styrene and 1-Olefins with Branched Side Chains

1-Olefins with normal side chains polymerize faster than styrene, resulting in lower incorporation of styrene into their copolymers. The lower reactivity of styrene is attributed to steric hindrance presented by the phenyl group. In the copolymerization of styrene and 1-hexene it has been established that the catalyst coordinates preferentially with styrene. Therefore, the copolymerization rate reflects the rate of styrene polymerization, although the greater reactivity of 1-hexene is reflected in the final copolymer structure.

1-Olefins with branched side chains such as 3-methyl-1-butene, and 4-methyl-1-pentene possess steric features similar to styrene. Therefore we thought that it would be interesting to determine the copolymer structures and copolymerization rates when styrene and branched chain 1-olefins are copolymerized. Table 7 shows the results.

It is clear from Table 7 that (*a*) the rate of copolymerization of styrene and 3-methyl-1-butene is lower than the homopolymerization rate of styrene, and (*b*) that of styrene and 4-methyl-1-pentene is slightly higher. This indicates that with the 1-olefins having branched side chains the copolymerization rate depends on the steric nature of the side chains.

Table 7 shows the copolymer composition in relation to the feed composition of poly(styrene-co-4-methyl-1-pentene). The copolymer composition was determined by infrared spectral analysis following the relationship established by Kissin *et al.* (10) and given below (eq. [8]):

$$[8] \quad \frac{D1388}{D1603} = 1.68\left(\frac{1}{C\ \text{styrene}} - 1\right) + 0.25$$

where D1388 and D1603 are the absorbance in the infrared spectrum of the copolymers at 1388 cm^{-1} (methyl group) and 1603 cm^{-1} (benzene ring) respectively.

It is expected that the above relationship should be applicable in the infrared analysis of poly(styrene-co-3-methyl-1-butene). The results obtained for this copolymer are based on that assumption.

Data from Table 7 show that the copolymerization rates and copolymer compositions involving branched 1-olefins and styrene can be very susceptible to the steric structure of the side chain of the 1-olefins. Thus, it is really interesting to note that more styrene than 1-olefin can be incorporated into the copolymer structure in poly(styrene-co-3-methyl-1-butene), a situation completely opposite to that in poly(styrene-co-1-hexene).

A novel approach to the synthesis of a variety of aminodeoxy-α-D-glycopyranosides

RAYMOND U. LEMIEUX, FAWZY F. Z. GEORGES,[1] AND ZYGFRYD SMIATACZ[2]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received October 14, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

RAYMOND U. LEMIEUX, FAWZY F. Z. GEORGES, and ZYGFRYD SMIATACZ. Can. J. Chem. **59**, 1433 (1981).

Conditions for the replacement of the 3-acetoxy group of ethyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-oximino-α-D-*arabino*-hexopyranoside (**1**) by nucleophiles including azide, phthalimide, hydride, and thiophenoxide are reported. The reaction was discovered through the formation of dimeric and trimeric derivatives of deacetylated **1** in the course of its alkaline hydrolysis. The possible use of the replacement reaction to achieve precursors for the formation of 3-deoxy-, 3-amino-3-deoxy-, 2-amino-2,3-dideoxy-, 2,3-diamino-2,3-dideoxy-, and 2-amino-2,3,4-trideoxy-α-glycopyranosides is demonstrated.

RAYMOND U. LEMIEUX, FAWZY F. Z. GEORGES et ZYGFRYD SMIATACZ. Can. J. Chem. **59**, 1433 (1981).

On rapporte les conditions qui permettent de remplacer le groupe acétoxy en position 3 du tri-*O*-acétyl-3,4,6 déoxy-2-oximino-2-α-D-arabino hexopyrannoside d'éthyle (**1**) par des nucléophiles comprenant: l'azoture, la phtalimide, l'hydrure et le thiophénolate. On a découvert cette réaction par le biais de la formation de dérivés dimères et trimères du composé **1** désacétylé au cours de son hydrolyse alcaline. On démontre l'utilisation possible de cette réaction de déplacement pour obtenir les précurseurs nécessaires à la formation de déoxy-3, amino-3-déoxy-3, amino-2-didéoxy-2,3, diamino-2,3 didéoxy-2,3 et amino-2-tridéoxy-2,3,4-α-glycopyrannosides.

[Traduit par le journal]

A wide variety of aminocyclitol-type antibiotics (1) possess the 3-amino-3-deoxy-α-D-glucopyranosyl group. Others, such as kasugamycin, sisomycin, tobramycin, and the lividomycin antibiotics contain a 2-amino-2,3-dideoxyglycosyl group. The 2,3-diamino-2,3-dideoxyglycosyl group occurs in the antibiotic seldomycin factor 5 (2). Furthermore, a 2-amino-2,3,4-trideoxyglycosyl derivative is present in the gentamicin C antibiotics (3). All these structural units represent either glycopyranosides or glycopyranosaminides modified at the 3-position. It is evident, therefore, that a general synthetic methodology for the replacement of the 3-hydroxyl group of glycopyranosides or glycopyranosaminides either by a hydrogen atom or an amino group is of substantial interest to this important field of inquiry. Since all of these glycosyl groups occur as α-anomers, it would be of special interest if the methodology produced the groups in this configuration. That these requirements can, in principle, be met by way of suitably 3-*O*-substituted 2-deoxy-2-oximino-α-glycopyranosides (4) was the subject of a preliminary communication (5). In the following discussion of the results, the various transformations which were observed starting with such a glycoside (**1**) are first to be outlined. The evidence for the structural assignments is then presented.

Discussion of Results

The reaction of the nitrosyl chloride adducts of acetylated glycals with alcohols in *N*,*N*-dimethylformamide (DMF) was shown (6) to provide acetylated 2-deoxy-2-oximino-α-glycopyranosides in high yield. Furthermore, the further processing of these oximinoglycosides under acidic and neutral conditions provided access to both α-glycosides (7) and 2-amino-2-deoxy-α-glycosides (8). However, a number of observations made at that time showed the acetylated oximinoglycosides to be alkali labile and this lability was tacitly attributed to the reversal of the glycosylation reaction. That the situation was more complex became apparent in the course of an attempt to de-*O*-acetylate ethyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-oximino-α-D-glucopyranoside (**1**) using triethylamine in aqueous methanol. In addition to the formation of the expected product (**2**), the dimeric (**3**) and trimeric (**4**) forms of **2** were also formed. Indeed, **3** was the major product of the reaction (49% isolated yield). The products **2**, **3**, and **4** were formed in nearly the following ratios, 4:6:1, respectively. Once the nature of the products **3** and **4** was established, it was apparent that the 3-substituent of a 2-oximino-α-glycoside can compete with the aglycon as leaving group in the alkaline degradation to form nitrosoalkene (**5**). In the event that elimination of the 3-substituent (route 1) is more rapid than elimination of the aglycon (route 2), the route for the formation of compounds **3** and **4** is evident. Once formed, compound **2** was highly stable under the conditions

2 3 4

which led to the formation of **3** and **4** from **1** in keeping with the fact that the acetate ion is a much better leaving group than the hydroxyl ion.

The above described results suggested a novel route for the preparation of glycosides modified at the 3-position. In order to test this possibility, **1** was treated with sodium azide in commercial DMF at room temperature. Indeed, a slow transformation occurred which led to the formation of a nearly equimolar mixture of the azides **6** and **7**. The *Z*-configuration of the oximino groups was assigned on the basis of the ^{1}H nmr chemical shifts of H-1 (6.02 and 5.90 ppm) as compared to that for H-1 (6.00 ppm) of **1** (9). The reaction was much more rapid at 65°C. Under these conditions, the *E*-isomer **8** was formed (10% yield). As expected (9), the change in the configuration of the oximino group of **7** to form **8** resulted in a deshielding of H-3 by 0.9 ppm and shielding of H-1 by 0.75 ppm.

An attempt to convert **1** into the azides **6**, **7**, and **8** using specially dried DMF failed. However, the reaction observed using commercial DMF readily occurred on adding water (1%) to the reaction mixture prepared using dry DMF. The effect of the water appears to be related to the energy required to separate the sodium and azide ions, since the reaction occurred at a useful rate on adding 18-Crown 6 (10) to the reaction mixture prepared in the pure DMF. Furthermore, the remarkable sensitivity to solvent of the reaction involving replacement of the 3-acetoxy group of **1** was observed in deacetylation reactions. As noted above, treatment of **1** with triethylamine in aqueous methanol led to the formation of compounds **3** and **4**. However, only **2** was formed in appreciable amount when dry methanol was used as solvent. This is not likely due to too rapid deacetylation since **3** was formed when sodium methoxide was used as the base in dry methanol. These matters are noteworthy since they show the elimination of the acetoxy group to be dependent on the presence in the medium of an efficient proton acceptor (B^-). Compounds **6**, **7**, and **8** were formed on reaction of **1** with sodium azide at elevated temperatures in aqueous dioxane and it therefore appears that a wide range of solvents may be used. Treatment of either **6** or **7** with sodium azide in wet DMF converted the compound to the near 1:1 equilibrium mixture. When, instead of the ethyl glycoside **1**, the corresponding *tert*-butyl glycoside was used, the azides corresponding to replacement of the 3-acetoxy group were formed. However, attempts to replace the 3-acetoxy groups of the 4,5-di-*O*-(3,4,6-tri-*O*-acetyl-2-deoxy-2-oximino-α-D-*arabino*-hexopyranosyl) derivative of *N*,*N*′-dicarbobenzoxy-2,5-dideoxystreptamine led to cleavage of the glycosyl bonds (route 2 as shown for compound **1**). It appears, therefore, that applications of the reaction for the formation of complex aminoglycosides may require a leaving group at the position α to the oximino group which is superior to the acetate ion. It was not possible to further investigate this matter.

In order to achieve greater stereochemical con-

trol of the replacement than that provided by sodium azide, the use of potassium phthalimide as nucleophilic reagent was examined. Under the conditions used, the acetylated form of the dimeric product (**3**) was the main product. However, a 25% yield of the desired *arabino*-phthalimido compound **10** was obtained as the only phthalimide product of the reaction. Reaction conditions which may be more favorable to the formation of **10** were not investigated.

It could be anticipated that the proposed nitrosoalkene intermediate would be reduced by borohydride and, if so, the reaction would provide a new access to either 3-deoxyglycosides or 2,3-dideoxy-2-aminoglycosides. Indeed, the 3-deoxyoxime **11** was obtained in 70% yield on reaction of **1** with sodium borohydride in DMF.

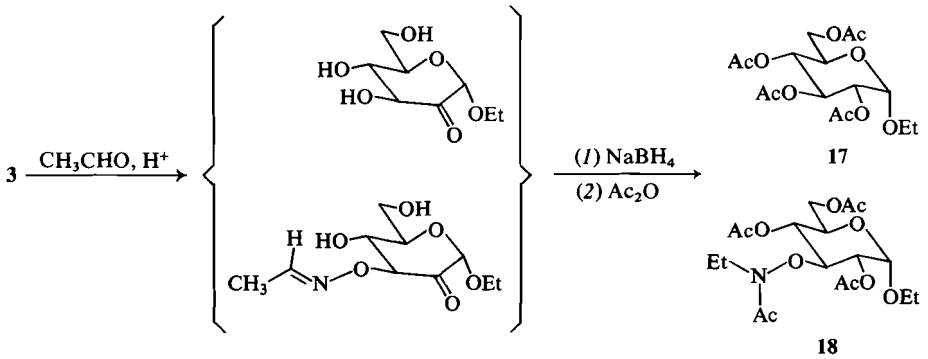
When sodium thiophenoxide was used as the nucleophilic reagent, the reaction with **1** in acetonitrile was nearly complete in 1.5 h at 75°C and the main product of the reaction was the α,β-unsaturated oxime **16**. The expected products of substitution, namely, **14** and **15**, were also present in the reaction mixture. It is apparent that H-3 of these latter compounds is sufficiently acidic to render facile the elimination of the 4-acetoxy group to form **16**. In the course of the deoximation of **14** using an acidic solution of acetaldehyde, followed by borohydride reduction and acetylation, the 4-acetoxy group was lost since reductive desulfurization of the olefinic product produced ethyl 2,6-di-*O*-acetyl-3,4-dideoxy-α-D-*erythro*-hexopyranoside (**23**).

The structure of compounds **3** and **4** were evident from the ^{1}H nmr spectral data. Deoximation of **3** with acetaldehyde, then borohydride reduction, followed by acetylation of the product to form **17** and **18** confirmed these conclusions.

The structure of **6**, which could be assigned on the basis of the ^{1}H nmr spectrum, was confirmed by deoximation followed by borohydride reduction and acetylation to form the azide **9** which was converted to ethyl 3-acetamido-2,4,6-tri-*O*-acetyl-3-deoxy-α-D-glucopyranoside (**19**). Similarly, **7** was converted to ethyl 3-acetamido-2,4,6-tri-*O*-acetyl-3-deoxy-α-D-allopyranoside (**20**). The phthalimide **10** was unequivocally characterized by its ^{1}H nmr spectrum.

The azido groups in compounds **6** and **7** could be preferentially hydrogenated to amine groups. *N*-Acetylation then provided the products **21** and **22**. It is fully expected that borane reduction (8) of compounds **6** and **7** will produce 2,3-diamino-2,3-dideoxyglycosides but this matter was not investigated.

Borane reduction of **11** and acetylation of the product gave ethyl 2-acetamido-4,6-di-*O*-acetyl-2,3-



17

25, R = H, R′ = NHAc

dideoxy-α-D-*ribo*-hexopyranoside, the *O*-acetylated form of **12**, in 80% yield. Deoximation of **11** followed by borohydride reduction provided ethyl 3-deoxy-α-D-*ribo*-hexopyranoside (**13**) in 85% yield.

Reductive desulfurization of **14** and acetylation of the product provided ethyl 2-acetamido-6-*O*-acetyl-2,3,4-trideoxy-α-D-*erythro*-hexopyranoside (**24**) in 77% yield along with the D-*threo*-isomer (**25**) in 15% yield. The same products were obtained on the similar treatment of compounds **15** and **16**.

The foregoing transformations are considered to demonstrate the potential value of the elimination of groups neighboring to an oximino group for the preparation of a wide range of deoxy and aminodeoxysugars of special interest to the general area of aminoglycoside antibiotics.

Experimental

Thin-layer chromatography was performed on Merck silica gel plates type 60 F_{254}, layer thickness 0.25 mm. Spots were made visible by heating the plates sprayed with 5% sulfuric acid in methanol. Unless otherwise indicated, the following systems were used as chromatographic solvents: carbon tetrachloride – acetone mixtures A, 1:1; B, 3:1; and C, 5:1; D, carbon tetrachloride – ether 4:3; E, benzene – ethyl acetate 10:1; F, 3% methanol in chloroform; G, ethyl acetate – petroleum ether 1:2.

Unless specified otherwise, the ^{1}H nmr data refer to 100 MHz spectra obtained with $CDCl_3$ as solvent (lock signal, tetramethylsilane). External TMS was used when D_2O was the solvent. The ^{13}C nmr data refer to 22.6 MHz spectra recorded on a Bruker HFX-90 spectrometer. The optical rotations were measured at room temperature (21–23°C).

The column chromatograms employed silicic acid (Merck 7736, type 60 for thin-layer chromatography) using 20 g per gram of reaction product with the specified developing solvents.

*Products **2**, **3**, and **4**. Deacetylation of Ethyl 3,4,6-Tri-O-acetyl-2-deoxy-2-oximino-α-D-*arabino*-hexopyranoside (**1**)*

With Triethylamine in Aqueous Methanol

Compound **1** (2.09 g, 6 mmol) was dissolved in 80 mL of methanol–water (1:1) containing 4.2 mL of triethylamine. On standing at 4°C for 6 h, tlc (solvent B) showed the presence of three products in the approximate ratio 1:1.5:0.1. Solvent removal left a crystalline mass which was subjected to column chromatography (solvent A).

The first fraction (0.40 g, 30% yield) was characterized (^{1}H nmr, mass spectrum) to be ethyl 2-deoxy-2-oximino-α-D-*arabino*-hexopyranoside (**2**), mp 136°C; $[\alpha]_D$ 94° (ethanol). *Anal.* calcd. for $C_8H_{15}NO_6$: C 43.43, H 6.78, N 6.33; found: C 43.34, H 6.72, N 5.46.

The second fraction (0.62 g, 49% yield) crystallized from acetone, mp 146–150°C; $[\alpha]_D$ +138° (ethanol), was characterized (^{1}H nmr, mass spectrum) as the dimer **3**. The ^{1}H nmr spectrum (D_2O) showed singlets for H-1 and H-1′ at 6.14 and 6.18 ppm. The ^{13}C nmr showed nine lines for ring atoms with the signals for C-1, C-5, and C-6 superimposed. *Anal.* calcd. for $C_{16}H_{28}N_2O_{11} \cdot 2H_2O$: C 41.73, H 6.13, N 6.09; found: C 41.15, H 5.95, N 5.77.

The third fraction (0.10 g, 8% yield) was assigned the structure **4** on the basis of its nmr spectra and was not further investigated.

The oxime **2** (221 mg, 1 mmol) was dissolved in water (5 mL), 1 *N* hydrochloric acid (1 mL), and acetaldehyde (3 mmol). After 3.5 h at room temperature, the stirred solution was cooled to 0°C and treated with sodium borohydride (189 mg, 5 mmol) in small portions. After 30 min, the solution was kept at room temperature for 2 h. After neutralization with acetic acid, the solvent was removed and the residue was acetylated with acetic anhydride in pyridine. An 80% yield of ethyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside (**17**) was obtained.

The dioxime **3** was treated as described above. The product was chromatographed (solvent C) to yield two fractions. One product was identical to **17**. The other product, obtained in low yield, gave nmr spectra in accord with expectations for structure **18**. As expected, de-*O*-acetylation provided a product possessing (^{1}H nmr) an *O*-ethyl, an *N*-ethyl, and an acetyl group. Spin decoupling required the substituent to be at the 3-position.

*Ethyl 4,6-Di-O-acetyl-3-azido-2,3-dideoxy-2-Z-oximino-α-D-arabino-pyranoside (**6**) and the Z- and E-ribo-Isomers (**7** and **8**)*

(a) In Dimethylformamide at Room Temperature

The glycoside **1** (1.04 g, 3 mmol) and sodium azide (780 mg, 12 mmol) were stirred together in DMF (50 mL, Fisher Reagent Grade) for 30 h at room temperature. Complete conversion of **1** into two new products was revealed by tlc (solvent E, 3 developments). The mixture was treated with anhydrous ether and the inorganic salts were removed by filtration. The filtrate was diluted with dichloromethane (250 mL) and washed with water (4 × 50 mL), dried over magnesium sulfate, and taken to dryness. Column chromatography of the residue by use of solvent E provided ethyl 4,6-di-*O*-acetyl-3-azido-2,3-dideoxy-2-*Z*-oximino-α-D-*arabino*-hexopyranoside (**6**) in 40% yield (400 mg), mp 88–90°C (recrystallized from ethyl acetate – hexane); $[\alpha]_D$ 55° (*c* 1, in chloroform); ir_{max}: 2100 (N_3) cm^{-1}; ^{1}H nmr data: 6.02 (s, 1H, H-1), 5.06 (t, 1H, $J_{4,5}$ = 10 Hz, H-4), 4.43 (d, 1H, $J_{3,4}$ = 10 Hz, H-3). *Anal.* calcd. for $C_{12}H_{18}N_4O_7$ (330.2): C 43.63, H 5.45, N 16.96; found: C 43.83, H 5.58, N 17.10.

Further developments of the column gave ethyl 4,6-di-*O*-acetyl-3-azido-2,3-dideoxy-2-*Z*-oximino-α-D-*ribo*-hexopyranoside (**7**) (400 mg, 40%), mp 73–75°C; $[\alpha]_D$ 123° (*c* 1, in chloroform); ir_{max}: 2105 (N_3) cm^{-1}; ^{1}H nmr data: 5.90 (s, 1H, H-1), 4.94 (q, 1H, $J_{4,5}$ = 9 Hz, H-4), 4.75 (d, 1H, $J_{3,4}$ = 4 Hz, H-3). *Anal.* calcd. for $C_{12}H_{18}N_4O_7$ (330.2): C 43.63, H 5.45, N 16.96; found: C 43.39, H 5.54, N 16.93.

(b) In Dimethylformamide at 65°C

A mixture of glycoside **1** (796 mg, 2.3 mmol) and sodium azide (1.52 g, 23.4 mmol) in the commercial DMF (25 mL) was heated at 65°C for 3 h. Thin-layer chromatography (solvent E) then indicated complete conversion of **1** into two major products that were accompanied by a small proportion of a third product. The mixture was brought to room temperature and processed as described in (*a*). Column chromatography (solvent E) of this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

mixture furnished **6** (240 mg, 32%), **7** (230 mg, 30.6%), and its *E*-isomer **8** as an oil (75 mg, 10%); $[\alpha]_D$ 57° (*c* 1, in chloroform); ir_{max}: 2100 (N_3) cm^{-1}; ^1H nmr data: 5.15 (s, 1H, H-1), 5.64 (d, 1H, $J_{3,4}$ = 3 Hz, H-3), 4.87 (q, 1H, $J_{4,5}$ = 9 Hz, H-4).

(c) In Dry Dimethylformamide

An attempt to repeat the preparation reported in (*b*) above using DMF distilled from phosphorus pentoxide failed to indicate an appreciable extent of reaction after 12 h at 65°C. However, on making the solution 1% in water, the rates of reaction and products formed were comparable to those mentioned in (*b*) above.

(d) In Dry Dimethylformamide and Using 18-Crown 6 (10)

Under the conditions reported in (*c*) above using dry DMF but adding equivalent amounts of the sodium azide and the crown ether, the reaction at 65°C was complete in 2 h to give the same mixture of **6**, **7**, and **8** obtained in (*b*) above. The reaction took 18 h at room temperature.

(e) In Aqueous Dioxane

To a solution of the oxime **1** (3.0 g, 8.6 mmol) in dioxane (30 mL) was added a saturated aqueous solution (4 mL) of sodium azide (1.7 g, 25.9 mmol), and the stirred mixture was heated under reflux for 8 h. Solvent removal *in vacuo* left a residue which was extracted into ethyl acetate and filtered through Celite. Evaporation of the solvent and column chromatographic separation of the resulting syrup as above, gave **6**, **7**, and **8** in 40, 45, and 10% yield, respectively.

*Ethyl 3-Acetamido-2,4,6-tri-*O*-acetyl-3-deoxy-α-D-gluco-pyranoside (**19**)*

Compound **6** (300 mg, 0.9 mmol) was deoximated and the uloside directly reduced with borohydride as was described above for the conversion of **2** to **17**. The crude product was stirred in methanol (10 mL) and a hydrogen atmosphere in the presence of 5% palladium on charcoal (300 mg) for 24 h at room temperature. The product of acetylation with acetic anhydride in pyridine was recrystallized from ethyl acetate – heptane (212 mg, 63% yield), mp 132–134°C; $[\alpha]_D$ 94° (*c* 1, in chloroform); ^1H nmr: 6.03 (d, broad, exchangeable with D_2O, *J* = 9 Hz, N—H), 4.95 (d, 1H, $J_{1,2}$ = 3 Hz, H-1), 2.08 (s, 6H, 2 × OAc), 2.05 (s, 3H, OAc), 1.90 (s, 3H, NAc). *Anal.* calcd. for $C_{16}H_{25}NO_9$ (375.3): C 51.19, H 6.7, N 3.73; found: C 50.79, H 6.61, N 3.51.

De-*O*-acetylation of **19** with triethylamine in methanol gave the ethyl 3-acetamido-3-deoxy-α-D-glucopyranoside in 85% yield, mp 194–195°C (recrystallized from ethanol – ethyl acetate – Skellysolve B); $[\alpha]_D$ 126° (*c* 1, in ethanol); ^1H nmr (D_2O): 5.20 (d, 1H, $J_{1,2}$ = 3 Hz, H-1), 4.36 (t, 1H, $J_{2,3}$ = $J_{3,4}$ = 10 Hz, H-3), 2.32 (s, 3H, NAc). *Anal.* calcd. for $C_{10}H_{19}NO_6$ (249.2): C 48.18, H 7.68, N 5.61; found: C 48.12, H 7.89, N 5.59.

*Ethyl 3-Acetamido-2,4,6-tri-*O*-acetyl-3-deoxy-α-D-allo-pyranoside (**20**)*

In the same manner as described for the preparation of **19**, the azide **7** was converted in 61% yield to the title compound, mp 120–121°C; $[\alpha]_D$ 85° (*c* 0.7, in chloroform); ^1H nmr: 6.89 (d, broad, exchangeable with D_2O, *J* = 7.4 Hz, N—H), 2.08 (s, 3H, OAc), 2.03 (s, 3H, OAc), 2.00 (s, 3H, NAc). *Anal.* calcd. for $C_{16}H_{25}NO_9$ (375.3): C 51.19, H 6.71, N 3.73; found: C 51.11, H 6.75, N 3.54.

*Ethyl 4,6-Di-*O*-acetyl-2,3-dideoxy-2-Z-oximino-3-phthalimido-α-D-*arabino*-hexopyranoside (**10**)*

A solution of **1** (1.74 g, 5 mmol) and potassium phthalimide (1.5 g) in DMF was stirred for 10 h at room temperature. Solvent removal and extraction of the residue with benzene provided a product which was chromatographed on a column of silicic acid and eluted with diethyl ether – heptane (1:1). The first fraction was unreacted compound **1** (200 mg). The second fraction was the title compound (**10**) (550 mg, 25%) which was recrystallized from chloroform – petroleum ether, mp 157–158°C; $[\alpha]_D$ 71° (*c* 1, in chloroform); ^1H nmr: 7.68 (m, 4H, Ar), 6.00 (s, 1H, H-1), 5.74 (t, 1H, $J_{3,4}$ = $J_{4,5}$ = 10 Hz, H-4), 5.22 (d, 1H, $J_{3,4}$ = 10 Hz, H-3). *Anal.* calcd. for $C_{20}H_{22}N_2O_9$ (434.4): C 55.29, H 5.10; found: C 55.43, H 5.19.

The third fraction proved to be the acetylated form of **3**, ethyl 4,6-di-*O*-acetyl-2-deoxy-3-*O*-(ethyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-iminyl-α-D-*arabino*-hexopyranoside)-2-oximino-α-D-*arabino*-hexopyranoside which crystallized from ethyl acetate – petroleum ether. Yield, 635 mg (20%), mp 178–179°C; $[\alpha]_D$ 44.6° (*c* 0.15, in chloroform); ^1H nmr data: 6.03 (s, 1H, H-1′), 5.90 (s, 1H, H-1), 5.72 (d, 1H, $J_{3,4}$ = 10 Hz, H-3′). *Anal.* calcd. for $C_{26}H_{38}N_2O_{16}$ (634.6): C 49.20, H 6.03; found: C 49.40, H 5.78.

*Mixture of Ethyl 4,6-Di-*O*-acetyl-2,3-dideoxy-2-Z-oximino-α-D-*erythro*-hexopyranoside (**11**) and its* E*-Isomer*

The *Z*-oxime **1** (2.0 g, 5.7 mmol) was dissolved in dry DMF (20 mL) and treated with sodium borohydride (1.06 g, 28.0 mmol) in portions over a period of 30 min. After stirring for 16 h at room temperature, excess borohydride was destroyed by the addition of methanol with cooling. The solvent was then removed *in vacuo* and several portions of methanol were successively evaporated from the remaining residue which was finally purified through a column of silicic acid by means of solvent G. The syrupy product thus obtained (1.13 g, 70%) was found to be a mixture of the isomeric *Z*- and *E*-oximes, in the ratio of 1:2, by the appearance, in the ^1H nmr spectrum, of singlets at 5.87 and 5.03 corresponding to the anomeric protons of these isomers, respectively.

*Ethyl 2-Acetamido-2,3-dideoxy-α-D-*ribo*-hexopyranoside (**12**)*

A 1 *M* solution of borane–tetrahydrofuran complex (20 mL) was added under nitrogen to a stirred solution of the above mixture of oximes (**11**) (0.6 g, 2.07 mmol) in tetrahydrofuran (1 mL), cooled to −5°C. The solution was then kept at room temperature for 24 h. The excess borane was reacted with methanol and solvent removal left a residue which was dissolved in methanol and treated with Dowex 1-X8 resin (hydroxide form). Acetic anhydride (0.45 mL) was added to the filtered solution and the mixture was stirred at room temperature for 1 h. Excess commercial sodium methoxide was then added cautiously until the solution became basic (~pH 9). Stirring was continued for an additional hour prior to treatment with Amberlite IR-120 (H^+) ion exchange resin. Solvent removal left a syrupy residue which was washed several times with ether. Crystallization from ethyl acetate furnished pure **12** (385 mg, 80%), mp 186–188°C; $[\alpha]_D$ 140° (*c* 0.25, in methanol) (lit. (11) mp 185–187°C; $[\alpha]_D$ 149° (*c* 1.05, in methanol). The ^1H nmr data (in D_2O): 5.02 (d, 1H, $J_{1,2}$ = 3.8 Hz, H-1), 3.85 (complex m, 7H), 2.07 (multiplet including a sharp singlet at 2.20, 5H, H-3a, H-3e, and NAc); ^{13}C nmr: 174.2 (C=O), 9.58 (C-1), 73.2 (C-5), 64.8 (C-4, or OCH_2), 64.3 (OCH_2 or C-4), 61.3 (C-6), 48.3 (C-2), 32.4 (C-3), 22.4 ($AcCH_3$), 14.7 (CH_3) ppm.

*Ethyl 3-Deoxy-α-D-*ribo*-hexopyranoside (**13**)*

The mixture of **11** and its *E*-isomer (0.5 g, 1.7 mmol) was deoximated and the uloside reduced with borohydride as described for the preparation of **17**. For purposes of purification, the crude product was acetylated with acetic anhydride and pyridine in the usual way and, after isolation, was deacetylated with sodium methoxide in methanol. Treatment of the solution with Amberlite IR-120 (H^+) resin, filtration, and solvent removal left a residue which was washed with cold chloroform and recrystallized from chloroform – petroleum ether. Yield, 283 mg (85%), mp 92–93°C; $[\alpha]_D$ 144.8° (*c* 1.75, in methanol); ^1H nmr (in D_2O): 4.84 (d, 1H, $J_{1,2}$ = 3 Hz, H-1), 3.88 (m, 7H), 2.34 (m, 1H, H-3e), 1.91 (m, 1H, H-3a). *Anal.* calcd. for $C_8H_{16}O_5$ (192.2): C 49.98, H 8.39; found: C 49.71, H 8.23.

*Products **14**, **15** and **16**. Reaction of Ethyl 3,4,6-Tri-O-acetyl-2-deoxy-2-oximino-α-D-*arabino*-hexopyranoside (**1**) with Sodium Thiophenoxide*

Compound **1** (1.44 g, 4 mmol) was added to a suspension of sodium thiophenoxide (1.9 g, 14.4 mmol) in acetonitrile (75 mL) and the mixture was stirred at 75°C for 1.5 h. Filtration and removal of the solvent left a solid which was taken up in chloroform, washed with water, dried, and taken to dryness. The yellow solid, which tlc (solvent E) indicated to be a mixture of three products together with some unreacted starting material, was applied to a column of silicic acid and the chromatogram developed with solvent E. The following compounds were obtained in order of elution.

Ethyl 4,6-di-*O*-acetyl-2,3-dideoxy-2-oximino-3-*S*-phenyl-3-thio-α-D-*ribo*-hexopyranoside (**15**), (90 mg, 5.5%), mp 96–97°C; $[\alpha]_D$ 164° (*c* 1.5, in chloroform). The ^{1}H nmr data: 7.36 (m, 5H, Ar), 5.90 (s, 1H, H-1), 5.06 (q, 1H, $J_{3,4}$ = 4.25 Hz, $J_{4,5}$ = 10 Hz, H-4), 4.70 (d, 1H, $J_{3,4}$ = 4.25 Hz, H-3). *Anal.* calcd. for $C_{18}H_{23}NO_7S$ (397.4): C 54.39, H 5.83; found: C 54.71, H 5.84.

Ethyl 6-*O*-acetyl-2,3,6-trideoxy-2-oximino-3-*S*-phenyl-3-thio-α-D-*glycero*-hex-3-enopyranoside (**16**) as an oil (485 mg, 35%); $[\alpha]_D$ 84° (*c* 1, in chloroform). The ^{1}H nmr data: 7.39 (m, 5H, Ar), 6.00 (s, 1H, H-1), 5.62 (d, 1H, $J_{4,5}$ = 2 Hz, H-4), 4.67 (sextet, 1H, $J_{4,5}$ = 2 Hz, $J_{5,6}$ = $J_{5,6'}$ = 4.5 Hz, H-5), 4.11 (d, 2H, $J_{5,6}$ = $J_{5,6'}$ = 4.5 Hz, H-6 and 6'). *Anal.* calcd. for $C_{16}H_{20}NO_5S$ (338.3): C 56.78, H 5.95, S 9.47; found: C 56.05, H 5.74, S 9.52.

Ethyl 4,6-di-*O*-acetyl-2,3-dideoxy-2-*Z*-oximino-3-*S*-phenyl-α-D-*arabino*-hexopyranoside (**14**) (410 mg, 24.9%) as a syrup which solidified on standing, mp 80–85°C; $[\alpha]_D$ 64° (*c* 1, in chloroform). The ^{1}H nmr data: 7.34 (m, 5H, Ar), 6.00 (s, 1H, H-1), 5.18 (t, 1H, $J_{3,4}$ = $J_{4,5}$ = 9 Hz, H-4), 4.30 (d, 1H, $J_{3,4}$ = 9 Hz, H-3). *Anal.* calcd. for $C_{18}H_{23}NO_7S$ (397.4): S 8.06; found: S 7.69.

Unreacted starting material (120 mg, 8.3% recovery).

*Compounds **24** and **25**. Reaction of **14** with Raney Nickel*

The glycoside **14** (300 mg, 0.75 mmol) was treated in methanol (10 mL) with Raney Nickel in the presence of hydrazine hydrate (1 mL) under reflux for 5 h. The catalyst was then removed by filtration and washed with methanol. The combined filtrates gave, upon evaporation, 160 mg of white solid, which was acetylated with acetic anhydride in pyridine. An oil (120 mg) was obtained which was found by tlc (solvent B, 5 developments) to consist of two products. Column chromatography with solvent F yielded ethyl 2-acetamido-6-*O*-acetyl-2,3,4-trideoxy-α-D-*erythro*-hexopyranoside (**24**) (150 mg, 77%), mp 58–61°C; $[\alpha]_D$ 121° (*c* 1, in chloroform); ^{1}H nmr data: 4.72 (d, 1H, $J_{1,2}$ = 3.5 Hz, H-1), 1.65 (m, 4H, H-3a, H-3e, H-4a, and H-4e). *Anal.* calcd. for $C_{12}H_{21}NO_5$ (259.2): C 55.59, H 8.15; found: C 55.53, H 7.94.

Further elution of the column afforded ethyl 2-acetamido-6-*O*-acetyl-2,3,4-trideoxy-α-D-*threo*-hexopyranoside (**25**) as an oil (30 mg, 15.4%); $[\alpha]_D$ 79° (*c* 0.5, in chloroform); ^{1}H nmr: 4.62 (s, 1H, H-1), 1.59 (m, 4H, H-3a, H-3e, H-4a, and H-4e). *Anal.* calcd. for $C_{12}H_{21}NO_5$ (259.2): C 55.59, H 8.15; found: C 55.15, H 7.89.

Compounds **24** and **25** were also obtained when the unsaturated glycoside **16** was treated in the same manner.

Products from interaction of aromatic nitrocompounds with argon metastables inside a gas chromatograph[1]

WALTER A. AUE, VELUPPILLAI PARAMASIGAMANI,[2] AND JAE H. KIM

Chemistry Department, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received August 12, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

WALTER A. AUE, VELUPPILLAI PARAMASIGAMANI, and JAE H. KIM. Can. J. Chem. **59**, 1439 (1981).

The neutral products resulting from the degradation of aromatic nitrocompounds, following interaction with argon metastables (presumably by Penning ionization), have been studied inside a gas chromatographic system. The simplest but typical example, nitrobenzene, yields benzene and phenol. Product ratios sometimes resemble results of mass spectrometry more than they do data obtained by pyrolysis. The ease of elimination of substituents from monohalogenated nitrobenzenes follows the order I > NO_2 > Br > Cl. Ratios of the products resulting from loss of NO (rearrangement) versus loss of NO_2 have been measured for a variety of compounds. The leaving NO_2 group can be replaced by I if the system is doped with iodine vapour. Reduction of the nitro group and ring closures are observed with some of the more complex substrates, similar to results known from discharge chemistry.

WALTER A. AUE, VELUPPILLAI PARAMASIGAMANI et JAE H. KIM. Can. J. Chem. **59**, 1439 (1981).

On a étudié dans un système de chromatographie en phase gazeuse, les produits neutres de dégradation des composés nitrés aromatiques résultant d'une interaction avec des métastables de l'argon (probablement par une ionisation de Penning). L'échantillon à la fois le plus simple et le plus représentatif, le nitrobenzène, conduit au benzène et au phénol. Les rapports des produits ressemblent quelquefois d'avantage aux résultats de la spectrométrie de masse qu'aux données obtenues par pyrolyse. La facilité d'élimination des substituants à partir des nitrobenzènes monohalogénés varie selon l'ordre suivant: I > NO_2 > Br > Cl. On a mesuré, pour un certain nombre de composés, les rapports entre les quantités de produits provenant de la perte de NO (transposition) et ceux dus à la perte de NO_2. Le groupe labile NO_2 peut être remplacé par I si on ajoute de la vapeur d'iode au système. Dans le cas de substrats plus complexes, on observe la réduction du groupe nitro et des annellations; ces résultats ressemblent à ceux observés dans la chimie de la décharge.

[Traduit par le journal]

Introduction

Aromatic nitro compounds are used widely as explosives, propellants, biocides, and intermediates for chemical synthesis. As a consequence, they are often found dispersed at trace levels in the environment. In this form they pose a formidable challenge to the analyst.

Not the least of the analyst's problems is the need for confirmation. Popular methods involve chemical derivatization and, more often, degradation methods that monitor ions such as mass spectrometry.

In contrast, methods that monitor *neutral* products of gas-phase degradations are far less common. To wit: gas chromatography – mass spectrometry (gc–ms) is the most esteemed of all confirmation methods, while gas phase pyrolysis of gc peaks (1) is rarely encountered in the literature. There are good reasons for this, for instance the great advantage of knowing accurate fragment masses, the much larger ms literature, and the difference between ionic and radical degradation processes.

Beyond this relatively narrow analytical context, the gas-phase reactions of aromatic nitro compounds, ionic or radical, have been the subject of numerous studies in organic and physical chemistry. This study, although undertaken with future analytical goals in mind, reports likewise on the characteristic behaviour of nitro compounds in a particular type of gas-phase degradation. It starts with ionization but ends with the determination of neutral products.

In past years we had performed various ionic and radical degradation processes right inside a two-dimensional gas chromatograph. This was done to produce and separate neutral products that would be indicative of the original analyte.

Some of the chosen fragmentation techniques, e.g. electron capture (2) or photolysis (3), worked to our satisfaction. However, these could be used only for compounds that suitably capture electrons or absorb radiation, and then only within relatively limiting concentration ranges.

A third approach, which could be used on a much more varied selection of compounds, involved Penning ionization. The term denotes ionization by electronically excited neutrals, particularly by noble gas atoms in long-lived states.

$$Ar^* + M \rightarrow Ar + M^+ + e^-$$

This is the basis of the well-known gc "argon detector" (4, 5), which monitors ionization of organic solute molecules by argon metastables.

We have shown that the use of an argon plasma is feasible for *in situ* degradation of gas chromatographic peaks (6). Argon was chosen for similar reasons as apply to the argon detector. It is inexpensive enough to be used as a gc carrier gas and it can be easily purified. Its metastable states ($^3P_2$ and $^3P_0$, 11.54 and 11.72 eV, lifetime at atmospheric pressure 0.2×10^{-6} s; also argon molecules, about 10.1 eV, lifetime 3.4×10^{-6} s, as cited in ref. 5) are suitably long-lived. Their energy is high enough to ionize most organic compounds, yet low enough to avoid excessive degradation. (It should be noted, however, that Penning ionization is only one of a number of processes, both ionic and radical, that can initiate degradation in an argon plasma.)

In our experiments, argon (or other noble gases) could be used, while nitrogen could not. The latter carrier degraded the analyte but did not yield significant fragmentation products. In fact, small amounts of nitrogen in argon inhibited formation of gc-separable products. This was taken as indication that the products do indeed arise from initial Penning ionization. There are prominent metastable states of N_2 much below the ionization potential of organic compounds, and N_2 reacts efficiently with Ar*. The glow originating from the latter reaction is often used as a test for the presence of argon metastables.

Degradation techniques that start with the molecular cation should show similarities to processes postulated for EI-ms, CI-ms, API-ms and plasma chromatography, although, of course, the latter systems recognize only ionic products while the gas chromatographic approach is restricted to volatile, neutral species. Also, there should be similarities to the discharge chemistry of larger organic molecules (7). It must be realized, however, that syntheses in discharges are assumed to involve mainly *radical* processes, although ionic intermediates have been postulated for certain cases and there is a general lack of mechanistic information in this area.

Regardless of the nature of the intermediates, however, the fact that products have to be neutral and relatively stable to be recognized in either technique makes for some similarity. After all, there is only a limited number of stable structures that one can reasonably expect to emerge from a given substrate. Furthermore, even the fragmentation of positive ions generates various neutral species. These would not be directly "seen" in a mass spectrometer, but they, or their fragments, can form compounds separable by gc. Especially important in this context are larger radicals that can emerge as stable compounds via hydrogen abstraction from a suitable substrate.

It needs to be emphasized here that the pressure in our system is the highest of all degradation methods mentioned so far, ranging typically between two and three atmospheres. This has obvious consequences for the probability of ion–molecule reactions vs. unimolecular degradations.

The literature of the various ionic degradation methods for nitro compounds is an interesting one. A part of it relating to explosives has recently been reviewed (8). The nitro group can leave in either anionic, radical, or cationic form. The second prominent fragmentation pathway is the loss of NO (9).

There is little, if any, evidence for such losses in plasma chromatography (10, 11). The ions observed by this technique are usually MH^+ or M^-. The loss of NO_2 is thought to occur only at higher energy. Halogenated nitroaromatics lose Cl, Br, or I, but not NO_2 (12). In an API source, *o*- and *p*-chloronitrobenzene exchange the halide against oxygen (from O_2 traces), but the *meta* isomer forms the molecular anion (13).

The neutral products from pentachloro- and tetrachloronitrobenzene in an electron capture detector, however, do show loss of NO_2: pentachloro- and tetrachlorobenzene are the primary products and there is no evidence for products that retained the nitro group (14). Generally, though, nitro compounds are assumed to engage in associative, halogen compounds in dissociative, electron capture. The lifetimes of a great number of relevant negative ions have been determined (15).

Considerable work has been done with free radicals from the pyrolysis of nitro compounds. Parallel to electron impact mass spectrometry, the primary losses are those of NO and NO_2 (16). In this review as well as in a later paper (17), attention is drawn to the fact that widely disparate degradation methods, presumably based on totally different principles and/or processes, can lead to surprisingly similar results.

Thus it is also with the results obtained in this study. The neutral products of gas chromatographic peaks subjected to Penning ionization conditions showed general similarities to mass spectroscopy on the one, to discharge chemistry on the other hand.

It must be mentioned that Penning ionization mass spectra have been described (ref. 18 and literature cited therein). Unfortunately, the number of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

such spectra is very small. When comparisons with mass spectra are made in this paper, they refer therefore to electron-impact ms.

Experimental

The instrument used for this study has been recently described (6). Its essential capability is that a gc peak of interest can be separated from other sample components on a first gc column and routed to a flow-through reactor. Reactors with parallel plate and pin-cup geometries employ ^{63}Ni-coated gold foils, and are operated in constant-current mode (typically 20 to 200 μA) or, less often, in constant-voltage mode (typically 2000–4000 V). The approximate argon flow through the reactor is 50 mL/min, its temperature 250°C. (These settings are not overly critical.) The degradation products plus residual analyte flow on to a second gc column where they are separated.

In this study, FID detection and highly purified argon carrier gas were used throughout. On occasion, the fragmentation took place in the presence of small amounts of dopants such as hydrogen and iodine. Hydrogen was added directly to the effluent from the first column. Iodine was introduced at the same junction by a low flow of argon that had passed over I_2 crystals at room temperature ($vp_{I_2} \approx 0.3$ Torr; or $\approx 10^{-5}$ g I_2 per min).

Model compounds were injected, degraded at various voltage or current settings, and the nature and relative yield of major degradation products determined. Frequent "blanks" (with the power supply turned off) had to be run to ensure that the observed products did not arise from extraneous reactions (i.e. solute degradation in the chromatographic system).

Identification of products was done only by retention, sometimes on two different columns, and co-chromatography with authentic standards. It must be stressed that, as a consequence, the results are subject to the well-known limitations of gas chromatography in this respect. However, the simplicity of product patterns and their obvious relationship to the parent compound leave little doubt about the general correctness of structural assignments.

Mass spectra were obtained on a CEC 21-104 instrument, operated with a source temperature of 150°C and an anode current of 10^{-4} A. Its approximate resolution was 600, thus certain important doublets were unresolved.

Results and Discussion

Besides the uncertainties peculiar to qualitative analysis by gc, a few very general and fairly obvious points need to be kept in mind whenever the output of the system, a series of gas chromatographic peaks, is subjected to speculation concerning their origin. Such speculation is likely to arise, mainly because this particular degradation methodology may well transcend its original analytical mission. The following points will therefore be discussed in some detail.

First, analyte reactions with argon metastables at a pressure of two to three atmospheres can be considered a relatively "soft" degradation method. The energy of the metastables is not far above the ionization potentials of most organic compounds, and dissipation of excess energy is relatively easy. The high pressure favors two and three-body processes and the establishment of equilibria.

Second, degradation of solute molecules may be initiated by processes other than Penning ionization.

While the system has been devised with Penning ionization in mind, and while evidence gathered so far does not deny the assumption that this mode prevails, the fact is that relatively complex organic molecules are used as substrates and that the chromatogram can describe only the final result of a possibly quite complex sequence of reactions. Different types of analytes may differ in regard to breakdown mechanism and, at best, only very thorough, detailed, and comprehensive studies could establish with some degree of certainty their mechanistic classification. This is a predicament shared with, among other established approaches, discharge synthesis. And the fact that ours is a technique yet in its infant stage certainly aggravates the problem.

What processes, beside Penning ionization by the argon $^3P_2$ and $^3P_0$ species, could initiate compound degradation? There is the obvious possibility that higher excited states may become involved, and the fact that the plasma can be pushed to degrade even methane (whose ionization potential is higher than the energy available from the metastables) certainly attests to that. There are the possibilities of associative (Hornbeck–Molnar) ionization

$$Ar^* + M \rightarrow ArM^+ + e^-$$

dissociative ionization

$$Ar^* + MX \rightarrow Ar + M^+ + X^- \text{ (or } X + e^-)$$

and ionizations with various types of rearrangements. Generally, however, Penning ionization yielding the molecular cation is perceived as a main, but not the exclusive, ionic reaction channel on the basis of experiments with relatively simple molecules (19). One would assume that the complex organic molecules of this study are even more likely to react in this manner.

Ionization of analyte molecules can also occur by charge transfer from Ar^+ (ionization potential of argon 15.76 eV), from Hornbeck–Molnar species such as Ar_2^+ or ArM^+, or from various other ions of lower energy that are present when a peak passes through the reactor. After all, the current is usually around 1×10^{-4} A or 1×10^{-9} F/s (compared with a typical 10 s peak of 10^{-4} g or 10^{-7} mole/s). To be noted in this context, though, are calculations by Collinson *et al.* (5) showing that, for a particular argon detector geometry, the number of metastables generated is ca. 55 times as large as the number of positive ions. (If this applies also to our system, the number of metastables would be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

roughly of the same order of magnitude as the number of solute molecules.)

Another possibility of cation (or possibly ion-pair) formation is electron impact. Collisions with electrons also excite the neutral molecules and lead to radical fragmentation, i.e. processes that are considered responsible for most of discharge chemistry. The preferred status of noble gases, however, militates against a major role for this process in our system.

Radicals are sure to be present, though. For one, the fragmentation of a radical cation usually produces an even-electron ion and a radical. While radicals (and their further products) are not "seen" in ms, they can proceed to form stable compounds recognizable by gc.

Another possibility about which little is known, but which cannot be easily discounted with compounds carrying nitro or halogen substituents, is negative ion formation. In EI-ms systems, anion abundance is highly dependent on pressure. The fact that, in our system, the random substitution typical of, say, the chlorine radical has not been observed, may indicate the presence of the alternative chloride anion.

Aside from electron impact and the fragmentation pathways of a molecular ion, excitation of analyte molecules and subsequent radical fragmentation can also occur by energy transfer from the same argon metastables that are responsible for Penning ionization. There is ample spectroscopic evidence for this process happening with a variety of simple molecules; in fact, excitation by argon metastables is an excellent way of obtaining certain interesting emission spectra (20). The question to what extent, and on what substrates, such processes compete with Penning ionization will, it is hoped, become somewhat clearer in the future as more product patterns become available.

Finally, there is the rather disturbing but ever-present possibility of wall reactions (21) without or with catalytic effects (e.g. on the Ni-63 foil). One would also expect the "cleanliness" of the reactor to be of importance in this context. Whether or not wall reactions do play a significant role in our system, however, is unclear at present.

Third, a variety of processes can or must occur before fragmentation products appear as chromatographic peaks on the recorder chart. Given that ions and radicals exist in the reactor, these species have to form stable compounds that can pass through a gc column. It should be noted that, in our system, 100% yields (of products plus residual analyte) would be quite rare, although values above 50% are not uncommon. (In fact, this is remarkably good for degradation processes of all sorts running at ~3 atm pressure. The present reactor cell has been in operation for over three years and has yet to be cleaned.) Still, low yields indicate the possibility that certain processes will go unnoticed because the species involved do not lead to peaks in the final chromatogram.

To produce peaks, ions have to neutralize, and little is known about the direct neutralization process (cation/anion or cation/electron). If such neutralization were to liberate energy anywhere close to the typical ionization energies, one would expect extensive fragmentation to result. If they are not neutralized in the gas phase, some ions should reach the electrodes, provided their lifetime in this particular environment allows them to do so. (Under typical conditions, it should take an ion about 10^{-4} s to traverse the reactor.) What happens then at the electrode is, again, a matter of speculation.

Ions can also transfer charge to become, often after hydrogen abstraction from a suitable substrate, stable compounds. This process could perhaps be considered the "softest" type of neutralization, and much more is known about it from chemical ionization mass spectrometry.

Fourth, the *same* product can be formed by different pathways. For instance, the formation of benzene from nitrobenzene, just counting mass spectrometric evidence, could start from a positive, neutral, or negative C_6H_5 species.

Fifth, the formation of stable compounds from ions or radicals often requires the presence of another reactant (e.g. a hydrogen donor for the phenoxy precursor of phenol). Also, degradation products can react with each other (for instance forming biphenyl from a substituted benzene).

Sixth, the yield of a product from a particular precursor reflects not only the rate of formation but also the rate of further degradation of that product. Elementary as that appears, it is easily overlooked in front of a pretty chromatogram presenting a number of "final" products.

Seventh, the geometry of the argon reactor, the flow patterns and field gradients in it, and the power level at which it is run, can all influence relative product yields. This is not too surprising and can be compared, perhaps, to the difference in mass spectra related to pressure and temperature, not to speak of the cleanliness of either degradation enclosure. As one point out of many, the lifetime of argon metastables (in argon at atmospheric pressure) allows them to diffuse about 10^{-4} cm from a position close to the anode (5). Obviously, solute molecules entering the cell in that spot are likely to

encounter a different reaction milieu than if they had entered, say, around the cathode. Product ratios can therefore vary.

To end the fairly obvious points on an experimental note, any quantitative comparison of product ratios from the argon reactor, such as in Tables 3 or 4, implies that these were obtained under conditions as similar as possible.

In Fig. 1, the degradation of nitrobenzene leads, as expected, to benzene and phenol, but very few other peaks are evident. One can compare this result (subject, as always, to the various caveats mentioned above) to results from pyrolysis (16) and from mass spectrometry (Table 1). When comparing mass spectrometric data in particular, one has to be aware of the rather tenuous connection between neutral molecules presumed to have arisen from initial Penning ionization, and the apparent cations (and, by inference, neutrals, radicals, and their possible fragments) from the mass spectrum that could have served as their precursors. Furthermore, the argon metastables are about 11.6 eV above ground state; therefore the ms has to be run pretty well at the lowest possible energy setting (in our case a nominal 13 eV). To indicate the direction in which electron energy influences relative ion intensity, a scan at 30 eV is included.

Table 1 suggests (based, however, on only one ratio) that the argon reactor results are closest to those of 13 eV electron-impact ms, as one would have expected for Penning ionization. In contrast, they seem to have little in common with the pyrolysis pattern. It should be realized, though, that the abundance of dimerization products is obviously concentration-dependent, hence less useful for comparison of product ratios. The significance of comparing the argon reactor data with mass spectrometry and pyrolysis lies, of course, in the fact that the former method starts with ionization, the latter with radical bond fission. By analogy, the assumption of Penning ionization as the decisive mechanism in the argon reactor is buttressed by such results.

The difference between the argon reactor and the pyrolyzer (16) is also evident in the degradation of 2-nitroethylbenzene (Table 2). While there are, of course, some common compounds, the main pyrolysis product, aniline, was not even detected in the argon reactor effluent. Conversely, the prominent argon plasma products *o*-ethylphenol and phenol seem not to have been formed in the pyrolyzer.

Table 2 also contains mass spectrometric infor-

mation, but the greater complexity of the test compounds makes meaningful comparisons close to impossible. For instance, the base peak, $(M - OH)^+$, has no directly equivalent neutral product, although one could consider it a precursor of indole. Obviously, Table 2 lists only selected ions. For further comparison, the 13 eV electron impact mass spectrum of *o*-nitroethylbenzene is reproduced in Fig. 2, together with that of nitrobenzene itself.

Sometimes it may be more fruitful to compare defined product ratios, rather than whole product patterns. For instance, one would expect the competition between rearrangement and elimination of the nitro group to provide such a comparison. That is, the ratio R—OH/R—H (arising from degradation of $R—NO_2$) should, first, decrease with increasing energy and, second, depend on the nature of the aromatic system and its substituents.

TABLE 3. R—OH/R—H ratios of products from $R—NO_2$

[b]Includes dibenzofuran.

To check out the first expectation one would have to use metastables of different energy. Some preliminary experiments in this direction have been done, but the results appear rather contradictory at present. They will be the subject of a separate study.

The second expectation was easier to pursue. Table 3 shows ratios from various aromatic nitro compounds. Certain trends are obvious, as can be seen, for instance, from a comparison of the three nitrobiphenyls to the three nitrotoluenes. In-

[b]Both isotopes considered for Cl and Br.

teresting is also the clear difference between the 1 and 2 positions on the naphthalene ring.

Mass spectrometric ratios have been included in Table 3. There is no clear-cut correlation, although some trends do correspond. This is not too surprising. Besides experimental variation, one could expect considerable differences between the behavior of, say, the tropylium ion in the low-pressure, essentially unipolar environment of the mass spectrometer and the high-pressure, bipolar argon reactor cell. Furthermore, some of the mass spectral data remain ambiguous in the absence of high-resolution measurements. For instance, our instrument cannot distinguish between the masses of NO and H_2CO and doublets are likely in some cases. In the tables we have, of necessity, ignored the problem, but it would have to be addressed if more than "trends" were at stake.

Peaks resulting from the elimination of either NO or NO_2 appeared prominent, and it was therefore interesting to compare them with peaks resulting from the loss of other substituents. Subject to the limited information content of peak amplitude and position as discussed above, a semi-quantitative answer can be given to the "ease of removal" of the NO_2 group vs. one of three halogens from various monohalonitrobenzene substrates. Figure 3 presents an example and Table 4 lists, aside from other data, the product peak height ratios of $\phi X/\phi NO_2$; i.e. an approximate measure of the extent to which NO_2 is removed in comparison to a particular halogen. Clearly, NO_2 leaving is more likely than Cl or Br but less likely than I; on average by factors of 6.3, 1.4, and 0.3 in this experimental series. It should be noted that these values can vary somewhat with current or voltage settings; however, the general sequence Cl < Br < NO_2 < I was always observed.

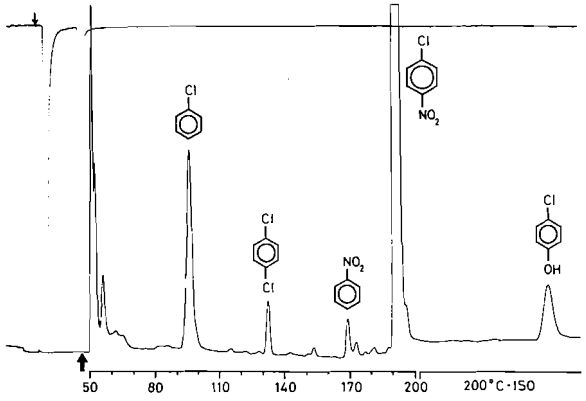

FIG. 3. Degradation pattern of *p*-chloronitrobenzene. Top chromatogram (inverted): Separation of title compound from solvent in column 1, as seen by FID-1, for introduction to plasma reactor. Column 1: 5% Carbowax 20M on Chromosorb W, 45/60 mesh, in 90 × 0.4 cm id borosilicate tube; isothermal at 190°C; Ar ca. 35 mL/min. Bottom chromatogram: Separation of degradation products by column 2, as seen by FID-2. Column 2: 5% Carbowax 20M on Chromosorb W, 45/60 mesh, in 200 × 0.4 cm id borosilicate tube; temperature-programmed as indicated; Ar ca. 50 mL/min.

Scanning through the argon-reactor numbers in Table 4 makes it obvious that, on a relative basis, halogen elimination from the *ortho* and *para* positions appears to be preferred to removal from *meta* ("appears" because the departure of halogen is only one of several processes necessary to bring about the finally observed result). The peculiar role of the *meta* position is, of course, well known from studies of aromatic substitution patterns in organic chemistry.

We have to admit to the temptation of drawing, in analogy, mesomeric structures of preferred transition states. However, this would be unmitigated speculation. At this early stage, we do not even know the forms assumed by the various leaving and

entering species. They may be cationic, radical, or anionic in free or associated states, not to mention their relative concentration if one species occurs in more than one form. The best one could do for now would be to use analogies from API, CI, or EI mass spectrometry or from plasma chromatography. None of these methods, however, uses energy transfer from noble gas metastables.

Valuable as comparisons of congeneric series are, there is always the complication of possible changes in mechanism. The argon reactor results vary relatively smoothly from chlorine to iodine, and predictions based on the carbon–halogen bond strength would have been qualitatively fulfilled. The trends are clearly evident from the data of Table 4.

Not so with the appended mass spectrometric data. Trends occur, but they are not as clearly expressed. "Mechanisms" change, as seen for instance by the varying relative contributions of HX^+ and X^+ to the removal of halogen. Even though our first quantitative results (on chloronitrobenzenes) promised good correlation between data from the argon reactor and the mass spectrometer, the scans involving bromine and iodine analogues did not follow suit.

Clearly, the matter is more complex than thought at first. What would be needed for a clean experimental approach is a mass spectrometer with a high-pressure Penning ionization source. This instrument does not exist at present, but would certainly be interesting, likely difficult, and probably most worthwhile to build. However, it might fit better into a lab that is not primarily chromatographic and analytical in nature as ours happens to be.

Chromatographically motivated, we have in the past used iodine doping in a two-dimensional gc system (22). Here, as in many other investigations from different fields, the addition of iodine leads to new products. In this study of nitro compounds, iodine was used with the intention of trapping reactive intermediates. An experiment of this sort is shown in Fig. 4. When NO_2 leaves, iodine and hydrogen compete for the vacant position. Whether this represents the usual radical-scavenging effect of the ground-state iodine molecule, or whether particularly reactive states of iodine are involved, is uncertain. Interesting is, in any case, the fact that NO_2 can be exchanged in this direct manner against I. In comparing Figs. 1 and 4, the formation of phenol (as could be expected from a reaction whose essential step is presumably an intramolecular rearrangement) appears undisturbed, while the abundance of products resulting

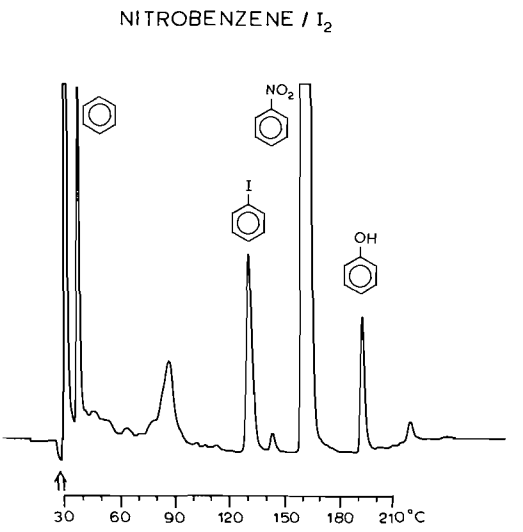

FIG. 4. Degradation pattern of nitrobenzene in iodine-doped argon; ca. 15 mL/min of argon, saturated with iodine at ambient temperature, were added to column 1 effluent prior to entering the reactor. Other conditions as in Fig. 1.

from elimination of NO_2 seems enhanced. However, no further study was made of this aspect.

One can further attempt to scavenge the intermediates from chloro- or bromonitrobenzene by iodine doping. Figure 5 demonstrates this for the former compound. The $\phi X/\phi NO_2$ ratios are not exactly duplicated by the corresponding $I\phi X/I\phi NO_2$ ratios. However, the same tendency is clearly evident, as can be seen from a comparison of Figs. 1 and 4 (X = H), and 3 and 5 (X = Cl).

Halogen can replace the nitro group not only when the former is present, as in the case of iodine, as a dopant. The halogen leaving a molecule of, say, chloronitrobenzene, is available for another

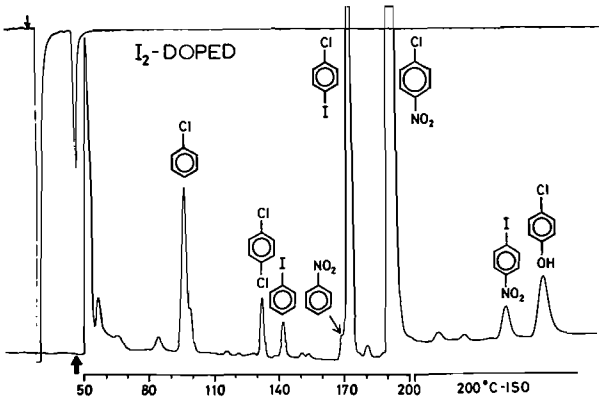

FIG. 5. Degradation pattern of *p*-chloronitrobenzene in iodine-doped argon; ca. 15 mL/min argon, saturated with iodine at ambient temperature, were added to column 1 effluent prior to entering the reactor. Other conditions as in Fig. 3.

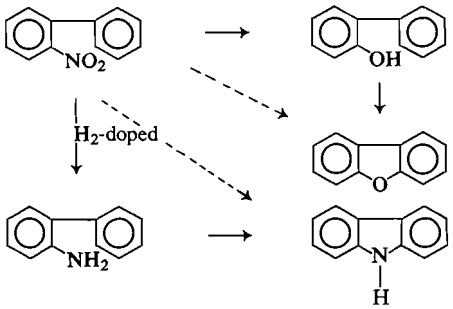
molecule that loses the nitro group, thus leading to the formation of dichlorobenzene (Figs. 3 and 5). Such products, whose structures are alien to that of the original analyte, are usually formed in relatively small amounts. Isomeric configuration, however, is preserved. For nitro compounds as well as for other compounds so far tested, a, say, *para* structure will generally not yield significant amounts of *ortho, meta*, or higher substituted products.

The nature and position of various substituents also appears to influence the relative amount of phenol formed. Tables 3 and 4 contain R—OH/R—H ratios for a variety of compounds. There are definite trends in these numbers, although the experimental evidence is too scarce and too imprecise to allow these to be formulated as rules. It appears that the formation of phenol is usually favored from the *ortho* and *para* positions. The mass spectrometric data of Table 4 correlate herein.

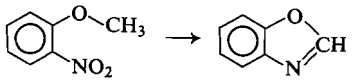
Returning to data of a more synthetic nature, a number of interesting cyclizations were noted. These often parallelled reactions of discharge chemistry, the "*ortho* effect" of mass spectrometry, etc. Correspondence of this sort is not too unusual. Although surprising in view of mechanistic model pathways clearly delineated one against the other, there exists a large amount of similarity among the results of various degradation methods designed to probe different properties of matter with different forms of energy (23). It may be that the stability of products, in this method perhaps more than in others, determines the experimental outcome. For instance, 2-nitrobiphenyl yielded, among others, the following products in regular and H_2-doped systems.



All of the above reactions are also found in discharge chemistry (24), except that, there, the presence of H_2 is not due to its deliberate introduction as a dopant.

2-Amino- and 2-hydroxybiphenyl, when degraded by themselves, do indeed yield carbazole and dibenzofuran, respectively. Whether the former neutral compounds are the main intermediates in the reaction of 2-nitrobiphenyl to the tricyclic structures, or whether they arise from common, higher-energy species has not been established.

Obviously, *meta* and *para* structures do not cyclize. Similarly, only the *ortho* isomer of nitroanisole leads to (among many other products) a second ring.



It must be noted that the formation of benzoxazole from *o*-nitroanisole was predicted for a pyrolysis system (16).

Further structures could undoubtedly be obtained from suitable precursors. In general, compounds formed in the argon reactor are of potential interest to a variety of areas. Three applications that come to mind most easily are that the products promise analytical methodology for solute identification or confirmation, that they may provide mechanistic inferences about other degradation methods such as mass spectrometry, and that they could offer synthetic routes to compounds difficult to obtain by conventional means. In each case, problems involving isomeric structure are particularly suitable ones to study with this system, owing to its chromatographic separation capabilities.

A nuclear Overhauser effect difference study and a two-dimensional *J* proton magnetic resonance study of (6*S*)-prostaglandin I_1 [1]

GEORGE KOTOVYCH,[2] GERDY H. M. AARTS, AND TOM T. NAKASHIMA
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 22, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

GEORGE KOTOVYCH, GERDY H. M. AARTS, and TOM T. NAKASHIMA. Can. J. Chem. **59**, 1449 (1981).

High-field nuclear Overhauser effect difference measurements allowed the assignment of the proton resonances for (6*S*)-prostaglandin I_1 in phosphate buffer solutions. The two-dimensional *J* proton magnetic resonance experiments complemented these studies, as they also allowed the structure of several multiplets to be obtained when these multiplets are hidden by nearby resonances in a normal spectrum. The chemical shifts and coupling constants are compared with the data obtained previously for (6*R*)-prostaglandin I_1.

GEORGE KOTOVYCH, GERDY H. M. AARTS et TOM T. NAKASHIMA. Can. J. Chem. **59**, 1449 (1981).

Les mesures de différence d'effet nucléaire Overhauser à haut champ permettent d'identifier les résonances des protons de la (6*S*)-prostaglandine I_1 dans des solutions tampon de phosphate. Des expériences de résonance magnétique du proton *J* en deux dimensions constituent un complément à cas études en ce sens qu'elles permettent également d'obtenir la structure de plusieurs multiplets lorsque ces derniers sont masqués par les résonances voisines dans un spectre normal. On a comparé les déplacements chimiques et les constantes de couplage aux données obtenues antérieurement avec la (6*R*)-prostaglandine I_1.

[Traduit par le journal]

Introduction

Prostacyclin (PGI_2) is extremely important in the cardiovascular system as a potent vasodilator and inhibitor of platelet aggregation (1–3, and references therein), as well as a potent inhibitor of gastric acid secretion (4).

Because of the PGI_2 instability and its extreme biological importance, a variety of stable analogs have been prepared, among them 5,6-dihydroprostacyclin, or prostaglandin I_1 (PGI_1) (5–10; see also Johnson *et al.*, ref. 2, pp. 17–29). The two epimers at C6 are designated (6*R*)-PGI_1 and (6*S*)-PGI_1 (11) (Figs. 1 and 2). The PGI_2 structure contains a double bond between C5 and C6, the hydrogen atom at C5 has the 5*Z* configuration, but the rest of the molecule is identical to PGI_1.

The biological activity of the 5,6-dihydro PGI_2 compounds has been studied (9, 12–17; see also Johnson *et al.*, ref. 2, pp. 17–29; and Whittle and Boughton-Smith, ref. 2, pp. 159–171). The results of one study (12) indicate that the orientation of the α chain may play a key role in explaining the potency of these compounds with respect to PGI_2. This suggests specificity in the platelet receptor which may prove useful for pharmacological manipulation (12). Compound (6*S*)-PGI_1 was always more active than (6*R*)-PGI_1 when the activity of both epimers was compared (13).

Nuclear Overhauser effect (nOe) difference measurements have proved to be invaluable in the nmr studies of PGI_2 (18) and (6*R*)-PGI_1 (19). In the present study, these measurements, together with two-dimensional *J* nmr studies and inversion-recovery experiments, are applied to obtain the chemical shifts and coupling constants for (6*S*)-PGI_1 (Figs. 1 and 2), also referred to as *exo* or 6β-PGI_1. These data are compared with those for (6*R*)-PGI_1 (19). In this way, we hope to correlate the structure and activity of these compounds in solution.

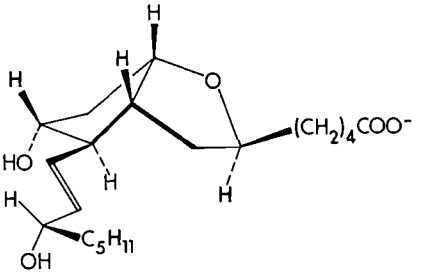

FIG. 1. The structure of (6*S*)-PGI_1.

Materials and Methods

Compound (6*S*)-PGI_1 was a gift from Dr. R. A. Johnson of the Upjohn Co., Kalamazoo, MI. The present measurements were carried out in phosphate buffer (0.2 *M*) in D_2O. The sample preparation was discussed in ref. 19. All of the data were collected in the Fourier transform mode using the Bruker WH-400/DS nmr spectrometer and the Aspect 2000 Data System utilizing 16 or 32K of data memory. All of the experiments were carried out at ambient temperature (298 K). The deuterium

resonance of the solvent was used for the lock signal. The chemical shifts and coupling constants were calculated to first order at 400 MHz and are reported with an accuracy of about ±0.010 ppm and ±0.20 Hz, respectively. For maximum accuracy, spectra were expanded to a width of 1 or 2 Hz/cm. The inversion-recovery experiments were carried out using the 180°–τ–90° two-pulse sequence.

The nOe difference experiments (18–23) involve the measurement of the intensity change of a proton resonance upon saturating another proton. A strong nOe indicates that the two protons are in close proximity. The experimental procedure for this technique has been described elsewhere (19).

The two-dimensional *J* nmr spectra (24–26) allow the possibility of restricting one nuclear parameter to one frequency dimension (the chemical shift) and the other parameter (coupling constant) to the other dimension. The structure of a multiplet can thus be obtained, even though in a normal spectrum it may overlap nearby multiplets. The present 2D *J* nmr spectra were obtained using the software provided by Bruker. The standard Hahn spin echo pulse sequence (90°–τ–180°–τ–Acq-RD-) was used with the 90° pulse equal to 10.7 μs and the 180° pulse equal to 21.4 μs. The relaxation delay (RD) was 10 s, and 48 scans per τ value were accumulated. The resolution was 0.610 Hz/point along both the *J* and δ axes corresponding to a spectral width of 39 Hz along the *J* axis (128 points) and 2500 Hz along the δ axis (8192 points). A Gaussian weighting function was applied to the data.

Results

The proton resonances were assigned on the basis of double resonance and nOe difference experiments. From inversion recovery measurements, the H-6 and H-15 multiplets and the H-8 and H-10β multiplets were resolved. The H-7β and H-10α multiplets were resolved from the many overlapping peaks in the region of 1.45 to 1.70 ppm by means of the 2D *J* nmr and the nOe difference experiments. The resonances for H-2, H-13, H-14, H-17 to H-19, and H-20 were assigned on the basis of their characteristic chemical shifts.

The results of the nOe experiments are as follows. When the H-13 and H-14 multiplet is saturated, enhancements are observed by H-15, H-11, H-8, and H-12. Saturation of the H-6 and H-15 protons, with the irradiation frequency centred on H-6, results in nOe's for H-13 and H-14, H-12, H-7α, and H-17 to H-19. Two broad multiplets also appear at ~1.55 ppm and these were assigned to H-5 and H-16, and H-5* and H-16*, respectively, as these protons are adjacent to H-6 and H-15. These assignments were confirmed by carrying out the nOe difference experiments on a (6*S*)-PGI_1 sample in $CDCl_3$ solution where the H-6 and the H-15 multiplets are resolved. The enhancements observed by H-12, H-7α, and H-5,5* are due to saturation of H-6. Saturation of H-11 results in enhancements for H-13 and H-14, H-9, H-10β, and H-8, as well as H-12. This confirms the assignment of H-10β.

Further nOe experiments are shown in Fig. 2. In Fig. 2B, H-10β as well as H-8 are saturated. The irradiation frequency is centred on H-10β. As expected, enhancements are observed by H-13 and H-14, H-9, H-11, and H-10α. This allows the assignment of the chemical shift and determination of the coupling constants for H-10α. The expanded H-10α multiplet is seen in the figure. The assignment of H-10β to low field of H-10α is in agreement with the torsion angle dependency of chemical shifts for five-membered prostanoid precursors (27). Finally, saturation of H-7α (Fig. 2C) results in nOe's for H-13 and H-14, H-6, H-12, H-7β, as well as a very small nOe for H-8. The large nOe experienced by H-6 confirms the assignment for H-7α. The detailed, expanded H-7β multiplet is also shown in Fig. 2C. The enhancement to H-12 cannot be quantitated since it is perturbed by the irradiating field, but a large nOe is also expected. Additional nOe experiments include irradiation of H-2, confirming the chemical shift for H-3. Irradiation of H-9 results in enhancements for H-11, H-8, and H-10β. Nuclear Overhauser effects across the ring, from H-7α to H-8 as seen in Fig. 2C, from H-11 to H-12, and from H-12 to H-11 (upon saturating H-12), were observed in the present nOe studies.

Since the H-7β and H-10α multiplets are buried under many other resonances, the chemical shifts and multiplicity of these multiplets were confirmed using 2D *J* nmr techniques. The results of these experiments are shown in Fig. 3. In this figure, the stacked plot of the partial two-dimensional *J* spectra is seen together with the projection of the tilted 2D *J* spectra to give the totally decoupled spectrum. The multiplicity for H-7β and H-10α, obtained by displaying the cross section of the 2D *J* spectra, is identical to that obtained by the nOe difference technique. These spectra are shown in Figs. 2B and 2C.

Other proton assignments were made on the basis of the homonuclear decoupling experiments. Decoupling of H-13 and H-14 results in a triplet for H-15, which appears to low field of the overlapping H-6 multiplet (Fig. 2A). As well, the H-12 multiplet is assigned, and it simplifies to a triplet with the removal of second order virtual coupling (28, 29). This indicates that $J(8–12)$ and $J(11–12)$ are equal to 10.0 Hz. Decoupling of H-12 results in a doublet of doublets for H-11, corresponding to $J(10\alpha–11)$ and $J(10\beta–11)$. When H-10β is decoupled, a triplet is observed for H-11 corresponding to $J(10\alpha–11)$ and $J(11–12)$. Decoupling of H-8 sharpens the H-7α resonances, indicating that $J(7\alpha–8) \cong 0.5$ Hz. Finally, the chemical shift for H-4 is determined by

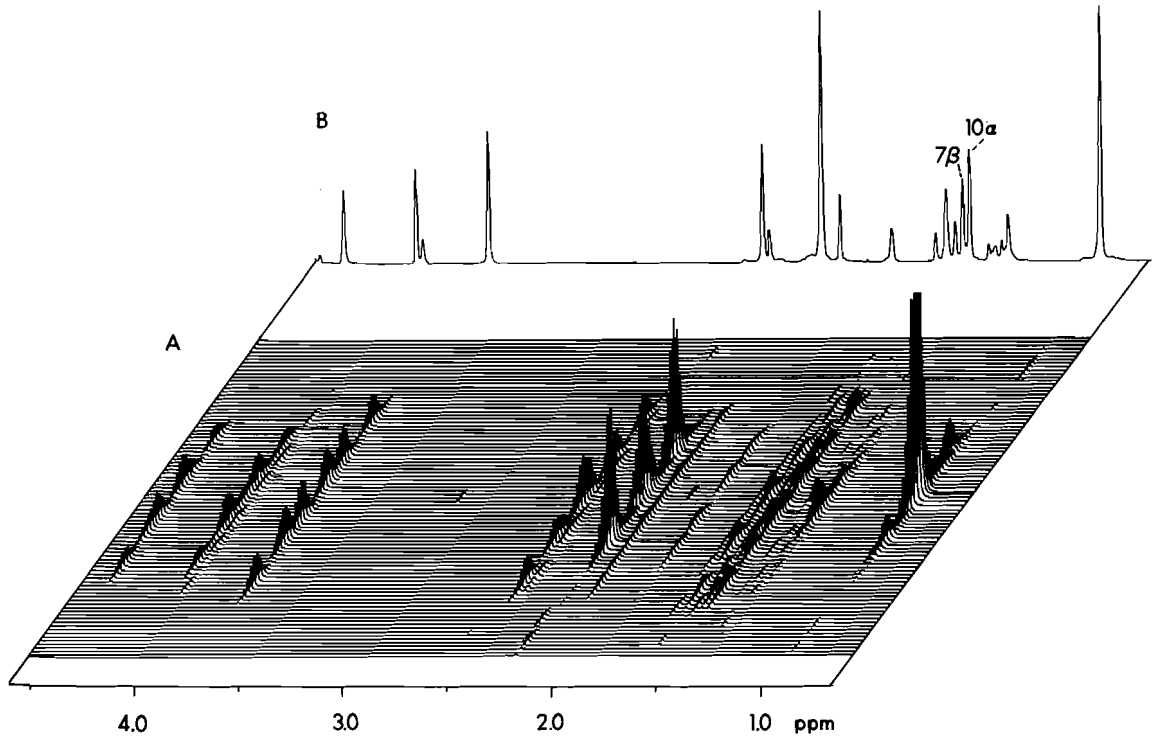

FIG. 3. (A). The stacked plot of the partial 2D *J* spectra. (B). Projection of the 2D *J* spectra to give the totally decoupled spectrum. The cross sections of the 2D *J* spectra for protons H-7β and H-10α are identical to those obtained using the nOe difference technique, shown in Figs. 2B and 2C.

integration, since the multiplet between 1.2 and 1.45 ppm corresponds to eight protons, including six for H-17 to H-19.

The results of the above experiments are tabulated in Table 1 and the proton magnetic resonance spectrum, including all assignments, is shown in Fig. 2A.

Discussion

The nOe difference experiments have been applied previously to the study of prostaglandins including PGI_2 (18), (6*R*)-PGI_1 (19), and prostaglandin E_2 (23). Very small effects can be measured, since a control spectrum without an nOe is subtracted from the spectrum with an nOe. In the present study, the nOe measurements proved invaluable in the assignment of the proton resonances, in the determination of chemical shifts, and in the evaluation of the coupling constants. The 2D *J* nmr experiments allowed the structure of several multiplets to be obtained, even though in a normal spectrum these multiplets are buried by many other multiplets. The data are in excellent agreement with the nOe difference results.

The proton chemical shifts and coupling constants are presented in Table 1. All data are calculated to first order. A comparison of these data with those obtained for (6*R*)-PGI_1 in phosphate buffer in D_2O at 25°C, pH 7.0 (19) can be made. The pH's are uncorrected meter readings. The largest observed changes in the chemical shifts are for H-7α and H-7β. For (6*S*)-PGI_1 these shifts are 1.86 and 1.52 ppm, respectively, whereas for (6*R*)-PGI_1 these shifts are 1.36 and 2.23 ppm, respectively. Obviously, changing the configuration of the chain at C-6 from the β-position in (6*S*)-PGI_1 to the α-position in (6*R*)-PGI_1 shifts H-7β from 1.52 ppm to 2.23 ppm. At the same time, H-7α shifts from 1.86 ppm to 1.36 ppm. Hence the H-7 proton that is *cis* to the C-6 substituent is always more shielded, due to the anisotropy of the C-5—C-6 bond. On the other hand, the next-nearest neighbors in the ring, namely H-8, H-9, H-10α, and H-12 are deshielded by the side chain. For (6*S*)-PGI_1 these shifts are 2.44, 4.49, 1.48, and 2.11 ppm, respectively, whereas for (6*R*)-PGI_1 these shifts are 2.38, 4.25, 1.61, and 2.20 ppm, respectively. These long-range effects are much smaller and difficult to explain.

In comparing the coupling constants, the largest difference is observed for $J(7\alpha\text{–}8)$. For (6*S*)-PGI_1 it is 0.5 Hz, whereas for (6*R*)-PGI_1 it is 5.0 Hz. Hence

[c]Value obtained from inversion recovery spectra.
[d]Value obtained from decoupled spectra.
[e]Value obtained from 2D *J* nmr experiment.

in (6*S*)-PGI$_1$, the H-7α to H-8 dihedral angle is about 90°. In (6*R*)-PGI$_1$, the large value for this coupling constant indicates that the dihedral angle is larger. For both molecules this indicates that the chain at C-6 adopts the pseudo-equatorial conformation. The other coupling constants between the ring protons are consistent with this view.

In summary, the nOe difference experiments are extremely valuable in assigning the proton multiplets for (6*S*)-PGI$_1$ in phosphate buffer solutions. The 2D *J* nmr measurements complemented these studies, as they also allowed the structure of several multiplets to be obtained when these multiplets are hidden by nearby resonances in a normal spectrum.

Acknowledgements

The authors are grateful to Dr. R. A. Johnson of the Upjohn Company in Kalamazoo, MI, for providing the sample of (6*S*)-PGI$_1$, the Natural Sciences and Engineering Research Council of Canada for a grant towards the purchase of the Bruker WH-400 nmr spectrometer, and the Natural Sciences and Engineering Research Council, the Alberta Heart Foundation and the University of Alberta for generous financial assistance.

Synthesis and properties of silicon, germanium, and tin derivatives of cyclopentadienyltricarbonylrhenium

D. F. DONG, J. K. HOYANO, AND W. A. G. GRAHAM

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 20, 1980

This paper is dedicated to Professor Walter E. Harris on the occasion of his retirement from the University of Alberta

D. F. DONG, J. K. HOYANO, and W. A. G. GRAHAM. Can. J. Chem. **59**, 1455 (1981).

The preparation and properties of a series of rhenium compounds of the general formula $(\eta\text{-}C_5H_5)Re(CO)_2XY$ in which X or Y or both is a silyl, germyl, or stannyl ligand are reported. The silyl hydrides *cis*-$(\eta\text{-}C_5H_5)Re(CO)_2(SiR_3)H$ (R = Ph, CH_2Ph) and *cis*-$(\eta\text{-}C_5H_5)Re(CO)_2(SiPh_2H)H$ were obtained by ultraviolet irradiation of $(\eta\text{-}C_5H_5)Re(CO)_3$ and the appropriate silane. The hydrides *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2XH$ (X = $SiPh_3$, $GeCl_3$, $GeBr_3$, $SnCl_3$) were obtained by protonation of the corresponding anions. These new anions $[(\eta\text{-}C_5H_5)Re(CO)_2X]^-$ also reacted with other electrophiles to yield compounds of the type *trans*-$(\eta\text{-}C_5H_5)$-$Re(CO)_2XY$ (Y = Me, halogen, SnR_3). The reaction of $(\eta\text{-}C_5H_5)Re(CO)_3$ with Cl_3GeH or Ph_3SnH yielded only the compounds *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)_2$ and *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2(SnPh_3)_2$ respectively. Infrared and ^1H nmr spectra are reported for all compounds, and v(Re–H) values for the hydrides have been obtained from Raman spectra.

D. F. DONG, J. K. HOYANO et W. A. G. GRAHAM. Can. J. Chem. **59**, 1455 (1981).

On rapporte la synthèse et les propriétés d'une série de composés du rhénium de formule générale $(\eta\text{-}C_5H_5)Re(CO)_2XY$ dans lesquels X ou Y ou les deux à la fois représentent un ligand silyle, germyle ou stannyle. On a obtenu les hydrures silylés $(\eta\text{-}C_5H_5)Re(CO)_2(SiR_3)H$ *cis* (R = Ph, CH_2Ph) et $(\eta\text{-}C_5H_5)Re(CO)_2(SiPh_2H)H$ *cis*, par irradiation ultraviolette du $(\eta\text{-}C_5H_5)Re$-$(CO)_3$ et du silane approprié. Par protonation des anions correspondants, on obtient les hydrures $(\eta\text{-}C_5H_5)Re(CO)_2XH$(X-$SiPh_3$, $GeCl_3$, $GeBr_3$, $SnCl_3$). Ces nouveaux anions $[(\eta\text{-}C_5H_5)Re(CO)_2X]^-$ réagissent également avec d'autres agents électrophiles et conduisent aux composés du type $(\eta\text{-}C_5H_5)Re(CO)_2XY$ *trans* (Y = Me, halogène, SnR_3). La réaction de $(\eta\text{-}C_5H_5)Re(CO)_3$ avec Cl_3GeH ou Ph_3SnH conduit uniquement aux composés $(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)_2$ *trans* et $(\eta\text{-}C_5H_5)Re(CO)_2(SnPh_3)_2$ *trans*. On rapporte les spectres infrarouges et RMN du ^1H de tous les composés ainsi que les valeurs v(Re—H) de ces hydrures obtenus à partir des spectres Raman.

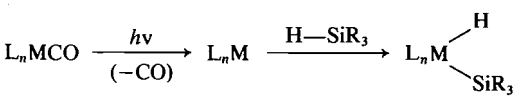
Introduction

Earlier work from this laboratory (1–4) has shown that reactions of silanes with transition metal carbonyls provide a useful synthetic route to compounds having silicon – transition-metal bonds. In particular, the photochemical reaction shown below in general terms has afforded numerous silyl transitional-metal – hydrides which exhibit interesting structural, spectroscopic, and kinetic features (4–7). We now describe the synthesis and properties of a series of rhenium compounds of the type $(\eta\text{-}C_5H_5)Re(CO)_2XY$. These are *formally* the products of oxidative addition reactions on $(\eta\text{-}C_5H_5)Re(CO)_3$ by various silicon, germanium, and tin species. However, most of them are not accessible by such a direct route, so alternative pathways have been developed.

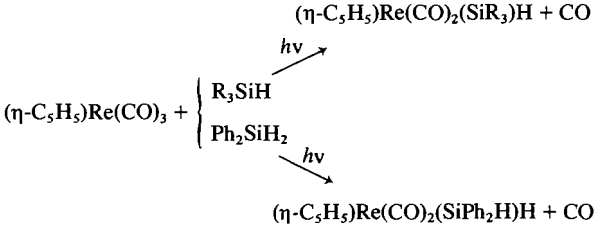
At present, very few dicarbonyl-η-cyclopentadienylrhenium(III) derivatives are known. The first to be reported was $(\eta\text{-}C_5H_5)Re(CO)_2Br_2$ (8), followed by several of its derivatives such as $(\eta\text{-}C_5H_5)Re(CO)_2(Br)CH_3$, $(\eta\text{-}C_5H_5)Re(CO)_2$-$(CH_3)_2$, and $(\eta\text{-}C_5H_5)Re(CO)_2(Br)H$ (9). The alkylrhenium hydride $(\eta\text{-}C_5H_5)Re(CO)_2(CH_2Ph)H$ was reported in 1978 (10). The present work on silicon, germanium, and tin derivatives was undertaken to extend our knowledge of this potentially large but currently underdeveloped class of compounds.



Results and Discussion

Preparation of Hydrides

The silyl hydrides were obtained by ultraviolet irradiation of the appropriate silane with $(\eta\text{-}C_5H_5)Re(CO)_3$ in hydrocarbon solvent:



where R = Ph, CH_2Ph. This reaction is completely analogous to our previously reported photochemical reactions of silanes with metal carbonyls, and a likely mechanism of formation has been discussed

[a]X = halogen.

(4, 6). Compared to the corresponding manganese derivatives (4, 7, 11), those of rhenium are much more stable. Purifications require column chromatography on silica gel followed by recrystallization. The complex (η-C_5H_5)Re(CO)$_2$($SiPh_3$)H obtained in the above manner is the *cis* (or lateral) isomer (see spectroscopic section below for discussion of the stereochemical assignments). The corresponding *trans* (or diagonal) isomer was obtained by deprotonation of this *cis* hydride followed by reprotonation with phosphoric acid at 0°C:

cis-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H + KOH
→ (EtOH)
[(η-C_5H_5)Re(CO)$_2$($SiPh_3$)]$^-$
→ (H^+(0°C))
trans-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H

Deprotonation of silyl hydrides has been effected with amines such as Et_3N (12), but the low acidity of the above rhenium hydride requires the stronger base ethanolic KOH. The anion [(η-C_5H_5)Re(CO)$_2$($SiPh_3$)]$^-$ has been isolated as the moderately air-stable tetraethylammonium salt; other reactions of this anion are described below.

Reactions of germanes of the type R_3GeH with (η-C_5H_5)Re(CO)$_3$ do not yield any isolable amounts of the expected germyl hydrides of rhenium. In some cases, complexes such as (η-C_5H_5)Re(CO)$_2$($GeCl_3$)$_2$ were obtained, and these are discussed in the next section. Similarly, tin hydrides did not produce the anticipated hydride products. However, as an alternative route, the new anions [(η-C_5H_5)Re(CO)$_2$(EX_3)]$^-$ were prepared, and subsequent protonation gave the *trans* hydrides:

[Et_4N][EX_3] + (η-C_5H_5)Re(CO)$_3$
→ (THF, *hν*)
[Et_4N][(η-C_5H_5)Re(CO)$_2$(EX_3)]
→ (H^+)
trans(η-C_5H_5)Re(CO)$_2$(EX_3)H

(E = Ge, X = Cl, Br; E = Sn, X = Cl). The corresponding anions of manganese have been previously reported by Ruff (13), and the preparations here were carried out in a similar manner (see Experimental).

The physical properties and analytical data for the hydrides and anions described are listed in Table 1. All the complexes are moderately air-stable in the solid state.

The rhenium hydrides undergo a reductive elimination reaction with PPh_3 in the same way as the manganese analogs (7):

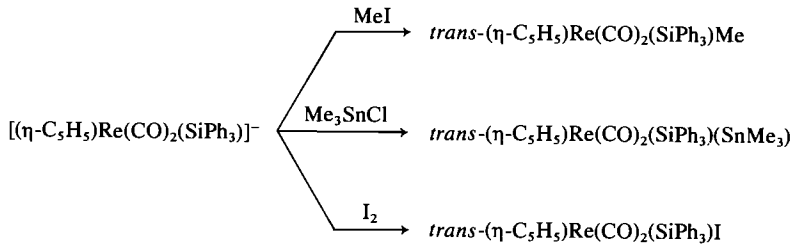
(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H + PPh_3
↓
(η-C_5H_5)Re(CO)$_2$(PPh_3) + $HSiPh_3$

However, the reaction is much slower than for the corresponding manganese complex, presumably owing to differences in the M—H and M—Si bond strengths.

Preparation of other Group IV Metal Derivatives

Besides protonation, the anions described above were found to undergo a number of other reactions. The triphenylsilyl derivative reacts with electrophiles in a way similar to the more familiar carbonylate anions such as $Re(CO)_5^-$ and $Mn(CO)_5^-$, and to the more closely related anions such as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.



$[Ru(CO)_4SiMe_3]^-$ (14) and $[(\eta\text{-}C_5H_5)Mn(CO)_2SiCl_3]^-$ (12). The following equations summarize the reactions, which indicate that the anion is a moderately strong nucleophile.

The germanium- and tin-containing anions are trihalogeno species, and it is not surprising that their nucleophilicity is lower than that of the triphenylsilyl analogs, as their reactions suggest. In particular, the $[(\eta\text{-}C_5H_5)Re(CO)_2(EX_3)]^-$ anions *did not react* with MeI, EtI, Me_3SnCl, $MeGeCl_3$, or acetyl chloride. The methyl compounds were obtained when stronger alkylating agents were used:

$[(\eta\text{-}C_5H_5)Re(CO)_2(EX_3)]^- \xrightarrow{Me_3OPF_6 \text{ or } MeOSO_2F} trans\text{-}(\eta\text{-}C_5H_5)Re(CO)_2(EX_3)Me$

(E = Ge, X = Cl, Br; E = Sn, X = Cl). We note that the nucleophilicity of $[(\eta\text{-}C_5H_5)Mn(CO)_2(SiCl_3)]^-$ (12) appears to be greater than that of the trihalogeno-germanium and -tin rhenium anions.

While the trihalogenogermanium anions react normally with iodine, the tin–rhenium bond is cleaved in the reaction. Covalent bonds of tin of transition metals often undergo cleavage of this type (15).

$[(\eta\text{-}C_5H_5)Re(CO)_2(GeX_3)]^- \xrightarrow{I_2} trans\text{-}(\eta\text{-}C_5H_5)Re(CO)_2(GeX_3)I$

$[(\eta\text{-}C_5H_5)Re(CO)_2(SnCl_3)]^- \xrightarrow{I_2} trans\text{-}(\eta\text{-}C_5H_5)Re(CO)_2I_2$

As mentioned above, reactions of the germanium and tin hydrides did not yield the corresponding rhenium hydrides. Instead, germanium and tin complexes of rhenium were obtained as shown in the equations below:

$(\eta\text{-}C_5H_5)Re(CO)_3 + Cl_3GeH \xrightarrow{20°C} trans\text{-}(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)_2$

$(\eta\text{-}C_5H_5)Re(CO)_3 + Ph_3SnH \xrightarrow{h\nu} trans\text{-}(\eta\text{-}C_5H_5)Re(CO)_2(SnPh_3)_2$

It would be reasonable to suppose that in both of these reactions, the first step is the formation of an intermediate rhenium hydride. For the trichlorogermane reaction, there is good evidence for this. An infrared spectrum taken immediately after mixing showed bands of both *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)H$ and *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)_2$; the latter species was dominant, and the only one remaining after an hour. A separate experiment showed that the following reaction proceeds easily under similar conditions:

trans-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)H + Cl_3GeH \xrightarrow[\text{hexane}]{20°C} trans\text{-}(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)_2$

This step of the reaction must occur more rapidly than the first since even with a slight excess of $(\eta\text{-}C_5H_5)Re(CO)_3$, $(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)_2$ is the major product observed immediately after mixing.

The first step of the reaction for Ph_3SnH clearly involves oxidative addition to the photochemically generated 16-electron $(\eta\text{-}C_5H_5)Re(CO)_2$ fragment. It is remarkable, however, that reaction of Cl_3GeH with the rather inert $(\eta\text{-}C_5H_5)Re(CO)_3$ proceeds *in the dark* at room temperature within minutes if excess Cl_3GeH is used. We think this unusual reaction can be understood on the assumption that Cl_3GeH is sufficiently acidic to protonate the rhenium atom to some extent forming $[(\eta\text{-}C_5H_5)Re(H)(CO)_3]^+$. A carbonyl group in this cation would then be displaced by the Cl_3Ge^-. Precedent for labilization of carbonyls by protonation is found, for example, in the catalysis of exchange between carbon monoxide and iron pentacarbonyl by trifluoroacetic acid (16).

The physical properties and analytical data for the complexes described in this section are shown in Table 2. The following section describes the structures and spectroscopic properties of the prepared complexes.

Spectroscopic Properties and Structures

Except for the anionic species, all complexes prepared in this study are of the general form $(\eta\text{-}$

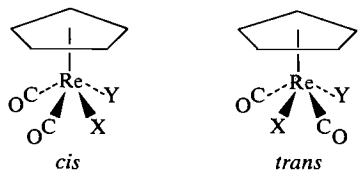
[a]In cyclohexane solution unless otherwise noted; w = weak, m = medium, s = strong.
[b]Dichloromethane solution.

$C_5H_5)Re(CO)_2XY$ where the ligands X and Y may be different or the same. For this formulation two stereoisomers are possible, the *cis* and *trans*, as shown below; recently the terms lateral and diagonal have been suggested as being more precise because the "*trans*" angles are not 180° (17).



cis *trans*

The assignments of *cis* or *trans* configuration for the complexes reported here are based mainly on the relative intensities of the two carbonyl stretching bands in the infrared spectrum, and this method of assignment is now fairly well established as being correct (16, 17). Basically, the *cis* arrangement is assigned to complexes with a more intense higher energy (symmetric) stretching band, while the *trans* arrangement is assigned to complexes with a more intense lower energy (asymmetric) stretching band. For the compounds reported here, Table 3 shows the ir carbonyl stretching bands and the stereochemical assignments.

For $(\eta\text{-}C_5H_5)Re(CO)_2(SiPh_3)H$, both *cis* and *trans* isomers were obtained in pure form as described above, while the compound $(\eta\text{-}C_5H_5)Re(CO)_2[Si(CH_2Ph)_3]H$ appears to exist as a

mixture of *cis* and *trans* forms, at least in solution. The other hydrides (the Ge and Sn species) were obtained only in the *trans* form. The other derivatives, which contain two bulkier ligands, were found only in the *trans* form, and this would be the more stable form on steric grounds. As Table 3 shows, infrared bands appear at higher frequencies for the *trans* form in those cases where both stereochemistries have been observed, and this is consistent with what is observed for *cis*- and *trans*-(η-C_5H_5)Re(CO)$_2$$Br_2$ (17). Although stable in the solid state, *trans*-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H readily converts to the *cis* form in solution (10 h at 70°C, or at room temperature in the presence of Et_3N); this is opposite to (η-C_5H_5)Re(CO)$_2$$Br_2$, where the *cis* isomer is converted to the *trans* upon heating in solution.

Table 4 summarizes the proton nmr data. All the compounds exhibit a sharp singlet for the cyclopentadienyl protons in the expected region. The hydride complexes show characteristic high field resonances due to transition metal bonded hydrogen, and there is little variation in the chemical shifts among the complexes. The cyclopentadienyl resonance in *trans*-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H lies 0.09 ppm to higher field than in the *cis*-isomer. For (η-C_5H_5)Re(CO)$_2$$Br_2$ (17), the *trans* resonance lies 0.40 ppm to higher field than *cis*. However, this is not generally true even for the small number of cases where both isomers are known; in the tribenzylsilyl hydride (Table 4) it would appear that in the *cis–trans* mixture, the cyclopentadienyl resonances are accidentally degenerate.

All the neutral compounds listed in Table 3 exhibited the expected isotope patterns for the molecular ions in the mass spectra, while the fragmentation patterns were consistent with the proposed formulations. Some of the spectra showed features of special interest. All complexes showed ions due to the successive loss of one and two carbonyl groups from the parent ion. The spectrum of *cis*-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H showed a medium intensity peak due to Ph_3Si^+ and only a weak peak due to Ph_3SiH^+, whereas the corresponding manganese compound exhibited Ph_3SiH^+ as the strongest peak in the spectrum. This property is reflected in the facile displacement of Ph_3SiH in the manganese compound (7). The mass spectra of *trans*-(η-C_5H_5)Re(CO)$_2$(EX_3)H (E = Ge, Sn) showed strong peaks due to the loss of HX from the molecular ions.

An interesting structural feature of a hydride complex like *cis*-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H is the possibility of an attractive interaction between the hydrogen and silicon, as found in the X-ray structure determinations of analogous manganese compounds (7, 18, 19). The infrared, Raman, and other spectroscopic properties have been discussed, and at present there is no clear cut diagnostic spectroscopic indicator of this interaction. The transition-metal hydride stretching modes have been observed at normal terminal M–H frequencies, although they may be very weak or absent in the infrared spectra. Recently it has been suggested that broadening of the hydrogen mode in the Raman spectrum may be an indication of the Si–H interaction (20). Also, rather than an inherently attractive interaction, steric factors have been suggested as forcing the close approach of silicon to hydrogen in related compounds (21).

Some of the cyclopentadienylrhenium(III) hydrides reported here were investigated with regard to this possible Si–H interaction. All the hydrides described here, including the *trans* isomers, showed no detectable bands in the infrared spectra which could be assigned to the rhenium–hydrogen

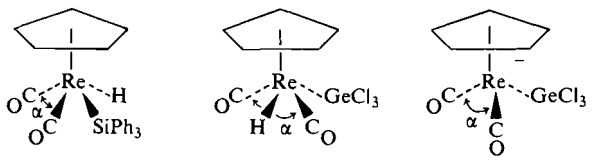
[a]Solid-state spectra.

stretching mode. However, ν(Re–H) bands were observed in the Raman spectra, and these bands shifted to appropriate energies for the deuterides (see Table 5). A bridging interaction in the *trans* isomer is highly unlikely, so the mere absence of an ir band for ν(Re–H) appears not to be diagnostic either way. As stated above, the nmr and mass spectra showed no major differences among the various hydrides.

Single-crystal X-ray structures have now been determined for *cis*-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H **1** (22), *trans*-(η-C_5H_5)Re(CO)$_2$($GeCl_3$)H **2** (23), and [Et_4N][(η-C_5H_5)Re(CO)$_2$($GeCl_3$)] **3** (23), and some interesting features have emerged. The assigned stereochemistries have been confirmed as evidenced by the OC—Re—CO angles of 84° and 103° for the silyl- and germyl-hydride complexes, respectively. Also, the structure of the deprotonated germanium anion **3** has a corresponding angle of



1 (α = 84°) **2** (α = 103°) **3** (α = 89°)

89°, suggesting the proton has been removed from the position *trans* to the germanium atom. The hydrogens were not located in these X-ray determinations, although for *cis*-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H it is estimated (22) that the hydrogen-to-silicon distance is 2.2 Å, relatively short but longer than in the manganese analogue (18). It appears that a neutron diffraction study may be required to resolve the issue.

Experimental

Materials and General Methods

A nitrogen atmosphere was maintained during all reactions and during work-up procedures by the use of Schlenk apparatus. Irradiations were carried out in quartz vessels and using a Hanovia utility lamp (Model 30620, 140 W) or the more powerful Hanovia lamp (No. L699A, 450 W) in conjunction with a water-jacketed sample compartment. The (η-C_5H_5)Re(CO)$_3$ was prepared by a slight modification of a published procedure (24). The silicon, germanium, and tin compounds were purchased from commercial suppliers or prepared according to published procedures. All reagents and solvents were purified or dried according to standard methods.

Melting points were obtained using a microscope with a Kofler hot stage. Microanalyses were performed in the microanalytical laboratory of this department. Infrared spectra were obtained using a Perkin-Elmer 337 spectrometer with scale expansion and calibration as previously described (1). Raman spectra were obtained on a Spex Laser Raman spectrometer (Ramalog) using argon on krypton lasers. Varian A-60, 56-60A, or HA-100 instruments were used to record nmr spectra. Mass spectra were obtained on Associated Electrical Industries MS-9 or MS-12 spectrometers.

Preparation of cis-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H

A solution of (η-C_5H_5)Re(CO)$_3$ (2.3 g or 6.9 mmol) and triphenylsilane (5.0 g, 19 mmol) in 200 mL of cyclohexane was irradiated with the 450 W source for 7 h. The reaction mixture was then suction filtered through a 100 g silicic acid column (compounds adsorbed on column). Elution with 300 mL *n*-hexane removed all of the unreacted triphenylsilane. Then the column was eluted with two 100 mL portions of 30% dichloromethane – *n*-hexane; the first fraction contained (η-C_5H_5)Re(CO)$_3$ (1.0 g), and the second fraction contained the product and a small amount of (η-C_5H_5)Re(CO)$_3$. Sublimation of the second fraction at 60°C removed the tricarbonyl; crystallization of the unsublimed solid from dichloromethane–hexane afforded white crystals of *cis*-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H (0.55 g, 15%).

The complexes *cis*-(η-C_5H_5)Re(CO)$_2$($SiPh_2$H)H and (η-C_5H_5)Re(CO)$_2$($Si(CH_2Ph)_3$)H were prepared in the same way, with yields of the pure products being 10% and 36% respectively. The yields in these reactions appear to be low, but the unreacted starting materials can be recovered and recycled to yield more product.

Preparation of [Et_4N][(η-C_5H_5)Re(CO)$_2$($SiPh_3$)]

Solid *cis*-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H (0.40 g, 0.70 mmol) was magnetically stirred with 5 mL of 1.0 *M* ethanolic KOH; the hydride solid slowly dissolved and a clear yellow solution formed after 1.5 h of stirring. Addition of Et_4NBr (0.95 mmol in 3 mL ethanol) gave an immediate pale-yellow precipitate. The mixture was centrifuged and the ethanol was decanted. The remaining solid was dried *in vacuo*; crystallization from dichloromethane–hexane yielded pale-yellow prisms of the product (0.35 g, 72%).

Preparation of trans-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)H

A solution of [Et_4N][(η-C_5H_5)Re(CO)$_2$($SiPh_3$)] (0.10 g, 0.14 mmol) in 20 mL of dichloromethane was vigorously stirred with 0.5 mL of phosphoric acid at 0°C for 30 min. After allowing the mixture to settle, the dichloromethane layer was decanted and evaporated at reduced pressure (0°C). The white solid was recrystallized from hexane–dichloromethane to yield crystals of the pure *trans* product (0.06 g, 75%).

Preparation of trans-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)Me

A solution of methyl iodide (0.1 mL) and [Et_4N][(η-C_5H_5)Re(CO)$_2$($SiPh_3$)] (0.05 g, 0.07 mmol) in 15 mL of dichloromethane was stirred at 20°C for 30 min. After removal of solvent and excess methyl iodide at reduced pressure, recrystallization from hexane–dichloromethane afforded white crystals of the product (0.03 g, 55%).

Preparation of trans-(η-C_5H_5)Re(CO)$_2$($SiPh_3$)($SnMe_3$)

A solution of $ClSnMe_3$ (0.04 g, 0.2 mmol) and [Et_4N][(η-C_5H_5)Re(CO)$_2$($SiPh_3$)] (0.1 g, 0.14 mmol) in 25 mL of dichloro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

methane was stirred for 30 min. Removal of solvent at reduced pressure and crystallization from hexane–chloroform afforded white crystals of the products (0.09 g, 70%).

Preparation of trans-$(\eta\text{-}C_5H_5)Re(CO)_2(SiPh_3)I$

A solution of I_2 (0.05 g) and $[Et_4N][(\eta\text{-}C_5H_5)Re(CO)_2(SiPh_3)]$ (0.05 g, 0.07 mmol) in 10 mL of dichloromethane was stirred for 1 h. Removal of solvent at reduced pressure and crystallization from hexane–chloroform afforded yellow crystals of the product (0.35 g, 65%).

Preparation of $[Et_4N][(\eta\text{-}C_5H_5)Re(CO)_2GeCl_3]$

A solution of $(\eta\text{-}C_5H_5)Re(CO)_3$ (2.45 g, 7.35 mmol) and $[Et_4N][GeCl_3]$ (5.55 g, 18.0 mmol) in 300 mL of THF was irradiated at reflux temperature with the 140 W source for 26 h. After irradiation, the solution was reduced in volume to about 20 mL on a rotary evaporator and 75 mL of methanol was then added. Cooling to −20°C afforded 2.04 g yellow crystals, after filtering, washing with cold methanol, and drying *in vacuo*. Reducing the volume of the mother liquor to about 30 mL afforded a second crop of 0.44 g (total yield 55%).

The complexes $[Et_4N][(\eta\text{-}C_5H_5)Re(CO)_2(GeBr_3)]$ and $[Et_4N][(\eta\text{-}C_5H_5)Re(CO)_2(SnCl_3)]$ were prepared in a similar fashion, and the yields were 33% and 73% respectively.

Preparation of trans-$(\eta\text{-}C_5H_5)Re(CO)_2(GeBr_3)H$

To a rapidly stirred solution of $[Et_4N][(\eta\text{-}C_5H_5)Re(CO)_2(GeBr_3)]$ (1.1 g, 1.5 mmol) in 10 mL of dichloromethane was added dropwise 3 mL of phosphoric acid. Stirring was continued for 2.5 h, after which the bottom of the tube was cooled to −78°C. As soon as the acid had solidified and the suspended solids had settled to the bottom, the dichloromethane solution was syringed into another Schlenk tube. Cooling of this solution by slow immersion into a −78°C bath initiated crystallization; addition of small amounts of heptane to the cold solution completed crystallization and afforded pale-brown crystals of *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2(GeBr_3)H$ (0.49 g, 53%).

The other hydrides *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)H$ and *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2(SnCl_3)H$ and their corresponding deuterides were prepared by the same method, and the yields were in the 30–60% range.

Preparation of trans-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)Cl$

Chlorine gas was bubbled rapidly for 2 min through a solution of $[Et_4N][(\eta\text{-}C_5H_5)Re(CO)_2GeCl_3]$ (0.20 g, 0.32 mmol) in 20 mL of dichloromethane. Removal of solvent on a rotary evaporator and vacuum sublimation at 80°C yielded 0.035 g (21%) of microcrystalline product.

Preparation of trans-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)Br$

A solution of $[Et_4N][(\eta\text{-}C_5H_5)Re(CO)_2GeCl_3]$ (0.30 g, 0.49 mmol) and bromine (0.030 mL, 0.55 mmol) in 10 mL of dichloromethane was stirred for 10 min. Crystallization was effected by adding cold diethylether (10 mL), and then cold petroleum ether. Subsequent cooling to −20°C gave 0.21 g (75%) of orange *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)Br$.

The complex *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)I$ was prepared by the same method in 98% yield.

Preparation of trans-$(\eta\text{-}C_5H_5)Re(CO)_2I_2$

A solution of $[Et_4N][(\eta\text{-}C_5H_5)Re(CO)_2SnCl_3]$ (0.66 g, 1.0 mmol) and iodine (0.25 g, 1.0 mmol) in 15 mL of dichloromethane was stirred for 1 h. Addition of 10 mL of petroleum ether, removal of a small amount of solvent at reduced pressure, and cooling to −20°C yielded red–brown crystals of *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2I_2$ (0.17 g, 30%).

Preparation of trans-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)Me$

A mixture of $[Et_4N][(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)]$ (0.72 g, 1.2 mmol) and $MeOSO_2F$ (0.30 g, 2.6 mmol) in 10 mL of toluene was rapidly stirred for 8 h. The fine white precipitate was filtered off and heptane was added to the filtrate until turbidity occurred. Cooling slowly to −78°C afforded pale-brown crystals of the product (0.41 g, 58%).

Preparation of trans-$(\eta\text{-}C_5H_5)Re(CO)_2(GeCl_3)_2$

A solution of $(\eta\text{-}C_5H_5)Re(CO)_3$ (0.335 g, 1.00 mmol) and Cl_3GeH (1.84 g, 10.0 mmol) in 10 mL of hexane was stirred for 1 h. Excess Cl_3GeH was destroyed by reaction with 20 mL of methanol, and then solvents were removed *in vacuo*. Extraction of the residue with 100 mL of hot heptane and cooling the extract to −20°C afforded white crystals of product (0.20 g, 30%).

Preparation of trans-$(\eta\text{-}C_5H_5)Re(CO)_2(SnPh_3)_2$

A solution of $(\eta\text{-}C_5H_5)Re(CO)_3$ (1.0 g, 3.0 mmol) and $HSnPh_3$ (2.1 g, 6.0 mmol) in 200 mL of petroleum ether was irradiated with the 450 W source for 23 h. The solution and solid residues washed out with dichloromethane were combined and the mixture was reduced to dryness on a rotary evaporator. Unreacted $(\eta\text{-}C_5H_5)Re(CO)_3$ was sublimed off, and the residue was adsorbed onto a 100 g silicic acid column in a small amount of 1:1 petroleum ether – dichloromethane. Elution by suction filtration with 300 mL of petroleum ether and 100 mL of a 1:1 mixture of petroleum ether – dichloromethane removed most of the remaining $(\eta\text{-}C_5H_5)Re(CO)_3$. Further elution with 200 mL acetone led to a solution containing the product and a small amount of $(\eta\text{-}C_5H_5)Re(CO)_3$, which was sublimed off after removal of the solvent. Recrystallization of the residue from dichloromethane–heptane gave pale-brown crystals of *trans*-$(\eta\text{-}C_5H_5)Re(CO)_2(SnPh_3)_2$ (50 mg, 1.7%).

Acknowledgments

The structure of benzoylphenyldiazomethane

MARTIN COWIE[1] AND MICHELE D. GAUTHIER

Chemistry Department, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 5, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

MARTIN COWIE and MICHELE D. GAUTHIER. Can. J. Chem. **59**, 1463 (1981).

The structure of benzoylphenyldiazomethane has been established by an X-ray structure determination. The packing of the molecules within the unit cell is related to the complex esr spectral results. Apart from the observed N—N distance of 1.132(5) Å the structural parameters in the molecule suggest conjugation between the diazo and carbonyl functions. The N—N distance is probably anomalously short owing to thermal vibration of the diazo moiety. Benzoylphenyldiazomethane crystallizes in the space group $P2_12_12_1$ with $a = 5.600(1)$, $b = 13.347(2)$, $c = 15.018(3)$, and $Z = 4$. Based on 888 unique observed reflections the structure has been refined to $R = 0.052$ and $R_w = 0.070$.

MARTIN COWIE et MICHELE D. GAUTHIER. Can. J. Chem. **59**, 1463 (1981).

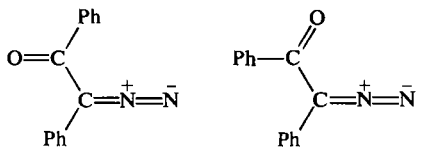
On a déterminé la structure du benzoylphényldiazométhane par diffraction de rayons-X. L'entassement des molécules dans la maille explique la complexité des spectres de rpe. A l'exception de la distance de 1,132(5) Å observée pour la liaison N—N, les paramètres structuraux de la molécule suggèrent une conjugaison entre les fonctions diazo et carbonyle. Il est probable que la distance N—N est anormalement courte à cause de la vibration thermique de la portion diazo. Le benzophényldiazométhane cristallise dans le groupe d'espace $P2_12_12_1$ avec $a = 5,600(1)$, $b = 13,347(2)$, $c = 15,018(3)$ et $Z = 4$. En se basant uniquement sur 888 réflexions observées, on a affiné la structure jusqu'à des valeurs de $R = 0,052$ et de $R_w = 0,070$.

[Traduit par le journal]

Introduction

The esr spectrum of benzoylphenyldiazomethane, commonly known as azibenzil, has been reported by Trozzolo (1) and by Murai, Torres, and Strausz (2). The latter group noted that photolysis of a microcrystalline sample of $PhCOCN_2Ph$ at 77 K resulted in a complex esr spectrum, consisting of a strong and a weak triplet signal and a quintet signal. The strong triplet was assigned to the *trans* conformer of the benzoylphenylmethylene radical, which is formed through loss of N_2 from the starting diazoketone molecule, also assumed to have the *trans* geometry in the solid state. The weak triplet was assigned to the presence of small amounts of the *cis* conformer of this radical, and the novel quintet state was attributed to a triplet–triplet radical pair formed by the pairwise interaction of two triplet state benzoylphenylmethylene radicals. For such a radical pair to form, two radicals must be in close proximity in the crystal, which could result if, in a crystal of the parent diazoketone species, two molecules were oriented such that there were close interactions between the diazo functions. A determination of the structure of benzoylphenyldiazomethane was therefore undertaken to determine the intermolecular interactions within the crystal in order to gain a further understanding of the esr spectrum and to confirm the proposed trans geometry of the molecule.

Semiempirical CNDO/2 calculations (3) on benzoylphenyldiazomethane indicate that two geometries are preferred, having the carbonyl and diazo groups either *cis* or *trans* across the single bond, and having an essentially planar molecular framework. Other conformations resulting from rotations about the C—C bond were not favored. However, the measured electric dipole moments (4) are compatible with either two *cis–trans* conformers in equilibrium or with only a single skewed conformer.



trans *cis*

In addition, few diazoalkane molecules have been structurally characterized (5–10). Therefore the structure of $PhCOCN_2Ph$ is important as a basis for comparison with other diazoalkane molecules to help establish structural and chemical trends within these molecules.

[1]Besides local programs the following were used in the solution and refinement of the structure: AGNOST, the Northwestern University absorption program which includes Coppens-Leiserowitz-Rabinowvich logic for Gaussian integration; FORDAP, the Fourier summation program by A. Zalkin; MULTAN, for the automatic solution of Crystal Structures using the weighted tangent formula, by G. Germain, P. Main, and M. M. Woolfson; ORFFE, for calculating bond lengths, angles, and associated standard deviations by W. Busing and H. A. Levy; ORTEP, plotting program by C. K. Johnson; SFLS-5, structure factor and least-squares refinement by C. J. Prewitt.

TABLE 1. Summary of data and intensity collection for benzoylphenyldiazomethane

Formula	$C_{14}H_{10}N_2O$
Formula weight	222.25
Cell parameters	
a	5.600(1) Å
b	13.347(2) Å
c	15.018(3) Å
V	1122.5 Å^3
Z	4
Density	1.315 g cm^{-3} (calcd.) 1.30(1) g cm^{-3} (exptl., flotation)
Space group	$D_2^4 - P2_12_12_1$
Crystal dimensions	0.384 × 0.216 × 0.129 mm^3
Crystal volume	0.0107 mm^3
Crystal shape	Orthorhombic prism with faces $0\bar{1}1$, 011, $0\bar{1}2$, $01\bar{2}$, 100, $\bar{1}00$
Temperature	20°C
Radiation	CuKα_1 (λ = 1.540562 Å); Ni filter
μ	6.447 cm^{-1}
Transmission factors	0.854–0.924
Receiving aperture	4 mm × 4 mm; 30 cm from the crystal
Takeoff angle	5.50°
Scan speed	2° in 2θ/min
Scan range	1.0° below Kα_1 to 1.0° above Kα_2
Background counting time	20 s
2θ limits	3.0°–123°
2θ limits for centered reflections	50.0° ≤ 2θ ≤ 70.0°
Final number of parameters	94
Unique data collected	1068
Unique data used ($F_0^2 \geq 3\sigma(F_0^2)$)	888
Error in observation of unit weight	1.948 electrons
R	0.052
R_w	0.070

Experimental

Orange needles of benzoylphenyldiazomethane recrystallized from ether were kindly supplied by Dr. M. Torres and Professor O. P. Strausz (University of Alberta). A suitable crystal fragment, cut from one of the needles, was mounted in the air on a glass fibre. Preliminary film data showed Laue symmetry mmm with systematic absences ($h00$, $h = 2n + 1$; $0k0$, $k = 2n + 1$; $00l$, $l = 2n + 1$) consistent with the space group $P2_12_12_1$. The cell parameters along with the pertinent crystal data and intensity collection details are listed in Table 1.

Data were collected by the θ–2θ scan method on a Picker four-circle automated diffractometer, equipped with a scintillation counter and pulse height analyzer tuned to accept 90% of the CuKα peak. Background counts were measured at both ends of the scan range with both crystal and counter stationary. Standard deviations in the intensities were calculated using a p factor of 0.05 (11). The intensities of three standard reflections were measured every 100 reflections. No significant decrease in these intensities was noted.

Structure Solution and Refinement

The structure was solved by direct methods using the program MULTAN (12). The solution was based on 300 reflections having $|E| > 1.03$ and 2000 phase relationships. The E-map corresponding to the solution with the best combined figure of merit yielded the positions of all non-hydrogen atoms. All hydrogen atoms were found in a subsequent electron density difference map phased on the heavier atom framework. Full matrix least-squares techniques were used, with atomic scattering factors from Cromer and Waber (13) for all atoms except hydrogen, for which the values from Stewart, Davidson, and Simpson (14) were used. Anomalous dispersion terms for O, N, and C (15) were included in F_c. All non-hydrogen atoms were refined as individual atoms, with the phenyl carbon atoms having isotropic thermal parameters, and the rest having anisotropic thermal parameters. The hydrogen atoms were included as fixed contributions in their idealized positions, with thermal parameters of 1 Å^2 greater than the equivalent isotropic B for the corresponding carbon atom. Absorption corrections were applied to the data using Gaussian integration.[1] In the final electron density difference map, the top 20 residuals ranged from 0.31 to 0.14 e/Å^3, and were in the vicinities of the two phenyl rings. In earlier difference Fourier maps, a typical hydrogen atom had an electron density of about 0.27 e/Å^3.

A stereoview of the unit cell is shown in Fig. 1. Figure 2 showing a perspective view of the molecule indicates the numbering scheme used within the molecule (hydrogen atoms have the same number as their attached carbon atoms). The final positional and thermal parameters for the non-hydrogen atoms are listed in Table 2. Selected interatomic distances are listed in Table 3, while bond angles and torsion angles are presented in Table 4. A listing of the observed and calculated structure amplitudes, the table of idealized hydrogen positions and thermal parameters, and the table of least-squares planes are available.[2]

Description of Structure and Discussion

Within the unit cell of benzoylphenyldiazomethane there are four discrete molecules. Figure 1

[2]This material (5 pages) is available, at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

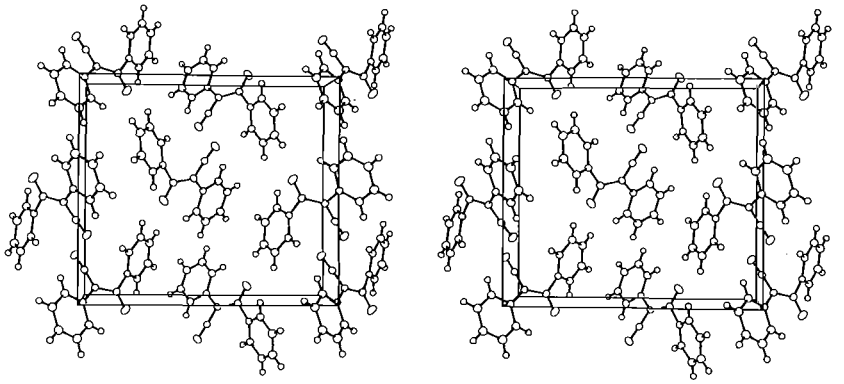

FIG. 1. A stereoview of the unit cell of benzoylphenyldiazomethane. The x-axis goes into the page, the y-axis runs from top to bottom, and the z-axis is from right to left. 20% thermal ellipsoids are drawn, except for hydrogen atoms which are drawn artificially small. Extra molecules are shown as an aid in visualizing the packing.

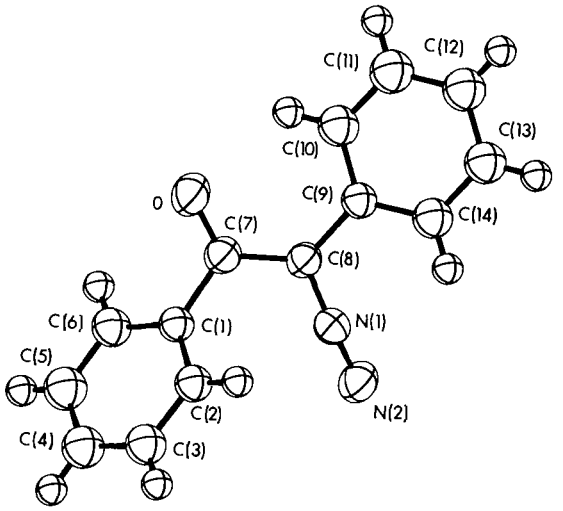

FIG. 2. A perspective view of benzoylphenyldiazomethane showing the numbering scheme. 50% thermal ellipsoids are drawn.

indicates that these molecules can be grouped in pairs along the crystallographic screw axis in the x-direction. In this arrangement the molecules have their diazomethylene groups directed towards each other but inclined somewhat along a such that zig-zag arrays of diazomethylene groups, parallel to the a axis, result. These diazomethylene groups therefore come into rather close contact; the N(2)—N(2)′ distance along the zig-zag chain is 3.238(4) Å.[3] Although it is difficult to establish a normal van der Waals contact for such an interaction, this contact can be related to the radius of an aromatic ring (1.85 Å) (16). It is not unreasonable to assume that the π system of the diazomethylene function is similar to that of an aromatic ring, and thus we estimate that a normal van der Waals contact between two diazo functions is approximately 3.70 Å. As such, the N(2)—N(2)′ distance in the present structure indicates a significant interaction between the two diazomethylene groups.

In the esr study by Strausz and co-workers (2), photolysis of a microcrystalline sample of the title complex at 77 K resulted in the production of the benzoylphenylmethylene radical. Since the elimination of N_2 at this temperature in the solid state is not expected to change the geometry of the molecule, the cell packing diagram shown in Fig. 1 should be representative of the orientation of the radicals immediately after photolysis and should prove useful in interpreting the esr results. Initially, the esr spectrum showed a strong triplet signal (assigned to the *trans* configuration of the benzoylphenylmethylene radical), a weak triplet signal (assigned to the *cis* configuration of this group), and a quintet signal. The quintet signal was thought to arise from the pairwise interaction of two neighboring triplet radicals (2). Within the unit cell of benzoylphenyldiazomethane, there are two close contacts between neighboring carbene carbon atoms which could give rise to this interaction. The first is along the zig-zig chain, where the C(8)—C(8)′ separation is 6.133(6) Å, and the second occurs between molecules separated by one unit cell translation in a, in which the C(8)—C(8)′ distance is 5.600(1) Å. Both possibilities are consistent with the separation expected between radical pairs producing the quintet signal, as indicated by the small zero field splitting parameter, D(0.0943 cm^{-1}) (2), which is a function of the separation of unpaired electrons in the radicals.

Upon warming the sample from 77 K to 90 K, the quintet esr signal decays to a new triplet signal which was postulated to result from the formation of a diradical through spin inversion and a single,

[3]Primed atoms are related to unprimed atoms by the symmetry transformations shown in Table 3.

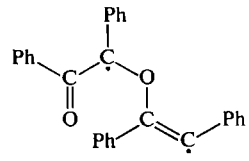
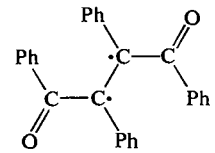
[a]Atom is located at the position $-\frac{1}{2} + x, \frac{1}{2} - y, 1 - z$.
[b]Atom is located at the position $\frac{1}{2} - x, 1 - y, -\frac{1}{2} + z$.
[c]Atom is located at the position $\frac{1}{2} + x, \frac{1}{2} - y, 1 - z$.
[d]Atom is located at the position $1 + x, y, z$.
[e]Atom is located at the position $-1 + x, y, z$.
[f]Atom is located at the position $\frac{1}{2} - x, 1 - y, \frac{1}{2} + z$.

covalent bond formation (2). Based on an inspection of the packing of the molecules, two mechanisms seem possible for formation of the new triplet signal. The first could result from a covalent bond formation between the carbene carbon of one diradical and a carbonyl group of another leading to a species as shown in **a**.



a



b

This bond formation would require some reorientation of the radicals in the crystal (see Fig. 1) and it is uncertain whether at 90 K the required reorientation is possible. From a structural point of view, possibly the more obvious mechanism would involve covalent bond formation between two adjacent carbene carbon atoms, which are related by the crystallographic screw axis, resulting in the diradical shown in **b**. As can be seen in Fig. 1 very little molecular reorientation is required in this case. However, it seems that based on the small zero-field splitting parameters obtained from the esr spectrum (D = 0.0189 cm^{-1} and E = 0.0008 cm^{-1}), the required separation of the unpaired electrons is too great to accommodate diradical **b** but seems consistent with the diradical **a** formed from C—O bond formation (2, 17). Based on the present crystallographic study both mechanisms seem feasible. The closest contacts of type **a** occur between molecules separated by one cell translation along the a axis, where the O—C(8)′ distance is 5.541(6) Å. The next closest such interaction is 6.251(5) Å (see Table 3). The two closest in-

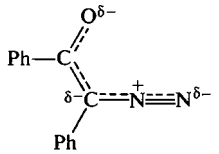
For personal use only.

teratomic distances between carbene carbon atoms (C(8)–C(8)′) are 5.600(1) and 6.133(6) Å (*vide supra*).

Within the molecule, the carbonyl and diazo groups are *trans* to each other across the C—C single bond, as expected from the esr results (2). This geometry and the *cis* conformation are the two which are favored owing to π-delocalization within the molecule, as has been suggested by theoretical calculations (3). The preference of one of these two conformations over the other is dependent on both electronic and steric factors. For optimum delocalization of the π electrons, the whole molecular fragment should be planar (18). This planarity is opposed by steric interactions, the greatest of which occurs between the two phenyl groups in the *cis* configuration. Thus, the two phenyl rings cannot both be coplanar with the carbonyl and diazo groups, and delocalization through the phenyl rings is lost in this conformation. However, the *cis* conformation is stabilized by an electrostatic attraction between the carbonyl and diazo functions, as shown below, which is not possible in a *trans* geometry.



The *trans* conformation is favoured by steric considerations since this allows the bulky phenyl groups to avoid each other. Which of the two preferred conformations is favored will depend on which of the above stabilizing or destabilizing forces predominate. In the present compound, the observed *trans* geometry implies that the steric repulsion between the two phenyl groups predominates. It is also possible that the observed *trans* conformer may be favored in the present structure by packing considerations.

In the present structure the molecule is not totally planar but is skewed somewhat. For example, the O—C(7)—C(8)—N(1) torsion angle is −165.3(4)° and the torsion angle between phenyl ring 2 and the diazomethylene group (C(10)—C(9)—C(8)—N(1)) is 161.9(4)°. These two values suggest that some conjugation may be possible between the carbonyl and diazomethylene groups and between the diazomethylene group and the adjacent phenyl ring since the skewing from planarity is only 14.7(4)° and 18.1(4)°, respectively. On the other hand the C(1)—C(6) phenyl ring is twisted considerably from the adjacent carbonyl group (torsion angle C(2)—C(1)—C(7)—O = −133.9(4)°), allowing very little electron delocalization between this phenyl and the carbonyl group. This twisting probably results from steric interactions between the phenyl ring and the diazo and carbonyl groups, with the phenyl rings skewing to avoid contacts with these groups.

The C—C distances within ring 1 (C(1)—C(6), average 1.383(13) Å)[4] and ring 2 (C(9)—C(14), average 1.379(10) Å) are somewhat shorter than the values found in benzene and its derivatives (19). This apparent bond shortening probably results from thermal vibrations of the rings, with the shortest C—C distances occurring at the C(4) and C(12) ends of the rings, where the thermal motion is the greatest. The C(1)—C(7) and C(8)—C(9) distances (1.491(5) and 1.484(6) Å) agree well with the predicted value for a single bond between sp^2 hybridized carbon atoms (16), indicating that there is little actual delocalization between either of the phenyl rings and the carbonyldiazomethylene backbone. The C(7)—C(8) bond length (1.458(6) Å), on the other hand, is intermediate between a single and a double bond (18*a*) and suggests significant conjugation between the carbonyl and diazomethylene functions. A similar pattern of C—C bond lengths was observed in dibenzoyldiazomethane (20) where the C—C_{Ph} bond lengths (1.486(2) and 1.485(3) Å) indicated little conjugation and the C—C distances between carbonyl and diazomethylene carbon atoms (1.472(3) and 1.476(3) Å) showed some delocalization between these groups. The carbonyl distance (C(7)—O) in the present compound, at 1.231(4) Å, is normal for a C=O double bond (21) but is somewhat longer than the analogous distance of 1.222(2) Å observed in the related compound, dibenzoyldiazomethane. However, we expect that these observed C—O distances are somewhat shorter than the true values owing to thermal vibrations involving the carbonyl groups (22).

The diazomethylene fragment of the present structure is virtually linear (177.5(4)°) as expected and the C(8)—N(1) bond length of 1.325(5) Å is intermediate between a single and a double bond (23). This latter value is comparable with the analogous distance of 1.338(2) Å in dibenzoyldiazomethane (20) and can be compared with the values predicted for C=N double and C—N single bonds (1.29 and 1.47 Å, respectively) based on covalent radii (18*b*). The N(1)—N(2) bond length,

[4]For average quantities, the estimated standard deviation is the larger of an individual standard deviation or the standard deviation of a single observation as calculated from the mean.

O—C(7)—C(8)—C(9)	11.9(7)
O—C(7)—C(8)—N(1)	−165.3(4)
C(10)—C(9)—C(8)—N(1)	161.9(4)
C(2)—C(1)—C(7)—O	−133.9(4)

at 1.132(5) Å, is significantly longer than the analogous distances reported for other diazoalkane structures (5–10) and is longer than that observed (20) in dibenzoyldiazomethane (1.113(2) Å). As a comparison, typical N—N triple and double bond distances are 1.10 Å (24) and 1.24 Å (25), respectively. This observed N(1)—N(2) distance, like those previously reported, is unexpectedly short considering that the C(8)—N(1) bond length corresponds to a bond order of 1.5. Again however, as with the C(7)—O bond length, we suggest that this shortening is apparent, resulting from thermal vibration of the diazomethylene moiety. Ideally diffraction data should be collected at low temperature to minimize these effects.

The present structural parameters for benzoylphenyldiazomethane indicate that there is a significant amount of conjugation between the carbonyl and diazomethylene groups. However there seems to be very little, if any, conjugation between the phenyl rings and the carbonyl or diazomethylene groups. For ring 1 which is skewed significantly from the carbonyl–diazomethylene plane this is not surprising, however, for ring 2 which is twisted only 14.8° from this plane, this is rather surprising. Finally, taken as a whole, the structural parameters indicate more delocalization in the benzoylphenyldiazomethane compound than is observed in the similar species, dibenzoyldiazomethane (20).

Epithermal neutron activation analysis with a SLOWPOKE nuclear reactor

DONALD CRAIG STUART[1] AND DOUGLAS EARL RYAN

Trace Analysis Research Centre, Chemistry Department, Dalhousie University, Halifax, N.S., Canada B3H 4J1

Received June 18, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

DONALD CRAIG STUART and DOUGLAS EARL RYAN. Can. J. Chem. **59**, 1470 (1981).

Epithermal neutron activation analysis is examined using a SLOWPOKE nuclear reactor. Data are given for 69 elements using cadmium and boron shielding. Cadmium ratios calculated from literature values of resonance integrals are compared with experimental values. All elements except cadmium are shielded more effectively by boron. Advantage factors for a selection of elements under cadmium, natural boron, and enriched boron shields are given. Boron shields are of particular practical value for rapid instrumental analysis.

DONALD CRAIG STUART et DOUGLAS EARL RYAN. Can. J. Chem. **59**, 1470 (1981).

On examine l'analyse par l'activation épithermique des neutrons en utilisant un réacteur nucléaire du type SLOWPOKE. On rapporte des données relatives à 69 éléments en utilisant un écran au cadmium et au bore. On compare les valeurs expérimentales des taux de cadmium à celles calculées à partir des valeurs rapportées dans la littérature pour des intégrales de résonance. A l'exception du cadmium tous les éléments sont mieux protégés par le bore. On rapporte les facteurs qui favorisent la sélection des éléments sous des écrans de cadmium, de bore naturel et de bore enrichi. Les écrans de bore sont d'une valeur pratique particulière pour une analyse instrumentale rapide.

[Traduit par le journal]

Introduction

A number of researchers (1–13) have demonstrated the usefulness of irradiating samples surrounded by a thermal neutron shield. The activation of many elements can be greatly reduced in this way, whereas the activation of a number of other elements is only reduced by a small amount, since the activation of these is largely due to higher energy neutrons which are not absorbed appreciably by the shield. The usefulness of this epithermal neutron activation analysis (ENAA) technique in a given situation thus depends upon whether or not any significant advantage over interfering elements can be obtained for the elements that are to be determined.

For the most part, cadmium has been utilized as a shield material. This method of ENAA has been applied to silicate rocks with particular success (3–7, 12, 13). Other applications include aerosols (9), coal and fly ash (11), and biological materials (8, 10).

A recent compilation of resonance integrals by Gryntakis and Kim (14) is very extensive and shows how calculations may be carried out by the Westcott method (15) or by a simplified "normal" method (16, 17) to estimate the relative effects of cadmium shielding. Unfortunately, as the authors point out (14), values frequently vary an order of magnitude or more, depending on the technique used.

In attempting to apply ENAA to chemical analysis, it would be more valuable to have a consistent set of results produced under practical analytical conditions, such as the data of Brunfelt and Steinnes (3) for some twenty elements with half-lives greater than two days.

Van Der Linden and co-workers have compiled a list of resonance integrals (18) following the practical method of Hogdahl (19), using a cylindrical cadmium box with a wall thickness of 1 mm as the shield. These values were derived from data in three irradiation sites where the thermal-to-epithermal flux ratios were estimated to be 23.8:1, 18.3:1, and 144:1. Another compilation by Van Der Linden *et al.* gives values for fifteen very short-lived isotopes in a site with a ratio of 14.7:1 (20).

Other neutron filter materials besides cadmium may be used. The possibility of using boron is discussed by Rossitto *et al.* (21). Hanna and Al-Shahristani (22) and Randa (23) have compared some combinations of shield materials for a few elements, and arsenic, gallium, and bromine have been determined in some standard reference materials (24, 25).

The use of boron as a shield material may offer several distinct advantages over cadmium. Boron may be advantageous in utilizing very short-lived isotopes for rapid analysis, since the shield itself is not strongly activated so that post-irradiation handling is simplified. Boron absorbs neutrons with

higher energy than does cadmium, so that it should form a more effective shield for many elements. Also, varying the boron thickness will vary the effective neutron cutoff energy of the shield over quite a wide range (21). This may allow some discrimination among elements, depending upon the energy of epithermal neutron resonance absorptions.

This paper presents results of an examination of ENAA utilizing a SLOWPOKE nuclear reactor (26). Data obtained under consistent experimental conditions are given for 69 elements using cadmium and boron shielding, so that results may be directly compared in a practical way. The advantages of utilizing a boron shield for ENAA are emphasized.

Experimental and Results

Irradiation and Counting

A "standard" set of conditions consisting of a 10 min irradiation (at a neutron flux of 1×10^{12} n cm^{-2} s^{-1}), a 1 min decay, and a 10 min accumulation of the γ-ray spectrum from the sample has been previously described, with data given for the peak areas obtained for 78 elements (26). These conditions have again been used in this work to establish the effectiveness of the shielding by cadmium and by boron, so that results are directly comparable, with the exception that in the present study the neutron flux employed was 5×10^{11} n cm^{-2} s^{-1}, exactly one-half that used in ref. 26.

The γ-ray spectrometer used consisted of a 60 cm^3 Canberra high-resolution Ge(Li) detector, 1.88 keV FWHM at the 1.33 MeV ^{60}Co peak, peak-to-Compton ratio 35:1, and a 9.5% (of NaI) efficiency, in conjunction with a Tracor Northern TN 11 pulse-height analyzer.

Thermal Neutron Shields

Cadmium shields were fashioned from 1 mm thick sheets in a cylindrical shape with top and bottom discs to completely enclose the sample.

Table 1 gives the experimentally determined cadmium ratios for 69 elements, where the cadmium ratio is the peak area obtained for the unshielded sample divided by the peak area obtained when the sample was irradiated under the cadmium shield. The actual peak areas obtained for 1 μg of unshielded material, and the γ-ray energies, are given in Table 3 of ref. 26.

Following the simple practical method of Hogdahl (19), the cadmium ratio, R_{Cd}, is given by the formula,

$$R_{Cd} = \frac{A}{A_{Cd}} = \frac{\sigma_{th}\phi_{th} + I_0\phi_{epi}}{I_0\phi_{epi}} = \frac{\sigma_{th}\phi_{th}}{I_0\phi_{epi}} + 1$$

where A and A_{Cd} are the sample activities from irradiation without and with cadmium cover, σ_{th} = thermal neutron cross section, ϕ_{th} = thermal neutron flux, I_0 = the resonance integral (includes $1/v$ contribution), ϕ_{epi} = epithermal neutron flux.

The SLOWPOKE reactor cadmium ratio for gold for an inner site is 2.1. Using the above equation and the I_0/σ_{th} ratio for gold of 15.7, the thermal-to-epithermal flux ratio is estimated to be 17.3:1. From this, the cadmium ratios expected may be calculated from literature values of resonance integrals, for comparison purposes with the experimental values. Calculated values using data from refs. 18 and 20 are included in Table 1. For the most part, agreement is very good. Titanium and mercury show particularly large discrepancies. For titanium, the expected cadmium ratio calculated from the resonance integral determined by Ryves (27) is 27, more in line with the present work.

Boron shields were formed using a mixture of boron carbide powder and paraffin wax. The mixture was heated to about 70°C (paraffin melting point = 56°C) and cast into cylindrical forms. A central hole was made in the form as it solidified by using a heated metal rod of appropriate diameter, which was centred in a guide tube through which it moved to a fixed depth into the form. This resulted in a cylindrical shield with a central cavity, closed at one end. Samples were sealed in plastic and placed in the cavity, and then a top placed over the open end to totally enclose the samples. The open end of the form was made concave to accommodate a convex-shaped top, in order to avoid neutron leaks but to allow rapid assembly and dis-assembly of the capsules.

These shields may be re-used many times. The wall thickness was 4 mm and corresponded to an approximate neutron energy cutoff of 10 eV (21). It should be noted that while this method of construction is very simple and convenient, this type of shield is only suitable for a low temperature reactor such as SLOWPOKE, because if the paraffin melts (with considerable expansion), the integrity of the shield will be lost.

Table 2 gives data for the experimentally obtained boron ratios, under conditions directly comparable with those for the data in Table 1. All elements save cadmium are shielded more effectively by the boron shield. Isotopes having resonance absorption at low neutron energy are particularly well shielded by boron. These include Dy, Eu, Au, In, Ir, Rh, Sc, and Tm. At the same time, there are many isotopes which exhibit a small boron ratio suggesting that those elements could be advantage-

ously determined in a matrix containing elements with high boron ratios (e.g. Al, Cl, Na). The use of thicker boron shields to give a higher effective neutron energy cutoff has also been investigated. This has been done by maintaining the same shield geometry, but replacing the boron carbide with boron powder which is 92.94% enriched in ^{10}B. The estimated effective neutron energy cutoff of these shields is approximately 150 eV. Table 3 gives data for a selection of elements and demonstrates that in all cases greater shielding has been obtained.

The data in Tables 1–3 have been presented in a format which allows a decision to be quickly formed as to whether or not one of these shields can be employed to advantage for any specific sample being analyzed. In general, a given sample type will exhibit several isotopes which dominate the γ-ray spectrum (e.g. Al, Cl, Mn, Na, Sc). These will often cause serious interference in determining other isotopes of interest, particularly ones which give minor peaks in the spectrum. It is noteworthy that the elements that typically cause interference can be

highly shielded. ^{24}Na is often taken as an example to estimate the advantage factor obtainable using the ENAA technique. The advantage factor (1) is calculated as the shield ratio for sodium divided by the shield ratio for the isotope of interest (e.g. in the case of gold under a cadmium shield, the advantage factor for gold over sodium is 28/2.1 = 13). The advantage factor represents the degree to which the particular interference will be reduced by using the shield.

Table 4 gives advantage factors over sodium for a selection of elements under the three shields (data from Tables 1–3). For elements with very low energy resonances (Au, Hf, In, Ir, Rh) cadmium gives the best advantage factor. For a number of others (Ba, Cd, Mo, Rb, Ru, Sr, Zn) a thick boron shield is best. This is especially true for fast-neutron induced reactions such as for ^{204}Pb(n,n')^{204m}Pb or ^{29}Si(n,p)^{29}Al, or ^{19}F(n,p)^{19}O. However, for many elements (As, Br, Co, Ga, I, La, Pd, Pt, Sm, Th, Sn, W, Zr) the advantage factor is optimised by the "intermediate" cutoff energy afforded by the natural boron shield.

Thus it is indeed possible to optimise the shield-

ing conditions to discriminate among the elements present in a sample, in order to give the largest advantage to elements of particular interest.

We have found the use of boron shields to be of particular practical advantage for rapid instrumental analysis in a number of instances, including the analysis for the trace element content of a natural salt matrix, analysis for the fluorine content of soil, analysis for the silicon content of geological material, and as part of an instrumental NAA scheme for the essentially complete determination of the major, minor, and trace components of rock, sediment, and soil samples (to be published).

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

D. G. GREEN, L. W. GREEN, J. A. PAGE, J. S. POLAND, and G. VAN LOON. Can. J. Chem. **59**, 1476 (1981).

The application of anodic stripping voltammetry to the determination of Cu, Pb, and Cd in acidified sea water samples has been examined. The analyses were carried out using a thin film mercury electrode prepared *in situ* by the method of Florence. The electrode was rotated in the collection step but held stationary in the stripping step. The stripping involved a linear DC potential ramp and background compensation was employed. Resolution of the stripping peaks required "curve fitting" of the baseline.

In the acidified sea water electrolyte it was found that the Pb and Cd stripped to Pb(II) and Cd(II) while the Cu stripped to Cu(I). A good correlation was found between the stripping signals and predictions based on the Levich equation for deposition at a rotating disk electrode and the De Vries and Van Dalen equation for stripping from a thin film electrode. The effect of sample acidity was examined and it was concluded that in unpolluted, filtered sea water the total metal was free for analysis at pH 2. Calibration was by the method of standard addition and intercalibration studies showed that the results agreed well with those obtained by other methods.

D. G. GREEN, L. W. GREEN, J. A. PAGE, J. S. POLAND et G. VAN LOON. Can. J. Chem. **59**, 1476 (1981).

On a étudié la possibilité d'appliquer la technique de redissolution anodique au dosage du Cu, du Pb et du Cd dans des échantillons d'eau de mer acidifiée. Les analyses ont été faites en utilisant une électrode à film mince de mercure préparée *in situ* par la méthode de Florence. On fait tourner l'électrode lors du dépôt des cations mais on la maintient fixe lors de l'étape de redissolution. La redissolution est effectuée avec un balayage linéaire du potentiel en utilisant une compensation du courant résiduel. La résolution des pics de redissolution requiert un ajustement de la ligne de base.

On a trouvé que dans l'eau de mer acidifiée, la Pb et le Cd se redissolvent sous forme de Pb(II) et de Cd(II) tandis que le Cu se redissout sous forme de Cu(I). On observe une bonne corrélation entre les pics de redissolution et les prévisions faites à partir de l'équation de Levich pour le dépôt sur une électrode à disque tournant et l'équation de De Vries et Van Dalen pour la redissolution à partir d'une électrode à film mince. On a étudié l'effet de l'acidité de l'échantillon et on en conclut que, dans le cas de l'eau de mer non polluée et filtrée, la quantité totale de métal est sous forme libre lors des analyses à un pH de 2. La calibration a été faite par la méthode des additions standard et des études d'intercalibration ont montré que les résultats sont en bon accord avec ceux obtenus par d'autres méthodes.

[Traduit par le journal]

Introduction

The determination of trace metals in seawater (SW) is receiving increasing attention because of the interest in the spatial and temporal variation of the elements and their role in the biochemical and geochemical cycles of the oceans. However, despite considerable past efforts reliable data are still difficult to obtain and there are presently active programs concerned with the development and evaluation of appropriate analytical methods (1). The analyses are difficult because almost all of the elements of interest in unpolluted sea water are in the sub μg L^{-1} concentration range; in addition there are major questions concerning the speciation or form of the trace element and even uncertainties regarding the sampling and storage procedures used. The questions cannot be resolved until the accuracy and precision of the analytical techniques have been satisfactorily established.

Riley (2) has reviewed the analytical methods currently used in the analysis of sea water; of the various instrumental techniques anodic stripping voltammetry (ASV) appears particularly advantageous for the determination of trace Cu, Zn, Cd, and Pb. The technique is sensitive and requires only simple instrumentation; it is also unique in that it can directly probe the sea water matrix after a minimal pretreatment of the sample. The "concentration step" prerequisite to the application of most instrumental methods in trace analysis becomes a simple deposition that does not require the addition of reagents or other sample manipulation; anodic stripping of the deposited metal in the "analytical step" yields the current signal used for quantitative evaluation. Both steps are carried out using a single working electrode under programmed potential control. The technique is somewhat restricted and works best with those elements that can be deposited and collected as amalgams at a mercury electrode; even here the metal must strip from the amalgam at potentials that do not result in oxidation of the mercury itself.

However, there are variants involving direct deposition on other substrates and these permit the determination of additional elements; this and other aspects have been considered in detail in the monograph by Vdyra *et al.* (3), while Nurnberg (4) has discussed the potentialities of the method as regards sea water analysis.

An important feature of ASV analysis is that only the metal that is in a "labile" form for deposition ultimately yields an analytical stripping signal. It is recognized that a trace metal can be present in a variety of forms in sea water and whether a particular species is ASV "labile" or "inert" is mainly dependent upon the kinetics of dissociation of the complex as well as the electrode potential and electrode parameters in the deposition stage (5). ASV analysis is usually carried out with calibration by the method of standard additions and while this approach might be expected to give a value for the total metal concentration in the sample this would occur only if the added standard correctly proportioned itself amongst all the forms of the metal in the sample. The slope of the resultant standard addition plot would depend upon the proportion of added standard in the ASV labile form while the intercept on the concentration axis would give the true value for the total metal.

At another extreme, standard addition ASV analysis would be expected to give values for the true labile metal concentration if the added standard proportioned itself (only) amongst the ASV labile species in the sample. The slope of the standard addition plot would then be constant and independent of the proportions of labile and inert metal species.

In the case of a sea water sample the form and distribution of the metal in the sample is unknown as is the partition of an added standard amongst the various forms. The interpretation of a set of standard addition ASV results may then be complex. It is known that the absolute value of an ASV signal generally increases with acidification of a sea water sample, suggesting a conversion of inert to labile metal, but the distribution of an added standard can still be uncertain.

The "total" metal in a sample can be unambiguously ascertained if the sea water is treated in such a way as to convert all of a metal to ASV labile forms. In most procedures for the ASV analysis of sea water the sample is filtered through a conventional 0.45 μm filter and then acidified to pH ~2; it is assumed that on standing in the weakly acid solution the metals are quantitatively converted to labile forms for the analysis. Other more intensive treatments including ultraviolet irradiation and nitric acid digestion have been used to ensure complete conversion (6) but these involve sample handling and reagent addition and are liable to produce significant contamination at the trace level. In many cases the need for such robust treatment is questionable and at least one paper (7) implies that it is unnecessary in the case of unpolluted sea water samples.

The actual "speciation" of the trace metal in sea water is of interest since the form determines the properties of the metal. Davison (8) has reviewed the use of electroanalytical techniques to actually define the metal species present in natural waters; a variety of ASV experiments were summarized including titration with either metal or ligand to determine the complexing capacity and properties of the sample, model experiments to determine the behaviour of metal species added to the sample, and direct probing of real samples. In the latter experiments the ASV response is usually determined as a function of acidity; any increase in analytical signal with acidity is interpreted in terms of displacement of active metal from inert complex species. Other than model studies, this approach has been exploited only to a limited extent with sea water because of the low concentrations of the metals and the difficulties in analysis of the trace level.

In the present study the determination of Cu, Cd, and Pb in sea water by ASV was examined. There have been a number of recent papers concerned with the determination of these elements (sometimes with an accompanying Zn determination) and the variants include differential pulse ASV at a hanging mercury drop electrode (9) and direct ASV (10), potentiometric stripping (11), and differential pulse ASV (12) at a thin film mercury electrode (TFME). In the present study a thin film mercury electrode was used; the electrode was rotated in the collection step but stripping was carried out from a stationary electrode using a linear potential ramp. The method was chosen over other variants because it had the requisite sensitivity and importantly because the deposition and stripping parameters are well defined and it is possible to correlate the stripping signal and unknown concentration without calibration. Unlike some of the other studies the simultaneous determination of Zn was not examined since the element, if deposited, can interfere in the ASV determination of Cu, Cd, and Pb by the formation of intermetallic compounds (3, 13). This effect can be severe in the relatively concentrated amalgams formed at thin

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

film electrodes but the difficulty can be avoided if the analyses are carried out without deposition of Zn in the collection step.

The reported determinations of Zn in sea water have been by differential pulse ASV at a mercury drop electrode with the sample normally buffered in the pH 4–5 range. One method has been reported with the sample acidified to pH 1 in the presence of additional added chloride (9), but such an acid level produces a severe depression of the Zn differential pulse stripping peak. In the present work some attempts were made to determine Zn by the differential pulse technique using a mercury drop electrode with samples buffered to pH 4.5, but the results with the various sea water samples appeared high and a measure of Zn contamination was suspected.

Experimental

An EG and G Princeton Applied Research Model 174A Polarographic Analyzer was used for the ASV measurements. The instrument has an I/E converter with a maximum sensitivity corresponding to a full scale output of 10 V for a 20 nA electrolysis current. The 174A unit was linked to a programmable timer[3] that provided bias voltages and switching for automation of the ASV cycle.

The actual Faradaic stripping peaks were found to be superimposed on a relatively large background process and could not be recorded without a partial compensation of this part of the signal. This was achieved using an instrumentation amplifier to subtract a linear ramp from the stripping signal. The ramp was derived from the *X* axis drive of the 174A instrument; this output tracks the ramp signal fed to the summing amplifier in the stripping process. The signal fed to the instrumentation amplifier was generated using the *X* output as the input to an operational amplifier with calibrated variable gain. The compensated stripping signals were recorded on a Hewlett Packard Model 7005 X-Y recorder; a 10× normal expansion of the stripping peaks was achieved by recording the current at a *Y* axis sensitivity of 0.1 V/in. While other methods of background compensation including storage and subtraction of a blank scan (14) and dual electrodes operating in a subtractive mode (15) have been suggested, they were not employed in this study. The latter technique was investigated but found impractical because of the difficulty in matching the background characteristics of the dual electrodes while the former requires complex digital circuitry. A block diagram of the apparatus is given in Fig. 1*A*, while a diagram of a quartz ASV cell with a rotatable TFME is shown in Fig. 1*B*.

The cells were made either from quartz glass or machined from polytetrafluoroethylene (PTFE) rod. These materials were chosen to minimize contamination problems. The sample compartment of each cell had a diameter of ~1.6 cm and a 5–10 cm^3 sample capacity. The auxiliary electrode was a Pt wire while the reference was either a Ag/AgCl/SW electrode (−0.010 V vs. SCE) prepared from Ag wire or a $Hg/Hg_2Cl_2/SW$ electrode (+0.045 V vs. SCE). The latter electrode was formed from a slug of Hg packed in a small diameter passage through a PTFE insert in the cell wall. Contact with the Hg was made using a clean

[3]The timer was based on a National Semiconductor MM57161N SIT processor chip. Circuit diagrams are available from the authors.

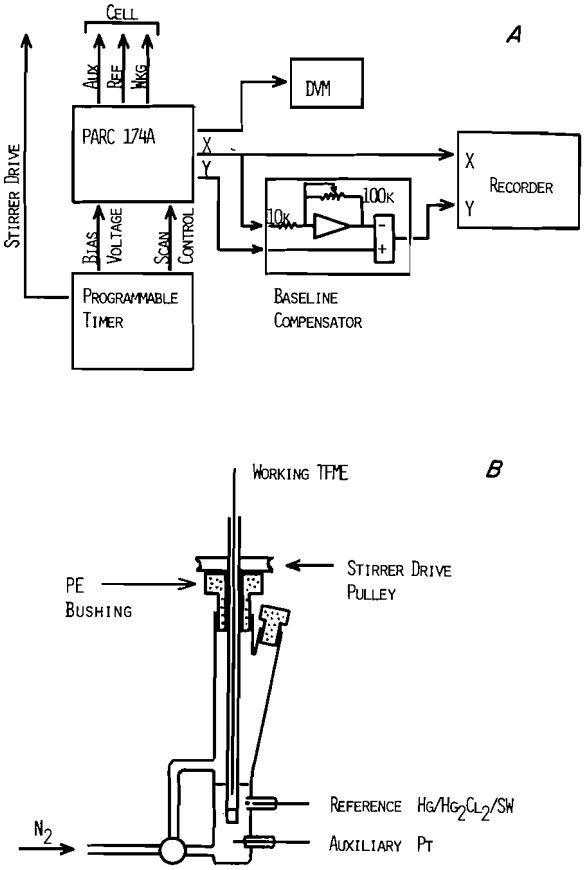

FIG. 1. *A*, block diagram of apparatus; *B*, quartz ASV cell with rotated TFME. IA is Analog Devices 603K, OA is Analog Devices 43K.

amalgamated Pt wire press fitted into the passage. After electrolytic conditioning of the Hg to produce a surface layer of Hg_2Cl_2, the reference was well poised with a potential independent of the presence of any Hg(II) added to the acidified SW samples. The use of this electrode eliminated the standard saturated calomel reference probe as a source of contamination in the trace analysis experiments. The ASV analyses were carried out with the electrolyte at room temperature (25 ± 2°C); O_2 was rigorously removed and excluded from the electrolyte by an initial deaeration and subsequent blanketing with N_2 gas. The N_2 gas used was purified by passage over hot BASF Cu catalyst to remove trace O_2, then thoroughly scrubbed by passage through H_2O before use.

The TFME was prepared according to Florence (16) by *in situ* electrodeposition after the addition of Hg(II) to the sample. The substrate consisted of a disk of GC-20 glassy carbon supplied by the Tokai Electrode Manufacturing Company. The material was in the form of 3 mm *d* × 4 mm *l* rod mounted and sealed in a glass tube with epoxy cement. The exposed face was polished, initially with 6 μm diamond dust and finally to a mirror finish with 0.05 μm alumina. The electrode had a surface area of 0.066 cm^2 and was rotated at precisely 1800 rpm (N = 30 Hz) in the deposition and conditioning stages of the ASV cycle; electrical contact was made through a stationary Pt wire inserted into Hg contained in the electrode tube. The electrode was mounted in the cell through a polyethylene (PE) bearing with PE bushings bored to allow free true rotation of the electrode. In any series of

For personal use only.

analyses there was a continual deposition and thickening of the film and the Hg was removed from the substrate after each set of analyses using a clean nylon brush. Between analyses the electrode was stored in distilled water. Good electrodes had a life span of up to 4 months with failure evident in the form of increased background currents in the stripping process. The failure was usually attributed to deterioration of the epoxy seal rather than to change in the substrate surface.

In some studies of the SW with pH as a variable the addition of Hg(II) to the sample was undesired and "preformed" films, prepared in a separate experiment by electrodeposition from an acid Hg(II) electrolyte, were used in the ASV experiments. Such films were difficult to handle and gave more irreproducible results than the *in situ* formed films.

The sample vessels, glassware, cells, and electrodes used were conditioned before use by long soaking in aqueous 3 *M* nitric acid followed by thorough rinsing with distilled water. Stringent precautions were taken to exclude contamination and the sample handling, transfer operations, and cell experiments were carried out in a laminar flow clean hood. The approximately sized SW samples were transferred directly from the sample vessel to the cell with the sample volume determined after the analysis. On occasion a number of attempts with successive emptying and refilling of the cell with fresh sample were required before low and consistent analytical results could be obtained. If pH was a variable, the adjustments were made by the addition of calculated amounts of reagent to the sample or cell electrolyte; glass electrodes were found to be a source of metal contamination and measurements were made only after the sample was removed from the cell or alternatively the pH was tracked in a separate parallel experiment. Standard solutions were prepared determinately from pure metals dissolved in excess nitric acid; the stock solutions were diluted using a 0.1 *M* HNO_3 electrolyte as required. The reagents used were BDH "Aristar" quality and the HNO_3 and HCl acids were redistilled in quartz apparatus before use. The distilled water was obtained from a well aged and conditioned three stage borosilicate glass still.

ASV Analysis

A standard procedure with optimized parameters was developed for the SW analyses; potentials are quoted relative to the $Hg/Hg_2Cl_2/SW$ reference electrode.

The cell was rinsed and filled with sample adjusted to pH 2 and 25 μL of a 10 m*M* Hg(II) solution was added for each 5 mL of sample. This gave a Hg(II) concentration of 50 μ*M* (10 ppm) for the *in situ* film deposition. After deaeration for 15 min under open circuit conditions, a preliminary deposition of Hg was made at −1.00 V with the electrode rotated; deposition was continued for 30 min to produce a film thickness of ~100 nm as estimated from the deposition current (~5 μA). The electrode was then scanned to −0.10 V and conditioned at that potential, with rotation, for 40 s. This stripped the metals which had codeposited with the Hg film back into the electrolyte in preparation for the subsequent series of analyses involving the sample and calibration.

The analysis for the metals was then carried out using a deposition potential of −1.00 V with electrode rotation and a collection period (τ) typically of 300 s. At the end of this period the potential was maintained for a further 30 s without electrode rotation to establish quiescent conditions for the stripping stage.

The deposited metals were then stripped from the Hg film by scanning from −1.00 V to −0.10 V with $dE/dt = 0.050$ V s^{-1} and a predetermined level of background compensation. The Cd, Pb, and Cu stripping peaks appeared near −0.75, −0.56, and −0.35 V respectively. On reaching −0.10 V the scan was terminated and the Hg film conditioned at that potential for a minimum period of 40 s before continuing with replicate analysis. Calibration was by the method of standard additions and the microaliquots of standard solution were added at this stage. Potentiostatic control of the electrode potential was maintained throughout. In an analysis the increments of the three metals were made simultaneously and the total of the standard additions was chosen to give an ~2× increase of each stripping peak.

For each single analysis the unknown and three standard additions were run; in general each instrumental measurement in this set was repeated three times. During the series of analyses there was a continued growth of Hg film thickness from the *in situ* deposition but the non-dependence of the stripping signal on the film thickness can be demonstrated provided a film of minimum thickness has been predeposited. The calibration line and the best single estimate of unknown concentration (z) and standard error (s_z) were determined from the set of data by linear regression (17, 18). When replicate analyses were carried out the individual concentration values were pooled to give a mean concentration ($\Sigma z/n$), an estimated standard deviation (s), and the standard error ($s/\sqrt{n}$). The errors associated with the individual calibration lines were also combined to give a pooled standard error ($(s_z)_p$); this pooled error is a measure of imprecision in the instrumental procedure (19). The data given in this paper (Tables 2 and 5) show the standard error of the concentration values is in general only marginally greater than the pooled standard error of the individual calibration lines; this indicates that handling of the sample for replicate analyses is only a marginally greater source of error than the measurement itself. When comparisons were possible with the work of other investigators (Table 2), the imprecision of the ASV results was found comparable to that obtained in analyses involving atomic absorption measurements.

The metal concentrations in uncontaminated SW are at the sub μg L^{-1} level and the linearity of the response over the concentration ranges typically investigated is demonstrated by the correlation coefficients in Table 1. A time dependency of the ASV signals after a standard addition was not detected with acidified SW samples. In separate experiments the calibrations were extended to ~10 μg L^{-1} of each metal; there was no evidence of curvature and the slopes of the calibration lines remained consistent with those obtained over the working ranges of concentration.

Figure 2 shows stripping curves as obtained in the analysis of a typical SW sample; the diagram shows both an uncompensated curve and a curve as recorded with an appropriate degree of linear compensation. The compensation level has been adjusted to give an output with a small positive slope over the mid range of the stripping ramp and this results in rapidly changing base line values at the beginning and end of the potential range. These changes occur at potentials corresponding to the cessation of H^+ discharge and the onset of Hg oxidation respectively. In Fig. 3, a "blank" curve obtained using a SW sample and an analysis cycle with zero deposition time ($\tau = 0$) is compared with an analytical curve obtained on the same sample ($\tau = 300$ s). A shift in the baseline between the blank and the analytical curve is evident in the region of the Cu stripping peak even though the compensation level and output offset were unchanged between recordings.

The stripping peaks for the three metals were resolved from the background by "curve fitting"; the background curve was approximated graphically using the blank curve to estimate the position of the baseline under the individual stripping peaks. While "tangent fitting" of the baseline was considered this would have produced peak values for Cu significantly less than the true value while blank subtraction would have produced peak values greater than the true value. Table 1 gives the responses for the

three metals in the SW electrolyte in terms of the slope of the standard addition calibration plots obtained with the given set of experimental and kinetic parameters. The comparison in the response of the three metals is probably best made in terms of molar concentrations but weight/volume relations are typically used in trace analysis and both conventions are expressed.

ASV Response

The equations that relate the kinetic parameters to both the deposition current at the rotated TFME or "disk" electrode and the anodic current peak in the subsequent stripping step are well defined (for definition of symbols, see Table 3) and it is possible to predict the ASV response for a given concentration of analyte.

For the deposition of the metal under conditions of limiting mass transfer, the current can be related to the apparent diffusion layer thickness:

$$[1]\quad M^{n+} + ne \xrightarrow{\text{TFME}} M(Hg)$$
$$i_l = (nFA)D_0(C_0^*/\delta)$$

In the special case of a rotated disk electrode, the limiting current can be calculated according to Levich (20) and is given by:

$$[2]\quad i_l = 0.62(nFA)D_0^{2/3}\omega^{1/2}\gamma^{-1/6}C_0^*$$

If the reduction of the metal ion is unaffected by the coreduction of other species and if there is no significant depletion of the active species in the collection period, the amount of metal deposited is proportional to the deposition time and

$$[3]\quad n_r = (i_l\tau)/(nF)$$

In the subsequent oxidation, the peak anodic stripping current from the TFME can be estimated according to De Vries and Van Dalen (21) and is given by:

$$M(Hg) - n'e \xrightarrow{\text{TFME}} M^{n'+}$$
$$[4]\quad i_p = 0.30(n'FA)\sigma l C_r = 0.30(n'F)\sigma n_r;\quad \sigma = (n'F/RT)v$$

The relation as derived applies only to homogeneous amalgam films sufficiently thin that diffusion of reduced metal to the film surface is not a limiting feature of the oxidation. De Vries and Van Dalen estimate the relation is valid within 2% if their defined kinetic parameter is sufficiently small ($H < 0.144$, $H = l^2\sigma/D_r$) and in the present case it can be shown that this holds for any film thickness less than 10^{-3} cm. These authors also estimated the half-width of the stripping peak and the effect of the kinetic parameters on the stripping peak potential:

$$[5]\quad n'b_{1/2} = 0.0755V\quad (H < 0.45)$$

$$[6]\quad n'(E_p - E_{1/2}) = 0.0014V + 0.02958V \log H$$

These equations permit correlation of the concentration of metal ion in a sample to the peak stripping current and Table 1 includes the predicted responses (i_p/C^*) for the three metals in the SW electrolyte. The values are based on the standard electrode and kinetic parameters as defined in the procedure, values of the diffusion coefficients determined from polarography, and the known kinematic viscosity of the SW electrolyte. In the case of Cu the response value is based on an (assumed) 1-electron

stripping process giving a response factor that would be 1/4 × that for Cd and Pb, other than for differences in the diffusion coefficients of the metal species. The predicted responses can be compared to the slopes of the experimental standard calibration addition plots.

In the cases of Cd and Pb the stripping peaks were well defined and readily resolved from the background. The height and half-width of the peaks were in keeping with 2-electron processes and the slopes of the experimental calibration plots were reproducible and showed little variation from sample to sample. The agreement with the predicted value was best with Pb; in the case of Cd the calibration slope was somewhat low. The result with Cd is probably best rationalized by assuming that there is a slow step in the deposition of the metal and the limiting current is less than that predicted by eq. [2]. This would not be unexpected at the potential used for the deposition.

In the case of Cu, the resolved stripping peak had a half-width consistent with a 1-electron stripping process giving a stable Cu(I) species. However, it appeared that the deposition and stripping processes were much more dependent on the state of the electrode than in the cases of Pb and Cd. The slopes of the Cu calibration plots were somewhat variable but always significantly less than the value calculated for the possible 2-electron stripping process; the experimental values approached but never exceeded that for a 1-electron stripping process. It was found that the calibration line slopes could vary from run to run when replicates of a given sample were analyzed though the calibration slopes for Cd and Pb remained constant. Despite such variation in slope good standard addition calibration plots and consistent values of Cu concentration were obtained in replicate analyses.

The resolution from the background and measurement of the Cu peak was dependent upon "curve fitting". When blank subtraction as shown in Fig. 3 ($A - B$) was used to resolve the Cu peak it was apparent that the (resolved) 1-electron oxidation peak was accompanied by a second process giving a broad background peak. The nature of this second process was not established though it did not appear to be a Faradaic process associated with a further oxidation of the Cu(I) product. It was found that the background peak grew only to a limit with increasing time at the deposition potential and the limiting value was independent of the magnitude of the resolved Cu stripping peak. Some experiments were carried out in which the SW

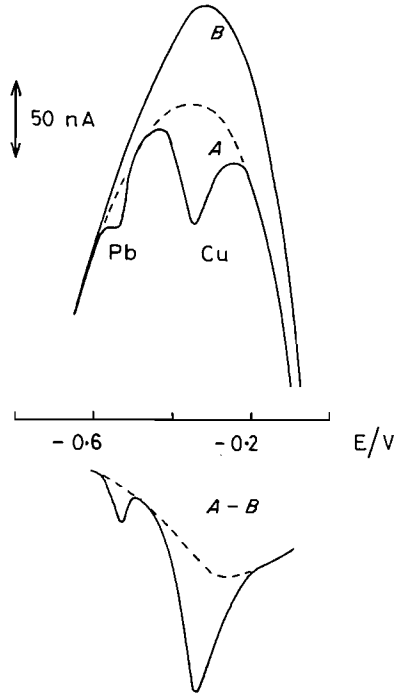

FIG. 3. ASV stripping peaks: SW sample at pH 2, TFME, Hg/Hg_2Cl_2/SW reference; *A*, sample (τ = 300 s); *B*, blank (τ = 0 s); ($A - B$), difference of sample and blank signal.

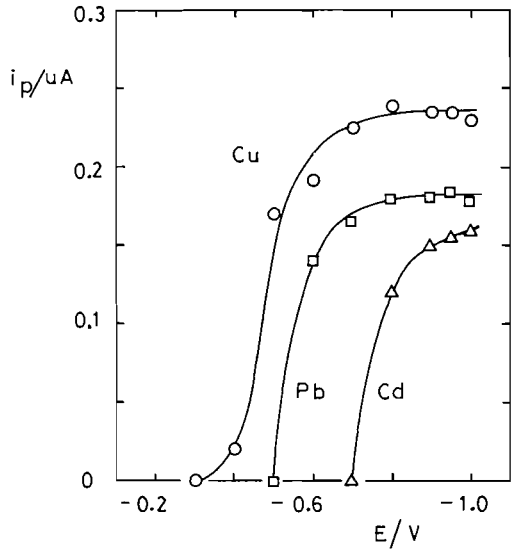

FIG. 4. ASV stripping signals as function of deposition potential: spiked SW sample at pH 2, TFME, $Hg/Hg_2Cl_2/SW$ reference.

samples were exposed to ultraviolet irradiation or digested to destroy organic material. This treatment was found to eliminate a component from the background although the resolved Cu stripping peak was unchanged. The component removed was positive to the Cu stripping peak potential and shaded into the Hg oxidation process; the background under the stripping peak itself was unchanged.

Other electrochemistry is in keeping with the assumed 1-electron Faradaic stripping process for Cu in the SW electrolyte. The polarography of Cu(II) spiked SW samples at pH 2 shows a two step reduction; $E_{1/2}$ for the reduction of the Cu(II) to Cu(I) is more positive than the potential for oxidation of the Hg of the electrode itself, while $E_{1/2}$ for the second stage of the Cu(II) reduction occurs at −0.20 V vs. SCE. Triangular wave voltammetry using a Hg drop electrode and a scan rate of 0.050 V s^{-1} shows composite behaviour with a cathodic peak on the forward scan corresponding to the reduction of Cu(I) to Cu at −0.25 V vs. SCE, and an anodic peak corresponding to the formation of Cu(I) at −0.17 V on the reverse scan; the peaks for the initial reduction and reoxidation to Cu(II) occur at potentials more positive than those for the oxidation of the Hg electrode. While the Cu stripping process in SW has not been previously so characterized other workers have observed related behaviour; Zirino and Kounaves (22) noted the apparent reduction of Cu(II) to Cu(I) in the stripping polarography of SW at a Hg drop electrode, while Pinchin and Newham (23) observed a "mixed" ASV stripping of Cu to Cu(I) and Cu(II) at a TFME in a buffered pH 5–0.2 *M* chloride electrolyte. In the latter case, the apparent *n* values were non-integral and the two stripping reactions could not be resolved.

In the cases of Cd and Pb, the slopes of the experimental calibration plots were quite reproducible and in close keeping with prediction, but with Cu there was considerably more variability. While all the analytical results reported in this paper were based on calibration by the method of standard additions, absolute analysis based solely on measurements on the sample and the calculated i_p/C^* values appears possible. The statistical evaluation of the results of such analysis will be presented in a subsequent paper.

Optimization of ASV Parameters

The procedure for the ASV analyses employed the following standard set of parameters:

SW: pH 1.5–2.0; 50 μ *M* added Hg(II); ~0.005 L sample
TFME: $A = 0.066\ cm^2$, $l > 100$ nm, $N = 30$ Hz
E_d: −1.00 V vs. $Hg/Hg_2Cl_2/SW$, $\tau = 300$ s
ASV: $dE/dt = 0.050\ V\ s^{-1}$, stationary TFME

A series of experiments was carried out to study the effect of variation of some of these parameters; in each case the value of one parameter was varied while the others were maintained, if possible, at their standard values.

(1) Deposition Potential (E_d)

A spiked SW sample was analyzed with E_d varied in steps from −0.5 to −1.0 V. The plot of i_p vs. E_d shown in Fig. 3 then gives the collection efficiency of each element at a given deposition potential. For each element there is a characteristic rising curve and a range of potentials over which a limiting deposition rate is indicated. In the case of Cd the rising part of the curve is less steep than in the case of Cu and Pb and the potentials corresponding to the limiting deposition plateau are relatively cathodic to the polarographic $E_{1/2}$ given in Table 1. This indicates a measure of kinetic control in the electron transfer step and while the limiting plateau for the Cd deposition was barely defined at −1.0 V, more negative potentials were not employed since these would favour Zn codeposition and H^+ reduction from the SW electrolyte. The choice of E_d for the ASV analyses may then be responsible for the less than expected slopes reported for the Cd calibration lines in Table 1. The potentials corresponding to the limiting deposition plateau of Cu are also relatively cathodic to the $E_{1/2}$ for the polarographic Cu(I) → Cu(Hg) step but this may result from the limited solubility of Cu in the Hg substrate. The Pb deposition appeared to proceed smoothly without hindrance.

(2) Film Thickness (l)

This variable was studied in a series of repetitive experiments beginning without predeposition of a Hg film. When unspiked SW or low level spiked samples were subjected to analysis the stripping peaks grew to a limiting value over the initial 2–3 analysis cycles, then remained constant through the 20 cycles investigated in the experiments. It was assumed that the initial low values of the stripping peaks resulted either from incomplete coverage of the substrate with Hg so that only a fraction of the electrode area was operative in the collection step, or perhaps to saturation of the Hg film with the metals deposited in an analysis cycle. This would also be expected to reduce the collection efficiency of the electrode and both effects would decrease as the amount of Hg present on the substrate increased from cycle to cycle. The deposition current resulting from the 50 μ*M* Hg(II) added to the SW was ~5 μA and this corresponds to a film growth of ~17 nm in each 300 s deposition period provided the film is uniform and depletion of the added Hg(II) is not significant. Complete deposition of the Hg(II) from a 0.005 L sample would correspond to a maximum film thickness of ~550 nm.

The standard procedure is based on a 30 min predeposition of the Hg, corresponding to a film thickness of ~100 nm. It was assumed that this gave a uniform film with complete coverage of the substrate and the Hg was in excess of that required to amalgamate the amounts of Cu, Pb, and Cd deposited in an analysis. Of the three metals, Cu has a limited solubility (0.01 atom% (24, 25)) and would be most likely to give saturated films. In the absence of predeposition, the solubility data indicate that film saturation would be expected only if Cu(II) > 0.3 μg L^{-1}, provided that the Hg and Cu deposit together in a similar fashion and the added Hg(II) is present at the 50 μ*M* level. However, if a 100 nm film is predeposited, calculations based on eq. [1] and the appropriate kinetic factors indicate that amalgam saturation would occur in a 300 s deposition only if Cu(II) > 3.0 μg L^{-1}.

TABLE 3. Definitions and units of symbols

Symbol	Definition	Unit
A	Surface area of electrode	
$b_{1/2}$	Stripping peak width at half maximum	V
C_0*	Bulk concentration of reducible M^{n+}	mol L^{-1}
C_r	Concentration of reduced M in amalgam	mol L^{-1}
D_0	Diffusion coefficient of reducible ion $\sim 7 \times 10^{-6}$ cm^2 s^{-1} for M_{aq}^{2+} in SW	
D_r	Diffusion coefficient of metal in amalgam $\sim 2 \times 10^{-5}$ cm^2 s^{-1} for M in Hg (3)	
E_p	Stripping peak potential	V
$E_{1/2}$	Polarographic half-wave potential	V
F	Faraday	96 485 C mol^{-1}
H	Kinetic parameter ($= l^2\sigma/D_r$) (21)	
i_l	Limiting current in deposition step	A
i_p	Peak stripping current	A
l	Thin layer film thickness	cm
n_r	Amount of metal collected for stripping	mol
δ	Diffusion layer thickness	cm
γ	Kinematic viscosity of electrolyte $\sim 9.4 \times 10^{-3}$ cm^2 s^{-1} for SW at 298 K (33)	
v	Potential scan rate in stripping step (dE/dt)	V s^{-1}
σ	$n(F/RT)v = n(38.92\ V^{-1})v$ at 298 K	s^{-1}
ω	Angular rotation velocity of electrode $= 2\pi N$ where N is frequency of rotation	s^{-1}
τ	Deposition time with electrode rotation	s

If the Cu collected should exceed the solubility limits then a multi phase deposit with a complex stripping behaviour might be expected. However, Stojek *et al.* (26) found that even with a calculated 160× excess of total over amalgamated Cu the ASV peak was "somewhat asymmetric, thinner and displaced" but still close to the form and shape predicted for the homogeneous amalgam. Pinchin and Newham (23) also studied the stripping of Cu from a TFME and found that while film saturation produces an anodic shift in peak potential the stripping peak height remains proportional to the amount of Cu present. Figure 5 shows the results obtained in this study with a heavily spiked SW sample; the concentration of Cu(II) was estimated from the peak stripping currents as $\sim 5\ \mu g\ L^{-1}$, a value sufficiently high that film saturation is conceivable in the initial stages of the experiment. The experiment was carried out without film predeposition and through the initial cycles the Cu stripping peak was sharp and narrow with a shape characteristic of the stripping of a solid deposit. As the number of cycles and the amount of Hg on the substrate increased, the peak height decreased but both the peak width and peak area grew until limiting values characteristic of amalgam stripping were obtained. With Cu(II) at 5 $\mu g\ L^{-1}$, it can be estimated that a 300 s deposition would saturate a ~ 167 nm film and some 10 ASV cycles would be required to produce this film thickness. The behaviour shown in Fig. 5 is near prediction in this respect although the initial behaviour of the Cu can also be explained by incomplete coverage of the electrode with Hg and deposition and stripping of Cu directly from the substrate. With Pb and Cd the stripping peaks grew to a limiting value through the initial 1–5 cycles with the shapes of the peaks always characteristic of amalgam stripping. It would appear that predeposition of a 100 nm Hg film is sufficient for ASV analyses at the higher levels of Cu, Pb, and Cd.

(3) pH

The dependency of the ASV experiment on the pH of the electrolyte was investigated using fresh but unacidified SW samples that had been filtered through a 3 μm polycarbonate filter (Nucleopore™). The cell was initially filled with sample of pH ~ 8 and ASV measurements, using preformed TFME electrodes, were made as a function of pH. The results showing the ASV response are shown in Fig. 6.

At the natural pH of the SW sample there was little response in the case of Cu and Pb although Cd gave a well defined stripping peak. The ASV peaks increased with acidity with limiting peak heights appearing near pH 4. The increases are likely a combination of changing electrode response and displacement of metal from inert forms by the increased proton activity. It was assumed that at pH 2 all the metals are in a form labile to ASV deposition; this assumption is supported by the near theoretical slopes of the standard addition calibration plots, the lack of a time dependency to the ASV signal after a standard addition increment, and the lack of any significant increase in the ASV signals after ultraviolet irradiation of the SW samples.

(4) Rotation Rate ($\omega = 2\pi N$)

The Levich relation as given in eq. [2] predicts that the amount of a metal collected in the deposition step at the rotated TFME is proportional to $\omega^{1/2}$. Since the parameters in the stripping step are independent of those in the collection step one would predict that the sensitivity of the method would increase with $\omega^{1/2}$ and the electrode rotation rate should be as large as possible. Experiments were carried out using spiked SW samples with N varied from 10 to 60 Hz; for each metal i_p was found to vary linearly with $\omega^{1/2}$ over the range of rotation rates studied. However, considerations concerned with bearing wear at the rotating electrode dictated a practical upper value for the rotation rate and the analyses were carried out with $N = 30$ Hz.

(5) Scan Rate (dE/dt, v)

Equation [4] predicts that the stripping current peak is directly proportional to the rate of potential scan but background processes associated with charging of the double layer at the electrode surface would be expected to increase at the same rate (27) so that a gain in the signal-to-noise ratio would not be expected.

Experiments were carried out using spiked SW samples with dE/dt in the stripping step varied from 0.005 to 0.1 V s^{-1}. The highest scan rate investigated was just within the ability of the

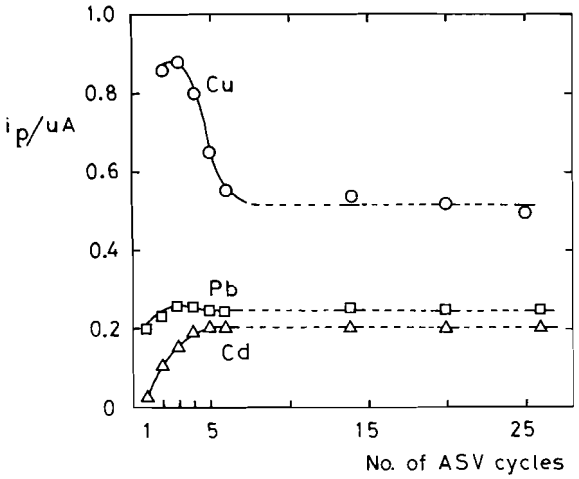

FIG. 5. ASV stripping signals as function of Hg film growth: spiked SW sample at pH 2, TFME, Hg/Hg_2Cl_2/SW reference, no Hg film predeposition.

recorder to accurately track the stripping peaks. Over the range investigated the peak heights were proportional to scan rate but there was little change in the apparent signal-to-noise ratio. However, the peak potentials and background currents were a function of scan rate and it was found that the Cd peak was best resolved from the initial rapid change in background at fast scan rates while the Cu peak was best resolved from the final rapid change in background at slow scan rates. A compromise scan rate was selected and the stripping analyses were carried out with $dE/dt = 0.05\ V\ s^{-1}$.

(6) Deposition Time (τ)

Equation [3] predicts that the amount of a metal deposited and the sensitivity of the method should increase directly with deposition time. Experiments with spiked SW showed a direct correlation between the observed stripping peak currents and deposition time provided that the time at the deposition potential with rotation was sufficiently large ($\tau > 100$ s) that the additional metal deposited in the 30 s period without rotation is not significant. A deposition with $\tau = 300$ s was selected for the analyses and the calibration data are based on this value. Longer deposition times will increase the sensitivity of the method at the expense of analysis time.

Results and Discussion

(1) Blank Analysis

It is not possible to obtain or directly synthesize a "blank" SW, that is a sample containing insignificant background concentrations of the analyte elements. Nevertheless it is useful to measure blank values on other appropriate samples as a measure of the extent of contamination during the course of an ASV analysis.

A blank NaCl solution with ionic strength equivalent to that of SW was prepared (0.55 mol L^{-1} NaCl). The solution had a pH of 7.5 and it was stripped of trace metals by a single pass through a 1 cm × 15 cm column of Chelex 100 (100–200 mesh, Na form, flow rate ~1 mL min^{-1}) (28). The eluent was acidified to pH 2 with HCl and then analyzed for Cu, Cd, and Pb. Detectable ASV peaks were observed for each element with peak signals marginally greater than the limit of detection but less than 1 nA corresponding to < 11 ng L^{-1} Cu, < 6 ng L^{-1} Cd, and < 7 ng L^{-1} Pb (as determined from the experimental calibration slopes in Table 1). Such blank signals with stripping peaks of less than 1 nA were consistently obtained using the sample handling and cell pretreatment procedures developed in this study. Comparison of the blank with the results given for typical SW samples in Tables 2, 4, and 5 show the values to be of the order of 10% of the SW values. The question remains as to whether such blank values should be deducted from the SW sample values. Correction should be made if the NaCl blanks represent contamination from sample handling or reagent addition during the procedure but no correction is required if these values are in fact only the base line levels of the metals remaining after the Chelex 100 exchange.

Other experiments were carried out to assess possible sources of contamination. In one set of experiments, the concentration of Hg(II) added to the NaCl blank for the *in situ* film formation was increased stepwise to 150 μM and in another set, the blank solutions were allowed to stand in the ASV cell for periods of up to 12 h before analysis. Detectable changes in the ASV signals were not observed, indicating that the metals found in the blank were not related to the added Hg(II) and there was no significant net release of metal from the cell. There is the possibility that low blank values are in part due to the adsorption of metals on the cell walls. However, the increased signals resulting from 20 ng L^{-1} additions of metal to the NaCl blank showed no time dependency and the slope of the resultant standard addition plots were comparable to those given in Table 1 for real SW samples (mean values: Cu 5.1; Pb 28.4; Cd 22.9 A/(mol L^{-1})). It was concluded that a blank correction was not required in the SW analyses.

(2) Intercalibration Studies

Although low blanks are a prerequisite for trace analysis, they are not a test of accuracy. The conventional means of testing accuracy of an analytical method is to analyze standard reference materials of the same matrix as the sample. However, there are no standard reference seawater samples (29) and thus an alternate test of accuracy must be employed.

Two intercalibration studies were undertaken for this purpose. The first involved a coastal sea water sample obtained from the Atlantic Regional Laboratory of the National Research Council of Canada

in Halifax, Nova Scotia. The sample had been filtered through a 0.45 μm filter, acidified to pH 1.6 and stored in a PE bottle. The sample was also analyzed by the Analytical Section Laboratories of the National Research Council in Ottawa, Ontario using graphite furnace atomic absorption spectrometry after a preconcentration of the trace metals (30). The comparative results are given in Table 2 and the agreement is good. The atomic absorption procedure involved solvent extraction of samples adjusted to pH 4 (and digested at 80°C) while the ASV procedure was a direct probing of the SW as supplied at pH 1.6. The agreement in the results would reasonably indicate that all of a metal in the SW is labile to the two procedures or alternatively the proportion of inert metal is unaffected by the alteration of electrolyte conditions.

A second intercalibration study involved samples taken as part of the 1978 fourth round intercalibration study organized by International Council for the Exploration of the Sea (ICES). The samples were obtained as the residual water supplied to an original participant and the analytical data have been presented as part of the ICES report (31). The results are summarized in Table 4 and the values obtained are in good agreement with the high preci-

For personal use only.

sion values selected from the results of the other participants in the study. Again it would appear that the three metals are completely labile to the ASV procedure.

(3) Sandy Cove Water

In order to integrate the ASV procedures described into a total system of analysis a sampling excursion was undertaken to Sandy Cove, Nova Scotia. Water from this site has been analyzed in other studies (30, 32) and it is considered to be representative of relatively unpolluted but near shore SW. The samples were collected on June 7, 1979 at a distance of 0.8 km from shore (44° 28′ N, 63° 34′ W) and at a depth of 20 m. The SW had a salinity of 30.9‰, a pH of 8.06, and a temperature of 9.5°C.

The samples were collected using a water sampler designed as part of this work and constructed entirely of high purity polymethylmethacrylate and PE plastics. The sampler is described elsewhere (18) and has been shown capable of retrieving uncontaminated sub-surface samples. Of the samples taken one was filtered through a 0.45 μm cellulose acetate filter (Millipore™) and stored without acidification and another was filtered through a 3 μm polycarbonate filter (Nucleopore™) then acidified to pH 1.8 with HCl. The samples were stored in preconditioned PE bottles and subsequently analyzed. The analyses were carried out by the standard ASV procedure with the sample stored at the natural pH and brought to pH 2 with HCl prior to analysis.

The results are given in Table 5 and the values for Cd and Cu are near those for the 1978 ICES acidified samples. The ICES samples were similar in that they were taken from the Scotian Shelf but at a depth of 180 m and 100 km offshore. The Pb values are much less than the ICES replicates, supporting a suggestion that Pb contamination occurred during sampling and handling for that intercalibration study. The results are thought to represent typical values for the total trace Cu, Cd, and Pb in the samples and there seems to be no significant differences between the two samples despite the differences in filtration and storage with and without acidification.

A simple method to characterize feed-coals for liquefaction

SUJIT K. CHAKRABARTTY

Coal Research Department, Alberta Research Council, 11315-87th Avenue, Edmonton, Alta., Canada T6G 2C2

Received July 15, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

SUJIT K. CHAKRABARTTY. Can. J. Chem. **59**, 1487 (1981).

The analytical techniques for identification of coal-properties relevant to liquefaction processes are not well-developed. A simple method is described to satisfy this need.

SUJIT K. CHAKRABARTTY. Can. J. Chem. **59**, 1487 (1981).

Les techniques analytiques d'identification des propriétés du charbon correspondant aux procédés de liquéfaction ne sont pas bien développées. On décrit une méthode simple qui vient combler cette lacune.

Introduction

The problem of declining supplies of petroleum and natural gas has encouraged the industrial nations of the world to expand R and D work for better utilization of coal reserves which make up to 47% of the energy content of the recoverable resources of the planet's fossil fuels. Two conversion techniques for producing transportable fuels from coal, namely, solvent refining and liquefaction, are now being considered as advanced technology for the eighties. The essential aspects of these conversion processes are broadly described (1) as a thermal fragmentation of macromolecular units in the presence of a hydrogen-donor solvent at the temperature range 375–425°C, associated with the scrambling of hydrogen atoms in the reactants to produce pyridine-soluble solids, and the progressive hydrogenation of the fragmented products to yield finally a transportable fuel or synthetic crude oils.

The rates of the fragmentation reactions are very fast and depend on the nature of coals. The microcomponents, as identified by the microscopic examination of coal particles as "vitrinite" and "exinites", are the most reactive materials which undergo rapid fragmentations. The other components, known as "semifusinite" and "fusinite", produce insignificant amounts of liquid products but may act as nuclei for coke-formation which might be deleterious to ultimate conversion.

Presently, the selection of coals for these processes is conducted on the basis of very expensive and time-consuming autoclave tests in high-pressure laboratory facilities. In this report, a simplified analytical version of the autoclave test procedure is presented. The method is based on the chemistry of coal–solvent interactions and identifies the yield of products generated by the very fast kinetic paths only.

Experimental

The sample coal with solvent is flash-heated in a reactor tube for a specified time and subsequently quenched by immersing the tube in cold water. The reactor tube, shown in Fig. 1, is made from pressure-rated 316 type stainless steel tubing, closed at one end, and fitted with swagelock fittings, thermocouple, and pressure gauge. A metal bath, electrically heated up to 500°C, is used as heat source. A typical experimental procedure is described below.

A sample of anhydrous subbituminous coal from Alberta, (−10 +30 Tyler particle sizes, 5 g) was placed in the reactor along with the solvent, tetrahydronaphthalene (73 mol). The vessel was purged with hydrogen until all air was removed. A nominal gauge pressure of 10 psi was maintained after closing the shut-off valve to isolate the pressure gauge. (The pressure gauge has to be isolated from the reactor vessel during reaction to avoid condensation of solvent vapors and products in the cooler chamber of the gauge.) The vessel was dipped into the hot metal bath maintained at 400°C. The temperature of the reactants reached the bath temperature in 3 min. A series of experi-

†Duplicate run with finer particle size.

ments was undertaken under this condition varying the length of the reaction times and the particle sizes of the coal. At the end of the specified times, the vessel was taken out of the metal bath and cooled by water spraying. After the contents of the vessel attained room temperature, pressure was recorded to calculate the gas yield. An increase of 74 psig pressure was noted in a 60 min run with this specific coal.

The system was connected to the gas-sampling port of a Carle's analytical gas chromatography apparatus to analyze the gas composition. After venting out the gases inside a fume hood, the contents of the reaction tube were poured onto 200 mL of *n*-pentane solvent. After thorough mixing and transferring all the products from the tube, the solids were separated by filtration, and the pentane-soluble materials were subjected to gc–ms analysis. The pentane-insoluble solid was extracted with chloroform at room temperature until the extract was colorless. The total conversion of coal to gas and extractable matters (bitumen) was calculated based on the residue left after chloroform extraction.

Results and Discussion

The following results are described as an example to demonstrate the usefulness of the proposed method in terms of simplicity, reproducibility, and efficiency to meet the necessary objectives, viz. screening of coal for liquefaction-processes.

When coal is heated in a slurrying vehicle, it is "liquefied" at 400–500°C. Though the reaction-mechanism involving conversion of coal to oil is very complex, it appears that the interaction of coal with solvent at the initial stage of the reactions plays the vital role to determine the sequential conversion of coal substances – first to a pyridine-soluble solid and thereafter to benzene-soluble liquid hydrocarbons and light oils (2). Thus the isolation and identification of the products of coal–solvent interactions to yield pyridine-soluble matter may provide information regarding the suitability of the sample-coal for liquefaction. The experimental results, given in Table 1, show the effects of residence time on the sequential reactions and ultimate conversion-yields. The gc–ms analysis of the pentane-soluble products indicated that light oils (C_8–C_{12} hydrocarbons) started to form after 30 min along with decahydronaphthalene, methyltetrahydronaphthalene, methylnaphthalene, and indene. The gas yield reached the maxima at this point and was stabilized afterward with minor fluctuation in C_1–C_4 hydrocarbon yields. Increasing the residence time beyond 30 min showed gradual improvement of liquid conversion values. From this observation, it was surmised that the reaction up to 30 min was predominately due to coal–solvent interaction. The gradual decrease of tetrahydronaphthalene in the reaction mixture associated with gradual increase of dehydrogenated and methylated solvent with reaction time possibly indicated that these products were derived from solvent, and not from coal. At the initial stages, tetrahydronaphthalene and naphthalene contributed to more than 99% of the total extract on pentane-free basis.

Tetrahydronaphthalene, by itself, was found to be stable under these temperature and pressure conditions. In the presence of coal, tetrahydronaphthalene is dehydrogenated very rapidly. In the absence of solvent (Table 2), liquid conversion yield was negligible, though the yield and composition of the gaseous products remained similar to earlier results. Repeating the experiment with nitrogen instead of hydrogen as gaseous atmosphere, did not show any significant differences in the

Tetralin/H_2/400°C/60 min	Nil	100% recovery of the starting material					

results, indicating that molecular hydrogen present in the gas-phase did not participate in the initial stages of coal-liquefaction. The solvolysis reaction with the test coal was conducted earlier (3) in a standard 300 cm^3 autoclave with tetrahydronaphthalene as solvent. The rate of heating was approximately 4.5°C per min, and the reaction time of 60 min was measured from the moment the autoclave had reached 400°C. The conversion as defined on the basis of benzene-insoluble matters was 26.8% dry basis (30% as dry, ash-free basis). The value is lower than the conversion obtained in tube-reactor for the 30 min run (Table 2). Due to long heat-up and cooling time in an autoclave run, the reactions cannot be quenched at the initial stage of coal–solvent interaction and are difficult to define. The quenching of the reactions before the light oils started to form would identify the yield of products generated by the very fast kinetic path only.

From this discussion it can be concluded that the reactivity of coal towards tetrahydronaphthalene can be determined by the described procedure and the results used to characterize the feed coal for liquefaction processes. Since the different micro-components react differently, it would be necessary to separate them as several gravity-cut by flotation technique, and establishing their reactivities separately. The reactivity of the as-mined coal (composite sample), along with the reactivities of micro-components, would be a valuable parameter. The test method would also provide data for yield and composition of gaseous products, and minimum hydrogen requirement that has to be fed in the reactor using solvent as a carrier. The spectroscopic characterization of the extractable matters would provide information helpful in down-stream processing of the primary liquefaction products.

The extraction of alkali metal picrates by polyurethane foam using crown ether

ANJUM S. KHAN, W. G. BALDWIN, AND A. CHOW
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received July 30, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

ANJUM S. KHAN, W. G. BALDWIN, and A. CHOW. Can. J. Chem. **59**, 1490 (1981).

The distribution of alkali metal picrates between water and polyurethane foam was studied in the presence of dicyclohexyl 18-crown-6 (DCHC-6). The extraction constants and dissociation constants for the ion pair (MCrA) in polyurethane foam were determined. The extraction constant sequence of the alkali metal ions with DCHC-6 is $K^+ > Rb^+ > Cs^+ > Na^+$ and mainly depends on the stability of the alkali metal – crown ether complex.

ANJUM S. KHAN, W. G. BALDWIN et A. CHOW. Can. J. Chem. **59**, 1490 (1981).

On a étudié la distribution des picrates de métaux alcalins entre l'eau et la mousse de polyuréthane en présence de l'éther dicyclohexyl-18 couronne-6 (DCHC-6). On a déterminé les constantes d'extraction et de dissociation de la paire d'ions (MCrA) dans la mousse de polyuréthane. La constante d'interaction des ions de métaux alcalins avec le DCHC-6 varie dans l'ordre suivant: $K^+ > Rb^+ > Cs^+ > Na^+$ et dépend principalement de la stabilité du complexe métal alcalin éther couronne.

During the last few years, the high distribution coefficients obtained (1) and the ease of handling of the system have aroused considerable interest in using polyurethane foam for the extraction and separation of inorganic and organic species from aqueous solutions (2, 3). Recently the extraction of platinum metals from organic media by polyurethane foam has also been reported (4). Polyurethane foam has been used for the extraction of Fe(III) (5), Ga(III) (6), Sn(IV) (7), Sb(III) and Sb(IV) (8) from acidic chloride systems. The extraction of thiocyanate complexes of Ru, Pd, Rh, Os, and Pt has also been reported with distribution coefficients as high as 10^5 (9). Even higher values were reported for the Co/SCN system (1).

Crown ethers, first prepared by Pedersen (10), form stable complexes with a number of metal ions, particularly the alkali metal ions. In a typical cation – crown ether complex, the cation is located in the center of the main ring in the plane or almost in the plane, of the oxygen atoms (10). The complexation is said to result mainly from electrostatic ion–dipole attraction between the metal ion and the oxygen atoms surrounding it (11). The stability and the stoichiometry of the complexes depend mainly on the ratio of the ionic size of the cation to the cavity size of the crown ether (12). If the ionic diameter of the cation is such that it just fits into the cavity of the crown ether, a stable complex is formed. However, if the cation is too small to closely fit into the cavity of the ring, either incomplete complexation or the formation of 2:1 and 3:2 (M:L) complexes may result. Similarly a metal ion of relatively large size may form 1:2 or 2:3 complexes (13). The charge of the cation, the nature of anion and the solvent can also influence the stability of the complexes (12). The ionic diameters of alkali metals and cavity sizes of some crown ethers are listed in Table 1. From these data it is seen that 18-crown-6 is optimum in size for K^+ and 15-crown-5 for Na^+.

Although some solvent extraction studies of alkali metal cations in the presence of crown ethers have appeared in the literature (14), there is no reported use of polyurethane foam for the extraction of alkali metal – crown ether complexes. The present study was undertaken to explore the use of polyurethane foam for the extraction of alkali metal cations with crown ethers and to determine the extraction constants for the alkali metal – crown ether/picrate ion system between polyurethane foam and water.

Dicyclohexyl 18-crown-6 (DCHC-6) was chosen for the present study because this cyclic polyether has been thoroughly investigated and forms stable complexes with alkali metals. Since a large anion is easily extracted into a low dielectric constant media, the picrate anion was used as the counter anion. The effect of other anions on the extraction has also been investigated.

Experimental

Apparatus

The absorption and pH measurements were made on a model 306 Perkin Elmer atomic spectrometer and a Fisher Accumet model 520 digital pH meter respectively.

Reagents

Dicyclohexyl 18-crown-6 (DCHC-6) was obtained from Aldrich Chemical Co. and was used without further purification. No attempt was made to separate the two isomers, therefore the results are valid only for the isomeric mixture. KCl, NaCl, LiCl, RbCl, and CsCl were of reagent grade. 8-Anilino-1-napthalene sulphonic acid as the magnesium salt (ANS) was obtained from Eastman Kodak Co. A 0.05 *M* solution of picric acid was prepared from BDH reagent grade picric acid hydrate and was standardized potentiometrically with sodium hydroxide. A sheet of commercial polyurethane foam (polyether type) was used. The water used was doubly distilled and deionized.

Procedure

Small cubes of approximately 0.2 g each were cut from the polyurethane foam sheet. These foam cubes were soaked in 0.5 *M* HNO_3 for 12 h, washed with double distilled water, extracted with acetone in a Soxhlet apparatus for 6 h and finally, air dried.

The sample solution and foam were placed in one of the glass cells shown in Fig. 1. The foam was squeezed by means of the plunger at 15 min intervals for 6 h at room temperature. The amount of metal extracted was determined by measuring the concentration before and after extraction with the foam, using atomic absorption or flame emission.

The distribution coefficient for metal ion is given by the ratio of the concentration of the metal on the foam to the concentration of the metal left in solution at equilibrium and is equal to:

$$[1] \quad D = \frac{\text{amount of metal on foam}}{\text{weight of foam}} \times \frac{\text{volume of solution}}{\text{amount of metal left in solution}}$$

Defined in this way, D has the units of volume per weight, i.e., of mL g^{-1} or of L kg^{-1}.

Trial experiments showed little or no extraction of the metal ions if either the crown ether or picric acid was absent from the alkali metal solution.

The Distribution Coefficient of Crown Ether and Picric Acid

The distribution ratio between foam and water for DCHC-6 was determined as follows. A 50 mL aliquot of crown ether solution was first equilibrated with polyurethane foam as in the metal extraction procedure. After 6 h, 25 mL of solution was transferred to a separatory funnel and a large excess of KOH and picrate solution added. This was then extracted with an equal volume of methylene chloride. A second 25 mL aliquot of crown ether solution, not previously equilibrated with foam, had a large excess of KOH and picric acid solution added, and the resulting solution extracted with an equal volume of methylene chloride. Under these conditions crown ether is extracted together with an equivalent quantity of picrate ion (14*b*). Thus the spectrophotometric analysis of picrate in the two methylene chloride extracts allowed us to calculate the concentration of crown ether before and after foam extraction. The amount of crown ether extracted by foam was thus easily determined. The distribution ratio of crown ether was determined in this way for a number of initial crown ether concentrations between 0.001 and 0.01 mol L^{-1}. The average distribution coefficient (K_{1ex}) was found to be 15 ± 3 L kg^{-1} (the standard deviation of 10 measurements is given).

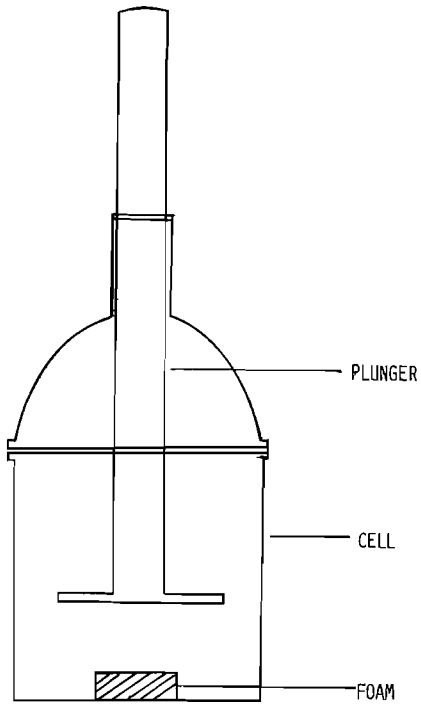

FIG. 1. Cell used in squeezing.

The distribution ratio for picrate ion between water and polyurethane foam was determined by studying the extraction of picric acid in the absence of both alkali metal ions and crown ether. The picric acid extraction was studied using solutions with an initial picric acid concentration of 4×10^{-3} mol L^{-1} in the aqueous phase, and over a pH range of 2.0 to 8. The picrate ion concentration was determined spectrophotometrically. The distribution ratios thus obtained were found to be constant over the pH range 2.5 to 8. The average value, together with the standard deviation was found to be 35 ± 5 L kg^{-1}.

Results and Discussion

The overall extraction equilibrium between an aqueous phase containing a metal ion (M^+), picrate ion (A^-), a crown ether (Cr), and the polyurethane foam may be represented by the following equation:

$$[2] \quad M^+(aq) + Cr(aq) + A^-(aq) \rightleftharpoons MCrA(f)$$

$$[3] \quad K_{ex} = [MCrA(f)]/[M^+(aq)][Cr(aq)][A^-(aq)]$$

where MCrA represents the ion pair between the metal – crown ether cation MCr^+ and picrate anion A^-. The labels "aq" and "f" denote the aqueous and foam phases respectively. The overall equilibrium is thought to consist of the following equilibria:

(*a*) The distribution of free crown ether between foam

For personal use only.

and aqueous phases

[4] $Cr(aq) \underset{}{\overset{K_{1ex}}{\rightleftharpoons}} Cr(f)$

[5] $K_{1ex} = [Cr(f)]/[Cr(aq)]$

(*b*) The distribution of picric acid between the two phases:

[6] $HA(aq) \overset{K_{2ex}}{\rightleftharpoons} HA(f)$

[7] $K_{2ex} = [HA(f)]/[HA(aq)]$

(*c*) The dissociation of picric acid in both phases:

(i)

[8] $HA(aq) \overset{K_{3d}}{\rightleftharpoons} H^+(aq) + A^-(aq)$

[9] $K_{3d} = [H^+(aq)][A^-(aq)]/[HA(aq)]$

(ii)

[10] $HA(f) \overset{K_{3d}^*}{\rightleftharpoons} H^+(f) + A^-(f)$

[11] $K_{3d}^* = [H^+(f)][A^-(f)]/[HA(f)]$

(*d*) The reaction of the metal ion with the crown ether:

[12] $M^+(aq) + Cr(aq) \overset{K_4}{\rightleftharpoons} MCr^+(aq)$

[13] $K_4 = [MCr^+(aq)]/[M^+(aq)][Cr(aq)]$

(*e*) The association of complexed cation with the picrate anion

[14] $MCr^+(aq) + A^-(aq) \overset{K_5}{\rightleftharpoons} MCrA(aq)$

[15] $K_5 = [MCrA(aq)]/[MCr^+(aq)][A^-(aq)]$

(*f*) The distribution of the ion pair between the two phases:

[16] $MCrA(aq) \overset{K_{5ex}}{\rightleftharpoons} MCrA(f)$

[17] $K_{5ex} = [MCrA(f)]/[MCrA(aq)]$

(*g*) The dissociation of the ion pair in the foam:

[18] $MCrA(f) \overset{K_{5d}^*}{\rightleftharpoons} MCr^+(f) + A^-(f)$

[19] $K_{5d}^* = [MCr^+(f)][A^-(f)]/[MCrA(f)]$

(*h*) The dissociation of the metal ion – crown ether complex in the foam:

[20] $MCr^+(f) \overset{K_{4d}^*}{\rightleftharpoons} M^+(f) + Cr(f)$

[21] $K_{4d}^* = [M^+(f)][Cr(f)]/[MCr^+(f)]$

The distribution of picric acid in the absence of both metal ion and crown ether was studied at different pH values and was found to be constant over the pH range from 2.5 to 8. The distribution ratio, D', of picrate in the absence of metal ion is equal to:

[22] $$D' = \frac{\text{total picrate per unit weight foam}}{\text{total picrate per unit volume of solution}} = ([HA(f)] + [A^-(f)])/([HA(aq)] + [A^-(aq)])$$

Substituting for the values of [HA(f)] and [HA(aq)] using eqs. [9] and [11],

[23] $$D' = \left\{\frac{[H^+(f)][A^-(f)]}{K_{3d}^*} + [A^-(f)]\right\} \Big/ \left\{\frac{[H^+(aq)][A^-(aq)]}{K_{3d}} + [A^-(aq)]\right\}$$

[24] $$= \frac{[A^-(f)]}{[A^-(aq)]} \frac{K_{3d}([H^+(f)] + K_{3d}^*)}{K_{3d}^*([H^+(aq)] + K_{3d})}$$

The value of K_{3d} has been determined (15) as 0.51 mol L^{-1}. Thus, at pH values higher than 2, $([H^+(aq)] + K_{3d})$ is approximately equal to K_{3d} and the expression for D' reduces to

[25] $$D' = \frac{[A^-(f)]}{[A^-(aq)]} \frac{K_{3d}([H^+(f)] + K_{3d}^*)}{K_{3d}^* K_{3d}}$$

Since the distribution ratio for picric acid was constant over the pH range from 2.5 to 8, it seems reasonable to assume that $([H^+(f)] + K_{3d}^*)$ is approximately equal to K_{3d}^* over the pH range studied. Thus

[26] $D' = [A^-(f)]/[A^-(aq)]$

over the pH range 2.5 to 8.

The distribution of crown ether was also studied in the absence of both picrate and of metal ion. The distribution ratio

[5] $K_{1ex} = [Cr(f)]/[(Cr(aq)]$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/06/12
For personal use only.

was determined for various initial concentrations of crown ether (0.001 to 0.01 mol L^{-1}) and was found to be constant with a value of 15 ± 3 L kg^{-1}.

The distribution ratio of the metal ion is defined as

$$[1] \quad D = \frac{\text{total metal on foam per unit weight of foam}}{\text{total metal in solution per unit volume of solution}}$$

Thus, using the equilibria in [4] through [21]

$$[27] \quad D = \frac{[M^+(f)] + [MCr^+(f)] + [MCrA(f)]}{[M^+(aq)] + [MCr^+(aq)] + [MCrA(aq)]}$$

Substituting from eqs. [13], [15], [17], [19], and [21] gives

$$[28] \quad D = \frac{K_{4d}{}^*K_{5d}{}^*K_{5ex}K_5K_4mca/c_fa_f + K_{5d}{}^*K_{5ex}K_5K_4mca/a_f + K_{5ex}K_5K_4mca}{m + K_4mc + K_5K_4mca}$$

where $m = [M^+(aq)]$, $c = [Cr(aq)]$, $a = [A^-(aq)]$, $c_f = [Cr(f)]$, $a_f = [A^-(f)]$. Substituting for c_f and a_f using eqs. [5] and [26] respectively

$$[29] \quad D = \frac{K_{4d}{}^*K_{5d}{}^*K_{5ex}K_5K_4/K_{1ex}D' + K_{5d}{}^*K_{5ex}K_5K_4c/D' + K_{5ex}K_5K_4ca}{1 + K_4c + K_5K_4ca}$$

Since for all the experiments the total metal ion is always less than 1/10th of the total crown ether, it seems reasonable to approximate

$$vCr_T = vc + wc_f$$

where Cr_T is the initial concentration of crown ether in the aqueous phase, v is the volume of solution, and w is the weight of foam used. Thus,

$$[30] \quad vCr_T = vc + wK_{1ex}c$$

$$[31] \quad c = Cr_T/(1 + K_{1ex}w/v)$$

Similarly,

$$[32] \quad a = A_T/(1 + D'w/v)$$

Substituting these values of c and a into eq. [29] gives:

$$[33] \quad D = \frac{\frac{K_{4d}{}^*K_{5d}{}^*K_{5ex}K_5K_4}{K_{1ex}D'} + \frac{K_{5d}{}^*K_{5ex}K_5K_4Cr_T}{D'(1 + K_{1ex}w/v)} + K_{5ex}K_5K_4Cr_TA_T/(1 + K_{1ex}w/v)(1 + D'w/v)}{1 + K_4Cr_T/(1 + K_{1ex}w/v) + K_5K_4Cr_TA_T/(1 + K_{1ex}w/v)(1 + D'w/v)}$$

Both K_{1ex} and D' have been determined above. The stability constants of alkali metal ion – DCHC-6 complexes, K_4 in the above equation, have been reported in the literature (12, 16) and are listed in Table 2.

The ion pair association constants, K_5, have not been determined. They may be estimated using the following equation derived by Fuoss (17) for ions in contact

$$[34] \quad K = 2.524 \times 10^{-3}\mathring{a}^3e^b$$

$$[35] \quad b = Z^2/aDkT$$

where Z is the electron charge, a is the center-to-center distance of the ions in a pair, D is the dielectric constant of the medium, and k is Boltzmann's constant. Using the Pauling ionic radii given in Table 1 and a value of 2.23 Å for the radius of the picrate ion (18), values for the ion pair association constants, K_5, were estimated. The values are given in Table 2. Substituting the appropriate values of K_4, K_5, Cr_T, and A_T, it can be seen that the denominator in eq. [33] can be approximated by

$$1 + K_4Cr_T/(1 + K_{1ex}w/v)$$

Thus, after rearranging it can be seen that plots of $D(1 + K_4Cr_T/(1 + K_{1ex}w/v))$ against both A_T and

Cr_T will be straight lines, the slopes and intercepts of which allow us to estimate K_{4d}*, K_{5d}*, and K_5K_{5ex}.

The extraction behaviour of the cations Na^+, K^+, Rb^+, and Cs^+ (lithium showed no extraction under the conditions of the experiments) into polyurethane foam from aqueous solution containing DCHC-6 and picric acid was studied as a function of the total initial picric acid concentration, A_T. The concentration of the picric acid was varied from 0.5×10^{-3} to 15×10^{-3} mol L^{-1} for each cation (1×10^{-4} mol L^{-1}) with the crown ether concentration kept constant at 4×10^{-3} mol L^{-1}. The results are shown in Fig. 2 where it is clear that the extraction of metal ion increases with an increase in the picric acid concentration.

The effect of crown ether concentration on extraction of K^+, Rb^+, Cs^+, and Na^+ was studied at constant initial picric acid concentration and constant metal ion concentration. The results shown in Fig. 3 indicate that the extraction increases with an increase in crown ether concentration. The extraction behaviour of the cations shown in Figs. 2 and 3 is consistent with the ion pair extraction of cation – crown ether and picrate complexes as predicted from eq. [33].

Figure 4 shows the plot of D vs. initial crown ether concentration for three different concentrations of K^+

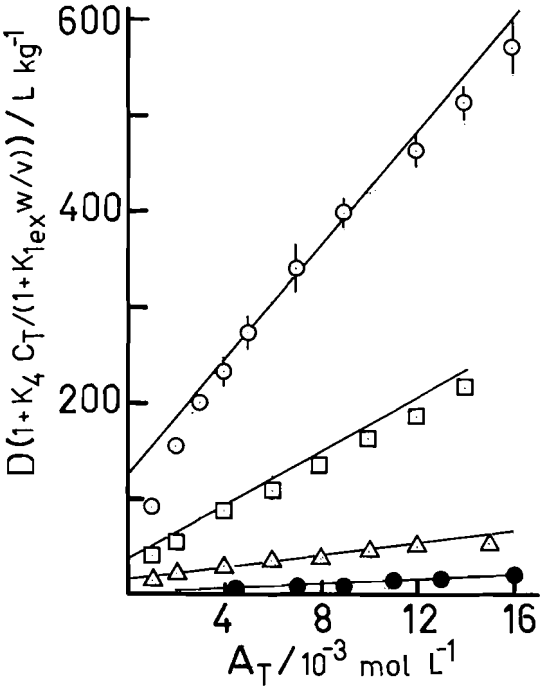

FIG. 2. The effect of varying the initial concentration of picric acid, A_T, on the distribution ratio, D, for the distribution of various alkali metal cations between polyurethane foam and aqueous solution. Total metal ion concentration 1×10^{-4} mol L^{-1}; total crown ether concentration 4×10^{-3} mol L^{-1}; weight of foam 0.2 g; volume of solution 40 mL: K^+ (○), Rb^+ (□), Cs^+ (△), and Na^+ (●).

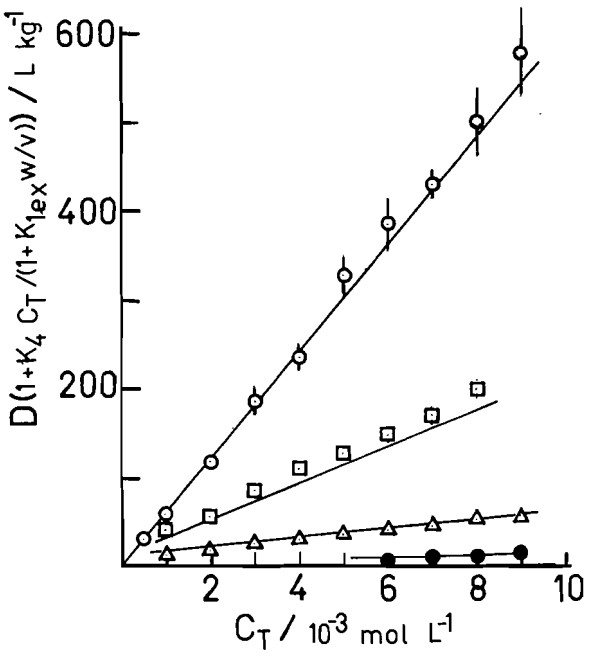

FIG. 3. The effect of varying the initial concentration of crown ether, C_T, on the distribution ratio, D, for the distribution of various alkali metal cations between polyurethane foam and aqueous solution. Initial metal ion concentration 1×10^{-4} mol L^{-1}; initial picric acid concentration 4×10^{-3} mol L^{-1}; weight of foam 0.2 g; volume of solution 40 mL: K^+ (○), Rb^+ (□), Cs^+ (△) and Na^+ (●).

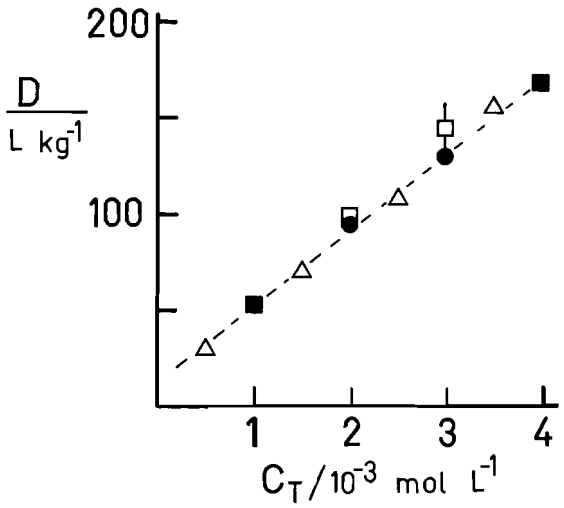

FIG. 4. Distribution coefficient as a function of initial concentration of DCHC-6 at different total concentrations of K^+: $K^+ = 0.25 \times 10^{-4}$ *M* (●), 0.5×10^{-4} *M* (□), 1×10^{-4} *M* (△), [picric acid] = 4×10^{-3} *M*. Weight of foam 0.2 g.

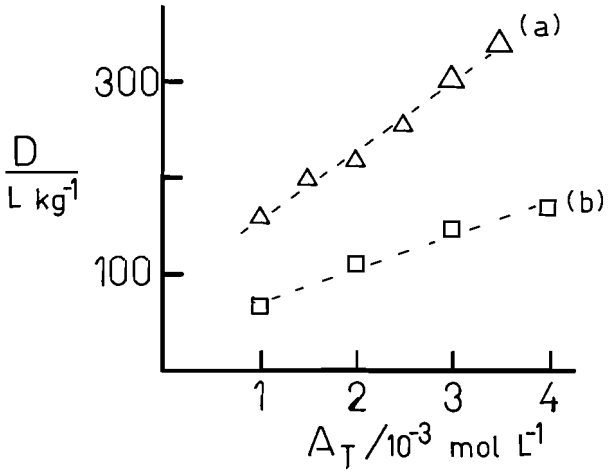

FIG. 5. Distribution coefficient as a function of initial concentration of anions, ANS (△), picric acid (□), $[K^+]$ 1×10^{-4} *M*, [DCHC-6] 4×10^{-3} *M*. Weight of foam 0.2 g.

with picric acid concentration constant at 4×10^{-3} *M*. The results shown in Fig. 4 indicate that the extraction is independent of metal ion concentration under these conditions (i.e. $[M^+]_T < [A_T]$ and $[Cr_T]$). This behaviour is predicted from eq. [33]. In Fig. 5, curves *a* and *b* show the plot of *D* vs. the initial concentration of picric acid and ANS respectively at constant initial concentration of K^+ and DCHC-6. It is expected that the bulky anions are more hydrophobic and therefore ought to enhance the extraction into foam. This is clearly shown in Fig. 5 for K^+, where the *D* values are higher for ANS than for picric acid. Under similar conditions no extraction was observed with 2,6- and 2,4-dinitrophenols. These findings demonstrate that the efficiency of ion pair extraction depends, in addition to the other factors mentioned, on the nature of the counter ion.

The effect of pH on the extraction of K^+ was studied at constant picric acid and crown ether concentrations. The pH values were adjusted by the addition of hydrochloric acid or tetraethyl ammonium hydroxide (10% solution in H_2O). The extraction increases rapidly with the increase in pH, reaching a maximum at pH ~ 2.5 and remaining constant up to pH 8. From this result, it is obvious that the *D* values are independent of hydrogen ion concentration above pH 2.5, which is in agreement with our approximations.

Values for the constants K_5K_{5ex}, K_{4d}*, and K_{5d}* were calculated according to eq. [33] from the values of the slopes and intercepts obtained from Figs. 2 and 3. A best fit was made to the data. The preferred or "best" values for the constants are given in Table 2. The solid lines in Figs. 2 and 3 were calculated using these best fit values.

Similar results have been reported for the solvent extraction of ion pairs of Na^+, K^+, and Ca^{2+} complexes of DCHC-6 with picrate and other anions (14*d*). Solvent extraction data are commonly reported as overall extraction coefficients, K_{ex}, defined analogously to eq. [3]. From eqs. [17], [15], and [13], it can be shown that

$$K_{ex} = K_5K_{5ex}K_4$$

Values of K_{ex} have been calculated, and are given in Table 2. It is seen from these K_{ex} values that the extraction increases in the order $Na^+ < Cs^+ < Rb^+ < K^+$. This is consistent with the results obtained by previous workers (14) for solvent extraction studies and is due to the fact that the stability of the cation – crown ether complex depends mainly on the ratio of the ionic size of the cation to the cavity size of the crown ether (12). From Table 1, one might have predicted that K^+ just barely fits into the DCHC-6 ring. The cations larger (Rb^+ and Cs^+) or smaller (Na^+ and Li^+) than the optimum size form less stable complexes because in the former case the cation is too large to fit into the cavity, while in the latter case, the ring is too large and thus the cation cannot be simultaneously close to all the oxygens. Thus a weaker complexation of Li^+, Na^+, Rb^+, and Cs^+ with DCHC-6 results in the poor extraction of these cations compared to K^+, which forms the most stable complex with DCHC-6 (Table 2).

The similarity of our results to those for solvent extractions (14) tends to suggest that extraction of alkali metals in the presence of crown ether and

picric acid by polyurethane foam from an aqueous system can be considered as the ion pair extraction of MCrA by an organic solvent of moderate dielectric constant.

Solvent extraction of anionic surfactants. The stearic acid – metal triethylenetetramine chelate ion-pair

DAVID JEFFRIES AND JAMES FRESCO

Otto Maass Chemistry Building, McGill University, Montreal, P.Q., Canada H3A 2K6

Received August 5, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

DAVID JEFFRIES and JAMES FRESCO. Can. J. Chem. **59**, 1497 (1981).

The solvent extraction behaviour of nickel(II) and copper(II) chelates of triethylenetetramine with stearic acid in a cyclohexane–isobutanol mixed solvent has been investigated. The results indicate that carboxylic acid selectivity by charged chelate extraction is based on partition constant differences rather than ion-pair formation constants. A computational technique for determination of partition and dimerization constants of high molecular weight carboxylic acids has been tested.

DAVID JEFFRIES et JAMES FRESCO. Can. J. Chem. **59**, 1497 (1981).

On a étudié le comportement, lors d'extraction par des solvants, des chélates de Ni(II) et du Cu(II) de la triéthylènetétramine avec l'acide stéarique dans un solvant mixte cyclohexane–isobutanol. Les résultats indiquent que la sélectivité de l'acide carboxylique par rapport à l'extraction du chélate chargé, est relié à des différences de constante de partage plutôt qu'aux constantes de formation de paire d'ions. On a vérifié une technique de calcul des constantes de partage et de dimérisation des acides carboxyliques de poids moléculaire élevé.

[Traduit par le journal]

Introduction

The determination of low-level concentrations of surfactants is achieved by solvent extraction and colorimetric analysis of a suitable chromophore-containing component of the extracted ion-pair (1). In this manner alkyl sulphates and alkane sulphonates in polluted waters and environmental samples have been measured employing substituted 1,10-phenanthroline and 2,2′-bipyridine chelates of iron(II) (2–4). In addition to organic sulphates and sulphonates, long chain carboxylate surfactants have been determined in mineral flotation liquors by means of the copper(II) chelate of triethylenetetramine (5).

The success of this analysis after modifying the detection system to include an atomic absorption spectrometer (6) provoked the present investigation. The analysis of stearic acid using copper(II) trien and nickel(II) trien was chosen for detailed study to expose significant features of this extraction system and as a consequence advance surfactant analysis.

Experimental

Chemicals

Triethylenetetramine (trien) supplied by Fisher Scientific Co. was purified by preparation of the dihydrate of the sulphate salt (7). The purity of the product was determined as 99.9% by potentiometric titration with standard sodium hydroxide.

Copper-61 and -64 were coproduced by proton bombardment of a 99.99% pure copper foil target positioned in the McGill University Foster Radiation Laboratory Synchrocyclotron. After dissolution of the foil, traces of Co, Ni, and Zn were separated by anion exchange chromatography (8). The radiochemical purity of the copper from each irradiation was checked by analysis of the two-component decay curves obtained.

Nickel-56 and -57 were obtained by proton bombardment of 99.9% pure nickel powder enclosed in an aluminum capillary. The irradiation facility and radiochemical purification procedure were similar to those used for ^{61}Cu and ^{64}Cu. γ-Ray spectra obtained for each nickel irradiation after ion exchange separation did not show peaks for nuclides other than those expected for nickel.

All other chemicals and solvents were either reagent or spectral grade and were used without further purification.

Solutions

Isobutanol/cyclohexane mixed solvent used as the organic phase was prepared by mixing 200 mL isobutanol and 800 mL cyclohexane.

Stearic acid stock solutions were prepared by dissolution of weighed portions of stearic acid in the mixed solvent. For the extraction studies further dilutions were performed as required.

Trien solutions were prepared by dissolution of 7.56 g of triethylenetetrammonium sulphate in 50 mL 1.6 *M* sodium hydroxide. A 90% reduction in volume was achieved under vacuum in a rotary evaporator and the resultant slurry of concentrated trien and solid Na_2SO_4 was filtered. After dilution of the filtrate to 100 mL this 2% trien solution possessed pH 11.8.

Metal(II) trien solutions were prepared by dilution of a fraction of the metal-containing effluent from the ion-exchange column with 2% trien solution. The concentration of these intermediate metal ion solutions was determined colorimetrically. Aqueous phases were prepared by mixing aliquots of the standardized metal trien solutions with sufficient small volumes of HCl and dilution to volume with 2% trien solution. The pH after extraction ranged from 10 to 12.

Procedure

The extractions were conducted at ambient temperature, 24 ± 1°C, and the aqueous phase ionic strength ranged between 0.010 and 0.015 *M*. Aliquots of 4 mL of the metal(II) trien solutions and stearic acid in 20% isobutanol/80% cyclohexane mixed sol-

vent were transferred to 10 mL centrifuge tubes. After capping, the tubes were shaken for 10 min and then centrifuged to separate the phases. Equilibration was checked by examining the phases after shorter and longer periods of agitation. The less dense organic phase was sampled first and the aqueous phase was sampled by applying positive pressure to a pipet as it was lowered through the residual organic phase.

The aliquots of each phase were delivered to separate 150 mm × 10 mm test tubes and capped. The metal ion activities were measured in a γ-well counter and the pH values of the equilibrated aqueous phases were recorded. The aqueous phase volume increase and organic phase volume decrease both by a factor of 5% were considered in the calculations.

Calculations

Resolution of mixed nuclide activities: since the half-life of ^{61}Cu was significant relative to the duration of the counting measurements, the observed activities were resolved and extrapolated to an initial time before distribution ratios were calculated. The observed counting rate for a sample containing mixed activities can be expressed by eq. [1] (10):

$$[1] \quad Y_j = \sum_{i=1}^{n} x_i \exp(-\lambda_i t_j) \frac{1 - \exp[-\lambda_i(\Delta t)_j]}{\lambda_i(\Delta t)_j}$$

where Y_j is the activity observed in the jth measurement, λ_i is the decay constant of the ith species, x_i is the contribution to the initial activity from the ith species at time t_0, t_j is the time relative to t_0 at the beginning of the jth measurement, and Δt_j is the duration of the jth measurement.

This equation was solved for the coefficients x_i by a weighted least-squares method using data obtained for a reference sample monitored during the counting of the separated phases. The weighting of data was achieved by dividing eq. [1] by the standard deviation of Y_j. Values for the initial activities of ^{61}Cu and ^{64}Cu were calculated by a FORTRAN subroutine in the data reduction program *vide infra*.

The activity of each sample was corrected to an arbitrarily selected time, t_0, using eq. [2].

$$[2] \quad Z_0 = \frac{G/\Delta t_G - B/\Delta t_B}{\sum_{i=1}^{n} f_i \exp(-\lambda_i t) \frac{1 - \exp(-\lambda_i \Delta t_G)}{\lambda_i \Delta t_G}}$$

where Z_0 is total activity corrected to time t_0, G is the gross count at time t, B is the background count, Δt_G and Δt_B are the durations of these counts, f_i the fraction of Z_0 due to the ith species is determined from the values of x_i.

Accordingly, the extraction data were corrected for decay before distribution ratios were calculated. The average of the sums of the corrected aqueous and organic phase activities for each extraction was within one sd of the activity of the resolution standard.

The magnitude of the Nitrien^{2+} and Cutrien^{2+} formation constants (9), excess trien employed, and range of pH values of the aqueous phases studied precluded existence of significant metal species other than the chelate. Plots of the logarithm of the metal ion distribution ratio, D, for the Mtrien^{2+} – stearic acid system versus pH or log stearate ion concentration first increased according to a slope of two and then changed continuously toward slope zero. The span of log D values was from less than −2 to 0.8 for copper and 1.2 for nickel while log stearate ion concentrations ranged from less than −4.5 to −2.5. On this basis the extractable species was assigned as the chelate distearate, MtrienA$_2$, and the observed values for the distribution ratio was represented as

$$D = \overline{[\text{MtrienA}_2]}/([\text{MtrienA}_2] + [\text{MtrienA}^+] + [\text{Mtrien}^{2+}])$$

Inversion and introduction of equilibrium constants give

$$1/D = 1/K_{D_C} + 1/K_{D_C}K_2[A^-] + 1/K_{D_C}K_1K_2[A^-]^2$$

which is a binomial equation with respect to $[A^-]^{-1}$ where K_{D_C} is the partition constant for the distearate species and K_1 and K_2 are the stepwise formation constants of the same species. The equation is solvable for the coefficients $1/K_{D_C}$, $1/K_{D_C}K_2$, and $1/K_{D_C}K_1K_2$ after values for $[A^-]$ are established.

Since the total stearic acid concentration, $[HA]_T$, was much greater than the total metal concentration, the free stearate ion concentration is obtained by solving the quadratic equation

$$2K_P H^2 K_{D_R}{}^2[A^-]^2/K_a{}^2 + (H + K_a + HK_{D_R})[A^-]/K_a - [HA]_T = 0$$

where H is the hydrogen ion concentration and K_P, K_{D_R}, and K_a are the dimerization constant, partition constant, and dissociation constant of stearic acid. A value for K_a of 1.29×10^{-5} typical for fatty acids above C_8 was assumed. The values K_{D_R} and K_P were too large to be determined directly by a two-phase titration or the analytical procedure on which this study is based. These constants were evaluated simultaneously with those for K_{D_C}, K_1, and K_2 according to the following method.

Trial values for K_{D_R} and K_P were varied independently in an iterative computer program. For each pair of values, the weighted least-squares solution of eq. [1] was carried out by von Holdt's matrix method (10). The values of all five constants were taken to be those values for which χ^2 was a minimum. A three-dimensional plot of χ^2 vs. log K_{D_R} and log K_P showed one marked minimum for both metals studied and the corresponding coordinates were assigned to log K_{D_R} and log K_P.

Results and Discussion

Enhanced extraction of uncharged chelates through neutral adduct formation has been extensively studied and summarized (11). Although the extraction of charged chelates and metal carboxylates (12) has considerable practical importance, detailed information on the formation of extractable species of the former type is meagre. In this work the distribution ratio of the charged substrate has been employed to indirectly establish properties of the free ligand heretofore ignored or determined independently.

The computer solution for the partition coefficients and stepwise formation constants of metal trien distearates was tested by using the published data for the extraction of thorium(IV) with acetylacetone (13) as well as results obtained for the iron(III) and vanadium(V) chelates of β-isopropyltropolone using the program OMNITAB (14). Agreement was excellent for all constants. Unsuccessful attempts to determine the partition and dimerization constants of stearic acid by two-phase titrations and extractions using either Gregory's method (5) or radiotracer copper trien as a stearate ion monitor indicated that log K_{D_R} for stearic acid would be greater than 5, if dimerization was negligible.

The results of the extraction studies of copper(II) and nickel(II) trien distearates appear in Table 1. Dimerization and partition constants have been reported for acetic, propionic, and butyric acids in the CCl_4/H_2O system (15). However, the precision of the extraction data for valeric acid would not permit the calculation of the corresponding constants.

Dimerization constants of C_2 to C_6 carboxylic acids have been shown to be independent of chain length (16) by solvent extraction. This study also showed that for the same series of acids the value of log K_{D_R} increases by 0.56–0.60 for every methylene group added. The values of K_{D_R} and K_P for propionic acid in cyclohexane (16) are −2.54 and 3.71, respectively. Accordingly, log K_{D_R} for stearic acid should have a value between 5.6–6.2.

The predictions for stearic acid in the cyclohexane/water system may be compared to the values in Table 1 where the organic solvent was 80% cyclohexane – 20% isobutanol. The agreement between the dimerization constants obtained by the copper and nickel extractions is considerably better than that obtained for the partition constant of stearic acid, the value of which may be considered $(1.0 \pm 0.3) \times 10^6$. The presence of isobutanol would be expected to depress the dimerization constant and enhance the partition constant. This trend was only apparent in the case of the dimerization constant.

The composition of the phases extracted was similar to that described by Gregory (5) except ethanolamine was excluded from the present study. Since carboxylic acids of chain lengths less than C_{14} were not extracted by Cutrien^{2+}, the results of this study suggest the basis of the carboxylic acid selectivity is the magnitude of K_{D_C} values rather than differences in adduct formation constants.

It is of further interest to examine the basis for the nonextractability of Cutrien distearate into cyclohexane in the absence of isobutanol reported earlier (5). If stearate ions had occupied the axial positions of the metal ion in the extractable species, a significant difference between copper and nickel adduct formation constants would have been almost certainly observed. Since this was not the case, the axial positions were probably occupied by isobutanol and the extraction of "solvent-separated" ion pairs occurred. The larger partition constant of Nitrien distearate could reflect tighter bonding of the adduct and consequent increase in shielding of the metal ion.

TABLE 1. Equilibrium constants of nickel(II) and copper(II) triethylenetetramine distearate for the H_2O/cyclohexane–isobutanol solvent pair

Parameter	Value			
	NitrienA$_2$		CutrienA$_2$	
log K_{D_R}	6.2		5.6	
log K_P	3.2		3.4	
log K_{D_C}	1.49	$\binom{+0.10}{-0.13}$	0.87	$\binom{+0.05}{-0.06}$
log K_1		*	2.99	$\binom{+0.23}{-0.51}$
log K_2		*	2.9	$\binom{+0.3}{-1.3}$
log K_1K_2	6.10	$\binom{+0.11}{-0.15}$	6.02	$\binom{+0.08}{-0.09}$

*log K_1 and log K_2 values for nickel were unresolvable.

Basicity of *N*-substituted anilines and pyridine in dimethylsulfoxide

ROBERT L. BENOIT, MOYRA J. MACKINNON, AND LÉON BERGERON[1]

Département de Chimie, Université de Montéal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Received August 8, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

ROBERT L. BENOIT, MOYRA J. MACKINNON, and LÉON BERGERON. Can. J. Chem. **59**, 1501 (1981).

The ionization constants of the conjugated acids BH^+ of aniline, *N*-methyl- and *N*,*N*-dimethylaniline, and pyridine have been determined potentiometrically in Me_2SO. The heats of neutralization of the amines B and their heats of solution have been obtained by calorimetry. The p*K*'s and enthalpies of ionization of these BH^+ ions and alkylammonium ions are linearly related. Comparisons with gas phase data show that the abnormal basicity order of the amines B in Me_2SO is mainly due to the decreasing exothermicity of the heat of solution of the BH^+ ions with the number of N—H protons available for H-bonding to Me_2SO. The large increase in basicity difference between equally substituted aromatic and alkylamines, when passing from the gas phase to Me_2SO, is linked to the larger heat of vaporization of the aromatic amines.

ROBERT L. BENOIT, MOYRA J. MACKINNON et LÉON BERGERON. Can. J. Chem. **59**, 1501 (1981).

Les constantes d'ionisation des acides conjugués BH^+ de l'aniline, de la *N*-méthyl et la *N*,*N*-diméthylaniline, et de la pyridine on été déterminées par potentiométrie dans le Me_2SO. Les chaleurs de neutralisation des amines B et leurs chaleurs de solution ont été obtenues par calorimétrie. On a trouvé une relation linéaire entre les p*K* et les enthalpies d'ionisation de ces ions BH^+ et d'autres ions alkylammonium. Des comparaisons avec des données en phase gazeuse montrent que l'ordre anormal de basicité des amines B dans le Me_2SO est principalement dû à l'exothermicité décroissante de la chaleur de solution des ions BH^+ celle-ci étant fonction du nombre de protons N—H pouvant former des liaisons hydrogène avec le Me_2SO. L'augmentation importante de la différence de basicité entre les amines aromatiques et les alkylamines également substituées, lorsque l'on passe de la phase gazeuse au Me_2SO, provient de la plus grande chaleur de vaporisation des amines aromatiques.

While the acid–base properties of compounds belonging to related series often follow a rational sequence in the gas phase, the sequence can be complex when the compounds are present as solutes. The modifications in the basicity of alkylamines B according to the nature and number of alkyl substituents is a case in point (1, 2). For example, in the gas phase the basicity order is

$$Me_3N > Me_2NH > n\text{-}PrNH_2 > EtNH_2 > MeNH_2 > NH_3$$

while in the solvent dimethylsulfoxide (Me_2SO) the order becomes

$$MeNH_2 \sim EtNH_2 > n\text{-}PrNH_2 > NH_3 \sim Me_2NH \gg Me_3N$$

thus NH_3 is more basic than Me_3N by 2.0 p*K* units. Then in water, the sequence changes to

$$Me_2NH \sim EtNH_2 \sim MeNH_2 \sim n\text{-}PrNH_2 > Me_3N > NH_3$$

so that NH_3 is now a weaker base than Me_3N with a 0.6 p*K* difference. Comparison of amines protonation data in solvents and in the gas-phase provides a full understanding of the solvent effect and reveals some interesting variations in the solvation of both B and BH^+. We have recently reported such a comparison (2) and we present here the results of our work on the solution and protonation of four aromatic amines in Me_2SO, aniline (ϕNH_2), *N*-methyl- ($\phi NHMe$) and *N*,*N*-dimethylaniline (ϕNMe_2), and pyridine (Py). Potentiometric and calorimetric determinations were carried out to provide the necessary data in Me_2SO and some supplementary data in water and CCl_4.

Experimental

Materials

Me_2SO (BDH) was reagent grade. It was dried (water content less than 0.02%) and stored over 4A molecular sieves. Aniline (Anachemia), *N*,*N*-dimethylaniline (Fisher Scientific), and pyridine (BDH, 99.5% purity) were reagent grade and used without further purification. *N*-Methylaniline (Eastman Kodak practical grade) was distilled under reduced pressure and the middle fraction used. Trifluoromethanesulfonic acid (3M Chemical) was used as received, as were tetraethylammonium iodide (Baker reagent grade) after drying 12 h at 50°C and tetraethylammonium perchlorate (Eastman reagent) after similar drying.

Potentiometric Determinations

Potentiometric titrations of Me_2SO solutions of the amines (2×10^{-3} to 1×10^{-2} *M*) with standardized solutions of HCF_3SO_3 in Me_2SO were carried out in a glove box under a stream of dry nitrogen. The solution in the cell was maintained at 25.0°C by means of a jacket through which temperature-controlled water circulated. The electrodes used were a glass electrode (Radiometer G202B) which was calibrated twice with standard HCF_3SO_3 to give a 62.4 ± 0.3 mV slope (intercept: 85.76 ± 0.10 mV, $r = 0.9999$) in a ΔE vs. log [HA] plot, and an I^-/I_3^- reference electrode consisting of a platinum wire in a Me_2SO solution 10^{-2} *M* in I_2 and 2×10^{-2} *M* in Et_4NI (2). The junction consisted of a 0.10 *M* Et_4NClO_4 solution in Me_2SO. An essentially constant ionic strength was maintained in the amine solutions by making them initially 0.1 *M* in Et_4NI. The potentiometer used was a Tacussel Model Aries 10 000–15 562. Titration of the anilines and pyridine, which are weak bases, did not show a

©1981 National Research Council of Canada/Conseil national de recherches du Canada

sharp end-point so their concentration was pre-determined by weight.

Calorimetry

The heats of solution and of neutralization of the liquid amines were measured at 25.0°C with a LKB Model 8725-2 isoperibol calorimeter as previously described (3), the amount of amine dissolved or reacted being known from the weight of the glass ampoules. An excess of 0.1 *M* HCF_3SO_3 in Me_2SO and 0.1 *N* HCl in water were used in the neutralization experiments. For each amine 3–6 separate determinations were made at different concentrations.

Results

Potentiometry

The values of the ionization constants *K* of the ammonium ions BH^+ were obtained from the potentiometric titration curves for each amine B. Analyses were made of each plot giving ΔE against $\log R$ where

$$R = \frac{C_B - (C_{HA} - [H^+])}{C_{HA} - [H^+]}$$

C_B representing the intial amine concentration, and C_{HA} the concentration of added HCF_3SO_3. The average slopes of the plots for $-0.2 < \log R < +0.5$ were respectively 64.2 ± 1.5 mV (ϕNH_2), 63.0 ± 1.0 mV (ϕNHMe), 62.9 ± 1.1 mV (ϕNMe_2), and 63.6 ± 1.4 mV (Py). These values are in satisfactory agreement with 62.4 mV, the calibration slope obtained with HCF_3SO_3, a strong acid in Me_2SO (4). From the values of the half-neutralization potentials, ΔE for $\log R = 0$, the p*K* values listed in Table 1 were calculated and averaged ($\Delta pK \leq 0.02$). Our values for aniline and pyridine are in good agreement with data from previous investigators who used different electrode systems and calibration techniques (1, 5).

Calorimetry

Table 2 presents our values of the heat of solution, ΔH_s^0(B), of the liquid amines in Me_2SO and also of aniline in water. The final concentrations of the amines ranged from 0.03 to 0.3 *M* and since the average deviation of the 3–6 values of the molar heats of solution was less than 2%, the average value was assumed to be equal to ΔH_s^0(B). The solubilities of ϕNHMe and ϕNMe_2 in water are low so that their ΔH_s^0 values for this solvent could not be determined. Literature values of the heat of vaporization ΔH_v^0 of aniline and pyridine (6) are also given in Table 2. Since no values of ΔH_v^0 for ϕNHMe and ϕNMe_2 were available, two methods were used for their estimation. First, the heats of solution of ϕNH_2, ϕNHMe, and ϕNMe_2 were determined in CCl_4 at 25°C and extrapolated to zero concentration since there is a slight concentration effect between 0.02 and 0.06 *M*. The values are listed in Table 2. Then, it was assumed that the heat of vaporization of the three amines from dilute CCl_4 would be equal. This led to the following two ΔH_v^0 values: 52.7 kJ mol^{-1} (ϕNHMe) and 47.7 (ϕNMe_2). In the second method, ΔH_v^0 was estimated from the extrapolated linear relations between ΔH_v^0 and t_{eb} given by Wadsö (7) for aliphatic amines, since we found that the values for ϕNH_2 also obeyed this relation. The ΔH_v^0 values thus obtained were: 56.5 kJ mol^{-1} (ϕNHMe) and 52.7 (ϕNMe_2). The values reported in Table 2 are averages from both methods. Table 3 gives values of $\Delta H_{n,s}^0$ the heat of neutralization of the liquid amines by HCF_3SO_3 in Me_2SO for the reaction

$$B(l) + H^+(s) = BH^+(s)$$

These $\Delta H_{n,s}^0$ values are averages of 4 determinations, the average deviation being less than 3%. The $\Delta H_{n,s}^0$ values for the aqueous neutralization of ϕNHMe and ϕNMe_2, respectively −24.7 ± 2.1 kJ mol^{-1} and −31.4 ± 5.0 kJ mol^{-1} have uncomfortably large margins of error caused by the slow rate of reaction of these poorly soluble amines. The calculated heat of protonation of the amines $\Delta H_{p,s}^0$ for reaction

$$B(s) + H^+(s) = BH^+(s)$$

were obtained by combining ΔH_s^0(B) values from Table 2 and the previous $\Delta H_{n,s}^0$ values. These $\Delta H_{p,s}^0$ values are presented in Table 4.

Discussion

Considering first the ionization constants K of the conjugate acids BH^+ of aniline, N-methyl, and N,N-dimethylaniline, the data in Table 1 indicate that the addition of an N-methyl substituent lowers the anilines basicity in Me_2SO according to

$$\phi NH_2 > \phi NHMe > \phi NMe_2$$

The effect is similar to that found for the methylamines (2) where

$$MeNH_2 > Me_2NH > Me_3N$$

On the other hand the trend of the pK values in water for the three anilinium ions (8) is opposite, and this time in agreement with the expected methyl base-strengthening effect. It is then clear why the pK differences of these BH^+ ions in Me_2SO and water, $pK_s - pK_w$, increase with the number of Me substituents: −0.9 (ϕNH_3^+), −2.0 (ϕNH_2Me^+), −2.6 ($\phi NHMe_2^+$) (Table 1). Values for the pK of a large series of substituted alkylammonium ions BH^+ in Me_2SO and water (1, 2, 5) also exhibit similar trends, although the $pK_s - pK_w$ differences are less negative and change sign: +1.2 (NH_4^+), +0.4 (RNH_3^+), −0.6 ($R_2NH_2^+$), and −1.5 (R_3NH^+), the R_3NH^+ difference being close to that for PyH^+, −1.7.

The data in Tables 1 and 4 for the pK of the conjugate acids BH^+ and the enthalpy of protonation of the amines B in Me_2SO both follow the same basicity sequence

$$\phi NH_2 > Py > \phi NHMe \gtrsim \phi NMe_2$$

The implied correlation between free energy ($\Delta G^0_{i,s} = 5.68\,pK$) and enthalpy of ionization ($\Delta H^0_{i,s} = -\Delta H^0_{p,s}$) of BH^+ ions indicates an ionization entropy contribution $\Delta S^0_{i,s}$ either approximately constant or linearly related to $\Delta H^0_{i,s}$. First, we calculated $\Delta S^0_{i,s}$ and found indeed that the values varied by less than 8.3 J K^{-1} mol^{-1}. However, when we included data for alkylammonium ions (2) and plotted the pK values against $\Delta H^0_{i,s}$ (Fig. 1), we obtained a good straight line,

$$\Delta H^0_{i,s} = 6.855pK + 4.907 (r = 0.997)$$
$$\text{for } 2.5 < pK < 11.0$$

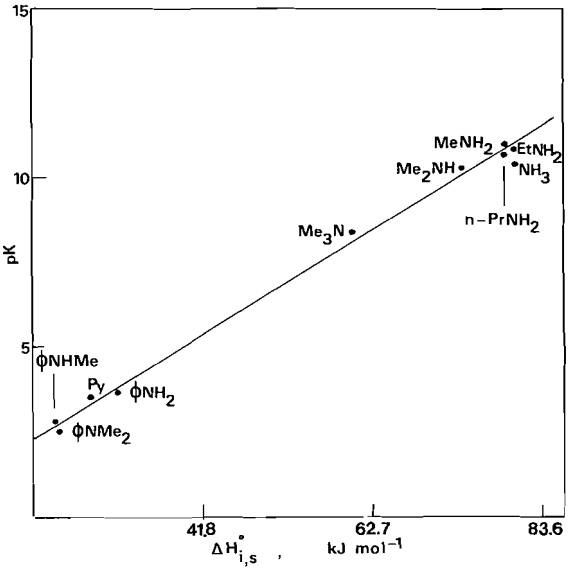

FIG. 1. Constants and enthalpies of ionization of conjugate acids of substituted amines in dimethylsulfoxide.

This is evidence of a clear enthalpy–entropy type relationship (9) since both $\Delta H^0_{i,s}$ and $pK(\Delta G^0_{i,s})$ are independently determined. We have recently found a similar relationship for HCl and 8 carboxylic acids ($2.0 < pK < 11.5$) in Me_2SO (10):

$$\Delta H^0_{i,s} = 5.43pK - 15.9 (r = 0.983)$$

while Arnett *et al.* (11) obtained

$$\Delta H^0_{i,s} = 5.64pK + 2.5 (r = 0.97)$$

for 12 weaker acids ($10 < pK < 30$) but an average slope of 7.06 for the correlation line for the deprotonation of neutral anilines and diphenylamines. Not only the slopes of the lines then depend on the class of acids but they also vary with the dipolar aprotic solvent used (10).

The basicity sequence obtained in Me_2SO

$$\phi NH_2 > Py > \phi NHMe \gtrsim \phi NMe_2$$

is at odds with the intrinsic gas phase order

$$\phi NH_2 < \phi NHMe < Py < \phi NMe_2$$

deduced from the amines proton affinity ($PA = -\Delta H^0_{p,g}$) (12, 13) listed in Table 4. This quasi-reversal of the basicity order in Me_2SO can be analyzed by using a thermodynamic cycle to relate the protonation processes in both media. The following equation is then deduced to connect both enthalpies of protonation:

$$[1]\quad \Delta H^0_{p,s} = \Delta H^0_{p,g} - \Delta H^0_s(B)_g + \Delta H^0_s(BH^+)_g - \Delta H^0_s(H^+)_g$$

with

$$\Delta H^0_s(B)_g = -\Delta H^0_v(B) + \Delta H^0_s(B)$$

TABLE 5. Heats of solution of gaseous amines B and BH^+ ions in Me_2SO (in kJ mol^{-1} at 25°C)

[a]Reference 2.

where $\Delta H_s^0(X)_g$ is the enthalpy of solution of gaseous X. The corresponding free energy equation could not be used here because the low volatility of the anilines made the determination of $\Delta G_s^0(B)_g$ impracticable. We calculated $\Delta H_s^0(BH^+)_g$ from eq. [1], data in Tables 4, 2 and $\Delta H_s^0(H^+)_g = -1154.1$ kJ mol^{-1} (2). The values of $\Delta H_s^0(BH^+)_g$, as well as those of $\Delta H_s^0(B)_g$ obtained from data in Table 2, are listed in Table 5. These data show conclusively that the increasing exothermicity of the gas-phase protonation in the order $\phi NH_2 < \phi NHMe < \phi NMe_2$ is reversed in Me_2SO essentially because the heat of solution of BH^+ ions becomes much less exothermic according to $\phi NH_3^+ > \phi NH_2Me^+ > \phi NHMe_2^+$. The changes in $\Delta H_s^0(B)_g$ have a small opposite effect. When comparing ϕNMe_2 and Py, the basicity reversal in Me_2SO is due to changes in both $\Delta H_s^0(BH^+)_g$ and $\Delta H_s^0(B)_g$, the latter being now more important.

We can now compare the values of $\Delta H_s^0(BH^+)_g$ for the anilinium and pyridinium ions with values for the methylammonium ions $MeNH_3^+$, $Me_2NH_2^+$, and Me_3NH^+ (2) listed in Table 5. We see that the heat of solution in Me_2SO is nearly the same for each pair of primary and secondary ammonium ions and for the three tertiary ammonium ions. This corroborates previous findings (2, 14) that the exothermic heat of solution of substituted ammonium ions $R_{4-n}NH_n^+$ decreases with the number n of N—H protons which can H-bond to the solvent, the size of the substituent R being of lesser importance. There is an interesting consequence of the closeness of the heats of solution of equally substituted ammonium ions in both methylamine and aniline series. In the gas phase, the anilines are only slightly less basic than the corresponding methylamines: for example, the proton affinity of ϕNH_2 is only 10.9 kJ mol^{-1} less than that of $MeNH_2$ (i.e. 1.8 units on the pK scale). In contrast, in Me_2SO the corresponding heats of protonation differ by 48.1 kJ mol^{-1} (i.e. 8.4 units on the pK scale), the pK's being 3.7 and 10.9 respectively (Fig. 1), so that ϕNH_2 is now a much weaker base than $MeNH_2$. Since the heat of solution of ϕNH_3^+ und $MeNH_3^+$ are nearly identical (Table 5), the 37.7 kJ mol^{-1} increase in basicity difference between ϕNH_2 and $MeNH_2$ from the gas phase to Me_2SO must come from a large difference in the heat of solution of gaseous ϕNH_2 and $MeNH_2$, and this is indeed shown by the $\Delta H_s^0(B)$ values in Table 5, −64.8 and −26.8 kJ mol^{-1} respectively. The same comparisons could be made between $\phi NHMe$ and Me_2NH on the one hand, and ϕNMe_2, Py, and NMe_3 on the other hand. We can then conclude that the much weaker basicity of the anilines and pyridine in Me_2SO when compared with that of the alkylamines comes from a much larger heat of solution of the gaseous aromatic amines. Moreover since the heats of solution of the liquid alkylamines in Me_2SO are low (2), as are also those of the aromatic amines (the most exothermic one if for ϕNH_2 probably because of H-bonding) (Table 2), we can further advance that the large increase in basicity difference between the aromatic and alkylamines, when passing from the gas phase to Me_2SO, is essentially due to the larger heat of vaporization of the aromatic amines (i.e. 55.6 kJ mol^{-1} for ϕNH_2 against 24.3 kJ mol^{-1} for $MeNH_2$).

Nuclear magnetic resonance studies of the solution chemistry of metal complexes. XVII. Formation constants for the complexation of methylmercury by sulfhydryl-containing amino acids and related molecules

R. Stephen Reid and Dallas L. Rabenstein[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 26, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

R. Stephen Reid and Dallas L. Rabenstein. Can. J. Chem. **59**, 1505 (1981).

Complexation of methylmercury, $CH_3Hg(II)$, by mercaptoacetic acid, mercaptoethanol, mercaptosuccinic acid, cysteine, penicillamine, homocysteine, and *N*-acetylpenicillamine has been studied by ^1H nuclear magnetic resonance spectroscopy. The equilibrium constant for displacement of mercaptoacetic acid from its $CH_3Hg(II)$ complex by each of the other thiols was measured over a wide range of pH. From the displacement constants and a literature value for the formation constant of the mercaptoethanol complex of $CH_3Hg(II)$, formation constants were calculated for thiol complexes with the other ligands, including microscopic formation constants for cysteine and penicillamine complexes in which the amino groups are protonated and deprotonated. Detailed information on the acid–base chemistry of the free amino and carboxylic acid groups in the complexes is also reported. The formation constants increase as the Brønsted basicity of the deprotonated sulfhydryl group increases according to the relation $\log K_f = pK + 6.86$. The conditional formation constants of the $CH_3Hg(II)$ complexes are strongly pH dependent due to competitive reactions involving hydrogen and hydroxide ions at low and high pH. The results at physiological pH are discussed with reference to the effectiveness of mercaptosuccinic acid, *N*-acetylpenicillamine, and penicillamine as antidotes for methylmercury poisoning.

R. Stephen Reid et Dallas L. Rabenstein. Can. J. Chem. **59**, 1505 (1981).

Utilisant la spectroscopie de rmn du ^1H, on a étudié la complexation du méthylmercure, $CH_3Hg(II)$, par l'acide mercaptoacétique, le mercaptoéthanol, l'acide mercaptosuccinique, la cystéine, la pénicillamine, l'homocystéine et la *N*-acétylpénicillamine. Dans un large intervalle de pH, on a mesuré la constante d'équilibre de la réaction de déplacement de l'acide mercaptoacétique de son complexe avec le $CH_3Hg(II)$ par chacun des autres thiols. En utilisant les constantes de déplacement et les données de la littérature relatives à la constante de formation du complexe de $CH_3Hg(II)$ avec le mercaptoéthanol, on a calculé les constantes de formation des complexes de thiol avec d'autres ligands en incluant les constantes de formation microscopiques des complexes de la cystéine et de la pénicillamine dans lesquels les groupes amino sont protonés et déprotonés. On rapporte également une information détaillée de la chimie acide–base des groupes carboxyliques libres de ces complexes. Les constantes de formation augmentent avec la basicité de Brønsted du groupe sulfhydryle déprotonée selon l'équation: $\log K_f = pK + 6{,}86$. Les constantes de formation conditionnelle des complexes de $CH_3Hg(II)$ dépendent fortement du pH à cause des réactions compétitives qui font intervenir les ions hydrogènes et hydroxyles aux pH faible et élevé. On discute des résultats au pH physiologique dans le but d'évaluer l'efficacité de l'acide mercaptosuccinique, de la *N*-acétylpénicilline et de la pénicillamine comme antidotes lors d'empoisonnement par le méthylmercure.

[Traduit par le journal]

Introduction

Mercury ions bind strongly to sulfur donor groups. For example, methylmercury(II) ($CH_3Hg(II)$) binds preferentially to the sulfhydryl group of amino acids and small peptides from $pH < 1$ to >13 (1, 2). Since the toxicity of mercury results from the formation of such complexes, a good understanding of their solution chemistry is desirable. Surprisingly, however, detailed stability data are sparse, due possibly to the difficulty in measuring such large stability constants. Schwarzenbach and Schellenberg (3) measured the formation constant of the $CH_3Hg(II)$–mercaptoethanol complex potentiometrically, using competition with iodide to lower the equilibrium constant into a measurable range. Simpson (4) estimated formation constants for the $CH_3Hg(II)$ complexes of cysteine and glutathione by means of halide competition and toluene extraction.

This paper reports formation constants for the $CH_3Hg(II)$ complexes of several thiol and amino acids of biological and pharmaceutical interest. The formation constants have been measured by allowing two thiols, RSH and R′SH, to compete for $CH_3Hg(II)$.

$$RSHgCH_3 + R'S^- \overset{K_d}{\rightleftharpoons} RS^- + R'SHgCH_3$$

K_d has been determined from ^1H nmr chemical shift data. Since two thiols are competing for the $CH_3Hg(II)$, K_d is relatively small and the equilibrium position can be measured precisely. Mercaptoacetic acid (MAA), which displays only a single ^1H resonance in aqueous solution, is used as one of the thiols throughout in competition experiments with mercaptoethanol (ME), penicillamine (PSH), *N*-

acetylpenicillamine (NPSH), cysteine (CYS), homocysteine (HCYS), and mercaptosuccinic acid (MSA). The formation constant for the mercaptoacetic acid complex is obtained from the K_d for the competition experiment with mercaptoethanol and the formation constant for the mercaptoethanol complex (3). Formation constants for the other complexes are then obtained from competition experiments with the other thiols. Various other parameters, including acid dissociation constants for $CH_3Hg(II)$-complexed species, are obtained simultaneously. The characterization of the solution chemistry of the complex is then complete, and the apparent thiol affinity for $CH_3Hg(II)$ can be predicted at any pH.

Experimental

Chemicals

Mercaptoethanol, mercaptoacetic acid (Eastman Kodak Co.), cysteine, penicillamine, 2-mercaptosuccinic acid (Aldrich Chem. Co.), *N*-acetylpenicillamine (Sigma Chem. Co.), and homocysteine (Nutritional Biochemicals Corp.) were used as received. The determination of purity and preparation of solutions is described below.

Methylmercury(II) iodide (Alfa Division, Ventron Corp.) was converted to a solution of methylmercury(II) hydroxide by reaction with silver oxide. In a typical preparation, 0.100 mol of Ag_2O was reacted with 0.022 mol of CH_3HgI in 50 mL of water. Since Ag_2O is sparingly soluble in water, the more water-insoluble CH_3HgI was used in slight excess to ensure no silver contamination of the product solution. After stirring for 10 h, the solution was vacuum filtered through paper and then through a 0.2 μm Nalgene millipore filter (Nalge Sybron Corp.), and diluted to volume in a 100 mL volumetric flask. The solution was standardized with respect to $CH_3Hg(II)$ by titration with chloride (1). The conversion of CH_3HgI to CH_3HgOH was quantitative with respect to the equivalents of silver ion added. Because of the toxicity of $CH_3Hg(II)$, this concentrated stock solution was opened only in the fumehood, and handled with gloves.

Iodoacetamide (Aldrich Chem. Co., Sigma Chem. Co.) was used as received. All other chemicals were reagent grade and were used without further purification. Water used in making solutions was doubly distilled and deionized by passage through a Barnstead D8902 Ultrapure mixed bed ion-exchange resin.

pH Measurements

All pH measurements were made at 25 ± 1°C with an Orion Model 701 digital pH meter, equipped with either a standard glass electrode – porous ceramic junction reference electrode pair, or a microcombination electrode. Fisher certified buffers of nominal pH values 4.00, 7.00, and 10.00 were used for three-point calibration of the pH meter. The exact pH of each of these buffers was established, and periodically checked, by comparison with freshly prepared N.B.S. pH standard solutions (5).

^1H Nuclear Magnetic Resonance Measurements

^1H nmr spectra were obtained on a Varian A60D spectrometer at a probe temperature of 25 ± 1°C. Spectra were recorded at a sweep rate of 0.1 Hz s^{-1}. Chemical shifts were measured relative to either the central resonance of the triplet for the tetramethylammonium ion or the singlet for 1,4-dioxane. A small amount of the reference compound was added to solutions before pH adjustments. Chemical shifts are reported relative to the methyl resonance of sodium 2,2-dimethyl-2-silapentane-5-sulphonic acid (DSS). Positive shifts correspond to resonances of protons less shielded than the methyl protons of DSS.

Solution Preparation

(i) Thiol solutions. Procedures used for preparation of thiol solutions were designed to minimize oxidation of the sulfhydryl group. Na_2H_2EDTA was added to freshly deionized water to a concentration of 2×10^{-5} *M*. The solution was purged with argon, and then thiol was added in an amount to give a concentration of ~0.3 *M*. When necessary, the final pH was adjusted to <7 by the addition of nitric acid. With the exception of *N*-acetylpenicillamine, the thiols are all readily soluble at the 0.3 *M* level. To attain this concentration with *N*-acetylpenicillamine, the pH was repeatedly increased to ~6 following the addition of small amounts of *N*-acetylpenicillamine. After filling the air space with argon, the flasks were stoppered and stored at 4°C. Under these conditions, the thiols appeared to show little oxidation with time, as determined by the iodoacetamide procedure described below (6). Homocysteine, the least stable, showed only slight oxidation after 2 days. At the other extreme, mercaptoacetic acid showed no measurable loss of thiol content over a period of 4 months.

The thiol content of the stock solutions was determined by reaction of the thiol with iodoacetamide, followed by reaction of the protons displaced from the thiol group with strong base (6). For the concentration of protons displaced and titrated to equal the concentration of sulfhydryl group, the initial and final pH must be the same, and also low enough to ensure that the thiol is quantitatively in the RSH form. However, to obtain precise endpoints, the pH should also be in a region where buffering does not occur. To illustrate, details will be given here for standardization of mercaptoacetic acid solutions. Since the p*K*'s of the carboxyl and sulfhydryl groups of MAA are 3.50 and 10.08, the above conditions are satisfied at pH 7. So that reaction would occur in a reasonable time, the pH was raised to approximately 9 midway through the reaction. pH adjustments were followed and endpoints located by color matching using mixtures of phenolphthalein and bromothymol blue. This mixture of indicators is yellow at low pH, through green at pH 7 to blue, and then purple above pH 9. The mixture of indicators was added to water, the solution purged with argon for 5 min, and an aliquot of the MAA stock solution added. The solution was brought to pH 7. Iodoacetamide (0.2 g in 5 mL of water) was added to the flask, followed by a measured amount of standardized base to raise the pH to 9. As reaction proceeded and the pH decreased, more base was added to maintain the pH at 9. When reaction was complete (generally after 2 min), the solution was titrated back to pH 7 with standardized acid. Three or four replicate titrations were normally done, with a precision of 5 ppt or better.

This procedure gave satisfactory results for mercaptoacetic acid and mercaptosuccinic acid. For ligands with a sulfhydryl p*K* below 10, a similar procedure employing an initial and final pH of 5 and a methyl red/phenolphthalein indicator system was used. For all standardizations, a blank titration was performed.

(ii) Solutions for pK measurements. In cases where no literature p*K* values were available, or where those available were considered questionable, they were determined by ^1H nmr. Solutions were 0.05–0.10 *M* in the compound of interest, and the ionic strength was brought to 0.3 *M* by adding KNO_3. Typically, 10 to 30 mL of solution were prepared under argon, and the pH was adjusted to the highest value desired with KOH. Solution (0.3 mL) was then trans-

TABLE 1. Acid dissociation constants for the thiol ligands[a,b,c]

ferred to an nmr tube, and the tube was flushed with argon before being capped. Nitric acid was then added to adjust the pH, and the next sample removed. Following each adjustment of pH, the approximate ionic strength was calculated, and KNO_3 or distilled water added as necessary to restore the ionic strength to 0.3 *M*.

(iii) Solutions for formation constant measurements. The main requirement in preparing solutions for the formation constant determinations was that the relative amounts of MAA, $CH_3Hg(II)$, and competing thiol be known. Usually the mole ratio was 1:1:1. The procedure followed was to first prepare a MAA–$CH_3Hg(II)$ solution having an exact 1:1 stoichiometry, and then to add the desired amount of competing thiol stock solution. The 1:1 stoichiometry for the MAA–$CH_3Hg(II)$ solution was achieved with an nmr titration procedure. Sufficient MAA stock solution to make the final solution 0.07 *M* in MAA was transferred to a beaker. An amount of $CH_3Hg(II)$ stock solution corresponding to 99% of the MAA was then added, the volume adjusted with water, and the pH increased to ~12 with base. A 0.3 mL sample was transferred to an nmr tube. The additional amount of $CH_3Hg(II)$ solution necessary to give a 1:1 stoichiometry was calculated from the chemical shift of the MAA singlet resonance, which is the weighted average of that for the free and the complexed MAA due to rapid ligand exchange. The competing thiol ligand was then added and samples for ^1H nmr measurements were withdrawn as the pH was lowered with nitric acid. To maintain a reasonably constant ionic strength, the necessary amount of KNO_3 was added to give an initial ionic strength of 0.40 *M*. The nitric acid solution used for pH adjustment was 0.3 *M* in KNO_3. Calculations indicate that the ionic strength remained between 0.4 and 0.25 *M*. Activity coefficients, as estimated by the Davies equation (7), vary only slightly in this ionic strength range.

Results

Determination of Acid Dissociation Constants

Reliable literature values were available for the acid dissociation constants of most of the ligands. Ionic strength corrections to the present conditions were made using the Davies equation (7). The values so obtained are listed in Table 1.

Because of the lack of agreement among literature values for MAA (8–11) and the central nature of MAA to this work, its acid dissociation constants were redetermined. The equilibria and associated constants are:

[1] $HSCH_2CO_2H \rightleftarrows HSCH_2CO_2^- + H_3O^+$

For personal use only.

$$[2] \quad K_1 = \frac{[HSCH_2CO_2^-]a_{H_3O^+}}{[HSCH_2CO_2H]}$$

$$[3] \quad HSCH_2CO_2^- \rightleftarrows {}^-SCH_2CO_2^- + H_3O^+$$

$$[4] \quad K_2 = \frac{[{}^-SCH_2CO_2^-]a_{H_3O^+}}{[HSCH_2CO_2^-]}$$

K_1 and K_2 are mixed concentration–activity constants, as are all the other constants listed in Table 1. Proton exchange involving the various MAA species is rapid on the nmr time scale. The chemical shift of the exchange-averaged resonance is the weighted average of the chemical shifts of the various species:

$$[5] \quad \delta_{obs} = P_1\delta_1 + P_2\delta_2 + P_3\delta_3$$

where δ_{obs} is the observed chemical shift, δ_1, δ_2, and δ_3 the chemical shifts, and P_1, P_2, P_3 the fractional concentrations of $HSCH_2CO_2H$, $HSCH_2CO_2^-$, and ${}^-SCH_2CO_2^-$ respectively. P_1, P_2, and P_3 can be expressed in terms of K_1 and K_2, which leads to:

$$[6] \quad \delta_{obs} = (a_{H^+}{}^2\delta_1 + a_{H^+}K_1\delta_2 + K_1K_2\delta_3)/D$$

where $D = a_{H^+}{}^2 + a_{H^+}K_1 + K_1K_2$. δ_1, δ_2, and δ_3 were determined by inspection from Fig. 1*A*. K_1 and K_2 were obtained by fitting chemical shift vs. pH data for MAA to eq. [6] using the nonlinear least-squares curve fitting program KINET (12). Satisfactory correlations were observed in this and all cases discussed. The results for MAA are listed in Table 1. For comparison, literature values are: $pK_1 = 3.40$ and $pK_2 = 10.07$ (8); $pK_1 = 3.53$ (9); $pK_1 = 3.27$, $pK_2 = 10.05$ (10); and $pK_1 = 3.53$ and $pK_2 = 10.40$ (11).

The acid dissociation constant for the carboxylic acid group of homocysteine (K_1 in Table 1) was measured since no literature value was available. The method used was similar to that for MAA, except that the system was treated as a monoprotic acid since dissociation of the carboxylic acid group is essentially complete before dissociation of the sulfhydryl and ammonium groups begins. The resonance pattern for the methine proton on the α carbon was used.

Acid dissociation constants were also determined for the carboxylic and ammonium groups of the sulfhydryl-complexed ligands. To distinguish them from acid dissociation constants for the free ligands, they are primed, e.g. K_1'. In most cases, these constants were obtained from the formation constant studies, as described below. The exceptions are the acid dissociation constants for the carboxylic groups of CH_3Hg(II)-complexed MAA and *N*-acetylpenicillamine, which were determined directly from the exchange-averaged chemical shifts of ligand resonances. For the MAA complex, the resonance

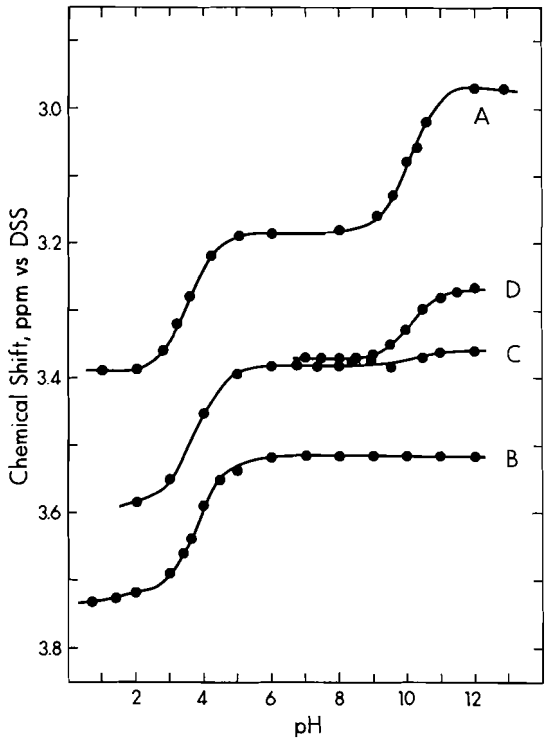

FIG. 1. pH dependence of the chemical shift of mercaptoacetic acid (MAA) in solutions containing (*A*) 0.10 *M* MAA, (*B*) 0.10 *M* MAA and 0.10 *M* CH_3Hg(II), (*C*) 0.10 *M* MAA, 0.10 *M* CH_3Hg(II), and 0.10 *M* mercaptoethanol, and (*D*) 0.10 *M* MAA, 0.10 *M* CH_3Hg(II), and 0.10 *M* *N*-acetylpenicillamine. 0.25–0.4 *M* ionic strength and 25°C. The solid curves are theoretical curves calculated from formation constants determined in this work. Approximately one-half the experimental points are shown.

for the methylene protons of MAA was used; for the *N*-acetylpenicillamine complex, the chemical shift separation between the resonances for the nonequivalent methyl groups of *N*-acetylpenicillamine was used. Results are reported in Table 2.

Determination of Formation Constants

Formation constants for the CH_3Hg(II)–thiol complexes were determined from the exchange-averaged chemical shift measured over a wide range of pH values, of the MAA resonance in solutions containing MAA, CH_3Hg(II), and the various thiols. For example, chemical shift data are shown in Fig. 1 for the methylene protons of MAA in (*A*) a solution containing only free MAA, (*B*) a solution containing the CH_3Hg(II)–MAA complex, and (*C*) a solution containing MAA, CH_3Hg(II), and mercaptoethanol in a 1:1:1 ratio. Throughout the entire pH range, curve *C* lies between curves *A* and *B*, indicating displacement of some of the complexed MAA by ME and fast exchange of the MAA between its free and complexed forms. Also, the position of

[a]25°C and 0.3 *M* ionic strength.

curve *C* relative to curves *A* and *B* is pH-dependent, indicating that the relative affinities of MAA and ME for $CH_3Hg(II)$ are pH-dependent.

The calculation procedure will be illustrated for the general case with the competing thiol RSH. At high pH, the ligand exchange reaction is

$$[7] \quad RS^- + CH_3HgSCH_2CO_2^- \rightleftarrows RSHgCH_3 + {}^-SCH_2CO_2^-$$

for which we define a displacement constant

$$[8] \quad K_d = \frac{[RSHgCH_3][{}^-SCH_2CO_2^-]}{[RS^-][CH_3HgSCH_2CO_2^-]} = \frac{K_{f,RSH}}{K_{f,MAA}}$$

where

$$[9] \quad K_{f,RSH} = \frac{[CH_3HgSR]}{[CH_3Hg^+][RS^-]}$$

$$[10] \quad K_{f,MAA} = \frac{[CH_3HgSCH_2CO_2^-]}{[CH_3Hg^+][{}^-SCH_2CO_2^-]}$$

K_d does not depend upon $[CH_3Hg^+]$, and thus the changes in speciation of $CH_3Hg(II)$ in solution with pH (13) need not be considered. For systems having a MAA:$CH_3Hg(II)$:RSH mole ratio of 1:1:1, substitution of eqs. [9], [10], and the acid dissociation constant expressions for the various acidic groups into eq. [8], yields the equation

$$[11] \quad K_d = \left(\frac{P_f}{1 - P_f}\right)^2 \frac{\alpha_1\alpha_3}{\alpha_2\alpha_4}$$

where P_f is the fraction of MAA present in the free, uncomplexed form, α_1 is the fraction of this MAA in the fully deprotonated form ($= K_1K_2/(a_{H^+}{}^2 + a_{H^+}K_1 + K_1K_2)$), α_2 is the fraction of $CH_3Hg(II)$-complexed MAA present in the $CH_3HgSCH_2CO_2^-$ form ($= K_1'/(a_{H^+} + K_1')$), α_3 is the fraction of the complexed RSH in the fully deprotonated form, and α_4 is the fraction of the free RSH in the fully deprotonated form. Equations for α_3 and α_4 for the various competing thiols are given below.

P_f was determined over a range of pH values from the exchange-averaged chemical shift of the MAA methylene resonance, whose observed chemical shift, δ_{obs}, is given by

$$[12] \quad \delta_{obs} = \delta_f P_f + (1 - P_f)\delta_c$$

δ_f and δ_c are the chemical shifts of the free and complexed forms. Rearrangement of eq. [12] gives

$$[13] \quad P_f = \frac{\delta_{obs} - \delta_c}{\delta_f - \delta_c}$$

P_f was calculated at each sample pH using δ_{obs} and calculated values for δ_f and δ_c. In these calculations, K_1, K_2, and K_1' for MAA and the $CH_3Hg(II)$–MAA complex were set equal to the values determined above. K_d and any unknown acid dissociation constants for the $CH_3Hg(II)$-complexed form of the competing thiol were then calculated by fitting the P_f vs. pH data to eq. [11] using the non-linear least-squares curve fitting program KINET (12). $K_{f,RSH}$ was calculated from K_d using the relation $K_{f,RSH} = K_{f,MAA}K_d$.

$K_{f,MAA}$ was calculated from K_d for the MAA–$CH_3Hg(II)$–mercaptoethanol system, using the value reported by Schwarzenbach and Schellenberg for $K_{f,mercaptoethanol}$ (3). For the mercaptoethanol system, $\alpha_3 = 1$ and $\alpha_4 = K_1/(a_{H^+} + K_1)$ where K_1 is the acid dissociation constant for mercaptoethanol. K_d is calculated to be 0.16 ± 0.01 from the data in Fig. 1*C*. The formation constant calculated for the MAA complex is listed in Table 3. The quality of the fit can be judged by the agreement between the experimental points of Fig. 1*C* and the smooth curve,

which was calculated using the derived formation constant.

Chemical shift vs. pH data for the competition experiment with *N*-acetylpenicillamine are shown in Fig. 1*D*. Samples were prepared over the pH region 12 to 1.5. However, as the pH was lowered from 12, the MAA resonance became very broad due to relatively slow exchange of MAA between its free and complexed forms in this region. Below pH 7, no signal was observed. Since the amide group of *N*-acetylpenicillamine is nonbasic, the molecule has only two ionizable groups. Its acid–base scheme is therefore identical to that of MAA, differing only in the values of the dissociation constants. However, since at pH 7 the carboxylic acid group is fully deprotonated in the free and bound forms, the data above pH 7 can be fitted to the same scheme as used for the mercaptoethanol system. Non-linear least-squares calculations yielded $K_d = 0.70 \pm 0.02$, from which the formation constant listed in Table 3 for the *N*-acetylpenicillamine complex was calculated.

Chemical shift vs. pH data for the penicillamine system are shown in Fig. 2*C*. Penicillamine is a triprotic acid, whose acid–base chemistry is further complicated by the dissociation of the sulfhydryl and ammonium groups over approximately the same pH range (14). A full description of its acid–base chemistry at the molecular level requires the use of microconstants (Fig. 3); however the definition of K_d in eq. [7] is in terms of fully-deprotonated species, which can be calculated using the macroscopic acid dissociation constants K_1, K_2, and K_3 for PSH. Thus α_3 in eq. [11] is $K_1K_2K_3/(a_{H^+}{}^3 + K_1a_{H^+}{}^2 + K_1K_2a_{H^+} + K_1K_2K_3)$. The $CH_3Hg(II)$ complex of

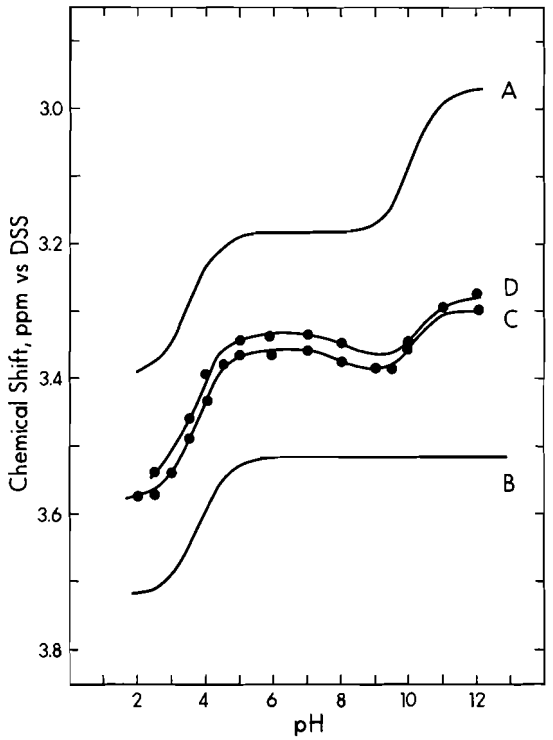

FIG. 2. pH dependence of the chemical shift of MAA in solutions containing (*A*) 0.10 *M* MAA, (*B*) 0.10 *M* MAA and 0.10 *M* $CH_3Hg(II)$, (*C*) 0.10 *M* MAA, 0.10 *M* $CH_3Hg(II)$, and 0.10 *M* penicillamine, and (*D*) 0.10 *M* MAA, 0.10 *M* $CH_3Hg(II)$, and 0.10 *M* cysteine. 0.25–0.4 *M* ionic strength and 25°C. Approximately one-half the experimental points are shown.

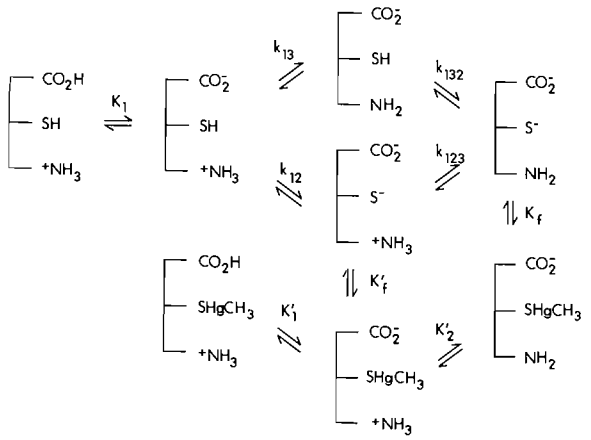

FIG. 3. Microscopic acid–base and complexation equilibria for cysteine and penicillamine in solutions containing $CH_3Hg(II)$.

PSH has two acidic groups. Assigning K_1' and K_2' respectively to the carboxylic acid and ammonium groups $\alpha_4 = K_1'K_2'/(a_{H^+}{}^2 + K_1'a_{H^+} + K_1'K_2')$. K_d, K_1', and K_2' were obtained by fitting the data in Fig. 2*C* to eq. [11]. The value obtained for $K_d = 1.06 \pm 0.02$; those obtained for K_1' and K_2' are listed in Table 2. The formation constant calculated for the $CH_3Hg(II)$ complex with the fully deprotonated form of PSH is listed in Table 3. Using this value for K_f, the value for K_2' in Table 2 and the value in Table 1 for the microscopic acid dissociation constant k_{123}, the microscopic formation constant listed in Table 3 for the complexation of $CH_3Hg(II)$ by the amino protonated form of penicillamine (K_f') was calculated with the relation $K_f' = k_{123}K_f/K_2'$.

Data for the cysteine, homocysteine, and mercaptosuccinic acid systems are presented in Figs. 2*D*, 4*C*, and 4*D*, respectively. The acid–base chemistry of the free forms of each of these ligands and their $CH_3Hg(II)$ complexes can be described by the same macroscopic dissociation schemes as for PSH and its $CH_3Hg(II)$ complex. Thus α_3 and α_4 are defined as for the PSH system. Fitting of the data in Figs. 2*D*, 4*C*, and 4*D* yielded $K_d = 0.57 \pm 0.01$, 0.34 ± 0.005, and 2.50 ± 0.06 for the cysteine, homocysteine, and mercaptosuccinic acid systems and the values listed in Table 2 for K_1' and K_2'. The values calculated for K_f for each of the complexes with the fully deprotonated ligands are given in Table 3.

The microscopic formation constant K_f' listed in Table 3 for complexation of $CH_3Hg(II)$ by the amino-protonated form of cysteine was calculated as described above for the penicillamine complex. K_f' could not be calculated for the analogous homocysteine complex because microscopic acid dissociation constants are not available for homocysteine.

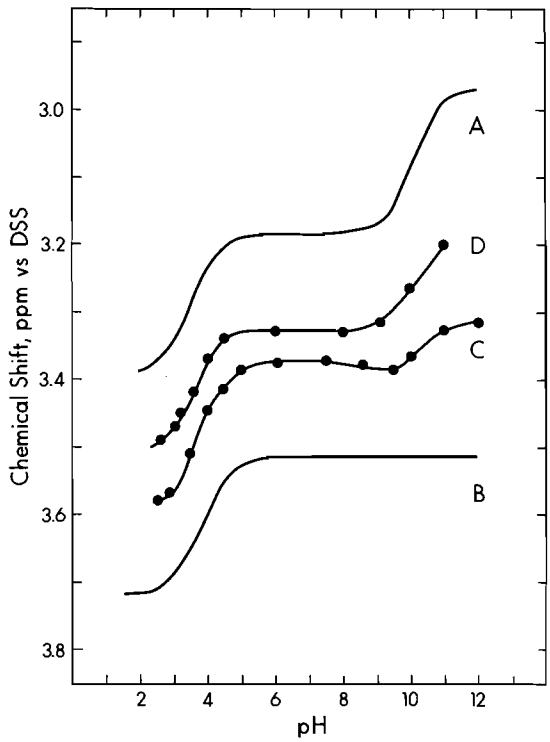

FIG. 4. pH dependence of the chemical shift of MAA in solutions containing (*A*) 0.1 *M* MAA, (*B*) 0.10 *M* MAA and 0.10 *M* $CH_3Hg(II)$, (*C*) 0.10 *M* MAA, 0.10 *M* $CH_3Hg(II)$, and 0.10 *M* homocysteine, and (*D*) 0.10 *M* MAA, 0.10 *M* $CH_3Hg(II)$, and 0.10 *M* mercaptosuccinic acid. 0.25–0.4 *M* ionic strength at 25°C. Approximately one-half the experimental points are shown.

Discussion

The thiol ligands studied contain various combinations of carboxylate, amino, and sulfhydryl groups, all of which can complex $CH_3Hg(II)$. Most of these ligands can form chelate complexes; however, the mercury in $CH_3Hg(II)$ has a strong tendency towards linear two-coordination (2). The complexation of $CH_3Hg(II)$ by these ligands is therefore considered to involve binding to a single donor group. Since previous experiments have shown that the sulfhydryl group binds $CH_3Hg(II)$ most strongly over the pH range <1 to >13 (1, 2) and since the competition experiments were performed with a thiol to $CH_3Hg(II)$ stoichiometry of 2:1, we can assume that only sulfhydryl complexes are formed. Crystallographic studies have shown the $CH_3Hg(II)$ in $CH_3Hg(II)$–cysteine and $CH_3Hg(II)$–penicillamine complexes of 1:1 stoichiometry to be bonded to the deprotonated sulfhydryl group (21, 22).

The acid dissociation constants for the ammonium and carboxylic acid groups of the $CH_3Hg(II)$-complexed ligands (Table 2) show no trend due to

$CH_3Hg(II)$ complexation. For example, complexation of the sulfhydryl groups of mercaptoacetic acid, penicillamine, cysteine, and mercaptosuccinic acid causes a decrease in the acidity of the carboxylic acid group, whereas complexation of the sulfhydryl groups of *N*-acetylpenicillamine and homocysteine causes, respectively, an increase and no change in the acidity of their carboxylic acid groups. The acid dissociation constants for the ammonium groups of the sulfhydryl complexed forms of both cysteine and penicillamine are closer to k_{13} than to k_{123} in the microscheme shown in Fig. 4. This was also found for the analogous trimethyllead(IV) ($(CH_3)_3Pb(IV)$) complexes of these ligands (15). It appears that, when complexed to the sulfhydryl group, both $CH_3Hg(II)$ and $(CH_3)_3Pb(IV)$ closely mimic a similarly bonded hydrogen ion, in terms of their effect on the acid strength of neighboring ammonium groups.

Although the $CH_3Hg(II)$ is bonded to the deprotonated sulfhydryl group in each of the complexes, formation constants listed in Table 3 cover a range of values. The plot of log K_f vs. pK of the thiol group in Fig. 5 clearly shows the Brønsted basicity of the deprotonated sulfhydryl group to be a major factor in determining the magnitude of the formation constant. From the results in Fig. 5, which also include formation constants for $CH_3Hg(II)$ complexes of fully deprotonated glutathione (h) and amino-protonated glutathione (i), the relation between formation constant and acid dissociation constant is found to be log K_f = pK + 6.86. A similar dependence has been reported for carboxylic acid complexes of $CH_3Hg(II)$ (23).

It is worth comparing the formation constant determined in this work for the cysteine complex with that reported by Simpson (4). The latter is one of few values in the literature for complexation of $CH_3Hg(II)$ by a biological thiol ligand and consequently has been used in many discussions of the chemistry of $CH_3Hg(II)$ in biological systems. The constant reported by Simpson is an "association constant", which was calculated in terms of the macroscopic acid–base chemistry of cysteine rather than the microscheme shown in Fig. 4. Thus this constant actually reflects a composite of complexation, sulfhydryl acid–base, and amino acid–base behavior. Recalculation of Simpson's association constant using more recent pK values for cysteine (18) yields a value of 15.3. The "association constant" calculated from the formation constant determined in this work is 15.2. Similar agreement is observed for the glutathione–$CH_3Hg(II)$ complex association constants (25).

Such good agreement is not obtained with the results of Hojo *et al.* for the $CH_3Hg(II)$ complexes of penicillamine and cysteine (26). CH_3HgCl was used as the source of $CH_3Hg(II)$ in that study, but no mention was made of correcting for the competitive complexation of $CH_3Hg(II)$ by chloride ion or for $CH_3Hg(II)$ speciation (13).

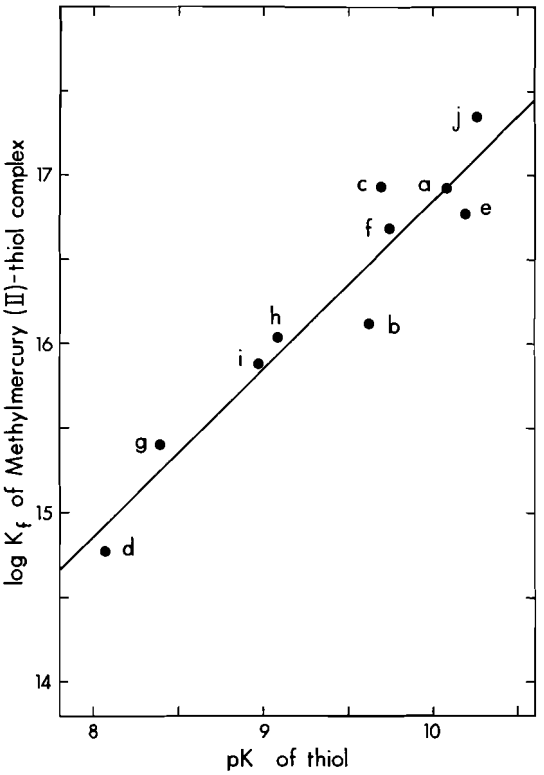

FIG. 5. Correlation between log K_f of the $CH_3Hg(II)$–thiol complexes and the pK of the thiol groups. The letters a–j refer to the complexes of MAA, ME, PSH (amino deprotonated), PSH (amino protonated), NPSH, CYS (amino deprotonated), CYS (amino protonated), glutathione (amino deprotonated), glutathione (amino protonated), and MSA, respectively.

The formation constants listed in Table 3 show the affinity for $CH_3Hg(II)$ to decrease in the order

mercaptosuccinic acid > penicillamine > mercaptoacetic acid > *N*-acetylpenicillamine > cysteine > homocysteine > mercaptoethanol

However, because of competing reactions, this order of stability is rather misleading with respect to effective binding strength. For ligands such as penicillamine and cysteine, the situation is further complicated by the dependence of the pK of the thiol group on the protonation states of acidic groups in the ligand. For example, the formation constant of the penicillamine complex decreases from log K_f = 16.94 to 14.79 upon protonation of the amino group, while that for the cysteine complex decreases from 16.67 to 15.38.

These effects can be most easily visualized with conditional formation constants, K_{fc}, which are defined as pH-dependent equilibrium constants for the reaction

$$CH_3Hg_{free} + L_{free} \rightleftarrows CH_3HgL_{total}$$

where CH_3Hg_{free} and L_{free} include all the free forms of $CH_3Hg(II)$ and ligand and CH_3HgL_{total} includes all the complexed forms of the ligand.

The logarithm of K_{fc} is plotted vs. pH in Fig. 6. In all cases, the conditional formation constant is orders of magnitude smaller than the formation constant listed in Table 3 due to competing reactions. Also, the conditional formation constants are pH dependent, reaching a maximum in each case around neutral pH, and decreasing at higher and lower pH values due to competing reactions involving hydroxide ion and hydrogen ion, respectively. The various curves in Fig. 6 show that the exact pH dependence of K_{fc} for the different complexes is strongly dependent on the acid–base chemistry of the sulfhydryl group, with the striking result that the order of relative affinity for $CH_3Hg(II)$ undergoes some major changes with change in pH. Thus, at pH 10, K_{fc} for the mercaptosuccinic acid complex is largest while at pH 4 it is smallest. At pH 10, K_{fc} for the cysteine complex is second smallest while at pH 4 it is largest.

Of particular interest with respect to the chemistry

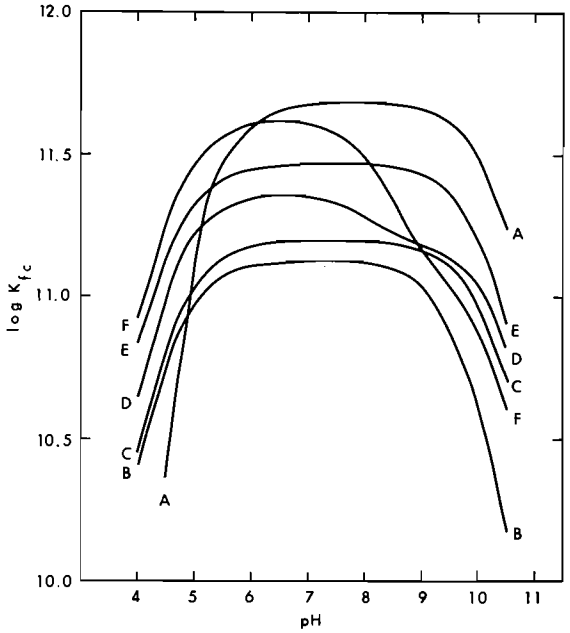

FIG. 6. pH dependence of the conditional formation constants for the $CH_3Hg(II)$–thiol complexes of (*A*) MSA, (*B*) ME, (*C*) NPSH, (*D*) PSH, (*E*) MAA, and (*F*) CYS.

TABLE 4. Conditional formation constants for the methylmercury(II)–thiol complexes at pH 7.4

Ligand	log $K_{f,conditional}$
Mercaptoethanol	11.13
Mercaptoacetic acid	11.47
N-Acetylpenicillamine	11.20
Penicillamine	11.33
Cysteine	11.57
Homocysteine	11.15
Mercaptosuccinic acid	11.68

of methylmercury toxicology are the relative binding affinities at pH 7.4 (24). From the conditional formation constants listed in Table 4, the order of decreasing ligand affinity for $CH_3Hg(II)$ at pH 7.4 is

mercaptosuccinic acid > cysteine > mercaptoacetic acid > penicillamine > *N*-acetylpenicillamine > homocysteine > mercaptoethanol

The logarithm of K_{fc} for the $CH_3Hg(II)$ complex of glutathione is 11.48 at pH 7.4 (25), which places glutathione with mercaptoacetic acid in the above sequence. Of these ligands, mercaptosuccinic acid, penicillamine, and *N*-acetylpenicillamine have been found to increase the rate of elimination of $CH_3Hg(II)$ in animal studies of antidotes for methylmercury poisoning (27–30). Considering that K_{fc} for the glutathione complex is larger than those for the penicillamine and *N*-acetylpenicillamine complexes at pH 7.4 and that glutathione is quite abundant in most cellular systems it is perhaps surprising that penicillamine and *N*-acetylpenicillamine are effective antidotes. For example, glutathione is present at a level of about 2 m*M* in human red blood cells (31, 32). The order of effectiveness as antidotes for methylmercury poisoning in animal studies is (30)

mercaptosuccinic acid > *N*-acetylpenicillamine > penicillamine

It appears that factors in addition to relative binding strengths are important, such as the ease with which the thiol ligand can penetrate cellular membranes and convert the nondiffusible intracellular $CH_3Hg(II)$ into a freely diffusible complex (27).

Electroreduction of uranyl ion in aqueous calcium nitrate solutions

NAROTTAM P. BANSAL[1] AND JAMES A. PLAMBECK

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 26, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

NAROTTAM P. BANSAL and JAMES A. PLAMBECK. Can. J. Chem. **59**, 1515 (1981).

The electroreduction of uranyl ions in buffered and unbuffered 0.5 *M* calcium nitrate has been studied using polarography, cyclic voltammetry, chronopotentiometry, and chronoamperometry. The results are compared with those in molten calcium nitrate tetrahydrate.

NAROTTAM P. BANSAL et JAMES A. PLAMBECK. Can. J. Chem. **59**, 1515 (1981).

Faisant appel à la polarographie, la voltamétrie cyclique, la chronopotentiométrie et la chronoampérométrie, on a étudié la réduction électrolytique des ions uranyles dans des solutions 0,5 *M* de nitrate de calcium tamponnées et non tamponnées. On a comparé les résultats à ceux obtenus dans du nitrate de calcium tétrahydrate fondu.

[Traduit par le journal]

Introduction

In electrochemical studies both in aqueous solvents and in melts, little attention appears to have been paid to the application of the same techniques to systems of some electrochemical complexity in an aqueous solution and also in a fused-salt melt as comparable as possible to the aqueous solution. We have previously studied (1) the reduction of uranyl ion in fused calcium nitrate tetrahydrate. The present paper compares aqueous results with those obtained in the hydrated melt.

The reduction of U(VI) has been extensively studied in aqueous media by different electrochemical methods (2–14).[2] Most of these studies have been carried out in acidic ($HClO_4$, HCl, H_2SO_4, HNO_3) media (2–11). In sufficiently acidic solution, the reduction mechanism (12) is that uranyl is reduced in a one-electron step and that the resulting U(V) species disproportionates, regenerating U(VI). The disproportionation rate has been found to be first order in H^+ concentration according to the following scheme:

(E) $UO_2^{2+} + e^- \rightleftarrows UO_2^+$

(C) $UO_2^+ + H^+ \rightleftarrows UO_2H^{2+}$

(D) $UO_2^+ + UO_2H^{2+} \rightleftarrows UO_2^{2+} + UO_2H^+$

(E) $UO_2H^{2+} + e^- \rightleftarrows UO_2H^+$

followed by other reactions to yield stable forms of U(IV). These steps following the initial reduction of U(VI) to U(V) are all strongly pH-dependent. Reaction of the electrochemically produced U(V) or U(IV) with components of the solution (nitrate ion) is also possible.

In less acidic solutions the situation is simplified because the disproportionation of U(V) does not take place (13), but studies in weakly acid to neutral aqueous media (13, 14) are few.

The studies were carried out in unbuffered aqueous 0.5 *M* $Ca(NO_3)_2$ and aqueous 0.5 *M* $Ca(NO_3)_2$ buffered at pH 3.65 or 4.65 with acetate. The latter was used to help elucidate processes in the unbuffered solution, since electroreduction of uranyl requires protons and the solution in the immediate vicinity of the electrode is more basic than the bulk electrolyte in unbuffered solution. These solutions at 25°C are compared with molten calcium nitrate tetrahydrate at 55°C. The temperature difference is unavoidable because comparison with aqueous work at 25°C is necessary. The ratio of H_2O to Ca^{2+} changes from about 110:1 (aqueous) to 4:1 (melt), with concomitant changes in structure and viscosity.

Experimental

The electrochemical cell was a Princeton Applied Research (P.A.R.) Model 9300-9301 polarographic cell employed in a three electrode configuration. The working electrode was either a P.A.R. Model 9323 hanging mercury drop electrode (HMDE) or a P.A.R. Model 172A dropping mercury electrode (DME). These electrodes were set up using triply distilled mercury (Englehard). For the HMDE, a fresh mercury drop of constant known area (0.0176 or 0.0349 cm^2) was taken for each observation. The auxiliary electrode was a large platinum flag. A saturated calomel reference electrode (sce), Corning 47600 with fibre junction, was used. All values of potential in this work are with reference to this sce.

The polarographic behavior was studied using a P.A.R. Model 174A polarographic analyzer. The chronopotentiometric potential–time curves and the chronoamperometric current–time curves were obtained with a P.A.R. Model 173 potentiostat/galvanostat. The cyclic voltammetry was performed with the Model 173 coupled to a P.A.R. Model 175 universal programmer. The polarograms, current–time curves, some of the potential–time traces, and the cyclic voltammograms at slow

scan rates (< 1 V/s) were recorded with an $x-y$ and $x-t$ recorder (Houston Instrument Type 2000). The cyclic voltammograms at higher scan rates and the chronopotentiograms were photographed from the screen of a Tektronix Model 535A oscilloscope. The polarographic currents were corrected for the residual current of the base electrolyte, which was 0.5 M $Ca(NO_3)_2$ throughout; at this concentration, no additional supporting electrolyte is necessary. The pH of the unbuffered aqueous solutions were measured and found to be 3.65 ± 0.05 depending on the batch of $Ca(NO_3)_2 \cdot 4H_2O$ employed. Buffered solutions were buffered at 3.65 ± 0.02 or 4.65 ± 0.02 with acetate.

Before electrolysis, all solutions were purged with purified pre-saturated wet nitrogen for at least 15 min and blanketed with it during the run. Analytical reagent grade uranyl nitrate and calcium nitrate tetrahydrate (BDH AnalaR), acetic acid, and sodium acetate were used without further purification. The experiments were all carried out at 25°C.

Results

Polarograms of aqueous uranyl solutions (Fig. 1) show two reduction waves. In all solutions the first wave is a reversible one-electron reduction of uranyl to U(V), as it is in the melt, as shown by Heyrovsky–Ilkovic plots. The values of the half-wave potential are: unbuffered aqueous, −0.180 ± 0.005 V; pH 3.65 buffer, −0.254 ± 0.05 V; pH 4.65 buffer, −0.323 ± 0.005 V; melt (silver reference), −0.475 ± 0.005 V (1). The plateau height is directly proportional to uranyl concentration.

The second wave near −1.0 V in unbuffered solutions is absent in both of the buffered solutions; it is an artifact of the local basicity produced by use of hydrogen ions near the electrode of the unbuffered solution in the electroreduction of uranyl. In the region of −1.0 V the shape of the current–time curves for individual drops is anomalous, though both positive and negative of this region it appears normal (Fig. 2).

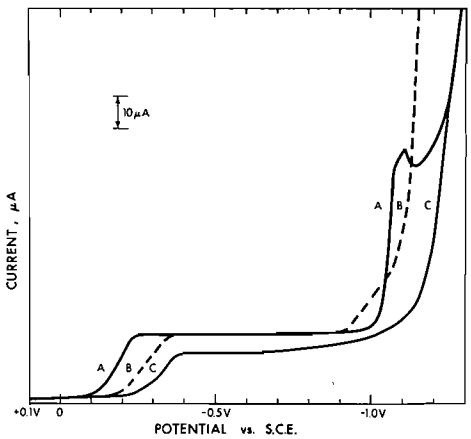

FIG. 1. Polarograms of reduction of uranyl ion in aqueous solution. Curve A, unbuffered, pH 3.65; curve B, acetate buffer, pH 3.65; curve C, acetate buffer, pH 4.65. 0.5 M $Ca(NO_3)_2$, maximum current, controlled drop time 2 s, uranyl concentration 1.00 mmol/L (A, B), 0.70 mmol/L (C).

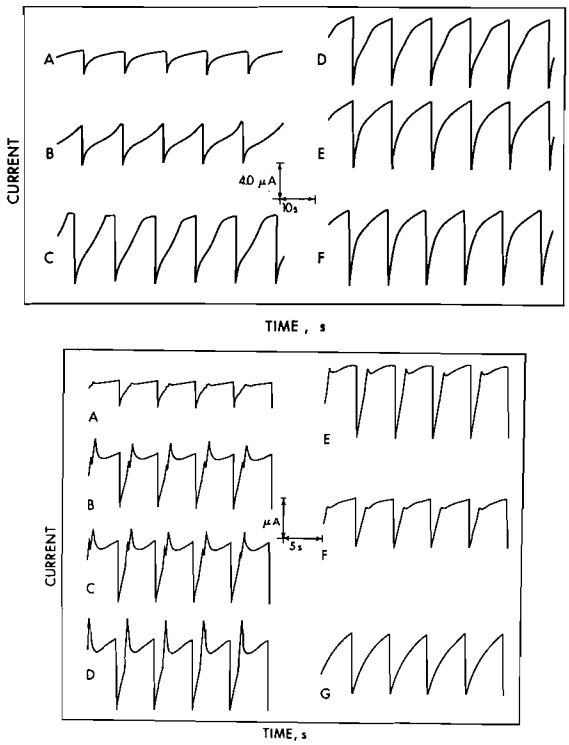

FIG. 2. Variation of instantaneous current during drop life. Upper data, unbuffered solution, 1.006 mmol/L uranyl, current scale 4 μA/unit; curve A, −0.90 V; B, −0.95 V; C, −0.98 V; D, −1.00 V; E, −1.02 V; F, −1.10 V. Lower data, solution buffered at pH 4.65, 1.016 mmol/L uranyl; curve A, −0.20 V, 4 μA/unit; B, −0.40 V, 10 μA/unit; C, −0.60 V, 10 μA/unit; D, −0.80 V, 10 μA/unit; E, −1.00 V, 10 μA/unit; F, −1.10 V, 20 μA/unit; G, −1.15 V, 50 μA/unit. Data in buffered solution of pH 3.65 is intermediate between these.

In unbuffered solution (Fig. 3) the chronopotentiometric curves show one sharp transition with quarter-time potential $E_{\tau/4}$ of −0.175 ± 0.010 V. The Sand plot of $\tau^{1/2}$ against the reciprocal of the current density for this process was a straight line passing through the origin. The Karaoglanoff plot of E vs. log $(\tau^{1/2} - t^{1/2})/t^{1/2}$ was a straight line of slope 0.061 V which is in reasonable agreement with the theoretical value of 0.059 V for a reversible, single-electron, reduction process at 25°C where the product of the electrode reaction is soluble. For a reversible process (15), the polarographic half-wave potential, $E_{1/2}$, is equal to $E_{\tau/4}$ whereas for the reoxidation process after the current reversal, it should correspond to the potential at time $0.222\tau'$. For the first transition both $E_{\tau/4}$ and the potential at $0.222\tau'$ were found to be the same as $E_{1/2}$ regardless of the time at which the current was reversed.

Chronopotentiometry with current reversal was carried out at various points in the $E-t$ curve, i.e.

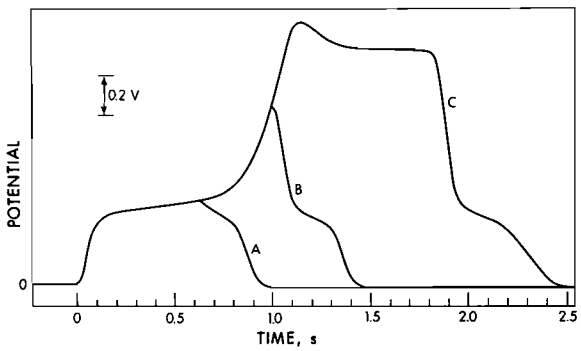

FIG. 3. Chronopotentiograms obtained on reduction of UO_2^{2+} in unbuffered solution. Curve *A*, current reversed on first plateau; *B*, current reversed on rising portion following first plateau; *C*, current reversed on second plateau at time 1.81 s. Concentration of UO_2^{2+}, 1.006 mmol/L; current density 0.285 mA/cm² both forward and reverse.

towards the end of the first transition, at the rising portion after the first transition and after the appearance of the peak where the second process commences (Fig. 3*A*, *B*, *C*). When the direction of the electrolysis current was reversed even at some time after the peak, the electrode potential immediately dropped to a value corresponding to the first reduction process. The value of the *first* forward to reverse transition times, τ_f/τ_r, was found to be approximately three in all cases and independent of the length of time beyond τ_f. These observations show that the product of the second reduction reaction cannot be reoxidized at more negative potential than the product of the first process and that the product of the first process is being regenerated, perhaps catalytically, during the second reduction reaction. These results are similar to those obtained in the melt (1).

Cyclic voltammetry was employed in all three solutions using voltage scan rates v between 0.02 and 100 V/s. In all solutions, the first process was the reversible one-electron U(VI)/U(V) system, for which the peak current is proportional to $v^{1/2}$ and the cathodic/anodic peak ratio is unity. If the potential scan was restricted, only this process was observed (Fig. 4); the value of ΔE_p corresponds to a reversible one-electron process. If the scan range extended to or beyond −1.0 V a large cathodic peak was obtained and the anodic wave was distorted in buffered or unbuffered solutions.

The curves obtained using potential-step chronoamperometry in unbuffered solution are presented in Fig. 5. The shape of the *I–t* curves was normal for applied potentials corresponding to the first reduction step, up to −0.92 V. The curves show maxima for applied potentials in the range −0.94 to −1.12 V corresponding to the second electrode process, but are of normal shape at more negative potentials. After the initial capacitive current decay, the current increases and then slowly decreases after reaching a maximum. The position and intensity of the maxima depend upon the potential step; the height of the maximum increases and it appears after shorter times as the potential is stepped to more negative values. No maxima in the *I–t* curves are observed at applied potentials more negative than −1.12 V. At such negative potentials, it may be that the maxima appear at such a short time interval that it is not possible to detect them on the pen recorded transients and only the usual diffusion controlled curves, in which *I* is proportional to $t^{-1/2}$, are observed. The *I–t* curves for buffered solutions are similar but with more regular progression.

It is easier to interpret the chronoamperometric curves by integration rather than directly because the separation of the different processes can then be achieved. The integrated area (16) from $t = 0$ to $t = 16$ s is plotted in Fig. 6. This length of time was necessary in order to include the peak of *D*, Fig. 5, but even such a long time does not permit inclusion of the peak of *C* so that the point at −0.94 V on Fig. 6 is anomalously low. The contribution of double-layer charging on this time scale is negligible but the coulombs due to the first reduction of UO_2^{2+} are not. Since, however, the process is reversible this charge can be calculated by integration of the Cottrell equation as $Q = 2nFC(Dt/\pi)^{1/2}$. Using the experimental values of 16 s, 1.006 mmol/L, 1 electron/ion, and appropriate values of the fundamental constants, *Q* is an insensitive function only of the diffusion coefficient of uranyl ion. The diffusion coefficient obtained in this and other work is 7.7 × 10^{-6} cm²/s, which yields 1.22 mC/cm² for charge due to the UO_2^{2+} reduction to UO_2^{+}. This value, plotted as a solid horizontal line in Fig. 6, is in excellent agreement with the coulombs observed for the first wave. For the second wave even a value of three times this, plotted as a broken line in Fig. 6, cannot describe the coulometry of this process which then cannot be $UO_2^{2+} \rightarrow$ U(III). Indeed, it

cannot be limited by diffusion of UO_2^{2+} at all and thus must correspond to the catalytic reduction of nitrate, whose concentration is sufficiently great that the observed coulombs can be passed without exceeding the limit imposed by mass transport.

Discussion

The experimental results described above are consistent with a coherent interpretation in which the first step of the reduction is the one-electron reversible reduction of UO_2^{2+} to UO_2^{+}. The absence of complications in this process can be observed from the Heyrovsky–Ilkovic polarographic plot, the variation of current during drop life, the current-reversal chronopotentiometry, and the chrono-amperometric and cyclic voltammetric studies.

This uranyl reduction is simpler than that in neutral 0.1 *M* aqueous KCl, in which Harris and Kolthoff (14) observed two polarographic waves. The diffusion current constant for the first wave decreased when the concentration of uranyl ions present in the solution was decreased. They attrib-

uted this to the hydrolysis of the uranyl ion, the first wave resulting from the one-electron reduction of UO_2^{2+} alone; the hydrolyzed species UO_2OH^+ is not reduced at the potential of the first wave. The degree of hydrolysis of UO_2^{2+} increases, and its relative concentration decreases, with decreasing concentration resulting in the decrease of the diffusion current constant. In the present study the polarographic diffusion current constant and the factor $I_p v^{-1/2}/C^\circ$ in cyclic voltammetry are independent of the bulk uranyl concentration, indicating the absence of the hydrolysis of UO_2^{2+} in 0.5 *M* $Ca(NO_3)_2$.

Collat and Lingane (17) have shown that U(VI) or U(V) is reduced at a potential of −1.1 V vs. sce in aqueous KCl at pH 2–3. In the absence of uranium, nitrate ion is not reduced at this potential; the reduction of nitrate occurs at potentials about 0.2 V more negative than the half-wave potential (−1.58 V) for the hydrogen ion wave. But during the uranium-catalyzed reduction of nitrate the nitrate ion is reduced by a lower oxidation state of uranium at the electrode surface, this uranium being reoxidized to U(V) which is rapidly re-reduced to produce a catalytic cycle. The reduction of nitrate removes hydrogen ions. The catalytic reaction at this pH is not complicated by insolubility of UO_2, which precipitates in more basic solutions (14) and in the melt (1), or by the more complex behavior observed in highly acidic solutions (2–10).

The aqueous mechanism is similar to that in the melt, though precipitation of $UO_{2(s)}$ does not occur. The results are consistent with the UO_2^{2+}/UO_2^+ reversible reduction followed by onset of catalytic nitrate reductions at −1.0 V. The variation in drop shape with onset of the catalytic reduction (Fig. 2) is consistent with initial diffusion-controlled reduction of U(V) followed by catalysis of nitrate reduction leading to eventual diffusion control by nitrate at much higher current. The changeover appears more clearly in the buffered solution because reduction of both UO_2^+ and NO_3^- consumes hydrogen ions; the pH in the immediate vicinity of the

electrode in unbuffered solution is increased more than in the buffered solutions. The greater pH increase also appears in Figs. 1 and 6; the unbuffered curve shifts, as the catalytic reaction becomes greater, toward the curve obtained at a buffered pH higher than that of the unbuffered bulk solution.

Infrared and thermogravimetric studies of the thermal degradation of chrysotile asbestos fibers: evidence for matrix effects

CARMEL JOLICOEUR AND DANIEL DUCHESNE

Centre d'Application en Calorimétrie et Thermodynamique (C.A.C.T.U.S.), Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received August 26, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

CARMEL JOLICOEUR and DANIEL DUCHESNE. Can. J. Chem. **59**, 1521 (1981).

Thermal decomposition of short chrysotile asbestos fibers under static heating has been studied by infrared spectroscopy and thermogravimetry. The spectral changes were monitored at room temperature for fibers heated (*a*) in the free state or (*b*) in KBr matrix. In either case dehydration occurs sharply near 550°C. However, subsequent transformations of the chrysotile anhydride were found to be markedly different for (*a*) and (*b*), suggesting important matrix effects. This provides an explanation for earlier observations in which the thermal decomposition scheme appeared dependent of the size of the chrysotile fibers.

CARMEL JOLICOEUR et DANIEL DUCHESNE. Can. J. Chem. **59**, 1521 (1981).

La décomposition thermique de fibres courtes d'amiante chrysotile en chauffage statique a été étudiée par spectroscopie infrarouge et par analyse thermogravimétrique. Les spectres infrarouges ont été enregistrés à la température ambiante avec les fibres incorporées dans des fenêtres de KBr. L'influence de la température de chauffe sur les spectres a été étudiée pour (*a*) des fibres libres et (*b*) des fibres déjà incorporées dans le KBr. En chauffage statique, la déshydratation du chrysotile se produit de façon abrupte près de 550°C et la réaction semble peu dépendante de l'état physique des fibres lors du traitement thermique. Les réactions subséquentes de l'anhydride diffèrent, toutefois, selon l'état des fibres, suggérant l'existence d'effets de matrice. De tels effets permettent d'expliquer les observations antérieures concernant l'influence de la grosseur des fibres sur leur mécanisme de décomposition thermique.

Introduction

The thermal stability of fibrous magnesium silicates is of obvious relevance to many high-temperature uses of asbestos fibers or composite materials containing such fibers. Consequently, the surface and structural transformations resulting from heat treatment of these fibrous minerals have been the subject of numerous physico-chemical investigations using various techniques namely, X-ray diffraction, infrared spectroscopy, electron microscopy, differential thermal analysis, and thermogravimetric analysis. Summaries of the conclusions from much of the previous work may be found, for example, in reviews by Hodgson (2), Harington *et al.* (3), Martinez (4), and Brett and MacKenzie (5).

In the case of chrysotile asbestos,[1] which is the most abundant and most widely investigated, the various steps involved in the thermal degradation (dehydration, dehydroxylation, structural transformations) have been characterized within reasonable limits, and mechanisms for dehydroxylation and structural rearrangements have been proposed by Ball and Taylor (6) and Brindley and Hayami (7–9). From the data available, it is noteworthy, however, that the dehydroxylation temperature and that for the breakdown of the chrysotile structure, are markedly dependent on the physical properties (size, specific area) of the fibers. While such effects are expected and frequently observed in dynamic heating experiments (e.g. DTA, TGA (10–13)), static heating investigations have also shown significant variations in thermal decomposition behavior. For instance, Naumann and Dresher (11) reported variations in the dehydroxylation and recrystallization temperatures which were related to the surface area of the chrysotile fibers (essentially brucite-free, Cassiar chrysotile). Also in static heating experiments, Murphy and Ross (14) showed that a chrysotile material having a high brucite content (~10%) retained the chrysotile silicate structure at temperatures higher than brucite-free samples. Both of these observations point out the possibility of matrix effects, whether these are related to the "ease of water removal" and "degree of cementation" of the monofibers (11) or to "solid–solid interactions" between chrysotile fibers and interstitial brucite (14).

To unravel the intrinsic decomposition behavior of chrysotile fibers and the influence of confining matrices, it appeared desirable to carry out further quantitative investigations of the surface and structural modifications, first, of finely divided fibers (ideally monofibers) and, second, of the same fibers

[1]The morphology and chemical structure of chrysotile fibers have been described in a preceding paper (1) and we refer to the latter for details; only those aspects essential to the present discussion will be recalled here.

incorporated in various solid matrices. The present work was undertaken with this aim, using short fibers obtained by an aqueous sedimentation method described in a previous paper (1). The infrared absorption and thermogravimetric results presented below have been used to characterize the thermal dehydroxylation and structural changes of these fibers in the "free" state and incorporated in KBr matrices.

Experimental

(a) Materials

The chrysotile fibers used throughout this work were extracted by a selective aqueous sedimentation technique (1) from bulk 4-T-30 commercial fibers (Johns Manville, Quebec). The chemical and structural characterization of these fibers was described in detail elsewhere (1) and may be summarized as follows. The fibers have the chrysotile composition and structure, with a low brucite content (~1%) as determined from X-ray and DTA analyses. The average length of these fibers is of the order of 0.5 μm; their length distribution peaks at ~0.3 μm and the distribution width-at-half-height is 0.5 μm. The surface area of the fibers is 20 m^2/g from N_2 adsorption and 28 m^2/g from H_2O adsorption. Taking a specific area of 25 m^2/g and a bulk density of 2.5 g cm^{-3}, the average cylinder diameter of the fiber is readily calculated as 64 nm which is approximately three times larger than that of monofibers, ca. 25 nm (15). For all experiments, the fibers were previously heated to 110°C for 24 h to ensure removal of physisorbed water.

The KBr was BDH reagent grade, used after heating for 24 h at 120°C.

(b) Methods

The KBr discs used for all infrared measurements (13 mm diameter, ~0.5 mm thick) were prepared from 200 mg of finely ground KBr and various amounts ranging between 1 and 3 mg of dry (110°C, 24 h) chrysotile fibers. In part of this work, a fixed amount of potassium thiocyanate was added as internal standard (16) for quantitative absorbance measurements. The powder mixture was transferred into an evacuable die (Beckman model K-13) and slowly compressed at 10 000 psi, producing pellets having 50–80% transmittance. The disc was dried at 120°C overnight and the ir spectra recorded immediately after. In cases where heating led to a significant loss of transparency due to microfractures, the discs were recompressed as described above.

The infrared spectra were recorded at room temperature in the range 300–4000 cm^{-1} using a double beam Perkin-Elmer spectrometer model 621 under scanning rates between 0.5 and 3 cm s^{-1}. The frequency calibration was checked against absorption bands of a polystyrene film; the accuracy of the frequencies reported here varies between 3 and 20 cm^{-1}, and the uncertainty is mainly due to the width of the absorption lines, especially in the Si—O region. Frequency measurements on the relatively narrow O—H stretching bands in five independent samples showed a standard deviation inferior to 1 cm^{-1}.

(c) Heat Treatment

As mentioned earlier, the chrysotile samples were heat-treated following two distinct procedures. In the first method, loose chrysotile fibers were heated to a given temperature for 3–4 h (8); after cooling in a desiccator over P_2O_5, the sample was weighed and, part of it was pressed in a KBr disc for spectral studies. The remaining loose fiber sample was then heated to the next higher temperature for 3–4 h and the procedure repeated at several temperatures between 110 and 900°C.

In the second method, five KBr–chrysotile discs were prepared from the same fiber stock sample, and these were heat-treated under conditions given above for the loose fiber samples. Since KBr melts at 730°C, the maximum achievable temperature in these experiments was 700°C.

Thermogravimetric analyses of loose chrysotile fibers were also carried out under a scanning rate of 5°C/min, using a SETARAM thermal analyser Model 1133.

Results and Discussions

A partial cross section of a chrysotile fiber is illustrated in Fig. 1, showing the concentric layer structure of the chrysotile fiber. Each layer is formed by the superimposition of a plane of silica tetrahedra and arrays of MgO and MgOH groups. As is readily seen, one out of every four Mg—OH groups is pointing inwards to the chain of silicates, while the remaining three are oriented towards the external surface.

The main events in the thermal decomposition pattern of chrysotile ($3\,MgO \cdot 2SiO_2 \cdot 2H_2O$) containing some adsorbed water (xH_2O) and varying amounts of brucite ($yMg(OH)_2$) are given in Fig. 2, as generally observed in dynamic heating studies, DTA or TGA. Between room temperature and ~250°C, a chrysotile sample looses 1–2 wt.% due to sorbed water (monolayer coverage was earlier shown as 0.8 wt.% (1)). Near 400°C, the excess brucite present is dehydrated, and at significantly higher temperatures (≃600°C), dehydroxylation of

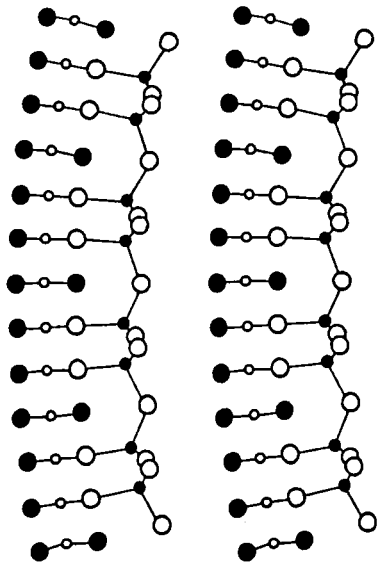

FIG. 1. Schematic representation of the concentric layer structure of chrysotile. Each layer consists of a plane of silica tetrahedra which are interlinked by three apices; this plane is overlayed with a sheet of Mg—OH groups (redrawn from Martinez (4)). A chrysotile monofiber will contain some 10–20 such combined layers in concentric or spiral arrangements. Symbols: ●, —OH; ○, oxygen; ○, Mg; ●, Si.

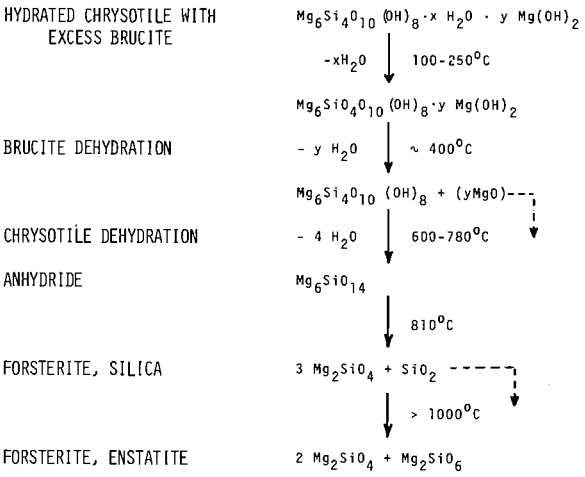

FIG. 2. Overall thermal reaction scheme of chrysotile fibers under dynamic heating conditions (DTA, TGA).

the Mg—OH groups in the chrysotile lattice occurs with a weight loss of ≃13% (theoretical: 13.0%). The amorphous (or partially amorphous) anhyride product of this reaction recrystallizes exothermically into forsterite and amorphous silica at ≃810°C; further heating to temperatures above 1000°C yields some enstatite.

The reaction mechanisms proposed by Ball and Taylor (6) and Brindley and Hayami (8) for these various events are illustrated in the comparison diagram given by the latter authors (Fig. 3). Both mechanisms invoke a concept of "donor–acceptor regions", although they differ in the stoichiometries of these regions and in the transfer of ions or atoms (H, Mg, Si) between them. The two mechanisms account for chrysotile lattice dehydration (≃600°C) on the basis of proton migration from the acceptor to the donor region; water is formed in the latter by reaction with hydroxyl groups, and expelled leaving either pores (6) or silica (8), depending on the extent of the inverse Si migration. It does not appear that any distinction was required for the two different types of OH groups in the chrysotile lattice (one internal vs. three external), in spite of the different environments of these groups. There seems, however, no specific evidence that both types of hydroxyl groups are removed simultaneously, and this question will be considered further below.

Another significant difference in the mechanisms proposed by Ball and Taylor (6) and Brindley and Hayami (8) concerns the structure of the dehydration products. In the former, an anhydride is formed which is converted to forsterite at higher temperatures following further ion migration (Si, Mg); in the Brindley–Hayami mechanism, disordered forsterite is formed immediately, and crystallizes at higher temperatures (≃800°C). This difference in reaction pathways could also result from matrix effects as shown below.

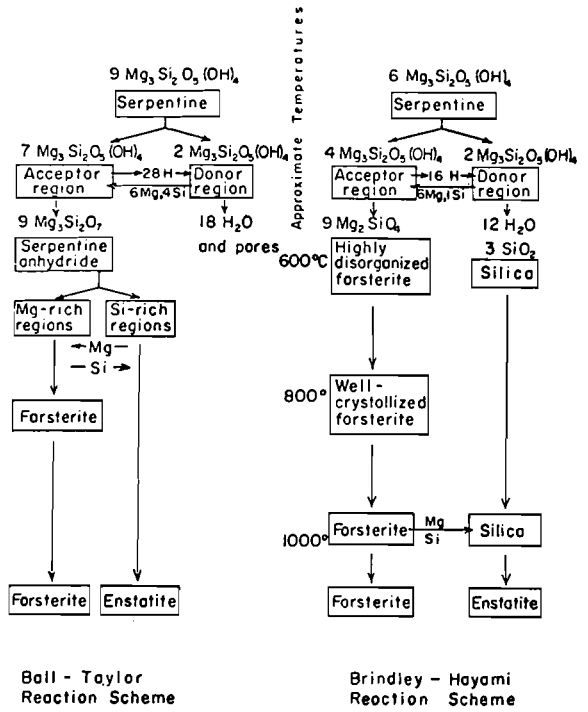

FIG. 3. Comparison of the reaction pathways proposed by Ball and Taylor (6) and Brindley and Hayami (8) for the thermal degradation of chrysotile structure (reproduced from ref. 8 with permission).

(a) Thermogravimetric Results for Dehydration

The fractional weight loss observed upon heating samples of loose chrysotile fibers is illustrated in Fig. 4 as function of temperature for dynamic and stepwise heating. The TGA curve obtained under continuous scanning (5°C/min) is comparable to those reported by other authors (2, 4, 5, 17, 18) and not markedly dependent on the sample size between 50–600 mg. The curve exhibits three distinct portions corresponding to removal of residual water up to ≃200°C, brucite dehydration at ≃400°C, and chrysotile dehydration between 600 and 800°C. By comparison, the data from stepwise heating show that chrysotile dehydration is essentially complete at 650°C. The results at lower temperatures $T < 550$°C are in good agreement with those of Chowdhury (19) who showed that the brucite and chrysotile dehydration occurs distinctly.

The difference between the mid-point temperatures for dehydration of the chrysotile under dynamic and static heating illustrates the slow kinetics of the diffusion-controlled process (9).

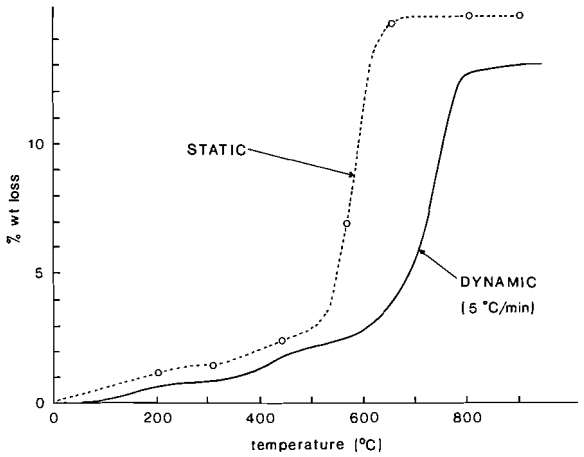

FIG. 4. Fractional weight loss of chrysotile fibers as function of temperature in dynamic heating (5°C/min) and stepwise heat treatments (3–4 h at constant temperature).

(b) Infrared Spectra in the OH Stretching Region

The infrared absorption spectrum of short chrysotile fibers in the hydroxyl stretching region is illustrated in Fig. 5 as a function of heat treatment temperature. The spectra shown are those obtained with fibers heated in their KBr matrix, but these are identical to spectra recorded with fibers heated before incorporation in KBr discs, except for changes in the broad band at ~3450 cm^{-1}. Such differences could not be established reliably, however, since water adsorbed in, or on, the KBr discs during manipulations also shows absorption in this region.

The OH stretching spectrum exhibits three fairly well resolved components, the frequencies of which are given in Table 1, along with data for brucite and other reference materials. The values reported here are consistent with data from various other sources for chrysotile (20–26), brucite (20, 27), and other minerals (20, 26–29). The sharp doublet (ca. 3687 cm^{-1}) is of particular interest in relation to the lattice OH groups. Because brucite exhibits only a single sharp OH absorption (27), and since the short fibers are randomly oriented in the KBr matrix, the OH doublet is readily assigned to Mg—OH groups in different environments.

The peak absorbance of the two bands was determined after graphical deconvolution assuming symmetry of the 3687 cm^{-1} component. Overlap of the doublet band with the broad low frequency band (3450 cm^{-1}) was also accounted for by subtraction of the high frequency tail of the 3450 cm^{-1} band. A plot of A_{3687} vs. A_{3644} for data obtained in the temperature range 120–555°C yielded a slope of 2.96 with a standard deviation of 0.05. This confirms the assignment of the OH doublet to the

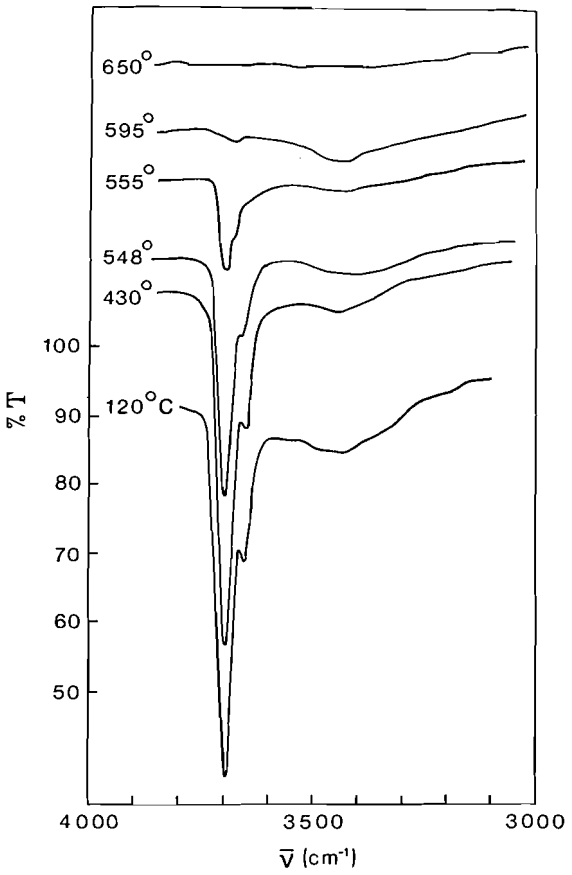

FIG. 5. Infrared spectra of the OH stretching region for short chrysotile fibers in KBr discs as function of heat treatment temperatures.

external and internal Mg—OH groups present in a 3:1 molar ratio, and further shows that dehydration of chrysotile under static heating occurs by simultaneous removal of these OH groups.

A correlation of the ir and thermogravimetric data is illustrated in Fig. 6, where the temperature dependence A_{3687} is shown for three different samples of chrysotile fibers heat-treated in KBr discs.[2] The thermogravimetric results obtained under stepwise heating clearly demonstrate related behaviors, as expected.

(c) Infrared Results in the Si—O Region

The infrared absorption of minerals in the Si—O region has been extensively investigated, for example, by Saskena (31) and Chen (25) and the

[2]The results of experiments where the loose fibers are heated and subsequently incorporated in KBr are not significantly different from those in Fig. 6. For such experiments, however, the absorbances had to be measured relative to that of an internal standard (KCNS) and the overall uncertainty was found larger.

results generally indicate absorption bands sufficiently characteristic to identify a particular mineral, or group of minerals. Of special interest in chrysotile studies is the ν_3 mode of SiO_4 tetrahedra which is degenerated in the isolated tetrahedron, but not in chain silicate minerals. Because of the lower symmetry in the chrysotile lattice, the degeneracy is lifted and the ν_3 mode of SiO_4 appears as a triplet (ca. 1085, 1017, and 962 cm^{-1} (31)) characteristic of chain silicate structures. The frequencies observed in the present work are reported in Table 1 with similar data for amorphous silica and forsterite.

The influence of the heat treatment temperature on the infrared absorption of chrysotile fibers in the Si—O stretching region is illustrated in Fig. 7. The spectra shown in Fig. 7*A* correspond to fibers heated stepwise and later pressed into KBr discs. The triplet structure of the ν_3 mode, initially well resolved, coalesces in samples heat-treated above 600°C; at 650°C, the absorption is a broad structureless band, typical of amorphous materials. In samples heated at still higher temperatures (795°C), the bands of forsterite (984 cm^{-1} and 885 cm^{-1}) become clearly resolved. Changes observed following heat treatment to 900°C (e.g. increase in intensity at ~940 cm^{-1}) may be attributed to the appearance of enstatite (4). Except for the occurrence of enstatite at temperatures lower than 1000°C, these observations are in full agreement with the reaction scheme of Ball and Taylor (6), forsterite appearing only after complete dehydration of the chrysotile into an amorphous anhydride.

The temperature dependence of the Si—O spectral features of chrysotile fibers heat-treated in KBr

For personal use only.

discs (Fig. 7*B*) shows marked departure from the behavior described above. For temperatures lower than ~450°C, the ν_3 triplet lineshape is fairly independent of the fiber history, i.e., whether they are heated before pressing into a KBr matrix or heated within the matrix. However, heating at 550°C results in sharp loss of the triplet structure (between 545 and 555°C), while the 885 cm^{-1} band of forsterite becomes clearly evident. The appearance of the latter band before the complete disappearance of the chrysotile triplet is compatible with the mechanism of Brindley and Hayami (8) who proposed the formation of forsterite immediately after dehydration at 600°C based on X-ray diffraction results

The observations described here are strikingly analogous to those reported by Nauman and Dresher (11) in their X-ray diffraction studies of the thermal decomposition of chrysotile fibers of different sizes. Under static heating, coarse chrysotile fibers (specfic area 12 m^2/g) convert to forsterite between 550 and 600°C. However, when the same material is defibrilated in a ball mill to a specific area of 40 m^2/g, static heating in the range 550–600°C leads to an amorphous phase which converts to forsterite only at higher temperatures, ca. 650–700°C. The similar effects found here with chrysotile fibers in a completely different matrix suggest a general basis for explanation of matrix effects involving mostly physical factors such as pressure or stress on the fibers. Whether more specific interactions (electrostatic, chemical reactions) also play a significant part remains to be determined from studies involving different types of matrices. This would clearly seem a worthy investigation, considering the many applications where chrysotile fibers are used as reinforcing agents in high-temperature materials.

Received September 8, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

D. Lorne Ball, E. D. Cooke, Jean M. Cooley, M. Coreen Hamilton, and Robert Schutte. Can. J. Chem. **59**, 1527 (1981).

A simple and rapid method has been developed to measure the bitumen, water, and solids content of Athabasca oil sand samples in order to efficiently serve both plant operations and research needs. A solvent blend of 74% toluene and 26% isopropyl alcohol extracts both the bitumen and the water from the solids producing a homogeneous liquid phase. The bitumen is determined gravimetrically on an aliquot of this solution. A Karl Fischer titration is used to measure the water concentration. Solids are measured gravimetrically or can be reported by difference. Mass balances between 99.05 and 100.25% are achieved routinely.

D. Lorne Ball, E. D. Cooke, Jean M. Cooley, M. Coreen Hamilton et Robert Schutte. Can. J. Chem. **59**, 1527 (1981).

Dans le but d'aider tant les opérations industrielles que la recherche, on a mis au point une méthode simple et rapide pour mesurer le bitume, l'eau et les solides contenus dans des échantillons de sable bitumineux de l'Athabasca. Grâce à un mélange de solvant formé de 74% de toluène et de 26% d'alcool isopropylique on peut extraire le bitume et l'eau des solides et former une phase liquide homogène. Grâce à la gravimétrie, on peut déterminer le contenu en bitume d'un échantillon de cette solution. On utilise le titrage de Karl Fischer pour mesurer la teneur en eau. On mesure les solides par gravimétrie ou par différence. On effectue de façon courante des bilans qui valent entre 99,05 et 100,25%.

Introduction

The extensive Athabasca oil sands are assuming an increasing role in supplying Canada's liquid hydrocarbon needs. One commercial plant, Suncor Inc., has operated since 1967. It extracts bitumen from the oil sands and subsequently upgrades it to synthetic crude oil. Syncrude Canada Ltd., which is designed to produce 109 000 barrels of synthetic crude per day, began production in 1978. Fundamental to the successful utilization of this oil sand resource and to the economic operation of the extraction plant is a reliable analytical method for the assessment of bitumen in reserves and plant feed. Because economics require that only feed of 6% bitumen or greater enters the process and because different grades of oil sand require changes in process conditions for efficient operation, the analytical method must also be rapid and efficient.

Oil sand is a variable mixture of organics (bitumen), water, and solids. The bitumen content varies between 0 and 16% by weight, the water content between 0 and 8% by weight, and the solids make up the remainder of the sample. Methods for measuring the bitumen as well as the water and solids in oil sand samples have been used for many years. A well established procedure is the modified Dean–Stark method (1). In that method the bitumen is extracted with hot toluene, and, as with the solids, is determined gravimetrically. The water is collected in the Dean–Stark trap and determined volumetrically. The method yields highly reliable results as exemplified in a 1973 study by the Canadian Petroleum Association Tar Sands Council (2). A serious disadvantage of the method, however, is the extraction time of at least 8 h and an elapsed time of 24 h. For feedback to plant operators and often for research purposes such a long turnaround time cannot be tolerated. Therefore, a need existed for a faster method for analysis of oil sand.

Specifically, the criteria for a new method of bitumen, water, and solids analysis in oil sand are: an analysis time of less than 1 h per sample, the technique must be simple, the reagents must be safe, all three components must be able to be determined from a single sample, higher operator productivity than with the current method, and the maintenance of accuracy and precision of the method in current use.

Because oil sand is highly variable, the parameters by which it can be assayed are limited. Bitumen itself is a complex mixture of a large number of organic molecules and is therefore difficult to be measured quantitatively. Spectroscopic techniques have been investigated, but as Patel reported (3), measuring bitumen from its response at 530 nm is valid only if the standards and samples are obtained from within the same imme-

diate area of the deposit which is not practical in the commercial laboratory. Furthermore, Syncrude's experience has shown that spectrophotometric response for bitumen obtained from different depths of the same core hole can vary as much as 30%. Severe response variations in the infrared and ultraviolet regions were similarly encountered, and these techniques were necessarily discarded. The use of gravimetric/ashing and pyrolysis techniques was also eliminated because of the random presence of finely divided coal. As a consequence, mass was identified as the only reliable parameter by which bitumen could be determined. The choice of this parameter demanded an initial separation of the bitumen from the solids.

Although water is present in the oil sands in a complex manner, its determination was considered to be relatively straightforward and possible by a variety of techniques, e.g., Karl Fischer titration or gas chromatography.

The determination of solids was complicated by the extreme variation in solids composition, ranging in all combinations from sand to silt to clay. Thus, it required a determination by mass.

Experimental

Analytical Procedure

The extraction solvent, 74% toluene (conforming to ASTM D841-50 for nitration grade), 26% isopropyl alcohol (ACS reagent grade) blend (vol.%) is prepared by mixing the appropriate volumes of each solvent in a large closed container. Type 4A molecular sieves are added to dry the solvent. Unless the weather is unusually humid, the solvent should dry within 24 h. The density of this blend is 0.8440 kg/L at 20°C and this value is used as a check on its composition. The solvent density, which should be kept in the range 0.8435 to 0.8445 kg/L, is measured daily and recorded. The solvent blend is also analyzed daily by Karl Fischer titration to ensure that it is dry.

Six standard water solutions, in the range of 0.2–2.0 g water per 100 mL solution, are prepared by weighing distilled water (to the nearest 0.0001 g) into a volumetric flask and diluting it to volume with the toluene/isopropyl alcohol solvent blend. The solutions are mixed, transferred to 125 mL serum bottles and sealed. These solutions keep for several months if the glassware used for their preparation and storage has been treated with a silylating agent, dimethyldichlorosilane, to prevent adsorption of the water from the solutions.

A Photovolt Aquatest II Automatic Karl Fischer Titrator is calibrated daily using the standard water solutions. A 200 μL Hamilton push button syringe is adjusted to deliver a volume of 100 μL. The syringe is then rinsed three times with the most dilute water standard, a minute is allowed for the syringe to return to its equilibrium volume, the syringe filled, and the aliquot injected into the titration cell of the instrument. The value of the aliquot titre is recorded and two more aliquots of the same standard solution are titrated. In the same manner, three aliquots of each of the five remaining standard water solutions are titrated.

An oil sand sample (between 20 and 50 g) is transferred to a preweighed 500 mL Nalgene bottle (linear polyethylene) and its weight is recorded. Approximately 250 mL of the solvent blend is then added. The bottle is tightly capped, and reweighed to determine the exact quantity of solvent added. The Nalgene bottle is then placed on a reciprocating shaker (40 mm stroke, 5 cycles/s) and the oil sand/solvent mixture shaken for at least 10 min. When the bottle is removed from the shaker, it is allowed to stand upright for 3 min to settle the coarse solids. Aliquots of the resultant extract solution are analyzed for bitumen and water content.

Fifteen cm diameter glass fiber filters are dried in a 110°C oven for 1 h, cooled, and then weighed to the nearest 0.0001 g. For the bitumen analysis approximately 10 mL of the extract solution is filtered to remove fine solids. A 0.45 μm 25 mm Millipore Millex filter assembly is attached to a Luer-lok syringe and the filtrate is collected in a small Erlenmeyer flask which is then stoppered. A calibrated 5 mL transfer pipet is rinsed with the filtered extract solution and then used to distribute an aliquot of the extract to a weighed glass fiber filter. This is hung for 15 min to evaporate the water and the solvent and then reweighed to measure the bitumen present.

If the water determination is not done immediately after the Nalgene bottle is removed from the shaker, the bottle is shaken by hand and then a 100 μL aliquot is analyzed by Karl Fischer titration following the procedure used for the water standard.

After the aliquots of sample extract solution have been removed for bitumen and water analyses, the remaining extract is filtered to separate the solids. A 350 mL fine pore glass frit filtering funnel is filled with a 30 mm layer of Celite 499 filter aid and then weighed to the nearest 0.01 g. The funnel is placed on a filtering flask, the filter aid is wetted with solvent blend, and the vacuum turned on. The sample extract solution and solids are poured into the filtering funnel. The inside of the Nalgene bottle is washed with solvent blend and the washings are also poured into the funnel. The solids in the funnel are washed with several portions of solvent blend until the effluent appears colourless. The clean solids are finally washed with acetone to aid in drying. The funnel and solids are dried in the oven at 110°C, allowed to cool and then reweighed.

Calculations

The Karl Fischer titrator calibration data are subjected to a linear regression analysis to obtain the slope and the intercept of the median Karl Fischer titrator reading versus water standard concentration.

The volume of the extract solution is calculated using correction factors to account for non-ideal solution mixing. Volume of extract solution = solvent volume + 1.02 (grams of bitumen in sample) + 0.98 (grams of water in the sample). By solving simultaneous equations the percent bitumen and water can be computed. If the solids were measured the percent solids and mass balance check are then calculated.

Results and Discussion

Solvent Composition

Bitumen is defined as the toluene extractable portion of an oil sand sample (4). After extensive experimentation a solvent blend of 74 vol.% toluene and 26 vol.% isopropyl alcohol proved to have the optimum extraction capability for both the bitumen and water in the amounts likely to be found in oil sand. It is a relatively non-toxic blend and readily available. Simple mixing of an oil sand sample with a quantity of this solvent blend will effect extraction within 10 min.

Aliquot pipetted	Weight on filter* (g) After 9 min	After 11 min	After 13 min	After 15 min	After 18 min	After 20 min	After 25 min	After 45 min
2.5 mL solvent	0.0007	0.0001	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000
2.5 mL sample extract	0.0481	0.0470	0.0470	0.0468	0.0466	0.0464	0.0462	0.0460
5.0 mL solvent	0.0016	0.0008	0.0003	0.0000	0.0000	0.0000	0.0000	0.0000
5.0 mL sample extract	—	0.0955	0.0945	0.0938	0.0937	0.0937	0.0934	0.0926

*Each number is the average of six determinations.

Bitumen Measurement

A fast gravimetric determination requires rapid evaporation of the solvent and water from the extract solution. A 15 cm glass fiber filter adequately absorbs 5 mL of a sample extract solution and, when hung on a clip to dry, exposes a very large area to the atmosphere, permitting the solvent to evaporate quickly. The pipet used to transfer the aliquot must be calibrated with a solution that approximates the sample extract solution, and the evaporation time of the solvent from the filter must be carefully controlled. Data are shown in Table 1 for the weight of glass fiber filters as a function of time for filters on which aliquots of pure solvent blend or sample extract solutions have been pipetted. These data indicate that incorrect evaporation times will result in an error in the bitumen analysis. Too short an evaporation time will give a high result while too long an evaporation time will give a low bitumen result, presumably due to loss of volatile bitumen components. These data also show that there is more leeway in the evaporation time for a 5 mL aliquot (15–20 min) than for a 2.5 mL aliquot (11–13 min), suggesting that the 5.0 mL aliquot measurement will be less operator sensitive and more suitable for routine laboratory use. Determinations on a 5.0 mL aliquot are also more precise than those on a 2.5 mL aliquot. For example, ten 2.5 mL determinations on a typical oil sand extract solution give an average of 0.0418 g bitumen with a standard deviation of 0.0004 g. Ten 5.0 mL measurements on the same solution give an average bitumen value of 0.0836 g and a standard deviation of 0.0002 g. Extrapolating this uncertainty from the 5 mL aliquot to the bulk extract solution (approximately 250 mL total volume) gives an uncertainty of 0.010 g. For a 30 g sample containing 10% bitumen this means an uncertainty of 0.033% (absolute) or 0.33% (relative) in the bitumen determination.

Water Measurement

The Karl Fischer method of water determination was chosen because it is a fast and reliable way to obtain water measurements of high accuracy and precision. The Aquatest II Karl Fischer Titrator is a constant current coulometer which needs minimal maintenance and calibration. However, the instrument is calibrated daily to compensate for fluctuations in the current and to eliminate the need to measure the volume of sample delivered by the syringe. It titrates 10^{-5} g of water per second so only small volumes of sample are analyzed to allow the titration to be completed quickly. The Hamilton push button syringe delivers the sample with excellent repeatability. Calibration data are given in Table 2 for solutions of solvent blend containing various amounts of water. The calibration data indicate that there is a linear relationship between the instrument response and the water concentration over the entire range of water solubility in the solvent blend.

Solids Measurement

Even samples containing large proportions of fine material filter easily with no detectable loss of fines when a filter aid, such as Celite 499, is used to separate the sample solids from the extract solution.

Calculations

To determine the percent bitumen and water in the sample the total volume of the extract solution

TABLE 2. Calibration data for the Aquatest II Automatic Karl Fischer Titrator*

Concentration of standard (g H_2O/100 mL)	Titrator readings	Median reading

TABLE 3. Comparison of the modified Dean–Stark and Syncrude bitumen, water, solids analyses on subsamples of a medium grade oil sand

Method	No. of samples analyzed	% Bitumen (average ± std. dev.)	% Water (average ± std. dev.)	% Solids (average ± std. dev.)
Modified Dean–Stark	12	11.14 ± 0.21	4.48 ± 0.16	84.38 ± 0.25
This method	12	11.00 ± 0.26	4.49 ± 0.15	84.50 ± 0.22

must be determined. The volume of extract solution is calculated from the amount of solvent blend used to extract the sample and the weights of bitumen and water extracted into the solvent. Volume correction factors for the dissolution of bitumen (1.02 mL/g) and water (0.98 mL/g) have been determined.

Accuracy and Precision

In the absence of primary standards or standard reference materials the accuracy of this method cannot be determined. The absence of determinate errors was shown by comparing the results of analysis by this method to the results by the modified Dean–Stark procedure for subsamples of the same bulk oil sand sample. Results by the two methods compare favourably. Data are shown in Table 3 for the bitumen/water/solids analysis by the two methods for subsamples of a medium grade oil sand sample. The precision of the analyses of all three components is comparable to the precision obtained from the modified Dean–Stark analyses, and is well within the 5% relative standard deviation limit expected by the Canadian Petroleum Association Tar Sands Council (2).

The method has been used routinely in Syncrude Canada Ltd.'s laboratories for several years. All types and compositions of oil sands were amenable to analysis by this method. Less than 5% of a set of 3000 core oil sand analyses had to be repeated because of analyses falling outside the 99.05 to 100.25% mass balance limits which Syncrude requires for both methods.

Conclusions

A new method was developed which allows the accurate analysis of an oil sand sample within a 40 min turnaround time. The bitumen and water in the sample are extracted from the oil sand by shaking the sample with a known quantity of dry solvent. The solvent blend, 74% toluene, 26% isopropyl alcohol (vol.%), dissolves both the bitumen and the water and results in a homogeneous liquid phase plus the solids. An aliquot of this extract is filtered and evaporated to remove the solvent and water, and the bitumen is determined gravimetrically. Another aliquot of the extract is analyzed for water content by an automatic Karl Fischer titrator. Before the percentages of bitumen and water are calculated the volume of solvent blend used is corrected to take into account dissolved bitumen and water. Solids are routinely filtered, dried, and weighed so that a mass balance check is obtained on the analysis. The elapsed time for the analysis of a single sample (solids by difference) is 40 min and the total elapsed time for a set of 10 samples (solids by difference) is 2 h. The determination of the solids content of a set of 10 samples requires an additional 40 min.

This method is a fast, safe, and reliable method for determining the bitumen, water, and solids content of oil sand samples. Analytical results can be obtained in a significantly shorter time than with the conventional method, and with equal accuracy and precision.

Streaming current detector for reversed-phase liquid chromatography

SHIGERU TERABE, KIYOSHI YAMAMOTO, AND TEIICHI ANDO

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto, 606 Japan

Received September 8, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

SHIGERU TERABE, KIYOSHI YAMAMOTO, and TEIICHI ANDO. Can. J. Chem. **59**, 1531 (1981).

Fundamental characteristics of the electrokinetic detector for high performance liquid chromatography, whose operating principle is based on the measurement of the streaming current between both ends of a bundle of glass capillaries, were studied under reversed-phase chromatographic conditions. The detector is specifically sensitive to ionizable compounds like carboxylic acids and amines, but is also universally responsive to nonionic compounds. The detection limit for the former compounds was about 10^{-8} g and for the latter about 10^{-4} g. The lowest amount actually measured was 5.8×10^{-9} g. The universal detectability makes this type of detector unsuitable for gradient elution. The observed streaming current was in the range of 10^{-7} to 10^{-8} A and was highly dependent on the flow rate of the mobile phase. Characteristics of the detectors equipped with some packed beds prepared from porous materials instead of glass capillaries were also investigated.

SHIGERU TERABE, KIYOSHI YAMAMOTO et TEIICHI ANDO. Can. J. Chem. **59**, 1531 (1981).

En utilisant la chromatographie en phase inversée, on a étudié les caractéristiques fondamentales d'un détecteur électrocinétique pour un chromatographie en phase liquide à haute performance, dont le principe d'opération repose sur la mesure du courant gazeux aux extrémités d'un groupe de tubes capillaires en verre. Le détecteur est sensible spécifiquement aux composés susceptibles de s'ioniser tels les acides carboxyliques et les amines, mais d'une façon générale il est également sensible aux composés non ioniques. La limite de détection des premiers composés est d'environ 10^{-8} g et dans le cas des derniers la limite est d'environ 10^{-4} g. La plus faible quantité mesurée actuellement est de $5{,}8 \times 10^{-9}$ g. La détection universelle rend ce type de détecteur impropre à l'utilisation de gradients d'élution. Le courant observé varie de 10^{-7} à 10^{-8} A et il dépend fortement de la vitesse d'écoulement de la phase mobile. On a également étudié les caractéristiques de détecteurs équipés de lits entassés à partir de matériels poreux au lieu de tubes de verre.

[Traduit par le journal]

Introduction

Among various detecting devices for high performance liquid chromatography (HPLC), uv photometers and refractometers are now mainly used although their performance characteristics are not always satisfactory. New detectors having higher sensitivity or higher specificity than the currently available detectors are desirable for many purposes.

A new type of detector, whose operating principle is based on the measurement of electrokinetic phenomenon, has been developed by Czechoslovak chemists (1, 2). They have investigated the generation of the streaming current in low-conductivity liquids both by theory and by experiment. This paper describes the results of our studies which were made in order to explore the performance characteristics of such a detector under reversed-phase chromatographic conditions.

When a liquid is forced to flow through a capillary or a packed bed, an electrical potential is produced between its ends. This potential is called the streaming potential, and is given by (3)

$$E = (\varepsilon\zeta/4\pi\eta\kappa)P$$

where ε, κ, and η are the permittivity, specific conductivity, and viscosity of the liquid, respectively, ζ is the ζ-potential, and P is the pressure drop of the liquid transported through a capillary or a packed bed.

The parameters appearing in the above equation, ε, ζ, η, and κ, are all dependent on the composition of the liquid. When the composition of the mobile phase is kept constant, i.e., under isocratic conditions, the variation of the composition with a solute is very slight and the permittivity and viscosity of the eluent and the pressure drop can be assumed to remain practically unchanged.

This implies that the detection of a solute in the eluent by measurement of the streaming current, if possible, should be based on the change in the ζ-potential and conductivity of the eluent, and leads to the expectation that such a detector should be specifically sensitive to ionic compounds because both the ζ-potential and the conductivity are highly dependent on the concentration of ionic species in the liquid. The ζ-potential is also dependent on the material of which a capillary or a packed bed is made.

In this study, two kinds of streaming current detector cells, i.e., a bundle of glass capillaries and a polytetrafluoroethylene (PTFE) tube packed with various porous materials (porous beds) were prepared and their fundamental characteristics as a

detector, such as the dependence of baseline current on the kind, composition, and flow rate of the mobile phase, the dynamic range of the response, and the detection limits for various compounds, were investigated under reversed-phase chromatographic conditions adopted most widely in modern HPLC.

Experimental

Schematic diagram of the streaming current detector is shown in Fig. 1. The eluent from a separation column was transported to the detector cell through PTFE tubing of 0.25 mm id and 1.5 mm od. The entrance end of the cell was grounded and the electrical current from the exit end to the ground was measured with a Takeda Riken TR-8651 electrometer, used as an electronic ammeter. The direction of the current was designated positive when it flowed from the exit end to the ground. The input resistance of the electrometer was chosen so that it did not exceed 1% of the resistance of the liquid in the detector cell. It was usually in the range of 10^4–10^6 Ω. In some cases, the current was measured with different input resistances in order to confirm the correct choice of the input resistance.

Figure 2 shows scanning electronmicrographs of a cross section of the bundle of glass capillaries used in this study as detector cell. The bundle was made by drawing a glass tube of 3.4 mm id and 5 mm od packed with glass capillaries of 0.1 mm id and 0.15 mm od. The glass capillary cell used was 1.5 mm od, 2 cm in length, and contained about 300 capillaries of 15–20 μm in diameter. Packed beds used for detector cells are listed in Table 1.

Three combinations of a pump and an injector were used: a Waters 6000A pump and a Waters U6K injector, a Jasco Tri Rotar and a Jasco VL-611, and a Jasco A700 and a Rheodyne 7120. When 6000A or Tri Rotar was employed, not only the pulse damper belonging to each pump but also an air damper of a stainless tube of 8 mm id and 50 cm in length were used to reduce pulsating flows generated by the reciprocating pump. In some cases, a variable-wavelength photometric detector, a Cecil CE212 or a Jasco Uvidec-100-II, was connected with the streaming current detector in series in order to evaluate the detector. Two sizes of chromatographic columns, 4.6 mm id × 20 cm and 4.6 mm id × 10 cm, were used and they were packed with Nucleosil $7C_{18}$, average particle size 7.5 μm (Macherey-Nagel & Co., Düren, G.F.R.) by the modified viscosity method recommended by the manufacturer. A column of 20 cm in length was used unless otherwise mentioned.

Methanol and acetonitrile were of HPLC-quality; acetone and tetrahydrofuran (THF) were of reagent grade. The carboxylic acids, amines, and other chemicals used as injection samples were of reagent grade and used without further purification. All the solvents and chemicals were purchased from Nakarai Chemicals Ltd. (Kyoto, Japan) or Wako Pure Chemical Industries Ltd. (Osaka, Japan). Water was purified by means of an ion-exchange column followed by single distillation in glassware.

Results and Discussion

Baseline Current

Dependence of the streaming current (baseline current) on the flow rate of the mobile phase was first examined with a glass capillary detector cell. As shown in Fig. 3, the current was directly proportional to the flow rate for all solvents tested: e.g., an increase of the flow rate of water by 0.1 mL/min caused an increase of the current by about 1.8×10^{-8} A. On the other hand, the change of the baseline current by an eluted sample is usually less than 10^{-8} A as will be shown later. This means that the fluctuation of the flow rate of the mobile phase should be kept as small as possible to assure high sensitivity in detection.

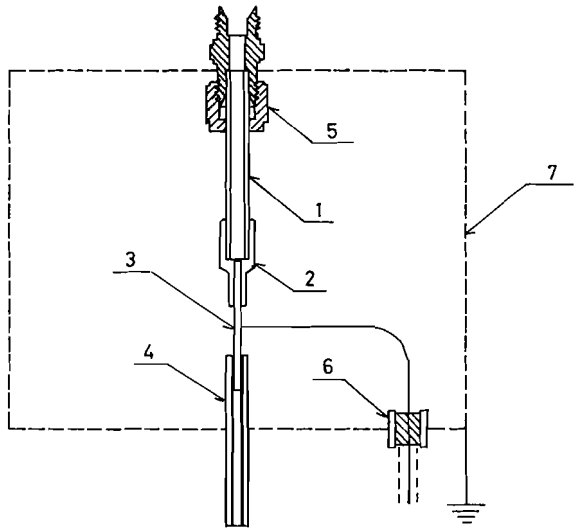

FIG. 1. Schematic diagram of the streaming current detector. *1* = Detector cell (bundle of glass capillaries or packed bed); *2* = shrinkable PTFE tubing; *3* = platinum tubing (0.25 mm id × 10 mm); *4* = PTFE tubing for draining off the mobile phase or for connecting to another detector; *5* = Swagelok union (1/16 in.); *6* = connector to electrometer; *7* = shielding box of aluminum (7 cm × 7 cm × 5 cm).

The same type of dependency was observed when the packed beds listed in Table 1 were used instead of the glass capillaries. Table 2 shows the baseline currents observed for four kinds of solvents at the flow rate of 1.0 mL/min with glass capillary and porous bed cells. The direction of the current was positive in all cases.

In Fig. 4 is shown the dependence of the baseline current on the composition of aqueous organic solvents used as mobile phase. Examples shown in Fig. 4 were obtained when the bundle of glass capillaries was used as detector cell at the flow rate of 1.0 mL/min. Dependence of the current on the compositions was also examined for the porous bed cells by using mixtures of methanol and water. No linear relationship was observed between the current and the composition of the mobile phase except for the methanol–water system in glass capillaries.

The substantial variation of the streaming current with the composition of the mobile phase makes the streaming current detector unsuitable for the gradient elution technique.

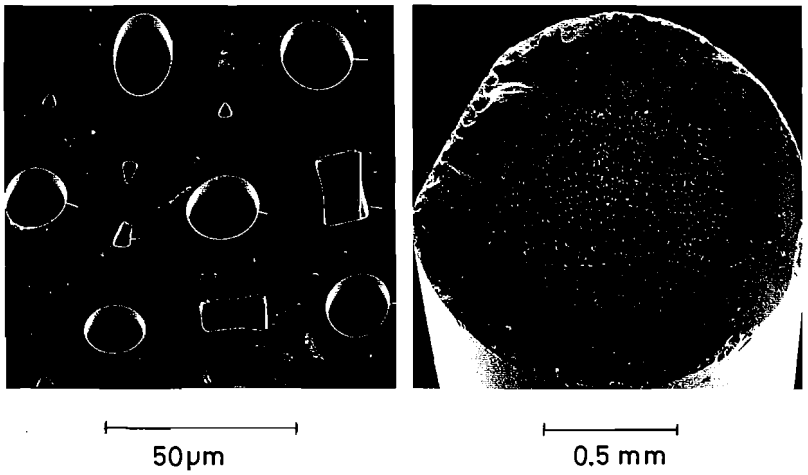

FIG. 2. Scanning electronmicrographs of a cross section of a bundle of glass capillaries.

TABLE 1. Packed beds in PTFE tubing used for the streaming current detector

Packed bed	Packing material	Size
Alumina	Woelm, neutral, 70 μm	0.5 mm id × 7 mm
Silica gel	Du Pont, Zipax, 25–37 μm	0.5 mm id × 7 mm
Silica gel	M.-Nagel, Polygosil, 10 μm	0.8 mm id × 5 mm
ODS	Du Pont, Permaphase, 25–37 μm	0.5 mm id × 7 mm
Titania	Alfa, crashed in a mortar	0.8 mm id × 10 mm

Linear Dynamic Range

As a response characteristic of the streaming current detector, the relationship between the quantity of the sample injected and the peak area was investigated. Since the change of the baseline current caused by the solute in the eluent was small relative to the baseline current, it was necessary to operate the electrometer at a higher sensitivity than for measuring the baseline current. It was performed by shifting the baseline current to near zero by means of the current compensator belonging to the electrometer.

Calibration curves for nonanoic acid, 3,4-xylidine, and *p*-nitrophenol, obtained with the glass capillary cell, are shown in Fig. 5. All the calibration curves obtained were straight in the range of two orders of sample quantity, regardless of the

mobile phase or the flow rate. When the sample quantity exceeded a certain limit, the curve altered to a convex one, as indicated in Fig. 5 for nonanoic acid.

It was also noticed that the peak heights were nearly proportional to the sample quantity in the linear region of the calibration curve but not in the non-linear region: an increase of the sample quantity caused little or no increase of the peak height but a substantial increase of the peak width instead in the non-linear region.

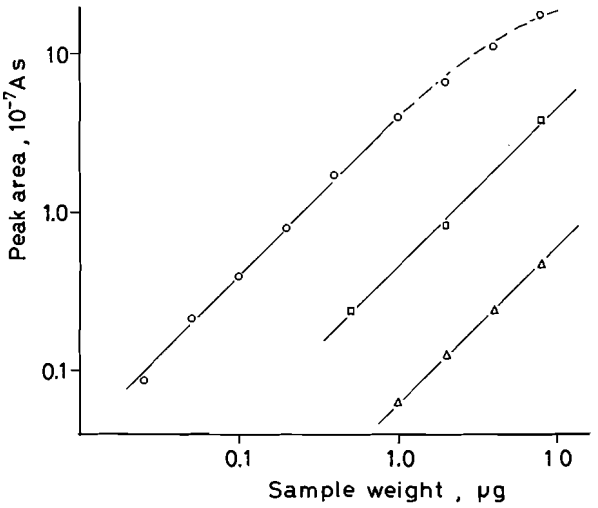

FIG. 5. Dependence of detector response on the amount of sample injected. Detector cell, bundle of glass capillaries; sample, nonanoic acid (○), 3,4-xylidine (□), and *p*-nitrophenol (△); see Table 3 concerning other conditions.

To learn the reason for this abnormal peak shape, a variable-wavelength uv photometer was connected in series with the streaming current detector and the linear dynamic ranges of the two detectors were compared by use of compounds absorbing uv light such as toluic acids. Peak heights with the uv detector were proportional to the sample quantity even in the non-linear region of the calibration curve obtained with the streaming current detector. These results evidently show that abnormal peak shapes observed at the non-linear region are not due to overloading on the separation column but to the intrinsic nature of the streaming current detector.

The linear dynamic range of the porous bed detector cells was also found to be about two orders of the quantity of the carboxylic acids investigated. No substantial differences in the linear dynamic ranges were recognized among the porous bed detector cells tested.

Noises

Two chromatograms of a mixture of three isomeric toluic acids were simultaneously recorded, as shown in Fig. 6, with the glass-capillary type streaming current detector and a uv detector connected in series. The uv detector was operated at 264 nm, where the three toluic acids had nearly the same molar absorptivity.

The marked deviation of the baseline at the injection point in the chromatogram with the streaming current detector can be attributed to the instantaneous pressure drop caused by the large volume (about 2 mL) of the sample loading loop of a Waters U6K injector, which was at atmospheric pressure before injection.

The chromatogram shown in Fig. 7 is another example of the detection with the streaming current detector; the titania bed was used as detector cell and six fatty acids having an even number of carbon atoms from C_{12} to C_{22} as samples. Periodic fluctuation observed in the baselines in Figs. 6 and 7 were associated with the pulsating flow by the reciprocating pumps employed, although the frequencies were different because of the difference in pumping mechanism of the two pumps.

This pulsating flow, which could not completely be eliminated even by the use of an air damper in addition to the pulse damper belonging to each pump, was the dominant factor responsible for the detector noises.

Relationship between Sensitivity and Streaming Current

The baseline current increased linearly with the flow rate of the mobile phase as mentioned above.

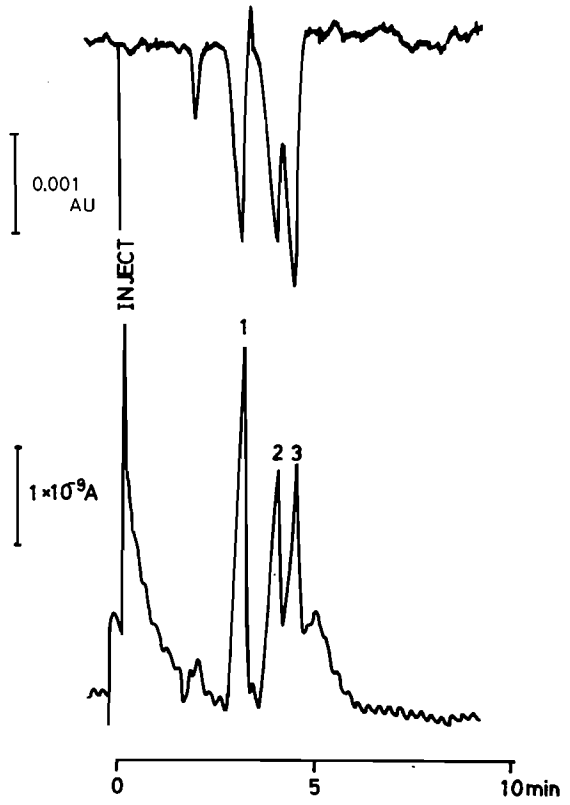

FIG. 6. Chromatogram of toluic acids obtained with the streaming current and a uv detector. Detector, a Cecil CE212 variable-wavelength uv photometer at 264 nm (upper trace) and the streaming current detector equipped with a bundle of glass capillaries (lower trace); pump, a Waters 6000A; injector, a Waters U6K; mobile phase, methanol–water (40:60); flow rate, 0.7 mL/min; sample, mixture of equal amounts (0.17 μg each) of *o*-(*1*), *m*-(*2*), and *p*-toluic acid (*3*).

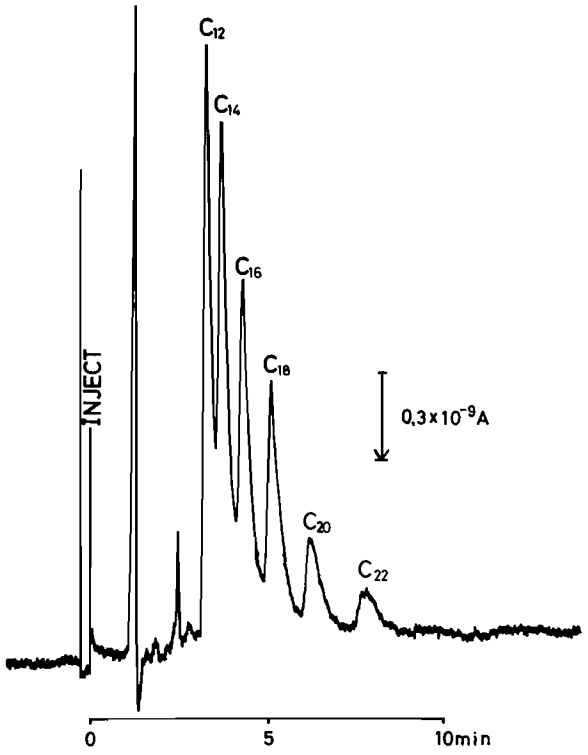

FIG. 7. Chromatogram of fatty acids of C_{12}–C_{22} obtained with the streaming current detector. Detector cell, packed bed with titania; pump, a Jasco Tri Rotar; injector, a Jasco VL-611; mobile phase, methanol; flow rate, 1.0 mL/min; sample, 1 μg each.

An example of the dependence of the detector sensitivity on the flow rate is given in Fig. 8. Peak heights were practically proportional to the flow rate, but peak areas were virtually independent of the flow rate because peak widths ordinarily decreased with an increase of the flow rate. This is a characteristic of the streaming current detector distinctly different from other detectors widely used in modern HPLC such as uv photometer, refractometer, and fluorimeter, where peak heights are independent of, but peak areas are dependent on, the flow rate.

The detection limits of this detector for various kinds of compounds will be given later. The relationship between the detection limit and the flow rate was examined under the following conditions: palmitic acid as sample, methanol as mobile phase, and the glass capillaries as detector cell. It was found that the detection limit was inversely proportional to the flow rate, i.e, the larger the baseline current, the smaller the detection limit. The same relationship was observed when the porous beds were used instead of the glass capillaries.

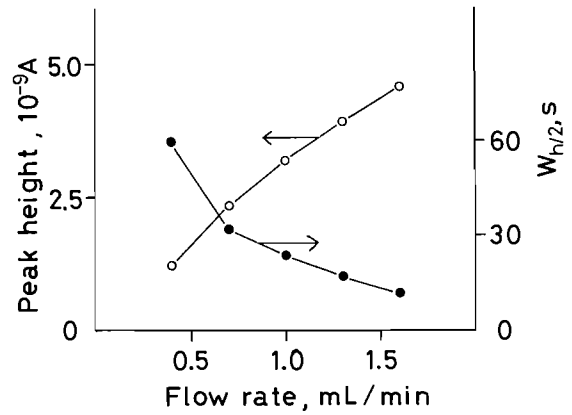

FIG. 8. Dependence of peak height and peak width at half-height on the flow rate of mobile phase. Detector cell, bundle of glass capillaries; mobile phase, methanol; sample, palmitic acid 0.3 μg.

The baseline current was seriously affected by the addition of a small amount of a salt. For exam-

[d]Column, Nucleosil $7C_{18}$ 4.6 mm id × 10 cm.

ple, when sodium nitrate (1 m*M*) was added to the water as mobile phase, the baseline current was reduced to one-fifth and concurrently the sensitivity to one-tenth of the values obtained with pure water.

These results clearly show that the streaming current detector must be used at a baseline current as large as possible to secure high sensitivity in detection.

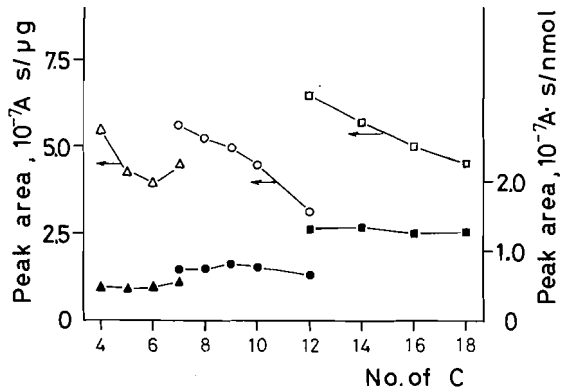

FIG. 9. Dependence of sensitivities (peak area per μg and per μmol) on the number of carbon atoms of fatty acids. Detector cell, bundle of glass capillaries; mobile phase and flow rate, methanol–water (50:50) and 0.6 mL/min (△,▲), methanol–water (70:30) and 0.7 mL/min (○,●), and methanol–water (90:10) and 1.0 mL/min (□,■).

Detection Limits for Various Compounds

Figure 9 shows the relationship between the peak area expressed per weight or per mole and the number of carbon atoms of fatty acids having C_4–C_{18} straight chains. The peak area per mole was practically constant irrespective of the number of carbon atoms, if the mobile phase was unchanged. Very probably, the constancy of the peak area per mole for fatty acids is closely related to their similarity in pK_a values (4).

The detection limit, expressed as the quantity of an injected sample which gave a peak height equal to twice the peak-to-peak noise level, was evaluated for various kinds of compounds. Values of detection limits obtained with the glass capillaries as detector cell are summarized in Table 3. The direction of peak is also indicated in the table. As a rule, acidic compounds caused a decrease of the baseline current, i.e., they gave negative peaks; on the contrary, basic compounds generally gave rise to positive peaks.

As shown in Fig. 6, the streaming current detector and a variable-wavelength uv photometer gave

[b]Mobile phase, methanol–water (40:60); flow rate, 1.0 mL/min unless otherwise mentioned.
[c]Flow rate, 0.8 mL/min.

nearly equal sensitivities for aromatic carboxylic acids. The relationship between the detection limits for acidic compounds and their pK_a values (4) can be summarized as follows: the detection limits for the compounds whose pK_a values are less than 5, such as fatty acids, picric acid, toluic acid, etc., are nearly identical, whereas that for *p*-nitrophenol (pK_a 7.1) is two-orders higher and that for *m*-nitrophenol (pK_a 8.4) three-orders higher than those for the acids cited above.

The same type of pK_a effect is also found in Fig. 6, a chromatogram of a mixture of equal amounts of three isomeric toluic acids. The peak of *o*-toluic acid (pK_a 3.9) is definitely higher than those of *m*- (pK_a 4.3) and *p*-isomer (pK_a 4.4).

The detection limit for toluene is much larger than for acids, as shown in Table 3. This low sensitivity for toluene may be interpreted as follows. It is reasonable to assume that ionic dissociation of toluene in the neutral mobile phase (aq. methanol) can be neglected. If 1 mg of toluene, which is twice the detection limit, is injected, the concentration of toluene in the eluent from the separation column is expected to be more than 0.1%. The change of this order in the composition of the eluent must affect its ζ-potential, permittivity, and viscosity rather than its specific conductivity. Under such circumstances the detector can act only non-selectively and with low sensitivity. This characteristic seems to render an advantage to the detector for use in the preparative liquid chromatography.

In contrast, the ζ-potential and the conductivity are dominant factors determining the sensitivity for ionic compounds and, therefore, in such cases it can be expected that the larger the pK_a of the sample, the larger the detection limit.

Table 4 lists the detection limits of the detector equipped with porous beds for palmitic acids and *o*-toluic acids. The directions of the peak were all negative except for a silica gel (Polygosil) bed. There was no significant difference among the porous beds in any other performance characteristic including detection limits.

In conclusion, the bundle of glass capillaries is superior to the porous beds as detector cell with respects to baseline stability, reproducibility, and sensitivity, whereas the porous beds are preferred in ease of preparation and handling. Since the volume of the cell is very small, the detector has an advantage that it can be connected with another detector without any peak broadening. The streaming current detector is expected to be useful especially in specific and sensitive detection of ionic species such as carboxylic acids, amines, inorganic ions, etc.

Acknowledgements

The authors gratefully acknowledge the assistance of Mr. T. Kadono of Shionogi Research Laboratory for preparation of the bundle of glass capillaries. One of the authors (S.T.) wishes to express his gratitude to Professor R. S. Juvet, Jr. for giving him the opportunity to start this study, and to Professor W. E. Harris for generous encouragement. Simulation of electrochemical processes by orthogonal collocation. Spherical electrode geometry

B. STANLEY PONS

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 16, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

B. STANLEY PONS. Can. J. Chem. **59**, 1538 (1981).

Discretization formulas for the digital simulation of the diffusional processes associated with a variety of electrochemical processes at a spherical electrode are given. The formulas are based on orthogonal collocation techniques. Several mechanisms are represented, and the technique is demonstrated for chronoamperometry, chronopotentiometry, and cyclic voltammetry.

B. STANLEY PONS. Can. J. Chem. **59**, 1538 (1981).

On donne des formules uniques pour la simulation numérique des processus diffusionnels associées à différentes réactions électrochimiques au niveau d'une électrode sphérique. Les formules sont établies à partir des techniques de collocation orthogonale. On représente plusieurs mécanismes, et on démontre l'application de cette technique à la chronoampérométrie, à la chronopotentiométrie et à la voltamétrie cyclique.

Orthogonal collocation techniques for the simulation of second order partial differential equations have been demonstrated for a variety of problems in electrochemistry (1–7), chemical engineering (8–11), differential scanning calorimetry (12), and other fields (13). The advantages over other methods have been described, but noteworthy is generally increased accuracy for decreased computational effort (1–7).

In electrochemical diffusion problems, the algorithms needed to compute concentration profiles, chronopotentiograms, chronoamperometric responses, spectrophotometric responses of individual species, cyclic voltammograms, and chronocoulometric responses, all to planar electrode configurations, have been given. This paper deals with some of the same experiments applied to a common configuration, the static spherical electrode (Fig. 1).

The programs for solving the equations described herein have been given (7). Basically, the orthogonal collocation technique is implemented by the following steps. (*1*) Make the Ficks laws equations suitably dimensionless. (*2*) Discretize the resulting equations at the roots (zeros) of an orthogonal polynomial of suitable symmetry. The resulting set of equations now consists of first order ordinary differential equations. (*3*) Integrate the set of simultaneous differential equations to obtain the set of concentration profiles with respect to distance from the electrode surface and with time. (*4*) Use these concentrations in the suitably discretized equations to obtain the desired electrochemical parameter (current, absorbance, etc.).

Chronoamperometry

We will only consider diffusion on the solution side of the electrode–solution interface. For a chronoamperometric experiment on the simple charge transfer mechanism at a spherical electrode

$$[1] \quad A \overset{ne^-}{\rightleftharpoons} B$$

we have the following imposed conditions:

$$[A]_{R,0} = [A]_{\infty,T} = [A^0]$$

$$[2] \quad [A]_{r_0,T} = [B]_{\infty,T} = [B]_{R,0} = 0$$

$$\left(\frac{\delta[A]}{\delta R}\right)_{R=r_0} = -\left(\frac{\delta[B]}{\delta R}\right)_{R=r_0}$$

where R is the distance parameter (radial) from the center of the spherical electrode and r_0 = the radius of the electrode. Since interpolation methods using orthogonal polynomials are simpler to use in a [0,1] interval, we will define M as some distance in the R direction such that no diffusion effects are experienced there during the time frame of the experiment. The differential equation for the A species is:

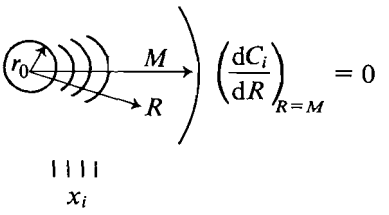

FIG. 1. Spherical electrode geometry.

$$[3] \quad \frac{\delta[A]}{\delta T} = \frac{D_A \delta^2[A]}{\delta R^2} + \frac{2D_A}{R}\frac{\delta[A]}{\delta R}$$

For dimensionless variables, we choose

$$[4] \quad c_A = \frac{[A]}{[A^0]}; \qquad t = \frac{DT}{(M - r_0)^2}; \qquad r = \frac{R - r_0}{M - r_0}$$

We note then that

$$[5] \quad dT = \frac{(M - r_0)^2}{D_A} dt; \qquad \text{and} \qquad dR = (M - r_0)\, dr$$

Substitution of the new variables [4] into [3] gives

$$[6] \quad \frac{D_A[A^0]\delta c_A}{(M - r_0)^2 \delta t} = \frac{D_A[A^0]\delta^2 c_A}{(M - r_0)^2 \delta r^2} + \left(\frac{2D_A}{(M - r_0)r + r_0}\right)\frac{[A^0]\delta c_A}{(M - r_0)\delta r}$$

which, after simplification, leads to

$$[7] \quad \frac{\delta c_A}{\delta t} = \frac{\delta^2 c_A}{\delta r^2} + \frac{2}{r + \beta}\frac{\delta c_A}{\delta r}$$

where

$$\beta = \frac{r_0}{M - r_0}$$

The general spatial derivatives in terms of their polynomial interpolation coefficients (1) are given by

$$[8a] \quad \left(\frac{dQ}{dX}\right)_{X=X_i} = \sum_{j=1}^{N+2} A_{i,j} Q(X_j, t)$$

$$[8b] \quad \left(\frac{d^2Q}{dX^2}\right)_{X=X_i} = \sum_{j=1}^{N+2} B_{i,j} Q(X_j, t)$$

where N is the order of the approximation polynomial chosen, the X_i represents the roots of that polynomial collocation points, and A_{ij} and B_{ij} are given by (10)

$$[9] \quad [A_{ij}] = \begin{bmatrix} dX_1^0/dX & dX_1^1/dX & \cdots & dX_1^{N+2}/dX \\ dX_2^0/dX & & & \\ dX_{N+2}^0/dX & & \cdots & dX_{N+2}^{N+2}/dX \end{bmatrix} \begin{bmatrix} \\ S \\ \\ \end{bmatrix}^{-1}$$

and

$$[10] \quad [B_{ij}] = \begin{bmatrix} d^2X_1^0/dX^2 & d^2X_1^1/dX^2 & \cdots & d^2X_1^{N+2}/dX \\ d^2X_2^0/dX^2 & & & \\ d^2X_{N+2}^0/dX^2 & & \cdots & d^2X_{N+2}^{N+2}/dX \end{bmatrix} \begin{bmatrix} \\ S \\ \\ \end{bmatrix}^{-1}$$

The matrix $[S]$ is given by

$$[11] \quad [S] = \begin{bmatrix} X_0{}^0 X_0{}^1 \ldots X_0{}^{N+2} \\ X_1{}^0 \quad \ldots \\ X_{N+2}{}^0 \quad \ldots X_{N+2}{}^{N+2} \end{bmatrix}$$

The algorithms for finding the roots of any orthogonal polynomial and the corresponding $[A_{ij}]$ and $[B_{ij}]$ matrices have been given previously (9). The $N + 2$ terms arise because $X = 0$ and $X = 1$ are included as roots to the orthogonal polynomial. The concentration profile will be evaluated at the collocation point, i.e. at concentric spheres surrounding the spherical electrode. Each sphere has radius $r = X_1, X_2, X_3$, etc., i.e. at the collocation points.

Equation [7] is thus written in terms of [8*a*] and [8*b*] at the discrete points X_i:

$$[12] \quad \left.\frac{dc_A}{dt}\right|_{r_i=X_i} = \sum_{j=1}^{N+2} B_{ij}c_A(r_j, t) + \frac{2}{r_i + \beta}\sum_{j=1}^{N+2} A_{ij}c_A(r_j, t)$$

Thus we have $N + 2$ simultaneous first order differential equations to solve for the $N + 2$ $c_A(r_j,t)$ unknowns. Any one of several methods may be used for solving this system of equations (1, 4, 9).

Inserting the boundary conditions [2] further defines the electrochemical method used, and reduces the number of equations from $N + 2$ to N. This is done by first expanding eq. [12] partially, exposing the boundary points at $r_1 = X_1 = 0$ and $r_{N+2} = X_{N+2} = 1$:

$$[13] \quad \left.\frac{dc_A}{dt}\right|_{r_i=X_i} = B_{i,1}c_A(0, t) + B_{i,N+2}c_A(1, t) + \sum_{j=2}^{N+1} B_{ij}c_A(r_j, t) + \frac{2}{r_i + \beta}\left[A_{i,1}c_A(0, t) + A_{i,N+2}c_A(1, t) + \sum_{j=2}^{N+1} A_{ij}c_A(r_j, t)\right]$$

We have from the original boundary conditions [2] that $c_A(0,t) = 0$ and $c_A(1,t) = 1$, so [13] becomes

$$[14] \quad \left.\frac{dc_A}{dt}\right|_{r_i=X_i} = B_{i,N+2} + \sum_{j=2}^{N+1} B_{ij}c_A(r_j, t) + \frac{2}{r_i + \beta}\left[A_{i,N+2} + \sum_{j=2}^{N+1} A_{ij}c_A(r_j, t)\right]$$

So we have one equation to solve at each of the N interior collocation points X_i, $i = 2, \ldots, N + 1$ for the N unknown $c_A(r_j,t)$.

The concentration profile for the B species is derived similarly, and leads to identically the same result as eq. [12]:

$$[15] \quad \left.\frac{dc_B}{dt}\right|_{r_i=X_i} = \sum_{j=1}^{N+2} B_{ij}c_B(r_j, t) + \frac{2}{r_i + \beta}\sum_{j=1}^{N+2} A_{ij}c_B(r_j, t)$$

Partial expansion leads again to eq. [13] with $c_B(r_j,t)$ substituted for the $c_A(r_j,t)$. However, even though it is true that one boundary condition, $c_B(i,t) = 1$ may be immediately substituted, the other boundary condition $c_B(0,t)$ is not known explicitly. This problem is easily resolved in collocation methods. We note the flux relation

$$[16] \quad D_A\left.\frac{dc_A}{dr}\right|_{r_1=X_1=0} = -D_B\left.\frac{dc_A}{dr}\right|_{r_1=X_1=0}$$

We will let $D_A = D_B$ here for convenience even though it presents no problem in setting up the equations if we do not (1, 4). The flux relation is replaced by eq. [8*a*] on each side:

$$[17] \quad \sum_{j=1}^{N+2} A_{1,j}c_A(r_j, t) = -\sum_{j=1}^{N+2} A_{1,j}c_B(r_j, t)$$

Partially expanding so that known conditions may be inserted, we have

$$[18] \quad A_{1,1}c_A(0, t) + A_{1,N+2}c_A(1, t) + \sum_{j=2}^{N+2} A_{1,j}c_A(r_j, t) = -\left[A_{1,1}c_B(r_j, t) + A_{1,N+2}c_B(1, t) + \sum_{j=2}^{N+1} A_{1,j}c_B(r_j, t)\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Inserting known quantities, we deduce

$$[19]\quad A_{1,N+2} + \sum_{j=1}^{N+1} A_{1,j}c_A(r_j, t) = -\left[A_{1,1}c_B(0, t) + \sum_{j=2}^{N+1} A_{1,j}c_B(r_j, t)\right]$$

Solving for our unknown boundary condition,

$$[20]\quad c_B(0, t) = U + \sum_{j=2}^{N+1} C_{1,j}(c_A(r_j, t) + c_B(r_j, t))$$

where

$$U = -\frac{A_{1,N+2}}{A_{1,1}}; \qquad \text{and} \qquad C_{1,j} = -\frac{A_{1,j}}{A_{1,1}}$$

We can now substitute this explicit value for $c_B(0,t)$ in eq. [15], along with $c_B(1,t) = 0$ to obtain the equation necessary to represent the concentration profiles for B:

$$[21]\quad \left.\frac{dc_B}{dt}\right|_{r_i=X_i} = V_i + \sum_{j=2}^{N+1} D_{ij}c_A(r_j, t) + \sum_{j=2}^{N+1} E_{ij}c_B(r_j, t)$$

where

$$V_i = B_{i,1}U + \frac{2A_{i,1}U}{r_i + \beta}$$

$$D_{ij} = C_{1,j}\left[B_{i,1} + \frac{2A_{i,1}}{r_i + \beta}\right]$$

$$E_{ij} = B_{ij} + C_{1,j}\left[B_{i,1} + \frac{2A_{i,1}}{r_i + \beta}\right] + \frac{2A_{ij}}{r_i + \beta}$$

Again we have N equations in the N unknown $c_B(r_j,t)$ to solve simultaneously.

Table 1 compares results obtained for the current obtained by eq. [33] and the analytic solution for this case, which is

$$[22]\quad i = \frac{nFAD_A^{1/2}[A^0]}{\pi^{1/2}T^{1/2}} + \frac{nFAD_A[A^0]}{r_0}$$

We use, by example, $D_A = 1 \times 10^{-5}$ cm^2 s^{-1}, $[A^0] = 10^{-6}$ mol cm^{-3}, A $= \pi r_0^2$, $r_0 = 0.1$ cm, and $n = 1$. β for the example was 10^4.

For the mechanism

$$A \rightleftharpoons B \xrightarrow{k} C$$

the profile for the A species is the same as eq. [14]. The B species has a different profile due to loss of material through the chemical reaction, i.e.

$$[23]\quad \frac{\delta[B]}{\delta t} = D_B\frac{\delta^2[B]}{\delta R^2} + \frac{2D_B}{R}\frac{\delta[B]}{\delta R} - k[B]$$

After discretization to the collocation points and insertion of the dimensionless variables [4], we have

$$[24]\quad \left.\frac{dc_B}{dt}\right|_{r_i=X_i} = \sum_{j=1}^{N+2} B_{i,j}c_B(r_j, t) + \frac{2}{r_i + \beta}\sum_{j=1}^{N+2} A_{i,j}c_B(r_j, t) - \alpha c_B(r_i, t)$$

where

$$\alpha = \frac{k(M - r_0)^2}{D_B}$$

Continuing precisely as for the simple electron transfer case, except with the addition of this last chemical kinetic term, we find that

TABLE 1. Comparison of exact and simulated currents for the simple change transfer chronoamperometric experiment. ($N = 6$ collocation points), see text for parameters

Time (s)	i_{exact} (mA)	$i_{simulated}$ (mA)
1×10^{-5}	1.7104	1.7104
1×10^{-4}	0.5411	0.5412
1×10^{-3}	0.1713	0.1712
1×10^{-2}	0.0054	0.0054
1×10^{-1}	0.0017	0.0017
1×10^{0}	0.0001	0.0001

$$[25] \quad \left.\frac{dc_B}{dt}\right|_{r_i=X_i} = V_i + \sum_{j=2}^{N+1} D_{ij}c_A(r_j, t) + \sum_{j=2}^{N+1} E_{ij}c_B(r_j, t) - \alpha c_B(r_j, t)$$

For the catalytic mechanism

$$[26] \quad A \rightleftharpoons B \xrightarrow{k} C + A$$

both the A and B profiles are modified by the presence of the chemical reaction. The differential equations are

$$[27] \quad \frac{\delta[A]}{\delta t} = D_A\frac{\delta^2[A]}{\delta R^2} + \frac{2D_A}{R}\frac{\delta[A]}{\delta R} + k[B]$$

$$\frac{\delta[B]}{\delta t} = D_B\frac{\delta^2[B]}{\delta R^2} + \frac{2D_A}{R}\frac{\delta[B]}{\delta R} - k[B]$$

The boundary conditions are exactly as the previous cases, so that discretization is the same. We find that

$$[28] \quad \left.\frac{dc_A}{dt}\right|_{r_i=X_i} = B_{i,N+2} + \sum_{j=2}^{N+1} B_{ij}c_A(r_j, t) + \frac{2}{r_i + \beta}\left[A_{i,N+2} + \sum_{j=2}^{N+1} A_{ij}c_A(r_j, t)\right] + \alpha c_B(r_j, t)$$

$$[29] \quad \left.\frac{dc_B}{dt}\right|_{r_i=X_i} = V_i + \sum_{j=2}^{N+1} D_{ij}c_A(r_j, t) + \sum_{j=2}^{N+1} E_{ij}c_B(r_j, t) - \alpha c_B(r_j, t)$$

again letting $D_A = D_B$.

To calculate the current at any time for the mechanisms listed above under the chronoamperometric experiment, we note the following:

$$[30] \quad i = nFAD_A\left(\frac{d[A]}{dR}\right)_{R=0}$$

where A is the electrode surface area and F is the Faraday constant. The flux term is converted to dimensionless terms by insertion of the newly defined variables (4).

$$[31] \quad i = \frac{nFAD[A^0]}{M - r_0}\left(\frac{dc_A}{dr}\right)_{r_1=X_1=0}$$

The flux term may then be discretized to

$$[32] \quad i = \frac{nFAD[A^0]}{M - r_0}\left[A_{1,1}c_A(0, t) + A_{1,N+2}c_A(1, t) + \sum_{j=2}^{N+1} A_{1,j}c_A(r_j, t)\right]$$

or

$$[33] \quad i = \frac{nFAD[A^0]}{M - r_0}\left[A_{1,N+2} + \sum_{j=2}^{N+1} A_{1,j}c_A(r_j, t)\right]$$

after insertion of the known values of $c_A(0,t)$ and $c_A(1,t)$.

So the current i may be calculated at any time $T = (M - r_0)^2t/D$ by insertion of the calculated concentrations from eqs. [14] or [28] into eq. [33]. If there are additional electroactive species in the mechanism,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

their contribution is simply added into eq. [33], since generally,

$$[34] \quad i = \frac{nFAD[A^0]}{M - r_0} \sum_{n=1}^{m} \left(\frac{dc_n}{dr}\right)_{r=X_1=0}$$

where m is the total number of electroactive species.

The charge or spectroelectrochemical absorbance can be calculated by use of Gaussian quadrature weights (4, 9, 10) for the integration of the current in time or the concentration profiles in time.

Cyclic Voltammetric Response

Several modifications have to be made to the method of Speiser and Rieker (6) to develop the cyclic voltammetric responses for the spherical electrode. We define new dimensionless time and distance variables

$$[35] \quad t = \frac{DTa}{(M - r_0)^2} \quad \text{and} \quad r = \frac{(R - r_0)a^{1/2}}{M - r_0}$$

where

$$a = nFv/R'T'$$

with v = the potential sweep rate in V s^{-1}, R' the gas constant, and T' the temperature. Thus,

$$dT = (M - r_0)^2 dt/aD$$

and

$$[36] \quad dR = (M - r_0)dr/a^{1/2}$$

For the simple electron transfer reaction [1], the differential equation [6] becomes

$$[37] \quad \frac{aD[A^0]\delta c_A}{(M - r_0)^2 \delta t} = \frac{aD[A^0]\delta^2 c_A}{(M - r_0)^2 \delta r^2} + \frac{2D[A^0]}{((M - r_0)r + r_0)(M - r_0)} \frac{\delta c_A}{\delta r}$$

which simplifies to

$$[38] \quad \frac{\delta c_A}{\delta t} = \frac{\delta^2 c_A}{\delta r^2} + \frac{2a^{1/2}}{r + \beta} \frac{\delta c_A}{\delta r}$$

The derivation now proceeds as described by Speiser and Rieker (6).

The cyclic voltammetric boundary conditions are

$$[39] \quad \begin{aligned} &[A]_{R,0} = [A]_{\infty,t} = [A^0] \\ &[B]_{R,0} = [B]_{\infty,t} = 0 \\ &(\delta[A]/\delta R)_{R=0} = -(\delta[A]/\delta R)_{R=0} \\ &[A]_{0,T}/[B]_{0,T} = \exp[nF/R'T'(E^{\ominus}_{A/B} - E)] = \theta_{A/B} S_\lambda(t) \end{aligned}$$

Inserting the potential sweep rate [14] v, we have

$$\theta_{A/B} = \exp[nF/R'T'(E^{\ominus}_{A/B} - E_{START})]$$

$$[40] \quad S_\lambda(T) = \begin{cases} \exp(-nFvT/R'T') = \exp(-aT) & \text{for } T \le T_\lambda \\ \exp(at - 2aT_\lambda) & \text{for } T_\lambda \le T \le 2T \end{cases}$$

where T is the time when the forward potential sweep is reversed.

We convert eqs. [39] to dimensionless form normalized to t and M:

$$[41] \quad \begin{aligned} &c_A(r, 0) = c_A(1, t) = 1 \\ &c_B(r, 0) = c_B(1, t) = 0 \\ &\left(\frac{\delta c_A}{\delta r}\right)_{r=0} = \left(\frac{-\delta c_B}{\delta r}\right)_{r=0} \\ &\frac{c_A(0, t)}{c_B(0, t)} = \theta_{A/B} S_\lambda(t) \end{aligned}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Discretizing using eqs. [8*a*] and [8*b*] on [38], we have

$$[42]\quad \left.\frac{dc_A}{dt}\right|_{r_i=X_i} = \sum_{j=1}^{N+2} B_{ij}c_A(r_j, t) + \frac{2a^{1/2}}{r_i + \beta}\sum_{j=1}^{N+2} A_{ij}c_A(r_j, t)$$

or after partial expansion

$$[43]\quad \left.\frac{dc_A}{dt}\right|_{r_i=X_i} = B_{i,1}c_A(0, t) + B_{i,N+2}c_A(1, t) + \sum_{j=2}^{N+1} B_{ij}c_A(r_j, t) + \frac{2a^{1/2}}{r_i + \beta}\left[A_{i,1}c_A(0, t) + A_{i,N+2}c_A(1, t) + \sum_{j=2}^{N+1} A_{ij}c_A(r_j, t)\right]$$

Inserting the explicit boundary conditions, we have

$$[44]\quad \left.\frac{dc_A}{dt}\right|_{r_i=X_i} = B_{i,1}c_A(0, t) + B_{i,N+2} + \sum_{j=2}^{N+1} B_{ij}c_A(r_j, t) + \frac{2a^{1/2}}{r_i + \beta}\left[A_{i,1}c_A(0, t) + A_{i,N+2} + \sum_{j=2}^{N+1} A_{ij}c_A(r_j, t)\right]$$

Identical treatment for the B species yields

$$[45]\quad \left.\frac{dc_B}{dt}\right|_{r_i=X_i} = B_{i,1}c_B(0, t) + \sum_{j=2}^{N+1} B_{ij}c_B(r_j, t) + \frac{2a^{1/2}}{r_i + \beta}\left[A_{i,1}c_B(0, t) + \sum_{j=2}^{N+1} A_{ij}c_B(r_j, t)\right]$$

We discretize the flux relation in [41] to get an equation relating $c_A(0,t)$ and $c_B(0,t)$, presently implicit boundary conditions.

$$[46]\quad \sum_{j=1}^{N+2} A_{k,j}c_A(r_j, t) = -\sum_{j=1}^{N+2} A_{i,j}c_B(r_j, t)$$

Speiser and Rieker (6) showed that after expansion of eq. [46], one may then substitute in eq. [44] and arrive at the following result giving the time (potential) dependence of $c_A(0,t)$ and $c_B(0,t)$:

$$[47]\quad \begin{aligned} c_A(0, t) &= -\frac{\theta_{A/B}S_\lambda(t)}{A_{1,1}[1 + \theta_{A/B}S_\lambda(t)]}A_{1,N+2} + \sum_{j=2}^{N+1} A_{1,j}(c_A(r_j, t) + c_B(r_j, t)) \\ c_B(0, t) &= -\frac{1}{A_{1,1}[1 + \theta_{A/B}S_\lambda(t)]}A_{1,N+2} + \sum_{j=2}^{N+1} A_{1,j}(c_A(r_j, t) + c_B(r_j, t)) \end{aligned}$$

Inserting these time-dependent boundary conditions into the discretized eqs. [44] and [45] yield the $2N$ simultaneous first order differential equations necessary to solve for the concentration profiles in time:

$$[48]\quad \begin{aligned} \left.\frac{dc_A}{dt}\right|_{r_i=X_i} &= W_i + \sum_{j=2}^{N+1} F_{ij}c_A(r_j, t) + \sum_{j=2}^{N+1} G_{ij}c_B(r_j, t) \\ \left.\frac{dc_B}{dt}\right|_{r_i=X_i} &= X_i + \sum_{j=2}^{N+1} H_{ij}c_A(r_j, t) + \sum_{j=2}^{N+1} I_{ij}c_B(r_j, t) \end{aligned}$$

with

$$W_i = \frac{\theta_{A/B}S_\lambda(t)}{A_{1,1}[1 + \theta_{A/B}S_\lambda(t)]}\left[B_{i,1}A_{1,N+2} + \frac{2a^{1/2}}{r_i + \beta}A_{i,1}A_{1,N+2}\right] + B_{i,N+2} + \frac{2a^{1/2}}{r_i + \beta}A_{i,N+2}$$

$$F_{ij} = B_{ij} + \frac{2a^{1/2}}{r_i + \beta}A_{ij} - \frac{2a^{1/2}A_{i,1}A_{1,j}\theta_{A/B}S_\lambda(t)}{(r_i + \beta)A_{1,1}[1 + \theta_{A/B}S_\lambda(t)]} - \frac{B_{i,1}A_{1,j}\theta_{A/B}S_\lambda(t)}{A_{1,1}[1 - \theta_{A/B}S_\lambda(t)]}$$

$$G_{ij} = \frac{\theta_{A/B}S_\lambda(t)}{A_{1,1}[1 + \theta_{A/B}S_\lambda(t)]}\left[B_{i,1}A_{1,j} + \frac{2a^{1/2}A_{i,1}A_{1,j}}{(r_i + \beta)}\right]$$

$$W_i = -\frac{1}{A_{1,1}[1 + \theta_{A/B}S_\lambda(t)]}\left[B_{i,1}A_{1,N+2} + \frac{2a^{1/2}}{r_i + \beta}A_{i,1}A_{1,N+2}\right]$$

$$H_{ij} = -\frac{1}{A_{1,1}[1 + \theta_{A/B}S_\lambda(t)]}\left[B_{i,1}A_{1,j} - \frac{2a^{1/2}A_{i,1}A_{1,j}}{r_i + \beta}\right]$$

$$I_{ij} = B_{ij} + \frac{2a^{1/2}}{r_i + \beta}A_{ij} - \frac{2a^{1/2}A_{j,1}A_{1,j}}{(r_i + \beta)A_{1,1}[1 + \theta_{A/B}S_\lambda(t)]} - \frac{B_{i,1}A_{1,j}}{A_{1,1}[1 + \theta_{A/B}S_\lambda(t)]}$$

The $2N$ equations [48] are solved simultaneously as before to get $c_A(r_j,t)$ and $c_B(r_j,t)$. The current response is represented similar to the chronoamperometric case:

$$[49] \quad i = nFAD_A\left(\frac{\delta[A]}{\delta R}\right)_{R=0}$$

or in the dimensionless space

$$[50] \quad i = \frac{nFAD_A[A^0]a^{1/2}}{(M - r_0)}\left(\frac{dc_A}{dr}\right)_{r_1 = X_1 = 0}$$

Discretizing the flux and inserting the boundary conditions leads to [6]

$$[51] \quad \left.\frac{dc_A}{dr}\right|_{r_1 = X_1} = \frac{1}{1 + \theta_{A/B}S_\lambda(t)}\left[A_{1,N+2} + \sum_{j=2}^{N+1} A_{1,j}c_A(r_j, t) - \theta_{A/B}S_\lambda(t)\sum_{j=2}^{N+1} A_{1,j}c_B(r_j, t)\right]$$

So that

$$[52] \quad i = \frac{nFAD_A[A^0]a^{1/2}}{(M - r_0)}\left[\frac{1}{1 + \theta_{A/B}S_\lambda(t)}\left[A_{1,N+2} + \sum_{j=2}^{N+1} A_{1,j}c_A(r_j, t) - \theta_{A/B}S_\lambda(t)\sum_{j=2}^{N+1} A_{1,j}c_B(r_j, t)\right]\right]$$

The concentrations $c_A(r_i,t)$ and $c_B(r_i,t)$ found at each time $T = (M - r_0)^2t/aD$ are used in eq. [52] to determine the current as a function of time and hence potential by the relation

$$[53] \quad E = \begin{cases} E_{START} + \dfrac{(M - r_0)^2tR'T'}{nFD} & t \leq t \\ E_{START} + 2vt_\lambda - \dfrac{(M - r_0)^2tR'T'}{nFD} & t \leq t \leq 2t \end{cases}$$

where t is the dimensionless potential sweep reversal time

$$t_\lambda = \frac{aDT_\lambda}{(M - r_0)^2}$$

Chronopotentiometry

The chronopotentiometric case for planar electrodes was described in a previous paper. For a chronopotentiometric response to the simple reversible charge transfer reaction, we must consider the following conditions:

$$[54] \quad \begin{aligned} &[A]_{r,0} = [A]_{\infty,T} = [A^0] \\ &[B]_{r,0} = [B]_{\infty,T} = 0 \\ &E + E^{\ominus}_{A/B} - \frac{R'T'}{nF}\ln[B]_{r_0} \end{aligned}$$

$$[55] \quad \left(\frac{\delta[A]}{\delta R}\right)_{r_0} = -\left(\frac{\delta[B]}{\delta R}\right)_{r_0}$$

$$i = nFAD_A\left(\frac{\delta[A]}{\delta R}\right)_{R=r_0} = \text{constant}$$

The new dimensionless parameters are

$$[56] \quad t = T/\tau; \qquad r = \frac{R - r_0}{M - r_0}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

where τ is the transition time of the experiment. Insertion of these values into the differential equation [3] and simplification yields

$$[57]\quad \frac{\delta c_A}{\delta t} = \alpha \frac{\delta^2 c_A}{\delta r} + \frac{2\alpha}{r + \beta} \frac{\delta c_A}{\delta r}$$

where

$$\alpha = D\tau/(M - r_0)^2$$

The conditions [54] and [55] in dimensionless form become

$$[58]\quad \begin{aligned} c_A(r,0) &= c_A(1,t) = 1 \\ c_B(r,0) &= c_B(1,t) = 0 \\ \left(\frac{\delta c_A}{\delta r}\right)_{r_0} &= -\left(\frac{\delta c_B}{\delta r}\right)_{r_0} \end{aligned}$$

$$[59]\quad i = \frac{nFAD[A^0]}{(M - r_0)} \left(\frac{dc_A}{dr}\right)_{r_0} = \frac{nFAD^{1/2}[A^0]\alpha^{1/2}}{\tau^{1/2}} \left(\frac{dc_A}{dr}\right)_{r_0}$$

The flux relation at the electrode is given from [8*a*]

$$[60]\quad \begin{aligned} \left(\frac{dc_A}{dr}\right)_{r_0} &= \sum_{j=1}^{N+2} A_{1,j} c_A(r_j, t) \\ \left(\frac{dc_B}{dr}\right)_{r_0} &= \sum_{j=1}^{N+2} A_{1,j} c_B(r_j, t) \end{aligned}$$

Upon entering the known boundary conditions and expanding, and then substituting these into [59] we have

$$[61]\quad \begin{aligned} c_A(0, t) &= Q - \sum_{j=2}^{N+1} a_j c_A(r_j, t) \\ c_B(0, t) &= R - \sum_{j=2}^{N+1} a_j c_B(r_j, t) \end{aligned}$$

with

$$Q = \frac{1}{A_{1,1}} \left[\frac{i\tau^{1/2}}{nFA[A^0]D^{1/2}\alpha^{1/2}} - A_{1,N+2}\right]$$

$$R = \frac{1}{A_{1,1}} \left[\frac{i\tau^{1/2}}{nFA[A^0]D^{1/2}\alpha^{1/2}}\right]$$

$$a_j = \frac{A_{1,j}}{A_{1,1}}$$

The discretized equations for A and B are thus

$$[62]\quad \begin{aligned} \left.\frac{dc_A}{dt}\right|_{r_i = X_i} &= \sum_{j=1}^{N+2} B_{ij} c_A(r_j, t) + \frac{2\alpha}{r_i + \beta} \sum_{j=1}^{N+2} A_{ij} c_A(r_j, t) \\ \left.\frac{dc_B}{dt}\right|_{r_i = X_i} &= \sum_{j=1}^{N+2} B_{ij} c_B(r_j, t) + \frac{2\alpha}{r_i + \beta} \sum_{j=1}^{N+2} A_{ij} c_B(r_j, t) \end{aligned}$$

The known boundary conditions from eqs. [58] and [61] are entered, and we have

$$[63]\quad \begin{aligned} \left.\frac{dc_A}{dt}\right|_{r_i = X_i} &= \alpha Q_i' + \alpha \sum_{j=2}^{N+1} b_{ij} c_A(r_j, t) \\ \left.\frac{dc_B}{dt}\right|_{r_i = X_i} &= \alpha R_i' + \alpha \sum_{j=2}^{N+1} b_{ij} c_B(r_j, t) \end{aligned}$$

For personal use only.

where

$$Q_i' = B_{i,1}Q + B_{i,N+2} + \frac{2\alpha}{r_i + \beta}(A_{i,1}Q + A_{i,N+2})$$

$$R_i' = B_{i,1}R + \frac{2A_{i,1}R}{r_i + \beta}$$

$$b_{ij} = -B_{i,1}a_j + B_{ij} = \frac{2}{r_i + \beta}(A_{i,1}a_j - A_{ij})$$

The usual display of the response is given by

$$[64] \quad E = E^{\circ}_{A/B} - \frac{R'T'}{nF} \ln \left(\frac{c_B(0, t)}{c_A(0, t)}\right)$$

where the two concentration terms in parentheses are found from eq. [61]. The concentration terms in [61] are found by integration of the simultaneous equation [63] by the methods described (1, 4, 5, 9) previously.

Ionic strength effect on extraction of potassium complexed with crown ether 18-crown-6. Preliminary communication

IZAAK MAURITS KOLTHOFF

Department of Chemistry, University of Minnesota, 207 Pleasant Street SE, Minneapolis, MN 55455, U.S.A.

Received October 15, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

IZAAK MAURITS KOLTHOFF. Can. J. Chem. **59**, 1548 (1981).

As part of a broad study of the factors which affect extraction of salts of cations, complexed with an uncharged ligand, L, a critical study has been made of the extraction into dichloromethane of K^+ complexed with 18-crown ether-6 in the form of picrate (LKPi). In using extraction analysis for the determination of very small concentrations of K^+ in the presence of other salts activities of $(K^+)_w$ and $(Pi^-)_w$ in the aqueous phase must be written in the expression for K^{ext}(LKPi). The salting out effect on $P(L) = [L]_o/[L]_w$ can greatly affect the concentration of potassium ions left in the aqueous phase. Selectivity of K^+/Na^+ in extractions with 18-crown-6 has been determined.

The extraction method is very suitable for the determination of traces of potassium in salts of sodium, magnesium, and calcium after calibration with, e.g., potassium chloride in potassium-free salts and also, after proper calibration, in routine analysis of liquids which contain little K^+ and a large excess of Na^+ (e.g. sea water, blood serum).

IZAAK MAURITS KOLTHOFF. Can. J. Chem. **59**, 1548 (1981).

Dans le cadre d'une étude complète des facteurs influençant l'extraction des sels des cations, complexés à un ligand non chargé, L, on a réalisé une étude critique de l'extraction à l'aide de dichlorométhane de K^+, existant sous formes picrates (LKPi), complexés par de l'éther 18-couronne-6. Lors de l'utilisation de l'analyse par extraction dans le but de déterminer des concentrations très faibles d'ions K^+ en présence d'autres sels, on doit décrire les activités $(K^+)_w$ et $(Pi^-)_w$ en phase aqueuse par l'expression K^{ext}(LKPi). L'effet de relargage sur $P(L) = [L]_o/[L]_w$ peut affecter d'une façon importante la concentration résiduelle en ions potassium de la phase aqueuse. On a déterminé la sélectivité K^+/Na^+ lors d'extractions à l'éther 18-couronne-6.

La méthode d'extraction est très appropriée à la détermination de traces de potassium dans des sels de sodium, de magnésium et de calcium après calibration avec, par exemple, du chlorure de potassium dans des sels libres de potassium et également, après une calibration convenable, à l'analyse de routine de liquides qui contiennent peu de K^+ et un grand excès de Na^+ (par exemple l'eau de mer, le sérum sanguin).

[Traduit par le journal]

Introduction

In recent years a large number of papers, many of them from Japanese laboratories, have been published dealing with extraction constants of salts composed of alkali or alkaline earth ions complexed with a crown ether and a lipophilic anion (usually picrate). Eisenman *et al.* (1) represented the extraction equilibrium as

$$[1] \quad M^+_w + A^-_w + L_o \rightleftharpoons (LMA)_o$$

in which the subscripts w and o denote the aqueous and organic phases, while L denotes the ligand. The equilibrium constant of reaction [1] was designated by them as the extraction constant K^{ext}.

$$[2] \quad K^{ext} = [LMA]_o/(a_{M^+})_w(a_{A^-})_w[L]_o = [LMA]_o/y_{M^+}[M^+]_w y_{A^-}[A^-]_w[L]_o$$

Eisenman, as well as Frensdorff (2), who with Pedersen (3) was the first to apply crown ethers in extractions, used such low ionic concentrations (potassium and sodium) that the activity coefficients y_{M^+} and y_{A^-} in eq. [2] could be taken equal to unity. This is also the situation in more recent publications in which "extraction constants"

$$K^{ext}_{conc} = [LMA]_o/[M^+]_w[A^-]_w[L]_o$$

have been reported where concentrations have been used instead of activities. As a result of the slight dissociation of electrolytes in the low dielectric constant organic phase, even at high ionic strengths in the aqueous phase, the activity of L in the organic phase can be taken equal to its concentration. The effect of ionic strength on the distribution of L

$$[3] \quad P(L) = [L]_o/[L]_w$$

can be large on $[M^+]_w$ at extraction equilibrium. The extraction method has been applied at appreciable ionic strengths, e.g. for determination of K^+ in blood serum (4) and in sea water (5) when K^{ext}_{conc} differs considerably from K^{ext} in eq. [2].

At present we are engaged in a detailed study of various factors which affect extraction constants of potassium and sodium, including selectivity of K^+/Na^+ with various crown ethers, extraction of

homoconjugated ($LMA \cdot (HA)_n$) and heteroconjugated ($LMA \cdot (HX)_n$) salts, effect of organic polar additives to the aqueous phase, and effect of temperature.

In the present note we report mainly the effect of ionic strength on the extraction constant of potassium, using 18-crown-6 as the ligand, L, and picrate (Pi^-) as the anion. Examples of the use of extraction analysis for determination of traces of potassium in lithium and sodium salts are also presented. Dichloromethane has served as an extractant.

Experimental

The ligand, 18-crown-6, was a Parish Co., Provo, Utah, product. Its purity was estimated by the following extraction procedure: aqueous solutions of the sample, which were 3.5×10^{-4} to 1.2×10^{-3} *M* in L, 5×10^{-3} *M* in potassium picrate, and 2.5×10^{-2} *M* in potassium hydroxide, were extracted with an equal volume of dichloromethane. The extraction of the residual aqueous phase was repeated. It appeared that no more LKPi was extracted after the second extraction, as the absorbance became practically equal to zero. The concentration of LKPi in the organic phase was determined spectrophotometrically at 370 nm. The molar extinction coefficient, ε, was determined using known amounts of potassium picrate in dichloromethane saturated with water and containing $1.4–2.7 \times 10^{-3}$ *M* 18-crown-6. The value of ε was $1.7_9 \times 10^4$ cm^{-1} M^{-1} at 25°C. By the above method the sample of 18-crown-6 used in the present work was 97% pure.

Lithium chloride (Mallinckrodt), sodium chloride (Fisher), potassium hydroxide (Matheson, Coleman & Bell) were analytical reagent grade, while lithium hydroxide was from Ventron Corp. Sodium and potassium picrates were prepared by neutralizing Baker Co. picric acid with the hydroxides in water, while lithium picrate (dihydrate), calcium and magnesium picrates were prepared by neutralization of picric acid with the corresponding carbonate (General Chemical or Mallinckrodt). Lithium carbonate was recrystallized from hot water; the picrates were recrystallized from water. All salts were dried *in vacuo* at 100°C. Dichloromethane (MCB Omnisolv) was found to contain 0.3 ppm residue upon evaporation and 0.004% water. The solubility of water in CH_2Cl_2 given in the literature (6) is 1.30% by weight (0.153 *M*) and that of CH_2Cl_2 in water 1.98% (0.145 *M*).

Extraction Procedure

Lithium picrate was usually added to the aqueous phase in a concentration of 2×10^{-3} *M* or less. In order to avoid presence of picric acid, all mixtures were made 5×10^{-5} *M* in lithium hydroxide. In all experiments equal volumes of the aqueous and organic phases were used. No volume change was observed upon attainment of extraction equilibrium. The quantity $[\sum LMPi]_0$ was determined spectrophotometrically at 370 nm. From the value thus found and the estimated dissociation constant $K^d(LMPi)$, the concentration of undissociated $(LMPi)_0$ was found. Under all conditions $[LK^+]_w$ was negligibly small.

Results

The partition coefficient *P*(L) at zero ionic strength (eq. [3]) between water and dichloromethane of 18-crown-6 was found equal to 4.50 at 25°C. This value is much larger than those reported in benzene at 25°C, 0.0634 (7) and 0.0572 (8). In Table 1 are reported values of K^{ext} (eq. [2]) and of $K^d(LMPi)$ in the organic phase of potassium and sodium, both as picrates. For comparison are added literature values of K^{ext}_{conc} of two substituted 18-crown-6 ligands and of K^{ext}_{conc} between water and benzene with 18-crown-6.

Effect of Ionic Strength on $K^{ext}(LKPi)$

The effect of ionic strength was determined by adding lithium chloride (labelled to contain 0.01% K^+; by extraction analysis we found 0.024%, v.i.). Values of *P*(L) were determined at various concentrations of lithium chloride and are reported in Table 2. These values of *P*(L) were used to calculate K^{ext}. Values of $K^{ext}(LKPi)$ were calculated using eq. [2] in which the activity coefficients, *y*, of $[K^+]_w$ and $[Pi^-]_w$ were computed from the partially extended Debye–Hückel relation

$$-\log y = 0.5115\sqrt{\pi}/(1 + 0.329a\sqrt{\pi})$$

taking $a = 3.0$ for K^+ and 7.0 for Pi^-. In this way values of $y_{K^+}y_{Pi^-}$ were found to be 0.70, 0.59, and 0.53 at lithium chloride concentrations of 0.04, 0.12, and 0.20 *M*, respectively (Table 2). In Table 2 K^{ext} is a true constant within experimental error, up to an ionic strength of 0.12. At higher ionic strengths deviations from constancy must be attributed to uncertainties in calculated values of $y_{K^+}y_{Pi^-}$. Clearly, the ionic strength and salting out effects must be considered in quantitative analysis by extraction of electrolytes complexed with an uncharged ligand. The smaller values of K^{ext}_{conc}, reported by Smid *et al.* (9), than that reported in the present study (Table 1) may be attributed to the fact that these authors determined K^{ext}_{conc} at an ionic strength of 0.01 (or greater).

Effect of Temperature

A few extractions of K^+ have been carried out at 20°C and 15°C as well as at 25°C. Using a total potassium concentration of 4×10^{-4} *M* and of 18-crown-6 of 4×10^{-3} *M*, the percentages of K^+ extracted were 46.5 at 25°C, 42.0 at 20°C, and 40.5 at 15°C. More work is planned in order to find the effects over a larger range of temperature on *P*(L), K^{ext}, and stability constants of LK^+ in water and dissociation constant of LKPi in dichloromethane.

Determination of K^+ *in Salts of* Na^+, Li^+, Ca^{2+}, *and* Mg^{2+}

Sodium has a value of log K^{ext} of 3.3_4 as compared to 6.2_1 of K^+ (Table 1). This corresponds to a selectivity of K^+/Na^+ of 750 when extracted with 18-crown-6 as picrate. In the determination by ex-

traction of small amounts of K^+ in sodium salts the effect of sodium upon the extraction of K^+ can be calculated, but this calculation becomes quite involved as the ionic strength effect on both K^{ext}(LKPi) and K^{ext}(LNaPi) must be taken into account.

It is much simpler to determine empirically the effect of sodium on the percentage of K^+ extracted by adding known amounts of K^+ to solutions of a pure sodium salt. For example, in solutions which were 4×10^{-4} M in K^+, 2×10^{-3} M in picrate, 2.7×10^{-3} M in 18-crown-6, and 0, 0.008, and 0.02 M in pure sodium chloride the amounts of picrate extracted, expressed in % of K^+_{total}, were 46.5, 46.0, and 46.8, respectively. Under the above conditions the ionic strength effect of the large excess of sodium is compensated by $[LNaPi]_0$ extracted (expressed as K^+). It is easy to find conditions to carry out the determination of less than 0.2% of K^+ in sodium salts by extraction analysis.

The extractibility of Li^+ and of Mg^{2+} as picrate with 18-crown-6 is very small. We determined the K^+ content of a Mallinckrodt C.P. lithium chloride product in the following way: a solution was prepared which was 0.2 M in LiCl, 0.002 M in LiPi, and 0.0025 M in 18-crown-6. The picrate found in the first extract corresponded to an apparent concentration of 8.5×10^{-5} M K^+ in the aqueous phase. After the first extraction the concentrations of L and LiPi in the aqeuous phase were adjusted to their original values. After the second, third, fourth, and fifth extractions the concentration of $\sum[LMPi]_0$ corresponded to 6.2×10^{-5}, 5.2×10^{-5}, 5.0×10^{-5}, and 5.0×10^{-5} M in the aqueous phase. Thus, the concentration of lithium, extracted as picrate from 0.2 M LiCl solution was 5×10^{-5} M, and the potassium content of the 0.2 M LiCl solution was 4.7×10^{-5} M. Thus, under the above conditions all the potassium was in the organic phase after three extractions. The lithium chloride appeared to contain 0.02_4 mol or wt% K (it was labelled to contain 0.01% K).

From 2.5×10^{-3} M solutions the amount of Mg^{2+} extracted was 0.6 of that of lithium, while that of calcium was 30 times greater than that of lithium. Thus K^+ can be determined simply in magnesium salts in the same way as was done in lithium chloride. The determination of K^+ in calcium salts can be done in the same way as described for sodium salts.

Discussion

From the results in Table 1 it is seen that the selectivity K^+/Na^+ expressed as log $K^{ext}(K^+)$ − log $K^{ext}(Na^+)$ using dichloromethane as extractand is 2.9 with L = 18-crown-6, 2.1 with L = dicyclohexyl-18-crown-6 (mixed isomers) (2), and 2.4 with 4′-vinylmonobenzo-18-crown-6 (9). In unpublished work we find with dibenzo-18-crown-6 a selectivity of 2.3. With 18-crown-6, but in benzene as extract-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

and, the selectivity is reported to be 2.7 (ref. 8, Table 1).

Quite generally, for analytical purposes, solvents like benzene, toluene, chloroform are preferred over the polar solvent dichloromethane as ionic dissociation of $(LMPi)_0$ in the organic phase is negligibly small and need not be considered when use is made of eq. [2].

It is of interest to add that in dichloromethane, $K^q(LMPi)_0$ of sodium has been reported with three crown ethers (Table 1) to be three times as large as that of potassium. Whether this indicates that an equilibrium between solvent separated and contact ion pairs of LNaPi is more favorable towards the former than that of LKPi needs further study.

Extraction analysis for determination of traces of potassium in lithium, sodium, and calcium salts is very suitable, particularly when calibration is made using potassium-free salts. It is also suitable for routine analysis for potassium in liquids which contain large but only slightly variable excesses of sodium, like sea water and blood serum.

Rational orbitals for two-electron ^1S states

F. W. BIRSS AND W. DEN HERTOG

Department of Chemistry, University of Alberta, Edmonton, Alta, Canada T6G 2G2

Received August 28, 1980

This paper is dedicated to Professor W. E. Harris on the occasion of his retirement from the University of Alberta

F. W. BIRSS and W. DEN HERTOG. Can. J. Chem. **59**, 1552 (1981).

The concept of rational orbitals is introduced, based upon finding that pair of orbitals which yield the single configuration function which maximally overlaps with a configuration interaction wave function. They are simply obtained from the natural orbitals by an elementary orthogonal transformation and are more appropriate than natural orbitals to analysis of functions for open-shell states. The CI wave functions of a number of ^1S states of helium are analyzed and the nature of the rational orbitals investigated.

F. W. BIRSS et W. DEN HERTOG. Can. J. Chem. **59**, 1552 (1981).

On propose le concept d'orbitales rationnelles, en se basant sur la découverte de la paire d'orbitales qui conduit à la fonction de configuration unique qui assure un recouvrement maximal avec une fonction d'onde d'interaction de configuration. On les obtient simplement à partir des orbitales naturelles par une transformation orthogonale élémentaire et elles sont plus appropriées que les orbitales naturelles pour l'analyse des fonctions des états où la couche électronique est incomplète. On a analysé les fonction d'onde IC d'une série d'états ^1S de l'helium on a étudié la nature des orbitales rationnelles.

[Traduit par le journal]

I. Natural Orbitals for ^1S States

The concept of natural orbitals was first developed by Löwdin (1) in the context of density matrix theory. For states of two-electron systems they provide a particularly efficient expression of a configuration interaction wave function (2). Consider such a function:

$$[1] \quad \Phi = \sum_{(kl)} C_{(kl)}[\chi_k\chi_l]$$

The summation is taken over independent pairs of orthonormal one-electron basis functions χ_k, χ_l. $[\chi_k\chi_l]$ indicates a symmetry adapted, antisymmetrized, and normalized single configuration function constructed from such a pair. The natural orbital expansion of the same function is

$$[2] \quad \Phi = \sum_k C_k{}^N[\chi_k{}^N\chi_k{}^N]$$

which represents a significant reduction in the number of terms required for expression of the function.

Natural orbitals for the ^1S two-electron case can be discovered as the answer to the question: what is the single determinant, $[\chi_1{}^N\chi_1{}^N]$ which maximally overlaps with the original CI wave function? We thus seek to maximize

$$[3] \quad S = \langle[\chi_1{}^N\chi_1{}^N]\|\Phi\rangle$$

subject to the normalization constraint

$$[4] \quad \langle\chi_1{}^N|\chi_1{}^N\rangle = 1$$

The natural orbitals are expanded in the basis of functions used to construct the CI function,

$$[5] \quad \chi_i{}^N = \sum_j \chi_j N_{ji}$$

Substituting for Φ and $\chi_1{}^N$ in [3] and [4] we obtain (assuming all orbitals to be real and orthonormal),

$$[6] \quad S = \sum_{(kl)} C_{(kl)}(1 + \delta_{kl})^{1/2} N_{k1} N_{l1}$$

$$[7] \quad \langle\chi_1{}^N|\chi_1{}^N\rangle = \sum_k N_{k1}{}^2 = 1$$

The condition for maximum overlap is obtained by applying the Lagrange method of undetermined multipliers. It is

$$[8] \quad \sum_l C_{(kl)}(1 + \delta_{kl})^{1/2} N_{l1} = \lambda_1 N_{k1}$$

with $-\lambda_1$ the multiplier used upon the constraint [7]. Defining the elements of the matrix **D** as

$$[9] \quad D_{kl} = D_{lk} = C_{(kl)}(1 + \delta_{kl})^{1/2}$$

and N_1 as the vector with components N_{i1}, [8] may be written as the matrix equation

$$[10] \quad \mathbf{D}N_1 = N_1\lambda_1$$

The matrix **D** is the "fundamental" matrix defined by Löwdin (1), with eigenvectors the coefficients of the basis χ in the expansion of the natural orbitals and eigenvalues the coefficients, $C_k{}^N$, in the expansion of the CI function in the basis of configurations constructed from natural orbitals.

II. Rational Orbitals for ^1S States

For approximate closed shell state functions, the determinant associated with the dominant $C_k{}^N$

should be a reasonable approximation to the Hartree–Fock function if an adequate basis set of functions has been used in constructing the CI function (3). For excited states the best one-term approximation would be of the form $[\chi_k\chi_l]$ with $k \neq l$. Thus the usual natural orbital expansion in determinants involving double occupied orbitals is inappropriate for truncation to a single term. We define rational orbitals in this situation by requiring maximal overlap of a single term of the form $[\chi_1{}^R\chi_2{}^R]$ with a CI wave function ascribable to a state for which the orbital description would be two singly occupied orbitals. In terms used in Section I, we can obtain the matrix **R** defined by

$$[11] \quad \boldsymbol{\chi}^R = \boldsymbol{\chi}\mathbf{R}$$

by requiring **R** to be that matrix which effects the transformation

$$[12] \quad \mathbf{D}^R = \mathbf{R}^\dagger\mathbf{D}\mathbf{R}$$

such that the (1,2) and (2,1) elements of $\mathbf{D}^R$ have maximum magnitude.

Consider the natural orbital transformation

$$[13] \quad \boldsymbol{\lambda} = \mathbf{N}^\dagger\mathbf{D}\mathbf{N}$$

and the subsequent transformation which modifies only the (1,1), (2,2), (1,2), and (2,1) elements:

$$[14] \quad \mathbf{D}^R = \mathbf{Q}^\dagger\boldsymbol{\lambda}\mathbf{Q} = \mathbf{Q}^\dagger\mathbf{N}^\dagger\mathbf{D}\mathbf{N}\mathbf{Q} = \mathbf{R}^\dagger\mathbf{D}\mathbf{R}$$

We now prove the implied statement of [14]: it is this transformation which maximizes the magnitude of the (1,2) and (2,1) elements of $\mathbf{D}^R$, presuming the λ_i to be ordered in decreasing magnitude. Consider the elementary orthogonal matrix $\mathbf{Q}^{(ij)}$ which differs form the unit matrix only by having

$$[15] \quad \begin{aligned} Q_{ii}^{(ij)} &= Q_{jj}^{(ij)} = \cos\theta \\ Q_{ji}^{(ij)} &= -Q_{ij}^{(ij)} = \sin\theta \end{aligned}$$

The effect of the transformation by $\mathbf{Q}^{(12)}$ upon the ordered diagonal matrix $\boldsymbol{\lambda}$ is to yield

$$[16] \quad D_{12}{}^R = D_{21}{}^R = (\lambda_2 - \lambda_1)\sin\theta\cos\theta$$

which maximizes the magnitude $D_{12}{}^R$ and $D_{21}{}^R$ when $\theta = \pi/4$ (or, equivalently, $3\pi/4$, $5\pi/4$, etc.). Then

$$[17] \quad \begin{aligned} D_{11}{}^R &= D_{22}{}^R = \tfrac{1}{2}(\lambda_1 + \lambda_2) \\ D_{12}{}^R &= D_{21}{}^R = \tfrac{1}{2}(\lambda_2 - \lambda_1) \end{aligned}$$

A further transformation with $\mathbf{Q}^{(ij)}$ in an attempt to increase the magnitude of $D_{12}{}^R$ and $D_{21}{}^R$ must have either i or j equal to 1 or 2 in order to affect the values of the elements. Since $D_{11}{}^R$ and $D_{22}{}^R$ are equal, either i or j equal to either 1 or 2 leads to an equivalent result. Consider the transformation using $\mathbf{Q}^{(1j)}$ with $j \neq 1$ or 2. Then

$$[18] \quad D_{12}{}^{R\prime} = D_{12}{}^R\cos\theta + D_{j2}{}^R\sin\theta$$

But, since $D_{j2}{}^R$ is zero except for $j = 1$ and 2, this is simply $D_{12}{}^R\cos\theta$. Since $\theta = n\pi$ is the only choice which leaves $D_{12}{}^R$ maximal in magnitude, $\mathbf{Q}^{(1j)}$ is a trivial multiple of the unit matrix.

Thus the process of obtaining the rational orbital transformation matrix **R** is first to perform the diagonalization of the fundamental matrix which yields **N** and $\boldsymbol{\lambda}$ and then to selectively "disdiagonalize" $\boldsymbol{\lambda}$ by the elementary orthogonal transformation $\mathbf{Q}^{(ij)}$ with $\theta = \pi/4$; i and j are chosen to select those λ_i and λ_j which yield the largest possible magnitude of the symmetric pair of off-diagonal elements in $\mathbf{D}^R$. Then **R** is $\mathbf{N}\mathbf{Q}^{(ij)}$.

III. Configuration Interaction Functions for Helium

In the two series of calculations reported here the original configuration functions were prepared from Slater type orbitals with symmetry adaptation and antisymmetrization after inclusion of spin.

In the first series of calculations the selected Slater type orbitals were the eight s functions with $1 \leq n \leq 8$, the six p functions with $2 \leq n \leq 7$, the four d functions with $3 \leq n \leq 6$ and the two f functions with $4 \leq n \leq 5$. Since the intent of this series was to obtain energies and wave functions of high precision, all seventy possible configurations of ^1S type were ultimately used. The orbital exponents were varied independently for each of the five lowest states in order to achieve minimum energy for the state in question. Thus, from the point of view of the calculations, there was no relation between the orbital exponents and CI coefficients, $C_{(kl)}$, obtained for any two states. The minimization with respect to orbital exponents was carried out in stages. First the energy was minimized using the 36 configurations constructed from the s functions, varying their orbital exponents. The 21 configurations constructed from the six p functions were then added and exponent variation for the p functions carried out. The s functions were not further varied. The d and f functions were in turn similarly treated.

Since the original configuration functions were constructed from Slater orbitals, they were not orthonormal. Some difficulty was experienced with loss in numerical precision in the orthogonalization carried out as a preliminary to solution of the eigenvalue problem. A test of the quality of the unit matrix which should be generated by transforming the metric matrix with the orthogonalization matrix

was performed. It was found that selection of the orbital exponents from sets of relatively low and high magnitudes obviated precision difficulties without jeopardizing the quality of the energies obtained.

The intent of the second series was to obtain reasonably good results for a broad range of more highly excited states using a common basis of configurations. The Slater type s functions consisted of three $1s$, two $2s$ and one function each with $3 \leq n \leq 25$. The orbital exponents of two of the $1s$ and one of the $2s$ functions were obtained by minimization of the ground state energy obtained in the basis of the six configurations constructed using these three functions. The orbital exponent of the third $1s$ function was fixed at 2.0. The orbital exponents of the second $2s$ and functions of higher n were determined by the formula

$$[19] \quad \zeta_n = a + b/n + c/n^2$$

The coefficients, a, b, and c, were determined by collective minimization of the fifth through the second highest eigenvalues; i.e., if alteration of a coefficient resulted in the sum of the changes of those eigenvalues being negative, that alteration was considered acceptable.

The configurations were constructed as described above but not all those possible were used. The six configurations involved in the selection of the orbital exponents of the two $1s$ and one $2s$ functions were included plus those involving the $1s$ function with orbital exponent 2.0 with itself and with each of the remaining functions. There were thus $N + 6$ configurations constructed from s functions, with N the n of the highest order s function used. The configurations involving p, d, and f functions were those determined for the fifth state in the first series of calculations, carried over unchanged.

IV. The First Series

The energies obtained for the five lowest ^1S states of helium[1] are gathered in Table 1. The headings $1s^2$, $1s2s$, etc., are used here and elsewhere as state labels according to the dominant orbital description. The exact energies are the results of Pekeris and co-workers (4).

Although the criterion for obtaining the dominant term is that it shall maximally overlap with the total CI function, it should be a reasonable approximation to the Hartree–Fock function obtained on the basis of minimum energy for a single configuration. The comparison between the Hartree–Fock and rational orbital single-term energies is included in Table 1. It is clear that, for the excited states, as correlation plays a less important role in contributing to the description of the state, the two wave functions approach each other more closely. What is particularly remarkable is the goodness of the approximation to Hartree–Fock in the closed-shell case. To a certain extent this is consistent with the relative behaviour of the ground and excited states upon inclusion of terms which take correlation into account. For the excited states, the quantity Δs of Table 1, which gives the energy lowering upon inclusion of s configurations beyond the rational orbital level, is greater than $\Delta p + \Delta d + \Delta f$, which gives the energy lowering upon subsequent inclusions of angular correlation. The opposite is the case for the ground state.

In Table 2 are given the configuration occupation numbers for the states considered in the first series. These numbers are the squares of the coefficients, C_{ij}^R and C_k^N, in the rational-natural orbital expansion:

$$[20] \quad \Phi = C_{12}^R[\chi_1^R\chi_2^R] + C_{11}^R[\chi_1^R\chi_1^R] + C_{22}^R[\chi_2^R\chi_2^R] + \sum_{k\geq 3} C_k^N[\chi_k^N\chi_k^N]$$

The $1s$ state is expanded only in natural orbitals

[1]The orbital exponents and expansion coefficients are available from F.W.B. upon request.

which are the rational orbitals for a doubly occupied state in the orbital description.

In all cases the occupation numbers indicated that addition of further functions of the symmetries already used would have a minor effect upon the energy. Further major improvement should be sought in functions of higher l quantum number, a conclusion parallel to that of Weiss (7) in similar work on the helium ground state.

As the degree of excitation increases, the importance of correlation decreases sharply so that the accuracy of functions, such as these, based upon the same number and type of configurations, increases correspondingly. It is this feature, coupled with the technique of adapting the basis functions to a particular state, which holds promise for the use of the CI method for excited states of larger atoms and molecules.

Consistent with the decreasing importance of correlation, the weight of the dominant term approaches unity more closely as more highly excited states are considered. This number is also the square of the overlap between the single term and the total CI function. This same trend is displayed by the stepwise energy quantities, Δs, Δp, Δd, and Δf given in Table 1. The single-term function takes into account a greater portion of the total energy and the convergence is more rapid as more highly excited states are considered.

V. The Second Series

The energy results for this series[1] are given in Table 3 for $N = 20$, i.e., for configurations constructed with s Slater functions of this maximum principle quantum number. The italicized value indicates the end of the range of eigenvalues included in the process of collective minimization for obtaining the values

$$a = 1.3 \times 10^{-4}, b = 1.1113, c = 9.2 \times 10^{-4}$$

of [19]. The results of Pekeris and co-workers (4) are given for comparison. The hydrogenic energies are based upon the idealized situation of a $1s$ orbital of He^+, with no perturbation by the outer electron, and a ns orbital of H, with perfect shielding by the inner electron.

For personal use only.

The configuration occupation numbers for the dominant s configurations are given in the latter columns of Table 3. The trends already evident in the lower states are continued here, with both angular and radial correlation playing a less important role as greater excitation is encountered. It is evident that the $1s18s$ function is of poorer quality than the others since the trend toward unity of the s_1s_2 configuration occupancy is abruptly interrupted at this point. It was this observation that led us to choose only up to the $N - 2$ state for collective minimization: without seriously sacrificing the quality of the upper bounds for a large number of lower states, one cannot achieve reasonable approximations to the upper bounds of the highest three states. This feature was also found in the calculations with $N = 15$ and 25, which were performed as a check upon the convergence of the results reported here.

VI. Conclusion

The modification of the natural orbital analysis to obtain rational orbitals for excited states of two-electron species has been useful in exposing some aspects of the structure of such states. As the need arises, the technique can be extended to open shell states of many-electron systems.

The particular results for the helium atom have not contained any surprises but the analysis does provide a firm numerical basis for the discussion of excited states in terms of the relative importance of various aspects of the model: the Hartree–Fock level, radial correlation and angular correlation.

Acknowledgments

This work was supported by the Natural Sciences and Engineering Research Council of Canada with the award of a PIER fellowship and a grant-in-aid of research. The use of the facilities of the Computing Services of the University of Alberta and the assistance of Mr. Peter Senn in helping with the calculations are gratefully acknowleged.

Synthesis of *N*-acyl-1,3-oxathiol-2-imines

MARSHALL KULKA
Research Laboratories, Uniroyal Limited, Guelph, Ont., Canada N1H 6N3
Received November 27, 1980

MARSHALL KULKA. Can. J. Chem. **59**, 1557 (1981).

A facile synthesis of *N*-acyl-1,3-oxathiol-2-imines, **7**, is reported. It comprises the reaction of *O*-alkyl acylcarbamothioates, **4**, with 2-chloroketones in the presence of alcoholic sodium alkoxide. The resulting *O*-alkyl-*S*-substituted-*N*-acylcarbonimidothiates, **6**, undergo cyclization with elimination of alcohol, spontaneously, or upon heating in boiling toluene to form **7**.

MARSHALL KULKA. Can. J. Chem. **59**, 1557 (1981).

On rapporte une synthèse facile des *N*-acyl oxathiol-1,3 imines-2 (**7**). Cette synthèse fait intervenir la réaction des *O*-alkyl acylcarbamothioates (**4**) avec les chloro-2 cétones en présence d'un alcoolate de sodium. Les *O*-alkyl *N*-acylcarbonimidothiates portant un substituant sur le soufre (**6**) obtenus se cyclisent avec élimination d'alcool soit spontanément, soit par chauffage dans le toluène bouillant et conduisent aux dérivés (**7**).

[Traduit par le journal]

Prior to 1966 few simple 1,3-oxathioles were known (1). Since that time there has been some activity in this field but not to any great extent. Kuhlmann and Dittmer (2) found that by treating 2-thiocyanato-2-phenylacetophenone with excess sodium hydride, 2,4,5-triphenyl-1,3-oxathiole was formed in 55% yield. Kempe *et al.* (3) demonstrated that dehydrobromination of 1-(2-oxo-2-phenylethyl)-2,5-dihydrothiophenium bromide, followed by heating, resulted in a 55% yield of 2-benzoyl-5-phenyl-1,3-oxathiole. Ried and Kaiser (4) reacted 3-phenyl-2-propynethioamides ($C_6H_5C{\equiv}CCSNHR$) with 2-bromoketones in the presence of triethylamine and obtained 2-phenylethynyl-5-substituted-1,3-oxathiol-2 amines. Russian workers (5) report that 2,4,5-trimethyl-1,3-oxathiole was formed in 30% yield when acetylene and sodium sulfide were heated. A number of *N*-phenyl- and *N*-butyl-1,3-oxathiol-2 imines (6) have been prepared by the reaction of *N*-phenyl- and *N*-butyl-carbonochlorimidothioic acid chlorides (C_6H_5- and C_4H_9—N=C(SCl)(Cl) with ketones.

This paper reports a facile synthesis of *N*-acyl-1,3-oxathiol-2-imines, **7**, from *O*-alkyl acylcarbamothioates, **4**, and 2-chloroketones, **5**. The *O*-methyl acylcarbamothioates, **4**, were readily obtained through the reaction of acid chlorides, **1**, with ammonium thiocyanate, **2**, and addition of methanol to the resulting acyl isothiocyanates, **3**, (7, 8). Phenylmethyl chloride and 2-chloroketones, **5**, reacted with *O*-methyl acylcarbamothioates, **4**, at room temperature in the presence of methanolic sodium methoxide to yield the corresponding *O*-methyl-*S*-substituted-*N*-acylcarbonimidothioates. The products, **6**, of the reaction of 2-chloroketones, **5**, with **4** were found to be quite unstable. They liberated methanol and underwent cyclization at room temperature or upon heating in toluene to form the *N*-acyl-1,3-oxathiol-2-imines (**7**). Thus when *O*-methyl benzoylcarbamothioate (**4**, R = phenyl) was treated with ethyl 2-chloroacetoacetate (**5**, R′ = CH_3. R″ = $COOC_2H_5$) in methanol solution in the presence of sodium methoxide at room temperature, ethyl 2-benzoylimino-5-methyl-1,3-oxathiole-4-carboxylate (**7**, R = phenyl, R′ = CH_3, R″ = $COOC_2H_5$) precipitated in 87% yield and no intermediate **6** could be isolated. *O*-Methyl (2-furanyl)carbonylcarbamothioate (**4**, R = 2-furanyl) reacted similarly with ethyl 2-chloroacetoacetate to produce the corresponding 1,3-oxathiole directly, and no intermediate.

On the other hand, when *O*-methyl benzoylcarbamothioate (**4**, R = phenyl) was treated with 2-oxo-2-phenylethyl chloride (**5**, R′ = phenyl, R″ = H) under the same conditions, the intermediate *O*-methyl *S*-(2-oxo-2-phenylethyl)-*N*-benzoylcarbonimidothioate (**6**, R = R′ = phenyl, R″ = H) precipitated in 85% yield. To cyclize this intermediate to **7** (R = R′ = phenyl, R″ = H) it was necessary to heat it under reflux in toluene. In most of the other preparations the reactions of **4** with **5** yielded mixtures of the intermediate **6** and the 1,3-oxathiole **7** and it was necessary to heat the isolated **6** or the mixture in toluene in order to produce the maximum yield of **7**. Structural assignments were based on nmr and ir spectra and elemental analysis.

The 2-chloroketones that successfully reacted with **4** to give the corresponding *N*-acyl-1,3-oxathiol-2-imines were ethyl 2-chloroacetoacetate, 3-chloro-2,4-pentanedione, 2-chloro-*N*,*N*-dimethylacetoacetamide, ethyl 2-chlorobenzoylacetate,

2-oxo-2-phenylethyl chloride, 2-chloro-3-butanone, 2-chloro-1-(4-methylphenyl)propanone, 2-chloro-1-(2,4-dimethylphenyl) propanone, and 2-chlorocyclohexanone. 1-Chloro-2-propanone and 2-chloroacetoacetanilide failed in this synthesis.

Experimental

Infrared spectra were obtained on Perkin-Elmer 237B or 521 grating ir spectrometers. The nmr spectra were recorded using an R-20 Hitachi Perkin-Elmer spectrometer and are expressed in ppm (δ values) relative to tetramethylsilane as standard. Melting points were determined on a Gallenkamp melting point apparatus and are uncorrected. Analyses were performed on a Perkin-Elmer 240 elemental analyzer. Ultraviolet spectra were obtained on a Varian model G34 spectrophotometer.

O-*Methyl (5,6-Dihydro-2-methyl-1,4-oxathiin-3-yl)carbonyl carbamothioate (4, R = 5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)*

5,6-Dihydro-2-methyl-1,4-oxathiin-3-carbonyl isothiocyanate (3, R = 5,6-dihydro-2-methyl-1,4-oxathiin-3-yl) prepared (8) from 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxylic acid (40 g) and ammonium thiocyanate was treated with methanol (100 mL) and then allowed to stand at room temperature overnight. The excess methanol was distilled off *in vacuo*, the residue dissolved in toluene (500 mL), and the solution washed with water. Concentration of the toluene solution *in vacuo* and allowing the concentrate to cool yielded 35 g (60%) of light-yellow crystals melting at 86–88°C. Two crystalline modifications could be obtained, one melting at 89–91°C when recrystallized from aqueous methanol and the other melting at 98–100°C when recrystallized from methanol alone. Solutions of these in chloroform gave identical ir and nmr spectra; ir (KBr): 3350, 1675, and 1580 cm^{-1}; nmr ($CDCl_3$): 9.38(1H, s, NH), 4.42(2H, m, OCH_2), 4.12(3H, s, OCH_3), 2.96(2H, m, SCH_2), 2.25(3H, s, CH_3). *Anal.* calcd. for $C_8H_{11}NO_3S_2$: C 41.20, H 4.76, N 6.01; found: C 41.34, H 4.66, N 6.19.

O-*Ethyl (2-Furanyl)carbonylcarbamothioate*

This was prepared in 57% yield as above from 2-(furanyl)-carbonyl isothiocyanate and absolute ethanol, mp 67–69°C; nmr ($CDCl_3$): 9.40(1H, s, NH), 7.60(1H, m, aromatic), 7.30(1H, m, aromatic), 6.60(1H, m, aromatic), 4.55(2H, q, CH_2), 1.42(3H, t, CH_3). *Anal.* calcd. for $C_8H_9NO_3S$: C 48.24, H 4.56, N 7.03; found: C 48.52, H 4.68, N 7.04.

O-*Methyl 3-Methylbenzoylcarbamothioate*

This was prepared in 80% yield as above from 3-methylbenzoyl isothiocyanate and methanol, mp 75–77°C; nmr ($CDCl_3$): 9.40 (1H, s, NH), 7.60(2H, m, aromatic), 7.35(2H, m, aromatic), 4.15(3H, s, OCH_3), 2.40(3H, s, CH_3). *Anal.* calcd. for $C_{10}H_{11}NO_2S$: C 57.41, H 5.30, N 6.70; found: C 57.61, H 5.24, N 6.68.

O-*Methyl*-S-*phenylmethyl*-N-*(5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)carbonyl Carbonimidothioate*

To a solution of sodium (1.1 g) in methanol (75 mL) cooled to 15°C was added *O*-methyl (5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)carbonylcarbamothioate **4** (10 g) and phenylmethyl chloride (6.2 g). The resulting solution was allowed to stand at room temperature for 5 h. The precipitated sodium chloride was filtered and the filtrate concentrated to about half the original volume and allowed to crystallize. The white prisms melted at 87–89°C after recrystallization from methanol. The yield was 10 g (60%); nmr ($CDCl_3$): 7.28 (5H, s, aromatic), 4.25 (2H, m, OCH_2), 4.14 (2H, s, CH_2), 3.98 (3H, s, OCH_3), 2.86 (2H, m, SCH_2), 2.37 (3H, s, CH_3). *Anal.* calcd. for $C_{15}H_{17}NO_3S_2$: C 55.72, H 5.30, N 4.33; found: C 55.69, H 5.35, N 4.20.

Other O-*alkyl*-S-*substituted*-N-*acylcarbonimidothioates* ($RCON{=}C(O\text{-alk})SCH_2Ar$) prepared, for which yields, analyses and nmr spectra are available from the Depository of Unpublished Data,[1] are: R = C_6H_5, Alk = CH_3, Ar = C_6H_5, mp 80–82°C; R = C_6H_5, Alk = CH_3, Ar = 4-OCH_3-3-BrC_6H_3, mp 96–98°C; R = 3-$CH_3C_6H_4$, Alk = CH_3, Ar = 4-ClC_6H_4, mp 81–82°C; R = 5,6-dihydro-2-methyl-1,4-oxathiin-3-yl, Alk = CH_3, Ar = 4-ClC_6H_4, mp 102–104°C; R = 2-furanyl, Alk = C_2H_5, Ar = 4-ClC_6H_4, mp 103–104°C.

N-*Benzoyl-5-phenyl-1,3-oxathiol-2-imine (7, R = R′ = phenyl, R″ = H)*

To a solution of sodium (1.85 g) in methanol (100 mL) was added *O*-methyl benzoylcarbamothioate (7) (**4**, R = phenyl) (15.6 g). To the resulting solution was added a solution of 2-oxo-2-phenylethyl chloride (**5**, R′ = phenyl, R″ = H) (12.3 g) in methanol (50 mL) and the reaction mixture was allowed to stand 3 h. The precipitated O-*methyl*-S-*(2-oxo-2-phenylethyl)*-N-*benzoylcarbonimidothioate (6, R = R′ = phenyl, R″ = H)* containing sodium chloride was filtered off, washed with water and with aqueous methanol, and dried, yielding 21.4 g (85%) of white crystals melting at 97–99°C. Recrystallization from methanol did not change the melting point; nmr ($CDCl_3$): 8.20 (2H, m, aromatic), 8.00 (2H, m, aromatic), 7.55 (6H, m, aromatic), 4.42 (2H, s, CH_2), 4.02 (3H, s, CH_3). *Anal.* calcd. for $C_{17}H_{15}NO_3S$: C 65.17, H 4.82, N 4.47; found: C 65.05, H 4.67, N 4.51.

The intermediate *O*-methyl-*S*-(2-oxo-2-phenylethyl)-*N*-benzoylcarbonimidothioate (**6**, R = R′ = phenyl, R″ = H) (11.3 g) was dissolved in toluene (50 mL) and the solution heated under reflux for 1 h. The resulting solution was concentrated and allowed to cool, when white crystals, mp 164–165°C, were obtained. The yield of *N*-benzoyl-5-phenyl-1,3-oxathiol-2-imine (**7**, R = R′ = phenyl, R″ = H) was 10 g (85%). Ultraviolet (CH_3OH) λ_{max}: 334.5 nm (ε 21 285); nmr ($CDCl_3$): 8.32 (2H, m, aromatic), 7.70 (2H, m, aromatic), 7.40 (6H, m, aromatic), 6.80 (1H, s, CH). *Anal.* calcd. for $C_{16}H_{11}NO_2S$: C 68.32, H 3.94, N 4.98; found: C 68.15, H 4.18, N 4.90.

Ethyl 2-(5,6-Dihydro-2-methyl-1,4-oxathiin-3-yl)-carbonyl-imino-5-methyl-1,3-oxathiole-4-carboxylate (7, R = 5,6-Dihydro-2-methyl-1,4-oxathiin-3-yl, R′ = CH_3, R″ = $COOC_2H_5$)

To a solution of sodium (1.1 g) in methanol (40 mL) was added *O*-methyl (5,6-dihydro-2-methyl-1,4-oxathiin-3-yl)carbonyl-carbamothioate (**4**, R = 5,6-dihydro-2-methyl-1,4-oxathiin-3-yl) (10 g). To the resulting solution was added ethyl 2-chloroacetoacetate (8.0 g). The reaction mixture was allowed to stand for 5 h, then the precipitate was filtered, washed with methanol and with water, and dried. The 1,3-oxathiole (4.0 g) melted at 159–160°C after recrystallization from methanol. The filtrate from the reaction mixture was taken to "dryness" *in vacuo* and the residue was dissolved in ether and extracted with ice-cold dilute aqueous sodium hydroxide. The alkaline extract was acidified with cold dilute hydrochloric acid and extracted with ether. The ether extract was washed with water and the ether distilled, leaving a residue of the crude intermediate, **6** (R = 5,6-dihydro-2-methyl-1,4-oxathiin-3-yl, R′ = CH_3, R″ = $COOC_2H_5$). This was dissolved in toluene (25 mL), the solution heated under reflux for 45 min and then allowed to stand overnight. The precipitate was filtered, washed with toluene and with methanol, and dried, yielding 5.9 g more of the above 1,3-oxathiole, mp 159–160°C. The total yield was 9.9 g (70%). Ultraviolet (CH_3OH) λ_{max}: 304 nm (ε 11 432); nmr ($CDCl_3$): 4.38 (2H, m, OCH_2), 4.30 (2H, m, CH_2), 3.00 (2H, s, SCH_2), 2.62 (3H, s, CH_3), 2.46 (3H, s, CH_3), 1.35 (3H, t, CH_3). *Anal.* calcd. for $C_{13}H_{15}NO_5S_2$: C 47.42, H 4.59, N 4.25; found: C 47.42, H 4.67, N 4.35.

Other N-*Acyl-1,3-oxathiol-2-imines*

Other *N*-acyl-1,3-oxathiol-2-imines prepared, for which yields, analyses, and uv and nmr spectra are available from the Depository of Unpublished Data[1] are 7 where R = C_6H_5, R′ = CH_3, R″ = $CO_2C_2H_5$, mp 167–169°C; R = C_6H_5, R′ = CH_3, R″ = $COCH_3$, mp 196–197°C; R = C_6H_5, R′ = CH_3, R″ = $CON(CH_3)_2$, mp 106–107°C; R = C_6H_5, R′ = R″ = CH_3, mp 162–164°C; R = R′ = C_6H_5, R″ = $CO_2C_2H_5$, mp 160–161°C; R = 3-$CH_3C_6H_4$, R′ = CH_3, R″ = $CO_2C_2H_5$, mp 132–134°C; R = 3-$CH_3C_6H_4$, R′ = CH_3, R″ = $CON(CH_3)_2$, mp 101–103°C; R = C_6H_5, R′ = 4-$CH_3C_6H_4$, R″ = CH_3, mp 149–150°C; R = C_6H_5, R′ = 2,4-di$CH_3C_6H_3$, R″ = CH_3, mp 105–106°C; R = 5,6-dihydro-2-methyl-1,4-oxathiin-3-yl, R′ = C_6H_5, R″ = H, mp 178–180°C; R = 5,6-dihydro-2-methyl-1,4-oxathiin-3-yl, R′ and R″ together = -$CH_2CH_2CH_2CH_2$-, mp 143–145°C; R = 5,6-dihydro-2-methyl-1,4-oxathiin-3-yl, R′ = C_6H_5, R″ = $CO_2C_2H_5$, mp 158–160°C; R = 2-furanyl, R′ = CH_3, R″ = $CO_2C_2H_5$, mp 126–127°C; R = 2-furanyl, R′ = CH_3, R″ = $COCH_3$, mp 179–180°C; R = 2-furanyl, R′ = R″ = CH_3, mp 143–145°C; R = 2-furanyl, R′ = CH_3, R″ = $CON(CH_3)_2$, mp 163–165°C; R = 2-furanyl, R′ = C_6H_5, R″ = $CO_2C_2H_5$, mp 163–165°C; R = C_2H_5O, R′ = CH_3, R″ = $CO_2C_2H_5$, mp 64–65°C; R = cyclohexyl, R′ = CH_3, R″ = $CO_2C_2H_5$, mp 55–56°C.

Medium effects in protonation equilibrium studies. Accurate acidity constants using the excess acidity method[1]

ROBIN A. COX AND KEITH YATES

Department of Chemistry, University of Toronto, 80 St. George St., Toronto, Ont., Canada M5S 1A1

Received November 20, 1980

ROBIN A. COX and KEITH YATES. Can. J. Chem. **59**, 1560 (1981).

Ultraviolet spectra of *N-tert*-butylbenzamide taken in 0–92% sulfuric acid solutions clearly show that two processes, having roughly equal effects on the spectra, take place over this acidity range. One is protonation of the molecule, and the other is either tautomerization from N- to O-protonated forms, or a pronounced medium effect on the latter. Attempted separation of these two processes using characteristic vector analysis fails. However, separation is possible using an analysis based on the excess acidity (*X*-function) method. This shows that the second process is a medium effect. The analysis permits accurate calculation of pK_{BH^+} and m^* values in the presence of medium effects on the acid form, the base form, or both.

ROBIN A. COX et KEITH YATES. Can. J. Chem. **59**, 1560 (1981).

Les spectres ultraviolets de la *N-tert*-butylbenzamide dans des solutions d'acide sulfurique à des concentrations allant de 0 à 92% révèlent clairement que, sur cet intervalle d'acidité, deux processus se superposent et qu'ils ont chacun à peu près le même effet sur le spectre. L'un deux est la protonation de la molécule tandis que l'autre correspond soit à une tautomérisation de la forme N-protonée en forme O-protonée, soit à un effet du milieu assez prononcé sur la dernière forme. Il est impossible de différencier ces deux processus en utilisant une analyse vectorelle caractéristique. Cependant il est possible d'obtenir une différenciation en utilisant une analyse basée sur la méthode d'excès d'acidité (fonction de *X*). Ceci révèle que le deuxième procédé est un effet du milieu, L'analyse a permis de calculer d'une façon précise les valeurs du pK_{BH^+} et de m^* en présence des effets du milieu sur la forme acide, sur la forme basique ou sur les deux à la fois.

[Traduit par le journal]

Introduction

The site of protonation is of central importance to the study of amide protonation equilibria (1) and hydrolysis mechanisms (2). Much evidence now exists in favour of oxygen protonation; for instance McClelland and Reynolds' decisive ^{13}C nmr study showed oxygen protonation of *N,N*-dimethylformamide at all acidities (3), and recently Benedetti *et al.* presented an X-ray structure of *N,N*-dimethylacetamide hydrochloride (4), in which a difference-Fourier synthesis clearly shows the molecule to be oxygen-protonated in the solid state. However, the latter workers (4) leave open the possibility of a tautomeric equilibrium between N- and O-protonated forms in solution, as has been suggested by Liler (5). Also, a recent theoretical study (6), which favours oxygen protonation in the gas phase, finds that increasing "pyramidization" of the NH_2 group, which might occur in solution, increases the nitrogen and decreases the oxygen basicity.

In view of this we decided to apply the method of characteristic vector analysis (CVA) (7, 8) to uv spectra of amides taken over the whole sulfuric acid concentration range. In this case CVA separates the data into orthogonal vectors according to eq. [1], where D is optical density at

$$[1] \quad D_\lambda = \bar{D}_\lambda + c_1 v_{1\lambda} + c_2 v_{2\lambda} + \ldots$$

eq. [1], where D is optical density at wavelength λ, $\bar{D}$ is the average D at that wavelength over the acidity range, v's are vectors, independent of acidity, and c's are weighting coefficients, independent of wavelength. The protonation information is supposedly contained in c_1 when the method is used to separate protonation from medium effects (8–10). For a separation into different vectors to occur the effects involved must be orthogonal, i.e. independent of one another (7). This should apply, at least formally, to subsequent protonation and tautomerism (eq. [2]), insofar as

[2] 
the first equilibrium involves a proton, and so would be acidity-dependent, whereas the second does not.

This approach, the problems found with it, and the excess acidity (11) analysis of medium effects on protonation equilibrium measurements which

was developed as a result, form the subject of this paper, with *N-tert*-butylbenzamide being used as an example. Other examples will be found in the following paper (12), which uses this method for dissecting medium effects from protonation equilibria in the protonation of many different amides and lactams.

Experimental

The CVA program was written from Simonds' (7) algorithm and is essentially the same as that used by Edward and Wong (8).[2] The *X*-function analysis program was an adaptation of the general-purpose curve-fitting program CURFIT due to Bevington (13), quite similar to that used before for calculating *X*-functions for HCl and HBr (14), and for fitting kinetic equations (15). Details may be obtained from the authors; most computer centres offer similar curve-fitting routines. The uv spectra of *N-tert*-butylbenzamide were already available (12, 16) (Fig. 1). Ten absorbance measurements, at 5 nm intervals over the wavelength range 212.5–257.5 nm, were taken from each of 26 spectra covering the acidity range from water to 92% H_2SO_4. These data were arranged into a 26 row by 10 column matrix and used for both CVA and the excess acidity analysis without further modification.[2]

Characteristic Vector Analysis

The uv spectra of *N-tert*-butylbenzamide at different acidities are illustrated in Fig. 1. At low acidities a peak is present at about 225 nm, which shifts to some 237 nm at intermediate acidities and continues shifting to the 245–250 nm region in strongly acidic solutions. Clearly more than one process is occurring; presumably protonation, and either tautomerization as in eq. [2] or a pronounced medium effect, are taking place. It is also apparent that each of the two spectral processes contributes approximately equally to the total spectral variation.

This is contradicted by the CVA results, however. The analysis found two statistically significant vectors, the first accounting for 92.4% of the observed variation and the second 5.0%, the remaining 2.6% of the variation being random. The spectra reconstituted using the vectors and coefficients obtained were in good agreement with the originals, the root-mean-square residual error being ±0.010 absorbance units. The coefficients of the two vectors are plotted as a function of $-H_0$ (17), for illustrative purposes, in Fig. 2. Now simple

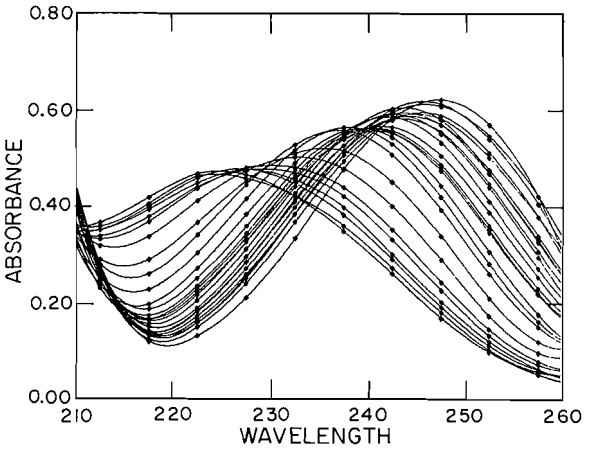

FIG. 1. Ultraviolet spectra of *N-tert*-butylbenzamide at different acidities. Points are the data points used in the CVA and the excess acidity analysis. The acidity ranges from water to 92% sulfuric acid at approximately 3.7% intervals, increasing from top to bottom at the left of the figure and from bottom to top at the right.

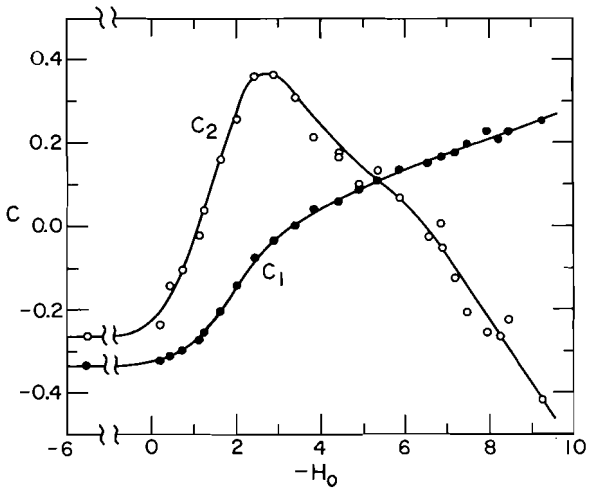

FIG. 2. Coefficients of the first and second characteristic vectors resulting from CVA of the spectra in Fig. 1, plotted as a function of $-H_0$.

protonation would give a sigmoid titration curve, changing from a constant c_B to a constant c_{BH^+}, when plotted in this way. It is evident that c_1 behaves like this initially, but does not reach a stable final value, continuing to vary slowly, and roughly linearly, with $-H_0$. This behaviour is very similar to that observed in some cases by Reeves (9), in his study of phenylazobenzenes and phenylazonaphthols in sulfuric acid. The only reasonable conclusion is that both protonation and the second effect are contained in c_1, which accounts for most

[2]The CVA program, together with the data matrix used, the derived vectors and coefficients, the reconstituted data matrix provided by the program, and the residuals, are on deposit and may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2. The *X*-function analysis program is given as a supplement to the following paper (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

of the variation; c_2 has no obvious physical or chemical counterpart (8).

Ultraviolet spectra as a function of acidity were obtained for many of the amides studied in the following paper (12), in addition to *N-tert*-butylbenzamide. Application of CVA resulted in very similar behaviour for all of them, with one vector accounting for almost all of the observed variation; in some cases this was the only statistically significant vector obtained. It should be emphasized that *N-tert*-butylbenzamide is quite typical; in fact when CVA is used in this way this behaviour is very common (8–10).

In hindsight this is what would be expected. CVA as used (7–10) is in fact *principle component* analysis (18), i.e., first the maximum possible variation is assigned to the first *eigen*vector, then the maximum amount of the remainder is assigned to the second, and so on. This unique eigenvector orientation is based solely on mathematical, not chemical, properties, and the eigenvectors which result may be linear combinations of chemical properties rather than the properties themselves (18). This seems to be the case here. Coordinate rotation is generally required to obtain the true chemical properties; some criteria for this have been given (18). A suitable linear combination of the vectors obtained may well give the proper sigmoid acidity dependence for the coefficients,[3] but the CVA method (7) as used here and elsewhere (8–10) evidently does not. It is true that spectra reconstituted according to eq. [1] using only $\bar{D}$ and v_1 show excellent isosbestic points, as spectra should when only one process is taking place, exemplified in papers by Edward and Wong (8), Reeves (9), and Zalewski (10). However, an isosbestic point necessarily results whenever v_1 is zero (see eq. [1]), which happens at least once in all cases (8–10), so this behaviour is forced upon the system.

Therefore we had to abandon unmodified CVA as a method for separating these different spectral processes. However, Fig. 2 is useful insofar as it shows that the second process is more likely to be a medium effect than a tautomerization. A process such as eq. [2] would likely produce two superimposed sigmoid curves, reaching a constant value at high acidity, rather than the continuous increase with $-H_0$ that is found for c_1. Also the observed nonseparation makes tautomerization seem less likely. Accordingly we determined to see whether the new excess acidity method, which has had considerable success in measuring pK_{BH^+} values (11, 14) and in the study of organic reaction mechanisms in these nonideal strong acid systems (15, 19), could be used for the determination of pK_{BH^+} values from spectral measurements in the presence of medium effects.

[3]Of course when only one statistically significant vector results none of this is possible.

Excess Acidity Analysis

The chemical process of interest is a base B being protonated to an acid A (as abbreviated here for convenience, usually written HA or BH^+), the dissociation constant of A being K_a (or K_{BH^+}), as in eq. [3]. According to the excess acidity method (11, 14), in terms of molarity C and molar activity coefficient f the pK_a is given by eq. [4]. The basic assumption of this treatment is eq. [5], where B* is a standard reference base (11, 14); eqs. [4] and [5] are well-tested and have been shown to be valid (11, 20).

$$[3]\quad B + H^+ \underset{}{\overset{K_a}{\rightleftharpoons}} A \qquad I = C_A/C_B$$

$$[4]\quad \log I - \log C_{H^+} = pK_a + m^*X$$

$$[5]\quad \log (f_B f_{H^+}/f_A) = m^* \log (f_{B^*} f_{H^+}/f_{A^*}) = m^*X$$

Since K_a as defined is solvent-independent, that is, the states of hydration of B, A, and H^+ are not specified, a series of equations like eq. [3], with the same K_a, can be written for different states of hydration (say 1 and 2) of A and B, as in eq. [6].

$$[6]\quad \begin{aligned} B_1 + H^+ &\overset{K_a}{\rightleftharpoons} A_1 \qquad I_1 = C_{A_1}/C_{B_1} \\ B_1 + H^+ &\overset{K_a}{\rightleftharpoons} A_2 \qquad I_2 = C_{A_2}/C_{B_1} \\ B_2 + H^+ &\overset{K_a}{\rightleftharpoons} A_1 \qquad I_3 = C_{A_1}/C_{B_2} \\ &\vdots \qquad\qquad \vdots \end{aligned}$$

Now by definition $a_{A_1} = a_{A_2} = \ldots = a_A$ and $a_{B_1} = a_{B_2} = \ldots = a_B$; as the medium is changed, the activities of the different hydrates remain equal, but the concentrations do not. If state 1 is more hydrated than state 2, its activity coefficient will increase and its concentration decrease as the medium becomes more acidic and more dehydrating, and vice versa. If the states have different physical properties (uv spectrum, nmr chemical shift) this will cause a medium effect as the acidity is varied.

Excess acidity equations are easily derived for eq. [6] as in eq. [7]. By considering the equilibria between states 1 and 2, eq. [8], the ratios I_A and I_B can be obtained by subtracting the appropriate X-function equations in eq. [7], giving eq. [9] for the base B and eq. [10] for the acid A. If the states 1 and 2 have different properties, then Δm_B^* and $\Delta m_A^* \neq 0$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

and a real medium shift will be apparent.

$$\begin{aligned} \log I_1 &= pK_a + \log C_{H^+} + m_1{}^*X \\ \log I_2 &= pK_a + \log C_{H^+} + m_2{}^*X \\ \log I_3 &= pK_a + \log C_{H^+} + m_3{}^*X \\ &\vdots \end{aligned} \quad [7]$$

$$B_1 \underset{}{\overset{K=1}{\rightleftharpoons}} B_2 \quad I_B = C_{B_2}/C_{B_1} = I_1/I_3 \quad [8]$$

$$A_1 \underset{}{\overset{K=1}{\rightleftharpoons}} A_2 \quad I_A = C_{A_2}/C_{A_1} = I_2/I_1 \quad [8]$$

$$\log I_B = \log I_1 - \log I_3 = (m_1{}^* - m_3{}^*)X = \Delta m^*{}_B X \quad [9]$$

$$\log I_A = \log I_2 - \log I_1 = (m_2{}^* - m_1{}^*)X = \Delta m^*{}_A X \quad [10]$$

Now one protonation equation, say that for $\log I_1$ in eq. [7], and the two medium effect equations [9] and [10], suffice to describe the variation of (say) optical density with the changing medium:

$$\begin{aligned} C_T &= C_{B_1} + C_{B_2} + C_{A_1} + C_{A_2} \\ &= C_{B_1}(1 + I_B + I_1 + I_1 I_A) \end{aligned}$$

$$\begin{aligned} D &= \varepsilon_{B_1} l C_{B_1} + \varepsilon_{B_2} l C_{B_2} + \varepsilon_{A_1} l C_{A_1} + \varepsilon_{A_2} l C_{A_2} \\ &= \frac{C_T(\varepsilon_{B_1} l + \varepsilon_{B_2} l I_B + \varepsilon_{A_1} l I_1 + \varepsilon_{A_2} l I_1 I_A)}{1 + I_B + I_1(1 + I_A)} \end{aligned}$$

$$D = \frac{D_{B_1} + D_{B_2} I_B + D_{A_1} I_1 + D_{A_2} I_1 I_A}{1 + I_B + I_1(1 + I_A)} \quad [11]$$

(since $\varepsilon_{B_1} l C_T = D_{B_1}$, etc.). In the aqueous reference state $X = 0$ (11) and $I_A = I_B = 1$ (also $\log I_1 = pK_a - pH$), and eq. [11] reduces to

$$D = \frac{(D_{B_1} + D_{B_2})/2 + I_1(D_{A_1} + D_{A_2})/2}{1 + I_1}$$

Thus in water we can write $D_{Baq} = (D_{B_1} + D_{B_2})/2$ and $D_{Aaq} = (D_{A_1} + D_{A_2})/2$. D_{B_1}, D_{A_2} etc. are hypothetical limits, never attained in practice because it is not possible to observe B_1 in the *absence* of B_2, etc. (It may be convenient to regard state 1 as being solvated by all the water molecules present and state 2 as being unsolvated.) So now we may make the more practical definition above, based on the aqueous reference state, and define a medium shift δ:

$$D_{B_2} = D_{Baq} + \delta D_B \qquad D_{A_2} = D_{Aaq} + \delta D_A$$

With these substitutions eq. [11] becomes:

$$D = \frac{D_{Baq} + \delta D_B\left(\frac{I_B - 1}{1 + I_B}\right) + D_{Aaq}\left(\frac{I_1(1 + I_A)}{1 + I_B}\right) + \delta D_A\left(\frac{I_1(I_A - 1)}{1 + I_B}\right)}{1 + \frac{I_1(1 + I_A)}{1 + I_B}}$$

From the definitions of I_1, I_A, and I_B it is apparent that

$$I_1(1 + I_A)/(1 + I_B) = (C_{A_1} + C_{A_2})/(C_{B_1} + C_{B_2}) = C_A/C_B = I$$

and that

$$I_1(I_A - 1)/(1 + I_B) = I(I_A - 1)/(1 + I_A)$$

For simplicity we define

$$\begin{aligned} (I_A - 1)/(1 + I_A) &= I'_A \\ (I_B - 1)/(1 + I_B) &= I'_B \end{aligned}$$

With these substitutions we obtain

$$D = \frac{D_{Baq} + \delta D_B I'_B + I(D_{Aaq} + \delta D_A I'_A)}{1 + I} \quad [12]$$

Equation [12] is a general equation with eight unknowns (D_{Baq}, D_{Aaq}, δD_B, δD_A, pK_a, m^*, $\Delta m_B{}^*$ and $\Delta m^*{}_A$). Thus large amounts of good data over the entire acidity range will be required if eq. [12] is to be used directly; however, it can be simplified.

Case 0

No medium effect; $\delta D_B = \delta D_A = 0$. Equation [12] becomes

$$D = (D_B + I D_A)/(1 + I) \quad [13]$$

with

$$\log I = pK_a + \log C_{H^+} + m^*X$$

(In water, $I_B = I_A = 1$ and $I'_B = I'_A = 0$, so the same equation applies, only with $\log I = pK_a - pH$.)

Case 1

Compounds which protonate in weak acid, medium effects on the base form not observable, $\delta D_B = 0$; eq. [12] becomes

$$D = (D_B + I(D_{Aaq} + \delta D_A I'_A))/(1 + I) \quad [14]$$

with

$$I'_A = (I_A - 1)/(1 + I_A) \quad \text{and} \quad \log I_A = \Delta m^*{}_A X$$

Case 2

Compounds protonating in strong acid, medium

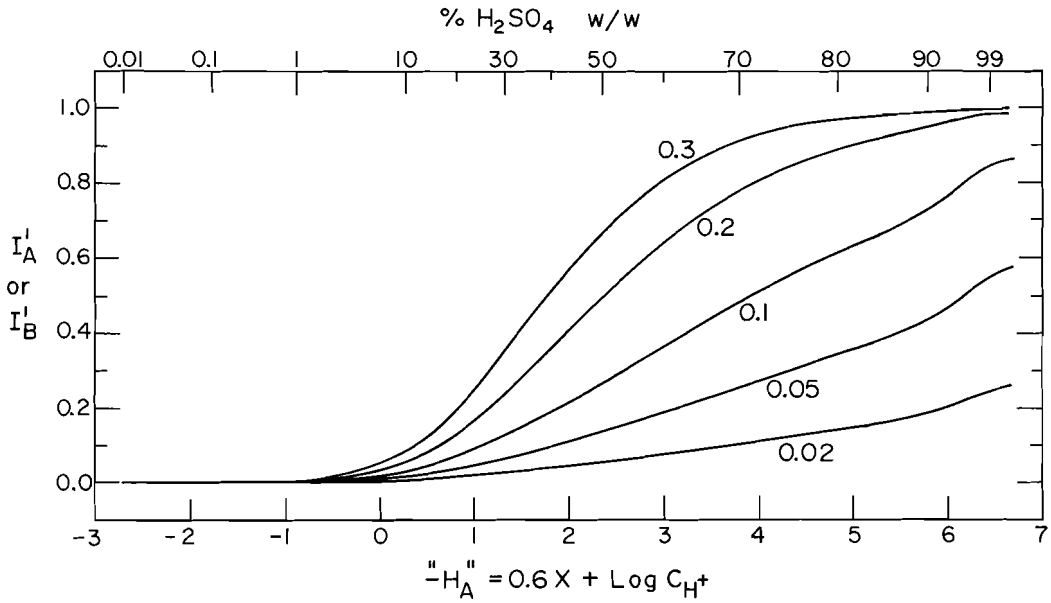

FIG. 3. I'_A or I'_B for various values of Δm^*, plotted against an acidity function for average amides. For comparison purposes a percent H_2SO_4 scale is included at the top of the figure.

effects on the acid form not observable, $\delta D_A = 0$; eq. [12] becomes

[15] $$D = (D_{Baq} + \delta D_B I'_B + I D_A)/(1 + I)$$

with

$$I'_B = (I_B - 1)/(1 + I_B) \quad \text{and} \quad \log I_B = \Delta m^*_B X$$

These equations make intuitive sense. When medium effects are absent, eq. [13] with constant D_A and D_B values applies; if medium effects are present, either D_A or D_B or both become variable functions of acidity, e.g. $D_A = D_{Aaq} + \delta D_A I'_A$, exactly as would be expected. I_B and I_A have limiting values of unity, since X cannot be negative (11); both must be ≥ 1 since the states of hydration of B and BH^+ must decrease with increasing acidity, i.e. $B_1 \rightarrow B_2$ and $A_1 \rightarrow A_2$. Thus Δm^*_B and Δm^*_A must be positive. I'_A and I'_B have limiting values of zero, in the aqueous standard state, and unity, when I_A and I_B are very large.

The behaviour of I' as a function of changing acidity (in terms of an acidity function for average amides (11), "$-H_A$" = $0.6X + \log C_{H^+}$) is illustrated for various values of Δm^* in Fig. 3. For $\Delta m^* \leq 0.1$, I' is practically linear with acidity functions over the 20–95% H_2SO_4 range, in agreement with experience (9, 21, 22); for instance Katritzky *et al.* (21) found that the medium effect on protonated amides was accounted for by assuming that ε_{BH^+} ($\equiv D_A$ here) was linear in $-H_0$, and Yates and McClelland (22) found that the same assumption applied to the unprotonated form (D_B) in ester protonation studies. This agreement is gratifying; it must be pointed out that it is not "built into" the excess acidity method, as the only assumption used in obtaining eq. [12] is that of eq. [5] above. Our experience has been that $\Delta m^* \simeq 0.1$ in most cases (12); occasionally $\Delta m^* > 0.1$, however, and plots of D_A or D_B against acidity functions are curved. An example is given in a following paper (12). If the data are insufficient to permit calculation of six coefficients using eq. [14] or eq. [15], fixing Δm^* at 0.1 (or 0.05) and calculating pK_a, m^*, D_{Baq}, D_{Aaq}, and δD is usually satisfactory (12). Often D_{Baq} is accurately known too. In extreme cases m^* can also be fixed at a likely value (11), but this is far less satisfactory. Equations [12]–[15] are best solved using a computer curve-fitting routine (see Experimental); only the familiar (11, 23) eq. [13] can be conveniently linearized (using fixed D_A and D_B values). Values of $\log C_{H^+}$ and X for use with these equations are available (11, 14).

Results and Discussion

Amides protonate in relatively dilute sulfuric acid (1, 16), so only medium effects on the acid form should be visible, Case 1 above. Accordingly eq. [14] was used, with the data already available from the characteristic vector analysis. These data consist of optical density measurements at 10 separate wavelengths, in 26 different sulfuric acid solutions, so the equation solved was actually ten separate eq. [14]'s, each one with different D_B,

D_{Aaq}, and δD_A values, but with the same pK_a, m^*, and Δm^*_A applying to all of them. Techniques for fitting a series of equations of this type were already available (14). One advantage to this is that 260 data points are used to calculate $3 \times 10 + 3 = 33$ coefficients, which is 7.9 points per coefficient, as compared to only 4.3 points per coefficient if 26 points are used to calculate 6 coefficients at a single wavelength, so the precision is higher. Another advantage is that the resulting D_B, D_{Aaq}, and δD_A values can be used to construct theoretical uv spectra for comparison with experiment.

For *N-tert*-butylbenzamide, $pK_a = -1.34 \pm 0.05$, $m^* = 0.68 \pm 0.05$, and $\Delta m^*_A = 0.107 \pm 0.007$ (12). The computer-drawn spectra constructed using these and the calculated D_B, D_{Aaq}, and δD_A values are given in Fig. 4. As can be seen the comparison between Figs. 1 and 4 is very good; the root-mean-square deviation between theory and experiment on the data points is marginally better than that given by the CVA, ± 0.009 optical density units, mainly due to the minor substrate concentration fluctuations to be expected from the experimental method used (12, 16). The appearance that the spectra would have in the absence of medium effects can also be determined, by assuming that D_A remains constant at D_{Aaq} and using eq. [13]; this is presented in Fig. 5. This shows that in water the protonated form has a λ_{max} of 237 nm, compared to 225 nm for the free amide. Similarly the medium effect on the protonated form can be examined in isolation, using $D_A = D_{Aaq} + \delta D_A I'_A$, and is given in Fig. 6. The λ_{max} of the acid form is seen to shift from 237 nm in water to 247 nm in 92% sulfuric acid. The second process is clearly revealed to be a medium effect by the regular shift pattern and the

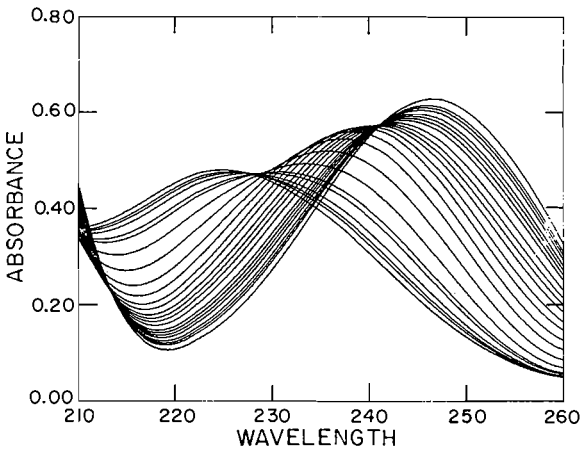

FIG. 4. Reconstructed uv spectra of *N-tert*-butylbenzamide at different acidities, resulting from the excess acidity analysis of the data in Fig. 1 via eq. [14]. See Fig. 1.

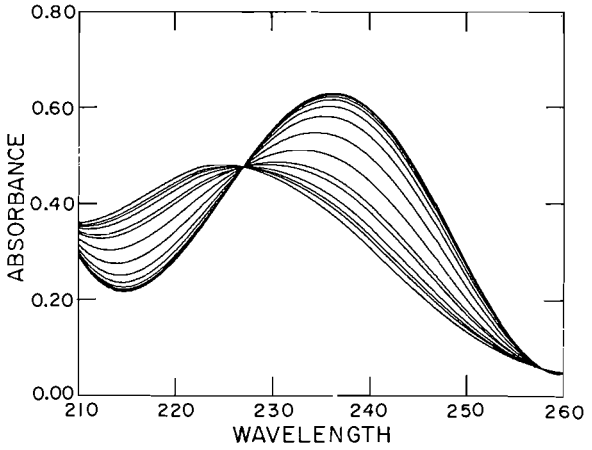

FIG. 5. Protonation; how the uv spectra of *N-tert*-butylbenzamide at different acidities would appear in the absence of a medium effect. See text and Fig. 1.

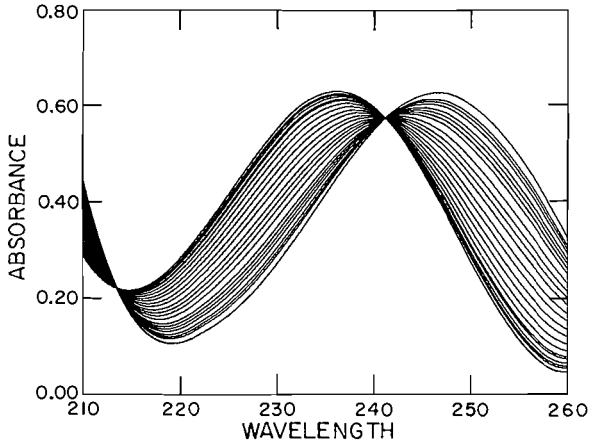

FIG. 6. The medium effect; how the uv spectra of protonated *N-tert*-butylbenzamide at different acidities would appear in the absence of spectral changes due to protonation. See text and Fig. 1.

closely similar peak shapes. Protonation is essentially complete at the 13th spectral scan (60% H_2SO_4); subsequent spectra only show the medium effect.

Returning to the CVA results and Fig. 2, eq. [14] should apply to c_1 also, if c_1 contains both medium effect and protonation information. Accordingly eq. [14] was written in terms of c (dropping the subscript 1 for clarity) and recast as eq. [16], in

$$[16] \quad (c(1 + I) - c_B)/I = c_{Aaq} + \delta c_A I'_A$$

order to determine c_{Aaq} and δc_A. The values of pK_a, m^*, and Δm^*_A given above were used to calculate I and I'_A, and c_B was taken to be the value in water, -0.335; the resulting plot was accurately linear (correlation coefficient 0.998 over 24 points),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12

showing that the analysis does indeed apply to c_1 also. An intercept, $c_{Aaq} = -0.118 \pm 0.003$, and a slope, $\delta c_A = 0.486 \pm 0.007$, were obtained; these were used to calculate a theoretical curve, and to dissect c_1 into two parts, as before, and the result is compared with the experimental points in Fig. 7. Here c_1 is plotted against the proper substrate acidity function (11) for *N-tert*-butylbenzamide, $-H_S = \log C_{H^+} + m^*X$, rather than $-H_0$; the values of c_{Aaq}, c_B, and δc_A are also indicated. As can be seen, agreement with the experimental c_1 values is excellent; the sigmoid protonation curve is seen to account for slightly less than half of the total variation. The true pK_a occurs half-way along such titration curves, as shown; it differs considerably from the value that would be chosen if the entire c_1 curve was taken as being due to protonation. The fact that this dissection of c_1 into two parts works so well reinforces the conclusion reached earlier, that CVA as used *does not* separate medium effects from protonation equilibria.

The possibility that the second process is a tautomerization, and not a medium effect, can now be discounted. Without going into detail, it is not difficult to derive X-function equations like eq. [14] based on this possibility, only now I' involves a ΔpK_a for protonation at the two sites, as well as a Δm^*, which would be the difference in m^* between protonation at N and O atoms, 0.4 or more (11). In order to obtain the good agreement with eq. [14] found in this work Δm^* would have to be 0.1, as found, and ΔpK_a would have to be zero. Thus tautomerism seems highly improbable on this basis. The uv spectra of benzamide given by Liler (5), which she takes as evidence of tautomerism, are in fact very similar to the *N-tert*-butylbenzamide spectra in this paper; undoubtedly they represent a medium effect in that case also. Very large medium shifts are found for other carbonyl compounds in strong acids, e.g. acetone (24), and it is unreasonable not to expect them for amides too; dilute and concentrated H_2SO_4 are, after all, very different media (25). The only evidence of Benedetti *et al.* for tautomerism is that a solution of dimethylacetamide hydrochloride in water does not have the same uv spectrum as does a solution in HCl (4). Presumably the aqueous solution would not have a pH lower than about one, as the only source of acid is the dimethylacetamide hydrochloride itself, at low uv spectral concentrations. This is insufficient to support full protonation of dimethylacetamide (diethylacetamide has a pK_{BH^+} of -0.33 (12)), and the observed spectrum will be that of a combination of free and protonated amides, not a combination of N- and O-protonated amides as stated (4).

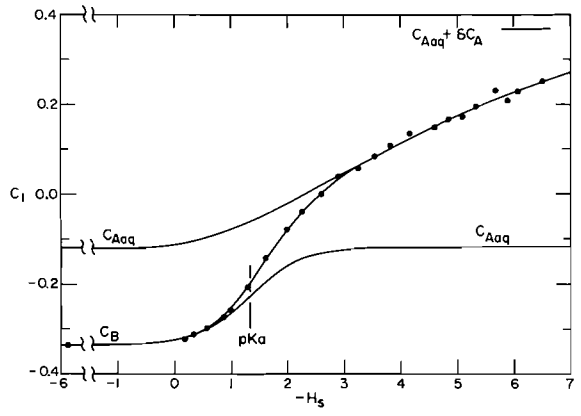

FIG. 7. The first characteristic vector coefficients from Fig. 2 compared with the theoretical curve from eq. [14], as a function of $-H_S$, the substrate acidity function for *N-tert*-butylbenzamide. Also shown is the dissection into the protonation titration curve and the medium effect curve (see text).

Summarizing: characteristic vector analysis as used does *not* separate medium effects from protonation equilibria, and its use for this purpose requires modification; medium effects are of major importance in the protonation of amides, as shown here and in a following paper (12); the excess acidity method enables accurate pK_{BH^+} determinations in the presence of large medium effects via eqs. [12]–[15]; and oxygen protonation is the only observable protonation process for amides at any acidity.

Protonation acidity constants for 27 benzamides, acetamides, and lactams have been determined. Ultraviolet, and ^{13}C and ^{1}H nmr, spectroscopic methods were used; almost all the spectra were found to be subject to medium effects, some quite severe, as the sulfuric acid concentration was increased. Despite this, the excess acidity (X-function) method gave accurate pK_{BH^+} and m^* values. In all cases protonation, followed by a medium shift in the spectrum of the protonated form, was the only process taking place; protonation was essentially complete in 60% H_2SO_4. The results for the different bases are interpreted in terms of the resonance, inductive, and steric effects in operation in the acid and base forms.

ROBIN A. COX, LINDA M. DRUET, ADI E. KLAUSNER, TOMASZ A. MODRO, PETER WAN et KEITH YATES. Can. J. Chem. **59**, 1568 (1981).

On a déterminé les constantes d'acidité de la protonation de 27 benzamides, acétamides et lactames. A cette fin on a utilisé la rmn du ^{1}H et du ^{13}C ainsi que la spectroscopie ultraviolette; lorsque la concentration en acide sulfurique augmente, presque tous les spectres subissent des effets de milieu qui sont quelquefois très importants. En dépit de cette influence, la méthode d'excès d'acidité (fonction X) donne des valeurs précises de pK_{BH^+} et de m^*. Dans tous les cas, la protonation, suivie d'un déplacement moyen dans le spectre de la forme protonée, est le seul processus qui a lieu; la protonation est tout à fait complète dans du H_2SO_4 à 60%. On interprète les résultats des différentes bases en fonction de la résonance ainsi que des effets inductifs et stériques présents dans les formes acide et basique.

[Traduit par le journal]

Introduction

A knowledge of the acidity constants of weakly basic substrates is of central importance to the study of the mechanisms of reactions which take place in acidic media (1), one example of which is the hydrolysis reaction of amides (2, 3) and lactams (4) in moderately concentrated aqueous sulfuric acid. Acidity constants are obtained from an analysis of the variation of some physical property of the substrate with changing acid concentration. The three properties most commonly used are the uv–visible spectrum (1), and the ^{1}H and ^{13}C nmr spectra (5, 6); the change observed with increasing acidity is from a spectrum characteristic of the free base to that of the protonated base. For carbonyl compounds the situation is more complex, however, since the spectra of one or both forms are usually subject to substantial medium effects (6–8). In view of this we recently developed a method for obtaining accurate acidity constants in spite of possible medium effects, based on the excess medium acidity X, which is a measure of the deviation of the acid system from ideality with increasing acid concentration (9).

The variation of ionization ratio, $I = C_{BH^+}/C_B$, with medium acidity is given for the protonation process of eq. [1] by eq. [2] according to the excess acidity (X-function) method (10); C_{H^+} is the proton concentration and X the excess acidity, values of which as a function of weight percent composition are available for the aqueous sulfuric acid system (10), and other common acid media (10, 11). The acidity constant pK_{BH^+} is as defined in eq. [1], and

$$[1]\quad B + H^+ \overset{K_{BH^+}}{\rightleftharpoons} BH^+$$

$$[2]\quad \log I = pK_{BH^+} + \log C_{H^+} + m^*X$$

inclusion of the slope parameter m^*, which expresses the sensitivity of the substrate to the changing acidity, obviates the necessity for considering differing acidity function behaviour among different substrates (10). When medium effects are present, a second ionization ratio is introduced, defined as in eq. [3]; I'_A when the medium effect is on the acid form BH^+, and I'_B for the base form B (9). Here the

$$[3]\quad I'_A = (I_A - 1)/(1 + I_A);\ \log I_A = \Delta m^*_A X$$

slope parameter Δm^*_A reflects the differing sensitivities to the medium of BH^+ in strongly hydrated (aqueous media) and weakly hydrated (strong acid media) forms (9). Amides protonate in relatively weak acid (2, 3), and so come under Case 1 in the accompanying paper (9), i.e. medium effects on the base form are assumed to be negligible, $\Delta m^*_B = 0$. The equation that describes the variation of optical density (or nmr chemical shift) D with changing acidity in this case is eq. [4] (9), where D_B and D_{BH^+aq} are the optical densities of the pure B and

BH^+ forms in water, and δD_{BH^+} is a medium shift term, i.e. $D_{BH^+} = D_{BH^+aq} + \delta D_{BH^+} I'_A$. If medium effects are absent the simpler form of eq. [4] with $\delta D_{BH^+} = 0$ can be used.

$$[4] \quad D = \frac{D_B + I(D_{BH^+aq} + \delta D_{BH^+} I_A')}{1 + I}$$

As a result of continuing kinetic studies in this area (2–4) we needed accurate pK_{BH^+} values for a number of lactams, acetamides, and benzamides, **1–27**. For practical reasons (e.g. the acetamides and lactams do not have useful uv spectra), and in order to test the general applicability of eq. [4], uv, ^1H and ^{13}C spectroscopy were all used in this work.

Experimental

Most of the amides and lactams were available commercially or had been previously prepared (2–4). *N*-benzyl- and α-methyl-*N*-benzylbenzamide were prepared according to Beckmann (12); benzoyl piperidine was obtained using Pasto and Johnson's procedure (13) and purified by column chromatography over alumina. Literature preparations were also available for *N-tert*-butyl- (14), *N*-benzyl- (15), *N-p*-methoxybenzyl- (15), and *N-p*-chlorobenzylacetamide (16). All synthesized compounds had appropriate spectral properties and melting points in agreement with literature values. Sulfuric acid solutions were diluted from the commercial acid and analyzed by measuring their densities at 25°C, using available tabulated composition/density data (17) and a DMA 02C digital precision density meter from Anton Paar.

Unicam SP 1800 or Cary 14 spectrophotometers and matched 1 cm cuvettes were used for the uv measurements, with the cell holders thermostatted at 25°C. Stock substrate solutions in methanol were prepared, of sufficient concentration that adding several microlitres to 3 mL of the test acid by syringe gave optical densities between 0.5 and 0.8, in general. Ultraviolet spectra in the 200–280 nm range were measured for each substrate in at least 20 acids covering the water – 90% H_2SO_4 region, in most cases, using as reference the same acid/methanol mixture, which was subsequently analyzed for concentration if the methanol content was greater than 0.2%. Optical density values at several different wavelengths for each acid were analyzed by computer as described before (9).[1]

A Varian CFT-20 instrument was used for the ^{13}C nmr spectroscopy studies; measurements were relative to a dioxane insert reference, at the probe temperature of 33 ± 2°C. At least 25 different acid strengths between zero and 90% were used; the substrate concentration was 0.5 *M*. For the pK_{BH^+} analysis differences in chemical shift between two carbons in the molecule were employed; 2–4 data columns could be obtained per substrate, which were analyzed in the same way as the uv data (9). Shift differences changed sufficiently with acidity to allow accurate analysis in all cases; for the 9-membered lactam **19**, however, the changes were quite small. Proton nmr measurements were obtained and analyzed in a similar fashion, using Varian T-60 and EM-360 instruments. In this case the number of data columns for analysis was occasionally reduced due to substrate peaks being swamped by solvent peaks at some acidities. For β-propiolactam **14**, very little difference between protonated and unprotonated spectra was apparent, and only approximate results could be obtained.[1]

Results

The benzamides **1–13** were all studied by uv spectroscopy. Data were already available for **1**, **2**, and **10** (18); the available spectra for **3**, **4**, **7**, and **11** (3) were supplemented by measurements at additional acidities. Optical density readings at several different wavelengths were read from spectra taken at each of 20–30 different acid concentrations. Using these data, eqs. [2]–[4] were solved using a computer curve-fitting program (9, 19).[1] For each base, values of D_B, D_{BH^+aq}, and δD_{BH^+} at each of the wavelengths used, as well as pK_{BH^+}, m^*, and Δm^*_A, were obtained, as already described for *N-tert*-butylbenzamide (9). The latter values for all of the compounds studied are given in Table 1, together with the number of data columns analyzed, the total number of data points, the root-mean-square error σ_y and the percent sulfuric acid concentration at which each compound is half-protonated. Occasionally the data did not permit calculation of Δm^*_A; in these cases it was given a fixed value, 0.2, 0.1, or 0.05 (9), and the one which resulted in the lowest σ_y used. In any case pK_{BH^+} and m^* did not vary by more than ±0.02 regardless of Δm^*_A. Those cases in which no

[1]The computer program used, and all of the experimental optical density and chemical shift data for **1–27**, are on deposit and may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[h]Fixed value.

medium effect was apparent are indicated in the Table by $\Delta m^*_A = 0$.

Using the calculated D_B, D_{BH^+aq}, and δD_{BH^+} values at several different wavelengths, the Table 1 data, and eqs. [2]–[4], it is possible to construct theoretical uv spectra in several different ways. Some of the possibilities are illustrated for *N*-*tert*-butylbenzamide in an accompanying paper (9); the behaviour of all the benzamides was very similar to this. For all compounds spectra for pure B and pure BH^+ in water were derived, as were spectra for BH^+ in 80% H_2SO_4, enabling λ_{max} to be obtained under standard conditions. The resulting spectra were very similar for all of the monoalkylbenzamides, with which benzamide itself is included. For Baq, BH^+aq, and BH^+(80% H_2SO_4), respectively, λ_{max} (ε) was 227 ± 1 (10 500 ± 300), 238 ± 1 (13 200 ± 200), and 246 ± 1 (12 700 ± 300) nm, averaging over **1–9**. The only exception was *N*-*tert*-butylbenzamide, **9**, with almost the same λ_{max} values but slightly reduced extinction coefficients at 9700, 12 700, and 12 000 (not included in the averages). Again for the dialkylbenzamides the spectra were similar; only a trailing end absorption was visible for Baq, but BH^+aq and BH^+(80% H_2SO_4) had λ_{max} (ε) of 230 ± 4 (8 700 ± 200) and 238 ± 2 (8900 ± 200) nm, averaging over **10–13**. Here the exception was *N*,*N*-diisopropylbenzamide, **12**, with considerably reduced extinction coefficients of 5 500 and 5 800. In general the dialkylbenzamide peaks were broader than the monoalkylbenzamide ones.

The lactams **15–20** and the acetamides **21**, **22**, and **27** were studied by ^{13}C nmr spectroscopy. Carbon chemical shifts δ at 20–30 different acidities were recorded, and differences in δ between pairs of carbon atoms were used as data, 2–4 data columns showing reasonable changes with acidity being recorded.[1] For instance, for the lactam **16** ($\delta_\alpha - \delta_\beta$) and ($\delta_\delta - \delta_\gamma$) both gave noticeable changes, as illustrated in Fig. 1. Differences in δ were used in order to avoid bulk susceptibility corrections, and in the hope that medium effects would be minimized (6). This hope was not realized, however, as Fig. 1 clearly shows. Rather than a simple sigmoid curve between B and BH^+, a considerable

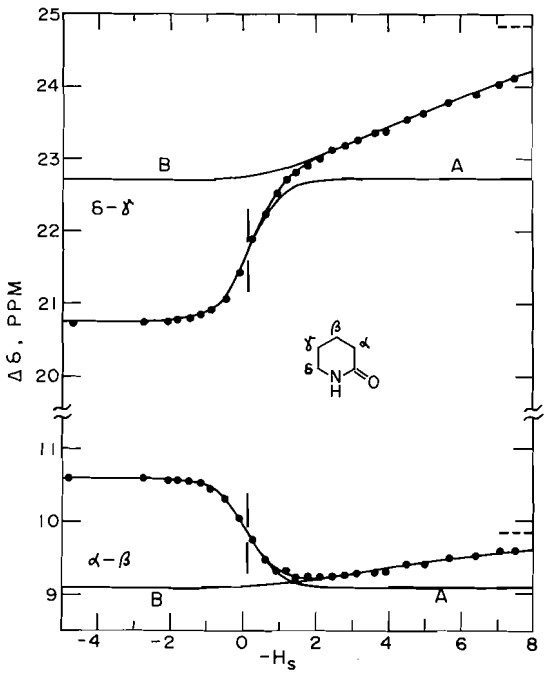

FIG. 1. ^{13}C chemical shift differences $\Delta\delta$ for δ-valerolactam as a function of its substrate acidity function $-H_S$. Points are experimental, curves theoretical for (A) protonation alone, (B) medium effect on the protonated form BH^+ alone, (through points) both protonation and medium effect. Upper, $\delta_\delta - \delta_\gamma$; lower, $\delta_\alpha - \delta_\beta$. The pK_{BH^+} is indicated by the vertical lines, and the theoretical $\Delta\delta$ for unsolvated BH^+ by the dashed lines at the right.

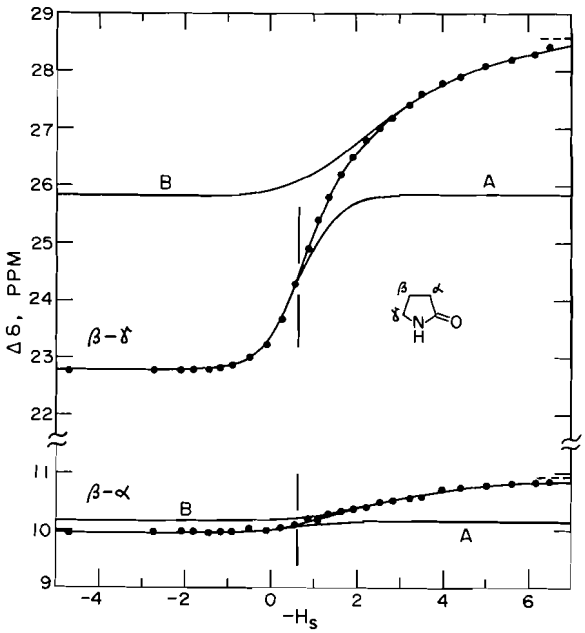

FIG. 2. ^{13}C chemical shift differences for 2-pyrrolidone as a function of $-H_S$. Upper, $\delta_\beta - \delta_\gamma$, lower, $\delta_\beta - \delta_\alpha$; see Fig. 1.

medium effect on the BH^+ form is apparent. Both large and small medium effects were observed, either augmenting the change due to protonation (upper part of Fig. 1) or opposing it (lower part). In some cases the medium effect caused larger changes in the spectrum than protonation itself, as illustrated for the lactam **15** in Fig. 2. As can be seen, without a method for allowing for the medium effect it would be difficult or impossible to assign an accurate pK_{BH^+} for this compound.

Because of the evident medium effects, the data were treated in exactly the same way as the uv data, using eqs. [2]–[4]. The results are in Table 1; the data are fitted to ±0.03 ppm on average, this representing excellent agreement between theory and experiment. In addition to pK_{BH^+}, m^*, and Δm^*_A, values of $\Delta\delta_B$, $\Delta\delta_{BH^+aq}$, and $\delta\Delta\delta_{BH^+}$ were obtained; e.g. for **16** these were 10.58 ± 0.01, 9.09 ± 0.01, and 0.76 ± 0.07, and 20.74 ± 0.01, 22.70 ± 0.02, and 2.11 ± 0.14 ppm, respectively, for the two shift differences in Fig. 1. Using these with eqs. [2]–[4] as before, theoretical curves can be constructed for comparison with experiment, as can curves to illustrate protonation in the absence of a medium effect, and the medium effect alone (9). These are all illustrated in Figs. 1 and 2, showing the large contribution from the medium effect.

Proton nmr was used for the acetamides **23–26**, and the β-lactam **14**. The procedure was the same as for the ^{13}C measurements, and the results are in Table 1.[1] Again chemical shift differences plotted as a function of acidity sometimes showed appreciable medium effects, as illustrated for **23**, *N-tert*-butylacetamide, in Fig. 3.[2] Here only one data column was available for the excess acidity analysis, the difference in δ between the CH_3 and $C(CH_3)_3$ protons, and replicate measurements were made to compensate for this. The precision, ±0.5–1.5 Hz, was not as high as it was for the ^{13}C measurements, but the method had compensating advantages, in that the medium effects were in general not as severe, and that measurements were faster. This was an important consideration for the easily hydrolysable compound **14** (4), which did not survive long enough in the more concentrated acids to allow time for the accumulation of adequate ^{13}C signals. Even so, the pK_{BH^+} and m^* values for **14** in Table 1 are only approximate, since the spectral change on protonation was very small.

[2]In Fig. 3, as in Figs. 1 and 2, $\Delta\delta$ is plotted as a function of the substrate acidity function $-H_S = \log C_{H^+} + m^*X$ (**10**); e.g. use of m^* for **23** means that $-H_S$ is specifically applicable to **23**. For comparison purposes a percent H_2SO_4 concentration scale is included at the top of Fig. 3.

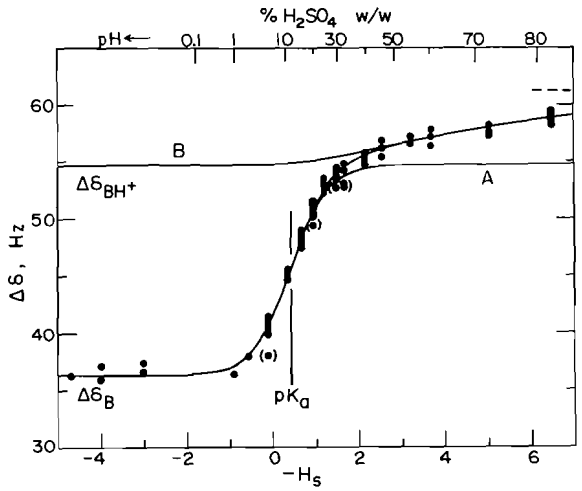

FIG. 3. Proton chemical shift differences for *N-tert*-butylacetamide as a function of $-H_S$; see Fig. 1. For convenience a percent sulfuric acid concentration scale is included at the top of the figure.

Discussion

For *N-tert*-butylbenzamide we have previously shown that the fact that the protonation data were so well fitted by eq. [4] was only consistent with protonation on oxygen, in the presence of a medium effect on the protonated form, and that the evidence was not consistent with a tautomerization from nitrogen- to oxygen-protonated isomers (9). The compounds studied in this work further support this conclusion; the experimental data are fitted by eq. [4] to high precision. In general, protonation of all the amides in this study was complete by about 60% H_2SO_4, further changes in the spectra with increasing acidity being entirely due to the medium effect.

Many of the trends in the pK_{BH^+} values in Table 1 run counter to intuition, and several factors must be taken into account when comparing them. For instance, it is apparent from Table 1 that acetamide is more basic than benzamide by 0.81 pK units. Part of this must be due to the higher electronegativity of the sp^2 carbons in benzamide, causing electron withdrawal and making protonation more difficult, but this should be counteracted by the resonance stabilization of positive charge into the ring possible in benzamide, making it a stronger base and the protonated form a weaker acid. However, this is an effect on the enthalpy, and pK (i.e. free energy) also contains an entropy contribution. Substituting phenyl for methyl is worth +3 to +8 entropy units in acid ionizations in water (somewhat less in the gas phase (20)), e.g. methylammonium ion, ΔS = −4.7 eu (21), anilinium ion, ΔS = +3.7 eu (22); acetic acid, −22.1 (21), benzoic acid, −19.0 (21). The 1–3 kcal/mol available from this at 25°C may be enough to overcome the resonance effect. Benzoic acid, for instance, is stronger than acetic acid, pK 4.213 vs. 4.756 (21), despite resonance stabilization of the acid form.

Steric effects should be apparent for those compounds with substituents bulky enough to interfere with the coplanarity of the molecule. Here, for the benzamides, we have independent evidence, from their uv spectra. All of the monoalkylbenzamides have the same spectrum except for *N-tert*-butylbenzamide, **7**, which has slightly reduced extinction coefficients. Application of the equation $\cos^2\theta = \varepsilon/\varepsilon_0$ (23) reveals that it is twisted with respect to benzamide by some 14°. Similarly the dialkylbenzamides are twisted with respect to the monoalkyl ones by 34°, with *N*,*N*-diisopropylbenzamide **12** twisted an additional 37°; this is supported by the 8 nm shift to high energy for the dialkyl compounds, indicative of reduced conjugation. The degree of twist is the same for the free base and protonated forms; addition of a proton has no effect on the coplanarity. Examination of Table 1 reveals that, with the exception of the *N*-benzyl compounds **8** and **9**, increased twisting changes the pK from benzamide-like to acetamide-like; the dialkylbenzamides are about 0.5 pK units more basic than the monoalkyl ones, and **7** and **12** have increased basicities within their series. This shows that whatever the nature of the effect which causes benzamide to be less basic than acetamide, the degree of coplanarity in the molecule is important to it.

Alkyl groups attached to nitrogen should have an acid-weakening effect; in the gas phase increasing methyl substitution in the series $HCONH_2$, $HCONHCH_3$, and $HCON(CH_3)_2$ stabilizes the protonated form by about 4 pK units per methyl group (24). This can be seen in the acetamides **21–23** and **27** in Table 1; for instance going from zero to one to two *N*-ethyl groups increases the pK from −0.7 to −0.5 to −0.3. However, this effect is not apparent in the benzamides, where benzamide and the monoalkylbenzamides all have pK's of −1.5; the increase to −1.0 in the dialkyl compounds is partly due to the steric effect discussed above. Something is counteracting the expected acid-weakening effect, and the most likely possibility appears to be steric inhibition of solvation. Protonated benzamide can partially delocalize its positive charge into the solvating water molecules; this will be more difficult when NH_2 becomes NHR, almost regardless of the size of R, and will be more difficult in any case with a phenyl group pres-

ent, rather than a methyl. Thus there is more charge requiring internal stabilization in the *N*-alkylbenzamides, and presumably this is fortuitously exactly neutralized by the inductive effect of the alkyl group in going from benzamide to a monoalkylbenzamide.

This factor, steric inhibition of solvation countering the inductive effect, may also account for the reduced basicity of the *N*-benzyl compounds **8–9** and **24–26**. Entropy effects, discussed above, may also be important. The same situation may apply to **15** and **20**, where *N*-methylation of 2-pyrrolidone has a slight acid-strengthening effect, counter to intuition. The situation may clarify when more amide (particularly benzamide) gas-phase basicity measurements are available for comparison. The trends apparent in the p*K*'s of the lactams **14–19** have been discussed elsewhere (4); in general they are acetamide-like in their behaviour.

The m^* values in Table 1 offer no real clues to the behaviour of these compounds. By analogy with Bunnett–Olsen ϕ values (25), $m^* > 1$ should indicate a larger than usual change in solvation by water molecules in going from $B + H^+$ to BH^+ (perhaps due to low solvation of BH^+ (25), as in carbonium ions (11)), and $m^* < 1$ should indicate the opposite. The average of the values in Table 1 is 0.63 ± 0.12 (excluding the fixed value for **26** and the less certain one for **14**), typical of amides (10). Three compounds, **9**, **13**, and **22**, have anomalously low values and another four, **16**, **23**, **24**, and **27**, have high ones. It is apparent that the lactams and acetamides show more variation in m^* than the benzamides; this is reasonable, since the latter can better delocalize charge internally by resonance and induction, resulting in less interaction with the solvent and less influence of structure upon m^*. Further work in this area, including temperature studies with determination of ΔS, may help to clarify the situation.

The medium effect coefficient Δm^*_A should reflect the differing sensitivity to the medium of BH^+ in highly solvated and unsolvated forms (9). However, much more information will have to be collected before significance can be attached to this quantity. For those cases in which Δm^*_A could be calculated, the average from Table 1 is 0.107 ± 0.036. For $\Delta m^*_A < 0.1$, the medium effect upon the spectrum of BH^+ is almost linear with acidity functions, in agreement with experience (8), as can be seen in Figs. 1 and 3. For Δm^*_A values considerably in excess of 0.1, curvature becomes noticeable, however, as is apparent for 2-pyrrolidone in Fig. 2. In general, it appears that, although all three experimental methods used here are susceptible to medium effects, they are less troublesome for proton nmr, and worst for ^{13}C spectroscopy.

Enzymes in organic syntheses. 19.[1] Evaluation of the stereoselectivities of horse liver alcohol dehydrogenase; catalyzed oxidoreductions of hydroxy- and ketothiolanes, -thianes, and -thiepanes

J. Bryan Jones and Harold M. Schwartz

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 5, 1980

J. Bryan Jones and Harold M. Schwartz. Can. J. Chem. **59**, 1574 (1981).

The specificity of horse liver alcohol dehydrogenase (HLADH) with respect to unsubstituted five-, six-, and seven-membered ring 3- and 4-thiaketone and -thiaalcohol substrates has been examined. The enzyme is found to have a broad tolerance of the structural variations within this series. HLADH also exhibits encouraging (up to 46%) enantiotopic and enantiomeric specificity in preparative-scale reduction and oxidation reactions of the heterocyclic ketones and alcohols respectively.

J. Bryan Jones et Harold M. Schwartz. Can. J. Chem. **59**, 1574 (1981).

On étudie la spécificité de la déshydrogénase d'alcool provenant du foie de cheval par rapport à des substrats thiacétones et thialalcools en positions 3 ou 4 de cycles à 5, 6 et 7 chaînons ne portant pas de substituants. On a trouvé que l'enzyme présente une grande tolérance vis-à-vis des variations structurales à l'intérieur de cette série. Cette déshydrogénase présente également une spécificité énantiotope et énantiomère encourageante (jusqu'à 46%) lors de réactions préparatives de réduction et d'oxydation respectivement de cétones et d'alcools hétérocycliques.

[Traduit par le journal]

The broad range of asymmetric synthetic opportunities provided by exploitation of the ability of horse liver alcohol dehydrogenase (HLADH)[2] to effect stereospecific oxidations and reductions of a broad structural range of alcohol and ketone substrates has been extensively documented (2, 3). Up till now, the substrates evaluated have been almost exclusively carbocyclic in nature, and with very few exceptions (2*c*, 3–5), heterocyclic compounds have received little attention as potential substrates. Accordingly, in view of the considerable asymmetric synthetic value of chiral heterocyclic synthons, we have initiated a general survey of the structural- and stereospecificity of HLADH towards substrates containing heteroatoms.

Sulfur was the heteroatom chosen for our initial studies. Its selection was dictated by several considerations. The enzyme was known to be tolerant of the sulfide functional group (2*c*, 4, 5) and the facilities of oxidoreductions of cyclic thiaketones and -alcohols were expected to parallel those of their well documented carbocyclic analogues. Also, it was anticipated that the carbocyclic substrate-derived active site model for predicting substrate stereospecificity would be equally applicable to thia-compounds since the longer C—S bond lengths and smaller C—S—C bond angles (6) do not alter the basic geometries of the rings sufficiently to invalidate the diamond lattice coordinate analyses normally applied (2*a*). Furthermore, subsequent application of the methodology of sulfur chemistry to enzyme-derived chiral thia-products of predictable absolute configurations opens up exciting asymmetric synthon possibilities. The additional benefit of providing access to otherwise difficult-to-prepare acyclic alcohols of predetermined chiralities via desulfurization of enzymically produced chiral cyclic thia-alcohols and ketones has been noted previously (2*c*).

In this paper we report on the specificity of HLADH-catalyzed oxidations and reductions of the hydroxy- and ketothiolanes, -thianes, and -thiepanes **1–10**.

The relative rates of HLADH-catalyzed reductions of the ketones **1–5** and of their five-, six-, and seven-membered ring carbocyclic analogues are recorded in Table 1, together with the steady-state kinetic constants for each substrate. The corresponding data for HLADH-catalyzed oxidations of **6–10** and of cyclopentanol, cyclohexanol, and cycloheptanol are given in Table 2. With the exception of 4-thiepanone (**5**), all thia-compounds of Tables 1 and 2 were sufficiently good substrates for preparative-scale reactions to be undertaken with confidence.

The preparative-scale HLADH-catalyzed oxidoreductions of **1**, **2**, **4**, **6**, **7**, **9**, **10** were carried out on ~1 g of substrate. Ketone **3** and alcohol **8** were omitted because both substrates and products are achiral. The results for enzyme-mediated reductions of **1**, **2**, and **4** are summarized in Table 3 and for oxidation of (±)-**6** – (±)-**10** in Table 4.

The stereochemical course of HLADH-catalyzed oxidation of (±)-3-thianol (**7**) was seen to be anomalous, since the thianol recovered from both it and the corresponding reduction of 3-thianone had the same, 3*S*, configuration. Accordingly, the oxidation reaction was repeated in the presence of semicarbazide to trap the ketone as it was formed. (3*R*)-Thianol was then obtained, as shown in Scheme 1.

The enantiomeric excesses (ee) of the chiral alcohols were determined by preparing their MTPA esters (7) and monitoring the 220 MHz ^{1}H nmr absorptions of the diastereotopic methoxyl protons in the presence of Eu(fod)$_3$. The $\Delta\Delta\delta$ values observed for the racemic MTPA esters are recorded in Table 5. The ee values determined by this procedure are given in Tables 3 and 4.

The absolute configurations of the chiral thia-alcohols **6**, **7**, **9**, and **10** obtained enzymically were assigned by their desulfurization with lithium in diethylamine (8) to optically active 2-butanol, 2-pentanol, 2-hexanol, and 3-hexanol respectively. These were converted directly to their hydrogen phthalate esters (9), the absolute configurations of which were known (10–13). The absolute configuration assignments are recorded in Tables 3 and 4.

Discussion

In general, we have found that any substrate which undergoes HLADH-catalyzed reduction or oxidation at a rate > 1–2% of that of the reference substrates cyclohexanone or cyclohexanol respectively will be a satisfactory candidate for preparative-scale reactions. From the relative velocity data of Tables 1 and 2, it is seen that with the exception of 4-thiepanone (**5**), each of the thia-compounds evaluated is a good candidate for preparative-scale reactions. However, the relative oxidation rate of (±)-3-thiolanol (**6**) is only 3% of that of cyclohexanol, thus placing it at the lower limit of preparative viability.

The steady-state kinetic descriptors K_m(app) and V_{max} were obtained using Lineweaver–Burk plots. No deviations from linearity were observed in any of the ketone plots (Table 1) but cyclopentanol, cyclohexanol, cycloheptanol, and (±)-3-thiepanol (**9**) showed substrate activation at high substrate concentration in the presence of saturating coenzyme levels.

For HLADH-catalyzed oxidoreductions, the mechanism is often a highly ordered one with enzyme–coenzyme (E–CoE) association preceding the binding of substrate (S). The hydride transfer step takes place following the formation of the E–CoE–S ternary complex. For many simple carbonyl and alcohol substrates the final step of the mechanism, dissociation of the enzyme-reacted coenzyme complex, is rate-determining (2*a*, *d*, 14). However, for all of the carbonyl substrates of Table 1, the V_{max} values are slower than that observed when $E.NAD^+$ dissociation is rate limiting (2*a*, *d*, 14). Thus hydride transfer is at least partially rate-limiting to varying degrees for each of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

the thiaketones **1**–**5**. The situation is quite different for oxidation (Table 2), E.NADH dissociation is rate-determining for cyclohexanol oxidation (2*a*, 14), and is also largely so for the thiaalcohols **7**–**10**, whose V_{max}'s are of a similar magnitude. Only for the five-membered ring alcohols are the V_{max} values significantly lower. This indicates that the hydride-transfer step is sufficiently slower for these substrates to become kinetically dominant.

V_{max}/K_m(app) ratios (or their equivalents) can serve as useful indicators of overall substrate reactivity when coenzyme release is rate-limiting (2*d*, 15). It is of interest to note that even for the thia-compounds of Tables 1 and 2, which do not all meet the rate-determining E–CoE dissociation condition, the V_{max}/K_m (app) variations tend to parallel those of the V_{rel} values.

The ring-size effects are similar for both carbocyclic- and thia-substrate series. In the reduction mode the reactivity order is clearly six- > seven- > five-membered ring ketone. For the corresponding alcohols, the variations are much less marked, but the five-membered ring alcohols remain the poorest substrates.

Although the substrate activities of analogous carbocyclic and thia-compounds are similar, the introduction of sulfur is seen to have a dramatic activating effect on the ketone reduction rates, particularly for the 3-thiaketones **1**, **2**, and **4** (Table 1). The reasons for these activating effects cannot be identified from the current data.[3] In contrast, the replacement of methylene by sulfur in the cyclic alcohol substrates was found to be uniformly deleterious (Table 2).

All preparative-scale HLADH-catalyzed reactions were carried out using ethanol as the coupled-substrate for NADH-recycling (16) and FMN for NAD^+-recycling (2*e*). Since the enantiomeric excesses attained were not high enough to be of great asymmetric synthesis value, no attempt was made to optimize the reaction conditions. The enantiomeric excesses were conveniently determined by nmr analysis of the Mosher esters (7). Desulfurizations of the thiaalcohols **6**, **7**, **9**, and **10** were first attempted using Raney nickel under the conditions previously found satisfactory (2*c*). However, these experiments met with little success and lithium-diethylamine was used instead. The results with the latter reagent paralleled the literature reports, with only one C—S bond cleaved at −78°C (17) and complete desulfurization being achieved at 0°C (8).

[3]There is ample evidence in the literature of the importance of electronic factors in sulfur–carbonyl interactions. Details are provided in the Ph.D. thesis of H.M.S., University of Toronto, 1979, and are available on request.

Initially, the fact that the alcohol (−)-**7** produced by reduction of 3-thianone (**2**) and recovered from oxidation of (±)-3-thianol (**7**) had the same (3*S*)-configuration was puzzling. Subsequently, this anomaly was found to be the result of (±)-3-thianol (**7**) being a slowly oxidized substrate while 3-thianone (**2**) was reduced with great facility. Accordingly, the 3-thianone being produced by HLADH-catalyzed oxidation of (±)-**7** was undergoing reduction back to (−)-**7** under the Table 4 reaction conditions. When the initial thiaketone product **2** was trapped with semicarbazide (4) to prevent this reverse reaction, the expected (3*R*)-alcohol (+)-**7** accumulated (Scheme 1).

The ee levels recorded in Tables 3 and 4 are of moderate magnitude only and are not of immediate chiral synthon value. Nevertheless, when it is considered that HLADH has been able to make these significant degrees of enantiotopic and enantiomeric distinctions on the basis of such a minor structural difference as the position of the sulfur atom in the ring, the enantiomeric excesses achieved are truly remarkable. It is clear that the enzyme has a broad structural tolerance of cyclic sulfur-containing substrates and that much higher (up to 100% (2*c*)) ee levels can be attained with larger and more dissymmetric molecules as substrates. These studies are now in hand.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. Spectra were obtained on the following instruments: ir, Perkin-Elmer 237; nmr (TMS internal standard), Varian T60 and HR220; ms, Bell and Howell 21-490. Optical rotations were measured on a Perkin-Elmer 141 polarimeter and glc analyses were performed on a Hewlett-Packard 5710A instrument using 3% QF1 or OV101 on Chromosorb 6 columns. All substrates used were glc-pure. NAD^+ was purchased from Kyowa Hakko Kogyo Co., New York, and NADH from Sigma. HLADH was a gift from Hoffmann La-Roche Inc. (18). The activity of the enzyme was determined (19) prior to each use and the amounts of HLADH quoted refer to milligrams of active enzyme. (±)-3-Thianol (**7**) was purchased from Aldrich.

Preparation of Substrates

All substrates were prepared by literature methods, or unexceptional modifications thereof, as follows.

3-Thiolanone (**1**), bp 68–70°C/12 Torr (lit. (20) bp 74.5°C/15 Torr), by the procedure of Woodward and Eastman (20).

3-Thianone (**2**), bp 42–44°C/0.25 Torr (lit. (21) bp 55–60°C/0.1 Torr), via the method of Young and Heitz (21).

4-Thianone (**3**), mp 61–63°C after recrystallization from pentane (lit. (22) mp 58–62°C), by the procedure of Barkenbus *et al.* (23).

3-Thiepanone (**4**), bp 80°C/1.5 Torr (lit. (24) bp 55°C/0.55 Torr, by the route of Leonard and Figueras (24).

4-Thiepanone (**5**), bp 80°C/0.5 Torr (lit. (25) bp 72–75°C/1.5 Torr), using the route reported by Overberger and Katchman (25).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

(±)-3-Thiolanol (**6**), bp 40–42°C/0.3 Torr (lit. (26) bp 53°C/0.25 Torr), by the method of Wilson and Albert (26).

(±)-4-Thianol (**8**), mp 49–50°C after recrystallization from pentane (lit. (27) mp 48–49°C), with the procedure as for (±)-**6** above.

(±)-3-Thiepanol (**9**), bp 80°C/5 Torr and *(±)-4-thiepanol* (**10**), bp 75°C/2 Torr (lit. (25) bp 75–77°C/1 Torr), by the method of Borsdorf *et al.* (28).

Relative Rate and Kinetic Studies of HLADH-catalyzed Reductions of 1–5 and Oxidations of 6–10

These were performed by the assay methods described previously (2*c*, *d*). The results obtained (correlation coefficients 0.95–0.99) are recorded in Tables 1 and 2.

Preparative-scale HLADH-catalyzed Oxidoreductions

Reductions of 1, 2, and 4

The following general procedure was employed. The thiaketone (~1 g) was dissolved in 0.1 *M* potassium phosphate buffer, pH 7, (500 mL) at 20°C. NAD^+ (~1 g) and ethanol (~2 g) were added and the reaction was initiated with HLADH (30–40 mg). The extent of reaction was monitored periodically by glc. After an appropriate conversion level, the mixture was continuously extracted with chloroform for 1 day. The dried ($MgSO_4$) chloroform extract was evaporated and the residual oil (~quantitative recovery) was separated into its components by thick layer chromatography on silica gel (230–400 mesh) with $CHCl_3$/CCl_4 (4:1) development followed by Kugelrohr distillation. The overall data are summarized in Tables 3 and 4. The individual reactions gave the following results.

Reduction of 3-thiolanone (**1**, 990 mg, 9.7 mmol) with enzyme (37 mg), NAD^+ (1.0 g, 1.4 mmol), and ethanol (2 g, 43 mmol) for 4 days gave unchanged **1** (329 mg) and (−)-(3*S*)-thiolanol (**6**, 411 mg, 33% ee), bp 44–48°C/0.3 Torr; $[\alpha]_D^{25}$ −4.31° (*c* 1.1, $CHCl_3$); ir (film): 3356 cm^{-1}; ^1H nmr (C^2HCl_3) δ: 1.5–2.4 (2H, m), 2.6–3.2 (4H, m), and 3.6 (1H, s) ppm.

Oxidations of (±)-6, -7, -9, and -10

In the general procedure used, the thiaalcohol (~1 g), NAD^+ (~1 g), and FMN (~10 g) were dissolved in 0.1 *M* glycine – NaOH buffer, pH 9, (500 mL) at 20°C. The enzyme (15–40 mg) was then added and the pH readjusted to 9 with 10 *M* aqueous NaOH. The course of the reaction was monitored by glc and when an acceptable conversion level had been reached, the solution was continuously extracted with chloroform for 1 day. The extract was filtered through a plug of silica (2 g), dried ($MgSO_4$), and evaporated to give an oil which was separated into its components by thick layer chromatography on silica gel 60 (230–400 mesh) with $CHCl_3$/CCl_4 (4:1) development. Final purification was effected by Kugelrohr distillation.

Oxidation of (±)-3-thiolanol (**6**, 980 mg, 9.4 mmol) with enzyme (38 mg), NAD^+ (1.0 g, 1.4 mmol), and FMN (10.0 g, 20.9 mmol) for 4 days, followed by further addition of enzyme (8 mg) and 3 more days reaction time gave 3-thiolanone (**1**, 67 mg) and (+)-(3*R*)-thiolanol (**6**, 453 mg, 9% ee), bp 40°C/0.3 Torr; $[\alpha]_D^{25°}$ +1.44° (*c* 1.04, $CHCl_3$); ir and nmr spectra identical with those detailed above.

Oxidation of (±)-3-thianol (**7**, 1.1 g, 9.32 mmol) with HLADH (37 mg), NAD^+ (1.0 g, 1.3 mmol), and FMN (10.0 g, 20.0 mmol) for 2.5 days gave 3-thianone (**2**, 183 mg) and (−)-(3*S*)-thianol (**7**, 390 mg, 8% ee), bp 40°C/0.25 Torr, $[\alpha]_D^{25°}$ −3.89° (*c* 1.0, $CHCl_3$); ir and nmr spectra identical with those detailed above.

Oxidation of (±)-4-thiepanol (**10**, 802 mg, 6.08 mmol) with enzyme (25 mg), NAD^+ (1.0 g, 1.4 mmol), and FMN (10.0 g, 20.9 mmol) for 5 h gave 4-thiepanone (**5**, 52% by glc, removed by treatment with Girard T reagent) and (−)-(4*S*)-thiepanol (**10**, 235 mg, 25% ee), bp 76°C/2 Torr; $[\alpha]_D^{25°}$ −2.69° (*c* 1.0, $CHCl_3$); ir and nmr spectra identical with those detailed above.

Enantiomeric Excess Determinations

The optically active and, for calibration purposes, the racemic alcohols **6**, **7**, **9**, and **10** were converted to their MTPA esters in quantitative yields by the standard literature procedure (7) using freshly prepared (+)-(2*R*)-2-methoxy-2-trifluoromethylphenylacetyl chloride, $[\alpha]_D^{25°}$ +128.2° (*c* 0.93, CCl_4) (lit. (7) $[\alpha]_D^{25°}$ 129° (*c* 5.17, CCl_4)). The enantiomeric excesses of the HLADH-derived MTPA esters were determined by 220 MHz ^1H nmr examination of the methoxyl protons in the presence of $Eu(fod)_3$, using the corresponding racemic alcohol MTPA esters for reference. The ΔΔδ values for each pair of diastereotopic methoxyl groups are shown in Table 5.

Absolute Configuration Determinations

The absolute configurations of the optically active alcohols (−)-**6**, (−)-**7**, (−)-**9**, and (−)-**10** (Tables 3 and 4) were established by desulfurization. The procedure for (−)-**6** is representative.

To a stirred solution of (−)-3-thiolanol (**6**, 270 mg, 2.6 mmol, $[\alpha]_D^{25°}$ −4.37° (*c* 2.01, $CHCl_3$)) in anhydrous ethylamine (5 mL) at 0°C was added lithium (1 g, 144 mmol) in small chunks. The mixture was stirred for 10 h at 0°C and was then added slowly to an ether (100 mL) – ice (20 g) mixture at −78°C. The ether layer was then separated, dried ($MgSO_4$), and evaporated to give an oil (97 mg, 1.31 mol). This was converted directly into its hydrogen phthalate ester with resublimed phthalic anhydride (271 mg, 1.83 mmol) in dry pyridine (5 mL). The mixture was refluxed for 3 h, stirred overnight at 20°C, and then poured onto ice (5 g). Concentrated hydrochloric acid (1.75 mL) was added and the aqueous mixture extracted with chloroform (3 × 50 mL). The chloroform extract was dried ($MgSO_4$) and evaporated to give the (−)-hydrogen phthalate ester of (2*R*)-butanol (253 mg), mp (±) 58–58.5°C after recrystallization from hexane (lit. (10) mp 56–57°C); $[\alpha]_D^{25}$ −4.35° (*c* 0.09, $CHCl_3$) (lit. (10) (+)-2*S*-enantiomer, $[\alpha]_D^{25}$ +33.54° ($CHCl_3$)); ir (film): 3700–2200, 1735, and 1700 cm^{-1}; ^1H nmr (C^2HCl_3) δ: 0.8–1.2 (3H, t, *J* = 6 Hz), 1.2–1.9 (5H, overlapping q, *J* = 6 Hz and d, *J* = 6 Hz), 5.2 (1H, sextet, *J* = 6 Hz), 7.4–8.1 (4H, m), and 11.9 (1H, s) ppm.

The alcohols (−)-7, (−)-**9**, and (−)-**10** were treated similarly.

Desulfurization of (−)-3-thianol (**7**, 192 mg, 1.63 mmol, $[\alpha]_D^{25}$ −17; 2° (*c* 1.0, $CHCl_3$)) yielded the (−)-hydrogen phthalate ester of (2*R*)-pentanol (149 mg), mp(±) 63.5–64.5°C, after recrystallization from hexane (lit. (10) mp 60–61°C); $[\alpha]_D^{25}$ −12.01° (*c* 0.33, $CHCl_3$) (lit. (10) (+)-(2*S*) enantiomer $[\alpha]_D^{25}$ +36.94° ($CHCl_3$)); ir (film): 3600–2200, 1735, and 1700 cm^{-1}; ^1H nmr (C^2HCl_3): 0.8–2.0 (10H, m overlapping and at δ 1.3, *J* = 6 Hz), 5.3 (1H, sextet, *J* = 6 Hz), 7.4–8.0 (4H, m), and 11.1 (1H, s) ppm.

Desulfurization of (−)-3-thiepanol (**9**, 151 mg, 1.15 mmol, $[\alpha]_D^{25}$ −9.38° (*c* 1.06, $CHCl_3$)) produced the (−)-hydrogen phthalate ester of (2*R*)-hexanol (159 mg), mp (±) 48–48.5°C after recrystallization from hexane (lit. (10) mp 48°C), $[\alpha]_D^{25}$ −12.33° (*c* 1.59, $CHCl_3$) (lit. (10) (+)-(2*S*)-enantiomer $[\alpha]_D^{25}$ +43.39° ($CHCl_3$)); ir (film): 3600–2200, 1735, and 1700 cm^{-1}; ^1H nmr (C^2HCl_3) δ: 0.8–2.0 (12H, m overlapping d at δ 1.3, *J* = 6 Hz), 5.3 (1H, sextet, *J* = 6 Hz), 7.4–8.0 (4H, m), and 10.8 (1H, s) ppm.

Desulfurization of (−)-4-thiepanol (**10**, 150 mg, 1.14 mmol, $[\alpha]_D^{25}$ −2.69° (*c* 1.3, $CHCl_3$)) afforded the (−)-hydrogen phthalate ester of (3*R*)-hexanol (218 mg), mp (±) 75.5–77°C after recrystallization from hexane (lit. Reçu le 30 octobre 1980

Y. UMETSU, J. P. BAILLON, D. L. PIRON et G. BÉLANGER. Can. J. Chem. **59**, 1580 (1981).

Les alliages Nb–Co sont stables à la corrosion à circuit ouvert en présence d'oxygène dans une solution de 25% KOH en autant que le pourcentage en poids de Co excède 50%. En deça de cette valeur des coupons soumis à ces conditions se sont désagrégés après 30 jours. Lorsque les alliages sont soumis à une polarisation anodique, on observe la dissolution active suivie d'une passivation et en présence de cobalt, la réaction du dégagement d'oxygène se manifeste. L'analyse par spectroscopie électronique Auger (SEA) du niobium pur et des alliages 30 et 90% de Co montre que le film d'oxyde croît de façon irrégulière selon la nature de la surface. Ainsi pour une polarisation anodique identique (0,845V vs. ENH pendant 6 heures) le film d'oxyde passe de $4{,}13 \times 10^{-2}$ µm pour le Nb pur à 0,10 µm pour l'alliage à 30% de Co et redevient aussi mince que 8×10^{-4} µm pour l'alliage à 90% de Co. Le profil de concentration révélé par SEA indique une dissolution préférentielle du Nb comparativement au Co dans le film d'oxyde.

Y. UMETSU, J. P. BAILLON, D. L. PIRON, and G. BÉLANGER. Can. J. Chem. **59**, 1580 (1981).

Niobium–cobalt alloys are stable to corrosion in an open circuit in the presence of oxygen in 25% KOH solution as long as the weight percentage of cobalt exceeds 50%. Below this value, samples submitted to these conditions disintegrate after 30 days. When these alloys are submitted to anodic polarization an active dissolution is noted followed by passivation and in the presence of cobalt production of oxygen occurs. Electronic Auger Spectroscopic (EAS) analysis of pure niobium and its alloys with 30% and 90% cobalt indicates that the oxide film grows in an irregular manner according to the nature of the surface. Thus, for an identical anodic polarization (0.845 V vs. ENH for 6 hours) the oxide film changes from 4.13×10^{-2} µm for pure Nb to 0.10 µm for the 30% Co–Nb alloy and becomes as thin as 8×10^{-4} µm for the 90% Co–Nb alloy. The concentration profile as shown by EAS indicates a preferential dissolution of Nb over Co in the oxide film.

Introduction

Dans le cadre des travaux de notre groupe sur la réaction du dégagement de l'hydrogène (RDH), une série de mesures furent réalisées illustrant certains avantages électrocatalytiques du niobium (1–3) et ses alliages avec le Ni (4, 5). En effet, lors d'une polarisation cathodique, le niobium acquiert une activité catalytique comparable au nickel pour la RDH (2, 3). En alliant le niobium au nickel, cette activité se manifeste pour l'alliage 30% Ni (4); cependant la surface de ce matériau se désintègre sous la formation d'hydrure. Une activité accrue par rapport au Nb se retrouve en alliant celui-ci au Co mais dans une moindre mesure que l'alliage Ni–Nb (6). Pour compléter notre évaluation des alliages Ni–Nb, nous avons étudié le comportement de ceux-ci à l'état de repos dans une solution aérée de KOH de même que sous l'effet d'une polarisation anodique (5); les alliages à basse teneur de Ni sont rapidement corrodés à l'état de repos. Par contre, le niobium pur soutient une croissance d'un oxyde lors d'une polarisation anodique (5, 7, 8).

Dans cette présente étude, nous avons étendu nos travaux pour évaluer le comportement anodique des alliages Co–Nb en milieu alcalin; les observations électrochimiques ont été complétées par l'évaluation par spectroscopie Auger de la composition chimique de la surface après une polarisation anodique prolongée.

Partie expérimentale

La préparation des alliages et leur montage en électrodes de 5 × 5 × 3 mm ont été décrits précédemment (6). L'électrolyte utilisé a été une solution de 25% (en poids) de KOH dans l'eau distillée. Les solutions furent désaérées pendant 4 h sous argon avant le début des polarisations.

La technique de polarisation potentiostatique à l'équilibre fut utilisée dans le cours des mesures électrochimiques (2, 3); le saut de potentiel a été de 50 mV et le courant noté après 2 min sous une polarisation constante. La gamme de potentiels explorés a été à partir du potentiel de repos jusqu'au dégagement de l'oxygène. Les essais électrochimiques furent réalisés en utilisant une électrode calomel saturée comme référence mais les potentiels rapportés dans ce travail furent ramenés à l'électrode normale de l'hydrogène (−245 mV vs. ECS).

Les essais de corrosion furent réalisés en immergeant les échantillons dans une solution de 25% KOH saturée d'air de 100 mL pendant 30 jours.

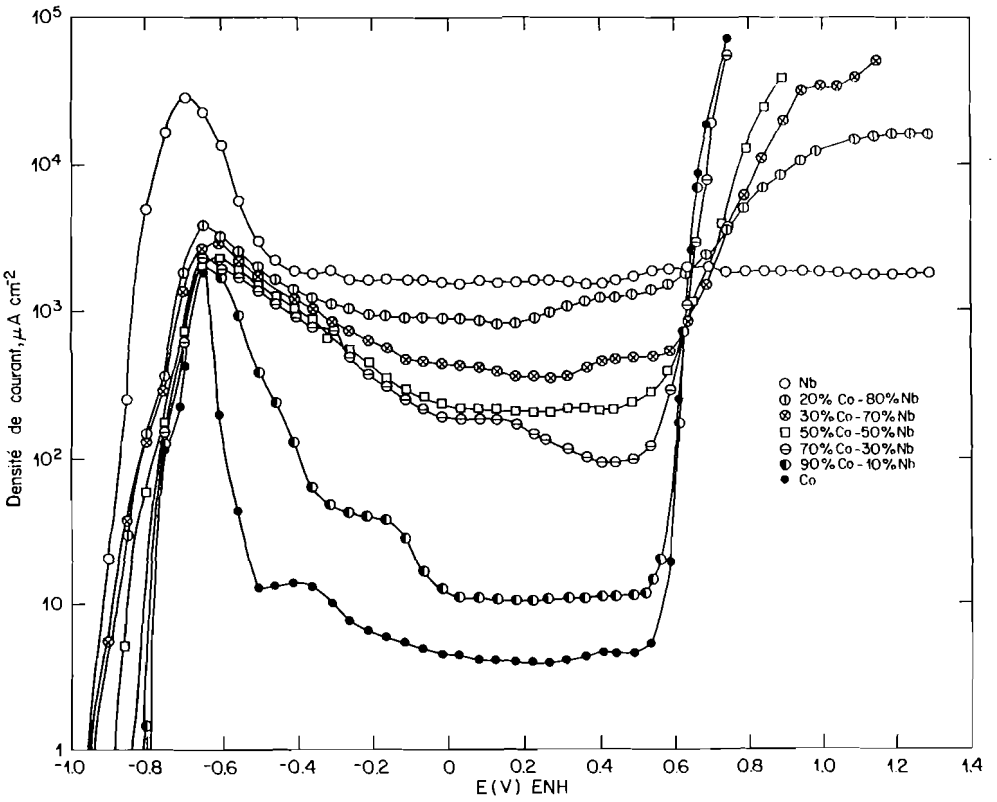

FIG. 1. Courbe potentiostatique à l'équilibre du comportement anodique du Nb et des alliages Nb–Co: 25% KOH (par poids); 25°C.

Les profils de concentration du Nb, Co et de l'oxygène dans les films d'oxyde furent déterminés pour le Nb et des alliages typiques soit 30 et 90% Co. Pour ces expériences, les échantillons furent polarisés dans la solution de KOH à 845 mV vs. ENH pendant 6 h. Après ce traitement anodique, l'électrode fut lavée abondamment à l'eau distillée et asséchée dans un desiccateur. Les analyses des films d'oxyde par spectroscopie électronique Auger (SEA) ont été réalisées dans un système de la compagnie Varian. Les conditions expérimentales étaient les suivantes: (*a*) faisceau d'électrons primaires: énergie, 3 keV; courant, 15 μA; diamètre du faisceau ≃ 5 μm; modulation, 2 V crête à crête; (*b*) décapage ionique: ions d'argon de 1 keV; densité de courant ≃ 85 μA cm^{-2}; pression ≃ 5×10^{-5} Torr. Sous ces conditions, la vitesse de décapage est approximativement de l'ordre de 5×10^{-5} μm (0.5 Å) par seconde pour les couches d'oxyde de niobium.

Résultats et discussion

(a) Essais de corrosion

Après 30 jours d'immersion dans une solution aérée de 25% KOH les alliages 10, 20 et 30% Co sont sérieusement attaqués et on y note la formation de grains ou de poudres. Pour les alliages de 50% Co et plus, seul celui contenant 90% Co montre une certaine attaque du milieu.

L'alliage 10% Co a subi une attaque le long des limites des grains et s'est fissuré en de petites unités séparées. Les alliages de 20 et 30% Co se sont désintégrés en fine poudre. En conclusion, seuls les alliages de 50% et plus montrent une stabilité à la corrosion en milieu alcalin en présence d'oxygène; ces mêmes échantillons en solution désaérée ne présentent pas de corrosion notable.

(b) Polarisation anodique

Les courbes de polarisation anodique sont illustrées à la fig. 1. A l'encontre des alliages Ni–Nb, les alliages de Co montrent une région de dissolution active à des potentiels de −800 mV vs. ENH. Le niobium pur illustre le comportement typique d'un métal "valve" où suite à une dissolution, un oxyde de surface croît jusqu'à de grandes épaisseurs (7, 8).

La présence de cobalt ne modifie pas le potentiel de courant maximum bien que le potentiel de repos subisse en déplacement anodique.

Les alliages à forte teneur de Co montrent une passivation importante; le courant anodique chute de façon abrupte à des potentiels plus anodiques que −600 mV. Ce phénomène est très marqué pour le Co pur ainsi que pour l'alliage 90% Co.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

Pour les alliages, on observe un dégagement d'oxygène à des potentiels de 600 mV ou plus. Pour les alliages de 20 à 50% Co, un film à la surface de l'électrode se manifeste suite à une polarisation prolongée. Pour les alliages de 70% et plus, l'effet du niobium est pratiquement absent et les courbes de polarisation de la réaction du dégagement d'oxygène se confondent avec celles observées pour le cobalt pur.

A la fig. 2 on a rapporté la densité de courant à un potentiel de 445 mV (dans la région de passivation). On remarque une chute importante de ce courant suite à l'augmentation de la teneur en Co des alliages; la densité de courant tombe à 3 $\mu A\,cm^{-2}$ pour le Co pur comparativement à 1,5 $mA\,cm^{-2}$ pour le Nb pur.

(c) Profils de concentrations dans les films anodiques

La réaction du dégagement d'oxygène (RDO) se déroule sur un film d'oxyde et les caractéristiques de celui-ci déterminent à la fois le mécanisme de la réaction et aussi les propriétés anodiques du métal. Pour le niobium pur, le film d'oxyde forme une barrière au dégagement d'oxygène (7, 8) et la croissance de cet oxyde confère au métal des propriétés diélectriques particulières; un tel comportement se retrouve pour l'aluminium et le tantale entre autres (7, 8). La formation de films d'oxydes conducteurs électroniques permet à la RDO de se produire et c'est le cas des métaux précieux (Pt, Au) ou d'autres métaux catalytiques Ni et Co.

Récemment Romand *et al.* (9) ont rapporté l'analyse par spectroscopie Auger des films anodiques d'oxyde sur le Nb et certains de ses alliages à l'exclusion des alliages CoNb. En plus de la complexité du film d'oxyde, on doit noter que la composition chimique des alliages du système NbCo présente certains traits particuliers. Comme l'ont rapporté Shunk (10) et Dwight (11), on note la présence de deux composés intermétalliques soit le NbCo et le $NbCo_2$ ainsi que des phases de Laves. Les alliages étudiés dans ce travail comportaient deux phases (6).

Le spectre électronique Auger (SEA) pour le film anodique du Nb pur pour différents temps de décapage ionique est illustré à la fig. 3. Le changement de l'amplitude crête à crête des signaux du Nb et de l'oxygène indique la présence d'un profil de concentration de ces éléments dans le film. La fig. 4 illustre ce profil en traçant l'amplitude du signal en fonction du temps de décapage ionique. On remar-

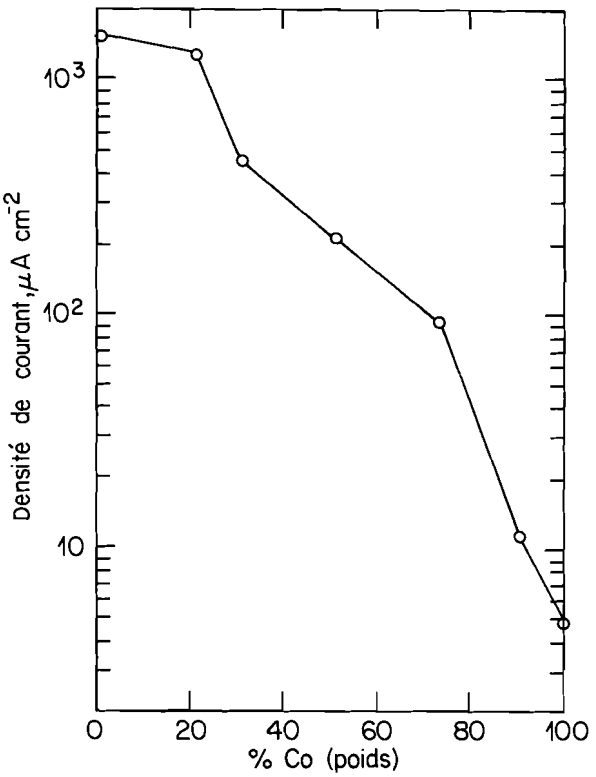

FIG. 2. Densité de courant à 445 mV en fonction de la composition de l'alliage Nb–Co; 25% KOH à 25°C.

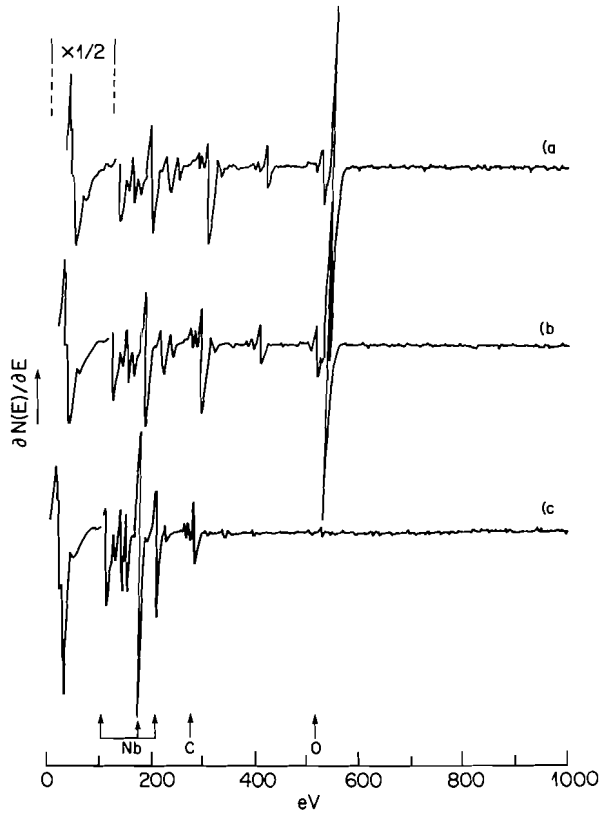

FIG. 3. Spectre électronique Auger du niobium anodisé pour différents temps de décapage ionique de la surface: (a) 20 s; (b) 40 s; (c) 1100 s.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

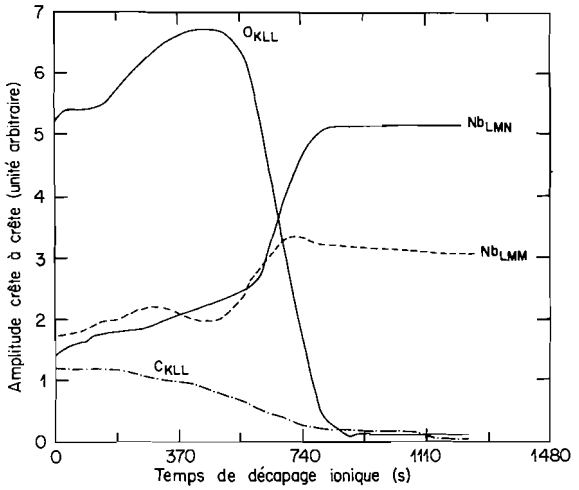

FIG. 4. Profil des amplitudes crête à crête des pics Auger en fonction du temps de décapage ionique pour la surface anodisée du niobium.

que que le signal associé à l'oxygène tombe pratiquement à zéro après environ 825 s; à ce même moment, le signal associé au Nb demeure constant indiquant la fin du film d'oxyde ce qui représente $4{,}13 \times 10^{-2}$ µm d'épaisseur. La présence du carbone est associée au contact de l'échantillon avec l'air ambiant tel que suggère par Lumsden et Staehle (12).

On remarque que la concentration d'oxygène augmente légèrement sous la couche superficielle de l'oxyde mais que cette concentration tombe rapidement à zéro lorsque le métal est atteint. Les deux signaux du Nb (Nb_{LMN} et Nb_{LMM}) ont essentiellement un comportement identique.

A la fig. 5, le SEA pour l'alliage 30% Co polarisé anodiquement est présenté; on remarque que les pics du Nb, de l'oxygène et du Co sont bien séparés l'un de l'autre et les amplitudes crête à crête représentent bien les concentrations respectives de ces éléments. La fig. 6 illustre donc les profils de concentration en fonction du temps de décapage de la surface. Il est à noter que le temps nécessaire pour atteindre le métal est plus long que celui nécessaire pour se débarrasser de l'oxyde de niobium. Cette observation nous donne à penser que l'épaisseur du film d'oxyde est plus importante pour l'alliage 30% Co–Nb que pour le Nb pur et ceci pour une période de polarisation identique. En utilisant la même vitesse de décapage on arrive à une épaisseur de l'ordre de 0,10 µm. On peut remarquer qu'à l'interface métal–oxyde, le film est plus riche en oxygène qu'à la surface; cette augmentation de l'oxygène est couplée à une diminution correspondante du Co et Nb. La concentration du Co dans le film d'oxyde est très voisine de celle dans le coeur de l'alliage mais ce n'est pas le cas

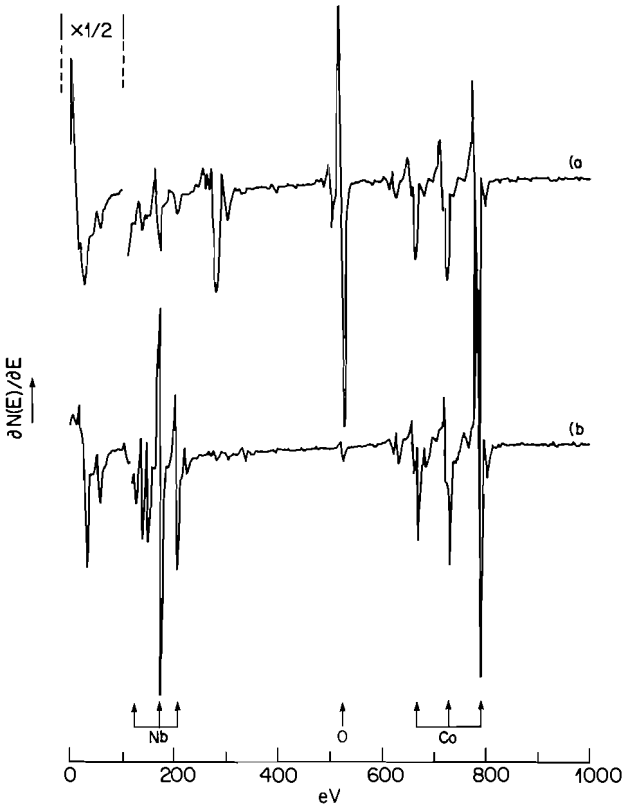

FIG. 5. Spectre électronique Auger de l'alliage Nb–Co (30%) anodisé pour deux temps de décapage ionique de la surface: (a) 20 s; (b) 3500 s.

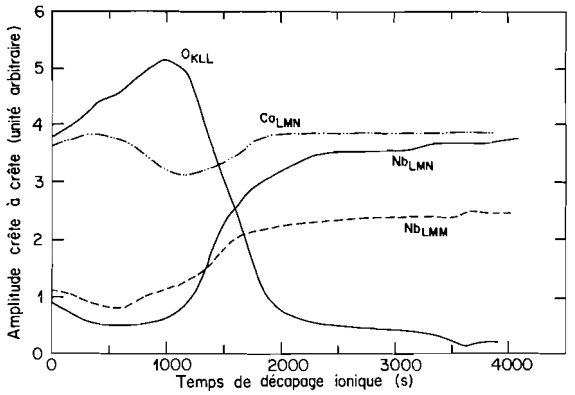

FIG. 6. Profil des amplitudes crête à crête des pics Auger en fonction du temps de décapage ionique de la surface anodisée de l'alliage Nb–Co (30%).

pour le Nb. La polarisation anodique semble donc favoriser une dissolution active du Nb mais une croissance de l'oxyde de Co.

Les résultats du SEA de l'alliage de 90% Co sont illustrés aux figs. 7 et 8. Pour cet alliage, le film d'oxyde est très mince ($\simeq 8 \times 10^{-4}$ µm); en plus, le niobium s'est complètement dissous à la surface et par l'analyse des résultats illustrés à la fig. 8, on

peut conclure que la surface est essentiellement composée d'un film d'oxyde de Co.

Compte tenu de la sensibilité analytique voisine de la transition Nb_{LMN} et du Co_{LMN}, nous pouvons conclure par l'examen de la fig. 6 que le faisceau électronique s'est concentré sur un point où la composition de l'alliage était essentiellement le composé NbCo. Les analyses microscopiques réalisées précédemment (6) ont montré que cet alliage était composé de deux phases: la phase γ (le NbCo) en majeure partie et la phase δ qui est essentiellement une solution solide de Nb. En plus, la fig. 6 illustre une diminution sensible de la concentration du Nb dans le film d'oxyde.

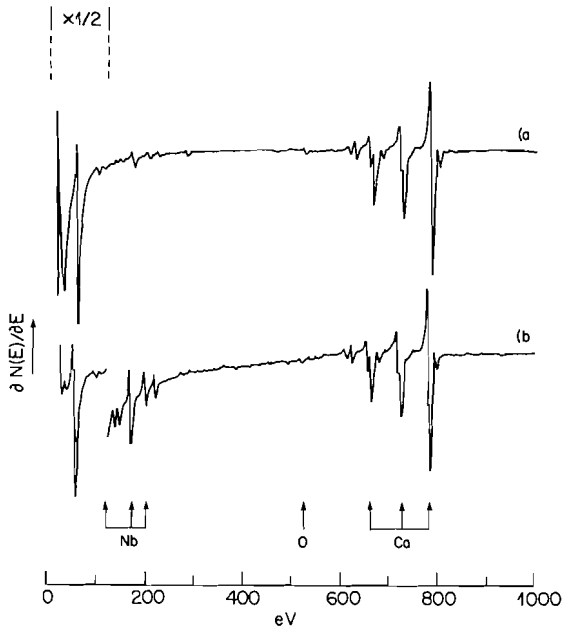

FIG. 7. Spectre électronique Auger de l'alliage Nb–Co (90%) anodisé pour deux temps de décapage ionique de la surface: (a) 40 s; (b) 200 s.

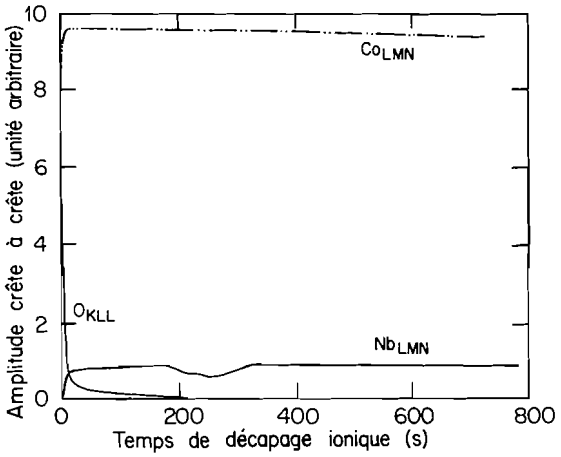

FIG. 8. Profil des amplitudes crête à crête des pics Auger en fonction du temps de décapage ionique de la surface anodisée de l'alliage Nb–Co (90%).

Conclusion

Dans cette étude, le comportement sous polarisation anodique des alliages Nb–Co fut déterminé; cette évaluation électrochimique fut complétée par une étude par spectroscopie électronique Auger des profils de concentration de surface de certains alliages typiques. Les résultats peuvent se regrouper ainsi.

(*a*) Les alliages de Co–Nb ayant une teneur en Co inférieure à 50% sont fortement corrodés par une solution aérée de 25% KOH. En absence d'oxygène tous les alliages sont stables à circuit ouvert.

(*b*) L'alliage du Nb par le Co ne déplace pas le potentiel de passivation mais ce procédé réduit la densité de courant dans l'état de passivation.

(*c*) Sous potentiel anodique, la surface du niobium pur se couvre d'un film d'oxyde bleuâtre qui augmente en épaisseur en fonction du potentiel anodique de polarisation. Même à des tensions anodiques importantes, aucune évolution d'oxygène ne fut observée.

(*d*) La présence de cobalt permet à la réaction du dégagement d'oxygène de se manifester: pour les alliages de 70% Co et plus, la RDO se confond avec celle observée sur le Co pur.

(*e*) Pour les alliages, le niobium se dissout sous polarisation anodique et la concentration de cet élément dans le film d'oxyde est plus faible que dans le coeur de l'alliage. Le cobalt demeure pratiquement stable pour les alliages étudiés (30% et 90%) à la fois au travers le film comme dans l'alliage métallique lui-même.

An ^{129}I Mössbauer study of organotin iodides

C. H. W. JONES AND M. DOMBSKY
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6
Received September 9, 1980

C. H. W. JONES and M. DOMBSKY. Can. J. Chem. **59**, 1585 (1981).

Iodine-129 Mössbauer data for SnI_4, $MeSnI_3$, Me_2SnI_2, Me_3SnI, $Me_3SnI_2^-$, $Me_3SnI.py$, and $Me_2SnI_2.2py$ are reported. The data are compared with available nqr data for the corresponding chlorides and bromides. The Mössbauer data are interpreted as evidence that $MeSnI_3$, Me_2SnI_2, and Me_3SnI are distorted from tetrahedral geometry in the solid state. The applicability of the additive model in interpreting ^{119}Sn quadrupole splittings in these compounds is commented on.

C. H. W. JONES et M. DOMBSKY. Can. J. Chem. **59**, 1585 (1981).

On rapporte des données de Mössbauer relatives à l'iode-129 présent dans les composés suivants: SnI_4, $MeSnI_3$, Me_2SnI_2, Me_3SnI, $Me_3SnI_2^-$, $Me_3SnI.py$ et $Me_2SnI_2.2py$. On a comparé ces données à celles de rqn disponibles pour les chlorures et bromures correspondants. Les données de Mössbauer indiquent qu'à l'état solide les composés $MeSnI_3$, Me_2SnI_2 et Me_3SnI sont déformés par rapport à la géométrie tétraédrique. On discute de l'utilisation du modèle additif dans l'interprétation des dédoublements quadrupolaires du ^{119}Sn dans ces composés.

Introduction

There have been a large number of studies in the past relating to the nature of the bonding in, and the structure of, the organotin halides, $R_{4-n}SnX_n$ (R = alkyl or aryl; X = Cl, Br, or I; n = 1, 2, or 3). In particular, a number of crystal structures have been reported (1–4), while ir (5), ^{119}Sn Mössbauer (see ref. 6 and references therein) and halogen nqr (7–9) spectroscopy have all been used to probe the bonding and structure in the solid state. These compounds have also been studied in solution by proton nmr (10, 11) while electron diffraction techniques have provided information on the molecular geometry in the gas phase (12).

Marks *et al.* (13) have recently studied the ^{129}I Mössbauer spectra of Me_3SnI and $MeSnI_3$ in frozen solutions in methylcyclohexane. They interpreted the ^{119}Sn and ^{129}I Mössbauer data, together with the proton nmr data of the solutions, in terms of the valence shell orbital populations on the tin and iodine. In their interpretation they assumed that the coordination about the tin is close to tetrahedral in both the solid state and in solution. This assumption appears to be at variance with the findings drawn from other studies, where it has generally been concluded that the methyltin halides are distorted from regular tetrahedral geometry in the solid state.

In the present study the ^{129}I Mössbauer spectra of SnI_4, $MeSnI_3$, Me_2SnI_2, Me_3SnI, Ph_3SnI, $Me_3SnI.py$, $[Bu_4N^+][Me_3SnI_2^-]$, and $Me_2SnI_2.2py$ have been measured at 4.2 K. The Mössbauer data are interpreted in the light of the previous ir, nqr and crystal structure studies in terms of the coordination about the tin.

Results

The ^{129}I Mössbauer parameters are reported in Table 1 and sample spectra are given in Fig. 1. The ^{119}Sn Mössbauer spectra of these compounds were also recorded to help in their identification and these results are reported in Table 2.

The ^{129}I parameters obtained in the present work for solid $MeSnI_3$ (Table 1) are in excellent agreement with those reported for the frozen solution experiment in ref. 13, suggesting that the iodine environment is similar in the two cases. The isomer shifts, coupling constants, and asymmetry parameters for Me_3SnI as a solid and in frozen solution do not show as good an agreement, although the values are similar. It may be noted that in the ^{129}I frozen solution spectrum of Me_3SnI reported in ref. 13, the absorption at $-6\,mm\,s^{-1}$ was exceptionally broad and showed evidence of structure, while a pronounced shoulder at $+4\,mm\,s^{-1}$ was clearly not part of the major component of the spectrum. However, the key point is that the iodine atoms again appear to be in similar environments in both the solid and the frozen solution.

The iodine coupling constant for Me_2SnI_2 (Table 1) lies between that of $MeSnI_3$ and Me_3SnI. Bryuchova *et al.* (23) have reported the ^{127}I nqr spectrum of Et_2SnI_2 at 77 K and observed resonances equivalent to $e^2qQ(127) = -971\,MHz$ ($\eta = 0.122$) in comparison with $-1035\,MHz$ ($\eta = 0$) for Me_2SnI_2 found here.

The compound Ph_3SnI yielded a coupling constant e^2qQ (127) of -1020 MHz which is much larger than that of Me_3SnI. A previous ^{127}I nqr study of Ph_3SnI (22) yielded only one resonance which, assuming that this corresponds to the 1/2–3/2 transition, gives a $|e^2qQ\ (127)| = 1028$ MHz.

The X-ray crystal structure of $Me_3SnCl.py$ has shown this compound to be trigonal bipyramidal with the chlorine and pyridine ligands in axial positions (22). The vibrational spectra (4) of $[Bu_4N][Me_3SnI_2]$ and $Me_3SnI.py$ are consistent with the tin being in a similar environment. The ^{119}Sn

quadrupole splittings (Table 2) are also consistent with this assignment. These compounds yielded ^{129}I coupling constants much smaller than that of Me_3SnI. In the compound $Me_2SnI_2.2py$ the tin is octahedrally coordinated and the methyl groups are *trans* and the iodine ligands *cis*. (5) This compound has an ^{129}I coupling constant comparable with that of $[Bu_4N][Me_3SnI_2]$ and $Me_3SnI.py$.

Discussion

As noted above, the present Mössbauer data appear to be in reasonable agreement with the previous ^{129}I solution work and the limited amount of ^{127}I nqr data available. The data of Table 1 clearly show that there is a decrease in the iodine coupling constant, and hence an increase in the Sn—I bond ionicity, in the order $SnI_4 < MeSnI_3 < Me_2SnI_2 < Me_3SnI < MeSnI_2.2py < Me_3SnI.py \sim Me_3SnI_2^-$ while the Sn—I bond in Ph_3SnI is more covalent than that in Me_3SnI.

The present data are compared in Table 3 and Fig. 2 with the previously published ^{35}Cl and ^{81}Br nqr data for the corresponding chlorides and bromides. The data are compared in terms of reduced coupling constants,[1] defined (6) as the experimentally observed coupling constant divided by the appropriate atomic coupling constants (^{35}Cl 109.746 MHz, ^{81}Br 643.032 MHz, ^{127}I 2292.712 MHz, ^{129}I 1607.0 MHz). It can be seen from Fig. 2 that the trends in halogen reduced coupling constants for

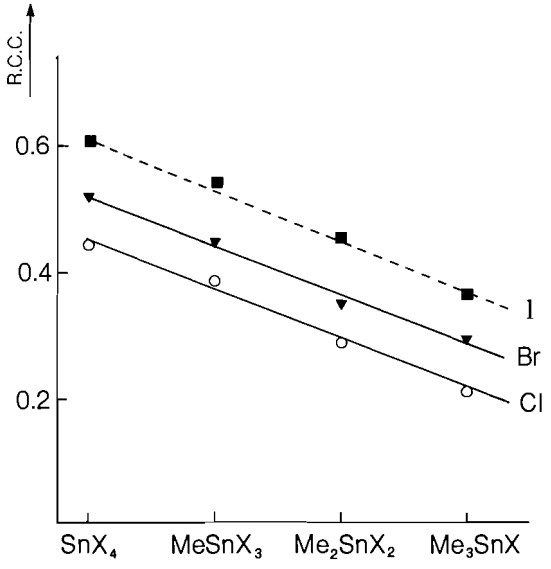

FIG. 2. The halogen reduced coupling constants of the organotin halides.

[1]The reduced coupling constant is also called the *p*-orbital imbalance, U_p.

the organotin iodides parallel those for the chlorides and bromides throughout the series $Me_{4-n}SnX_n$ (n = 1 to 3). It may be noted in Table 3 that there are discrepancies in the literature values for the ^{35}Cl and ^{81}Br coupling constants for Me_3SnCl and Me_3SnBr. From the trends of Fig. 2 it would appear that the values of 0.208 and 0.291 are the more consistent for the reduced coupling constants for Me_3SnCl and Me_3SnBr, respectively.

From Table 3 it is also apparent that the small reduced coupling constants for $Me_3SnI.py$ and $Me_2SnI_2.2py$ are reasonably consistent with the small ^{81}Br values observed for the corresponding bromine compounds. Similarly, the fact that Ph_3SnI yields a significantly larger coupling constant than Me_3SnI is consistent with the observation that for the phenyltin chlorides $Ph_{4-n}SnCl_n$, the ^{35}Cl coupling constants are greater, for any given value of n, than for the corresponding methyl compounds.

While ^{35}Cl and ^{81}Br nqr measurements on polycrystalline samples yield only the magnitude of the coupling constant, ^{129}I Mössbauer spectroscopy also allows the determination of the sign of the coupling constant, the magnitude of the asymmetry parameter, and the sign and magnitude of the isomer shift. For SnI_4, $MeSnI_3$, Me_2SnI_2, and Me_3SnI e^2qQ is negative in sign and the asymmetry parameter was zero except for Me_3SnI where η = 0.18.

The Mössbauer isomer shift can be used to crudely estimate the number of p-electrons, h_p, removed from the iodine in bonding, assuming that the s-electrons are not bonding; i.e., $h_s = 0$. This can be done employing the empirical equation (13)

$$\delta = 1.5\,h_p - 0.54$$

Moreover, the coupling constant yields the p-orbital imbalance in the usual way (13):

$$U_p = e^2qQ/e^2q_0Q$$

For a nonbridging Sn—I bond, h_p should just be equal to U_p. The values of h_p and U_p are given in Table 4. There is reasonable agreement between h_p and U_p for SnI_4, $MeSnI_3$, and Me_2SnI_2 assuming h_s = 0. (In ref. 13 an error was made in calculating h_s for $MeSnI_3$ and rather than a value of 0.07 a value of 0.004 should have been obtained.) However, for Me_3SnI where $\eta \neq 0$, h_p and U_p, as calculated on this overly simplistic model, are not in good agreement.

The significance of these observations is that for $MeSnI_3$ and Me_2SnI_2 the iodine Mössbauer data suggest that the Sn—I bond is axially symmetrical, that the bonding to iodine occurs through an iodine 5p orbital, and that there is no evidence for significant intermolecular interactions in either compound. For Me_3SnI the presence of a small asymmetry parameter, together with the fact that $h_p < U_p$, may be interpreted as evidence for an intermolecular interaction in which the Sn—I...Sn linkage is not linear, although such an interaction would not appear to be very strong. The participation of a small amount of iodine 5s character in bonding could lead to a nonlinear bridging interaction and this would also result in the apparently low value of h_p.

TABLE 4. The p-hole and p-orbital imbalances calculated from δ and e^2qQ, respectively

	h_p	U_p
SnI_4	0.61	0.60
$MeSnI_3$	0.54	0.54
Me_2SnI_2	0.38	0.45
Me_3SnI	0.22	0.36 (η = 0.18)

The X-ray crystal structures of Me_2SnCl_2, Me_3SnCl, Ph_2SnCl_2, Ph_3SnCl, and Et_2SnX_2 (X = Cl, Br, or I) have all been reported (Table 5) and the dihalides all exhibit a significant distortion from tetrahedral geometry, the environment about the tin being distorted octahedral with two distant bridging halogen contacts. The weight of the evidence suggests (24) that in the dichlorides and dibromides these distant contacts represent weak intermolecular bonds while in Et_2SnI_2, these contacts are greater than the sum of the van der Waal's radii. The compounds Me_3SnCl and Ph_3SnCl also show distortion from regular tetrahedral geometry, although the distortion is much greater in the former than the latter. In Me_3SnCl the Me_3Sn group approaches a planar geometry (4) and a relatively short Sn---Cl bridging contact completes a ψ-tbp environment about the tin.

Evidence from ir spectra also suggests that in the trimethyltin halides the Me_3Sn-moiety is nearly planar, consistent with a ψ-tbp environment about the tin with the halogens bridging. The Sn—X stretching frequencies also give some evidence for association in the Me_2SnX_2 compounds.

The marked similarity in the behaviour of the halogen reduced coupling constants illustrated in Fig. 2, together with the structures of Me_2SnCl_2, Et_2SnI_2, and Me_2SnCl_2 noted above, suggest that in the methyltin iodides in the solid state there is increasing distortion from tetrahedral geometry in the series $SnI_4 < MeSnI_3 < Me_2SnI_2 < Me_3SnI$. As the number of methyl groups attached to the tin increases the Sn—I bond becomes more ionic and the iodine coupling constant decreases.

The compounds $[Bu_4N][Me_3SnI_2]$ and $Me_3SnI.py$

are important in this context since they provide the coupling constant for iodine bound to tin in a tbp environment, the methyl groups occupying equatorial positions. It can be seen that in Me_3SnI the iodine coupling constant is intermediate between that of SnI_4, on the one hand, and $Me_3SnI_2^-$ or Me_3SnI.py on the other. Again, this would be consistent with distortion from tetrahedral towards tbp geometry in Me_3SnI.

There is no evidence for intermolecular bridging in the ^{129}I Mössbauer data for $MeSnI_3$ or Me_2SnI_2 and this is consistent with the known structure of Et_2SnI_2 referred to above. For Me_3SnI the ^{129}I data is consistent with the presence of a nonlinear Sn—I---Sn intermolecular interaction analogous to that observed in Me_3SnCl.

It has been recognized for some considerable time that the ^{119}Sn quadrupole splittings in the organotin halides do not accord to a simple point charge or additive model (see ref. 25 and references therein), and this was itself interpreted as evidence for divergence from tetrahedral geometry in these compounds. It is interesting to note that the halogen nqr and ^{129}I Mössbauer data are consistent with the ^{119}Sn quadrupole splittings. Thus, in Table 6 the ^{119}Sn quadrupole splittings for some methyl and phenyl chlorides and iodides are compared along with the reduced halogen coupling constants. For $MeSnCl_3$ and $PhSnCl_3$ the ^{119}Sn Δ values are very similar, as expected on a point-charge model, and the Sn—Cl bonds are very similar as reflected in the halogen coupling constants. On the other hand, Me_3SnCl and Ph_3SnCl yield very different ^{119}Sn Δ values. For these compounds the Sn—Cl bonds are significantly different as reflected in the chlorine coupling constants and in the crystal structures of these compounds. Thus the Sn—Cl bond length in Ph_3SnCl is 2.316 Å and that in Me_3SnCl 2.434 Å. Similarly, for Me_3SnI and Ph_3SnI the ^{119}Sn quadrupole splittings are significantly different and the iodine coupling constants point to a considerable difference in the Sn—I bonds.

Thus for both the chlorides and the iodides the methyl compounds appear to show a greater divergence from tetrahedral geometry as the number of methyl groups on the tin increases than is the case for the phenyl compounds. This is reflected both in the ^{119}Sn quadrupole splittings and in the halogen coupling constants. The phenyl group would appear to be more electronegative than the methyl group in these compounds.

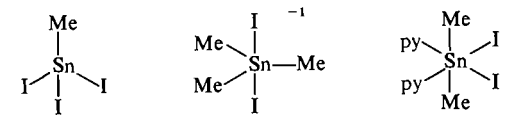
Another point concerns the application of the additive model to the ^{119}Sn quadrupole splittings of molecules of different geometry. It can be shown (26) that the relative [L] values for ligands bonded to tin in complexes of given geometry are given by



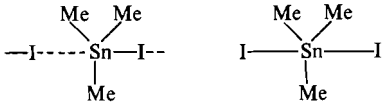
$$-\frac{3}{10}\langle r\rangle_p^{-3}\sigma_{tet.} \qquad -\frac{1}{5}\langle r\rangle_p^{-3}\sigma_{tbp}^{ax.} \qquad -\frac{1}{5}\langle r\rangle_p^{-3}\sigma_{oct.}$$

where the terms 3/10, 1/5, and 1/5 reflect the relative p character of sp^3, pd, and sp^3d^2 hybrids on the tin atom, respectively, and the σ terms are the populations of those tin hybrid orbitals. From the iodine coupling constants of $MeSnI_3$, $Me_3SnI_2^-$, and Me_2SnI_2.py it can be seen that the $\sigma_{tet.} = 0.54$, $\sigma_{tbp}^{ax.} = 0.20$, and $\sigma_{oct.} = 0.22$. Not surprisingly, the σ values are very different for an sp^3 hybrid orbital

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

on tin bonded to iodine and for a *pd* hybrid orbital, since the latter gives rise to a much longer bond in which much of the electron density resides on the iodine. Thus in addition to taking account of the different hybrid orbitals used, the wide variations in σ should also be taken into account when attempting to apply the additive model to tin compounds of different geometry.

Finally, it may also be noted that the iodine coupling constant in Me_3SnI is roughly twice that in $Me_3SnI_2^-$ while the ^{119}Sn quadrupole splittings of the two are very similar. In Me_3SnI the Sn—I bond will have considerable tin *5p* orbital character. In $Me_3SnI_2^-$ the I–Sn–I linkage may be viewed as involving a single tin *5p* orbital in a *3c–2e* bond or alternatively as involving *pd* hybrids on the tin.



In terms of a simple additive model, it would be anticipated that the former would give rise to an iodine coupling constant roughly twice that of the latter and this is indeed observed. Thus the point-charge model appears to retain its validity and Me_3SnI is more appropriately compared with $Me_3SnI_2^-$ than with $MeSnI_3$.

Experimental

The ^{129}I was obtained as $Na^{129}I$ in Na_2SO_3 solution from Oak Ridge National Laboratory and was converted into pure dry solid, $Na^{129}I$ by oxidation to I_2, extraction into CCl_4, reduction back to I^- with thiosulphate, precipitation as PbI_2, treatment with aqueous Na_2CO_3 to produce NaI in solution, and finally, evaporation and drying on heating.

Tin tetraiodide, $MeSn^{129}I_3$, $Me_2Sn^{129}I_2$, and $Ph_3Sn^{129}I$ were prepared by stirring a small excess of $Na^{129}I$ solid with the corresponding chloride compounds, either in dry chloroform or dry ethanol, for several hours. The preparations were carried out under dry nitrogen and the resulting solutions were finally evaporated in a stream of nitrogen in the Teflon holders in which Mössbauer measurements were to be subsequently made.

The compound $Me_3Sn^{129}I$ was made by addition of dry elemental $^{129}I_2$ to Me_6Sn_2 in stoichiometric quantity. This reaction was again carried out under nitrogen in the Teflon holder in which the Mössbauer spectrum was to be recorded.

The pyridine adducts $Me_3Sn^{129}I.py$ and $Me_2Sn^{129}I_2.2py$ were prepared by the addition of an excess of dry pyridine to the parent methyltin iodide and removal of the excess of pyridine in a stream of dry nitrogen. The compound $[Bu_4N]Me_3Sn^{129}I_2$ was prepared by adding $Bu_4N^{127}I$ to $Me_3Sn^{129}I$ in dry methanol and subsequently evaporating off the solvent in a stream of dry nitrogen.

Each of the above preparations was initially carried out using $Na^{127}I$ and $^{127}I_2$ both on a larger scale and also on the scale to be used in the ^{129}I preparations. The compounds were characterized, where appropriate, by nmr in solution, by C, H, and N analysis in the cases of the pyridine adducts and the tetrabutyl ammonium salt, and by ^{119}Sn Mössbauer spectroscopy. The $J(^{119}Sn—C—^1H)$ frequencies in Hz were found to be $MeSnI_3$ 76(73), Me_2SnI_2 64(62.5), Me_3SnI 59(58.5), and $Me_3SnI.py$ 65(64), where the values in brackets are those reported in the literature (10, 11). The spectra of the first three compounds were recorded in $CDCl_3$ and that of the last compound in pyridine, using a Varian 56A/60 spectrometer. The ^{129}I Mössbauer spectra were recorded using a 100 mg $Zn^{129m}Te$ source, prepared by heating zinc and elemental tellurium, labelled with ^{129m}Te, *in vacuo*. The ^{129m}Te was obtained as $^{129m}TeO_3^{2-}$ in aqueous solution from New England Nuclear and this was reduced to elemental tellurium with SO_2 in 6 *M* HCl. The source had an initial activity of 2 mCi. Each absorber contained 10–15 mg cm^{-2} of ^{129}I and was mounted in a Teflon holder with screw cap. Spectra were recorded with the source and absorbers immersed in liquid helium in a Harwell Instruments MHC 200 cryostat. The source was driven in constant acceleration using a Harwell Instruments 200 series transducer, function generator, and attenuator. The spectrometer was routinely calibrated using a $^{57}Co/Pd$ (New England Nuclear) source and iron foil and α-Fe_2O_3 absorbers at room temperature. The ^{129}I parameters in Table 1 for SnI_4, I_2, and NaI also provide a calibration of the spectrometer.

The ^{119}Sn Mössbauer spectra were recorded, using a $Ba^{119m}SnO_3$ source supplied by New England Nuclear, with the source and absorbers at 77 K.

The Mössbauer spectra were computer fitted to independent Lorentzians and in the analysis of the ^{129}I data the approach outlined by Pasternak (27) was followed, although the revised value (28) of $Q^*/Q = 1.238$ for ^{129}I was used.

Stability and reactivity of the benzyl and tropylium cations in the gas phase

D. K. SEN SHARMA AND P. KEBARLE

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 4, 1980

D. K. SEN SHARMA and P. KEBARLE. Can. J. Chem. **59**, 1592 (1981).

A measurement of equilibrium [4]: $t\text{-}C_4H_9^+ + BzCl = t\text{-}C_4H_9Cl + C_7H_7^+$ led to equilibrium constants K_4 which are in fair agreement with earlier work by Abboud *et al.* However, the present temperature dependence predicts a ΔS_4^0 which is sufficiently different from that by Abboud *et al.* to put in question the indentification of $C_7H_7^+$ as Bz^+ on the basis of the measured ΔS_4^0 value. Therefore experiments were made to confirm that $C_7H_7^+$ produced in [4] is Bz^+ and not the tropylium cation. A $C_7H_7^+$ cation was produced by hydride abstraction from 1,3,5-cycloheptatriene. The behaviour of that $C_7H_7^+$ ion was entirely different from $C_7H_7^+$ produced by chloride abstraction from BzCl or hydride abstraction from toluene. While the benzyl derived $C_7H_7^+$ engaged in a number of reactions like hydride abstraction, chloride abstraction, addition, condensation, etc., the $C_7H_7^+$ from the heptatriene remained completely unreactive. On this basis the $C_7H_7^+$ ions were identified as Bz^+ and tropylium$^+$, respectively. Rate constants for several reactions of Bz^+ were determined. It is concluded that a rearrangement from benzyl to tropylium cations and vice versa does not occur at least up to 300°C. The ions also retain their identity if they are produced with considerable internal excitation energy.

D. K. SEN SHARMA et P. KEBARLE. Can. J. Chem. **59**, 1592 (1981).

Une mesure de l'équilibre [4]: $t\text{-}C_4H_9^+ + BzCl = t\text{-}C_4H_9Cl + C_7H_7^+$ a permis de déterminer la valeur de la constante d'équilibre K_4 qui est en bon accord avec les travaux antérieurs de Abboud *et al.* Cependant l'influence de la température suggère que le ΔS^0_4 est assez différent de celui de Abboud et ses collaborateurs pour remettre en question l'identification de $C_7H_7^+$ en tant que Bz^+, en se basant sur la valeur mesurée de ΔS^0_4. En conséquence, on a effectué des expériences afin de confirmer que le $C_7H_7^+$ produit dans l'équilibre [4] est bien le Bz^+ et non le cation tropylium. On a produit un cation $C_7H_7^+$ par enlèvement d'un hydrure du cycloheptatriène-1,3,5. Le comportement de cation $C_7H_7^+$ est complètement différent de celui obtenu par enlèvement de chlorure du BzCl ou par enlèvement d'un hydrure du toluène. Le $C_7H_7^+$ provenant du chlorure de benzyle peut donner des réactions comme l'enlèvement d'un hydrure, l'enlèvement d'un chlorure, l'addition, la condensation, etc., alors que le $C_7H_7^+$ provenant de l'heptatriène est complètement inactif. A partir de ces faits, on a identifié les deux ions $C_7H_7^+$ comme étant respectivement le Bz^+ et le tropylium. On a déterminé les constantes de vitesse de plusieurs réactions du Bz^+. On en conclut qu'il ne se produit pas de transposition entre le cation benzyle et le cation tropylium, du moins jusqu'à 300°C. Les ions retiennent leur identité également s'ils sont produits avec une grande énergie d'excitation interne.

[Traduit par le journal]

Introduction

A number of studies dealing with the benzyl and tropylium cations in the gas phase have been published. Interest in the identity and properties of the two ions was first aroused by Meyerson and co-workers (1) who in 1957 suggested that the $C_7H_7^+$ ions, formed by electron impact from toluene and other alkyl derivatives of benzene, do not have the expected benzyl structure but are tropylium cations. The evidence of Meyerson was largely based on a comparison of the mass spectra of various deuterated ethyl benzenes and toluenes. The formation of tropylium from toluene may proceed by two routes. The excited $C_7H_8^+$ ion of toluene structure may rearrange to $C_7H_8^+$ with the cycloheptatriene structure. This is followed by dissociation to the tropylium cation, (see route [a,b], eq. [1]). In the second alternative the toluene ion dissociates to the benzyl cation which then rearranges to tropylium (see route [c,d] eq. [1]). Meyerson pointed out that his results favored the route [a,b].

[1] $C_7H_8^+$ (toluene$^+$) $\xrightarrow{a}$ $C_7H_8^+$ (*c*-heptatriene)

$\downarrow c$ $\qquad\qquad$ $\downarrow b$

$C_7H_7^+$ (benzyl$^+$) + H $\xrightarrow{d}$ $C_7H_7^+$ (tropylium$^+$) + H

McLafferty and co-workers (2) studied the collisional activation spectra of $C_7H_7^+$ ions produced by electron impact from various parent compounds. Analysis of the rather complex results led these authors to conclude that the $C_7H_7^+$ ions obtained from electron impact on substituted toluenes are composed of as many as five isomers, benzyl, tropylium, and the *o*, *m*, and *p*-tolyl cations. McLafferty and Winkler also concluded that, probably, the tropylium ions obtained from toluene are due to a rearrangement to the C_7 ring structure prior to dissociation, i.e. they are produced by route [a,b], eq. [1].

The reactivity of the $C_7H_7^+$ ions produced by electron impact with toluene was studied in high pressure mass spectrometers by Giardini-Guidoni and Zocchi (3) and by Wexler and Clow (4), who found that most of the ions react with toluene to give two products as shown in eqs. [2] and [3]. A

[2] $C_7H_7^+ + C_6H_5CH_3 = C_{14}H_{15}^+$

[3] $C_7H_7^+ + C_6H_5CH_3 = C_8H_9^+ + C_6H_6$

small fraction of the $C_7H_7^+$ ions were found to be unreactive. More recently Dunbar and co-workers (5) using an ICR spectrometer also observed that the $C_7H_7^+$ ions obtained by electron impact from toluene divide into a larger fraction of reactive ions and a smaller fraction which is unreactive towards toluene. These authors suggested that the unreactive $C_7H_7^+$ ions are tropylium cations while the reactive ions are mostly benzyl. Dunbar also concluded that the tropylium ions are probably made from the cyclic $C_7H_8^+$ ion, i.e. via route [a,b].

In spite of the conclusions by Meyerson and coworkers (1), McLafferty and Winkler (2) and Dunbar and coworkers (5) that tropylium is formed by route [a,b], i.e. not by a rearrangement of the benzyl cation, there has been concern amongst gas phase chemists that the benzyl rearrangement might be occurring. For example, Lossing (6) considered the isomerization [d] as a possible complication in measurements of the ionization potential of the benzyl radical. More recently Abboud *et al.* (7) felt it pertinent to provide evidence for the stable existence of the benzyl cation in the gas phase. The major experimental feature in this work was a measurement of the temperature dependence of the equilibrium [4]

$$[4]\quad C_6H_5CH_2Cl + (CH_3)_3C^+ \underset{r}{\overset{f}{\rightleftharpoons}} C_7H_7^+ + (CH_3)_3CCl$$

observed in an ICR mass spectrometer. The equilibrium constant K_4 was measured at two temperatures, 303 and 408 K. This allowed the determination of ΔH^0_4 and ΔS^0_4. One expects (7) a $\Delta S_4 \approx 0$ for $C_7H_7^+$ being benzyl. On the other hand, the high symmetry of the tropylium cation would lead (7) to a $\Delta S^0_4 \approx -4$ eu. The experimental ΔS^0_4 was -0.5 eu which is evidence that the $C_7H_7^+$ produced by chloride abstraction from benzyl chloride is the benzyl cation and that the benzyl cation does not rearrange to tropylium.

Recently, in this laboratory, we initiated studies of chloride and hydride transfer equilibria involving various carbonium ions. These studies are planned to provide ladders of chloride and hydride affinities and thus result in useful new thermochemical data on carbocations. One series of ions that we were interested in was *o*, *m*, and *p*-substituted benzyl cations. A preliminary report of this work has been presented (8). In connection with this work it was of some importance to convince ourselves that the cations obtained from chloride abstraction from benzyl chlorides were actually benzyl and not tropylium. It was also necessary to obtain a connection of our ladder of free energy changes to some standard ion whose heat of formation is presumed to be well known. Since t-$C_4H_9^+$ is a much used standard, we decided to remeasure the chloride transfer equilibrium [4] and extend the determinations of Abboud *et al.* over a wider temperature range. To our surprise we could not confirm the $\Delta S^0_4 \approx 0$ obtained by Abboud *et al.* (7). In fact the preliminary ΔS^0_4 obtained by us agreed with that expected for $C_7H_7^+$ being tropylium. Since we expected that the $C_7H_7^+$ occurring in [4] is in fact benzyl we saw ourselves challenged to investigate the situation more closely. The present work consists of three parts: (*a*) the measurement of the equilibrium [4] over an extended temperature range and a kinetic study of [4] and the side reactions involved, (*b*) studies of the reactivity of $C_7H_7^+$ produced from chloride and hydride abstraction from benzyl chloride and toluene, and (*c*) studies of the reactivity and the behaviour of $C_7H_7^+$ obtained by hydride abstraction from 1,3,5-cycloheptatriene.

Experimental

The measurements were made with a pulsed electron beam high pressure ion source mass spectrometer which has been described previously (9).

Most of the rate constants quoted in Results and Discussion were obtained by the following technique. Consider the reaction $A^+ + B = C^+ +$ neutrals. A^+ may be an ion present at time $t = 0$ or a reaction product which appears at a later time. Since the neutral reactants are in vast excess over the ions all ionic reactions are pseudo first order. The reaction frequency equals $\nu = k[B]$. Integration of: $d[C^+]/dt = \nu[A^+]$ leads to:

$$[C^+]_t - [C^+]_{t_o} = \nu \int_{t_o}^{t} [A^+]dt$$

Plots of $[C^+]_t$ versus the integral obtained by graphical integration of the concentration–time dependence of A^+ lead to straight lines with slope ν. Since [B] is known k can be evaluated.

Results and Discussion

(*a*) *The Chloride Transfer Equilibrium of Benzyl and* tert-*Butylchloride and Side Reactions*

The chloride transfer equilibrium [4] was measured over the temperature range 300 K–640 K. A van't Hoff plot of the equilibrium constants K_4 is shown in Fig. 1. The results of Abboud *et al.* (7) and a more recent determination by Lias and coworkers (10) at room temperature are also included in Fig. 1. Inspection of Fig. 1 shows that at room temperature there is relatively good agreement between the present determinations of K_4 and those of Abboud *et al.* (7) and Lias and coworkers (10). However, the present results agree less well with Abboud's single measurement at 408 K, where Abboud's K_4 is higher by a factor of 1.6. The van't

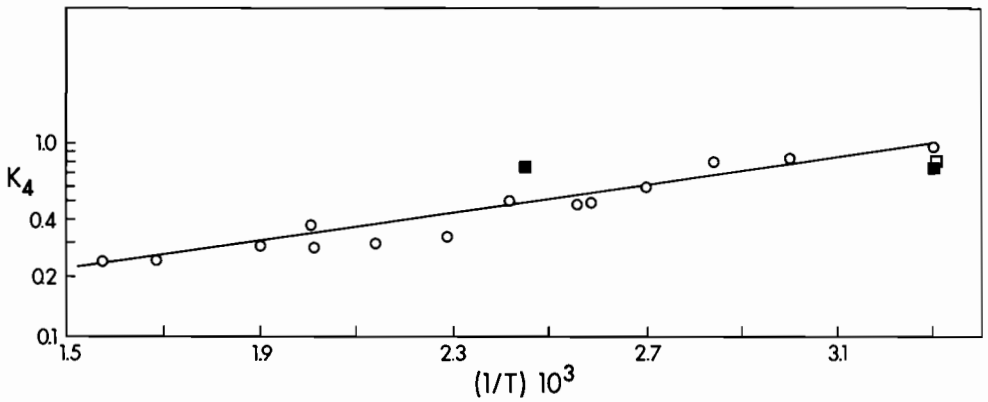

FIG. 1. van't Hoff plot for equilibrium [4]: t-$C_4H_9^+ + BzCl = t$-$C_4H_9Cl + C_7H_7^+$. ○ Present work, ■ Abboud *et al.* (7), □ Jackson *et al.* (10). Although present results are close to those of Abboud *et al.*, the temperature dependence predicted is somewhat different. Present results predict $\Delta S_4 \approx -4$ eu, while Abboud *et al.*'s data lead to $\Delta S_4 = -0.5$ eu. Present results, if correct, invalidate Abboud *et al.*'s entropy argument identifying $C_7H_7^+$ as Bz^+.

Hoff plot based on the present results shown in Fig. 1 leads to $\Delta H^0_4 = -0.8 \pm 0.3$ kcal/mol, $\Delta S^0_4 = -4.1 \pm 0.6$ cal/degree, and $\Delta G^0(300) = 0.0$ kcal/mol $\pm$ 0.3 kcal/mol while Abboud's data based on the two-point determination are $\Delta H^0_4 = 0.03$ kcal/mol, $\Delta S^0_4 = -0.05$ cal/degree, and $\Delta G^0_4(300) = +0.2$ kcal/mol. Thus the enthalpies agree within 0.8 kcal/mol and the entropies within 4 cal/degree. This is not a serious disagreement; however the present data, if correct, invalidate the entropy argument used by Abboud *et al.* (7) to show that the $C_7H_7^+$ ion is the benzyl cation. In fact the present entropy difference fits the predicted entropy change (7) for $C_7H_7^+$ being tropylium. We shall present evidence later showing that the $C_7H_7^+$ ion is in fact benzyl. Accepting this result one has two choices. Either the ΔS^0_4 predicted on the basis of symmetry numbers alone (7) is incorrect or the decrease of K_4 with temperature, observed in the present work (Fig. 1), is not a valid result. In an attempt to resolve this difficulty a detailed examination of the reaction system in which the equilibrium [4] occurred was made.

The ion concentration – time dependence observed in a typical run at room temperature is shown in Fig. 2. Ionization by electron impact and fast ion molecule reactions in pure methane lead to CH_5^+ and $C_2H_5^+$ which are roughly in 1:1 ratio. In the presence of benzyl chloride and *tert*-butyl chloride, these ions produce almost exclusively $C_7H_7^+$ and $C_4H_9^+$. The ethyl cation can produce these ions by chloride abstraction from the parent compounds. CH_5^+ must be protonating the chlorides which then decompose to HCl and the corresponding carbocation, t-$C_4H_9^+$ and $C_7H_7^+$, respectively. Since, for the concentrations used in Fig. 2, all the above reactions are fast, $C_4H_9^+$ and

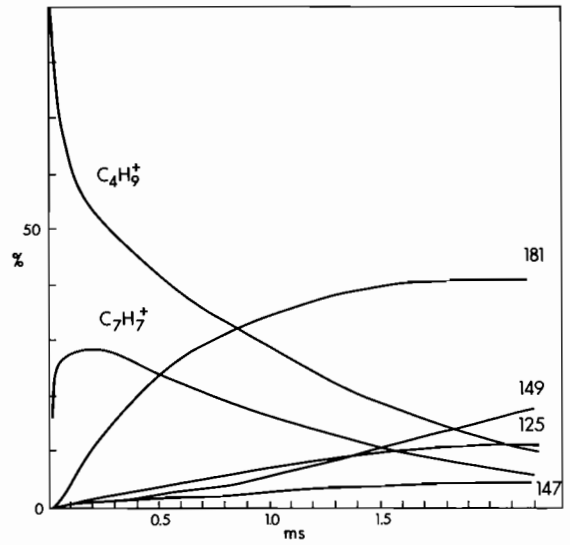

FIG. 2. Concentration time dependence for a run used for measurement of equilibrium [4]. 30°C (4 Torr CH_4, 0.2 mTorr t-BuCl, 0.1 mTorr BzCl). Equilibrium [4] between $C_4H_9^+$ and $C_7H_7^+$ leads to a constant concentration ratio for these ions after some 0.3 ms. Ion $m = 181$ is formed by the condensation reaction [5] involving $C_7H_7^+$ and BzCl, while ion $m = 125$ is formed by hydride abstraction, [7] and [8], from $BzCl^{35}$. The Cl^{37} isotope leads to $m = 127$. The intensity of this ion was added to $m = 125$ shown in the figure.

$C_7H_7^+$ appear as the initial ions. After a short ($\sim$200 μs) kinetic stage, $C_4H_9^+$ and $C_7H_7^+$ reach equilibrium, i.e. their concentration ratio becomes constant. However, the concentrations of both ions decrease with time due to a number of relatively slow reactions. Three ions of molecular mass $m = 181$, 147, and 125 were observed to be major reaction products under a variety of conditions. The production of these ions can be explained by reactions [5]–[8].

[5] $Bz^+ + BzCl =$  $+ HCl$

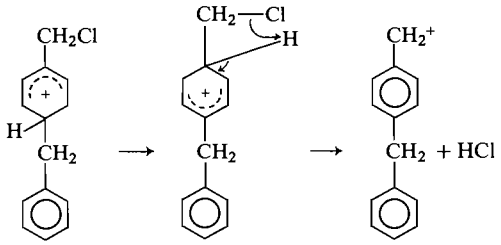
$m = 181$

[6] $t\text{-}C_4H_9^+ + BzCl =$  $+ HCl$

$m = 147$

[7] $Bz^+ + BzCl = BzH +$ 
$m = 125$

[8] $t\text{-}C_4H_9^+ + BzCl = \text{iso-}C_4H_{10} +$ 
Reactions [5] and [6] are analogous. One might assume that this type of reaction proceeds in two steps, alkylation of the benzene ring by the electrophilic attack of the carbocation, as shown in structure **1**, and migration of the proton followed by loss of HCl as shown in **2**. The $C_7H_7^+$ ion participating in [5]and [7] is shown in the equations as Bz^+. It will be shown later that tropylium$^+$ does not add to BzCl and does not hydride abstract from benzyl chloride. Reactions [7] and [8] are hydride abstractions. The new benzyl cation created is chlorosubstituted in the α position. Electron pair donation from the chlorine atom makes this ion more stable than benzyl, therefore reactions [7] and [8] are exothermic (8).



1 **2** **3**

Results from a run at the considerably higher temperature 218°C are shown in Fig. 3. Again, after a short time (~250 μs) the ratio $C_4H_9^+/C_7H_7^+$ becomes stationary. Evidently reaction [5], which was the major side reaction at 30°C, is very much slower at higher temperature. The ion $m = 181$ is now only a minor product. The corresponding *tert*-butyl reaction [6], leading to $m = 147$, and the hydride transfer reactions [7] and [8], leading to $m = 125$, are still observed. The major long reaction time product is an ion of mass 107. This mass corresponds to protonated xylene. The origin of this product is unclear.

Taking into consideration that the $C_4H_9^+$ and $C_7H_7^+$ do not only participate in the chloride transfer equilibrium [4] but also engage in side reactions like [5]–[7] one may ask whether these side reactions could be affecting the equilibrium measurements. For the evaluation of the equilibrium constant K_4 in Fig. 1 we have used the stationary ratio $[C_7H_7^+]/[C_4H_9^+]$ observed at longer reaction times. However, that ratio will be the equilibrium ratio only if the rates of the side reactions are relatively slow compared with the equilibrium rates.

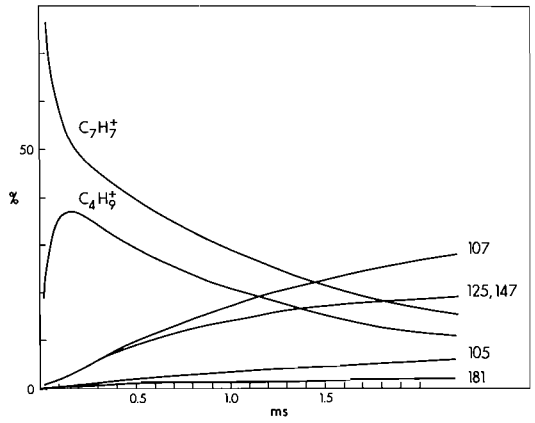


FIG. 3. Equilibrium [4] and side reactions: 218°C, (4 Torr CH_4 2.5 mTorr BzCl, 0.5 mTorr *t*-BuCl).

In order to examine the effect of the side reactions on the equilibrium, we fitted the concentrations observed in Fig. 3 by computer calculated concentrations for a reaction system consisting of the forward [4_f] and reverse [4_r] of the equilibrium

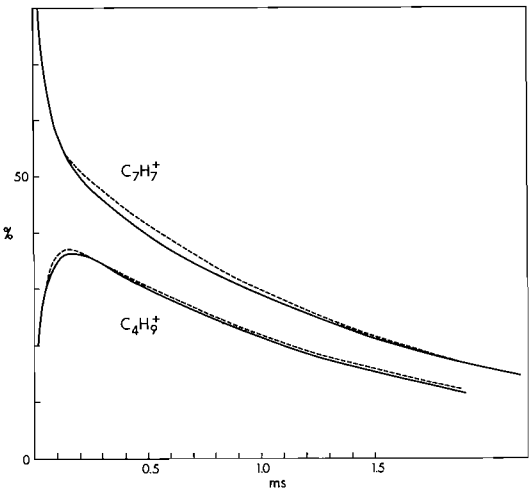

FIG. 4. Computer fit of equilibrium [4].—Experimental results from Fig. 3. ------ Computer fit of reaction system. Computer fit provides values for forward and reverse rate constants k_{4f} and k_{4r}. From these equilibrium constant $K_4 = k_{4f}/k_{4r}$ is evaluated. This result is essentially identical to K_4 obtained from stationary ratio of $C_7H_7^+$ and $C_4H_9^+$ at long reaction times. This means that side reactions are too slow to affect equilibrium measurement.

TABLE 1. Summary of rate and equilibrium constants determinations[a]

	Reaction	Constants
[4]	$BzCl + t\text{-}C_4H_9^+ = Bz^+ + t\text{-}C_4H_9Cl$	$\Delta G^0(300) = 0.0$ kcal/mol (0.2)[b] $\Delta H^0 = -0.8 \pm 0.3$ kcal/mol (0.03)[b] $\Delta S^0_4 = -4.1 \pm 0.6$ cal/deg (−0.5)[b] k_4(forward) = 1.4×10^{-9}(303 K); 2.8×10^{-10} (491 K) k_4(reverse) = 1.3×10^{-9}(303 K); 9.7×10^{-10} (451 K)

[21]	$Bz^+ +$ 1,3,5-*c*-heptatriene $=$ tropylium$^+ + C_6H_5CH_3$	$\Delta H_{22} \approx -40.9$ kcal/mol[g]

[a]Units for all second order rate constants are cm^3 molecules^{-1} s^{-1}.
[b]Abboud *et al.* (7).
[c]Thermal decomposition [14] was assumed to be first order. However, reaction requires thermal activation and might be second order. To obtain second order rate constant divide by methane concentration, 9×10^{16} (molecules·cm^{-3}).
[d]Reaction assumed to be second order. However, since association occurs, reaction may be third order. To obtain third order rate constant divide by methane concentration, 9×10^{16} (molecules·cm^{-3}).
[e]From ΔH_4 and $\Delta H_f(t\text{-BuCl}) = -43.7$ kcal/mol, $\Delta H_f(BzCl) = 4.5$ kcal/mol.
[f]From lower limit of equilibrium constant K_{21}, present work.
[g]From estimate of Jackson *et al.* (10) $\Delta H_f(Bz^+) - \Delta H_f(\text{tropylium}^+) = 9$ kcal/mol.

and a fictitious reaction [9]. Since the origin of the

[9] $Bz^+ + BzCl$ or $BuCl \rightarrow$ Products (m = 107, 125, 147 etc.)

long reaction times products m = 107, 125, 147, etc. could not be assigned unambiguously to Bz^+ or t-but$^+$, we assume in reaction [9] that they are all due to Bz^+. The computer fit of the concentrations is shown in Fig. 4. From the rate constants k_{4f} and k_{4r} obtained from the computer fit one evaluates a $K_4 = 0.29$. The K_4 obtained by taking the constant ratio $[C_7H_7^+]/[C_4H_9^+]$ observed at long reaction times is $K_4 = 0.27$. The two equilibrium constants are essentially identical. Reaction [9] induces a (maximum) lowering of the $[C_7H_7^+]/[C_4H_9^+]$ stationary ratio at long reaction times. The fact that the equilibrium constants K_4 are nearly identical means that the side reactions are too slow to affect the equilibrium concentrations. The rate constants k_{4f} and k_{4r} obtained from the computer fit are given in Table 1. A similar treatment of the low temperature results in Fig. 2 showed that, there again, the ratio of $[C_7H_7^+]/[C_4H_9^+]$ read off from the figure at long reaction times leads to a K_4 which is nearly identical to a K_4 calculated from k_{4f}/k_{4r}. From the above considerations we conclude that the side reactions cannot be affecting the equilibrium measurements shown in the van't Hoff plot Fig. 1.

Thermal decomposition of the BzCl in the ion source could be a source of error. Such decomposition will lower the actual concentration of BzCl present at higher temperatures and lead to an apparent decrease of K_4. It is not easy to detect directly the occurrence of thermal decomposition with the apparatus used; however thermal decomposition is unlikely for the following reasons. Assuming that K_4 is independent of temperature, the van't Hoff plot in Fig. 1 becomes equivalent to an Arrhenius plot for the thermal decomposition. The resulting activation energy is only ~1 kcal/mol, a value much too small even for a surface catalyzed thermal decomposition of benzyl chloride on the metal surface of the ion source.

Thermal decomposition was also shown not to occur by the following experiment. The flow rate of gas through the ion source was slowed down at constant ion source pressure. Decrease of the flow rate increases the residence time of benzyl chloride in the ion source. In the presence of thermal decomposition this would lead to a decrease of the benzyl chloride concentration and an apparent decrease of K_4. Such a decrease was not observed.

We come to the conclusion that our result, $\Delta S^0_4 = -4$ cal/mol may be the true value. It may also be an erroneous result due to causes that we don't understand at present.

(b) Reactions of the Benzyl Cation with Benzyl Chlorides and Toluene

Reactions [5] and [7] involving $C_7H_7^+$ produced by chloride abstraction from benzyl chloride were considered in section (a). A more extensive study of these reactions was undertaken in runs where only BzCl and the major gas methane were present. The results from a run at the intermediate temperature of 73°C are shown in Fig. 5. The condensation product $m = 181$ formed by reaction [5] is now the major product. The next most abundant ion is $C_6H_5CHCl^+$ $m = 125$, formed by the hydride abstraction [8]. The hydrocarbon ions $C_8H_9^+$ $m = 105$, $C_8H_{11}^+$ $m = 107$, $C_{13}H_{12}^+$ $m = 155$, and $C_{15}H_{17}^+$ $m = 197$ were observed in this and other runs at low and intermediate temperatures. Their origin is not understood.

A run at the considerably higher temperature 250°C is shown in Fig. 6.

The $[C_7H_7^+]$ decrease, observed at this temperature, is slower, even though the benzyl chloride reactant is present at 30 times higher concentration. This means that the rate of the overall reaction [10] decreases greatly with temperature.

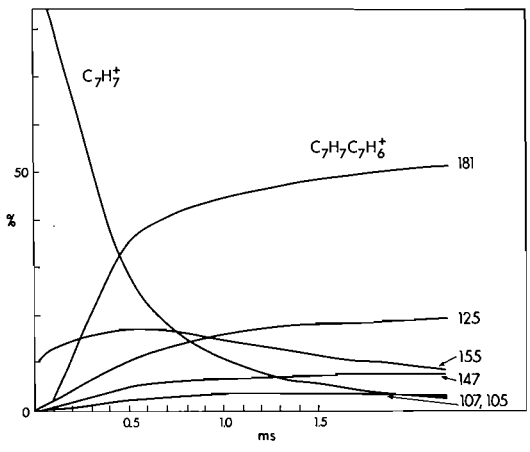

FIG. 5. Reactions of Bz^+ ($C_7H_7^+$) with BzCl: 73°C, (4 Torr CH_4, 0.5 mTorr BzCl). The two main reactions are the condensation [5] leading to $m = 181$ and the hydride abstraction [7] leading to $m = 125$, $C_6H_5CHCl^+$.

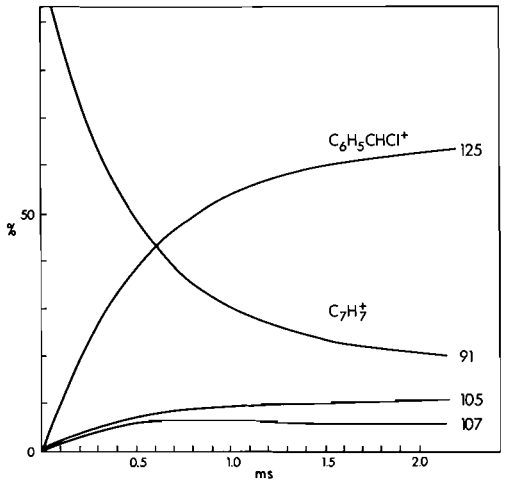

FIG. 6. Reactions of Bz^+ with BzCl at higher temperature: 250°C (4 Torr CH_4, 15 mTorr BzCl). Condensation [5] leading to $m = 181$ is very slow at this temperature, main reaction now is hydride abstraction [7] leading to $m = 125$.

[10] $Bz^+ + BzCl =$ products (other than $BzCl + Bz^+$)

The major product now is $C_6H_5CHCl^+$, $m = 125$, produced by the hydride abstraction [7]. The condensation product **3**, $m = 181$ from reaction [5] was barely visible at this temperature. A large decrease of the rate of [5] with temperature was observed also in the preceding section, Figs. 2 and 3.

The temperature dependence of the rate constants k_7 and k_{10} was determined in a series of runs, like those in Figs. 5 and 6, made in the temperature range 73 to 250°C. These results are shown in Fig. 7. The hydride abstraction [7] has a negative temperature dependence, $k_7 = 3.2 \times 10^{-11}$ at 73°C decreases to 3×10^{-12} (cm^3 $molecules^{-1}$ s^{-1}) at 250°C. Salomon and co-workers (11–13) have observed negative temperature dependence for several hydride transfer reactions involving alkyl cations. The rate constant k_{10} has a much larger negative temperature dependence than k_7 (see Fig. 7). This reflects the very large negative temperature dependence of the condensation [5]. At low temperatures $k_{10} \approx k_5$, while at high temperatures $k_{10} \approx k_7$. The very large negative temperature dependence for the condensation [5] is expected. Reactions involving a complex rearrangement of the reaction intermediate (see structures **1**, **2**, **3**) require a long lived intermediate (a tight reaction complex). At high temperature the lifetime of the complex is shorter and simpler reactions like back dissociation to $Bz^+ + BzCl$ and hydride transfer [7] will dominate.

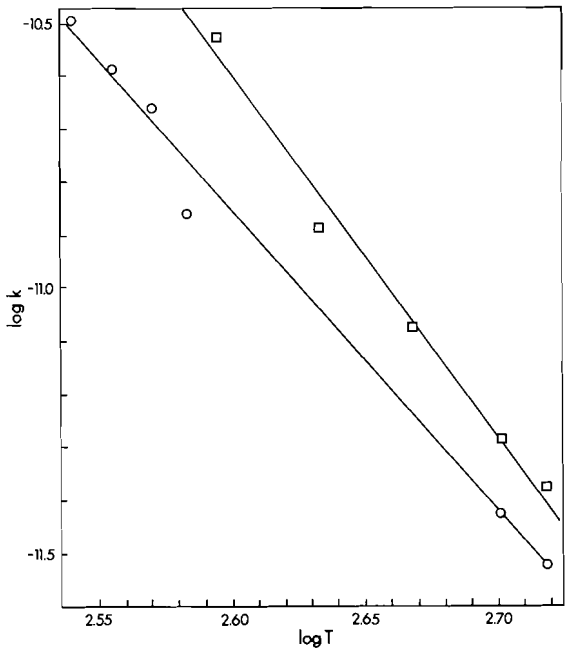

FIG. 7. Plots of log k versus log T for rate constants of reactions [7] and [10]; ○ k_7, □ k_{10}.

Meot-Ner *et al.* [12, 13] found that hydride abstraction can increase up to the Langevin collision rate as the temperature is lowered. Evidently this cannot be the case for the systems studied here, where symmetric chloride transfer and the condensation [5] are fast reactions that dominate over the hydride transfer [7] at low temperature.

A number of chloride transfer equilibria involving $C_7H_7^+$ produced by chloride abstraction from BzCl were observed and measured (X = *o*, *m*, *p*-F, o, *m*, *p*-Cl, *o*, *m*, *p*-Me). The thermodynamic data obtained from these measurements will be described elsewhere (8). The point of interest in connection with the present discussion is that ions produced by chloride abstraction from substituted benzyl chlorides like *p*-Me, which led to more stable cations, were able to shift the equilibrium [11] completely to the right i.e. to the almost complete disappearance of the $C_7H_7^+$ ion. In contrast to this, as will be shown in the next section, $C_7H_7^+$ produced by hydride abstraction from 1,3,5-cycloheptatriene did not abstract chloride from any of the substituted benzyl chlorides, i.e. had a lower chloride affinity than any of the substituted benzyl ions.

[11] $C_6H_5CH_2^+ + XC_6H_4CH_2Cl = C_6H_5CH_2Cl + XC_6H_4CH_2^+$

Reactions of the benzyl cation with toluene observed at two temperatures are shown in Figs. 8 and 9. The reaction mixture of 4 Torr CH_4 and 10 mTorr isobutane produces, after a few micro-

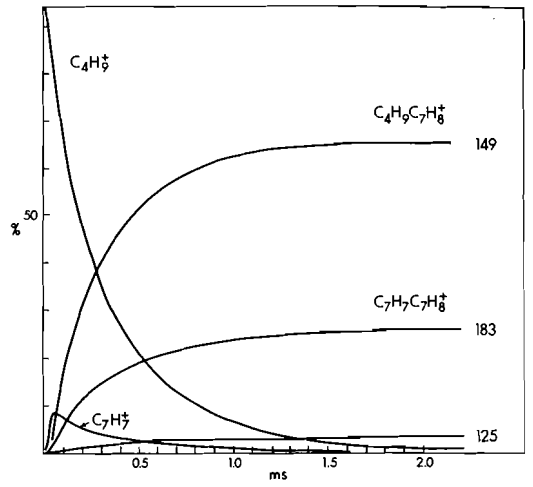

FIG. 8. Reactions of the benzyl cation with toluene. 31°C, (4 Torr CH_4, 10 mTorr isobutane, 0.1 mTorr BzCl, 0.1 mTorr toluene). $Bz^+(C_7H_7^+)$, produced via chloride abstraction by $C_4H_9^+$ from BzCl, forms adduct m = 183 with toluene. Adduct is thermally stable at this temperature.

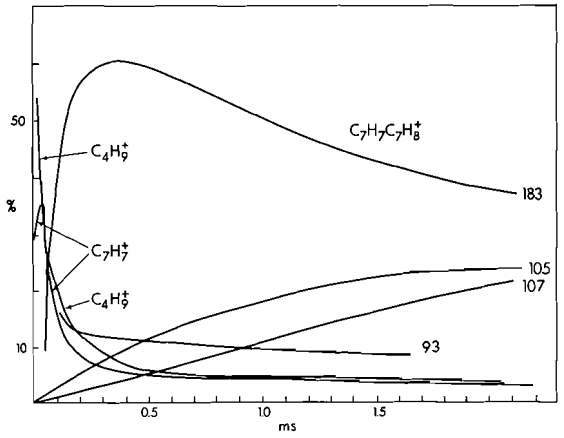

FIG. 9. Reactions of the benzyl cation with toluene. 168°C (4 Torr CH_4, 10 mTorr isobutane, 1 mTorr BzCl, 1 mTorr toluene). The adduct formed from Bz^+ and toluene, m = 183, is thermally unstable at this temperature and decomposes to m = 105, $CH_3C_6H_4CH_2^+$.

seconds, $C_4H_9^+$ as the only ion. In the presence of small amounts of toluene and benzyl chloride, (each at 0.1 mTorr, see Fig. 8), $C_4H_9^+$ produces $C_7H_7^+$. Most of the $C_7H_7^+$ is due to the fast chloride abstraction from BzCl; a smaller amount should result from the slow hydride abstraction from toluene. A side reaction is the addition of $C_4H_9^+$ to toluene, i.e. reaction [12]. The addition of Bz^+ to

[12] $C_4H_9^+ + \text{toluene} =$  (m = 149)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

[13] Bz^+ + toluene =  (m = 183)

[14] (m = 183) (m = 105)

toluene is also observed. The rate constant for the addition reaction k_{13} obtained from data in Fig. 8 is given in Table 1.

The concentration changes in Fig. 9 show what happens at higher temperature. Since all reactions are slower, 10 times higher concentrations of toluene and BzCl were used. The higher yield of the addition product of Bz^+ to toluene (m = 183) can be explained by the virtual absence of the addition product of Bu^+ to toluene (m = 149). The Bu^+ addition product must be unstable at this temperature, i.e. it back-dissociates to Bu^+ and toluene. Thus, at this higher temperature more Bu^+ is available to produce more Bz^+ by [1]. It is interesting to note that at the higher temperature, the adduct of Bz^+ and toluene (m = 183) also dissociates, but slowly, to give an ion m = 105, (see Fig. 9). The mechanism for this reaction, [14], was suggested by Dunbar and co-workers (5). Reactions [13] and [14] are the same as [2] and [3] observed by earlier workers (3–5, 10). Dunbar and co-workers observed, with their ICR mass spectrometer, only the ion m = 105 and not the adduct precursor m = 183. At the very low total pressures used in the ICR instrument ($p \approx 10^{-5}$ Torr) collisional stabilization of the excited adduct m = 183 is slow, therefore, even at room temperature, the adduct undergoes back dissociation or dissociation to the xylyl cation, m = 105.

From several runs like those in Figs. 8 and 9, performed in the temperature range 30–180°C, the temperature dependence of k_{14} could be determined. In the evaluation of k_{14} it was assumed that the xylyl cation m = 105 reacts further to give m = 107. This reaction is indicated in Fig. 9 (and more clearly in other runs which are not shown) by the different shapes of the concentration curves of m = 105 and 107 at short and long reaction times. An Arrhenius plot of k_{14} gave a good straight line which defined k_{14} as shown in eq. [15].

[15] $k_{14} = A \exp -E_{14}/RT$

E_{14} = 32.5 kcal/mol, $A_{14} = 5.9 \times 10^{18}$ s^{-1}

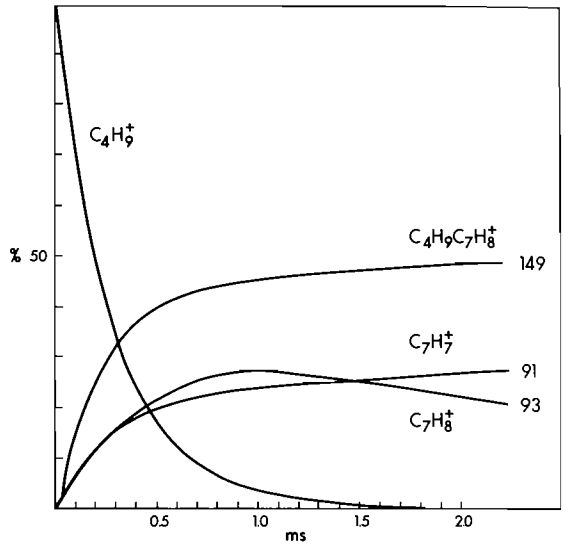

FIG. 10. Production and reactivity of the tropylium cation. 179°C (4 Torr isobutane, 0.4 mTorr 1,3,5-cycloheptatriene) $C_7H_7^+$ ion produced via hydride abstraction by t-$C_4H_9^+$ from the heptatriene, cannot be Bz^+ since Bz^+ cannot exist in 4 Torr isobutane. The $C_7H_7^+$ present has a very low hydride affinity and can be only the tropylium cation.

We have assumed k_{14} is first order. We worked at constant total pressure of 4 Torr. Probably [14] is second order due to third body requirement for activation at low pressures.

(c) Reactions of the Tropylium Cation

Tropylium was produced from 1,3,5-cycloheptatriene. Concentration changes with time of one such experiment are shown in Fig. 10. The final ion in pure isobutane is t-Bu^+. In the presence of small quantities of the heptatriene, t-Bu^+ engages in three reactions: addition, protonation, and hydride abstraction. Reactions [16] and [17] are alkylation

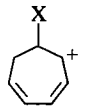
[16] t-$C_4H_9^+$(57) + c-heptatriene (92) = $C_4H_9 \cdot C_7H_8^+$(149)

[17] t-$C_4H_9^+$(57) + c-heptatriene (92) = $C_7H_9^+$(93) + iso-C_4H_8

[18] t-$C_4H_9^+$(57) + c-heptatriene (92) = $C_7H_7^+$(91) + iso-C_4H_{10}

[19] $C_7H_9^+$ + c-heptatriene = $C_7H_7^+$(91) + C_7H_{10}

and protonation at a double bond of the heptatriene. The resulting structure is probably **4**, where X



4

is t-Bu or H respectively. The rate constant k_{16} was measured in the temperature range 423–473 K. It was found to have a small negative temperature dependence, see Table 1. The rate constant for the protonation and hydride abstraction reactions [17]

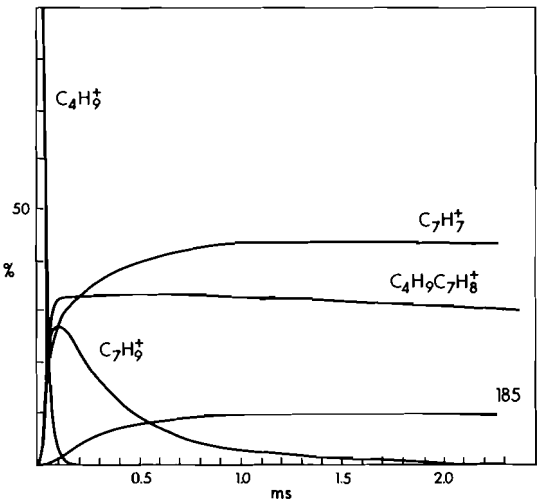


FIG. 11. Production and reactivity of the tropylium cation, 179°C (4 Torr isobutane, 5 mTorr 1,3,5-cycloheptatriene). The higher concentration of heptatriene used in this run makes reaction [19] more clearly visible. Protonated cycloheptatriene, $m = 93$, hydride abstracts from cycloheptatriene to yield tropylium $m = 91$. Almost 100% tropylium can be obtained with same concentrations of neutrals at higher reaction temperatures.

and [18] were found to be very similar, see Fig. 10. At 179°C, $k_{17} \approx k_{18} = 10^{-10}$ cm^3 molecules^{-1} s^{-1}. The rate for hydride transfer reactions is generally lower than the Langevin collision rate. On the other hand, protonation, when exothermic, generally proceeds at near collision rate. The relatively low value of the protonation rate constant k_{17} suggests that this reaction is slightly endothermic, i.e. PA(*c*-heptatriene) < PA(isobutene). 1,3-Pentadiene has a proton affinity which is some 5 kcal/mol higher than that of isobutene (14). One would expect the proton affinity of the straight chain 1,3,5-heptatriene to be even higher. However, 1,3,5-cycloheptatriene is a highly strained molecule. Molecular models show that protonation to structure **4** does not cause significant removal of strain. The ion remains twisted and π conjugation is highly hindered. This indicates a low proton affinity and makes PA(*c*, 1,3,5-cycloheptatriene) < PA(isobutene), rather likely.

The protonated *c*-heptatriene reacts with *c*-heptatriene to give more $C_7H_7^+$ (tropylium), see eq. [19]. This reaction is clearly indicated in Fig. 11, which gives results for a run at the same temperature as Fig. 10 but at 20 times higher concentration of heptatriene. The hydride abstraction [19] is considerably slower than the hydride abstraction by *t*-Bu$^+$ [18]. Thus, at 179°C, $k_{18} \approx 10^{-10}$ cm^3 molecules^{-1} s^{-1}, while $k_{19} \approx 2.5 \times 10^{-11}$ cm^3 molecules^{-1} s^{-1}. The operation of reactions [18] and [19] results in high yields of $C_7H_7^+$ (tropylium) as is evident from Fig. 11. Even higher yields are obtained at higher temperatures because of the negative temperature dependence of the addition reaction [16] and an observed thermal decomposition of the addition product $C_4H_9 \cdot C_7H_8^+$.

The fact that $C_7H_7^+$ produced from *c*-heptatriene can exist in pure isobutane at 4 Torr pressure is a direct proof that this species is very different from the $C_7H_7^+$(benzyl$^+$) obtained from benzyl chloride or toluene. The enthalpy change $\Delta H_4 = -0.8$ kcal/mol obtained in section (a) taken together with the heats of formation: ΔH_f(*t*-BuCl) = −43.7, ΔH_f(BzCl) = 4.5 and ΔH_f(iso-C_4H_{10}) = −32.4, ΔH_f(toluene) = 11.99 (all in kcal/mol) (15) leads to $\Delta H_{20} = 3.8$ kcal/mol. This result shows that benzyl could not have been observed under the conditions of the experiments in Figs. 10 and 11. The presence of isobutane at vast excess (4 Torr) would have converted all Bz$^+$ to *t*-Bu$^+$ by the reverse of [20].

[20] t-$C_4H_9^+ + C_6H_5CH_3 =$ iso-$C_4H_{10} + C_7H_7^+$(benzyl)

[21] t-$C_4H_9^+ +$ 1,3,5-*c*-heptatriene = iso-$C_4H_{10} + C_7H_7^+$(tropylium)

[22] $C_7H_7^+$(benzyl) + 1,3,5-*c*-heptatriene = $C_6H_5CH_3 + C_7H_7^+$(tropylium)

The $C_7H_7^+$ observed in these runs is a species which is much more stable than Bz$^+$, i.e. it must be tropylium. The concentrations observed in Fig. 10 permit one to set an upper limit to $\Delta G^0_{21} \approx \Delta H^0_{21}$. Taking $C_7H_7^+ = 28\%$ and $C_4H_9^+ = 0.1\%$ one obtains $\Delta G^0_{21} < -13.4$ kcal/mol. Lias and coworkers (10) have estimated that the heat of formation of tropylium$^+$ is 9 kcal/mol lower than that of benzyl$^+$. Using this value, ΔH_f(1,3,5-cycloheptatriene) = 43.9 kcal/mol and $\Delta H_{20} = 3.8$ kcal/mol, one evaluates $\Delta H_{21} = -37.1$ kcal/mol. The $\Delta G^0_{21} < -13.4$ kcal/ mol from the present experiments is consistent with the thermochemical ΔH_{21}, but it is obvious that a reactant with much lower hydride affinity than *t*-butyl$^+$ will be required if one is to achieve a hydride transfer equilibrium with tropylium.

The enthalpy change $\Delta H_{22} = -40.9$ kcal/mol calculated with the Lias (10) estimate for ΔH_f tropylium$^+$ predicts a hydride affinity of tropylium some 41 kcal/mol lower than that of benzyl. This vast difference is due to 9 kcal/mol difference in the heats of formation of benzyl$^+$ and tropylium$^+$ and 32 kcal/mol difference in the heats of formation of the heptatriene and toluene. The very low hydride affinity of the tropylium cation is thus not so much a result of the greater stability of tropylium$^+$ versus Bz$^+$, but the much lower stability of the very strained cycloheptatriene as compared to that of toluene.

Several experiments were made in which the reactivity of the $C_7H_7^+$(tropylium) produced by hydride abstraction from cycloheptatriene was tested. These experiments showed that the tropylium ion is completely unreactive, i.e. does not engage in any of the reactions observed with Bz^+. Thus the chloride transfer equilibria [4] in the presence of heptatriene shifted completely to $C_7H_7^+$ as final cation. The $C_7H_7^+$ was tropylium produced by hydride abstraction. Substituted benzyl cations like p-CH_3-benzyl, which are more stable than unsubstituted Bz^+, were also found to completely disappear in the presence of the heptatriene and produce the tropylium cation. The tropylium cation was found not to hydride abstract from various substituted benzyl chlorides, i.e. did not engage in reactions analogous to [7]. The tropylium cation did not add to benzyl chloride or toluene, i.e. it did not undergo reactions analogous to [5] and [13] + [14]. Addition of water vapor to benzyl produced ions of mass corresponding to protonated benzyl alcohol and higher hydrates $Bz(OH_2)_n^+$. No such hydrates were observed with tropylium under the same conditions.

The experiments in the present and preceding section show that the benzyl and tropylium cations preserve their distinctive characteristics at temperatures up to 300°C. There are no rearrangements from benzyl to tropylium and vice versa. Even extremely exothermic reactions like the chloride abstraction by ethyl from benzyl chloride (exothermicity ~83 kcal/mol) in which a considerable fraction of the exothermicity may be expected to be present as excitation energy in the newly created Bz^+, do not cause the conversion from benzyl to tropylium. Similarly the highly exothermic hydride abstraction by t-Bu^+ from cycloheptatriene (exothermicity ~42 kcal/mol) produces only tropylium.

The present findings support earlier conclusions in the literature. Tropylium must be created by electron impact on toluene, it cannot have resulted from a rearrangement of benzyl$^+$ to tropylium$^+$ (1, 2, 5). The unreactive $C_7H_7^+$ ion created by electron impact from toluene must be tropylium$^+$, (5, 10). It is the benzyl cation produced by electron impact from toluene that engages in the reactions [12] and [13] with toluene, (5, 10).

It is interesting to note that no rearrangements of tropylium$^+$ to Bz^+ and vice versa seem to have been reported in the voluminous organic literature (16) dealing with the reactions of the benzyl and tropylium cations in condensed media. The present work shows that there is also no rearrangement in the gas phase. One qualification may be added. In the present work only electronic ground state benzyl and tropylium cations were involved. Therefore, the present results do not preclude rearrangements of benzyl$^+$ to tropylium$^+$ and vice versa for electronically excited species or ground state species with extremely large internal excitation, i.e. excitation sufficient to lead to fragmentation of these ions.

A study of aqueous sodium cholate by ^2H nmr

WILLIAM B. SMITH AND GARETH D. BARNARD
Texas Christian University, Fort Worth, TX 76129, U.S.A.
Received November 17, 1980

WILLIAM B. SMITH and GARETH D. BARNARD. Can. J. Chem. **59**, 1602 (1981).

Solutions of aqueous sodium 7-^2H-cholate have been studied as a function of cholate concentration by ^2H nmr. Relaxation times and solution viscosities have been used to show that cholate is monomeric in solution at 0.1 *M*. Increasing concentration leads to tetramer formation which is complete at 0.1 *M*. The tetramer solutions are stable up to 55°C. Solutions of cholate in aqueous pyridine also form tetramers in the same fashion. Evidence was found, however, for a weak hydrogen bonding interaction between the two.

WILLIAM B. SMITH et GARETH D. BARNARD. Can. J. Chem. **59**, 1602 (1981).

Des solutions aqueuses du sel sodique de l'acide cholique-7-^2H ont été étudiés par rmn du ^2H en fonction de la concentration en cholate. Des mesures de temps de relaxation et de viscosité démontrent que le sel est monomère en solution centimolaire. Un accroissement de la concentration entraîne la formation d'un tetramère et celle-ci s'avère complète à une concentration de 0.1 *M*. Ces solutions de tetramère sont stables jusqu'à 55°C. En solution aqueuse de pyridine, il se forme également des tetramères. Nous observons cependant une faible interaction cholate–pyridine par liaison hydrogène.

Because of their complex biological function the solution properties of the bile acids and their salts continue as a subject of considerable interest (1–5). Recently, it was demonstrated that chloroform solutions of noninteractive steroids such as cholesteryl chloride and cholesteryl acetate are well behaved in the sense that their ^{13}C spin lattice relaxation time (T_1's) follow the viscosity relation of the simple Stokes–Einstein–Debye approach (4). In contrast, the methyl esters of a series of bile acids showed a more complex behavior attributable to hydrogen bond formation between the molecules. Furthermore, this interaction varied with the number of available hydroxyl groups and their steric environments in a rational fashion.

It has been known for years that sodium cholate and sodium deoxycholate form micelles in aqueous media. Small *et al.* (1, 2) have combined data from light scattering, ultracentrifugation, and proton nmr to provide a model in which sodium cholate forms a dimeric primary micelle at the critical micelle concentration (cmc). These dimers were postulated to have their hydrophobic β-sides inward and their hydroxyl-bearing α-sides outward in the polar medium. Such a model is, of course, quite different from that required to explain the behavior of the bile acid esters referred to above.

Recently, Oakenfull and Fisher (5) reported on the conductivity of aqueous sodium cholate and deoxycholate. They noted for both cases a sharp break in the curve of equivalent conductance versus the square root of the concentration about the cmc (ca. 0.01 *M* bile salt). They conclude that premicellar aggregation is occurring. At the cmc higher aggregates (tetramers) are formed. While a hydrophobic interaction between dimers might be possible, they propose that these higher aggregates are formed by polyfunctional hydrogen bonding since there is a negative volume of micelle formation at the cmc.

Because of these two divergent models which have been used to describe the aggregation of bile salts in aqueous media, we felt it worthwhile to extend our previous nmr relaxation measurements to these systems. Because both the proton and ^{13}C nmr spectra of solutions of sodium cholate are poorly resolved and suffer from low signal to noise ratios, ^2H nmr was used on singly labeled sodium cholate. The use of deuterium for such studies offers the advantage that the relaxation times are determined solely by the quadrupolar mechanism. Previously, Fung and Peden (3) had determined ^2H relaxation times for solutions of specifically deuterated sodium deoxycholate over the range of 0.12–0.17 *M*. They concluded that within this range the deoxycholate is a tetramer.

As an adjunct to the above study, we have also carried out studies in dilute solutions of aqueous pyridine. Earlier, Liebfritz and Roberts (6) had shown by ^{13}C nmr that methylnaphthalene undergoes some sort of restrictive interaction when solubilized within a sodium deoxycholate micelle. Pyridine is capable of both hydrophilic and hydrophobic interactions with the bile salt micelle. Furthermore, the molecular motions of perdeuteropyridine have been previously studied (7).

Experimental

Cholic acid (mp 195–196°C) and perdeuteropyridine were from Steraloids and Aldrich respectively. Sodium cholate was

from ICN Pharmaceuticals. Since the ^{13}C nmr spectra of the steroids indicated no impurities, they were used directly.

Cholic acid was partially oxidized to the 7-ketoacid by the method of Hoehn and Linsk (8). The crude reaction product was then reduced as the potassium salt with sodium deuteroborohydride (Ventron). The crude 7-^2H-acid was recovered and crystallized from methanol, mp 194–195°C, mixture melting point with starting acid was undepressed. The borohydride reduction of the 7-ketocholanic acid to the 7-α-hydroxyacid is known to proceed in 75% yield with no isolable amount of the 7-β-hydroxyacid (9). The ^{13}C nmr of the reaction product was that of pure cholic acid except that the intensity of the C-7 line at 68 ppm was greatly reduced. Sodium cholate was prepared by careful titration with standard sodium hydroxide and evaporation to dryness.

Viscosities were measured in a standard Ostwald viscometer at the appropriate temperature with flow times in excess of 100 s so that no correction for kinetic energy was required.

All nmr measurements were made at 9.19 MHz on a JEOL FX-60 instrument using 8K transforms. Pyridine relaxation times (T_1's) were determined by the standard inversion-recovery technique with a pulse repetition time in excess of $5 \times T_1$. The 90° pulse on this instrument was 400 μs. The standard auto-T_1 program was used. The T_1's for neat perdeuteropyridine at 23°C were 0.72, 0.79, and 0.74 s respectively for the α-, β-, and γ-positions. These are in good agreement with the values of 1.14, 1.17, and 1.20 s determined at 30°C by Kintzinger and Lehn (7). The ^{13}C T_1 values for neat pyridine were determined three times giving an average value of 17.1 ± 0.7 s for the combined data of the three carbon types (10). The ^{13}C and ^2H relaxation times can be compared by the equation

$$[1] \quad \frac{T_1(^{13}C)}{T_1(^2H)} = \frac{3\pi^2\chi_D^2 r^6}{2N\hbar^2\gamma_C^2\gamma_H^2}$$

where χ_D is the nuclear quadrupole coupling constant, r is the C—H bond length, N is the number of hydrogens attached to the carbon, and γ_C and γ_H are the magnetogyric ratios for ^{13}C and ^1H respectively (11). The value of χ_D for pyridine of Kintzinger and Lehn (193 KHz) was used (7). The average C—H bond length for pyridine is 1.08 Å (12). On this basis, the calculated ^2H-T_1 value for neat pyridine is 0.70 s in good agreement with the experimental values.

The FX-60 does not have sufficiently short pulse interval times to allow determination of the short T_1 values found for aqueous sodium cholate (below 0.01 s for the most part). Consequently, the width of the ^2H-line at half height was used to get a T_2 value. A correction for magnetic field inhomogeneity was made where appropriate using the natural line width of perdeuteroacetone which was routinely found to be 1.5 Hz. The assumption was made that for the small aggregates found here the motional narrowing condition was fulfilled, i.e. $T_2 = T_1$. While this method of determining T_1's is less desirable than the standard pulse method, line widths here were 50–200 Hz and reproducible to ±10%, i.e., about the same as the inversion-recovery method. Furthermore, the above was checked as follows. Four inversion-recovery ^{13}C determinations were carried out on a 0.2 M solution of sodium cholate at 30°C giving a value of 0.063 ± 0.01 s for the monoprotonated carbons. The appropriate ^2H value was then calculated from the equation above. The C—H bond length of the C-7 hydrogen was taken as 1.05 Å from the value of the hydroxyl-bearing carbons in myo-inositol (13). The values of χ_D used were 165 KHz (CH_3OH) and 170 KHz (cyclohexane) (14). This range leads to calculated values of 4.0 to 4.2 ms in excellent agreement with the line width determined ^2H-T_2 for a comparable solution of sodium 7-^2H-cholate of 4.0 ms.

Results and Discussion

Small (1) has surveyed the various literature values for the critical micelle concentration (cmc) of aqueous sodium cholate. It would be best to say that the value falls in the range of 0.01 to 0.02 M since different experimental techniques have provided different values. Equilibrium ultracentrifugation data were interpreted as indicating a dimer as the first formed micelle (1*a*). As the concentration increases dimer formation persists until at some unspecified point "secondary" micelle formation sets in with the formation of tetramers and higher aggregates. Ekwall *et al.* (15) proposed the association process to be divided into three concentration regions for each bile salt, i.e., monomer, primary micelle, and secondary micelles. The previously mentioned structure for the cholate dimer derives primarily from observation of line width changes in the proton nmr of cholate solutions (2). It was reported that the methyl absorptions widen with increasing concentration as does the methylene envelope. Unfortunately, no consideration was given to viscosity effects on these spectra or to the variety of inter- and intramolecular phenomena which can influence proton relaxation times.

In contrast, deuterium relaxation times are determined primarily by nuclear quadrupole interactions (16). When combined with the Stokes–Einstein approximation and Debye theory (17) the relaxation time may be written as:

$$[2] \quad \frac{1}{T_1} = \frac{3(\pi^2)(\chi_D^2)\tilde{V}_m}{2RT}\eta$$

where $\tilde{V}_m$ is the apparent molar volume of interest and η is the viscosity in poise. Strictly speaking, eq. [2] applies only to a spherical molecule, and η is a rotational microviscosity. However, it has been established that these approximations are valid for noninteracting steroids (4), and that ^2H nmr can be used to demonstrate that the deoxycholate ion is a monomer in methanol but a tetramer in water (3). The use of an experimental translational viscosity for η seems warranted on the basis that steroid tumbling must always move a substantial number of solvent molecules out of the way. It is likely that more linear hydrogen bonded complexes do not follow the form of [2].

The ^2H-T_2's for sodium 7-^2H-cholate in water and in dilute pyridine solutions are given in Table 1. Viscosities for the solutions in water and in 0.14 M pyridine are shown in a semi-log plot in Fig. 1. The viscosity data for the 0.07 M and 0.28 M pyridine systems were indistinguishable from those plotted.

Low molecular weight aggregates should fall in

For personal use only.

the region of motional narrowing, i.e. $1/T_1 = 1/T_2$ and eq. [2] above should apply for T_2. The justification for this assumption applied to solutions of sodium cholate is given in the Experimental. In Fig. 2, plots are given of $1/T_2$ vs. viscosity for aqueous sodium cholate at 23°C and 55°C and for sodium cholate in dilute pyridine solutions at 23°C. These plots are characteristic of all the data in Table 1. In each case, the plot is linear over the range of 0.01 to 0.10 *M* cholate. The value of T_2 decreases rapidly over the range, while viscosity increases only slightly. Beyond a viscosity of ca. 1.0 (approximately 0.1 *M*) the plot shows a change of slope as though some aspect of structure of the system had been subject to a discontinuity in the 0.10 to 0.12 *M* region of cholate concentration. Above this point the plot appears to be more curvilinear. Unfortunately, the conductivity data of Oakenfull and Fischer (5) did not extend to this concentration.

Application of eq. [2] to the data for 0.01 *M* cholate at 23°C gives an experimental molar volume of 464 mL. A density determination of 0.1 *M* sodium cholate gives an apparent molar volume of 363 mL in good agreement with the published value (5). Small (1) has published the value of 325 mL for the "anhydrous" molar volume. Thus, one concludes that at 0.01 *M* sodium cholate at 23°C the bile salt is essentially a mixture of monomers and dimers in approximately equal amounts. Due to limits of instrument sensitivity it is impracticable to make determinations below 0.01 *M* sodium cholate so we can not confirm the break observed in the conductivity curve in this region.

In Fig. 2*a* at 0.11 *M*, the calculated molar volume is 1.3×10^3 mL corresponding to an aggregation number of 4 using Small's molar volume. It appears that the discontinuity occurs at that concentration where tetramer formation is complete. The linear behavior of the $1/T_2$ vs. viscosity plot from 0.01 to 0.10 *M* cholate rationally results from the fact that over this region there is very little change in the viscosity. Consequently, the experimental value of $1/T_2$ can be shown to be a linear function of the corresponding terms for the monomer, dimer, and

tetramer. Beyond 0.11 *M* cholate the viscosity changes rapidly, and the linear relationship breaks down.

Small *et al.* (2) found the line widths of the proton nmr spectra of sodium cholate solutions to be decreased on raising the temperature. This was interpreted as implying a dissociative process which became complete above 70°C. Unfortunately, these data are hard to interpret. No viscosity measurements were made, and so decreasing line widths could be due entirely to viscosity effects. Furthermore, the methylene envelope is a forest of lines caused by the many different proton chemical shifts and the strong spin–spin couplings between many of these nuclei. Conclusions based on the width of the methylene envelope are fraught with difficulty.

The ^{2}H-T_2 for a 0.10 *M* sodium 7-^{2}H-cholate solution was determined at several temperatures up to 55°C. The viscosities of these solutions were also determined. The data are given in Fig. 3 in the form of semi-log plots of $1/T_2$ and of η respectively against $1/T$. Over this range of temperatures linear behavior is observed as expected for a simple first order process. There is a slight divergence of slopes as can be seen. However, the calculated molar volume of the cholate micelle at 55°C is 93% of that at 23°C, so dissociation has not yet become very significant at that temperature.

Finally, it had been our expectation that the presence of pyridine would alter the pattern of cholate micelle formation. The data in Table 1 and in Figs. 1 and 2 do not support that expectation. In Fig. 4 are plotted the $1/T_1$ vs. viscosity data for the α-^{2}H of perdeuteropyridine (0.14 *M*) with increasing concentrations of cholate. The interpretation of the ^{2}H-T_1's for pyridine are made complex by the fact that the molecule possesses a significant rotation in the molecular plane negating the application

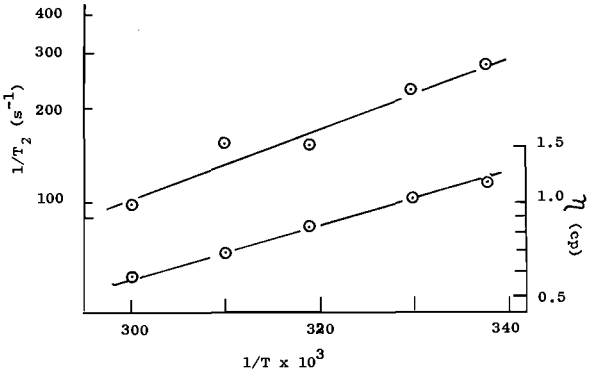

FIG. 3. The relation of $1/T_2$ (upper) and of log viscosity respectively to the reciprocal of the Kelvin temperature for 0.10 *M* sodium cholate.

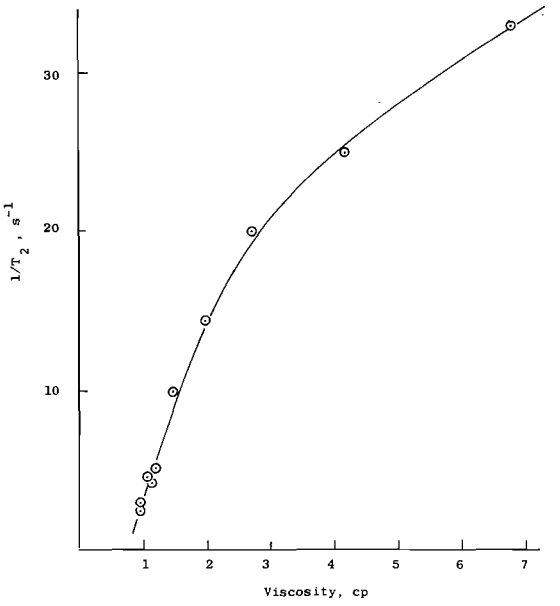

FIG. 4. The change in $1/T_2$ for perdeuteropyridine (0.14 *M*) at 23°C in varying concentrations of sodium cholate.

of eq. [2] (7). However, if the pyridine were to be rigidly bound to the micelle both would have the same correlation time for rotation. Such is not the case here.

Yet there is a bit of evidence for a cholate–pyridine interaction. In keeping with the absence of a preferred rotational axis, the ^{2}H-T_1's for neat pyridine are the same at all positions. In aqueous 0.14 *M* pyridine the ratio of $T_{1\alpha}/T_{1\gamma}$ is 1.35. The introduction of hydrogen bonding to water produces a preferred rotation axis about the C_γ—N axis. Upon addition of 0.01 *M* cholate this ratio increases to 1.46, and with 0.025 *M* cholate is found to be 1.50. Beyond this point the γ-^{2}H resonance becomes too broad to measure and merges with the β-^{2}H line. These results suggest that some hydrogen bonding of the pyridine to the cholate occurs, but reasonably this might be on the outer surface of the micelle.

Quantum yield of solution photolysis of bicyclo[3.1.0]hexan-3-one and derivatives[1]

KARL R. KOPECKY AND RODRIGO RICO GOMEZ[2]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2
Received November 21, 1980

KARL R. KOPECKY and RODRIGO RICO GOMEZ. Can. J. Chem. **59**, 1607 (1981).

The quantum yields for photolysis of 0.25 *M* solutions of bicyclo[3.1.0]hexan-3-one, 1,5-dimethylbicyclo[3.1.0]hexan-3-one, and tricyclo[4.3.1.0]decan-8-one in pentane or cyclohexane with 313 nm light are 0.44, 0.52, and 0.32, respectively.

KARL R. KOPECKY et RODRIGO RICO GOMEZ. Can. J. Chem. **59**, 1607 (1981).

Les rendements quantiques de la photolyse à 313 nm de la bicyclo[3.1.0]hexanone-3, de la diméthyl-1,5 bicyclo[3.1.0]hexanone-3 et de la tricyclo[4.3.1.0]décanone-8 en solution à 0,25 *M* dans le pentane ou le cyclohexane sont respectivement de 0,44, 0,55 et 0,32.

[Traduit par le journal]

Introduction

The yield of excited cyclopentanone formed from 3,3:4,4-dibutano-1,2-dioxetane, **1**, as measured by the amount of 4-pentenal formed, eq. [1],

[1] 
1

is subject to considerable uncertainty because the ratio of cyclopentanone to 4-pentenal is quite large (1). This is because of a small yield of excited cyclopentanone and a moderate quantum yield for photolysis of cyclopentanone to 4-pentenal, Φ = 0.27 (1), so that a small error in the absolute yield of 4-pentenal results in a large error in the calculated yield of excited cyclopentanone. Use of a 1,2-dioxetane which would produce a ketone that photolyzed with a much higher quantum yield might provide more accurate results.

It was felt that bicyclo[3.1.0]hexan-3-one, **2**, might undergo photodecomposition in solution with a higher quantum yield than does cyclopentanone. In the gas phase both cyclopentanone (2) and **2** (3) are destroyed with high quantum efficiencies, Φ = 0.69 and 0.77, respectively, independent of pressure. However, the product distribution from cyclopentanone is affected considerably by pressure while that from **2** is not. A change from the gas phase to solution should affect the photolysis of cyclopentanone more than that of **2**.

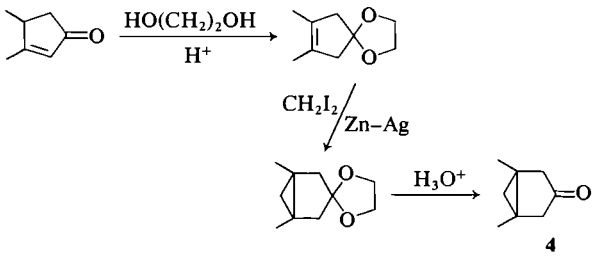
[1]This research was supported by the Natural Sciences and Engineering Research Council of Canada.

[2]Present address: Departamento de Quimica Organica, Facultad de Ciencias, Universidad de Malaga, Malaga, Spain.

The solution photolysis of **2** and of several derivatives has been studied (4) but the quantum yields have not been determined. In the present work the quantum yields for photolysis in solution of **2** and of its 1,5-butano and 1,5-dimethyl derivatives, **3** and **4**, respectively, have been determined.

Results

The ketones **2** (3) and **3** (4*a*) were prepared as described and **4** was prepared from 3,4-dimethyl-2-cyclopentenone (6) by the sequence shown in Scheme 1.



SCHEME 1

Degassed solutions containing about 0.25 *M* ketone were irradiated with 313 nm light from a medium pressure mercury arc. From each ketone only the one product indicated, eqs. [2], [3], and

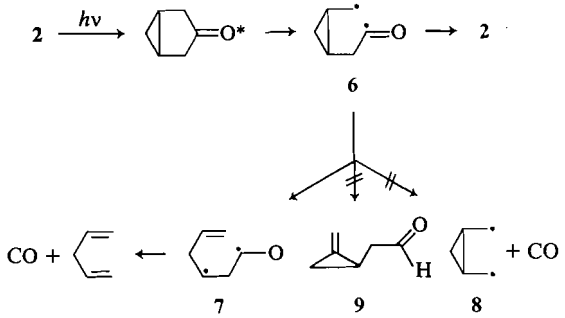
[4], could be detected by gc, in agreement with the report that the photolysis of **3** in solution produced 1,3-dimethylenecycloheptane in 100% yield (4*a*). Cyclopentanone, 0.26 *M* in pentane, was irradiated in parallel with the other ketones to about 5% conversion and served as the actinometer. The quantum yield of 4-pentenal formation was taken as 0.27 (1). Quantum yields for formation of the dienes from the other ketones are given in the equations.

Discussion

In the gas phase, photolysis of **2** produces 1,4-pentadiene, vinylcyclopropane, and 1,3-butadiene in about a 7:1:0.2 ratio (3). The latter two products were not found in solution. Similarly, ethylene and cyclobutane, which are major products of the photolysis of cyclopentanone in the gas phase (2) are formed only in trace amounts in solution (5). As well, the quantum yield for photolysis of these two ketones is smaller in solution. The excess vibrational energy of the intermediates is quenched much more quickly in solution than in the gas phase.

The quantum yields for solution photolysis of **2**, **3**, and **4** vary from a value nearly double that of cyclopentanone to one only slightly greater. The results may be rationalized if the assumption is made that the amount of α-cleavage (7), Scheme 2, is nearly the same for **2**, **3**, and **4**. The quantum yield for α-cleavage is not known but is likely greater than that for diene formation. The only information on this point is that there is epimerization of the isomeric thujones during photolysis (4*b*). Cyclization of the diradical **6** would give back starting ketone **2** and opening of the cyclopropane ring would produce the secondary diradical **7**. The latter process would be retarded by the butano bridge of the corresponding diradical from **3** and favored by the relief of strain between the two methyl groups of the corresponding diradical from **4**. The trend in quantum yields is consistent with the predicted effects of the substituents. There would be little or no effect of substituents if the initial diradical **6** lost CO to give the diradical **8** more rapidly than ring opening to **7** occurred. Intramolecular hydrogen atom transfer to give **9** does not take place at all on solution photolysis of **2**, although the corresponding process occurs with moderate efficiency on photolysis of cyclopentanone.

Although the quantum yields for photolysis of **2**, **3**, and **4** are greater than that for cyclopentanone, the improvement is not large enough to make these ketones significantly better than cyclopentanone for measurement of excited state yields from 1,2-dioxetanes.



SCHEME 2

Experimental

Boiling points are uncorrected. Nuclear magnetic resonances were recorded on Varian A56-60A and Bruker WH200 spectrometers in carbon tetrachloride with tetramethylsilane as internal standard. Gas chromatographic analyses were carried out on an Aerograph A-90-P3 gas chromatograph using a 5 ft × ¼ in. column of FFAP on 60/80 Chromosorb W at 70°C to analyze reaction mixtures from photolysis of cyclopentanone and of **3**, and a 10 ft × ¼ in. column of 23% dimethylsulfolane on 60/80 Chromosorb P at 48°C to analyze reaction mixtures from photolysis of **2** and **4**. Solutions were dried with magnesium sulfate. Microanalyses were performed by Mrs. Darlene Mahlow and staff.

Compounds **2** (3),[3] **3**(4*a*), 1,4-pentadiene (8),[3] and 4-pentenal (9) were prepared according to literature directions; 1,3-dimethylenecycloheptane was prepared by photolysis (4*a*) of **3**; 2,4-dimethyl-1,4-pentadiene was obtained from K and K Chemicals. Reagent grade cyclopentanone was distilled just prior to use.

3,4-Dimethyl-3-cyclopentenespiro-(2',5'-dioxacyclopentane)

A mixture of 3,4-dimethyl-2-cyclopentenone (6) (7.5 g), 1,2-ethanediol (100 g), benzene (200 mL), and toluenesulfonic acid (0.15 g) was heated under reflux for 30 h in a round-bottomed flask fitted with a Soxhlet thimble which contained calcium carbide (10). The reaction mixture was cooled and some sodium hydroxide pellets and aqueous sodium bicarbonate were added. The organic layer was shaken twice with water, dried, and the solvent removed to leave a dark brown oil which was distilled at 15 Torr through a short-path still to give 4 g of a colorless oil, bp 108–140°C, which was shown to consist of a mixture of acetal and starting ketone. The mixture was separated by flash chromatography (11) through a 5 × 15 cm column of silica gel, Merck No. 9385, using 85:15 ether–pentane as eluent. The product was purified by bulb-to-bulb distillation at 710 Torr, 180°C pot temperature to give 1.9 g (20%) of a colorless oil; ^{1}H nmr τ: 8.34 (t, J = 1 Hz, 6H), 7.48 (q, J = 1 Hz, 4H), 6.06 (s, 4H). *Anal.* calcd. for $C_9H_{14}O_2$: C 70.09, H 9.15; found: C 70.23, H 9.12.

3,4-Dimethylbicyclo[3.1.0^{3,4}]hexanespiro(2',5'-dioxacyclopentane)

The above olefinic acetal, 1.18 g, was converted to the cyclopropyl derivative with 8.4 g diiodomethane using the zinc–silver couple method (12) to give 1.89 g (95%) of a colorless oil which had a moderate carbonyl absorption in the infrared spectrum. This product was purified by flash chromatography (10) on a 5 × 30 cm column of silica gel using 75:25 ether–pentane as eluent to give 1.5 g product which was isolated by bulb-to-bulb distillation at 15 Torr and 80°C (pot); ^{1}H nmr τ: 6.18

[3]We thank Mr. A. Miller for these preparations.

(d, J = 3 Hz, 2H), 6.22 (d, J = 3 Hz, 2H), 8.04 (s, 4H), 8.88 (s, 6H), 9.11 (m, 1H), 9.98 (m, 1H). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.42, H 9.52; found: C 70.79, H 9.76.

1,5-Dimethylbicyclo[3.1.0]hexan-3-one **4**

A stirred mixture of 3 g silica gel (28–200 mesh) in 5 mL dichloromethane was treated with 0.4 mL of 10% aqueous oxalic acid (13), then 0.8 g of the above acetal was added and the resulting mixture was stirred for 20 h, after which hydrolysis was complete. The mixture was filtered, solvent removed from the filtrate, and the residual oil was distilled from bulb to bulb at 710 Torr and 180°C (pot) to give 0.5 g product. The ^{1}H nmr τ: 7.65 (m, 4H), 8.75 (s, 6H), 9.58 (H_{6exo}, m, 1H), 9.73 (H_{6endo}, d, J = 5 Hz, 1H). *Anal.* calcd. for $C_8H_{12}O$: C 77.37, H 9.66; found: C 76.62, H 9.66.

Quantum Yields

Degassed pentane solutions 0.25 M in **3** and **4** and degassed cyclohexane solutions 0.25 M in **2** were irradiated in parallel with degassed pentane solutions 0.26 M in cyclopentanone, which served as the actinometer, at 22°C on a merry-go-round apparatus (14) with a 200 W medium pressure Hanovia lamp and a potassium chromate filter to isolate the 313 nm line. Pyrex tubes were used and the irradiations were carried out to no more than 4% decomposition of cyclopentanone. The amounts of photolysis products were determined by gc using solutions of known concentrations of these materials to make calibration charts. The quantum yield of 4-pentenal was taken to be 0.27 (1).

Nickel(III)–tris(di-imine) complexes: a series of strong one-electron oxidants

J. C. BRODOVITCH, R. I. HAINES, AND A. MCAULEY[1]

Department of Chemistry, University of Victoria, P.O. Box 1700, Victoria, B.C., Canada V8W 2Y2

Received November 14, 1980

J. C. BRODOVITCH, R. I. HAINES, and A. MCAULEY. Can. J. Chem. **59**, 1610 (1981).

The complexes $[Ni(III)(LL)_3](ClO_4)_3$ (LL = phen, bipy, and substituted derivatives) have been isolated as products of the electrolysis in acetonitrile of the corresponding nickel(II) species. Electron spin resonance measurements for all nickel(III) species in frozen anhydrous CH_3CN and in frozen 4.0 *M* $HClO_4$ solutions (77 K) show a single near symmetric line shape ($g \approx 2.10$) with fine structures appearing only in the presence of mixed solvent systems. In a CH_3CN/5% H_2O glass (77 K) quintets in the $g_{||}$ and $g_{\perp}$ regions are observed ($g_{||} \approx 2.03$, $A_{||} \approx 22$ G; $g_{\perp} \approx 2.135$, $A_{\perp} \approx 16$ G) consistent with Jahn–Teller distortion expected for a low-spin d^7 system. Ultraviolet–visible spectra are also reported. Electrode potentials for the $Ni(LL)_3^{3+/2+}$ couples in CH_3CN (0.1 *M* $NaClO_4$) lie in the range 1.51 V ($Ni(4,4'\text{-}Me_2bipy)_3^{3+}$) to 1.82 V ($Ni(5\text{-}NO_2\text{-}phen)_3^{3+}$) and the powerful oxidizing nature of these species has been confirmed in reaction with both organic and inorganic substrates.

J. C. BRODOVITCH, R. I. HAINES et A. MCAULEY. Can. J. Chem. **59**, 1610 (1981).

On a isolé les complexes de $[Ni(III)(LL)_3]$ $(ClO)_4)_3$ (LL = phen, bipy et des dérivés substitués) comme produits de l'électrolyse des espèces correspondantes du nickel(II) dans l'acétonitrile. Les spectres de rpe de toutes ces espèces du nickel(III) dans du CH_3CN anhydre solide et dans des solutions solides de $HClO_4$ 4,0 *M* (77 K) se présentent tous sous la forme d'une raie unique presque symétrique ($g \approx 2{,}10$) sur laquelle se superpose une structure fine uniquement en présence de systèmes de solvants mixtes. Dans du CH_3CN/5% H_2O (77 K), on observe des quintuplets dans les régions $g_{||}$ et $g_{\perp}$ ($g_{||} \approx 2{,}03$, $A_{||} \approx 22\,G$; $g_{\perp} \approx 2{,}135$ $A_{\perp} \sim 16\,G$) qui sont en accord avec la distorsion de Jahn–Teller attendue pour un système de faible spin d^7. On rapporte également les spectres uv–visible. Les potentiels d'électrode du couple $Ni(LL)_3^{3+/2+}$ dans le CH_3CN (0,1 *M* $NaClO_4$) varient de 1,51 V pour ($Ni(Me_2bipy\text{-}4,4')_3^{3+}$) à 1,82 V pour ($Ni(NO_2\text{-}phen\text{-}5)_3^{3+}$) et la réaction de ces produits avec des substrats organiques et inorganiques confirme la nature fortement oxydante de ces espèces.

[Traduit par le journal]

There has been considerable recent interest in the characterization and reactions of nickel(III) complexes. In many instances (1–4), tetraazamacrocyclic ligands have been used to stabilize this higher oxidation state of the metal and although considerable stability is shown in acetonitrile (5), only when the macrocycle is saturated are these species stable with respect to intramolecular reduction in aqueous media (2, 4, 6–8). A feature of many of these studies has been the interpretation of esr spectra (1, 9) where, owing to the localization of the unpaired electron in the d_z^2 orbital of these low spin d^7 complexes, differing g values are observed for the $g_{||}$ and $g_{\perp}$ parameters. In this paper we wish to report the results of studies on nickel(III)–di-imine complexes which in some cases, although relatively easily prepared in acetonitrile, exhibit very powerful oxidizing capabilities. The complex ion $Ni(bipy)_3^{3+}$ has been prepared electrolytically in strongly acidic aqueous media (10, 11) and results of oxidations of H_2O_2 (10), Br^- (10), and N_3^- (11) have been published. The complexes were not, however, isolated as solids. In the present study, the results of esr, uv–visible, and cyclic voltammetric investigations on these systems are presented.

Experimental

Reagent grade acetonitrile was refluxed for 24 h over calcium hydride and copper(II) chloride, then distilled onto molecular sieves prior to use. Tetraethylammonium perchlorate (G. F. Smith) and silver nitrate (Englehardt) were used as received.

Nickel(II) complexes were prepared as their perchlorate salts by addition of 3.5 equivalents of ligand to 1 equivalent of nickel(II) perchlorate in methanol. The precipitated products were washed copiously with methanol and ether and dried *in vacuo*. Abbreviations used in this paper are: phen = 1,10-phenanthroline; bipy = 2,2'-bipyridyl; (5-Me phen), (4,4'-Me_2-phen), (5-Cl-phen), and (5-NO_2-phen) refer to the substituents in the ring positions noted. The corresponding nickel(III) complex perchlorates were prepared by electrolysis of an acetonitrile solution of the nickel(II) precursor (ca. 0.1 g/50 mL) containing 0.1 *M* tetraethylammonium perchlorate as supporting electrolyte. The procedure was carried out in the dark at 5°C overnight at a constant potential of 15 V using Pt wire electrodes. Products were isolated by slow evaporation of solvent at 5°C. The dark-green crystalline solids were filtered, washed with a little cold acetonitrile, and dried *in vacuo*. All products were found to be quite stable in the solid state in the dark, except the chloro and nitro substituted ligand complexes which reverted to the nickel(II) state generally within 24 h. In some instances dilute solutions of the nickel(III) complexes were prepared in acetonitrile containing 0.1 *M* $NaClO_4$. Electron spin resonance spectra derived from this source showed no differences from those prepared similarly from solid samples.

Electrode potentials and cyclic voltammograms were measured using a Princeton Applied Research polarographic analyser model 174. Studies were made using 10^{-4} *M* solutions of the nickel(II) complex in CH_3CN containing 0.1 *M* $NaClO_4$. The three-compartment cell was constructed with two medium

porosity glass scinters separating the anode and cathode assemblies. The centre section was filled with a solution of 0.1 *M* $NaClO_4$ in acetonitrile. In this way any diffusion was reduced to a minimum. The working electrode was a Pt sphere, with a Pt-wire counter electrode. An agar bridge (containing $NaClO_4$) led to an aqueous solution (0.1 *M* $NaClO_4$) into which the reference electrode (calomel/saturated NaCl) was introduced. A constant stream of dry N_2 gas was passed through the reacting solution. All solutions were prepared in the cell in a dry box prior to measurements being made.

Electron spin resonance spectra of the series of nickel(III) complexes were measured in frozen acetonitrile solutions at 77 K, using a Varian E6 spectrometer; *g* values were determined from spectra using a scan range of 400 G and DPPH ($g = 2.0037$) was used as an internal reference standard. As observed previously (12), better resolution of esr spectra may be obtained with frozen samples of mixed solvent solutions. Results presented include those obtained from binary mixtures of 4 *M* $HClO_4$/5–10% CH_3CN or acetone, or CH_3CN/5–10% H_2O or acetone.

Ultraviolet–visible spectra were measured using either a Cary 17 or Beckman DU8 spectrometer. Extinction coefficients were determined using solutions prepared from solid samples or by electrolytic oxidation of a solution of the corresponding nickel(II) complex. Nickel(III) concentrations were derived by potentiometric titration with either hydroquinone (CH_3CN medium) or ferrous ammonium sulphate (4.0 *M* $HClO_4$).

Results and Discussion

The unequivocal existence of nickel(III) complexes rather than nickel(II)–radical systems has been confirmed in many instances using esr data (1, 4, 9, 11). For a low spin d^7 tetragonally distorted octahedral ion values of $g_{\|} \sim 2.00$ and $g_{\perp} \sim 2.2$ are consistent with the axially symmetric systems (13). Also, the unpaired electron has been shown to occupy principally the d_z^2 orbital as evidenced by the observed superhyperfine splitting of the $g_{\|}$ feature, owing to interaction of the electron with the axially bound ligands (e.g. in $Ni(cyclam)Cl_2^+$, the septet observed centred at $g_{\|} \sim 2.027$ is attributed to this effect) (4, 14). Table 1 shows the data for the nickel(III) di-imine complexes and in Fig. 1 the spectrum of the $Ni(bipy)_3^{3+}$ complex ion is presented, being typical of all such data for these complexes. If the electron were delocalized into

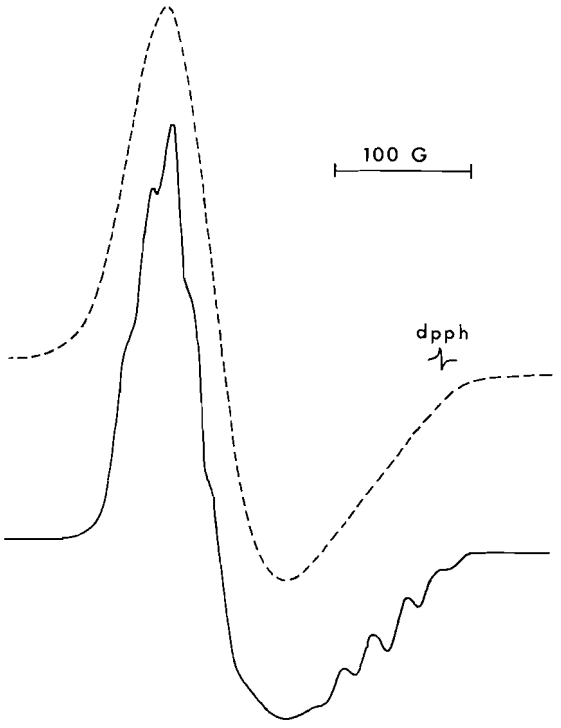

FIG. 1. Electron spin resonance spectra of frozen solutions at 77 K; $Ni(bipy)_3(ClO_4)_3$ --- in CH_3CN (0.1 *M* $NaClO_4$), — binary mixture CH_3CN/5% H_2O.

the bipyridyl ligand systems in what may be written formally as a (Ni(II)–LL$^{\cdot}$) radical complex ion, a *g* value very close to 2.00 would be expected (15, 16) for the (principally *C* centred) paramagnetic species. Frozen solutions at 77 K using only one solvent system (either CH_3CN or 2–4 *M* $HClO_4$) yielded only a near symmetric isotropic signal ($g_{iso} \approx 2.10$). This is in agreement with the previous observation of Wells and co-workers (11) using frozen aqueous perchloric acid solutions where partial oxidation to nickel(III) had occurred ($g = 2.095 \pm 0.002$). In the latter study, the possibility of weak features at higher fields indicating *g* aniso-

tropy could not be discerned owing to interference from the resonance of the unoxidized Ni(II) present in excess. Greater resolution of the spectra was obtained in all cases using mixed solvent systems (Fig. 1). Quintets in the $g_{\|}$ and $g_{\perp}$ regions are observed with $g_{\|} \approx 2.027$, $A_{\|} \approx 22$ G, $g_{\perp} \approx 2.137$, and $A_{\perp} \approx 15$ G. This is consistent with the assignment of the metal centre as Ni(III) and with a local symmetry of D_{4h} around the nickel as would be expected for a Jahn–Teller distorted low spin d^7 species. Interaction with the two axial nitrogen atoms gives rise to the observed quintets. The use of mixed solvents (H_2O/5–20% propane-diol) has been shown to provide a greatly enhanced spectral resolution in the study of cobalt(II)–corrin complexes (12). In frozen aqueous solutions, variations in the packing of the solute and solvent molecules occur and inhomogeneities in solute concentrations are to be expected. This effect may give rise to a variable microcrystalline environment for each paramagnetic centre and so lead to variation in spin Hamiltonian parameters and broadening of spectral lines. Local high concentrations of paramagnetic species have an adverse influence on spin–relaxation processes. In a glassy solid (solvent/H_2O mixtures), however, a vitreous rather than a polycrystalline medium is obtained on rapid freezing. A more uniform distribution of solute molecules is expected under these conditions, reducing the line broadening by spin–spin relaxation. It is of interest, in comparing the hyperfine coupling constants derived in the present systems with those for other macrocyclic nickel(III) complex ions, that $A_{\|}$ values of similar magnitude (25 ± 3 G) are observed whereas the $A_{\perp}$ coupling (≈ 15 G) in the tris di-imine complexes is greater than that for the saturated tetra-aza 14-membered ring systems (4). (< 5 G).

Electrochemical measurements on Ni(II)/Ni(III) systems have commonly employed acetonitrile as solvent (5), since it permits a wide range of potentials to be covered without decomposition and because the nickel(III) complexes are generally stable for long periods in the anhydrous medium. Results of electrolytic studies are presented in Table 2 where some measurements on the oxidation of iron(II)–di-imine complexes have been included. Whereas the iron(II)/(III) data show reasonable reversibility with peak separations of 60–70 mV, the values for the nickel(III) complexes are higher (Fig. 2). This quasi-reversibility has been shown to be a feature of several studies on nickel(III) systems (9). The most marked feature of these data is the very strongly oxidizing nature of the nickel(III) complexes. In some instances (e.g. the 5-chloro and 5-nitro species) the oxidation peaks were close to the limit possible for study without oxidation of the solvent. Comparison with the iron(III) species shows the nickel complexes to be much more powerful oxidants. This has been observed previously in aqueous media by Wells and co-workers (11). An attempt may be made to estimate the redox potentials of the nickel(III) complexes in aqueous media. Data for three iron(III) complexes, presented in Table 2, include the E^0 values in 1.0 M $HClO_4$ (17). In all cases the $Fe(LL)_3^{3+}$ cations are known to be fairly strongly oxidizing (18) and react via an outer sphere electron transfer mechanism. For the three systems shown, $\Delta E'$ (the differences between the potentials in 1.0

M $HClO_4$ and CH_3CN (0.1 M $NaClO_4$)) measured with the present reference system are 85 mV, 71 mV, and 85 mV respectively for $Fe(phen)_3^{3+}$, $Fe(5\text{-Me-phen})_3^{3+}$, and $Fe(bipy)_3^{3+}$. Estimates for the $Ni(LL)_3^{3+}$ ions in 1.0 M aqueous acidic media have been made (Table 2) by adding 85 mV to the potential for these species in CH_3CN. The redox potentials are all in excess of 1.59 V and the complexes are among the strongest one-electron oxidants available both in aqueous and nonaqueous media. The value for $Ni(phen)_3^{3+}$ (1.73 V) is almost identical (1.70 V) to that of Ce(IV) in $HClO_4$ (19) and only slightly lower than that (1.84 V) for $Co(III)_{aq}$ (20) in the same medium. The very high values (>1.8 V) for the 5-chloro and 5-nitro complexes may be the reason for the observation that even in the solid state the complexes decomposed readily. The preparation in CH_3CN requires rigorous exclusion of moisture since the potentials are in excess of that necessary to oxidize water.

In general, tervalent nickel complexes have been reported characteristically as dark green (1, 5), unless axially coordinated non-ammine ligands are present (14). Intense absorptions in the range 200–300 nm are also observed for these species (5) and have been assigned to metal–ligand charge transfer. This description may also be applied to the Ni(III) $(LL)_3^{3+}$ complex ions. For example, the $Ni(bipy)_3^{3+}$ ion shows maxima at wavelengths ($\varepsilon >$ 10^4 $M^{-1}cm^{-1}$) at 225 nm, 267 nm, and 292 nm in CH_3CN, associated with the ligand system. In the range λ = 300–450 nm, in both CH_3CN and 4.0 M $HClO_4$, increased absorbance of the Ni(III) complexes over the Ni(II) species was observed. In Fig. 3 the characteristic absorbance of nickel(III) ($Ni(bipy)_3^{3+}$ in CH_3CN is presented with evidence for the weak transition at ~620 nm (ε = 275 ± 25 $M^{-1}cm^{-1}$). The corresponding spectrum of $Ni(bipy)_3^{3+}$ in 4.0 M $HClO_4$ agrees with that of Wells and co-workers (11) in 2 M acid. The measured extinction coefficient at 350 nm, 5300 ± 300 $M^{-1}cm^{-1}$ may be compared with an interpolated value of ~6000 $M^{-1}cm^{-1}$ (ref. 11). A similar value at 350 nm (ε = 6020 ± 300 $M^{-1}cm^{-1}$) is observed in acetonitrile. For $Ni(III)(phen)_3^{3+}$ the high wavelength transition (λ = 620 nm) has been confirmed in 5.0 M $HClO_4$.

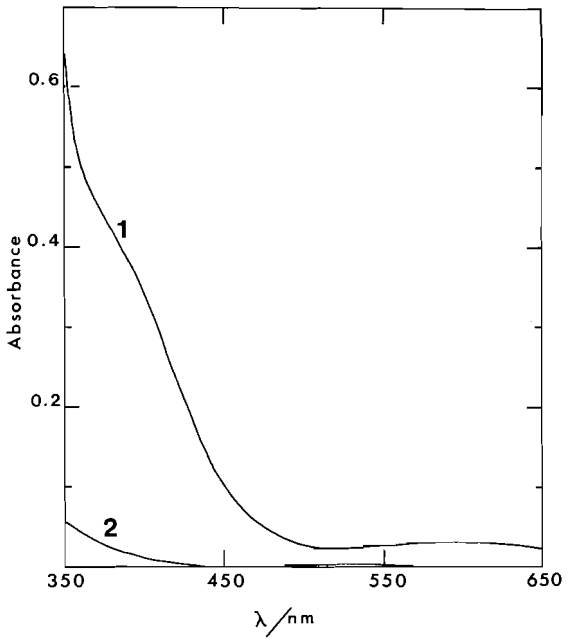

FIG. 3. Ultraviolet–visible spectra of $Ni(bipy)_3^{2+/3+}$ complexes in CH_3CN; (1) 1.2 × 10^{-4} M $Ni(bipy)_3^{3+}$ containing 1 × 10^{-4} M $Ni(bipy)_3^{2+}$, (2) solution (1) reduced to $Ni(II)(bipy)_3^{2+}$.

Previous kinetic measurements were made at 350 nm where interference from Ni(II) is negligible. Solutions of Ni(III) (prepared from the solid form) were reacted against various concentrations of either hydroquinone (H_2Q) or iodide. Spectrophotometric titrations confirmed the reaction stoichiometries:

$$2Ni(LL)_3^{3+} + H_2Q \rightarrow 2Ni(LL)_3^{2-} + Q + 2H^+$$

and

$$2Ni(LL)_3^{3+} + 3I^- \rightarrow 2Ni(LL)_3^{2+} + I_3^-$$

Concentrations of nickel(III) solutions prepared electrolytically were confirmed using such reactions and spectra and extinction coefficients (to ±6%) derived using solutions diluted from these stocks. The increased stability of solutions of these complexes in anhydrous CH_3CN was confirmed by the very small changes in absorbance (<1–2%) over two–three week periods when stored in the dark at 0°C compared with the aqueous media where reduction occurred over a matter of hours.

The outer-sphere nature of the redox reactions of $Ni(bipy)_3^{3+}$ has been demonstrated in aqueous perchloric acid solutions (10, 11), in reactions with H_2O_2, HN_3, and Br^-. Preliminary results of studies with metal ion reductants confirm these observations. The oxidation of $Ni^{II}(cyclam)^{2+}$ (~10^{-4} M) by $Ni(bipy)_3^{3+}$ in 1.5 M $HClO_4$ is too fast for measurement in the stopped-flow system (ΔE^0 ~ 0.75 V), whereas the reaction with Ce^{3+} under the same conditions (ΔE^0 < 0.1 V) is much slower ($t_{\frac{1}{2}}$ ~ 200 s). In the reaction of $Fe(phen)_3^{2+}$ with $Ni(bipy)_3^{3+}$ in 1.0 M H_2SO_4, ($\Delta E^0 \approx$ 0.6 V) the second order rate constant is ~10^5 $M^{-1}s^{-1}$. These redox processes are at present being studied.

In nonaqueous media, a parallel chemistry with a

similar reaction mechanism may be investigated. In these media, oxidation of Cu(I), Tl(I), hydroquinone, and I^- are all observed. Also, the powerful oxidizing nature of the species is confirmed in the transient formation of the radical cation from the polynuclear aromatic perylene (21). Further work on these systems is in progress.

SCOTT D. TANNER, GERVASE I. MACKAY, and DIETHARD K. BOHME. Can. J. Chem. **59**, 1615 (1981).

Flowing afterglow measurements are reported which provide rate constants and product identifications at 298 ± 2 K for the gas-phase reactions of OH^- with CH_3OH, C_2H_5OH, CH_3OCH_3, CH_2O, CH_3CHO, CH_3COCH_3, CH_2CO, HCOOH, $HCOOCH_3$, $CH_2{=}C{=}CH_2$, $CH_3{-}C{\equiv}CH$, and $C_6H_5CH_3$. The main channels observed were proton transfer and solvation of the OH^-. Hydration with one molecule of H_2O was observed either to reduce the rate slightly and lead to products which are the hydrated analogues of the "nude" reaction, or to stop the reaction completely, $k \leq 10^{-12}$ cm^3 molecule^{-1} s^{-1}. The reaction of $OH^-{\cdot}H_2O$ with $CH_3{-}C{\equiv}CH$ showed an uncertain intermediate behaviour.

SCOTT D. TANNER, GERVASE I. MACKAY et DIETHARD K. BOHME. Can. J. Chem. **59**, 1615 (1981).

On rapporte des mesures avec la technique de la lueur d'écoulement qui permettent d'obtenir les constantes de vitesse et d'identifier les produits des réactions en phase gazeuse à 298 ± 2 K de l'ion OH^- avec CH_3OH, C_2H_5OH, CH_3OCH_3, CH_2O, CH_3CHO, CH_3COCH_3, CH_2CO, HCOOH, CH_3COOH, $CH_2{=}C{=}CH_2$, $CH_3{-}C{\equiv}CH$ et $C_6H_5CH_3$. Les principales voies observées sont celles du transfert du proton et de la solvatation du OH^-. On a observé que l'hydratation par une molécule d'eau provoque soit l'arrêt complet de la réaction, $k \leq 10^{-12}$ cm^3 molécule^{-1} s^{-1}, soit une légère réduction de la vitesse avec la formation de produits qui sont les analogues hydratés de la réaction "nue". La réaction entre $OH^-{\cdot}H_2O$ et $CH_3{-}C{\equiv}CH$ présente un comportement incertain de l'intermédiaire.

[Traduit par le journal]

Introduction

The hydroxide anion is a relatively strong base in the gas phase where it can be readily generated in a variety of ways. Consequently it is often implicated in the chemical evolution of negative ions in electronegative plasmas such as hydrocarbon flames (1) and planetary ionospheres (2). One important practical consequence of the reactivity and ease of production of OH^- has been its use in negative chemical ionization mass spectrometry (3). While certain qualitative aspects of the gas-phase reactivity of OH^- have been well documented in the literature, only a few quantitative studies have been reported so far. Here we present an extensive flowing afterglow study of the kinetics and mechanisms of reactions of OH^- with a variety of oxygen-containing hydrocarbons, allene, propyne, and toluene. The results complement our earlier flowing afterglow studies of reactions of OH^- with olefins (4, 5), acetylene (6), simple cyanides (7), nitromethane (8), silane (9), and halogenated methanes (10), and therefore serve to extend our understanding of the intrinsic reactivity patterns of this ion. As such they also provide a benchmark for the reactivity of OH^- in solution where its basicity is much depressed as a result of solvation. An attempt is also made in this study to begin to explore the influence of hydration on the intrinsic reactivity of this ion.

Experimental

The measurements were carried out in a conventional flowing plasma mass spectrometer (flowing afterglow) system which has been described previously (11). The OH^- and $OH^-{\cdot}H_2O$ ions were established by introducing water vapor past the electron gun in either a flowing helium or hydrogen plasma. In certain instances, to avoid the presence of water vapor, OH^- was produced by the reaction of O^- with CH_4 with O_2 serving as the source gas for O^-.

The reactant neutrals were added into the reaction region either in their pure form or diluted with helium. The determination of their flows required separate viscosity measurements as has been described (12). The sources of most of the neutral reactants and their purities have also been given previously (13). The allene, propyne, and toluene were of normal research grade. Rate constants were determined in the usual manner from measurements of the $m/e = 17$ and $m/e = 35$ signals as a function of added reactant. The contribution due to $^{35}Cl^-$ was subtracted to arrive at the true $OH^-{\cdot}H_2O$ signal. The magnitude of $^{35}Cl^-$ was derived from the 37 isotope which was monitored concomitantly with product ions. The operating conditions in these experiments encompassed total gas pressures, P, in the range 0.20 to 0.53 Torr, average gas velocities, $\bar{v}$, from 7.3 to 8.0 × 10^3 cm s^{-1}, effective reaction lengths, L, between 45 and 125 cm, and a gas temperature, T, of 298 ± 2 K.

Results and Discussion

The results of the measurements are summarized in Tables 1 and 2. The sources of uncertainty associated with the determination of the rate constants have been described previously (11). Initial measurements of the charge transfer reaction:

$OH^-\cdot H_2O + C_6H_5CH_3 \rightarrow$ products	$\lesssim$ 0.001

[a] The measured rate constant along with the estimated uncertainty in units of 10^{-9} cm^3 molecule^{-1} s^{-1}.

provided a rate constant of $(1.1 \pm 0.4) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} in exact agreement with the accepted value (14). The following section provides a more detailed account of the observed hydroxide ion chemistry.

CH_3OH, C_2H_5OH, CH_3OCH_3

The reaction with CH_3OH was investigated over a wide range in total gas pressure (0.307 to 0.52 Torr) and effective reaction length (59, 85, and 120 cm). Also the flow of H_2O was varied over a large range from 7.8×10^{16} to 9.3×10^{19} molecules^{-1} s^{-1} in an attempt to drive reaction [2] to equilibrium:

[2] $OH^- + CH_3OH \rightleftharpoons CH_3O^- + H_2O$

Proton transfer was the only observed reaction channel and k_2 was determined to be $(2.2 \pm 0.6) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. Significant amounts of reverse reaction, as manifested by curvature in the decay of OH^-, became apparent only at the highest additions of H_2O ($>10^{19}$ molecules s^{-1}) and the long reaction lengths ($L > 85$ cm). However, under these relatively extreme conditions, a variety of competing and secondary reactions came into play as both the OH^- and CH_3O^- were observed to cluster with H_2O (up to $OH^-\cdot 3H_2O$) and CH_3OH (up to $CH_3O^-\cdot CH_3OH$), respectively. Also, the observation of mixed cluster ions of the type $CH_3O^-\cdot nH_2O$ ($n = 1$ to 3) and $CH_3O^-\cdot H_2O\cdot CH_3OH$ was indicative of some interconversion between cluster ions. These complicating reactions apparently prevented the establishment of equilibrium for the unsolvated reaction [2]. The ratio of the rate constants, k_2/k_{-2}, determined from our usual fitting procedure (11) was strongly dependent on the H_2O concentration as were the mass discrimination plots which exhibited strong curvature. Also, the ratio plots were observed to be curved for all additions of CH_3OH. Such a behaviour is expected for a reaction with a large equilibrium constant proceeding in the presence of secondary reactions. Indeed, available thermochemical information indicates a very large value for K_2 of $(2.2 \pm 0.4) \times 10^7$

(15). Equilibrium did appear to be established between several of the cluster ions as we have recently reported in a study which followed the transition in the relative acidity of water and methanol, viz. the magnitude of K_2, from the completely unsolvated behaviour in the gas phase to that in solution.

The proton-transfer reaction of OH^- with ethanol was also observed to proceed rapidly at room temperature.

[3] $OH^- + C_2H_5OH \rightarrow C_2H_5O^- + H_2O$

with $k_3 = (2.7 \pm 0.8) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. Equilibrium could again not be achieved under the available operating conditions. Solvation with one molecule of water reduced the reactivity of the hydroxide ion only slightly. The rate constant for the hydrated proton transfer [4] was

[4] $OH^-\cdot H_2O + C_2H_5OH \rightarrow C_2H_5O^-\cdot H_2O + H_2O$

measured to be $(2.1 \pm 0.5) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. The hydrated product ion was readily observed. Formation of "nude" $C_2H_5O^-$ is endothermic since the 25 kcal mol^{-1} of hydration energy for OH^- (16) exceeds the 10 kcal mol^{-1} of exothermicity for reaction [4] (17).

Dimethyl ether failed to react with OH^-, $k < 10^{-12}$ cm^3 molecule^{-1} s^{-1}. The failure to observe proton transfer in this case is a manifestation of the low gas-phase acidity of dimethyl ether.

CH_2O, CH_3CHO, CH_3COCH_3

Formaldehyde was observed to react quite rapidly with OH^-, but not by proton transfer; an ion with mass 47 was produced instead. Apparently an association reaction was taking place but with an unexpectedly large rate. At the total pressure of the measurements (0.56 Torr) the observed OH^- decay was equivalent to a three-body rate constant of $(2 \pm 1) \times 10^{-26}$ cm^6 molecule^{-2} s^{-1}. This value is much larger than those expected for association reactions involving a similar number of atoms in which a "loose" adduct is formed through electrostatic interaction or proton bonding. Therefore it has been taken as a manifestation of the formation of a "tight" adduct through chemical bonding to a tetrahedrally coordinated carbon atom (18):

[5] $OH^- + C{=}O \rightarrow [HO{-}C{-}O^-]^* \xrightarrow{He} H_2C(O^-)(OH)$

Formation of the conjugate base of methyl peroxide, $CH_3O_2^-$, would require extensive chemical redisposition and so is not expected to occur efficiently. We have observed a similar addition of hydride and methoxide to formaldehyde (18).

Acetaldehyde and acetone were both observed to react rapidly with OH^- by proton transfer (see Table 1). Deuterium-labeling experiments have established previously that acetaldehyde loses the proton from the methyl position (19). Figure 1 shows a representative result obtained with acetaldehyde. Solvation with a single water molecule was seen to leave the reactivity of OH^- essentially unchanged. Since the singly-hydrated product ions were observed, we may write:

[6] $OH^-\cdot H_2O + CH_3CHO \rightarrow {}^-CH_2CHO\cdot H_2O + H_2O$

[7] $OH^-\cdot H_2O + CH_3COCH_3 \rightarrow CH_3COCH_2^-\cdot H_2O + H_2O$

Both of these reactions were measured to proceed with a rate constant of $(3 \pm 1) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}.

CH_2CO

Ketene was observed to react rapidly with the hydroxide ion with $k = (2.2 \pm 0.5) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} to form a mass 41 ion for which the following resonance structure may be written

[8] $H{-}\bar{C}{=}C{=}O \leftrightarrow H{-}C{\equiv}C{-}O^-$

Figure 2 shows the formation of a secondary product ion with mass 39. The HC_2O^- apparently was being consumed further by reaction with ketene to produce $C_3H_3^-$ for which the following

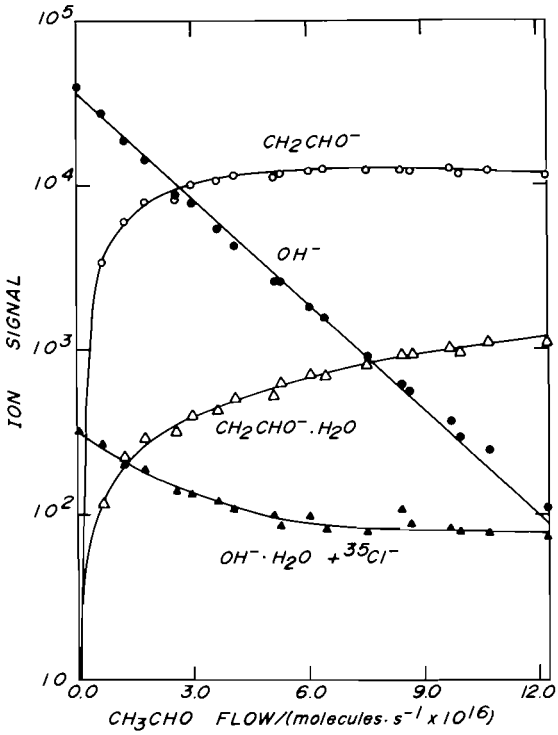

FIG. 1. The observed variation in the dominant ion signals recorded upon the addition of acetaldehyde into a flowing H_2/H_2O plasma; $T = 298$ K, $P = 0.312$ Torr, $\bar{v} = 7.8 \times 10^3$ cm s^{-1}, and $L = 84$ cm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

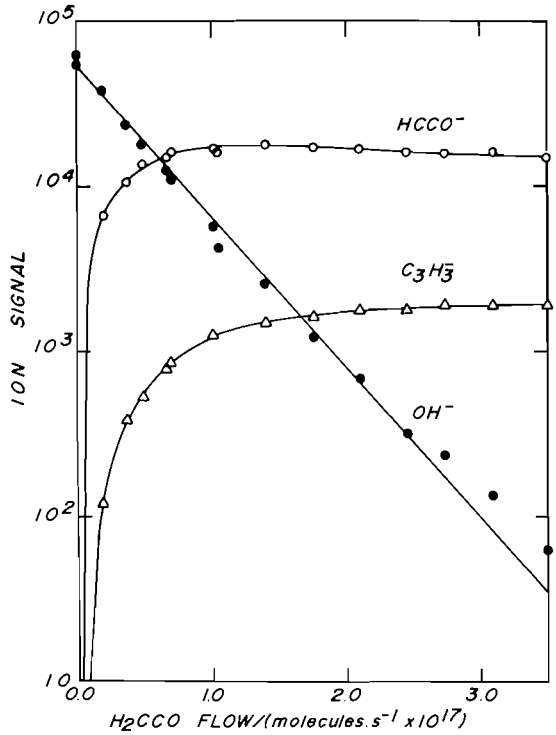

FIG. 2. The observed variation in the dominant ion signals recorded upon the addition of ketene into a flowing H_2/H_2O plasma; T = 298 K, P = 0.301 Torr, $\bar{v}$ = 7.9 × 10^3 cm s^{-1}, and L = 59 cm.

resonance structures may be written:

[9] $H—\bar{C}=C=CH_2 \leftrightarrow H—C\equiv C—\bar{C}H_2$

The mechanism of this latter reaction presumably involves the formation of a four-centered intermediate which fragments to eliminate CO_2:

[10] 
The $C_3H_3^-$ in turn appeared to react further with ketene to regenerate the HC_2O^- by proton transfer,

[11] $C_3H_3^- + H_2C_2O \rightarrow HC_2O^- + C_3H_4$

This reaction, together with the previous reaction which produces $C_3H_3^-$, represents an ion-catalyzed reaction scheme for the conversion of ketene into CO_2 and C_3H_4,

[12] $H_2C_2O + H_2C_2O \rightarrow CO_2 + C_3H_4$

The overall exothermicity of reaction [12] is 18.9 kcal mol^{-1} for the formation of allene. An analysis of the steady-state ion abundance ratio for $HC_2O^-/C_3H_3^-$ indicated a value for the ratio of rate constants k_{11}/k_{10} approximately = 10.

HCOOH

The analysis of the formic acid data also indicated a high rate, k = (2.2 ± 0.7) × 10^{-9} cm^3 $molecule^{-1}$ s^{-1}, but with only 0.75 ± 0.05 of the reactive collisions leading to the proton-transfer product, HCO_2^-. The remaining 0.25 ± 0.05 of the collisions gave rise directly (in a bimolecular fashion) to singly-hydrated OH^-,

[13*a*] $OH^- + HCOOH \rightarrow HCO_2^- + H_2O$

[13*b*] $\rightarrow OH^-\cdot H_2O + CO$

For the experimental results shown in Fig. 3, the reactant OH^- was produced by the reaction of O^- with CH_4 to eliminate all but impurity H_2O and so to minimize the direct association of OH^- with H_2O. The initial signal at mass 35 was entirely accounted for under these conditions by the chlorine isotope, $^{35}Cl^-$. The change in this signal with

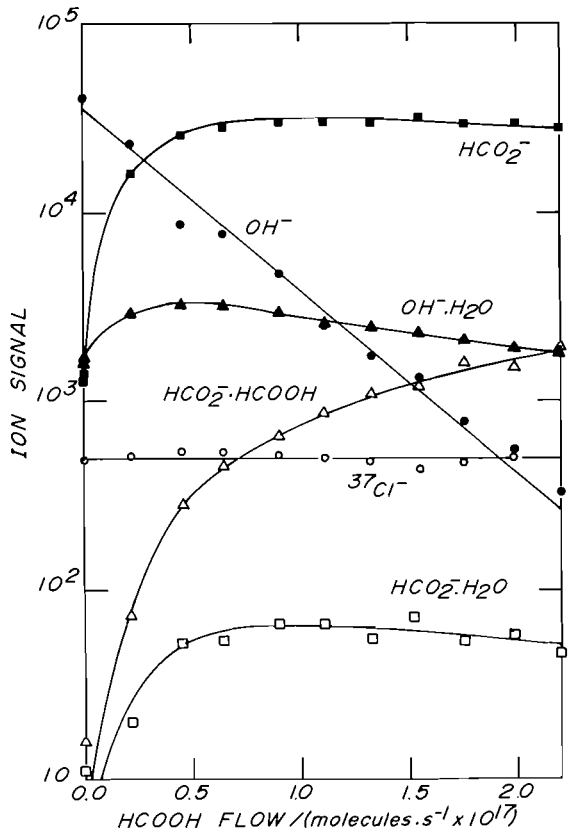

FIG. 3. The observed variation in the dominant ion signals recorded upon the addition of formic acid into a flowing $He/O_2/CH_4$ plasma; T = 301 K, P = 0.450 Torr, $\bar{v}$ = 8.4 × 10^3 cm s^{-1}, and L = 47 cm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

addition of formic acid could then be attributed entirely to the bimolecular formation of $OH^-\cdot H_2O$ and its subsequent reaction. The channel leading to the formation of the cluster ion is rendered exothermic by the hydration energy of OH^-, 25 kcal mol^{-1} (16), without which it would be endothermic by 6 kcal mol^{-1} (16). Its mechanism may involve a nearly concerted loss of CO and capture of the water molecule by the OH^-:

[14] $OH^- + HCOOH \longrightarrow$ 
$H_2O\cdot OH^- + CO$

The products of the reaction of the cluster ion were not established with certainty. They may include the following:

[15*a*] $OH^-\cdot H_2O + HCOOH \rightarrow HCO_2^- + 2H_2O$

[15*b*] $\rightarrow HCO_2^-\cdot H_2O + H_2O$

[15*c*] $\rightarrow OH^-\cdot 2H_2O + CO$

Channel [15*a*] was masked by the production of HCO_2^- from "nude" OH^-. Channel [15*c*] is the analogue of channel [13*b*]. The $OH^-\cdot 2H_2O$ was observed above the background only in those experiments in which the initial OH^- was produced from H_2O and higher signals of $OH^-\cdot H_2O$ were present initially. Channel [15*b*] was observed only in depressed amounts due to a secondary "solvent switching" reaction with HCOOH:

[16] $HCO_2^-\cdot H_2O + HCOOH \rightarrow HCO_2^-\cdot HCOOH + H_2O$

The reactivity of the nude hydroxide ion is reminiscent of the behaviour reported previously by Isolani and Riveros (20) in their ICR study of analogous reactions of negative ions with esters of formic acid. In the next section we report a study of the reaction of OH^- with the first member of this homologous series, methyl formate.

$HCOOCH_3$

Two main products were observed in the ICR studies of the reaction on OH^- with methyl formate at water pressures of 5×10^{-5} Torr (21):

[17*a*] $OH^- + HCOOCH_3 \rightarrow HCO_2^- + CH_3OH$

[17*b*] $\rightarrow CH_3O^-\cdot H_2O + CO$

The rate constant k_{17} and branching ratio [17*a*]/[17*b*] were reported to be 1.5×10^{-9} cm^3 $molecule^{-1}$ s^{-1} and 0.80, respectively. The results of the flowing afterglow measurements for this reaction are virtually identical: $k_{17} = 1.9 \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1} and [17*a*]/[17*b*] = 1.0 ± 0.2 for the measurements carried out with and without added water vapour. The $CH_3O^-\cdot H_2O$ product rapidly reacted further, $k > 9 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}, apparently to produce an ion at $m/e = 63$, presumably $CH_3O^-\cdot CH_3OH$, which is known to be formed from the "nude" CH_3O^- (22). The mechanism of reaction [17] has been reviewed by Nibbering (23).

The singly-hydrated OH^- appeared to react in a fashion analogous to the bare ion. The reaction was rapid, $k = (1.6 \pm 0.5) \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}, and ions were observed to be produced which correspond to the singly-hydrated counterparts of the products of reaction [17]:

[18*a*] $OH^-\cdot H_2O + HCOOCH_3 \rightarrow CH_3O^-\cdot 2H_2O + CO$

[18*b*] $\rightarrow HCO_2^-\cdot H_2O + CH_3OH$

The assignment of the latter product ion was ambiguous since it has the same mass as the $CH_3O^-\cdot CH_3OH$ believed to be produced by $CH_3O^-\cdot H_2O$. In contrast, the second hydrate, $OH^-\cdot 2H_2O$, reacted in a much slower fashion, $k < 3 \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1}.

C_3H_4

Both allene and propyne were observed to lose a proton to OH^-. The rate constant measured for the reaction with allene

[19] $OH^- + CH_2{=}C{=}CH_2 \rightarrow CH_2{=}C{=}CH^- + H_2O$

was $(1.7 \pm 0.4) \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}, which exceeds an earlier value of $(7.5 \pm 2.3) \times 10^{-10}$ cm^3 $molecule^{-1}$ s^{-1} (4). The reaction with propyne

[20*a*] $OH^- + CH_3{-}C{\equiv}CH \rightarrow {}^-CH_2{-}C{\equiv}CH + H_2O$

[20*b*] $\rightarrow CH_3{-}C{\equiv}C^- + H_2O$

was observed to be equally rapid with $k = (1.7 \pm 0.3) \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}. Previous deuterium-labelling experiments (19) have shown that ≥ 60% of the deprotonation of propyne initially produces $^-CH_2{-}C{\equiv}CH$ which may relax to the more stable allenyl anion, $CH_2{=}C{=}CH^-$ (24). The allenyl anion is computed to be less stable than $CH_3{-}C{\equiv}C^-$ but the profile for this interconversion shows a high energy barrier (25). We have probed the relative reactivity of the $C_3H_3^-$ ions produced from allene and propyne in a separate study (25). The observed relative reactivity with methyl formate suggested that only 10 ± 5% of the deprotonation of propyne in fact occurs at the C≡CH position. Nonempirical molecular orbital calculations predict that the acetylenic proton is slightly more acidic than the proton at the methyl position (26). Such an order of acidity would imply that the deprotonation observed experimentally is controlled kinetically rather than thermodynamic-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

ally. Indeed, on the basis of the electrostatic interaction during a collision of OH^- with polar propyne, deprotonation by OH^- can be expected to proceed preferentially at the positive methyl end of propyne.

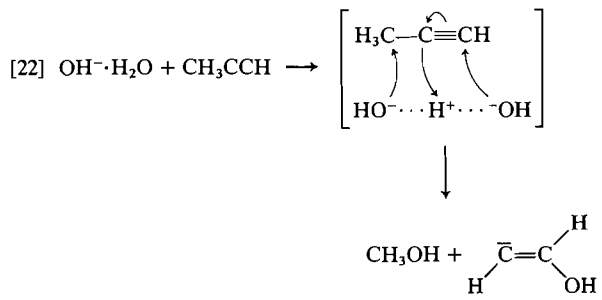
Hydration of OH^- stops the reaction with allene, $k \leq 10^{-12}$ cm^3 molecule^{-1} s^{-1}. Apparently the exothermicity of the bare reaction, together with the hydration energy of the $C_3H_3^-$, is insufficient to compensate for the 25 kcal mol^{-1} of hydration energy of OH^-. The reaction of $OH^-\cdot H_2O$ with propyne showed the more surprising result given in Fig. 4. A slow decay is observed with addition of propyne which corresponds to a rate constant of $(5.8 \pm 2.3) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}. An ion with $m/e = 43$ rises concomitantly, in part due to the association of C_2H^- with H_2O. A number of options are allowed by stoichiometry, for example:

$$[21a]\quad OH^-\cdot H_2O + CH_3CCH \rightarrow C_3H_7^- + O_2$$

$$[21b]\quad \rightarrow C_2H^-\cdot H_2O + CH_3OH$$

$$[21c]\quad \rightarrow {}^-CH_2CHO + CH_3OH$$

Channel [21*a*] is unattractive on both energetic and mechanistic grounds. Channel [21*b*] corresponds to a hydrated nucleophilic displacement reaction which is probably endothermic because of the endothermicity of the bare reaction and the high hydration energy of OH^-. However, separate experiments have shown that C_2H^- hydrates with a three-body association rate constant similar in magnitude to that for the hydration of OH^-. This result suggests that the two hydration energies may be similar, at least to the extent that these rate constants correlate with the stability of the associated species (18). The slow reaction observed would be consistent with a hydrated nucleophilic displacement reaction endothermic by 2 kcal mol^{-1}. Channel [21*c*] is exothermic but would require an unlikely reaction mechanism. A fourth option might involve the formation of an enol type ion such as $HOCHCH^-$ which is isomeric with the $C_2H^-\cdot H_2O$ cluster ion and ${}^-CH_2CHO$, the conjugate base of acetaldehyde. The enol anion might result from a 1,3 nucleophilic attack in the following manner:



The stability of this ion is likely to fall in between the lower stability of $C_2H^-\cdot H_2O$ and the higher stability of ${}^-CH_2CHO$. Consequently its formation may well be exothermic.

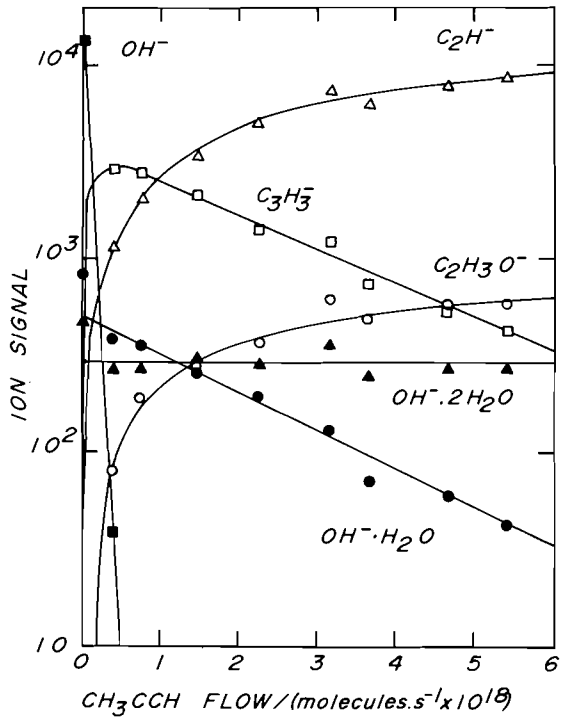


FIG. 4. The observed variation in the dominant ion signals recorded upon the addition of propyne into a flowing H_2/H_2O plasma; $T = 296$ K, $P = 0.354$ Torr, $\bar{v} = 7.6 \times 10^3$ cm s^{-1}, and $L = 46$ cm.

$C_6H_5CH_3$, $C_6H_5CH_2D$

The proton transfer from toluene to the bare hydroxide ion was also observed to be rapid, $k = (2.6 \pm 0.6) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. Deuteration at one of the methyl positions failed to reveal an isotope effect; the new rate constant was measured to be $(2.8 \pm 0.7) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. Furthermore, in those experiments in which OH^- was produced from O^- and CH_4 in the absence of added water vapour in helium buffer, the branching ratio [23*a*]/[23*b*] was observed to be 0.5 ± 0.1:

$$[23a]\quad OH^- + C_6H_5CH_2D \rightarrow C_6H_5CH_2^- + HOD$$

$$[23b]\quad \rightarrow C_6H_5CHD^- + HOH$$

The implication of this result is that the proton transfer proceeds in a direct fashion rather than through a long-lived complex for which complete scrambling would produce a branching ratio of 1.0 rather than 0.5. In those experiments in which OH^- was derived from water vapour the observed product ion ratio $[C_6H_5CH_2^-]/[C_6H_5CHD^-]$ was a

For personal use only.

function of the added water vapour, becoming as large as 11 at the highest additions. This was interpreted to reflect a rapid H/D exchange between H_2O and $C_6H_5CHD^-$. Stewart *et al.* have previously reported that $C_6H_5CH_2^-$ will exchange two hydrogen atoms in the presence of D_2O (19).

Several unsuccessful attempts were made with additions of water vapour as large as 4.2×10^{19} molecules s^{-1} at a reaction length of 125 cm to drive to equilibrium the reaction

[24] $OH^- + C_6H_5CH_3 \rightarrow C_6H_5CH_2^- + H_2O$

We can report only a limit to the equilibrium constant of $K \geq 3 \times 10^5$.

Summary

The bare hydroxide ion has been observed to react rapidly, $k > 10^{-9}$ cm^3 molecule^{-1} s^{-1}, by proton transfer, with a variety of oxygen and carbon acids stronger than H_2O in the gas phase. With formic acid and methyl formate the proton transfer competes with the formation of a solvated hydroxide ion.

Hydration of the bare ion with one molecule of water was observed to result in either a slightly or a considerably reduced reactivity depending on the nature of the acid and the exothermicity of the bare reaction. The reactivity remains high when the hydration energy of the conjugate base produced is comparable to that of OH^-, or the exothermicity of the "nude" reaction is correspondingly high. The products are then also analogous to those observed for the "nude" reaction. Such was the case with the observed reactions of OH^- with C_2H_5OH, CH_3CHO, HCOOH, and $HCOOCH_3$. For the reactions with allene, propyne, and toluene, proton transfer was closed to the hydrated OH^- in the gas phase. Apparently the hydration energy of the carbanions produced in these cases is not sufficient to compensate for the high hydration energy of OH^- so that the acidity of the conjugate acids relative to that of H_2O has been reversed. The reaction with propyne showed an uncertain intermediate behaviour. The reduced reactivity in this case may be associated with a change in mechanism with solvation from proton transfer to hydrated displacement.

Crystallographic studies and physico-chemical properties of π-electron compounds. Part I. Crystal and molecular structure of 6-*N*,*N*-diacetylaminochrysene (DAAC)

TADEUSZ WIĘCKOWSKI AND TADEUSZ M. KRYGOWSKI

Department of Chemistry, University of Warsaw, 02093 Warsaw, ul. Pasteura 1, Poland

Received August 1, 1980

TADEUSZ WIĘCKOWSKI and TADEUSZ M. KRYGOWSKI. Can. J. Chem. **59**, 1622 (1981).

The molecules of 6-*N*,*N*-diacetylaminochrysene, $C_{22}H_{17}NO_2$, crystallize in orthorhombic space group *Pbca* with $a = 15.120(1)$ Å, $b = 7.8706(9)$ Å, and $c = 28.504(2)$ Å, $Z = 8$, $V = 3392.3(6)$ Å^3, $D_x = 1.28$ g cm^{-1}. The structure was essentially solved by direct phase determination with assistance of Fourier and difference Fourier maps and finally was refined to $R = 0.050$ for 2320 reflections. The DAA-group is almost perpendicular to the plane of chrysene moiety. The simple harmonic oscillator model for calculating the stabilization energy of π-electron systems by means of negative value of energy deformation necessary to transform the real molecule (or its fragments) to its Kekulé structure is presented. It shows high delocalization of π-electrons in both independent π-electron systems of DAAC molecule: the DAA-group and the chrysene moiety.

TADEUSZ WIĘCKOWSKI et TADEUSZ M. KRYGOWSKI. Can. J. Chem. **59**, 1622 (1981).

Les molécules de *N*,*N*-diacétylamino-6 chrysène, $C_{22}H_{17}NO_2$, cristallisent dans le groupe d'espace orthorhombique *Pbca* avec $a = 15,120(1)$ Å, $b = 7,8706(9)$ Å et $c = 28,504(2)$ Å, $Z = 8$, $V = 3392,3(6)$ Å^3, $D_x = 1,28$ g cm^{-1}. On a résolu la structure essentiellement par la détermination directe de la phase en s'appuyant sur des diagrammes et des différences de diagrammes de Fourier et on l'a affinée jusqu'à une valeur de $R = 0,050$ pour 2320 réflexions. Le groupe DAA est presque perpendiculaire au plan de la portion chrysène. On présente le modèle d'oscillation harmonique simple pour le calcul de l'énergie de stabilisation du système d'électrons π au moyen de la valeur négative de l'énergie de déformation nécessaire pour transformer la molécule réelle (ou son fragment) en sa structure de Kékulé. Il révèle une forte délocalisation des électrons π dans les deux systèmes indépendants d'électrons π de la molécule DAAC: le groupe DAA et le noyau chrysène.

[Traduit par le journal]

Crystal and molecular structure of benzenoid hydrocarbons and some of their derivatives has long been studied by means of various diffraction techniques (1–4). Chrysene (5) and its derivatives (6–8) have often been studied for their possible carcinogenic properties. 6-*N*,*N*-Diacetylaminochrysene DAAC is supposed to be also carcinogenic (9) and additionally in its molecule one may find two interesting features: (*i*) interference between two π-electron systems, i.e. chrysene moiety and *N*,*N*-diacetylamine-group (DAA), and (*ii*) a considerable overcrowding of hydrogen atoms in the chrysene moiety as well as of some fragments in the DAA-group. The above mentioned problems are discussed in this paper on the basis of full X-ray diffraction studies of DAAC-crystals.

Experimental

Preparation and Crystallization

A solution of 6-aminochrysene in acetic anhydride was refluxed for 2 h, cooled somewhat, and diluted to cloudiness with water. 6-*N*,*N*-Diacetylaminochrysene was separated in the shape of glistening tan needles. A sample for analysis, recrystallized twice from benzene – petroleum ether mixtures, using decolorizing carbon, formed large colorless prisms, mp 222.5–223.5°C. *Anal.* calcd. for $C_{22}H_{17}NO_2$: C 80.71, H 5.24, N 4.28; found: C 80.80, H 5.18, N 4.26%.

Optical Properties

The refraction coefficients were measured by applying the immersion method by Berek's (Leitz) microrefractometer in Na-light at 20°C. The coefficients $n\alpha_D$ and $n\beta_D$ were determined in the mixture of 1-bromonapththalene and petroleum and were equal to 1.609 ± 0.001 and 1.658 ± 0.001, respectively. The coefficient $n\gamma_D$ was determined in methylene iodide with addition of small amounts of sulphur and phosphorus and was equal to 1.867 ± 0.001. The microrefractometer was adjusted by use of Jolley's refractometer and testing plates. The angle between optical axes, $2V_\gamma$, was measured applying the conoscope method in the Waldmann's sphere in which the crystal was mounted, and the sphere filled up with a fluid of refractive index $n\beta_D$. The $2V_\gamma$ quantity was calculated applying the measured refractive indices $n\alpha_D$, $n\beta_D$, and $n\gamma_D$ and the value obtained was 56°46′ whereas the measured quantity was 56±1°. The dihedral of the acute angle is directed to γ and hence the optical sign of the crystal is positive. The plane of optical axes is parallel to (100).

Crystallographic Measurements

Preliminary cell dimensions and the space group were determined from oscillation and Weissenberg photographs indicating that the crystal belongs to the orthorhombic system. For data collection a prismatic crystal, 0.31 × 0.31 × 0.35 mm, was mounted on a Syntex $P2_1$ four-circle computer-controlled diffractometer. X-Ray diffraction data were measured with graphite-monochromated CuKα radiation. Least-squares fitting of 2θ, ω, and χ for 15 intense reflections centred on a diffractometer gave accurate cell constants. Crystal data (at 20°C) are:

$C_{22}H_{17}NO_2$ fw = 327.37

Orthorhombic, $a = 15.120(1)$, $b = 7.8706(9)$, $c = 28.504(2)$ Å, $V = 3392.3(6)$ Å^3, $\rho_m = 1.28$ (flotation in aqueous KI), $Z = 8$, $\rho_c = 1.28$ g cm^{-3}, $F(000) = 1376$, $\mu(CuK\alpha) = 6.6$ cm^{-1}, $\lambda(CuK\alpha) = 1.54178$ Å, mp: 222.5–223.5°C. Absent reflections $0kl$, $k \neq 2n$; $h0l$, $l \neq 2n$; $hk0$, $h \neq 2n$. Space group *Pbca*. A variable-speed (2.01 to 29.30° min^{-1}) θ–2θ scan technique was used in measuring 2320 independent reflections to a maximum 2θ of 115.0°. 1606 reflections from the data set had $I > 1.960\sigma(I)$ and were used in

the analysis. Structure factors and normalized structure factors were derived from the intensities by application of the Lorentz-polarization corrections. The absorption and extinction corrections were negligible because of the low value of μ. The reflections were adjusted to an absolute scale by Wilson statistics; a Wilson plot (10) gave an overall isotropic temperature factor of 3.04 Å^2.

Structure Solution and Refinement

The structure was essentially solved by direct phase determination with the MULTAN system using 235 E's $\geq$ 1.58 for which 3768 Σ_2 relationships were generated. 16 phase sets were derived using one special and two general multisolution phases, and an E map with the highest combined figure of merit CFOM (2.990) obtained with the unit weight of ABSFOM (1.169) and RESID (21.75) gave initial coordinates for 24 out of 25 non-hydrogen atoms of the asymmetric unit. The missing C atom was easily located on Fourier and difference Fourier maps. Full-matrix least-squares refinement of all non-hydrogen atoms positional and isotropic thermal parameters converged at R = 0.133. The vibrational model was then changed to an anisotropic one and a similar least-squares refinement was attempted; R reduced to 0.101. The positional parameters of all the H atoms were found from two successive difference Fourier syntheses. The isotropic thermal factor for each H atom was fixed at 1.0 Å^2 greater than that for the C to which it is bounded. These H atoms contributions were included in the structure factor calculations but their positions and temperature factors were not refined. Three subsequent cycles of refinement gave agreement indices $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.050$ and $R_w = [\Sigma w(F_o - F_c)^2/\Sigma wF_o^2]^{1/2} = 0.046$. The quantity minimized in the least-squares calculations was $\Sigma w(|F_o| - |F_c|)^2$. The weighting scheme was based on counting statistics; $w = 1/\sigma^2(F_o)$. The final fractional coordinates and thermal parameter from the last cycle of the least-squares refinement for non-hydrogen and hydrogen atoms, respectively, are given in Tables 1, 2, and 3.[1]

All calculations were performed on a Nova minicomputer with the Syntex XTL programs for structure determination (11).

Results

The atom labelling scheme and the anisotropic thermal ellipsoids of the DAAC are shown in Fig. 1. Bond lengths and angles are listed in Tables 4*a* and 4*b*[1] whereas in Fig. 2 there are presented distances between non-bonded H-atoms, bond lengths, and displacements of atoms from the best plane for atoms: C5, C6, C7, C8, C9, C14, C15, C16, C17, C18. Table 5 gives the best planes for fixed sets of atoms and displacements of atoms from them, whereas Table 6 presents angles between the above mentioned planes. Table 7 presents the torsion angles for the DAA-fragment. Figures 3 and 4 present projections of the elementary cell contents on planes *ab* and *ac*, respectively.

Discussion

There are a few problems which seem to be more general and deserve a greater interest. The electronic properties of the *N*,*N*-diacetylamine group (DAA) need comment since as a result of the high delocalization of π-electrons in the group no tendency of conjugation between DAA group and chrysene moiety occurs. In order to tackle the problem of π-electron delocalization in DAA-group the HOSE (13) model is extended in this paper into the system with such bonds as CN and CCH_3. Another problem worth mentioning and deeper discussion here is the presence of very short and very long CC-bonds as well as the overcrowding of protons leading to non-planarity of the chrysene moiety.

(i) Extension of the Harmonic Oscillator Model of Calculating Stabilization Energy from Bond Lengths and Electronic Properties of the DAA-group

When the bonds of a real molecule are deformed to the lengths such as in the Kekulé structure of the molecule the deformation energy, E_{def}, may be calculated by means of applying a simple harmonic

[1]The structure factor table and Tables 2 (thermal parameters for non-H atoms), 3 (fractional coordinates and isotropic temperature factors for H-atoms), 4*b* (bond lengths and valency angles involving H-atoms), 5 (equations of the best planes and distances of individual atoms from them), 6 (angles between normals to planes), 7 (torsion angles) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

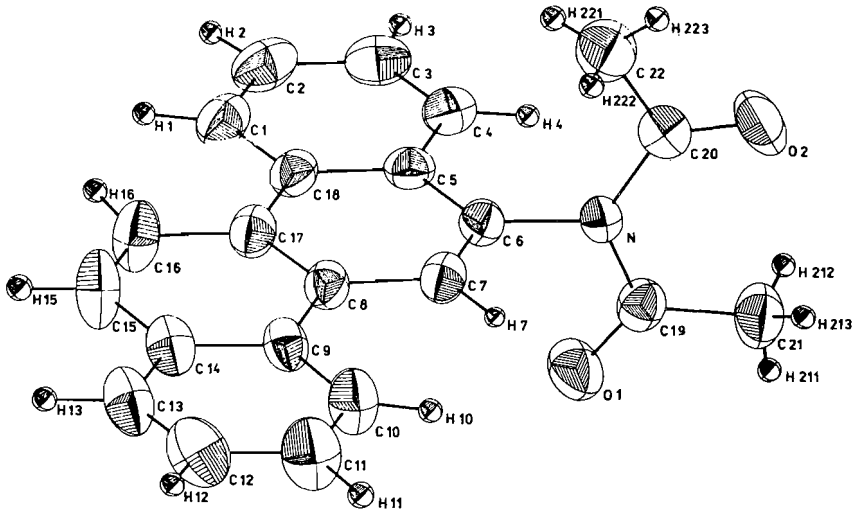

FIG. 1. Thermal ellipsoid plot (ORTEP, Johnson (12)) showing vibration ellipsoids at the 50% probability level.

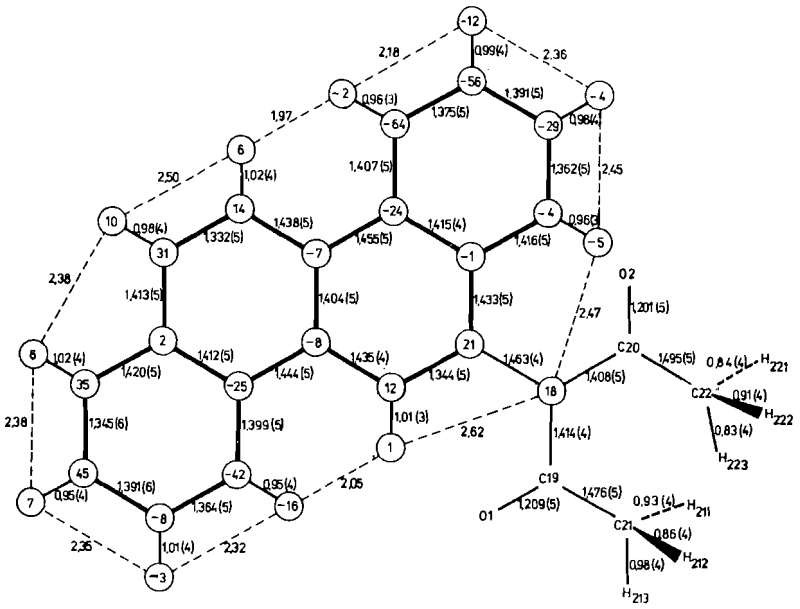

FIG. 2. Displacements of atoms from the best plane C5 through C9, C14 through C18 in circles. For non-hydrogen atoms × 10^3 Å, for hydrogen atoms × 10^2 Å. Bond lengths (Å) along bonds whereas distances (Å) between non-bonded hydrogen atoms are given along dotted lines.

oscillator model in the following way (13):

$$[1]\quad E_{\text{def}} = -\frac{1}{2}\left[\sum_{r=1}^{n_1}(R_r - R_r^0)^2 k_r' + \sum_{r=1}^{n_2}(R_r - R_r^0)^2 k_r''\right]$$

where R_r are the bond lengths in the real molecule, n_1 and n_2 are numbers of single and double bonds in the Kekulé structure, respectively. In the process of deformation the n_1 longest CC-bonds are lengthened and the n_2 shortest CC-bonds are shortened to the bond lengths R_r^0 for C—C and C=C, respectively. The R_r^0-values for C—C and C=C are adopted such as those in acyclic polyenes. In our case we have taken bond lengths for butadiene–1,3 (14). In the case of bonds other than CC the properly chosen reference bonds have to be used. These data for CC, CO, and CN bonds are collected in Table 8 together with appropriate force constants k for each of the single and double bonds. k' and k'' in eq. [1] are the force constants for bonds which are lengthened and shortened, respectively. Assuming reverse proportionality k_r against R_r as

given below:

[2] $k_r = a + bR_r$

and applying the data of Table 8 the sets of constants[2] were obtained: for CC-bond $a = 44.39$ and $b = -26.02$, for CN bond $a = 43.18$ and $b = -25.73$, and for CO bond $a = 52.35$ and $b = -32.88$. These constants permit the estimation of force constants k_r for a bond with a given bond length R_r.

Resonance energy (RE), is usually defined as an excess of energy over the additive sum of energy of a reference molecule calculated for the molecule with "purely" single and double bonds (for hydrocarbons these are C=C and C—C as in acylic polyenes), cf. refs. 21, 22. In the model proposed in this paper, the RE is approximated by the negative value of E_{def} calculated by use of the harmonic oscillator, and hence called stabilization energy, abbreviated HOSE (harmonic oscillator stabilization energy). It is the energy which must be applied to deform the real molecule to its Kekulé structure. Due to this energy the real molecule is more stable than its Kekulé structure. Combining eqs. [1] and [2] we may write the formula for HOSE in a convenient way for calculating:

[3] $$\text{HOSE} = C\left[\sum_{r=1}^{n_1}(a + bR_r')(R_r' - R_r^0)^2 + \sum_{r=1}^{n_2}(a + bR_r'')(R_r'' - R_r^0)^2\right]$$

where $C = 301.15$ is a constant converting HOSE's into kJ whereas the bond lengths are in Å, R_r' and R_r'' are the bond lengths for bonds shortened and lengthened in the process of deformation respectively.[3] There are n_1 bonds of the first kind, i.e. the number of single bonds in the Kekulé structure; n_2 is the number of double bonds (R'') in the Kekulé structure, a and b in [3] are constants as estimated by eq. [2] chosen dependent on the bond in question, and summations in [3] have to run over all the bonds of interest. It is important to know that [3] may be applied to fragments of π-electron systems as it has been done for the DAA-group. The HOSE-value for it, calculated from experimental bond lengths (Table 4*a*), results in 19.0 kJ,

TABLE 8. Bond lengths and appropriate force constants applied to get eq. [2]

Bond	Bond length (Å)	Stretching force constant (15) (dyn cm^{-1} × 10^5)
	1.337[a]	9.6
	1.533[b]	4.5
	1.208[c]	12.6
	1.428[d]	5.4
	1.270[e]	10.5

i.e. 2.7 kJ per one bond. If the CN-bond linking the DAA-group with the chrysene moiety is excluded from the calculation, the HOSE/bond value for DAA becomes still higher resulting in 3.1 kJ, the value which is not far from the HOSE/bond for the rings in chrysene. In Table 9 there are collected HOSE as well as HOSE/bond-values for some more familiar systems for the scale of comparison with the data for DAAC. From these data one derives that the substituted ring is somewhat destabilized in comparison with other rings in chrysene moiety. The same tendency is observed in the case of substituted benzenes for which the HOSE-values are lower than for their parent system, i.e. benzene itself.

In calculation of HOSE for DAA we have chosen R^0 for $\diagdown\!\!=\!\!\diagup C—CH_3$ equal to 1.510 Å, i.e. that estimated by electron diffraction studies for *trans*-butene-2 (16).

The results of the HOSE-model are in line with an independent description of DAA by means of inductive and resonance substituent constants. For the DAA-group these constants are (23) $\sigma_R = -0.04$ and $\sigma_I = 0.37$. Due to the opposite electron the properties of the N-atom in the amine group, $\sigma_R = -0.48$ and $\sigma_I = 0.12$, and in the acetyl groups, $\sigma_R = -0.16$ and $\sigma_I = 0.28$, a rather strong delocalization of π-electrons within the frame of the DAA-group may be expected. Hence its conjugation with the chrysene moiety may be low and it is chiefly an inductive effect of DAA that seems to operate. Thus it is not a surprise that the plane of the DAA-group is almost perpendicular to the plane of chrysene: the angle between them is 91.06°. As a result of the inductive effect of DAA on chrysene the valence angle at C_6 is 122.1° and remarkably higher than that observed for amine derivatives of benzene where $\alpha = 118.4°$ (24). It is quite comparable with the α value for nitro- or cyano-derivatives of benzene for which $\alpha = 122.1$ and 121.8° (24), respectively. The relationship between valence angle at the substituted carbon and the nature of the substituent may be discussed (25) in terms of Walsh's (26) rule. It implies an increase of the value of the endocyclic angle, at the substituted carbon with an increase of electronegativity of the substituent. Hence, the electronegativity of the DAA-group may be assumed to be close to that of CN- or NO_2-groups. This finding is also supported by the values of σ_I for these two groups which are 0.65 and 0.67, respectively in comparison with 0.37 for DAA.

Analyzing the bond lengths in the DAA-group the π-electron delocalization within the group is argued by: (*i*) the shortening of NC_{20} and NC_{19} bonds, which are 1.408 and 1.414 Å, respectively, in comparison with NC_6 bond length 1.463 Å which by no means is influenced by the mesomeric effect, (*ii*) $C_{19}C_{21}$ and $C_{20}C_{22}$ bond lengths are 1.476 Å and 1.495 Å, respectively, and they are distinctly shorter than $C—CH_3$ bond lengths in xylene (1.510 Å (27)) where the mesomeric effect seems to be much lower.

TABLE 9. HOSE-values for DAAC and its fragments. For comparison there are added HOSE's for several π-electron compounds

Compound	Hose (kJ)	HOSE/bond (kJ)
DAAC 	150.2	5.4
Chrysene moiety	131.2	6.2
Rings: 1	46.8	7.8
2	42.1	7.0
3	36.4	6.1
4	46.9	7.8
DAA-group	19.0	2.7
DAA-group without CN linkage	18.8	3.1
Benzene (13)	79.9	13.3
Anthracene (13)	103.5	6.5
Pyrene (13)	132.8	7.0
Chrysene (13)	164.4	7.8
p-N,N-Dimethylnitroaniline (13)	58.3	9.7
p-Nitrobenzoic acid (13)	77.2	12.9

(ii) Too Short and too Long CC-bonds and the Problems of Overcrowding

In the DAAC molecule there are both very short CC-bonds, 1.332 Å or 1.344 Å, and very long ones, 1.455 or 1.444 Å. Since the X-ray diffraction measurement for a CC bond in ethene yields 1.337 Å (28) the values reported here are not very striking. The short CC bond lengths measured by X-ray diffraction are shortened as a result of non-sphericity of electron clouds around C-atoms involved in the C=C bond by some 0.02 Å. It seems to be a rule that the shortened CC-bonds are those of HC=CH type and shorter than 1.375 Å. For this kind of bond the difference between X-ray and neutron (N) – or electron (E) – diffraction bond lengths $\overline{R}(X) - \overline{R}(N \text{ or } E) = 0.019$ Å. This difference between mean values of $\overline{R}(X)$ and $\overline{R}(N \text{ or } E)$ was calculated applying the data concerning the following molecules: phenanthrene (29), naphthalene (30), anthracene (30), pyrene (31), and triphenylene (32). It seems to be another rule, at least for angular benzenoid hydrocarbons, that most often very short bonds are located opposite very long bonds: in the DAAC molecule such pairs may be distinguished, i.e. C_6C_7 and $C_{17}C_{18}$ as well as $C_{15}C_{16}$ and C_8C_9 as it is well shown in Fig. 2. Following the ideas of Coulson and Haigh

For personal use only.

(33) the lengthening of $C_{17}C_{18}$ and C_8C_9 bonds is caused by the overcrowding of hydrogens H_{16} and H_1 as well as H_7 and H_{10}, which are as close as 1.97 Å and 2.05 Å, respectively. It is much less than the sum of the van der Waals radii of hydrogen, i.e. 2.12 Å for the closest H···H distance between non-bonded hydrogens. Another consequence of the overcrowding is a considerable nonplanarity of the chrysene moiety, as presented in Fig. 2, where displacement of the atoms from the best plane C_5 through C_9 and C_{14} through C_{18} are given in Å × 10^3 for non-hydrogen atoms and in Å × 10^2 for hydrogen atoms. It is immediately apparent that the chrysene moiety of DAAC is twisted in such a way that the fragments containing $C_1H_1C_2H_2$- and $C_{10}H_{10}C_{11}$-H_{11}-atoms are bent out off the plane of the figure, whereas fragments containing $C_{15}H_{15}C_{16}H_{16}$ and C_7H_7 and C_6 and the CN-bond are twisted in an opposite direction. As a result of the overcrowding the saddle-type shape of the chrysene moiety is observed. Quantitatively it is seen from the angles between the normals to the planes of the successive rings. In Table 6 one may readily find these quantities: they are 0.66°, 2.28°, and 2.76°, the latter value being the angle of overall bending of the chrysene moiety. This property of the chrysene moiety is clearly expressed by a high value of a standard deviation of carbon atom displacements from plane 2, SD = 0.026, whereas this quantity is much lower for particular rings, being in the range from 0.004 (plane 4) to 0.008 (plane 6). According to Coulson and Haigh (33) the overcrowding of H···H in a chrysene molecule may result in the lengthening of C_8C_9- and $C_{17}C_{18}$-bonds by some 0.02 Å, whereas C_5C_6-, C_7C_8-, $C_{14}C_{15}$-, and $C_{16}C_{17}$-bonds are lengthened by some 0.01 Å. The same kind of interactions is expected to occur in a DAAC-molecule. It is supported by a decrease of HOSE-values for rings 2 and 3, 42.0 and 36.4 kJ, respectively. In comparison with HOSE ≃ 47 for rings 1 and 4 where no particular overcrowding effect is present. Another consequence of overcrowding is perpendicularity of the DAA-group and chrysene moiety. If the DAA-group was coplanar with the chrysene moiety, the H_4-atom would have to be surrounded by three H-atoms of the methyl group (C_{22}), with the closest distance between H_4 and C_{22} equal to about 0.3 Å. This is certainly the main reason of non-coplanarity of these two π-electron systems, which is additionally supported by their own mesomeric effects causing a very low tendency for any mesomeric interactions to occur between DAA and the chrysene moiety. However, a slight deviation from exact perpendicularity is observed, the torsion angles $C_7C_6NC_{20}$ and $C_5C_6NC_{20}$ being −94.97° and 86.52°, respectively. This asymmetry of the torsion angles may be explained in terms of very different bond lengths 1.344 and 1.433 Å for C_6C_7- and C_5C_6-bonds, respectively. The plane of DAA is inclined towards the longer C_5C_6-bond because of the larger space in this direction. The overcrowding is also a reason of equal interatomic distances H_{212} and O_2 as well as O_2 and H_{223}, which are 2.40 Å, whereas the sum of van der Waals radii for H and O is 2.64 Å (34).

(iii) Comparison with Other Studies of Chrysene or its Derivatives

It should be mentioned that there are some differences and similarities between our results and those referring to other studies of similar structures. As a rule, precision of refinement is not high enough to draw too far reaching conclusions but it seems likely that certain characteristic features are common.

(*i*) Very short CC-bonds are usually in the same places in molecules, ranging from 1.365 Å for chrysene (5) through 1.353 Å for the chrysene 7,7,8,8-tetracyanoquinodimethane CT-complex (6) ending up with 1.370 Å for the fluoranilchrysene CT-complex (7). In the case of DAAC this bond is as short as 1.332 Å.

(*ii*) Very long CC-bonds are usually also in the same region of the molecules as a result of overcrowding. In the above mentioned CT-complex (6) the longest CC-bonds in the chrysene moiety are in the same places as in DAAC and are equal to 1.461 Å in comparison with 1.455 Å for 1.444 Å in DAAC. The CT-interactions, as we can see, do not influence the lengthening significantly. In a slightly different molecule, dibenzo (q,p) chrysene (8) the longest CC-bonds are also present in the same region being in the range of 1.444–1.467 Å. In this case, however, the overcrowding should be expected to be stronger due to q and p benzene rings added to the chrysene moiety.

As it is easily seen from Fig. 3 the stacking in the DAAC-crystal is different from that in chrysene (5) or the chrysene–TCNQ complex (6).

Orthophosphoric acid: calculation of concentration quotients for the first ionization equilbrium at 25.0°C[1]

DONALD S. GAMBLE

Chemistry and Biology Research Institute, Agriculture Canada, Ottawa, Ont., Canada K1A 0C6

Received November 19, 1980

DONALD S. GAMBLE. Can. J. Chem. **59**, 1630 (1981).

Equilibrium concentration quotients, K_1, have been calculated for the first ionization step of orthophosphoric acid at 25.0°C. Literature information for γ_{HCl} in mixed orthophosphate–chloride solutions has made it possible to use the published electrochemical data of Bates and Nims for this purpose. K_1 is found to be a function of two independent variables for orthophosphate concentrations from 9×10^{-2} *m* down to at least 1.0×10^{-2} *m*. K_1 is described in terms of total orthophosphate concentration C_T and the degree of ionization, α_1. Linear multiple regression analysis was used to produce the empirical equation $K_1 = K_1^* + A_0 C_T^{1/2} - \beta\alpha_1 C_T^{1/2}$, in which K_1^* is an experimental constant not identified with the thermodynamic equilibrium constant, $\mathcal{K}_1$.

DONALD S. GAMBLE. Can. J. Chem. **59**, 1630 (1981).

On a calculé les quotients K_1 de concentration à l'équilibre pour la première ionisation de l'acide orthophosphorique à 25°C. Les données de la littérature relatives à γ_{HCl} dans des solutions mixtes de orthophosphate et de chlorure ont rendu possible l'utilisation des données électrochimiques rapportées par Bates et Nims dans ce but. On a trouvé que K_1 est une fonction de deux variables indépendantes pour des concentrations d'orthophosphate allant de 9×10^{-2} *m* jusqu'à au moins 1×10^{-2} *m*. On décrit K_1 en fonction de la concentration totale C_T en orthophosphate et du degré d'ionisation α_1. On a utilisé l'analyse par regression multiple linéaire pour obtenir l'équation empirique $K_1 = K_1^* + A_0 C_T^{1/2}\ \beta\alpha_1 C_T^{1/2}$ dans laquelle K_1^* est une constante expérimentale qui n'est pas reliée à la constante d'équilibre thermodynamique $\mathcal{K}_1$.

[Traduit par le journal]

Introduction

Equilibrium data for the first step of orthophosphoric acid ionization are required for various practical purposes. One of these is the investigation of aluminum orthophosphate complexes in soil solutions (1). Also included are instrument calibrations for the measurement of H^+ concentrations (1), and conventional pH measurements (2). The first two of these applications require that concentrations rather than activities be calculated with the use of equilibrium data from the literature. The available activity coefficient data are based, however, on the assumption that aqueous orthophosphoric acid solutions contain only such monomers as H_3PO_4, $H_2PO_4^-$, and H^+ (3, 4). Published experimental evidence indicates that this is not the case (5–10). Fortunately, an alternative procedure exists for the calculation of equilibrium concentrations. Instead of the thermodynamic equilibrium constant being used with activity coefficients, a more direct procedure is the use of the corresponding concentration quotient. This requires that the concentration quotient be a known function of solution composition.

The objective of this work was therefore to determine the concentration quotient K_1 for the first ionization step, as a function of solution composition at 25.0°C. It is intended that an empirical description be produced for use in accurate practical calculations. Experimental data and observations published by Bates (11), Nims (12), and Elmore *et al.* (6) have been used for this purpose. Bates and Nims used their electrochemical data only for evaluating the extrapolation functions with which they determined the thermodynamic constant, $\mathcal{K}_1$. Their extrapolation functions were derived solely from Debye–Hückel equations, since orthophosphate dimers were not yet suspected. Bates quite properly pointed out that thermodynamically rigorous values of $\gamma_H\gamma_{Cl}$ were then unavailable for orthophosphate–chloride mixed systems. Rigorous calculations of K_1 were therefore impossible. Elmore *et al.* (6) have since published an important experimental observation which removes this difficulty. They found that for orthophosphate–chloride solutions with total concentration less than 1 *m*, $\gamma_H\gamma_{Cl}$ has the same values as for HCl solutions at the same ionic strengths. The high concentration theoretical results of Pitzer and Silvester (13) show no disagreement with this experimental observation by Elmore *et al.* The theoretical parameters of Pitzer and Silvester were evaluated empirically for pure electrolytes having concentrations up to 6 *m*. With allowance for extrapolation and other assumptions, no disagreement can be shown for the mixed electrolyte at ionic strengths below 9×10^{-2} *m*. Rigorous calculations of K_1 from the electrochem-

ical data of Bates (11) and Nims (12) have therefore become possible.

It was found necessary to do the chemical calculations and the computing in a sequence of four steps: (*1*) the calculation of K_1 from the hydrogen electrode measurements of Bates and Nims; (*2*) the identification and separation of independent variables; (*3*) development of an analytical equation that describes K_1 in terms of the independent variables; (*4*) obtaining optimum statistical use of the data, by fitting them to the analytical equation by multiple regression analysis.

1. Calculation of the Concentration Quotient, K_1, *for the First Ionization Step*

Using hydrogen and Ag–AgCl electrodes in cells without liquid junction, Bates (11) made measurements on samples prepared with ranges of KH_2PO_4 to HCl mole ratios, and ranges of total concentrations. He tabulated experimental values of

$$[1] \quad \log (m_H\gamma_H\gamma_{Cl}) = -\left[\frac{(E - E^0)F}{2.3026RT} + \log m_{HCl}\right]$$

together with values of m_{HCl} and the mole ratio

$$[2] \quad \alpha = C_T/m_{HCl}$$

m is the molality of the indicated reagent or chemical species, and C_T is the molality of total orthophosphate. Other symbols have the usual electrochemical meanings.

The first part of the present calculation used the following working equations, which are well known relationships employed by Bates:

$$[3] \quad \mu = c_1 + m_H$$

$$[4] \quad \mu_0 \approx c_1 + (m_H\gamma_H\gamma_{Cl})$$

$$[5] \quad \gamma_{HCl} \equiv \sqrt{\gamma_H\gamma_{Cl}} = f(\mu)$$

$$[6] \quad \log m_H = -\left[\frac{(E - E^0)F}{2.3026RT} + \log m_{HCl}\right] - 2 \log \gamma_{HCl}$$

μ is the ionic strength and μ_0 is its zero order approximation, c_1 is the molality of total orthophosphate singly ionized, E is the experimental cell potential, and E^0 is the standard cell potential of the Ag–AgCl reference electrode. The relationship in eq. [5] was obtained from the data of Harned and Owen (3). μ, γ_{HCl}, and m_H were calculated together in a simple iterative procedure until m_H values had converged to within four or five significant figures. This typically required three or four iterations. The concentration quotient and the degree of ionization were next calculated according to eqs. [7] and [8],

$$[7] \quad K_1 = c_1 m_H/c_p$$

$$[8] \quad \alpha_1 = c_1/C_T$$

in which c_p is the molality of total unionized orthophosphoric acid.

Nims (12) had previously done the same kind of electrochemical experiment, with the published results tabulated as values of E, E^0, and m_{HCl}. After the calculation of log $(m_H\gamma_H\gamma_{Cl})$ according to eq. [1], the calculations were the same as those using Bates' data.

The calculation results are listed in Table 1 for subsequent use.

2. The Identification and Separation of Independent Variables

The composition variables of fundamental chemical interest include total orthophosphate concentration, degree of ionization, and ionic strength. H^+ concentration is of practical and operational interest, primarily because it provides the experimental means for adjusting one or more of the other variables.

A plot of the K_1 data in Table 1 against any one of the composition variables produces a family of curves rather than a single curve. Figure 1 gives an example. This confirms the report by Elmore *et al.* (6) that K_1 is a function of at least two independent variables. The results of Elmore *et al.* were reported for somewhat higher concentrations. With the three composition variables C_T, α_1, and μ, and one constraint imposed by the ionization equilibrium, the net result is two independent variables. Because of their direct practical importance, C_T and α_1 are chosen for totally specifying the chemical composition of the system. That is, at the constant temperature,

$$[9] \quad K_1 = f_1(C_T,\alpha_1)$$

The analytical form of this function must be determined, so that the data of Table 1 may be fitted in a multiple regression analysis. To achieve separation of the independent variables for this purpose, the data were fitted to empirical polynomials by the method of least squares, and interpolated. This was done in two steps:

(*a*) For each of the eight experiments of Table 1 taken in turn, K_1 and α_1 were separately fitted as functions of C_T, and interpolated at the same round values of C_T. This produced data for a family of K_1 vs. α_1 curves, for which C_T is the parameter.

(*b*) Each of these K_1 vs. $\alpha_1$curves was fitted, and all of them were interpolated at the same round

*The required error analyses have been produced by the subsequent computing and are given with the rest of the computing results in Tables 2 and 3. The rounding off to significant figures has been done after the computing, in order to avoid truncation errors.

values of α_1. This in turn provided a family of K_1 vs. C_T curves, for which α_1 is the parameter.

3. *The Analytical Form of the Function* $K_1 = f(C_T, \alpha_1)$

Examination of the K_1 vs. C_T family of curves from step (*b*) of the data processing has yielded three important observations:

(*a*) At constant α_1, K_1 is found by least-squares fit to be a linear function of $C_T^{1/2}$. Figure 2 shows the resulting family of straight lines,

$$[10] \quad K_1 = K_1^* + AC_T^{1/2}$$

(*b*) K_1^* is independent of α_1, so that the whole family of straight lines has a common intercept. K_1^* is a totally empirical constant, and because of long extrapolations one cannot assume a priori that it may be identified with the thermodynamic constant, $\mathcal{K}$.

(*c*) Figure 3 shows that for $\alpha_1 > 0.55$, A is a decreasing linear function of α_1,

$$[11] \quad A = A_0 - \beta\alpha_1$$

The available data do not permit conclusions to be drawn for $\alpha_1 < 0.55$, but from the appearance of

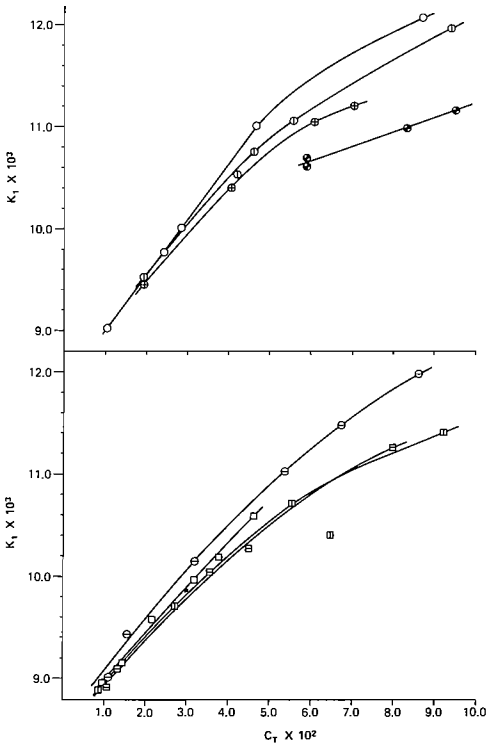

FIG. 1. $K_1 = c_1 m_H / c_p$ at 25.0°C. Bates' experiments: ○, $0.40 < \alpha_1 < 0.65$; ⊖, $0.41 < \alpha_1 < 0.68$; ◑, $0.49 < \alpha_1 < 0.64$; ⊕, $0.63 < \alpha_1 < 0.72$; ◕, $0.85 < \alpha_1 < 0.86$. Nims' experiments: □, $0.64 < \alpha_1 < 0.78$; ⊟, $0.72 < \alpha_1 < 0.85$; ◫, $0.73 < \alpha_1 < 0.84$.

Fig. 3 it is postulated that in this region,

[12] $A = A_0, \neq A(\alpha_1)$

Substituting for A this gives:

[13] $\alpha_1 > 0.55, K_1 = K_1^* + A_0 C_T^{1/2} - \beta\alpha_1 C_T^{1/2}$

$\alpha_1 < 0.55, K_1 = K_1^* + A_0 C_T^{1/2}$

The K_1 vs. α_1 family of curves obtained from step (*a*) of the data processing has the following characteristics:

(*a*) At constant C_T, a least-squares fit produces the decreasing linear function seen in Fig. 4,

[14] $K_1 = C_0 + C_1\alpha_1$

(*b*) C_0 is an increasing linear function of $C_T^{1/2}$,

[15] $C_0 = 7.40 \times 10^{-3} + 18.67 \times 10^{-3} C_T^{1/2}$

$\sigma = \pm 0.69\%$

But $C_0 \equiv K_1(C_T, 0)$ is the $\alpha_1 = 0$ limiting case of the family of curves in Fig. 2. K_1 therefore depends strongly on total orthophosphate concentration even in the limit of zero ionic strength.

(*c*) The computing results show that the experimental and calculation errors in C_1 are too large to permit their quantitative interpretation. Semiquantitatively it is found however, that

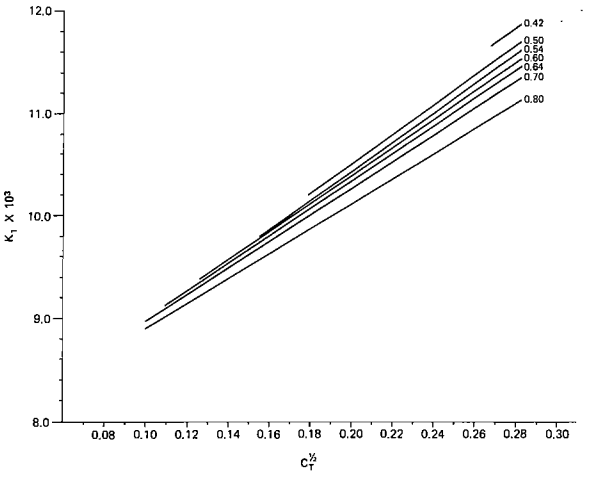

FIG. 2. $K_1 = K_1^* + Ac_T^{1/2}$, 25.0°C. Values of α_1 as the parameter are indicated for the curves. $\sigma = \pm 0.20\%$ to 0.46%. A $\equiv (\partial K_1/\partial C_T^{1/2})_{\alpha_1} = f(\alpha_1)$. For all of the curves, $K_1^* = 7.69 \times 10^{-3} \pm 0.69\%$.

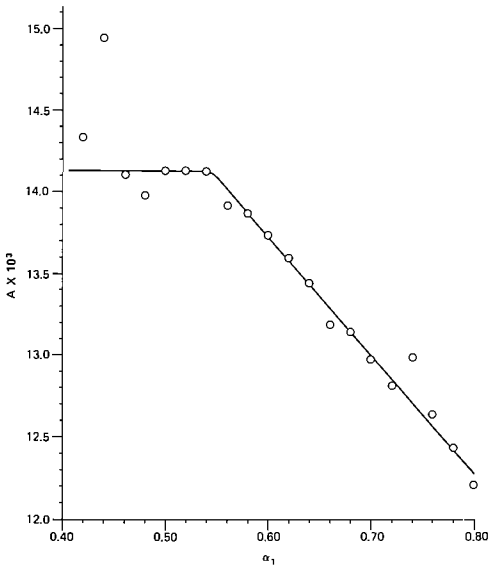

FIG. 3. $A \equiv (\partial K_1/\partial C_T^{1/2})_{\alpha_1} = f(\alpha_1)$, 25.0°C, ○, interpolated data points.

[16] $C_1 \equiv \left(\frac{\partial K_1}{\partial C_T^{1/2}}\right)_{\alpha_1} = f(C_T)$

The reason for the large error in C_1 is that K_1 is a much less sensitive function of α_1 than it is of C_T.

It is concluded from these results that eq. [13] is the function required for multiple regression analysis.

4. Linear Multiple Regression Analysis of $K_1 = K_1(C_T^{1/2}, \alpha_1)$

Data from Table 1 were fitted to eq. [13] for the case in which $\alpha_1 > 0.55$. The linear multiple

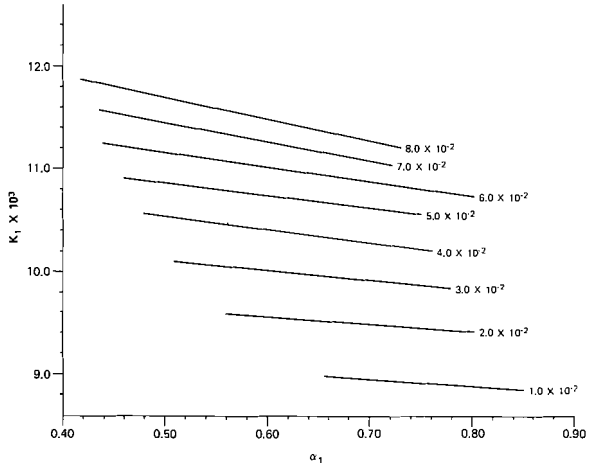

FIG. 4. $K_1 = C_0 + C_1\alpha$, 25.0°C. Values of C_T as the parameter are indicated for the curves. $\sigma = \pm 0.3\%$ to 0.7%. $C_1 \equiv (\partial K_1/\partial\alpha_1)_{C_T} = -f_1(C_T)$. $C_0 = 7.40 \times 10^{-3} + 18.67 \times 10^{-3} C_T^{1/2}$; $a = \pm 0.69\%$.

regression was carried out with a Fortran V program "SOO4C Regression" provided by the Engineering and Statistical Research Institute, Research Branch, Agriculture Canada. The linear regression required the transformation of variables according to eq. [17].

$$[17] \quad \begin{aligned} Y_4 &= C_T^{1/2} \\ Y_5 &= \alpha_1 C_T^{1/2} \end{aligned}$$

The transformed variables were added to the function consecutively in the computed order of importance. Table 2 gives the regression analysis results.

For the simpler case in which $\alpha_1 < 0.55$, K_1 vs. $C_1^{1/2}$ was fitted to a straight line by the ordinary linear least-squares procedure. The results are tabulated in Table 3 for comparison with the multiple regression output in Table 2.

Discussion

Preston and Adams (14) investigated orthophosphoric acid by laser Raman spectroscopy, over wide ranges of concentrations and pressures. Although their data had considerable scatter, they were able to observe that up to 0.1 *m* total orthophosphate, $K_1/\mathcal{K}_1$ attained values greater than 2. In addition to the limitations of the spectroscopic method, variable α_1 may have contributed to the experimental scatter. Qualitatively however, their results agree with those of Table 1. Elmore *et al.* (6) found K_1 to be a function of two independent variables for the relatively large concentrations 0.1 *m* to 10 *m*. This is now found to be true down to at least 0.01 *m* total orthophosphate, and for $\alpha_1 > 0.55$. At 1×10^{-3} *m* total orthophosphate, however, moderate changes in α_1 will have only slight effects on K_1.

The computed order of importance found in Table 2 for the terms in eq. [13] proves that $C_T^{1/2}$ is a more important independent variable than is α_1. A comparison of Tables 2 and 3 also shows that for the same value of A_0 to be obtained in the two cases of $\alpha_1 < 0.55$ and $\alpha_1 > 0.55$, the extra term $\beta\alpha_1 C_T^{1/2}$ must be added for the higher range of α_1 values. This is consistent both with the observation that α_1 is an important variable when $\alpha_1 > 0.55$, and with the postulate that K_1 becomes independent of α_1 below $\alpha_1 = 0.55$.

It is now clear why Bates' extrapolation to log $\mathcal{K}_1$ in his Fig. 2 exist as a family of curves. His use of the extended Debye–Hückel equation in his extrapolation formula for the calculation of log $\mathcal{K}_1$ introduced one independent variable, ionic

For personal use only.

strength, but left the second independent variable unaccounted for. The result is a family of curves having a common intercept, in just the same way that the present Fig. 2 does. His procedure required however, the arbitrary adjustment of the Debye–Hückel ion size parameter, in order to obtain the common intercept for the family of curves. Recognition that K_1 is a function of two independent variables, for example $K_1 = f_1(C_T^{1/2}, \alpha_1)$, avoids this difficulty. Some of the observations by Pitzer and Silvester (13) lead to the same conclusion. Nims followed a very similar extrapolation procedure for the calculation of log $\mathcal{K}_1$, and his set of plotted curves is comparable. By using the limiting Debye–Hückel equation, Nims avoided the problem of the arbitrarily adjusted ion size parameter.

There are three indications that the behaviour of K_1 is not properly accounted for by the Debye–Hückel ion cloud model, as originally assumed first by Nims and later by Bates.

(*a*) K_1 is not just a function of ionic strength as required by the Debye–Hückel theory, but instead is a function of two independent variables.

(*b*) K_1 is a decreasing function of α_1, and therefore the apparent activity coefficient quotient is an *increasing* function of α_1,

$$[18] \quad \left(\frac{\gamma_\pm^2}{\gamma_p}\right)_{app} = \frac{\mathcal{K}_1}{K_1} = f_{app}(\alpha_1)$$

If α_1 simply reflected the ionic strength μ, then this result would be contrary to the predictions of the Debye–Hückel theory.

(*c*) According to the empirical result in eq. [15], K_1 increases substantially as $C_T^{1/2}$ increases, even when the ionic charge approaches zero.

It is concluded from these observations that the behaviour of K_1 is caused by something more than simply ionic charge. Several authors have presented evidence for the existence of orthophosphate dimers. The observed dependence of K_1 on $C_T^{1/2}$ is consistent with the existence of dimers, assuming some reaction such as that of eq. [19]:

$$[19] \quad H_3PO_4 \overset{K_{dim}}{\rightleftharpoons} \tfrac{1}{2}[H_2PO_4^-]_2 + H^+$$

Any equilibrium model postulated for the interpretation of the properties of K_1 must account for three points:

(*a*) It must be shown how the effects of the dimer concentration may be related to the observed behaviour of total orthophosphate concentration;

(*b*) It is necessary to account for a second independent variable;

(*c*) The dependence of K_1 on α_1 instead of $(\alpha_1 C_T)^{1/2}$ requires that some phenomenon other than ordinary ionic strength be invoked.

A preliminary examination reveals that a model meeting such requirements will have a more complicated mathematical description. This would make any calculations employing it more speculative, and it would also tend to magnify the experimental errors. The need for practical calculations and the importance of providing chemical insight have requirements that are to some extent mutually exclusive. The empirical description offered here is intended to serve the first objective. An equilibrium model should be separately postulated, for the purpose of interpretation. Its development, verification, and demonstration constitute a substantial problem outside the scope of the present report.

It follows from these results that the Debye–Hückel theory alone is not directly applicable to extrapolation functions for the calculation of $\mathcal{K}_1$. A family of K_1 vs. μ curves having an appropriate parameter may give the correct numerical value of $\mathcal{K}_1$ however, simply because μ reflects total orthophosphate concentration when α_1 does not vary too widely.

It is of some interest to note that in Table 2, K_1^* is greater than the $\mathcal{K}_1$ values of 7.11×10^{-3} and 7.52×10^{-3} calculated by Bates and Nims, while its value in Table 3 is moderately close to Bates' value. These eqs. [13] are strictly empirical, however, and the interpretation of constants such as β, A_0, and K_1^* should be deferred until a chemical equilibrium model is available for the first ionization step.

Rearrangement studies with ^{14}C. XLV. The decomposition of *cis*- and *trans*-1,2-dianisyl-2-phenyl[2-^{14}C]vinylphenyltriazenes in acetic acid

CHOI CHUCK LEE AND CRAIG A. OBAFEMI

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received November 19, 1980

CHOI CHUCK LEE and CRAIG A. OBAFEMI. Can. J. Chem. **59**, 1636 (1981).

The decomposition of *cis*- or *trans*-1,2-dianisyl-2-phenyl[2-^{14}C]vinylphenyltriazene (*cis*- or *trans*-**1**-NNNHPh-2-^{14}C) in HOAc gave a 1:1 mixture of *cis* and *trans* products which showed about 3% scrambling of the label from C-2 to C-1 due to 1,2-phenyl shifts in the 1,2-dianisyl-2-phenylvinyl cation. The presence of the more nucleophilic acetate ion from the addition of different amounts of NaOAc was found to decrease or even completely suppress the extent of isotopic scrambling. Comparisons with earlier data such as those obtained from the decomposition of trianisyl[2-^{14}C]vinylphenyltriazene (**2**-NNNHPh-2-^{14}C) led to a calculated $k_{r(An)}/k_{r(Ph)}$ of about 25 for the relative anisyl to phenyl migration ratio. A k_{OAc}/k_{HOAc} ratio of about 1.5×10^3 for the product forming capture reactions in the 1,2-dianisyl-2-phenylvinyl cation from the decomposition of **1**-NNNHPh-2-^{14}C was also obtained.

CHOI CHUCK LEE et CRAIG A. OBAFEMI. Can. J. Chem. **59**, 1636 (1981).

La décomposition des dianisyl-1,2 phényl-2[^{14}C-2] vinylphényltriazènes *cis* ou *trans* (NNNHPh-**1** ^{14}C-2 *cis* ou *trans*) dans du AcOH donne un mélange 1:1 de produits *cis* et *trans* dont le marquage est échangé d'environ 3% entre C-2 et C-1 par suite des déplacements 1,2 du phényle du cation dianisyl-1,2 phényl-2 vinyle. On a trouvé que la présence d'un ion acétate plus nucléophile, provenant de l'addition de différentes quantités de AcONa, diminue ou même supprime complètement le degré d'échange isotopique. Une comparaison avec des données antérieures, comme celles obtenues à partir de la décomposition du trianisyl[^{14}C-2]vinylphényltriazène (NNNHPh-**2** ^{14}C-2), a conduit à une valeur calculée de $k_{r(An)}/k_{r(Ph)}$ d'environ 25 pour le rapport de migration de l'anisyle vers le phényle. On a également obtenu un rapport k_{AcO}/k_{AcOH} d'environ $1,5 \times 10^3$ pour le produit engendrant les réactions de capture dans le cation dianisyl-1,2 phényl-2 vinyle à partir de la décomposition du NNNHPh-**1** ^{14}C-2.
[Traduit par le journal]

The isomeric *cis*- and *trans*-1,2-dianisyl-2-phenylvinyl bromides and chlorides (*cis*- and *trans*-**1**-Br and **1**-Cl) were prepared and their stereochemistry determined in 1969 by Rappoport and Apeloig (1). Solvolytic studies in various solvents, with or without added nucleophiles, gave a 1:1 mixture of the *cis* and *trans* products and it was concluded that S_N1 reactions took place via the dissociated 1,2-dianisyl-2-phenylvinyl cation. Further work with *cis*- and *trans*-**1**-Br, *cis*-**1**-Cl, and the methanesulfonates *cis*- and *trans*-**1**-OMs, including kinetic studies and *cis–trans* isomerization in the recovered reactant, were reported in 1975 (2, 3). The results were interpreted by a mechanism involving formation of an ion-pair, which gave internal return with isomerization, or further ionization to dissociated ions, which could either give external ion return or solvolysis product. In 1976, Lee and Oka (4) reported that the reaction of either *cis*- or *trans*-1,2-dianisyl-2-phenyl[2-^{13}C]vinyl bromide (*cis*- or *trans*-**1**-Br-2-^{13}C) with HOAc–AgOAc gave a 1:1 mixture of *cis*- and *trans*-**1**-OAc-2-^{13}C with no isotopic scrambling, indicating no detectable degenerate rearrangement from 1,2-phenyl shifts in the 1,2-dianisyl-2-phenylvinyl cation under the conditions employed. A similar lack of scrambling was reported by Rappoport and co-workers (5) for the solvolysis in HOAc–NaOAc of a 5:1 mixture of *cis*- and *trans*-1-anisyl-2-*p*-[$^2H_3$]methoxyphenyl-2-phenylvinyl bromides (*cis*- and *trans*-**1**-Br-2-methoxy-d_3), but some scrambling was observed in the solvolysis of this D-labeled substrate in aqueous ethanol or in 2,2,2-trifluoroethanol. In the present work, a study was made on the possible degenerate rearrangement from 1,2-phenyl shifts in the 1,2-dianisyl-2-phenylvinyl cation generated from the decomposition in HOAc of 1,2-dianisyl-2-phenyl[2-^{14}C]vinylphenyltriazene (**1**-NNNHPh-2-^{14}C). Since the extents of degenerate rearrangement arising from 1,2-anisyl shifts in the trianisylvinyl cation generated from the decomposition of trianisyl[2-^{14}C]vinylphenyltriazene (**2**-NNNHPh-2-^{14}C) have already been reported (6), isotopic scrambling data from the present work with **1**-NNNHPh-2-^{14}C may be compared with those from **2**-NNNHPh-2-^{14}C to provide information such as the relative anisyl to phenyl migration ratio in vinyltriazene decompositions.

Using $[^{14}C]CO_2$ instead of $[^{13}C]CO_2$ as the source of label, *cis*- and *trans*-**1**-Br-2-^{14}C were synthesized in the same way as reported for the synthesis of *cis*- and *trans*-**1**-Br-2-^{13}C (4). The pure *cis*- or *trans*-**1**-Br-2-^{14}C, separated by fractional crystallization (4), was converted to the corresponding Grignard reagent and then treated with

phenyl azide to give the triazene, *cis*- or *trans*-**1**-NNNHPh-2-^{14}C (6). Decomposition of either *cis*- or *trans*-**1**-NNNHPh-2-^{14}C was carried out in HOAc or HOAc containing various amounts of NaOAc and the product obtained was a 1:1 mixture of the *cis*- and *trans*-acetates, *cis*- and *trans*-**1**-OAc-1,2-^{14}C, scrambling of the ^{14}C-label from C-2 to C-1 being observed in some of the experiments. Degradation of the product was effected by $LiAlH_4$ reduction to an *erythro* and *threo* mixture of 1,2-dianisyl-2-phenyl[1,2-^{14}C]ethanol (**3**-1,2-^{14}C) (4), followed by $KMNO_4$ oxidation to give anisyl phenyl [^{14}C]ketone (**4**-^{14}C) (7). The difference in specific activities between **3**-1,2-^{14}C and **4**-^{14}C gave the extent of scrambling of the ^{14}C-label from C-2 to C-1 in the original reaction product. The results are summarized in Table 1. An alternative degradation was carried out on the first set of experiments (Table 1) and this involved the separation of the *cis* and *trans* product mixture, with the aid of added carrier, to give the pure *trans*-**1**-OAc-1,2-^{14}C, followed by ozonolysis to **4**-^{14}C (8). Essentially the same extent of scrambling was obtained, thus confirming the validity of the degradation method used on the mixture of *cis*- and *trans*-**1**-OAc-1,2-^{14}C.

The acid catalyzed decomposition of triazenes presumably proceeds via the diazonium ion which gives rise to the dissociated triarylvinyl cation (6, 9). The isotopic scramblings observed in the present system would arise from 1,2-phenyl shifts in the 1,2-dianisyl-2-phenylvinyl cation as depicted in Scheme 1. The formation of a 1:1 mixture of *cis* and *trans* products from either *cis* or *trans* reactant and the suppression of or decrease in the extent of scrambling (Table 1) by the presence of the more nucleophilic acetate ion in the reaction medium (8–10) are observations that would also support the formation of the dissociated cation as reaction intermediate.

From Table 1, it is seen that the largest extent of scrambling observed in the present work was only about 3%, which was found in the decomposition of *cis*- or *trans*-**1**-NNNHPh-2-^{14}C in HOAc with no added NaOAc. This relatively low degree of degenerate rearrangement could be attributable to a low migratory aptitude for the phenyl group and a relatively high stability of an α-anisyl substituted triarylvinyl cation. In discussing the relative amounts of scrambling arising from 1,2-phenyl shifts in the triphenylvinyl, 2-phenyl-1,2-ditolylvinyl, and 1,2-dianisyl-2-phenylvinyl cations generated from reactions of the corresponding bromides with HOAc–AgOAc (11), it was pointed out

TABLE 1. Data from the decomposition of *cis*- or *trans*-1,2-dianisyl-2-phenyl[2-^{14}C]vinylphenyltriazene in HOAc with or without the presence of added NaOAc

Expt.	Triazene	Reaction medium	Specific activities (10^{-6} × dpm/mmol)				Scrambling from C-2 to C-1 (%)	
			An(Ph)CHCH(OH)An		AnCOPh

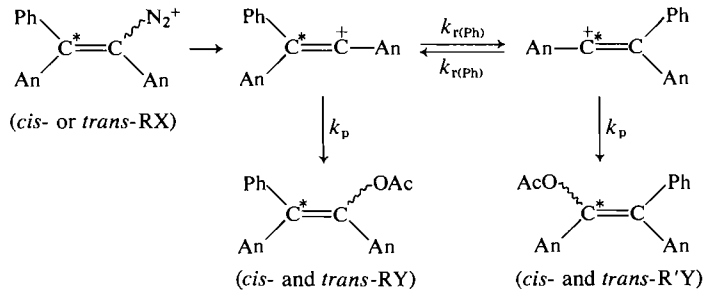
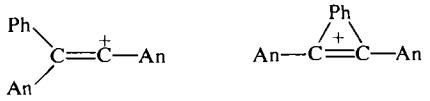
[a]Essentially the same results were obtained using an alternative degradation involving ozonolysis of the purified *trans*-1,2-dianisyl-2-phenyl[1,2-^{14}C]vinyl acetate product.



SCHEME 1

that if one were to consider a bridged ion as a model of the transition state for the 1,2-aryl shift, in going from a linear triarylvinyl cation such as **5** to a bridged transition state such as **6**, the higher stability of an α-anisyl substituted vinyl cation would lead to a higher activation energy and hence a lower extent of scrambling. Such an effect likely also contributed to the observed relatively low extents of scrambling in the present study.



5 6

In the decomposition of trianisyl[2-^{14}C]-vinylphenyltriazene (**2**-NNNHPh-2-^{14}C) (6), the scrambling arising from 1,2-anisyl shifts in the trianisylvinyl cation was found to be 37.8 and 38.4% in duplicate runs. Obviously, a higher migratory aptitude for the anisyl group relative to that of the phenyl group would play an important role in giving rise to the greater extent of scrambling than the 3.0–3.1% observed in the present study with **1**-NNNHPh-2-^{14}C. Relative migratory aptitudes for aryl groups in triarylvinyl cations have been evaluated using isotopic scrambling data (11–13). Thus for a scrambling mechanism as depicted in Scheme 1, it has been shown that eq. [1] would apply (11–13),

$$[1] \quad [RY]/[R'Y] = 1 + (k_p/k_{r(Ph)})$$

It is seen from eq. [1] that the extent of scrambling, related to [RY]/[R'Y], would be independent of the initial concentration of the substrate RX, and this is in agreement with the finding that the same 3.0–3.1% scrambling was obtained whether the initial concentration of **1**-NNNHPh-2-^{14}C was 144 m*M* or 15 m*M* (Table 1).

Using eq. [1] and a mean scrambling value of 3.05% for the decomposition of **1**-NNNHPh-2-^{14}C in HOAc, $k_p/k_{r(Ph)}$ can be calculated as given in eq. [2].

$$[2] \quad k_p/k_{r(Ph)} = (96.95/3.05) - 1 = 30.8$$

For the similar decomposition of **2**-NNNHPh-2-^{14}C in HOAc, a statistical factor of 2 should be applied to the 1,2-anisyl shift in the trianisylvinyl cation and eq. [1] is modified to give eq. [3] (13), from which $k_p'/k_{r(An)}$ can be obtained for the mean scrambling of 38.1% as given in eq. [4]. By dividing [2] by [4], one would obtain $k_p k_{r(An)}/k_p' k_{r(Ph)}$. If one were to assume that in the triazene decomposition in HOAc, k_p and k_p' for the product formation from the 1,2-dianisyl-2-phenylvinyl and trianisylvinyl cations are about equal, then $k_{r(An)}/k_{r(Ph)}$ would be 30.8/1.25 = 25.

$$[3] \quad [RY]/[R'Y] = 1 + (k_p'/2k_{r(An)})$$

$$[4] \quad k_p'/k_{r(An)} = 2[(61.9/38.1) - 1] = 1.25$$

It is of interest to note that a similar calculation using scrambling data from reactions with HOAc–AgOAc for triphenyl[2-^{14}C]vinyl and *trans*-2-anisyl-1-phenyl-2-[$^2H_5$]phenylvinyl bromides gave a $k_{r(An)}/k_{r(Ph)}$ ratio of 162 (13), which is considerably different from the presently obtained value of 25. This difference, however, is not unexpected since the calculations were based on data from two types of reactions (decomposition of triazene and reaction of bromide with HOAc–AgOAc) involving different triarylvinyl cations. In a recent book on vinyl cations, it was pointed out that in saturated cationic systems, the anisyl to phenyl migratory ratios have been found to be about 6 to 500 for solvolysis and related reactions and much lower (1.2 to 2.0) for deamination reactions (14). For vinyl cationic systems, various values for the anisyl to phenyl migration ratio have also been obtained and it was concluded that the $k_{r(An)}/k_{r(Ph)}$ ratios of ≥ 11 to ≥ 67 for these vinyl cations are much higher than unity, thus showing similar behavior to the saturated carbocations (14). The present results would also fit into this general conclusion.

As indicated earlier, the effect of added NaOAc in decreasing or even suppressing the extent of scrambling has been regarded as evidence for the formation of dissociated triarylvinyl cations in a

mechanism as shown in Scheme 1 since, in the presence of the more nucleophilic OAc^- ion, the scrambling process would compete less effectively with product formation (8–10). From the actually observed decrease in scrambling, calculations can be made to give the selectivity of the cation in its product forming capture reactions with OAc^- and with HOAc, k_{OAc}/k_{HOAc}. In the decomposition of 2-NNNHPh-2-^{14}C in HOAc, the presence of 1.7 equiv. (240 m*M*) of NaOAc was found to decrease the mean scrambling from 38.1% to 16.8% (6). These data led to a calculated k_{OAc}/k_{HOAc} of 3.9×10^2 (10). In the present work, the decomposition of 1-NNNHPh-2-^{14}C in HOAc with no added NaOAc gave 3.0–3.1% scrambling, while the presence of 45 and 74 m*M* NaOAc, respectively, decreased the scrambling to about 0.6 and 0.4% (Expts. 7 and 8). Since these scrambling values are very small, calculated k_p/k_r using variations of eq. [1] are subjected to large deviations with small changes in the observed scrambling. Nevertheless, utilizing the data from Expts. 6, 7, and 8, and employing the same method used in the treatment of the data from 2-NNNHPh-2-^{14}C (10), k_{OAc}/k_{HOAc} values of the order of 1.5×10^3 were obtained for the decomposition of 1-NNNHPh-2-^{14}C, but this value is considerably different from the k_{OAc}/k_{HOAc} of 3.9×10^2 found for the decomposition of 2-NNNHPh-2-^{14}C (10).

Some difference in the k_{OAc}/k_{HOAc} values for 1-NNNHPh-2-^{14}C and 2-NNNHPh-2-^{14}C is to be expected since two different cations (the trianisylvinyl and 1,2-dianisyl-2-phenylvinyl cations) and widely different concentrations of added OAc^- are involved in the reactions with 1-NNNHPh-2-^{14}C and 2-NNNHPh-2-^{14}C. Even for the same reaction involving the same cation as in the solvolysis of trianisyl[2-^{14}C]vinyl bromide (2-Br-2-^{14}C) in 70% HOAc – 30% H_2O with the presence of varying amounts of added NaOAc (10), the calculated $k_{OAc}/k_{SOH'}$, $k_{SOH'}$ being defined as $[HOAc]k_{HOAc} + [H_2O]k_{H_2O} + [OAc^-]k_{OAc}$, was found to vary with changing amounts of added NaOAc. It was pointed out (10) that a major factor that contributed to these variations could be due to the use of concentrations rather than activities in the calculations, and corrections for such effects would be greater the higher the concentration of the added NaOAc. In the present work, the k_{OAc}/k_{HOAc} ratio was obtained from Expts. 7 and 8 involving the use of 45 and 75 m*M* of added NaOAc. In the calculation of k_{OAc}/k_{HOAc} based on data from the decomposition of 2-NNNHPh-2-^{14}C, a much higher acetate concentration of 240 m*M* was utilized and its wider deviation from the true acetate activity would lead to a lower calculated k_{OAc}/k_{HOAc}, as was obtained.

Experimental

cis- *or* trans-*1,2-Dianisyl-2-phenyl[2-^{14}C]vinylphenyltriazene (*cis- *or* trans-**1**-*NNNHPh-2-^{14}C)*

The pure *cis*- or *trans*-1,2-dianisyl-2-phenyl[2-^{14}C]vinyl bromide (*cis*- or *trans*-**1**-Br-2-^{14}C), prepared as previously described for the analogous ^{13}C-labeled compound (4), was converted to the corresponding Grignard reagent and then treated with phenyl azide to give the desired triazene (6). A typical preparation is described below.

To a mixture of 0.75 g (30 mmol) of Mg in 60 mL of anhydrous ether in a 3-neck flask and under N_2 a small amount of bromoethane was added to initiate the Grignard reaction. A solution of 10.0 g (25 mmol) of *cis*-**1**-Br-2-^{14}C in 30 mL of anhydrous ether was added dropwise with stirring, and then the mixture was heated under reflux for 2 days. The resulting Grignard solution was cooled in an ice bath and a solution of 3.0 g (25 mmol) of freshly prepared phenyl azide (15) in 25 mL of anhydrous ether was slowly added. The mixture was stirred at room temperature for 3 h before being treated with a solution of 10% NH_4OH – 10% NH_4Cl. The ether layer was separated and the aqueous layer was extracted with more ether. After drying over $MgSO_4$ and removal of the ether, the resulting yellow oil partially solidified upon refrigeration. The material was stirred with a 1:10 mixture of $CHCl_3$–hexane, leaving some undissolved crystalline material which proved to be *cis*-1,2-dianisyl-2-phenylethylene, showing the same mp and ^{1}H nmr spectrum as previously reported for this olefin (1). The $CHCl_3$–hexane solution was evaporated off at room temperature under reduced pressure. The residual oil was purified by passage through an alumina column using 90% petroleum ether – 10% ether as eluant (6). More *cis*-1,2-dianisyl-2-phenylethylene was removed as a first fraction, and the desired product, *cis*-**1**-NNNHPh-2-^{14}C, was recovered as a second component. After recrystallization from hexane containing a small amount of $CHCl_3$, 3.3 g (30%) of *cis*-**1**-NNNHPh-2-^{14}C was obtained, mp 110–112°C (dec.); ^{1}H nmr δ($CDCl_3$): 3.69, 3.73 (two CH_3O, two singlets), 6.63–7.43 (aromatic, m). *Anal.* calcd. for $C_{28}H_{25}N_3O_2$: C 77.22, H 5.79, N 9.65; found: C 77.18, H 5.48, N 9.80.

The *trans*-isomer, *trans*-**1**-NNNHPh-2-^{14}C, prepared in the same way from *trans*-**1**-Br-2-^{14}C, melted at 125–126°C (dec.); ^{1}H nmr δ($CDCl_3$): 3.70, 3.79 (two CH_3O, two singlets), 6.67–7.61 (aromatic, m). *Anal.* calcd. for $C_{28}H_{25}N_3O_2$: C 77.22, H 5.79, N 9.65; found: C 77.51, H 5.45, N 9.71. Both *cis*- and *trans*-**1**-NNNHPh-2-^{14}C were stored in the dark since they appeared to decompose slowly in the presence of light.

Decomposition of cis- *or* trans-*1-NNNHPh-2-^{14}C*

The conditions used in the various experiments are summarized in Table 1. A typical experiment (Expt. 2) is described below.

A mixture of 500 mg (1.15 mmol) of *cis*-**1**-NNNHPh-2-^{14}C and 472 mg (5.76 mmol) of NaOAc in 8.0 mL of glacial HOAc was stirred at room temperature for 10 min, evolution of N_2 being observed in the first couple of min. Most of the solvent was then removed at room temperature under reduced pressure. The residual oil was redissolved in ether and washed with a saturated $NaHCO_3$ solution and then with H_2O. After drying over $MgSO_4$, removal of the ether gave 360 mg (84%) of product mixture, the nmr spectrum of which showed it to be a 1:1 mixture of *cis*- and *trans*-**1**-OAc-1,2-^{14}C (4) (1:1 ratio of the two AcO absorptions at δ($CDCl_3$) 1.95, 2.00 ppm).

Degradation Procedures

The 1:1 mixture of *cis* and *trans* acetate products was treated twice (7) with $LiAlH_4$ to give a mixture of *erythro*- and *threo*-1,2-dianisyl-2-phenyl[1,2-^{14}C]ethanol (**3**-1,2-^{14}C) as previously described (4). Oxidation of the **3**-1,2-^{14}C from each

experiment with alkaline $KMNO_4$ (7) gave the anisyl phenyl [^{14}C]ketone (**4**-^{14}C) which melted alone or in admixture with an authentic sample at 61–63°C.

In Expt. 1, about one-half of the *cis* and *trans* acetate product was mixed with about 700 mg of *trans*-**1**-OAc as carrier, the latter being prepared and purified by fractional crystallization as described by Rappoport and Apeloig (1). Repeated crystallizations from CH_3OH gave the pure *trans*-**1**-OAc-1,2-^{14}C, mp 140–142°C (lit. (1), mp 140–141°C). Ozonolysis of this sample of *trans*-**1**-OAc-1,2-^{14}C using the same procedure as previously employed in the ozonolysis of trianisylethylene (8) gave **4**-^{14}C and the extent of scrambling.

Bridged-ring steroids. II. The synthesis of bridged steroids with a bicyclo[2.2.1]heptane ring A system[1]

PETER YATES AND FRANÇOISE M. WINNIK[2]

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 4, 1980

PETER YATES and FRANÇOISE M. WINNIK. Can. J. Chem. **59**, 1641 (1981).

Bridged steroids with a bicyclo[2.2.1]heptane ring A system are formed on thermolysis of 5-vinyl 3-keto steroids. 5-Vinyl-5α-cholestan-3-one (**26**) on being heated at 350°C in decalin gave 2α,5-(*syn*-methylmethano)-5α-cholestan-3-one (**27**). Similar treatment of 17β-hydroxy-5-vinyl-5β-estran-3-one (**21**) gave 17β-hydroxy-2β,5-(*syn*-methylmethano)-5β-estran-3-one (**30**), which was also obtained by reduction of 2β,5-(*syn*-methylmethano)-5β-estrane-3,17-dione (**31**) with sodium borohydride on alumina. Compound **31** was formed as the major product on thermolysis of 5-vinyl-5β-estrane-3,17-dione (**24**) at 350°C, together with 5-(*trans*-propenyl)-*A*-nor-5β-estrane-3,17-dione (**32**). Compounds **27**, **30**, and **31** are considered to arise via intramolecular ene reactions of the Δ^2-enols of compounds **26**, **21**, and **24**, respectively. Compound **32** is postulated to be formed via an analogous reaction of the Δ^3-enol of **24**, followed by thermolysis of the resulting 3′-methyl-4β,5-dihydrocyclopropa[4, 5]-5β-estrane-3,17-dione (**36**). Photolysis of **30** in methanol results in α-cleavage of the C2—C3 bond and the formation of a ketene-derived ester and two enal-derived oxetanes.

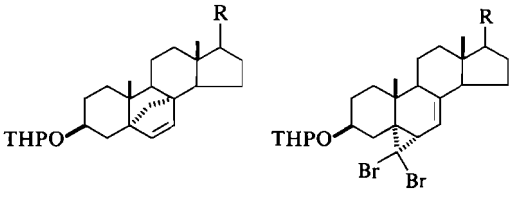
PETER YATES et FRANÇOISE M. WINNIK. Can. J. Chem. **59**, 1641 (1981).

La thermolyse des vinyl-5 céto-3 stéroïdes conduit à la formation de stéroïdes pontés portant au niveau du cycle A un bicyclo[2.2.1] heptane. Si on chauffe la vinyl-5 5α-cholestanone-3 (**26**) dans de la décaline à 350°C, on obtient la (méthylméthano *syn*)-2α,5 5α-cholestanone-3 (**27**). L'hydroxy-17β vinyl-5 5β-estranone-3 (**21**), traitée de la même façon, fournit l'hydroxy-17β (méthylméthano *syn*)-2β,5 5β-estranone-3 (**30**) que l'on obtient également par réduction de la (méthylméthano *syn*)-2β,5 5β-estranedione-3,17 (**31**) par le borohydrure de sodium sur l'alumine. Le composé **31** se forme comme le produit principal de la thermolyse de la vinyl-5 5β-estranedione-3,17 (**24**) à 350°C à côté de la (propènyl-*trans*)-5 A-nor 5β-estranedione-3,17 (**32**). On considère que les composés **27**, **30** et **31** proviennent respectivement de réactions *ène* intramoléculaires des Δ^2 énols des composés **26**, **21** et **24**. On pense que le composé **32** se forme par l'intermédiaire d'une réaction analogue du Δ^3 énol de **24** suivie de la thermolyse de la méthyl-3′ dihydro-4β,5 cyclopropa[4,5] 5β-estranedione-3,17 (**36**). La photolyse du composé **30** dans le méthanol provoque un clivage α de la liaison C2—C3 et la formation d'un ester provenant d'un cétène et de deux oxétanes provenant d'un énal.

[Traduit par le journal]

Bridged steroids are of interest both because of their potential biological activity and because they can serve as substrates for the study of the effects of the constraints imposed on bridged bicyclic systems by the steroid skeleton in the course of the reactions of such systems.

We and others have previously investigated the synthesis of steroids incorporating a bicyclo-[2.2.2]octane (2, and references therein quoted) or bicyclo[3.2.1]octane system (3). Here we are concerned with the incorporation of a bicyclo-[2.2.1]heptane system. Solo *et al.* have made extensive investigations of bridged ring D steroids of this type, which they synthesized by Diels–Alder addition of dienophiles to steroid 14,16-dienes (4, and earlier papers in this series). However, the only previous work to our knowledge that led to the incorporation of a bicyclo[2.2.1]heptane system into a steroid ring other than ring D is that of Nazer (5), who obtained compounds **1***a* and **1***b* by treatment of **2***a* and **2***b*, respectively, with lithium aluminum hydride. We report now on the synthesis of ring-A bicyclo[2.2.1]-steroids.[3]



1 **2**

a, R = $CH(CH_3)CH{=}CHCH(CH_3)CH(CH_3)_2$
b, R = $CH(CH_3)CH_2CH_2CH(CH_3)CH(CH_3)_2$

Three types of ring-A bicyclo[2.2.1]-steroid can be envisaged with a one-carbon bridge between C1 and C4 (**3**), C2 and C5 (**4**), or C3 and C10 (**5**) (the last being possible only in the 19-nor series). Our initial approach was to a system of type **3**. It was thought possible that this could be obtained by a Diels–Alder reaction of the known des-A-cholestane derivative **6** with cyclopentadiene. However, neither this nor the α,β-unsaturated nitrile **7** could be induced to undergo cycloaddition to cyclopentadiene. It

[1]For Part I, see ref. 1; for a preliminary account of part of this work, see ref. 2.

[2]Née Françoise M. Walliser.

[3]We use the term bicyclo[2.2.1]-steroid to denote a steroid incorporating a bicyclo[2.2.1]heptane system in one of its rings.

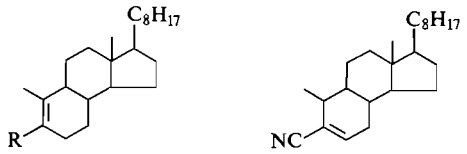
3 4 5

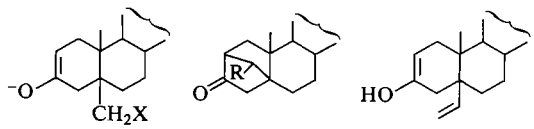
had been planned to isomerize **7** to **8** in order to obtain a system of type **3** via the Diels–Alder route. However, the failure of **7** to undergo cycloaddition led us to abandon this approach.



6, R = OAc
8, R = CN

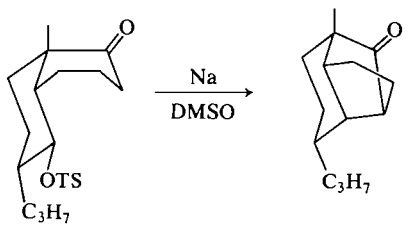
7

We then turned our attention to the synthesis of bridged compounds of type 4. We chose target molecules with a carbonyl function at C3 both because this is a common feature of conventional steroids and because one of our eventual aims was to study the photochemistry of bicyclo[2.2.1]-steroidal ketones. Such targets suggested two types of approach: carbon–carbon bond formation either by nucleophilic displacement of a leaving group X in the enolate ion **9** to give **10** or by an intramolecular ene reaction of the enol **11** to give **12**.



9 **10**, R = H; **12**, R = CH_3 11

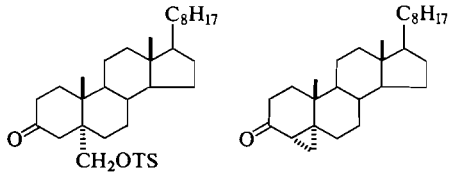
The former approach is not without intrinsic interest since in terms of Baldwin's rules (6) it is a favored *exo*-5 process and a disfavored *endo*-5 process at the same time. In terms of precedent it may be compared with the closure of **13** to the sativene precursor **14** (7). However, this approach showed little promise in the case of **15** because of our failure to generate the Δ^2 rather than the Δ^3



13 14

enolate ion and the ready closure of the latter ion to the cyclopropane **16**.

The approach via an intramolecular ene reaction of a compound of type **11** has ample precedent in the case of simpler systems in the extensive work of Conia and LePerchec (8). It has the advantage

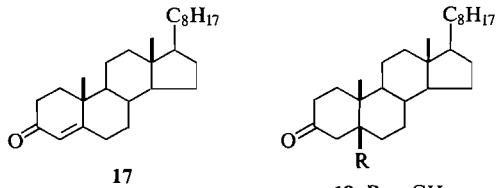


15 16

over the route via compounds of type **15** that closure to cyclopropyl ketones via the Δ^3 enol is reversible while closure to the bicyclo[2.2.1]-heptane system via the Δ^2 enol is not (9). Interestingly the closure of **11** to **12** is again an ambiguous type of reaction in terms of Baldwin's rules.

The most direct route to the 5-vinyl 3-keto steroids related to **11** that were required for this approach appeared to be the conjugate addition of lithium divinylcuprate to the corresponding Δ^4-3-keto steroids. It is known that both lithium dimethylcuprate and diethylcuprate add to cholest-4-en-3-one (**17**) to give exclusively the 5β-methyl derivative **18** (10) and 5β-ethyl derivative **19** (11), respectively. In spite of the reported greater reactivity of lithium divinylcuprate relative to lithium dimethylcuprate (12) we were unable to effect vinylation either in the presence of dimethyl sulfide (13) or tri-*n*-butylphosphine (14). This failure may be related to the lower thermostability of lithium divinylcuprate (15).

However, success was achieved in the vinylation by this method of a Δ^4-3-keto steroid lacking a C19



17

18, R = CH_3
19, R = C_2H_5

methyl group. Treatment of 19-nortestosterone (**20**) with lithium divinylcuprate – tri-*n*-butylphosphine complex gave a product that is assigned structure **21**. Its gross structure follows from its ir (2.80 (w), 5.86, 6.08 (w), 10.1 (w), 10.90 (w) μm), uv (272–282 nm (ε 21)), and ^{1}H nmr spectra (δ 0.80 (s, 3H), 3.5–3.8 (m, 1H), 4.8–6.0 (m, 3H)). The 5β-vinyl configuration is assigned on the basis of analogy with the 5β configuration of the addition products **18** and **19**; the stereochemistry of the formation of these has been interpreted in terms of

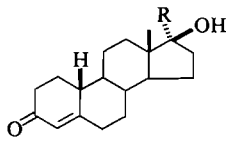
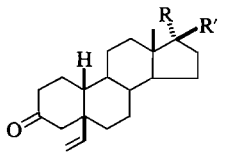
hindrance of α attack by the axial 7α and 9α hydrogens (16) and it is to be expected that the absence of a C19 methyl group in **20** would yet further favor β over α attack. Furthermore, the reaction of the closely related enone **22** with vinylmagnesium bromide catalyzed by cupric acetate has been shown to give the 5β product **23** (17). Oxidation of **21** with chromium trioxide gave the dione **24**, as shown by its ir spectrum (5.75, 5.84, 6.09 (w), 10.10 (w), 10.90 (w) μm).

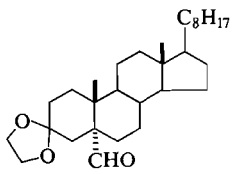


20, R = H
22, R = CH_3

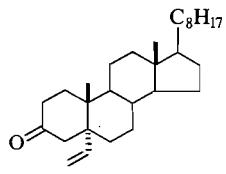


21, R = H, R′ = OH
23, R = CH_3, R′ = OH
24, R, R′ = O

Since it was desired to examine bridge formation in both the 5β and 5α series, the preparation of a 5α-vinyl 3-keto steroid was also undertaken. Because of the high β stereoselectivity of the addition reactions discussed above, it was necessary to take a more pedestrian approach to the 5α-vinyl compound. Cholest-4-en-3-one (**17**) was converted in several steps to the aldehyde **25** (18),[4] which in turn was converted by a Wittig reaction followed by trans-ketalization to the 5α-vinyl 3-keto steroid **26**.

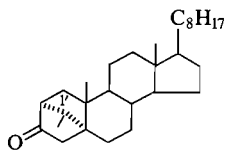


25

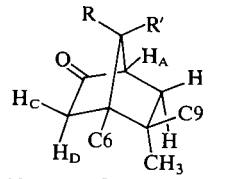


26

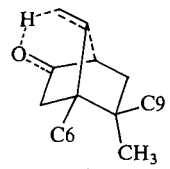
Heating of a 3% solution of **26** in decalin in a sealed tube at 350°C for 14 h gave a product in 41% yield that is assigned the desired structure **27**. Its ir spectrum showed a carbonyl-stretching band at 5.74 μm, characteristic of a bicyclo[2.2.1]heptan-2-one. A maximum at 280 nm (ε 50) in its uv spectrum and a signal at δ 218.5 in its ^{13}C nmr spectrum are also in accord with the presence of this system.[5] As expected, its ^1H nmr showed no signals downfield of δ 2.70. Recording of this spectrum at 80 MHz in conjunction with lanthanide-induced shift experiments utilizing increasing amounts of $Eu(fod)_3$ established the *syn*-stereochemistry of the methyl group at C1′ (the latter carbon is assigned the α configuration on the basis of the configuration at C5 in **26**).[6] These experiments permitted the assignment of signals in the δ 1.9–2.7 region as follows (cf. **28***a*): δ 1.92 (d, J = 17 Hz, H_C), 2.08 (dd, J = 17, 3.5 Hz, H_D), 2.33 (br d, J = 5 Hz, H_A), 2.61 (v br q, J = 8 Hz, H_B). The splitting pattern of the H_D signals shows that in addition to geminal coupling with H_C (J = 17 Hz) it is coupled with another proton (J = 3.5 Hz); this is only possible in the *syn* isomer **27** (**28***a*), where long range coupling with the H_B proton will occur as a result of the "W" arrangement of these protons; in the *anti* isomer **28***b* no such coupling is to be anticipated (19). The H_B signal appears as a very broad quartet (J = 8 Hz); the primary coupling is with the C1′ methyl protons and the broadness is attributable to further, unresolved coupling with



27



28*a*, R = CH_3, R′ = H_B
28*b*, R = H_B, R′ = CH_3



29

H_A and H_D. The configuration assigned to C1′ in **27** on this basis is that anticipated in terms of the transition state for the ene reaction of the enol of **26** (cf. **29**).

Thermolysis of the 19-nortestosterone derivative **21** is complicated by the presence of the thermally unstable 17β hydroxyl group. Under the optimum conditions for the isomerization of **26** to **27**, **21** gave a complex mixture, including aromatic compounds, as indicated by the ^1H nmr spectrum of the crude product. A pure product could be isolated in 11% yield whose spectra showed it to be **30** (the *syn* configuration at C1′ is assigned by analogy with **27**). In this case the signal of the C1′ methyl group at δ 0.87 (d, J = 8 Hz) could readily be identified in the ^1H nmr spectrum of the product; in the case of **27**, the corresponding signal was obscured by the side chain signals. Attempts to improve the yield of the ene reaction by protection of the hydroxyl group of **21** as the acetate or

[4]This aldehyde was also an intermediate in the preparation of **15** (see Experimental).

[5]The ^{13}C nmr spectra of **27** and related compounds will be discussed in full elsewhere.

[6]The terms *syn* and *anti* refer to the relationship of the bridge methyl group to the C3 carbonyl group.

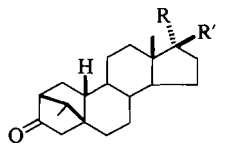
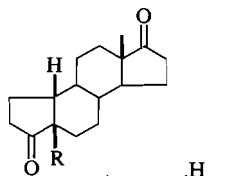
For personal use only.

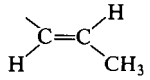
tert-butyldimethylsilyl ether were unsuccessful. However, thermolysis of the corresponding dione **24** proceeded much more smoothly to give a 41% yield of a product assigned structure **31** on the basis of its spectroscopic properties (as in the case of **30**, the signal of the C1′ methyl group is readily discernible in the ^{1}H nmr spectrum of the product at δ 0.88 (d, J = 8 Hz)) and the fact that it is selectively reduced by sodium borohydride adsorbed on alumina (20) to **30** and is formed on chromic acid oxidation of the latter. Compound **31** was also formed in significant amount (~10%) on thermolysis of **21** when the decalin solution was not carefully freed of oxygen, presumably resulting from oxidation of the C17 hydroxyl group by decalin hydroperoxide formed by oxidation of decalin at 350°C.



30, R = H, R′ = OH
31, R, R′ = O

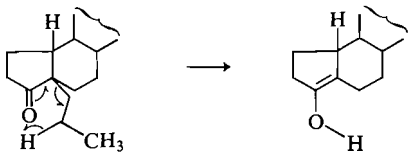


32, R =



33, R = $CH_2CH_2CH_3$

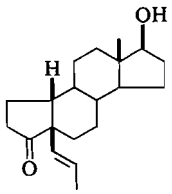
A second product was isolated in 7% yield from the thermolysate of **24**. This product is isomeric with **31** and is assigned structure **32** based on the following considerations. It has two five-membered ring ketonic groups as revealed by a strong carbonyl-stretching band in its ir spectrum at 5.74 μm and signals at δ 218.5 and 220.8 in its ^{13}C nmr spectrum.[5] The presence of a *trans*-1-propenyl group is vouchsafed by a two-proton multiplet at δ 5.20–5.42 and a three-proton broad doublet (J = 5 Hz) at δ 1.61 in its ^{1}H nmr spectrum, and a band at 10.35 μm in its ir spectrum. The *trans* stereochemistry is also indicated by the occurrence of the vinyl methyl signal at δ 18.2 in its ^{13}C nmr spectrum.[5] The intensity of the $n \rightarrow \pi^*$ band at 296 nm (ε 200) in its uv spectrum suggests that there is homoconjugative interaction between the ethylenic bond and one of the carbonyl groups and thus that it is a β,γ unsaturated ketone (21). Hydrogenation gave a dihydro compound that is assigned structure **33**. The mass spectrum of this product has a weak molecular ion at *m/e* 302 (4%) and a base peak at *m/e* 260 that results from loss of a fragment C_3H_6, as shown by accurate mass measurement. This loss can readily be interpreted in terms of a McLafferty rearrangement:



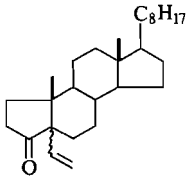
m/e 302 → *m/e* 260 + CH_2=$CHCH_3$

The occurrence of this rearrangement confirms that the *n*-propyl group in **33**, and thus the *trans*-propenyl group in **32**, is in the α relationship to one of the carbonyl groups.

The configuration of **32** at C5 is assigned on the basis of the sign of the Cotton effect shown by the C3 carbonyl group. In order to determine this it was necessary to remove the C17 carbonyl group, and this was accomplished by selective reduction to **34** with sodium borohydride adsorbed on alumina (20). The mass spectrum of the product showed it to be a dihydro compound and the fact that the C17 rather than the C3 carbonyl group is reduced is evidenced by a shift of the C18 methyl signal from δ 0.90 in the ^{1}H nmr spectrum of **32** to δ 0.80 in that of **34** (22) and by the retention of enhanced $n \rightarrow \pi^*$



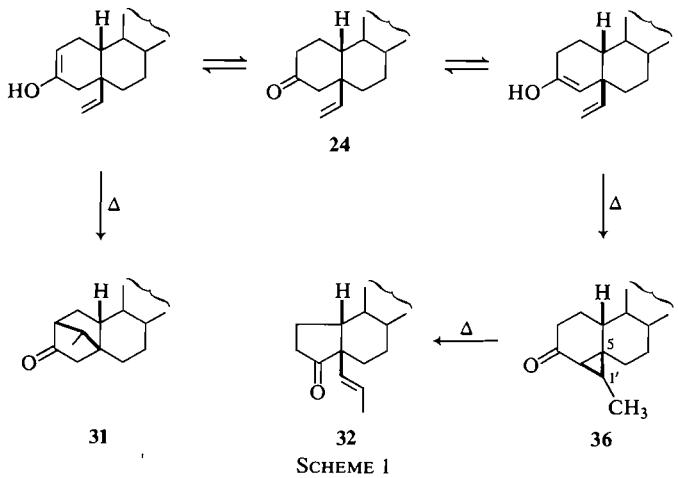
34



35*a*, 5α
35*b*, 5β

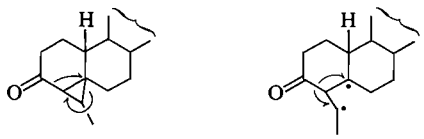
absorption in the uv spectrum of **34** (296 nm (ε 185)). The 17β configuration is assigned to **34** by analogy with the reduction of **31** to **30** by this reagent. It has been found for ketones **35***a* and **35***b* that the CD may be considered as a special case of the ketone octant rule where the double bond has the effect of increasing the magnitude of the chiroptical effect (11). Application of similar considerations to the closely related case of **34**, which exhibits a positive Cotton effect, leads to the assignment of the *cis* stereochemistry of the ring A/B junction as depicted. The amplitude of the chiroptical effect is smaller than that reported for **35***b* and this may be attributed in part to the additional methyl substituent on the double bond, which is located in a negative octant.

The formation of **32** in addition to **31** in the thermolysis of **24** may be interpreted as involving the intermediacy of the cyclopropyl ketone **36**,



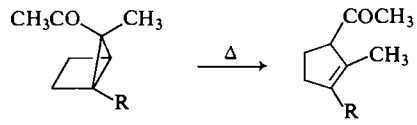
SCHEME 1

formed by an ene reaction of the Δ^3 enol of **24** (Scheme 1). This ketone can revert to **24**, but can also undergo a cyclopropyl–allylic rearrangement to give **32**. Such a rearrangement could occur by cleavage of the C5—C1′ bond and migration of the carbonyl group in either a concerted (cf. **37***a*) or stepwise fashion (cf. **37***b*). A precedent for such a rearrangement is found in the thermal rearrangement of **38** to **39** (23), which on the basis of kinetic evidence has been proposed to involve a concerted $_{\sigma}2_s + {}_{\sigma}2_a$ process analogous to that shown in **37***a*. In



37*a* **37***b*

the present case the observation of the formation of only the A/B-*cis* isomer provides some grounds for favoring the concerted mechanism. The *trans* configuration of the olefinic bond in the final product may have no mechanistic significance, since thermal isomerization of this bond could occur after its formation.



38 **39**

We conclude by referring briefly to the results of a preliminary study of the photochemistry of **30** in methanol. Three products were formed in a ~2:3:4 ratio as shown by vpc analysis. One product was separated by column chromatography and identified by its spectra as the ester **40**. The other two products, which could not be separated from each other by column chromatography are assigned structures **41** and **42**. The three products are considered to arise by the routes shown in Scheme 2, which are analogous to processes previously observed in the photochemistry of bicyclo[2.2.1]-heptan-2-ones (24, 25). Three features are noteworthy in comparison with the photochemistry of the simpler 7-*syn* substituted bicyclo[2.2.1]heptan-2-ones, camphor (**46**) (26) and apocamphor (**47**) (24, 25). First, the postulated enal intermediate **44** could not be detected among the products, while in the cases of **46** and **47** the enals of type **48** are the major isolated products and oxetane formation is only observed upon prolonged irradiation. Second, no products could be detected that arise from closure of the diradical **43** to a cyclic oxacarbene, whereas products derived from oxacarbene **49** are formed in the cases of **46** and **47**. Third, ketene **45** is implicated as an intermediate although ketene-derived products are not observed in the cases of **46** and **47**. We attribute these special features to the geometrical restrictions imposed by the steroidal framework in **43** and **44**. In the former case we suggest that these favor hydrogen transfer to give **45** over cyclization to an oxacarbene; a similar proposal has been made previously (25) to account for the formation of the ketene-derived product **50** on photolysis of carvonecamphor (**51**) in methanol (27). In the latter case we suggest that these favour exciplex formation between the $n \rightarrow \pi^*$ singlet state of the carbonyl group and the olefinic bond (28), thus facilitating oxetane formation. It may finally be noted that the formation of enal **44** from **43** rather than enal **52**, which would give rise to oxetanes distinguishable from **41** and **42**, confirms the earlier *syn* assignment of the methyl group at

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected.The ir and nmr spectra were taken in $CHCl_3$ and $CDCl_3$ solutions, respectively. The relative abundance (%) of low resolution mass spectral peaks is given in parentheses after their *m/e* values. Vapor phase chromatographic (vpc) analyses were carried out on a Varian 2700 gas chromatograph, equipped with a flame ionization detector. The temperature of the in-column injector and detector were set at 325°C and 340°C, respectively; oven temperatures ranging from 240°C to 280°C were used. The flow rate of the carrier gas (nitrogen) was adjusted at 40 mL/min. A 6 ft. glass column (od 1/8 in., id 2 mm) packed with 3% OV-17 on Chromosorb W-HP, 80/100 was utilized. The relative intensities and retention times were determined with a Varian chromatography Data System 111C. Analytical thin-layer chromatography (tlc) was carried out on 70 × 20 × 0.25 mm silica gel Q6-F plates from Quantum Industries. After elution, they were sprayed with a solution of ethanol/concentrated sulfuric acid 3:1 v/v containing a small amount of vanillin, and developed at 150°C for a few seconds. Preparative tlc was carried out on 20 × 20 cm plates coated with a 1-mm or 2-mm silica gel layer and activated at 150°C for 30 min prior to use. Column chromatography was performed on silica gel (Grace Davison, grade 923, 100/200) or neutral alumina (Woelm, activity I, 70/290, pH 7.5).

In a standard work-up the organic solution was washed twice with 5% aqueous sodium bicarbonate solution, twice with distilled water, and twice with brine. It was dried over anhydrous magnesium sulfate and concentrated *in vacuo* on a rotary evaporator under water aspirator pressure. All diethyl ether and pentane used for extraction was distilled prior to use.

*10α-des-*A*-Cholestan-5-one and 10β-des-*A*-Cholestan-5-one*

A solution of 5-oxo-*A*-nor-3,5-secocholestan-3-oic acid (29) (1.69 g, 4.2 mmol) in methanol (25 mL) was titrated with 0.2 *N* methanolic sodium hydroxide (22.3 mL). At the end-point a drop of very dilute aqueous hydrochloric acid was added. Evaporation of the solvent afforded the sodium salt of the acid (1.54 g, 86%). An intimate mixture of the salt (0.80 g, 1.85 mmol) and sodium phenylacetate (3.0 g, 19.0 mmol) was heated at 295°C in a 40:7:53 w/w/w $NaNO_2/NaNO_3/KNO_3$ bath under reduced pressure (0.05 Torr) for 3 h (30). The cooled reaction mixture was dissolved in diethyl ether. The usual work-up and chromatography on silica gel with benzene gave 10α-des-*A*-cholestan-5-one (0.50 g, 81%), which was recrystallized from methanol; mp 58–60°C (lit. (30) mp 62–63°C); λ_{max}: 5.85 μm; $^{H}\delta$: 0.70–2.60 (m), 0.76 (s, 3H), 1.01 (d, J = 6 Hz, 3H); *m/e*: 332 (100) (M^+). Further elution gave 10β-des-*A*-cholestan-5-one (80 mg, 13%), which was crystallized from methanol; mp 71–72°C; λ_{max}: 5.86 μm; $^{H}\delta$: 0.70–2.60 (m), 0.76 (s, 3H), 1.10 (d, J = 7 Hz, 3H); *m/e*: 332 (100) (M^+). *Anal.* calcd. for $C_{23}H_{40}O$: C 83.07, H 12.12, Mol. Wt. 332.3079; found: C 82.81, H 12.15, Mol. Wt. (ms) 332.3077.

*Epimerization of 10β-des-*A*-Cholestan-5-one*

A 3 *M* solution of sodium ethoxide in dry ethanol (5 drops) was added to a solution of 10β-des-*A*-cholestan-5-one (10 mg, 0.03 mmol) in dry ethanol (2 mL). After 90 min the 1:6 equilibrium mixture of this with 10α-des-*A*-cholestan-5-one was obtained, as determined by tlc with benzene as eluent.

*des-*A*-Cholest-5(10)-en-5-yl Acetate (6)*

A solution of 10α-des-*A*-cholestan-5-one (170 mg, 0.51 mmol) in carbon tetrachloride (3 mL) was treated with freshly distilled acetic anhydride (0.80 mL) and 70% aqueous perchloric acid (1 drop) and kept at room temperature for 24 h. The dark brown solution was diluted with diethyl ether (30 mL) and worked up in the usual manner to give a mixture of des-*A*-cholest-5(10)-

en-5-yl acetate (**6**) and 10α-des-*A*-cholest-5-en-5-yl acetate in an approximately 7:3 ratio (30). Chromatography with benzene on a 2-mm silica gel preparative plate afforded pure **6** (95 mg, 50%), which was crystallized from methanol/acetone; mp 72–74°C (lit. (30) mp 73–74°C); λ_{max}: 5.74, 6.15 (w) μm; $^H\delta$: 0.7–2.2 (m), 0.70 (s, 3H), 1.45 (br s, 3H), 2.10 (s, 3H).

*Reaction of des-*A*-Cholest-5(10)-en-5-yl Acetate (6) with Cyclopentadiene*

(*i*) Dicyclopentadiene (30 mg, 0.23 mmol) and **6** (270 mg, 0.45 mmol) were heated in a sealed tube at 180°C for 12 h. Purification of the reaction mixture by column chromatography on silica gel eluted with pentane followed by pentane/benzene (4:1 v/v) afforded 10α-des-*A*-cholestan-5-one (90 mg) and unconsumed **6** (10 mg).

(*ii*) A solution of **6** (140 mg, 0.38 mmol) and cyclopentadiene (50 mg, 0.76 mmol) in freshly distilled acetic anhydride (4 mL) was heated in a sealed tube at 180°C for 17 h. Evaporation of the solvent and chromatography on a 2-mm silica gel preparative plate eluted with benzene yielded unconsumed starting material (85 mg).

(*iii*) Aluminum trichloride (15 mg, 0.12 mmol) was added to a solution of **6** (45 mg, 0.12 mmol) and cyclopentadiene (15 mg, 0.25 mmol) in dry dichloromethane (15 mL). The reaction mixture was stirred at room temperature under nitrogen for 15 h. Slow addition of water followed by the usual work-up afforded an oil (41 mg), which was a complex mixture, as indicated by tlc analysis.

*des-*A*-Cholest-5-en-5-carbonitrile (7)*

Potassium cyanide (3.0 g, 0.046 mol) was added to a solution of 10α-des-*A*-cholestan-5-one (0.55 g, 1.6 mmol) in absolute ethanol (25 mL). Glacial acetic acid (3.2 mL) was added dropwise to the mixture kept at 0°C. At the end of the addition the reaction mixture was stirred at 0°C for 1 h and at room temperature for 2 h. Addition of water, extraction with ether, and the usual work-up afforded 5ξ-cyano-10α-des-*A*-cholestan-5ξ-ol (500 mg, 87%) as a white powder; λ_{max}: 2.90 (w), 4.48 (w) μm; $^H\delta$: 0.60–2.30 (m), 0.69 (s, 3H), 1.05 (d, J = 7 Hz, 3H), 3.55 (br s, 1H).

A solution of 5ξ-cyano-10α-des-*A*-cholestan-5ξ-ol (220 mg, 0.63 mol) and phosphorus oxychloride (0.2 mL) in pyridine (3 mL) was heated at reflux under nitrogen for 18 h. The reaction mixture was poured into ice-water acidified with concentrated hydrochloric acid (1 mL). Extraction with diethyl ether followed by the usual work-up and chromatography with benzene on a 2-mm silica gel preparative plate afforded **7**; λ_{max}: 4.50 (w), 6.08 (w) μm; $^H\delta$: 0.70–2.30 (m), 0.70 (s, 3H), 1.20 (d, J = 7 Hz, 3H), 6.45–6.75 (m, 1H).

Reaction of 7 with Cyclopentadiene

A mixture of **7** (130 mg, 0.38 mmol) and cyclopentadiene (25 mg, 0.40 mmol) was heated in a sealed tube at 170°C for 14.5 h. After evaporation of the solvent and of the remaining cyclopentadiene, **7** was recovered together with polymeric compounds, as shown by tlc analysis and ir and ^{1}H nmr spectroscopy. A similar result was obtained when the reaction was carried out for 4 days at 180°C with a tenfold excess of cyclopentadiene.

5-Cyano-5α-cholestan-3-one and 5-Cyano-5β-cholestan-3-one

(*i*) *Potassium Cyanide in Methanol*

5-Cyano-5α-cholestan-3-one was obtained in 10% yield by reaction of potassium cyanide and cholest-4-en-3-one (**17**) in aqueous methanol, as described by Nagata *et al.* (31); mp 182–184°C (lit. (31) mp 182–184°C); λ_{max}: 4.52 (w), 5.83 μm; $^H\delta$: 0.65–2.30 (m), 0.66 (s, 3H), 1.11 (s, 3H), 2.32–2.45 (m, 2H); *m/e*: 411 (50) (M^+).

(*ii*) *Calcium Cyanide in* N*-Methylpyrrolidone*

Calcium cyanide (90%, 0.50 g, 5.2 mmol)[7] was added to a solution of cholest-4-en-3-one (**17**) (0.50 g, 1.3 mmol) in dry *N*-methylpyrrolidone (50 mL) (32). The suspension was stirred at room temperature for 6 days. The gray suspension was poured into water and the mixture was extracted with ethyl acetate. The usual work-up followed by column chromatography on silica gel with hexane/ethyl acetate (85:15 v/v) as eluent afforded 5-cyano-5α-cholestan-3-one (135 mg, 25%), mp 181–183°C, and 5-cyano-5β-cholestan-3-one (255 mg) contaminated by a small amount of **17** as indicated by ir and ^{1}H nmr spectroscopy; λ_{max}: 4.52 (w), 5.83 μm; $^H\delta$: 0.70 (s 3H), 1.28 (s, 3H).

5-Cyano-5α-cholestan-3-one Ethylene Acetal

A solution of 5-cyano-5α-cholestan-3-one (1.70 g, 40 mmol), ethylene glycol (1.37 g, 22 mol), and *p*-toluenesulfonic acid (76 mg, 0.80 mmol) in dry toluene (150 mL) was heated at reflux in a Dean-Stark apparatus for 21 h (18). The usual work-up afforded 5-cyano-5α-cholestan-3-one ethylene acetal (1.54 g, 85%); λ_{max}: 4.55 (w) μm; $^H\delta$: 0.65–2.10 (m), 0.66 (s, 3H), 0.95 (s, 3H), 3.70–4.30 (m, 4H); *m/e*: 455 (75) (M^+).

3,3-Ethylenedioxy-5α-cholestane-5-carbaldehyde (25)[8]

To a solution of 5-cyano-5α-cholestan-3-one ethylene acetal (1.20 g, 3.74 mmol) in hexane (freshly distilled from $LiAlH_4$; 110 mL) kept at 0°C under nitrogen diisobutylaluminum hydride (1 *M* in hexane; 10 mL, 10 mmol) was added over a period of 1 h.[9] The mixture was stirred for 1 h at 0°C and for 18 h at room temperature and then added to saturated aqueous sodium sulfate (1 mL). No immediate reaction occurred, but after 10 min the temperature of the solution increased (29°C) and a white gel formed; after 1 h the temperature had decreased and the white solid formed was separated by filtration. The usual work-up of the filtrate afforded 5-iminomethyl-5α-cholestan-3-one ethylene acetal (1.26 g, 74%); λ_{max}: 3.10 (w), 6.11 (w) μm; $^H\delta$: 0.65–2.10 (m), 0.66 (s, 3H), 1.10 (s, 3H), 3.70–3.85 (m, 5H), 8.46 (br s, 1H); *m/e*: 457 (100) (M^+).

A solution of the iminomethyl compound (140 mg, 0.31 mmol) and dilute aqueous acetic acid (10%, 4 mL) in THF (15 mL) was kept at room temperature for 1 h and then neutralized with aqueous 5% $NaHCO_3$. Extraction with diethyl ether and the usual work-up afforded **25** (114 mg, 81%), which crystallized from diethyl ether; mp 113–114°C (lit. (18) mp 110–112°C); λ_{max}: 5.86 μm; $^H\delta$: 0.6–2.1 (m), 0.66 (s, 3H), 1.03 (s, 3H), 3.5–4.0 (m, 4H), 9.9 (s, 1H); *m/e*: 458 (1) (M^+).

5-Tosyloxymethyl-5α-cholestan-3-one (15)

Compound **25** was reduced with lithium aluminum hydride (35) to yield 5-hydroxymethyl-5α-cholestan-3-one ethylene acetal (91 mg, 82%),[8] which was recrystallized from acetone: mp 170–171°C (lit. (35) mp 175–177°C); λ_{max}: 2.95 (w) μm; $^H\delta$:

[7]Identical results were obtained with calcium cyanide that was purified before use by formation of the ammonia complex $[Ca(CN)_2 \cdot 2NH_3]$ (33).

[8]This experiment was conducted under rigorously anhydrous conditions under a positive pressure of argon or nitrogen.

[9]Cf. ref. 34 for a related reduction with diisobutylaluminum hydride, where, however, the iminomethyl compound was not isolated; cf. also the reduction of 5-cyano-5α-cholestan-3-one ethylene acetal with lithium triethoxyaluminum hydride to give the iminomethyl compound (18).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/06/12
For personal use only.

0.60–2.20 (m), 0.63 (s, 3H), 1.03 (s, 3H), 2.20–2.60 (br m, 1H, absent after D_2O treatment), 3.30–4.10 (br m, 4H); *m/e*: 460 (35) (M^+).

The 5-hydroxymethyl acetal was converted to the corresponding tosylate, 5-tosyloxymethyl-5α-cholestan-3-one ethylene acetal (65 mg, 47%) (36); λ_{max}: 6.24 (w), 8.50 μm; $^H\delta$: 0.60–2.0 (m), 0.61 (s, 3H), 1.00 (s, 3H), 2.43 (br s, 3H), 3.70–3.80 (m, 4H), 4.33 and 4.60 (AB system, J = 10 Hz, 2H), 7.26 and 7.76 (AB system, J = 8 Hz, 4H).

A solution of the tosyloxymethyl acetal (23 mg, 0.03 mmol) and *p*-toluenesulfonic acid hydrate (1 mg, 0.005 mmol) in acetone (5 mL) was heated at reflux for 1 h. The acetone was evaporated and the residue was extracted with chloroform. Work-up in the usual manner afforded a mixture of 5-tosyloxymethyl-5α-cholestan-3-one (**15**) and 4α,5-dihydro-3′*H*-cyclopropa[4,5]-5α-cholestan-3-one (**16**) as a white solid (17 mg). Fractional crystallization from ether afforded **15** (10 mg, 58%); mp 129–131°C (lit. (36) mp 116–117°C); λ_{max}: 5.85, 6.24 (w), 8.48 μm; $^H\delta$: 0.65–2.10 (m), 0.66 (s, 3H), 1.18 (s, 3H), 2.15–2.24 (m, 2H), 2.45 (br s, 3H), 4.33 and 4.60 (AB system, J = 10 Hz, 2H), 7.26 and 7.76 (AB system, J = 8 Hz, 4H); *m/e*: 398 (100) (M^+ − 172).

3′,4β-Dihydrocyclopropa[4,5]-5α-cholestan-3-one (16)

A solution of **15** (15 mg, 0.028 mmol) and *p*-toluenesulfonic acid (1 mg, 0.005 mmol) in acetone (4 mL) was heated at reflux for 5 h. The acetone was evaporated and the residue was extracted with chloroform. Work-up in the usual manner afforded **16** (10 mg, 90%), which was crystallized from diethyl ether/methanol; mp 135–137°C (lit. (36) mp 134–137°C); λ_{max}: 5.94 μm; λ_{max} (hexane) (ε): 272 (48) nm; $^H\delta$: 0.50–2.50 (m), 0.70 (s, 3H), 1.08 (s, 3H); *m/e*: 398 (100) (M^+).

Attempted Cyclization of 15 via its Δ^2 Enolate[8]

(*i*) To a solution of diisopropylamine (9.8 μL, 0.70 mmol) in THF (5 mL) cooled to −78°C, methyllithium in diethyl ether (1.67 *M*, 31 μL, 0.05 mmol) was added, and the resulting solution was stirred at −78°C for 1 h. A solution of **15** (31 mg, 0.050 mmol) in THF (5 mL) was added over a period of 10 min, and the reaction mixture was stirred at −78°C for 1 h, then at room temperature for 1 h. The excess base was decomposed by addition of water, and the reaction mixture was diluted with diethyl ether. Work-up in the usual manner afforded a crystalline material (27 mg), identified by ir and ^{1}H nmr spectroscopy as starting material.

(*ii*) The reaction was carried out under the same conditions as in (*i*) except that the reaction mixture was boiled under reflux for 4 h after it had warmed up to room temperature. After work-up, a solid product was obtained; λ_{max}: 5.80 (w), 5.94 μm; this was shown by tlc analysis to be a mixture of at least two products, one of which was identified as **16**; no spectroscopic evidence for the formation of a bicyclo[2.2.1]heptan-2-one system was obtained.

(*iii*) A solution of **15** (34 mg, 0.060 mmol) in 1,2-dimethoxyethane (2 mL) was added at −78°C over a period of 15 min to a solution of lithium diisopropylamide (0.080 mmol) in 1,2-dimethoxyethane, prepared at −78°C. The reaction mixture was stirred at −78°C for 1 h, then at room temperature for 16 h. After the usual work-up, a white solid was obtained, which by tlc analysis appeared to be a mixture of three compounds, including **16**; no spectroscopic evidence for the formation of a bicyclo-[2.2.1]heptan-2-one system was obtained.

17-β-Hydroxy-5-vinyl-5β-estran-3-one (21)[8]

A solution of vinyllithium in THF (1.56 *M*, titrated before use (37); 10.39 mL, 16.2 mmol) was added slowly under argon to a cooled (−78°C), stirred, solution of tetrakis[iodotri-(*n*-butylphosphine)copper(I)] (3.19 g, 8.14 mmol) (38) in THF (220 mL). The first-formed dark suspension became a clear yellow-orange solution when the addition of vinyllithium was complete. A solution of 17β-hydroxyestr-4-en-3-one (19-nortestosterone; **20**) (446 mg, 1.63 mmol) in THF (25 mL) was added slowly to the lithiumdivinyl cuprate solution kept at −78°C. After completion of the addition, the reaction mixture was stirred at −78°C for 2 h, allowed to warm up slowly to 0°C, and maintained at 0°C for 2 h; the initially clear solution became black after a few minutes at 0°C. The reaction mixture was poured into a saturated aqueous ammonium chloride solution and stirred overnight. The mixture was extracted with diethyl ether, and the combined extracts were washed with dilute aqueous ammonia, water, and brine, and dried over anhydrous magnesium sulfate. Evaporation of the solvent afforded an oil (420 mg, 85%),which crystallized from diethyl ether to give **21**, mp 171–172°C; λ_{max}: 2.80 (w), 5.86, 6.08 (w), 10.10 (w), 10.90 (w) μm; λ_{max} (CH_3OH) (ε): 272–282 (21) nm; $^H\delta$: 0.78–3.0 (m), 0.80 (s, 3H), 3.50–3.80 (m, 1H), 4.80–5.96 (m); *m/e*: 302 (60) (M^+). *Anal.* calcd. for $C_{20}H_{30}O_2$: C 79.42, H 10.00; found: C 79.43, H 9.92.

5-Vinyl-5β-estrane-3,17-dione (24)[8]

Chromium trioxide (dried *in vacuo* over P_2O_5; 0.60 g, 6.10 mmol) was added to a stirred solution of pyridine (distilled from barium oxide; 948 mg, 965 μL, 12 mmol) in dry dichloromethane (30 mL) under nitrogen at room temperature. The deep red solution was stirred at room temperature for 15 min and then a solution of **21** (300 mg, 1.00 mmol) in dichloromethane (5 mL) was added all at once. The orange-brown suspension was stirred for 20 min and filtered. The filtrate was diluted with diethyl ether (30 mL), washed with aqueous 5% sodium hydroxide and aqueous 10% hydrochloric acid, and subjected to the usual work-up. Compound **24** was obtained as a white solid (244 mg, 81%) and recrystallized from diethyl ether; mp 138–139°C; λ_{max}: 5.75, 5.84, 6.09 (w), 10.10 (w), 10.90 (w) μm; λ_{max} (CH_3OH) (ε): 285–291 (56) nm; $^H\delta$: 0.90–2.90 (m), 0.91 (s, 3H), 4.80–5.96 (m, 3H); *m/e*: 300 (100) (M^+). *Anal.* calcd. for $C_{20}H_{28}O_2$: C 79.96, H 9.39; found: C 79.90, H 9.29.

5-Vinyl-5α-cholestan-3-one (26)

5-Vinyl-5α-cholestan-3-one ethylene acetal was prepared from compound **25** by treatment with methylenetriphenylphosphorane (39); λ_{max}: 6.13 (w), 10.31 (w), 11.0 (w) μm; $^H\delta$: 0.65–2.0 (m), 0.65 (s, 3H), 1.05 (s, 3H), 3.80–3.92 (m, 4H), 4.73–5.22 (AB portion of ABX system), 6.30 (X portion of ABX system, $J_{AX} + J_{BX}$ = 27 Hz, 1H).

A solution of the 5-vinyl acetal (172 mg, 0.48 mmol) and *p*-toluenesulfonic acid (10 mg, 0.05 mmol) in acetone (20 mL) was heated at reflux for 1 h. After cooling, the solvent was evaporated, and the residue was dissolved in chloroform. The usual work-up afforded **26** (152 mg, 97%), which was recrystallized from diethyl ether/methanol (1:1 v/v); mp 141–143°C (lit. (39) mp 144–145°C); λ_{max}: 5.84, 6.12 (w), 10.28, 10.84 μm; $^H\delta$: 0.65–2.40 (m), 0.66 (s, 3H), 1.16 (s, 3H), 4.81–5.26 (AB portion of ABX system), 6.35 (X portion of ABX system, $J_{AX} + J_{BX}$ = 27 Hz, 1H); *m/e*: 412 (100) (M^+).

*2α,5-(*syn*-Methylmethano)-5α-cholestan-3-one (27)*

A solution of 5-vinyl-5α-cholestan-3-one (**26**) (85 mg, 0.21 mmol) in decalin (3 mL) was heated at 350°C for 14 h.[10] Evaporation of the decalin and chromatography on silica gel with elution with chloroform afforded **27** (35 mg, 41%) and unconsumed **26** (16 mg). Compound **27** was crystallized from methanol; mp 87–88°C; λ_{max}: 5.74 μm; λ_{max} (CH_3OH) (ε): 280 (50) nm; $^H\delta$: 0.65–2.38 (m), 0.66 (s, 3H), 0.93 (s, 3H), 2.38–2.70

[10]For details of the thermolytic conditions, see the thermolysis of compound **24** described below.

For personal use only.

(br q, J = 6 Hz, 1H); *m/e*: 412 (50) (M^+). *Mol. Wt.* calcd. for $C_{29}H_{48}O$: 412.3705; found (ms): 412.3720.

*17β-Hydroxy-2β,5-(*syn-*methylmethano)-5β-estran-3-one (30)*

(i) Thermolysis of 17β-Hydroxy-5-vinyl-5β-estran-3-one (21)

Compound **21** (500 mg, 1.66 mmol) was thermolyzed in decalin (15 mL).[10] A complex mixture was obtained, as indicated by tlc and vpc analysis. After evaporation of the decalin and chromatography on silica gel with ethyl acetate/hexane (1:4 v/v), a small amount of compound **30** (54 mg, 11%) was isolated. This was crystallized from methanol; mp 205–206°C; λ_{max}: 2.80 (w), 2.90 (w), 5.75 μm; λ_{max} (CH_3OH) (ε): 271–284 (36) nm; $^H\delta$: 0.75–2.42 (m), 0.76 (s, 3H), 0.87 (d, J = 8 Hz, 3H), 3.55–3.76 (m, 1H); *m/e*: 302 (100) (M^+). *Mol. Wt.* calcd. for $C_{20}H_{30}O_2$: 302.2246; found (ms): 302.2248.

*(ii) Reduction of 2β,5-(*syn-*Methylmethano)-5β-estrane-3,17-dione (31)*

A solution of **31** (120 mg, 0.40 mmol) (*vide infra*) in diethyl ether (25 mL) was added all at once to a vigorously stirred suspension of $NaBH_4/Al_2O_3$[11] (1.20 g, 12.7 mmol $NaBH_4$) in diethyl ether. After 5.5 h tlc analysis indicated that all the starting material had reacted to give one major product together with a minor product of higher polarity. Filtration, evaporation of the solvent, and chromatography on a 2-mm silica gel preparative plate with hexane/ethyl acetate (7:3 v/v) afforded **30** (73 mg, 60%), which crystallized from methanol; mp 205–206°C; the ir, ^1H nmr, and mass spectra of the reduction product were identical to those of the product obtained as in (*i*).

*Thermolysis of 24. Formation of 2β,5-(*syn-*Methylmethano)-5β-estrane-3,17-dione (31) and 5-(*trans-*Propenyl)-*A-*nor-5β-estrane-3,17-dione (32)*

A solution of **24** (0.800 g, 2.67 mmol) in decalin (distilled under reduced pressure from $LiAlH_4$ and kept in the dark over molecular sieves; 12 mL) was transferred into three pyrolysis tubes, previously rinsed with an alkaline solution, then with distilled water, and dried at 120°C for 3 h. These tubes were connected to a vacuum line and after two freeze–thaw cycles were sealed under vacuum. The ampoules were placed inside a 1-L stainless steel Parr bomb containing decalin (120 mL) and heated at 350°C for 14 h.[12] At the end of this period the tubes were cooled to room temperature, opened, and the decalin was evaporated to give a pale yellow oil. Chromatography on a silica gel column with elution with hexane/ethyl acetate (9:1 v/v and 4:1 v/v) afforded three fractions: unconsumed **24** (147 mg), **31** (326 mg, 41%), and **32** (57 mg, 7%). Compound **31** was recrystallized from methanol; mp 191–192°C; λ_{max}: 5.74 μm; λ_{max} (CH_3OH) (ε): 269–276 (110) nm; $^H\delta$: 0.80–2.90 (m), 0.88 (d, J = 8 Hz, 3H), 0.90 (s, 3H); *m/e*: 300 (100) (M^+). *Anal.* calcd. for $C_{20}H_{28}O_2$: C 79.96, H 9.39, *Mol. Wt.* 300.2089; found: C 79.54, H 9.36, *Mol. Wt.* (ms) 300.2094.

Compound **32** was crystallized from diethyl ether; mp 195–196°C; λ_{max}: 5.74, 10.35 (w) μm; λ_{max} (methanol) (ε): 295–297 (200) nm; $^H\delta$:0.85–2.90 (m), 0.90 (s, 3H), 1.61 (br d, J = 5 Hz, 3H), 5.20–5.42 (m, 2H). *Mol. Wt.* calcd. for $C_{20}H_{28}O_2$: 300.2089; found (ms): 300.2091.

Compound **31** was also obtained by oxidation of **30** with Jones reagent under the conditions used for the oxidation of **21** to **24**.

[11]Prepared by addition of a slurry of $NaBH_4$ (1.0 g) in distilled water (1.0 mL) to neutral alumina (10 g); the mixture was stirred for 6 h until it was homogeneous and dried overnight *in vacuo* (20).

[12]Alternatively, the tubes were inserted into an electrically heated, cylindrical glass-oven and heated at 350°C.

*5-(*n-*Propyl)-*A-*nor-5β-estrane-3,17-dione (33)*

A solution of **32** (20 mg, 0.067 mmol) in ethyl acetate (5 mL) was added to a stirred suspension of activated Adams catalyst (3 mg) in ethyl acetate (3 mL) under atmospheric pressure of hydrogen. After 1 h one equivalent of hydrogen (1.6 mL) had been taken up. The catalyst was removed by filtration and the ethyl acetate was evaporated to give **33** as a white amorphous solid; λ_{max}: 5.76 μm; $^H\delta$: 0.85–2.80 (m), 0.90 (s); *m/e*: 302 (4) (M^+), 260 (100) (M^+-42). *Mol. Wt.* calcd. for $C_{20}H_{30}O_2$: 302.2246; found (ms): 302.2245; calcd. for $C_{17}H_{24}O_2$: 260.1776; found (ms): 260.1795.

*17β-Hydroxy-5-(*trans-*propenyl)-*A-*nor-5β-estran-3-one (34)*

A solution of **32** (20 mg, 0.067 mmol) in diethyl ether (2 mL) was added all at once to a stirred suspension of $NaBH_4/Al_2O_3$[11] (500 mg; 5.28 mmol $NaBH_4$) in diethyl ether (5 mL). After 1 h all the starting material had been converted into a single product, as indicated by tlc and vpc analysis. Filtration and evaporation of the solvent from the filtrate gave **34** (17 mg, 85%) as a white amorphous solid; λ_{max}: 2.90 (w), 5.75, 10.44 (w) μm; λ_{max} (ε): 296 (185) nm; $^H\delta$: 0.70–2.20 (m), 0.80 (s, 3H), 1.61 (d, J = 5 Hz, 3H), 3.45–3.90 (m, 1H), 5.20–5.40 (m, 2H); *m/e*: 302 (100) (M^+); CD (*c* 1.24, MeOH) 22°C: $[\theta]_{340}$ 0, $[\theta]_{297}$ +1200, $[\theta]_{240}$ 0. *Mol. Wt.* calcd. for $C_{20}H_{30}O_2$: 302.2246; found (ms): 302.2242.

*Irradiation of 17β-Hydroxy-2β,5-(*syn-*methylmethano)-5β-estran-3-one (30)*

A solution of **30** (100 mg, 0.33 mmol) in methanol (boiled under reflux over magnesium and then distilled; 20 mL) was irradiated in Pyrex under nitrogen with a Hanovia 450-W medium-pressure mercury arc lamp for 12 h to give a mixture of three components in the approximate ratio 2:3:4, as determined by vpc analysis. The usual work-up and chromatography on a 2-mm silica gel preparative plate afforded two major fractions. The slower moving fraction (10 mg) was shown by vpc analysis to be a single product, compound **40**; λ_{max}: 2.80 (w), 5.78 μm; $^H\delta$: 0.55–2.22 (m), 0.75 (s, 3H), 0.91 (br d, J = 6 Hz, 3H), 3.61 (s, 3H), 3.4–3.6 (br m); *m/e*: 334 (9) (M^+), 260 (100) (M^+-74). *Mol. Wt.* calcd. for $C_{21}H_{34}O_3$: 334.2508; found (ms) 334.2500; calcd. for $C_{18}H_{28}O$: 260.2140; found: 260.2135.

The second fraction was a mixture of **41** and **42**; λ_{max}: 2.80 (w), 10.5 (m), 11.0 (m) μm; $^H\delta$: 3.5–3.8 (m), 4.5–4.7 (m). Gas chromatographic – mass spectral analysis showed that one component has *m/e* 320 (M^+) and 260 ($M^+ - C_2H_2O$; base peak) and the other *m/e* 302 (M^+) and 258 ($M^+ - C_2H_4O$; base peak).

Microbial hydroxylation of steroids. 7. Hydroxylation of *B*-nortestosterone and related compounds by *Rhizopus arrhizus* ATCC 11145, and ^{13}C nuclear magnetic resonance spectra of some *B*-norsteroids

HERBERT L. HOLLAND

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received December 29, 1980

HERBERT L. HOLLAND. Can. J. Chem. **59**, 1651 (1981).

The incubation of *B*-norandrost-4-ene-3-ones and *B*-nor-3β-hydroxyandrost-5-enes with *Rhizopus arrhizus* ATCC 11145 has been described. The products are consistent with a mechanism of oxidation at C-6 in which the stereochemistry of substitution at C-6 is controlled by stereoelectronic interactions in the substrate, and is not dictated by enzymic constraint during the reaction. The carbon-13 nuclear magnetic resonance spectra of several *B*-nor-Δ^4 and Δ^5 steroids have been presented.

HERBERT L. HOLLAND. Can. J. Chem. **59**, 1651 (1981).

On décrit l'incubation des *B*-norandrostène-4 ones-3 et des *B*-norhydroxy-3β androstènes-5 avec le *Rhizopus arrhizus* ATCC 11145. Les produits sont en accord avec un mécanisme d'oxydation au niveau du carbone en position 6 dans lequel la stéréochimie de la substitution en C-6 est contrôlée par des interactions stéréoélectroniques dans le substrat et elle n'est nullement due à une contrainte enzymatique au cours de la réaction. On présente les spectres de résonance magnétique nucléaire du C-13 de plusieurs *B*-nor-Δ^4 et Δ^5 stéroides.

[Traduit par le journal]

Introduction

The mechanism of the hydroxylation of androst-4-ene-3,17-dione (**1***a*) at C-6β by the fungus *Rhizopus arrhizus* ATCC 11145 has been studied in some detail (1–6). The reaction proceeds by enzymic enolization of the Δ^4-3-ketone, followed by stereoelectronically controlled axial addition of electrophilic oxygen to the resulting enol, giving rise to **1***b* stereospecifically. A feature of this mechanism is that the stereochemistry of substitution at C-6 of the product is determined largely by conventional stereoelectronic interactions during the oxidation process, rather than being dictated by constraints placed upon the reactants by their interaction with the enzyme.

In this paper, the incubations with *R. arrhizus* of the Δ^4-3-keto-*B*-norsteroids **2***a* and **3***a*, and of the Δ^5-*B*-norsteroids **4***a* and **4***b* are described, which support the mechanistic interpretation outlined above. In addition, the ^{13}C nuclear magnetic resonance spectra of several *B*-norsteroids are presented.

Results and Discussion

B-norandrost-4-ene-3,17-dione (**2***a*) was metabolized by *R. arrhizus* to give three products in low yield. The difficulty of separation of these products precluded their large scale preparation, but by repeated chromatography pure samples were obtained and identified as *B*-nortestosterone (**3***a*), and the 6α- and 6β- hydroxy-*B*-norandrost-4-ene-3,17-diones, (**2***c*) and (**2***b*) respectively. The identification of **3***a* was trivial, and **2***c* has been reported previously as the product of microbial transformation of **2***a* by *Absidia orchidis* (7, 8). Confirmation of the structures of **2***b* and **2***c* rested largely on comparisons of their ^1H nmr spectral data (Table 1) with those of **1***b* and **1***c*, and, more significantly, with those of **3***b* and **3***c*. The ^1H nmr spectra of the latter two compounds, the only products of the incubation of *B*-nortestosterone (**3***a*) with *R. arrhizus*, were analysed by spin decoupling experiments.[1] In each case the C-4 hydrogen, which

*Solvent $CDCl_3$ unless otherwise stated.
†Solvent $CDCl_3$/DMSO-d_6, 1:1.

appears in the undecoupled spectrum as a doublet, collapsed to a singlet upon irradiation at the resonance position of the hydrogen geminal to hydroxyl, thus confirming the location of the latter functional group at C-6. The chemical shifts observed for the C-19 methyl hydrogens, diagnostic of the stereochemistry of substitution at C-6 (9), are also consistent with the structures presented, as are their ^{13}C nmr data (*vide infra*).

R. arrhizus has been reported to hydroxylate 17α-methyl-*B*-nortestosterone at C-6α, C-6β, and C-11α, but without quantification or discussion of the results (10). Hydroxylation of **2***a* or **3***a* at C-11α was not observed in the present study but hydroxylation at C-6 of both substrates occurred, to give α and β isomers in approximately equal amounts in each instance. Control experiments in which **3***b* and **3***c* were used as substrate demonstrated that epimerization at C-6 does not occur under the conditions of the incubation or work-up, the C-6 alcohols being recovered unchanged in each case. The concurrent formation of both α and β alcohols at C-6 from **2***a* and **3***a* is consistent with the mechanism outlined in the Introduction: the conformation of the 5-membered B ring of *B*-norsteroids is such that both α and β positions at C-6 are stereochemically equivalent with respect to the plane of the O—C-3—C-4—C-5 enone system. This is reflected in the observed multiplicity of the C-4 hydrogen signal in the ^1H nmr spectra of **2***a* and **3***a*, appearing as a symmetrical triplet (J = 1.5 Hz) (Table 1) due to the influence of both hydrogens at C-6. Interaction of developing electron density at C-6 from a $\Delta^{3,5}$ enol of **2***a* or **3***a* with an electrophilic oxidizing species will therefore occur equally favourably on both α and β faces of the molecule. This assumes that the transition state for the reaction is product-like, an assumption which is consistent with available data on such processes (2, 11, 12).

The reaction of a $\Delta^{3,5}$ enol acetate or enol ether with *m*-chloroperoxybenzoic acid has been used successfully as a model system to study the stereoelectronic control of product formation during electrophilic oxidation at C-6 in the normal steroid series (3) and related bicyclic enones (1, 3). In an attempt to use this reaction in the *B*-nor series, the preparation of compounds **8***a* and **8***b* was undertaken, using standard procedures for the preparation of $\Delta^{3,5}$ enol ethers (13) and acetates (14) from Δ^4-3-ketosteroids. Although tlc analysis indicated that product formation had occurred, all attempts at isolation resulted in reversion to the Δ^4-3-ketone. An alternative procedure, successful in converting a bicyclo [4.3.0] nonenone to its enol acetate **10**, (15), was used with *B*-nortestosterone (**3***a*) as starting material in an effort to produce the enol diacetate **9**; once again, although **9** was apparently formed in the reaction, it reverted to *B*-nortestosterone acetate on attempts at isolation. Compound **10** is reportedly unstable (15), and the extra steric strain in ring B of the steroid caused by the presence of rings C and D can account for an increased reactivity of **8***a*, **8***b*, and **9** with respect to **10**. It has therefore not been possible to pursue the model oxidations of **8***a*, **8***b*, or **9**.

The lack of enzyme control of oxidation at C-6 is observed more strikingly in the oxidation of the Δ^5-*B*-norsteroids **4***a* and **4***b* by *R. arrhizus*. Both gave identical products, the ester function of **4***b* being hydrolyzed in conjunction with oxidative metabolism. The product of hydroxylation at C-11α, **4***c*, was identified by spectral analysis (see tables) and by comparison of physical data with those published (7, 8). The 5,6α epoxide **5** was identified by ^1H and ^{13}C nmr spectral data (Tables 1 and 2). This compound has also previously been reported as the result of the transformation of **4***a* by *Rhizopus nigricans* (7, 8).

The stereospecific formation of the 5,6α epoxide by a micro-organism which produces the C-6β alcohol from Δ^4-3-keto substrates of the normal steroid series once again emphasizes that the stereochemistry of oxidation in this region of the molecule is controlled by the configuration and conformation of the substrate and is largely independent of the enzyme; peracid oxidation of the 5,6-double bond in *B*-norsteroids proceeds stereoselectively from the α side (16).

Product characterization in this study relied heavily upon the interpretation of carbon-13 nuclear magnetic resonance data, presented in Tables 2 and 3. The chemical shifts of the unsubstituted Δ^4-3-keto-*B*-norsteroids **2***a* and **3***a* and of the Δ^5-*B*-norsteroids **4***a*, **4***b*, **6***a*, **6***b*, and **7** were readily assigned by comparison with published data for analogous *B*-norcholestenes (Rings A and B) (17) and androstane derivatives (Rings C and D) (18). Compound **4***c* shows chemical shifts in accord with

those anticipated for C-11α hydroxyl substitution (in normal steroids) (18), while **5** shows shifts, particularly those of C-1 and C-9, which confirm the α stereochemistry of the epoxide (19). The 6-hydroxy-*B*-norsteroids **2***b* and **2***c* were not obtained in sufficient quantity for acceptable ^{13}C spectra to be easily obtained, but chemical shift assignments for the analogous *B*-nortestosterone derivatives **3***b* and **3***c* are presented in Table 3.

The observed shifts at C-6, C-8, C-14, and C-19, with respect to those of the corresponding carbons of **3***a*, are characteristic of the stereochemistry of substitution at C-6 and are entirely consistent with the structures proposed.

Experimental

Apparatus, Materials, and Methods

The apparatus and techniques used were as previously described (3, 19). Analytical samples were purified and final separation of **3***b* and **3***c* performed by chromatography using a Perkin-Elmer series 3A HPLC. Incubations with *R. arrhizus* were performed as described earlier (1).

Preparation of Substrates

The following compounds were prepared by published procedures: *B*-norandrost-4-ene-3,17-dione (**2***a*) (20, 21), 3β-acetoxy-*B*-norandrost-5-ene-17-one (**4***b*) (20), *B*-norandrost-5-ene-3β-ol-17-one (**4***a*) (20), *B*-norandrost-5-ene-3β,17β-diol (**6***a*) (20), 3β,17β-diacetoxy-*B*-norandrost-5-ene (**6***b*) (20), 3β-acetoxy-*B*-norpregn-5-ene-20-one (**7**) (20). All compounds had analytical (mp) and spectral (ir) properties consistent with those reported previously (20, 21). The ^1H nmr and ^{13}C nmr data are presented in the tables.

B-*Norandrost-4-ene-17β-ol-3-one* (B-*nortestosterone*), (**3***a*)

This was prepared by the procedure used by Eder for the preparation of testosterone from androst-4-ene-3,17-dione (22). A solution of *B*-norandrost-4-ene-3,17-dione (**2***a*) (7 g) in toluene (400 mL) was flushed with N_2 and heated until 200 mL of solvent had been distilled out. The solution was then cooled to 0°C, and a solution of di-isobutyl aluminum hydride in toluene (35 mL, 25%) added by syringe over a period of 10 min. The solution was stirred at 0°C for 1 h, and then acetone (14 mL) was added, followed by 2-propanol (14 mL). The resulting mixture was allowed to stand at room temperature for 3 h, and then poured onto *N* H_2SO_4 (200 mL). The product was then extracted into ether, (4 × 200 mL), and the extract washed (saturated $NaHCO_3$, water, and brine), dried (Na_2SO_4), and evaporated. The residue (6.1 g) on crystallization from ethyl acetate afforded *B*-nortestosterone (**3***a*), (5.8 g, 83%), mp 163–165°C (lit. (21) mp 163–164°C).

Incubations with R. arrhizus *ATCC 11145*

B-*Norandrost-4-ene-3,17-dione* (2a)

Incubation of **2***a* (1 g) by the standard procedure (1) gave extracts from the medium (0.9 g) and mycelium (1.3 g). The latter contained endogenous fungal material, plus **2***a* as the only readily detectable steroid. The former extract was chromatographed on silica gel using benzene–ether gradient elution and afforded **2***a* (0.7 g) and a mixture of **3***a*, **2***b*, and **2***c* (total 0.18 g), which was separated by repeated preparative layer chromatography (Merck Silica gel 60 F_{254}, 3% methanolic chloroform) to give, in order of decreasing R_f, *B*-nortestosterone (**3***a*) (35 mg), identified by mp, tlc, and spectral comparison with an authentic sample prepared as above; 6α-hydroxy-*B*-norandrost-4-ene-3,17-dione (**2***c*) (8 mg after crystallization from ethyl acetate – hexane), mp 205–210°C (lit. (7, 8) mp 210–213°C); ir ν_{max}: 1670, 1750, 3450 cm^{-1}; *ms m/e* (%): 288 (100), 273 (35), 270 (20), 260 (15), 255 (15), 244 (40), 242 (25), 232 (60); ^1H nmr, see tables; and 6β-hydroxy-*B*-norandrost-4-ene-3,17-dione (**2***b*) (6 mg after crystallization from ethyl acetate – hexane), mp 195–198°C; ir ν_{max}: 1670, 1750, 3450 cm^{-1}; ms, M^+ calcd. for $C_{18}H_{24}O_3$: 288.172; found: 288.169; *m/e* (%): 288 (100), 273 (45), 270 (20), 260 (30), 255 (25), 244 (35), 242 (20), 232 (40); ^1H nmr, see tables.

B-*Nortestosterone* (3a)

Incubation of **3***a* (2 g) gave extracts from the mycelium (1.8 g) and medium (1.6 g). The former contained **3***a* as the only readily detectable steroid. The latter extract was chromatographed on silica gel using benzene–ether – 2% methanolic ether as eluting solvents, and gave **3***a* (0.66 g), identified by comparison with a sample of authentic material, and a mixture of **3***b* and **3***c* (total 0.81 g, ca. 1:1) separated by high pressure liquid chromatography on a column of silica gel (Whatman Partisil 20, 800 × 7.8 mm) using chloroform – ethyl acetate (40:60) as eluting solvent. Crystallization from ethyl acetate – hexane gave 6β-hydroxy-*B*-nortestosterone (**3***b*), mp 172–174°C; ir ν_{max}: 1660, 3450 cm^{-1}; ms, M^+ calcd. for $C_{18}H_{26}O_3$: 290.188; found: 290.181; *m/e* (%): 290 (100), 288 (20), 275 (50), 272 (46), 257 (57), 246 (16), 234 (70), 215 (80), 213 (70); R_f, benzene – ethyl acetate 30:70, 4 elutions, 0.5; chloroform – ethyl acetate 30:70, 4 elutions, 0.63; nmr, see tables; and 6α-hydroxy-*B*-nortestosterone (**3***c*), mp 191–193°C; ir ν_{max}: 1660, 3450 cm^{-1}; ms, M^+ calcd. for $C_{18}H_{26}O_3$: 290.188; found: 290.184; *m/e* (%): 290 (28), 288 (6), 275 (12), 272 (20), 257 (32), 246 (30), 234 (100), 215 (40), 213 (42); R_f benzene – ethyl acetate 30:70, 4 elutions, 0.42; chloroform – ethyl acetate 30:70, 4 elutions, 0.56; nmr, see tables.

3β-*Hydroxy*-B-*norandrost-5-ene-17-one* (*4a*)

Incubation of **4***a* (2.4 g) gave extracts from the medium (1.8 g) and mycelium (0.8 g). The latter contained starting material as the only readily detectable steroid (tlc) and was not examined further. The extract from the incubation medium was chromatographed on silica gel (gradient elution from benzene through ether to 5% methanolic ether) and gave **4***a* (0.57 g), identified by

comparison with authentic material, 5,6α-epoxy-3β-hydroxy-*B*-nor-5α-androstan-17-one (**5**) (0.45 g from ethyl acetate – hexane), mp 193–196°C (lit. (8) mp 195–198°C); ms *m/e* (%): 290 (100), 275 (35), 272 (66), 257 (52), 244 (46), 217 (63), 215 (95); nmr, see tables; and 3β,11α-dihydroxy-*B*-norandrost-5-ene-17-one (**4***c*) (0.49 g from ethyl acetate – hexane), mp 135–138°C (softening at 115°C) (lit. (8) mp 114–120°C (from ethyl acetate)), ms *m/e* (%): 290 (100), 275 (24), 272 (24), 257 (25), 246 (36), 231 (18), 228 (27), 215 (30), 213 (32); nmr, see tables.

3β-*Acetoxy*-B-*norandrost-5-ene-17-one* (**4***b*)

Incubation of **4***b* (1 g), and work-up as described above for the incubation of **4***a*, gave **4***b* (trace), **4***a* (trace), **4***c* (0.25 g), and **5** (0.09 g). Compounds **4***c* and **5** produced in this way were identical with samples produced by incubation of **4***a* with *R. arrhizus*.

Attempted Preparations of 3-Acetoxy- and 3-Ethoxy-B-*norandrosta-3,5-diene-17-one* (**8**a *and* **8**b), *and 3,17*β*-Diacetoxy*-B-*norandrosta-3,5-diene* (**9**)

3-Acetoxy-B-*norandrosta-3,5-diene-17-one* (**8**a)

Perchloric acid (8 μL, 70%) was added to a solution of *B*-norandrost-4-ene-3,17-dione (**2***a*) (0.1 g) in dry ethyl acetate (20 mL) and freshly distilled acetic anhydride (2 mL). The reaction was allowed to stand at room temperature, and was monitored by tlc analysis. After a period of 2 h, when reaction was judged to be virtually complete, the mixture was poured onto 2*M* sodium bicarbonate and the product extracted into ethyl acetate. The extract was washed with water, dried (Na_2SO_4), and evaporated to yield an oil which by ^{1}H nmr analysis was found to consist of a mixture of **2***a* (ca. 80%) and the desired product (**8***a*) (ca. 20%). All attempts at separation of this mixture by chromatography on silica gel or alumina resulted only in the recovery of **2***a*.

3-Ethoxy-B-*norandrosta-3,5-diene-17-one* (**8**b)

B-Norandrost-4-ene-3,17-dione (**2***a*) (1.5 g) was dissolved in acetone cyanohydrin (3 mL) by gentle warming, and then aqueous ammonia (sg. 0.880, 4 drops) added to the solution. The resulting mixture was allowed to stand at room temperature for 3 h, and then filtered to yield 17ξ-cyano-17ξ-hydroxy-*B*-norandrost-4-ene-17-one (1.35 g), which was washed with ether and dried *in vacuo* to give a sample of mp 163–165°C; ir ν_{max}: 1660, 2220, 3350 cm^{-1}; ^{1}H nmr δ: 0.95 (3H, s, C-18H), 1.10 (3H, s, C-19H), 5.86 (1H, br s, C-4H); ms *m/e* (%): 299 (1), 284 (2), 272 (54), 257 (14), 274 (29), 230 (100). *Anal.* calcd. for $C_{19}H_{25}NO_2$: C 76.21, H 8.41, N 4.69%; found: C 75.98, H 8.39, N 4.59%.

The above cyanohydrin (1.1 g) was dissolved in benzene (20 mL), and then 10 mL of solvent was removed by distillation. When the solution had cooled to 65°C, freshly distilled ethyl orthoformate (2.0 mL), absolute ethanol (0.9 mL), and ethanolic HCl (80 μL of a solution of 15 mL concentrated HCl in 65 mL ethanol) were added. The resulting mixture was maintained at 65°C for 2½ h, after which time tlc analysis indicated that formation of **8***b*-cyanohydrin was essentially complete. The mixture was then neutralized by the addition of pyridine (14 μL) and evaporated *in vacuo* to yield a pale yellow solid (1.31 g), which was subsequently redissolved in 95% ethanol (20 mL) containing pyridine (2 drops). This solution was heated (steam bath) for 20 min, and then diluted with hot water and allowed to crystallize to yield 1.0 g of a solid, which by ^{1}H nmr analysis was found to consist of a mixture of **2***a* (ca. 60%) and **8***b* (ca. 40%). Attempted separation as described above gave only **2***a*.

*3*β*,17*β*-Diacetoxy*-B-*norandrosta-3,5-diene* (**9**)

Preparation of **9** was attempted using the method of Peet and Cargill (15) on *B*-nortestosterone (0.515 g). The only isolable product was *B*-nortestosterone acetate (0.47 g).

Orientations of the hydroxyl and isopropyl groups in the *cis* and *trans* conformers of 2-isopropylphenol and 2-isopropyl-6-methylphenol

TED SCHAEFER, BRENDA M. ADDISON, RUDY SEBASTIAN, AND TIMOTHY A. WILDMAN

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 28, 1980

TED SCHAEFER, BRENDA M. ADDISON, RUDY SEBASTIAN, and TIMOTHY A. WILDMAN. Can. J. Chem. **59**, 1656 (1981).

Measurement of the long-range spin–spin coupling constants between methine or hydroxyl protons and the ring protons in 2-isopropylphenol shows that the *trans* conformer is favored by 2.5 ± 0.3 kJ/mol for a 2 mol% solution in CCl_4 at 305 K. In this conformer the methine C—H bond of the isopropyl group points towards the hydroxyl group. In the *cis* conformer, the C—H bond points away from the hydroxyl group. In 2-isopropyl-6-methylphenol the conformation in which the O—H bond lies *trans* to the isopropyl group is preferred by 1.2 ± 0.3 kJ/mol in free energy at 305 K in CCl_4 solution. This result agrees with an additive superposition of the conformational preferences of the hydroxyl groups in the monosubstituted phenol derivatives. Molecular orbital calculations do not agree with the existence of a *cis* conformer.

TED SCHAEFER, BRENDA M. ADDISON, RUDY SEBASTIAN et TIMOTHY A. WILDMAN. Can. J. Chem. **59**, 1656 (1981).

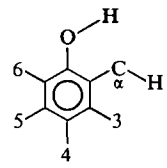
La mesure des constantes de couplage à longue distance entre les protons méthinique ou hydroxyle et les protons du cycle de l'isopropyl-2 phénol montre que le conformère *trans* est favorisé par 2,5 ± 0,3 kJ/mol pour une solution à 2 mol% dans le CCl_4 à 305 K. Dans ce conformère, la liaison C—H du méthine de l'isopropyle est orientée vers le groupe hydroxyle. Dans le conformère *cis*, la liaison C—H est orientée en *trans* par rapport à l'hydroxyle. Dans l'isopropyl-2 méthyl-6 phénol, la conformation privilégiée est celle où la liaison O—H se situe en position *trans* par rapport au groupe isopropyle; du point de vue de l'énergie libre, cette conformation est favorisée par 1,2 ± 0,3 kJ/mol à 305 K en solution dans le CCl_4. Ce résultat est en accord avec une superposition additive des préférences conformationnelles des groupes hydroxyles dans les dérivés monosubstitués du phénol. Les calculs d'orbitales moléculaires ne sont pas en accord avec l'existence d'un conformère *cis*.

[Traduit par le journal]

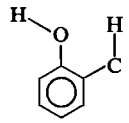
Introduction

If intermolecular proton exchange can be retarded sufficiently (1–8), then the measurement of the stereospecific long-range proton–proton coupling constants over five bonds, ${}^5J_m{}^{H,OH}$, provides a direct measure of the *cis–trans* equilibrium in phenol derivatives. This measurement may be the only direct method for some phenols, e.g., 2-methylphenol (2), for which hydroxyl stretching bands cannot be resolved into two components (9) and for which low-frequency Raman and infrared vibrations cannot be assigned unambiguously (10, 11).

The hydroxyl stretching band in 2-isopropylphenol is also unresolvable (9), and is shifted by only 2 cm^{-1} from the phenol value. The twofold barrier to internal rotation of the isopropyl group in isopropylbenzene is 8.4 ± 0.8 kJ/mol. The preferred conformation has the methine C—H bond in the plane of the aromatic framework (12). Again, phenol prefers a planar conformation to the extent of 14.6 kJ/mol (13, 14). At ambient temperatures, the equilibrium **1***a*/**1***b* appears as an hypothesis; the barriers to rotation about the C—O and exocyclic C—C bonds being rather larger than kT. Intuitively, **1***a* should be *much* less stable than **1***b*, as is suggested by molecular orbital calculations, and consistent with the infrared data. The present experiments show otherwise. Note that correlated orientations of the sidechains are implied by **1***a* and **1***b*.



1*a cis*



1*b trans*

Experimental

A solution containing 1.9$_5$ mol% of 2-isopropylphenol (Ethyl Corporation) and 4.0 mol% of tetramethylsilane (TMS) in CCl_4 was transferred to a 5 mm od nmr sample tube, was degassed by five freeze–thaw–pump cycles, and was then flame-sealed. Intermolecular hydroxyl proton exchange was retarded as described previously (7). The ^1H nmr spectrum was recorded on an HA100 spectrometer in the frequency sweep mode at a probe temperature of 305 K. Calibrations involved the reading of sweep and lock oscillator frequencies for markers placed at ca. 5 Hz intervals. Fivefold repetition of this procedure and interpolation sequences yielded peak frequencies whose standard deviations were typically ≤ 0.02 Hz.

A 6.0 mol% solution in CCl_4 of 2-isopropyl-6-methylphenol, prepared from the aniline derivative (Ethyl Corporation) via diazotization, was degassed and flame sealed into a 5 mm od nmr sample tube. Its ^1H nmr spectrum was recorded at 100 MHz and a probe temperature of 205 K. Decoupling of methyl protons yielded a spectrum in which fine structure in the hydroxyl proton band could be resolved. The peaks due to H-3 were broadened by small couplings to the isopropyl substituent. The ring proton region was not calibrated precisely.

Calculations at the STO 3G level of *ab initio* molecular orbital

theory (15), as well as at the INDO level of semiempirical MO theory (16), were performed on an Amdahl 470/V7 system.

Results and Discussion

Spectral Analysis

The spectral parameters for **1** in Table 1 were obtained via the computer program LAME (17, 18). There were no substantial correlations between the parameters. However, the peaks due to H-3 were broadened by small couplings to the methyl protons. Decoupling procedures did not lead to linewidths for H-3 acceptable in a precise analysis, perhaps because one of the CH_3 peaks occurred near 120 Hz from the lock frequency. The H-3 peaks were therefore not assigned in the iterations, nor were those of the methine proton. Nevertheless 110 of the 128 calculated transitions of the other four protons were assigned and led to a calculated spectrum in good agreement with experiment. Figure 1 displays the calculated and observed spectra for the hydroxyl proton. The distortion of the experimental spectrum *may* arise from unresolved interactions with the isopropyl protons. Such distortions do not occur for 4-chloro-2-methylphenol (2).

The ring proton spectrum of 2-isopropyl-6-methylphenol corresponds to a loosely coupled ABC spin system, complicated by long-range couplings to the hydroxyl proton, to the protons of the methyl substituent, to the methine proton of the isopropyl group, and, for H-3, by additional small couplings with the six methyl protons of the isopropyl substituent. Precise spectral parameters for the ring protons were not obtainable. Approximate δ values are 6.83, 6.67, and 6.92 ppm for H-5, H-4, and H-3, respectively.

TABLE 1. ^{1}H nmr spectral parameters for a 2 mol% solution of 2-isopropylphenol in CCl_4 at 305 K

Parameter	Value	Parameter	Value
ν_{OH}[a]	438.684(3)[b]	$^5J_o^{CH,OH}$	0.0
ν_{CH}	318.4	$^5J_m^{H_3,OH}$	0.509(6)

[a] In Hz at 100.001 MHz (centreband) to low field of TMS.
[b] Numbers in parentheses are standard deviations in the last significant figure.
[c] Excluding 32 for H-3 and 32 for the methine proton (see text).

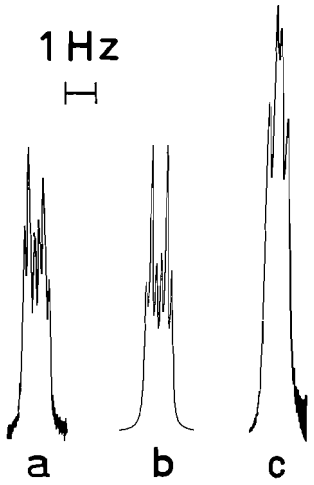

FIG. 1. In (a) is shown the ^{1}H nmr spectrum at 100 MHz of the hydroxyl proton of a 1.9_5 mol% solution of 2-isopropylphenol in CCl_4. δ_{OH} is 4.387 ppm at 305 K. The calculated spectrum in (b) used the parameters in Table 1 and a linewidth at half height of 0.10 Hz. Some of the distortion and broadening (compare Fig. 1 in ref. 2) may arise from unresolved couplings to the methine and/or methyl protons. No coupling to H-4 was indicated by decoupling experiments. In (c) is displayed the hydroxyl proton resonance of 2-isopropyl-6-methylphenol. The methyl protons are being decoupled, the probe temperature is 305 K, δ_{OH} is 4.381 ppm, and some residual coupling to isopropyl protons may be present. $^5J_m^{H_3,OH}$ is 0.38 ± 0.02 Hz and $^5J_m^{H_5,OH}$ is 0.24 ± 0.02 Hz. Corrections for overlapping Lorentzian lines would give 0.42 nd 0.26 Hz.

The hydroxyl proton is coupled to the 6-methyl protons (very likely by a proximate interaction) by an amount sufficient to obscure its interactions with the ring protons. Irradiation at δ_{CH_3}= 2.182 ppm yielded the hydroxyl proton spectrum at δ = 4.381 ppm shown in Fig. 1c (a 3.6 mol% solution had δ_{OH} as 4.365 ppm). It is clear that the couplings to H-3 and H-5 are unequal.

Under these conditions, the ring proton spectrum allowed the extraction of $^5J_m^{H_4,CH}$ as 0.375 ± 0.02 Hz and also showed that the smaller $^5J_m^{H,OH}$ involves H-5. The ring proton chemical shift assignment, based initially on the broadened lines from H-3, was confirmed by irradiation of the hydroxyl proton band. The ensuing spectrum showed that $^6J_p^{H,CH}$ is (−)0.24 ± 0.02 Hz, $^6J_p^{H,CH_3}$ is (−)0.6 Hz, and $^4J_o^{H,CH_3}$ is (−)0.7 Hz. Consequently, no doubt exists about the assignment of the H-3 and H-5 multiplets. The methine proton of the isopropyl group resonates at 3.140 ppm.

The cis–trans *Equilibrium*

The sum of the two $^5J_m^{H,OH}$ values is 0.69_8 Hz, as compared to 0.69_5 Hz for a 2.5 mol% solution of 2-methylphenol (2). It is therefore assumed that ^5J_m

depends only on the conformational equilibria, the latter being different for the two compounds. If $^5J_m^{H_3,OH}$ in **1***a* and $^5J_m^{H_5,OH}$ in **1***b* are negligibly small (see refs. 3 and 4 for more extensive discussions of this point), it follows that the free energy difference between **1***a* and **1***b* is $-RT \ln K = -RT \ln 0.509/0.189 = -2510 \pm 290$ J/mol. The quoted error assumes that the standard deviations in Table 1 are to be multiplied by 3 (99% confidence limits). In 2-methylphenol in CCl_4 solution at the same temperature (305 K), the *trans* form is favored by 1590 ± 170 J/mol in free energy.

No coupling between the *para* proton, H-4, and the hydroxyl proton could be detected, strongly indicating (3, 8) that conformers in which the O—H bond lies out of the benzene plane can be ignored in this discussion.

The Conformations of the Isopropyl Group

$^5J_m^{H,CH}$ is stereospecific in benzene derivatives containing sidechains such as CHO (19–21), $CHCl_2$ (22), $CHBr_2$ (23), and CHI_2 (24). All the evidence points to a vanishing magnitude of couplings analogous to $^5J_m^{H_4,CH}$ in **1***a* and $^5J_m^{H_6,CH}$ in **1***b*. Furthermore, substituents on the ring cause only minor changes in the magnitude of $^5J_m^{H,CH}$. In particular, in *p*-nitroisopropylbenzene (25) $^5J_m^{H,CH}$ is 0.30 ± 0.02 Hz, i.e. the coupling analogous to $^5J_m^{H_6,CH}$ in **1***a* or $^5J_m^{H_4,CH}$ in **1***b* would be 0.60 ± 0.04 Hz. In *p*-fluoroisopropylbenzene, $^5J_m^{H,CH}$ is 0.31 ± 0.02 Hz (26). The sum of the two $^5J_m^{H,CH}$ values in 2-isopropylphenol is 0.62_8 ± 0.04 Hz (error equal to three times the sum of the standard deviations).

Accordingly, if the orientation of the isopropyl group is correlated with that of the hydroxyl group as indicated by **1***a* and **1***b*, the free energy difference favoring **1***a* can also be written as $-RT \ln 0.450/0.178 = -2340 \pm 420$ J/mol. The quoted error again assumes that the standard deviations in the individual $^5J_m^{H,CH}$ values are to be tripled. It appears that **1***a* and **1***b* are good approximations to the preferred orientations of the sidechains. The structures are discussed further below.

cis–trans *Equilibrium in 2-Isopropyl-6-methylphenol*

Decoupling of the methyl protons yielded the spectrum of the hydroxyl proton in Fig. 1c. Some residual breadth of the lines suggests that the splittings should be corrected for overlap of Lorentzian peaks (see figure caption). The free energy difference favoring the conformer in which the hydroxyl group lies *trans* to the isopropyl group is 1200 ± 290 J/mol (1170 ± 330 J/mol if the uncorrected couplings are used). The additive preference derived from the monosubstituted phenols is (−1590 ± 170) + (2510 ± 290) or 920 ± 460 J/mol.

$^5J_m^{H_4,CH}$ is $0.37_5 \pm 0.02$ Hz. If methyl substitution does not cause a significant perturbation of this parameter, one may write the free energy difference favoring the *trans* conformer as $-RT \ln (0.628 - 0.375)/0.375 = 990 \pm 335$ J/mol. Again, the isopropyl group apparently points towards the hydroxyl group when the latter lies *trans* to the isopropyl substituent.

The Methine and Hydroxyl Proton Shifts

At 308 K, δ_{OH} of phenol at infinite dilution in CCl_4 is 4.26 ppm (27). The first important association process very likely (27–30) involves trimerization. The assumption that *only* trimerization occurs yields a δ_{OH} of 7.89 ppm for the trimer (27), an association shift of 3.63 ppm. The first important association in 2-methylphenol apparently is also trimerization (2). If this is true for 2-isopropylphenol, the δ_{OH} of 4.39 ppm for the 2 mol% solution in CCl_4 at 305 K (Table 1) suggests that, at this concentration, more than 90% exists as monomer. This suggestion contains the additional assumption that δ_{OH} in the 2-isopropylphenol is not appreciably different from δ_{OH} in phenol. For 2-isopropyl-6-methylphenol, δ_{OH} is 4.38 ppm at 305 K for a 6 mol% solution in CCl_4 and is 4.36_5 ppm for a 3.6 mol% solution. These numbers are also consistent with a small degree of self-association.

In the crystal, the isopropyl group of 2-isopropyl-5-methylphenol is turned (31) so that the two methyl groups are as far as possible from the oxygen atom (compare structure **1***b*). By way of contrast, in dilute solution 2-isopropylphenol exhibits also a *cis* conformer, **1***a*.

There is evidence from Schroeder–Lippincott potential functions (32) for very weak C—H···O hydrogen bonds, perhaps as much as 1.2 kJ/mol in energy for a geometry such as in **1***b*. The chemical shift, δ_{CH}, in **1***b* may be obtained as follows. A 2 mol% solution of isopropylbenzene in CCl_4 had δ_{CH} as 2.86_4 ppm, whereas δ_{CH} is 3.18_4 ppm for the 2 mol% solution of 2-isopropylphenol. Assuming that δ_{CH} in **1***a* is the same as in isopropylbenzene and knowing that the fraction of **1***b* is 0.72, one has δ_{CH} as 3.30_8 ppm in **1***b*. Then the shift due to the C—H···O interaction is 0.43 ppm to low-field, i.e. a deshielding interaction. This number is *consistent* with a weak hydrogen-bonding (attractive) interaction in **1***b*. The early surmise (33), that the methine C—H bond prefers to lie *cis* to the hydroxyl group, is correct for the form **1***b*.

In 2-isopropyl-6-methylphenol δ_{CH} is 3.14_0 ppm. Since the fraction of the conformer analogous to **1***b*

is 0.61 (see above), the predicted δ_{CH} is 3.13_5 ppm. This number assumes that δ_{CH} in the conformer analogous to **1***a* is the same as in isopropylbenzene. Therefore the observed δ_{CH} suggests that the isopropyl group in the two conformers of 2-isopropyl-6-methylphenol orients in the same way as in the analogous conformers **1***a* and **1***b* (note that the methyl substituent is *meta* to the isopropyl group and is therefore not expected to alter significantly the electron density at the methine proton).

Molecular Orbital Calculations

STO 3G calculations involving optimization of external bond angles and of C—O and O—H bond lengths gave **1***b* as the stable conformer (−417.471739 au in energy), but found **1***a* at least 50 kJ/mol less stable than **1***b*; dipole moments of **1***a* and **1***b* were 1.59 and 0.99 D, respectively. On the other hand, a conformer, **1***c*, in which the O—H and the methine C—H bonds were *trans*, was calculated as only 1.8 kJ/mol above **1***b* in energy and had a dipole moment of 1.17 D. Such a distribution of conformers **1***b* and **1***c* (67 and 33% at 305 K) would reproduce the observed $^5J_m^{H,CH}$ numbers in Table 1. However, the available evidence (1–8) would then suggest that $^5J_m^{H_5,OH}$ be zero or at least much smaller than the observed value of 0.19 Hz. Furthermore, the conformer distribution of 2-isopropyl-6-methylphenol then cannot be derived on an additive basis, as it can for other hydrocarbon groupings (1). Solvent effects (34) are not large enough to stabilize the more polar **1***a* by the required 32 kJ/mol.

Accordingly, the STO 3G predictions are rejected. INDO MO computations on the STO-3G geometries gave **1***c* as at least 8.9 kJ/mol more stable than **1***a* or **1***b* and are therefore also inadequate.

A. CHATT, K. N. DESILVA, J. HOLZBECHER, D. C. STUART, R. E. TOUT, and D. E. RYAN. Can. J. Chem. **59**, 1660 (1981).

A rapid pneumatic transfer cyclic system for use with the SLOWPOKE reactor has been designed which allows detection of nuclides with half-lives as short as 0.8 s. Reliable reproducibility is achieved with a 1 s transfer period from reactor to detector. Both accuracy and relative standard deviation are significantly improved with some matrices as the number of cycles is increased but the gains in detection limits increase with the square root of the number of cycles. Cyclic instrumental neutron activation analysis has been successfully applied to the determination of Ag, F, Hf, Pb, Rb, Sc, and Se in a variety of biological and metallurgical matrices. The detection limits ranged from 0.01 to 2.2 ppm for all elements studied except Pb.

A. CHATT, K. N. DESILVA, J. HOLZBECHER, D. C. STUART, R. E. TOUT, and D. E. RYAN. Can. J. Chem. **59**, 1660 (1981).

On propose un système cyclique de transfert pneumatique rapide, pouvant être utilisé de concert avec le réacteur SLOWPOKE, qui permet de détecter les noyaux dont les demi-vies pourraient aller jusqu'à 0,8 s. On obtient une reproductibilité parfaite avec une période de transfert de 1s du réacteur au détecteur. On améliore de façon importante la précision ainsi que la déviation normale relative à l'aide de quelques matrices lorsque le nombre de cycles augmente; toutefois les gains sur les limites de détection augmentent selon la racine carré du nombre de cycles. On applique avec succès l'analyse intrumentale cyclique de l'activation du neutron à la détermination de Ag, F, Hf, Pb, Sc et Se dans différentes matrices biologiques et métallurgiques. Pour tous les éléments étudiés, à l'exception du Pb, les limites de détection se situent entre 0,01 et 2,2 ppm.

[Traduit par le journal]

Instrumental neutron activation analysis (INAA) involving conventional irradiation, decay, and counting periods has been widely applied for multielement determination in biological and metallurgical samples. Short (<30 s) irradiation, decay, and counting times have been used in recent years for measuring the levels of a few selected elements (1–3). At least 38 stable elements, however, produce short- (and long-) lived nuclides under thermal neutron bombardment. Many of these short-lived nuclides can be used for sensitive determinations of a number of trace elements in a variety of sample matrices (4).

To detect the γ-rays emitted by short-lived (half-life <65 s) nuclides, it is necessary to develop methods based on the principles of cyclic activation analysis. In cyclic INAA (CINAA), a sample is irradiated for a short time, is rapidly transferred to a detector for counting, and the entire process is repeated for a number of cycles. The CINAA technique was suggested in 1960 (5) and the theory of CINAA has been recently described in detail (6). The concentrations of trace elements in biological and environmental materials have been determined during the past few years using this technique (7–13).

A pseudo-cyclic INAA method, which involved manual transfer of samples, was initially developed for use with the Dalhousie University SLOWPOKE-2 Reactor (DUSR) facility; it was successfully applied to multielement determinations in biological samples (14, 15). A rapid automated transfer cyclic system has been subsequently designed and installed. The design and timing parameters of this system are described here. CINAA methods for the determination of several elements in biological and metallurgical samples are reported in this paper. Precision, accuracy, and detection limits are also discussed.

Experimental

Irradiations

All samples and standards were irradiated in the pneumatic site #1 of the DUSR facility. The composition, homogeneity, and reproducibility of the DUSR neutron flux were determined and reported in a previous publication (16). The excellent stability and reproducibility of the DUSR neutron flux are particularly advantageous for CINAA methods where samples and comparator standards have to be irradiated separately in an identical flux.

Counting System

Neutron irradiated samples were counted using a 35-cm^3 PGT Ge(Li) detector with a full width at half maximum of 2.4 keV at the 1332-keV photopeak of ^{60}Co, peak-to-Compton ratio of 30:1, and an efficiency of 7.1%. The detector was coupled to a TN-1700 model 4096-Channel pulse height analyzer.

Cyclic System

A rapid automated transfer cyclic system was designed in collaboration with Atomic Energy of Canada Limited, Commercial Products. The system consists of two main components: a recycle irradiation controller and a switching unit. The recycle irradiation controller contains an irradiation timer, a delay timer, a counting timer, and a recycle counter. The

switching unit contains two 2-way diverters and a solenoid valve. A schematic diagram of this system is shown in Fig. 1.

The cyclic system was operated according to the following sequence. A carefully sealed polyethylene capsule containing the sample to be irradiated was manually placed in the breech. The recycle option of the transfer system was switched on for automatic recycling of the sample between the reactor core and the Ge(Li) detector. The irradiation, delay, and counting timers were then set to desired time intervals. The required number of cycles was selected on the recycle counter. The polyethylene capsule was inserted into the reactor from the breech by pushing a button. The capsule photodetector unit located in the irradiation tube at the top of the reactor signalled the passage of the capsule; this signal, in turn, started the irradiation timer. At the end of the set irradiation time, the capsule was ejected to the detector. The counting system and the counting timer were activated when the delay timer reached zero from a preset time. The capsule was reinserted into the reactor when the counting time expired. The capsule was recycled (i.e., re-irradiated and re-counted) for the preselected number of cycles, and then was ejected to the capsule receiver through the diverter and the Y-section of the switching unit.

The various factors which could influence the transit time of a capsule between reactor and detector were studied. These factors included weight of a capsule, shape of the top and bottom portions of a capsule, and air pressure in the pneumatic tube. The variation of air pressure between 30 and 60 p.s.i. appeared to make little difference on the transit time of a capsule of a given weight. Capsules weighing between 4 and 6 g were generally used at an air pressure of about 40 p.s.i. in developing the CINAA methods. The time taken to transfer a capsule from the reactor core to the detector surface under the above operating conditions was approximately 600 ms at best. In order to achieve reliable reproducibility, a delay time of 1 s was normally sufficient.

Sealing of Irradiation Capsules

The irradiation capsules used were polyethylene vials (5.5 cm length, 1.6 cm outer diameter, and 7 cm^3 capacity) fitted with polyethylene snap caps and were supplied by the Durham Aircraft Corporation, New York. The snap cap was always heat-sealed to the vial prior to irradiation. The general method of sealing (consisting of fitting the cap on the vial, trimming the sides of the cap, and heat-sealing the edges) although ideal for conventional one-shot irradiation, could not be used in cyclic irradiations. Rough edges at the top of the vial lengthened transfer time and vial caps came off after a few recycle periods ($n < 5$). A sealing technique that permits a large number of cycles with minimum transfer time consists of inserting an inverted snap cap (edges trimmed) of an irradiation vial into the vial and heat sealing the edges of the vial and cap together. The sealed vials could be transferred within 600 ms from reactor to detector, and could be used for a large number ($n > 100$) of recycling periods.

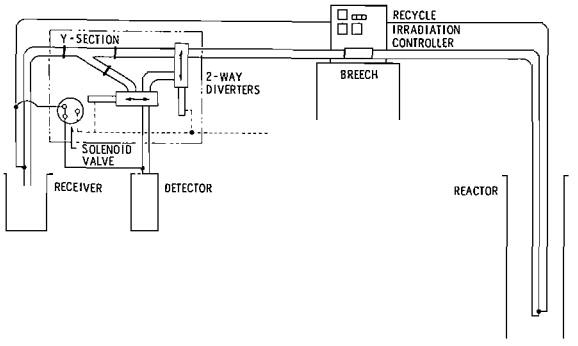

FIG. 1. A schematic diagram of the DUSR cyclic system.

Standards and Samples

Monoelement comparator standards were prepared by depositing microlitre portions of "atomic absorption standard solutions (Alfa-Ventron Corporation)" on either Nucleopore polycarbonate membrane or prewashed (with HNO_3 and H_2O) Whatman #1 filters. The spotted filters were evaporated to dryness at low heat under an infrared lamp and then sealed in a precleaned polyethylene envelope. Ultrapure lead wires were used as comparator standards for lead.

Two standard reference materials (SRM) were analyzed to evaluate the precision and accuracy (22, 23) of the CINAA method. These included Orchard Leaves (NBS SRM-1571) and Bovine Liver (NBS SRM-1577) supplied by the U.S. National Bureau of Standards (NBS).

Other analyzed samples were: Fish Flour obtained from the International Council for the Exploration of the Sea (ICES), cod liver collected from fish caught off the coast of Prince Edward Island, Canada (1); hair obtained from a population group previously studied (17); "Analyzed Brass" from Thorn Smith; "Specpure" zirconium salts from Johnson-Matthey Co.; and ultrapure zirconium wires supplied by Alfa-Ventron Corporation.

All samples were contained in precleaned polyethylene envelopes which were then heat-sealed. Each envelope was placed in a separate 1.5 cm^3 polyethylene vial which was then inserted into the irradiation vial. A second vial was used as a spacer to keep the bottom vial in place and to prevent any impulses on the sealed cap. The irradiation vial was then sealed according to the procedure described in a preceding section.

Results and Discussion

Seven short-lived neutron activation products which decay by the emission of γ-rays have been investigated in the present work; their nuclear data are given in Table 1. Photopeaks used are free from interference under the experimental conditions described. The isotopic abundances of the targets are generally high except for ^{76}Se. The cross sections are also fairly large (i.e. $\geq$0.10b) except those of ^{19}F and ^{206}Pb. The combination of high isotopic abundance and cross section indicates that most of the nuclides listed in Table 1 will be produced in high yields. Since the half-lives of these nuclides vary over two orders of magnitude, different timing parameters (i.e. irradiation, decay and counting times) had to be developed for their sensitive measurements. The composition of sample matrix also needed to be considered for selecting appropriate timing parameters.

For the determinations of Ag, F, Rb, Sc, and Se in biological materials (namely, cod liver and otolith, Fish Flour, Bovine Liver, and Orchard Leaves), the timing parameters selected were: irradiation time (t_i) = 10 s, decay time (t_d) = 2 s,

TABLE 1. Nuclear data for elements determined by CINAA[a]

Element	Target isotope	Isotopic abundance %	Cross section,[b]	Product nuclide	Half-life, s	γ-Ray energy used, keV	Intensity of γ-ray, %
Ag	^{109}Ag	48.17	89	^{110}Ag	24.4	658	4.52
F	^{19}F	100	0.0098	^{20}F	11.0	1633	100

[a]Reference 26.

counting time (t_c) = 10 s, and number of cycles (n) = 12. The Se content of scalp hair was measured using t_i = 60 s, t_d = 1 s, t_c = 60 s, and n = 10. Macroquantities of Pb were determined with t_i = 3 s, t_d = 1 s, t_c = 3 s, and n = 10. Concentrations of Hf in "specpure" zirconium salts and wires were measured using t_i = 60 s, t_d = 1.5 s, t_c = 60 s, and n = 10. Results are shown in Table 2.

The fluorine content of ICES Fish Flour was determined through its only thermal neutron activation product, ^{20}F. The same nuclide could also be produced by two interfering reactions: ^{23}Na(n,α)^{20}F and ^{20}Ne(n,p)^{20}F. Appropriate corrections were made considering the sodium content of biological materials and neon content of the empty space in irradiation capsules; contributions from the interfering reactions were experimentally determined.

The concentrations of Ag, Rb, Sc, and Se could also be determined using long-lived nuclides of these elements. However, the use of short-lived nuclides not only reduces total experimental time but also improves the precision of measurements. No competing reactions interfered in the determinations of these nuclides under the experimental conditions and sample matrices used.

The determination of Hf in Zr is an example of a system particularly amenable to CINAA. Measurement of trace amounts of Hf in the presence of a large excess of Zr (or vice versa) is ordinarily very difficult because of the extreme similarities in chemical properties of these two elements and their ions. In samples analyzed by CINAA, however, the matrix element (Zr) does not become activated to any significant degree under the experimental conditions used (t_i = 60 s, t_d = 1.5 s, t_c = 60 s, and n = 10) while ^{179m1}Hf is formed in sufficient amounts so that microgram quantities of Hf in ultrapure Zr standard wires can be determined. The hafnium content of spectrographically analyzed (specpure) Zr salts was determined by CINAA. The Hf level of the zirconium sulfate was too high to be analyzed directly; a sample was therefore dissolved in dilute sulfuric acid and microlitre portions were deposited onto filter papers for analysis. The sample was found to contain 0.741 ± 0.009% by CINAA compared to the spectrographic estimation of 0.7%. The hafnium content of "specpure" ZrO_2 was directly determined by CINAA at a reduced flux of 5×10^9 n cm^{-2} s^{-1}. The activity due to ^{179m1}Hf was high in comparison to other Zr–Hf samples analyzed, but its concentration could be estimated (1.67%).

TABLE 2. Typical elemental content of biological and metallurgical samples determined by CINAA

Element	Sample material	Content, ppm
Ag	Cod liver	0.65 ± 0.05
F	Fish Flour	62 ± 8
Hf	Zirconium standard wire	195 ± 2
	"Specpure" zirconium sulfate	0.741 ± 0.009[a]
	Zirconium dioxide	1.67 ± 0.01[a]
Pb	Brass #16	19 ± 2.4[a]
Rb	Cod liver	0.50 ± 0.04
Sc	Cod otolith	0.48 ± 0.05
Se	Cod liver	0.67 ± 0.04
	Hair	0.42 ± 0.03

[a]Content expressed in %.

The determination of Pb through ^{207m}Pb by CINAA using the present cyclic system is not very sensitive. An attempt was made, however, to measure macroquantities of Pb in an alloy because of the advantages (over classical techniques) of speed and ease of analysis of solid samples. Brass was analyzed for Pb using the timing parameters described earlier at a flux of 5×10^{10} n cm^{-2} s^{-1}; this 10-fold reduction in normal flux was necessary to reduce matrix activity. To minimize errors due to shielding, a brass sample with a certified Pb content was used as a comparator standard. The Pb levels determined by CINAA could be in error by as much as 15% relative because of coincidence losses as indicated by high dead times. Methods are presently being developed to correct for such losses.

Although CINAA was generally used for single

		Orchard Leaves	Bovine Liver	Coal
^{77m}Se	17.4	19(5–32)	13(5–32)	19(5–32)
^{179m_1}Hf	18.7	19(5–32)	19(5–34)	19(6–32)
^{110}Ag	24.4	19(6–42)	19(6–42)	22(6–42)

element measurement, it can be applied to simultaneous multielement determinations (18–20). Using a computer program for optimizing timing parameters (21), the maximum value of the significance of a photopeak (S_{max}) and the range of 90% S_{max} have been calculated for a number of nuclides; the results are presented in Table 3. It is evident from the table that a value of $t_i = t_c = 11$ s will produce values of $S \geq 90\%\ S_{max}$ for nuclides with half-lives ranging between 5.3 and 49 s in all three matrices. This means that only one CINAA experiment need to be performed for the simultaneous detection of several short-lived nuclides with varying half-lives.

Precision of measurement generally improves in CINAA with an increasing number of cycles (n). The precision of determining Sc in the Orchard Leaves by CINAA is shown in Fig. 2. The improvement in precision was almost four-fold. The relative standard deviation decreased from 34% in the first cycle to 9% in the twelfth cycle. A relative standard deviation of 10% was achieved at $n = 8$; an increase in the number of cycles from 9 to 12 decreased the relative standard deviation by only

1%. Accuracy of measurement was evaluated by analyzing two well-characterized SRM provided by the NBS. The averages of 3 determinations for each element are shown in Table 4. The agreement with certified values (23) is generally good, wherever such comparison is feasible.

Limits of detection, defined by $2\sqrt{\mu_B}$, where μ_B is the number of background counts under the photopeak, were calculated for each of the elements analyzed. The limits are shown in Table 5. Except for Pb, the limits are generally low and of the order that is required of a trace analytical technique. Both qualitative detection limit (L_D) and quantitative determination limit (L_Q), as defined by Currie (24), were also calculated; the results for Sc in Orchard Leaves are shown in Fig. 2.

It is also evident from Fig. 2. that although detection limits decrease with increasing number of cycles, the rate of decrease slows down consider-

For personal use only.

ably after 7 or 8 cycles. The detection limit of an element is highly dependent on the composition of a given sample matrix. For example, the detection limit of Se in Bovine Liver (high background activity due to ^{24}Na, ^{38}Cl, and ^{28}Al) is approximately 3 times poorer than that in hair (very little background activity).

The pneumatic transfer cyclic system used in this work needs to be modified for detecting nuclides with half-lives less than 800 ms. Due to complexity of diverters used in the present system (Fig. 1), the capsule transit time occasionally reached values greater than 1 s. Extensive dead time corrections are necessary to determine trace element concentrations with high accuracy. With the availability of low energy photon detectors and improved cyclic systems, a number of very short-lived (half-life < 0.80 s) nuclides can be used for multielement determinations.

Crystal and molecular structure of [dimethyl(3,5-dimethyl-1-pyrazolyl)(ethanolamino)gallato ($N(2),O,N(3)$)](η^3-cycloheptatrienyl)dicarbonylmolybdenum

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C. V6T 1Y6

Received December 3, 1980

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **59**, 1665 (1981).

Crystals of [dimethyl(3,5-dimethyl-1-pyrazolyl)(ethanolamino)gallato($N(2),O,N(3)$)](η^3-cycloheptatrienyl)dicarbonylmolybdenum are monoclinic, $a = 10.511(1)$, $b = 8.335(1)$, $c = 24.138(3)$ Å, $\beta = 102.22(1)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to $R = 0.028$ and $R_w = 0.046$ for 3708 reflections with $I \geq 3\sigma(I)$. The crystal structure consists of discrete molecules linked by N—H...O hydrogen bonds (N...O = 2.929(5) Å). The Mo atom is in a distorted octahedral environment with the η^3-C_7H_7 ligand occupying one coordination site, trans to the amino nitrogen, as a π-donating ligand. Important bond distances (corrected for libration) are: Mo—O, 2.245(2), Mo—N(amino), 2.249(3), Mo—N(pyrazolyl), 2.270(3), Mo—C(O), 1.950(4) and 1.947(4), Mo—C(C_7H_7), 2.176(4), 2.364(4), and 2.380(4), Ga—O, 1.919(3), Ga—N, 1.984(3), and Ga—C, 1.982(5) and 1.983(5) Å. An unusual type of disorder is present in which a second image of the molecule, approximately mirrored by the plane $y = 1/4$, is in evidence at low occupancy.

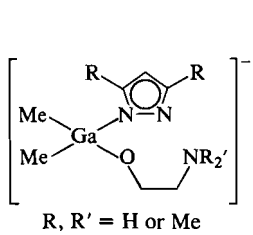
KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **59**, 1665 (1981).

Les cristaux de [diméthyl(diméthyl-3,5 pyrazolyl-1) (éthanolamino) gallato ($N(2),O,N(3)$)] (η^3-cycloheptatriényl) dicarbonylmolybdène sont monocliniques avec $a = 10,511(1)$, $b = 8,335(1)$, $c = 24,138(3)$ Å, $\beta = 102,22(1)°$, $Z = 4$, groupe d'espace $P2_1/c$. On a résolu la structure à l'aide des synthèses de Fourier et de Patterson et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0,028$ et de $R_w = 0,046$ pour 3708 réflexions avec $I \geq 3\sigma(I)$. Du point de vue structural, le cristal est constitué de molécules discrètes liées par des liaisons hydrogènes N—H...O (N...O) 2,929(5) Å. L'atome de Mo est dans un environnement tétraédrique déformé avec le ligand η^3-C_7H_7 occupant un des sites de coordination en position *trans* par rapport à l'azote du groupement amino comme un ligand donneur π. Les distantes importantes de liaison (corrigées pour la libration) sont: Mo—O, 2,245(2), Mo—N(amino), 2,249(3), Mo—N(pyrazolyl), 2,270(3), Mo—C(O), 1,950(4) et 1,947(4), Mo—C(C_7H_7), 2,176(4), 2,364(4) et 2,380(4), Ga—O, 1,919(3), Ga—N, 1,984(3) et Ga—C, 1,982(5) et 1,983(5) Å. On trouve un type inhabituel de désordre dans lequel on rencontre une deuxième image de la molécule qui est approximativement réfléchie par le plan $y = 1/4$, et qui ne correspond qu'à un faible taux d'occupation.

[Traduit par le journal]

Introduction

The synthesis and coordinating properties of the anionic ligands **1** have been discussed in a number of previous publications (1–9). Recently a series of $LM(CO)_2(C_7H_7)$ (where L = **1** and M = Mo or W) derivatives was described (10). The present paper describes the crystal structure analysis of the complex $[Me_2Ga(N_2C_5H_7)OCH_2CH_2NH_2]Mo(CO)_2(\eta^3\text{-}C_7H_7)$, **2**. The structure confirms our earlier predictions (10) regarding the *fac* tridentate chelating nature of the organogallate ligand and the presence of an η^3-C_7H_7 grouping. Steric factors which influence the position of substitution of the C_7H_7 group in the pseudo-octahedral complex are discussed.



R, R' = H or Me

2

Experimental

The preparation of the title complex has been described in a previous publication (10). Crystals suitable for X-ray analysis were obtained by recrystallization from benzene. A crystal ca. 0.18 × 0.40 × 0.14 mm in size was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo K_α radiation ($\lambda = 0.71073$ Å). Crystal data at 22°C are:

$C_{18}H_{26}GaMoN_3O_3$ f.w. = 498.09

Monoclinic, $a = 10.511(1)$, $b = 8.335(1)$, $c = 24.138(3)$ Å, $\beta = 102.22(1)°$, $V = 2066.6(4)$ Å^3, $Z = 4$, $\rho_c = 1.601$ g cm^{-3}, $F(000) = 1008$, μ(Mo K_α) = 19.8 cm^{-1}. Absent reflections: $h0l$, $l \neq 2n$ and $0k0$, $k \neq 2n$ uniquely indicate the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite-monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–θ scan at 1.26–10.06° min^{-1} over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to $2\theta = 55°$. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within ±2%. After data reduction, an absorption correction was applied using the Gaussian integration method (11, 12). Transmission factors ranged from 0.692 to 0.793 for 224

sampling points. Of the 4740 independent reflections measured, 3708(78%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

The positions of the Mo and Ga atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent Fourier synthesis. After full-matrix least-squares refinement with anisotropic thermal parameters to $R = 0.083$ a difference map showed one large peak related to the Mo atom by reflection in the plane $y = 1/4$ and second peak similarly related to the Ga atom. Careful inspection of the difference map showed that an image of the original molecule, approximately mirrored by the plane $y = 1/4$, was present at a relatively low occupancy. Before continuing the refinement additional photographs were taken using several different crystals including that used for data collection. Even after long exposures, no evidence of twinning nor of a supercell was discovered. The original choice of space group and cell parameters was confirmed and the structure assumed to possess this unusual type of disorder.

Occupancy factors were estimated from the relative peak heights of the two partial Mo atoms on a Fourier map and were later adjusted to give nearly equal equivalent isotropic thermal parameters for the Mo atoms. These values were determined to be 0.895 and 0.105 and were not subsequently varied. Eventually the non-hydrogen atoms of the low-occupancy molecule as well as the hydrogen atoms associated with the predominant structure were located by Fourier synthesis. A three-dimensional model indicated that several atoms were too close for individual refinement. These atoms were included in the refinement as fixed atoms, their coordinates being taken from the Fourier maps. Thermal parameters for fixed low-occupancy O and C atoms were fixed at values near those observed for the high-occupancy counterparts. Fixed hydrogen atoms were assigned U values related to the equivalent isotropic U of the atom to which they are bonded ($U_H = k \cdot U_C$, where $k = 1.25$ for Me—H and 1.10 for other types). The scattering factors of ref. 13 were used for non-hydrogen atoms and those of ref. 14 for hydrogen atoms. Anomalous scattering factors from ref. 15 were used for the Mo and Ga atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.028$ and $R_w = 0.046$ for 3708 reflections with $I \geq 3\sigma(I)$. For all 4740 reflections $R = 0.047$ and $R_w = 0.046$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corrsponded to 0.13 and 2.4σ respectively. The mean error in an observation of unit weight was 1.572. A final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (16) using the compuer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0025 Å^2. Analysis of all 26 non-hydrogen atoms of the high-occupancy molecule gave rms $\Delta U_{ij} = 0.0065$ Å^2 and physically reasonable rigid-body parameters. The appropriate bond distances have been corrected for libration (17), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear along with the uncorrected values in Table 3. The esd's of the corrected bond lengths are assumed to be the same as those obtained from the least-squares for the uncorrected values. Corrected bond angles are not different from the uncorrected values in Table 4 by more than 1σ. Intra-annular torsion angles defining the ring conformations are listed in Table 5. Derived results presented in Tables 3–5 refer to the predominant molecule, those for the low-occupancy structure being far less accurate. The low-occupancy Ga–Me_2 moiety is not well resolved and represents the only region of the low-occupancy model which differs significantly from that of the predominant structure, most likely a result of the overlap.

[1]The structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and Discussion

The crystal structure of **2** consists of discrete molecules, each linked to two others along the crystallographic b axis by weak symmetric bifurcated N—H...O hydrogen bonds involving one of the carbonyl oxygen atoms (N(3)—H(N3a)/H(N3b)...O(1) ($1 - x$, $1/2 + y$, $1/2 - z$), O...N = 2.929(5), O...H = 2.42(4) and 2.43(5) Å, O...H—N = 122(4) and 120(4), C—O...H = 161(1) and 159(1)°). All other intermolecular distances correspond to normal van der Waals contacts.

The ligand **1** displays *fac* coordination as in **3** (2), resulting in a distorted pseudo-octahedral coordination geometry about the Mo atom with an η^3-C_7H_7 ligand occupying one coordination site as a π-donating ligand. Unlike **3**, in which the η^3-2-methylallyl ligand is situated *trans* to the pyrazolyl nitrogen, the allylic portion of the η^3-C_7H_7 ligand is located *trans* to the amino nitrogen. Steric effects are most likely responsible for this difference. If the cycloheptatrienyl ligand were *trans* to the pyrazolyl nitrogen close contacts with the amino group would occur. In the observed orientation two of the C_7H_7 protons are near the pyrazolyl nitrogen and may even be weakly interacting with the pyrazolyl π-system (N(1)...H(11) = 2.59(4) and N(1)...H(5) = 2.65(5) Å). This stereochemical difference between **2** and **3** leads to significant differences between the coordination spheres of these two closely related molecules.

The orientation of the allylic portion of the η^3-C_7H_7 ligand is normal, the central carbon atom

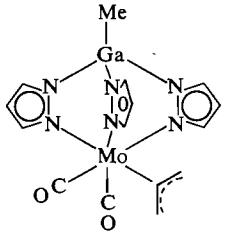
*Primed atoms have occupancy 0.105, all others are 0.895.

being directed away from the carbonyl groups and closest to the Mo atom as in the related complexes **4** (18), **5** (19), $[H_2B(N_2C_5H_7)_2]Mo(CO)_2(\eta^3\text{-}C_7H_7)$ **6** (20), and $[PhB(N_2C_3H_3)_3]Mo(CO)_2$(allyl) (21) where allyl = η^3-C_7H_7, **7**, or η^3-C_3H_5, **8**. This is in contrast to the "reverse" orientation of the η^3-C_4H_7 ligand in **3** where the Mo—C bond to the central carbon atom is the longest of the three. In the η^3-C_7H_7 complexes **2**, **6**, and **7** the central Mo—C(allyl) bond is about 0.19 Å shorter than the "outer" Mo—C bonds. This difference is larger than that generally observed for η^3-C_3H_5 or η^3-C_4H_7 complexes and is the result of steric effects. The distance from the Mo atom to the centre of mass of the three coordinated allylic carbon atoms (*D′*) in **2** is 2.051 Å, shorter than the values found for the closely related structures of **3–8** which range from 2.067 Å in **4** to 2.103 Å in **3**. A structural *trans* effect is probably responsible since the allylic ligands in **3–8** are *trans* to a pyrazolyl nitrogen while that in **2** is *trans* to an amino nitrogen atom. All of these Mo—*D′* distances are in the usual range of 2.02–2.10 Å observed for d^4-M(allyl)L_5 complexes (22).

The Mo—O distance of 2.245(2) Å is significantly shorter than the values of 2.269(2) and 2.272(4)



5

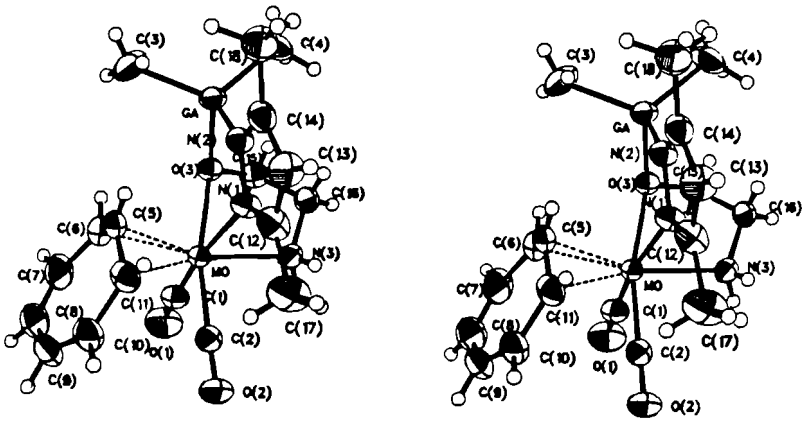


FIG. 1. Stereo view of the [dimethyl(3,5-dimethyl-1-pyrazolyl)(ethanolamino) gallato (*N(2),O, N(3)*](η³-cycloheptatrienyl) dicarbonylmolybdenum molecule. 50% thermal ellipsoids are shown for the non-hydrogen atoms.

O(3)—C(15)	1.446(5)	1.447	C(15)—C(16)	1.503(7)	1.505
N(1)—N(2)	1.393(4)	1.395			

Å observed for **3** and **4** respectively. As noted previously (2, 18–21) the Mo—N bonds *trans* to the allylic ligand are significantly shortened relative to those *trans* to CO. The Mo—N(amino) bond in **2**, *trans* to the η^3-C_7H_7 ligand, at 2.249(3) Å, is significantly shorter than the corresponding bond of 2.285(2) Å *trans* to CO in **3**. The Mo—N(pyrazolyl) distance of 2.270(3) Å is shorter than the corresponding distances (*trans* to CO) of 2.283(4)–2.328(3) Å in the pyrazolyl gallate complexes **4** and **5**, but is longer than the values of 2.222(5)–2.260(3) Å in the pyrazolyl borate structures **6–8**. The Mo—N(pyrazolyl) distances which are *trans* to the allylic ligands in **3–8** are shorter, ranging from 2.173(5) Å in **6** to 2.242(4) Å in **4**. The longer Mo—N(pyrazolyl) bond in **2** relative to that in **3** is compensated by a significant shortening of the Ga—N distance, from 2.006(2) Å in **3** to 1.984(3) Å in **2**.

The two Mo—C(O) distances in **2** (1.950(4) and 1.947(4) Å) are equal within experimental error, in sharp contrast to the markedly different values in **3** (1.961(2) Å *trans* to amino N and 1.902(3) Å *trans* to (O)). The two C—O distances, however, differ by 2.4σ and the O(2)—C(2) distance of 1.179(5) Å is one of the longest observed in this type of compound (2). The ν_{CO} values for **2** in cyclohexane solution of 1932 and 1855 cm^{-1} (10) are reasonably consistent with the solid state C—O distances (2) although involvement of carbonyl oxygen atoms in hydrogen-bonding (in **2** and **3**) as well as crystal packing forces tend to reduce the probability of

good correlation between solution ν_{CO} values and solid state C—O distances.

The remaining bond lengths and angles in the molecule are as expected. The pyrazolyl ring is slightly, but significantly, non-planar ($\chi^2 = 13.7$ for N_2C_3) with the metal atoms considerably displaced from the mean plane of the pyrazolyl ring (Mo by 0.4425(3) and Ga by −0.1903(8) Å). The cycloheptatrienyl ring has six atoms roughly coplanar with C(5), the central coordinated atom, displaced from the plane defined by the other atoms (see torsion angles in Table 5). The η^3-C_7H_7 ligand was found to be fluxional in solution (10), a result also noted for the complexes **6** and **7** (20, 21).

Methyl group inequivalence and rotational barrier heights from ^{1}H nmr lineshapes: dimethylsulphoxide and trimethylsulphoxonium iodide[1]

J. A. RIPMEESTER

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received December 16, 1980

J. A. RIPMEESTER. Can. J. Chem. **59**, 1671 (1981).

The ^{1}H nmr lineshapes obtained for a solid solution of DMSO-d_3 in DMSO-d_6 and for $CH_3(CD_3)_2SO^+I^-$ indicated the presence of inequivalent methyl groups in each solid. The effect of methyl group tunnelling on the lineshapes at low temperatures was used to derive barrier heights of 4.15 and 5.0 kcal/mol of a DMSO and 3.70 and 3.85 kcal/mol for $CH_3(CD_3)_2SO^+I^-$. Using ^{1}H nmr lineshapes, including temperature dependent effects, may well be one of the more sensitive techniques to detect inequivalent methyl groups.

J. A. RIPMEESTER. Can. J. Chem. **59**, 1671 (1981).

La forme des lignes obtenues en rmn du ^{1}H pour des solutions solides de DMSO-d_3 dans du DMSO-d_6 et pour le $CH_3(CD_3)_2SO^+I^-$ indique qu'il existe dans chaque solide des groupes méthyles qui ne sont pas équivalents. On a utilisé l'effet tunnel du groupe méthyle sur la forme des lignes à basse température pour déduire les hauteurs des barrières qui sont de 4,15 et 5,0 kcal/mol pour le DMSO et de 3,7 et 3,85 kcal/mol pour le $CH_3(CD_3)_2SO^+I^-$. L'utilisation de la forme des lignes en incluant l'effet de la température, peut bien être une des techniques les plus sensibles pour détecter des groupes méthyles non équivalents.

[Traduit par le journal]

Introduction

In most molecules containing more than one methyl group bonded to a single centre, the methyl groups are equivalent in the gas or liquid phases. On freezing, crystal packing forces may well render such chemically equivalent methyl groups crystallographically inequivalent. Unless detailed crystal structures are available, information on methyl group inequivalence in a solid must be obtained by spectroscopic techniques. Crystal field effects may cause factor group splittings in vibrational spectroscopy or detectable differences in nuclear shielding in nmr spectroscopy. If there are significant differences in methyl group barrier heights, low frequency vibrational spectroscopy or inelastic neutron scattering may be used to detect torsional bands, or ^{1}H nmr may be used to measure distinct methyl group rotation activation energies.

In this contribution the use of CW nmr lineshapes to detect methyl group inequivalence will be illustrated. Solid systems studied include dimethylsulphoxide and trimethylsulphoxonium iodide.

Experimental

Dimethylsulphoxide-d_6 was obtained from Merck, Sharp and Dohme Ltd.; methyl iodide was reagent grade material.

Trimethylsulphoxonium-d_6 iodide ($CH_3(CD_3)_2SO^+I^-$) was prepared by heating dimethylsulphoxide-d_6 and methyliodide (1) together in a sealed tube for a week. The resulting crystalline material was purified by recrystallization from water acidified with HCl to suppress H–D exchange. A solution of DMSO-d_3 in DMSO-d_6 was prepared by heating the $CH_3(CD_3)_2SO^+I^-$ to 190°C under vacuum and fractionating the decomposition products in a series of cold traps (1). In order to suppress exchange, the solution was frozen and stored as a solid.

The nmr samples were prepared by sealing in Pyrex tubes small quantities of the appropriate materials. A low pressure of helium gas was included to ensure good thermal contact of the samples with the tube walls. The ^{1}H nmr lineshapes were recorded at ~56 MHz using a low level marginal oscillator. Low temperatures were achieved using the crystal and control systems described earlier (2).

Results and Discussion

Dimethyl Sulphoxide

In order to illustrate that methyl group inequivalence often is not observed, although expected, the relevant data on solid DMSO will be reviewed.

Two X-ray structure determinations, one for DMSO-d_6 at −60°C (3), the other for DMSO at 5°C (4), agree that the methyl groups are crystallographically inequivalent. For normal DMSO, the two S—C bond lengths were found to be significantly different, 1.766 and 1.827 Å (4). For the deuterated solid, however, both bond lengths were found to be 1.801 Å (3). A wide-line ^{1}H nmr study (5) as a function of temperature showed that above ~120 K, both methyl groups rotate at a rate faster than several tens of kHz. Solid state nmr studies did not show evidence of inequivalence in nuclear shielding for either ^{1}H or ^{13}C nuclei (6, 7). In a study (8) of the low frequency vibrational spectrum, a single band was assigned to methyl torsion. Two bands were assigned to methyl torsion in an inelastic

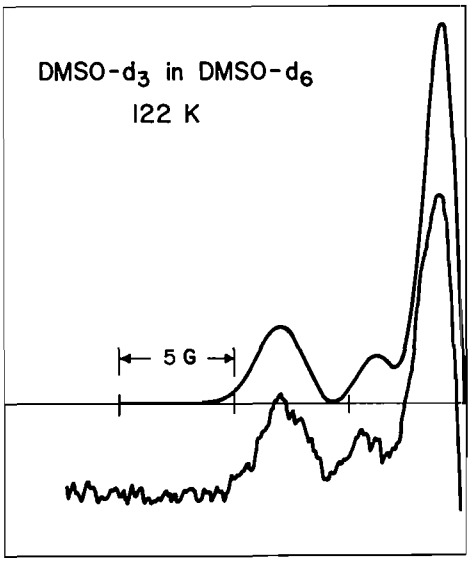

FIG. 1. Experimental (bottom) and calculated ^{1}H nmr lineshapes at 122 K for a solid solution of DMSO-d_3 in DMSO-d_6.

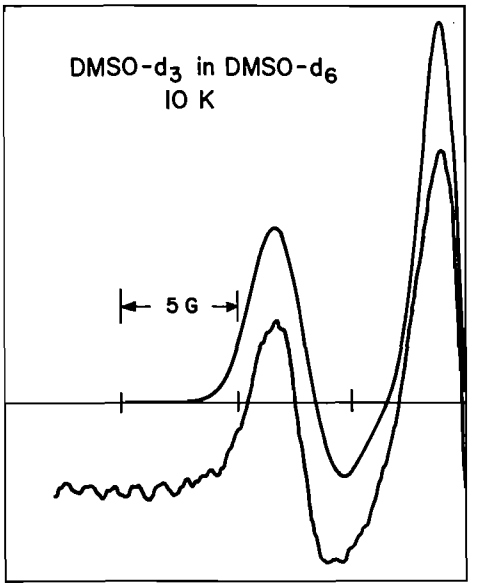

FIG. 2. Experimental (bottom) and calculated ^{1}H nmr lineshapes at 10 K for a solid solution of DMSO-d_3 in DMSO-d_6.

neutron scattering study (9), although the assignment may be somewhat in doubt (8). Two minima in the ^{1}H relaxation time vs. temperature plot were interpreted in terms of dynamically inequivalent methyl groups in a pulsed nmr study (10). Activation energies for methyl group reorientation were found to be 3.0 and 3.8 kcal/mol. This brief summary illustrates that only the X-ray technique and nuclear relaxation, and perhaps inelastic neutron scattering, showed there to be inequivalent methyl groups.

In view of the large difference in methyl group rotational activation energies found from nuclear relaxation measurements, there should be a limited temperature region where half the methyl groups are rotating, and half stationary, on an nmr timescale. Examination of the ^{1}H lineshapes shown in ref. 5 shows that the intermethyl nuclear dipolar coupling obscures fine structure in the temperature region of interest.

In order to reduce the effect of intermethyl group broadening, a sample of DMSO-d_3 in DMSO-d_6 was prepared and the ^{1}H lineshape studied between 100 and 150 K. Between ~120 and 130 K distinct contributions from static and rotating methyl groups are observable. The lineshape observed at 122 K is shown in Fig. 1; the feature ~8 G from the centre is contributed by static methyl groups, the feature ~4 G from the centre mainly by rotating methyl groups. The upper lineshape in Fig. 1 was calculated using the equations given by Andrew and Bersohn (11) assuming there to be equal numbers of static and rotating methyl groups.

Under certain assumptions, the ^{1}H nmr lineshape for a methyl group in its torsional ground state, because of a perturbation of the dipolar energy levels due to tunnelling, can give information on the methyl group barrier heights (12, 13). The lineshape for a 50% DMSO-d_3/DMSO-d_6 solid solution recorded at 10 K is shown in Fig. 2. Distinguishable features for the two distinct methyl groups are not evident.

The lineshape was simulated using the formalism of Apaydin and Clough (14), again assuming there to be two methyl groups each with its distinct tunnelling frequency. The parameters used in the simulation procedure are J, μd, and β. Here $3J/\hbar$ is the tunnelling frequency, $\mu = \gamma\hbar/2$, $d = (3/2)\mu/R^3$, γ is the proton gyromagnetic ratio, R is the interproton distance, and β the Gaussian broadening parameter to account for intermethyl group broadening. Using a value of a $\mu d/\hbar = 7.82$ kHz, the lineshape can be simulated reasonably well using $J/\mu d$ ratios of 0.1 and 0.8. For the geometry assumed, this leads to tunnelling frequencies of 12.3 and 18.8 kHz. The relation derived by Hecht and Dennison (15) may then be used to derive methyl group barrier heights of 4.15 and 5.0 kcal/mol.

It should be noted that the Hecht and Dennison relation (15), although aproximate, agrees within a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

few percent with explicit calculations of the dependence of tunnelling splitting on barrier heights based on a solution of the Matthieu equation for a threefold sinusoidal potential. Uncertainties in the barrier heights obtained are more likely to occur because of approximations such as the assumption of a threefold sinusoidal shape for the barrier, or uncertainties in the moment of inertia of the methyl group.

The activation energies for methyl group rotation derived from the spin–lattice relaxation methods (10), 3.0 and 3.8 kcal/mol, are much lower than the barrier heights derived. Some of the difference may be accounted for by the zero point energy, although significant errors may also occur because of the method used to derive activation energies. Limiting slopes of the log T_1 vs. inverse temperature plots were used, rather than fitting or simulation procedures in order to resolve the double T_1 minimum.

By considering the crystal structure (4), the barrier heights may be assigned to specific methyl groups. Since methyl group I has three short intermolecular C—O distances indicative of hydrogen bond formation, as opposed to methyl group II which has only one such distance, this group can be assigned the higher barrier height.

It is relevant to point out that SCF-MO calculations (19) have indicated that thio-organic molecules in general, and DMSO in particular, can easily distort in the presence of even weak intermolecular interactions.

Trimethylsulphoxonium Iodide

Relatively little is known about the structure of the trimethylsulphoxonium ion. In solution, it has C_{3v} symmetry (16), whereas in the solid the symmetry is generally lower. In the perchlorate salt (17), two of the methyl groups in the ion are related by a mirror plane, in the tetrafluoroborate (18) salt the ion has no symmetry elements although in neither salt are distortions from C_{3v} symmetry severe.

A single band in the far infrared spectrum (16) of the iodide was assigned to methyl torsion and the corresponding methyl group rotational barrier was calculated to be 3.4 kcal/mol.

The ^{1}H nmr lineshape of the partially deuterated salt $CH_3(CD_3)_2SO^+I^-$ recorded at 2.4 K is shown in Fig. 3. In simulating the lineshape (Fig. 3), emphasis was placed on fitting the position and amplitude of tunnelling sidebands. The best fit was achieved by assuming there to be two methyl groups with a $J/\mu d$ ratio of 2.5, and one with $J/\mu d$ of 1.6; the

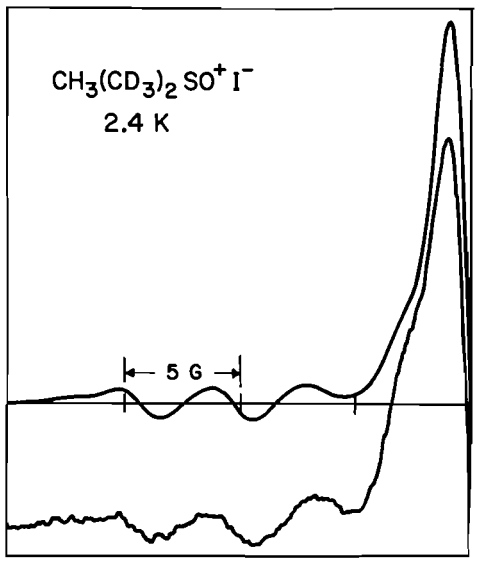

FIG. 3. Experimental (bottom) and calculated ^{1}H nmr lineshapes at 2.4 K for solid $CH_3(CD_3)_2SO^+I^-$.

Gaussian broadening parameter β was taken to be 0.9. Assuming $\mu d/\hbar$ to be 7.82 kHz, this leads to tunnelling frequencies of 58.7 and 37.5 kHz, and application of the Hecht and Dennison relation (15) yields barrier heights of 3.70 and 3.85 kcal/mol.

In molecular solids, crystal forces which render methyl groups inequivalent are usually much weaker than the bonding forces within the molecule. The use of barrier heights and/or motional properties of methyl groups to detect methyl group inequivalence should be quite sensitive as these properties usually depend on the crystal forces as well. The success of the technique depends on resolution of dipolar fine structure either with or without the effect of tunnelling perturbations so that magnetic dilution is often necessary. Under favourable conditions it should be possible to resolve methyl groups with barrier height differences greater than ~5–10% provided at least one of the barriers is greater than 3.5 kcal/mol.

Acid-catalyzed rearrangement of cyclobutanones. VI.[1] Syntheses of chrysenes and steroid-like substances

EDWARD LEE-RUFF, ALAN C. HOPKINSON, AND LE H. DAO
Department of Chemistry, York University, Downsview, Ont., Canada M3J 2R3

Received December 2, 1980

EDWARD LEE-RUFF, ALAN C. HOPKINSON, and LE H. DAO. Can. J. Chem. **59**, 1675 (1981).

Cyclobutanones derived from 1-naphthylketenes and 1,3-cycloalkadienes were prepared. These undergo acid rearrangements under a variety of conditions to give tetracyclic ketones. The tetracyclic ketones were converted to chrysene and substituted cyclopentenophenanthrenes. A mechanistic scheme is proposed for the rearrangement process.

EDWARD LEE-RUFF, ALAN C. HOPKINSON et LE H. DAO. Can. J. Chem. **59**, 1675 (1981).

On a préparé des cyclobutanones à partir de naphtyl-1 cétènes et de cycloalcadiènes-1,3. Ces cétones se transposent en milieux acides variés en donnant des cétones tétracycliques. On a pu transformer ces cétones tétracycliques en chrysène et en cyclopentenophénanthrènes substitués. On propose un mécanisme pour la transposition.

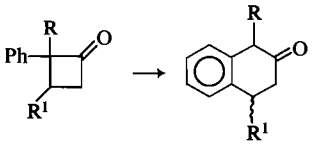
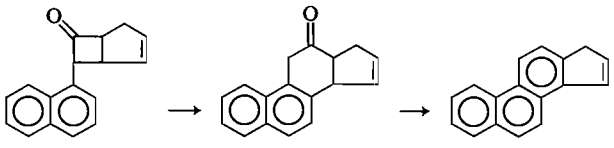
Cyclobutanones have recently attracted considerable interest as synthetic intermediates (2). Their stereoselective formation (3) and their often spontaneous ring-opening reactions (4) resulting from ring strain permit the preparation of stereoselectively functionalized olefins and ring systems found in natural products. We have been interested in the acid-catalyzed ring-opening processes of cyclobutanones both from a theoretical standpoint in view of the well-studied cyclobutyl–cyclopropyl–carbinyl – allylcarbinyl cation interconversions (5) as well as developing novel approaches to ring annelations and syntheses of polycyclic systems. Our recent findings that α-arylcyclobutanones (i.e. **1**) substituted by a β-positive charge-stabilizing group rearrange under



1 **2**

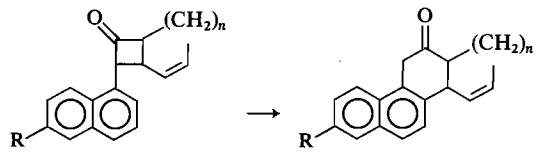


3a *4a* *7a*

acid catalysis to β-tetralones (i.e. **2**) led us to develop a synthesis of tetracyclic steroid analogues (1). In a preliminary communication (1*c*) we reported that the α-naphthylcyclobutanone **3***a* could be converted to the steroid-like derivative **4***a* and aromatized to cyclopenteno[*a*]phenanthrene (**7***a*). We would like to report here the full details of this conversion as well as extensions of this reaction to include the preparation of *D*-homosteroid and chrysene derivatives. Compounds such as **7** as well as substituted chrysenes are of current interest in environmental pollution and have been implicated in the initiation of cancer (6).

Results and Discussion

The cyclobutanone derivatives **3** *a–c* were prepared by the *in situ* generation of 1-naphthylketenes (from dehydrochlorination of 1-naphthylacetyl chloride) in the presence of 3- to 5-fold



3*a* R = H *n* = 1 **4***a* R = H *n* = 1
b R = H *n* = 2 *b* R = H *n* = 2
c R = OCH_3 *n* = 1 *c* R = OCH_3 *n* = 1

excess of 1,3-cyclopentadiene or 1,3-cyclohexadiene. The yields of the cyclobutanones vary from 40–65% depending upon temperature and concentration effects. Aldoketenes are known to spontaneously dimerize (7) and specific experimental conditions have to be met to maximize the yield of competing olefin cycloadditions. All of these derivatives are heat sensitive and revert to naphthylketene dimer and 1,3-cycloalkadienes at higher temperatures. The structures are assigned

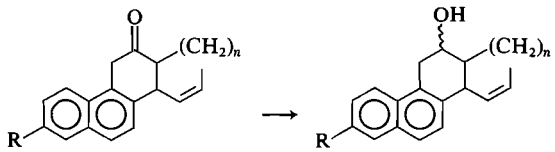
based on spectral and analytical data and by analogy with other ketene 1,3-diene cycloaddition products (8). The regiospecificity of cycloadditions of ketenes is well established (9, 10); however, the stereochemistry of the naphthyl group with respect to the ring junction has not been unequivocally defined, although there is evidence that when two ketene substituents differ in steric bulk the larger one tends to occupy the more hindered *endo* position in the product (11, 12). In all three derivatives it appears that one major stereoisomer is formed.

The acid-catalyzed rearrangements were accomplished using a variety of conditions including methanesulfonic acid (ethereal solution of ketone added to acid at ambient temperature), refluxing trifluoroacetic acid in chloroform solutions, refluxing toluenesulfonic acid in benzene solutions, polyphosphoric acid heated to 100°C, and stannic chloride in benzene. Yields of the rearranged products ranged from 20% to 80%. Optimum yields were obtained using methanesulfonic acid. The structures of ketones **4** *a–c* were assigned based on their



4*a* R = H *n* = 1
b R = H *n* = 2
c R = OCH_3 *n* = 1

5*a* R = H *n* = 1

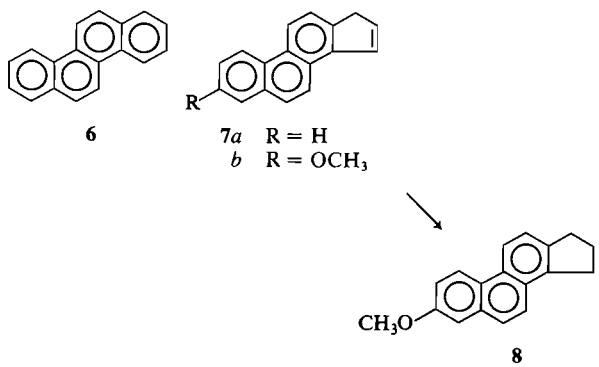
c R = OCH_3 *n* = 1

spectral and analytical data as well as their conversions to the alcohols **5** *a–c* with lithium aluminum hydride and subsequent dehydration and dehydrogenation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) to the known chrysene (**6**) and cyclopentenophenanthrene (**7***a*) (from **5***a* and *b*, respectively[2]). The aromatized products **6** and **7***a* were found to be identical in all respects with authentic samples. In the case of ketone **4***c*, the above sequence of conversions resulted in its conversion to cyclopentenophenanthrene **7***b*. This derivative was hydrogenated to the known cyclopentanophenanthrene which was obtained independently from Wolff–Kischner reduction and dehydrogenation of equilenin methyl ether. The stereochemistry of the C/D ring junction was assigned to **4** *a–c*, the *cis* configuration based on the nmr coupling constants for the bridgehead protons (J = 4–7 Hz). *trans* Diaxial hydrogen coupling constants are of the order of 12–15 Hz (16).

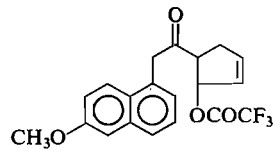


6

7*a* R = H
b R = OCH_3

8

It is noteworthy and contrary to expectation that cyclobutanone **3***c* demonstrates a marked inertness in its tendency towards rearrangement. Using trifluoroacetic acid in refluxing benzene, **3***c* gave the half reacted trifluoroacetate **11** and attempts to

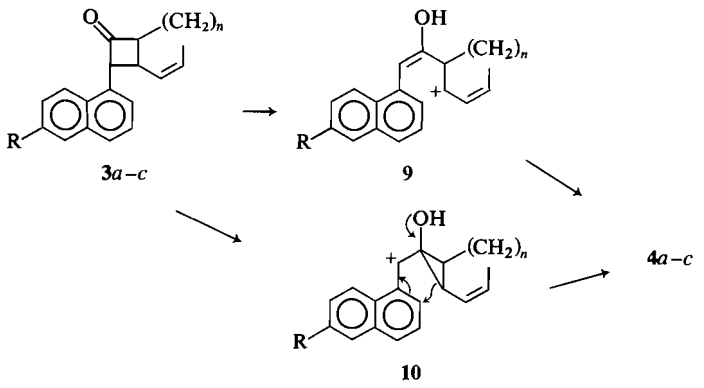


11

cyclize **11** to the tetracyclic ketone **4***c* failed under a variety of conditions. The rearrangement could only be accomplished using stannic chloride in benzene.

These rearrangements can be rationalized according to Scheme 1. Ring opening of protonated cyclobutanone **3** results in formation of ions **9** and/or **10** (classical structure) or a nonclassical ion which is represented by canonical forms **9** and **10**. The subsequent ring annelation could proceed from ion **9** by the known electrophilic substitution pathway for aromatic systems or proceed via ion **10** via cyclopropane ring opening and nucleophilic annelation on aromatic carbon. The observation that no cyclization occurs at the more electron-rich *peri* position of the naphthalene ring, the decreased reactivity of the 6-methoxyl derivative **3***c*, as well as the absence of products derived from ring annelation of the other allylic site in the delocalized ion **9**, suggest that it is not the immediate precursor to the rearrangement product. On the other hand, **10** could conceivably provide two regioisomeric products resulting from the two different modes of

[2]Higher yields of the aromatized products **6** and **7** could be obtained by dehydration of the alcohols **5***a* and *b* with P_2O_5 followed by dehydrogenation with DDQ.



SCHEME I

cyclopropane ring opening processes. Analysis of the reaction product **7***a* derived from **3***a* indicated regiospecific formation of **4***a* during the acid rearrangement, barring any equilibration between **7***a* and its regioisomer 15*H*-cyclopentenophenanthrene during the dehydration/dehydrogenation process.

In view of current interest in specific site alkylated polynuclear hydrocarbons and functionalized steroids we investigated the alkylations of ketones **4** *a–c* by Grignard and alkyl lithium reagents. Mainly starting material and aldol type dimers were observed with both of these reagents. This would suggest that the benzylic hydrogens at C-11 (steroid numbering system) are quite acidic and susceptible to being abstracted by these very strong bases. Attempted electrophilic alkylations at C-11 by way of the enolate using alkyl halides did not provide any transformed material. The alkylation of the carbonyl function was, however, successfully accomplished by nucleophilic addition to the starting cyclobutanones **3** *a–b* and subsequent acid rearrangements of the corresponding cyclobutanols. These observations will be reported in a subsequent paper. The acid-catalyzed rearrangements of α-naphthyl bicyclic cyclobutanones provide a novel entry in the synthesis of steroids, *D*-homosteroids, cyclopentenophenanthrenes, and chrysenes. Work is in progress to specifically alkylate derivatives **4** *a–c* in order to obtain analogues of physiologically active oestrogens.

Experimental

Melting points were determined on a Reichert melting point apparatus and were uncorrected. The ir spectra were recorded on a Unicam SP1000 instrument. The nmr spectra were recorded on a Varian EM-360 spectrometer using $CDCl_3$ solutions and TMS as internal standard. Mass spectra were recorded on a V.G. Micromass 16F spectrometer. Microanalyses were performed by Guelph Chemical Laboratories Ltd. Naphthylacetic acid and 1,3-cyclohexadiene were obtained from Aldrich chemicals and not further purified. 1,3-Cyclopentadiene was obtained by pyrolysis of its dimer (Aldrich chemicals). 6-Methoxy-1-naphthylacetic acid was prepared using a modified literature preparation (14).

Preparation of 1-Naphthylacetyl Chlorides

The acid chlorides were prepared by stirring neat carboxylic acid with 5 mole equivalents of thionyl chloride for 3–24 h at room temperature. The excess thionyl chloride was evaporated and the residual acid chlorides (1-naphthylacetyl chloride and 6-methoxy-1-naphthylacetyl chloride) were used without further purification; ir: 1810 cm^{-1} (C=O of acid chloride).

Preparation of Cyclobutanones **3** a–c

A solution of 10 mmol of acid chloride was dissolved in 50 mL of dry benzene. To this solution was added 50 mmol of 1,3-cyclopentadiene or 1,3-cyclohexadiene and the solution heated to reflux for **3***a* and **3***b* but only to 50°C for **3***c*. Triethylamine (11 mmol) was added over a period of 15 min. After complete addition the reaction mixture was stirred for 30 min at room temperature. It was then poured over 50 mL of ice-water and 50 mL of ether was added. The organic layer was washed with water, 2 × 20 mL of 2 *N* HCl solution, 3 × 30 mL of saturated $NaHCO_3$ solution, and further washed with water. The ether extract was dried over anhydrous $MgSO_4$ and evaporated. In the case of **3***a* and **3***b*, the oily residue was crystallized in boiling hexane. In the case of **3***c* the residue was chromatographed on silica gel using $CH_2Cl_2/CHCl_3$ gradient eluents. Isolated yields for **3** *a–c* are 55, 60, and 30% respectively.

Cyclobutanone **3**a: mp: 114–115°C; ir: 1770, 1600, 1510 cm^{-1}; nmr δ: 2.70 (2H, m), 4.10 (2H, m), 5.40 (2H, m), 5.38 (1H, m), 7.25–8.00 (7H, m); ms (70 ev): 234 (M^+), 168 (naphthylketene, 100%). *Anal.* calcd. for $C_{17}H_{14}O$: C 87.18, H 5.98; found: C 86.60, H 5.85%.

Cyclobutanone **3**b: mp: 126–127°C; ir: 1770 (C=O), 1590, 780 cm^{-1}; nmr δ: 0.9–2.2 (4H, complex multiplet), 3.7 (2H, broad singlet), 4.9–5.3 (2H, m), 5.4–5.8 (1H, m), 7.3–8.0 (7H, m). *Anal.* calcd. for $C_{18}H_{16}O$: C 87.10, H 6.45; found: C 87.26, H 6.59%.

Cyclobutanone **3**c: mp: 86°C; ir (KBr): 1780, 1725, 1632, 1600, 1520, 1480, 1430 cm^{-1}; nmr δ: 2.70 (2H, m), 3.54 (1H, m), 3.90 (3H, s), 4.30 (1H, m), 5.20 (1H, m), 5.70 (2H, m), 7.10–8.00 (6H, m); ms (70 ev); 264 (M^+), 198 ($M^+ - C_5H_6$). *Anal.* calcd. for $C_{18}H_{16}O_2$: C 81.82, H 6.06; found: C 82.24, H 5.92%.

Acid-Catalyzed Rearrangements of Cyclobutanones **3** a–c

The following general methods were used for the acid-catalyzed rearrangements.

Method A

A solution of polyphosphoric acid was prepared by heating a 1:1 mixture of P_2O_5 and orthophosphoric acid for 12 h. To 5 mL of polyphosphoric acid heated to 100°C was added 500 mg of cyclobutanone derivative and the mixture stirred vigorously for 5 min. To this mixture was added ice-water and 75 mL of ether. The ether extract was washed with saturated aqueous sodium bicarbonate solution and then with water. The ether extract was then dried over $MgSO_4$ and evaporated. The residue was directly crystallized from ether or chromatographed on a silica gel column.

Method B

To 50 mL of chloroform was added 10 mmol of cyclobutanone and 10 mmol of trifluoroacetic acid. The mixture was refluxed for 4–10 h. This mixture was diluted with 30 mL of benzene and washed with aqueous saturated sodium bicarbonate solution, water, and subsequently dried over $MgSO_4$. After evaporation the residue was chromatographed on a silica gel column and the products eluted with benzene.

Method C

To 10 mL of neat methanesulphonic acid stirred at 0°C was added 2 mmol of cyclobutanone dissolved in 20 mL of ether. The solution in all cases developed a deep colour (brown to purple). After stirring at room temperature for one hour the mixture was poured over crushed ice in water and extracted with 3 × 50 mL of ether. The ether extract was washed with saturated $NaHCO_3$ solution, water, and dried with anhydrous $MgSO_4$. After evaporation the residue was crystallized from ether or ether–ethanol mixtures.

Method D

To a 10^{-2} *M* benzene solution of cyclobutanone was added 50 mg of toluenesulphonic acid. The solution was heated to reflux for 1–4 h. After cooling, the solution was diluted with ether, washed with aqueous $NaHCO_3$ solution, water, and dried with $MgSO_4$. After evaporation the residue was chromatographed on a silica gel column and eluted with benzene.

Method E

To a solution containing 5 mmol of cyclobutanone in 50 mL of benzene was added 1.30 g (5 mmol) of stannic chloride. The reaction mixture was stirred at room temperature. After usual work-up (see above) the residue was chromatographed on a silica gel column and eluted with benzene.

Ketone **4**a Percentage yields from method A: 40%; B: 70%; C: 85%; D: 30%;mp: 84–85°C; ir (Nujol): 1715 cm^{-1} (C=O); nmr δ: 2.90 (2H, m), 3.30 (1H, m, J = 4Hz, 7 Hz), 3.95 (2H, s), 4.52 (1H, br d), 5.88 (2H, m, J = 7 Hz), 7.25–8.05 (6H, m); ms (70 ev): 234 (M^+). *Anal.* calcd. for $C_{17}H_{14}O$: C 87.18, H 5.98; found: C 87.43, H 6.03%.

Ketone **4**b Percentage yields from method A: 70%; B: 35%; C: 85%; D: 30%; mp: 132–133°C; ir (KBr): 1710 cm^{-1}; nmr δ: 1.6–2.7 (4H, m), 2.90 (1H, d of d, J = 2Hz, 7 Hz), 4.0 (3H, s superimposed on m, J = 7 Hz), 5.70 (2H, s) 7.3–8.0 (6H, m); ms (70 ev): 248 (M^+). *Anal.* calcd. for $C_{18}H_{16}O$: C 87.10, H 6.45; found: C 86.78, H 6.57%.

Ketone **4**c Percentage yields from method E: 20%; mp: 103–104°C; ir (KBr): 1720 cm^{-1} (C=O), 1632, 1610, 1520, 1480, 1445; nmr δ: 2.80 (2H, m), 3.70 (1H, m), 3.90 (5H, s), 4.10 (1H, m), 5.80 (2H, m), 7.2–7.8 (5H, m); ms (70 ev): 264 (M^+). *Anal.* calcd. for $C_{18}H_{16}O_2$: C 81.82, H 6.06; found: C 82.17, H 5.85.

Trifluoroacetic Acid Reaction of Cyclobutanone **3**c

A solution of 1.32 g of **3***c* (5 mmol) and 0.57 g (5 mmol) of trifluoroacetic acid in 20 mL of dry chloroform was heated to reflux for 10 h. The cooled mixture was diluted with 20 mL of benzene, washed with water, $NaHCO_3$ and water, and dried over $MgSO_4$. After evaporation the yellow oil crystallized from hexane to give yellow-green crystals of **11**; mp: 64°C; ir (Nujol): 1790, 1740, 1632, 1610, 1510, 1440 cm^{-1}; nmr δ: 2.80 (2H, m), 3.80 (2H, s), 3.90 (3H, s), 4.00 (1H, m), 4.88 (1H, m), 5.80 (2H, m), 7.10–7.80 (6H, m); ms (70 ev): 378 (M^+), 266, 264, 250, 238, 222, 211.

General Method for Reduction of Ketones **4** a–c *to Alcohols* **5** a–c

0.1 *M* Ethereal solutions of ketones **4** *a–c* were added to a dispersion of 3 equiv. of $LiAlH_4$ in anhydrous ether. The mixtures were stirred for 3 h at room temperature. A solution containing 10% NH_4Cl in water (2 mL) was used to quench the excess $LiAlH_4$. The precipitate was filtered off and the filtrate was washed neutral with water, dried over $MgSO_4$, and evaporated. The crude residue was used for the subsequent transformation.

Alcohol **5**a: ir: 3400, 1600, 1518 cm^{-1}; nmr δ: 2.5–2.8 (2H, m), 3.20 (1H, m), 3.80 (2H, t, J = 7 Hz), 4.20 (2H, m), 5.80 (2H, m), 7.10–8.00 (6H, m); ms (70 ev): 236 (M^+), 218.

Alcohol **5**b: ir: 3600, 3460–3200, 1580, 1385, 890 cm^{-1}; nmr δ: 1.7–2.3 (6H, m), 2.90 (1H, t, J = 6 Hz), 3.45 (1H, br, t, J = 8 Hz), 4.50 (1H, t, J = 8 Hz), 5.0 (1H, br t, J = 6 Hz), 5.80 (2H, quintet), 7.2–8.2 (6H, m); ms (70 ev): 250 (M^+), 232.

Alcohol **5**c: mp: 108°C; ir: 3400 cm^{-1}; nmr δ: 3.70 (2H, m), 3.90 (3H, s), 7.10–8.00 (7H, m); ms (70 ev): 246 (M^+), 205.

Dehydrogenation of Alcohols **5** a–c *with DDQ*

To a 50 mL solution (0.1 *M*) of alcohols **5** *a–c* in benzene was added 2.3 g (11 mmol) of DDQ. The solution was heated to reflux for 3 h. The solution was concentrated to 15 mL and chromatographed on a silica gel column and eluted with hexane–benzene mixtures.

Hydrocarbon **7**a: Yield 60% (crystallized from hexane); mp: 169–170°C (lit. (14) mp 164–165°C); ir (Nujol): 1600, 1490, 1420; nmr δ: 3.68 (2H, d of t), 6.71 (2H, m), 7.30–8.10 (6H, m), 8.50–8.80 (2H, m); ms (70 ev): 216 (M^+); uv and ir identical with authentic sample (15).

Chrysene: Yield 55%; ir, nmr, uv identical with a commercial sample.

Ether **7**b: Yield 60%; mp 108–109°C; nmr δ: 3.70 (2H, m), 3.90 (3H, s), 7.10–8.00 (7H, m); ms (70 ev): 246 (M^+), 205, 171, 161, 141, 129, 115.

Hydrogenation of Ether **7**b

A solution of 0.126 g of **7***b* and 0.1 g of Pd on charcoal in ethyl acetate was stirred under H_2 in a closed system containing a gas burette. Reaction was complete after one equivalent of H_2 was absorbed. The solution was filtered and evaporated to give an oily residue which crystallized from hot 95% ethanol to give 0.084 g of **8**; mp: 135–137°C (lit. (13) mp 136–137°C); ms (70 ev): 248 (M^+). A sample was prepared by a literature method (13) from equilenin and found identical (tlc and ms) to the sample prepared above.

Acknowledgements

We would like to thank the Natural Sciences and Engineering Research Council of Canada for financial support and Miss Susan Strach for technical assistance. We are grateful to Ayerst (Montreal) Labs for providing a sample of equilenin.

Received December 18, 1980

JIA-SEN LIU, MEI-FEN HUANG, YAO-LIANG GAO, and JOHN A. FINDLAY. Can. J. Chem. **59**, 1680 (1981).

A new lignan, chicanine, isolated from the fruit of *Schisandra sp.*, is shown to possess structure **1**, 2*S*-(3-methoxy-4-hydroxyphenyl)-3*R*,4*S*-dimethyl-5*S*-(3,4-methylenedioxyphenyl)tetrahydrofuran, from spectra analysis and chemical conversions. The tetrahydrofuran ring exists in a "twist envelope" conformation.

JIA-SEN LIU, MEI-FEN HUANG, YAO-LIANG GAO et JOHN A. FINDLAY. Can. J. Chem. **59**, 1680 (1981).

A partir d'une analyse spectrale et de transformations chimiques, on montre qu'un nouveau lignan, la chicanine, que l'on a isolé du fruit de *Schisandra sp.*, possède la structure **1**, (méthoxy-3 hydroxy-4 phényl)-2*S*, diméthyl-3*R*,4*S* (méthylènedioxy-3,4 phényl)-5*S* tétrahydrofuranne. Le cycle tétrahydrofuranne existe selon une conformation "enveloppe croisée".

It was reported (1–3) that several dibenzocyclooctadiene lignan compounds, schisantherin A, B, C, D, and schisanhenrin, which were isolated from the fruits of *Schisandra sphenanthera* Rehd et Wils and *S. henryi* Clarke, had been used in clinical studies to lower abnormally high serum glutamic-pyruvic transaminase (SGPT) levels of patients suffering from chronic virus hepatitis. In the process of searching for new active principles, an unknown lignan compound named chicanine was isolated from the fruits of *Schisandra sp.* which had been collected in the district of Xiangfan, Hubei province of China. In pharmacological tests of mice with abnormally high SGPT levels induced by carbon tetrachloride, chicanine was shown to be ineffective but it was evident that chicanine is a tetrahydrofuran type lignan and not a dibenzocyclooctadiene type, the usual constituent of this genus. Furthermore, chicanine is the first tetrahydrofuran lignan to be isolated from this genus. This paper reports the elucidation of the structure **1** for chicanine by means of spectral analysis and chemical conversions.

Chicanine, $C_{20}H_{22}O_5$ (M^+ 342.1459), mp 122–124°C, $[\alpha]_D^{31}$ +118.8° (*c* 4.568, $CHCl_3$), affords the same ultraviolet spectrum (uv) and mass spectrum (ms) as those of austrobailignan-7, **5** (4), but the compounds differ in other respects (see Table 1). Also, their proton magnetic resonance (^1H nmr) spectra indicate significant differences in signals for H-2, H-3, and H-4 (see Table 2). It was evident that chicanine is a diastereomer of austrobailignan-7.

The relative stereochemistry of chicanine was elucidated by decoupling experiments and by measuring intramolecular nuclear Overhauser effects (nOe) on dinitrochicanine ethyl ether **6**. On irradiation at H-3 (δ 3.04) of compound **6**, the signals for H-2 (δ 5.95) and CH_3-3 (δ 0.64) were decoupled simultaneously and a 10.5% nOe enhancement of H-2 was introduced, indicating the *cis* configuration between H-3 and H-2. On respective irradiation at CH_3-4 (δ 1.00) and CH_3-3 (δ 0.64), 12.5% and 10% nOe enhancements of H-5 (δ 5.72) were observed, and when H-4 (δ 2.50) was irradiated, both signals of CH_3-4 and H-5 were decoupled. This indicates *cis* relationships also for CH_3-3, CH_3-4, and H-5. In addition, by a series of reactions, *vide infra*, chicanine **1** was converted into *meso*-dihydroguaiaretic acid dimethyl ether **12**, which can only be explained if a *cis* relationship exists between CH_3-3 and CH_3-4. Thus, all the facts mentioned above lead to the conclusion that H-5, CH_3-4, CH_3-3, and Ar-2 are *cis*, and thus the aromatic moieties Ar-2 and Ar-5 are *trans*.

The positions of the aromatic substituents at C-2 and C-5 can also be established independently by the results of other nOe experiments on dinitrochicanine ethyl ether **6**. When the ethoxyl methylene (δ 4.13) and the methoxyl (δ 3.93) were irradiated, the signals of H-5′ (δ 7.48) and H-2′(δ 7.12) showed 25% and 12.5% nOe enhance-

TABLE 2. Comparison of ^1H nmr parameters of chicanine and austrobailignan-7[a]

Compounds	CH_3-3	CH_3-4	H-3, H-4	OCH_3	H-5	H-2	OH	$-OCH_2O-$	Ar-H
Chicanine **1**	0.54 d, 7	0.94 d, 7	2.10–2.50 m	3.80 s	4.48 d, 8.5	5.24 d, 4.0	5.20 br	5.80 s	6.60–6.80 m
Austrobailignan-7 **5** (4)	0.63 d, 6.6	1.02 d, 6.1	1.45–2.40 m	3.82 s	4.33 d, 8.8	5.07 d, 8.2	5.68 br	5.92 s	6.50–7.10 m

[a] In $CDCl_3$. Chemical shifts in ppm relative to internal TMS. Coupling constants, J, in Hz.

ment, respectively. Also, the signals of H-2′ and H-2″ (δ 7.28) showed 21% and 7% nOe enhancement, respectively, when H-2 (δ 5.95) and H-5 (δ 5.72) were irradiated. These results showed that the 3-methoxy-4-hydroxyphenyl group must be attached to C-2 and the 3,4-methylenedioxyphenyl group to C-5.

In order to elucidate the absolute stereochemistry, the following chemical conversions were carried out. First, chicanine **1** was hydrogenated in the presence of palladium oxide, giving a mixture of **7** and **8**, which on demethylation in acetic acid/sulfuric acid and phloroglucinol afforded desoxydemethylenechicanine **9** and demethyldihydroguaiaretic acid **10**. These were separated and methylated with dimethyl sulfate. The known isoguaiacin dimethyl ether **11** (*5a*) and *meso*-dihydroguaiaretic acid dimethyl ether **12** (*5a*, 6) were obtained from **9** and **10**, respectively. Next, treatment of chicanine methyl ether **3** with 2% perchloric acid in acetic acid gave anhydrochicanine **13**, which was hydrogenated in the presence of platinum oxide, affording (+)galcatin **14**, the enantiomer of the known (−)galcatin (7–10), isolated from *Himantandra baccata* Bail.

Since the absolute configuration of isoguaiacin dimethyl ether **11** has been previously established as 3*R*,2*R* (*5a*), it follows that the absolute configuration of chicanine **1** is 3*R*,4*S* and 2*S*,5*S* since C-3 and C-4 are unchanged in the above-mentioned transformations. Confirmation of this assignment is provided by the transformation of chicanine into (+)galcatin **14**, enantiomer of (−)galcatin (7–10), of known absolute configuration.

Consistent with coupling constant data, ($J_{2,3} \cong$ 4.0 Hz and $J_{4,5} \cong$ 8.5 Hz) from the ^1H nmr spectrum of chicanine, the dihedral angles between H-2 and H-3 and between H-4 and H-5 should be about 40° and 150°, respectively. This suggests that the tetrahydrofuran ring possesses the "twist envelope" conformation, readily explained by the mutual steric repulsion of the *cis* substituents CH_3-3, CH_3-4, and Ar-2. Thus, the structure of chicanine should be written as **1**, namely, 2*S*-(3-methoxy-4-hydroxyphenyl)-3*R*,4*S*-dimethyl-5*S*-(3,4-methylenedioxyphenyl)tetrahydrofuran.

Experimental

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Infrared spectra were obtained with a Unicam SP-100 or Perkin-Elmer 727B spectrophotometer and uv spectra with a Unicam SP-1800 instrument. Jeol PS-100 and Varian T-60 spectrometers were employed for recording ^1H nmr spectra and the former for measuring nOe in 4% $CDCl_3$ solution. Varian MAT-711 or AEI MS 50 were used for

Chicanine Acetate 2

Chicanine **1** was acetylated in acetic anhydride/pyridine at room temperature for 3 days, affording its acetate in quantitative yield which crystallized as plates from methanol, mp 95–97°C; $[\alpha]_D^{18}$ +133.1° (*c* 0.969, $CHCl_3$); uv (MeOH) λ_{max} nm (log ε): 222 (sh, 4.01), 278 (sh, 3.70), 282 (3.74), 288 (sh, 3.59); ir (nujol) ν_{max}: 1760 (>C=O) cm^{-1}. No hydroxyl. ^1H nmr (CCl_4) δ_{TMS}: 0.56, 1.01 (d, each 3H, J = 7, CH_3-3, CH_3-4), 2.16 (s, 3H, CH_3CO), 2.32 (m, 2H, H-3, H-4), 3.74 (s, 3H, OCH_3), 4.55 (d, 1H, J = 8.5, H-5), 5.26 (d, 1H, J = 4.0, H-2), 5.82 (s, 2H, —OCH_2O—), 6.60–6.90 (m, 6H, Ar-H × 6); ms *m/e*: 384 (M^+), 341 (M − Ac), 234 (M − $(CH_2O_2)\phi CHO$).

Chicanine Methyl Ether 3

Chicanine **1** was methylated in the usual manner with dimethyl sulphate and potassium carbonate in acetone, affording its methyl ether (~70%) which crystallized as plates from acetone/methanol, mp 135–136°C, $[\alpha]_D^{18}$ +125.2° (*c* 1.31, $CHCl_3$); uv (MeOH) λ_{max} nm (log ε): 233 (4.12), 284 (3.86). ir (KBr) ν_{max}: no OH absorption; ^1H nmr (CCl_4) δ_{TMS}: 0.54, 0.94 (d, each 3H, J = 7, CH_3-3, CH_3-4), 2.28 (m, 2H, H-3, H-4), 3.70, 3.72 (s, each 3H, OCH_3 × 2), 4.46 (d, 1H, J = 8.5, H-5), 5.22 (d, 1H, J = 4.0, H-2), 5.80 (s, 2H, —OCH_2O—), 6.60–6.80 (m, 6H, Ar-H × 6). ms *m/e*: 356 (M^+), 192, 178, 175.

Chicanine Ethyl Ether 4

Chicanine (100 mg) in dichloromethane was refluxed for 40 h with bromoethane (0.3 mL) in the presence of potassium carbonate (300 mg) and a trace of 18-crown-6. The reaction mixture was chromatographed on a silica gel column eluting with hexane/ether (3:1). The early fractions gave chicanine ethyl ether **4** (70%) which crystallized as plates from ether/hexane, mp 80–81°C; ^1H nmr (CCl_4) δ_{TMS}: 0.54, 0.94 (d, each 3H, J = 7, CH_3-3, CH_3-4), 1.34 (t, 3H, J = 7, CH_3CH_2O—), 2.30 (m, 2H, H-3, H-4), 3.74 (s, 3H, OCH_3), 3.92 (q, 2H, J = 7, OCH_2CH_3), 4.46 (d, 1H, J = 8.5, H-5), 5.24 (d, 1H, J = 4.0, H-2), 5.80 (s, 2H, —OCH_2O—), 6.60–6.80 (m, 6H, Ar-H × 6); ms *m/e*: 370.1730 (26.90%, $C_{22}H_{26}O_5$, ca. 370.1780, M^+), 220.1465 (96.78%, $C_{14}H_{20}O_2$, M − $(CH_2O_2)\phi CHO$), 218.0925 (5.62%, $C_{13}H_{14}O_3$, M − $\phi(OCH_3)$ (OCH_2CH_3) − H), 208.1124 (11.64%, $C_{12}H_{16}O_3$, (CH_3O) $(CH_3CH_2O)\phi CH$—$CHCH_3$]$^+$), 205.1256 (31.49%,

$C_{13}H_{17}O_2$, M − $(CH_2O_2)\phi CHO$ − CH_3), 192.1168 (100%, $C_{12}H_{16}O_2$, (CH_3O) $(CH_3CH_2O)\phi CH{=}CHCH_3]^+$), 190.1026 (61.93%, $C_{12}H_{14}O_2$, M − (CH_3CH_2O) $(CH_3O)\phi CHO$), 175.0750 (41.51%, $C_{11}H_{11}O_2$, M − (CH_3CH_2O) $(CH_3O)\phi CHO$ − CH_3), 164.0830 (11.00%, $C_{10}H_{12}O_2$, $(CH_2O_2)\phi CH{=}CHCH_3]^+$), 135,0390 (9.66%, $C_8H_7O_2$, $(CH_2O_2)\phi CH_2]^+$).

Dinitrochicanine Ethyl Ether 6

Nitric acid (0.5 mL, d 1.42) in acetic acid/acetic anhydride (0.5 mL, 1:1) cooled to −5 to −10°C was added to chicanine ethyl ether (200 mg) in acetic acid/acetic anhydride (2.5 mL, 1:1) at −5 to −10°C. The mixture was kept for 15 min at that temperature, then poured into ice water. The solid product was chromatographed on silica gel column with ether/hexane (1:2). The early and late fractions contained impurities. The middle fractions yielded dinitrochicanine ethyl ether (105 mg) which crystallized as yellow plates, mp 144–146°C from chloroform/hexane; ^1H nmr ($CDCl_3$), δ_{TMS}: 0.64, 1.00 (d, each 3H, J = 7, CH_3-3, CH_3-4), 1.44 (t, 3H, J = 7, OCH_2CH_3), 2.50 (m, 1H, H-4), 3.04 (m, 1H, H-3), 3.93 (s, 3H, OCH_3), 4.13 (q, 2H, J = 7, —OCH_2CH_3), 5.72 (d, 1H, J = 9.5, H-5), 5.95 (d, 1H, J = 5.5, H-2), 6.08 (s, 2H, OCH_2O), 7.12, 7.28, 7.48, 7.55 (s, each 1H, H-2′, H-2″, H-5′, H-5″); ms *m/e*: 460 (M^+), 264 (M − ϕ(OC-H_3)$(OCH_2CH_3)(NO_2)$), 250 (M − $(CH_2O_2)\phi(CHO)(NO_2)$ − CH_3), 234 (M − $\phi(OCH_3)(OCH_2CH_3)(CHO)(NO_2)$ − H).

Desoxydemethylenechicanine 9 and Demethyldihydroguaiaretic Acid 10

Chicanine (1 g) in ethanol (20 mL) was hydrogenated in the presence of palladium oxide (230 mg) at 60–70°C for 2 h. The reaction mixture was chromatographed on silica gel column with ether/hexane (1:3). The early fractions gave a mixture of **7** and **8** (0.7 g) (ratio 4:1) as shown by ^1H nmr (3.63 (d, 0.80H, J = 7), 3.80 (s, 2.40H), 5.83 (s, 1.60H), and 6.37 (s, 0.80H) for respective H-4, OCH_3, —OCH_2O— and H-5 of **7**; 3.80 (s, 0.60H) and 5.90 (s, 0.40H) for respective OCH_3 and —OCH_2O— of **8**) and ms data (*m/e* 326, M^+ of **7**; 328, M^+ of **8**). The mixture of **7** and **8** (0.69 g) in acetic acid (30 mL) was heated with phloroglucinol (1 g) and 50% sulfuric acid (20 mL) under nitrogen on a steam bath for 2 h, then diluted with water (50 mL) and extracted with ether. The extract was chromatographed on a silica gel column using ether/hexane (2:1). The phenolic fractions (detected by $FeCl_3$) were rechromatographed on a silica gel column and eluted with the same solvent. The early fractions yielded desoxydemethylenechicanine **9** (110 mg) which crystallized as needles from methanol, mp 153–155°C; $[\alpha]_D^{26}$ −40.7° (*c* 0.08116, MeOH). The late fractions afforded demethyldihydroguaiaretic acid **10** (30 mg), a pale yellow solid. Infrared values for **9** ($CHCl_3$) ν_{max}: 3610, 3560, 3300 (br). The ord (MeOH) of **9**: $[\phi]_{300}$ = +5223 pk, $[\phi]_{284}$ = −18959 tr, $a \times 10^{-2}$ = +242, $[\phi]_{242}$ = −8899 tr; ^1H nmr ($CDCl_3$) of **9** δ_{TMS}: 0.90 (d, 6H, J = 7, CH_3-2, CH_3-3), 1.80–2.30 (m, 2H, H-2, H-3), 2.55 (d, 1H, J = 7, H-1a), 2.78 (d, 1H, J = 5, H-1e), 3.60 (d, 1H, J = 7, H-4), 3.84 (s, 3H, OCH_3), 6.35 (s, 1H, H-5), 6.40–6.90 (m, 4H, H-2′, H-5′, H-6′, H-8), 6.38 (br, 3H, exchangeable with D_2O, OH × 3); ms of **9** *m/e*: 314.1520 (100%, $C_{19}H_{22}O_4$, ca. 314.1518, M^+), 258.0880 (20.48%, $C_{15}H_{14}O_4$, M − C_4H_8), 257.0814 (35.62%, $C_{15}H_{13}O_4$, M − C_4H_9), 241.0863 (33.34%, $C_{15}H_{13}O_3$, M − C_4H_8 − OH), 227.0706 (61.08%, $C_{14}H_{11}O_3$, M − C_4H_8—OCH_3), 226.0628 (19.06%, $C_{14}H_{10}O_3$, M − C_4H_9 − OCH_3), 197.0603 (12.23%, $C_{13}H_9O_2$, M − C_5H_9 − OCH_3 − OH), 190.0987 (22.68%, $C_{12}H_{14}O_2$, M − ϕ(OH)(OCH_3) − H), 175.0759 (21.10%, $C_{11}H_{11}O_2$), 137.0603 (9.49%, $C_8H_9O_2$, $(CH_3O)(OH)\phi CH_2^+$). Infrared values for **10** ($CHCl_3$) ν_{max}: 3600, 3550, 3300 (br); ^1H nmr ($CDCl_3$) of **10** δ_{TMS}: 0.85 (d, 6H, J = 6.5, >$CHCH_3$ × 2), 1.50–2.00 (m, 2H, >CH— × 2), 2.06–2.90 (m, 4H, Ar-CH_2- × 2), 3.85 (s, 3H, OCH_3), 5.30 (br, 3H, exchangeable with D_2O, OH × 3), 6.50–6.90 (m, 6H, Ar-H × 6); ms of **10** *m/e*: 316 (M^+), 137 $(CH_3O)(OH)\phi CH_2^+$).

Isoguaiacin Dimethyl Ether 11

The desoxydemethylenechicanine in acetone was methylated in the usual manner with dimethyl sulphate in the presence of potassium carbonate, affording isoguaiacin dimethyl ether **11** (~95%) (*5a*) which crystallized as needles from methanol, mp 100–101°C; $[\alpha]_D^{26}$ −46° (*c* 0.1054, $CHCl_3$). The ir spectrum in $CHCl_3$ was identical with that of its enantiomer, isogalbulin (*5b*); ord (MeOH): $[\phi]_{295}$ = +4052 pk, $[\phi]_{282}$ = −16883 tr, $a \times 10^{-2}$ = +209, $[\phi]_{242}$ = −21273 tr; ^1H nmr ($CDCl_3$) δ_{TMS}: 0.90 (d, 6H, J = 7, CH_3-2, CH_3-3), 1.70–2.30 (m, 2H, H-2, H-3), 2.57 (d, 1H, J = 7, H-1a), 2.77 (d, 1H, J = 5, H-1e), 3.70, 3.83 (s, each 3H, OCH_3 × 2), 3.90 (s, 6H, OCH_3 × 2), 3.75 (d, 1H, J = 7, covered, H-4), 6.37 (s, 1H, H-5), 6.40–6.90 (m, 4H, H-2′, H-5′, H-6′, H-8); ms *m/e*: 356.1990 (100%, $C_{22}H_{28}O_4$, ca. 356.1987, M^+), 299.1271 (10.42%, $C_{18}H_{19}O_4$, M − C_4H_9), 285.1129 (6.77%, $C_{17}H_{17}O_4$, M − C_5H_{11}), 269.1170 (78.31%, $C_{17}H_{17}O_3$, M − C_4H_8 − OCH_3), 238.0993 (6.42%, $C_{16}H_{14}O_2$, M − C_4H_8 −

$(OCH_3)_2$), 218.1304 (7.45%, $C_{14}H_{18}O_2$, M − $\phi(OCH_3)_2$ − H), 187.1124 (3.18%, $C_{13}H_{15}O$, M − $\phi(OCH_3)_2$ − H − OCH_3), 165.0914 (3.19%, $C_{10}H_{13}O_2$), 151.0750 (8.41%, $C_9H_{11}O_2$, $(CH_3O)_2\phi CH_2^+$), 150.0678 (7.65%, $(CH_3O)_2\phi CH^{+\cdot}$).

meso-*Dihydroguaiaretic Acid Dimethyl Ether 12*

Compound **12** was obtained by methylation of compound **10** with dimethyl sulfate by the above-mentioned method and crystallized as colorless needles from ether/hexane, mp 99–101°C; $[\alpha]_D^{26}$ 0° (*c* 0.2018, EtOH); ^{1}H nmr ($CDCl_3$) δ_{TMS}: 0.85 (d, 6H, *J* = 6, $>CHCH_3$ × 2), 1.77 (m, 2H, >CH— × 2), 2.10–2.95 (m, 4H, $ArCH_2$ × 2), 3.87 (s, 12H, OCH_3 × 4), 6.60–6.80 (m, 6H, Ar-H × 6); ms *m/e*: 358.2137 (38.93%, $C_{22}H_{30}O_4$, ca. 358.2144, M^+), 179.1069 (4.52%, $C_{11}H_{15}O_2$, $ArCH_2CHCH_3$), 151.0754 (100%, $C_9H_{11}O_2$, $ArCH_2^+$). All the data agreed with that in literature (*5a*, 6).

Anhydrochicanine Methyl Ether 13

Chicanine methyl ether **4** (100 mg) was dissolved in acetic acid (5 mL) containing 2% perchloric acid and kept at room temperature for 1.5 h. Then the reaction mixture was poured into a solution of sodium hydroxide (15 mL). The solid products were chromatographed on a silica gel column eluting with hexane/ether (5:1). Anhydrochicanine methyl ether (80 mg) was obtained from the early fractions and crystallized as needles from methanol, mp 70–72°C; $[\alpha]_D^{26}$ −108.05° (*c* 0.17158, MeOH); ord (MeOH): $[\phi]_{308}$ = −16991 tr, $[\phi]_{254}$ = +74857 pk, $a \times 10^{-2}$ = −918; ^{1}H nmr ($CDCl_3$) δ_{TMS}: 1.09 (d, 3H, *J* = 7.5, CH_3-3), 1.80 (d, 3H, *J* = 1.5, CH_3-2), 2.40 (q, d, 1H, *J* = 7.5, *J* = 3.5, H-3), 3.66 (d, 1H, *J* = 3.5, H-4), 3.83, 3.86 (s, each 3H, OCH_3 × 2), 5.86 (s, 2H, —OCH_2O—), 6.12 (q, 1H, *J* = 1.5, H-1), 6.41–6.70 (m, 5H, Ar-H × 5); ms *m/e*: 338.1518 (100%, $C_{21}H_{22}O_4$, ca. 338.1518, M^+), 323,1288 (44.76%, $C_{20}H_{19}O_4$, M − CH_3), 307.1322 (12.12%, $C_{20}H_{19}O_3$, M − OCH_3), 292.1089 (10.51%, $C_{19}H_{16}O_3$, M − CH_3 − OCH_3), 200.0832 (23.45%, $C_{13}H_{12}O_2$, M − $\phi(OCH_3)_2$), 151.0744 (16.95%, $C_9H_{11}O_2$, $(CH_3O)_2\phi CH_2^+$).

(+) *Galcatin 14*

Anhydrochicanine methyl ether **13** (100 mg) in ethanol (10 mL) was hydrogenated in the presence of platinum oxide (30 mg). Thin-layer chromatography showed two products, the major product having higher R_f. After chromatography on a silica gel column using hexane/ether (5:1) as eluant, the main product, (+)galcatin **14**, was obtained (90 mg) and crystallized as prisms from methanol, mp 111–113°C. This compound showed identity in all respects with data reported for (−)galcatin (7–10) except for the sign of optical rotation: $[\alpha]_D^{26}$ +9.8° (*c* 0.10206, $CHCl_3$); ord (MeOH): $[\phi]_{304}$ = +10327 pk, $[\phi]_{285}$ = −24319 tr, $a \times 10^{-2}$ = +346, $[\phi]_{264}$ = +1999 pk, $[\phi]_{252}$ = 0 tr; ^{1}H nmr ($CDCl_3$) δ_{TMS}: 0.86, 1.06 (d, each 3H, *J* = 6, CH_3-2, CH_3-3), 1.57 (m, 2H, H-2, H-3), 2.67 (d, 2H, *J* = 5.8, H-1), 3.40 (d, 1H, *J* = 9.5, H-4), 3.85, 3.90 (s, each 3H, OCH_3 × 2), 5.85 (s, 2H, —OCH_2O—), 6.20 (s, 1H, H-5), 6.50–6.80 (m, 4H, Ar-H × 4); ms *m/e*: 340.1671 (100%, $C_{21}H_{24}O_4$, ca. 340.1674, M^+), 283.0972 (15.21%, $C_{17}H_{15}O_4$, M − C_4H_9), 269.0816 (5.06%, $C_{16}H_{13}O_4$, M − C_5H_{11}), 253.0857 (94.81%, $C_{16}H_{13}O_3$, M − C_4H_8 − OCH_3), 238.0632 (5.70%, $C_{15}H_{10}O_3$, M − C_5H_{11} − OCH_3), 222.0680 (5.08%, $C_{15}H_{10}O_2$, M − C_4H_8 − $(OCH_3)_2$), 202.0987 (12.67%, $C_{13}H_{14}O_2$, M − $\phi(OCH_3)_2$ − H), 187.0760 (9.97%, $C_{12}H_{11}O_2$, M − $\phi(OCH_3)_2$ − H − CH_3).

COMMUNICATION

Annelation of β-keto thiolesters and synthetic application

HSING-JANG LIU, LI-KANG HO, AND HOI KIONG LAI
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2
Received March 5, 1981

HSING-JANG LIU, LI-KANG HO, and HOI KIONG LAI. Can. J. Chem. **59**, 1685 (1981).

The use of β-keto thiolesters in the construction of fused (e.g. **8**) and bridged (e.g. **12**) ring systems possessing a functionalized substituent at the angular position is described. Some synthetic applications of the annelation procedure are demonstrated including: selective reduction of the thiol ester group; the concomitant removal of ketone carbonyl and reduction of thiolester to the alcohol level via thioketal intermediate; and direct conversion of the ketone carbonyl to a *gem*-dimethyl group using lithium dimethylcuprate.

HSING-JANG LIU, LI-KANG HO et HOI KIONG LAI. Can. J. Chem. **59**, 1685 (1981).

On décrit l'utilisation de β-cétothiolesters dans l'édification des systèmes cycliques condensés (par exemple **8**) et des systèmes cycliques ayant un pont (par exemple **12**) possédant des substituants fonctionnels en position angulaire. On démontre quelques applications synthétiques de la méthode d'annellation incluant: la réduction sélective du groupe thiolester; l'élimination concomitante du carbonyle de la cétone et la réduction du thiolester en alcool via un intermédiaire thiocétal; et la transformation directe du groupe carbonyle de la cétone en *gem*-diméthyle par le diméthylcuprate de lithium.

[Traduit par le journal]

Robinson annelation[1] and the closely related reaction leading to bridged polycyclic systems[2] are important synthetic processes. We wish to describe the first examples of annelation reactions using a β-keto thiolester moiety[3] which facilitates the formation of polycyclic compounds possessing a functionalized substituent at the angular position.

In the presence of a tertiary amine, β-keto thiolesters were found to undergo Michael reaction readily with conjugated enones. Several amines were examined including triethylamine, 1,5-diazabicyclo[4.3.0]non-5-ene, 1,8-diazabicyclo[5.4.0]undec-7-ene, and 1,4-diazabicyclo[2.2.2]octane (DABCO). Of these, DABCO was shown to be most effective, giving consistently high yields of the products under mild conditions. In a typical experiment, DABCO (497 mg, 4.43 mmol) and methyl vinyl ketone (311 mg, 4.43 mmol) were added to a solution of 2-ethylthiocarbonylcyclohexanone (690 mg, 3.7 mmol) in 1,2-dimethoxyethane (15 mL). After stirring at room temperature under a nitrogen atmosphere for 24 h, the reaction mixture was acidified with 1 *N* aqueous hydrochloric acid and extracted with ether. The usual work-up of the organic solution, followed by column chromatography of the crude product on silica gel eluting with ether–benzene (3:7), gave adduct **1** (944 mg; 100% yield). The generality of this procedure is illustrated by the additional examples listed in Table 1 which also includes a case involving an α,β-unsaturated aldehyde.

The Michael adducts were readily cyclized to the octalone system under the influence of *p*-toluenesulfonic acid using a well-documented procedure (1). Treatment of diketone **1** with a small amount (1/6 of **1** by weight) of *p*-toluenesulfonic acid in refluxing benzene (Dean–Stark trap) for 10 h gave rise to a 98% yield of enone **8**. Similarly, reaction of diketone **2** gave enone **9** in quantitative yield. The cyclization of the two five-membered ring compounds **4** and **5** was shown to be equally facile and the resulting enones **10** and **11** were obtained in a yield of ca. 90% each.

The second possible mode of aldol condensation leading to a bridged system could be effected using sulfuric acid (2). For instance, when diketone **2** (150 mg) was exposed to cold (2–4°C) concentrated H_2SO_4 (0.2 mL) in benzene (1 mL) for 1 h, enone **12** was formed in 95% yield. Other examples gave similar results (e.g. **1** → **13** (93%), **4** → **14** (53%), **6** → **15** (100%), and **7** → **16** (81%)). The cyclization of keto aldehyde **3** was not as successful. In the best case the yield of the desired enone **17** was 20%.

This method provides a viable alternative to the

TABLE 1. Michael addition of β-keto thiolesters to conjugated enones.

β-Keto thiolester	Enone	Time (h)	Product	Yield (%)
	CH_2=CHCOCH$_3$	24		
			1 R = CH_3	100
	CH_2=CHCOCH$_2$CH$_3$	16	**2** R = CH_2CH_3	88
	CH_2=CHCHO	11	**3** R = H	88
	CH_2=CHCOCH$_3$	2.5		
			4 R = CH_3	100
	CH_2=CHCOCH$_2$CH$_3$	6	**5** R = CH_2CH_3	98
	CH_2=CHCOCH$_3$	48		
			6 R = CH_3 (Two isomers)	97
	CH_2=CHCOCH$_2$CH$_3$	48	**7** R = CH_2CH_3 (Two isomers)	100

commonly used β-keto ester approach (1, 2) to the construction of bridged and fused ring systems with concomitant introduction of a reactive functionalized substituent at the angular position. The thiol ester group may be transformed to a number of other important functionalities, often under mild and specific conditions (5), thus providing greater flexibility in the annelation reaction. A feature which is of obvious synthetic utility is the direct reduction of the thiolester to the alcohol using Raney nickel without need of protection of the ketone carbonyl. This worked particularly well in the case of the bridged compounds. Thus, treatment of enone **13** with ca. ten-fold (by weight) excess of W-2 Ra-Ni in benzene for 0.5 h resulted in the formation of alcohol **18** in 88% yield. Comparable yields were also obtained for alcohols **19**, **20**, and **21** from enones **12**, **15**, and **16** respectively. In the fused system, however, this selective reduction process was found to be less satisfactory due to the competing elimination of the thiol ester group.[4] Even under carefully controlled conditions using deactivated (refluxing acetone; 20 min) Ra-Ni, this side reaction could not be completely suppressed and the reduction of enone **8** gave only a modest yield (45%) of the corresponding alcohol **22**.

Another area of synthetic utility is illustrated in the following examples, which show that the removal of the ketone carbonyl of the annelation product and the reduction of the angular substituent to the alcohol level can be simultaneously effected via a thioketal derivative. Treatment of enone **9** with 1,2-ethanedithiol in methylene chloride in the presence of a catalytic amount of boron trifluoride etherate gave the corresponding thioketal **23** (89% yield), which was subjected to reduction with Ra-Ni in benzene at room temperature for 1.5 h to give a 75% yield of alcohol **24**. Similarly, thioketalization of **10** followed by reduction afforded alcohol **25** in an overall yield of 88%.

We also examined the reaction of enone **8** with lithium dimethylcuprate. The reaction was expected to give diketone **26** as a result of a conjugate addition of the reagent to the enone moiety (7) with simultaneous conversion of the thiol ester substituent into a methyl ketone (5*h*). Towards this end, enone **8** was treated with lithium dimethylcuprate (4 mol equiv.) in ether at −40°C for 2 h. Contrary to expectation, an acidic product, mp 88–88.5°C, was formed in 78% yield, to which structure **27** was readily assigned on the basis of the spectroscopic

[4]For examples of reductive elimination of the thiol ester group of β-keto thiolesters with Ra-Ni, see refs. 3 and 6.

data.[5] The structural assignment was further confirmed by esterification (CH_3I–K_2CO_3–acetone) to give **28**, which was identical with an authentic sample prepared from 3,3-dimethylcyclohexanone by an unambiguous route.

The direct conversion of a ketone carbonyl into a *gem*-dimethyl group by the action of lithium dimethylcuprate is, to our knowledge, unprecedented. This transformation appears to be general for compounds structurally related to enone **8**. Consistent results were obtained for enones **9** and **10** which gave directly and in comparable yields acids **29** (mp 105–106°C) and **30** (mp 92.5–93.5°C), respectively, upon treatment with $(CH_3)_2$-LiCu at −40°C.

It is worth noting that the formation of **27** from **8** is in sharp contrast to the result obtained for the *O*-ester analog **31**, which on similar treatment with

ally, the unusual replacement of a ketone carbonyl with a *gem*-dimethyl may be rationalized by invoking a lactone intermediate such as **34**. In agreement with this postulation are the following observations. Treatment of enone **8** with methyllithium in ether at −78°C for 1 h resulted in the formation of a single alcohol **35**[6] (88% yield), which was readily cyclized to lactone **34** using sodium hydride in 1,2-dimethoxyethane at room temperature.[7] When lactone **34** was treated with lithium dimethylcuprate (3 mol equiv.) in ether at −40°C for 2 h, acid **27** was isolated in 85% yield.

In conjunction with the easy accessibility of the required precursors, the unique and efficient transformation —CO— → —$C(CH_3)_2$— described above should have broad synthetic application, particularly in the area of pentacyclic triterpenoids, many of which have D/E ring systems similar to that of **27** (8).

We are currently examining the coupling reaction of allyl pivalates and organocopper reagents. Preliminary results are encouraging.

[6]It is noteworthy that on treatment with methyllithium the *O*-ester analog **31** gave quantitatively a mixture of alcohols **32** and **33** in 1:3.5 ratio as compared with the 3:1 ratio obtained using $(CH_3)_2LiCu$ (*vide supra*).

[7]Our initial attempts to prepare lactone **34** from alcohol **33** were unsuccessful. Whereas no cyclization occurred even after prolonged treatment with sodium hydride in 1,2-dimethoxyethane at room temperature, at reflux temperature alcohol **33** gave exclusively 3-methylbicyclo[4.4.0]deca-1(6),2-diene, apparently as a result of lactone formation followed by a retro-Diels–Alder reaction.

An investigation of the ^1H nmr isotropic shifts for some methyl-substituted bipyridine complexes with Ni(II) and Co(II)

T. L. JOSEPH HUANG AND DOUGLAS G. BREWER[1]

Department of Chemistry, University of New Brunswick, P.O. Box 4400, Fredericton, N.B., Canada E3B 5A3

Received November 13, 1980

T. L. JOSEPH HUANG and DOUGLAS G. BREWER. Can. J. Chem. **59**, 1689 (1981).

In order to extend existing ideas on isotropic spin transfer mechanisms in bipyridine–metal complexes, a series of unsymmetrical methyl-substituted bipyridine ligands, and their nickel(II) and cobalt(II) complexes, have been prepared, and their ^1H nmr isotropic shifts measured experimentally. Simulating different electron spin density transfer mechanisms, from direct σ-electron density transfer to indirect π-mechanisms involving spin polarization or hyperconjugation, various INDO calculations have been performed on model cations and anions of the free ligand, producing good agreement with the experimental results.

T. L. JOSEPH HUANG et DOUGLAS G. BREWER. Can. J. Chem. **59**, 1689 (1981).

Dans le but d'étendre les concepts existants relatifs aux mécanismes de transfert isotrope de spin dans les complexes bipyridine–métal on a préparé une série de ligands bipyridines non symétriques portant des substituants méthyles ainsi que leurs complexes de Ni(II) et de Co(II) et on a mesuré expérimentalement leurs déplacements isotropes en rmn du ^1H. Simulant divers mécanismes de transfert de densité de spin électronique, allant du transfert direct de la densité d'électron σ jusqu'à des mécanismes π indirects impliquant la polarisation du spin ou l'hyperconjugaison, on a réalisé divers calculs INDO sur des modèles de cations et d'anions du ligand libre et l'on a obtenu un bon accord avec les résultats expérimentaux.

[Traduit par le journal]

Introduction

The isotropic chemical shifts in the ^1H nmr spectra of nickel(II) complexes of pyridines and some methyl-substituted pyridines have previously been studied in solution (1–8). In a perfectly octahedral crystal field, the ground term ^3F of Ni(II) is split into two ^3T excited states and one $^3A_{2g}$ ground level; this $^3A_{2g}$ level corresponds to an isotropic magnetic susceptibility. In a slightly distorted octahedral field, since the energy separation between the ground state and the excited state is large (9, 10) ($\gg 800\ cm^{-1}$), spin–orbit coupling may be insignificant. For this reason, the contribution to the chemical shifts of protons from dipolar interactions is usually neglected and the isotropic shifts are attributed solely to Fermi contact hyperfine interaction. In such cases, electron spin densities on nuclei of the ligand in Ni(II) pyridine-type complexes result primarily from charge transfer between metal and ligand via a σ-mechanism, as described by Happe and Ward (1).

Work has also been done previously on some Co(II) complexes with pyridine-type ligands (11–14). Using ligand field theory, Abragam and Pryce (15) have shown that the Co(II) ground term ^4F is split by an octahedral field producing a $^4T_{1g}$ ground state. Because there is strong spin–orbit coupling, this $^4T_{1g}$ state is further split into six doubly degenerate levels (Kramer's doublets) (16, 17) with the energy difference between two consecutive levels being less than $\sim 200\ cm^{-1}$. At room temperature, the electrons are distributed over all of these levels, with the population in each level being related to the Boltzmann distribution factor. Therefore the experimentally determined magnetic susceptibility for a cobalt complex will only correspond closely to the calculated spin-only value when the sample is cooled to liquid helium temperature. At other temperatures, the second-order Zeeman mixing terms make an important contribution to the magnetic susceptibility (18).

Wicholas and Drago (19) have assumed that the mechanism for the electron spin transfer and distribution in a Co(II) complex is similar to that in the corresponding Ni(II) complex. If this were true, the correlation of the isotropic shift in a Ni(II) compound to the difference between the isotropic shift and the dipolar shift, on an equivalent proton of the corresponding Co(II) compound, should be unity. Many studies have shown that this is not the case. To accurately calculate the dipolar and contact shifts in Co(II) complexes is somewhat difficult, since one needs to know the molecular structure and the magnetic moments along the principal axes (20, 21). Horrocks (22) used Krishnan's critical torque (flip angle) method (23) to measure the magnetic susceptibilities along the principal axes of a single crystal of Co(2,2′-bipyridine)$_3$·Br_2·$6H_2O$. Using this information, the second-order Zeeman terms can then be included in the magnetic mo-

ments at that temperature, and the dipolar and contact shift terms are determinable. The contact shifts of the Co(II) complexes determined in this way will therefore represent a mixture of contributions from first and second order Zeeman terms. If data on the temperature variation of these observed shifts had been available (this was not possible with the instrumentation available in this laboratory) then a more exact analysis according to McGarvey (17, 24) might have been attempted. Moreover, several "pure" spin-orbitals are in reality mixed in each Kramer's doublet state function, and therefore the hyperfine coupling constant of a particular nucleus in the complexed ligand would no longer be directly proportional to the electron density at that nucleus because of spin–orbital coupling. Thus eq. [3], used later in this paper, is not strictly valid; however, within the accuracy of the simplified calculations used in this investigation, and in the absence of isotropic shift temperature data, further refinement was deemed unnecessary.

La Mar and Van Hecke (25) claimed that it is impossible for a π-spin transfer mechanism to account for the isotropic shifts in octahedral Ni(II) complexes because there is no unpaired electron in the t_{2g}-orbitals. However, a π-spin transfer mechanism was reported to predominate in the ^1H nmr isotropic shifts of some octahedral Schiff base Ni(II) complexes (26–29). The charge transfer from metal to ligand via a π-mechanism in the divalent tris(2,2′-bipyridine) metal complexes of the first transition metals was also confirmed by Torii and co-workers (30), by Felix *et al.* (31), and by Nakamoto and co-workers (32). The isotropic proton chemical shifts of 2,2′-bipyridine and its symmetrical methyl-substituted Ni(II) complexes have been investigated by Wicholas and Drago (33). However, the calculated electron spin densities for the protons of bipyridine via the EHT (Extended Huckel Theory) method, neglecting the contribution from the π-back-donation mechanism, gave poor agreement with the experimental values.

In unsymmetrical methyl-substituted 2,2′-bipyridine Ni(II) complexes, the isotropic shifts show multiple resonance peaks for a particular proton, similar to that of the Co(II) and Cr(II) complexes. La Mar and Van Hecke (34, 35) indicated that there are two isomers (*cis* and *trans*) formed, and the multiple peaks are due to the unpaired d^{π}-electron(s) being unequally delocalized in the three ligands. In this work, both σ- and π-spin transfer mechanisms were considered operable in both Ni(II) and Co(II) complexes, and the theoretical estimation of the spin densities at the ligand nuclei was carried out via the INDO (intermediate neglect of differential overlap) method. The valence orbitals of the metal fragment were excluded in this simplified treatment, although calculations including the valence orbitals of the metal ion are technically feasible (36–38).

Experimental

A. *Preparation of Ligands*

2,2′-Bipyridine was purchased from Aldrich Chemical Co. Inc.; 4,4′- and 5,5′-dimethyl-2,2′-bipyridine were prepared by the procedures of Case (39) and Sasse and Whittle (40). The unsymmetrical methyl-substituted 2,2′-bipyridines were synthesized via the schemes designed by Krohnke (41), as follows.

(*1*) *4,5-Dimethyl-2,2′-bipyridine*: 1-(2-acetyl-pyridine)-pyridinium iodide and a stoichiometric amount of 2-methyl-2-butenal with excess ammonium acetate in methanol as solvent were stirred on a water bath (35–40°C) for 4–5 h. The methanol was evaporated and the residue was extracted with ethyl ether. The pure compound was recrystallized from light petroleum ether.

(*2*) *4-Methyl-2,2′-bipyridine*: the preparation was similar to the procedure (*1*) above, except 2-butenal was used in place of 2-methyl-2-butenal and the temperature was controlled at 60–65°C. The mixture of products was extracted with ethyl ether and then with hexane, and separated on a basic alumina column, eluting with hexane/acetone (9:1) mixture. The pure compound was recrystallized from 8% ethanol.

(*3*) *5-Methyl-2,2′-bipyridine*, *6-methyl-2,2′-bipyridine*, *4,6-dimethyl-2,2′-bipyridine*, *and 5,6-dimethyl-2,2′-bipyridine* were prepared in the same manner, using 2-methylpropenal, methyl vinyl ketone, 3-penten-2-one, and 3-methyl-3-buten-2-one, respectively, reacting with stoichiometric amounts of 1-(2-acetyl-pyridine)-pyridinium iodide in excess ammonium acetate in formamide, and heating in a water bath at 60–70°C for 6–8 h. The purification involved the same method as for 4-methyl-2,2′-bipyridine.

The starting material 1-(2-acetyl-pyridine)-*pyridinium* iodide was prepared according to the procedure of Krohnke and Gross (42). The elemental microanalysis and/or the molecular weight from high resolution mass spectroscopy for these compounds are tabulated in Table 1.

For the sake of brevity, the 2,2′-bipyridine is abbreviated to "bipy", and the substituents are identified according to the numbering scheme in Fig. 1. Also, a mono-methyl substituent is simplified as "me", and dimethyl substituents as "dm".

B. *Preparation of Ni(II) Complexes*

The tris ligand 2,2′-bipyridine, 4,4′-dm-bipy, and 5,5′-dm-bipy Ni(II) chloride complexes were prepared according to the procedure of Wicholas and Drago (33). Tris-ligand 4-me-bipy and 4,5-dm-bipy Ni(II) chloride complexes were prepared according to the procedure for $Ni(5,5'\text{-dm-bipy})_3Cl_2$.

The bis-ligand 4,6-dm-bipy, 5,6-dm-bipy, 5-me-bipy, and 6-me-bipy Ni(II) chloride complexes were prepared according to the following procedure. An excess amount of ligand was added to a solution of $NiCl_2 \cdot 6H_2O$ in a minimum amount of absolute ethanol and stirred for a few minutes. The solution immediately changed to a reddish-purple color. Ethyl ether was added dropwise until a slight turbidity was noticed. The green crystals were filtered, washed with ether, and dried in vacuum over P_5O_5.

The elemental analyses of these unsymmetric methyl-substituted bipyridine Ni(II) complexes are given in Table 2.

C. *Preparation of Co(II) Complexes*

$Co(2,2'\text{-bipyridine})_3(PF_6)_2$ was prepared by dissolving a stoi-

chiometric amount of $CoCl_2 \cdot 6H_2O$ in absolute ethanol, and then adding an excess of 2,2′-bipyridine, which was previously dissolved in ethanol. The mixture was stirred and refluxed for one-half hour. After the solution had cooled to room temperature, a large amount of water was added to dilute the solution and an excess amount of NH_4PF_6 in water was added. The precipitate formed immediately. After filtering and washing, first with water, then with ethanol, the complex was dried under vacuum over P_2O_5, and then was recrystallized from acetone/methanol mixture. In this preparation all the solvents were completely degassed before using and the whole procedure was performed in a glove bag under nitrogen. All other methyl-substituted 2,2′-bipyridine Co(II) di(hexafluorophosphorate) complexes were prepared in a similar manner to that of $Co(2,2'\text{-bipyridine})_3(PF_6)_2$.

The $Co(2,2'\text{-bipyridine})_3Br_2 \cdot 2H_2O$ complex was prepared by mixing a stoichiometric amount of $CoBr_2 \cdot 6H_2O$ with an excess of 2,2′-bipyridine in absolute ethanol, and then refluxing for one-half hour. After allowing the solution to cool to room temperature, ethyl ether was added dropwise until the solution turned cloudy. The precipitate was filtered, washed with ether, and dried under vacuum over P_2O_5. The same precautions must be taken as in the previous preparation. Elemental analyses of all complexes as performed by Analytical Laboratory, Elbach (Germany) are given in Table 3.

D. *Spectral Measurements*

The ^1H nmr spectra of unsymmetrical methyl-substituted 2,2′-bipyridines in 0.1 *M* CCl_4 solution were taken on a Varian T-60 nmr spectrometer, with TMS as internal standard at a temperature of 35 ± 1°C. The proton chemical shifts of the metal complexes were measured at ca. 35°C with a Varian 4300B high resolution nmr spectrometer with 56.4 MHz radio frequency oscillator. A side band technique using a model 225C universal counter–timer (Computer Measurement Company) was employed to measure the proton resonance peaks, against an internal reference TMS in CD_3OD solution. The Co(II) complexes with hexafluorophosphorate as the anion were dissolved in acetone-d_6 and those with bromine as the anion were dissolved in methanol-d_4. TMS was used as reference.

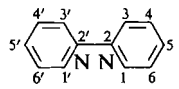

FIG. 1

E. *Measurement of Magnetic Susceptibility*

A single-temperature Gouy Balance SG1 (Newport Instruments) using a Newport 1.5 in. electromagnet (type C) was employed. The sample tube was calibrated using $[Ni(en)_3]S_2O_3$.

F. *Theoretical Calculations*

INDO open-shell calculations were performed on an IBM 370-158 computer system, using the CNINDO program obtained through the quantum chemistry program exchange (43). Bond angles and bond lengths for 2,2′-bipyridine were estimated using the structural parameters for $[Cu(bipy)_2I]I$ (44).

Experimental Results

Assignment of ^1H nmr Spectra of Free Ligand

The ^1H nmr spectra of unsymmetrical methyl-substituted 2,2′-bipyridines are similar to those for the symmetrical methyl derivatives, and by inspection and comparison, these peaks can be assigned uniquely. All proton chemical shifts for 2,2′-bipyridine and its methyl derivatives are listed in Table 4.

bipyridine and its symmetrical methyl-substituted complexes were assigned on the basis of line widths and the results of methyl substitution on the aromatic rings by Wicholas and Drago (33). The assignments for the tris(4,5-dm-bipy) and tris(4-me-bipy) nickel(II) complexes prepared in this study are listed in Table 5. In general, the ^1H nmr spectra have similar features to those of the simple pyridine complex. The 6,6'-proton resonance is too broad to be observed and the 4,4'-proton peak has a small half-width. The other two protons have similar half-widths and give resonances at ca. −45 ppm and ca. −60 ppm with intensity 1:1 for 4-me-bipy and 0.5:1 for 4,5-dm-bipy complexes, respectively. Since methyl substitution causes very little change in the position of the aromatic ring proton peaks compared to their positions in the unsubstituted bipyridine Ni(II) complex, the upper field resonance at ca. −45 ppm is assigned to the 5,5'-protons and the lower field one at ca. −60 ppm to the 3,3'-protons.

In complexes having a 6-methyl substituted ligand, the 3,3'- and 5,5'-protons multiple resonance peaks are spread over the region from ca. −45 to −60 ppm. Obviously, this is evidence of *cis* and *trans* isomers of the tris-ligand Ni(II) complexes, as in the case of unsymmetrical methyl-substituted 1,10-phenanthroline Cr(II), Fe(III), and Co(II) complexes (25). When the ligand/Ni(II) ratio is increased from 1:1 to 3:1, the ^1H nmr spectra show proton chemical shifts which can be interpreted in terms of the ligand changing from a uni-chelate to a bis-chelate, and then to a tris-chelate. For a ratio less than 1:1, the major species is the uni-chelated ligand. One can unambiguously assign each peak to its corresponding proton position from the resonance peak shape (45) and the ^1H nmr chemical shifts of each ligand in these complexes are listed in Table 5.

Assignment of ^1H nmr Spectra of Co(II) Complexes

For the tris unsymmetrical methyl-substituted 2,2'-bipyridine Co(II) complexes, the ^1H nmr spectra show four resonance peaks with equal intensities for each particular proton. Obviously, two stereoisomers exist for these complexes, and the concentrations of the two isomers are established statistically resulting in a ratio of *cis*/*trans* = 1:3. The methyl substituent in the bipyridine Co(II) complexes has no effect on the magnetic properties of the unsubstituted tris complex and the chemical shifts are consistent for each particular proton. This allows each peak to be assigned unambig-

uously, as tabulated in Table 6. The magnetic properties of these Co(II) complexes are also not affected by a variation in the anion group, as has been confirmed by a study of the chemical shifts in Co(2,2′-bipyridine)$_3$X$_2$ with X = Cl^-, Br^-, ClO_4^-, and PF_6^-. The *cis* form of the Co(II) complexes belongs to a monoclinic system with approximate D_3 symmetry, similar to that of tris-(2,2′-bipyridyl) Ni(II) sulphate hydrate and trisacetylacetonato Co(II) (46, 47).

Discussion and Results

The ^{1}H nmr chemical shifts of a paramagnetic metal complex can be written as:

$$[1] \quad \Delta\nu_{obsd} = \Delta\nu_{con} + \Delta\nu_{dip} + \Delta\nu_{dia}$$

where $\Delta\nu_{obsd}$ is the observed proton chemical shift of a paramagnetic complex from a reference (TMS) peak; $\Delta\nu_{con}$ and $\Delta\nu_{dip}$ are the shifts contributed from contact and dipolar interactions, respectively; $\Delta\nu_{dia}$ is the proton chemical shift of either an analogous diamagnetic complex or the free ligand.

For the Co(II) complexes with a cylindrically symmetric susceptibility tensor, the contact and dipolar shifts have been expressed in a simple form by Jesson (48, 49):

$$[2] \quad \left(\frac{\Delta\nu_{dip}}{\nu_0}\right) = \frac{-1}{3r^3}(3\cos^2\theta - 1)(\chi_{\parallel} - \chi_{\perp})$$

and

$$[3] \quad \left(\frac{\Delta\nu_{con}}{\nu_0}\right) = -\frac{A_N}{6\hbar\gamma_N\beta}\left(\frac{\chi_{\parallel}g_{s\parallel}}{g_{\parallel}} + \frac{2\chi_{\perp}g_{s\perp}}{g_{\perp}}\right)$$

where A_N is the Fermi hyperfine coupling constant of the proton N, and can be expressed as

$$[4] \quad A_N = \frac{16\pi}{3}\hbar\gamma_N\beta\sum_i \delta(r_i)$$

For a complex possessing an essentially spin-only magnetic moment, the contact shift can be shown to exhibit Curie behaviour.

$$[5] \quad \left(\frac{\Delta\nu_{con}}{\nu_0}\right) = -A_N\frac{g\beta S(S+1)}{\gamma_N\hbar\cdot 3kT}$$

A. *The Fermi Contact Shifts of Ni(II) Complexes*

In the study of a series of solutions of varying ligand/Ni(II) ratio, the ^{1}H nmr resonance for a particular proton has a shift range which is not affected by the number of bipyridines coordinated with the metal ion. The isotropic shifts of these unsymmetrical methyl-substituted bipyridines were determined by subtracting the diamagnetic ligand shifts from the uni-chelated Ni(II) complexes ligand shifts, and are listed in Table 9. These Ni(II) complexes have a $^3A_{2g}$ ground state which is isotropic, and then the dipolar contribution can usually be neglected. In this situation, the isotropic shift arises solely from the Fermi contact interaction, which is proportional to the hyperfine coupling constant resulting from electron spin delocalization on the proton, as shown in eq. [5].

B. *The Fermi Contact Shifts of Co(II) Complexes*

As indicated previously, the octahedrally axial Co(II) complexes have a $^4T_{1g}$ ground state, and thus magnetic anisotropy is expected. The isotropic shifts are interpreted in terms of Fermi contact and dipolar hyperfine interactions.

(*i*) *Dipolar Shifts*

To calculate the dipolar shifts of the protons in these Co(II) complexes, one has to determine the magnetic susceptibilities along the principal axes of the complexes. Horrocks (22) studied the single crystal Co(2,2′-bipyridine)$_3$Br$_2$·6H$_2$O and found the molar magnetic susceptibilities are $\chi_{\parallel}^M = 7500 \times 10^{-6}$ and $\chi_{\perp}^M = 12250 \times 10^{-6}$ cgsu/mol at 40°C. For the methyl-substituted 2,2′-bipyridine Co(II) complexes, these principal magnetic susceptibilities are unavailable. In this work, the average magnetic susceptibility of some tris-ligand complexes was measured by the Gouy method. The main contribution to the magnetic susceptibility of the complex is due to the paramagnetic metal ion, χ_{corr}^M, and is nearly constant (within ± 3%) for all tris-ligand complexes. It is therefore assumed that the methyl-substituents in these complexes only slightly affect the magnetic properties along the principal axes and that any such effect can be neglected. The ratio of $\chi_{\parallel}^M$ and $\chi_{\perp}^M$ was chosen as 0.61, i.e. ($7500 \times 10^{-6}/12250 \times 10^{-6}$), for these Co(II) complexes. The values of $\chi_{\parallel}^M$ and $\chi_{\perp}^M$ were estimated from the solution of the following two equations and are tabulated in Table 7.

$$[6] \quad \chi^M = 1/3(2\chi_{\perp}^M + \chi_{\parallel}^M)$$

$$[7] \quad \chi_{\parallel}^M/\chi_{\perp}^M = 0.61$$

For calculation of the geometric factor $(3\cos^2\theta - 1)/r^3$ as shown in eq. [1], the geometric parameters of bipyridine Co(II) complex are taken from the data of X-ray structure of [Cu(2,2′-bipyridine)$_2$I]I compound (44); the bond length of Co—N was chosen as 2.00 Å with a bond angle for N—Co—N as 82°. For the *trans* isomer of the methyl-substituted bipyridine Co(II) complexes, there is no symmetry axis. The angle θ is taken from the corresponding value for the *cis* form, since the isotropic shifts have been averaged over all isomers (*vide infra*). The calculated geometric factors of

‡$\Delta\nu_{iso} = \Delta\nu_{obsd} - \Delta\nu_{dip}$.
¶Data ($\Delta\nu_{dip}$) from dipolar shifts calculation.
§Fermi contact shifts $\Delta\nu_{con}$, $\Delta\nu_{con} = \Delta\nu_{iso} - \Delta\nu_{dip}$.
§§Shifts are the average of all corresponding protons on bipyridine ring. $\chi_{||}^M$ and $\chi_{\perp}^M$ are taken from the average value of tris-methyl-substituted bipyridine Co(PF$_6$)$_2$ complexes.

these protons are given by the following values (in Å^{-3} unit):

6,6′-H	5,5′-H	4,4′-H	3,3′-H	4-CH$_3$	5-CH$_3$	6-CH$_3$
0.03099	0.00344	−0.00136	−0.00730	−0.00095	0.00339	0.02363

Basically, these values agree well with those of Horrocks (22), except for that of the 4,4′-H. This high discrepancy (18%) can be rationalized by considering the two pyridyl rings in bipyridine as being slightly bent towards the metal ion. The calculated dipolar shifts using eq. [1] are given in Table 8. When the 6-proton on the bipyridine is substituted by a methyl group, dipolar shift calculations predict an isotropic shift for the methyl protons of some +70 ppm. An attempt to verify this directly failed, since the compounds Co(6-me-bipy)$_3$(PF$_6$)$_2$ and Co(4,6-dm-bipy)$_3$(PF$_6$)$_2$ could not be prepared, apparently due to strong steric hindrance by the 6-methyl groups. However, the tris-mixed complexes Co(6-me-bipy)(bipy)$_2$(PF$_6$)$_2$, Co(4,6-dm-bipy)(bipy)$_2$(PF$_6$)$_2$, and Co(5,6-dm-bipy)-(bipy)$_2$(PF$_6$)$_2$ have been prepared and their ^{1}H nmr spectra studied. In the calculation of the dipolar shifts of these compounds the magnetic susceptibilities ($\chi_{||}^M$ = 6500, $\chi_{\perp}^M$ = 10600 VVK) are taken from the average values of all Co(II) dihexafluorophosphate complexes. The isotropic shift of the protons indicated in Table 8 is the average of the values for all corresponding protons on the mixed ligand set.

(*ii*) *Fermi Contact Shifts*

The isotropic shifts were determined by subtracting the diamagnetic ligand shifts from the average values of equivalent protons of ligand shifts in *cis* and *trans* stereoisomers of tris-chelated Co(II) complexes, in a way similar to the determination of the isotropic shifts in Ni(II) complexes. The contact shifts of protons were determined by the difference between the isotropic shifts and the dipolar shifts, Table 8. Since the unpaired electrons fluctuate between the multiple levels (six Kramer's doublets), and with the mixing of several "pure" spin orbitals in each Kramer's doublet state function, a quantitative study of the unpaired electron

*Numbers in parentheses are contact shifts ($\Delta\nu_{con}$) in ppm.
†Values for unsymmetrical ligands are taken from the average of the equivalent protons.

spin densities at the protons is impossible without data on the temperature dependence of the observed shifts. Therefore at a particular temperature, the contact shift of the proton in a Co(II) complex is taken to be approximately proportional to the hyperfine coupling constant, which is related to the unpaired electron spin density at the proton as shown in eq. [3].

C. *Electron Spin Transfer Mechanisms in Ni(II) and Co(II) Complexes*

When one considers the dynamics of bond for-

mation in these complexes, the lone pair electrons on the ligand are first donated to the metal ion forming a σ-bond. To reduce the build-up of high electron density on the central metal ion, some electron density will be back-donated from the d^{π}-orbitals of the metal to a π*-bonding orbital of the ligand (50). The σ-mechanism results in cationic character being attributed to the ligand, while the π-mechanism imparts anionic character to the ligand. These σ-donations and π-back-donations have been well documented by measurement of infrared stretching bands (30) and by electronic absorptions (32).

In this work, the INDO method has been used to calculate the electron spin density at each nucleus in both σ- and π-orbitals of the ligand, for a model free ligand cation (representing unpaired electron density on the σ-orbitals of the ligand) and a model free ligand anion (representing unpaired electron density on the π*-bonding orbital of the ligand). The valence *d*-orbitals of Ni(II) or Co(II) were excluded in this simplified treatment. The electron spin density of the protons on the aromatic ring and that of the protons on the methyl substituent have been considered separately.

(*i*) *Aromatic Protons on the Bipyridine Ring*

For a σ-spin transfer mechanism, the free ligand cation is used to simulate the ligand with α-spin in its σ-orbitals, and the calculated hyperfine coupling constants (A_H^{σ}) arise from electron spin density on the 1*s*-orbital on the protons.

To calculate any "induced" electron spin density on a proton (28), the free ligand anion is used to simulate the ligand with α-spin in its π*-orbital, and the hyperfine coupling constant (A_H^{π}) is obtained from McConnell's relation $A_H^{\pi} = Q_{CH}\rho_C^{\pi}$ (51), where all notations are standard (44). Q_{CH} has a value of 22.5 gauss.

The resultant calculated hyperfine coupling constant of the proton, A_H, is a combination of A_H^{σ} and A_H^{π}, of the general form $A_H = C_{\sigma}A_H^{\sigma} \pm C_{\pi}A_H^{\pi}$. In several trial fits with the experimental data, it was determined that the coefficients C_{σ} and C_{π} were very nearly equal, and therefore in this calculation were both assigned a value of unity. Note that if α-spin is used for the calculation for both the cation and the anion models, the hyperfine coupling constant is the sum of these two factors, i.e. $A_H = A_H^{\sigma} + A_H^{\pi}$. If β-spin is used for the anion model, only the difference of A_H^{σ} and A_H^{π} fits the experimental results, that is, $-A_H^{\pi}$ (β-spin) is equal to A_H^{π} (α-spin). Thus one can infer that the unpaired electron densities in the σ- and π*-bonding orbitals of the ligand have the same spin (α-spin). The values of the calculated A_H are listed in Table 9.

In comparing the calculated and experimental results, it can be seen that there is qualitative agreement in both Ni(II) and Co(II) complexes; the proton peaks for the 6,6′-positions are shifted to very low field and the protons in the 4,4′-positions show a very slight shift. While the calculated A_H for the 5,5′- and 3,3′-protons and the measured contact shifts are in reasonable agreement, the positions are reversed. This may result from neglecting the interactions between the two pyridyl rings of the 2,2′-bipyridine in the complexes.

(*ii*) *Protons on the Methyl Substituent(s)*

The calculated hyperfine coupling constant of the methyl proton A_{CH_3} is considered to have arisen primarily from a σ-mechanism, and any "induced" electron spin density arising from a hyperconjugative π-back donation mechanism has been neglected. This is consistent with the scheme described by La Mar (52) for paramagnetic complexes where the hybrid σ-orbitals of the methyl group already possess some unpaired spin density before any π-back donation occurs, and because of electron repulsions, is probably not significant. The values of A_{CH_3} are calculated from the cation model with α-spin on the ligand and are listed in Table 4. Comparison of the calculated A_{CH_3} with the experimental contact shift of the methyl protons shows that the sign of the 6- and 4(4′)-methyl protons are all negative, having an upfield shift with respect to TMS, and the sign of the 5(5′)-methyl protons is positive, having a downfield shift. The magnitude of the calculated values of A_{CH_3} is in reasonable agreement with the experimental results, with those for the 6- and 4(4′)-positions being noticeably better than those for the 5(5′)-positions.

Etude d'interactions moléculaires en solution par analyse de la relaxation quadripolaire du deutérium. II.[1] Associations de l'albumine sérique de bœuf en solution aqueuse

YVES VAN HAVERBEKE, ANDRÉ MAQUESTIAU, ROBERT MULLER ET LUCE VANDER ELST[2]
Département de chimie organique, Université de l'Etat, 7000 Mons, Belgique

Reçu le 19 novembre 1980

YVES VAN HAVERBEKE, ANDRÉ MAQUESTIAU, ROBERT MULLER et LUCE VANDER ELST. Can. J. Chem. **59**, 1701 (1981).

Les associations de plusieurs substances organiques avec de l'albumine sérique de bœuf (BSA) ont été analysées soit par l'étude directe de leur affinité pour la macromolécule, soit par le biais de leur compétition vis à vis d'un équilibre de référence. Cette dernière méthode évite l'enrichissement isotopique de la drogue à tester.

L'examen de l'influence du pH sur l'association de la pyridine-d_5 et de l'albumine sérique permet de préciser la nature de l'interaction. Plusieurs aspects des procédures de mesures sont discutés.

YVES VAN HAVERBEKE, ANDRÉ MAQUESTIAU, ROBERT MULLER, and LUCE VANDER ELST. Can. J. Chem. **59**, 1701 (1981).

Deuterium longitudinal relaxation time is used for assessing the interaction between bovine serum albumin (BSA) and some drugs. The study of unenriched compounds by means of a reference equilibrium is successfully applied.

The deuterium relaxation rate of pyridine versus the pH profile allows a better understanding of the nature of the interactions. Some experimental aspects are discussed.

Introduction

Parmi l'éventail des méthodes d'investigation de la dynamique moléculaire, la relaxation nucléaire occupe une position privilégiée. Cependant, tandis que l'intérêt revêtu par le phénomène apparaît clairement, le choix du noyau et des procédures expérimentales appropriés à l'examen d'un système donné relève souvent du cas d'espèce. Les noyaux quadripolaires dont la relaxation est généralement dominée par un seul mécanisme se prêtent particulièrement bien à l'approche des mobilités et des associations moléculaires. Ainsi, Baldeschwieler et coll. (1–3), ont-ils étudié les structures et associations de quelques protéines par examen de la relaxation transversale du ^{35}Cl dans des systèmes marqués par des groupes chloromercuriques.

Le noyau de deutérium qui possède une constante de couplage quadripolaire relativement faible peut être examiné au sein d'un lien covalent. Les divers avantages que présente l'étude de la relaxation de ce noyau dans le cadre de la dynamique moléculaire ont été démontrés par plusieurs auteurs (4–12).

Dans le présent travail, nous examinons les interactions entre petites molécules organiques et l'albumine sérique de bœuf (BSA) par extension des procédures appliquées au cours d'une étude antérieure (12). Notre choix s'est porté sur cette macromolécule en raison de l'important rôle de vecteur qu'elle assure vis à vis de très nombreuses substances chimiques.

[1]Pour la première partie, voir réf. 12.

[2]Titulaire d'un mandat d'aspirant au F.N.R.S.

Partie expérimentale

1. *Appareillage*

Les spectres de rmn du ^2H sont relevés à 9,2 MHz à la température de 30 ° ± 1°C, sur un appareil Bruker WP-60 équipé d'un calculateur Nicolet-BNC-12 (8K données, 4K programme).

Les solutions sont contenues soit dans des tubes de 8 mm concentriques à des tubes de 10 mm renfermant de l'hexafluorobenzène utilisé pour la stabilisation champ-fréquence (lock ^{19}F), soit dans des tubes de 10 mm, la stabilisation champ-fréquence est alors assurée par un lock ^2H externe.

Tous les signaux de précession libre sont enregistrés sur 1K mémoire et la transformé de Fourier est effectuée sur 4K (zero filling).

Les séquences d'impulsions utilisées sont les séquences d'inversion–récupération (IRFT et FIRFT) décrites par Freeman et Hill (13), et Canet *et al.* (14); la durée de l'impulsion nécessaire à l'inversion de la magnétisation est égale à 21 μs. Les valeurs de T_1 sont calculées par régression linéaire sur la droite de $\ln (M_\infty - M_\tau)$ en fonction de τ et sont reproductibles à ±5%.

Le pH des solutions est mesuré avant et après chaque série de mesures au moyen d'un appareil Metrohm type E 353 B équipé d'une électrode Orion (91-15).

2. *Produits*

La pyridine-d_5, le 1,4-dioxanne-d_8 et l'acétonitrile-d_3 sont des produits commerciaux (Merck). Le sulfacétamide est synthétisé suivant la méthode de Bretschneider et Klotzer (15) par acylation du sulfanilamide (16). Le *N*-acétyl-d_3-benzènesulfonamide est obtenu par addition de chlorure d'acétyle-d_3 sur le benzènesulfonamide (17).

Deux lots d'albumine sérique sont utilisés; ils proviennent des firmes Cabiochem Behring (cat no. 12659, pureté électrophorétique >95%) et Boehringer-Mannheim (cat no. 238031, électrophorétiquement pure Mol. Wt.: 68 000) et seront dénommés respectivement lot I et lot II dans la suite du texte.

3. *Préparation des échantillons*

Le tampon utilisé est le tris(hydroxyméthyl) aminométhane. Une série de mesures effectuées sur des solutions tamponnées au dihydrogénophosphate de potassium a montré que la nature du tampon ne jouait aucun rôle. Le pH des solutions est compris

entre 7,4 et 8,2. Les échantillons sont préparés par mélange de solutions stock de macromolécule et de drogues; leur volume total est égal à 1 mL. Pour les mesures à pH variable, le pH est ajusté par addition de solutions de NaOH et HCl.

Résultats expérimentaux et discussion

La vitesse de relaxation longitudinale observée pour un noyau de deutérium situé au sein d'un substrat S de petite taille interagissant, de manière réversible et rapide, avec une macromolécule A dont la concentration est très inférieure à celle du substrat vaut (18, 19):

$$[1] \quad \frac{1}{T_1^{obs}} = \frac{a^0}{K_D + s^0}\frac{1}{T_1^c} + \frac{1}{T_1^1}$$

avec $a°$: concentration totale en macromolécule; $s°$: concentration totale en substrat; K_D: constante de dissociation de l'équilibre $A + S \rightleftharpoons AS$; T_1^c: T_1 du noyau au sein de la molécule complexée; T_1^1: T_1 du noyau au sein de la molécule libre et $T_1^c \ll T_1^1$; T_1^{obs}: T_1 observé.

A $s°$ constante, la vitesse de relaxation observée varie linéairement en fonction de la concentration totale en macromolécule. Grâce à un minimum de deux séries de mesures à concentrations totales en drogue différentes, il est donc possible de déterminer K_D et T_1^c par la pente des droites expérimentales (méthode à $s°$ constante).

Par transformation de l'éq. [1], on obtient la relation [2]:

$$[2] \quad \left(\frac{1}{T_1^{obs}} - \frac{1}{T_1^1}\right)^{-1} = \frac{K_D}{a^0}T_1^c + \frac{s^0}{a^0}T_1^c$$

A $a°$ constante et moyennant une détermination préalable de la vitesse de relaxation de la drogue en l'absence de protéine, la pente de la droite de $(1/T_1^{obs} - 1/T_1^1)^{-1}$ en fonction de $s°$ fournit le temps de relaxation du complexe tandis que l'ordonnée à l'origine permet de calculer la constante de dissociation (méthode à $a°$ constante).

Les résultats obtenus pour l'équilibre pyridine-d_5/BSA (lot I) sont très voisins quelle que soit la méthode employée (tableau 1 et figs. 1 et 2). La valeur du T_1^c déterminée expérimentalement concorde bien avec celle que l'on estime grossièrement par la relation de Stokes–Einstein sur base du rapport des masses des entités libres et complexées.

Pour le *N*-acétyl-d_3-benzènesulfonamide, la différence sensible entre les T_1^c calculés par le rapport des masses et observés est due à la rotation indépendante du groupe méthyle sur lequel porte la mesure. L'erreur commise au niveau des temps de corrélation se répercute sur la valeur de K_D.

La méthode de détermination des T_1^c et K_D à $a°$ constante s'étant avérée plus rapide et précise, son utilisation a été généralisée pour la suite de l'étude des équilibres simples.

Trois séries de mesures effectuées sur un échantillon différent de BSA (lot II) témoignent de façon reproductible d'une interaction plus faible avec la pyridine-d_5. Cette différence de comportement doit être mise en rapport avec le degré de pureté des deux lots d'albumine.

Les interactions du 1,4-dioxanne-d_8 et de l'acétonitrile-d_3 sont, quant à elles, nettement plus faibles que celles enregistrées pour la pyridine-d_5.

Equilibres compétitifs

Dans un travail précédent (12), nous avons montré qu'il est possible de caractériser l'interaction d'un compétiteur quelconque (C) avec une entité déterminée (A) en mesurant simplement la perturbation que ce compétiteur provoque sur un équilibre de référence (A + S).

Un traitement analogue à celui utilisé pour les équilibres simples permet d'obtenir une relation linéaire entre l'inverse de l'accroissement de la vitesse de relaxation du substrat et la concentration en compétiteur lorsque les quantités $a°$ et $s°$ sont maintenues constantes (éq. [3]).

$$[3] \quad \left(\frac{1}{T_1^{obs}} - \frac{1}{T_1^1}\right)^{-1} = \frac{K_{D_1} + s^0}{a^0}T_1^c + \frac{c^0}{a^0}\frac{K_{D_1}}{K_{D_2}}T_1^c$$

K_{D_1}: constante de dissociation de l'équilibre de référence; K_{D_2}: constante de dissociation de l'équilibre de compétition; $c°$: concentration totale en compétiteur.

Si l'on a déterminé indépendamment l'un des deux paramètres de l'équilibre de référence (T_1^c ou K_{D_1}), la pente et l'ordonnée à l'origine du graphique de $(1/T_1^{obs} - 1/T_1^1)^{-1}$ en fonction de la quantité de compétiteur ajoutée permettent le calcul de l'autre paramètre (K_{D_1} ou T_1^c) et celui de la constante de dissociation de l'équilibre compétitif.

Pour tous les systèmes étudiés, on observe une augmentation du temps de relaxation longitudinal du substrat (S), la pyridine-d_5, lors de l'addition de *N*-acétyl-d_3-benzènesulfonamide, de sulfacétamide, de 1,4-dioxanne-d_8 ou d'acétonitrile-d_3. Ceci témoigne de l'existence d'une interaction compétitive des deux ligands pour la macromolécule. On peut également envisager que l'association avec le compétiteur modifie la structure de la protéine d'une manière néfaste à la liaison avec le substrat.

Tant pour l'équilibre de référence relatif à l'association pyridine-d_5/albumine que pour les inter-

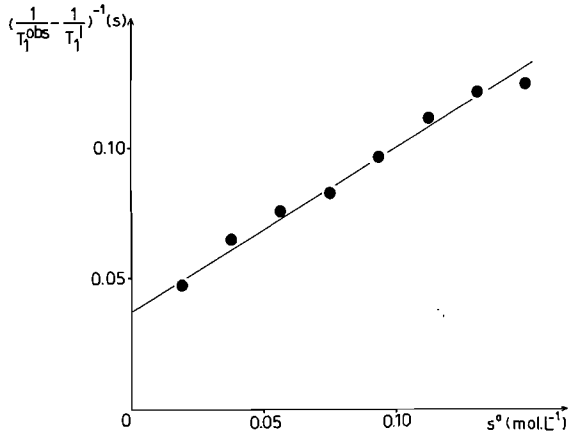

FIG. 2. Variation de $(1/T_1^{obs} - 1/T_1^l)^{-1}$ en fonction de $s°$ à $a°$ constante pour le système pyridine-d_5/BSA (lot I); ●: $a° = 7{,}12\ 10^{-4}$ mol L^{-1}.

actions compétitives, les valeurs de K_D obtenues ici concordent très bien avec celles qui ont été déterminées plus haut (tableaux 1 et 2). Vis à vis de cet équilibre de référence, le *N*-acétyl-d_3-benzènesulfonamide, le 1,4-dioxanne-d_8 et l'acétonitrile-d_3 sont des compétiteurs "faibles" contrairement au sulfacétamide.

Influence du pH

La figure 3 représente la variation de la vitesse de relaxation d'une solution pyridine-d_5/BSA en fonction du pH. La courbe présente vers pH 5,25, un point d'inflexion correspondant au pK_a de la pyridine. Le temps de relaxation à pH 2 est égal à celui de la pyridine-d_5 en solution aqueuse de même acidité; on peut donc admettre que l'ion pyridinium n'interagit pratiquement pas avec l'albumine.

La vitesse de relaxation est maximale dans une zone de pH s'étendant de 7 à 9. Ceci reflète une meilleure fixation à la protéine et non un phénomène d'agrégation des macromolécules puisque le palier se situe dans une zone de pH nettement supérieure au pH isoélectrique de la protéine (pI ≃ 4.7).

Enfin, la diminution importante de la vitesse de relaxation observée pour les pH supérieurs à 9, correspond à la déprotonation des groupements $NH_3^{(+)}$ et OH des acides aminés à chaîne latérale basique (lysine, histidine, arginine, tyrosine) qui

représentent 28% de la composition totale de l'albumine sérique de bœuf (20).

Conclusions

L'analyse de la relaxation nucléaire du deutérium peut être considérée, à plusieurs titres, comme une excellente méthode d'approche de la dynamique moléculaire. Le présent travail démontre l'efficacité de la démarche dans le cadre d'une application à l'étude d'associations en phase aqueuse.

Il est important de remarquer que l'affinité d'un substrat quelconque pour une macromolécule peut être rapidement appréciée, notamment par le biais de sa compétition avec un équilibre de référence. Cette procédure qui rend superflu le marquage isotopique du substrat peut s'avérer particulièrement rentable pour des études systématiques portant sur des séries de composés.

Il convient enfin de souligner que les valeurs observées dépendent étroitement du degré de pureté du matériel biologique utilisé.

Ion exchange properties of trialkylammonium salts

MICHEL GÉRIN AND JAMES FRESCO[1]
Department of Chemistry, McGill University, Montreal, P.Q., Canada, H3A 2K6
Received February 25, 1981[2]

MICHEL GÉRIN and JAMES FRESCO. Can. J. Chem. **59**, 1705 (1981).

Two phase acid–base titrations of amines from tributyl to tridodecyl and their salts have been performed for the nitrobenzene–water system. Hydrolysis constants were determined and from these anion-exchange constants were calculated. For these series of salts values of hydrolysis and anion-exchange constants were independent of the amine and strongly influenced by the nature of the anions.

MICHEL GÉRIN et JAMES FRESCO. Can. J. Chem. **59**, 1705 (1981).

Dans un système biphase nitrobenzène–eau on a effectué des titrages acide–base d'amines et de leurs sels allant de tributyl à tridodecyl. On a déterminé les constantes d'hydrolyse et on en a déduit les constantes d'échange anionique. Pour ces séries de sels les constantes d'hydrolyse et d'échange anionique sont indépendantes de l'amine et fortement dépendantes de la nature de l'anion.

Introduction

To date studies of phase transfer catalysts have been focussed most usually on crown ethers and quaternary ammonium salts. Recently tridodecylammonium bisulphate has been used as a phase transfer reagent in inorganic synthesis for the first time (1). That differences in phase transfer properties exist between tetraalkylammonium ions and comparable trialkylammonium ions is suggested by the stability of their simple salts. Formation constants of salts of the latter ion are at least 100 times greater than the former, when the alkyl is butyl (2).

Values of partition constants have been reported (3) for a series of low to medium molecular weight tertiary alkylammonium salts of the type R_3NHX. These values were combined with dissociation constants, K_d, established in nitrobenzene (2) to provide partition coefficients, K_p, for the nitrobenzene–water system. Partition constants were not obtainable beyond alkyl chain lengths of five or six. In addition, conductivity measurements of the most concentrated nitrobenzene solutions of the salts indicated the possibility of triple-ion aggregation.

It is possible (4–7) to compare properties of higher molecular weight tertiary ammonium salts on the basis of two-phase equilibria of the type

$$\overline{R_3NHX} \rightleftarrows \overline{R_3N} + H^+ + X^-$$

The corresponding hydrolysis constant, K, representing the inverse of the formation constant of the salt from the organic dissolved amine and aqueous acid, has been evaluated by several methods (8). The two-phase emf titration technique (9, 10) and subsequent slope analysis of a log–log plot of the data (11) provide a rapid description of the nature of solute aggregation. This approach has been applied here to higher molecular weight salts from tributylammonium perchlorate to the tridodecylamine halides.

Experimental

Aqueous Solutions

After drying potassium halides at 120°C, stock molar aqueous solutions of KCl, KBr, KI, $NaClO_4$, HCl, HBr, HI, and $HClO_4$ were prepared. The molarity of the sodium perchlorate stock solution was determined by titration of the acid equivalent displaced on a cation exchange resin (12). A standardized decimolar NaOH solution was used to determine the normalities of the aqueous acids. The NaOH solution was prepared from a carbonate-free 50% solution. The carbonate was removed from a stock KOH solution (ca. 1.5 *M*) by addition of small quantities of concentrated $BaCl_2$ solutions until no more precipitate formed. After filtration through glass fibres, alkali solutions were stored in polyethylene bottles and protected from atmospheric carbon dioxide during delivery. Primary standard potassium hydrogen phthalate was used for standardization.

All other solutions were prepared by dilution of the stock solutions and when necessary their normalities were checked by standard methods. Water used to prepare solutions was distilled, deionized, and boiled shortly before use, and saturated with nitrobenzene at room temperature.

Organic Solutions

Organic trialkylammonium salt solutions of sixteen different salts were prepared. These were the chlorides, bromides, iodides, and perchlorates of tridodecylammonium, TLA, to tributylammonium, TBA, with the exceptions of TBAHCl, TBAHBr, TBAHI, and tripentylammonium chloride, TPTAHCl. The preparation of trialkylammonium salts and the purification of trialkylamines and nitrobenzene have been described (3). Solutions were prepared by either direct dissolution of the salt or solvent extraction from the organic amine solution. These were identical to procedures previously described (2). The decimolar solutions were standardized by potentiometric titration with ethanolic KOH. Centimolar and millimolar solutions were prepared by dilution.

Organic decimolar trialkylamine solutions were prepared by

direct dissolution of the purified amines. Pipettes were not used to deliver volumes of these solutions since these were found to deliver unevenly. Known quantities were thus transferred gravimetrically. The decimolar solutions were standardized by titration with $HClO_4$ in acetic acid. The procedure used was the same as the one described for amines (3).

Potential Measurements

The electrodes used were a Beckman double shielded 39000 glass electrode and a Fisher calomel electrode #13-639-51. The originally saturated calomel electrode was modified to a 1 *M* KCl calomel electrode.

The calomel electrode was separated from the solution in which a potential measurement was to be done by a salt bridge of 1 *M* KCl provided by a Remote Reference Junction (Fisher #13-639-55). The reference electrode was placed ca. one foot above the solution, dipping three cm in a 125 mL separatory funnel connected by the stem to the remote reference through Tygon tubing. The funnel, tubing, and remote reference were filled with 1 *M* KCl solution. The hydrostatic head gave improved stability to the flow of electrolyte in the porous ceramic plug serving as liquid junction between the salt bridge and the solution. Stable potentials could be read with a reproducibility of ± 0.2 mV shortly after inserting the solutions.

The potential of the electrode pair was measured using a Fisher Accumet pH meter Model 320 with expanded scale. The expanded mV scale only was used and calibrated using a precision potentiometer (Leeds and Northrup Volt Potentiometer #8687). Overlap of the different scales was adjusted. The meter was found not to be perfectly linear in the low mV range.

Experimental Procedure

The two-phase emf titrations were carried out in a 100-mL jacketed beaker maintained at 25.0°C by circulation of thermostated water. A 50 mL volume of aqueous constant ionic strength (0.1 *M* KCl, KBr, KI, or $NaClO_4$) solution was pipetted into the beaker which was later covered with a lid to maintain a nitrogen blanket. The solution was agitated for 30 min in order to degas. The organic phase was then introduced, usually by means of a 10 mL pipette. Decimolar amine solutions were transferred directly from their flasks and the volume calculated by weight difference. The electrodes were introduced through holes in the lid. The titrant was added from a burette, the tip of which was inserted in another hole in the lid.

For each salt six titrations were performed covering approximately three decades of total organic salt concentrations from 10^{-1} to 10^{-4} *M*. Three titrations were performed by titrating the amine in nitrobenzene with aqueous acidic titrant and have been referred to as direct titrations elsewhere. Three titrations involved titrating the ammonium salt in nitrobenzene with base and were described as reverse titrations. The three titrations covered an organic amine or salt concentration which was successively decimolar, centimolar, and millimolar. For each titration five points were usually recorded, i.e. at 10%, 20%, 40%, 60%, and 80% of equivalence.

After addition of titrant the two phases were mixed by means of a magnetic bar immersed in the lower organic phase. Equilibrium was attained when the potential reached a stable value. The speed of rotation of the stirrer had no significant influence on the equilibrium potential reading. It had, however, an influence on the equilibration time. A high enough rotation speed was adopted so that equilibrium could be reached in less than one hour for each point. The two phases never formed a stable emulsion and separated quickly into two transparent phases when stirring was stopped.

For the various 0.1 *M* aqueous salt solutions the potential of the glass – reference electrode pair was found to conform to the equation, $E = E_A^0 + 59.16 \log [H^+]$. The constant E_A^0 was determined before and after every titration by measuring the potential of an appropriate standard acid solution. Values for the ion product of water in each aqueous salt medium were established according to Liberti and Light (13).

Calculations

Values of the total concentration of ammonium salt (ion-paired, dissociated, or aggregated) in the organic phase, $[\overline{R_3NHX}]_T$, and $[\overline{R_3N}][H^+][X^-]$ are related through the concentration quotient, Q', expressed in logarithms as $\log [\overline{R_3NHX}]_T = \log [\overline{R_3N}][H^+][X^-] - \log Q'$. In the region where the salt exists essentially as an ion-pair a plot of the first term versus the second term of the preceding equation will be a straight line of slope one. A straight line of slope ½ is obtained for the case of a completely dissociated salt. Where the salt exists as a dimer in the organic phase, the slope of the plot would be two.

Proceeding from low concentrations the shape of a log–log plot reflects changing solute conditions from, for example, dissociated ions to ion-pairs to dimers etc. Values for the concentration quotient, Q', are determined from two phase titration data. After replacing $\overline{R_3NHX}_T$ by $\overline{R_3NHX}$ a corrected quotient, Q, is obtained. The relationship between Q and K is $K = Q\,\gamma_\pm^2$ where $\gamma_\pm$ is the mean activity coefficient of HX.

For each point in a two-phase emf titration the quantities $[\overline{R_3NHX}]_T$, $[\overline{R_3N}]$, $[H^+]$, and $[X^-]$ can be determined from the potential measurement and the initial concentrations: the total concentration of amine, c_B^0 (or ammonium salt, c_A^0) in the organic phase of volume V_{org} and the alkali metal salt concentration c of MX in the aqueous phase of volume V_{aq}^0. A known volume V_{add} of titrant of known composition is added and the concentration of H^+ ions in the aqueous phase is determined by the potentiometric measurement. The number of mequiv. of acid (or base) introduced by the titrant was denoted as n_{H^+} (or n_{OH^-}) and $V_{aq} = V_{aq}^0 + V_{add}$.

The following expressions can be deduced for direct titrations:

$$[1]\quad \overline{[R_3N]} = c_B^0 - \frac{n_{H^+}}{V_{org}} + \frac{V_{aq}}{V_{org}}\{[H^+] - [OH^-]\}$$

$$[2]\quad \overline{[R_3NHX]}_T = \frac{n_{H^+}}{V_{org}} - \frac{V_{aq}}{V_{org}}\{[H^+] - [OH^-]\}$$

$$[3]\quad [X^-] = c + [H^+] - [OH^-]$$

In the reverse titration of the organic ammonium salt by aqueous alkali, eqs. [1] and [2] are changed to:

$$[4]\quad \overline{[R_3N]} = \frac{n_{OH^-}}{V_{org}} + \frac{V_{aq}}{V_{org}}\{[H^+] - [OH^-]\}$$

$$[5]\quad \overline{[R_3NHX]}_T = c_A^0 - \frac{n_{OH^-}}{V_{org}} - \frac{V_{aq}}{V_{org}}\{[H^+] - [OH^-]\}$$

In the cases described above the ammonium salt is considered absent from the aqueous phase. However, for some medium and low molecular weight species a significant fraction of the ammonium salt might migrate to the aqueous phase.

Constants, K_p, representative of the equilibrium $\overline{R_3NHX} \rightleftarrows R_3NH^+ + X^-$ have been reported previously (3). The partition ratio $[R_3NH^+]/[\overline{R_3NHX}]_T$ of salt between nitrobenzene and the aqueous phase can be equated to $K_p/\gamma_\pm^2\, c$ and the percentage loss of organic salt to the aqueous phase to $100\, K_p V_{aq}/\gamma_\pm^2 V_{org}\, c$, i.e. ca. $8000\, K_p$. If an error of 1% (corresponding to the potentiometric error of 0.2 to 0.3 mV) is incurred, the maximum value of K_p, acceptable before appreciable loss of organic salt to the aqueous phase occurs, is seen to be: $K_p = 1/8000 = 1.25 \times$

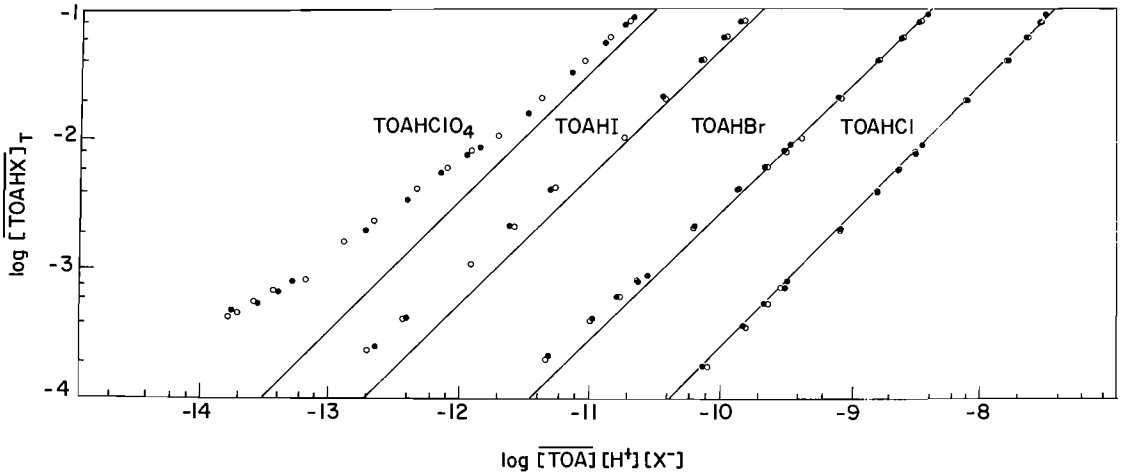

FIG. 1. Log–log plots of two phase titration measurements for trioctylamine salts, TOAHX, where X denotes ClO_4, I, Br, and Cl. Solid and open circles represent values obtained by direct and reverse titrations respectively.

10^{-4}. On this basis the following thirteen salts were considered to be negligibly extracted into the aqueous phase: TLAHCl, TOAHCl, TLAHBr, TOAHBr, THAHBr, TLAHI, TOAHI, THAHI, TPTAHI, $TLAHClO_4$, $TOAHClO_4$, $THAHClO_4$, and $TPTAHClO_4$ where TLAH denotes trilaurylammonium, TOAH trioctylammonium, THAH trihexylammonium, TPTAH tripentylammonium, TBAH tributylammonium, and TPRAH tripropylammonium.

For the other salts of low molecular weight in each series, eqs. [2], [3], and [5] do not apply. Appropriate expressions were derived for these by including K_p. The range of applicability was, however, limited to the less water partitioned salts; THAHCl,TPTAHBr, and $TBAHClO_4$.

In the preceding considerations the assumption was made that the free amine dissolved in the organic phase did not migrate significantly to the aqueous phase. This was verified for tripropylamine. The constant corresponding to the equilibrium $\overline{R_3N} \rightleftarrows R_3N$ was measured to be ca. 10^{-3}. Constants for higher molecular weight amines were considered to be even smaller and the concentration of free amine in the aqueous phase to be in all cases negligible.

The partition of MX between the aqueous medium and the nitrobenzene phase was disregarded since conductivity measurements performed on nitrobenzene phases equilibrated with 0.1 *M* aqueous solutions of $NaClO_4$, KI, KBr, or KCl showed the concentration of ionized inorganic salt in nitrobenzene was negligible in all cases.

Results

Log–log plots for the trioctylammonium salts which appear in Fig. 1 are typical of the results obtained from two phase emf titrations of all the amine salts studied.

In the low concentration decade, 10^{-3} to 10^{-4} *M* in total ammonium salt, drift and oscillations were frequently observed. Drifty values were not recorded and oscillating values were averaged. In the case of the iodide salt solutions systematic drifts towards lower *E* values were observed in the three concentration decades for solutions with *E* values above certain thresholds. This seems to indicate the onset of a decomposition reaction and renders uncertain the values recorded even for the more stable points. It was found that in this system all values would eventually drift in the low concentration ranges (10^{-2} to 10^{-4} *M* total ammonium salt). No attempt was made to clarify the reaction responsible for these drifts. One possibility is oxidation of iodide.

Chloride System

The plots for all R_3NHCl salts were linear with a slope of one. On this basis the solute should exist in the form of an ion-pair over the concentration range studied. No significant dissociation was evident. Values of *Q*, the concentration quotient, were essentially constant from the trihexyl to the tridodecylammonium salt.

Bromide System

Plots for R_3NHBr appeared linear with a slope of one over the 10^{-1} *M* concentration decade. Deviations which appeared in the 10^{-2} *M* decade increased in the 10^{-3} *M* decade. The solute may be considered as ion-paired at higher concentrations and to undergo progressive dissociation in the lower concentration ranges. Values of *Q* determined from the first decade were constant from the tripentyl to the tridodecylammonium salt.

Iodide System

Behaviour similar to that of the bromide system was observed for R_3NHI. However, deviations from a slope one in the lower concentration decades were larger than in the bromide plots, indicating greater dissociation. Values of *Q* determined over the first decade were constant from tripentyl to tridodecyl salts.

Perchlorate System

All plots showed similar behaviour. The slope decreased regularly from high to low concentrations of R_3NHClO_4 corresponding to a value close to one to a value close to one-half. Thus ion-pairs seemed to be predominant at high concentration and dissociated ions at low concentrations. The relative positions of the plots at high concentration seemed to indicate that Q values are similar from tributyl to tridodecylammonium perchlorates.

Examination of the region of highest amine salt concentrations on all log–log plots showed that in no system did the experimental curve have a slope significantly larger than one. This indicated no appreciable formation of species of higher molecular weight than the ion-pair occurred in the range of concentration studied.

Since the systems can be represented by two equilibria corresponding to the constants K and K_d, a graphical procedure was devised to obtain preliminary values for the constants. A family of curves was calculated to represent the theoretical log–log plots of a number of systems for a general Q value with varying K_d values. The straight line of slope one represents the system without dissociation; systems with varying K_d values (from 10^{-5} to 7×10^{-3}) increasingly deviate from the straight line. The deviation is small for $K_d = 10^{-5}$ and detectable only at the lowest concentrations. A change in Q value does not change this pattern but shifts the set of curves horizontally on the log–log plot. The set of curves was calculated by an iteration method.

The experimental log–log plots were compared to the standard curves by superimposition. The K_d values obtained for the amine chlorides were $<10^{-5}$, bromides $\sim 5 \times 10^{-5}$, iodides $\sim 2 \times 10^{-4}$, and perchlorates $\sim 3 \times 10^{-3}$. The corresponding Q values were chlorides 3.5×10^{-7}, bromides 3.5×10^{-8}, iodides 2.0×10^{-9}, and perchlorates 3.0×10^{-10}. The relative error for Q ranged between 5–10%.

Final values for Q were calculated directly from the data by an iteration method where each $[\overline{R_3NHX}]_T$ value yielded a value of $[\overline{R_3NHX}]$ for a given K_d value and Q was calculated for each point as $[R_3N][H^+][X^-]/[\overline{R_3NHX}]$. If the correct value of K_d has been selected, Q, should be a constant over the whole concentration range and the plot of $[\overline{R_3NHX}]$ vs. $[\overline{R_3N}][H^+][X^-]$ should be a straight line of slope one.

A series of K_d values were tested starting with the graphically determined K_d value. The value that minimized the spread on Q values was selected together with the corresponding Q value. In Fig. 1 straight lines of slope one were drawn on this basis.

The Chloride Series

These salts gave log–log plots which were linear and of slope one and computation of Q or K by iteration was unnecessary. Values of Q' calculated directly for each data point were averaged over the entire concentration range giving the following results: THAHCl, $Q = (3.6 \pm 0.2) \times 10^{-7}$; TOAHCl, $Q = (3.3 \pm 0.2) \times 10^{-7}$; TLAHCl, $Q = (3.4 \pm 0.2) \times 10^{-7}$.

The Bromide Series

Values of K_d over the range 10^{-5} to 10^{-4} were used to minimize the standard deviation of Q. The corresponding Q values are TPTAHBr, $Q = (4.2 \pm 0.2) \times 10^{-8}$, $K_d = (5 \pm 3) \times 10^{-5}$; THAHBr, $Q = (3.7 \pm 0.2) \times 10^{-8}$, $K_d = (5 \pm 3) \times 10^{-5}$; TOAHBr, $Q = (3.7 \pm 0.2) \times 10^{-8}$, $K_d = (7 \pm 3) \times 10^{-5}$; TLAHBr, $Q = (3.6 \pm 0.3) \times 10^{-8}$, $K_d = (5 \pm 4) \times 10^{-5}$.

The Iodide Series

Since relatively few stable data points were found in this system and all of these in the upper concentration decade, a direct computation of K_d and Q was not attempted but rather the results from the graphical method were believed to give a reasonable value for Q. These were TPTAHI 2.0×10^{-9}, THAHI 1.9×10^{-9}, TOAHI 1.8×10^{-9} and TLAHI 2.0×10^{-9}. In the case of iodides the accuracy of the graphical method was close to ± 5%. To this a standard deviation of 10% was added giving a range of ± 15% around the preceding values.

The Perchlorate Series

Values for K_d ranging between 10^{-3} and 4.5×10^{-3} were tested and the corresponding values of Q obtained were $TBAHClO_4$, $Q = (3.0 \pm 0.3) \times 10^{-10}$, $K_d = (2.0 \pm 0.5) \times 10^{-5}$; $TPTAHClO_4$, $Q = (2.7 \pm 0.2) \times 10^{-10}$, $K_d = (2.0 \pm 0.5) \times 10^{-5}$; $THAHClO_4$, $Q = (2.5 \pm 0.3) \times 10^{-10}$, $K_d = (2.0 \pm 0.5) \times 10^{-5}$; $TOAHClO_4$, $Q = (2.7 \pm 0.3) \times 10^{-10}$, $K_d = (2.0 \pm 0.5) \times 10^{-5}$, $TLAHClO_4$, $Q = (3.0 \pm 0.4) \times 10^{-10}$, $K_d = (2.5 \pm 1.0) \times 10^{-5}$.

In all cases attainment of equilibrium in the two-phase emf titrations was verified by comparing data points on the log–log plots obtained by direct and reverse titrations (see Fig. 1). In general, titrations of organic amine by acid and of organic ammonium salt by base in the same concentration decade gave data points that agreed within 5% or less. The difference arose in large part from potentiometric errors (0.2/0.3 mV or 1% in concentration on each potential reading).

Final K *Values and Ion Exchange Constants,* K_{12}

The thermodynamic constant K was obtained

TABLE 1. Hydrolysis constants, $-\log K$, of trialkylammonium salts at 25.0°C

Salt	Cl^-	Br^-	I^-	ClO_4^-
$TBAH^+$				9.71 ± 0.05
$TPTAH^+$		7.58 ± 0.02	8.90 ± 0.06	9.77 ± 0.03
$THAH^+$	6.65 ± 0.03	7.64 ± 0.02	8.90 ± 0.06	9.76 ± 0.05
$TOAH^+$	6.69 ± 0.03	7.64 ± 0.02	8.95 ± 0.06	9.74 ± 0.05
$TLAH^+$	6.67 ± 0.03	7.65 ± 0.03	8.90 ± 0.06	9.69 ± 0.06

from Q values, by applying the extended form of the Debye–Hückel law. A value of 0.79 for $\sqrt{\gamma_{H^+}\gamma_{X^-}}$ was obtained in all cases.

In Table 1 the log K values are presented.

The constants K can be combined for each series of salts to give ion exchange equilibrium constants. The equilibria

$$\overline{R_3NHX_1} \rightleftarrows \overline{R_3N} + H^+ + X_1^-$$

and

$$\overline{R_3NHX_2} \rightleftarrows \overline{R_3N} + H^+ + X_2^-$$

with constants K_1 and K_2, are combined to yield the following equilibrium

$$\overline{R_3NHX_1} + X_2^- \rightleftarrows \overline{R_3NHX_2} + X_1^-$$

This equilibrium describes the exchange of anion X_1 from the ion-paired salt in nitrobenzene R_3NHX_1 for anion X_2 in the aqueous solution.

The constant for the ion-exchange equilibrium is K_{12} with:

$$K_{12} = \frac{\overline{[R_3NHX_2]}[X_1^-]}{\overline{[R_3NHX_1]}[X_2^-]} = \frac{K_1}{K_2}$$

Similarly for the salts of low to middle molecular weight for which no value of K was obtainable, K_p values (3) can be combined to obtain the ion exchange constants:

$$K_{12} = K_{p1}/K_{p2}$$

In Table 2 the ion exchange constants for the couples Cl^-/Br^-, Br^-/I^-, I^-/ClO_4^- are listed for each trialkylammonium series.

For THAH Cl^-/Br^-, Br^-/I^- and TPTAH Br^-/I^-, I^-/ClO_4^- log K_{12} values obtained from partition constants were also available and except for possibly THAH Cl^-/Br^- there was no significant difference between the two values.

TABLE 2. Ion exchange constants, log K_{12}, of trialkylammonium salts at 25.0°C

Salt	Cl^-/Br^-	Br^-/I^-	I^-/ClO_4^-
$TPRAH^+$	1.01 ± 0.01*	1.26 ± 0.03*	0.92 ± 0.04*
$TBAH^+$	0.98 ± 0.01*	1.35 ± 0.03*	0.82 ± 0.03*
$TPTAH^+$	1.01 ± 0.03*	1.32 ± 0.08	0.87 ± 0.09
$THAH^+$	0.99 ± 0.05	1.26 ± 0.08	0.86 ± 0.11
$TOAH^+$	0.95 ± 0.05	1.26 ± 0.08	0.84 ± 0.11
$TLAH^+$	0.98 ± 0.06	1.25 ± 0.09	0.79 ± 0.12

*Obtained from K_p values.

Discussion

Dissociation constants obtained by two-phase emf titration are comparable to values previously obtained by conductometry (2). The pK_d values by conductometry (chlorides ~ 5.0, bromides ~ 4.5, iodides ~ 3.4, perchlorates ~ 2.4) are in fair agreement with values from two-phase emf titrations (chlorides < 5, bromides ~ 4.3, iodides ~ 3.7, perchlorates ~ 2.7). Since the errors associated with the constants obtained by potentiometry were large, subtle differences that might arise from chain length differences, for example, were not observed.

Conductometric studies (3) did not entirely exclude the possibility of limited triple ion formation at the most concentrated extreme of the chloride and bromide systems. The analysis of two-phase titration data does not support the possibility of significant aggregation other than simple ion pairs beyond the conductometric concentration maximum.

Several hydrolysis constants, $-\log K$, presented in Table 1 have been reported previously by other workers: TOAHCl, 6.75 (4) vs. 6.69 ± 0.03; TLAHCl, 6.78 (6) vs. 6.67 ± 0.03; TLAHBr, 7.70 (6) vs. 7.65 ± 0.03; TLAHI, 9.00 (6) vs. 8.90 ± 0.06. The agreement is satisfactory if the errors of the early measurements were comparable to the recent values. Müller and Diamond (6) gave a value of $pK = 7.45$ for $TLAHClO_4$ corresponding to the following equilibrium

$$\overline{R_3NH^+} + \overline{ClO_4^-} \rightleftarrows \overline{R_3N} + H^+ + ClO_4^-$$

A corresponding value from this work would be 7.0 ± 0.1 (calculated as $pK - pK_d$). The Müller and Diamond treatment, however, was approximate since association of separated ions to ion-pairs was ignored.

From an examination of K values obtained in this work for a variety of salts two major elements appear, the constancy of K with increasing carbon chain length for the same anion and the marked influence of the nature of the anion.

No significant trend was evident in the K values for any series of salts proceeding up the series from tributyl or tripentylamine to tridodecylamine (Table 1). If the acid–base reaction in the organic solvent

$$\overline{R_3NHX} \rightleftarrows \overline{R_3N} + \overline{HX}$$

is considered, the corresponding equilibrium constant K_a is related to K as $K_a = KK_{HX}$ where K_{HX} represents the partition equilibrium constant of HX corresponding to the partition reaction:

$$H^+ + X^- \rightleftarrows \overline{HX}$$

For a given anion, K_{HX} is a constant and since K does not vary with alkyl chain length, $\overline{K_a}$ is a constant too. This suggests that the basicity of trialkylamines in nitrobenzene does not change with increasing chain length from tributylamine.

The inductive effect should increase the basicity of trialkylamines as alkyl chain length is increased (14). This effect has been observed in water proceeding from trimethyl to tributylamine (15). Trémillon (16), by a spectrophotometric method, found that the base strength of amines in various solvents was not significantly influenced by the chain length from tributyl to trioctylamine. Grinstead (7) reported a similar affinity of THA and TOA for HCl in toluene.

The influence of the nature of the anion on the values of the hydrolysis constant is large. Hydrolysis assumes increasing importance in the order $ClO_4^- < I^- < Br^- < Cl^-$. There is approximately an order of magnitude difference in the hydrolysis constant when going from ClO_4^- to I^-, from I^- to Br^-, and from Br^- to I^-. Anion exchange constants (Table 2) also reflect these differences. As is the case with basicity of the amine, ion exchange does not seem to be influenced significantly by alkyl chain length for the series C_3–C_{12} reported here.

The order of anion exchange can be attributed to the nature of the aqueous and organic phases. In the organic phase, cation–anion interaction through electrostatic interaction and hydrogen bonding should favor the extraction of Cl^- vs. Br^-, Br^- vs. I^-, and I^- vs. ClO_4^- (3). However, this interaction is believed to be less important than interactions in the aqueous phase. Hydration is more favorable in the case of a smaller more basic anion. Furthermore, anions of larger diameter are also energetically more favored in the organic phase than small anions because of the water structure breaking factor.

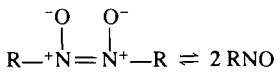
JOSEPH ARMAND, YVETTE ARMAND, LINE BOULARES, MICHÈLE PHILOCHE-LEVISALLES, and JEAN PINSON. Can. J. Chem. **59**, 1711 (1981).

It is shown by X-ray crystallography that 2-nitrosoquinoxaline crystallizes as a dimer, the structure of which is established. In solution the monomeric form predominates and the dimerisation equilibrium constant is measured. The electrochemical reduction of 2-nitrosoquinoxaline in acidic medium leads to the oxime of quinoxaline (1*H*)-2-one (**3**) through the intermediate hydroxylamine. **3** is electrochemically reoxidized directly to 2-nitrosoquinoxaline.

JOSEPH ARMAND, YVETTE ARMAND, LINE BOULARES, MICHÈLE PHILOCHE-LEVISALLES et JEAN PINSON. Can. J. Chem. **59**, 1711 (1981).

Les données cristallographiques obtenues par diffraction des rayons X montrent que la nitroso-2 quinoxaline cristallise sous forme de dimère dont la structure est établie. En solution le monomère prédomine et la constante d'équilibre est mesurée. La réduction électrochimique de la nitroso-2 quinoxaline en milieu acide conduit à l'oxime de la quinoxaline (1*H*)-one-2 (**3**) par l'intermédiaire de l'hydroxylamine correspondante. **3** est réoxydée par électrochimie directement en nitroso-2 quinoxaline.

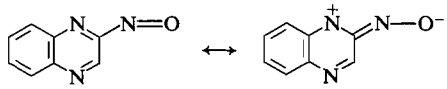
There has been considerable recent interest in the structure of monomeric and dimeric nitroso-compounds, both in the solid state and in solution, as well as in the monomer dimer equilibrium (**1**).



[A]

In the aromatic series, nitrosobenzenes have been mostly investigated. In the solid state, nitrosobenzene itself exists as a dimer (2), while its derivatives bearing an electron-donating group crystallize as monomers (3). In solution, the constant of equilibrium [A] depends on the electron-donating or -withdrawing ability of the substituents but also on their steric bulkiness. Correlations have been established between the redox potentials of monomers and the uv absorption frequencies (4, 5) on one side and the equilibrium constants k_A (6) on the other side.

As 2-nitrosoquinoxaline is one of the few nitroso heterocyclic derivatives we became interested in its structure both in the solid state and in solution. As in the case of *p*-aminonitrosobenzene (3) and of 9-nitrosojulolidine (7) a resonance form (*b*) resembling an oxime ion can be written which may contribute significantly to the structure of the monomer:



(*a*) (*b*)

In relation with the structure in solution we investigated the electrochemical behaviour as several possible schemes were possible: reduction of the quinoxaline ring, of the nitroso group, or of the azodioxide group.

(1) Structure in the Solid State

Atomic positions are given in Table 1. Tables of observed and calculated structure factor amplitudes and of temperature factors are available from the Depository of Unpublished Data.[1] Table 2 lists the bond lengths and Table 3 the bond angles. Figure 1 is an ORTEP (9) diagram of the crystal structure and the crystal packing is shown in Fig. 2.

The results of the X-ray analysis show that 2-nitrosoquinoxaline exists in the solid state in the *cis*-azodiquinoxaline dioxide structure **1**. While the results obtained with the crystals of pentafluoro-nitrosobenzene (10) show that it is possible for monomeric and dimeric aromatic nitroso com-

pounds to coexist in the crystalline state, in the case of the crystals 2-nitrosoquinoxaline there is no evidence for the existence of any species other than **1**.

The dimer of 2-nitrosoquinoxaline has a *cis* configuration as the dimer of nitrosobenzene (2). In both cases the central azodioxide group is not planar, and an important twist is observed along the N—N bond, coupled with some displacement of the nitrogen atoms from the plane defined by its three bonded neighbours. For the *cis*-azobenzene dioxide, the C(phenyl)—N—N—C(phenyl) and O—N—N—O torsion angles are 18.0 and 3.0° respectively while the out-of-plane distortions at N(1) and N(2) are 0.048 Å and 0.049 Å. In the case of **1**, the corresponding torsion angles are 11° 05′ and 5° 04′ while the out-of-plane distortions are 0.015 Å and 0.025 Å. The N—O, N—N, and C_1—N_1 bond lengths in **1** and *cis*-azobenzene dioxide are quite similar within experimental errors.

The existence of 2-nitrosoquinoxaline under a dimeric structure in the solid state points to a very low weight of resonance structure (*b*).

(2) Structure in Solution

A solution of 2-nitrosoquinoxaline shows a uv maximum at λ_{max} = 800 nm corresponding to the n → π* transition of the nitroso group which is classically observed between 630 and 830 nm.

The molar extinction coefficient ε_0 of the monomer **2** has been determined by linear extrapolation (Ostwald law) of the usual (11) ε vs. $\varepsilon^2 c_0$ plots (where c_0 is the concentration of total nitroso compounds all figured as monomer) to zero concentration: ε_0 = 30 L mol^{-1} cm^{-1}. The constant K_A of equilibrium [A] was then determined to be 3×10^{-2} mol L^{-1} at 20°C, this value corresponding to 32% of monomers in a $c_0 = 0.1\ M$ solution. As in the case of nitrosobenzene (6) the nature of the solvent plays a minor role; the percentage of monomer in $CHCl_3$ for a $c_0 = 0.1\ M$ solution is 29%. The value of the equilibrium constant K_A was also determined in a 50–50 water–dimethylformamide mixture at pH 1.7, the solvent in which the electrochemical in-

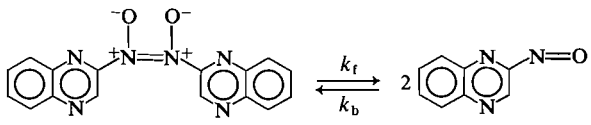
vestigation was carried out. The value obtained, $K = 1.28 \times 10^{-2}$ mol L^{-1} at 20°C leads, for a value of $c_0 = 10^{-3}$ M, to 6% of the dimer, i.e. to a value of $c_2 = 0.6 \times 10^{-4}$ M.



$$K_A = k_f/k_b$$

The rate constant of the forward dimer → monomer rate constant was measured by the stopped-flow technique and was found to be $k_f = 7.8\ s^{-1}$, which leads to $k_b = 6.1 \times 10^2\ M^{-1}\ s$.

The above value of K_A obtained for 2-nitrosoquinoxaline is much lower than that obtained for nitrosobenzene, in this last case, the percentage of monomer is higher than 99% for $c_0 = 0.1\ M$ (11). The value of K_A for 2-nitrosoquinoxaline is of the same order of magnitude as that of 2,4,6-trimethylnitrosobenzene (6). For this latter compound the lower value of K_A has been assigned to a steric inhibition of resonance in the monomer (6) or in the dimer (12). In our case it is difficult to rationalize the origin of the decreased value of K_A from the different influences of the phenyl and quinoxalyl rings.

(3) Electrochemical Reduction

In an hydroorganic medium, 2-nitrosoquinoxaline is unstable above pH 4. In a 50/50 water–dimethylformamide solution at pH 1.7, the polarogram shows two waves, the first one is a 2 F wave the half-wave potential of which cannot be measured at the dropping mercury electrode ($E_{1/2} > 0.2$ V), the second one is a 4 F wave with an $E_{1/2} = -0.48$ V. This second wave is that of the oxime of quinoxaline (1*H*)-2-one (**3**) which evidences the same cathodic wave. Besides a preparative electrolysis of 2-nitrosoquinoxaline at the level of the first wave gives **3**.

The voltammogram recorded at 200 mV s^{-1} on a vitreous carbon electrode shows, besides the peak of **3** at −0.48 V, two cathodic peaks I*c*, II*c*, and two anodic peaks III*a* and IV*a* (Fig. 3). The same voltammogram is obtained starting from the oxime of quinoxaline (1*H*)-2-one **3** and scanning +1.0 V → 0 V → +1.0 V. Peak I*c*, $E_p = +0.28$ V, corresponds to the transfer of two electrons. On a rotating vitreous carbon disc electrode, the height of the wave corresponding to peak I*c* varies linearly with the square root of the rotation speed, $\omega^{1/2}$, indicating that this plateau of the wave is diffusion-controlled. Upon increasing the scan rate peak I*c* shifts to more negative potentials.

Peak II*c* is a small peak which appears at +0.15 V, its height which is rather irreproducible from one experiment to the other never reaches more than 20% of that of I*c*. Upon scanning repetitively between +0.1 V and 0 V its height decreases less than 10% of its initial height. Upon increasing the scan rate peak II*c* becomes symmetrical and spiky. Thus peak II*c* appears as an adsorption peak. Peak III*a* ($E_p = +0.33$ V at 200 mV s^{-1}) is not related to peak II*c*; indeed when the cathodic scan is reversed before peak II*c*, peak III*a* still appears on the voltammogram. The height of peak III*a* increases with the sweep rate: while it is not observed at a scan rate of 0.025 V s^{-1} it reaches about one third of the height of peak I*c* at 20 V s^{-1}. Besides, this peak is not observed in a solution of **3** when scanning from 0 to +1 V.

Peak IV*a* corresponds to the oxidation of **3** into **2**. Indeed, in a solution of **3** under the same conditions as above the first anodic scan (0 → +1.0 V) shows an anodic peak identical to peak IV*a* and on

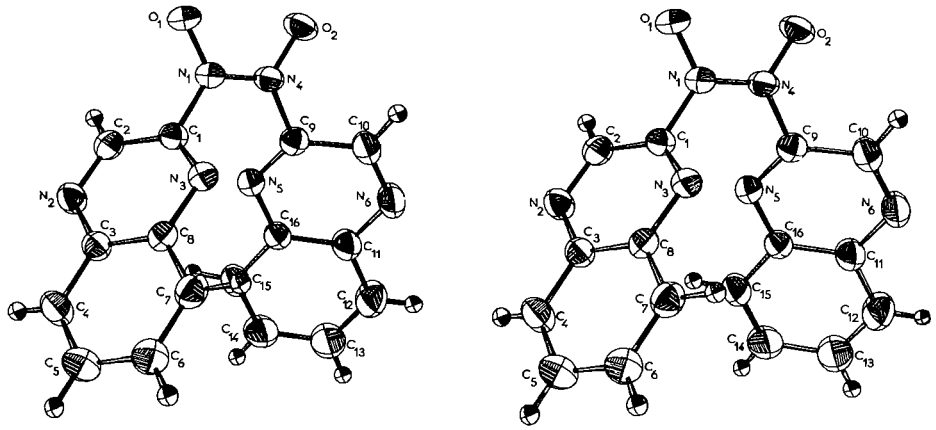


FIG. 1. Stereoscopic view of the solid state structure of *cis*-azodiquinoxaline dioxide.

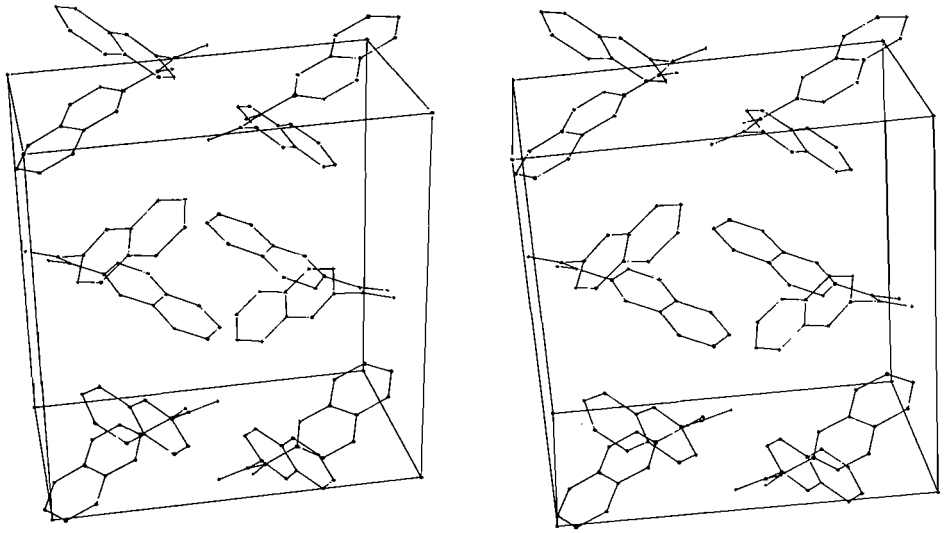

FIG. 2. Crystal packing of *cis*-azodiquinoxaline dioxide.

the reverse cathodic scan peaks Ic and IIc are observed. The height of peak IV*a* is equal to that of peak Ic at 0.025 V s^{-1} and decreases with the sweep rate, at 20 V s^{-1} it is reduced to one third of that of Ic and is nearly equal to that of II*a*.

Discussion

Our results show that while 2-nitrosoquinoxaline is entirely in a dimeric form in the solid state, the monomer predominates in the solution. Let us first consider the problem of the dimer, i.e., does one of the peaks observed on the voltammogram correspond to the dimer? The only azodioxide which has been investigated by electrochemistry is the 4,5,9,10- tetraza-4,5-pyrene di-*N*-oxide (14). Mugnier and Laviron have shown, by voltammetry, that the first 2 F reduction peak corresponds to the cleavage of an oxygen atom, while the second 4 F peak corresponds to the reduction of the azoxy derivative into the corresponding hydrazo compound. The potential difference between the two peaks is about 0.2 V. Thus if peak IIc was that of the dimer **1**, one should observe the peak of the azoxyquinoxaline at about −0.05 V. No peak is observed in this region of the voltammogram, in the same way the polarogram shows only a clean plateau between +0.1 V and −0.4 V. Besides the height of peak IIc does not increase significantly with the concentration between $c_0 = 5 \times 10^{-4}$ and 2×10^{-3} *M*. This leads to the conclusion that peak IIc does not belong to the dimer and that monomer **2** is the only species which is reduced at the electrode, equilibrium [A] is drawn to the right by reduction of **2**.

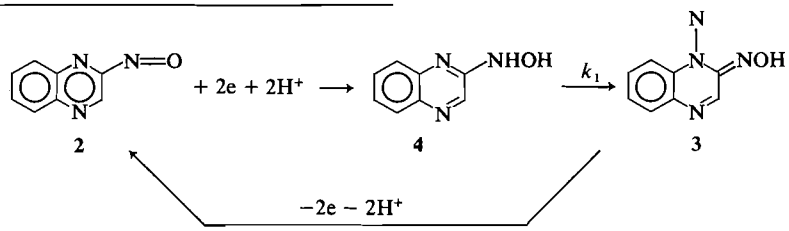
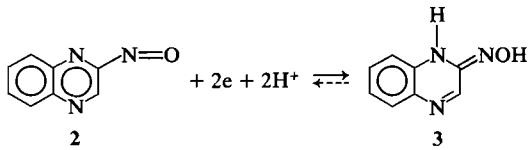
Two mechanisms can be taken into account for the reduction of 2-nitrosoquinoxaline (*i*) a reduction into 2-hydroxylaminoquinoxaline **4** followed by its rearrangement into **3**:



(*ii*) a direct electrochemically irreversible reduction of **2** into **3**



The appearance of peak II*a* on the voltammogram of **2** clearly indicates that the first mechanism is operative. This peak must correspond to the intermediate hydroxylamine **4**. The difference $E_p(Ic) - E_p(IIIa) = 50$ mV which is close to that of the reversible system nitrosobenzene–phenylhydroxylamine also observed on vitreous carbon (13). It is not observed on the first anodic scan of a solution of **3** but it appears on the reverse anodic scan of a solution of **2** and its height increases with the sweep rate. Peak IV*a* corresponds to the direct reoxidation of **3** into **2**. The **2/3** couple thus appears as an electrochemically irreversible but chemically reversible couple.

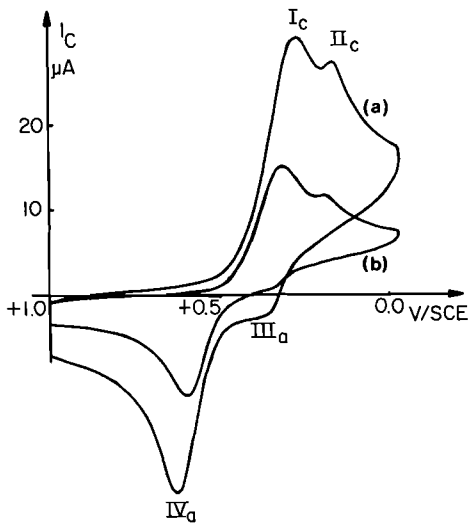


FIG. 3. Cyclic voltammogram of 2-nitrosoquinoxaline–water –dimethylformamide 50/50, pH 1.7, $c_0 = 10^{-3}$ *M*, on a vitreous carbon electrode. Scan rate (*a*), 0.2 V s^{-1}; (*b*), 0.025 V s^{-1}.

Experimental

The 2-nitrosoquinoxaline as well as the oxime of quinoxaline (1*H*)-2-one have been prepared according to ref. 15. The monocrystal used in the crystallographic study was obtained by slow evaporation of a methanolic solution.

Crystallographic Study

Crystal data are as follows:

$C_{16}H_{10}N_6O_2$ f.w. = 318.29

Monoclinic, $a = 7.019$ (2), $b = 14.143$ (3), $c = 14.788$ (3) Å, $\beta = 96.12$ (1)°, $V = 1459.62$ Å^3, $Z = 4$, $\rho_c = 1.44$ g cm^{-3}, $\rho_0 = 1.48$ (2) g cm^{-3} (20°C, MoK$_\alpha\lambda = 0.707$ Å, $\mu = 1.0$ cm^{-1}). Preliminary X-ray photographs showed the following systematic absences: $h0l, l = 2n + 1$; $0k0, k = 2n + 1$. The space group is the $P2_1/c$. A crystal (0.60 × 0.15 × 0.35 mm) was mounted with the *a* axis parellel to the ϕ axis of a Philips automated diffractometer equipped with a graphite monochromator. The intensities of all reflection having 2θ less than 50° were measured using the variable ω–2θ scan technique. During the course of the data collection three standard reflections were measured every 54 reflections. A total of 2572 independent reflections were measured 1665 of which had $I > 4\sigma(I)$. The data were reduced to $|F_o|$ by the routine procedure. Lorentz and polarization but not absorption or extinction corrections were applied. The scattering factors for neutral atoms were taken from ref. 16. The structure was determined by direct methods (MULTAN) (17) and refined by large block least-squares $(\Sigma\omega|F_o| - |F_c|)^2 = \min$ with $\omega = 1/\sigma^2$. The refinement with anisotropic thermal parameters on the non-hydrogen atoms converged with $R = 0.068$. At this stage, a difference Fourier map revealing the position of all the hydrogens was calculated; refinement of their positional parameters was carried out using the thermal parameters of the corresponding heavy atoms at the end of isotope refinement. The refinement including all atoms and all observed reflections converged with $R = 0.040$ and $R_w = 0.046$.

Electrochemical techniques have been previously described (18). All the potentials are referred to the aqueous saturated calomel electrode. A vitreous carbon electrode (3 mm diameter) was used, it was polished with 1 μ diamond paste before each experiment. The uv spectra have been recorded on Beckmam model 25 apparatus.

The rate constant of the dimer → monomer reaction has been determined with a Durrum stopped-flow spectrophotometer D 150, the cell compartment of which was maintained at 20 ± 0.5°C. Equal volumes of a pH 1.7 solution of **1** ($c_0 = 3 \times 10^{-3}$ *M*) containing 50% of dimethylformamide and of the same solution without **1** were mixed and the optical density vs. time curve recorded at $\lambda = 800$ nm.

Preparative Electrolysis

It was performed on mercury in a cell previously described (8), the cathodic compartment contained 100 mL of an aqueous

solution containing 500 mg of **1** (which were only partly dissolved), 50 mL of methanol, and 10 mL of H_2SO_4; the anodic compartment contained the same solution without depolarizer. The potential was set at −0.2 V. After consumption of 600 C (2F/mol = 607 C) the current decreased to less than 3 mA and the cell was disconnected. The cathodic solution was filtered, neutralized to pH 7 with sodium carbonate, the methanol was evaporated *in vacuo* at room temperature. The solid which precipitated was filtered, washed with water, and dried to give 320 mg (yield 64%) of **3** mp = 200°C (dec.) (lit. (15) mp = 198–200°C (dec.)). This compound was identified by comparison (ir, nmr) with an authentic sample (15).

5,5-Dimethylcyclohexane-1,3-dione and its derivatives were shown to isomerize to give 5,6-dihydropyran-4-ones on irradiation in FSO_3H or 98% H_2SO_4. The 2,2-dimethyl derivative, lacking hydrogen on C2, failed to give any products under the same conditions. A similar type of isomerization was also observed with thiolane-2,4-dione and its derivatives, while no photoisomerization was observed with their nitrogen or oxygen analogs. A possible reaction mechanism is proposed.

KIMITOSHI SAITO, HIDETAKA YUKI, TOSHIYUKI OHYAMA, RYOHEI NAKANE, KATSUYUKI NAGUMO et TADASHI SATO. Can. J. Chem. **59**, 1717 (1981).

En milieu acide à 98% H_2SO_4 ou à FSO_3H, nous avons obtenu la dihydro-5,6 pyrane-4, par isomérisation sous l'action de l'irradiation, de la diméthyl-5,5 cyclohexenedione-1,3 et de ses dérivés. Par contre, le dérivé 2,2-diméthylé, sans hydrogène en C2, n'est pas isomérisé dans les mêmes conditions expérimentales. Le même type de photoisomérisation a été obtenu avec la thiolanedione-2,4 sauf avec ses composés oxygénés et azotés. Nous proposons ici un des méchanismes possibles de réaction.

The photochemistry of ketones in strong acid media has been characterized by a unique reaction pattern induced by controlled excitation due to the protonation on the carbonyl group. The reaction has been extensively investigated particularly in cyclic dienone systems, and isomerization to bicyclo systems or ring contraction has been identified as the typical reaction pattern (2–7).

Previously, we reported that the photoreaction of ketones in methanol in the presence of $TiCl_4$ or UO_2Cl_2 proceeds through C—C bond formation, and proposed a scheme involving the coordination of the ketone and methanol to the metal ion as an essential step for the reaction to proceed (8–10). In connection with this reaction, we thought it of interest to compare the catalytic effect of Lewis acids with that of protonic acids. Childs and Hor (11) investigated the effects of boron trihalides and protonic acid on the photobehavior of eucarvone, and observed a similarity in their catalytic effects for the major reaction paths.

We have studied the effect of protonic acids on the photoreaction of a variety of carbonyl compounds, and found a novel reaction pattern with cyclic β-dicarbonyl compounds upon irradiation in strong acid media.

[1]Preliminary report, see ref. 1.

Results and Discussion

Irradiation of 5,5-dimethylcyclohexane-1,3-dione, **1***a*, in FSO_3H or 98% H_2SO_4 with quartz-filtered light from a high pressure mercury lamp for 24 h, and subsequent work-up with water gave 2,6,6-trimethyl-5,6-dihydro-4*H*-pyran-4-one, **2***a*, as sole product in 19% yield. The acid solution became darkened toward the end of the irradiation, and the longer irradiation times did not increase the yield. Olah *et al.* (12) reported that carbonyl compounds such as **1***a* and **2***a* exist in a protonated form, **1***aH* and **2***aH*, respectively. We confirmed this result from the nmr spectra of **1***a* and **2***a* in FSO_3H as shown in Table 1. Although the isolated yield of **2***a* was low, the ^1H nmr analysis of the acid solution after the irradiation revealed that no other signals were noticeable except those of **2***aH* and the starting material, **1***aH*. Although the 2-methyl derivative, **1***b*, afforded **2***b* in 18% yield, the 2,2-dimethyl derivative, **1***c*, lacking hydrogen on C2, failed to give any products under the same conditions. The structures of **2***a* and **2***b* were identified by comparing the spectroscopic data with the reported values (13).

It has been reported that the photo-induced ring contraction of protonated cyclic dienones proceeds through the initial electrocyclic opening of the ring, while the ring contraction of protonated cyclo-

hexenones proceeds through the initial 1,2-shift (14). Since the concerted 1,3-shift of C5 from C4 to oxygen is unlikely due to the structural requirement, we envisaged the isomerization **1** → **2** as a stepwise reaction involving ring-opening and recyclization. The ring-opening could proceed through either electrocyclic opening of the cyclohexadienone system, **3**, which could possibly exist as a minor equilibrium component even in strong acid media (Scheme 1), or simple 1,2-bond fission of the protonated species (Scheme 2, see later).

In order to distinguish between the two plausible paths, we carried out the irradiation in deuterated sulfuric acid. When **1***a* was irradiated in D_2SO_4 and then worked up with H_2O, a deuterated **2***a* was obtained. The ^{1}H nmr and mass spectroscopic analyses of this product indicated that 100% of one proton on the C2-methyl group and 84% of the C3-proton had been exchanged with deuterium. On the other hand, the irradiation of **1***a* in H_2SO_4 and subsequent work-up with D_2O gave **2***a*, in which a major portion (62%) of the C3-proton had been exchanged with deuterium. This result indicates that the C3-proton of **2***a* is exchangeable with solvent proton with great ease, and we concluded that the primary product of the reaction in D_2SO_4 is a dideuterated compound, **4**, from which 16% of C3-D was expelled by proton during the work-up procedure. In spite of the deuteration at the C3 and C2-methyl groups, no indication of deuteration at C5 was observed at all, and the possibility of intervening in the electrocyclic opening as shown in Scheme 1 was thus eliminated.

The presence of *gem*-dimethyl substituents at C5 in the starting material is necessary for the present reaction to proceed, and compounds **5***a–c* were recovered unchanged under the same irradiation conditions. These findings induced us to propose the following scheme for the present isomerization (Scheme 2). As mentioned above, the starting material **1***a* exists in a protonated form **1***aH* under the present reaction conditions. This was also suggested from the comparison of the ultraviolet spectra in organic solvents and acidic media (Table 2). This cationic species undergoes a C4–C5 bond fission upon irradiation to give a cation, **6***aH*, followed by cyclization at carbon and oxygen atoms to give **2***aH*. Upon work-up, it affords the observed

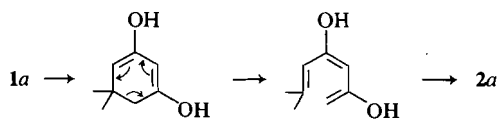
12

product **2***a*. Presumably, the stabilization of the positive charge in **6***aH* by the *gem*-dimethyl groups would play an important role in the success of the reaction.

In view of Scheme 2, it is hard to rationalize the unreactivity of the phenyl derivative **5***c*. In our previous communication, we ascribed the inertness to protonation on the phenyl ring. However, we observe now that such a speculation is erroneous in view of the ^1H nmr data as shown in Table 1. Probably a different type of excited state might be responsible, although no experimental work has been carried out on this problem.

The same type of rearrangement was also observed in sulfur-containing cyclic β-diketones. Irradiation of thiolane-2,4-dione, **7***aS*, in FSO_3H and subsequent work-up with water afforded 5-methyl-3-oxo-3*H*-1,2-oxathiole, **8***a*, in 76% yield. Similarly, the 3-acetyl derivative, **7***bS*, afforded **8***b* in 49% yield. Although the ultraviolet spectra of



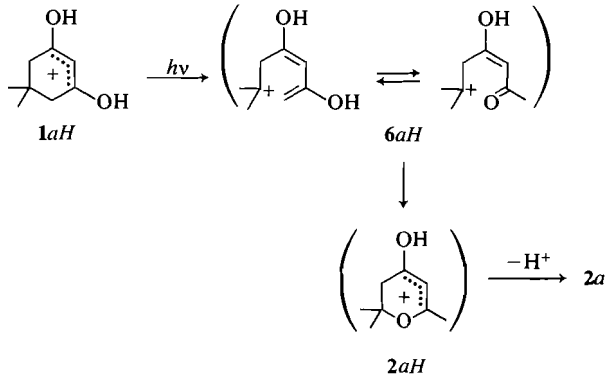
3

SCHEME 1

7*aS* and **7***bS* in 98% H_2SO_4 showed three absorption maxima in the range of 220–340 nm (Table 2), the yields of **8***a* and **8***b* were almost independent of whether the light was filtered by quartz or Pyrex. Presumably, the absorption at the longer wavelength might be responsible for the reaction. The ^1H nmr analysis indicated that no other products except the starting materials are present in the acid solution after the irradiation.

There seems to be no precedent for the 3-oxo-3*H*-1,2-oxathiole ring system, and the structure of the product, **8***b*, was determined by its elemental analysis and ^1H and ^{13}C nmr spectra. Since the spectroscopic analyses alone do not eliminate another possible structure **10** for the product, we attempted its synthesis. However, every effort to convert the known compound **9** (15) into **10** failed, and we could not elaborate any other way but to compare the spectroscopic data of **8***b* with those of **9**.

Hall and Wemple (16) have reported that the ^{13}C nmr signals of the carbonyl carbon and the carbon α to the carbonyl function in thiol esters are shifted downfield relative to those of the corresponding carboxylic acid derivatives. The comparison of ^{13}C nmr data of **8***b* and **9** revealed that the chemical shift of the ring carbonyl carbon appears at higher field in **9** relative to **8***b*, while the chemical shifts of the carbon β to the ring carbonyl function



1*aH* **6***aH* **2***aH*

SCHEME 2

and the methyl carbon on the ring appear at lower field in **9** relative to **8***b*. The ^1H nmr shift of the methyl group in **9** (δ 2.92) also appears at lower field as compared with that in **8***b* (δ 2.50). All these trends could be explained more satisfactorily by assuming the different orientation of the S—O moiety in the ring system, rather than by assuming a different substituent effect between carboxylic and acetyl groups. Although there remains some ambiguity in the structure **8***b* in view of the lack of

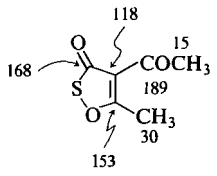
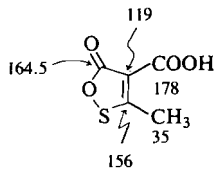
independent synthesis, we believe structure **8***b* is the most probable among other alternatives.

Although the isolated product from 7*aS* was too unstable to permit elemental analysis, the spectroscopic data were consistent with the structure **8***a* (see Experimental).

In contrast with the facile rearrangement in sulfur analogs, both the nitrogen analog, 7*bN*, and oxygen analog, 7*bO*, were stable when irradiated in FSO_3H, and most of the starting materials were recovered.



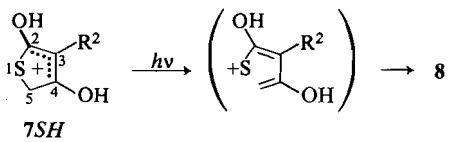
8*b*



9

The ^1H nmr spectra of 7*aS* and 7*bS* in FSO_3H (Table 1) are indicative of the formation of the corresponding hydroxyl cations, 7*SH*, under these conditions. By analogy with the case of the carbocyclic β-dicarbonyl system, we envisaged the photoisomerization as involving S—C5 bond fission and subsequent recyclization with S—O bond formation (Scheme 3). Again, the stabilization of the open-chain cationic species would be responsible for the isomerization. It is known that a sulfenium cation is more stable than the univalent oxygen or nitrogen cations (17), and this trend reflects the facile rearrangement of sulfur compounds only.

As a reference, the photoreaction of these cyclic



7*SH*

SCHEME 3

β-diketones under unprotonated conditions was investigated. It is reported (18) that the irradiation of **1***c* in benzene gives δ-lactone, **11**, by the C1—C2 bond cleavage and subsequent recyclization. This reaction proceeds irrespective of the presence or absence of the methyl group(s) on C5. In the present study, we confirmed that cyclic β-diketones having no methyl group on C2, such as **1***a*, were photochemically inert when irradiated in methanol. Thiolane-2,4-dione, 7*S*, and its oxygen or nitrogen analogs, 7*bO* or 7*bN*, were also intact under neutral conditions in methanol except in the case of 7*aS* in which 4-methoxy-2-oxo-2,5-dihydrothiophene, **12**, was obtained as the main product accompanied by a 22% yield of methyl acetoacetate (19).

Experimental

General

The mass spectra were obtained with a Hitachi RMS-4 spectrometer, the ir spectra with a Hitachi 215 spectrometer, the ^1H nmr spectra with a JEOL PS-100 spectrometer (with Me_4Si as the internal standard), and ^{13}C nmr spectra with a JEOL FX-10 spectrometer operated at 25.1 MHz.

Materials

The starting materials **1***a* and **5***a* were commercial samples, and **1***b*(20), **1***c*(20), **5***b*(21), **5***c*(22), 7*aS*(23), 7*bS*(24), 7*bN*(25), 7*bO*(26), and **9**(27) were prepared according to the procedures described in the literature cited. FSO_3H was prepared from 60% fuming sulfuric acid and H_2KF (28) and distilled twice under N_2 before use. D_2SO_4 was prepared by anhydrous sulfuric acid and D_2O (29).

General Procedure for the Photolysis in FSO_3H or 98% H_2SO_4

Starting ketone was dissolved in FSO_3H or 98% H_2SO_4, and the solution (0.1–0.3 *M*) was irradiated in Pyrex or quartz test tubes by means of a high pressure mercury lamp (Ushio UM 452 (450 W)) for 24 h. After the irradiation, the solution was poured onto crushed ice, and then extracted with chloroform. The chloroform solution, after washing with 10% aqueous sodium carbonate solution, was dried over sodium sulfate and evaporated *in vacuo*. The residue was treated as indicated below.

Photolysis of **1**a *or* **1**b

The viscous residue obtained by the general procedure was purified by vacuum distillation. Compound **2***a* or **2***b* was isolated

as a single product; **2***a*, bp 87°C/18 Torr (lit.12) bp 63°C/1 Torr); **2***b*, bp 110°C/18 Torr (lit.(12) bp 62°C/1 Torr). The structures of **2***a* and **2***b* were identified by comparing spectroscopic data with the reported values (12).

Photolysis of **1**a *in* D_2SO_4

A solution of **1***a* in 60% deuteriosulfuric acid was irradiated for 6 h. The viscous residue obtained by the general procedure, after work-up with H_2O, gave dideuterated compound, **4**; ^{1}H nmr (CCl_4) δ: 1.4(s, 6H), 1.92 (t, 2H, one proton of C2-methyl was deuterated), 2.3 (s, 2H), and no C3-proton was detected; mass/intensity ratio of *m/e* 140(M^+): 141 (M^+ + 1): 142 (M^+ + 2) was calculated to be 1:4.5:24.

A solution of **1***a* in 98% H_2SO_4 was irradiated for 6 h. After the irradiation, the solution was poured onto crushed ice mixed with D_2O, and then extracted with chloroform. The chloroform solution was dried over sodium sulfate and then evaporated *in vacuo*. The residue was analysed by ^{1}H nmr spectroscopy; ^{1}H nmr (CCl_4) δ: 1.4(s, 6H), 1.92(s, 3H), 2.3(s, 2H), and 5.1(s, 0.387H; H–D exchange ratio is calculated to be 61.3%).

Photolysis of **7**aS *or* **7**bS

The viscous residue obtained from **7***bS* by the general procedure gave white crystals of **8***b* upon sublimation at 55–65°C (bath)/18 Torr. In the same way, the crude solid of **8***a* was obtained from **7***aS*. Since **8***a* was unstable, the analysis was carried out on a sample without purification. For **8***a*, ir (CCl_4) ν: 1745–1710 cm^{-1}; the ^{1}H nmr spectral data are shown in Table 1; mass spectrum *m/e*: 116 (M^+), 88, and 43. For **8***b*, mp 66°C; ir(CCl_4) ν: 1745, 1650, and 1610 cm^{-1}; the ^{1}H nmr spectral data are shown in Table 1, and the ^{13}C nmr spectral data are given in the text. Mass spectrum *m/e*: 158 (M^+), 114, 87, and 43. *Anal.* calcd. for $C_4H_6O_3S$: C 45.58, H 3.83; found: C 44.82, H 3.70.

Received January 23, 1981

KIMITOSHI SAITO, HIDETAKA YUKI, TOMOYUKI SHIMADA, and TADASHI SATO. Can. J. Chem. **59**, 1722 (1981).

When five- and six-membered cyclic β-dicarbonyl compounds having an acetyl group on the 2-position were irradiated in methanol in the presence of $TiCl_4$, a coupling reaction between the acetyl carbonyl atom and the α-carbon atom of the methanol took place, giving γ-ketoaldehydes or dihydrofurans as the main product.

KIMITOSHI SAITO, HIDETAKA YUKI, TOMOYUKI SHIMADA et TADASHI SATO. Can. J. Chem. **59**, 1722 (1981).

Lors de l'irradiation de composés β-dicarbonylés cycliques formés de 5 ou 6 chaînons et portant un groupement acétyle en position 2 dans le méthanol et en présence de $TiCl_4$, il y a formation principalement des γ-cétoaldéhydes ou des dihydrofurannes par suite d'une réaction de couplage du carbonyle du groupement acétyle et l'atome de carbone en α du méthanol.

[Traduit par le journal]

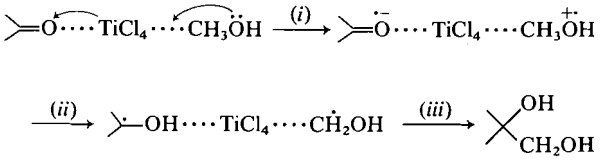
Previously we reported that a cyclic β-dicarbonyl compound, **1**, when irradiated in methanol in the presence of $TiCl_4$, underwent a novel type of reaction with the formation of a C—C bond between the substrate and the alcohol, and produced



SCHEME 1

an acetal, **2** (1). The photoreaction has been pictured as involving (*i*) a photo- and metal-assisted electron transfer from alcohol to carbonyl compound, (*ii*) the succeeding proton transfer, and (*iii*) the cross-coupling of the two species to give a 1,2-diol (Scheme 1). The whole process is believed to proceed within the coordination sphere of the titanium (2). The intermediate 1,2-diols, which are in some cases isolable, further decomposed to aldehydes by dehydration, and then to the final products.

In our preceding paper (3), we described a novel effect of protonic acids on the photoreaction of five- and six-membered cyclic β-dicarbonyl compounds having an acetyl group on the 2-position. We next carried out the $TiCl_4$-catalyzed photoreaction on these compounds in order to see whether there is a similarity in the effects of $TiCl_4$ and protonic acids, and which of the three carbonyl groups is susceptible to the photoreaction under these conditions.

Results and Discussion

When a methanol solution of **3***aS* was irradiated in the presence of $TiCl_4$ for 4 h, a γ-ketoaldehyde, **5***aS*, and its acetal, **4***aS*, were obtained in 18% and 29% yields, respectively, along with a cyclization product, **6***a* (9%). Similarly, the 2-methyl deriva-

tive, **3***bS*, gave **4***bS* (25%), **5***bS* (17%), and **6***b* (9%) under the same irradiation conditions. Acetals **4***aO* and **4***aN* were also obtained as the main products from the photolyses of **3***aO* and **3***aN*. The ^{1}H nmr signal of the furan proton of **6***a* at δ 7.17 splits into a triplet (J = 1.25 Hz) due to the coupling with methylene protons, and the alternative structure **7** was thus eliminated. Evidently, **4** and **5** are products from hydroxymethylation at the acetyl carbonyl group, while **6** is a product from hydroxymethylation at the ring carbonyl group. The $TiCl_4$-catalyzed reaction on **3***aC* and **8** resulted in hydroxymethylation exclusively on the acetyl carbonyl group, and **9** and **10** were isolated as major products, respectively.

In conclusion, it was found that there was no similarity in the reaction patterns of $TiCl_4$- and proton-catalyzed photoreactions, and the acetyl carbonyl group is more reactive towards the $TiCl_4$-catalyzed reactions as compared with the carbonyl group in the ring system.

Experimental

General

The mass spectra were obtained with a Hitachi RMS-4 spectrometer, the ir spectra with a Hitachi 215 spectrometer, and the ^{1}H nmr spectra with a JEOL PS-100 spectrometer (with Me_4Si as the internal standard).

Materials

The starting materials **3***aS* (4), **3***bS* (4), **3***aN* (5), **3***aO* (6), **3***aC* (7), and **8** (8) were prepared according to the procedures described in the literature cited.

General Procedures for the Photolysis in Methanol in the Presence of $TiCl_4$

Unless otherwise noted, a solution (0.02–0.03 *M*) of the starting material containing an equivalent amount of $TiCl_4$ was irradiated in a Pyrex test tube by means of a high pressure mercury lamp (Ushio UM 452 (450 W)) for 4 h. After the irradiation, the solution was concentrated *in vacuo*, and the crude residue was placed on a short Florisil column and then eluted with chloroform. The solvent was removed *in vacuo* from the eluate, and the residue was treated as indicated below.

Photolysis of **3**aS *or* **3**bS

The viscous residue obtained from **3***aS* by the general procedure was purified by preparative tlc (silica gel, 10% methanol in chloroform). Compounds **4***aS* and **5***aS* were isolated, along with **6***a*; **4***aS*, ir (CCl_4) ν: 2980, 1780, 1690, 1640, 1220, and 1020 cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.05 (d, J = 7.5 Hz, 3H), 2.02 (m, 1H), 3.26 (s, 1H), 3.38 (s, 3H), 3.55 (s, 3H), 3.70 (s, 2H), and 4.38 (d, J = 3.3 Hz, 1H). Compound **5***aS*, ir ($CHCl_3$) ν: 2970, 1760, 1720, 1620, and 1420 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.31 (d, J = 7 Hz, 3H), 2.04 (m, 1H), 3.32 (s, 1H), 3.94 (s, 2H), and 8.56 (s, 1H). Compound **6***a*, mp 99°C; ir ($CHCl_3$) ν: 1730, 1700, 1620, 1570, and 860 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.46 (s, 3H), 4.15 (d, J = 1.25 Hz, 2H), and 7.17 (t, J = 1.25 Hz, 1H); mass spectrum *m/e*: 154 (m$^+$), 126, 125, 112, 111, 97, 83, 65, and 43. *Anal.* calcd. for $C_7H_6O_2S$: C 54.53; H 3.92; found: C 54.09, H 4.02.

Similarly, **3***bS* afforded a viscous residue by the general procedure. The formation and yield of **4***bS*, **5***bS*, and **6***b* were determined by means of their ^{1}H nmr spectra (tetrachloroethane was used as the internal standard) without further purification; ^{1}H nmr ($CDCl_3$) δ: 3.34 (s, OMe of **4***bS*), 3.91 (s, OMe of **4***bS*), 7.04 (s, furan proton of **6***b*), 8.47 (s, CHO of **5***bS*), and others.

Photolysis of **3**aN *or* **3**aO

When the viscous residue obtained from **3***aN* or **3***aO* by the general procedure was chromatographed on a Florisil column (chloroform), **4***aN* or **4***aO* was obtained as a main product; **4***aN*, ^{1}H nmr ($CDCl_3$) δ: 1.10 (d, J = 7 Hz, 3H), 3.55 (s, 3H), 3.96 (s, 2H), 4.22 (d, J = 3 Hz, 1H), and others. Compound **4***aO*, ^{1}H nmr ($CDCl_3$) δ: 1.07 (d, J = 7 Hz, 3H), 3.45 (s, 3H), 3.64 (s, 3H), 4.54 (s, 2H), and others.

Photolysis of **3**aC

When the viscous residue obtained from **3***aC* by the general procedure was chromatographed by preparative tlc (silica gel, 5% methanol in chloroform), **4***aC* and **9** were isolated; **4***aC*, ir (CCl_4) ν: 1695, 1640, 1465, 1270, and 1080 cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.05 (d, J = 7 Hz, 3H), 2.3–3.0 (m, 5H), 3.20 (s, 3H), 3.32 (s, 3H), 3.92 (s, 3H), and 4.75 (d, J = 10 Hz, 1H). Compound **9**, ir ($CHCl_3$) ν: 1712 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.06 (d, J = 7.5 Hz, 3H), 2.27–2.64 (m, 4H), 3.45 (s, 3H), and others.

Photolysis of **8**

When the solid obtained from **8** by the general procedure was washed with carbon tetrachloride, **10** was obtained as a single product; ir ($CHCl_3$) ν: 1640, 1600, 1570, 1490, and 1400 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.48 (s, 3H), 1.85 (s, 3H), 3.83 (ABq, J = 12 Hz, 2H), 5.93 (s, 1H), and 7.1–7.7 (m, 5H).

The synthesis of a series of macrocyclic polyethers (crown ethers) of interest as carriers for the countertransport of metal ions and protons across artificial membranes is described. Thallium mediated cyclization of oligoethyleneglycol diiodides with (+)−*N*,*N*,*N*′,*N*′-tetramethyltartaramide gave 15-crown-5 and 18-crown-6 diamides which were converted, via the diacids and anhydrides, to crown ether monoamides bearing long chain alkyl groups (octyl, tetradecyl, and octadecyl). The alkali metal salts and complexes of these carriers are soluble in nonpolar solvents and alkali metal ions are extracted from aqueous solutions into chloroform solutions of the carriers. Acidity constants and stability constants for complex formation in methanol/water (90:10 v/v) solutions have been determined using a combination of ion selective electrode and pH-metric techniques. Deprotonation of the ligand carboxylic acid group results not only in more stable complexes but also more selective complexation. Implications for membrane transport are discussed.

LAUREL A. FREDERICK, THOMAS M. FYLES, NARINE P. GURPRASAD et DENNIS M. WHITFIELD. Can. J. Chem. **59**, 1724 (1981).

On décrit la synthèse de polyéthers macrocycliques (éthers couronnes) qui sont intéressants en tant que phases mobiles pour le transport en sens contraire des ions métalliques et des protons à travers les membranes artificielles. La cyclisation des diiodures d'oligoéthylèneglycols avec la (+)−*N*,*N*,*N*′*N*′tétraméthyltartramide initiée par le thalium donne les diamides 15-couronne-5 et 18-couronne-6 que l'on transforme par l'intermédiaire des diacides et des anhydrides monoamides d'éthers couronnes portant une longue chaîne alkylée (octyle, tétradécyle et octadécyle). Les sels des métaux alcalins et les complexes de ces supports sont solubles dans les solvants non polaires et on extrait les ions des métaux alcalins des solutions aqueuses à l'aide des solutions des phases mobiles dans le chloroforme. On a déterminé les constantes d'acidité et de stabilité de la formation des complexes dans des solutions de méthanol/eau (90:10 v/v) en utilisant une combinaison d'électrode ionique sélective et les techniques de mesure de pH. La déprotonation du groupe acide carboxylique du ligand conduit non seulement à des complexes plus stables mais aussi à une complexation plus sélective. On discute des implications pour le transport à travers les membranes.

[Traduit par le journal]

The coupled flow of different substances across membranes is an essential feature of biological systems (1). The realization of artificial model systems which mimic the transport behaviour of natural membranes should allow detailed mechanistic analyses of single components of complex natural systems and in addition should lead to applications in analytical chemistry and separation science. Simple model systems are known. Naturally occurring ionophore antibiotics (2) and synthetic macrocyclic compounds such as the crown ethers (3) and cryptands (4) have been shown to carry metal ions across hydrophobic liquid membranes. Transport occurs by carrier mediated facilitated diffusion (5) in the direction of the concentration gradient of the transported ion.

Of particular interest from the point of view of eventual applications is the ability of biological membranes to exploit ion or proton gradients to "pump" a solute of interest from a region of low concentration to a region of higher concentration. Again, several artificial systems which model this type of behaviour have been reported. All involve a mobile carrier in the membrane phase which forms a complex with the solute of interest. The complex crosses the membrane by diffusion and the solute is released to the receiving phase. The ion whose gradient drives the process either diffuses with the complex (co-transport) or diffuses with the carrier on its return to the intake side of the membrane (countertransport) (6). For example, picrate anion can be accumulated against its concentration gradient by the co-transport of potassium ion using crown ethers as carriers (7). Similarly, crown ethers act as carriers for the countertransport of thallium and sodium ions, the gradient in sodium pumping the thallium (8). These and other similar schemes (9) are hampered by very slow transport rates, low efficiencies, and low selectivities, hence are suited neither as models for biological membranes nor as the basis for potentially useful separation schemes.

Schemes exploiting proton gradients appear to be more generally promising. In these cases the carrier is a weak acid and cations are pumped from basic to acidic solution by the countertransport of protons. Phosphatidylethanolamine (10) and stearic acid (11) have been reported to act as

carriers for the countertransport of potassium ions and protons. These carriers are, however, unselective and the transport rates were low. A more efficient system uses the ionophore antibiotic, monensin (2), as the carrier (12). The antibiotic, as the carboxylate, forms a stable and selective complex with sodium ion in which the carrier molecule is wrapped around the cation in a fashion similar to many other types of alkali metal ion inclusion complexes (13). Transport rates with this carrier are much higher than those reported for other model systems and, in addition, the carrier selectively transports sodium ion as the sodium complex is more stable than complexes of the other alkali metal ions. This monensin-based transport system thus bears at least qualitative resemblance to some naturally occurring transport systems (1).

Our interest in this area was stimulated by the possibilities for the design and synthesis of other carriers which, like monensin, could mediate the countertransport of protons and alkali metal ions, but unlike the natural product would be susceptible to extensive structural modifications. These modifications could influence factors such as liposolubility, overall shape, and size, and would thus influence the *rate* of transport or could influence the ability of the carrier to complex metal ions and hence would influence the *selectivity* of transport. A systematic investigation of the relationship between structure and function would thus be possible.

We chose initially to examine carriers based upon a macrocyclic polyether (crown ether) framework. Compounds of this type form inclusion complexes with metal ions; a large number of these compounds have been prepared (14) and many of the structural factors which influence complex structure, stability, and selectivity have been investigated (15). In addition lipophilic crown ethers have been shown to extract metal ions into nonpolar solvents (16) and, as described above, to act as carriers for the collapse of ion gradients across artificial and natural membranes. Crown ethers thus appeared to be a suitable starting point for consideration.

In order to mimic monensin, the proposed carrier must be a carboxylic acid, must contain donor sites for ion complexation (the crown ether), and must bear enough hydrophobic groups to render the carrier and its salt complexes soluble in a nonpolar membrane phase. In addition, the carboxylate group should be located so as to provide additional stabilization for a metal ion held in the crown ether. Several types of crown ethers (17) and "noncyclic" crown ethers (18) bearing pendant carboxylic acid groups have been described. In basic solution, the carboxylate can act as the counter-ion for a complexed metal ion (electrostatic stabilization) and, if suitably positioned, can act as an addition binding site (coordinative stabilization). The X-ray crystal structures of monensin (19) and related antibiotics of the nigericin group (2) reveal both types of behaviour. If optimally positioned, a coordinating carboxylate or other convergent binding site could result in substantially more stable and selective complexes than would be possible using the crown ether monocycle alone. This effect has been clearly demonstrated by Cram and co-workers (20). However, the additional conformational demands of such a complex imply a more elaborate molecular architecture than would be required if electrostatic stabilization alone were considered. The only structural requirement in this case is that the distance between the carboxylate group and the coordinated metal ion be as minimal as possible. In order to achieve some stabilization without the expenditure of considerable synthetic effort, we chose initially to examine carriers bearing carboxylic acid groups directly attached to the crown ether periphery. Compounds of this type have been prepared (21, 22) and the expected stabilization has been clearly revealed (23). The effect is apparently electrostatic in nature but coordination of the metal ion by the carboxylate cannot be excluded.

A large number of potential candidate carriers have structures consistent with all the design requirements cited above. One of the synthetically simplest types, of which compounds **1***a–c* and **2***a–d* are examples, was chosen for initial investigation. This paper describes the synthesis and characterization of carriers **1***a–c* and **2***a–d*. An adjoining paper describes the transport behaviour of an artificial membrane system containing **1***a–c* and **2***a–c* as carriers for the coupled countertransport of protons and alkali metal ions (24). A preliminary account of part of this work has appeared (25).

Results and Discussion

Synthesis

The syntheses of **1***a–c* and **2***a–d* were accomplished from (+)-tartaric acid. Although chiral crown ethers have been shown to exhibit chiral recognition in the complexation and transport of chiral ammonium salts (26), this feature is not at issue in this case since the substrates, metal ions, are achiral. Rather, in order to limit the number of stereoisomers, we chose to begin with a precursor

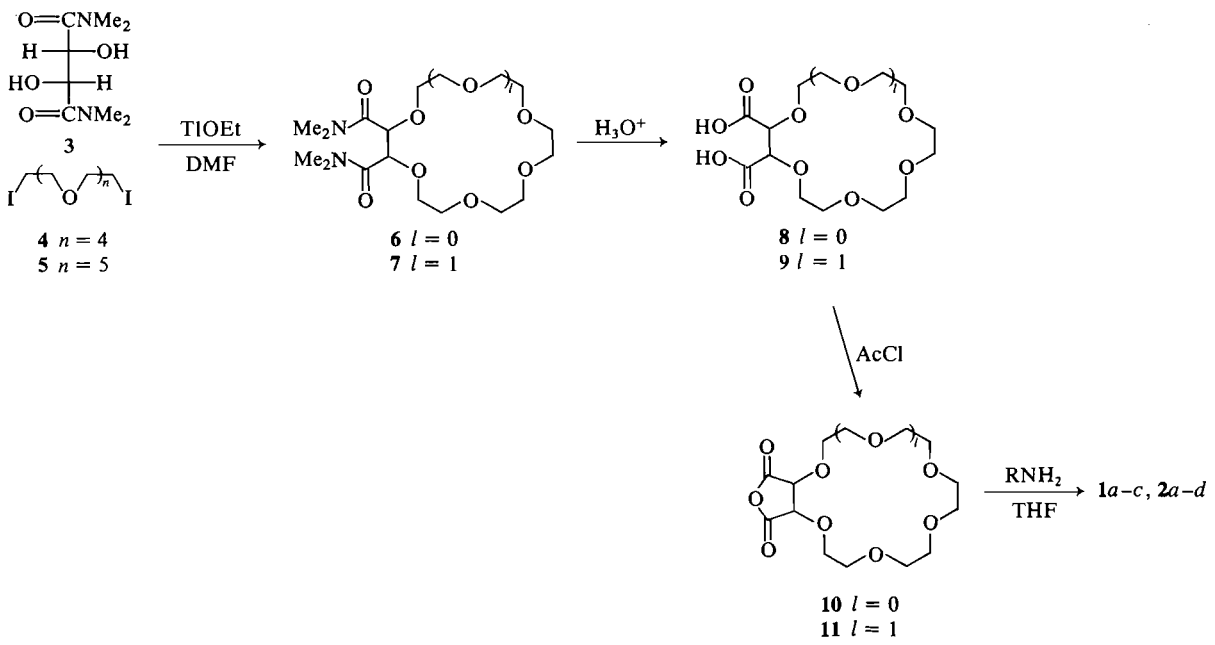

FIG. 1

of known configuration and to employ methods which would permit this configuration to be retained in the final product. Thus of the four potential isomers we have prepared only the 2*R*,3*R* isomers from 2*R*,3*R*-(+)-tartaric acid.

The synthetic scheme is outlined in Fig. 1. The bis-dimethylamide **3** (27) and the oligoethyleneglycol diiodides **4** and **5** (28) were prepared by literature methods. Alkylation of thallium(I) alkoxides is a useful modification of the Williamson ether synthesis which is compatible with readily racemized chiral centers and has been used to prepare ethers of tartaric acid (29) and crown ethers containing 2 or 3 tartarate-derived moieties (21, 22) without loss of configuration. Thus treatment of **3** in DMF with two equivalents of thallium ethoxide led to an immediate precipitation of the dithallium salt of **3**. On addition of **4** the precipitate slowly turned to the orange color of thallium iodide. Removal of TlI by filtration and evaporation of the solvent gave a yellow oil from which the 15-crown-5 diamide **6** could be isolated by chromatography.[2] In a similar fashion **3** and **5** gave the 18-crown-6 derivative **7**. Yields in both cases were ca. 40%.

Acidic hydrolysis of **6** or **7** gave the diacids **8** and **9** respectively[2] which on reflux with a vast excess of acetyl chloride were smoothly dehydrated to the crown ether anhydrides **10** and **11**. The carriers **1***a–c* and **2***a–d* were prepared from **10** or **11** by treatment with 2.2 equivalents of octylamine, tetradecylamine, octadecylamine, or butylamine in dry THF. The product initially isolated by evaporation of the solvent is the corresponding alkylammonium salt of **1***a–c* or **2***a–d*. In the case of **2***d*, butylammonium was removed by extraction with aqueous acid. In the other cases, ion exchange was necessary as the alkylammonium halides are water insoluble. However, even after several treatments with strongly acidic ion exchange resins, significant amounts of the alkylammonium salts remained, which may be in part due to the complexation of the ammonium group by the crown ether. The carriers **1***a–c* and **2***a–c* could be freed of the last traces of ammonium salt by gel permeation chromatography, in which the salt or complex having the higher molecular weight and larger size was eluted first, or by reverse phase chromatography in which the more polar salt was eluted first.

Properties

With the exception of **2***d* which was prepared primarily for thermodynamic studies, the carriers are all clear viscous oils or low melting waxy solids. They are soluble in all organic solvents but are virtually insoluble in water. Attempts to determine coefficients for the distribution of the carriers between chloroform and various aqueous solutions (acidic, basic, with or without metal ions) met with

[2]Another independent synthesis of **6** and **8** by the same methods has recently been reported (37).

only limited success. Basic or metal ion containing solutions inevitably gave emulsions which separated to three phases after long times. Deprotonation with or without metal ion binding produces an amphiphilic molecule, hence emulsion formation is not surprising. In cases where emulsions did not form (acidic solution, no metal ions) the distribution coefficients ($D = [X]_{org}/[X]_{aq,org} = CDCl_3$) were large; log D ca. 3.8 for **2***a*, log D ca. 3.0 for **1***a* as estimated by nmr (15). The corresponding values for **1***b*,*c* and **2***b*,*c* are larger but the method was insufficiently sensitive for the accurate determination of the small amounts of the carriers in the aqueous phase.

Qualitatively, all the potential extraction equilibria favour forms in which the carrier or its complexes remain in the organic phase. The potassium, sodium, and rubidium salts of the carriers can be prepared by gently stirring a chloroform solution of the carrier with aqueous solutions of the metal hydroxide. The carriers will dissolve solid alkali metal salts into chloroform solution. None of the carriers can be extracted into homogeneous aqueous solution, either by bases or by alkali metal ion solutions. It is thus probable that during the transport experiments, little, if any of the carrier would be lost from the membrane phase.

Acidity and Stability Constants

In order to define suitable conditions for transport experiments and to rationalize observed transport selectivities (24) we have determined the acidity constants of the carriers and the concentration stability constants for complex formation with alkali metal cations (30). Consider the following set of equilibria involving a ligand (the carrier) in its protonated (LH) and deprotonated forms (L) and a metal ion (M).[3]

[1] $LH \rightleftharpoons L + H$ $\qquad K_a = [L][H]/[LH]$

[2] $LH + M \rightleftharpoons LHM$ $\qquad K_1 = [LHM]/[LH][M]$

[3] $L + M \rightleftharpoons LM$ $\qquad K_2 = [LM]/[L][M]$

Equation [1] defines the normal acidity constant for LH, eq. [2] defines the concentration stability constant K_1 for formation of the 1:1 complex LHM from LH and M, and eq. [3] defines a stability constant K_2 for a 1:1 complex between L and M. Additional equilibria involving other complex stoichiometries are possible. Of interest is the apparent acidity constant for the complex LHM, defined by eq. [4].

[4] $LHM \rightleftharpoons LM + H$ $\qquad K_{a'} = [LM][H]/[LHM]$

Equations [1]–[4] overdefine the set of 1:1 complexes between L, H, and M, and it is straightforward to show that:

[5] $K_{a'} = (K_2/K_1)K_a$

or

[6] $pK_a - pK_{a'} = \log K_2 - \log K_1$

Independent determinations of K_a, $K_{a'}$, K_1, and K_2 will allow the data to be internally tested using [6]. Should the relationship [6] be found to hold, other equilibria involving other complexes must therefore be unimportant under the conditions of the experiment and the equilibria [1]–[3] may be assumed to adequately model the solution behaviour of L, H, and M.

The acidity constants $K_{a'}$ were determined from the pH metric titration curves obtained on addition of tetramethylammonium hydroxide to a methanol/water (90:10 v/v) solution of the free acid. The data were analysed as previously described (31) using a modified version of the program SCOGS (32). The stability constants for complex formation with sodium, potassium, and rubidium ions were determined using glass electrodes sensitive to these ions. Commercially available potassium electrodes are sufficiently sensitive to rubidium to allow the direct determination of rubidium ion (in the absence of interfering potassium ion). The method has been previously described (30) and our modifications are outlined in the Experimental. Solutions were buffered to ensure that to a good approximation only LH or L was present. The stability constant determined in acidic solution is thus K_1 and the stability constant determined in basic solution is K_2.

A knowledge of K_1 and K_2 permits an estimation of the minimum metal ion concentration at which effectively all the ligand, whether protonated or not, will be present as a metal ion complex. Determination of an acidity constant under these conditions will give the apparent acidity constant of the complex LHM, i.e. $K_{a'}$. The results of these determinations are reported in Table 1 for the case of **2***d*, together with the value of $pK_{a'}$ calculated using eq. [6]. The agreement between the measured and calculated values of $pK_{a'}$ is good and well within the limits of the experimental errors. This confirms that the eqs. [1]–[3] adequately model the solution behaviour of L, H, and M.

With this assurance we can turn to a more efficient method of determining K_1 and K_2 directly from pH metric titration data albeit with the loss of

[3]Charges are omitted throughout for clarity. In all cases LH and LM are neutral, L is negatively charged, and M and H are unipositively charged.

For personal use only.

the internal cross checks of the ion selective electrode determinations. Consider a generalized cumulative association constant defined as

$$[7] \quad \beta_{lmh} = [L_l M_m H_h]/[L]^l[M]^m[H]^h$$

where l, m, and h are integers including zero which denote the number of ligands, metal ions, and protons respectively, bound in a given species. Thus β_{110} is the formation constant for a species containing one ligand, one metal ion, and no protons, i.e. K_2 as defined by eq. [3]. It can be similarly shown that $\beta_{101} = 1/K_a$ and $\beta_{111} = K_1/K_a$ ($\log \beta_{101} = -pK_a$ and $\log \beta_{111} = \log K_1 + pK_a$). In a fashion analogous to that previously described with respect to the complexation of anions by polyguanidinium salts (31), computer analysis of the pH-metric titration curves obtained at various ratios of L/M gave a set of β_{lmh} which described the system, from which values of K_1 and K_2 were calculated.

The results for the various different types of analyses for alkali metal ions and the carriers prepared are given in Table 2. It appeared unnecessary and redundant to determine all the stability constants for all pairs of ligand and metal ions as the effect of varying the alkyl side chain on complex formation was expected to be small. Thus **1***a* and **2***d* were chosen as "typical" representative 15-crown-5 and 18-crown-6 derivatives and a complete set of constants was determined for these two ligands. Spot checks of the above assumption proved it to be substantially correct; **1***a*/K^+ the same as **1***c*/K^+ and **2***d*/Na^+ the same as **2***a*/Na^+.

Insofar as acidity constants are concerned, all carriers were found to have $pK_a = 5.95 \pm 0.10$. As such they are somewhat stronger acids than acetic (pK_a 7.15 in methanol/water (90:10 v/v) under our conditions). It is not clear what the pK_a would be in pure water. In general, simple carboxylic acids are ca. 1–2 pK_a units weaker acids in methanol/water solution (31) than in water itself. A pK_a in water of about 4 is not inconsistent with the transport results reported in the accompanying paper which suggest an apparent pK_a at the water/chloroform interface greater than 3.3 (24).

[d]Using eq. [6].

The stability constants follow the expected trends. The 18-crown-6 derivatives show peak selectivity (30) for potassium; the 15-crown-5 derivatives show complex stability decreasing along the series Na^+, K^+, Rb^+. The increase in complex stability between the acidic and basic forms of the ligand is also expected. Work with related systems (22, 23) has shown that carboxylate groups stabilize ammonium and metal ion complexes by electrostatic interactions. The effect can be very large, up to a factor of 5000 for ammonium complexation in water solution induced by the presence of four carboxylate groups. The factors of 5–25 fold stabilization observed in our case are perhaps smaller than might have been expected but the different solvents involved may partly explain the smaller effect. Since methanol/water mixtures are less polar than pure water, complexation of any type is to be favoured, hence the importance of other interactions must be diminished.

It is interesting to note, especially with reference to the complexes of **2***d*, that the electrostatic stabilization afforded the ion by the carboxylate group is most pronounced for the ion which is most strongly complexed. Thus K^+, selectively complexed by **2***d*, is a factor of 20 times more strongly complexed in basic solution than in acidic solution compared to factors of 10 and 12 times for Rb^+ and Na^+ respectively. Looked at from another point of view, the basic forms of the ligands are more selective than are the acidic forms; the K^+/Na^+ selectivity of **2***d* in acidic solution is ca. 16 while in basic solution it is ca. 25. These results suggest additional structural recognition of the ion by the ligand, possibly with the carboxylate acting as an additional binding site.

These thermodynamic results hold a number of implications for the transport of alkali metal ions using carriers **1***a–c* and **2***a–c*. It has been noted in other systems that transport rate is a complex function of many parameters including the stability of the complex formed (33, 34). The optimal value of the equilibrium constant for complexation is about 10^5–10^6 ($6 \gtrsim \log K \gtrsim 5$) in methanol (34); complexes less stable than this are not efficiently extracted, while complexes more stable than this are too efficiently held in the membrane. Our values suggest that of the ions and carriers considered, potassium will be selectively transported by 18-crown-6 derivatives while overall rates will be lower with 15-crown-5 derivatives but selective for sodium. The potassium ion complex of **2***d* has a log K_2 value within the optimal range. The thermody-

namic results also suggest that extraction and transport of ions from a basic solution will be a more selective process for a given carrier than extraction and transport of the same ions from an acidic solution. The transport scheme envisaged involves the pumping of ions from basic to acidic solution; pumping is likely therefore to be more selective than any "leakage" from the acidic to the basic side which might occur. In a system of this type, the membrane selectivity might then be enhanced by *allowing* the membrane to leak, for example by providing a liposoluble anion in the acidic phase (3, 33).

Experimental

General Details

Melting points were taken using a Koefler hotstage microscope and are uncorrected. The ir spectra were recorded using a Perkin Elmer 283 spectrometer in $CHCl_3$ as solvent unless otherwise stated. The proton nmr spectra were recorded using a Perkin Elmer R12B (60 MHz) or R32 (90 MHz) spectrometer using $CDCl_3$ as solvent containing tetramethylsilane (TMS) as internal standard. The carbon nmr spectra were recorded using a Nicolet TT14 spectrometer (15.1 MHz) in $CDCl_3$ containing TMS unless otherwise specified. The mass spectra were recorded using a Finnegan 3300 GC-MS using methane chemical ionization. Specific rotations were calculated from optical rotation values obtained using a Perkin Elmer 141 polarimeter and a 1 dm cell in $CHCl_3$ as solvent unless otherwise stated. Elemental analyses were performed by Canadian Microanalytical Services, Vancouver, B.C.

Precursors

(*a*) *R,R*-(+)-*N,N,N',N'*-Tetramethyltartaramide (**3**) was prepared from (+)-tartaric acid by dimethylammonolysis of the diester (27); $[\alpha]_D^{20}$ +43.2° (*c* 3.0, ethanol) (lit. (19) +42.7° (*c* 3.6, ethanol)).

(*b*) 1,11-Diiodo-3,6,9-trioxaundecane (**4**) was prepared from tetraethylene glycol via the dichloride (28); bp 95°C/0.5 Torr (lit. (28) "about 95°C/0.4 Torr"). The dichloride in acetone was allowed to reflux overnight with a fivefold excess of NaI and the solution was concentrated to a thick sludge which was taken up in water, extracted with CH_2Cl_2, the organic layer dried over Na_2SO_4 and evaporated to yield a thick yellow oil. The crude diiodide was used directly without further purification; ^1H nmr δ: 3.70 (4H) and 3.30 (4H) (A_2B_2, J_{AB} 7 Hz, OCH_2CH_2I), 3.60 (10H, brs, all other protons).

(*c*) 1,14-Diiodo-3,6,9,12-tetraoxatetradecane (**5**) was prepared by a sequence similar to that described for (**4**). Triethylene glycol was converted to the dichloride (bp 65°C/1 Torr). The dichloride was heated in ethylene glycol containing 2.2 equivalents of sodium to give pentaethylene glycol (28) (bp 155–160°C/1 Torr) which gave the dichloride (bp 120°C/1 Torr) and finally the diiodide **5**; ^1H nmr δ: 3.70 (4H) and 3.30 (4H) (A_2B_2 J_{AB} 7 Hz, OCH_2CH_2I), 3.60 (12H, brs, all other protons).

2R,3R-(+)-N,N,N',N',-Tetramethyl-2,3-dicarboxamido-1,4,7,10,13-pentaoxacyclopentadecane (7) (37)

A 2 L 3-neck flask fitted with an argon inlet and bubbler, condenser, and mechanical stirrer was charged with 1600 mL of dry dimethylformamide (DMF) and 20.5 g (0.100 mol) of **3**. The solution was heated to 90°C under a stream of argon and 14.5 mL

(14.0 mequiv./mL, 0.200 equiv.) of thallium ethoxide (35) was added via a syringe which resulted in immediate formation of a white precipitate, presumably the dithallium salt of **3** (21, 22). To this slurry was added a total of 42.5 g (0.21 equiv.) of diiodide **4** in 20 mL of DMF via syringe over a period of 10 min. The resultant mixture was stirred at 90°C and gradually turned orange as thallium iodide was formed. After 4 h the mixture was cooled to room temperature, 100 mL of water was added, and the precipitate was removed by filtration. The bulk of the solvent was removed on a rotary evaporator and the crude product containing DMF and traces of thallium iodide was passed through a short column (10 cm) of alumina followed by a washing with 250 mL of chloroform. The combined filtrates were evaporated and pumped at high vacuum overnight. The crude product was taken up in chloroform, absorbed on 50 g of Celite, and pumped at high vacuum for a second night. In this fashion the bulk of the DMF was removed. The subsequent chromatographic separation is strongly dependent upon the proportion of DMF remaining at this stage. The crude product on Celite was added to the top of a column of alumina (activity II, 5 × 80 cm) and eluted with a gradient of methanol in chloroform (0 → 4% v/v, 4 L total volume). Depending on the amount of DMF the product was eluted at about 2% methanol in chloroform. Fractions were monitored by tlc (10% methanol in chloroform, alumina, R_f **6** ~ 0.7) and by nmr. Product containing fractions were combined and rechromatographed on the same size of alumina column using the same solvent gradient to give 14.8 g of a clear, colorless oil. This material is sufficiently pure to carry on to further reactions.[4] Gel permeation chromatography (Sephadex LH20, 2.5 × 90 cm, 3.0 mL/min, 5.0 mL fractions, $CHCl_3/CH_3OH$ 2:1 (v/v) as eluent) of a 0.50 g sample of this oil gave a small faster moving fraction (35 mg) enriched in the cyclic dimer, a 30-crown-10 derivative (37) and a well separated slower moving major fraction (465 mg) of **6** as a clear colorless oil; ir cm^{-1}: 2880, 2920 (CH), 1650 (C=O), 1120 (C—O); $[\alpha]_D^{20}$ +74.7 (*c* 5.8); ^1H nmr δ: 4.78 (2H, s, OCHC=O), 3.65 (16H, brs, CH_2O), 3.15 and 2.90 (6H, s, CH_3N); ^{13}C nmr δ: 169.5 (C=O), 76.5 (CH), 70.6–68.8 (CH_2O), 37.3 and 35.6 (CH_3N); ms *m/e*: 363 (M + 1, 95), 290 (M − DMF + 1, 15), 245 (characteristic of a 15-crown-5 bearing a carbonyl, i.e. 15-crown-5 $C{\equiv}O^+$, 100). *Anal.* calcd. for $C_{16}H_{30}N_2O_7$: C 53.02, H 8.34, N 7.73; found: C 52.81, H 8.31, N 7.59.

2R,3R-(+)-N,N,N′,N′-Tetramethyl-2,3-carboxamido-1,4,7,10,13,16-hexaoxacyclooctadecane (7)

By a method analogous to that described for **6**, 20.5 g of **3**, 14.5 mL of thallium ethoxide, and 46.5 g of **5** gave 16.1 g of **7** (40%) as a clear colorless oil. A small sample was crystallized from hexane/ether but the bulk of the sample was used as an oil; mp 69.5–70°C; ir cm^{-1}: 1660 (C=O), 1120 (C—O); $[\alpha]_D^{20}$ +51.5° (*c* 2.6); ^1H nmr δ: 4.80 (2H, s, OCHC=O), 3.65 (20H, brs, CH_2—O), 3.15 and 2.88 (6H, s, CH_3N); ^{13}C nmr δ: 169.5 (C=O), 76.6 (CH—O), 70.6–68.9 (CH_2O), 37.3 and 35.6 (CH_3N); ms *m/e*: 407 (M + 1, 100), 289 (characteristic of 18-crown-6 + carbonyl, i.e. 18-crown-6 $C{\equiv}O^+$, 20). *Anal.* calcd. for $C_{18}H_{34}N_2O_8$: C 53.19, H 8.43, N 6.89; found: C 52.96, H 8.39, N 6.71.

2R,3R-(+)-2,3-Dicarboxyl-1,4,7,10,13-pentaoxacyclopentadecane (8) (37)

A mixture of 13.0 g of **6**, 25 mL of concentrated hydrochloric acid, and 100 mL of water was stirred at reflux overnight. The resultant solution was cooled, concentrated to about 50 mL total volume, placed in a heavy liquid continuous extractor, and extracted for 4 days with purified (alcohol-free) dichloromethane. The extract was dried over Na_2SO_4 and evaporated to give a viscous oil which contained a small amount of water. Complete drying of this oil by azeotropic distillation or by pumping at high vacuum was not successful. The hydrate could be crystallized from wet acetone/ether (overall yield 65%); mp ca 60°C; ir (KBr) cm^{-1}: 3600–2400 (OH), 1750 (C=O), 1120 (C—O); $[\alpha]_D^{20}$ +14.5 (*c* 0.7); ^1H nmr (D_2O, external TMS) δ: 4.40 (2H, s, $CHCO_2H$), 3.65 (16H, brs, CH_2O); ^{13}C nmr (D_2O, external TMS) δ: 174 (CO_2H), 80.7 ($CHCO_2H$), 72–71.2 (CH_2O); ms *m/e*: 309 (hydrate − H_2O + 1, 100), 245 (15-crown-5 $C{\equiv}O^+$, 25). *Anal.* calcd. for $C_{12}H_{20}O_{10}$ (8·H_2O): C 44.17, H 6.79; found: C 43.81, H 6.89.

2R,3R-(+)-2,3-Dicarboxyl-1,4,7,10,13,16-hexaoxacyclooctadecane (9)

By a method analogous to that described for **8**, **7** gave **9** in 75% yield; mp 108°C (acetone/ether); ir (KBr) cm^{-1}: 3500–2500 (OH), 1745 (C=O), 1100 (C—O); $[\alpha]_D^{25}$ +34.7 (*c* 1.5, H_2O); ^1H nmr (D_2O, external TMS) δ: 4.48 (2H, s, $CHCO_2H$), 3.70 (20H, brs, CH_2O); ^{13}C nmr (D_2O, external TMS) δ: 174.5 (CO_2H), 80.5 ($CHCO_2H$), 70.0 (CH_2O); ms *m/e*: 353 (M + 1, 100), 289 (18-crown-6 $\overset{+}{C}{\equiv}O$, 20). *Anal.* calcd. for $C_{14}H_{24}O_{10}$: C 47.72, H 6.87; found: C 47.81, H 6.86.

General Method for the Preparation of Crown Ether Monoamides

The diacid (**8** or **9**) was dissolved in acetyl chloride (~15 mL/g diacid) and stirred at reflux overnight. The solution was cooled and evaporated four times with 20 mL of benzene and pumped at high vacuum for 2 h. The crude anhydrides **10** or **11** were not further purified; for **10**, ir cm^{-1}: 1880, 1805 (5 membered cyclic anhydride); ^1H nmr δ: 4.84 (2H, s, —CHCO), 4.0 (2H, m), 3.70 (14H, brs); for **11**, ir cm^{-1}: 1880, 1805 (5 membered cyclic anhydride); ^1H nmr δ: 4.91 (2H, s, CHC=O), 4.0 (2H, m), 3.72 (16H, brs), 3.65 (2H, m).

The crude anhydride (**10** or **11**) was taken up in 10 mL/g freshly dried THF and treated with 2.2 equivalents of a primary alkyl amine. The mixture was stirred at reflux for 2 h, cooled, and evaporated to dryness. The crude alkylammonium crown ether amidocarboxylate was dissolved in isopropanol/chloroform (1:3 v/v) and passed slowly through a bed of strongly acidic cation exchange resin in the same solvent. The resin was washed exhaustively and the combined washings were evaporated to oils. Purification was achieved in two ways: (*1*) by gel permeation chromatography on Sephadex LH20 (2.5 × 90 cm column, 3.0 mL/min gravity flow, 5.0 mL fractions) using chloroform/methanol (4:3 v/v) as eluent, in which case the heavier impurity was eluted first, or (*2*) by reverse phase chromatography on RP-8 (Merck Lobar prepacked column, pressurized with 150 Torr of argon, 3.0 mL/min, 5.0 mL fractions) using 0–15% chloroform in methanol as eluent, in which case the desired product was eluted after the impurities. Fractions were monitored by tlc (reverse phase Merck RP2 on glass, 25% methanol in chloroform, R_f ~ 0.7–0.8 for **1***a–c*, **2***a–c*) and by ^1H nmr. In the acidity constant determination, alkylammonium contamination could be detected below 1.0

[4]Purification of the oil is not required as the cyclic dimer is mostly removed at the diacid (tetracid) stage and finally eliminated during final gel permeation chromatography of **1***a–c*. A recent synthesis of **6** by an analogous route (37) reports **6** as a solid mp 65°C. Solid samples of **6** may be obtained from our oily fraction on lengthy standing to give physical properties identical with those reported (37) except the ^1Hmr spectra show additional very broad signals at 10.5–9.5 (about 3H). Elemental analyses suggest these solids are hydrates. *Anal.* calcd. for $C_{16}H_{33}O_{8.5}N_2$(**6**,1.5H_2O): C 49.34, H 8.54, N 7.19; found: C 49.44, H 8.48, N 7.51. The solids go to oils on drying in vacuum and give correct elemental analyses for the anhydrous material.

wt.%. All samples were better than this level of purity. In this fashion were prepared the following.

2R,3R-(+)-N-Octyl-2-carboxamido-3-carboxyl-1,4,7,10,13-pentaoxacyclopentadecane (1a)

Purified by gel permeation, as a clear colorless oil in 70% yield from **8**; ir (neat) cm^{-1}: 3340 (NH), 3600–2400 (OH), 1745 (CO_2H), 1670, 1635, 1540 (amide), 1120 (C—O); $[\alpha]_D^{20}$ +16.4 (*c* 5.4); ^1H nmr δ: 8.4 (1H, br, CO_2H), 7.4 (1H, brt, NH), 4.48 and 4.35 (2H, dd, AB, J_{AB} 3 Hz, O—CH—CH—O), 3.60 (16H, brs, CH_2O), 3.30 (2H, m, CH_2N), 1.30 (12H, brs, —CH_2—), 0.90 (3H, brt, CH_3); ^{13}C nmr δ: 172.0, 169.2 (CO_2H, CONH), 80.3, 79.4 (CH—CH), 70.6–69.4 (CH_2O), 39.5 (CH_2N), 31.8 (—CH_2—), 29.3, 26.9, 22.6, 14.1 (alkyl chain end); ms *m/e*: 420 (M + 1, 100), 245 (15-crown-5 C≡O^+, 25). *Anal.* calcd. for $C_{20}H_{37}NO_8$: C 57.26, H 8.89, N 3.34; found: C 57.60, H 8.97, N 3.39.

2R,3R-(+)-N-Tetradecyl-2-carboxamido-3-carboxyl-1,4,7,10,13-pentaoxacyclopentadecane (1b)

Purified by gel permeation, as a waxy solid in 60% yield from **8**; ir cm^{-1}: 3320 (NH), 3600–2400 (OH), 1740 (CO_2H), 1670, 1635, 1530 (amide), 1120 (C—O); $[\alpha]_D^{20}$ +16.8 (*c* 5.0); ^1H nmr δ: 7.4 (1H, brt, NH), 6.5 (1H, brs, CO_2H + trace H_2O), 4.48 and 4.35 (2H, dd, AB, J_{AB} 2.5 Hz, OCH—CHO), 3.65 (16H, brs, CH_2O), 3.30 (2H, m, CH_2N), 1.30 (24H, brs, —CH_2—), 0.9 (3H, brt, CH_3); ^{13}C nmr δ: 172.2, 168.9 (CO_2H, CONH), 80.5, 79.5 (CH—CH), 70.7, 70.3, 69.8, 69.4 (CH_2O), 39.5 (CH_2N), 31.9 (—CH_2—), 29.6, 26.9, 22.7, 14.1 (alkyl chain end); ms *m/e*: 504 (M + 1, 100), 245 (15-crown-5 C≡O^+, 60). *Anal.* calcd. for $C_{24}H_{49}NO_8$: C 62.00, H 9.80, N 2.78; found: C 61.83, H 9.72, N 2.64.

2R,3R-(+)-N-Octadecyl-2-carboxamido-3-carboxyl-1,4,7,10,13-pentaoxacyclopentadecane (1c)

Purified by reverse phase chromatography, as a waxy solid, recrystallized from pentane in 78% yield from **8**, mp 57°C; ir cm^{-1}: 3340 (NH), 3600–2500 (OH), 1745 (CO_2H), 1670, 1635, 1550 (amide), 1120 (C—O); $[\alpha]_D^{20}$ +16.8 (*c* 4.8); ^1H nmr δ: 8.6 (1H, brs, CO_2H), 7.4 (1H, brt, NH), 4.45 and 4.35 (2H, dd, AB J_{AB} 2.5 Hz, CH—CH), 3.65 (16H, brs, CH_2O), 3.30 (2H, m, CH_2N), 1.30 (32H, brs, —CH_2—), 0.90 (3H, brt, CH_3); ^{13}C nmr δ: 172.3, 168.8 (CO_2H, CONH), 80.6, 79.5 (CH—CH), 70.6–69.4 (CH_2O), 39.5 (CH_2N), 31.9 (—CH_2—), 29.7, 26.9, 22.7 and 14.1 (alkyl chain end); ms *m/e*: 542 (M − H_2O + 1, 100), 245 (15-crown-5 C≡O^+, 70), no M + 1. *Anal.* calcd. for $C_{30}H_{57}NO_8$: C 64.37, H 10.26, N 2.50; found: C 64.37, H 10.48, N 2.60.

2R,3R-(+)-N-Octyl-2-carboxamido-3-carboxyl-1,4,7,10,13,16-hexaoxacyclooctadecane (2a)

Purified by gel permeation, as a wax in 80% yield from **9**; ir cm^{-1}: 3360 (NH), 3600–2400 (OH), 1750 (CO_2H), 1670, 1635, 1540 (amide), 1110 (C—O); $[\alpha]_D^{20}$ +28.7 (*c* 7.3); ^1H nmr δ: 8.5 (1H, brs, CO_2H), 7.40 (1H, brt, NH), 4.42 and 4.34 (2H, dd, AB J_{AB} 2.0 Hz, CH—CH), 3.64 (20H, brs, CH_2O), 3.30 (2H, m, CH_2N), 1.30 (12H, brs, —CH_2—), 0.9 (3H, t, CH_3); ^{13}C nmr δ: 171.8, 169.5 (CO_2H, CONH), 81.0, 80.0 (CH—CH), 70.1 (CH_2O), 39.4 (CH_2N), 31.8 (—CH_2—), 29.3, 27.0, 22.6 and 14.1 (alkyl chain end); ms *m/e*: 464 (M + 1, 60), 446 (M − H_2O + 1, 100), 289 (18-crown-6 C≡O^+, 51). *Anal.* calcd. for $C_{22}H_{41}NO_9$: C 57.00, H 8.91, N 3.02; found: C 57.04, H 9.04, N 3.09.

2R,3R-(+)-N-Tetradecyl-2-carboxamido-3-carboxyl-1,4,7,10,13,16-hexaoxacyclooctadecane (2b)

Purified by reverse phase chromatography, as a clear oil in 61% yield from **9**; ir cm^{-1}: 3350 (NH), 3600–2400 (OH), 1740 (CO_2H), 1670, 1630, 1530 (amide), 1110 (C—O); $[\alpha]_D^{20}$ +28.4 (*c* 6.6); ^1H nmr δ: 7.8 (1H, br, CO_2H), 7.3 (1H, brt, NH), 4.42 and 4.32 (2H, dd, AB J_{AB} 3 Hz, —CH—CH—), 3.64 (20H, brs, CH_2O—), 3.30 (2H, m, CH_2N—), 1.30 (24H, brs, —CH_2—), 0.9 (3H, brt, CH_3); ^{13}C nmr δ: 171.5, 169.1 (CO_2H, CONH), 80.9, 80.4 (CH—CH), 69.9 (CH_2O), 39.4 (CH_2N), 31.9 (—CH_2—), 29.6, 26.9, 22.7 and 14.1 (alkyl chain end); ms *m/e*: 548 (M + 1, 100), 289 (18-crown-6 C≡O^+, 31). *Anal.* calcd. for $C_{28}H_{53}NO_9$: C 61.40, H 9.75, N 2.55; found: C 61.53, H 9.91, N 2.59.

2R,3R-(+)-N-Octadecyl-2-carboxamido-3-carboxyl-1,4,7,10,13,16-hexaoxacyclooctadecane (2c)

Purified by reverse phase chromatography, followed by gel permeation, as a wax in 58% yield from **9**; ir cm^{-1}: 3360 (NH), 3600–2500 (OH), 1740 (CO_2H), 1670, 1635, 1540 (amide), 1110 (C—O); $[\alpha]_D^{20}$ +29.0 (*c* 9.75); ^1H nmr δ: 8.5 (1H, br, CO_2H), 7.30 (1H, brt, NH), 4.42 and 4.38 (2H, dd, AB J_{AB} 2.5 Hz, —CH—CH—), 3.65 (20H, brs, CH_2—O—), 3.30 (2H, m, CH_2N), 1.30 (32H, brs, —CH_2—), 0.9 (3H, brt, CH_3); ^{13}C nmr δ: 172.3, 169.6 (CO_2H, CONH), 81.2, 80.3 (CH—CH), 70.3 (CH_2O), 39.4 (CH_2N), 31.9 (—CH_2—), 29.7, 27.0, 22.7 and 14.1 (alkyl chain end); ms *m/e*: 604 (M + 1, 100), 586 (M − H_2O + 1, 65), 289 (18-crown-6 C≡O^+, 12). *Anal.* calcd. for $C_{32}H_{61}NO_9$: C 63.65, H 10.18, N 2.32; found: C 63.48, H 10.28, N 2.38.

2R,3R-(+)-N-Butyl-2-carboxamido-3-carboxyl-1,4,7,10,13,16-hexaoxacyclooctadecane (2d)

The crude product was isolated as described above, taken into chloroform and stirred (gently) with three portions of aqueous HCl for 1 h each portion. The product obtained on evaporation of the solvent was ammonium free and was crystallized from ether/pentane to give **2d** in 90% yield from **9**; mp 93°C; ir cm^{-1}: 3420, 3350 (NH), 3600–2500 (CO_2H), 1755 (CO_2H), 1670, 1530 (amide), 1120 (C—O); $[\alpha]_D^{20}$ +45.5 (*c* 8.1); ^1H nmr δ: 10.0 (1H, br, CO_2H), 7.40 (1H, brt, NH), 4.46 and 4.35 (2H, dd, AB J_{AB} 3.0 Hz, —CH—CH—), 3.64 (20H, brs, CH_2O—), 3.30 (2H, m, CH_2N), 1.7–1.3 (4H, m, CH_2CH_2), 0.95 (3H, t, *J* 6 Hz, CH_3); ^{13}C nmr δ: 171.7, 169.0 (CO_2H, CONH), 81.2, 80.6 (CH—CH—), 71.4, 70.3 (CH_2—O), 39.0 (CH_2N), 31.6, 20.0 and 13.8 (alkyl chain); ms *m/e*: 408 (M + 1, 100), 436 (M + 29, 18), 390 (M − H_2O, 40), 289 (18-crown-6 C≡O^+, 20). *Anal.* calcd. for $C_{18}H_{30}NO_9$: C 53.06, H 8.16, N 3.43; found: C 53.47, H 8.50, N 3.43.

Determination of Acidity and Stability Constants

Apparatus and Materials

Titrant was delivered from a Radiometer Autoburet ABU11 in aliquots of 10.0 μL to a 5.0 mL cell jacketed to permit thermostating (25 ± 0.1°C for all determinations). Electrodes used: pH electrode, Fisher glass electrode; reference electrode, Ag/AgCl linked to the cell by a porous plug salt bridge containing 1.0*M* tetramethylammonium chloride in methanol/water (M/W) (90:10 v/v); sodium selective glass electrode, Phillips type G15Na; potassium selective glass electrode, Phillips type G15K or AH Thomas type 4202 Q10. The electrodes were conditioned in M/W for several days before use. Cell potential was read using a Fisher Accumet 610 pH/mV meter. All salts were analytical grade or better, water was purified using a Barnsted Nanopure water purifier, and methanol was HPLC grade.

Methods

Methanol/water solutions were prepared from 1 part water made to 10 parts with methanol.

(*1*) *Standardization of pH** Three buffers, interpolated from the data of deLigny *et al.* (36) for solutions 90:10 v/v M/W (87.68 wt.% methanol) were used as primary standards; pH* 3.59, 0.01*m* oxalic acid/0.01*m* ammonium hydrogen oxalate from 0.7639 g of oxalic acid dihydrate plus 0.2870 g of diammonium oxalate monohydrate dissolved in 50.0 mL of water and made to 500.0 mL with methanol; pH* 6.55, 0.01*m* succinic

acid/0.01 *m* lithium hydrogen succinate from 0.9540 g of succinic acid plus 0.1695 g of lithium hydroxide monohydrate dissolved in 50.0 mL of water and made to 500.0 mL with methanol; pH* 9.80, $7.4 \times 10^{-3} m$ hexylamine/$1.095 \times 10^{-3} m$ hexylammonium chloride from 0.1517 g of freshly distilled hexylamine plus 0.861 mL of 1.0 *M* HCl plus 9.14 mL of water made to 100.0 mL with methanol. Cell potentials for the three buffers were used to give a linear regression line from which pH* could be calculated. Before every set of determinations, a standard solution of ethylene diammonium dihydrochloride was titrated with tetramethylammonium hydroxide. The pK_a values calculated from this titration were compared with previous determinations. Day to day and long term variations were always less than ± 0.1 pK_a unit.

(*2*) *pH Metric Determinations* Duplicate M/W solutions, $2.5 \times 10^{-3} M$ in ligand containing tetramethylammonium chloride (0.1 *M*) to maintain ionic strength, were titrated with $5.0 \times 10^{-2} M$ tetramethylammonium hydroxide in M/W. The titration data were analysed as previously described (31). In cases where metal ions were present, some tetramethylammonium chloride was omitted so that the total ionic strength remained at 0.1 *M*. Acidity constants are precise to $pK_a \pm 0.10$ and stability constants from pH metric determinations are precise to $\log K \pm 0.2$ as assessed from the accuracy and reproducibility of the measurements.

(*3*) *Ion Selective Electrode Determinations* Electrodes were conditioned in buffered M/W solutions $10^{-2} M$ in MCl for several days before use. Selectivity is sufficiently poor for the potassium electrodes that they could be used as rubidium selective electrodes following a few days of conditioning in rubidium salt solutions. Buffers: acidic solution, $1.0 \times 10^{-3} M$ HCl, pH* 3.01; basic solution, tris-hydroxymethylaminomethane (Tris)/Tris·HCl, $2.5 \times 10^{-2} M$ in Tris, from pH 8.60 Tris buffer in water, [Tris] = $2.5 \times 10^{-1} M$ (24) diluted tenfold with methanol, pH* 9.30. Methanol/water solutions containing 0.1 *M* tetramethylammonium chloride in the appropriate buffer were titrated with $2.5 \times 10^{-2} M$ metal chlorides in M/W. Potential as a function of $\log [M]_{total}$ was plotted and the process was repeated until a stable series of straight lines was obtained. Duplicate M/W solutions of ligand, $5 \times 10^{-4} M$ to $2.5 \times 10^{-3} M$ (depending on *K* (30)) containing 0.1 *M* tetramethylammonium chloride in the buffer were titrated under conditions identical with the calibration. The standard curve was checked between each solution. Curves of potential as a function of $\log [M^+]_{total}$ were plotted. For all ligands clear end points at 1 equivalent of added metal ion were observed, indicating 1:1 complex formation. For the formation of a 1:1 complex the concentration stability constant, *K*, can be calculated using:

$$K = ([M]_{tot} - [M]_{free})/[M]_{free}([L]_{tot} - [M]_{tot} + [M]_{free})$$

where $[M]_{tot}$ and $[L]_{tot}$ are the total metal ion and ligand concentrations and $[M]_{free}$ is the free metal ion concentration sensed by the electrode (30). A value of *K* was calculated for each titration point between 0.2 and 0.8 equivalents of added metal ion and the results were averaged. Further experimental considerations are to be found in ref. 30. Stability constants determined by this method are precise to $\log K \pm 0.2$ in the range $2 < \log K < 5$ (outside this range $\log K \pm 0.3$) as assessed from the accuracy and reproducibility of the measurements.

Membrane transport systems. II. Transport of alkali metal ions against their concentration gradients

THOMAS M. FYLES,[1] VIRGINIA A. MALIK-DIEMER, AND DENNIS M. WHITFIELD

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received December 12, 1980

THOMAS M. FYLES, VIRGINIA A. MALIK-DIEMER, and DENNIS M. WHITFIELD. Can. J. Chem. **59**, 1734 (1981).

An artificial membrane system based on a series of macrocyclic polyether carriers (crown ethers) is described. Under the influence of a proton gradient the carriers move alkali metal ions from basic to acidic solution through a chloroform membrane phase. Transport occurs against the concentration gradient of the transported ion as a result of a coupled counterflow of protons. Different transport behaviors are observed depending upon the metal ion concentration. At high metal ion concentration the amount transported is a linear function of time; at lower metal ion concentration the amount transported is a complex function of time which may be described as the result of a pair of consecutive first order processes. Effects of metal ion, carrier, and proton concentration on transport rate are considered. The rate increases with increasing metal ion or carrier concentration but is essentially independent of the pH of either aqueous phase. Increased lipophilicity of the carrier also results in a rate increase. Carriers derived from 18-crown-6 transport potassium selectively and all ions more rapidly than 15-crown-5 derivatives which are, however, selective for sodium. The overall efficiency of the system is discussed in terms of competing "leak" reactions, either of cations from the basic phase or of anions from the acidic phase.

THOMAS M. FYLES, VIRGINIA A. MALIK-DIEMER et DENNIS M. WHITFIELD. Can. J. Chem. **59**, 1734 (1981).

On décrit un système de membrane artificielle basée sur une série de polyéthers macrocycliques (éthers couronnes) en tant que phases mobiles. Sous l'influence d'un gradient de proton, les phases mobiles déplacent les ions des métaux alcalins d'une solution basique vers une solution acide à travers la phase chloroforme de la membrane. Le transport se fait à l'opposé du gradient de concentration des ions transportés; ceci est dû à un contre-courant simultané de protons. On observe différents comportements lors du transport en fonction de la concentration de l'ion métallique. Pour une concentration élevée de l'ion métallique, la quantité transportée est une fonction linéaire du temps; pour une plus faible concentration de l'ion métallique, la quantité transportée est une fonction complexe du temps qui peut être décrite comme le résultat de deux processus consécutifs de premier ordre. On considère les effets de l'ion métallique, de la phase mobile et de la concentration du proton sur la vitesse de transport. La vitesse augmente avec la concentration de l'ion métallique ou de la phase mobile mais elle est essentiellement indépendante du pH d'une phase aqueuse quelconque. L'augmentation de la lipophilicité de la phase mobile augmente également la vitesse. Les phases mobiles dérivées des éthers 18-couronne-6 transportent sélectivement le potassium et tous les ions plus rapidement que celles dérivant des éthers 15-couronne-5 qui sont cependant sélectives vis-à-vis du sodium. On discute de l'efficacité globale du système en fonction de réactions compétitives impliquant des fuites soit de cations à partir de la phase basique soit d'anions à partir de la phase acide.

[Traduit par le journal]

The ability of macrocyclic polyethers (crown ethers) to selectively dissolve or extract metal ions into nonpolar solvents has been exploited in a wide range of applications from fundamental studies of ion solvation to phase transfer catalysis (1). However, one of the potentially most useful areas of application, that of the transport of ions through membranes, remains relatively unexplored. Of particular interest is the possibility that an ion of interest could be "pumped" against its concentration gradient by a coupled counterflow of ions (2), electrons (3), or protons (4). Potential applications include the separation and concentration of specific chemical species, the decontamination of wastes or biological fluids, or the direct analysis of a particular substrate in a mixture (5). Such applications will depend on a complete analysis of the mechanisms of transport and the effects of structural modifications of the carrier on transport rate, efficiency, and selectivity.

We have recently described the synthesis and characterization of a series of crown ether derivatives **1***a–c* and **2***a–c* (6) which in principle could act, like the ionophore antibiotic monensin (7), as carriers for the coupled counterflow of cations and protons across bulk liquid membranes. This simple system is susceptible to extensive structural modification, hence many of the features mentioned above may be examined in a much more detailed fashion than is possible either with natural biological transport systems (8) or with natural ionophores in artificial membranes (7, 9).

We envisage the transport to occur by the schematic mechanism outlined in Fig. 1. The carrier, by virtue of its lipophilic nature, remains dissolved in the hydrophobic membrane phase. At the left interface the carrier, a carboxylic acid, gives up a proton to the basic aqueous phase. To maintain electroneutrality in the membrane a metal ion is extracted to form the salt of the carrier which is also a crown ether – cation inclusion complex (1). The complex diffuses down its concentration grad-

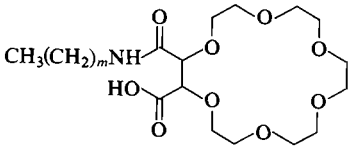
1*a* $m = 7$
1*b* $m = 13$
1*c* $m = 17$



2*a* $m = 7$
2*b* $m = 13$
2*c* $m = 17$

ient to the right acidic interface, whereupon it becomes protonated. Again, in order to maintain electroneutrality, the metal ion must be lost to the aqueous phase (or a counter ion must be extracted, see later discussion). The free carrier diffuses down its own concentration gradient to the left interface to recommence the cycle. The net result is the transport of a metal ion from left to right at the expense of a proton transported from right to left. If the metal ion concentration is greater on the right (acidic) side than on the left side, the metal ion is pumped against its own concentration gradient. The necessary energy is provided by the flux of protons in the opposite sense, from acidic to basic solution.

That the carriers 1*a–c* and 2*a–c* do in fact pump alkali metal ions from basic to acidic solution was the subject of a preliminary communication (10). The present article seeks to outline the phenomenon in detail and to address the questions of mechanism, efficiency, and selectivity using this model system.

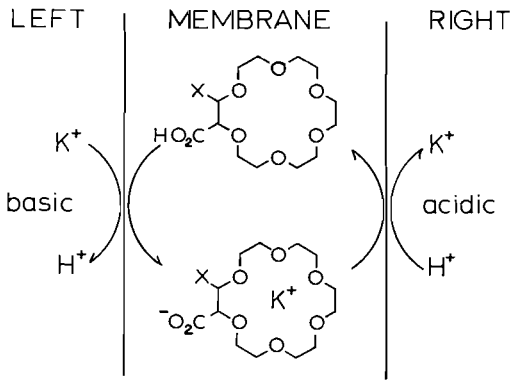


FIG. 1. A schematic mechanism for the carrier mediated countertransport of a metal ion and a proton.

Experimental

Apparatus

Transport experiments were performed in a U-shaped apparatus similar to those previously described (11), constructed of 15 mm id Pyrex tubing bent to a 20 mm radius bend. Two cell volumes were used (25 and 100 mL total volume). The bends in both cases were identical but one cell had flared arms to provide a larger volume. The "membrane," chloroform (12 mL), was placed in the base of the U and filled the cell into the vertical portions of the arms. The interface was thus of constant and reproducible area (1.54 cm^2). The two aqueous solutions were added simultaneously to the arms of the U and floated on the chloroform. All phases were efficiently stirred at 450 Hz. Dyes placed in any compartment were completely distributed throughout the compartment after ten seconds of stirring. The interfaces were only slightly perturbed by the constant stirring. The entire cell was jacketed and thermostated at 25 ± 0.1°C.

Materials

The synthesis and purification of the carriers 1*a–c* and 2*a–c* has been described (6). Other carriers are commercially available, monensin (Cal Biochem), dicyclohexano 18-crown-6 (Aldrich, a mixture of isomers), and were used as received. Alkali metal salts were of analytical grade or better, materials for buffer solutions were reagent or analytical grade and were analysed for alkali metal content before use. Water was purified using a Barnsted Nanopure water purifier, chloroform was distilled and stored under water to give a constant source of water saturated chloroform. Stock acidic buffer solutions were prepared from 0.5 mol of phosphoric acid in 0.750 L of water. A base (tetramethylammonium hydroxide pentahydrate, tetraethylammonium hydroxide 20% in water or triethanolamine) was added to give a target value of pH (1.25, 2.0, 3.0) and the solution was made to 1 L with water. Stock basic buffers were prepared similarly from 0.5 mol of tris(hydroxymethyl)aminomethane (Tris) or glycine in 0.750 L of water made to a target pH (8.50, 10.50) with concentrated hydrochloric acid or tetramethylammonium hydroxide pentahydrate, respectively, and then made to 1 L with water. Solutions for transport experiments were made up, from 0.1 *M* stock solutions of the alkali metal chlorides and the stock buffers, to result in a twofold dilution of the buffer.

Analytical Methods

The U cell was charged with chloroform and the two aqueous solutions then equilibrated for ca. 1 h. A stock solution of carrier (usually 1.0 mL) was injected to make the membrane phase to 12.0 mL total volume. The time of injection was taken as time = 0. Samples were withdrawn by microliter syringe from the aqueous solutions at various times. Sample size depended upon the metal ion concentration and the analysis required (typically 10–25 μL for metal ion concentration alone or 1.1 mL for proton concentration plus metal ion concentration). Metal ion samples (Na^+, K^+, Rb^+) were diluted with 1.0 mL of water and analysed by atomic emission spectrometry using a Varian 475 atomic absorption spectrometer. Values were typically in the range 0.5–5 ppm for which the method was reproducible to ±0.05 ppm between duplicates. Cesium ion concentrations were determined by pulse polarography. Proton transport rates were determined by acid/base titration of a 1.0 ml sample in 4.0 mL of 0.1 *M* KCl solution. Titration curves of pH vs. volume were plotted and end points were determined graphically. Kinetic data were analysed as described in the text. The reported transport rates are accurate to ±15% as assessed from the precision and reproducibility of the methods used and the long term repeatability of the experiments using different stock solutions and samples of carriers.

Results and Discussion

Cation–Proton Countertransport: the Phenomenon

The membrane transport of alkali metal cations by carriers **1***a–c* and **2***a–c* was studied using a U-shaped apparatus. The "membrane," chloroform, was placed in the base of the U and aqueous solutions were added to the arms of the U and floated on the chloroform. The aqueous solutions were initially of equal metal ion concentration but were buffered to impose a proton gradient across the membrane. The carrier was added to the membrane and aliquots of the aqueous solutions were withdrawn at various time intervals thereafter and analysed for metal ion and proton concentration. The counter transport of protons and alkali metal cations can be readily demonstrated with reference to Fig. 2 for the case of potassium and **2***b*. On the basic side of the membrane (the lower dashed line), the potassium ion concentration *decreases* with time while on the acidic side (the upper solid line) it *increases*. At the same time the proton concentration on the basic side of the membrane *increases* while on the acidic side it *decreases*. Qualitatively the change in potassium concentration roughly parallels the change in proton concentration for each side of the membrane although the two sides are different. The form of the curves is complex and is further complicated by the fact that part of the "transport" is due to the removal of samples for analysis. Thus some of the decrease in potassium concentration on the basic side is simply due to sampling while on the acidic side the increase is not as large as it would have been in the absence of sampling. The effect is not small; about 30% of the initial volume was consumed in samples.

Nonetheless, the cation–proton stoichiometry of countertransport may be demonstrated using this example since sampling of equal volumes occurred at equal times for both sides of the cell and perturbed the potassium and proton concentrations of a given compartment by an equal amount. "Transport" due to sampling is thus a constant factor and may be eliminated by plotting the change in proton concentration to a given time as a function of the change in potassium ion concentration to the same time (Fig. 3). The solid line is the linear regression line for all the data points and has a slope of 0.98 (residual 0.995) clearly indicating that the exchange of a single proton for a single potassium ion has occurred as is required by the schematic mechanism of Fig. 1. Furthermore, since the line has essentially the theoretical slope, the *efficiency* of the transport must be high. Little or no "leakage" of potassium from acidic to basic solution can have occurred (see later discussion).

Kinetic Analysis of Transport Data

Having outlined the basic features of the coupled countertransport of cations and protons we turned to a more precise method for the determination of transport rates using a smaller cell (10 mL aqueous phases) and a much smaller sample size (10–25 μL). Perturbations due to sampling are thus small, even with respect to uncontrollable

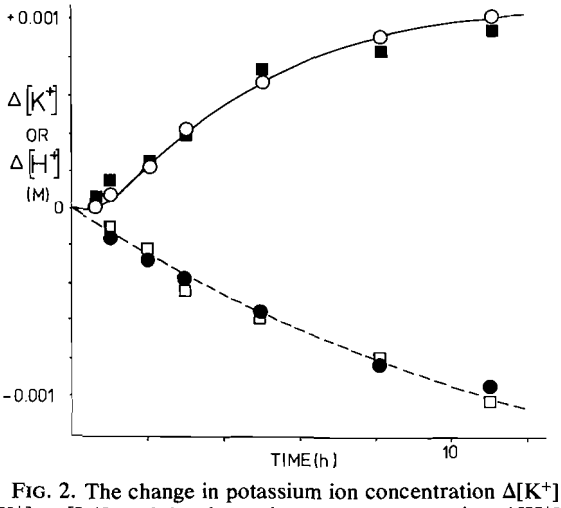

FIG. 2. The change in potassium ion concentration $\Delta[K^+] = [K^+]_t - [K^+]_0$ and the change in proton concentration, $\Delta[H^+] = [H^+]_0 - [H^+]_t$, as functions of time for the carrier **2***b*. The cell initially consisted of: 5×10^{-3} *M* KCl in 5×10^{-3} *M* Tris/Tris-HCl buffer (pH 8.69) || **2***b* 5.0×10^{-4} *M* in $CHCl_3$ || 5×10^{-3} *M* KCl in 1×10^{-2} *M* HCl (pH 2.15), ○, ●, Δ [K⁺]; □, ■ Δ [H⁺]; dashed line, basic side; solid line, acidic side.

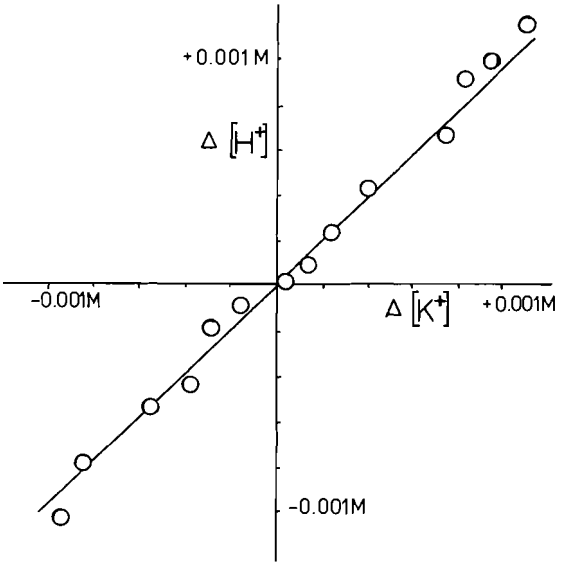

FIG. 3. The change in proton concentration, $\Delta [H^+] = [H^+]_0 - [H^+]_t$ as a function of the change in potassium ion concentration, $\Delta [K^+] = [K^+]_t - [K^+]_0$. Data taken from the experiment of Fig. 2.

variations in volume due to evaporation (ca. 0.2 mL/day). Detailed proton transport rates in these cases are unknown but are assumed to follow a pattern similar to those of Fig. 2. Checks of the final pH values of the aqueous phases allowed a calculation of the approximate number of moles of protons absorbed or liberated by the buffers. Values consistent with the number of moles of cation transport were obtained in all cases.

Two types of transport are observed depending upon the relative amounts of carrier and of metal ion. When the metal ion is present in a large excess, the amount of metal ion transported is a linear function of time (Fig. 4) referred to hereafter as type A behavior. The transport is apparent zero order in metal ion and the amount of metal ion at any time is given by

$$[1] \quad M_t^+ = M_0^+ \pm k_0 t$$

where M_t^+, M_0^+ are the amounts of metal ion in the phase of interest at a time t or initially, + refers to the acidic side and − refers to the basic side, and k_0 is the apparent zero order rate constant in units of moles per unit time (typically μmol h^{-1}). The rate constant k_0 must be dependent upon carrier concentration and proton concentration but these are imposed as constants for a given experiment. In type A cases there is commonly a brief induction period for the acidic side while the membrane achieves a steady state. The rates of uptake and of release are typically the same within experimental error but this is not uniformly observed.

The second type of transport (type B behavior), illustrated in Fig. 5, is more complex and occurs

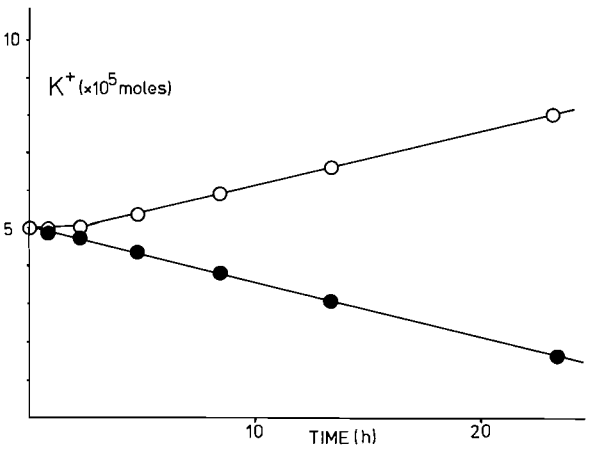

FIG. 4. The number of moles of potassium ion transported as a function of time by the carrier **2***b* showing typical type A behavior. The cell initially consisted of: 5 × 10^{-3} *M* KCl in tetramethylammonium glycinate buffer (pH 10.54) || 5.5 × 10^{-4} *M* **2***b* in $CHCl_3$ || 5 × 10^{-3} *M* KCl in tetramethylammonium dihydrogenphosphate buffer (pH 2.30). Data of the experiment of entry 14, Table 1; ●, basic side; ○, acidic side.

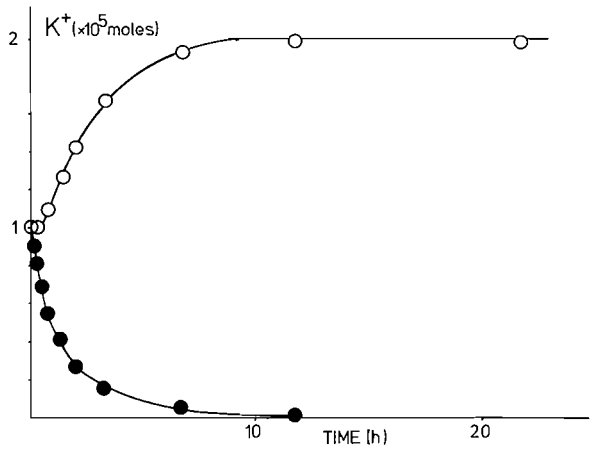

FIG. 5. The number of moles of potassium transported as a function of time by the carrier **2***b* showing typical type B behavior. The cell initially consisted of: 1 × 10^{-3} *M* KCl in Tris/Tris HCl buffer (pH 8.56) || 1.14 × 10^{-3} *M* **2***b* in $CHCl_3$ || 1 × 10^{-3} *M* KCl in tetramethylammonium dihydrogenphosphate buffer (pH 3.35). Data of the experiment of entry 13, Table 1; ●, basic side; ○, acidic side.

when the amounts of metal ion and of carrier are comparable. The kinetic behavior can be described by assuming a pair of consecutive first order processes.

$$[2] \quad \mathbf{A} \xrightarrow{k_1} \mathbf{B} \xrightarrow{k_2} \mathbf{C}$$

A in this case is the metal ion in the basic aqueous solution, **B** is presumably the carrier/metal ion complex in the membrane, and **C** is the metal ion in the acidic aqueous solution. Both **A** and **C** are observable as a function of time; **B** can be calculated from a knowledge of **A** and **C** and the total amount of metal ion initially present. The rate constant, k_1, is the rate at which a metal ion is taken into the membrane at the basic interface in exchange for a proton and k_2 is the rate of the reverse reaction occurring at the acidic interface.

Values for both k_1 and k_2 can be determined by standard methods (12). The decrease in metal ion concentration in the basic solution is a simple first order case from which k_1 is readily determined. The ratio of the rate constants $\kappa = k_2/k_1$ can be estimated graphically (12) to give an initial estimate for k_2 from the known value of k_1. The value of k_2 was further refined by an iterative procedure[2] to

[2]Since the value of t is known to a few seconds in several hours, the time at each experimental point was treated as an exact value. Using the values of k_1 and k_2, the potassium ion concentration in the acidic phase was calculated for each experimental time. The squares of the differences between experimental and calculated potassium concentrations were summed for the entire curve and this parameter was minimized by varying the value of k_2.

give a value which best reproduced the experimental curve of metal ion concentration in the acidic phase as a function of time. The solid lines of Fig. 5 are typical of curves calculated using this "best fit" pair of rate constants.

Data from type A experiments are in the form of moles of metal ion transported per unit time whereas data from type B experiments are in the form of time^{-1}. In order to compare the two cases we consider the **maximum rate of release** of the metal ion to the acidic phase. This is just k_0 for the acidic side of type A experiments. In type B experiments, the rate will be maximal when the concentration of **B**, the carrier complex, is at a maximum. It can be shown (12) that the **time**, t_{max}, at which **B** is a maximum is given by

$$[3] \quad t_{max} = \ln \kappa / k_1(\kappa - 1)$$

where $\kappa = k_2/k_1$.

The value of t_{max} can be calculated from k_1 and k_2 and gives the time at which the rate of formation of **C**, that is the rate that metal is released to the acidic phase, is at a maximum. From the integrated rate equation (12),

$$[4] \quad \left(\frac{dC}{dt}\right)_{max} = \frac{k_2 k_1 A_0}{k_2 - k_1} \times [\exp(-k_1 t_{max}) - \exp(-k_2 t_{max})]$$

where A_0 is the initial concentration of **A** and k_1, k_2, and t_{max} are defined above. All the parameters to the right of eq. [4] are known, thus the maximum rate of release of the metal ion to the acidic phase can be calculated.

This analysis permits comparisons between the two types of behavior but obscures the fact that these are only **apparent** rates of transport. As can be seen from the explicit derivation above, the maximum release rate contains terms in the initial concentration of metal ion on the basic side of the membrane, the rate of uptake, and the rate of release. In addition, each of the latter must have some dependence upon carrier and proton concentration. Nonetheless, the composite value is useful in examining the system as a whole and for comparing the effect of a change on the total behavior of the system.

The results obtained with carriers **1***a*–*c* and **2***a*–*c* for a variety of metal ions, concentrations and proton gradients are given in Table 1. Also included are results obtained with other carriers: monensin, stearic acid, and dicyclohexano 18-crown-6. Before going on to a detailed examination of the data, it would be useful to examine the type of information which is wholly or partly obscured by the analysis used. Firstly, the maximum release rate of the metal ion is clearly a composite value as shown by the data of entries 5 and 6. The overall behavior of these two systems is very similar and this is reflected by the similar maximum release rates. However, for **2***b* the uptake of potassium is rate limiting, while for **2***c* the release is rate limiting. The simple conclusion that **2***b* and **2***c* will always behave in a similar fashion is not borne out by the data. Presumably in other cases, e.g., entries 20 and 21 or 25 and 26, these competing effects cancel one another to different extents to result in different overall transport rates. A different sort of effect can be seen in the data of entries 5 and 12 and 13. Clearly in this case uptake rate controls the overall behavior of the system even though the release rates vary somewhat as well. This latter fact is lost in the maximum release rate calculation.

The extent to which these problems are to be found among the type A cases is not clear. Certainly after a miminum period of time the system will achieve a steady state. Subsequent to this time the release and uptake rates cannot be totally independent. The difference between the apparent zero order rates of uptake and of release might thus be considerably attenuated from the values for the individual isolated reactions. Even with these reservations, the data of Table 1 clearly reveal specific concentration and structural effects on the rate, selectivity, and efficiency of transport.

Influence of Concentration on Transport

Using our experimental cell, the antibiotic monensin pumps sodium ion against a concentration gradient at the rate of 1.03 μmol h^{-1} (entry 28). From the data of Choy *et al.* (7), a rate of ca. 1220 μmol h^{-1} for the transport of sodium across a thin octanol membrane of the same area as our cell by an amount of monensin 400 times greater than in our cell can be calculated. The form of the concentration dependence is not known either in their system or in ours. Assuming the rate increases as a direct linear function of the carrier concentration gives an estimate of about 3 μmol h^{-1} for monensin at the same concentration as in our experiment, in reasonable agreement with our value. Any differences can be attributed to the assumptions required and to the different liquid phases involved. Comparison of monensin/Na^+ with **2***a*–*c*/K^+ (entries 8, 10, and 11) reveals that, at the same concentration level in the same experimental cell, the model system performs as well as or better than the natural product. Admittedly, this is a comparison of best cases; carriers **2***a*–*c* are relatively ineffective carriers of Na^+, monensin is a relatively ineffective carrier of K^+ (7). Comparisons between **1***a*–*c* or

2*a*–*c* and other "carriers," e.g., stearic acid (entry 29), are even more favorable.

In principle, the carrier of the ion and the carrier of the proton need not be in the same molecule. Coupling between the substrate and pumping fluxes would be electrostatic, the carboxylate of the acid providing a liposoluble counter ion for the extracted metal ion. This is the basis of a redox driven cation pump (3) and various anion pumps (13). As the data of entry 30 show, however, this approach was not very successful in our system. The separated carriers were a factor of 80 times less efficient than 2*b*–*c*. The extraction rate is somewhat larger than with stearic acid alone but the net transport is the same with or without crown ether. Quite apart from other considerations, separate carriers must be entropically disfavored and would likely require an organized aggregation at the interface in order to achieve ion extraction and proton release by an efficient low-energy pathway.

Examination of Table 1 reveals a variety of general effects which have been noted in other

systems (14) or might be predicted from simple considerations. The rate of transport increases with increasing carrier concentration (e.g., entries 5 and 7) and with increasing metal ion concentration (e.g., entries 7–9). It is not straightforward to obtain data suitable for the determination of the kinetic order in carrier or in metal ion, as the observed transport behavior is strongly dependent upon the relative concentrations of carrier and of metal ion. The fivefold concentration increase in potassium ion between the experiments of entries 7 and 8 was sufficient to change the system from type B to type A behavior.

The dependence of transport rate on proton gradient was investigated in the experiments of entries 5, 12, and 13 and 8, 14, and 15. As is evident for 5, 12, and 13, the extraction step is rate limiting, hence it is not surprising that there is no change in rate due to changes in the acidic phase. It is not clear, however, why there should be virtually no rate changes produced by changes in the pH of the basic solution. The analysis of Cussler (15) predicts a dependence of 1/rate on $1/[M^+]\ [OH^-]$ for the basic side of the membrane and this relationship was found to hold for the carriers cholanic acid and monensin (7). The data of entries 8, 14, and 15 vary the hydroxide ion concentration by three orders of magnitude; the rate remains essentially unchanged (within the experimental error). The analysis referred to above explicitly assumed that all chemical reactions (i.e., proton release, metal ion extraction), are fast with respect to diffusion. It is not unreasonable to suppose that this criterion is not met in our well-stirred system and that the rate of extraction or release controls the transport. This conclusion is supported by the observation that extraction is not always rate limiting (entry 6, possibly 11 and 26). In order for the acidic side to play any role at all, some diffusional processes must have already occurred. This is not to imply that the pH plays no role whatsoever in determining rate; as the pH approaches the pK_a of the carrier, some effect due to diminished concentrations of the protonated or deprotonated carrier should be observable. The cases examined are remote from this value and are sufficient to check for an effect similar to that predicted by Cussler (15) but do not adequately examine the more complex questions associated with smaller proton gradients.

Structural Influences on Transport

Since diffusional restraints in our system appear to be unimportant, it is not surprising to note that increasing the length of the alkyl chain, which must decrease the ability of the carrier to diffuse freely, does not result in a rate decrease. On the contrary, in most cases the maximum release rates increase along the series octyl < tetradecyl < octadecyl (entries 4–6, 14, 10 and 15, 24–26, etc.). This is reasonable; in most cases intake is rate limiting and this rate should increase with increasing lipophilicity. The data of entries 4–6 reflect this trend but show in addition that the release rates pass through a maximum at the tetradecyl derivative. The thermodynamic data (6) show that the metal ion complexes of **2***a–c* are of comparable stability, hence both these trends must reflect changes in the lipophilicity of the carrier. The issue is further clouded by the observation that, although separated spatially, the intake and release reactions are formally the forward and reverse directions of the proton–cation exchange equilibrium [5]

$$[5] \quad M^+ (aq) + HCrn (org) \rightleftharpoons MCrn (org) + H^+ (aq)$$

where HCrn and MCrn are the carrier and metal ion complex respectively.

If the reaction occurs by a common pathway at both interfaces, microscopic reversibility will require that factors which accelerate the forward reaction will retard the reverse reaction. This is incompatible with the rate maximum at the acidic interface which is absent at the basic interface (entries 4–6). Special or extenuating circumstances at the acidic interface of the experiment of entry 4 such as the loss of **2***a* into the aqueous phase are not supported by other data. The potassium concentrations of these entries show the expected evolution with time and the values of k_1 and k_2 accurately reproduce the experimental curves. The distribution data (6) suggest that less than 0.2% of the **2***a* initially present would be lost to achieve equilibrium with the aqueous phase.

It is therefore evident that although eq. [5] formally represents the process, the uptake and release reactions must occur by different sequences of events and the relative rates within the sequence must change according to the lipophilicity of the carrier. Although speculation is possible, a more detailed discussion will be retained for a more comprehensive kinetic analysis of the isolated reactions.

Turning from comparisons within a structurally related series to comparisons between series, the data show that in general the 18-crown-6 derivatives (**2**) transport all ions more effectively than do the 15-crown-5 derivatives (**1**). This is presumably related to the stability of the complexes formed. The stability constants for complex formation have been determined in methanol/water solution (M/W

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

90:10 v/v) (6). Typically, 18-crown-6 carboxylates complex K^+ (log K = 5.8) more strongly than Na^+ (log K = 4.4) or Rb^+ (log K = 5.0) as well as more strongly than 15-crown-5 carboxylates (Na^+, log K = 3.4; K^+, log K = 3.0; Rb^+, log K = 2.7). The relationship between complex stability determined in homogeneous solution (usually methanol) and transport rate has been investigated in other systems (16) and is found to pass through a maximum about log K (methanol) ≈5–6. Complexes less stable than this do not extract the ion sufficiently well; complexes more stable than this fail to release the ion (14–16). All the values for **1***a–c* and **2***a–c* lie to the low side of the optimal value, hence one would expect to observe only an increase in rate with an increase in log K. The 18-crown-6 derivatives would thus be expected to transport ions more effectively than the 15-crown-5 derivatives on this basis alone.

An additional effect may also be important. As discussed above, an increase in lipophilicity results in an increase in metal ion extraction rate. Comparing the coefficients for the distribution of **1***a* and **2***a* between chloroform and aqueous acid (6) shows that **1***a* is less lipophilic than **2***a* even though both bear octyl side chains. The 15-crown-5 head group must thus be less lipophilic than the 18-crown-6 head group. Although there is no other quantitative data to support this view, there is a large body of qualitative evidence. Among other observations, the synthetic precursors in the 15-crown-5 series are uniformly more difficult to extract from water and to dry than are the 18-crown-6 counterparts.

The two effects (complex stability and lipophilicity) act in the same sense and allow one to predict that for a given side chain, the rate of intake should decrease along the series K^+/**2** > Rb^+/**2** > Na^+/**2** > Na^+/**1** > K^+/**1** > Rb^+/**1**. This is clearly found for both the octyl and octadecyl series. The tetradecyl case is less clear cut as the rates for Rb^+/**2**, Na^+/**2**, and Na^+/**1** are the same within the experimental error. In general, therefore, it is clear that the uptake rates are dominated by these two factors; an increase in complex stability or in ligand lipophilicity results in an increased rate of extraction.

This being the case, one might expect that membrane selectivity might be simply explained in terms of the selectivity of complexation determined from stability constants. In general, this is found to be the case; the 18-crown-6 derivatives complex K^+ selectively and transport K^+ most effectively. Unfortunately, the magnitude of the two effects is not the same. Whereas the carboxylates of the 18-crown-6 derivatives exhibit a K^+/Na^+ selectivity (thermodynamic selectivity) of about 20 (6) this results in a transport K^+/Na^+ selectivity of only 4 (entries 8 and 20 or 11 and 21, etc.). Other thermodynamic selectivities are similarly diminished to modest transport selectivities with the exception of the Na^+/K^+ selectivity of **1***a* which remains roughly the same (but small). This attenuation can be noted in other systems; monensin shows a thermodynamic Na^+/K^+ selectivity of 7 (9) in methanol which translates to a transport selectivity of 3 (7); the cryptand [2.2.C_8] (14, 17) exhibits a thermodynamic K^+/Na^+ selectivity of 22 (18) but a transport selectivity of only 2.8 (14, 19). In all these cases the membrane retains some selectivity and the overall behavior is closely controlled by the magnitude of the constant of stability. It therefore seems reasonable to suppose that the transport selectivity truly reflects the thermodynamic selectivity of the carrier in the **medium where complexation occurs**. Both complex stability and selectivity are strongly medium dependent and in general both values tend to increase as the solvent polarity decreases (18). For example, the K^+/Na^+ selectivity of the cryptand [2.2.C_8] increases from 22 to 50 as the solvent is changed from M/W (95:5 v/v) to pure methanol (18). The change from water to M/W is more dramatic: a tenfold increase in the K^+/Na^+ selectivity of the cryptand [2.2.2] is reported (18).

The selectivities of **1***a–c* and **2***a–c* were determined in M/W (90:10 v/v) (6). The ligands are insoluble in water, hence the values in this solvent are unobtainable, but may safely be assumed to be less than the values determined. A K^+/Na^+ selectivity of 3 has been reported for dicyclohexano 18-crown-6 (isomer A) in water (20). The transport selectivities observed in our system are consistent with a thermodynamic selectivity of about this magnitude and suggest therefore that the complexation step occurs in a predominantly aqueous environment.

Other Aspects

There are a variety of other aspects of the membrane system which serve to outline the general phenomenon. Electrostatic effects have been widely investigated in both a biological and chemical context (9) and are due to the potential created by the concentration gradient across the membrane. In our system (e.g., the cell of entry 8), the potential was ca. 260 mV and fell to 205 mV after all the potassium had been removed from the basic phase. The cell potential may be eliminated using a voltage clamp (21) (an applied potential which opposes the membrane potential). Transport with a membrane potential of 0 mV occurred at the same rate as with the full membrane potential. This is a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

case of an "electrically silent antiport" transport mechanism (8) as is observed in both biological (9) or chemical (7) systems and is consistent with the mechanism outlined above (Fig. 1). The species within the membrane must therefore migrate as undissociated molecules or as tight ion pairs.

Turning to the question of **efficiency**, it is of interest to enquire why the system functions in such a highly efficient fashion (Figs. 2 and 3). Efficiency in this system refers to the ratio of protons to metal ions transported; the value 1 indicates an efficient system, larger values indicate that more protons must be expended to pump the same amounts of metal ions. The question arises since one might expect the carrier to act, not only to create a concentration gradient, but also to collapse the gradient so created. This question may be analysed in terms of a competition at the acidic interface between the pumping reaction [6] and a "leak" reaction [7].

[6] $MCrn\ (org) + H^+\ (aq) \rightleftharpoons HCrn\ (org) + M^+\ (aq)$

[7] $MCrn\ (org) + H^+\ (aq) + X^-\ (aq) \rightleftharpoons MHCrn^+X^-\ (org)$

In the pumping reaction [6], protonation of the carrier results in metal ion release. The "leak" reaction [7] occurs by extraction of an anion X^- to form a protonated carrier ion pair complex which can diffuse to the basic interface. This results in proton transfer with no net metal ion transfer. Membrane efficiency might be determined by the relative rates of the two forward reactions or by the relative positions of the two equilibria. For whatever reason, reaction [6] clearly dominates in our system.

The efficiency may be partly explained in terms of the relative stabilities of the two complexes. The thermodynamic data (6) show that the complexes of the protonated carriers are an order of magnitude less stable than the complexes of the deprotonated carriers, presumably as a result of lost electrostatic stabilization (22). As demonstrated above, the weaker complex would be expected to be transported less quickly, hence the reaction [7] would be expected to result in lower transport rates than the uptake rates for the same carrier at the basic interface. However, this effect is probably not large enough to explain the efficiency obtained. The thermodynamic data demonstrate that the K^+/18-crown-6 complex in acidic solution is about as stable as the Na^+/18-crown-6 complex in basic solution (6). Taking the Na^+ transport rates as a model for the rate of transport of K^+ by a protonated carrier, the difference in stability constant is seen to amount to at most a fivefold difference in rate. This is insufficient to account for the observed efficiency.

It is more likely that the efficiency is related to the anion dependence of the leak. In order for [7] to occur, an anion must be extracted from aqueous solution. This process strongly depends upon the solvation of the anion in both phases and may be referred to in qualititative terms as the "liposolubility" of the anion (14). The "anion effect" has been noted several times in membrane systems involving the transport of cations with an associated anion and can be very large (over eight orders of magnitude difference between the liposoluble anion picrate and the hydrophilic anion fluoride) (23). The effect roughly correlates with the free energy of hydration of the anion (23). The standard experiment has chloride (5×10^{-3} *M*), hydrogen phosphate (HPO_4^{2-}, $\sim 1 \times 10^{-3}$ *M*), and dihydrogenphosphate ($H_2PO_4^{2-}$, ~ 0.1 *M*) as extractible anions. Insofar as [7] is concerned, neither the Cl^- nor the HPO_4^{-2} present a suitable choice for X^-; both are highly solvated, are not liposoluble anions (23, 24), and are present at low concentration. The role of the $H_2PO_4^-$ is less clear; it may (23) or may not (3) be a liposoluble anion and it is present in large excess. In our system it is clear that $H_2PO_4^-$ is not a liposoluble anion as is shown by the following observations: (*i*) varying the $H_2PO_4^-$ concentration over a factor of 100 resulted in no change in rate of transport (entries 5, 12, and 13); (*ii*) the metal ion transport rate did not change when phosphate buffers were replaced by aqueous HCl; and, (*iii*) a standard cell, maintained for three days after the transport of 1.5×10^{-4} moles of K^+ had occurred, showed only 1.25 ppm of phosphorus (as phosphate) on the basic side of the membrane. This latter result indicates that an $H_2PO_4^-$ dependent leak is negligible to the level of 0.01% of the K^+ transported.

The membrane can be induced to "leak" by the use of KPF_6 or $KClO_4$ as the salts for the transport experiment (entries 31 and 32). Both perchlorate and hexafluorophosphate are much more liposoluble than chloride, hence the importance of [7] would be expected to be enhanced. This is borne out by the data; the system still pumps K^+ but at a reduced rate. The KPF_6 results suggest that on average, one protonated carrier/metal ion complex in three extracts an anion instead of releasing a metal ion to the aqueous solution. These results corroborate the discussion of the liposolubility of $H_2PO_4^-$. Relatively minor amounts of liposoluble anions observably disrupt the system; it follows that $H_2PO_4^-$ is not liposoluble or the transport would be unobservable.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/06/12
For personal use only.

Having examined anion dependent leaks, it is important to examine cation leaks as well in order to verify that such leaks could occur but did not in the standard experiment. The leak may be envisaged again, in terms of a competition between the pumping reaction and the leak at either the basic or acidic interfaces.

[8] $CrnH\ (org) + M^+\ (aq) + OH^-\ (aq) \rightleftharpoons CrnM\ (org) + H_2O$

[9] $CrnH\ (org) + C^+\ (aq) + OH^-\ (aq) \rightleftharpoons CrnC\ (org) + H_2O$

[10] $CrnM\ (org) + H^+\ (aq) \rightleftharpoons CrnH\ (org) + M^+\ (aq)$

[11] $CrnM\ (org) + C^+\ (aq) \rightleftharpoons CrnC\ (org) + M^+\ (aq)$

At the basic interface ([8]/[9]), the competition is between the ion of interest M^+ and an interfering cation C^+. At the acidic interface ([10]/[11]), the competition is between a proton and an interfering cation C^+. Both leak reactions generate the complex CrnC in the membrane, will result in a scrambling of C^+ between the two aqueous phases, and will degrade efficiency by disrupting the apparent M^+/H^+ stoichiometry. The available cations in the standard experiment are, on the basic side, tris(hydroxymethyl)ammoniomethane ($TrisH^+$) and on the acidic side, tetramethylammonium. The roles of both these cations as potential cation leaks were shown to be negligible by varying buffer concentration (no effect on rate) and by varying the cation. On the basic side, tetramethylammonium glycinate gave the same metal ion transport rates as the $TrisH^+$ buffers (entries 8 and 14) and on the acidic side tetramethylammonium, tetraethylammonium, and triethanolammonium dihydrogenphosphate buffers all gave the same transport rates for potassium. These results are somewhat surprising considering that the tetramethylammonium salts of the carriers are extremely soluble in chloroform and are easily prepared from aqueous tetramethylammonium hydroxide and the carriers in chloroform. However, the stability constants for complex formation were all determined in the presence of a vast excess of tetramethylammonium. A log K of 5.8 for the 18-crown-6 derivatives with K^+ thus means that the K^+ complex is at least six orders of magnitude more stable than a tetramethylammonium "complex."

Nonetheless, the membrane can be induced to leak tetramethylammonium by using $5 \times 10^{-3}\ M$ KCl in $0.1\ M$ tetramethylammonium chloride and $0.01\ M$ tetramethylammonium hydroxide as the basic aqueous phase. A plot similar to that of Fig. 3 in this case showed a line of slope 5, that is five times as many protons were transported as potassium ions. This is an extreme case; the other experiments in which the basic solution contained tetramethylammonium had at least a tenfold lower concentration of the interfering cation. At this level the leak is undetectable.

To summarize the question of efficiency, it appears likely the efficient functioning of the system depends upon the absence of interfering counterions. Among the cations available on the basic side, only the desired metal ion is sufficiently extractible to be drawn into the membrane. On the acidic side, protonation and metal ion release are preferred over the extraction of an anion since the choice of anions is so poor. The net result is that the system does what it was designed to do: pumps metal ions from basic to acidic solution.

The epr spectral parameters for some $F_3CN(\dot{O})C(R_1R_2)OR$ radicals have been measured over a range of temperatures. These radicals are probably non-planar at nitrogen. Their OR groups are in the eclipsed position with respect to the N $2p_z$ orbital, a conformational preference which is attributed to a combination of steric factors and the anomeric effect. For $F_3CN(\dot{O})CH_2OR$ the *H* hyperfine splittings (hfs) are of unusually small magnitude. It is pointed out that all other known $R_3N(\dot{O})CHR_2OR$ also have anomalously low *H* hfs. It is suggested that this is due to the anomeric effect which not only promotes the eclipsed conformation but also causes the OR group to bend towards the semioccupied orbital, thereby moving *H* and R_2 towards the nodal plane of this orbital.

C. CHATGILIALOGLU et K. U. INGOLD. Can. J. Chem. **59**, 1745 (1981).

Opérant à différentes températures et faisant appel à la rpe, on a mesuré les paramètres spectraux de quelques radicaux $F_3CN(\dot{O})C(R_1R_2)OR$. Ces radicaux ne sont probablement pas plans au niveau de l'azote. Leurs groupes OR sont dans une position décalée par rapport à l'orbitale $2p_z$ de l'azote; on attribue cette préférence conformationnelle à une combinaison de facteurs stériques et de l'effet anomérique. Dans le cas du $F_3CN(\dot{O})CH_2OR$ les découplages hyperfins du H (fhs) ont une valeur qui est anormalement faible. On signale le fait que tous les autres radicaux $R_3N(\dot{O})CHR_2OR$ connus ont également des valeurs anormales de *H* hfs. On suggère que cela est dû à l'effet anomérique qui non seulement favorise la conformation décalée mais provoque également une déformation du groupe OR vers l'orbitale semi-occupée, déplaçant ainsi *H* et R_2 ver le plan nodal de cette orbitale.

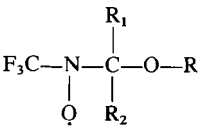
Introduction

The configurations and conformations of free radicals[3] can frequently be determined from the absolute magnitudes and/or the temperature coefficients of the hyperfine splittings (hfs) of various nuclei in the electron paramagnetic resonance (epr) spectra of the radicals (1).[4] During the course of an investigation into the mechanism by which radicals having the general structure **1** are formed



1

"spontaneously" when trifluoronitrosomethane is mixed with ethers or alcohols (3), we became intrigued by the fact that the N and F hfs for some **1** exhibited large temperature coefficients which were of *opposite* sign to those reported by Scheidler and Bolton (4) for bistrifluoromethyl nitroxide, $(CF_3)_2N\dot{O}$ (see also ref. 5). This prompted the present more detailed epr spectroscopic study of certain alkoxyalkyl and hydroxyalkyl trifluoromethyl nitroxides.[5] This leads us to conclude that in their configuration **1** are probably non-planar (at nitrogen) and that the conformations of **1** and of other alkoxyalkyl and hydroxyalkyl nitroxides are, in part, determined by anomeric effects (for leading references see ref. 6).

Experimental

Radicals were generated by mixing CF_3NO and the ether or alcohol in $CFCl_3$ and in CF_2Cl_2 with the usual freeze–thaw degassing. Spectra were recorded on a Varian E-104 EPR spectrometer. The epr parameters were measured by Griller and Preston's (7) very accurate procedure which utilizes an nmr field marker and a microwave frequency counter. A least-squares treatment is then used to obtain the best fit for all the measured lines. No sample was heated above room temperature because of the danger of bursting the epr tubes from the internal pressure.

Results

The $CF_3N(\dot{O})CR_1R_2OR$ radicals studied and their epr parameters at various temperatures are summarized in Table 1. The N and F hfs for four of these radicals ($R_1 = R_2 = H$ and CH_3, $R = H$ and CH_3) have been plotted against temperature in

Figs. 1 and 2, respectively, together with the epr data of Scheidler and Bolton (4) for $(CF_3)_2N\dot{O}$.

Discussion

Configuration

As can be seen from Figs. 1 and 2 $\partial a^N/\partial T$ is positive and $\partial a^F/\partial T$ is negative for bis-trifluoromethyl nitroxide. Scheidler and Bolton (4) suggested that the sign of these temperature coefficients, together with the small value of the N hfs relative to that for $[(CH_3)_3C]_2N\dot{O}$, resulted from conjugation of the fluorine *p* orbitals with the nitrogen $2p_z$ orbital. As they pointed out (4), the direct transfer of electron spin to the fluorine atoms must be significant because Rogers and Whiffen's study (8) of the single crystal epr spectra of the $HOOC—CH_2—\dot{C}F—COOH$ radical has shown that most of the spin density in the two β-fluorines lies in *p*-orbitals perpendicular to the C—F bond. This implies that there is a direct across-space interaction with the semi-occupied orbital. When the central atom is nitrogen this effect may be more pronounced because C—N bonds are shorter than C—C bonds.[6] Scheidler and Bolton therefore predicted that there should be a partial hindering of rotation about the C—N bonds. However, Morokuma (10) later concluded, on the basis of INDO calculations, that the average spin density of the fluorines in the two most stable planar conformers were the same, thus ruling out hindered rotation as a cause of the F hfs temperature coefficient. More detailed INDO calculations by Underwood and Vogel (ref. 11*a*, for related calculations on $H_2NO^{\cdot}$ see ref. 11*b*) showed that the structure of minimum energy was non-planar at nitrogen with a low barrier to inversion. Furthermore, the temperature dependence of the N hfs for $(CF_3)_2N\dot{O}$ could best be accounted for as being due to an increase in the out-of-plane vibration amplitude with increase in temperature, the energy required to produce such deformation being quite small (11*a*). The increase in the N hfs as the temperature rises is due to the fact that the amount of *s* character in the semi-occupied orbital will increase as the radical becomes, on average, less planar. Underwood *et al.* (11*c*) have also concluded that spin is transmitted to the fluorines by hyperconjugation rather than via the fluorine *p* orbitals. Since there is disagreement regarding the relative importance of the two mechanisms of spin transmission to fluorine the origin of the temperature dependence of the F hfs in $(CF_3)_2N\dot{O}$ remains uncertain.

There can, however, be no doubt that $(CF_3)_2N\dot{O}$ is non-planar. This has been shown by electron diffraction; the angle between the NO bond and the CNC plane being $22 \pm 3°$ (12). Furthermore, we (13) have shown by ^{17}O labelling that the unusually small N hfs of $(CF_3)_2N\dot{O}$ is due to a high spin density on oxygen (compared to dialkyl nitroxides) and not to spin transfer to the fluorine atoms.

The theory of the symmetric double minimum

potential energy function for out-of-plane bending as it relates to epr hfs parameters is now firmly established (14–17). For a radical, $A_\gamma B_\beta \dot{C}_\alpha D$, dissolved in an ideal (i.e., non-interacting) solvent:

(*i*) A *negative* tempertature coefficient for C_α implies a double minimum potential function (i.e., non-planarity at C_α) with at least three vibrational levels lying below the top of the barrier to inversion. Furthermore, it implies that the measurements were made at relatively low temperatures.[7]

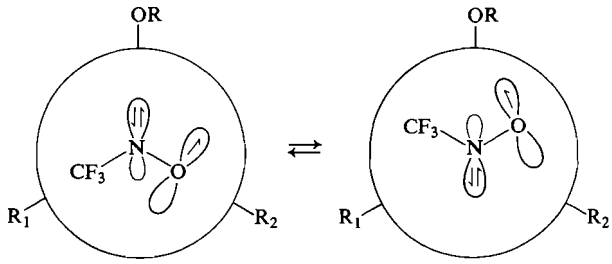
(*ii*) A *positive* temperature coefficient for C_α may be observed under three different sets of conditions: (*1*) $AB\dot{C}D$ prefers a planar configuration (single potential minimum) but out-of-plane vibration is substantial (i.e., is thermally excited). (*2*) $AB\dot{C}D$ prefers a non-planar configuration but there are fewer than three vibrational levels below the top of the barrier. (*3*) $AB\dot{C}D$ prefers a non-planar configuration and has more than three vibrational levels below the top of the barrier but the measurements have been made at high temperatures.[7]

(*iii*) Provided the *conformation* of the radical is temperature independent (i.e., provided hindered rotation is unimportant) the temperature coefficients for A_γ and C_α will generally[8] be of opposite sign whether the out-of-plane motion is governed by a single (7) or a double (14, 17) minimum potential function.

Since $(CF_3)_2N\dot{O}$ is *non-planar* (12) it follows that the observation that its N and F hfs are temperature dependent[9] with positive and negative coefficients, respectively, means only that there is relatively little resistance to further out-of-plane deformation at nitrogen.

There are only a few other reports of trifluoromethyl nitroxides for which the N and F hfs have been shown to be temperature dependent (19–21). For $CF_3N(\dot{O})C(CH_3)_3$ (19), and for $CF_3N(\dot{O})CH[C(O)CH_3]_2$ and $CF_3N(\dot{O})COCH_3$ (20), the temperature dependencies of the N and F hfs are positive and negative, respectively, i.e., they are of the same sign as those for $(CF_3)_2N\dot{O}$. These three radicals may, therefore, be *either planar or non-planar*. The only *firm* conclusion that can be drawn from the experimental observations is that they all undergo extensive out-of-plane bending motion in the temperature range in which they were examined.

The results with most of the $CF_3N(\dot{O})C(R_1R_2)OR$ radicals, **1**, we have examined stand in sharp contrast to this earlier work in that the temperature coefficients for the N hfs are *negative* (or zero within the limits of our experimental accuracy) and for the F hfs are *positive* (see Table 1 and Figs. 1 and 2). It would appear, therefore, that most radicals of this type are probably non-planar, undergo extensive out-of-plane vibration, and have more than three vibrational levels below the top of the inversion barrier. Unfortunately, our experimental procedure confined us to ambient temperatures and below. We were therefore unable to observe even one example of a change in the sign of the temperature coefficients of the N and F hfs at high temperatures, which is predicted both on theoretical grounds (14–17) and by analogy with the observed behavior of *tert*-butyl (17). The preferred conformation of **1** has the C—O bond and the time averaged axis of the semi-occupied orbital eclipsed (*vide infra*) and so inversion at nitrogen can be represented by the non-equivalent structures, **2** and **3**.



2 **3**

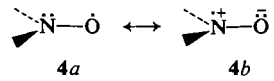
It must be added that the negative temperature coefficient for the N hfs can be explained *without* invoking a non-planar radical configuration. In a polar, or polarizable, solvent the interaction between the N—O dipole of the radical and neighbouring solvent molecules will become more important as the temperature decreases (22). That is, canonical structure **4***b* will become favored relative to **4***a* at lower temperatures and this means that the N hfs will increase with a decrease in temperature.[10] The experimental data do not, therefore, allow a decision to be made as to whether **1** are planar or non-planar. However, the latter seems the more probable in view of the known non-planarity of $(CF_3)_2N\dot{O}$ (12) and many (23), though perhaps not all (24), dialkyl nitroxides.

[7]Low and high temperature are defined in terms of the barrier height (15).

[8]Exceptions are known. For example, in $(CH_3)_3\dot{C}$, the out-of-plane motion of which is probably governed by a double minimum potential function, the maximum in a^H and the minimum in a^{13C_α} do not occur at the same temperature in all solvents (17).

[9]$|\partial a^N/\partial T| < |\partial a^F/\partial T|$ because N is "less sensitive" than F to *s* spin density. The calculated (18) hfs for an electron in an N 2*s* orbital (i.e., A_0^N) is 646 G and in a F 2*s* orbital it is 18 866 G.

[10]That is, the change in hfs with temperature may be due to the change in volume of the solvent; there being no intrinsic change with temperature at constant volume (22). However, changes in N hfs with temperature from this cause are fairly small (22).



4a 4b

There are two **1** for which the temperature coefficients of the hfs differ from those generally observed. The first, $CF_3N(\dot{O})C(CH_3)_2OH$, has coefficients for N and F with the *same* sign as $(CF_3)_2N\dot{O}$ (see Figs. 1 and 2). Provided this radical is non-planar it would appear to have a lower barrier to out-of-plane motion than most other **1**. The second $CF_3N(\dot{O})CH_2OC(CH_3)_3$ has a positive temperature coefficient for both the N and F hfs. The same unusual behavior has been previously observed for the $CF_3N(\dot{O})C(CH_3)_2C(O)CH_3$ radical (21), and we suggest it arises either because of hindered rotations in these two radicals (which is certainly the case for $CF_3N(\dot{O})CH_2OC(CH_3)_3$, see footnote *h* to Table 1) or because of a greater than "normal" difference in energy between 2 and 3 (which would imply that out-of-plane motion will be easier in one direction than in the other).

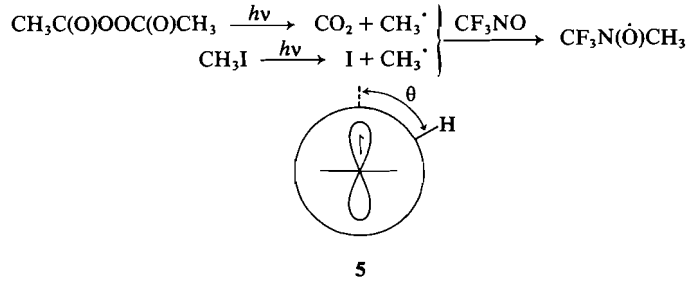
To summarize, $(CF_3)_2N\dot{O}$ is unquestionably non-planar (12) and it has $\partial a^N/\partial T > 0 > \partial a^F/\partial T$. However, these temperature coefficients *do not require* that the radical be non-planar. In contrast, most $CF_3N(\dot{O})C(R_1R_2)OR$ radicals have $\partial a^N/\partial T < 0 < \partial a^F/\partial T$. *Unless* these temperature coefficients are due to solvent effects (22) these radicals must be non-planar *and* have a barrier to inversion which is higher than 3 vibrational levels. It seems likely that other radicals of this particular type *and* other radicals having the general structure[11] $CF_3N(\dot{O})CRR_1R_2$ (19–21) are non-planar. That is, theoretical calculations not withstanding, we think it probable that *all* $CF_3N(\dot{O})CRR_1R_2$ radicals are non-planar at nitrogen.

Conformation

The magnitude of the hfs of the hydrogen(s) directly attached to C_β provides a simple method for determining the approximate conformation of the $ROCHR_2$ group with respect to the $CF_3N(\dot{O})$ moiety. For a radical with a planar configuration the magnitude of a^H is related to the dihedral angle (θ) between the C_β—*H* bond and the axis of the semi-occupied orbital (see **5**) by the equation:

$$[1] \quad a^H = A + B\cos^2\theta$$

In this equation A and B are constants and A is generally taken to be zero (1, 2). For any new family of radicals B is assumed to be twice a^H for the methyl group because this group is not subject to hindered rotation and therefore the average value of θ is 45°. In the present instance the required radical, i.e., methyl trifluoromethyl nitroxide, was unknown. We therefore prepared it by photolysis of acetyl peroxide or methyl iodide and CF_3NO in $CFCl_3$.



5

The epr parameters for $CF_3N(\dot{O})CH_3$ are given in Table 2. The hfs show small but interesting temperature dependencies in that the F hfs increases and the H hfs decreases with an increase in temperature. We prefer not to speculate on whether this is due to different mechanisms of spin transmission to H and F or to the different dynamic properties of the CH_3 and CF_3 groups. The H hfs is ca. 10.6 G (the necessary distinction between the H and F hfs having been achieved by preparing $CF_3N(\dot{O})CD_3$), and therefore $B \approx 21.2$ G for alkyl trifluoromethyl nitroxides.

Although this value of B can be used to obtain "exact" values of θ for many of the radicals listed in Table 1, there is a problem with the $CF_3N(\dot{O})CH_2OR$ radicals. For these radicals θ will have its *maximum* value when the RO group is in the eclipsed position (see structures **2** and **3**). This maximum is 60°, which would lead to a predicted *minimum* a^H value of $B/4 = 5.3$ G. However, all three $CF_3N(\dot{O})CH_2OR$ radicals have a^H values which are less than 4 G (see Table 1).

Unexpectedly small a^H values have been re-

[11]Represented in this way to exclude radicals such as $CF_3N(\dot{O})C_6H_5$ which are more likely to be planar. For a variable temperature epr study of some aryl fluoroalkyl nitroxides see ref. 25.

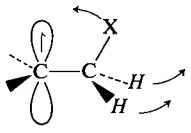
[b] Peak-to-peak line width in G.

ported on several occasions. The 2-chloroethyl radical, $ClCH_2CH_2^{\bullet}$, provides a well known case in point (1). For this radical a^H = 10.2 G while the estimated value (based on a^H = 26.87 G in $CH_3CH_2^{\bullet}$) for θ = 60° is 13.4 G (1). Many other examples of the same phenomenon are known (1). They are usually interpreted in terms of the eclipsed conformation *plus* an attractive interaction between the heteroatom, or heteroatom-centered group, X, and the semi-occupied orbital which causes X to move towards the radical center (1, 26). As a consequence the hydrogens of the CH_2X group are displaced towards the nodal plane and their interaction with the unpaired electron decreases (1, 26), see **6**. It has also been suggested



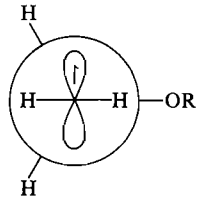
6

that the electron-attracting X will reduce a^H simply by reducing the electron releasing power of the C_β—H bonds (27).

Either of the above explanations might account for the small H hfs of $CF_3N(\dot{O})CH_2OR$ radicals. There is, in addition, the possibility that with non-planar radicals the A term in eq. [1] is not so small that it can be neglected.

While there may be some doubt about the reason for their small a^H values, there can be no doubt that $CF_3N(\dot{O})CH_2OR$ radicals preferentially adopt a conformation with the RO group in the eclipsed position, i.e., **2** and **3**. The same would seem to be true for $CF_3N(\dot{O})CH(R_2)OR$ radicals and is presumably true for $CF_3N(\dot{O})C(R_1R_2)OR$ radicals. This conformational preference contrasts with that of 2-alkoxyethyl and 2-hydroxyethyl radicals which prefer the staggered conformation, **7** (1, 2).

We attribute the preference of **1** for the eclipsed conformation to a combination of steric factors and the anomeric effect (6). Steric factors must be significant since even $CF_3N(\dot{O})CH_2CH_3$ would appear, from its a^H value of 7.5 G at 300 K (28), to have



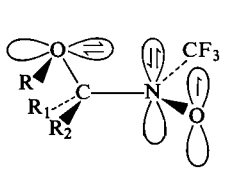
7

the methyl group close to the eclipsed position. The anomeric effect, which results from delocalization of a heteroatom lone pair into the region of an adjacent polar bond, produces an increase in the stability of conformations in which the lone pair is in the same plane as the polar bond (6). In **1** the interaction between the N lone pair (or, more correctly, the NO 3 electron system) and the antibonding σ_{CO}^* orbital will favor RO being in the eclipsed position. Furthermore, this interaction is attractive and thus provides a simple explanation for the small magnitudes of H hfs in $CF_3N(\dot{O})CH_2OR$ radicals (*vide supra*, cf. 6) and in other alkoxyalkyl and hydroxyalkyl nitroxides (*vide infra*).

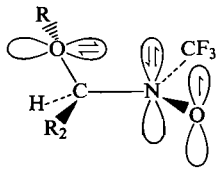
A second anticipated manifestation of the anomeric effect would be between the *p*-type lone pair on the oxygen of the RO group and the polar C_β—$N(O)CF_3$ bond. This interaction will favor conformations in which the R—O bond is approximately perpendicular to the N—C_β—O plane, i.e., **8** and **9**. This will lead to restricted rotation about the C_β—O bond. However, in many **1** conformations **8** and **9** may not be attained because of overriding steric interactions (e.g., those between R and R_2 in **8** and possibly those between R and CF_3 in **9**).

At low temperatures the methylene hydrogens in $CF_3N(\dot{O})CH_2OR$ radicals become non-equivalent. For R = CH_3 this inequivalence manifests itself as two distinct H hfs at 210 K and below, while for R = H and R = $C(CH_3)_3$ inequivalence manifests itself as a broadening of the central line of the 1:2:1 triplet which becomes noticeable at 174 K and 248 K, respectively. Assuming that inversion at N has only a low barrier (*vide supra*), the non-equivalence of the hydrogens implies that rotation about both the C_β—O bond (**10** ⇄ **11**) and C_β—N bond (**11** ⇄ **12**) can be frozen-out.

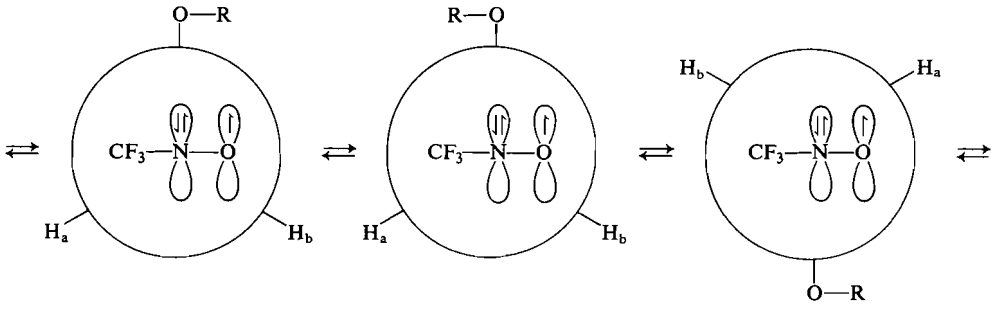
Finally, attention is drawn to the unusually large H hfs of $CF_3N(\dot{O})C(CH_3)_2OCH(CH_3)_2$ (ca. 4 G, see



8 $R_1 = R_2$

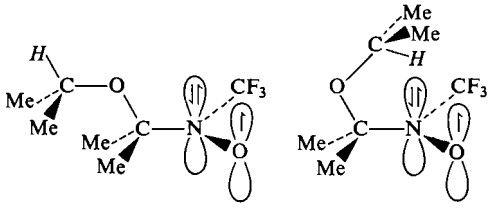


9 R_2 = alkyl



10 11 12

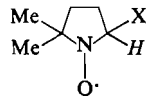
Table 1). It is clear that this radical is quite firmly locked in a conformation which allows a long-range H hfs. This might be a W, **13**, an anti-W, or a U, **14**, conformation (29). It would seem that in this radical steric factors override the anomeric effect, which favors conformation **8**.



13 14

Other Alkoxyalkyl and Hydroxyalkyl Nitroxides

As far as we can tell all alkoxyalkyl and hydroxyalkyl nitroxides, i.e., all $R_3N(\dot{O})CHR_2OR$ radicals which have been reported have anomalously low *H* hfs (30). For example, $(CH_3)_3CN(\dot{O})CH_3$ has $a^H = 11.3$ G, which yields a "minimum" a^H for $(CH_3)_3CN(\dot{O})CH_2X$ radicals of 5.5 G (i.e. for $\theta = 60°$), yet for $(CH_3)_3CN(\dot{O})CH_2OH$ a^H has a value of 4.8 G in methanol at 298 K (31), 4.1 G (32*a*) or 4.0 G (32*b*) at 195 K and 4.5 G (32*c*) or 4.0 G (32*d*) at 228 K. As a second example, spin-trapping of HO· and RO· radicals by 5,5-dimethyl-1-pyrroline-1-oxide has yielded nitroxides, **15**,

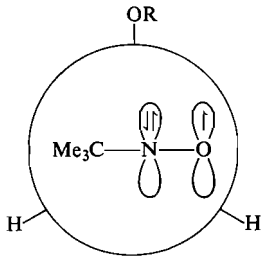


15

X	a^H (G)	Reference
H	18.9	34
CH_3	20.5	33
HO	15.3	35
MeO	7.6	33
EtO	7.0	33
Me_3CO	7.9	33

which also exhibit unexpectedly small *H* hfs (33–37).

No self-consistent explanation of the above results has been advanced.[12] However, they can be simply explained as a consequence of the anomeric effect which favors conformation **17** for



17

$(CH_3)_3CN(\dot{O})CH_2OR$ radicals and **18** for **15** having X = HO and RO. Distortions of 5-membered rings from planarity are known in related structures (9) which can also be attributed to anomeric effects.

[12]A proposal by Janzen *et al.* (34) that the nitroxyl function becomes more and more non-planar as the electronegativity of X increases would, as these authors point out, lead to an increase in a^N which is contrary to their observations. A polar or inductive effect from X was suggested as an offsetting factor (34).

Charge exchange mass spectra of some C_5H_{10} isomers

YIP HOI LI, JAN A. HERMAN,[1] AND ALEX. G. HARRISON

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received October 13, 1980

This paper is dedicated to Dr. F. P. Lossing of the National Research Council of Canada on the occasion of his 65th birthday

YIP HOI LI, JAN A. HERMAN, and ALEX. G. HARRISON. Can. J. Chem. **59**, 1753 (1981).

Reagent gas systems are described for use in a single-source chemical ionization mass spectrometer which permit charge exchange mass spectra to be obtained using $CS_2^{+\cdot}$ (~ 10.2 eV), $COS^{+\cdot}$ (11.2 eV), $Xe^{+\cdot}$ (~ 12.5 eV), $CO^{+\cdot}$ (14.0 eV), $N_2^{+\cdot}$ (15.3 eV), and $Ar^{+\cdot}$ (15.8 eV) (recombination energies in brackets) as the major reactant ions. Using these reagent gas systems the charge exchange mass spectra of cyclopentane, 1-pentene, 3-methyl-1-butene, 2-methyl-1-butene, 2-pentene, and 2-methyl-2-butene have been obtained. It is shown that these spectra can be used to construct breakdown graphs which adequately depict the relative energy dependences of the fragmentation pathways and rationalize the 70 eV electron impact mass spectra.

YIP HOI LI, JAN A. HERMAN et ALEX. G. HARRISON. Can. J. Chem. **59**, 1753 (1981).

Des spectres de masse de transfert de charge ont été obtenus avec un spectromètre de masse muni d'une source simple à chimiionisation en utilisant des milieux réactionnels comportant comme ion réactif principal l'une des espèces suivantes: $CS_2^{+\cdot}$ (~ 10.2 eV), $COS^{+\cdot}$ (11.2 eV), $Xe^{+\cdot}$ (~ 12.5 eV), $CO^{+\cdot}$ (14.0 eV), $N_2^{+\cdot}$ (15.3 eV) et $Ar^{+\cdot}$ (15.8 eV) (énergie de recombinaison données entre parenthèses). Cette étude a porté sur les cyclopentane, pentène-1, méthyl-3 butène-1, méthyl-2 butène-1, pentène-2 et méthyl-2 butène-2. Ces spectres de transfert de charge peuvent ensuite servie à construire des diagrammes de seuil d'apparition permettant de décrire les dépendances énergétiques relatives des voies de fragmentation et de rendre compte des spectres de masse par impact électronique à 70 eV.

When a gaseous sample of a polyatomic molecule, M, of ionization energy, IE, is bombarded with a beam of electrons of energy, E, the molecular ions produced possess internal energies ranging from 0 to E − IE, with a distribution which is unknown but depends on the electron energy E and the identity of the molecule M. The mass spectrum observed results from a series of competing and consecutive unimolecular fragmentation reactions, starting from $M^{+\cdot}$, each with rate coefficients dependent on the internal energy, summed over the unknown internal energy distribution (1). In effect, the primary kinetic data, i.e., the reaction channels and the relative rates of competing channels, are obscured by the summation procedure. Although qualitative kinetic information can be obtained by varying the energy of the impacting electrons, quantitative data, in the form of a breakdown graph, can be obtained only by determining the normalized second derivatives of the ion signals as a function of the ionizing electron energy (2).

The breakdown graph, i.e., the fractional ion intensities as a function of the internal energy of $M^{+\cdot}$, provides detailed information on the fragmentation channels of $M^{+\cdot}$ and on the competition between these channels as a function of internal energy. It has long been recognized (3, 4) that breakdown graphs can be obtained directly by charge exchange ionization (reaction [1]),

$$[1] \quad R^{+\cdot} + M \rightarrow M^{+\cdot} + R$$

where the internal energy of $M^{+\cdot}$ is determined by the difference between the recombination energy (RE) of the reactant ion $R^{+\cdot}$ and the ionization energy (IE) of the molecule M. The internal energy of $M^{+\cdot}$ can be varied in a controlled manner by suitable choice of reagent ions $R^{+\cdot}$. Most charge transfer experiments to date have been performed using tandem mass spectrometers (3, 4) and, for the most part, have studied in detail relatively simple molecules with the aim of comparing experimental breakdown graphs with those calculated from theory (4, 5), although several recent publications (6–8) have been concerned with the question of distinguishing among isomeric molecules from their charge exchange mass spectra.

With the advent of high pressure chemical ionization mass spectrometry, a number of groups have used charge exchange ionization either separately, or in conjunction with proton transfer ionization in analytical applications (9–14). However, with the exception of two reports by Einolf and Munson (15, 16), there have been no attempts to develop charge exchange reagent ion systems covering a range of recombination energies suitable for the derivation of breakdown graphs from single-source experiments. Such data for complex molecules should provide considerable information on fragmentation mechanisms and the energy dependence of the reactions occurring. The present work reports the development of charge exchange reagent ion sys-

tems covering recombination energies from ~10 eV to ~16 eV and the application of the systems developed to the determination of the charge exchange mass spectra of six C_5H_{10} isomers. Some years ago Turk and Shapiro (17) reported breakdown graphs for a number of simple ketones obtained from single-source experiments using the method of Cermak and Herman (18). This method suffers from a number of experimental problems and it appeared that the approach of high pressure mass spectrometry might prove to be simpler and more useful.

We have chosen to study the C_5H_{10} isomers in part because they have been extensively studied by electron impact. In particular, the energetics of formation of the molecular ion and the $C_4H_7^+$ fragment ion have been clearly established by Lossing (19); this allows us to evaluate the recombination energies achieved in the present high pressure systems. The 70 eV mass spectra of the C_5 olefins are quite similar (20, 21), the most striking difference being the enhanced loss of C_2H_4 from the molecular ion of 1-pentene. Similarly, the mass spectrum of cyclopentane shows a dominant loss of C_2H_4 from the molecular ions (20, 21). The major low energy fragmentation reactions, which are observed as metastable peaks, correspond to loss of CH_3 and to loss of C_2H_4 from the molecular ion; the ratio of metastable peak intensities is independent of molecular structure (22) making distinction among the isomers impossible on this basis. In addition, the collisional activation mass spectra of the C_5H_{10} isomers are very similar (23), making isomer identification by this method extremely difficult. Thus, the study also provides a test of the utility of charge exchange mass spectrometry in distinguishing among isomers.

Charge Exchange Reagent Ions

$CS_2^{+\cdot}$

Electron impact ionization of a mixture of 10–20% CS_2 in N_2 at ~0.2 Torr total pressure gave $CS_2^{+\cdot}$ as the major reactant (>80%) with minor yields of $S_2^{+\cdot}$ (<10%), $(CS_2)_2^{+\cdot}$ (<10%), and a very small amount of CS_3^+. The use of CS_2/N_2 mixtures to produce $CS_2^{+\cdot}$ as a low energy charge exchange reagent has been reported previously (24, 25).

The photoelectron spectrum of CS_2 shows (26) the lowest energy ionic state as a doublet and yields ionization energies of 10.06 and 10.12 eV, with very little vibrational structure apparent. The $\tilde{A}^2\pi_\mu$ state of $CS_2^{+\cdot}$ with an energy of 12.69 eV could be formed by charge exchange from $N_2^{+\cdot}$. This state has a lifetime of ~4 μs (27) and could play a role in subsequent charge exchange reactions. Lindholm (3, 4) reports the recombination energy of $CS_2^{+\cdot}$ to be ~9.5 or 10 eV. The recombination energy of $(CS_2)_2^{+\cdot}$ should be lower than that of $CS_2^{+\cdot}$ while the recombination energy of $S_2^{+\cdot}$ should be equal to or less than the ionization energy of 9.4 eV (28).

$COS^{+\cdot}$

Attempts to prepare $COS^{+\cdot}$ by electron impact ionization of COS/N_2 mixtures resulted in $S_2^{+\cdot}$ as the major product ion. Presumably charge exchange of $N_2^{+\cdot}$ with COS resulted largely in formation of $S^{+\cdot}$ (AE = 13.6 eV (28)) which reacts with COS by reaction [2], as previously reported (29).

[2] $S^{+\cdot} + COS \rightarrow S_2^{+\cdot} + CO$

By contrast electron impact ionization of a 10% COS – 90% CO mixture at 0.1–0.2 Torr pressure yielded $COS^{+\cdot}$ (~76%) with $S_2^{+\cdot}$ (~14%), $CS_2^{+\cdot}$ (~4%), and $(COS)_2^{+\cdot}$ (~4%) as the major ions; the $(COS)_2^{+\cdot}/COS^{+\cdot}$ intensity ratio increased with increasing pressure as expected. Kebarle *et al.* (29) have reported the ion–molecule reaction

[3] $COS^{+\cdot} + COS \rightarrow S_2^{+\cdot} + 2CO$

This reaction probably accounts for the major part of the $S_2^{+\cdot}$ observed.

The photoelectron spectrum of COS shows (26) the lowest energy band as a doublet (ionization energies of 11.18 and 11.23 eV) with weak vibrational structure. Bands at higher energies give ionization energies of 15.5 eV, 16.0 eV, and 18.0 eV. The $\tilde{A}^2\pi$ state (15.5 eV) has an upper lifetime for decay by fluorescence of 30 ns, the major decay channel being predissociation to S^+ (^4S) (27). The role of the higher states in charge exchange is not known. Lindholm (3, 4) reports a recombination energy of 11.2 eV for $COS^{+\cdot}$. The major impurity of $S_2^{+\cdot}$, with a recombination energy ≤9.4 eV could effect ionization of molecules with IE's below this value, but in the present system would not lead to fragment ion formation.

$Xe^{+\cdot}$

Electron impact ionization of Xe at source pressures of ~0.1 Torr yielded only Xe^+ ions. The recombination energy of $Xe^{+\cdot}$ is 12.13 eV for the $^2P^0_{3/2}$ state and 13.44 eV for the $^2P^0_{1/2}$ state (3, 4). In construction of the breakdown graphs in the following, a mean recombination energy of 12.5 eV has been used; this assumes the 66:33 statistical weights of the two states. Electron impact on Xe could produce the long-lived $^3P_2$ and $^3P_0$ states of Xe which could react by Penning ionization (30);

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/06/12
For personal use only.

the energies of these states are 8.31 eV and 9.44 eV, respectively (31), with the result that only molecular ion formation should occur and only for C_5H_{10} isomers of low ionization energy.

$CO^{+\cdot}$

Electron impact ionization of CO at source pressures of 0.1–0.2 Torr yielded $CO^{+\cdot}$ with only a minor yield of $(CO)_2^{+\cdot}$. The photoelectron spectrum of CO yields (32) ionization energies of 14.01, 16.54, and 19.67 eV. The lifetime of the latter (*B*) state has been reported as 54 ns (33). Lindholm (3, 4) reports a recombination energy of 14.0 eV for $CO^{+\cdot}$.

$N_2^{+\cdot}$

Electron impact ionization of N_2 at 0.1–0.2 Torr produced $N_2^{+\cdot}$ with only minor amounts of $(N_2)_2^{+\cdot}$. The photoelectron spectrum of N_2 shows (32) ionization energies of 15.58, 16.69, and 18.26 eV; the latter state has a lifetime of ~60 ns (33). Lindholm (3, 4) reports a recombination energy of 15.3 eV for $N_2^{+\cdot}$. Penning ionization by long-lived neutral states of N_2 has been reported (34–36) and attributed (34) to two states capable of releasing energy in the range 11.4–11.6 eV and 10.2–11.4 eV. Single-source experiments (37) indicate that the ion currents produced by Penning ionization are less than 5% of the ion currents resulting from charge exchange using N_2; it does not appear that this mode of ionization will seriously affect the present results.

$Ar^{+\cdot}$

The $Ar^{+\cdot}$ reactant ion was produced by electron impact ionization of argon at 0.1–0.2 Torr source pressure. The recombination energies of $Ar^{+\cdot}$ are 15.76 eV ($^2P^0_{3/2}$) and 15.94 eV ($^2P^0_{1/2}$) (3, 4). Penning ionization by the long-lived $^3P_2$ and $^3P_0$ states of Ar (11.54 and 11.72 eV respectively) may occur; earlier work (37, 38) indicates that Penning ionization normally is less than 5% of that resulting from charge exchange involving $Ar^{+\cdot}$.

Charge Exchange Mass Spectra

The complete charge exchange mass spectra of cyclopentane, 1-pentane, 3-methyl-1-butene, 2-methyl-1-butene, 2-pentene, and 2-methyl-2-butene, obtained with the reagent gas systems described above, are recorded in tables in the Depository of Unpublished Data.[2] The essential data are summarized in the form of breakdown graphs

[2]Complete set of data may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

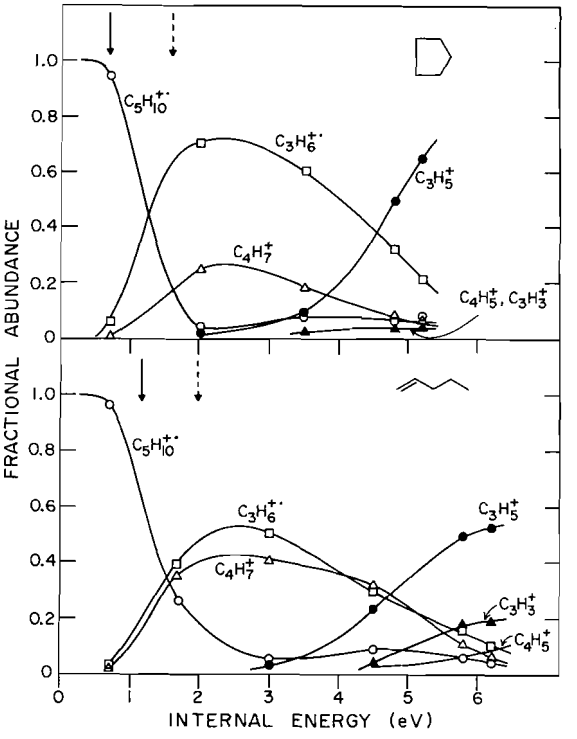

FIG. 1. Breakdown graphs for cyclopentane and 1-pentene: —, critical energy for formation of $C_3H_6^{+\cdot}$ and $C_4H_7^+$; --- critical energy for formation of $C_3H_5^+$. Data points in order of increasing energy from $CS_2^{+\cdot}$, $COS^{+\cdot}$, $Xe^{+\cdot}$, $CO^{+\cdot}$, N_2^+, and $Ar^{+\cdot}$ charge exchange (cyclopentane graphs begin with $COS^{+\cdot}$ charge exchange).

for the six isomers shown in Figs. 1 to 3. These graphs have been constructed by plotting the fractional ion intensities as a function of the internal energy of the $M^{+\cdot}$ ion, taken as RE − IE, using the IE values given in Table 1. The recombination energies used were those given in the above discussion except for $CS_2^{+\cdot}$ where an effective value of ~10.2 eV is indicated by more extensive but unpublished work in this laboratory. The charge exchange mass spectra showed (usually) low intensity $C_5H_9^+$ ion signals. These ions may arise by H^- abstraction reactions rather than by dissociative charge exchange; consequently, they have not been included in deriving the breakdown graphs. In the ionization of cyclopentane with the CS_2/N_2 reagent system $C_5H_9^+$ was the major product ion with only a minor (~4%) yield of $C_5H_{10}^{+\cdot}$. The ionization energy of cyclopentane (10.49 eV) is above the recombination energy of ground state $CS_2^{+\cdot}$; the low intensity $C_5H_{10}^{+\cdot}$ ion signal may result from reaction of the $\tilde{A}\,^2\pi_\mu$ state of $CS_2^{+\cdot}$, present in low abundance, or from reaction of vibrationally excited $CS_2^{+\cdot}$ ions. The $C_5H_9^+$ product presumably

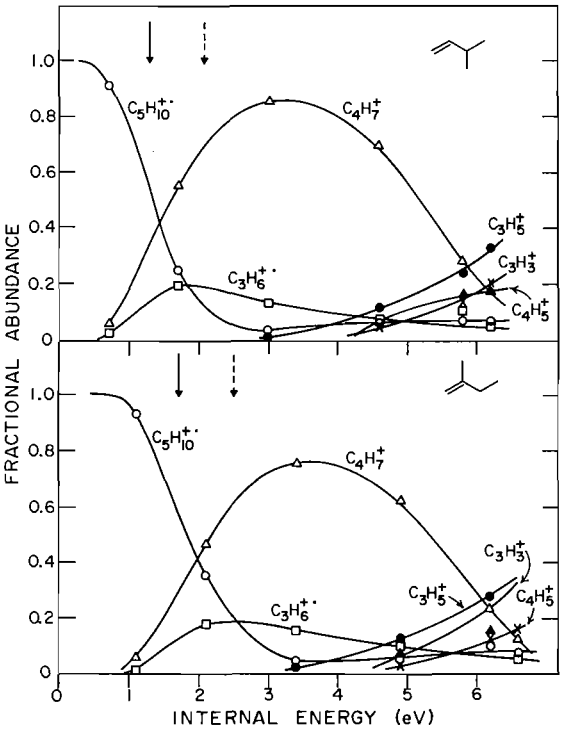

FIG. 2. Breakdown graphs for 3-methyl-1-butene and 2-methyl-1-butene, see caption for Fig. 1.

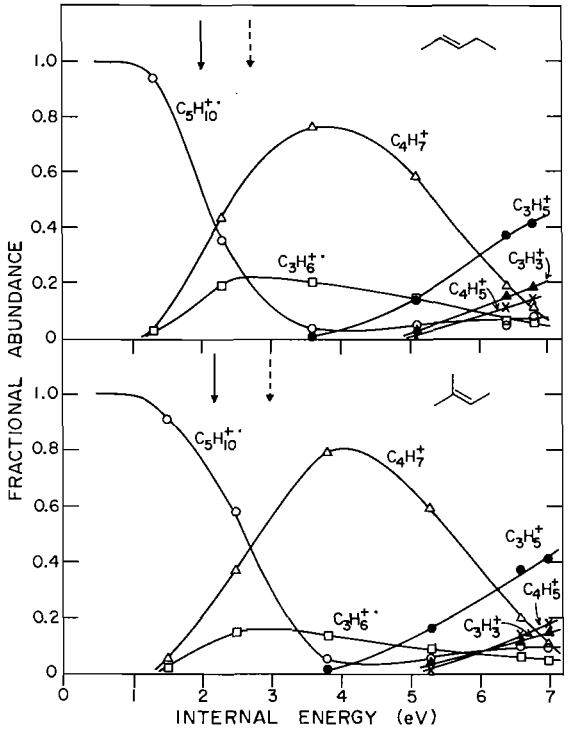

FIG. 3. Breakdown graphs for 2-pentene and 2-methyl-2-butene, see caption for Fig. 1.

arises by H^- abstraction although the reactant ion is unknown. It should be noted that the total additive ion signal was considerably lower in the CS_2/N_2–cyclopentane system than in any of the other systems studied. The lowest energy data for the cyclopentane breakdown graph are derived from the $COS^{+\cdot}$ charge exchange spectrum.

The discussion which follows is based on the energetics data for the major ions summarized in Table 1 and the fragmentation scheme, Scheme 1.

For each isomer the calculated appearance energy for formation of $C_3H_6^{+\cdot}$ is identical, within experimental error, with the measured appearance energy for $C_4H_7^+$. These appearance energies, translated into critical energies for fragmentation, are shown as the single solid arrows on the breakdown graphs. Also shown by dashed arrows are the critical energies for formation of $C_3H_5^+$ by the process indicated in Scheme 1.

With the exception of cyclopentane the ionization energies of the C_5H_{10} isomers are below $RE(CS_2^{+\cdot})$ and charge exchange to give $C_5H_{10}^{+\cdot}$ is the dominant reaction channel; however, in all cases low yields of $C_3H_6^{+\cdot}$ and/or $C_4H_7^+$ are observed despite the fact that the critical energies for formation of these fragments are 0.2 to 0.7 eV higher than the energy transferred by ground state $CS_2^{+\cdot}$. A minor participation of a higher energy species, possibly the $\tilde{A}^2\pi_\mu$ state of $CS_2^{+\cdot}$ is indicated.

The $COS^{+\cdot}$ ion has a recombination energy of 11.2 eV. This is above the IE of cyclopentane but almost coincident with the appearance energies of $C_3H_6^{+\cdot}$ and $C_4H_7^+$; charge exchange leads predominantly to formation of $C_5H_{10}^{+\cdot}$ with only minor fragmentation to form $C_3H_6^{+\cdot}$. For the isomeric acyclic olefins $RE(COS^{+\cdot})$ is above the appearance energies of $C_3H_6^{+\cdot}$ or $C_4H_7^+$ and extensive, structure dependent, fragmentation of the molecular ion is observed. The charge exchange mass spectra using $Xe^{+\cdot}$, $CO^{+\cdot}$, $N_2^{+\cdot}$, and $Ar^{+\cdot}$ as reagent ions all show low yields of molecular ions which are most readily interpreted in terms of a minor contribution from a species of low recombination energy; as discussed above, Penning ionization is a possibility for the rare gases and N_2. Another, less likely, explanation is deactivation of the $M^{+\cdot}$ ions by collision with the gas bath mole-

cules. At the source pressures used the bimolecular collision rate is $\sim 10^7\ s^{-1}$. It would be expected that most molecular ions, particularly those of higher internal energies, would fragment before undergoing a collision; hence collisional deactivation should play only a minor role.

Although the data points for the breakdown graphs are rather widely separated they have been connected by smooth curves; consequently fine structure will not be seen but only the major trends will be. This procedure also has the result that significant fragmentation of the molecular ion is indicated below the critical energy for fragmentation of the acyclic isomers. The graphs could have been drawn with the onset of fragmentation coinciding with the critical onset energies; this would not have altered the major features. The breakdown graphs summed over the appropriate internal energy distribution produced by electron impact should yield the electron impact mass spectra. Approximate internal energy distribution functions can be obtained from photoelectron spectra (39). The He I photoelectron spectra of the C_5 olefins (see that for 2-pentene in Fig. 4) show a highly structured band at threshold with a broad band having an onset ~ 2 eV above threshold which peaks between 3 and 4 eV and drops off sharply at higher energies. Comparison of this distribution with the breakdown graphs shows that ionization to the states below 1 eV will lead predominantly to molecular ion formation while ionization to the states above 2 eV will lead to the $C_4H_7^+$ and/or $C_3H_6^{+\cdot}$ fragment ion depending on the isomer. The major peaks in the 70 eV electron impact mass spectra (40) of the C_5H_{10} isomers are indicated in Table 2. Clearly the electron impact mass spectra are in accord with the breakdown graphs and the approximate energy distribution function suggested by the photoelectron spectra. The relatively low yield of $C_3H_5^+$ is to be expected in light of the small yield of molecular ions with internal energies >6 eV where this fragment dominates the breakdown graph. The onset of formation of $C_3H_5^+$ in the breakdown graphs is considerably higher than the calculated critical energy, most likely a reflection of a kinetic shift (2, 41).

Although the present study of C_5H_{10} isomers was designed primarily to assess the properties of the

charge exchange reagent systems developed rather than to solve significant problems of ion chemistry, some comment on the fragmentation of the different isomers appears desirable. Despite the fact that the critical energies for formation of $C_4H_7^+$ and $C_3H_6^{+\cdot}$ are identical, $C_4H_7^+$ is the dominant ion in the breakdown graphs for 2-pentene and the methylbutenes while $C_3H_6^{+\cdot}$ is the dominant ion in the breakdown graph of cyclopentane and is more important than $C_4H_7^+$ for 1-pentene. This differing behaviour is not reflected in the metastable ion intensity ratios which are similar for all isomers (22). The metastable ion intensity ratios reflect primarily the relative critical decomposition or fragmentation energies. By contrast, the relative intensities observed at higher internal energies in the breakdown graphs are influenced not only by the relative critical fragmentation energies but also by the energy independent terms (or so-called frequency factors) in the $k(E)$ expressions for the fragmentation reactions. It is clear that, for the $C_5H_{10}^{+\cdot}$ ions derived from cyclopentane and 1-pentene, the fragmentation reactions leading to $C_3H_6^{+\cdot}$ must have a more favourable frequency factor than the reactions leading to $C_4H_7^+$, while the converse is true for the other isomers. It follows that over the major part of the internal energy range studied the $C_5H_{10}^{+\cdot}$ ions derived from cyclopentane and 1-pentene are not isomerizing to a common structure (or mixture of structures) accessible to the remaining $C_5H_{10}^{+\cdot}$ molecular ions, although such an isomerization is indicated (22) for long-lived ions fragmenting in drift regions (metastable ions). It is interesting to note that the $C_5H_{10}^{+\cdot}$ ions derived from the cyclopentane and 1-pentene structures can yield $C_3H_6^{+\cdot}$ by relatively simple pathways, reactions [5] and [6],

[5] 
[6] 
which should have relatively favourable frequency factors. Deuterium labelling studies (42) of the electron impact induced fragmentation of cyclopentane and 1-pentene cannot be explained solely on the basis of these reactions; however, the EI studies represent a summation of reactions of molecular ions covering a wide range of internal energies and, hence, lifetimes and more than one fragmentation route could be involved. Charge exchange studies of labelled compounds should provide useful information on the energy, and lifetime, dependence of these routes. In principle, it should be possible to quantitate these arguments through calculation of the breakdown graphs by suitable application of absolute rate theory (5). However, such calculation requires a knowledge of the vibrational frequencies not only of the molecular ion but also of the transition states leading to $C_4H_7^+$ and $C_3H_6^{+\cdot}$. In view of our rudimentary knowledge of the transition state structures, let alone vibrational frequencies, calculations do not appear fruitful at the present time.

Finally, we note that the $COS^{+\cdot}$ charge exchange mass spectra of the C_5H_{10} isomers (Table 3) show large differences in the relative intensities of the $C_5H_{10}^{+\cdot}$, $C_4H_7^+$, and $C_3H_6^{+\cdot}$ ions. Clearly, with the exception of 2-methyl-1-butene and 2-pentene, the isomeric molecules can be identified by the charge exchange mass spectra obtained with reactant ions of recombination energies of ~11.2 eV. The differences are more pronounced than those observed in the 70 eV mass spectra, while both the metastable ion spectra (22) and the collisional activation spectra (23) are incapable of distinguishing among the isomers.

Experimental

The charge exchange mass spectra were obtained using a Du Pont 21-490 mass spectrometer equipped with a high pressure source. The ionizing electron energy was 70 eV with the repellers held at cage potential. The ion source temperature was ~100°C, with the C_5H_{10} samples being introduced from a heated inlet system at ~100°C.

Reagent gas mixtures were prepared by pressure–volume measurements. All reagent gases and liquids and C_5H_{10} isomers were commercially available samples of high purity.

Received October 22, 1980

This paper was presented at a Special Symposium "The Structure and Thermochemistry of Gaseous Ions", held in honour of Dr. F. P. Lossing of the National Research Council of Canada, during the Second Canadian Conference on the Gas Phase Chemistry of Ions, Trent University, June 5–8, 1980, and is dedicated to him on the occasion of his 65th birthday

SCOTT D. TANNER, JOHN M. GOODINGS and DIETHARD K. BOHME. Can. J. Chem. **59**, 1760 (1981).

The natural hydrocarbon ions $C_nH_x^{\pm}$ ($n \geq 2$, $x \geq 0$) present in premixed, fuel-rich, nearly sooting, CH_4–C_2H_2–O_2 flames at atmospheric pressure were studied as a probe of the early chemical stages of soot formation. Ion concentration profiles were measured mass-spectrometrically along the flame axis through the reaction zone into the burnt gas downstream. Total ionization profiles were examined for their dependence on both temperature and equivalence ratio, ϕ. Families of individual $C_nH_x^-$ negative ion profiles exhibit concentration peaks in three distinct regions; predominantly oxygenated ions occur upstream, giving way to moderately unsaturated hydrocarbon ions near the end of the reaction zone, leading to highly unsaturated carbonaceous ions further downstream. The concentrations of the downstream ions alternate with the parity of n, the even-n species being larger. Series of $C_nH_x^+$ positive ion profiles, for a given n, show profile peak positions which move steadily downstream with decreasing x, indicative of progressive dehydrogenation. The positive ion chemistry of these series is essentially independent of n. As ϕ is increased at constant temperature towards the sooting point, the concentrations of $C_nH_x^{\pm}$ ions increase while those of the oxygenated ions decrease; the positive ions show a relative enhancement of species having high values of n.

SCOTT D. TANNER, JOHN M. GOODINGS et DIETHARD K. BOHME. Can. J. Chem. **59**, 1760 (1981).

Dans le but d'évaluer la nature des réactions impliquées dans les stades préliminaires de la formation de la suie, on a étudié les ions des hydrocarbures naturels, $C_nH_x^{\pm}$ ($n \geq 2$, $x \geq 0$), présents à la pression atmosphériques dans des flammes de CH_4–C_2H_2–O_2, riches en combustible, prémélangés et pratiquement au point de former de la suie. On a mesuré les profils des concentrations des ions par spectrométrie de masse en fonction de l'axe de la flamme traversant la zone de réaction et procédant vers la section des gaz brûlés. On a examiné les profils d'ionisation totale tant au point de vue de l'influence de la température que du point de vue du rapport d'équivalence, ϕ. Les familles individuelles d'ions négatifs $C_nH_x^-$ présentent des pics de concentrations dans trois régions distinctes; près de la zone de réaction, on retrouve principalement des ions oxygénés et si on procède vers la zone des gaz brulés on retrouve d'abord des ions d'hydrocarbures modérément insaturés puis des ions carbonés fortement insaturés. Les concentrations des ions dans la zone des gaz brulés alternent avec la parité de n; les concentrations des espèces où n est pair sont plus élevées. Les séries de profils des ions positifs $C_nH_x^+$, pour une valeur donnée de n, indiquent que le profil des positions du pic se déplace d'une façon régulière vers la zone des gaz brulés lorsque n diminue; ceci indique une déshydrogénation progressive. La chimie des ions positifs de ces séries est pratiquement indépendante de n. Lorsqu'augmente ϕ, à température constante, vers le point de formation de suie, les concentrations des ions $C_nH_x^{\pm}$ augmentent alors que celles des ions oxygénés diminuent et les concentrations des ions positifs sont relativement plus élevés lorsque les valeurs de n sont élevées.

Introduction

Flame chemists are divided on the mechanism of soot formation in hydrocarbon combustion. There are proponents of both an ion-based synthesis of carbon and a neutral chemistry scheme. Most of the research which has been done on soot has been directed at its phenomenology in the burnt gas (1). This is too late in the flame to gain information about the initial chemistry of soot formation. One technique with which it is possible to study the reaction zone of a flame involves the measurement of ion concentrations and their axial profiles with a flame-ion mass spectrometer. An understanding of the relevant ion–molecule reactions then allows the flame-ion data to be interpreted to give insight into both the ionic and the neutral chemical evolution of the flame.

Detailed studies of the ionic composition of flames have very recently been reported for fuel-rich methane combustion by Goodings *et al.* (2, 3) and for fuel-rich and sooting acetylene and ethylene flames by Tse *et al.* (4) and Delfau *et al.* (5). In each of these works particular attention was drawn to the observation of high-mass carbonaceous ions in the burnt gas just downstream of the luminous flame front. Goodings *et al.* (2, 3) measured concentration profiles for all detectable ions of both polarities for $m/e < 100$ amu. The chemistry of their formation, interconversion, and loss was discussed. The observation of carbonaceous positive ions for $m/e < 200$ amu in the reaction zone of a

fuel-rich acetylene flame was taken by Tse *et al.* (4) to indicate early pyrolysis of the fuel. The novel application of a 360° magnetic mass analyzer by Delfau *et al.* (5) permitted the observation of positive ions up to $m/e \simeq 7000$ amu downstream in sooting flames.

The present work was undertaken in order to provide some insight into the mechanisms of formation of these carbonaceous ions in the belief that they constitute a source of information about the early chemical stage of soot formation. The evolution of the flame-ion distribution was monitored through the reaction zones of a fuel-rich methane–oxygen flame and a nearly-sooting flame with acetylene added to the methane fuel. The excellent spatial resolution provided by the flame-ion mass spectrometer employed for these studies permitted the ion distribution of these flames to be mapped in detail. Additional measurements were made to record the response of this distribution when sooting conditions are approached.

The experimental results of this investigation and a preliminary discussion are presented in this paper. A considerable range of observations is organized in summary form at the end of the paper. The detailed interpretation of these data will be discussed in a later publication.

Experimental

The ion concentration data were obtained with a flame-ion mass spectrometer which has been described previously (2). A fuel-rich premixed, laminar flame was stabilized vertically on a simple, cylindrical, quartz burner at atmospheric pressure. The flame was conical with a base diameter of about 4 mm and a height of about 6 mm with a rounded tip. It was surrounded by a flowing argon shield to exclude atmospheric air. Compressed methane and oxygen of CP grade (>99% CH_4, >99.6% O_2) and acetylene of Purified grade (>99.6% C_2H_2 dissolved in acetone) were used directly from the cylinders without further purification.

Two flames were studied in detail in this work. One of these was a pure methane–oxygen flame having an equivalence ratio $\phi = 2.15$ (alternatively, a carbon/oxygen ratio C/O = 0.538). Ionic data for this flame have been reported previously (2, 3). A more fuel-rich methane flame with added acetylene having the same burnt-gas temperature as measured with a pneumatic probe (6) was also studied. The equivalence ratio for such a mixed-fuel flame of unburnt composition CH_4:C_2H_2:$O_2 = a:b:c$ is given by $\phi = (4a + 5b)/2c$ (C/O = $(a + 2b)/2c$). A more fuel-rich flame is cooler than another one nearer to stoichiometric composition, whereas C_2H_2–O_2 mixtures burn at higher temperatures than do CH_4–O_2 mixtures. Therefore, by properly choosing the CH_4–C_2H_2 fuel mixture, a fuel-rich flame may be burned having the same temperature as a less fuel-rich pure CH_4–O_2 flame. It was found that a flame having $\phi = 2.47$ (C/O = 0.696) and containing 17.7% C_2H_2 in the fuel had a temperature in the burnt gas at a distance $z = 3$ mm downstream of the reaction zone which was the same as that measured at the same point for the methane–oxygen flame with $\phi = 2.15$. The flames were of the same shape and size so that the distance scales upstream of, and within, the reaction zones were comparable. A faint yellow luminescence from soot particles was observed for the more fuel-rich flame.

The burner itself was mounted on a motor-driven carriage, and the flame axis was carefully aligned with respect to the mass spectrometer sampling orifice. A voltage proportional to the calibrated displacement of the burner carriage was fed to the *X*-axis of an *XY* recorder such that 0.1 mm along the flame axis corresponded to either 1.00 cm or 0.75 cm on the recorder. In a typical experiment, the quadrupole mass filter was tuned to a specific m/e and the output from an electrometer connected to a Faraday cage was coupled to the *Y*-axis of the *XY* recorder. In this manner, the concentration profile of the ion species corresponding to the specified m/e was recorded as a function of distance axially through the tip of the flame. Total ionization profiles were obtained in the same fashion by removing the dc voltage from the mass filter. The pressure in the second vacuum chamber of the mass spectrometer was monitored with an ionization gauge and displayed on a second *XY* recorder. The pressure profile derived in this manner showed a minimum corresponding to the downstream edge of the reaction zone. This minimum was adopted as a reproducible origin ($z = 0$ mm) *in the flame* for the distance scale of the ion profiles.

In the experiments reported previously from this laboratory, the flame ions were sampled through a pinhole 0.1 mm in diameter in a platinum–iridium disc welded into a water-cooled stainless-steel mounting. The flat disc against which the flame burned was approximately 2.0 mm in diameter. For the present experiments, this sampling nozzle was replaced with a thin-walled chromium cone which had a sharp-edged orifice of diameter 0.10 mm at its apex and a total tip diameter of approximately 0.28 mm. This sampling cone was made in a manner similar to that suggested by Burdett and Hayhurst (7). The change in orifice design considerably decreased the thickness of the thermal/momentum boundary layer which covers the sampling plate as discussed in the work of Hayhurst and co-workers (8, 9). It is known that the gas sample may be chemically perturbed during passage through the boundary layer. One reaction which proceeds in this region is the three-body hydration of H_3O^+ (9). In the present study, the ratio $R = [H_3O^+ \cdot H_2O]/[H_3O^+]$ was observed to decrease from a value of $R = 0.34$ obtained with the "old" Pt/Ir sampling disc to $R = 0.09$ with the Cr nozzle. This may be taken as evidence of a considerable decrease in the thickness of the boundary layer. An additional advantage of using the sharp-tipped Cr nozzle over the blunt Pt/Ir disc is an increased spatial resolution. This may be understood by making reference to the flow streamline calculations of Hayhurst *et al.* (8) for a conical nozzle similar to that employed in the present study. The tip of this Cr nozzle is blunt over a radius which is less than the stagnation radius. The Pt/Ir disc, on the other hand, is considerably more blunt causing a thicker momentum boundary layer; this, in turn, causes an increase in the stagnation radius. As a result, some of the ions included in the sample drawn through the Pt/Ir nozzle are taken from a region further from the flame axis than are included in the sample passing through the Cr nozzle. When sampling upstream in a conical flame, gas originating at a point further from the flame axis can derive from a region in the flame downstream of the sampling point, thereby decreasing the spatial resolution.

Differences between the ion profiles presented here and those reported earlier for the same $\phi = 2.15$ flame (2, 3) may be ascribed to these changes in sampling conditions. In fact, the maximum total positive ion signal detected with the two different sampling nozzles was the same within experimental error, although the maximum negative ion signal decreased by a

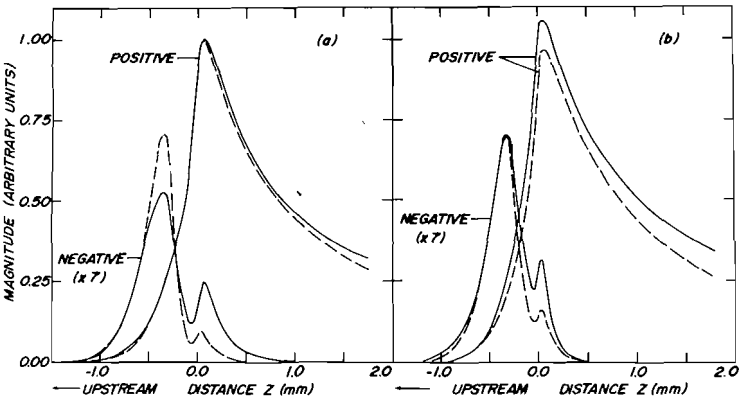

FIG. 1. Total positive and negative ionization profiles: (*a*) for two flames having similar adiabatic flame temperatures, T_{ad} but different equivalence ratios, ϕ. Dashed curves: $\phi = 2.15$ (C/O = 0.538), no C_2H_2, $T_{ad} = 2455$ K. Solid curves: $\phi = 2.47$ (C/O = 0.696), 17.7% C_2H_2, $T_{ad} = 2443$ K. % C_2H_2 refers to the percentage in the fuel; (*b*) for two CH_4–C_2H_2–O_2 flames having similar ϕ's but different values of T_{ad}. Dashed curves: $\phi = 2.22$ (C/O = 0.560), 1.1% C_2H_2, $T_{ad} = 2401$ K. Solid curves: $\phi = 2.23$ (C/O = 0.587), 7.1% C_2H_2, $T_{ad} = 2488$ K.

factor of 3.5 when the Cr nozzle was used (c.f. Fig. 1(*a*) here with Fig. 1(*b*) of ref. 3). This latter decrease is expected because the boundary layer cooling is reduced when sampling with the new nozzle. Consequently, negative ion equilibria shift in the endothermic direction causing electron detachment from negative ions; the free electron concentration is enhanced at the expense of the negative ion concentration. It should be clearly understood, however, that all of the data considered hereafter, including those for the $\phi = 2.15$ flame, were obtained using the new Cr sampling nozzle.

A quadrupole mass filter discriminates to some extent against the transmission of larger *m/e* ions. The effect is more pronounced when the resolving power of the filter is increased. For most of the experiments reported here, a relatively high resolving power was employed in order to distinguish between neighbouring ions of high *m/e*. For this reason, care was taken to assure that the resolving power was maintained constant for all the experiments involving relative magnitudes. In this way, the mass discrimination profile was maintained constant, and trends in the relative magnitudes of ion signals at the same mass numbers in different flames are still valid. In a few instances, the resolving power was lowered either to gain an appreciation for the extent of the mass discrimination or to increase the sensitivity for the larger *m/e* ions.

In order to achieve a consistent set of ion signals, a reference ion profile was recorded frequently during the experiments. The magnitude of each profile was normalized to the maximum signal measured for the total ionization profile of the same polarity. These normalized ion signal magnitudes (all < 1.0) are referred to as *relative magnitudes*, although those for positive ions have been multiplied by 10^4 and those for negative ions by 10^3 to eliminate cumbersome negative powers of ten. Magnitude ratios for individual ion profiles for different flames may be obtained by using the ratio of the peak magnitudes of the total ionization profiles as a multiplier applied to the relative magnitudes. The relevant peak magnitudes are given in Fig. 1.

Results and Preliminary Discussion

Total Ionization Profiles

Total ionization profiles for the two flames which were studied in detail in this work are given in Fig. 1(*a*). The phenomenology of the profiles for the flame having $\phi = 2.15$ (C/O = 0.538) has been discussed previously (3); the improved spatial resolution is apparent in the negative ionization profile whose minimum between the two peaks earlier had been hidden when sampling with the Pt/Ir nozzle. The profiles may be contrasted with those given in Fig. 1(*b*) for two flames which have similar equivalence ratios but distinctly different adiabatic flame temperatures.

Several observations can be made from these results. The first is that the peak magnitude of the total positive ionization curve increases with increasing flame temperature. Such a trend is consistent with an increase in the rate of chemi-ionization with temperature.

Secondly, the magnitude of the upstream peak of the negative ionization profile seems to depend mainly on the equivalence ratio of the unburnt gas. Several reasons for this dependence may be envisaged. The decrease with increasing ϕ (or C/O ratio) may result from a decreased rate of attachment of electrons as would result, for example, from a decrease in the concentration of O_2. Alternatively, the rate of loss of negative ions may be enhanced by an increase in the non-equilibrium concentration of radicals, especially H, which participate in ion–radical associative detachment reactions.

Finally, the magnitude of the downstream maximum of the total negative ionization profile is seen to increase considerably with an increase in both ϕ (or C/O ratio) and the flame temperature. This behaviour is consistent with an increase in the rate of electron attachment to hydrocarbon neutrals, for example polyacetylenes or their radicals, whose

concentrations increase rapidly with both equivalence ratio and temperature.

Downstream Ion Spectra

A more detailed view of the ionic composition of the flame is provided by measurements of the ion mass spectra. Figure 2 presents the spectra measured at a distance $z = 0.05 \pm 0.02$ mm downstream of the reaction zone of the flame with $\phi = 2.47$. At this point in the flame the total positive and negative ionization profiles maximize. It should be noted that the sampling position is referenced to an origin within the flame itself. Such a procedure is necessary given the high spatial resolution of this method. Our experience has shown that the observed mass spectra can be extremely sensitive to small changes in the sampling position within, and downstream of, the reaction zone.

Negative Ions: It is significant that the dominant negative ions in this fuel-rich flame are the highly unsaturated hydrocarbons $C_nH_x^-$ with $n \geq 2$ and $x \leq 5$. Operation of the mass filter at low resolving power permitted the detection of groups of ions spaced by roughly 12 amu having values of n up to and including 10. These are shown in Fig. 2(*a*) which, for the most part, gives the mass numbers of the maximum signals for the various ion groups. The individual ions which compose these broad groups were resolved at high resolving power, as shown in Fig. 2(*b*). It was noticed that the ions corresponding to C_2H^- and C_4H^- have significantly higher concentrations than do the ions with odd values of n. In fact, this alternation of intensity with the parity of n was observed all the way up to $n \sim 10$ in the experiments with low resolving power, and is consistent with the earlier observations reported by Green (10). This alternation attests to the importance of polyacetylenes or their radicals at this point in the flame. Nearly all of the hydrocarbon ions are more abundant in the more fuel-rich flame.

Positive Ions: The groups of $C_nH_x^+$ ions observed in the positive ion spectrum shown in Fig. 2(*c*) are remarkable for their similarity to one another in structure. The lower-x, more unsaturated components of each family seem to be strongly preferred; the largest signal in each family occurs for $x = 3$. Since the spectra for the different families are similar, it would seem that the chemistry of the $C_nH_x^+$ ions is essentially independent of n. The fall-off in the magnitudes of the $C_nH_x^+$ ion groups with increasing n may reflect to some extent an increase in mass discrimination of the quadrupole mass filter with increasing mass number at the high resolving power used to obtain these data. Consequently, this overall trend in the magnitudes of the $C_nH_x^+$ ion signals with n is not included in the summary of results given at the end of the paper. A comparison with the spectrum obtained at the same position in the more fuel-lean ($\phi = 2.15$, no C_2H_2) flame (not shown) revealed several other noteworthy features (11). Ions corresponding to $n \leq 2$ and oxygenated species have higher concentrations in the flame with $\phi = 2.15$, whereas ions corresponding to $n > 2$ seem to be more abundant in the more fuel-rich flame. The degree of this enhancement increases with increasing n. Furthermore, within a group of given n, there is a relative enhancement of ions with small x.

Reaction Zone

A view of the evolution of the ionic composition requires measurements of the axial concentration profiles for the individual ion species. In this section we present profiles measured with the intent to characterize their early behaviour upstream in the reaction zone.

Positive Ions: Figure 3 shows normalized profiles measured for the $C_4H_x^+$ family of ions from 49 to 57 amu. There is a clearly-resolved progression downstream from high to low mass ions. This behaviour is exemplary of that observed for the other $C_nH_x^+$ families.

More than 70 individual positive ion concentration profiles were measured for each flame studied. This vast amount of detailed information is unwieldy to manipulate. The data for the flame with $\phi = 2.47$ are presented in Fig. 4 in such a manner as to provide a simplified overview. The mass of each ion is plotted against the position (distance coordinate, z) at which the corresponding profile was observed to maximize. We have called such a plot a profile–peak–position or 3P plot. It provides an appreciation for the spatial relationships of the various ion concentration maxima at a glance. Similar data for the $\phi = 2.15$ flame are available (11). Of course, the details of the shapes of the profiles are necessarily lost in such a treatment. In addition to the profile peaks noted in Fig. 4, several profiles displayed broad peaks with maxima well downstream, given in Table 1. These involve the protonation of major combustion products in the burnt gas (H_2O, CO, CO_2 and their isotopic derivatives; a small amount of nitrogen is present from air entrainment, which leads to NH_3).

In the interpretation of this 3P plot it should be remembered that the precise locations and magnitudes of the profile maxima are intimately related to

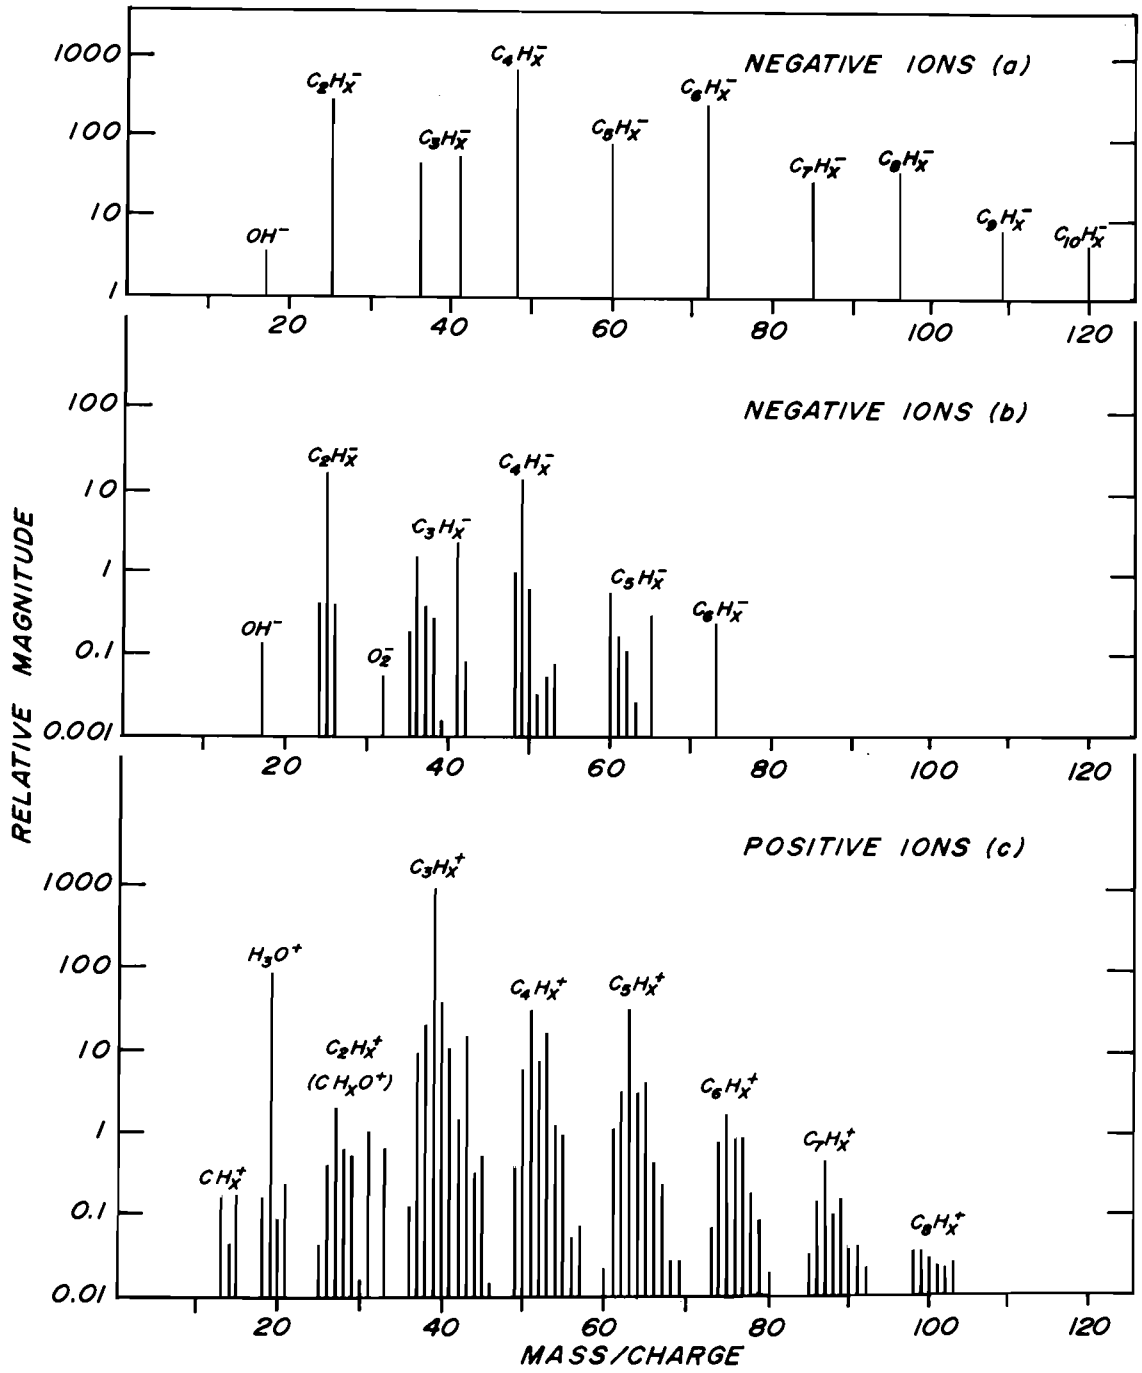

FIG. 2. Ion mass spectra recorded at a distance $z = 0.04 \pm 0.02$ mm downstream of the reaction zone of a CH_4–C_2H_2–O_2 flame (ϕ = 2.47, 17.7% C_2H_2). (*a*) Negative ions, low resolving power. (*b*) Negative ions, high resolving power. (*c*) Positive ions, high resolving power.

the rates of the formation and loss processes of the ions concerned. A large relative magnitude in the peak concentration of an ion may indicate either a relatively lower reactivity of the ion or a more prolific source.

Figure 4 shows eight distinct series of concentration maxima. The members of each series shift monotonically downstream with decreasing amu. Each series originates well upstream near the beginning of the reaction zone with its highest amu

TABLE 1. Peak positions of positive ion concentration profiles which showed broad maxima downstream of $z = 0.4$ mm

amu	Assignment	Peak position[a]	Relative magnitude
18	H_2O^+ (NH_4^+)	>3.3	>3.1
19	H_3O^+	2.68±0.08	384
20	H_2DO^+	2.60±0.10	0.31
21	$H_3{}^{18}O^+$	2.70±0.08	0.82
29	CHO^+	2.59±0.09	0.80
37	$H_3O^+ \cdot H_2O$	2.93±0.09	20.5
45	CHO_2^+	0.72±0.08	0.70
46	$^{13}CHO_2^+$, CDO_2^+, $CH^{17}O^{16}O^+$	0.68±0.09	0.02

[a]Measured in mm with respect to the origin ($z = 0$) at the end of the reaction zone.

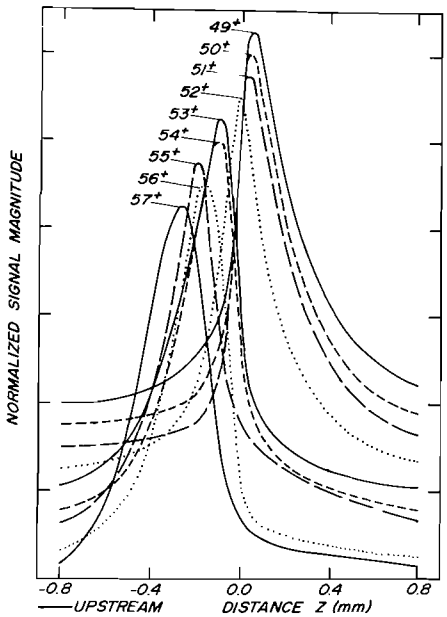

FIG. 3. Positive ion profiles observed for the ions from 49 to 57 amu. The magnitudes of the profiles have been normalized, and the zero baseline has been displaced vertically by a 1/4 scale interval per amu. These data were obtained for the flame with $\phi = 2.22$, 1.1% C_2H_2, $T_{ad} = 2401$ K.

members, and ends downstream at about $z = 0.1$ mm where its lowest amu members are gathered. The series are separated from each other by approximately 12 amu.

The relative magnitudes of the peak concentrations alternate quite regularly within each series, with those for ions of odd amu being appreciably larger than those for even amu ions. Over the limited mass range of any one of the eight series, mass discrimination effects are not significant. On the other hand, mass discrimination may play a significant role in the apparent decay in the relative magnitudes observed for the eight series, particularly beyond about 60 amu, at the high resolving power employed for these measurements. Therefore, this latter trend is not included in the summary of results given at the end of the paper. The actual concentrations of the higher mass ions may be quite considerable and comparable to the concentrations of the lower mass ions.

With the exception of a number of ions which may constitute sub-series of empirical formulae $C_nH_xO^+$ corresponding, for example, to protonated alcohols and aldehydes, the majority of the detected ions appear to be of the type $C_nH_x^+$ with n taking the values 1 through 8 and x taking values in the range 0 to $(2n + 3)$. Each value of n denotes a separate series for which the peak positions of the individual members are determined by the value of x. The spatial evolution of each series reflects a stepwise dehydrogenation leading to the highly unsaturated carbonaceous products at the end of the reaction zone. Presumably the higher-n homologues of these series ($n > 8$) are also present, but these were beyond the range of detection.

Negative Ions: The negative ion 3P plot for the flame with $\phi = 2.47$ is given in Fig. 5. It shows rather less structure than that for the positive ions and provides less insight into the assignment of the corresponding ion identities. Nearly all of the negative ion profiles show a maximum well upstream near the beginning of the reaction zone. All of these subsequently show a rather abrupt decrease with many recovering to a secondary maximum just downstream of the reaction zone. Some of these profiles show one additional maximum in the "valley" of the total ionization profile.

The larger of the upstream negative ion peaks are likely to be associated with oxygenated ions such as CHO_2^- and $C_2H_5O^-$ (45 amu), O_2^- (32 amu), $CHCO^-$ (41 amu), CO_3^- (60 amu), HCO_3^- (61 amu), and CH_2CHO^- (43 amu). One exception is the ion at 25 amu corresponding to C_2H^-.

The major downstream ions are readily identified as very highly unsaturated hydrocarbons. The most abundant of these are the acetylenic species

C_2H^- (25 amu) and C_4H^- (49 amu) with some C_6H^- (73 amu). The downstream odd-number carbon ion signals appear largest for $x = 0$ and 5; i.e., for C_3^- (36 amu), $C_3H_5^-$ (41 amu), and C_5^- (60 amu), $C_5H_5^-$ (65 amu).

The species C_2H^- and C_4H^- also show strong peaks in the intermediate valley region (as do their ^{13}C isotopic counterparts at 26 and 50 amu). The ion at 41 amu, which has been assigned as $CHCO^-$ upstream and as $C_3H_5^-$ downstream, also shows a major peak in this region. The remaining ions in the valley show much smaller maxima; interpreted as $C_nH_x^-$, these ions may represent moderately unsaturated intermediates in the overall dehydrogenation which appears to proceed through the reaction zone.

Variations with Fuel Composition

A comparison of the 3P plots for the flame having $\phi = 2.47$ (Figs. 4 and 5) with those for the flame having $\phi = 2.15$ (not shown) exhibited some interesting variations in both peak positions and magnitudes, albeit the gross features were quite insensitive to the change in equivalence ratio (11). As regards changes in peak positions, it was noticed that the upstream ion peak positions shifted downstream while the downstream ion peak positions shifted upstream with the change to the more fuel-lean flame. These features may reflect a real change in the width of the reaction zone resulting from changes in the reaction rates and burning velocity, and a change in the flame geometry. For the most part, however, these changes were only of the order of 0.05 mm. In general the peak magnitudes changed by not more than a factor of 5, although for a few ions changes as large as a factor of 20 were observed.

Of course, for a full appreciation of changes due to a change in fuel composition, there is no substitute for the profiles themselves. For example, the 3P plots do not contain information about the actual shapes of the peaks which reflect rates of formation and loss. Most of the observed peaks are skewed: the upstream peaks upstream and the downstream peaks downstream.

Some of the differences in shapes as well as peak magnitudes and positions observed with the change in fuel composition are illustrated in Figs. 6, 7, and 8 for several positive and negative ion profiles. It can be readily seen that the shapes in fact do not change dramatically over the range of conditions adopted in this study. This attests to the usefulness of the 3P-plot treatment introduced earlier.

As a general observation, the peak magnitudes of ions upstream decrease whereas the downstream peak magnitudes increase. This is illustrated for positive ions in Fig. 6. The increase downstream in the ions at mass 49 amu (C_4H^+) and 61 amu (C_5H^+) would appear to be associated with the increase in the acetylene concentration. The reason for the decrease in the upstream profile at 61 amu is less clear. A likely cause is proton transfer from protonated acetic acid to acetone present as an impurity in the added acetylene. The dramatic decrease in the intermediate CH_3^+ peak at 15 amu no doubt is due to its rapid reaction with C_2H_2 yielding $C_3H_3^+$ (12). A corresponding result is recorded for negative ions in Fig. 7. Here the downstream profiles at 25 and 60 amu (C_2H^- and C_5^-) increase with the addition of acetylene to the fuel. Of the upstream ions, C_2H^- increases at the expense of OH^- (and O^-, not shown) which is known to react with acetylene (13). The decrease in the upstream portion of the profile at 60 amu (CO_3^-) is likely a result of the depletion of its source ion, O^-.

As regards the individual ion profiles, only a few showed shifts in peak positions which were significantly larger than the small shifts of ± 0.05 mm discussed earlier. Notable amongst these are the profiles for H_3O^+, its hydrate $H_3O^+ \cdot H_2O$ and HCO^+. The last of these is shown in Fig. 8, where its peak is seen to shift by 1.79 ± 0.18 mm. The sharp peak upstream which does not show a shift may be identified as $C_2H_5^+$. The late downstream rise of HCO^+ may be related to the unusual persistence of $C_3H_3^+$. These two ions are believed to be coupled through the reaction (14)

$$C_3H_3^+ + O \rightleftharpoons HCO^+ + C_2H_2$$

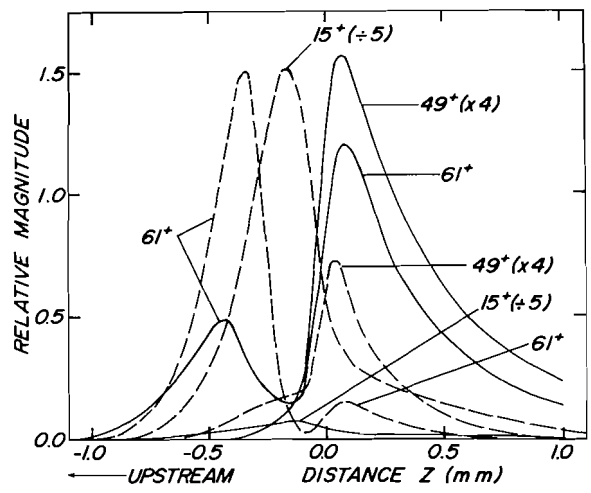

FIG. 6. A comparison of selected positive ion profiles which show significant changes in peak magnitudes measured for the flames having $\phi = 2.47$ (solid curves) and $\phi = 2.15$ (dashed curves).

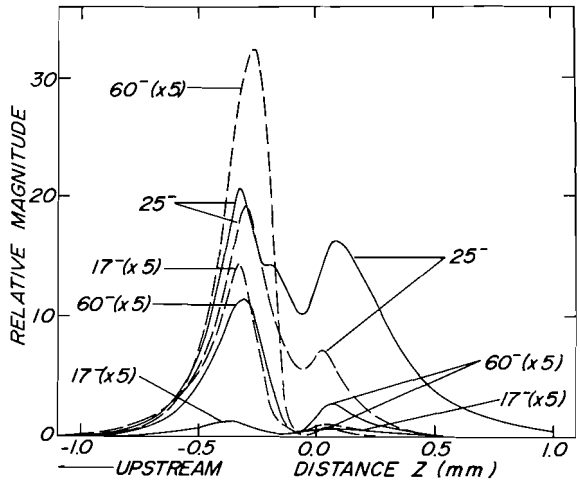

FIG. 7. A comparison of selected negative ion profiles which show significant changes in peak magnitudes measured for the flames having $\phi = 2.47$ (solid curves) and $\phi = 2.15$ (dashed curves). It should be noted that the peak magnitudes have been normalized to the maximum signal measured for the total negative ionization profile (see Fig. 1(*a*)).

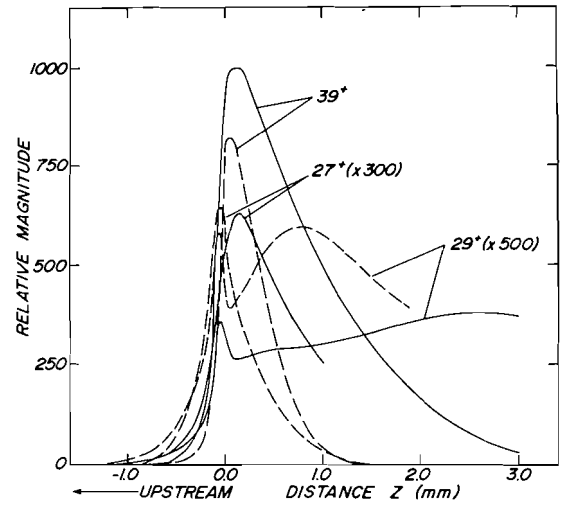

FIG. 8. A comparison of selected positive ion profiles which show significant changes in peak positions measured for the flames having $\phi = 2.47$ (solid curves) and $\phi = 2.15$ (dashed curves).

whose reverse rate will be enhanced by the added acetylene. Finally, the $C_2H_3^+$ profile at 27 amu shows the transition from a symmetric profile typical of intermediate ions to a more skewed profile characteristic of the more persistent ions downstream of the reaction zone. The small concomitant shift reflects the continued protonation of acetylene.

Summary

A large amount of experimental data has been presented in this report employing improved methods for the measurement of the flame-ion concentration profiles with high spatial resolution and novel approaches for their analysis. The following list summarizes many of the observations made in this study.

1. The spatial resolution of ion profile data is increased by the use of a conical sampling nozzle compared with a nozzle of more blunt geometry, for the same-sized orifice.

2. The peak magnitude of the total positive ionization curve increases with an increase in temperature; chemi-ionization has a positive temperature dependence (T-dependence).

3. The total negative ion profile is double-peaked. For fuel-rich flames, the magnitude of the upstream peak decreases with increasing equivalence ratio (negative ϕ-dependence) and has little T-dependence. The magnitude of the downstream peak shows both positive ϕ- and T-dependence.

4. The negative ion profile peaks for $C_nH_x^-$ ions appear in three distinct regions. (*i*) Oxygenated anions are found upstream; C_2H^- is an exception. (*ii*) Very highly unsaturated hydrocarbon ions are observed downstream peaking just beyond the reaction zone. Their concentrations alternate with the parity of n, the even-n species being larger. This implicates acetylene or its polymers in the anionic chemistry. For even n, the most abundant carbonaceous species are the acetylenic anions C_2H^-, C_4H^-, C_6H^-, ... with $x = 1$. For n odd, the most abundant tend to be those with $x = 0$ and 5. (*iii*) Moderately unsaturated hydrocarbon ions seem to be present in the intermediate region.

5. The positive ion peaks are observed to form a number of series through the flame reaction zone. (*i*) Each series is defined by the value of n, and the profile peak positions evolve downstream through the flame front with decreasing values of x, amounting to progressive dehydrogenation. (*ii*) The peak magnitudes tend to be larger for small values of x; the largest signal in each series is obtained for $x = 3$. Within each series, there is a fairly regular alternation in magnitude with x; the larger peaks are associated with odd values of x. (*iii*) The positive ion chemistry of these series seems to be essentially independent of the value of n.

6. As ϕ of a fuel-rich flame is increased at constant temperature towards the sooting point by the addition of acetylene, a number of changes occur. (*i*) The concentrations of the unsaturated positive and negative hydrocarbon ions within and

For personal use only.

downstream of the reaction zone increase; the upstream (oxygenated) ions decrease. (*ii*) The profile peaks due to hydrocarbon ions spread out somewhat both upstream and downstream; possibly the thickness of the reaction zone is increased. (*iii*) The shapes of these profiles do not change greatly, except that they become more skewed in the downstream direction; a key factor to be considered is chemical reactions involving acetylene. (*iv*) The concentrations of positive ions having high n-values are enhanced relative to those of low n; the degree of this enhancement appears to increase with increasing n. Also, within a series of given n, there is a relative enhancement of ions with small x.

This paper was presented at a Special Symposium "The Structure and Thermochemistry of Gaseous Ions", held in honour of Dr. F. P. Lossing, of the National Research Council of Canada, during the Second Canadian Conference on the Gas Phase Chemistry of Ions, Trent University, June 5–8, 1980, and is dedicated to him on the occasion of his 65th birthday

G. I. MACKAY, H. I. SCHIFF, and D. K. BOHME. Can. J. Chem. **59**, 1771 (1981).

The flowing afterglow and selected-ion flow tube (SIFT) techniques have been applied in room-temperature measurements of the kinetics for proton-transfer reactions of ethane with HeH^+, H_3^+, N_2H^+, CH_5^+, N_2OH^+, and HCO^+. The fragmentation of $C_2H_7^+$ was followed over a range in excess energy of 100 kcal mol^{-1}. Equilibrium constants were measured at low excess energies for the proton-transfer reactions with HCO^+ and N_2OH^+. The latter provided values for the proton affinity of ethane and $\Delta H_f^0(C_2H_7^+)$ and, indirectly, values for the proton affinity of ethylene and $\Delta H_f^0(C_2H_5^+)$. Additional measurements of the kinetics of the reactions of C_2H_6 with H^+ itself, O^+, OH^+, and H_2O^+ provided insight into the competition between proton-transfer and other reaction channels and the fragmentation associated with the $C_2H_6^+$ ion.

G. I. MACKAY, H. I. SCHIFF et D. K. BOHME. Can. J. Chem. **59**, 1771 (1981).

Opérant à la température ambiante, on a utilisé les techniques de la lueur d'écoulement et de tube à écoulement d'ions sélectionnés (TEIS) pour mesurer la cinétique des réactions de transfert de proton de l'éthane avec HeH^+, H_3^+, N_2H^+, CH_5^+, N_2OH^+ et HCO^+. On a contrôlé la fragmentation de $C_2H_7^+$ sur une large étendue d'énergie en excès de 100 kcal mol^{-1}. On a mesuré les constantes d'équilibre en utilisant de faibles énergies en excès pour les réactions de transfert du proton avec HCO^+ et N_2OH^+. Ces dernières permettent de déterminer les valeurs de l'affinité de l'éthane pour le proton et le $\Delta H_f^0(C_2H_7^+)$ et, indirectement, les valeurs de l'affinité de l'éthylène pour le proton ainsi que la $\Delta H_f^0(C_2H_5^+)$. Des mesures additionnelles des cinétiques des réactions du $C_2H_6^+$ avec H^+ lui-même, O^+, OH^+ et H_2O^+ fournissent de nouvelles connaissances quant à la compétition entre le transfert de proton et d'autres voies de réaction et de la fragmentation associée avec l'ion $C_2H_6^+$.

[Traduit par le journal]

Introduction

The low stability of $C_2H_7^+$ against dissociation into $C_2H_5^+$ and H_2 has presented a special challenge to the determination of the tendency for ethane to gain a proton. Here we report a systematic investigation of the kinetics and energetics for the protonation of ethane by reactions of the type:

$$[1] \quad AH^+ + C_2H_6 \rightarrow [C_2H_7^+]^* + A \xrightarrow{} C_2H_5^+ + H_2$$

We adopted the approach which we have recently applied to studies of the dissociative protonation of other molecules such as nitromethane (1), formic and acetic acid (2), and several formate and acetate esters (3). The method involves the preparation of a variety of acids, AH^+, by prereaction in a Flowing Afterglow or Selected Ion Flow Tube apparatus, which are then invoked systematically in proton-transfer reactions of type [1]. The concomitant variation in excess energy allowed the nature and extent of the fragmentation of $C_2H_7^+$ to be monitored in a controlled fashion as a function of the degree of its chemical activation by AH^+. Furthermore, several relatively mild acids were identified for which the fragmentation was minimal. Their reactions with ethane permitted the involvement of $C_2H_7^+$ in an equilibrium state and consequently the determination of the relative proton affinity of ethane from equilibrium constant measurements (4). An extension of these studies to radical cations and H^+ itself introduced still other competing channels together with the fragmentation associated with the $C_2H_6^+$ ion.

Experimental

The experiments were carried out using both the Flowing Afterglow, FA, and Selected Ion Flow Tube, SIFT, techniques for which details of construction and methods of operation have been described elsewhere (4, 5). The equilibrium measurements were made with the conventional flowing afterglow using H_2 as the carrier gas. N_2OH^+ and HCO^+ ions were produced from H_3^+ according to the following rapid reactions:

$$[2] \quad H_3^+ + N_2O \rightarrow N_2OH^+ + H_2$$

$$[3] \quad H_3^+ + CO \rightarrow HCO^+ + H_2$$

The H_3^+ itself was established as usual by the rapid reaction of H_2 with H_2^+ produced by electron impact on the carrier gas in the region of the electron gun. The ethane was added sufficiently downstream of the ion production region to ensure that reactions [2] and [3] had gone to completion and that the N_2OH^+ and HCO^+ ions had thermalized to the ambient temperature of 298 ± 2 K.

Except for the reaction of ethane with CH_5^+ which was

followed in a H_2 carrier in the flowing afterglow mode, the kinetic measurements were carried out with the apparatus in the SIFT configuration. Helium was employed as the carrier gas in the reaction region while both H_2 and He were used in the source region at total pressures of ca. 0.5 Torr. CH_5^+ was produced in the manner of reactions [2] and [3]. H_3^+, HCO^+, and N_2H^+ were produced in the SIFT source as in the FA mode. The OH_x^+ ions were produced from water vapour introduced into a SIFT source containing a weak He plasma.

The purities of the gases have been given previously (6) except that for ethane which was 99.9% (Matheson Research Grade).

Results

The data analysis associated with the determination of rate constants and equilibrium constants has been described in detail elsewhere together with the various sources of error (4, 5).

H^+, HeH^+, H_3^+

With the SIFT quadrupole tuned to H_3^+ both H^+ and HeH^+ were observed to be produced in the reaction tube containing helium buffer at pressures in the range 0.357 to 0.50 Torr. The translational energy acquired by the H_3^+ apparently was sufficient to cause some collisional dissociation:

[4*a*] $H_3^+ + He \rightarrow H^+ + H_2 + He$

and to overcome the endothermicity of the proton-transfer reaction:

[4*b*] $H_3^+ + He \rightarrow HeH^+ + H_2$

Figure 1 shows the response of these ions to the addition of ethane into the reaction region sufficiently downstream to allow for their thermalization. All three are rapidly replaced by the ions $C_2H_3^+$, $C_2H_4^+$, and $C_2H_5^+$ in a distribution with respect to the three individual reactant ions which is not readily discernable from the data. The $C_2H_3^+$ is known to react further with ethane to produce $C_2H_5^+$ (7). There was no evidence for the formation of $C_2H_7^+$ (< 1%).

$C_2H_5^+$ is the only one of the three observed product ions which may be formed exothermically by the reaction of ethane with thermalized H_3^+, so that we may write:

[5] $H_3^+ + C_2H_6 \rightarrow C_2H_5^+ + 2H_2$

The formation of both $C_2H_3^+$ and $C_2H_5^+$ is exothermic for the reaction with HeH^+:

[6] $HeH^+ + C_2H_6 \rightarrow C_2H_5^+ + H_2 + He$
$\rightarrow C_2H_3^+ + 2H_2 + He$

Because of the small initial signal of HeH^+ only a small fraction of the observed $C_2H_3^+$ can be attributed to reaction [6]. The $C_2H_4^+$ and most of the $C_2H_3^+$ must, by elimination, come from the free protons:

[7] $H^+ + C_2H_6 \rightarrow C_2H_4^+ + H_2 + H$
$\rightarrow C_2H_3^+ + 2H_2$

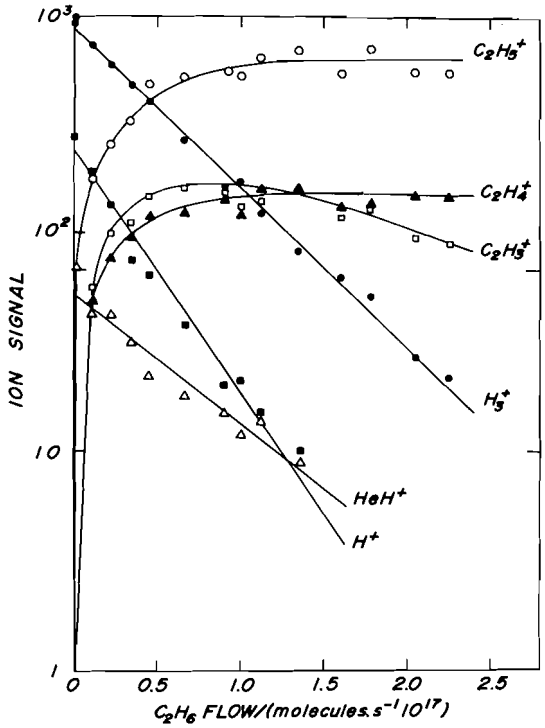

FIG. 1. The variation in ion signals detected upon the addition of C_2H_6 into the reaction region with the SIFT quadrupole tuned to H_3^+ and He Buffer gas in the flow tube. $T = 297$ K, $L = 46$ cm, $P = 0.366$ Torr, and $\bar{v} = 8.5 \times 10^3$ cm s^{-1}.

N_2H^+, CH_5^+

The reaction of N_2H^+ with ethane was investigated in the SIFT mode with H_2 as carrier gas. Figure 2 shows a representative observation of changes in ion signals. The decay of the N_2H^+ is masked in this case by the rise in $C_2H_5^+$ at $m/e = 29$ as is evident from the concomitant rise in the $m/e = 30$ isotope of $C_2H_5^+$. A fit to the rise in the $m/e = 31$ signal provided a rate constant of 1.3×10^{-9} cm^3 molecule^{-1} s^{-1} with an uncertainty of 35%. 87% of the reactive collisions apparently lead to $C_2H_5^+$:

[8] $N_2H^+ + C_2H_6 \rightarrow C_2H_5^+ + H_2 + N_2$
$\rightarrow C_2H_7^+ + N_2$

The association reaction:

[9] $C_2H_5^+ + H_2 \rightarrow C_2H_7^+$

which may ensue in the H_2 buffer is too slow to alter significantly the $C_2H_5^+/C_2H_7^+$ branching ratio under our operating conditions. Experiments in which $C_2H_5^+$ was injected into H_2 buffer at typical

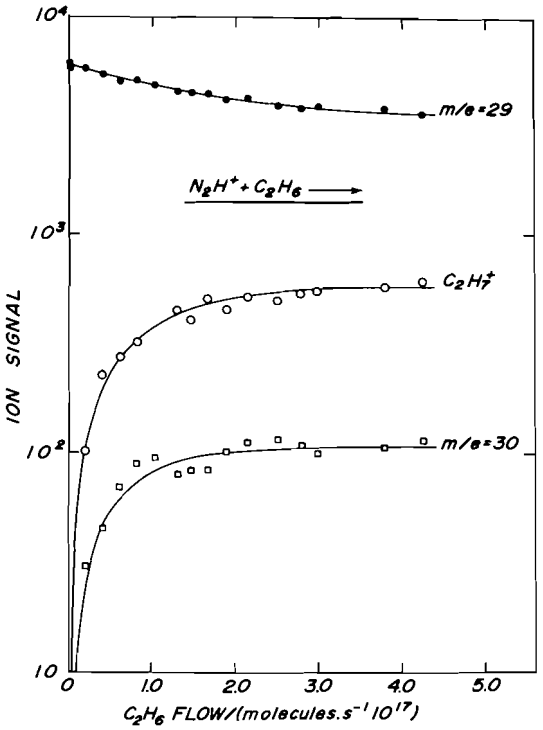

FIG. 2. The variation in ion signals recorded upon the addition of C_2H_6 into the reaction region with the SIFT quadrupole tuned to N_2H^+ and H_2 buffer gas in the flow tube. T = 300 K, L = 46 cm, P = 0.347 Torr, and $\bar{v}$ = 7.6 × 10^3 cm s^{-1}.

operating pressures failed to reveal any formation of $C_2H_7^+$. This observation is consistent with the results obtained by Hiraoka and Kebarle (8) who observed reaction [9] to be second order overall at H_2 pressures down to 2.4 Torr and to have a rate constant of only about 1 × 10^{-14} cm^3 molecule^{-1} s^{-1} at 298 K.

The protonation of ethane by CH_5^+ was investigated in a H_2 buffered flowing afterglow at total pressures from 0.420 to 0.51 Torr. The decays of CH_5^+ were observed to be linear and indicated rapid reaction with k = 1.5 × 10^{-9} cm^3 molecule^{-1} s^{-1} and an estimated uncertainty of ± 25%. Both $C_2H_7^+$ and $C_2H_5^+$ were observed as product ions in the ratio of 5.5 ± 1.0 to 1 under these operating conditions:

[10] $CH_5^+ + C_2H_6 \rightarrow C_2H_7^+ + CH_4$
$\rightarrow C_2H_5^+ + H_2 + CH_4$

The linearity of the observed CH_5^+ decays persisted for at least three orders of magnitude over a range of methane flows from 4.27 × 10^{17} up to 1.9 × 10^{19} molecules s^{-1} which is indicative of a slow reverse reaction and a high equilibrium constant.

N_2OH^+

Rapid protonation of ethane was also observed to occur in H_2 buffer in which N_2OH^+ was initially a dominant ion. Other exothermic channels which lead to the formation of a m/e = 31 ion are conceivable but these involve considerable bond redisposition and could be ruled out on the basis of the observed m/e = 32 ion which had the correct isotopic abundance for $C_2H_7^+$. Some formation of an ion at m/e = 29($C_2H_5^+$) was again apparent but in much smaller relative amounts, about 5%:

[11] $N_2OH^+ + C_2H_6 \rightarrow C_2H_7^+ + N_2O$
$\rightarrow C_2H_5^+ + H_2 + N_2O$

Sufficient curvature was introduced into the N_2OH^+ decays at flows of N_2O from 5.25 × 10^{17} to 1.87 × 10^{19} molecules s^{-1} to allow for the analysis of the kinetics for the reverse reaction and the establishment of equilibrium for the reaction:

[11a] $N_2OH^+ + C_2H_6 = C_2H_7^+ + N_2O$

as demonstrated in Fig. 3 and Fig. 4, respectively. The total pressure was in the range from 0.300 to 0.424 Torr.

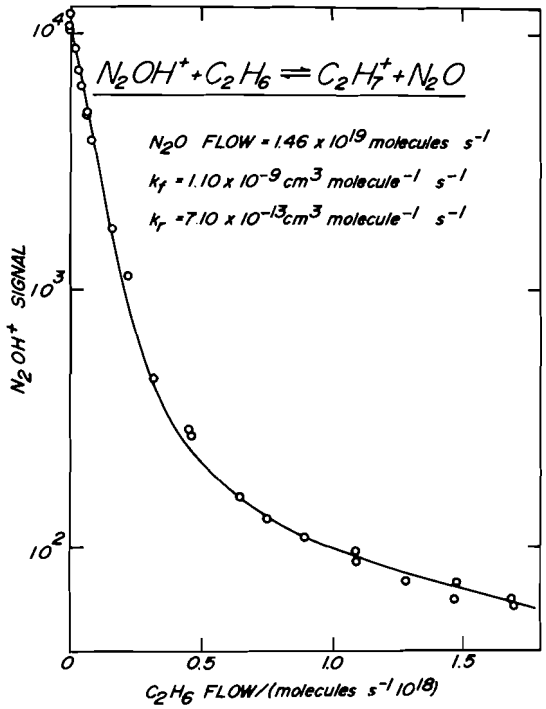

FIG. 3. The variation of the N_2OH^+ signal observed as a function of the flow of ethane at a fixed flow of N_2O in the flowing afterglow mode. T = 296 K, L = 85 cm, P = 0.405 Torr, and $\bar{v}$ = 8.3 × 10^3 cm s^{-1}. The open circles are experimental and the curve is calculated using the values indicated for k_f, k_r, and the flow of N_2O.

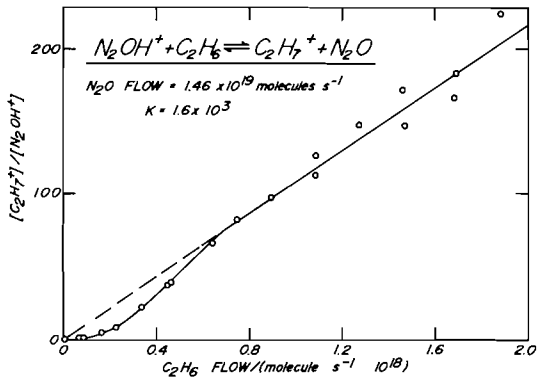

FIG. 4. The observed variation in the ion concentration ratio $[C_2H_7^+]/[N_2OH^+]$ (corrected for mass discrimination) as a function of ethane addition showing the approach to and attainment of equilibrium at a fixed flow of N_2O in the flowing afterglow. The best straight line through the open circles at high ethane flows yields the indicated value for the equilibrium constant.

Thirteen runs provided a value for the forward rate constant of $(1.1 \pm 0.2) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}. In nine of these runs the curvature in the decays of N_2OH^+ provided a reverse rate constant of $(6.9 \pm 2.1) \times 10^{-13}$ cm^3 molecule^{-1} s^{-1} and a ratio of rate constants of $(1.5 \pm 0.45) \times 10^3$. The measured ratio of equilibrium concentrations provided a value for K of $(1.5 \pm 0.3) \times 10^3$ which is identical to the rate constant ratio.

HCO^+

The proton-transfer reaction of HCO^+ with ethane was expected to have a small equilibrium constant on the basis of the N_2OH^+ results and the known proton affinities of N_2O and CO (9). Indeed, strong curvature was observed in the decays of HCO^+ at all flows of CO which ranged from 1.53×10^{18} to 9.9×10^{19} molecules s^{-1} and at total pressures from 0.331 to 0.420 Torr. Equilibrium appeared to be established in the flowing afterglow already at small additions of ethane. The curvature in the HCO^+ decay was fitted to provide a ratio of rate constants of 10.8 ± 3.2. Because of the early establishment of equilibrium the fitting procedure could not yield unique values for the individual rate constants. The analysis of the equilibrium ratio plots yielded a value for K of 11.9 ± 4.0 which combines with the measured ratio of rate constants to provide a true value for the thermodynamic equilibrium constant of 11.3 ± 2.4. This value is in excellent accord with the ratio of equilibrium constants $(1.5 \pm 0.3) \times 10^3/(1.4 \pm 0.2) \times 10^2 = 11 \pm 4$ derived from the equilibrium constant measurements for reactions [11*a*] and [12] (10):

[12] $N_2OH^+ + CO = HCO^+ + N_2O$

The SIFT measurements performed with H_2 buffer gas at pressures between 0.283 and 0.451 Torr and in the absence of CO in the reaction region, provided a rate constant for the protonation of ethane by HCO^+ of $(1.2 \pm 0.2) \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. There was no evidence for any formation of $C_2H_5^+$.

OH_x^+

The reactions of O^+, OH^+, and H_2O^+ with ethane were investigated in the SIFT mode in helium buffer gas at pressures in the range 0.298 to 0.359 Torr. All three ions reacted rapidly with the added ethane and at least two product ions were apparent in each case. With O^+ the apparent reaction was the following:

[13] $O^+ + C_2H_6 \rightarrow C_2H_4^+ + (H_2O)$
$\rightarrow C_2H_5^+ + (OH)$

The observed branching ratio $C_2H_4^+/C_2H_5^+$ was 7/3. The proton affinity of O is close to that of N_2 (9) so that the proton transfer from OH^+ to ethane is quite exothermic. But so are many other reaction channels in this instance. Indeed, the product spectrum observed in this case was quite elaborate:

[14*a*] $OH^+ + C_2H_6 \rightarrow C_2H_4^+ + (H_2 + OH)$

[14*b*] $\rightarrow C_2H_5^+ + (H_2 + O)$

[14*c*] $\rightarrow H_3O^+ + C_2H_4$

[14*d*] $\rightarrow C_2H_6^+ + OH$

[14*e*] $\rightarrow C_2H_7^+ + O$

The observed branching ratio was a:b:c:d:e = 65:20:10:3:2. Proton transfer appears to be completely swamped by other reaction channels in the case of H_2O^+ for which it is still exothermic but now only slightly so. The observed product spectrum was the following:

[15*a*] $H_2O^+ + C_2H_6 \rightarrow H_3O^+ + C_2H_5$

[15*b*] $\rightarrow C_2H_4^+ + H_2 + H_2O$

[15*c*] $\rightarrow C_2H_6^+ + H_2O$

[15*d*] $\rightarrow C_2H_5^+ + H + H_2O$

Evidently H-atom transfer predominates almost exclusively as the branching ratio a:b:c:d was estimated to be 83:12:4:1.

Discussion

The measurements reported in this study yield both rate and equilibrium data for the protonation of ethane. The latter provides the basis for a determination of the proton affinity of ethane as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/06/12
For personal use only.

will be discussed in a later section. The former provides insight into the efficiency of protonation, the stability of the resulting $C_2H_7^+$ against further dissociation, and the degree to which proton transfer competes with other reaction channels when these become viable options, as is the case with radical ions.

Kinetics of Protonation

Table 1 summarizes the rate constants determined in this study along with the observed product ion distributions. Except for the reaction of HCO^+ which proceeds at only about 10% efficiency, all of the reactions in Table 1 proceed within 25% of the collision rate calculated from the Langevin (11) or Average-Quadrupole-Orientation, AQO, theories (12, 13).

The free protons were observed to react most rapidly. Their reaction proceeded at 80% of the AQO rate. The observed $C_2H_4^+$ and $C_2H_3^+$ product ions may be envisaged to arise from what is formally a dissociative hydride ion transfer:

$$[16]\quad H^+ + C_2H_6 \rightarrow [C_2H_7^+]^* \rightarrow \begin{cases} [C_2H_5^+]^* + H_2 \\ \rightarrow C_2H_4^+ + H \\ \rightarrow C_2H_3^+ + H_2 \end{cases}$$

and/or by dissociative charge transfer:

$$[17]\quad H^+ + C_2H_6 \rightarrow [C_2H_6^+]^* + H \begin{cases} \rightarrow C_2H_5^+ + H \\ \rightarrow C_2H_4^+ + H_2 \end{cases}$$

However, the formation of $C_2H_3^+$ by dissociative charge transfer may be ruled out since it is endothermic.

It is interesting to compare the reaction with protons to that with O^+ ions since H and O atoms have essentially identical ionization potentials. The reaction with O^+ seems more efficient with the measured rate constant being 25% larger than the calculated collision rate constant. $C_2H_4^+$ is a major product but $C_2H_3^+$ is not observed even though the overall exothermicities of the H^+ and O^+ reactions are very similar. $C_2H_5^+$ appears as a product ion instead. The higher stability of $C_2H_5^+$ in this case may arise from a larger amount of the excess energy appearing in the neutral OH in the analogue of reaction [16].

An inspection of the product distributions in Table 1 for the reactions of the even-electron acids $AH^+ = HeH^+$, H_3^+, N_2H^+, CH_5^+, N_2OH^+, and HCO^+, reveals the trend expected on the basis of the dissociative proton-transfer mechanism expressed in eq. [1]. The most energetic product ions $C_2H_3^+$ and $C_2H_5^+$ are associated with the strongest acid HeH^+ for which the excess energy is largest, while the least energetic product ion $C_2H_7^+$ is associated predominantly with the weakest acid in this series, HCO^+, for which the excess energy is smallest.

TABLE 1. Summary of rate constants and product distributions for reactions with ethane measured in this study at 298 ± 2 K

Reactant ion	Product ions	Product distribution	Rate constant[a]
H^+	$C_2H_4^+$ $C_2H_3^+$ $(C_2H_5^+)$		3.9 ± 0.8
O^+	$C_2H_4^+$ $C_2H_5^+$	0.7 0.3	1.9 ± 0.4
OH^+	$C_2H_4^+$ $C_2H_5^+$ H_3O^+ $C_2H_6^+$ $C_2H_7^+$	0.65 0.20 0.10 0.03 0.02	1.6 ± 0.3
H_2O^+	H_3O^+ $C_2H_4^+$ $C_2H_6^+$ $C_2H_5^+$	0.83 0.12 0.04 0.01	1.6 ± 0.3
HeH^+	$C_2H_5^+$ $C_2H_3^+$		2.1 ± 0.4
H_3^+	$C_2H_5^+$	1.00	2.4 ± 0.5
N_2H^+	$C_2H_5^+$ $C_2H_7^+$	0.87 0.13	1.3 ± 0.5
CH_5^+	$C_2H_7^+$ $C_2H_5^+$	0.85 0.15	1.5 ± 0.3
N_2OH^+	$C_2H_7^+$ $(C_2H_5^+)$	0.95 0.05	1.1 ± 0.2
HCO^+	$C_2H_7^+$	1.00	0.12 ± 0.02

[a]Rate constant for the total loss of the reactant ion along with the estimated accuracy in units of 10^{-9} cm^3 molecule^{-1} s^{-1}.

The trend in the product distribution with reaction exothermicity observed in this study for the protonation of C_2H_6 is shown in the form of a bargraph in Fig. 5. Clearly the fraction of $C_2H_7^+$ ions which have sufficient energy to decompose, and do so under the experimental conditions, increases dramatically when the reaction exothermicity exceeds the 13.0 kcal mol^{-1} required for the dissociation as is indicated in the potential energy diagram shown in the insert in Fig. 5. The observed efficiency of dissociative proton transfer will depend on the total energy initially deposited in the $C_2H_7^+$ product, the dependence of the rate constant of the fragmentation on this internal energy, and the degree to which the internal energy is moderated by collisions with the buffer gas molecules. Since the time between collisions with the buffer gas molecules is ca. 1 μs, fragmentations

TABLE 2. Product distributions observed for various degrees of excitation of ions in reactions with ethane

Reaction	Product ions[a]	Product distribution: Tandem-ICR[b] Excited	Tandem-ICR[b] Relaxed	FA[c]
$N_2H^+ + C_2D_6/C_2H_6$	$C_2D_6H^+$	0.00	0.09	0.13
	$C_2D_5^+ + C_2D_4H^+$	1.00	0.91	0.87
$CD_5^+/CH_5^+ + C_2H_6$	$C_2H_6D^+$	0.26	0.58	0.85
	$C_2H_5^+ + C_2H_4D^+$	0.74	0.42	0.15
$N_2OD^+/N_2OH^+ + C_2H_6$	$C_2H_6D^+$		0.89	0.95
	$C_2H_5^+$, $C_2H_4D^+$		0.11	0.05
$DCO^+/HCO^+ + C_2D_6/C_2H_6$	$C_2D_7^+$		0.84	1.00
	$C_2D_5^+$		0.16	0.00

[a]Only the deuterated product ions observed in the tandem-ICR experiments are indicated. The FA experiments were carried out only with undeuterated reactants.

[b]Reactions proceeded at average ion translational energies of 0.1 eV and typical pressures of 10^{-6} Torr. The average number of ion–neutral collisions of an ion prior to reaction was varied between 0 and 10 collisions by increasing the pressure in the ion source.

[c]Product distributions measured in the flowing afterglow or SIFT mode at 298 ± 2 K.

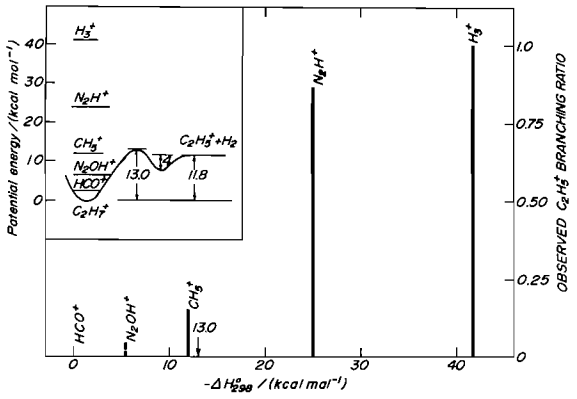

FIG. 5. The observed trend in the extent of dissociative proton transfer to C_2H_6 with reaction exothermicity. The exothermicities have been calculated from the proton affinities determined previously in this laboratory (9) and that of C_2H_6 derived in the text. The potential energy diagram is based on rate and equilibrium measurements for the association of $C_2H_5^+$ and H_2 as a function of temperature carried out by Hiraoka and Kebarle (8).

which require more time than this may be discriminated against and so obscure the initial product distribution in that they may appear as stabilized $C_2H_7^+$ product ions.

It is interesting to compare, as is done in Table 2, the product distributions observed at the relatively high pressures of the FA/SIFT experiments with those obtained previously at the much lower pressures, viz. 10^{-6} Torr, of tandem-ICR experiments (14). In the latter experiments the product distributions were found to be quite sensitive to the excitation of the reactant ion AH^+, shifting towards decreased dissociation of the $C_2H_7^+$ with an increase in the average number of ion–neutral collisions experienced by AH^+ prior to reaction. The product distributions obtained in the FA/SIFT experiments, in which the reactant ions experience a sufficient number of ion–neutral collisions to be thermalized to the buffer gas temperature, are consistent with the trend established at the low pressures in that they show a still further shift towards $C_2H_7^+$ formation. The further shift is expected since there still is a spread in internal energies of several tenths of an eV associated with the "relaxed" AH^+ ions in the tandem-ICR experiments. For example, for the proton-transfer reaction with HCO^+ for which the flowing afterglow measurements show no dissociation, and indeed the dissociation is clearly endothermic, the tandem-ICR experiments show that 16% of the reaction produces $C_2H_5^+$. Dissociative proton-transfer is also endothermic for N_2OH^+ but in this case the energetics are somewhat unique in that several other exothermic routes are possible for the observed formation of the ion at $m/e = 29$:

$$[18a]\quad N_2OH^+ + C_2H_6 \rightarrow C_2H_5^+ + H_2O + N_2$$

$$[18b]\quad \rightarrow N_2H^+ + C_2H_5OH/(C_2H_4 + H_2O)$$

Channels [18*a*] and [18*b*] are exothermic by 69 and 36/(26) kcal mol^{-1}, respectively. Channel [18*a*] seems more probable on mechanistic grounds since it can be viewed to proceed by hydride transfer to N_2OH^+ followed by the dissociation of the resulting neutral species into stable N_2 and H_2O.

Proton Affinity of Ethane

The results of the pertinent equilibrium constant

measurements are shown in Table 3. They provide a best estimate of the true value of the equilibrium constant for the protonation of ethane by HCO^+ of 11.2 ± 2.1:

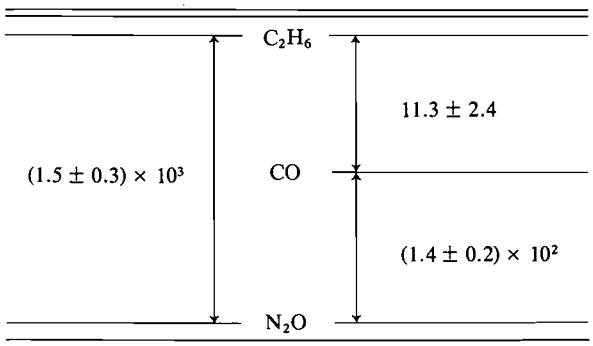
[19] $HCO^+ + C_2H_6 = C_2H_7^+ + CO$

This result is very useful for the determination of the proton affinity of ethane since the proton affinity of CO is well established. The equilibrium constant corresponds to a standard free energy change at 298 K for reaction [19] of -1.43 ± 0.11 kcal mol^{-1}. A standard entropy change of $+2.3 \pm 2.2$ cal mol^{-1} K^{-1} may be estimated from the absolute entropies for HCO^+, $C_2H_7^+$, and CO, of 48.04 ± 0.2 (15), 54.9 (16), 58 ± 3, and 47.21 (17) cal mol^{-1} K^{-1}. The entropy of $C_2H_7^+$ was estimated from a comparison with the entropies of the isoelectronic species CH_3NH_2 and CH_3OH and ethane itself (16). The standard free energy and entropy changes can be combined to provide a value for the standard enthalpy change of -0.74 ± 0.77 kcal mol^{-1}, or a difference in the proton affinities of C_2H_6 and CO, $\Delta PA(C_2H_6, CO) = 0.7 \pm 0.8$ kcal mol^{-1}. With a value for PA(CO) of 141.4 ± 0.4 kcal mol^{-1} as in ref. 9, the value for $PA(C_2H_6)$ becomes 142.1 ± 1.2 kcal mol^{-1}. This result is consistent with the limiting values $136 < PA(C_2H_6) < 159$ kcal mol^{-1} which we obtained previously from bracketing measurements (18), but it exceeds the value of 127.0 ± 1.0 kcal mol^{-1} obtained on the basis of mass-spectrometer ion-source measurements (19) of the proton-transfer reaction:

[20] $CH_5^+ + C_2H_6 = C_2H_7^+ + CH_4$

This discrepancy has been discussed previously (18). *Ab initio* molecular orbital calculations (20) of the geometry and energy of $C_2H_7^+$ have led to a theoretical value for $PA(C_2H_6) = 140.1$ kcal mol^{-1} (not corrected for zero point vibrations) which compares very favourably with our experimental value. Accepted heats of formation for ethane and the proton (16, 17) lead to a heat of formation for $C_2H_7^+$ of 204.8 ± 1.3 kcal mol^{-1}.

TABLE 3. Summary of equilibrium constants measured at 298 ± 2 K for proton-transfer reactions of the type $XH^+ + Y \rightleftharpoons YH^+ + X$. The preferred direction of proton transfer is towards the top of the table



Proton Affinity of Ethylene

Having established a value for the proton affinity of ethane, we may take advantage of previous measurements of the equilibrium constant for the association reaction [9] to derive a value for the proton affinity of ethylene. Equilibrium [9] has been investigated by Hiraoka and Kebarle (8) between 358 and 473 K in a high-pressure ion-source mass spectrometer. The corresponding van't Hoff plot provided a value for the standard enthalpy change for reaction [9] of -11.8 ± 0.4 kcal mol^{-1}. $PA(C_2H_4)$ is related to this enthalpy change and $PA(C_2H_6)$ by the equation:

[21] $PA(C_2H_4) = PA(C_2H_6) + \Delta H_f^0(C_2H_4) - \Delta H_f^0(C_2H_6) - \Delta H_9^0$

The accepted values for the heats of formation of ethylene and ethane (16) lead to a value for $PA(C_2H_4) = 163.0 \pm 1.7$ kcal mol^{-1}. Also the heat of formation of $C_2H_7^+$ determined above leads to a heat of formation for $C_2H_5^+$ of 216.6 ± 1.7 kcal mol^{-1}.

The heat of formation of $C_2H_5^+$ has recently received renewed attention. Previous values have been based exclusively on non-equilibrium studies of the appearance of this ion by dissociative ionization and by the ionization of the ethyl radical and have led to a higher value of 220.5 kcal mol^{-1} (21) (here the electron is treated as a conventional element (17)). The shortcomings of these two methods have been described recently by Baer in connection with a report of results obtained by him in a photoionization and photoion-photoelectron coincidence (PIPECO) study of the appearance of $C_2H_5^+$ from C_2H_5I (22). The onset of $C_2H_5^+$ in the I atom loss process:

[22] $h\nu + C_2H_5I \rightarrow C_2H_5^+ + I + e$

was measured in delayed coincidence with zero energy electrons. The kinetic energy release was also measured and found to be zero at the dissociation onset. Baer has derived from these observations a room-temperature heat of formation for $C_2H_5^+$ of 216.8 ± 1.0 kcal mol^{-1} (or 215.3 ± 1.0 kcal mol^{-1} with the stationary electron convention (21)) which is in excellent agreement with the value obtained in our study.

Relative methylmercury cation affinities in the gas phase determined by high pressure mass spectrometry

JOHN A. STONE AND DENA E. SPLINTER
Chemistry Department, Queen's University, Kingston, Ont., Canada K7L 3N6

Received November 5, 1980

This paper is dedicated to Dr. F. P. Lossing of the National Research Council of Canada on the occasion of his 65th birthday

JOHN A. STONE and DENA E. SPLINTER. Can. J. Chem. **59**, 1779 (1981).

A pulsed electron beam, high pressure mass spectrometer has been used to determine equilibrium constants for the exchange of CH_3Hg^+ between bases; $CH_3Hg{\cdot}B_1^+ + B_2 \rightleftharpoons CH_3Hg{\cdot}B_2^+ + B_1$. A series of aromatic, hydrocarbon bases has been studied at 417 K and several nitrogen bases have been studied at 580 K. There is a good linear correlation between differences in CH_3Hg^+ affinity (ΔG^0) and H^+ affinity for bases in each series. The single sulfur base examined ($(C_3H_7)_2S$) shows anomalously high relative affinity for CH_3Hg^+ compared with H^+ while two oxygen bases (CH_3COOCH_3 and $C_6H_5NO_2$) show lesser relative affinity. These results are in qualitative agreement with the hard–soft acid base theory. ΔH^0 and ΔS^0 values have been obtained from Arrhenius plots. For a pair of aromatic bases (toluene–ethylbenzene) ΔH^0 is of the same magnitude as that for H^+ and ΔS^0 may be calculated using partition functions for translation and external rotation. For toluene/methylacetate the difference in binding energy is much greater for H^+ than for CH_3Hg^+ and a similar calculation of ΔS^0 gives a result not consistent with the experimental value.

JOHN A. STONE et DENA E. SPLINTER. Can. J. Chem. **59**, 1779 (1981).

On a utilisé un spectromètre de masse à haute pression et à faisceau pulsé d'électrons pour déterminer les constantes d'équilibre de l'échange de CH_3Hg^+ entre des bases: $CH_3Hg{\cdot}B_1^+ + B_2 \rightleftharpoons CH_3Hg{\cdot}B_2^+ + B_1$. On a étudié à 417 K une série d'hydrocarbures aromatiques agissant comme bases et à 580 K plusieurs bases azotées. Dans chacune des séries, on a noté une bonne corrélation linéaire entre les différences d'affinités (ΔG^0) des bases pour CH_3Hg^+ et H^+. La seule base sulfurée étudiée ($(C_3H_7)_2S$) présente une affinité anormalement élevée pour CH_3Hg^+ par rapport à son affinité pour le H^+; toutefois les deux bases oxygénées (CH_3COOCH_3 et $C_6H_5NO_2$) montrent une affinité relative beaucoup plus faible. Ces résultats sont en accord quaiitatif avec la théorie des acides et des bases durs et mous. On a obtenu les valeurs de ΔH^0 et de ΔS^0 à partir des courbes d'Arrhénius. Pour une paire de bases aromatiques (toluène–éthylbenzène), le ΔH^0 est du même ordre de grandeur que celui de H^+; on peut calculer le ΔS^0 en utilisant les fonctions de partition pour la translation et la rotation externe. Dans le cas du toluène/acétate de méthyle, la différence du point de vue de l'énergie de liaison est beaucoup plus grande pour H^+ que pour CH_3Hg^+ et un calcul analogue de ΔS^0 conduit à des résultats qui ne concordent pas avec la valeur expérimentale.

[Traduit par le journal]

Introduction

The gas phase basicities of a very large number of molecules have now been reported and both qualitative and quantitative interpretations of the values have been given. The majority of these values have been obtained with respect to the proton as acid but the present concept of acidity encompasses many other cations and as has been emphasized, a basicity scale is dependent on the particular acid employed in obtaining it (1). Basicities with respect to a small but growing number of singly charged gas phase metallic ions are now being reported (2).

One of the concepts that has found some favour in qualitative explanations of chemical reactivity in solution is that of hard and soft acids and bases (3). This idea correlates with the covalent (soft) and ionic (hard) contributions to acid base interactions and although its severe limitations have been noted (4) it is still popular. The proton is classified as a hard acid, as are the alkali metal ions, while soft acids are represented by ions such as Ag^+, Hg^{2+}, and CH_3Hg^+ (5). The metal ions which have received the most study in the gas phase are those of the alkali metals which are readily obtained from thermionic sources. Kebarle (6) has summarized the results obtained. Gas phase metal ions from other groups of the periodic table are less easy to produce in a controlled manner and hence have received much less attention. Castleman and coworkers (7) studied the singly charged alkaline earth ions and found, for example, significantly stronger binding to H_2O than for the alkali ions. This he associated with an increasing covalent character to the binding. In order to obtain a greater understanding of the behaviour of acids and bases in the gas phase it is now necessary to extend the range of acid types.

We reported earlier (8) that CH_3Hg^+, obtained by chemical ionization of $(CH_3)_2Hg$ in a high pressure ion source, forms complexes with both π- and n-donor bases. We also reported an ordering of

basicities with respect to CH_3Hg^+ for a range of molecules at ambient temperature. This work has now been extended to obtain absolute values for the differences in gas phase basicities (ΔG^0) for a variety of bases with this cation.

Experimental

The high pressure mass spectrometer is patterned after the one described by Kebarle (9). The basic instrument is a Hitachi RMU-6E from which the original ion source and ion multiplier housings have been removed. Figure 1 illustrates the new ion source, ion focusing lens, and electron gun and their housing. The original small diffusion pump now pumps only the flight tube and detector. The flight tube is separated from the lens housing by a fixed source slit of dimensions 10 × 0.5 mm. The lens housing is pumped by an Edwards 2 in. diffusion pump while the ion source housing is pumped by an Edwards 4 in. diffusion pump. All diffusion pumps are backed by the same Edwards 660 L min^{-1} rotary pump. When the ion source pressure is 1 Torr, the pressures in the flight tube, ion lens housing, and ion source housing are roughly 10^{-6}, 2×10^{-5}, and 2×10^{-4} Torr, respectively.

All seals in the stainless steel ion source have gold gaskets. The electron entrance and ion exit slits are fabricated by spot welding razor blades over holes drilled through the thin ends of stainless steel flanges. They have dimensions 1.5 × 0.025 mm^2. Four cartridge heaters embedded in a copper block surrounding the ion source allow operation up to 600 K, as measured with a copper–constantan thermocouple. The electron gun is mounted well away from the ion source and the focussed 2000 V, 2μA electron beam reaching the source has a negligible heating effect.

In dc operation the ionizing electron beam of $3–10 \times 10^{-8}$ μA gives good, intense spectra. This beam strength can be measured at an electron collector inside the ion source when no gas is present. In actual operation the source is used in the field-free mode with no ion repeller and with the electron collector shorted to the chamber. In the pulsed mode the electron beam is gated on for 50 μs every 10 ms by removing a 90 V bias on the first electrode of the electron gun. Ions escaping through the ion exit slit are accelerated through 1900 V, subjected to mass analysis and detected by a Galileo 4800 continuous dynode ion multiplier which is operated at 1200–1400 V in the analogue mode and at 2200 V for ion counting which is used in the pulsed mode. In the latter mode the individual multiplier pulses are amplified by a factor of 200 with an Ortec 9302 amplifier–discriminator the output pulses of which go to a Nicolet 1170 signal averager. In most runs the dwell time per channel is 35 μs and data are collected in 150 channels after the start of the electron pulse. Accumulation of data from many individual pulses is required to obtain ion residence time curves. The number required varies from 2×10^3 to 16×10^3 depending on the signal strength.

Results and Discussion

We have previously described the behaviour of dimethylmercury in the chemical ionization source with CH_4 as the reagent gas (8). We will first present a brief account of this behaviour together with details of subsequent experiments which further clarify our knowledge.

Low concentrations of $(CH_3)_2Hg$ in CH_4 form $(CH_3)_3Hg_2^+$ as the major product at all temperatures from 300 to 600 K. $(CH_3)_3Hg_2^+$ may be regarded as the CH_3Hg^+ adduct of $(CH_3)_2Hg$ just as $(CH_3)_2Hg{\cdot}H^+$ is the proton adduct. The latter ion

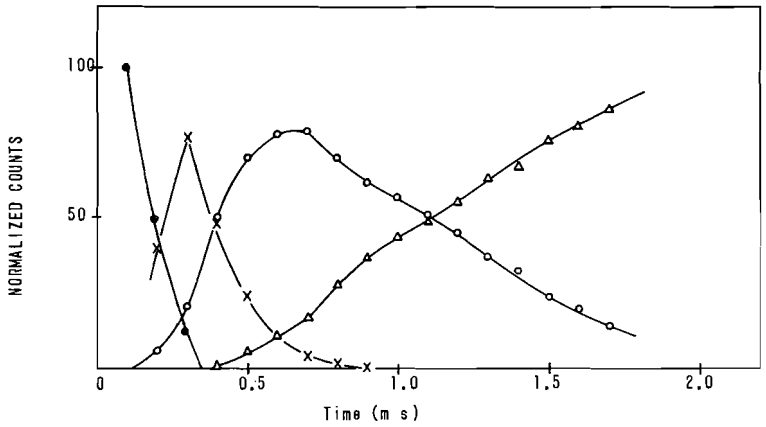

FIG. 2. Normalized ion intensities as functions of residence time in the ion source for 4×10^{-4} Torr $(CH_3)_2Hg$ in 1 Torr CH_4 at 340 K. ●, CH_5^+; ×, H_3O^+; ○, CH_3Hg^+; △, $(CH_3)_3Hg_2^+$.

is observed, together with CH_3Hg^+, at 300 K and both are presumed to be precursors of $(CH_3)_3Hg_2^+$ although this could not be verified because of the extremely low ion currents. At temperatures above 400 K, $(CH_3)_2Hg{\cdot}H^+$ is not observed and presumably dissociates to $CH_3Hg^+ + CH_4$. Reactions [1]–[4] summarize the presumed ambient temperature chemistry.

$$[1] \quad CH_5^+ + (CH_3)_2Hg \rightarrow CH_4 + (CH_3)_2Hg{\cdot}H^{+*}$$

$$[2a] \quad (CH_3)_2Hg{\cdot}H^{+*} \rightarrow CH_3Hg^+ + CH_4$$

$$[2b] \quad \xrightarrow{M} (CH_3)_2Hg{\cdot}H^+$$

$$[3] \quad CH_3Hg^+ + (CH_3)_2Hg \xrightarrow{M} (CH_3)_3Hg_2^+$$

$$[4] \quad (CH_3)_2Hg{\cdot}H^+ + (CH_3)_2Hg \rightarrow (CH_3)_3Hg_2^+ + CH_4$$

Above 400 K the yield of CH_3Hg^+ relative to that of $(CH_3)_3Hg_2^+$ increases but is always very small. Figure 2 shows the normalized, time resolved ion intensities for a system containing a very low concentration of $(CH_3)_2Hg$ in CH_4 in the absence of SF_6. No precautions were taken to dry any of the reagents and the intermediate H_3O^+ ion signifies the presence of a considerable amount of water. Under normal operating conditions the signal due to H_3O^+ is insignificant since all bases used, including $(CH_3)_2Hg$, have much higher proton affinities than H_2O. The sequence of ions determined by the results in Fig. 1 is,

$$CH_4^+ \xrightarrow{a} CH_5^+ \xrightarrow{b} H_3O^+ \xrightarrow{c} CH_3Hg^+ \xrightarrow{d} (CH_3)_3Hg^{2+}$$

There is no equilibrium observed in step *d* which prevents the direct determination of thermodynamic data for the association reaction forming $(CH_3)_3Hg_2^+$ (reaction [3]).

When a base B is added to the $CH_4/(CH_3)_2Hg/SF_6$ system, three new products appear. There is competition between B and $(CH_3)_2Hg$ for reaction with CH_5^+ and H_3O^+ and since $(CH_3)_2Hg$ has a proton affinity between those of benzene and toluene (10), any base with a proton affinity greater than that of benzene shows a BH^+ peak with intensity directly dependent on the molar ratio of B and $(CH_3)_2Hg$. The other two products CH_3M^+ and CH_3Hg. M^+ arise from the reaction of the base with CH_3Hg^+ and $(CH_3)_3Hg_2^+$. The relative yields are pressure dependent, that of CH_3HgM^+ increasing with increasing total pressure as seen in Fig. 3 for M = *m*-xylene. Obviously collisional deactivation of an initially formed excited complex is occurring.

$$[5] \quad CH_3Hg^+ + C_6H_4(CH_3)_2 \rightarrow CH_3Hg{\cdot}C_6H_4(CH_3)_2^{+*}$$

$$[6a] \quad CH_3Hg{\cdot}C_6H_4(CH_3)_2^{+*} \xrightarrow{M} CH_3Hg{\cdot}C_6H_4(CH_3)_2^+$$

$$[6b] \quad \rightarrow CH_3{\cdot}C_6H_4(CH_3)_2^+ + Hg$$

The half-life of the excited complex may be estimated from Fig. 3. Assuming that stabilization

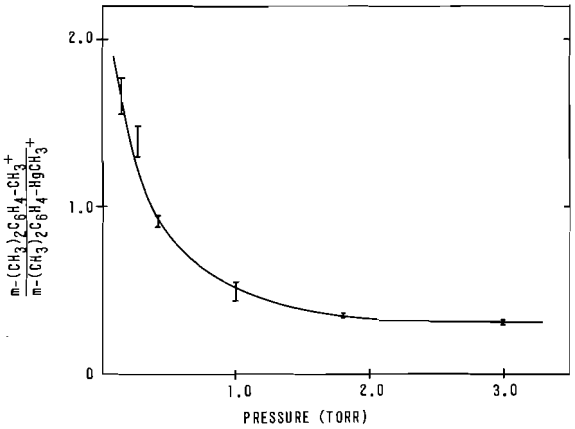

FIG. 3. The ratio of the *m*-xylene·CH_3^+ and *m*-xylene·$HgCH_3^+$ yields as a function of ion source pressure. Sample composition (mole fractions) *m*-xylene, 4×10^{-3}; $(CH_3)_2Hg$, 8×10^{-3}; SF_6, 2×10^{-3}; methane, 0.99 (588 K).

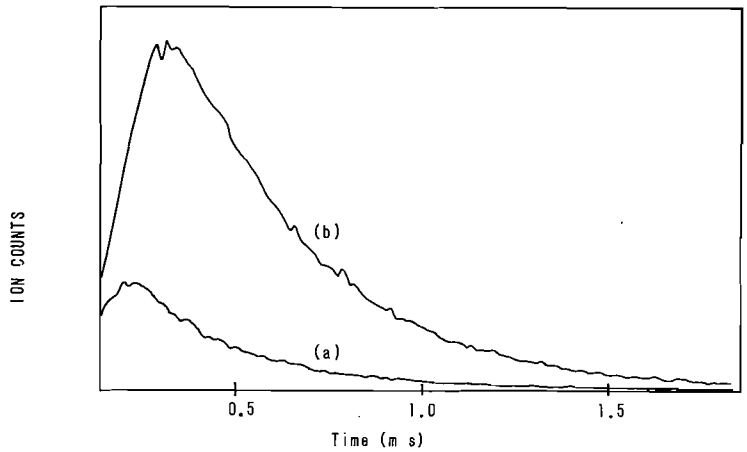

FIG. 4. Ion counts as functions of ion residence times in the ion source for (*a*) (*o*-xylene·$HgCH_3$)$^+$ and (*b*) (mesitylene·$HgCH_3$)$^+$, 2.1×10^{-3} Torr *o*-xylene, 1.8×10^{-3} Torr mesitylene, 8×10^{-3} Torr $(CH_3)_2Hg$, 1.4 Torr methane (577 K).

occurs at every collision with a neutral molecule and since 50% stabilization occurs at a pressure of ~0.25 Torr (8×10^{15} molecules cm^{-3}) and taking the collision rate to be 10^{-9} cm^3 $molecule^{-1}$ s^{-1}, the pseudo first order rate constant for [6*a*] is $\sim 10^{-9} \times 8 \times 10^{15}$ s^{-1}, i.e. $t_{1/2} \geq 1 \times 10^{-7}$ s. It is possible that $CH_3Hg \cdot M^{+*}$ formed in reaction [5] is a π complex which is a precursor of the more stable $CH_3Hg \cdot M^+$ and $CH_3 \cdot M^+$ σ complexes.

$(CH_3)_3Hg_2^+$ also reacts with bases, the reaction being the transfer of CH_3Hg^+ from the weak base $(CH_3)_2Hg$. Again, both CH_3^+ and CH_3Hg^+ addition products are observed.

[7*a*] $CH_3Hg \cdot (CH_3)_2Hg^+ + C_6H_4(CH_3)_2 \rightarrow CH_3 \cdot C_6H_4(CH_3)_2^+ + Hg + (CH_3)_2Hg$

[7*b*] $\rightarrow CH_3Hg \cdot C_6H_4(CH_3)_2^+ + (CH_3)_2Hg$

All the bases studied yield a CH_3^+ adduct. For aromatic bases these will be initially the ipso-protonated form of a higher aromatic, for example benzene forms protonated toluene. When a mixture of two bases is studied then the relative yields of the methyl adducts change as functions of ion residence time due to the setting up of proton transfer equilibria. These CH_3^+ addition products were not mentioned in our earlier communication since they were ascribed to the presence of impurities. They were not investigated further but might be usefully employed in low pressure icr studies to obtain additional information on ipso-protonation.

Figure 4 shows the intensities of the CH_3Hg^+ adducts of *o*-xylene and mesitylene as functions of time from the start of the electron pulse. The constancy of the ratio of the two ion intensities after ~0.5 ms^{-1} is shown when the normalized ion intensities are considered (Fig. 5). This time invariance of the ratio at long residence times indicates the attainment of the equilibrium

[8] $CH_3Hg \cdot C_6H_4(CH_3)_2^+ + C_6H_3(CH_3)_3 \rightarrow C_6H_4(CH_3)_2 + CH_3Hg \cdot C_6H_3(CH_3)_3^+$

The equilibrium constant is obtained from this constant ratio and the known molar ratio of the bases

$$K = \frac{[C_6H_4(CH_3)_2]}{[C_6H_3(CH_3)_3]} \cdot \frac{i_{CH_3Hg \cdot C_6H_3(CH_3)_3^+}}{i_{CH_3Hg \cdot C_6H_4(CH_3)_2^+}} = \exp \frac{-\Delta G^0}{RT}$$

The usual criteria for confirmation of the attainment of equilibrium are found to apply, i.e. K is independent of total pressure (0.5–3.5 Torr) and independent of the molar ratio of the two bases over more than a 10-fold range.

Reaction [8] may be considered the difference of two reactions

[9] $CH_3Hg^+ + C_6H_3(CH_3)_3 \rightarrow CH_3Hg \cdot C_6H_3(CH_3)_3^+$

[10] $CH_3Hg^+ + C_6H_4(CH_3)_2 \rightarrow CH_3Hg \cdot C_6H_4(CH_3)_2^+$

$$\Delta G^0 = -RT \ln K = \Delta G_9^0 - \Delta G_{10}^0$$

ΔG_9^0 and ΔG_{10}^0 will be defined as the gas phase methylmercury cation basicities (MMCB) of mesitylene and *o*-xylene respectively. Only differences in these values are measurable by this technique, neither the absolute values for MMCB nor the binding energies of CH_3Hg^+ to the bases (ΔH^0) being at present obtainable either experimentally or theoretically. Table 1 gives the differences in MMCA values for a series of bases, mainly aromatic, at 425 K, the values being checked for consistency by the usual ladder technique. Similarly Table 2 gives the differences in MMCB values for

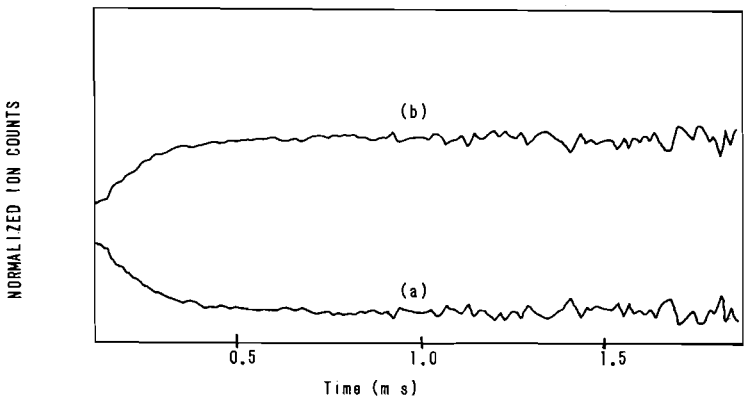

FIG. 5. The normalized yields of $(o\text{-xylene}\cdot HgCH_3)^+$ (*a*) and $(\text{mesitylene}\cdot HgCH_3)^+$ (*b*) from the data in Fig. 4.

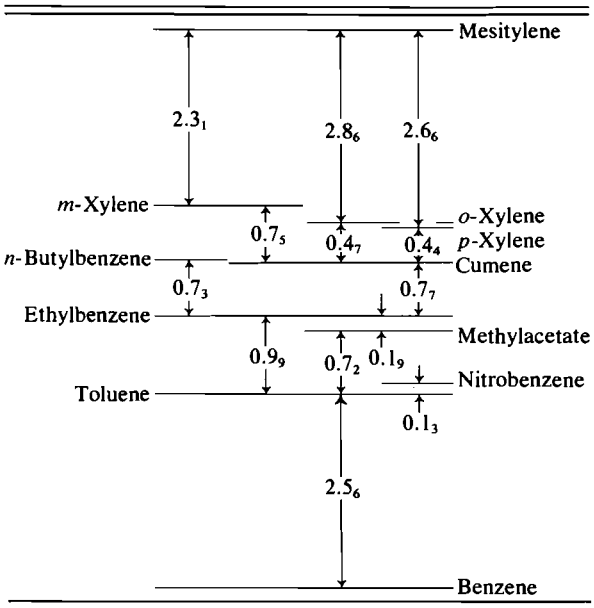
TABLE 1. Free energy differences (kcal mol^{-1}) for the attachment of CH_3Hg^+ to aromatic and ester bases, the direction of increasing basicity is upwards (425 K)



several nitrogen and one sulfur base at 580 K. This higher temperature was required to overcome problems associated with solvation. We have so far not obtained a linking up of the two series, but 2-chloropyridine is more basic than mesitylene at the same temperature.

The effect of molecular structure on gas phase basicity with respect to the proton has been presented and discussed in detail (11, 12) and it is of interest to seek comparisons with MMCB values (Figs. 6 and 7). The correspondence between the two scales of basicity is striking. In both cases basicity increases with increasing alkyl chain length in both π-donor (benzene<toluene<ethylbenzene<*n*-butylbenzene) and n-donor bases $((C_2H_5)_3N < (C_3H_7)_3N)$, and with increasing methyl or ethyl substitution (benzene<toluene<xylene <mesitylene), $((C_2H_5)_2NH<(C_2H_5)_3N)$. Even the finer nuances of basicity in the xylenes is the same (*p*<*o*<*m*). These correlations surely prove that the aromatic binding sites of the adducts are the same in both the H^+ and CH_3Hg^+ complexes. H^+ addition leads to the formation of an arenium ion and the same must hold true for CH_3Hg^+ addition. Such σ bonded adducts have been postulated on the evidence of nmr spectroscopy in strongly acidic solutions of dialkylmercury compounds (13, 14).

The slope of the line drawn through the points for the lower aromatic bases in Fig. 6 is 0.7 which implies that the changes in absolute basicity with change in substituent is almost the same for

TABLE 2. Free energy differences (kcal mol^{-1}) for the attachment of CH_3Hg^+ to N and S bases, the direction of increasing basicity is upwards (580 K)

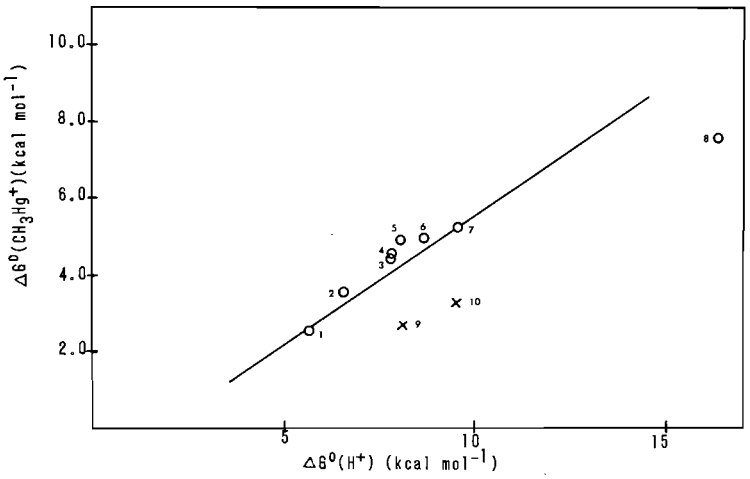

FIG. 6. Gas phase basicities (relative to that of benzene) with respect to the acids H^+ and CH_3Hg^+. *1*, toluene; *2*, ethylbenzene; *3*, cumene; *4*, *n*-butylbenzene; *5*, *p*-xylene; *6*, *o*-xylene; *7*, *m*-xylene; *8*, mesitylene; *9*, methylacetate; *10*, nitrobenzene (417 K).

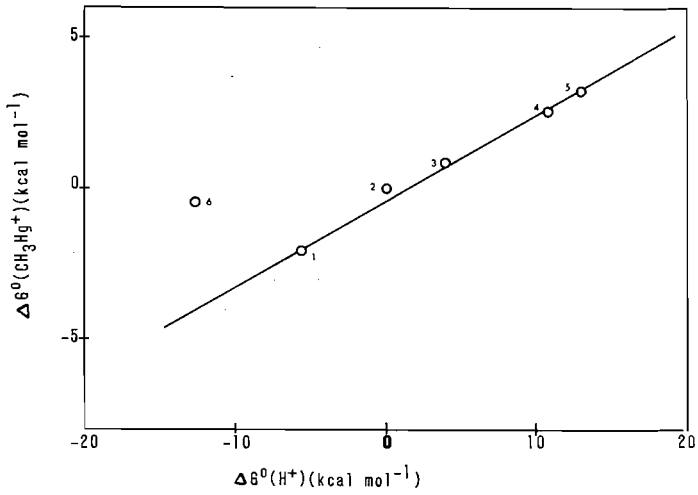

FIG. 7. Gas phase basicities (relative to that of pyridine) with respect to the acids H^+ and CH_3Hg^+. *1*, 2-chloropyridine; *2*, pyridine; *3*, diethylamine; *4*, triethylamine; *5*, tri-*n*-propylamine; *6*, di-*n*-propylsulfide (580 K).

CH_3Hg^+ as for H^+. This is in spite of the fact that the strengths of the bonds formed are vastly different. (An upper limit of 24 kcal mol^{-1} has been estimated for $D(CH_3Hg^+—C_6H_6)$ (8) while $D(H^+—C_6H_6)$ is 186 kcal mol^{-1} (10).) Both nitrobenzene and methylacetate protonate on oxygen and presumably this is also the basic site for CH_3Hg^+. Compared with the π-donor bases, a relatively weaker interaction with CH_3Hg^+ is indicated.

The slope of the line in Fig. 7 is 0.3 showing a lesser discrimination for nitrogen compounds by CH_3Hg^+ relative to H^+ than for the aromatics. However, $(C_3H_7)_2S$ is well off the line, signifying a much stronger relative interaction with CH_3Hg^+ than for the nitrogen bases. This is in contrast to the much weakened basicity (enthalpy of binding) of $(CH_3)_2S$ compared with $(CH_3)_2O$ or $(CH_3)_3N$ for Li^+ relative to that for H^+ (15). An increased covalent character relative to both H^+ and Li^+ of the binding of the larger CH_3Hg^+ to the more polarizable second row element is indicated. In a qualitative sense this is in keeping with the idea of the hard–soft acid base interaction.

Basicity is defined in terms of a change in free energy but in this ΔG^0 term entropy changes may be dominant. Of more immediate interest is the relative change in binding energy. For proton

TABLE 3. Thermochemical data derived from temperature studies of the equilibrium $AX^+ + B \rightleftharpoons A + BX^+$

A	B	X	$-\Delta H^\circ$ (kcal mol^{-1})	$-\Delta S^\circ$ (cal K^{-1} mol^{-1})
Toluene	Ethylbenzene	CH_3Hg^+	1.2_6	0.6_9
Toluene	Ethylbenzene	H^{+a}	0.9	0
Toluene	Methylacetate	CH_3Hg^+	1.9_4	3.0
Toluene	Methylacetate	H^{+a}	6.7	0

[a]Data from ref. 11 in which ΔH^0 values are obtained from isothermal (300 K) ΔG^0 values using calculated ΔS^0 values which are based on changes in rotational symmetry.

transfer equilibria most enthalpy changes have been obtained from free energy differences using the approximation that the entropy change is calculable from changes in external rotation symmetry numbers (16). The moment of inertia of a molecule changes little upon protonation but there will be drastic changes when CH_3Hg^+ is added and simple symmetry calculations will not be sufficient for determining ΔS^0. In addition, vibrational modes involving Hg will be of very low frequency and may also be of significance in the ΔS^0 term. Theoretical calculations of entropy changes are not immediately possible and experimental values of ΔH^0 must be obtained from plots of log K vs. $1/T$ (6). Two such plots are shown in Fig. 8 and the derived thermodynamic data are shown in Table 3 where they are compared with data for the corresponding proton transfer equilibria.

The difference in energy for binding CH_3Hg^+ to toluene and ethylbenzene is comparable to that for the proton. ΔS^0 is small for the reaction since the ions are very similar in geometry. It is therefore expected that only rotational and translational partition functions need be considered in calculating entropy changes. Therefore for the equilibrium

$$CH_3HgT^+ + E \rightleftarrows T + CH_3Hg{\cdot}E^+$$

where T = toluene and E = ethylbenzene

$$\Delta S^0 = \Delta S^0_{trans} + \Delta S^0_{rot}$$

$$= \frac{3}{2} R \ln \left[\frac{M_{CH_3Hg\cdot E} + M_T}{M_{CH_3Hg\cdot T} + M_E}\right] + \frac{3}{2} R \ln \left[\frac{I_{CH_3Hg\cdot E} + I_T}{I_{CH_3Hg\cdot T} + I_E} \frac{\sigma_{CH_3Hg\cdot T} + \sigma_E}{\sigma_{CH_3Hg\cdot E} + \sigma_T}\right]$$

where M is the molar mass, I the moment of inertia about the centre of mass, σ the rotational symmetry number, and T and E are toluene and ethylbenzene respectively (17). The moments of inertia were calculated for structures in which CH_3Hg was bonded to an sp^3 hybridized carbon in the para position of the aromatic ring with unchanged C—C distances. ΔS^0 (calcd) = -0.8 cal mol^{-1} K^{-1} is in excellent agreement with ΔS^0 (expt) = -0.7 cal mol^{-1} K^{-1}.

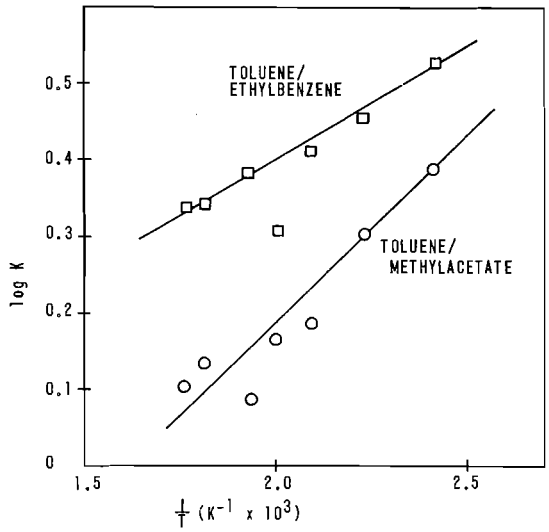

FIG. 8. Van't Hoff plots for the equilibrium $A{\cdot}HgCH_3^+ + B \rightleftharpoons B{\cdot}HgCH_3^+ + A$ for the A/B pairs toluene/ethylbenzene and toluene/methylacetate.

The increase in binding energy from toluene to methylacetate is much greater for H^+ than for CH_3Hg^+ which may signify a decrease in the covalent contribution to the binding energy for the more electronegative oxygen base. The measured change in entropy (-3.0 cal mol^{-1} K^{-1}) is relatively large and is also in the opposite direction to that calculated by neglecting vibrational partition function contributions ($+1.3$ cal mol^{-1} K^{-1}). Obviously the latter must be considered when mercury changes its bonding from carbon to oxygen. The assessment of binding energy differences from experimental free energy differences must therefore be treated with caution for equilibria involving heavy atoms. Initially at least experimental determinations of ΔH^0 will be essential.

Ion–molecule equilibria measurements by high pressure mass spectrometry. Some recent advances in concepts and technique

JAN SUNNER, TOM F. MAGNERA, AND PAUL KEBARLE
Department of Chemistry, University of Alberta, Edmonton, Alta, Canada T6G 2G2

Received November 17, 1980

This paper was presented at a Special Symposium "The Structure and Thermochemistry of Gaseous Ions", held in honour of Dr. F. P. Lossing of the National Research Council of Canada, during the Second Canadian Conference on the Gas Phase Chemistry of Ions, Trent University, June 5–8, 1980, and is dedicated to him on the occasion of his 65th birthday

JAN SUNNER, TOM F. MAGNERA, and PAUL KEBARLE. Can. J. Chem. **59**, 1787 (1981).

Two efforts to improve ion–molecule equilibrium measurement methodology and instrumentation are described. The first part deals with dissociation of ions AB^+ in the mass analysis system of the mass spectrometer. To measure the equilibrium constant of the association equilibrium $A^+ + B = AB^+$ one needs to sample both A^+ and AB^+. The AB^+ ions escaping from the high pressure ion source have a thermal energy distribution. A fraction f_{ex} has internal energy which is higher than the dissociation energy for $AB^+ \rightarrow A^+ + B$. This fraction can dissociate before detection. A theoretical analysis for the system $K^+(H_2O)_n$ is made which is based on calculated vibrational frequencies and geometries of $K^+(H_2O)_n$. From these $f_{n,ex}$ can be evaluated. RRKM calculations also provide rates for the dissociation of the AB^+_{ex}. It is found that severe dissociation during mass analysis can occur if the experimental conditions are not selected carefully. Results for $H^+(H_2O)_2$ and $(C_6H_6^+)_2$ are also presented. Measurements of the association equilibria must be done at low pressures of B in the presence of high pressure of an inert bath gas.

By connecting the repeller to a gated radio frequency source, pulses of RF can be applied in the high pressure ion source. These increase the internal energy of the ions. If the reaction system was at equilibrium a displacement of the equilibrium is produced by the RF pulse. The system relaxes to the original state after the RF has been shut off. Kinetic measurements of the relaxation times provide rate constants form which an equilibrium constant not affected by ion mass discrimination can be determined. Fast reaction kinetics also can be studied with this technique.

JAN SUNNER, TOM F. MAGNERA et PAUL KEBARLE. Can. J. Chem. **59**, 1787 (1981).
